Abstract—**Repairing locality is an appreciated feature for distributed storage, in which a damaged or lost data share can be repaired by accessing a subset of other shares much smaller than is required for decoding the complete data. However for Secret Sharing (SS) schemes, it has been proven theoretically that local repairing can not be achieved with perfect security for the majority of threshold SS schemes, where all the shares are equally regarded in both secret recovering and share repairing. In this paper we make an attempt on decoupling the two processes to make secure local repairing possible. Dedicated repairing redundancies only for the repairing process are generated, which are random numbers to the original secret. Through this manner a threshold SS scheme with improved repairing locality is achieved on the condition that security of repairing redundancies is ensured, or else our scheme degenerates into a perfect access structure that is equivalent to the best existing schemes can do. To maximize security of the repairing redundancies, a random placement mechanism is also proposed.**

I. INTRODUCTION

A. Backgrounds

(k, n) threshold Secret Sharing (SS) scheme was first proposed by Shamir [1] and Blakley [2] independently in 1979. With Secret Sharing, a secret can only be recovered if threshold k number of shares from the total n is reached. Any number of shares less than k reveals zero information about the secret so security is well-guaranteed. The difference between $n - k$ can be regarded as some safeguard against share failures, so the secret will not be jeopardized should one or two shares fail. However in practical systems, failed shares should be repaired or replaced in time to maintain a comfortable $n - k$ margin. In most cases a failed share will be repaired with the help of other participants, preferably those in the neighborhood so minimum network resources are involved in the process.

The most simple way of repairing a share is to first recover the secret and then generate a new share with it. However this process requires accessing at least a threshold of shares and the revealing of the secret itself. To solve these issues, existing repairable SS schemes can be divided into two

categories. The repairability of the first category is based on enrollment protocols [3]–[12] while the other is based on combining SS with regenerating codes. Enrollment protocols are used to repair a secret share by only using coded version of other shares, so the shares and the secret themselves are not revealed. However, these enrollment protocols can only be applied to specific SS schemes so the generality is lost.

Dimakis et. al. applied network coding to distributed storage system and proposed the concept of regenerating codes then analysed the trade-off between the cost of storage and bandwidth [13]. In recent years, the combination of SS and regenerating codes appears. They make any failed share repairable via cooperation of no less than d participants, where d is called repairing degree. In 2014, Guang et. al. pointed out that a naive combination may lead to loss of perfect security and proposed a GLF scheme as a solution without loss of perfect security [14]. Rawat et. al. proposed a centralized multi-node repairing scheme, in which MBR and MDR codes were discussed [15]. In 2016, Stinson et. al. proposed another solution based on ramp scheme, which achieved the "restricted repairing" that the authors defined, then compared it with the GLF scheme.

However, in these schemes, repairing degree d should be no less than threshold k: according to their definitions, when $d < k$, since any set of d participants can repair any number of failed shares so effectively secret-recovery threshold k is lowered to d. To compromise the conflict between repairing mechanism and threshold in the context, most existing schemes assume that $d > k$. Better efficiency in repairing is achieved by requiring only a smaller amount of data from each of the d nodes so the total amount is reduced.

In the repairing process, we may also hope repair to be done by accessing a smaller than k number of other nodes, because shares can be widely distributed and accessing nodes far away can also be very costly. The notion of locally repairable codes [16] can be extended into SS schemes. In a code with locality r, any symbol of a codeword can be deduced by at most r other symbols of the codeword. Unfortunately, it was proven theoretically that a threshold SS scheme is not locally repairable. Still, there exists perfect access structures with small r [17]. This means under the

threshold paradigm, introduction of erasure codes leads to loss of locality or the threshold scheme turns out to be a general access structure.

The main purpose of this paper is to provide new mechanisms for repairing secret shares while satisfying perfect security under some conditions where the repair degree d less than SS threshold k. We make an attempt on decoupling the two processes by setting dedicated repairing redundancies only for repairing process. Then IDA is adopted to make the data separated: one part is "secret recovery only" while the other is "repairing only". Then we get a weak result: When security of repairing data is ensured, a threshold SS scheme with improved repairing locality is achieved, or else our scheme degenerates into a perfect access structure, which is equivalent to what locally repairable codes can do. Finally, a random placement mechanism is proposed to maximize security of repairing data so this condition can be better satisfied.

