ABSTRACT

36

35

The first three months of sky-survey operation with the *Fermi Gamma Ray Space Telescope (Fermi)* Large Area Telescope (LAT) reveals 132 bright sources at $|\mathbf{b}| > 10^{\circ}$ with test statistic greater than 100 (corresponding to about 10σ). Two methods, based on the CGRaBS, CRATES and BZCat catalogs, indicate high-confidence associations of 106 of these sources with known AGNs. This sample is referred to as the LAT Bright

AGN Sample (LBAS). It contains two radio galaxies, namely Centaurus A and NGC 1275, and 104 blazars consisting of 57 flat spectrum radio quasars (FSRQs), 42 BL Lac objects, and 5 blazars with uncertain classification. Four new blazars were discovered on the basis of the LAT detections. Remarkably, the LBAS includes 10 high-energy peaked BL Lacs (HBLs), sources which were so far hard to detect in the GeV range. Another 10 lower-confidence associations are found. Only thirty three of the sources, plus two at $|\mathbf{b}| < 10^{\circ}$, were previously detected with *EGRET*, probably due to the variable nature of these sources. The analysis of the gamma-ray properties of the LBAS sources reveals that the average GeV spectra of BL Lac objects are significantly harder than the spectra of FSRQs. No significant correlation between radio and peak gamma-ray fluxes is observed. Blazar log N - log S and luminosity functions are constructed to investigate the evolution of the different blazar classes, with positive evolution indicated for FSRQs but none for BLLacs. The contribution of LAT-blazars to the total extragalactic γ -ray intensity is estimated.

1. Introduction

The Gamma ray Large Area Space Telescope (GLAST) was launched on 11 June 2008, and re-⁴¹ named the Fermi Gamma Ray Space Telescope shortly after entering its scientific operating mission, ⁴² which began on 11 August, 2008. The Large Area Telescope (LAT) on Fermi provides an increase ⁴³ in sensitivity by more than an order-of-magnitude over its predecessor EGRET, the Energetic ⁴⁴ Gamma Ray Experiment Telescope on the Compton Gamma Ray Observatory (Thompson et al. ⁴⁵ 1993), and the Italian Space Agency Satellite AGILE (Astro-rivelatore Gamma a Immagini Leg-⁴⁶ gero; Tavani et al. 2008). In sky survey mode, the LAT observes all parts of the sky every 3 hours, ⁴⁷ providing effectively uniform exposure on longer timescales.

One of the major scientific goals of the *Fermi Gamma Ray Space Telescope* is to provide new 49 data about γ -ray activity of AGNs. Rapidly varying fluxes and large luminosities of extragalactic 50 γ -ray sources are best explained if the γ rays are emitted from collimated jets of charged particles 51 moving at relativistic speeds (Blandford & Rees 1978; Maraschi et al. 1992). *Fermi*-LAT observa-52 tions will help determine how these particles are accelerated, where the gamma rays are emitted, 53 what the energy and power budgets of the supermassive black-hole engines are, what this says for 54 the fueling and growth of black holes, and the reasons for the differences between radio-loud and 55 radio-quiet AGNs, and FSRQs and BL Lac objects. These are just a few of the questions that 56 γ -ray AGN studies with the *Fermi*-LAT are helping to answer (see Atwood et al. 2009, for more 57 discussion of these goals).

In a companion publication (Abdo et al. 2009c), 132 bright sources at $|b| > 10^{\circ}$ with test

statistic (TS) > 100 are found in the preliminary three month *Fermi* all-sky survey. As expected from the EGRET legacy, a large fraction of these sources are AGNs. Detailed results of the subset of the *Fermi* bright source list that are associated with AGNs are presented here.

Sixty-six high-confidence blazars are listed in the Third *EGRET* catalog of high-energy gamma-63 ray sources (3EG catalog; Hartman et al. 1999), with the majority of them, $\approx 77\%$, identified 64 as flat spectrum radio quasars (FSRQs), and the remaining $\approx 23\%$ identified as belonging to 65 the BL Lac class.¹ The recently released catalog of high-confidence *AGILE* gamma-ray sources² 66 (Pittori et al. 2008) shows a somewhat higher percentage of BL Lacs. Unlike AGN surveys at 67 optical or X-ray energies, in which the majority of AGNs are radio quiet (e.g., della Ceca et al. 68 1994; Ivezić et al. 2002), all AGNs detected at $\gtrsim 100$ MeV energies are also significant radio sources. 69 This includes the 3EG and *AGILE* blazars, which are so far identified with flat spectrum (radio 70 spectral index $\alpha_r > -0.5$ at GHz frequencies) radio-loud AGNs, and most show superluminal 71 motion (Jorstad et al. 2001; Kellermann et al. 2004). Moreover, the redshift distribution is broad, 72 with the largest redshift AGN known in the 3EG catalog at z = 2.286.

Here we present a source list of bright AGNs found in the set of the 132 bright LAT sources at 74 $|b| > 10^{\circ}$. Identification of variable γ -ray sources with blazars depends on the statistical likelihood 75 of positional association and correlated variability of the γ -ray emissions with lower-frequency 76 radiations (e.g. Sowards-Emmerd et al. 2003). The 106 sources having high-confidence associations 77 with known blazars and radio-galaxies constitute the LAT Bright AGN Sample (LBAS). Included in 78 this list are mean fluxes, weekly peak fluxes, spectral indices, locations, and variability information. 79 Only sources with confidence levels greater than 10σ are retained in the LBAS. This list is not, 80 however, complete, as we already know of many more sources at lower significance. The limiting 81 flux depends on both the source sky location and the spectral hardness.

In Section 2, observations with the LAT, analysis methods, and the source detection procedure are presented. Section 3 describes the association method and gives the list of bright *Fermi*-LAT detected blazars. Key properties of the LBAS, including flux and spectral index, are presented to so the radio/gamma-ray connection. Population studies, including source types and redshifts, are presented in Section 7, where the log N - log S flux distributions and luminosity functions of the LBAS are constructed. The results are discussed in Section 8, including implications of the results of the results are volution. We summarize in Section 9.

In the following we use a Λ CDM cosmology with values given within 1 σ of the WMAP results 91 (Komatsu et al. 2008), namely h = 0.71, $\Omega_m = 0.27$ and $\Omega_{\Lambda} = 0.73$. Here the Hubble constant

¹In contrast to the prominent optical emission lines found in FSRQs, BL Lac objects are radio-loud, rapidly variable sources displaying nearly featureless continua with emission-line equivalent widths < 5 Å (for review, see Urry & Padovani 1995).

 $_{92} H_0 = 100h \text{ km s}^{-1} \text{ Mpc}^{-1} \text{ is used.}$

93

2. Observations with the Large Area Telescope

The Fermi-LAT is a pair-conversion gamma-ray telescope sensitive to photon energies greater 95 than 20 MeV. It is made of a tracker (composed of two sections, front and back, with different 96 capabilities), a calorimeter and an anticoincidence system to reject the charged-particle background. 97 The LAT has a large peak effective area ($\sim 8000 \text{ cm}^2$ for 1 GeV photons in the event class considered 98 here), viewing ≈ 2.4 sr of the full sky with excellent angular resolution (68% containment radius 99 $\approx 1^{\circ}$ at E = 1 GeV for the front section of the tracker and about a factor of 2 larger for the back 100 section). A full description of the LAT instrument and its predicted performance are reported in 101 Atwood et al. (2009). During the first year, the telescope operates in sky-survey mode observing 102 the whole sky every 3 hours. The overall coverage of the sky is fairly uniform, with variations of 103 around $\simeq 15\%$ around the mean value.

The LAT data used here were collected during the first 3-month all-sky survey, from August 4 105 to October 30 2008. We refer to the companion paper (Abdo et al. 2009c) for a full description of 106 the data selection and analysis. In order to avoid background contamination from the bright Earth 107 limb, time intervals where the Earth entered the LAT Field-of-View (FoV) were excluded from this 108 study (corresponding to a rocking angle < 47 deg). In addition, events that were reconstructed 109 within 8° of the Earth limb were excluded from the analysis (corresponding to a zenith angle cut 110 of 105°). Due to uncertainties in the current calibration, only photons belonging to the "Diffuse" 111 class with energies above 100 MeV were retained. These photons provide the purest gamma-ray 112 dataset. The energy range was even more restricted in the source detection and spectral fitting 113 analyses described below, where only photons with E >200 MeV were selected. The list of sources 114 reported in Tables 1 and 2 was obtained as the result of the source detection, localization and 115 significance estimate analyses described in detail in Abdo et al. (2009c).

The source detection step made use of two wavelet algorithms, (mr_filter) (Starck & Pierre 117 1998) and (PGWAVE) (Ciprini et al. 2007). The algorithms were run independently for different 118 energy bands associated with different localization power and the results were cross-checked. The 119 positions of the sources for which the detection significance was above threshold (4σ) were then 120 refined using (*pointfit*), a simplified likelihood method (see Abdo et al. (2009c)). This algorithm 121 uses photons with E>500 MeV and returns the optimized sky position as well as an estimate of the 122 error radius for most detected sources. As discussed in Abdo et al. (2009c), the final error in the 123 source position was estimated by multiplying the error radius returned by the algorithm by a factor 124 close to 1.4 and adding 0.04° in quadrature (estimated from the residuals between the estimated 125 and expected position of Vela). The 95% confidence error radius was then evaluated assuming a 126 2-D normal distribution.

¹²⁷ To better estimate the source significance, we used the maximum likelihood algorithm imple-

¹²⁸ mented in (*gtlike*) a tool that is part of the standard *Fermi*-LAT *ScienceTools* software package³. ¹²⁹ The flux, photon index and test statistic (TS) of each source in the energy range 0.2-100 GeV were $_{130}$ determined by analyzing regions of interest (ROI) typically 15° in radius. The model of the ROI ¹³¹ used to fit the data was built taking into account of all the sources detected within a given ROI. 132 The isotropic background and Galactic Diffuse background models used in the fit are discussed in 133 Abdo et al. (2009c). Each source was modeled with a simple power law (kE^{- Γ}) for photons E> 200 ¹³⁴ MeV. The flux [E>100 MeV] (F₁₀₀), which is conventionally reported, was then calculated with the 135 fitted parameters. This flux will be used throughout this paper. The spectral energy distributions ¹³⁶ of some bright sources show clear evidence for a break or curvature. A fit with a single power law ¹³⁷ function is certainly not the most appropriate choice for these sources but the resulting photon 138 index does reflect the spectral hardness. A more detailed spectral analysis of the LBAS sources 139 is beyond the scope of this paper. The source fluxes were also estimated by fitting independent ¹⁴⁰ power law functions in two energy bands (0.1-1 GeV) and (1-100 GeV) and summing up the two ¹⁴¹ obtained fluxes. These fluxes (F_25 in Table 3) are the same as those reported in the *Fermi* bright ¹⁴² source list paper (Abdo et al. 2009c). For most sources, the fluxes obtained by the two methods $_{143}$ are consistent within 30%.

The same procedure was applied to generate weekly light curves (spanning a 12-week period). ¹⁴⁵ From those, the weekly peak flux as well as a variability index (corresponding to a simple χ^2 ¹⁴⁶ criterion) were derived. The variability tag reported in this paper is set for sources associated with ¹⁴⁷ a probability of being constant lower than 1%. A few representative light curves are displayed in ¹⁴⁸ Fig. 1.

