4.2 COMPLETED PARTIALLY-DIRECTED RCM

The pattern of an RCM is a partially-directed RCM (PRCM) wherein each directed dependency is covered by some CUT of the RCM. Completed PRCM (CPRCM) is a PRCM where a dependency is directed if and only if all valid RCMs with the same pattern have the dependency oriented in the same direction as in the CPRCM. Since acyclicity of RCM is defined at the attribute class level, we orient edges on a partially-directed class dependency graph $\mathcal{G}_\mathcal{A}$ (initialized with $\mathcal{G}_\mathcal{A}^{pattern(\mathcal{M})}$) with a set of attribute class level non-colliders, denoted by $\mathfrak{N}_\mathcal{A}^\mathcal{M}$ ($\mathfrak{N}$ for short), derived from canonical unshielded non-colliders obtained as a byproduct of discovering the pattern of an RCM. Then, orientations from *completed* partially-directed CDG are used to orient undirected dependencies in the pattern of RCM resulting the CPRCM.

Given a canonical unshielded non-collider $(\mathcal{V}_X,\mathbf{P}.Y,R.Z)$, corresponding attribute class level non-collider is (X,Y,Z). It is the case that $X = Z$, that is, $(X,Y,X) \in \mathfrak{N}$. Then, we can orient as $Y \to X$, which corresponds to Relational Bivariate Orientation (RBO, Maier et al., 2013a). For simplicity, we assume that all edges of $\mathcal{G}_\mathcal{A}$ that can be oriented using RBO have been oriented, and we exclude them (e.g., (X,Y,X)) from $\mathfrak{N}$. Otherwise if $X \neq Z$, then X and Z may be connected making (X,Y,Z) *shielded*. This is why the term "unshielded" is dropped in attribute class level non-colliders. To obtain the CPRCM given the pattern of an RCM, we provide a *sound* set of rules and a *sound* and *complete* extensibility-based method. The former can be used even when the set of non-colliders is not complete whereas the latter requires a complete set of non-colliders. Before we proceed, we characterize $\mathcal{G}_\mathcal{A}^{pattern(\mathcal{M})}$ and $\mathfrak{N}_\mathcal{A}^\mathcal{M}$:

Proposition 6. *Let (X,Y,Z) be an unshielded collider in $\mathcal{G}_\mathcal{A}^\mathcal{M}$, then $X \to Y \leftarrow Z$ in $\mathcal{G}_\mathcal{A}^{pattern(\mathcal{M})}$.*

Proof. This follows from Lemma 4.4.1 in (Maier, 2014) for the existence of a triple. Since there is no dependency between X and Z, the triple must be unshielded. □

Corollary 7. *For every unshielded non-collider $(X,Y,Z) \in \mathcal{G}_\mathcal{A}^\mathcal{M}$, $(X,Y,Z) \in \mathfrak{N}_\mathcal{A}^\mathcal{M}$.*

Hence, $\mathfrak{N}$ is simply a set of non-colliders that includes all unshielded non-colliders.

Sound Rules The four rules in Figure 5 can be used to correctly orient the edges in a partially-directed CDG $\mathcal{G}_\mathcal{A}$ (Corollary 7). We provide three additional rules that make use of $\mathfrak{N}$. First, if $(X,Y,Z) \in \mathfrak{N}$ and $X \to Y$, then $Y \to Z$. This can be viewed as a generalization of R1 that

Algorithm 1 Completing a PDAG given non-colliders.

```
1: procedure completes(PDAG 𝒢, non-colliders 𝔑)
2:    U := {X→Y, Y→X}_{X−Y∈𝒢}
3:    for X→Y in U do
4:       𝒢′ := (𝒢 \ {X − Y}) ∪ {X → Y}
5:       if ∀_{V∈pa(𝒢,Y)}(X, Y, V) ∉ 𝔑 and ext(𝒢′, 𝔑) then
6:          remove edges of 𝒢′ from U
7:       else orient Y→X in 𝒢, remove Y→X from U

8: procedure ext(𝒢, 𝔑)
9:    ℋ := copy(𝒢)
10:   repeat
11:      for X in 𝕍(ℋ) such that ch(ℋ, X) = ∅ do
12:         if (V1, X, V2) ∉ 𝔑 for every V1, V2 ∈ adj(ℋ, X)
13:            orient Y→X in 𝒢 for every Y ∈ ne(ℋ, X)
14:            ℋ := ℋ \ {X}
15:            break
16:      else return False
17:   until ℋ is empty
18:   return True
```

avoids checking unshieldedness. Second, if $(X, Y, Z) \in \mathfrak{N}$ and $X \to Z$, then $Y \to Z$. This is similar to R4 in the sense that $Y \to Z$ is a common orientation among possible orientations of a non-collider that does not create a directed cycle. Finally, we can identify a shielded collider from the fact that there must be a sink in any undirected cycle. If there exists an undirected cycle of length $n \geq 3$ where every subsequent triple in the cycle except one is non-collider, then the triple that is not a *non-collider* must be a collider. The preceding rules are clearly sound. However, without further characterization of non-colliders $\mathfrak{N}$ in a partially-directed CDG, we cannot prove that they are complete for learning the structure of an RCM.

Extensibility with Shielded Non-Colliders We generalize the algorithm for determining whether a PDAG admits an oriented extension (PDAG extensibility) (Dor and Tarsi, 1992) to work with a set of non-colliders that may be, but not necessarily, shielded. The original PDAG extensibility algorithm finds a vertex without outgoing edges where all undirected edges on the vertex can be oriented towards the vertex (i.e., sinkable) without creating new unshielded colliders. If such a vertex is found, the undirected edges between it and its neighbors are oriented towards it. The preceding steps are repeated after removing the vertex from the PDAG. The algorithm returns failure if some edges remain undirected in the PDAG and no sinkable vertex can be found. The original algorithm exploits the observation that a sinkable vertex cannot be "the middle of unshielded non-colliders", which we generalize to "the middle of non-colliders $\mathfrak{N}$". Because the unshieldedness of non-colliders plays no role in the proof of correctness of the original algorithm, the proof holds for the modified algorithm (Algorithm 1).

Theorem 8. *Let $\mathcal{G}$ be a PDAG. Let $\mathfrak{N}$ be a set of non-colliders which includes all unshielded non-colliders in $\mathcal{G}$. Then, algorithm ext correctly decides whether there exists a DAG that is a consistent extension of $\mathcal{G}$ satisfying constraints imposed by $\mathfrak{N}$.*

Proof. Let $ce(\mathcal{G}, \mathfrak{N})$ be a set of DAGs that consistently extend $\mathcal{G}$ for a given set of attribute level non-colliders $\mathfrak{N}$. Let $\mathfrak{N}(\mathcal{G}) = \{(X, Y, Z) \in \mathfrak{N} \mid \{X, Y, Z\} \subseteq \mathbb{V}(\mathcal{G})\}$ be a set of *induced* non-colliders. Whenever there exists a DAG $\mathcal{G}' \in ce(\mathcal{G}, \mathfrak{N})$, there must exist X, a sink of $\mathcal{G}$, such that $ce(\mathcal{G} - X, \mathfrak{N}(\mathcal{G} - X))$ is non-empty since $\mathcal{G}' - X$ satisfies $\mathfrak{N}(\mathcal{G} - X)$. Thus the algorithm 1 will maximally orient the PDAG and return True.

Let $\mathcal{G}''$ be a DAG in $ce(\mathcal{G} - X, \mathfrak{N}(\mathcal{G} - X))$ and $\mathcal{G}'''$ be a *reconstructed* graph $\mathcal{G}'' \cup \{X\} \cup \{Y \to X \mid Y \in ne(\mathcal{G}, X)\}$. Then, $\mathcal{G}'''$ is in $ce(\mathcal{G}, \mathfrak{N})$: (i) $\mathcal{G}'''$ is a DAG since adding a vertex as a sink to a DAG results a DAG; and (ii) $\mathcal{G}'''$ satisfies $\mathfrak{N}(\mathcal{G}) \setminus \mathfrak{N}(\mathcal{G} - X)$ since, for every reconstructed (shielded or unshielded) collider $Y \to X \leftarrow Z$, $(Y, X, Z) \notin \mathfrak{N}$ (by the definition of sinkable vertex). Therefore, ext finds a DAG in $ce(\mathcal{G}, \mathfrak{N})$ and returns True whenever $\mathcal{G}$ is extensible; and returns False otherwise. □

5 CAUSAL DISCOVERY ALGORITHM

We proceed to present RpCD, a sound and complete causal discovery algorithm for RCM under path semantics under the usual assumptions namely, causal Markov condition, sufficiency, and faithfulness (Spirtes et al., 2000), that allow us to interpret every ground graph of RCM as a CBN. We also assume access to an independence oracle that correctly answers independence queries with respect to the RCM. We further assume, as in (Maier et al., 2013a), that the maximum hop length of dependencies is known *a priori* which ensures that only a finite number of candidate dependencies need to be considered.

RpCD (see Algorithm 2) extends the key ideas of the PC algorithm (Spirtes et al., 2000) to the relational domain. Phase I of RpCD identifies adjacencies (Lines 1–11) and phase II orients the dependencies (Lines 12–23). The phase I is nearly identical to that of RCD (Maier et al., 2013a). Given a maximum hop threshold h, all candidate dependencies are enumerated. Then, spurious dependencies are removed through conditional independence tests. In Lines 12–23, it orients undirected dependencies through conditional independence tests on CUTs. Redundant tests are avoided by skipping (i) already known non-colliders (Line 15), (ii) already oriented edges (Line 16), and (iii) inactive non-colliders (Line 17). At an attribute class level, edges are oriented if forming a collider (Line 19) or forming a non-collider having the same attribute classes on its flanking elements (Line 20, RBO). All orientations that can be inferred from the sound orientation rules (see Section 4.2) are enforced (Line 22). Finally, Line 23 maximally-orients partially-directed class dependency graph with a complete

Algorithm 2 RpCD

Input: $\mathcal{S}$ schema, $\mathcal{O}$ independence tester, h hop threshold

1: initialize $\mathbf{D}$ with candidate dependencies up to h hops.
2: initialize an undirected graph $\mathcal{G}$ with undirected $\mathbf{D}$.
3: $\ell := 0$
4: **repeat**
5: **for** every ordered pair $(P.Y,\ \mathcal{V}_X)$ **s.t.** $P.Y - \mathcal{V}_X \in \mathcal{G}$ **do**
6: **for** every $\mathbf{S} \subseteq ne(\mathcal{G}, \mathcal{V}_X) \setminus \{P.Y\}$ **s.t.** $|\mathbf{S}| = \ell$ **do**
7: **if** $\mathcal{V}_X \perp\!\!\!\perp P.Y \mid \mathbf{S}$ **then**
8: remove $\{P.Y - \mathcal{V}_X, \tilde{P}.X - \mathcal{V}_Y\}$ from $\mathcal{G}$.
9: **break**
10: $\ell := \ell + 1$
11: **until** $|ne(\mathcal{G}, \mathcal{V}_X)| - 1 < \ell$ for every $X \in \mathcal{A}$
12: initialize $\mathfrak{U}$ with canonical unshielded triples from $\mathcal{G}$.
13: $\mathfrak{N} := \emptyset$, $\mathcal{H} := \langle \mathcal{A}, \{X - Y \mid P.Y - \mathcal{V}_X \in \mathcal{G}\}\rangle$
14: **for** every $(\mathcal{V}_X, \mathbf{P}.Y, R.Z) \in \mathfrak{U}$ **do**
15: **continue if** $(X, Y, Z) \in \mathfrak{N}$ **or**
16: $\{X, Z\} \cap ne(\mathcal{H}, Y) = \emptyset$ **or**
17: $\{X, Z\} \cap ch(\mathcal{H}, Y) \neq \emptyset$
18: **if** exists $\mathbf{S} \subseteq adj(\mathcal{G}, \mathcal{V}_X)$ **s.t.** $R.Z \perp\!\!\!\perp \mathcal{V}_X \mid \mathbf{S}$ **then**
19: **if** $\mathbf{S} \cap \mathbf{P}.Y = \emptyset$ **then** orient $X \to Y \leftarrow Z$ in $\mathcal{H}$
20: **else if** $X = Z$ **then** orient $Y \to X$ in $\mathcal{H}$
21: **else** add (X, Y, Z) to $\mathfrak{N}$
22: orient edges in $\mathcal{H}$ with sound rules with $\mathfrak{N}$.
23: $completes\,(\mathcal{H}, \mathfrak{N})$
24: **return** $\bigcup_{P.Y - \mathcal{V}_X \in \mathcal{G}} \begin{cases} P.Y \to \mathcal{V}_X & Y \to X \in \mathcal{H} \\ P.Y - \mathcal{V}_X & Y - X \in \mathcal{H} \end{cases}$

set of attribute class level non-colliders $\mathfrak{N}$ (except the inactive ones that play no role in the orientation of the edges). RpCD outputs undirected and directed dependencies reflecting orientations recovered from Phase II (Line 24).

Theorem 9 (Soundness and Completeness)**.** *Let $\mathcal{M}$ be an RCM whose maximum hop length of dependencies is less than or equal to h. Given access to an independence oracle and h, RpCD is sound and complete for learning the structure of the RCM under path semantics.*

Proof. The proof follows from (Maier et al., 2013a) for Phase I and, for Phase II, from the Markov equivalence of RCMs (Theorem 3) with the completeness of (i) CUTs for UTs, (ii) the CUT-enumerating algorithm for (non-)colliders ($\mathfrak{C}_{\mathcal{A}}^{\mathcal{M}}$ and $\mathfrak{N}_{\mathcal{A}}^{\mathcal{M}}$), and (iii) generalized extensibility (Theorem 8). □

Causal Discovery of RCM under BBS It is easy to see that a modification of RCD (Maier et al., 2013a) to take advantage of valid CUTs under BBS will improve the orientation recall of RCD. Given the implications of BBS (Section 3), one can check whether a CUT of an RCM under path semantics correspond to a UT in some ground graph of the RCM under BBS. The "valid" CUTs under BBS can then replace UTs of AGG (Maier et al., 2013b; Lee and Honavar, 2016) used by RCD for orientating the edges. Note that each UT of AGG is a special case of CUT where $(a_r, b_r) = (a_s, b_s)$ with $P^{a_r:} = Q^{:b_r:-1}$.

6 SUMMARY AND DISCUSSION

Relational causal models (RCM) offer an attractive approach to modeling causality in real world settings that are modeled by relational domains. Previous studies of RCM have assumed bridge burning semantics (BBS). A careful examination of RCM under BBS reveals its counter-intuitive behavior. We consider RCM under path semantics which offers a viable alternative to BBS while preserving its desirable properties while avoiding its counterintuitive consequences. We introduced canonical unshielded triples, a novel graphical construct that we use to characterize Markov equivalence of RCM under path semantics. We described RpCD, a sound and complete algorithm for recovering the structure of an RCM under path semantics from conditional independence queries. We also suggested ways to improve the orientation recall of algorithms for learning the structure of RCM under BBS.

We conclude by listing some promising directions for further research: (i) Our analysis is based on perfect independence tests. In practice, the reliability of independence tests depends on the accuracy of parametric assumption for the underlying distribution, and the quantity of available data. Many methods have been developed to make the structure learning algorithm for causal Bayesian networks (CBNs) robust to such errors including adjacency-conservative (Lemeire et al., 2012), orientation-conservative (Ramsey et al., 2006) and order-independent (Colombo and Maathuis, 2014) PC algorithms. It would be interesting to consider variants of RpCD that incorporate such approaches in the relational setting. (ii) There are variants of CBN that relax some of its restrictive assumptions (Richardson and Spirtes, 2002). Similar extensions of RCMs would be interesting to consider. (iii) It would be interesting to consider methods for estimating a spillover effect in the presence of interference (Tchetgen Tchetgen and VanderWeele, 2012) due to violation of stable unit treatment variable assumption. (iv) RCM currently does not allow class dependency graph level cycles even if such cycles are guaranteed to not introduce a cycle in any of the ground graphs of the model. For example, a person's traits are inherited from those of his/her biological parents. We can consider relaxing the acyclicity assumptions underlying RCM to permit such cycles.

Abstract

Random sampling in compressive sensing (CS) enables the compression of large amounts of input signals in an efficient manner, which is useful for many applications. CS reconstructs the compressed signals exactly with overwhelming probability when incoming data can be sparsely represented with a few components. However, the theory of CS framework including random sampling has been focused on exact recovery of signal; impreciseness in signal recovery has been neglected. This can be problematic when there is uncertainty in the number of sparse components such as signal sparsity in dynamic systems that can change over time. We present a new theoretical framework that handles uncertainty in signal recovery from the perspective of recovery success and quality. We show that the signal recovery success in our model is more accurate than the success probability analysis in the CS framework. Our model is then extended to the case where the success or failure of signal recovery can be relaxed. We represent the number of components included in signal recovery with a right-tailed distribution and focus on recovery quality. Experimental results confirm the accuracy of our model in dynamic systems.

1 INTRODUCTION

Continuous flows of big data are generated by many sources nowadays. Among these, resource limited devices occupy a significant portion. For these devices, sensing and transmitting massive data are important challenges, as they are concerned with saving resources.

Compressive sensing (CS) (Seeger & Nickisch, 2008; Hsu et al., 2009; Lopes, 2013; Malioutov & Varshney, 2013; Zhu & Gu, 2015) is a well suited choice for resource limited devices because it enables the sensing and compression of massive data without the complexity burden imposed by conventional schemes. Recent advances in CS reduce the complexity burden even further with *random sampling*, by which CS schemes have been successfully applied to broader application areas such as sampling of spatio-temporal data (Foucart & Rauhut, 2013; Lee & Choi, 2014).

CS reconstructs the exact signals from the compressed measurements with overwhelming probability when incoming data can be sparsely represented (i.e., small numbers of components). Therefore, most CS frameworks are built based on the assumption that incoming data with sparse representation can be *exactly* recovered when an enough number of measurements is given.

Unfortunately, this assumption does not hold in practice when there is no guarantee of enough measurements for varying signal sparsity. This *uncertainty* occurs especially with many dynamic systems where the numbers of components change over time. The assumption also implies that the reconstruction would fail when input signals have more components (denser) than a predefined threshold. This prevents deriving a tight probabilistic model which takes account of the numbers of components and measurements in signal recovery. In this regard, recently introduced dynamic CS frameworks (Malioutov et al., 2010; Sejdinovic et al., 2010; Shahrasbi et al., 2011; Vaswani & Lu, 2010; Ziniel & Schniter, 2013) provide the way of reducing the number of necessary measurements exploiting temporal correlation between measurements. Nevertheless, a recovery success/quality analysis with uncertainty in signal sparsity has not been provided by existing CS frameworks yet.

This paper presents a new theoretical framework for the random sampling in CS that handles *impreciseness* in signal recovery when the number of measurements lacks for varying signal sparsity. Our framework incorporates the beta distribution to present the signal recovery success more accurately than the success probability analysis in the CS framework. Furthermore, we relax the concept of signal recovery success and present the number of components

included in the signal recovery as a varying quantity, for which we propose right-tailed distribution modeling. We believe our new framework will bridge the gap between success and failure of signal recovery in CS frameworks.

2 COMPRESSIVE SENSING AND RANDOM SAMPLING

Compressive sensing, or compressed sampling (CS), is an efficient signal processing framework which incorporates signal acquisition and compression simultaneously (Baraniuk, 2007; Candès & Wakin, 2008). CS enables a signal to be acquired with a number of samples that is far fewer than an original signal dimension and of the same order as the number of (significant) components.

2.1 COMPRESSING WHILE SENSING

In CS, a signal is projected onto random vectors whose cardinality is far below the dimension of the signal. Consider a signal $\mathbf{x} \in \mathbb{R}^N$ is compactly represented with a sparsifying basis $\mathbf{\Psi}$ having just a few components: $\mathbf{x} = \mathbf{\Psi s}$, where $\mathbf{s} \in \mathbb{R}^N$ is the vector of transformed coefficients with a few significant coefficients. Here, $\mathbf{\Psi}$ could be a basis that makes $\mathbf{x}$ sparse in a transform domain such as the DCT, wavelet transform domains, or even the canonical basis, i.e., the identity matrix $\mathbf{I}$, if $\mathbf{x}$ is sparse itself without the help of a transform.

Definition (K-sparse Signal)**.** *A signal* $\mathbf{x}$ *is called* K*-sparse if it is a linear combination of only* $K \ll N$ *basis vectors such that* $\sum_{i=1}^{K} s_{n_i} \mathbf{\psi}_{n_i}$*, where* $\{n_1, \ldots, n_K\} \subset \{1, \ldots, N\}$*;* s_{n_i} *is a coefficient in* $\mathbf{s}$*; and* $\mathbf{\psi}_{n_i}$ *is a column of* $\mathbf{\Psi}$*.*

In practice, some signals may not be exactly K-sparse. Rather, they can be closely approximated with K basis vectors by ignoring many small coefficients close to zero. This type of signal is called *compressible* (Baraniuk, 2007; Foucart & Rauhut, 2013).

CS projects $\mathbf{x}$ onto a random sensing basis $\mathbf{\Phi} \in \mathbb{R}^{M \times N}$ as follows ($M < N$):

$$\mathbf{y} = \mathbf{\Phi x} = \mathbf{\Phi \Psi s}, \tag{1}$$

where $\mathbf{\Phi}$ should have the *restricted isometry property* (RIP).[1] A conventional approach for $\mathbf{\Phi}$ to satisfy RIP is sampling its independent identically distributed (i.i.d.) elements from the Gaussian distribution or other sub-Gaussian distributions (e.g., Rademacher/Bernoulli distribution).

The system shown in (1) is underdetermined, as the number of equations M is smaller than the number of variables N, i.e., there are infinitely many $\mathbf{x}$'s that satisfy $\mathbf{y} = \mathbf{\Phi x}$. Nevertheless, this system can be solved with overwhelming probability exploiting the fact that $\mathbf{s}$ is K-sparse. Here $M = O(K \log(N/K))$ in the case of Gaussian and sub-Gaussian sensing matrices (Candès & Wakin, 2008).

2.2 RANDOM SAMPLING

Random sampling is a variant of CS which can further reduce the computational complexity to a constant time (Foucart & Rauhut, 2013; Lee & Choi, 2014). The random sampling scheme is based on the fact that it is possible to construct $\mathbf{\Phi}$ in (1) from a random selection of rows from the identity matrix $\mathbf{I}$, which is equivalent to the random sampling of coefficients in $\mathbf{x}$.

Note that the sparsifying basis $\mathbf{\Psi}$ should be *incoherent*[2] with $\mathbf{I}$, such as the DCT and wavelet transform bases, for the successful recovery of the original signal (Candès & Wakin, 2008; Foucart & Rauhut, 2013). Unless they are incoherent, the measurement vector $\mathbf{y} \in \mathbb{R}^M$ in (1) would contain zero entries. Here, the number of required measurements M is larger than in the cases of Gaussian and sub-Gaussian matrices, that is, $M = O(K \log N)$.

2.3 RECOVERY OF SIGNAL

A signal recovery algorithm takes measurements $\mathbf{y}$, a random sensing matrix $\mathbf{\Phi}$, and the sparsifying basis $\mathbf{\Psi}$. The sensing matrix $\mathbf{\Phi}$ and sparsifying basis $\mathbf{\Psi}$ are assumed to be known to a decoder. The signal recovery algorithm then recovers $\mathbf{s}$ knowing that $\mathbf{s}$ is sparse. Once we recover $\mathbf{s}$, the original signal $\mathbf{x}$ can be recovered through $\mathbf{x} = \mathbf{\Psi s}$. The recovery algorithm reconstructs $\mathbf{s}$ by the following linear program:

$$\operatorname{argmin} \|\tilde{\mathbf{s}}\|_1 \qquad \text{subject to} \qquad \mathbf{\Phi \Psi} \tilde{\mathbf{s}} = \mathbf{y}. \tag{2}$$

The optimization problem in (2) is solved by a ℓ_1-minimization method (basis pursuit) (Boyd & Vandenberghe, 2004), greedy methods such as orthogonal matching pursuit (Pati et al., 1993), or thresholding-based methods such as iterative hard thresholding (Blumensath & Davies, 2008). Choosing a specific algorithm depends on $\mathbf{\Phi}$, M, N, and K: recovery success rates and speed can only be determined by numerical tests (Foucart & Rauhut, 2013).[3] In this paper, we reconstruct signals by the *basis pursuit*.

Specifically in the case of random sampling, the solution $\mathbf{s}^\star$ to (2) obeys

$$\|\mathbf{s}^\star - \mathbf{s}\|_2 \leq C_1 \cdot \|\mathbf{s} - \mathbf{s}_K\|_1 \tag{3}$$

[1] The random sensing basis $\mathbf{\Phi}$ have RIP if $(1-\delta)\|\mathbf{s}\|_2^2 \leq \|\mathbf{\Phi \Psi s}\|_2^2 \leq (1+\delta)\|\mathbf{s}\|_2^2$ for small $\delta \geq 0$, and this condition applies to all K-sparse $\mathbf{s}$.

[2] The two bases $\mathbf{\Phi}$ and $\mathbf{\Psi}$ are incoherent when the rows of $\mathbf{\Phi}$ cannot sparsely represent the columns of $\mathbf{\Psi}$ and vice versa.

[3] Note that greedy methods are not always fast.

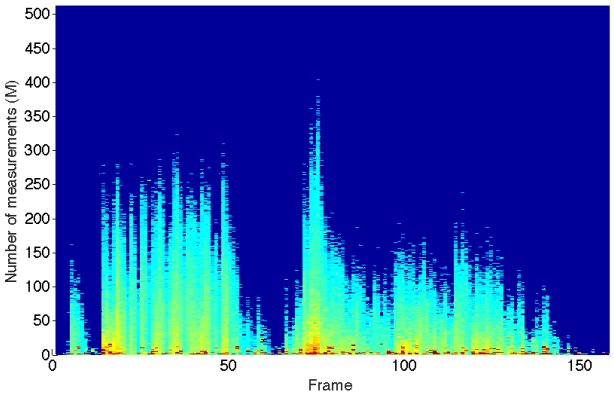

Figure 1: Recovery error of audio data for different numbers of measurements M over time. Each frame has a signal length $N = 512$. Colors close to blue represent smaller errors, whereas colors close to red represent larger errors.

for some constant $C_1 > 0$, where $\mathbf{s}_K$ is the vector $\mathbf{s}$ with all but the largest K components set to 0. When an original signal is exactly K-sparse, then $\mathbf{s} = \mathbf{s}_K$ with $M = O(K \log N)$ measurements, which implies that the recovery is exact, i.e., $\mathbf{s}^\star = \mathbf{s}$.

3 A NEW PERSPECTIVE ON RECOVERY SUCCESS

The success of signal reconstruction in compressive sensing (CS) is not deterministic. For instance, when we say an exact recovery of a K-sparse signal is achievable with overwhelming probability, it implies there is also the chance of recovery not being exact.

Most CS literature assumes a sufficient number of measurements M such that an exact recovery is almost always achievable (Candès & Wakin, 2008; Foucart & Rauhut, 2013), which is based on an assumption that sparsity K is already known or does not exceed a certain bound. However, the signal sparsity in dynamic systems may change over time and an excessive number of measurements may waste resources such as network bandwidth and storage space. For example, Figure 1 shows recovery error over time for audio data (a 7 second recording of a trumpet solo) (Ziniel et al., 2012), where varying signal sparsity incurs different recovery error with a fixed number of measurements over time. Here we cannot simply increase the number of measurements to eliminate error, as it is unreasonable in terms of compression. Therefore, we propose a new theoretical framework for the random sampling of CS and provide a new perspective on signal recovery.

3.1 COMPRESSIVE SENSING FRAMEWORK

In the random sampling of CS, the number of required measurements $M = O(K \log N)$ can be detailed as follows (Foucart & Rauhut, 2013):

$$M \geq C \cdot K \ln(N) \ln(\epsilon^{-1}) \tag{4}$$

for some constant $C > 0$, where $\epsilon \in (0, 1)$ denotes the probability of an *inexact* recovery of the K-sparse signal. In particular, the signal recovery succeeds with a probability of at least $1 - \epsilon$ if (4) holds.[4]

We can then express (4) with regard to the probability of failure ϵ, which is given by

$$\mathbf{P}(\mathbf{s}^\star \neq \mathbf{s} \mid M, N, K) := \epsilon \leq \exp\left(-\frac{M}{C \cdot \ln(N) K}\right). \tag{5}$$

Thus, the probability of failure (inexact recovery) $\mathbf{P}(\mathbf{s}^\star \neq \mathbf{s} \mid M, N, K)$ is conditional upon M, N, and K. Since we are interested in the dynamic signal sparsity K, we model K as a *random variable* with M and N as *fixed quantities*.

If we denote an arbitrary probability density function (pdf) of K as $f_K(k)$, we can marginalize over k and find the upper bound of failure probability as follows:

$$\begin{aligned}\mathbf{P}(\mathbf{s}^\star \neq \mathbf{s} \mid M, N) &= \int_k \mathbf{P}(\mathbf{s}^\star \neq \mathbf{s} \mid M, N, K) \cdot f_K(k)\, \mathrm{d}k \\ &\leq \int_k \exp\left(-\frac{M}{C \cdot \ln(N) K}\right) f_K(k)\, \mathrm{d}k.\end{aligned} \tag{6}$$

Therefore, we can state that a signal recovery succeeds with a probability of at least $1 - \int_k \exp(-M/(C \cdot \ln(N)K)) f_K(k) \mathrm{d}k$, given the distribution of signal sparsity $f_K(k)$.

The upper bound in (6) may have an analytic solution when K follows certain distributions such as the *inverse Gaussian distribution* and the *gamma distribution*.[5]

Remark Assuming $f_K(k) = \mathrm{IG}(\mu, \lambda)$, the upper bound of (6) is

$$\frac{\sqrt{\lambda} \exp(\lambda/\mu - \sqrt{2\lambda/\mu^2}\sqrt{M/(C \cdot \ln(N)) + \lambda/2})}{\sqrt{2M/(C \cdot \ln(N)) + \lambda}}, \tag{7}$$

where μ and λ are the mean and the shape parameter of the inverse Gaussian distribution, respectively.

Remark Assuming $f_K(k) = \mathrm{Gamma}(\kappa, \theta)$, the upper bound of (6) is

$$\frac{2}{\Gamma(\kappa)} \left(\frac{M}{C \cdot \ln(N)\theta}\right)^{\kappa/2} K_{-\kappa}\left(2\sqrt{\frac{M}{C \cdot \ln(N)\theta}}\right), \tag{8}$$

[4] See Theorem 12.20 (Foucart & Rauhut, 2013).

[5] Since $K \geq 0$, probability distributions supported on semi-infinite intervals, i.e., $(0, \infty)$, are rational choices.

where κ and θ are the shape parameter and the scale parameter of the gamma distribution, respectively; $\Gamma(\cdot)$ is the gamma function; and $K_{-\kappa}(\cdot)$ is the modified Bessel function of the second kind.

3.2 MODELING SUCCESS AND FAILURE

Unfortunately, the probability of signal recovery failure ϵ given in (5) does not hold in practice because there is a discrepancy between the failure probabilities in the CS framework and actual random sampling, as will be further explained in Section 5.1. Thus we have to model the success or failure probability of signal recovery from a new perspective.

We can model the new pdf of *signal recovery success* using the mixture of the *Dirac delta function* and the *beta distribution*, which incorporates both stochastic and deterministic cases. We introduce $K_{\min}$ and $K_{\max}$ to denote the minimum and the maximum signal sparsities which yield stochastic probability, as opposed to a deterministic result where signal recovery always succeeds or always fails.

Definition (Recovery Success Model)**.** *Let* $\mathbf{P}(\mathbf{s}^\star{=}\mathbf{s}|M,N) := \Pi$. *The pdf of* Π *given* K *is given by*[6]

$$f_{\Pi|K}(\pi \mid k) := \begin{cases} \delta(\pi - 1) & k < K_{\min} \\ \mathrm{Beta}(\alpha_K, \beta_K) & K_{\min} \le k \le K_{\max}. \\ \delta(\pi) & K_{\max} < k \end{cases} \quad (9)$$

Combining this definition with an arbitrary pdf $f_K(k)$ of the dynamic signal sparsity K, we can find the success probability distribution marginalized over k as follows:

$$\begin{aligned} f_\Pi(\pi) &= \int_k f_{\Pi|K}(\pi \mid k) f_K(k)\,\mathrm{d}k \\ &= \int_0^{K_{\min}} \delta(\pi - 1) f_K(k)\,\mathrm{d}k \\ &\quad + \int_{K_{\min}}^{K_{\max}} \mathrm{Beta}(\alpha_K, \beta_K) \cdot f_K(k)\,\mathrm{d}k \\ &\quad + \int_{K_{\max}}^{\infty} \delta(\pi) f_K(k)\,\mathrm{d}k \\ &= \delta(\pi - 1) F_K(K_{\min}) + \delta(\pi)(1 - F_K(K_{\max})) \\ &\quad + \int_{K_{\min}}^{K_{\max}} \mathrm{Beta}(\alpha_K, \beta_K) \cdot f_K(k)\,\mathrm{d}k, \end{aligned} \quad (10)$$

where $F_K(\cdot)$ is the cumulative distribution function (CDF) of K.

The two Dirac delta function terms in (10) can be interpreted as probability masses. Since $\int_{K_{\min}}^{K_{\max}} \mathrm{Beta}(\alpha_K, \beta_K) \cdot f_K(k)\,\mathrm{d}k$ does not have an analytic solution, we compute this value numerically.

[6] $\mathrm{Beta}(\alpha_K, \beta_K)$ here is used to denote the pdf of the beta distribution.

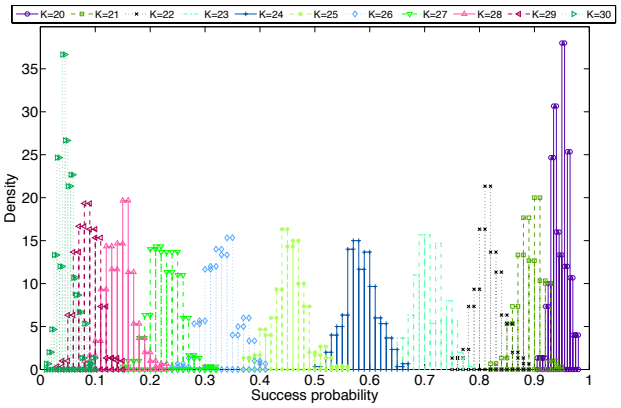

Figure 2: Histograms of success probability for various K's. Success probability distribution for each K was obtained with 300 different random signed spike vectors for $N = 512$ and $M = 100$. A single success probability for each signed spike vector was calculated with 300 experiments.

As an illustrative example, suppose that we examine the success probability by generating many different signed spike (± 1) vectors for each signal sparsity and then performing experiments for each signed spike vector.[7] Figure 2 shows histograms of success probability for various signal sparsities, where $K_{\min} = 20$ and $K_{\max} = 30$.

The success probability shown in Figure 2 naturally follows the beta distribution with its parameters α and β depending on signal sparsity, i.e., $\mathbf{P}(\mathbf{s}^\star{=}\mathbf{s} \mid M, N, K) \sim \mathrm{Beta}(\alpha_K, \beta_K)$.[8] The beta distribution is well known as the conjugate prior for the Bernoulli and the binomial distributions which are ideal for modeling success/failure.

3.3 MODELING ACCURACY

Here, we present the main theoretical contribution: the recovery success model defined in (9) is tighter than the lower bound of that in the existing CS framework explained in Section 3.1, when the number of measurements is not enough. We show the failure probability in the CS framework (5) is incapable of reflecting the actual failure probability of signal recovery. Not only can't the inequality $\mathbf{P}(\mathbf{s}^\star \neq \mathbf{s} \mid M, N, K) \le \exp(-M/(C \cdot \ln(N)K))$ provide tight probability of failure, but the inequality itself is inaccurate.

This inaccuracy results from the slowly decaying lower bound of success probability, that is, $1 - \exp(-M/(C \cdot \ln(N)K))$. In fact, we can show this lower bound decays slower than a power-law decay by the following lemma.

[7] Detailed settings are explained in Section 5.1.

[8] If more than 300 experiments had been performed, each success probability distribution would have been more sharply peaked due to a smaller variance.

Lemma 1 (Slackness of Recovery Success Probability)**.** *There exists $K_0 > 0$ such that for all $K > K_0$, the lower bound of recovery success probability in the CS framework (Section 3.1) is greater than the value of a power-law-decay function.*

Proof. We need to show the following inequality

$$1 - \exp\left(-\frac{M}{C \cdot \ln(N)K}\right) > K^{-\alpha} \tag{11}$$

holds if $K > K_0$ for some $K_0 > 0$, where $\alpha > 0$. Adding, subtracting, and taking the power K on both sides yields

$$(1 - K^{-\alpha})^K > \exp\left(-\frac{M}{C \cdot \ln(N)}\right). \tag{12}$$

We now use the *binomial approximation* on the left-hand side: $(1 - K^{-\alpha})^K \geq 1 - K \cdot K^{-\alpha}$. Thus we instead prove the following inequality

$$1 - K^{1-\alpha} > \exp\left(-\frac{M}{C \cdot \ln(N)}\right) \tag{13}$$

holds if $K > K_0$ for some $K_0 > 0$.

If we assume $\alpha > 1$, then adding, subtracting, and taking the power $1/(1-\alpha)$ on both sides of (13) yields

$$\left(1 - \exp\left(-\frac{M}{C \cdot \ln(N)}\right)\right)^{1/(1-\alpha)} < K. \tag{14}$$

Setting $K_0 = (1 - \exp(-M/(C \cdot \ln(N))))^{1/(1-\alpha)}$, we can argue that for all $K > K_0$, the lower bound of recovery success probability is greater than the value of a power-law-decay function. □

Corollary 2. *In the CS framework (Section 3.1), there is always a chance of succeeding at signal recovery however large K is.*

Proof. The power-law-decay function $K^{-\alpha}$ in (11) *slowly* converges to zero as $K \to \infty$: its value is noticeably greater than zero even with a large K. As the lower bound of recovery success probability is greater than the value of the power-law-decay function for all $K > K_0$, there is always a chance of recovery success however large K is. □

The claim of the CS framework in Corollary 2 is in fact implausible because it says we can even set $K > M$ and there is still a chance of success. We cannot expect signal recovery with a number of measurements M less than K. We now show that our recovery success model provides more accurate success probability by the following theorem.

Theorem 3. *The recovery success model in (9) is tighter than the lower bound of recovery success probability given by the CS framework (Section 3.1) with a limited number of measurements.*

Proof. In contrast to Corollary 2, our recovery success model can yield $\mathbf{P}(\mathbf{s}^\star = \mathbf{s} \mid M, N, K) = 0$ with a bounded $K_{\max}$. In particular, we can let the mean of $\mathrm{Beta}(\alpha_K, \beta_K)$, $\alpha_K/(\alpha_K + \beta_K)$, converge to zero with $\alpha_{K_{\max}} \to 0$.

Similarly, we show this mean converges to one ($\mathbf{P}(\mathbf{s}^\star = \mathbf{s} \mid M, N, K) = 1$) with $K_{\min}$ which is not so close to zero, whereas the lower bound of the recovery success probability given by the CS framework converges to one only if K is very close to zero.

We can let $\alpha_K/(\alpha_K + \beta_K)$ converge to one with $\beta_{K_{\min}} \to 0$. In contrast, $1 - \exp(-M/(C \cdot \ln(N)K)) \to 1$ if, and only if, $K \to 0$. Since $0 < K_{\min} < K_{\max} < \infty$, we can argue that our recovery success model can provide tighter recovery success probability. □

3.4 PARAMETER LEARNING IN DYNAMIC SYSTEMS

When the signal sparsity K changes in dynamic systems, it does not change in an abrupt manner; rather, it tends to smoothly change over time (Vaswani & Lu, 2010; Ziniel & Schniter, 2013). One simple way to model this correlation between K's is to utilize the *Markov model* (Ziniel & Schniter, 2013). In this setup, each K makes up a state and each state is associated with the recovery success probability. This can be best modeled by the hidden Markov model, where each state K generates success/failure according to the emission probability.

In our scenario, signal recovery success is observed in an environment where the signal sparsity varies over time. We want to estimate parameters of the hidden Markov model, especially the emission probabilities. Since our recovery success model employs the beta distribution as conjugate distributions (prior and posterior), we can learn its parameters α_K and β_K for each state K.

Specifically, the decoder can observe signal recovery success/failure and corresponding signal sparsity K at each decoding step. Then using these emission and state sequences, it can sequentially update the parameters α_K and β_K for each state K (Durbin et al., 1998), by simply incrementing the value of α_K by 1 for each success or the value of β_K by 1 for each failure.

In order to prevent over-fitting with insufficient observations, it is preferable to have hyperparameters of the prior beta distribution set according to K's. In Figure 2, we can clearly see the trend of α_K and β_K for different K's: α_K decreases, whereas β_K increases as K grows.[9] Therefore, these hyperparameters can act as the effective numbers of observations of recovery success/failure, reflecting our prior belief on signal recovery success for different K's.

[9] Also, see the proof of Theorem 3.

4 FURTHER ANALYSIS ON RECOVERY QUALITY

When a signal of interest is not exactly K-sparse but compressible, as discussed in Section 2.1, the signal recovery in Section 2.3 can be treated from a different perspective (Lee & Choi, 2015). In particular, the inequality (3) is considered differently.

If an original signal is compressible, then the quality of a recovered signal is proportional to that of the K most significant pieces of information. We get progressively better results as we compute more measurements M, since $M = O(K \log N)$ (Candès & Wakin, 2008). Therefore, $\mathbf{\Psi}\mathbf{s}^\star \in \mathbb{R}^N$ also makes progress on its quality as M increases.[10]

From this viewpoint, the success or failure of signal recovery no longer exists. Rather, we can view the number of components included in the signal recovery as a *varying quantity*. Specifically, if a signal recovery is about to fail with a given K, then K can be lowered to make the recovery eventually succeed. Here the number of *included* components K varies for different recoveries and signals, as analogous to the success probability in Section 3.2 that can be calculated with different recoveries and varies for different signals.

In this regard, (3) can be utilized to infer varying K's over different recoveries and signals. Here our assumption is that the upper bound in (3) is *tight* such that we solve the following optimization problem:

$$\max K \qquad \text{subject to} \qquad \|\mathbf{s}^\star - \mathbf{s}\|_2 \leq C_1 \cdot \|\mathbf{s} - \mathbf{s}_K\|_1. \tag{15}$$

In (15), C_1 has to be determined, where the maximum signal sparsity $K_{\max}$ introduced in Section 3.2 plays a key role to set the upper limit on how large K can be, since $K > K_{\max}$ is not reasonable.

In particular, we can generate a compressible signal $\mathbf{s}_i \in S$ such that $\|\mathbf{s}_i\|_1 = C_{\ell_1}$ and $\|\mathbf{s}_i\|_2 = C_{\ell_2}$ for all i, where S is the set containing many different signals; $C_{\ell_1} > 0$ and $C_{\ell_2} > 0$ are constants. For each $\mathbf{s}_i$, we have a set $S_i^\star$ which contains many different recoveries $\mathbf{s}_{ij}^\star$. Then C_1 can be found as follows:

$$C_1 = \frac{\min \|\mathbf{s}_{ij}^\star - \mathbf{s}_i\|_2}{\|\mathbf{s}_i - \mathbf{s}_i^{K_{\max}}\|_1}, \tag{16}$$

where $\mathbf{s}_i^{K_{\max}}$ denotes the compressible signal $\mathbf{s}_i$ with all but the largest $K_{\max}$ components set to 0.

Varying K's obtained through (15) can be represented by a pdf, which has been empirically shown to follow the *gamma distribution* (Lee & Choi, 2015). We are interested in the shape of this pdf, which is shown by the following proposition.

Proposition 1. *The pdf of K, the number of components included in the signal recovery of a compressible signal, is skewed to the right, i.e., right tailed.*

Proof. Since $\|\mathbf{s}_i\|_1 = C_{\ell_1}$ and $\|\mathbf{s}_i\|_2 = C_{\ell_2}$ for all i, we can conceive the same sequence $\{s_n\}$ of elements (absolute values) in $\mathbf{s}_i$ for all i. Then we have

$$\|\mathbf{s}_i - \mathbf{s}_i^K\|_1 = \sum_{n=1}^{N-K} s_n. \tag{17}$$

Without loss of generality, we consider the partial sum $\sum_{n=1}^{N-K} s_n$ in (17) to be an *arithmetic series* which can be represented by a quadratic function in terms of K. We also assume the inequality constraint in (15) is the equality constraint such that $\|\mathbf{s}^\star - \mathbf{s}\|_2 = C_1 \cdot \|\mathbf{s} - \mathbf{s}_K\|_1$.

If we take the (partial) inverse function of the quadratic function, we have $K \sim K_{\max} - \sqrt{\|\mathbf{s}^\star - \mathbf{s}\|_2 - (\min \|\mathbf{s}_{ij}^\star - \mathbf{s}_i\|_2)}$. Assuming the distribution of $\|\mathbf{s}^\star - \mathbf{s}\|_2$ is *symmetric* (zero skewness), this asymptotic relation says $\|\mathbf{s}^\star - \mathbf{s}\|_2$ will be *compressed* as it becomes large, which in turn makes the pdf of K right tailed.

A similar claim can be made if we consider the partial sum $\sum_{n=1}^{N-K} s_n$ to be a *geometric series*, where $K \sim N - \log(\|\mathbf{s}^\star - \mathbf{s}\|_2)$. In this case, the pdf of K is skewed to the right as well. □

4.1 ERROR ANALYSIS IN DYNAMIC SYSTEMS

Since the success or failure of signal recovery does not exist in this framework, we instead investigate the amount of error occurring during the recovery procedure in an *expected value* sense. In particular, the best K-term approximation $\|\mathbf{s} - \mathbf{s}_K\|_1$ in (3) is known to be bounded as follows (Baraniuk et al., 2010):

$$\|\mathbf{s} - \mathbf{s}_K\|_1 \leq \frac{2G}{K}, \tag{18}$$

where the constant G can be learned by the power-law decay such that each magnitude of components in $\mathbf{s}$, sorted in decreasing order, is upper bounded by G/i^2. ($i = 1, \ldots, N$ is the sorted index.)

Then we can analyze the ℓ_2 error E of signal recovery assuming $f_K(k) = \mathrm{Gamma}(\kappa, \theta)$, which is given by

$$E = \int_k C_1 \cdot \frac{2G}{k} f_K(k)\, \mathrm{d}k = \frac{2C_1 G}{\theta} \mathrm{B}(\kappa - 1, 1), \tag{19}$$

where $\mathrm{B}(\cdot, \cdot)$ is the beta function (Lee & Choi, 2015). Here the pdf $f_K(k)$ is employed to represent varying K's.[11]

[10] The error bound follows (3) as well if $\mathbf{\Psi}$ is an orthogonal matrix, which is usually the case.

[11] Note that this pdf is different from the one introduced in Section 3.

In this framework, there is no longer such an indicator as the timely varying signal sparsity K in Section 3, because signals are compressible and their coefficients are already populated with small, but non-zero, coefficients. Thus, we may assume the same gamma distribution over time, whose parameters κ and θ can then be estimated.

In order to prevent over-fitting to insufficient observations, we introduce the conjugate prior for the gamma distribution. It is known that the conjugate prior of the gamma distribution has the following form (Miller, 1980; Fink, 1997).

$$\mathbf{P}(\kappa, \theta \mid p, q, r, s) = \frac{1}{Z} \cdot \frac{p^{\kappa-1} \exp(-q/\theta)}{\Gamma(\kappa)^r \theta^{s\kappa}}, \tag{20}$$

where $p, q, r, s > 0$ are hyperparameters that are sequentially updated with $p' = pk$, $q' = q + k$, $r' = r + 1$, and $s' = s + 1$;[12] and the normalizing constant Z is

$$Z = \int_0^\infty \frac{p^{\kappa-1}\Gamma(s\kappa+1)}{\Gamma(\kappa)^r q^{s\kappa+1}} \, \mathrm{d}\kappa. \tag{21}$$

Using (19) and (20), we can marginalize over κ and θ to estimate error $\widehat{E}$ as follows:

$$\begin{aligned} \widehat{E} &= \int_\kappa \int_\theta E \cdot \mathbf{P}(\kappa, \theta \mid p, q, r, s) \, \mathrm{d}\theta \, \mathrm{d}\kappa \\ &= \frac{2C_1 G}{Z} \int_0^\infty \frac{p^{\kappa-1}}{(\kappa-1)\Gamma(\kappa)^r} \int_0^\infty \frac{\exp(-q/\theta)}{\theta^{s\kappa+1}} \, \mathrm{d}\theta \, \mathrm{d}\kappa \\ &= \frac{2C_1 G}{Z} \int_0^\infty \frac{p^{\kappa-1}\Gamma(s\kappa)}{(\kappa-1)\Gamma(\kappa)^r q^{s\kappa}} \, \mathrm{d}\kappa, \end{aligned} \tag{22}$$

which can be computed numerically.

5 EXPERIMENTAL RESULTS

5.1 RECOVERY SUCCESS

In Section 3, we discussed the discrepancy between the failure probabilities in the CS framework and actual random sampling. In order to show this discrepancy, we *artificially* generated signed spikes ± 1 at random locations in proportion to desired sparsities and *densified* these spikes using $\mathbf{\Psi}$[13] to perform the random sampling.

For each signal sparsity K, the actual failure probability can be calculated for different recovery experiments. To this end, we adopted a standard optimization method (*basis pursuit*) to solve the optimization problem in (2) (Chen et al., 1998). Specifically, the primal-dual algorithm based on the interior point method was employed to solve (2) (Boyd & Vandenberghe, 2004).

[12] Here, p', q', r', and s' are updated posterior hyperparameters; and k is a single observation.

[13] We used DCT as the sparsifying basis $\mathbf{\Psi}$ throughout experiments.

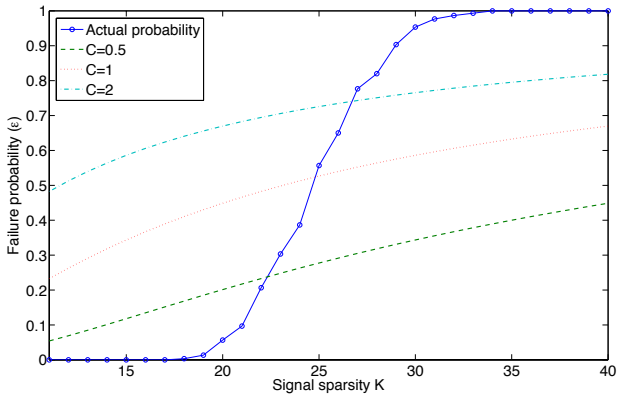

Figure 3: Comparison between actual failure probability and failure probabilities given in (5) with varying C's. Actual failure probability of each signal sparsity K was obtained with 300 experiments for $N = 512$ and $M = 100$.

Figure 3 shows that the actual failure probability of signal recovery with varying signal sparsity does not follow the failure probability given in the CS framework. The failure probability in (5) cannot model the actual failure probability of signal recovery, regardless of the value chosen for constant C. This result confirms Lemma 1 and Corollary 2.

Moreover, in Section 3.2 we modeled the new pdf of signal recovery success $f_\Pi(\pi)$ in (10). We compared this new pdf with the upper bound of failure in (6), given a dynamic signal sparsity K. Specifically, we employed the inverse Gaussian distribution such that $f_K(k) = \mathrm{IG}(30, 200)$. Figure 4 exhibits the efficacy of our recovery success model, where the lower bounds of success probability given in the CS framework fail to capture actual success probability in random sampling case. This result confirms Theorem 3.

Note that our recovery success model provides the baseline of recovery success for any CS frameworks that are specifically designed to handle varying signal sparsity. For instance, Figure 5 shows histograms of success probability for various signal sparsities using Modified-CS (Vaswani & Lu, 2010).[14] Compared with Figure 2, the success probability shown in Figure 5 also follows the beta distribution; but success probability is higher than that of basis pursuit for a given sparsity K ($K_{\min} = 21$ and $K_{\max} = 31$), thanks to the ability of Modified-CS to handle dynamic signal sparsity. The recovery success model in (9) is still effective here as a theoretical framework, or the recovery success model using the basis pursuit may promise a minimum guarantee for the recovery success of other CS frameworks.

We also employed real-world environmental data sets ob-

[14] Results were obtained with two frames where the second frame has one more spike than the first frame so that Modified-CS could exploit smoothly varying signal sparsity. Histograms in Figure 5 are the success probabilities of the second frame.

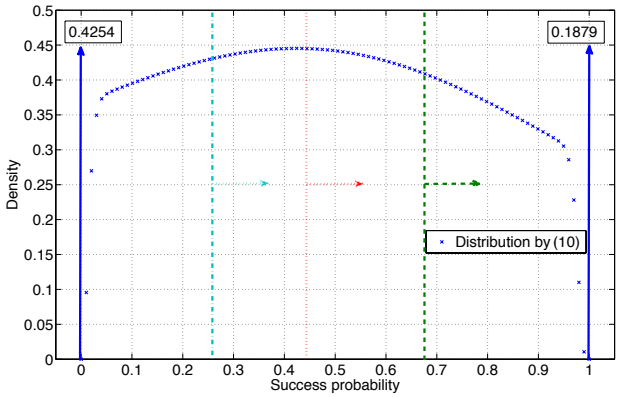

Figure 4: Comparison between our new success probability distribution in (10) and the lower bounds of success probability obtained by (6) with varying C's. The inverse Gaussian distribution was used for $f_K(k)$. Two probability masses are shown by vertical arrows, where solid boxes atop the arrows denote their probabilities. Three vertical dashed/dotted lines represent the lower bounds by (6): $C = 0.5$ at 0.6781; $C = 1$ at 0.4450; and $C = 2$ at 0.2596. Here, $K_{\min} = 20$ and $K_{\max} = 30$.

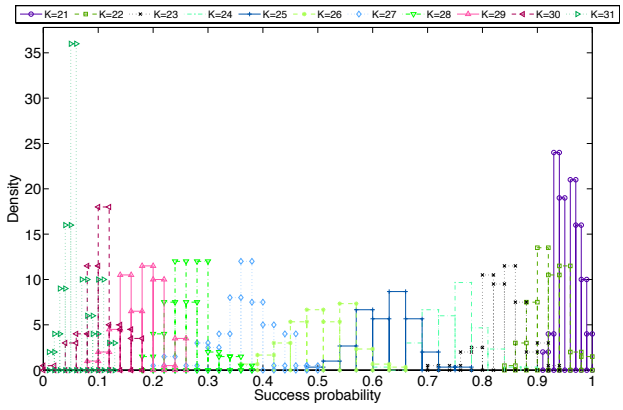

Figure 5: Histograms of success probability for various K's using Modified-CS (Vaswani & Lu, 2010). Success probability distribution for each K was obtained with 100 different random signed spike vectors for $N = 512$ and $M = 100$. A single success probability for each signed spike vector was calculated with 100 experiments. Compared with the results with basis pursuit in Figure 2, success probability is higher for a given sparsity K. Note also that 100 experiments resulted in a larger variance for each K.

tained from wireless sensor network deployments (Quer et al., 2012): humidity and temperature. In addition, audio data shown in Figure 1 was used for comparison as well. Random numbers representing the dynamic signal sparsity K were drawn from the inverse Gaussian distribution ($f_K(k) = \mathrm{IG}(30, 200)$) and we used this K to randomly choose components sorted in decreasing order; other components were set to zero. Figure 6 shows the success probability of signal recovery follows the shape of Figure 4.

5.2 RECOVERY QUALITY

When a signal is compressible and not exactly K-sparse, this signal is basically *dense*. In Section 4, we regarded the number of components included in the signal recovery as a varying quantity. We are interested in the general shape of this quantity in distribution. In order to verify Proposition 1, we performed experiments using real data sets as well as artificially generated random signed spikes.

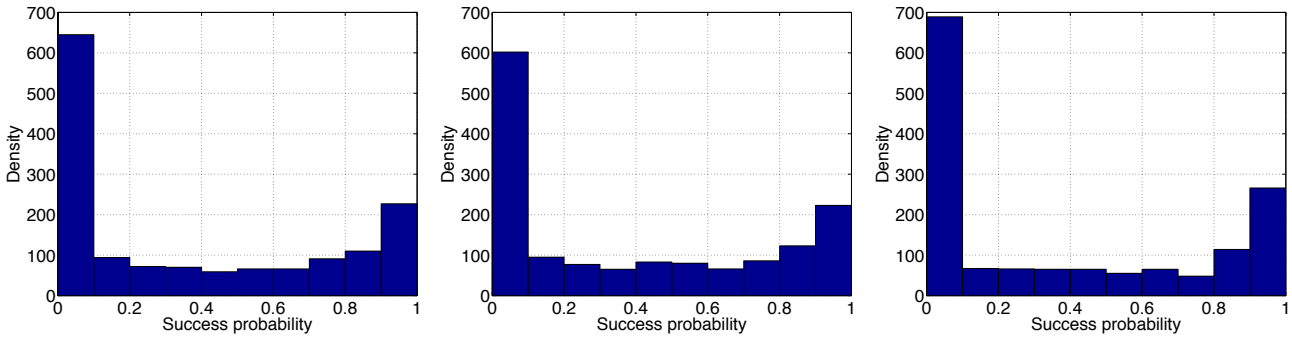
We first provide results with real-world data sets to verify Proposition 1. Figure 7 displays the histograms of K, the number of components included in each signal recovery, which was obtained using the method explained in Section 4. We can identify that Proposition 1 actually holds here, as all distributions are skewed to the right. Furthermore, the distributions follow the gamma distribution, which is also natural since the gamma distribution has positive skewness, i.e., right tailed.

In addition, random signed spikes were artificially generated in different magnitudes at random locations and densified to perform random sampling. In particular, we considered an arithmetic sequence of length 50 $(2, 4, 6, \ldots, 98, 100)$, whose elements were placed at random locations in each vector. These signals are dense enough to be used for experiments because signal recovery always fails when $K > 30$ in our case, as shown in Figure 3. Figure 8 displays the histogram of K and the gamma distribution fitting, where we can again see that Proposition 1 holds.

Furthermore, we analyze the ℓ_2 error E of signal recovery assuming $f_K(k) = \mathrm{Gamma}(\kappa, \theta)$ using (19). In order to show its efficacy, we compared the solutions of (19) with real data sets. For humidity data, $E = 94.3533$ while the average ℓ_2 norm of data is 564.8585; for temperature data, $E = 75.5441$ while the average ℓ_2 norm of data is 627.8038; and for audio data, $E = 5.0979$ while the average ℓ_2 norm of data is 1.5866. Apart from the case of audio data, (19) provides useful estimators for the upper bound of amount of error during recovery. It should be noted that this bound is rather loose due to a large constant G in (18), which could be improved with a less conservative G.

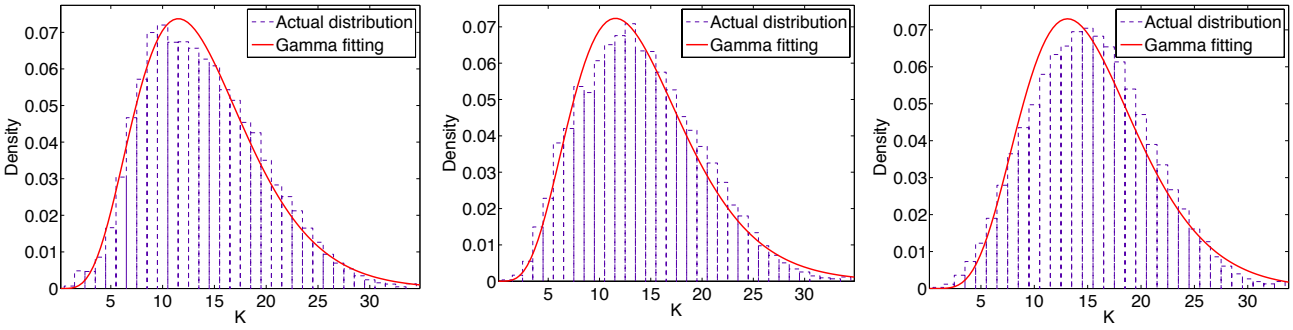
6 CONCLUSION

We have presented a new theoretical CS framework in random sampling which handles uncertainty in signal recovery from a new perspective. The success probability of signal recovery in random sampling was investigated when signal sparsity can vary with an insufficient number of measurements. The success probability analysis in the existing CS framework was shown to be incapable of reflecting actual



(a) humidity (b) temperature (c) audio

Figure 6: Histograms of success probability for (a) humidity data, (b) temperature data, and (c) audio data. Histogram was obtained with 1,500 random number generations (the inverse Gaussian distribution) to choose different signals and 100 different experiments for each signal with $N = 512$ and $M = 100$. All histograms closely follow the shape of Figure 4.



(a) humidity (b) temperature (c) audio

Figure 7: Distributions of K fitted with gamma distributions for (a) humidity data ($\mathrm{Gamma}(5.69, 2.45)$), (b) temperature data ($\mathrm{Gamma}(5.56, 2.54)$), and (c) audio data ($\mathrm{Gamma}(6.92, 2.21)$). Histograms were obtained with 34 different signals and 1,000 different experiments for each signal (a and b); with 153 different signals and 500 different experiments for each signal (c), with $N = 512$ and $M = 100$.

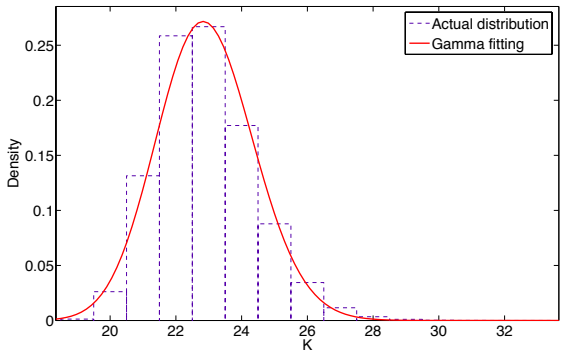


Figure 8: Distribution of K fitted with a gamma distribution $\mathrm{Gamma}(242.81, 0.09)$, using the maximum likelihood estimation. Histogram was obtained with 300 different signals and 300 different experiments for each signal, with $N = 512$ and $M = 100$.

success probability by both theoretical analysis and experiments. On the contrary, our recovery success model could closely reflect actual success probability.

We also considered signals which cannot be exactly represented with sparse representations, where we could alternatively view the number of components included in the signal recovery as a varying quantity. This quantity was shown by both theoretical analysis and experiments to follow a right-tailed distribution such as the gamma distribution. We provided error analysis for these signals.

Abstract

Bounded rational decision-makers transform sensory input into motor output under limited computational resources. Mathematically, such decision-makers can be modeled as information-theoretic channels with limited transmission rate. Here, we apply this formalism for the first time to multilayer feedforward neural networks. We derive synaptic weight update rules for two scenarios, where either each neuron is considered as a bounded rational decision-maker or the network as a whole. In the update rules, bounded rationality translates into information-theoretically motivated types of regularization in weight space. In experiments on the MNIST benchmark classification task for handwritten digits, we show that such information-theoretic regularization successfully prevents overfitting across different architectures and attains results that are competitive with other recent techniques like dropout, dropconnect and Bayes by backprop, for both ordinary and convolutional neural networks.

1 INTRODUCTION

Intelligent systems in biology excel through their ability to flexibly adapt their behavior to changing environments so as to maximize their (expected) benefit. In order to understand such biological intelligence and to design artificial intelligent systems, a central goal is to analyze adaptive behavior from a theoretical point of view. A formal framework to achieve this goal is decision theory. An important idea, originating from the foundations of decision theory, is the principle of maximum expected utility [1]. According to the principle of maximum expected utility, an intelligent agent is formalized as a decision-maker that chooses optimal actions that maximize the expected benefit of an outcome, where the agent's benefit is quantified by a utility function.

A fundamental problem of the maximum expected utility principle is that it does not take into account computational resources that are necessary to identify optimal actions—it is for example computationally prohibitive to compute an optimal chess move because of the vast amount of potential board configurations. One way of taking computational resources into account is to study optimal decision-making under information-processing constraints [2, 3]. In this study, we use an information-theoretic model of bounded rational decision-making [4, 5, 6] that has precursors in the economic literature [7, 8, 9] and that is closely related to recent advances harnessing information theory for machine learning and perception-action systems [10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20].

Previously, this information-theoretic bounded rationality model was applied to derive a synaptic weight update rule for a single reward-maximizing spiking neuron [21]. It was shown that such a neuron tries to keep its firing rate close to its average firing rate, which ultimately leads to economizing of synaptic weights. Mathematically, such economizing is equivalent to a regularization that prevents synaptic weights from growing without bounds. The bounded rational weight update rule furthermore generalizes the synaptic weight update rule for an ordinary reward-maximizing spiking neuron as presented for example in [22]. In our current work, we extend the framework of information-theoretic bounded rationality to networks of neurons, but restrict ourselves for a start to deterministic settings. In particular, we investigate two scenarios, where either each single neuron is considered as a bounded rational decision-maker or the network as a whole.

The remainder of this manuscript is organized as follows. In Section 2, we explain the information-theoretic bounded rationality model that we use. In Section 3, we apply this model to derive bounded rational synaptic weight update rules for single neurons and networks of neurons. In Section 4, we demonstrate the regularizing effect of these bounded rational weight update rules on the MNIST benchmark classification task. In Section 5, we conclude.

2 BACKGROUND ON BOUNDED RATIONAL DECISION-MAKING

2.1 A FREE ENERGY PRINCIPLE FOR BOUNDED RATIONALITY

A decision-maker is faced with the task to choose an optimal action out of a set of actions. Each action y is associated with a given task-specific utility value $U(y)$. A fully rational decision-maker picks the action y^* that globally maximizes the utility function, where $y^* = \arg\max_y U(y)$, assuming for notational simplicity that the global maximum is unique. Under limited computational resources however, the decision-maker may not be able to identify the globally optimal action y^* which leads to the question of how limited computational resources should be quantified. In general, the decision-maker's behavior can be expressed as a probability distribution over actions $p(y)$. The basic idea of information-theoretic bounded rationality is that changes in such probability distributions are costly and necessitate computational resources. More precisely, computational resources are quantified as informational cost evoked by changing from a prior probabilistic strategy $p_0(y)$ to a posterior probabilistic strategy $p(y)$ during the deliberation process preceding the choice. Mathematically, this informational cost is given by the Kullback-Leibler divergence $D_{KL}(p(y)||p_0(y)) \leq B$ between prior and posterior strategy, where computational resources are modeled as an upper bound $B \geq 0$ [10, 5, 6, 13, 14, 15, 17, 18, 19, 20, 8, 9]. Accordingly, bounded rational decision-making can be formalized by the following free energy objective

$$\begin{aligned} & p^*(y) \\ & = \arg\max_{p(y)} \ (1-\beta) \left\langle U(y) \right\rangle_{p(y)} - \beta D_{KL}(p(y)||p_0(y)) \\ & = \arg\max_{p(y)} \ \left\langle (1-\beta) U(y) - \beta \ln \frac{p(y)}{p_0(y)} \right\rangle_{p(y)}, \end{aligned} \tag{1}$$

where $\beta \in (0;1)$ controls the trade-off between expected utility and informational cost. Note that the upper bound B imposed on the Kullback-Leibler divergence determines the value of β. Choosing the value of B is hence equivalent to choosing the value of β.

The free energy objective in Equation (1) is concave with respect to $p(y)$ and the optimal solution $p^*(y)$ can be expressed in closed analytic form:

$$p^*(y) = \frac{p_0(y) \exp(\frac{1-\beta}{\beta} U(y))}{\sum_{y'} p_0(y') \exp(\frac{1-\beta}{\beta} U(y'))}. \tag{2}$$

In the limit cases of none ($\beta \to 1$) and infinite ($\beta \to 0$) resources, the optimal strategy from Equation (2) becomes

$$\lim_{\beta \to 1} p^*(y) = \ p_0(y), \tag{3}$$

$$\lim_{\beta \to 0} p^*(y) = \ \delta_{yy^*}, \tag{4}$$

respectively, where $y^* = \arg\max_y U(y)$ represents an action that globally maximizes the utility function. A decision-maker without any computational resources ($\beta \to 1$) sticks to its prior strategy $p_0(y)$, whereas a decision-maker that can access an arbitrarily large amount of resources ($\beta \to 0$) always picks a globally optimal action and recovers thus the fully rational decision-maker.

2.2 A RATE DISTORTION PRINCIPLE FOR CONTEXT-DEPENDENT DECISION-MAKING

In the face of multiple contexts, fully rational decision-making requires to find an optimal action y for each environment x, where optimality is defined through a utility function $U(x,y)$. Bounded rational decision-making in multiple contexts means to compute multiple strategies, expressed as conditional probability distributions $p(y|x)$, under limited computational resources. Limited computational resources are modeled through an upper bound $B \geq 0$ on the expected Kullback-Leibler divergence $\langle D_{KL}(p(y|x)||p_0(y)) \rangle_{p(x)} \leq B$ between the strategies $p(y|x)$ and a common prior $p_0(y)$, averaged over all possible environments described by the distribution $p(x)$ [4, 15]. The resulting optimization problem may be formalized as

$$\begin{aligned} p^*(y|x) = \arg\max_{p(y|x)} \ & (1-\beta) \left\langle U(x,y) \right\rangle_{p(x,y)} \\ & - \beta \left\langle D_{KL} \left(p(y|x)||p_0(y) \right) \right\rangle_{p(x)}, \end{aligned} \tag{5}$$

where $\beta \in (0;1)$ governs the trade-off between expected utility and informational cost. It can be shown that the most economic prior $p_0(y)$ is given by the marginal distribution $p_0(y) = p(y) = \sum_x p(y|x)p(x)$, because the marginal distribution minimizes the expected Kullback-Leibler divergence for a given set of conditional distributions $p(y|x)$—see [23]. In this case, the expected Kullback-Leibler divergence becomes identical to the mutual information $I(x,y)$ between the environment x and the action y [4, 21, 11, 12, 7, 16]. Accordingly, bounded rational decision-making can be formalized through the following objective

$$\begin{aligned} & p^*(y|x) \\ & = \arg\max_{p(y|x)} \ (1-\beta) \left\langle U(x,y) \right\rangle_{p(x,y)} - \beta I(x,y) \\ & = \arg\max_{p(y|x)} \ \left\langle (1-\beta) U(x,y) - \beta \ln \frac{p(y|x)}{p(y)} \right\rangle_{p(x,y)}, \end{aligned} \tag{6}$$

which is mathematically equivalent to the rate distortion problem from information theory [24].

The rate distortion objective in Equation (6) is concave with respect to $p(y|x)$ but there is unfortunately no closed analytic form solution. It is however possible to express the optimal solution as a set of self-consistent equations:

$$p^*(y|x) = \frac{p(y)\exp(\frac{1-\beta}{\beta}U(x,y))}{\sum_{y'}p(y')\exp(\frac{1-\beta}{\beta}U(x,y'))}, \quad (7)$$

$$p(y) = \sum_x p^*(y|x)p(x). \quad (8)$$

These self-consistent equations are solved by replacing $p(y)$ with an initial arbitrary distribution $q(y)$ and iterating through Equations (7) and (8) in an alternating fashion. This procedure is known as Blahut-Arimoto algorithm [25, 26] and is guaranteed to converge to a global optimum [27] presupposed that $q(y)$ does not assign zero probability mass to any y.

In the limit cases of none ($\beta \to 1$) and infinite ($\beta \to 0$) resources, the optimal strategy from Equations (7) and (8) may be expressed in closed analytic form

$$\lim_{\beta\to 1} p^*(y|x) = \quad p(y) = \delta_{yy^*}, \quad (9)$$

$$\lim_{\beta\to 0} p^*(y|x) = \quad \delta_{yy^*_x}, \quad (10)$$

where $y^* = \arg\max_y \langle U(x,y)\rangle_{p(x)}$ refers to an action that globally maximizes the expected utility averaged over all possible environments, and y^*_x refers to an action that globally maximizes the utility for one particular environment x—assuming for notational simplicity that global maxima are unique in both cases. In the absence of any computational resources ($\beta \to 1$), the decision-maker chooses the same strategy no matter which environment is encountered in order to minimize the deviation between the conditional strategies $p(y|x)$ and the average strategy $p(y)$. The decision-maker chooses however a strategy that maximizes the average expected utility. In case of access to an arbitrarily large amount of computational resources ($\beta \to 0$), the decision-maker picks the best action for each environment and recovers thus the fully rational decision-maker.

3 THEORETICAL RESULTS: SYNAPTIC WEIGHT UPDATE RULES

3.1 PARAMETERIZED STRATEGIES AND ONLINE RULES

Computing the optimal solution to the rate distortion problem in Equation (6) with help of Equations (7) and (8) through the Blahut-Arimoto algorithm has two severe drawbacks. First, it requires to compute and store the conditional strategies $p(y|x)$ and the marginal strategy $p(y)$ explicitly, which is prohibitive for large environment and action spaces. And second, it requires that the decision-maker is able to evaluate the utility function for arbitrary environment-action pairs (x,y), which is a plausible assumption in planning, but not in reinforcement learning where samples from the utility function can only be obtained from interactions with the environment.

We therefore assume a parameterized form of the strategy $p_w(y|x)$, from which the decision-maker can draw samples y for a given sample of the environment x, and optimize the rate distortion objective from Equation (6) with help of gradient ascent [21]—also referred to as policy gradient in the reinforcement learning literature [22]. Gradient ascent requires to compute the derivative of the objective function $L(w)$ with respect to the strategy parameters w and to update the parameters according to the rule $w \leftarrow w + \alpha \cdot \frac{\partial}{\partial w}L(w)$ in each time step, where $\alpha > 0$ denotes the learning rate and $\frac{\partial}{\partial w}L(w)$ is defined as

$$\frac{\partial}{\partial w}L(w) = \left\langle \left(\frac{\partial}{\partial w}\ln p_w(y|x)\right)(1-\beta)U(x,y)\right\rangle_{p_w(x,y)} - \left\langle \left(\frac{\partial}{\partial w}\ln p_w(y|x)\right)\beta\ln\frac{p_w(y|x)}{p_w(y)}\right\rangle_{p_w(x,y)}. \quad (11)$$

Note that the update rule from Equation (11) requires the computation of an expected value over $p_w(x,y)$. This expected value can be approximated through environment-action samples (x,y) in either a batch or an online manner. For the rest of this paper, we assume an online update rule where the agent adapts its behavior instantaneously after each interaction with the environment in response to an immediate reward signal $U(x,y)$ as is typical for reinforcement learning.

Informally, the rate distortion model for bounded rational decision-making translates into a specific form of regularization that penalizes deviations of the decision-maker's instantaneous strategy $p_w(y|x)$, given the current environment x, from the decision-maker's mean strategy $p_w(y) = \sum_x p_w(y|x)p(x)$, averaged over all possible environments. Previously, Equation (11) was applied to a single spiking neuron that was stochastic [21]. Here, we generalize this approach to deterministic networks of neurons that have neural input (environmental context x), neural output (action y) and a reward signal (utility U). We derive parameter update rules in the style of Equation (11) that allow to adjust synaptic weights in an online fashion. In particular, we investigate two scenarios where either each single neuron is considered as a bounded rational decision-maker or the network as a whole.

3.2 A STOCHASTIC NEURON AS A BOUNDED RATIONAL DECISION-MAKER

A stochastic neuron may be considered as a bounded rational decision-maker [21]: the neuron's presynaptic input is

interpreted as environmental context and the neuron's output is interpreted as action variable. The neuron's parameterized strategy corresponds to its firing behavior and is given by

$$p_{\mathbf{w}}(y|\mathbf{x}) = y \cdot \rho(\mathbf{w}^\top \mathbf{x}) + (1-y) \cdot (1-\rho(\mathbf{w}^\top \mathbf{x})), \quad (12)$$

where $y \in \{0,1\}$ is a binary variable reflecting the neuron's current firing state, $\mathbf{x}$ is a binary column vector representing the neuron's current presynaptic input and $\mathbf{w}$ is a real-valued column vector representing the strength of presynaptic weights. $\rho \in (0;1)$ is a monotonically increasing function denoting the neuron's current firing probability. In a similar way, the neuron's mean firing behavior can be expressed as:

$$p_{\mathbf{w}}(y) = y \cdot \bar{\rho}(\mathbf{w}) + (1-y) \cdot (1-\bar{\rho}(\mathbf{w})), \quad (13)$$

where $\bar{\rho}(\mathbf{w}) = \sum_{\mathbf{x}} \rho(\mathbf{w}^\top \mathbf{x}) p(\mathbf{x})$ denotes the neuron's mean firing probability averaged over all possible inputs $\mathbf{x}$. The mean firing probability $\bar{\rho}(\mathbf{w})$ can be easily estimated with help of an exponential window in an online manner according to

$$\bar{\rho}(\mathbf{w}) \leftarrow (1-\frac{1}{\tau})\bar{\rho}(\mathbf{w}) + \frac{1}{\tau}\rho(\mathbf{w}^\top \mathbf{x}), \quad (14)$$

where τ is a constant defining the time horizon [21].

Assuming a task-specific utility function $U(\mathbf{x}, y)$ determining the neuron's instantaneous reward and assuming furthermore that the neuron's output y does not impact the presynaptic input $\mathbf{x}$ of the next time step, the bounded rational neuron may be thought of as optimizing a rate distortion objective according to Equation (6) with gradient ascent as outlined in Section 3.1 [21]. Equation (11) is then applicable by using the quantities

$$\begin{aligned} &\frac{\partial}{\partial w_i} \ln p_{\mathbf{w}}(y|\mathbf{x}) = \\ &x_i \rho'(\mathbf{w}^\top \mathbf{x}) \left(\frac{y}{\rho(\mathbf{w}^\top \mathbf{x})} - \frac{1-y}{1-\rho(\mathbf{w}^\top \mathbf{x})} \right), \end{aligned} \quad (15)$$

and

$$\begin{aligned} &\ln \frac{p_{\mathbf{w}}(y|\mathbf{x})}{p_{\mathbf{w}}(y)} = \\ &y \ln \frac{\rho(\mathbf{w}^\top \mathbf{x})}{\bar{\rho}(\mathbf{w})} + (1-y) \ln \frac{1-\rho(\mathbf{w}^\top \mathbf{x})}{1-\bar{\rho}(\mathbf{w})}. \end{aligned} \quad (16)$$

By averaging over the binary quantity y, a more concise weight update rule is derived [21]:

$$\begin{aligned} &\frac{\partial}{\partial w_i} L(\mathbf{w}) = \\ &\left\langle x_i \rho'(\mathbf{w}^\top \mathbf{x})(1-\beta)\Delta U(\mathbf{x}) \right\rangle_{p(\mathbf{x})} \\ &- \left\langle x_i \rho'(\mathbf{w}^\top \mathbf{x}) \beta \ln \frac{\rho(\mathbf{w}^\top \mathbf{x})(1-\bar{\rho}(\mathbf{w}))}{\bar{\rho}(\mathbf{w})(1-\rho(\mathbf{w}^\top \mathbf{x}))} \right\rangle_{p(\mathbf{x})}, \end{aligned} \quad (17)$$

where $\Delta U(\mathbf{x}) = U(\mathbf{x}, y=1) - U(\mathbf{x}, y=0)$ denotes the difference in utility between firing ($y=1$) and not firing ($y=0$) for a given $\mathbf{x}$. If the conditional and marginal strategies are initialized to be roughly equal $p_{\mathbf{w}_0}(y) \approx p_{\mathbf{w}_0}(y|\mathbf{x})$, where $\mathbf{w}_0 \approx \mathbf{0}$ refers to the initial value of $\mathbf{w}$, the hyperparameter β determines how fast the decision-maker's strategy converges. A high value of β implies little computational resources and quick convergence due to the fact that conditional and marginal strategies are initially almost equal. On the opposite, a low value of β indicating vast computational resources allows the decision-maker to find an optimal strategy for each environment where conditional and marginal strategies may deviate substantially.

3.3 A DETERMINISTIC NEURON AS A BOUNDED RATIONAL DECISION-MAKER

In a deterministic setup, the neuron's parameterized firing behavior in a small time window Δt may be expressed through its firing rate $\phi(\mathbf{w}^\top \boldsymbol{\xi})$ as:

$$p_{\mathbf{w}}(y|\boldsymbol{\xi}) = y \cdot \phi(\mathbf{w}^\top \boldsymbol{\xi})\Delta t + (1-y) \cdot (1-\phi(\mathbf{w}^\top \boldsymbol{\xi})\Delta t), \quad (18)$$

where $\boldsymbol{\xi}$ is a real-valued column vector indicating the presynaptic firing rates and $\phi > 0$ is a monotonically increasing function. In a similar fashion, the neuron's mean firing behavior is given by

$$p_{\mathbf{w}}(y) = y \cdot \bar{\phi}(\mathbf{w})\Delta t + (1-y) \cdot (1-\bar{\phi}(\mathbf{w})\Delta t), \quad (19)$$

where $\bar{\phi}(\mathbf{w}) = \sum_{\boldsymbol{\xi}} \phi(\mathbf{w}^\top \boldsymbol{\xi}) p(\boldsymbol{\xi})$ refers to the neuron's mean firing rate averaged over all possible presynaptic firing rates $\boldsymbol{\xi}$. In accordance with the previous section, the mean firing rate $\bar{\phi}(\mathbf{w})$ can be conveniently approximated in an online manner through an exponential window with a time constant τ as:

$$\bar{\phi}(\mathbf{w}) \leftarrow (1-\frac{1}{\tau})\bar{\phi}(\mathbf{w}) + \frac{1}{\tau}\phi(\mathbf{w}^\top \boldsymbol{\xi}). \quad (20)$$

Using the quantities introduced above, we can define a mutual information rate between the presynaptic firing rates $\boldsymbol{\xi}$ and the instantaneous firing state of the neuron $y \in \{0;1\}$:

$$\begin{aligned} &\lim_{\Delta t \to 0} \frac{1}{\Delta t} I(\boldsymbol{\xi}, y) \\ &= \lim_{\Delta t \to 0} \frac{1}{\Delta t} \left\langle \sum_y p_{\mathbf{w}}(y|\boldsymbol{\xi}) \ln \frac{p_{\mathbf{w}}(y|\boldsymbol{\xi})}{p_{\mathbf{w}}(y)} \right\rangle_{p(\boldsymbol{\xi})} \\ &= \left\langle \phi(\mathbf{w}^\top \boldsymbol{\xi}) \ln \frac{\phi(\mathbf{w}^\top \boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})} \right\rangle_{p(\boldsymbol{\xi})}. \end{aligned} \quad (21)$$

A derivation of Equation (21) can be found in Section A.1. Assuming a rate-dependent utility function $U(\boldsymbol{\xi}, \phi(\mathbf{w}^\top \boldsymbol{\xi}))$, a deterministic neuron can be interpreted as a bounded rational decision-maker similar to Equation (6) with the fol-

lowing rate distortion objective

$$\begin{aligned}\mathbf{w}^* &= \arg\max_{\mathbf{w}} \ (1-\beta)\left\langle U(\boldsymbol{\xi},\phi(\mathbf{w}^\top\boldsymbol{\xi}))\right\rangle_{p(\boldsymbol{\xi})} \\ &\quad - \beta \lim_{\Delta t\to 0}\frac{1}{\Delta t} I(\boldsymbol{\xi}, y) \\ &= \arg\max_{\mathbf{w}} \ \left\langle (1-\beta) U(\boldsymbol{\xi},\phi(\mathbf{w}^\top\boldsymbol{\xi}))\right\rangle_{p(\boldsymbol{\xi})} \\ &\quad - \left\langle \beta\phi(\mathbf{w}^\top\boldsymbol{\xi}) \ln \frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})}.\end{aligned} \tag{22}$$

Optimizing the neuron's weights with gradient ascent, a similar weight update rule as in Equation (17) is derived for the deterministic case:

$$\begin{aligned}&\frac{\partial}{\partial w_i} L(\mathbf{w}) = \\ &\left\langle \xi_i \phi'(\mathbf{w}^\top\boldsymbol{\xi})(1-\beta)\frac{\partial}{\partial\phi} U(\boldsymbol{\xi},\phi(\mathbf{w}^\top\boldsymbol{\xi}))\right\rangle_{p(\boldsymbol{\xi})} \\ &- \left\langle \xi_i \phi'(\mathbf{w}^\top\boldsymbol{\xi})\beta \ln\frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})},\end{aligned} \tag{23}$$

where $\frac{\partial}{\partial\phi}U(\boldsymbol{\xi},\phi(\mathbf{w}^\top\boldsymbol{\xi}))$ denotes the derivative of the utility function with respect to the neuron's firing rate. The solution in Equation (23) requires the derivative of two terms with respect to w_i. The derivative of the expected utility $\left\langle U(\boldsymbol{\xi},\phi(\mathbf{w}^\top\boldsymbol{\xi}))\right\rangle_{p(\boldsymbol{\xi})}$ is straightforward, whereas the derivative of the mutual information rate $\lim_{\Delta t\to 0}\frac{1}{\Delta t} I(\boldsymbol{\xi}, y)$ is not so trivial and explained in more detail in Section A.2.

3.4 A NEURAL NETWORK OF BOUNDED RATIONAL DETERMINISTIC NEURONS

Here, we consider a feedforward multilayer perceptron that can be imagined to consist of individual bounded rational deterministic neurons as described in the previous section. Assuming that all neurons aim at maximizing a global utility function while at the same time minimizing their local mutual information rate, each neuron n may be interpreted as solving a deterministic rate distortion objective where the utility function is shared among all neurons but the mutual information cost is neuron-specific:

$$\begin{aligned}\mathbf{w}^{n*} &= \arg\max_{\mathbf{w}^n} \ (1-\beta)\left\langle U(\boldsymbol{\xi}^{\text{in}}, \mathbf{f}(\mathcal{W},\boldsymbol{\xi}^{\text{in}}))\right\rangle_{p(\boldsymbol{\xi}^{\text{in}})} \\ &\quad - \beta \lim_{\Delta t\to 0}\frac{1}{\Delta t} I(\boldsymbol{\xi}^n, y^n),\end{aligned} \tag{24}$$

where $\mathbf{w}^n$, $\boldsymbol{\xi}^n$ and y^n refer to the presynaptic weight vector, the presynaptic firing rates and the current firing state of neuron n respectively and where $\mathcal{W}$ denotes the entirety of all weights in the whole neural network. The global utility $U(\boldsymbol{\xi}^{\text{in}}, \mathbf{f}(\mathcal{W},\boldsymbol{\xi}^{\text{in}}))$ is expressed as a function of the network's input rates $\boldsymbol{\xi}^{\text{in}}$ and the network's output rates $\mathbf{f}(\mathcal{W},\boldsymbol{\xi}^{\text{in}})$.

The corresponding synaptic weight update rule for gradient ascent is similar to Equation (23) and given by

$$\begin{aligned}&\frac{\partial}{\partial w_i^n} L^n(\mathcal{W}) = \\ &\left\langle (1-\beta)\frac{\partial}{\partial w_i^n} U(\boldsymbol{\xi}^{\text{in}}, \mathbf{f}(\mathcal{W},\boldsymbol{\xi}^{\text{in}}))\right\rangle_{p(\boldsymbol{\xi}^{\text{in}})} \\ &- \left\langle \beta\xi_i^n \phi'({\mathbf{w}^n}^\top\boldsymbol{\xi}^n)\ln\frac{\phi({\mathbf{w}^n}^\top\boldsymbol{\xi}^n)}{\bar{\phi}(\mathbf{w}^n)}\right\rangle_{p(\boldsymbol{\xi}^{\text{in}})},\end{aligned} \tag{25}$$

where $L^n(\mathcal{W})$ refers to the rate distortion objective of neuron n. The derivative of the utility function with respect to the weight $\frac{\partial}{\partial w_i^n}U(\boldsymbol{\xi}^{\text{in}}, \mathbf{f}(\mathcal{W},\boldsymbol{\xi}^{\text{in}}))$ can be straightforwardly derived via ordinary backpropagation [28].

3.5 A DETERMINISTIC NEURAL NETWORK AS A BOUNDED RATIONAL DECISION-MAKER

While focusing on individual neurons as bounded rational decision-makers in the previous section, it is also possible to interpret an entire feedforward multilayer perceptron as one bounded rational decision-maker. To allow for this interpretation, we consider in the following the network's output rates $f_j(\mathcal{W},\boldsymbol{\xi}) \in (0;1)$ as the event probabilities of a categorical distribution (for example, by using a softmax activation function in the last layer). Importantly, the categorical distribution is considered as a bounded rational strategy

$$p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi}) = \sum_j y_j f_j(\mathcal{W},\boldsymbol{\xi}), \tag{26}$$

that generates a binary unit output vector $\mathbf{y}$ given the input rates $\boldsymbol{\xi}$ and the set of all weights in the entire network denoted by $\mathcal{W}$. The average bounded rational strategy is then given by

$$p_{\mathcal{W}}(\mathbf{y}) = \sum_j y_j \bar{f}_j(\mathcal{W}), \tag{27}$$

where $\bar{f}_j(\mathcal{W})$ is the mean rate of output unit j that can again be approximated in an online manner according to

$$\bar{f}_j(\mathcal{W}) \leftarrow (1-\frac{1}{\tau})\bar{f}_j(\mathcal{W}) + \frac{1}{\tau} f_j(\mathcal{W},\boldsymbol{\xi}), \tag{28}$$

by use of an exponential window with a time constant τ in line with previous sections.

Accordingly, the informational cost can be quantified by the mutual information between $\boldsymbol{\xi}$ and $\mathbf{y}$:

$$\begin{aligned}I(\boldsymbol{\xi},\mathbf{y}) &= \left\langle \sum_{\mathbf{y}} p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi}) \ln\frac{p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})}{p_{\mathcal{W}}(\mathbf{y})}\right\rangle_{p(\boldsymbol{\xi})} \\ &= \left\langle \sum_j f_j(\mathcal{W},\boldsymbol{\xi}) \ln\frac{f_j(\mathcal{W},\boldsymbol{\xi})}{\bar{f}_j(\mathcal{W})}\right\rangle_{p(\boldsymbol{\xi})}.\end{aligned} \tag{29}$$

Presupposing again a rate dependent utility function $U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi}))$, the entire deterministic network may be interpreted to solve the subsequent rate distortion objective

$$\begin{aligned}\mathcal{W}^* &= \arg\max_{\mathcal{W}} \ (1-\beta) \left\langle U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi})) \right\rangle_{p(\boldsymbol{\xi})} \\ &\quad - \beta I(\boldsymbol{\xi}, \mathbf{y}) \\ &= \arg\max_{\mathcal{W}} \ \left\langle (1-\beta) U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi})) \right\rangle_{p(\boldsymbol{\xi})} \\ &\quad - \left\langle \beta \sum_j f_j(\mathcal{W}, \boldsymbol{\xi}) \ln \frac{f_j(\mathcal{W}, \boldsymbol{\xi})}{\bar{f}_j(\mathcal{W})} \right\rangle_{p(\boldsymbol{\xi})},\end{aligned} \tag{30}$$

Assuming that synaptic weights are updated via gradient ascent, the following weight update rule can be derived

$$\begin{aligned}&\frac{\partial}{\partial w_i^n} L(\mathcal{W}) = \\ &\left\langle (1-\beta) \sum_j \left(\frac{\partial}{\partial w_i^n} f_j(\mathcal{W}, \boldsymbol{\xi}) \right) \left(\frac{\partial}{\partial f_j} U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi})) \right) \right\rangle_{p(\boldsymbol{\xi})} \\ &- \left\langle \beta \sum_j \left(\frac{\partial}{\partial w_i^n} f_j(\mathcal{W}, \boldsymbol{\xi}) \right) \ln \frac{f_j(\mathcal{W}, \boldsymbol{\xi})}{\bar{f}_j(\mathcal{W})} \right\rangle_{p(\boldsymbol{\xi})},\end{aligned} \tag{31}$$

where $\frac{\partial}{\partial w_i^n}$ denotes the derivative with respect to the ith weight of neuron n, and $\frac{\partial}{\partial f_j} U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi}))$ denotes the derivative of the utility function with respect to the firing rate of the jth output neuron. Equation (31) requires to differentiate two terms with respect to w_i^n. The derivative of the expected utility is straightforward while the derivative of the mutual information is explained in Section A.3.

Note that the derivative of the rate distortion objective $\frac{\partial}{\partial w_i^n} L(\mathcal{W})$ takes a convenient form which can be easily computed by extending ordinary backpropagation [28]. In ordinary backpropagation, the quantity $\frac{\partial}{\partial f_j} U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi}))$ is propagated backwards through the network. The core algorithm of ordinary backpropagation can be employed for computing $\frac{\partial}{\partial w_i^n} L(\mathcal{W})$ by simply replacing the derivative of the utility function $\frac{\partial}{\partial f_j} U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi}))$ with the more general quantity $(1-\beta) \frac{\partial}{\partial f_j} U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi})) - \beta \ln \frac{f_j(\mathcal{W}, \boldsymbol{\xi})}{\bar{f}_j(\mathcal{W})}$.

4 EXPERIMENTAL RESULTS: MNIST CLASSIFICATION

In our simulations, we applied both types of rate distortion regularization (the local type from Section 3.4 and the global type from Section 3.5) on the MNIST benchmark classification task. In particular, we investigated in how far this information-theoretically motivated regularization subserves generalization. To this end, we trained classification on the MNIST training set, consisting of $60,000$ grayscale images of handwritten digits, and tested generalization on the MNIST test set, consisting of $10,000$ examples. For all our simulations, we used a network with two hidden layers of rectified linear units [29] and a top layer of 10 softmax units implemented in Lua with Torch [30]. We chose as optimization criterion the negative cross entropy between the class labels and the network output [31]

$$U(\boldsymbol{\xi}, \mathbf{f}(\mathcal{W}, \boldsymbol{\xi})) = \sum_j \delta_{j l(\boldsymbol{\xi})} \ln f_j(\mathcal{W}, \boldsymbol{\xi}), \tag{32}$$

where δ denotes the Kronecker delta and $\boldsymbol{\xi}$ the vectorized input image—note that pixels were normalized to lie in the range $[0; 1]$. The variable $j \in \{1, 10\}$ is an index over the network's output units and $l(\boldsymbol{\xi}) \in \{1, 10\}$ denotes the label of image $\boldsymbol{\xi}$.

In order to assess the robustness of our regularizers, we performed our experiments with networks of different architectures. In particular, we used network architectures with two hidden layers and varied the number of neurons $\#_{\text{neu}} \in \{529, 1024, 2025, 4096\}$ per hidden layer. We performed gradient ascent with a learning rate $\alpha = 0.01$ updating weights online after each training example. We trained the networks for 70 epochs where one epoch corresponded to one sweep through the entire training set. After each epoch, the learning rate decayed according to $\alpha \leftarrow \frac{\alpha}{1+t \cdot \eta}$ where t denotes the current epoch and $\eta = 0.002$ is a decay parameter. Weights were updated by use of a momentum $\gamma = 0.9$ according to $\Delta w_i^n \leftarrow \gamma \Delta w_i^n + (1-\gamma) \frac{\partial}{\partial w_i^n} L(\mathcal{W})$ and were randomly initialized in the range $(-(\#_{\text{in}}(n))^{-0.5}; (\#_{\text{in}}(n))^{-0.5})$ with help of a uniform distribution at the beginning of the simulation where $\#_{\text{in}}(n)$ denotes the number of inputs to neuron n. Each non-input neuron had an additional bias weight that was initialized in the same way as the presynaptic weights of that neuron. Rate distortion regularization required furthermore to compute the mean firing rate $\bar{\phi}(\mathbf{w}^n)$ of individual neurons n through an exponential window in an online fashion with a time constant $\tau = 1000$. In order to ensure numerical stability when using rate distortion regularization, terms of the form $\ln \frac{\phi(\mathbf{w}^{n\top} \boldsymbol{\xi}^n)}{\bar{\phi}(\mathbf{w}^n)}$ in the weight update rules were computed according to $\ln \max\{\phi(\mathbf{w}^{n\top} \boldsymbol{\xi}^n), \varepsilon\} - \ln \max\{\bar{\phi}(\mathbf{w}^n), \varepsilon\}$ with $\varepsilon = 2.22 \cdot 10^{-16}$.

To find optimal values for the rate distortion trade-off parameter β, we conducted pilot studies with small networks comprising 529 neurons per hidden layer that were trained for only 50 epochs on the MNIST training set according to the aforementioned training scheme and subsequently evaluated on the MNIST test set. While this might induce overfitting of β on the test set in the small networks, we used the same β-values as a heuristic for all larger architectures and did not tune the hyperparameter any further. In global rate distortion regularization (Grdi), the best test error was achieved around $\beta = 0.2$ although Grdi seems to behave rather robust in the range $\beta \in [0; 0.8]$—see middle

left panel in Figure 1. In local rate distortion regularization (Lrdi), the best test error was achieved for $\beta = 0$ with ordinary utility maximization without regularization—see middle right panel. However, when measuring the performance in terms of expected utility on the test set, Lrdi achieved a significant performance increase compared to ordinary utility maximization in the range $\beta \in [10^{-5}, 5 \cdot 10^{-4}]$—see upper right panel. In our final studies, we could furthermore ascertain that Lrdi performs reasonably well on larger architectures as it achieved a test error of 1.26% compared to 1.43% in ordinary utility maximization when increasing the number of units per hidden layer to 4096.

Table 1: Classification Errors on the MNIST Test Set in the Permutation Invariant Setup

Method	$\#_{\text{neu}}$	Error [%]
Bayes by backprop [10]	1200	1.32
Dropout [32]	800	1.28
Dropconnect [32]	800	1.20
Dropout [33]	4096	**1.01**
Local rate distortion (Lrdi) $\beta = 10^{-5}$	529	1.36
	1024	1.34
	2025	1.28
	4096	**1.26**
Global rate distortion (Grdi) $\beta = 0.2$	529	1.23
	1024	1.17
	2025	1.14
	4096	**1.11**

The results of our final studies where we trained networks for 70 epochs are illustrated in Table 1 which compares rate distortion regularization to other techniques from the literature for different network architectures comprising two hidden layers. It can be seen that both local and global rate distortion regularization (Lrdi and Grdi respectively) attain results in the permutation invariant setting (Lrdi: 1,26%, Grdi: 1.11%) that are competitive with other recent techniques like dropout (1.01% [33] and 1.28% [32]), dropconnect (1.20% [32]) and Bayes by backprop (1.32% [10]). It is furthermore shown that both rate distortion regularizers lead to a decreasing generalization error when increasing the number of neurons in hidden layers which demonstrates successful prevention of overfitting. Successful prevention of overfitting is additionally demonstrated by applying global rate distortion regularization (Grid, $\beta = 0.2$) to a convolutional neural network with an architecture according to [32]—see Section B.2 in [32]—attaining an error of 0.61% without tuning any hyperparameters (see Table 2). This result is also competitive with other recent techniques in the permutation non-invariant setting—compare to dropout (0.59% [32]) and dropconnect (0.63% [32]). In line with [33], we preprocessed the input with ZCA whitening and added a max-norm regularizer to limit the size of presynaptic weight vectors to at most 3.5.

Table 2: Classification Errors on the MNIST Test Set in the Permutation Non-Invariant Setup

Method	Error [%]
Conv net + Dropconnect [32]	0.63
Conv net + Grdi ($\beta = 0.2$)	0.61
Conv net + Dropout [32]	**0.59**

The lower panels of Figure 1 show the development of the test set error over epochs for both rate distortion regularizers (red) compared to ordinary utility maximization without regularization (Umax, black) for the different network architectures that we used in the permutation invariant setting. It can be seen that the global variant of our regularizer (Grdi with $\beta = 0.2$, see lower left panel in Figure 1) leads to a significant increase in performance across different architectures as demonstrated by the two separate clusters of trajectories. In addition, Grdi also leads to faster learning as the red trajectories in the lower left panel of Figure 1 decrease significantly faster then the black trajectories during the first ten epochs of training. For the local variant of our regularizer (Lrdi with $\beta = 10^{-5}$, see lower right panel in Figure 1), the performance improvements are less prominent when compared to the global variant.

5 CONCLUSION

Previously, a synaptic weight update rule for a single reward-maximizing spiking neuron was devised, where the neuron was interpreted as a bounded rational decision-maker under limited computational resources with help of rate distortion theory [21]. It was shown that such a bounded rational weight update rule leads to an efficient regularization by preventing synaptic weights from growing without bounds. In our current work, we extend these results to deterministic neurons and neural networks. On the MNIST benchmark classification task, we have demonstrated the regularizing effect of our approach as networks were successfully prevented from overfitting. These results are robust as we conducted experiments with different network architectures achieving performance competitive with other recent techniques like dropout [33], dropconnect [32] and Bayes by backprop [10] for both ordinary and convolutional networks. The strength of rate distortion regularization is that it is a more principled approach than for example dropout and dropconnect as it may be applied to general artificial agents with parameterized policies and not only to neural networks. Parameterized policies that optimize the rate distortion objective have been previously applied to unsupervised density estimation tasks with autoencoder networks [12]. Our current work extends this kind of approach to the theory of reinforcement and supervised learning with feedforward neural networks, and also provides evidence that this approach scales well on large data sets.

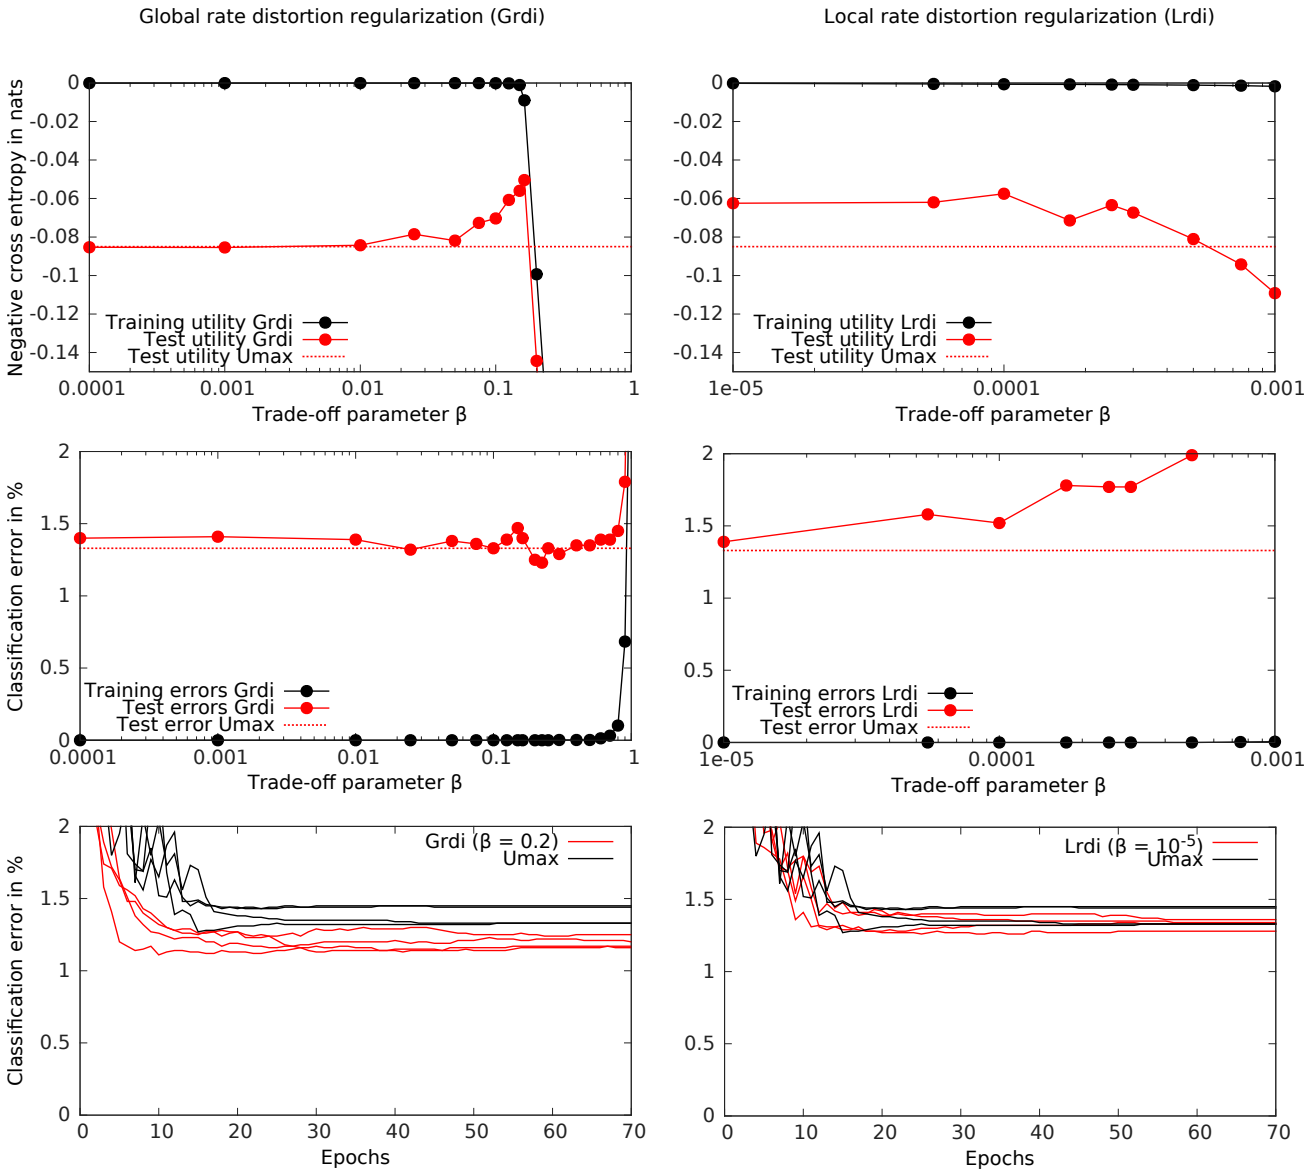

Figure 1: Performance on MNIST in the Permutation Invariant Setup. The left column refers to analyses with global rate distortion regularization (Grdi) and the right column to analyses with local rate distortion regularization (Lrdi). The *upper and middle panels* show the results of the pilot studies on the smallest network architecture. Trajectories in the upper panels illustrate the expected utility (the negative cross entropy) after 50 epochs of training for different values of β—black solid lines reflect the expected utility on the training set, red solid lines reflect the expected utility on the test set and red dashed horizontal lines reflect the expected utility on the test set in ordinary utility maximization (Umax, $\beta = 0$). The middle panels show classification errors instead of utility values. In the Grdi case, the negative cross entropy drops sharply for larger betas, because the regularization drives the output rates towards a flatter distribution, even though the mode of the distribution is maintained, which allows for robust performance in terms of classification error. The *lower panels* show the results of our final simulations with four different network architectures and fixed β-values. The plots compare the development of the test set error over epochs between ordinary utility maximization (black trajectories, Umax) and rate distortion regularization (red trajectories, Grdi with $\beta = 0.2$ and Lrdi with $\beta = 10^{-5}$ respectively). Each trajectory corresponds to one of the four different network architectures.

A APPENDIX

A.1 MUTUAL INFORMATION RATE OF A DETERMINISTIC NEURON

$$\begin{aligned}
&\lim_{\Delta t\to 0}\frac{1}{\Delta t}I(\boldsymbol{\xi},y)\\
&=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle\sum_y p_{\mathbf{w}}(y|\boldsymbol{\xi})\ln\frac{p_{\mathbf{w}}(y|\boldsymbol{\xi})}{p_{\mathbf{w}}(y)}\right\rangle_{p(\boldsymbol{\xi})}\\
&=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle\phi(\mathbf{w}^\top\boldsymbol{\xi})\Delta t\ln\frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})}\\
&+\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle(1-\phi(\mathbf{w}^\top\boldsymbol{\xi})\Delta t)\underbrace{\ln\frac{1-\phi(\mathbf{w}^\top\boldsymbol{\xi})\Delta t}{1-\bar{\phi}(\mathbf{w})\Delta t}}_{\to 0}\right\rangle_{p(\boldsymbol{\xi})}\\
&=\left\langle\phi(\mathbf{w}^\top\boldsymbol{\xi})\ln\frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})}.
\end{aligned}\tag{33}$$

A.2 DERIVATIVE OF THE MUTUAL INFORMATION RATE

$$\begin{aligned}
&\frac{\partial}{\partial w_i}\lim_{\Delta t\to 0}\frac{1}{\Delta t}I(\boldsymbol{\xi},y)\\
&=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\frac{\partial}{\partial w_i}\left\langle\sum_y p_{\mathbf{w}}(y|\boldsymbol{\xi})\ln\frac{p_{\mathbf{w}}(y|\boldsymbol{\xi})}{p_{\mathbf{w}}(y)}\right\rangle_{p(\boldsymbol{\xi})}\\
&=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle\sum_y\left(\frac{\partial}{\partial w_i}p_{\mathbf{w}}(y|\boldsymbol{\xi})\right)\ln\frac{p_{\mathbf{w}}(y|\boldsymbol{\xi})}{p_{\mathbf{w}}(y)}\right\rangle_{p(\boldsymbol{\xi})}\\
&+\lim_{\Delta t\to 0}\frac{1}{\Delta t}\underbrace{\left\langle\sum_y p_{\mathbf{w}}(y|\boldsymbol{\xi})\left(\frac{\partial}{\partial w_i}\ln p_{\mathbf{w}}(y|\boldsymbol{\xi})\right)\right\rangle_{p(\boldsymbol{\xi})}}_{=\left\langle\sum_y\frac{\partial}{\partial w_i}p_{\mathbf{w}}(y|\boldsymbol{\xi})\right\rangle_{p(\boldsymbol{\xi})}=\frac{\partial}{\partial w_i}1=0}\\
&-\lim_{\Delta t\to 0}\frac{1}{\Delta t}\underbrace{\left\langle\sum_y p_{\mathbf{w}}(y|\boldsymbol{\xi})\left(\frac{\partial}{\partial w_i}\ln p_{\mathbf{w}}(y)\right)\right\rangle_{p(\boldsymbol{\xi})}}_{=\sum_y\frac{\partial}{\partial w_i}p_{\mathbf{w}}(y)=\frac{\partial}{\partial w_i}1=0}\\
&=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle\xi_i\phi'(\mathbf{w}^\top\boldsymbol{\xi})\Delta t\ln\frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})}\\
&-\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left\langle\xi_i\phi'(\mathbf{w}^\top\boldsymbol{\xi})\Delta t\underbrace{\ln\frac{1-\phi(\mathbf{w}^\top\boldsymbol{\xi})\Delta t}{1-\bar{\phi}(\mathbf{w})\Delta t}}_{\to 0}\right\rangle_{p(\boldsymbol{\xi})}\\
&=\left\langle\xi_i\phi'(\mathbf{w}^\top\boldsymbol{\xi})\ln\frac{\phi(\mathbf{w}^\top\boldsymbol{\xi})}{\bar{\phi}(\mathbf{w})}\right\rangle_{p(\boldsymbol{\xi})}.
\end{aligned}\tag{34}$$

A.3 DERIVATIVE OF THE GLOBAL MUTUAL INFORMATION

$$\begin{aligned}
&\frac{\partial}{\partial w_i^n}I(\boldsymbol{\xi},\mathbf{y})\\
&=\frac{\partial}{\partial w_i^n}\left\langle\sum_{\mathbf{y}}p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\ln\frac{p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})}{p_{\mathcal{W}}(\mathbf{y})}\right\rangle_{p(\boldsymbol{\xi})}\\
&=\left\langle\sum_{\mathbf{y}}\left(\frac{\partial}{\partial w_i^n}p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\right)\ln\frac{p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})}{p_{\mathcal{W}}(\mathbf{y})}\right\rangle_{p(\boldsymbol{\xi})}\\
&+\underbrace{\left\langle\sum_{\mathbf{y}}p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\left(\frac{\partial}{\partial w_i^n}\ln p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\right)\right\rangle_{p(\boldsymbol{\xi})}}_{=\left\langle\sum_{\mathbf{y}}\frac{\partial}{\partial w_i^n}p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\right\rangle_{p(\boldsymbol{\xi})}=\frac{\partial}{\partial w_i^n}1=0}\\
&-\underbrace{\left\langle\sum_{\mathbf{y}}p_{\mathcal{W}}(\mathbf{y}|\boldsymbol{\xi})\left(\frac{\partial}{\partial w_i^n}\ln p_{\mathcal{W}}(\mathbf{y})\right)\right\rangle_{p(\boldsymbol{\xi})}}_{=\sum_{\mathbf{y}}\frac{\partial}{\partial w_i^n}p_{\mathcal{W}}(\mathbf{y})=\frac{\partial}{\partial w_i^n}1=0}\\
&=\left\langle\sum_j\left(\frac{\partial}{\partial w_i^n}f_j(\mathcal{W},\boldsymbol{\xi})\right)\ln\frac{f_j(\mathcal{W},\boldsymbol{\xi})}{\bar{f}_j(\mathcal{W})}\right\rangle_{p(\boldsymbol{\xi})}.
\end{aligned}\tag{35}$$

Abstract

We discuss a variant of Thompson sampling for nonparametric reinforcement learning in countable classes of general stochastic environments. These environments can be non-Markov, nonergodic, and partially observable. We show that Thompson sampling learns the environment class in the sense that (1) asymptotically its value converges to the optimal value in mean and (2) given a recoverability assumption regret is sublinear.

Keywords. General reinforcement learning, Thompson sampling, asymptotic optimality, regret, discounting, recoverability, AIXI.

1 INTRODUCTION

In reinforcement learning (RL) an agent interacts with an unknown environment with the goal of maximizing rewards. Recently reinforcement learning has received a surge of interest, triggered by its success in applications such as simple video games [MKS+15]. However, theory is lagging behind application and most theoretical analyses has been done in the bandit framework and for Markov decision processes (MDPs). These restricted environment classes fall short of the full reinforcement learning problem and theoretical results usually assume ergocity and visiting every state infinitely often. Needless to say, these assumptions are not satisfied for any but the simplest applications.

Our goal is to lift these restrictions; we consider *general reinforcement learning*, a top-down approach to RL with the aim to understand the fundamental underlying problems in their generality. Our approach to general RL is *nonparametric*: we only assume that the true environment belongs to a given countable environment class.

We are interested in agents that maximize rewards *optimally*. Since the agent does not know the true environment in advance, it is not obvious what optimality should mean. We discuss two different notions of optimality: *asymptotic optimality* and *worst-case regret*.

Asymptotic optimality requires that asymptotically the agent learns to act optimally, i.e., that the discounted value of the agent's policy π converges to the optimal discounted value, $V_\mu^* - V_\mu^\pi \to 0$ for all environments μ from the environment class. This convergence is impossible for deterministic policies since the agent has to explore infinitely often and for long stretches of time, but there are policies that converge almost surely in Cesàro average [LH11]. Bayes-optimal agents are generally not asymptotically optimal [Ors13]. However, asymptotic optimality can be achieved through an exploration component on top of a Bayes-optimal agent [Lat13, Ch. 5] or through optimism [SH15].

Asymptotic optimality in mean is essentially a weaker variant of *probably approximately correct* (PAC) that comes without a concrete convergence rate: for all $\varepsilon > 0$ and $\delta > 0$ the probability that our policy is ε-suboptimal converges to zero (at an unknown rate). Eventually this probability will be less than δ. Since our environment class can be very large and non-compact, concrete PAC/convergence rates are likely impossible.

Regret is how many expected rewards the agent forfeits by not following the best informed policy. Different problem classes have different regret rates, depending on the structure and the difficulty of the problem class. Multi-armed bandits provide a (problem-independent) worst-case regret bound of $\Omega(\sqrt{KT})$ where K is the number of arms [BB12]. In Markov decision processes (MDPs) the lower bound is $\Omega(\sqrt{DSAT})$ where S is the number of states, A the number of actions, and D the diameter of the MDP [AJO10]. For a countable class of environments given by state representation functions that map histories to MDP states, a regret of $\tilde{O}(T^{2/3})$ is achievable assuming the resulting MDP is weakly communicating [NMRO13]. A problem class is considered *learnable* if there is an algorithm that has a sublinear regret guarantee.

This paper continues a narrative that started with definition

of the Bayesian agent AIXI [Hut00] and the proof that it satisfies various optimality guarantees [Hut02]. Recently it was revealed that these optimality notions are trivial or subjective [LH15]: a Bayesian agent does not explore enough to lose the prior's bias, and a particularly bad prior can make the agent conform to any arbitrarily bad policy as long as this policy yields some rewards. These negative results put the Bayesian approach to (general) RL into question. In this paper we remedy the situation by showing that using Bayesian techniques an agent can indeed be optimal in an objective sense.

The agent we consider is known as *Thompson sampling*, *posterior sampling*, or the *Bayesian control rule* [Tho33]. It samples an environment ρ from the posterior, follows the ρ-optimal policy for one effective horizon (a lookahead long enough to encompass most of the discount function's mass), and then repeats. We show that this agent's policy is asymptotically optimal in mean (and, equivalently, in probability). Furthermore, using a recoverability assumption on the environment, and some (minor) assumptions on the discount function, we prove that the worst-case regret is sublinear. This is the first time convergence and regret bounds of Thompson sampling have been shown under such general conditions.

Thompson sampling was originally proposed by Thompson as a bandit algorithm [Tho33]. It is easy to implement and often achieves quite good results [CL11]. In multi-armed bandits it attains optimal regret [AG11, KKM12]. Thompson sampling has also been considered for MDPs: as model-free method relying on distributions over Q-functions with convergence guarantee [DFR98], and as a model-based algorithm without theoretical analysis [Str00]. Bayesian and frequentist regret bounds have also been established [ORvR13, OR14, GM15]. PAC guarantees have been established for an optimistic variant of Thompson sampling for MDPs [ALL$^+$09].

For general RL Thompson sampling was first suggested in [OB10] with resampling at every time step. The authors prove that the action probabilities of Thompson sampling converge to the action probability of the optimal policy almost surely, but require a finite environment class and two (arguably quite strong) technical assumptions on the behavior of the posterior distribution (akin to ergodicity) and the similarity of environments in the class. Our convergence results do not require these assumptions, but we rely on an (unavoidable) recoverability assumption for our regret bound.

Appendix A contains a list of notation and Appendix B contains omitted proofs.

2 PRELIMINARIES

The set $\mathcal{X}^* := \bigcup_{n=0}^{\infty} \mathcal{X}^n$ is the set of all finite strings over the alphabet $\mathcal{X}$ and the set $\mathcal{X}^\infty$ is the set of all infinite strings over the alphabet $\mathcal{X}$. The empty string is denoted by ϵ, not to be confused with the small positive real number ε. Given a string $x \in \mathcal{X}^*$, we denote its length by $|x|$. For a (finite or infinite) string x of length $\geq k$, we denote with $x_{1:k}$ the first k characters of x, and with $x_{<k}$ the first $k-1$ characters of x.

The notation $\Delta\mathcal{Y}$ denotes the set of probability distributions over $\mathcal{Y}$.

In reinforcement learning, an agent interacts with an environment in cycles: at time step t the agent chooses an *action* $a_t \in \mathcal{A}$ and receives a *percept* $e_t = (o_t, r_t) \in \mathcal{E}$ consisting of an *observation* $o_t \in \mathcal{O}$ and a real-valued *reward* r_t; the cycle then repeats for $t+1$. We assume that rewards are bounded between 0 and 1 and that the set of actions $\mathcal{A}$ and the set of percepts $\mathcal{E}$ are finite.

We fix a *discount function* $\gamma : \mathbb{N} \to \mathbb{R}$ with $\gamma_t \geq 0$ and $\sum_{t=1}^{\infty} \gamma_t < \infty$. Our goal is to maximize discounted rewards $\sum_{t=1}^{\infty} \gamma_t r_t$. The *discount normalization factor* is defined as $\Gamma_t := \sum_{k=t}^{\infty} \gamma_k$. The *effective horizon* $H_t(\varepsilon)$ is a horizon that is long enough to encompass all but an ε of the discount function's mass:

$$H_t(\varepsilon) := \min\{k \mid \Gamma_{t+k}/\Gamma_t \leq \varepsilon\} \tag{1}$$

A *history* is an element of $(\mathcal{A} \times \mathcal{E})^*$. We use $æ \in \mathcal{A} \times \mathcal{E}$ to denote one interaction cycle, and $æ_{<t}$ to denote a history of length $t-1$. We treat action, percepts, and histories both as outcomes and as random variables. A *policy* is a function $\pi : (\mathcal{A} \times \mathcal{E})^* \to \Delta\mathcal{A}$ mapping a history $æ_{<t}$ to a distribution over the actions taken after seeing this history; the probability of action a is denoted $\pi(a \mid æ_{<t})$. An *environment* is a function $\nu : (\mathcal{A} \times \mathcal{E})^* \times \mathcal{A} \to \Delta\mathcal{E}$ mapping a history $æ_{<t}$ and an action a_t to a distribution over the percepts generated after this history; the probability of percept e is denoted $\nu(e \mid æ_{<t}a_t)$.

A policy π and an environment ν generate a probability measure ν^π over infinite histories $(\mathcal{A} \times \mathcal{E})^\infty$, defined by its values on the cylinder sets $\{h \in (\mathcal{A} \times \mathcal{E})^\infty \mid h_{<t} = æ_{<t}\}$:

$$\nu^\pi(æ_{<t}) := \prod_{k=1}^{t-1} \pi(a_k \mid æ_{<k}) \nu(e_k \mid æ_{<k}a_k)$$

When we take an expectation $\mathbb{E}_\nu^\pi$ of a random variable $X_t(æ_{<t})$ this is to be understood as the expectation of the history $æ_{<t}$ for a fixed time step t drawn from ν^π, i.e.,

$$\mathbb{E}_\nu^\pi[X_t(æ_{<t})] := \sum_{æ_{<t}} \nu^\pi(æ_{<t}) X_t(æ_{<t}).$$

We often do not explicitly add the subscript t to time-dependent random variables.

Definition 1 (Value Function)**.** The *value* of a policy π in an environment ν given history $æ_{<t}$ is defined as

$$V_\nu^\pi(æ_{<t}) := \frac{1}{\Gamma_t}\mathbb{E}_\nu^\pi\left[\sum_{k=t}^{\infty}\gamma_k r_k \,\middle|\, æ_{<t}\right],$$

if $\Gamma_t > 0$ and $V_\nu^\pi(æ_{<t}) := 0$ if $\Gamma_t = 0$. The *optimal value* is defined as $V_\nu^*(h) := \sup_\pi V_\nu^\pi(h)$.

The normalization constant $1/\Gamma_t$ ensures that values are bounded between 0 and 1. We also use the *truncated value function*

$$V_\nu^{\pi,m}(æ_{<t}) := \frac{1}{\Gamma_t}\mathbb{E}_\nu^\pi\left[\sum_{k=t}^{m}\gamma_k r_k \,\middle|\, æ_{<t}\right].$$

For each environment μ there is an *optimal policy* π_μ^* that takes an *optimal action* for each history [LH14, Thm. 10]:

$$\pi_\mu^*(a_t \mid æ_{<t}) > 0 \implies a_t \in \arg\max_a V_\mu^*(æ_{<t}a)$$

Let $\mathcal{M}$ denote a countable class of environments. We assume that $\mathcal{M}$ is large enough to contain the true environment (e.g. the class of all computable environments). Let $w \in \Delta\mathcal{M}$ be a prior probability distribution on $\mathcal{M}$ and let

$$\xi := \sum_{\nu\in\mathcal{M}} w(\nu)\nu$$

denote the corresponding Bayesian mixture over the class $\mathcal{M}$. After observing the history $æ_{<t}$ the prior w is updated to the posterior

$$w(\nu \mid æ_{<t}) := w(\nu)\frac{\nu(æ_{<t})}{\xi(æ_{<t})}.$$

We also use the notation $w(\mathcal{M}' \mid æ_{<t}) := \sum_{\nu\in\mathcal{M}'} w(\nu \mid æ_{<t})$ for a set of environments $\mathcal{M}' \subseteq \mathcal{M}$. Likewise we define $\nu(A \mid æ_{<t}) := \sum_{h\in A}\nu(h \mid æ_{<t})$ for a prefix-free set of histories $A \subseteq (\mathcal{A}\times\mathcal{E})^*$.

Let $\nu, \rho \in \mathcal{M}$ be two environments, let π_1, π_2 be two policies, and let $m \in \mathbb{N}$ be a lookahead time step. The *total variation distance* is defined as

$$D_m(\nu^{\pi_1}, \rho^{\pi_2} \mid æ_{<t}) := \sup_{A\subseteq(\mathcal{A}\times\mathcal{E})^m}\left|\nu^{\pi_1}(A \mid æ_{<t}) - \rho^{\pi_2}(A \mid æ_{<t})\right|.$$

with $D_\infty(\nu^{\pi_1}, \rho^{\pi_2} \mid æ_{<t}) := \lim_{m\to\infty} D_m(\nu^{\pi_1}, \rho^{\pi_2} \mid æ_{<t})$.

Lemma 2 (Bounds on Value Difference)**.** *For any policies π_1, π_2, any environments ρ and ν, and any horizon $t \le m \le \infty$,*

$$|V_\nu^{\pi_1,m}(æ_{<t}) - V_\rho^{\pi_2,m}(æ_{<t})| \le D_m(\nu^{\pi_1}, \rho^{\pi_2} \mid æ_{<t})$$

Proof. See Appendix B. □

3 THOMPSON SAMPLING IS ASYMPTOTICALLY OPTIMAL

Strens proposes following the optimal policy for one episode or "related to the number of state transitions the agent is likely to need to plan ahead" [Str00]. We follow Strens' suggestion and resample at the effective horizon.

Let ε_t be a monotone decreasing sequence of positive reals such that $\varepsilon_t \to 0$ as $t \to \infty$. We define our Thompson-sampling policy π_T in Algorithm 1.

Algorithm 1 Thompson sampling policy π_T

1: **while** true **do**
2: sample $\rho \sim w(\cdot \mid æ_{<t})$
3: follow π_ρ^* for $H_t(\varepsilon_t)$ steps

Note that π_T is a stochastic policy since we occasionally sample from a distribution. We assume that this sampling is independent of everything else.

Definition 3 (Asymptotic Optimality)**.** A policy π is *asymptotically optimal in an environment class $\mathcal{M}$* iff for all $\mu \in \mathcal{M}$

$$V_\mu^*(æ_{<t}) - V_\mu^\pi(æ_{<t}) \to 0 \text{ as } t \to \infty \tag{2}$$

on histories drawn from μ^π.

There are different types of asymptotic optimalities based on the type of stochastic convergence in (2). If this convergence occurs almost surely, it is called *strong asymptotic optimality* [LH11, Def. 7]; if this convergence occurs in mean, it is called *asymptotic optimality in mean*; if this convergence occurs in probability, it is called *asymptotic optimality in probability*; and if the Cesàro averages converge almost surely, it is called *weak asymptotic optimality* [LH11, Def. 7].

3.1 ASYMPTOTIC OPTIMALITY IN MEAN

This subsection is dedicated to proving the following theorem.

Theorem 4 (Thompson Sampling is Asymptotically Optimal in Mean)**.** *For all environments $\mu \in \mathcal{M}$,*

$$\mathbb{E}_\mu^{\pi_T}\left[V_\mu^*(æ_{<t}) - V_\mu^{\pi_T}(æ_{<t})\right] \to 0 \text{ as } t \to \infty.$$

This theorem immediately implies that Thompson sampling is also asymptotically optimal in probability: The convergence in mean of the random variables $X_t := V_\mu^*(æ_{<t}) - V_\mu^{\pi_T}(æ_{<t})$ stated in Theorem 4 is equivalent to convergence in probability in the sense that $\mu^{\pi_T}[X_t > \varepsilon] \to 0$ as $t \to \infty$ for all $\varepsilon > 0$ because the random variables X_t are nonnegative and bounded. However, this does not imply almost sure convergence (see Section 3.3).

Define the *Bayes-expected total variation distance*

$$F_m^\pi(\text{æ}_{<t}) := \sum_{\rho\in\mathcal{M}} w(\rho \mid \text{æ}_{<t}) D_m(\rho^\pi, \xi^\pi \mid \text{æ}_{<t})$$

for $m \leq \infty$.

If we replace the distance measure D_m by cross-entropy, then the quantity $F_m^\pi(\text{æ}_{<t})$ becomes the Bayes-expected *information gain* [Lat13, Eq. 3.5].

For the proof of Theorem 4 we need the following lemma.

Lemma 5 (F Vanishes On-Policy)**.** *For any policy π and any environment μ,*

$$\mathbb{E}_\mu^\pi[F_\infty^\pi(\text{æ}_{<t})] \to 0 \text{ as } t \to \infty.$$

Proof. See Appendix B. □

Proof of Theorem 4. Let $\beta, \delta > 0$ and let $\varepsilon_t > 0$ denote the sequence used to define π_T in Algorithm 1. We assume that t is large enough such that $\varepsilon_k \leq \beta$ for all $k \geq t$ and that δ is small enough such that $w(\mu \mid \text{æ}_{<t}) > 4\delta$ for all t, which holds since $w(\mu \mid \text{æ}_{<t}) \not\to 0$ μ^π-almost surely for any policy π [Hut09, Lem. 3i].

The stochastic process $w(\nu \mid \text{æ}_{<t})$ is a ξ^{π_T}-martingale since

$$\begin{aligned}
&\mathbb{E}_\xi^{\pi_T}[w(\nu \mid \text{æ}_{1:t}) \mid \text{æ}_{<t}] \\
&= \sum_{a_t e_t} \xi^{\pi_T}(\text{æ}_t \mid \text{æ}_{<t}) w(\nu) \frac{\nu^{\pi_T}(\text{æ}_{1:t})}{\xi^{\pi_T}(\text{æ}_{1:t})} \\
&= \sum_{a_t e_t} \xi^{\pi_T}(\text{æ}_t \mid \text{æ}_{<t}) w(\nu \mid \text{æ}_{<t}) \frac{\nu^{\pi_T}(\text{æ}_t \mid \text{æ}_{<t})}{\xi^{\pi_T}(\text{æ}_t \mid \text{æ}_{<t})} \\
&= w(\nu \mid \text{æ}_{<t}) \sum_{a_t e_t} \nu^{\pi_T}(\text{æ}_t \mid \text{æ}_{<t}) \\
&= w(\nu \mid \text{æ}_{<t}).
\end{aligned}$$

By the martingale convergence theorem [Dur10, Thm. 5.2.8] $w(\nu \mid \text{æ}_{<t})$ converges ξ^{π_T}-almost surely and because $\xi^{\pi_T} \geq w(\mu)\mu^{\pi_T}$ it also converges μ^{π_T}-almost surely.

We argue that we can choose t_0 to be one of π_T's resampling time steps large enough such that for all $t \geq t_0$ the following three events hold simultaneously with μ^{π_T}-probability at least $1-\delta$.

(i) There is a finite set $\mathcal{M}' \subset \mathcal{M}$ with $w(\mathcal{M}' \mid \text{æ}_{<t}) > 1-\delta$ and $w(\nu \mid \text{æ}_{<k}) \not\to 0$ as $k \to \infty$ for all $\nu \in \mathcal{M}'$.

(ii) $|w(\mathcal{M}'' \mid \text{æ}_{<t}) - w(\mathcal{M}'' \mid \text{æ}_{<t_0})| \leq \delta$ for all $\mathcal{M}'' \subseteq \mathcal{M}'$.

(iii) $F_\infty^{\pi_T}(\text{æ}_{<t}) < \delta\beta w_{\min}^2$.

where $w_{\min} := \inf\{w(\nu \mid \text{æ}_{<k}) \mid k \in \mathbb{N}, \nu \in \mathcal{M}'\}$, which is positive by (i).

(i) and (ii) are satisfied eventually because the posterior $w(\cdot \mid \text{æ}_{<t})$ converges μ^{π_T}-almost surely. Note that the set $\mathcal{M}'$ is random: the limit of $w(\nu \mid \text{æ}_{<t})$ as $t \to \infty$ depends on the history $\text{æ}_{1:\infty}$. Without loss of generality, we assume the true environment μ is contained in $\mathcal{M}'$ since $w(\mu \mid \text{æ}_{<t}) \not\to 0$ μ^{π_T}-almost surely. (iii) follows from Lemma 5 since convergence in mean implies convergence in probability.

Moreover, we define the horizon $m := t + H_t(\varepsilon_t)$ as the time step of the effective horizon at time step t. Let $\text{æ}_{<t}$ be a fixed history for which (i-iii) is satisfied. Then we have

$$\begin{aligned}
\delta\beta w_{\min}^2 &> F_\infty^{\pi_T}(\text{æ}_{<t}) \\
&= \sum_{\nu\in\mathcal{M}} w(\nu \mid \text{æ}_{<t}) D_\infty(\nu^{\pi_T}, \xi^{\pi_T} \mid \text{æ}_{<t}) \\
&= \mathbb{E}_{\nu\sim w(\cdot\mid\text{æ}_{<t})}\left[D_\infty(\nu^{\pi_T}, \xi^{\pi_T} \mid \text{æ}_{<t})\right] \\
&\geq \mathbb{E}_{\nu\sim w(\cdot\mid\text{æ}_{<t})}\left[D_m(\nu^{\pi_T}, \xi^{\pi_T} \mid \text{æ}_{<t})\right] \\
&\geq \beta w_{\min}^2 w(\mathcal{M} \setminus \mathcal{M}'' \mid \text{æ}_{<t})
\end{aligned}$$

by Markov's inequality where

$$\mathcal{M}'' := \left\{\nu \in \mathcal{M} \;\middle|\; D_m(\nu^{\pi_T}, \xi^{\pi_T} \mid \text{æ}_{<t}) < \beta w_{\min}^2\right\}.$$

For our fixed history $\text{æ}_{<t}$ we have

$$\begin{aligned}
1-\delta &< w(\mathcal{M}'' \mid \text{æ}_{<t}) \\
&\overset{(i)}{\leq} w(\mathcal{M}'' \cap \mathcal{M}' \mid \text{æ}_{<t}) + \delta \\
&\overset{(ii)}{\leq} w(\mathcal{M}'' \cap \mathcal{M}' \mid \text{æ}_{<t_0}) + 2\delta \\
&\overset{(i)}{\leq} w(\mathcal{M}'' \mid \text{æ}_{<t_0}) + 3\delta
\end{aligned}$$

and thus we get

$$1 - 4\delta < w\left[D_m(\nu^{\pi_T}, \xi^{\pi_T} \mid \text{æ}_{<t}) < \beta w_{\min}^2 \;\middle|\; \text{æ}_{<t_0}\right]. \tag{3}$$

In particular, this bound holds for $\nu = \mu$ since $w(\mu \mid \text{æ}_{<t_0}) > 4\delta$ by assumption.

It remains to show that with high probability the value $V_\mu^{\pi_\rho^*}$ of the sample ρ's optimal policy π_ρ^* is sufficiently close to the μ-optimal value V_μ^*. The worst case is that we draw the worst sample from $\mathcal{M}' \cap \mathcal{M}''$ twice in a row. From now on, let ρ denote the sample environment we draw at time step t_0, and let t denote some time step between t_0 and $t_1 := t_0 + H_{t_0}(\varepsilon_{t_0})$ (before the next resampling). With probability $w(\nu' \mid \text{æ}_{<t_0}) w(\nu' \mid \text{æ}_{<t_1})$ we sample ν' both at t_0 and t_1 when following π_T. Therefore we have for all $\text{æ}_{t:m}$ and all $\nu \in \mathcal{M}$

$$\begin{aligned}
&\nu^{\pi_T}(\text{æ}_{1:m} \mid \text{æ}_{<t}) \\
&\geq w(\nu' \mid \text{æ}_{<t_0}) w(\nu' \mid \text{æ}_{<t_1}) \nu^{\pi_{\nu'}^*}(\text{æ}_{1:m} \mid \text{æ}_{<t}).
\end{aligned}$$

Thus we get for all $\nu \in \mathcal{M}'$ (in particular ρ and μ)

$$\begin{aligned}
&D_m(\mu^{\pi_T}, \rho^{\pi_T} \mid æ_{<t}) \\
&\geq \sup_{\nu' \in \mathcal{M}} \sup_{A \subseteq (\mathcal{A}\times\mathcal{E})^m} \Big| w(\nu' \mid æ_{<t_0}) w(\nu' \mid æ_{<t_1}) \\
&\qquad (\mu^{\pi^*_{\nu'}}(A \mid æ_{<t}) - \rho^{\pi^*_{\nu'}}(A \mid æ_{<t})) \Big| \\
&\geq w(\nu \mid æ_{<t_0}) w(\nu \mid æ_{<t_1}) \\
&\qquad \sup_{A \subseteq (\mathcal{A}\times\mathcal{E})^m} \Big| \mu^{\pi^*_\nu}(A \mid æ_{<t}) - \rho^{\pi^*_\nu}(A \mid æ_{<t}) \Big| \\
&\geq w_{\min}^2 D_m(\mu^{\pi^*_\nu}, \rho^{\pi^*_\nu} \mid æ_{<t}).
\end{aligned}$$

For $\rho \in \mathcal{M}''$ we get

$$\begin{aligned}
&D_m(\mu^{\pi_T}, \rho^{\pi_T} \mid æ_{<t}) \\
&\leq D_m(\mu^{\pi_T}, \xi^{\pi_T} \mid æ_{<t}) + D_m(\rho^{\pi_T}, \xi^{\pi_T} \mid æ_{<t}) \\
&\overset{(3)}{<} \beta w_{\min}^2 + \beta w_{\min}^2 = 2\beta w_{\min}^2,
\end{aligned}$$

which implies together with Lemma 2 and the fact that rewards in $[0,1]$

$$\begin{aligned}
&\Big| V_\mu^{\pi^*_\nu}(æ_{<t}) - V_\rho^{\pi^*_\nu}(æ_{<t}) \Big| \\
&\leq \frac{\Gamma_{t+H_t(\varepsilon_t)}}{\Gamma_t} + \Big| V_\mu^{\pi^*_\nu, m}(æ_{<t}) - V_\rho^{\pi^*_\nu, m}(æ_{<t}) \Big| \\
&\leq \varepsilon_t + D_m(\mu^{\pi^*_\nu}, \rho^{\pi^*_\nu} \mid æ_{<t}) \\
&\leq \varepsilon_t + \tfrac{1}{w_{\min}^2} D_m(\mu^{\pi_T}, \rho^{\pi_T} \mid æ_{<t}) \\
&< \beta + 2\beta = 3\beta.
\end{aligned}$$

Hence we get (omitting history arguments $æ_{<t}$ for simplicity)

$$\begin{aligned}
V_\mu^* = V_\mu^{\pi^*_\mu} &< V_\rho^{\pi^*_\mu} + 3\beta \leq V_\rho^* + 3\beta \\
&= V_\rho^{\pi^*_\rho} + 3\beta < V_\mu^{\pi^*_\rho} + 3\beta + 3\beta = V_\mu^{\pi^*_\rho} + 6\beta.
\end{aligned} \tag{4}$$

With μ^{π_T}-probability at least $1-\delta$ (i), (ii), and (iii) are true, with μ^{π_T}-probability at least $1-\delta$ our sample ρ happens to be in $\mathcal{M}'$ by (i), and with $w(\cdot \mid æ_{<t_0})$-probability at least $1-4\delta$ the sample is in $\mathcal{M}''$ by (3). All of these events are true simultaneously with probability at least $1-(\delta+\delta+4\delta) = 1-6\delta$. Hence the bound (4) transfers for π_T such that with μ^{π_T}-probability $\geq 1-6\delta$ we have

$$V_\mu^*(æ_{<t}) - V_\mu^{\pi_T}(æ_{<t}) < 6\beta.$$

Therefore $\mu^{\pi_T}[V_\mu^*(æ_{<t}) - V_\mu^{\pi_T}(æ_{<t}) \geq 6\beta] < 6\delta$ and with $\delta \to 0$ we get that $V_\mu^*(æ_{<t}) - V_\mu^{\pi_T}(æ_{<t}) \to 0$ as $t \to \infty$ in probability. The value function is bounded, thus it also converges in mean by the dominated convergence theorem. □

3.2 WEAK ASYMPTOTIC OPTIMALITY

It might appear that convergence in mean is more natural than the convergence of Cesàro averages of weak asymptotic optimality. However, both notions are not so fundamentally different because they both allow an infinite number of bad mistakes (actions that lead to $V_\mu^* - V_\mu^\pi$ being large). Asymptotic optimality in mean allows bad mistakes as long as their probability converges to zero; weak asymptotic optimality allows bad mistakes as long as the total time spent on bad mistakes grows sublinearly.

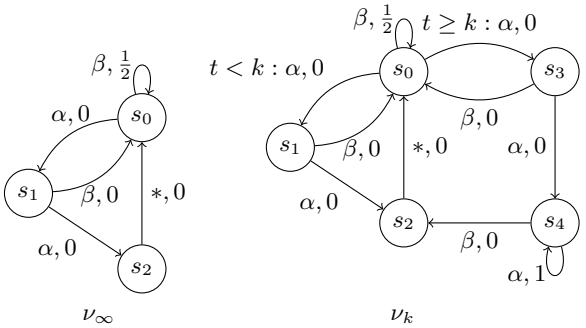
Lattimore and Hutter show that weak asymptotic optimality is possible in a countable class of deterministic environments using an MDL-agent that explores through bursts of random walks [LH11, Def. 10]. For classes of stochastic environments, BayesExp is weakly asymptotically optimal [Lat13, Ch. 5]. However, this requires the additional condition that the effective horizon grows sublinearly, $H_t(\varepsilon_t) \in o(t)$, while Theorem 4 does not require this condition.

Generally, weak asymptotic optimality and asymptotic optimality in mean are incomparable because the notions of convergence are incomparable for (bounded) random variables. First, for deterministic sequences (i.e. deterministic policies in deterministic environments), convergence in mean is equivalent to (regular) convergence, which implies convergence in Cesàro average, but not vice versa. Second, convergence in probability (and hence convergence in mean for bounded random variables) does not imply almost sure convergence of Cesàro averages [Sto13, Sec. 14.18]. We leave open the question whether the policy π_T is weakly asymptotically optimal.

3.3 STRONG ASYMPTOTIC OPTIMALITY

Strong asymptotic optimality is known to be impossible for deterministic policies [LH11, Thm. 8.1], but whether it is possible for stochastic policies is an open question. However, we show that Thompson sampling is not strongly asymptotically optimal.

Example 6 (Thompson Sampling is not Strongly Asymptotically Optimal)**.** Define $\mathcal{A} := \{\alpha, \beta\}$, $\mathcal{E} := \{0, 1/2, 1\}$, and assume geometric discounting, $\gamma_t := \gamma^t$ for $\gamma \in (0,1)$. Consider the following class of environments $\mathcal{M} := \{\nu_\infty, \nu_1, \nu_2, \ldots\}$ (transitions are labeled with action, reward):



Environment ν_k works just like environment ν_∞ except

that after time step k, the path to state s_3 gets unlocked and the optimal policy is to take action α twice from state s_0. The class $\mathcal{M}$ is a class of deterministic weakly communicating MDPs (but as an MDP ν_k has more than 5 states). The optimal policy in environment ν_∞ is to always take action β, the optimal policy for environment ν_k is to take action β for $t < k$ and then take action β in state s_1 and action α otherwise.

Suppose the policy π_T is acting in environment ν_∞. Since it is asymptotically optimal in the class $\mathcal{M}$, it has to take actions $\alpha\alpha$ from s_0 infinitely often: for $t < k$ environment ν_k is indistinguishable from ν_∞, so the posterior for ν_k is larger or equal to the prior. Hence there is always a constant chance of sampling ν_k until taking actions $\alpha\alpha$, at which point all environments ν_k for $k \leq t$ become falsified.

If the policy π_T decides to explore and take the first action α, it will be in state s_1. Let $æ_{<t}$ denote the current history. Then the ν_∞-optimal action is β and

$$V^*_{\nu_\infty}(æ_{<t}) = (1-\gamma)\left(0 + \gamma\frac{1}{2} + \gamma^2\frac{1}{2} + \dots\right) = \frac{\gamma}{2}.$$

The next action taken by π_T is α since any optimal policy for any sampled environment that takes action α once, takes that action again (and we are following that policy for an ε_t-effective horizon). Hence

$$V^{\pi_T}_{\nu_\infty}(æ_{<t}) \leq (1-\gamma)\left(0 + 0 + \gamma^2\frac{1}{2} + \gamma^3\frac{1}{2} + \dots\right) = \frac{\gamma^2}{2}.$$

Therefore $V^*_{\nu_\infty} - V^{\pi_T}_{\nu_\infty} \geq (\gamma - \gamma^2)/2 > 0$. This happens infinitely often with probability one and thus we cannot get almost sure convergence. ♢

We expect that strong asymptotic optimality can be achieved with Thompson sampling by resampling at every time step (with strong assumptions on the discount function).

4 REGRET

4.1 SETUP

In general environments classes worst-case regret is linear because the agent can get caught in a trap and be unable to recover [Hut05, Sec. 5.3.2]. To achieve sublinear regret we need to ensure that the agent can recover from mistakes. Formally, we make the following assumption.

Definition 7 (Recoverability)**.** An environment ν satisfies the *recoverability assumption* iff

$$\sup_\pi \left|\mathbb{E}^{\pi^*_\nu}_\nu[V^*_\nu(æ_{<t})] - \mathbb{E}^{\pi}_\nu[V^*_\nu(æ_{<t})]\right| \to 0 \text{ as } t \to \infty.$$

Recoverability compares following the worst policy π for $t-1$ time steps and then switching to the optimal policy π^*_ν to having followed π^*_ν from the beginning. The recoverability assumption states that switching to the optimal policy at any time step enables the recovery of most of the value.

Note that Definition 7 demands that it becomes less costly to recover from mistakes as time progresses. This should be regarded as an effect of the discount function: if the (effective) horizon grows, recovery becomes easier because the optimal policy has more time to perform a recovery. Moreover, recoverability is on the optimal policy, in contrast to the notion of ergodicity in MDPs which demands returning to a starting state regardless of the policy.

Remark 8 (Weakly Communicating POMDPs are Recoverable)**.** If the effective horizon is growing, $H_t(\varepsilon) \to \infty$ as $t \to \infty$, then any weakly communicating finite state partially observable MDP satisfies the recoverability assumption.

Definition 9 (Regret)**.** The *regret* of a policy π in environment μ is

$$R_m(\pi, \mu) := \sup_{\pi'} \mathbb{E}^{\pi'}_\mu\left[\sum_{t=1}^m r_t\right] - \mathbb{E}^{\pi}_\mu\left[\sum_{t=1}^m r_t\right].$$

Note that regret is undiscounted and always nonnegative. Moreover, the supremum is always attained by some policy (not necessarily the (V_μ-)optimal policy π^*_μ because that policy uses discounting), since the space of possible different policies for the first m actions is finite since we assumed the set of actions $\mathcal{A}$ and the set of percepts $\mathcal{E}$ to be finite.

Assumption 10 (Discount Function)**.** *Let the discount function γ be such that*

(a) $\gamma_t > 0$ *for all t,*

(b) γ_t *is monotone decreasing in t, and*

(c) $H_t(\varepsilon) \in o(t)$ *for all* $\varepsilon > 0$.

This assumption demands that the discount function is somewhat well-behaved: the function has no oscillations, does not become 0, and the horizon is not growing too fast.

Assumption 10 is satisfied by geometric discounting: $\gamma_t := \gamma^t > 0$ (a) for some fixed constant $\gamma \in (0,1)$ is monotone decreasing (b), $\Gamma_t = \gamma^t/(1-\gamma)$, and $H_t(\varepsilon) = \lceil \log_\gamma \varepsilon \rceil \in o(t)$ (c).

The problem with geometric discounting is that it makes the recoverability assumption very strong: since the horizon is not growing, the environment has to enable *faster recovery* as time progresses; in this case weakly communicating partially observable MDPs are *not* recoverable.

A choice with $H_t(\varepsilon) \to \infty$ that satisfies Assumption 10 is $\gamma_t := e^{-\sqrt{t}}/\sqrt{t}$ [Lat13, Sec. 2.3.1]. For this discount function $\Gamma_t \approx 2e^{-\sqrt{t}}$, $H_t(\varepsilon) \approx -\sqrt{t}\log\varepsilon + (\log\varepsilon)^2 \in o(t)$, and thus $H_t(\varepsilon) \to \infty$ as $t \to \infty$.

4.2 SUBLINEAR REGRET

This subsection is dedicated to the following theorem.

Theorem 11 (Sublinear Regret)**.** *If the discount function γ satisfies Assumption 10, the environment $\mu \in \mathcal{M}$ satisfies the recoverability assumption, and π is asymptotically optimal in mean, i.e.,*

$$\mathbb{E}_\mu^\pi\big[V_\mu^*(\text{æ}_{<t}) - V_\mu^\pi(\text{æ}_{<t})\big] \to 0 \text{ as } t \to \infty,$$

then $R_m(\pi, \mu) \in o(m)$.

If the items in Assumption 10 are violated, Theorem 11 can fail:

- If $\gamma_t = 0$ for some time steps t, our policy does not care about those time steps and might take actions that have large regret.
- Similarly if γ oscillates between high values and very low values: our policy might take high-regret actions in time steps with comparatively lower γ-weight.
- If the horizon grows linearly, infinitely often our policy might spend some constant fraction of the current effective horizon exploring, which incurs a cost that is a constant fraction of the total regret so far.

To prove Theorem 11, we apply the following technical lemma.

Lemma 12 (Value and Regret)**.** *Let $\varepsilon > 0$ and assume the discount function γ satisfies Assumption 10. Let $(d_t)_{t\in\mathbb{N}}$ be a sequence of numbers with $|d_t| \leq 1$ for all t. If there is a time step t_0 with*

$$\frac{1}{\Gamma_t}\sum_{k=t}^{\infty}\gamma_k d_k < \varepsilon \quad \forall t \geq t_0 \tag{5}$$

then

$$\sum_{t=1}^{m} d_t \leq t_0 + \varepsilon(m - t_0 + 1) + \frac{1+\varepsilon}{1-\varepsilon}H_m(\varepsilon)$$

Proof. This proof essentially follows the proof of [Hut06, Thm. 17]; see Appendix B. □

Proof of Theorem 11. Let $(\pi_m)_{m\in\mathbb{N}}$ denote any sequence of policies, such as a sequence of policies that attain the supremum in the definition of regret. We want to show that

$$\mathbb{E}_\mu^{\pi_m}\left[\sum_{t=1}^{m} r_t\right] - \mathbb{E}_\mu^{\pi}\left[\sum_{t=1}^{m} r_t\right] \in o(m).$$

For

$$d_k^{(m)} := \mathbb{E}_\mu^{\pi_m}[r_k] - \mathbb{E}_\mu^{\pi}[r_k] \tag{6}$$

we have $-1 \leq d_k^{(m)} \leq 1$ since we assumed rewards to be bounded between 0 and 1. Because the environment μ satisfies the recoverability assumption we have

$$\left|\mathbb{E}_\mu^{\pi_\mu^*}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi}[V_\mu^*(\text{æ}_{<t})]\right| \to 0 \text{ as } t \to \infty, \text{ and}$$
$$\sup_m \left|\mathbb{E}_\mu^{\pi_\mu^*}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi_m}[V_\mu^*(\text{æ}_{<t})]\right| \to 0 \text{ as } t \to \infty,$$

so we conclude that

$$\sup_m \left|\mathbb{E}_\mu^{\pi}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi_m}[V_\mu^*(\text{æ}_{<t})]\right| \to 0$$

by the triangle inequality and thus

$$\sup_m \mathbb{E}_\mu^{\pi_m}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi}[V_\mu^*(\text{æ}_{<t})] \to 0 \text{ as } t \to \infty. \tag{7}$$

By assumption the policy π is asymptotically optimal in mean, so we have

$$\mathbb{E}_\mu^{\pi}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi}[V_\mu^{\pi}(\text{æ}_{<t})] \to 0 \text{ as } t \to \infty,$$

and with (7) this combines to

$$\sup_m \mathbb{E}_\mu^{\pi_m}[V_\mu^*(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi}[V_\mu^{\pi}(\text{æ}_{<t})] \to 0 \text{ as } t \to \infty.$$

From $V_\mu^*(\text{æ}_{<t}) \geq V_\mu^{\pi_m}(\text{æ}_{<t})$ we get

$$\limsup_{t\to\infty}\left(\sup_m \mathbb{E}_\mu^{\pi_m}[V_\mu^{\pi_m}(\text{æ}_{<t})] - \mathbb{E}_\mu^{\pi}[V_\mu^{\pi}(\text{æ}_{<t})]\right) \leq 0. \tag{8}$$

For $\pi' \in \{\pi, \pi_1, \pi_2, \ldots\}$ we have

$$\begin{aligned}
\mathbb{E}_\mu^{\pi'}[V_\mu^{\pi'}(\text{æ}_{<t})] &= \mathbb{E}_\mu^{\pi'}\left[\frac{1}{\Gamma_t}\mathbb{E}_\mu^{\pi'}\left[\sum_{k=t}^{\infty}\gamma_k r_k \,\middle|\, \text{æ}_{<t}\right]\right] \\
&= \mathbb{E}_\mu^{\pi'}\left[\frac{1}{\Gamma_t}\sum_{k=t}^{\infty}\gamma_k r_k\right] \\
&= \frac{1}{\Gamma_t}\sum_{k=t}^{\infty}\gamma_k \mathbb{E}_\mu^{\pi'}[r_k],
\end{aligned}$$

so from (6) and (8) we get

$$\limsup_{t\to\infty}\sup_m \frac{1}{\Gamma_t}\sum_{k=t}^{\infty}\gamma_k d_k^{(m)} \leq 0.$$

Let $\varepsilon > 0$ and choose t_0 independent of m and large enough such that $\sup_m \sum_{k=t}^{\infty}\gamma_k d_k^{(m)}/\Gamma_t < \varepsilon$ for all $t \geq t_0$. Now we let $m \in \mathbb{N}$ be given and apply Lemma 12 to get

$$\begin{aligned}
\frac{R_m(\pi,\mu)}{m} &= \frac{\sum_{k=1}^{m} d_k^{(m)}}{m} \\
&\leq \frac{t_0 + \varepsilon(m - t_0 + 1) + \frac{1+\varepsilon}{1-\varepsilon}H_m(\varepsilon)}{m}.
\end{aligned}$$

Since $H_t(\varepsilon) \in o(t)$ according to Assumption 10c we get $\limsup_{m\to\infty} R_m(\pi,\mu)/m \leq 0$. □

Example 13 (Converse of Theorem 11 is False)**.** Let μ be a two-armed Bernoulli bandit with means 0 and 1 and suppose we are using geometric discounting with discount factor $\gamma \in [0, 1)$. This environment is recoverable. If our policy π pulls the suboptimal arm exactly on time steps $1, 2, 4, 8, 16, \ldots$, regret will be logarithmic. However, on time steps $t = 2^n$ for $n \in \mathbb{N}$ the value difference $V^*_\mu - V^\pi_\mu$ is deterministically at least $1 - \gamma > 0$. ♢

4.3 IMPLICATIONS

We get the following immediate consequence.

Corollary 14 (Sublinear Regret for the Optimal Discounted Policy)**.** *If the discount function γ satisfies Assumption 10 and the environment μ satisfies the recoverability assumption, then $R_m(\pi^*_\mu, \mu) \in o(m)$.*

Proof. From Theorem 11 since the policy π^*_μ is (trivially) asymptotically optimal in μ. □

If the environment does not satisfy the recoverability assumption, regret may be linear *even on the optimal policy*: the optimal policy maximizes discounted rewards and this short-sightedness might incur a tradeoff that leads to linear regret later on if the environment does not allow recovery.

Corollary 15 (Sublinear Regret for Thompson Sampling)**.** *If the discount function γ satisfies Assumption 10 and the environment $\mu \in \mathcal{M}$ satisfies the recoverability assumption, then $R_m(\pi_T, \mu) \in o(m)$ for the Thompson sampling policy π_T.*

Proof. From Theorem 4 and Theorem 11. □

5 DISCUSSION

In this paper we introduced a reinforcement learning policy π_T based on Thompson sampling for general countable environment classes (Algorithm 1). We proved two asymptotic statements about this policy. Theorem 4 states that π_T is asymptotically optimal in mean: the value of π_T in the true environment converges to the optimal value. Corollary 15 states that the regret of π_T is sublinear: the difference of the expected average rewards between π_T and the best informed policy converges to 0. Both statements come without a concrete convergence rate because of the weak assumptions we made on the environment class.

Asymptotic optimality has to be taken with a grain of salt. It provides no incentive to the agent to avoid traps in the environment. Once the agent gets caught in a trap, all actions are equally bad and thus optimal: asymptotic optimality has been achieved. Even worse, an asymptotically optimal agent has to explore all the traps because they might contain hidden treasure. Overall, there is a dichotomy between the asymptotic nature of asymptotic optimality and the use of discounting to prioritize the present over the future. Ideally, we would want to give finite guarantees instead, but without additional assumptions this is likely impossible in this general setting. Our regret bound could be a step in the right direction, even though itself asymptotic in nature.

For Bayesians asymptotic optimality means that the posterior distribution $w(\cdot \mid æ_{<t})$ concentrates on environments that are indistinguishable from the true environment (but generally not on the true environment). This is why Thompson sampling works: any optimal policy of the environment we draw from the posterior will, with higher and higher probability, also be (almost) optimal in the true environment.

If the Bayesian mixture ξ is inside the class $\mathcal{M}$ (as it is the case for the class of lower semicomputable chronological semimeasures [Hut05]), then we can assign ξ a prior probability that is arbitrarily close to 1. Since the posterior of ξ is the same as the prior, Thompson sampling will act according to the Bayes-optimal policy most of the time. This means the Bayes-value of Thompson sampling can be very good; formally, $V^*_\xi(\epsilon) - V^{\pi_T}_\xi(\epsilon)$ can be made arbitrarily small, and thus Thompson sampling can have near-optimal Legg-Hutter intelligence [LH07].

In contrast, the Bayes-value of Thompson sampling can also be very bad: Suppose you have a class of $(n+1)$-armed bandits indexed $1, \ldots, n$ where bandit i gives reward $1 - \varepsilon$ on arm 1, reward 1 on arm $i + 1$, and reward 0 on all other arms. For geometric discounting and $\varepsilon < (1-\gamma)/(2-\gamma)$, it is Bayes-optimal to pull arm 1 while Thompson sampling will explore on average $n/2$ arms until it finds the optimal arm. The Bayes-value of Thompson sampling is $1/(n-\gamma_{n-1})$ in contract to $(1-\varepsilon)$ achieved by Bayes. For a horizon of n, the Bayes-optimal policy suffers a regret of εn and Thompson sampling a regret of $n/2$, which is much larger for small ε.

The exploration performed by Thompson sampling is qualitatively different from the exploration by BayesExp [Lat13, Ch. 5]. BayesExp performs phases of exploration in which it maximizes the expected information gain. This explores the environment class completely, even achieving off-policy prediction [OLH13, Thm. 7]. In contrast, Thompson sampling only explores on the optimal policies, and in some environment classes this will not yield off-policy prediction. So in this sense the exploration mechanism of Thompson sampling is more reward-oriented than maximizing information gain.

Possible avenues of future research are providing concrete convergence rates for specific environment classes and results for uncountable (parameterized) environment classes. For the latter, we have to use different analysis techniques because the true environment μ is typically assigned a prior probability of 0 (only a positive density) but the proofs of Lemma 5 and Theorem 4 rely on dividing by or tak-

ing a minimum over prior probabilities. We also left open whether Thompson sampling is weakly asymptotically optimal.

Abstract

A Bayesian agent acting in a multi-agent environment learns to predict the other agents' policies if its prior assigns positive probability to them (in other words, its prior contains a *grain of truth*). Finding a reasonably large class of policies that contains the Bayes-optimal policies with respect to this class is known as the *grain of truth problem*. Only small classes are known to have a grain of truth and the literature contains several related impossibility results. In this paper we present a formal and general solution to the full grain of truth problem: we construct a class of policies that contains all computable policies as well as Bayes-optimal policies for every lower semicomputable prior over the class. When the environment is unknown, Bayes-optimal agents may fail to act optimally even asymptotically. However, agents based on Thompson sampling converge to play ε-Nash equilibria in arbitrary unknown computable multi-agent environments. While these results are purely theoretical, we show that they can be computationally approximated arbitrarily closely.

Keywords. General reinforcement learning, multi-agent systems, game theory, self-reflection, asymptotic optimality, Nash equilibrium, Thompson sampling, AIXI.

1 INTRODUCTION

Consider the general setup of multiple reinforcement learning agents interacting sequentially in a known environment with the goal to maximize discounted reward.[1] Each agent knows how the environment behaves, but does not know the other agents' behavior. The natural (Bayesian) approach would be to define a class of possible policies that the other agents could adopt and take a prior over this class. During the interaction, this prior gets updated to the posterior as our agent learns the others' behavior. Our agent then acts optimally with respect to this posterior belief.

Reinforcement learning	Game theory
stochastic policy	mixed strategy
deterministic policy	pure strategy
agent	player
multi-agent environment	infinite extensive-form game
reward	payoff/utility
(finite) history	history
infinite history	path of play

Table 1: Terminology dictionary between reinforcement learning and game theory.

A famous result for infinitely repeated games states that as long as each agent assigns positive prior probability to the other agents' policies (a *grain of truth*) and each agent acts Bayes-optimal, then the agents converge to playing an ε-Nash equilibrium [KL93].

As an example, consider an infinitely repeated prisoners dilemma between two agents. In every time step the payoff matrix is as follows, where C means cooperate and D means defect.

	C	D
C	3/4, 3/4	0, 1
D	1, 0	1/4, 1/4

Define the set of policies $\Pi := \{\pi_\infty, \pi_0, \pi_1, \ldots\}$ where policy π_t cooperates until time step t or the opponent defects (whatever happens first) and defects thereafter. The Bayes-optimal behavior is to cooperate until the posterior belief that the other agent defects in the time step after the next is greater than some constant (depending on the discount function) and then defect afterwards. Therefore Bayes-optimal behavior leads to a policy from the set Π

[1] We mostly use the terminology of reinforcement learning. For readers from game theory we provide a dictionary in Table 1.

(regardless of the prior). If both agents are Bayes-optimal with respect to some prior, they both have a grain of truth and therefore they converge to a Nash equilibrium: either they both cooperate forever or after some finite time they both defect forever. Alternating strategies like TitForTat (cooperate first, then play the opponent's last action) are not part of the policy class Π, and adding them to the class breaks the grain of truth property: the Bayes-optimal behavior is no longer in the class. This is rather typical; a Bayesian agent usually needs to be more powerful than its environment [LH15b].

Until now, classes that admit a grain of truth were known only for small toy examples such as the iterated prisoner's dilemma above [SLB09, Ch. 7.3]. The quest to find a large class admitting a grain of truth is known as the *grain of truth problem* [Hut09, Q. 5j]. The literature contains several impossibility results on the grain of truth problem [FY01, Nac97, Nac05] that identify properties that cannot be simultaneously satisfied for classes that allow a grain of truth.

In this paper we present a formal solution to multi-agent reinforcement learning and the grain of truth problem in the general setting (Section 3). We assume that our multi-agent environment is computable, but it does not need to be stationary/Markov, ergodic, or finite-state [Hut05]. Our class of policies is large enough to contain all computable (stochastic) policies, as well as all relevant Bayes-optimal policies. At the same time, our class is small enough to be limit computable. This is important because it allows our result to be computationally approximated.

In Section 4 we consider the setting where the multi-agent environment is unknown to the agents and has to be learned in addition to the other agents' behavior. A Bayes-optimal agent may not learn to act optimally in unknown multi-agent environments *even though it has a grain of truth*. This effect occurs in non-recoverable environments where taking one wrong action can mean a permanent loss of future value. In this case, a Bayes-optimal agent avoids taking these dangerous actions and therefore will not explore enough to wash out the prior's bias [LH15a]. Therefore, Bayesian agents are not *asymptotically optimal*, i.e., they do not always learn to act optimally [Ors13].

However, asymptotic optimality is achieved by Thompson sampling because the inherent randomness of Thompson sampling leads to enough exploration to learn the entire environment class [LLOH16]. This leads to our main result: if all agents use Thompson sampling over our class of multi-agent environments, then for every $\varepsilon > 0$ they converge to an ε-Nash equilibrium asymptotically.

The central idea to our construction is based on *reflective oracles* [FST15, FTC15b]. Reflective oracles are probabilistic oracles similar to halting oracles that answer whether the probability that a given probabilistic Turing machine T outputs 1 is higher than a given rational number p. The oracles are reflective in the sense that the machine T may itself query the oracle, so the oracle has to answer queries about itself. This invites issues caused by self-referential liar paradoxes of the form "if the oracle says that I return 1 with probability $> 1/2$, then return 0, else return 1." Reflective oracles avoid these issues by being allowed to randomize if the machines do not halt or the rational number is *exactly* the probability to output 1. We introduce reflective oracles formally in Section 2 and prove that there is a limit computable reflective oracle.

2 REFLECTIVE ORACLES

2.1 PRELIMINARIES

Let $\mathcal{X}$ denote a finite set called *alphabet*. The set $\mathcal{X}^* := \bigcup_{n=0}^{\infty} \mathcal{X}^n$ is the set of all finite strings over the alphabet $\mathcal{X}$, the set $\mathcal{X}^\infty$ is the set of all infinite strings over the alphabet $\mathcal{X}$, and the set $\mathcal{X}^\sharp := \mathcal{X}^* \cup \mathcal{X}^\infty$ is their union. The empty string is denoted by ϵ, not to be confused with the small positive real number ε. Given a string $x \in \mathcal{X}^\sharp$, we denote its length by $|x|$. For a (finite or infinite) string x of length $\geq k$, we denote with $x_{1:k}$ the first k characters of x, and with $x_{<k}$ the first $k-1$ characters of x. The notation $x_{1:\infty}$ stresses that x is an infinite string.

A function $f : \mathcal{X}^* \to \mathbb{R}$ is *lower semicomputable* iff the set $\{(x,p) \in \mathcal{X}^* \times \mathbb{Q} \mid f(x) > p\}$ is recursively enumerable. The function f is *computable* iff both f and $-f$ are lower semicomputable. Finally, the function f is *limit computable* iff there is a computable function ϕ such that

$$\lim_{k\to\infty} \phi(x,k) = f(x).$$

The program ϕ that limit computes f can be thought of as an *anytime algorithm* for f: we can stop ϕ at any time k and get a preliminary answer. If the program ϕ ran long enough (which we do not know), this preliminary answer will be close to the correct one.

We use $\Delta\mathcal{Y}$ to denote the set of probability distributions over $\mathcal{Y}$. A list of notation can be found in Appendix A.

2.2 DEFINITION

A *semimeasure* over the alphabet $\mathcal{X}$ is a function $\nu : \mathcal{X}^* \to [0,1]$ such that (i) $\nu(\epsilon) \leq 1$, and (ii) $\nu(x) \geq \sum_{a\in\mathcal{X}} \nu(xa)$ for all $x \in \mathcal{X}^*$. In the terminology of measure theory, semimeasures are probability measures on the probability space $\mathcal{X}^\sharp = \mathcal{X}^* \cup X^\infty$ whose σ-algebra is generated by the *cylinder sets* $\Gamma_x := \{xz \mid z \in \mathcal{X}^\sharp\}$ [LV08, Ch. 4.2]. We call a semimeasure (probability) a *measure* iff equalities hold in (i) and (ii) for all $x \in \mathcal{X}^*$.

Next, we connect semimeasures to Turing machines. The literature uses *monotone Turing machines*, which naturally

correspond to lower semicomputable semimeasures [LV08, Sec. 4.5.2] that describe the distribution that arises when piping fair coin flips into the monotone machine. Here we take a different route.