B. Contributions

The contributions of this paper are summarized as below:

1) **Repairing Locality.** In existing scenarios, maintenance of threshold results in loss of repairing locality. In our mechanism the repairing process is bounded inside node groups so locality of repairing process is achieved, which can reduce the repairing degree d much lower than the SS threshold k.

2) **Decoupled Repairing Process.** This paper proposes a weak condition (security of repairing data) such that:
   (1) When security of repairing data is ensured, the local repairing process relies on redundancies that are decoupled from the original SS so a threshold SS scheme with improved repairing locality is achieved.
   (2) When the repairing data security is lost, the security level of our scheme is no worse than the best existing schemes (equivalent to a perfect access structure with locally repairable codes).

3) **Redundancy Distribution Protocol.** For the sake of maximizing security of repairing data (the weak condition in last item), a random placement mechanism is proposed to hide the redundancy shares during the distribution in IDA process.

C. Paper outline.

The rest of the paper is organized as follows. In section II, some preliminaries and related work will be introduced briefly. In section III, a localized repairable grouped SS scheme based on grouping scheme and repairing function along with 2 toy models are constructed. In section IV, parameters in our model will be discussed in details. In section V, properties will be discussed and comparison with regenerating codes will be made. Finally, the conclusion will be drawn in section VI.

II. PRELIMINARIES AND RELATED WORK

A. Secret Sharing

1) Backgrounds: (k, n) threshold SS scheme was first proposed by Shamir [1] and Blakley [2] independently in 1979. Afterwards, various SS scheme based on different mathematical models are proposed: SS scheme based on Chinese Remainder Theorem(CRT) by Asmuth-Bloom [20]; SS scheme based on matrix multiplication by Karnin et. al. [21]Among those schemes Shamir's (k, n) threshold scheme is the most commonly used one due to its manifest representation and perfect security.

2) Ramp Scheme: In 1985, ramp scheme was proposed by Blakley et. al [22]. It possesses two thresholds $k_1 < k_2$ such that:

(1) The secret s can be recovered with the cooperation of no less than k_2 participants.

(2) No information should be revealed about the secret s under the cooperation of less than k_1 participants so perfect security is achieved.

(3) When the number of collected secret shares is between k_1 and k_2, the revealed information increases linearly with the increase of the former.

When $k_1 = k_2 - 1$, a ramp scheme turns out to be a threshold scheme. In 2012, Kurihara et. al. proposed a perfect secure parameter m to build a new regenerating code then proved the security of that scheme is equivalent to a ramp scheme [23].

B. Repairable Secret Sharing Schemes

In 1998, the first repairing mechanism based on enrollment protocol was proposed by Herzberg et. al. [24] This protocol is based on Shamir SS scheme. The spirit is: make k surviving participants add some specific polynomials to their secret shares so they are not revealed then send the addition to the share-loser. The loser can recover his share via Lagrange interpolation. Still, these schemes will cause too much cost in bandwidth and the loss of generality is also concerned.

A type of enrollment protocols can be applied to repairing process in SS. For instance, [3]–[6] proposed an enrollment protocol based on Shamir scheme, which is similar to that proposed by Herzberg et. al. [7] An enrollment protocol based on public-verifiable SS schemes is proposed in [8], [9], which introduced public-verifiable functionality based on [10]. Moreover, Saxena et. al. proposed enrollment protocol based on bivariate polynomial SS [11]. Yue et. al. proposed enrollment protocol based on vector space SS [12].

Still, these enrollment schemes mostly depend on specific SS schemes so they are poor in generality, and the repairing still needs k nodes. Hence, new repairable SS schemes without loss of generality and universality is still missing.

C. Regenerating Codes

Dimakis et. al. applied network coding to distributed storage system and proposed the concept of regenerating codes then

analysed the trade-off between the cost of storage and band-width [13]. The principle of (n, k, d, α, β) is: code the original files then save them into n nodes. Each of the nodes keeps data of size α. When any of these nodes fails, the system repairs it via downloading data from d surviving nodes. Each of them offers data of size β. Meanwhile, any k participants should be able to recover the original file. In recent years, several construction of regenerating codes were proposed [25], [26].