This analysis was performed with the preflight instrument response functions (P6_V1). In ¹⁵⁰ flight, the presence of pile-up signals in the LAT tracker and calorimeter left by earlier particles ¹⁵¹ was revealed in periodic-trigger events. This feature leads to a reduction of the real acceptance as ¹⁵² compared to the predicted one as fewer events pass the rejection cuts, most notably for low-energy ¹⁵³ photons. The magnitude of this reduction is still under investigation, but the fluxes reported here ¹⁵⁴ may be lower than the true ones by as much as 30% and the photon indices greater than the true ¹⁵⁵ ones by as much as 0.1 (true spectra could be softer by 0.1 unit in the photon index). Because ¹⁵⁶ of the current uncertainty, no correction has been applied to the results. This uncertainty applies ¹⁵⁷ uniformly to all sources. Our relative errors are much smaller (about 3% on the flux, Abdo et al. ¹⁵⁸ 2009c). With the acceptance used in this analysis, the measured fluxes of the 3 bright pulsars, ¹⁵⁹ Vela, Geminga and Crab (Abdo et al. 2009c) are found to be compatible within 11% with those ¹⁶⁰ reported in the 3EG catalog.

Fig. 2 shows the 3-month flux sensitivity for TS=100 and a photon index=2.2 as a function of the sky position, calculated by a semi-analytical, maximum likelihood estimate of the significance. This estimate takes the actual exposure, the PSF and the different backgrounds (galactic diffuse, textragalactic diffuse and instrumental) into account. The limiting flux is higher at low galactic

³http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Cicerone/

¹⁶⁵ latitude due to a higher galactic diffuse background and close to the celestial south pole (l $\simeq 302^{\circ}$, ¹⁶⁶ b $\simeq -27^{\circ}$) where the exposure is lower.

The final result of the detection analysis is a list of 205 sources with a (TS > 100, ~ 10 σ), 167 The final result of the detection analysis is a list of 205 sources with a (TS > 100, ~ 10 σ), 168 composing the LAT Bright Source (0FGL) list (see Table 6. in Abdo et al. 2009c). For comparison, 169 31 sources detected by EGRET have a significance greater than 10 σ in the 3EG (Hartman et al. 170 1999) and EGR (Casandjian & Grenier 2008) catalogs. Of these, only 13 were detected at $|b| > 10^{\circ}$. 171 In the 0FGL, a total of 132 sources, including 7 pulsars, are present at $|b| > 10^{\circ}$. We have explored 172 the possibility of associating AGNs with the 125 remaining sources.

3. Source association

Any source association procedure primarily relies on spatial coincidence. Fig. 3 shows the 175 95% error radius vs (TS) for the sources considered here. This radius depends on both the flux 176 and the photon index, with a mean of 0.14°. For comparison, the average corresponding radius 177 for the blazars in the 18 month *EGRET* sky survey is 0.62°. Of the 186 |b| > 10° 3EG sources, 178 66 (35%) had "high" (but unspecified) confidence positional associations with blazars in the 3EG 179 catalog. Another 27 positional coincidences were noted at lower significance. Although subsequent 180 work (e.g. Mattox et al. 2001; Sowards-Emmerd et al. 2003) did find additional associations, ~40% 181 of the high-latitude 3EG sources remained unidentified.

Although the LAT localization accuracy is much better than those of previous gamma-ray tele-¹⁸³ scopes, it is not good enough to enable a firm identification of a LAT source based solely on spatial ¹⁸⁴ coincidence. For the LAT, a firm identification is assumed only if correlated variability is observed ¹⁸⁵ at different wavelengths. In order to find associations between LAT sources and AGNs, two differ-¹⁸⁶ ent approaches were pursued. The first method is based on a procedure similar to that developed ¹⁸⁷ by Sowards-Emmerd et al. (2003) for associating *EGRET* blazars with radio counterparts using an ¹⁸⁸ observational figure of merit (FoM). The second one is based on the calculation of source association ¹⁸⁹ probabilities following a Bayesian approach (de Ruiter et al. 1977; Sutherland & Saunders 1992), ¹⁹⁰ similar to that used by Mattox et al. (2001) to associate *EGRET* sources with radio sources. This ¹⁹¹ method is described in Abdo et al. (2009c).

Several catalogs were used by the two association methods, the most important ones being 193 the Combined Radio All-Sky Targeted Eight GHz Survey (CRATES; Healey et al. 2007) catalog 194 and the *Roma-BZCAT*⁴ (Massaro et al. 2007). The CRATES catalog contains precise positions, 195 8.4 GHz flux densities, and radio spectral indices for more than 11,000 flat-spectrum sources over 196 the entire $|b| > 10^{\circ}$ sky. The *Roma-BZCAT* is a master list of blazars based on an accurate 197 examination of literature data and presently includes about 2700 sources, all observed at radio 198 and optical frequencies and showing proper characteristics of blazars. Sources are classified as BL

173

⁴http://www.asdc.asi.it/bzcat

¹⁹⁹ Lacertae objects (BZB), flat spectrum radio quasars (BZQ) or as blazars of uncertain type (BZU).

200

3.1. The Figure-of-Merit Method

The figure of merit (FoM) approach requires a large, uniform all-sky sample of radio sources from which to draw; for this purpose, we use the Combined Radio All-Sky Targeted Eight GHz Survey (CRATES; Healey et al. 2007) catalog. In order to quantify the correlation between CRATES sources and LAT detections, we compare the average number of positional coincidences between LAT sources and CRATES sources to the number of positional coincidences between LAT sources and sources drawn from 1,000 randomized simulations of the radio sky. We count as a positional coincidence any occurrence of a radio source (real or simulated) within twice the 95% error radius of a LAT source, and we generate the simulated radio skies by scrambling the Galactic coordinates post the CRATES sources while keeping their radio flux densities, spectral indices, and counterpart RASS fluxes intact.

We define the excess fractional source density of radio/ γ -ray matches as $n = 1 - (N_{\text{rand}}/N_{\text{CRATES}})$ 211 ²¹² and we compute this quantity in bins of radio flux density $S_{8.4}$ at 8.4 GHz, radio spectral index α , ²¹³ and X-ray flux F_X from the ROSAT All-Sky Survey (RASS; Voges et al. 1999). These functions— $214 n(S), n(\alpha), \text{ and } n(F_X)$ — constitute the counterpart spectral energy distribution (SED) components ²¹⁵ of the FoM. The final component is the dependence on the offset between the radio position and 216 the LAT position, which we model simply as $n_{\rm pos} = 1 - CL$, where CL is the confidence limit ²¹⁷ of the LAT localization contour passing through the radio position. The FoM is then given by $_{218}$ 100 × n(S) × $n(\alpha)$ × $n(F_X)$ × n_{pos} . To evaluate the significance of the FoM, we again generated, in ²¹⁹ the manner described above, 1,000 random simulations of the radio sky and computed the average ²²⁰ distribution of FoM. We compared this to the distribution of FoM for the real CRATES sky by ²²¹ again computing the excess fractional source density as a function of FoM. This fractional excess 222 can be directly interpreted as a probability P_i of radio/ γ -ray association for source i, giving an ²²³ immediate mapping from FoM to association probability for each individual source (i.e., $1 - P_i$ is ²²⁴ the probability of a false positive association). We find that 1,000 simulated skies result in sufficient 225 statistics in each FoM bin to ensure that the mapping is robust. Very similar results are obtained 226 with 10,000 simulations.

The results of this association procedure are shown in Table 1 and Table 2. Most of the associated radio sources are in the Candidate Gamma-Ray Blazar Survey (CGRaBS; Healey et al. 229 2008), an optical survey of the 1,625 CRATES sources that were most similar in their radio and 230 X-ray properties to the 3EG blazars. Optical spectroscopy of the sources with unknown redshifts is 231 ongoing. We also considered the possibility of an association with a non-CRATES radio source when 232 no CRATES association was found. Indeed, a FoM can be computed for any object for which the 233 necessary radio data are available. Thus, for those LAT sources without CRATES associations, we 234 drew candidate counterparts from the 1.4 GHz NRAO VLA Sky Survey (NVSS; Condon et al. 1998) 235 or the 843 MHz Sydney University Molonglo Sky Survey (SUMSS; Mauch et al. 2003), searched ²³⁶ NED for archival 8.4 GHz data, and calculated the FoM for each candidate. These procedures ²³⁷ find high-confidence (P > 0.90) associations for 101 of the 125 non-pulsar sources in the 0FGL ²³⁸ list with $|b| > 10^{\circ}$ for an association rate of 81%. We also find low-confidence FoM associations ²³⁹ (0.40 < P < 0.90) for 14 more sources, bringing the total association rate to 92%. Thus, the ²⁴⁰ radio-bright blazar population continues to dominate the extragalactic sky.

The individual association probabilities can be used to estimate the number of false positives 242 in a given sample: if the probabilities P_i are sorted from highest to lowest, then the number of false 243 positives in a sample of k sources is $N_{\text{false}} \approx \sum_{i=1}^{k} (1 - P_i)$. Among the high-confidence associations, 244 there are ~3 false positives, and less than one of the 74 most probable associations should be false.

We also studied the power of the FoM analysis to reject a blazar association for a LAT source. 245 246 We considered NVSS/SUMSS sources in the direction of the unassociated LAT sources and com-²⁴⁷ puted the FoM that each source would have if (A) it were as bright as the 4.85 GHz flux density 248 upper limit from the Green Bank 6 cm survey (GB6; Gregory et al. 1996) or the Parkes-MIT-NRAO 249 survey (PMN; Griffith & Wright 1993) (unless the source had an actual GB6/PMN detection, in ²⁵⁰ which case we used the measured flux density) or (B) its radio spectrum were as severely inverted $_{251}$ as $\alpha = +0.75$ between 1.4 GHz and 4.85 GHz, whichever constraint was tighter. From the low-252 frequency radio spectrum (or upper limits), we extrapolated the implied 8.4 GHz flux density. If ²⁵³ the resulting FoM indicated that the source could conceivably be a flat-spectrum blazar, then we 254 drew no conclusion, but if we found that the "best-case" association probability were 0%, then 255 we concluded that the LAT source was not associated with any typical member of the population 256 of flat-spectrum blazars, and we refer to such cases as "anti-associations." Note that the spectral $\alpha = +0.75$ is an extremely conservative cutoff. The most inverted radio spectrum for any 258 actual association has $\alpha < 0.65$. We are able to secure anti-associations for 10 sources. In fact, five ²⁵⁹ of these turn out to be high-latitude LAT pulsars and pulsar candidates. This shows that, given a ²⁶⁰ reliable LAT error circle, the FoM analysis is capable of indicating definitively that a source is not 261 a blazar

262

3.2. Summary of association results

The combination of the FoM (described above) and positional association methods yields a number of 106 high-confidence ($P \ge 0.90$) associations (constituting the LBAS) and 11 lowconfidence (0.40 < P < 0.90) associations listed in Table 1 and 2 respectively. Simple extrapolation of these numbers implies that the LAT should be detecting some 20-25 blazars through the Galactic plane at $|b| < 10^{\circ}$. Indeed, several have already been located, e.g. 0FGL J0036.7+5951 (1ES 0033+595), 0FGL J0730.4-1142 (PKS 0727-11), 0FGL J0826.0-2228 (PKS 0823-223), 0FGL J1802.6-3939 (PMN J1802-3940), 0FGL J1833.4-2106 (PKS 1830-211). A more complete search of Galactic background blazars, incorporating spectrum, variability and multiwavelength properties is in progress. Tables 1 and 2 report, for each source, the LAT name, the name of the associated source 273 based on the FoM method, the value of the FoM parameter and its probability, the name of the 274 positionally associated source and its probability, the redshift and the AGN class. Fig. 4 shows 275 the sky location of the LBAS AGNs.

One source, 0FGL J10340+6051 reported in Table 1, merits special comment. Two radio 277 associations were found by the FoM method for this γ -ray source, one with very high probability and 278 one with lower, but still significant, probability reported in Table 2. Although the high-probability 279 source likely dominates the γ -ray emission, it is entirely plausible that the low-probability source 280 contributes non-negligibly to the total γ -ray flux. We believe that as the LAT detects more sources 281 and confusion of the γ -ray sky increases, the power of the FoM formalism will become increasingly 282 important to the identification of multiple lower-energy counterparts of complex γ -ray sources.

