### **ABSTRACT**

In an era when Facebook and Twitter dominate the market for social media, Google has made another attempt to become a player by introducing Google+ (G+). This begs the question that "whether G+ can sustain a meaningful growth to become a relevant player in this market despite the dominance of Facebook and Twitter?". The conflicting reports on G+ mostly focus on high level statistics that do not offer a meaningful answer. To tackle this question, this paper presents a detailed measurement study to characterize the key features of G+. Our results suggest that the shortterm growth of G+ during its first 10 months far outpaced other OSNs. However, we do not observe a bandwagon effect (characteristic of other popular OSNs) in the growth of active users who represent 10.3% of the whole population. Furthermore, only 43.5% of G+ users form the largest connected component that has connectivity features similar to other popular OSNs. Finally, despite the small fraction of users that frequently visit G+, the aggregate daily activity has increased over 50% due to the dramatic growth in the total population of users.

Google+, Online Social Networks, Measurement, Characterization

#### 1. INTRODUCTION

During the past decade, the Internet has witnessed the rise and fall (or at least moderate success) of several Online Social Networks (OSN) (e.g. Bebo, Friendster, MySpace, Orkut). However, two major OSNs with rather different features, namely Facebook and Twitter, have enjoyed an increasing popularity over the past few years. This raises the interesting question that whether a new OSN can become popular despite the dominance of Facebook and Twitter. Interestingly, the launch of a new OSN by Google, called Google+ (G+), provided an opportunity to examine this issue. Since the inception of G+ in June 2011, periodic reports from Google claimed an impressive growth in the population of G+ users (170M users in April 2012) [1] while some other indicators and experts called G+ a "ghost

town" [2]. Apart from their conflicting content, these reports merely focused on a couple of characteristics of G+ (e.g. users population and average daily time that G+ users spend on the OSN). Clearly, such a narrow view of G+ does not offer a clear and meaningful picture of its growth and thus does not shed much light on the above question.

This paper presents a measurement-based study to characterize all the basic properties of G+ during its first 10 months (June 2011 to April 2012). Leveraging the numerical IDs for G+ users, we developed a simple, parallel technique to crawl the connectivity structure of G+ and captured its largest connected component (LCC). Since sampling random G+ users through generating random IDs is infeasible, we carefully leverage its search API to collect random users. Using these random samples, we estimate the fraction of G+ users that are located in its LCC, small partitions or the singletones (i.e. isolated nodes). We also collect the profile information for sampled users and characterize the level of information sharing (specified attributes in the profile) among G+ users. Using G+ API, we crawl the publicly visible posts (along with their timestamps) by sample users and leverage this information to identify active users, assess their level of activity, and estimate their account creation time along with the recency of their last visit. This information enables us to characterize both the short-term and long-term patterns of growth in the number of active users. Furthermore, we explore the level of activity among users both for individual users and the whole population. Finally, we examine the node level connectivity across G+ users in the LCC and compare its features with Twitter.

Our main findings can be summarized as follows: (i) While the growth of G+ during its first 10 months far outpaced other OSNs, only 43.5% of its current users form the largest connected component, and more interestingly, just around 10.3% of all users are active (i.e. make at least one public post); (ii) The temporal growth of publicly active users exhibits two phases: a first one dominated by three short-term spikes and a second one with a roughly linear growth; (iii) The

aggregate level of daily activity among users shows a steady growth except for the aforementioned spikes; (iv) the node in- and out-degree distribution of G+ users are rather similar to that of Twitter in a mature status, (v) the fraction of publicly active users who visit G+ on a daily and weekly basis are relatively small, (vi) G+ users share (publicly) few attributes, typically related to their professional activity. This suggests that G+ is being used for professional purposes.

Several measurement studies have characterized connectivity [15, 6, 12], the level of activity [9, 8, 13], user interactions [11, 9, 8] and growth of population [11, 13] among users in different OSNs. However, we are only aware of a single (to-be-published) study on G+ by Schiöberg et al. [14]. In this paper the authors perform a measurement study of G+ between September and October 2011. They leverage Google's site-maps to gather G+ user IDs and then crawl users' information. As acknowledged by the authors this technique is no longer feasible and this has limited the duration of their analysis. The paper studies the users connectivity and the growth of the system over a two months period when G+ was just 3 months old. Furthermore, the authors address the geographical properties of G+ users and links. Our study characterizes the main components of G+ structure and the level of activity and recency of visits among G+ users for first time. Furthermore, we examine the connectivity of G+ in a more mature stage (after 10 months) and characterize the growth of active users over the entire G+ lifespan.

