We propose the concept of a terahertz (THz) uncooled bolometer based on n-type and p-type graphene layers (GLs), constituting the absorbing regions, connected by an array of undoped graphene nanoribbons (GNRs). The GLs absorb the THz radiation with the GNR array playing the role of the barrier region (resulting in nGL-GNR-pGL bolometer). The absorption of the incident THz radiation in the GL n- and p- regions leads to variations of the effective temperature of electrons and holes and of their Fermi energy resulting in the variation of the current through the GNRs. Using the proposed device model, we calculate the dark current and the bolometer responsivity as functions of the GNR energy gap, applied voltage, and the THz frequency. We demonstrate that the proposed bolometer can surpass the hot-electron bolometers using traditional semiconductor heterostructures.

I. INTRODUCTION

Owing to the gapless energy spectrum [1], graphene layers (GLs) absorb electromagnetic radiation in a wide spectral range (from the ultraviolet to terahertz) due to the interband transitions [2–4]. Therefore, GLs can be used in photodetectors, light sources, modulators, and mixers using the interband transitions [5–17]. The performance of these devices can be enhanced by utilizing multiple-GL structures [18]. For the infrared and visible spectral ranges, the interband absorption prevails over the intraband (Drude) absorption. However, in the terahertz (THz) range, especially at low THz frequencies, the Drude absorption can dominate. The intraband absorption in GLs can also be used in different devices for THz modulation and detection. The THz detectors, including uncooled detectors, exploiting the effect of electron or hole heating (hot-electron or hot-hole bolometers) in two-dimensional electron (hole) heterostructures made of A_3B_5 , CdHgTe, and other compound systems were realized previously [19–23]. In this paper, we propose and analyze THz uncooled bolometric detectors based on GL structures. We demonstrate that such bolometers can exhibit fairly high responsivity, effectively operating at room temperatures and surpassing THz bolometers based on the traditional semiconductor heterostructures. The main advantages of GL-based room temperature bolometers are associated with the following three factors: (i) high electron and hole THz conductivities at room temperature [1] and, hence, elevated Drude absorption; (ii) the dominant mechanism establishing the interband and intraband equilibrium is the interaction with optical phonons [24, 25]; (iii) long time of the electron and hole energy relaxation via optical phonons due to their large energy $\hbar\omega_0 \simeq 200 \text{ meV}$ [1] (this time is proportional to a factor $\exp(\hbar\omega_0/T_0)$ and is very large for GLs even at room temperature $T_0 = 300$ K).

II. MODEL AND MAIN EQUATIONS

Figures 1(a) and 1(b) show the proposed nGL-GNRpGL bolometers. The bolometers consist of two gapless n-type and p-type GL absorbing regions connected by an undoped array of GNRs with sufficiently large energy gap Δ (serving as the barrier region). The GLs can be doped chemically [as in Fig. 1(a)] or "electrically" (using the conducting gates with the bias voltages, $\pm V_q$, of different polarity, as shown in Fig. 1(b)). The gates which control the electron and hole densities can be made using GLs [17, 26, 27]. It is assumed that the GNR width, d, is sufficiently small, so that the energy gap $\Delta \propto v_W/d$, (where $v_W \simeq 10^8$ cm/s is the characteristic velocity of electrons and holes in GLs) is large enough to provide essential confinement of electrons in the n-GL and holes in the p-GL due to the formation of the barrier. The room temperature operation of field-effect transistors with sub 10 nm GNRs exhibiting fairly large energy gap was reported in Ref. [28]. The energy barrier in such GNRs ensures a relatively strong dependence of the current on the effective temperature of electrons and holes enhancing the bolometer responsivity.

Figure 1(c) shows the resulting device band structure at sufficiently large bias voltage $V > -V_{bi} = 2\mu_0/e$, where V_{bi} is the built-in voltage, μ_0 is the Fermi energy of electrons and holes in GLs in equilibrium, and e is the electron charge.