Fig. 5 shows the overall, normalized angular separation distributions for both sets of sources 284 (i.e. high- and low-confidence associations). The solid curve corresponds to the expected distribu-285 tion (χ^2 distribution with 2 d.o.f.) for real associations, the dashed one for accidental associations. 286 This figure provides confidence that most associations are real. From this figure, it appears that the 287 1.4 correction factor applied to the error radius is somewhat overestimated. This overly conservative 288 factor will be significantly reduced with additional analysis updates.

Four new blazars were discovered. Two of these, CRATES J1012+2439, and CRATES J1032+6051 were classified as FSRQ blazars while CRATES J0144+2705 is a BL Lac. The classification of these three sources was made on the basis of the broad lines observed in their optical spectrum obtained after the LAT detection (Shaw et al., in preparation). The forth new LAT detected blazar is CLASS J1054+2210. Its classification as a BL Lac object was made possible by the analysis of its optical spectrum available at the SDSS on-line archive. As discussed above, CRATES J1032+6051 is the source which has a low probability to be associated with 0FGL J10340+6051.

The other sources listed in Table 1 and 2 were classified as FSRQ or BLLac following the *Roma*-BZCat and CRATES/CGRaBS catalogs. Some sources, which cannot be properly classified because of the scarcity of available data or which show optical spectra intermediate between those of BL Lacs, FSRQs or radio galaxies, were assigned to the "uncertain class" ("Unc" label in the ano tables).

Based on this classification, the LBAS comprises 57 FSRQs, 42 BL Lac objects, 5 blazars of uncertain type, and 2 radio-galaxies (RGs). The relevant *EGRET* sample of reference corresponds to that of the 18 month *EGRET* all-sky survey during Phase 1 of the CGRO mission (Fichtel et al. 1994; Dermer 2007). This survey had relatively uniform exposure, and contained 60 sources, 46 sof FSRQs, 14 BL Lacs. BL Lacs make up 40% of the LBAS blazars, a fraction significantly higher than found with *EGRET* (23%). The detection of hard sources (BL Lac objects, see below) by the LAT is intrinsically favored over soft ones (FSRQs). This is partly due to the strongly energy-dependent PSF. The larger bandpass and higher energy for the peak sensitivity (in the ~ 1-5 GeV range) of the LAT as compared to *EGRET* adds to this effect. Eleven LBAS sources are associated with blazars already detected in the TeV energy range by the ground based imaging air Cherenkov telescopes. Among these, 7 are classified as high-frequency peaked BL Lacs (HBLs): 1ES 1011+496, Mrk 421, PG 1553+11, Mrk 501, 1ES 1959+650, PKS 2005-489 and PKS 2155-304; 3 are low-frequency peaked BL Lacs (LBLs): 3C 66A, W Com and BL Lac and one is a FSRQ: 3C 279. These 11 sources represent more than 50% of the blazars detected so far (21). The results of simultaneous observations that cover the optical, Aharonian et al. (2009). Another three HBLs in the LBAS are not yet detected in the TeV range: KUV00311-1938, 1ES0502+675, B3 0133+388. A total of 10 HBLs are thus present in the LBAS, are remarkable feature given that sources in this class were difficult to detect in the GeV range. Many 220 of these sources were not particularly flaring at other wavelengths during the period of observation.

We compared the broad-band (radio, optical, X-ray) properties of our sample of *Fermi*-LAT detected blazars with those of the known blazars listed in the *Roma*-BZCat catalog and found that the broadband properties of the *Fermi*-LAT detected BL Lacs and FSRQs are consistent with the parent population of FSRQs and BL Lacs. This is illustrated in Fig. 6 displaying the soft X-ray flux set vs radio flux density (at 1.4 GHz) diagram for the Fermi-LAT blazars and the full blazar catalog.

The LBAS includes 13 sources (10 FSRQs and 3 BL Lacs) that were detected in a flaring state promptly announced to the community through Astronomical Telegrams. Among these, 0FGL J2254.0+1609, associated with 3C 454.3, is the brightest gamma-ray extra-galactic source observed in the 3-month *Fermi*-LAT survey and is studied in detail in Abdo et al. (2009a).

The *Fermi*-LAT has discovered gamma-ray emission from a source having an high-confidence an association with NGC 1275, the supergiant elliptical galaxy at the center of the Perseus galaxy cluster. EGRET observations yielded only an upper limit to the NGC 1275 gamma-ray emission. an All the details about the gamma-ray properties of this source will be reported in Abdo et al. (2009b).

³³⁴ Cen A is the nearest radio galaxy to us and it was one of the few radio galaxies associated with ³³⁵ a 3EG source (J1324–4314; Sreekumar et al. 1999). It is included in the LBAS and the position ³³⁶ of its nucleus is well inside the 95% confidence error radius of the source 0FGL J1310.6–4301. ³³⁷ The measured *Fermi* flux is $F_{100} \simeq 2.3 \times 10^{-7}$ ph cm⁻² s⁻¹, about a factor of 2 greater than that ³³⁸ measured by *EGRET* (Sreekumar et al. 1999).

Recently, two more sources reported in the 3EG catalog were tentatively associated with ato radio galaxies, 3C 111 (Hartman et al. 2008), and possibly NGC 6251 (Mukherjee et al. 2002; at Foschini et al. 2005). These objects are not LBAS sources but the number of radio-galaxies deat tected at high-energy is expected to increase in the near future as more data accumulate.

Table 4 lists the 33 sources associated with 3EG sources (two more located at $|b| < 10^{\circ}$ were at also incorporated). Three bright EGRET blazars associated with 0827+243, PKS 1622-297 and 345 1730-130 (NRAO 530), whose average EGRET fluxes are in the range of (25 - 47) ×10⁻⁸ ph(E >at 100 MeV) cm⁻² s⁻¹ do not appear in the LBAS. Presumably, these blazars are simply in a lower at flux state than when EGRET was in operation. These 3 sources are also among the 22 sources in ³⁴⁸ the pre-launch LAT monitored list⁵. Of these 22 sources, 17 have high-significance LAT detections ³⁴⁹ in the first 3-months of data. The remaining two monitored sources (H 1426+428, 1ES 2344+514) ³⁵⁰ did not have previous 3EG detections and thus were not expected to be very bright GeV sources.

We note that the LBAS object B2 0218+35 is a well-known gravitational lens. The source J52 PMN J0948+0022, associated with 0FGL J0948.3+0019, has a flat radio spectrum, but shows an optical spectrum with only narrow emission lines, making it an "uncertain"-type object in the J54 Roma-BZCat.

355

356

4. Gamma-ray properties of the LBAS

4.1. Introduction

Table 3 lists the key properties of the 116 sources associated with AGNs (sources with low-358 confidence associations are in italics): the name, equatorial and galactic coordinates, the TS pa-359 rameter measuring the significance of the detection, the photon index (Γ), the photon flux F₁₀₀, 360 the weekly peak flux, the photon flux F₂₅ and the variability flag. The uncertainties are statistical 361 only. From Table 3 (last column), 40 FSRQs (70%), 12 BL Lacs (29%) and 1 Uncertain blazar 362 (0FGL J0714.2+1934) present in the LBAS show evidence for variability. The observed variability 363 for FSRQs is thus higher than for BL Lacs. One must be careful in interpreting this result as the 364 flux distributions are different for the two classes (see Fig. 7), making the detection of variability 365 easier for FSRQs. An in-depth variability analysis of the LBAS is beyond the scope of this paper.

Table 4 gives similar parameters for the subset of 35 sources (including both high-confidence ³⁶⁷ and low-confidence associations, plus two at $|\mathbf{b}| < 10^{\circ}$) corresponding to 3EG sources. This subset ³⁶⁸ will be discussed in more detail in section 5.

The source photon index is plotted as a function of the flux in Fig. 7. It is already visible 370 in this figure that the photon indices of BL Lac objects (open circles) and FSRQs (closed circles) 371 are quite distinct. The flux sensitivity (calculated in the same way as for the map shown in Fig. 2 372 and depicted as solid lines for two different galactic latitudes) is fairly strongly dependent on the 373 photon index. The upper envelope in the spectral index - flux (>100 MeV) plot reflects that the 374 peak sensitivity of the LAT is at energies much higher than 100 MeV. These ranges of spectral 375 index and apparent flux limits translate to approximately constant limits above 1 GeV. For a 376 photon index of 2.2, the 10 σ flux sensitivity $F_{100} \simeq 5 \times 10^{-8}$ ph cm⁻² s⁻¹, about 3 times lower 377 than that of the Third *EGRET* catalog.

⁵http://fermi.gsfc.nasa.gov/ssc/data/policy/LAT_Monitored_Sources.html

4.2. Flux

It makes sense to compare the LBAS fluxes with those reported in the Third EGRET Catalog for the EGRET sample. As several analyses (e.g. Mücke & Pohl 2000; Dermer 2007) used the mean flux (maximum flux in all EGRET viewing periods), instead of the mean flux because of the fairly non-uniform coverage in the EGRET Catalog, comparisons will be performed both for mean and peak flux distributions. For *EGRET*, both distributions are biased as observations were preferentially made of sources known to be highly variable in the gamma-ray band, and some the observations were triggered by ToO requests when an object was brightly flaring in other wavebands. No such bias exists for the LAT.

Fig. 8a compares the mean flux distribution measured in the LBAS with that measured in the EGRET sample. The high-flux ends of these distributions look similar. This observation points EGRET sample. The high-flux ends of these distributions look similar. This observation points EGRET sample. The high-flux ends of these distributions look similar. This observation points EGRET sample constant global gamma-ray luminosity of detectable blazars at a given time, as can EGRET naively be expected. In stark contrast, the weekly peak flux distributions (Fig. 8b) look different, EGRET sample. This feature probably arises from EGRET sample. This feature probably arises from EGRET here, a given source had much less opportunity to explore very different states than in EGRET observations were conducted. Another illustration of this EGRET is given in Fig. 8c,d where the peak flux vs the mean flux and the peak flux/mean flux ratio EGRET variability timescales of months to years is well confirmed by the observation that only $\simeq 30\%$ of EGRET blazars are still detected by the LAT at a comparable flux.

399

4.3. Photon index

The photon index distribution gives insight into the emission and acceleration processes acting 401 within the AGN jets, as it enables some of the physical parameters involved in these processes to 402 be constrained. Moreover, it can be used to test whether the BL Lac and FSRQ populations have 403 different γ -ray emission properties.

Fig. 9 top displays the photon index distribution for all the LBAS sources. This distribution 405 looks fairly similar to that observed for the *EGRET* sample (Nandikotkur et al. 2007): it is roughly 406 symmetric and centered at $\gamma = 2.25$. The corresponding distributions for FSRQs and BL Lacs are 407 shown in Fig. 9 middle and bottom respectively. These distributions appear clearly distinct, with 408 little overlap between them. This is a remarkable feature, given that the statistical uncertainty 409 typically amounts to 0.1 for most sources. The distributions have (mean, rms)=(1.99, 0.22) for 410 BL Lacs and (2.40, 0.17) for FSRQs. We used a Kolmogorov-Smirnov (KS) test to test the null 411 hypothesis that both index samples are drawn from the same underlying distribution and found

378

⁴¹² a probability of 2×10^{-12} ⁶. Although indications for the existence of two spectrally distinct ⁴¹³ populations (BL Lacs and FSRQs) in the *EGRET* blazar sample were mentioned in the literature ⁴¹⁴ (Pohl et al. 1997; Venters & Pavlidou 2007), this is the first time that the distinction appears so ⁴¹⁵ clearly. The mean photon index of the 10 HBLs included in the LBAS is 1.76, i.e significantly lower ⁴¹⁶ (sources are harder) than the mean of the whole BL Lac subset as expected for these high-energy ⁴¹⁷ peaked sources.