D. Locally Repairable Codes

Locally repairable code is proposed to trade more storage space for lower repairing bandwidth. The number of nodes to be accessed during repairing process is lower than the case of other erasure codes. Rawat et. al. proposed a specific locally repairable code scheme in 2014 [27]. In their paper, they deeply discussed repairing locality and grouping schemes. Shahabinejad et. al. discussed a binary locally repairable code to realize fast repairing functionality for several nodes in failure [28], [29]. [30]optimized LRC based on maximum rank distance Gabidulin codes. [31]considered locally repairable codes over small fields and proposed new constructions of optimal binary and q-ary cyclic (and linear) codes with locality and availability.

III. A LOCALIZED REPAIRABLE GROUPED SS SCHEME BASED ON GROUPING SCHEME AND REPAIRING FUNCTION

Our scheme is based on grouping the secret shares. For the sake of locality, the participants of the original SS are divided into disjoint groups, preferably in a compatible way to the access structure or some multilevel SS property.

In practice, the grouping may need to consider multiple factors such as physical location of the servers or different ranks in the multilevel cases. Sometimes these factors may conflict with each other and if that occurs, we should treat the problem thoughtfully to achieve the best overall grouping result. For example, in multilevel SS schemes, the grouping should comply more with the level of participants than the distance among them.

Moreover, the grouping should have no affect on their role and functionality in the SS scheme. Or in other words, the original SS won't see this grouping and treat all shares as they originally should be. This means that the shares in each group should keep as they are and cannot be re-encoded for the repairing capability.

A. Construction

Now, we will build our model on the base of these SS groups and repairing functions. Firstly, a repairing function is introduced inside each group to make the repairing local and secure without modifying the secret shares. The participants of the group constitute a repairing function and a repairing redundancy to keep information of that function is generated. The function should contain all information to repair the secret shares within the group. The local repairing information are stored through the generated repairing function of each group.

It can be defined as: given a set of points (x_i, y_i), a repairing function of these point is a function $y = f(x)$ such that $y_i = f(x_i)$.

Furthermore, saving all the coefficients of that polynomial or saving only a determining point for the polynomial is also a consideration. So we introduce the notion of strong repairing redundancy and weak repairing redundancy to measure the significance of the repairing redundancy:

Strong repairing redundancy. A redundancy is called *strong repairing redundancy* if it can determine the whole repairing function independently. For example in the following toy model, the combination of all the coefficients of the polynomial is a strong repairing redundancy.

Weak repairing redundancy. A redundancy is called *weak repairing redundancy* if it can determine the repairing function with the cooperation from others. For example in the following toy model, the redundant point of the polynomial at P_λ is a weak repairing redundancy.

For the convenience of understanding, a toy model based on polynomial repairing function is given in the following context.

1) Difference between trivial Shamir SS scheme and the one used in our model: In Shamir scheme, secret shares are in the form of (x_i, y_i). We can either save the pair as the secret share or only y_i and make x_i public. Making x_i public will not affect the secrecy because it is the polynomial who determines the secret, and without the corresponding y_i, the knowledge of x_i reveals zero information about the secret. However, to make local repair possible inside a group we cannot save the (x_i, y_i) pair together, because in that case when the share fails we lose both x_i and y_i. For Shamir SS there are still enough shares to recover the polynomial and the secret, so it can choose a new random x_i' and the corresponding y_i' to replace the failed one. However the shares from one group are not sufficient to recover the polynomial for the secret, so the local repair has to find the exact (x_i, y_i) of the failed share back, or the global SS will fall apart. In our repairing function, x_i can be the identification of the storage server or some other common information. The publicity can be carried out in two ways: one is to publish every x_i to every participants while the other is to put x_is to some common place.

Publication of x_i***.*** As discussed before, in our model we don't want x_is to be part of the secret shares so we should publish x_i. In practical applications, the storage servers are sometimes equipped with well-defined identity numbers due to some design or operational considerations, and these numbers can be used as x_i for the i-th server. If such easy solution is not possible, we need to have our own publishing mechanism.