The rest of this paper is organized as follows: Section 2 presents a short overview of G+. In Section 3, we describe our data collection techniques and datasets. We study the size of G+ and its different components in Section 4. Section 5 analyzes the growth of G+. Section 6 and 7 address activity and connectivity properties of G+, respectively. Finally, Section 9 concludes the paper.

#### 2. GOOGLE+: AN OVERVIEW

Google+ (G+) is a new OSN that Google launched on June  $28^{th}$  2011. Users were initially allowed to join by invitation until September  $20^{th}$  when it became open to public. In November 2011, the G+ Pages service was launched that enables businesses to connect with interested users and the registration process was integrated with other Google services (e.g., Gmail, YouTube)[4, 5]. For example after this integrated registration, as we explicitly verified, the creation of a new Gmail account automatically generates a G+ account for the user. The published reports from Google [1] indicates that the population of G+ users increased from 10M in early July 2011 to 25M in beginning of August. It reached 40M and 90M in October 2011 and January 2012, respectively, and passed 100M in March 2012. The most

Dataset	Start/End	Num	Collected
name	Date	Users	Information
LCC	Mar 15/ Apr 13	51.8M	P-C
Random	April 18/ May 8	2.16M	P-C
Act-Random	April 18/ May 8	630K	P-C-A

Table 1: Datasets description: all the dates refer to 2012. The collected information can be Profile (P), Connectivity (C) and Activity(A)

recent update in April  $11^{th}$  2012 indicated that G+ user population has reached 170M.

G+ features have some similarity to Facebook and Twitter. Each user has a stream (similar to Facebook wall) where any activity performed by the user or any of her contacts appears. However different from Facebook and similar to Twitter the relationships in G+ are unidirectional. For example user A can follow any other user B (as a friend) in G+ and view all the public posts made by B without requiring the relationship to be reciprocated. A user can also control the visibility of a post to a specific subset of its followers by grouping them into a circle. This feature imitates Facebook approach to control visibility of shared content.

G+ assigns a numerical user ID and a profile to each user. The user ID is a 21-digit integer where the highest order digit is always 1 (e.g. 113104553286769158393)<sup>1</sup>. This extremely large ID space ( $10^{20}$ ) makes identifying valid user IDs by generating random numbers infeasible.

#### 3. DATA COLLECTION AND DATASETS

Our methodology for estimating the total size of G+ users and its break down across different group of users based on their connectivity requires the following datasets: (i) A complete snapshot of G+'s largest connected component (LCC), and (ii) A random set of G+ users. For users in both datasets, we collect public connectivity information (i.e. list of friends and followers) by reproducing the Ajax queries used by the G+ website and profile information through an html parser. It is worth noting that it is not feasible to distinguish between a missing and a private attribute. Finally, we need to obtain the activity information, namely public posts by user for some of our analysis. Table 1 summarizes the main properties of our datasets which we describe next.

#### 3.1 Capturing LCC

To capture the LCC of G+ network, we used a few high-degree users as starting seeds and crawled the structure using a breadth-first search (BFS) strategy in order to discover a large number of users. We crawled around 25M users and then changed our crawling strategy to speed up the process. We noticed that IDs of crawled users are evenly distributed across the ID space. We leveraged this feature and performed our crawl in se-

<sup>&</sup>lt;sup>1</sup>Our preliminary examination of the assigned IDs did not reveal any obvious strategy for ID assignment.

quential rounds as follows: We divided the ID space to Sequal-size segments (S=10). A separate crawler collects the information (list of friends and followers, and profile attributes) of all the known users-ids for each segment. In this process new user IDs are discovered that serve as the list of user IDs to be crawled in the next round (note that the first round uses the initial list of 25M user IDs as input). This parallel crawling strategy enabled us to effectively speed up our data collection up to our available resources because it does not require any coordination among crawlers. We performed 4 rounds and discovered 19.4M, 4.1M, 600K and 100K new users in each round, respectively. After the 4th round only the last 100K users remained uncrawled. We dedicated a single crawler to recursively collect the information of these 100K users and the new users learnt from them. The crawling process took 29 days and produced a full LCC snapshot. We note that any user u that is connected to LCC through user v after we crawled v, will not be captured. However, as we show in the next section, the fraction of missing LCC users is very small. We refer to this dataset as LCC.