To infer physical properties of the blazar populations from the observed photon index distri-419 butions, possible instrumental and/or statistical effects have to be assessed. A systematic bias may 420 indeed arise in the likelihood analysis of sources with low photon statistics. To quantify this possi-421 ble bias we performed a simulation study with the *gtobssim* tool which is part of the *Science Tools*. 422 This tool allows observations to be simulated using the instrument response functions and the real 423 orbit/attitude parameters. Both instrumental and diffuse backgrounds were modeled on the basis 424 of the real backgrounds observed by the LAT.

1. Samples of sources (100 FSRQs and 100 BL Lacs) with random positions in the $|b| > 10^{\circ}$ sky were simulated.

427 2. The real spacecraft orbit and attitude profiles spanning 94 days starting from Aug 4 2008
428 were used.

3. The sources were assumed to have a power-law energy distributions. The photon index was drawn from a gaussian distribution with (mean, sigma)= (2.0,0.3) for BL Lacs and (2.3,0.3) for FSRQs. These distributions are referred to as "input" probability distribution functions (pdfs).

433 4. Fluxes were generated according to a lognormal distribution $f(x) = \frac{1}{x\sigma\sqrt{2\pi}} \exp \frac{-(\ln x - \mu)^2}{2\sigma^2}$ with 434 $\mu = \ln 10^{-7}$ and $\sigma = 0.4$

A likelihood analysis was performed for all sources. The pdfs of the spectral indices and fluxes
were built for sources with TS>100 ("like" pdfs). The TS cut was also applied to the "input"
pdfs.

Possible bias arising from the likelihood analysis as well as the robustness of the separation 439 between BL Lac and FSRQ "like " pdfs were studied by means of KS tests. "Input" and "like" pdfs 440 were found to be consistent with a probability of 99.5%, 88.4% for BLLacs and FSRQs respectively, 441 excluding any sizeable bias coming from the likelihood analysis. The TS cut was observed to only 442 affect the distribution tails. Concerning the separation between BL Lacs and FSRQs, the KS test 443 returned that the probability for the two distributions to result from the same parent distribution 444 is 7×10^{-7} .

 $^{^{6}}$ We are aware of the fact that the KS test is not optimal for binned data, but it is accurate enough to reject the null hypothesis

5. Sources already detected by EGRET

After an elapsed time of about 10 years, it is interesting to look at the fraction of the AGNs 446 447 that were active in the EGRET era and are detected again by the LAT with a comparable flux. 448 Out of 116 sources in the *Fermi*-LAT sample, 3 sources have positions compatible with sources in ⁴⁴⁹ the Third *EGRET* Catalog. Two additional sources, 0FGL J1802.6–3939 and 0FGL J1833.4–2106 $_{450}$ located at $|\mathbf{b}| < 10^{\circ}$ fulfills this condition as well. The 35 sources are listed in Table 4, along with 451 the mean fluxes and photon indices measured by the *Fermi*-LAT and *EGRET* as well as the AGN 452 class. These 35 AGNs are composed of 20 FSRQs, 11 BL Lacs, 3 of uncertain type and 1 AGN 453 (Cen A). The BL Lacs are again overrepresented (with a fraction of 31%) as compared to the 454 1st year sky survey EGRET sample (14 out of 60, i.e. 23%). The (non-simultaneous) fluxes and 455 indices measured by both intruments are compared in Fig. 12. The large scatter observed when 456 comparing the fluxes (Fig. 12 left) can be expected from the variable nature of the blazar emission. 457 The scatter observed when comparing the photon indices is more moderate, as could be expected 458 from the fairly strong correlation between photon index and blazar class mentioned above. For 459 many sources, and most especially for BL Lacs, the indices are measured by the Fermi-LAT with 460 a much better accuracy.

461

445

6. Radio gamma-ray connection

With 116/125 high |b|, non-pulsar LAT bright sources associated with radio sources in the 463 CRATES/CGRaBS and the *Roma*-BZCAT lists, we confirm the findings of the 3EG catalog. In 464 particular, 98/106 (~ 92%) of our high confidence associations have flux density above 100 mJy at 465 8.4 GHz. In terms of the radio luminosity $L_r = \nu L(\nu)$, the sources in the present sample with a 466 measured redshift span the range $10^{39.09} < L_r < 10^{45.33} \text{ erg s}^{-1}$. As shown by the histogram in Fig. 467 13, BL Lacs and FSRQ are not uniformly distributed in this interval, with the former on average 468 at lower radio luminosities ($\log L_{r, BL Lacs} = 42.8 \pm 1.1 \text{ [erg s}^{-1}$]) than the latter ($\log L_{r, FSRQ} =$ 469 44.4 ± 0.6 [erg s⁻¹]). Blazars of uncertain type generally lack a redshift. Of the two radio galaxies 470 associated with objects in the LBAS, NGC 1275 is similar to BL Lacs ($L_r = 10^{42.21} \text{ erg s}^{-1}$), while 471 Cen A lies at the very lower end of the radio power distribution, with $L_r = 10^{39.09} \text{ erg s}^{-1}$.

⁴⁷² Cen A, the source associated with 0FGL J1325.4–4303, is also the only source showing a ⁴⁷³ significant amount of extended radio emission at low frequency ($S_{8.4}/S_{low} = 0.005$). For all other ⁴⁷⁴ sources with a low frequency (typically, 365 MHz from the Texas survey, 325 MHz from the WENSS, ⁴⁷⁵ or 408 MHz from the B2) and a high frequency, high resolution (typically at 8.4 GHz from CRATES) ⁴⁷⁶ flux density measurement, we find little or no evidence of significant deviation from $L_{low} = L_{8.4}$. ⁴⁷⁷ Therefore, we find not only that all the sources in our sample are radio emitters, but that they ⁴⁷⁸ also possess compact cores with flat radio spectral index and much higher luminosity than those of ⁴⁷⁹ radio galaxies of similar or larger power (Giovannini et al. 1988).

480 Thanks to the comparatively large number of LBAS sources, it is worthwhile to perform a

⁴⁸¹ statistical comparison of their properties in the gamma-ray and radio bands. Previous studies based ⁴⁸² on EGRET data for 38 extragalactic point sources have been reported (Mücke et al. 1997), which ⁴⁸³ did not support claims of correlations between radio and gamma-ray luminosities. In particular, ⁴⁸⁴ the analysis of possible correlations needs to be treated with care, because of the many biases that ⁴⁸⁵ can arise, e.g. from the common redshift dependence when one considers luminosities, or from the ⁴⁸⁶ reduced dynamical range when one considers mean flux densities, just to name a few.

We have therefore looked at several possible pairs of observables, and we summarize our results in Table 5. In general, we apply the K-correction to the luminosities but not to the fluxes, since this would introduce a bias for the sources without a known redshift. We show in Fig. 14 (left and panel) the peak gamma-ray flux $S_{E>100 \text{ MeV}}$ vs the radio flux density $S_{8.4 \text{ GHz}}$ from CRATES (or and NED, in the few cases in which the source is not in the CRATES list). In general, BL Lacs tend to create correlations artificially from purely combining both populations. Given their different and redshift distributions, this would be even more apparent in the luminosity plane. For this reason, the redshift distributions, the significance of a radio-to-gamma-ray connection to be marginal at most on the analysis show the significance of a radio-to-gamma-ray connection to be marginal at most on the analysis of the present data, in particular for the FSRQs. Clearly, there is need for a deeper analysis and enlarged sample regarding this issue, including Monte-Carlo simulations, which we defer to an enlarged sample regarding this issue, including Monte-Carlo simulations, which we defer to an enlarged sample regarding this issue, including Monte-Carlo simulations, which we defer to an forthcoming paper.

Finally, we show in the right panel of Fig. 14 the radio luminosity vs. gamma-ray spectral index plane. Thanks to the large LAT energy range, the separation between BL Lacs and FSRQs is readily seen, showing a trend of softer spectral indices for more luminous radio sources. Moreover, this plot seems quite effective at finding sources of a different nature, such as the radio galaxy Cen A, whose gamma-ray index is much softer than that of other low power radio sources. For instance, 0FGL J00174-0503 is a FSRQ at z = 0.227 (Healey et al. 2008) with index = 2.71 and radio luminosity $L_r = 10^{42.36} \text{ erg s}^{-1}$, which could then be a rare case of low-energy peak and low radio luminosity blazar. The other source with large photon index (2.60) and comparatively low radio luminosity ($L_r = 10^{43.22} \text{ erg s}^{-1}$) is associated with the peculiar source PMN J0948+0022.

509

7. Population Studies

As described before, the LBAS includes 57 FSRQs, 42 BL Lac objects, 5 blazars of uncertain 511 type and 2 radio galaxies. Ten other sources have lower confidence associations with known blazars. 512 This sample is already comparable with that provided by EGRET and can be used to derive some 513 *early* results about the redshift and source count distributions and the luminosity function of blazars.

7.1. Redshifts

Fig. 15 and Fig. 16 display the redshift distributions for FSRQs and BL Lac objects, respec-516 tively, and their comparison with those of the parent distributions in the BZCat catalog. Please 517 note that 12 of 42 BL Lacs have no measured redshifts. BL Lac objects are generally found at low, 518 $z \leq 0.5$, redshift, whereas the peak of the FSRQ redshift distribution is around $z \approx 1$. Similar dis-519 tributions were observed for the *EGRET* blazars (Mukherjee et al. 1997). In the future, as fainter 520 sources become visible, detection of additional nearby radio-galaxies will enhance the number of 521 very low redshift objects in the AGN redshift distributions measured with the *Fermi* LAT.

Fig. 17 shows the luminosities of the detected sources plotted as a function of their redshifts. The isotropic gamma-ray luminosity L_{γ} was derived using:

$$L_{\gamma} = 4\pi S d_L^2 / (1+z)^{1-\alpha} \,. \tag{1}$$

⁵²² Here, S is the γ -ray energy flux (E > 100 MeV), α is the energy index and d_L is the luminosity ⁵²³ distance. A beaming factor $\delta = 1$ was assumed. The solid curve corresponds to a flux limit of F_{100} ⁵²⁴ = 4 × 10⁻⁸ ph cm⁻²s⁻¹.

525

526

7.2. log N - log S

7.2.1. Monte Carlo Simulations

Proper population studies must rely on a thorough understanding of the properties of the 527 ⁵²⁸ survey where these objects have been detected. In order to properly estimate the source-detection ⁵²⁹ efficiency and biases, we performed detailed Monte Carlo simulations. The method we adopted ⁵³⁰ is the one developed for ROSAT analysis (Hasinger et al. 1993) and lately used (Cappelluti et al. 531 2007) for the analysis of the XMM-COSMOS data. For each source population (blazars, FSRQs ⁵³² and BL Lacs) we created a set of >20 LAT all-sky images with background patterns resembling ⁵³³ as close as possible the observed ones. The simulations were performed using a similar method as 534 that described in section 4.3. An extragalactic population of pointlike sources was added to each 535 simulated observation. The coordinates of each source were randomly drawn in order to produce $_{536}$ an isotropic distribution on the sky. Source fluxes were randomly drawn from a standard log N- $_{537}\log S$ distribution with parameters similar to the one observed by LAT (see next section). Even ⁵³⁸ though the method we adopt to derive the survey sensitivity does not depend on the normalization $_{539}$ or the slope of the input log N-log S, using the real distribution allows us to produce simulated 540 observations which closely resemble the real LAT sky. The photon index of each source was also $_{541}$ drawn from a Gaussian distribution with observed mean and 1σ width consistent with the real ⁵⁴² population. Thus, for the three simulation sets we adopted the following photon indices similar to 543 the measured ones:

• 2.24 ± 0.25 for the total blazar population;

514

• 2.41 ± 0.17 for the FSRQ population;

• 1.98 ± 0.22 for the BL Lac population.