A trivial consideration is setting a dedicated server to offer services about renewing and maintaining these numbers for the servers. When any server is down or replaced, the dedicated server should give the replacement server the correct sequence number x_i. Of course when the number of storage servers becomes huge, keeping all x_i at one server may become an issue. In that case we may want to store the x_is of the group members inside the group.

Fig. 1. A repairing function for $((x_1, y_1), (x_2, y_2), (x_3, y_3), (x_4, y_4))$ is a polynomial passes through these points with degree 3. (x_λ, y_λ) is a random point on that curve.

Fig. 2. Process of grouped SS along with repairing function

Furthermore, that dedicated server becomes a single-point-of-failure of the whole repairing mechanism. To relief that problem we can put the x_is of the group members together with the repairing function as the repairing redundancies and distribute it to group members.

The publication of x_is is the first step of our model.

2) A toy model of grouped SS with repairing function: Firstly, we build a normal (k, n) SS, let's say $(8, 12)$, and divide the 12 shares into 3 groups with 4 shares each. In each group, a local repairing function is generated that is only available to that group, which helps repair failed shares of the group. Let's consider group 1 whose participants are (P_1, P_2, P_3, P_4) with secret shares $((x_1, y_1), (x_2, y_2), (x_3, y_3), (x_4, y_4))$. The process is summarized in the following steps.

Step 1: Generate a 3-degree polynomial with coefficients (b_1, b_2, b_3, b_4). Determine their values with the points at $((x_1, y_1), (x_2, y_2), (x_3, y_3), (x_4, y_4))$.

Step 2: Choose a random x_λ distinct to existing x_is. Get the corresponding y_λ from the polynomial. Note here the generated y_λ is just a random point to the global secret S. As shown in Fig. 1.

Step 3: Treat (b_1, b_2, b_3, b_4) or y_λ as the sub-secret of the group and save it to a reliable server inside group 1 that we call P_λ.

Analysis: When any of the shares at (P_1, P_2, P_3, P_4) is missing, we can access P_λ to recover the missing share. However, this will cause extra cost in hardware dedicated just for repair. On the other hand, P_λ can play a largely different role with regard to the original shares of the group. If we store (b_1, b_2, b_3, b_4) in it, anyone with the public $x_i (i \in \{1, 2, 3, 4\})$ can get y_i from P_λ, which means P_λ effectively possesses all shares of the group. In this case, P_λ is a strong repairing redundancy that needs careful treatment. If we just store y_λ in it, group 1 simply becomes a local $(4, 5)$ threshold scheme for the sub-secret. In this case, y_λ is a weak redundancy. When the repairing redundancy is too abundant, it may be a clear target for attack and weak point for security. Still, saving too much data outside the group leads to loss of locality in repairing
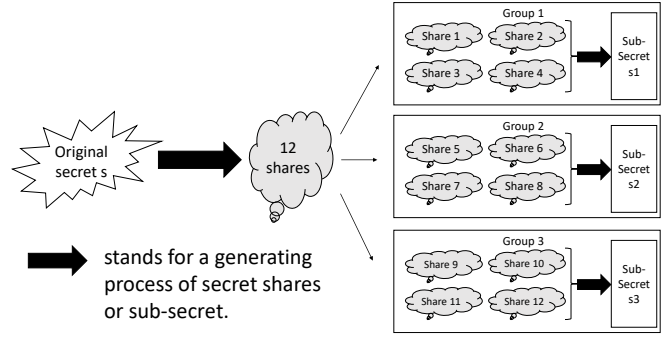

process.

We suggest Information Distribution Algorithms (IDA) to get rid of the dedicated servers and hide the repairing redundancies deeper inside the system. It should be carefully chosen according to the specific repairing redundancy. For example, Shamir's scheme maybe too much of a overkill for weak redundancy, for which we can use other more cost-efficient SS schemes to reduce the cost to match with its significance, for example with the SS-made-short scheme proposed by H. Krawczyk [18].

In the following part we will show Second Secret Sharing (SSS) as a toy model of IDA for weak redundancy.