#### 3.2 Random Samples

The extremely large size of the ID space makes it infeasible to identify random users by generating random IDs. To cope with this problem, we leverage the G+ search API to efficiently identify a large group of random users. The search API provides a list of up to 1000 users whose name matches a given keyword. After manual inspection of search results for a few surnames, we noticed that G+ seems to organize the provided results based on the level of connectivity and activity, i.e. at the beginning of the list we find well connected and active users and if possible singletons are avoided. Searching for popular names is likely to result in much more than 1000 users which allows G+ to only report 1000 typically well-connected and/or active users. To minimize this bias, we randomly selected a collection of 13K American last names<sup>2</sup> with low to moderate popularity as reported by the US census [3], and used the search API to locate matched G+ users. We consider the list of users in a search result as random samples only if the list has less than 1000 users. We refer to this dataset as Random.

#### 3.3 Users' Activity

Level of activity of individual users in an OSN is an important indicator of their interest, and thus, it is a good metric to measure the OSN popularity. Despite its importance, we are not aware of any prior study that examined this issue among G+ users. Toward this end, we

use G+ API to crawl all public posts of individual G+ users and their corresponding timestamp. Note that this metric represents a lower bound of the actual activity of G+ users that can include private posting but also other activities such as chatting or hangouts that cannot be retrieved. G+ API limits the number of daily queries to 10K per registered application. This implies that collecting the posts for all users in our Random dataset within a reasonable time is not feasible. Therefore, we randomly select 630K users from our Random dataset and collect user posts only for this representative subset of users. We refer to this smaller dataset as Act-Rand. Note that only 10.33% of the Act-Rand users have contributed at least one post and thus are considered active. We also take advantage of collected posts to estimate two other important characteristics of active users for our analysis in the rest of the paper as follows: (i) Account Creation Time: We assume that genuine users generate a post shortly after creating their account. Thus, we use the timestamp of the first post by user u as an estimate of her account creation time; (ii) Time Since Last Activity: We use the timestamp of the last post by user u as a lower estimate for her last activity. Thus, the gap between our measurement time and the last post provides an upper estimate for the time since last visit for user u.

## 4. ESTIMATING THE SIZE OF G+ & ITS COMPONENTS

Similar to any other OSN, the connectivity structure among G+ users should consist of three types of elements: (i) largest connected component (LCC), (ii) smaller partitions, and (iii) singletons. Our goal is to estimate the total population of G+ users, and their break down across these three types of elements. Since users in our random dataset (Random) provide representative samples, their mapping across different types of elements provides a good estimate of the fraction of total users population that are associated with each type of element. Careful examination of random samples revealed that a 38.3% of them are part of the captured LCC and a 55.1% are indeed singletons (i.e. without any friends or followers). While the remaining 6.6% of random samples are intuitively expected to be part of small partitions, we perform a BFS crawl from each one of them to verify their status. Our investigation revealed that 21% of these nodes are indeed part of small partitions between 2 to 46 nodes (90\% of them are smaller than 5 users) and the remaining 79% are connected to LCC. This latter group represents a 5.2% G+ accounts that are those users that joined the LCC during our crawl and were missed by our crawler. By adding this latter group, the fraction of users within the LCC increases to 43.5%. The small percentage of these missed users suggests that our captured LCC snapshot

 $<sup>^2</sup>$ US is the most represented country in G+ [14]. Furthermore, the high immigration level of US allows to find surnames from different geographical regions.

Element	% users	% users	% users
		public attr.	public posts
LCC	43.49	27.43	8.93
Partitions	1.41	0.5	0.13
Singletons	55.10	1.77	1.27
All	100	29.69	10.33

Table 2: Percentage of users, users with public profile's attributes and users with public activity across the G+ elements

is rather accurate. Table 2 summarizes the percentage of users who are part of the LCC, singletons or small partitions. To validate the accuracy of our methodology we have obtained the 99.9% confidence intervals for the relative size of the LCC using a Student's ttest. The confidence intervals are  $43.49\pm0.1\%$ . This indicates that our dataset is representative enough to produce accurate results. In addition, we note that a user that makes her list of both friends and followers private could be incorrectly identified as a singleton in our analysis. However, the percentage of such an error should be negligible because the connectivity of user uto others is discovered from her neighbors with public friends or followers list. Indeed 6% of users in LCC dataset have no friends or followers (due to their private settings) but their connection to LCC was revealed through their neighbors.