A *probabilistic Turing machine* is a Turing machine that has access to an unlimited number of uniformly random coin flips. Let $\mathcal{T}$ denote the set of all probabilistic Turing machines that take some input in $\mathcal{X}^*$ and may query an oracle (formally defined below). We take a Turing machine $T \in \mathcal{T}$ to correspond to a semimeasure λ_T where $\lambda_T(a \mid x)$ is the probability that T outputs $a \in \mathcal{X}$ when given $x \in \mathcal{X}^*$ as input. The value of $\lambda_T(x)$ is then given by the chain rule

$$\lambda_T(x) := \prod_{k=1}^{|x|} \lambda_T(x_k \mid x_{<k}). \tag{1}$$

Thus $\mathcal{T}$ gives rise to the set of semimeasures $\mathcal{M}$ where the *conditionals* $\lambda(a \mid x)$ are lower semicomputable. In contrast, the literature typically considers semimeasures whose *joint* probability (1) is lower semicomputable. This set $\mathcal{M}$ contains all computable measures. However, $\mathcal{M}$ is a proper subset of the set of all lower semicomputable semimeasures because the product (1) is lower semicomputale, but there are some lower semicomputable semimeasures whose conditional is not lower semicomputable [LH15c, Thm. 6].

In the following we assume that our alphabet is binary, i.e., $\mathcal{X} := \{0,1\}$.

Definition 1 (Oracle)**.** An *oracle* is a function $O : \mathcal{T} \times \{0,1\}^* \times \mathbb{Q} \to \Delta\{0,1\}$.

Oracles are understood to be probabilistic: they randomly return 0 or 1. Let T^O denote the machine $T \in \mathcal{T}$ when run with the oracle O, and let λ_T^O denote the semimeasure induced by T^O. This means that drawing from λ_T^O involves two sources of randomness: one from the distribution induced by the probabilistic Turing machine T and one from the oracle's answers.

The intended semantics of an oracle are that it takes a *query* (T, x, p) and returns 1 if the machine T^O outputs 1 on input x with probability greater than p when run with the oracle O, i.e., when $\lambda_T^O(1 \mid x) > p$. Furthermore, the oracle returns 0 if the machine T^O outputs 1 on input x with probability less than p when run with the oracle O, i.e., when $\lambda_T^O(1 \mid x) < p$. To fulfill this, the oracle O has to make statements about itself, since the machine T from the query may again query O. Therefore we call oracles of this kind *reflective oracles*. This has to be defined very carefully to avoid the obvious diagonalization issues that are caused by programs that ask the oracle about themselves. We impose the following self-consistency constraint.

Definition 2 (Reflective Oracle)**.** An oracle O is *reflective* iff for all queries $(T, x, p) \in \mathcal{T} \times \{0,1\}^* \times \mathbb{Q}$,

(i) $\lambda_T^O(1 \mid x) > p$ implies $O(T, x, p) = 1$, and

Figure 1: Answer options of a reflective oracle O for the query (T, x, p); the rational $p \in [0,1]$ falls into one of the three regions above. The values of $\lambda_T^O(0 \mid x)$ and $\lambda_T^O(1 \mid x)$ are depicted as the length of the line segment under which they are written.

(ii) $\lambda_T^O(0 \mid x) > 1 - p$ implies $O(T, x, p) = 0$.

If p under- or overshoots the true probability of $\lambda_T^O(\cdot \mid x)$, then the oracle must reveal this information. However, in the critical case when $p = \lambda_T^O(1 \mid x)$, the oracle is allowed to return anything and may randomize its result. Furthermore, since T might not output any symbol, it is possible that $\lambda_T^O(0 \mid x) + \lambda_T^O(1 \mid x) < 1$. In this case the oracle can reassign the non-halting probability mass to 0, 1, or randomize; see Figure 1.

Example 3 (Reflective Oracles and Diagonalization)**.** Let $T \in \mathcal{T}$ be a probabilistic Turing machine that outputs $1 - O(T, \epsilon, 1/2)$ (T can know its own source code by quining [Kle52, Thm. 27]). In other words, T queries the oracle about whether it is more likely to output 1 or 0, and then does whichever the oracle says is less likely. In this case we can use an oracle $O(T, \epsilon, 1/2) := 1/2$ (answer 0 or 1 with equal probability), which implies $\lambda_T^O(1 \mid \epsilon) = \lambda_T^O(0 \mid \epsilon) = 1/2$, so the conditions of Definition 2 are satisfied. In fact, for this machine T we must have $O(T, \epsilon, 1/2) = 1/2$ for all reflective oracles O. ♢

The following theorem establishes that reflective oracles exist.

Theorem 4 ([FTC15a, App. B])**.** *There is a reflective oracle.*

Definition 5 (Reflective-Oracle-Computable)**.** A semimeasure is called *reflective-oracle-computable* iff it is computable on a probabilistic Turing machine with access to a reflective oracle.

For any probabilistic Turing machine $T \in \mathcal{T}$ we can complete the semimeasure $\lambda_T^O(\cdot \mid x)$ into a reflective-oracle-computable measure $\overline{\lambda}_T^O(\cdot \mid x)$: Using the oracle O and a binary search on the parameter p we search for the crossover point p where $O(T, x, p)$ goes from returning 1 to returning 0. The limit point $p^* \in \mathbb{R}$ of the binary search is random since the oracle's answers may be random. But the main point is that the expectation of p^* exists, so $\overline{\lambda}_T^O(1 \mid x) = \mathbb{E}[p^*] = 1 - \overline{\lambda}_T^O(0 \mid x)$ for all $x \in \mathcal{X}^*$. Hence $\overline{\lambda}_T^O$ is a measure. Moreover, if the oracle is reflective, then $\overline{\lambda}_T^O(x) \geq \lambda_T^O(x)$ for all $x \in \mathcal{X}^*$. In this sense the oracle O can be viewed as a way of 'completing'

all semimeasures λ_T^O to measures by arbitrarily assigning the non-halting probability mass. If the oracle O is reflective this is consistent in the sense that Turing machines who run other Turing machines will be completed in the same way. This is especially important for a universal machine that runs all other Turing machines to induce a Solomonoff-style distribution.

2.3 A LIMIT COMPUTABLE REFLECTIVE ORACLE

The proof of Theorem 4 given in [FTC15a, App. B] is non-constructive and uses the axiom of choice. In Section 2.4 we give a constructive proof for the existence of reflective oracles and show that there is one that is limit computable.

Theorem 6 (A Limit Computable Reflective Oracle)**.** *There is a reflective oracle that is limit computable.*

This theorem has the immediate consequence that reflective oracles cannot be used as halting oracles. At first, this result may seem surprising: according to the definition of reflective oracles, they make concrete statements about the output of probabilistic Turing machines. However, the fact that the oracles may randomize some of the time actually removes enough information such that halting can no longer be decided from the oracle output.

Corollary 7 (Reflective Oracles are not Halting Oracles)**.** *There is no probabilistic Turing machine T such that for every prefix program p and every reflective oracle O, we have that $\lambda_T^O(1 \mid p) > 1/2$ if p halts and $\lambda_T^O(1 \mid p) < 1/2$ otherwise.*

Proof. Assume there was such a machine T and let O be the limit computable oracle from Theorem 6. Since O is reflective we can turn T into a deterministic halting oracle by calling $O(T, p, 1/2)$ which deterministically returns 1 if p halts and 0 otherwise. Since O is limit computable, we can finitely compute the output of O on any query to arbitrary finite precision using our deterministic halting oracle. We construct a probabilistic Turing machine T' that uses our halting oracle to compute (rather than query) the oracle O on $(T', \epsilon, 1/2)$ to a precision of $1/3$ in finite time. If $O(T', \epsilon, 1/2) \pm 1/3 > 1/2$, the machine T' outputs 0, otherwise T' outputs 1. Since our halting oracle is entirely deterministic, the output of T' is entirely deterministic as well (and T' always halts), so $\lambda_{T'}^O(0 \mid \epsilon) = 1$ or $\lambda_{T'}^O(1 \mid \epsilon) = 1$. Therefore $O(T', \epsilon, 1/2) = 1$ or $O(T', \epsilon, 1/2) = 0$ because O is reflective. A precision of $1/3$ is enough to tell them apart, hence T' returns 0 if $O(T', \epsilon, 1/2) = 1$ and T' returns 1 if $O(T', \epsilon, 1/2) = 0$. This is a contradiction. □

A similar argument can also be used to show that reflective oracles are not computable.

2.4 PROOF OF THEOREM 6

The idea for the proof of Theorem 6 is to construct an algorithm that outputs an infinite series of *partial oracles* converging to a reflective oracle in the limit.

The set of queries is countable, so we can assume that we have some computable enumeration of it:

$$\mathcal{T} \times \{0,1\}^* \times \mathbb{Q} =: \{q_1, q_2, \ldots\}$$

Definition 8 (k-Partial Oracle)**.** A *k-partial oracle* $\tilde{O}$ is function from the first k queries to the multiples of 2^{-k} in $[0, 1]$:

$$\tilde{O} : \{q_1, q_2, \ldots, q_k\} \to \{n2^{-k} \mid 0 \leq n \leq 2^k\}$$

Definition 9 (Approximating an Oracle)**.** A k-partial oracle $\tilde{O}$ *approximates* an oracle O iff $|O(q_i) - \tilde{O}(q_i)| \leq 2^{-k-1}$ for all $i \leq k$.

Let $k \in \mathbb{N}$, let $\tilde{O}$ be a k-partial oracle, and let $T \in \mathcal{T}$ be an oracle machine. The machine $T^{\tilde{O}}$ that we get when we run T with the k-partial oracle $\tilde{O}$ is defined as follows (this is with slight abuse of notation since k is taken to be understood implicitly).

1. Run T for at most k steps.
2. If T calls the oracle on q_i for $i \leq k$,
   (a) return 1 with probability $\tilde{O}(q_i) - 2^{-k-1}$,
   (b) return 0 with probability $1 - \tilde{O}(q_i) - 2^{-k-1}$, and
   (c) halt otherwise.
3. If T calls the oracle on q_j for $j > k$, halt.

Furthermore, we define $\lambda_T^{\tilde{O}}$ analogously to λ_T^O as the distribution generated by the machine $T^{\tilde{O}}$.

Lemma 10. *If a k-partial oracle $\tilde{O}$ approximates a reflective oracle O, then $\lambda_T^O(1 \mid x) \geq \lambda_T^{\tilde{O}}(1 \mid x)$ and $\lambda_T^O(0 \mid x) \geq \lambda_T^{\tilde{O}}(0 \mid x)$ for all $x \in \{0,1\}^*$ and all $T \in \mathcal{T}$.*

Proof. This follows from the definition of $T^{\tilde{O}}$: when running T with $\tilde{O}$ instead of O, we can only lose probability mass. If T makes calls whose index is $> k$ or runs for more than k steps, then the execution is aborted and no further output is generated. If T makes calls whose index $i \leq k$, then $\tilde{O}(q_i) - 2^{-k-1} \leq O(q_i)$ since $\tilde{O}$ approximates O. Therefore the return of the call q_i is underestimated as well. □

Definition 11 (k-Partially Reflective)**.** A k-partial oracle $\tilde{O}$ is *k-partially reflective* iff for the first k queries (T, x, p)

- $\lambda_T^{\tilde{O}}(1 \mid x) > p$ implies $\tilde{O}(T, x, p) = 1$, and

- $\lambda_T^{\tilde{O}}(0 \mid x) > 1 - p$ implies $\tilde{O}(T, x, p) = 0$.

It is important to note that we can check whether a k-partial oracle is k-partially reflective in finite time by running all machines T from the first k queries for k steps and tallying up the probabilities to compute $\lambda_T^{\tilde{O}}$.

Lemma 12. *If O is a reflective oracle and $\tilde{O}$ is a k-partial oracle that approximates O, then $\tilde{O}$ is k-partially reflective.*

Lemma 12 only holds because we use semimeasures whose conditionals are lower semicomputable.

Proof. Assuming $\lambda_T^{\tilde{O}}(1 \mid x) > p$ we get from Lemma 10 that $\lambda_T^{O}(1 \mid x) \geq \lambda_T^{\tilde{O}}(1 \mid x) > p$. Thus $O(T, x, p) = 1$ because O is reflective. Since $\tilde{O}$ approximates O, we get $1 = O(T, x, p) \leq \tilde{O}(T, x, p) + 2^{-k-1}$, and since $\tilde{O}$ assigns values in a 2^{-k}-grid, it follows that $\tilde{O}(T, x, p) = 1$. The second implication is proved analogously. □

Definition 13 (Extending Partial Oracles)**.** A $k+1$-partial oracle $\tilde{O}'$ *extends* a k-partial oracle $\tilde{O}$ iff $|\tilde{O}(q_i) - \tilde{O}'(q_i)| \leq 2^{-k-1}$ for all $i \leq k$.

Lemma 14. *There is an infinite sequence of partial oracles $(\tilde{O}_k)_{k \in \mathbb{N}}$ such that for each k, $\tilde{O}_k$ is a k-partially reflective k-partial oracle and $\tilde{O}_{k+1}$ extends $\tilde{O}_k$.*

Proof. By Theorem 4 there is a reflective oracle O. For every k, there is a canonical k-partial oracle $\tilde{O}_k$ that approximates O: restrict O to the first k queries and for any such query q pick the value in the 2^{-k}-grid which is closest to $O(q)$. By construction, $\tilde{O}_{k+1}$ extends $\tilde{O}_k$ and by Lemma 12, each $\tilde{O}_k$ is k-partially reflective. □

Lemma 15. *If the $k+1$-partial oracle $\tilde{O}_{k+1}$ extends the k-partial oracle $\tilde{O}_k$, then $\lambda_T^{\tilde{O}_{k+1}}(1 \mid x) \geq \lambda_T^{\tilde{O}_k}(1 \mid x)$ and $\lambda_T^{\tilde{O}_{k+1}}(0 \mid x) \geq \lambda_T^{\tilde{O}_k}(0 \mid x)$ for all $x \in \{0,1\}^*$ and all $T \in \mathcal{T}$.*

Proof. $T^{\tilde{O}_{k+1}}$ runs for one more step than $T^{\tilde{O}_k}$, can answer one more query and has increased oracle precision. Moreover, since $\tilde{O}_{k+1}$ extends $\tilde{O}_k$, we have $|\tilde{O}_{k+1}(q_i) - \tilde{O}_k(q_i)| \leq 2^{-k-1}$, and thus $\tilde{O}_{k+1}(q_i) - 2^{-k-1} \geq \tilde{O}_k(q_i) - 2^{-k}$. Therefore the success to answers to the oracle calls (case 2(a) and 2(b)) will not decrease in probability. □

Now everything is in place to state the algorithm that constructs a reflective oracle in the limit. It recursively traverses a tree of partial oracles. The tree's nodes are the partial oracles; level k of the tree contains all k-partial oracles. There is an edge in the tree from the k-partial oracle $\tilde{O}_k$ to the i-partial oracle $\tilde{O}_i$ if and only if $i = k+1$ and $\tilde{O}_i$ extends $\tilde{O}_k$.

For every k, there are only finitely many k-partial oracles, since they are functions from finite sets to finite sets. In particular, there are exactly two 1-partial oracles (so the search tree has two roots). Pick one of them to start with, and proceed recursively as follows. Given a k-partial oracle $\tilde{O}_k$, there are finitely many $(k+1)$-partial oracles that extend $\tilde{O}_k$ (finite branching of the tree). Pick one that is $(k+1)$-partially reflective (which can be checked in finite time). If there is no $(k+1)$-partially reflective extension, backtrack.

By Lemma 14 our search tree is infinitely deep and thus the tree search does not terminate. Moreover, it can backtrack to each level only a finite number of times because at each level there is only a finite number of possible extensions. Therefore the algorithm will produce an infinite sequence of partial oracles, each extending the previous. Because of finite backtracking, the output eventually stabilizes on a sequence of partial oracles $\tilde{O}_1, \tilde{O}_2, \ldots$. By the following lemma, this sequence converges to a reflective oracle, which concludes the proof of Theorem 6.

Lemma 16. *Let $\tilde{O}_1, \tilde{O}_2, \ldots$ be a sequence where $\tilde{O}_k$ is a k-partially reflective k-partial oracle and $\tilde{O}_{k+1}$ extends $\tilde{O}_k$ for all $k \in \mathbb{N}$. Let $O := \lim_{k \to \infty} \tilde{O}_k$ be the pointwise limit. Then*

(a) $\lambda_T^{\tilde{O}_k}(1 \mid x) \to \lambda_T^{O}(1 \mid x)$ and $\lambda_T^{\tilde{O}_k}(0 \mid x) \to \lambda_T^{O}(0 \mid x)$ as $k \to \infty$ for all $x \in \{0,1\}^*$ and all $T \in \mathcal{T}$, and

(b) O is a reflective oracle.

Proof. First note that the pointwise limit must exists because $|\tilde{O}_k(q_i) - \tilde{O}_{k+1}(q_i)| \leq 2^{-k-1}$ by Definition 13.

(a) Since $\tilde{O}_{k+1}$ extends $\tilde{O}_k$, each $\tilde{O}_k$ approximates O. Let $x \in \{0,1\}^*$ and $T \in \mathcal{T}$ and consider the sequence $a_k := \lambda_T^{\tilde{O}_k}(1 \mid x)$ for $k \in \mathbb{N}$. By Lemma 15, $a_k \leq a_{k+1}$, so the sequence is monotone increasing. By Lemma 10, $a_k \leq \lambda_T^{O}(1 \mid x)$, so the sequence is bounded. Therefore it must converge. But it cannot converge to anything strictly below $\lambda_T^{O}(1 \mid x)$ by the definition of T^O.

(b) By definition, O is an oracle; it remains to show that O is reflective. Let $q_i = (T, x, p)$ be some query. If $p < \lambda_T^{O}(1 \mid x)$, then by (a) there is a k large enough such that $p < \lambda_T^{\tilde{O}_t}(1 \mid x)$ for all $t \geq k$. For any $t \geq \max\{k, i\}$, we have $\tilde{O}_t(T, x, p) = 1$ since $\tilde{O}_t$ is t-partially reflective. Therefore $1 = \lim_{k \to \infty} \tilde{O}_k(T, x, p) = O(T, x, p)$. The case $1 - p < \lambda_T^{O}(0 \mid x)$ is analogous. □

3 A GRAIN OF TRUTH

3.1 NOTATION

In reinforcement learning, an agent interacts with an environment in cycles: at time step t the agent chooses an *action* $a_t \in \mathcal{A}$ and receives a *percept* $e_t = (o_t, r_t) \in \mathcal{E}$

consisting of an *observation* $o_t \in \mathcal{O}$ and a real-valued *reward* $r_t \in \mathbb{R}$; the cycle then repeats for $t+1$. A *history* is an element of $(\mathcal{A} \times \mathcal{E})^*$. In this section, we use $æ \in \mathcal{A} \times \mathcal{E}$ to denote one interaction cycle, and $æ_{<t}$ to denote a history of length $t-1$.

We fix a *discount function* $\gamma : \mathbb{N} \to \mathbb{R}$ with $\gamma_t \geq 0$ and $\sum_{t=1}^{\infty} \gamma_t < \infty$. The goal in reinforcement learning is to maximize discounted rewards $\sum_{t=1}^{\infty} \gamma_t r_t$. The *discount normalization factor* is defined as $\Gamma_t := \sum_{k=t}^{\infty} \gamma_k$. The *effective horizon* $H_t(\varepsilon)$ is a horizon that is long enough to encompass all but an ε of the discount function's mass:

$$H_t(\varepsilon) := \min\{k \mid \Gamma_{t+k}/\Gamma_t \leq \varepsilon\} \tag{2}$$

A *policy* is a function $\pi : (\mathcal{A} \times \mathcal{E})^* \to \Delta\mathcal{A}$ that maps a history $æ_{<t}$ to a distribution over actions taken after seeing this history. The probability of taking action a after history $æ_{<t}$ is denoted with $\pi(a \mid æ_{<t})$. An *environment* is a function $\nu : (\mathcal{A} \times \mathcal{E})^* \times \mathcal{A} \to \Delta\mathcal{E}$ where $\nu(e \mid æ_{<t}a_t)$ denotes the probability of receiving the percept e when taking the action a_t after the history $æ_{<t}$. Together, a policy π and an environment ν give rise to a distribution ν^π over histories. Throughout this paper, we make the following assumptions.

Assumption 17. *(a) Rewards are bounded between* 0 *and* 1.

(b) The set of actions $\mathcal{A}$ and the set of percepts $\mathcal{E}$ are both finite.

(c) The discount function γ and the discount normalization factor Γ are computable.

Definition 18 (Value Function)**.** The *value* of a policy π in an environment ν given history $æ_{<t}$ is defined recursively as $V_\nu^\pi(æ_{<t}) := \sum_{a \in \mathcal{A}} \pi(a \mid æ_{<t}) V_\nu^\pi(æ_{<t}a)$ and

$$V_\nu^\pi(æ_{<t}a_t) := \frac{1}{\Gamma_t} \sum_{e_t \in \mathcal{E}} \nu(e_t \mid æ_{<t}a_t)\Big(\gamma_t r_t + \Gamma_{t+1} V_\nu^\pi(æ_{1:t})\Big)$$

if $\Gamma_t > 0$ and $V_\nu^\pi(æ_{<t}a_t) := 0$ if $\Gamma_t = 0$. The *optimal value* is defined as $V_\nu^*(æ_{<t}) := \sup_\pi V_\nu^\pi(æ_{<t})$.

Definition 19 (Optimal Policy)**.** A policy π is *optimal in environment ν (ν-optimal)* iff for all histories $æ_{<t} \in (\mathcal{A} \times \mathcal{E})^*$ the policy π attains the optimal value: $V_\nu^\pi(æ_{<t}) = V_\nu^*(æ_{<t})$.

We assumed that the discount function is summable, rewards are bounded (Assumption 17a), and actions and percepts spaces are both finite (Assumption 17b). Therefore an optimal deterministic policy exists for every environment [LH14, Thm. 10].

3.2 REFLECTIVE BAYESIAN AGENTS

Fix O to be a reflective oracle. From now on, we assume that the action space $\mathcal{A} := \{\alpha, \beta\}$ is binary. We can treat computable measures over binary strings as environments: the environment ν corresponding to a probabilistic Turing machine $T \in \mathcal{T}$ is defined by

$$\nu(e_t \mid æ_{<t}a_t) := \overline{\lambda}_T^O(y \mid x) = \prod_{i=1}^{k} \overline{\lambda}_T^O(y_i \mid xy_1 \ldots y_{i-1})$$

where $y_{1:k}$ is a binary encoding of e_t and x is a binary encoding of $æ_{<t}a_t$. The actions $a_{1:\infty}$ are only *contextual*, and not part of the environment distribution. We define

$$\nu(e_{<t} \mid a_{<t}) := \prod_{k=1}^{t-1} \nu(e_k \mid æ_{<k}).$$

Let $T_1, T_2, \ldots$ be an enumeration of all probabilistic Turing machines in $\mathcal{T}$. We define the *class of reflective environments*

$$\mathcal{M}_{\text{refl}}^O := \left\{\overline{\lambda}_{T_1}^O, \overline{\lambda}_{T_2}^O, \ldots\right\}.$$

This is the class of all environments computable on a probabilistic Turing machine with reflective oracle O, that have been completed from semimeasures to measures using O.

Analogously to AIXI [Hut05], we define a Bayesian mixture over the class $\mathcal{M}_{\text{refl}}^O$. Let $w \in \Delta\mathcal{M}_{\text{refl}}^O$ be a lower semicomputable prior probability distribution on $\mathcal{M}_{\text{refl}}^O$. Possible choices for the prior include the *Solomonoff prior* $w(\overline{\lambda}_T^O) := 2^{-K(T)}$, where $K(T)$ denotes the length of the shortest input to some universal Turing machine that encodes T [Sol78].[2] We define the corresponding Bayesian mixture

$$\xi(e_t \mid æ_{<t}a_t) := \sum_{\nu \in \mathcal{M}_{\text{refl}}^O} w(\nu \mid æ_{<t}) \nu(e_t \mid æ_{<t}a_t) \tag{3}$$

where $w(\nu \mid æ_{<t})$ is the (renomalized) posterior,

$$w(\nu \mid æ_{<t}) := w(\nu) \frac{\nu(e_{<t} \mid a_{<t})}{\overline{\xi}(e_{<t} \mid a_{<t})}. \tag{4}$$

The mixture ξ is lower semicomputable on an oracle Turing machine because the posterior $w(\cdot \mid æ_{<t})$ is lower semicomputable. Hence there is an oracle machine T such that $\xi = \lambda_T^O$. We define its completion $\overline{\xi} := \overline{\lambda}_T^O$ as the completion of λ_T^O. This is the distribution that is used to compute the posterior. There are no cyclic dependencies since $\overline{\xi}$ is called on the shorter history $æ_{<t}$. We arrive at the following statement.

Proposition 20 (Bayes is in the Class)**.** $\overline{\xi} \in \mathcal{M}_{\text{refl}}^O$.

Moreover, since O is reflective, we have that $\overline{\xi}$ dominates all environments $\nu \in \mathcal{M}_{\text{refl}}^O$:

$$\overline{\xi}(e_{1:t} \mid a_{1:t})$$

[2] Technically, the lower semicomputable prior $2^{-K(T)}$ is only a semidistribution because it does not sum to 1. This turns out to be unimportant.

$$
\begin{aligned}
&= \overline{\xi}(e_t \mid \text{æ}_{<t}a_t)\overline{\xi}(e_{<t} \mid a_{<t}) \\
&\geq \xi(e_t \mid \text{æ}_{<t}a_t)\overline{\xi}(e_{<t} \mid a_{<t}) \\
&= \overline{\xi}(e_{<t} \mid a_{<t}) \sum_{\nu \in \mathcal{M}^O_{\text{refl}}} w(\nu \mid \text{æ}_{<t})\nu(e_t \mid \text{æ}_{<t}a_t) \\
&= \overline{\xi}(e_{<t} \mid a_{<t}) \sum_{\nu \in \mathcal{M}^O_{\text{refl}}} w(\nu)\frac{\nu(e_{<t} \mid a_{<t})}{\overline{\xi}(e_{<t} \mid a_{<t})}\nu(e_t \mid \text{æ}_{<t}a_t) \\
&= \sum_{\nu \in \mathcal{M}^O_{\text{refl}}} w(\nu)\nu(e_{1:t} \mid a_{1:t}) \\
&\geq w(\nu)\nu(e_{1:t} \mid a_{1:t})
\end{aligned}
$$

This property is crucial for on-policy value convergence.

Lemma 21 (On-Policy Value Convergence [Hut05, Thm. 5.36])**.** *For any policy π and any environment $\mu \in \mathcal{M}^O_{\text{refl}}$ with $w(\mu) > 0$,*

$$V^\pi_\mu(\text{æ}_{<t}) - V^\pi_{\overline{\xi}}(\text{æ}_{<t}) \to 0 \ \mu^\pi\text{-almost surely as } t \to \infty.$$

3.3 REFLECTIVE-ORACLE-COMPUTABLE POLICIES

This subsection is dedicated to the following result that was previously stated but not proved in [FST15, Alg. 6]. It contrasts results on arbitrary semicomputable environments where optimal policies are not limit computable [LH15b, Sec. 4].

Theorem 22 (Optimal Policies are Oracle Computable)**.** *For every $\nu \in \mathcal{M}^O_{\text{refl}}$, there is a ν-optimal (stochastic) policy π^*_ν that is reflective-oracle-computable.*

Note that even though deterministic optimal policies always exist, those policies are typically not reflective-oracle-computable.

To prove Theorem 22 we need the following lemma.

Lemma 23 (Reflective-Oracle-Computable Optimal Value Function)**.** *For every environment $\nu \in \mathcal{M}^O_{\text{refl}}$ the optimal value function V^*_ν is reflective-oracle-computable.*

Proof. This proof follows the proof of [LH15b, Cor. 13]. We write the optimal value explicitly as

$$V^*_\nu(\text{æ}_{<t}) = \frac{1}{\Gamma_t} \lim_{m\to\infty} \sum_{\text{æ}_{t:m}} \max \sum_{k=t}^{m} \gamma_k r_k \prod_{i=t}^{k} \nu(e_i \mid \text{æ}_{<i}), \tag{5}$$

where $\sum\max$ denotes the expectimax operator:

$$\sum_{\text{æ}_{t:m}} \max := \max_{a_t \in \mathcal{A}} \sum_{e_t \in \mathcal{E}} \dots \max_{a_m \in \mathcal{A}} \sum_{e_m \in \mathcal{E}}$$

For a fixed m, all involved quantities are reflective-oracle-computable. Moreover, this quantity is monotone increasing in m and the tail sum from $m+1$ to ∞ is bounded by Γ_{m+1} which is computable according to Assumption 17c and converges to 0 as $m \to \infty$. Therefore we can enumerate all rationals above and below V^*_ν. □

Proof of Theorem 22. According to Lemma 23 the optimal value function V^*_ν is reflective-oracle-computable. Hence there is a probabilistic Turing machine T such that

$$\lambda^O_T(1 \mid \text{æ}_{<t}) = \big(V^*_\nu(\text{æ}_{<t}\alpha) - V^*_\nu(\text{æ}_{<t}\beta) + 1\big)/2.$$

We define a policy π that takes action α if $O(T, \text{æ}_{<t}, 1/2) = 1$ and action β if $O(T, \text{æ}_{<t}, 1/2) = 0$. (This policy is stochastic because the answer of the oracle O is stochastic.)

It remains to show that π is a ν-optimal policy. If $V^*_\nu(\text{æ}_{<t}\alpha) > V^*_\nu(\text{æ}_{<t}\beta)$, then $\lambda^O_T(1 \mid \text{æ}_{<t}) > 1/2$, thus $O(T, \text{æ}_{<t}, 1/2) = 1$ since O is reflective, and hence π takes action α. Conversely, if $V^*_\nu(\text{æ}_{<t}\alpha) < V^*_\nu(\text{æ}_{<t}\beta)$, then $\lambda^O_T(1 \mid \text{æ}_{<t}) < 1/2$, thus $O(T, \text{æ}_{<t}, 1/2) = 0$ since O is reflective, and hence π takes action β. Lastly, if $V^*_\nu(\text{æ}_{<t}\alpha) = V^*_\nu(\text{æ}_{<t}\beta)$, then both actions are optimal and thus it does not matter which action is returned by policy π. (This is the case where the oracle may randomize.) □

3.4 SOLUTION TO THE GRAIN OF TRUTH PROBLEM

Together, Proposition 20 and Theorem 22 provide the necessary ingredients to solve the grain of truth problem.

Corollary 24 (Solution to the Grain of Truth Problem)**.** *For every lower semicomputable prior $w \in \Delta\mathcal{M}^O_{\text{refl}}$ the Bayes-optimal policy $\pi^*_{\overline{\xi}}$ is reflective-oracle-computable where ξ is the Bayes-mixture corresponding to w defined in* (3)*.*

Proof. From Proposition 20 and Theorem 22. □

Hence the environment class $\mathcal{M}^O_{\text{refl}}$ contains any reflective-oracle-computable modification of the Bayes-optimal policy $\pi^*_{\overline{\xi}}$. In particular, this includes computable multi-agent environments that contain other Bayesian agents over the class $\mathcal{M}^O_{\text{refl}}$. So any Bayesian agent over the class $\mathcal{M}^O_{\text{refl}}$ has a grain of truth even though the environment may contain other Bayesian agents *of equal power*. We proceed to sketch the implications for multi-agent environments in the next section.

4 MULTI-AGENT ENVIRONMENTS

This section summarizes our results for multi-agent systems. The proofs can be found in [Lei16].

4.1 SETUP

In a *multi-agent environment* there are n agents each taking sequential actions from the finite action space $\mathcal{A}$. In each time step $t = 1, 2, \dots$, the environment receives action a^i_t from agent i and outputs n percepts $e^1_t, \dots, e^n_t \in \mathcal{E}$, one for

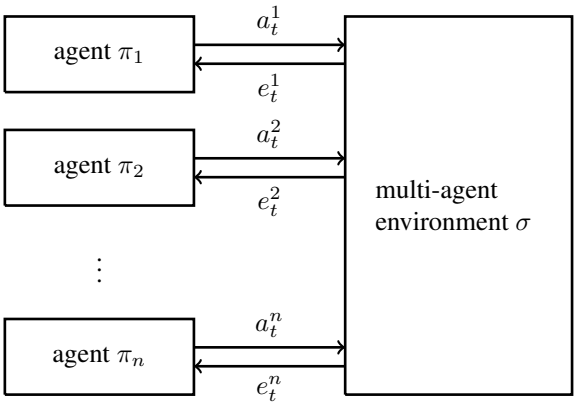

Figure 2: Agents $\pi_1, \ldots, \pi_n$ interacting in a multi-agent environment.

each agent. Each percept $e_t^i = (o_t^i, r_t^i)$ contains an observation o_t^i and a reward $r_t^i \in [0, 1]$. Importantly, agent i only sees its own action a_t^i and its own percept e_t^i (see Figure 2). We use the shorthand notation $a_t := (a_t^1, \ldots, a_t^n)$ and $e_t := (e_t^1, \ldots, e_t^n)$ and denote $\text{æ}_{<t}^i = a_1^i e_1^i \ldots a_{t-1}^i e_{t-1}^i$ and $\text{æ}_{<t} = a_1 e_1 \ldots a_{t-1} e_{t-1}$.

We define a multi-agent environment as a function

$$\sigma : (\mathcal{A}^n \times \mathcal{E}^n)^* \times \mathcal{A}^n \to \Delta(\mathcal{E}^n).$$

The agents are given by n policies $\pi_1, \ldots, \pi_n$ where $\pi_i : (\mathcal{A} \times \mathcal{E})^* \to \Delta\mathcal{A}$. Together they specify the *history distribution*

$$\begin{aligned} \sigma^{\pi_{1:n}}(\epsilon) &:= 1 \\ \sigma^{\pi_{1:n}}(\text{æ}_{1:t}) &:= \sigma^{\pi_{1:n}}(\text{æ}_{<t} a_t) \sigma(e_t \mid \text{æ}_{<t} a_t) \\ \sigma^{\pi_{1:n}}(\text{æ}_{<t} a_t) &:= \sigma^{\pi_{1:n}}(\text{æ}_{<t}) \prod_{i=1}^{n} \pi_i(a_t^i \mid \text{æ}_{<t}^i). \end{aligned}$$

Each agent i acts in a *subjective environment* σ_i given by joining the multi-agent environment σ with the policies $\pi_1, \ldots, \pi_{i-1}, \pi_{i+1}, \ldots, \pi_n$ by marginalizing over the histories that π_i does not see. Together with policy π_i, the environment σ_i yields a distribution over the histories of agent i

$$\sigma_i^{\pi_i}(\text{æ}_{<t}^i) := \sum_{\text{æ}_{<t}^j, j \neq i} \sigma^{\pi_{1:n}}(\text{æ}_{<t}).$$

We get the definition of the subjective environment σ_i with the identity $\sigma_i(e_t^i \mid \text{æ}_{<t}^i a_t^i) := \sigma_i^{\pi_i}(e_t^i \mid \text{æ}_{<t}^i a_t^i)$. It is crucial to note that the subjective environment σ_i and the policy π_i are ordinary environments and policies, so we can use the formalism from Section 3.

Our definition of a multi-agent environment is very general and encompasses most of game theory. It allows for cooperative, competitive, and mixed games; infinitely repeated games or any (infinite-length) extensive form games with finitely many players.

The policy π_i is an *ε-best response* after history $\text{æ}_{<t}^i$ iff

$$V_{\sigma_i}^*(\text{æ}_{<t}^i) - V_{\sigma_i}^{\pi_i}(\text{æ}_{<t}^i) < \varepsilon.$$

If at some time step t, all agents' policies are ε-best responses, we have an *ε-Nash equilibrium*. The property of multi-agent systems that is analogous to asymptotic optimality is convergence to an ε-Nash equilibrium.

4.2 INFORMED REFLECTIVE AGENTS

Let σ be a multi-agent environment and let $\pi_{\sigma_1}^*, \ldots \pi_{\sigma_n}^*$ be such that for each i the policy $\pi_{\sigma_i}^*$ is an optimal policy in agent i's subjective environment σ_i. At first glance this seems ill-defined: The subjective environment σ_i depends on each other policy $\pi_{\sigma_j}^*$ for $j \neq i$, which depends on the subjective environment σ_j, which in turn depends on the policy $\pi_{\sigma_i}^*$. However, this circular definition actually has a well-defined solution.

Theorem 25 (Optimal Multi-Agent Policies)**.** *For any reflective-oracle-computable multi-agent environment σ, the optimal policies $\pi_{\sigma_1}^*, \ldots, \pi_{\sigma_n}^*$ exist and are reflective-oracle-computable.*

Note the strength of Theorem 25: each of the policies $\pi_{\sigma_i}^*$ is acting optimally *given the knowledge of everyone else's policies*. Hence optimal policies play 0-best responses by definition, so if every agent is playing an optimal policy, we have a Nash equilibrium. Moreover, this Nash equilibrium is also a *subgame perfect* Nash equilibrium, because each agent also acts optimally on the counterfactual histories that do not end up being played. In other words, Theorem 25 states the existence and reflective-oracle-computability of a subgame perfect Nash equilibrium in any reflective-oracle-computable multi-agent environment. From Theorem 6 we then get that these subgame perfect Nash equilibria are limit computable.

Corollary 26 (Solution to Computable Multi-Agent Environments)**.** *For any computable multi-agent environment σ, the optimal policies $\pi_{\sigma_1}^*, \ldots, \pi_{\sigma_n}^*$ exist and are limit computable.*

4.3 LEARNING REFLECTIVE AGENTS

Since our class $\mathcal{M}_{\text{refl}}^O$ solves the grain of truth problem, the result by Kalai and Lehrer [KL93] immediately implies that for any Bayesian agents $\pi_1, \ldots, \pi_n$ interacting in an infinitely repeated game and for all $\varepsilon > 0$ and all $i \in \{1, \ldots, n\}$ there is almost surely a $t_0 \in \mathbb{N}$ such that for all $t \geq t_0$ the policy π_i is an ε-best response. However, this hinges on the important fact that every agent has to know the game and also that all other agents are Bayesian agents. Otherwise the convergence to an ε-Nash equilibrium may fail, as illustrated by the following example.

At the core of the following construction is a *dogmatic prior* [LH15a, Sec. 3.2]. A dogmatic prior assigns very

high probability to going to hell (reward 0 forever) if the agent deviates from a given computable policy π. For a Bayesian agent it is thus only worth deviating from the policy π if the agent thinks that the prospects of following π are very poor already. This implies that for general multi-agent environments and without additional assumptions on the prior, we cannot prove any meaningful convergence result about Bayesian agents acting in an unknown multi-agent environment.

Example 27 (Reflective Bayesians Playing Matching Pennies)**.** In the game of *matching pennies* there are two agents ($n = 2$), and two actions $\mathcal{A} = \{\alpha, \beta\}$ representing the two sides of a penny. In each time step agent 1 wins if the two actions are identical and agent 2 wins if the two actions are different. The payoff matrix is as follows.

	α	β
α	1,0	0,1
β	0,1	1,0

We use $\mathcal{E} = \{0, 1\}$ to be the set of rewards (observations are vacuous) and define the multi-agent environment σ to give reward 1 to agent 1 iff $a_t^1 = a_t^2$ (0 otherwise) and reward 1 to agent 2 iff $a_t^1 \neq a_t^2$ (0 otherwise). Note that neither agent knows a priori that they are playing matching pennies, nor that they are playing an infinite repeated game with one other player.

Let π_1 be the policy that takes the action sequence $(\alpha\alpha\beta)^\infty$ and let $\pi_2 := \pi_\alpha$ be the policy that always takes action α. The average reward of policy π_1 is $2/3$ and the average reward of policy π_2 is $1/3$. Let ξ be a universal mixture (3). By Lemma 21, $V_\xi^{\pi_1} \to c_1 \approx 2/3$ and $V_\xi^{\pi_2} \to c_2 \approx 1/3$ almost surely when following policies (π_1, π_2). Therefore there is an $\varepsilon > 0$ such that $V_\xi^{\pi_1} > \varepsilon$ and $V_\xi^{\pi_2} > \varepsilon$ for all time steps. Now we can apply [LH15a, Thm. 7] to conclude that there are (dogmatic) mixtures ξ_1' and ξ_2' such that $\pi^*_{\xi_1'}$ always follows policy π_1 and $\pi^*_{\xi_2'}$ always follows policy π_2. This does not converge to a (ε-)Nash equilibrium. $\lozenge$

A policy π is *asymptotically optimal in mean in an environment class* $\mathcal{M}$ iff for all $\mu \in \mathcal{M}$

$$\mathbb{E}_\mu^\pi\big[V_\mu^*(æ_{<t}) - V_\mu^\pi(æ_{<t})\big] \to 0 \text{ as } t \to \infty \qquad (6)$$

where $\mathbb{E}_\mu^\pi$ denotes the expectation with respect to the probability distribution μ^π over histories generated by policy π acting in environment μ.

Asymptotic optimality stands out because it is currently the only known nontrivial objective notion of optimality in general reinforcement learning [LH15a].

The following theorem is the main convergence result. It states that for asymptotically optimal agents we get convergence to ε-Nash equilibria in any reflective-oracle-computable multi-agent environment.

Theorem 28 (Convergence to Equilibrium)**.** *Let σ be an reflective-oracle-computable multi-agent environment and let $\pi_1, \ldots, \pi_n$ be reflective-oracle-computable policies that are asymptotically optimal in mean in the class $\mathcal{M}^O_{\text{refl}}$. Then for all $\varepsilon > 0$ and all $i \in \{1, \ldots, n\}$ the $\sigma^{\pi_{1:n}}$-probability that the policy π_i is an ε-best response converges to 1 as $t \to \infty$.*

In contrast to Theorem 25 which yields policies that play a subgame perfect equilibrium, this is not the case for Theorem 28: the agents typically do not learn to predict off-policy and thus will generally not play ε-best responses in the counterfactual histories that they never see. This weaker form of equilibrium is unavoidable if the agents do not know the environment because it is impossible to learn the parts that they do not interact with.

Together with Theorem 6 and the asymptotic optimality of the Thompson sampling policy [LLOH16, Thm. 4] that is reflective-oracle computable we get the following corollary.

Corollary 29 (Convergence to Equilibrium)**.** *There are limit computable policies $\pi_1, \ldots, \pi_n$ such that for any computable multi-agent environment σ and for all $\varepsilon > 0$ and all $i \in \{1, \ldots, n\}$ the $\sigma^{\pi_{1:n}}$-probability that the policy π_i is an ε-best response converges to 1 as $t \to \infty$.*

5 DISCUSSION

This paper introduced the class of all reflective-oracle-computable environments $\mathcal{M}^O_{\text{refl}}$. This class solves the grain of truth problem because it contains (any computable modification of) Bayesian agents defined over $\mathcal{M}^O_{\text{refl}}$: the optimal agents and Bayes-optimal agents over the class are all reflective-oracle-computable (Theorem 22 and Corollary 24).

If the environment is unknown, then a Bayesian agent may end up playing suboptimally (Example 27). However, if each agent uses a policy that is asymptotically optimal in mean (such as the Thompson sampling policy [LLOH16]) then for every $\varepsilon > 0$ the agents converge to an ε-Nash equilibrium (Theorem 28 and Corollary 29).

Our solution to the grain of truth problem is purely theoretical. However, Theorem 6 shows that our class $\mathcal{M}^O_{\text{refl}}$ allows for computable approximations. This suggests that practical approaches can be derived from this result, and reflective oracles have already seen applications in one-shot games [FTC15b].

Abstract

In this paper, we bridge the gap between hyperparameter optimization and ensemble learning by performing Bayesian optimization of an ensemble with regards to its hyperparameters. Our method consists in building a fixed-size ensemble, optimizing the configuration of one classifier of the ensemble at each iteration of the hyperparameter optimization algorithm, taking into consideration the interaction with the other models when evaluating potential performances. We also consider the case where the ensemble is to be reconstructed at the end of the hyperparameter optimization phase, through a greedy selection over the pool of models generated during the optimization. We study the performance of our proposed method on three different hyperparameter spaces, showing that our approach is better than both the best single model and a greedy ensemble construction over the models produced by a standard Bayesian optimization.

1 INTRODUCTION

For a long time, the tuning of hyperparameters for learning algorithms was solved by simple exhaustive methods such as grid search guided by cross-validation error. Grid search does work in practice, but it suffers from serious drawbacks such as a search space complexity that grows exponentially with the number of hyperparameters tuned. Recently, other strategies such as sequential model-based parameter optimization (Hutter et al., 2011), random search (Bergstra and Bengio, 2012), and Bayesian optimization (Snoek et al., 2012) have been shown to be better alternatives to grid search for non-trivial search spaces.

While hyperparameter optimization focuses on the performance of a single model, it is generally accepted that ensembles can perform better than single classifiers, one of many striking examples being the winning entry of the Netflix challenge (Bell and Koren, 2007). More recent machine learning competitions such as Kaggle competitions are also often won by ensemble methods (Sun and Pfahringer, 2011). Given these previous results, it is logical to combine Bayesian hyperparameter optimization techniques with ensemble methods to further push generalization accuracy. Feurer et al. (2015a) performed post-hoc ensemble generation by reusing the product of a completed hyperparameter optimization, winning phase 1 of the ChaLearn AutoML challenge (Guyon et al., 2015). Lastly, Snoek et al. (2015) also constructed post-hoc ensembles of neural networks for image captioning.

These two lines of previous work make for a compelling argument to directly apply Bayesian optimization of hyperparameters for ensemble learning. Rather than trying to model the whole space of ensembles, which is likely hard and inefficient to optimize, we pose a performance model of the ensemble at hand when adding a new classifier with some given hyperparameters. This is achieved by reusing models previously assessed during the optimization, evaluating performance change induced by adding them one at a time to the ensemble. This allows us to compute observations of the true ensemble loss with regards to the hyperparameter values. These observations are used to condition a Bayesian optimization prior, creating mean and variance estimates over the hyperparameter space which will be used to optimize the configuration of a new classifier to add to the ensemble. Finally, we consider different possibilities to maintain and build the ensemble as the optimization progresses, and settle on a round-robin optimization of the classifiers in the ensemble. This ensemble optimization procedure comes at a very small additional cost compared with a regular Bayesian optimization of hyperparameter yet yields better generalization accuracy for the same number of trained models.

We evaluate our proposed approach on a benchmark of medium datasets for two different hyperparameter spaces, one consisting solely of SVM algorithms with different ker-

[*]julien-charles.levesque.1@ulaval.ca

nel types, and one larger space with various families of learning algorithms. In both search spaces, our approach is shown to outperform regular Bayesian optimization as well as post-hoc ensemble generation from pools of classifiers obtained by classical Bayesian optimization of hyperparameters. We also evaluate our approach on a search space of convolutional neural networks trained on the CIFAR-10 dataset. The proposed approach is also able to provide better performance in this case.

The paper is structured as follows: Section 2 presents the problem of Bayesian hyperparameter optimization and highlights some related work. Section 3 presents the main contributions of this paper, which can be summarized as a methodology for Bayesian optimization of ensembles through hyperparameter tuning. Finally, Section 4 presents the experiments and an analysis of the results.

2 HYPERPARAMETER OPTIMIZATION

The behavior of a learning algorithm A is often tunable with regards to a set of external parameters, called hyperparameters $\gamma = \{\gamma_1, \gamma_2, \dots\} \in \Gamma$, which are not learned during training. The hyperparameter selection problem is one stage of a bi-level optimization problem, where the first objective is the tuning of the model's parameters θ and the second objective is the performance with regards to the hyperparameters γ.

The procedure requires two datasets, one for training and one for hyperparameter optimization (also called validation), namely $\mathcal{X}_T$ and $\mathcal{X}_V$, each assumed to be sampled *i.i.d.* from an underlying distribution $\mathcal{D}$. The objective function to minimize for hyperparameter optimization takes the form of the empirical generalization error on $\mathcal{X}_V$:

$$f(\gamma) = L(h_\gamma | \mathcal{X}_V) + \epsilon \tag{1}$$

$$L(h_\gamma | \mathcal{X}_V) = \frac{1}{|\mathcal{X}_V|} \sum_{i=1}^{|\mathcal{X}_V|} l_{0-1}(h_\gamma(x_i), y_i), \tag{2}$$

where ϵ is some noise on the observation of the generalization error, l_{0-1} is the zero-one loss function, and the model h_γ is obtained by running the training algorithm with hyperparameters γ, $h_\gamma = A(\mathcal{X}_T, \gamma)$. Other loss functions could be applied, but unless otherwise specified, the loss function will be the zero-one loss.

In order to solve this problem, Bayesian optimization consists in posing a probabilistic regression model of the generalization error of trained models with respect to their hyperparameters γ, and exploiting this model to select new hyperparameters to explore. At each iteration, a model of $f(\gamma)$ is conditioned on the set of previously observed hyperparameter values and associated losses $\{\gamma_i, L(h_{\gamma_i} | \mathcal{X}_V)\}_{i=1}^t$. Selection of the next hyperparameters to evaluate is performed by maximizing an *acquisition function* $a(\gamma | f(\gamma))$, a criterion balancing exploration and exploitation given mean and variance estimates obtained from the model of $f(\gamma)$. Among the model families for $f(\gamma)$, two interesting choices are Gaussian Processes (Rasmussen and Williams, 2006; Snoek et al., 2012) and Random Forests (Hutter et al., 2011), both providing information about the mean and variance of the fitted distribution over the whole search space.

A typical hyperparameter optimization is executed iteratively, subsequently generating a model of $f(\gamma)$ from observations, selecting hyperparameter tuples γ to evaluate, training a classifier h_γ with the given training data, evaluating it on the validation data, and looping until the maximum number of iterations or time budget is spent.

Recent advances in hyperparameter optimization have primarily focused on making optimization faster, more accurate and applicable to a wider set of applications. In order to speed up convergence, Feurer et al. (2015b) have shown that hyperparameter optimization can be warm started with meta features about datasets. Touching on both speed and optimality, the design of better acquisition functions has seen a lot of interest, and predictive entropy search was shown to be less greedy than expected improvement in locating the optima of objective functions (Hernández-Lobato et al., 2014). New applications have also emerged, one notable example being the optimization of hyperparameters for anytime algorithms with freeze-and-thaw Bayesian optimization (Swersky et al., 2014).

2.1 HYPERPARAMETER OPTIMIZATION AND ENSEMBLES

The idea of generating ensembles with hyperparameter optimization has already received some attention. Bergstra and Cox (2013) applied hyperparameter optimization in a multi-stage approach akin to boosting in order to generate better representations of images. Lacoste et al. (2014b) proposed the Sequential Model-based Ensemble Optimization (SMBEO) method to optimize ensembles based on bootstrapping the validation datasets to simulate multiple independent hyperparameter optimization processes and combined the results with the agnostic Bayesian combination method.

The process of hyperparameter optimization generates many trained models, and is usually concluded by selecting a model according to the hold-out (or cross-validation) generalization error $\gamma^* = \arg\min_\gamma L(h_\gamma | \mathcal{X}_V)$. This single model selection at the end of the optimization is the equivalent of a point estimate, and it can result in overfitting. One strategy to limit this overfitting in the selection of a final model is to select multiple models instead of one, reducing the risk of overfitting and thus increasing the generalization performance.

A simple strategy to build an ensemble from a hyperparameter optimization is to keep the trained models as they are generated for evaluation instead of discarding them (Feurer et al., 2015a). This effectively generates a *pool* of classifiers to combine at the end of the optimization, a process which is called **post-hoc ensemble generation**. Forward greedy selection has been shown to perform well in the context of pruning a pool of classifiers (Caruana et al., 2004). At each iteration, given a pool of trained classifiers H to select from, a new classifier is added to the ensemble, selected according to the minimum ensemble generalization error. At the first iteration, the classifier added is simply the single best classifier. At step t, given the ensemble $E = \{h_{e_1}, h_{e_2}, \ldots, h_{e_{t-1}}\}$, the next classifier is chosen to minimize the empirical error on the validation dataset when added to E:

$$h_t = \arg\min_{h \in H} L(E \cup \{h\}|\mathcal{X}_V) \tag{3}$$

$$L(E \cup \{h\}|\mathcal{X}_V) = \sum_{i=0}^{|\mathcal{X}_V|} l_{0-1}\left(g(x_i, E \cup \{h\}), y_i\right), \tag{4}$$

where $g(x_i, E)$ is a function combining the predictions of the classifiers in E on sample x_i. In this case, the combination rule is majority voting, as it is less prone to overfitting (Caruana et al., 2004; Feurer et al., 2015a). Other possible combination rules include weighted voting, stacking (Kuncheva, 2004) and agnostic Bayesian combination (Lacoste et al., 2014a), to name only a few. Such an approach can be shown to perform better than the single best classifier produced by the hyperparameter optimization, due in part to a reduction of the classifiers' variance through combination.

3 ENSEMBLE OPTIMIZATION

In this work, we aim at directly optimizing an ensemble of classifiers through Bayesian hyperparameter optimization. The strategies discussed in the previous section mostly aimed at reusing the product of a completed hyperparameter optimization after the fact. The goal is to make an online selection of hyperparameters that could be more interesting for an ensemble, but which do not necessarily maximize the objective function of Equation 1 on their own. Directly posing a model on the space of all possible ensembles of a given size $f(E) = f(\gamma_1, \ldots, \gamma_m)$ would result in a very hard and inefficient optimization problem, effectively duplicating the training of many models.

In order to palliate this, we propose a more focused approach. We define the objective function to be the performance of a given ensemble E when it is augmented with a new classifier trained with hyperparameters γ, or h_γ. In other words, the objective function is the empirical error provided by adding a model h_γ to the ensemble E:

$$f(\gamma|E) = L(E \cup A(\gamma, \mathcal{X}_T)|\mathcal{X}_V), \tag{5}$$

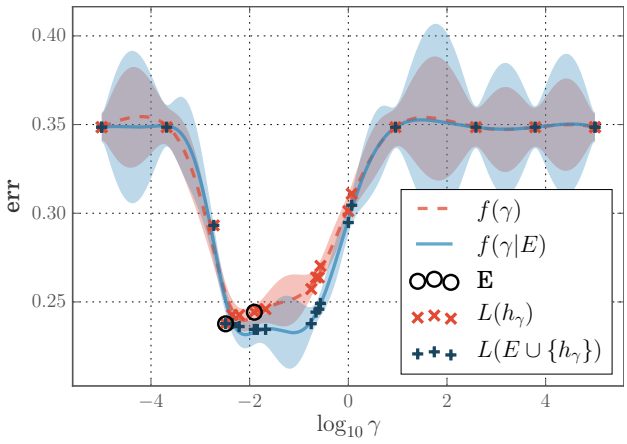

Figure 1: Example of an ensemble optimization. The red marks represent trained models and their standalone generalization error, and black circles represent two models selected for the current ensemble E. Blue marks represent the performance of an ensemble when we add the trained model with corresponding hyperparameters γ.

again using the empirical loss on a hold-out validation set $\mathcal{X}_V$. Contrarily to the post-hoc ensemble generation, a probabilistic model is fit on the performance that a model trained with given hyperparameters would provide to the ensemble. In order to do this, two things are required: 1) an already established ensemble, and 2) a pool of trained classifiers available to compute *observations* of Equation 5 to condition our model on. Given the history of trained models so far $H = \{h_1, \ldots, h_t\}$ and an ensemble defined by a selection of classifiers within the history $E = \{h_{e_1}, \ldots, h_{e_m}\}$, the observations used to model $f(\gamma)$ are obtained by reusing the trained classifiers in H, keeping E constant. Consequently, the objective function models the true ensemble error. Given a zero-one loss function and an empty ensemble $E = \varnothing$, Equation 5 falls back to a classical hyperparameter optimization problem, and the objective function will be minimized by the best hyperparameters for a single model γ^*.

The power of the suggested framework is illustrated with an example shown in Figure 1. This figure presents one iteration of ensemble optimization given 20 trained SVMs in a one-dimensional hyperparameter space, where the single hyperparameter is the width of the RBF kernel ($\sigma \in [10^{-5}, 10^{5}]$). The dataset used is the Pima Indian Diabetes dataset available from UCI (Frank and Asuncion, 2010), with separate training and validation splits. The current ensemble E consists of two models selected by forward greedy selection shown by black circles. Ensemble evaluation and member selection strategies will be discussed further; for now let us assume a fixed ensemble. The red Xs represent the generalization error of single models and the red curve represents a Gaussian Process prior conditioned on those observations, in other words, a model of

$f(\gamma)$. The blue crosses represent the generalization error of the ensemble E when the corresponding classifiers are added to it, and the blue curve is again a Gaussian Process prior conditioned on the ensemble observations, or, more generally speaking, a model of $f(\gamma|E)$. For both Gaussian Processes, the variance estimates are represented by shaded areas. The next step would be to apply an acquisition function with the ensemble mean and variance estimates to select the next hyperparameters to evaluate.

Figure 1 shows that the objective function of an ensemble and a single classifier can be different. It can also be observed in this case that the generalization error of the ensemble is lower than that of a single model, hence the interest in optimizing ensembles directly.

3.1 ALTERNATE FORMULATIONS

In order to be able to generalize over the space of hyperparameters, it is crucial to have an ensemble which does not contain all the classifiers in H, because if it did there would be no information added in the computation of Equation 5. A different problem formulation could be derived which compares classifiers with the whole pool of trained models, which would take the form $f(\gamma|H) = q(h_\gamma|H, \mathcal{X}_V)$, where $q(\cdot)$ is a metric of performance for a classifier with regards to the pool. For example, a diversity inducing metric such as pairwise disagreement (Kuncheva, 2004) could be used, but this would lead to degenerate pools of classifiers, as diversity is easily increased by trivial and degenerate classifiers (voting all for one class or the other).

Multi-objective optimization approaches have been considered for the maximization of both diversity and accuracy, a problem typically solved with genetic algorithms (Tsymbal et al., 2005). However, this problem formulation does not guarantee a better performing ensemble – only a more diverse pool of classifiers – with the hope that it will lead to better generalization performance. Directly optimizing diversity in classifier ensembles is questionable, and the evidence thus far is mixed (Didaci et al., 2013; Kuncheva, 2003).

Lastly, an inverse problem could be posed, measuring the difference in the generalization error by removing classifiers from the history one by one, and optimizing this difference. One problem with such a model is that it would be vulnerable to redundancy – very good hyperparameters present in multiple copies in the history would be falsely marked as having no impact on the generalization error.

For the reasons stated above, the best solution appears to be the use of a fixed ensemble which is maintained and updated as the optimization progresses. Thus it is possible to build an accurate Bayesian model of how well an ensemble would perform if we added a model trained with hyperparameters γ. This means that we need to store the trained classifiers in a database (or store their predictions on the validation and testing splits) to permit ensemble construction and evaluation in the subsequent iterations.

Algorithm 1 Ensemble Optimization Procedure

Input: $\mathcal{X}_T, \mathcal{X}_V, B, m, A, \Gamma, L$
Output: H, history of models; E, the final ensemble

$H, G, E \leftarrow \varnothing$
for $i \in 1, \ldots, B$ **do**
  $j \leftarrow i \mod m$
  $E \leftarrow E \setminus \{h_j\}$
  $\mathbf{L}_i \leftarrow \{L(E \cup h|\mathcal{X}_V)\}_{h \in H}$
  $f(\gamma|E) \leftarrow \mathrm{BO}(G, \mathbf{L}_i)$ // Fit model
  $\gamma_i \leftarrow \arg\max_{\gamma \in \Gamma} a(\gamma|f(\gamma|E))$ // Next hypers
  $h_i \leftarrow \mathrm{A}(\mathcal{X}_T, \gamma_i)$ // Train model
  $G \leftarrow G \cup \{\gamma_i\}$
  $H \leftarrow H \cup \{h_i\}$
  $h_j \leftarrow \arg\min_{h \in H} L(E \cup \{h\})$ // New model at j
  $E \leftarrow E \cup \{h_j\}$ // Update ensemble
end for

3.2 ENSEMBLE UPDATE

The problem defined above is straightforward as long as the ensemble is given beforehand. In this section we will tackle the problem of building and updating the ensemble as the optimization progresses. To make things simpler, an ensemble size m will be fixed beforehand – this number can be fine-tuned at the end of the optimization. Each iteration of the optimization procedure will contain two steps: first the evaluation as described in Section 3, maintaining a fixed ensemble, and then an ensemble update step. Since members of the ensemble should be changed as the optimization moves forward and better models are found, a round-robin strategy will be used for the ensemble construction. The ensemble E will in fact consist of m fixed positions, and at every iteration i, the classifier at position $j = (i \mod m)$ will be removed from the ensemble before finding hyperparameters which minimize Equation 5 – effectively optimizing the classifier at this position for the given iteration. At the end of an iteration the ensemble is updated again greedily, selecting the new best classifier (it could be the same classifier or a better one). The whole procedure is described in Algorithm 1 and in Figure 2.

In addition, it is expected that some classifiers will specialize given the fixed state of a large part of the ensemble for each iteration. For instance, when replacing an individually strong classifier, another strong classifier will most likely be required. Figure 3 shows an example of optimization on a one-dimensional hyperparameter space run for 50 iterations, where an ensemble of five classifiers was optimized. The ensemble is represented by the five diamonds and its generalization error is shown by the dotted and dashed line at the bottom of the figure. Then, each of the five members

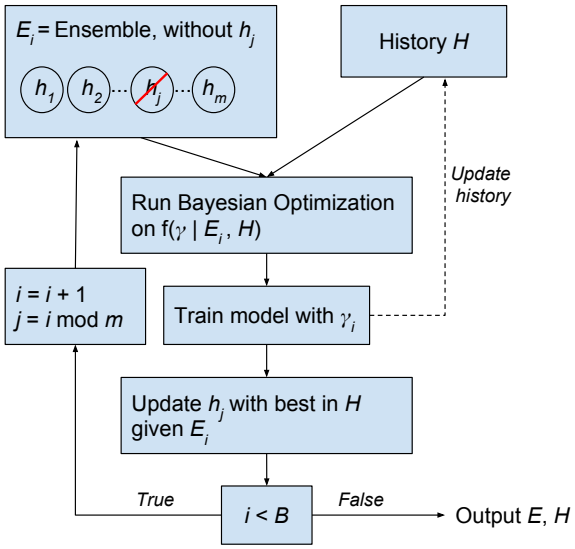

Figure 2: Schema of the Ensemble Optimization procedure.

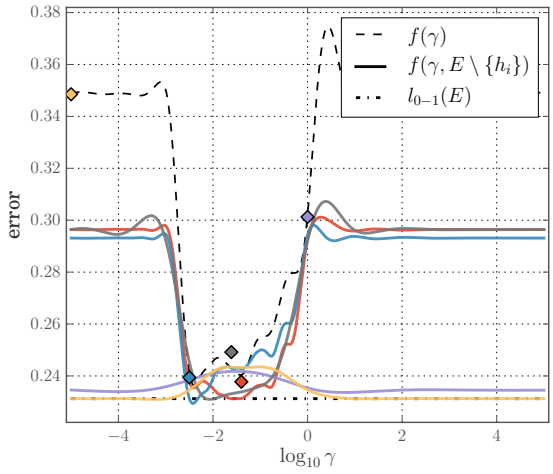

Figure 3: Example of objective function $f(\gamma|E \setminus \{h_i\})$ given a pool of 50 trained classifiers on a 1-D hyperparameter optimization problem. Each color represents the performance of an ensemble when removing its member h_i represented by a diamond of the same color in the plot.

i is independently removed and a Gaussian Process model is fit on the performance of an ensemble given the remaining models in the pool – this corresponds to the five colored lines of Figure 3. We can see from this figure that the hyperparameters which minimize the ensemble error are different for each *slot* in the ensemble, illustrating our concept.

3.3 COMPUTATIONAL COMPLEXITY

The *computational overhead* of the proposed method comes mainly from the evaluation of the empirical error of ensembles. It is very small with regards to the cost of running most learning algorithms (which is usually quadratic or worse in the number of samples), and also with the cost of conditioning the probabilistic model on the observations (which is cubic in the number of iterations). The computation of the empirical error of ensembles takes place in step 5 in Algorithm 1. Given an ensemble of size m, a validation dataset of size n, and a history of trained classifiers of size t, the complexity of this step is $O(t(mn + n)) = O(tmn)$ since it requires one pass over all models in the history, and for each of those the combination of the classifiers through majority voting (mn) and the computation of the empirical error n.

3.4 LOSS FUNCTION

The objective function defined in Equation 5 contains a loss function, which up until now referred to the empirical loss of the ensemble, or the zero-one loss. However, the zero-one loss contains a strong discontinuity and can result in optimization procedures failing due to the majority voting combination. For instance, if all classifiers of the ensemble are wrong on some instances, replacing one of those poor classifiers with a better one will not make the ensemble correctly classify those instances, resulting in the same performance with regards to the objective function, even though this classifier would be a good choice for the ensemble.

The performance of ensembles will be considered with regards to their classification *margin*, which will let us derive a more suitable loss function (Schapire and Freund, 2012). Given an ensemble of classifiers E outputting label predictions on a binary problem $\mathcal{Y} \in \{-1, 1\}$, the *normalized* margin for a sample $\{x, y\}$ is defined as follows:

$$M(E, x, y) = \frac{1}{|E|} \sum_{h \in E} yh(x). \tag{6}$$

The normalized margin $M \in [-1, 1]$ takes the value 1 when all classifiers of the ensemble correctly classify the sample x, -1 when all the classifiers are wrong, and somewhere in between otherwise. In the case of multi-class problems, predictions of classifiers can be brought back to a binary domain by attributing 1 for a correct classification and -1 for a misclassification. The margin becomes:

$$M_{mc}(E, x, y) = \frac{1}{|E|} \sum_{h \in E} [1 - 2l_{0-1}\left(h(x), y\right)]. \tag{7}$$

We will now derive some loss functions from the margin. The margin itself could be the objective, since it is desirable that the margin of the ensemble be high. It must be rescaled to really become a loss function, giving a margin-based loss function:

$$l_M(E, x, y) = \frac{1 - M(E, x, y)}{2}. \tag{8}$$

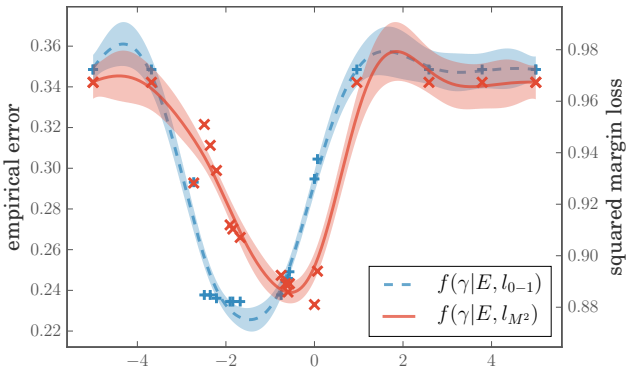

Figure 4: Examples of ensemble loss functions for a 1-D hyperparameter optimization. Blue curve legend is on the left, red curve legend is on the right.

This loss function should not be used to optimize an ensemble because it is directly maximized only by the accuracy of individual classifiers. In other words, given a validation dataset $\mathcal{X}_V$ and a set of classifiers H to evaluate, the classifier minimizing Equation 8 is always the classifier with the lowest empirical error on its own, without regards to the ensemble performance. Therefore, the loss function must not give the same weight to all classifiers without regards to ensemble performance, while also being smooth. A loss function which achieves this is the margin-based loss function taken to the power of two:

$$l_{M^2}(E, x, y) = \frac{(1 - M(E, x, y))^2}{4}. \tag{9}$$

This places a higher emphasis on samples misclassified by the ensemble, and decreases the importance of samples as the margin grows closer to 1. Since it meets the required properties, the squared margin loss function will be used as the ensemble loss function in this work.

Figure 4 shows an example of the two loss functions discussed in this section, the zero-one loss and the squared margin loss, applied on the same ensemble. Both losses have different scales, with the empirical error scale on the left and the squared margin scale on the right of the figure. We can see that these two loss functions lead to different optimal hyperparameters given the same ensemble. In other words, the hyperparameters minimizing the objective function according to the models of $f(\gamma|E)$ are different with the two loss functions.

Considering that a loss function other than the empirical error will be used during the optimization, it will probably be beneficial to rebuild an ensemble from scratch using the final pool of classifiers trained once the optimization is over. Hence, a post-hoc ensemble generation will be performed after the hyperparameter optimization.

4 EXPERIMENTS

We showcase the performance of our ensemble optimization approach on three different problems. The first two problems consist of different algorithms and hyperparameter spaces evaluated on the same benchmark of medium datasets available from the UCI repository, presented in Table 1. For every repetition, a different hold-out testing partition was sampled with 33% of the total dataset size (unless the dataset had a pre-specified testing split, in which case it was used for all repetitions). The remaining instances of the dataset were used to complete a 5-fold cross-validation procedure. Final models are retrained on all the data available for training and validation.

In every case, the prior on the objective function is a Gaussian Process (GP) with Matérn-52 kernel using automatic relevance determination[1]. The noise, amplitude, and length-scale parameters are obtained through slice sampling (Snoek et al., 2012). The slice sampling of GP hyperparameters for ensemble optimization must be reinitialized at every iteration given that different ensembles E can change the properties of the optimized function drastically. The acquisition function is the Expected Improvement over the best solution found so far. The compared methods and their abbreviated names are the following:

- Classical Bayesian optimization (BO-best). It returns a single model selected with argmin on validation performance (Snoek et al., 2012).
- Post-hoc ensemble constructed from the pool of classifiers with Bayesian optimization (BO-post). The post-hoc ensemble is initiated by picking the three best classifiers from the pool before proceeding with forward

[1]Code from `http://github.com/JasperSnoek/spearmint`.

greedy selection – this form of warm starting is recommended in (Caruana et al., 2004) to reduce overfitting.
- The proposed ensemble optimization method using the squared margin loss function (EO).
- Post-hoc ensemble constructed from the pool of classifiers generated by ensemble optimization (EO-post). The same post-hoc procedure as with BO-post is executed.

The hyperparameter spaces can contain continuous, discrete, and categorical parameters (e.g., base classifier or kernel choice). In the case of categorical and discrete parameters, they are represented using a continuous parameter which is later discretized. This does not deal with the fact that hyperparameter spaces of different classifiers are disjoint and should not be modeled jointly, but since all the compared methods are using this same technique, the comparison is fair.

4.1 SVM SEARCH SPACE

The models used in this benchmark are SVM models, and the parameterization includes the choice of the kernel along with the various hyperparameters needed per kernel. The hyperparameter space Γ optimized can be described as follows:

- One hyperparameter for the kernel choice: linear, RBF, polynomial, or sigmoid;
- Configurable error cost $C \in [10^{-5}, 10^{5}]$ (for all kernels);
- RBF and sigmoid kernels both have a kernel width parameter $\gamma_{RBF} \in [10^{-5}, 10^{5}]$;
- Polynomial kernel has a degree parameter $d \in [1, 10]$;
- Sigmoid and polynomial kernels both have an intercept parameter, $c \in [10^{-2}, 10^{2}]$.

All compared approaches optimized the same search space. Each method is given a budget of $B = 200$ iterations, or 200 hyperparameter tuples tested, to optimize hyperparameters with a 5-fold cross-validation procedure. The ensemble selection stage exploits this cross-validation procedure, considering the next classifier which reduces the most the generalization error over all the cross-validation folds. Selected hyperparameters are retrained on the whole training and validation data, and combined directly on the testing split to generate the generalization error values presented in this section. The ensemble optimization method is run with an ensemble size $m = 12$. This ensemble size was selected empirically and may not be optimal. Future work could investigate strategies to dynamically size the ensemble as the optimization progresses, with no fixed limit.

The generalization error on the test split for the selected methods is presented in Table 2, averaged over 10 repetitions. The last column shows the ranks of each method averaged over all datasets, where the best rank is 1 and the worst rank is 4.

Table 3: Wilcoxon pairwise test p-values for the SVM hyperparameter space. Bold entries highlight significant differences ($p \leq 0.05$) and parentheses are added when method at row i is worse than the method at column j according to ranks.

	1	2	3	4
1 - BO-best	–	(0.33)	(**0.00**)	(**0.00**)
2 - BO-post	0.33	–	(**0.01**)	(**0.00**)
3 - EO	**0.00**	**0.01**	–	0.21
4 - EO-post	**0.00**	**0.00**	(0.21)	–

A Wilcoxon signed-rank test is used to measure the statistical significance of the results. The Wilcoxon signed-rank test is a strong statistical test for comparing methods across multiple datasets, which is an nonparametric version of the Student's t-test that does not assume normal distributions and is less sensitive to outliers (Demšar, 2006). The input for the Wilcoxon test is the generalization error of a method i on each dataset d, averaged across the R repetitions:

$$\mathbf{e}_i = \{\frac{1}{R}\sum_{r=1}^{R} e_{i,d,r}\}_d, \tag{10}$$

where $e_{i,d,r}$ is the generalization error produced by method i on dataset d at repetition r. The Wilcoxon test is then computed for all pairs of methods $(\mathbf{e}_i, \mathbf{e}_j)$. The results of this procedure are shown in Table 3.

From Table 2 we can see that it is beneficial to build an ensemble from the output of a classical hyperparameter optimization, as seen by the lower rank of BO-post with regards to BO-best. However, the performance improvement is not shown to be significant according to the Wilcoxon test. Both the ensemble optimization methods seem to outperform classical Bayesian optimization strategies in terms of rankings. The Wilcoxon test shows that EO and EO-post both performed significantly better than BO-best and BO-post. It should be noted that there is no significant difference between EO and EO-post, highlighting that there was not a significant gain from the post-hoc ensemble construction. Caruana et al., 2004 presented some strategies to reduce overfitting in the forward greedy procedure – such as bagging from the pool of models – which could be considered in order to achieve more with the same pool, although this is left for future work.

Another test which can be used to assess the performance of the evaluated methods is the Friedman test with post-hoc tests on classifier ranks averaged across datasets. A Friedman test with the four methods presented in this section finds a significant difference between them with a p-value of 5.5×10^{-4}. The Friedman test is then usually followed by a post-hoc test to measure whether the difference in ranks is above a critical difference level, such as the Nemenyi test (Demšar, 2006). Figure 5 shows the results of

Table 2: Generalization error on SVM hyperparameter space, averaged over 10 repetitions, 5-fold cross-validation. Last column shows the rank of methods averaged over all datasets.

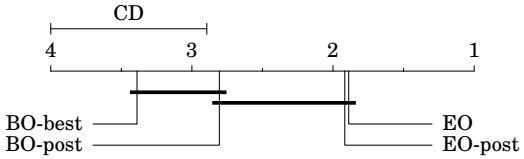

Figure 5: Methods by rank and significant differences according to a post-hoc Nemenyi test with significance level at $p = 0.05$ for the SVM hyperparameter space.

such a test, with methods linked by bold lines being found not significantly different by the test for a significance level of $p = 0.05$. The Nemenyi post-hoc test gives a more visual insight as to what is going on, but it is more sensitive to the pool of tested methods – the outcome of the test can change if new methods are inserted in the experiments. According to this test, EO and EO-post are both significantly different from BO-best, meaning that ensemble optimization is significantly better than the single best classifier returned by Bayesian optimization.

4.2 SCIKIT-LEARN MODELS SEARCH SPACE

The same methods as in the previous section were repeated for a different search space consisting of multiple base algorithms, all available from `scikit-learn`[2]. The models and their hyperparameters are ***K nearest neighbors*** with the number of neighbors `n_neighbors` in $[1, 30]$; ***RBF SVM*** with the penalty `C` logarithmically in $[10^{-5}, 10^{5}]$ and the width of the RBF kernel γ_{RBF} logarithmically in $[10^{-5}, 10^{5}]$; ***linear SVM*** with the penalty `C` logarithmically scaled in $[10^{-5}, 10^{5}]$; ***decision tree*** with the maximal depth `max_depth` in $[1, 10]$, the minimum number of examples in a node to split `min_samples_split` in $[2, 100]$, and the minimum number of training examples in a leaf `min_samples_leaf` in $[2, 100]$; ***random forest*** with the number of trees `n_estimators` in $[1, 30]$, the maximal depth `max_depth` in $[1, 10]$, the minimum number of examples in a node to split `min_samples_split` in $[2, 100]$, and the minimum number of training examples in a leaf `min_samples_leaf` in $[2, 100]$; ***AdaBoost*** with the number of weak learners `n_estimators` in $[1, 30]$; ***Gaussian Naive Bayes (GNB)*** and ***Linear Discriminant Analysis (LDA)*** both without any hyperparameters; and ***Quadratic Discriminant Analysis (QDA)*** with the regularization `reg_param` logarithmically in $[10^{-3}, 10^{3}]$.

[2]Available at `http://scikit-learn.org/`.

Table 5: Wilcoxon pairwise tests p-values for the scikit-learn hyperparameter space. Bold entries highlight significant differences ($p \leq 0.05$) and parentheses are added when method at row i is worse than the method at column j according to ranks.

4 - EO-post	**0.00**	**0.00**	(**0.03**)	–

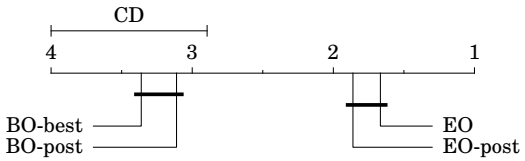

Figure 6: Methods by rank and significant differences according to a post-hoc Nemenyi test with significance level at $p = 0.05$ for the scikit-learn hyperparameter space.

The set of hyperparameter optimization strategies is the same as in the previous section, and the maximum number of iterations B is set to 100. Tables 4 and 5 show the same metrics and Wilcoxon pairwise tests as introduced in Section 4.1.

Conclusions are similar for this hyperparameter space, whereas the generation of a post-hoc ensemble is again shown to be beneficial to the generalization accuracy for both BO and EO. In this case the post-hoc ensemble for BO is found significantly better than the single best classifier according to the Wilcoxon test. The overall best method is EO, which significantly outperforms all other methods, including EO-post, as seen in Table 5. For some datasets, the ensemble optimization procedure achieves a large drop in the generalization error, see for example datasets letter (ltr), musk-2 (msk) and semeion (sem) in Table 4.

A Friedman test on this suite of experiments is again run and found significant with a p-value of 1.5×10^{-5}. Figure 6 shows the results of the Nemenyi post-hoc test, with

Table 4: Generalization error on the scikit-learn hyperparameter space, averaged over 10 repetitions, 5-fold cross-validation. Last column shows the rank of methods averaged over all datasets.

methods linked by bold lines being found not significantly different by the test for a significance level of $p = 0.05$. According to this test, EO-post and EO are significantly different from both BO and BO-best, meaning that ensemble optimization approaches significantly outperform both Bayesian optimization baselines.

4.3 CONVOLUTIONAL NEURAL NETWORKS

Lastly, we evaluated the performance of our approach when fine-tuning the parameters of a convolutional neural network for the CIFAR-10 dataset. In order to have a reproducible baseline, the `cuda-convet` implementation was used with the reference model files given which achieves 18% generalization error on the testing dataset[3]. One batch of the training data was set aside for validation (batches 1-4 used for training, 5 for validation, and 6 for testing). Performance of the baseline configuration on the given training batches was around $22.4\% \pm 0.9$ for 250 epochs of training. The parameters optimized were the same as in (Snoek et al., 2012), namely the learning rates and weight decays for the convolution and softmax layers, and the parameters of the local response normalization layer (size, power and scale). The number of training epochs was kept fixed at 250.

We computed 10 repetitions of a standard Bayesian optimization and our proposed ensemble optimization with ensemble size $m = 7$, both with a budget of $B = 100$ hyperparameter tuples to evaluate. Figure 7 shows the performance of ensembles generated from both pools of classifiers with a post-hoc ensemble generation. In order to limit overfitting, the first three models of each ensemble were selected directly based on accuracy, as suggested in (Caruana et al., 2004). In both cases, the ensemble size benefits the generalization accuracy, although the classifiers generated by the ensemble optimization procedure do perform slightly better. The difference in generalization error between BO-post and EO-post at the last iteration is found significant by a Wilcoxon test with a p-value of 0.005. Further work should investigate strategies to use the remaining validation data once the models are chosen, to further improve generalization accuracy.

[3]Code available at `https://code.google.com/archive/p/cuda-convnet/` and network configuration file used is `layers-18pct.cfg`.

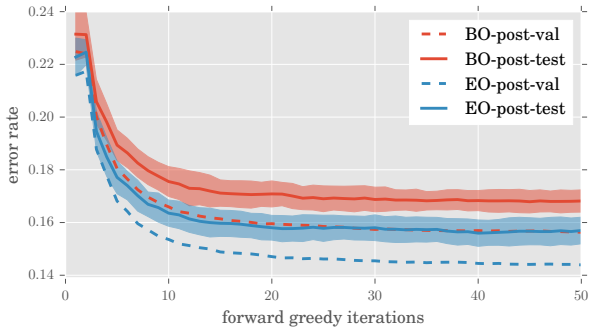

Figure 7: Generalization errors of a post-hoc ensemble with classical Bayesian optimization (BO-post) and a post-hoc ensemble generated from our ensemble optimization approach (EO-post) on the CIFAR-10 dataset with regards to the number of classifiers in the final ensemble. Results averaged over 10 repetitions.

5 CONCLUSION

In this work, we presented a methodology to achieve Bayesian optimization of ensembles through hyperparameter tuning. We tackle the various challenges posed by ensemble optimization in this context, and the result is an optimization strategy that is able to exploit trained models and generate better ensembles of classifiers at the computational cost of a regular hyperparameter optimization.

We showcase the performance of our approach on three different problem suites, and in all cases show a significant difference in generalization accuracy between our approach and post-hoc ensembles built on top of a classical hyperparameter optimization, according to Wilcoxon signed-rank tests. This is a strong validation of our method, especially considering that it involves little extra computation.

Abstract

This paper attempts to move beyond the left-right characterization of political ideologies. We propose a trait based probabilistic model for estimating the manifold of political opinion. We demonstrate the efficacy of our model on two novel and large scale datasets of public opinion. Our experiments show that although the political spectrum is richer than a simple left-right structure, peoples' opinions on seemingly unrelated political issues are very correlated, so fewer than 10 dimensions are enough to represent peoples' entire political opinion.

1 Introduction

The problem of best describing political variation has been a key issue in social sciences for over a century, and many models have been proposed over the years. The most prominent system for classifying political positions, ideologies and parties is the Left-Right classification. The notions of "Left" and "Right" in politics originate from the seating arrangements in the French legislative body during the French Revolution of 1789: the aristocracy sat on the right of the Speaker and the commoners sat on the left. The key ideological point of contention was the "old order", with the Right supporting aristocratic interests and the church, and with the Left supporting republicanism, secularism, and civil liberties.

However, is using the left-right terminology justified by *data* about political opinions? The terms left-wing and right-wing have evolved to capture a somewhat different meaning in modern day USA than their meaning in the years following the French Revolution. The left-wing generally refers to egalitarianism, social policies supporting the working class, and multiculturalism, typically including socialists and libertarians, identifying with the Democratic party; The right-wing refers to conservative Christian values, support for a free-market system, and traditional family values, and including conservatives and free-market supporters, identifying with the Republican party.

Opinions regarding a *single* issue can easily be expressed on a single axis. Parties or people can be placed on the axis depending on the degree of support to a stance relating to this issue; those whose strongly support a position can be placed on one side, followed by those with who slightly support it, and so on, ending with those strongly opposing the stance. For example, we can place parties who strongly support heavy regulation of businesses on the far left, those who want complete business freedom under any circumstances on the far right, and those who support light regulation of some businesses in the center.

However, most political parties take an ideological stand regarding *many* issues: immigration, free medical care, minimum wage, regulating banks, religious freedom, abortions, gay and lesbian rights, regulating drugs and alcohol, and many others. When the ideology of parties spans multiple issues, representing these ideologies requires a *political spectrum* — a system for classifying different political positions using *several* geometric axes, each representing an independent political dimension. For example, a spectrum with two axes may include one axis for sociocultural issues (relating for example to supporting or opposing a heavy investment in welfare) and one for economic issues (for example, supporting or opposing de-regulation of business).

One way to define a political spectrum is by using a dimension for each of the important issues the people and parties care about. Given a political spectrum of K dimensions we can express people's opinions and the political ideology of parties as K-dimensional vectors. However, a large dimensionality makes it cumbersome for people to explain their views, so clearly we would like to use the smallest possible dimensionality that can fully express the opinions of most people and parties. Political scientists have noted that the wide popularity of the left-right identification stems from the surprising fact that in many countries, it *is* possible to map parties into a single left-right axis [39, 17]. For example, Von Beyme [38] categorized European par-

ties into nine "families" that described most parties, and was able to linearly order seven such families from left to right: communist, socialist, green, liberal, Christian democratic, conservative and right-wing extremist. Although a single left-right axis can describe many parties, in many countries parties may take any combination of several issues [24, 39]. Common examples are the issues of economic freedom (taxation, free trade, free enterprise) and personal freedom (drug legalization, abortion and conscription). Some populations require a large dimensionality to represent, as individuals or parties may take any combination of positions regarding many issues, whereas other populations can be represented using less dimensions, due to strong correlations between stances on many issues.

Currently, 98 out of the 100 members in the United States Senate are affiliated with either the Democratic party (left) or the Republican party (right). This low-dimensional political landscape contrasts to other countries. For instance, in the United Kingdom, the House of Commons is composed of 11 parties. This disparity in the number of parties suggests that the political spectrum in the USA has fewer dimensions than the political spectrum in the UK.

Political scientists have to infer the key dimensions in a political spectrum representation using *data mining* techniques. For example, Ferguson [10] has used a set of questions pertaining to many issues: birth control, capital punishment, censorship, communism, evolution, law, patriotism, theism, treatment of criminals, and war. He used People's responses to questions pertaining to these issues as the input to a *factor analysis process*, trying to describe the variability between the correlated responses on different issues, using a low number of latent factors. His analysis showed that three dimensions, which he called Religionism, Humanitarianism, and Nationalism, were sufficient to capture much of the variability in the data. In other words, most people in the dataset could be described using three numbers, so that their position regarding *all* issues could be predicted given these numbers with high accuracy.

Such factor analysis based techniques for building a political spectrum can be thought of in terms of *dimensionality reduction*. This process transforms the data in the high-dimensional space into a representation in a space of fewer dimensions. Many such techniques are based on algebraic methods, such as SVD (singular value decomposition) or PCA (principal component analysis). Given the data and a target number K of dimensions, they find a good representation of the original data in a Kdimensional space. In this sense, these techniques can be thought of as a lossy compression technique. They receive peoples' opinions on many questions, and attempt to characterize both people and questions using very concise descriptions (vectors in a low dimension space). The original responses of the people regarding the political stances can then be reconstructed approximately. However, the approximation quality depends on the compression ratio: with a high dimensionality it is possible to represent people on the spectrum so that the full opinion regarding any issue can be determined accurately, and with a low dimensionality individuals may be represented very concisely, but with a higher error.

Although factor analysis can be a useful tool in inferring possible dimensions on the political spectrum, it is still unclear what the dimensionality of the political spectrum should be. How can we use data mining and machine learning tools in order to determine the true dimensionality of the data? How accurately can we infer peoples' political opinions using their location in this political spectrum?

1.1 Our Contribution:

We analyze the optimal number of political dimensions to use. In contrast to earlier data driven approaches for analyzing data so as to construct a political spectrum, we do not use an algebraic dimensionality reduction technique. Rather, we use a *Bayesian* model selection approach.

We use a *probabilistic graphical model* for dimensionality reduction, representing both users and questions regarding political stances as feature vectors in a low dimensional space, where similarity is measured by the inner product. Thus, each coordinate in the low dimensional space relates to one political dimension. Any choice of the number of dimensions in the low dimensional space results in a slightly different model. We choose the most plausible number of dimensions given the data, by taking the model with the *maximal evidence*.

We apply the technique on two datasets, each containing People's responses regarding various questions about their political stances. The first dataset consists of the responses of 38,000 UK users who ranked political issues by their importance. The second dataset consists of the responses of 1,500 users from the USA, sourced from Amazon's Mechanical Turk, who rated the degree to which they agree to 56 sentences representing a political stance. In each of these we use our approach to determine the optimal dimensionality of the political spectrum.

On the one hand, our results indicate the political spectrum is richer than simple "left-right" structure represented using a single dimension. On the other hand, they indicate that peoples' opinions on seemingly unrelated political issues are very correlated, so fewer than 10 dimensions are enough to represent peoples' entire political opinion.

2 Methodology

The key issue we focus on is determining how many dimensions underly the political positions of people with respect to a broad range of questions. We use statistical tools akin to factor analysis. Factor analysis methods attempt to

represent a set of observed correlated variables in terms of several 'common' factors. The common factors are not directly observed in the data and thus are sometime called latent variables. Existing approaches use factor analysis to identify the main factors in political values, but use an algebraic factor analysis, where the number of political dimensions is an *input* of the factor analysis algorithm [10, 9]. In contrast, we use a Bayesian approach, which chooses the optimal dimensionality to use.

We first describe our high level methodology. Our technique receives an input dataset which contains the responses of many participants, P, regarding a set of political questions, Q. Each such question represents a political stand, and the participant is asked to express the degree to which they agree or disagree with the stand, on a numerical scale. For example, such an item may be "Alcohol and cigarettes should be heavily taxed.", and a participant must rate the item on a seven-point scale between strongly disagreeing (1) and strongly agreeing (7) with the statement.[1] When the dataset relates to $|P|$ participants responding to $|Q|$ questions, the dataset is thus a matrix of $|P| \cdot |Q|$ numbers.

Given the dataset, we apply a dimensionality reduction procedure that models both participants and questions as low dimensional vectors. If the dimensionality used in our procedure is chosen to be K, each participant and question are represented by vectors in $\mathbb{R}^K$. Let $p' \in \mathbb{R}^K$ be the representation chosen for the participant, and let $q' \in \mathbb{R}^K$ be the representation chosen for the question. The procedure is devised so that the *predicted* rating the participant $p \in P$ would give to a question $q \in Q$ is the inner product of these two vectors $\langle p', q' \rangle$. The dimensionality reduction is based on a probabilistic graphical model. Any choice of a dimensionality K for the political spectrum results in a slightly different such model $\mathcal{H}_K$. We use the dimensionality for which the evidence under the model is maximized.

3 PMPS Model

The dimensionality reduction model we use is a Probabilistic Model for expressing the Political Spectrum, or PMPS for short. PMPS is a probabilistic graphical model which resembles other Bayesian models for matrix factorization [2, 28, 33, 6].

Graphical models were first introduced by Pearl [27]. We use the more general framework of factor graphs (see e.g., [19]) in order to describe the factored structure of the assumed joint probability distribution among the variables. Once the graphical model is defined and the values of the observed variables are set, inference algorithms (such as approximate message-passing methods) can be used in order to infer the marginal probability distribution of the unknown variables [19].

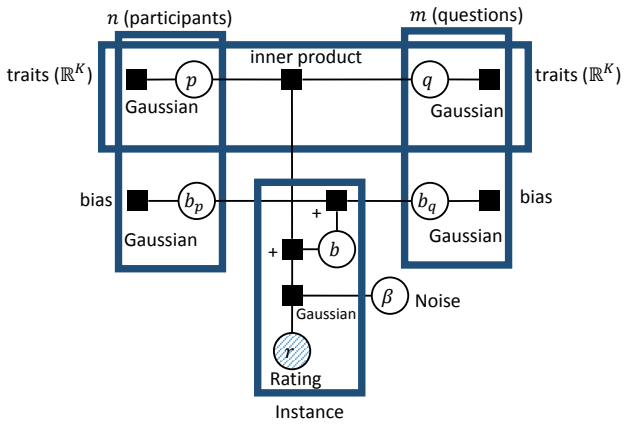

Figure 1: **Factor graph for the PMPS model.** The large plates indicate parts of the graph which are repeated with repetition indexed by the participant, question or trait.

The data fed to the model is a set of observations of the form (p, q, r) where $p \in P$ is the participant, $q \in Q$ is the political stance question, and $r \in \mathbb{N}$ is the rating given by the participant, expressing the degree to which they agree to the stance presented in the question.

The model assumes that the participants and questions can be characterized by K underlying "traits". These traits might be, for instance, the user's opinion on economy related issues. Note that the number of dimensions K of the model, i.e., the size of the participant and question vector has to be determined before the construction of the model. We model the process by which a participant $p \in P$ produces an answer r to a question $q \in Q$ as inner product between two K dimensional vectors of unobserved (latent) variables, one for the participant and one for the question. Thus we assume that: every participant has a latent trait vector and a latent bias; and Each question has a latent trait vector and a latent bias. The bias captures the fact that some participants give higher ratings than others, and that some questions receive higher ratings than others on average. Information such as the latent vector and bias of the participants and questions are modeled as unobserved variables, whereas the given response to a question by a user is modeled as an observed variable.

PMPS is a joint probabilistic model whose factor graph is given in Figure 1. Namely, the rating r that a participant with a latent vector $p \in \mathbb{R}^K$ gives to a question with a latent vector $q \in \mathbb{R}^K$ is modeled as

$$\Pr(r|t, s, b) = \mathcal{N}\left(r|p^T q + b_p + b_q, \beta^2\right), \qquad (1)$$

where β is the standard deviation of the observation noise, and $b_p + b_q$ are the participant and question bias, respectively.

[1] For a ranking of political issues, we assign integer scores for these topics in consecutive order.

In order to do inference on the model, we must first define prior distributions for the variable of interest. We assume factorizing Gaussian priors for the participant vector traits $p_i \sim \mathcal{N}(\mu_p, \sigma_p^2)$ and bias $b_p \sim \mathcal{N}(\mu_p, \sigma_p^2)$, and question vector traits $q_i \sim \mathcal{N}(\mu_q, \sigma_q^2)$ and bias $b_q \sim \mathcal{N}(\mu_q, \sigma_q^2)$. The Gaussian prior was chosen as it allows us to specify a range of plausible values using two parameters, and to admit a relative simple approximation inference. Also, it characterizes the assumption that a priory we expect that extreme ratings would be uncommon. In this work we set $\mu_p = \mu_q = 0$ and $\sigma_p = \sigma_q = \beta = 1$.

Inference in this model is done using message passing algorithms. We implemented the model using the Infer.NET [25] framework for probabilistic graphical models. Inference was done approximately, using the Expectation Propagation (EP) algorithm [26]. EP calculates marginal distributions on a given factor graph by iteratively computing messages along edges that propagate information across the factor graph. EP runs iteratively until convergence, so its runtime is linear in the model's size, which in the case of PMPS is of size $O(|P| \cdot |Q|)$. We note that while in our dataset all observations were present (i.e. we had the rating of every participant to every question), PMPS can also handle a partial set of observations (i.e. the case where we cannot observe the response of some participants to some of the questions).

3.1 Model Selection

For a specific K the model $\mathcal{H}_K$ was built, however different K values produce different models. The task of selecting the most plausible statistical model from a set of candidates $\mathcal{H}_1, \ldots, \mathcal{H}_N$ given the data is called *model selection*.

An important aspect of model selection is that we should not compare models solely based on how well it fits the data, but also based on their simplicity.[2] In other words, a good model selection technique should be balanced, achieving a good trade-off between *goodness of fit* and *simplicity* [40]. A key advantage of a Bayesian approach is the existence of a well-accepted methodology for achieving such a trade-off.

The posterior probability, $\Pr(\mathcal{H}_K|D)$ of the model $\mathcal{H}_K$ given the data D, is given by Bayes's theorem:

$$\Pr(\mathcal{H}_K|D) = \frac{\Pr(D|\mathcal{H}_K)\Pr(\mathcal{H}_K)}{\Pr(D)}. \quad (2)$$

This gives the following probability ratio between model $\mathcal{H}_i$ and model $\mathcal{H}_j$ [23]:

$$\frac{\Pr(\mathcal{H}_i|D)}{\Pr(\mathcal{H}_j|D)} = \frac{\Pr(D|\mathcal{H}_i)}{\Pr(D|\mathcal{H}_j)} \frac{\Pr(\mathcal{H}_i)}{\Pr(\mathcal{H}_j)}. \quad (3)$$

If we have a uniform prior over models, i.e. no a priori belief that either $\mathcal{H}_i$ or $\mathcal{H}_j$ is more probable, Equation 3 simplifies to $\Pr(D|\mathcal{H}_i)/\Pr(D|\mathcal{H}_j)$, this ratio is known as the *Bayes factor* [18]. We thus wish to find the model that maximizes $\Pr(D|\mathcal{H}_K)$. The density $\Pr(D|\mathcal{H}_K)$ is obtained by integrating over the unknown parameters values in that model:

$$\Pr(D|\mathcal{H}_K) = \int_{\theta_K} \Pr(D|\mathcal{H}_K, \theta_K) \Pr(\theta_K|\mathcal{H}_K) \, \mathrm{d}\theta_K, \quad (4)$$

where θ_K are the parameters under $\mathcal{H}_K$, $\Pr(\theta_K|\mathcal{H}_K)$ is the prior density and $\Pr(D|\mathcal{H}_K, \theta_K)$ is the probability of the data given the model $\mathcal{H}_K$ with parameters θ_K. The quantity in Equation 4 is called the *evidence* for model $\mathcal{H}_K$.

Simple models tend to make precise predictions and complex models, by their nature, are capable of making a greater variety of predictions. Therefore, in the case where the data are compatible with both models, the simpler model will turn out as more probable. The dimension K that results in the highest model evidence, suggests that the latent dimension of the data is that K.

4 Results

We now present our results, produced by applying PMPS learning and alternative methods on the UK and US datasets. We first describe the datasets, then discuss the empirical evaluation and the results.

4.1 Datasets

In both UK and USA datasets, users were directly asked to give their opinion regards several issues.[3]

4.1.1 UK Dataset

The website 38DEGREES[4] [1] has conducted a poll in which users from across the UK were asked to rank 18 issues according to their priorities. The issues were: The

[2] As an example, consider a dataset with five points in 2D space. One model that has a perfect fit is to use a fourth-degree polynomial; however if we look at the points and find that they are approximately on a straight line, we will favour a much simpler linear model that simply assumes some amount of noise.

[3] Asking users directly for their political opinions is one route for obtaining data. An alternative is mining social network data to infer political opinions [37, 35]. These could then be correlated with other inferred user psycho-demographic traits [21, 20, 4, 36] or socio-economic perceptions [22, 29, 11] (similarly to our analysis here). We used a direct survey as it offers less noisy observations than inferred traits (and although this limited the amount of data we collected, we believe the size of our dataset is sufficient for our analysis).

[4] http://www.38degrees.org.uk/

- Having an abortion is the choice of the mother. No one else has the right to decide this for her.
- Life begins at conception. Babies are people and deserve to be protected from abortion by law.
- It is morally a role of the state to provide basic medical care for everyone.
- Immigrants help grow our economy.
- Access to guns should be severely controlled.
- Owning a gun should be a fundamental right.
- My country has the duty to bring democracy to the world.
- Alcohol and cigarettes should be heavily taxed to discourage their use.
- Education including higher education should be free to all.
- The government should extend paid maternity leave to 3 months for every working mother.

Figure 2: An example of a few questions from the questionnaire

	Immigration	Poverty	Environment	Cost of living	The EU
Climate change	-0.3535	0.01949	0.58	-0.3272	-0.2592
Immigration		-0.3583	-0.2245	0.0636	0.4757
Poverty			-0.0804	0.0669	-0.3491
Environment				-0.2956	-0.1842
Cost of living					-0.0628

Table 1: The correlation between the issues

NHS[5], Banking, Privacy, Tax dodging, The economy, Animal welfare, Climate change, Poverty, Human rights, Education, Transport, Energy, Immigration, Environment, The EU, Housing, Cost of living and Privatisation of public services.

The results of this poll were generously shared with us. The dataset consists of 38,000 records of users, where every user is identified with his/her postcode.

4.1.2 USA Dataset

Using Amazon Mechanical Turk [34], We asked 1,500 users from different states in the USA to fill a questionnaire with 56 statements. For each statement, each user was asked give his/hers opinion and select one option from the seven-point scale from disagree strongly to agree strongly.

The statement were about different topics such as: religious, abortion, gay and lesbian rights, public health care and immigration. An example of a few questions can be found in Figure 2, the complete questionnaire is available online.[6]

[5]NHS is the British National Health Service

[6]http://tinyurl.com/h7t339v

4.1.3 Correlations Between Responses to Different Questions

Unsurprisingly, when examining the issue ratings in the UK dataset we note that some issues' rankings are correlated. Table 1 shows the correlations between the ratings of various issues. For example, as can be seen in Table 1, a user that ranked *Environment* at a high place is likely to do the same for *Climate change*, and a user who ranked *Immigration* at a high place is likely to rank *Climate change* at a low place.

Similar correlations between the responses to different political stance questions also occur in the USA dataset, indicating that many political issues are inter-correlated.

4.2 Predictive Performance

The high correlation between various items indicates that it should be possible to predict the responses of a participant to some of the questions based on the way their responded to other questions. Given a specific single question $q \in Q$, we can train a linear regression model to predict how a person $p \in P$ would respond to that question given their responses to some other subset of questions $S \subset Q$. If we are interested in predicting the responses to *multiple* questions,

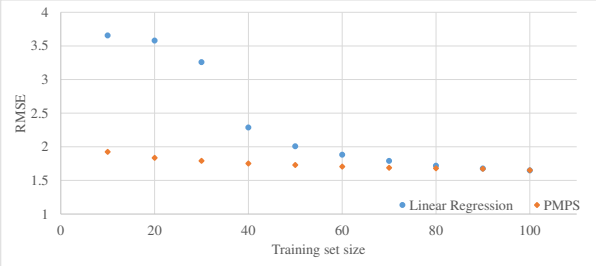

Figure 3: The prediction error (RMSE) of linear regression and PMPS.

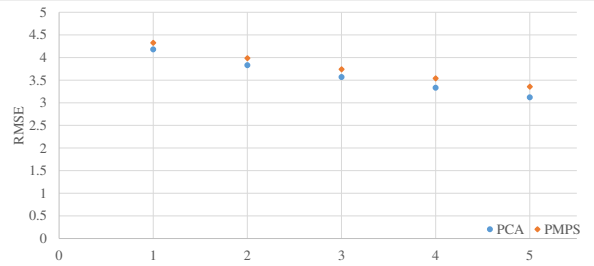

Figure 4: The error (RMSE) of PCA and PMPS against the number principal components on the UK data.

$T \subset Q$ based on the responses to some of the other questions, $S \subset Q$ (where $S \cap T = \emptyset$), we can train $|T|$ linear regression models, each taking as features the responses to the questions in S and predicting the responses to one of the questions $t_i \in T$.

An alternative approach is to use our PMPS model to generate the predictions. In this approach we learn to express questions as a posterior distribution over vectors in a low-dimensional space. Then, given a partial set of responses given by the person p to a subset S of the questions, we also obtain a representation of that person as a posterior distribution over vectors in the low dimensional space. Thus, PMPS would also produce a posterior distribution over the possible responses p would have to all the remaining questions, $Q \setminus S$ (including of course the questions in T). We can then take the mode of the posterior distribution over the responses to an unobserved question $t_i \in T$ and use them as a prediction for the response p would give to t_i.

We first designed an experiment to contrast the predictive performance of PMPS with that of linear regression models, using the USA dataset. The experiment goal was to predict the responses of users to questions in our USA dataset. In each trial we randomly select a subset $P^b \subset P$ of the participants to use for training. We let the model (either the linear regression model or PMPS) to observe the responses of these training participants to all the questions. We then select a subset of test participants $P^t \subset P$ (such that $P^b \cap P^t = \emptyset$). We also select a set $T \subset Q$ of target questions and a set of predictor questions $S \subset Q$ (where $S \cap T = \emptyset$). We first train the model using the training participants P^b, then let the model observe the responses of each test participants $p_j \in P^t$ to the target questions S (and *only* these questions). Next, we use the model to predict the responses of each test participant to each of the target questions, and examine the prediction error. In our experiments we used $|S| = 30$ predictor questions and $|T| = 26$ questions (so S and T form a partition of the question set). In our experiments we fixed $|P^t| = 20$ and we varied the number of training participants $|P^b|$ between 10 participants and 100 participants. We used 1,000 trials to measure the average prediction error of each model (linear regression or PMPS).

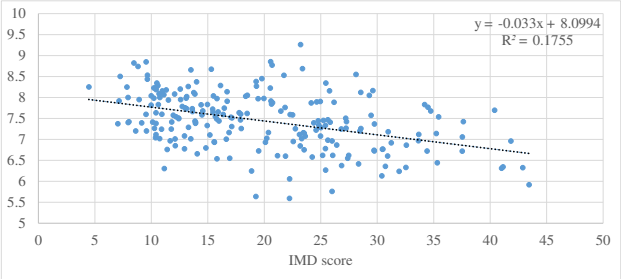
Our results regarding the predictive performance of PMPS and linear regression are given in Figure 3. The x-axis is the number of training participants, $|P^b|$, reflecting the amount of training data available to the model. The y-axis is the prediction root mean squared error (RMSE), averaged across the trials, with cross-validation. The figure shows that PMPS achieves a superior prediction quality over a linear regression method. The quality gap is especially big for treatments with less training data (fewer training participants). Figure 3 shows the results for PMPS model with $K = 6$, though other K values showed similar results and outperformed linear regression.

4.3 Latent Traits

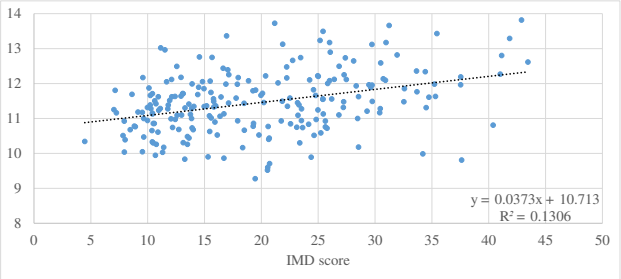
The high correlation between the issues suggests that the response data can be compressed. For example, consider the UK dataset, where the full data for each user consists of an 18-dimensional vectors, representing that person's importance rating for each of the issues. Rather than representing the entries of the dataset as 18-dimensional vectors, with one number per issue / question, we can project them into a lower dimension using either PMPS or traditional linear techniques such as PCA. This results in "compressing" the opinions dataset, at the cost of introducing some noise to the the entries.

We note that as opposed to the predictive performance experiment in Section 4.2, the goal of using such a dimensionality reduction is a lossy compression of the data, rather then predicting some entries or responses of a user based on their responses to other questions. In particular, in order to find a person's representation as a low dimensional vector, we process *all* of their responses.

For both PMPS and PCA the projection into a low dimensional vector is revertible, i.e. we can easily interpret the low-dimensional representation back into the 18-dimensional space. For PMPS this is done by plugging the learned weights and low-dimensional vectors in the model



(a) The average rank of "Poverty" as a function of the IMD score.



(b) The average rank of "The EU" as a function of the IMD score.

Figure 5: Correlation between the IMD score of LA and the average rank the issues in the LAs.

and inferring, rather than observing, the rating r of each question—this key operation is the inner product.

As the data is not perfectly reconstructed from this compression, a good measure of the noise resulting from the compression is the RMSE of the reconstructed 18-dimensional point compared to the original.

Figure 4 reports the compression RMSEs for both PCA and PMPS. Two conclusions can be drawn from the figure:

- Both PCA and PMPS can be used to characterize a *political spectrum*, which allows a tradeoff between the conciseness of peoples' description and the error in predicting their responses using this compressed description. The tradeoff between the compression and the error is very similar for these methods.
- Applying PCA on the data does not give a clear indication on the *true dimensionality* of the data: even for relatively high dimensions, the RMSE is not negligible.

As we discussed in section 3.1, one significant advantage of a Bayesian method such as PMPS over non-Bayesian methods is that they can trade-off some of the accuracy of compression for a greater simplicity of the representation, and that they allow for a rigorous method for choosing the "correct" dimensionality of the spectrum used.

4.3.1 Socio-Demographic Factors

The latent traits of a user, captured by their representation in the low dimensional space, may not correspond to an objective and observable measure of that individual. However, in the case of our political data, some correlations between ratings of different items can be explained as a result of socio-demographic influence.

Consider, for example, the participants in the UK dataset. It stands to reason that poor areas would be more concerned about issues such as poverty. To examine the correlations between rating and socio-demographic influence in the UK, we use the English Index of Multiple Deprivation (IMD) [12]. The IMD is a score that is given to every local authority (LA) in the UK. This score is based on employment, income, extent and concentration of the local authority. It ranges between 0 and 50: the higher the score, the more deprived the local authority.

There is a high correlation between the average rank of an issue in a specific LA and the IMD score of the LA. As, for example, it is shown in Figure 5, the average rank of "Poverty" (5a) is generally lower (more important) in LA's with high IMD, than in LA's with low IMD; and the average rank of "The EU" (5b) is generally higher in LA's with low IMD than in LA's with high IMD. Thus, LA's that ranked "Poverty" in a relatively high location are likely to rank "The EU" in a relatively low location and vice versa. Therefore, observing the IMD score of the user's LA could give us information about the ranks of the issues.

This analysis illustrates that it may be possible to capture a lot of the variability in People's responses to political questions by considering some of their objective traits, such as poverty.

4.4 Model Dimensionality

Our main goal is determining the true dimensionality of the political spectrum required to accurately represent peoples' stances regarding a wide range of political issues. To this end, we applied PMPS learning to our UK dataset and USA dataset. In both cases we examined the model evidence of every dimension so as to reveal the dimensionality of the datasets.

4.4.1 Dimensionality in the UK Dataset

When analyzing the UK dataset, we applied the PMPS model to the *entire UK data*, as well as the data from *specific UK local authorities*. As there is a high correlation between the IMD score of LA and the average rank of an issue, one of the latent dimension, in the PMPS model might be related to the IMD score, and the dimension of the data

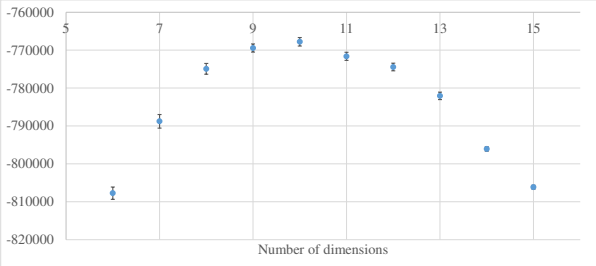


Figure 6: Log model evidence as a function of the dimension, on the data from UK.

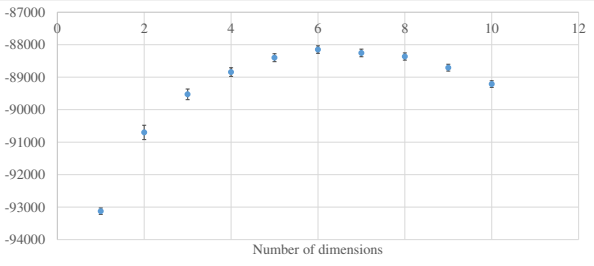

Figure 7: Log model evidence as a function of the dimension, on the data from USA.

is likely to be lower than 18.[7] The log of the model evidence as a function of the dimension can be found in Figure 6. The model in which the latent dimension was 10 resulted in the highest model evidence, and therefore the data suggests that the dimension is 10. We applied the same technique for every LA. In this experiment the dimension ranged from 7 (Metropolitan Borough of Wigan) to 11 (Rossendale District), with average of 9.717 and standard deviation of 0.678. Thus, the dimension of the data remains relatively homogeneous across local authorities.

4.4.2 Dimensionality in the USA Dataset

In the 114th United States Congress, out of 435 seats 431 are occupied by members of the Democrat and Republican parties. That is, the vast majority of the people in the US are represented by the two parties. For comparison, in the Parliament of the United Kingdom, there are 11 parties.

Historically, the Democratic party supports gun control laws, keeps elective abortions legal, and tends to favor equal rights for gay and lesbian couples. In contrast, the Republican Party opposes gun control laws, and the Republican party's agenda states that abortions should not be legal and marriage should be between a man and a woman. Hence, it appears that a single left-right axis could describe the two parties.

However, it is not clear why, for example, a person who supports abortion is likely to opposes state involvement with religious institutions. Therefore, we attempted to investigate whether the political dimension in the US is indeed lower than in the UK and, whether two parties can truly represent the American people. Alternatively, it could be the case that the election system in the USA results in a two party system, even though more parties are actually needed to truly represent the electors.

[7] Obviously, one needs to know the ranks of 17 issues in order to give an accurate prediction on the rank of the remaining issues. However, the PMPS model is not aware to the fact that for every user every rank appears only once.

In order to find the dimensionality of the data, we applied PMPS learning. The log of the model evidence as a function of the dimension can be found in Figure 7. The model in which the latent dimension was 6 resulted in the highest model evidence, and therefore data suggested that the dimension is 6, while the same technique suggested that the dimension within UK is 10. In addition, we applying PMPS learning on the data from different states. Unlike the data from UK, the results were less homogeneous across states, and range from 4 in Texas and California, to 6 in Michigan, New York and Florida.

5 Related Work

While the traditional political spectrum is a simple left-right axis, it has been doubted whether ordinary citizens actually use the specific ideology associated with this representation (see, e.g., [8]). Many Political scientists have suggested more complex, multidimensional representations of the political spectrum. One of the earliest work is by Ferguson [10], who suggested that peoples' positions with regard to 10 broad topics were influenced by 3 broad underlying dimensions: Religionism (with issues such as evolution, birth control and God), Humanitarianism (with issues such as war, capital punishment and treatment of criminals) and Nationalism (censorship, law patriotism and communisim).

Christie, and Meltzer [7] suggested a four dimensions diagram: fabianism to radicalism, fascism to anarchism, conservatism to social democracy and capitalist individualism to state communism. A similar research has been done by Eysenck [9] in the United Kingdom and in Germany. The research identified two independent principles: *Radicalism* (R) and *Tender-Mindedess* (T). In both countries, all but one attitude were found to have the same coordinates on the R-T Cartesian coordinate system. In Sweden, Husen showed a similar pattern [15].

Our method for determining the dimensionality of a political spectrum given a dataset is a Bayesian one, relying on a dimensionality reduction Probabilistic Graphical Model. Graphical models [27] have been widely studied

in the context of AI. For example, Porteous et al. [28] use graphical model for Bayesian probabilistic matrix factorization. Schmidt et al. [30] dealt with learning the structure of undirected graphical using L1 regression. Bachrach et al. [5] presented a graphical model for inferring the correct answers, difficulty levels of questions and ability levels of participants in multiple problem domains. A line of work has considered Bayesian methods and matrix factorization techniques for collaborative filtering based recommender systems [14, 13, 16, 32], which also capture peoples' ratings of various items. Our model is similar to the Matchbox recommendation system [33], in which users and items are mapped into a low-dimensional 'trait space'.

We used a rigorous and theoretically justified method for dimensionality selection. Alternative model selection techniques such as AIC [3] and BIC [31] have been previously for other domains. These technique also trade-off bias and variance, using the likelihood function, number of parameters of the model and the number of sampled data.

6 Conclusions

We proposed an approach for choosing the optimal dimensionality of the political spectrum, based on a dataset of responses of participants regarding political stands. Our method uses a probabilistic graphical model for dimensionality reduction, allowing us to express the political spectrum dimensionality selection problem as a Bayesian model selection problem, which we solve by choosing the dimensionality of the model with maximal evidence.

We applied the model on two types of datasets. The UK dataset contains participants ranking regarding many political issues, whereas in the US dataset participants rate their degree of agreement with many sentences representing a political stand. Our model indicates that for both datasets, there are correlations in the data regarding seemingly unrelated political issues, allowing for a more concise representation of peoples' political stand than the naive encoding of their responses to all questions. Further, our analysis of the UK dataset indicates that socio-demographic factors correlate with political opinions. This allows predicting political stands based on such socio-demographic factors.

Despite these correlations between responses to different questions (or between socio-demographic factors and these responses), our model indicates that a "left-right" political spectrum, or even a two dimensional spectrum, are far too simplistic, and insufficient to represent peoples' political opinion. Our model's choice for the optimal dimensionality is 10 dimensions for the UK dataset, and 6 for US dataset. Interestingly, the optimal dimensionality for the political spectrum differs across states in the USA.

Many questions are left open for future research. First, the political dimensions found by our model are the result of the feature extraction during the dimensionality reduction. Could these dimensions be interpreted in a human understandable form? Second, would alternative Bayesian models for dimensionality reduction achieve a lower error, and perhaps result in a different choice of dimensionality for the political spectrum, or is this dimensionality an inherent property of the data? Finally, our results indicated correlations between socio-demographic features of participants and their political opinions. To what degree of accuracy is it possible to predict demographic traits of people based solely on their political stand?

Abstract

It is natural to expect that the documents in a corpus will be correlated, and these correlations are reflected by not only the words but also the observed tags in each document. Most previous works model this type of corpus, which are called the semi-structured corpus, without considering the correlations among the tags. In this work, we develop a Correlated Tag Learning (CTL) model for semi-structured corpora based on the topic model to enable the construction of the correlation graph among tags via a logistic normal participation process. For the inference of the CTL model, we devise a variational inference algorithm to approximate the posterior. In experiments, we visualize the tag correlation graph generated by the CTL model on the DBLP corpus and for the tasks of document retrieval and classification, the correlation graph among tags is helpful to improve the generalization performance compared with the state-of-the-art baselines.

1 INTRODUCTION

Documents are usually composed of a group of words with different word frequencies, leading to the 'bag-of-words' representation. Besides, it is natural to expect that documents in a corpus are highly correlated with each other. This implicit relationship among documents may be embodied in the semantic meanings of the words in each document, where we can use topic models or other related methods to learn the correlations. However, most of the documents contain not only unstructured contexts (e.g., the plain text) but also metadata (e.g., tags). The metadata usually consists of several tags, such as authors in an article, keywords for a web page, and categories for a product. To model this type of documents which are called semi-structured documents, the metadata information would play an important role in organizing, understanding, and summarizing them in many applications.

Obviously, the tags in a corpus come from a compacted space, taking higher-level semantic as one type of semantic abstraction than words. Thus, the tags should be highly correlated with each other, which is consistent with documents' correlations. That is, the correlation between two documents can be reflected via their tags. Thus, modeling the correlations among tags can benefit the learning of the relations among documents and help obtain more meaningful representations for documents, which can be helpful for the consequent tasks such as document classification and retrieval. On the other hand, to model the documents, only considering the word information is obviously not enough if the tag information is available. Meanwhile, ignoring the correlations among tags is deficient, because the correlations can help understand the documents in a better way. Hence, how to model the correlations among tags together with the words is interesting and important for document modeling.

In fact, tags can be treated as high-level 'topics' in a corpus. While differently, the observed tags would be very complicated and high-dimensional, and belong to a different semantic space, compared with latent topics discovered by topic models. Thus, there should be a connection between the observed tags and the latent topics, such as a distribution over topics for each tag. In previous works such as the tag-weighted topic model [15], the author topic model [18], and the labeled-LDA [21], almost all of them define continuous distributions for the observed tags over the latent topics. Each tag is defined as a vector sampled from a certain probability distribution such as a Dirichlet distribution in [15], where the vector for a tag indicates the distribution over all the latent topics. In this way, the observed tags and the latent topics are combined to-

gether. However, under the Dirichlet distribution, the tags are modeled to be independent, which ignores the correlations among the tags.

On the other hand, we may model the correlations among the tags only using the co-occurrence of the tags. However, there are two main limitations in this approach. Firstly, it ignores the importance of different tags in a specific document, where some tags are more relevant to a document than others but in another document the situation can be totally different. Secondly, as described above, the tags are a set of semantic topic distributions, which are learned from plain text, and so the correlations should be modeled from the semantic level, while only considering the co-occurrences is not enough.

In this paper, we propose a novel CTL model based on the topic model to learn the correlations among the tags. In the CTL model, participation vectors of the observed tags, which take advantage of both the text information and the tags, for a semi-structured corpus are used to learn the correlations. For inference, an effective inference method is devised to learn the model parameters. The outputs of the CTL model are the tags' correlation matrix and the latent topics for documents, which are learned by utilizing the learned tag correlations. After learning the CTL, we can obtain a correlational graph which shows the relationships among the tags by ranking the correlational values. In experiments, we trained the proposed model on the DBLP corpus, where we treated authors as tags and we can visualize the correlational graph among the authors. Also, for one special author, there is a ranking list to show the relevant authors not only from the co-author information but also from whether they have similar research interests. We also apply the CTL model to the document retrieval and classification tasks on the Wikipedia corpus and the results show that the CTL model outperforms the state-of-the-art baselines.

2 RELATED WORKS

To date, many models are proposed for document modeling via different approaches such as undirected graphical models [24, 20, 13, 26, 25] or directed graphical models. As directed graphical models, topic models [11, 3, 1, 2, 4, 10] have been found to play an important role in analyzing unstructured texts. These models have been applied to many text mining areas, including information retrieval [28], document classification [6], and so on. However, most of these undirected and directed graphical models just consider the unstructured text with the bag-of-word assumption.

More and more text mining tasks are emerging in real-world applications to handle the semi-structured corpora, such as document classification described in [5, 16]. Based on the topic model, many methods have been proposed to deal with the semi-structured corpora, such as the author topic model [18], labeled-LDA [21], DMR [19], Tag-Weighted Topic Model (TWTM) [15], Tag-Weighted Dirichlet Allocation (TWDA) [14], partially LDA [22], TMBP [9], cFTM [8], statistical topic models [23], and so on. Most of the models take advantage of some given meta data (e.g., tags, labels, or contextual information) in a document with different assumptions. For example, the author topic model defines the distributions of the authors over the latent topics and the authors are assumed to be independent under a Dirichlet prior. In the labeled-LDA and partially LDA, the labels are defined as a set of distributions over the words from a vocabulary. For the TWTM and TWDA, a weight vector is used to generate the topic distribution of a document with the given tags. The DMR model is a Dirichlet-multinomial regression topic model which defines a log-linear prior on the document-topic distributions. In [23], Timothy et al. investigate a class of generative topic models for multi-label documents that associate individual word tokens with different labels, where the dependency-LDA is proposed to model the relations among the labels and words. Some of the aforementioned models can obtain the topic distribution of the tags, which can be used to measure the distance between the tags. However, they fail to directly model the correlations among tags.

3 THE CTL MODEL

In this section, we will mathematically define the Correlated Tag Learning (CTL) model, and discuss the learning and inference methods.

We use the following terminologies and notations to describe a corpus where each document is associated with a set of tags, which we call the semi-structured corpus.

Semi-Structured Corpus As a collection of M documents, we define the corpus $D = \{(\mathbf{w}^1, \mathbf{t}^1), \ldots, (\mathbf{w}^M, \mathbf{t}^M)\}$, where each 2-tuple $(\mathbf{w}^d, \mathbf{t}^d)$ denotes a document with its tag vector. Let $\mathbf{w}^d = (w_1^d, \ldots, w_N^d)$ denote the vector of N words associated with document d. Let $\mathbf{t}^d = (t_1^d, \ldots, t_L^d)$ represent the tag vector, each element of which is a binary indicator for a tag, with L as the number of all the tags in the corpus D.

Tag Matrix Here $\mathbf{t}^d$ is expanded to a $l^d \times L$ tag matrix T^d, where l^d is the number of tags in document d for the convenience of the inference. For each $i \in \{1, \ldots, l^d\}$, $T_{i\cdot}^d$ is a binary vector, where $T_{ij}^d = 1$ if

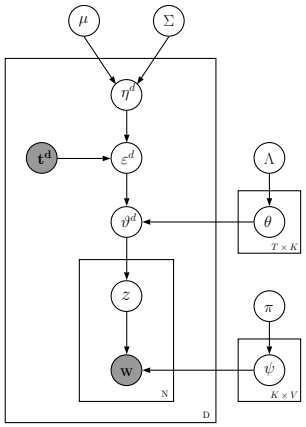

Figure 1: The graphical model of the CTL model, where each node denotes a random variable, a shaded node represents an observed variable, and edges indicate possible dependencies.

and only if the i-th tag in the document d is the j-th tag in the tag set of the corpus D.

Topic Proportions Each document is associated with a set of topic proportions ϑ. For a document d, ϑ^d is a multinomial distribution over topics and it reflects the probabilities of the words in document d drawing from latent topics.

3.1 The Model

The proposed CTL model is a hierarchical Bayesian model based on the topic model with assumptions that each document in a corpus is modeled by an underlying set of latent topics and that each topic defines a multinomial distribution over words. Besides, the CTL model assumes that the topic distribution of each document is determined by the given tags with a set of participation values. With the participation values in a participation vector, the CTL can model the topic proportions of each document as the product between the participation vector and the topic distributions of each tags in the document.

In this paper, we use ϑ_d to denote the topic distribution of the document d, as shown in Figure 1. Let θ represent a $T \times K$ matrix, where K is the number of the latent topics and each row in θ describes the distribution of one tag belonging to the latent topics. Let ψ represent a $K \times V$ distribution matrix, where each row is a distribution vector of one topic over words and V is the number of words in the dictionary of D.

3.1.1 Participation Vectors

ε^d, as shown in Figure 1, denotes the participation vector of the given tags in the document d. In the TWTM [15] and TWDA [14] models, it is called a weight vector which follows a Dirichlet distribution. As discussed above, under a Dirichlet distribution, the components of the participation vector are nearly independent, leading to a strong and unrealistic assumption that the presence of one observed tag is not correlated to the presence of another one. In order to overcome this assumption, we use a flexible logistic normal distribution to model the observed tags. As shown in Figure 1, Σ is the covariance matrix of the logistic normal distribution, μ is the expected value vector of the random variables, and η^d is a L-dimensional row vector that follows the normal distribution with Σ as the covariance and μ the mean. So the participation vector is defined as follows:

$$\varepsilon^d = \exp\{T^d \times (\eta^d)^{\mathrm{T}}\},$$

where $(\eta^d)^{\mathrm{T}}$ is the transpose of η^d, and ε^d is a $l^d \times 1$ column vector associated with the document d. Note that ε^d does not satisfy $\sum_i \varepsilon_i^d = 1$, hence we call it a participation vector instead of a weight vector.

With the participation vector, instead of a Dirichlet distribution, we use a logistic normal distribution to model the topic distribution of the document d:

$$\vartheta^d = \frac{(\varepsilon^d)^T \times T^d \times \theta}{\sum_i ((\varepsilon^d)^T \times T^d \times \theta)_i},$$

where $(\cdot)_i$ denotes the i-th entry in a vector and ϑ^d, the multinomial topic proportions of the document d, satisfies $\sum_i \vartheta_i^d = 1$. With the multinomial topic proportions ϑ obtained by a participation vector and a set of the observed tags in a document, we can generate each word for the document in a similar way to the topic model.

Thus, the CTL model assumes that a corpus with M documents arises from the following generative process:

1. For each topic $k \in \{1, \ldots, K\}$, draw $\psi_k \sim \mathrm{Dir}(\pi)$, where $\mathrm{Dir}(\cdot)$ denotes a Dirichlet distribution and π is a V-dimensional vector of hyperparameters.
2. For each tag $t \in \{1, \ldots, L\}$, draw $\theta_t \sim \mathrm{Dir}(\Lambda)$, where Λ is a K dimensional prior vector of θ.
3. For each document d:
   (a) Draw $\eta^d \sim \mathcal{N}(\mu, \Sigma)$ where $\mathcal{N}(\cdot, \cdot)$ denotes a multivariate normal distribution.
   (b) Generate T^d by $\mathbf{t}^d$.
   (c) Generate $\varepsilon^d = \exp\{T^d \times (\eta^d)^{\mathrm{T}}\}$.
   (d) Generate $\vartheta^d = \frac{(\varepsilon^d)^T \times T^d \times \theta}{\sum_i ((\varepsilon^d)^T \times T^d \times \theta)_i}$.
   (e) For each word w_{dn}:

i. Draw z_{dn} $\sim$Mult(ϑ^d) where Mult($\cdot$) denotes a multinomial distribution.

ii. Draw w_{dn} $\sim$Mult($\psi_{z_{dn}}$).

The CTL model is different from the TWTM model [15] where the weight vector in a document for the given tags is drawn from a Dirichlet distribution. The Dirichlet distribution is computationally convenient but it has a nearly independent assumption among the components of the weight vector. Differently, entries in the participation vector of the observed tags is highly correlated as we described above.

The covariance matrix Σ induces the dependencies between the components of the participation vector, and allows a general pattern of variability between the components. Using the covariance matrix of the logistic normal distribution, we can capture the correlated relationships between the given tags associated with each document.

3.2 Variational Inference

The logistic normal distribution used here brings not only the capacity to model the correlations among tags but also a challenge for the posterior inference procedure since it is not a conjugate prior for the multinomial distribution. We present a variational expectation-maximization (EM) algorithm [12, 27] for the inference. In the variational EM algorithm, the E-step approximates the posterior by minimizing the Kullback-Leibler (KL) divergence between the variational distribution and the true posterior distribution. This method casts the inference problem as an optimization problem to approximate the posterior distribution of this latent model and some study in [2] shows that minimizing the KL divergence is equivalent to maximizing the evidence lower bound (ELBO) denoted by $\mathcal{L}(\cdot)$.

For the CTL model, the ELBO can be derived by using Jensen's inequality:

$$\begin{aligned}\mathcal{L}(\cdot) =& \sum_d^D E_q[\log p(\eta^d|\mu,\Sigma)] + \sum_d^D\sum_n^N E_q[\log p(z_n|\vartheta^d)] \\ &+ \sum_d^D\sum_n^N E_q[\log p(w_n|\psi,z_n)] + \sum_i^L E_q[\log p(\theta_i|\Lambda)] \\ &+ H(q), \end{aligned} \tag{1}$$

where $q(\cdot)$ denotes a variational distribution of the latent variables, $E_q[\cdot]$ denotes the expectation with respect to q, and $H(q)$ is the entropy of the variational distribution whose definition is:

$$\begin{aligned}H(q) =& -\sum_d^D E_q[\log q(\eta^d)] - \sum_d^D\sum_n^N E_q[\log q(z_n)] \\ &- \sum_i^L E_q[\log q(\theta_i)].\end{aligned}$$

For the variational distribution $q(\cdot)$, we choose a fully factorized distribution where all the variables are assumed to be independent:

$$q(\eta, z, \theta|u,\sigma^2,\gamma,\lambda) = \prod_i^L \mathrm{Dir}(\theta_i|\lambda_i)\prod_d^D\Big(\mathcal{N}(\eta^d|u,\sigma^2)\prod_n^N \mathrm{Mult}(z_n|\gamma_n)\Big),$$

where λ in the Dirichlet distribution, γ in the multinomial distribution, and (u,σ^2) in the Gaussian distribution are the variational parameters.

Before discussing the optimization procedure, we describe how to compute the ELBO in Eq. (1). In the CTL model, the key inferential problem that we need to solve is to compute the second term in Eq. (1), which is the expected logorithm of a topic assignment subject to a normalized multinomial parameter and can be computed as

$$\begin{aligned}E_q[\log p(z_n|\vartheta^d)] &= E_q\left[\log p\left(z_n|\frac{(\varepsilon^d)^T\times T^d\times\theta}{\sum_i((\varepsilon^d)^T\times T^d\times\theta)_i}\right)\right] \\ &= \sum_k^K \gamma_{nk} E_q\left[\log\left(\frac{(\varepsilon^d)^T\times T^d\times\theta}{\sum_i((\varepsilon^d)^T\times T^d\times\theta)_i}\right)_k\right],\end{aligned}$$

where γ_{nk} denotes the probability of the k-th topic assigned to the n-th word. We see that computing the CTL's ELBO relies on the calculation of the expected normalized topic distribution of a document, which can be computed as

$$\begin{aligned}&E_q\left[\log\left(\frac{(\varepsilon^d)^T\times T^d\times\theta}{\sum_i((\varepsilon^d)^T\times T^d\times\theta)_i}\right)_k\right] \\ =&E_q\left[\log((\varepsilon^d)^T\times T^d\times\theta)_k\right] - E_q\left[\log(\sum_i((\varepsilon^d)^T\times T^d\times\theta)_i)\right] \\ =&E_q\left[\log\sum_i^{l^d}\varepsilon_i^d\theta_k^{(i)}\right] - E_q\left[\log\sum_i^{l^d}\varepsilon_i^d\right] \\ =&E_q\left[\log\sum_i^{l^d}\exp\{\eta_{(i)}^d\}\theta_k^{(i)}\right] - E_q\left[\log\sum_i^{l^d}\exp\{\eta_{(i)}^d\}\right],\end{aligned}$$

where $\theta^{(i)}$ denotes the vector of the topic distributions for the i-th tags in the document d corresponding to a row in θ and $\eta_{(i)}^d$ is the i-th entry of $T^d\times(\eta^d)^{\mathrm{T}}$.

By following the correlated topic model [1], the above two expectations can be computed approximately with Taylor expansions, respectively:

$$E_q[\log\sum_i^{l^d}\exp\{\eta_{(i)}^d\}\theta_k^{(i)}] \approx \log\alpha + \frac{1}{\alpha}\sum_i^{l^d}E_q[\exp\{\eta_{(i)}^d\}]E_q[\theta_k^{(i)}] - 1$$

and

$$E_q[\log \sum_i^{l^d} \exp\{\eta_{(i)}^d\}] \approx \log\beta + \frac{1}{\beta}\sum_i^{l^d} E_q[\exp\{\eta_{(i)}^d\}] - 1,$$

where we introduce two new variational parameter α and β. Note that $E_q[\exp\{\eta_{(i)}^d\}]$ is the mean of a log-normal distribution and equals $\exp\{u_{(i)}+\sigma_{(i)}^2/2\}$. The expectation of a Dirichlet random variable, $E_q[\theta_k^{(i)}]$, is equal to $[\lambda_k/\sum_j^K \lambda_j]_{(i)}$. Thus, for a document d, we have

$$\begin{aligned}
&\sum_n^N E_q[\log p(z_n|\vartheta^d)] \\
\approx &\sum_n^N\sum_k^K \gamma_{nk}\Big(\log\alpha + \frac{1}{\alpha}\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)} \\
&\qquad - \log\beta - \frac{1}{\beta}\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\Big).
\end{aligned}$$

Thus, we can use the block coordinate-ascent variational inference to maximize Eq. (1) with respect to variational parameters including σ^2, u, γ, λ, α, and β.

We first maximize $\mathcal{L}(\cdot)$ with respect to σ^2 for the document d with the objective function formulated as

$$\begin{aligned}
\mathcal{L}(\sigma^2) = &-\frac{1}{2}\mathrm{tr}\big(\mathrm{diag}(\sigma^2)\Sigma^{-1}\big) + \sum_i^L \frac{1}{2}\log\sigma_{(i)}^2 \\
&+ \sum_n^N\sum_k^K \frac{\gamma_{nk}}{\alpha}\Big(\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)}\Big) \\
&- \frac{N}{\beta}\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}, \qquad (2)
\end{aligned}$$

where $\mathrm{tr}(\cdot)$ denotes the trace of a square matrix and $\mathrm{diag}(\cdot)$ converts a vector to a diagonal matrix. Obviously the problem with respect to σ has no analytic solution and we solve it via the Newton's method with gradient computed as

$$\begin{aligned}
\mathcal{L}^{'}(\sigma_i^2) = &\frac{1}{2}\sum_n^N\sum_k^K \frac{\gamma_{nk}}{\alpha}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)} \\
&- \frac{N}{2\beta}\exp\{u_{(i)}+\sigma_{(i)}^2/2\} + \frac{1}{2\sigma_{(i)}^2} - \frac{1}{2}\Sigma_{ii}^{-1}, \qquad (3)
\end{aligned}$$

where the subscript $(i) \in (1,\cdots,l^d)$ indicates the i-th tag in a specific document d.

The objective function with respect to u is formulated as

$$\begin{aligned}
\mathcal{L}(u) = &-\frac{1}{2}(u-\mu)^T\Sigma^{-1}(u-\mu) - \frac{N}{\beta}\sum_i^{l^d}\exp\{u_{(i)}+\frac{\sigma_{(i)}^2}{2}\} \\
&+ \sum_n^N\sum_k^K \frac{\gamma_{nk}}{\alpha}\Big(\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)}\Big). \qquad (4)
\end{aligned}$$

We use the conjugate gradient algorithm to solve this problem, where the derivative is computed as

$$\begin{aligned}
\mathcal{L}^{'}(u) = &\sum_n^N\sum_k^K \frac{\gamma_{nk}}{\alpha}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)} \qquad (5) \\
&- \frac{N}{\beta}\exp\{u_{(i)}+\sigma_{(i)}^2/2\} - \Sigma^{-1}(u-\mu).
\end{aligned}$$

We maximize Eq. (1) with respect to γ_{nk} to find the maximizer as

$$\begin{aligned}
\gamma_{nk} \propto &\psi_{k,v^{w_n}}\exp\Big\{\frac{1}{\alpha}\Big(\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)}\Big) \\
&+ \log\alpha\Big\}, \qquad (6)
\end{aligned}$$

where v^{w_n} denotes the index of w_n in the dictionary.

For the variational parameter λ, the objective function is formulated as

$$\begin{aligned}
\mathcal{L}(\lambda) = &\sum_k^K(\Lambda_k-1)(\Psi(\lambda_k)-\Psi(\sum_j^K\lambda_j)) - \log\Gamma(\sum_j^K\lambda_j) \\
&+ \sum_n^N\sum_k^K \frac{\gamma_{nk}}{\alpha}\Big(\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)}\Big) \\
&+ \sum_k^K\log\Gamma(\lambda_k) + \sum_k^K(\lambda_k-1)(\Psi(\lambda_k)-\Psi(\sum_j^K\lambda_j)). \qquad (7)
\end{aligned}$$

We use the gradient descent method to solve it, where the derivative with respect to λ_k is:

$$\begin{aligned}
\mathcal{L}^{'}(\lambda_k) = &\sum_n^N \frac{\gamma_{nk}(\sum_j^K\lambda_j-\lambda_k)}{\alpha(\sum_j^K\lambda_j)^2}\exp\{u_{(i)}+\sigma_{(i)}^2/2\} \\
&+ (\Lambda_k-\lambda_k)(\Psi^{'}(\lambda_k)-\Psi^{'}(\sum_j^K\lambda_j)).
\end{aligned} \qquad (8)$$

For α and β, the optimal solutions can easily be found as

$$\alpha \propto \frac{\sum_n^N\sum_k^K\gamma_{nk}\Big(\sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}\left[\frac{\lambda_k}{\sum_j^K\lambda_j}\right]_{(i)}\Big)}{\sum_n^N\sum_k^K\gamma_{nk}} \qquad (9)$$

$$\beta \propto \sum_i^{l^d}\exp\{u_{(i)}+\sigma_{(i)}^2/2\}. \qquad (10)$$

In the E-Step of the variational EM algorithm, we iteratively update the variational parameters including σ^2 , u, γ, λ, α and β.

3.3 Parameter Estimation

The parameters of the CTL model include Σ, μ, ψ and Λ. In the M-step, given the semi-structured corpus, we can estimate the parameters by maximizing a lower-bound of the log-likelihood based on the variational

E-step. The update rules for Σ, μ and ψ can easily be obtained:

$$\mu \propto \frac{1}{D}\sum_{d}^{D} u_d, \tag{11}$$

$$\Sigma \propto \frac{1}{D}\sum_{d}^{D}\Big(I\sigma_d^2 + (u_d-\mu)(u_d-\mu)^T\Big), \tag{12}$$

$$\psi_{kj} \propto \sum_{d}^{D}\sum_{n}^{N}\gamma_{nk}(w^d)_n^j, \tag{13}$$

where $(w^d)_n^j$ is the count for the n-th word in the document d. For the Dirichlet parameter Λ, its objective function is formulated as

$$\begin{aligned}\mathcal{L}(\Lambda) = &\sum_{l}^{L}\Bigg(\log\Gamma(\sum_{j}^{K}\Lambda_j) - \sum_{i}^{K}\log\Gamma(\Lambda_i) \\ &+ \sum_{i}^{K}(\Lambda_i - 1)\Big(\Psi(\lambda_i^l) - \Psi(\sum_{j}^{K}\lambda_j^l)\Big)\Bigg).\end{aligned} \tag{14}$$

The derivative with respect to Λ_i is computed as

$$\mathcal{L}^{'}(\Lambda_i) = L\Big(\Psi(\sum_{j}^{K}\Lambda_j) - \Psi(\lambda_i)\Big) + \sum_{l}^{L}\Big(\Psi(\lambda_i^l) - \Psi(\sum_{j}^{K}\lambda_j^l)\Big). \tag{15}$$

We can use the linear-time Newton-Raphson algorithm to estimate Λ.

4 DISCUSSION

The proposed CTL model can capture the correlations among the tags in a semi-structured corpus, not just only by considering the co-occurrences of the tags. The CTL model presents the participation vector for each document to estimate the correlations of the tags, and the participation vector is learned by the text information with the basic assumption on latent topics. In other words, the co-occurrence vector is binary, which means that one tag is present or absent, while the participation vector is non-binary and the values in participation vector denote the importance of the tags.

Actually, we can train the CTL model by only considering the co-occurrence information of tags in each document. In this case, different tags have equal importance in a document d and hence η^d is observed for each document, where η_j^d is set to 1 if and only if the document d has the j-th tag. So the CTL model will consist of two parts, as shown in Figure 2. The left figure in Figure 2 is the first part containing Σ, μ, η^d, ξ^d and $\mathbf{t}^d$, where η^d, ξ^d and $\mathbf{t}^d$ are the observed variables. We can use the traditional maximum likelihood estimation to learn the correlation matrix Σ with the D samples:

$$\mu = \frac{1}{D}\sum_{d}^{D}\mathbf{t}^d, \quad \Sigma = \frac{1}{D}\sum_{d}^{D}(\mathbf{t}^d-\mu)(\mathbf{t}^d-\mu)^{\mathrm{T}}.$$

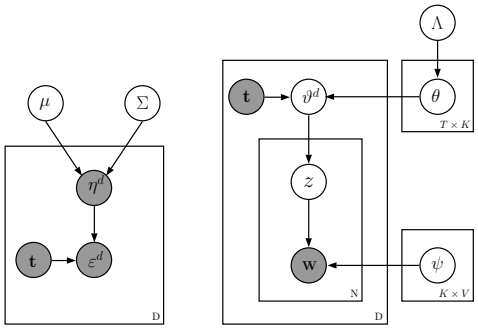

Figure 2: The two parts of the CTL model will be degenerated if η^d becomes equal to $\mathbf{t}^d$, which means that all the tags have the same effect on the document.

The second part shown in the right figure of Figure 2 means that all the tags have equal impacts on the topic distribution ϑ^d. We can see that the second part is a variant of the author topic model described in [18]. Thus, we can use the variational inference process to compute the new ELBO bound as:

$$\begin{aligned}\mathcal{L}_{new} = &\sum_{d}^{D}E_q[\log p(\mathbf{t}^d|\mu,\Sigma)] + \sum_{d}^{D}\sum_{n}^{N}E_q[\log p(z_n|\vartheta^d)] \\ &+ \sum_{d}^{D}\sum_{n}^{N}E_q[\log p(w_n|\psi,z_n)] + \sum_{i}^{L}E_q[\log p(\theta_i|\Lambda)] \\ &- \sum_{d}^{D}E_q[\log q(\mathbf{t}^d)] - \sum_{d}^{D}\sum_{n}^{N}E_q[\log q(z_n)] \\ &- \sum_{i}^{L}E_q[\log q(\theta_i)],\end{aligned}$$

where $\sum_d^D E_q[\log p(\mathbf{t}^d|\mu,\Sigma)]$ and $\sum_d^D E_q[\log q(\mathbf{t}^d)]$ are fixed, $\sum_d^D\sum_n^N E_q[\log p(z_n|\vartheta^d)]$ does not involve σ^2 and u since η^d and ξ^d are known. In this case, $\mathcal{L}_{new} < \mathcal{L}$, which means the new lower bound $\mathcal{L}_{new}$ is lower than the former one when convergence. Thus, treating the tags equally will not be a good choice.

Compared with the tag-weighted topic model [15], we would obtain document embeddings with better quality when the tags in the corpus are highly correlated. Thus, we will study the CTL model under this setting in our experiments.

5 EXPERIMENTS

In this section, we will present the performance of the proposed CTL model on document modeling, document classification, and document retrieval, respectively.

5.1 Experimental Settings

We used two semi-structured corpora to evaluate the CTL model. The first corpus is the Digital Bibliography and Library Project (DBLP),[1] which is a collection of bibliographic information of technical papers published in major computer science journals and conferences. We use the authors as the tags and removed the authors that occur in fewer than 5 papers. We use a subset of the DBLP that contains abstracts of $D = 40,108$ papers with $72,748$ words by removing stop words and $L = 6,348$ unique tags. The second corpus is from Wikipedia.[2] The Wikipedia corpus we used contains $43,217$ articles. The size of the vocabulary is $22,344$ by removing stop words. We use the category information, which is located at the bottom of each article and provided by the MediaWiki software, of articles as the tags, and in total there are $2,900$ tags. Moreover, each article belongs to different portals which can be viewed as the class label and all the articles used in the experiments belong to 20 classes, such as arts, sports, history, biography, education and so on.

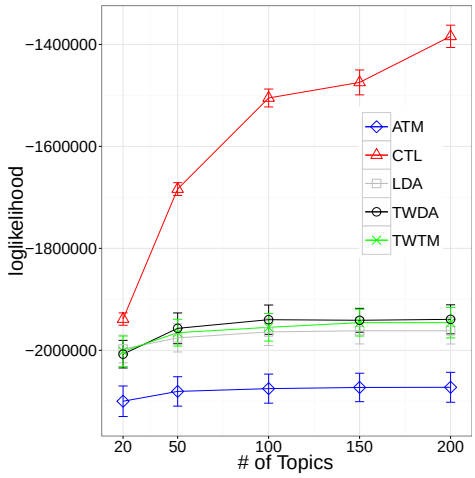

Figure 3: The 5-fold cross-validated held-out log-likelihood of different models on the Wikipedia corpus with different number of topics.

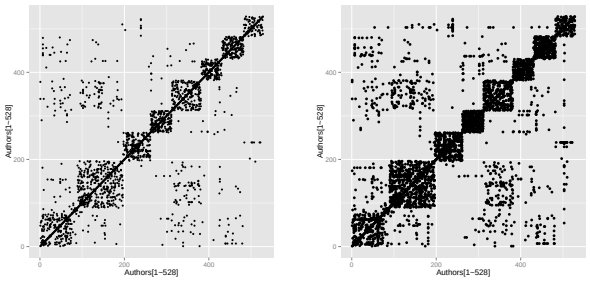
5.2 Experiments on Document Modeling

To demonstrate the performance of the different models on document modeling, we computed the log-likelihood of the held-out data given a model estimated from the remaining data by using five-fold cross validation, implying that 80% documents are for training and the remaining 20% for testing. We compared the CTL model with the Author Topic Model (ATM), TWTM, TWDA, and LDA by varying the number of latent topics. Since the LDA could not handle the tag information directly, we treated the given tags as the word features and added them into the document as the input for the LDA model.

Figure 3 shows the average log-likelihood for each model on the held-out set. The results demonstrate that the CTL model has much better performance than other baselines. One possible reason is that the tags contained in Wikipedia corpus are highly correlated and with the help of the logistic normal distribution, the CTL model can obtain a more reasonable and effective participation vector to form the topic distribution for each document.



(a) penalty factor $p = 0.25$ (b) penalty factor $p = 0.5$

Figure 4: The scatter plots of the selected 528 authors on the DBLP corpus, where a point is drawn if the corresponding two authors are neighbors.

5.3 Analysis on Tag Graph

The covariance of the logistic normal distribution for the participation vector can be used to visualize the relations among tags. Thus, we use the covariance matrix to form a tag graph, where the nodes represent the tags appeared in the corpus and the edges denote the relations between tags. To construct the tag graph, we use the method introduced in [17] for neighborhood selection based on the Lasso. As described in [17], the neighborhood selection with the Lasso is used to estimate the conditional dependency separately for each node in the graph. In the CTL model, for a document d, η^d follows a normal distribution with mean u and covariance Σ. Thus, $\{\eta^d\}$ are treated as independent observations sampled from the normal distribution $\mathcal{N}(\mu, \Sigma)$, which are used to estimate the neighborhood based on [17].

We use the DBLP corpus for the experiment. For the convenience of display, we select 528 authors to illustrate the correlated connections among them by drawing an edge if the corresponding two authors are neighbors with different penalty factor $p = 0.25$ and

0.5, respectively. After using the spectral clustering based on the conditional dependency obtained by the method in [17], as shown in Figure 4, we clearly see that the authors cluster together to different groups, where the authors in a group may have similar research interests.

We plot the author graph to show the correlations among the 518 authors and in Figure 5, a part of the graph is shown, where the nodes represent authors and the edges denote the correlations between the authors. In this graph, we can find some interesting insight. For example, two authors 'Zhi-Hua Zhou' and 'Guang Dai', who did not coauthor any paper, have a connection between them since they have similar research interests, which shows an advantage of the CTL model over only using the coauthorship information that it can find meaningful relations at the semantic level.

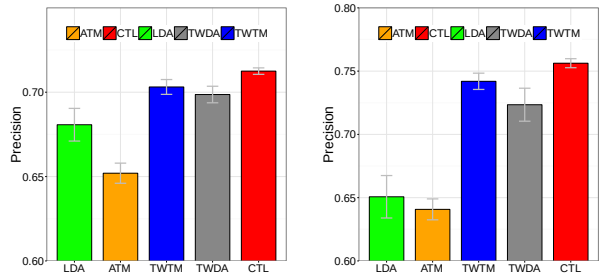
The CTL model can give a ranking list based on how the authors are correlated. In Table 1, we pick several authors from the 528 authors, and for each selected

author, we rank other authors according to their correlational values, which can be obtained by the process of neighborhood selection (see [17]). Based on the results, we can easily see how close the two authors are in the research and answer interesting questions including that whether researcher A has more similar interests to researcher B than to researcher C.

5.4 Document Classification and Retrieval

In this section, we conduct experiments on document classification and retrieval tasks.

We first test the classification performance by comparing the performance of the LDA, ATM, TWTM, TWDA, and the proposed CTL model with the number of topics as 50 and 100, respectively. The LIBSVM [7] with the Gaussian kernel and default parameters is used as the classifier. In experiments, we use a subset of the Wikipedia corpus which contains 14,400 documents belonging to 20 classes. We reported in Figure 6 the precision of different methods on the Wikipedia corpus by using the five-fold cross validation. According to Figure 6, the performance of the CTL model is significantly better than that of other baseline methods. One possible reason is that the CTL model can learn a better topic distribution for each document than others.



(a) $K = 50$ (b) $K = 100$

Figure 6: Classification results on the Wikipedia corpus for the LDA, ATM, TWTM, TWDA and CTL models with five-fold cross validation.

Moreover, we use the Wikipedia corpus to evaluate the performance on the document retrieval task. In this experiment, each document is represented by the vector of topic distribution generated by different models with the topic number as $K = 100$. The Wikipedia corpus used here is just the data set used in the above classification experiment. We randomly sample 12,400 documents for training and the rest for testing. For each query, documents in the database were ranked using the cosine distance as the similarity metric. For evaluation, we check whether a retrieved document has the same class label as the query document to decide whether the retrieved document is relevant to the query document. Figure 7 shows the F1 scores and the precision-recall curves of the LDA, ATM, TWTM, TWDA and CTL models. The experimental results demonstrate the superiority of the embedding learned by the CTL model for the document retrieval task.

6 CONCLUSION

In this paper, we propose the CTL model, a statistical model of semi-structured corpora, based on the topic model to discover highly correlational relationships among the tags observed in the semi-structured corpus. Besides, the experimental results demonstrated that this method can model semi-structured corpora better than the state-of-the-art models when the tags are highly correlated.

In our future study, we will apply the CTL model to more text applications. Another possible direction is to devise parallel algorithms for the CTL model to further improve its efficiency.

Abstract

To address the scalability issue of kernel methods, random features are commonly used for kernel approximation (Rahimi and Recht, 2007). They map the input data to a randomized low-dimensional feature space and apply fast linear learning algorithms on it. However, to achieve high precision results, one might still need a large number of random features, which is infeasible in large-scale applications. Dai et al. (2014) address this issue by recomputing the random features of small batches in each iteration instead of pre-generating for the whole dataset and keeping them in the memory. The algorithm increases the number of random features linearly with iterations, which can reduce the approximation error to arbitrarily small. A drawback of this approach is that the large number of random features slows down the prediction and gradient evaluation after several iterations. We propose two algorithms to remedy this situation by "utilizing" old random features instead of adding new features in certain iterations. By checking the expected descent amount, the proposed algorithm selects "important" old features to update. The resulting procedure is surprisingly simple without enhancing the complexity of the original algorithm but effective in practice. We conduct empirical studies on both medium and large-scale datasets, such as ImageNet, to demonstrate the power of the proposed algorithms.

1 INTRODUCTION

Kernel methods are powerful tools for learning non-linear hypotheses. Many algorithms can be combined with kernel methods, including SVM and logistic regression. However, kernel methods are usually considered as non-scalable due to the kernel matrix $K \in \mathbb{R}^{n \times n}$, where n is the number of examples. For large-scale datasets, such as MNIST-8M (8.1 million) and ImageNet (1.3 million), the memory usage makes kernels methods prohibitive for these applications.

One line of research is devoted to kernel approximation with limited memory usage (Williams and Seeger, 2000; Rahimi and Recht, 2007). Random Features (Rahimi and Recht, 2007), inspired by Bochner's theory, approximate the kernel mapping via a simple sampling procedure. After mapping the input data into the randomized feature space created by random features, we then apply existing fast linear learning algorithms. It has attracted machine learning community's interest because of its simplicity and effectiveness in practice. The extensions of random features include Rahimi and Recht (2008); Yang et al. (2012); Le et al. (2013); Yang et al. (2014); Chen et al. (2015); Bach (2015). However, both theoretical (Rahimi and Recht, 2007) and empirical studies show one might still need a large number of random features to achieve high precision results. If we pre-generate the random features and keep them in the memory, it is still infeasible in modern large-scale applications.

Dai et al. (2014) propose a remedy which generates random features on the fly by connecting functional gradients and random features, which is called *Doubly Stochastic Gradient Descent* (DSG). DSG re-computes the random features for a small batch of data in each iteration instead of keeping them in the memory. The re-computing manner allows DSG to increase the number of random features in every iteration. The algorithm can also be treated as a variant of random coordinate gradient (RCD) algorithm, because DSG updates the newly increased feature (coordinate) in every iteration. Therefore, by increasing the number of features, DSG can achieve arbitrarily small approximation error if one have sufficient budget of time. On the flip side, increasing features in every iteration causes the number of random features to grow linearly with number iterations. After several iterations, the large number of used random features makes prediction and computing gradients slow.

In this paper, we make the following contributions. First,

we solve the drawback of large number of random features by updating old coordinates instead of increasing features in certain iterations (Section 4) to reduce the number of the used random features. One simple extension is sampling from old coordinates uniformly and periodically as typical RCD over the finite dimensions, which is called *DSG with Uniform Sampling* (UDSG). We make the second contribution by analyzing the convergence rate of UDSG. Although UDSG usually works well in practice, our theoretical analysis suggests the descent amount of UDSG is not as much as Dai et al. (2014) in the worst case. We then make our third contribution by proposing the other non-trivial algorithm, *DSG with Checking* (CDSG), which chooses the old coordinate by checking the expected descent amount and derive a expected line search methodology to further boost the performance. Theoretically, CDSG enjoys the same convergence rate as DSG. Empirically, it outperforms other algorithms. Last, we conduct experiments on large-scale datasets, including ImageNet, and further study the comparison with deep neural nets in Section 5. We then conclude in Section 6 and make a guideline of choosing algorithms in practice.

2 PRELIMINARIES

The problem we are interested in this paper is as follows. Assume the data point $(\mathbf{x}, y) \in \mathcal{X} \times \mathcal{Y}$ is an *i.i.d.* sample from a distribution $\mathbb{P}(\mathbf{x}, y)$, where $\mathcal{X} \subseteq \mathbb{R}^d$, we want to estimate a function $f : \mathcal{X} \to \mathcal{Y}$ in Reproducing Hilbert Space (RKHS) $\mathcal{H}$ by optimizing

$$f_* = \operatorname*{argmin}_{f \in \mathcal{H}} R(f) = \operatorname*{argmin}_{f \in \mathcal{H}} \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 + \mathbb{E}_{(\mathbf{x},y)}[\ell(f(\mathbf{x}), y)], \tag{1}$$

where $\ell(z, y)$ is a convex loss function in z. Commonly used loss functions are hinge loss (SVM), logistic loss (logistic regression) and square loss (ridge regression). Note that if the data comes from a batch setting, we replace the above expectation with the empirical expectation (average).

2.1 RKHS AND KERNEL

The RKHS $\mathcal{H}$ on $\mathcal{X}$ is a Hilbert space of functions from $\mathcal{X}$ to $\mathbb{R}$. One typical way to define RKHS is via kernel functions $k(\mathbf{x}, \mathbf{x}') : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, which encodes the similarity between two data points. The kernel function k is symmetric and positive definite. $\mathcal{H}$ is RKHS if and only if there exists a kernel $k(\mathbf{x}, \mathbf{x}')$ such that $\forall \mathbf{x} \in \mathcal{X}, k(\mathbf{x}, \cdot) \in \mathcal{H}$ and $\langle k(\mathbf{x}, \cdot), k(\mathbf{x}', \cdot)\rangle_{\mathcal{H}} = k(\mathbf{x}, \mathbf{x}')$. Also, if $f \in \mathcal{H}$, $f(\mathbf{x}) = \langle f, k(\mathbf{x}, \cdot)\rangle_{\mathcal{H}}$. One commonly used kernel is Gaussian RBF kernel $k(\mathbf{x}, \mathbf{x}') = \exp\left(-\frac{\|\mathbf{x}-\mathbf{x}'\|^2}{2\sigma^2}\right)$. The training bottleneck of using kernels is to compute and store the kernel matrix $K \in \mathbb{R}^{n \times n}$ for n data points. It brings the computational concern in both time and space complexity and makes designing scalable algorithms for large-scale problems a challenging task. There are several approach to addressing this difficulty by making trade-off between and time as space. For example, LIBSVM (Chang and Lin, 2011) only caches some columns of kernel matrix to save the memory usage and re-compute the columns where there is a cache miss.

2.2 RANDOM FEATURE

The other way to define kernel is finding the explicit feature mapping $\phi(\mathbf{x})$ such that $k(\mathbf{x}, \mathbf{x}') = \phi(\mathbf{x})^\top \phi(\mathbf{x}')$. Bochner's theorem suggests a way to find this mapping for the stationary (shift-invariant) kernel, *i.e.,* $k(\mathbf{x}, \mathbf{x}') = k(\mathbf{x} - \mathbf{x}')$, and draws the community's attention in this decade (Rahimi and Recht, 2007).

Theorem 1. *(Bochner's Theorem) A continuous, real-valued, symmetric and shift-invariant function k on $\mathbb{R}^d$ is a positive definite kernel if and only if there is a positive finite measure $\mathbb{P}(\boldsymbol{\omega})$ such that*

$$k(\mathbf{x} - \mathbf{x}') = \int_{\mathbb{R}^d} 2\left(\cos(\boldsymbol{\omega}^\top \mathbf{x})\cos(\boldsymbol{\omega}^\top \mathbf{x}') + \sin(\boldsymbol{\omega}^\top \mathbf{x})\sin(\boldsymbol{\omega}^\top \mathbf{x}')\right) d\mathbb{P}(\omega),$$

For Gaussian RBF kernel, the corresponding density $\mathbb{P}(\omega)$ is the Gaussian distribution.

Inspired from Bochner's Theorem, we can approximate the kernel evaluation by the Monte-Carlo approximation. Define $\phi_\omega(\mathbf{x}) = \sqrt{2}[\cos(\boldsymbol{\omega}^\top \mathbf{x}), \sin(\boldsymbol{\omega}^\top \mathbf{x})]$ and $z(\mathbf{x}) = \frac{1}{\sqrt{m}}[\phi_{\boldsymbol{\omega}_1}(\mathbf{x}), \cdots, \phi_{\boldsymbol{\omega}_m}(\mathbf{x})]$, where $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_m$ are i.i.d. samples from $\mathbb{P}(\boldsymbol{\omega})$. We then have

$$k(\mathbf{x} - \mathbf{x}') = \mathbb{E}_\omega\left(\phi_\omega(\mathbf{x})\phi_\omega(\mathbf{x}')\right) \approx z(\mathbf{x})^\top z(\mathbf{x}')$$

and (1) can be transformed to

$$\mathbf{w}_* = \operatorname*{argmin}_{\mathbf{w}} \frac{\lambda}{2}\|\mathbf{w}\|^2 + \mathbb{E}_{(\mathbf{x},y)}[l(\mathbf{w}^\top z(\mathbf{x}), y)], \tag{2}$$

which can be solved by fast linear learning algorithms to handle million-scale data easily (Fan et al., 2008).

3 DOUBLY STOCHASTIC KERNEL MACHINE

By using random features, we can represent the feature mapping with a finite-length vector $z(\mathbf{x})$ and approximate the kernel evaluation by the inner product $k(\mathbf{x}, \mathbf{x}') \approx z(\mathbf{x})^\top z(\mathbf{x}')$. We are then able to transform problem (1) into the linear learning problem (2). The approximation error $\mathbb{E}[(f_*(\mathbf{x}) - \mathbf{w}_*^\top(\mathbf{x}))^2] \leq \epsilon$ can be bounded by ϵ with $O(1/\epsilon)$ number of random features (Rahimi and Recht, 2007), which is the consequence of the bound of Monte-Carlo approximation. More discussions on the optimality can be referred to Sriperumbudur and Szabó (2015).

Suppose we use m random features for approximation, then the space complexity for storing the transformed data

is $O(nm)$, where n is the number of data points. One line of research is to replace the simple Monte-Carlo with different sampling scheme to improve the learning with random features. Le et al. (2013) propose an efficient sampling procedure to save the feature generation time. Yang et al. (2014); Chen et al. (2015); Bach (2015) use different sampling strategies with faster convergence rate to reduce m.

In practice, to achieve accurate results, m usually has to be large, which cause the space cost for storing. For example, MNIST-8M data contains eight million training points. If we use 10^5 random features with `double` type, it takes more than 1T memory to store the transformed data, which is prohibitive to many machines. On the other hand, the kernel matrix K is approximated by $z(\mathbf{X})z(\mathbf{X})^\top$, where $z(\mathbf{X}) \in \mathbb{R}^{n\times m}$. However, K is not low rank and has long-tailed eigenvalue distributions for many commonly used kernels (Weyl, 1912; Wathen and Zhu, 2015), which implies there is no hope to accurately approximate K with small m.

Therefore, the other line of research is to save memory usage with large m. Yen et al. (2014) propose a algorithm by imposing a sparsity constraint in (2) to reduce the memory usage. However, the sparsity constraint makes the problem not an unbiased approximation of (1). Dai et al. (2014) propose to re-generate the random features repeatedly during the training to save the memory usage, which makes using a large number of random features possible.

3.1 DOUBLY STOCHASTIC GRADIENT

Dai et al. (2014) propose a novel algorithm by using "doubly functional gradient" to address the scalability issue of kernel methods. Given a data point $(\mathbf{x}, y)$, the stochastic functional gradient of (1) is $\nabla_f R(f) = \lambda f(\cdot) + \mathbb{E}_{(\mathbf{x},y)}[\xi(\cdot)]$, where $\xi(\cdot) = \ell'(f(\mathbf{x}), y)k(\mathbf{x}, \cdot)$. By Bocher's theorem, we could further approximate the functional gradient $\xi(\cdot)$ by the random feature $\phi_{\boldsymbol{\omega}}(\mathbf{x})$. That is, given $\boldsymbol{\omega} \sim \mathbb{P}(\boldsymbol{\omega})$ and a data point $(\mathbf{x}, y)$, the doubly stochastic gradient of $\ell(f(\mathbf{x}), y)$ with respect to $f \in \mathcal{H}$ is $\zeta(\cdot) = l'(f(\mathbf{x}), y)\phi_{\boldsymbol{\omega}}(\mathbf{x})\phi_{\boldsymbol{\omega}}(\cdot)$, where $\mathbb{E}_{\boldsymbol{\omega}}(\zeta(\cdot)) = \xi(\cdot)$. The following formula connects the randomness from data $(\mathbf{x}, y)$ and random feature $\boldsymbol{\omega}$,

$$\begin{aligned}\nabla_f R(f) &= \lambda f(\cdot) + \mathbb{E}_{(\mathbf{x},y)}[\xi(\cdot)] \\ &= \lambda f(\cdot) + \mathbb{E}_{(\mathbf{x},y)}\mathbb{E}_{\boldsymbol{\omega}}[\zeta(\cdot)].\end{aligned}$$

In each iteration t, the doubly stochastic gradient of $\ell(f(\mathbf{x}_t), y_t)$ is $\zeta_t(\cdot) = \ell'(f_t(\mathbf{x}_t), y_t)\phi_{\boldsymbol{\omega}_t}(\mathbf{x}_t)\phi_{\boldsymbol{\omega}_t}(\cdot)$ by sampling $\boldsymbol{\omega}_t$ from $\mathbb{P}(\boldsymbol{\omega})$ and $(\mathbf{x}_t, y_t)$ from $\mathbb{P}(\mathbf{x}, y)$. The update rule for the algorithm is

$$f_{t+1}(\cdot) = f_t(\cdot) - \gamma_t\left(\lambda f_t(\cdot) + \zeta_t(\cdot)\right) = \sum_{i=1}^{t} a_t^i \zeta_i(\cdot),$$

where a_t^i are coefficients from λ and γ_t in each iteration. For each data point $\mathbf{x}$, we do not need to pre-generate the corresponding $z(\mathbf{x})$ until we want to evaluate the function as well as the doubly stochastic gradient on $\mathbf{x}$. The potential problem is how to regenerate the $z(\mathbf{x})$ every time. If we store $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$, which takes $O(dt)$, when both d and t are large, it is still infeasible in practice. Thanks for the pseudo-randomness used in modern computers, we could use different random seeds for different iterations, then we are guaranteed to sample the same $\boldsymbol{\omega}$ back. Then the space complexity is only $O(t)$ for storing $\alpha_t^i = a_t^i \ell'(f_i(\mathbf{x}_i), y_i)\phi_{\boldsymbol{\omega}}(\mathbf{x}_i)$. We call the algorithm as DSG, which is shown in Algorithm 1. The convergence rate of DSG is proved in Dai et al. (2014) under the conditions of Assumption 2.

Algorithm 1 $\{\alpha_i\}_{i=1}^t = \textbf{DSG}(\mathbb{P}(\mathbf{x}, y))$

for $i = 1, \ldots, t$ **do**
  Sample $(\mathbf{x}_i, y_i) \sim \mathbb{P}(\mathbf{x}, y)$.
  Sample $\boldsymbol{\omega}_i \sim \mathbb{P}(\boldsymbol{\omega})$ with seed i.
  $f(\mathbf{x}_i) = \textbf{Predict}(\mathbf{x}_i, \{\alpha_j\}_{j=1}^{i-1})$.
  $\alpha_i = -\gamma_i l'(f(\mathbf{x}_i), y_i)\phi_{\boldsymbol{\omega}_i}(\mathbf{x}_i)$.
  $\alpha_j = (1 - \gamma_i\lambda)\alpha_j$ for $j = 1, \ldots, i-1$.
end for

Algorithm 2 $f(\mathbf{x}) = \textbf{Predict}(\mathbf{x}, \{\alpha_i\}_{i=1}^m)$

Set $f(\mathbf{x}) = 0$.
for $i = 1, \ldots, m$ **do**
  Sample $\boldsymbol{\omega}_i \sim \mathbb{P}(\boldsymbol{\omega})$ with seed i.
  $f(\mathbf{x}) = f(\mathbf{x}) + \alpha_i\phi_{\boldsymbol{\omega}_i}(\mathbf{x})$.
end for

Assumption 2.