3) Grouped SS with Second Secret Sharing: We propose our final model as a localized repairable grouped SS model armed with SSS method. In this model, weak repairing redundancies are chosen to be the sub-secrets in order to recover the repairing function. SS is used a second time as IDA to distribute weak redundancy. It is organized in the following steps:

1) Consider a (k, n) threshold SS, divide the n participants $(P_1, P_2, ..., P_n)$ into m disjoint groups $(G_1, G_2, ..., G_m)$ to form a (m, n) grouped SS scheme. Each P_i keeps a share of (x_i, y_i).
2) Suppose the number of members in group G_i to be N_i. Generate a $(N_i - 1)$-degree polynomial based on the points determined by the secret shares of the group. As shown in Fig.2.
3) Choose another random point on that polynomial. Treat this random point as the sub-secret.
4) Perform a SSS to share the sub-secret to group members. As shown in Fig.3.

B. Further Design about SSS

1) Security/locality trade-off in SSS process:
Example. As an example, we use the same $(8, 12)$ toy model from last subsection, which is grouped into (G_1, G_2, G_3) with 4 shares each. For G_1 with participants (P_1, P_2, P_3, P_4), a y_λ is generated with the steps just mentioned. Next, the y_λ is treated as the sub-secret s_1 of the group and another Shamir SS scheme is used to distribute s_1 to G_1 members.
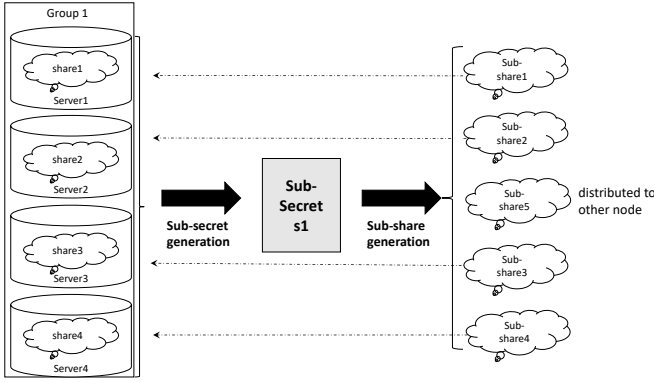

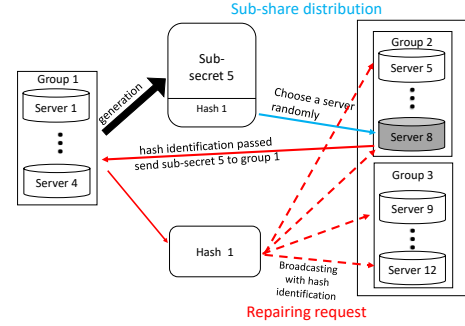

Fig. 3. SSS in Group 1 as an example

Fig. 4. Redundancy Distribution Protocol

The threshold of this sub-secret distribution can not be lower than 4, or otherwise it will affect the threshold of the original SS: for example with a (3,4) scheme, when any 3 out of 4 group members are revealed to an attacker, y_1 and consequently the repairing function can be recovered, with which the attacker can figure out the 4th share by himself.

Here in this paper a (4,5) scheme is recommended, therefore we need a server outside the group to put the extra sub-share on. However the location of that extra sub-share should be hidden in some way to avoid abuse of repairing mechanism from attackers who own intact data from a subset of nodes. As shown in Fig. 4, here we are proposing a *redundancy distribution protocol* of random placement to maximize the security:

1) Assume that each node owns a unique sign, perfectly comes from hardware to verify its identity, for example a MAC address. When any data fails, it propose a repairing request and recover the lost data. Repairing request of any node must be proposed by the server who loses its data, cooperating with the 3 other nodes. This means a repairing request should be authorized by every member of that group.
2) Choose a random server outside the group and store the sub-share there, and give a hash identity calculated with combination of MAC addresses form all 4 nodes in the group.
3) The group doesn't remember the chosen server, and the latter doesn't know which group the sub-share belongs to, so true randomness is achieved.
4) During a repairing process the node who claims a repairing service requests for the sub-share by broadcasting the hash identity, and the server who passes the identity check sends the extra sub-share back to the group.
5) The missing secret share is repaired through repairing function and only revealed to the proposer.

This design is a trade-off between locality and security. With the protocol proposed, extra shares should be stored out of the group, so improvement of security leads to tiny loss of locality.