More than 30000 sources were simulated for each population. The mock observations were processed applying the same filtering criteria used for real in-flight data. Source detection was performed on E>200 MeV photons with a simplified version of the detection algorithm⁷. For every pair of input-output sources, we computed the quantity:

$$R^{2} = \left(\frac{x - x_{0}}{\sigma_{x}}\right)^{2} + \left(\frac{y - y_{0}}{\sigma_{y}}\right)^{2} + \left(\frac{S - S_{0}}{\sigma_{S}}\right)^{2}$$
(2)

⁵⁴⁷ where x, y and S are the source coordinates and flux of the detected sources while x_0, y_0 and S_0 are ⁵⁴⁸ the corresponding values of the input sources and $\sigma_x, \sigma_y, \sigma_S$ the associated statistical uncertainties. ⁵⁴⁹ We then flagged those with the minimum value of \mathbb{R}^2 as the most likely associations. Only sources ⁵⁵⁰ at $|b| \ge 10^\circ$ are retained.

The goal of these simulations is to derive the probability of detecting a source (with given 552 mean properties, e.g. photon index and flux) in the LAT survey as a function of source flux. This 553 can be computed from the simulations reported above as the ratio between the number of detected 554 and input sources in a given flux bin. The detection efficiencies for the three source populations 555 are reported in Fig. 18. A few things can be noted readily. First, the bias of the LAT survey 556 against soft sources (i.e. FSRQs) is apparent. Second, the LAT $|b| \ge 10^{\circ}$ survey becomes *complete* 557 for $F(>100 \text{ MeV}) \ge 2 \times 10^{-7} \text{ ph cm}^{-2} \text{ s}^{-1}$ irrespective of the source photon index or its location in 558 the sky. Multiplying these functions by the solid angle Ω of the survey (34089.45 deg² in case of a 559 $|b| \ge 10^{\circ}$ cut) yields the so called sky coverage which is used for the statistical studies reported in 560 the next sections.

561

7.2.2. Incompleteness of the Extragalactic Sample

We report in Table 6 the composition of the $|\mathbf{b}| \ge 10^{\circ}$ sample. The number of sources with high-confidence associations is 106. Of these 57 are FSRQs and 42 are BL Lacs. As already shown the previous sections, FSRQs and BL Lacs are represented in almost equal fractions in the LAT bigs survey. The 5 blazars with uncertain classifications are likely split between these two categories two categories as the redshift-luminosity plane (Fig. 17) shows. The incompleteness factor varies as a function of the sample under study. When considering the non-pulsar part of the high-confidence sample, the however, when considering the FSRQ and BL Lac samples separately one must also include the

⁷The complexity of the official detection algorithm makes it virtually impossible to apply it to a large number of data sets. We tested on real data that, for the scope of this investigation, our simplified detection algorithm produces results consistent with more elaborate ones.

⁵⁷⁰ sources with uncertain classifications. Thus the incompleteness factor of the FSRQ and BL Lac ⁵⁷¹ samples rises to ~ 15 %. A reasonable and simple hypothesis is one which assumes that these sources ⁵⁷² reflect the composition of the identified portion of the sample. This would mean that there are ⁵⁷³ an additional ~ 9 FSRQs and ~ 7 BL Lacs are hiding among the unidentified/unassociated/low-⁵⁷⁴ confidence sources. These uncertainties will be used in the next sections.

7.2.3. Source Counts Distributions

581

The source counts distribution, also known as the log N-log S, flux, or size distribution, is readily computed once the sky coverage is known through the expression:

$$N(>S) = \sum_{i=1}^{N_S} \frac{1}{\Omega_i} \deg^{-2},$$
(3)

where N_S is the total number of detected sources with fluxes greater than S, and Ω_i (i.e. Fig. 18 multiplied by the solid angle) is solid angle associated with the flux of the *i*th source. The variance of the source number counts is defined as

$$\sigma_i^2 = \sum_{i=1}^{N_S} \left(\frac{1}{\Omega_i}\right)^2. \tag{4}$$

⁵⁸² In building the source counts distributions, we used the source flux averaged over the three month ⁵⁸³ timescale. The log N-log S of the entire extragalactic sample (excluding pulsars) is shown in ⁵⁸⁴ Fig. 19.

We fitted the source counts distribution with a power-law model of the type:

$$\frac{dN}{dS} = n(S) = A \left(\frac{S}{10^{-7}}\right)^{-\alpha}.$$
(5)

A common practice in this case (e.g., see Ajello et al. 2008) is to fit the unbinned dataset employing a maximum likelihood (ML) algorithm. For this purpose the ML estimator can be written as

$$\mathcal{L} = -2\sum_{i} \ln \frac{n(S_i)\Omega(S_i)}{\int n(S)\Omega(S)dS} , \qquad (6)$$

⁵⁸⁵ where *i* runs over the detected sources. The 1σ error associated to the fitted parameters (in this ⁵⁸⁶ case α) is computed by varying the parameter of interest, while the others are allowed to float, ⁵⁸⁷ until an increment of $\Delta \mathcal{L}=1$ is achieved. This gives an estimate of the 68% confidence region for ⁵⁸⁸ the parameter of interest (Avni 1976). In this formulation of the ML function, the normalization ⁵⁸⁹ A is not a parameter of the problem. Once the slope α is determined, the normalization is derived ⁵⁹⁰ as the value which reproduces the number of observed sources. An estimate of its statistical error ⁵⁹¹ is given by the Poisson error of sources used to build the log N-log S.

Since the sky coverage is somewhat uncertain at very low fluxes, the fit is performed above $F(>100 \text{ MeV})= 7 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ even though all the data are displayed. The results of the best fits to the different source counts distributions are summarized in Table 7. It is clear that all fits to the different source counts distributions are summarized in Table 7. It is clear that all for distributions are compatible, within their errors, with a Euclidean distribution ($\alpha = 2.5$). In order to check the stability of our results we have shifted the sky coverage of Fig. 18 by 20% on either fits the best fit values of the slope are 2.47 and 2.62 for the -20% and +20% case respectively. These values are consistent within the error (e.g. 2.59 ± 0.12), showing that at bright fluxes our analysis for does not suffer from major systematic uncertainties in the sky coverage. The same result holds for for the other log N-log S distributions reported in Table 7.

The log N- log S distributions for FSRQs and BL Lacs are shown in Fig. 20 and 21. We do for not find any indication of a break in the source counts distributions of the two populations. As the fitting results of Table 7 show, there might be an intrinsic difference between the log N-log Sfor of both populations, with the source counts distribution of BL Lacs being flatter than that of of FSRQs. However, both of them are compatible within 1 σ errors with the Euclidean value of 2.5. Moreover, the analysis of the *flux-limited* sample (see bottom part of Table 7) confirms the results for of the main sample, showing that incompleteness is not a main issue in this study.

For the *EGRET* sample, a surface density for $F_{100} \ge 10^{-7}$ ph cm⁻² s⁻¹ of FSRQs and BL Lacs of 3.31 sr⁻¹ and 0.83 sr⁻¹, respectively, is reported (Mücke & Pohl 2000). From LAT we derive that the surface density (above $F_{100} \ge 10^{-7}$ ph cm⁻² s⁻¹) of FSRQs and BL Lacs is 4.41±0.72 sr⁻¹ and $_{12} 1.01\pm 0.17$ sr⁻¹ respectively. Thus the LAT results are in good agreement with *EGRET*.

A measurement of the number fluence using the average three-month fluxes of bright *Fermi* blazars of different classes is readily obtained from the log N-log S distributions through the expression:

$$F_{diffuse} = \int_{f_{min}}^{f_{max}} \frac{dN}{dS} S \, dS \,. \tag{7}$$

⁶¹³ Unless otherwise stated, we adopt a value for f_{min} of 4×10^{-8} ph cm⁻² s⁻¹. To compare with the ⁶¹⁴ EGRET results, the upper limit of integration cannot be set to infinity. Indeed, all point sources ⁶¹⁵ detected above $F_{100} \sim 10^{-7}$ ph cm⁻² s⁻¹ in the Second EGRET Catalog (2EG; Thompson et al. ⁶¹⁶ 1995) were subtracted in the measurement of the extragalactic diffuse γ -ray background (EDGB) ⁶¹⁷ (Sreekumar et al. 1998). Thus, we set f_{max} to 10^{-7} ph cm⁻² s⁻¹. The integral in Eq. 7 yields a ⁶¹⁸ total flux of $1.06(\pm 0.09) \times 10^{-6}$ ph cm⁻² s⁻¹ sr⁻¹ This can be compared with the intensity of the ⁶¹⁹ EDGB, as measured by EGRET, of 1.45×10^{-5} ph cm⁻² s⁻¹ sr⁻¹. Already in this small flux range, ⁶²⁰ LAT is resolving into pointlike sources $\sim 7 \%$ of the *EGRET* EDGB. Preliminary analysis of the log ⁶²¹ N-log S distributions shows that LAT is expected to resolve a much larger fraction of the EDGB ⁶²² within the next few months of observation.

623

7.3. Evolution of Blazars

624 7.3.1. Evolutionary Test

A simple and robust test of evolution is the V/V_{MAX} test Schmidt (1968). The quantity V/V_{MAX} is the ratio between the (comoving) volume within which the source has been detected and the maximum comoving volume available for its detection. For a given source, V/V_{MAX} is expected to be uniformly distributed between 0 and 1. For a population uniformly distributed in Euclidean space (and with constant properties with z) and non-evolving, the average V/V_{MAX} sources. A value of $< V/V_{\text{MAX}} > 0.5$ indicates positive evolution (more sources or brighter sources at earlier times), and the opposite indicates negative evolution.

The comoving volume for a *ith* source is given by

$$V = \int_{z=0}^{z=z_i} \frac{dV}{dz} \ \Omega(L_i, z) dz, \tag{8}$$

⁶³³ where dV/dz is the comoving volume element per unit redshift and unit solid angle (see e.g. Hogg ⁶³⁴ 1999) and $\Omega(L_i, z)$ is the aforementioned sky coverage for the source with rest-frame luminosity ⁶³⁵ L_i at redshift z. We note that the definition of the V/V_{MAX} reported in Eq. 8 encompasses also ⁶³⁶ the definition of the V_e/V_a test (Avni & Bahcall 1980), which for the purposes here are formally ⁶³⁷ equivalent.

⁶³⁸ We computed the average $\langle V/V_{MAX} \rangle$ for FSRQs, BL Lacs and all sources in the high-⁶³⁹ confidence sample with measured redshift (these includes the sources with uncertain classification). ⁶⁴⁰ The results are summarized in Table 8. All 57 FSRQs present in the extragalactic sample (see ⁶⁴¹ Table 6) have a measured redshift. The V/V_{MAX} shows that the population of FSRQs detected ⁶⁴² by LAT evolves positively (i.e. there were more FSRQs in the past or they were more luminous) ⁶⁴³ at the 3σ level. This result is also confirmed by the analysis of the 29 FSRQs which constitute a ⁶⁴⁴ flux-limited sample (see lower part of Table 6).