Since the total size of the captured LCC is 51.8M and it makes up roughly 38% of G+ accounts<sup>3</sup>, the total population of G+ users should be around  $\frac{51.8M}{0.38}$  = 136M. Our LCC snapshot was collected during a period of 29 days and then it is not representative of a specific date. Furthermore, during our crawl new users join the LCC and just a fraction of them are actually captured. Then, we consider that the 136M is a rough estimation of the size of G+ in the middle of our measurement period (March  $29^{th}$  2012). Google reported that G+ crossed 100M accounts in March 2012 (let's assume March  $1^{st}$ ) and reached 170M in April  $11^{th}$  2012. By a simple linear regression method of these official values, G+ would have roughly 149.5M users in March  $29^{th}$ . Our estimate is roughly 9% lower than this value what suggests that our technique is reasonably accurate.

To assess the level of activity and information sharing across all G+ users, we examine users in our Random dataset. As shown at the bottom row in Table 2, 10.3% of G+ users have generated at least one public post and 29.7% of them share at least one attribute in their profile. Furthermore, the Table presents the break down of these statistics across different elements. As expected, the LCC is clearly the most relevant part of the system including 86% and 92% of users with some public activity and some public attributes, respectively.

Figure 1: G+ growth: all vs active users (Top); Relative growth of active users: G+, Twitter and Myspace (Bottom)

#### 5. GROWTH OF ACTIVE USERS

The rather regular report from Google on the population of G+ users offers a coarse-grain estimate of the rate of growth in user population over time. As shown in Figure 1 (top), Google reports indicate an increasing rate of growth over time. However, this simple approach has two limitations: (i) it does not reveal short term (e.g. daily or weekly) changes in user population, (ii) it only provides the growth in the total number of created G+ accounts without any details on specific group of users (e.g. active users, singletons).

Overall Growth of Active Users: Our goal is to examine the daily growth in the number (or fraction) of active G+ users because it offers a more meaningful measure of growth for an OSN. We leverage 10.33% of active users in our Act-Rand dataset who provide an unbiased samples of all active G+ users. Given the estimated account creation time for these active users, we can determine the fraction of them who created their account on each date since the inception of G+. Figure 1 (top) depicts the cumulative number of active G+ users during its first 288 days of existence and shows that the total number of active users in April  $11^{th}$  2012 is 17.5M, i.e. 10.33% of the total reported population of 170M. As Figure 1 (top) clearly demonstrates, the growth of active and total users over time paint a very different picture. While the growth in the total population exhibits an increasing rate, active users have joined G+ at a lower rate. This led to a widening gap between these two groups that corresponds to the large fraction of singletons and inactive users reported in Section 4. Daily Growth of Active Users: We examine the rate of growth for active G+ users and deepen our insight as follows. First, the left vaxis in Figure 1 (bottom) shows

the percentage from those 17.5M active G+ users who

joined the system each day since G+'s inception date

(Jun  $28^{th}$  2011). Interestingly, this figure illustrates

 $<sup>^3</sup>$ Note that our LCC dataset does not include the 5.2% of LCC users identified by post-processing the partitions. Then the 51.8M represent a 38% of G+ accounts.

two separated phases. The first 150 days (5 months), are dominated by the presence of three major spikes that collectively are responsible of 35% out of the 55% active users registered during that time. These three pronounced spikes appear to be perfectly aligned with the following events: (i) initial launch (invitation-only phase), (ii) the public launch, and (iii) release of G+Pages service. The second phase presents a small but constant growth rate in which 0.3% of the 17.5M active users register every day in average.

Comparison with Twitter & MySpace: To put the growth of active G+ users in perspective, we use the dataset from our earlier study [13] to compare it with the temporal growth in Twitter and Myspace during their first 288 days. Twitter and MySpace had roughly 1.07M and 2.19M total users after this time, respectively, which is significantly smaller than the total population of G+ users. In fact even the active G+ users after 288 days are much larger than the total population of Twitter and Myspace. The success of G+ in attracting such a large number of users compared to Twitter and MySpace can be attributed to two factors: (i) The level of interest among average users and businesses to OSNs during the past 10 months is much higher than in the time when Twitter and MySpace were launched, (ii) The provided support and incentive by a major company such as Google would certainly result in an implicit (e.g. as a result of creating a Gmail account) or explicit membership of many users in G+.