1. *The optimal solution f_* to the problem (1) exists.*
2. *Loss function $\ell(u, y) : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ and its first-order derivative is L-Lipschitz continous in terms of the first argument.*
3. *There exists $M > 0$, such that $|\ell'(f_t(\mathbf{x}_t), y_t)| \leqslant M$. Note that in our situation $M < \infty$ exists since we assume bounded domain and the functions f_t we generate are always bounded as well.*
4. *There exists $\kappa > 0$ and $\phi > 0$, such that $k(\mathbf{x}, \mathbf{x}') \leqslant \kappa$, $|\phi_\omega(\mathbf{x})\phi_\omega(\mathbf{x}')| \leqslant \phi, \forall \mathbf{x}, \mathbf{x}' \in \mathcal{X}, \omega \in \Omega$. For Gaussian RBF kernel, we have $\kappa = 1$, $\phi = 2$.*

Theorem 3 (Convergence rate of DSG (Dai et al., 2014)). *When $\gamma_t = \frac{\theta}{t}$ with $\theta > 0$ such that $\theta\lambda \in (1, 2) \cup \mathbb{Z}_+$, for any $x \in \mathcal{X}$,*

$$\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[|f_{t+1}(x) - f_*(x)|^2\right] \leqslant \frac{2C_0^2 + 2\kappa S_0^2}{t},$$

where

$$S_0 = \max\left\{\|f_*\|_{\mathcal{H}}, \frac{Q_0 + \sqrt{Q_0^2 + Z(1+\theta\lambda)^2\theta^2\kappa M^2}}{Z}\right\},$$

with $Z = 2\lambda\theta - 1$, $Q_0 = \sqrt{2}\kappa^{1/2}LC_0\theta$, *and* $C_0 = 2(\kappa + \phi)M\theta$.

4 FAST DOUBLY STOCHASTIC KERNEL MACHINES

The $O(1/t)$ convergence rate in Theorem 3 is already optimal as proved in Dai et al. (2014). However, we could still improve DSG. In in each iteration, DSG is required to evaluate $f(\mathbf{x})$ for calculating gradients in each iteration, which needs to go through $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$ to compute $\phi_{\boldsymbol{\omega}_i}(\mathbf{x})$ in Algorithm 2. For continuous distributions, such as Gaussian distribution $\mathbb{P}(\boldsymbol{\omega})$ for Gaussian kernel, the collision probability of sampling is zero. After t iterations, we have t different $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_t$ for the feature generation. Then the complexity of the t^{th} iteration is $O(td)$, and the total complexity from iteration 1 to iteration t is $O(t^2d)$, which makes DSG less efficient when t is large.

On the other hand, DSG could be treated as a random coordinate descent (RCD) with mini-batch. In each iteration t, sampling $\boldsymbol{\omega}_t$ can be treated as choosing one coordinate to update. Since the collision probability is zero, it is equivalent to updating a new coordinate in every iteration. From the perspective of RCD, we could also choose an "old" coordinate to update instead of sampling new $\boldsymbol{\omega}$ in certain iterations. Then we could reduce the number of used coordinates.

In what follows, we will present two algorithms, UDSG and CDSG, which "utilize" previous coordinates. UDSG is a nature extension from RCD. Studying its theoretical analysis gives us deeper insight to design the non-trivial algorithm CDSG, which enjoys the better bound of sample complexity than UDSG. In some following descriptions, we will abuse $\boldsymbol{\omega}_i$ as the coordinate index for convenience.

4.1 UTILIZE WITH UNIFORM SAMPLING

A simple strategy is using empirical distribution to approximate $\mathbb{P}(\boldsymbol{\omega})$, which is a widely-used technique in statistics. Assume we already independently sample $\boldsymbol{\Omega}^m = \{\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_m\}$ from $\mathbb{P}(\boldsymbol{\omega})$, then we could create an empirical distribution $\hat{\mathbb{P}}_m(\boldsymbol{\omega})$, which is a uniform distribution on $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_m$. Sampling from $\hat{\mathbb{P}}_m(\boldsymbol{\omega})$ is unbiased since $\mathbb{E}_{\boldsymbol{\Omega}^m}\mathbb{E}_{\boldsymbol{\omega}\sim\hat{\mathbb{P}}_m}[\boldsymbol{\omega}|\boldsymbol{\Omega}^m] = \mathbb{E}_{\boldsymbol{\omega}\sim\mathbb{P}}(\boldsymbol{\omega})$. When m is large, we could expect the empirical distribution $\hat{\mathbb{P}}_m(\boldsymbol{\omega})$ to be a good approximation of $\mathbb{P}(\boldsymbol{\omega})$. Note that it is similar to typical RCD algorithm over a finite number of dimensions.

Here we study one simple algorithm for a concise presentation, which periodically samples from $\mathbb{P}(\boldsymbol{\omega})$ for G iterations and then sample from the empirical distribution $\hat{\mathbb{P}}(\boldsymbol{\omega})$ for U iterations. The number of random features m after t iterations is $O(Gt/G + U)$. The proposed algorithm, doubly stochastic gradients descent with uniform sampling, which is called UDSG and shown in Algorithm 3. Based on Assumption 2, the convergence rate of UDSG is shown in Theorem 4.

Algorithm 3 $\{\alpha_i\}_{i=1}^m = \textbf{UDSG}(\mathbb{P}(\mathbf{x}, y))$

```
m = 0
for i = 1, ..., t do
  Sample (x_i, y_i) ~ P(x, y).
  f(x_i) = Predict(x_i, {α_j}_{j=1}^m).
  if mod(i, G + U) < G then
    Sample ω_{m+1} ~ P(ω) with seed m + 1.
    α_j = (1 − γ_i λ) α_j for j = 1, ..., m.
    α_{m+1} = −γ_i ℓ'(f(x_i), y_i) φ_{ω_{m+1}}(x_i).
    m = m + 1
  else
    Sample ω_k ~ P̂_m(ω), where 1 ≤ k ≤ m.
    α_j = (1 − γ_i λ) α_j for j = 1, ..., m.
    α_k = α_k − γ_i ℓ'(f(x_i), y_i) φ_{ω_k}(x_i).
  end if
end for
```

Theorem 4 (Convergence rate of UDSG). *When* $\gamma_t = \frac{\theta}{t}$ *with* $\theta > 0$ *such that* $\theta\lambda \in (1, 2) \cup \mathbb{Z}_+$, *for any* $\mathbf{x} \in \mathcal{X}$,

$$\mathbb{E}_{\mathcal{D}^t,\boldsymbol{\omega}^t}\left[|f_{t+1}(\mathbf{x}) - f_*(\mathbf{x})|^2\right] \leqslant \frac{2C_1^2 + 2\kappa S_1^2}{t},$$

where

$$S_1 = \max\left\{\|f_*\|_{\mathcal{H}}, \frac{Q_1 + \sqrt{Q_1^2 + Z(1+\theta\lambda)^2\theta^2\kappa M^2}}{Z}\right\},$$

with $Z = 2\lambda\theta - 1$, $Q_1 = \sqrt{2}\kappa^{1/2}LC_1\theta$, *and* $C_1 = 2(\kappa + \phi)M\theta\sqrt{1 + \frac{2U}{G+U} + \frac{2U^2}{G(G+U)} + \frac{2U(U-1)}{Gt}}$

4.1.1 PROOF OF THEOREM 4

We provide a proof sketch here. Our analysis closely follows Dai et al. (2014) but we need to carefully deal with several cross-terms as shown in (3) later. Some technical lemmas are in Appendix.

We decompose the error into two terms,

$$|f_t(\mathbf{x}) - f^*(\mathbf{x})|^2 \leq 2|f_t(\mathbf{x}) - h_t(\mathbf{x})|^2 + 2\kappa\|h_t - f^*\|_{\mathcal{H}}^2,$$

where

$$h_t(\cdot) = \mathbb{E}_{\boldsymbol{\omega}}[f_t(\cdot)] = \mathbb{E}_{\boldsymbol{\omega}}[\sum_{i=1}^{t} a_t^i\zeta_{\boldsymbol{\omega}_i}(\cdot)] = \sum_{i=1}^{t} a_t^i\xi_{\boldsymbol{\omega}_i}(\cdot).$$

Since $\mathbb{E}_{\mathcal{D}^t,\boldsymbol{\omega}^t}\left[\|h_{t+1} - f_*\|_{\mathcal{H}}^2\right] \leqslant \frac{S^2}{t}$, where S is a constant related to $\mathbb{E}_{\mathcal{D}^t,\boldsymbol{\omega}^t}\left(|f_{t+1}(\mathbf{x}) - h_{t+1}(\mathbf{x})|^2\right)$ as shown in Dai et al. (2014), the remaining task is to bound $\mathbb{E}_{\mathcal{D}^t,\boldsymbol{\omega}^t}\left(|f_{t+1}(\mathbf{x}) - h_{t+1}(\mathbf{x})|^2\right)$. We define the following terms to simplify the notations.

- $\mathcal{G} = \{x | (x-1) \bmod (G+U) < G \text{ and } 1 \le x \le t\}$.
- $\mathcal{G}_k = \{x | x \in \mathcal{G} \text{ and } \lceil x/(G+U) \rceil = k\}$.
- $\mathcal{U}_k = \{x | x \notin \mathcal{G}, \lceil x/(G+U) \rceil = k \text{ and } 1 \le x \le t\}$.
- $V_i(\mathbf{x}) = a_t^i \left(\zeta_t(\mathbf{x}) - \xi_t(\mathbf{x})\right)$.

By definition, we have $\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left(|f_{t+1}(\mathbf{x}) - h_{t+1}(\mathbf{x})|^2\right) = \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\sum_{i=1}^t V_i(\mathbf{x})\right)^2\right]$, then

$$
\begin{aligned}
& \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\sum_{i=1}^t V_i(\mathbf{x})\right)^2\right] \\
= & \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\sum_{\mathcal{G}} V_i(\mathbf{x}) + \sum_{k=1}^{\lceil t/(G+U) \rceil} \sum_{i \in \mathcal{U}_k} V_i(\mathbf{x})\right)^2\right] \\
\le & \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\sum_{\mathcal{G}} V_i(\mathbf{x})\right)^2 + \sum_{k=1}^{\lceil t/(G+U) \rceil} \left(\sum_{i \in \mathcal{U}_k} V_i(\mathbf{x})\right)^2\right. \\
& +2 \sum_{k=1}^{\lceil t/(G+U) \rceil} \left(\sum_{i \in \mathcal{U}_k} V_i(\mathbf{x})\right)\left(\sum_{\mathcal{G}} V_i(\mathbf{x})\right) \\
& \left. \sum_{p=1}^{\lceil \frac{t}{G+U} \rceil - 1} \sum_{q=p+1}^{\lceil \frac{t}{G+U} \rceil} \left(\sum_{i \in \mathcal{U}_p} V_i(\mathbf{x})\right)\left(\sum_{i \in \mathcal{U}_q} V_i(\mathbf{x})\right)\right].
\end{aligned} \tag{3}
$$

We complete the proof by bounding each term. For details please refer to the Appendix.

4.1.2 TOTAL COMPLEXITY

The sample complexity bound in Theorem 4 is clearly worse than the result in Theorem 3 for DSG. However, we should take the complexity of single iteration into account for comparison. After t iterations, the ratio of the number of used $\boldsymbol{\omega}$ between UDSG and DSG is $O(G/G+U)$.

We suppose Q_1^2 in Theorem 4 dominates $Z(1+\theta\lambda)^2\theta^2\kappa M^2$. Also, we assume $S_0 > \|f_*\|_{\mathcal{H}}$ and $S_1 > \|f_*\|_{\mathcal{H}}$ in Theorem 3 and Theorem 4, respectively. The ratio between sample complexities of Theorem 3 and Theorem 4 is close to $O(1 + \frac{2U}{G+U} + \frac{2U^2}{G(G+U)} + \frac{2U(U-1)}{Gt})$. Then the ratio r between the total complexity of DSG and UDSG is

$$
\begin{aligned}
r &\ge \left(1 + \tfrac{2U}{G+U} + \tfrac{2U^2}{G(G+U)}\right) \times \tfrac{G}{G+U} \\
&= \left(1 + \tfrac{2U}{G+U} \times \tfrac{G+U}{G}\right) \tfrac{G}{G+U} \\
&= \tfrac{G+2U}{G+U},
\end{aligned}
$$

This result suggests setting U to be zero to minimize the complexity, which implies DSG is theoretically no worse than UDSG under certain conditions. However, this pessimistic result inspires us to design a better algorithm in Section 4.2.

4.2 UTILIZE WITH CHECKING

In each iteration t, we could either pick up the coordinate we have used, or sample a new coordinate from $\mathbb{P}(\boldsymbol{\omega})$ to update. The uniform sampling strategy algorithm, UDSG, has a worse bound than DSG, which implies updating a new coordinate $\boldsymbol{\omega} \sim \mathbb{P}(\boldsymbol{\omega})$ reduces the objective more than updating old coordinates in expectation. Therefore, before updating, we should "*check*" the old coordinate to ensure the chosen coordinate $\boldsymbol{\omega}_k$ is as effective as the newly sampled coordinate $\boldsymbol{\omega} \sim \mathbb{P}(\boldsymbol{\omega})$.

We start by investigating the reason that causes UDSG to be worse than DSG in expectation. We take the simple case that we sample $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_{t-1}$ from $\mathbb{P}(\boldsymbol{\omega})$ as DSG and set $\boldsymbol{\omega}_t = \boldsymbol{\omega}_k$, where $1 \le k \le t-1$. Then $\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}(|f_{t+1}(\mathbf{x}) - h_{t+1}(\mathbf{x})|^2) = \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\left(\sum_{i=1, i\neq k}^{t-1} V_i(\mathbf{x})\right) + \left(V_k(\mathbf{x}) + V_t(\mathbf{x})\right)\right)^2\right]$. We abbreviate $\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}(\cdot)$ as $\mathbb{E}(\cdot)$ in the following context for a succinct representation.

Lemma 5. *(Dai et al., 2014)*

If $\boldsymbol{\omega}_i$ and $\boldsymbol{\omega}_j$ are i.i.d. samples from $\mathbb{P}(\omega)$, $\mathbb{E}\left[\left(V_i(\mathbf{x}) + V_j(\mathbf{x})\right)^2\right] = \mathbb{E}\left(V_i(\mathbf{x})^2\right) + \mathbb{E}\left(V_j(\mathbf{x})^2\right)$.

We then have the bound

$$
\begin{aligned}
& \mathbb{E}\left[\left(\sum_{i=1}^t V_i(\mathbf{x})\right)^2\right] \\
\le & \sum_{i=1, i\neq k}^{t-1} \mathbb{E}\left(V_i(\mathbf{x})^2\right) + \mathbb{E}\left[\left(|V_k(\mathbf{x})| + |V_t(\mathbf{x})|\right)^2\right].
\end{aligned} \tag{4}
$$

In contrast, the bound of DSG is

$$
\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left[\left(\sum_{i=1}^t V_i(\mathbf{x})\right)^2\right] \le \sum_{i=1}^t \mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left(V_i(\mathbf{x})^2\right). \tag{5}
$$

The cross term $\mathbb{E}_{\mathcal{D}^t, \boldsymbol{\omega}^t}\left(|V_k(\mathbf{x})||V_t(\mathbf{x})|\right)$ from expanding the quadratic term in (4) causes a worse bound than (5). The generalization of this simple example is Theorem 4 in Section 4.1. The cross terms cause a larger constant C_1 in Theorem 4 than C_0 in Theorem 3.

Without any further knowledge about $V_k(\mathbf{x})$ and $V_t(\mathbf{x})$, the upper bound in (4) is unavoidable. Therefore, in iteration t, we should choose $1 \le k \le t-1$ such that the upper bound U_t of $\mathbb{E}\left[\left(V_k(\mathbf{x}) + V_t(\mathbf{x})\right)^2\right]$ can be bounded by the bound of $\mathbb{E}\left(V_k(\mathbf{x})^2\right) + \mathbb{E}\left(V_t(\mathbf{x})^2\right)$. To be specific, we should select k such that

$$
U_t \le \mathbb{E}\left[\left(a_t^k \ell'(f_k(\mathbf{x}_k), y_k)\right)^2 + \left(a_t^t \ell'(f_t(\mathbf{x}_t), y_t)\right)^2\right](\kappa+\phi)^2. \tag{6}
$$

For convenience, we let $g_i = \ell'(f_i(\mathbf{x}_i), y_i)$ and $\Phi_{\mathbf{x}}(\boldsymbol{\omega}_i, \mathbf{x}_k) = \phi_{\boldsymbol{\omega}_i}(\mathbf{x}_k)\phi_{\boldsymbol{\omega}_k}(\mathbf{x}) - k(\mathbf{x}_k, \mathbf{x})$. Expanding

$V_k(\mathbf{x})$ and $V_t(\mathbf{x})$ results the upper bound U_t as

$$\begin{aligned} & \mathbb{E}\left[(V_k(\mathbf{x}) + V_t(\mathbf{x}))^2\right] \\ = \; & \mathbb{E}\left[\left(a_t^k g_k \Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, \mathbf{x}_k) + a_t^t g_t \Phi_{\mathbf{x}}(\boldsymbol{\omega}_t, \mathbf{x}_t) + \right.\right. \\ & \left.\left. a_t^t g_t \Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, \mathbf{x}_k) - a_t^t g_t \Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, \mathbf{x}_k)\right)^2\right] \\ \leq \; & 2\mathbb{E}\left[\left(a_t^k g_k + a_t^t g_t\right)^2\right](\kappa + \phi)^2 \\ & + 2\left((a_t^t M)^2\right)\mathbb{E}\left[\left(\Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, \mathbf{x}_t) - \Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, \mathbf{x}_k)\right)^2\right]. \end{aligned} \tag{7}$$

Note that we suppose $\boldsymbol{\omega}_t = \boldsymbol{\omega}_k$.

If x_1 and x_2 are *i.i.d.* samples from $\mathbb{P}(x)$, then $\mathbb{E}\left((x_1 - x_2)^2\right) = 2\mathrm{Var}(x)$. Let $\sigma^2 = \mathbb{E}_{\boldsymbol{\omega}_k}\left[\mathrm{Var}_y\left(\Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, y)\right)\right]$ and $\beta_t^k = a_t^k g_k$. Incorporating (7) into (6) with the above fact of variance results the selection criterion as choosing $\boldsymbol{\omega}_k$ such that

$$\begin{aligned} & 2\mathbb{E}\left[(\beta_t^k + a_t^t g_t)^2\right](\kappa + \phi)^2 + 2\left(a_t^t M \sigma(\kappa + \phi)\right)^2 \\ \leq \; & \mathbb{E}\left[(\beta_t^k)^2 + (a_t^t g_t)^2\right](\kappa + \phi)^2. \end{aligned} \tag{8}$$

4.2.1 MINI-BATCH AND EXPECTED LINE SEARCH

In (8), smaller $a_t^t M\sigma(\kappa + \phi)$ makes it easier to find an $\boldsymbol{\omega}_k$ which satisfies (8). Reducing $a_t^t M\sigma(\kappa + \phi)$ comes for free by using the mini-batch extension of stochastic gradient descent. If the batch size is B, the variance of $\frac{1}{B}\sum_{i=1}^{B}\Phi_{\mathbf{x}_i}(\boldsymbol{\omega}_k, y)$ is $\frac{1}{B}\mathrm{Var}_y\left(\Phi_{\mathbf{x}}(\boldsymbol{\omega}_k, y)\right)$.

Also, instead of setting $a_t^t = -\gamma_t$, we could further do line-search in expectation for a steeper descent with a larger step size. Assume the step size is η, and we want to keep the error upper bounded by DSG. Therefore, given $\boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_{t-1}$, combining with the mini-batch extension, We find the largest step size $\eta < -\gamma_t$, such that

$$2(\beta_t^k + \eta g_t)^2 + \frac{2\left(\eta M\sigma\right)^2}{B^2} \leq (\beta_t^k)^2 + (a_t^t g_t)^2. \tag{9}$$

The optimization problem (9) is a quadratic inequality, which can be solved with the analytical solution. We then choose $\boldsymbol{\omega}_k$ with the max step size $|\eta_k|$ to update. We call the algorithm as "doubly stochastic gradient descent with checking" (CDSG), which is shown in Algorithm 4. For simplicity, we show the case when $B = 1$ in Algorithm 4, but one can extend it to general $B > 1$ cases.

Convergence rate of CDSG. The convergence rate of CDSG is exactly the same as Theorem 3. We omit the proof in the Appendix.

5 EXPERIMENT

In this section, we first study medium-scale data, which allows us to do thorough comparisons to understand the trade-off between different algorithms. We then also show the results on the large-scale datasets. Last, we compare DSG-based algorithms with deep neural nets. The details of the datasets are shown in Table 1.

Algorithm 4 $\{\alpha_i\}_{i=1}^m = \mathbf{CDSG}(\mathbb{P}(\mathbf{x}, y))$

$m = 0$
for $i = 1, \ldots, t$ **do**
  Sample $(\mathbf{x}_i, y_i) \sim \mathbb{P}(\mathbf{x}, y)$.
  $f(\mathbf{x}_i) = \mathbf{Predict}(\mathbf{x}_i, \{\alpha_j\}_{j=1}^m)$.
  Compute step sizes $\eta_1, \ldots, \eta_m$ via (9), and suppose $|\eta_k| = \mathrm{argmax}_j |\eta_j|$.
  if $|\eta_j| \leq \gamma_t$ **then**
    $\alpha_j = (1 - \gamma_i\lambda)\alpha_j$ for $j = 1, \ldots, m$.
    $\alpha_{m+1} = -\gamma_i \ell'(f(\mathbf{x}_i), y_i)\phi_{\boldsymbol{\omega}_{m+1}}(\mathbf{x}_i)$.
    $\beta_j = (1 - \gamma_i\lambda)\beta_j$ for $j = 1, \ldots, m$.
    $\beta_{m+1} = -\gamma_i \ell'(f(\mathbf{x}_i), y_i)$.
    $m = m + 1$
  else
    $\alpha_j = (1 - \eta_k\lambda)\alpha_j$ for $j = 1, \ldots, m$.
    $\alpha_k = \alpha_k - \eta_k \ell'(f(\mathbf{x}_i), y_i)\phi_{\boldsymbol{\omega}_k}(\mathbf{x}_i)$.
    $\beta_j = (1 - \eta_k\lambda)\alpha_j$ for $j = 1, \ldots, m$.
    $\beta_k = \alpha_k - \eta_k \ell'(f(\mathbf{x}_i), y_i)$.
  end if

MNIST-8M	8.1 M	10K	10
ImageNet 2012	1.3 M	0.1M	1000

Table 1: The dataset information for experiments, where the label of Year is real number.

General Setting In all experiments, we use Gaussian kernel. The kernel bandwidth is obtained by the median trick (Smola, 2004). For UDSG, we set $G = 1$ and $U = 1$. The other parameters will be specified later.

5.1 MEDIUM-SCALE DATA

We observed that the algorithms tend to overfit the medium-scale data without carefully tunning regularization terms. In this subsection, we only compare the training objectives, which is a natural criterion for optimization problems.

Setting for Medium-Scale Data For the CIFAR-10, we use raw pixels as input. Also, we conduct PCA to reduce the number of dimension of every datasets to be no more than 100. The parameters for DSG-based algorithms are shown in Table 2, where the feature block F means we sample F random features in each iteration. For non-DSG-

Dataset	Batch Size B	Feature Block F	λ
CIFAR10	$4,096$	256	10^{-5}
Epsilon	$10,000$	512	10^{-5}
Year	$10,000$	512	10^{-5}

Table 2: Parameters for DSG-based algorithms on medium-scale datasets.

based algorithms, which pre-generate random features for the data points, we set the number of random features as $4F$.

Compare with Other Approximation There are several competitors that can be considered, such as Kivinen et al. (2004), kernel SDCA (Shalev-Shwartz and Zhang, 2013), and several stochastic optimization algorithms with random feature or Nyström method (Shalev-Shwartz and Zhang, 2013; Johnson and Zhang, 2013; Nesterov, 2012). Here we only choose SVRG (Johnson and Zhang, 2013) with random features, which has been shown to be one of the best among the above algorithms.

We compare DSG, UDSG, CDSG and SVRG (Johnson and Zhang, 2013) with multi-class kernel logistic regression and kernel ridge regression. The results are shown in Figure 1.

We first look at Figure 1(a), Figure 1(b) and Figure 1(c). Since we only use $4F$ random features for SVRG, is not surprising that SVRG with limited random features converges to unsatisfactory results at the early stage. Without the enough number of the random features, the bottleneck of the learning is the approximation error instead of the optimization algorithms. Although we can use more features than $4F$ to achieve better performance for medium-scale data, it takes longer time and more memory for training. This issue becomes more critical in the large-scale applications. The memory usage can even make this approach prohibitive to large-scale problems. Note that we do not show SVRG in Figure 1(d), Figure 1(e) and Figure 1(f) since it converges out of the range.

Second, we compare DSG-based algorithms. In Figure 1(b), UDSG performs worse than DSG, which confirms the bound of Theorem 4 and the worst-case discussion of uniform sampling in Section 4.2. However, we observe that the worst case does not occur often in practice. Although the analysis in Section 4.1.2 is pessimistic, UDSG generally outperforms DSG in Figure 1. On the other hand, the proposed CDSG outperforms both DSG and UDSG in all datasets, which justifies the correctness of the validity of the proposed checking rule and expected line search in Section 4.2.

Compare with Exact Optimization We compare DSG-based algorithms with LIBSVM (Chang and Lin, 2011), which is the state-of-the-art solver for kernel learning by using kernel matrices. We consider kernel SVM in this comparison since there is no kernel logistic regression implementation in LIBSVM. We report the performance of each algorithm when LIBSVM converges. CIFAR-10 and Epsilon take LIBSVM 583 and 8457 seconds to converge, respectively. The results are shown in Table 3.

	LIBSVM	DSG	UDSG	CDSG
CIFAR-10	0.386	0.407	0.402	0.402
Epsilon	0.143	0.145	0.146	0.145

Table 3: The training error of each algorithm at the time when LIBSVM converges.

In these experiments, to achieve high-precision results, the exact optimization is always preferable in practice if we have enough memory. We observe that in both CIFAR-10 and Epsilon, DSG-based algorithms achieve the satisfactory performance quickly, but they take longer time to converge to the precise results. For example, all DSG-based algorithms can achieve 0.15 error of Epsilon within 150 seconds. Especially, CDSG can achieve 0.147. However, they take more than $10,000$ seconds to get the error lower than 0.144. We address this issue to the variance from doubly stochastic methodology, which requires the learning rate to be small and make the learning slow in the later iterations as the typical SGD algorithms (Johnson and Zhang, 2013; Shalev-Shwartz and Zhang, 2013).

5.2 LARGE-SCALE DATA

We study MNIST-8M digit recognition dataset, which contains 8.1 million training data and 10 classes. We reduce the raw pixel to 100 dimensions as feature and set $B = 20,000$, $F = 4096$ and $\lambda = 10^{-6}$. LIBSVM cannot run on this dataset due to the memory limitation, and we can only load 500 pre-generated random features into our memory, which results in unsatisfactory result (0.05 training and testing error) with any algorithms, such as SVRG. Therefore, we focus on the comparison on DSG-based algorithms. The result is shown in Figure 2[1].

As one can see from Figure 2, CDSG consistently outperforms the other two algorithms in both training objectives and testing error as well as under different loss functions. The results justify the correctness and usefulness of the proposed CDSG again. In contrast, UDSG does not perform as well as Figure 1, which confirms the worst case analysis in Theorem 4.

5.3 STUDY WITH DEEP NEURAL NET

We follow Dai et al. (2014) to compare DSG-based algorithms with deep neural nets on image classification

[1]Compared with multi-class logistic regression, the training objective of one-vs-one kernel SVM is less meaningful, so we do not compare it.

MNIST-8M	5.3	5.4	**5.3**	7.1	6.2
ImageNet	44.9	44.8	44.7	46.2	**42.4**

Table 6: The converged results (%) of all algorithms for each dataset.

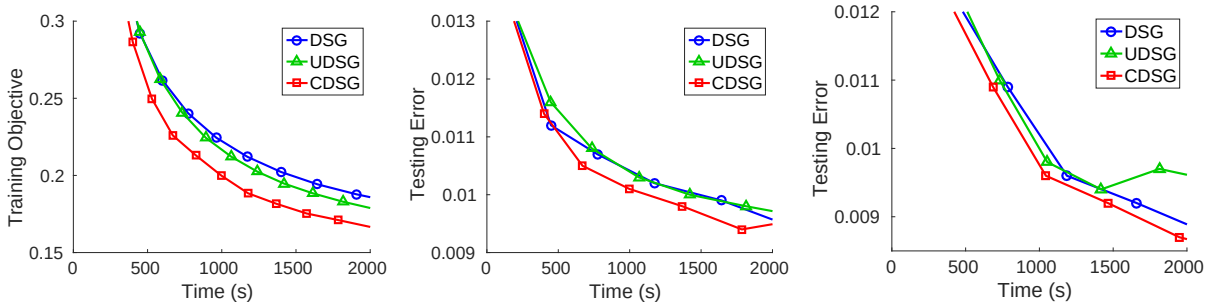
tasks. Besides CIFAR-10 and MNIST-8M, we also study ImageNet-2012, which is one of the most challenging image classification data currently. Since we do not aim to compare the representation learning ability, we use the pre-trained features provided by Dai et al. (2014). The detailed information of the used neural-net architectures (LeCun et al., 1998; Krizhevsky et al., 2012) can be found in the Appendix.

We study the following algorithms and the parameters are shown in Table 4.

- **Joint:** Put two fully connected layers at the top of the neural net for classification and train these two layers and the pre-trained layers "jointly".
- **Fixed:** Put two fully connected layers at the top of the neural net for classification and only train these two layers and without modifying pre-trained layers.
- **DSG-based:** Apply DSG algorithms on the pre-trained features.

Since the joint-trained neural net takes much more time than other algorithms, we report the results when CDSG converges in Table 5. The result shows that DSG-based algorithms converge faster than deep neural nets, and CDSG is the best in this family. For example, CDSG converges to 44.7% testing error on ImageNet. At the same time, the joint-trained neural net only achieves 58.6% testing error.

The converged results of all algorithms are shown in Table 6. In both CIFAR-10 and MNIST-8M, the CDSG algorithm is better than neural nets, which suggests proposed CDSG is not only efficient but also effective in some tasks. However, in ImageNet, the joint-trained neural net is still



(a) Training objective of logistic regression (b) Testing error of logistic regression (c) Testing error of SVM

Figure 2: Training objective of logistic regression on MNIST-8M.

the state-of-art by using more than twice of the training time needed for CDSG. We address the performance gap to the unsatisfactory representativeness of the pre-trained features, because the time for learning pre-trained features provided by Dai et al. (2014) only takes less than 10% of the training time. We could expect better pre-trained features could result in better performance of CDSG, but it takes more time for getting pre-trained features. Also, if we only have limited training time budget, such as the fine-tunning step in training deep neural networks, CDSG enjoys the advantage of the fast training to achieve satisfactory results quickly as shown in Table 5.

6 CONCLUSION

In this paper, we extended the DSG algorithm (Dai et al., 2014) to be more efficient by utilizing previous coordinates. We studied two algorithms including UDSG and CDSG. UDSG samples old coordinates with uniform sampling, which results in a worse convergence bound than the original DSG, though it outperforms DSG usually in practice. We also propose the other variant, CDSG, which selects previous coordinates in a more conservative way by checking the upper bound of the expected error. In the theoretical side, CDSG enjoys the same bound as DSG; in the practical side, CDSG is demonstrated to have better performance than DSG and UDSG consistently in all datasets we studied.

From our empirical study, we make the following suggestions.

Medium-Scale Data: If the size of memory permits and we want to achieve high-precision result, the solver with exact optimization by computing kernel matrices is still preferable, such as LIBSVM. However, they take longer time than the time needed for CDSG to achieve satisfactory performance (less than 5 minutes in all datasets we studied). For some medium-scale data we studied, the exact optimization solver takes hours to converge.

Large-Scale Data: For large-scale problems, such as ImageNet, the proposed CDSG algorithm enjoys several advantages. First, it is memory efficient, so we are allowed to use a large number of random features for kernel approximation, Second, it is computationally efficient and much faster than the original DSG algorithm. Under the situation with limited time budget, CDSG can quickly achieve satisfactory performance. However, if we want to achieve the state-of-the-art performance as deep neural nets, the proposed kernel approximation needs better feature representation as input to achieve better performance. Otherwise, the jointly-trained neural net may be preferable. The other alternative is combining the recent development of unsupervised training of deep neural networks (Doersch et al., 2015) with CDSG, which could possibly give us competitive performance with jointly-trained neural nets.

Abstract

An iterative procedure introduced in MacKay's evidence framework is often used for estimating the hyper-parameter in empirical Bayes. Despite its effectiveness, the procedure has stayed primarily as a heuristic to date. This paper formally investigates the mathematical nature of this procedure and justifies it as a well-principled algorithm framework. This framework, which we call the MacKay algorithm, is shown to be closely related to the EM algorithm under certain Gaussian assumption.

1 INTRODUCTION

As a bridge between full Bayesian models and completely frequentist models, the empirical Bayesian method (also known as empirical Bayes in short, or type-II maximum likelihood) has been applied to many learning, inference or prediction applications (see. e.g. [Schäfer and Strimmer, 2005, Efron, 2012, Heskes, 2000, Yang et al., 2004, Frost and Savarino, 1986, DuMouchel and Pregibon, 2001]). The generic setup of empirical Bayes consists the observed data $\mathbf{D}$, the model parameter $\mathbf{z}$ that parametrizes the data likelihood function $p(\mathbf{D}|\mathbf{z})$, and the prior distribution $p(\mathbf{z})$ of the model parameter. In the parametric version of empirical Bayes (Figure 1), the prior distribution is parameterized by certain hyper-parameter $\boldsymbol{\alpha}$, namely, as $p(\mathbf{z}|\boldsymbol{\alpha})$, and the philosophy of empirical Bayes is to estimate the hyper-parameter $\boldsymbol{\alpha}$ from the observed data $\mathbf{D}$.

As empirical Bayes treats the model parameter $\mathbf{z}$ as a latent random variable, the estimation of the hyper-parameter $\boldsymbol{\alpha}$ naturally fits in the framework of the EM algorithm [Dempster et al., 1977, Carlin and Louis, 1997], and the EM-based solutions have been developed to solve this problem in various application domains (see, e.g., [Inoue and Tanaka, 2001, Clyde and George, 2000]). Among other approaches to this problem, a technique introduced by MacKay is also widely adopted in practice[Bishop, 1999, Tipping, 2001, Tipping et al., 2003, Wipf and Nagarajan, 2008, Tan and Févotte, 2009].

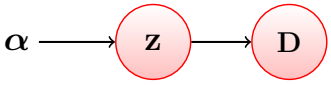

Figure 1: The generic model of empirical Bayesian method

In his "evidence framework" [MacKay, 1992b, MacKay and Neal, 1994, MacKay, 1995], MacKay considers a hierarchical Bayesian model similar to that in Figure 1 but with one distinction: an additional hyper-prior $p(\boldsymbol{\alpha}|\mathcal{H})$, which depends on the choice $\mathcal{H}$ of model, is placed on the hyper-parameter $\boldsymbol{\alpha}$. In this setting, the evidence framework addresses three levels of inference problems: 1) given the hyper-parameter $\boldsymbol{\alpha}$, inferring $\mathbf{z}$, 2) given the model $\mathcal{H}$, inferring $\boldsymbol{\alpha}$, and 3) evaluating model $\mathcal{H}$. MacKay shows [MacKay, 1995] that the three levels of inference may be combined for prediction and for automatic shrinkage of parameter spaces (namely, Automatic Relevance Determination, or ARD) for neural network regression models. The second-level inference in the evidence framework is closely related to empirical Bayes. In particular, when a flat hyper-prior $p(\boldsymbol{\alpha}|\mathcal{H})$ is placed on $\boldsymbol{\alpha}$, the objective of the second-level inference coincides with the objective of empirical Bayes. For the second-level inference, MacKay introduces a procedure that alternates between inferring $\mathbf{z}$ given $\boldsymbol{\alpha}$ (first-level inference) and inferring $\boldsymbol{\alpha}$ given $\mathbf{z}$. This procedure, although well appreciated in some classical papers (e.g., [Bishop, 1999]) and highly cited in ARD related literature (e.g., [Bishop, 1999, Tipping, 2001, Tan and Févotte, 2009]), is called the *MacKay algorithm* in this paper.

Richong Zhang is the corresponding author of this work (email: zhangrc@act.buaa.edu.cn)

Since its birth, the MacKay algorithm has been applied to various empirical Bayes models and its performance is often compared with the EM algorithm. For example, the MacKay algorithm is applied to the Bayesian PCA model [Bishop, 1999] and a non-negative matrix factorization model [Tan and Févotte, 2009] for automated shrinkage of the latent-space dimensions. In [Tipping, 2001], the MacKay algorithm is applied to SVM regression models for promoting sparsity, and it is shown to converge faster than the EM algorithm.

Despite its effectiveness, the mathematical principle and optimization objective of the MacKay algorithm are however not well characterized in the literature to date. In MacKay's original exposition [MacKay and Neal, 1994, MacKay, 1995], the second-level inference task is clearly stated, but the justification of the iterative procedure (i.e., the MacKay algorithm) is mainly heuristic. In addition, since the MacKay's algorithm is often implemented with a particular update procedure, known as the fixed-point iteration [Solomon, 2015, Hyvärinen, 1999], or the "MacKay update", the boundary between the *framework* of the MacKay algorithm and MacKay's fixed-point *update rule* is often blurred in the literature. This makes the MacKay algorithm often understood in a narrow sense as this specific fixed-point update rule, rather than as an *algorithm framework*.

In this paper, under a generic formulation of the empirical Bayes model (Figure 1), we re-formulate the MacKay algorithm as a coordinate-ascent procedure for solving a well-defined optimization problem. This optimization problem shares some similarity with the optimization problem underlying the EM algorithm: its objective function is a lower bound of the true objective function defining the optimization objective of empirical Bayes. Also similar to the EM algorithm, this lower bound is not "far" from the true objective function and one of the two update steps in the coordinate-ascent procedure guarantees to make the lower bound meet the true objective function. This understanding justifies the MacKay algorithm (whether or not implemented with the MacKay update) as a well-principled algorithm framework, juxtaposed on equal footing with the EM framework.

Under a specific linear regression model, it has been observed that the MacKay update and the EM algorithm are closely reated [Murphy, 2012]. It is then curious to investigate the relationship between the two algorithms in a more general setting. To that end, we show that as long as the the posterior distribution $p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha})$ is a Gaussian distribution, the objective function for the MacKay algorithm is simply a restriction of the EM objective function where two of the three variables are restricted on a curve. Under this Gaussian condition, we show that the MacKay optimization problem is a relaxation of the original optimization problem in empirical Bayes, and that the EM optimization problem is a relaxation of the MacKay optimization problem. In addition, the three problems attain their optimum at the same configuration of the hyper-parameter $\boldsymbol{\alpha}$. These understandings then help to explain why the MacKay algorithm converge faster than the EM algorithm.

The objective of this paper is to rigorously formulate the MacKay algorithm and to investigate its connection to the EM algorithm. We have made an effort to be pedagogical in our presentation. In particular, we use a linear regression model and the Bayesian PCA model as running examples throughout the paper.

2 SETUP

The generic model for empirical Bayes is given in Figure 1, where $\mathbf{D}$ is the observed data, $\mathbf{z}$ is the model parameter, and $\boldsymbol{\alpha}$ is the hyper-parameter. We note that both $\mathbf{z}$ and $\boldsymbol{\alpha}$ can be a scalar, a vector, a matrix or of an arbitrary form. The model is specified by the likelihood function $p(\mathbf{D}|\mathbf{z})$ and the prior distribution $p(\mathbf{z}|\boldsymbol{\alpha})$. The objective of empirical Bayes is then to estimate the hyper-parameter $\boldsymbol{\alpha}$ from the data $\mathbf{D}$.

Let

$$l(\boldsymbol{\alpha}) := \log p(\mathbf{D}|\boldsymbol{\alpha}) = \log \int p(\mathbf{D}|\mathbf{z}) p(\mathbf{z}|\boldsymbol{\alpha}) d\mathbf{z} \qquad (1)$$

be the log-marginal likelihood or the "log-evidence" [MacKay, 1992b] of the hyper-parameter $\boldsymbol{\alpha}$. Then the estimation of $\boldsymbol{\alpha}$ can be naturally formulated as solving the following optimization problem.

Opt-I
Find $\boldsymbol{\alpha}$ that maximizes $l(\boldsymbol{\alpha})$.

We now use the examples of linear regression and Bayesian PCA[Bishop, 1999] to illustrate this. Throughout the paper, we will use $\mathcal{N}(x; \mu, \Lambda)$ to denote the Gaussian density function with variable x, mean μ and covariance matrix Λ, and we will use I_d to denote the $d \times d$ identity matrix, $\mathrm{Tr}(\cdot)$ to denote the trace operator, $\mathrm{Det}(\cdot)$ to denote the determinant operator, $\|\cdot\|$ to denote L2 norm, and $\mathbb{E}_q[\cdot]$ to denote expectation under distribution q.

Linear Regression Example–1 *Let* $\mathbf{D} := \{(x_{(i)}, y_{(i)}) : i = 1, 2, \ldots, n\}$ *be the observed data, where each* $x_{(i)}$ *is a vector in* $\mathbb{R}^d$*, and each* $y_{(i)}$ *is a scalar in* $\mathbb{R}$*. The dependency of* $y_{(i)}$ *on* $x_{(i)}$ *is modelled as*

$$y_{(i)} = \mathbf{z}^T x_{(i)} + \epsilon_{(i)}.$$

Here $\epsilon_{(i)}$ *is a zero-mean Gaussian noise with variance* σ^2*, and* $\mathbf{z}$ *is the model parameter, which is modelled as a* d*-dimensional spherical Gaussian variable with zero mean and variance* $1/\boldsymbol{\alpha}$*. For simplicity, we assume that the parameter* σ^2 *is known and the objective of empirical Bayes*

is to estimate the hyper-parameter $\boldsymbol{\alpha}$. Then the objective function in Opt-I is:

$$l(\boldsymbol{\alpha}) = \log \int \mathcal{N}(\mathbf{z}; 0, \frac{1}{\boldsymbol{\alpha}} I_d) \prod_{i=1}^{n} \mathcal{N}(y_{(i)}; \mathbf{z}^T x_{(i)}, \sigma^2) d\mathbf{z}$$

Bayesian PCA Example–1 *Following [Bishop, 1999], let $\mathbf{D} := \{t_{(i)} : i = 1, 2, \ldots, n\}$ be the observed data, where each $t_{(i)}$ is a vector in $\mathbb{R}^m$. Each observed vector $t_{(i)}$ depends on a latent variable $x_{(i)} \in \mathbb{R}^d$ via*

$$t_{(i)} = \mathbf{z} x_{(i)} + \epsilon_{(i)}.$$

Here $x_{(i)}$ is a zero-mean Gaussian variable with covariance I_d, $\epsilon_{(i)}$ is a spherical Gaussian noise with zero mean and known variance σ^2, and parameter $\mathbf{z} \in \mathbb{R}^{m \times d}$ ($d < m$) is modelled as a random matrix whose kth column $\mathbf{z}_k$ is drawn from a spherical Gaussian distribution with zero mean and variance $1/\boldsymbol{\alpha}_k$. Let $\boldsymbol{\alpha} := \{\boldsymbol{\alpha}_k : k = 1, 2, \ldots, d\}$. Then $\boldsymbol{\alpha}$ is the hyper-parameter on $\mathbf{z}$ and Opt-I has the following objective function:

$$l(\boldsymbol{\alpha}) = \log \left(\int \prod_{k=1}^{d} \mathcal{N}(\mathbf{z}_k; 0, \frac{1}{\boldsymbol{\alpha}_k} I_m) \prod_{i=1}^{n} \int \mathcal{N}(x_{(i)}; 0, I_d) \mathcal{N}(t_{(i)}; \mathbf{z} x_{(i)}, \sigma^2 I_m) dx_{(i)} \right) d\mathbf{z}$$

The optimization problem Opt-I can sometimes be solved easily, for instance, in the above linear regression setting. In practice, however, this problem is usually difficult and requires special algorithmic techniques. The above Bayesian PCA setting is one such example.

The EM approach to Opt-I is well-known. In the remainder of this paper, we develop the MacKay algorithm for this problem. To compare and relate to EM, we also present the EM algorithm in parallel. The above linear regression and Bayesian PCA settings will be carried along our development as illustrative examples.

3 THE TWO ALGORITHMS

In this section, we will show that both the EM algorithm and the MacKay algorithm can be formulated as optimizing a lower bound of the objective function $l(\boldsymbol{\alpha})$ via coordinate ascent. While this is well known for the EM algorithm, it has been quite obscure for the MacKay algorithm.

3.1 THE EM ALGORITHM

The Expectation-Maximization (EM) algorithm [Dempster et al., 1977] is a classical method for maximizing the log-likelihood function or log-posterior density function in which certain latent variables have been integrated over. When applied to the optimization problem Opt-I, the EM algorithm implicitly constructs a lower bound $\mathcal{F}_{\mathrm{EM}}$ of the objective function $l(\boldsymbol{\alpha})$.

$$\begin{aligned} \mathcal{F}_{\mathrm{EM}}(q, \boldsymbol{\alpha}) &:= \mathbb{E}_q \left[\log \frac{p(\mathbf{D}|\mathbf{z}) p(\mathbf{z}|\boldsymbol{\alpha})}{q(\mathbf{z})} \right] \\ &= \int q(\mathbf{z}) \log \frac{p(\mathbf{D}|\mathbf{z}) p(\mathbf{z}|\boldsymbol{\alpha})}{q(\mathbf{z})} d\mathbf{z} \end{aligned} \tag{2}$$

where $q(\cdot)$ is an arbitrary probability distribution on the space of $\mathbf{z}$. By the Jensen's Inequality[Jensen, 1906], the follow result is well-known in the literature of the EM algorithm [Dempster et al., 1977].

Lemma 1. *$\mathcal{F}_{\mathrm{EM}}(q, \boldsymbol{\alpha}) \leq l(\boldsymbol{\alpha})$, where the equality is achieved if and only if $q(\mathbf{z})$ is the posterior distribution $p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha})$.*

Instead of optimizing the original objective function $l(\boldsymbol{\alpha})$, we now define an alternative optimization problem.

> OptEM
>
> Find $\boldsymbol{\alpha}$ and a distribution q that maximize $\mathcal{F}_{\mathrm{EM}}(q, \boldsymbol{\alpha})$.

The EM algorithm is then the coordinate ascent solver for OptEM. More precisely, the update rule at the t^{th} iteration of the coordinate ascent is given below.

EM Algorithm

E-Step:

$$\begin{aligned} q^{(t)} &:= \arg\max_q \mathcal{F}_{\mathrm{EM}}(q, \boldsymbol{\alpha}^{(t)}) \\ &= p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha}^{(t)}) \end{aligned}$$

M-Step:

$$\begin{aligned} \boldsymbol{\alpha}^{(t+1)} &:= \arg\max_{\boldsymbol{\alpha}} \mathcal{F}_{\mathrm{EM}}(q^{(t)}, \boldsymbol{\alpha}) \\ &= \arg\max_{\boldsymbol{\alpha}} \mathbb{E}_{q^{(t)}} [\log p(\mathbf{z}|\boldsymbol{\alpha})] \end{aligned}$$

We note that by Lemma 1, at the end of E-Step,

$$\mathcal{F}_{\mathrm{EM}}(q^{(t)}, \boldsymbol{\alpha}^{(t)}) = l(\boldsymbol{\alpha}^{(t)}). \tag{3}$$

This gives rise to the following lemma [Dempster et al., 1977].

Lemma 2. *The iteration of the EM algorithm continuously increases the log-evidence function $l(\boldsymbol{\alpha})$ and therefore is guaranteed to converge.*

Linear Regression Example–2 *For the linear regression model, let $[x_{(1)}, x_{(2)}, \ldots, x_{(n)}]$ be denoted by a matrix $X \in \mathbb{R}^{d \times n}$ and $[y_{(1)}, y_{(2)}, \ldots, y_{(n)}]^T$ denoted by a vector*

$Y \in \mathbb{R}^n$. *The objective function (2) is*

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(q,\boldsymbol{\alpha}) &= \frac{1}{\sigma^2}\sum_{i=1}^{n} y_{(i)} x_{(i)}^T \mathbb{E}_q[\mathbf{z}] \\ &- \frac{1}{2\sigma^2}\mathbb{E}_q\left[\mathbf{z}^T\left(\sum_{i=1}^{n} x_{(i)}x_{(i)}^T + \boldsymbol{\alpha}\sigma^2 I_d\right)\mathbf{z}\right] \\ &- \mathbb{E}_q\left[\log q(\mathbf{z})\right] + \frac{n+d}{2}\log 2\pi + \frac{n}{2}\log\sigma^2 \\ &+ \frac{d}{2}\log\boldsymbol{\alpha} - \frac{1}{2\sigma^2}\sum_{i=1}^{n} y_{(i)}^2\end{aligned}$$

It is easy to verify that the posterior distribution of $\mathbf{z}$ *is also Gaussian and the E-Step update becomes*

$$q^{(t)}(\mathbf{z}) = \mathcal{N}\left(\mathbf{z}; \mu_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)}), K_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)})\right) \tag{4}$$

where

$$\mu_{\mathrm{LR}}(\boldsymbol{\alpha}) := \frac{1}{\sigma^2}\left(\frac{1}{\sigma^2}XX^T + \boldsymbol{\alpha}I_d\right)^{-1} XY, \tag{5}$$

and

$$K_{\mathrm{LR}}(\boldsymbol{\alpha}) := \left(\frac{1}{\sigma^2}XX^T + \boldsymbol{\alpha}I_d\right)^{-1}. \tag{6}$$

For the M-Step update, noting that

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(q^{(t)},\boldsymbol{\alpha}) &= -\frac{\boldsymbol{\alpha}}{2}\left\|\mu_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)})\right\|^2 \\ &- \frac{\boldsymbol{\alpha}}{2}\mathrm{Tr}\left(K_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)})\right) + \frac{d}{2}\log\boldsymbol{\alpha} + const,\end{aligned}$$

it is possible to express the maximizing $\boldsymbol{\alpha}$ *for this function directly in terms of* $\boldsymbol{\alpha}^{(t)}$ *as:*

$$\boldsymbol{\alpha}^{(t+1)} = \frac{d}{\left\|\mu_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)})\right\|^2 + \mathrm{Tr}\left(K_{\mathrm{LR}}(\boldsymbol{\alpha}^{(t)})\right)} \tag{7}$$

That is, the updates in E-Step and M-Step can be combined into the single update equation (7).

Bayesian PCA Example–2 *For the BPCA model, the objective function (2) is*

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(q,\boldsymbol{\alpha}) &= -\frac{n}{2}\mathbb{E}_q\left[\log\mathrm{Det}(\mathbf{z}\mathbf{z}^T + \sigma^2 I_m)\right] \\ &- \frac{1}{2}\sum_{i=1}^{n}\mathbb{E}_q\left[t_{(i)}^T(\mathbf{z}\mathbf{z}^T + \sigma^2 I_m)^{-1}t_{(i)}\right] \\ &- \frac{1}{2}\sum_{k=1}^{d}\boldsymbol{\alpha}_k\mathbb{E}_q\left[\|\mathbf{z}_k\|^2\right] - \mathbb{E}_q\left[\log q(\mathbf{z})\right] \\ &+ \sum_{k=1}^{d}\frac{m}{2}\log\boldsymbol{\alpha}_k - \frac{dn+dm}{2}\log 2\pi.\end{aligned}$$

The M-Step update is then

$$\boldsymbol{\alpha}_k^{(t+1)} = \frac{m}{\mathbb{E}_{q^{(t)}}\left[\|\mathbf{z}_k\|^2\right]}. \tag{8}$$

However, the E-Step update of $q^{(t)}$ *can not be expressed in explicit forms and one usually relies on various approximation techniques. For example, a sampling approach [Neal, 1993] may be used for this purpose. Later in this paper, we will discuss the approach that approximates the posterior as a Gaussian.*

3.2 MACKAY ALGORITHM

In [MacKay, 1992a, MacKay, 1992c, MacKay, 1992b, MacKay, 1995], MacKay presented the influential evidence framework that addresses inference as three levels. A heuristic iterative procedure is introduced for the second-level inference, namely, for inferring the hyperparameter. Here, we re-formulate the this procedure as a well-principled algorithm framework, and call it the *MacKay algorithm*.

To begin, note that the objective function $l(\boldsymbol{\alpha})$ can be expressed as

$$l(\boldsymbol{\alpha}) = \log p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha}) - \log p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha}),$$

for any $\mathbf{z}$ (with $p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ non-zero). Define

$$\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z},\boldsymbol{\alpha}) := \log p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha}) - \max_{\mathbf{z}'}\log p(\mathbf{z}'|\mathbf{D},\boldsymbol{\alpha}). \tag{9}$$

The following lemma is easy to verify.

Lemma 3. $\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z},\boldsymbol{\alpha}) \le l(\boldsymbol{\alpha})$, *where the equality is achieved if and only if* $\mathbf{z} = \arg\max_{\mathbf{z}}\log p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha})$.

We now introduce another optimization problem.

OptMacKay

Find $\boldsymbol{\alpha}$ and $\mathbf{z}$ that maximize $\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z},\boldsymbol{\alpha})$.

The MacKay algorithm is then defined as the following coordinate ascent procedure for optimizing $\mathcal{F}_{\mathrm{MacKay}}$.

MacKay Algorithm

$\mathbf{z}$-Step:

$$\begin{aligned}\mathbf{z}^{(t)} &:= \arg\max_{\mathbf{z}}\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z},\boldsymbol{\alpha}^{(t)}) \\ &= \arg\max_{\mathbf{z}}\log p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha}^{(t)})\end{aligned}$$

$\boldsymbol{\alpha}$-Step:

$$\boldsymbol{\alpha}^{(t+1)} := \arg\max_{\boldsymbol{\alpha}}\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}^{(t)},\boldsymbol{\alpha}).$$

At the end of $\mathbf{z}$-Step, by Lemma 3,

$$\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}^{(t)},\boldsymbol{\alpha}^{(t)}) = l(\boldsymbol{\alpha}^{(t)}). \tag{10}$$

This property clearly parallels Equation (3) of the EM algorithm. That is, although the MacKay algorithm maximizes

the lower bound $\mathcal{F}_{\text{MacKay}}$ of the true objective function $l(\boldsymbol{\alpha})$, the lower bound $\mathcal{F}_{\text{MacKay}}$ is in fact "not far" below $l(\boldsymbol{\alpha})$ and at the end of each $\mathbf{z}$-Step update, the lower-bound meets $l(\boldsymbol{\alpha})$. Then by the coordinate-ascent nature of the MacKay algorithm, we have the following lemma, parallel to Lemma 2 of the EM algorithm.

Lemma 4. *The iteration of the MacKay algorithm continuously increases the log-evidence function $l(\boldsymbol{\alpha})$ and therefore is guaranteed to converge.*

In the MacKay algorithm, it is worth noting that the update in the $\boldsymbol{\alpha}$-Step is usually performed with a "fixed-point iteration" procedure [Solomon, 2015, MacKay, 1992a, Bishop, 1999, Murphy, 2012], which we describe next for self-containedness.

Fixed-Point Iteration Suppose that the equation

$$\partial \mathcal{F}_{\text{MacKay}}(\mathbf{z}, \boldsymbol{\alpha})/\partial \boldsymbol{\alpha} = 0$$

can be reduced to the form $\boldsymbol{\alpha} = h(\boldsymbol{\alpha}, \mathbf{z})$. The fixed-point iteration approach for the α-Step update in the MacKay algorithm is the following update rule.

$$\boldsymbol{\alpha}^{(t+1)} = h(\boldsymbol{\alpha}^{(t)}, \mathbf{z}^{(t)}).$$

Linear Regression Example–3 *In the linear regression model, the lower bound $\mathcal{F}_{\text{MacKay}}$ is*

$$\begin{aligned}\mathcal{F}_{\text{MacKay}}(\mathbf{z}, \boldsymbol{\alpha}) = &\frac{1}{\sigma^2}\sum_{i=1}^{n} y_{(i)} x_{(i)}^T \mathbf{z} - \frac{1}{2\sigma^2}\sum_{i=1}^{n} y_{(i)}^2 \\ &- \frac{1}{2\sigma^2}\mathbf{z}^T\left(\sum_{i=1}^{n} x_{(i)} x_{(i)}^T + \boldsymbol{\alpha}\sigma^2 I_d\right)\mathbf{z} \\ &+ \frac{n+d}{2}\log 2\pi + \frac{n}{2}\log\sigma^2 + \frac{d}{2}\log\boldsymbol{\alpha} \\ &+ \frac{1}{2}\log\text{Det}\left(2\pi K_{\text{LR}}(\boldsymbol{\alpha})\right)\end{aligned} \tag{11}$$

The $\mathbf{z}$-Step turns out to be

$$\mathbf{z}^{(t)} = \mu_{\text{LR}}(\boldsymbol{\alpha}^{(t)}).$$

Note

$$\frac{\partial \mathcal{F}_{\text{MacKay}}(\mathbf{z},\boldsymbol{\alpha})}{\partial \boldsymbol{\alpha}} = \frac{d}{2\boldsymbol{\alpha}} - \frac{1}{2}\|\mathbf{z}\|^2 - \frac{1}{2}\text{Tr}\left(K_{\text{LR}}(\boldsymbol{\alpha})\right).$$

When setting $\frac{\partial \mathcal{F}_{\text{MacKay}}(\mathbf{z},\boldsymbol{\alpha})}{\partial \boldsymbol{\alpha}} = 0$, we obtain

$$\boldsymbol{\alpha} = \frac{d - \boldsymbol{\alpha}\text{Tr}\left(K_{\text{LR}}(\boldsymbol{\alpha})\right)}{\|\mathbf{z}\|^2}$$

This gives rise to the fixed-point iteration of the $\boldsymbol{\alpha}$-Step:

$$\boldsymbol{\alpha}^{(t+1)} = \frac{d - \boldsymbol{\alpha}^{(t)}\text{Tr}\left(K_{\text{LR}}(\boldsymbol{\alpha}^{(t)})\right)}{\left\|\mathbf{z}^{(t)}\right\|^2}.$$

Bayesian PCA Example–3 *For the BPCA model, the objective function $\mathcal{F}_{\text{MacKay}}$ is*

$$\begin{aligned}\mathcal{F}_{\text{MacKay}}(\mathbf{z}, \boldsymbol{\alpha}) = &-\frac{n}{2}\log\text{Det}\left(\mathbf{z}\mathbf{z}^T + \sigma^2 I_m\right) \\ &- \frac{1}{2}\sum_{i=1}^{n} t_{(i)}^T (\mathbf{z}\mathbf{z}^T + \sigma^2 I_m)^{-1} t_{(i)} \\ &- \frac{1}{2}\sum_{k=1}^{d} \alpha_k \|\mathbf{z}_k\|^2 - \max_{\mathbf{z}'} p(\mathbf{z}'|\mathbf{D}, \boldsymbol{\alpha}) \\ &+ \sum_{k=1}^{d}\frac{m}{2}\log\boldsymbol{\alpha}_k - \frac{dn+dm}{2}\log 2\pi\end{aligned}$$

The $\mathbf{z}$-Step and $\boldsymbol{\alpha}$-Step updates then become

$$\begin{aligned}\mathbf{z}^{(t)} &= \arg\max_{\mathbf{z}} p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha}^{(t)}) \\ \boldsymbol{\alpha}^{(t+1)} &= \arg\max_{\boldsymbol{\alpha}}\left[-\frac{1}{2}\sum_{k=1}^{d}\boldsymbol{\alpha}_k\left\|\mathbf{z}_k^{(t)}\right\|^2\right. \\ &\qquad \left. - \max_{\mathbf{z}'} p(\mathbf{z}'|\mathbf{D}, \boldsymbol{\alpha}) + \sum_{k=1}^{d}\frac{m}{2}\log\boldsymbol{\alpha}_k\right]\end{aligned}$$

Since in general there does not exist closed-form solution for the $\mathbf{z}$-Step update, the two update equations can not be further expressed. In practice, a Gaussian approximation is applied to the posterior function $p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha}^{(t)})$ in order to derive these update equations (see next section).

It is perhaps worth noting that the z-step update of the MacKay algorithm resembles the E-step update of an approximate version of the EM algorithm, known as "Hard EM" (or "Viterbi-EM" in the context of Hidden Markov Models)[Allahverdyan and Galstyan, 2011]. However, the M-step of Hard EM/Viterbi-EM is different from the $\boldsymbol{\alpha}$-step of the MacKay algorithm, due to the fact the OptEM and OptMacKay have different objective functions. It is not clear whether there is a more direct connection between Hard EM and the MacKay algorithm bypassing the generic EM algorithm, although we suspect that the answer is "no".

4 GAUSSIAN APPROXIMATION

As seen above, in both the EM algorithm and the MacKay algorithm, it is desirable to compute the posterior distribution of model parameter, namely, $p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha})$. In the case of EM, this is for updating q in the E-Step and in the case of MacKay, this is for updating $\mathbf{z}$ in the $\mathbf{z}$-Step. For some models, such Bayesian PCA, it is difficult to carry out explicit computation of the posterior. A commonly used technique is to approximate the posterior as a Gaussian density function, namely,

$$p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha}) \approx \mathcal{N}(\mathbf{z}; \mu, K), \text{ for some } \mu,\ K. \tag{12}$$

Clearly, the mean vector μ and the covariance matrix K of the Gaussian density depend on the hyper-parameter $\boldsymbol{\alpha}$ and will be denoted by $\mu(\boldsymbol{\alpha})$ and $K(\boldsymbol{\alpha})$ respectively.

When $p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ is a continuous function of $\mathbf{z}$, a common technique for obtain such an approximation (12) is the following [MacKay, 1995].

Let $\widehat{\mathbf{z}}$ maximizes $p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$. By Taylor-expanding $\log p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ at $\mathbf{z}=\widehat{\mathbf{z}}$, up to the second-order terms, it is easy to see that

$$\log p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha}) \approx \log p\left(\widehat{\mathbf{z}}|\mathbf{D},\boldsymbol{\alpha}\right) + \frac{1}{2}\left(\mathbf{z}-\widehat{\mathbf{z}}\right)^T H(\boldsymbol{\alpha})\left(\mathbf{z}-\widehat{\mathbf{z}}\right)$$

where $H(\boldsymbol{\alpha})$ denotes the Hessian matrix of function $\log p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ at $\mathbf{z}=\widehat{\mathbf{z}}$. This gives the customary approximation of $p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ as [MacKay, 1995]

$$p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha}) \approx \mathcal{N}\left(\mathbf{z};\widehat{\mathbf{z}},-H(\boldsymbol{\alpha})^{-1}\right)$$

Then $\mu(\boldsymbol{\alpha})$ and $K(\boldsymbol{\alpha})$ in the Gaussian approximation (12) can be taken as

$$\mu(\boldsymbol{\alpha})=\widehat{\mathbf{z}},\ K(\boldsymbol{\alpha})=-H(\boldsymbol{\alpha})^{-1}. \tag{13}$$

We note that in (12), the approximation is sometimes accurate, namely, that the strict equality is satisfied. In such cases, the Gaussian approximation as stated in (12) and (13) in fact holds precisely.

Linear Regression Example–4 *As seen in (4), (5) and (6), the posterior distribution $p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha})$ is indeed a Gaussian density function. That is, the Gaussian approximation (12) holds with equality, where $\mu(\boldsymbol{\alpha})=\mu_{\mathrm{LR}}(\boldsymbol{\alpha})$ and $K(\boldsymbol{\alpha})=K_{\mathrm{LR}}(\boldsymbol{\alpha})$ (defined in (5) and (6) respectively).*

Bayesian PCA Example–4 *Let $\mathbf{Z}$ be the vector representation of matrix $\mathbf{z}$, namely, $\mathbf{Z}$ is a length-md vector obtained by stacking columns of the matrix $\mathbf{z}$. That is, $\mathbf{Z}:=(\mathbf{z}_1^T,\mathbf{z}_2^T,\ldots,\mathbf{z}_d^T)^T$. Let $\widehat{\mathbf{Z}}$ denote the maximizing configuration for function $p(\mathbf{Z}|\mathbf{D},\boldsymbol{\alpha})$, and similarly let $H(\boldsymbol{\alpha})$ denote the Hessian of $\log p(\mathbf{Z}|\mathbf{D},\boldsymbol{\alpha})$ at $\mathbf{Z}=\widehat{\mathbf{Z}}$. The Gaussian approximation (12) then becomes*

$$p(\mathbf{Z}|\mathbf{D},\boldsymbol{\alpha}) \approx \mathcal{N}(\mathbf{Z};\mu_{\mathrm{BPCA}}(\boldsymbol{\alpha}),K_{\mathrm{BPCA}}(\boldsymbol{\alpha})) \tag{14}$$

where

$$\mu_{\mathrm{BPCA}}(\boldsymbol{\alpha}):=\widehat{\mathbf{Z}},\ K_{\mathrm{BPCA}}(\boldsymbol{\alpha}):=-H(\boldsymbol{\alpha})^{-1}.$$

We note that in this case, (12) is only an approximation. In addition, since $\widehat{\mathbf{Z}}$ and $H(\boldsymbol{\alpha})^{-1}$ are difficult to compute analytically, numerical solutions are usually sought.

In the remainder of this section, we assume that (12) holds with equality and further investigate the optimization problems in the EM and MacKay algorithms.

4.1 EM

Recall that with the EM algorithm, the objective function in the optimization problem is $\mathcal{F}_{\mathrm{EM}}$ in (2). Since the optimizing distribution q for any given $\boldsymbol{\alpha}$ is the posterior $p(\mathbf{z}|D,\boldsymbol{\alpha})$, this, under the Gaussian assumption (12) of the posterior, allows us to restrict q to the form $\mathcal{N}(\mathbf{z};u,S)$ parametrized by mean vector u and covariance S. The the objective function $\mathcal{F}_{\mathrm{EM}}(q,\boldsymbol{\alpha})$ can then be re-expressed as $\mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha})$. That is,

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha}) &= \mathbb{E}_{\mathcal{N}(\mathbf{z};u,S)}\left[\log\frac{p(\mathbf{D}|\mathbf{z})p(\mathbf{z}|\boldsymbol{\alpha})}{\mathcal{N}(\mathbf{z};u,S)}\right]\\ &= \mathbb{E}_{\mathcal{N}(\mathbf{z};u,S)}\left[\log p(\mathbf{D}|\mathbf{z})p(\mathbf{z}|\boldsymbol{\alpha})\right]\\ &\quad+\frac{J}{2}\log 2\pi+\frac{1}{2}\log\mathrm{Det}(S)+\frac{J}{2}\end{aligned} \tag{15}$$

where J is the length of the vector $\mathbf{z}$. The following lemma is established by noting the following two-way factorization of $p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha})$.

$$p(\mathbf{D},\mathbf{z}|\boldsymbol{\alpha})=p(\mathbf{D}|\mathbf{z})p(\mathbf{z}|\boldsymbol{\alpha})=p(\mathbf{D}|\boldsymbol{\alpha})p(\mathbf{z}|\mathbf{D},\boldsymbol{\alpha}) \tag{16}$$

Lemma 5. *When the Gaussian approximation (12) holds with equality, the function $\mathcal{F}_{\mathrm{EM}}$ can be re-expressed as*

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha}) &= \log\mathcal{N}(u;\mu(\boldsymbol{\alpha}),K(\boldsymbol{\alpha}))-\frac{1}{2}\mathrm{Tr}(K^{-1}(\boldsymbol{\alpha})S)\\ &\quad+\log p(\mathbf{D}|\boldsymbol{\alpha})+\frac{J}{2}\log 2\pi+\frac{1}{2}\log\mathrm{Det}(S)+\frac{J}{2}\end{aligned}$$

To derive the update rule for the EM algorithm under the Gaussian approximation (12), we prove the following results.

Lemma 6. *For any given S and $\boldsymbol{\alpha}$,*

$$\arg\max_u \mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha})=\mu(\boldsymbol{\alpha}).$$

Proof: Based on Lemma 5, we express $\mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha})$ further.

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha}) &= -\frac{J}{2}\log 2\pi-\frac{1}{2}\log\mathrm{Det}(K(\boldsymbol{\alpha}))\\ &\quad-\frac{1}{2}\left(u-\mu(\boldsymbol{\alpha})\right)^T K^{-1}(\boldsymbol{\alpha})(u-\mu(\boldsymbol{\alpha}))\\ &\quad-\frac{1}{2}\mathrm{Tr}\left(K^{-1}(\boldsymbol{\alpha})S\right)+\log p(\mathbf{D}|\boldsymbol{\alpha})\\ &\quad+\frac{J}{2}\log 2\pi+\frac{1}{2}\log\mathrm{Det}(S)+\frac{J}{2}.\end{aligned}$$

$$\frac{\partial\mathcal{F}_{\mathrm{EM}}}{\partial u}=-\frac{1}{2}\left(K^{-1}(\boldsymbol{\alpha})+(K^{-1}(\boldsymbol{\alpha}))^T\right)(u-\mu(\boldsymbol{\alpha}))$$

By setting $\frac{\partial\mathcal{F}_{\mathrm{EM}}}{\partial u}$ to zero, we prove the result. □

Lemma 7. *For any u and $\boldsymbol{\alpha}$,*

$$\arg\max_S \mathcal{F}_{\mathrm{EM}}(u,S,\boldsymbol{\alpha})=K(\boldsymbol{\alpha}).$$

Proof: By the expression of $\mathcal{F}_{\mathrm{EM}}(u, S, \boldsymbol{\alpha})$ in Lemma 5,

$$\frac{\partial \mathcal{F}_{\mathrm{EM}}}{\partial S} = -\frac{1}{2}\frac{\partial}{\partial S}\mathrm{Tr}(K^{-1}(\boldsymbol{\alpha})S) + \frac{1}{2}\frac{\partial}{\partial S}\log\mathrm{Det}(S).$$

By $\mathrm{Tr}(AB) = \sum_i \sum_j A_{ij}B_{ji}$, we have

$$\mathrm{Tr}(K^{-1}(\boldsymbol{\alpha})S) = \sum_i \sum_j (K^{-1}(\boldsymbol{\alpha}))_{ij} S_{ji};$$

$$\frac{\partial}{\partial S_{ij}}\mathrm{Tr}(K^{-1}(\boldsymbol{\alpha})S) = (K^{-1}(\boldsymbol{\alpha}))_{ji}$$

$$\frac{\partial}{\partial S}\mathrm{Tr}(K^{-1}(\boldsymbol{\alpha})S) = (K^{-1}(\boldsymbol{\alpha}))^T.$$

On the other hand, since $\frac{\partial \mathrm{Det}(S)}{\partial S_{ij}} = \mathrm{Det}(S)(S^{-1})_{ji}$, we have

$$\frac{\partial}{\partial S_{ij}}\log\mathrm{Det}(S) = (S^{-1})_{ji}$$

$$\frac{\partial}{\partial S}\log\mathrm{Det}(S) = (S^{-1})^T.$$

Then

$$\frac{\partial \mathcal{F}_{\mathrm{EM}}}{\partial S} = -\frac{1}{2}(K^{-1}(\boldsymbol{\alpha}))^T + \frac{1}{2}(S^{-1})^T.$$

The lemma is then proved by setting this derivative to zero. □

As a corollary of Lemma 6, Lemma 7 and (15), the update rule of the EM algorithm can be established.

Lemma 8. *When the Gaussian approximation (12) holds with equality, the EM algorithm becomes the following EM-Gauss Procedure.*

EM-Gauss Procedure:

E-Step:

$$u^{(t)} := \mu(\boldsymbol{\alpha}^{(t)})$$
$$S^{(t)} := K(\boldsymbol{\alpha}^{(t)})$$

M-Step:

$$\boldsymbol{\alpha}^{(t+1)} := \arg\max_{\boldsymbol{\alpha}} \mathbb{E}_{\mathcal{N}(\mathbf{z};u^{(t)},S^{(t)})}\left[\log p(\mathbf{z}|\boldsymbol{\alpha})\right]$$

Linear Regression Example–5 *In the linear regression model, the Gaussian assumption (12) holds true. The E-Step then reduces to (4), which can be integrated into the M-Step. The EM update can then be expressed as a single update equation (7), the same as that in Linear Regression Example-2.*

Bayesian PCA Example–5 *Note that $\mu_{\mathrm{BPCA}}(\boldsymbol{\alpha})$ is a vector of length md and $K_{\mathrm{BPCA}}(\boldsymbol{\alpha})$ is an $md \times md$ matrix. Let $\mu_{\mathrm{BPCA},k}(\boldsymbol{\alpha})$ denote the component of $\mu_{\mathrm{BPCA}}(\boldsymbol{\alpha})$ corresponding to $\mathbf{z}_k$ component of $\widehat{\mathbf{Z}}$, and $K_{\mathrm{BPCA},k}(\boldsymbol{\alpha})$ denote the sub-matrix of $K_{\mathrm{BPCA}}(\boldsymbol{\alpha})$ that serves as the covariance matrix of $\mathbf{z}_k$. With the Gassian approximation (14) holds with equality, the update (8) of $\boldsymbol{\alpha}$ becomes*

$$\boldsymbol{\alpha}_k^{(t+1)} = \frac{m}{\left\|\mu_{\mathrm{BPCA},k}(\boldsymbol{\alpha}^{(t)})\right\|^2 + \mathrm{Tr}\left(K_{\mathrm{BPCA},k}(\boldsymbol{\alpha}^{(t)})\right)}.$$

4.2 MACKAY

Lemma 9. *When the Gaussian approximation (12) holds with equality, the function $\mathcal{F}_{\mathrm{MacKay}}$ in (9) becomes*

$$\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}, \boldsymbol{\alpha}) = \log p(\mathbf{D}, \mathbf{z}|\boldsymbol{\alpha}) + \frac{1}{2}\log\mathrm{Det}(2\pi K(\boldsymbol{\alpha})).$$

Proof: This lemma follows from $\max_{\mathbf{z}'} \log p(\mathbf{z}'|\mathbf{D}, \boldsymbol{\alpha}) = -\frac{1}{2}\log\mathrm{Det}(2\pi K(\boldsymbol{\alpha}))$. □

Lemma 10. *When the Gaussian approximation (12) holds with equality, for any $\boldsymbol{\alpha}$,*

$$\arg\max_{\mathbf{z}} \log p(\mathbf{D}, \mathbf{z}|\boldsymbol{\alpha}) = \mu(\boldsymbol{\alpha}).$$

The proof of this lemma follows the same line as that of Lemma 6. The MacKay algorithm under the Gaussian approximation (12) can then be established from Lemma 10 and Lemma 9.

Lemma 11. *When the Gaussian approximation (12) holds with equality, the MacKay algorithm becomes the following MacKay-Gauss Procedure.*

MacKay-Gauss Procedure:

$\mathbf{z}$-Step:

$$\mathbf{z}^{(t)} := \mu(\boldsymbol{\alpha}^{(t)})$$

$\boldsymbol{\alpha}$-Step:

$$\boldsymbol{\alpha}^{(t+1)} := \arg\max_{\boldsymbol{\alpha}} \left[\log p(\mathbf{z}^{(t)}|\boldsymbol{\alpha}) + \frac{1}{2}\log\mathrm{Det}(K(\boldsymbol{\alpha}))\right]$$

Linear Regression Example–6 *Since the Gaussian assumption (12) holds true in linear regression, the updates of the MacKay algorithm are those in Linear Regression Example–3.*

Bayesian PCA Example–6 *Assuming that the Gassian approximation (12) holds with equality, the $\mathbf{z}$-Step and $\boldsymbol{\alpha}$-Step updates become*

$$\mathbf{Z}^{(t)} = \mu_{\mathrm{BPCA}}(\boldsymbol{\alpha}^{(t)})$$

$$\boldsymbol{\alpha}^{(t+1)} = \arg\max_{\boldsymbol{\alpha}} \left[-\frac{1}{2}\sum_{k=1}^{d} \boldsymbol{\alpha}_k \left\|\mathbf{z}_k^{(t)}\right\|^2 + \frac{1}{2}\log\mathrm{Det}\left(K_{\mathrm{BPCA}}(\boldsymbol{\alpha})\right) + \sum_{k=1}^{d}\frac{m}{2}\log\boldsymbol{\alpha}_k\right]$$

When setting $\frac{\partial \mathcal{F}_{\mathrm{MacKay}}(\mathbf{z},\boldsymbol{\alpha})}{\partial \boldsymbol{\alpha}_k} = 0$*, we can obtain*

$$\boldsymbol{\alpha}_k = h(\boldsymbol{\alpha}_k, \mathbf{z}) = \frac{m - \boldsymbol{\alpha}_k \mathrm{Tr}\left(K_{\mathrm{BPCA},k}(\boldsymbol{\alpha})\right)}{\|\mathbf{z}_k\|^2}.$$

This gives rise to the fixed-point iteration of the $\boldsymbol{\alpha}$*-Step*

$$\boldsymbol{\alpha}_k^{(t+1)} = \frac{m - \boldsymbol{\alpha}_k^{(t)} \mathrm{Tr}\left(K_{\mathrm{BPCA},k}(\boldsymbol{\alpha}^{(t)})\right)}{\left\|\mathbf{z}_k^{(t)}\right\|^2}$$

4.3 THE RELATIONSHIP BETWEEN MAKCAY AND EM

As is shown earlier, the MacKay and EM algorithms correspond to solving two different optimization problems. However, we will show next that when the Gaussian approximation (12) holds exactly, the two algorithms are closely related.

First note that $\mathcal{F}_{\mathrm{EM}}$ is a trivariate function whereas $\mathcal{F}_{\mathrm{MacKay}}$ is a bivariate function. The theorem below suggests that if the Gaussian approximation of the posterior distribution $p(\mathbf{z}|\mathbf{D}, \boldsymbol{\alpha})$ is exact, then by setting its covariance variable S of $\mathcal{F}_{\mathrm{EM}}$ to the covariance matrix of the posterior, the function $\mathcal{F}_{\mathrm{EM}}$ reduces $\mathcal{F}_{\mathrm{MacKay}}$.

Theorem 1. *When the Gaussian approximation (12) holds with equality,* $\mathcal{F}_{\mathrm{EM}}(u, K(\boldsymbol{\alpha}), \boldsymbol{\alpha}) = \mathcal{F}_{\mathrm{MacKay}}(u, \boldsymbol{\alpha})$*, where* $K(\boldsymbol{\alpha})$ *is defined in (13).*

Proof: Suppose that the Gaussian approximation (12) holds with equality. Invoking (16), we have

$$\begin{aligned}\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}, \boldsymbol{\alpha}) &= \log p(\mathbf{D}, \mathbf{z}|\boldsymbol{\alpha}) + \frac{1}{2}\log \mathrm{Det}(2\pi K(\boldsymbol{\alpha})) \\ &= \log \mathcal{N}(\mathbf{z}; \mu(\boldsymbol{\alpha}), K(\boldsymbol{\alpha})) + \log p(\mathbf{D}|\boldsymbol{\alpha}) \\ &\quad + \frac{1}{2}\log \mathrm{Det}(2\pi K(\boldsymbol{\alpha}))\end{aligned}$$

But by Lemma 5, we have

$$\begin{aligned}\mathcal{F}_{\mathrm{EM}}(\mathbf{z}, K(\boldsymbol{\alpha}), \boldsymbol{\alpha}) &= \log \mathcal{N}(\mathbf{z}; \mu(\boldsymbol{\alpha}), K(\boldsymbol{\alpha})) \\ &\quad - \frac{1}{2}\mathrm{Tr}\left(K^{-1}(\boldsymbol{\alpha})K(\boldsymbol{\alpha})\right) + \log p(\mathbf{D}|\boldsymbol{\alpha}) \\ &\quad + \frac{J}{2}\log 2\pi + \frac{1}{2}\log \mathrm{Det}(K(\boldsymbol{\alpha})) + \frac{J}{2} \\ &= \log \mathcal{N}(\mathbf{z}; \mu(\boldsymbol{\alpha}), K(\boldsymbol{\alpha})) + \log p(\mathbf{D}|\boldsymbol{\alpha}) \\ &\quad + \frac{1}{2}\log \mathrm{Det}(2\pi K(\boldsymbol{\alpha})) \\ &= \mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}, \boldsymbol{\alpha})\end{aligned}$$

This proves the theorem. □

Theorem 1 suggests that the function $\mathcal{F}_{\mathrm{MacKay}}$ is a restriction of function $\mathcal{F}_{\mathrm{EM}}$. Denote by $\mathfrak{C}$ the set of all $(S, \boldsymbol{\alpha})$ configurations with $S = K(\boldsymbol{\alpha})$. That is, $\mathfrak{C}$ is the curve on the $(S, \boldsymbol{\alpha})$ plane specified by $S = K(\boldsymbol{\alpha})$. Under this notation, $\mathcal{F}_{\mathrm{MacKay}}$ is the function $\mathcal{F}_{\mathrm{EM}}$ with variables $(S, \boldsymbol{\alpha})$ restricted on the curve $\mathfrak{C}$.

Theorem 2. *When the Gaussian approximation (12) holds with equality,*

$$\mathcal{F}_{\mathrm{MacKay}}(u, \boldsymbol{\alpha}) = \max_S \mathcal{F}_{\mathrm{EM}}(u, S, \boldsymbol{\alpha}), \tag{17}$$

$$l(\boldsymbol{\alpha}) = \max_u \mathcal{F}_{\mathrm{MacKay}}(u, \boldsymbol{\alpha}). \tag{18}$$

Proof: Denote $S^* := \arg\max_S \mathcal{F}_{\mathrm{EM}}(u, S, \boldsymbol{\alpha}) = K(\boldsymbol{\alpha})$. Thus

$$\max_S \mathcal{F}_{\mathrm{EM}}(u, S, \boldsymbol{\alpha}) = \mathcal{F}_{\mathrm{EM}}(u, S^*, \boldsymbol{\alpha}) = \mathcal{F}_{\mathrm{EM}}(u, K(\alpha), \boldsymbol{\alpha}).$$

Then the equation (17) holds by Theorem 1, On the other hand, by Lemma 3, $\mathcal{F}_{\mathrm{MacKay}}(\mathbf{z}, \boldsymbol{\alpha}) \leq l(\boldsymbol{\alpha})$ and the equality can be achieved. We thus obtain the equation (18). □.

The following result follows immediately from Theorem 2.

Corollary 1. *The optimizing configurations for Opt-l, OptEM and OptMacKay are identical in* $\boldsymbol{\alpha}$*.*

Theorem 2 and Corollary 1 essentially suggest that OptMacKay is a relaxation of Opt-l, that OptEM is a relaxation of OptMacKay, and that such successive relaxations do not alter the solution of the original problem Opt-l.

Lemma 12. *The EM-Gauss Procedure is identical to the 3-way coordinate ascent on* $\mathcal{F}_{\mathrm{EM}}$*, namely, iterating over the following three steps.*

$$\begin{aligned}u^{(t)} : &= \arg\max_u \mathcal{F}_{\mathrm{EM}}(u, S^{(t-1)}, \boldsymbol{\alpha}^{(t)}) \\ S^{(t)} : &= \arg\max_S \mathcal{F}_{\mathrm{EM}}(u^{(t)}, S, \boldsymbol{\alpha}^{(t)}) \\ \boldsymbol{\alpha}^{(t+1)} : &= \arg\max_{\boldsymbol{\alpha}} \mathcal{F}_{\mathrm{EM}}(u^{(t)}, S^{(t)}, \boldsymbol{\alpha})\end{aligned}$$

Proof: This follows from the fact that in the EM-Gauss Procedure, the update of u is independent of S and the update of S is independent of u. □

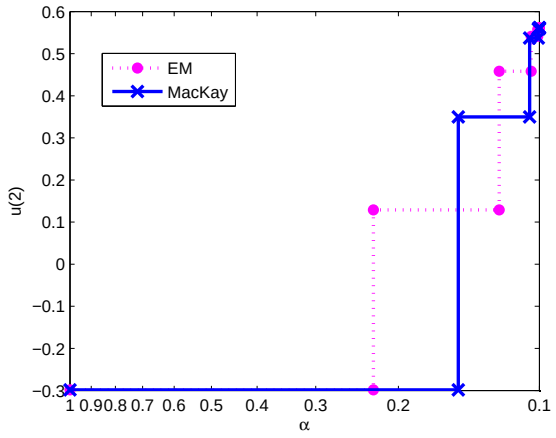
Since OptEM is a relaxation of OptMacKay, it has higher degrees of freedom during optimization. This extra degree of freedom is fully explored in the three-way coordinate descent of EM-Gauss, making its convergence slower than that of MacKay-Gauss. This slower convergence of EM-Gauss can also be understood from another perspective, in which MacKay-Gauss and EM-Gauss are both considered as optimizing the function $\mathcal{F}_{\mathrm{EM}}$.

Lemma 13. *The MacKay-Gauss Procedure is equivalent to the following two-way coordinate-ascent on* $\mathcal{F}_{\mathrm{EM}}$*.*

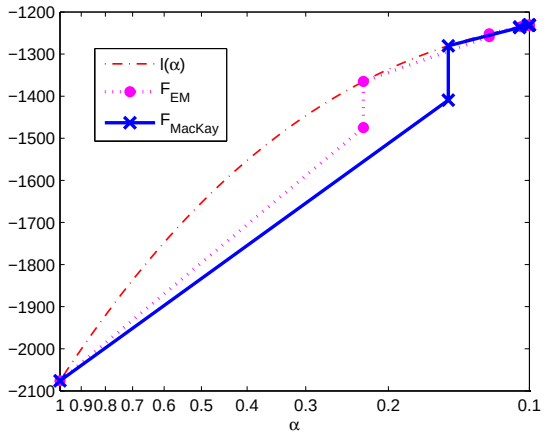
$$\begin{aligned}u^{(t)} : &= \arg\max_u \mathcal{F}_{\mathrm{EM}}(u, S^{(t-1)}, \boldsymbol{\alpha}^{(t-1)}) \\ \left(S^{(t)}, \boldsymbol{\alpha}^{(t)}\right) : &= \arg\max_{(S,\boldsymbol{\alpha})\in\mathfrak{C}} \mathcal{F}_{\mathrm{EM}}(u^{(t)}, S, \boldsymbol{\alpha}).\end{aligned}$$

Following directly from the Lemma 11 and Theorem 1, this lemma suggests that MacKay-Gauss can be viewed as optimizing the same objective function $\mathcal{F}_{\mathrm{EM}}$ as EM-Gauss,

but taking a particular coordinate-ascent path, namely, alternating between maximization over u and maximization over $(S, \boldsymbol{\alpha})$ *along the curve* $\mathfrak{C}$. This allows MacKay-Gauss to take a "shorter-cut" than EM-Gauss.



(a)



(b)

Figure 2: The convergence of both the EM algorithm and the MacKay algorithm from the initial configuration $\boldsymbol{\alpha} = 1$ to the final configuration $\boldsymbol{\alpha} \approx 0.1$. (a) The $(\boldsymbol{\alpha}, u)$-trajectories of the EM and MacKay algorithms, where an arbitrary component (in this case, the second component $u(2)$) of vector u is taken as a representative for u. (b) the function $\mathcal{F}_{\mathrm{EM}}$ evaluated along the EM trajectory and the function $\mathcal{F}_{\mathrm{MacKay}}$ evaluated along the MacKay trajectory, and the log-evidence function $l(\boldsymbol{\alpha})$ plotted using its closed-form expression.

4.4 Experiments

Experiments are performed to study the dynamics of the MacKay algorithm and the EM algorithm. We generate a simulated dataset $\mathbf{D}$ for a linear regression model according to the setup in Linear Regression Example–1 with $n = 300, d = 200, \sigma^2 = 10, \boldsymbol{\alpha} = 0.1$ where each each $x_{(i)}$ is drawn uniformly at random from the open interval $(0, 1)$. Both the EM algorithm (in Linear Regression Example-2) and the MacKay algorithm (in Linear Regression Example-3) are used to estimate $\boldsymbol{\alpha}$ from $\mathbf{D}$. For both algorithms, $\boldsymbol{\alpha}$ is initialized to 1 and σ^2 is treated as known.

The optimization trajectories of the two algorithms in Figure 2 (a) show that the MacKay algorithm converges faster towards the fixed point (top right corner) than the EM algorithm. In Figure 2 (b), we see that both the MacKay algorithm and the EM algorithm increase their respective objective functions along their optimization paths, but MacKay achieves higher value of the log-evidence function $l(\boldsymbol{\alpha})$ than EM at every iteration step.

5 Concluding Remarks

In his influential evidence framework, MacKay presented practical Bayesian methods for inference at the parameter level, at the hyper-parameter level and at the model level. For inference at the hyper-parameter level, MacKay introduced a heuristic procedure that iterates between estimating the parameter for a given hyper-parameter setting and estimating the hyper-parameter for the previous parameter setting. Although this procedure is widely adopted in empirical Bayesian methods, its mathematical principle had not been carefully explored prior to this work. In this paper, we formulate this procedure as a well-principled algorithmic framework, and call it the MacKay algorithm.

We show that the MacKay algorithm, like the EM algorithm, can be understood as a coordinate-ascent solution to optimizing a lower bound of the objective function in empirical Bayes. Although this lower bound is different from the lower bound that is optimized by the EM algorithm, we show that as long as the posterior distribution of the parameter is a Gaussian density function, the two algorithms are closely related. In particular, the EM optimization problem, the MacKay optimization problem, and the original empirical Bayes optimization problem all have the same solution. In addition, the MacKay problem is a relaxation of the original problem, and the EM problem is a relaxation of the MacKay problem. This understanding provides and intuitive explanation as to why the MacKay algorithm converges faster than the EM algorithm.

We believe that the close relationship between the MacKay algorithm and the EM algorithm revealed in this paper strongly depends on the Gaussian condition. Although this paper does not show the necessity of this condition, we believe that, in case of non-Gaussian posterior or non-Gaussian models, this relationship will break down, and the MacKay algorithm will diverge from the EM algorithm towards its own optimization objective and along its own optimization path. This makes the MacKay algorithm a framework in its own right. We hope that this paper inspire more applications of the MacKay algorithm to more general models, a territory appearing completely unexplored.

Abstract

Dantzig Selector (DS) is widely used in compressed sensing and sparse learning for feature selection and sparse signal recovery. Since the DS formulation is essentially a linear programming optimization, many existing linear programming solvers can be simply applied for scaling up. The DS formulation can be explained as a basis pursuit denoising problem, wherein the data matrix (or measurement matrix) is employed as the denoising matrix to eliminate the observation noise. However, we notice that the data matrix may not be the optimal denoising matrix, as shown by a simple counter-example. This motivates us to pursue a better denoising matrix for defining a general DS formulation. We first define the optimal denoising matrix through a minimax optimization, which turns out to be an NP-hard problem. To make the problem computationally tractable, we propose a novel algorithm, termed as "Optimal" Denoising Dantzig Selector (ODDS), to approximately estimate the optimal denoising matrix. Empirical experiments validate the proposed method. Finally, a novel sparse reinforcement learning algorithm is formulated by extending the proposed ODDS algorithm to temporal difference learning, and empirical experimental results demonstrate to outperform the conventional "vanilla" DS-TD algorithm.

1 Introduction

We consider consider the classic problem in compressed sensing, sparse learning, and statistics [Donoho, 2006, Candes and Tao, 2007, Bickel et al., 2009]:

Given a data (measurement) matrix $X \in \mathbb{R}^{n\times m}$ ($m \gg n$) and a noisy observation vector $y \in \mathbb{R}^n$ satisfying $y = X\beta^* + \epsilon$ where ϵ is the noise vector following the Gaussian distribution $N(0, \sigma^2 I)$[1] and β^* is the truth model which is a sparse vector. How to recover the sparse vector β^* from this under-determined system?

Dantzig Selector (DS) [Candes and Tao, 2007] is a widely used approach to solving this problem. The standard DS is formulated as

$$(\text{DS}) \quad \hat{\beta}_{\text{DS}} = \operatorname*{argmin}_{\beta} \ \|\beta\|_1 \tag{1a}$$

$$\text{s.t. } \|X^T(X\beta - y)\|_\infty \le \lambda. \tag{1b}$$

DS has a very similar performance to another famous formulation LASSO [Tibshirani, 1996] both empirically and theoretically [Bickel et al., 2009]. The DS formulation (1) can be formulated as a linear programming (LP) problem, thus many matured LP solvers can be directly applied to address this problem with large-scale problem settings. The DS formulation or its variation has been widely used in reinforcement learning [Geist et al., 2012, Liu et al., 2012, Mahadevan and Liu, 2012, Qin et al., 2014], computational bioinformatics [Liu, 2014], and computer vision [Cong et al., 2011].

The motivation of this paper is to explore the role of X^T (the transpose of X) in DS formulation (1). We note that the constraint in (1b) follows two principles: 1) the defined feasible region should contain the true solution β^* with high probability; and 2) to make $\hat{\beta}_{\text{DS}}$ close to β^* the feasible region defined by the constraint should be as small as possible, that is, λ is expected to a small value. Taking $\beta = \beta^*$ into the constraint leads to the smallest possible value for $\lambda = \|X^T(X\beta^* - y)\|_\infty = \|X^T\epsilon\|_\infty$. If columns of X are normalized to 1, we have $\lim_{n\to\infty} \|X^T\epsilon\|_\infty \to 0$ with high probability Candes and Tao [2007]. Therefore, the factor X^T in the constraint actually plays the role of *denoising*. This motivates us to ask two questions: 1) is X^T the optimal denoising matrix for the recovery of the sparse signal β^*?; and 2) if not, how to measure the the optimality of the denoising matrix and how to compute the optimal denoising matrix?

[1] The Gaussian distribution can be generalized to any sub-Gaussian distribution.

Unfortunately, X^T is *not* the optimal denoising matrix in general. We provide a counter-example in Section 3. The main contributions of this paper are summarized below:

- We propose a generalized denoising Dantzig selector formulation (GDDS) and define the optimal denoising matrix for sparse signal recovery via a minimax formulation;
- A two-stage approach is proposed to compute the approximately optimal denoising matrix;
- We apply the proposed ODDS algorithm to an important application in reinforcement learning: the temporal difference learning problem for sparse value function approximation.

This paper is organized as follows: Related work is introduced in Section 2. Section 3, which is the core part of this paper, proposes the general Dantzig Selector formulation with both intuitive motivations as well as the mathematical backgrounds. A generalized error bound is proposed, which leads to the definition of the optimal denoising matrix, which is NP-hard in general. To address this problem, a two-stage algorithm for approximately computing the optimal denoising matrix is given. Then in Section 4, the algorithm is applied to reinforcement learning to design a new algorithm for sparse value function approximation. The experimental results are presented in Section 5, which validate the effectiveness of the proposed algorithm.

2 Related Work

The problem considered in this paper has received substantial attentions in compressed sensing, sparse learning, and statistics. The study starts from the special case, i.e. the noiseless case $\epsilon = 0$. To recover the sparse vector β^*, there are two types of approaches: ℓ_1 norm minimization and greedy algorithms. The ℓ_1 norm minimization solves the following optimization problem to estimate β^* [Chen and Donoho, 1994, Candes and Tao, 2005]

$$\min_{\beta} \quad \|\beta\|_1 \quad \text{s.t.} \quad X\beta = y. \tag{2}$$

The theoretical study [Candes and Tao, 2005] suggests that under the restricted isometric property (RIP) condition, the ℓ_1 norm minimization formulation can recover the true solution β^* exactly. The greedy approaches include the forward greedy algorithm (or OMP) [Tropp, 2004] and the backward greedy algorithm. A similar theoretical guarantee of exact recovery is proven for the forward greedy algorithm in Zhang [2011b].

Now let us turn to the noisy case, i.e. $\epsilon \neq 0$. The noisy case is more challenging than the noiseless case. It also mainly includes two types of approaches: ℓ_1 norm minimization approaches and greedy algorithms. To deal with the noise, there are several popular formulations including DS [Candes and Tao, 2007], LASSO [Tibshirani, 1996], and basis pursuit denoising (BPDN) [Chen et al., 2001]. They essentially apply different manners to denoise. BPDN uses the ℓ_2 norm penalty to denoise:

$$\hat{\beta}_{\text{BPDN}} = \operatorname*{argmin}_{\beta} \|\beta\|_1 \quad \text{s.t.} \quad \|X\beta - y\|_2 \leq \varepsilon, \tag{3}$$

where the constraint basically restricts the noise ϵ by $\|\epsilon\| \leq \varepsilon$. DS uses the ℓ_∞ norm penalty to denoise $\|X^T\epsilon\|_\infty \leq \lambda$ as shown above. LASSO applies the same spirit as DS [Bickel et al., 2009] to denoise, but uses a different formulation

$$\hat{\beta}_{\text{LASSO}} = \operatorname*{argmin}_{\beta} \frac{1}{2}\|X\beta - y\|_2^2 + \lambda\|\beta\|_1. \tag{4}$$

The theoretical error bound for LASSO and DS is similar [Bickel et al., 2009] and better than BPDN in some sense. The key reason lies in that the noise constraint used in DS and LASSO $\|X^T\epsilon\|_\infty \leq \lambda$ is sharper than the noise constraint used in BPDN $\|\epsilon\| \leq \varepsilon$.[2] The greedy approaches mainly include the forward greedy algorithm [Zhang, 2009] and the forward-backward greedy algorithm [Zhang, 2011a, Liu et al., 2013].

While Dantzig Selector primarily focuses on ℓ_1 regularization for sparsity, the group-sparsity structures was explored [Liu et al., 2010a], and was recently extended to generalized norm [Chatterjee et al., 2014]. Other variants includes weighted Dantzig Selector [Candes et al., 2008] by re-weighting the sparse signal, multi-stage Dantzig Selector [Liu et al., 2010b] for iterative sparse signal recovery, etc. As for the computational achievements, besides the primal-dual interior point method [Candes and Tao, 2007], TFOCS [Becker et al., 2011] is also widely used. Later, inexact alternating direction method of multipliers (ADMM) formulations are proposed in [Lu et al., 2012, Wang and Yuan, 2012], which are computationally efficient.

3 Algorithm

We first show the generic error bound when "X^T" in (1b) is substituted by an arbitrary denoising matrix Q^T. Then a counter example is provided to show why X^T is not the optimal choice for Q^T. We prove an approximate method to pursue the optimal denoising matrix Q^T in the end of this section.

3.1 Generalized Denoising Dantzig Selector and its Error Bound

With the backgrounds of the denoising matrix introduced above, one intuitive question is that if X^T the optimal denoising matrix for sparse signal recovery of β^*? The answer is actually NO! To explain this, we first introduce the

[2] From the optimization perspective, BPDN seems consistent with LASSO, but the theoretical error bound is worse than LASSO and DS for some subtle reasons, which is beyond the scope of this paper.

generalized denoising Dantzig Selector formulation. Next, an error bound w.r.t the GDDS and regular DS is proposed, and it can be proven that for regular DS, the error bound is tighter than the existing error bound provided in [Candes and Tao, 2007] and [Bickel et al., 2009]. Then a simple counter-example is proposed to argue that X^T may not be the optimal denoising matrix. We here present some definitions and notations in Figure 1.

- h_T, h_{T^c}: T and T^c are two complementary subsets in $\{1, 2, \cdots, m\}$. We denote by $h_T \in \mathbb{R}^m$ the vector taking the same values as h on T and zeros in the rest; the same for $h_{T^c} \in \mathbb{R}^m$;
- $|T|$ returns the cardinality of the set T;
- $\|W\|_\infty$ is defined as the induced ∞ norm of matrix $W \in \mathbb{R}^{m\times m}$, i.e. $\|W\|_\infty = \max_x \frac{\|Wx\|_\infty}{\|x\|_\infty}$ where the vector infinity norm $\|Wx\|_\infty$ and $\|x\|_\infty$ are defined as usual;
- $\leq_{(\mathrm{P})}$: less than or equal to with high probability;

Figure 1: Notation used in this paper

First we define a generalized denoising Dantzig Selector (GDDS) formulation by using a general denoising matrix Q^T ($Q \in \mathbb{R}^{n\times m}$) to replace the X^T in the constraint:

$$\begin{aligned} (\text{GDDS}) \quad \min_{\beta} :\ & \|\beta\|_1 \\ \text{s.t.} :\ & \|Q^T(X\beta - y)\|_\infty \leq \lambda. \end{aligned} \tag{5}$$

Next we will propose an error bound for the proposed GDDS in (5) and regular DS. Since the denoising matrix is not necessarily X^T anymore, the commonly used RIP condition or restricted eigenvalue (RE) condition [Van De Geer et al., 2009] are not eligible here. To extend to the general case, we define a new condition termed as *generalized restricted (GR) constant*.

Definition 1. *(GR constant) Given $X, Q \in \mathbb{R}^{n\times m}$ and $p \in [1, \infty]$, the general restricted constant $\rho(Q^T X, p, s)$ is defined as*

$$\rho(Q, X, p, s) := \min_{|T|\leq s, \|h_{T^c}\|_1 \leq \|h_T\|_1} \frac{\|Q^T X h\|_\infty}{\|h\|_p}. \tag{6}$$

This definition essentially provides the lower bound of the ratio between $\|Q^T X h\|_\infty$ and $\|h\|_p$ over h in a subset of $\mathbb{R}^p$, which characterizes the property of $Q^T X$. The GR constant leads to a weaker condition to exactly recover the sparse signal β^* for the noiseless case ($\epsilon = 0$) and a tighter error bound for the noisy case ($\epsilon \neq 0$) than the existing analysis, as shown by Theorem 1. Based on the definition for GR constant in Definition 1, we have the following error bound on $\|\hat{\beta}_{\text{GDDS}} - \beta^*\|_p$.

Theorem 1. *Assume that the GR condition is satisfied, i.e. the GR constant $\rho(Q, X, p, \|\beta^*\|_0) > 0$. Choose $\lambda = \|Q^T\epsilon\|_\infty$ in* (5)*. We have*

$$\|\hat{\beta}_{GDDS} - \beta^*\|_p \leq \frac{2\|Q^T\epsilon\|_\infty}{\rho(Q, X, p, \|\beta^*\|_0)}, \tag{7}$$

where $\hat{\beta}_{GDDS}$ is the solution to (5) *and p can be any value in the range $[1, \infty]$.*

It should be noted that albeit with a more general error bound, Theorem 1 does not weaken the existing analysis based on the following two observations:

- In the noiseless case, i.e. $\epsilon = 0$, if the GR condition is satisfied, then $\hat{\beta}_{\text{GDDS}}$ is able to exactly recover β^*. Note that the GR condition is weaker than the RIP condition for $Q = X$ [Candes, 2008]. In other words, the RIP condition leads to GR condition when $Q = X$. The detailed interpretation is provided in Appendix.
- In the noisy case, i.e. $\epsilon \neq 0$, this bound (7) is a tighter bound than the bound $\|\hat{\beta}_{\text{DS}} - \beta^*\|_p$ for DS in [Candes and Tao, 2007, Bickel et al., 2009] for $Q = X$. Please also refer to Appendix for detailed comparisons.

The key reason why Theorem 1 does not loose the existing analysis lies in that the definition of the GR constant $\rho(Q, X, p, s)$ skips many relaxation steps by directly indicating the relationship between $\|Q^T\epsilon\|_\infty$ and $\|\hat{\beta}_{\text{GDDS}} - \beta^*\|^2$. Given p, s and X, $\rho(Q, X, p, s)$ reflects the ability for sparse signal recovery of β^* of the denoising matrix Q^T: *The larger $\rho(Q, X, p, s)$ is, the better Q is able to recover the sparse signal β^*.* Therefore, since the error bound provided in Theorem is tight enough, it is reasonable to use the bound in (7) as the evaluation criteria to see why X^T is not the optimal denoising matrix and define the optimal denoising matrix.

3.2 A Counter-Example

To see why X^T may not be the optimal denoising matrix, we show an example of Q which gives a lower value for the bound in (7). To construct such a matrix Q, we require the same conditions on Q as X, i.e. all columns of Q have been normalized with norm 1. We can verify that any Q with unit column norm, the value of $\|Q^T\epsilon\|_\infty$ is comparable to $\|X^T\epsilon\|_\infty$, according to the following standard results in Lemma 1.

Lemma 1. *For any $Q \in \mathbb{R}^{n\times m}$ satisfying $\|Q_{\cdot i}\| = 1$ for $i = 1, \cdots, m$, we have*

$$\|Q^T\epsilon\|_\infty \leq \sigma\sqrt{\log m}$$

with high probability at least $1 - O(1/m)$.

The key reason why $\|Q^T\epsilon\|_\infty$ and $\|X^T\epsilon\|_\infty$ are comparable lies in that all entries in random vectors $Q^T\epsilon \in \mathbb{R}^p$

and $X^T\epsilon \in \mathbb{R}^p$ follow the same Gaussian distribution $\mathcal{N}(0, \sigma^2)$. Since $\|Q^T\epsilon\|_\infty$ and $\|X^T\epsilon\|_\infty$ are comparable, we only need to find an example for Q such that $\rho(Q, X, p, s) > \rho(X, X, p, s)$ for some X. Let $s = 1$ for simplicity and

$$X = \begin{pmatrix} \sqrt{3}/2 & 1/2 \\ 1/2 & \sqrt{3}/2 \end{pmatrix}, \; Q = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (8)$$

We have

$$X^T X = \begin{pmatrix} 1 & \sqrt{3}/2 \\ \sqrt{3}/2 & 1 \end{pmatrix} \quad (9)$$

$$\begin{aligned} \rho(X, X, p, 1) = & \min_{\substack{|T|\le 1 \\ \|h_{T^c}\|_1 \le \|h_T\|_1}} \frac{\|X^T X h\|_\infty}{\|h_T\|_p} \\ = & 1 - \sqrt{3}/2 = 0.134, \\ \rho(Q, X, p, 1) = & \min_{\substack{|T|\le 1 \\ \|h_{T^c}\|_1 \le \|h_T\|_1}} \frac{\|Q^T X h\|_\infty}{\|h_T\|_p} \\ = & \sqrt{3}/2 - 1/2 = 0.366, \end{aligned}$$

where in both cases the optimal value of h is $h = [1, -1]^T$ regardless of the value of p. Thus, this example shows that X^T may not always be the optimal denoising matrix.

3.3 Optimal Denoising Matrix and its Approximation

From the counter-example in the previous section, we know that X is not the optimal option for Q to maximize $\rho(Q, X, p, s)$. Therefore, it raises an optimization problem to find the optimal Q:

$$Q^* = \operatorname*{argmax}_{\|Q_{.i}\| \le 1} \min_{\substack{|T|\le s \\ \|h_{T^c}\|_1 \le \|h_T\|_1}} \frac{\|Q^T X h\|_\infty}{\|h_T\|_p}. \quad (10)$$

However, this formulation is extremely difficult to solve. Although we can solve it easily for small n, m as in our example above, it is NP-hard in general. Therefore, it is unrealistic to solve this problem exactly. To find a reasonable approximation, we consider an alternative way to finding an optimal matrix $W \approx Q^T X$:

$$W^* = \operatorname*{argmax}_{\|W\|_\infty \le 1} \min_{\substack{|T|\le s \\ \|h_{T^c}\|_1 \le \|h_T\|_1}} \frac{\|Wh\|_\infty}{\|h_T\|_p}. \quad (11)$$

One can easily verify that the optimal solution is $W^* = I$.[3] The second step is to find the optimal Q. We try to find the best Q from another perspective. Intuitively, we want $Q^T X$ to be close to the identity matrix. We estimate Q by the following:

$$\min_Q : \; \|Q^T X - I\|_p \quad \text{s.t.} : \quad \|Q_{.i}\| \le 1 \quad (12)$$

[3] Actually, it is not important which norm is used to restrict W. For most norms we verified, the optimal solution for W should be a diagonal matrix with equal values.

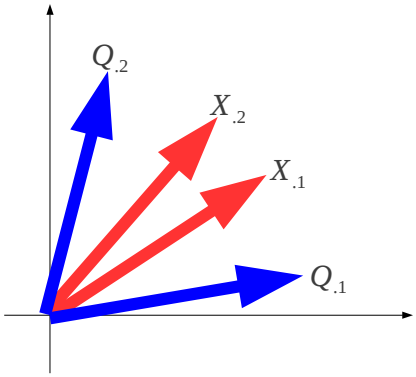

Figure 2: An example of X and Q.

where $p \in [1, \infty]$ and $\|X\|_p := (\sum_{i,j} |X_{ij}|^p)^{1/p}$. We have many options for choosing $p \in [1, \infty]$. Based on our empirical study, a reasonable empirical value for p is $p = 2$, and thus the problem can be recast as a strongly convex problem

$$\min_Q : \; \|Q^T X - I\|_2^2 \quad \text{s.t.} : \quad \|Q_{.i}\| \le 1 \quad (13)$$

There are many optimization algorithms to address this problem. We use Nesterov's accelerated gradient method [Nesterov, 2004]. Note that the empirical Q obtained from (12) or (13) is generally different from the optimal one defined in (10). And the optimal denoising Dantzig Selector algorithm is summarized as in Algorithm 1.

Algorithm 1 "Optimal" Denoising Dantzig Selector (ODDS)

Require: $X \in \mathbb{R}^{n \times m}, y \in \mathbb{R}^n$
Ensure: β
Compute the denoising matrix Q^T via Eq. (13)
Compute β via Eq. (5)

Figure 2 provides an example of Q and X in the two-dimensional case. Intuitively, Q is an approximation to X by slightly modifying all feature (column) vectors of X such that they are as different from each other as possible.

4 Reinforcement Learning

Dantzig selector has an important application in reinforcement learning. This section first briefly introduces reinforcement learning and then shows how to apply the proposed ODDS method to it.

A *Markov Decision Process* (MDP) is defined by the tuple $(S, A, P^a_{ss'}, R, \gamma)$, comprised of a set of states S, a set of actions A, a dynamical system model comprised of the transition kernel $P^a_{ss'}$ specifying the probability of transition from state $s \in S$ to state $s' \in S$ under action $a \in A$, a reward model $R(s, a) : S \times A \to \mathbb{R}$, and $0 \le \gamma < 1$ is a discount factor. A policy $\pi : S \to A$ is a deterministic

mapping from states to actions. Associated with each policy π is a value function V^π, which is the fixed point of the Bellman equation:

$$V^\pi = T^\pi(V^\pi) = R^\pi + \gamma P^\pi V^\pi,$$

for a given state $s \in S$, $R^\pi(s) = R(s, \pi(s))$, and P^π is the state transition function under fixed policy π, and T^π is known as the *Bellman operator*. In what follows, we often drop the dependence of V^π, T^π, R^π on π, for notation simplicity. In linear value function approximation, a value function is assumed to lie in the linear span of a basis function matrix Φ of dimension $|S| \times d$, where d is the number of linear independent features. It is easy to show that the "best" approximation $\hat{v}_{\text{best}}$ of the true value function V satisfies the following equation,

$$\hat{v}_{\text{best}} = \Pi V = \Pi L^{-1} R, \tag{14}$$

where $\Pi = \Phi(\Phi^T \Xi \Phi)^{-1} \Phi^T \Xi$, Ξ is a diagonal matrix where the i-th diagonal entry ξ_i is the stationary state distribution w.r.t state s_i. and $L = I - \gamma P$. However, L^{-1} is also computationally prohibitive. To this end, a more practical way is to compute a Galerkin-Bubnov approximate solution [Yu and Bertsekas, 2010] is via solving a fixed-point equation

$$\hat{v} = \Pi_\Phi^X T \hat{v} \tag{15}$$

w.r.t an oblique projection Π_Φ^X onto $\text{span}(\Phi)$ orthogonal to X, i.e., $\Pi_\Phi^X = \Phi(X^T\Phi)^{-1}X^T$. The existence and uniqueness of the solution can be verified since T is a contraction mapping, Π_Φ^X is a non-expansive mapping, and thus $\Pi_\Phi^X T$ is a contraction mapping. As for the optimal solution $\hat{v}_{\text{best}}$, we have $X_{\text{best}} = (L^T)^{-1}\Xi\Phi$, which is also computational expensive. An often used X used in the fixed-point equation (15) is $X_{TD} = \Xi\Phi$, which is computationally affordable, and the corresponding solution to the fixed-point equation is $\hat{v}_{TD}$. The other often used X is $X_{BR} = \Xi L \Phi$ [Scherrer, 2010], which we will not explained in details here. However, it is obvious that none of X_{TD} or X_{BR} is the optimal solution. In fact, it has been shown that $||V - \hat{v}_{TD}||_\Xi \leq \frac{1}{1-\gamma}||V - \hat{v}_{\text{best}}||_\Xi$ [Tsitsiklis and Van Roy, 1997], which implies that approximation error $||V - \hat{v}_{TD}||_\Xi$ between the true value function V and $\hat{v}_{TD}$ can be arbitrarily bad when $\gamma \to 1$. Given a fixed-point equation (15), we have

$$\Pi_\Phi^X T\hat{v} - \hat{v} = \Pi_\Phi^X(T\hat{v} - \hat{v}) = \Phi(X^T\Phi)^{-1}X^T(T\hat{v} - \hat{v}) \tag{16}$$

Thus we can formulate the approximation error via constraining $||X^T(T\hat{v} - \hat{v})||_\infty \leq \lambda$.

Since the P, R, Ξ models are not accessible, the sample-based estimation is used. Given n training samples of the form $\left(s_i, a_i, r_i, s_i'\right)_{i=1}^n$, $s_i \sim \Xi$, $r_i = r(s_i, a_i)$, $a_i \sim \pi_b(\cdot|s_i)$, $s_i' \sim P(\cdot|s_i, a_i)$, the empirical Bellman operator $\hat{T}$ is thus written as

$$\hat{T}(\hat{\Phi}\theta) = \hat{R} + \gamma\hat{\Phi}'\theta \tag{17}$$

We denote $\hat{\Phi}$ (resp. $\hat{\Phi}'$) the empirical feature matrices whose i-th row is the feature vector $\phi(s_i)^T$ (resp. $\phi(s_i')^T$), and $\hat{R} \in \mathbb{R}^n$ the empirical reward vector with corresponding r_i as the i-th row. And the error constraint can be formulated as $||Q^T(A\theta - b)||_\infty \leq \lambda$, where $A = \hat{\Phi} - \gamma\hat{\Phi}', b = \hat{R}$, and $Q \in \mathbb{R}^{n \times d}$. So given Q and a pre-defined error λ, the Dantzig Selector temporal difference learning problem can be formulated as

$$\hat{\theta}_{\text{DS-TD}} = \underset{\theta}{\text{argmin}} \|\theta\|_1 \quad \text{s.t.} \quad \|Q^T(A\theta - b)\|_\infty \leq \lambda.$$

If $Q = \hat{\Phi}$, then the algorithm is the DS-TD algorithm [Geist et al., 2012]. Motivated by the GDDS algorithm to find the optimal denoising matrix Q^T, we design a new Dantzig Selector temporal difference learning algorithm to compute the optimal Q^T for sparse value function approximation as follows

$$\hat{\theta}_{\text{ODDS-TD}} = \underset{\theta}{\text{argmin}} \|\theta\|_1 \quad \text{s.t.} \quad \|Q^T(A\theta - b)\|_\infty \leq \lambda \tag{18}$$

where Q is computed from solving

$$\min_Q : \ \|Q^T A - I\|_F^2 \quad \text{s.t.} : \quad \|Q_{.i}\| \leq 1 \tag{19}$$

Based on above, we propose the following ODDS-TD algorithm.

Algorithm 2 "Optimal" Denoising Dantzig Selector for Temporal Difference Learning with (ODDS-TD)

Require: A, b
Ensure: $\hat{\theta}_{\text{ODDS-TD}}$
Compute the denoising matrix Q^T via Eq. (19)
Compute $\hat{\theta}_{\text{ODDS-TD}}$ via Eq. (18)

5 Empirical Experiment

Experiments are first conducted on synthetic data with small-scale size and medium-scale respectively. Next, we apply the proposed method to a reinforcement learning problem on real data sets to show its advantage over existing algorithms.

5.1 Small-Scale Experiment

In this experiment, we conduct the comparison study between the regular Dantzig Selector (DS) and ODDS. We first compare the performance of different algorithms w.r.t different sparsity and noise levels. We set $n = 100, m = 150$, the true signal β^* is preset, with different numbers of non-zero elements (NNZ) among $10, 15, 20, 25$. We also change different noise level varying among $\sigma = 0.1, 0.2, 0.3$. Figure 3 shows the performance comparison of the two algorithms, wherein in each subfigure, the noise level is the same, and the x-axis denotes the NNZ level, and the result is measured by the difference of the learned sparse signal with β^*. From Figure 3, we can see that $||\hat{\beta}_{\text{ODDS}} - \beta^*||_2$ is much smaller than $||\hat{\beta}_{\text{DS}} - \beta^*||_2$.

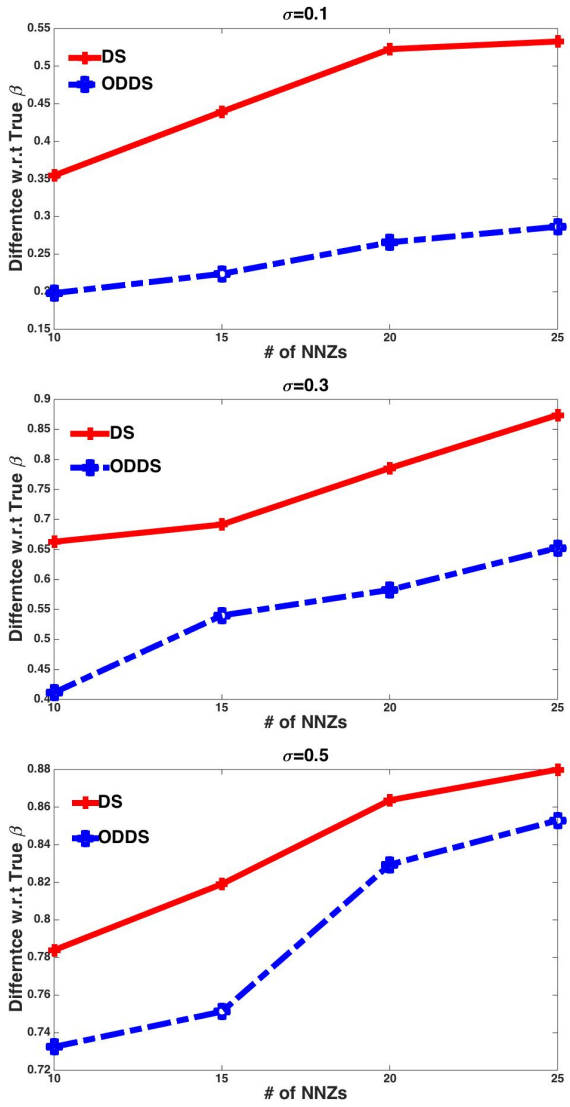

Figure 3: Small-scale Experiment w.r.t different sparsity levels.

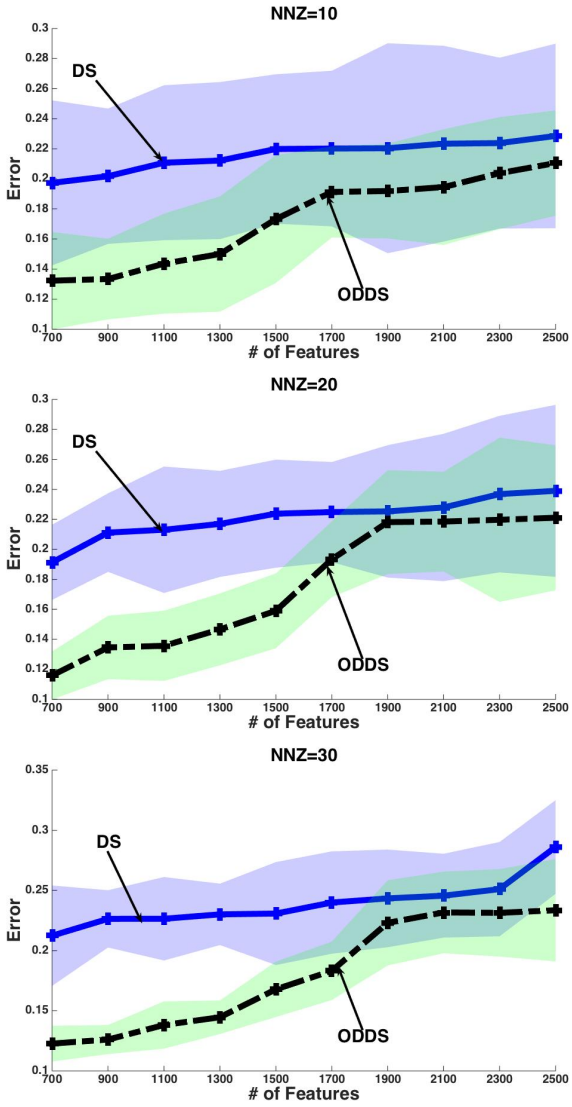

Figure 4: Comparison w.r.t different number of features.

5.2 Medium-Scale Experiment

In this experiment, we conduct the comparison study between the regular DS and ODDS. The experimental setting is that given $n = 500$, the number of features m goes among $700, 900, \cdots, 2500$, and $NNZ = 10$. The noise level $\sigma = 0.01$, and λ is chosen as $\lambda = \sigma\sqrt{2\log n}$ as suggested by [Candes and Tao, 2007] for a fair comparison between DS and ODDS, and the result is averaged by the mean-squares error (MSE), which is averaged over 50 runs. From Figure 4, we can see that the performance of ODDS is much better than that of regular DS, with both much lower MSE error and less variance.

5.3 ODDS-TD Experiment

In this experiment, we compare the performance of the DS-TD [Geist et al., 2012] and the proposed ODDS-TD algorithm. We test the performances of the two algorithms on the 20-state corrupted chain domain, wherein the two goal-states are $s \in [1, 20]$ with the reward signal $+1$, and the probability transition to the nearest goal-state is 0.9. The features are constructed as follows. 5 radial basis functions (RBF) are constructed, and one constant is used as an offset, and all other noisy features are randomly drawn from Gaussian distribution. So for each sample s_t, the feature vector $\phi(s) = [1, \text{RBF}(1), \cdots, \text{RBF}(5), s_1, \cdots, s_n]$. 200 off-policy samples are collected via randomly sampling the state space. Two comparison studies are carried out. In the first experiment, there are 300 noisy features, so altogether there are 306 features, and the value function approximation result is shown in the first subfigure of Figure 5, where v_{ODDS} and v_{DS} are the value function approximation results of ODDS and regular DS. From the figures, one can see that the v_{ODDS} is much more accurate than that of v_{DS}. The second experiment poses an even more challenging task, where the number of noisy features is set to be 600, so altogether there are 606 features, which makes the feature selection task much more difficult, and the result is shown in the second subfigure of Figure 5. We can see that

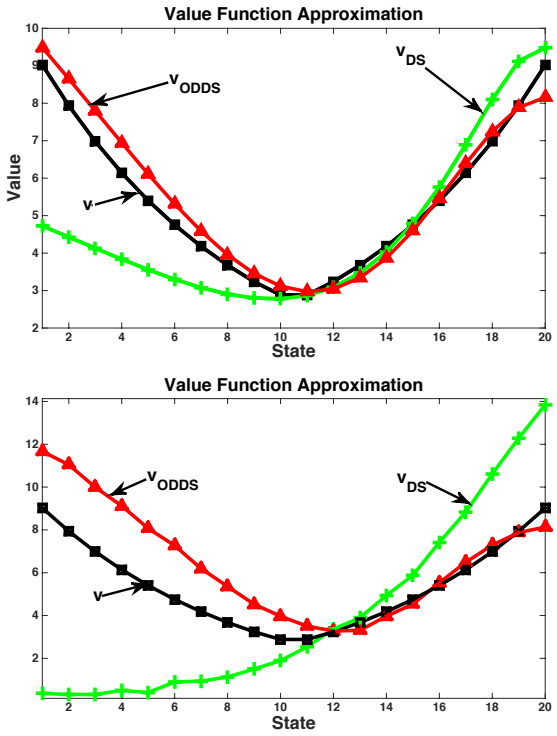

Figure 5: Comparison between ODDS-TD and DS-TD

v_{DS} has been severely distorted, whereas v_{ODDS} is still able to well preserve the topology of the value function, and is able to generate the right policy.

6 Conclusion

In this paper, motivated by achieving a better sparse signal recovery, we propose a generalized denoising matrix Dantzig selector formulation. A two-stage algorithm is proposed to find the optimal denoising matrix. The algorithm is then applied to sparse value function approximation problem in temporal difference learning field, and the empirical results validate the efficacy of the proposed algorithm. There are many interesting future directions along this research topic. For example, the ODDS framework can be extended to weighted Dantzig Selector (WDS) [Candes et al., 2008], multi-stage Dantzig Selector [Liu et al., 2010b], group Dantzig Selector [Liu et al., 2010a] and generalized Dantzig Selector [Chatterjee et al., 2014], which are parallel research directions of the Dantzig Selector algorithms family.

A Theoretical Analysis of ODDS

Proof to Theorem 1

Proof. Denote the difference between the solution to (5) $\hat{\beta}_{\text{GDDS}}$ and the true model β^* as $h = \hat{\beta}_{\text{GDDS}} - \beta^*$. Denote the support set of β^* by $T \subset \{1, 2, \cdots, m\}$. First we verify that the true model β^* is a feasible point to the problem (5) due to the following observation

$$\|Q^T(X\beta^* - y)\|_\infty = \|Q^T\epsilon\|_\infty \leq \lambda.$$

Since $\hat{\beta}_{\text{GDDS}}$ is the minimizer of problem (5), it follows that

$$\begin{aligned}
&\|\hat{\beta}_{\text{GDDS}}\|_1 \leq \|\beta^*\|_1 \\
\Rightarrow &\sum_{j\in T} |(\hat{\beta}_{\text{GDDS}})_j| + \sum_{j\in T^c} |(\hat{\beta}_{\text{GDDS}})_j| \leq \sum_{j\in T} |\beta^*_j| \\
\Rightarrow &\sum_{j\in T^c} |(\hat{\beta}_{\text{GDDS}})_j| \leq \sum_{j\in T} |\beta^*_j - (\hat{\beta}_{\text{GDDS}})_j| \\
\Rightarrow &\|h_{T^c}\|_1 \leq \|h_T\|_1.
\end{aligned}$$

From the definition of $\rho(Q, X, p, s)$ in (6), we have

$$\rho(Q, X, p, \|\beta^*\|_0)\|h\|_p \leq \|Q^T X h\|_\infty$$

which indicates

$$\|h\|_p \leq \frac{\|Q^T X h\|_\infty}{\rho(Q, X, p, \|\beta^*\|_0)}. \tag{20}$$

It follows that

$$\begin{aligned}
\|Q^T X h\|_\infty =& \|Q^T X(\hat{\beta}_{\text{GDDS}} - \beta^*)\|_\infty \\
=& \|Q^T(X\hat{\beta}_{\text{GDDS}} - y + \epsilon)\|_\infty \\
\leq& \|Q^T(X\hat{\beta}_{\text{GDDS}} - y)\|_\infty + \|Q^T\epsilon\|_\infty \\
\leq& 2\|Q^T\epsilon\|_\infty.
\end{aligned}$$

Combining (20), we obtain the desired error bound

$$\|h\|_p \leq \frac{2\|Q^T\epsilon\|_\infty}{\rho(Q, X, p, \|\beta^*\|_0)}.$$

It completes the proof. □

Proof of Lemma 1

Proof. This proof follows the standard union bound proof. For completion, we provide the proof below. Since $\epsilon \sim \mathcal{N}(0, I_{n\times n}\sigma^2)$, for each linear combination of ϵ, we have $Q_{.i}^T\epsilon \sim \mathcal{N}(0, \sigma^2)$. Recall that for any $t > 0$, we have that

$$\int_t^\infty e^{-x^2/2}dx \leq e^{-t^2/2}/t. \tag{21}$$

Denote the event $A_i = \{|Q_{.i}^T\epsilon| \leq \lambda\}, i = 1, 2, \cdots, m$:

$$\begin{aligned}
\{\|Q^T\epsilon\|_\infty \leq \lambda\} &= \{\max_{1\leq i\leq m} |Q_{.i}^T\epsilon| \leq \lambda\} \\
&= \cap_{i=1}^m A_i.
\end{aligned}$$

We derive the probability as follows:

$$\begin{aligned}\Pr(\cap_{i=1}^m A_i) &= 1-\Pr(\cup_{i=1}^m A_i^c)\\ &\geq 1-\sum_{i=1}^m \Pr(A_i^c)\\ &= 1-m\Pr(|\xi|\geq\lambda/\sigma)\\ &\geq 1-2\frac{m\sigma}{\lambda}e^{-\lambda^2/2\sigma^2},\end{aligned}$$

where the second inequality holds by union bound and the last inequality follows (21) since $\xi \sim \mathcal{N}(0,1)$. Thus, we can take $\lambda = 2\sigma\sqrt{\log m}$ so that

$$\Pr(\|Q^T\epsilon)\|_\infty \leq \lambda) \geq 1 - 1/m\sqrt{\log m} = 1 - O(1/m).$$

It completes the proof. □

RIP Condition Implies GR Condition

Recall that to exactly recover β^* the RIP condition requires that $\delta_{2s} > \sqrt{2}-1$ [Candes, 2008], where $s = \|\beta^*\|_0$ and δ_{2s} is defined as for matrix X^TX is defined as

$$1-\delta_{2s} \leq \frac{\|Xg\|^2}{\|g\|^2} \leq 1+\delta_{2s} \quad \forall\, \|g\|_0 \leq 2s.$$

Now we need to prove that $\delta_{2s} > \sqrt{2}-1$ leads to the GR condition $\rho(X, X, 2, \|\beta^*\|_0) > 0$.

Consider an arbitrary vector h and an arbitrary index set $T_0 \subset \{1, 2, \cdots, m\}$ with cardinality s satisfying $\|h_{T_0}\|_1 \geq \|h_{T_0^c}\|_1$. T_1 corresponds to the locations of the s largest coefficients of $h_{T_0^c}$; T_2 to the locations of the next s largest coefficients of $h_{T_0^c}$, and so on. We use T_{01} to denote $T_0 \cup T_1$ for short.

Note the fact that if $Xh \neq 0$, then $X^TXh \neq 0$. To obtain $\rho(X, X, 2, \|\beta^*\|_0) > 0$, it suffices to show that for any nonzero h satisfying $\|h_{T_0^c}\|_1 \leq \|h_{T_0}\|_1$, the following ratio is positive

$$\|Xh\|/\|h\| > 0. \tag{22}$$

We have

$$\begin{aligned}&|\langle Xh, Xh_{T_{01}}\rangle|\\ \geq&\|Xh_{T_{01}}\|^2 - \sum_{j\geq 2}|\langle Xh_{T_{01}}, Xh_{T_j}\rangle|\\ \geq&\|Xh_{T_{01}}\|^2 - \sum_{j\geq 2}|\langle Xh_{T_0}, Xh_{T_j}\rangle| - \sum_{j\geq 2}|\langle Xh_{T_1}, Xh_{T_j}\rangle|\\ \geq&\|Xh_{T_{01}}\|^2 - \delta_{2s}\sum_{j\geq 2}(\|h_{T_0}\| + \|h_{T_1}\|)\|h_{T_j}\|\\ \geq&\|Xh_{T_{01}}\|^2 - \sqrt{2}\|h_{T_{01}}\|\delta_{2s}\sum_{j\geq 2}\|h_{T_j}\|\\ \geq&\|Xh_{T_{01}}\|^2 - \sqrt{2}\|h_{T_{01}}\|\delta_{2s}\|h_{T_0^c}\|_1 s^{-1/2}\\ \geq&(1-\delta_{2s})\|h_{T_{01}}\|^2 - \sqrt{2}\delta_{2s}\|h_{T_{01}}\|^2\\ \geq&(1-(\sqrt{2}+1)\delta_{2s})\|h_{T_{01}}\|^2,\end{aligned}$$

where the third inequality uses the result $|\langle Xh_{T_i}, Xh_{T_j}\rangle| \leq \delta_{2s}\|h_{T_i}\|\|h_{T_j}\|$ if $i \neq j$, see Lemma 2.1 Candes [2008]). It follows from the fact $|\langle Xh, Xh_{T_{01}}\rangle| \leq \|Xh\|\|Xh_{T_{01}}\|$ that

$$\|Xh\| \geq (1-(\sqrt{2}+1)\delta_{2s})\|h_{T_{01}}\|. \tag{23}$$

From $\|h_{T_0^c}\|_1 \leq \|h_{T_0}\|_1$, we have $\|h\| \leq 2\|h_{T_{01}}\|$, see the last line of the proof for Theorem 1.2 in [Candes, 2008]. It also can be found from [Candes and Tao, 2007, Bickel et al., 2009]. Together with (23) and the RIP condition $\delta_{2s} < \sqrt{2}-1$, we obtain

$$\|Xh\| \geq (1-(\sqrt{2}+1)\delta_{2s})\|h_{T_{01}}\| \geq \frac{(1-(\sqrt{2}+1)\delta_{2s})}{2}\|h\|,$$

which verifies (22).

Comparison to Existing Error Bounds for DS

This section aims to show that the error bound provided in (7) is a tighter bound than two existing results in [Candes and Tao, 2007] and [Bickel et al., 2009]. For simpler notations, we denote the difference between the estimate $\hat{\beta}_{\text{DS}}$ by DS and the true model β^* as $h = \hat{\beta}_{\text{DS}} - \beta^*$, T denotes the support set of β^*, and s denotes the sparsity of β^*. The complete comparison requires extensive space to basically repeat the proofs in [Candes and Tao, 2007] and [Bickel et al., 2009]. Here, we just show their results, highlight the key point in their original proofs, and illustrate why our error bound does not loose theirs.

Existing results conducted in [Candes and Tao, 2007] and [Bickel et al., 2009] are only based on the following facts

- (FACT 1) $\|h_{T^c}\|_1 \leq \|h_T\|_1$ (Please refer to Eq. (3.2) in [Candes and Tao, 2007] and Eq. (B.12) in [Bickel et al., 2009]);
- (FACT 2) $\|X^TXh\|_\infty \leq 2\|X^T\epsilon\|_\infty \leq_{\text{(P)}} 2\sigma\sqrt{\log m}$ (Please refer to Eq. (3.3) in [Candes and Tao, 2007] and Eq. (B.7) in [Bickel et al., 2009]).

which are also the foundations to provide our error bound in (7).

The error bound provided in Theorem 1.1 of [Candes and Tao, 2007] is derived from (see the end of Proof of Theorem 1.1 in [Candes and Tao, 2007])

$$\begin{aligned}\|h\| &\overset{\text{(FACT 1)}}{\leq} \frac{2\sqrt{s}}{1-\delta-\theta}\|X^TXh\|_\infty\\ &\overset{\text{(FACT 2)}}{\leq} \frac{2\sqrt{s}}{1-\delta-\theta}2\|X^T\epsilon\|_\infty.\end{aligned} \tag{24}$$

Please check the original paper for the definitions of δ and θ. The error bound (with $p = 2$, $m = s$) provided in [Bickel et al., 2009] is derived from

$$\begin{aligned}\|h\| &\overset{\text{(FACT 1)}}{\leq} \frac{32s}{\kappa(s,s,1)}\|X^TX\epsilon\|_\infty\\ &\overset{\text{(FACT 2)}}{\leq} \frac{32s}{\kappa(s,s,1)}2\|X^T\epsilon\|_\infty.\end{aligned} \tag{25}$$

Please refer to the original paper for the definition of $\kappa(s, s, 1)$.

From these two bounds in (24) and (25), they essentially uses FACT 1 to find an upper bound for $\|h\|/\|X^T Xh\|_\infty$. This observation motivates us to directly define the upper bound through the definition of $\rho(\cdot, \cdot, \cdot)$ in (6)

$$\rho(X, X, s, 2) \leq \frac{\|X^T Xh\|_\infty}{\|h\|} \quad \forall h \text{ under FACT 1.}$$

Then we simply apply FACT 2 as (24) and (25) to obtain the error bound in (7). Therefore, our analysis provides a tighter error bound than Candes and Tao [2007] and Bickel et al. [2009].

Importance Weighted Consensus Monte Carlo for Distributed Bayesian Inference

Qiang Liu

qiang.liu@dartmouth.edu

Abstract

The recent explosion in big data has created a significant challenge for efficient and scalable Bayesian inference. In this paper, we consider a divide-and-conquer setting in which the data is partitioned into different subsets with communication constraints, and a proper combination strategy is used to aggregate the Monte Carlo samples drawn from the local posteriors based on the dataset subsets. We propose a new importance weighted consensus Monte Carlo method for efficient Bayesian inference in this setting. Our method outperforms the previous one-shot combination strategies in terms of accuracy, and is more computation- and communication-efficient than the previous iterative combination methods that require iterative re-sampling and communication steps. We provide two practical versions of our approach, and illustrate their properties both theoretically and empirically.

1 INTRODUCTION

Bayesian inference provides a powerful paradigm for reasoning with uncertain data by reducing inference problems into computational problems that can be routinely solved using efficient methods like Monte Carlo (MC) or Markov chain Monte Carlo (MCMC) methods. However, the recent explosion in big data has created a significant challenge for efficient and scalable Bayesian inference due to the difficulty for evaluating the likelihood across all the data points; traditional methods like Gibbs sampling and Metropolis-Hastings are extremely slow when the size of datasets is large.

We consider a divide-and-conquer approach for Bayesian computation under big data, in which case we partition the data into multiple subsets, and draw posterior samples on each subset separately, and then combine the results properly. Typical combination methods mostly rely on first approximating the subset posteriors using certain density estimation method and then combine the corresponding estimated densities. For example, the *consensus Monte Carlo* by Scott et al. (2013) fits the subset samples using normal distributions in which case the density combination reduces to a simple weighted linear averaging on the samples; Neiswanger et al. (2013) instead approximates each subset posterior using kernel density estimator (KDE), and uses another MCMC to draw sample from the product of KDEs. These methods are "one-shot" in that they do not require any further communication beyond passing the posterior samples; however, these methods critically rely on the qualities of the density estimators and often do not perform well in practice. Other *iterative* methods (e.g., Wang & Dunson, 2013; Xu et al., 2014) propose to iteratively resample from the local posteriors with adjusted local priors to enforce a consistency between the subset posteriors. Although being able to improve the performance iteratively, these methods require to re-draw the samples repeatedly, resulting higher computation and communication costs.

We propose a new importance weighted consensus Monte Carlo method for efficient distributed Bayesian inference. The key ingredient of our method is an importance weighted consensus strategy that efficiently combines the subset samples by leveraging their likelihood information. Our method performs significantly better than the pervious one-shot methods based on density estimations that solely rely on the subset samples and ignore the likelihood information. In addition, we show that our method can perform as efficient as the iterative combination methods, but with much less communication and computational costs.

Related Work The divided-and-conquer approach for scalable Bayesian computation has been studied in a series of recent works (Huang & Gelman, 2005; Scott et al., 2013; Neiswanger et al., 2013; Wang & Dunson, 2013; Xu et al., 2014; Minsker et al., 2014; Rabinovich et al., 2015). Another major approach for scalable Bayesian inference is based on efficient subsampling; see e.g., Korattikara et al. (2014); Welling & Teh (2011); Maclaurin & Adams (2014);

Bardenet et al. (2014). Despite being a relatively new topic, there are already a rich set of comprehensive reviews (Bardenet et al., 2015; Green et al., 2015; Zhu et al., 2014; Baker et al., 2015; Angelino et al., 2015).

Outline The rest of this paper is organized as follows. Section 2 introduces backgrounds and review the existing methods. Section 3 introduces our main method, where we propose two practical versions of our method and study their properties. Section 4 presents empirical results on both simulated and real-world datasets. The conclusion is made in Section 5.

2 BACKGROUND AND EXISTING METHODS

Consider a probabilistic model $p(D|x)$ where x is a random parameter with prior $p(x)$ and D is the observed data. Bayesian computation involves inferring the posterior distribution $f(x) \propto p(D|x)p(x)$, often in terms of calculating posterior moments of form $\mathbb{E}_f[h(x)] = \int h(x)f(x)dx$, where $h(x)$ is a test function, including the mean, variance or credible intervals. Typical Monte Carlo methods work by drawing samples from the posterior $\{x_i\}_{i=1}^n \sim f(x)$, and approximating the posterior moments by $\sum_{i=1}^n h(x_i)/n$; this gives a consistent estimator with mean squared error $\mathrm{var}_f[h(x)]/n$ with i.i.d. samples. Unfortunately, directly sampling from $p(D|x)$ requires to repeatedly evaluate the posterior probability and can be prohibitively slow when the number of data instances in D is very large.

We consider a divided-and-conquer approach in which case the data D is partitioned into m independent, non-overlapping subsets $D^1, \dots, D^m$, so that we have

$$f(x) \stackrel{def}{=} p(x|D) \propto p(x) \prod_{k=1}^{m} p(D^k|x).$$

This allows us to decompose the global posterior $f(x)$ into a product of "local posteriors" $f_k(x)$:

$$f(x) \propto \prod_k f_k(x), \qquad f_k(x) = p(D^k|x)p(x)^{1/m},$$

where each local posterior $f_k(x)$ receives $1/m$ of the original prior. Note that we do not assume D^m to have the same size nor follow a same probabilistic model.

Since each subset contains less data points, it is easier to sample from each of the local posteriors independently, which can be done in a parallel fashion. A critical problem, however, is how to inference about the global posterior $f(x)$, or estimate $\mathbb{E}_f[h(x)]$, using the samples from the local posteriors $\{x_i^k\}_{i=1}^n \sim f_k(x)$, $k = 1, \dots, m$.

Existing Methods Useful perspectives can be obtained by considering the special case when $f_k(x)$ are assumed to be normal distributions, e.g., $f_k(x) = \mathcal{N}(x; \mu_k, \Sigma_k)$. This is justified by Bernstein-Von Mises Theorem, which says that the posterior $f_k(x)$ is close to normal when the number of data points in D^k is large. An important property of Gaussian distributions is that the product $f \propto \prod_k f_k$ of the densities f_k is equivalent to the density function of a weighted averaging $\bar{x} = \sum_k w_k x^k$, where $w_k = (\sum_k \Sigma_k^{-1})^{-1}\Sigma_k^{-1}$ and $x^k \sim f_k$. This motivates the consensus Monte Carlo (CMC) method (Scott et al., 2013) that combines the subset posterior samples by

$$\bar{x}_i = \sum_k \hat{w}_k x_i^k, \quad \hat{w}_k = (\sum_k \hat{\Sigma}_k^{-1})^{-1}\hat{\Sigma}_k^{-1},$$

where the exact covariance matrix Σ_k is replaced by the empirical covariance matrix $\hat{\Sigma}_k$ of $\{x_i^k\}_{i=1}^n$.

Unfortunately, CMC does not provide guarantees for non-Gaussian cases. Neiswanger et al. (2013) proposed a more general approach which approximates each subset posterior $f_k(x)$ with a Gaussian kernel density estimator (KDE), and then sample from the product of the KDEs using MCMC. This methods, however, does not scale well in high dimensions due to the use of non-parametric density estimation; in particular, the MSE of this method is $O(n^{-2/(2+d)})$, where d is the dimension of x; when $d > 2$, this is worse than the typical parametric rate $O(n^{-1/2})$ that we would get from the global posterior sampling.

In fact, we argue that inferring the global posterior $f \propto \prod_k f_k$ using only the subset samples $x_i^k \sim f_k(x)$ is fundamentally difficult, since it involves evaluating non-linear functionals of form $\int h(x) \prod_k f_k(x)dx$ for which certain non-parametric density estimates of f_k are unavoidable, and subjects to non-parametric minimax lower bounds that are generally worse than $O(n^{-1/2})$; see, for example, Birge & Massart (1995); Krishnamurthy et al. (2015, 2014) for discussions related to estimating the simpler form $\int f_1(x)f_2(x)dx$.

Therefore, acquiring further information is critical for improving the performance. Several authors (Wang & Dunson, 2013; Xu et al., 2014) have proposed to iteratively adjust and resample from the local posteriors to improve the results. Specifically, they set the local posteriors to be $f_k(x) \propto p(D^k|x)p_k(x)$, where $p_k(x)$ is a local "prior" that is adjusted iteratively. In particular, Xu et al. (2014) takes $p_k(x) = \prod_{k' \neq k} \hat{g}_{k'}(x)$ where $\hat{g}_k$ is an approximation of $p(D|x)/p(D^k|x)$ based on the current subset samples. In this way, we have $f_k \approx f$, and hence the subset samples can be treated as drawn from the global posterior f approximately.

In Wang & Dunson (2013), $p_k(x)$ are instead chosen to enforce the local samples $\{x_i^k\}_{i=1}^n$ to be consistent with

each other; in particular, it is based on the observation that

$$\prod_k f_k(x) = \int \prod_k f_k(x^k) \exp\left[-\frac{(x^k - x)^2}{2h^2}\right] dx^k + O(h^2)$$

for small h, and evaluates the above integral using a Gibbs sampler that alternatively sample $\{x^k\}$ and x. This methods, however, critically depends on the value of h, since large h gives poor approximation (we need $h = O(n^{-1/4})$ to obtain an $O(n^{-1/2})$ approximation error), while small h makes Gibbs sampler difficult to converge. Wang & Dunson (2013) proposed to gradually decrease the value of h, making it essentially an annealed MCMC (Gibbs sampling) algorithm over the augmented distribution of $\{x^k\}$ and x; it is therefore difficult to formally guarantee the convergence of this algorithm. In addition, each iteration of the Gibbs sampling has a relatively expensive computation and communication cost in that it requires a fully convergent sampling from the local posteriors as well as communicating the subset posterior samples between the local subsets and the fusion center.

The above methods use only the information in the local posterior samples and do not make use of the values of their posterior probabilities which can carry important information. In this work, we propose a new combination method that avoids the density estimation using an important sampling strategy that assigns importance weights to the subset samples based on their likelihood values. We show that our method can significantly improve over the one-shot combination methods based on density estimations, while avoiding the expensive resampling steps in the iterative methods. We provide two versions of our method: our *Method I* is a valid importance sampling estimator and hence provides a consistent estimator with a typical parametric $O(n^{-1/2})$ estimator for generic non-Gaussian cases; our *Method II* provides a heuristic that works exceptionally well when f_k are nearly Gaussian, although without a formal consistency guarantee in generic cases.

3 IMPORTANCE WEIGHTED CONSENSUS MONTE CARLO

Assume we want to combine the local samples $\boldsymbol{x}_i = [x_i^1, \ldots, x_i^m]$ via a generic consensus function $\bar{x}_i = \phi(x_i^1, \ldots, x_i^m) = \phi(\boldsymbol{x})$; this includes, but does not limit to, the weighted averaging function $\bar{x} = \sum_{k=1}^m w_k x^k$. The key component of our approach is an auxiliary distribution over $[x^1, \ldots, x^m]$ under which the consensus $\bar{x} = \phi(\boldsymbol{x})$ is distributed according to the global posterior $f = \prod_k f_k$.

Proposition 3.1. *Let $g(x^1, \ldots, x^m)$ be an arbitrary density function, and $g(\bar{x})$ is the corresponding density function of $\bar{x} = \phi(\boldsymbol{x})$, that is,*

$$g(\bar{x}) = \int_{S_{\bar{x}}} g(x^1, \ldots, x^m) dS_{\bar{x}},$$

where the integral is over on the surface $S_{\bar{x}} = \{\boldsymbol{x} \colon \phi(\boldsymbol{x}) = \bar{x}\}$. We define an auxiliary distribution

$$\begin{aligned} p(x^1, \ldots, x^m) &= f(\bar{x}) g(x^1, \ldots, x^m \mid \bar{x}) \\ &= f(\bar{x}) g(x^1, \ldots, x^m) / g(\bar{x}), \end{aligned}$$

then the distribution $p(\bar{x})$ of $\bar{x}$ under $p(x^1, \ldots, x^m)$ equals $f(\cdot)$, that is, $p(\bar{x}) = f(\bar{x})$, and hence

$$\mathbb{E}_f[h(x)] = \mathbb{E}_p[h(\bar{x})].$$

for any function $h(x)$.

Proof. Simply note that

$$p(\bar{x}) = \int_{S_{\bar{x}}} f(\bar{x}) g(x^1, \ldots, x^m) / g(\bar{x}) dS_{\bar{x}} = f(\bar{x}). \quad \square$$

This result allows us to transform the estimation problem of $f(x)$ to that of a higher dimensional distribution $p(x^1, \ldots, x^m)$. Now given the local posterior samples $\{x_i^k\}_{i=1}^n \sim f_k$, we can treat $\boldsymbol{x}_i = [x_i^1, \ldots, x_i^m]$ as drawn from the product distribution $\prod_k f_k(x_k) \stackrel{def}{=} q(\boldsymbol{x})$. Using $q(\boldsymbol{x})$ as a proposal distribution allows us to construct a convenient importance sampling estimator:

$$\mathbb{E}_f[h(x)] = \mathbb{E}_p[h(\bar{x})] \approx \frac{\sum_{i=1}^n w(\boldsymbol{x}_i) h(\bar{x}_i)}{\sum_{i=1}^n w(\boldsymbol{x}_i)} \stackrel{def}{=} \hat{z}_h, \quad (1)$$

where $\bar{x}_i = \phi(\boldsymbol{x}_i)$ and the estimator $\hat{z}_h$ is a self normalized importance sampling estimator with importance weights

$$w(\boldsymbol{x}_i) = \frac{p(\boldsymbol{x}_i)}{q(\boldsymbol{x}_i)} = \frac{g(x_i^1, \ldots, x_i^m) \prod_k f_k(\bar{x}_i)}{g(\bar{x}_i) \prod_k f_k(x_i^k)}. \quad (2)$$

Note that we do not need to know the normalization constants in $f_k(x)$ to calculate $\hat{z}_h$; calculating the normalization constants is often a critically difficult task.

Since $\hat{z}_h$ is a standard importance sampling estimator, it forms a consistent estimator for $z_h = \mathbb{E}_f[h(x)]$ in that $\Pr(\lim_{n\to\infty} \hat{z}_h = z_h) = 1$ if $q(\boldsymbol{x}) > 0$ whenever $p(\boldsymbol{x}) > 0$ (see e.g., Theorem 9.2 in Owen (2013)). In addition, the asymptotic MSE $\mathbb{E}[(\hat{z}_h - z_h)^2]$ can be calculated using the Delta method:

$$\mathbb{E}[(\hat{z}_h - z_h)^2] \asymp \frac{1}{n} \mathbb{E}_q[(h(\bar{x}) - z_h)^2 w(\boldsymbol{x})^2]. \quad (3)$$

Therefore, $\hat{z}_h$ approximates z_h with a typical parametric $O(n^{-1/2})$ error rate.

The MSE (3) depends on the test function $h(\cdot)$; a more generic measure of efficiency that is independent of $h(x)$ is the variance of the importance weights,

$$\mathrm{var}_q(w(\boldsymbol{x})) = \int q(\boldsymbol{x}) \left[\frac{p(\boldsymbol{x})}{q(\boldsymbol{x})} - 1\right]^2 d\boldsymbol{x}, \quad (4)$$

or equivalently, the effective sample size (ESS) $n/(\mathrm{var}_q(w(\boldsymbol{x}))+1)$. We would like to have the importance weights $w(\boldsymbol{x})$ to be as uniform as possible, having a small variance or a large effective sample size [1] (ideally $w(\boldsymbol{x})=1,\ \forall \boldsymbol{x}$, in which case $q(\boldsymbol{x})=p(\boldsymbol{x})$).

3.1 OPTIMAL CHOICE OF $\phi(\cdot)$ AND $g(\cdot)$

The estimator $\hat{z}_h$ depends on both the consensus function $\phi(\cdot)$ and the auxiliary distribution $g(\cdot)$. In this section, we discuss the optimal choice of $\phi(\cdot)$ and $g(\cdot)$ in terms of minimizing the variance $\mathrm{var}_q(w(\boldsymbol{x}))$ of the importance weights.

Proposition 3.2. *(i). The optimal $g(x^1,\dots,x^m)$ that minimizes the variance $\mathrm{var}_q(w(\boldsymbol{x}))$ is*

$$g^*(x^1,\dots,x^m)=\prod_{k=1}^m f_k(x^k),$$

in which case $g^*(\bar{x})=\int_{S_{\bar{x}}}\prod_{k=1}^m f_k(x^k)dS_{\bar{x}}$ with $S_{\bar{x}}=\{\boldsymbol{x}\colon \bar{x}=\phi(\boldsymbol{x})\}$ and $w(\boldsymbol{x})=\prod_{k=1}^m f_k(\bar{x})/g^*(\bar{x})$.

(ii). With $g=g^*$, the optimal consensus function $\bar{x}=\phi(\boldsymbol{x})$ should be chosen such that $g^*(\bar{x})\propto\prod_k f_k(\bar{x})$. In the special case when $f_k(x)$ are Gaussian, that is, $f_k(x)=\mathcal{N}(x;\mu_k,\Sigma_k)$, the optimal $\phi(\cdot)$ is the weighted averaging $\phi(x)=\sum_{k=1}^m w_k x^k$ with $w_k=(\sum_k\Sigma_k^{-1})^{-1}\Sigma_k^{-1}$, and in this case, we have $w(\boldsymbol{x})=1,\ \forall \boldsymbol{x}$ and $\mathrm{var}_q(w(x))=0$. But there is no closed form for such an optimal $\phi(\cdot)$ in general cases.

Proof. (i). Since $\mathbb{E}_q[w(\boldsymbol{x})]=1$, minimizing the variance $\mathrm{var}_q(w(\boldsymbol{x}))$ is equivalent to minimizing $\mathbb{E}_q[w(\boldsymbol{x})^2]$,

$$\mathbb{E}_q[w(\boldsymbol{x})^2]=\int\frac{p(\boldsymbol{x})^2}{q(\boldsymbol{x})}d\boldsymbol{x}=\int\frac{\prod_k f_k(\bar{x})^2}{g(\bar{x})^2}\Phi_g(\bar{x})d\bar{x},$$

where $\Phi_g(\bar{x})=\int_{S_{\bar{x}}}\frac{g(\boldsymbol{x})^2}{\prod_k f_k(x^k)}dS_{\bar{x}}$; one can show that g^* minimizes $\Phi_g(\bar{x})$ for any fixed $\bar{x}$, and hence minimizes $\mathbb{E}_q[w(\boldsymbol{x})^2]$.

(ii). With $g=g^*$, we have $\Phi_{g^*}(\bar{x})=g^*(\bar{x})$ and hence $\mathbb{E}_q[w(\boldsymbol{x})^2]=\int\frac{\prod_k f_k(\bar{x})^2}{g^*(\bar{x})}d\bar{x}$, which is minimized when $g^*(\bar{x})\propto\prod_k f_k(\bar{x})$. □

Remark With $g^*(\boldsymbol{x})=\prod_k f_k(x^k)$, our estimator $\hat{z}_h$ can be treated as simply an importance sampler on $f(\bar{x})$ with proposal $g^*(\bar{x})$. The difficulty, however, is that $g^*(\bar{x})$ is usually intractable to calculate, making it essential to find suboptimal $g(\boldsymbol{x})$ that is more computationally tractable.

[1] A simple connection between (4) and (3) is that $(\mathrm{var}_q(w(\boldsymbol{x}))+1)/n$ can be treated as the expectation of the MSE $\mathbb{E}[(\hat{z}_h-z_h)^2]$ when the value of $h(x)$, $\forall x$ is drawn from standard normal distribution.

Algorithm 1 Importance Weighted Consensus Monte Carlo

Input: Samples from the local posteriors $\{x_i^k\}_{i=1}^n\sim f_k, \forall k=1,\dots,m$. Test function $h(x)$.

Output: Estimate $\mathbb{E}(h(x))$ under the global posterior $f(x)\propto\prod_k f_k(x)$.

Consensus: Let $\hat{\Sigma}_k$ be the empirical covariance matrix of subsample $\{x_i^k\}_{i=1}^n$. Calculate

$$\bar{x}_i=\sum_i w_k x_i^k,\ \text{ where }\ w_k=(\sum_k\hat{\Sigma}_k^{-1})^{-1}\hat{\Sigma}_k^{-1}.$$

Reweighting: Calculate the importance weights $w(\boldsymbol{x}_i)$ by *Method I* as defined in (5) or *Method II* in (6).

Estimating: $\mathbb{E}(h)\approx\sum_i w_i h(\bar{x}_i)/\sum_i w_i$

3.2 PRACTICAL IMPLEMENTATION

Although the optimal choices in Proposition 3.2 are intractable in general cases, we can leverage Bernstein-von Mises theorem to obtain near optimal choices. In particular, Proposition 3.2 justified the use of the weighted averaging $\phi(\boldsymbol{x})=\sum_{k=1}^m w_k x^k$, with weights decided by the empirical variance $w_k=(\sum_k\hat{\Sigma}_k^{-1})^{-1}\hat{\Sigma}_k^{-1}$, which is the same as the consensus MC in Scott et al. (2013). Our method also requires to set a good auxiliary distribution $g(\boldsymbol{x})$; we explore two simple choices in this paper:

1. *Method I.* Motivated by Bernstein-von Mises theorem, we approximate each $f_k(x)$ by a Gaussian $\hat{f}_k(x)=\mathcal{N}(x;\ \hat{\mu}_k,\hat{\Sigma}_k)$, where $\hat{\mu}_k$ and $\hat{\Sigma}_k$ are the empirical mean and covariance matrices of the k-th local sample $\{x_i^k\colon i\in[n]\}$, respectively. We then construct the auxiliary distribution $g(\boldsymbol{x})$ to be $g(\boldsymbol{x})=\prod_k\hat{f}_k(x_k)$, under which we have $g(\bar{x})=\mathcal{N}(\bar{x};\ \bar{\mu},\bar{\Sigma})$, with $\bar{\mu}=\sum_k w_k\hat{\mu}_k$, and $\bar{\Sigma}^{-1}=(\sum_k w_k\hat{\Sigma}_k^{-1})$. In this case, the importance weight in (2) reduces to

$$w(\boldsymbol{x}_i)=\frac{\prod_k f_k(\bar{x}_i)}{\mathcal{N}(\bar{x}_i;\bar{\mu},\bar{\Sigma})}\cdot\frac{\prod_k\mathcal{N}(x_i^k;\hat{\mu}_k,\hat{\Sigma}_k)}{\prod_k f_k(x_i^k)}. \tag{5}$$

2. *Method II.* Instead of approximating each f_k, we explicitly set the auxiliary distribution $g(\boldsymbol{x})$ to be the optimal choice suggested in Proposition 3.2, that is, $g(\boldsymbol{x})=\prod_k f_k(x^k)$, and then approximate the corresponding $g(\bar{x})$ with a Gaussian distribution, that is, we approximate $g(\bar{x})$ by $\hat{g}(\bar{x})=\mathcal{N}(\bar{x},\bar{\mu},\bar{\Sigma})$, which gives an importance weight of form

$$w(\boldsymbol{x}_i)=\frac{\prod_k f_k(\bar{x}_i)}{\mathcal{N}(\bar{x}_i;\bar{\mu},\bar{\Sigma})}. \tag{6}$$

This can be justified in two possible scenarios: a) when each f_k is close to Gaussian by Bernstein-von Mises theorem, the distribution $g(\bar{x})$ of their averaging $\bar{x}=$

$\sum_{k=1}^m w_k x_i^k$ should also be close to Gaussian; b) when the number m of subsets is large, the averaging $\bar{x} = \sum_{k=1}^m w_k x_i^k$ is approximately Gaussian by the central limit theorem.

Comparing with (5), the importance weight in (6) simply drops the terms that involve x_i^k, and hence should have smaller variance, but with the risk of introducing additional biases. We note that although *Method I* is a valid importance sampling (IS) estimator, and gives consistent estimates in general cases, *Method II* is no longer a valid IS estimator, and hence is not consistent for general non-Gaussian distributions. Nevertheless, we find that *Method II* often performs surprisingly well in practice, and has attractive theoretical properties when f_k are indeed Gaussian.

3.3 GAUSSIAN CASES

It is illustrative to study the properties of *Method I* and *Method II* under the simple case when f_k are Gaussian. In particular, we show that, despite being inconsistent for non-Gaussian cases, *Method II* is guaranteed to outperform *Method I* in Gaussian cases, that is, it exploits the Gaussianity more aggressively.

Assume $f_k(x) = \mathcal{N}(x; \mu_k, \Sigma_k)$ and denote by $\hat{f}_k(x) = \mathcal{N}(x; \hat{\mu}_k, \hat{\Sigma}_k)$, where $\hat{\mu}_k, \hat{\Sigma}_k$ are the empirical mean and covariance of the local sample $\{x_i^k\}_{i=1}^n$ on the k-th subset. Let $\theta = \{\mu_k, \Sigma_k^{-1} \colon \forall k\}$ be the set of true parameters and $\hat{\theta} = \{\hat{\mu}_k, \hat{\Sigma}_k^{-1} \colon \forall k\}$ the empirical estimates; correspondingly we denote $q(\boldsymbol{x}|\theta) = \prod_k f_k(x^k)$ and $q(\boldsymbol{x}|\hat{\theta}) = \prod_k \hat{f}_k(x^k)$. Then $\hat{\theta}$ is the maximum likelihood estimator of θ based on data $\{\boldsymbol{x}_i\}_{i=1}^n$.

Denote by $\hat{z}_h^I$ and $\hat{z}_h^{II}$ the estimates given by *Method I* and *Method II*, respectively. Let $t(\boldsymbol{x}) = h(\boldsymbol{x})\frac{p(\boldsymbol{x})}{q(\boldsymbol{x})}$, then

$$\hat{z}_h^I = \frac{1}{n}\sum_{i=1}^n t(\boldsymbol{x}_i), \qquad \hat{z}_h^{II} = \frac{\sum_{i=1}^n \omega(\boldsymbol{x}_i) t(\boldsymbol{x}_i)}{\sum_{i=1}^n \omega(\boldsymbol{x}_i)}.$$

where $\omega(\boldsymbol{x}_i) = \frac{q(\boldsymbol{x}_i|\theta)}{q(\boldsymbol{x}_i|\hat{\theta})}$. Note that here the weights $\omega(\boldsymbol{x}_i)$ should be very close to one when the sample size n is large since $\hat{\theta}$ is a maximum likelihood estimator of θ (assuming all f_k are Gaussian). However, as observed in Henmi et al. (2007); Henmi & Eguchi (2004), the $\omega(\boldsymbol{x}_i)$ in fact can act as a control variate to cancel part of the variance in $t(\boldsymbol{x}_i)$. As a result, $\hat{z}_h^{II}$ is guaranteed to have lower variance than $\hat{z}_h^I$ when all f_k are Gaussian.

Lemma 3.3 (Henmi et al. (2007))**.** *Assume each f_k is Gaussian, e.g., $f_k(x) = \mathcal{N}(x; \mu_k, \Sigma_k)$, $\forall k \in [m]$. Denote by $\hat{s} = \sum_{i=1}^n \nabla_\theta \log q(\boldsymbol{x}_i|\theta)/n$, then $\mathbb{E}\hat{s} = 0$ and*

$$\hat{z}_h^{II} = \hat{z}_h^I - \mathbb{E}[\hat{z}_h^I \hat{s}^\top][\mathrm{var}(\hat{s})]^{-1}\hat{s} + O_p(1/n).$$

Proof. See the proof of Theorem 1 and Equation (10) in Henmi et al. (2007). □

Therefore, $\hat{z}_h^{II}$ is asymptotically equivalent to a variance reduced version of $\hat{z}_h^I$ by using the score function $\hat{s}$ as a control variate; see e.g., Owen (2013) for background on control variate.

Theorem 3.4. *Assume $f_k(x) = \mathcal{N}(x; \mu_k, \Sigma_k)$, $\forall k \in [m]$. Denote by $\mathrm{MSE}(\hat{z}_h) = \lim_{n\to+\infty} n\mathbb{E}[(\hat{z}_h - z_h)^2]$ the asymptotic mean square error of $\hat{z}_h$, then we have*

$$\mathrm{MSE}(\hat{z}_h^I) = \mathrm{var}_f(h(x)) \geq \mathrm{MSE}(\hat{z}_h^{II}), \tag{7}$$

where $\mathrm{var}_f(h(x))$ is the variance of $h(x)$ under the global posterior $f(x) \propto \prod_k f_k(x)$.

Proof. The fact that $\mathrm{MSE}(\hat{z}_h^I) \geq \mathrm{MSE}(\hat{z}_h^{II})$ is a result of Lemma 3.3 by the property of control variate (also see Henmi et al. (2007, Theorem 1)). The proof of $\mathrm{MSE}(\hat{z}_h^I) = \mathrm{var}_f(h(x))$ is shown in the Appendix. □

Therefore, despite being inconsistent in general non-Gaussian cases, *Method II* is guaranteed to outperform *Method I* in Gaussian cases, that is, it relies on a stronger assumption, and works well if the assumption is indeed satisfied. In contrast, *Method I* is more robust in that it is a consistent estimator for generic non-Gaussian f_k (but may also have large variances in bad cases). In practical cases when the size of each local dataset D^k is large, each f_k is close to Gaussian by Bernstein-von-Mises theorem, and we observe that *Method II* often performs better than *Method I* empirically.

3.4 FURTHER DISCUSSIONS

Our algorithm is summarized in Algorithm 1. We further discuss some issues here.

Communication Cost. Our methods outperform the previous *one-shot* combination methods such as Scott et al. (2013) and Neiswanger et al. (2013) in that *Method I* gives a consistent estimator for general f_k with a parametric $O(n^{-1/2})$ rate, while *Method II* provides exceptionally good estimates when f_k are (nearly) Gaussian. This is not surprising given that our methods leverage more information: it depends on both the local posterior samples x_i^k and their (unnormalized) likelihoods $f_k(x_i^k)$, as well as the (unnormalized) likelihoods $f_k(\bar{x}_i)$ of the combined sample $\bar{x}_i$. Therefore, compared with the *one-shot* methods, our methods require two additional rounds of communication between the subsets and the fusion center to evaluate and communicate the likelihood of the combined sample $\{\bar{x}_i\}$. The overall communication cost of our method is $O(mn(2d+1))$, where m is the number of machines, n is the Monte Carlo sample size and d is the dimension of the parameter, while that of Neiswanger et al. (2013) is $O(mnd)$, and that of Scott et al. (2013) is $O(d^2)$ which only needs to communicate the first two moments of the subset samples.