In the following, we assume that the interband absorption is relatively weak in comparison with the intraband absorption. This occurs when the energy of photons, $\hbar\Omega$, of the incident THz radiation is relatively small (corresponding to the frequency about few THz and lower). If $\hbar\Omega < 2\mu_0 < \Delta$, the interband transitions are forbidden due to the Pauli blocking. We assume that due to relatively high electron and hole densities, the intercar-

FIG. 1: Schematic views of bolometers under consideration with (a) chemically doped GLs, (b) electrically doped GLs, and (c) the bolometer energy diagram under bias voltage V(wavy arrows correspond to intraband transitions due to absorption of photons in GLs, smooth arrows indicate propagation of electrons and holes above the pertinent barriers in GNRs).

rier scattering time is sufficiently short to provide fast Maxwellization (or Fermization) of the photoexcited electrons and holes. Therefore, the electron and hole systems in GLs are characterized by quasi-Fermi energy μ and by the effective temperature T. The heating of the electron and hole gases in the pertinent sections, i.e., the deviation of the effective temperature T from the lattice temperature T_0 leads to the deviation of the Fermi energy μ from its equilibrium (dark) value μ_0 . The quantities μ and Tare related by the following equation:

$$\int_{0}^{\infty} \frac{d\varepsilon\varepsilon}{1 + \exp\left(\frac{\varepsilon - \mu}{T}\right)}$$
$$-\int_{0}^{\infty} \frac{d\varepsilon\varepsilon}{1 + \exp\left(\frac{\varepsilon + \mu}{T}\right)} = \frac{\pi}{2}\hbar^{2}v_{W}^{2}\Sigma_{0}.$$
 (1)

In the case of chemical doping, the quantity Σ_0 is equal to the donor (acceptor) density. In the detectors with

electric doping, Σ_0 is given by $\Sigma_0 = (kV_g/4\pi eW)$, so that $\mu_0 = \hbar v_W \sqrt{kV_g/4eW}$, where k and W are the dielectric constant and the thickness of the layer separating GLs and the gates and V_g is the gate voltage [see Fig. 1(b)]. In the case under consideration, the electron and hole systems are sufficiently strongly degenerated ($\mu_0 \gg T_0$), hence, the Fermi energy is given by $\mu_0 \simeq \hbar v_W \sqrt{\pi \Sigma_0}$.

Considering the one-dimensional electron and hole transport in GNRs and the Fermi distributions of electrons and holes in GLs, in particular, near the GNR edges at $V > 2\mu/e$, the sum of the electron and hole currents (i.e., the terminal current) between the p- and n-regions through N parallel GNRs is equal to

$$J = \frac{8eN}{2\pi\hbar} \int_{\Delta/2}^{\infty} d\varepsilon_{GNR} \left\{ \left[\exp\left(\frac{\varepsilon_{GNR} - \mu}{T}\right) + 1 \right]^{-1} - \exp\left[\left(\frac{\varepsilon_{GNR} - \mu - eV}{T}\right) + 1\right]^{-1} \right\}.$$
 (2)

Here ε_{GNR} is the kinetic energy of electrons and holes in GNR. In the absence of illumination, i.e., when $\mu = \mu_0$ and $T = T_0$, Eq. (2) yields the following expression for the dark current J_0 :

$$J_0 \simeq \frac{4eT_0N}{\pi\hbar} \ln\left[\exp\left(\frac{\mu_0 - \Delta/2}{T_0}\right) + 1\right].$$
 (3)

Setting $\Delta/2 - \mu_0 = 25$ meV, and N = 1, for $T_0 = 300$ K we obtain $J_0 \simeq 2.64 \ \mu$ A. This value is in a good agreement with experimental results [28].

At relatively weak irradiation, $|T - T_0| \ll T_0$ and $|\mu - \mu_0| \ll T_0$. Considering this, the variation of the current through the GNR array, $(J - J_0)$, i.e., the photocurrent, can be presented in the following form:

$$J - J_0 \simeq \frac{4eT_0 N}{\pi\hbar} \frac{\exp\left(\frac{\mu_0 - \Delta/2}{T_0}\right)}{\left[\exp\left(\frac{\mu_0 - \Delta/2}{T_0}\right) + 1\right]} \times \left[\left(\frac{\Delta/2 - \mu_0}{T_0} + 1\right)\frac{(T - T_0)}{T_0} + \frac{(\mu - \mu_0)}{T_0}\right].$$
 (4)

The first and the second terms in the right-hand side of Eq. (4) describe the effect of variation of the effective temperature and the quasi-Fermi energy due to heating by the THz radiation. However, as follows from Eq. (1), when $\mu_0 \gg T_0$, the variation of the quasi-Fermi energy is relatively small, hence, the last term in the right-hand side of Eq. (4) can be omitted. Considering that the energy relaxation due to the processes governed by the interaction with optical phonons, the electron and hole effective temperature T and the number of optical phonons \mathcal{N}_0 obey the following equations:

$$R_0^{intra} = R^{decay},\tag{5}$$

$$\hbar\omega_0 R^{decay} = \hbar\Omega I_\Omega \beta g_\Omega^{intra}.$$
 (6)