We take a close look at the normalized growth rate of active users for G+, Twitter and MySpace during their first 288 days as shown with the right y axis in Figure 1 (bottom). Each line shows the relative percentage users that have joined the system during the first 288 days. This figure illustrates the fundamental difference between the growth of G+ and other OSNs. The slope of growth for Twitter and MySpace is always positive and steadily increasing. This pattern of growth is known as the bandwagon effect [7, 10], which leads to the long term exponential growth of the system [13]. In contrast, after the handful of spikes in the first 5 months (without equivalence in the other studied OSNs) that attracted a significant portion of active users, the growth for G+ became linear, thus not presenting the aforementioned bandwagon effect.

In a nutshell, G+ has attracted an impressively large number of (active) users in its first months of life. This is an indication of a short-term success. However, the growth rate does not present the bandwagon effect common in other successful OSNs which may impact the growth of the network in the long-term.

#### 6. USERS' ACTIVITY

We now turn our attention to the level of activity and engagement among G+ users to assess their interest. In this analysis, we consider the active users in the Act-Rand dataset as random samples of active G+ users.

**Per-User Activity:** We collect public posts of these users and calculate their average daily public posts rate as a measure of their activity. Since we cannot capture the private posts and other type of activities, our measure should be viewed as a lower bound for their activity. Figure 2 (top) shows the distribution for the average daily post rate among active LCC users. This figure also plots the distribution of the level of activity (in terms of average tweet rate) among 80K random Twitter users collected between July 6 and 25 of 2011 for comparison. We can observe that the median level of activity, although low in both systems, is higher in G+ than in Twitter (1 post every 43 days vs 1 tweet every 56 days). However the variation of activity rate among G+ users  $(3*10^{-3} \text{ to } 73 \text{ posts/day})$  is a couple of order of magnitude smaller than that for Twitter users  $(6*10^{-4} \text{ to } 628 \text{ tweets/day})$ . In particular, 26% of Twitter users send 1 tweet every week while only 14% of G+ users exhibit the same level of activity. This reveals that the fraction of users with a significant amount of activity is higher in Twitter than in G+.

Recency of Activity: To characterize how often active users make a post (and possibly visit G+), we measure the time between the last post by each user and the time of our data collection. Figure 2 (bottom) presents the distribution of the time (in days) since the most recent post across active users in Act-Rand dataset. We also present the same distribution for Twitter and MySpace using the dataset from our earlier study [13] where the time of the last tweet and the explicit time of the last visit are used for the most recent activity in Twitter and MySpace, respectively. Since the maximum age for a G+ account is smaller than that for Twitter and MySpace users (288 days vs more than 1000 and 2000, respectively), the comparison between the larger values in these distributions is not appropriate. Therefore, we focus our discussion on the x values smaller than 100 days (roughly lower than 50% of values). This result reveals that the fraction of very active users who visited Twitter during the past day is around 10% and drops to 6\% and 2.5\% for MySpace and G+, respectively. Twitter users who visited during the last week make up around 20% of users while this number is limited to 11% for both MySpace and G+.

Temporal Pattern of Aggregate Activity: We now characterize the temporal pattern of the aggregate level of daily activity across all of our sampled active users using two metrics: (i) fraction of daily number of posts across all active users, and (ii) fraction of number of active users per day. Figure 3 shows the evolution of these two metrics among active G+ users and demonstrate the following points: First, the aggregate daily number of post and the aggregate number of active users ex-

**Figure** 2: Daily rate Posts/Tweets:  $\mathbf{v}\mathbf{s}$ ter (top); Time since last visit: users (bottom) per day for G+ G+. Twitter, MySpace (bottom)

of Figure 3: Aggregate number of Figure 4: CCDF of #follow-Twit- public posts (top) and active ers (top) and #friends (bottom): G+ vs Twitter

hibit a very similar temporal pattern. This indicates that the distribution of daily activity among the corresponding users is fairly even. Second, the three visible peaks in these figures are aligned with the peaks in daily number of active users who joined G+ (Figure 1). This suggests that both the arrival of new users and overall activity were correlated with the importance of these three events. Third, excluding the three spikes, we observe a monotonically increasing rate in the aggregate daily activity. Specifically, the median fraction of daily active users and daily number of posts for the first 100 days are 0.28% and 0.26%, respectively, whereas if we consider the last 100 days these values increase by 0.42% and 0.44%, respectively. This suggests an increase over 50% in the median daily activity during the first 10 months. Given, that the daily activity is roughly even among the active users, this increase is a consequence of the additive effect of new active users continuously joining the system reported in Figure 1. Finally, we note that the saw-tooth shape of both curves is due to a weekly pattern in which the activity over the weekend is smaller than in weekdays.