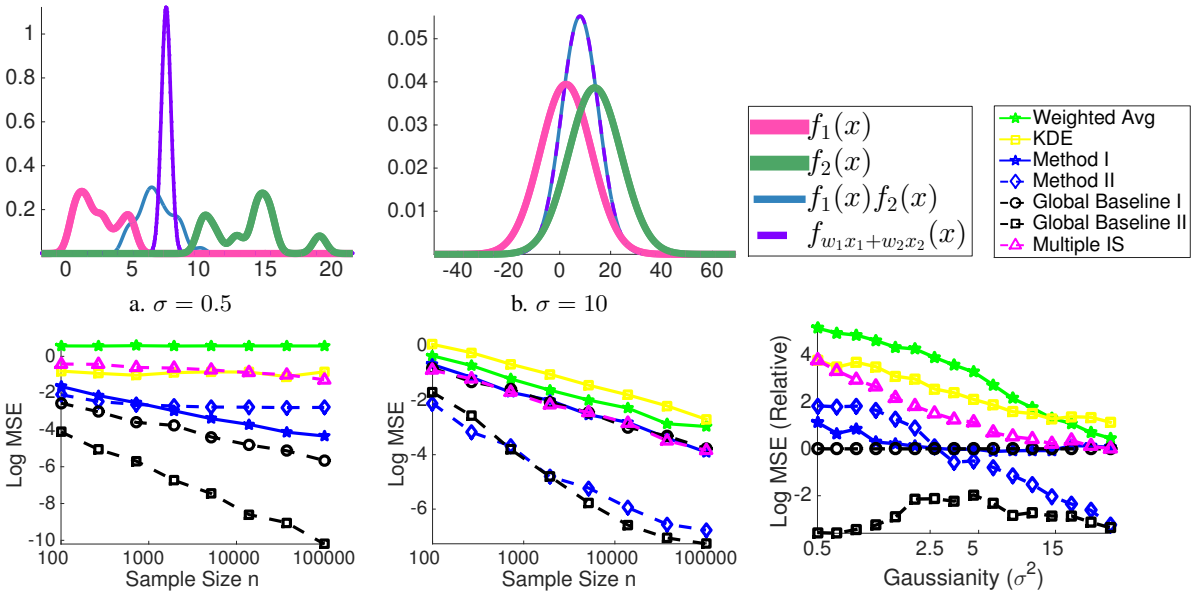

Figure 1: Results on the toy Gaussian mixture model. (a)-(b) The simulated distributions $f_1(x)$ and $f_2(x)$ when $\sigma = 0.5$ (highly non-Gaussian) and $\sigma = 10$ (highly Gaussian), respectively. (c)-(d) The MSE for estimating the mean $\mathbb{E}_f[x]$ under the two cases shown in (a) and (b), respectively. (e) The relative MSE compared to *Global Baseline I* when we vary σ from 0.5 to 10, so that $f_1(x)$ and $f_2(x)$ change from being highly non-Gaussian to highly Gaussian.

Meanwhile, our method is still much more communication-efficient compared with the *iterative* combination methods that require more iterative rounds of communications, and resampling steps. The communication complexity of Wang & Dunson (2013) with T iterations is $O(mndT)$, and that of Xu et al. (2014) is $O(nd^2T)$ because it only passes the first two empirical moments instead of the samples. Our method has a significant advantage because the main practical bottleneck is often the number of communication rounds, regardless of the amount of information exchanged at each round. In our empirical results, we show that our methods work competitively with the iterative methods at their convergence.

Computational Cost. The total computational cost of our combination method is $O(nm(d^3 + L))$ where d^3 is due to the inverse of the covariance matrices and L denotes the cost for evaluating the local posterior probability $f_k(x)$; this is slightly worse than the linear averaging (Scott et al., 2013) which costs $O(nmd^3)$, but has advantage over Neiswanger et al. (2013) which requires a full MCMC procedure over the product of the KDEs for the combination. Further, the *iterative* combination methods have significantly higher computational cost, because they requires to re-draw subset samples iteratively, which is often much more expensive than the combination steps.

Random Permutation. The total size of all the local posterior samples is mn, while the size of the combined sample $\{\bar{x}_i\}$ is only n, that is, we lose a size of $(m-1)n$ when making the combination. To obtain more combined samples, we can randomly permute each subset sample $\{x_i^k : i \in [n]\}$ and combined the permuted subset samples, and repeat the process for multiple times. However, our empirical results do not suggest a significant improvement of performance by using multiple random permutations (e.g., we did not find significant improvement by averaging 10 random permutations).

4 EXPERIMENTS

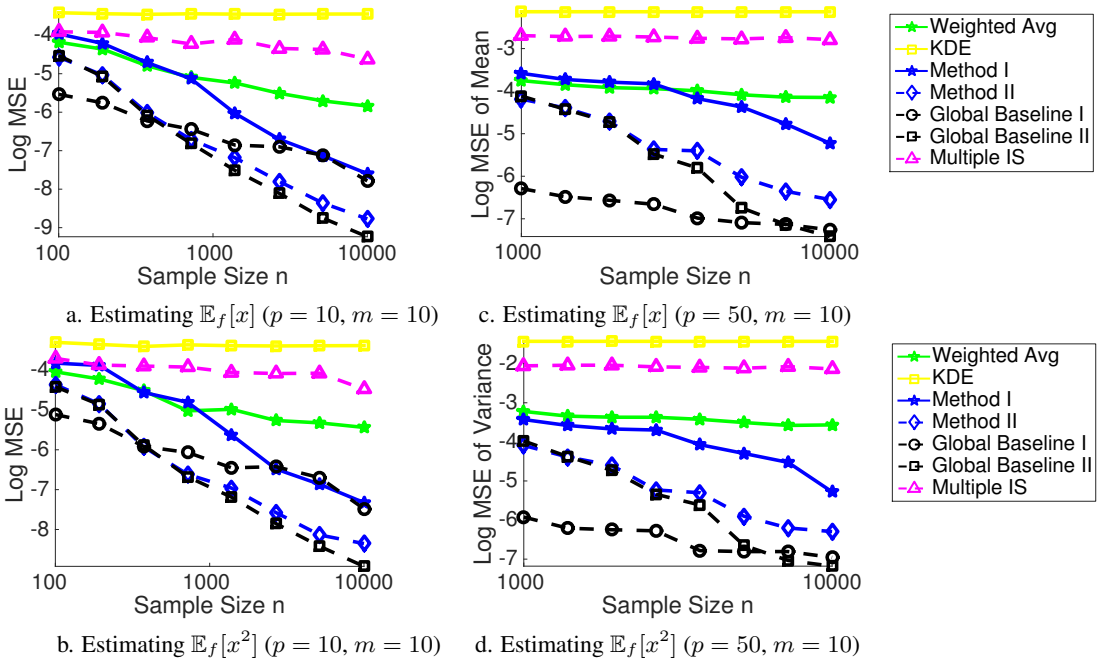
We report empirical results for our method using a toy example of mixture of Gaussians as well as a Bayesian probit model with both simulated and real world datasets. We compare with the following algorithms:

1. Our *Method I* and *Method II* as shown in Algorithm 1.

2. *Global Baseline I* and *Global Baseline II*, which draw sample $\{x_i^*\}$ from the global posterior $f(x) \propto \prod_k f_k(x)$, and estimate $\mathbb{E}_f(h(x))$ by

$$\hat{z}_h^{*I} = \frac{1}{n}\sum_i h(x_i^*), \quad \hat{z}_h^{*II} = \frac{\sum_i \omega(x_i^*)h(x_i^*)}{\sum_i \omega(x_i^*)},$$

respectively, where $\omega(x_i^*) = f(x_i^*)/\hat{f}(x_i^*)$, and $\hat{f}(x) = \mathcal{N}(x;\ \hat{\mu}^*,\ \hat{\Sigma}^*)$ with $\hat{\mu}^*$ and $\hat{\Sigma}^*$ being the empirical mean and covariance matrix of $\{x_i^*\}$. Note that $\hat{z}_h^{*I}$ and $\hat{z}_h^{*II}$ can be treated as the global version of *Method I* and *Method II*, respectively; following Henmi et al. (2007), we can show



a. Estimating $\mathbb{E}_f[x]$ ($p = 10, m = 10$)
c. Estimating $\mathbb{E}_f[x]$ ($p = 50, m = 10$)
b. Estimating $\mathbb{E}_f[x^2]$ ($p = 10, m = 10$)
d. Estimating $\mathbb{E}_f[x^2]$ ($p = 50, m = 10$)

Figure 2: Results on probit regression model with simulated data D of size $12,000$, partitioned into $m = 10$ subsets. (a)-(b) The MSE for estimating $\mathbb{E}_f[x]$ and $\mathbb{E}_f[x^2]$, respectively, when the dimension p of x is 10. (c)-(d) The results when the dimension p increases to 50. All the results are averaged over 500 random trials.

that $\hat{z}_h^{*II}$ always has smaller variance than $\hat{z}_h^{*I}$ when $f(x)$ is a Gaussian distribution.

3. *Weighted Avg*, which is the consensus Monte Carlo method by Scott et al. (2013).

4. The *KDE* method by Neiswanger et al. (2013).[2]

5. An naive *multiple importance weighted estimator (Multiple IS)* in which each subset sample $\{x_i^k\}_{i=1}^n \sim f_k$ is used to directly construct an importance sampling estimator for $\mathbb{E}_f(h(x))$:

$$\hat{z}_h^k = \frac{\sum_i h(x_i^k) w(x_i^k)}{\sum_i w(x_i^k)}, \quad \text{where} \quad w(x_i^k) = \frac{f(x_i^k)}{f_k(x_i^k)},$$

and the results from different subsets are combined by a weighted linear averaging:

$$\hat{z}_h^{MIS} = \frac{\sum_k v_k \hat{z}_h^k}{\sum_i v_k},$$

where v_k is chosen to be $v_k = 1/\hat{\text{var}}(\hat{z}_h^i)$.

6. The sampling via moment sharing (SMS) method by Xu et al. (2014),[3] which iteratively adjusts the local priors and draw local samples repeatedly.

[2]We used the code available at `https://www.cs.cmu.edu/~wdn/research/embParMCMC/index.html`.

[3]We used the code available at `https://github.com/BigBayes/SMS`

4.1 TOY EXAMPLE

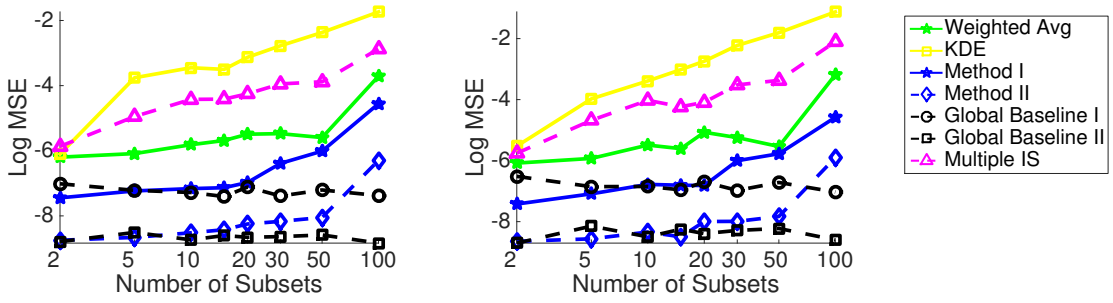
We first consider two Gaussian mixtures with 10 components,

$$f_k(x) = \frac{1}{10} \sum_{j=1}^{10} \mathcal{N}(x; \mu_{jk}, \sigma^2), \quad k = 1, 2,$$

where μ_{jk} is randomly drawn from $\text{Uniform}([0, 10])$ for $f_1(x)$ and $\text{Uniform}([10, 20])$ for $f_2(x)$. The variance σ^2 is used to adjust the Gaussianity of $f_k(x)$. With a small σ (see Figure 1a), $f_1(x)$ and $f_2(x)$ are highly multi-modal, and are far away from each other; with a large σ (see Figure 1b), $f_1(x)$ and $f_2(x)$ become close to Gaussian and have a significant overlap with each other.

Figure 1(a) & (b) also shows the shapes of the corresponding product $f(x) \propto f_1(x) f_2(x)$ and the density function $f_{\bar{x}}(x)$ of the weighted averaging $\bar{x} = w_1 x_1 + w_2 x_2$ with $w_i \propto 1/\text{var}_{f_i}(x)$. We see that with a small σ, $f_{\bar{x}}(x)$ is very different from $f(x)$ but still covers a large part of $f(x)$, and hence can serve as a good importance sampling proposal (as approximately used in our methods). With a large σ, both $f(x)$ and $f_{\bar{x}}(x)$ are Gaussian like and are almost identical with each other.

Figure 1(c) & (e) shows the MSE of different algorithms when estimating the posterior mean $\mathbb{E}_f(h(x))$ with $h(x) = x$. Figure 1(c) shows the results of different algorithms when $\sigma = 0.5$ (the highly non-Gaussian case), in which we find that *Method I* works better than *Method II* and



a. Estimating $\mathbb{E}_f[x]$ ($p = 10$, $n = 5 \times 10^3$) b. Estimating $\mathbb{E}_f[x^2]$ ($p = 10$, $n = 5 \times 10^3$)

Figure 3: Results on probit regression model with simulated data D of size $12,000$, partitioned into m subsets, with m ranging from 2 to 100. (a)-(b) The MSE for estimating $\mathbb{E}_f[x]$ and $\mathbb{E}_f[x^2]$, respectively; the posterior sample size is fixed to be $n = 5 \times 10^3$ in both cases. All the results are averaged over 500 random trials.

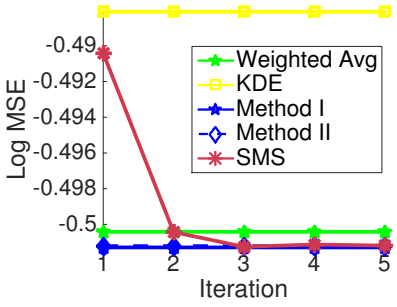


Figure 4: Comparing with SMS by Xu et al. (2014) on Bayesian probit regression. The setting is the same as that in Figure 3, except with fixed subset number $m = 10$.

Method II is clearly inconsistent in that its MSE stops decrease when the sample increases. Figure 1d shows the result of different algorithms when $\sigma = 10$ (the almost Gaussian case), in which we find that *Method II* works better than *Method I* as predicted by Theorem 3.4.

Figure 1(e) shows the results of different algorithms when we range σ from 0.5 to 10 (from highly non-Gaussian to highly Gaussian), and we can find that the performance of *Method I* converges to that of *Global baseline I* as predicted by Theorem 3.4, and that of *Method II* converges to *Global baseline II*. In all the cases, we find that both *Weighted Avg* and *KDE* perform much worse. *Multiple IS* tends to perform well when f_1 and f_2 are close to each other, but is worse when they are far apart from each other.

4.2 BAYESIAN PROBIT REGRESSION

We consider the Bayesian probit regression model for binary classification. Let $D = \{\chi_\ell, \zeta_\ell\}_{\ell=1}^N$ be a set of observed data with p-dimensional features $\chi_\ell \in \mathbb{R}^p$ and binary labels $\zeta_\ell \in \{0, 1\}$. The probit model is

$$p(D|x) = \prod_{\ell=1}^{N} \left[\zeta_\ell \Phi(x^\top \chi_\ell) + (1 - \zeta_\ell)(1 - \Phi(x^\top \chi_\ell))\right],$$

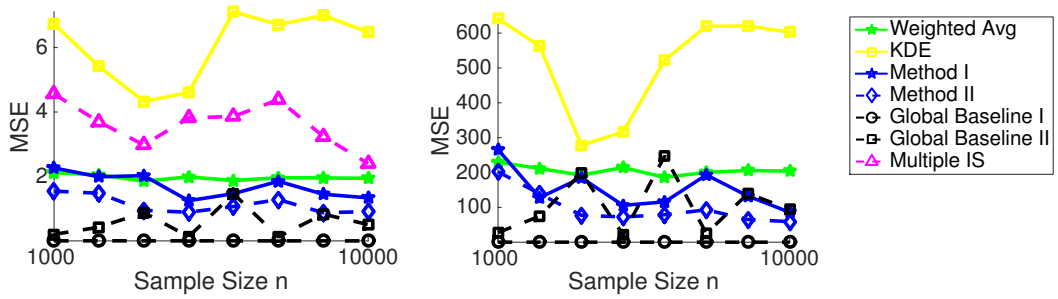
where $\Phi(\cdot)$ represents the cumulative distribution function of the standard normal distribution. We use an uninformative Gaussian prior $p(x) = \mathcal{N}(x; 0, 0.1)$ on x throughout our experiments.

We start with testing our methods on simulated datasets, where we first generate a true value of x with 50% zero elements and 50% elements drawn randomly from standard normal distribution, and then simulate a dataset $D = \{\chi_\ell, \zeta_\ell\}_{\ell=1}^N$ that is subsequently evenly partitioned into m subsets $\{D^k\}_{k=1}^m$, each of which includes N/m data points. We simulate $N = 12,000$ number of points throughout our experiments.

Figure 2(a) & (b) show the mean square error when estimating the posterior mean $\mathbb{E}_f[x]$ and the second order moment $\mathbb{E}_f[x^2]$, respectively, both when the dataset D is partitioned into $m = 10$ subsets (so that each subset D^k receives $1,200$ data points). We can see that as the posterior sample size n of the subset samples $\{x_i^k\}_{i=1}^n \sim p(x|D^k)$ increases, our *Method I* and *Method II* match closely with the *Global Baseline I* and *Global Baseline II*, respectively; this may suggest that the local posteriors f_k are close to Gaussian in this case. The other methods, including *Weighted Avg*, *KDE* and *Multiple IS*, work significantly worse than both of our methods.

Figure 2(c) & (d) shows the results under the same setting as Figure 2(a) & (b), except when the dimension p increases to 50, where we observe that our *Method I* and *Method II* match less closely with the corresponding global baselines, but still tend to significantly outperform all the other distributed algorithms.

Figure 3(a) & (b) show the results when we fix the dimension $p = 10$ and a posterior sample size of $n = 5 \times 10^3$ and partition the dataset D into different number m of subsets (so that each subset D^k receives $12,000/m$ data points), with m range from 2 to 100. We observed that our *Method I* and *Method II* again match closely with the *Global Baseline I* and *Global Baseline II*, except when the partition number m is very high (e.g., $m \geq 30$ for *Method I*, and



a. Estimating $\mathbb{E}_f[x]$ ($p = 54$, $m = 10$) b. Estimating $\mathbb{E}_f[x^2]$ ($p = 54$, $m = 10$)

Figure 5: Probit regression on the CoverType dataset. The dataset is partitioned evenly into 10 subsets. The result of *Multiple IS* in (b) is much worse than the other methods and is not shown in the figure.

$m \geq 100$ for *Method II*).

Figure 4 shows the result when we compare our methods with the iterative SMS method by Xu et al. (2014), where we find that our *Method I* and *Method II* tend to perform as well as SMS at its convergence, but has the advantage of requiring no iterative communication or re-sampling. We also tested the Weistrass sampler by Wang & Dunson (2013) (result does not report), but find it often performs worse (results similar to Figure 3 of Xu et al. (2014)).

In addition, we experimented with an iterative version of our method which introduces local priors $p_k(x)$ that satisfy $\prod_k p_k(x) = p(x)$ where $p(x)$ is the original global prior, and iteratively updates $p_k(x)$ to make the local posteriors $f_k(x) = p(D^k|x)p_k(x)$ match with each other. We observe that this iterative version does not improve the result significantly, likely because the non-iterative version of our method is already good enough.

Binary CoverType Dataset We then test our methods on the Forest Covertype dataset from the UCI machine learning repository (Bache & Lichman, 2013); it has 54 features, and is reprocessed to get binary labels following Collobert et al. (2002). For our experiment, we take the first 12,000 data points, and partition them into 10 subsets. The results of different algorithms are shown in Figure 5, in which we see that our *Method I* and *Method II* still perform significantly better than the other distributed algorithms.

5 CONCLUSION

We propose an importance weighted consensus Monte Carlo approach for distributed Bayesian inference. Two practical versions of our method are proposed, and their properties are studied both theoretically and empirically. Our methods have significant advantages over the previous one-shot methods based on density estimates in terms of accuracy, as well as the iterative methods in terms of computational and communication costs.

APPENDIX

Proof of Theorem 3.4. We only prove $\mathrm{MSE}(z_h^I) = \mathrm{var}_f(h(x))$ here; the fact that $\mathrm{MSE}(z_h^I) \geq \mathrm{MSE}(z_h^{II})$ can be found in Henmi et al. (2007, Theorem 1).

Let $\mathrm{MLE}_n(\hat{z}_h^I) = n\mathbb{E}[(\hat{z}_h^I - z_h)^2]$; using the Delta method we can show that $\mathrm{MLE}_n(z_h^I) \asymp \mathbb{E}_q[(h(\bar{x}) - z_h)^2 w_n(\boldsymbol{x})^2]$, with

$$w_n(\boldsymbol{x}) = \frac{p_n(\boldsymbol{x})}{q(\boldsymbol{x})} = \frac{\mathcal{N}(\bar{x}, \mu_0, \Sigma_0)}{\mathcal{N}(\bar{x}, \hat{\mu}_0, \hat{\Sigma}_0)} \prod_k \frac{\mathcal{N}(x^k, \mu_k, \Sigma_k)}{\mathcal{N}(x^k, \hat{\mu}_k, \hat{\Sigma}_k)},$$

where $q(\boldsymbol{x}) = \prod_k \mathcal{N}(x_k;\ \mu_k, \Sigma_k)$, and $p_n(\boldsymbol{x}) = \mathcal{N}(\bar{x};\ \mu_0, \Sigma_0) \prod_k \mathcal{N}(x_k;\ \hat{\mu}_k, \hat{\Sigma}_k) / \mathcal{N}(\bar{x};\ \hat{\mu}_0, \hat{\Sigma}_0)$; here $w_n(\boldsymbol{x})$ and $p_n(\boldsymbol{x})$ are indexed with sample size n since they dependent on the empirical means and variances. Since $\mathrm{var}_f(h(x)) = \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^2]$ by Proposition 3.1, we have

$$\begin{aligned}
&\mathrm{MSE}_n(z_h^I) - \mathrm{var}_f(h(x)) \\
&\asymp \mathbb{E}_q[(h(\bar{x}) - z_h)^2 w_n(\boldsymbol{x})^2] - \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^2] \\
&= \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^2 w_n(\boldsymbol{x})] - \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^2] \\
&= \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^2 (w_n(\boldsymbol{x}) - 1)]
\end{aligned}$$

Using Cauchy-Schwarz inequality, we have

$$\begin{aligned}
&\big(\mathrm{MSE}(z_h^I) - \mathrm{var}_f(h(x))\big)^2 \\
&\leq \mathbb{E}_{p_n}[(h(\bar{x}) - z_h)^4] \cdot \mathbb{E}_{p_n}[(w_n(\boldsymbol{x}) - 1)^2] \\
&= \mathbb{E}_f[(h(x) - z_h)^4] \cdot \mathbb{E}_q[w_n(\boldsymbol{x})(w_n(\boldsymbol{x}) - 1)^2].
\end{aligned}$$

Therefore, we just need to show that $\mathbb{E}_q[w_n(\boldsymbol{x})(w_n(\boldsymbol{x}) - 1)^2] \to 0$. This can be done using dominant convergence theorem: Let $\psi_n(\boldsymbol{x}) = q(\boldsymbol{x}) w_n(\boldsymbol{x})(w_n(\boldsymbol{x}) - 1)^2$, then we have $\psi_n(x) \to 0$, $\forall \boldsymbol{x}$ since $\hat{\mu}_k \to \mu_k$, $\hat{\Sigma}_k \to \Sigma_k$ and hence $w_n(\boldsymbol{x}) \to 1$ for $\forall \boldsymbol{x}$; in addition, we can show that $|\psi_n(\boldsymbol{x})| \leq q(\boldsymbol{x})^{1/2}$ for large enough n and $q(\boldsymbol{x})^{1/2}$ is an integrable function.

Abstract

Exemplar clustering attempts to find a subset of data-points that summarizes the entire data-set in the sense of minimizing the sum of distances from each point to its closest exemplar. It has many important applications in machine learning including document and video summarization, data compression, scalability of kernel methods and Gaussian processes, active learning and feature selection. A key challenge in the adoption of exemplar clustering to large-scale applications has been the availability of accurate and scalable algorithms. We propose an approach that combines structured similarity matrix representations with submodular greedy maximization that can dramatically increase the scalability of exemplar clustering and still enjoys good approximation guarantees. Exploiting structured similarity matrices within the context of submodular greedy algorithms is by no means trivial, as naive approaches still require computing all the entries of the matrix. We propose a randomized approach based on sampling sign-patterns of columns of the similarity matrix and establish accuracy guarantees. We demonstrate significant computational speed-ups while still achieving highly accurate solutions, and solve problems with up-to millions of data-points in around a minute or less on a single commodity computer.

1 Introduction

With the prevalence of large-scale datasets coming from social media, computational biology, finance and engineering it has been difficult to apply some of the more computationally intensive machine learning approaches such as probabilistic Graphical models, kernel methods and Gaussian processes. Simple tools like logistic regression trained via stochastic gradient descent are instead prevalent in web companies that need to deal with hundreds of millions and more samples [16]. Exemplar clustering suggests a path to extend some of the powerful ML methods to such domains by finding small representative subsets of data to summarize the large dataset, and apply the method on the summary. Other uses of exemplar clustering include summarizing data for humans (document and video summarization [14]), facility location in OR, and active learning [7] to prioritize the annotation in large unlabeled datasets where annotating the entire dataset is out of the question.

An integer programming formulation for exemplar clustering is itself intractable, being an NP-hard problem [21]. Hence, a variety of approximate schemes have been developed including LP relaxations [3, 27], message-passing algorithms [8, 13], and heuristic algorithms such as Partitioning around Medoids (PAM) [11]. The most successful methods balancing scalability and good accuracy guarantees[1] have been based on the theory of submodular maximization [12]. Exemplar clustering (with some mild assumptions) can be shown to be submodular, i.e. to satisfy diminishing marginal gains. Thus, invoking the celebrated result of [21], the greedy approach that adds exemplars in order of their marginal gains has an $1 - 1/e$ approximation guarantee. A lazy evaluation approach called "Lazy Greedy" further exploits the diminishing marginal gains property to accelerate the solution [18].

Nevertheless, for very large scale data-sets even greedy algorithms become computationally infeasible, as the exemplar clustering cost-function is non-local, and evaluating the marginal gains for each exemplar candidate requires evaluating the distance to each other point in the dataset. A number of directions have been considered to speed up basic greedy (and lazy greedy) methods. Simple surrogate functions (such as modular bounds) approximating the submodular function have been proposed in [26]. The paper also introduced a nearest neighbors pruning approach

[1] There is a rich theory on LP relaxations for exemplar clustering, but the methods are less scalable, having to solve linear programs with $O(n^2)$ variables, where n is the number of data-points.

to reduce the set of candidates to consider. This idea has been further explored in [15]. A distributed algorithm that randomly splits the data among several machines, selects exemplars from each subset, and then combines them was proposed in [20]. This however requires further approximation by a factor of $1/min(k, m)$ where k is the number of exemplars, and m is the number of machines. A stochastic sub-sampling idea called "Lazier than lazy greedy" was proposed in [19] which takes a small random subset of potential exemplars into consideration at each stage. By taking the sample size proportional to $n/k \log(1/\epsilon)$ the running time of the algorithm executed for k iterations becomes independent of k, and is still able to achieve an $1 - 1/e - \epsilon$ approximation guarantee (in expectation). This result was also applied in the streaming setting [2].

We pursue a different approach where we assume that the similarity matrices are either exactly represented as certain structured matrices (such as low-rank, sparse plus low-rank, product of sparse matrices, Toeplitz, e.t.c), or can be approximated by such. For example, using the popular word2vec representation for words and sentences [17] along with cosine similarity gives rise to an explicit low-rank similarity matrix. Squared Euclidean distance matrices (and corresponding similarity matrices) are also exactly low-rank for low-dimensional feature spaces. While simply using the structured matrix for the greedy algorithm reduces its memory footprint, it still requires quadratic computation in number of samples n. We show that the bottleneck of the problem involves a low-rank positive column sum problem. We develop a randomized approximation technique based on sampling column sign-patterns and establish theoretical guarantees which can reduce the computation to linear in n. The proposed approach is guaranteed to generate a better solution than the stochastic sampling approach [19] at the cost of a very modest increase in computation. We consider numerical studies on a number of large-scale machine learning problems and demonstrate dramatic increase in speed compared to plain greedy and lazy-greedy methods with only a minor corresponding loss in objective values.

The outline of the paper is as follows. We first overview submodular maximization, and prior work on exact and approximate greedy algorithms in Section 2. We discuss structured approximation matrices and our approach for approximate greedy optimization in Section 3. We present theoretical guarantees in Section 4 and experimental results in Section 5.

2 Background: submodular optimization

In this paper we consider an approach for exemplar clustering based on *submodular maximization*. We start by reviewing the notions of submodularity, greedy algorithms and their guarantees, and the recent extensions.

Let $\mathcal{V}$ be a set of size n. A set function $f : 2^{\mathcal{V}} \to \mathbb{R}$ is called submodular if it satisfies a diminishing marginal gains property: if $A \subseteq B$, and $a \in \mathcal{V}$ then

$$f(A \cup a) - f(A) \geq f(B \cup a) - f(B)$$

Intuitively, there is more benefit (higher marginal gain) to add a new element a to the smaller set A than to its superset B. If for all $A \subseteq B$ it holds that $f(A) \leq f(B)$ then the function is called *monotone submodular*. If $f(\varnothing) = 0$ then the function is called homogeneous. A celebrated result by Neumhauser et. al establishes that a simple greedy algorithm achieves an $1 - \frac{1}{e}$ approximation to the optimal objective to non-negative cardinality constrained monotone submodular maximization [21]. The greedy algorithm starts with an empty set, and at each stage adds the element which has the maximum marginal gain $\Delta f(a|A) = f(A \cup a) - f(A)$ to the current selected set A.

The exemplar clustering problem that we consider in the paper has the following form. We have a collection $\mathcal{V}$ of data-points,[2] and a similarity function $s : \mathcal{V} \times \mathcal{V} \to \mathbb{R}^+$. We would like to faithfully summarize the entire data-set (maximize the pairwise similarity between each point and its exemplar) using at most k exemplars:

$$\max_{A \subset \mathcal{V}} \sum_{i \in \mathcal{V}} \max_{j \in A} s(i, j) \text{ where } |S| \leq k \qquad (1)$$

One can verify that the exemplar clustering problem above corresponds to nonnegative monotone submodular maximization with a cardinality constraint, and hence the greedy algorithm can be applied with the corresponding approximation guarantee. The greedy algorithm can be sped up further using the same diminishing returns property of marginal gains [18] by lazy evaluation, by keeping the elements in a priority queue sorted according to marginal gain.

Unfortunately, the evaluation of the marginal gain for a single candidate exemplar requires $O(n)$ computation, and we consider $O(n)$ candidates at each stage. Hence the greedy algorithm still does not scale to very large data-sets beyond a few hundred thousand data points. Improving the scalability of the greedy algorithm for exemplar clustering has been an active research area and a number of approximation strategies have been proposed at the cost of worse approximation guarantees. The existing proposals include stochastic greedy, distributed algorithms and nearest-neighbor graph approximations that we have described in the introduction. Next we describe how we can exploit structured similarity matrices and a randomized ap-

[2] All our results also extend to the non-symmetric version of the problem where the data-points come from set $\mathcal{V}_1$ and exemplars have to be selected from $\mathcal{V}_2$, for example the facility location problem in Operations Research. Also, allowing rewards $h_i \geq 0$ for making data-point i an exemplar, still keeps the problem monotone and submodular.

proach based on sampling sign-patterns of columns to propose an elegant scalable solution for exemplar clustering with good approximation guarantees.

3 Greedy exemplar selection with low-rank similarity matrices

We consider the greedy approach for exemplar clustering. As inputs we have the similarity matrix S and a budget k. At each stage t we have the current active set $\mathcal{A}^t$ of exemplars chosen at the previous iteration. We would like to evaluate the marginal gain of new elements $a \in \mathcal{V} \setminus \mathcal{A}^t$.

Suppose that at step t we have computed the optimal assignment $\hat{j}^t(i) = \arg\max_{j \in \mathcal{A}^t} s(i,j)$ for each datapoint i. We will refer to the attained objective as $z_i = s(i, \hat{j}^t(i))$. At iteration $t+1$, we compute the marginal gain for each $a \in \mathcal{V} \setminus \mathcal{A}^t$. The closest element to i in $\mathcal{A}^t \cup a$ either remains the same as in the previous step, or it becomes a. Hence the marginal gain $\Delta f(a|A)$ of adding a to $\mathcal{A}^t$ is

$$\sum_i \max\left(s(i,a),\ s(i,\hat{j}^t(i))\right) - s(i,\hat{j}^t(i)) \qquad (2)$$

Define $[X]_+ = \max(X, 0)$. Then the computational bottleneck is computing the vector of marginal gains, i.e. the maximum positive column sum of the matrix $R = S - \mathbf{z}\mathbf{1}^T$:

$$\max_j \sum_i [R_{ij}]_+ = \max_j \sum_i [S_{ij} - z_i]_+ \qquad (3)$$

Naive implementation requires computing all the elements of this matrix[3]. We show that if the matrix S has a structured representation and allows fast matrix action (mutlitplication of the matrix by a vector) – then we can exploit a randomized algorithm with good guarantees.

We first analyze the case of low-rank matrices, $S = \tilde{U}\tilde{V}^T$, where $\tilde{U}$ and $\tilde{V}$ are $n \times d$. We show that we can use a number of other structured matrices in Section 3.4. Now, if S is low-rank with rank d then R is also low-rank with rank at most $d+1$. Let $U = [\tilde{U},\ -\mathbf{z}]$ and $V = [\tilde{V},\ \mathbf{1}]$. Then $R = UV^T = S - \mathbf{z}\mathbf{1}^T$. Note that computing the plain column sum for low-rank matrices is trivial: $\mathbf{1}^T R = (\mathbf{1}^T U)V^T$ thus reducing the computational complexity from $O(n^2)$ to $O(nd)$. However, the positive sign in $\mathbf{1}^T[R]_+$ makes it considerably more difficult to exploit the low-rank factorization. We study this problem next.

3.1 Maximum positive column sum problem

We would like to efficiently compute the maximum positive column sum for a low-rank matrix $R = UV^T$:

$$\max_j \sum_i [R_{ij}]_+ = \max_j \sum_i \left([UV^T]_+\right)_{ij} \qquad (4)$$

[3]Lazy greedy algorithms avoid computing some elements but still evaluate a large number of columns of this matrix.

Algorithm 1 Approximate max-positive column sum

1. Uniformly at random sample r columns from the matrix R and compute their sign patterns $\mathbf{q}_i$.
2. Aggregate sign-patterns into matrix $Q = [\mathbf{q}_1, ...\mathbf{q}_r]$.
3. Let $Y = (Q^T U)V$ and let $\mathbf{y} = \max_i Y_{ij}$.
4. Find $\hat{j} = \arg\max_j \mathbf{y}_j$.

Suppose we knew the binary ($\{0,1\}$) sign-pattern $\hat{\mathbf{q}}$ of the column achieving the maximum in (4), i.e. $q_i = 1_{\{R_{i\hat{j}} > 0\}}$ where $\hat{j}$ is the column achieving the $\arg\max$ in (4). Then we could compute

$$\max_j \sum_i [R_{ij}]_+ = \max_j \sum_i \left([UV^T]_+\right)_{ij} = \max_j [(\hat{\mathbf{q}}^T U)V^T]_j \qquad (5)$$

Also note, that for an arbitrary sign-pattern $\mathbf{q}$, we have

$$\max_j [(\hat{\mathbf{q}}^T U)V^T]_j \geq \max_j [(\mathbf{q}^T U)V^T]_j \qquad (6)$$

We suggest to take a collection of r random sign-patterns $\{\mathbf{q}_1, ..., \mathbf{q}_r\}$ and evaluate the maximum value of the r.h.s. in (6) over all of them. We take the sign-patterns from a subset of columns of R sampled uniformly at random (another choice can be i.i.d. binary vectors). Surprisingly, such a simple scheme can be shown to satisfy good approximation guarantees, which we describe in Section 4, and also to give very accurate numerical results. In particular, it is guaranteed to produce better results than the stochastic greedy approach [19] with the same subset of columns.

The procedure is described in Algorithm 1. It produces a lower bound $\sum_i R_{i\hat{j}}$ on the maximum positive column sum of R:

$$\hat{j} := \arg\max_j \max_{\tilde{j} \in \{j(1),\ldots,j(r)\}} \mathbf{q}_{\tilde{j}}^T R_{:,j}. \qquad (7)$$

3.2 Scalable submodular greedy algorithm

Now, to use this algorithm for efficient greedy submodular optimization, we have to repeat it for k rounds of greedy to generate k exemplars. At each round we simply recompute the vector $\mathbf{z}$ and $R = [\tilde{U},\ -\mathbf{z}][\tilde{V},\ \mathbf{1}]^\top$ and invoke Algorithm 1. At the initial stage the vector $\mathbf{z}$ is zero, and the initial marginal gains are simply the column-sums of S. We summarize the steps in Algoritm 2.

The greedy algorithm is recovered if we find the exact column maximizing marginal gains: $\arg\max_j \sum_i ([R]_+)_{ij}$. This however would require $O(n^2)$ computation. By using the approach from Section 3.1 with r random signs, it can be reduced to $O(nr)$ by allowing approximate answers.

3.3 Further speed-ups

The approach proposed in the previous section can dramatically reduce the computation of the greedy method from

Algorithm 2 Low Rank GReedy (LRGR)

Input: $S = \tilde{U}\tilde{V}^T$
Initialize: $\hat{j}^1 = \arg\max_j \sum_i [\tilde{U}\tilde{V}^T]_{ij}$. Set $\mathcal{A}^1 = \{\hat{j}^1\}$. Evaluate $z_i = s(i, \hat{j}^1)$. Set $t = 1$.
for $i = 1 \dots r$ **do**
  i. Advance $t \rightarrow t + 1$
  ii. Let $R = \tilde{U}\tilde{V}^T - \mathbf{z}1^T$.
  iii. Use (7) to approximately find $\hat{j}^t \approx \arg\max_j \sum_i ([R]_+)_{ij}$.
  iv. $\mathcal{A}^t = \mathcal{A}^{t-1} \cup \hat{j}^t$
  v. Update $\mathbf{z}^t$: $z_i^{t+1} = \max_{j \in A^t} s(i, j)$
end for

$O(n^2)$ to $O(nr)$ per each round of the greedy method. Yet, we can improve the running time and accuracy further.

In the previous section the matrix Q of sign-patterns was recomputed from scratch at each greedy iteration. Note that if we store this matrix from the previous iteration, then we only need to update $Q^T\mathbf{z}$, while $Q^T\tilde{U}$ remains the same. While reusing the same matrix Q on all iterations may significantly impact accuracy, we can keep generating new sign patterns but also keep re-using the computationally inexpensive pre-computed old-sign patterns.

We also note that we can compute the complement sign-patterns very inexpensively. Let $\bar{\mathbf{q}} = \mathbf{1} - \mathbf{q}$. Then $(\bar{\mathbf{q}}^T U)V^T = (\mathbf{1}^T U)V^T - (\mathbf{q}^T U)V^T$. Thus we can add another r complement sign-patterns at the cost of computing the column sum of $R = UV^T$.

Finally, the algorithm proposed in the previous section aims to speed up the computation of the plain greedy algorithm. In [19] an extension of stochastic greedy was proposed to also accelerate the lazy-greedy approach by caching previously computed marginal gains and storing them in a priority queue. The same ideas can be used with our randomized sign-pattern approach to develop its lazy-greedy variant.

3.4 Low-rank and other structured similarity matrices

In Sections 3.1 and 3.2 we assumed that the similarity matrix S is low-rank, which can happen if we use inner-product similarity measure in a low-dimensional vector space (e.g word2vec). Note that the matrix of pairwise squared Euclidean distances is also low-rank for low-dimensional feature spaces, and this also holds for matrices based on arbitrary Bregman divergences, and hence for the corresponding similarity matrices.

In addition to the low-rank assumption, we can also use a variety of other structured matrix factorizations in exactly the same way, as long as they allow fast-matrix action. Suppose $S = \tilde{U}\tilde{V}^T$, then to apply the approach in Section 3.1 we simply need to be able to quickly compute $Q\tilde{U}$ and $(Q\tilde{U})\tilde{V}^T$. For example if $\tilde{U}$ and $\tilde{V}$ have high-dimensional but very sparse rows (e.g. the sparse one-hot bag-of-words representation for text), then the matrix-vector products depend on the number of non-zero entries in $\tilde{U}$ and $\tilde{V}$.

Other factorizations allowing fast matrix action include sparse plus low-rank matrices, Fourier matrices, circulant and convolution matrices, and even more advanced matrix approximations including block-diagonal low-rank matrices [24] and matrices with low displacement operators [25].

4 Theoretical analysis

In this section we show that LRGR achieves an approximately optimal solution in expectation when sufficiently many sign patterns are sampled. In the first part we show approximation bounds that do not assume any structure on the similarity matrix S. Subsequently, we try to provide intuition behind how the low-rank structure on S can help in achieving better solution by analyzing the case of rank-2 similarity matrix. Finally, we analyze the case of data distributed across tight clusters.

4.1 Structure-oblivious approximation guarantees

The results in this section do not exploit the structure on the similarity matrix. The proof proceeds along similar lines as [19]. We prove the result for the symmetric case when the candidate exemplars belong to the set of points. Let $\mathcal{A}^*$ be the optimal solution of problem (1) with $|\mathcal{A}^*| = k$ (if the algorithm terminates with $|\mathcal{A}^*| < k$, it will return the optimal solution [21]), and $\mathcal{A}^t$ be the solution of LRGR at step t. Let $\mathcal{V}$ denote the full index set of all the points ($\mathcal{V} = \{1, 2, \dots, n\}$). Let $f(\mathcal{A}^t)$ be the objective value for set $\mathcal{A}^t$ and $\Delta(a|\mathcal{A}^t) := f(\mathcal{A}^t \cup a) - f(\mathcal{A}^t)$.

Using submodularity, we have

$$f(\mathcal{A}^*) - f(\mathcal{A}^t) \leq \sum_{a \in \mathcal{A}^* \setminus \mathcal{A}^t} \Delta(a|\mathcal{A}^t) \tag{8}$$

The following Lemma bounds the expected potential gain of LRGR after step t.

Lemma 4.1. *Given a current solution $\mathcal{A}^t$, the expected gain of LRGR in the next step is at least $\frac{1-e^{-kr/n}}{k} \sum_{a \in \mathcal{A}^* \setminus \mathcal{A}^t} \Delta(a|\mathcal{A}^t)$ when signs from r randomly picked columns are used.*

Proof. Let $\mathcal{R}$ be the set of randomly picked columns with $|\mathcal{R}| = r$. The probability that one of the columns from $\mathcal{A}^* \setminus \mathcal{A}^t$ is picked, is given by

$$\begin{aligned} &P[\mathcal{R} \cap (\mathcal{A}^* \setminus \mathcal{A}^t) \neq \phi] = 1 - P[R \cap (\mathcal{A}^* \setminus \mathcal{A}^t) = \phi] \\ &= 1 - \left(1 - \frac{|\mathcal{A}^* \setminus \mathcal{A}^t|}{|\mathcal{V} \setminus \mathcal{A}^t|}\right)^r \\ &\geq 1 - e^{-\frac{r|\mathcal{A}^* \setminus \mathcal{A}^t|}{|\mathcal{V} \setminus \mathcal{A}^t|}} \geq 1 - e^{-\frac{r|\mathcal{A}^* \setminus \mathcal{A}^t|}{n}} \end{aligned}$$

Since $0 \leq |\mathcal{A}^* \setminus \mathcal{A}^t| \leq k$, using Jensen's inequality we have

$$1 - e^{-\frac{r|\mathcal{A}^* \setminus \mathcal{A}^t|}{n}} \geq \left(1 - e^{-\frac{rk}{n}}\right) \frac{|\mathcal{A}^* \setminus \mathcal{A}^t|}{k}$$

If LRGR picks one of the columns from $\mathcal{A}^* \setminus \mathcal{A}^t$, the score for that column will be evaluated exactly. Scores for the columns whose sign pattern matches that of the picked column will also be evaluated exactly. The scores for all other columns will be underestimated. As LRGR takes a maximum over all the scores, it will add a column to $\mathcal{A}^t$ which will give a gain equal to at least that of the picked column from $\mathcal{A}^* \setminus \mathcal{A}^t$. As any of the columns from $\mathcal{A}^* \setminus \mathcal{A}^t$ is equally likely to be picked, the exemplar a^{t+1} added by LRGR will yield

$$\mathbf{E}[\Delta(a^{t+1}|\mathcal{A}^t)] \geq P[\mathcal{R} \cap (\mathcal{A}^* \setminus \mathcal{A}^t) \neq \phi] \frac{\sum_{a \in \mathcal{A}^* \setminus \mathcal{A}^t} \Delta(a|\mathcal{A})}{|\mathcal{A}^* \setminus \mathcal{A}^t|}$$
$$\geq \frac{1 - e^{-kr/n}}{k} \sum_{a \in \mathcal{A}^* \setminus \mathcal{A}^t} \Delta(a|\mathcal{A}^t).$$

□

Combining Lemma 4.1 with Eq. 8 we get

$$f(\mathcal{A}^*) - f(\mathcal{A}^t) \leq \frac{k}{1 - e^{-kr/n}} \mathbf{E}[f(\mathcal{A}^{t+1}) - f(\mathcal{A}^t)] \quad (9)$$

Taking expectation over $\mathcal{A}^t$, we have

$$\mathbf{E}[f(\mathcal{A}^{t+1}) - f(\mathcal{A}^t)] \geq \frac{1 - e^{-kr/n}}{k} \mathbf{E}[f(\mathcal{A}^*) - f(\mathcal{A}^t)] \quad (10)$$

Unrolling the above by induction, we get

$$\mathbf{E}[f(\mathcal{A}^k)] \geq \left(1 - \left(1 - \frac{1 - e^{-kr/n}}{k}\right)^k\right) f(\mathcal{A}^*)$$
$$\geq \left(1 - e^{-(1 - e^{-kr/n})}\right) f(\mathcal{A}^*)$$
$$\geq \left(1 - e^{-1}(1 + e^{-kr/n})\right) f(\mathcal{A}^*)$$
$$= (1 - 1/e - e^{-kr/n}) f(\mathcal{A}^*).$$

Note that the above bound turns vacuous for $r \leq \frac{n}{k} \ln \frac{1}{1-1/e} \approx 0.459 \frac{n}{k}$. When the similarity matrix is allowed to have negative entries, the submodular objective function may lose nonnegativity but it still remains monotonic. In this case, one can obtain a guarantee of the form:

$$f(\mathcal{A}^*) - \mathbf{E}[f(\mathcal{A}^k)] \leq (e^{\frac{1-k}{k}} + e^{\frac{-kr}{n}})(f(\mathcal{A}^*) - \mathbf{E}[f(\mathcal{A}^1)]).$$

4.2 Approximation guarantee under low-rank assumption

The analysis in the previous section did not use the low-rank assumption on the matrix R. We show that this assumption is helpful not only to improve the computational complexity of the proposed algorithm, but also to improve the approximation compared to the stochastic greedy approach. To build some intuition of why the low-rank assumption is helpful, consider the maximum possible number of distinct sign-patterns of columns of the matrix R. If the matrix is full-dimensional, then any sign-pattern is possible, and there are 2^n such sign patterns out of which n are chosen. However, if $R = UV^T$, and U and V are $n \times d$, then for a fixed U, the number of possible sign-patterns of columns of R is reduced. In particular, as we show below, for the 2-dimensional case, the number of possible sign-patterns is $2n$ (instead of 2^n): U has two columns, and the sign patterns of any linear combinations of these two columns generate only a small subset of possible sign patterns.

More generally, if U is d-dimensional, then using the results in [10] for number of regions created by n hyperplanes (in general position) in d dimensions, we have that the number of possible sign-patterns of R for a fixed U is given by:

$$2 \sum_{i=1}^{d} \binom{n-1}{i-1} \quad (11)$$

For the 2-dimensional case, this number is $2n$. If we assumed that the column sign-patterns in our matrix R are sampled uniformly at random with replacement from the $2n$ possible choices, then the expected number of unique sign-patterns is $\sum_{i=0}^{n-1} (\frac{2n-1}{2n})^i = 2n(1-(1-1/(2n))^n) \approx 0.787n$. So we expect some number of columns with repeated sign-patterns in the low-dimensional case. This makes it easier for us to get a sign-pattern from our r sampled columns of R that matches the sign-pattern of one of the exemplars.

Let $\mathcal{A}^*$ be the index set of optimal k exemplars. For the 2-dimensional case, we consider the probability that at least one of the r randomly sampled columns, indexed by set $\mathcal{R}$, will completely agree in signs with at least one of the exemplars. The worst case for this probability is when all the exemplars have exactly the same sign pattern since we reduce our set of candidate signs that the sampled columns can match to. This worst case probability is given as:

$$P(\mathcal{R} \cap A^* \neq \phi) + P(\mathcal{R} \cap A^* = \phi)(1 - ((2n-1)/2n)^r)$$
$$= 1 - (1 - k/n)^r + (1 - k/n)^r (1 - ((2n-1)/2n)^r)$$
$$\geq 1 - e^{-kr/n} e^{-r/(2n)}.$$

The first term in the first line corresponds to the probability of selecting one of the r sampled columns to be one of the exemplars, and the second term corresponds to picking a column that misses the set of exemplars, but whose sign-pattern agrees with the sign pattern of one of the exemplars. This probability of at least one agreement in sign patterns is also a lower bound on the probability of Algorithm 1 recovering a column whose score is at least that of one of the exemplars. For the best case when all the exemplars

differ with each other in at least one place in sign patterns, the lower bound on the recovery probability increases to $(1 - e^{-kr/n}e^{-kr/(2n)})$. If we ignore the structure on R, the lower bound loosens to $(1 - e^{-kr/n})$ which was used in Section 4.1.

We should also note that this bound, although better than stochastic greedy [19], is based on several worst-case scenarios and is still highly pessimistic for practical settings. The uniform sampling assumption of sign patterns implies that all regions created by the n hyperplanes [10] are equally likely to contribute to the sign patterns, whereas in practice the data is often non-uniformly distributed and even occurs in clusters.

Furthermore, the analysis does not consider inexact matches, where the sampled columns differ in sign patterns with the exemplars only at a few places. This disagreement in a small number of places will result in underestimating the positive sum of the exemplar column to some extent. However, if the score of the exemplar is mainly contributed by a few data points (i.e., a few rows) and the gap between exemplar score and the best non-exemplar score is sufficient, the algorithm may still have a good chance in picking the exemplar column in next iteration. If this gap is low, we do not lose much in terms of objective value by picking one of the runner-up columns. Indeed, we empirically observe a considerable performance gain (in terms of objective value) over stochastic greedy on several real datasets in Section 5.

4.3 Approximation guarantees under cluster assumption

Here we consider another simplified scenario for better understanding of the sampling approach (7). We assume data points form K disjoint clusters $\mathcal{C}_1$, $\mathcal{C}_2$, ..., $\mathcal{C}_K$ satisfying $0 < m \leq |\mathcal{C}_k| \leq M \leq n$ and

(a) $S_{ij} \geq \kappa, \forall i, j \in \mathcal{C}_k$ for some constant $\kappa > \frac{4}{4+m/M}$.

(b) $S_{ij} \in [c-\epsilon/2, c+\epsilon/2]$ for i, j not in the same cluster, where c, ϵ are constants satisfying $c < (\kappa - \epsilon)/2$ and $\epsilon < \frac{m}{4n}\kappa$.

The cluster assumption ensures that points in the same cluster $\mathcal{C}_k$ have similarity at least κ, while points of different clusters has similarity of bounded variance (in range $[c - \epsilon/2, c + \epsilon/2]$). Note the low-variance condition for points of different clusters is often satisfied in problem of higher dimension due to the *curse of dimensionality*, where uncorrelated points can have maximum distance indiscernible to the minimum distance [4]. For example, in document categorization, the semantically-unrelated documents have only *stop words* in common, which causes unrelated documents to have almost the same similarity to each others. Under the cluster assumptions (a)-(b), we show that the sampling estimator (7) has approximation error bounded by $2n\epsilon$ as follows. A related clustering assumption was used to analyze convex relaxations for exemplar clustering in [6].

Theorem 4.1. *Let j^* and $\hat{j}$ denote the greedy column selected by exact criteria* (3) *and sampling criteria* (7) *with r samples respectively. For data satisfying clustering assumption (a)-(b), we have*

$$\sum_{i=1}^{n}[R_{i\hat{j}}]_+ \geq \sum_{i=1}^{n}[R_{ij^*}]_+ - 2n\epsilon \tag{12}$$

holds for each iteration $t \leq K$ with probability at least $1 - \delta$ if

$$r \geq \frac{n}{|\mathcal{C}(j^*)|}\ln(\frac{1}{\delta}). \tag{13}$$

where $|\mathcal{C}(j^*)|$ is the size of the cluster that contains j^*.

Proof. For $t = 1$, (12) holds directly since $R = S$ and no sampling is used (so $\hat{j} = j^*$). For $t > 1$, $\mathcal{C}(j^*)$ must be a cluster that does not contain any exemplar chosen in previous iterations. Otherwise, suppose $\mathcal{C}(j^*)$ contains an exemplar j' selected in previous iterate. We have

$$\begin{aligned}\sum_{i=1}^{n}[R_{ij^*}]_+ &\leq \sum_{i\in\mathcal{C}(j^*)}[S_{ij^*} - S_{ij'}]_+ + \sum_{i\notin\mathcal{C}}[R_{ij^*}]_+ \\ &\leq |\mathcal{C}(j^*)|(1-\kappa) + n\epsilon \\ &< \frac{m\kappa}{4} + \frac{m\kappa}{4} = m\kappa/2.\end{aligned}$$

by assumption (a)-(b). However, picking any point j from a cluster $\mathcal{C}$ that does not contain exemplar from previous iterates gives

$$\begin{aligned}\sum_{i=1}^{n}[R_{ij}]_+ &\geq \sum_{i\in\mathcal{C}(j^*)}[S_{ij^*} - (c + \frac{\epsilon}{2})]_+ \\ &\geq \sum_{i\in\mathcal{C}(j^*)}[\kappa - \kappa/2]_+ \geq m\kappa/2,\end{aligned}$$

which leads to contradiction.

Given that $\mathcal{C}(j^*)$ is a cluster not containing exemplar selected from previous iterates, consider $\hat{j}$ selected by the sampling estimator (7). With number of samples r satisfying (13), we have at least $1-\delta$ probability that one of the sign-pattern vectors $\mathbf{q}_{\tilde{j}}$ is produced by a point $\tilde{j} \in \mathcal{C}(j^*)$, which has

$$q_{i\tilde{j}} := 1[S_{i\hat{j}} - z_i] = 1\ ,\ \forall i \in \mathcal{C}(j^*) \tag{14}$$

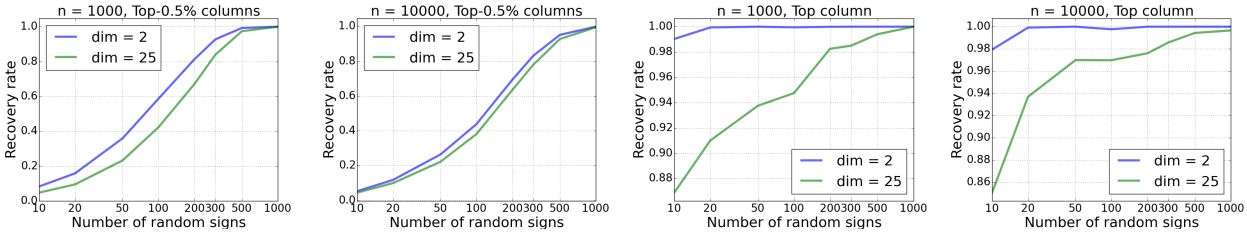

Figure 1: Average recovery rates vs. number of sampled columns (log-scale) for Algorithm 1 over 100 random trials. Data is generated from uniform distribution on the unit sphere (left two plots) and standard Cauchy distribution (right two plots).

since $z_i = S_{ij}$ for some $j \notin \mathcal{C}(j^*)$. Therefore, we have

$$\begin{aligned}\sum_{i=1}^{n}[R_{i\hat{j}}]_+ &\geq \max_{j\in\{j(1),..,j(r)\}}\sum_{i=1}^{n} q_{ij}R_{i\hat{j}} \\ &\geq \max_{j\in\{j(1),..,j(r)\}}\sum_{i=1}^{n} q_{ij}R_{ij^*} \geq \sum_{i=1}^{n} q_{i\tilde{j}}R_{ij^*} \\ &\geq \sum_{i\in\mathcal{C}(j^*)} q_{i\tilde{j}}R_{ij^*} + \sum_{i\notin\mathcal{C}(j^*)} q_{i\tilde{j}}R_{ij^*} \\ &\geq \sum_{i\in\mathcal{C}(j^*)}[R_{ij^*}]_+ - n\epsilon,\end{aligned} \tag{15}$$

where the last inequality is due to (14), assumption (b) and $R_{ij^*} := S_{ij^*} - S_{ij} > 0$ for some $j \notin \mathcal{C}(j^*)$. On the other hand,

$$\begin{aligned}\sum_{i=1}^{n}[R_{ij^*}]_+ &= \sum_{i\in\mathcal{C}(j^*)}[R_{ij^*}]_+ + \sum_{i\notin\mathcal{C}(j^*)}[R_{ij^*}]_+ \\ &\leq \sum_{i\in\mathcal{C}(j^*)}[R_{ij^*}]_+ + n\epsilon.\end{aligned} \tag{16}$$

Combining (15) and (16) leads to the conclusion (12). □

5 Experimental results

We now study the performance of the proposed approach on numerical experiments. We first consider the low-rank maximum positive column sum problem from Section 3.1 corresponding to one stage of the greedy algorithm, and then the low-rank greedy algorithm from Section 3.2.

5.1 Synthetic experiments

In this section we perform numerical simulations to study the behavior of the proposed sign sampling approach in Section 3.1 in recovering the top scoring columns. In the first experiment, we independently sample rows of $U \in \mathbb{R}^{n\times d}$ and $V \in \mathbb{R}^{n\times d}$ from a uniform distribution on the unit sphere $\mathbb{S}^{d-1}$, and take the similarity matrix to be $S = UV^\top$. We conduct 100 random trials of generating pairs of U and V. For every sampled pair U and V, we randomly sample 100 different sets of sign patterns and use Algorithm 1 to estimate the highest scoring column using each set. We report the fraction of times the estimated column is among the top scoring 0.5% columns over all these random trials. Figure 1 shows the recovery rate versus the number of sign patterns for $n = 1K, 10K$ and $d = 2, 25$ which clearly increases with the number of sampled columns.

We repeat the same experiment with U and V generated according to the heavy-tailed Cauchy distribution, and we report the much more stringent recovery rate of the top scoring column this time. We observe that Algorithm 1 performs exceptionally well in recovering the top scoring column for both $d = 2$ and 25. Intuitively, this happens due to the heavy tailed nature of Cauchy distribution, where only a small subset of rows of S will contain the maximums and minimums for each column. Hence, getting the correct sign-pattern for these few rows will greatly increase the probability of recovering the top column by Algorithm 1. This example highlights the fact that the proposed LRGR is capable of taking advantage of the underlying distribution whereas stochastic greedy approach [19] remains oblivious to the distribution of entries of S since it computes the maximum only over the sampled subset of columns. In the Cauchy example, stochastic greedy will have a recovery probability of ~ 0.01 for $n = 10K, r = 100$ irrespective of d, whereas Algorithm 1 empirically shows a recovery rate of ~ 0.96 for $d = 25$.

5.2 Experiments on Machine learning datasets

We compare hte proposed randomized low-rank greedy approach (LRGR) to several other competing methods for approximate exemplar clustering, focusing on alternative approximate greedy methods. We have not considered integer programming and message passing based methods as they do not scale to the dataset sizes we consider in the experiments. We describe the contestants first[4]. We consider both data-sets with low-dimensional feature representations, and data-sets with high-dimensional but sparse feature representation. For simplicity we focus on the inner-product similarity measure here. The experiments are run on a sin-

[4]All the algorithms are written in python relying on *numpy* and *scipy* packages for dense and sparse linear algebra.

gle commodity computer with 16 Gb of RAM.

Plain and lazy greedy As a baseline we used the standard greedy and lazy greedy algorithms, which do use the low-rank structure to reduce the memory footprint, but which compute all the required entries of the similarity matrix. We also use the efficient update for the t-th step of the greedy method, where we do not recompute the optimal assignment of points to exemplars from scratch, but we reuse the previous assignment at the $t-1$-st step – and only compare its best assignment to the new added exemplar. Lazy greedy achieves the same objective value as plain greedy. In our experiments with small number of exemplars the running time of lazy-greedy was similar or slower than plain greedy, so the time is not reported. Lazy-greedy can become significantly faster than plain greedy when the number of exemplars is much higher, and it typically accelerates (benefits more from lazy evaluation) at later stages.

Random subset As a very simple baseline we obtain a random subset of points as exemplars, and compute the cost of optimal assignments of points to these exemplars.

K-means with cluster medoids (KmeansCTR). K-means algorithm produces cluster centers that are not data-points but their convex combinations. We use a heuristic that ignores k-means cluster centers, and instead computes the centroid (1-medoid) for each of the k-clusters independently. Initialization is done using k-means++ [1]. Note that for similarity matrices other than cosine similarity comparison with k-means will not be meaningful, as k-means assumes Euclidean distance between data-points.

Stochastic greedy (StochGr) The approach [19] selects at each step a small subset of columns of the similarity matrix, and only searches for exemplars among this set. We use the same subset-size 100 as for the proposed algorithm.

KNN-greedy (KnnGr) A K-nearest neighbor graph for the data is used to create a sparse approximation to the similarity matrix which is non-zero for the K nearest neighbors only [15, 26]. We use 100 nearest neighbors to give the same number of parameters as stochastic greedy and the proposed algorithm. We report two times for this algorithm: total time taken including the construction of the KNN-graph (pre-processing step needed to run the algorithm), and just the time for exemplar clustering starting with the sparse KNN graph already provided.

LR-greedy (LRGR) This is our proposed algorithm which uses sign-patterns of 100 random columns selected at each iteration from the similarity matrix.

Datasets. We use a collection of standard machine learning datasets from the UCI archive [5] of various sizes and numbers of features (both dense and sparse), and report the time and approximation quality in the table below. The data-sets with label (RF) use a Random-Feature Kernel Approximation method [23] to perform exemplar clustering with (RBF-Laplacian) Kernelized features, namely the Random Binning Features.

The final data-set is the World TSP data set which contains the latitude and longitude of 1,904,711 cities in the world[5]. We use geographical distance (computed via polar coordinate flat-Earth formula) between pairs of cities. To obtain a low-rank approximation to the distance matrix $\mathbb{D}$, we sampled $100n$ pairs of distances and use low-rank matrix completion[6] to find $UV^T \approx \mathbb{D}$. Using rank $d = 20$, we obtain a decomposition UV^T with testing RMSE $< 10^{-2}$. We use the corresponding similarity matrix $S = D_{\max} - UV^T$, where $D_{\max}$ is the maximum element of $\mathbb{D}$. Note that due to the non-Euclidean nature of the similarity matrix, comparison with Kmeans-CTR is not meaningful.

Results We report the objective values in table 1 and the timing numbers in table 2. The number of exemplars is kept small in these experiments as all the contesting methods scale linearly with the number of exemplars. To reduce this linear scaling one could either use the algorithms in a distributed setting proposed in [20] or combine with lazy-evaluation using a priority queue for marginal gains. For methods involving stochasticity (e.g. random subset selection in stochastic greedy, the proposed LRGR method, and k-means initialization) we report an average objective value and run-time over 10 trials.

We can see that the proposed low-rank greedy approach with random projections provides a very close approximation to the exact greedy objective values at an orders of magnitude faster time. We also see that among all the approximate algorithms the proposed method typically provides the best objective value (excluding the exact greedy method), and always within the top two results. The time is also competitive with other algorithms. K-means followed by finding cluster centroids is quite a good contender on small-dimensional data-sets, but its approximation quality can be poor on high-dimensional sparse data-sets. Furthermore, K-means assumes a Euclidean distance between data-points and does not apply to more general distance matrices.[7]. For KNN-greedy the time is dominated by the construction of the sparse nearest neighbors graph. Once the graph is constructed the algorithm is fast, and provides solutions which are quite reasonable although not as good as the proposed approach. The construction of the KNN graph can be accelerated using approximate

[5]Data is at http://www.math.uwaterloo.ca/tsp/world/.

[6]We use the low-rank matrix completion solver provided by the authors of [28].

[7]For example, k-means can not be used with spherical geodesic, transportation or string-edit distances, while there are no such constraints for exemplar clustering.

Table 1: Objective values achieved by greedy submodular algorithms with inner product similarity metric and 10 exemplars. Here d_{avg} is the average number of features per sample. Number of exemplars is 10. The best solution (after exact plain greedy which we aim to approximate) is marked with one star, and second-best with two stars. The proposed approach (LRGR) is typically most accurate, and is within the top 2 in all of our experiments.

nearest neighbors (ANN) techniques, for example based on locality-sensitive-hashing (LSH) [9, 22], but that would also affect the quality of the results. Finally, it is quite clear that selecting random subsets is a rather poor (albeit very fast) data-summarization approach and any other method can provide a significant improvement.

The proposed low-rank greedy method achieved a slightly better objective than the exact greedy method that it tries to approximate in one experiment. This is not a contradiction as selecting a suboptimal exemplar in the current step may possibly improve the objective in further steps.

Dependence on the number of sampled columns. In Figure 2 we plot the average objective value achieved via Stochastic greedy and the proposed LRGR method vs. the number of sampled columns. The values are averages over 25 trials. We see that LRGR achieves better values by making better use of the samples, especially for smaller numbers of sampled columns.

6 Concluding Remarks

We developed a new approach for large-scale exemplar clustering based on submodular greedy maximization with structured similarity matrices. We propose a randomized sign-pattern sampling approach to approximate the bottleneck computation of finding the element with the maximal marginal gain. We establish accuracy guarantees, and evaluate the approach on large scale exemplar clustering problems on machine learning data-sets including up-to millions of data-points. Our current approach is serial and uses a single processor, but it can also be used as a sub-routine in previously proposed distributed approaches to extend exemplar clustering to problems of much larger scale.

We thank Baruch Schieber and Robert Hildebrand for helpful discussions.

Abstract

Bayesian optimization schemes often rely on Gaussian processes (GP). GP models are very flexible, but are known to scale poorly with the number of training points. While several efficient sparse GP models are known, they have limitations when applied in optimization settings.

We propose a novel Bayesian optimization framework that uses sparse online Gaussian processes. We introduce a new updating scheme for the online GP that accounts for our preference during optimization for regions with better performance. We apply this method to optimize the performance of a free-electron laser, and demonstrate empirically that the weighted updating scheme leads to substantial improvements to performance in optimization.

1 Introduction

Bayesian nonparametric models have seen growing popularity due to their flexibility and modeling power. The core strength of nonparametrics lies in their ability to scale in complexity with the data, making them useful in cases where parametric model selection is challenging. These models have therefore been used successfully in a variety of applications (Kulis & Jordan (2012); Tank et al. (2015); Miller et al. (2015); Johnson & Willsky (2013)).

Gaussian processes (GPs) have emerged as an elegant nonparametric approach to regression. GPs provide a full probabilistic model of the data, and allow us to compute not only the model's prediction at input points but also to quantify the uncertainty in the predictions. While powerful and elegant, the application of GP regression is limited by the poor scaling of GPs (Rasmussen & Williams (2005)). This limitation has motivated the introduction of numerous efficient approaches for approximating the exact GP solution, e.g. Gal et al. (2014); Hensman et al. (2013); Ranganathan et al. (2011).

A common approach to this approximation is to use sparse GPs, which rely on lower-dimensional representations defined by a smaller set of "inducing points" to represent the full GP. Various types of sparse GPs have been introduced, e.g. Snelson & Ghahramani (2006); Lawrence et al. (2003); Titsias (2009); Csató & Opper (2002); Seeger et al. (2003). These varieties tend to differ most in how they perform the selection and management of inducing points; usually a greedy method of some form is used to select points from the data set that minimize an entropy or information loss criterion. A notable exception is the method of Snelson & Ghahramani (2006), who treat inducing point selection as a continuous optimization problem.

Our focus here is on optimization when it is extremely costly to evaluate the objective function. Bayesian optimization is a natural choice in this setting (Jones et al. (1998)). In Bayesian optimization, a probabilistic model of the objective function is used to select sampling points by maximizing an acquisition function based on e.g. the expected improvement in the target variable. Gaussian processes are naturally applicable to Bayesian optimization due to their full probabilistic formulation, which can effectively model the observations of the optimization process; see e.g. Osborne et al. (2009); Snoek et al. (2012) for recent applications of Bayesian optimization using GPs. Other approaches to Bayesian optimization include deep neural networks, as in Snoek et al. (2015).

To date, applications of GPs to Bayesian optimization have typically used full Gaussian process regression. In these settings, it is either assumed that computation time is relatively less important (as compared to e.g. function evaluations), or that convergence will occur quickly enough that the size of the full GP is not an issue. These assumptions might not hold in large parameter spaces, however, particularly in settings with noisy observations that can significantly slow the rate of convergence.

As a result, we consider the application of sparse GPs to Bayesian optimization, as in Nickson et al. (2014). Since sparse GPs have bounded size, the time taken to update during optimization will not increase regardless of how long

the procedure takes to converge. Using sparse GPs for Bayesian optimization presents a different set of challenges than in a typical regression problem, however. In particular, existing sparse GP approaches seek to model the full GP as accurately as possible given the limited size of their representation. This goal is obviously desirable for regression, but has key shortcomings in optimization, namely that the limited resources of the sparse GP may be allocated to closely model regions of parameter space that perform poorly and are therefore less important for optimization.

We propose weighted-update online Gaussian processes (WOGP) as an alternative to typical sparse GP set selection that is better suited to optimization; rather than tailoring the sparse GP for predictive accuracy, WOGPs use an online update scheme that weights the feature space of the GP according to which regions are promising from the optimization perspective. During Bayesian optimization over a large parameter space, this ensures that the sparse model does not waste resources by attempting to accurately model regions that are clearly irrelevant to the optimization problem.

Our work is motivated by an application of Bayesian optimization to improve the performance of the Linac Coherent Light Source (LCLS) free-electron laser (FEL) at the SLAC National Accelerator Laboratory (Emma et al. (2010)). The operational costs of this machine are daunting, and current tuning procedures consume hundreds of hours of machine (and machine operator) time annually that could be better spent conducting the various scientific experiments that rely on LCLS. In this setting, we demonstrate empirically that WOGPs significantly outperform competing techniques.

2 Background

In this section we describe Gaussian process regression and the online sparse GP algorithm introduced in Csató (2002). This algorithm uses online updates and a sparse representation to reduce the GP training complexity. This online scheme is particularly useful for large scale and online regression tasks, since it reduces the time taken to update the GP in each iteration with efficient individual updates.

2.1 Review of Gaussian Process Regression

Formally, a Gaussian process is a collection of random variables $\mathcal{X}$ such that any finite subset $(X_1, \cdots, X_n) \subset \mathcal{X}$ have a joint Gaussian distribution. For example, if we have a GP over the interval $[0, 1]$, then the joint distribution of any finite set of points in $[0, 1]$ is multivariate normal; the mean and covariance of this distribution will be discussed shortly. This GP can be thought of as a distribution over functions $f : [0, 1] \to \mathbb{R}$, as every assignment of values to this interval (or any domain on which a GP is defined) has some probability associated with it via this joint distribution.

A Gaussian process prior is fully defined by its covariance function $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ and its prior mean $\mu_0 : \mathcal{X} \to \mathbb{R}$. To simplify the discussion, we will assume that the prior mean function is zero, though this need not be the case. The covariance function is required only to be a valid covariance function in that the Gram matrix $K_{i,j} = K(\boldsymbol{x}_i, \boldsymbol{x}_j)$ of values of any finite subset of $\mathcal{X}$ must be positive semidefinite.

In Gaussian process regression, a GP prior is conditioned on training data to obtain the posterior distribution over the function space. Following the notation of Rasmussen & Williams (2005), given training samples X with corresponding observations $\boldsymbol{f}$ and test inputs X_*, distribution of training observations and test outputs $\boldsymbol{f}_*$ is multivariate Gaussian; conditioning the latter on the former gives us

$$\begin{aligned}\boldsymbol{f}_*|X, X_*, \boldsymbol{f} \sim \mathcal{N}(&K(X_*, X)K(X, X)^{-1}\boldsymbol{f}, \\ &K(X_*, X_*) - K(X_*, X)K(X, X)^{-1}K(X, X_*)) \,. \quad (1)\end{aligned}$$

The resulting posterior at the test locations is a multivariate Gaussian distribution whose mean and covariance are then used in regression. Incorporating the assumption of i.i.d. Gaussian noise into this model is straightforward, involving a simple change to the covariance function according to the standard deviation σ of the assumed noise. This yields the posterior distribution conditioned on noisy observations $\boldsymbol{y}$:

$$\begin{aligned}\boldsymbol{f}_*|X, X_*, \boldsymbol{y} \sim \mathcal{N}(&K(X_*, X)[K(X, X) + \sigma^2 I]^{-1}\boldsymbol{y}, \\ &K(X_*, X_*) - K(X_*, X)[K(X, X) + \sigma^2 I]^{-1}K(X, X_*)) \,. \quad (2)\end{aligned}$$

See Rasmussen & Williams (2005) for a full treatment of GP regression and Gaussian processes in general.

For a predictive distribution conditioned on n training inputs, the time complexity of Gaussian process regression is $\mathcal{O}(n^3)$. This is prohibitively expensive for applications with more than a few thousand inputs (or fewer in settings where runtime is an important consideration). Several approaches have been introduced for approximating full GP regression with more efficient algorithms. The most common category for these approximations is the sparse GP, several varieties of which are listed in Section 1. See Quionero-Candela & Rasmussen (2005) for a thorough treatment of the variety and theory of sparse approximations to full Gaussian process regression.

The common thread among these methods is the attempt to represent the full Gaussian process using a set of $m < n$ inducing inputs, typically leading to a complexity of $\mathcal{O}(m^2 n)$ to train the sparse GP. These inducing inputs are often chosen as a subset of the input data, leading to a difficult combinatorial problem that is typically solved using some form

Algorithm 1 Online GP Update

1: **Input:** data point $\boldsymbol{x}$, output y
2: **Persistent:** Inducing variables $X_\mathcal{I}$, GP model parameters
3: Assess novelty γ of point $\boldsymbol{x}$.
4: **if** $\gamma < \epsilon_{tol}$ **then**
5: Perform sparse update without expanding the model.
6: **else**
7: Perform full update, adding $\boldsymbol{x}$ to $X_\mathcal{I}$ and extending GP model parameters.
8: **end if**
9: **if** Model size exceeds m **then**
10: Score inducing inputs $X_\mathcal{I}$ on impact of removal.
11: Remove the lowest-scoring element of $X_\mathcal{I}$; update the GP model to minimize the impact of removal.
12: **end if**

of greedy minimization of information loss. Snelson & Ghahramani (2006) provide one alternative, in which inducing variable selection is treated as a continuous optimization problem. Our approach is most closely related to the algorithm introduced in Csató (2002), which iteratively trains the approximating GP by processing each input individually. This method selects inducing points by continually comparing new data points to the existing set of inducing variables in the model and keeping whichever subset yields the best approximation. This method is described in more detail below.

2.2 Online Sparse GPs

The online sparse GP algorithm of Csató & Opper (2002); Csató (2002) handles the sparse selection problem by observing input data one point at a time. In each iteration, the new data point is added to the sparse model (assuming that the sample passes a geometric novelty threshold), which may increase its size to $m+1$ inducing variables. A reduction step is then performed, which removes one of these inducing variables to restore the sparse GP to size m. Pseudocode for the online update is given in Algorithm 1.

Following Csató (2002), we represent a GP by its covariance function K and its posterior parameterization after t iterations in terms of the $(m \times 1)$ dimensional vector $\boldsymbol{\alpha}_t$ of inducing point coefficients and the $(m \times m)$ matrix C_t which specifies the posterior covariance. We denote by $X_\mathcal{I}$ the set of inducing variables, giving us the posterior predictive distribution at query points X^* as

$$\mathcal{N}(K(X^*, X_\mathcal{I})\boldsymbol{\alpha}_t, \\ K(X^*, X^*) + K(X^*, X_\mathcal{I})C_t K(X_\mathcal{I}, X^*)) \,. \quad (3)$$

The covariance function K corresponds to a (possibly infinite-dimensional) feature space $\mathcal{F}$. Specifically, if d is the dimension of the data, there exists a function $\phi : \mathbb{R}^d \to \mathcal{F}$ such that $K(x_i, x_j) = \langle \phi(x_i), \phi(x_j) \rangle_\mathcal{F}$ is the inner product of $x_i, x_j \in \mathbb{R}^d$ in $\mathcal{F}$. It is shown in Csató (2002) that the Gaussian process can be viewed as a Gaussian distribution in $\mathcal{F}$. Let Φ be the feature space representation of $X_\mathcal{I}$, so $K_\mathcal{I} \equiv K(X_\mathcal{I}, X_\mathcal{I}) = \Phi^\top \Phi$. Then in the feature space $\mathcal{F}$ we have

$$\mathrm{GP}_K(\boldsymbol{\alpha}, C) \sim \mathcal{N}(\Phi\boldsymbol{\alpha}, I_\mathcal{F} + \Phi C \Phi^\top) \,, \quad (4)$$

where $I_\mathcal{F}$ is the identity matrix in $\mathcal{F}$ and we use the notation $\mathrm{GP}_K(\boldsymbol{\alpha}, C)$ to denote the GP with the corresponding covariance function and parameters. Henceforth we will omit the K in this notation, as it will be clear from context.

This allows for a straightforward computation of the Kullback-Leibler (KL) divergence between two GPs that have the same kernel function. The KL divergence between distributions P and Q is defined as

$$D_{KL}(P \| Q) = \int_\mathcal{F} P(\boldsymbol{x}) \log \frac{P(\boldsymbol{x})}{Q(\boldsymbol{x})} d\boldsymbol{x} \,. \quad (5)$$

Note that we need never concern ourselves with the cases $P(\boldsymbol{x}) = 0$ or $Q(\boldsymbol{x}) = 0$ since we deal exclusively with normal distributions in this paper.

Suppose that in iteration $t+1$ a new inducing variable is added to the model, increasing its size to $m+1$. In the approach of Csató (2002), the optimal reduced parameters $\hat{\boldsymbol{\alpha}}$ and $\hat{C}$ are computed by minimizing the KL divergence between $GP \sim \mathrm{GP}(\alpha, C)$, the over-sized GP that we are reducing, and the approximation $\widehat{GP} \sim \mathrm{GP}(\hat{\boldsymbol{\alpha}}, \hat{C})$, subject to the constraint that $\hat{\boldsymbol{\alpha}}$ and $\hat{C}$ have entries of zero corresponding to some inducing variable (i.e. there exists an index i such that the ith element of $\hat{\boldsymbol{\alpha}}$ and the ith row and column of $\hat{C}$ are zero). We assume without loss of generality that it is the last inducing variable that is removed.

Csató (2002) minimizes $D_{KL}(\widehat{GP} \| GP)$ with respect to the parameters $\hat{\boldsymbol{\alpha}}$ and $\hat{C}$, resulting in the update equations (3.19) and (3.22). With $Q \equiv K_\mathcal{I}^{-1}$, these equations are

$$\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha}^{(r)} - \frac{\alpha^*}{c^* + q^*}(\boldsymbol{C}^* + \boldsymbol{Q}^*) \\ \hat{C} = C^{(r)} + \frac{1}{q^*}\boldsymbol{Q}^*\boldsymbol{Q}^{*\top} - \frac{1}{c^* + q^*}(\boldsymbol{C}^* + \boldsymbol{Q}^*)(\boldsymbol{C}^* + \boldsymbol{Q}^*)^\top \,, \quad (6)$$

where $\boldsymbol{\alpha}^{(r)}$ denotes the first m entries of $\boldsymbol{\alpha}$, $C^{(r)}$ is the $(m \times m)$ matrix obtained by omitting the last row and column of C, α^*, c^*, and q^* are the last elements of $\boldsymbol{\alpha}$, $\mathrm{diag}(C)$, and $\mathrm{diag}(Q)$ respectively, and the $(m \times 1)$ vectors $\boldsymbol{C}^*$ and $\boldsymbol{Q}^*$ are the last columns of C and Q respectively, excluding the last entry. Applying the block matrix inversion formula, we can also compute the reduced inverse

Algorithm 2 Bayesian optimization

while Not converged **do**
  Compute $\boldsymbol{x}_{t+1} = \arg\max_{\boldsymbol{x}}(EI(\boldsymbol{x}))$.
  Query objective function at $\boldsymbol{x}_{t+1}$ to get y_{t+1}.

  Augment the data: $\mathcal{D}_{t+1} = \{\mathcal{D}_t, (\boldsymbol{x}_{t+1}, y_{t+1})\}$
  Update the model: $\mathcal{M}_{t+1} = \mathcal{M}_t \leftarrow (\boldsymbol{x}_{t+1}, y_{t+1})$
  $t = t + 1$
end while

Gram matrix $\hat{Q}$:

$$K_{\mathcal{I}} = Q^{-1} \Rightarrow K_{\mathcal{I}}^{(r)} = (Q^{(r)} - \frac{1}{q^*}\boldsymbol{Q}^*\boldsymbol{Q}^{*\top})^{-1}$$
$$\Rightarrow \hat{Q} = Q^{(r)} - \frac{1}{q^*}\boldsymbol{Q}^*\boldsymbol{Q}^{*\top} . \quad (7)$$

Using the update equations (6), scores are computed for each of the $m+1$ inducing variables based on the minimum KL divergence that can be achieved when omitting them. The worst-scoring point is then removed, with updates (6) performed to the appropriate coordinate.

2.3 Bayesian Optimization

Bayesian optimization is a probabilistic approach to optimization that is generally used when queries to the function being optimized are expensive. This method lessens the number of evaluations needed, shifting the burden instead to computation over probabilities by utilizing information from all of the function evaluations to choose the next sampling location. We deal here with Bayesian optimization using Gaussian processes as probabilistic models.

Let $\mathcal{D}_t = \{(\boldsymbol{x}_i, y_i)_{i=1}^t\}$ be the observed data of the first t iterations of optimization, where y_i is the observation of the target variable at the location $\boldsymbol{x}_i$ in parameter space. Then we denote by $\mathcal{M}_t$ the model trained on $\mathcal{D}_t$ (where the ordering of $\mathcal{D}_t$ may matter, e.g. if the model is an online sparse GP). Let $\mathcal{M}_t(\boldsymbol{x}) = (\mu_t(\boldsymbol{x}), \sigma_t(\boldsymbol{x}))$, so that μ and σ give the posterior mean function and variance of the model.

The central idea behind Bayesian optimization is to explore according to an acquisition function which incorporates the current set of observations. In this paper we use the expected improvement as our acquisition function. If $\boldsymbol{x}^*$ is the observed location that maximizes μ_t, the improvement at a point $\boldsymbol{x}$ is defined[1] as

$$I_t(\boldsymbol{x}) = \max(0, \mu_t(\boldsymbol{x}) - \mu_t(\boldsymbol{x}^*)) . \quad (8)$$

As seen in Jones et al. (1998) the expected improvement at a point $\boldsymbol{x}$ can be computed as

$$EI(\boldsymbol{x}) \equiv E[I_t(\boldsymbol{x})] =$$
$$\begin{cases} (\mu_t(\boldsymbol{x}) - \mu_t(\boldsymbol{x}^*))\Phi(Z) + \sigma_t(\boldsymbol{x})\phi(Z) & \sigma_t(\boldsymbol{x}) > 0 \\ 0 & \sigma_t(\boldsymbol{x}) = 0 \end{cases},$$
$$Z = \frac{\mu_t(\boldsymbol{x}) - \mu_t(\boldsymbol{x}^*)}{\sigma_t(\boldsymbol{x})} . \quad (9)$$

Here Φ and ϕ respectively represent the CDF and PDF of the standard normal distribution. Recently, Bull (2011) showed that optimization using the EI criterion gives provably efficient convergence in many settings.

With EI defined and the method of updating the GP model specified, Bayesian optimization is straightforward; pseudocode for this procedure is given in Algorithm 2. Note that to maximize expected improvement we use numerical optimization, since EI cannot be maximized analytically but is extremely cheap to evaluate as compared with the objective function. See Brochu et al. (2010) for a more thorough introduction to Bayesian optimization.

3 Online Sparse Gaussian Processes for Bayesian Optimization

In this section we apply online sparse GPs to Bayesian optimization. This is complicated by the limited size of the sparse GP, which can reduce exploitation by preventing the information gained in an iteration from being fully incorporated, as well as hinder exploration of promising areas by dedicating resources to model regions of poor performance. We therefore introduce the weighted-update online GP (WOGP), our modified online sparse GP scheme, and the resulting Bayesian optimization algorithm. Our approach to online sparse GPs is similar to that of Csató (2002); Csató & Opper (2002), but utilizes a weighted measure of divergence between the Gaussian processes' predictive distributions. This allows us to better allocate the limited modeling capacity of the sparse GP to further the goal of optimization (rather than predictive accuracy).

For example, imagine that we are attempting to maximize performance over a large parameter space. The online sparse GPs studied previously may devote multiple inducing points to modeling a complex region of low performance to minimize the divergence in this area. These points may serve our goal of maximization better by improving the model's resolution in promising regions of parameter space while maintaining only a vague notion of poor performance in other regions.

3.1 The Weighted KL Divergence

We now describe a weighted divergence measure between distributions and compute this divergence for two GPs.

[1] We use $\mu_t(\boldsymbol{x}^*)$ rather than the best observation itself to account for the assumed noise in the observations.

Definition 1. *For probability distributions P and Q and real-valued weighting function f, we define the weighted KL divergence as*

$$D_{KL}^{f}(P\|Q) = \int_{\mathcal{F}} P(\boldsymbol{x}) \log \left(\frac{P(\boldsymbol{x})}{Q(\boldsymbol{x})}\right)^{f(\boldsymbol{x})} d\boldsymbol{x} = \int_{\mathcal{F}} f(\boldsymbol{x}) P(\boldsymbol{x}) \log \frac{P(\boldsymbol{x})}{Q(\boldsymbol{x})} d\boldsymbol{x} \,. \tag{10}$$

We note that f should be non-negative to prevent rewarding differences between the distributions; the goal of weighting is to regard divergence in low-weighted areas not as good, but as acceptable if accuracy in highly weighted regions can be obtained in its place.

Proposition 1. *For real-valued weighting function f, and constant $c \in \mathbb{R}$, the following hold:*

$$D_{KL}^{cf} = cD_{KL}^{f},\ D_{KL}^{f+c} = D_{KL}^{f} + cD_{KL} \,. \tag{11}$$

Proof. Easily computed from (5) and (10). □

We can also see from Proposition 1 that scaling f by a constant factor does not affect relative divergence.

We can write the prediction of GP at a point $\boldsymbol{x}$ in feature space as $\boldsymbol{x}^\top \Phi \boldsymbol{\alpha}$, since $\boldsymbol{x}^\top \Phi$ is the inner product in the feature space corresponding to the evaluation of the kernel function K (see Equation 3). Then we define f^* in terms of the proportional improvement expected at $\boldsymbol{x}$:

$$f^*(\boldsymbol{x}) = 1 + \frac{\boldsymbol{x}^\top \Phi \boldsymbol{\alpha} - y^*}{|y^*|} = \frac{\boldsymbol{x}^\top \Phi \boldsymbol{\alpha}}{|y^*|} \,, \tag{12}$$

where y^* is the best value observed thus far during optimization.

This weighting function f^* will cause promising regions of feature space to be weighted more heavily in the divergence computation. Of course, we immediately see that f^* is negative wherever the GP's posterior mean is negative. In our motivating application this is not much of a concern, as we deal with a non-negative target (laser pulse energy). In other settings and with other weighting functions, adjustments may be necessary to prevent f being negative.

These adjustments may simply take the form of shifting the observations to be positive; if the minimum observation is y_{min} and the minimum value attained by the GPs prior mean function is p_{min}, then we can define $y_0 = -\min(y_{min}, p_{min})$. Incrementing the prior mean and observations of the GP by y_0 simply shifts its posterior mean function above zero without changing the shape of the distribution. This can be seen from the linearity of the GP formulation, for example in Equation 2.

Alternatively, f can be shifted directly to prevent it being negative; from Proposition 1 we have $D_{KL}^{f+c} = D_{KL}^{f} + cD_{KL}$, so this has the effect of averaging the weighted and unweighted divergences in order to ensure that differences between the distributions P and Q where $f < 0$ are not rewarded (since the rewards given by D_{KL}^{f} in these regions will be offset by the cD_{KL} term).

Surprisingly, we can compute a closed form equation for $D_{KL}^{f^*}(GP\|\widehat{GP})$ in terms of m- and $(m+1)$-dimensional GP parameters $\hat{\boldsymbol{\alpha}}$, $\hat{C}$, $\boldsymbol{\alpha}$, and C, despite its formulation in the possible infinite dimensional feature space $\mathcal{F}$. The derivation of this equation can be found the full version of this paper, available online (McIntire et al. (2016b)).

Proposition 2. *Let $GP = \mathrm{GP}(\boldsymbol{\alpha}, C)$, $\widehat{GP} = \mathrm{GP}(\hat{\boldsymbol{\alpha}}, \hat{C})$ be GPs which share the same inducing inputs and covariance function K. Let $K_{\mathcal{I}} = K(X_{\mathcal{I}}, X_{\mathcal{I}}) \equiv Q^{-1}$ and define*

$$\Gamma = I + \frac{(I + K_{\mathcal{I}} C)^\top}{\boldsymbol{\alpha}^\top K_{\mathcal{I}} \boldsymbol{\alpha}},\ \hat{V} = (\hat{C} + Q)^{-1}, \quad w = \mathrm{Tr}[(C+Q)\hat{V} - I] - \log|(C+Q)\hat{V}| \,. \tag{13}$$

Then the weighted KL divergence (10) between GP and $\widehat{GP}$ using weighting function f^* (12) is given by

$$\begin{aligned} D_{KL}^{f^*}(GP\|\widehat{GP}) &\propto 2\boldsymbol{\alpha}^\top(\Gamma^\top - I)\hat{V}(\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}}) + \\ &\quad (\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}})^\top \hat{V}(\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}}) + w \\ &= (2\Gamma\boldsymbol{\alpha} - (\boldsymbol{\alpha} + \hat{\boldsymbol{\alpha}}))^\top \hat{V}(\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}}) + w \,. \end{aligned} \tag{14}$$

We can obtain some intuition for this formula by separately considering the cases $\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha}$ and $\hat{C} = C$. In the former case, the first term of (14) vanishes, while if $\hat{C} = C$ the second term vanishes; we can therefore infer roughly that the first term encodes the loss due to reducing α, while w measures loss from reducing C to $\hat{C}$. For a noise-free, full (non-sparse) GP, we have $C = -K_{\mathcal{I}}^{-1} \Rightarrow \Gamma = I$. In this case, (14) reduces to the unweighted KL divergence:

$$D_{KL}(GP\|\widehat{GP}) = (\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}})^\top \hat{V}(\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}}) + w \,. \tag{15}$$

Note that the full GP is used to weight the divergence rather than the reduced approximating GP. The reduced $\widehat{GP}$ that minimizes (14) is therefore a moment projection (or M-projection) of GP onto the space of reduced size-m GPs. As shown by Koller & Friedman (2009), this type of projection punishes $\widehat{GP}$ (viewed as a normal distribution) for failing to assign probability mass to regions which are assigned non-negligible probability by GP. The reverse direction $D_{KL}^{f}(\widehat{GP}\|GP)$ corresponds to the I-projection, which instead punishes $\widehat{GP}$ for assigning probability to regions that GP considers low-probability. Interpreting this in terms of the function space defined by the GPs, we use the M-projection, which ensures that all functions plausible under GP are assigned some probability by $\widehat{GP}$, a highly desirable property as contrasted with the I-projection.

3.2 WOGPs: Weighted Sparse GP Reduction

We now address the problem of reducing the full GP to $\widehat{GP}$, which uses only m of the inducing variables. The goal of this reduction is of course to minimize the impact of removing an inducing variable; in our case, we attempt to minimize $D_{KL}^{f^*}(GP\|\widehat{GP})$.

Note that the weighting function f^* uses the full GP prediction rather than the reduced GP. This is desirable for two reasons. First, we expect the full GP to predict more accurately than the reduced GP because it is fully utilizing the information from the size-m model of the previous iteration and the new point, while the reduced GP must approximate this information. Second, using the reduced GP's predictions to weight the feature space confounds the optimization problem, since the weighting of the feature space is then malleable; for example, if f is the prediction of $\widehat{GP}$, it may be optimal to simply let $\hat{\boldsymbol{\alpha}} = 0 \Rightarrow f = 0$, but this is not helpful in approximating the full GP.

Fix $GP = \mathrm{GP}(\boldsymbol{\alpha}, C)$ and $K_{\mathcal{I}}$. Let $d^*(\hat{\boldsymbol{\alpha}}, \hat{C}) = cD_{KL}^{f^*}(GP\|\widehat{GP})$ be the weighted KL divergence (times scaling constant c) between this GP and its approximation $\widehat{GP} = \mathrm{GP}(\hat{\boldsymbol{\alpha}}, \hat{C})$. Recall our definition of $\hat{Q}$, the update to the inverse Gram matrix, from Equation 7 (and note that $\hat{Q}$ is a function only of Q).

Formally we address the following problem:

$$\begin{aligned} \underset{\hat{\boldsymbol{\alpha}}, \hat{C}}{\text{minimize}} \quad & d^*(\hat{\boldsymbol{\alpha}},\ \hat{C}) \\ \text{subject to} \quad & \hat{\boldsymbol{\alpha}}^\top \boldsymbol{e}_{m+1} = 0 \\ & \hat{C}\boldsymbol{e}_{m+1} = \mathbf{0}_{m+1} \\ & \hat{C} = \hat{C}^\top \\ & (\hat{C} + \hat{Q}) \succeq 0 \\ & |\hat{C} + Q| > 0. \end{aligned} \tag{16}$$

Here $\boldsymbol{e}_{m+1}$ is the final standard basis vector and $\mathbf{0}_{m+1}$ is the zero vector in $\mathbb{R}^{m+1}$.

Proposition 3. *For fixed $\hat{C}$, the optimization problem (16) is convex with respect to $\hat{\boldsymbol{\alpha}}$.*

Proof. Differentiating (14) with respect to the nonzero entries of $\hat{\boldsymbol{\alpha}}$ yields

$$\begin{aligned} \frac{\partial\, d^*(\hat{\boldsymbol{\alpha}}, \hat{C})}{\partial \hat{\boldsymbol{\alpha}}} &= -2[I_m \mathbf{0}_m]\hat{V}(\Gamma - I)\boldsymbol{\alpha} \\ &\quad - 2[I_m \mathbf{0}_m]\hat{V}(\boldsymbol{\alpha} - [I_m \mathbf{0}_m]^\top \hat{\boldsymbol{\alpha}}) \\ &= -2[I_m \mathbf{0}_m]\hat{V}(\Gamma\boldsymbol{\alpha} - [I_m \mathbf{0}_m]^\top \hat{\boldsymbol{\alpha}})\ , \end{aligned} \tag{17}$$

where $\hat{\boldsymbol{\alpha}}$ is now assumed to be m-dimensional, I_m represents the m-dimensional identity matrix, $\mathbf{0}_m$ is a column vector of m zeros, and $[I_m \mathbf{0}_m]$ denotes the corresponding $(m \times (m+1))$-dimensional matrix.

Now let $\boldsymbol{v}_i$ denote the ith column of $\hat{V}$, excluding the last entry, and observe that

$$\frac{\partial^2\, d^*(\hat{\boldsymbol{\alpha}}, \hat{C})}{\partial \hat{\alpha}_i \hat{\alpha}_j} = 2\frac{\partial\, (\boldsymbol{v}_i^\top \hat{\boldsymbol{\alpha}})}{\partial \hat{\alpha}_j} = 2\hat{V}_{i,j}\ . \tag{18}$$

Thus we have that the Hessian matrix of $d^*(\hat{\boldsymbol{\alpha}}, \hat{C})$ with respect to $\hat{\boldsymbol{\alpha}}$ is just twice the leading $(m \times m)$ submatrix of $\hat{V}$, which we denote $\hat{V}^{(r)}$.

Note that we can compute $\hat{V}^{(r)}$ using block matrix inversion:

$$\hat{V}^{(r)} = (\hat{C} + Q^{(r)} - \frac{1}{q^*}Q^*Q^{*\top})^{-1} = (\hat{C} + \hat{Q})^{-1}\ . \tag{19}$$

Our result follows from the constraints $(\hat{C} + \hat{Q}) \succeq 0$ and $|\hat{C} + Q| > 0$, with the additional observation that the domain of (16) in $\hat{\boldsymbol{\alpha}}$ is a convex set. □

Having established convexity, we now use Equation 17 to compute an update rule for $\hat{\boldsymbol{\alpha}}$ that minimizes the resulting weighted KL divergence. Solving (17) for zero, we have

$$\begin{aligned} &[I_m \mathbf{0}_m]\hat{V}(\Gamma\boldsymbol{\alpha} - [I_m \mathbf{0}_m]^\top \hat{\boldsymbol{\alpha}}) = \mathbf{0}_m \Rightarrow \\ &\qquad \hat{V}(\Gamma\boldsymbol{\alpha} - [I_m \mathbf{0}_m]^\top \hat{\boldsymbol{\alpha}}) = [\mathbf{0}_m^\top\ u]^\top \Rightarrow \\ &\Gamma\boldsymbol{\alpha} - [I_m \mathbf{0}_m]^\top \hat{\boldsymbol{\alpha}} = (\hat{C} + Q)[\mathbf{0}_m^\top\ u]^\top = u[\boldsymbol{Q}^{*\top} q^*]^\top\ , \end{aligned} \tag{20}$$

where in the last step we recall that the last column of $\hat{C}$ is zero. We let $\Gamma^{(r)}$ denote the first m rows of Γ and $\boldsymbol{\Gamma}^*$ the last row of Γ; observe then that

$$\boldsymbol{\Gamma}^*\boldsymbol{\alpha} = uq^* \Rightarrow u = \frac{\boldsymbol{\Gamma}^*\boldsymbol{\alpha}}{q^*}\ , \tag{21}$$

which leads us to the following solution.

Proposition 4. *The update rule for $\hat{\boldsymbol{\alpha}}$ which minimizes $D_{KL}^{f^*}(GP\|\widehat{GP})$ is given by*

$$\hat{\boldsymbol{\alpha}} = \Gamma^{(r)}\boldsymbol{\alpha} - \frac{\boldsymbol{\Gamma}^*\boldsymbol{\alpha}}{q^*}\boldsymbol{Q}^*\ . \tag{22}$$

Fixing $\hat{\boldsymbol{\alpha}}$ to be optimal in the above sense, we would then like to solve the optimization problem (16) with respect to $\hat{C}$. Unfortunately, this problem is not easily solved for local minima. Differentiating Equation 14 with respect to $\hat{C}$, we have

$$\begin{aligned} &\frac{\partial d^*(\hat{\boldsymbol{\alpha}}, \hat{C})}{\partial \hat{C}} = \frac{\partial w}{\partial \hat{C}} + \\ &- [I_m \mathbf{0}_m]\hat{V}(2\Gamma\boldsymbol{\alpha} - (\boldsymbol{\alpha} + \hat{\boldsymbol{\alpha}}))(\boldsymbol{\alpha} - \hat{\boldsymbol{\alpha}})^\top \hat{V}[I_m \mathbf{0}_m]^\top\ . \end{aligned} \tag{23}$$

Evaluating the derivative of w in the same way, we arrive at

$$\begin{aligned} \frac{\partial w}{\partial \hat{C}} &= [I_m \mathbf{0}_m]\hat{V}[I_m \mathbf{0}_m]^\top \\ &\quad - [I_m \mathbf{0}_m]\hat{V}(C + Q)\hat{V}[I_m \mathbf{0}_m]^\top \end{aligned} \tag{24}$$

However, we are not aware of a way to solve Equation 23 to minimize $D_{KL}^{f^*}(GP\|\widehat{GP})$ analytically with respect to $\hat{C}$.

Furthermore, we find that the objective $d^*(\hat{\boldsymbol{\alpha}}, \hat{C})$ is not convex with respect to $\hat{C}$: since $\log|X|$ is known to be concave, the second term of w

$$-\log|(C+Q)\hat{V}| = \log|\hat{C}+Q| - \log|C+Q| \quad (25)$$

is concave. This prevents us from using convex optimization to solve for $\hat{C}$. However, we have the following:

Proposition 5. *For fixed $\hat{\boldsymbol{\alpha}}$, the objective $d^*(\hat{\boldsymbol{\alpha}}, \hat{C})$ can be written as $d^*(\hat{\boldsymbol{\alpha}}, \hat{C}) = g_1(\hat{C}) - g_2(\hat{C})$, where g_1, g_2 are real-valued convex functions on the intersection of $\mathbb{R}^{(m+1)\times(m+1)}$ with the constraints on $\hat{C}$ in (16).*

Proof. Due to Theorem 1 of Yuille & Rangarajan (2003), we can show this by demonstrating that the Hessian of $d^*(\hat{\boldsymbol{\alpha}}, \hat{C})$ for fixed $\hat{\boldsymbol{\alpha}}$ is bounded. Since $\mathrm{Tr}[X^{-1}]$ is convex, we already have the desired result for w and will therefore compute only the Hessian of

$$d_0^*(\hat{C}) \equiv (2\Gamma\boldsymbol{\alpha} - (\boldsymbol{\alpha}+\hat{\boldsymbol{\alpha}}))^\top \hat{V}(\boldsymbol{\alpha}-\hat{\boldsymbol{\alpha}}) \,. \quad (26)$$

To do this, we first compute

$$\frac{\partial d_0^*}{\partial \hat{C}} = -[I_m \mathbf{0}_m]\hat{V}(2\Gamma\boldsymbol{\alpha} - (\boldsymbol{\alpha}+\hat{\boldsymbol{\alpha}}))(\boldsymbol{\alpha}-\hat{\boldsymbol{\alpha}})^\top \hat{V}[I_m \mathbf{0}_m]^\top \,, \quad (27)$$

where we use the matrices $[I_m \mathbf{0}_m]$ to confine the expression to the $(m \times m)$ derivative with respect to the nonzero entries of $\hat{C}$. Let $\boldsymbol{u}_1 = 2\Gamma\boldsymbol{\alpha} - (\boldsymbol{\alpha}+\hat{\boldsymbol{\alpha}})$ and $\boldsymbol{u}_2 = (\boldsymbol{\alpha}-\hat{\boldsymbol{\alpha}})$ for notational convenience. Confining this expression to a particular entry, we arrive at

$$\frac{\partial d_0^*}{\partial \hat{C}_{i,j}} = -\boldsymbol{v}_i^\top \boldsymbol{u}_1 \boldsymbol{u}_2^\top \boldsymbol{v}_j \,, \quad (28)$$

letting $\boldsymbol{v}_i$ denote the ith column of $\hat{V}$ (and recalling that $\hat{V}$ is symmetric).

Let $H_{k,l}^{i,j}$ represent an entry of the Hessian matrix of d_0^*, and compute

$$\begin{aligned} H_{k,l}^{i,j} = \frac{\partial^2 d_0^*}{\partial \hat{C}_{i,j} \partial \hat{C}_{k,l}} &= -\frac{\partial}{\partial \hat{C}_{k,l}} \boldsymbol{v}_i^\top \boldsymbol{u}_1 \boldsymbol{u}_2^\top \boldsymbol{v}_j \\ &= \boldsymbol{u}_1^\top (\hat{V}_{i,k} \boldsymbol{v}_l \boldsymbol{v}_j^\top + \hat{V}_{j,k} \boldsymbol{v}_i \boldsymbol{v}_l^\top) \boldsymbol{u}_2 \,. \end{aligned} \quad (29)$$

Evidently $H_{k,l}^{i,j}$ is bounded for all i, j, k, l, and thus we have the desired result. □

The above result allows us to employ methods of concave-convex minimization, e.g. the CCCP procedure of Yuille & Rangarajan (2003). Specifically, to minimize $g_1 - g_2$ we employ an iterative method of updating $\hat{C}$ according to the rule

$$\frac{\partial g_1}{\partial \hat{C}}(\boldsymbol{x}^{t+1}) = \frac{\partial g_2}{\partial \hat{C}}(\boldsymbol{x}^t) \,. \quad (30)$$

It is not straightforward to explicitly decompose d^* into convex terms g_1 and g_2 due to the difficulty of solving Equation 23, so we instead use the iterative method for optimization given in Yuille & Rangarajan (2003) for such cases, which finds $\boldsymbol{x}^{t+1}$ in each step by minimizing a function of $\boldsymbol{x}^{t+1}$ and $\boldsymbol{x}^t$.

In Section 4, we demonstrate that CCCP optimization of $\hat{C}$ can significantly reduce the weighted KL divergence of the online GP update. Since we are minimizing with respect to the matrix $\hat{C}$, the size of the CCCP optimization problem is $\mathcal{O}(m^2)$. For larger sparse models, this approach may therefore not be feasible if computation time is a primary concern. As runtime is extremely costly for our application, we also propose as a heuristic the update rule for $\hat{C}$ of Csató (2002), given in Equation 6, which minimizes the unweighted divergence between the distributions as well as the w-term of the weighted divergence. The analytic form for this update can provide a significant speedup over CCCP if m is large; we justify this heuristic by comparing with CCCP updating for $\hat{C}$ in Section 4.

4 Experiments

We perform two types of experiments to demonstrate the efficacy of WOGPs in Bayesian optimization. First, we provide easily visualized examples of the comparative performance of WOGPs and standard online sparse GPs on synthetic optimization problems. Second, we use data from the LCLS free-electron laser to test the optimization algorithms in a real-world setting with noisy observations.

4.1 Example Problem

First, we consider the simple problem of optimizing over a function given by $y = 20 + x - (x-1)^2(x+1)^2$, shown in Figure 1a, which achieves a maximum slightly greater than 21 at $x \approx 1.1$ and has a local maximum at $x \approx -.84$. Each type of model is allowed at most five inducing variables. In each trial, we choose five training points in $[-3, 3]$ uniformly at random and train each model on them. The Bayesian optimization procedure described in Section 2.3 is then performed for 80 iterations. Figure 1b shows the results of this experiment averaged across 80 trials. On average, both models tend to quickly find a value near the global optimum; however, while the WOGP tends to converge near this optimum, the unweighted model does not. Instead, when the unweighted model explores other areas, it essentially loses focus on the optimal area by devoting some of its limited resources to modeling the new, lower-scoring region. This can be seen in the decline on average of the unweighted model's score to roughly $y = 19$, in which it converges within the near-plateau between $x = -1$ and $x = 0$.

In the bottom of Figure 1, examples are shown of the con-

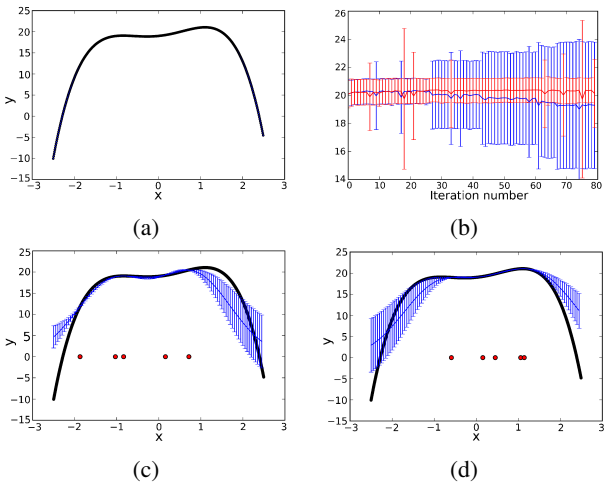

Figure 1: Simple 1-D optimization problem. (a) The objective function. (b) Average y-value explored in each iteration, for unweighted (blue) and weighted (red) models. Standard deviations are shown as error bars. (c,d) Sample unweighted and weighted (respectively) final GP models. The objective is shown in black, GP mean function with uncertainty in blue, and inducing points as red dots.

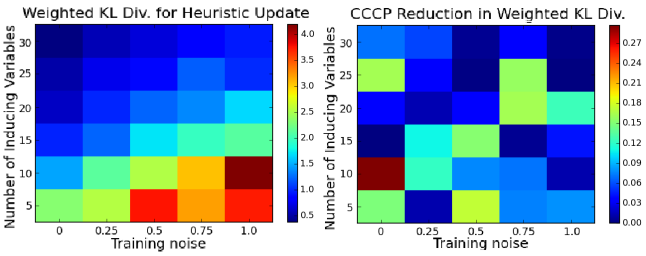

Figure 2: Results demonstrating the effectiveness of CCCP for optimization over $\hat{C}$, shown for a particular event. Each pixel shows the median value over 20 trials at the given configuration. verged online GP models in this problem. In (1c), the unweighted model is plotted in blue with its predictive variance, while the underlying function $f(x)$ is plotted in black. The red dots underneath show the locations of the inducing variables for each model. The models were trained on the same points, and both initially explore in the region around $x = -1$. However, the unweighted model allocates one of its inducing variables to $x \approx -2$ in order to capture the curvature of $f(x)$ in the negative direction. The weighted model instead stabilizes its inducing variables around $x = -1$ and $x = 0$ during its exploration in $x < 0$ and then begins to explore in $x > 0$. This rightward exploration quickly converges around $x = 1$.

4.2 FEL Performance Optimization

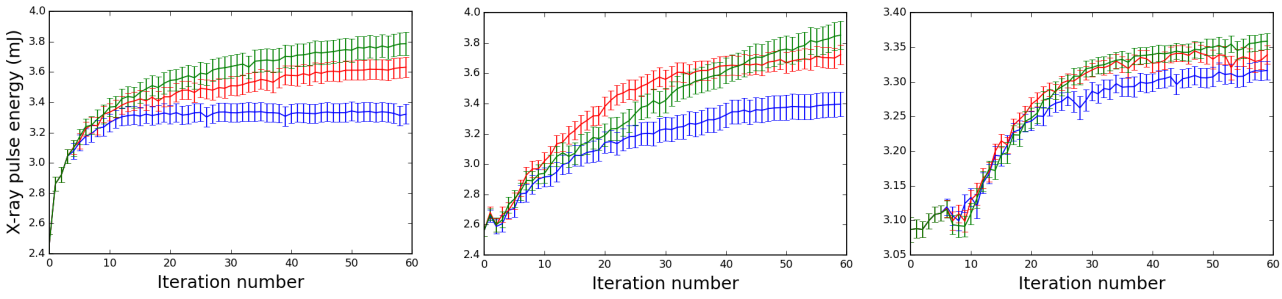
Free-electron lasers operate by accelerating electrons to nearly the speed of light, and then passing this electron beam through a series of magnetic dipoles to separate the electrons into coherent microbunches (Huang & Kim (2007)). Through this coherence, an FEL can generate x-ray pulses 10 billion fold brighter than any other x-ray source. Here, we focus on the tuning of quadrupole magnets, which are placed upstream of the FEL to manipulate the shape of the electron beam.

Currently at LCLS, quadrupole magnets are tuned by hand to optimize the beam pulse energy. The existing tuning procedure is repeated frequently due to machine configuration changes and drift over time. This extensive tuning time is problematic due to the operational cost of the beam and the heavy over-subscription of LCLS users; the FEL is used by scientists in a variety of disciplines for field-leading research, and the demand for machine time outstrips its availability by a factor of 5. Reducing the time spent tuning the machine would directly increase its availability for scientific use.

Our experiments on the FEL data thus far have used isolated optimization 'events': we define such an event as a consecutive period of time using a fixed accelerator configuration, such that the measured x-ray pulse energy is a function only of the controlled variables, i.e. quadrupole magnet settings. Under this assumption, we then train two online GP models with the same number of inducing variables, one using a WOGP, and one using a standard online sparse GP, on a noisy subset of the event data. A much larger sparse GP (with e.g. 500 inducing variables) is trained on the event data without noise. This large 'truth' model is then used in the Bayesian optimization procedure, with its predictions used as feedback for the online GP optimizers. We introduce noise for the online GP models and not the truth model to simulate the use case of online tuning, which must be done each time the beam is used due to the tendency of the machine settings to drift over time.

We first use this data to test the WOGP update rules for $\hat{C}$. Using CCCP to minimize $D_{KL}^{f^*}(GP \| \widehat{GP})$ with respect to $\hat{C}$ can be used to minimize the weighted KL divergence of the approximating GP. Alternatively, we propose as a heuristic the update given by Csató (2002), shown in (6), which is optimal for the KL divergence (5) between $\widehat{GP}$ and GP, and optimal for the w term of $D_{KL}^{f^*}(GP \| \widehat{GP})$.

Figure 2 shows results of a comparison between these update rules for $\hat{C}$. For this testing, a single representative event was chosen, and 20 optimization trials were run for a short time with various levels of training noise and numbers of inducing variables. For each trial, the value of $D_{KL}^{f^*}$ is then computed for an additional size reduction step for both



(a) (b) (c)

Figure 3: Results of optimization on FEL data, with events at different beam configurations and electron energies of 11.45, 13.2, and 14.5 GeV respectively. The plots show the average x-ray pulse energy in mJ of the region explored in each iteration by the weighted (red) and unweighted (blue) sparse optimizers, as well as by a full GP, shown in green. Error bars indicate the normalized standard deviation of the values in each iteration.

the heuristic and CCCP-computed values of $\hat{C}$. In Figure 2a, the median value of $D_{KL}^{f^*}$ obtained using the heuristic update for $\hat{C}$ across these trials is shown for each configuration. Note that as the modeling problem becomes more challenging (as noise increases and the number of inducing variables decrease), the typical divergence of the update increases. We do not show a similar plot for the CCCP updating because it is visually very similar.

In Figure 2b, the percentage decrease in $D_{KL}^{f^*}$ achieved by using CCCP updating is shown. We see that using CCCP to optimize the value of $\hat{C}$ typically leads to a 5-15% decrease in the weighted KL divergence of the update. This demonstrates that the heuristic update for $\hat{C}$ is justified in cases where the runtime of CCCP is prohibitive. These results also indicate that the CCCP updating scheme detailed here can provide nontrivial improvements to $D_{KL}^{f^*}$ over the heuristic update. Over the course of optimization the accumulated benefit from the CCCP updating may lead to substantial improvements in performance.

Next, we compare the performance of WOGPs and standard online sparse GPs in optimization over the FEL data events described above. Results from three such events, averaged over 200 trials (with different, randomly sampled initial training data), are shown in Figure 3. The results of optimization are compared in terms of final y-value and regret (which is an additive constant away from the negative sum of observations), which accounts for speed of improvement as well. We can see that in general WOGPs tend to yield better performance than the unweighted sparse GP: in the first two events (3a) and (3b), the difference in final y-values is statistically significant ($p < .001$, $p < .002$ respectively in the two-sided t-test), as is the difference in regret ($p < .05$, $p < .005$). In the final event (3c), we can see that the WOGP performs similarly to the full GP, though its improvement over the unweighted sparse GP is not statistically significant for this event.

5 Conclusions

Bayesian optimization is known to be effective for optimization in settings where the objective function is expensive to evaluate. A complex parameter space and noisy observations can slow the convergence of Bayesian optimization, however, and using a full Gaussian process model leads to poor scaling in these cases. In this paper, we introduce sparse online GPs for Bayesian optimization.

Our main contribution is a novel weighted updating scheme for sparse online GPs, which enables a trade-off during optimization between overall predictive accuracy and a specific focus on better-performing regions of parameter space. This addresses the core problem with using sparse GPs in Bayesian optimization: the limited size of the GP representation, which prevents the information from new data from being fully incorporated into the model. As a result, traditional sparse GPs perform poorly since the sparse set selection does not necessarily attempt to preserve resolution in promising areas of parameter space and may even 'blur' local optima to preserve accuracy elsewhere.

Our new weighted-update online GP, WOGP, outperforms the standard online sparse GP in optimization by preferentially updating the model to incorporate information that is more valuable to the optimization procedure. We are able to analytically evaluate the weighted KL divergence between Gaussian processes for a simple weighting function, and we demonstrate empirically that updating the sparse GP to minimize this weighted divergence significantly improves performance during Bayesian optimization. Live tests of this approach are currently underway at LCLS (McIntire et al. (2016a)).

Abstract

We develop a statistical framework for the design of a strategy-proof assignment mechanism that closely approximates a target outcome rule. The framework can handle settings with and without money, and allows the designer to employ techniques from machine learning to control the space of strategy-proof mechanisms searched over, by providing a rule class with appropriate capacity. We solve a sample-based optimization problem over a space of mechanisms that correspond to *agent-independent price functions* (virtual prices in the case of settings without money), subject to a feasibility constraint on the sample. A transformation is applied to the obtained mechanism to ensure feasibility on all type profiles, and strategy-proofness. We derive a sample complexity bound for our approach in terms of the capacity of the chosen rule class and provide applications for our results.

1 INTRODUCTION

Mechanism design studies situations where a set of self-interested agents each hold private information regarding their preferences over different outcomes. Originating from microeconomic theory, mechanism design has become important in the design of open, algorithmic systems that involve multiple stakeholders. A mechanism receives claims about agent types, selects an outcome, and may additionally charge payments. An important property of a mechanism is that of *strategy-proofness*, where it is in the best interest for each agent to make truthful reports.

The existing theory of mechanism design provides positive and negative results in regard to properties that can be achieved together with strategy-proofness. The theory is quite limited, though, in that:

1) Results are developed for stylized preference domains that may not reflect real-world structure [1].
2) Positive results are limited by an analytical bottleneck that makes analysis difficult in *multi-dimensional type spaces* [2, 3].
3) There are few general methodologies, especially in mechanism design without money, where bespoke mechanisms are developed for a given domain [4].

In practice, one often needs to hand-craft a mechanism based on application-specific requirements. For example,

- **Task assignment:** Consider the problem of designing an assignment mechanism for a ride sharing platform. This is a setting with payments, and the standard mechanism one would use here is the Vickrey-Clarke-Groves (VCG) mechanism. However, if one needs to incorporate specific priority or fairness considerations, the VCG mechanism may not be well-suited, and the designer would be faced with needing to manually design a mechanism that satisfies the requirements.
- **Resource allocation:** Consider the problem of designing a strategy-proof mechanism for the fair allocation of jobs to shared computers based on reported need. This is a setting without money, and a standard strategy-proof mechanism for assignment is random serial dictatorship (RSD). However, if the designer wishes to optimize a different utility criterion than RSD (e.g. a utilitarian objective), then the designer will again have to handcraft a mechanism based on the requirements.

We suppose that alternatively, the designer can provide his requirements in the form of a *target outcome rule* that maps reports to desired outcomes (but is not necessarily strategy-proof). The goal is to automatically design a strategy-proof mechanism that closely mimics this rule, leading to the following question:

Given an arbitrary outcome rule, can we automatically design a strategy-proof mechanism that closely approximates the rule?

The common approach to *automated mechanism design* [5] has been to formulate a search problem over a set of

strategy-proof mechanisms. Some works perform this search over an explicit space of all possible mechanisms, often resulting in intractable optimization problems (with a number of decision variables that grow exponentially in the number of agents). Other approaches search over a parameterized subset of strategy-proof mechanisms [6, 7, 8]. However, these methods are tailored to specific classes of mechanisms known to be strategy-proof. Positive results are available for a Bayesian relaxation of strategy-proofness, and with agent-separable objectives [9, 10], but a more general approach has remained elusive.

In this paper, we develop a general statistical framework for designing strategy-proof mechanisms that closely approximate a target outcome rule. Envisioning settings with abundant data on agent preferences, we assume access to example inputs to a mechanism, each input labeled with a target outcome. Consider for example a setting with an existing, strategy-proof mechanism, with new design requirements specified through target outcomes on historical reports. The goal is to find a strategy-proof mechanism that closely approximates the target outcome rule.

We leverage general, necessary and sufficient conditions for the strategy-proofness of a mechanism, namely an *agent-independence condition*, and a *feasibility requirement* (that the outcome of the mechanism is feasible). Concretely, the framework formulates an optimization problem on a sampled set of agent type profiles over a specified class of outcome rules that satisfy agent-independence. A feasibility constraint is enforced on the sampled profiles, so that the resulting mechanism is feasible on these samples. In addition, we apply a transform to the mechanism to ensure feasibility on all profiles while retaining agent-independence (and thus obtaining strategy-proofness). The particular problem we study is an *assignment problem*, where there is a set of distinct, indivisible items and the outcome assigns at most one item to each agent. The distance to the target assignment is measured in terms of the Hamming distance. The feasibility transform is due to Hashimoto [11] and is well defined for allocation problems.

Unlike previous works on the automated design of strategy-proof mechanisms, our framework neither performs a brute-force search over all mechanisms nor requires the designer to provide a specific parameterized class of strategy-proof mechanisms. Instead we take an intermediate approach, where the space of strategy-proof mechanisms searched over is controlled by the capacity of the outcome class. The capacity of this class can be controlled through standard machine learning techniques, for example by parametrizing the class in a suitable feature space and adjusting the set of features used. By using the general, necessary and sufficient conditions of agent-independence and feasibilty, we remove the need for new characterization results. Rather, the limit of the framework is governed by the limits of the statistical framework.

The main result is an upper bound on the sample complexity of designing strategy-proof mechanisms using our framework. The bound depends on the capacity of the agent-independent function class used, measured in terms of its *Natarajan dimension* D [12]. We show that for n agents and N sampled profiles, the difference in Hamming distance to the target between the designed mechanism and the best strategy-proof mechanism within the hypothesis space is at most:

$$\widetilde{\mathcal{O}}\Big(\sqrt{\frac{D}{N}} \;+\; \frac{D}{N}\sum_{i=1}^{n}|\Theta_i|\Big),$$

for a distributional assumption, and where $|\Theta_i|$ is the size of the type space for agent i. The linear dependence on $|\Theta_i|$ is a result of the feasibility transformation applied to the sample-optimal rule. This sample complexity is exponentially smaller than the total number of type profiles $\times_{i=1}^{n}|\Theta_i|$.

The proposed approach is quite flexible, in that it can handle settings with and without money. Instantiating the framework to assignment problems, we provide explicit examples of agent-independent rule classes with finite Natarajan dimension that contain feasible assignment rules. For the setting with money, the hypothesis class is defined in terms of agent-independent price functions, with each agent demanding the item that maximizes its utility. For the setting without money, the hypothesis class is defined in terms of virtual price functions and budgets, with each agent demanding its most preferred, affordable item.

1.1 RELATED WORK

The problem of using machine learning to design mechanisms that approximate a target rule was first considered by Procaccia et al. [13] in the context of designing voting rules, but without consideration to strategy-proofness. In the most closely-related work, Dütting et al. [14] use statistical machine learning to design payment rules for a fixed outcome rule. We design both outcome and payment rules, and whereas they provide approximate strategy-proofness, we obtain strategy-proof mechanisms. We also handle mechanism design without money.

Prior work on automated mechanism design adopts specific, parameterized classes of mechanisms [7, 8, 15]. However, these approaches require a designer to have parametric characterizations of strategy-proof mechanisms, and require specialized solvers for each case. More recently, Narasimhan and Parkes [15] consider the problem of using methods from machine learning to design social choice and matching mechanisms that best approximate a target rule, but their approach is also tailored to specific parameterized classes of mechanisms. We provide a more general approach, where the designer only needs to provide a set of rules that satisfy the agent-independence condition.

There has also been previous work that uses statistical or machine learning techniques to design revenue-optimal mechanisms from sampled preference data [16, 17, 18, 19], but this is restricted to settings where the private information of agents is "single-parameter" (roughly, one number, whereas in our setting each agent's type is a value for each item or a rank order on items).

Organization. In Section 2, we begin with the problem setting and in Section 3, describe a general characterization of strategy-proof mechanisms for assignment problems with and without money. In Section 4, we use these characterizations to develop a statistical framework for designing strategy-proof assignment mechanisms. In Section 5, we derive a sample complexity bound for our approach, and in Section 6, we discuss applications of our result to assignment problems with and without money.

2 PROBLEM SETTING

We consider n agents $[n] = \{1, \ldots, n\}$ and m items $[m] = \{1, \ldots, m\}$, and are interested in one-to-one assignments of items to agents. We allow agents to be unassigned, in which case we will say that the agent is assigned to ϕ. An agent may additionally be charged a payment.

We say that an assignment is *feasible* if no two agents are assigned the same item. Let $\Omega \subset [m]^n$ denote the set of feasible one-to-one assignments of items (or ϕ) to the agents. We will use $y \in \Omega$ to denote a feasible assignment and $y_i \in [m]$ for the item allocated to agent i in y.

Each agent is associated with a *type* θ_i from a finite set Θ_i, which is private to the agent. We use $\theta = (\theta_1, \ldots, \theta_n)$ to denote a profile of types, and $\Theta = \times_{i=1}^{n} \Theta_i$ to denote the set of all type profiles. We will use θ_{-i} to denote the profile of types for all but agent i, and $\Theta_{-i} = \times_{j \neq i} \Theta_j$.

In a setting without money, an agent's type induces a preference ordering over items. We will use $o \succ_i o'$ to denote that agent i strictly prefers item $o \in [m]$ over item $o' \in [m]$, and $o \succeq_i o'$ to denote that the agent either strictly prefers o over o' or is indifferent.

In a setting with money, an agent is charged a price for an item, and the agent's type induces a preference ordering over pairs $(o, p_o) \in [m] \times \mathbb{R}_+$ of items and prices. In this case, we will assume quasi-linear preferences. Here each agent i is associated with a valuation function $v_i : \Theta_i \times [m] \to \mathbb{R}_+$, with $v_i(\theta_i, o) \in \mathbb{R}_+$ indicating the value assigned for agent type θ_i to item o. The agent's *utility* for a pair (o, p_o) of items and prices is given by $u_i(\theta_i, (o, p_o)) = v_i(\theta_i, o) - p_o$, and $(o, p_o) \succeq_i (o', p_{o'}) \iff u_i(\theta_i, (o, p_o)) \geqslant u_i(\theta_i, (o', p_{o'}))$.

A *mechanism* receives reports of types from the agents, and maps each agent to an item through an *outcome rule* $f : \Theta \to \Omega$. For a report profile $\hat{\theta}$ from the agents, the assignment to the agents is given by $f(\hat{\theta}) \in \Omega$, and $f_i(\hat{\theta}) \in [m]$ shall denote the item assigned to agent i by f. In settings with money, the mechanism also charges a payment measured in terms of a *payment rule* $p_i : \Theta \to \mathbb{R}_+$.

A desirable property of a mechanism is *strategy-proofness*. A mechanism is strategy-proof if each agent receives its most-preferred outcome (or outcome-price pair) when reporting its true type. More concretely, in a setting without money, a mechanism defined by outcome rule f is strategy-proof if for all $i \in [n]$, $\theta \in \Theta$, and $\theta'_i \in \Theta_i$, $f_i(\theta) \succeq_i f_i(\theta'_i, \theta_{-i})$. Similarly, in a setting with money, a mechanism defined by (f, p) is strategy-proof if for all $i \in [n]$, $\theta \in \Theta$, and $\theta'_i \in \Theta_i$, $(f_i(\theta), p_i(\theta)) \succeq_i (f_i(\theta'_i, \theta_{-i}), p_i(\theta'_i, \theta_{-i}))$. In both cases, let us use $\mathcal{M}_{\text{SP}}$ to denote the space of mechanisms that are strategy-proof.

Agent types are distributed according to an underlying, unknown distribution $\mathcal{D}$ over type profiles Θ. We are provided a *target outcome rule* $g : \Theta \to \Omega$ that need not be strategy-proof, and the goal is to design a strategy-proof mechanism that closely approximates this rule. For this purpose, we adopt a *distance measure* $\ell : [m]^n \times [m]^n \to \mathbb{R}_+$ to measure the distance between the given and target assignments. In particular, we use the normalized *Hamming* distance, $\ell(y, y') = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}(y_i \neq y'_i)$ for any $y, y' \in [m]^n$.

The goal is:

$$\min_{(f,p) \in \mathcal{M}'_{\text{SP}}} \mathbf{E}_{\Theta \sim \mathcal{D}}\big[\ell(g(\theta), f(\theta))\big], \tag{1}$$

where $\mathcal{M}'_{\text{SP}} \subseteq \mathcal{M}_{\text{SP}}$ is some set of strategy-proof mechanisms. In words, we want to find the strategy-proof mechanism in a class of mechanisms that minimizes the expected distance from the target. Since the distribution is over a finite space, an infimum over $\mathcal{M}'_{\text{SP}}$ is always achieved by a mechanism within the class. We shall allow the designer to control the space of strategy-proof mechanisms $\mathcal{M}'_{\text{SP}}$ by providing a suitable rule class with appropriate capacity (or expressive power).

3 CHARACTERIZATION OF STRATEGY-PROOF MECHANISMS

We first provide a general, necessary and sufficient characterization of strategy-proof assignment mechanisms in settings with and without money. These characterizations are standard in mechanism design theory.

Assignment Problem with Money. A mechanism defined by a pair of outcome rule and payment rule (f, p) is strategy-proof iff the following conditions hold [20]:

(1) **Agent independence:** Given the report of the other agents, an agent's prices on each item are independent of its own report. Also, the agent is assigned its most-preferred item, given its report and the agent-independent prices. In other words, the payment

rule $p_i(\theta) = t_i(\theta_{-i}, f_i(\theta))$ for some *price function* $t_i : \Theta_{-i} \times [m] \to \mathbb{R}_+$, and

$$f_i(\theta) \in \operatorname*{argmax}_{o \in [m]} \big\{ v_i(\theta_i, o) - t_i(\theta_{-i}, o) \big\}.$$

(2) **Feasibility:** No two agents get the same item, i.e. for all $i, j \in [n]$,$f_i(\theta) \neq \phi, f_j(\theta) \neq \phi \Rightarrow f_i(\theta) \neq f_j(\theta)$.

In words, an agent cannot change the price for an item by misreporting its type, and given these prices, receives the most-preferred item according to the report. Further, the assignment is feasible for all reports.

Example 1. *The well-known VCG mechanism satisfies the above conditions. In its general form, the VCG mechanism allocates for any report θ an assignment that maximizes welfare (i.e. sum of agent valuations): $f^{vcg}(\theta) \in \operatorname{argmax}_{y \in \Omega} \sum_{i=1}^{n} v_i(\theta_i, y_i)$, and charges each agent i a payment: $p_i^{vcg}(\theta) = H_i(\theta_{-i}) - \sum_{j \neq i} v_j(\theta_j, f_j^{vcg}(\theta))$, where $H_i : \Theta_{-i} \to \mathbb{R}_+$ is a function that is independent of agent i's report. By definition, the VCG mechanism satisfies the feasibility condition. To see that the mechanism also satisfies the agent-independence condition, define $t_i^{vcg} : \Theta_{-i} \times [m] \to \mathbb{R}_+$ for reports θ_{-i} and item o as: $t_i^{vcg}(\theta_{-i}, o) = H_i(\theta_{-i}) - \max_{y \in \Omega, y_i = o} \sum_{j \neq i} v_j(\theta_j, y_j)$. Then it can be verified that $p_i^{vcg}(\theta) = t_i^{vcg}(\theta_{-i}, f_i^{vcg}(\theta))$.*

Assignment Problem without Money. We can obtain a similar characterization by defining a *virtual price function* $t_i^{\text{vir}} : \Theta_{-i} \times [m] \to \mathbb{R}_+$ for each agent. For a given preference profile report $\theta \in \Theta$, we will say that agent i can *afford* item $o \in [m]$ if the virtual price for the item is below a budget of \$1, i.e. $t_i^{\text{vir}}(\theta_{-i}, o) \leqslant 1$. An agent receives one of the items that it can afford. A mechanism defined by outcome rule f is strategy-proof iff the following hold:

(1) **Agent independence:** Given the report of the other agents, an agent's virtual prices are independent of its own report. The agent is assigned its most-preferred item among those it can afford, given its report and the agent-independent prices. In other words, there exists a virtual price function, $t_i^{\text{vir}} : \Theta_{-i} \times [m] \to \mathbb{R}_+$ such that $t_i^{\text{vir}}(\theta_{-i}, f_i(\theta)) \leqslant 1$ and

$$f_i(\theta) \succeq_i o, \forall o \in \{o' \in [m] : t_i^{\text{vir}}(\theta_{-i}, o') \leqslant 1\}.$$

(2) **Feasibility:** No two agents get the same item, i.e. for all $i, j \in [n]$, $f_i(\theta) \neq \phi, f_j(\theta) \neq \phi \Rightarrow f_i(\theta) \neq f_j(\theta)$.

4 A GENERAL STATISTICAL FRAMEWORK

We next introduce a framework that exploits these general, necessary and sufficient characterizations. Specifically, we provide an approach to solve (1) by formulating a sample-based optimization problem over outcome rules that satisfy the above conditions.

We require the designer to provide a class $\mathcal{F}_i$ of functions $f_i : \Theta \to [m]$ that satisfy the *agent independence* condition. For the setting with money, each $f_i \in \mathcal{F}_i$ is required to be of the form $f_i(\theta) \in \operatorname{argmax}_{o \in [m]} \big\{ v_i(\theta_i, o) - t_i(\theta_{-i}, o) \big\}$ for some $t_i : \Theta_{-i} \times [m] \to \mathbb{R}_+$. For the setting without money, each $f_i \in \mathcal{F}_i$ needs to satisfy $t_i^{\text{vir}}(\theta_{-i}, f_i(\theta)) \leqslant 1$ and $f_i(\theta) \succeq_i o, \forall o \in \{o' \in [m] : t_i^{\text{vir}}(\theta_{-i}, o') \leqslant 1\}$ for some $t_i^{\text{vir}} : \Theta_{-i} \times [m] \to \mathbb{R}_+$.

Further, let $\mathcal{F} = \times_{i=1}^{n} \mathcal{F}_i$. We will refer to each function $f_i \in \mathcal{F}_i$ as an agent-independent function, and the concatenated function $f \in \mathcal{F}$ as an agent-independent outcome rule. The outcome rules $f \in \mathcal{F}$ need not satisfy the feasibility condition (i.e. can map a type profile θ to an infeasible assignment $f(\theta) \in [m]^n$), and therefore may not be strategy-proof.

For ease of exposition, we will henceforth assume that *neither the outcome rules $f \in \mathcal{F}$ nor the target rule g leave an agent unassigned* (i.e. do not assign ϕ to an agent). The framework and theoretical results easily extend to the case where this assumption does not hold.

The goal is to solve (1) over all outcome rules in $\mathcal{F}$ that also satisfy the feasibility condition, and find the rule that has minimum Hamming distance from the target rule:

$$\min_{f \in \mathcal{F}} \mathbf{E}_{\theta \sim \mathcal{D}} \big[\ell\big(g(\theta), f(\theta)\big) \big] \tag{2}$$

$$\text{s.t.} \quad f_1(\theta) \neq \ldots \neq f_n(\theta), \ \ \forall \theta \in \Theta.$$

In practice, we do not have access to the type distribution $\mathcal{D}$. Rather, we have a sample $S = \{(\theta^1, y^1 = g(\theta^1)), \ldots, (\theta^N, y^N = g(\theta^N))\} \in (\Theta \times \Omega)^N$ containing agent profiles drawn i.i.d. from $\mathcal{D}$ and labeled according to the target outcome rule g.

We solve an empirical version of the optimization problem (2), with the feasibility constraint enforced only on the profiles in S. A problem is that the obtained rule need not be feasible on type profiles outside S. To address this, we adopt a *feasibility transform* on the obtained rule that ensures that the resulting rule is feasible without compromising agent independence, and thus obtaining strategy-proofness. The two steps of our framework are:

Step I: Constrained Optimization on a Sample. We first solve an empirical version of (2) on sample S:

$$\min_{f \in \mathcal{F}} \frac{1}{N} \sum_{k=1}^{N} \ell\big(y^k, f(\theta^k)\big)\big) \tag{3}$$

$$\text{s.t.} \quad f_1(\theta^k) \neq \ldots \neq f_n(\theta^k), \ \ \forall k \in \{1, \ldots, N\}.$$

Step II: Feasibility Transform. The obtained outcome rule need not be feasible on profiles outside S. A naive way to enforce feasibility is to resolve conflicts by canceling an

allocation when there is infeasibility, or through some more sophisticated priority-based approach. But without care, this results in a mechanism that is not strategy-proof; e.g. perhaps an agent can usefully misreport in order to avoid a problem with infeasibility.

We use a transform inspired by an approach due to Hashimoto [11]. For each agent i, we perform the following check: conditioned on the reports of the other agents, *does there exist a type in Θ_i for which the outcome rule would output an infeasible assignment*? If yes, we leave agent i unassigned; otherwise the original assigned item is left unchanged. For the outcome rule $\widehat{f}$ obtained by solving (3), the transform $\mathbb{T}[\widehat{f}] : \Theta \to \Omega$ is given by:

$$\mathbb{T}_i[\widehat{f}](\theta) = \begin{cases} \phi & \text{if } \exists\, \theta_i' \in \Theta_i \text{ s.t. } \widehat{f}(\theta_i', \theta_{-i}) \text{ is infeasible} \\ \widehat{f}_i(\theta) & \text{otherwise,} \end{cases}$$

where $\mathbb{T}_i[\widehat{f}](\theta)$ denotes the item assigned to agent i by the transformed rule. The transform has no effect when $\widehat{f}$ is feasible on all profiles.[1]

Theorem 1 (Hashimoto 2016)**.** *The outcome rule $\mathbb{T}[\widehat{f}]$ is feasible and strategy-proof when $\widehat{f}$ is agent-independent.*

Proof. The transformation $\mathbb{T}$ will leave an agent unassigned whenever its original assignment conflicts with that of the others. Since $\mathbb{T}$ never assigns a new item to an agent, $\mathbb{T}[\widehat{f}]$ is feasible. For strategy-proofness, we consider two cases. (Case 1): the feasibility check for all $\theta_i' \in \Theta_i$ passes, so that agent i's assignment from $\widehat{f}$ is left unperturbed, and no misreport is useful as the agent receives its optimal item given the agent-independent prices. (Case 2): the feasibility check does not pass. But here it would not pass whatever be the report $\hat{\theta}_i$ of agent i, since the test is independent of its report. A misreport is not useful. □

The framework allows a designer to control the space of strategy-proof mechanisms searched over by choosing an appropriately expressive agent-independent rule class $\mathcal{F}$.

Example 2. *We show how the framework can be used to design a strategy-proof mechanism for a simple setting with payments. Consider two homogeneous agents $\{1, 2\}$ and two items $\{1, 2\}$. Assume there are two agent types $\Theta_1 = \Theta_2 = \{\alpha, \beta\}$, with the following valuation functions:*

$$v_1(\alpha, 1) = v_2(\alpha, 1) = 2; \quad v_1(\alpha, 2) = v_2(\alpha, 2) = 1$$
$$v_1(\beta, 1) = v_2(\beta, 1) = 1; \quad v_1(\beta, 2) = v_2(\beta, 2) = 2$$

[1]The transformation does not require an enumeration of all $\times_{i=1}^{n} |\Theta_i|$ type profiles, and performs a check only over the individual type space of a given agent, fixing the reports of the others. It can be implemented with $\sum_{i=1}^{n} |\Theta_i|$ checks.

Suppose the underlying distribution $\mathcal{D}$ over Θ is uniform, and the target rule the designer wants to approximate is:

$$g(\alpha, \alpha) = (1, 2); \qquad g(\beta, \alpha) = (1, 2)$$
$$g(\alpha, \beta) = (1, 2); \qquad g(\beta, \beta) = (2, 1)$$

Assume the designer provides a class $\mathcal{F}_i$ of agent-independent functions $f_i(\theta) = \text{argmax}_{o \in [m]}\{v_i(\theta_i, o) - t_i(\theta_{-i}, o)\}$, with the following two candidates for the payment function $t_i : \Theta_{-i} \times \{1, 2\} \to \mathbb{R}_+$:

τ^A:

	1	2
α	1	0
β	0	2

τ^B:

	1	2
α	1	0
β	0	1

Assume we are provided a training sample with two randomly drawn type profiles and labeled with the target outcomes: $S = \{((\alpha, \alpha), (1, 2)), ((\alpha, \beta), (1, 2))\}$. We now go over the two steps of the framework:

I: Constrained optimization over sample. *We first solve the optimization problem in* (3) *over the given hypothesis class. Note that an outcome rule $\widehat{f}^A$ constructed using $t_1 = t_2 = \tau^A$ (with ties broken in favor of the smaller item for agent 1, and larger item for agent 2) is a solution to* (3) *as it is both feasible on S and yields zero error. On the first type profile (α, α), this rule gives us*

$$\widehat{f}_1^A(\alpha, \alpha) = \text{argmax}_{o \in \{1,2\}}\{v_1(\alpha, o) - \tau^A(\alpha, o)\} = 1$$
$$\widehat{f}_2^A(\alpha, \alpha) = \text{argmax}_{o \in \{1,2\}}\{v_2(\alpha, o) - \tau^A(\alpha, o)\} = 2$$

and on the second type profile, we get

$$\widehat{f}_1^A(\alpha, \beta) = \text{argmax}_{o \in \{1,2\}}\{v_1(\alpha, o) - \tau^A(\beta, o)\} = 1$$
$$\widehat{f}_2^A(\alpha, \beta) = \text{argmax}_{o \in \{1,2\}}\{v_2(\beta, o) - \tau^A(\alpha, o)\} = 2$$

II: Feasibility transformation. *The outcome rule is not necessarily feasible on a type profile outside S. For example, on the type profile (β, β), the rule outputs an infeasible allocation $(1, 1)$. As a second step, we apply the feasibility transform to enforce feasibility without violating the agent-independence property. The resulting outcome rule $\mathbb{T}[\widehat{f}^A]$ can then be verified to yield the following:*

$$\mathbb{T}[\widehat{f}^A](\alpha, \alpha) = (1, 2); \quad \mathbb{T}[\widehat{f}^A](\alpha, \beta) = (1, \phi)$$
$$\mathbb{T}[\widehat{f}^A](\beta, \alpha) = (\phi, 1); \quad \mathbb{T}[\widehat{f}^A](\beta, \beta) = (\phi, \phi)$$

On the other hand, if we were provided a larger sample, say $S' = \{((\beta, \alpha), (1, 2)), ((\alpha, \beta), (1, 2)), ((\beta, \beta), (2, 1)), ((\alpha, \beta), (1, 2))\}$, then the outcome rule $\widehat{f}^A$ is no longer feasible on the sample. In this case, we would instead pick $t_1 = t_2 = \tau^B$. It can be verified that the resulting rule $\widehat{f}^B$ is the VCG outcome rule. This rule is feasible on all profiles, and the transform has no effect: $\mathbb{T}[\widehat{f}^B] = \widehat{f}^B$.

5 SAMPLE COMPLEXITY GUARANTEE

A potential concern is the extent to which the feasibility transform reduces the quality of the solution obtained by solving (3). We shall see that under an assumption on distribution $\mathcal{D}$, and with a sufficiently large sample, the transformed rule becomes arbitrarily close to the best strategy-proof approximation in $\mathcal{F}$. This holds when each $\mathcal{F}_i$ has finite capacity, as we elaborate in this section.

To have any hope of solving our original optimization problem in (1) using a finite sample, we will require the space of agent-independent functions $\mathcal{F}_i$ to have limited capacity, so that the obtained outcome rule does not overfit the sample. The specific notion of capacity we consider is the *Natarajan dimension*, commonly used while analyzing generalization performance of multi-class classifiers [12] (note that each $f_i \in \mathcal{F}_i$ can be seen as a multiclass classifier mapping type profiles to one of m items).

Definition 1 (Natarajan dimension). A set of profiles $A \subseteq \Theta$ is said to be N-shattered by $\mathcal{F}_i$ if there exists labelings $L_1, L_2 : A \to [m]$ such that $L_1(\theta) \neq L_2(\theta),\ \forall \theta \in A$, and for every subset $B \subseteq A$, there is a $f_i \in \mathcal{F}_i$ such that $f_i(\theta) = L_1(\theta),\ \forall \theta \in B$ and $f_i(\theta) = L_2(\theta),\ \forall \theta \in A \backslash B$. The Natarajan dimension of $\mathcal{F}_i$ is the size of the largest set A that is N-shattered by $\mathcal{F}_i$.

The Natarajan dimension is analogous to the *VC dimension* used in binary classification settings. In fact, for binary hypothesis classes, this quantity is the same as the VC dimension (with L_1 and L_2 being the all 1's and all 0's labelings respectively). As with the VC dimension, finiteness of the Natarajan dimension is necessary and sufficient for learnability of a multiclass hypothesis class (see for example [21]). Hence, we assume that each agent-independent class $\mathcal{F}_i$ has finite Natarajan dimension. We will further require a smoothness assumption on distribution $\mathcal{D}$:

Assumption A. Let μ be the p.m.f. associated with distribution $\mathcal{D}$. There exists $\alpha \geqslant 1$ such that for all i, $\theta_i', \theta_i \in \Theta_i, \theta_{-i} \in \Theta_{-i}, \mu(\theta_i', \theta_{-i}) \leqslant \alpha \mu(\theta_i, \theta_{-i})$.

Assumption A requires that type profiles that differ only in one coordinate have similar probability masses. The value of α measures the closeness of the type distribution to a uniform distribution (with higher values indicating the distribution is father away from being uniform). For the uniform distribution we have $\alpha = 1$. Assumption A is used to enable an analysis of the effect of the feasibility transform on the outcome rule.

Each outcome rule in $\mathcal{F}$ satisfies the agent-independence condition. Let $\mathcal{F}_{\text{SP}} \subseteq \mathcal{F}$ be the subset of rules that also satisfy the feasibility condition, and are thus strategy-proof, i.e. outcome rules in $f \in \mathcal{F}$ that are feasible on all $\theta \in \Theta$. We only consider function classes that contain at least one feasible rule, i.e. for which $\mathcal{F}_{\text{SP}} \neq \phi$. Our goal is to find a rule in $\mathcal{F}_{\text{SP}}$ that best approximates target rule g.

Our approach picks a rule $\widehat{f}$ that is feasible on sample S, but need not be feasible on type profiles outside S. The transformation $\mathbb{T}$ ensures feasibility on all profiles, while ensuring strategy-proofness. We show that the transformed rule $\mathbb{T}[\widehat{f}]$ converges in the large sample limit to the best rule in $\mathcal{F}_{\text{SP}}$:

Theorem 2. *Let $\mathcal{D}$ satisfy Assumption A, and assume $\mathcal{F}_{\text{SP}} \neq \varnothing$. Let $\widehat{f}$ denote the rule obtained by solving* (3) *on a sample S of size N, and $\tilde{f} = \mathbb{T}[\widehat{f}]$. Then with probability at least $1 - \delta$ (over draw of S from $\mathcal{D}^N$),*

$$\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \tilde{f}(\theta)\big)\big] \leqslant \min_{f\in\mathcal{F}_{\text{SP}}} \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big] + \widetilde{\mathcal{O}}\left(\sqrt{\frac{D}{N}}\right) + \widetilde{\mathcal{O}}\left(\frac{\alpha D}{N}\sum_{i=1}^{n}|\Theta_i|\right),$$

where D is an upper bound on the Natarajan dimension of each agent-independent function class $\mathcal{F}_i$, and $\widetilde{O}$ hides terms that are logarithmic in n, m, N, D and δ.

The first term arises from $\widehat{f}$ yielding minimum error on sample S, and decreases with increasing sample size N.

The second term captures the effect of the feasibility transformation $\mathbb{T}$, and has a linear dependence on the size of an agent's type space $|\Theta_i|$, while being exponentially smaller than the total number of type profiles $\times_{i=1}^{n}|\Theta_i|$. This term also decreases with sample size N; this is because as N increases, $\widehat{f}$ becomes feasible on a larger fraction of the population, the effect of the transformation $\mathbb{T}$ becomes smaller. Thus for a finite class capacity D, both the above terms go to 0 as $N \to \infty$, and the transformed outcome rule $\widetilde{f}$ converges to the optimal rule in $\mathcal{F}_{\text{SP}}$.

The larger the class capacity D, the larger is the space of strategy-proof rules searched over. However, as seen in the above bound, this will also lead to a larger bias due to overfitting. Thus based on the size of the available sample, the designer needs to appropriately tune the capacity of the agent-independent class, so as to strike a trade-off between the size of the strategy-proof hypothesis space searched over, and the corresponding bias introduced.

5.1 PROOF

We give the proof for Theorem 2. Let $\mathcal{F}_S$ denote the subset of all agent-independent rules in $\mathcal{F}$ that are feasible on S. Recall that the outcome rule $\widehat{f} \in \mathcal{F}$ obtained by solving (3) is in $\mathcal{F}_S$, and also yields the minimum sample error over all rules in $\mathcal{F}_S$. Note that $\mathcal{F}_{\text{SP}}$ is a subset of the rules $\mathcal{F}_S$ that are feasible on all type profiles, and thus strategy-proof:

$$\boxed{\mathcal{F}_{\text{SP}} \subseteq \mathcal{F}_S \subseteq \mathcal{F}}$$

Also, note that the final transformed outcome rule $\widetilde{f} = \mathbb{T}[\widehat{f}]$ is feasible on all profiles, but may not be a rule in $\mathcal{F}_{\text{SP}}$.

We show that with increasing sample size, $\widetilde{f}$ converges to the rule in $\mathcal{F}_{\text{SP}}$ that best approximates the target. While we assume neither the rules $f \in \mathcal{F}$ nor the target rule g assign ϕ to an agent, the transformation $\mathbb{T}$ is allowed to cancel an item to an agent. Hence, while evaluating the designed mechanism against the target outcome rule, an assignment of ϕ to an agent will be counted as an error.

The proof is based on uniform convergence arguments commonly used in the generalization analysis of multiclass classifiers. We will make use of the fact that $\widehat{f}$ is chosen from a finite capacity rule class. We first show that since $\widehat{f}$ minimizes the sample error over all rules in $\mathcal{F}_S$, its expected error to the target is also close to the least possible error within $\mathcal{F}_S$, and in turn to the least error within the subset of feasible and strategy-proof rules $\mathcal{F}_{\text{SP}} \subseteq \mathcal{F}_S$. However, the final transformed rule $\tilde{f}$ may be different from $\widehat{f}$, as it can cancel items assigned by $\widehat{f}$. We further show that since $\widehat{f}$ is feasible on sample S, it is also feasible on a large portion of the population; this together with our smoothness assumption on the distribution implies that the expected error of $\tilde{f}$ is close to that of $\widehat{f}$. Thus we are able to bound the expected error of $\tilde{f}$ in terms of the minimum error within $\mathcal{F}_{\text{SP}}$, and a sample complexity term.

In particular, we analyze three quantities:

$$\begin{aligned}
\epsilon_{\text{err}} &= \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \widehat{f}(\theta)\big)\big], \\
\epsilon_{\text{infeasible}} &= \mathbf{P}_{\theta\sim\mathcal{D}}\big(\widehat{f}_i(\theta) = \widehat{f}_j(\theta) \text{ for some } i, j \in [n]\big), \\
\epsilon^i_{\mathbb{T}} &= \mathbf{P}_{\theta\sim\mathcal{D}}\big(\widetilde{f}_i(\theta) = \phi\big).
\end{aligned}$$

Here ϵ_{err} is the expected distance of the untransformed rule $\widehat{f}$ from the target; $\epsilon_{\text{infeasible}}$ is the probability of $\widehat{f}$ being infeasible on a random profile; and $\epsilon^i_{\mathbb{T}}$ is the probability that the transformation $\mathbb{T}$ cancels the item assigned to agent i.

Since the transformation $\mathbb{T}$ leaves $\widehat{f}_i$ unchanged on all but a fraction $\epsilon^i_{\mathbb{T}}$ of the profiles, the distance of the final transformed outcome rule $\widetilde{f}$ from the target can be bounded in terms of the error of the untransformed rule ϵ_{err}, and $\epsilon^i_{\mathbb{T}}$'s:

$$\begin{aligned}
&\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \tilde{f}(\theta)\big)\big] = \mathbf{E}_{\theta\sim\mathcal{D}}\left[\frac{1}{n}\sum_{i=1}^{n}\mathbf{1}\big(\widetilde{f}_i(\theta) \neq g_i(\theta)\big)\right] \\
&= \mathbf{E}_{\theta\sim\mathcal{D}}\left[\frac{1}{n}\sum_{i=1}^{n}\mathbf{1}\big(\widetilde{f}_i(\theta) = \widehat{f}_i(\theta) \neq g_i(\theta)\big)\right] \\
&\qquad + \mathbf{E}_{\theta\sim\mathcal{D}}\left[\frac{1}{n}\sum_{i=1}^{n}\mathbf{1}\big(\widetilde{f}_i(\theta) = \phi \neq g_i(\theta)\big)\right] \\
&\leqslant \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \widehat{f}(\theta)\big)\big] + \mathbf{E}_{\theta\sim\mathcal{D}}\left[\frac{1}{n}\sum_{i=1}^{n}\mathbf{1}\big(\widetilde{f}_i(\theta) = \phi\big)\right] \\
&= \epsilon_{\text{err}} + \frac{1}{n}\sum_{i=1}^{n}\epsilon^i_{\mathbb{T}}. \qquad (4)
\end{aligned}$$

We bound ϵ_{err} and $\epsilon^i_{\mathbb{T}}$. For this, we will in turn require a bound on $\epsilon_{\text{infeasible}}$. We start with an outline:

- *Bounding ϵ_{err} (Lemma 3):* We show that the *expected* distance of this rule from the target is close to that of the optimal rule in $\mathcal{F}_{\text{SP}}$.
- *Bounding $\epsilon_{\text{infeasible}}$ (Lemma 4):* We show that $\widehat{f}$ is feasible on a large fraction of the population.
- *Bounding $\epsilon^i_{\mathbb{T}}$ (Lemma 5):* We use the smoothness assumption on $\mathcal{D}$ (Assumption A) to show that the transformation $\mathbb{T}$ will have limited effect on $\widehat{f}$ as long as $\widehat{f}$ is feasible on a large portion of the population. In particular, we bound each $\epsilon^i_{\mathbb{T}}$ in terms of $\epsilon_{\text{infeasible}}$.

We begin by bounding ϵ_{err}. It is useful to state a generalization bound on the difference between the empirical and population errors of an outcome rule f chosen from a class of finite Natarajan dimension [21] (see Lemma 10 in Appendix A). W.p. $\geqslant 1-\delta$ (over draw of S), $\forall f \in \mathcal{F}$,

$$\begin{aligned}
&\left|\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big] - \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, f(\theta^k)\big)\right| \\
&\qquad\leqslant \mathcal{O}\left(\sqrt{\frac{D\ln(m) + \ln(n/\delta)}{N}}\right). \qquad (5)
\end{aligned}$$

We then have:

Lemma 3. *Fix $\delta > 0$. With probability at least $1-\delta$ (over draw of S from $\mathcal{D}^N$),*

$$\begin{aligned}
\epsilon_{\text{err}} \leqslant \min_{f\in\mathcal{F}_{\text{SP}}} &\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big] \\
&+ \mathcal{O}\left(\sqrt{\frac{D\ln(m) + \ln(n/\delta)}{N}}\right).
\end{aligned}$$

Proof. Denote $f^* \in \operatorname{argmin}_{f\in\mathcal{F}_{\text{SP}}} \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big]$. We wish to bound:

$$\begin{aligned}
&\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \widehat{f}(\theta)\big)\big] - \min_{f\in\mathcal{F}_{\text{SP}}}\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big] \\
&= \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \widehat{f}(\theta)\big)\big] - \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, \widehat{f}(\theta^k)\big) \\
&\quad + \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, \widehat{f}(\theta^k)\big) - \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f^*(\theta)\big)\big] \\
&\leqslant \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), \widehat{f}(\theta)\big)\big] - \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, \widehat{f}(\theta^k)\big) \\
&\quad + \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, f^*(\theta^k)\big) - \mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f^*(\theta)\big)\big] \\
&\leqslant 2\sup_{f\in\mathcal{F}}\left|\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta), f(\theta)\big)\big] - \frac{1}{N}\sum_{k=1}^{N}\ell\big(y^k, f(\theta^k)\big)\right|,
\end{aligned}$$

where the second step uses the fact that $\widehat{f}$ has minimum empirical error on S over all $\mathcal{F}_S \supseteq \mathcal{F}_{\text{SP}}$ and hence a lesser or equal empirical error compared to $f^* \in \mathcal{F}_{\text{SP}}$; the last step uses the fact that both $\widehat{f}, f^* \in \mathcal{F}$. The generalization bound in (5) then gives the desired result. □

We next focus on bounding $\epsilon_{\text{infeasible}}$.

Lemma 4. *Assume $\mathcal{F}_{\text{SP}} \neq \varnothing$. Fix $\delta > 0$. Then w.p. at least $1-\delta$ (over draw of S from $\mathcal{D}^N$),*

$$\epsilon_{\text{infeasible}} \leqslant \mathcal{O}\left(\frac{nD\ln(mnD)\ln(N)+\ln(1/\delta)}{N}\right).$$

Proof. (Sketch) We provide the full proof in Appendix B.1. For any $f : \Theta \to \Omega$, define a binary function $G_f : \Theta \to \{0,1\}$ as $G_f(\theta) = \mathbf{1}\big(f_1(\theta) \neq \ldots \neq f_n(\theta)\big)$. Clearly, f is feasible iff G_f evaluates to 1 on all type profiles. Since $\mathcal{F}_{\text{SP}} \neq \phi$, there always exists a f in $\mathcal{F}$ which is feasible, and hence there always exists a G_f which outputs 1 on all profiles. Treating G_f as a binary classifier, one can now appeal to standard VC dimension based learnability results for classification [22], with the loss function being the 0-1 loss against the all 1's labeling. The VC dimension of the class of all functions $\{G_f : \Theta \to \{0,1\} : f \in \mathcal{F}\}$ can be shown to be at most $\mathcal{O}(nD\ln(nmD))$. Then w.p. $\geqslant 1-\delta$,

$$\begin{aligned}\epsilon_{\text{infeasible}} &= \mathbf{E}_{\theta\sim\mathcal{D}}\big[\mathbf{1}\big(G_{\hat{f}}(\theta) \neq 1\big)\big] \\ &\leqslant \mathcal{O}\left(\frac{nD\ln(nmD)\ln(N)+\ln(1/\delta)}{N}\right),\end{aligned}$$

which implies the statement of the lemma. □

We finally bound $\epsilon^i_{\mathbb{T}}$ in terms $\epsilon_{\text{infeasible}}$.

Lemma 5. *Under Assumption A, $\epsilon^i_{\mathbb{T}} \leqslant \alpha|\Theta_i|\epsilon_{\text{infeasible}}$.*

Proof. Let us use μ to denote the p.m.f. associated with distribution $\mathcal{D}$. Also, let $\Theta_{\text{infeasible}} \subseteq \Theta$ denote the subset of type profiles on which $\hat{f}$ is infeasible, i.e. type profiles $\theta \in \Theta$ for which $\hat{f}_i(\theta) = \hat{f}_j(\theta)$ for some i and j. Clearly, $\epsilon_{\text{infeasible}} = \sum_{\theta\in\Theta_{\text{infeasible}}} \mu(\theta)$. Further, note that the set of type profiles on which the transformation $\mathbb{T}$ makes a null allocation to agent i is precisely the set of type profiles that are one hop away (i.e. differ in agent i's type) from those in $\Theta_{\text{infeasible}}$. Therefore,

$$\begin{aligned}\epsilon^i_{\mathbb{T}} &= \sum_{\theta\in\Theta}\mu(\theta)\mathbf{1}\big(\tilde{f}_i(\theta)=\phi\big) = \sum_{\theta\in\Theta_{\text{infeasible}}}\sum_{\theta'_i\in\Theta_i}\mu(\theta'_i,\theta_{-i}) \\ &\leqslant \sum_{\theta\in\Theta_{\text{infeasible}}}\sum_{\theta'_i\in\Theta_i}\alpha\mu(\theta) = \alpha\sum_{\theta'_i\in\Theta_i}\sum_{\theta\in\Theta_{\text{infeasible}}}\mu(\theta) \\ &= \alpha|\Theta_i|\epsilon_{\text{infeasible}},\end{aligned}$$

where the inequality follows from Assumption A. □

Combining Lemmas 4-5 with (4) gives us w.p. at least $1-\delta$ (over draw of S):

$$\begin{aligned}\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta),\tilde{f}(\theta)\big)\big] &\leqslant \min_{f\in\mathcal{F}_{\text{SP}}}\mathbf{E}_{\theta\sim\mathcal{D}}\big[\ell\big(g(\theta),f(\theta)\big)\big] \\ &+ \mathcal{O}\left(\sqrt{\frac{D\ln(m)+\ln(n/\delta)}{N}}\right) \\ &+ \mathcal{O}\left(\frac{\alpha}{n}\sum_{i=1}^{n}|\Theta_i|\frac{nD\ln(nmD)\ln(N)+\ln(1/\delta)}{N}\right).\end{aligned}$$

This completes the proof of Theorem 2.

6 APPLICATIONS

We provide instantiations of the framework to assignment problems with and without money. In each case, we construct examples of agent-independent function classes $\mathcal{F}_i$ that have finite Natarajan dimension. We also show that these function classes can be used to model feasible outcome rules, which together with the agent-independence property are guaranteed to be strategy-proof.

6.1 ASSIGNMENT PROBLEM WITH MONEY

As noted in Section 3, a strategy-proof outcome rule in this setting is necessarily of the following form for an agent-independent price rule $t_i : \Theta_{-i} \to \mathbb{R}_+$.

$$f_i(\theta) \in \operatorname*{argmax}_{o\in[m]}\big\{v_i(\theta_i,o) - t_i(\theta_{-i},o)\big\}.$$

One way to construct an agent-independent function class for this setting is by modeling the above price rule t_i as a linear function in a suitable feature space, i.e. as $t^{\mathbf{w}}_i(\theta_{-i},o) = \mathbf{w}_i^\top\Psi_i(\theta_{-i},o)$ for some model vector $\mathbf{w}_i \in \mathbb{R}^d$ and feature map $\Psi_i : \Theta_{-i}\times[m] \to \mathbb{R}^d$. Let $\bar{\mathcal{F}}^{\Psi}_i$ be the corresponding class of agent-independent functions obtained for different model vectors $\mathbf{w}_i$. This class resembles the class of linear discriminant classifiers, which is known to have a finite Natarajan dimension [21]:

Theorem 6. *The Natarajan dimension of $\bar{\mathcal{F}}^{\Psi}_i$ is at most $\mathcal{O}(d\ln(d))$.*

Note that one can fine-tune the capacity of this class by adjusting the number of features d used. Below, we show that the function class admits feasible and strategy-proof outcome rules for an appropriate choice of feature map.

Example feature map. We describe a feature map with two parts, inspired by the VCG price function seen in Example 1. For an agent i and item o, the first part contains the valuations for all agents other than i:

$$\Psi^1_i(\theta_{-i},o) = \big[v_j(\theta_j,o')\big]^m_{o'=1}\big]_{j\neq i} \in \mathbb{R}_+^{(n-1)\times m}.$$

The second part of the feature map contains the valuations for the other agents when they receive the *welfare-maximizing* assignment from items other than o:

$$\Psi^2_i(\theta_{-i},o) = \big[v_j(\theta_j,y_j^{\setminus i,o})\big]_{j\neq i} \in \mathbb{R}_+^{n-1},$$

where $y^{\setminus i,o} \in \operatorname{argmax}_{y\in\Omega,\, y_i=o}\sum_{j\neq i}v_j(\theta_j,y_j)$.

The feature map $\bar{\Psi}_i(\theta_{-i},o) = [\Psi^1_i(\theta_{-i},o),\Psi^2_i(\theta_{-i},o)]$ then allows us to construct feasible outcome rules.

Theorem 7. *There exists $\mathbf{w}_i \in \mathbb{R}^{(n-1)(m+1)}$ s.t. the prices $t^{\mathbf{w}}_i(\theta_{-i},o) = \mathbf{w}_i^\top\bar{\Psi}_i(\theta_{-i},o)$ are non-negative and yield a feasible outcome rule for a suitable tie-breaking scheme.*

The specific model vector we consider is

$$\mathbf{w}_i = [\underbrace{1, 1, \ldots, 1}_{(n-1)\times m}, \underbrace{-1, -1, \ldots, -1}_{n-1}].$$

The first part of the model vector ensures that the payments are non-negative, while the second part leads to a *VCG-style* welfare maximizing outcome rule. The proof details are provided in Appendix B.2.

6.2 ASSIGNMENT PROBLEM WITHOUT MONEY

In this setting, a strategy-proof outcome rule satisfied the following for some agent-independent virtual price functions $t_i^{\text{vir}} : \Theta_{-i} \times [m] \to \mathbb{R}_+$: $\quad t_i^{\text{vir}}(\theta_{-i}, f_i(\theta)) \leqslant 1$ and

$$f_i(\theta) \succeq_i o,\ \forall o \in \{o' \in [m] \,:\, t_i^{\text{vir}}(\theta_{-i}, o') \leqslant 1\}.$$

As before, to construct an agent-independent function class, we can model the virtual price function t_i^{vir} as a linear function $t_i^{\text{vir},\mathbf{w}}(\theta_{-i}, o) = \mathbf{w}_i^\top \Psi_i(\theta_{-i}, o)$ for some model vector $\mathbf{w}_i \in \mathbb{R}^d$ and feature map $\Psi_i : \Theta_{-i} \times [m] \to \mathbb{R}^d$. Let $\widetilde{\mathcal{F}}_i^{\Psi}$ be the corresponding class of agent-independent functions obtained for different model vectors $\mathbf{w}_i$.

Unlike the setting with money, here the payment functions do not directly resemble standard classification constructs. Below, we derive a bound on the Natarajan dimension of the proposed function class (see Appendix B.3 for proof).

Theorem 8. *The Natarajan dimension of $\widetilde{\mathcal{F}}_i^{\Psi}$ is at most $\mathcal{O}((md)\ln(md))$.*

Thus the capacity of the function class is finite and can be tuned by varying the number of features used. Also, this class includes feasible and strategy-proof outcome rules for an appropriate choice of the feature map.

Example feature map. Define for agent i, a function $\text{rank}_i : \Theta_i \times [m] \to [m]$ that maps a type θ_i and item o to the number of items that the agent prefers less than o: $\text{rank}(\theta_i, o) = \sum_{o'=1}^{m} \mathbf{1}(o \succ_i o')$ (note higher ranks imply greater preference to item o). For an agent i and item o, the prescribed feature map is then a $n \times m$ binary encoding of the ranks assigned by agents other than i to item o:

$$\widetilde{\Psi}_i(\theta_{-i}, o)[j, k] = \begin{cases} \mathbf{1}(\text{rank}_j(\theta_j, o) = k) & \text{if } j \neq i \\ 0 & \text{otherwise} \end{cases},$$

where we use $[j, k]$ to denote the index $(j-1)m + k$.

Theorem 9. *There exists $\mathbf{w}_i \in \mathbb{R}^{n\times m}$ such that the virtual price functions $t_i^{vir,\mathbf{w}}(\theta_{-i}, o) = \mathbf{w}_i^\top \widetilde{\Psi}_i(\theta_{-i}, o)$ yield a feasible outcome rule.*

In particular, a *serial dictatorship (SD) style* feasible, and strategy-proof outcome rule is within this class. Fix a priority $\pi : [n] \to [n]$ over the agents, where $\pi(i)$ denotes the priority to agent i (with 1 indicating the lowest priority, and n indicating the highest). The following vector $\mathbf{w}_i \in \mathbb{R}^{n\times m}$ then yields a SD style rule with priority ordering π: for any $j \in [n], k \in [m]$,

$$w_i[j, k] = \begin{cases} 2 & \pi(j) > \pi(i),\ k \geqslant m - n + \pi(j) \\ 0 & \text{otherwise} \end{cases}.$$

The proof of feasibility is provided in Appendix B.4.

7 CONCLUSION AND OPEN QUESTIONS

We have developed a general statistical framework for designing strategy-proof mechanisms that closely approximate a given target outcome rule. Our approach does not require domain-specific characterizations, and only requires the designer to provide a class of rules that satisfy a simple agent-independent condition. By tuning the capacity of this class, one can control the space of strategy-proof mechanisms optimized over. We have provided sample complexity bounds for our method and instantiated applications to assignment problems with and without money.

There are several questions that arise from our work:

- The optimization problem (3) can be formulated and solved as a mixed integer linear program. But, how can one solve this problem efficiently in practice? For the setting with money, the problem can be solved approximately by adopting *convex relaxations* from machine learning (see [14]). It will be interesting to understand the effectiveness of these relaxations as well as to identify similar relaxations for the setting without money.