Only 31 out of the 42 BL Lac objects have a measured redshift. The V/V_{MAX} test is compatible within ~ 1 σ with no evolution. Assigning the mean redshift value of the BL Lac sample (i.e. $\langle z \rangle = 0.38$) to those objects without a without a redshift produces a value of $\langle V/V_{\text{MAX}} \rangle = 0.472 \pm 0.046$. The result does not change if the redshift is drawn from a Gaussian distribution with mean and dispersion consistent with the observed redshift distribution of BL Lacs. However, it is difficult to assess the validity of both these hypotheses. Indeed, the fact that these objects show a featureless for continuum might suggest that their redshifts could be the largest in the sample (Padovani et al. ⁶⁵² 2007). In this case, their true redshift would produce a larger value of the V/V_{MAX} statistic. The ⁶⁵³ V/V_{MAX} of all the objects with a measured redshift in the high-confidence sample is compatible ⁶⁵⁴ with no evolution.

655

7.3.2. Luminosity Function of FSRQs

We estimate the gamma-ray luminosity function (GLF) in fixed redshift bins using the $1/V_{MAX}$ method (equivalent in our formalism to the $1/V_a$ method). For each bin of redshift the GLF can be expressed as

$$\Phi(L_{\gamma}, z) = \frac{dN}{dL_{\gamma}} = \frac{1}{\Delta L_{\gamma}} \sum_{i=1}^{N} \frac{1}{V_{MAX,i}}$$
(9)

⁶⁵⁶ where $V_{MAX,i}$ is the maximum comoving volume associated with the i_{th} source (see Eq. 8). The ⁶⁵⁷ cumulative and differential luminosity functions of FSRQs, in three redshift bins, are reported in ⁶⁵⁸ Fig. 22. One thing is readily apparent from this figure. FSRQs are strongly evolving. A non-⁶⁵⁹ evolving population would have GLFs which are continuous across different redshift bins. In the ⁶⁶⁰ case of FSRQs we note a change in space density (or luminosity) with redshift. Also, one can see ⁶⁶¹ that the space density of intermediate-luminosity FSRQs (e.g. $L_{\gamma} \sim 10^{47} \text{ erg s}^{-1}$) is increasing with ⁶⁶² redshift. On the other hand, the most luminous FSRQs have an almost constant space density ⁶⁶³ with redshift. This might be a sign of a cut-off in the evolution of FSRQs. A decline in the space ⁶⁶⁴ density of luminous FSRQs has also been determined at radio and X-ray energies (e.g., Wall et al. ⁶⁶⁵ 2005; Padovani et al. 2007; Ajello et al. 2009). We derive from the GLF that the space density of ⁶⁶⁶ FSRQs with $L_{\gamma} > 7 \times 10^{45} \text{ erg s}^{-1}$ is 1.05±0.13 Gpc⁻³.

We made a Maximum Likelihood fit to the three unbinned datasets using a simple GLF model defined as

$$\Phi(L_{\gamma}, z) \propto L_{\gamma}^{-\beta} . \tag{10}$$

The ML estimator can be expressed similarly to Eq. 6 by the expression

$$\mathcal{L} = -2\sum_{i} \ln \frac{\Phi(L_{\gamma,i}, z_i) V(L_{\gamma,i}, z_i)}{\int \Phi(L_{\gamma}, z) V(L_{\gamma}, z) dL_{\gamma}} .$$
(11)

⁶⁶⁷ The results of the ML fits to the GLF of FSRQs are summarized in Table 9. For $z \ge 1$, the GLF ⁶⁶⁸ can be successfully parametrized by a single power-law model. The slope is compatible with the ⁶⁶⁹ canonical value of 2.5–2.8 determined for X–ray selected samples of radio-quiet AGNs (Ueda et al. ⁶⁷⁰ 2003; Hasinger et al. 2005; Silverman et al. 2008). This indicates that at high redshifts the *Fermi*-⁶⁷¹ LAT is sampling the bright end of the luminosity distribution of FSRQs. For $z \le 1$, the best-fit ⁶⁷² value of the slope β is 1.56±0.10, compatible with luminosity function slopes found in radio/X-ray ⁶⁷³ selected samples (Padovani et al. 2007). This is much flatter than the canonical value of $\beta = 2.5$. ⁶⁷⁴ As the cumulative GLF shows (left panel of Fig. 22), there might be a hint of a break with respect ⁶⁷⁵ to a simple power-law model in the GLF. A more detailed analysis, comparing different methods ⁶⁷⁶ to derive the GLF and its evolution, will be considered in future publications.

7.3.3. Luminosity Function of BL Lacs

The luminosity function of BL Lacs, reported in Fig. 23, is in agreement with the results of V/V_{MAX} test. Indeed, sub-dividing the entire BL Lac sample in two bins of redshift produces two GLFs which connect smoothly to each other. A simple power-law GLF describes the entire dataset well. The GLF slope is $\beta = 2.17 \pm 0.05$ and is well in agreement with the value of 2.12 ± 0.16 reported for a radio/X-ray selected sample of BL Lacs (Padovani et al. 2007). The GLF 2.12 ± 0.16 reported for a radio/X-ray selected sample of BL Lacs (Padovani et al. 2007). The GLF 2.12 ± 0.16 reported for evolution, with a GLF slope $\beta = 2.37\pm0.3$. Past claims (e.g., Rector et al. 2.000; Beckmann et al. 2003) of negative evolution of BL Lac objects, selected mainly in the X-ray 2.000; Beckmann et al. 2003) of negative evolution of BL Lac objects, selected mainly in the X-ray 2.000; Beckmann et al. 2003) of negative evolution of BL Lac objects, selected mainly in the X-ray 2.000; Beckmann et al. 2003) of negative evolution of BL Lac objects, selected mainly in the X-ray 2.000; Beckmann et al. 2003) of negative evolution of BL Lac objects, selected mainly in the X-ray 2.000; Beckmann et al. 2003) in space density. From our GLF we derive that the density of BL Lac 2.000; Beckmann et al. $2.003 \times 10^{44} \text{ erg s}^{-1}$ is $1.9(\pm0.4) \times 10^{-7} \text{ Mpc}^{-3}$.

Above a luminosity of $L_{\gamma} \sim 10^{47} \text{erg s}^{-1}$, the cumulative density of BL Lacs and FSRQs is comparable, with BL Lacs being ~ 3 times less numerous than FSRQs. However, given the fact that they reach lower luminosities, BL Lacs are ~ 200 times more abundant than FSRQs above their respective limiting luminosities.

693

677

8. Discussion

The value TS > 100 defining the detection significance for bright sources corresponds to $\geq 10 \sigma$ significance, or a limiting flux over the entire high-latitude sky of $\approx (3 - 10) \times 10^{-8}$ ph(> 100 MeV) 696 cm⁻² s⁻¹ during the three-month sky survey. In comparison, *EGRET* reached a 5 σ high-confidence 697 on-axis flux limit of $\approx 15 \times 10^{-8}$ ph(> 100 MeV) cm⁻² s⁻¹ for a two-week pointing over ≈ 0.5 sr 698 of the sky, only becoming complete at $S F_{100} \approx 25 \times 10^{-8}$ ph (cm⁻² s⁻¹ (Dermer 2007). Of the 699 66 high-confidence and 27 lower-confidence AGN associations in the 3EG catalog (Hartman et al. 700 1999), 32 sources in the *Fermi*-LAT sample were also detected with *EGRET*. An additional source 701 is detected at $|\mathbf{b}| < 10^{\circ}$. Many of the other high-confidence *EGRET* sources are detected with 702 *Fermi*-LAT at TS < 100, reflecting the rapid variability and periods of activity of γ -ray blazars on 703 timescales of years or longer.

During the 18-month *EGRET* all-sky survey when exposure to all parts of the sky was relatively ros uniform compared to the remainder of the mission, 60 high-confidence blazars consisting of 14 BL ros Lacs and 46 FSRQs were found (Fichtel et al. 1994). Compared with $\approx 23\%$ of *EGRET* blazars ror being BL Lac objects, nearly 40% of the *Fermi*-LAT blazars are BL Lac objects. The larger fraction ros of BL Lac objects in the *Fermi* bright AGN sample is partly a consequence of the good sensitivity ros to high-energy emission by *Fermi*-LAT, whereas self-vetoing in *EGRET* reduced its effective area to rho photons with energies $\gtrsim 5$ GeV(Thompson et al. 1993). Consequently, dim hard-spectrum sources run are favored to be detected with the *Fermi*-LAT compared to *EGRET*. A clear separation between the spectral indices of FSRQs and BL Lacs is found in the *Fermi*r13 LAT data (Fig. 9), with mean photon indices of $\Gamma = 2.40\pm0.17$ (rms) for FSRQs and $\Gamma = 1.99\pm0.22$ r14 (rms) for BL Lac objects. A KS test gives a probability of 2×10^{-12} for the two index samples to be r15 drawn from the same parent distribution. Moreover, the SEDs of bright flaring blazars in the cases r16 of 3C 454.3 and AO 0235+164 show a spectral softening at $E \gtrsim 2$ GeV. If this behavior persists r17 in weaker FSRQs, then an even greater fraction of BL Lac objects will be found in *Fermi*-LAT r18 analyses over longer times, because signal-to-noise detection significance for weak hard-spectrum r19 sources becomes better than for weak soft-spectrum sources due to the reduced background at r20 higher photon energies.

Another reason for the larger fraction of BL Lac objects in the *Fermi*-LAT blazars could be r22 related to the redshift distribution of the bright AGNs. The BL Lac objects are dominated by r23 low-redshift, $z \leq 0.5$ blazars, with a tail extending to $z \approx 1$, whereas the FSRQs have a broad r24 distribution peaking at $z \approx 1$ and extending to $z \approx 3$ (see Fig. 15 and Fig. 16). These distributions r25 are similar to the distribution of *EGRET* blazars (Mukherjee et al. 1997). Because the peak of the r26 *EGRET* FSRQ redshift distribution is already at $z \approx 1$, detection of higher redshift FSRQs with r27 the more sensitive *Fermi*-LAT would be impeded by cosmological factors that strongly reduce the r28 received fluxes. Moreover, the period of dominant AGN activity was probably at $z \approx 1$ or 2. The r29 increased sensitivity for the BL Lac objects with *Fermi*-LAT, on the other hand, allows it to probe r30 beyond the low-redshift population of BL Lac objects detected with *EGRET* where the detectable r31 volume is still rapidly increasing with z. The likelihood of detecting $z \approx 1$ BL Lac objects does r32 depend, however, on their evolution.

The simplest index of population evolution is the V/V_{MAX} test. We found $\langle V/V_{MAX} \rangle =$ 734 0.43±0.055 for the BL Lac objects with redshift in the LBAS (Table 8), so that the BL Lac objects 735 are within $\approx 1\sigma$ of showing no evidence for evolution. For the FSRQs in the LBAS, by contrast, we 736 found $\langle V/V_{MAX} \rangle = 0.64 \pm 0.04$, so that the FSRQs exhibit strong positive evolution. The strong 737 positive evolution of FSRQs and weakly negative or no evolution of BL Lac objects in the LBAS is 738 contrary, however, to our reasoning that population evolution of the lower redshift BL Lac objects 739 explains the larger fraction of BL Lacs in the LBAS compared with the BL Lac fraction observed 740 with EGRET. As indicated by the indices of the log $N - \log S$ (eq. 6 and Table 7), which show 741 much weaker evidence for evolution than given by the V/V_{MAX} test, the actual situation may be 742 more complicated and depend on both density and luminosity evolution.

The BL Lac objects are found to display systematically harder spectra, with νF_{ν} spectra rising 744 at GeV energies, compared to the powerful FSRQs where the peak of the νF_{ν} spectrum is at photon 745 energies $\leq 100 \text{ MeV} - \text{GeV}$. This is generally attributed to a different dominant radiation process; 746 self-Compton scattering of the jet electron's synchrotron emission in the case of BL Lac objects, 747 and Compton scattering of external radiation fields in the case of FSRQs if leptonic processes 748 dominate the radiation output (recently reviewed in Böttcher 2007). The excellent sensitivity and 749 full-sky coverage of the *Fermi* LAT is, for the first time, giving us broadband evolving SEDs from 750 the radio to the γ -ray regime in sources like 3C 454.3, PKS 2155-304, and others that will require ⁷⁵¹ detailed spectral modeling to assess the relative importance of self-Compton and external Compton⁷⁵² scattering processes in the different blazar classes.