In summary, we observe a steady increase in the overall activity of the system. However, the estimated fraction of active users who visit G+ on a daily basis is still significantly smaller than in other popular OSNs.

#### 7. NODE LEVEL CONNECTIVITY

This section focuses on the most important part of G+ structure, namely LCC, and briefly characterizes its node level connectivity. Specifically, we examine the CCDF of the number of followers and friends across all users in LCC. Note that we consider users with a public list of followers and friends, respectively. Since G+ and Twitter both have a directed structure, we compare their distribution of friends and followers across their LCC users in Figure 4. Twitter results were derived from the snapshot captured by Kwak et al. [9] in June 2009 where Twitter was 3 year old and had an LCC of comparable size (41M users) to our G+ LCC. Interestingly, both the distribution of followers and friends in G+ and Twitter have a very similar shape. Specifically, the Kolmogorov-Smirnov distances between the distributions of followers and friends are 0.12 and 0.07, respectively. This indicates that the maximum gap between their CDF versions is limited to 12% and 7%, respectively. Note that the abrupt cutoff of G+ friends distribution at x=5000 is due to the explicit limit that G+ imposes on the maximum number of friends.

In summary, the distribution of in- and out-degree across users in a roughly same-size LCC for G+ (after 10 months) and Twitter (after 3 years) are very similar.

#### LEVEL OF INFORMATION SHARING

One of the most profitable business behind OSNs is marketing and advertisement that to a large extend depends on the level of information sharing by individual users to the public. We characterize the level of information that G+ users publicly share in their profile. Each line in Figure 5 presents the distribution of the number of provided non-mandatory attributes (out of maximum 18) across the fraction of random users who are mapped to LCC, singletons and small partitions. We recall that there is no distinction between a missing and a private (and thus invisible) attribute in these analysis.

We observe that the level of information sharing is low. Specifically, 50% of the users within the LCC provide a single attribute and 92% of them share less than 5 attributes. Furthermore, as expected, users in LCC share publicly more attributes than users in small partitions that in turn share more than singletons. The small number of provided attributes by G+ users can be due to a few factors as follows: (i) the users do not perceive/consider any value in providing this information and their overall experience in using G+, (ii) the

Figure 5: Distribution of the number of attributes (out of 18 possibles) publicly revealed by users in LCC, small partitions and singletons

users might be sensitive in publicly sharing certain personal information and do not want to deal with complex privacy setting, (iii) Users who implicitly join G+ as a results of opening a Gmail account only share the gender in their profile.

We deepen our analysis by exploring the fraction of users in each group who publicly post each attribute in their profiles in Table 3. We observe that users are more inclined to share attributes related to the professional aspects of their life such as location, education, companies and occupation<sup>4</sup>. In contrast, they are less willing to share attributes that reveal rather more private aspects of their life such as their relationships (e.g. single, married) or what they are looking for? (e.g. friendship, love). This suggests that G+ is being used for professional purposes (or by professional rather then average users). The visibly larger number of professionals from the hi-tech companies among the top-20 users in G+ (e.g. Google CEO, Virgin CEO, Myspace founder) supports this observation.

#### 9. CONCLUSION

In this paper we have tried to shed light into the intense debate regarding the popularity of the new OSN launched by Google in June 2011. To this end we have conducted a comprehensive measurement study to analyze different key aspects of G+ including: size, growth pattern and users' activity and connectivity. Our results suggest that G+ have attracted an impressively large number of users in its 10 months of existence. Furthermore, the growth in the number of active users in this period has led to over 50% increase in overall system activity. However, less than 43.5% of all users belongs to the LCC and just 10.3% of them are active. In addition, the pattern of growth in number of active users does not show the bandwagon effect present in

Table 3: Percentage of users making publicly available each profile attribute for different groups: LCC, small partitions and singletons.

other successful OSNs. Finally, we made three important observations at the node level. First, the median level of activity across G+ users is low but surprisingly higher than in Twitter users. However, the fraction of active users that visit the system every day is significantly larger in Twitter compared to G+. Second, the in- and out-degree distributions across users from G+ LCC (after ten months) are similar to the ones observed for Twitter (after three years). This suggests that the connectivity graph of G+ LCC has already reached a relative mature state. Third, the exploration of the information shared by the users in their profiles and the presence of professional of Hi-Tech companies among the most popular users suggest that G+ is being used for professional purposes with a Hi-Tech flavour.