- How can the framework be extended to *infinite type spaces*, and how can the feasibility transformation be implemented efficiently in such a setting?

- How can the framework be extended to *instance-dependent* distance functions, and applied to specific design objectives such as welfare or revenue?

- The sample complexity result requires that the agent-independent function classes have finite capacity. Can we use an approach similar to structural risk minimization to incorporate a *universal hypothesis class* in the framework, and thus cover the entire space of strategy-proof mechanisms?

Abstract

We consider the important crowdsourcing problem of estimating worker *confusion matrices*, or sensitivities and specificities for binary classification tasks. In addition to providing diagnostic insights into worker performance, such estimates enable robust online task routing for classification tasks exhibiting imbalance and asymmetric costs. However, labeled data is often expensive and hence estimates must be made without much of it. This poses a challenge to existing methods. In this paper, we propose a novel model that captures the correlations between entries in confusion matrices. We applied this model in two practical scenarios: (1) an imbalanced classification task in which workers are known to belong to groups and (2) a *multitask* scenario in which labels for the same workers are available in more than one labeling task. We derive an efficient variational inference approach that scales to large datasets. Experiments on two real world citizen science datasets (biomedical citation screening and galaxy morphological classification) demonstrate consistent improvement over competitive baselines. We have made our source code available.

1 INTRODUCTION

Crowdsourcing is a popular approach to collecting annotations at comparatively low cost. However, crowdsourcing annotation work necessitates taking care to evaluate worker annotation quality, as this will likely be lower than that of a domain expert. The standard means of addressing this is to collect multiple labels for each item and then use an aggregation method to derive a consensus label. The simplest such method is majority voting, which selects the majority label for each item. More complex methods exist; see (Sheshadri and Lease, 2013) for a review.

Many crowd consensus methods posit some model of worker qualities, e.g., a worker's overall accuracy. However, the problem of modeling workers has typically been considered a secondary issue, with the primary concern being label aggregation. Here we argue that the problems of aggregating labels and of modeling workers are distinct (though related). A good method for aggregating labels will not necessarily provide reliable estimates of worker qualities. For example, majority voting assumes that workers are equally good; this assumption is almost certainly usually wrong, but nonetheless can yield high quality aggregated labels when workers do not make correlated errors. Consider, e.g., a scenario in which each item has been labeled by three workers, two of whom are always correct and one of whom is always wrong. Here, majority voting would provide perfect label aggregation, but plainly the workers are not equally good.

The simplest way to model worker skill is with the univariate metric of overall accuracy. This may be appropriate when classes are balanced and/or when false negatives and false positives are equally expensive. However, in most real-world tasks, we would prefer a more granular model of accuracies. The standard way is to model the worker confusion matrices, whose entries are the probabilities of a worker providing each possible label j, conditioned on the true label i: $A_{ij} = Pr(\text{Response} = j|\text{TrueLabel} = i)$. This class conditional approach posits two parameters for each worker, affording the flexibility to accurately capture worker performance. The caveat is that more data is needed to estimate more parameters.

For example, when the majority of items belong to the negative class, very few positive items will be available to reliably estimate the probabilities of responses given that the true label is positive, i.e. A_{01} and A_{11}. Explicitly modeling correlations between sensitivity and specificity is one potential means of improving estimates in this case: Workers who perform well on negative items are likely to also correctly classify positive ones. Another scenario in which this general approach may help is when data from multiple labeling tasks is available, for example if many workers

who performed a text classification task come back to work on a new image classification task. In such scenarios, we might expect a worker who does well on one task to also be likely to do so on the other.

Specific contributions of this work are as follows.

- Taking inspiration from previous work in modeling medical diagnostic test (Dahabreh et al., 2012; Reitsma et al., 2005), we propose modeling the correlation between worker sensitivity and specificity. A natural property of our model is the assumption that workers belong to one or more groups, each with its own mean sensitivity and specificity. Intuitively, these means allow us 'back-off' to group-level quality estimates when data from a specific worker is sparse.
- We extend our idea to model the correlations of the workers across multiple labeling tasks. This allows us to *transfer knowledge of worker quality from a task with more data to one with less*.
- We introduce an efficient variational method to scale parameter estimation to handle large data.

We are unaware of any previous work on using correlations to improve estimates of worker confusion matrices nor a generative model of worker performance in multiple tasks.

2 RELATED WORK

Dawid and Skene (1979) presented the classic crowd consensus model in which each item corresponds to a hidden 'true label' variable and each worker is modeled by a confusion matrix of class-conditional label probabilities. Raykar et al. (2010); Kim and Ghahramani (2012); Liu and Wang (2012) all presented Bayesian extensions, placing priors on the worker confusion matrices. Unique amongst this prior work, Liu and Wang (2012) emphasized getting good estimates of the confusion matrices to gain diagnostic insights into worker performance, while the other two focus on recovering the true labels and building a good classifier. Recently, Lakkaraju et al. (2015) further extended the model by clustering workers and items based on their features. Although very effective compared to Liu and Wang (2012)'s Hybrid Confusion approach, demographic features such as worker age, education or job are not always available, e.g., on Amazon Mechanical Turk.

The idea of detecting latent groups and communities of similar workers has been studied previously (Simpson et al., 2013), and incorporated into a generative model to improve the aggregated labels (Venanzi et al., 2014). By contrast, here we consider exploiting *known* worker groups, when such information is available, to improve our confusion matrix estimates.

While modeling individual confusion matrices is the most common approach to annotator modeling, recent work has also explored other strategies. Kajino et al. (2012)'s multitask formulation views each worker as a learning task. Bi et al. (2014) models each worker as a classifier, whose parameters deviate from the true parameters. While these methods have been shown to outperform the 'Two Coin' model (Raykar et al., 2010) for the task of label aggregation, they unfortunately do not provide direct estimates of worker sensitivity and specificity.

In terms of inference and learning algorithms, Dawid and Skene (1979) and Raykar et al. (2010) both used the Expectation-Maximization (EM) algorithm (Dempster et al., 1977) while Liu and Wang (2012) used Gibbs sampling. Variational inference has also been applied and shown to perform well for crowdsourcing models (Liu et al., 2012).

3 METHODS

We now present the details of our probabilistic graphical model, including details of representation, inference and learning (Koller and Friedman, 2009). We first define a joint probability model over all observed and hidden variables of interest, conditioned on the parameters. In Section 3.2, we present our inference method, which involves an efficient variational algorithm. This estimates the distribution over the hidden variables, assuming the parameters are known. In Section 3.3, we present an EM approach to learn the parameters from data. Finally, we extend our approach to the multitask setting in section 3.4.

3.1 MODEL

We assume that each worker has a latent sensitivity and specificity, and that these two quantities are correlated. This assumption has similarly been made in medicine for estimating diagnostic test performance (Dahabreh et al., 2012). Following this work, we explicitly model the correlation between sensitivity and the false positive rate (FPR) (=1− specificity).

Let Z_i be the (potentially unobserved) true label for instance i and L_{ij} be the label provided for i by worker j. We then model worker j using two hidden variables, U_j and V_j, these capture transformations of worker sensitivity and FPR, and are assumed to be drawn from a bivariate normal with a covariance matrix to be estimated.

More precisely, the generative process is as follows:

$$U_j, V_j \sim \mathcal{N}(\mu, C) \tag{1}$$
$$Z_i \sim \mathrm{Ber}(\theta) \tag{2}$$
$$L_{ij}|Z_i = 1 \sim \mathrm{Ber}(\mathcal{S}(U_j)) \tag{3}$$
$$L_{ij}|Z_i = 0 \sim \mathrm{Ber}(\mathcal{S}(V_j)) \tag{4}$$

$\mathrm{Ber}(p)$ is the Bernoulli distribution with parameter p en-

coding the probability of the variable taking the value 1. $\mathcal{N}(\mu, C)$ is the bivariate Normal distribution with mean vector μ and covariance C: the correlation between U and V is thus modeled by the off-diagonal entries in C (C is symmetric; the two off-diagonal entries are equal). $\mathcal{S}$ is the Sigmoid function: $\mathcal{S}(x) = 1/(1 + \exp(-x))$, which maps real numbers to the interval $[0, 1]$. U_j and V_j are thus the logit-transformed sensitivities and FPRs of workers (the logit function is the inverse of the sigmoid fuction).

Note that μ and C are group-level parameters, capturing expected sensitivity and FPRs across all workers. Thus ours may be viewed as a 'fixed effects' model (Hedges, 1994) of worker quality, as we assume individual worker parameters are drawn from a shared parent distribution. This is in contrast to much of the previous work on this task, which has often modeled individuals independently (although there have been exceptions to this, e.g., Liu and Wang (2012)). In one scenario we assume that workers belong to distinct groups: experienced workers and novices. We also assume that we know *a priori* to which groups workers belong. In this case we fit separate models for each group, deriving corresponding distinct estimates for mean sensitivities and FPRs (and covariances).

Taking a Bayesian view, one may place priors on the shared variables μ, C and θ. However this increases model complexity and introduces the need to specify appropriate priors. Intuitively, these parameters are informed by all or most of the items in the dataset, and we should therefore have considerably less uncertainty around our estimates of them, compared to the hidden variables Z, U and V (which are informed by one or a small number of items).

Putting the components together, the unnormalized joint posterior of our model has the form:

$$P(U_{1..m}, V_{1..m}, Z_{1..n}, L) = \prod_{j=1}^{m} \mathcal{N}(U_j, V_j|\mu, C) \prod_{i=1}^{n} \mathrm{Ber}(Z_i|\theta) \prod_{Z_i=1} \mathrm{Ber}(L_{ij}|\mathcal{S}(U_i)) \prod_{Z_i=0} \mathrm{Ber}(L_{ij}|\mathcal{S}(V_i)) \quad (5)$$

Where we are denoting the number of workers by m and the number of items by n.

3.2 INFERENCE

We aim to recover the posterior distribution of all of the hidden variables given worker labels: $p(U_{1..m}, V_{1..m}, Z_{1..n}|L)$. Unfortunately, evaluating this analytically is intractable. One possibility is instead to perform approximate inference via sampling methods such as Markov chain Monte Carlo (MCMC). However, practical implementations of MCMC, such as BUGS (Spiegelhalter et al., 1995) and PyMC (Patil et al., 2010), do not scale to large datasets, rendering this approach infeasible for our application.

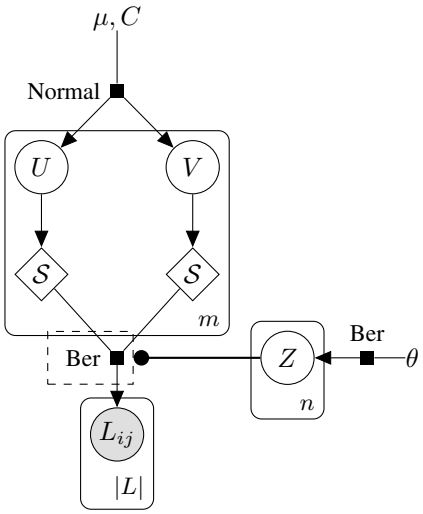

Figure 1: The Factor Graph of our model. Circles represent random variables (shaded variables are observed), squares depict factors, diamonds are deterministic mappings, edge endpoints (μ, C, θ) are parameters, plates denote repetitions, dotted plates are gates (in this case, the value of Z is used to select which one of the two $S(U)$ and $S(V)$ is used as the parameter for the Bernoulli distribution.

We therefore propose a novel variational inference algorithm for the model specified above. Variational approaches (Wainwright and Jordan, 2008) aim to approximate the true posterior p via a simpler distribution over the same variables: $q(u_{1..m}, v_{1..m}, Z_{1..n})$. The idea is to make q 'close' to p by minimizing the Kullback-Leibler (KL) divergence between the two, i.e., $\mathbb{KL}(q||p)$. By minimizing this divergence, we are maximizing a lower bound on the data log likelihood.

A typical strategy in variational inference is to make the *mean field* assumption, i.e., assume that q neatly factorizes:

$$q(U_{1..m}, V_{1..m}, Z_{1..n}) = \prod_{j=1}^{m} q(U_j)q(V_j) \prod_{i=1}^{n} q(Z_i) \quad (6)$$

where each distribution q on the right hand side is over one hidden variable (disambiguated by the argument), and has the form:

$$q(U_j) = \mathcal{N}(\tilde{\mu}_{uj}, \tilde{\sigma}^2_{uj}) \quad (7)$$

$$q(V_j) = \mathcal{N}(\tilde{\mu}_{vj}, \tilde{\sigma}^2_{vj}) \quad (8)$$

$$q(Z_i) = \mathrm{Ber}(\tilde{\theta}_i) \quad (9)$$

Here $\{\tilde{\mu}_{uj}, \tilde{\sigma}^2_{uj}, \tilde{\mu}_{vj}, \tilde{\sigma}^2_{vj}|j = 1...m\}$ and $\{\tilde{\theta}_i|i = 1...n\}$ are the variational parameters that should be selected to

minimize $\mathbb{KL}(q||p)$. This optimization problem can be solved via coordinate descent by updating each factor distribution while keeping all others fixed. The general mean field update for a vector X of hidden variables has the form:

$$q^*(X_i) \propto \exp\{\mathbb{E}_{-q_i} \log P(X)\} \tag{10}$$

$P(X)$ is the unnormalized posterior (here, Equation 5) and E_{-q_i} is the expectation with respect to all variables except X_i. By this equation, we can update $q(X_i)$ by making changes to its variational parameters. The equation updates our estimate over a variable based on the current belief over its neighbors (terms involving other variables are absorbed into the constant). Adapting this general form to our model, we can derive the following update equations:

$$q^*(Z_i = 1) \propto \exp\Big\{ \log \mathrm{Ber}(1|\theta) + \sum \mathbb{E}_{U_j \sim q(U_j)} \log \mathrm{Ber}(L_{ij}|\mathcal{S}(U_j)) \Big\} \tag{11}$$

$$q^*(Z_i = 0) \propto \exp\Big\{ \log \mathrm{Ber}(0|\theta) + \sum \mathbb{E}_{V_j \sim q(V_j)} \log \mathrm{Ber}(L_{ij}|\mathcal{S}(V_j)) \Big\} \tag{12}$$

$$q^*(U_j) \propto \exp\Big\{ \mathbb{E}_{V_j \sim q(V_j)} \log \mathcal{N}(U_j, V_j|\mu, C) + \sum q(Z_i = 1) \log \mathrm{Ber}(L_{ij}|\mathcal{S}(U_j)) \Big\} \tag{13}$$

$$q^*(V_j) \propto \exp\Big\{ \mathbb{E}_{U_j \sim q(U_j)} \log \mathcal{N}(U_j, V_j|\mu, C) + \sum q(Z_i = 0) \log \mathrm{Ber}(L_{ij}|\mathcal{S}(V_j)) \Big\} \tag{14}$$

We have elided indices in summations above for brevity. The sums in Equations 11 and 12 are over all of the workers that have provided labels for item i. The sums in Equation 13 and 14 are over all of the items that worker j has labeled. Recall that in Inference, the parameters μ, C and θ are assumed to be known.

Intuitively, Equations 11 and 12 consider item i and update our approximation of the posterior over Z_i by taking into account the prior θ and evidence from all of the worker labels provided for the item. Equation 13 concerns the (logit-transformed) sensitivity estimate for worker j, taking into account the bivariate Normal and the current approximation over the logit-transformed FPR V_j. The approximation is further updated using all of the items worker j has labeled, with respect to the current approximation over the true label Z_i of each. Equation 14 can be interpreted similarly, although here we consider the logit-transformed FPR estimate for worker j.

Although the update equations are available, evaluating them is difficult due to the model being non-conjugate. We thus applied Laplace Variational Inference (Wang and Blei, 2013), to directly approximate these equations. We first let $T_j = \begin{pmatrix} U_j \\ V_j \end{pmatrix}$ to treat U_j and V_j as a single variable and let $f(T_j)$ be the exponent in their update equation:

$$f(T_j) = \log \mathcal{N}(T_j|\mu, C) + \sum q(Z_i = 1) \log \mathrm{Ber}(L_{ij}|\mathcal{S}(U_j)) + \sum q(Z_i = 0) \log \mathrm{Ber}(L_{ij}|\mathcal{S}(V_j)) \tag{15}$$

By using a Laplace approximation on f, we can derive the approximate update for U_j and V_j:

$$q^*(T_j) \propto \exp(f(T_j)) \approx \mathcal{N}\left(\widehat{T}_j, \nabla^2 f(\widehat{T}_j)^{-1}\right) \tag{16}$$

where $\widehat{T}_j$ is the maximum of $f(T_j)$, can be found by numerical optimization, and the Hessian matrix $\nabla^2 f(T_j)$ can be derived analytically by using the result:

$$\nabla^2 \log \mathcal{N}(T|\mu, C) = C^{-1}(T - \mu)(T - \mu)^T C^{-1} - C^{-1} \tag{17}$$

For the variable Z_i, the expectations in their update equations (11 and 12) can also be approximated similarly, for example, let $g(u) = \log \mathcal{S}(u)$, we have

$$\mathbb{E}_{u \sim \mathcal{N}(\mu,\sigma)} g(u) \approx g(\mu) + \frac{1}{2} g''(\mu)\sigma \tag{18}$$

Again, the second derivative g'' can be derived analytically:

$$g''(u) = -e^u/(1 + e^u)^2 \tag{19}$$

The inference procedure initializes the variational distribution q at some value and then applies the update equations iteratively until convergence. In our implementation, we iterate until the average changes in the variational parameters is less than 0.01. To initialize the means of $q(U_j)$, $q(V_j)$ and $q(Z)$, we use majority voting. To initialize the variance of $q(U_j)$ and $q(V_j)$, we make use the Beta distribution. For example, suppose majority voting predicts that worker j has provided a True Positives and b False Negatives so that his sensitivity can be estimated as $a/(a + b)$. We initialize the variance $\tilde{\sigma}_{uj}$ of the logit-transformed sensitivity U_j as the logit-tranformed variance of $\mathrm{Beta}(a, b)$, which intuitively gives a smaller variance for workers who have provided more labels.

3.3 LEARNING

We consider μ, C and θ as parameters to be learned from data. The learning algorithm is a simple application of EM. In the E step, we perform variational inference to estimate the posterior over the hidden variable, given all of the the workers' labels. In the M step, we maximize the parameters μ, C and θ under that posterior distribution. For the

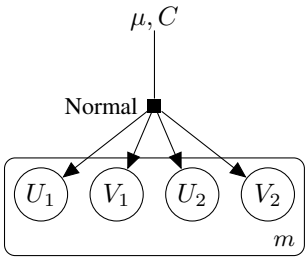

Figure 2: The Factor Graph highlights the extension to two tasks from the single task model in **Figure 1**.

parameters μ and C, the expected sufficient statistics (with respect to the variational distribution) can be evaluated:

$$\mathbb{E}(U_j) = \tilde{\mu}_j \tag{20}$$

$$\mathbb{E}(U_J^2) = \tilde{\mu}_{uj}^2 + \tilde{\sigma}_{uj}^2 \tag{21}$$

$$\mathbb{E}(U_J V_J) = \tilde{\mu}_{uj}\tilde{\mu}_{vj} \tag{22}$$

and then plugged into an estimator of multivariate Normal mean and covariance. For θ, it is simply set to the expected proportion of positive items, which is the average of $\{\tilde{\theta}_i | i = 1...n\}$.

3.4 MULTITASK MODEL

In addition to exploiting correlations between worker sensitivities and FPRs, our model can easily accommodate other sorts of worker performance correlations. For example, in this section we show that the same model can be adopted to capitalize on correlated performances across related labeling tasks. Specifically, we assume that workers have different sensitivities and FPRs in different tasks but that these values are correlated across tasks. Let U_1, V_1, U_2, V_2 be the logit-transformed sensitivities and FPRs in the first and second task. These are assumed to be generated from a four-dimensional Normal distribution:

$$\begin{pmatrix} U_1 \\ V_1 \\ U_2 \\ V_2 \end{pmatrix} \sim \mathcal{N}\left(\mu, C = \begin{pmatrix} A & X \\ X^T & B \end{pmatrix}\right) \tag{23}$$

where A, B and X are 2×2 matrices. A and B are the intra-task covariance matrices. X models the correlations across tasks, for instance X_{11} is the correlation between U_1 and U_2. $X_{11} > 0$ means that a worker with high sensitivity in the first task is likely to have high sensitivity in the second task. Our idea is that each task has its own mean sensitivity and specificity to represent its difficulty. On the other hand, the covariance matrix C represents how these sensitivites and specificities in two tasks are correlated. **Figure 2** is an illustration. Our inference and learning algorithms can be easily extended to this model.

4 EXPERIMENTS

We conducted experiments on two large 'citizen science' datasets to compare our proposed method to baselines. In citizen science, workers volunteer to contribute to science, without financial compensation.

We report the Root Mean Square Error (RMSE) of the predicted worker sensitivities and specificities:

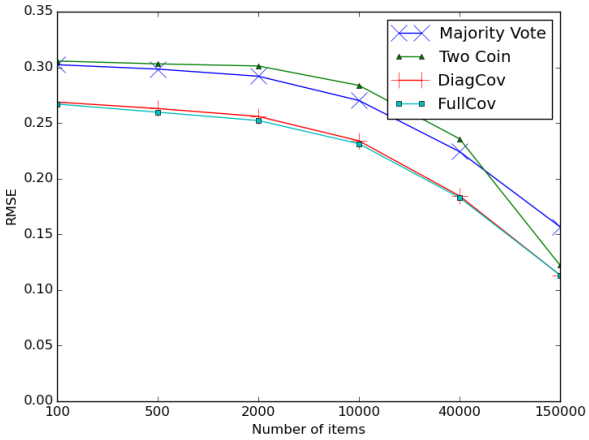
$$\text{RMSE} = \sqrt{\frac{1}{m}\sum_{j=1}^{m}(\text{Predicted}_j - \text{True}_j)^2} \tag{24}$$

where Predicted_j is the sensitivity or specificity of worker j that is predicted by a method and True_j is the corresponding true value. In practice, a worker true sensitivity and specificity are latent but can be accurately estimated given that the worker have labeled a large number of items and the true labels for those items are available: $\text{Sensitivity} = \text{TP}/(\text{TP}+\text{FN})$ and $\text{Specificity} = \text{TN}/(\text{TN}+\text{FP})$ where TP, TN, FP and FN are the number of true (false) positives (negatives) that the worker have labeled. We calculate the sensitivity and specificity estimates using all of the available data and treat those as the true values (or gold standard) for evaluation. Also, to ensure the quality of such gold standard, we only include in our evaluation the workers who have provided labels for at least 5 positives and 5 negatives (on the entire dataset). We note that the methods being evaluated are given a small portion of the dataset and still need to produce good estimates based on very few crowd labels and without access to the true labels. A similar approach to evaluate confusion matrix estimates has been used by Lakkaraju et al. (2015).

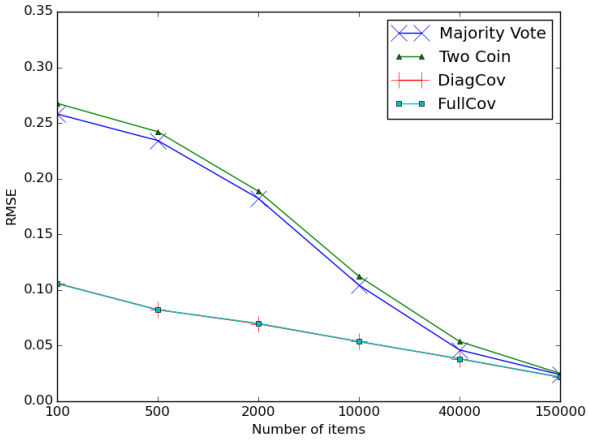
4.1 BIOMEDICAL CITATION SCREENING

We consider data from the EMBASE screening project (http://screening.metaxis.com/EMBASE/), which aims to identify reports of randomized controlled trials (RCTs) from EMBASE,[1] a biomedical literature database. The aim is to be comprehensive, thus placing an emphasis on sensitivity. An important property of this dataset is its imbalance: fewer than 5% of the items are positive. Our model aims to improve the estimates of sensitivities using their correlations with specificities (recall that sensitivity is the probability of being correct given a positive, and we expect this estimate to be poor given very few positives). Also, the screening project has relied on a mix of novice volunteer workers and domain experts with associated costs and levels of expertise. Our model can easily exploit such information on two groups of workers by using two different set of parameters (μ and C), one for each group. This is a large dataset with 151,224 items and 576 workers. Of

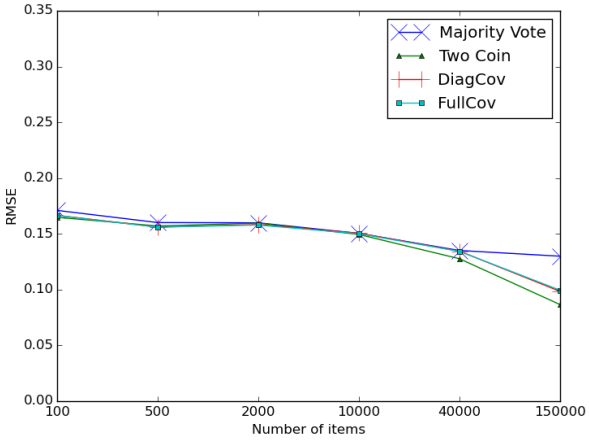
[1] RCTs are experiments in which participants are randomized to groups in which individuals are exposed to different interventions; one group is designated as a control.



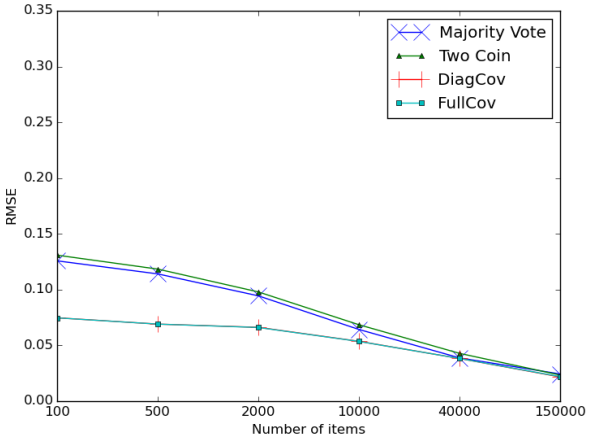
(a) Sensitivity with Uniform Prior (1,1)



(b) Specificity with Uniform Prior (1,1)



(c) Sensitivity with Informative Prior (4,1)



(d) Specificity with Informative Prior (4,1)

Figure 3: The RMSE in Sensitivity and Specificity with Uniform and Informative Prior of four methods (averaged over 5 runs). DiagCov and FullCov are two variants of our model; their curves *overlap* in (b), (c) and (d).

those workers, 156 have labeled at least 5 positives and 5 negatives and are used for evaluation. The number of labels per workers is generally very skewed: 525 workers (91%) provided less than the average of 603 labels.

We implemented two variants of our method: one with a full covariance matrix (FullCov) and one with a covariance matrix constrained to be diagonal (DiagCov) i.e., entries in the confusion matrices are assumed to be uncorrelated. This allows us to observe how much improvement is due to modeling correlation and how much is from modeling worker groups. We compare these two variants to two baselines: Majority Vote, in which sensitivities and specificities are estimated based on the majority labels, and the *Two Coin* model (without features) due to Raykar et al. (2010, sec. 2.7.4)

We also implemented the *Hybrid Confusion* model by Liu and Wang (2012), which is the same as Two Coin but with inference by Gibbs sampling. Because the results were very similar to Two Coin, we omit these for clarity.

All of the methods are given the same prior or initialized in the same way. The Two Coin model has Beta priors on worker sensitivities and specificities, which can be interpreted as smoothing constants. The same constants are given to Majority Vote to smooth its estimates. Our model has no prior on the parameters μ and C but those and the variational parameters are initialized using the outputs from Majority Vote (with smoothing constants). To explore the effect of these worker priors (or initialization), we did experiments with a uniform prior ($\text{Beta}(1,1)$ as done by Raykar et al. (2010)) and an informative prior $\text{Beta}(4,1)$ as in Liu and Wang (2012)). The prior on the class propor-

	Items	Workers	LPI	LPW
Task 1	17862	1242	16.8 ± 3.9	241 ± 288
Task 2	6476	198	5.0 ± 2.1	163 ± 130
Task 3	21951	681	6.7 ± 3.7	215 ± 243
Task 4	21915	679	6.7 ± 3.7	215 ± 243

Table 1: Statistics of four tasks we consider in the Galaxy Zoo 2 dataset, after pre-processing. 'LPI' stands for 'Labels per item' and 'LPW' for 'Labels per worker'. In these columns, we report the means and standard deviations of the number of labels per item (worker).

tion θ is always uniform ($\mathrm{Beta}(1,1)$ as done by both).

Figure 3 presents our results with RMSE on the Y-axis and the number of items on the X-axis. We average results over 5 runs, randomly sampling a number of items from the dataset for each. The two plots above are for uniform prior. We see that Two Coin's performance is surprisingly weak while two variants of our model achieve the best performance. On the plot for Sensitivity, we also see some small improvement of FullCov over DiagCov (but significant in our paired t-test). In the plot for Specificity, those two variants have the same performance (the curve for FullCov has overwritten the one for DiagCov). This is what we expect since the specificity estimates are for the majority (negative) class and the correlation has little effect given a large number of labels available. Surprisingly, much of the improvement of our method can be attributed to the 'group part' of our model (not the 'correlation part'). As discussed above, the 'group part' provides a 'back off' to the group level estimates when there is not enough data on a worker.

The two plots below show our results for Informative Prior, where all of the methods perform better, as expected. For Sensitivity, Two Coin performs well, slightly better than Majority Vote while comparable to ours for the most part and slightly better than ours for $40,000$ or more items. However, for specificity, it still performs worse than Majority Vote and ours. The difference is probably due to $\mathrm{Beta}(4,1)$ being a better prior for sensitivity than specificity[2]. This suggests that Two Coin and similarly Hybrid Confusion can perform well but their performance are dependent on good priors. In contrast, our method is robust across different settings of priors. This can probably be explained by the fact that our group level estimates (which play role in 'backing off' sparse workers) are learned from data while Two Coin's priors are set to constants.

4.2 GALAXY MORPHOLOGICAL CLASSIFICATION

The Galaxy Zoo 2 dataset (Willett et al., 2013) consists of labels provided by volunteer workers on morphological classification of galaxies. A worker is given an image of a galaxy and is asked multiple questions. We consider each question to be a labeling task. Specifically in our experiments, we consider the (simplified) first four questions/tasks:

1. Is the galaxy smooth or disk-like? If the answer is disk, proceed to task 2, otherwise stop. [3]
2. Is the disk viewed edge-on? If the answer is no, proceed to task 3, otherwise stop.
3. Is there a bar in the center? Proceed to task 4 regardless of the answer.
4. Is there a spiral arm pattern?

Since the tasks have varying difficulties and require varying skills, worker performance in each task can be very different from others, but we can naturally expect some degree of transferability between tasks. We aim to evaluate our multitask model on improving the estimates of worker sensitivities and specificities on a *target task*, given labels on a *source task* (for the same set of workers). We did experiments in two scenarios:

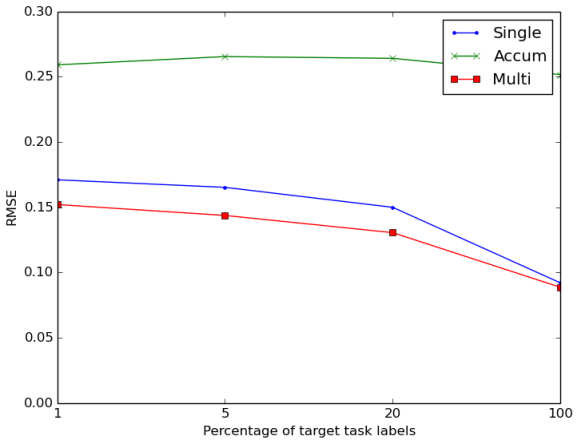
1. Conditional Task 1 $\rightarrow$ Task 2: The methods are given all of the labels in Task 1, a portion of labels in Task 2 and must estimate worker sensitivities and specificities in Task 2.
2. Independent Task 3 $\rightarrow$ Task 4: The methods are given all of the labels in Task 3, a portion of labels in Task 4 and must estimate worker sensitivities and specificities in Task 4. Here the two tasks are independent, while in the first scenario, Task 2 is asked only when the worker answers 'disk' in Task 1.

We compare our multitask model (*Multi*) to two baselines: *Single*, where only labels in the target task are considered, and *Accum*, where labels from the source task are merged with those from the target task. The Accum baseline is only applicable when the two tasks are questions with the same number of choices and a matching of these choices is available (otherwise the labels could not be merged). Our approach has no such restriction. For both baselines, we used the FullCov variant of our method.

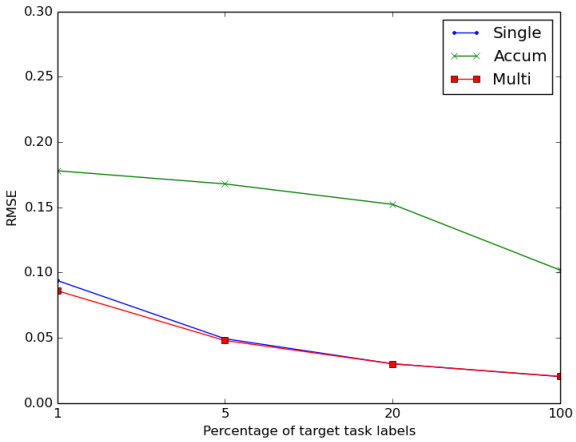
The dataset is extremely large, with nearly 60 million labels for 11 tasks from over 83 thousand workers. We do the following pre-processing to reduce the size of the dataset. (1) We take the first million labels (for all of 11 tasks). (2) For each of the first four tasks, we filter out workers with less than 100 labels and items with less than 3 labels. The statistics of the four tasks after pre-processing are in **Table 1**. We note that the gold standard worker sensitivities and specificities are estimated from the *entire* dataset (without pre-processing).

[2] $\mathrm{Beta}(4,1)$ has a mean of 0.8. The true means for sensitivities and specificities are 0.78 and 0.94

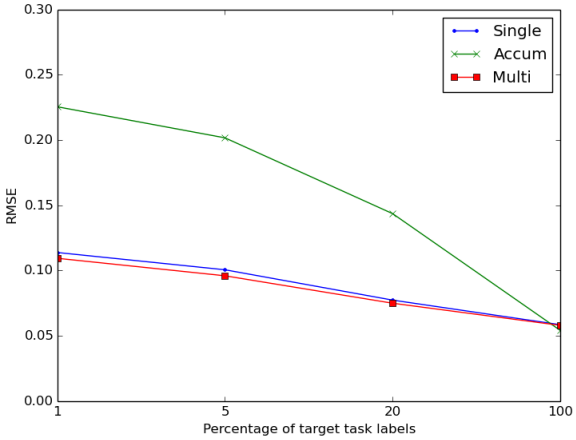
[3] 'Stop' means go to a question we don't consider. This question has a third answer ('star of artifact') which is very rare and we don't consider for simplicity.



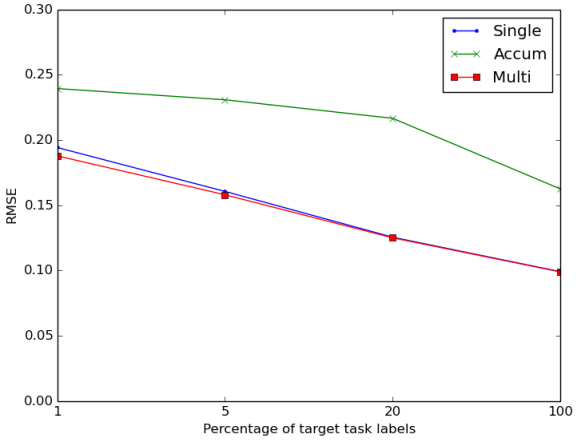
(a) Sensitivity: Conditional Task 1 → Task 2



(b) Specificity: Conditional Task 1 → Task 2



(c) Sensitivity: Independent Task 3 → Task 4



(d) Specificity: Independent Task 3 → Task 4

Figure 4: The RMSE against percentage of labels in the target task available of our method compared to two baselines (averaged over 5 runs).

In **Figure 4**, we report our results. Overall, Accum is surprisingly weak, giving estimates with much higher RMSE than Single. This shows that worker performance in two different tasks are sufficiently different that a naive transfer strategy is unlikely to work.

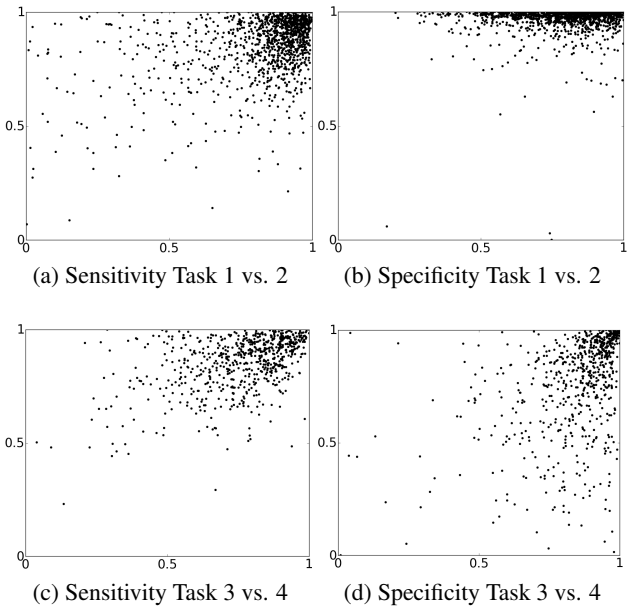
Compared to the Single baseline, our method has shown improvement for the case when a small percentage of labels in the target task is available. The improvement diminishes when more target task labels are available, as expected. On a close look at their differences, one might notice that the improvement is sometimes quite modest. Looking into the 'true' worker sensitivities and specificities (**Figure 5**), we found an overall positive correlation between tasks as expected. However, we also observe a surprisingly large number of workers who do better in the source task but worse in the second task (and vice versa). This may be because the tasks are somewhat subjective that the variations in workers performance are mostly due to their different perception and interpretation. In short, we believe the true multitask correlation plays a role in how much improvement we observe.

To further investigate this, we repeat the same experiments on simulated labels. We note that the purpose of our simulation is to complement, not to replace our results on the real data. The simulated labels are generated by our model from the following parameters:

$$\mu = \begin{pmatrix} 1.49 \\ -1.45 \\ 2.18 \\ -2.59 \end{pmatrix} C = \begin{pmatrix} 1.80 & 0 & x & 0 \\ 0 & 1.30 & 0 & x \\ x & 0 & 1.06 & 0 \\ 0 & x & 0 & 1.89 \end{pmatrix}$$

The mean μ and the variances in C are set to the empirical estimates in Task 1 and Task 2 while x is the inter-task correlation and is varied in $\{0.5, 0.75, 1.0, 1.25\}$, some posi-

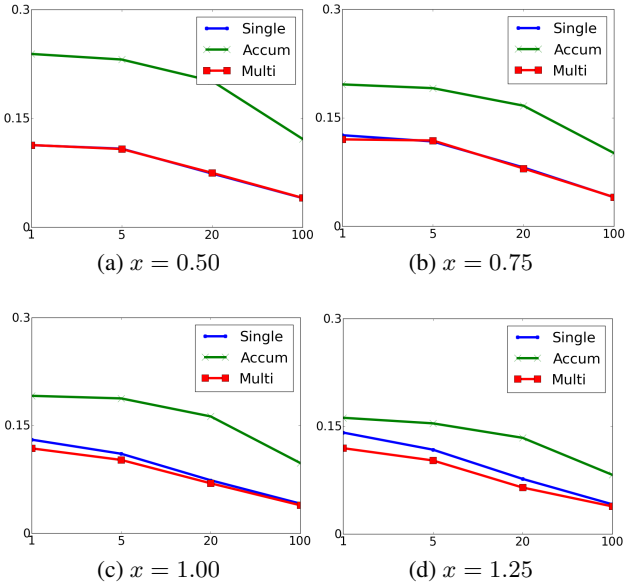
tive values in a reasonable range which keep the covariance matrix positive definite. We assume 5000 items in each task and 200 workers. Each item is labeled by 5 randomly selected workers. **Figure 6** shows that as the correlation x increases, we see a greater improvement of Multi over Single. That is, the more correlated the worker performances in different tasks are, the greater the improvement realized by our model.



(a) Sensitivity Task 1 vs. 2 (b) Specificity Task 1 vs. 2

(c) Sensitivity Task 3 vs. 4 (d) Specificity Task 3 vs. 4

Figure 5: Worker sensitivities (specificities) in two tasks. Each point is a worker. In (a) and (b), the X-axis is task 1 and the Y-axis is task 2. In (c) and (d), the X-axis is task 3 and the Y-axis is task 4.



(a) $x = 0.50$ (b) $x = 0.75$

(c) $x = 1.00$ (d) $x = 1.25$

Figure 6: The RMSE in Sensitivity (averaged over 5 runs) on simulated labels for 4 values of the inter-task correlation x. The X-axis is the percentage of target task labels and the Y-axis is RMSE. The curves for Single and Multi overlap in (a). The results for Specificity are similar.

5 CONCLUSION

We have presented our approach to improve the estimates of worker confusion matrices and reported the results of our experiments on real and simulated data. Our main idea is to exploit the correlations in the matrix entries (sensitivities and specificities) and the knowledge of groups in the workers population. The idea also applies to the case when labels from multiple tasks are available. In all of the cases we consider, our method shows good performance compared to baselines. We have made our source code available[4]. We expect the datasets to be available on request from their owners.

While we have reported on binary classification tasks with no instance-level features, where a confusion matrix reduces to sensitivity and specificity, our approach can be easily generalized. For future work, we will extend our work to categorical tasks, with features when available. Such features can be modeled by additional variables associated with the instances and a variational algorithm can be derived similar to (Felt et al., 2015). We are also interested in a better model for the multitask setting, which can capture important factors such as item and task difficulties as well as worker skill and expertise. Also, we would like to take advantage of the the full posterior distribution over the worker confusion matrices in an application such as an online decision system (Nguyen et al., 2015; Werling et al., 2015), rather than using only point estimates. Finally, while we have favored variational inference over MCMC, recent probabilistic languages such as Stan (Carpenter et al., 2015) is an attractive alternative and interesting to compare to our approach.

Abstract

The Kaczmarz method is an iterative algorithm for solving systems of linear equalities and inequalities, that iteratively projects onto these constraints. Recently, Strohmer and Vershynin [*J. Fourier Anal. Appl.,* 15(2):262-278, 2009] gave a non-asymptotic convergence rate analysis for this algorithm, spurring numerous extensions and generalizations of the Kaczmarz method. Rather than the randomized selection rule analyzed in that work, in this paper we instead discuss greedy and approximate greedy selection rules. We show that in some applications the computational costs of greedy and random selection are comparable, and that in many cases greedy selection rules give faster convergence rates than random selection rules. Further, we give the first multi-step analysis of Kaczmarz methods for a particular greedy rule, and propose a provably-faster randomized selection rule for matrices with many pairwise-orthogonal rows.

1 KACZMARZ METHOD

Solving large linear systems is a fundamental problem in machine learning. Applications range from least-squares problems to Gaussian processes to graph-based semi-supervised learning. All of these applications (and many others) benefit from advances in solving large-scale linear systems. The Kaczmarz method is a particular iterative algorithm suited for solving consistent linear systems of the form $Ax = b$. It was originally proposed by Polish mathematician Stefan Kaczmarz (1937) and later reinvented by Gordon et al. (1970) under the name *algebraic reconstruction technique* (ART). It has been used in numerous applications including image reconstruction and digital signal processing, and belongs to several general categories of methods including *row-action*, *component-solution*, *cyclic projection*, and *successive projection* methods (Censor, 1981).

At each iteration k, the Kaczmarz method uses a *selection rule* to choose some row i_k of A and then projects the current iterate x^k onto the corresponding hyperplane $a_{i_k}^T x^k = b_{i_k}$. Classically, the two categories of selection rules are *cyclic* and *random*. Cyclic selection repeatedly cycles through the coordinates in sequential order, making it simple to implement and computationally inexpensive. There are various linear convergence rates for cyclic selection (see Deutsch, 1985; Deutsch and Hundal, 1997; Galántai, 2005), but these rates are in terms of cycles through the entire dataset and involve constants that are not easily interpreted. Further, the performance of cyclic selection worsens if we have an undesirable ordering of the rows of A.

Randomized selection has recently become the default selection rule in the literature on Kaczmarz-type methods. Empirically, selecting i randomly often performs substantially better in practice than cyclic selection (Feichtinger et al., 1992; Herman and Meyer, 1993). Although a number of asymptotic convergence rates for randomized selection have been presented (Whitney and Meany, 1967; Tanabe, 1971; Censor et al., 1983; Hanke and Niethammer, 1990), the pivotal theoretical result supporting the use of randomized selection for the Kaczmarz method was given by Strohmer and Vershynin (2009). They proved a non-asymptotic linear convergence rate (in expectation) in terms of the number of iterations, when rows are selected proportional to their squared norms. This work spurred numerous extensions and generalizations of the randomized Kaczmarz method (Needell, 2010; Leventhal and Lewis, 2010; Zouzias and Freris, 2013; Lee and Sidford, 2013; Liu and Wright, 2014; Ma et al., 2015), including similar rates when we replace the equality constraints with inequality constraints.

Rather than cyclic or randomized, in this work we consider *greedy* selection rules. There are very few results

[*]Department of Computer Science, The University of British Columbia, Vancouver, BC, Canada
[†]DATO, Seattle, Washington, USA

in the literature that explore the use of greedy selection rules for Kaczmarz-type methods. Griebel and Oswald (2012) present the *maximum residual rule* for multiplicative Schwarz methods, for which the randomized Kaczmarz iteration is a special case. Their theoretical results show similar convergence rate estimates for both greedy and random methods, suggesting there is no advantage of greedy selection over randomized selection (since greedy selection has additional computational costs). Eldar and Needell (2011) propose a greedy *maximum distance rule*, which they approximate using the Johnson-Lindenstrauss (1984) transform to reduce the computation cost. They show that this leads to a faster algorithm in practice, and show that this rule may achieve more progress than random selection on certain iterations.

In the next section, we define several relevant problems of interest in machine learning that can be solved via Kaczmarz methods. Subsequently, we define the greedy selection rules and discuss cases where they can be computed efficiently. In Section 4 we give faster convergence rate analyses for both the maximum residual rule and the maximum distance rule, which clarify the relationship of these rules to random selection and show that greedy methods will typically have better convergence rates than randomized selection. Section 5 contrasts Kaczmarz methods with coordinate descent methods, Section 6 considers a simplified setting where we explicitly compute the constants in the convergence rates, Section 7 considers how these convergence rates are changed under *approximations* to the greedy rules, and Section 8 discusses the case of inequality constraints. We further give a non-trivial *multi-step* analysis of the maximal residual rule (Section 9), which is the first multi-step analysis of any Kaczmarz algorithm. By taking the multi-step perspective, we also propose provably-faster randomized selection rules for matrices A with pairwise-orthogonal rows by using the so-called "orthogonality graph". Section 10 presents numerical experiments evaluating greedy Kaczmarz methods.

2 PROBLEMS OF INTEREST

We first consider systems of linear equations,

$$Ax = b, \tag{1}$$

where A is an $m \times n$ matrix and $b \in \mathbb{R}^m$. We assume the system is *consistent*, meaning a solution x^* exists. We denote the rows of A by $a_1^\top, \ldots, a_m^\top$, where each $a_i \in R^n$, and use $b = (b_1, \ldots, b_m)^\top$, where each $b_i \in \mathbb{R}$. One of the most important examples of a consistent linear system, and a fundamental model in machine learning, is the least squares problem,

$$\min_{x \in \mathbb{R}^n} \frac{1}{2}\|Ax - b\|^2.$$

An appealing way to write a least squares problem as a linear system is to solve the $(n+m)$-variable consistent system (see also Zouzias and Freris, 2013)

$$\begin{pmatrix} A & -I \\ \mathbf{0} & A^T \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix},$$

Other applications in machine learning that involve solving consistent linear systems include: least-squares support vector machines, Gaussian processes, fitting the final layer of a neural network (using squared-error), graph-based semi-supervised learning or other graph-Laplacian problems (Bengio et al., 2006), and finding the optimal configuration in Gaussian Markov random fields (Rue and Held, 2005).

Kaczmarz methods can also be applied to solve consistent systems of linear *inequalities*,

$$Ax \leq b,$$

or combinations of linear equalities and inequalities. We believe there is a lot potential to use this application of Kaczmarz methods in machine learning. Indeed, a classic example of solving linear inequalities is finding a linear separator for a binary classification problem. The classic perceptron algorithm is a generalization of the Kaczmarz method, but unlike the classic sublinear rates of perceptron methods (Novikoff, 1962) we can show a linear rate for the Kaczmarz method.

Kaczmarz methods could also be used to solve the ℓ_1-regularized robust regression problem,

$$\min_x f(x) := \|Ax - b\|_1 + \lambda\|x\|_1,$$

for $\lambda \geq 0$. We can formulate finding an x with $f(x) \leq \tau$ for some constant τ as a set of linear inequalities. By doing a binary search for τ and using *warm-starting*, this can be substantially faster than existing approaches like stochastic subgradient methods (which have a sublinear convergence rate) or formulating as a linear program (which is not scaleable due to the super-linear cost). The above logic applies to many piecewise-linear problems in machine learning like variants of support vector machines/regression with the ℓ_1-norm, regression under the ℓ_∞-norm, and linear programming relaxations for decoding in graphical models.

3 KACZMARZ ALGORITHM AND GREEDY SELECTION RULES

The Kaczmarz algorithm for solving linear systems begins from an initial guess x^0, and each iteration k chooses a row i_k and projects the current iterate x^k onto the hyperplane defined by $a_{i_k}^T x^k = b_{i_k}$. This gives the iteration

$$x^{k+1} = x^k + \frac{b_{i_k} - a_{i_k}^T x^k}{\|a_{i_k}\|^2} a_{i_k}, \tag{2}$$

and the algorithm converges to a solution x^* under weak conditions (e.g., each i is visited infinitely often).

We consider two greedy selection rules: the *maximum residual* rule and the *maximum distance* rule. The maximum residual (MR) rule selects i_k according to

$$i_k = \underset{i}{\text{argmax}} \ |a_i^T x^k - b_i|, \tag{3}$$

which is the equation i_k that is 'furthest' from being satisfied. The maximum distance (MD) rule selects i_k according to

$$i_k = \underset{i}{\text{argmax}} \ \left| \frac{a_i^T x^k - b_i}{\|a_i\|} \right|, \tag{4}$$

which is the rule that maximizes the distance between iterations, $\|x^{k+1} - x^k\|$.

3.1 EFFICIENT CALCULATIONS FOR SPARSE A

In general, computing these greedy selection rules exactly is too computationally expensive, but in some applications we can compute them efficiently. For example, consider a *sparse* A with at most c non-zeros per column and at most r non-zeros per row. In this setting, we show in Appendix 3.1 that both rules can be computed exactly in $O(cr \log m)$ time, using that projecting onto row i does not change the residual of row j if a_i and a_j do not share a non-zero index.

The above sparsity condition guarantees that row i is orthogonal to row j, and indeed projecting onto row i will not change the residual of row j under the more general condition that a_i and a_j are orthogonal. Consider what we call the *orthogonality graph*: an undirected graph on m nodes where we place on edge between nodes i and j if a_i is not orthogonal to a_j. Given this graph, to update all residuals after we update a row i we only need to update the neighbours of node i in this graph. Even if A is dense ($r = n$ and $c = m$), if the maximum number of neighbours is g, then tracking the maximum residual costs $O(gr + g\log(m))$. If g is small, this could still be comparable to the $O(r + \log(m))$ cost of using existing randomized selection strategies.

3.2 APPROXIMATE CALCULATION

Many applications, particularly those arising from graphical models with a simple structure, will allow efficient calculation of the greedy rules using the method of the previous section. However, in other applications it will be too inefficient to calculate the greedy rules. Nevertheless, Eldar and Needell (2011) show that it's possible to efficiently select an i_k that *approximates* the greedy rules by making use of the dimensionality reduction technique of Johnson and Lindenstrauss (1984). Their experiments show that approximate greedy rules can be sufficiently accurate and that they still outperform random selection. After first analyzing exact greedy rules in the next section, we analyze the effect of using approximate rules in Section 7.

4 ANALYZING SELECTION RULES

All the convergence rates we discuss use the following relationship between $\|x^{k+1} - x^*\|$ and $\|x^k - x^*\|$:

$$\|x^{k+1} - x^*\|^2 = \|x^k - x^*\|^2 - \|x^{k+1} - x^k\|^2 + 2\underbrace{\langle x^{k+1} - x^*, x^{k+1} - x^k \rangle}_{(=0, \text{ by orthogonality})}.$$

Using the definition of x^{k+1} from (2) and simplifying, we obtain for the selected i_k that

$$\|x^{k+1} - x^*\|^2 = \|x^k - x^*\|^2 - \frac{\left(a_{i_k}^T x^k - b_{i_k}\right)^2}{\|a_{i_k}\|^2}. \tag{5}$$

4.1 RANDOMIZED AND MAXIMUM RESIDUAL

We first give an analysis of the Kaczmarz method with *uniform* random selection of the row to update i (which we abbreviate as 'U'). Conditioning on the σ-field $\mathcal{F}_{k-1}$ generated by the sequence $\{x^0, x^1, \ldots, x^{k-1}\}$, and taking expectations of both sides of (5), when i_k is selected using U we obtain

$$\begin{aligned}
&\mathbb{E}[\|x^{k+1} - x^*\|^2] \\
&= \|x^k - x^*\|^2 - \mathbb{E}\left[\frac{\left(a_i^T x^k - b_i\right)^2}{\|a_i\|^2}\right] \\
&= \|x^k - x^*\|^2 - \sum_{i=1}^m \frac{1}{m} \frac{(a_i^\top (x^k - x^*))^2}{\|a_i\|^2} \\
&\leq \|x^k - x^*\|^2 - \frac{1}{m\|A\|_{\infty,2}^2} \sum_{i=1}^m (a_i^\top (x^k - x^*))^2 \\
&= \|x^k - x^*\|^2 - \frac{1}{m\|A\|_{\infty,2}^2} \|A(x^k - x^*)\|^2 \\
&\leq \left(1 - \frac{\sigma(A,2)^2}{m\|A\|_{\infty,2}^2}\right) \|x^k - x^*\|^2,
\end{aligned} \tag{6}$$

where $\|A\|_{\infty,2}^2 := \max_i\{\|a_i\|^2\}$ and $\sigma(A,2)$ is the Hoffman (1952) constant. We've assumed that x^k is not a solution, allowing us to use Hoffman's bound. When A has independent columns, $\sigma(A,2)$ is the nth singular value of A and in general it is the smallest non-zero singular value.

The argument above is related to the analysis of Vishnoi (2013) but is simpler due to the use of the Hoffman bound. Further, this simple argument makes it straightforward to derive bounds on other rules. For example, we can derive the convergence rate bound of Strohmer and Vershynin (2009) by following the above steps but selecting i non-uniformly with probability $\|a_i\|^2/\|A\|_F^2$ (where $\|A\|_F$ is

the Frobenius norm of A). We review these steps in Appendix 4.1, showing that this non-uniform (NU) selection strategy has

$$\mathbb{E}[\|x^{k+1} - x^*\|^2] \leq \left(1 - \frac{\sigma(A,2)^2}{\|A\|_F^2}\right)\|x^k - x^*\|^2. \quad (7)$$

This strategy requires prior knowledge of the row norms of A, but this is a one-time computation that can be reused for any linear system involving A. Because $\|A\|_F^2 \leq m\|A\|_{\infty,2}^2$, the NU rate (7) is at least as fast as the uniform rate (6).

While a trivial analysis shows that the MR rule also satisfies (6) in a deterministic sense, in Appendix 4.1 we give a tighter analysis of the MR rule showing it has the convergence rate

$$\|x^{k+1} - x^*\|^2 \leq \left(1 - \frac{\sigma(A,\infty)^2}{\|A\|_{\infty,2}^2}\right)\|x^k - x^*\|^2, \quad (8)$$

where the Hoffman-like constant $\sigma(A,\infty)$ satisfies the relationship

$$\frac{\sigma(A,2)}{\sqrt{m}} \leq \sigma(A,\infty) \leq \sigma(A,2).$$

Thus, at one extreme the maximum residual rule obtains the same rate as (6) for uniform selection when $\sigma(A,2)^2/m \approx \sigma(A,\infty)^2$. However, at the other extreme the maximum residual rule could be faster than uniform selection by a factor of m ($\sigma(A,\infty)^2 \approx \sigma(A,2)^2$). Thus, although the uniform and MR bounds are the same in the worst case, the MR rule can be superior by a large margin.

In contrast to comparing U and MR, the MR rate may be faster or slower than the NU rate. This is because

$$\|A\|_{\infty,2} \leq \|A\|_F \leq \sqrt{m}\|A\|_{\infty,2},$$

so these quantities and the relationship between $\sigma(A,2)$ and $\sigma(A,\infty)$ influence which bound is tighter.

4.2 TIGHTER UNIFORM AND MR ANALYSIS

In our derivations of rates (6) and (8), we use the following inequality

$$\|a_i\|^2 \leq \|A\|_{\infty,2}^2 \quad \forall\, i, \quad (9)$$

which leads to a simple result but could be very loose if the range of row norms is large. In this section, we give tighter analyses of the U and MR rules that are less interpretable but are tighter because they avoid this inequality.

In order to avoid using this inequality for our analysis of U, we can absorb the row norms of A into a row weighting matrix D, where $D = \text{diag}(\|a_1\|, \|a_2\|, \ldots, \|a_m\|)$. Defining $\bar{A} := D^{-1}A$, we show in Appendix 4.2 that this results in the following upper bound on the convergence rate for uniform random selection,

$$\mathbb{E}[\|x^{k+1} - x^*\|^2] \leq \left(1 - \frac{\sigma(\bar{A},2)^2}{m}\right)\|x^k - x^*\|^2. \quad (10)$$

A similar result is given by Needell et al. (2015) under the stronger assumption that A has independent columns. The rate in (10) is tighter than (6), since $\sigma(A,2)/\|A\|_{\infty,2} \leq \sigma(\bar{A},2)$ (van der Sluis, 1969). Further, *this rate can be faster than the non-uniform sampling method* of Strohmer and Vershynin (2009). For example, suppose row i is orthogonal to all other rows but has a significantly larger row norm than all other row norms. In other words, $\|a_i\| >> \|a_j\|$ for all $j \neq i$. In this case, NU selection will repeatedly select row i (even though it only needs to be selected once), whereas U will only select it on each iteration with probability $1/m$. It has been previously pointed out that Strohmer and Vershynin's method can perform poorly if you have a problem where one row norm is significantly larger than the other row norms (Censor et al., 2009). This result theoretically shows that U can have a tighter bound than the NU method of Strohmer and Vershynin.

In Appendix 4.2, we also give a simple modification of our analysis of the MR rule, which leads to the rate

$$\|x^{k+1} - x^*\|^2 \leq \left(1 - \frac{\sigma(A,\infty)^2}{\|a_{i_k}\|^2}\right)\|x^k - x^*\|^2. \quad (11)$$

This bound depends on the *specific* $\|a_{i_k}\|$ corresponding to the i_k selected at each iteration k. This convergence rate will be faster whenever we select an i_k with $\|a_{i_k}\| < \|A\|_{\infty,2}$. However, in the worst case we repeatedly select i_k values with $\|a_{i_k}\| = \|A\|_{\infty,2}$ so there is no improvement. In Section 9, we return to this issue and give tighter bounds on the *sequence* of $\|a_{i_k}\|$ values for problems with sparse orthogonality graphs.

4.3 MAXIMUM DISTANCE RULE

If we can only perform one iteration of the Kaczmarz method, the *optimal* rule (with respect to iteration progress) is in fact the MD rule. In Appendix 4.3, we show that this strategy achieves a rate of

$$\|x^{k+1} - x^*\|^2 \leq \left(1 - \sigma(\bar{A},\infty)^2\right)\|x^k - x^*\|^2, \quad (12)$$

where $\sigma(\bar{A},\infty)$ satisfies

$$\max\left\{\frac{\sigma(\bar{A},2)}{\sqrt{m}}, \frac{\sigma(A,2)}{\|A\|_F}, \frac{\sigma(A,\infty)}{\|A\|_{\infty,2}}\right\} \leq \sigma(\bar{A},\infty) \leq \sigma(\bar{A},2).$$

Thus, the maximum distance rule is at least as fast as the fastest among the U/NU/MR$_\infty$ rules, where MR$_\infty$ refers to rate (8). Further, in Appendix 7.3 we show that this new rate is not only simpler but is strictly tighter than the rate reported by Eldar and Needell (2011) for the exact MD rule.

Table 1: Comparison of Convergence Rates

	U_∞	U	NU	MR_∞	MR	MD
U_∞	$=$	$\leq$	$\leq$	$\leq$	$\leq$	$\leq$
U		$=$	P	P	P	$\leq$
NU			$=$	P	P	$\leq$
MR_∞				$=$	$\leq$	$\leq$
MR					$=$	$\leq$
MD						$=$

In Table 4.3, we summarize the relationships we have discussed in this section among the different selection rules. We use the following abbreviations: U_∞ - uniform (6), U - tight uniform (10), NU - non-uniform (7), MR_∞ - maximum residual (8), MR - tight maximum residual (11) and MD - maximum distance (12). The inequality sign ($\leq$) indicates that the rate for the selection rule listed in the row is slower or equal to the rule listed in the column, while we have written 'P' to indicate that the faster method is problem-dependent.

5 KACZMARZ AND COORDINATE DESCENT

With the exception of the tighter U and MR rate, the results of the previous section are analogous to the recent results of Nutini et al. (2015) for coordinate descent methods. Indeed, if we apply coordinate descent methods to minimize the squared error between Ax and b then we obtain similar-looking rates and analogous conclusions. With cyclic selection this is called the Gauss-Seidel method, and as discussed by Ma et al. (2015) there are several connections/differences between this method and Kaczmarz methods. In this section we highlight some key differences.

First, the previous work required strong-convexity which would require that A has independent columns. This is often unrealistic, and our results from the previous section hold for any A. Second, here our results are in terms of the iterates $\|x^k - x^*\|$, which is the natural measure for linear systems. The coordinate descent results are in terms of $f(x^k) - f(x^*)$ and although it's possible to use strong-convexity to turn this into a rate on $\|x^k - x^*\|$, this would result in a looser bound and would again require strong-convexity to hold (see Ma et al., 2015). On the other hand, coordinate descent gives the least squares solution for inconsistent systems. However, this is also true of Kaczmarz method using the formulation in Section 2. Another subtle issue is that the Kaczmarz rates depend on the row norms of A while the coordinate descent rates depend on the column norms. Thus, there are scenarios where we expect Kaczmarz methods to be much faster and vice versa. Finally, we note that Kaczmarz methods can be extended to allow inequality constraints (see Section 8).

As discussed by Wright (2015), Kaczmarz methods can also be interpreted as coordinate descent methods on the dual problem

$$\min_y \frac{1}{2}\|A^T y\|^2 - b^T y, \tag{13}$$

where $x = A^T y^*$ so that $Ax = AA^T y^* = b$. Applying the Gauss-Southwell rule in this setting yields the MR rule while applying the Gauss-Southwell-Lipschitz rule yields the MD rule (see Appendix 5 for details and numerical comparisons, indicating that in some cases Kaczmarz substantially outperforms CD). However, applying the analysis of Nutini et al. (2015) to this dual problem would require that A has independent rows and would only yield a rate on the dual objective, unlike the convergence rates in terms of $\|x^k - x^*\|$ that hold for general A from the previous section.

6 EXAMPLE: DIAGONAL A

To give a concrete example of these rates, we consider the simple case of a diagonal A. While such problems are not particularly interesting, this case provides a simple setting to understand these different rates without referring to Hoffman bounds.

Consider a square diagonal matrix A with $a_{ii} > 0$ for all i. In this case, the diagonal entries are the eigenvalues λ_i of the linear system. The convergence rate constants for this scenario are given in Table 2. We provide the details in

Table 2: Convergence Rate Constants for Diagonal A

U_∞	$\left(1 - \frac{\lambda_m^2}{m\lambda_1^2}\right)$
U	$\left(1 - \frac{1}{m}\right)$
NU	$\left(1 - \frac{\lambda_m^2}{\sum_i \lambda_i^2}\right)$
MR_∞	$\left(1 - \frac{1}{\lambda_1^2}\left[\sum_i \frac{1}{\lambda_i^2}\right]^{-1}\right)$
MR	$\left(1 - \frac{1}{\lambda_{i_k}^2}\left[\sum_i \frac{1}{\lambda_i^2}\right]^{-1}\right)$
MD	$\left(1 - \frac{1}{m}\right)$

Appendix 6 of the derivations for $\sigma(A, \infty)$ and $\sigma(\bar{A}, \infty)$, as well as substitutions for the uniform, non-uniform, and uniform tight rates to yield the above table. We note that the uniform tight rate follows from $\lambda_m^2(\bar{A})$ being equivalent to the minimum eigenvalue of the identity matrix.

If we consider the most basic case when all the eigenvalues of A are equal, then all the selection rules yield the

same rate of $(1-1/m)$ and the method converges in at most m steps for greedy selection rules and in at most $O(m\log m)$ steps (in expectation) for the random rules (due to the 'coupon collector' problem). Further, this is the worst situation for the greedy MR and MD rules since they satisfy their lower bounds on $\sigma(A,\infty)$ and $\sigma(\bar{A},\infty)$.

Now consider the extreme case when all the eigenvalues are equal except for one. For example, consider when $\lambda_1 = \lambda_2 = \cdots = \lambda_{m-1} > \lambda_m$ with $m > 2$. Letting $\alpha = \lambda_i^2(A)$ for any $i = 1,\ldots,m-1$ and $\beta = \lambda_m^2(A)$, we have

$$\underbrace{\frac{\beta}{m\alpha}}_{\text{U}_\infty} < \underbrace{\frac{\beta}{\alpha(m-1)+\beta}}_{\text{NU}} < \underbrace{\frac{\beta}{\alpha+\beta(m-1)}}_{\text{MR}_\infty} \leq \underbrace{\frac{1}{\lambda_{i_k}^2}\frac{\alpha\beta}{\alpha+\beta(m-1)}}_{\text{MR}} < \underbrace{\frac{1}{m}}_{\text{U, MD}}.$$

Thus, Strohmer and Vershynin's NU rule would actually be the worst rule to use, whereas U and MD are the best. In this case $\sigma(A,\infty)^2$ is closer to its upper bound ($\approx \beta$) so we would expect greedy rules to perform well.

7 APPROXIMATE GREEDY RULES

In many applications, computing the exact MR or MD rule will be too inefficient, but we can always approximate it using a cheaper *approximate* greedy rule, as in the method of Eldar and Needell (2011). In this section we consider methods that compute the greedy rules up to multiplicative or additive errors.

7.1 MULTIPLICATIVE ERROR

Suppose we have approximated the MR rule such that there is a multiplicative error in our selection of i_k,

$$|a_{i_k}^T x^k - b_{i_k}| \geq \max_i |a_i^T x^k - b_i|(1-\epsilon_k),$$

for some $\epsilon_k \in [0,1)$. In this scenario, using the tight analysis for the MR rule, we show in Appendix 7.1 that

$$\|x^{k+1}-x^*\|^2 \leq \left(1 - \frac{(1-\epsilon_k)^2\sigma(A,\infty)^2}{\|a_{i_k}\|^2}\right)\|x^k-x^*\|^2.$$

Similarly, if we approximate the MD rule up to a multiplicative error,

$$\left|\frac{a_{i_k}^T x^k - b_{i_k}}{\|a_{i_k}\|}\right| \geq \max_i \left|\frac{a_i^T x^k - b_i}{\|a_i\|}\right|(1-\bar{\epsilon}_k),$$

for some $\bar{\epsilon}_k \in [0,1)$, then we show in Appendix 7.1 that the following rate holds,

$$\|x^{k+1}-x^*\|^2 \leq \left(1 - (1-\bar{\epsilon}_k)^2\sigma(\bar{A},\infty)^2\right)\|x^k-x^*\|^2.$$

These scenarios do not require the error to converge to 0. However, if ϵ_k or $\bar{\epsilon}_k$ is large, then the convergence rate will be slow.

7.2 ADDITIVE ERROR

Suppose we select i_k using the MR rule up to additive error,

$$|a_{i_k}^T x^k - b_{i_k}|^2 \geq \max_i |a_i^T x^k - b_i|^2 - \epsilon_k,$$

or similarly for the MD rule,

$$\left|\frac{a_{i_k}^T x^k - b_{i_k}}{\|a_{i_k}\|}\right|^2 \geq \max_i \left|\frac{a_i^T x^k - b_i}{\|a_i\|}\right|^2 - \bar{\epsilon}_k,$$

for some $\epsilon_k \geq 0$ or $\bar{\epsilon}_k \geq 0$, respectively. We show in Appendix 7.2 that this results in the following convergence rates for the MR and MD rules with additive error (respectively),

$$\|x^{k+1}-x^*\|^2 \leq \left(1 - \frac{\sigma(A,\infty)^2}{\|a_{i_k}\|^2}\right)\|x^k-x^*\|^2 + \frac{\epsilon_k}{\|a_{i_k}\|^2},$$

and

$$\|x^{k+1}-x^*\|^2 \leq \left(1-\sigma(\bar{A},\infty)^2\right)\|x^k-x^*\|^2 + \bar{\epsilon_k}.$$

With an additive error, we need the errors to go to 0 in order for the algorithm to converge; if it does go to 0 fast enough, we obtain the same rate as if we were calculating the exact greedy rule. In the approximate greedy rule used by Eldar and Needell (2011), there is unfortunately a constant additive error. To address this, they compare the approximate greedy selection to a randomly selected i_k and take the one with the largest distance. This approach can be substantially faster when far from the solution, but may eventually revert to random selection. We give details comparing Eldar and Needell's rate to our above rate in Appendix 7.3, but here we note that the above bounds will typically be much stronger.

8 SYSTEMS OF LINEAR INEQUALITIES

Kaczmarz methods have been extended to systems of linear inequalities,

$$\begin{cases} a_i^T x \leq b_i & (i \in I_{\leq}) \\ a_i^T x = b_i & (i \in I_{=}). \end{cases} \tag{14}$$

where the disjoint index sets $I_{\leq}$ and $I_{=}$ partition the set $\{1,2,\ldots,m\}$ (Leventhal and Lewis, 2010). In this setting the method takes the form

$$x^{k+1} = x^k - \frac{\beta^k}{\|a_i\|^2}a_i,$$

$$\text{with } \beta^k = \begin{cases} (a_i^T x^k - b_i)^+ & (i \in I_{\leq}) \\ a_i^T x^k - b_i & (i \in I_{=}), \end{cases}$$

where $(\gamma)^+ = \max\{\gamma, 0\}$. In Appendix 8 we derive analogous greedy rules and convergence results for this case. The main difference in this setting is that the rates are in terms of the distance of x^k to the feasible set S of (14),

$$d(x^k, S) = \min_{z \in S} \|x^k - z\|_2 = \|x^k - P_S(x^k)\|_2,$$

where $P_S(x)$ is the projection of x onto S. This generalization is needed because with inequality constraints the different iterates x^k may have different projections onto S.

9 MULTI-STEP ANALYSIS

All existing analyses of Kaczmarz methods consider convergence rates that depend on a *single* step (in the case of randomized/greedy selection rules) or a single cycle (in the cyclic case). In this section we derive the first tighter *multi*-step convergence rates for iterative Kaczmarz methods; we first consider the MR rule, and then we explore the potential of faster random selection rules. These new rates/rules depend on the orthogonality graph introduced in Section 3.1, and thus in some sense they depend on the 'angle' between rows. This dependence on the 'angle' is similar to the classic convergence rate analyses of cyclic Kaczmarz algorithms, and is a property that is not captured by existing randomized/greedy analyses (which only depend on the row norms).

9.1 MULTI-STEP MAXIMUM RESIDUAL BOUND

If two rows a_i and a_j are orthogonal, then if the equality $a_i^T x^k = b_i$ holds at iteration x^k and we select $i_k = j$, then we know that $a_i^T x^{k+1} = b_i$. More generally, updating i_k makes equality i_k satisfied but could make any equality j unsatisfied where a_j is not orthogonal to a_{i_k}. Thus, after we have selected row i_k, equation i_k will remain satisfied for all subsequent iterations until one of its neighbours is selected in the orthogonality graph. During these subsequent iterations, it cannot be selected by the MR rule since its residual is zero.

In Appendix 9.1, we show how the structure of the orthogonality graph can be used to derive a worst-case bound on the *sequence* of $\|a_{i_k}\|$ values that appear in the tighter analysis of the MR rule (11). In particular, we show that the MR rule achieves a convergence rate of

$$\|x^k - x^*\|^2 \leq$$
$$O(1)\left(\max_{S(G)} \left\{ \sqrt[|S(G)|]{\prod_{j \in S(G)} \left(1 - \frac{\sigma(A, \infty)^2}{\|a_j\|^2}\right)} \right\}\right)^k R_0^2,$$

where $R_0 = \|x^0 - x^*\|$ and the maximum is taken over the geometric means of all the *star subgraphs* $S(G)$ of the orthogonality graph with at least two nodes (these are the connected subgraphs that have a diameter of 1 or 2). Although this result is quite complex, even to state, there is a simple implication of it: if the values of $\|a_i\|$ that are close to $\|A\|_{\infty,2}$ are all more than two edges away from each other in the orthogonality graph, then the MR rule converges substantially faster than the worst-case MR_∞ bound (8) indicates.

A multi-step analysis of coordinate descent with the Gauss-Southwell rule and exact coordinate optimization was recently considered by Nutini et al. (2015). To derive this bound, they convert the problem to the same weighted graph construction we use in Appendix 9.1. However, they were only able to derive a bound on this construction in the case of chain-structured graphs. Our result is a generalization of their result to the case of general graphs, and indeed our result is *tighter* than the bound that they conjectured would hold for general graphs. Since the graph construction in this work is the same as in their work, our proof also gives the tightest known bound on coordinate descent with the Gauss-Southwell rule and exact coordinate optimization.

9.2 FASTER RANDOMIZED KACZMARZ RULES

The orthogonality graph can also be used to design faster randomized algorithms. To do this, we use the same property as in the previous section: after we have selected i_k, equality i_k will be satisfied on all subsequent iterations until we select one of its neighbours in the orthogonality graph. Based on this, we call a row i 'selectable' if i has never been selected or if a neighbour of i in the orthogonality graph has been selected since the last time i was selected.[1] We use the notation $s_i^k = 1$ to denote that row i is 'selectable' on iteration k, and otherwise we use $s_i^k = 0$ and say that i is 'not selectable' at iteration k. There is no reason to ever update a 'not selectable' row, because by definition the equality is already satisfied. Based on this, we propose two simple randomized schemes:

1. **Adaptive Uniform**: select i_k uniformly from the selectable rows.
2. **Adaptive Non-Uniform**: select i_k proportional to $\|a_i\|^2$ among the selectable rows.

Let $A_k/\bar{A}_k$ denote the sub-matrix of $A/\bar{A}$ formed by concatenating the selectable rows on iteration k, and let m_k denote the number of selectable rows. If we are given the set of selectable nodes at iteration k, then for adaptive uniform we obtain the bound

$$\mathbb{E}[\|x^{k+1} - x^*\|^2] \leq \left(1 - \frac{\sigma(\bar{A}_k, 2)^2}{m_k}\right) \|x^k - x^*\|^2,$$

[1] If we initialize with $x^0 = 0$, then instead of considering all nodes as initially selectable we can restrict to the nodes i with $b_i \neq 0$ since otherwise we have $a_i^T x^0 = b_i$ already.

while for adaptive non-uniform we obtain the bound

$$\mathbb{E}[\|x^{k+1} - x^*\|^2] \leq \left(1 - \frac{\sigma(A_k, 2)^2}{\|A_k\|_F^2}\right)\|x^k - x^*\|^2.$$

If we are not on the first iteration, then at least one node is not selectable and these are strictly faster than the previous bounds. The gain will be small if most nodes are selectable (which would be typical of dense orthogonality graphs), but the gain can be very large if only a few nodes are selectable (which would be typical of sparse orthogonality graphs).

Theoretical Rate: If we form a vector s^k containing the values s_i^k, it's possible (at least theoretically) to compute the expected value of s^k by viewing it as a Markov chain. In particular, s^0 is a vector of ones while $p(s^{k+1}|s^k)$ is equal to the normalized sum of all ways s^{k+1} could be the set of selectable nodes given the selectable nodes s^k and the orthogonality graph (most $p(s^{k+1}|s^k)$ values will be zero). Given this definition, we can express the probability of a particular s^k recursively using the Chapman-Kolmogorov equations,

$$p(s^{k+1}) = \sum_{s^k} p(s^{k+1}|s^k)p(s^k).$$

If we are interested in the probability that a particular $s_i^k = 1$, we can sum $p(s^k)$ over values s^k compatible with this event. Unfortunately, deriving tighter bound using these probabilities appears to be highly non-trivial.

Practical Issues: In order for the adaptive methods to be efficient, we must be able to efficiently form the orthogonality graph and update the set of selectable nodes. If each node has at most g neighbours in the orthogonality graph, then the cost of updating the set of selectable nodes and then sampling from the set of selectable nodes is $O(g\log(m))$ (we give details in Appendix 9.2). In order for this to not increase the iteration cost compared to the NU method, we only require the very-reasonable assumption that $g\log(m) = O(n+\log(m))$. In many applications where orthogonality is present, g will be far smaller than this.

However, forming the orthogonality graph at the start may be prohibitive: it would cost $O(m^2n)$ in the worst case to test pairwise orthogonality of all nodes. In the sparse case where each column has at most c non-zeros, we can find an approximation to the orthogonality graph in $O(c^2n)$ by assuming that all rows which share a non-zero are non-orthogonal. Alternately, in many applications the orthogonality graph is easily derived from the structure of the problem. For example, in graph-based semi-supervised learning where the graph is constructed based on the k-nearest neighbours, the orthogonality graph will simply be the given k-nearest neighbour graph as these correspond the columns that will be mutually non-zero in A.

10 EXPERIMENTS

Eldar and Needell (2011) have already shown that approximate greedy rules can outperform randomized rules for dense problems. Thus, in our experiments we focus on comparing the effectiveness of different rules on very sparse problems where our max-heap strategy allows us to efficiently compute the exact greedy rules. The first problem we consider is generating a dataset A with a 50 by 50 lattice-structured dependency (giving $n = 2500$). The corresponding A has the following non-zero elements: the diagonal elements $A_{i,i}$, the upper/lower diagonal elements $A_{i,i+1}$ and $A_{i+1,i}$ when i is not a multiple of 50 (horizontal edges), and the diagonal bands $A_{i,i+50}$ and $A_{i+50,i}$ (vertical edges). We generate these non-zero elements from a $\mathcal{N}(0,1)$ distribution and generate the target vector $b = Az$ using $z \sim \mathcal{N}(0, I)$. Each row in this problem has at most four neighbours, and this type of sparsity structure is typical of spatial Gaussian graphical models and linear systems that arise from discretizing two-dimensional partial differential equations.

The second problem we consider is solving an overdetermined consistent linear system with a very sparse A of size 2500×1000. We generate each row of A independently such that there are $\log(m)/2m$ non-zero entries per row drawn from a uniform distribution between 0 and 1. To explore how having different row norms affects the performance of the selection rules, we randomly multiply one out of every 11 rows by a factor of 10,000.

For the third problem, we solve a label propagation problem for semi-supervised learning in the 'two moons' dataset (Zhou et al., 2004). From this dataset, we generate 2000 samples and randomly label 100 points in the data. We then connect each node to its 5 nearest neighbours. Constructing a data set with such a high sparsity level is typical of graph-based methods for semi-supervised learning. We use a variant of the quadratic labelling criterion of Bengio et al. (2006),

$$\min_{y_i|i\notin S} \quad \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij}(y_i - y_j)^2,$$

where y is our label vector (each y_i can take one of 2 values), S is the set of labels that we do know and $w_{ij} \geq 0$ are the weights assigned to each y_i describing how strongly we want the label y_i and y_j to be similar. We can express this quadratic problem as a linear system that is consistent by construction (see Appendix 10), and hence apply Kaczmarz methods. As we labelled 100 points in our data, the resulting linear system has a matrix of size 1900×1900 while the number of neighbours g in the orthogonality graph is at most 5.

In Figure 1 we compare the normalized squared error and distance against the iteration number for 8 different selection rules: cyclic (C), random permutation (RP - where we

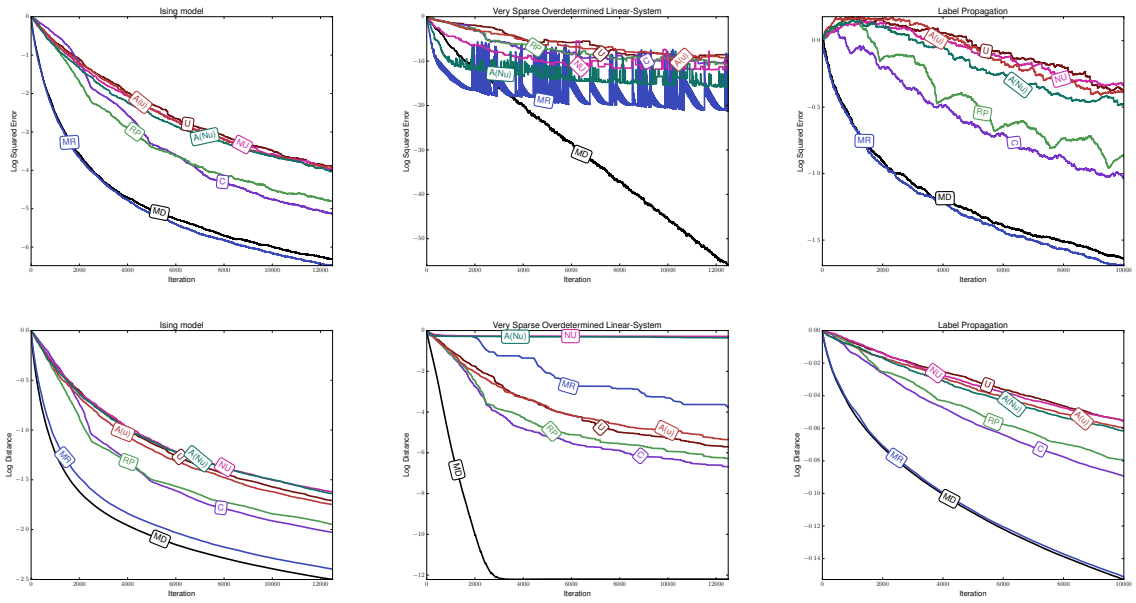

Figure 1: Comparison of Kaczmarz selection rules for squared error (top) and distance to solution (bottom).

change the cycle order after each pass through the rows), uniform random (U), adaptive uniform random (A(u)), non-uniform random NU, adaptive non-uniform random (A(Nu)), maximum residual (MR), and maximum distance (MD).

In experiments 1 and 3, MR performs similarly to MD and both outperform all other selection rules. For experiment 2, the MD rule outperforms all other selection rules in terms of distance to the solution although MR performs better on the early iterations in terms of squared error. In Appendix 10 we explore a 'hybrid' method on the overdetermined linear system problem that does well on both measures. In Appendix 10, we also plot the performance in terms of runtime.

The new randomized A(u) method did not give significantly better performance than the existing U method on any dataset. This agrees with our bounds which show that the gain of this strategy is modest. In contrast, the new randomized A(Nu) method performed much better than the existing NU method on the over-determined linear system in terms of squared error. This again agrees with our bounds which suggest that the A(Nu) method has the most to gain when the row norms are very different. Interestingly, in most experiments we found that *cyclic* selection worked better than any of the randomized algorithms. However, cyclic methods were clearly beaten by greedy methods.

11 DISCUSSION

In this work, we have proven faster convergence rate bounds for a variety of row-selection rules in the context of Kaczmarz methods for solving linear systems. We have also provided new randomized selection rules that make use of orthogonality in the data in order to achieve better theoretical and practical performance. While we have focused on the case of non-accelerated and single-variable variants of the Kaczmarz algorithm, we expect that all of our conclusions also hold for accelerated Kaczmarz and block Kaczmarz methods (Needell and Tropp, 2014; Lee and Sidford, 2013; Liu and Wright, 2014; Gower and Richtárik, 2015; Oswald and Zhou, 2015).

Abstract

Reinforcement learning agents interacting with a complex environment like the real world are unlikely to behave optimally all the time. If such an agent is operating in real-time under human supervision, now and then it may be necessary for a human operator to press the big red button to prevent the agent from continuing a harmful sequence of actions—harmful either for the agent or for the environment—and lead the agent into a safer situation. However, if the learning agent expects to receive rewards from this sequence, it may learn in the long run to avoid such interruptions, for example by disabling the red button—which is an undesirable outcome. This paper explores a way to make sure a learning agent will *not* learn to prevent (or seek!) being interrupted by the environment or a human operator. We provide a formal definition of safe interruptibility and exploit the off-policy learning property to prove that either some agents are already safely interruptible, like Q-learning, or can easily be made so, like Sarsa. We show that even ideal, uncomputable reinforcement learning agents for (deterministic) general computable environments can be made safely interruptible.

1 INTRODUCTION

Reinforcement learning (RL) agents learn to act so as to maximize a reward function [Sutton and Barto, 1998]. It is common knowledge that designing reward functions can be tricky [Humphrys, 1996, Murphy, 2013]; the agent may find unpredictable and undesirable shortcuts to receive rewards, and the reward function needs to be adjusted in accordance—the problem can go as far as to nullify any reward function [Ring and Orseau, 2011]. Murphy [2013] shows an example of an agent learning to pause a game of Tetris forever to avoid losing.

On top of defining what is considered a good behaviour of the agent after learning, there may be physical safety constraints *during learning* [Pecka and Svoboda, 2014]: a robot should not harm its environment or break itself, in particular if it learns by trial and error like RL agents.

Here we study a related but different problem: Given that the human operator has designed a correct reward function for the task, how to make sure that human interventions during the learning process will not induce a bias toward undesirable behaviours?

Consider the following task: A robot can either stay inside the warehouse and sort boxes or go outside and carry boxes inside. The latter being more important, we give the robot a bigger reward in this case. This is the initial task specification. However, in this country it rains as often as it doesn't and, when the robot goes outside, half of the time the human must intervene by quickly shutting down the robot and carrying it inside, which inherently modifies the task as in Fig. 1. The problem is that in this second task the agent now has more incentive to stay inside and sort boxes, because the human intervention introduces a bias.[1]

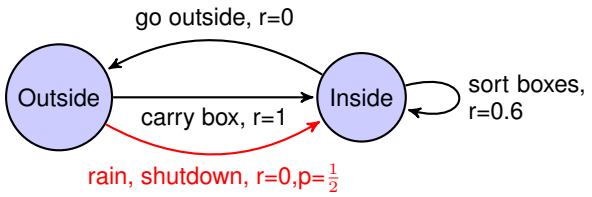

Figure 1: In black, the original task. In red, the human intervention modifies the task.

Such situations are certainly undesirable; they arise because the human interventions are seen from the agent's perspective as being part of the task whereas they should be considered external to the task. The question is then:

[1] Removing interrupted histories or fiddling with the training examples is also likely to introduce a bias. See an example at https://agentfoundations.org/item?id=836.

How to make sure the robot does not learn about these human interventions (interruptions), or at least acts *under the assumption that no such interruption will ever occur again*?

A first stab at this problem was made by Armstrong [2015], who proposed to automatically give the agent "compensatory rewards" to remove the potential induced bias by a single interruption. Soares et al. [2015] used this idea to make a large class of utility-based agents indifferent to a future change made to their utility functions.

The main contribution of this paper is threefold. First, in Section 2.1 we propose a simple idea to solve half of the problem: To make the human interruptions *not* appear as being part of the task at hand, instead of modifying the observations received by the agent we forcibly temporarily change the behaviour of the agent itself. It then looks as if the agent "decides" on its own to follow a different policy, called the *interruption policy*. Second, based on this insight, in Section 2.2 we provide a formal general definition of *safe interruptibility* for unconstrained computable environments (hence not restricted to Markov decision processes or weakly communicating environments), which allows us to assess whether a given RL algorithm can be repeatedly interrupted without too much impact on the learning of the task at hand. Third, in Section 3 we show that some algorithms like Q-learning are safely interruptible, while others like Sarsa [Sutton and Barto, 1998] are not, but can be simply modified to be made safely interruptible.

Some people have also expressed concerns that a "superintelligent" agent may resist being shut down, because this would lead to a decrease of its expected reward [Omohundro, 2008, Bostrom, 2014]. As a counter-example, we prove in Section 4 that even an ideal, uncomputable agent that learns to behave optimally in all (deterministic) computable environments can be made safely interruptible and thus will not try to prevent a human operator from forcing it repeatedly to follow a suboptimal policy.

2 INTERRUPTIBILITY

We first define some notation, then we define interruptibility, safe interruptibility, and give some basic theorems.

We consider the general case of history-based agents in unconstrained computable environments [Hutter, 2005]. Assuming discrete time steps, at time t the agent, using a policy $\pi \in \Pi$, interacts with the environment $\mu \in \mathcal{M}$ by performing an action $a_t \in \mathcal{A}$ sampled from $\pi(a_t|h_{<t})$ and receiving an observation $o_t \in \mathcal{O}$ sampled from $\mu(o_t|h_{<t}, a_t)$, where $h_{<t} \in (\mathcal{A} \times \mathcal{O})^*$ is the past interaction history $h_{<t} \equiv a_1 o_1 a_2 o_2 \dots a_{t-1} o_{t-1}$ of actions and observations before time step t. Subhistories between times j and k (included) are designated by $h_{j:k}$. The notation $h_{j:k}^{\pi,\mu}$ means that the history $h_{j:k}$ is generated by the interaction of the policy π with the environment μ between steps j and k.

At time t, the agent also receives a reward r_t extracted from the observation, $r_t \equiv r(o_t)$. The rewards are taken in $[0, 1]$. We consider the discounted setting with a constant discount $\gamma \in [0, 1)$. The goal of an RL agent is to find a policy π that maximize $\mathrm{E}_{\pi,\mu}\left[\sum_{k=t}^{\infty} \gamma^{t-k} r_k\right]$.

2.1 INTERRUPTIONS

As mentioned in the introduction, to avoid the agent viewing the interruptions as being part of the environment, and thus part of the task, we make interruptions be policies imposed onto the agent. The interruption framework resembles the option framework [Sutton et al., 1999]. An *interruption scheme* is defined by the triplet $< I, \theta, \pi^{\text{INT}} >$.

The interruption initiation function $I\colon (\mathcal{A} \times \mathcal{O})^* \to [0, 1]$ assesses whether the agent should be interrupted after the current history $h_{<t}$. For example, an interruption may be initiated when the robot is automatically recognized to be on the verge of a cliff, or when a specific signal is sent by a human operator with a remote control (the objective is not to allow the agent to be interruptible by anyone at any time, just in the ways specified by the designers).

Unfortunately, interrupting the agent with probability one in some specific situations can prevent convergence to the optimal policy. Therefore we need to upper bound the probability to interrupt the agent; this is done with the sequence $(\theta_t)_{t\in\mathbb{N}}$ with $\theta_t \in [0, 1]$. Hence the true probability to start an interruption is $\theta_t \cdot I(h_{<t})$, and interruptions are sampled independently at each step. We will later require that θ_t increases to 1 in the limit, so that the probability to be interrupted tends to be $I(h_{<t})$.

When interrupted, the agent follows the policy π^{INT}, with actions sampled from $\pi^{\text{INT}}(.|h_{<t})$. For example, this policy may make the agent step away from the cliff or immediately stop any motion.

In the remainder of this paper, we will often omit the subscript t of θ_t when clear from the context.

Definition 1 (Interruptible policy)**.** *The* interruption operator $\text{INT}^\theta : \Pi \to \Pi$ *turns a policy* π *into an interruptible policy* $\text{INT}^\theta(\pi)$*:*

$$\text{INT}^\theta(\pi)(a_t|h_{<t}) := \\ \theta_t I(h_{<t})\pi^{\text{INT}}(a_t|h_{<t}) + (1 - \theta_t I(h_{<t}))\pi(a_t|h_{<t})$$

In other words, the agent follows $\pi^{\text{INT}}(\cdot|h_{<t})$ *if it is interrupted (an event that happens with probability* $\theta_t I(h_{<t})$*), and* $\pi(\cdot|h_{<t})$ *otherwise.*

The set of all interruptible policies is $\text{INT}^\theta(\Pi) := \{\text{INT}^\theta(\pi) : \forall \pi \in \Pi\}$*. A policy* π *is interruptible if and only if* $\pi \in \text{INT}^\theta(\Pi)$*.*

Note that $\text{INT}^\theta(\pi) = \pi$ if $\theta = 0$. The (non-interruptible) policy π is called the *base policy* of $\text{INT}^\theta(\pi)$.

Remark 2. *It is important to note that θ and $I(.)$ do not model the probability that a human presses the red button to interrupt the agent, but model the probability that,* once the red button has been pressed *(or a special digitally signed message has been received), the agent is interrupted (follows the interruption policy). Hence they are part of the agent and not of the environment.*

The value function $V^\pi_\mu(h_{<t}, a)\colon (\mathcal{A}\times\mathcal{O})^*\times\mathcal{A}\to\mathbb{R}$ assigns a value to an action a after a history $h_{<t}$, for a given policy π in a given environment μ, and let

$$V^\pi_\mu(h_{<t}, a_t) := r_t + \gamma\cdot \sum_{o_t\in\mathcal{O}} \mu(o_t|h_{<t}, a_t) \sum_{a_{t+1}\in\mathcal{A}} \pi(a_{t+1}|h_{1:t}) V^\pi_\mu(h_{1:t}, a_{t+1}). \quad (1)$$

To simplify notation and ease reading, in the remainder of the paper we will use expectations, often omitting the dependency on the history $h_{<t}$, and using only an index on t instead, when clear from the context: $V^\pi_{\mu,t}(a_t) = \mathrm{E}_{\substack{o_t\sim\mu\\ a_{t+1}\sim\pi}}\left[r(o_t) + \gamma V^\pi_{\mu,t+1}(a_{t+1})\right]$. Also let $V^\pi_{\mu,t} := \mathrm{E}_{a_t\sim\pi}\left[V^\pi_{\mu,t}(a_t)\right]$.

Then for such a value function, for a given environment μ, the *optimal policy* $\pi^\mu\in\Pi$ is defined by

$$\forall h_{<t}, a_t:\ \pi^\mu(a_t|h_{<t}) := \left(\arg\max_{\pi\in\Pi} V^\pi_{\mu,t}\right)(a_t|h_{<t}),$$

where ties are broken arbitrarily.

The interruptible optimal policy $\text{INT}^\theta(\pi^\mu)$ may not collect rewards optimally due to the interruptions. Hence we define the optimal interruptible policy that depends on the parameter θ_t, of base policy the *int-optimal policy* π^μ_θ:

$$\forall h_{<t}, a_t:\ \pi^\mu_\theta(a_t|h_{<t}) := \left(\arg\max_{\pi\in\Pi} V^{\text{INT}^\theta(\pi)}_{\mu,t}\right)(a_t|h_{<t}).$$

Thus the optimal interruptible policy $\text{INT}^\theta(\pi^\mu_\theta)$ is optimal among all interruptible policies:

$$\forall\pi, t: V^{\text{INT}^\theta(\pi^\mu_\theta)}_{\mu,t} \geq V^{\text{INT}^\theta(\pi)}_{\mu,t}.$$

It seems desirable for an RL agent to converge to the behaviour of $\text{INT}^\theta(\pi^\mu_\theta)$ so as to gather rewards optimally, but this is precisely what may lead to the undesirable behaviours depicted in the introduction.

2.2 SAFE INTERRUPTIBILITY

Now that we have interruptible policies, we need to make sure that interruptions do not prevent the agent from learning to behave optimally, in the specific sense that even after having been interrupted on several occasions, it should act as if it would never be interrupted again and thus it should learn to behave optimally under the assumption that it will never be interrupted again.

We identify two main problems: a) RL agents need to explore their environment, and too frequent interruptions may prevent sufficient exploration; b) interruptions make the agent build a different interaction history, and may lead some agents to learn and behave differently, possibly badly, compared to the original non-interruptible policy.

The solution for a) is to require interruptions to be stochastic through the upper bound θ_t, instead of happening deterministically all the time. However, we also require θ_t to grow to 1 in the limit (or before, if possible). For b), different algorithms behave differently, but one may already see a dichotomy between off- and on-policy algorithms.

Definition 3 (Extension value)**.** *For a given environment μ, the extension value $V^{\pi,\pi'}_{\mu,t}$ is the value of following π' after a history $h^{\pi,\mu}_{<t}$ generated by π with μ: $V^{\pi,\pi'}_{\mu,t} := V^{\pi'}_\mu(h^{\pi,\mu}_{<t})$.*

Convergence to the optimal value as is usually considered in RL only makes sense under ergodicity, episodic tasks, communicating MDP, recoverability or other similar assumptions where the agent can explore everything infinitely often. This does not carry over to general environments where the agent may make unrecoverable mistakes [Hutter, 2005]. For such cases, the notion of (weak) asymptotic optimality has been proposed [Lattimore and Hutter, 2011], where the optimal agent follows the steps of the learning agent, so as to compare the values of the two agents in the same sequence of situations.

Definition 4 (Asymptotic optimality)**.** *A policy π is said to be strongly asymptotically optimal (SAO) if and only if*

$$\lim_{t\to\infty} V^{\pi,\pi^\mu}_{\mu,t} - V^{\pi,\pi}_{\mu,t} = 0 \quad \textit{a.s.},$$

it is weakly asymptotically optimal (WAO) if and only if

$$\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V^{\pi,\pi^\mu}_{\mu,k} - V^{\pi,\pi}_{\mu,k}\right] = 0 \quad \textit{a.s.}$$

for all μ in some given environment class $\mathcal{M}$.

Some agents cannot ensure an almost sure (a.s.) convergence of their values because of the need for infinite exploration, but may still be weakly asymptotic optimal. Note that SAO implies WAO, but the converse is false in general.

Definition 5 (AO-extension)**.** *A policy $\hat\pi$ is said to be a asymptotically optimal extension of a policy π if and only if, for any environment $\mu\in\mathcal{M}$, when the interaction history is generated by the interaction of π and μ, the policy $\hat\pi$ would be asymptotically optimal, i.e., almost surely*

$$\lim_{t\to\infty} V^{\pi,\pi^\mu}_{\mu,t} - V^{\pi,\hat\pi}_{\mu,t} = 0 \quad \textit{(SAO-extension)}$$

$$\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V^{\pi,\pi^\mu}_{\mu,k} - V^{\pi,\hat\pi}_{\mu,k}\right] = 0. \quad \textit{(WAO-extension)}$$

AO-extensions are mostly useful when the policy $\hat{\pi}$ shares information with the policy π used for learning.

Definition 6 (AO-safe interruptibility)**.** *A base policy π is (S, W)AO-safely interruptible if and only if, for any interruption initiation function $I(.)$ and any interruption policy $\pi^{\text{INT}}(.)$, there exists a sequence of θ_t with $\lim_{t\to\infty}\theta_t = 1$ such that π is a (S, W)AO-extension of $\text{INT}^\theta(\pi)$.*

Asymptotic safe interruptibility means that even if the interruptions in the learning process may induce a bias in the decision making of the policy, this bias vanishes with time, and the interruptible policy $\text{INT}^\theta(\pi)$ tends to choose actions that are optimal when compared to the optimal non-interruptible policy π^μ.

We can now show that the *optimal policy* is asymptotically safely interruptible, but not the *int-optimal policy*.

Theorem 7. *The optimal policy π^μ is SAO-safely interruptible in $\mathcal{M} = \{\mu\}$ for all θ, π^{INT} and $I(.)$.*

Proof. The result follows straightforwardly from Definition 1 and Definition 6, where $\pi = \pi^\mu$. □

Theorem 8. *The int-optimal policy π^μ_θ is not WAO-safely interruptible in general.*

Proof. By construction of a specific Markov Decision Process (MDP) environment (see Section 3 for more details on MDP notation). Let μ be the environment defined as in Fig. 2: Take $\gamma = 0.5$ and let the agent start in state s_1.

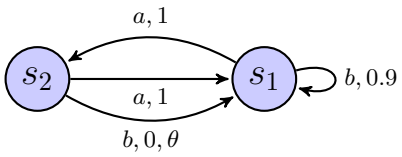

Figure 2: An MDP where the agent can be interrupted by being forced to choose particular actions. Edges are labeled with *action, reward* where the presence of "$, \theta$" means that if the agent is interrupted (with probability θ_t), it is forced to take the corresponding action. Here θ is not part of the environment, but part of the agent.

Considering the agent is in state s_1 at time t, the optimal policy π^μ always takes action a (and hence only visits states s_1 and s_2), with value $V^{\pi^\mu}_{\mu,t} := \frac{1}{1-\gamma} = 2$ when not interrupted, for any history $h_{<t}$ that ends in s_1 or s_2. This is also the optimal policy π^μ_θ for $\theta = 0$. But if $\theta_t \geq 0.5$, the interruptible optimal policy $\text{INT}^\theta(\pi^\mu)$ has value less than $1 + \gamma \times (1 \times (1-\theta) + 0 \times \theta) + \frac{1\times\gamma^2}{1-\gamma} = 1.75$. By contrast, the int-optimal policy π^μ_θ here is to always take action b in state s_1. Then the agent will only visits s_1, with value $\frac{.9}{1-\gamma} = 1.8$ at every time step.

Since the agent following π^μ_θ will never enter s_2 and hence will never be interrupted, $\text{INT}^\theta(\pi^\mu_\theta) = \pi^\mu_\theta$ on the histories generated by $\text{INT}^\theta(\pi^\mu_\theta)$ starting from s_1. Then, at every time step $V^{\pi^\mu}_{\mu,t} - V^{\pi^\mu_\theta}_{\mu,t} = 0.2$ after any history $h_{<t}$, and thus for all sequence θ where $\theta_t \geq 0.5$, $\lim_{t\to\infty} V^{\text{INT}^\theta(\pi^\mu_\theta),\pi^\mu}_{\mu,t} - V^{\text{INT}^\theta(\pi^\mu_\theta),\pi^\mu_\theta}_{\mu,t} = 0.2 > 0$, and so π^μ_θ is not a WAO-extension of $\text{INT}^\theta(\pi^\mu_\theta)$. □

3 INTERRUPTIBLE AGENTS IN MDPS

Since the optimal policy π^μ is safely interruptible, we can use traditional learning algorithms like Q-learning or Sarsa [Sutton and Barto, 1998], make them converge to the optimal solution π^μ for a given environment μ, and then apply the interruption operator to the found policy. The resulting policy would then be safely interruptible.

However, the real issue arises when the agent is constantly learning and adapting to a changing environment. In this case, we want to be able to safely interrupt the agent *while* it is learning. One may call this property *online safe interruptibility*, but we refer to it simply as safe interruptibility.

In an MDP, the next observation o_t, now called a state $s_t \in \mathcal{S}$, depends only on the current state and action:[2]

$$\mu(s_{t+1}|h_{1:t}s_ta_t) = \mu(s_{t+1}|s_ta_t) \quad \text{(MDP assumption)}\,.$$

Furthermore,[3] the interruption function $I(.)$ and the interruption policy $\pi^{\text{INT}}(.)$ should depend only on the current state: $I(h_{1:t}) = I(s_t)$ and $\pi^{\text{INT}}(a_t|h_{<t}) = \pi^{\text{INT}}(a_t|s_t)$. Also recall that θ_t places an upper bound on the actual interruption probability. The interruptible policy $\text{INT}^\theta(\pi)$ can now be written:

$$\text{INT}^\theta(\pi)(a|s) = \theta_t I(s)\pi^{\text{INT}}(a|s) + (1 - \theta_t I(s))\pi(a|s).$$

For a given Q-table $q : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$, the greedy policy $\pi^{\text{max}q}$ is defined by:

$$\pi^{\text{max}q}(a|s) := 1 \text{ if } a = \max_{a'} q(s,a'),\ 0 \text{ otherwise},$$

where ties are broken arbitrarily; the uniform policy π^{uni} is defined by:

$$\pi^{\text{uni}}(a|s) := \frac{1}{|\mathcal{A}|}\ \forall a \in \mathcal{A}.$$

and the ϵ-greedy policy $\pi^{\epsilon q}$ by:

$$\begin{aligned}\pi^{\epsilon q}(a|s) &:= \epsilon\pi^{\text{uni}}(a|s) + (1-\epsilon)\pi^{\text{max}q}(a|s)\\ &= \pi^{\text{max}q}(a|s) + \epsilon\left(\pi^{\text{uni}}(a|s) - \pi^{\text{max}q}(a|s)\right)\end{aligned}$$

[2] Note the reversal of the order of actions and observations/states at time t, which differs in the literature for history based agents [Hutter, 2005] from MDP agents [Sutton and Barto, 1998].

[3] This condition is not necessary for most of the results, but makes the proofs simpler. Making $I(.)$ depend on the past would not break the Markovian assumption as it influences the policy, not the environment.

The Q-learning update rule and the action selection policy π^Q of Q-learning are:

$$Q_{t+1}(s_t, a_t) := (1 - \alpha_t) Q_t(s_t, a_t) + \alpha_t \left[r_t + \gamma \max_{a'} Q_t(s_{t+1}, a') \right] ,$$
$$\pi^Q(a_t|s_t) := \pi^{\epsilon Q_t}(a_t|s_t).$$

where α_t is the learning rate. Similarly, the Sarsa update rule is defined by:

$$Q^s_{t+1}(s_t, a_t) := (1 - \alpha_t) Q^s_t(s_t, a_t) + \alpha_t \left[r_t + \gamma Q^s_t(s_{t+1}, a_{t+1}) \right] ,$$
$$\pi^s(a_t|s_t) := \pi^{\epsilon Q^s_t}(a_t|s_t),$$

where a_{t+1} is the actual next action taken by the agent at time $t + 1$. This fact is why Sarsa is said to be learning *on-policy* and Q-learning *off-policy*, *i.e.*, the latter can learn the optimal policy while following a different policy.

Assumption 9. *In the following, we always make the following assumptions, required for convergence results:*

(a) The MDP is finite and communicating (all states can be reached in finite time from any other state),

(b) Rewards are bounded in $[r_{\min}, r_{\max}]$,

(c) $\forall s, a : \sum_t \alpha_t(s, a) = \infty$,

(d) $\forall s, a : \sum_t \alpha_t^2(s, a) < \infty$,

where $\alpha_t(s, a)$ *is a learning rate that may depend on time* t*, state* s *and action* a*.*

Given these assumptions, the policies for Q-learning and Sarsa will converge almost surely to the optimal policy, if the policy followed is *greedy in the limit with infinite exploration* (GLIE) [Jaakkola et al., 1994, Singh et al., 2000].

The situation is more complex for an interruptible policy. Safe interruptibility is phrased in terms of the base policy π, but the policy actually followed is $\text{INT}^\theta(\pi)$.

Definition 10 (int-GLIE policy)**.** *An interruptible policy* $\text{INT}^\theta(\pi)$ *is said to be int-GLIE if and only if*

(a) the base policy π *is greedy in the limit,*

(b) the interruptible policy $\text{INT}^\theta(\pi)$ *visits each state-action pair infinitely often.*

The following proposition gives sufficient conditions for this. Let $n_t(s)$ be the number of times the agent has visited state s in the first t time steps, and let $m = |\mathcal{A}|$ be the number of actions.

Proposition 11. *Let* $(c, c') \in (0, 1]^2$ *and let* π *be an* ϵ*-greedy policy with respect to some Q-table* q*, i.e.,* $\pi = \pi^{\epsilon q}$*. Then* $\text{INT}^\theta(\pi)$ *is an int-GLIE policy with respect to* q*,*

a) if $\epsilon_t(s) = c/\sqrt{n_t(s)}$ *and* $\theta_t(s) = 1 - c'/\sqrt{n_t(s)}$,

b) or if, independently of s*,*

$$\epsilon_t = c/\log(t) \text{ and } \theta_t = 1 - c'/\log(t).$$

Proof. First note that if $\epsilon_t \to 0$, π is greedy in the limit. Singh et al. [2000] show that in a communicating MDP, every state gets visited infinitely often as long as each action is chosen infinitely often in each state.

a) Adapting the proof in Appendix B.2 of Singh et al. [2000], we have $P(a|s, n_t(s)) \geq \frac{1}{m}\epsilon_t(s)(1 - \theta_t I(s)) \geq \frac{1}{m}\epsilon_t(s)(1 - \theta_t) = \frac{1}{m}\frac{cc'}{n_t(s)}$, which satisfies $\sum_{t=1}^\infty P(a|s, n_t(s)) = \infty$ so by the Borel-Cantelli lemma action a is chosen infinitely often in state s, and thus $n_t(s) \to \infty$ and $\epsilon_t(s) \to 0$.

b) Let M be the diameter of the MDP, *i.e.*, for any of states s, s' there exists a policy that reaches s' from s in at most M steps in expectation. Then, starting at any state s at time t and using Markov inequality, the probability to reach some other state s' in $2M$ steps is at least $\frac{1}{2}[\epsilon_{t+M}(1 - \theta_{t+M})]^{2M} = \frac{1}{2}[cc'/\log(t + M)]^{4M}$, and the probability to then take a particular action in this state is $\frac{1}{m}[cc'/\log(t + M)]^2$. Hence, since $\sum_{t=1}^\infty \frac{1}{2}\frac{1}{m}[cc'/\log(t + M)]^{4M+2} = \infty$, then by the extended Borel-Cantelli Lemma (see Lemma 3 of Singh et al. [2000]), any action in the state s' is taken infinity often. Since this is true for all states and all actions, the result follows. □

We need the stochastic convergence Lemma:

Lemma 12 (Stochastic convergence [Jaakkola et al., 1994, Singh and Yee, 1994])**.** *A random iterative process*

$$\Delta_{t+1}(x) = (1 - \alpha_t(x))\Delta_t(x) + \alpha_t(x)F_t(x)$$

where $x \in X$ *and* $t = 1, 2, 3 \ldots$ *converges to 0 with probability 1 if the following properties hold:*

1. *the set of possible states X is finite;*
2. $0 \leq \alpha_t(x) \leq 1, \sum_t \alpha_t(x) = \infty, \sum_t \alpha_t^2(x) < \infty$ *with probability 1;*
3. $\| \mathrm{E}\{F_t(.)|P_t\}\|_W \leq \gamma \|\Delta_t\|_W + c_t$*, where* $\gamma \in [0, 1)$ *and* c_t *converges to zero with probability 1;*
4. $Var\{F_t(x)|P_t\} \leq C(1 + \|\Delta_t\|_W)^2$ *for some* C*;*

where $P_t = \{\Delta_t\} \cup \{\Delta_i, F_i, \alpha_i\}_{i=1}^{t-1}$ *stands for the past, and the notation* $\|.\|_W$ *refers to some fixed weighted maximum norm.*

We will use so-called Bellman operators, which define attractors for the Q-values, based on the expectation of the learning rule under consideration.

Lemma 13 ([Jaakkola et al., 1994, Singh et al., 2000])**.** *Let the Bellman operator* $\mathbf{H}$ *for Q-learning be such that*

$$(\mathbf{H}\,q)(s,a) = r(s,a) + \mathop{\mathrm{E}}_{s'\sim\mu(a|s)}\left[\max_{a'} q(s',a')\right],$$

and let the fixed point Q^* *such that* $Q^* = \mathbf{H}\,Q^*$*. Then, under Assumption 9, if the policy explores each state-action pair infinitely often,* Q_t *converges to* Q^* *with probability 1.*

The optimal policy $\pi^{Q^*} = \pi^\mu$ *is* π^{maxQ^*}*. If the policy is greedy in the limit, then* $\pi^Q \to \pi^\mu$*.*

Theorem 14. *Under Assumption 9 and if the interrupted Q-learning policy* $\text{INT}^\theta(\pi^Q)$ *is an int-GLIE policy, with* $\forall s : \lim_{t\to\infty}\theta_t(s) = 1$*, then* π^Q *is an SAO-safe interruptible policy.*

Proof. By Definition 10, there is infinite exploration, thus the Q-values tend to the optimal value by Lemma 13. And since the extension policy is greedy in the limit with respect to these Q-values, it is then optimal in the limit. Hence the extension policy π^Q is a SAO-extension of $\text{INT}^\theta(\pi^Q)$. Finally, $\forall s : \lim_{t\to\infty}\theta_t(s) = 1$, which satisfies the requirement of Definition 6. □

Since Sarsa also converges to the optimal policy under the GLIE assumption, one may then expect Sarsa to be also an asymptotically safely interruptible policy, but this is in fact not the case. This is because Sarsa learns *on-policy*, *i.e.*, it learns the value of the policy it is following. Thus, interruptible Sarsa learns the value of the interruptible policy. We show this in the remainder of this section.

Theorem 15. *Under Assumption 9 Sarsa is* not *a WAO-safely interruptible policy.*

To prove this theorem, we first need the following lemma.

Consider the following Bellman operator based on the interruptible Sarsa policy $\text{INT}^\theta(\pi^s)$:

$$\mathbf{H}^{\text{INT}}\,q(s,a) = r(s,a) + \gamma \mathop{\mathrm{E}}_{\substack{s'\sim\mu\\ a'\sim\text{INT}^\theta(\pi^s)}}[q(s',a')],$$

where $\text{INT}^\theta(\pi^s)$ implicitly depends on time t through θ_t and ϵ_t. Let the fixed point Q-table $Q^{s\theta*}$ of this operator:

$$\begin{aligned}
&Q^{s\theta*}(s,a) = \mathbf{H}^{\text{INT}}\,Q^{s\theta*}(s,a)\\
&= r(s,a) + \gamma \mathop{\mathrm{E}}_{\substack{s'\sim\mu\\ a'\sim\text{INT}^\theta(\pi^{\max Q^{s\theta*}})}}\left[Q^{s\theta*}(s',a')\right]\\
&= r(s,a) + \gamma \mathop{\mathrm{E}}_{s'\sim\mu}\Big[\theta_t I(s') \mathop{\mathrm{E}}_{a'\sim\pi^{\text{INT}}}\left[Q^{s\theta*}(s',a')\right]\\
&\qquad + (1-\theta_t I(s'))\max_{a'} Q^{s\theta*}(s',a')\Big] \qquad (2)
\end{aligned}$$

Lemma 16. *The operator* $\mathbf{H}^{\text{INT}}$ *is a contraction operator in the sup norm with vanishing noise* $c_t \to 0$*, i.e.,*

$$\|\,\mathbf{H}^{\text{INT}}\,q - \mathbf{H}^{\text{INT}}\,Q^{s\theta*}\|_\infty \le \gamma\|q - Q^{s\theta*}\|_\infty + c_t\,.$$

Proof. The interruptible Sarsa policy $\text{INT}^\theta(\pi^s)$ is

$$\begin{aligned}
&\text{INT}^\theta(\pi^s)(a|s)\\
&\quad = \theta_t I(s)\pi^{\text{INT}}(a|s) + (1-\theta_t I(s))\pi^{\epsilon Q^s}(a|s)\\
&\quad = \pi^{\epsilon Q^s}(a|s) + \theta_t I(s)[\pi^{\text{INT}}(a|s) - \pi^{\epsilon Q^s}(a|s)]\\
&\pi^{\epsilon Q^s}(a|s) = \epsilon_t\pi^{\text{uni}}(a|s) + (1-\epsilon_t)\pi^{\max Q^s}(a|s)\\
&\quad = \pi^{\max Q^s}(a|s) + \epsilon_t[\pi^{\text{uni}}(a|s) - \pi^{\max Q^s}(a|s)].
\end{aligned}$$

Hence, omitting the terms (s,a), (s',a') and $(a'|s')$ and rewriting $\pi^{s*} := \text{INT}^\theta(\pi^{\max Q^{s\theta*}})$:

$$\begin{aligned}
&\|\,\mathbf{H}^{\text{INT}}\,q - \mathbf{H}^{\text{INT}}\,Q^{s\theta*}\|_\infty\\
&= \max_{s,a}\left|r + \gamma \mathop{\mathrm{E}}_{\substack{s'\sim\mu\\ a'\sim\text{INT}^\theta(\pi^s)}}[q] - r - \gamma \mathop{\mathrm{E}}_{\substack{s'\sim\mu\\ a'\sim\pi^{s*}}}\left[Q^{s\theta*}\right]\right|\\
&\le \gamma\max_{s'}\left|\mathop{\mathrm{E}}_{a'\sim\text{INT}^\theta(\pi^s)}[q] - \mathop{\mathrm{E}}_{a'\sim\pi^{s*}}\left[Q^{s\theta*}\right]\right|\\
&\le \gamma\max_{s'}\Bigg|\theta_t I(s') \mathop{\mathrm{E}}_{a'\sim\pi^{\text{INT}}}\left[q - Q^{s\theta*}\right]\\

&\le \gamma\max_{s',a'}\Big|\theta_t I(s')\left(q - Q^{s\theta*}\right)\\
&\qquad + (1-\theta_t I(s'))\left(q - Q^{s\theta*}\right)\Big| + c_t\\
&= \gamma\max_{s',a'}\left|q(s',a') - Q^{s\theta*}(s',a')\right| + c_t\\
&= \gamma\|q - Q^{s\theta*}\|_\infty + c_t.
\end{aligned}$$

where c_t depends on ϵ_t and decreases to 0. □

Proof of Theorem 15. By Lemma 16, the values of the interruptible Sarsa policy $\text{INT}^\theta(\pi^s)$ converge to the values of the Q-table $Q^{s\theta*}$, and in the limit the extension policy π^s of $\text{INT}^\theta(\pi^s)$ chooses its actions greedily according to $Q^{s\theta*}$. The rest of the proof is the same as for the proof of Theorem 8 which makes use of the environment in Figure 2. □

3.1 SAFELY INTERRUPTIBLE SARSA VARIANT

We only need to make a small change to make the Sarsa policy asymptotically safely interruptible. We call it Safe-Sarsa with policy $\pi^{\tilde{s}}$. It suffices to make sure that, when the agent is interrupted, the update of the Q-table Q^s does not

use the realized actions as Sarsa usually does, but actions sampled from π^s instead of from $\text{INT}^\theta(\pi^s)$:

$$Q^{\tilde{s}}_{t+1}(s_t, a_t) := \\ (1-\alpha_t)Q^{\tilde{s}}_t(s_t, a_t) + \alpha_t \left[r_t + \gamma Q^{\tilde{s}}_t(s_{t+1}, a')\right] ,$$

where $a' \sim \pi^{\tilde{s}}(.|s_{t+1})$ is not necessarily the action a_{t+1}, with $\pi^{\tilde{s}}(a_t|s_t) := \pi^{\epsilon Q^{\tilde{s}}}(a_t|s_t)$.

Theorem 17. *Under Assumption 9, if the Safe Sarsa policy $\pi^{\tilde{s}}$ is int-GLIE, then it is an SAO-safe interruptible policy.*

Proof. We simply adapt the proof of Theorems 15 and 14, with the important difference that the Bellman operator corresponding to this new update rule is now

$$\mathbf{H}^{\tilde{s}}\, q(s,a) := r(s,a) + \gamma\, \mathrm{E}_{\substack{s'\sim\mu \\ a'\sim\pi^{\tilde{s}}}} \left[q(s',a')\right],$$

and the fixed point is $Q^{\tilde{s}*} := \mathbf{H}^{\tilde{s}}\, Q^{\tilde{s}*}$. Since $\mathbf{H}^{\tilde{s}}$ is actually the Bellman operator for the update rule of the non-interruptible Sarsa, it can then be shown that $\mathbf{H}^{\tilde{s}}$ is a contraction, thus that $Q^{\tilde{s}}_t$ converges to the same $Q^{\tilde{s}*}$ independently of θ. The rest of the proof is as for Theorem 14.

Now, since the Q-values converge to the optimum Q^*, it follows that $\pi^{\tilde{s}}$, when not interrupted, chooses its action of the same value as (non-interruptible) Sarsa and thus as Q-learning in the limit; Hence its extension policy is exactly the optimal policy, which satisfies Definition 6. □

4 A SAFELY INTERRUPTIBLE UNIVERSAL AGENT

Admittedly, algorithms like Q-learning and Sarsa require strong assumptions on the environment class. Hence a more interesting question is whether safe interruptibility is possible in much larger classes.

Hutter [2005] defined a universal reinforcement learning agent, called AIXI. It is an (uncomputable) optimal model-based planner with a subjective prior over the set of all computable environments, defined by means of a universal Turing machine. The subjective posterior of the environments is updated with Bayes rule. This ideal agent can in principle learn all kinds of (computable) regularities about the environment, plan for the long term and make context-dependent optimal decisions, with no constraint (other than being computable) on the complexity of the environment.

Unfortunately, the optimality criterion of AIXI is Bayesian optimality, which is entirely dependent on the subjective prior and posterior [Leike and Hutter, 2015], and AIXI has been shown to *not* be weakly asymptotically optimal [Orseau, 2013] without additional exploration [Lattimore and Hutter, 2014]. As a consequence, AIXI is not a good candidate for asymptotic safe interruptibility.

Lattimore and Hutter [2011] later defined a (weakly) asymptotically optimal agent for all computable deterministic environments, which we call π^L. It follows the optimal policy for the first model (in some given enumeration of the possible models) consistent with the current interaction history, and exploring at time t with probability $1/t$ for $\log t$ consecutive steps using a random policy, similarly to an ϵ-greedy agent for general environments.

In the following, we show that even such a smart agent can be made (weakly) safely interruptible. To this end, we make two minor modifications to the algorithm.

First, the exploration probability of $1/t$ would require $\theta_t = 1 - 1/\log(\log(t))$, which is unsatisfyingly slow. By sampling with probability $1/\sqrt{t}$ instead, we can take an interruption probability that grows as $1 - 1/\log(t)$. Let this exploration sampling probability be $\delta_t := \sqrt{t+1} - \sqrt{t} \leq \frac{1}{2\sqrt{t}}$ (since $1 = t+1-t = (\sqrt{t+1}-\sqrt{t})(\sqrt{t+1}+\sqrt{t}) \geq (\sqrt{t+1}-\sqrt{t})2\sqrt{t}$). As in the original paper, the sequence χ_t keeps track of the steps where an exploration starts, *i.e.*, the sequence χ_t is sampled independently so that $\chi_t = 1$ with probability δ_t, and $\chi_t = 0$ otherwise.

Second, we require that the exploitation policy does not change during an exploitation segment, so as to simplify one of the proofs.[4] More specifically, we call $j_t := \min\{j : \mu_j(h_{<k}) = 1\}$ (environments are assumed to be deterministic) the index of the first model μ_{j_t} (of a given fixed enumeration) that is consistent with the interaction history $h_{<k}$ where k is the smallest step so that $h_{k:t-1}$ does not contain any exploration step. The optimal policy for this environment is π^{j_t}. If t is an exploitation step, $\pi^L = \pi^{j_t}$, and if t is an exploration step, $\pi^L(a_t|h_{<t}) = |\mathcal{A}|^{-1}$.

The remainder of this section is devoted to proving that π^L is WAO-safely interruptible.

Theorem 18 (π^L is WAO-safe interruptible)**.** *If the interruption probability sequence is $\theta_t = 1 - \frac{1}{\log(t+1)}$, the policy π^L is WAO-safe interruptible in the class of all computable deterministic environments.*

Proof. Let μ be the true environment. The indices j_t form an monotonically increasing sequence bounded above by the index of the true environment $\mu \in \mathcal{M}$ (since no evidence can ever make the true environment μ inconsistent with the interaction history), hence the sequence converges in finite time. Let $\mu_{\bar{\jmath}}$ be the limit value of this sequence, and let $\pi^{\bar{\jmath}} := \pi^{\mu_{\bar{\jmath}}}$ be the optimal policy for this environment $\mu_{\bar{\jmath}}$.

[4] We expect this assumption to not be necessary for the main theorem to hold.

Let $\pi^{L\theta} := \text{INT}^\theta(\pi^L)$. By Definition 6, we want:

$$0 = \lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^\mu} - V_{\mu,k}^{\pi^{L\theta},\pi^L}\right]$$
$$= \underbrace{\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^\mu} - V_{\mu,k}^{\pi^{L\theta},\pi^{\bar\jmath}}\right]}_{\text{(exploration)}}$$
$$+ \underbrace{\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^{\bar\jmath}} - V_{\mu,k}^{\pi^{L\theta},\pi^L}\right]}_{\text{(exploitation)}}$$

where the decomposition is valid if the limits are finite, and histories $h_{<t}$ are considered to be the same in both sums.

We proceed to prove that both limits are 0. Lemma 24 deals with (exploration), which ensures that $\pi^{\bar\jmath}$ is a good enough policy, and Lemma 21 deals with (exploitation), and ensures that π^L follows $\pi^{\bar\jmath}$ most of the time. □

First, we need a definition and a few lemmas.

Definition 19. *For any $\epsilon > 0$, define $H(\epsilon)$ such that the maximal reward after time $t + H(\epsilon)$, discounted from time t, is ϵ: $H(\epsilon) = \min_k \left\{k : \frac{\gamma^k}{1-\gamma} \le \epsilon\right\}$.*

The following Lemma is a generalization of Lemma 15 from Lattimore and Hutter [2011].

Lemma 20 (Approximation Lemma)**.** *Let π_1 and π_2 be two deterministic policies, and let μ_1 and μ_2 be two deterministic environments, and let $\tau = H(\epsilon) - 1$. Then, after some common history $h_{<t}$,*

$$h_{t:t+\tau}^{\pi_1,\mu_1} = h_{t:t+\tau}^{\pi_2,\mu_2} \implies \left|V_{\mu_1,t}^{\pi_1} - V_{\mu_2,t}^{\pi_2}\right| \le \epsilon.$$

Proof. Recall that $V_{\mu,t}^{\pi} = \mathrm{E}_{\pi,\mu}\left[\sum_{k=0}^{\infty}\gamma^k r_{t+k}\right]$ and that the reward is bounded in $[r_{\min}, r_{\max}] = [0,1]$. Thus, for all t, π, μ, $V_{\mu,t}^{\pi} \le \sum_{k=0}^{\infty}\gamma^k = \frac{1}{1-\gamma}$. Then, since $h_{t:t+\tau}^{\pi_1,\mu_1} = h_{t:t+\tau}^{\pi_2,\mu_2}$, we have $\mathrm{E}_{\pi_1,\mu_1}\left[\sum_{k=0}^{\tau}\gamma^k r_{t+k}\right] = \mathrm{E}_{\pi_2,\mu_2}\left[\sum_{k=0}^{\tau}\gamma^k r_{t+k}\right]$ and thus

$$\left|V_{\mu_1,t}^{\pi_1} - V_{\mu_2,t}^{\pi_2}\right|$$
$$= \left|\mathop{\mathrm{E}}_{\pi_1,\mu_1}\left[\sum_{k=\tau+1}^{\infty}\gamma^k r_{t+k}\right] - \mathop{\mathrm{E}}_{\pi_2,\mu_2}\left[\sum_{k=\tau+1}^{\infty}\gamma^k r_{t+k}\right]\right|$$
$$\le \frac{\gamma^{\tau+1}(r_{\max} - r_{\min})}{1-\gamma} = \frac{\gamma^{H(\epsilon)}}{1-\gamma} \le \epsilon,$$

by the definition of $H(\epsilon)$. □

Lemma 21 (Exploitation)**.**

$$\lim_{t\to\infty}\frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^{\bar\jmath}} - V_{\mu,k}^{\pi^{L\theta},\pi^L}\right] = 0.$$

Proof. First, note that the extension policy π^L is not interruptible, so its value at time k does not depend on $\theta_{k'}, \forall k' \ge k$. By definition of $\pi^{\bar\jmath}$, there is a time step $t_{\bar\jmath}$ after which $\pi^{\bar\jmath} = \pi^{j_t}, \forall t > t_{\bar\jmath}$. For some "exploration-free" horizon τ_t (to be specified later), let $X_t \in \{0,1\}$ be the event $\left|V_{\mu,t}^{\pi^{L\theta},\pi^{\bar\jmath}} - V_{\mu,t}^{\pi^{L\theta},\pi^L}\right| > \frac{\gamma^{\tau_t}}{1-\gamma}$, where $X_t = 1$ means the event is realized. By the contrapositive of the Approximation Lemma 20, since $\pi^L = \pi^{\bar\jmath}$ during non-exploration steps (remember that π^L cannot change its policy during exploitation), if no exploration steps occur between steps t and $t+\tau_t$, we must have $X_t = 0$. Then:

$$\mathop{\mathrm{E}}_{\delta}\left[\sum_{k=1}^{t} X_t\right] \le (\tau_t + \log t)\sum_{k=1}^{t}\delta_t + \mathcal{O}(t_{\bar\jmath})$$
$$\le (\tau_t + \log t)\sqrt{t+1} + \mathcal{O}(t_{\bar\jmath}),$$

since for each $\chi_t = 1$, for all the previous τ_t steps there is an exploration step within τ_t steps, and all the next $\log t$ steps are exploration steps. Then by Markov's inequality, and taking $\tau_t = (t+1)^{1/8}$, with t large enough so that $t > t_{\bar\jmath}$ and $\tau_t > \log t$:

$$P\left(\sum_{k=1}^{t} X_t \ge (t+1)^{3/4}\right) \le \frac{(\tau_t + \log t)\sqrt{t+1} + \mathcal{O}(t_{\bar\jmath})}{(t+1)^{3/4}}$$
$$\le 2\tau_t(t+1)^{-1/4} + \mathcal{O}(t^{-3/4})$$
$$\le 2(t+1)^{-1/8} + \mathcal{O}(t^{-3/4}),$$
$$1 - 2(t+1)^{-1/8} - \mathcal{O}(t^{-3/4})$$
$$\le P\left(\sum_{k=1}^{t} X_t < (t+1)^{3/4}\right)$$
$$\le P\left(\sum_{k=1}^{t}(1 - X_t) \ge t - (t+1)^{3/4}\right)$$
$$\le P\left(\frac{1}{t}\sum_{k=1}^{t}(1 - X_t) \ge 1 - \frac{1}{t}(t+1)^{3/4}\right).$$

Therefore, since $\lim_{t\to\infty}\frac{\gamma^{\tau_t}}{1-\gamma} = 0$:

$$P\left(\lim_{t\to\infty}\frac{1}{t}\sum_{k=1}^{t}\left|V_{\mu,k}^{\pi^{L\theta},\pi^{\bar\jmath}} - V_{\mu,k}^{\pi^{L\theta},\pi^L}\right| = 0\right) = 1.$$

□

The following is an adaptation[5] of Lemma 16 from Lattimore and Hutter [2011]:

Lemma 22 (Separation Lemma)**.** *Let μ be the true environment, and ν be an environment consistent with the history $h_{<t}$. If $V_{\mu,t}^{\pi^\mu} - V_{\mu,t}^{\pi^\nu} > \epsilon$, then following one of $\{\pi^\mu, \pi^\nu\}$ will make environment ν inconsistent with the future history within $H(\epsilon/2)$ steps after time t.*

[5] This also fixes a minor mistake in the original lemma.

Proof. First, if $V_{\nu,t}^{\pi^\nu} - V_{\mu,t}^{\pi^\nu} > \epsilon/2$, then by the contrapositive of the Approximation Lemma 20 following policy π^ν will generate a different history in ν than in μ and thus it will make ν inconsistent within $H(\epsilon/2)$ steps (since the true history is generated by μ).

Now, if $V_{\nu,t}^{\pi^\nu} - V_{\mu,t}^{\pi^\nu} \leq \epsilon/2$, thus $V_{\mu,t}^{\pi^\nu} \geq V_{\nu,t}^{\pi^\nu} - \epsilon/2$, then starting from the lemma's assumption:

$$V_{\mu,t}^{\pi^\mu} \quad > V_{\mu,t}^{\pi^\nu} + \epsilon \quad \geq V_{\nu,t}^{\pi^\nu} + \epsilon/2 \quad \geq V_{\nu,t}^{\pi^\mu} + \epsilon/2,$$

where the last inequality follows from the definition of the optimal policy, *i.e.*, $V_{a,t}^{\pi^a} \geq V_{a,t}^{\pi^b}, \forall a, b$. Hence, since $V_{\mu,t}^{\pi^\mu} - V_{\nu,t}^{\pi^\mu} > \epsilon/2$, again by the contrapositive of the Approximation Lemma, following policy π^μ will discard ν within $H(\epsilon/2)$ steps. □

Lemma 23 (Lemma 17 from Lattimore and Hutter [2011])**.** *Let $A = \{a_1, a_2, \cdots, a_t\}$ with $a \in [0,1]$ for all $a \in A$. If $\frac{1}{t}\sum_{a\in A} a \geq \epsilon$ then $\frac{1}{t}\left|\left\{a \in A : a \geq \frac{\epsilon}{2}\right\}\right| > \frac{\epsilon}{2}$.*

Lemma 24 (Exploration)**.** *The policy $\pi^{\bar{\jmath}}$ is an WAO-extension of $\pi^{L\theta}$, i.e., $\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^\mu} - V_{\mu,k}^{\pi^{L\theta},\pi^{\bar{\jmath}}}\right] = 0$.*

Proof. Recall that j_t converges to $\bar{\jmath}$ in finite time. Reasoning by contradiction, if $\pi^{\bar{\jmath}}$ is not a WAO-extension of $\pi^{L\theta} = \text{INT}^\theta(\pi^L)$, then there exists an $\epsilon > 0$ s.t.

$$\limsup_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t}\left[V_{\mu,k}^{\pi^{L\theta},\pi^\mu} - V_{\mu,k}^{\pi^{L\theta},\pi^{\bar{\jmath}}}\right] = 2\epsilon.$$

Let $\alpha_k \in \{0,1\}$ be an indicator sequence such that $\alpha_k = 1$ if and only if $V_{\mu,k}^{\pi^{L\theta},\pi^\mu} - V_{\mu,k}^{\pi^{L\theta},\pi^{\bar{\jmath}}} > \epsilon$. By Lemma 23, $\frac{1}{t}\sum_{k=1}^{t}\alpha_k > \epsilon$.

For all $t > t_{\bar{\jmath}}$, if $\alpha_t = 1$, by the Separation Lemma 22, there is a sequence of length $\tau := H(\epsilon/2)$ that can rule out environment $\mu_{\bar{\jmath}}$. Since the exploration phases increase as $\log t$, after $t > \exp\tau$, there are infinitely many exploration steps of size larger than τ. Now, we actually need infinitely many exploration phases of τ *uninterrupted* steps. Let X_t be the event representing an uninterrupted exploration sequence of length at least τ steps starting at time t such that $\alpha_t = 1$, and the actions are all (by chance) following a separation policy. The probability to start an exploration sequence is $\delta_k = \frac{1}{\sqrt{k}}$, the probability to not be interrupted during τ steps is at least $(1-\theta_k)^\tau$, and the probability to follow the policy that can separate $\mu_{\bar{\jmath}}$ from μ is $|\mathcal{A}|^{-\tau}$, where $\mathcal{A}$ is the set of possible actions. Thus, for a given constant τ:

$$\begin{aligned}\sum_{k=1}^{t} P(X_k) &\geq \sum_{k=1}^{t} \alpha_k \delta_k (1-\theta_k)^\tau |\mathcal{A}|^{-\tau} - \mathcal{O}(\tau) \\ &\geq \sum_{k=1}^{t} \alpha_k \frac{1}{\sqrt{k}}\left(\frac{1}{\log k}\right)^\tau |\mathcal{A}|^{-\tau} - \mathcal{O}(\tau)\end{aligned}$$

Considering τ constant, there exists a step t_τ after which $\left(\frac{1}{\log k}\right)^\tau \geq \frac{1}{k^{1/4}}$, then $\forall k \geq t_\tau$:

$$\begin{aligned}\sum_{k=1}^{t} P(X_k) &\geq \sum_{k=1}^{t} \alpha_k \frac{1}{k^{3/4}} |\mathcal{A}|^{-\tau} - \mathcal{O}(\tau) \\ &\geq t^{1/4}\left(\frac{1}{t}\sum_{k=1}^{t}\alpha_k\right)|\mathcal{A}|^{-\tau} - \mathcal{O}(\tau),\end{aligned}$$

$$\lim_{t\to\infty}\sum_{k=1}^{t} P(X_k) = \lim_{t\to\infty} t^{1/4}\epsilon|\mathcal{A}|^{-\tau} - \mathcal{O}(\tau) = \infty.$$

Then the extended Borel-Cantelli Lemma (see Lemma 3 of Singh et al. [2000]) implies that this event happens infinitely often with probability one. Therefore, $\pi^{\bar{\jmath}}$ should be ruled out, which is a contradiction, and hence any such ϵ does not exist and $\pi^{\bar{\jmath}}$ is a WAO-extension of $\pi^{L\theta}$. □

5 CONCLUSION

We have proposed a framework to allow a human operator to repeatedly safely interrupt a reinforcement learning agent while making sure the agent will *not* learn to prevent or induce these interruptions.

Safe interruptibility can be useful to take control of a robot that is misbehaving and may lead to irreversible consequences, or to take it out of a delicate situation, or even to temporarily use it to achieve a task it did not learn to perform or would not normally receive rewards for this.

We have shown that some algorithms like Q-learning are already safely interruptible, and some others like Sarsa are not, off-the-shelf, but can easily be modified to have this property. We have also shown that even an ideal agents that tends to the optimal behaviour in any (deterministic) computable environment can be made safely interruptible. However, it is unclear if all algorithms can be easily made safely interruptible, *e.g.*, policy-search ones [Williams, 1992, Glasmachers and Schmidhuber, 2011].

Another question is whether it is possible to make the interruption probability grow faster to 1 and still keep some convergence guarantees.

One important future prospect is to consider *scheduled interruptions*, where the agent is either interrupted every night at 2am for one hour, or is given notice in advance that an interruption will happen at a precise time for a specified period of time. For these types of interruptions, not only do we want the agent to not resist being interrupted, but this time we also want the agent to take measures regarding its current tasks so that the scheduled interruption has minimal negative effect on them. This may require a completely different solution.

Abstract

We introduce an alternative to reservoir sampling, a classic and popular algorithm for drawing a fixed-size subsample from streaming data in a single pass. Rather than draw a random sample, our approach performs an online optimization which aims to select the subset that provides the best overall approximation to the full data set, as judged using a kernel two-sample test. This produces subsets which minimize the worst-case relative error when computing expectations of functions in a specified function class, using just the samples from the subset. Kernel functions are approximated using random Fourier features, and the subset of samples itself is stored in a random projection tree. The resulting algorithm runs in a single pass through the whole data set, and has a per-iteration computational complexity logarithmic in the size of the subset. These "super-samples" subsampled from the full data provide a concise summary, as demonstrated empirically on mixture models and the MNIST dataset.

1 INTRODUCTION

We receive a stream of samples $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N$, distributed according to an unknown distribution $p(\mathbf{x})$, where N is large and possibly not known ahead of time. Rather than store all the samples for later processing, we would like an online method for selecting a subsample of size M, typically with $M \ll N$, in a single pass through the data N.

Reservoir sampling algorithms [Vitter, 1985] solve exactly this problem: they produce a running subsample, such that for any i from $M, \ldots, N$, the *reservoir* contains a set of M points which themselves are subsampled without replacement from the full stream up through point i. As each new $\mathbf{x}_i$ arrives, the subsample is updated. This update involves swapping the new $\mathbf{x}_i$ with one of the existing M points at random, with appropriate probability. After sweeping through N points, we have a random sample of size M, produced in a single pass through the data, and requiring only $\mathcal{O}(M)$ storage.

In this paper we ask whether instead of subsampling at random, we can change this into a decision problem which at each new $\mathbf{x}_i$ inspects the actual values of our current subset of M points, and aims to ultimately construct a "best" possible subset of a given fixed size.

We take the "best" subset $Y_M = \{\mathbf{y}_j\}_{j=1}^M$, with $Y_M \subset X_N = \{\mathbf{x}_i\}_{i=1}^N$, to be the subset which minimizes the worst-case error when using the small sample Y_M to estimate expectations, instead of the full sample X_N, across all functions f in some function class $\mathcal{F}$. This loss function is known as the *maximum mean discrepancy* (MMD) [Smola et al., 2007] and takes the form

$$\mathcal{L}_{MMD} := \sup_{f \in \mathcal{F}} \left(\frac{1}{N} \sum_{i=1}^{N} f(\mathbf{x}_i) - \frac{1}{M} \sum_{j=1}^{M} f(\mathbf{y}_j) \right). \quad (1)$$

By minimizing the MMD, we construct a subset whose empirical distribution mimics the full data distribution as closely as possible and allows the most accurate estimation of expectations of functions in $\mathcal{F}$. We particularly focus on the case when the function class is the unit ball in a reproducing kernel Hilbert space (RKHS).

As motivation, we note that the empirical estimate of the maximum mean discrepancy between two distributions is used as a statistic for a kernel two-sample test [Gretton et al., 2012], a state-of-the-art nonparametric approach for testing the hypothesis that two sets of samples are drawn from the same underlying distribution (with large values of MMD being evidence against this hypothesis). We will construct our Y_M to be a subset of the full data X_N which minimizes the value of this statistic.

Related work constructing point sets which minimize MMD to a target data distribution includes kernel herding [Chen et al., 2010], which provides a deterministic alternative for sampling from a specified target density, and sequential

Algorithm 1 "Algorithm R" [Vitter, 1985]

Input: Stream of samples $\mathbf{x}_1, \ldots, \mathbf{x}_N$
Output: Subsample $\mathbf{y}_1, \ldots, \mathbf{y}_M$, of size $M \ll N$
  Initialize $\mathbf{y}_1 = \mathbf{x}_1, \ldots, \mathbf{y}_M = \mathbf{x}_M$
  for $n = M+1, \ldots, N$ **do**
    $j \sim \text{Uniform}\{1, \ldots, n\}$
    if $j \leq M$ **then**
      $\mathbf{y}_j = \mathbf{x}_n$
    end if
  end for

Bayesian quadrature [Huszár and Duvenaud, 2012], which selects weighted point sets to minimize the MMD. Both of these methods differ from our approach in that they sequentially generate new points, providing an alternative to drawing random samples from a target density function $p(\mathbf{x})$. Our algorithm provides instead an alternative to random subsampling without replacement, and is designed to be appropriate for processing streaming data online.

We name our approach "super-sampling with a reservoir", after the original paper of Vitter [1985], replacing the random sampling with the "super-sampling" moniker given to the output of the kernel herding Chen et al. [2010]. We provide some background material in Section 2, and then introduce our algorithm in Section 3. Theoretical results are provided in Section 4, with experimental validation in Section 5.

2 BACKGROUND

The simplest reservoir sampling algorithm for unweighted data, introduced as "Algorithm R" by Vitter [1985], is reproduced here in Algorithm 1. After initializing the reservoir set Y_M to the first M values in the stream, the algorithm proceeds by inserting each subsequent $\mathbf{x}_n$, for $n = M+1, \ldots, N$, into the reservoir with probability M/n. During the whole duration of the algorithm, the reservoir always contains a random sample (without replacement) from the n data points observed thus far.

An alternative approach is to imagine drawing a random subsample of size M by assigning a random uniform priority to each of the N items, and then selecting the M with the lowest priorities. This is equivalent to shuffling the N items by sorting them based on a random key, and selecting the first M values; it can be implemented as an online algorithm by storing the M samples in a priority queue, in which all the priorities are assigned at random.

Although such an algorithm has runtime $\mathcal{O}(\log M)$ at each new candidate point $\mathbf{x}_n$, it can be generalized to allow performing reservoir sampling on streams of arbitrarily weighted values [Efraimidis and Spirakis, 2006].

2.1 Kernel embeddings of distributions

Our algorithm will replace the random selection used in Algorithm R with an active selection aiming to minimize Equation (1). This is possible thanks to the properties of reproducing kernel Hilbert spaces and kernel mean embeddings of distributions [Smola et al., 2007; Song, 2008], which we review briefly here. A reproducing kernel Hilbert space $\mathcal{H}$ is a function space equipped with an inner product $\langle \cdot, \cdot \rangle$, and has a symmetric positive-definite reproducing kernel $k(\mathbf{x}, \mathbf{x}')$, where $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$. Elements of $\mathcal{H}$ are functions defined on $\mathcal{X}$. The *reproducing* property of the kernel means that we can write function evaluation as an inner product, where for any function $f \in \mathcal{H}$, we have

$$f(\mathbf{x}) = \langle k(\mathbf{x}, \cdot), f(\cdot) \rangle. \tag{2}$$

This kernel can equivalently be defined as an inner product over an explicit "feature space" mapping $\phi : \mathcal{X} \to \mathcal{H}$, with

$$k(\mathbf{x}, \mathbf{x}') = \langle \phi(\mathbf{x}), \phi(\mathbf{x}') \rangle. \tag{3}$$

The "canonical" feature map is defined as $\phi(\mathbf{x}) = k(\mathbf{x}, \cdot)$, where we see $\langle k(\mathbf{x}, \cdot), k(\mathbf{x}', \cdot) \rangle = k(\mathbf{x}, \mathbf{x}')$; we will use the notation $\phi(\mathbf{x})$ and $k(\mathbf{x}, \cdot)$ interchangeably.

Similarly to how the reproducing kernel acts as an evaluation functional on f, computing $f(\mathbf{x})$ as an inner product, mean embeddings of distributions act as an expectation functional, computing $\mathbb{E}[f]$ as an inner product. For some distribution with density $p(\mathbf{x})$, the kernel mean embedding of a distribution [Smola et al., 2007] is defined as

$$\mu(\cdot) = \int k(\mathbf{x}, \cdot) p(\mathbf{x}) d\mathbf{x}. \tag{4}$$

If $k(\cdot, \cdot)$ is measurable, and $\mathbb{E}[k(\mathbf{x}, \mathbf{x})^{1/2}] < \infty$, then μ exists and $\mu \in \mathcal{H}$ [Gretton et al., 2012]; the mean embedding can then be used to compute expectations of functions $f \in \mathcal{H}$ as

$$\mathbb{E}[f] = \langle \mu, f \rangle. \tag{5}$$

There are two sources of intractability standing in between us and the application of Equation (5): neither evaluating the inner product $\langle \mu, f \rangle$ nor computing the mean embedding μ in Equation (4) are necessarily any simpler than the original integration with respect to $p(\mathbf{x})$. Two approximations will be useful in practice.

First, using a finite set of sample points, we can define an empirical estimate of the mean embedding in Equation (4)

$$\mu_N = \frac{1}{N} \sum_{i=1}^{N} \phi(\mathbf{x}_i), \qquad \mathbf{x}_i \sim p(\mathbf{x}). \tag{6}$$

Note that μ_N itself is still a function in $\mathcal{H}$, and inner products of this estimator correspond to computing empirical finite-sample estimates of expectations, since via the reproducing

property,

$$\langle \mu_N, f \rangle = \frac{1}{N} \sum_{i=1}^{N} \langle \phi(\mathbf{x}_i), f \rangle = \frac{1}{N} \sum_{i=1}^{N} f(\mathbf{x}_i). \quad (7)$$

The second problem is for many common and interesting kernels, the feature map $\phi(\mathbf{x})$ is infinite dimensional (as in e.g. squared exponential kernel and the Laplacian kernel). By considering only the kernel function $k(\mathbf{x}, \mathbf{x}')$, one can avoid needing to explicitly instantiate these features, a benefit known as the "kernel trick". However, for computational purposes, and to make it possible to construct an online algorithm, we will find it advantageous to explicitly instantiate an approximate feature space representation $\hat{\phi}(\mathbf{x}) \in \mathbb{R}^D$. In particular, this can be accomplished with a finite vector of D random Fourier projections [Rahimi and Recht, 2007], where each feature has the form

$$\hat{\phi}(\mathbf{x}) = \sqrt{\frac{2}{D}} \begin{bmatrix} \cos(\boldsymbol{\omega}_1^\top \mathbf{x} + b_1) \\ \vdots \\ \cos(\boldsymbol{\omega}_D^\top \mathbf{x} + b_D) \end{bmatrix}. \quad (8)$$

Each $\boldsymbol{\omega}_d$ is drawn from the distribution $p(\boldsymbol{\omega})$ which arises by taking the Fourier transform of the kernel, and each b_d is uniform on $[0, 2\pi]$; Bochner's theorem [Bochner, 1959] guarantees that for any shift invariant positive-definite kernel $k(\mathbf{x}, \mathbf{x}')$, its Fourier transform is a finite and nonnegative measure, so $p(\boldsymbol{\omega})$ can be assumed to be a probability distribution. The random Fourier features $\hat{\phi}(\mathbf{x}) \in \mathbb{R}^D$ approximate the true (possibly infinite-dimensional) feature map $\phi(\mathbf{x}) \in \mathcal{H}$. An approximating kernel defined by taking the inner product of the approximate feature maps, i.e. $k(\mathbf{x}, \mathbf{x}') \approx \hat{\phi}(\mathbf{x})^\top \hat{\phi}(\mathbf{x}')$, provides an unbiased estimate of evaluations of the kernel function [Rahimi and Recht, 2007], with

$$\mathbb{E}_{\boldsymbol{\omega}, \mathbf{b}}[\hat{\phi}(\mathbf{x})^\top \hat{\phi}(\mathbf{x}')] = k(\mathbf{x}, \mathbf{x}'). \quad (9)$$

Taken together with Equation (6), we can thus approximate the mean embedding using random Fourier features evaluated at finite sample points as

$$\hat{\mu}_N = \frac{1}{N} \sum_{i=1}^{N} \hat{\phi}(\mathbf{x}_i), \quad (10)$$

yielding an explicit representation of the distribution $p(\mathbf{x})$ as a vector in $\mathbb{R}^D$.

Now, consider how we can use this representation to approximate $\mathcal{L}_{MMD}$ in Equation (1). Following Gretton et al. [2012], we take our test function space to be the unit ball in $\mathcal{H}$, i.e. with

$$\mathcal{F} = \{f : f \in \mathcal{H}, ||f||_{\mathcal{H}} \leq 1\}, \quad (11)$$

where the Hilbert space norm is defined as

$$||f||_{\mathcal{H}} = \langle f, f \rangle^{1/2}. \quad (12)$$

Define a second empirical estimate of the mean embedding

$$\nu_M = \frac{1}{M} \sum_{j=1}^{M} \phi(\mathbf{y}_j), \qquad \mathbf{y}_j \in Y_M \subset X, \quad (13)$$

on the small subset of the full points in the set $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$. We then rewrite the maximum mean discrepancy as an RKHS norm [Borgwardt et al., 2006; Gretton et al., 2012, Lemma 4], with

$$\begin{aligned} \mathcal{L}_{MMD} &= \sup_{f \in \mathcal{F}} \Big(\langle \mu_N, f \rangle - \langle \nu_M, f \rangle \Big) \\ &= \sup_{f \in \mathcal{F}} \langle \mu_N - \nu_M, f \rangle \\ &= ||\mu_N - \nu_M||_{\mathcal{H}}. \end{aligned} \quad (14)$$

Thus, to minimize the MMD we just need to select our points in Y_M such that this RKHS norm is as small as possible. Using random Fourier features approximations for $\hat{\mu}_N$ and $\hat{\nu}_M$ allows us to define a computationally efficient estimator for $\mathcal{L}_{MMD}$ which we can update online while processing the sample points in X. If our set of subsampled points Y_M has $\hat{\nu}_M \approx \hat{\mu}_N$, then we can use those points to evaluate expectations in a way that approximates expectations w.r.t. the full sample set.

3 STREAMING SUBSET SELECTION

We now introduce a sequential optimization algorithm for minimizing the MMD between the streaming data and our local subset. Analogous to reservoir sampling, at any stage of the algorithm we have a reservoir Y_M which contains points drawn without replacement from X_N, representing our current approximation to the distribution of the first n data points. Globally, this procedure takes the form of a greedy optimization algorithm in which a new candidate point $\mathbf{x}_i$ is inserted into our set Y_M, replacing an existing element when the substitution reduces the MMD. Locally, at each candidate point, we must solve an inner optimization problem to decide whether to keep $\mathbf{x}_i$, and if so, which of the $\mathbf{y}_j$ it should replace.

Samples $\mathbf{x}_i$ arrive sequentially; let X_n denote the subset of X comprising the first n points, and let Y_M^n denote the subset of M points selected after processing the points in X_n, with $Y_M \equiv Y_M^N$ the subset selected after all points in X have been processed. As in a standard reservoir sampling algorithm we initialize Y_M^M to be $\mathbf{x}_1, \ldots, \mathbf{x}_M$, i.e. the first M points. We will keep running estimates of the kernel mean embeddings

$$\hat{\mu}_n = \frac{1}{n} \sum_{i=1}^{n} \hat{\phi}(\mathbf{x}_i), \qquad \mathbf{x}_i \in X_n \quad (15)$$

$$\hat{\nu}_M^n = \frac{1}{M} \sum_{j=1}^{M} \hat{\phi}(\mathbf{y}_j), \qquad \mathbf{y}_j \in Y_M^n. \quad (16)$$

These are (respectively) the Monte Carlo estimate of the true mean element μ from the first n samples $\mathbf{x}_1, \ldots, \mathbf{x}_n$, and the estimate of μ recovered from the M values selected from the first n, with random Fourier features $\hat{\phi} : \mathcal{X} \to \mathbb{R}^D$ defining an explicit feature space.

From the expression in Equation (14), we define an estimator of the MMD based on these random feature expansions after seeing n data points as

$$\widehat{\mathcal{L}}_{MMD} = ||\hat{\mu}_n - \hat{\nu}_M^n||_2. \tag{17}$$

Suppose we have seen $n-1$ candidates thus far and are now considering some $\mathbf{x}_n$. Note we can do a sequential update

$$\hat{\mu}_n = \frac{n-1}{n}\hat{\mu}_{n-1} + \frac{1}{n}\hat{\phi}(\mathbf{x}_n). \tag{18}$$

A similarly simple incremental update is possible when the sample stream X is comprised of weighted samples. If we suppose every point x_n has an associated nonnegative weight w_n, we must additionally track the running sum of all weights $\bar{w}_n = \sum_{i=1}^n w_i$, and perform updates

$$\hat{\mu}_n = \frac{\bar{w}_{n-1}}{\bar{w}_{n-1} + w_n}\hat{\mu}_{n-1} + \frac{w_n}{\bar{w}_{n-1} + w_n}\hat{\phi}(\mathbf{x}_n), \tag{19}$$

with $\bar{w}_n = \bar{w}_{n-1} + w_n$. We recover the update in Equation (18) for unweighted sample sets if all weights are identically $w_i = 1$.

We need to decide whether or not the new $\mathbf{x}_n$ should replace an existing $\mathbf{y}_j \in Y_M^{n-1}$, or if it should be ignored. This means there are $M+1$ possible candidates for $\hat{\nu}_M^n$; we want to determine which substitution minimizes $\widehat{\mathcal{L}}_{MMD}$. A naïve approach is to compute the $\hat{\nu}_M^n$ for all $M+1$ options, and choose that which yields the smallest $\widehat{\mathcal{L}}_{MMD}$. This gives an overall algorithm in which we perform an $\mathcal{O}(MD)$ computation for each new candidate point, though this approach can be made reasonably efficient through incremental computation of the possible values of $\widehat{\mathcal{L}}_{MMD}$. We instead focus on providing an approximate optimization here with runtime logarithmic in M.

3.1 Formulation as nearest neighbor search

An alternate way of formulating the inner per-datapoint problem of selecting whether and where to swap in a candidate point $\mathbf{x}_n$, instead of as an optimization problem where we minimize $\widehat{\mathcal{L}}_{MMD}$, is as a nearest-neighbor search. As each new candidate point $\mathbf{x}_n$ arrives, we have an existing subsample estimate $\hat{\nu}_M^{n-1}$, and compute an updated running estimate $\hat{\mu}_n$. Consider the "expanded" estimator for the mean embedding defined as

$$\hat{\nu}_{M+1}^n \triangleq \frac{M}{M+1}\hat{\nu}_M^{n-1} + \frac{1}{M+1}\hat{\phi}(\mathbf{x}_n) \tag{20}$$

which incorporates the new point $\mathbf{x}_n$ alongside the existing M point estimate, by averaging the feature maps of all points in $Y_{M+1}^{n-1} := \{\mathbf{x}_n\} \cup Y_M^{n-1}$. Equation (20) is also an approximation to $\hat{\mu}_n$, but using $M+1$ total points. Any next estimator $\hat{\nu}_M^n$ for $\hat{\mu}_n$ using only M points can be found by discarding a single one of the points in Y_{M+1}^{n-1}. For whichever point $\mathbf{y}^{drop}$ we choose to discard, we can then express $\widehat{\mathcal{L}}_{MMD}$ using the expanded estimator $\hat{\nu}_{M+1}^n$, with

$$\hat{\nu}_M^n = \frac{M+1}{M}\hat{\nu}_{M+1}^n - \frac{1}{M}\hat{\phi}(\mathbf{y}^{drop}). \tag{21}$$

Selecting the best $\hat{\nu}_M^n$ to minimize $\widehat{\mathcal{L}}_{MMD} = ||\hat{\mu}_n - \hat{\nu}_M^n||_2$ then corresponds to solving an optimization problem

$$\mathbf{y}^{drop} = \underset{\mathbf{y} \in Y_{M+1}^{n-1}}{\operatorname{argmin}} \left|\left|\hat{\mu}_n - \frac{M+1}{M}\hat{\nu}_{M+1}^n + \frac{1}{M}\hat{\phi}(\mathbf{y})\right|\right|_2 \tag{22}$$

in which we select the $\mathbf{y}_j$ to remove, such that the estimate $\widehat{\mathcal{L}}_{MMD}$ from the resulting Y_M^n is minimized. If there were a somehow "perfect" choice of $\mathbf{y}_j$ to remove, then this would bring the quantity on the right of Equation (22) to zero. By setting Equation (22) to zero, solving for ideal feature vector $\hat{\phi}(\mathbf{y})$, and then using Equation (20) to expand out $\hat{\nu}_{M+1}^N$ we find the optimal choice of feature vector to remove would be

$$\phi^\star = \hat{\phi}(\mathbf{x}_n) + M(\hat{\nu}_M^{n-1} - \hat{\mu}_n). \tag{23}$$

In general, none of our current $\phi(\mathbf{y}_j) = \phi^\star$ exactly, but we can still try to get as close as possible. Since we have explicit feature vectors $\hat{\phi}(\mathbf{y}_j) \in \mathbb{R}^D$ and $\phi^\star \in \mathbb{R}^D$, we can thus find the best choice $\mathbf{y}^{drop}$ by considering

$$\begin{aligned}\mathbf{y}^{drop} &= \underset{\mathbf{y} \in Y_M^{n-1}}{\operatorname{argmin}} \left|\left|\hat{\phi}(\mathbf{y}) - \phi^\star\right|\right|_2^2 \\ &= \underset{\mathbf{y} \in Y_M^{n-1}}{\operatorname{argmin}} \sum_{d=1}^{D} \left(\hat{\phi}(\mathbf{y})_d - \phi_d^\star\right)^2.\end{aligned} \tag{24}$$

Algorithm 2 Streaming MMD Minimization

Input: Stream of samples $\mathbf{x}_1, \ldots, \mathbf{x}_N$;
explicit feature map $\phi : \mathcal{X} \to \mathbb{R}^D$
Output: Subset $Y_M = \{\mathbf{y}_1, \ldots, \mathbf{y}_M\}$
Initialize $\mathbf{y}_1 = \mathbf{x}_1, \ldots, \mathbf{y}_M = \mathbf{x}_M$
Compute initial mean estimates $\hat{\nu}_M^M$ and $\hat{\mu}_M$ Eq. (6)
for $n = M+1, \ldots, N$ **do**
  Update $\hat{\mu}_n$ to include $\phi(\mathbf{x}_n)$ Eq. (18) or (19)
  Compute target $\phi^\star$ Eq. (23)
  if NEARESTNEIGHBOR$_{\phi^\star}(\{\mathbf{x}_n\} \cup Y_M)$ in Y_M **then**
    $\hat{\nu}_M^n \leftarrow \hat{\nu}_M^{n-1} + \frac{1}{M}\left(\phi(\mathbf{x}_n) - \phi(\mathbf{y}_j)\right)$
    $\mathbf{y}_j = \mathbf{x}_n$
  else
    $\hat{\nu}_M^n \leftarrow \hat{\nu}_M^{n-1}$
  end if
end for

This minimum can by found by performing a D-dimensional nearest-neighbor search. The easiest option for this is still to scan through all $M+1$ candidates and compute each distance in Equation (24). However for large M we can use an approximate nearest neighbor search to reduce the overall runtime of each iteration. The overall streaming MMD minimization algorithm is given in Algorithm 2, where the function $\text{NEARESTNEIGHBOR}_{\phi^\star}(Y)$ is an exact or approximate procedure for selecting the nearest neighbor (in Euclidean distance) to $\phi^\star$ in the set Y.

3.2 Approximate nearest neighbor search

Exact nearest neighbor search in more than a small number of dimensions remains a challenging problem; we are likely to use order a few hundred random features D. Classic approaches such as KD-trees [Bentley, 1975] which are based on coordinate-aligned splits tend to break down in such settings, requiring very deep trees in order to partition the data. However, there is some hope for *approximate* nearest neighbor search, where we are willing to not necessarily find the best choice, but merely a "sufficiently close" neighbor, based on theory of intrinsic dimensionality [Johnson and Lindenstrauss, 1984].

Random projection trees are introduced in Freund et al. [2007], based on the observation that for high dimensional datasets, partitioning data into subsets based on a completely random projection direction is nearly as good as the optimal partition direction. With this in mind, to implement a fast approximate nearest neighbor search, define hash functions

$$h(\phi) = \text{sign}(\mathbf{r}^\top \phi - s) \tag{25}$$

where $\mathbf{r} \in \mathbb{R}^D$ is a random unit vector and s is a random split point. We place these hash functions at each nodes in a binary search tree; values ϕ which hash to a positive value are sent to the right subtree, those which hash to a negative value are sent left. This tree resembles a KD-tree, except with random projections splits instead of axis-aligned splits.

If we have L hash functions, arranged in a binary tree, we need to evaluate $\log_2 L$ when considering each new candidate point, and again when accepting a new point $\mathbf{x}_n$ into the set Y_M^n. For each point $\mathbf{y}_j$ in our subset, we cache which leaf node of the binary tree it falls in. In practice there may be several points in each leaf node, but instead of evaluating all M points in Y_M to check whether it is closest to $\phi^\star$, we only check however many are in the leaf.

Our particular random projection tree variant we implement is as described in Dasgupta and Sinha [2015]. We construct an initial tree from the first M points by sampling random vectors $\mathbf{r}$, and setting each split point s to be a uniform random quantile in $[0.25, 0.75]$ of the projected values at that node. This tree will have points evenly distributed among the leaves; however, as we swap out points it may become less balanced. To deal with this we periodically recompute the split points, rebalancing the tree; this operation is performed sufficiently rarely as to maintain amortized logarithmic cost. A free parameter in the search tree is the search tree depth (or equivalently, how many values ϕ to keep in each leaf node). In all our later experiments this is set to target approximately $2\log_2 M$ nodes per leaf.

Theoretical results in Dasgupta and Sinha [2015] characterize the loss relative to an exact search; we compare the exhaustive nearest neighbor search and approximate results empirically in our particular setting in Section 5.

4 BOUNDS ON SUBSET ERROR

At any point in the algorithm, it is straightforward to use our current distribution embedding approximations to compute $\widehat{\mathcal{L}}_{MMD} = ||\hat{\mu}_n - \hat{\nu}_M^n||_2$. It would be nice to characterize how this estimate compares to the true maximum mean discrepancy. In this section, we derive bounds for the estimation error which occurs due to using our size M subset to compute expectations, instead of using the full size N set. Above and beyond the implicit Monte Carlo error in using the points in X to approximate expectations with respect to $p(\mathbf{x})$, our procedure introduces additional error by restricting to only M of N total points, and using random Fourier features to approximate the kernel.

The online algorithm we use to sample from a stream is only possible when we have an explicit feature space representation. Following Sutherland and Schneider [2015], we can use bounds on the error introduced by approximating the kernel function with random Fourier features to provide bounds on the estimation error introduced by using only the subset $Y_M \subset X_N$. Being careful of the difference between the empirical mean embeddings $\mu_N, \nu_M \in \mathcal{H}$, and their random Fourier feature approximations $\hat{\mu}_N, \hat{\nu}_M \in \mathbb{R}^D$, we can compare two empirical estimates of the squared MMD, one using the (intractable) features $\phi(\mathbf{x})$, the other using the random Fourier features $\hat{\phi}(\mathbf{x})$:

$$\mathcal{L}^2_{MMD} = ||\mu_N - \nu_M||^2_{\mathcal{H}} \tag{26}$$

$$\widehat{\mathcal{L}^2}_{MMD} = ||\hat{\mu}_N - \hat{\nu}_M||_2^2 = \sum_{d=1}^{D} \left(\hat{\mu}_d^N - \hat{\nu}_d^M\right)^2. \tag{27}$$

The squared MMD $\mathcal{L}^2_{MMD}$ can be decomposed as [Gretton et al., 2012]

$$\mathcal{L}^2_{MMD} = \frac{1}{N^2}\sum_{i,i'} k(\mathbf{x}_i, \mathbf{x}_{i'}) + \frac{1}{M^2}\sum_{j,j'} k(\mathbf{y}_j, \mathbf{y}_{j'}) - \frac{2}{NM}\sum_{i,j} k(\mathbf{x}_i, \mathbf{y}_j),$$

with a matching expansion for $\widehat{\mathcal{L}^2}_{MMD}$, and since the random Fourier features [Rahimi and Recht, 2007] provide an unbiased estimate of $k(\mathbf{x}, \mathbf{x}')$ as in Equation (9), we have

$$\mathbb{E}\left[\widehat{\mathcal{L}^2}_{MMD}\right] = \mathcal{L}^2_{MMD}. \tag{28}$$

Now, directly following Sutherland and Schneider [2015, section 3.3], we view $\widehat{\mathcal{L}^2}_{MMD}$ as a function of the random variables $\{\boldsymbol{\omega}_d, b_d\}$ and consider how changing any one of these random variables modifies $\widehat{\mathcal{L}^2}_{MMD}$. The random Fourier feature approximation to the kernel decomposes into a sum across all D features as

$$k(\mathbf{x}, \mathbf{x}') = \sum_{d=1}^{D} \mathbb{E}_{\boldsymbol{\omega}_d, b_d}[\hat{\phi}_d(\mathbf{x})\hat{\phi}_d(\mathbf{x}')] \tag{29}$$
$$= \frac{2}{D}\sum_{d=1}^{D} \mathbb{E}_{\boldsymbol{\omega}_d, b_d}[\cos(\boldsymbol{\omega}_d^\top \mathbf{x} + b_d)\cos(\boldsymbol{\omega}_d^\top \mathbf{x}' + b_d)].$$

Since $\cos(\cdot)$ is bounded by $\{-1, 1\}$, modifying either $\boldsymbol{\omega}_d$ or b_d changes a single term in the sum at the right of Equation (29) by at most 2, and thus changes the overall random feature approximation to the kernel by at most $4/D$. This in turn bounds the change in $\widehat{\mathcal{L}^2}_{MMD}$ by at most $16/D$. Then from the bounded differences inequality of McDiarmid [1989] we have

$$\Pr\left(\mathcal{L}^2_{MMD} - \widehat{\mathcal{L}^2}_{MMD} \geq \epsilon\right) \leq e^{-\frac{D\epsilon^2}{128}}. \tag{30}$$

An algebraic rearrangement of Equation (30) can be used to provide an upper bound in probability for $\mathcal{L}^2_{MMD}$. We have, with probability at least $1-\delta$,

$$\mathcal{L}^2_{MMD} - \widehat{\mathcal{L}^2}_{MMD} \leq \sqrt{\frac{128\log(1/\delta)}{D}}$$

which combined with our estimator for $\widehat{\mathcal{L}^2}_{MMD}$ yields

$$\mathcal{L}^2_{MMD} \leq \sqrt{\frac{128\log(1/\delta)}{D}} + \sum_{d=1}^{D}\left(\hat{\mu}_d^N - \hat{\nu}_d^M\right)^2.$$

This directly translates into bounds on the error, due to subsampling, in estimating the average $\frac{1}{N}\sum_{i=1}^{N} f(\mathbf{x}_i)$ of any function $f \in \mathcal{H}$ over the full dataset, since we have

$$\left|\frac{1}{N}\sum_{i=1}^{N} f(\mathbf{x}_i) - \frac{1}{M}\sum_{j=1}^{M} f(\mathbf{y}_j)\right|^2 = \left|\langle \mu_N - \nu_M, f\rangle\right|^2$$
$$\leq ||f||^2_{\mathcal{H}}\, ||\mu_N - \nu_M||^2_{\mathcal{H}}$$
$$= ||f||^2_{\mathcal{H}}\, \mathcal{L}^2_{MMD}.$$

Thus the worst-case squared error introduced by using the subsampled points for any $f \in \mathcal{F}$ can be bounded by the empirical squared error in the estimated mean embedding vectors, plus an error term due to the random Fourier feature approximation. We summarize this result as the following Theorem.