Such results will be important to determine whether FSRQs and BL Lac objects may have r54 a direct evolutionary relationship, or instead represent separate unrelated tracks of supermassive r55 black hole fueling and growth. A scenario whereby BL Lac objects are the late stages of FSRQs, r56 as the gas and dust produced in a galaxy merger or tidal interaction fuels the supermassive black r57 hole (Böttcher & Dermer 2002; Cavaliere & D'Elia 2002), provides a framework to understand the r58 blazar phenomenology and makes definite predictions about the relative black hole masses in the r59 two classes. The more abundant scattered radiation and fueling in the evolution from FSRQ to BL r60 Lac object would then lead to a blazar sequence like behavior (Fossati et al. 1998; Ghisellini et al. r61 1998) if the amount of accreting matter controls black hole power and the surrounding radiation r62 field.

It is still premature to compare the number of blazars in this bright source list with prelaunch r64 predictions (Mücke & Pohl 2000; Stecker & Salamon 2001; Narumoto & Totani 2006; Dermer 2007; r65 Inoue & Totani 2008) made on the basis of differing assumptions, to sensitivities $\approx 5\sigma$ rather than r66 10 σ , and over different spans of time. Nevertheless, nearly complete surveys with far more sources r67 than detected with *EGRET* are now available for calculating luminosity and number evolution, r68 with implications that can be compared with results from the *EGRET* era.

This study can be used to examine the observational basis for assuming an underlying radio/ γ ray connection used to calculate the blazar contribution to the γ -ray background (Stecker & Salamon radio). Figure 14 shows that except for a (at most) weak correlation of the brightest γ -ray blazars with the most radio-bright blazars, the γ -ray and radio fluxes display a large amount of scatter. Whether a stronger correlation can be found by radio fluxes with radio fluxes will require further study. But even at this early ratio fluxes of the *Fermi* mission, we find that the bright sources can already comprise about 7% of the radio fluxes extragalactic γ -ray background flux measured with *EGRET* (Sreekumar et al. 1998).

⁷⁷⁷ We conclude this study by noting that the *Fermi*-LAT results imply the non-thermal luminosity ⁷⁷⁸ density of AGNs on various size scales. A γ -ray blazar makes a contribution to the non-thermal ⁷⁷⁹ emissivity $\propto L/V$ in terms of γ -ray luminosity L_{γ} and injection volume V derived from redshift. The ⁷⁸⁰ *Fermi*-LAT results from Table 2 show that BL Lac objects provide local emissivities $\ell_{BL} \gtrsim 10^{31}$ W ⁷⁸¹ Mpc⁻³, whereas FSRQs have $\ell_{FSRQ} \approx 10^{30}$ W Mpc⁻³. Cen A, because of its proximity at $d \approx 3.5$ ⁷⁸² Mpc, dominates the non-thermal luminosity, with $\ell_{CenA} \approx 3 \times 10^{31}$ W Mpc⁻³ (Dermer et al. ⁷⁸³ 2008). Sources of UHECRs must have a luminosity density within the GZK radius, ≈ 100 Mpc, ⁷⁸⁴ of $\ell_{UHECR} \approx 3 \times 10^{29}$ W Mpc⁻³ or $\ell_{UHECR} \approx 10^{44}$ ergs Mpc⁻³ yr⁻¹ (Waxman & Bahcall 1999). ⁷⁸⁵ To have sufficient emissivity within the GZK radius, if AGNs are the sources of the UHECRs ⁷⁸⁶ (The Pierre AUGER Collaboration et al. 2007), the *Fermi*-LAT results would therefore seem to ⁷⁸⁷ favor BL Lac objects over FSRQs as the source of the UHECRs.

9. Summary

We have presented a list of 116 bright, $\gtrsim 10\sigma$ sources at $|b| \ge 10^{\circ}$ taken from the list of bright row sources (Abdo et al. 2009c) observed with the *Fermi*-LAT in its initial three-month observing period row August 4 to October 30 of 2008. Of these sources, 106 are associated with blazars row with high confidence and compose the LBAS. The number of low-confidence AGN associations is row 11 (one source having two possible associations - one high and one low confidence). At $|b| \ge 10^{\circ}$, row 5 sources out of a total of 125 non-pulsar sources remain unidentified. Two of the AGNs are row 5 associated with radio galaxies. The purpose of this work is to present the key properties of the row AGN population of this bright GeV source list. The main results are summarized as follows:

- With a ~ 90% success rate from correlating the bright gamma-ray source list with AGN radio
 catalogs (CRATES/CGRABS, BZCAT) the bright extragalactic gamma-ray sky continues to
 be dominated by radio-bright AGNs.
- 2. The number of HBLs in the LBAS detected at GeV energies (even when not flaring) has
 risen to at least 10 (out of 42 BL Lacs) as compared to one (out of 14 BL Lacs) detected by *EGRET*. Seven LBAS HBLs are known TeV-blazars.
- 3. Only $\sim 30\%$ of the bright Fermi AGN list were also detected by *EGRET*. This may be a consequence of the duty cycle and variability behavior of GeV blazars.
- 4. BL Lac objects make up almost half of the bright Fermi AGN sample (consisting of 57 FSRQs, 42 BL Lac objects, 2 radio galaxies, and only 5 AGN remain unclassified), while the BL Lac fraction in the 3EG catalog was only $\sim 23\%$. This feature most probably arises from the different instrument responses of the LAT and *EGRET*.
- 5. The mean flux distribution of the *Fermi* AGN remains similar to the corresponding one based on the *EGRET* sample, while the peak flux distributions differ appreciably.
- 6. We find a spectral separation between BL Lacs and FSRQs in the GeV gamma-ray band with FSRQs having significantly softer spectra than BL Lac objects. This confirms earlier indications for the existence of spectrally distinct populations in the *EGRET* blazar sample. The average photon index is 1.99 ± 0.22 (rms) for BL Lacs, with a tendency of HBLs displaying even harder spectra, and 2.40 ± 0.17 (rms) for FSRQs. A KS test gives a probability of 2×10^{-12} for the two index samples to be drawn from the same parent distribution.
- 7. Fermi FSRQs in the bright source list are on average more luminous and more distant than the Fermi-detected BL Lac objects in that list. I.e., FSRQs exhibit a broad redshift distribution, starting with z = 0.158 (3C 273), peaking at $z \approx 1$ and extending up to $z \approx 3$ while BL Lacs are mostly found in the ~ 0.1 redshift bin with a tail extending up to $z \approx 1$. No significant relation between the gamma-ray photon index and redshift is found within each source class, in agreement with corresponding studies based on the EGRET AGN samples.

788

8. The peak gamma-ray flux is at best only weakly related to the 8.4 GHz radio flux, with the
brightest gamma-ray AGNs having the largest radio flux densities.

9. Using mean fluxes the Log N-Log S distribution of all the bright sources (except the pulsars) appears compatible with an Euclidean distribution without any breaks. This is also true within 1σ for the source counts distributions of the FSRQ and BL Lac sample separately. Surface densities of 4.28 ± 0.72 sr⁻¹ and 1.01 ± 0.17 sr⁻¹ ($F_{100} \ge 10^{-7}$ ph cm⁻² s⁻¹) for FSRQs and BL Lacs, respectively, are reached.

10. The combined emission in the flux range $F_{100,\text{mean}} \approx (7-10) \times 10^{-8} \text{ph cm}^{-2} \text{ s}^{-1}$ observed from these individually resolved AGN during this three-month period already corresponds to $\sim 7\%$ of the *EGRET* detected extragalactic diffuse gamma-ray background.

11. A V/V_{max} analysis shows positive evolution at the 3 σ level for the bright *Fermi*-detected FSRQs with the most luminous FSRQs having an almost constant space density with redshift, while for the *Fermi*-detected BL Lacs no evolution within one σ is apparent.

12. The gamma-ray luminosity function of bright FSRQs can be described by a single power-law 836 with index ~ 2.5 and ~ 1.5 for the high (≥ 0.9) and low (≤ 0.9) redshift range, respectively, 837 while the BL Lac gamma-ray luminosity function follows a power law with index ~ 2.1 . The 838 space density of gamma-ray emitting BL Lacs of $\sim 190 \text{ Gpc}^{-3}$ above their limiting luminosity, 839 $\sim 3 \times 10^{44} \mathrm{erg s}^{-1}$, is a factor ~ 200 larger than for the *Fermi*-detected FSRQ population above 840 their limiting luminosity, $\sim 7 \times 10^{45}$ erg s⁻¹. Thus, within the *Fermi* bright AGN list BL Lacs 841 are intrinsically more numerous than FSRQs. Bright Fermi detected BL Lacs and FSRQs 842 display comparable cumulative number counts above $\sim 10^{47} \mathrm{erg s^{-1}}$, with BL Lacs being ~ 3 843 times more numerous than FSRQs. 844

These early results from the first three months of the science mission of the *Fermi Gamma ray* ⁸⁴⁶ Space Telescope demonstrate its exceptional capabilities to provide important new knowledge about ⁸⁴⁷ γ -ray emission from active galactic nuclei and blazars. As the *Fermi*-LAT data accumulate, many ⁸⁴⁸ more AGNs at lower flux levels will likely be detected- as well as flaring AGNs at brighter fluxes ⁸⁴⁹ than yet observed - helping to refine these results and improve our understanding of supermassive ⁸⁵⁰ black holes.

10. Acknowledgments

The *Fermi* LAT Collaboration acknowledges the generous support of a number of agencies and institutes that have supported the *Fermi* LAT Collaboration. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l'Energie Atomique and the Centre National de la Recherche Scientifique / Institut ⁸⁵⁶ National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale ⁸⁵⁷ Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, ⁸⁵⁸ Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) ⁸⁵⁹ and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, ⁸⁶⁰ the Swedish Research Council and the Swedish National Space Board in Sweden.

Additional support for science analysis during the operations phase from the following agention and the K. A. Wallenberg Foundation in Sweden for providing a grant in support of a Royal Swedish Academy of Sciences Research fellowship for JC.

MA acknowledges N. Cappelluti for extensive discussion about the sky coverage.

866 Facilities: Fermi LAT.

This preprint was prepared with the AAS ${\rm IAT}_{\rm E}{\rm X}$ macros v5.2.

Fig. 1.— Examples of weekly light curves for five bright blazars detected by *Fermi*-LAT and the Vela light curve for comparison (flux unit: $\times 10^{-8}$ photons cm⁻² s–1, please note the different scales). The dashed line is the average value and the grey area shows the 3% systematic error we have adopted. Different flux variability amplitudes and timescales are clearly visible in the blazar light curves.

Fig. 2.— Flux limit [E>100 MeV] (ph cm⁻²s⁻¹) as a function of sky location (in galactic coordinates), for a photon index=2.2

Fig. 3 - 95% error radius as a function of TS for the sources presented in this paper. FSRQs: closed circles, BL Lacs: open circles, Uncertain type: closed triangles, Radio galaxies: open stars.

Fig. 4.— Location of the LBAS sources. FSRQs: closed circles, BL Lacs: open circles, Uncertain type: closed triangles, RG: open stars.

Fig. 5.— Normalized angular separation between the *Fermi*-LAT location and that of the counterpart. The solid (dashed) histogram corresponds to the sources with high-(low-) confidence associations. The solid curve corresponds to the expected distribution (χ^2 distribution with 2 d.o.f.) for real associations, the dashed one for accidental associations.