IV. FURTHER DISCUSSION ABOUT OUR MODEL

A. Repairing Function

As we see, a repairing function is a map from published x_i's to the value of secret shares. Then the "secret" to be shared turns out to be a function rather than a value so it is essentially a function sharing process. In our model, currently a polynomial function is used which is completely determined by its coefficients. Thus, the repairing redundancy turns out to be a multi-SS process.

The polynomial repairing function is somehow similar to the repairing process of SS as discussed by Hayashi et. al. [19], which repairs or regenerates a broken share by first recovering the original secret along with the secret-distributing polynomial from enough surviving shares. With the knowledge of that polynomial any amount of shares can be repaired or regenerated. However, our repairing function is actually very different from this SS repairing mechanism because the purpose is quite the opposite to each other. The goal of SS is to generate a set of secret shares for a known secret s in hand while the goal of the repairing function (polynomial in this case) is to generate repairing information from existing shares that are already known and then create repairing redundancies based on this function. Thus, in repairing function, what is important is not the new "secret" (a_0 in the new polynomial) but the polynomial, which can be regarded essentially as a multi-SS process.

B. Repairing Redundancies

The concept of repairing redundancy is introduced to describe the significance of a redundancy. In the polynomial case, the coefficient b_i's and the share y_i's are elements of the same finite field so they are of the same size. In this sense, a share or a redundancy is equivalent to a coefficient. Thus, the significance of the generated redundancy can be measured by either how few cooperators it relies on to recover the sub-secret or how many coefficients it can independently determine.

For example in the toy model of repairing function, the weak redundancy is as significant as 1 share while the strong redundancy is as significant as all 4 shares. Clearly, using a strong redundancy is not wise now because it is strictly worse

than a simple replication scenario: the size is the same but more computation is involved. This is one reason why we choose weak redundancy in our model.

C. Decoupled Properties

Our repairing scheme is also different from existing repairable SS schemes that make use of erasure codes such as Reed-Solomon codes and regenerating codes, where the redundancies are simply liner combination of the original shares and therefore of the same global significance. These redundancies should be handled carefully because they may affect the properties of the original SS process.

In our scheme the secret recovery process and the share repairing process are decoupled in the sense that the repairing functions are local with no global significance to the original SS process. The repairing functions are the "secret" of grouped shares that works in the repairing process while the secret shares of the original SS work in the secret recovery process. The data repairing process is independent from secret shares so secret-recovering and share repairing process are decoupled.

V. MODEL ANALYSIS

A. Attack/Threat Scenarios

1) Repairing Function Generation: In this process, under the weak redundancy case, the generated local redundancy is kept in an additional server in each group. We will first discuss its resistance under attacks.

Let's consider a (8,12) threshold scheme divided into 3 groups with 4 shares each. From each group an attacker can collect 4 shares at most (direct or calculated through repairing) even when he compromise all 5 servers. Hence, we consider how difficult it is for an attacker to get all 4 shares of one group measured by the probability p.

Suppose all servers behave equally under attack and let us say the probability the attacker gets all data on one server is q. Hence, when there is no redundancy at all, the probability p_1 turns out to be:

$$p_1 = q^4 \tag{1}$$

In a (4,5) scheme, any 4 out 5 servers can provide all 4 shares of this group, the probability p_2 turns out to be:

$$p_2 = C_5^4 q^4(1-q) + q^5 = q^4(5-4q) \tag{2}$$

$$p_2 - p_1 = 4q^4(1-q) \tag{3}$$

Since $0 \le q \le 1$, $p_2 - p_1 \ge 0$.

Hence inside one group, we've proven that the introduction of new server increases the successful rate for attacks, because the additional server increases the number of targets. SSS is proposed to solve these problems.

2) SSS Process: We've discussed the decoupled property about SSS process in the last section. In this part we will analyze the impact on the secret recovery data when repairing data is under attack.

Let's quote the $(8, 12)$ scheme as an example again and consider secret recovery data. When data from compromised servers are not sufficient to carry out any local repair in

repairing data, the secret recovery threshold 8 is well-retained; otherwise additional shares can be obtained via the repairing process, which effectively lower the threshold. In the worst case minimally 6 compromised servers can reveal the original secret.