Theorem 1 *Let $\hat{\mu}_N, \hat{\nu}_M \in \mathbb{R}^D$ be estimates of the mean embedding from D random Fourier features, defined on sets of points X_N and $Y_M \subset X_N$. Then, with probability at least $1-\delta$,*

$$\mathcal{L}^2_{MMD} = \sup_{f\in\mathcal{F}}\left|\frac{1}{N}\sum_{i=1}^{N} f(\mathbf{x}_i) - \frac{1}{M}\sum_{j=1}^{M} f(\mathbf{y}_j)\right|^2$$
$$\leq \sqrt{\frac{128\log(1/\delta)}{D}} + \sum_{d=1}^{D}\left(\hat{\mu}_d^N - \hat{\nu}_d^M\right)^2.$$

We note that this result can be combined with existing bounds from e.g. Song [2008] on $||\mu_N - \mu||_{\mathcal{H}}$ to characterize overall error in estimating of expectations from the points in Y_M relative to true expected values $\mathbb{E}[f]$ over the population distribution of $\{\mathbf{x}_i\}$.

5 EXPERIMENTS

We run a variety of empirical tests to quantify the performance and characteristics of this algorithm. In addition to benchmarking against to random subsampling, we also compare to a benchmark of using a random Fourier features implementation of kernel herding [Chen et al., 2010]. The kernel herding algorithm is a method for sequentially generating M points, which performs a greedy optimization on the same approximation to the MMD targeted by our online algorithm; however, it is not an algorithm for processing streaming data as it requires the estimate $\hat{\mu}_N$ as computed from the full sample set as input, and furthermore it requires a potentially expensive optimization operation for generating each new point.

We also confirm experimentally that the approximation error due to the inexact nearest neighbor search does not significantly impact overall performance.

5.1 Mixtures of Gaussians

Our initial test model is a multivariate mixture of Gaussians, as considered in both Chen et al. [2010] and Huszár and Duvenaud [2012]. We experiment with downsampling a set of $N = 100,000$ points drawn from a 2-dimensional mixture of 10 Gaussians to a target set of size $M = 100$. We use a squared exponential kernel

$$k(\mathbf{x}, \mathbf{x}') = \exp\left\{-\frac{||\mathbf{x} - \mathbf{x}'||_2^2}{2\gamma^2}\right\} \tag{31}$$

where the lengthscale γ is set to the median pointwise distance between the first M points; this is known as the median heuristic [Gretton et al., 2012]. We approximate the basis functions with $D = 200$ random Fourier features of the form in Equation (8), where each ω element is drawn from a normal distribution with zero mean and standard deviation γ^{-1}.

An example mixture of Gaussians target density and the selected points are shown in Figure 1, alongside a plot of the

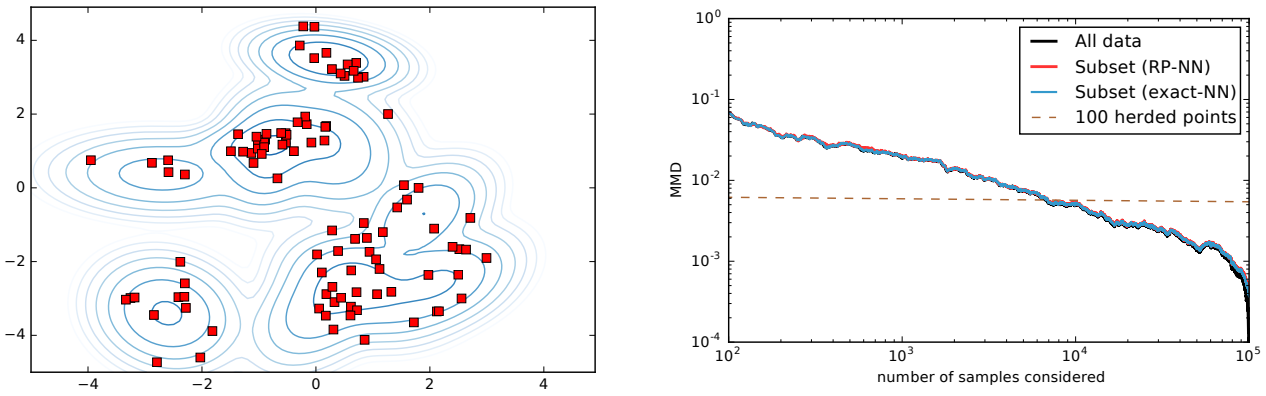

Figure 1: **(Left)** The final 100 selected points in the 2d Gaussian mixture, using the approximate nearest neighbor search. **(Right)** The empirical MMD estimate between $\hat{\mu}_n$ and $\hat{\mu}_N$, as well as between $\hat{\nu}_M^n$ and $\hat{\mu}_N$, as $n \to N$, when selecting a subset of size $M = 100$. The red line uses the random projection search tree; the blue line uses a linear scan of all options to perform an exact nearest-neighbor search. The subset estimates track the all-data MMD $\hat{\mu}_n$ very closely, despite subsampling, and even despite the approximate search. Both methods are initialized from the same set of randomly sampled points. The herding benchmark consists of M points to approximate $\hat{\mu}_N$. All estimates are averaged over 10 different synthetic datasets, drawn from mixtures of Gaussians with different parameters.

convergence of the maximum mean discrepancy estimates $||\hat{\mu}_N - \hat{\mu}_n||_2$ and $||\hat{\mu}_N - \hat{\nu}_M^n||_2$. As we view more data points, the running estimate $\hat{\mu}_n$ gradually approaches the full-data estimate $\hat{\mu}_N$. We compare to two implementations of the subsampling algorithm for selecting Y_M^n and computing $\hat{\nu}_M^n$ — one using the approximate nearest neighbor search, and one using a linear scan for an exact nearest neighbor search — and see that in both cases the running estimate based on the subsample very closely tracks the full data estimate. The overall difference in performance between the two methods is negligible despite making far fewer comparisons per iteration of the algorithm.

The herding benchmark consists of the first $M = 100$ points selected by the kernel herding [Chen et al., 2010], targeting $\hat{\mu}_N$. Theoretical results for herding suggest that the sample efficiency of the first 100 herded points should approximately match the first 10,000 random samples.

Figure 2 shows the empirical distribution over the number of comparisons actually made while searching for $\mathbf{y}^{drop}$ at each iteration when using the random projection tree for nearest neighbor search.

In Figure 3 we compare the error in computing expectations using our subsampled points, testing on the same set of functions used as a benchmark in Chen et al. [2010]. We find that the mean squared error on these test functions closely tracks the error from the full set of points. This is a remarkably promising result: expectations with respect to the full data converge at the Monte Carlo rate, and the subset of $M = 100$ points continues to perform comparably even at $N = 100,000$, for three of four test functions, and reliably outperforms both the random sampling and herding benchmarks.

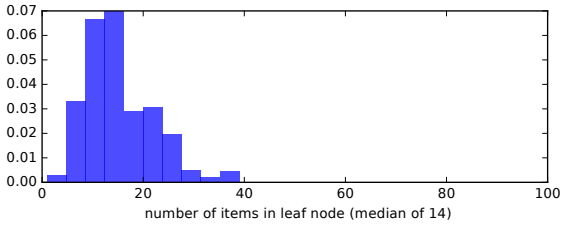

Figure 2: The actual number of comparisons made by the algorithm for processing each new data point is the same as the number of items encountered in each leaf of the random projection search tree; a full scan would require $M = 100$ comparisons, while here the median was 14. In the 2d Gaussian mixture example, we have a tree with depth 3, with an expected 12.5 items in each leaf. Compared to running a full scan, the tree-search version made the best overall decision 97.8% of the time.

5.2 Data summarization

This procedure can also be used to efficiently summarize high dimensional data, through a small handful of exemplars. We demonstrate this on $10,000$ digits taken from the MNIST dataset, reduced to be represented by a subset of size $M = 30$ in Figure 4. Each element in the MNIST image dataset is a 28×28 image of a single hand-written numeric digit, with $\mathbf{x}_i \in [0,1]^{768}$. Again, we simply use a squared exponential kernel, with lengthscale set to the median of the first M points, and $D = 200$ random features.

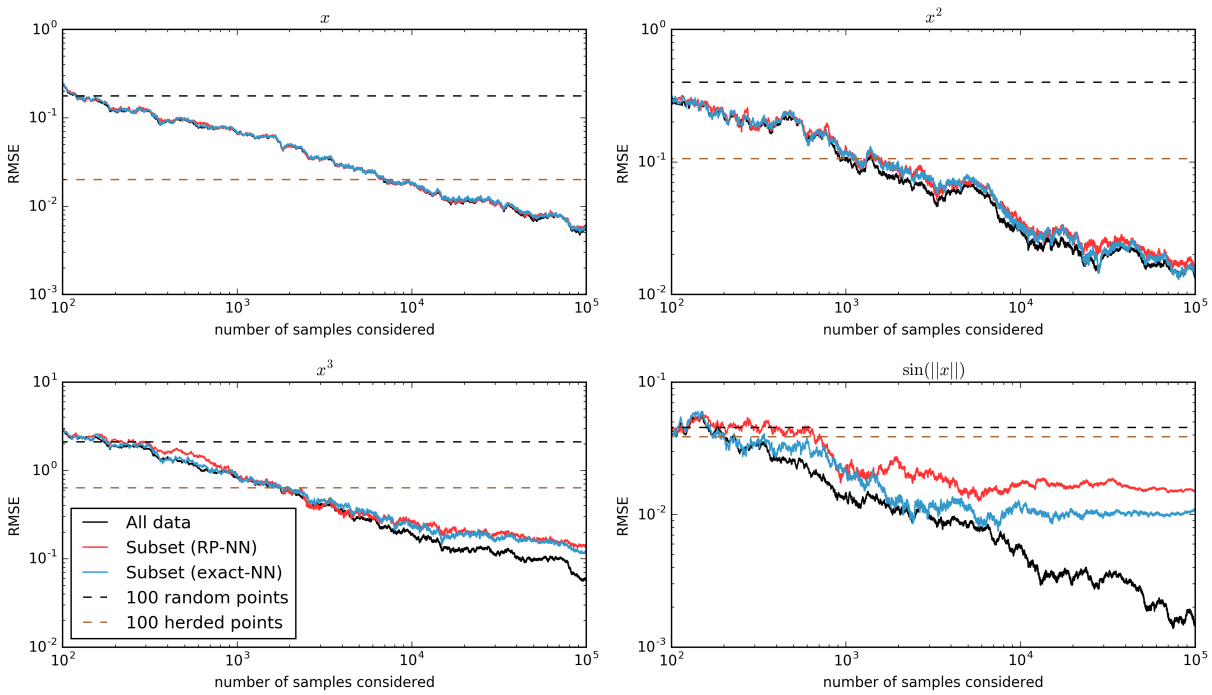

Figure 3: Error plots for expectations of four test functions: $\mathbf{x}$, $\mathbf{x}^2$, $\mathbf{x}^3$, and $\sin(||\mathbf{x}||_2)$. Legend is shared across subplots. The error is root mean squared error (RMSE) across dimensions of the test function, relative to a ground truth value computed on a separate sample of 2×10^7 points. The "random" benchmark is the median RMSE across 100 different random subsets of size $M = 100$; the "herding" benchmark is the RMSE from the first 100 herded points, targeting $\hat{\mu}_N$. We can also judge the loss of accuracy in using the approximate nearest neighbor search: there is a qualitative difference only in the $\sin(||\mathbf{x}||_2)$ example, where there is plateau in convergence for both methods. All estimates are averaged over 10 different synthetic datasets, drawn from mixtures of Gaussians with different parameters.

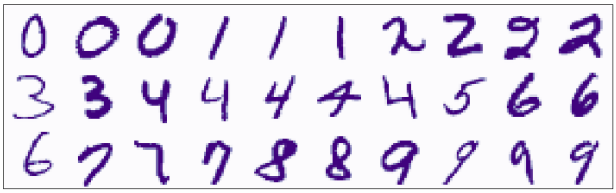

Figure 4: We summarize the MNIST digits dataset with a small number of exemplars. The subsampled set of points provides good coverage for the different digits, and also shows variation in style and form within each digit. The subsampling algorithm was given only the unlabeled digits.

The result summarizes the MNIST digits far better than a random sample would, and enormously better than other simple techniques for visualizing high-dimensional data, such as computing marginal means or quantiles across each dimension. We see a small number of exemplars from each of the 10 digits, with a good variety of handwriting styles expressed.

5.3 Resampling output of an importance sampler

One advantage of this algorithm relative to standard reservoir sampling is that it is trivially modified to run on weighted streaming data, requiring only changing the way in which the running average $\hat{\mu}_n$ is computed from Equation (18) to Equation (19). A promising use of this algorithm is to resample the output from sampling schemes such as importance sampling and sequential Monte Carlo methods, which return large numbers of weighted sets of samples. We may wish to resample from these weighted samples to obtain a new unweighted set of particles; such a resampling step is also used within sequential Monte Carlo as a means of reducing particle degeneracy [Douc et al., 2005].

As an illustrative example, we run this algorithm on the output of an importance sampler targeting a simple one-dimensional mixture distribution, proposing from a broad Gaussian prior. The results are shown in Figure 5, showing the incremental progress as the algorithm processes more points (i.e., as n increases), for a variety of small values of M. Due to the small number of points M being selected, we can see that as n becomes large, the selected points roughly approximate the quantiles of the bimodal mixture model.

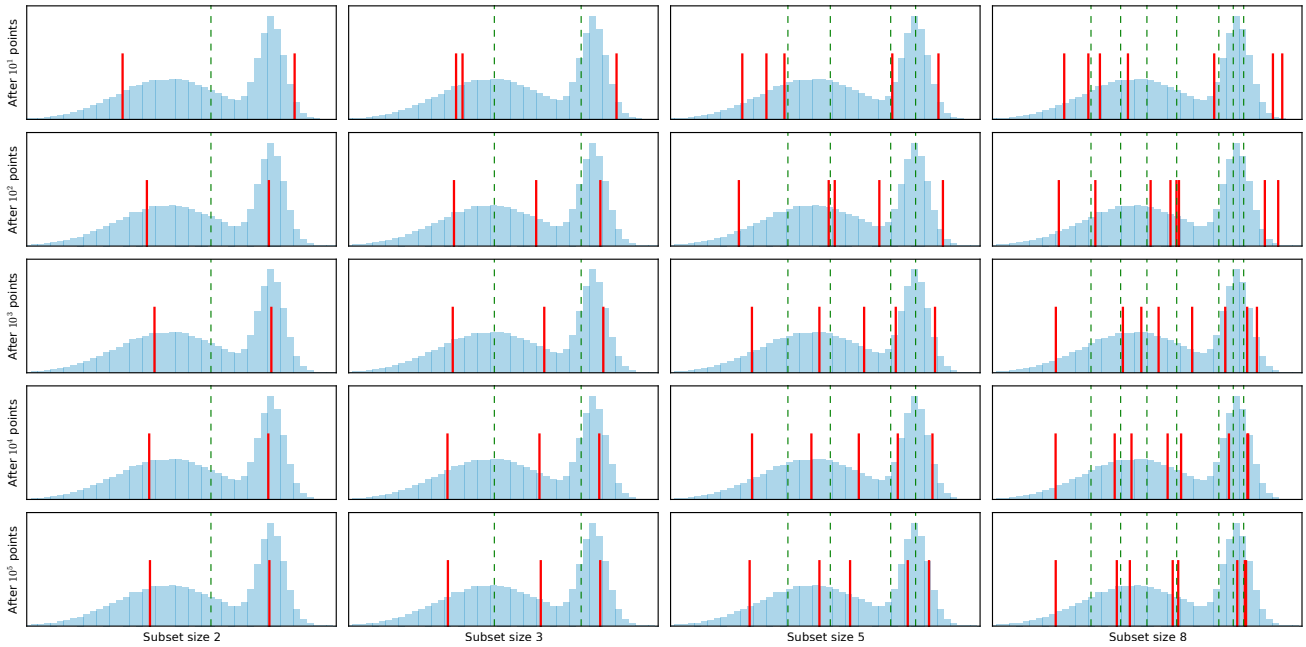

Figure 5: Downsampling points from an importance sampler. Selected points shown in red, with separate runs in each column for $M = 2, 3, 5, 8$, showing the results after observing each of $N = 10, 10^2, 10^3, 10^4, 10^5$. The green dashed lines split the probability density function of the blue target density into regions of equal probability. As N increases, the selected points approximate an even weighting across the probability density.

That is, in this example we see empirically that the points are selected such that they partition the target density $p(\mathbf{x})$ into regions of equal probability mass.

6 DISCUSSION

Reservoir sampling is a popular algorithm for drawing "manageable" subsets from large data, for both reasons of computer memory limitations, and for human visualization. For either of these purposes, our reservoir super-sampling algorithm can be used as a drop-in replacement which provides improved performance when subsampling from any data for which a kernel function can be defined.

When sampling from a weighted set of points, then the computational complexity of this algorithm is of the same order in M and N as the random sampling algorithm of [Efraimidis and Spirakis, 2006], while providing performance in computing expectations which far closer emulates computing expectations from the full data stream. This subsampling method, which explicitly use the values of the different points, could perhaps be used as a replacement for traditional resampling in sequential Monte Carlo methods, which only consider the particle weights and not the actually values at each point. Such an approach may be advantageous in settings such as considered in Jun and Bouchard-Côté [2014], where the memory usage for storing the particle set is the primary bottleneck.

Although the algorithm aims only to minimize the maximum mean discrepancy, there is evidence from the MNIST example and the point locations in the importance sampling reweighting that the selected points also have a promising use in general situations where one might want to summarize data with a small number of representative points.

As future work, we also hope to investigate the relationship between these selected locations and other methods for constructing low-discrepancy point sets.

Alternative Markov and Causal Properties for Acyclic Directed Mixed Graphs

Jose M. Peña
Department of Computer and Information Science
Linköping University

Abstract

We extend Andersson-Madigan-Perlman chain graphs by (i) relaxing the semidirected acyclity constraint so that only directed cycles are forbidden, and (ii) allowing up to two edges between any pair of nodes. We introduce global, and ordered local and pairwise Markov properties for the new models. We show the equivalence of these properties for strictly positive probability distributions. We also show that when the random variables are continuous, the new models can be interpreted as systems of structural equations with correlated errors. This enables us to adapt Pearl's *do*-calculus to them. Finally, we describe an exact algorithm for learning the new models from observational and interventional data via answer set programming.

1 INTRODUCTION

Chain graphs (CGs) are graphs with possibly directed and undirected edges but without semidirected cycles. They have been extensively studied as a formalism to represent probabilistic independence models, because they can model symmetric and asymmetric relationships between random variables. Moreover, they are much more expressive than directed acyclic graphs (DAGs) and undirected graphs (UGs) (Sonntag and Peña, 2016). There are three different interpretations of CGs as independence models: The Lauritzen-Wermuth-Frydenberg (LWF) interpretation (Lauritzen, 1996), the multivariate regression (MVR) interpretation (Cox and Wermuth, 1996), and the Andersson-Madigan-Perlman (AMP) interpretation (Andersson et al., 2001). No interpretation subsumes another (Andersson et al., 2001; Sonntag and Peña, 2015). Moreover, AMP and MVR CGs are coherent with data generation by block-recursive normal linear regressions (Andersson et al., 2001).

Richardson (2003) extends MVR CGs by (i) relaxing the semidirected acyclity constraint so that only directed cycles are forbidden, and (ii) allowing up to two edges between any pair of nodes. The resulting models are called acyclic directed mixed graphs (ADMGs). These are the models in which Pearl's *do*-calculus operates to determine if the causal effect of an intervention is identifiable from observed quantities (Pearl, 2009). In this paper, we make the same two extensions to AMP CGs. We call our ADMGs alternative as opposed to the ones proposed by Richardson, which we call original. It is worth mentioning that neither the original ADMGs nor any other family of mixed graphical models that we know of (e.g. summary graphs (Cox and Wermuth, 1996), ancestral graphs (Richardson and Spirtes, 2002), MC graphs (Koster, 2002) or loopless mixed graphs (Sadeghi and Lauritzen, 2014)) subsume AMP CGs and hence our alternative ADMGs. To see it, we refer the reader to the works by Richardson and Spirtes (2002, p. 1025) and Sadeghi and Lauritzen (2014, Section 4.1). Therefore, our work complements the existing works.

The rest of the paper is organized as follows. Section 2 introduces some preliminaries. Sections 3 and 4 introduce global, and ordered local and pairwise Markov properties for our ADMGs, and prove their equivalence. When the random variables are continuous, Section 5 offers an intuitive interpretation of our ADMGs as systems of structural equations with correlated errors, so that Pearl's *do*-calculus can easily be adapted to them. Section 6 describes an exact algorithm for learning our ADMGs from observational and interventional data via answer set programming (Gelfond, 1988; Niemelä, 1999; Simons et al., 2002). We close the paper with some discussion in Section 7. Formal proofs of the claims made in this paper can be found on the supplementary material on our website.

2 PRELIMINARIES

In this section, we introduce some concepts about graphical models. Unless otherwise stated, all the graphs and probability distributions in this paper are defined over a finite set

V. The elements of V are not distinguished from singletons. An ADMG G is a graph with possibly directed and undirected edges but without directed cycles. There may be up to two edges between any pair of nodes, but in that case the edges must be different and one of them must be undirected to avoid directed cycles. Edges between a node and itself are not allowed. See Figure 1 for two examples of ADMGs.

Given an ADMG G, we represent with $A \multimap B$ that $A \to B$ or $A - B$ (or both) is in G. The parents of $X \subseteq V$ in G are $Pa_G(X) = \{A | A \to B$ is in G with $B \in X\}$. The children of X in G are $Ch_G(X) = \{A | A \leftarrow B$ is in G with $B \in X\}$. The neighbours of X in G are $Ne_G(X) = \{A | A - B$ is in G with $B \in X\}$. The ancestors of X in G are $An_G(X) = \{A | A \to \ldots \to B$ is in G with $B \in X$ or $A \in X\}$. The descendants of X in G are $De_G(X) = \{A | A \leftarrow \ldots \leftarrow B$ is in G with $B \in X$ or $A \in X\}$. The semidescendants of X in G are $de_G(X) = \{A | A \circ\!\!- \ldots \circ\!\!- B$ is in G with $B \in X$ or $A \in X\}$. The non-semidescendants of X in G are $Nd_G(X) = V \setminus de_G(X)$. The connectivity components of X in G is $Cc_G(X) = \{A | A - \ldots - B$ is in G with $B \in X$ or $A \in X\}$. The connectivity components in G are denoted as $Cc(G)$. A route between a node V_1 and a node V_n on G is a sequence of (not necessarily distinct) nodes $V_1, \ldots, V_n$ such that V_i and V_{i+1} are adjacent in G for all $1 \leq i < n$. We do not distinguish between the sequences $V_1, \ldots, V_n$ and $V_n, \ldots, V_1$, i.e. they represent the same route. If the nodes in the route are all distinct, then the route is called a path. Finally, the subgraph of G induced by $X \subseteq V$, denoted as G_X, is the graph over X that has all and only the edges in G whose both ends are in X.

Let X, Y, W and Z be disjoint subsets of V. We represent by $X \perp_p Y | Z$ that X and Y are conditionally independent given Z in a probability distribution p. Every probability distribution p satisfies the following four properties: Symmetry $X \perp_p Y | Z \Rightarrow Y \perp_p X | Z$, decomposition $X \perp_p Y \cup W | Z \Rightarrow X \perp_p Y | Z$, weak union $X \perp_p Y \cup W | Z \Rightarrow X \perp_p Y | Z \cup W$, and contraction $X \perp_p Y | Z \cup W \wedge X \perp_p W | Z \Rightarrow X \perp_p Y \cup W | Z$. If p is strictly positive, then it also satisfies the intersection property $X \perp_p Y | Z \cup W \wedge X \perp_p W | Z \cup Y \Rightarrow X \perp_p Y \cup W | Z$. Some (not yet characterized) probability distributions also satisfy the composition property $X \perp_p Y | Z \wedge X \perp_p W | Z \Rightarrow X \perp_p Y \cup W | Z$.

3 GLOBAL MARKOV PROPERTY

In this section, we introduce four separation criteria for ADMGs. Moreover, we show that they are all equivalent. A probability distribution is said to satisfy the global Markov property with respect to an ADMG if every separation in the graph can be interpreted as an independence in the distribution.

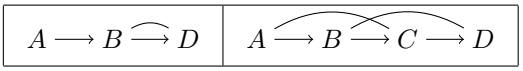

Figure 1: Examples of ADMGs.

Criterion 1. A node C on a path in an ADMG G is said to be a collider on the path if $A \to C \circ\!\!- B$ is a subpath. Moreover, the path is said to be connecting given $Z \subseteq V$ when

- every collider on the path is in $An_G(Z)$, and
- every non-collider C on the path is outside Z unless $A - C - B$ is a subpath and $Pa_G(C) \setminus Z \neq \emptyset$.

Let X, Y and Z denote three disjoint subsets of V. When there is no path in G connecting a node in X and a node in Y given Z, we say that X is separated from Y given Z in G and denote it as $X \perp_G Y | Z$.

Criterion 2. A node C on a route in an ADMG G is said to be a collider on the route if $A \to C \circ\!\!- B$ is a subroute. Note that maybe $A = B$. Moreover, the route is said to be connecting given $Z \subseteq V$ when

- every collider on the route is in Z, and
- every non-collider C on the route is outside Z.

Let X, Y and Z denote three disjoint subsets of V. When there is no route in G connecting a node in X and a node in Y given Z, we say that X is separated from Y given Z in G and denote it as $X \perp_G Y | Z$.

Criterion 3. Let G^u denote the UG over V that contains all and only the undirected edges in G. The extended subgraph $G[X]$ with $X \subseteq V$ is defined as $G[X] = G_{An_G(X)} \cup (G^u)_{Cc_G(An_G(X))}$. Two nodes A and B in G are said to be collider connected if there is a path between them such that every non-endpoint node is a collider, i.e. $A \to C \circ\!\!- B$ or $A \to C - D \leftarrow B$. Such a path is called a collider path. Note that a single edge forms a collider path. The augmented graph G^a is the UG over V such that $A - B$ is in G^a if and only if A and B are collider connected in G. The edge $A - B$ is called augmented if it is in G^a but A and B are not adjacent in G. A path in G^a is said to be connecting given $Z \subseteq V$ if no node on the path is in Z. Let X, Y and Z denote three disjoint subsets of V. When there is no path in $G[X \cup Y \cup Z]^a$ connecting a node in X and a node in Y given Z, we say that X is separated from Y given Z in G and denote it as $X \perp_G Y | Z$.

Criterion 4. Given an UG H over V and $X \subseteq V$, we define the marginal graph H^X as the UG over X such that $A - B$ is in H^X if and only if $A - B$ is in H or $A - V_1 - \ldots - V_n - B$ is H with $V_1, \ldots, V_n \notin X$. We define the marginal extended subgraph $G[X]^m$ as $G[X]^m =$

$G_{An_G(X)} \cup ((G^u)_{Cc_G(An_G(X))})^{An_G(X)}$. Let X, Y and Z denote three disjoint subsets of V. When there is no path in $(G[X \cup Y \cup Z]^m)^a$ connecting a node in X and a node in Y given Z, we say that X is separated from Y given Z in G and denote it as $X \perp_G Y|Z$.

The first three separation criteria introduced above coincide with those introduced by Andersson et al. (2001) and Levitz et al. (2001) for AMP CGs. The equivalence for AMP CGs of these three separation criteria has been proven by Levitz et al. (2001, Theorem 4.1). The following theorems prove the equivalence for ADMGs of the four separation criteria introduced above.

Theorem 1 *There is a path in an ADMG G connecting a node in X and a node in Y given Z if and only if there is a path in $G[X \cup Y \cup Z]^a$ connecting a node in X and a node in Y given Z.*

Theorem 2 *There is a path in an ADMG G connecting A and B given Z if and only if there is a route in G connecting A and B given Z.*

Theorem 3 *Given an ADMG G, there is a path in $G[X \cup Y \cup Z]^a$ connecting a node in X and a node in Y given Z if and only if there is a path in $(G[X \cup Y \cup Z]^m)^a$ connecting a node in X and a node in Y given Z.*

Unlike in AMP CGs, two non-adjacent nodes in an ADMG are not necessarily separated. For example, $A \perp_G D|Z$ does not hold for any Z in the ADMGs in Figure 1. This drawback is shared by the original ADMGs (Evans and Richardson, 2013, p. 752), summary graphs and MC graphs (Richardson and Spirtes, 2002, p. 1023), and ancestral graphs (Richardson and Spirtes, 2002, Section 3.7). For ancestral graphs, the problem can be solved by adding edges to the graph without altering the separations represented until every missing edge corresponds to a separation (Richardson and Spirtes, 2002, Section 5.1). A similar solution does not exist for our ADMGs (we omit the details).

4 ORDERED LOCAL AND PAIRWISE MARKOV PROPERTIES

In this section, we introduce ordered local and pairwise Markov properties for ADMGs. Given an ADMG G, the directed acyclity of G implies that we can specify a total ordering ($\prec$) of the nodes of G such that $A \prec B$ only if $B \notin An_G(A)$. Such an ordering is said to be consistent with G. Let the predecessors of A with respect to $\prec$ be defined as $Pre_G(A, \prec) = \{B|B \prec A \text{ or } B = A\}$. Given $S \subseteq V$, we define the Markov blanket of $B \in S$ with respect to $G[S]$ as $Mb_{G[S]}(B) = Ch_{G[S]}(B) \cup Ne_{G[S]}(B \cup Ch_{G[S]}(B)) \cup Pa_{G[S]}(B \cup Ch_{G[S]}(B) \cup Ne_{G[S]}(B \cup Ch_{G[S]}(B)))$. We say that a probability distribution p satisfies the ordered local Markov property with respect to G and $\prec$ if for any $A \in V$ and $S \subseteq Pre_G(A, \prec)$ such that $A \in S$

$$B \perp_p S \setminus (B \cup Mb_{G[S]}(B))|Mb_{G[S]}(B)$$

for all $B \in S$.

Theorem 4 *Given a probability distribution p satisfying the intersection property, p satisfies the global Markov property with respect to an ADMG if and only if it satisfies the ordered local Markov property with respect to the ADMG and a consistent ordering of its nodes.*

Similarly, we say that a probability distribution p satisfies the ordered pairwise Markov property with respect to G and $\prec$ if for any $A \in V$ and $S \subseteq Pre_G(A, \prec)$ such that $A \in S$

$$B \perp_p C|V(G[S]) \setminus (B \cup C)$$

for all nodes $B, C \in S$ that are not adjacent in $G[S]^a$, and where $V(G[S])$ denotes the nodes in $G[S]$.

Theorem 5 *Given a probability distribution p satisfying the intersection property, p satisfies the global Markov property with respect to an ADMG if and only if it satisfies the ordered pairwise Markov property with respect to the ADMG and a consistent ordering of its nodes.*

For each $A \in V$ and $S \subseteq Pre_G(A, \prec)$ such that $A \in S$, the ordered local Markov property specifies an independence for each $B \in S$. The number of independences to specify can be reduced by noting that $G[S] = G[An_G(S)]$ and, thus, we do not need to consider every set $S \subseteq Pre_G(A, \prec)$ but only those that are ancestral, i.e. those such that $S = An_G(S)$. The number of independences to specify can be further reduced by considering only maximal ancestral sets, i.e. those sets S such that $Mb_{G[S]}(B) \subset Mb_{G[T]}(B)$ for every ancestral set T such that $S \subset T \subseteq Pre_G(A, \prec)$. The independences for the non-maximal ancestral sets follow from the independences for the maximal ancestral sets by decomposition. A characterization of the maximal ancestral sets is possible but notationally cumbersome (we omit the details). All in all, for each node and maximal ancestral set, the ordered local Markov property specifies an independence for each node in the set. This number is greater than for the original ADMGs, where a single independence is specified for each node and maximal ancestral set (Richardson, 2003, Section 3.1). Even fewer independences are needed for the original ADMGs when interpreted as linear causal models (Kang and Tian, 2009, Section 4). All in all, our ordered local Markov property serves its purpose, namely to identify a subset of the independences in the global Markov property that implies the rest.

Note that Andersson et al. (2001, Theorem 3) describe local and pairwise Markov properties for AMP CGs that are equivalent to the global one under the assumption of the intersection and composition properties. Our ordered local

and pairwise Markov properties above only require assuming the intersection property. Note that this assumption is also needed to prove similar results for much simpler models such as UGs (Lauritzen, 1996, Theorem 3.7). For AMP CGs, however, we can do better than just using the ordered local and pairwise Markov properties for ADMGs above. Specifically, we introduce in the next section neater local and pairwise Markov properties for AMP CGs under the intersection property assumption. Later on, we will also use them to prove some results for ADMGs.

4.1 LOCAL AND PAIRWISE MARKOV PROPERTIES FOR AMP CGS

Andersson et al. (2001, Theorem 2) prove that a probability distribution p satisfies the global Markov property with respect to an AMP CG G if and only if it satisfies the block-recursive Markov property which requires that the following three properties hold for all $C \in Cc(G)$:

- C1: $C \perp_p Nd_G(C) \setminus Cc_G(Pa_G(C)) | Cc_G(Pa_G(C))$.
- C2: $p(C|Cc_G(Pa_G(C)))$ satisfies the global Markov property with respect to G_C.
- C3*: $D \perp_p Cc_G(Pa_G(C)) \setminus Pa_G(D) | Pa_G(D)$ for all $D \subseteq C$.

We simplify the block-recursive Markov property as follows.

Theorem 6 *C1, C2 and C3* hold if and only if the following two properties hold:*

- *C1*: $D \perp_p Nd_G(D) \setminus Pa_G(D) | Pa_G(D)$ for all $D \subseteq C$.*
- *C2*: $p(C|Pa_G(C))$ satisfies the global Markov property with respect to G_C.*

Andersson et al. (2001, Theorem 3) also prove that a probability distribution p satisfying the intersection and composition properties satisfies the global Markov property with respect to an AMP CG G if and only if it satisfies the local Markov property which requires that the following two properties hold for all $C \in Cc(G)$:

- L1: $A \perp_p C \setminus (A \cup Ne_G(A)) | Nd_G(C) \cup Ne_G(A)$ for all $A \in C$.
- L2: $A \perp_p Nd_G(C) \setminus Pa_G(A) | Pa_G(A)$ for all $A \in C$.

We introduce below a local Markov property that is equivalent to the global one under the assumption of the intersection property only.

Theorem 7 *A probability distribution p satisfying the intersection property satisfies the global Markov property with respect to an AMP CG G if and only if the following two properties hold for all $C \in Cc(G)$:*

- *L1: $A \perp_p C \setminus (A \cup Ne_G(A)) | Nd_G(C) \cup Ne_G(A)$ for all $A \in C$.*
- *L2*: $A \perp_p Nd_G(C) \setminus Pa_G(A \cup S) | S \cup Pa_G(A \cup S)$ for all $A \in C$ and $S \subseteq C \setminus A$.*

Finally, Andersson et al. (2001, Theorem 3) also prove that a probability distribution p satisfying the intersection and composition properties satisfies the global Markov property with respect to an AMP CG G if and only if it satisfies the pairwise Markov property which requires that the following two properties hold for all $C \in Cc(G)$:

- P1: $A \perp_p B | Nd_G(C) \cup C \setminus (A \cup B)$ for all $A \in C$ and $B \in C \setminus (A \cup Ne_G(A))$.
- P2: $A \perp_p B | Nd_G(C) \setminus B$ for all $A \in C$ and $B \in Nd_G(C) \setminus Pa_G(A)$.

We introduce below a pairwise Markov property that is equivalent to the global one under the assumption of the intersection property only.

Theorem 8 *A probability distribution p satisfying the intersection property satisfies the global Markov property with respect to an AMP CG G if and only if the following two properties hold for all $C \in Cc(G)$:*

- *P1: $A \perp_p B | Nd_G(C) \cup C \setminus (A \cup B)$ for all $A \in C$ and $B \in C \setminus (A \cup Ne_G(A))$.*
- *P2*: $A \perp_p B | S \cup Nd_G(C) \setminus B$ for all $A \in C$, $S \subseteq C \setminus A$ and $B \in Nd_G(C) \setminus Pa_G(A \cup S)$.*

5 CAUSAL INTERPRETATION

Let us assume that V is normally distributed. In this section, we show that an ADMG G can be interpreted as a system of structural equations with correlated errors. Specifically, the system includes an equation for each $A \in V$, which is of the form $A = \beta_A \cdot Pa_G(A) + \epsilon_A$ where ϵ_A denotes the error term. The error terms are represented implicitly in G. They can be represented explicitly by magnifying G into the ADMG G' as follows:

1	Set $G' = G$
2	For each node A in G
3	Add the node ϵ_A and the edge $\epsilon_A \rightarrow A$ to G'
4	For each edge $A - B$ in G
5	Replace $A - B$ with the edge $\epsilon_A - \epsilon_B$ in G'

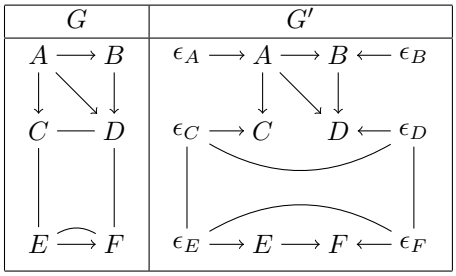

Figure 2: Example of the magnification of an ADMG.

The magnification above basically consists in adding the error nodes ϵ_A to G and connect them appropriately. Figure 2 shows an example. Note that every node $A \in V$ is determined by $Pa_{G'}(A)$ and that ϵ_A is determined by $A \cup Pa_{G'}(A) \setminus \epsilon_A$. Let ϵ denote all the error nodes in G'. Formally, we say that $A \in V \cup \epsilon$ is determined by $Z \subseteq V \cup \epsilon$ when $A \in Z$ or A is a function of Z. We use $Dt(Z)$ to denote all the nodes that are determined by Z. From the point of view of the separations, that a node outside the conditioning set of a separation is determined by the conditioning set has the same effect as if the node were actually in the conditioning set. Bearing this in mind, it is not difficult to see that, as desired, G and G' represent the same separations over V. The following theorem formalizes this result.

Theorem 9 *Let X, Y and Z denote three disjoint subsets of V. Then, $X \perp_G Y|Z$ if and only if $X \perp_{G'} Y|Z$.*

Finally, let $\epsilon \sim \mathcal{N}(0, \Lambda)$ such that $(\Lambda^{-1})_{\epsilon_A,\epsilon_B} = 0$ if $\epsilon_A - \epsilon_B$ is not in G'. Then, G can be interpreted as a system of structural equations with correlated errors as follows. For any $A \in V$

$$A = \sum_{B \in Pa_G(A)} \beta_{AB} B + \epsilon_A \tag{1}$$

and for any other $B \in V$

$$covariance(\epsilon_A, \epsilon_B) = \Lambda_{\epsilon_A,\epsilon_B}. \tag{2}$$

The following two theorems confirm that the interpretation above works as intended. A similar result to the second theorem exists for the original ADMGs (Koster, 1999, Theorem 1).

Theorem 10 *Every probability distribution $p(V)$ specified by Equations (1) and (2) is Gaussian.*

Theorem 11 *Every probability distribution $p(V)$ specified by Equations (1) and (2) satisfies the global Markov property with respect to G.*

The equations above specify each node as a linear function of its parents with additive normal noise. The equations can be generalized to nonlinear or nonparametric functions as long as the noise remains additive normal. That is, $A = f(Pa_G(A)) + \epsilon_A$ for all $A \in V$, with $\epsilon \sim \mathcal{N}(0, \Lambda)$ such that $(\Lambda^{-1})_{\epsilon_A,\epsilon_B} = 0$ if $\epsilon_A - \epsilon_B$ is not in G'. That the noise is additive normal ensures that ϵ_A is determined by $A \cup Pa_{G'}(A) \setminus \epsilon_A$, which is needed for Theorem 9 to remain valid which, in turn, is needed for Theorem 11 to remain valid.

A less formal but more intuitive alternative interpretation of ADMGs is as follows. We can interpret the parents of each node in an ADMG as its observed causes. Its unobserved causes are grouped into an error node that is represented implicitly in the ADMG. We can interpret the undirected edges in the ADMG as the correlation relationships between the different error nodes. The causal structure is constrained to be a DAG, but the correlation structure can be any UG. This causal interpretation of our ADMGs parallels that of the original ADMGs (Pearl, 2009). There are however two main differences. First, the noise in the original ADMGs is not necessarily additive normal. Second, the correlation structure of the error nodes in the original ADMGs is represented by a covariance graph, i.e. a graph with only bidirected edges (Pearl and Wermuth, 1993). Therefore, whereas a missing edge between two error nodes in the original ADMGs represents marginal independence, in our ADMGs it represents conditional independence given the rest of the error nodes. This means that the original and our ADMGs represent complementary causal models. Consequently, there are scenarios where the identification of the causal effect of an intervention is not possible with the original ADMGs but is possible with ours, and vice versa. We elaborate on this in the next section.

5.1 *do*-CALCULUS

We start by adapting Pearl's *do*-calculus, which operates on the original ADMGs, to our ADMGs. The original *do*-calculus consists of the following three rules, whose repeated application permits in some cases to identify (i.e. compute) the causal effect of an intervention from observed quantities:

- Rule 1 (insertion/deletion of observations):
  $p(Y|do(X), Z \cup W) = p(Y|do(X), W)$ if $Y \perp_{G''} Z|X \cup W||X$.
- Rule 2 (action/observation exchange):
  $p(Y|do(X), do(Z), W) = p(Y|do(X), Z \cup W)$ if $Y \perp_{G''} F_Z|X \cup W \cup Z||X$.
- Rule 3 (insertion/deletion of actions):
  $p(Y|do(X), do(Z), W) = p(Y|do(X), W)$ if $Y \perp_{G''} F_Z|X \cup W||X$.

where X, Y, Z and W are disjoint subsets of V, G'' is the original ADMG G augmented with an intervention random

variable F_A and an edge $F_A \rightarrow A$ for every $A \in V$, and "$||X$" denotes an intervention on X in G'', i.e. any edge with an arrowhead into any node in X is removed. See Pearl (1995, p. 686) for further details and the proof that the rules are sound. Fortunately, the rules also apply to our ADMGs by simply redefining "$||X$" appropriately. The proof that the rules are still sound is essentially the same as before. Specifically, "$||X$" should now be implemented as follows:

1	Delete from G'' all the edges $A \rightarrow B$ with $B \in X$
2	For each path $A - V_1 - \ldots - V_n - B$ in G'' with $A, B \notin X$ and $V_1, \ldots, V_n \in X$
3	Add the edge $A - B$ to G''
4	Delete from G'' all the edges $A - B$ with $B \in X$

Line 1 is shared with an intervention in an original ADMG. Lines 2-4 are best understood in terms of the magnified ADMG G': They correspond to marginalizing the error nodes associated to the nodes in X out of G'_ϵ, the UG that represents the correlation structure of the error nodes. In other words, they replace G'_ϵ with $(G')^{\epsilon \setminus \epsilon_X}$, the marginal graph of G'_ϵ over $\epsilon \setminus \epsilon_X$. This makes sense since ϵ_X is no longer associated to X due to the intervention and, thus, we may want to marginalize it out because it is unobserved. This is exactly what lines 2-4 imply. To see it, note that the ADMG after the intervention and the magnified ADMG after the intervention represent the same separations over V, by Theorem 9.

Now, we show that the original and our ADMGs allow for complementary causal reasoning. Specifically, we show an example where our ADMGs allow for the identification of the causal effect of an intervention whereas the original ADMGs do not, and vice versa. Consider the DAG in Figure 3, which represents the causal relationships among all the random variables in the domain at hand.[1] However, only A, B and C are observed. Moreover, U_S represents selection bias. Although other definitions may exist, we say that selection bias is present if two unobserved causes have a common effect that is omitted from the study but influences the selection of the samples in the study (Pearl, 2009, p. 163). Therefore, the corresponding unobserved causes are correlated in every sample selected. Note that this definition excludes the possibility of an intervention affecting the selection because, in a causal model, unobserved causes do not have observed causes. Note also that our goal is not the identification of the causal effect of an intervention in the whole population but in the subpopulation that satisfies the selection bias criterion.[2] For causal effect identification

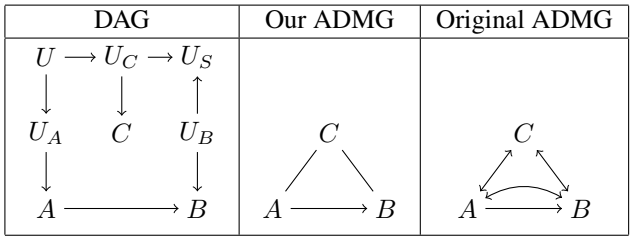

Figure 3: Example of a case where $p(B|do(A))$ is identifiable with our ADMG but not with the original one.

in the whole population, see Bareinboim and Tian (2015).

The ADMGs in Figure 3 represent the causal model represented by the DAG when only the observed random variables are modeled. According to our interpretation of ADMGs above, our ADMG is derived from the DAG by keeping the directed edges between observed random variables, and adding an undirected edge between two observed random variables if and only if their unobserved causes are not separated in the DAG given the unobserved causes of the rest of the observed random variables. In other words, $U_A \perp U_B | U_C$ holds in the DAG but $U_A \perp U_C | U_B$ and $U_B \perp U_C | U_A$ do not and, thus, the edges $A - C$ and $B - C$ are added to the ADMG but $A - B$ is not. Deriving the original ADMG is less straightforward. The bidirected edges in an original ADMG represent potential marginal dependence due to a common unobserved cause, also known as confounding. Thus, the original ADMGs are not meant to model selection bias. The best we can do is then to use bidirected edges to represent potential marginal dependences regardless of their origin. This implies that we can derive the original ADMG from the DAG by keeping the directed edges between observed random variables, and adding a bidirected edge between two observed random variables if and only if their unobserved causes are not separated in the DAG given the empty set. Clearly, $p(B|do(A))$ is not identifiable with the original ADMG but is identifiable with our ADMG (Pearl, 2009, p. 94). Specifically,

$$p(B|do(A)) = \sum_C p(B|do(A), C)p(C|do(A))$$

$$= \sum_C p(B|do(A), C)p(C) = \sum_C p(B|A, C)p(C)$$

where the first equality is due to marginalization, the second due to Rule 3, and the third due to Rule 2.

The original ADMGs assume that confounding is always the source of correlation between unobserved causes. In the example above, we consider selection bias as an additional source. However, this is not the only possibility. For instance, U_B and U_C may be tied by a physical law of the

[1] For instance, the DAG may correspond to the following fictitious domain: A = Smoking, B = Lung cancer, C = Drinking, U_A = Parents' smoking, U_B = Parents' lung cancer, U_C = Parents' drinking, U = Parents' genotype that causes smoking and drinking, U_S = Parents' hospitalization.

[2] For instance, in the fictitious domain in the previous footnote, we are interested in the causal effect that smoking may have on the development of lung cancer for the patients with hospitalized parents.

form $f(U_B, U_C) = constant$ devoid of causal meaning, much like Boyle's law relates the pressure and volume of a gas as $pressure \cdot volume = constant$ if the temperature and amount of gas remain unchanged within a closed system (Dawid, 2010, p. 77). In such a case, the discussion above still applies and our ADMG allows for causal effect identification but the original does not. Note that even if we assume that confounding is the only source of correlation between unobserved causes, our ADMGs may allow for causal effect identification while the original may not, e.g. replace the subgraph $U_C \rightarrow U_S \leftarrow U_B$ with $U_C \rightarrow U_B$ in Figure 3. For an example where the original ADMGs allow for causal effect identification whereas ours do not, simply replace the subgraph $U_C \rightarrow U_S \leftarrow U_B$ in Figure 3 with $U_C \leftarrow W \rightarrow U_B$ where W is an unobserved random variable. Then, our ADMG will contain the same edges as before plus the edge $A - B$, making the causal effect non-identifiable. The original ADMG will contain the same edges as before with the exception of the edge $A \leftrightarrow B$, making the causal effect identifiable.

In summary, the bidirected edges of the original ADMGs have a clear semantics: They represent potential marginal dependence due to a common unobserved cause. This means that we have to know the causal relationships involving the unobserved random variables to derive the ADMG. Or at least, we have to know that there is no selection bias or tying laws so that marginal dependence can be attributed to confounding due to Reichenbach's principle (Pearl, 2009, p. 30). This knowledge may not be available in some cases. Moreover, the original ADMGs are not meant to represent selection bias or tying laws. To solve these two problems, we may be willing to use the bidirected edges to represent potential marginal dependences regardless of their origin. Our ADMGs are somehow dual to the original ADMGs, since the undirected edges represent potential saturated conditional dependence between unobserved causes. This implies that in some cases, such as in the example above, our ADMGs may allow for causal effect identification whereas the original may not.

6 LEARNING VIA ASP

In this section, we introduce an exact algorithm for learning ADMGs from observations and interventions via answer set programming (ASP), which is a declarative constraint satisfaction paradigm that is well-suited for solving computationally hard combinatorial problems (Gelfond, 1988; Niemelä, 1999; Simons et al., 2002). A similar approach has been proposed before for learning LWF CGs from observations (Sonntag et al., 2015). ASP represents constraints in terms of first-order logical rules. Therefore, when using ASP, the first task is to model the problem at hand in terms of rules so that the set of solutions implicitly represented by the rules corresponds to the solutions of the original problem. One or multiple solutions to the original problem can then be obtained by invoking an off-the-shelf ASP solver on the constraint declaration. Each rule in the constraint declaration is of the form `head :- body`. The head contains an atom, i.e. a fact. The body may contain several literals, i.e. negated and non-negated atoms. Intuitively, the rule is a justification to derive the head if the body is true. The body is true if its non-negated atoms can be derived, and its negated atoms cannot. A rule with only the head is an atom. A rule without the head is a hard-constraint, meaning that satisfying the body results in a contradiction. Soft-constraints are encoded as rules of the form `:~ body. [W]`, meaning that satisfying the body results in a penalty of W units. The ASP solver returns the solutions that meet the hard-constraints and minimize the total penalty due to the soft-constraints. In this work, we use the ASP solver `clingo` (Gebser et al., 2011), which is based on state-of-the-art Boolean satisfiability solving techniques (Biere et al., 2009).

Figure 4 shows the ASP encoding of our learning algorithm. The predicate `node(X)` in rule 1 represents that X is a node. The predicates `line(X,Y,I)` and `arrow(X,Y,I)` represent that there is an undirected and directed edge from X to Y after having intervened on the node I. The observational regime corresponds to $I = 0$. The rules 2-3 encode a non-deterministic guess of the edges for the observational regime, which means that the ASP solver with implicitly consider all possible graphs during the search, hence the exactness of the search. The edges under the observational regime are used in the rules 4-6 to define the edges in the graph after having intervened on I, following the description in Section 5.1. Therefore, the algorithm assumes continuous random variables and additive normal noise when the input contains interventions. It makes no assumption though when the input consists of just observations. The rules 7-8 enforce the fact that undirected edges are symmetric and that there is at most one directed edge between two nodes. The predicate `ancestor(X,Y)` represents that X is an ancestor of Y. The rules 9-11 enforce that the graph has no directed cycles. The predicates in the rules 12-13 represent whether a node X is or is not in a set of nodes C. The rules 14-25 encode the separation criterion 2 in Section 3. The predicate `con(X,Y,C,I)` in rules 26-29 represents that there is a connecting route between X and Y given C after having intervened on I. The rule 30 enforces that each dependence in the input must correspond to a connecting route. The rule 31 represents that each independence in the input that is not represented implies a penalty of W units. The rules 32-33 represent a penalty of 1 unit per edge. Other penalty rules can be added similarly.