Fig. 6.— The X-ray (0.5 - 2.0 keV) vs radio flux density (1.4 GHz) plot of all X-ray detected blazars in the BZCAT catalog (small dots) and the *Fermi*-LAT detected blazars (BL Lacs: open circles, FSRQs: filled circles, blazars of uncertain type: triangles, radio galaxies: stars).

Fig. 7.— Flux [E>100 MeV] vs photon index for the 116 sources. FSRQs: closed circles, BL Lacs: open circles, Uncertain type: closed triangles, Radio galaxies: open stars. The solid curves represent the TS=100 limit estimated for two galactic latitudes b=20° and b=80°. The dashed curve represents the TS=100 limit for b=80° and 0.2 < E < 3 GeV.

Fig. 8.— a) Comparison of mean flux distribution for blazars detected by *Fermi*-LAT (solid) and *EGRET* (dashed). b) same of as a), for the peak flux distribution. c) Peak flux as a function of mean flux, for the *Fermi*-LAT (closed circles) and *EGRET* (open circles) AGNs. d) same as a), for the peak/mean flux ratio.

Fig. 9.— Photon index distributions for the LBAS blazars. Top: All sources. Middle: FSRQs. Bottom: BL Lacs.

Fig. 10.— Gamma-ray SED of 3 bright blazars calculated in five energy bands, compared with the power law fitted over the whole energy range. Left: 3C454.3 (FSRQ), middle: AO 0235+164 (IBL), right: Mkn 501 (HBL)

Fig. 11.— Left: LBAS photon index as a function of redshift. Same symbols as before. Right: same as left, for the *EGRET* sample.

Fig. 12.— Left: *Fermi*-LAT vs *EGRET* mean flux for the 33 AGNs present in both samples FSRQs: closed circles, BL Lacs: open circles, Uncertain type: closed triangles. Right: same as left, for photon index.

Fig. 13.— Histogram of the radio power distribution for LBAS sources, for all sources (upper panel), FSRQs (middle), and BL Lacs (bottom) only.

Fig. 14.— Radio vs. gamma-ray properties. Left: peak gamma-ray flux vs. radio flux density at 8.4 GHz; the dashed lines show the CRATES flux density limit and the typical LAT detection threshold. Right: gamma-ray photon index vs. radio luminosity.

Fig. 15.— Redshift distribution for the FSRQs in the LBAS (solid) and in the BZCat catalog (dashed).

Fig. 16.— Redshift distribution for the BL Lacs in the LBAS (solid) and in the BZCat catalog (dashed).

Fig. 17.— Gamma-ray Luminosity vs redshift for the LBAS. The solid line was drawn using a $F_{100} = 4 \times 10^{-8}$ ph cm⁻² s⁻¹ and a photon index of 2.2.

Fig. 18.— Detection efficiencies in the LAT $|\mathbf{b}| \ge 10^{\circ}$ survey as a function of flux. The solid line is for the entire blazar population while the dashed and long-dashed are for the FSRQs and BL Lacs respectively. The errors on the detection efficiency are due to the counting statistics in our Monte Carlo simulations.

Fig. 19.— Source count distribution for the whole extragalactic population (excluding the pulsars). The dashed line is the best power-law fit to the $F(>100 \text{ MeV}) \ge 7 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ data. The inset shows the differential distribution.

Fig. 20.— Source count distribution for FSRQs. The dashed line is the best power-law fit to the $F(>100 \text{ MeV}) \ge 7 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ data. The inset shows the differential distribution.

Fig. 21.— Source count distribution for BL Lacs. The dashed line is the best power-law fit to the $F(>100 \text{ MeV}) \ge 3 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ data. The inset shows the differential distribution.

Fig. 22.— Luminosity functions of FSRQs in bins of redshift. The cumulative and differential distributions are shown, respectively, on the left and on the right panel. The (color-coded) solid lines are the ML fits to the 3 different datasets using a simple power law to model the GLF.

Fig. 23.— Luminosity functions of BL Lacs in bins of redshift. The cumulative and differential distributions are shown, respectively, on the left and on the right panel. The (color-coded) solid lines are the ML fits to the 2 different datasets using a simple power law to model the GLF.

 $^{\mathrm{a}}\mathrm{Spectral}$ index derived from a single power-law fit over the 0.2-100 GeV energy range

 $^{\rm b}$ Flux (E > 100 MeV, in 10^{-8} ph cm⁻² s⁻¹) derived from a single power-law fit over the 0.2-100 GeV energy range

 $^{\rm c}{\rm Weekly}$ averaged peak flux ($E>100~{\rm MeV})$ in $10^{-8}~{\rm ph~cm^{-2}~s^{-1}}$

 $^{\rm d}$ Flux (E > 100 MeV, in 10^{-8} ph cm⁻² s⁻¹) obtained by adding the fluxes estimated in the two energy ranges 0.1 - 1 GeV and 1 - 100 GeV

[†]Flux at E > 1 GeV in $10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$. For these sources, only an upper limit is obtained for the 0.1–1 GeV flux (see Abdo et al. (2009c)).

Table 4. Sources in both *Fermi*-LAT and *EGRET* samples

 $^{\rm a}10^{-8}\,\rm ph\ cm^{-2}\,s^{-1}$

^bsource located at $|b| < 10^\circ$

Table 5. Correlation analysis for the radio and gamma-ray properties

Data	Method	Source type	# objects	Correlation coeff.	Chance probability ^a
$S_{8.4\mathrm{GHz}} - F_{>100\mathrm{MeV,peak}}$	Spearman rank	All	106	0.42	0.0000045
$\log L_r$ - $\log L_\gamma$	Sp. r., partial	All	90	0.46	0.0000025
$S_{8.4\mathrm{GHz}} - F_{>100\mathrm{MeV,peak}}$	$\operatorname{Spearman}$ rank	FSRQ	57	0.19	0.080
$\log L_r$ - $\log L_\gamma$	Sp. r., partial	FSRQ	57	0.34	0.0047
$S_{8.4\mathrm{GHz}}-F_{>100\mathrm{MeV,peak}}$	${\it Spearman} \ {\it rank}$	BL Lacs	42	0.49	0.00055
$\operatorname{Log} L_r$ - $\operatorname{Log} L_\gamma$	Sp. r., partial	BL Lacs	30	0.60	0.00023

^aif the samples were unbiased

CLASS	# objects
Total	132
FSRQs	57^{a}
BL Lacs	42^{a}
Uncertain ^b	5^{a}
Radio Galaxies	2^{a}
Pulsars	$7^{\rm c}$
Anti-associations	4
Low confidence associations	10
Unassociated sources	5

Table 6. Composition of the $|\mathbf{b}| \ge 10^{\circ}$ sample (TS ≥ 100).

^aPart of the high confidence sample.

^bBlazars with uncertain classification.

^cFive LAT detected pulsars plus 0FGL J0025.1-7202 (47 Tuc) and 0FGL J0538.4-6856 (associated with the Large Magellan Cloud, see Abdo et al. (2009c)).

Table 7. Results of the best power-law fits to the source counts distributions. Errors withinbrackets are systematic uncertainties due to the incompleteness of the sample. The lower part ofthe table shows the results for the *flux-limited* portion of the sample.

SAMPLE	# Objects	α	A^{a}	EDB fraction ^b
All ^c	121	$2.59{\pm}0.12$	$2.62 {\pm} 0.24$	7.2%
Blazars	106	$2.50{\pm}0.12$	$2.24 \pm 0.22 (\pm 0.24)$	6.1%
\mathbf{FSRQs}	57	$2.60{\pm}0.14$	$2.15 \pm 0.28 (\pm 0.32)$	3.1% d
BL Lacs	42	$2.34{\pm}0.15$	$0.41 \pm 0.06 (\pm 0.06)$	1.0%
FSRQs	29	$2.52{\pm}0.20$	$1.93 \pm 0.35 (\pm 0.09)$	$2.6\%^{ m d}$
BL Lacs	9	$2.50{\pm}0.37$	$0.48 {\pm} 0.16 ({\pm} 0.02)$	1.3%

^aIn units of $10^4 \text{ cm}^2 \text{ s deg}^{-2}$.

^bFraction of the EGRET diffuse extragalactic background (Sreekumar et al. 1998) resolved into sources by LAT for $4 \times 10^{-8} < F_{100} < 10^{-7} \text{ ph cm}^{-2} \text{ s}^{-1}$.

^cIncludes all sources except 7 pulsars and 4 anti-associated objects.

 $^{\rm d}{\rm The}$ lower limit of integration in Eq. 7 has been set to $6\times10^{-8}\,{\rm ph}~{\rm cm}^{-2}~{\rm s}^{-1}.$

_	60	_
---	----	---

SAMPLE	# Objects	$< V/V_{MAX} >$
FSRQs	57	0.645 ± 0.043
BL Lacs	31	$0.430\ {\pm}0.055$
BL $Lacs^a$	42	$0.472\ {\pm}0.046$
BL $Lacs^b$	42	$0.473\ {\pm}0.046$
All with $z>0$	92	$0.512\ {\pm}0.031$
FSRQs ^c	29	$0.654\ {\pm}0.061$
BL Lacs ^c	8	0.542 ± 0.103

Table 8. Results of the V/V_{MAX} test.

^aFor all the 11 BL Lacs without redshift, we have assumed $z = \langle z \rangle$ where $\langle z \rangle = 0.38$.

^bFor all the 11 BL Lacs without redshift, we have drawn a redshift measurement from a Gaussian distribution with mean 0.38 and dispersion 0.34.

^cFlux-limited sample.

Table 9. Results of best-fit power-law models to the GLFs of FSRQs in different redshift bins. The lower part of the table shows the results for the *flux-limited* portion of the sample. Errors represent the 68 % confidence level. Uncertainties within bracketes are systematic errors due to the incompleteness of the sample.

Redshift bin	# Objects	eta	Normalization ^a
$egin{array}{llllllllllllllllllllllllllllllllllll$	20 17 20	1.57 ± 0.10 2.56 ± 0.29 2.58 ± 0.19	$2.43 \pm 0.52 (\pm 0.36)$ $5.59 \pm 1.33 (\pm 0.83)$ $13.07 \pm 2.92 (\pm 1.96)$
	10 8 11	$\begin{array}{r} 2.53 \pm 0.13 \\ \hline 1.46 \pm 0.13 \\ 2.65 \pm 0.48 \\ \hline 2.63 \pm 0.30 \end{array}$	$\frac{13.07\pm2.92(\pm1.90)}{1.73\pm0.54(\pm0.08)}$ $6.62\pm2.34(\pm0.33)$ $17.76\pm5.35(\pm0.88)$

^aNormalization of the GLF model at 10^{48} erg s⁻¹ expressed in units of 10^{-11} erg⁻¹ s Mpc⁻³.

Table 10. Results of best-fit power-law models to GLFs of BL Lacs in different redshift bins. The lower part of the table shows the results for the *flux-limited* portion of the sample. Errors represent the 68% confidence level. Uncertainties within bracketes are systematic errors due to the incompleteness of the sample.

Redshift bin	# Objects	eta	Normalization ^a
z = 0.0 - 0.3	15	$2.08 {\pm} 0.16$	$7.67 \pm 1.98 (\pm 3.06)$
z > 0.3	16	$2.10{\pm}0.11$	$4.75 \pm 1.18 (\pm 1.90)$
z > 0.0	31	$2.17{\pm}0.05$	$4.19 \pm 0.75 (\pm 1.67)$
z > 0.0	8	$1.90 {\pm} 0.11$	$6.70 \pm 2.36 (\pm 0.33)$

^aNormalization of the GLF model at $10^{48} \text{ erg s}^{-1}$ expressed in units of $10^{-12} \text{ erg}^{-1} \text{ s} \text{ Mpc}^{-3}$.