Here, I_{Ω} is the THz photon flux, $\beta = \pi \alpha$, where $\alpha = e^2/c\hbar$, e is the electron charge, c is the speed of light, $R_0^{intra} = R_0^{intra}(T, \mathcal{N}_0)$ is the rate of the intraband transitions involving the emission and absorption of optical phonons, $R^{decay} = R^{decay}(\mathcal{N}_0)$ is the rate of optical phonon decay, and g_{Ω}^{intra} is proportional to the GL Drude ac conductivity [29, 30]:

$$g_{\Omega}^{intra} = \frac{4T_0\tau}{\pi\hbar(1+\Omega^2\tau^2)} \ln\left[\exp\left(\frac{\mu_0}{T_0}\right) + 1\right]$$
$$\simeq \frac{4\mu_0\tau}{\pi\hbar(1+\Omega^2\tau^2)},\tag{7}$$

where τ is the momentum relaxation time of electrons and holes, which, generally, is depending on μ_0 and T_0 . Equations (5) and (6) govern the balance of the energy of the electron-hole system and the number optical phonons in GLs explicitly accounting for all the energy received by the electron-hole-optical phonon system from THz radiation going eventually to the thermostat.

Since $\mu_0, T_0 \ll \hbar \omega_0$, the expression for the term R_0^{intra} can be simplified [31]:

$$R_0^{intra} = \frac{\Sigma_0}{\tau_0^{intra}} \left[(\mathcal{N}_0 + 1) \exp\left(-\frac{\hbar\omega_0}{T}\right) - \mathcal{N}_0 \right].$$
(8)

Here, τ_0^{intra} is the time of the intraband phonon-assisted processes: the quantity $\tau_0^{intra}/\mathcal{N}_0 \simeq \tau_0^{intra} \exp(\hbar\omega_0/T_0)$ plays the role of the effective energy relaxation time of electrons and holes. In equilibrium, Eqs. (5) and (6) yield $T = T_0$ and $\mathcal{N}_0 = \mathcal{N}_0^{eq}$.

For the rate of optical phonons decay due to the unharmonic contributions to the interatomic potential, resulting in the phonon-phonon scattering, one can use the following simplified equation:

$$R_0^{decay} = \frac{\Sigma_0(\mathcal{N}_0 - \mathcal{N}_0^{eq})}{\tau_0^{decay}},\tag{9}$$

where τ_0^{decay} is the decay time of optical phonons and $\mathcal{N}_0^{eq} \simeq \exp(-\hbar\omega_0/T_0)$ is the number of optical phonons in equilibrium. Considering high heat conductivity of GLs [32], the lattice temperature, i.e. the temperature of acoustic phonons, is assumed to be equal to the temperature of the contacts T_0 .

III. PHOTOCURRENT AND RESPONSIVITY

Using Eqs. (4)-(9), we obtain

FIG. 2: Responsivity of the bolometers as functions of the GNR energy gap for different τ .

FIG. 3: Normalized detectivity of the bolometers as functions of the GNR energy gap for different τ .

$$\frac{T - T_0}{T_0} = \beta I_{\Omega} \left(\frac{T_0 \Omega}{\hbar \omega_0^2}\right) \left(\frac{g_{\Omega}^{intra} \eta_0}{G_0^{eq}}\right) \left(1 + \frac{\tau_0^{decay}}{\tau_0^{intra}}\right).$$
(10)

Here we also have introduced the rate of the generation of the electron-hole pairs due to the absorption of equilibrium optical phonons $G_0^{eq} = (\eta_0 \Sigma_0 / \tau_0^{intra}) \exp(-\hbar\omega_0 / T_0)$ and parameter $\eta_0 = \tau_0^{intra} / \tau_0^{inter}$, where τ_0^{inter} is the time of the interband transitions. The difference between τ_0^{intra} and τ_0^{intra} is due to the features of the density of states in GLs. At $\mu_0 \gg T_0$, one obtains [33] $\eta_0 \simeq (\hbar\omega_0/\mu_0)^2/6$. The quantity G_0^{eq} weakly decreases with increasing the majority carrier concentration (if $\mu_0 \ll \hbar\omega_0$) and strongly (exponentially) drops with decreasing temperature. At room temperature $G_0^{eq} \simeq (1-10) \times 10^{20} \text{ cm}^{-2} \text{s}^{-1}$ (compare with [24]).

One can see from Eq. (10) that the intraband absorption of THz radiation leads to an obvious increase of the effective temperature T.