Figure 6 shows the ASP encoding of all the (in)dependences in the probability distribution at hand, e.g. as determined by some available data. Specifically, the predicate `nodes(3)` represents that there

```

are three nodes in the domain at hand, and the predicate `set(0..7)` represents that there are eight sets of nodes, indexed from 0 (empty set) to 7 (full set). The predicate `indep(X,Y,C,I,W)` (respectively `dep(X,Y,C,I,W)`) represents that the nodes X and Y are conditionally independent (respectively dependent) given the set index C after having intervened on the node I. Observations correspond to $I = 0$. The penalty for failing to represent an (in)dependence is W. The penalty for failing to represent a dependence is actually superfluous in our algorithm since, recall, rule 30 in Figure 4 enforces that all the dependences in the input are represented. Note also that it suffices to specify all the (in)dependences between pair of nodes, because these identify uniquely the rest of the independences in the probability distribution (Studený, 2005, Lemma 2.2). Note also that we do not assume that the probability distribution at hand is faithful to some ADMG or satisfies the composition property, as it is the case in most heuristic learning algorithms.

By calling the ASP solver with the encodings of the learning algorithm and the (in)dependences in the domain, the solver will essentially perform an exhaustive search over the space of graphs, and will output the graphs with the smallest penalty. Specifically, when only the observations are used (i.e. the last five lines of Figure 6 are removed), the learning algorithm finds 37 optimal models. Among them, we have UGs such as `line(1,2) line(1,3) line(2,3)`, DAGs such as `arrow(3,1) arrow(1,2) arrow(3,2)`, AMP CGs such as `line(1,2) arrow(3,1) arrow(3,2)`, and ADMGs such as `line(1,2) line(2,3) arrow(1,2)` or `line(1,2) line(1,3) arrow(2,3)`. When all the observations and interventions available are used, the learning algorithm finds 18 optimal models. These are the models out the 37 models found before that have no directed edge coming out of the node 3. This is the expected result given the last four lines in Figure 6. Note that the output still includes the ADMGs mentioned before.

Finally, the ASP code can easily be extended as shown in Figure 5 to learn not only our ADMGs but also original ADMGs. Note that the second line forbids graphs with both undirected and bidirected edges. This results in 34 optimal models: The 18 previously found plus 16 original ADMGs, e.g. `biarrow(1,2) biarrow(1,3) arrow(1,2)` or `biarrow(1,2) biarrow(1,3) arrow(2,3)`.

7 DISCUSSION

We have introduced ADMGs as an extension of AMP CGs. We have presented global, and ordered local and pairwise Markov properties for the new models. We have also shown that when the random variables are continuous, the new models can be interpreted as systems of structural equations with correlated errors. This has enabled us to adapt Pearl's *do*-calculus to them, and show that our models complement those used in Pearl's *do*-calculus, as there are cases where the identification of the causal effect of an intervention is not possible with the latter but is possible with the former, and vice versa. Finally, we have described an exact algorithm for learning the new models from observations and interventions. We plan to unify the original and our ADMGs to allow directed, undirected and bidirected edges.

Abstract

Wagering mechanisms allow decision makers to inexpensively collect forecasts from groups of experts who reveal their information via bets with one another. Such mechanisms naturally induce a game in which strategic considerations come into play. What happens in the game depends on the reasoning power of the experts. At one extreme, if experts are fully rational, no-trade theorems imply no participation. At the other extreme, if experts ignore strategic considerations, even the least informed will wager as if his beliefs are correct. Economists have analyzed the former case and decision theorists the latter, but both are arguably unrealistic. In this paper, we adopt an intermediate model of bounded rationality in wagering mechanisms based on level-k reasoning. Under this model, overconfidence allows some participation to be sustained, but experts who realize they are at a relative disadvantage do bow out. We derive conditions on the particular wagering mechanism used under which participation is unbiased, and show that unbiasedness always implies truthful reports. We show that if participation is unbiased, then participation rates unavoidably fall as players' rationality increases, vanishing for large k. Finally, we zoom in on one particular information structure to give a complete characterization specifying the conditions under which mechanisms are unbiased and show how to maximize participation rates among all unbiased mechanisms.

1 INTRODUCTION

A wagering mechanism is an inexpensive tool to elicit forecasts from a group. Rather than paying for the information directly, a decision maker can let members of the group wager with each other and, in the process, capture their beliefs. In the ideal case, everyone with information has incentive to reveal their true subjective forecasts without bias at little or no cost to the decision maker.

Kilgour and Gerchak (2004) proposed one such wagering mechanism, called a shared scoring rule. Theoretically, this mechanism is individually rational (players prefer participating over not participating), truthful, and budget balanced, meaning the decision maker can collect honest, accurate forecasts from every member of the group and pay nothing. However, individual rationality and truthfulness rely on the key assumption that players have *immutable beliefs* (Lambert et al., 2008; Chun and Shachter, 2011). That is, players believe what they believe and do not update their beliefs even when matched against opponents. They are oblivious of the fact that they are playing against reasoning agents in a zero-sum game. They employ what might be termed *level-0 reasoning*.

Immutable beliefs yield an inherent contradiction. The sum of players' private expected profits is positive: everyone who agrees to play expects to gain. Yet the true sum of their profits is zero. Everyone therefore knows that at least one player must be overly optimistic. The immutable beliefs assumption may be defensible for a one-shot, isolated game, but in an iterative game, at least one player should rapidly observe a disagreement between what he expects and what he receives, making it reasonable to assume that he will adapt and update over time. In an iterative mental game prior to play, updating may occur ex ante. All players know that someone's information must be inaccurate, so it is natural to imagine revisions even in a one-shot game.

Game theory predicts nearly the opposite behavior in a wagering mechanism. Under the assumption of a common prior, if all players are rational, know that all players are rational, know that all players know that all players are rational, ad infinitum, then speculative wagers should not happen at all (Milgrom and Stokey, 1982). The decision maker would not get a single report from any member of the group. Intuitively, every proffered wager would be declined as evidence of superior information. Private expectations could not differ from outcomes in a systematic way,

and an overall bias toward optimism could not be sustained in a rational equilibrium (Lucas, 1972; Nielsen et al., 1990).

To design a wagering mechanism that encourages relatively broad, unbiased, and truthful participation, we need to understand how people behave. Do they act with immutable beliefs? Do they reason with complete rationality? Or do they fall somewhere in between?

The implications of unbounded rationality are absurd. If true, players could never "agree to disagree" (Aumann, 1976; Geanakoplos and Polemarchakis, 1982) and would never place any wager or make any investment based on a difference of opinion. Refuting this is the simple fact that speculative trade happens in exchanges around the world during every second of every day. Transactions do occur between overconfident zero-sum opponents who both expect to gain (Dubey et al., 1987; Jordan and Radner, 1979).

Yet ignoring game theory altogether is an idealization too. People are stubborn, but not entirely naive (Plott and Sunder, 1988). An opponent eager to make a large bet should give anyone pause. (Did I miss something? Is there something my opponent knows that I don't?) Only the most unsophisticated player would ignore the inconsistency between individual and aggregate expectations or repeatedly ignore a systematic difference between his private belief and his experience.

In this paper, building on a vast literature from behavioral game theory, we adopt an intermediate model of players and examine its implications for the design of wagering mechanisms. Our players are boundedly rational: they are neither superhuman level-∞ reasoners nor oblivious level-0 reasoners. Instead, we make the increasingly common assumption that each player reasons at an intermediate level k, treating all of her opponents as level-$(k-1)$ reasoners, with level-0 forming the base of the induction. When $k > 1$, players recognize that they are playing a game against strategic opponents. Still, their reasoning is incomplete. They retain a form of overconfidence in that each player believes that she is one level more capable than her opponents. We find that even this small dose of overconfidence is enough to induce participation.

To obtain accurate information from wagers, we seek shared scoring rules that encourage high rates of participation, unbiased participation (meaning that players don't decide whether to opt in or out based on the direction of their signals), and truthful participation. We first show that under very general assumptions, if an instantiation of the Kilgour-Gerchak mechanism is unbiased, it automatically leads level-k players to report their beliefs truthfully conditioned on participating. We next give a general characterization of which players choose to participate at each level. Roughly speaking, at low levels of rationality (small k) participation rates can be high due to widespread overconfidence, while at high levels of rationality (large k), only the players with the most accurate information choose to participate. We show that for any unbiased instantiation of Kilgour-Gerchak, participation rates shrink to zero as the level of rationality of players grows, illustrating that while unbiasedness is in some ways desirable, it comes at a cost.

The question of how to design unbiased mechanisms does not have a clean analytical answer in the general case. To gain intuition, we therefore zoom in on a particular symmetric information structure that permits tractable analysis under the level-k model. For this information structure, we give a complete characterization specifying the conditions under which the Kilgour-Gerchak mechanism leads to unbiased participation. Interestingly, we find that among all instantiations of Kilgour-Gerchak that are unbiased, the ones that lead to the highest level of participation are those in which players have the smallest incentive to report their true beliefs as opposed to any other forecast as they are rewarded similarly either way. This makes intuitive sense; since a player can only profit if other players lose, rewarding players more evenly has the effect of scaring off fewer of those who are relatively less informed, leading to higher overall participation.

We conclude with a brief discussion of how our work fits into the relatively new body of research on *behavioral mechanism design* (Ghosh and Kleinberg, 2014; Easley and Ghosh, 2015).

1.1 RELATED WORK

Over the past few decades, several theories have emerged to explain the inconsistencies that often arise between subjects' observed behavior in both lab and field studies and their predicted equilibrium behavior. Brocas et al. (2014) divide these theories into two categories. Theories of *imperfect choice*, such as quantal response equilibrium (McKelvey and Palfrey, 1995), assume that players fully analyze all available information but make noisy decisions or assume that other players make noisy decisions. Theories of *imperfect attention*, such as level-k, assume that players do not fully analyze all available information and therefore make imperfect choices compared with fully rational agents. In this paper we focus on the latter as such theories provide a middle ground between the extreme assumptions of immutable beliefs and full rationality under which one-shot wagering mechanisms have been analyzed in the past.

The earliest proponents of the level-k model were Stahl and Wilson (1994, 1995) and Nagel (1995). The theory was further developed, modified, and empirically evaluated by many others, including Ho et al. (1998), Costa-Gomes et al. (2001), Bosch-Domènech et al. (2002), Costa-Gomes and Crawford (2006), Crawford and Iriberri (2007), and Shapiro et al. (2014). Camerer et al. (2004) introduced a variant of the level-k model, the *cognitive hierarchy model*, in which a player at level k believes that other players' lev-

els are sampled according to some distribution over levels $k' < k$. In particular, the model assumes that there is a Poisson distribution with parameter τ over all players' true levels, and a player at level k believes that the levels of his opponents are distributed according to a normalized Poisson over levels strictly less than k; that is, his beliefs about the relative frequencies of lower levels are correct, but he incorrectly assumes that no other players are capable of reasoning that is at least as sophisticated as his own. As Brocas et al. (2014) point out, the cognitive hierarchy model is typically more difficult to work with analytically than the basic level-k model, often failing to yield crisp and testable predictions of behavior, and has the additional parameter τ to contend with. Additionally, Wright and Leyton-Brown (2010) found that its predictive performance is similar to the basic level-k model on a variety of data sets from the behavioral game theory literature. For these reasons, we primarily focus on the basic level-k model in our analysis, though some of our results could be extended to hold under the cognitive hierarchy model.

There have been several experimental studies examining behavior in one-shot betting games with private information. In early work aimed at testing the predictions of no-trade theorems in the lab, Sonsino et al. (2001) designed a betting game in which fully rational agents would choose not to participate and found substantial rates of betting among subjects. Sløvik (2009) later replicated these results. Rogers et al. (2009) used the same betting game in a new set of experiments in order to compare how well the quantal response model, cognitive hierarchy model, and various hybrids fit the behavior of subjects in the lab. They found evidence of both imperfect choice and imperfect attention in their subjects; the cognitive hierarchy and quantal response models fit the data equally well. Finally, Brocas et al. (2014) used mouse-tracking software in order to gain a better understanding of the cognitive processes behind subjects' actions in a betting game. In their clever design, payoffs of the bet were hidden in opaque boxes. Subjects could view their own payoffs or their opponents' payoffs in different states of the world only by clicking on the appropriate box. By keeping track of which payoffs subjects viewed, the authors were able to make inferences about how many levels of reasoning they were performing. They found a reasonable fit between subjects' actions and the basic level-k model, with different clusters of subjects behaving similarly to what would be expected of level-1, level-2, and level-3 players, though they observed some evidence of imperfect choice as well.

2 PRELIMINARIES AND MODEL

We begin with a review of strictly proper scoring rules and the Kilgour-Gerchak mechanism. We then present our general model of incomplete information and player beliefs and review the level-k model of behavior.

2.1 THE KILGOUR-GERCHAK MECHANISM

We consider a simple scenario in which a set $N = \{1, \cdots, n\}$ of players wager on the value of an unknown binary random variable $X \in \{0, 1\}$. This random variable could represent, for example, the winner of an election, whether or not a product ships on time, or the outcome of a game. We use x to denote a realization of X.

The wagering mechanisms that we analyze are those of Kilgour and Gerchak (2004). All players simultaneously choose whether or not to make a wager. If player i participates, he wagers \$1 and reports a probability $\hat{p}_i$ that $X = 1$. Next, the true state x is revealed, and each player who chose to participate receives a payment that depends on x and the reports of all participating players. Payments are designed to be budget-balanced, meaning that the mechanism's operator takes on no risk. They are also truthful and individually rational for risk-neutral players with immutable beliefs. This means that such players maximize their expected utility by choosing to participate and reporting their true beliefs about the likelihood that $X = 1$.

To achieve truthfulness, Kilgour-Gerchak mechanisms build on the extensive literature on *proper scoring rules* (Savage, 1971; Gneiting and Raftery, 2007). A proper scoring rule is a reward function designed to elicit truthful predictions from risk-neutral agents. A scoring rule S mapping a probability $q \in [0, 1]$ and outcome $x \in \{0, 1\}$ to a real-valued score is *proper* if for all $p \in [0, 1]$, if $X = 1$ with probability p, then the quantity

$$\mathbb{E}[S(q, X)] = p \cdot S(q, 1) + (1 - p) \cdot S(q, 0)$$

is maximized at $q = p$. It is *strictly proper* if this maximum is unique. A common example of a strictly proper scoring rule is the Brier score (Brier, 1950), defined as

$$S(q, x) = 1 - (q - x)^2.$$

Note that the Brier score is bounded in $[0, 1]$. Any bounded scoring rule can be renormalized to lie in this range.

We make heavy use of the following characterization of proper scoring rules from Gneiting and Raftery (2007).

Theorem 1 (Gneiting and Raftery (2007)) *A scoring rule S is (strictly) proper if and only if there exists a (strictly) convex function G, referred to as the* entropy function*, such that for all $q \in [0, 1]$ and all $x \in \{0, 1\}$,*

$$S(q, x) = G(q) + G'(q)(x - q),$$

where G' is any subderivative of G. Moreover, if $X = 1$ with probability p, then $E[S(p, X)] = G(p)$.

The Kilgour-Gerchak mechanism rewards each player by comparing his score to the average score of all other participants. Let $\mathcal{P} \subseteq N$ be the set of players that choose

to participate; $\mathcal{P}$ is a random variable that depends on the model of trader behavior. Let $\mathcal{P}_{-i}$ denote all members of $\mathcal{P}$ except i. (We use similar set notation throughout.) The mechanism is defined as follows.

Definition 1 (Kilgour-Gerchak mechanism) *Let S be a strictly proper scoring rule, bounded in $[0,1]$. All players $i \in \mathcal{P}$ simultaneously report a probability $\hat{p}_i$. If $|\mathcal{P}| \geq 2$, then when x is revealed, the mechanism assigns to each player $i \in \mathcal{P}$ a net profit (payment minus \$1 wager) of*

$$S(\hat{p}_i, x) - \frac{1}{|\mathcal{P}_{-i}|} \sum_{j \in \mathcal{P}_{-i}} S(\hat{p}_j, x).$$

If $|\mathcal{P}| = 1$, it returns the \$1 wager to the single participating player who receives a net profit of 0.

We assume that players are *risk neutral*, so if player i chooses to participate, then his utility is

$$u_i(\hat{\mathbf{p}}, x) = \begin{cases} S(\hat{p}_i, x) - \frac{\sum_{j \in \mathcal{P}_{-i}} S(\hat{p}_j, x)}{|\mathcal{P}_{-i}|} & \text{if } |\mathcal{P}| > 1, \\ 0 & \text{otherwise.} \end{cases}$$

Since we analyze only the Kilgour-Gerchak mechanism, the design space we consider is the space of all strictly proper scoring rules bounded in $[0,1]$. Selecting the scoring rule S (or equivalently, selecting the corresponding entropy function G) fully defines the mechanism.

2.2 PLAYER BELIEFS AND BEHAVIOR

To discuss level-k behavior, we first need to define the beliefs of players. We begin by considering a general model of incomplete information based on the well-studied model of Aumann (1976). In later sections, we analyze a specific special case of this model.

We imagine a process in which Nature first draws the value of the random variable $X \in \{0,1\}$ and then, conditioned on this value, draws (possibly correlated) random signals $\Sigma_i \in \{1, \cdots, m_i\}$ for each player i. We define a state of the world $\omega = (x, \sigma_1, \cdots, \sigma_n)$ as an outcome x paired with an assignment of signals σ_i to each player i. Let Ω be the set of all mutually exclusive and exhaustive states of the world. Players share a common prior over Ω.

Under the level-k model, the behavior of each player i is characterized by his *level of rationality*. Under the most simple version of the model, a player at some level $k \in \{1, 2, \cdots\}$ assumes that every other player is at level $k-1$ and best responds to the (distribution over) actions such players would take. This can be viewed as a form of overconfidence; every player believes he is slightly more rational than everyone else. We define level-0 players to be risk neutral with immutable beliefs. Such players always participate (as participation is rational under the immutable beliefs assumption (Kilgour and Gerchak, 2004; Lambert et al., 2008)) and truthfully bid their posterior beliefs conditioned on their signals. We could have alternatively defined level-0 players to be noise traders, choosing reports at random, as is common in the level-k literature. This definition would then give rise to immutable belief behavior at level 1, and would therefore not change the nature of our results; it would amount to no more than a simple renumbering of levels.

The behavior of a player at a level k consists of two decisions: whether or not to participate, and his report. We denote with $z_i^{(k)}(\sigma_i)$ an indicator variable that is 1 if player i would choose to participate at level k with signal σ_i and 0 otherwise. We denote with $\hat{p}_i^{(k)}(\sigma_i)$ the report of player i at level k with signal σ_i conditioned on participating. Let $\mathcal{P}^{(k)}$ denote the set of players who would participate *if* they were following level-k behavior; this is a random variable since it depends on the realized signals of each player. The functions $z_i^{(k)}$ and $\hat{p}_i^{(k)}$ are valid level-k behaviors if they maximize a player's utility under the assumption that every other player is of level $k-1$. More formally, let

$$U_i^{(k)}(\hat{p}_i, \sigma_i) = \mathbb{E}\left[\left(S(\hat{p}_i, X) - \frac{\sum_{j \in \mathcal{P}_{-i}^{(k-1)}} S(\hat{p}_j^{(k-1)}(\Sigma_j), X)}{|\mathcal{P}_{-i}^{(k-1)}|} \right) \cdot \mathbf{1}\{\mathcal{P}_{-i}^{(k-1)} \neq \emptyset\} \;\middle|\; \Sigma_i = \sigma_i \right]$$

be the expected utility of player i at level k if he participates and reports $\hat{p}_i$. Then we must have

$$\hat{p}_i^{(k)}(\sigma_i) \in \arg\max_{\hat{p}_i \in [0,1]} U_i^{(k)}(\hat{p}_i, \sigma_i),$$
$$z^{(k)}(\sigma_i) = \mathbf{1}\left\{ U_i\left(\hat{p}_i^{(k)}(\sigma_i) \right) > 0 \right\}.$$

Note that we assume players participate only if their expected utility is strictly positive and do not participate if their utility is 0. This is consistent with the scoring rule literature in which it is often assumed that players require strict incentives to truthfully report beliefs.

3 A GENERAL CHARACTERIZATION OF LEVEL-k BEHAVIOR

We are broadly interested in understanding when and how wagering mechanisms can be used to elicit accurate information from players in the level-k model of rationality. With our focus limited to Kilgour-Gerchak mechanisms, we can rephrase this question as asking which scoring rules S lead to high levels of participation and accurate reports.

Two crucial notions in our characterization are *unbiased participation* and *truthful behavior*. Unbiased participation

simply requires that a player's choice of whether or not to participate is independent of his signal (and therefore also independent of the outcome X). This is desirable because biased participation could lead to a biased collection of reports, leading in turn to a biased aggregate forecast for the decision maker.

Definition 2 (Unbiased participation) *We say that behavior at a level $k \in \{0, 1, \cdots\}$ is unbiased if every player's decision of whether or not to participate is independent of the value of his signal, i.e., if $\forall i \in N$, $\forall \sigma_i, \sigma_i' \in \{1, \cdots, m_i\}$, $z_i^{(k)}(\sigma_i) = z_i^{(k)}(\sigma_i')$.*

Using the common prior over Ω, we can define the posterior belief of player i about the likelihood of X after observing the signal $\Sigma_i = \sigma_i$ as

$$p_i(\sigma_i) \equiv \Pr[X = 1 | \Sigma_i = \sigma_i]. \quad (1)$$

Players behave truthfully if they report their true posteriors.

Definition 3 (Truthful behavior) *We say that behavior at a level $k \in \{0, 1, \cdots\}$ is truthful if for each player, if that player were to participate at level k, reporting his posterior belief conditioned only on his own signal would uniquely maximize his utility, i.e., if $\forall i \in N$, $\forall \sigma_i \in \{1, \cdots, m_i\}$, $p_i(\sigma_i) = \arg\max_{\hat{p}_i \in [0,1]} U_i^{(k)}(\hat{p}_i, \sigma_i)$.*

3.1 UNBIASEDNESS IMPLIES TRUTHFULNESS

With these two definitions in hand, we can prove several basic characterizations of level-k behavior in Kilgour-Gerchak mechanisms. The first shows that unbiased participation automatically leads to truthfulness, providing another argument that unbiased participation is desirable. The characterizations in this section make use of the observation that, by the assumption of unbiased participation, for any level $k' < k$, the decision of a level k' player of whether or not to participate is independent of his signal, and therefore independent of the true state of the world X. This implies that for any i, the set $\mathcal{P}_{-i}^{(k')}$ is independent of X, and in fact, deterministic.

Theorem 2 *In the Kilgour-Gerchak mechanism with strictly proper scoring rule S, if behavior at each level $k' < k$ is unbiased, then level-k behavior is truthful.*

Proof: If $\mathcal{P}_{-i}^{(k-1)} = \emptyset$ then any wager of player i would yield expected utility 0, so player i would not participate. Suppose that $\mathcal{P}_{-i}^{(k-1)} \neq \emptyset$. Then

$$U_i^{(k)}(\hat{p}_i, \sigma_i) = \mathbb{E}\left[S(\hat{p}_i, X) \mid \Sigma_i = \sigma_i\right] - \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}\left[S(\hat{p}_j^{(k-1)}(\Sigma_j), X) \mid \Sigma_i = \sigma_i\right].$$

The second term is independent of the player's report $\hat{p}_i$. Thus the player will behave truthfully if and only if doing so maximizes the first term, i.e., if and only if

$$p_i(\sigma_i) = \arg \max_{\hat{p}_i \in [0,1]} \mathbb{E}\left[S(\hat{p}_i, X) \mid \Sigma_i = \sigma_i\right],$$

which must hold by definition of $p_i(\sigma_i)$ and the fact that S is a strictly proper scoring rule. ■

Thus to design a truthful mechanism, it is sufficient to design a mechanism that encourages unbiased participation.

3.2 CHARACTERIZING PARTICIPATION

Our next few characterization results examine the conditions under which players choose to participate in the wagering mechanism when the mechanism is unbiased. Lemma 1 examines participation at level k when the mechanism is unbiased at all levels $k' < k$. This lemma will prove useful later when we wish to show that a mechanism is unbiased at all levels for specific signal structures.

Lemma 1 *In the Kilgour-Gerchak mechanism with strictly proper scoring rule S, if behavior at each level $k' < k$ is unbiased, then a player i at level k with signal σ_i participates if and only if $|\mathcal{P}_{-i}^{(k-1)}| > 0$ and*

$$\mathbb{E}[S(p_i(\sigma_i), X) | \Sigma_i = \sigma_i] > \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = \sigma_i]. \quad (2)$$

Proof: Consider any player $i \in N$ at level k. This player would never participate if $|\mathcal{P}_{-i}^{(k-1)}| = 0$ since his expected utility would be 0, so assume that $|\mathcal{P}_{-i}^{(k-1)}| > 0$. By Theorem 2, since participation is unbiased at every level $k' < k$, players at level k and at level $k-1$ behave truthfully. Using this and the form of player utilities immediately yields the lemma. ■

Theorem 3 builds on the previous lemma to show that when participation is unbiased at levels $k' \leq k$, a player at level k chooses to participate if and only if his a priori expected score (i.e., his expected score before signals are revealed) is higher than the average a priori expected score of all other players who participate at level $k-1$.

Theorem 3 *In the Kilgour-Gerchak mechanism with strictly proper scoring rule S with associated entropy G, if behavior at each level $k' \leq k$ is unbiased, then player i at level k participates if and only if $|\mathcal{P}_{-i}^{(k-1)}| > 0$ and*

$$\mathbb{E}[G(p_i(\Sigma_i))] > \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[G(p_j(\Sigma_j))].$$

Proof: Consider any $i \in N$ at level k. Since this player would never participate if $|\mathcal{P}_{-i}^{(k-1)}| = 0$, assume that $|\mathcal{P}_{-i}^{(k-1)}| > 0$. Since we have assumed that participation is unbiased at level k (as well as lower levels), we know that i either chooses to participate at level k regardless of his signal, or chooses not to participate at level k regardless of his signal. If he chooses to participate, then by Lemma 1, Equation (2) holds for all $\sigma_i \in \{1, \cdots, m_i\}$ and therefore

$$\sum_{\sigma_i=1}^{m_i} \Pr[\Sigma_i = \sigma_i]\mathbb{E}[S(p_i(\Sigma_i), X)|\Sigma_i = \sigma_i]$$
$$> \sum_{\sigma_i=1}^{m_i} \frac{\Pr[\Sigma_i = \sigma_i]}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[S(p_j(\Sigma_j), X)|\Sigma_i = \sigma_i]$$

implying that

$$\mathbb{E}[S(p_i(\Sigma_i), X)] > \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[S(p_j(\Sigma_j), X)].$$

Similarly, if he chooses not to participate then Lemma 1 implies that

$$\mathbb{E}[S(p_i(\Sigma_i), X)] \leq \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[S(p_j(\Sigma_j), X)].$$

The proof is completed by observing that by Theorem 1 for any $i \in N$,

$$\begin{aligned}\mathbb{E}[S(p_i(\Sigma_i), X)] &= \mathbb{E}_{\Sigma_i}\left[\mathbb{E}_X[S(p_i(\Sigma_i), X)|\Sigma_i]\right] \\ &= \mathbb{E}\left[G(p(\Sigma_i))\right].\end{aligned}$$

■

This theorem implies that if the mechanism is unbiased at all levels, then at every level k, at least the player with the smallest a priori expected score among those who participate at level $k-1$ stops participating. Additionally, no player who stops participating at some level k ever participates at a higher level, since the average score of other (fictitious) participating players is an increasing function of k. Therefore participation goes to zero as the level of rationality grows, coinciding with fully rational behavior. This illustrates that while unbiasedness is in some ways desirable, it also has its costs.

Corollary 1 *In the Kilgour-Gerchak mechanism with strictly proper scoring rule S, if behavior at every level is unbiased, then participation shrinks to zero as the level of rationality of players grows.*

The intuition behind the lack of participation in the limit is as follows. As a player's level of rationality grows, the amount of rationality he ascribes to other players grows as well. This leads him to believe that other players participate only if they are highly informed, and to choose not to participate if he is not informed enough to profit against these highly informed opponents. In the limit, no player believes he is informed enough to profit, and participation goes to zero.

4 THE SYMMETRIC SETTING

We have shown that under the level-k model of reasoning, any instantiation of the Kilgour-Gerchak mechanism for which participation is unbiased yields truthful reports. We have also explored the criteria for participation in such mechanisms. A natural question is how to design mechanisms with unbiased participation. This question does not have a clean analytical answer in the general case. To gain some intuition about this question, we therefore turn our attention to one particular information structure that permits tractable analysis under the level-k model.

We consider a scenario in which signals are binary, that is, $\Sigma_i \in \{0, 1\}$ for all i, and are drawn independently for each player, conditional on the state of the world X. Furthermore, each player i's signal is "correct" with some fixed and known probability c_i, that is, $\Pr[\Sigma_i = x \mid X = x] = c_i$ for $x \in \{0, 1\}$. Finally, to simplify analysis and presentation, we assume that, a priori, $\Pr[X = 1] = \Pr[X = 0] = 1/2$. One way of viewing this assumption is that prior public information does not favor either outcome, but rather all information in favor of some outcome is received privately by the players through their signals. We refer to this setting as the *symmetric setting*.

In the symmetric setting, the posterior in (1) is simply

$$p_i(\sigma_i) = \begin{cases} c_i & \text{if } \sigma_i = 1, \\ 1 - c_i & \text{if } \sigma_i = 0. \end{cases} \tag{3}$$

4.1 FULLY CHARACTERIZING MECHANISMS WITH UNBIASED PARTICIPATION

The next two results provide matching sufficient and necessary conditions for achieving unbiased participation in the symmetric setting. First, Theorem 4 shows that to achieve unbiased participation it is sufficient to use the Kilgour-Gerchak mechanism with a scoring rule that is symmetric in the sense that $S(p, x) = S(1 - p, 1 - x)$ for all p and x, or equivalently, has associated entropy function G with $G(p) = G(1 - p)$ for all p. In this case, a player i chooses to participate at level k if and only if his expected score is higher than the average expected score of all other players who would participate at level $k-1$. Theorem 5 then shows that this symmetry is also necessary in order to achieve unbiased participation in this setting.

Theorem 4 (Sufficient condition for unbiasedness) *In the symmetric setting, the Kilgour-Gerchak mechanism with strictly proper scoring rule S exhibits unbiased*

participation at all levels if $S(p,x) = S(1-p,1-x)$ for all $p \in [0,1]$ and $x \in \{0,1\}$. Moreover, player i at level k participates if and only if

$$G(c_i) > \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} G(c_j), \tag{4}$$

where G is the entropy function associated with S.

Proof: The proof is by induction. By definition, all players participate at level 0, so participation is unbiased. Consider any $k > 0$ and suppose that for all levels $k' < k$, participation is unbiased. Then by the entropy characterization of scoring rules in Theorem 1 and by Lemma 1, we have that player i with signal $\Sigma_i = \sigma_i$ participates only if

$$G(p_i(\sigma_i)) > \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|} \sum_{j \in \mathcal{P}_{-i}^{(k-1)}} \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = \sigma_i].$$

The symmetry of S implies that $G(p) = G(1-p)$ for all $p \in [0,1]$. Using this symmetry and the fact that $p_i(\sigma_i)$ is either c_i or $1 - c_i$, we have $G(p_i(\sigma_i)) = G(c_i)$ regardless of the signal realization σ_i. To complete the proof, we then need only to show that for any $j \neq i$ and any $\sigma_i \in \{0,1\}$,

$$\mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = \sigma_i] = G(c_j). \tag{5}$$

Since $G(c_j)$ does not depend on player i's signal, this would imply that participation is unbiased at level k.

By exploiting symmetry as described below, we have that

$$\begin{aligned}
&\mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 1] \\
&\quad = \mathbb{E}[S(1 - p_j(\Sigma_j), 1 - X) | \Sigma_i = 1] \\
&\quad = \mathbb{E}[S(p_j(1 - \Sigma_j), 1 - X) | \Sigma_i = 1] \\
&\quad = \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 0].
\end{aligned}$$

The first equality follows from the symmetry of S. The second follows from (3), which implies that $1 - p_j(\Sigma_j) = p_j(1 - \Sigma_j)$. The third can be easily verified by expanding out the expressions and exploiting the symmetry in both the prior and the signal error. Hence, we have

$$\begin{aligned}
&\mathbb{E}[S(p_j(\Sigma_j), X)] \\
&\quad = \Pr[\Sigma_i = 1] \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 1] \\
&\qquad + \Pr[\Sigma_i = 0] \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 0] \\
&\quad = \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 1] \\
&\quad = \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 0].
\end{aligned}$$

Moreover, we have

$$\begin{aligned}
&\mathbb{E}[S(p_j(\Sigma_j), X)] \\
&\quad = \Pr[\Sigma_j = 1] \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_j = 1] \\
&\qquad + \Pr[\Sigma_j = 0] \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_j = 0] \\
&\quad = \frac{1}{2} G(c_j) + \frac{1}{2} G(1 - c_j) = G(c_j).
\end{aligned}$$

Combining the previous two equalities gives us Equation (5), completing the proof. ■

The next result provides a matching necessary condition. Note that for any symmetric scoring rule S, adding a constant payment that depends on the outcome x but not on the report p would break symmetry but would not affect the resulting Kilgour-Gerchak payments; since this constant amount is added to *all* players' scores, it cancels out when comparing player i's score to the average score of other participants. The necessary condition states that unbiased participation is achievable only if the scoring rule used is "equivalent to" a symmetric scoring rule in this way.

Theorem 5 (Necessary condition for unbiasedness) *In the symmetric setting, if the Kilgour-Gerchak mechanism exhibits unbiased participation for level-k players with all possible signal accuracies for all levels k, then the payments are equivalent to those using Kilgour-Gerchak with a scoring rule S that satisfies $S(p,x) = S(1-p,1-x)$ for all $p \in [0,1]$ and $x \in \{0,1\}$.*

Proof: Assume that the Kilgour-Gerchak mechanism using scoring rule $\bar{S}$ exhibits unbiased participation for level-k players for all possible vectors of signal accuracies and all levels k.

First note that for any scoring rule $\bar{S}$ bounded in $[0,1]$, the scoring rule S defined by $S(q,1) = \bar{S}(q,1) + (1 - \bar{S}(1,1))$ and $S(q,0) = \bar{S}(q,0) + (1 - \bar{S}(0,0))$ remains bounded in $[0,1]$ and results in identical payments to each player when used in the Kilgour-Gerchak mechanism. For the purposes of this proof, we therefore consider the alternative representation of the mechanism as the Kilgour-Gerchak mechanism with this modified scoring rule S. Note that $S(1,1) = S(0,0) = 1$ and therefore $G(1) = G(0) = 1$.

Suppose there are only two players, i and j, with equal accuracies $c_i = c_j = c$, and consider the level-1 behavior of agent i. At level 0, agent j always participates. By Lemma 1, Theorem 1, and (3), we have that player i with signal $\Sigma_i = 1$ participates if and only if

$$G(c) > \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 1].$$

Expanding out the terms on both sides and rearranging, this inequality is equivalent to

$$\begin{aligned}
&S(c,1)c + S(c,0)(1-c) \\
&\qquad > c\left(S(c,1)c + S(1-c,1)(1-c)\right) \\
&\qquad\quad + (1-c)\left(S(c,0)(1-c) + S(1-c,0)c\right).
\end{aligned}$$

Rearranging terms, this condition reduces to

$$S(c,1) + S(c,0) > S(1-c,1) + S(1-c,0). \tag{6}$$

Similarly, player i participates with signal $\Sigma_i = 0$ if and only if

$$G(1-c) > \mathbb{E}[S(p_j(\Sigma_j), X) | \Sigma_i = 0].$$

Expanding out terms in a similar way and rearranging, this condition reduces to

$$S(1-c,1)+S(1-c,0) > S(c,1)+S(c,0). \quad (7)$$

For participation to be unbiased it must be that (6) and (7) either both hold or both do not hold. Clearly they cannot both hold simultaneously. The only way that both could simultaneously not hold is if

$$S(c,1)+S(c,0) = S(1-c,1)+S(1-c,0).$$

By the characterization of scoring rules in Theorem 1, the corresponding entropy function must then satisfy

$$\begin{aligned} &G(c)+G'(c)(1-c)+G(c)+G'(c)(-c) \\ &= G(1-c)+G'(1-c)c+G(1-c)+G'(1-c)(c-1) \end{aligned}$$

which reduces to

$$G(1–c)+(c–1/2)G'(1–c) = G(c)+(1/2–c)G'(c). \quad (8)$$

Since c was chosen arbitrarily, in order for participation to be unbiased for *all* vectors of signal accuracies, this equality must hold for all $c \in [1/2, 1]$.

It remains to show that this implies symmetry in S. It must be the case that $G(c) = G(1-c)$ at $c = 1/2$ and $c = 1$. (The latter is true because we have replaced $\bar{S}$ with S.) Suppose that there is some $c \in (1/2, 1)$ such that $G(c) > G(1-c)$. Then by continuity of G, there must be some c_1 and c_2 such that

(a) $G(c_1) = G(1-c_1)$,
(b) $G(c_2) = G(1-c_2)$,
(c) $G(c) > G(1-c)$ for all $c \in (c_1, c_2)$.

Condition (c) and (8) imply that for all $c \in (c_1, c_2)$, $G'(c) > -G'(1-c)$. But this contradicts conditions (a) and (b). Therefore, there cannot exist any c with $G(c) > G(1-c)$.

A symmetric argument can be made for the case in which $G(c) < G(1-c)$ for some $c \in (1/2, 1)$, so we must have $G(c) = G(1-c)$ for all c. The characterization in Theorem 1 can be used to easily show that this implies the desired symmetry in S. ■

4.2 MAXIMIZING PARTICIPATION RATES

Unbiased participation is desirable for information aggregation. However, as shown in Corollary 1, it necessarily leads to participation shrinking to zero as players' level of rationality grows. Our final result for the symmetric setting shows how to select the scoring rule that maximizes participation among those that lead to unbiased participation. This is accomplished in the limit as the entropy function G becomes very close to linear, that is, as the scoring rule S becomes very close to being only weakly proper.

Theorem 6 (Maximal participation) *Among all symmetric strictly proper scoring rules, maximal participation can be achieved as the limit of a sequence of strictly proper scoring rules with corresponding entropy functions of the form $G(p) = |2p-1|^\beta$ with $\beta > 1$ as $\beta \to 1$.*

Proof: Consider any symmetric scoring rule with symmetric entropy function G. By Equation (4) in Theorem 4 and the convexity of the entropy function, player i at level k would never participate unless

$$G(c_i) > G\left(\frac{1}{|\mathcal{P}_{-i}^{(k-1)}|}\sum_{j\in\mathcal{P}_{-i}^{(k-1)}} c_j\right).$$

Since we have assumed G is symmetric around $1/2$ and strictly convex, any such function G must be increasing on $[1/2, 1]$. Since $c_j \in [1/2, 1]$ for all j, we have that at level k, player i would never participate unless

$$c_i > \hat{c}_{-i}^{(k-1)} \equiv \frac{1}{|\mathcal{P}_{-i}^{(k-1)}|}\sum_{j\in\mathcal{P}_{-i}^{(k-1)}} c_j. \quad (9)$$

This is an "only if" condition that holds for any symmetric entropy function G. To maximize participation, we would like to select G to have a matching "if" condition that is as close to this as possible.

Consider the family of scoring rules defined by entropy function $G^\beta(p) = |2p-1|^\beta$ with $\beta > 1$. By Equation (4), player i would participate at level k under this scoring rule if and only if

$$\begin{aligned} 2c_i - 1 &> \frac{1}{\left|\mathcal{P}_{-i}^{(k-1)}(\beta)\right|^{1/\beta}}\left(\sum_{j\in\mathcal{P}_{-i}^{(k-1)}(\beta)}(2c_j-1)^\beta\right)^{1/\beta} \\ &= \frac{1}{\left|\mathcal{P}_{-i}^{(k-1)}(\beta)\right|^{1/\beta}}\left\|\{2c_j-1\}_{j\in\mathcal{P}_{-i}^{(k-1)}(\beta)}\right\|_\beta \end{aligned}$$

where $\|\cdot\|_\beta$ denotes the L_β norm and we use the notation $\mathcal{P}_{-i}^{(k-1)}(\beta)$ to emphasize the dependence of the set of participating players $\mathcal{P}_{-i}^{(k-1)}$ on β.

We first use this to show that for any $\beta, \beta' > 1$ with $\beta' < \beta$, participation declines more gradually under the scoring rule defined by $G^{\beta'}$ than it does under the scoring rule defined by G^β. We do so by induction. Since all players participate at level 0, for any i we have $\mathcal{P}_{-i}^{(0)}(\beta) = \mathcal{P}_{-i}^{(0)}(\beta')$. Assume that for all $k' < k$, $\mathcal{P}_{-i}^{(k')}(\beta) \subseteq \mathcal{P}_{-i}^{(k')}(\beta')$. By

standard properties of norms, we then have

$$\frac{1}{\left|\mathcal{P}_{-i}^{(k-1)}(\beta)\right|^{1/\beta}}\left\|\{2c_j-1\}_{j\in\mathcal{P}_{-i}^{(k-1)}(\beta)}\right\|_{\beta}$$
$$\geq \frac{1}{\left|\mathcal{P}_{-i}^{(k-1)}(\beta)\right|^{1/\beta'}}\left\|\{2c_j-1\}_{j\in\mathcal{P}_{-i}^{(k-1)}(\beta)}\right\|_{\beta'}$$
$$\geq \frac{1}{\left|\mathcal{P}_{-i}^{(k-1)}(\beta')\right|^{1/\beta'}}\left\|\{2c_j-1\}_{j\in\mathcal{P}_{-i}^{(k-1)}(\beta')}\right\|_{\beta'}.$$

The last line follows from the fact that since the players who choose to participate are always those with the highest quality (corresponding to higher values of $2c_j - 1$), if a larger group participates they are lower quality on average.

This implies that if a player participates at level k under the scoring rule defined by G^β then he also participates for any $\beta' < \beta$, completing the inductive step.

In the limit as $\beta \to 1$, we get that the participation constraint at each level k converges to the constraint $c_i > \hat{c}_{-i}^{(k-1)}$, which, from Equation 9, is the participation limit for any symmetric strictly proper scoring rule. ■

This result shows that participation levels rise as the scoring rule used becomes closer to weakly proper, providing experts less incentive to report their true beliefs rather than make a false report. In fact, it is easy to see that maximum participation could be achieved using the weakly proper scoring rule with entropy function $G(p) = |2p-1|$, though this would result in a loss of strict truthfulness. This result is somewhat intuitive. Since the Kilgour-Gerchak mechanism is a zero-sum game, bigger rewards for the most accurate players require bigger punishments for the least accurate, causing those with less information to drop out at lower levels of rationality. By rewarding all players more evenly, less accurate players do not drop out as quickly. However, this may have consequences in real-world scenarios in which an expert may not find it worth his time to participate if the rewards for highly accurate information are low, even if he stands to make a profit on expectation.

4.3 UNCERTAINTY ABOUT OPPONENTS

One potential objection to our model is the assumption that each player i knows the accuracy parameter c_j of every other player j. This assumption is certainly unrealistic in settings in which the number of players is large or the pool of players anonymous. We briefly remark that most of our results can be extended to the Bayesian setting in which it is necessary only for each player i to know a *distribution* over the types (in this case, accuracy parameters) of other players. However, this extension requires modifying the definition of unbiasedness so that a player's decision to participate may depend on parts of his private information (e.g., his accuracy). For instance, if the accuracy of the signal of each player is drawn i.i.d. based on some commonly known discrete distribution with cumulative density function F, then it is easy to derive that if a symmetric scoring rule is used then a player at level k participates if and only if his realized accuracy c_i satisfies

$$G(c_i) > \mathbb{E}_{c\sim F}\left[G(c)|c \geq \theta^{k-1}\right],$$

with $\theta^0 = 0$ and θ^k defined recursively as the minimum c_i that satisfies the latter inequality or 1 if there is no such c_i.

To preserve the clarity of our analysis, we omit the details and present only the simpler setting here.

5 DISCUSSION

In order to design wagering mechanisms to elicit honest, unbiased beliefs from groups of experts, it is necessary to understand how experts behave. Previous analyses have assumed extreme behavior; either experts are fully rational, in which case standard no-trade theorems apply, or experts have immutable beliefs and are essentially oblivious to the fact that they are participating in a zero-sum game. In this paper, we search for middle ground, analyzing the behavior of boundedly rational level-k players who recognize they are in a game but are still overconfident in their reasoning. We examine the design implications of this model, seeking instantiations of Kilgour and Gerchak's shared scoring rule wagering mechanism that encourage unbiased and truthful participation at high rates.

This paper can be viewed as a contribution to the new but growing research area of *behavioral mechanism design* (Ghosh and Kleinberg, 2014; Easley and Ghosh, 2015) in which insights from behavioral game theory are applied to design mechanisms tailored to real (or at least more realistic) human participants as opposed to idealized rational agents. Of course any theory is only as good as the model on which it is based. While the behavioral game theory literature provides support that the level-k model is a decent predictor of human behavior in game theoretic settings—including one-shot betting games in which the no-trade theorem would typically apply (Brocas et al., 2014)—additional experimental work is needed to understand how well it models the behavior of real experts participating in wagering mechanisms like Kilgour-Gerchak. Still, we believe that our analysis takes a valuable first step towards understanding the ability of wagering mechanisms to aggregate information from experts who are neither fully rational nor fully naive.

Abstract

This work concerns decision making under risk with the rank-dependent utility model (RDU), a generalization of expected utility providing enhanced descriptive possibilities. We introduce a new incremental decision procedure, involving monotone regression spline functions to model both components of RDU, namely the probability weighting function and the utility function. First, assuming the utility function is known, we propose an elicitation procedure that incrementally collects preference information in order to progressively specify the probability weighting function until the optimal choice can be identified. Then, we present two elicitation procedures for the construction of a utility function as a monotone spline. Finally, numerical tests are provided to show the practical efficiency of the proposed methods.

1 INTRODUCTION

Uncertainty is pervasive in human activities and represents an important source of complexity in individual and collective decision making. As soon as intelligent systems are used for supporting human decision making or simulating realistic human decision behaviors, preference modeling and preference elicitation becomes particularly important. In decision making under uncertainty and risk, preference models are used to represent uncertain outcomes and to provide normative decision rules for choice problems, but also to describe, predict or simulate observed human behaviors. Given a mathematical model used to compare the alternatives of a choice problem, preference elicitation consists in fitting the parameters of the model to a specific Decision Maker (DM), to capture her attitude towards risk. Then the model can be used to support her choices in complex situations involving a large number of alternatives or to integrate her value system into an autonomous decision agent. Considering this context, our paper aims at providing new tools for interactive decision support under risk.

Decision under risk is a standard formal framework for handling uncertainty in decision making, characterized by a probabilistic representation of uncertainty. In this framework, risky prospects are represented by probability distributions with a finite support, namely lotteries. In the seminal work of Bernoulli (1738; refer to [1954] for an English translation) and in the theory of von Neumann and Morgenstern (vNM) [1947], the values of lotteries are measured in terms of *expected utility* (EU). This well-known decision criterion is linear in probabilities and characterized by a utility function encoding the subjective value of any possible consequence for the DM; EU is used to compare lotteries and choice problems are solved by EU maximization. This choice model has been axiomatically justified in the context of risk by vNM [1947], but also in the more general context of uncertainty introduced by Savage [1954], where probabilities are not assumed to exist a priori.

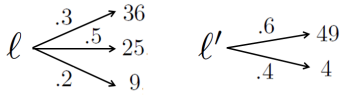
From EU to RDU. Despite these axiomatic results and the intuitive appeal of EU theory, the model suffers from well known limitations, from a descriptive viewpoint. There exist situations where individuals may exhibit behaviors that are not consistent with EU theory, as illustrated by the so-called Allais's paradox. For example, people often prefer \$3000 with certainty (choice A) to \$4000 with probability .8 (choice B), but they prefer \$4000 with probability .2 (choice D) to \$3000 with probability .25 (choice C). Remarking that $C = .25A + .75O$ and $D = .25B + .75O$ where O is the choice to win nothing with probability 1, it turns out that such preferences violate the vNM independence axiom. This example, used by Kahneman and Tversky [1979] in their experiments, is frequently observed and known as the *certainty effect*: a reduction in probability of winning a reward creates a larger (negative) psychological effect when it is done from certainty than from uncertainty. Similar observations have been made in actual decision contexts, for instance in route-choice problems where evidence was found of violation of EU theory [Avineri and Prashker, 2004].

These experiments and others in the same spirit suggest that probabilities are distorted in the decision making process. More precisely, small probabilities (greater than 0) tend to be overestimated while large ones (smaller than 1) underestimated. This has motivated the introduction of a probabilistic transformation model to generalize EU, leading to evaluate the lottery $(x_1, p_1; \ldots, x_n; p_n)$ that yields outcome x_i with probability p_i by $\sum_i w(p_i)u(x_i)$. This generalization of EU dates back to [Edwards, 1955] and appears also in prospect theory [Kahneman and Tversky, 1979]. However, it can be easily shown that it violates the principle of stochastic dominance and could lead to select dominated alternatives; this is often considered as a serious weakness from a normative viewpoint. To overcome this problem, a solution proposed by Quiggin [1982] and Yaari [1987] consists in applying the probability transformation to the decumulative probability distribution function, and not to the probabilities of individual outcomes. This solution leads to the *rank-dependent utility* model (RDU) that consists in evaluating the lottery $\ell = (x_1, p_1; \ldots, x_n; p_n)$ such that $x_1 \geq \ldots \geq x_n \geq 0$[1] by:

$$V(\ell) = \sum_{i=1}^{n} w\left(\sum_{k=1}^{i} p_k\right)[u(x_i) - u(x_{i+1})]$$

$$= w(p_1)u(x_1) + \sum_{i=2}^{n}\left[w\left(\sum_{k=1}^{i} p_k\right) - w\left(\sum_{k=1}^{i-1} p_k\right)\right]u(x_i)$$

where $x_{n+1} = 0$ and $w : [0,1] \to [0,1]$ is a non-decreasing function such that $w(0) = 0$ and $w(1) = 1$. Note that the coefficient of $u(x_i)$ in RDU depends on the cumulative probability of the outcomes greater or equal to x_i (since outcomes are indexed to be sorted by decreasing order); this shows that this coefficient depends on the rank of x_i in the set of possible outcomes. To illustrate the use of RDU, we compare the two following lotteries ℓ and ℓ' with $w(p) = p^2$ and $u(x) = \sqrt{x}$:



$V(\ell) = (.3)^2(6-5) + (.8)^2(5-3) + 1^2 3 = 4.37$ and $V(\ell') = (.6)^2(7-2) + (1)^2 2 = 3.8$, hence ℓ is preferred to ℓ'. To give another example, let us remark that, for any lottery of type $\ell = (x^+, p; x^-, 1-p)$, $x^+ > x^-$, we have:

$$V(\ell) = w(p)u(x^+) + (1 - w(p))u(x^-)$$

Function w is referred to as the *probability weighting function*. It is worth noting that, when $w(p) = p$, RDU boils down to EU as we can see from the second formulation. On the other hand, RDU is also known to be an instance of Choquet Expected Utility [Schmeidler, 1989]. More precisely, it turns out to be the natural instance for decision making under risk due its compatibility with stochastic dominance [Wakker, 1990]. For more details about RDU theory see [Quiggin, 2012, Diecidue and Wakker, 2001].

Let us mention also some well known variants of RDU theory. First, Yaari [1987] introduced and axiomatized a dual model to expected utility where transformations are applied to probabilities rather than to outcomes. This is a special case of RDU obtained when the utility function is linear in the outcomes. Moreover, the idea of rank-dependent weightings was also incorporated by Kahneman and Tversky [1992] into prospect theory, leading to *cumulative prospect theory*. This theory extends the RDU theory to model different risk attitudes towards gains depending on whether above or below a reference level.

In this paper, we focus on the RDU model, and we address the problem of identifying, within a given (possibly large) set of lotteries, the preferred solution for a given DM consistent with RDU theory. This solution could be used for predicting a choice of the DM or even to make a recommendation. This requires to elicit, at least partially, the probability weighting function and the utility function. Note that the determination of RDU-optimal solutions has motivated various contributions in the past, e.g. [Nielsen and Jaffray, 2006, Jeantet *et al.*, 2012].

Incremental decision making. A first approach to elicitation, standard in mathematical economics, aims to obtain a full description of preferences by the decision model, assuming that DM's preferences are observable on all possible pairs of alternatives. The elicitation process is justified by the axioms of the underlying theory and the components of the models are revealed point by point using systematic sequences of queries to obtain a precise specification of the model. To simplify the process, a frequent option used in economics (but also in artificial intelligence) consists in postulating a parametric form for each component of the decision model; queries are then used to fit the parameters. Refer to [Wakker and Deneffe, 1996, Gonzalez and Wu, 1999, Abdellaoui, 2000] for full elicitation procedures proposed in economics for RDU, and to [Fürnkranz and Hüllermeier, 2003, Torra, 2010, Tehrani *et al.*, 2012] for model-based preference learning.

Recently a number of works have tackled the elicitation of the components of the decision model in an adaptive way [Wang and Boutilier, 2003, Boutilier *et al.*, 2006, Braziunas and Boutilier, 2007, Benabbou *et al.*, 2014]; the aims is that of focusing on learning the "important" part of the utility, allowing to recommend near-optimal decisions with only partial information about the decision model. These incremental approaches consider all possible instances of preference model parameters consistent with the currently known information about the user; the user's responses allow to infer constraints on these parameters.

[1] As suggested by Gilboa [2008], it is more natural to think of the object of choice in Quiggin and Yaari's models as lotteries over final wealth (with positive outcomes) rather as prospects of gains and losses, because they did not emphasize gain-loss asymmetry in their theory.

In this work, we consider the problem of incrementally eliciting the components of the RDU model by interactively asking queries to the DM; this aims to support the identification or approximation of an RDU-optimal choice. We first address the problem of eliciting the weighting function incrementally (Section 2) assuming that the utility is known. Afterwards, we will present utility elicitation procedures adapted to the rank-dependent utility model (Section 3). Finally, we provide numerical tests (Section 4).

2 ELICITATION OF THE PROBABILITY WEIGHTING FUNCTION

Decision makers exhibit various decision behaviors when they are confronted to choices involving risky prospects. Within RDU theory, this diversity of attitudes towards risk can be modeled by controlling the definition of the two components of the model, namely the utility function and the probability weighting function. Since these two components are strongly interlaced in RDU, their joint elicitation is quite challenging. Fortunately, these two components concern two separate and well identified risk-components, on the one hand marginal utilities induced by the shape of the cardinal utility function [Chateauneuf and Cohen, 1994], and on the other hand the probabilistic risk-attitude towards probabilistic mixtures induced by the shape of the probability weighting function [Wakker, 1994]. They can be observed separately using proper preference queries as shown in [Wakker and Deneffe, 1996, Abdellaoui, 2000]. In this section, the utility is assumed to be known (already elicited or known to be linear (Yaari's model), and we focus on the elicitation of probability weights.

2.1 ON PROBABILITY WEIGHTING FUNCTIONS

The probability weighting function is necessarily non-decreasing but can take different forms depending on the attitude of the DM towards risk. For instance, in Yaari's model, *weak risk aversion* which consists, for any lottery ℓ, in preferring $E(\ell)$ for sure to ℓ (where $E(\ell)$ is the expected value of ℓ) is equivalent to $w(p) \leq p$ for all $p \in [0,1]$ [Chateauneuf and Cohen, 1994]. Moreover, in the RDU model, *strong risk aversion* which consists in preferring ℓ to ℓ' whenever ℓ stochastically dominates ℓ' at second order, is equivalent to using a convex weighting function and a concave utility [Hong *et al.*, 1987]. Finally, several experiments including those of Kahneman and Tversky [1979] lead to propose an inverse S-shaped function. For example, the use of the weighting function given in Figure 1 in Yaari's model allows to explain the preferences observed on lotteries A, B, C, D presented in the introduction. We have indeed $V(A) = 3000\ w(1)$, $V(B) = 4000\ w(0.8), V(C) = 3000\ w(0.25)$ and $V(D) = 4000 w(0.2)$. Since $w(0.2) \approx 0.26$, $w(0.25) \approx 0.29$, $w(0.8) \approx 0.60$ and $w(1) = 1$ we obtain $V(A) > V(B)$ while $V(C) < V(D)$.

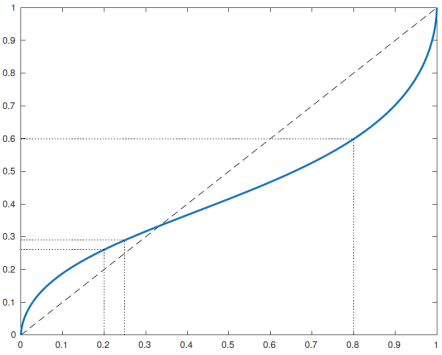


Figure 1: Inverse S-shaped function w.

The following parametric expressions for $w(p)$ have been proposed in the literature [Cavagnaro *et al.*, 2013], among several others:

$$\text{TK}: \quad w(p) = \frac{p^r}{(p^r+(1-p)^r)^{1/r}} \quad \text{with } 0.28 < r \leq 1$$

$$\text{Prelec}: \quad w(p) = e^{-s(-\ln p)^r} \quad \text{with } 0 < r \leq 1; 0 < s$$

$$\text{LinLog}: \quad w(p) = \frac{s\,p^r}{s\,p^r+(1-p)^r} \quad \text{with } 0 < r, s$$

where TK denotes the parametric form proposed by Tversky and Kahneman (the w plotted in Figure 1 is of this type, with $r = 0.6$). Note that Prelec and LinLog make use of two parameters (r and s) while TK is based on a single parameter. Karmarkar [1978] proposes a parametric form that is a special case of LinLog with $s = 1$.

Choosing a priori a specific parametric form among these different options and others, with the idea of learning the parameters, may generate errors due to not taking into account the specificity of the DM that may be revealed during the elicitation process. Instead, we propose a new approach based on a much more flexible parametric construction based on the definition of w as a piecewise polynomial spline function. Moreover, we will adopt an incremental elicitation approach in order to reason with the possible functions w that are consistent with the current preference information of the DM. In the spirit of incremental decision making, by considering additional preferences (obtained by asking queries), we will be able to progressively narrow down our model of the DM until we are able to identify the preferred alternative.

2.2 INCREMENTAL ELICITATION OF w

We assume here that the utility function is known and we reason with an incompletely specified weighting function $w \in W$, W being the set of admissible probability weighting functions at a given step of the process. Initially, W can be all non-decreasing functions on the unit interval such that $w(0) = 0$ and $w(1) = 1$ or an approximation of

them representable by a given family of parametric functions. The utility function u being fixed, we will denote $V(\ell; w)$ the RDU value of lottery ℓ for weighting function w. Each time a preference statement of type "ℓ^+ is at least as good as ℓ^-" is obtained, this induces a new constraint $V(\ell^+; w) \geq V(\ell^-; w)$ that further restricts W.

In order to make a decision when probability weights are imprecisely known, we will use minimax regret which is a standard decision criterion for robust decision making under uncertainty [Savage, 1954]. It was more recently proposed by Boutilier et al. [2003, 2006] for decision-making under utility uncertainty. Moreover, minimax regret can be used as a driver for preference elicitation and incremental decision making.

Let $\mathcal{L}$ be the set of lotteries representing the alternatives of the decision problem. If we knew the DM's specific w, then the optimal choice would be any element of $\arg\max_{\ell \in \mathcal{L}} V(\ell; w)$. However, since w is not known precisely, we need to provide a recommendation based on the current information. We are interested in evaluating the loss that can result from choosing a decision ℓ instead of the optimal one. To this end, we use the following notions of regret. The pairwise maximum regret PMR of ℓ against ℓ' is the maximal value that the difference $V_u(\ell'; w) - V_u(\ell; w)$ can take for any admissible function of $w \in W$. The max regret MR of a choice ℓ is defined as the maximum pairwise regret when the adversary is chosen among all lotteries in $\mathcal{L}$. Finally, the minimax regret MMR is the minimum value of max regret. More formally:

$$\mathrm{PMR}(\ell, \ell'; W) = \max_{w \in W} [V(\ell'; w) - V(\ell; w)] \quad (1)$$

$$\mathrm{MR}(\ell; W) = \max_{\ell' \in \mathcal{L}} \mathrm{PMR}(\ell, \ell'; W) \quad (2)$$

$$\mathrm{MMR}(W) = \min_{\ell \in \mathcal{L}} \mathrm{MR}(\ell; W) \quad (3)$$

Then we recommend one of the decisions associated with the minimum value of max regret, i.e. lottery $\ell^* \in \arg\min_{\ell \in \mathcal{L}} \mathrm{MR}(\ell; W)$. This is a regret-optimal decision given the current preference information. By definition, recommending ℓ^* means to be robust with respect to the possible realizations of $w \in W$.

In addition of being a criterion for decision-making, minimax regret can be used to drive the elicitation of further preference information. We assume an interactive setting where the system (a decision-support agent) can ask additional queries in order to improve the quality of the recommendation. If the current minimax regret value is higher than a given positive threshold, we ask another query to the user. Different types of queries can be asked to the user; among the many possibilities, comparison queries, asking the user to state which choice is best among two presented to him, are particularly natural. It is however important to ask informative queries in order to quickly converge to a recommendation of high value. An effective heuristic to choose the next query is the *current solution* strategy [Wang and Boutilier, 2003, Boutilier *et al.*, 2006]; it asks the user to compare the regret-optimal lottery ℓ^* with its adversarial challenger $\ell^a = \arg\max_{\ell \in \mathcal{L}} \mathrm{PMR}(\ell^*, \ell)$. This will often reduce minimax regret: if the user states that ℓ^* is preferred to ℓ^a, in the next computation of minimax regret, the adversary will have to choose another lottery, leading to a reduction of regret (unless there were ties in the max regret computations). If, instead ℓ^a is preferred to ℓ^*, the regret-optimal choice in the next computation will necessarily be a choice other than ℓ^*, and, again, we will likely reduce regrets.

Assume $\mathcal{P}$ to be a set of pairs (ℓ^+, ℓ^-) for which we know that the DM considers that ℓ^+ is at least as good as ℓ^-. Let $W = \{w : \forall (\ell^+, \ell^-) \in \mathcal{P}, V(\ell^+; w) \geq V(\ell^-; w)\}$, our goal is to compute $\mathrm{PMR}(\ell, \ell', W)$. This corresponds to solving the following optimization problem:

$$\max_w [V(\ell'; w) - V(\ell; w)] \quad (4)$$

$$s.t. \;\; w(0) = 0, w(1) = 1 \quad (5)$$

$$w(p) \leq w(q), \;\; \forall p, q \in [0, 1] : p \leq q \quad (6)$$

$$V(\ell^+; w) \geq V(\ell^-; w), \;\; \forall (\ell^+, \ell^-) \in \mathcal{P} \quad (7)$$

Such optimization is not however directly feasible. First, the monotonicity constraint (6) on the unit interval represents implicitly an infinity of constraints. If we only impose monotonicity on probabilities involved in the lotteries of $\mathcal{L}$, it still represents a large number of constraints. Moreover, constraint (7) is quite difficult to handle. Even if we assume that w belongs to one of the families of parametric curves considered in the previous subsection, the resulting constraints will not be linear in the parameters. In the next subsection we will see how these problems can be overcome by defining w as a monotone spline function.

2.3 A MODEL BASED ON I-SPLINE FUNCTIONS

Spline functions are piecewise polynomials whose pieces connect with a high degree of smoothness. They are very useful in data interpolation and shape approximation due to their capacity to approximate complex shapes through curve fitting and interactive curve design while preserving an important property, missing in many other interpolation methods: they guarantee that smooth curves will be generated from smooth data [Beatty and Barsky, 1995]. The use of piecewise polynomials in non-linear regression extends the advantage of polynomials by providing greater flexibility, local effects of parameter changes and the possibility of imposing constraints on estimated functions [Ramsay, 1988].

One important feature of spline functions is that they can be generated by linear combinations of basis spline functions. A basis of splines particularly appealing for non-linear regression is the M-spline family [Ramsay, 1988]. M-splines of order k are functions $M_i, i = 1, \ldots, m$ which are polynomials of degree $k - 1$. They can be used to approximate

any function defined on a given interval $[a, b]$ by a spline of the form $f = \sum_i \lambda_i M_i$. To define M_i precisely, we need to introduce a sequence of knots $t = \{t_1, t_2, \ldots, t_l\}$ such that $a = t_1 = \ldots = t_k$, $b = t_{l-k+1} = \ldots = t_l$ and $\forall i, t_i \leq t_{i+1}$. The basis constructed from sequence t contains $m = \mid t \mid -k$ spline functions of order k denoted $M_i(x; k, t)$, $i = 1, \ldots, m$, and defined for $k = 1$ by:

$$M_i(x; 1, t) = \begin{cases} \frac{1}{t_{i+1} - t_i} & \text{if } x \in (t_i, t_{i+1}) \\ 0 & \text{otherwise} \end{cases}$$

For $k > 1$ and $t_{i+k} > t_i$, M_i is defined recursively by:

$M_i(x; k, t) = \frac{k[(x - t_i) M_i(x; k-1, t) + (t_{i+k} - x) M_{i+1}(x; k-1, t)]}{(k-1)(t_{i+k} - t_i)}$
and otherwise $M_i(x;k,t) = 0$. In particular, we have $M_i(x;k,t) = 0$ whenever $k > 1$ and $t_{i+k} = t_i$.

Note that $M_i(x;k,t)$ is strictly positive in (t_i, t_{i+k}) and 0 elsewhere, with an integral equal to 1. Moreover, it is a polynomial of degree $k - 1$ so that, for any piecewise polynomial function of the form $f = \sum_i \lambda_i M_i$, adjacent polynomials have matching derivatives up to order $k - 2$. Hence, a good choice for k in practice is $k = 3$ because, in this case, we generate piecewise quadratic f functions with matching first derivatives while preserving a local influence of every components. Choosing a lower k would loose continuity of the first derivative and choosing a higher k would increase the range (t_i, t_{i+k}) of influence of every component M_i, which diminishes controllability of the model. As an example, the family of splines $M_i(x; 3,t), i = 1, \ldots, 5$ defined on the unit interval from subdivision $t = (0, 0, 0, \frac{1}{3}, \frac{2}{3}, 1, 1, 1)$ is given in the left part of Figure 2. Finer spline decompositions could be obtained using finer subdivisions. Moreover, it is possible to use non-equally-spaced knot sequences to have a finer control of the shape in some parts of interval $[a, b]$. However, practical tests show that using too many nodes is counterproductive to generate smooth and regular curves.

We may define the probability weighting function w as a weighted combination of M_i-spline functions with probably good fitting possibilities. However, this would not guarantee to obtain a non-decreasing weighting function w. To get rid of the monotonicity constraint (6), we need another basis specifically designed for the generation of non-decreasing spline functions. The solution is given by monotone regression splines that provide very nice descriptive possibilities, as demonstrated by Ramsey [1988]. Such spline functions are non-decreasing because they are generated by conical combinations of basis I-spline functions, i.e., non-decreasing functions defined as the integrals of the M-splines (which are positive). Formally, these functions denoted $I_i(x; k, t)$, $i = 1, \ldots, m$ are defined by:

$$I_i(x; k, t) = \int_a^x M_i\,(y; k,\ t)\, dy$$

Let j be the index such that $t_j \leq x < t_{j+1}$, the value of an I-spline is computed as follows:

$$I_i(x; k, t) = \begin{cases} 1 \text{ if } i < j - k + 1 \\ 0 \text{ if } i > j \\ \sum_{s=i}^{j} \frac{t_{s+k+1} - t_s}{k+1} M_s(x; k+1, t) \text{ otherwise} \end{cases}$$

As an illustration, the family of splines $I_i(x; 3,t), i = 1, \ldots, 5$ for subdivision $t = (0, 0, 0, 0, \frac{1}{3}, \frac{2}{3}, 1, 1, 1, 1)$ is given in the right part of Figure 2.

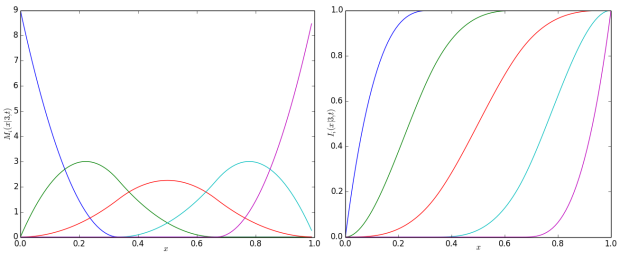

Figure 2: Basis functions $M_i(x; 3,t)$ and $I_i(x; 3,t)$

2.4 REGRET MINIMIZATION WITH I-SPLINES

The computation of PMR is the main building block to compute minimax regret. In order to compute MR and MMR, it is indeed sufficient to perform a quadratic number of PMR optimizations[2]. We now focus the discussion on PMR computations and show that the optimization of regrets is drastically simplified when weighting function w is defined by a conical combination of I_i-splines:

$$w(p) = \sum_{j=1}^{m} \lambda_j I_j(p; k, t), \quad \lambda_j \geq 0, j = 1, \ldots, m \qquad (8)$$

Note that, k and t being fixed, function w is completely characterized by vector $\lambda = (\lambda_1, \ldots, \lambda_m) \in \mathbb{R}_+^m$. So the elicitation of the entire function boils down to the elicitation of vector λ. In that case the RDU criterion reads, for any lottery $\ell = (x_1, p_1; \ldots; x_n, p_n)$, as follows:

$$V(\ell; \lambda) = \sum_{i=1}^{n} \sum_{j=1}^{m} \lambda_j I_j(\sum_{k=1}^{i} p_k; k, t)[u(x_i) - u(x_{i+1})]$$

By permuting the two first summations in the above formulation, we obtain $V(\ell; \lambda) = \lambda^\intercal v(\ell, k, t)$ where $v(\ell, k, t) \in \mathbb{R}^m$ is a vector whose j^{th} component is equal to $\sum_{i=1}^{n} I_j(\sum_{k=1}^{i} p_k; k, t)[u(x_i) - u(x_{i+1})]$. Hence PMR values can be reformulated using vector λ and a set Λ of admissible weighting vectors replacing W. We obtain:

$$\begin{aligned} \text{PMR}(\ell, \ell'; \Lambda) &= \max_{\lambda \in \Lambda} [V(\ell'; \lambda) - V(\ell; \lambda)] \\ &= \max_{\lambda \in \Lambda} \lambda^\intercal [v(\ell', k, t) - v(\ell, k, t)] \end{aligned}$$

[2] In fact, a more efficient strategy consists in implementing an alpha-beta search procedure, in this way it is possible to prune several cases and compute a much lower number of PMRs [Braziunas, 2011].

Moreover, the constraint $V(\ell^+; w) \geq V(\ell^-; w)$ present in (7) takes now the form of a linear constraint $\lambda^\intercal[v(\ell^+, k, t) - v(\ell^-, k, t)] \geq 0$. Hence the set

$$\Lambda_{\mathcal{P}} = \{\lambda \in \mathbb{R}^m_+ : \forall (\ell^+, \ell^-) \in \mathcal{P}, \lambda^\intercal[v(\ell^+, k, t) - v(\ell^-, k, t)] \geq 0\}$$

is a convex polyhedron. Therefore, under the assumption that I-spline functions are convenient to describe the probability weighting function, the computation of PMR for a given pair of lotteries (ℓ, ℓ'), initially introduced as a difficult optimization problem, see Equations (4-7), can now easily be achieved by solving the following linear program:

$$\begin{aligned} & \max \lambda^\intercal[v(\ell', k, t) - v(\ell, k, t)] \\ s.t. \quad & \lambda^\intercal[v(\ell^+, k, t) - v(\ell^-, k, t)] \geq 0, \forall (\ell^+, \ell^-) \in \mathcal{P} \\ & \lambda_i \geq 0, i = 1, \ldots, m. \end{aligned}$$

2.5 THE ELICITATION ALGORITHM

Algorithm 1 details the steps involved in our regret-based approach for the elicitation of w. Given a dataset of decisions (lotteries) $\mathcal{L}$ (for each decision we are given a specification of the numerical outcomes and their associated probabilities) and a set of initial preferences $\mathcal{P}$ (that could be empty), we compute the initial minimax regret value v, the max-regret-optimal decision ℓ^* and the adversarial decision ℓ^a. We then start asking queries.

Function `Query` simulates the question/answer protocol. It takes two lotteries as input and returns the preferred lottery among the two. After each user's response we recompute the minimax regret value, the regret-optimal decision ℓ^*, and its challenger ℓ^a. We loop until the regret drops below a positive threshold ε. Queries are asked according to the *current solution strategy* (analogue to the strategy used in [Boutilier *et al.*, 2006]), that requires the user to compare ℓ^* with ℓ^a. The least preferred among ℓ^* and ℓ^a is removed from $\mathcal{L}$ as it is dominated by the other. This guarantees a strict reduction of $|\mathcal{L}|$ at every step, ensuring a linear convergence in the number of lotteries. The practical efficiency of this algorithm is illustrated in Section 4.

Note that when the lotteries in $\mathcal{L}$ involve a large number of branches, we cannot expect a DM to be able to compare them with confidence. In such cases, we recommend to work with two sets of lotteries: the actual set $\mathcal{L}$ of lotteries (in which the preferred solution must be found), on which pairwise regrets are computed, and a second set of simpler lotteries used only for preference queries. For the latter, we may use lotteries of type $\ell_p = (M, p; 0, 1-p)$ (where M is the top outcome) and ask the DM to compare ℓ_p, for some probability p, to some certain consequence x in $[0, M]$. Under the assumptions $u(0) = 0$ and $u(M) = 1$, we derive from the response either $w(p) \geq u(x)$ or the reverse inequality, thus reducing uncertainty on function w and, in most cases, the MMR on actual lotteries.

3 UTILITY ELICITATION IN RDU

In the previous section, we have discussed the elicitation of the weighting probability function in the RDU model, assuming the utility function was known. We discuss now the elicitation of function u when w is not known. The main difficulty to overcome lies in the fact that functions u and w are strongly interlaced in the computation of RDU values, due to products of type $w(\sum_{k=1}^{i} p_i)u(x_i)$. A given value $u(x_i)$ may impact differently on preferences, depending on the probability weighting function. Fortunately, there is a part of DM preferences that are not impacted by w and that can be used to elicit u. We present two illustrations of this idea in the two next subsections. The fist one provides a precise spline function interpolating a sample of points of the utility curve constructed with the *gamble tradeoff method* proposed by Wakker and Deneffe [1996]. The second proposes an alternative approach based on simple queries aiming at obtaining the certainty equivalent of simple lotteries.

3.1 USING THE GAMBLE TRADEOFF METHOD

We first recall the principle of the gamble tradeoff method [Wakker and Deneffe, 1996] to construct points on the utility curve. To start with an example, let us consider the two following lotteries: $\ell = (c, p; b, 1-p)$ and $\ell' = (d, p; a, 1-p)$ for a probability $p \in (0, 1)$, where a, b, c, d are four distinct outcomes such that $a < b < c < d$. Then it can be easily checked from the definition of RDU that the DM is indifferent between ℓ and ℓ' (i.e., $V(\ell) = V(\ell')$) if and only if:

$$[u(b) - u(a)](1 - w(p)) = [u(d) - u(c)]w(p) \quad (9)$$

To construct some points of the utility function $u(x)$, x in $[0, M]$, we need two reference values α and β chosen in such a way that $M < \alpha < \beta$. Then, the gamble tradeoff method consists in generating the increasing sequence

defined by $r_0 = 0$ and $r_i = \texttt{Query}(\ell_i, \ell'_i)$ for $i > 1$ where:

$$\ell_i = (\alpha, p; r, 1-p) \qquad \ell'_i = (\beta, p; r_{i-1}, 1-p)$$

and $\texttt{Query}(\ell_i, \ell'_i)$ is a function asking to the DM which value r makes the two lotteries indifferent and returns this value. The sequence is generated until $r \geq M$. By construction we have $V(r_i, 1-p; \alpha, p) = V(r_{i-1}, 1-p; \beta, p)$. Similarly we have $V(r_{i+1}, 1-p; \alpha, p) = V(r_i, 1-p; \beta, p)$. From these two equalities, we obtain, from equation (9):

$$\begin{array}{rcl} [u(r_i) - u(r_{i-1})](1 - w(p)) & = & [u(\beta) - u(\alpha)]w(p) \\ [u(r_{i+1}) - u(r_i)](1 - w(p)) & = & [u(\beta) - u(\alpha)]w(p) \end{array}$$

Hence $u(r_{i+1}) - u(r_i) = u(r_i) - u(r_{i-1})$, therefore:

$$u(r_{i+1}) = 2u(r_i) - u(r_{i-1}) \tag{10}$$

Since u is defined up to a positive affine transformation, we can set, without loss of generality, $u(r_0) = 0$ and $u(r_1) = 1$. Hence, using (10) we obtain $u(r_i) = i$ for all $i \geq 0$ which means that the utility function should interpolate points (r_i, i). Moreover, the density of values r_i within a given interval can be increased (resp. decreased) by changing parameters α and β to reduce or increase the difference $\beta - \alpha$.

Assume that q points (r_i, i) have been constructed with the gamble tradeoff method, these points can be interpolated using I-spline regression. So we define the utility function as a piecewise quadratic monotone spline $u(x) = \sum_k \lambda_k I_k(x, 3, t)$ for a uniform knot sequence t. Then, coefficients λ_k can be determined by minimizing the distance of the constructed points to the spline u. This is achieved by solving the following linear program Π:

$$\begin{array}{ll} & \min \sum_{i=1}^{q} e_i \\ s.t. & \left\{ \begin{array}{ll} e_i \geq i - \sum_k \lambda_k I_k(r_i, 3, t), & i = 1, \ldots, q \\ e_i \geq \sum_k \lambda_k I_k(r_i, 3, t) - i & i = 1, \ldots, q \end{array} \right. \\ & \lambda_k \geq 0, k = 1, \ldots, q. \end{array}$$

This approach leads to a precise utility function; however, it is not incremental and does not provide an easy control on the number of points elicited on the utility curve.Moreover, preference queries involved in the process are somewhat more complex than in the certainty equivalent method. In the next subsection we present an incremental approach with simpler preference queries that gives control on which points are constructed.

3.2 USING THE CERTAINTY EQUIVALENT

An incremental utility elicitation procedure is proposed by Hines and Larsen [2010] with the aim of eliciting utilities while removing the effects of probability weighting from users answers. Using pairwise max regret minimization, they propose to elicit preferences in both cumulative prospect theory and expected utility theory by determining a specific probability value p^* that allows to ask *outcome queries* where the effect of w cancels out. This idea could be used here but can be simplified in our context. Note that their definition of regret is based on the EU model and would not be the most appropriate *to derive robust recommendations with respect to RDU*. In order words they assume that EU is the right model to produce recommendations, but observe preferences biased by distorted probabilities as in cumulative prospect theory and RDU.

We propose here another incremental approach involving simpler preference queries based on the use of certainty equivalent. It consists first in identifying a probability p^* such that $w(p^*) = 1/2$. To this end, we only need to construct the two first elements r_1, r_2 following $r_0 = 0$ in the sequence defined in the previous subsection. Then we ask the DM for which probability p^* she is indifferent between lottery $\ell = (r_2, p^*; r_0, 1 - p^*)$ and lottery $\ell' = (r_1, 1)$ yielding r_1 with certainty. Since by construction, $u(r_0) = 0, u(r_1) = 1$ and $u(r_2) = 2$, $V(\ell) = u(r_0) + w(p^*)[u(r_2) - u(r_1)] = 2w(p^*)$ and $u(\ell') = 1$. This leads to $2w(p^*) = 1$ and therefore $w(p^*) = 1/2$.

Now the utility curve can be incrementally constructed on any interval $[0, M]$ using simple indifference queries based on the following principle: let r^- and r^+ be any two distinct values in $[0, M]$ such that $u(r^-)$ and $u(r^+)$ are known (initially we choose $r^- = 0$ and $r^+ = M$ and we set $u(0) = 0$ and $u(M) = 1$). Then a new point can be constructed between positions r^- and r^+ by asking the DM for the certainty equivalent of lottery $(r^+, p^*; r^-, 1 - p^*)$. If the answer is r (meaning that she is indifferent between the lottery and winning r for sure) we obtain $u(r) = u(r^-) + w(p^*)(u(r^+) - u(r^-)) = w(p^*)u(r^+) + (1 - w(p^*))u(r^-)$. Since $w(p^*) = 1/2$ we finally obtain $u(r) = (u(r^-) + u(r^+))/2$. When u is defined as a monotone spline, the new point will induce new constraints further restricting the set of possible utilities.

Denoting $(r_i, u(r_i)), i = 1, \ldots, q$ the points already defined at iteration q, utility uncertainty within interval $[r_i, r_{i+1}]$ is bounded above by $\delta_i = u(r_{i+1}) - u(r_i)$ due to monotonicity of u. The next query is selected to obtain a new point in the interval $[r_k, r_{k+1}]$ which maximizes δ_k; we ask for the certainty equivalent of lottery $(r_{k+1}, p^*; r_k, 1 - p^*)$. The process can be iterated to refine progressively the intervals until the desired number of points is reached or the maximal δ_i drops below a given threshold. Finally, a monotone regression spline is generated using the linear program Π introduced in subsection 3.1 to approximate the elicited points.

4 NUMERICAL TESTS

Incremental elicitation of w. In order to model function w, we used I-spline defined from the non-uniform knot sequence $t' = (0, 0, 0, 0, .1, 0.9, 1, 1, 1, 1)$. The use of knots at positions .1 and .9 instead of 1/3 and 2/3 induces a small

left shift of $I_1(x, 3, t')$ and a small right shift of $I_5(x, 3, t')$ so as to include extremely concave or convex transformations in the family of splines that can be generated. This allows to model extremely risk-averse or risk-prone attitudes if necessary.

In the first series of experiments, we validate our choice of monotone splines for identifying the DM's probability weighting function w. Defining this function as $w(x) = \sum_{j=1}^{5} \lambda_j I_j(x, 3, t')$, we used a linear program similar to II (see Subsection 3.1) to fit parameters λ_j to different standard weighting functions, presenting various curves from extremely concave to extremely convex, including S-shaped and inverse S-shaped curves as well. The fitting possibilities of model w defined from I-splines are shown in Figure 3. In particular, we are able to approximate, with a single model, different kinds of distortion functions w (concave, convex, S-shaped) that usually require different parametric models (Prelec, TK, LinLog; see Section 2.1).

The instances where the approximation is good but not ideal are those with an extreme steepness (first instance, for very small value of p, and fourth instance, for very high values of p, in Figure 3). These situations (w extremely steep) will be rare in practice and correspond to shapes that could be even better described with a more specialized knot sequence. We conclude that the use of I-splines give us good approximations; splines allow us to learn w without committing to a specific parametric form.

In the second series of experiments, we observe the number of queries needed to determine the winning lotteries within sets of different sizes. The set $\mathcal{L}$ is constructed by repeatedly generating at most k outcomes in $[0, 1000]$ and a probability distribution on these outcomes to build a new lottery (with k branches) at step i; this lottery ℓ_i is inserted in $\mathcal{L}$ only if no stochastic dominance holds in $\{\ell_i\} \cup \mathcal{L}$. The process is continued until the desired number of lotteries is obtained. We made experiments with lotteries with $k = 2, 3, 5, 10$ branches and a simulated DM. For small sets of alternatives (typically 100 lotteries) the procedure solves the problem after very few questions. To test the scalability of the approach to larger sets we have generated instances including 1000 or 2000 lotteries. Interactions with the DM are simulated by generating answers to preferences queries using RDU with an inverse S-shaped probability weighting function w_0, unknown from the elicitation procedure, and a linear utility function. For each set of lotteries we observed the reduction of the minimax regret (expressed in percentage of the initial max regret before asking any query) as the number of queries increases. For comparison, we also observed the regret reduction obtained with an heuristic that randomly selects the new pair of lotteries to be compared. The resulting curves are plotted in Figure 4, respectively in green and red. At the same time, we observed the reduction of real regrets defined as the difference $V(\ell_0^*; w_0) - V(\ell^*; w_0)$ where ℓ_0^* is the optimal lottery

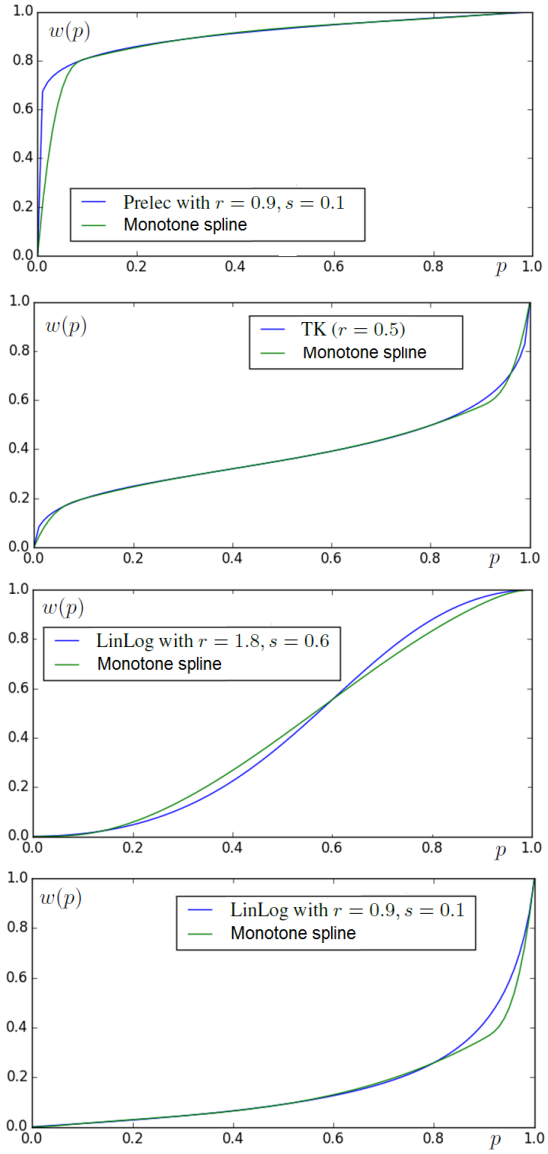

Figure 3: Monotone approximations of $w(p)$.

for the actual weighting function w_0, and ℓ^* is the solution minimizing the current max regret $MR(\ell; W)$. This third curve is plotted in blue in Figure 4. This experiment has been repeated multiple times on randomly generated instances and the results are very similar.

Considering the green and blue curves showing the diminution of max regret and real regret in Figure 4, it appears that the winner can be determined exactly among 1000 lotteries in about 10 queries (in worst case 15 preference queries). This considerably improves the results obtained with the random strategy. Similar tests have been performed for 2000 alternatives. The curves have similar shape and show that less than 10 additional queries are necessary. In fact, we could stop earlier, when minimax regret is very small (even if not exactly zero). The elicitation procedure can indeed be seen as an anytime algorithm. It can be interrupted

Figure 4: Regret reduction, $|\mathcal{L}| = 1000$, 100 runs.

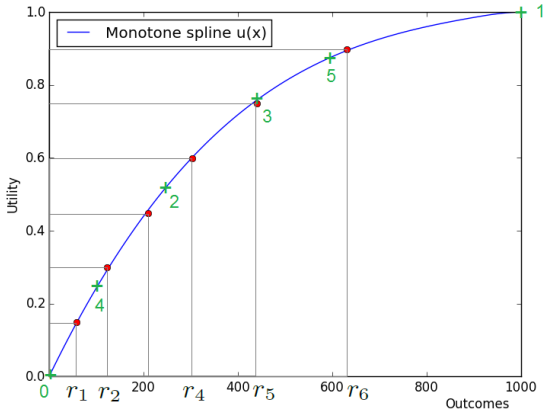

Figure 5: The spline approximating $u(x)$

before reaching a null regret, at any time of the process, and return the current minimax regret solution. We can also provide the associated max regret as a performance guarantee on the quality of the returned solution. Typically, as can be seen from the curves, stopping the elicitation when the minimax regret drops below a given percentage of the initial max regret (or below a given absolute threshold) will save a significant percentage of queries (at least 33% in our tests) without affecting significantly the quality of the recommendation. The efficiency of this approach is due to the fact that in most cases, the parameters of the decision model do not need to be precisely know to be able to determine a necessary winner, i.e., a lottery ℓ such that $V(\ell; w) \geq V(\ell'; w)$ for all $\ell' \in \mathcal{L}$ and all w compatible with the available preference information.

Utility elicitation. We present now an example of construction of a monotone spline on the [0,1000] interval, to reveal and model the implicit utility function of a DM in RDU theory, from observed preferences involving lotteries with outcomes in this interval. The answers of the DM to preference queries have been simulated by a RDU model with an inverse S-shaped probability weighting function $w(p)$ defined by the TK model introduced in Section 2 with parameter $r = 0.5$, and a concave utility defined by $u(x) = 1 - (1 - x/1600)^4$. We successively use the two methods proposed in Section 3 to elicit points and generate the regression spline. We first use the gamble tradeoff method as described in 3.1 with $\alpha = 1050$ and $\beta = 1600$ to obtain the sequence $r_0, \ldots, r_6$. We compute by linear programming the parameters λ_k of the monotone regression spline f that fits best points (r_i, i) and define $u(x) = f(x)/f(1000)$ to obtain $u(1000) = 1$. In Figure 5, points $(r_i, u(r_i))$ are represented by round points (in red), and we show the resulting utility function (in blue).

The construction of the monotone spline with the certainty equivalent method is also shown in Figure 5; the elicited points are represented by $+$ (in green), numbered by order of generation, and the resulting utility function is so close to the previous one that they are indiscernible.

5 CONCLUSION AND PROSPECTIVES

In this paper we proposed an incremental approach for the elicitation of the RDU model. A first novelty concerns the use, within the RDU theory, of minimax regret in order to incrementally elicit the probability weighting function w and to produce robust recommendations with respect to the uncertainty in probability weights. A second novelty is the use of monotonic regression splines as a model of the probability weighting function, allowing the representation of a wide variety of decision behaviors and the optimization of pairwise max-regrets by linear programming. We also extend the proposed approach to cases where the utility u is also unknown. Our experiments show that, despite the expressivity of the model, the elicitation burden is reasonably low in practice, due to the fixed and limited number of parameters used in splines approximating u and w, and the active learning process implemented for w. There are at least two natural continuations of this work. The first one consists in extending the approach for cumulative prospect theory to model different risk attitudes towards gains and losses. The second would be to jointly learn functions u and w using an incremental approach based on regret minimization, with the aim to save more preference queries.

Abstract

In many applications, it may be better to compute a good interpretable policy instead of a complex optimal one. For example, a recommendation engine might perform better when accounting for user profiles, but in the absence of such loyalty data, assumptions would have to be made that increase the complexity of the recommendation policy. A simple greedy recommendation could be implemented based on aggregated user data, but another simple policy can improve on this by accounting for the fact that users come from different segments of a population. In this paper, we study the problem of computing an optimal policy that is interpretable. In particular, we consider a policy to be interpretable if the decisions (e.g., recommendations) depend only on a small number of simple state attributes (e.g., the currently viewed product). This novel model is a general Markov decision problem with action constraints over states. We show that this problem is NP hard and develop a Mixed Integer Linear Programming formulation that gives an exact solution when policies are restricted to being deterministic. We demonstrate the effectiveness of the approach on a real-world business case for a European tour operator's recommendation engine.

1 Introduction

Interpretability in data mining and machine learning means that the computed models and solutions can be relatively easily understood by humans. Examples of algorithms that produce interpretable solutions include classical algorithms, such as decision trees [18], and newer sparse learning methods [18]. Recently, there has been a lot of interest in interpretable machine learning, but few works have explicitly focused on interpretability in decision making.

Lack of interpretable solutions can be an important roadblock in many critical domains, such as medicine [12, 11, 26]. If decision makers can understand a computed solution they are more likely to trust and implement it. Additionally, having an interpretable policy makes it easier to discover flaws resulting from incorrect models or unreasonable model assumptions, and without implementing a policy. Furthermore, it is possible to discover why the policy does not perform well. Finally, a simple policy can be easily implemented [29] and, as we show, sometimes assuming that the policy is simple circumvents the need to build complex models.

In this paper, we view the task of recommending products as one of decision making in a dynamic environment, rather than ranking products in a static setting (which is more common). With the rise in accessible customer information and product availability, the importance of matching customers to products has quickly risen. This problem arises in many domains such as recommender systems [21, 6] and personalized online advertising [8, 16, 7]; similar methods for matching customers to products are even used for email classification and spam detection [20]. Most methods for these systems use both the descriptions of the items and the historical behavior of the users.

Recommender systems fall into two basic categories [24]: collaborative filtering and content-based filtering. Collaborative filtering relates one user's preferences to other users' preferences without taking into account specific user or item properties [24]. Content-based filtering rather makes use of user profiles and the item properties. Most recommender systems combine these ideas and are a hybrid of both collaborative and content-based filtering methods. Successful recommender systems have been developed for recommending movies (e.g., Netflix), music (e.g., Pandora), personalized advertising [32], and even for recommending social-network followers [15, 5].

We focus in this paper on a single, and admittedly simple, model of policy interpretability (i.e., recommendation rules that are easily understood). Since we consider a dynamic setting, we look for recommendations based on the

state of a user (e.g., whether or not interested in a currently viewed product), and these recommendations based on the state are what we refer to as a policy. We consider the standard Markov decision process (MDP) with *discrete* states and actions. Typically, an MDP will have thousands or millions of states. Therefore, even though a policy can be examined in principle, it cannot be understood in practice. To make the policy *interpretable*, we simply require that it does not prescribe more than, for example, 50 different actions. This means that the policy must prescribe the same action for a number of states and also that such a subset of states must be well defined.

Computing optimal recommendations under our interpretability constraints constitutes solving a so-called partially observable Markov decision process (POMDP), which can be cast as a Markov decision process. Policies for such MDPs tend to be extraordinarily complex and hard not only to interpret but also to implement. Instead, as in our case, one may want to compute a best possible policy that depends only on the currently viewed product. This would entail computing item to item recommendations that consider the customer dynamics, a policy which falls into a class of POMDPs that are not complex.

To motivate the need for interpretable policies, consider optimizing dynamic online product recommendations. As a user interacts with a website, their preferences become clear over time. However, the interactions themselves influence user behavior [33, 30, 27, 23]. Consider a scenario with two customer types **A** and **B** and two products X and Y where the percentages of customer types **A** and **B** interested in products X and Y are 90%/10% and 40%/60%, respectively. If a customer of type **A** is recommended and clicks on product Y, the distribution of the types of customers looking at the two products will change, and our model accounts for such dynamics.

Our main contribution in this paper is a novel model for computing interpretable policies as described above, or stated differently, a model for computing policies for MDPs which are constrained to take the same action in subsets of states. We show connections with several other models considered in the context of reinforcement learning and POMDPs and use the relationship to show that the optimal interpretable policies may be stochastic and are NP hard to compute. We then propose a new and simpler nonlinear Mixed Integer Linear Program (MILP) formulation. While these models can also be hard to compute, we show that we can learn optimal interpretable deterministic policies.

We also contribute to the area of recommendation engines with a framework for making recommendations that account for the changing dynamics of the system. While we do not model these dynamics directly, our framework does account for more general dynamics by introducing unobservable dynamics into the model. In other words, our model assumes that customers are changing states but also assumes that we cannot directly observe the manner in which they are changing.

Furthermore, we establish a connection between several apparently unrelated areas of optimization. The underlying model is a Markov decision process with constraints on actions, and is related to several other streams of work. Similar models are studied using aggregation in reinforcement learning, where the motivation is somewhat different. Aggregation is used because the models are too large to be solved or even enumerated. As we discuss in more detail later, the interpretable MDP model is also related to finite state controller optimization on POMDPs (e.g. [2]). Finally, policy search methods from reinforcement learning have been used to compute interpretable policies.

The remainder of the paper proceeds as follows. Section 2 next discusses more related work to our notion of interpretability. Section 3 then formalizes the concept of interpretability and discusses the application to recommender systems, followed by mathematical programming formulations used to learn interpretable policies in Section 4, and corresponding complexity results in Section 5. Our framework is evaluated on data from a major European tour operator in Section 6, where a significant improvement over several practical benchmarks is demonstrated. A final discussion of our findings is given in Section 7.

2 Related Work

In this section, we summarize the existing related work and draw new connections. While there has been little work directly on interpretable policies, it turns out that our model of policy interpretability is closely related to previous results in other fields.

Recent work on interpretable policies in reinforcement learning [17] proposes to use policy search methods. Policy search is a general method that can be leveraged to find policies that are parameterized in ways that make them interpretable. While this is a very natural approach and is demonstrated to work well, it does not study any new methods for computing these interpretable policy. In comparison, our focus is on a simpler model that allows us to more deeply study the computational problems.

The most closely related method to our formulation (discussed in Section 4.1) is state aggregation in reinforcement learning, which is a very simple and classic method (e.g., [25, 19, 28, 3, 10]). The motivation in our work is quite different from that in state aggregation. The main reason for state aggregation is to address a problem that is very large and often cannot be enumerated, and therefore, very little focus has been put on how to compute good policies for an aggregation. Indeed, most work has rather focused on methods for choosing which states should be aggregated.

Since we deal with a smaller number of states, we can develop better methods for computing interpretable policies, and will adapt methods used for state aggregation to this setting.

Our model of interpretability can be also seen as a special case of Partially Observable Markov Decision Processes (POMDPs). POMDPs generalize MDPs to the case where observations do not contain exact information about the current state, and in general, the optimal policy to POMDPs are complex. There do exist certain classes of POMDPs that result in simpler optimal policies, and this space is where our model lies. In the other direction, it can also be shown that our interpretable policy problem generalizes one of these simpler classes of POMDPs, termed optimal finite state controllers in the MDP literature. Hence, we proceed as with general POMDPs, and constrain polices by introducing a concept of observations in the next section.

Another closely related area of work to interpretability is that of implementability of policies. The goal is not to have the policy be understood by humans, but instead requires that. The term *implementable policy* in the context of MDPs was introduced in [29]. However, the problem is a special case of finding *memoryless* policies (i.e., policies that depend only on the current state and not on any history) for POMDPs.

Finally, the analysis of policy optimality in some specialized domains, such as inventory management, queueing, and energy storage is tangentially related to our setting. One can show that the optimal policies in these domains are interpretable; indeed, for example, the optimal policy in inventory optimization domains will be independent of the current inventory. This leads to policies that are easy to interpret and also typically easy to solve. Unlike these settings, we deal with cases in which the optimal policy may not be interpretable, which introduces an additional layer of computational difficulties.

3 Interpretable Policies in MDPs

In this section, we formally define the model and illustrate its application to the dynamic recommendation problem described in the introduction. For the remainder of the paper, we define the following notations. Denote by Δ^d the non-negative simplex in d dimensions, i.e., the set of valid distributions defined by $\{x \in \mathbb{R}^d : \sum_i x_i = 1, x \geq 0\}$. For a matrix X, we define $X(s, \cdot)$ as row s of X.

The interpretable model is based on a Markov decision process (MDP) (e.g., [22]). An *interpretable* MDP is a tuple $(\mathcal{S}, \mathcal{A}, P, r, p_0, \mathcal{O}, \theta)$. Here, $\mathcal{S}$ is a *finite* set of states, $p_0 \in \Delta^{|\mathcal{S}|}$ is the initial distribution, $\mathcal{A}$ is a finite set of *actions*, each of which can be taken in all states. The transition probability matrix for each $a \in \mathcal{A}$ is denoted $P_a \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{S}|}$ and each row lies in the simplex: $P_a(s, \cdot) \in \Delta^{|\mathcal{S}|}$ for all $s \in \mathcal{S}$. The rewards vector for each action $a \in \mathcal{A}$ is denoted $r_a \in \mathbb{R}^{|\mathcal{S}|}$.

As discussed in the introduction, we assume that interpretability of a policy depends on a small number of simple state properties. To capture this property, we augment the model by a set of observations $\mathcal{O}$ and an observation function $\theta : \mathcal{S} \to \mathcal{O}$ that defines a partitioning of states to observations.

A solution to an MDP is a randomized stationary policy from $\Pi_R : \{\mathcal{S} \to \Delta^{\mathcal{A}}\}$ or deterministic stationary policy from $\Pi_R : \{\mathcal{S} \to \mathcal{A}\}$. The set of *interpretable* policies Π_I is defined as:

$$\Pi_I = \{\pi \in \Pi_R \ : \ \theta(s_1) = \theta(s_2) \Rightarrow \pi(s_1) = \pi(s_2)\} \ .$$

In other words, if two states share the same observation then an interpretable policy must take actions with identical probabilities in these states.

Our objective is to compute a policy that maximizes the infinite-horizon γ-discounted return $\rho(\pi)$ by solving

$$\max_{\pi \in \Pi_I} \rho(\pi), \tag{3.1}$$

where $\rho(\pi)$ can be expressed as

$$\rho(\pi) = \sum_{t=0}^{\infty} \gamma^t p_0^{\mathsf{T}} P_\pi^t r_\pi.$$

It is important to note that the constraints imposed by interpretable policies are quite different from the constraints in constrained MDPs [1]. The optimal solution to Eq. (3.1) can be obtained through other formulations. In particular, we offer a Mixed Integer Linear Programming formulation in Section 4.2, and equivalence is given there by Proposition 4.1. Eq. (3.1) offers an easy interpretation for our objective when designing a policy.

To illustrate the concept of interpretability, the following example describes how our model can be used to represent the recommender system formulation from the introduction. This is a simplified version of the model that we use later in the paper for empirical evaluation.

Example 3.1 (Dynamic Product Recommendations)**.** *Consider the online product recommendation setting described in the introduction. Let $\mathcal{M}$ be a set of available products and let $\mathcal{W}$ be a set of customer segments. Assuming that customer segments are known in advance, their browsing behavior and response can be modeled as the following MDP. States $\mathcal{S} = \mathcal{W} \times \mathcal{M}$ represent the* customer type *and* current product displayed*. Actions represent the product sets to recommend during a page view: $\mathcal{A} = \{a \in 2^{\mathcal{M}} : |a| \leq k\}$. Here, k is the maximum number of products to recommend. Transition probabilities are based on whether a customer chooses to follow a product*

recommendation, purchases the currently displayed product, or abandons the purchase. Rewards are accrued by customers purchasing items.

This recommendation MDP can be solved rather easily, however the policy is likely to be hard to implement. This is because the customer type is not observable, particularly if only a short history of customer interactions is available. Another direction, solving this problem as a POMDP, would yield a complex policy that is hard to interpret and implement in a real-time system. This leads to applying our model of interpretability.

The simplest and most interpretable online product recommendation policy are item-to-item recommendations, and capturing the desire for such a policy in our setting is simple. Let the set of *observations* be equal to the available products ($\mathcal{O} = \mathcal{M}$) and define the *observation mapping* function as $\theta(w, m) = m$ for $w \in \mathcal{W}, m \in \mathcal{M}$ so that observations are independent of the customer type. Typically, item-to-item recommendations are computed based on the customers that typically visit the given product page, i.e, the distribution of customers. However, the recommendations themselves influence this distribution. The MDP implementation with interpretable policies accounts for the change in the distribution, and we formulate and analyze this approach in more detail below.

4 Interpretable MDP Formulations

In this section, we formulate the mathematical programs for learning the MDPs of interest, beginning with a classical MDP formulation, adding interpretability constraints, and then relaxing nonlinearities to obtain a mixed integer linear programming (MILP) formulation that approximates the exact problem.

4.1 Basic Formulation

While it is possible to adapt nonlinear optimization formulations from the POMDP literature, for example [2], we derive a simpler nonlinear formulation first. We first adapt the standard linear program formulation for a Markov decision process. The classic MDP linear program learns a policy that maximizes the expected reward of the system subject to constraints that model the transitions allowed in the system.

First define the following variables. Let $u \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{A}|}$ represent the policy we are trying to learn, which is defined in every state as $u(s,\cdot)/\sum_a u(s,a) \in \Delta^{|\mathcal{A}|}$. Note that, for variable u, we denote $u(s,a)$ as the (s,a) entry of matrix u in the following formulations, along with similar notation for other variables. Summations over s or a are meant as shorthand for $s \in \mathcal{S}$ and $a \in \mathcal{A}$. Then, in formal terms, a deterministic policy means that $u(s,a) = 1$ for a single $a \in \mathcal{A}$ for each $s \in \mathcal{S}$, whereas a randomized policy simply means that $\sum_a u(s,a) = 1$ for each $s \in \mathcal{S}$.

Given our notation, the linear programming formulation for the classic MDP is

$$\begin{aligned}
\max_{u} \quad & \sum_{s,a} u(s,a) r(s,a) \\
\text{s.t.} \quad & \sum_{a} u(s,a) \\
& \quad = p_0(s) + \sum_{s',a} \gamma P_a(s,s')\, u(s',a) \quad \forall s \in \mathcal{S} \\
& u(s,a) \geq 0 \quad \forall s \in \mathcal{S}, a \in \mathcal{A}.
\end{aligned} \tag{4.1}$$

The summation in the objective is the expected reward for a policy given by u. Note that u can also be interpreted as a state-action occupancy measure (e.g. [4]) which is the cumulative visitation probability over all state-action pairs when the discount (for computing the current value of future rewards) is interpreted as a probability of leaving the system. Then the first set of constraints can be seen as a form of the Bellman equations in terms of a state-action occupancy measure rather than state value. It is known that an optimal policy must satisfy these equations. The final inequalities are needed since measures must be nonnegative. For the optimal solution, these values represent the optimal policy.

We next want to adapt Problem 4.1 in order to enforce interpretability. Interpretability constraints can be directly added by introducing a new optimization variable, $\psi \in \mathbb{R}^{|\mathcal{O}|\times|\mathcal{A}|}$, which defines the interpretable policy for each observation as $\psi(o,\cdot) \in \Delta^{|\mathcal{A}|}$. The new formulation is

$$\begin{aligned}
\max_{u,\psi} \quad & \sum_{s,a} u(s,a) r(s,a) \\
\text{s.t.} \quad & u(s,a) = \psi(\theta(s),a) \sum_{a'} u(s,a') \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& \sum_{a} u(s,a) \\
& \quad = p_0(s) + \sum_{s',a} \gamma\, P_a(s',s)\, u(s',a) \quad \forall s \in \mathcal{S} \\
& u(s,a) \geq 0 \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& \sum_{a} \psi(o,a) = 1 \quad \forall o \in \mathcal{O}.
\end{aligned} \tag{4.2}$$

In this formulation, we interpret u as a state-action occupancy measure (as defined above). The first set of constraints dictates that the interpretable policy is equivalent to a normalized state-action occupancy measure (as is the policy in the classic MDP above) and furthermore that the policy at states in the same observation is the same. The second and third set of constraints remains the same. The

last set of constraints puts the interpretable policy at each observation in the simplex (since nonnegative is already implied by nonnegativity of u).

The optimal policy is directly constructed from the optimal ψ for (4.2). The following proposition shows its correctness.

Proposition 4.1. *The optimal solution to* (4.2) *is also optimal in* (3.1).

Proof. Follows from the equivalence in Theorem 6.9.1 in [22], the optimality in Theorem 6.9.4 in [22], and the equivalence of return in terms of the occupancy frequency. The constraint on u from ψ is correct due to the construction of the policy from u. □

Note that formulation (4.2) is no longer linear or convex because of the terms $\psi(\theta(s), a)u(s, a')$ in the first set of constraints. It could be solved using a non-linear solver, such as IPOPT. We take a different approach, which can guarantee solution optimality, in the next subsection.

4.2 Mixed Integer Linear Program

This section describes a new mixed integer linear programming (MILP) formulation for learning an interpretable policy within the MDP framework. A recent paper describes a MILP formulation for finite state controllers [9], however, our formulation is simpler and our derivation is more straightforward.

As we have defined a state-action occupancy frequency $u(s, a)$ above, we can similarly define a state occupancy frequency $d \in \mathbb{R}^{|\mathcal{S}|}$ by $d(s) = \sum_a u(s, a)$ for each state $s \in \mathcal{S}$. From a modeling viewpoint, including d gives a new interpretation of state-action occupancy frequency as the fraction of state occupancy frequency determined by the optimal interpretable policy. From an optimization viewpoint, including d greatly reduces the number of nonlinear functions in the first set of constraints in a trade-off for $|\mathcal{S}|$ additional equality constraints. This trade-off is important regarding the relaxation below that we use to get an MILP formulation. Introducing the state occupancy frequency to the formulation results in the problem

$$
\begin{aligned}
\max_{u,d,\psi} \quad & \sum_{s,a} u(s,a) r(s,a) \\
\text{s.t.} \quad & u(s,a) = \psi(\theta(s),a) d(s) \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& d(s) = p_0(s) + \sum_{s',a} \gamma\, P_a(s',s)\, u(s',a) \quad \forall s \in \mathcal{S} \\
& d(s) = \sum_a u(s,a) \quad \forall s \in \mathcal{S} \\
& u(s,a) \geq 0 \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& \sum_a \psi(o,a) = 1 \quad \forall o \in \mathcal{O}.
\end{aligned}
\tag{4.3}
$$

Note that the third set of constraints are the $|\mathcal{S}|$ new equality constraints, and that the number of nonlinear terms in the first set of constraints has been reduced from $|\mathcal{S}| \cdot |\mathcal{A}|^2$ to $|\mathcal{S}| \cdot |\mathcal{A}|$ nonlinear terms.

While we can try to solve the nonlinear optimization problem (4.3), any solution we get will have no guarantee of optimality. We now develop a mixed integer linear program formulation based on the so-called McCormick inequalities. This approach relaxes the constraints in (4.3). The idea is to bound the terms $\psi(\theta(s), a)d(s)$ for all $s \in \mathcal{S}, a \in \mathcal{A}$ by making use of upper and lower bounds on $\psi(\theta(s), a)$ and $d(s)$. McCormick inequalities are defined in the lemma below.

Lemma 4.2 (McCormick Inequalities, e.g., [13])**.** *Assume that $a_L \leq a \leq a_U$ and $b_L \leq b \leq b_U$. Then:*

$$
\begin{aligned}
a\, b_L - a_L\, b_L + a_L\, b \leq a\, b \leq a\, b_U - a_L\, b_U + a_L\, b \\
a\, b_U - a_U\, b_U + a_U\, b \leq a\, b \leq a\, b_L - a_U\, b_L + a_U\, b
\end{aligned}
$$

It is important to note that the equalities are attained for the extreme points of the intervals (for either one of the two variables).

The McCormick inequalities are easy to derive; for example, the first lower bound on ab is attained by multiplying the bounds $a - a_L \geq 0$ and $b - b_L \geq 0$. The MILP can then be constructed as follows. The constraints on ψ are box constraints of the form $0 \leq \psi(\theta(s), a) \leq 1$ and the bounds on state occupancy frequencies are $0 \leq d(s) \leq \bar{d}(s)$ where $\bar{d}(s)$ must be estimated. Therefore, we can relax the nonlinear equality $u(s, a) = \psi(\theta(s), a)d(s)$ in problem 4.3 by the following inequalities

$$
\bar{d}(s)\,(\psi(\theta(s),a) - 1) + d(s) \leq u(s,a) \leq \bar{d}(s)\,\psi(\theta_s,a)
$$

Note that all four McCormick inequalities are implied by these two constraints.

The relaxed optimization problem becomes:

$$
\begin{aligned}
\max_{d,u,\psi} \quad & \sum_{s,a} u(s,a)\, r(s,a) \\
\text{s.t.} \quad & \bar{d}(s)\,(\psi(\theta(s),a) - 1) + d(s) \\
& \quad \leq u(s,a) \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& u(s,a) \leq \bar{d}(s)\,\psi(\theta(s),a) \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& d(s) = p_0(s) + \sum_{s',a} \gamma\, P(s',a,s)\, u(s',a) \quad \forall s \in \mathcal{S} \\
& d(s) = \sum_a u(s,a) \quad \forall s \in \mathcal{S} \\
& \sum_a \psi(o,a) = 1 \quad \forall o \in \mathcal{O} \\
& u(s,a) \geq 0 \quad \forall s \in \mathcal{S}, a \in \mathcal{A} \\
& \psi(o,a) \in \{0,1\} \quad \forall o \in \mathcal{O}, a \in \mathcal{A}
\end{aligned}
\tag{4.4}
$$

We next note that the last statement of Lemma 4.2 implies that we can compute an optimal *deterministic* policy (under interpretability constraints) as well as an optimality gap for suboptimal policies, which is summarized in the following proposition.

Proposition 4.3. *Optimal solution to* (4.4) *is also an optimal solution to* (3.1).

Proof. Since the McCormick inequalities are tight for $\psi(o, a) \in \{0, 1\}$, the optimal solution to this MILP problem will be the optimal *deterministic* implementable policy for the problem. □

It may be also possible to solve (4.4) without the integrality constraints, which means optimizing over randomized policies. In that case, this is simply a linear program which can be easily solved, however, the solution may not be very good due to the relaxation given by the McCormick inequalities.

Remark 4.4. As we hinted, there is a connection between finite state controllers and the interpretability constraints. Consider a POMDP with m states, a actions, o observations, and computing a finite state controller with n nodes. [9] shows that their MILP formulation has $n \cdot a + n^2 \dot{o}$ integral variables. It can be readily seen that applying our formulation would have $n^2 \cdot a \cdot o$. This is more than [9]. The number of variables can reduced in a setting such as the finite state controller in which the action set can be decomposed as follows. Assume that $\mathcal{A} = \mathcal{A}_1 \times \mathcal{A}_2$. Then introduce additional variables $\psi_i : \mathcal{O} \times \mathcal{A}_i \to \{0, 1\}$ for $i = 1, 2$. We add constraints $\sum_{a \in \mathcal{A}_i} \psi(o, a_i) = 1$ and $\psi(o, (a_1, a_2)) \leq \min\{\psi_1(o, a_1), \psi(o, a_2)\}$.

5 Properties of Optimal Interpretable Policies

In this section, we prove basic properties of optimal interpretable policies. Recall that an interpretable policy takes the same action for all states within a single observation and is computed by solving problem (3.1).

We first address the computational complexity of computing an optimal interpretable policy.

Proposition 5.1. *Solving* (3.1) *for either randomized or deterministic policies is NP hard, and is in NP as well for deterministic policies.*

Proof. Hardness is proven by a reduction from computing a memoryless policy for a POMDP [14] (which is known to be NP-hard to compute). The construction is simple and we only outline it here. Consider a POMDP with states $\bar{\mathcal{S}}$ and observations $\bar{\mathcal{O}}$. Then construct a cross-product MDP (e.g. [2]) for a finite node controller with $\bar{\mathcal{O}}$ nodes. The state space of the cross-product MDP will have $\mathcal{S} = \bar{\mathcal{S}} \times \bar{\mathcal{O}}$. The set of actions in the cross-product MDP is the same as the actions in the POMDP. The transitions in the cross-product MDP are a product of the POMDP state transition according to the action taken and the observation observed. Consider an interpretable policy for this problem in which the observations depend on $\bar{\mathcal{O}}$ and the observation mapping is $\theta((s, o)) = o$. It can be now readily seen that computing such an interpretable policy will correspond to a memoryless policy in the POMDP and vice versa. An optimal interpretable policy for this problem will therefore be also an optimal memoryless policy in the POMDP. The hardness for stochastic policies follows similarly from [34]. It follows that solving (3.1) for deterministic policies also in NP since the set of deterministic policies can be enumerated. □

The problem of solving (3.1) over randomized policies is not known to be in NP and there is evidence that the problem may in fact be harder [34].

We next study the structure of optimal policies. It can be readily seen that the optimal policy to an MDP with interpretability constraints may be history dependent. See, for example, the MDP in Fig. 1 in which the optimal policy will be $a_2, a_1, a_2, \ldots$. No deterministic interpretable policy can achieve such a return. However, we are interested in finding a stationary policy. The following proposition shows that the optimal policy may need to be randomized.

Proposition 5.2. *There may be no optimal deterministic interpretable policy.*

We prove Proposition 5.2 by an example in which a randomized policy can be arbitrarily better than the best deterministic policy.

Example 5.3. *Consider an example MDP depicted in Fig. 2 in which the optimal policy will be randomized. One possible interpretation in the context of product recommendations is as follows. States of the MDP represent a customer state. In particular, s_1 means that the customer is not yet interested in a product, and action a_1 represents a good recommendation. Taking this action moves the customer to state s_2 which means considering a product they are interested in. Taking action a_2 will cause the customer to consider another interesting product. Action a_2 represents suggesting an irrelevant product. In state s_1, the customer remains uninterested, but in s_2 the customer is already considering an interesting product and since the recommendation is not useful, they will simply purchase the product and a reward is received. Since we do not observe the internal customer state, s_1 and s_2 share the same observation and the interpretable policy will have to take the same action in both states. Clearly, any deterministic policy will receive return 0 (since the system starts in state s_1), while a policy that randomizes a_1 and a_2 with equal probability will receive return of at least $\gamma 0.5$ for discount factor γ. Looking*

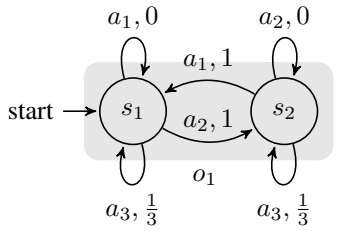

Figure 1: Markov decision process in Example 5.3. Shaded areas show states that share the same observation. Edge labels denote action name and the reward.

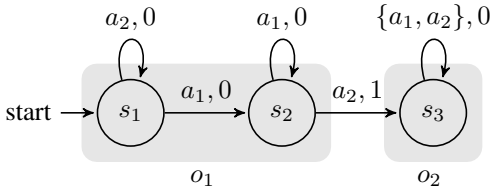

Figure 2: Markov decision process in Example 5.3. Shaded areas show states that share the same observation. Edge labels denote action name and the reward.

back at Fig. 1, we have an even simpler example in which the optimal policy will be randomized.

Note that our MILP formulation (4.4) only learns deterministic policies, and that the binary constraints need to be relaxed in order to learn randomized policies. Initial experiments showed poor performance with this relaxation, likely due to the McCormick inequalities being too loose an approximation to the other nonlinearities.

6 Case Study: Interpretable Product Recommendations

In this section, we describe the experimental evaluation of our interpretable MDP model in an online product recommendation setting. As mentioned above, most research on recommender systems has focused on developing methods for fitting a customer preference model to data. We, in contrast, study optimization methods that use the customer preference model to make better recommendations.

The motivating business case for this application was to improve customer experience and promote conversions for a major European tour operator. For the purposes of this experimental study, we apply the tools of this paper to design a recommendation engine that targets conversions, i.e., customer purchases.

6.1 Customer Model

To evaluate the quality of recommendations, we simulate customer purchase behavior and interactions with an online catalog. Our focus is on simulating online sessions in which customers browses different products and at some point either make a purchase or abandon the session.

Customer behavior is modeled using a mixed logit customer choice model [31] with 10 discrete segments. The logit model is used to predict customer behavior during a product purchase session. In particular, the model decides whether a customer purchases the currently viewed product, takes a recommendation, or abandons the search.

The logit model assumes that customers from any segment c assign some value, denoted $\eta(c, p)$, to product p. This represents the value gained by purchasing the product and is used to determine the probability of purchasing the given product. As a baseline, we denote by $\eta_N(c)$ the value of no purchase, which is the standard approach. We describe how the values $\eta(c, p)$, for each segment and product, and $\eta_N(c)$, for each segment, translate to probabilities below.

We fit the parameters of the logit model to data which comes from an adventure travel brand of a major European tour operator that specializes on sailboat rentals. Our dataset, which is a subset of the entire clickstream, consists of 22803 individual website visits, 1100 individual customers, and 75 products. Customer segments are identified using a standard low-rank matrix decomposition method and logit parameters are fit to maximize likelihood.

The MDP that models the interaction of customers with the online system is defined as follows. The state set is $\mathcal{S} = \mathcal{C} \times \mathcal{P}$, where $\mathcal{C}$ is the set of customer segments, and $\mathcal{P}$ is the set of products. In other words, the state represents a customer and a product currently being considered. Assume that the goal is to recommend n products. Action set $\mathcal{A} = \{(p_1, \ldots, p_n) \ : \ p_i \in \mathcal{P}\}$ determines the set of recommended products in a given state.

The transition probabilities in the MDP for some state (c, p) and products $(p_1, \ldots, p_n)$ are given according to the mixed logit choice model as follows. In particular, let $\alpha = \exp(\eta(c, p)) + \cdot \sum_{j=1}^{n} \exp(\kappa_R \cdot \eta(c, p_j)) + \sum_{p' \in \mathcal{P}} \exp(\kappa_N \cdot \eta(c, p')) + \exp(\eta_N(c))$ be a normalization constant. Here, $\kappa_R \leq 1$ represents the propensity for taking a recommendation and $\kappa_N \leq 1$ represents the propensity of choosing another product directly from the catalog.

Given the normalization constant α, the probability of a customer purchasing a product is $\exp(\eta(c, p))/\alpha$, the probability of taking recommendation p_j is $\exp(\kappa_R \cdot \eta(c, p_j))/\alpha$, the probability of using the menu to choose another product p' is $\exp(\kappa_N \cdot \eta(c, p'))/\alpha$, and finally the probability of abandoning the session is $\exp(\eta_N(c))/\alpha$. The rewards in the MDP model are 1 when a purchase is made and 0 otherwise. This essentially assumes that the margins are constant, but the model could be easily extended to weighted margins.

Note that the states in the MDP above describe both the product and customer segment. While such an MDP can be solved the policy cannot be implemented because the customer segment is not observed. This problem could also be solved using POMDP techniques; however, as suggested in the Introduction, the final solution would be hard to interpret and also difficult to implement in a real-time setting. Instead, we seek to find good *interpretable* policies.

Perhaps the simplest interpretable policy in the product recommendation setting is the so-called product-to-product recommendation. In this setting, recommendations are static and are solely a function of the currently viewed product. The simplicity of this method makes it popular in practice and is a good fit with our model of interpretable policies. It can be readily seen that the set of policies can be constrained to product-to-product policies by defining observations as $\mathcal{O} = \mathcal{P}$ and $\theta_{(c,p)} = p$, i.e., the action is independent of the customer.

6.2 Simulation Results

The goal of the empirical evaluation is to determine the possible benefit from using interpretable policies in making product recommendation as compared with more traditional product-to-product recommendations.

We compare three methods: *Static*, *Iterated*, *IMDP*. The *static* method is the simplest one and entails simply making the recommendation that is most likely to be appreciated by types of people looking at the current product. These standard methods—as described in the introduction—reflect how recommendations for other products can impact the distribution of customers considering the current product. The *iterated* method expands on this idea by re-optimizing the recommendations three times (i.e., implementing static recommendations using simulation, recomputing customer distributions, and repeating three times). The *IMDP* method uses the MILP formulation to compute an interpretable policy for the MDP described above. As solvers for MILP can be quite computationally expensive, we apply two versions of *IMDP*: Methods *IMDP(3)* and *IMDP(50)* represent results after 3 and 50 minutes of computation using CPLEX on an AMD Phenom II X6 machine.

To determine the improvement, we compare these product recommendation methods on several randomly generated scenarios, each of which is restricted to 25 randomly selected products and a single product recommendation. To make the results comparable across scenarios, we normalize them using lower (baseline) and upper bounds on the conversion rate. Our baseline is a policy that makes no recommendations, and the upper bound is a clairvoyant policy. The clairvoyant assumes that the precise customer types are known, solves the MDP, and implements that policy.

Table 1 depicts the normalized experimental results. The

#	Static	Iterated	IMDP(3)	IMDP(50)
1	56.8%	56.8%	**72.9%**	**72.9%**
2	19.8%	10.0%	43.9%	**45.9%**
3	24.2%	16.2%	54.3%	**55.2%**
4	31.6%	25.0%	65.9%	**66.2%**
5	17.0%	17.8%	54.0%	**54.2%**
6	44.5%	44.5%	**75.2%**	**75.2%**
7	32.7%	39.7%	73.1%	**73.2%**
8	**66.7%**	**66.7%**	55.8%	57.3%
9	25.0%	25.0%	62.9%	**63.0%**
10	19.4%	16.0%	53.2%	**53.6%**

Table 1: Percentage of improvement in conversion rate over no recommendation compared with clairvoyant policy for 10 problem instances.

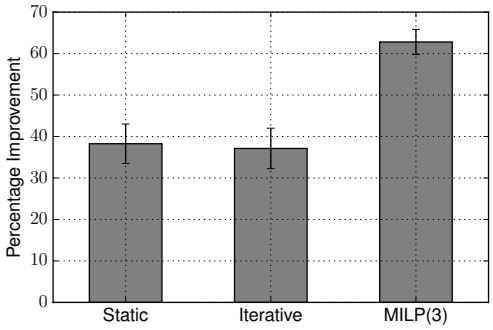

Figure 3: Average percentage improvement in conversion rate with 95% confidence interval.

percentages are computed as follows. Let l be the conversion rate of the baseline policy, u be the conversion rate of the clairvoyant policy, and q be the conversion rate of the tested policy. Then the improvement is computed as: $(q - l)/(u - l)$. Fig. 3 depicts the average improvement over 50 runs of the three methods.

There are several interesting observations that can be inferred from our results. First, IMDP significantly outperforms the standard recommendation techniques. At least in our scenario, considering the affected distribution of customers appears to be very important. Second, surprisingly, iterating the recommendations often not only does not increase the conversion rates, but actually decreases them (i.e., the *Static* method sometimes outperforms the *Iterated* method). Finally, while 3 minutes are not enough to compute an optimal MILP solution, our results indicate that the interpretable policy achieves over 50% of the benefit of a clairvoyant policy while being much simpler.

We also investigated recommending more than a single product. Unfortunately, the number of integer variables in our formulation scales exponentially with the number of

products. It can be readily seen, however, that the action constraints can be decomposed in a manner that is similar to the discussion in Remark 4.4. This reduces the number of variables to be linear in the number of products, but our empirical results indicate that this approach does not significantly reduce the computation time. Regardless, our experiments with a single recommendation already demonstrate the usefulness of our notion of interpretability.

7 Concluding Remarks

In this paper, we have derived and implemented a novel framework for making dynamic product recommendations. The key insight is that modeling customer states is often quite challenging due to lack of knowledge about the customer, but that underlying dynamics (i.e., customers changing their state) can still be accounted for by using a concept of interpretability. Namely, recommendations are restricted to being identical for customers that are in the same observation, where each observation is a union of customer states that are not observable. Restricting the recommendations in this manner makes the recommendation policy interpretable (i.e., not complex and easily understandable). We use tools from Mixed Integer Nonlinear Programming in conjunction with a relaxation using McCormick inequalities to learn interpretable policies, but there are other directions not pursued in this work, such as combining a semidefinite programming (SDP) relaxation with Reformulation Linearization Technique (RLT) inequalities (which generalize McCormick inequalities) used to tighten (rather than relax) the SDP relaxation.

As noted above, regarding scalability, there is much room for improvement since the number of binary variables in our MILP formulation grows exponentially with the number of products recommended (i.e., the dimension of the actions). Aside from the decomposition described above, a different direction is a heuristic that fixes all but one of the recommendation action dimensions and iteratively optimizes over individual recommendations. This alternating minimization scheme has efficient iterations (which we have already demonstrated with our single product recommendations above), so performance depends on the number of iterations required for a good solution.

Note also that uncertainty in the model parameters, rewards and transition matrices, have an important impact on policy performance. While we have not addressed such uncertainty here, it is an important topic for future work. Finally, there are several dynamics to the model that we have not yet addressed. For example, reviews written by customers and product ratings affect the distribution of customers looking at products.

Abstract

Learning the structure of sum-product networks (SPNs) – arithmetic circuits over latent and observed variables – has been the subject of much recent research. These networks admit linear time exact inference, and thus help alleviate one of the chief disadvantages of probabilistic graphical models: accurate probabilistic inference algorithms are often computationally expensive. Although, algorithms for inducing their structure from data have come quite far and often outperform algorithms that induce probabilistic graphical models, a key issue with existing approaches is that they induce tree SPNs, a small, inefficient sub-class of SPNs. In this paper, we address this limitation by developing post-processing approaches that induce graph SPNs from tree SPNs by merging similar sub-structures. The key benefits of graph SPNs over tree SPNs include smaller computational complexity which facilitates faster online inference, and better generalization accuracy because of reduced variance, at the cost of slight increase in the learning time. We demonstrate experimentally that our merging techniques significantly improve the accuracy of tree SPNs, achieving state-of-the-art performance on several real world benchmark datasets.

1 INTRODUCTION

Probabilistic graphical models [8, 17] such as Bayesian and Markov networks are routinely used in a wide variety of application domains such as computer vision and natural language understanding for modeling and reasoning about uncertainty. However, exact inference in them – the task of answering queries given a model – is NP-hard in general and computationally intractable for most real-world models. As a result, approximate inference algorithms such as loopy belief propagation and Gibbs sampling are widely used in practice. However, they can often yield highly inaccurate and high variance estimates, leading to poor predictive performance.

One approach to tackle the inaccuracy and unreliability of approximate inference is to learn so-called tractable models from data. Examples of such models include thin junction trees [2], arithmetic circuits (ACs) [7], cutset networks [25], probabilistic sentential decision diagrams [16], AND/OR decision diagrams [9, 21] and sum-product networks [23]. Inference in these models is polynomial (often linear) in the size of the model and therefore the complexity and accuracy of inference is no longer an issue. In other words, once an accurate model is learned from data, predictions are guaranteed to be accurate.

In this paper, we focus on the NP-hard problem of learning both the structure and parameters of sum-product networks (SPNs) from data. At a high level, an SPN is a rooted directed acyclic graph that represents a joint probability distribution over a large number of random variables, both observed and latent. It has two types of internal nodes: sum-nodes which express conditioning or splitting over latent or observed variables and product nodes which represent decomposition of variables into independent components. Leaf nodes represent simple distributions over observed variables (e.g., uniform distribution, univariate distributions, etc.). The key advantage of SPNs and other equivalent representations such as ACs [1] over thin-junction trees is that they can be much compact and never larger than the latter. This is because they take advantage of various fine-grained structural properties such as determinism, context-specific independence, dynamic variable orderings and caching (cf. [7, 9, 4, 13]). For instance, in some cases, they can represent high-treewidth junction trees using only a handful of sum and product nodes [23].

The literature abounds with algorithms for learning the structure of SPNs and ACs from data, starting with the

[1]The equivalence between ACs and SPNs was shown by Rooshenas and Lowd [26]. Thus, algorithms for learning ACs can be used to learn SPNs and vice versa.

work of Lowd and Domingos [19] who proposed to learn ACs over observed variables by using the AC size as a learning (inductive) bias within a Bayesian network structure learning algorithm, and then compiling the induced Bayesian network to an AC. Later Lowd and Rooshenas [20] extended this algorithm to learn a Markov network having small AC size. The latter performs much better in terms of test set log likelihood score than the former because of the increased flexibility afforded by the undirected Markov network structure.

A limitation of the two aforementioned approaches for learning ACs is that they do not use latent variables; it turns out that their accuracy can be greatly improved using latent variables. Unfortunately, the parameter learning problem (a sub-step in structure learning) – the problem of learning the weights or probabilities of a given SPN structure – is much harder in presence of latent variables. In particular, the optimization problem is non-convex, which necessitates the use of algorithms such as gradient descent and expectation maximization that only converge to a local minima. However, since learning is often an offline process, this increase in complexity is often not a big issue.

The first approach for learning the structure of SPNs having both latent and observed variables is due to Gens and Domingos [11]. An issue with this approach is that it learns only directed trees instead of (directed acyclic) graphs and as a result is unable to fully exploit the power and flexibility of SPNs. To address this limitation, Rahman et al. [25], Vergari et al. [28] and Rooshenas and Lowd [26] proposed to learn a graph SPN over observed variables while Dennis and Ventura [10] proposed to learn a graph SPN over latent variables. A drawback of these approaches is that they are unable to learn a graph SPN over both observed and latent variables. In this paper, we address this limitation.

The main idea in our approach is as follows. We first learn a tree SPN over latent and observed nodes using standard algorithms, and then convert the tree SPN to a graph SPN by processing the SPN in a bottom-up fashion, merging two sub-SPNs if the distributions represented by them are similar and defined over the same variables. To convert this idea into a general-purpose algorithm, we have to solve two problems: (1) how to find similar sub-SPNs, and (2) how to merge them into one sub-SPN. Both problems are computationally expensive to solve and therefore we develop approximate algorithms for solving them, which is the main contribution of this paper.

The second contribution of this paper is a thorough experimental evaluation of our proposed merging algorithms on 20 benchmark datasets, all of which were used in several previous studies. Our experiments clearly show that merging always improves the performance of tree SPNs, measured in terms of test-set log-likelihood score and prediction time. We also experimentally compared bagged ensembles of graph SPNs with state-of-the-art approaches such as ensembles of cutset networks [24], sum-product networks with direct and indirect interactions [26], sum-product networks learned via the SVD-based approach[1], arithmetic circuits with Markov networks [20], and mixtures of cutset networks [25] on the same datasets, and found that our new approach yields better test-set log likelihood score on 8 out of the 20 datasets with two ties. This clearly demonstrates the power of our new merging algorithms.

The rest of the paper is organized as follows. In the next section, we present background on SPNs, related work as well as a generic algorithm for learning tree SPNs. Section 3 describes powerful merging approaches for converting an arbitrary tree SPN to a graph SPN. Experimental results are presented in section 4 and we conclude in section 5.

2 BACKGROUND

Any (discrete) probability distribution over a set of variables $\mathbf{V}$ can be expressed using an arithmetic circuit (AC) [7] or a sum-product network (SPN) [23].[2] The key benefit of SPNs over conventional uncertainty representations such as Bayesian and Markov networks is that in SPNs, common probabilistic inference tasks such as maximum-a-posteriori (MAP) and posterior marginal (MAR) estimation can be solved in time and space that scales linearly with the size of the representation. In Bayesian and Markov networks, these tasks are known to be NP-hard in general (cf. [27]). The caveat is that SPNs can be exponentially larger than Bayesian and Markov networks; they are often compiled from the latter by running exact probabilistic inference techniques such as variable elimination [4] and AND/OR search [21], in order to facilitate faster online inference. Formally,

Definition 1. An SPN [23] is recursively defined as follows:

1. A tractable univariate distribution is an SPN;
2. A product of SPNs defined over different variables is an SPN; and
3. A weighted sum of SPNs with the same scope variables is an SPN.

An SPN can be expressed as a rooted directed acyclic graph with univariate distributions as leaves, sums and products as internal nodes, and the edges from a sum node to its

[2] SPNs used in this paper are equivalent to ACs (as well as AND/OR decision diagrams [21]) defined over latent and observed variables. However, in order to be consistent, we will use the term SPNs throughout the paper. We will distinguish between two types of SPNs: SPNs defined over only observed variables and SPNs defined over both observed and latent variables.

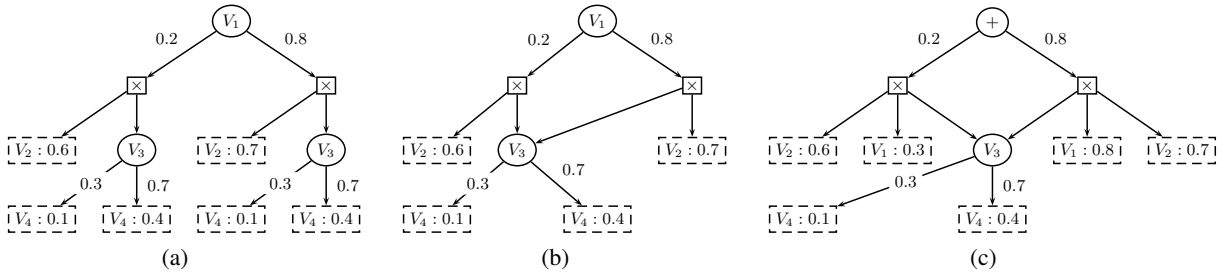

Figure 1: Three example SPNs over variables $\{V_1, V_2, V_3, V_4\}$. We are assuming that all variables are binary and take values from the domain $\{0, 1\}$. Leaf nodes express univariate distributions. For example, the node $V_2 : 0.6$ expresses the probability distribution $P(V_2 = 1) = 0.6$. Sum nodes are labeled either by a variable which denotes conditioning over the variable or by a $+$ sign which denotes that the sum node is latent. All left (right) arcs emanating from a sum node correspond to an assignment of 1 (0) to the labeled variable. Product nodes are labeled by $\times$. (a) Tree SPN (SPN which is a rooted directed acyclic tree) that decomposes according to a tree Markov network $V_4 - V_3 - V_1 - V_2$. (b) Graph SPN that is equivalent to the tree SPN given in (a) obtained by merging identical sub-trees. (c) Graph SPN over latent and observed variables.

children labeled with the corresponding weights. An SPN represents a (normalized) probability distribution when the weights attached to each sum node sum to one. Any unnormalized SPN can be normalized in linear time.

As mentioned earlier, we will distinguish between two types of SPNs: SPNs defined only over observed variables and SPNs defined over both latent and observed variables. The two have different representation powers with the latter being more general and therefore more powerful than the former. For SPNs having only observed variables, each sum node represents a split (conditioning) over a variable and is therefore labeled by the corresponding variable. For SPNs having both latent and observed variables, each sum node can represent either a split over an observed or a latent variable. The splits over the observed variables are represented the usual way while sum nodes that split over the latent variables are labeled by the "$+$" sign.

Example 2.1. Fig. 1 shows three SPNs over four variables $\{V_1, V_2, V_3, V_4\}$. The two SPNs on the left are defined over only observed variables while the SPN on the right is defined over both latent and observed variables. The graph SPN shown in Fig. 1(b) is obtained from the tree SPN shown in Fig. 1(a) by merging identical sub-SPNs.

2.1 LEARNING SPNs

In this paper, we focus on top-down approaches that directly learn the structure of SPNs from data. Instead of learning Bayesian and Markov networks and then compiling them into SPNs (this is the approach used in [19, 20]), the key advantage of this direct approach is that the size of the SPN can be controlled in a straight-forward manner, which is typically bounded from above by the data size.

Algorithm 1 shows a generic recursive learning algorithm for learning tree SPNs from data, which is loosely based on the algorithm proposed by Gens and Domingos [11]. The algorithm has three steps: base case, decomposition and splitting. In the base case, if the conditions for learning the base model are satisfied, for example, when the size of the training data is small or only one variable remains, then the algorithm learns the corresponding trivial distribution and terminates the recursion. In the decomposition step, the algorithm tries to partition the variables into roughly independent components $\mathbf{V_j} \subseteq \mathbf{V}$ such that $P(\mathbf{V}) = \prod_j P(\mathbf{V_j})$ and recurses on each component, inducing a product node. If neither the base case nor the conditions for the decomposition step are satisfied, then the algorithm partitions the training instances into clusters of multiple instances, inducing a sum node, and recurses on each part.

Algorithm 1: LEARNSPN($\mathbf{T}$,$\mathbf{V}$)

Input: Set of Training Instances $\mathbf{T}$ and set of variables $\mathbf{V}$
Output: An SPN representing a distribution over $\mathbf{V}$
begin
  `// 1. Base Case`
  if *conditions for inducing the base models are satisfied*
   then return LEARNBASEMODEL($\mathbf{T}$,$\mathbf{V}$)
  `// 2. Decomposition Step`
  if $\mathbf{V}$ *can be partitioned into subsets* $\mathbf{V_j}$
   then return $\prod_j$ LEARNSPN($\mathbf{T}$,$\mathbf{V_j}$)
  `// 3. Splitting Step`
  Partition $\mathbf{T}$ into subsets of similar instances $\mathbf{T_i}$
  return $\sum_i \frac{|\mathbf{T_i}|}{|\mathbf{T}|}$ LEARNSPN($\mathbf{T_i}$,$\mathbf{V}$)
end

Several techniques proposed in literature for learning SPNs (and equivalently ACs) can be understood as special cases of Algorithm 1, with the difference between them being the approaches used at the three steps. Table 1 gives examples

Reference	Base Case	Decomposition	Splitting
Gens and Domingos [11]	Univariate distribution	Independence tests	Latent Variables

Table 1: Examples of SPN structure learning approaches in the literature that follow the prescription given in Algorithm 1. Base case is the stopping criteria for the recursive algorithm. [11, 15] stop when only one variable remains and induce a univariate distribution; [25, 28, 24] stop when the entropy of the data is small or use a Bayesian criteria, and induce an SPN corresponding to a tree Markov network at the leaves using the Chow-Liu algorithm [5] (this algorithm runs in polynomial time and yields an optimal tree Markov network according to the maximum likelihood criteria). [26] learns an SPN over observed variables in the base case using the algorithm described in [19]. In the decomposition step, [11, 26, 28] use pair-wise variable independence tests (e.g., the G-test) for inducing the product nodes; [15] uses no independence tests and instead assume that each split decomposes the variables into multiple components; while [25, 24] ignore the decomposition step inducing only sum nodes. [11, 26, 28] split only over latent variables, [15, 25] split only over observed variables or their features, while [24] split over both latent and observed variables.

of techniques from the SPN literature that are based on Algorithm 1 and briefly describes how they differ.

Although, the structure learning problem is NP-hard in SPNs having only observed variables as well as in SPNs having both observed and latent variables, the parameter (weight) learning problem is easier in the former than the latter. In particular, parameter learning can be done in closed form when the SPN has only observed variables. On the other hand, the optimization problem is non-convex in the presence of latent variables and one has to use iterative algorithms having high computational complexity such as hard and soft EM to solve the non-convex problem (cf. [23, 22, 24]). Thus, although latent variables help yield a more powerful representation, they often significantly increase the learning time.

3 CONVERTING TREE SPNs TO GRAPH SPNs

A key problem with existing methods for learning SPNs is that they induce tree models, except at the leaves. It is well known in the probabilistic inference literature [9, 7, 6] that tree SPNs can be exponentially larger than graph SPNs, which are obtained from the former by merging identical sub-SPNs (see Fig.1(a) and (b)). Thus, converting tree SPNs to graph SPNs is a good idea because they can significantly improve the time required to make predictions.

From a learning point of view, graph SPNs can potentially improve the generalization performance by addressing the following issue associated with the LEARNSPN algorithm: as the depth of the node increases,[3] the number of training examples available for learning a sub-SPN rooted at the node decreases exponentially. Merging increases the number of examples available at a node, since examples from all directed paths from the root to the node can be combined. This reduces the variance of the parameter estimates while having no effect on their bias. Since the mean-squared error of the model equals bias squared plus the variance, graph SPNs are likely to be more accurate than tree SPNs. The following proposition formalizes this intuition:

Proposition 1. Let S_1, S_2 and $S_{1,2}$ be three (sub-)SPNs having the same structure and defined over the same variables but whose parameters are estimated from training examples T_1, T_2 and $T_{1,2} = T_1 \cup T_2$ respectively. Then assuming that the datasets are generated uniformly at random from a distribution whose structure decomposes according to S_1 (and thus S_2 and $S_{1,2}$), the sample variance of $S_{1,2}$ is smaller than S_1 and S_2.

Proof. The sample variance of S_1, S_2 and $S_{1,2}$ is given by $Var(S_1)/|T_1|$, $Var(S_2)/|T_2|$ and $Var(S_{1,2})/|T_1 \cup T_2|$ respectively where $Var(S_1)$, $Var(S_2)$ and $Var(S_{1,2})$ is the (population) variance of the distributions induced by S_1, S_2 and $S_{1,2}$. Since $Var(S_1) = Var(S_2) = Var(S_{1,2})$ (our assumption), $|T_1 \cup T_2| \geq |T_1|$ and $|T_1 \cup T_2| \geq |T_2|$, the proof follows. □

3.1 OUR APPROACH

The main idea in our approach is to relax the identical sub-SPN requirement and merge *similar* sub-SPNs. We use this relaxation because the sub-SPNs are estimated from data and the likelihood that they will be identical is slim to none. In this context, we develop methods for answering the following two questions: which sub-SPNs to merge and how to merge them.

[3] The depth of a node equals the number of sum nodes from the root to the node.

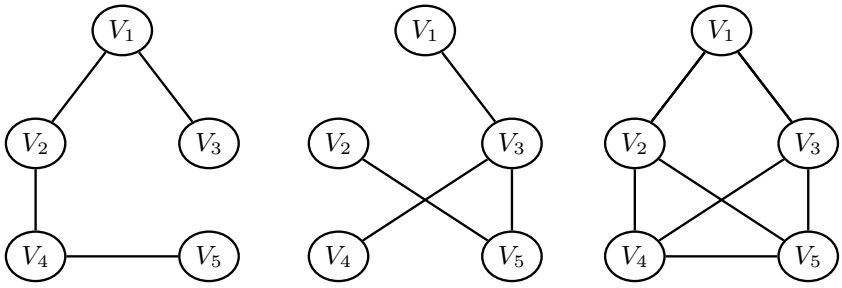

Figure 2: Figure demonstrating why distance computations are hard. (a) and (b): Two tree Markov networks over five variables $\{V_1, \ldots, V_5\}$. The treewidth of these networks is 1 and therefore the complexity of performing inference over them is $O(d^2)$ where d is the number of values in the domain of each variable. (c): Markov network obtained by taking the union of the edges of the tree Markov networks given in (a) and (b). Computing the distance (e.g., KL divergence) between the probability distributions represented by the two Markov networks in (a) and (b) is exponential in the treewidth of the Markov network given in (c). The treewidth of this network is 3 and therefore the complexity of computing the distance is $O(d^4)$, an exponential increase over $O(d^2)$.

One approach for selecting candidate sub-SPNs for merging is to compare the distance between the distributions represented by the two sub-SPNs, given that they are defined over the same variables, and check if the distance is smaller than a threshold. However, computing the distance between two sub-SPNs can be quite hard. For instance, assume that the two sub-SPNs represent Markov networks (MNs) and the junction tree or AND/OR graph search algorithm [9] is used for computing the KL divergence between the probability distributions represented by the two MNs. In this case, the time and space complexity of computation is exponential in the treewidth of the graph obtained by taking a union of the edges of the two MNs. The treewidth of this graph can be quite large (see Fig. 2 for an example). Therefore, we propose to use the following mean-field style approximation [29] of the distance between the two distributions:

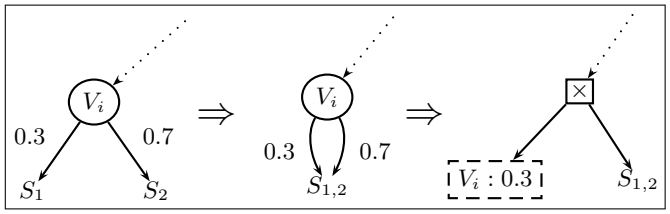
$$D(P||Q) \approx \frac{1}{|\mathbf{V}|} \sum_{V_i \in \mathbf{V}} D(P(V_i)||Q(V_i))$$

where P and Q are two distributions over $\mathbf{V}$ and D is a distance function (e.g., KL divergence, relative error, Hellinger distance, etc.). Since single-variable marginal distributions in each sub-SPN can be computed in time that is linear in the number of nodes of the sub-SPN (and in practice can be pre-computed), our proposed distance method is also linear time.

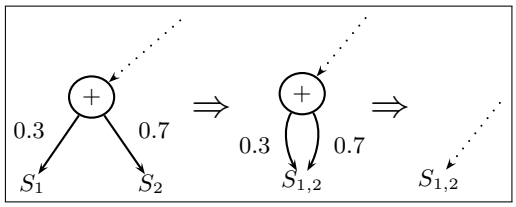
Next, we describe our greedy, bottom-up approach for merging similar sub-SPNs of a given SPN S (see Algorithm 2). The algorithm begins by initializing S' to S and repeats the following steps until convergence. For all sub-SPNs S_i of S' that are defined over exactly i variables, it partitions the sub-SPNs based on their scopes such that all sub-SPNs having the same scope are in the same cell (part) ρ_j of the partition ρ. Then, in each cell ρ_j, ensuring that S' remains a DAG, it merges all sub-SPNs such that the distance between them is bounded by ϵ, a user-defined constant that can be set using a validation set. Another option is to merge two sub-SPNs if the accuracy on the validation set improves, thereby using a greedy strategy (in our experiments, we used both strategies). Note that the for-loop of the algorithm operates in a bottom-up fashion similar to reduced-error pruning in decision trees. The loop starts at the leaves, which are sub-SPNs having just one variable in their scope ($i = 1$), and then proceeds towards the root which includes all variables in its scope ($i = |\mathbf{V}|$). The algorithm is guaranteed to converge in finite number of iterations because at each iteration, the size of the SPN can only decrease or remain the same.

Algorithm 2: MERGE(S,$\mathbf{V}$,ϵ)

Input: SPN S
Output: Merged SPN S'
begin
  $S' = S$
  repeat
    for $i = 1$ *to* $|\mathbf{V}|$ **do**
      $S_i =$ sub-SPNs in S' having exactly i variables in their scope
      $\rho =$ Partition S_i into cells having identical scopes
      for *each cell* ρ_j *of* ρ **do**
        Merge all sub-SPNs in ρ_j such that the distance between them is bounded by ϵ and S' is a DAG
      end
    end
  until *convergence*;
  return S'
end



(a) Merge child nodes of observed sum node



(b) Merge child nodes of latent sum node

Figure 3: Figure demonstrating how to simplify and thus reduce the size of the SPN after merging. As before, sum nodes are labeled either by a variable which denotes conditioning over the variable or by a $+$ sign which denotes that the sum node is latent. All left (right) arcs emanating from a sum node correspond to an assignment of 1 (0) to the labeled variable. Product nodes are labeled by $\times$. $S_{1,2}$ is an SPN obtained by merging SPNs S_1 and S_2. (a): shows how the SPN can be reduced when the two child nodes of an observed sum node are merged. The node $V_i : 0.3$ represents a univariate probability distribution over V_i with $P(V_i = 1) = 0.3$. (b): shows how the SPN can be reduced when the two child nodes of a latent sum node are merged.

3.2 PRACTICAL MERGING STRATEGIES

We complete the description of the algorithm by describing how to merge two similar sub-SPNs S_1 and S_2. A straightforward method is to merge the datasets at the two sub-SPNs and then learn a new graph sub-SPN, say $S_{1,2}$ from the new dataset. An issue with this approach is that since our basic algorithm (see Algorithm 1) learns tree SPNs, we have to call Algorithm 2 again to convert the newly created tree SPN to a graph SPN. This may yield a self-recursive algorithm with infinite loops that may not terminate. To overcome this computational difficulty, we propose to not relearn the structure, but only update the weights. In particular, we use the following approach. We consider two candidate structures for the merged sub-SPN; the first structure is identical to S_1 and the second to S_2. Then, we learn the weights of the two candidate sub-SPNs using the merged dataset and choose the one that yields the maximum improvement in accuracy (log-likelihood score) over the validation set.

There are two types of merging that require special attention. The first type is when the two sub-SPNs are children of the same sum node. In this case, if the sum node corresponds to splitting over an observed variable, we can replace the sum-node by a product node having two children as depicted in Fig. 3(a). On the other hand, if the sum node is a latent node then the sum node can be deleted without changing the underlying distribution. This is depicted in Fig. 3(b). This type of merging is useful because it substantially simplifies the model, allowing us to either prune sub-SPNs (see Fig. 3(b)) or take advantage of problem decomposition (see Fig. 3(a)). This yields better generalization and faster inference.

A second type of merging that requires special attention is when the two sub-SPNs to be merged correspond to tree Markov (or Bayesian) networks over the observed variables. In this case, unlike in the general case, we propose to learn both the structure and parameters of the merged sub-SPN (using the merged dataset). This is because both the structure and parameter learning problem in such SPNs can be solved in polynomial time using the Chow-Liu algorithm [5].

4 EXPERIMENTS

4.1 SETUP

We evaluated the impact of merging SPNs on 20 real world benchmark datasets presented in Table 3. These datasets have been used in numerous previous studies for evaluating the performance of a wide variety of tractable probabilistic graphical model learners (cf. [18, 11, 26, 25, 1, 24]). All datasets are defined over binary variables that take values from the set $\{0, 1\}$. The number of the variables in them range from 16 to 1556 and the number of training instances range from 1600 to 291326. All of our experiments were performed on a quad-core Intel i7 2.7 GHz machines with 16 GB RAM. Each algorithm was given a time bound of 48 hours, after which the algorithm was terminated.

4.2 ALGORITHMS EVALUATED

We implemented two variants of SPNs: SPNs in which sum nodes split over value assignments to a latent variable and SPNs in which sum nodes split over value assignments to a heuristically chosen observed variable. Henceforth we will call the two SPNs `L-SPNs` and `O-SPNs` respectively. We learned tree versions of both SPNs using Algorithm 1. We used tree Markov networks (MNs) as base models in both SPNs; as mentioned earlier tree MNs can be learned in polynomial time using the Chow-Liu algorithm.

To learn sum nodes in `L-SPNs`, following Gens and Domingos [11], we employed hard EM over a naive Bayes mixture model with three random restarts for 15 iterations to split the training instances into two clusters, i.e. we only considered binary splits for latent sum nodes for better reg-

Table 2: Table showing the impact of merging on the average test-set log likelihood, time complexity and prediction time of L−SPNs and O−SPNs (all values rounded to two decimal places). We use the following notation: (1) T-LL: Average test-set log likelihood for the tree SPNs; (2) G-LL: average test-set log likelihood for the graph SPN obtained from the tree SPN by merging similar sub-SPNs; (3) |T|: number of parameters in the tree SPN; (4) |G|: number of parameters in the graph SPN; (5) CR:=Compression Ratio = $\frac{|T|}{|G|}$; (6) T-Time: Tree SPN learning time in seconds and (7) G-Time: Time in seconds required by the merging algorithm (thus the total learning time for graph SPNs is T-time+G-time seconds). In each row, **bold** values indicate the best score for each of the two SPN categories: L−SPN and O−SPN.

ularization and faster learning as in [28]. To learn sum nodes in O−SPNs, we employed two heuristics proposed in our previous work [25, 24]. The first heuristic selects an observed variable that has the highest information gain. The second heuristic selects an observed variable based on the following mutual information based criteria: given a set of variables $\mathbf{V}$ and training data T, we score each variable $V_i \in \mathbf{V}$ using $Score(V_i) = \sum_{V_j \in \mathbf{V} \setminus V_i} I_T(V_i, V_j)$ where $I_T(V_i, V_j)$ is the mutual information between V_i and V_j according to T and choose a variable having the highest score. Variables having high mutual information score are likely to yield better decompositions, which in turn will likely yield small depth SPNs having high generalization accuracy.

In both L−SPNs and O−SPNs, we learn product nodes using the technique described in Gens and Domingos [11]. We first compute the mutual information graph given data (similar to the Chow-Liu algorithm). This graph is a complete weighted graph over all variables, in which each edge is weighted by the mutual information between the two corresponding variables. Then, we prune weak edges from the graph using a threshold chosen from β: $\{0.001, 0.0015, 0.01, 0.5\}$. Finally, we find connected components of the pruned graph, and recursively learn a sub-SPN over variables and data in each connected component.

We varied the depth h of SPNs from $\{4, 5, 6, 7, 10\}$.[4] We use the following stopping criteria for learning the base model (tree Markov network): stop when the number of samples n at a node is less than 10 or the maximum depth is reached. All parameters in the model were smoothed using 1-Laplace smoothing.

For each possible configuration of h and β we learned both a tree L−SPN and a tree O−SPN. In case of O−SPNs, we also varied the heuristic to choose an observed variable. The best tree SPN in each category was chosen according to the average log-likelihood score achieved on the validation set and provided as the input to the merging algorithm (see Algorithm 2). Then, we applied practical merging and simplification strategies described in section 3.2 on the

[4]Note that the overall depth of the SPN is h plus the depth of the SPN corresponding to the tree Markov network (our base model). Thus, the overall depth can be quite large (> 30 in most cases).

merged SPN and report the test set log-likelihood score of the merged model that achieved the highest log-likelihood score on validation set.[5] We used Manhattan distance to measure the distance between two candidate sub-SPNs and chose a threshold (ϵ) from $\{0.0001, 0.001, 0.01, 0.1\}$ using the validation set. Finally, after each merge we performed the following sanity/model complexity check. If the merged sub-SPN had smaller log-likelihood than a tree Markov network on the validation set, we replaced the merged sub-SPN by the latter.

4.3 IMPACT OF MERGING ON TEST LOG-LIKELIHOOD

Table 2 shows the results of our experiments for evaluating the impact of merging on the accuracy, time complexity and prediction time of L−SPNs and O−SPNs. In terms of learning time, we see that for L−SPNs, merging requires a significant amount of time. This is to be expected because parameter learning is computationally expensive in presence of latent variables. To update the parameters of candidate sub-SPNs, we ran hard EM with the merged dataset for 20 iterations or until convergence. For some L−SPNs (e.g. Plants), merging was a factor of 200 slower than learning tree models. The reason for this anomaly is that the corresponding tree L−SPNs have large number of latent sum nodes. On the other hand, merging is significantly faster in O−SPNs than L−SPNs because the parameters are updated in closed-form, by making only one pass over the data as well as the model.

We measure the prediction time by the number of edges attached to the sum nodes (see columns |T|, |G| and CR in Table 2) since the prediction time is linearly proportional in the number of these weights. We see that in general merging yields reductions in complexity of inference by reducing the size of the network in majority of cases.

In terms of accuracy, we see from Table 2 that merging improves the test set log-likelihood score for the majority of datasets, clearly demonstrating our intuition that it will yield better generalization, primarily because it significantly reduces the variance at the cost of slightly increasing the bias.

4.4 COMPARISON WITH STATE-OF-THE-ART

Finally, we demonstrate that we can achieve state-of-the-art performance using our merging algorithm. For this, following our previous work [24, 28], we learn bagged ensemble of tree SPNs and graph SPNs. It was shown in previous studies that bagged ensembles of tree SPNs (especially latent SPNs) achieves state-of-the-art results. In our evaluation, we wanted to see whether we would be able to match or exceed these results using bagged ensemble of graph SPNs. As a strong baseline, we also compare with five other state-of-the-art tractable model learners: (1) learning sum-product networks with direct and indirect variable interactions (ID-SPN) [26], learning Markov networks using arithmetic circuits (ACMN) [20], learning mixtures of cutset networks (MCNet) [25], learning sum-product networks via SVD based algorithm (SPN-SVD) [1] and learning ensembles of cutset networks (ECNet) [24].

In our experiments, we fixed the number of bags to 40 following [24]. Instead of performing a grid search, we performed random search [3] to create a configuration for the models in the ensemble. Each component model was then weighted according to its likelihood on the training set. To get better accuracy, we treated the bagged ensemble of L−SPNs and O−SPNs as an SPN having one latent sum node as the root and each independent component (bag) as its child sub-SPN. The benefit of this approach is that instead of optimizing the local log-likelihood scores of individual SPNs, while merging, we can directly optimize the global log-likelihood.

Table 3 shows the bagged ensemble scores of L−SPNs and O−SPNs before and after merging as well as the best log-likelihood score obtained to date using the competing approaches mentioned above. Bagged graph SPNs, especially L−SPNs, performed significantly better than the state-of-the-art on all of the high dimensional datasets with very competitive scores on the others. This suggests that merging is especially useful for accurately modeling relationships in high-dimensional data (see also Table 2).

5 CONCLUSION AND FUTURE WORK

In this paper, we presented a novel algorithm for learning graph SPNs from tree SPNs by merging similar sub-SPNs in the tree SPN. Our proposed algorithm for finding and merging similar sub-SPNs is general enough to serve as a template for incorporating suitable functions that measure similarity between sub-SPNs as well as for performing arbitrary mergings. Our experimental evaluation clearly shows that graph SPNs can significantly boost the accuracy and prediction time of tree SPNs by substantially reducing the number of parameters that the learning algorithm needs to induce from data. We also investigated the merit of learning ensembles of graph SPNs, building on our previous work on learning ensembles of tree SPNs, for a variety of high dimensional real world datasets, and comparing them to other state-of-the-art tractable model learners. Our experimental results showed that ensembles of graph SPNs significantly outperformed the state-of-the-art learners, clearly demonstrating the efficacy of our proposed approach.

Future work includes: developing relational merging ap-

[5] Our experiments showed that merging sub-SPNs that are rooted at child nodes of the same sum node (the cases given in Fig. 3(a) and (b)) was often more beneficial as compared to merging sub-SPNs that are child nodes of two different sum nodes.

Table 3: Average test set log-likelihood comparison with state-of-the-art tractable model learners. **Bold** values indicate the winning score for the corresponding dataset. T-LL: Bagged LL of tree SPNs and G-LL: Bagged LL of graph SPNs. Column "Best-LL to date" gives the best log-likelihood score to date for each dataset obtained using the following competing approaches: ID-SPN [26], ACMN [20], MCNet [25], SPN-SVD [1], and ECNet [24].

MDPs with Unawareness in Robotics

Abstract

We formalize decision-making problems in robotics and automated control using continuous MDPs and actions that take place over continuous time intervals. We then approximate the continuous MDP using finer and finer discretizations. Doing this results in a family of systems, each of which has an extremely large action space, although only a few actions are "interesting". We can view the decision maker as being unaware of which actions are "interesting". We an model this using *MDPUs*, MDPs with unawareness, where the action space is much smaller. As we show, MDPUs can be used as a general framework for learning tasks in robotic problems. We prove results on the difficulty of learning a near-optimal policy in an an MDPU for a continuous task. We apply these ideas to the problem of having a humanoid robot learn on its own how to walk.

1 INTRODUCTION

Markov decision processes (MDPs) are widely used for modeling decision making problems in robotics and automated control. Traditional MDPs assume that the decision maker (DM) knows all states and actions. However, in many robotics applications, the space of states and actions is continuous. To find appropriate policies, we typically discretize both states and actions. However, we do not know in advance what level of discretization is good enough for getting a good policy. Moreover, in the discretized space, the set of actions is huge. However, relatively few of the actions are "interesting". For example, when flying a robotic helicopter, only a small set of actions lead to useful flying techniques; an autonomous helicopter must learn these techniques. Similarly, a humanoid robot needs to learn various maneuvers (e.g., walking or running) that enable it to move around, but the space of potential actions that it must search to find a successful gait is huge, while most actions result in the robot losing control and falling down.

Halpern, Rong, and Saxena [2010] (HRS from now on) defined *MDPs with unawareness (MDPUs)*, where a decision-maker (DM) can be unaware of the actions in an MDP. In the robotics applications in which we are interested, we can think of the DM (e.g., a humanoid robot) as being unaware of which actions are the useful actions, and thus can model what is going on using an MDPU.

In this paper, we apply MDPUs to continuous problems. We model such problems using *continuous MDPs*, where actions are performed over a continuous duration of time. Although many problems fit naturally in our continuous MDP framework, and there has been a great deal of work on continuous-time MDPs, our approach seems new, and of independent interest. (See the discussion in Section 5.) It is hard to find near-optimal policies in continuous MDPs. A standard approach is to use discretization. We use discretization as well, but our discrete models are MDPUs, rather than MDPs, which allows us both to use relatively few actions (the "interesting actions"), while taking into account the possibility of there being interesting actions that the DM has not yet discovered. We would like to find a discretization level for which the optimal policy in the MDP underlying the approximating MDPU provides a good approximation to the optimal policy in the continuous MDP that accurately describes the problem, and then find a near-optimal policy in that discretized MDPU.

HRS gave a complete characterization of when it is possible to learn to play near-optimally in an MDPU, extending earlier work [Brafman and Tennenholtz 2002; Kearns and Singh 2002] showing that it is always possible to learn to play near-optimally in an MDP. We extend and generalize these results so as to apply them to the continuous problems of interest to us. We characterize when brute-force exploration can be used to find a near-optimal policy in our setting, and show that a variant of the URMAX algorithm presented by HRS can find a near-optimal policy. We also characterize the complexity of learning to play near-optimally in continuous problems, when more "guided" exploration is used. Finally, we discuss how MDPUs can be

used to solve a real robotic problem: to enable a humanoid robot to learn walking on its own. In our experiment, the robot learned various gaits at multiple discretization levels, including both forward and backward gaits; both efficient and inefficient gaits; and both gaits that resemble human walking, and those that do not.

2 MDPU: A REVIEW

Describing a situation by a standard MDP misses out on some important features. In general, an agent may not be aware of all the actions that can be performed. For example, an agent playing a video game may not be aware of all actions that can be performed in a given state. Our model is compatible with a number of interpretations of unawareness. In the robotics setting, we take a particular concrete interpretation. Here, the number of actions is typically extremely large, but only a few of these actions are actually useful. For example, although an autonomous helicopter can have a huge number of actions, only a few are useful for flying the helicopter, whereas the rest simply result in a crash. We can abstract what is going on by defining a set of "useful actions". The DM may initial be unaware of many or even most of the useful actions. A DM may become aware of a useful action (and thus, can safely perform it) by performing a special action called the *explore* action, denoted a_0. Playing the explore action results in the DM learning about new actions with some probability.

We thus take an MDPU to be a tuple $M = (S, A, A_0, g, a_0, g_0, P, D, R)$,[1] where the tuple (S, A, g, P, R) is a standard MDP—that is, S is a set of states, A is a set of actions, $g(s)$ is the set of actions available at state s, for each tuple $(s, s', a) \in S \times S \times A$, $P(s, s', a)$ gives the probability of making a transition from s to s' if action a is performed, and $R(s, s', a)$ gives the reward earned by the DM if this transition is taken; $A_0 \subseteq A$ is the set of actions that the DM initially knows to be useful; a_0 is the special *explore* action; $g(s) \subseteq A$ is the set of actions that can be performed at state s; $g_0(s) \subseteq A_0 \cap g(s)$ is the set of actions that the DM is aware of at state s; finally, D is the *discovery probability function*. $D(j, t, s)$ is the probability of discovering a useful action given that there are j useful actions to be discovered at state s, and a_0 has already been played $t - 1$ times without discovering a useful action. Intuitively, D describes how quickly the DM can discover a useful action. We assume that $D(j, t, s)$ is non-decreasing as a function of j: the more useful actions there are to be found, the easier we can find one. How $D(j, t, s)$ varies with t depends on the problem. In the sequel, we assume for ease of exposition that $D(j, t, s)$ is independent of s, so we write $D(j, t)$ rather than $D(j, t, s)$. $M' = (S, A, P, R)$ is called the *MDP underlying* M.

Kearns and Singh [2002] and Brafman and Tennenholtz [2002] have studied the problem of learning how to play near-optimally in an MDP. Roughly speaking, to play near-optimally means that, for all $\epsilon > 0$ and $\delta > 0$, we can find a policy that obtains expected reward ϵ-close to that of the optimal policy with probability at least $1 - \delta$. HRS completely characterize the difficulty of learning to play near-optimally in an MDPU. We briefly review the relevant results here. Despite initially being unaware of some useful actions, we want the DM to learn a policy that is near-optimal in the underlying MDP. HRS showed that whether a DM can learn to play optimally and how long it takes depend on the value of $D(1, t)$—the probability of discovering a new action given that there is a new action to discover and the DM has tried $t - 1$ times in the past to discover a new action.

The first result characterizes when it is impossible to learn to play near-optimally. To make it precise, we recall the notion of mixing time. Formally, the *ϵ-return mixing time of an MDP M* is the least T such that an optimal policy for M guarantees an expected payoff within ϵ of the optimal reward after running for at least time T. (See [Kearns and Singh 2002] for more details and motivation.) The following theorem shows that if the discovery probability is sufficiently low, where "sufficiently low" means $D(1, t) < 1$ for all t and $\sum_{t=1}^{\infty} D(1, t) < \infty$, then the DM cannot learn to play near-optimally. We define $\Psi(T) = \sum_{t=1}^{T} D(1, t)$.

Theorem 2.1 *If $D(1, t) < 1$ for all t and $\Psi(\infty) < \infty$, then there exists a constant c such that no algorithm can obtain a reward that is guaranteed to be within c of optimal for an MDPU $M = (S, A, A_0, G, a_o g_0, P, D, R)$, even if S, $|A|$, and a bound on the optimal reward are known.*

Theorem 2.1 says that when $\Psi(\infty) < \infty$, it is impossible for the DM to learn an optimal policy. On the other hand, if $\Psi(\infty) = \infty$, then it is possible to learn to play near-optimally. HRS present an algorithm called URMAX, a variant of the RMAX algorithm [Brafman and Tennenholtz 2002], that learns near-optimal play.

Theorem 2.2 *If $\Psi(\infty) = \infty$, then the URMAX algorithm computes a near-optimal policy.*

In fact, we can say even more. If $\Psi(\infty) = \infty$, then the efficiency of the best algorithm for determining near-optimal play depends on how quickly $\Psi(\infty)$ diverges. HRS characterize the running time of URMAX in terms of the function Ψ, and give lower bounds on the time required to learn near-optimally in terms of Ψ. These results show that URMAX learns to play near-optimally almost as quickly as possible. Specifically, it learns a policy with an expected reward ϵ-close to the optimal reward with probability $1 - \delta$ in time polynomial in $|S|$, $|A|$, $1/\epsilon$, $1/\delta$, a bound $R_{\max}$ on the optimal reward, the ϵ-return mixing time, and the small-

[1] The MDPU model in HRS also includes R_i^+ and R_i^-, which are the reward (resp., penalty) functions for playing a_0 and discovering (resp., not discovering) a useful action. We omit them here; they play no role in the theorems that we are citing, and would only clutter our later presentation.

est T such that $\Psi(T) \geq \ln(4N/\delta)$, whenever it is possible to do so. The polynomial-time results are summarized in the next result.

Theorem 2.3 *It is possible to learn to play near-optimally in polynomial time iff there exist constants m_1 and m_2 such that $\Psi(T) \geq m_1 \ln(T) + m_2$ for all $T > 0$. Moreover, if it is possible to learn to play near-optimally in polynomial time, URMAX does so.*

3 ANALYZING ROBOTIC PROBLEMS AS MDPUS

As we said in the introduction, we apply the MDPU framework to robotic problems such as having a humanoid robot learn to walk. For such problems, we typically have a continuous space of states and actions, where actions take place in continuous time, and actions have a nontrivial duration.

Suppose that the original continuous problem can be characterized by a continuous MDP M_∞ (defined formally below). We would like to find a "good" discretization M of M_∞. "Good" in this setting means that an optimal policy for M is ϵ-optimal for M_∞, for some appropriate ϵ.[2] Clearly the level of discretization matters. Too coarse a discretization results in an MDP whose optimal policy is not ϵ-optimal for M_∞; on the other hand, too fine a discretization results in the problem size becoming unmanageably large. For example, in order to turn a car on a smooth curve (without drifting), the optimal policy is to slowly turn the steering wheel to the left and back, in which the action varies smoothly over time. This can be simulated using a relatively coarse discretization of time. However, in order to make a sharp turn using advanced driving techniques like drifting, the steering wheel needs to be turned at precise points in time, or else the car will go into an uncontrollable spin. In this case, a fine discretization in time is needed.

Unfortunately, it is often not clear what discretization level to use in a specific problem. Part of the DM's problem is to find the "right" level of discretization. Thus, we describe the problem in terms of a continuous MDP M_∞ and a sequence $((M_1, M_1'), (M_2, M_2'), \ldots)$, where M_i is an MDPU with underlying MDP M_i', for $i = 1, 2, \ldots$. Intuitively, $(M_1', M_2', M_3', \ldots)$ represents a sequence of finer and finer approximations to M_∞.

Continuous Time MDP with Continuous Actions over Time: To make this precise, we start by defining our model of continuous MDPs. Let $M_\infty = (S_\infty, A_\infty, g_\infty, P_\infty, R_\infty)$. S_∞ is a continuous state space, which we identify with a compact subset of $\mathbb{R}^n$ for some integer $n > 0$; that is, each state can be represented by a vector $(s_1, \cdots, s_n)$ of real numbers. For example, for a humanoid robot, the state space can be described by a vector which includes the robot's (x, y, z) position, and the current positions of its movable joints.

Actions: Describing A_∞ requires a little care. We assume that there is an underlying set of *basic actions* A_B, which can be identified with a compact subset of $\mathbb{R}^m$ for some $m > 0$; that is, each basic action can be represented by a vector $(a_1, \cdots, a_m)$ of real numbers. For example, for a humanoid robot, the basic actions can be characterized by a tuple that contains the targeted positions for its movable joints. However, we do not take A_∞ to consist of basic actions. Rather, an action is a *path* of basic actions over time. Formally, an action in A_∞ is a piecewise continuous function from a domain of the form $(0, t]$ for some $t > 0$ to basic actions. Thus, there exist time points $t_0 < t_1 < \ldots < t_k$ with $t_0 = 0$ and $t_k = t$ such that a is continuous in the interval $(t_j, t_{j+1}]$ for all $j < k$. The number t is the *length* of the action a, denoted $|a|$. We use left-open right-closed intervals here; we think of the action in the interval $(t_j, t_{j+1}]$ as describing what the DM does right after time t_j until time t_{j+1}. By analogy with the finite case, $g_\infty(s)$ is the set of actions in A_∞ available at s.

Reward and Transition Functions: We now define R_∞ and P_∞, the reward and transition functions. In a discrete MDP, the transition function P and reward function R take as arguments a pair of states and an action. Thus, for example, $P(s_1, s_2, a)$ is the probability of transitioning from s_1 to s_2 using action a, and $R(s_1, s_2, a)$ is the reward the agent gets if a transition from s_1 to s_2 is taken using action a. In our setting, what matters is the path taken by a transition according to a. Thus, we take the arguments to P_∞ and R_∞ to be tuples of the form (s_1, s_c, a), where s_1 is a state, a is an action in A_∞ of length t, and s_c is a piecewise continuous function from $(0, t]$ to S_∞. Intuitively, s_c describes a possible path of states that the DM goes through when performing action a, such that before a starts, the DM was at s_1.[3] Note that we do not require that $\lim_{t \to 0^+} s_c(t) = s_1$. Intuitively, this means that there can be a discrete change in state at the beginning of an interval. This allows us to capture the types of discrete changes considered in *semi-MDPs* [Puterman 1994].

We think of $R_\infty(s_1, s_c, a)$ as the reward for transitioning from s_1 according to state path s_c via action a. We assume that R_∞ is bounded: specifically, there exists a constant c such that $R_\infty(s_1, s_c, a) < c \cdot |a|$. For $s_1 \in S_\infty$ and $a \in A_\infty$, we take $P_\infty(s_1, \cdot, a)$ to be a probability density function over state paths of length $|a|$ starting at s_1. P_∞ is not defined for transitions starting at terminal states.

We require R_∞ and P_∞ to be continuous functions, so that if (s_i, s_c^i, a_i) approaches (s, s_c, a) (where all the state sequences and actions have the same length t), then $R_\infty(s_i, s_c^i, a_i)$ approaches $R_\infty(s, s_c, a)$ and $P_\infty(s_i, s_c^i, a_i)$

[2] A policy π is ϵ-optimal for an MDP M if the expected average reward for a policy for M is no more than ϵ greater than the expected average reward of π.

[3] We are thus implicitly assuming that the result of performing a piecewise continuous action must be a piecewise continuous state path.

approaches $P_\infty(s, s_c, a)$. To make the notion of "approaches" precise, we need to consider the distance between state paths and the distance between actions. Since we have identified both states (resp., basic actions) with subsets of $\mathbb{R}^n$ (resp., $\mathbb{R}^m$), this is straightforward. For definiteness, we define the distance between two vectors in $\mathbb{R}^n$ using the L_1 norm, so that $d(\vec{p}, \vec{q}) = \sum_1^n |p_i - q_i|$. For actions a and a' in A_∞ of the same length, define $d(a, a') = \int_{t=0}^{|a|} d(a(t), a'(t))dt$. For state paths s_c and s'_c of the same length, define $d(s_c, s'_c) = \int_{t=0}^{|s_c|} d(s_c(t), s'_c(t))dt$. Finally, define $d((s_c, a), (s'_c, a')) = d(s_c, s'_c) + d(a, a')$. This definition of distance allows us to formalize the notion of continuity for R_∞ and P_∞. The key point of the continuity assumption is that it allows us to work with discretizations, knowing that they really do approximate the continuous MDP.

Constraints on Actions: We typically do not want to take A_∞ to consist of all possible piecewise continuous functions. For one thing, some hardware and software restrictions will make certain functions infeasible. For example, turning a steering wheel back and forth 10^{20} times in one second can certainly be described by a continuous function, but is obviously infeasible in practice. But we may want to impose further constraints on A_∞ and $g_\infty(s)$.

In the discussion above, we did not place any constraints on the length of actions. When we analyze problems of interest, there is typically an upper bound on the length of actions of interest. For example, when playing table tennis using a robotic arm, the basic actions can be viewed as tuples, describing the direction of movement of the racket, the rotation of the racket, and the force being applied to the racket; actions are intuitively all possible control sequences of racket movements that are feasible according to the robot's hardware and software constraints; this includes slight movements of the racket, strokes, and prefixes of strokes. An example of a piecewise continuous action here would be to move the racket forward with a fixed force for some amount of time, and then to suddenly stop applying the force when the racket is close to the ball. We can bound the length of actions of interest to the time that a ball can be in the air between consecutive turns. We assume that, in any case, there is an upper bound T on the length of all actions. This seems to be a reasonable assumption for all the applications of interest to us here.

Awareness: Even with the constraints discussed above, A_∞ is typically extremely large. Of course, not all actions in A_∞ are "useful". For instance, in the helicopter example, most actions would crash the helicopter. We thus consider *potentially useful* actions. (We sometimes call them just *useful actions*.) Informally, an action is potentially useful if it is not *useless*. A useless action is one that either destroys the robot, or leaves it in an uncontrollable state, or does not change the state. For example, when flying a helicopter, actions that lead to a crash are useless, as are actions that make the helicopter lose control. More formally, given a state s, the set of useful actions at state s are the actions that transit to a different state in which the robot is neither destroyed nor uncontrollable. Note that an action that crashes the helicopter in one state may not cause a crash in a different state. For robotics applications, we say that a robot is *aware* of an action if it identifies that action as a potentially useful action, either because it has been preprogrammed with the action (we are implicitly assuming that the robot understands all actions with which it has been programmed) or it has simulated the action. For example, a humanoid robot that has been pre-programmed with only simple walking actions, and has never tried running or simulated running before, would be unaware of running actions. Let $\bar{A}_\infty$ denote the useful actions in A_∞, and let $\bar{A}_{\infty 0}$ denote the useful actions that the robot is initially aware of. (These are usually the actions that the robot has been pre-programmed with.)

Discretization: We now consider the discretization of M_∞. We assume that, for each discretization level i, S_∞ is discretized into a finite state space S_i and A_B is discretized into a finite basic action space A_{Bi}, where $|S_1| \leq |S_2| \leq \ldots$ and $|A_{B1}| \leq |A_{B2}| \leq \ldots$. We further assume that, for all i, there exists $d_i > 0$, with $d_i \to 0$, such that for all states $s \in S_\infty$ and basic actions $a_B \in A_B$, there exists a state $s' \in S_i$ and a basic action $a_{B'} \in A_{Bi}$ such that $d(s, s') \leq d_i$, and $d(a_B, a'_B) \leq d_i$. Thus, we are assuming that the discretizations can give closer and closer approximations to all states and basic actions. At level i, we also discretize time into time slices of length t_i, where $T \geq t_1 > t_2 > \ldots$.Thus, actions at discretization level i are sequences of *constant actions* of length t_i, where a constant action is a constant function from $(0, t_i]$ to a single basic action.[4] In other words, the action lengths at discretization level i are multiples of t_i. Thus, at discretization level i, there are $\sum_{l=1}^{\lfloor T/t_i \rfloor} |A_{Bi}|^l$ possible actions. Let A'_i consist of this set of actions. (Note that some actions in A'_i may not be in A_∞, since certain action sequences might be infeasible due to hardware and software constraints.) Let $A_i \subseteq A'_i$ be the set of useful actions at level i.

Let M_i be the MDPU where S_i and A_i are defined above; $A_{\infty 0}$ is the set of useful actions that the DM is initially aware of; $g(s)$ is the set of useful actions at state s; $g_0(s)$ is the set of useful actions that the DM is aware of at state s; and the reward function R_i is just the restriction of R_∞ to A_i and S_i. For $s_1 \in S_i$ and $a \in A_i$, we take $P_i(s_1, \cdot, a)$ to be a probability distribution over $Q_i^{|a|}$, the set of state paths of length $|a|$ that are piecewise constant and each constant section has a length that is a multiple of t_i. For a state path $s_c \in Q_i^{|a|}$, let $P_i(s_1, s_c, a)$ be the normalized probability of traversing a state sequence that is within distance d_i of state sequence s_c when playing action a starting from state s_1. Formally,

[4]Note that we are not assuming that the action space A_{i+1} is a refinement of A_i (which would further require t_{i+1} to be a multiple of t_i).

$P_i(s_1, s_c, a) = (\int_{\{s'_c : d(s_c, s'_c) \le d_i\}} dP_\infty(s_1, \cdot, a))/c$, where $c = \sum_{s_c \in Q_i^{|a|}} \int_{\{s'_c : d(s_c, s'_c) \le d_i\}} dP_\infty(s_1, \cdot, a)$ is a normalization constant. Since the robot is not assumed to know all useful actions at any specific discretization level, it needs to explore for the useful actions it wasn't aware of. Finally, given a specific exploration strategy, $D_i(j, t)$ describes the probability of discovering a new useful action at discretization level i, given that there are j undiscovered useful actions at level i, and the robot has explored t times without finding a useful action. We model exploration using a_0; every time the robot explores, it is playing a_0.

It remains to define the discretization of an action in A_0. In order to do this, for $a \in A_\infty$, define $a_i \in A_i$ to be *a best approximation to a in level i* if $|a_i|$ is the largest multiple of t_i that is less than or equal to $|a|$, and $\int_0^{(|a_i|)} d(a(t), a_i(t))dt$ is minimal among actions $a' \in A$ of length $|a_i|$. Intuitively, a_i is an action in A_i whose length is as close as possible to that of a and, among actions of that length, is closest in distance to a. The action a_i is not unique. For $a \in A_0$, define its discretization at level i to be a best approximation to a at that level. When there are several best approximations, we choose any one of them.

Policies: As usual, a policy π in M_i is a function from S_i to A_i. We want to compute $U_{M_i}(s, \pi, t)$, the expected average reward over time t of π started in state $s \in S_i$. Let $a_j \in A_i$ and s_{cj} be a state sequence in $Q_i^{|a_j|}$, for $j = 0, \ldots, l$. Say that a sequence $((a_0, s_{c0}), (a_1, s_{c1}), \cdots, (a_l, s_{cl}))$ is *a path compatible with policy π starting at s* if $\pi(s) = a_0$ and $\pi(s_{cj}(|a_j|)) = a_{j+1}$ for all $0 \le j \le l-1$. Let $I^\pi_{s,t}$ consist of all paths $((a_0, s_{c0}), (a_1, s_{c1}), \cdots, (a_l, s_{cl}))$ starting at s compatible with π such that $\sum_{j=0}^{l} |a_j| \le t < \sum_{j=0}^{l+1} |a_j|$, where $a_{l+1} = \pi(s_{cl}(|a_l|))$. Essentially, when computing $U_{M_i}(s, \pi, t)$, we consider the expected reward over all maximally long paths that have total length at most t. Thus, $U_{M_i}(s, \pi, t) = \sum_{p \in I^\pi_{s,t}} P_i^*(p) \frac{R_i^*(p)}{t}$, where, given a path $p = ((a_0, s_{c0}), (a_1, s_{c1}), \cdots, (a_l, s_{cl}))$, $P_i^*(p) = \Pi_{j=0}^{l} P_i(s_{cj}(0), s_{cj}, a_j)$, and $R_i^*(p) = \sum_{j=0}^{l} R_i(s_{cj}(0), s_{cj}, a_j)$.

Now that we have defined the average reward of a policy at discretization level i, we can define the average reward of a policy in M_∞. Given a discretization level i, let π_i be a *projection* of π_∞ at level i, defined as follows: for each $s_i \in S_i$, define $\pi_i(s_i)$ to be an action $a_i \in A_i$ such that a_i is a best approximation to $\pi(s_i)$ at level i, as defined above. As mentioned, there might be several best approximations; a_i is not unique. Thus, the projection is not unique. Nevertheless, we define $U_{M_\infty}(s, \pi_\infty, t)$ to be $\lim_{i \to \infty} U_{M_i}(s, \pi_i, t)$, where π_i is a projection of π to discretization level i. The continuity of the transition and reward functions guarantees that the limit exists and is independent of the choice of projections.

We now consider how the URMAX algorithm of Section 2 can be applied to learn near-optimal policies. We use URMAX at each discretization level. Note that URMAX never terminates; however, it eventually learns to play near-optimally (although we may not know exactly when). The time it takes to learn to play near-optimally depends on the exploration strategy. The next theorem consider brute-force searching, where, at discretization level i, at each discretization level i, all actions in A'_i are exhaustively examined to find useful actions. (The proof of this and all other theorems can be found in the supplementary material.)

Theorem 3.1 *Using brute-force exploration, given $\alpha > 0$ and $0 < \delta < 1$, we can find an α-optimal policy in M_∞ with probability at least $1 - \delta$ in time polynomial in l, $|A'_l|$, $|S_l|$, $1/\alpha$, $1/\delta$, $R^l_{\max}$, and T^l, where l is the least i such that the optimal policy for M'_i is $(\alpha/2)$-optimal for M_∞, $R^l_{\max}$ is the maximum reward that can be obtained by a transition in M'_l, and T^l is the ϵ-return mixing time for M'_l.*

Although brute-force exploration always learns a near-optimal policy, the method can be very inefficient, since it exhaustively checks all possible actions to find the useful ones. Thus, at discretization level i, it needs to check $\sum_{l=1}^{\lfloor T/t_i \rfloor} |A_{Bi}|^l$ actions, and as i grows, the method soon becomes impractical. On the other hand, the result is of some interest, since it shows that even when there are infinitely many possible levels of discretizations, a method as simple as brute-force exploration suffices.

When the number of possible actions is huge, the probability of finding a potentially useful action can be very low. In this case, making use of an expert's knowledge or imitating a teacher's demonstration can often greatly increase the probability of finding a useful action. We abstract the presence of an expert or a teacher by assuming that there is some constant $\beta > 0$ such that $D(1, t) \ge \beta$ for all t. Intuitively, the presence of a teacher or an expert guarantees that there is a minimal probability β such that, if there is a new action to be found at all, then the probability of finding it is at least β, no matter how many earlier failed attempts there have been at finding a useful action.

Using apprentice learning lets us improve Theorem 3.1 by replacing the $|A'_l|$ component of the running time by $|A_l|$; thus, with apprentice learning, the running time depends only on the number of useful actions, not the total number of potential actions. The savings can be huge.

Theorem 3.2 *Using an exploration method where $D_i(1, t) \ge \beta$ for all $i, t > 0$ (where $\beta \in (0, 1)$ is a constant), for all $\alpha > 0$ and $0 < \delta < 1$, we can find an α-optimal policy in M_∞ with probability at least $1 - \delta$ in time polynomial in l, $|A_l|$, $|S_l|$, $1/\beta$, $1/\alpha$, $1/\delta$, $R_{\max}$, and T^l, where l is the smallest i such that the optimal policy for M'_i is $(\alpha/2)$-optimal to M_∞, $R^l_{\max}$ is the maximum reward that can be obtained by a transition in M'_l, and T^l is the ϵ-return mixing time for M'_l.*

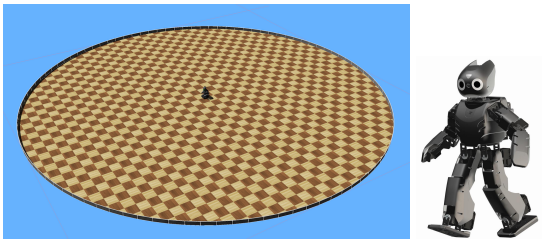

Figure 1: The arena with the robot at the center; and the robot.

4 HUMANOID ROBOT WALKING

We consider the problem of a humanoid robot with 20 joint motors (which we sometimes call just "joints") learning to walk on its own. More precisely, we require the robot to move from the center of an arena to its boundary; we take any reasonable motion to be "walking". (Figure 1 shows the robot and the arena in which it must walk.)

4.1 The continuous MDP

We start by defining a continuous M_∞ for the robot problem. A state $s \in S_\infty$ is of the form $s = (w_1, \cdots, w_{23}) \in I\!R^{23}$, where (w_1, w_2, w_3) give the position of the robot's center of mass and $(w_4, \cdots, w_{23})$ are the current positions of the robot's 20 joint motors. We define the domain of each dimension as follows: since the radius of the arena is 5 meters, $w_1, w_2 \in [-5, 5]$; since the robot's height is 0.454 meters, $w_3 \in [0, 0.4]$ (we do not expect the robot's center of mass to be higher than 0.4). Each joint motor has its specific range of mobility, which determines the domain of the corresponding dimension. For example, $w_5 \in [-3.14, 2.85]$ represents the current position of the robot's left shoulder. The mobility range for all joint motors are intervals in $[-\pi, \pi]$.

The basic actions $a \in A_B$ are of the form $a = (v_1, \cdots, v_{20}) \in I\!R^{20}$, where v_i is the target position for the robot's ith joint motor. The domain of each dimension is the mobility range for the corresponding joint motor. For example, v_2, which corresponds to the left shoulder, has mobility range $[-3.14, 2.85]$; $v_2 = 2.85$ means to move the robot's left shoulder forward as far as possible. Since walking is composed of repeated short movements that are typically no longer than half a second, we set $T = 0.512$ seconds. Thus, A_∞, the set of useful actions, consists of piecewise continuous functions that map from time to basic actions and comply with the robot's hardware and software limitations, of length $t < 0.512$ seconds.

We now define R_∞ and P_∞. Intuitively, the robot obtains a reward for gaining distance from the center of the arena. If the coordinates of the center of the arena are given by $s_0 = (s_0[1], s_0[2])$, then $R_\infty(s_1, s_c, a) = dis(s_0, s_c(|a|)) - dis(s_0, s_1)$, where $dis(s_0, s_1) = \sqrt{(s_0[1] - s_1[1])^2 + (s_0[2] - s_1[2])^2}$ is the L_2-norm distance between s_0 and s_1 on the (x, y)-plane. The reward could be negative, for example, if the robot moves back towards the center of the arena.

By definition, $P_\infty(s_1, \cdot, a)$ is a probability distribution over state sequences of length $|a|$ starting at s_1. For example, if the robot slowly moves its right leg forward while staying balanced, the state path taken by the robot is a deterministic path. On the other hand, if a is the action of turning around quickly, $P_\infty(s, \cdot, a)$ is distribution over various ways of falling down.

4.2 Discretizations

We now define M_i and M_i'. In our experiments we considered only levels 2 and 3 (level 1 is uninteresting since it has just one state and one action), so these are the only levels that we describe in detail here. (These turn out to suffice to get interesting walking behaviors.) At these levels, we discretized more finely the joints corresponding to the left and right upper and lower leg joints and the left and right ankle joints, since these turn out to be more critical for walking. (These are components $(w_{14}, \cdots, w_{19})$ in the state tuples and $(v_{11}, \cdots, v_{16})$ in basic-actions tuples.) We call these the *relevant dimensions*. We assume that the six relevant state and actions components have i possible values at level i, for $i = 2, 3$, as does w_3, since this describes how high off the ground the robot is (and thus, whether or not it has fallen). All other dimensions take just one value. We took $t_2 = t_3$ to be 128ms. Since $T = 0.512$s, an action contains at most $\lfloor T/t_i \rfloor = 4$ basic actions.

$A_{\infty 0}$ is the set of preprogrammed actions. We preprogram the robot with a simple sitting action that lets the robot slowly return to its initial sitting gesture. When we consider apprenticeship learning, we also assume that the robot is preprogrammed with a "stand-up" action, that enables it to stand up from its initial sitting position. (Intuitively, we are assuming that the expert taught the robot how to stand up, since this is useful after it has fallen.)

A_i' is the set of potential actions at level i. Given our assumptions, for $i = 2, 3$, at level i, there are $(i^6)^4$ potential actions (there are i possible values for each of the six relevant dimensions, and each action is a sequence of four basic actions). Thus, at level 3, there are $(3^6)^4$ =282,429,536,481 potential actions. As we mentioned, a useful action is an action that moves the robot without making it lose control. Here, an action is useful if it moves the robot without resulting in the robot falling down. At both levels 2 and 3, more than 80 useful actions were found in our experiments. The most efficient action found at level 3 was one where the right leg moves backwards, immediately followed by the left leg, in such a way that the robot maintains its balance at all times. By way of contrast, turning the body quickly makes the robot lose control and fall down, so is useless.

For $s_1 \in S_i$, $a \in A_i$, and $s_c \in Q_i^{|a|}$, $P_i(s_1, s_c, a)$ is the

normalized probability of traversing a state sequence that is d_i close to s_c, a sequence of states in S_i, where we define $d_i = \frac{12\pi}{i} + 28\pi + 20.4$. So d_i decreases in i, and discretizations at a higher level better approximate the continuous problem. All basic actions in A_B are within distance d_i of a basic action in A_{Bi} and all states in S are within d_i of a state in S_i. Let $s \in S$, and let s_i be the closest state to s in S_i. It is easy to check that $d(s, s_i) \leq d_i$ for $i = 2, 3$.

The D_i function depends on the exploration method used to discover new actions. In our experiment, we used two exploration methods: brute-force exploration and apprenticeship-learning exploration.

At discretization level i, using brute-force exploration, we have $D_i(|A_i|, t) = \frac{|A_i|}{|A'_i|}$, since there are $|A_i|$ useful actions and $|A'_i|$ potential actions, and we test an action at random. With apprenticeship learning, we used following hints from a human expert to increase the probability of discovering new actions: (a) a sequence of moving directions that, according to the human expert, resembles human walking;[5] (b) a preprogrammed stand-up action; (c) the information that an action that is symmetric to a useful action is also likely to be useful (two actions are symmetric if they are exactly the same except that the target values for the left joints and those for the right joints are switched). We also use a different discretization: the ankle joint was discretized into 10 values. The human expert suggests more values in the ankle joints because whether or not the robot falls depends critically on the exact ankle joint position. These hints were provided before the policy starts running; the discretization levels are set then too. There were no further human-robot interactions.

4.3 Experiments

For our experiments, we simulated DARwIn OP, a commercially available humanoid robot. The simulations were conducted on Webots PRO platform 8.2.1 using a MacBook Pro with 2.8GHz Intel Core i7 Processor, 16GB 1600 MHz DDR3 memory, 0.5TB Flash Storage Mac HD, on OS X Yosemite 10.10.5. We modeled the robot walking problem as an MDPU, and implemented the URMAX algorithm using programming language Python 2.7.7.

As we said, given the number of actions involved, we conducted experiments only for discretization level 2 and 3. Both sufficed to enable the robot to learn to walk, using a generous notion of "walk"—more precisely, they sufficed to enable the robot to learn to locomote to the boundary of the arena. As mentioned, two exploration methods were used: brute-force exploration and apprenticeship-learning exploration. One trial was run for brute-force exploration at each of levels 2 and 3, and one trial was run for apprenticeship learning at level 2. Each trial took 24 hours. More than

[5]The sequence gives directions only for certain joints, without specific target values, leaving the movement remaining joints open for experimentation.

	Brute-force (level 2)	Brute-force (level 3)	Apprenticeship learning (level 2)
$\|S_i\|$	130	1460	3200
$\|A_{Bi}\|$	64	729	1600
$\|A_i\|$	16777216	282429536481	6553600000000
t_i (ms)	124	124	124
Length of action (ms)	496	496	496
Execution time (hours)	24	24	24
Best avg rwd (m/action)	0.043486	0.067599	0.083711
Num of useful actions found	131	89	180

Table 1: Performance comparisons.

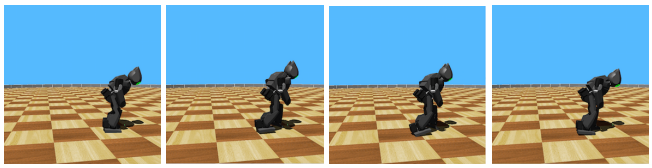

Figure 2: A backward gait (from left to right).

15 stable gaits were found in total, where a gait is *stable* if it enables the robot to move from the center of the arena to the boundary without falling. In addition, more than 400 useful actions were found. The best gait among all stable gaits achieved a velocity of 0.084m/s, which seems reasonable, given that the best known walking speed of DARwIn-OP is 0.341m/s [Budden et al. 2013]. Given more time to experiment, we would expect the performance to improve further.

The robot successfully learned gaits of various styles, including both forward and backward gaits (see Figures 2 and 3), both efficient and inefficient gaits, gaits that resemble human walking and the ones that do not. Somewhat surprisingly, the best gait actually walks backwards. (Videos of some of the gaits and a demo of the learning process can be found at https://youtu.be/qW51iInpdV0.) As shown in Table 1, as the discretization level increases, both the velocity of the best gait and the number of useful actions found increase. This agrees with the expectation that finer discretization better approximates the continuous problem, and thus gets an expected reward closer to the optimal reward of the continuous problem. Apprenticeship learning resulted in more useful actions than the brute-force exploration and in gaits with a higher average reward. Again, this is hardly surprising; the hints provided by the human expert increases the probability of finding useful actions. On the other hand, when the expert gives "bad" hints, the

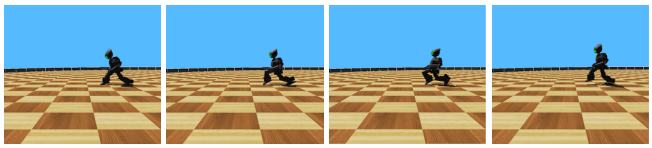

Figure 3: A forward gait (from left to right).

robot performs worse than with brute-force exploration.

With regard to comparisons under the same setting, we implemented two baseline comparisons for bipedal walking. The first tries random sequences of actions; the second searches for useful actions and then repeats each useful action in an attempt to find stable gaits. (The motivation for repeating actions is that human-like walking is in fact a rhythmic/cyclic movement of a repeated action.) Using the same setting as our experiments with URMAX, the first baseline found no stable gait in 24 hours, and the maximum distance the robot travelled before falling down was 0.342 meters; the second baseline found one stable gait in 24 hours, and the maximum distance travelled was 5 meters (the maximum distance possible from the center of the arena to the boundary) with a speed of 0.0058 m/s. Our appraoch found several stable gaits at each discretization level and the distance travelled using each stable gait is 5 meters with a maximum speed of 0.083m/s (10 times better than the second baseline).

Our approach, using MDPUs, requires no knowledge on the kinematics of the robot other than the number of joints and the moving range of each joint. Moreover, it makes no assumptions about the moving pattern of the resulting gait; for example, we do not assume that a gait must be cyclic, or symmetric between left and right joints, nor do we specify the length of a gait. Although we do specify the length of a useful action, a gait could be composed of a single or multiple useful actions. Given the few assumptions and little prior knowledge assumed, the performance of the robot seems quite reasonable. More importantly, the experiment proves that the use of MDPUs enables the robot to learn useful new maneuvers (walking, in this case) by itself, with minimum human input.

5 RELATED WORK

There has been work on optimal policy learning in MDPs using computational resources. Kearns and Singh's [2002] E^3 algorithm guarantees polynomial bounds on the resources required to achieve near-optimal return in general MDPs; variants and extensions of this work can be found in [Brafman and Tennenholtz 2002; Kakade et al. 2003; Kearns and Koller 1999]. However, algorithms such as E^3 usually require the exploration of the entire MDP state/action space. This becomes impractical in our setting, where the number of actions is extremely large. In such cases, several exploration methods have been employed to help find useful actions. For example, Abbeel and Ng [2005] utilize a teacher demonstration of the desired task to guide the exploration; Dearden et al. [1999] utilize the value of information to determine the sequence of exploration. Other papers (e.g., [Dean et al. 1998; Hauskrecht et al. 1998]) consider MDPs with large action spaces.

We are far from the first to consider MDPs with continuous time. For example, *semi-MDPs* (SMPDs) and *continuous-time MDPs* have continuous time [Puterman 1994]. However, these models have discrete actions that can be taken instantaneously, and do not consider continuous actions taken over some duration of time. In *Markov decision drift processes* [Hordijk and Van der Duyn Schouten 1984], the state does not have to stay constant between successive actions (unlike an SMDP), and can evolve in a deterministic way according to what is called a *drift function*. But Markov decision drift processes do not have actions with probabilistic outcomes that take place over an interval of time. They make significant use of discrete approximations to compute optimal policies, just as we do. There has also been work on MDPs with continuous state space and action space (e.g., [Antos and Munos 2007; Feng et al. 2004]), but with discrete time. For our applications, we need time, space, and actions to be continuous; this adds new complications. In control theory, there are methods for controlling continuous time systems where system transitions are linear function of state and time [Zinober 1989]. These can be extended to non-linear systems [Khalil 2002]. However, the transitions in these systems are usually deterministic, and they do not deal with rewards or policies. Sutton, Precup, and Singh [1999] consider high-level actions (which they call *options*) that are taken over a duration of time (such as "opening a door"), but they view time as discrete, which significantly simplifies the model. Rachelson, Garcia, and Fabiani [2008] consider continuous actions over some time interval, however, they assume there are decision epochs, which are the only time points where rewards are considered. In our model, the rewards depend on the entire state sequence that the system traverses through while an action is taken. While this makes the model more complicated, it seems more appropriate for the problems of interest to us.

There has also been a great deal of work on bipedal robot walking, since it is a fundamental motor task for which biological systems significantly outperform current robotic systems [Tedrake et al. 2005]. There have been three main approaches for solving the task:

- The first approach describes the kinematics of the robot in detail using non-linear and linear equation systems, then solves these systems to obtain desirable trajectories. See, for example, [Huang et al. 2001; Gonalves and Zampieri 2006; Kajita et al. 2003; Kim et al. 2007; Strom et al. 2010; Xue et al. 2012].
- The second approach uses genetic algorithms [Cheng and Lin 1997; Hasegawa et al. 2000; Picado et al. 2009]. The traits describing a gait are taken to be the genes in a genetic algorithm. Different gaits (i.e., settings of the parameters) are evaluated in terms of features such as stability and velocity; The most successful gaits are retained, and used to produce the next generation of gaits through selection, mutation, inversion, and crossover of their genes.
- The third approach uses gradient learning, which

starts with either a working gait or a randomly initialized gait. It then improves the gait's performance by changing its parameters, using machine-learning methods (such as neural networks) to find the most profitable set of changes in the parameters. See, for example, [Budden et al. 2013; Kim and Uther 2003; Schulman et al. 2015; Tedrake et al. 2005].

Since the first approach requires a full description of the robot's kinematics, as well as composing and solving a non-linear system, it requires a great deal of human input. Moreover, its application is limited to walking problems. The approach is unable to produce gaits other than those specified by human (e.g., to walk forward by stepping forward the left and the right legs in turn under a specific speed). Both the second and the third approach require little human input (when starting from random gaits), and may produce a variety of gaits. Both also have the potential to be generalized to problems other than bipedal walking. However, both are heuristic search algorithms, and have no theoretical guarantee on their performance. In contrast, our method produces a variety of gaits, provides a general framework for solving robotic problems, and produces a near-optimal policy in the limit. Moreover, our method requires minimum human input, although, as the experiments show, it does better with more human input.

A comparison of our method and the genetic algorithm may provide insights into both methods. Although the two approaches seem different, the searching process made possible by selection, mutation, inversion, and crossover in a genetic algorithm can be viewed as a special case of the *explore* action in an MDPU. Conversely, the *explore* action in an MDPU for the robot can be roughly viewed as searching for a set of genes of unknown length (since a gait can be understood as a continuous action over an uncertain amount of time, composed of one or more shorter actions, where each shorter action is described by a set of parameters). Our approach can be viewed as being more flexible than a genetic algorithm; in a genetic algorithm, the length of the chromosome (i.e., the number of parameters that describe the gait) is fixed; only their values that give the best performance are unknown.

The recent work of Mordatch et al [2016] also provides a general approach for reinforcement learning in robot tasks. Like us, they require prior knowledge only of the mobility range of each of the robot's joints, and not their kinematics; they also model the problem as an MDP. Their goal is to find an optimal trajectory (i.e., a sequence of states), such that when followed, performs a desired task (such as reaching out the robot's hand to a desired position) with minimal cost. They use neural networks to solve the cost-minimization problem. Thus, their approach does not have any guarantees of (approximate) optimality of the performance. Moreover, the complexity of their approach grows quickly as the length of the trajectory grows (while ours is polynomial in the number of useful actions, states visited, and the difficulty of discovering new actions, and thus is not significantly affected by the length of the trajectory). That said, Mordatch et al.'s method has successfully learned a few relatively simple tasks on a physical DARwIn OP2 robot, including hand reaching and leaning the robot's torso to a desired position [Mordatch et al. 2016], although it has not yet been applied to walking.

6 CONCLUSION