In the worst case, the attacker gets 6 shares from only two groups with 3 from each, and unfortunately for each of the two groups the repair redundancy is stored among the compromised servers of the other group. It is easy to see that a fourth share can be "repaired" from each group, so in total the attacker has 8 shares at hand which is sufficient to recover the original secret.

Similarly, if the data on the compromised servers are sufficient only for just one repairing, then the attacker needs to break minimally 7 servers. Actually we can increase the number of required servers from 6 to 7 for the worst case scenario, if we never store the redundancy to each other between any 2 groups, which is at the cost of less randomness in the redundancy distribution protocol.

All in all, the threshold scheme can be retained when data from compromised servers can not support any repair. The security of the redundancies in repairing data is protected by the randomness protocol. When repairing data is no longer secure, the secret recovery threshold breaks up and it turns out to be an access structure with perfect security. In any case, our model provides support to repairing locality so the condition that repairing degree $d <$ threshold k is no longer required.

B. Comparison with Regenerating Code

In this part, the performance of our model is compared with repairing mechanism based on regenerating codes.

1) Storage: In our model, repairing redundancies are generated and distributed by IDA. We've shown SSS as an example. In the following discussion, we are calculating the storage overhead in repairing redundancy generation and SSS process.

Repairing Redundancy Generation. Assume that the capacity of original secret s to be 1. During the SSS process, we have m groups with m sub-secrets s_i in total. In this process, the additional capacity turns out to be m.

SSS Process. In this process, each sub-secret inside each group is distributed to group members. The final result is that each server stores both an original secret share of secret s and a sub-share of generated sub-secret s_i, which means the capacity will be doubled to $2n$. Hence, the additional capacity turns out to be n.

2) Threshold: As shown in the context, in our model the maintenance of threshold is conditional, depending on the security of repairing data. When this condition is not met, the scenario turns out to be a perfect access structure rather than a threshold scheme.

3) Perfect Security: Both of them achieve perfect security.

4) Repairing Locality: Regenerating codes can not achieve repairing locality. In our model, the redundancy distribution protocol considers a trade-off between repairing locality and

security. Only 1 extra share is banished with a little impact on locality.

5) Computational Complexity.: We have pointed out in the previous discussion that one advantage of the grouping scenario is that it has lower computational complexity in the coding and decoding process. For example in the repairing function generation process, what we need is nothing but solving liner equations, which can be solved with a complexity between $O(n^2)$ and $O(n^3)$, where n is the total number of shares in a (k,n) SS scheme.

Consider the n participants who are divided into m groups. Suppose there are γ members in each group such that

$$n = m\gamma \tag{4}$$

Assume that:

1) In each group, at most 1 failure happens at any given moment.
2) In each group, the probability of server failure is q.

Then, the computational complexity turns out to be

$$O(qm\gamma^3) = O(qn\gamma^2) = O(\gamma^2 n) \tag{5}$$

When γ is determined and small, the complexity turns out to be $O(n)$. As we can see, from this aspect, γ should be made as low as possible to achieve lower computational complexity.

However, the upper boundary of the SS threshold turns out to be γ so it is better not to be too small or the security level will be low. In this paper the suggested value for γ is 4.

The results are listed in TABLE I.

TABLE I
PERFORMANCE COMPARISON WITH REGENERATING CODES

	Regenerating Codes	Our Model
Storage	-	additional
Perfect Security	yes	yes
Threshold	yes	conditional
Repairing Locality	no	feasible
Computational Complexity	high	low

VI. CONCLUSION

This paper aims at share repairing issues in a SS scheme. The studies in the literature will either lose threshold property of the original SS scheme or their repairing degrees are high. In this paper a grouped repairing mechanism based on repairing function is proposed, which splits secret shares into disjoint groups to achieve repairing locality. Repairing redundancies are generated to keep repairing informations. Furthermore, IDA is proposed to make the repairing process almost restricted inside groups so locality is achieved. Finally, we indicate in our scheme the maintenance of threshold property is conditional. In the worst case, with the loss of security of repairing data, the original threshold SS scheme turns out to be an access structure. Still, the secure level is equivalent to existing scenarios. In any case, both locality and perfect security are still remained.