Substituting $T - T_0$ from Eq. (10) into Eq. (4), we obtain

$$\frac{J - J_0}{N} \simeq \beta I_{\Omega} \left(\frac{4eT_0}{\pi\hbar}\right) \left(\frac{\Omega}{\omega_0}\right) \left(\frac{T_0}{\hbar\omega_0}\right) \frac{\eta_0 g_{\Omega}^{intra} \mathcal{H}}{G_0^{eq}}.$$
 (11)

Here

$$\mathcal{H} = \frac{\exp\left(\frac{\mu_0 - \Delta/2}{T_0}\right)}{\left[\exp\left(\frac{\mu_0 - \Delta/2}{T_0}\right) + 1\right]} \times \left(\frac{\Delta/2 - \mu_0}{T_0} + 1\right) \left(1 + \frac{\tau_0^{decay}}{\tau_0^{intra}}\right).$$
(12)

Using Eqs. (11) and (12), for the bolometer current responsivity $R_J = (J - J_0)/\hbar\Omega I_{\Omega}S$ (S is the area of GLs), we obtain

$$\frac{R_J}{N} \simeq \left(\frac{8\alpha \, e}{3\pi\hbar \, G_0^{eq} S}\right) \left(\frac{T_0}{\mu_0}\right) \left(\frac{T_0 \tau/\hbar}{1 + \Omega^2 \tau^2}\right) \mathcal{H}.\tag{13}$$

For instance, considering a quasi-optic THz bolometer with a single GNR (N = 1) integrated with a spiral antenna, we can assume that $\tau = 10^{-13}$ s, $\tau_0^{decay} = \tau_0^{intra}$, $S = 5 \ \mu\text{m}^2$, (about that in [22, 23], $T_0 = 300$ K, and $\Omega/2\pi = 1$ THz. Setting $\Delta = 150$ meV, $\mu_0 = 50$ meV, and $G_0^{eq} = 2.5 \times 10^{20} \text{ cm}^{-2} \text{s}^{-1}$, we find $R_J \simeq 1.25$ A/W. If the applied bias voltage V = 200 mV, setting $J_0 = 2.64 \ \mu\text{A}$, for the voltage responsivity $R_V = R_J V/J_0$ we obtain $R_V = 1 \times 10^5$ V/W. The later values of the current and voltage responsivities significantly exceed those for uncooled hot-electron bolometers based on the heterostructures made of the standard semiconductor (for example, CdHgTe hot-electron bolometers [22]).

Using Eqs. (3) and (13), one can calculate the bolometer dark current limited detectivity $D^* \propto R_J/\sqrt{J_0}$. Since $R_J \propto N$ and $J_0 \propto N$, $D^* \propto \sqrt{N}$ (for fixed S). At fixed value of μ_0 , the detectivity achieves its maximum at $\Delta/2 - \mu_0 \simeq T_0$.

Equation (12) shows that the heating of the optical phonon system due to the energy which this system receives from heated electrons and holes promotes an increase in the responsivity. The relative contribution of the optical phonon heating is determined by the factor $\tau_0^{decay}/\tau_0^{intra}$. This implies that the bolometric effect in question is not purely a hot-electron or hot-hole effect. The bolometer spectral characteristic is determined by the frequency dependence of the ac Drude conductivity, which, as seen from Eq. (13) at $\Omega \tau > 1$, results in $R_J \propto \Omega^{-2}$. If $\tau = 10^{-13}$ s, the responsivity roll-off occurs at $\Omega/2\pi > 1.6$ THz.

Figures 2 and 3 show the dependences of the responsivity and detectivity, respectively, on the energy gap in GNR, Δ , calculated for the THz bolometers with N = 1 and different momentum relaxation times τ for $\Omega/2\pi = 1$ THz. It is assumed that $\mu_0 = 50$ meV and $G_0^{eq} = 3 \times 10^{20}$ cm⁻²s⁻¹.

According to Eq. (13), the responsivity increases with increasing number, N, of GNRs, if the GL area S is fixed. However, an increase in N may require the related increase in the width of GLs and, consequently, in their area.

Similar bolometer can be based on n-GNR-n heterostructures. The results obtained above can also be applied to this device with small modifications: the dark current and responsivity given by Eqs. (3) and (13) should be multiplied by a factor $\simeq 1/2$, because the terminal dark current and photocurrent are due to the electrons injected from only one GL.

IV. CONCLUSION

In conclusion, novel THz uncooled bolometers based on nG-GNR-pG heterostructures have been proposed. Using the developed model, we calculated the bolometer dark current and responsivity and demonstrated that nGL-GNR-pGL can surpass the hot-electron bolometers based on traditional semiconductor heterostructures.