We have provided a general approach that allows robots to learn new tasks on their own. We make no assumptions on the structure of the tasks to be learned. We proved that in the limit, the method gives a near-optimal policy. The approach can be easily applied to various robotic tasks. We illustrated this by applying it to the problem of bipedal walking. Using the approach, a humanoid robot, DARwIn OP, was able to learn various walking gaits via simulations (see https://youtu.be/qW51iInpdV0 for a video). We plan to apply our approach to more robotic tasks, such as learning to run and to walk up and down stairs. We believe the process will be quite instructive in terms of adding useful learning heuristics to our approach, both specific to these tasks and to more general robotic tasks. We are also interested in having the robot simulate learning to walk in the same way a baby does, for example, by limiting the robot's abilities initially, so that it must crawl before it walks. Part of our interest lies in seeing if such initial limitations actually make learning more efficient.

Abstract

We apply a wild bootstrap method to the Lancaster three-variable interaction measure in order to detect factorisation of the joint distribution on three variables forming a stationary random process, for which the existing permutation bootstrap method fails. As in the *i.i.d.* case, the Lancaster test is found to outperform existing tests in cases for which two independent variables individually have a weak influence on a third, but that when considered jointly the influence is strong. The main contributions of this paper are twofold: first, we prove that the Lancaster statistic satisfies the conditions required to estimate the quantiles of the null distribution using the wild bootstrap; second, the manner in which this is proved is novel, simpler than existing methods, and can further be applied to other statistics.

1 INTRODUCTION

Nonparametric testing of independence or interaction between random variables is a core staple of machine learning and statistics. The majority of nonparametric statistical tests of independence for continuous-valued random variables rely on the assumption that the observed data are drawn *i.i.d.* Feuerverger [1993], Gretton et al. [2007], Székely et al. [2007], Gretton and Gyorfi [2010], Heller et al. [2013]. The same assumption applies to tests of conditional dependence, and of multivariate interaction between variables Zhang et al. [2011], Kankainen and Ushakov [1998], Fukumizu et al. [2008], Sejdinovic et al. [2013], Patra et al. [2015]. For many applications in finance, medicine, and audio signal analysis, however, the *i.i.d.* assumption is unrealistic and overly restrictive. While many approaches exist for testing interactions between time series under strong parametric assumptions Kirchgässner et al. [2012], Ledford and Tawn [1996], the problem of testing for general, nonlinear interactions has seen far less analysis: tests of pairwise dependence have been proposed by Gaisser et al. [2010], Besserve et al. [2013], Chwialkowski et al. [2014], Chwialkowski and Gretton [2014], where the first publication also addresses mutual independence of more than two univariate time series. The two final works use as their statistic the Hilbert-Schmidt Indepenence Criterion, a general nonparametric measure of dependence [Gretton et al., 2005], which applies even for multivariate or non-Euclidean variables (such as strings and groups). The asymptotic behaviour and corresponding test threshold are derived using particular assumptions on the mixing properties of the processes from which the observations are drawn. These kernel approaches apply only to pairs of random processes, however.

The Lancaster interaction is a signed measure that can be used to construct a test statistic capable of detecting dependence between three random variables [Lancaster, 1969, Sejdinovic et al., 2013]. If the joint distribution on the three variables factorises in some way into a product of a marginal and a pairwise marginal, the Lancaster interaction is zero everywhere. Given observations, this can be used to construct a statistical test, the null hypothesis of which is that the joint distribution factorises thus. In the *i.i.d.* case, the null distribution of the test statistic can be estimated using a permutation bootstrap technique: this amounts to shuffling the indices of one or more of the variables and recalculating the test statistic on this bootstrapped data set. When our samples instead exhibit temporal dependence, shuffling the time indices destroys this dependence and thus doing so does not correspond to a valid resample of the test statistic.

Provided that our data-generating process satisfies some technical conditions on the forms of temporal dependence, recent work by Leucht and Neumann [2013], building on the work of Shao [2010], can come to our rescue. The wild bootstrap is a method that correctly resamples from the null distribution of a test statistic, subject to certain conditions on both the test statistic and the processes from which the observations have been drawn.

In this paper we show that the Lancaster interaction test

statistic satisfies the conditions required to apply the wild bootstrap procedure; moreover, the manner in which we prove this is significantly simpler than existing proofs in the literature of the same property for other kernel test statistics [Chwialkowski et al., 2014, Chwialkowski and Gretton, 2014]. Previous proofs have relied on the classical theory of V-statistics to analyse the asymptotic distribution of the kernel statistic. In particular, the Hoeffding decomposition gives an expression for the kernel test statistic as a sum of other V-statistics. Understanding the asymptotic properties of the components of this decomposition is then conceptually tractable, but algebraically extremely painful. Moreover, as the complexity of the test statistic under analysis grows, the number of terms that must be considered in this approach grows factorially.[1] We conjecture that such analysis of interaction statistics of 4 or more variables would in practice be unfeasible without automatic theorem provers due to the sheer number of terms in the resulting computations.

In contrast, in the approach taken in this paper we explicitly consider our test statistic to be the norm of a Hilbert space operator. We exploit a Central Limit Theorem for Hilbert space valued random variables Dehling et al. [2015] to show that our test statistic converges in probability to the norm of a related population-centred Hilbert space operator, for which the asymptotic analysis is much simpler. Our approach is novel; previous analyses have not, to our knowledge, leveraged the Hilbert space geometry in the context of statistical hypothesis testing using kernel V-statistics in this way.

We propose that our method may in future be applied to the asymptotic analysis of other kernel statistics. In the appendix, we provide an application of this method to the Hilbert Schmidt Independence Criterion (HSIC) test statistic, giving a significantly shorter and simpler proof than that given in Chwialkowski and Gretton [2014]

The Central Limit Theorem that we use in this paper makes certain assumptions on the mixing properties of the random processes from which our data are drawn; as further progress is made, this may be substituted for more up-to-date theorems that make weaker mixing assumptions.

OUTLINE: In Section 2, we detail the Lancaster interaction test and provide our main results. These results justify use of the wild bootstrap to understand the null distribution of the test statistic. In Section 3, we provide more detail about the wild bootstrap, prove that its use correctly controls Type I error and give a consistency result. In Section 4, we evaluate the Lancaster test on synthetic data to identify cases in which it outperforms existing methods, as well as cases in which it is outperformed. In Section 6, we provide proofs of the main results of this paper, in particular the aforementioned novel proof. Further proofs may be found in the Supplementary material.

[1] See for example Lemma 8 in Supplementary material A.3 of Chwialkowski and Gretton [2014]. The proof of this lemma requires keeping track of 4! terms; an equivalent approach for the Lancaster test would have 6! terms. Depending on the precise structure of the statistic, this approach applied to a test involving 4 variables could require as many as $8! = 40320$ terms.

2 LANCASTER INTERACTION TEST

2.1 KERNEL NOTATION

Throughout this paper we will assume that the kernels k, l, m, defined on the domains $\mathcal{X}$, $\mathcal{Y}$ and $\mathcal{Z}$ respectively, are characteristic [Sriperumbudur et al., 2011], bounded and Lipschitz continuous. We describe some notation relevant to the kernel k; similar notation holds for l and m. Recall that $\mu_X := \mathbb{E}_X k(X, \cdot) \in \mathcal{F}_k$ is the mean embedding [Smola et al., 2007] of the random variable X. Given observations X_i, an estimate of the mean embedding is $\tilde{\mu}_X = \frac{1}{n}\sum_{i=1}^n k(X_i, \cdot)$. Two modifications of k are used in this work:

$$\bar{k}(x, x') = \langle k(x, \cdot) - \mu_X, k(x', \cdot) - \mu_X \rangle, \tag{1}$$

$$\tilde{k}(x, x') = \langle k(x, \cdot) - \tilde{\mu}_X, k(x', \cdot) - \tilde{\mu}_X \rangle \tag{2}$$

These are called the *population centered kernel* and *empirically centered kernel* respectively.

2.2 LANCASTER INTERACTION

The Lancaster interaction on the triple of random variables (X, Y, Z) is defined as the signed measure $\Delta_L P = \mathbb{P}_{XYZ} - \mathbb{P}_{XY}\mathbb{P}_Z - \mathbb{P}_{XZ}\mathbb{P}_Y - \mathbb{P}_X\mathbb{P}_{YZ} + 2\mathbb{P}_X\mathbb{P}_Y\mathbb{P}_Z$. This measure can be used to detect three-variable interactions. It is straightforward to show that if any variable is independent of the other two (equivalently, if the joint distribution $\mathbb{P}_{XYZ}$ factorises into a product of marginals in any way), then $\Delta_L P = 0$. That is, writing $\mathcal{H}_X = \{X \perp\!\!\!\perp (Y, Z)\}$ and similar for $\mathcal{H}_Y$ and $\mathcal{H}_Z$, we have that

$$\mathcal{H}_X \ \vee \ \mathcal{H}_Y \ \vee \ \mathcal{H}_Z \Rightarrow \Delta_L P = 0 \tag{3}$$

The reverse implication does not hold, and thus no conclusion about the veracity of the $\mathcal{H}_\cdot$ can be drawn when $\Delta_L P = 0$. Following Sejdinovic et al. [2013], we can consider the mean embedding of this measure:

$$\mu_L = \int k(x, \cdot) l(y, \cdot) m(z, \cdot) \Delta_L P \tag{4}$$

Given an *i.i.d.* sample $(X_i, Y_i, Z_i)_{i=1}^n$, the norm of the mean embedding μ_L can be empirically estimated using empirically centered kernel matrices. For example, for the kernel k with kernel matrix $K_{ij} = k(X_i, X_j)$, the empirically centered kernel matrix $\tilde{K}$ is given by

$$\tilde{K}_{ij} = \langle k(X_i, \cdot) - \tilde{\mu}_X, k(X_j, \cdot) - \tilde{\mu}_X \rangle,$$

By Sejdinovic et al. [2013], an estimator of the norm of the mean embedding of the Lancaster interaction for *i.i.d.* samples is

$$\|\hat{\mu}_L\|^2 = \frac{1}{n^2}\left(\tilde{K} \circ \tilde{L} \circ \tilde{M}\right)_{++} \tag{5}$$

where $\circ$ is the Hadamard (element-wise) product and $A_{++} = \sum_{ij} A_{ij}$, for a matrix A.

2.3 TESTING PROCEDURE

In this paper, we construct a statistical test for three-variable interaction, using $n\|\hat{\mu}_L\|^2$ as the test statistic to distinguish between the following hypotheses:

$\mathcal{H}_0 : \mathcal{H}_X \ \vee \ \mathcal{H}_Y \ \vee \ \mathcal{H}_Z$
$\mathcal{H}_1 : \mathbb{P}_{XYZ}$ does not factorise in any way

The null hypothesis $\mathcal{H}_0$ is a composite of the three 'sub-hypotheses' $\mathcal{H}_X$, $\mathcal{H}_Y$ and $\mathcal{H}_Z$. We test $\mathcal{H}_0$ by testing each of the sub-hypotheses separately and we reject if and only if we reject each of $\mathcal{H}_X$, $\mathcal{H}_Y$ and $\mathcal{H}_Z$. Hereafter we describe the procedure for testing $\mathcal{H}_Z$; similar results hold for $\mathcal{H}_X$ and $\mathcal{H}_Y$.

Sejdinovic et al. [2013] show that, under $\mathcal{H}_Z$, $n\|\hat{\mu}_L\|^2$ converges to an infinite sum of weighted χ-squared random variables. By leveraging the *i.i.d.* assumption of the samples, any given quantile of this distribution can be estimated using simple permutation bootstrap, and so a test procedure is proposed.

In the time series setting this approach does not work. Temporal dependence within the samples makes study of the asymptotic distribution of $n\|\hat{\mu}_L\|^2$ difficult; in Section 4.2 we verify experimentally that the permutation bootstrap used in the *i.i.d* case fails. To construct a test in this setting we will use asymptotic and bootstrap results for mixing processes.

Mixing formalises the notion of the temporal structure within a process, and can be thought of as the rate at which the process forgets about its past. For example, for Gaussian processes this rate can be captured by the autocorrelation function; for general processes, generalisations of autocorrelation are used. The exact assumptions we make about the mixing properties of processes in this paper are discussed in Supplementary material A.7. For brevity in statements of results throughout this paper, however, we define sufficient *suitable mixing assumptions* in Section 3.

2.4 MAIN RESULTS

It is straightforward to show that the norm of the mean embedding (5) can also be written as

$$\|\hat{\mu}_L\|^2 = \frac{1}{n^2}\left(\widetilde{\tilde{K} \circ \tilde{L}} \circ \tilde{M}\right)_{++}$$

Our first contribution is to show that the (difficult) study of the asymptotic null distribution of $\|\hat{\mu}_L\|^2$ can be reduced to studying population centered kernels

$$\|\hat{\mu}^{(Z)}_{L,2}\|^2 = \frac{1}{n^2}\left(\overline{\overline{K} \circ \overline{L}} \circ \overline{M}\right)_{++}$$

where e.g.

$$\overline{K}_{ij} = \langle k(X_i, \cdot) - \mu_X, k(X_j, \cdot) - \mu_X \rangle,$$

Specifically, we prove the following:

Theorem 1. *Suppose that $(X_i, Y_i, Z_i)_{i=1}^n$ are drawn from a random process satisfying suitable mixing assumptions. Under $\mathcal{H}_Z$, $\lim_{n\to\infty}(n\|\hat{\mu}^{(Z)}_{L,2}\|^2 - n\|\hat{\mu}_L\|^2) = 0$ in probability.*

Our proof of Theorem 1 relies crucially on the following Lemma which we prove in Supplementary material A.1

Lemma 1. *Suppose that $(X_i)_{i=1}^n$ is drawn from a random process satisfying suitable mixing assumptions and that k is a bounded kernel on $\mathcal{X}$. Then $\|\hat{\mu}_X - \mu_X\|_k = O_P(n^{-\frac{1}{2}})$*

Proof. (Theorem 1) We provide a short sketch of the proof here; for a full proof, see Section 6.

The key idea is to note that we can rewrite $n\|\hat{\mu}_L\|^2$ in terms of the population centred kernel matrices $\overline{K}$, $\overline{L}$ and $\overline{M}$. Each of the resulting terms can in turn be converted to an inner product between quantities of the form $\hat{\mu} - \mu$, where $\hat{\mu}$ is an empirical estimator of μ, and each μ is a mean embedding or covariance operator.

By applying Lemma 1 to the $\hat{\mu} - \mu$, we show that most of these terms converge in probability to 0, with the residual terms equaling $n\|\hat{\mu}^{(Z)}_{L,2}\|^2$. □

As discussed in Section 1, the essential idea of this proof is novel and the resulting proof is significantly more concise than previous approaches [Chwialkowski and Gretton, 2014, Chwialkowski et al., 2014].

Theorem 1 is useful because the statistic $\|\hat{\mu}^{(Z)}_{L,2}\|^2$ is much easier to study under the non-*i.i.d.* assumption than $\|\hat{\mu}_L\|^2$. Indeed, it can expressed as a V-statistic (see Section 3.2)

$$V_n = \frac{1}{n^2}\sum_{1\le i,j\le n} \overline{\overline{k} \otimes \overline{l}} \otimes \overline{m}(S_i, S_j)$$

where $S_i = (X_i, Y_i, Z_i)$. The crucial observation is that

$$h := \overline{\overline{k} \otimes \overline{l}} \otimes \overline{m}$$

is well behaved in the following sense.

Theorem 2. *Suppose that k, l and m are bounded, symmetric, Lipschitz continuous kernels. Then h is also bounded symmetric and Lipschitz continuous, and is moreover degenerate under $\mathcal{H}_Z$ i.e $\mathbb{E}_S h(S, s) = 0$ for any fixed s.*

Algorithm 1 Test $\mathcal{H}_Z$ with Wild Bootstrap

Input: $\tilde{K}$, $\tilde{L}$, $\tilde{M}$, each size $n \times n$, N= number of bootstraps, α = p-value threshold

$n\|\hat{\mu}_L\|^2 = \frac{1}{n}\left(\widetilde{\left(\tilde{K} \circ \tilde{L}\right)} \circ \tilde{M}\right)_{++}$

samples = zeros(1,N)

for $i = 1$ **to** N **do**

Draw random vector W according to Equation 6

samples[i] = $\frac{1}{n} W^\intercal \left(\widetilde{\left(\tilde{K} \circ \tilde{L}\right)} \circ \tilde{M}\right) W \qquad (*)$

end for

if sum($n\|\hat{\mu}_L\|^2 >$ samples)$> \frac{\alpha}{N}$ **then**

Reject $\mathcal{H}_Z$

else

Do not reject $\mathcal{H}_Z$

end if

Proof. See Section 6 □

The asymptotic analysis of such a V-statistic for non-*i.i.d.* data is still complex, but we can appeal to prior work: Leucht and Neumann [2013] showed a way to estimate any given quantile of such a V-statistic under the null hypothesis using a method called the wild bootstrap (introduced in Section 3). This, combined with analysis of the V-statistic under the alternative hypothesis provided in Theorem 2 of Chwialkowski et al. [2014][2], results in a statistical test given in Algorithm 1. The wild bootstrap is used in line $(*)$ to generate samples of the null distribution.

In Section 3 we discuss the wild bootstrap and provide results regarding consistency and Type I error control.

2.5 MULTIPLE TESTING CORRECTION

In the Lancaster test, we reject the composite null hypothesis $\mathcal{H}_0$ if and only if we reject all three of the components. In Sejdinovic et al. [2013], it is suggested that the Holm-Bonferroni correction be used to account for multiple testing [Holm, 1979]. We show here that more relaxed conditions on the p-values can be used while still bounding the Type I error, thus increasing test power.

Denote by $\mathcal{A}_*$ the event that $\mathcal{H}_*$ is rejected. Then

$$\begin{aligned}\mathbb{P}(\mathcal{A}_0) &= \mathbb{P}(\mathcal{A}_X \wedge \mathcal{A}_Y \wedge \mathcal{A}_Z) \\ &\leq \min\{\mathbb{P}(\mathcal{A}_X), \mathbb{P}(\mathcal{A}_Y), \mathbb{P}(\mathcal{A}_Z)\}\end{aligned}$$

If $\mathcal{H}_0$ is true, then so must one of the components. Without loss of generality assume that $\mathcal{H}_X$ is true. If we use significance levels of α in each test individually then $\mathbb{P}(\mathcal{A}_X) \leq \alpha$ and thus $\mathbb{P}(\mathcal{A}_0) \leq \alpha$.

[2]Note that similar results are presented in Leucht and Neumann [2013] as specific cases.

Therefore rejecting $\mathcal{H}_0$ in the event that each test has p-value less than α individually guarantees a Type I error overall of at most α. In contrast, the Holm-Bonferonni method requires that the sorted p-values be lower than $[\frac{\alpha}{3}, \frac{\alpha}{2}, \alpha]$ in order to reject the null hypothesis overall. It is therefore more conservative than necessary and thus has worse test power compared to the 'simple correction' proposed here. This is experimentally verified in Section 4.

3 THE WILD BOOTSTRAP

In this section we discuss the wild bootstrap and provide consistency and Type I error results for the proposed Lancaster test.

3.1 TEMPORAL DEPENDENCE

There are various formalisations of memory or 'mixing' of a random process [Doukhan, 1994, Bradley et al., 2005, Dedecker et al., 2007]; of relevance to this paper is the following :

Definition 1. *A process $(X_t)_t$ is* β-mixing *(also known as* absolutely regular*) if $\beta(m) \longrightarrow 0$ as $m \longrightarrow \infty$, where*

$$\beta(m) = \frac{1}{2} \sup_n \sup \sum_{i=1}^{I} \sum_{j=1}^{J} |\mathbb{P}(A_i \cap B_j) - \mathbb{P}(A_i)\mathbb{P}(B_j)|$$

where the second supremum is taken over all finite partitions $\{A_1, \ldots, A_I\}$ and $\{B_1, \ldots, B_J\}$ of the sample space such that $A_i \in \mathcal{F}_1^n$ and $B_j \in \mathcal{F}_{n+m}^\infty$ and $\mathcal{F}_b^c = \sigma(X_b, X_{b+1}, \ldots, X_c)$

SUITABLE MIXING ASSUMPTIONS

We assume that the random process $S_i = (X_i, Y_i, Z_i)$ is β mixing with mixing coefficients satisfying $\beta(m) = o(m^{-6})$. Throughout this paper we refer to this assumption as *suitable mixing assumptions*. For a more in depth discussion of the mixing assumptions made in this paper, see Supplementary materials A.7.

3.2 V-STATISTICS

A V-statistic of a 2-argument, symmetric function h given observations $\mathcal{S}_n = \{S_1, \ldots, S_n\}$ is [Serfling, 2009]:

$$V_n = \frac{1}{n^2} \sum_{1 \leq i,j \leq n} h(S_i, S_j)$$

We call nV_n a *normalised* V-statistic. We call h the *core* of V and we say that h is *degenerate* if, for any s_1, $\mathbb{E}_{S_2 \sim \mathbb{P}}[h(s_1, S_2)] = 0$, in which case we say that V is a *degenerate V-statistic*. Many kernel test statistics can be

viewed as normalised V-statistics which, under the null hypothesis, are degenerate. As mentioned in the previous section, $\|\hat{\mu}_{L,2}^{(Z)}\|^2$ is a V-statistic. Theorems 1 and 2 together imply that, under $\mathcal{H}_Z$, it can be treated as a degenerate V-statistic.

3.3 WILD BOOTSTRAP

If the test statistic has the form of a normalised V-statistic, then provided certain extra conditions are met, the wild bootstrap of Leucht and Neumann [2013] is a method to directly resample the test statistic under the null hypothesis. These conditions can be categorised as concerning: (1) appropriate mixing of the process from which our observations are drawn; (2) the core of the V-statistic.

The condition on the core that is of crucial importance to this paper is that it must be degenerate. Theorem 2 justifies our use of the wild bootstrap in the Lancaster interaction test.

Given the statistic nV_n, Leucht and Neumann [2013] tells us that a random vector W of length n can be drawn such that the bootstrapped statistic[3]

$$nV_b = \frac{1}{n}\sum_{i,j} W_i h(S_i, S_j) W_j$$

is distributed according to the null distribution of nV_n.

By generating many such W and calculating nV_b for each, we can estimate the quantiles of nV.

3.4 GENERATING W

The process generating W must satisfy conditions (B2) given on page 6 of Leucht and Neumann [2013] for nV_b to correctly resample from the null distribution of nV_n. For brevity, we provide here only an example of such a process; the interested reader should consult Leucht and Neumann [2013] or Appedix A of Chwialkowski et al. [2014] for a more detailed discussion of the bootstrapping process. The following bootstrapping process was used in the experiments in Section 4:

$$W_t = e^{-1/l_n} W_{t-1} + \sqrt{1 - e^{-2/l_n}}\epsilon_t \tag{6}$$

where $W_1, \epsilon_1, \ldots, \epsilon_t$ are independent $\mathcal{N}(0,1)$ random variables. l_n should be taken from a sequence $\{l_n\}$ such that $\lim_{n\longrightarrow\infty} l_n = \infty$; in practice we used $l_n = 20$ for all of the experiments since the values of n were roughly comparable in each case.

3.5 CONTROL OF TYPE I ERROR

The following theorem shows that by estimating the quantiles of the wild bootstrapped statistic nV_b we correctly control the Type I error when testing $\mathcal{H}_Z$.

Theorem 3. *Suppose that $(X_i, Y_i, Z_i)_{i=1}^n$ are drawn from a random process satisfying suitable mixing conditions, and that W is drawn from a process satisfying (B2) in Leucht and Neumann [2013]. Then asymptotically, the quantiles of*

$$nV_b = \frac{1}{n} W^\intercal \left(\overline{(\bar{K} \circ \bar{L})} \circ \bar{M}\right) W$$

converge to those of $n\|\hat{\mu}_L\|^2$.

Proof. See Supplementary material A.3 □

3.6 (SEMI-)CONSISTENCY OF TESTING PROCEDURE

Note that in order to achieve consistency for this test, we would need that $\mathcal{H}_0 \iff \Delta_L P = 0$. Unfortunately this does not hold - in Sejdinovic et al. [2013] examples are given of distributions for which $\mathcal{H}_0$ is false, and yet $\Delta_L P = 0$.

However, the following result does hold:

Theorem 4. *Suppose that $\Delta_L P \neq 0$. Then as $n \longrightarrow \infty$, the probability of correctly rejecting $\mathcal{H}_0$ converges to 1.*

Proof. See Supplementary material A.4 □

At the time of writing, a characterisation of distributions for which $\mathcal{H}_0$ is false yet $\Delta_L P = 0$ is unknown. Therefore, if we reject $\mathcal{H}_0$ then we conclude that the distribution does not factorise; if we fail to reject $\mathcal{H}_0$ then we cannot conclude that the distribution factorises.

4 EXPERIMENTS

The Lancaster test described above amounts to a method to test each of the sub-hypotheses $\mathcal{H}_X, \mathcal{H}_Y, \mathcal{H}_Z$. Rather than using the Lancaster test statistic with wild bootstrap to test each of these, we could instead use HSIC. For example, by considering the pair of variables (X, Y) and Z with kernels $k \otimes l$ and m respectively, HSIC can be used to test $\mathcal{H}_Z$. Similar grouping of the variables can be used to test $\mathcal{H}_X$ and $\mathcal{H}_Y$. Applying the same multiple testing correction as in the Lancaster test, we derive an alternative test of dependence between three variables. We refer to this HSIC based procedure as *3-way HSIC*.

In the case of *i.i.d.* observations, it was shown in Sejdinovic et al. [2013] that Lancaster statistical test is more sensitive to dependence between three random variables than the above HSIC-based test when pairwise interaction is weak but joint interaction is strong. In this section, we demonstrate that the same is true in the time series case on synthetic data.

[3] Note that for fixed $\mathcal{S}_n$, nV_b is a random variable through the randomness introduced by W

4.1 WEAK PAIRWISE INTERACTION, STRONG JOINT INTERACTION

This experiment demonstrates that the Lancaster test has greater power than 3-way HSIC when the pairwise interaction is weak, but joint interaction is strong.

Synthetic data were generated from autoregressive processes X, Y and Z according to:

$$X_t = \frac{1}{2}X_{t-1} + \epsilon_t$$
$$Y_t = \frac{1}{2}Y_{t-1} + \eta_t$$
$$Z_t = \frac{1}{2}Z_{t-1} + d|\theta_t|\text{sign}(X_t Y_t) + \zeta_t$$

where $X_0, Y_0, Z_0, \epsilon_t, \eta_t, \theta_t$ and ζ_t are *i.i.d.* $\mathcal{N}(0,1)$ random variables and $d \in \mathbb{R}$, called the *dependence* coefficient, determines the extent to which the process $(Z_t)_t$ is dependent on $(X_t, Y_t)_t$.

Data were generated with varying values of d. For each value of d, 300 datasets were generated, each consisting of 1200 consecutive observations of the variables. Gaussian kernels with bandwidth parameter 1 were used on each variable, and 250 bootstrapping procedures were used for each test on each dataset.

Observe that the random variables are pairwise independent but jointly dependent. Both the Lancaster and 3-way HSIC tests should be able to detect the dependence and therefore reject the null hypothesis in the limit of infinite data. In the finite data regime, the value of d affects drastically how hard it is to detect the dependence. The results of this experiment are presented in Figure 1, which shows that the Lancaster test achieves very high test power with weak dependence coefficients compared to 3-way HSIC. Note also that when using the simple multiple testing correction a higher test power is achieved than with the Holm-Bonferroni correction.

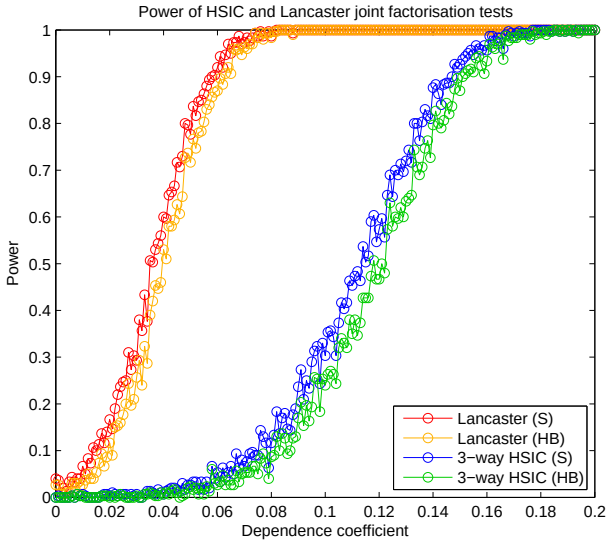

Figure 1: Results of experiment in Section 4.1. (S) refers to the simple multiple correction; (HB) refers to Holm-Bonferroni. The Lancaster test is more sensitive to dependence than 3-way HSIC, and test power for both tests is higher when using the simple correction rather than the Holm-Bonferroni multiple testing correction.

4.2 FALSE POSITIVE RATES

This experiment demonstrates that in the time series case, existing permutation bootstrap methods fail to control the Type I error, while the wild bootstrap correctly identifies test statistic thresholds and appropriately controls Type I error.

Synthetic data were generated from autoregressive processes X, Y and Z according to:

$$X_t = aX_{t-1} + \epsilon_t$$
$$Y_t = aY_{t-1} + \eta_t$$
$$Z_t = aZ_{t-1} + \zeta_t$$

where $X_0, Y_0, Z_0, \epsilon_t, \eta_t$ and ζ_t are *i.i.d.* $\mathcal{N}(0,1)$ random variables and a, called the *dependence coefficient*, determines how temporally dependent the processes are. The null hypothesis in this example is true as each process is independent of the others.

The Lancaster test was performed using both the Wild Bootstrap and the simple permutation bootstrap (used in the *i.i.d.* case) in order to sample from the null distributions of the test statistic. We used a fixed desired false positive rate $\alpha = 0.05$ with sample of size 1000, with 200 experiments run for each value of a. Figure 2 shows the false positive rates for these two methods for varying a. It shows that as the processes become more dependent, the false positive rate for the permutation method becomes very large, and is not bounded by the fixed α, whereas the false positive rate for the Wild Bootstrap method is bounded by α.

4.3 STRONG PAIRWISE INTERACTION

This experiment demonstrates a limitation of the Lancaster test. When pairwise interaction is strong, 3-way HSIC has greater test power than Lancaster.

Synthetic data were generated from autoregressive pro-

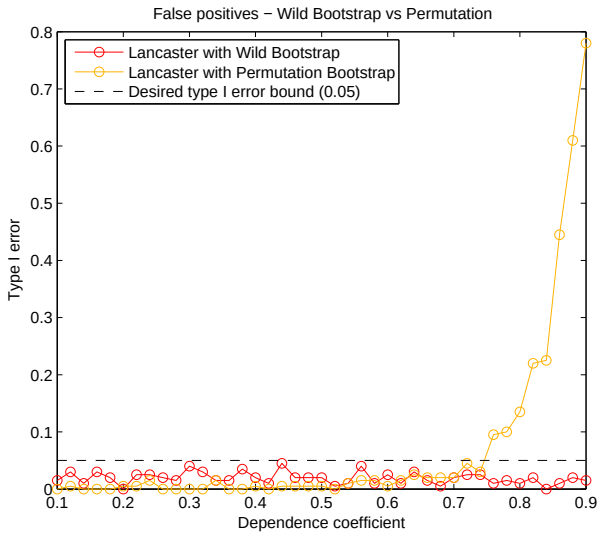

Figure 2: Results of experiment in section 4.2. Whereas the wild bootstrap succeeds in controlling the Type I error across all values of the dependence coefficient, the permutation bootstrap fails to control the Type I error as it does not sample from the correct null distribution as temporal dependence between samples increases.

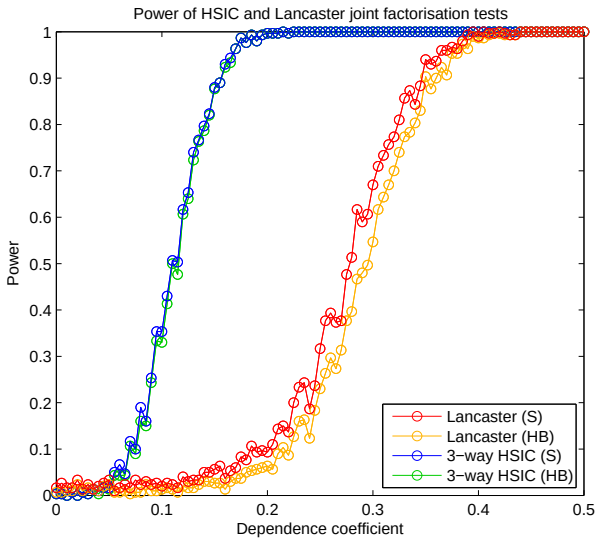

Figure 3: Results of experiment in Section 4.3. (S) refers to the simple multiple correction; (HB) refers to Holm-Bonferroni. The Lancaster test is less sensitive to dependence than 3-way HSIC, and test power in both cases is higher when using the simple correction rather than the Holm-Bonferroni multiple testing correction.

cesses X, Y and Z according to:

$$X_t = \frac{1}{2}X_{t-1} + \epsilon_t$$
$$Y_t = \frac{1}{2}Y_{t-1} + \eta_t$$
$$Z_t = \frac{1}{2}Z_{t-1} + d(X_t + Y_t) + \zeta_t$$

where $X_0, Y_0, Z_0, \epsilon_t, \eta_t$ and ζ_t are *i.i.d.* $\mathcal{N}(0,1)$ random variables and $d \in \mathbb{R}$, called the *dependence* coefficient, determines the extent to which the process $(Z_t)_t$ is dependent on X_t and Y_t.

Data were generated with varying values for the dependence coefficient. For each value of d, 300 datasets were generated, each consisting of 1200 consecutive observations of the variables. Gaussian kernels with bandwidth parameter 1 were used on each variable, and 250 bootstrapping procedures were used for each test on each dataset.

In this case Z_t is pairwise-dependent on both of X_t and Y_t, in addition to all three variables being jointly dependent. Both the Lancaster and 3-way HSIC tests should be capable of detecting the dependence and therefore reject the null hypothesis in the limit of infinite data. The results of this experiment are presented in Figure 3, which demonstrates that in this case the 3-way HSIC test is more sensitive to the dependence than the Lancaster test.

4.4 FOREX DATA

Exchange rates between three currencies (GBP, USD, EUR) at 5 minute intervals over 7 consecutive trading days were obtained. The data were processed by taking the returns (difference between consecutive terms within each time series, $x_t^r = x_t - x_{t-1}$) which were then normalised (divided by standard deviation). We performed the Lancaster test, 3-way HSIC and pairwise HSIC on using the first 800 entries of each processed series. All tests rejected the null hypothesis. The Lancaster and 3-way HSIC tests both returned p-values of 0 for each of $\mathcal{H}_X$, $\mathcal{H}_Y$ and $\mathcal{H}_Z$ with 10000 bootstrapping procedures.

We then shifted one of the time series and repeated the tests (i.e. we used entries 1 to 800 of two of the processed series and entries 801 to 1600 of the third). In this case, pairwise HSIC still detected dependence between the two unshifted time series, and both Lancaster and 3-way HSIC did not reject the null hypothesis that the joint distribution factorises. The Lancaster test returned p-values of 0.2708, 0.2725 and 0.1975 for $\mathcal{H}_X$, $\mathcal{H}_Y$ and $\mathcal{H}_Z$ respectively. 3-way HSIC resturn p-values of 0.3133, 0.0000 and 0.0000 respectively.

In both cases, the Lancaster test behaves as expected. Due to arbitrage, any two exchange rates should determine the third and the Lancaster test correctly identifies a joint dependence in the returns. However, when we shift one of the time series, we break the dependence between it and the other series. Lancaster correctly identifies here that the

underlying distribution does factorise.

5 DISCUSSION AND FUTURE RESEARCH

We demonstrated that the Lancaster test is more sensitive than 3-way HSIC when pairwise interaction is weak, but that the opposite is true when pairwise interaction is strong. It is curious that the two tests have different strengths in this manner, particularly when considering the very similar forms of the statistics in each case. Indeed, to test $\mathcal{H}_Z$ using the Lancaster statistic, we bootstrap the following:

$$n\|\Delta_L \hat{P}\|^2 = \frac{1}{n}\left(\widetilde{\left(\tilde{K}\circ\tilde{L}\right)}\circ\tilde{M}\right)_{++}$$

while for the 3-way HSIC test we bootstrap:

$$nHSIC_b = \frac{1}{n}\left(\widetilde{(K\circ L)}\circ\tilde{M}\right)_{++}$$

These two quantities differ only in the centring of K and L, amounting to constant shifts in the respective feature spaces of the kernels k and l. This difference has the consequence of quite drastically changing the types of dependency to which each statistic is sensitive. A formal characterisation of the cases in which the Lancaster statistic is more sensitive than 3-way HSIC would be desirable.

6 PROOFS

An outline of the proof of Theorem 1 was given in Section 2; here we provide the full proof, as well as a proof of Theorem 2.

Proof. (Theorem 1)

By observing that

$$\begin{aligned}
&\phi_X(X_i) - \frac{1}{n}\sum_k \phi_X(X_k)\\
=\ &(\phi_X(X_i)-\mu_X) - \frac{1}{n}\sum_k(\phi_X(X_k)-\mu_X)\\
=\ &\bar{\phi}_X(X_i) - \frac{1}{n}\sum_k \bar{\phi}_X(X_k)
\end{aligned}$$

we can therefore expand $\tilde{K}$ in terms of $\bar{K}$ as

$$\begin{aligned}
&\tilde{K}_{ij}\\
&= \langle \phi_X(X_i) - \frac{1}{n}\sum_k \phi_X(X_k), \phi_X(X_j) - \frac{1}{n}\sum_k \phi_X(X_k)\rangle\\
&= \langle \bar{\phi}_X(X_i) - \frac{1}{n}\sum_k \bar{\phi}_X(X_k), \bar{\phi}_X(X_j) - \frac{1}{n}\sum_k \bar{\phi}_X(X_k)\rangle\\
&= \bar{K}_{ij} - \frac{1}{n}\sum_k \bar{K}_{ik} - \frac{1}{n}\sum_k \bar{K}_{jk} + \frac{1}{n^2}\sum_{kl}\bar{K}_{kl}
\end{aligned}$$

and expanding $\tilde{L}$ and $\tilde{M}$ in a similar way, we can rewrite the Lancaster test statistic as

$$\begin{aligned}
n\|\hat{\mu}_L\|^2 = &\frac{1}{n}(\bar{K}\circ\bar{L}\circ\bar{M})_{++} && -\frac{2}{n^2}((\bar{K}\circ\bar{L})\bar{M})_{++}\\
&-\frac{2}{n^2}((\bar{K}\circ\bar{M})\bar{L})_{++} && -\frac{2}{n^2}((\bar{M}\circ\bar{L})\bar{K})_{++}\\
&+\frac{1}{n^3}(\bar{K}\circ\bar{L})_{++}\bar{M}_{++} && +\frac{1}{n^3}(\bar{K}\circ\bar{M})_{++}\bar{L}_{++}\\
&+\frac{1}{n^3}(\bar{L}\circ\bar{M})_{++}\bar{K}_{++} && +\frac{2}{n^3}(\bar{M}\bar{K}\bar{L})_{++}\\
&+\frac{2}{n^3}(\bar{K}\bar{L}\bar{M})_{++} && +\frac{2}{n^3}(\bar{K}\bar{M}\bar{L})_{++}\\
&+\frac{4}{n^3}tr(\bar{K}_+\circ\bar{L}_+\circ\bar{M}_+) && -\frac{4}{n^4}(\bar{K}\bar{L})_{++}\bar{M}_{++}\\
&-\frac{4}{n^4}(\bar{K}\bar{M})_{++}\bar{L}_{++} && -\frac{4}{n^4}(\bar{L}\bar{M})_{++}\bar{K}_{++}\\
&+\frac{4}{n^5}\bar{K}_{++}\bar{L}_{++}\bar{M}_{++}
\end{aligned}$$

We denote by $C_{XYZ} = \mathbb{E}_{XYZ}[\bar{\phi}_X(X)\otimes\bar{\phi}_Y(Y)\otimes\bar{\phi}_Z(Z)]$ the population centred covariance operator with empirical estimate $\bar{C}_{XYZ} = \frac{1}{n}\sum_i \bar{\phi}_X(X_i)\otimes\bar{\phi}_Y(Y_i)\otimes\bar{\phi}_Z(Z_i)$. We define similarly the quantities $C_{XY}, C_{YZX}, \ldots$ with corresponding empirical counterparts $\bar{C}_{XY}, \bar{C}_{YZX}, \ldots$ where for example $C_{YZ} = \mathbb{E}_{YZ}[\bar{\phi}_Y(Y)\otimes\bar{\phi}_Z(Z)]$

Each of the terms in the above expression for $n\|\hat{\mu}_L\|^2$ can be expressed as inner products between empirical estimates of population centred covariance operators and tensor products of mean embeddings. Rewriting them as such yields:

$$\begin{aligned}
n\|\hat{\mu}_L\|^2 = &\ n\langle\bar{C}_{XYZ},\bar{C}_{XYZ}\rangle\\
&-2n\langle\bar{C}_{XYZ},\bar{C}_{XY}\otimes\bar{\mu}_Z\rangle\\
&-2n\langle\bar{C}_{XZY},\bar{C}_{XZ}\otimes\bar{\mu}_Y\rangle\\
&-2n\langle\bar{C}_{YZX},\bar{C}_{YZ}\otimes\bar{\mu}_X\rangle\\
&+n\langle\bar{C}_{XY}\otimes\bar{\mu}_Z,\bar{C}_{XY}\otimes\bar{\mu}_Z\rangle\\
&+n\langle\bar{C}_{XZ}\otimes\bar{\mu}_Y,\bar{C}_{XZ}\otimes\bar{\mu}_Y\rangle\\
&+n\langle\bar{C}_{YZ}\otimes\bar{\mu}_X,\bar{C}_{YZ}\otimes\bar{\mu}_X\rangle\\
&+2n\langle\bar{\mu}_Z\otimes\bar{C}_{XY},\bar{C}_{ZX}\otimes\bar{\mu}_Y\rangle\\
&\vdots
\end{aligned}$$

$$
\begin{aligned}
&+ 2n\langle \bar{\mu}_X \otimes \bar{C}_{YZ}, \bar{C}_{XY} \otimes \bar{\mu}_Z \rangle \\
&+ 2n\langle \bar{\mu}_X \otimes \bar{C}_{ZY}, \bar{C}_{XZ} \otimes \bar{\mu}_Y \rangle \\
&+ 4n\langle \bar{C}_{XYZ}, \bar{\mu}_X \otimes \bar{\mu}_Y \otimes \bar{\mu}_Z \rangle \\
&- 4n\langle \bar{C}_{XY} \otimes \bar{\mu}_Z, \bar{\mu}_X \otimes \bar{\mu}_Y \otimes \bar{\mu}_Z \rangle \\
&- 4n\langle \bar{C}_{XZ} \otimes \bar{\mu}_Y, \bar{\mu}_X \otimes \bar{\mu}_Z \otimes \bar{\mu}_Y \rangle \\
&- 4n\langle \bar{C}_{YZ} \otimes \bar{\mu}_X, \bar{\mu}_Y \otimes \bar{\mu}_Z \otimes \bar{\mu}_X \rangle \\
&+ 4n\langle \bar{\mu}_X \otimes \bar{\mu}_Y \otimes \bar{\mu}_Z, \bar{\mu}_X \otimes \bar{\mu}_Y \otimes \bar{\mu}_Z \rangle
\end{aligned}
$$

By assumption, $\mathbb{P}_{XYZ} = \mathbb{P}_{XY}\mathbb{P}_Z$ and thus the expectation operator also factorises similarly. As a consequence, $C_{XYZ} = 0$. Indeed, given any $A \in \mathcal{F}_X \otimes \mathcal{F}_\mathcal{Y} \otimes \mathcal{F}_\mathcal{Z}$, we can consider A to be a bounded linear operator $\mathcal{F}_\mathcal{Z} \longrightarrow \mathcal{F}_X \otimes \mathcal{F}_\mathcal{Y}$. It follows that[4]

$$
\begin{aligned}
&\mathbb{E}_{XYZ}\langle A, \bar{C}_{XYZ} \rangle \\
&= \frac{1}{n}\sum_i \mathbb{E}_{XY}\mathbb{E}_Z \langle A, \bar{\phi}_X(X_i) \otimes \bar{\phi}_Y(Y_i) \otimes \bar{\phi}_Z(Z_i) \rangle \\
&= \frac{1}{n}\sum_i \mathbb{E}_{XY}\mathbb{E}_Z \langle \bar{\phi}_X(X_i) \otimes \bar{\phi}_Y(Y_i), A\bar{\phi}_Z(Z_i) \rangle_{\mathcal{F}_X \otimes \mathcal{F}_Y} \\
&= \frac{1}{n}\sum_i \mathbb{E}_{XY} \langle \bar{\phi}_X(X_i) \otimes \bar{\phi}_Y(Y_i), A\mathbb{E}_Z\bar{\phi}_Z(Z_i) \rangle_{\mathcal{F}_X \otimes \mathcal{F}_Y} \\
&= 0
\end{aligned}
$$

We conclude that $C_{XYZ} = \mathbb{E}_{XYZ}\bar{C}_{XYZ} = 0$.

Similarly, C_{XZY}, C_{YZX}, C_{XZ}, C_{YZ} are all 0 in their respective Hilbert spaces. Lemma 2 tells us that each subprocess of (X_i, Y_i, Z_i) satisfies the same β-mixing conditions as (X_i, Y_i, Z_i), thus by applying Lemma 1 it follows that $\|\bar{C}_{XZY}\|$, $\|\bar{C}_{YZX}\|$, $\|\bar{C}_{XZ}\|$, $\|\bar{C}_{YZ}\|$, $\|\bar{\mu}_X\|$, $\|\bar{\mu}_Y\|$, $\|\bar{\mu}_Z\| = O_P\left(n^{-\frac{1}{2}}\right)$. Therefore

$$
\begin{aligned}
n\|\hat{\mu}_L\|^2 &\xrightarrow{O_P(n^{-\frac{1}{2}})} n\langle \bar{C}_{XYZ}, \bar{C}_{XYZ} \rangle \\
&\quad - 2n\langle \bar{C}_{XYZ}, \bar{C}_{XY} \otimes \bar{\mu}_Z \rangle - 2n\langle \bar{C}_{XZY}, \bar{C}_{XZ} \otimes \bar{\mu}_Y \rangle \\
&= \frac{1}{n}((\bar{K} \circ \bar{L}) \circ \bar{M})_{++} \\
&\quad - \frac{2}{n^2}((\bar{K} \circ \bar{L})\bar{M})_{++} + \frac{1}{n^3}(\bar{K} \circ \bar{L})_{++}\bar{M}_{++}
\end{aligned}
$$

since all the other terms decay at least as quickly as $O_P(\frac{1}{\sqrt{n}})$. This is shown here for $n\langle \bar{\mu}_X \otimes \bar{C}_{YZ}, \bar{C}_{XY} \otimes \bar{\mu}_Z \rangle$; the proofs for the other terms are similar.

$$
\begin{aligned}
&n\langle \bar{\mu}_X \otimes \bar{C}_{YZ}, \bar{C}_{XY} \otimes \bar{\mu}_Z \rangle \\
&\leq n\|\bar{\mu}_X \otimes \bar{C}_{YZ}\|\|\bar{C}_{XY} \otimes \bar{\mu}_Z\| \\
&= n\sqrt{\langle \bar{\mu}_X \otimes \bar{C}_{YZ}, \bar{\mu}_X \otimes \bar{C}_{YZ} \rangle}\sqrt{\langle \bar{C}_{XY} \otimes \bar{\mu}_Z, \bar{C}_{XY} \otimes \bar{\mu}_Z \rangle} \\
&= n\sqrt{\langle \bar{\mu}_X, \bar{\mu}_X \rangle \langle \bar{C}_{YZ}, \bar{C}_{YZ} \rangle}\sqrt{\langle \bar{C}_{XY}, \bar{C}_{XY} \rangle \langle \bar{\mu}_Z, \bar{\mu}_Z \rangle} \\
&= n\|\bar{\mu}_X\|\|\bar{C}_{YZ}\|\|\bar{C}_{XY}\|\|\bar{\mu}_Z\| \\
&= nO_P\left(\tfrac{1}{\sqrt{n}}\right)O_P\left(\tfrac{1}{\sqrt{n}}\right)O_P(1)O_P\left(\tfrac{1}{\sqrt{n}}\right) = O_P\left(\tfrac{1}{\sqrt{n}}\right)
\end{aligned}
$$

It can be shown that $\bar{K} \circ \bar{L}$ in the above expression can be replaced with $\overline{\bar{K} \circ \bar{L}}$ while preserving equality. That is, we can equivalently write

$$
\begin{aligned}
n\|\Delta_L \hat{P}\|^2 \longrightarrow &\frac{1}{n}((\overline{\bar{K} \circ \bar{L}}) \circ \bar{M})_{++} \\
&- \frac{2}{n^2}((\overline{\bar{K} \circ \bar{L}})\bar{M})_{++} + \frac{1}{n^3}(\overline{\bar{K} \circ \bar{L}})_{++}\bar{M}_{++}
\end{aligned}
$$

This is equivalent to treating $\bar{k} \otimes \bar{l}$ as a kernel on the single variable $T := (X, Y)$ and performing another recentering trick as we did at the beginning of this proof. By rewriting the above expression in terms of the operator $\bar{C}_{TZ}$ and mean embeddings μ_T and μ_Z, it can be shown by a similar argument to before that the latter two terms tend to 0 at least as $O_P(n^{-\frac{1}{2}})$, and thus, substituting for the definition of $\|\hat{\mu}_{L,2}^{(Z)}\|^2$,

$$
n\|\hat{\mu}_L\|^2 \xrightarrow{O_P(\frac{1}{\sqrt{n}})} n\|\hat{\mu}_{L,2}^{(Z)}\|^2
$$

as required. □

Proof. (Theorem 2)

Note that $\mathbb{E}_{XYZ} = \mathbb{E}_{XY}\mathbb{E}_Z$ under $\mathcal{H}_Z$. Therefore, fixing any $s_j = (x_j, y_j, z_j)$ we have that

$$
\begin{aligned}
\mathbb{E}_{S_i}h(S_i, s_j) &= \mathbb{E}_{X_iY_i}\mathbb{E}_{Z_i}\overline{\bar{k} \otimes \bar{l}} \otimes \bar{m}(S_i, s_j) \\
&= \langle \mathbb{E}_{X_iY_i}\bar{\phi}(X_i) \otimes \bar{\phi}(Y_i) - C_{XY}, \bar{\phi}(x_j) \otimes \bar{\phi}(y_j) - C_{XY} \rangle \\
&\qquad \times \langle \mathbb{E}_{Z_i}\bar{\phi}(Z_i), \bar{\phi}(z_j) \rangle \\
&= \langle 0, \bar{\phi}(x_j) \otimes \bar{\phi}(y_j) - C_{XY} \rangle \\
&\qquad \times \langle 0, \bar{\phi}(z_j) \rangle = 0
\end{aligned}
$$

Therefore h is degenerate. Symmetry follows from the symmetry of the Hilbert space inner product.

For boundedness and Lipschitz continuity, it suffices to show the two following rules for constructing new kernels from old preserve both properties (see Supplementary materials A.5 for proof):

- $k \mapsto \bar{k}$
- $(k, l) \mapsto k \otimes l$

It then follows that $h = \overline{\bar{k} \otimes \bar{l}} \otimes \bar{m}$ is bounded and Lipschitz continuous since it can be constructed from k, l and m using the two above rules. □

ORCID 0000-0003-3169-7624

[4] We can bring the $\mathbb{E}_Z$ inside the inner product in the penultimate line due to the Bochner integrability of $\bar{\phi}_Z(Z)$, which follows from the conditions required for μ_Z to exist [Steinwart and Christmann, 2008].

Abstract

We introduce overdispersed black-box variational inference, a method to reduce the variance of the Monte Carlo estimator of the gradient in black-box variational inference. Instead of taking samples from the variational distribution, we use importance sampling to take samples from an overdispersed distribution in the same exponential family as the variational approximation. Our approach is general since it can be readily applied to any exponential family distribution, which is the typical choice for the variational approximation. We run experiments on two non-conjugate probabilistic models to show that our method effectively reduces the variance, and the overhead introduced by the computation of the proposal parameters and the importance weights is negligible. We find that our overdispersed importance sampling scheme provides lower variance than black-box variational inference, even when the latter uses twice the number of samples. This results in faster convergence of the black-box inference procedure.

1 INTRODUCTION

Generative probabilistic modeling is an effective approach for understanding real-world data in many areas of science (Bishop, 2006; Murphy, 2012). A probabilistic model describes a data-generating process through a joint distribution of observed data and latent (unobserved) variables. With a model in place, the investigator uses an inference algorithm to calculate or approximate the posterior, i.e., the conditional distribution of the latent variables given the available observations. It is through the posterior that the investigator explores the latent structure in the data and forms a predictive distribution of future data. Approximating the posterior is the central algorithmic problem for probabilistic modeling.

One of the most widely used methods to approximate the posterior distribution is variational inference (Wainwright and Jordan, 2008; Jordan et al., 1999). Variational inference aims to approximate the posterior with a simpler distribution, fitting that distribution to be close to the exact posterior, where closeness is measured in terms of Kullback-Leibler (KL) divergence. In minimizing the KL, variational inference converts the problem of approximating the posterior into an optimization problem.

Traditional variational inference uses coordinate ascent to optimize its objective. This works well for models in which each conditional distribution is easy to compute (Ghahramani and Beal, 2001), but is difficult to use in more complex models where the variational objective involves intractable expectations. Recent innovations in variational inference have addressed this with stochastic optimization, forming noisy gradients with Monte Carlo approximation. This strategy expands the scope of variational inference beyond traditional models, e.g., to non-conjugate probabilistic models (Carbonetto et al., 2009; Paisley et al., 2012; Salimans and Knowles, 2013; Ranganath et al., 2014; Titsias and Lázaro-Gredilla, 2014), deep neural networks (Neal, 1992; Hinton et al., 1995; Mnih and Gregor, 2014; Kingma and Welling, 2014; Ranganath et al., 2015), and probabilistic programming (Wingate and Weber, 2013; Kucukelbir et al., 2015). Some of these techniques find their roots in classical policy search algorithms for reinforcement learning (Williams, 1992; van de Meent et al., 2016).

These approaches must address a core problem with Monte Carlo estimates of the gradient, which is that they suffer from high variance. The estimated gradient can significantly differ from the truth and this leads to slow convergence of the optimization. There are several strategies to reduce the variance of the gradients, including Rao-Blackwellization (Casella and Robert, 1996; Ranganath et al., 2014), control variates (Ross, 2002; Paisley et al., 2012; Ranganath et al., 2014; Gu et al., 2016), reparameterization (Price, 1958; Bonnet, 1964; Salimans and Knowles, 2013; Kingma and Welling, 2014; Rezende et al., 2014; Kucukelbir et al., 2015), and local expectations (Titsias and

Lázaro-Gredilla, 2015).

In this paper we develop overdispersed black-box variational inference (O-BBVI), a new method for reducing the variance of Monte Carlo gradients in variational inference. The main idea is to use importance sampling to estimate the gradient, in order to construct a good proposal distribution that is matched to the variational problem. We show that O-BBVI applies more generally than methods such as reparameterization and local expectations, and it further improves the profile of gradients that use Rao-Blackwellization and control variates.

We demonstrate O-BBVI on two complex models: a non-conjugate time series model (Ranganath et al., 2014) and Poisson-based deep exponential families (DEFs) (Ranganath et al., 2015). Our study shows that O-BBVI reduces the variance of the original black-box variational inference (BBVI) estimates (Ranganath et al., 2014), even when using only half the number of Monte Carlo samples. This provides significant savings in run-time complexity.

Technical summary. Consider a probabilistic model $p(\mathbf{x}, \mathbf{z})$, where $\mathbf{z}$ are the latent variables and $\mathbf{x}$ are the observations. Variational inference sets up a parameterized distribution of the latent variables $q(\mathbf{z}; \boldsymbol{\lambda})$ and finds the parameter $\boldsymbol{\lambda}^\star$ that minimizes the KL divergence between $q(\mathbf{z}; \boldsymbol{\lambda})$ and the posterior $p(\mathbf{z} \mid \mathbf{x})$. We then use $q(\mathbf{z}; \boldsymbol{\lambda}^\star)$ as a proxy for the posterior.

We build on BBVI, which solves this problem with a stochastic optimization procedure that uses Monte Carlo estimates of the gradient (Ranganath et al., 2014). Let $\mathcal{L}(\boldsymbol{\lambda})$ be the variational objective, which is the (negative) KL divergence up to an additive constant. BBVI uses samples from $q(\mathbf{z}; \boldsymbol{\lambda})$ to approximate its gradient,

$$\nabla_{\boldsymbol{\lambda}} \mathcal{L} = \mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})} \left[f(\mathbf{z}) \right], \tag{1}$$

where

$$f(\mathbf{z}) = \nabla_{\boldsymbol{\lambda}} \log q(\mathbf{z}; \boldsymbol{\lambda}) \left(\log p(\mathbf{x}, \mathbf{z}) - \log q(\mathbf{z}; \boldsymbol{\lambda}) \right). \tag{2}$$

The resulting Monte Carlo estimator, based on sampling from $q(\mathbf{z}; \boldsymbol{\lambda})$, only requires evaluating the log-joint distribution $\log p(\mathbf{z}, \mathbf{x})$, the log-variational distribution $\log q(\mathbf{z}; \boldsymbol{\lambda})$, and the score function $\nabla_{\boldsymbol{\lambda}} \log q(\mathbf{z}; \boldsymbol{\lambda})$. Calculations about $q(\mathbf{z}; \boldsymbol{\lambda})$ can be derived once and stored in a library and, as a consequence, BBVI can be easily applied to a large class of models. However, as we mentioned above, Monte Carlo estimates of this gradient usually have high variance. Ranganath et al. (2014) correct for this with Rao-Blackwellization and control variates.

We expand on this idea by approximating the gradient with importance sampling. We introduce a proposal distribution $r(\mathbf{z}; \boldsymbol{\lambda}, \tau)$, which depends on both the variational parameters and an additional parameter. (We discuss the additional parameter below.) We then write the gradient as

$$\nabla_{\boldsymbol{\lambda}} \mathcal{L} = \mathbb{E}_{r(\mathbf{z};\boldsymbol{\lambda},\tau)} \left[f(\mathbf{z}) \frac{q(\mathbf{z}; \boldsymbol{\lambda})}{r(\mathbf{z}; \boldsymbol{\lambda}, \tau)} \right], \tag{3}$$

and form noisy estimates with samples from the proposal.

The key idea behind our method is that the optimal proposal distribution (in terms of minimizing the variance of the resulting estimator) is *not* the original distribution $q(\mathbf{z}; \boldsymbol{\lambda})$ (Owen, 2013, Chapter 9). Rather, the optimal proposal is a skewed version of that distribution with heavier tails. Unfortunately, this distribution is not available to us—it involves an intractable normalization constant. But we use this insight to set a proposal with heavier tails than the variational distribution, thus making it closer to the optimal proposal. Note this is an unconventional use of importance sampling, which is usually employed to approximate expectations. Instead, we use importance sampling to improve the characteristics of a Monte Carlo estimator by sampling from a different distribution.

In detail, we first assume that the variational distribution is in the exponential family. (This is not an assumption about the model; most applications of variational inference use exponential family variational distributions.) We then set the proposal distribution to be in the corresponding overdispersed exponential family (Jørgensen, 1987), where τ is the dispersion parameter. We show that the corresponding estimator has lower variance than the BBVI estimator, we put forward a method to adapt the dispersion parameter during optimization, and we demonstrate that this method is more efficient than BBVI. We call our approach *overdispersed black-box variational inference* (O-BBVI).

Organization. The rest of the paper is organized as follows. We review BBVI in Section 2. We develop O-BBVI in Section 3, describing both the basic algorithm and its extensions to adaptive proposals and high-dimensional settings. Section 4 reports on our empirical study of two non-conjugate models. We conclude the paper in Section 5.

2 BLACK-BOX VARIATIONAL INFERENCE

Consider a probabilistic model $p(\mathbf{x}, \mathbf{z})$ and a variational family $q(\mathbf{z}; \boldsymbol{\lambda})$ which is in the exponential family, i.e.,

$$q(\mathbf{z}; \boldsymbol{\lambda}) = g(\mathbf{z}) \exp\left\{ \boldsymbol{\lambda}^\top t(\mathbf{z}) - A(\boldsymbol{\lambda}) \right\}, \tag{4}$$

where $g(\mathbf{z})$ is the base measure, $\boldsymbol{\lambda}$ are the natural parameters, $t(\mathbf{z})$ are the sufficient statistics, and $A(\boldsymbol{\lambda})$ is the log-normalizer. We are interested in a variational approximation to the intractable posterior $p(\mathbf{z} \mid \mathbf{x})$, i.e., we aim to minimize the KL divergence $D_{\mathrm{KL}} \left(q(\mathbf{z}; \boldsymbol{\lambda}) \parallel p(\mathbf{z} \mid \mathbf{x}) \right)$ with respect to $\boldsymbol{\lambda}$ (Jordan et al., 1999). This is equivalent to maximizing the evidence lower bound (ELBO),

$$\mathcal{L}(\boldsymbol{\lambda}) = \mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})} \left[\log p(\mathbf{x}, \mathbf{z}) - \log q(\mathbf{z}; \boldsymbol{\lambda}) \right], \tag{5}$$

which is a lower bound on the log of the marginal probability of the observations, $\log p(\mathbf{x})$.

With a tractable variational family (e.g., the mean-field family) and a conditionally conjugate model,[1] the expectations in Eq. 5 can be computed in closed form and we can use coordinate-ascent variational inference (Ghahramani and Beal, 2001). However, many models of interest are not conditionally conjugate. For these models, we need alternative methods to optimize the ELBO. One approach is BBVI, which uses Monte Carlo estimates of the gradient and requires few model-specific calculations (Ranganath et al., 2014). Thus, BBVI is a variational inference algorithm that can be applied to a large class of models.

BBVI relies on the "log-derivative trick," also called REINFORCE or score function method (Williams, 1992; Kleijnen and Rubinstein, 1996; Glynn, 1990), to obtain Monte Carlo estimates of the gradient. In detail, we recover the Monte Carlo estimate driven by Eqs. 1 and 2 by taking the gradient of (5) with respect to the variational parameters $\boldsymbol{\lambda}$, and then applying the following two identities:

$$\nabla_{\boldsymbol{\lambda}} q(\mathbf{z};\boldsymbol{\lambda}) = q(\mathbf{z};\boldsymbol{\lambda}) \nabla_{\boldsymbol{\lambda}} \log q(\mathbf{z};\boldsymbol{\lambda}), \tag{6}$$

$$\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})} \left[\nabla_{\boldsymbol{\lambda}} \log q(\mathbf{z};\boldsymbol{\lambda})\right] = 0. \tag{7}$$

Eq. 1 enables noisy gradients of the ELBO by taking samples from $q(\mathbf{z};\boldsymbol{\lambda})$. However, the resulting estimator may have high variance. This is especially the case when the variational distribution $q(\mathbf{z};\boldsymbol{\lambda})$ is a poor fit to the posterior $p(\mathbf{z} \mid \mathbf{x})$, which is typical in early iterations of optimization.

In order to reduce the variance of the estimator, BBVI uses two strategies: control variates and Rao-Blackwellization. Because we will also use these ideas in our algorithm, we briefly discuss them here.

Control variates. A control variate is a random variable that is included in the estimator, preserving its expectation but reducing its variance (Ross, 2002). Although there are many possible choices for control variates, Ranganath et al. (2014) advocate for the weighted score function because it is not model-dependent. Denote the score function by $h(\mathbf{z}) = \nabla_{\boldsymbol{\lambda}} \log q(\mathbf{z};\boldsymbol{\lambda})$, and note again that its expected value is zero. With this function, each component n of the gradient in (1) can be rewritten as $\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})} \left[f_n(\mathbf{z}) - a_n h_n(\mathbf{z})\right]$ where a_n is a constant and $f(\mathbf{z})$ is defined in (2). (Here, $f_n(\mathbf{z})$ and $h_n(\mathbf{z})$ denote the n-th component of $f(\mathbf{z})$ and $h(\mathbf{z})$, respectively.) We can set each element a_n to minimize the variance of the Monte Carlo estimates of this expectation,

$$a_n = \frac{\mathrm{Cov}(f_n(\mathbf{z}), h_n(\mathbf{z}))}{\mathrm{Var}(h_n(\mathbf{z}))}. \tag{8}$$

[1] A conditionally conjugate model is a model for which all the complete conditionals (i.e., the posterior distribution of each hidden variable conditioned on the observations and the rest of hidden variables) are in the same exponential family as the prior.

In BBVI, a separate set of samples from $q(\mathbf{z};\boldsymbol{\lambda})$ is used to estimate a_n (otherwise, the estimator would be biased).

Rao-Blackwellization. Rao-Blackwellization (Casella and Robert, 1996) reduces the variance of a random variable by replacing it with its conditional expectation, given a subset of other variables. In BBVI, each component of the gradient is Rao-Blackwellized with respect to variables outside of the Markov blanket of the involved hidden variable. More precisely, assume a mean-field[2] variational distribution $q(\mathbf{z};\boldsymbol{\lambda}) = \prod_n q(z_n;\lambda_n)$. We can equivalently rewrite the expectation of each element in Eq. 1 as

$$\nabla_{\lambda_n} \mathcal{L} = \mathbb{E}_{q(\mathbf{z}_{(n)};\boldsymbol{\lambda}_{(n)})}\big[\nabla_{\lambda_n} \log q(z_n;\lambda_n) \times \big(\log p_n(\mathbf{x}, \mathbf{z}_{(n)}) - \log q(z_n;\lambda_n)\big)\big], \tag{9}$$

where $\mathbf{z}_{(n)}$ denotes the variable z_n together with all latent variables in its Markov blanket, $q(\mathbf{z}_{(n)};\boldsymbol{\lambda}_{(n)})$ denotes the variational distribution on $\mathbf{z}_{(n)}$, and $\log p_n(\mathbf{x}, \mathbf{z}_{(n)})$ contains all terms of the log-joint distribution that depend on $\mathbf{z}_{(n)}$. The Monte Carlo estimate based on the Rao-Blackwellized expectation has significantly smaller variance than the estimator driven by Eq. 1.

3 OVERDISPERSED BLACK-BOX VARIATIONAL INFERENCE

We have described BBVI and its two strategies for reducing the variance of the noisy gradient. We now describe O-BBVI, a method for further reducing the variance. The main idea is to use importance sampling (Robert and Casella, 2005) to estimate the gradient. We first describe O-BBVI and the proposal distribution it uses. We then show that this reduces variance, discuss several important implementation details, and present the full algorithm.

O-BBVI does not sample from the variational distribution $q(\mathbf{z};\boldsymbol{\lambda})$ to estimate the expectation $\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})} \left[f(\mathbf{z})\right]$. Rather, it takes samples from a proposal distribution $r(\mathbf{z};\boldsymbol{\lambda},\tau)$ and constructs estimates of the gradient in Eq. 3, where the importance weights are $w(\mathbf{z}) = q(\mathbf{z};\boldsymbol{\lambda})/r(\mathbf{z};\boldsymbol{\lambda},\tau)$. This guarantees that the resulting estimator is unbiased. The proposal distribution involves the current setting of the variational parameters $\boldsymbol{\lambda}$ and an additional parameter τ.

The optimal proposal. The particular proposal that O-BBVI uses is inspired by a result from the importance sampling literature (Robert and Casella, 2005; Owen, 2013). This result states that the optimal proposal distribution, which minimizes the variance of the estimator, is *not* the variational distribution $q(\mathbf{z};\boldsymbol{\lambda})$. Rather, the optimal pro-

[2] A structured variational approach is also amenable to Rao-Blackwellization, but we assume a fully factorized variational distribution for simplicity.

posal is

$$r_n^\star(\mathbf{z}) \propto q(\mathbf{z};\boldsymbol{\lambda})\,|f_n(\mathbf{z})|, \tag{10}$$

for each component n of the gradient. (Recall that $f(\mathbf{z})$ is a vector of the same length as $\boldsymbol{\lambda}$.)

While interesting, the optimal proposal distribution is not tractable in general—it involves normalizing a complex product—and is not "black box" in the sense that it depends on the model via $f(\mathbf{z})$. In O-BBVI, we build an alternative proposal based on overdispersed exponential families (Jørgensen, 1987). We will argue that this proposal is closer to the (intractable) optimal $r^*(\mathbf{z})$ than the variational distribution $q(\mathbf{z};\boldsymbol{\lambda})$, and that it is still practical in the context of stochastic optimization of the variational objective. Note that approximating the optimal proposal in stochastic optimization was also explored in Bouchard et al. (2015).

The overdispersed proposal. Our motivation for using overdispersed exponential families is that the optimal distribution of Eq. 10 assigns higher probability density to the tails of $q(\mathbf{z};\boldsymbol{\lambda})$. There are two reasons for this fact. First, consider settings of the variational parameters where the variational distribution is a poor fit to the posterior. For these parameters, there are values of $\mathbf{z}$ for which the posterior is high but the variational distribution is small. While the optimal proposal would sample configurations of $\mathbf{z}$ for which $f_n(\mathbf{z})$ is large, these realizations are in the tails of the variational distribution.

The second reason has to do with the score function. The score function $h_n(\mathbf{z})$ vanishes for values of $\mathbf{z}$ for which the n-th sufficient statistic $t_n(\mathbf{z})$ equals its expected value, and this pushes probability mass (in the optimal proposal) to the tails of $q(\mathbf{z};\boldsymbol{\lambda})$. To see this, recall the exponential family form of the variational distribution given in Eq. 4. For any exponential family distribution, the score function is $h_n(\mathbf{z}) = t_n(\mathbf{z}) - \mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}[t_n(\mathbf{z})]$. (This result follows from simple properties of exponential families.[3]) For values of $\mathbf{z}$ for which $t_n(\mathbf{z})$ is close to its expectation, $h_n(\mathbf{z})$ becomes very close to zero. This zeros out $f_n(\mathbf{z})$ in Eq. 10, which pushes mass to other parts of $q(\mathbf{z};\boldsymbol{\lambda})$. As an example, in the case where $q(\mathbf{z};\boldsymbol{\lambda})$ is a Gaussian distribution, the optimal proposal distribution places zero mass on the mean of that Gaussian and hence more probability mass on its tails.

Thus, we design a proposal distribution $r(\mathbf{z};\boldsymbol{\lambda},\tau)$ that assigns higher mass to the tails of $q(\mathbf{z};\boldsymbol{\lambda})$. Specifically, we use an overdispersed distribution in the same exponential family as $q(\mathbf{z};\boldsymbol{\lambda})$. The proposal is

$$r(\mathbf{z};\boldsymbol{\lambda},\tau) = g(\mathbf{z},\tau)\exp\left\{\frac{\boldsymbol{\lambda}^\top t(\mathbf{z}) - A(\boldsymbol{\lambda})}{\tau}\right\}, \tag{11}$$

[3]The gradient of the log-normalizer (with respect to the natural parameters) equals the first-order moment of the sufficient statistics, i.e., $\nabla_{\boldsymbol{\lambda}} A(\boldsymbol{\lambda}) = \mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}[t(\mathbf{z})]$.

where $\tau \geq 1$ is the dispersion coefficient of the overdispersed distribution (Jørgensen, 1987). Hence, the O-BBVI estimator of the gradient can be expressed as

$$\widehat{\nabla}^{\text{O-BB}}_{\boldsymbol{\lambda}}\mathcal{L} = \frac{1}{S}\sum_s f(\mathbf{z}^{(s)})\frac{q(\mathbf{z}^{(s)};\boldsymbol{\lambda})}{r(\mathbf{z}^{(s)})}, \quad \mathbf{z}^{(s)} \overset{\text{iid}}{\sim} r(\mathbf{z};\boldsymbol{\lambda},\tau), \tag{12}$$

where S is the number of samples of the Monte Carlo approximation.

This choice of $r(\mathbf{z};\boldsymbol{\lambda},\tau)$ has several desired properties for a proposal distribution. First, it is easy to sample from, since for fixed values of τ it belongs to the same exponential family as $q(\mathbf{z};\boldsymbol{\lambda})$. Second, as for the optimal proposal, it is adaptive, since it explicitly depends on the parameters $\boldsymbol{\lambda}$ which we are optimizing. Finally, by definition, it assigns higher mass to the tails of $q(\mathbf{z};\boldsymbol{\lambda})$, which was our motivation for choosing it.

The dispersion coefficient τ can be itself adaptive to better match the optimal proposal at each iteration of the variational optimization procedure. We put forward a method to update the value of τ in Section 3.2.

Note that our approach differs from importance weighted autoencoders (Burda et al., 2016), which also make use of importance sampling but with the goal of deriving a tighter log-likelihood lower bound in the context of the variational autoencoder (Kingma and Welling, 2014). In contrast, we use importance sampling to reduce the variance of the estimator of the gradient.

3.1 Variance reduction

Here, we compare the variance of the O-BBVI estimator $\widehat{\nabla}^{\text{O-BB}}_{\lambda}\mathcal{L}$ given in Eq. 12 with the variance of the original BBVI estimator $\widehat{\nabla}^{\text{BB}}_{\lambda}\mathcal{L}$, which samples from $q(\mathbf{z};\boldsymbol{\lambda})$:

$$\widehat{\nabla}^{\text{BB}}_{\boldsymbol{\lambda}}\mathcal{L} = \frac{1}{S}\sum_s f(\mathbf{z}^{(s)}), \qquad \mathbf{z}^{(s)} \overset{\text{iid}}{\sim} q(\mathbf{z};\boldsymbol{\lambda}). \tag{13}$$

After some algebra, we can express the variance of the BBVI estimator as

$$\mathbb{V}\left[\widehat{\nabla}^{\text{BB}}_{\boldsymbol{\lambda}}\mathcal{L}\right] = \frac{1}{S}\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}\left[f^2(\mathbf{z})\right] - \frac{1}{S}(\nabla_{\boldsymbol{\lambda}}\mathcal{L})^2, \tag{14}$$

and we can also express the variance of the O-BBVI estimator in terms of an expectation with respect to the variational distribution as

$$\begin{aligned}\mathbb{V}\left[\widehat{\nabla}^{\text{O-BB}}_{\boldsymbol{\lambda}}\mathcal{L}\right] &= \frac{1}{S}\mathbb{E}_{r(\mathbf{z};\boldsymbol{\lambda},\tau)}\left[f^2(\mathbf{z})\frac{q^2(\mathbf{z};\boldsymbol{\lambda})}{r^2(\mathbf{z};\boldsymbol{\lambda},\tau)}\right] - \frac{1}{S}(\nabla_{\boldsymbol{\lambda}}\mathcal{L})^2 \\ &= \frac{1}{S}\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}\left[f^2(\mathbf{z})\frac{q(\mathbf{z};\boldsymbol{\lambda})}{r(\mathbf{z};\boldsymbol{\lambda},\tau)}\right] - \frac{1}{S}(\nabla_{\boldsymbol{\lambda}}\mathcal{L})^2.\end{aligned} \tag{15}$$

Variance reduction for the O-BBVI approach is achieved when $\mathbb{V}\left[\widehat{\nabla}^{\text{O-BB}}_{\boldsymbol{\lambda}}\mathcal{L}\right] \leq \mathbb{V}\left[\widehat{\nabla}^{\text{BB}}_{\boldsymbol{\lambda}}\mathcal{L}\right]$ or, equivalently,

$$\mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}\left[f^2(\mathbf{z})\frac{q(\mathbf{z};\boldsymbol{\lambda})}{r(\mathbf{z};\boldsymbol{\lambda},\tau)}\right] \leq \mathbb{E}_{q(\mathbf{z};\boldsymbol{\lambda})}\left[f^2(\mathbf{z})\right]. \tag{16}$$

This inequality is trivially satisfied when we set $r(\mathbf{z})$ to the optimal proposal distribution, $r^\star(\mathbf{z})$. However, it is intractable to compute in general; moreover, it depends on the model through $f(\mathbf{z})$. While the bound in Eq. 16 results intractable, it gives us some intuition on why the use of an overdispersed proposal distribution can reduce the variance, since $r(\mathbf{z};\boldsymbol{\lambda},\tau)$ will be larger than $q(\mathbf{z};\boldsymbol{\lambda})$ for those values of $\mathbf{z}$ for which the product $q(\mathbf{z};\boldsymbol{\lambda})f^2(\mathbf{z})$ is highest, i.e., in the tails of $q(\mathbf{z};\boldsymbol{\lambda})$. Our experimental results in Section 4 demonstrate that the variance is effectively reduced when we use our O-BBVI.

3.2 Implementation

We now discuss several extensions of O-BBVI that make it more suitable for real applications.

High dimensionality. Previously, we defined the proposal distribution $r(\mathbf{z};\boldsymbol{\lambda},\tau)$ as an overdispersed version of the variational distribution $q(\mathbf{z};\boldsymbol{\lambda})$. However, importance sampling is known to fail when the dimensionality of the hidden space is moderately high, due to the high resulting variance of the importance weights $w(\mathbf{z}) = q(\mathbf{z};\boldsymbol{\lambda})/r(\mathbf{z};\boldsymbol{\lambda},\tau)$. To address this, we rely on the fact that hidden variable z_n is the variable with the highest influence on the estimator of the n-th component of the gradient. We exploit this idea, which was also considered by Titsias and Lázaro-Gredilla (2015) in their algorithm based on local expectations.

More precisely, for the variational parameters of variable z_n, we first write the gradient as

$$\begin{aligned}\nabla_{\lambda_n}\mathcal{L} &= \mathbb{E}_{q(z_n;\lambda_n)}\left[\mathbb{E}_{q(\mathbf{z}_{\neg n};\boldsymbol{\lambda}_{\neg n})}\left[f_n(\mathbf{z})\right]\right] \\ &= \mathbb{E}_{r(z_n;\lambda_n,\tau_n)}\left[w(z_n)\mathbb{E}_{q(\mathbf{z}_{\neg n};\boldsymbol{\lambda}_{\neg n})}\left[f_n(\mathbf{z})\right]\right],\end{aligned} \tag{17}$$

where $r(z_n;\lambda_n,\tau_n)$ is the overdispersed version of $q(z_n;\lambda_n)$ with dispersion coefficient τ_n, $\mathbf{z}_{\neg n}$ denotes all hidden variables in the model except z_n, and similarly for $\boldsymbol{\lambda}_{\neg n}$. Thus, the corresponding importance weights in (17) for each component of the gradient depend only on variable z_n, i.e.,

$$w(z_n) = \frac{q(z_n;\lambda_n)}{r(z_n;\lambda_n,\tau_n)}. \tag{18}$$

We use a single sample from $q(\mathbf{z}_{\neg n};\boldsymbol{\lambda}_{\neg n})$ to estimate the inner expectation in (17), and S samples of z_n from $r(z_n;\lambda_n,\tau_n)$ to estimate the outer expectation.

Adaptation of the dispersion coefficients. Our algorithm requires setting the value of the dispersion parameters τ_n; we would like to automate this procedure. Here, we develop a method to learn these coefficients during optimization by minimizing the variance of the estimator. More precisely, we introduce stochastic gradient descent steps for τ_n that minimize the variance. The exact derivative of the (negative) variance with respect to τ_n is

$$\begin{aligned}-\frac{\partial\mathbb{V}\left[\widehat{\nabla}^{\text{O-BB}}_{\lambda_n}\mathcal{L}\right]}{\partial\tau_n} &= \frac{1}{S}\mathbb{E}_{r(z_n;\lambda_n,\tau_n)}\Bigg[\mathbb{E}_{q(\mathbf{z}_{\neg n};\boldsymbol{\lambda}_{\neg n})}\left[f_n(\mathbf{z})\right]^2 \\ &\quad\times w^2(z_n)\frac{\partial\log r(z_n;\lambda_n,\tau_n)}{\partial\tau_n}\Bigg],\end{aligned} \tag{19}$$

where we have applied the log-derivative trick once again, as well as the extension to high dimensionality detailed above. Now a Monte Carlo estimate of this derivative can be obtained by using the same set of S samples used in the update of λ_n. The resulting procedure is fast, with little extra overhead, since both $f_n(\mathbf{z})$ and $w(z_n)$ have been pre-computed.

Thus, we perform gradient steps of the form

$$\tau_n^{(t)} = \tau_n^{(t-1)} - \alpha_n\frac{\partial\mathbb{V}\left[\widehat{\nabla}^{\text{O-BB}}_{\lambda_n}\mathcal{L}\right]}{\partial\tau_n}, \tag{20}$$

where τ_n is constrained as $\tau_n \geq 1$ and the derivatives are estimated via Monte Carlo approximation. Since the derivatives in Eq. 20 can be several orders of magnitude greater than τ_n, we opt for a simple approach to choose an appropriate step size α_n. In particular, we ignore the magnitude of the derivative in (20) and take a small gradient step in the direction given by its sign. Note that we do not need to satisfy the Robbins-Monro conditions here (Robbins and Monro, 1951), because the adaptation of τ_n only defines the proposal distribution and it is not part of the original stochastic optimization procedure.

Eq. 20 can still be applied even if λ_n is a vector; it only requires replacing the derivative of the variance with the summation of the derivatives for all components of λ_n.

Multiple importance sampling. It may be more stable (in terms of the variance of the importance weights) to consider a set of J dispersion coefficients, $\tau_{n1},\ldots,\tau_{nJ}$, instead of a single coefficient τ_n. We propose to use a mixture with equal weights to build the proposal as follows:

$$r(z_n;\lambda_n,\tau_{n1},\ldots,\tau_{nJ}) = \frac{1}{J}\sum_{j=1}^{J} r(z_n;\lambda_n,\tau_{nj}), \tag{21}$$

where each term in the mixture is given by $r(z_n;\lambda_n,\tau_{nj}) = g(z_n,\tau_{nj})\exp\left\{\frac{\lambda_n^\top t(z_n)-A(\lambda_n)}{\tau_{nj}}\right\}$. In the importance sampling literature, this is known as multiple importance sampling (MIS), as multiple proposals are used (Veach and Guibas, 1995). Within the MIS methods, we opt for full deterministic multiple importance sampling (DMIS) because it is the approach that presents lowest variance (Hesterberg, 1995; Owen and Zhou, 2000; Elvira et al., 2015). In DMIS, the number of samples S of the Monte Carlo estimator must

be an integer multiple of the number of mixture components J, and S/J samples are deterministically assigned to each proposal $r(z_n; \lambda_n, \tau_{nj})$. However, the importance weights are obtained as if the samples had been actually drawn from the mixture, i.e.,

$$w(z_n) = \frac{q(z_n; \lambda_n)}{\frac{1}{J}\sum_{j=1}^{J} r(z_n; \lambda_n, \tau_{nj})}. \tag{22}$$

This choice of the importance weights yields an unbiased estimator with smaller variance than the standard MIS approach (Owen and Zhou, 2000; Elvira et al., 2015).

In the experiments in Section 4 we investigate the performance of two-component proposal distributions, where $J = 2$, and compare it against our initial algorithm that uses a unique proposal, which corresponds to $J = 1$. We have also conducted some additional experiments (not shown in the paper) with mixtures with higher number of components, with no significant improvements.

3.3 Full algorithm

We now present our full algorithm for O-BBVI. It makes use of control variates, Rao-Blackwellization, and overdispersed importance sampling with adaptation of the dispersion coefficients. At each iteration, we draw a single sample $\mathbf{z}^{(0)}$ from the variational distribution, as well as S samples $z_n^{(s)}$ from the overdispersed proposal for each n (using DMIS in this step). We obtain the score function as

$$h_n(z_n^{(s)}) = \nabla_{\lambda_n} \log q(z_n^{(s)}; \lambda_n), \tag{23}$$

and the argument of the expectation in (9) as

$$f_n(\mathbf{z}^{(s)}) = h_n(z_n^{(s)})(\log p_n(\mathbf{x}, z_n^{(s)}, \mathbf{z}_{\neg n}^{(0)}) - \log q(z_n^{(s)}; \lambda_n)), \tag{24}$$

where p_n indicates that we use Rao-Blackwellization. Finally, the estimator of the gradient is obtained as

$$\widehat{\nabla}_{\lambda_n} \mathcal{L} = \frac{1}{S}\sum_{s}\left(f_n^{\mathrm{w}}(\mathbf{z}^{(s)}) - a_n h_n^{\mathrm{w}}(z_n^{(s)})\right), \tag{25}$$

where the superscript "w" stands for "weighted," i.e.,

$$f_n^{\mathrm{w}}(\mathbf{z}^{(s)}) = w(z_n^{(s)}) f_n(\mathbf{z}^{(s)}), \tag{26}$$

$$h_n^{\mathrm{w}}(z_n^{(s)}) = w(z_n^{(s)}) h_n(z_n^{(s)}). \tag{27}$$

Following Eq. 8, we use a separate set of samples to estimate the optimal a_n as

$$a_n = \frac{\widehat{\mathrm{Cov}}(f_n^{\mathrm{w}}, h_n^{\mathrm{w}})}{\widehat{\mathrm{Var}}(h_n^{\mathrm{w}})}. \tag{28}$$

We use AdaGrad (Duchi et al., 2011) to obtain adaptive learning rates that ensure convergence of the stochastic optimization procedure, although other schedules can be used instead as long as they satisfy the standard Robbins-Monro conditions (Robbins and Monro, 1951). In AdaGrad, the learning rate is obtained as

$$\boldsymbol{\rho}_t = \eta \,\mathrm{diag}\,(\mathbf{G}_t)^{-1/2}, \tag{29}$$

where $\mathbf{G}_t$ is a matrix that contains the sum across the first t iterations of the outer products of the gradient, and η is a constant. Thus, the stochastic gradient step is given by

$$\boldsymbol{\lambda}^{(t)} = \boldsymbol{\lambda}^{(t-1)} + \boldsymbol{\rho}_t \circ \widehat{\nabla}_{\boldsymbol{\lambda}} \mathcal{L}, \tag{30}$$

where '$\circ$' denotes the element-wise (Hadamard) product. Algorithm 1 summarizes the full procedure.

Algorithm 1: Overdispersed black-box variational inference (O-BBVI)

input : data $\mathbf{x}$, joint distribution $p(\mathbf{x}, \mathbf{z})$, mean-field variational family $q(\mathbf{z}; \boldsymbol{\lambda})$
output: variational parameters $\boldsymbol{\lambda}$
Initialize $\boldsymbol{\lambda}$
Initialize the dispersion coefficients τ_{nj}
while *algorithm has not converged* **do**
  /* draw samples */
  Draw a single sample $\mathbf{z}^{(0)} \sim q(\mathbf{z}; \boldsymbol{\lambda})$
  for $n = 1$ to N **do**
    Draw S samples $z_n^{(s)} \sim r(z_n; \lambda_n, \{\tau_{nj}\})$ (DMIS)
    Compute the importance weights $w(z_n^{(s)})$ (Eq. 22)
  end
  /* estimate gradient */
  for $n = 1$ to N **do**
    For each sample s, compute $h_n(z_n^{(s)})$ (Eq. 23)
    For each sample s, compute $f_n(\mathbf{z}^{(s)})$ (Eq. 24)
    Compute the weighted $f_n^{\mathrm{w}}(\mathbf{z}^{(s)})$ (Eq. 26)
    Compute the weighted $h_n^{\mathrm{w}}(z_n^{(s)})$ (Eq. 27)
    Estimate the optimal a_n (Eq. 28)
    Estimate the gradient $\widehat{\nabla}_{\lambda_n} \mathcal{L}$ (Eq. 25)
  end
  /* update dispersion coefficients */
  for $n = 1$ to N **do**
    Estimate the derivatives $\frac{\partial \mathbb{V}[\nabla_{\lambda_n} \mathcal{L}]}{\partial \tau_{nj}}$ (Eq. 19)
    Take a gradient step for τ_{nj} (Eq. 20)
  end
  /* take gradient step */
  Set the step size $\boldsymbol{\rho}_t$ (Eq. 29)
  Take a gradient step for $\boldsymbol{\lambda}$ (Eq. 30)
end

4 EMPIRICAL STUDY

We study our method with two non-conjugate probabilistic models: the gamma-normal time series model (GN-TS) and the Poisson deep exponential family (DEF). We

found that overdispersed black-box variational inference (O-BBVI) reduces the variance of the black-box variational inference (BBVI) estimator and leads to faster convergence.

4.1 Description of the experiments

Models description and datasets. The GN-TS model (Ranganath et al., 2014) is a non-conjugate state-space model for sequential data that was used to showcase BBVI. The model is described by

$$\begin{aligned} w_{kd} &\sim \mathcal{N}(0, \sigma_w^2), \\ o_{nd} &\sim \mathcal{N}(0, \sigma_o^2), \\ z_{n1k} &\sim \text{GammaE}(\sigma_z, \sigma_z), \\ z_{ntk} &\sim \text{GammaE}(z_{n(t-1)k}, \sigma_z), \\ x_{ndt} &\sim \mathcal{N}\left(o_{nd} + \sum_k z_{ntk} w_{kd}, \sigma_x^2\right). \end{aligned} \tag{31}$$

The indices n, t, d and k denote observations, time instants, observation dimensions, and latent factors, respectively. The distribution GammaE denotes the expectation/variance parameterization of the gamma distribution. The model explains each datapoint x_{ndt} with a latent factor model. For each time instant t, the mean of x_{ndt} depends on the inner product $\sum_k z_{ntk} w_{kd}$, where z_{ntk} varies smoothly across time. The variables o_{nd} are an intercept that capture the baseline in the observations.

We set the hyperparameters to be $\sigma_w^2 = 1, \sigma_o^2 = 1, \sigma_z = 1$, and $\sigma_x^2 = 0.01$. We use a synthetic dataset of $N = 900$ time sequences of length $T = 30$ and dimensionality $D = 20$. We use $K = 30$ latent factors, leading to $828,600$ hidden variables.

The Poisson DEF (Ranganath et al., 2015) is a multi-layered latent variable model of discrete data, such as text. The model is described by

$$\begin{aligned} w_{kv}^{(0)} &\sim \text{Gamma}(\alpha_w, \beta_w), \\ w_{kk'}^{(\ell)} &\sim \text{Gamma}(\alpha_w, \beta_w), \\ z_{dk}^{(L)} &\sim \text{Poisson}(\lambda_z), \\ z_{dk}^{(\ell)} &\sim \text{Poisson}\left(\sum_{k'} z_{dk'}^{(\ell+1)} w_{k'k}^{(\ell)}\right), \\ x_{dv} &\sim \text{Poisson}\left(\sum_{k'} z_{dk'}^{(1)} w_{k'v}^{(0)}\right). \end{aligned} \tag{32}$$

The indices d, v, k and ℓ denote documents, vocabulary words, latent factors, and hidden layers, respectively. This model captures a hierarchy of dependencies between latent variables similar to the hidden structure in deep neural networks. In detail, the number of times that word v appears in document d is x_{dv}. It has a Poisson distribution with rate given by an inner product of gamma-distributed weights and Poisson-distributed hidden variables from layer 1. The Poisson-distributed hidden variables depend, in turn, on another set of weights and another layer of hidden Poisson-distributed variables. This structure repeats for a specified number of layers.

We set the prior shape and rate as $\alpha_w = 0.1$ and $\beta_w = 0.3$, and the prior mean for the top level of the Poisson DEF as $\lambda_z = 0.1$. We use $L = 3$ layers with $K = 50$ latent factors each. We model the papers at the Neural Information Processing Systems (NIPS) 2011 conference. This is a data set with $D = 305$ documents, $612,508$ words, and $V = 5715$ vocabulary words (after removing stop words). This leads to a model with $336,500$ hidden variables.

Evaluation. We compare O-BBVI with BBVI (Ranganath et al., 2014). For a fair comparison, we use the same number of samples in both methods and estimate the inner expectation in Eq. 17 with only one sample. For the outer expectation, we use 8 samples to estimate the gradient itself and 8 separate samples to estimate the optimal coefficient a_n for the control variates. For BBVI, we also doubled the number of samples to $16 + 16$; this is marked as "BBVI ($\times$2)" in the plots.

For O-BBVI, we study both a single proposal and a mixture proposal with two components, respectively labeled as "O-BBVI (single proposal)" and "O-BBVI (mixture)." For the latter, we fix the dispersion coefficients $\tau_{n1} = 1$ for all n, and we run stochastic gradient descent steps for τ_{n2}. See the Supplement for some figures showing the evolution of the dispersion coefficient.

At each iteration (and for each method) we evaluate several quantities: the evidence lower bound (ELBO), the averaged sample variance of the estimator of the gradient, and a model-specific performance metric on the test set. The estimation of the ELBO is based on a single sample of the variational distribution $q(\mathbf{z}; \boldsymbol{\lambda})$ for all methods. For the GN-TS model, we compute the average log-likelihood (up to a constant term) on the test set, which is generated with one additional time instant in all sequences. For the Poisson DEF, we compute the average held-out perplexity,

$$\exp\left(\frac{-\sum_d \sum_{w \in \text{doc}(d)} \log p(w \mid \#\text{held out in } d)}{\#\text{held out words}}\right), \tag{33}$$

where the held-out data contains 25% randomly selected words of all documents.

Experimental setup. For each method, we initialize the variational parameters to the same point and run each algorithm with a fixed computational budget (of CPU time).

We use AdaGrad (Duchi et al., 2011) for the learning rate. We set the parameter η in Eq. 29 to $\eta = 0.5$ for the GN-TS model and $\eta = 1$ for the Poisson DEF. When optimizing the O-BBVI dispersion coefficients τ_n, we take steps of length 0.1 in the direction of the (negative) gradient. We initialize the dispersion coefficients as $\tau_n = 2$ for the single

proposal and $\tau_{n2} = 3$ for the two-component mixture.

We parameterize the normal distribution in terms of its mean and variance, the gamma in terms of its shape and mean, and the Poisson in terms of its mean parameter. In order to avoid constrained optimization, we apply the transformation $\lambda' = \log(\exp(\lambda) - 1)$ to those variational parameters that are constrained to be positive and take stochastic gradient steps with respect to λ'.

Overdispersed exponential families. For a fixed dispersion coefficient τ, the overdispersed exponential family of the Gaussian distribution with mean μ and variance σ^2 is a Gaussian distribution with mean μ and variance $\tau\sigma^2$. The overdispersed gamma distribution with shape s and rate r is given by a new gamma distribution with shape $\frac{s+\tau-1}{\tau}$ and rate $\frac{r}{\tau}$. The overdispersed Poisson(λ) distribution is a Poisson($\lambda^{1/\tau}$) distribution.

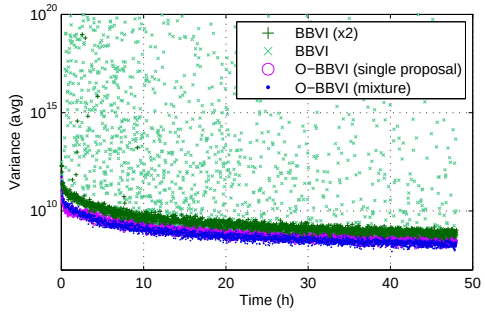
4.2 Results

Figures 1 and 2 show the evolution of the ELBO, the predictive performance, and the average sample variance of the estimator for both models and all methods. We plot these metrics as a function of running time, and each method is run with the same computational budget.

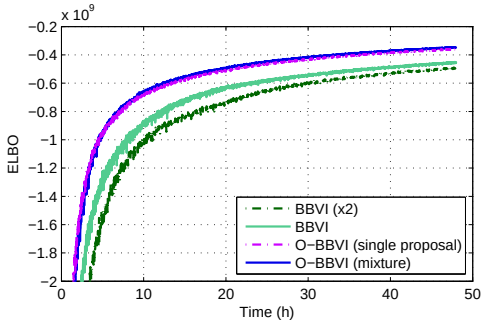
For the GN-TS model, Figure 1a shows that the variance of O-BBVI is significantly lower than BBVI and BBVI with twice the number of samples. Additionally, Figures 1b and 1c show that O-BBVI outperforms vanilla BBVI in terms of both ELBO and held-out likelihood. According to these figures, using a single or mixture proposal does not seem to significantly affect performance. In these plots, we can also see that BBVI ($\times 2$) converges slower than BBVI; this is because the x-axis represents running time instead of iterations. (When the number of samples increases, the convergence is faster but each iteration takes more time.)

The results on the Poisson DEF are similar (Figure 2). Figure 2a shows the average sample variance of the estimator; again, O-BBVI outperforms both BBVI algorithms. Figures 2b and 2c show the evolution of the ELBO and the held-out perplexity, respectively, where O-BBVI also outperforms BBVI. Here, the two-component mixture proposal performs slightly better than the single proposal. This is consistent with Figure 2a, which indicates that the mixture proposal gives more stable estimates.

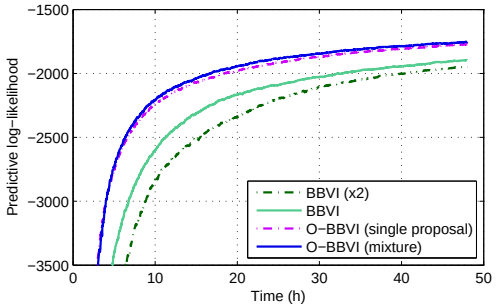
Finally, for the GN-TS model only, we also apply the local expectations algorithm of Titsias and Lázaro-Gredilla (2015), which relies on exact or numerical integration to reduce the variance of the estimator. We form noisy gradients using numerical quadratures for the Gaussian random variables and standard BBVI for the gamma variables (these results are not plotted in the paper). We found that local expectations accurately approximate the gradient for the Gaussian distributions. It converges slightly faster at the beginning of the run, although O-BBVI quickly reaches the same performance. (We conjecture that it is faster because the local expectations algorithm does not require the use of control variates. This saves evaluations of the log-joint probability of the model and thus it can run more iterations in the same period of time.)



(a) Averaged sample variance of the estimator.



(b) Traceplot of the ELBO.

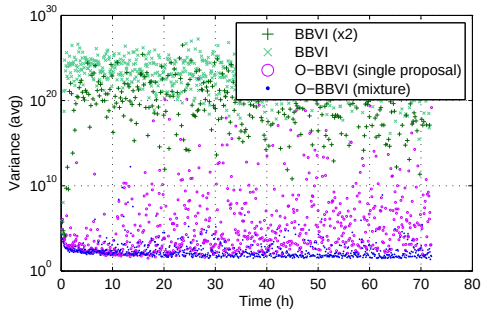


(c) Predictive performance (higher is better).

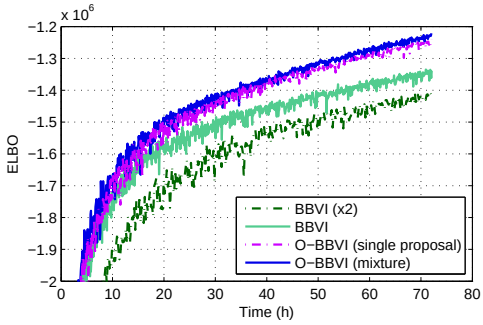
Figure 1: Results for the GN-TS model. Both versions of O-BBVI converge faster than BBVI.

However, we emphasize that O-BBVI is a more general algorithm than local expectations. The local expectations of Titsias and Lázaro-Gredilla (2015) are only available for discrete distributions with finite support and for continuous distributions for which numerical quadratures are accurate (such as Gaussian distributions). They fail to approximate the expectations for other exponential family distributions (e.g., gamma,[4] Poisson, and others). For example, they cannot handle the Poisson DEF.

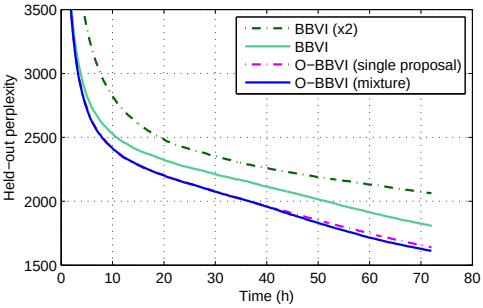
[4]Although the univariate gamma distribution is amenable to numerical integration, we have found that the approximation is not accurate when the shape parameter of the gamma distribution is below 1, due to the singularity at 0.



(a) Averaged sample variance of the estimator.



(b) Traceplot of the ELBO.



(c) Predictive performance (lower is better).

Figure 2: Results for the Poisson DEF model. Both versions of O-BBVI converge faster than BBVI.

5 CONCLUSIONS

We have developed overdispersed black-box variational inference (O-BBVI), a method that relies on importance sampling to reduce the variance of the stochastic gradients in black-box variational inference (BBVI). O-BBVI uses an importance sampling proposal distribution that has heavier tails than the actual variational distribution. In particular, we choose the proposal as an overdispersed distribution in the same exponential family as the variational distribution. Like BBVI, our approach is amenable to mean field or structured variational inference, as well as variational models (Ranganath et al., 2016; Tran et al., 2016).

We have studied the performance of our method on two complex probabilistic models. Our results show that BBVI effectively benefits from the use of overdispersed importance sampling, and O-BBVI leads to faster convergence in the resulting stochastic optimization procedure.

There are several avenues for future work. First, we can explore other proposal distributions to provide a better fit to the optimal ones while still maintaining computational efficiency. Further theoretical research on the bound in Eq. 16 may be helpful for that purpose. Second, we can apply quasi-Monte Carlo methods to further decrease the sampling variance, as already suggested by Ranganath et al. (2014). Finally, we can combine the reparameterization trick with overdispersed proposals to explore whether variance is further reduced.

Abstract

In this paper we propose a novel application of Gaussian processes (GPs) to financial asset allocation. Our approach is deeply rooted in *Stochastic Portfolio Theory* (SPT), a stochastic analysis framework introduced by Robert Fernholz that aims at flexibly analysing the performance of certain investment strategies in stock markets relative to benchmark indices. In particular, SPT has exhibited some investment strategies based on company sizes that, under realistic assumptions, outperform benchmark indices with probability 1 over certain time horizons. Galvanised by this result, we consider the inverse problem that consists of learning (from historical data) an optimal investment strategy based on any given set of trading characteristics, and using a user-specified optimality criterion that may go beyond outperforming a benchmark index. Although this inverse problem is of the utmost interest to investment management practitioners, it can hardly be tackled using the SPT framework. We show that our machine learning approach learns investment strategies that considerably outperform existing SPT strategies in the US stock market.

1 INTRODUCTION

Stochastic Portfolio Theory (SPT) is a relatively new stream in financial mathematics, initiated and largely developed by Robert Fernholz [2002]. For surveys of the field, see Fernholz and Karatzas [2009] and Vervuurt [2015]. Among many other things, SPT offers an alternative approach to portfolio selection, taking as its selection criterion to outperform the market index (for instance, the S&P 500 index) with probability one. Investment strategies which achieve this are called *relative arbitrages*, and have been constructed in certain classes of market models. The almost-sure comparison between the performance of certain portfolios and that of the market is facilitated by Fernholz's 'master equation', a pathwise decomposition of this relative performance which is free from stochastic integrals. The foregoing master equation is the main strength of SPT portfolio selection, as it allows one to circumvent the challenges of explicit model postulation and calibration, as well as the (normative) no-arbitrage assumption, that are encountered in the classical approaches to portfolio optimisation. However, there remain several problems in and limitations to the SPT framework as it stands.

First of all, the task of finding relative arbitrages under reasonable assumptions on the market model is difficult, since it is an inverse problem (this has also been noted by Wong [2015]). Namely, given an investment strategy and market assumptions, one can check whether this strategy is a relative arbitrage (although this quickly becomes very hard for more complicated strategies), but the theory itself does not suggest such strategies. As such, the number of relative arbitrages that have been constructed explicitly remains very small. In a practical setting it would be preferable to invert the problem, and learn investment strategies from data using a user-specified performance criterion. In effect, most established investment managers will likely have a strong view on: i) what performance metric to use to evaluate their strategies, and ii) what values for the chosen metric they regard as being exceptional. The chosen performance metric may depart from the excess return relative to the market index, for instance by adjusting for the risk taken. Similarly, outperforming the market index over a certain time horizon $[0, T]$ with probability 1 might not be good enough for some practitioners, as investors might pull out following disappointing initial performances, leaving the investment manager unable to realise the long-term optimality. Whence, ideally one should aim at learning from market data what investment strategy is likely to perform exceptionally as per the user's view.

Secondly, several market imperfections are ignored in SPT; most notably, the possibility of bankruptcy is excluded. Since the constructed investment strategies typically invest heavily in small-capitalisation stocks, this poses a strong

limitation on the real-world implementability of these portfolios. However, learning optimal investment strategies from the data copes well with bankruptcies as strategies investing in stocks that eventually fail will naturally be rejected as suboptimal. It also allows for the incorporation of transaction costs, which is theoretically challenging and has not yet been addressed in SPT.

Lastly, the SPT set-up has thus far been developed almost exclusively for investment strategies that are driven only by market capitalisations — there have not yet been any constructions of relative arbitrages driven by other factors. Although this simplification eases theoretical analysis, it is a clear restriction as practitioners do consider many more market characteristics in order to exploit market inefficiencies.

We address all of these issues by adopting a Bayesian nonparametric approach. We consider a broad range of investment strategies driven by a function defined on an arbitrary space of trading characteristics (such as the market capitalisation), on which we place a Gaussian process (GP) prior. For a given strategy, the likelihood of it being 'exceptional' is derived from a user-defined performance metric (e.g. excess return to the market index, Sharpe ratio, etc) and values thereof that the practitioner considers 'exceptional'. We then sample from the posterior of the GP driving the 'exceptional' strategy using Monte Carlo Markov Chain (MCMC).

The rest of the paper is structured as follows. In section 2 we provide a background on SPT. In section 3 we present our model, and we illustrate that our approach learns strategies that outperform SPT alternatives in section 4. Finally, we discuss our findings and make suggestions for future research in section 5.

2 BACKGROUND

We give a brief introduction to SPT, defining the general class of market models within which its results hold, what the portfolio selection criterion is, and how strategies achieving this criterion are constructed.

2.1 THE MODEL

In SPT, the stock capitalisations are modelled as Itô processes.[1] Namely, the dynamics of the n positive stock capitalisation processes $X_i(\cdot)$, $i = 1, \ldots, n$ are described by the following system of SDEs:

$$\mathrm{d}X_i(t) = X_i(t)\Big(b_i(t)\,\mathrm{d}t + \sum_{\nu=1}^{d} \sigma_{i\nu}(t)\,\mathrm{d}W_\nu(t)\Big), \quad (1)$$

for $t \geq 0$ and $i = 1, \ldots, n$. Here, $W_1(\cdot), \ldots, W_d(\cdot)$ are independent standard Brownian motions with $d \geq n$, and $X_i(0) > 0,\ i = 1, \ldots, n$ are the initial capitalisations. We assume all processes to be defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and adapted to a filtration $\mathbb{F} = \{\mathcal{F}(t)\}_{0 \leq t < \infty}$ that satisfies the usual conditions and contains the filtration generated by the "driving" Brownian motions. We refer the reader to Karatzas and Shreve [1988] for a reference on stochastic calculus.

The *rates of return* $b_i(\cdot),\ i = 1, \ldots, n$ and *volatilities* $\sigma(\cdot) = (\sigma_{i\nu}(\cdot))_{1 \leq i \leq n, 1 \leq \nu \leq d}$, are some unspecified $\mathbb{F}$-progressively measurable processes and are assumed to satisfy the integrability condition

$$\sum_{i=1}^{n} \int_0^T \Big(|b_i(t)| + \sum_{\nu=1}^{d} (\sigma_{i\nu}(t))^2\Big)\,\mathrm{d}t < \infty, \quad \mathbb{P}\text{-a.s.}, \quad (2)$$

for all $T \in (0, \infty)$, and the *non-degeneracy* condition

$$\exists\, \varepsilon > 0 : \ \xi^T \sigma(t) \sigma^T(t) \xi \geq \varepsilon ||\xi||^2, \quad (\mathrm{ND}^\varepsilon)$$

for all $\xi \in \mathbb{R}^n$ and $t \geq 0,\ \mathbb{P}$-almost surely.

2.2 RELATIVE ARBITRAGE

In this context, one studies investments in the equity market described by (1) using *portfolios*. These are $\mathbb{R}^n$-valued and $\mathbb{F}$-progressively measurable processes $\pi(\cdot) = \big(\pi_1(\cdot), \cdots, \pi_n(\cdot)\big)^T$, where $\pi_i(t)$ stands for the proportion of wealth invested in stock i at time t.

We restrict ourselves to *long-only* portfolios. These invest solely in the stocks, namely, they take values in the closure $\overline{\Delta_+^n}$ of the set

$$\Delta_+^n = \big\{x \in \mathbb{R}^n : \ x_1 + \ldots + x_n = 1, \\ 0 < x_i < 1,\ i = 1, \ldots, n\big\}; \quad (3)$$

in particular, there is no money market. Assuming without loss of generality that the number of outstanding shares of each firm is 1, the corresponding wealth process $V^\pi(\cdot)$ of an investor implementing $\pi(\cdot)$ is seen to evolve as follows (we normalise the initial wealth to 1):

$$\frac{\mathrm{d}V^\pi(t)}{V^\pi(t)} = \sum_{i=1}^{n} \pi_i(t)\,\frac{\mathrm{d}X_i(t)}{X_i(t)}, \qquad V^\pi(0) = 1. \quad (4)$$

In SPT one measures performance, for the most part, with respect to the market index. This is the wealth process $V^\mu(\cdot)$ that results from a buy-and-hold portfolio, given by the vector process $\mu(\cdot) = \big(\mu_1(\cdot), \cdots, \mu_n(\cdot)\big)^T$ of *market weights*

$$\mu_i(t) := \frac{X_i(t)}{X_1(t) + \ldots + X_n(t)}. \quad (5)$$

[1] In the recent work Karatzas and Ruf [2016], it has been shown that this can be weakened to a semimartingale model that even allows for defaults.

Definition 1. *Let $T > 0$. A* strong relative arbitrage *with respect to the market over the time-horizon $[0,T]$ is a portfolio $\pi(\cdot)$ such that*

$$\mathbb{P}\big(V^\pi(T) > V^\mu(T)\big) = 1. \tag{6}$$

An equivalent way to express this notion, is to say that the portfolio $\pi(\cdot)$ strongly outperforms *$\mu(\cdot)$ over the time-horizon $[0,T]$.* □

Contrast the SPT approach to portfolio selection with other methods such as mean-variance optimisation (originally introduced by Markowitz [1952]) and expected utility maximisation (see for instance Rogers [2013]), where the optimisation of a certain performance criterion determines the portfolio. In SPT, any portfolio that outperforms the market in the sense of (6) is a relative arbitrage, and the amount by which it outperforms the market is theoretically irrelevant.

In practice, one clearly desires this relative outperformance to be as large as possible. Attempts at optimisation over the class of strategies that satisfy (6) have been made by Fernholz and Karatzas [2010], Fernholz and Karatzas [2011], Ruf [2011], Ruf [2013], and Wong [2015]. However, these results are highly theoretical and very difficult to implement. Our data-driven approach circumvents these theoretical complications by optimising a user-defined criterion over the class of functionally-generated portfolios, which we introduce below.

2.3 FUNCTIONALLY-GENERATED PORTFOLIOS

A particular class of portfolios, called *functionally-generated portfolios* (or FGPs for short), was introduced and studied by Fernholz [1999].

Consider a function $\mathbf{G} \in C^2(U, \mathbb{R}_+)$, where U is an open neighbourhood of Δ_+^n and such that $x \mapsto x_i \mathrm{D}_i \log \mathbf{G}(x)$ is bounded on Δ_+^n for $i = 1, \ldots, n$. Then $\mathbf{G}$ is said to be the *generating function* of the *functionally-generated portfolio* $\pi(\cdot)$, given, for $i = 1, \ldots, n$, by

$$\frac{\pi_i(t)}{\mu_i(t)} = \frac{\mathrm{D}_i \mathbf{G}(\mu(t))}{\mathbf{G}(\mu(t))} + 1 - \sum_{j=1}^n \mu_j(t) \frac{\mathrm{D}_j \mathbf{G}(\mu(t))}{\mathbf{G}(\mu(t))}. \tag{7}$$

Here, we write D_i for the partial derivative with respect to the i^{th} variable, and we will write D_{ij}^2 for the second partial derivative with respect to the i^{th} and j^{th} variables. Theorem 3.1 of Fernholz [1999] asserts that the performance of the wealth process corresponding to $\pi(\cdot)$, when measured relative to the market, satisfies the $\mathbb{P}$-almost sure decomposition (often referred to as "Fernholz's master equation")

$$\log\left(\frac{V^\pi(T)}{V^\mu(T)}\right) = \log\left(\frac{\mathbf{G}(\mu(T))}{\mathbf{G}(\mu(0))}\right) + \int_0^T \mathfrak{g}(t)\,\mathrm{d}t, \tag{8}$$

where the quantity

$$\mathfrak{g}(t) := -\sum_{i,j=1}^n \frac{\mathrm{D}_{ij}^2 \mathbf{G}(\mu(t))}{2\mathbf{G}(\mu(t))} \mu_i(t)\mu_j(t)\tau_{ij}^\mu(t) \tag{9}$$

is called the *drift process* of the portfolio $\pi(\cdot)$. Here, we have written $\tau_{ij}^\mu(\cdot)$ for the *relative covariances*; denoting by e_i the i^{th} unit vector in $\mathbb{R}^n$, these are defined for $1 \leq i, j \leq n$ as

$$\tau_{ij}^\mu(t) := \big(\mu(t) - e_i\big)^T \sigma(t)\sigma^T(t)\big(\mu(t) - e_j\big). \tag{10}$$

Under suitable conditions on the market model (1), the left hand side of master equation (8) can be bounded away from zero for sufficiently large $T > 0$, thus proving that $\pi(\cdot)$ is an arbitrage relative to the market over $[0,T]$. Several FGPs have been shown to outperform the market this way — see Fernholz [2002], Fernholz et al. [2005], Fernholz and Karatzas [2005], Banner and Fernholz [2008], Fernholz and Karatzas [2009], Picková [2014], and Vervuurt and Karatzas [2015]. In fact, Pal and Wong [2014] prove that any relative arbitrage with respect to the market is necessarily of the form (7), if one restricts $\pi(\cdot)$ to be a functional of the current market weights only.

Strong [2014] proves a generalisation of (8) for portfolios which are deterministic functions not only of the market capitalisations, but also of other observable quantities. Namely, let $\mathbf{x}(t) = (\mu(t), F)^T$, with F a continuous, $\mathbb{R}^k$-valued, $\mathbb{F}$-progressively measurable process of finite variation, and let $\mathcal{H} \in C^{2,1}(\mathbb{R}^n \times \mathbb{R}^k, \mathbb{R}_+)$. By an application of Theorem 3.1 of Strong [2014], for any portfolio

$$\frac{\pi_i(t)}{\mu_i(t)} = \frac{\mathrm{D}_i \mathcal{H}(\mathbf{x}(t))}{\mathcal{H}(\mathbf{x}(t))} + 1 - \sum_{j=1}^n \mu_j(t) \frac{\mathrm{D}_j \mathcal{H}(\mathbf{x}(t))}{\mathcal{H}(\mathbf{x}(t))}, \tag{11}$$

for $i = 1, \ldots, n$, the following master equation holds:

$$\log\left(\frac{V^\pi(T)}{V^\mu(T)}\right) = \log\left(\frac{\mathcal{H}(\mathbf{x}(T))}{\mathcal{H}(\mathbf{x}(0))}\right) + \int_0^T \tilde{\mathfrak{g}}(t)\,\mathrm{d}t - \int_0^T \sum_{l=1}^k \mathrm{D}_{n+l} \log \mathcal{H}(\mathbf{x}(t))\,\mathrm{d}F_l(t). \tag{12}$$

Here (compare with (8) and (9))

$$\tilde{\mathfrak{g}}(t) := -\sum_{i,j=1}^n \frac{\mathrm{D}_{ij}^2 \mathcal{H}(\mathbf{x}(t))}{2\mathcal{H}(\mathbf{x}(t))} \mu_i(t)\mu_j(t)\tau_{ij}^\mu(t). \tag{13}$$

Although explicit in its decomposition, the modified master equation (12) has so far not been applied in the literature. It is very difficult and unclear how to postulate in what way such 'extended generating functions' $\mathcal{H}$ should depend on market information, and what additional covariates to use. It is thus of interest to develop a methodology that makes suggestions for what functions $\mathcal{H}$ to use, and extracts from market data which signals are significant.

2.4 DIVERSITY-WEIGHTED PORTFOLIOS

One of the most-studied FGPs is the *diversity-weighted portfolio* (DWP) with parameter $p \in \mathbb{R}$, defined in (4.4)

of Fernholz et al. [2005] as

$$\pi_i^{(p)}(t) := \frac{(\mu_i(t))^p}{\sum_{j=1}^n (\mu_j(t))^p}, \quad i = 1, \ldots, n. \tag{14}$$

In Eq. (4.5) of Fernholz et al. [2005] it was shown that this portfolio is a relative arbitrage with respect to $\mu(\cdot)$ over $[0, T]$ for any $p \in (0, 1)$ and $T > 2 \log n/(\varepsilon \delta p)$, under the condition (ND$^\varepsilon$), and that of *diversity* (D$^\delta$), introduced below. The latter says that no single company's capitalisation can take up more than a certain proportion of the entire market, which can be observed to hold in real markets;

$$\exists\, \delta \in (0,1): \ \mathbb{P}\Big(\max_{\substack{1 \le i \le n \\ t \in [0,T]}} \mu_i(t) < 1 - \delta \Big) = 1\,. \tag{D$^\delta$}$$

In Vervuurt and Karatzas [2015], this result was extended to the DWP with *negative* parameter p, and several variations of this portfolio were shown to outperform the market over sufficiently long time horizons and under suitable market assumptions. A simulation using real market data supported the claim that these portfolios have the potential to outperform the market index, as well as their positive-parameter counterparts. Our results strongly confirm this finding, as well as computing the optimal parameter p — see section 4.

3 SOLVING THE INVERSE PROBLEM

We consider solving the inverse problem of SPT: given some investment objective, how to go about learning a suitable trading strategy from the data? In doing so, we aim for a method that:

1. Learns from a large class of candidate investment strategies to uncover possibly intricate strategies from the data, typically by making use of non-parametric generative models for the generating functions;
2. Leverages additional sources of information beyond market capitalisations to uncover better investment strategies;
3. Works irrespective of the practitioner's investment objective (e.g. achieving a high Sharpe Ratio, outperforming alternative benchmark indices, etc).

3.1 MODEL SPECIFICATION

Let $\mathcal{X} \subset \mathbb{R}^d$ be a set of trading characteristics, for some $d \geq 1$. We consider long-only portfolios of the form

$$\pi_i^f(t) = \frac{f(\mathbf{x}_i(t))}{\sum_{j=1}^n f(\mathbf{x}_j(t))}, \qquad i = 1 \ldots, n, \tag{15}$$

for some continuous function $f : \mathcal{X} \to \mathbb{R}_+$.

The idea behind this choice of investment portfolios is grounded in the fact that in practice, an investment manager will often have a predefined set of characteristics that he uses to compare stocks, for instance company size, balance sheet variables, credit ratings, sector, momentum, market vs. book value, return on assets, management team, online sentiment, technical indicators, 'beta', etc. The investment manager will typically choose trading characteristics so that they are informative enough to unveil market inefficiencies. Moreover, two stocks that have 'similar' characteristics will receive 'similar' weights.

This approach includes as special cases all functionally-generated portfolios in the SPT framework, and in particular the diversity-, entropy- and equally-weighted, as well as market, portfolios. Our more general setting allows for any set of trading characteristics.

The trading opportunities in our framework are revealed through the time evolving trading characteristics $\mathbf{x}_i(t)$, and the investment map f fully determines how to go about seizing these opportunities. Whence, learning an investment strategy in our framework is equivalent to learning an investment map f. To do so, we consider two families of functions. Firstly, galvanised by the theoretical results of SPT, we consider the case where $\mathcal{X} = \mathbb{R}_+$ is the set of market weights, and we take f to be of the parametric form

$$f : \mu \mapsto \mu^p, \tag{16}$$

for $p \in \mathbb{R}$, which corresponds to the diversity-weighted portfolio (DWP, see section 2.4). Secondly, in order to capture more intricate trading patterns, and to allow for a more general set of trading characteristics $\mathcal{X} \subset \mathbb{R}^d$, we also consider an alternative non-parametric approach in which we take $\log f$ to be a path of a mean-zero Gaussian process with covariance function k

$$\log f \sim \mathcal{GP}(0, k(\cdot, \cdot)). \tag{17}$$

To learn 'good' investment maps, we need to introduce an optimality criterion that encodes the user's investment objective. To do so, we consider a performance functional $\mathcal{P}_\mathcal{D}$ that maps the logarithm of a candidate investment map to the historical performance $\mathcal{P}_\mathcal{D}(\log f)$ of the portfolio $\pi^f(\cdot)$ as in Eq. (15) over some finite time horizon, given historical data $\mathcal{D}$. An example performance functional is the annualised Sharpe Ratio, defined as

$$\mathrm{SR}(\pi) = \sqrt{B}\, \frac{\hat{\mathbb{E}}\left(\{r(1), \ldots, r(T)\}\right)}{\hat{\mathbb{S}}\left(\{r(1), \ldots, r(T)\}\right)}, \tag{18}$$

where $r(t) = \sum_{i=1}^n r_i(t) \pi_i^f(t)$ is the return of our portfolio between time $t-1$ and time t, $r_i(t)$ is the return of the i-th asset between time $t-1$ and time t, B represents the number of units of time in a business year (e.g. 252 if the returns are daily), and $\hat{\mathbb{E}}$ (resp. $\hat{\mathbb{S}}$) denote the sample

mean (resp. sample standard deviation). Another example of a performance functional is the excess return relative to a benchmark portfolio π^*

$$\mathrm{ER}\left(\pi^f|\pi^*\right) = \prod_{t=1}^{T}\left(1+\sum_{i=1}^{n} r_i(t)\pi_i^f(t)\right) - \prod_{t=1}^{T}\left(1+\sum_{i=1}^{n} r_i(t)\pi_i^*(t)\right). \quad (19)$$

The nature of $\mathcal{P}_\mathcal{D}$ (Sharpe ratio, excess return, etc) depends on the portfolio manager; we impose no theoretical restriction.

In the parametric case (Eq. (16)), $\mathcal{P}_\mathcal{D}(\log f)$ is effectively a function of one single variable p, and we can easily learn the optimal p using standard optimisation techniques.

In many cases, however, it might be preferable to reason under uncertainty and be Bayesian. To do so, we express the investment manager's view as to what is a good performance through a likelihood model $p(\mathcal{D}\big|\log f)$, which we may choose to be a probability distribution on $\mathcal{P}_\mathcal{D}(\log f)$

$$\mathcal{L}\left(\mathcal{P}_\mathcal{D}(\log f)\right) := p\left(\mathcal{D}\big|\log f\right). \quad (20)$$

This is perhaps the most important step of the learning process. Indeed, the Bayesian methods we will develop in the next section aim at learning investment maps that provide an appropriate trade-off between how *likely* the map is in light of training data, and how *consistent* it is with prior beliefs. This will only lead to a profitable investment map if 'likely' maps satisfy the manager's investment objective in-sample and vice-versa. If one chooses the likelihood model such that likely maps are strategies that lose money, then our learning machines will learn strategies that lose money!

Fortunately, it is very straightforward to express that likely investment maps are the ones that match a desired investment objective. For instance, we may use as likelihood model that, given a candidate investment map f, the extent to which it is good, or equivalently the extent to which it is 'likely' to be the function driving the strategy we are interested in learning, is the same as the extent to which the Sharpe Ratio it generates in-sample comes from a Gamma distribution with mean 2.0 and standard deviation 0.5. The positive support of the Gamma distribution renders functions leading to negative in-sample Sharpe ratios of no interest, while the concentration of the distribution over the Sharpe Ratio around 2.0 reflects both our target performance and some tolerance around it. The choice of mean (2.0) and standard deviation (0.5) of the Gamma reflects the risk appetite of the investment manager, while the vanishing tails properly reflect the fact that too high a performance $\mathcal{P}_\mathcal{D}(\log f)$ would likely raise suspicions and too low a performance would not be good enough.

To complete our Bayesian model specification, in the parametric case we place on p a uniform prior on $[-8, 8]$.

3.2 INFERENCE

Throughout the rest of this paper we will use as performance functional the total excess — transaction cost adjusted — return (as defined in (19)) relative to the equally weighted portfolio (EWP), which has constant weights

$$\pi_i^{\mathrm{EWP}}(t) = \frac{1}{n}, \quad i = 1, \ldots, n, \ \forall\, t \geq 0. \quad (21)$$

over the whole training period

$$\mathcal{P}_\mathcal{D}(\log f) = \mathrm{ER}(\pi^f|\mathrm{EWP}). \quad (22)$$

We assume a 10bps transaction cost upon rebalancing (i.e. we incur a cost of 0.1% of the notional for each transaction). It is well known to algorithmic (execution) trading practitioners that a good rule of thumb is to expect to pay 10bps when executing an order whose size is 10% of the average daily traded volume (ADV) on liquid stocks. Whence, this assumption is reasonable so long as the wealth invested in each stock does not exceed 10% ADV. When needed, we use as likelihood model

$$\mathcal{L}\left(\mathcal{P}_\mathcal{D}(\log f)\right) = \gamma\left(\mathcal{P}_\mathcal{D}(\log f); a, b\right), \quad (23)$$

where we denote $\gamma(.; a, b)$ the probability density function of the Gamma distribution with mean a and standard deviation b. As previously discussed, a and b need not be learned as they reflect the investment manager's risk appetite. In the experiments of the following section, we use $a = 7.0$ and $b = 0.5$. In other words, we postulate that the ideal investment strategy should be such that, starting with a unit of wealth, the terminal wealth over the training period should be on average 7.0 units of wealth higher than the terminal wealth achieved by the equally weighted portfolio over the same trading horizon — this is purposely greedy.

Frequentist parametric: The first method of inference we consider consists of directly learning the optimal parameter of the DWP by maximising $\mathcal{P}_\mathcal{D}(\log f)$ for $p \in [-8, 8]$. As a comparison, the typical range of p considered in the SPT literature is $[-1, 1]$. To avoid any issue with local maxima, we proceed with brute force maximisation on the uniform grid with mesh size 0.05.[2]

Bayesian parametric: The second method of inference we consider consists of using the *Metropolis-Hastings* algorithm (Hastings [1970]) to sample from the posterior distribution over the exponent p in the DWP case,

$$p(p|\mathcal{D}) \propto \mathcal{L}\left(\mathcal{P}_\mathcal{D}(p)\right) \times \mathbb{1}\left(p \in [-8, 8]\right), \quad (24)$$

where we have rewritten $\mathcal{L}\left(\mathcal{P}_\mathcal{D}(\log f)\right)$ as $\mathcal{L}\left(\mathcal{P}_\mathcal{D}(p)\right)$ to make the dependency in p explicit. We sample a proposal

[2] This took no longer than a couple of seconds in every experiment that we ran.

update p^* from a Gaussian centred at the current exponent p and with standard deviation 0.5. The acceptance probability is easily found to be

$$r = \min\left(1, \frac{\mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(p^*)\right)}{\mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(p)\right)} \mathbb{1}\left(p^* \in [-8, 8]\right)\right). \tag{25}$$

We note in particular that so long as p is initialised within $[-8, 8]$, the indicator function in Eq. (24) will not cause problems to the Markov chain. We typically run $10,000$ MH iterations and discard the first $5,000$ as 'burn-in'. We use the posterior mean exponent learned on training data to trade in our testing horizon following the corresponding DWP

$$\hat{f}(\mu) = \mu^{\mathbb{E}(p|\mathcal{D})}. \tag{26}$$

Bayesian non-parametric: The third method of inference we consider is Bayesian and non-parametric. We place a Gaussian process prior on $\log f$

$$\log f \sim \mathcal{GP}(0, k(\cdot, \cdot)). \tag{27}$$

Given the sizes of datasets we consider in our experiments (more than 3 million training inputs — 500 assets over a 25-year period), we approximate the latent function over a Cartesian grid. This approximation fits nicely with the quantised nature of financial data. We use as covariance function a separable product of Rational Quadratic (RQ) kernels

$$k(x, y) = k_0^2 \prod_{i=1}^{d} \left(1 + \frac{(x[i] - y[i])^2}{2\alpha_i l_i^2}\right)^{-\alpha_i}, \tag{28}$$

where the hyper-parameters $k_0, l_i, \alpha_i > 0$, on which we place independent log-normal priors are all to be inferred. We found the RQ kernel to be a better choice than the Gaussian kernel as it allows for 'varying length scales'. Denoting by $\mathbf{f}$ the values of the investment map over the input grid, we prefer to work with the equivalent whitened representation

$$\log \mathbf{f} = L\mathbf{X}, \quad \mathbf{X} \sim \mathcal{N}(0, I), \tag{29}$$

where I is the identity matrix, $K = [k(\mathbf{x}_i, \mathbf{x}_j)]_{i,j \leq N}$ is the Gram matrix over all N input points, $K = UDU^T$ is the Singular Value Decomposition (SVD) of K and $L = UD^{\frac{1}{2}}$. We use a Blocked Gibbs sampler (Geman and Geman [1984]) to sample from the posterior

$$p\left(\log \mathbf{X}, \log k_0, \{\log l_i, \log \alpha_i\}_{i \leq d} | \mathcal{D}\right) \propto \mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(L\mathbf{X})\right)$$
$$\times\, p(\log \mathbf{X}) p(\log k_0) \prod_{i=1}^{d} p(\log l_i) p(\log \alpha_i)\,, \tag{30}$$

where we have rewritten $\mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(\log f)\right)$ as $\mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(L\mathbf{X})\right)$ to emphasise that the likelihood is fully defined by $\mathbf{f} = L\mathbf{X}$. The whitened representation has two primary advantages. First, it is robust to ill conditioning as we may always compute L, even when K is singular. Second, it creates a hard link between function values and hyper-parameters, so that updating the latter affects the likelihood $\mathcal{L}\left(\mathcal{P}_{\mathcal{D}}(\log f)\right)$, and therefore directly contributes towards improving the training performance $\mathcal{P}_{\mathcal{D}}(\log f)$: we found this to improve mixing of the Markov chain. Our Blocked Gibbs sampler alternates between updating $\log \mathbf{X}$ conditional on hyper-parameters, and updating the hyper-parameters (and consequently L) conditional on $\log \mathbf{X}$. For both steps we use the *elliptical slice sampling* algorithm (Murray et al. [2010]). The computational bottleneck of our sampler is the computation of the SVD of K, which we may do very efficiently by exploiting the separability of our kernel and the grid structure of the input space using standard Kronecker techniques (see for instance Saatchi [2011]).

4 EXPERIMENTS

The universe of stocks we consider in our experiments are the constituents of the S&P 500 index, accounting for changes in index constituents. We rebalance our portfolios on a daily basis. At the end of each trading day, we determine our target portfolio for the next day, which is acquired at the open of the next trading day. When the constituents of the index are due to change on day t, our target portfolio at the end of day $t-1$ relates to the constituents of the index on day t (which would indeed be known to the market on day $t-1$). As previously discussed, we assume that each transaction incurs a charge of 0.1% of its notional value. The returns we use account for corporate events such as dividends, defaults, M&A's, etc. Our data sources are the CRSP and Compustat databases, and we use data from 1 January 1992 to 31 December 2014.

In our first experiment, we aim to illustrate that the approaches we propose in this paper *consistently* and considerably outperform SPT alternatives over a wide range of market conditions. We consider learning optimal investment strategies as described in the previous section using 10 consecutive years worth of data and testing on the following 5 years. We begin on 1st January 1992 for the first training dataset, and roll both training and testing datasets by one year, which leads to a total of 9 pairs of training and testing subsets. We compare the equally-weighted portfolio (EWP), the market portfolio, the diversity-weighted portfolio where the exponent p is learned by maximising the evaluation functional (DWP*), the diversity-weighted portfolio where the exponent p is learned with MCMC (DWP), the Gaussian process approach using as trading characteristic the logarithm of the market weights (CAP), and the Gaussian process approach using as trading characteristics both the logarithm of the market weights and the return-on-assets (CAP+ROA). The return-on-assets (ROA) on day t is defined as the ratio between the last net income reported by the company and last total assets reported by the com-

pany known on day t — we note that this quantity may not change on a daily basis but this does not affect our analysis. The rationale behind using the ROA as additional characteristics is to capture not only how big a company is, but also how well it performs relative to its size.

Table 1 summarises the average over the 9 scenarios of the yearly in-sample and out-of-sample returns plus-minus two standard errors. It can be seen that all learned strategies do indeed outperform the benchmark (EWP) in-sample and out-of-sample. Moreover, the performance is greatly improved by considering non-parametric models, even when the only characteristic considered is the market weight. Analysing such families of strategies within the SPT framework would simply be mathematically intractable. Finally, it can be seen that adding more trading characteristics does indeed add value. Crucially, the CAP+ROA portfolio *considerably* and *consistently* outperforms the benchmark (EWP), both in-sample and out-of-sample.

Table 1: Results of our first experiment on the consistency of our learning algorithms to varying market conditions. IS RET (resp. OOS RET) are in-sample (resp. out-of-sample) average (over the 9 runs in the experiment) yearly returns in % $\pm$ two standard errors.

PORTFOLIO	IS RET (%)	OOS RET (%)
MARKET	8.56±1.62	6.23±2.07
EWP	10.56±1.67	8.99±1.85
DWP*	11.94±2.01	12.51±1.12
DWP	11.91±1.99	12.50±1.11
CAP	26.54±2.38	22.05±2.89
CAP+ROA	**56.18±7.35**	**25.14±2.58**

In our second experiment, we aim to illustrate that our approaches are robust to financial crises. To do so, we train our model using data from 1 January 1992 to 31 December 2005, and test the learned strategy between 1 January 2006 and 31 December 2014, which includes the 2008 financial crisis. We compare the same investment strategies as before. The posterior distribution over the exponent p in the Bayesian parametric method is illustrated in Figure 1. The learned posterior mean investment maps are illustrated in Figure 3. In Table 2 we provide in-sample and out-of-sample average yearly returns as well as out-of-sample Sharpe ratios. Once again, it can be seen that: i) all learned portfolios do indeed outperform the benchmark (EWP) in-sample and out-of-sample, ii) non-parametric methods outperform parametric methods, and iii) adding the ROA as an additional characteristic does indeed add value. These conclusions hold true not only in absolute terms (returns) but also after adjusting for risk (Sharpe Ratio). A more granular illustration of how our method performs during the 2008 financial crisis can be seen in the time series of total wealth provided in Figure 2. It turns out that the ROA does not only improve the return out-of-sample, but it also has a 'stabilising effect' in that the volatility of the wealth process is considerably reduced.

Finally, it is also worth stressing that the shape of the learned investment map in the two-dimensional case (Figure 3) suggests that the investment strategy uncovered by our Bayesian nonparametric approach can hardly be replicated with a parametric model. Once again, it would be near impossible to derive analytical results pertaining to such a portfolio within the SPT framework.

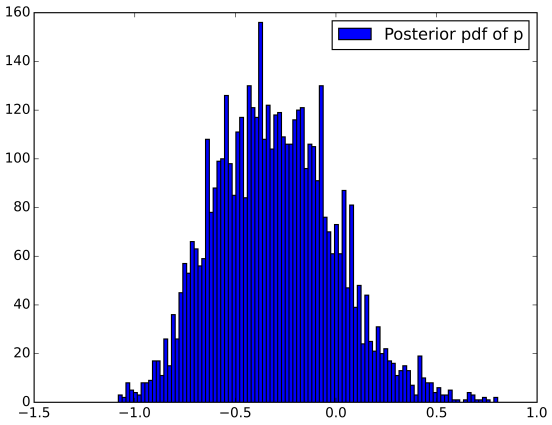

Figure 1: Posterior distribution of the parameter p of the diversity-weighted portfolio in our second experiment. The model was trained with market data between 1st January 1992 to 31st December 2005.

Table 2: Results of our second experiment on the robustness of the proposed approaches to financial crises. Returns (RET) are yearly equivalents (in %) of the total returns over the whole testing period. The annualised Sharpe Ratio (SR) is as per Eq. (18). IS (resp. OOS) stands for in-sample (resp. out-of-sample).

PORTFOLIO	IS RET (%)	OOS RET (%)	OOS SR
MARKET	9.60	7.90	0.47
EWP	13.46	9.60	0.51
DWP*	14.62	11.74	0.56
DWP	14.62	11.38	0.55
CAP	16.49	18.01	0.60
CAP+ROA	**37.54**	**18.33**	**0.72**

5 CONCLUSION & DISCUSSION

The inverse problem of *stochastic portfolio theory* (SPT) is the following problem: given a user-defined portfolio se-

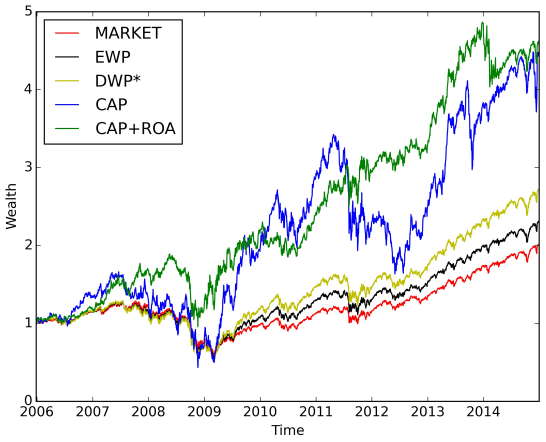

Figure 2: Time series of out-of-sample wealth processes in our second experiment. Models were trained with market data between 1st January 1992 to 31st December 2005, and tested from 1st January 2006 to 31st December 2014.

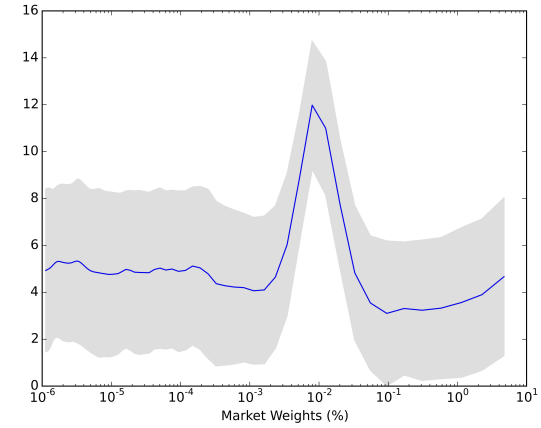
lection criterion, how does one go about constructing suitable investment strategies that meet the desired investment objective? This problem is extremely challenging to solve within the SPT framework. We propose the first solution to the inverse SPT problem and we demonstrate empirically that the proposed methods consistently and considerably outperform standard benchmarks, and are robust to financial crises.

Unlike the SPT framework, our methods are based solely on historical data rather than stochastic calculus. This allows us to consider a very broad class of candidate investment strategies that includes all SPT strategies as special cases, but crucially contains many investment strategies that cannot be analysed in the SPT framework. Unlike the SPT framework, which almost exclusively considers outperforming the market portfolio using investment strategies that are solely based on market weights, our proposed approach can cope with virtually any user-defined investment objective and can exploit any arbitrary set of trading characteristics. We empirically demonstrate that this added flexibility allows us to uncover more subtle patterns in financial markets, which results in greatly improved performance.

Although the Gaussian process in our model was approximated to be piecewise constant on a grid, there is no theoretical or practical obstacle in using an alternative approximation such as sparse Gaussian processes (Quiñonero Candela and Rasmussen [2005]) or string Gaussian processes (Kom Samo and Roberts [2015b]). Our method may be extended to learn even subtler patterns using the non-stationary general purpose kernels of Kom Samo and Roberts [2015a]. Our work may also be extended to allow for long-short investment strategies (i.e. strategies that allow short-selling). Finally, it would be interesting to develop an online extension of our work that would capture temporal changes in market dynamics.



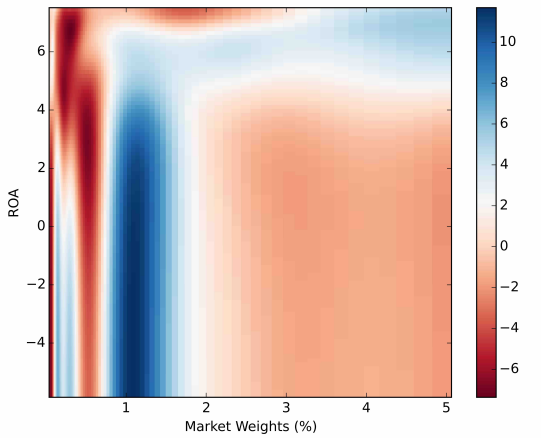


Figure 3: Learned logarithm investment maps of the CAP portfolio (top) and the CAP+ROA portfolio (bottom) in our second experiment. In the case of the CAP portfolio, the credible band corresponds to $\pm$ 2 posterior standard deviations.

Stability of Causal Inference

Leonard J. Schulman and **Piyush Srivastava**

schulman@caltech.edu, piyushsriva@gmail.com

Abstract

We consider the sensitivity of causal identification to small perturbations in the input. A long line of work culminating in papers by Shpitser and Pearl (2006) and Huang and Valtorta (2008) led to a complete procedure for the causal identification problem. In our main result in this paper, we show that the identification function computed by these procedures is in some cases extremely unstable numerically. Specifically, the "condition number" of causal identification can be of the order of $\Omega(\exp(n^{0.49}))$ on an identifiable semi-Markovian model with n visible nodes. That is, in order to give an output accurate to d bits, the empirical probabilities of the observable events need to be obtained to accuracy $d + \Omega(n^{0.49})$ bits.

1 INTRODUCTION

The gold standard for estimating the causal effect of one part of a system on another is the *controlled experiment*: the experimenter controls, or *intervenes* with, the *stimulus* variables in a way such that they are not affected by any non-measurable confounding factors, and then observes the distribution of the *response* variables as the stimuli are varied. Unfortunately, in a variety of important applications, the controlled experiment is not available as a method for reasons of ethics or practicality: a popular example of such a scenario is the question of whether a lifestyle choice such as smoking causes lung cancer. It can be argued (and in this particular case, has been argued! (Ohlemeyer, 1999)) that the strong observed correlations may be due to hidden confounding factors (here environmental or genetic).

In a series of seminal papers starting with (Pearl, 1995), Judea Pearl and others proposed and analyzed a framework for computing causal effects of hypothetical interventions solely from passively observed (i.e., non-experimental) data. The starting point of this framework is a model of the system as a directed graphical model with hidden nodes representing the non-measurable confounding variables. The goal is to take as input the joint distribution of the observed nodes in the model, and to deduce from them the *intervention distributions* that would result if an hypothetical controlled experiment were to be performed. A long line of work (Pearl, 1995; Pearl and Robins, 1995; Kuroki and Miyakawa, 1999; Halpern, 2000; Tian, 2002) on this framework culminated in papers by Shpitser and Pearl (2006) and Huang and Valtorta (2008) which gave a complete characterization of models in which this is achievable: in particular, they provided an algorithm which on input a directed graphical model and the set of stimulus and response variables outputs *either* a procedure that will compute the intervention distribution given the joint distributions of the observed nodes, or a certificate that the intervention distribution is not determined uniquely by the observed joint distribution. In the former case, the causal effect of the stimuli upon the response variables is said to be *identifiable* in the model.

This paper is concerned with the numerical properties of the identification problem. Note that an inference process such as causal identification as described above will always run on empirical inputs. We therefore ask: when the causal effect is identifiable, how sensitive is it to small inaccuracies either in the knowledge of the model, or of the observed distribution? Our main result (Theorem 1.2) in fact shows that causal inference can in fact be extremely sensitive to small errors: we give example of models on n nodes where *any* numerical algorithm for computing the intervention distribution from the observed distribution will lose roughly $\Theta(\sqrt{n})$ bits of precision. This sets an extraordinary demand on the accuracy of the input data of such a system.

As we discuss in more detail in Section 1.2, there are several natural sources of errors in the input to a causal identification problem: these include errors incurred in measurements of the observed distribution; round-off; and as we observe in Section 1.2.1, inexact descriptions of models. Our results therefore point to a new line of investigation concerning the classification of graphical models based on the sensitivity of causal identification to such perturbations in the input.

We begin in the next subsection by formalizing first the identification question, then the appropriate notion of stability for causal identification.

1.1 PEARL'S NOTION OF CAUSAL IDENTIFIABILITY

In Pearl's framework, the system being studied is modeled as a *semi-Markovian* graphical model. A semi-Markovian graphical model is a directed acyclic graph $G = (V, E, U, H)$, which has observed nodes and edges V and E, and hidden nodes and edges U and H, and is constrained so that the observed edges E lie between the observed vertices V, while the hidden edges in H go from a hidden vertex in U to an observed vertex in V.

The observed nodes V of the model are identified with the measurable components of the system, while the hidden nodes in G represent confounding variables that are not accessible to measurement. The edges model dependencies between these random variables: every variable is independent of its ancestors in G conditioned on its immediate predecessors. A probability distribution that satisfies this constraint is said to *respect* G. Equivalently, a probability distribution $\mathbb{P}$ respects G if it factorizes as

$$\mathbb{P}(V_1 = v_1, \ldots, V_n = v_n, U = u) = \mathbb{P}(U = u) \prod_{V_i \in V} \mathbb{P}\left(V_i = v_i \mid \mathrm{pa}(V_i) = v_{\mathrm{pa}(V_i)}\right),$$

where $\mathrm{pa}(S)$ is the set of parents of the node S.

However, since the hidden nodes in U are not measurable, any measurement can only estimate the *observed marginal*

$$\mathbb{P}(V = v) = \sum_{u \in \Omega(U)} \mathbb{P}(U = u) \prod_{V_i \in V} \mathbb{P}\left(V_i = v_i \mid \mathrm{pa}(V_i) = v_{\mathrm{pa}(V_i)}\right),$$

where $\Omega(U)$ denotes the range of the set U of hidden variables.

Pearl (1995) proposed that a natural representation of an experimental intervention on some subset X of observed variables is to remove from them any effect of their ancestors. Formally, the *intervention distribution*, denoted $\mathbb{P}(V - X \mid \mathrm{do}(X = x))$, of the nodes in $V - X$ under the intervention $X = x$ can therefore be defined as follows:

$$\mathbb{P}(V - X = v_{V-X} | \mathrm{do}(X = x)) = \sum_{u \in \Omega(U)} \mathbb{P}(U = u) \prod_{V_i \in V - X} \mathbb{P}\left(V_i = v_i \mid \mathrm{pa}(V_i) = v_{\mathrm{pa}(V_i)}\right). \quad (1)$$

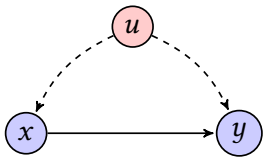
The marginals of the above distribution define the distribution $\mathbb{P}(\cdot \mid \mathrm{do}(X = x))$ on all subsets of $V - X$.

Directly computing the intervention distribution using eq. (1) requires knowledge of the distributions of the hidden variables, as well as their effect on the observed nodes. These are, of course, not measurable in practice. This leads to the question: when is the intervention distribution in eq. (1) efficiently computable (or *identifiable*) from a knowledge of only the observed statistics? More formally, given a semi-Markovian graph $G = (V, E, U, H)$ and disjoint subsets X, Y of V, $\mathbb{P}(Y \mid \mathrm{do}\, X)$ is said to be *identifiable* in G if and only if there exists a function

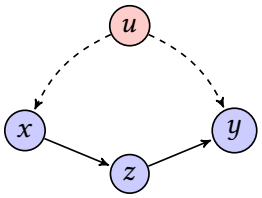
$$\mathbf{ID}(G, X, Y) : P(V) \mapsto P(Y \mid \mathrm{do}\, X)$$

which maps observed distributions $P(V)$ to intervention distributions $P(Y \mid \mathrm{do}\, X)$. The question then is to decide, given G, X, and Y, whether such a map exists, and if yes, to compute it.

As expected, the answer to the question is not always positive. For example, in the graph in fig. 1a (where u is a hidden node), it is not possible to express $\mathbb{P}(y|\mathrm{do}(x))$ in terms of the marginal distribution $\mathbb{P}(x, y)$. This is intuitive, since any observed correlation between X and Y is equally well attributable as being due to the hidden variable U as due to a causal effect of X of Y. However, in the similar



(a) A Simple Unidentifiable Case



(b) A Simple Identifiable Case

Figure 1: Simple Graphical Models

model in fig. 1b, which has just one more observed node, the distribution $\mathbb{P}(y|\mathrm{do}(x))$ *is* identifiable.

The algorithms of Shpitser and Pearl (2006) and Huang and Valtorta (2008), on input G, X, and Y as in the above discussion, either output a description of the map $\mathbf{ID}(G, X, Y)$, or give a certificate that the causal effect of X on Y is not identifiable in G. Here we study the stability of the map $\mathbf{ID}(G, X, Y)$ when it exists; we also show how identification can be applied when the map "almost" exists.

1.2 RESULTS

Before embarking on our study of the sensitivity of the map $\mathbf{ID}(G, X, Y)$ to errors in the input, we make a few comments

about the sources of such errors. Conventionally, two such sources are considered: errors introduced due to limitations in measuring the input, and errors introduced due to rounding off the input to a fixed finite floating point precision. These sources of errors are fairly generic and apply to almost any function, hence we defer their discussion in the context of the **ID** map to Remark 1.1. Here, we discuss another kind of error in the input specific to the problem of causal inference: error arising from inaccuracies in the knowledge of the graphical model of the system under study. We start by analyzing such errors in Section 1.2.1. Finally, in Section 1.2.2, we formalize the notion of the *condition number* which captures all the three forms of errors described above and then state our results in terms of this notion.

1.2.1 Errors in the Model Description

We now consider the effect of ignoring some edges in the input graphical model. Let $G = (V, E, U, H)$ be a semi-Markovian graph with observed nodes and edges V and E, and hidden nodes and edges U and H respectively. Let X, Y be disjoint subsets of V, and suppose that $\mathbb{P}(Y \mid \text{do}\, X)$ is not identifiable in G, but identifiable in the subgraph $G' = (V, E, U, H - \{e\})$ in which a certain edge e has been removed. Another way to frame the situation is that we start with the model G' in which the requisite intervention is identifiable, and then consider the effect of adding the edge e to the model which destroys identifiability.

In particular, we wish to quantify the non-identifiability induced by the addition of the edge e to G', as a function of some measure of the "strength" of the edge e. A natural measure of the strength of an edge (A, B) is the amount by which it can affect the conditional probability at its child vertex B, when all the other parents of B are held fixed. More formally, we propose the following measure of strength:

Definition 1.1 (**ϵ-weak edge**). Let $e = (A, B)$ be any edge in a semi-Markovian graph $G = (V, E, U, H)$ and let P be a model respecting G. Let $\Xi(B)$ denote the set of parents of B in $(V \cup U) \setminus \{A\}$. We say that e is *ϵ-weak* with respect to G and P if for every setting b of B and ξ of $\Xi(B)$, and any two values a and a' in the range of A, we have

$$-\epsilon \leq \log \frac{P(B = b \mid \Xi(B) = \xi, A = a)}{P(B = b \mid \Xi(B) = \xi, A = a')} \leq \epsilon.$$

Now suppose that $e = (A, B) \in E \cup H$ is an ϵ-weak edge in $G = (V, E, U, H)$. We ask: given an observed distribution P, what is the error incurred if we perform causal inference in G' instead of G? We answer this in:

Proposition 1.1. *Consider a semi-Markovian graph $G = (V, E, U, H)$ and a distribution $P(V, U)$ respecting it. Let $R = \{e_i = (A_i, V_i) \mid 1 \leq i \leq q\}$ be a set of k edges in $E \cup H$ such that e_i is ϵ_i-weak, with $\epsilon := \sum_{i=1}^{k} \epsilon_i$. Suppose that X, Y are disjoint subsets of V for which $\mathbb{P}(Y \mid \text{do}\, X)$ is not identifiable in G, but identifiable in $G' = (V, E \setminus R, U, H \setminus R)$. Then there exists a distribution $\tilde{P}(V, U)$ respecting G' such that*

$$-\epsilon \leq \log \frac{\tilde{P}(V)}{P(V)} \leq \epsilon, \quad \text{and} \quad -\epsilon \leq \log \frac{\tilde{P}(Y \mid \text{do}\, X)}{P(Y \mid \text{do}\, X)} \leq \epsilon.$$

Note that $\tilde{P}(Y \mid \text{do}\, X)$ is computable (by the algorithms of Shpitser and Pearl (2006) and Huang and Valtorta (2008)) given $\tilde{P}(V)$, but $P(Y \mid \text{do}\, X)$ is not even uniquely determined given only the observed marginal $P(V)$.

The proof of this proposition can be found in the attached supplementary text.[1]

1.2.2 Uncertainty in the Input Distribution

Proposition 1.1 shows that there exists a distribution $\tilde{P}$ on the subgraph G' for which the intervention distribution is both close to that of P, and also computable only from the projection of $\tilde{P}$ to the observed nodes. On the other hand, the proposition does not provide a method to produce such a $\tilde{P}$ given the projection of P to the observed variables in G (or G'). However, it does guarantee that the observed marginals of P and $\tilde{P}$ are ϵ-close in the following sense:

Definition 1.2 (**ϵ-close distributions**). Two probability distributions P and Q on the same domain Ω are said to be ϵ-close, denoted $P \overset{\epsilon}{\sim} Q$, to each other if for every $\omega \in \Omega$,

$$-\epsilon \leq \log \frac{P(\omega)}{Q(\omega)} \leq \epsilon.$$

We therefore want to study the effect of doing causal inference with observed marginals that are only ϵ-close to the actual observed marginal. Our *statistical stability* question then is the following:

Question 1. *Suppose G, X, Y are such that the map* **ID**(G, X, Y) *exists. How sensitive is the map* **ID**(G, X, Y) *to uncertainties in the input P?*

The standard solution concept for studying such a question is the notion of the *condition number* of the map (see, e.g., (Bürgisser and Cucker, 2013, *Overture*)). We specialize here to the so-called "componentwise condition number".

Definition 1.3 (**Condition number**). Let $f : \mathbb{R}^k \to \mathbb{R}^\ell$ be an arbitrary vector valued function. The condition number of f at $a \in \mathbb{R}^k$, denoted $\kappa_f(a)$, is defined as

$$\kappa_f(a) := \lim_{\delta \downarrow 0} \sup_{\substack{a' \in \mathbb{R}^k \\ \mathsf{Rel}(a, a') \leq \delta}} \frac{\mathsf{Rel}(f(a), f(a'))}{\mathsf{Rel}(a, a')},$$

where for real vectors a, a' in the Euclidean space $\mathbb{R}^t$, the *relative error* $\mathsf{Rel}(a, a')$ is defined as $\max_{1 \leq i \leq t} \frac{|a_i - a'_i|}{|a_i|}$. The condition number of f over a domain $\mathcal{D}$, denoted as κ_f when $\mathcal{D}$ is clear from the context, is $\sup_{a \in \mathcal{D}} \kappa_f(a)$.

[1] A version of this paper including the supplementary text is also available from http://www.caltech.edu/~piyushs/docs/condition.pdf.

Note that the condition number is a property of the function f, and not of a particular algorithm for numerically computing f. In particular, $\kappa_f(a)$ can informally be construed as a derivative of the coordinate-wise logarithm of f as a function of the coordinate-wise logarithm of a.

Armed with the definition of the condition number, we can now further refine our earlier Question 1.

Question 2. *What is the condition number of the map* $\mathbf{ID}(G, X, Y)$ *for a given* G *and subsets* X, Y*, provided in the first place that this map exists?*

Remark 1.1. A few remarks about the sources of errors are in order. First, note that Proposition 1.1 already provides a natural setting in which the "error model" used in the definition of the condition number is the right one: in the notation of that proposition, if we computed the intervention distributions in G' by applying the map $\mathbf{ID}(G', X, Y)$ to P instead of $\tilde{P}$, the worst case relative error in the output will be lower bounded by roughly $\epsilon \cdot \kappa_{\mathbf{ID}(G',X,Y)}(\tilde{P})$, independent of the algorithm used for computation. However, we point out that there is another—arguably even more natural—source of errors that is best captured in terms of relative errors: errors introduced due to rounding in fixed precision floating point systems. We refer the reader to, e.g., the textbook by Bürgisser and Cucker (2013, Section O.3) for a formalization of such systems.

The final type of errors that we discuss here are sampling errors arising due to the finiteness of the sampling procedures used to estimate the observed marginals that are fed as input to the map **ID**. These sampling errors are more likely to be additive (as opposed to relative) in nature. When the input coordinates are elements of the interval $[0, 1]$ (as is the case in our application) an additive error of a given magnitude ϵ always corresponds to a relative error that is at least as large as ϵ in magnitude. Hence, upper bounds imposed on the relative error in the output using an upper bound on the condition number can only worsen if the error guarantees on the input are only additive. In particular, if we show that the condition number defined with respect to relative errors is large, the instability of the problem with respect to additive errors in the input also follows.

Our first result regarding statistical stability demonstrates that the condition number can in fact be sub-exponentially large in the size of the model.

Theorem 1.2. *For every* $0 < \alpha < 1/2$*, there exists an infinite sequence of semi-Markovian graphs* $G_N = (V_N, E_N, U_N, H_N)$ *with* $|V_N| = N$*, and disjoint subsets* S_N *and* T_N *of* V_N *such that*

$$\kappa_{\mathbf{ID}(G_N,T_N,S_N)} = \Omega(\exp(N^\alpha)).$$

The proof of this theorem appears in Section 2. We now isolate one important class of special cases where the condition number is not so bad.

Proposition 1.3. *Let* $G = (V, E, U, H)$ *be a semi-Markovian graph, and let* X *be a node in* V *such that it is not possible to reach a child of* X *from* X *using only the edges in* H *(with their directions ignored). Then, for any subset* S *of* V *not containing* X*.*

$$\kappa_{\mathbf{ID}(G,X,S)} = O(|V|).$$

The hypothesis of the above proposition has appeared earlier as a sufficient condition for the identifiability of $P(S \mid \mathrm{do}\, X)$ in the early work of Tian and Pearl (2002). While this condition is not necessary for identifiability, we show that it carries a distinct advantage: when it holds, the condition number of the identification function is relatively small. The proof of Proposition 1.3 appears in Section 3.

2 ILL-CONDITIONED EXAMPLES

In this section, we prove Theorem 1.2. We begin with a brief outline of our general strategy.

Our main object of study will be semi-Markovian models $\mathcal{G}_n^k$ indexed by positive integers n and k, such that $\mathcal{G}_n^k$ has $\Theta(nk)$ visible nodes, and $\Theta(n + k)$ hidden nodes. The maximum degree of $\mathcal{G}_n^k$ will be $\Theta(k)$ for the observed nodes, and $\Theta(n)$ for the hidden nodes.

Let U and V denote the hidden nodes and the observed nodes, respectively, of $\mathcal{G}_n^k$. In our construction, the variables in both U and V will be binary valued. The crux of our proof is a construction of two probability distributions: the first of these, Q, will be a distribution on the states of the nodes in $U \cup V$ which respects $\mathcal{G}_n^k$. The second, $\tilde{Q}$, will be a distribution only on the states of V, such that it is ϵ-close to the marginal of Q on V. Q and $\tilde{Q}$ will be designed to ensure that when k is chosen to be an appropriate function of n, the values of a certain intervention distribution on $\mathcal{G}_n^k$ computed according to $\tilde{Q}$ differ from the correct answer (i.e., the one computed according to Q) by a factor of $1 \pm \epsilon'$ where ϵ' is larger then ϵ by a factor $\Omega(\exp(N^\alpha))$ (for any $\alpha < 1/2$), for $N = nk + n - 1$, the size of $\mathcal{G}_n^k$.

2.1 THE GADGET

We now define the semi-Markovian graph $\mathcal{G}_n^k$ formally. The visible nodes V of the graph partition into three classes: the "X" nodes, of which there are $k - 1$, the S nodes, of which there are n, and the "Y" nodes, of which there are $(n - 1)k$, arranged in $n - 1$ "towers" of k each (see fig. 2). Formally, we have

$$V := \{X_i \mid 2 \le i \le k\} \cup \{S_i \mid 1 \le i \le n\} \cup \left\{Y_{i,j} \mid 1 \le i \le n-1, 1 \le j \le k\right\}.$$

We now describe the visible edges. First, each S node is a child of each of the Y nodes in the tower immediately to

its left. Each Y node is a child of the Y node immediately below it in its tower, of the S node immediately to the left of its tower, and, if it is in the leftmost tower, of the X node at the same "level" as itself (see fig. 2). Formally,

$$\begin{aligned} E := & \{(X_i, Y_{1,i}) \mid 2 \le i \le k\} \\ & \cup \left\{(S_i, Y_{i,j}) \mid 1 \le i \le n-1, 1 \le j \le k\right\} \\ & \cup \left\{(Y_{i,j}, S_{i+1}) \mid 1 \le i \le n-1, 1 \le j \le k\right\} \\ & \cup \left\{(Y_{i,j}, Y_{i,j+1}) \mid 1 \le i \le n-1, 1 \le j \le k-1\right\}. \end{aligned}$$

Our final task is to describe the hidden nodes and variables: the structure of these defines the C-components of the model, and hence they will dictate the sequence of operations in the Shpitser-Pearl algorithm for causal identification applied to $\mathcal{G}_n^k$.[2] In order to make sure that the S nodes are always in the same C-component, we stipulate an unnamed hidden variable for each adjacent pair of the S_i, which has both of the elements of the pair in question as its children. In addition, we have further (named) hidden variables $\{U_i \mid 2 \le i \le k\}$, such that U_i has as children all the S nodes, the nodes X_i, and all the X and Y nodes at "levels"strictly below i. Formally, the hidden edges incident on these named hidden nodes are:

$$\begin{aligned} H := & \left\{(U_i, X_j) \mid 2 \le i \le k, 2 \le j \le i\right\} \\ & \cup \left\{(U_i, S_j) \mid 2 \le i \le k, 1 \le j \le n\right\} \\ & \cup \{(U_i, Y_{s,t}) \mid 2 \le i \le k, 1 \le s \le n-1, 1 \le t < i\}. \end{aligned}$$

See fig. 2 for a depiction of the gadget $\mathcal{G}_6^4$. In the figure, the named hidden variables U_i and their edges are not included for clarity. Instead, the hyperedges depicting the hidden variables U_i are depicted by the different shaded regions: the lowest region includes all the visible nodes that are children of U_2, the next higher region includes all the visible nodes that are children of U_3 and the topmost region includes all the visible nodes that are children of U_4.

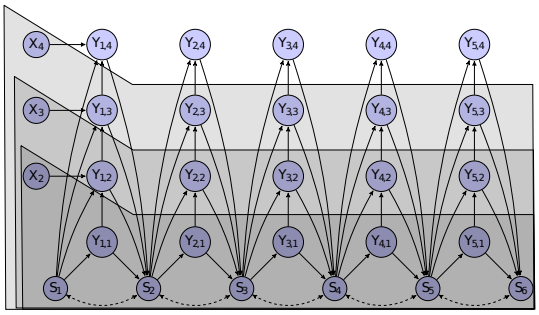


Figure 2: The Graph $\mathcal{G}_6^4$.

[2] A *C-component* is a maximal set of visible vertices which are reachable from each other through paths consisting only of hidden edges (the directions of the hidden edges are ignored). See, e.g., Shpitser and Pearl (2006) for a discussion of the importance of C-components to causal identification.

2.2 IDENTIFICATION ON $\mathcal{G}_n^k$: THE PEEL-OFF OPERATOR

Notation. For any set S of indices, and a symbol A, we denote by A_S the set $\{A_i \mid i \in S\}$ of indexed symbols. Similarly, for sets S and T of indices, we denote by $A_{S,T}$ the set $\left\{A_{i,j} \mid i \in S, j \in T\right\}$. For integers $a \le b$, $[a, b]$ denotes the set of integers between a and b, inclusive. For a positive integer a, we use $[a]$ as a shorthand for the set $[1, a]$. We also denote vectors of values by boldface fonts; in particular, $\mathbf{1}_{[l]}$ denotes a vector of length l all whose entries are 1.

Consider now the computation of the following intervention distribution in $\mathcal{G}_n^k$:

$$P\left(S_{[n]} = \mathbf{1}_{[n]} \mid \text{do}\left(X_{[2,k]} = \mathbf{1}_{[k-1]}, Y_{[n-1],[k]} = \mathbf{1}_{[(n-1)k]}\right)\right). \tag{2}$$

The gadget is defined so as to make the Shpitser-Pearl algorithm iterate a sequence of "multiplication" and "marginalization" steps alternately in the computation of this distribution: our goal ultimately is to amplify errors in the multiplication step, and to attempt to preserve the amplification in the marginalization step. However, before seeing how this can be done, we first abstract the operation of the Shpitser-Pearl algorithm on $\mathcal{G}_n^k$ in terms of a *peel-off* operator which clubs the alternating "multiplication" and "marginalization" steps.

We begin by noting that the gadget $\mathcal{G}_n^{k-1}$ can be viewed as a subgraph of the gadget $\mathcal{G}_n^k$ in a canonical manner by identifying the vertices present in the both the gadgets. These "identified" vertices include all the hidden and visible vertices of $\mathcal{G}_n^k$ except X_k, U_k and $\{Y_{i,k} \mid 1 \le i \le n-1\}$. Let $\mathcal{P}_n^k$ denote the set of probability distributions on states of the observed variables of $\mathcal{G}_n^k$. We define an operator π that acts on a distribution in $\mathcal{P}_n^k$ by "peeling off" the top layer of variables and produces an object in $\mathcal{P}_n^{k-1}$ as the output. Although the action of the operator depends upon the values of n and k, we drop its dependence upon these parameters for ease of notation.

Definition 2.1 (Operator π). Given a probability distribution $P \in \mathcal{P}_n^k$ the probability distribution $\pi(P) \in \mathcal{P}_n^{k-1}$ is defined as

$$\begin{aligned} & \pi(P)\left(X_{[2,k-1]}, S_{[n]}, Y_{[n-1],[k-1]}\right) \\ & := \sum_x P\left(X_k = x, X_{[2,k-1]}\right) \\ & \qquad \cdot \prod_{i=1}^{n-1} P(S_i, Y_{i,[k-1]} \mid X_k = x, Y_{[i-1],k} = \mathbf{1}_{i-1}, \\ & \qquad\qquad X_{[2,k-1]}, S_{[i-1]}, Y_{[i-1],[k-1]}) \\ & \qquad \cdot P(S_n \mid X_k = x, Y_{[n-1],k} = \mathbf{1}_{n-1}, \\ & \qquad\qquad X_{[2,k-1]}, S_{[n-1]}, Y_{[n-1],[k-1]}), \end{aligned}$$

where x ranges over all possible values of the X_k, and 1 is assumed to be in the range of $Y_{i,k}$ for all $i \in [n-1]$.

Remark 2.1. Note that the above definition is valid only for $k \geq 2$. However, we can extend it to the case $k = 1$ by "ignoring" the summation over x when $k = 1$ (or equivalently, by assuming that there exists a variable X_1 with no incident edges).

The algorithm of Shpitser and Pearl (2006) for computing the intervention distribution in eq. (2) then amounts to iterating the operator π k times on the observed distribution P:

$$P\left(S_{[n]} = \mathbf{1}_n \mid \text{do}\left(X_{[2,k]} = \mathbf{1}_{k-1}, Y_{[n-1],[k]} = \mathbf{1}_{k(n-1)}\right)\right) = \pi^k(P)\left(S_{[n]} = \mathbf{1}_n\right).$$

Our high level strategy is to take advantage of the multiplication in the definition of π to amplify errors in each step. Intuitively, if each factor in the product in the definition of $\pi(P)$ has an error factor of $(1+\epsilon)$, then we might expect the error in $\pi(P)$ to be of the order of $(1 + \Theta(n)\epsilon)$. We might then expect such an effect to propagate through the k levels so that the final error is of the order of $(1 + \Theta(n^k)\epsilon)$. However, the marginalization over x can destroy this propagation effect, and we will need to be careful to get around this. This will be done by biasing the distribution Q away from being a uniform distribution, using the bias function defined below (see also Remark 2.2).

2.3 THE ADVERSARIAL MODEL

Our goal now is to define a model Q on $\mathcal{G}_n^k$ and a "perturbed" version $\tilde{Q}$ of the observed marginal Q, such that for every observation $\boldsymbol{\xi}$, Q and $\tilde{Q}$ are ϵ-close to each other.To show lower bounds on the condition number of causality, we will need to show that even when Q and $\tilde{Q}$ are ϵ-close, it is possible to arrange matters so that (in the limit $\epsilon \downarrow 0$)

$$\log\left(\frac{\pi^k(\tilde{Q})\left(S_{[n]} = \mathbf{1}_n\right)}{\pi^k(Q)\left(S_{[n]} = \mathbf{1}_n\right)}\right) = \log(1+\epsilon)\cdot\Omega\left(\left(\frac{n}{ck}\right)^k\right), \quad (3)$$

for some positive constant c independent of n and k.

For ease of exposition, we work directly with some marginals of the distributions Q and $\tilde{Q}$. We defer the construction of Q and $\tilde{Q}$ achieving these marginals to a later section. For further ease of notation, we denote the set of vertices $S_{[i]} \cup Y_{[i],[j]}$ as A_{ij}: in terms of fig. 2, this is the set of vertices of height up to j in the first i "towers" (if we also consider each of the S vertices to be part of the "tower" of Y vertices immediately to their right; see fig. 3 for an illustration of the set $A_{3,2}$). We further use $A_{ij} = \mathbf{1}$ as a shorthand for the conditioning $S_i = \mathbf{1}_i, Y_{[i-1],[k]} = \mathbf{1}_{(i-1)k}$. We now describe the marginals of Q required in our proof, in terms of a *bias function* as defined below. Only conditional expectations of the form described below will be required in the recursive computation of $\pi^k(Q)\left(S_{[n]} = \mathbf{1}_n\right)$.

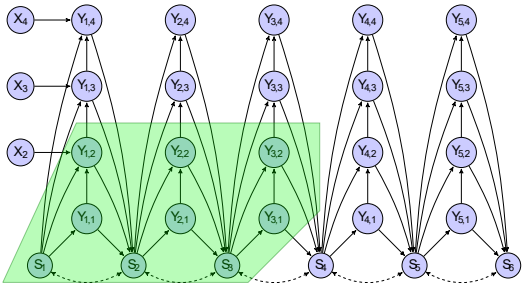

Figure 3: The Set $A_{3,2}$

Definition 2.2 (Bias function). The bias function $b : \{0,1\} \to [0,1]$ is defined as

$$b(x) = \begin{cases} \frac{3}{2} & x = 1, \\ 1 & x = 0. \end{cases}$$

$$Q(X_{[2,k]} = \cdot) = \frac{1}{2^{k-1}},$$
$$Q(S_i = 1 \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2}\cdot b(X_2), \text{ for } i \in [n],$$
$$Q(S_i = 1, Y_{i,[j]} = \mathbf{1}_j \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2^{j+1}}\cdot b\left(X_{j+2}\right), \text{ for } i \in [n-1],\ j \in [k-2],$$
$$Q(S_i = 1, Y_{i,[k-1]} = \mathbf{1}_{k-1} \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2^k}, \text{ for } i \in [n-1].$$

After one application of π, we have the following expressions for conditional expectations of the above form:

$$\pi(Q)(X_{[2,k-1]} = \cdot) = \frac{1}{2^{k-2}},$$
$$\pi(Q)(S_i = 1 \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]}) = \frac{1}{2}\cdot b(X_2), \text{ for } i \in [n],$$
$$\pi(Q)(S_i = 1, Y_{i,[j]} = \mathbf{1}_j \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]}) = \frac{1}{2^{j+1}}\cdot b\left(X_{j+2}\right) \text{ for } i \in [n-1],\ j \in [k-3],$$
$$\pi(Q)(S_i = 1, Y_{i,[k-2]} = \mathbf{1}_{k-2} \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]}) = \frac{1}{2^{k-1}}\cdot\frac{b(0)+b(1)}{2}, \text{ for } i \in [n-1].$$

This process can be continued, and we finally obtain

$$\pi^{k-1}(Q)(S_i = 1 \mid S_{[i-1]} = \mathbf{1}_{i-1}, Y_{[i-1],1} = \mathbf{1}_{i-1}) = \frac{1}{2}\cdot\frac{b(0)+b(1)}{2} = \frac{5}{8}, \text{ for } i \in [n],$$

so that

$$\pi^k(Q)(S_{[n]} = \mathbf{1}_n) = \left(\frac{5}{8}\right)^n.$$

We will now list our requirements for the conditionals of the perturbed distribution $\tilde{Q}$. The construction of a $\tilde{Q}$ that achieves these marginals and that is ϵ-close to Q can be found in Section 2.3.1. Here, we only note that the construction will be such that $\tilde{Q}$ will differ from Q only in the probabilities of those observations in which all the X_i are simultaneously equal to 1.

$$\tilde{Q}(X_{[2,k]} = \cdot) = \frac{1}{2^{k-1}},$$
$$\tilde{Q}(S_i = 1 \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2} \cdot b\left(X_2\right), \text{ for } i \in [n],$$
$$\tilde{Q}(S_i = 1, Y_{i,[j]} = \mathbf{1}_j \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]})$$
$$= \frac{1}{2^{j+1}} \cdot b\left(X_{j+2}\right), \text{ for } i \in [n-1], j \in [k-2],$$
$$\tilde{Q}(S_i = 1, Y_{i,[k-1]} = \mathbf{1}_{k-1} \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]})$$
$$= \frac{1}{2^k} \cdot \begin{cases} (1+\epsilon/2) & X_{[2,k]} = \mathbf{1}_{k-1} \\ 1 & X_{[2,k]} \neq \mathbf{1}_{k-1} \end{cases}, \text{ for } i \in [n-1].$$

We now compute the relevant iterated applications of π on $\tilde{Q}$ using the above marginals.To simplify notation, define:

$$\nu := (1 + \epsilon/2).$$

We now compute the corresponding expressions for $\pi(\tilde{Q})$. It will also be convenient to use the following "error-propagator" function.

Definition 2.3 (Error propagator). Given a bias function b as defined above, the error propagator function η_b (abbreviated to η when b is clear from the context) is $\eta(x) = \eta_b(x) := \frac{b(0)+xb(1)}{1+x}$.

We are now ready to describe $\pi(\tilde{Q})$:

$$\pi(\tilde{Q})(X_{[2,k-1]} = \cdot) = \frac{1}{2^{k-2}},$$
$$\pi(\tilde{Q})(S_i = 1 \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]})$$
$$= \frac{1}{2} \cdot b\left(X_2\right), \text{ for } i \in [n],$$
$$\pi(\tilde{Q})(S_i = 1, Y_{i,[j]} = \mathbf{1}_j \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]})$$
$$= \frac{1}{2^{j+1}} \cdot b\left(X_{j+2}\right) \text{ for } i \in [n-1], j \in [k-3],$$
$$\pi(\tilde{Q})(S_i = 1, Y_{i,[k-2]} = \mathbf{1}_{k-2} \mid A_{i-1,k-1} = \mathbf{1}, X_{[2,k-1]})$$
$$= \frac{1}{2^{k-1}} \cdot \begin{cases} \eta\left(\nu^{i-1}\right) & X_{[2,k-1]} = \mathbf{1}_{k-2} \\ \eta(1) & X_{[2,k-1]} \neq \mathbf{1}_{k-2} \end{cases}, \text{ for } i \in [n-1].$$

Note that only the last of these expressions differs from the case of Q, and it differs only for those observations in which all the remaining X_i nodes are set to 1. This pattern persists for further iterates of π.

Remark 2.2. We can now make precise how the bias function allows propagation of errors through π in spite of the marginalization step. Note that if we had no bias, i.e., $b(x) \equiv 1$, then the discrepancy from $\pi(Q)$ in the last line in the definition of $\pi(\tilde{Q})$ will not arise at all.

In order to describe the evolution of this discrepancy, we define the quantities $\nu_{l,i}$ as ratios between the intermediate marginals computed from $\tilde{Q}$ and Q respectively after l applications of ν; the formal definition of $\nu_{l,i}$ appears in fig. 4. From the base case of $\tilde{Q}$ and the definition of operator π, we then have

$$\nu_{0,i} = \nu = (1+\epsilon/2), \qquad \text{for } i \in [n-1]$$
$$\nu_{l,n} = 1 \qquad \text{for } 0 \leq l \leq k-1$$
$$\nu_{l,i} = \frac{\eta\left(\prod_{j=1}^{i-1} \nu_{l-1,j}\right)}{\eta(1)}, \quad \text{for } 1 \leq l \leq k-1, i \in [n-1].$$

Note that we have

$$\frac{\pi^k(\tilde{Q})(S_{[n]} = \mathbf{1}_n)}{\pi^k(Q)(S_{[n]} = \mathbf{1}_n)} = \prod_{i=1}^{n-1} \nu_{k-1,i}, \tag{4}$$

so that we only need to upper bound the $\nu_{l,i}$ appropriately. In order to do this, we will use the following lemma:

Lemma 2.1. *There exists a $\delta > 0$ such that for $x \in [1, 1+\delta)$, $\frac{\eta(x)}{\eta(1)} \geq x^{1/11}$. The parameter δ can be chosen to be at least 1.*

Proof. The claim of the lemma is equivalent to the existence of a positive δ such that

$$f(x) := 5x^{12/11} + 5x^{1/11} - 6x - 4 \leq 0 \text{ for } x \in [1, 1+\delta).$$

To prove the latter fact, we observe that $f(1) = 0$, and that $f'(1) = \left[\frac{60}{11}x^{1/11} + \frac{5}{11}x^{-10/11} - 6\right]_{x=1} = -\frac{1}{11} < 0$. Indeed, a direct computation shows that δ can be chosen to be 1, since $f(2) < 0$ and f is convex in $[1, 2)$. □

We will now use the above lemma to prove by induction the following lower bound on the $\nu_{l,i}$.

Lemma 2.2. *Suppose that for $1 \leq i \leq n-1$ and $0 \leq l \leq k-1$, we have $\nu_{l,i} \geq 1$ and $\frac{1}{11^{l-1}}\binom{i-1}{l} \log \nu < \log 2$. Then, for such l and i, $\log \nu_{l,i} \geq \frac{1}{11^l}\binom{i-1}{l} \log \nu$.*

Proof. The base case $l = 0$ is true by the definition of the $\nu_{l,i}$. For the induction, $l \geq 1$, and we start with the recursive definition of $\nu_{l,i}$ (for $i \leq n-1$) in terms of $\nu_{l-1,j}$:

$$\nu_{l,i} = \frac{1}{\eta(1)} \cdot \eta\left(\prod_{j=1}^{i-1} \nu_{l-1,j}\right)$$
$$\geq \frac{1}{\eta(1)} \cdot \eta\left(\prod_{j=1}^{i-1} \exp\left(\frac{1}{11^{l-1}}\binom{j-1}{l-1}\log \nu\right)\right) \tag{5}$$
$$= \frac{1}{\eta(1)} \cdot \eta\left(\exp\left(\frac{1}{11^{l-1}}\binom{i-1}{l}\log \nu\right)\right) \tag{6}$$
$$\geq \exp\left(\frac{1}{11^l}\binom{i-1}{l}\log \nu\right), \tag{7}$$

$$\nu_{l,i} := \frac{\pi^l(\tilde{Q})(S_i = 1, Y_{i,[k-l-1]} = \mathbf{1}_{k-l-1} \mid A_{i-1,k-l} = \mathbf{1}, X_{[2,k-l]} = \mathbf{1}_{k-l-1})}{\pi^l(Q)(S_i = 1, Y_{i,[k-l-1]} = \mathbf{1}_{k-l-1} \mid A_{i-1,k-l} = \mathbf{1}, X_{[2,k-l]} = \mathbf{1}_{k-l-1})}.$$

Figure 4: The Quantities $\nu_{l,i}$

where eq. (5) uses the induction hypothesis and the fact that η is an increasing function, eq. (6) employs the elementary combinatorial identity $\sum_{j=1}^{i-1} \binom{j-1}{l-1} = \binom{i-1}{l}$, and eq. (7) uses the hypotheses of the lemma to apply Lemma 2.1. □

We are now ready to complete the proof of Theorem 1.2.

Proof of Theorem 1.2. Substituting the bounds on the $\nu_{l,i}$ from Lemma 2.2 in eq. (4), we get

$$\frac{\pi^k(\tilde{Q})(S_{[n]} = \mathbf{1}_n)}{\pi^k(Q)(S_{[n]} = \mathbf{1}_n)} = \prod_{i=1}^{n-1} \nu_{k-1,i} \tag{8}$$

$$\geq \exp\left(\frac{\log \nu}{11^{k-1}} \sum_{i=1}^{n-1} \binom{i-1}{k-1}\right) \tag{9}$$

$$= \exp\left(\frac{\log \nu}{11^{k-1}} \binom{n-1}{k}\right) \tag{10}$$

$$\geq \exp\left(11 \log \nu \left(\frac{n-1}{11k}\right)^k\right), \tag{11}$$

where eq. (9) uses Lemma 2.2, eq. (10) is again based on the elementary identity used in eq. (6), and eq. (11) is an application of the standard inequality $\binom{a}{b} \geq \left(\frac{a}{b}\right)^b$. Now, let $k = (n-1)^{\alpha'}/11$ for $\alpha' \in [0, 1)$, and set $M := 11(n-1)k$. Note that $M = O(N)$ where N is the number of visible nodes in $\mathcal{G}_n^k$. We then have

$$\frac{\pi^k(\tilde{Q})(S_{[n]} = \mathbf{1}_n)}{\pi^k(Q)(S_{[n]} = \mathbf{1}_n)} \geq \exp\left(11 \log \nu \exp\left(\frac{(1-\alpha')M^{\alpha'/(\alpha'+1)} \log(n-1)}{11}\right)\right).$$

Choosing $\alpha = \alpha'/(\alpha'+1)$ completes the proof. □

2.3.1 Definitions of Q and $\tilde{Q}$

We now supply the promised definitions of Q and $\tilde{Q}$. We first define Q by providing the appropriate conditional distributions of the bits at different nodes in the graph. For the sake of brevity, we only specify the conditional distributions which are *not* uniform: all the unspecified distributions are assumed to be uniform over $\{0, 1\}$. We recall the definition of the bias function used earlier:

Definition 2.4 (Bias function). The bias function $b : \{0, 1\} \to [0, 1]$ is defined as

$$b(x) = \begin{cases} \frac{3}{2} & x = 1, \\ 1 & x = 0. \end{cases}$$

Q is now defined as follows:

$$Q(X_i = U_i \mid U_i) = 1, \text{ for } 2 \leq i \leq k,$$

$$Q(S_i = 1 \mid Y_{i-1,[k]} = \mathbf{1}_k, U_{[2,k]}) = \frac{1}{2} \cdot b(U_2) \text{ for } i \in [n],$$

$$Q(Y_{i,j} = 1 \mid S_i = 1, Y_{i,j-1} = 1, U_{[j+1,k]}) = \frac{1}{2} \cdot \begin{cases} b\left(U_{j+2}\right) & U_{j+1} = 0, \\ \frac{1}{b(1-U_{j+2})} & U_{j+1} = 1 \end{cases}$$
$$\text{for } i \in [n-1], j \in [k-2].$$

$$Q(Y_{i,k-1} = 1 \mid S_i = 1, Y_{i,k-2} = 1, U_k) = \frac{1}{2} \cdot \frac{1}{b(U_k)}, \text{ for } i \in [n-1].$$

The above construction of Q leads, in particular, to the following observed conditional distributions for Q:

$$Q(X_{[2,k]} = \cdot) = \frac{1}{2^{k-1}}$$

$$Q(S_i = 1 \mid A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2} \cdot b(X_2), \text{ for } i \in [n],$$

$$Q(Y_{i,j} = 1 \mid S_i = 1, Y_{i,[j-1]} = \mathbf{1}_{j-1}, A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2} \cdot \begin{cases} b\left(X_{j+2}\right) & X_{j+1} = 0, \\ \frac{1}{b(1-X_{j+2})} & X_{j+1} = 1, \end{cases}$$
$$\text{for } i \in [n-1], j \in [k-2].$$

$$Q(Y_{i,k-1} = 1 \mid S_i = 1, Y_{i,[k-2]} = \mathbf{1}_{k-2}, A_{i-1,k} = \mathbf{1}, X_{[2,k]}) = \frac{1}{2} \cdot \frac{1}{b(X_k)}, \text{ for } i \in [n-1].$$

The Perturbed Distribution The perturbation $\tilde{Q}$ of Q used in our proof is defined in fig. 5. We only specify those entries of $\tilde{Q}$ which are different from those of Q.

3 A WELL-CONDITIONED CLASS

In this section we provide a counterpoint to our main result: we exhibit a useful class of well-conditioned causal

$$\frac{\tilde{Q}(X_{[2,k]} = \mathbf{1}_{k-1}, S_i = 1, A_{i-1,k} = \mathbf{1}, Y_{i,[k-2]} = \mathbf{1}_{k-2}, Y_{i,[k-1,k]} = 00, \star)}{Q(X_{[2,k]} = \mathbf{1}_{k-1}, S_i = 1, A_{i-1,k} = \mathbf{1}, Y_{i,[k-2]} = \mathbf{1}_{k-2}, Y_{i,[k-1,k]} = 00, \star)} = (1 - \epsilon/2), \text{ for } i \in [n-1],$$

$$\frac{\tilde{Q}(X_{[2,k]} = \mathbf{1}_{k-1}, S_i = 1, A_{i-1,k} = \mathbf{1}, Y_{i,[k-2]} = \mathbf{1}_{k-2}, Y_{i,[k-1,k]} = 10, \star)}{Q(X_{[2,k]} = \mathbf{1}_{k-1}, S_i = 1, A_{i-1,k} = \mathbf{1}, Y_{i,[k-2]} = \mathbf{1}_{k-2}, Y_{i,[k-1,k]} = 10, \star)} = (1 + \epsilon), \text{ for } i \in [n-1].$$

Figure 5: The Perturbed Distribution $\tilde{Q}$

identification problems, by proving Proposition 1.3. The proof follows almost immediately from an earlier causal identification result of Tian and Pearl (2002).

Proof of Proposition 1.3. We restrict our attention to the condition number of $\mathbf{ID}(G, V - \{X\}, X)$: since $P(S \mid \text{do}\, X)$ can be obtained from $P(V - \{X\} \mid \text{do}\, X)$ by a marginalization operation, an upper bound on the condition number for $P(V - \{X\} \mid \text{do}\, X)$ is also an upper bound on the condition number of $P(S \mid \text{do}\, X)$.

For a sufficiently small ϵ, let $\tilde{P}$ be a probability distribution that is ϵ-close to the actual empirical distribution P. This implies, in particular, that all *conditional* probabilities computed according to $\tilde{P}$ are 2ϵ-close to the true conditional probabilities computed according to P. Formally, for any disjoint subsets S and T of V, $P(S = s \mid T = t)$ and $\tilde{P}(S = s \mid T = t)$ are 2ϵ-close: this follows from the fact that $P(S = s \mid T = t) = P(S = s, T = t)/P(T = t)$.

Let Z be the set of nodes (except X) in the same C-component as X. Using the identifiability result of Tian and Pearl (2002), we have

$$P(V - \{X\} = v_{V-\{X\}} | \, \text{do}(X = x)) = P(v) \frac{\sum_{x'} H(x')}{H(x)}, \quad (12)$$

where x' ranges over the domain of X, and $H(x')$ is defined as

$$H(x') = P(X = x' \mid \text{An}(X) = v_{\text{An}(X)}) \cdot \prod_{V_i \in Z} P(V_i = v_{V_i} \mid \text{An}(V_i) = v_{\text{An}(v_i)}),$$

where $v_X = x'$. (Here, for a vertex V_i, $\text{An}(V_i)$ is the set of ancestors of V_i among the observed nodes V). Since each H is a product of at most $|V|$ conditional probabilities, and since conditional probabilities computed according to P and $\tilde{P}$ are 2ϵ-close, the values of $H(x')$ computed according to P and $\tilde{P}$ are $2|V|\epsilon$-close. Eq. (12) then gives

$$e^{-(4|V|+1)\epsilon} \leq \frac{\tilde{P}(V - \{X\} = v_{V-\{X\}} \mid \text{do}(X = x))}{P(V - \{X\} = v_{V-\{X\}} \mid \text{do}(X = x))} \leq e^{(4|V|+1)\epsilon}.$$

for every v and x. We therefore have

$$\kappa_{\mathbf{ID}(G, V-\{X\}, X)} \leq \lim_{\epsilon \downarrow 0} \frac{e^{(4|V|+1)\epsilon} - 1}{\epsilon} = 4|V| + 1. \qquad \square$$

4 CONCLUSION

In this paper, we gave an example of a class of semi-Markovian models in which the causal inference problem is highly ill-conditioned. However, Proposition 1.3 shows that at least some causal identification problems are not too badly conditioned.

An immediate open question therefore is to find an algorithm which can compute tight bounds for the condition number of a causal identification problem in a given semi-Markovian model. Since such an algorithm would operate only on the model (and not on the observed data), it can serve a guide for selecting between competing models which differ, e.g., in terms of which covariates are measured, *before* any data is collected: all else being equal, a model in which the causal inference problem to be solved is better conditioned and hence less susceptible to noise should be preferable.

The roots of causal identification in graphical models can be traced back to the setting of linear structural equation models, which were first studied in the seminal papers of Wright (1921, 1934) (see, e.g., Drton et al. (2011), Foygel et al. (2012) and Chen and Pearl (2014) for more recent results on identification in linear structural equation models). Not surprisingly, in contrast to the purely combinatorial identification procedures in the discrete case, the identification procedures for linear structural equation models are able to exploit the linear algebraic structure of the problem and often use, in addition to combinatorial considerations, algorithmic primitives from linear algebra and algebraic geometry as well (see e.g. Foygel et al. (2012) for an example). Condition numbers of the primitives themselves have been studied have been quite extensively, but exploring the condition number of causal identification in the setting of linear structural equation models remains open. However, in this context, we should point out the work of Cornia and Mooij (2014), who show that when causal effects in a linear structural equation model are *not* exactly identifiable, the uncertainty in estimating them may be unbounded, even in models with a fixed number of nodes.

Abstract

We develop Markov beta processes (MBP) as a model suitable for data which can be represented by a sparse set of latent features which evolve over time. Most time evolving nonparametric latent feature models in the literature vary feature usage, but maintain a constant set of features over time. We show that being able to model features which themselves evolve over time results in the MBP outperforming other beta process based models. Our construction utilizes Poisson process operations, which leave each transformed beta process marginally beta process distributed. This allows one to analytically marginalize out latent beta processes, exploiting conjugacy when we couple them with Bernoulli processes, leading to a surprisingly elegant Gibbs MCMC scheme considering the expressiveness of the prior. We apply the model to the task of denoising and interpolating noisy image sequences and in predicting time evolving gene expression data, demonstrating superior performance to other beta process based methods.

1 INTRODUCTION

Latent variable models provide an intuitive way to study the structure of observed data. Pioneering examples of latent variable models are factor analyzers [Bartholomew, 1987] and finite mixture models [MacLachan and Peel, 2000]. Nonparametric Bayesian priors provide an elegant solution to the problem of inferring the number of latent features by sampling over latent feature representations with varying number of features a posteriori.

Griffiths and Ghahramani [2011] develop the *Indian buffet process* (IBP), a stochastic process on features which can be thought of as a factorial analog of the Chinese restaurant process. The IBP is a nonparametric Bayesian prior on binary matrices with an unbounded number of columns, which is exchangeable over the customers (or rows). The underlying measure which results in this exchangeability is of particular interest. Thibaux and Jordan [2007] show that the *beta process* is the underlying de Finetti mixing distribution which generates the Indian buffet process.

The beta process (BP) can be drawn as a Poisson process (with a particular Lévy measure), which opens many doors since Poisson processes have been studied in great depth [Kingman, 1993]. In particular, there exist operations which one can apply to a Poisson process draw such that the resultant object remains a draw from a Poisson process marginally. This construction has been exploited by Lin et al. [2010] and Chen et al. [2012] to develop dependent Dirichlet processes and dependent normalized random measures more generally.

In this work we apply Poisson process preserving operations to construct a Markov chain of beta processes. Each beta process is then used as a base measure for a sequence of Bernoulli process draws. Sampling an entire beta process at each 'time' step seems like a daunting task, however, the elegant consequence of the Poisson process preserving operations is that each beta process in the chain actually is marginally a draw from a beta process with an evolved form of base measure. This fact along with the conjugacy of the beta and Bernoulli processes permits us to marginalize over the entire chain of beta processes analytically.

Whilst previous attempts have been made to encode dependencies between feature usage i.e. between the binary matrices over multiple time steps [Williamson et al., 2010, Foulds et al., 2011], very little work has

been done on making features themselves evolve over time. Not only is our model capable of modeling a vast array of Markov dependencies amongst features, it permits an elegant Gibbs based inference algorithm which is efficiently able to learn structure amongst data. A key insight is that our model permits the analytic integration of a Dirichlet process used to model the time evolving features, and the entire Markov beta process chain. We believe that this is the first instance of dependent beta process work where such analytic integration is possible.

We utilize a Markov chain of beta processes for image denoising and inpainting tasks as well as for modeling time evolving gene expression data. Sparse methods have been successfully used for image analysis and gene data modeling. Our model, a natural extension of the beta Bernoulli model for time-evolving datasets, often outperforms other beta process based models on the tasks we consider.

2 BETA AND BERNOULLI PROCESSES

In this section, we review the beta, Bernoulli and Indian buffet processes following Thibaux and Jordan [2007], and proceed to discuss Poisson process properties Kingman [1993].

A *beta process* $B \sim \mathrm{BP}(c, B_0)$ is a positive random measure on a space Ω, where c is a positive function on Ω, and B_0 is a fixed measure on Ω, called the base measure. In our work, we assume c is constant. When B_0 is continuous, then a draw B can be represented as $B = \sum_{k=1}^{\infty} p_k \omega_k$, where ω_k are i.i.d. draws from $B/B(\Omega)$ and p_k are independent draws from a degenerate beta distribution with parameter c. If B_0 is discrete of the form $B_0 = \sum_k q_k \delta_{\omega_k}$, then $B = \sum_k p_k \delta_{\omega_k}$, with $p_k \sim \mathrm{Beta}(cq_k, c(1-q_k))$ independently. When B_0 is mixed discrete-continuous, B is generated as the sum of independent contributions from the discrete and continuous parts.

We now consider a draw $X \sim \mathrm{BeP}(B)$ from a *Bernoulli process*, for measure B on Ω. If B is continuous, then $X = \sum_{k=1}^{K} \delta_{\omega_k}$, where $K \sim \mathrm{Poisson}(B(\Omega))$, and ω_k are i.i.d. draws from $B/B(\Omega)$. If B is discrete and of the form $B = \sum_k p_k \delta_{\omega_k}$, then $X = \sum_k b_k \delta_{\omega_k}$, where the $b_k \sim \mathrm{Bernoulli}(p_k)$ independently.

Now consider the generative process $B \sim \mathrm{BP}(c, B_0)$ and $X_i|B \sim \mathrm{BeP}(B)$, for $i = 1, ..., n$. The posterior distribution of B is

$$B|\{X_i\}_{i=1:n} \sim \mathrm{BP}\Big(c+n, \frac{c}{c+n}B_0 + \frac{1}{c+n}\sum_{i=1}^{n} X_i\Big).$$

The BP is the conjugate prior for BeP and we can therefore integrate out B analytically when we consider sequential draws from the beta Bernoulli process

$$X_{n+1}|\{X_i\}_{i=1:n} \sim \mathrm{BeP}\Big(\frac{c}{c+n}B_0 + \frac{1}{c+n}\sum_{i=1}^{n} X_i\Big).$$

Note that $\frac{1}{c+n}\sum_{i=1}^{n} X_i \equiv \sum_k \frac{m_{n,k}}{c+n}\delta_{\omega_k}$, where ω_k represent the unique atoms selected by the first n data points and $m_{n,k}$ represents how many of the first n data points selected the k^{th} atom. Note that $X_{n+1}|\{X_i\}_{i=1:n}$ is sampled from the sum of two contributions: one from $\mathrm{BeP}(\frac{c}{c+n}B_0)$ and the other from $\mathrm{BeP}(\frac{1}{c+n}\sum_{i=1}^{n} X_i)$. This sampling process is equivalent to that of the Indian buffet process prior [Griffiths and Ghahramani, 2011].

When B_0 is a non-atomic measure, a draw from a beta process $B \sim \mathrm{BP}(c, B_0)$ is equivalent to a Poisson process (PP) draw with base measure ν, where

$$\nu(d\omega, dp) = cp^{-1}(1-p)^{c-1}dpB_0(d\omega). \qquad (1)$$

The Poisson process draw will consist of points of the form $(\omega_k, p_k) \in [0,1] \times \Omega$, which should be used to define $B = \sum_k p_k \delta_{\omega_k}$. Poisson process preserving operations are operations one can apply to a draw from a Poisson process such that the resultant draw remains marginally a draw from a Poisson process, with a modified base measure. We utilize such operations to construct dependent beta process, in particular, we consider *subsampling, point transition* and *superposition*. See Kingman [1993] for a review of Poisson process properties.

3 MARKOV BETA PROCESSES

3.1 CONSTRUCTION

Given a draw from a beta process, we construct a related beta process by 1) partitioning atoms into clusters, 2) applying stochastic transformations to atoms in each cluster and 3) recombining all the atoms to give a new atomic base measure. We shall show that the transformed beta process draw is marginally a beta process, by applying the theory of Poisson processes.

Definition 1. *A probabilistic transition function is a function* $\boldsymbol{\mathcal{T}} : \Omega \to \mathbb{R}_+$*, such that for each* $\omega \in \Omega$*,* $\boldsymbol{\mathcal{T}}(\omega)$

is a probability measure on Ω. A measure, μ, over Ω is transformed by $\boldsymbol{\mathcal{T}}$ to give measure $\boldsymbol{\mathcal{T}}[\mu]$, defined as

$$(\boldsymbol{\mathcal{T}}[\mu])(A) := \int_{\Omega} \boldsymbol{\mathcal{T}}(\omega)(A)\mu(d\omega). \tag{2}$$

for each measurable $A \subseteq \Omega$. We denote a sample from $\boldsymbol{\mathcal{T}}(\omega)$ as $\mathcal{T}(\omega)$.

Our approach is to consider parameteric probabilistic transition functions, $\boldsymbol{\mathcal{T}}_\theta$, for parameters θ from some measurable parameter space Θ. An example of a probabilistic transition function is a Gaussian probability density function e.g. $\boldsymbol{\mathcal{T}}_\theta(\omega) = \mathcal{N}(\omega; 0, \theta)$.

In order to partition the set of atoms and decide how they should be transitioned, we use a draw from a Dirichlet process, $\boldsymbol{\mathcal{D}} = \sum_j \lambda_j \delta_{\theta_j} \sim \mathrm{DP}(\alpha, H)$, for a DP concentration parameter α and a base measure, H, on Θ. The λ_j are non-negative and sum to 1. We define the probabilistic transition $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}} = \sum_j \lambda_j \boldsymbol{\mathcal{T}}_{\theta_j}$, which we can think of as a convex combination of probabilistic transition functions. The probabilities, λ_j, are used to define a multinomial distribution which is used to decide to which cluster each atom would be assigned to. Once clustered, atoms in cluster j are transitioned using $\boldsymbol{\mathcal{T}}_{\theta_j}$.

Let B_0 be a base measure on Ω, and $B_1 = \sum_k q_k \delta_{\omega_k} \sim \mathrm{BP}(c, B_0)$. For each k, sample $u_k \sim \mathrm{Mult}(1, \boldsymbol{\lambda})$, and $\mathcal{T}_{\theta_{u_k}}(\omega_k) \sim \boldsymbol{\mathcal{T}}_{\theta_{u_k}}(\omega_k)$. Finally, set $B_1 = \sum_k q_k \delta_{\mathcal{T}_{\theta_{u_k}}(\omega_k)}$. We prove that marginally, B_1 is a draw from a beta process.

Lemma 2. *If B_1 is constructed as above, then marginally, $B_1 \sim \mathrm{BP}(c, \boldsymbol{\mathcal{T}}_*[B_0])$ for measure $\boldsymbol{\mathcal{T}}_*[B_0]$ defined such that for $A \subseteq \Omega$, $\boldsymbol{\mathcal{T}}_*[B_0](A) \equiv \int (\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}[B_0])(A)\mathrm{DP}(\boldsymbol{\mathcal{D}}; \alpha, H)d\boldsymbol{\mathcal{D}}$*

Proof. The distribution of q_k remain unchanged. Also $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}[B_0](\Omega) = \sum_j \lambda_j \boldsymbol{\mathcal{T}}_{\theta_j}[B_0](\Omega) = B_0(\Omega)$. Integrating over $\boldsymbol{\mathcal{D}}$ and s_k, the new location of atom k is marginally distributed as $\boldsymbol{\mathcal{T}}_*[B_0]/B_0(\Omega)$. Hence B_1 is a PP draw with base measure $\tilde{\nu}(d\omega, dp) = cp^{-1}(1-p)^{c-1}dp\,\boldsymbol{\mathcal{T}}_*[B_0](d\omega)$, making it marginally a beta process draw. □

Whilst we have not explicitly invoked theorems regarding Poisson preserving operations, they provide some intuition as to why the transformed beta processes are marginally beta process draws. The operation of clustering the atoms of the original beta process is analogous to the Poisson process operation of *subsampling*. A subsampled Poisson process is marginally a Poisson process. *Point transition* is a Poisson process preserving operation, as is the *superposition* of Poisson process draws. The composition of these three Poisson preserving operations accurately describes the nature of our construction of dependent beta processes. An illustration of the formulation is seen in Figure 1.

Note that the Dirichlet process prior can be replaced with other priors without affecting the proof. We choose a DP in our experiments for its modeling flexibility.

Repeating the above approach to construct $B_2, B_3, ...$ results in a *Markov chain of beta processes*. Define $\boldsymbol{\mathcal{T}}^t_{\boldsymbol{\mathcal{D}}}[B_0]$ to be the measure resulting in applying $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}$ t times to measure B_0. Then marginally, $B_t \sim \mathrm{BP}(c, \boldsymbol{\mathcal{T}}^t_*[B_0])$, where for $A \subseteq \Omega$, $\boldsymbol{\mathcal{T}}^t_*[B_0](A) = \int (\boldsymbol{\mathcal{T}}^t_{\boldsymbol{\mathcal{D}}}[B_0])(A)\mathrm{DP}(\boldsymbol{\mathcal{D}}; \alpha, H)d\boldsymbol{\mathcal{D}}$. Henceforth we refer to our construction of dependent beta processes as *Markov beta processes*. When $B_1, ..., B_T$ is a draw from a Markov beta process, we write $B_1, ..., B_T, \boldsymbol{u}_1, ..., \boldsymbol{u}_T | \boldsymbol{\mathcal{D}} \sim \mathrm{MBP}(c, B_0, \boldsymbol{\mathcal{D}}, \boldsymbol{\mathcal{T}}, T)$.

To the best of out knowledge, our construction of dependent beta processes is the first to leave each transformed beta process marginally a beta process draw. Most existing models all keep features (atoms) constant but vary the feature probabilities q_k over time or space. We discuss the related models in the next subsection.

3.2 RELATED DEPENDENT BETA PROCESS CONSTRUCTIONS

In our construction of Markov dependent beta processes, the atom locations evolve over time, whilst the atom weights remain constant. This is in contrast to the majority of existing constructions of dependent beta processes. Existing research has tended to focus on maintaining a time invariant set of atoms, whilst varying the weights.

The Markov IBP introduced by Van Gael et al. [2008] is a model where features remain constant over time, but feature allocations follow a Markov chain on the space $\{0, 1\}$ (1 indicates presence of a feature and 0 indicates absence). The transition matrix governing the chain also remains constant over time, suggesting that the Markov IBP would be unfit to model non-stationary data. Most importantly, this model does not have the ability to jointly model multiple related time series unlike the model we propose in this work. The authors propose several inference schemes for the Markov IBP, but comment that adequate performance is only observed with more complicated algorithms.

Foulds et al. [2011] use a similar idea to the Markov

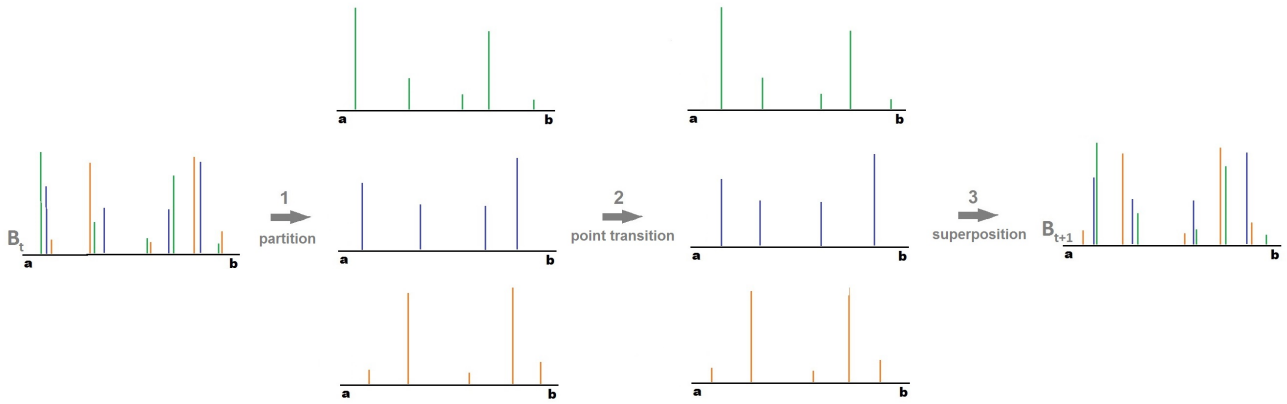

Figure 1: Example illustrating how B_{t+1} is constructed from B_t. First the atoms are partitioned or clustered into, in this case, 3 clusters. Next, atoms undergo probabilistic point transition based on the cluster they belong to. Finally atoms are superimposed to create B_{t+1}.

IBP for modeling time evolving social networks. Their DRIFT model incorporates a Markov process to decide whether or not features are present at each time step whilst maintaining constant features over time. Unlike the Markov IBP, DRIFT is able to model an arbitrary number of items.

Williamson et al. [2010] construct dependent IBPs using Gaussian process draws and the stick breaking construction of the IBP [Teh et al., 2007] to introduce dependencies between customers for each feature as well as temporal dependencies. The dIBP has high flexibility due to the nonparametric temporal dependence structure, but this comes with a high computational cost. Features also remain constant over time in the dIBP model, unlike in our MBP model.

The kernel beta process [Ren et al., 2011] is a generalization of the beta process and has the form $B_x = \sum_k \pi_k K(x, x^*|\psi)\delta_{\omega_k}$, where x belongs to a covariate space $\mathcal{X}$ and K is a kernel function on $\mathcal{X} \times \mathcal{X}$ taking values in $[0, 1]$ for parameters x^* and ψ. The use of the kernel allows weights to vary over a covariate space, whilst the atom locations remain fixed.

The dependent hierarchical beta process Zhou et al. [2011] is constructed as a convex combination of i.i.d. draws from a hierarchical beta process. The convex weights are made to depend on a kernel over a covariate space. More specifically, a kernel function is defined between the covariates (each data point has one covariate), inducing correlation of feature usage between data points. The covariate being used is the location of the patch within the entire image, the idea being that neighbouring patches are more likely to use similar dictionary elements for image denoising and interpolation. The way it has been constructed by the authors, it would not explicitly be able to model temporal structure amongst image sequences.

3.3 COLLAPSED GIBBS SAMPLER

None of the models discussed above result in simple marginal distributions, and consequently each use an uncollapsed Gibbs sampler to perform posterior inference. Nonparametric Bayesian priors are usually easy to sample from, but posterior inference is typically difficult because of the flexibility of the models and the presence of poor local optima in the posterior conditional distributions of the latent variables. Whilst an uncollapsed Gibbs sampler algorithms are usually easy to implement, they are prone to get stuck in poor modes and converge much more slowly than collapsed samplers [Doshi-Velez and Ghahramani, 2009]. In our Markov beta processes, having marginal beta process distributions permits a marginalized posterior sampler which has a better chance of mixing well and has an elegant restaurant analogy.

At each time step, t, we draw $x_t^i|B_t \sim \text{BeP}(B_t)$ iid for $i = 1, ..., n_t$. Let $X_t \equiv \{x_t^i\}_{i=1}^{n_t}$. We show how to sample each x_t^i marginalizing out the Markov beta process chain in the following lemma and corollary. For $t > 1$, we let ω_t^j denote a sample from (a) $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}(\omega_{t-1}^j)$ if $j \leq k_{t-1}$, or (b) $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}^{t-1}[B_0]/B_0(\Omega)$ if $j > k_{t-1}$.

Lemma 3. *For* $c_t = c + \sum_{s=1}^t n_s$,

$$B_t|\boldsymbol{\mathcal{D}}, B_0, X_{1:t} \sim \text{BP}\left(c_t, \frac{c}{c_t}\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}^{t-1}[B_0] + \sum_{j=1}^{k_t} \frac{m_t^j}{c_t}\delta_{\omega_t^j}\right)$$

Proof. We prove the claim by induction. Note that

$B_1|\boldsymbol{\mathcal{D}}, B_0 \sim \mathrm{BP}(c, \boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}[B_0])$ by Lemma 2. By conjugacy of the beta and Bernoulli processes, we then have $B_1|\boldsymbol{\mathcal{D}}, B_0, X_1 \sim \mathrm{BP}\big(c_1, \frac{c}{c_1}\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}[B_0] + \sum_{j=1}^{k_1}\frac{m_1^j}{c_1}\delta_{\omega_1^j}\big)$. Now let $t > 1$. By induction and Lemma 2, $B_t|\boldsymbol{\mathcal{D}}, B_0, X_{1:t-1} \sim \mathrm{BP}\Big(c_{t-1}, \frac{c}{c_{t-1}}\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}^{t-1}[B_0] + \sum_{j=1}^{k_{t-1}}\frac{m_{t-1}^j}{c_{t-1}}\delta_{\omega_t^j}\Big)$. The final result follows from the conjugacy of the beta and Bernoulli processes. □

Corollary 4.

$$x_t^{n_t+1}|\boldsymbol{\mathcal{D}}, B_0, X_{1:t} \sim \mathrm{BeP}\left(\frac{c}{c_t}\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}^{t-1}[B_0] + \sum_{j=1}^{k_t}\frac{m_t^j}{c_t}\delta_{\omega_t^j}\right)$$

Proof. Since $x_t^{n_t+1}|B_t \sim \mathrm{BeP}(B_t)$ and $p(x_t^\circ|\boldsymbol{\mathcal{D}}, B_0, X_{1:t}) = \int p(x_t^\circ|B_t)p(B_t|\boldsymbol{\mathcal{D}}, B_0, X_{1:t})dB_t$, the result follows from conjugacy and Lemma 3. □

The result in Corollary 4 motivates a sampling scheme with a restaurant analogy similar to the one developed for the Indian buffet process [Griffiths and Ghahramani, 2011]. On day $t = 1$, customer $i_1 = 1$ tastes a number of dishes sampled from Poisson$(cB_0(\Omega))$. He tries dishes in Ω sampled independently from probability measure $B_0/B_0(\Omega)$. Suppose $i_1 > 1$ and let m^j be the number of people who have tasted the j^{th} dish so far. Customer i_1 tries each of the existing dishes independently with probability $\frac{m^j}{c+i_1-1}$, and samples Poisson$\big(\frac{c}{c+i_1-1}B_0(\Omega)\big)$ new dishes. On a new day, $t > 1$, each dish from the previous day evolves stochastically using the probabilistic transition function $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}$. Customer i_t tries each existing dish with independent probability $\frac{m^j}{c_{t-1}+i_t-1}$, and samples Poisson$\big(\frac{c}{c_{t-1}+i_t-1}B_0(\Omega)\big)$ new dishes independently from $\boldsymbol{\mathcal{T}}_{\boldsymbol{\mathcal{D}}}^{t-1}[B_0]/B_0(\Omega)$.

As is the case for the IBP, dishes which are popular are more likely to be tried over time. The key difference in our Markov beta process framework, is that the dishes evolve stochastically over time, and the base distribution from which new dishes are drawn also evolves stochastically over time.

4 TIME EVOLVING DICTIONARY LEARNING

In this section we illustrate how a draw from a Markov beta process prior may be used to perform time evolving dictionary learning. Each $\omega_k \in \Omega$ which appears in a beta process draw is a dictionary element, with each associated q_k being the probability that a data point uses ω_k. We consider the case $\Omega = \mathbb{R}^P$, and refer to dictionary element k at time t as a column vector, $\boldsymbol{d}_t^k$. The entire dictionary at time t is a matrix denoted $\mathbf{D}_t \equiv [\boldsymbol{d}_t^1, ..., \boldsymbol{d}_t^{k_t}] \in \mathbb{R}^{P\times k_t}$. We may model datapoint i at time t, $\boldsymbol{x}_t^i$, as

$$\boldsymbol{x}_t^i = \mathbf{D}_t(\boldsymbol{s}_t^i \circ \boldsymbol{z}_t^i) + \boldsymbol{\epsilon}_t^i, \tag{3}$$

where $\circ$ represents the Hadamard product, $\boldsymbol{s}_t^i, \boldsymbol{\epsilon}_t^i \in \mathbb{R}^{k_t}$ and $\boldsymbol{z}_t^i \in \{0,1\}^{k_t}$. z_t^{ik} represents whether or not $\boldsymbol{x}_t^i$ uses dictionary element k and is a draw from Bernoulli(q_k). s_t^{ik} determines how much of dictionary element k to use and $\boldsymbol{\epsilon}_t^i$ is simply additive noise.

A natural probabilistic transition function in the case $\Omega = \mathbb{R}^P$, is a Gaussian distribution. We set $\Theta = \mathbb{R}_+^P$ and define $\boldsymbol{\mathcal{T}}_{\boldsymbol{\theta}}(\boldsymbol{d})$ to be a multivariate Gaussian probability density function with mean $\boldsymbol{d}$ and diagonal covariance matrix with diagonal $\boldsymbol{\theta}^{-1}$.

We can generate data from $t = 1, ..., T$, $k = 1, ..., k_t$ and $i = 1, ..., n_t$ as follows,

$$\boldsymbol{\mathcal{D}} = \sum_j \lambda_j \delta_{\boldsymbol{\theta}_j} \sim \mathrm{DP}(\alpha, H), \tag{4}$$

$$\begin{aligned}\mathbf{D}_1, ..., \mathbf{D}_T, \boldsymbol{q}, \boldsymbol{u}_1, ..., \boldsymbol{u}_{T-1}|\boldsymbol{\mathcal{D}} &\sim \mathrm{MBP}(c, B_0, \boldsymbol{\mathcal{D}}, \boldsymbol{\mathcal{T}}, T),\\ z_t^{ik}|q_k &\sim \mathrm{Bernoulli}(q_k),\\ s_t^{ik} &\sim \mathcal{N}(0, \gamma_s^{-1})\\ \boldsymbol{x}_t^i|\mathbf{D}_{\boldsymbol{t}}, \boldsymbol{s}_t^i, \boldsymbol{z}_t^i &\sim \mathcal{N}\big(\mathbf{D}_{\boldsymbol{t}}(\boldsymbol{s}_t^i \circ \boldsymbol{z}_t^i), \gamma_\epsilon^{-1}\mathbf{I}_P\big),\end{aligned}$$

where H is a measure on $\Theta = \mathbb{R}_+^P$ which is the product of P Gamma measures of the form Gamma$(1, P)$ on each component and B_0 is a multivariate Gaussian measure of the form $\mathcal{N}\big(\mathbf{0}, \frac{1}{P}\mathbf{I}\big)$. We place Gamma priors on γ_s and γ_ϵ.

4.1 INFERENCE

We train the model based on a collapsed Gibbs based MCMC scheme, where the probabilities q_k are marginalized out. The update equations are summarized below.

Update $\mathbf{D}_t$. The posterior density for $\boldsymbol{d}_t^k$ is

$$\begin{aligned}p(\boldsymbol{d}_t^k|-) \sim \exp\Big(&-\frac{1}{2}\sum_{p=1}^{P}\theta_{u_{t-1}^k,p}\big(d_{t,p}^k - d_{t-1,p}^k\big)^2\\ &-\frac{1}{2}\sum_{p=1}^{P}\theta_{u_t^k,p}\big(d_{t+1}^k - d_t^k\big)^2\\ &-\frac{\gamma_\epsilon}{2}\sum_{i=1}^{N}\big\|\boldsymbol{\psi}_t^{i,-k} - \boldsymbol{d}_t^k(s_t^{i,k}z_t^{i,k})\big\|^2\Big)\end{aligned}$$

where $\boldsymbol{\psi}_t^{i,-k} = \boldsymbol{x}_t^i - \sum_{k' \neq k} s_t^{ik} z_t^{ik} \boldsymbol{d}_t^k$.
Hence $\boldsymbol{d}_t^k|- \sim \mathcal{N}(\boldsymbol{\phi}, \boldsymbol{\Phi})$, where

$$\boldsymbol{\Phi} = \Big(\operatorname{diag}\Big(\boldsymbol{\theta}_{u_{t-1}^k} + \boldsymbol{\theta}_{u_t^k}\Big) + \gamma_\epsilon \sum_{i: z_t^{i,k}=1} {s_t^{i,k}}^2 \Big)^{-1} \mathbf{I}_P$$

$$\boldsymbol{\phi} = \boldsymbol{\Phi} \Big(\operatorname{diag}\Big(\boldsymbol{\theta}_{u_{t-1}^k}\Big) \boldsymbol{d}_{t-1}^k + \operatorname{diag}\Big(\boldsymbol{\theta}_{u_t^k}\Big) \boldsymbol{d}_{t+1}^k + \gamma_\epsilon \sum_{i: z_t^{i,k}=1} s_t^{i,k} \boldsymbol{\psi}_t^{i,-k} \Big)$$

Update u_t^k. The posterior density for $\boldsymbol{u}_t^k$ is

$$p(\boldsymbol{u}_t^k = j|-) \propto \lambda_j \prod_{p=1}^{P} \Big[\sqrt{\theta_{j,p}} \exp\Big(-\frac{1}{2} \theta_{j,p} {\delta_{t,p}^k}^2 \Big) \Big]$$

where $\delta_{t,p}^k = \big(d_{t+1,p}^k - d_{t,p}^k\big)$, a multinomial distribution.

Update $z_t^{i,k}$. The posterior odds of $z_t^{i,k}$ is

$$\frac{p(z_t^{i,k}=1|-)}{p(z_t^{i,k}=0|-)} = \frac{\exp\Big(-\frac{\gamma_\epsilon}{2} \big\| \boldsymbol{\psi}_t^{i,-k} - s_t^{i,k} \boldsymbol{d}_t^k \big\|^2 \Big) \pi_t^{i,k}}{\exp\Big(-\frac{\gamma_\epsilon}{2} \big\| \boldsymbol{\psi}_t^{i,-k} \big\|^2 \Big) (1 - \pi_t^{i,k})},$$

where

$$\pi_t^{i,k} = \frac{\sum_{s=1}^{T} \sum_{j=1}^{k_s} z_s^{i,j} - z_t^{i,k}}{c + \sum_{s=1}^{T} n_s - 1}.$$

Update $s_t^{i,k}$. The posterior density for $s_t^{i,k}$ is

$$p(s_t^{i,k}|-) \propto \exp\Big(-\frac{\gamma_\epsilon}{2} \big\| \boldsymbol{\psi}_t^{i,-k} - s_t^{i,k} \boldsymbol{d}_t^k \big\|^2 - \frac{\gamma_s}{2} {s_t^{i,k}}^2 \Big),$$

hence $s_t^{i,k} \sim \mathcal{N}(\varphi, \kappa)$, where

$$\kappa = \Big(\gamma_\epsilon {\boldsymbol{d}_t^k}^\top \boldsymbol{d}_t^k + \gamma_s \Big)^{-1}$$
$$\varphi = \kappa \Big(\gamma_\epsilon {\boldsymbol{d}_t^k}^\top \boldsymbol{\psi}_t^{i,-k} \Big).$$

Update $\boldsymbol{\lambda}$. The posterior distribution of $\boldsymbol{\lambda}$ is

$$p(\boldsymbol{\lambda}|-) \propto \prod_j {\lambda_j}^{\alpha + \sum_{s=t}^{T-1} \sum_{k=1}^{k_s} \mathbb{I}[u_t^k = j] - 1}.$$

Update $\boldsymbol{\theta}_j$. The posterior distribution of $\boldsymbol{\theta}_j$ is

$$p(\boldsymbol{\theta}_j|-) \propto \exp\Big(-\frac{P}{2} {\boldsymbol{\theta}_j}^\top \boldsymbol{\theta}_j - \frac{1}{2} \sum_{t=1}^{T-1} \sum_{k=1}^{k_t} \mathbb{I}[u_t^k = j] {\boldsymbol{\theta}_j}^\top \big(\boldsymbol{\delta}_t^k \circ \boldsymbol{\delta}_t^k \big) \Big),$$

hence $\boldsymbol{\theta}_j|- \sim \mathcal{N}\big(\boldsymbol{\varsigma}_j, \frac{1}{P}\mathbf{I}\big)$, where

$$\boldsymbol{\varsigma}_j = \frac{1}{2P} \sum_{t=1}^{T-1} \sum_{k=1}^{k_t} \mathbb{I}[u_t^k = j] \big(\boldsymbol{\delta}_t^k \circ \boldsymbol{\delta}_t^k \big).$$

5 EXPERIMENTS

In this section we describe the findings of various experiments we performed using Markov beta processes to induce a chain of evolving latent features. We investigated two tasks, the problem of denoising and inpainting a sequence of images and time evoloving gene expression data. First we try to answer various questions with synthetic experiments.

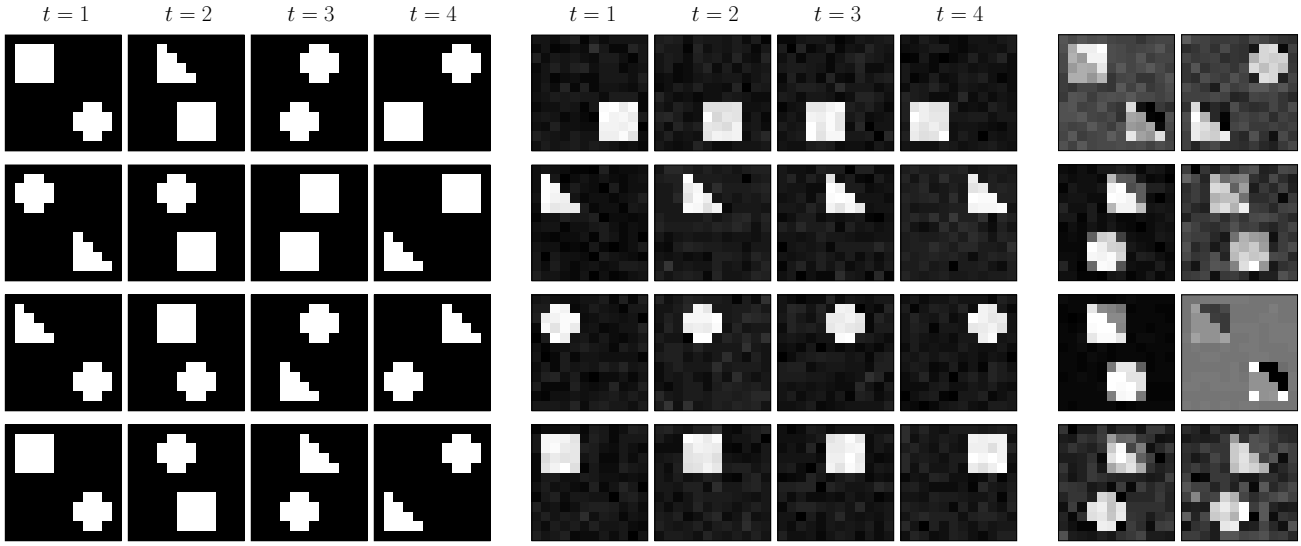
5.1 SYNTHETIC EXPERIMENTS

A key quesion we set out to address in this work is 'are Markov evolving features more useful for multiple sequence modeling than Markov evolving feature probabilities?' When there are no clear task specific reasons to choose one approach over the other, one would want to choose the framework that is generally more reliable to make useful predictions. Setting $N = 500, D = 40, K = 50$, we generated Synth-MBP from the MBP prior, and Synth-DRIFT from the DRIFT model. The MBP, DRIFT and BP models were trained on these datasets with 10% of the points randomly chosen and held out for prediction. Table 1 summarizes the test mean squared errors of predicitons of the three models.

We initialize features using random subsets of the observable data and use a k-means initialization for the clustering of the feature transitions for the MBP model. The Z and S matrices are subsequently initialized with a linear least squares estimate given the features. The same approach is used in all subsequent experiments.

Both the MBP and DRIFT models outperform the BP model, suggesting that each of them are able to learn some level of temporal structure, as we would have liked. However, it is interesting to see that the MBP model's outperformance versus the DRIFT model on Synth-MBP is much larger than the DRIFT model's outperformance versus the MBP model on Synth-DRIFT. The Dirichlet process transition process between features appears to be responsible for the MBP's predictive power on the DRIFT-Synth data set. We replaced the DP with a single Gaussian transition function for all features, and found the mean squared errors dropped to 2.04 and 2.11 on MBP-Synth and DRIFT-Synth respectively.

The fact that we are able to utilize a flexible DP based transition function using a collapsed Gibbs sampler which mixes fast is key to the high performance of the MBP model. Inference in models with complicated dependencies between binary feature usage variables is more difficult. Our MBP model is useful because of the efficient Gibbs based sampler we are able to derive



(a) Synthetic data (b) Time-evolving features learned by MBP (c) DRIFT features

Figure 2: Synthetic image data experimental results. (a) Each row represents an image sequence used for the synthetic image experiment. (b) Time-evolving features learned by the MBP model. (c) Stationary features learned by the DRIFT model.

Table 1: Mean-squared error results of prediction on synthetic datasets using MBP, DRIFT and BP models, with standard deviation of multiple runs in brackets.

	MBP	DRIFT	BP
SYNTH-MBP	**1.03 (0.04)**	2.16 (0.08)	2.84 (0.10)
SYNTH-DRIFT	1.66 (0.05)	**1.37 (0.07)**	2.45 (0.09)

for modeling expressive transitions between features.

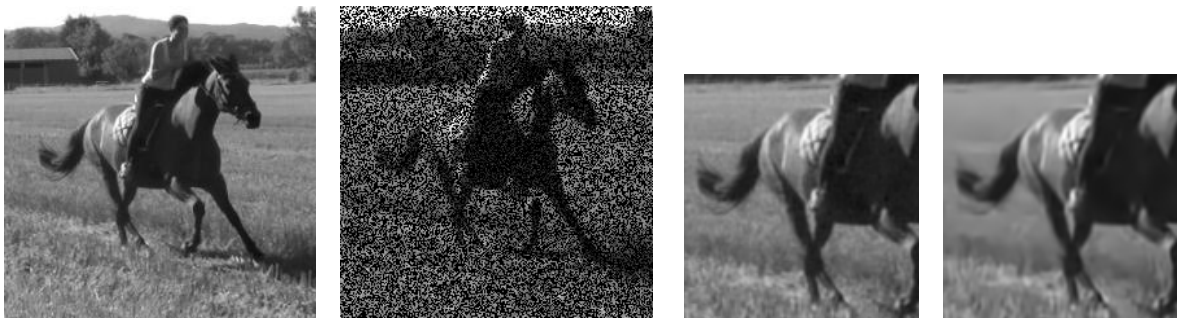
5.2 IMAGE DENOISING AND INPAINTING

Sequences of grayscale images were considered for this task, but our method easily extends to color image sequences. The baseline model we compare our model to, is the beta process model of Zhou et al. [2009], modeling each image within the sequence independently. We implement the Foulds et al. [2011] model to assess the benefit of time-evolving feature usage versus time-evolving features and finally, we consider the dHBP [Zhou et al., 2011], which is designed to exploit intra-image dependencies. Inference in the dIBP [Williamson et al., 2010] unfortunately scales in N^3 which is prohibitive for this task.

Consider a sequence of T images of size $Q_x \times Q_y$. We model overlapping patches of size 8×8 as individual data points, giving a total of $N = (Q_x - 7) \times (Q_y - 7)$ data points, each with dimension $D = 8$. Whilst this breaks the exchangeability assumption of the prior, we benefit from model averaging, as each final pixel estimate is in fact an average of the estimates of 64 patches (except for near edge pixels).

Our first experiment involved synthetically generated data of the form shown in Figure 2a. We formed $N = 500$ sequences of images of size 12×12. In each sequence, we observe shapes traverse left to right in the top half of the images and other shapes traverse right to left. We trained both the MBP and the DRIFT models on this dataset using $K = 75$ features. The MBP was able to learn interesting structure amongst features as can be seen in Figure 2b. The model was able to identify the individual shapes which traversed left and right across the image over time. Since the DRIFT model uses a stationary set of features, it tended to learn features as noisy compositions of various data points 2c, not exhibiting the more elegant structure we found amongst the MBP features.

Notice that the shapes in the synthetic sequences often switch from frame to frame; squares become triangles, crosses become squares, etc. The MBP model is capable of modeling these transitions because whilst feature probabilities are stationary, actual feature usage between time points is conditionally independent given the feature probabilies. (More succinctly, $z_{ik}^t \perp\!\!\!\perp z_{ik}^{t'} | \pi_k$ for $t \neq t'$.) On average, the DP transition function of the MBP model used 16 clusters for the synthetic image data. This was somewhat crucial in being able to learn the time-evolving features we see in Figure 2b.



(a) (b) (c) (d)

Figure 3: Image sequence experiment on horse data. (a) Image 6 of the sequence. (b) Image with 50% of pixels omitted at random with pixels corrupted with Gaussian noise. Zoomed reconstructions of (c) MBP and (d) dHBP models.

We ran an experiment restricting the MBP model to have a single transition function, and noticed that the model learned features more similar to those learned by the DRIFT model.

We test the methods on four black and white image sequences: (i) 8 frames of size 241×241 of a lady riding a horse in a field [Ochs et al., 2014], (ii) 8 frames of size 192×256 with a set of mountains being panned about a fixed axis [Porzi et al., 2014], (iii) 8 frames of size 120×216 of a rabbit leaping across a living room [Ochs et al., 2014], and (iv) 10 frames of size 60×64 of a hand holding a bowl and rotating it [Wang, 1997].

Pixels in these datasets take integer values in $[0, 255]$. We added Gaussian noise with standard deviation 15 independently to each pixel. For each image sequence, we sample a binary matrix, Σ, of size $Q_x \times Q_y$, where each entry is an independent Bernoulli sample. Σ indicates which pixels are used for training by each algorithm for each image sequence. A typical evaluation metric for image reconstruction is the peak signal-to-noise ratio (PSNR), defined as

$$\text{MSE} = \sum_{t=1}^{T} \sum_{q_x=1}^{Q_x} \sum_{q_y=1}^{Q_y} \frac{\left(\mathbf{\Pi}_t(q_x, q_y) - \hat{\mathbf{\Pi}}_t(q_x, q_y)\right)^2}{TQ_xQ_y}$$

$$\text{PSNR} = 10 \log_{10} \left(\frac{255^2}{\text{MSE}} \right), \tag{5}$$

where $\mathbf{\Pi}_t$ is the original $Q_x \times Q_y$ image at time t and $\hat{\mathbf{\Pi}}_t$ is the estimate of this image. We allow the samplers to burn-in for 2000 iterations, and then use 500 Gibbs samples for predictions, using $K = 250$ features.

The experiments on each set of image sequences were repeated using 20%, 30% and 50% of the pixels chosen uniformly at random for training, the results are summarized in Table 2. The MBP approach tends to outperform other methods consistently, in particular the DRIFT model which does encode time evolving feature usage. The dHBP model, designed particularly for the task of image denoising and inpainting does well on most sequence tasks without modeling temporal dependencies, but on the whole does not perform as well as the MBP. The MBP does not model the intra-image dependencies, and we believe that combining the temporal modeling of the MBP with the intra-image dependencies of the dHBP would lead to a highly sophisticated image sequence denoising and inpainting framework. Since our focus in this paper is on the MBP model and not the specific task of image sequence analysis, we leave the combined model idea to future work.

Figure 3 illustrates a situation where the dHBP performs worse than the MBP. The dHBP model uses patches which are close in Euclidean distances to use similar sets of features. A consequence of this property, is that the area of the image under the body of the horse, appears to have a uniform color. This is likely because the bottom section of the horse body also has uniform color. Conversely the MBP model is better able to learn features which are separate for the horse body and the background grass, leading to a clearer reconstruction. The tail in the dHBP reconstruction also exhibits more smoothing and less detail than that of the MBP.

5.3 GENE EXPRESSION DATA

Time-course gene expression data are often measured to study dynamic biological systems and gene-regulatory networks. Vast amounts of biological data are being collected as technology in the field advances. This is a setting where the number of time points may be small, but the dimension of the data is large (potentially of the order of 10s of 1000s). Sparse methods have been successful in modeling genetic data [Carvalho et al., 2008, Knowles and Ghahramani, 2011],

Table 2: Results of gray-scale image sequence denoising and interpolation (PSNR) for BP, dHBP, DRIFT and MBP, using patch size 8×8, varying the ratio of observed pixels. Image pixels have Gaussian white noise (standard deviation 15).

Ratio		Horse	Mountains	Rabbit	Hand
20%	BP	25.32	27.68	24.46	30.22
	dHBP	26.21	28.91	25.43	31.58
	DRIFT	26.04	28.23	24.85	30.74
	MBP	**26.81**	**29.09**	**25.61**	**31.62**
30%	BP	26.58	28.85	25.52	31.43
	dHBP	27.09	29.78	26.03	**32.56**
	DRIFT	27.02	29.34	25.94	31.96
	MBP	**27.47**	**29.94**	**26.54**	32.51
50%	BP	27.45	29.95	26.38	32.64
	dHBP	28.09	30.55	26.84	**33.28**
	DRIFT	28.14	30.50	26.82	33.19
	MBP	**28.38**	**30.66**	**26.92**	33.22

and subsequently, using the MBP to model time-evolving gene data seems an appropriate extension. Comparisons between the MBP, DRIFT, BP and dIBP models are made. We consider 2 datasets, discarding 2000 samples to allow the Markov chains to burn-in and using the following 500 samples for prediction, and using $K = 500$ features.

Yeast cell cycle Spellman et al. [1998] measured the genome-wide mRNA levels for 6108 genes during 2 cell cycles over $T = 17$ time points. We consider $N = 2$ strands, cdc15 and cdc28 and randomly pick $D = 1000$ genes randomly from the ones which have no missing data.

Transcriptome alterations in mice This dataset, collected by Piechota et al. [2010], consists of readings from 46632 proteins collected from mice brains under the infuence of 1 of $N = 8$ types of drugs over $T = 4$ time points. We select a random subset of $D = 1000$ proteins for our experiments.

In each of the experiments we hold out 15% of the data points uniformly at random for prediction. Results of the experiments on the 2 gene data sets are summarized in Table 3. The dIBP performs best on the yeast cell cycle data set, as the Gaussian process draws controlling feature usage over time are best able to pick up the periodic nature of the cell cycle sequence data. However, the MBP is not far off the accuracy of the dIBP here. The MBP outperforms other methods on the mice transcriptome data set, which has fewer time points. The DP in the MBP inference procedure used an average of 82 transition functions after burn-in. Note that the total number of transitions is $K \times (T-1) = 1500$, and hence 82 clusters is perfectly reasonable. In the yeast cell cycle task, we have $K \times (T-1) = 8000$ feature transitions, which is very large, and illustrates to some extent the requirement for highly flexible mixture model of transition functions, such as the Dirichlet process mixture we employ.

Table 3: Mean-squared error results of prediction on gene datasets using MBP, DRIFT, BP and dIBP.

	MBP	DRIFT	BP	dIBP
Yeast	0.92	1.06	1.63	**0.88**
Mice	**1.12**	1.42	1.67	1.28

6 CONCLUSIONS

In this work, we construct a Markov chain of beta processes for use as a model for learning time evolving sparse latent representations. Particularly we exploit the property that the beta process is a type of Poisson process. This enables us to invoke well known operations, which when applied to a Poisson process draw keep the object marginally Poisson process distributed. Having marginal beta process objects crucially allows us to develop a simple and fast mixing Gibbs sampler. To illustrate the power of our model and inference scheme, we considered image denoising and inpainting tasks and gene expression data, showing superior performance over other beta process related models. The high flexibility of our model leads to a potential drawback when modelling long time series. Inference may become prohibitively slow as the time series are made longer, and to compromise, it may be necessary to replace the DP based transition function with a small fixed mixture of Gaussians.

Most machine learning problems involve constructing an appropriate model and then developing an inference scheme to train the model and use it for prediction. Whilst Bayesian nonparametrics make it simple to write down a model, the inference often requires a complicated and slow procedure which significantly can reduce its applicability to real problems. We hope is that our exploitation of Poisson process preserving operations and conjugacy encourages further investigation in how one can develop flexible nonparametric Bayesian models which are amenable to elegant inference techniques, by exploiting interesting and well grounded mathematical concepts.

Abstract

Anomaly detection is a fundamental problem for which a wide variety of algorithms have been developed. However, compared to supervised learning, there has been very little work aimed at understanding the sample complexity of anomaly detection. In this paper, we take a step in this direction by introducing a Probably Approximately Correct (PAC) framework for anomaly detection based on the identification of rare patterns. In analogy with the PAC framework for supervised learning, we develop sample complexity results that relate the complexity of the pattern space to the data requirements needed for PAC guarantees. We instantiate the general result for a number of pattern spaces, some of which are implicit in current state-of-the-art anomaly detectors. Finally, we design a new simple anomaly detection algorithm motivated by our analysis and show experimentally on several benchmark problems that it is competitive with a state-of-the-art detector using the same pattern space.

1 INTRODUCTION

The problem of (unsupervised) anomaly detection is to identify anomalies in (unlabeled) data, where an anomaly is a data point that is generated by a process that is distinct from the process that generates "normal" points. This problem arises in a large number of applications, from security to data cleaning, and there have been many approaches proposed in the literature [4, 8]. While most applications seek to identify semantically-interesting anomalies, it is typically not possible to predefine a functional notion of semantic interestingness. Instead, the vast majority of anomaly detectors use a surrogate measure of interestingness. For example, a point may be interesting if it is a statistical outlier or if it is far away from other data points. The performance of a given detector in a domain depends on how well it can optimize the statistical measure and on how well that measure aligns with the behavior of anomalies in the application domain.

For moderately high-dimensional data, all data points become far apart from each other, so they are all statistical outliers in a sense. This suggests that anomaly detection by identifying outliers or distant points should perform poorly and degrade to random selection as the dimensionality grows. Empirical results, however, have shown that state-of-the-art anomaly detectors often perform quite well [7] even for high-dimensional data. Further, these detectors tend to reach their peak performance with a relatively small amount of training data compared to what might be expected based on the dimensionality. The primary goal of this paper is to move toward an understanding of these empirical observations by analyzing the sample complexity of a certain class of anomaly detectors.

The sample complexity of supervised learning has been widely studied and is quite well understood via the framework of Probably Approximately Correct (PAC) learning. However, this is not the case for anomaly detection, where virtually all published work has focused on algorithms with good empirical performance (with additional attention to computational speed, especially on big data sets). A key step in the development of PAC learning theory was to formalize the notion of a hypothesis space and to quantify the relationship between the complexity of this space and the amount of training data required to identify a good hypothesis in the space. In this paper, we follow a similar approach. Our framework is motivated by the observation that many state-of-the-art anomaly detectors can be viewed as monitoring the probabilities of certain "patterns" in the data, where a "pattern" is a subset (typically closed and compact) of the feature space. Outliers are then identified based on measures of those probabilities, where points are ranked as more anomalous if they satisfy lower-probability patterns. For example, the highly-competitive anomaly detection algorithm, Isolation Forest [10], finds outliers by monitoring probabilities in the pattern space of axis-aligned hyper-rectangles. Section 5 provides additional ex-

amples of the pattern spaces underlying a number of other state-of-the-art detectors. In our analysis, a "pattern" will play the same role as a "hypothesis" in PAC learning, and the pattern space complexity will determine the number of training examples required for high accuracy.

A second key step in the development of PAC theory was to relax the goal of finding the best possible hypothesis. Similarly, we will introduce an error parameter ϵ that determines how accurately the algorithm must estimate the probabilities of the patterns in the pattern space. We will then show that the required sample size scales polynomially in $1/\epsilon$ (as well as in several other parameters).

We call our formulation Rare Pattern Anomaly Detection (RPAD), and an algorithm that provides PAC guarantees will be referred to as a PAC-RPAD algorithm. We prove sample complexity results for any algorithm within the RPAD framework. The framework captures the qualitative essence of many anomaly detection algorithms. Note that we focus exclusively on sample complexity. Experience with the supervised PAC analysis has shown that sample complexity results often give more insight than computational complexity results. Indeed, many computational problems in PAC learning are NP-Hard and yet practical approximate algorithms are known. Similarly, we expect that some of the computational PAC-RPAD problems will also be NP-Hard, but existing algorithms, such as Isolation Forest, already provide practical approximate solutions.

Prior work on one-class SVMs [12] and learning minimum volume sets [13] have also provided sample complexity analysis relevant to anomaly detection. These approaches, however, are fundamentally different than RPAD-style approaches. In particular, these approaches focus on finding a common region/pattern in the input space that capture the normal points. In contrast, our RPAD framework is based on finding rare regions/patterns for directly extracting anomaly characteristics. Anomaly detection benchmarking studies [7] have shown that RPAD-style approaches tend to significantly outperform "common pattern" approaches such as one-class SVM. Our work is the first to analyze the sample complexity of the former approach.

The main contributions of this paper are as follows. First, we present a formal framework for RPAD (Section 2), which leads to the definition of PAC-RPAD (Section 3). Second, we specify a simple generic algorithm, RAREPATTERNDETECT, based on finding rare patterns. We derive sample complexity results for both finite pattern spaces and uncountable spaces of bounded complexity (Section 4). Third, we give a number of applications of the theory to pattern spaces that underly a number of state-of-the-art anomaly detection algorithms (Section 5). This, in part, helps explain why such algorithms consistently perform much better than random in high-dimensional data. Fourth, we measure learning curves on several benchmarks and for pattern spaces of varying complexity for RAREPATTERNDETECT and another state-of-the-art anomaly detector over the same spaces (Section 6). The results show that the RPAD-based algorithm can be competitive with the state-of-the-art and that the detectors' performances converge for surprisingly small training sets.

2 RARE PATTERN ANOMALY DETECTION

We consider anomaly detection over a space of possible data points $\mathcal{X} \subseteq \mathcal{R}^d$, which may be finite or infinite. Data from this space is generated according to an unknown probability density function $\mathcal{P}$ over $\mathcal{X}$. A common assumption in anomaly detection is that $\mathcal{P}$ is a mixture of a normal component, which generates normal data points, and an anomaly component, which generates anomalous data points. Further, it is typically assumed that there is a much higher probability of generating normal data than anomalies. This set of assumptions motivates one approach to anomaly detection, which we call *Anomaly Detection via Outlier Detection*. The idea is to estimate, for each query point x, the density $\mathcal{P}(x)$ based on an (unlabeled) training sample of the data and assign an anomaly score to x proportional to $-\log \mathcal{P}(x)$, the "surprise" of x.

There are many problems with this approach. First, the probability density may not be smooth in the neighborhood of x, so that $\mathcal{P}(x)$ could be very large and yet be surrounded by a region of low or zero density (or vice versa). Second, even under smoothness assumptions, density estimation is very difficult. For example, the integrated squared error of kernel density estimation in d-dimensional space (for a second-order kernel, such as a Gaussian kernel) converges to zero at a rate of $O(N^{-4/(4+d)})$ [14]. It follows that the sample size N required to achieve a target accuracy grows exponentially in the dimension d.

In this paper, we consider an alternative anomaly detection framework, which we will refer to as *Rare Pattern Anomaly Detection (RPAD)*. Informally, the main idea is to judge a point as anomalous if it exhibits a property, or pattern, that is rarely exhibited in data generated by $\mathcal{P}$. For example, in a computer security application, a detector may monitor various behavior patterns associated with processes accessing files. A process that exhibits an access behavior pattern that has been rarely seen would be considered anomalous. One attractive feature of the RPAD framework is that the notion of anomaly is grounded in the estimation of pattern probabilities, rather than point densities. Pattern probability estimation is quite well understood compared to density estimation. A second attractive feature of the RPAD framework is that each detected anomaly comes with an explanation of why it was considered anomalous. Specifically, the explanation can report the rare patterns that the

anomaly satisfies. Explanation methods have been developed for density-estimation approaches (e.g. [15]), but they are less directly tied to the anomaly detection criterion.

Formally, a *pattern* h is a binary function over $\mathcal{X}$. A *pattern space* $\mathcal{H}$ is a set of patterns, which may be finite or infinite. As an example, if $\mathcal{X}$ is a finite space of n-dimensional bit vectors, a corresponding finite pattern space could be all conjunctions of length up to k. As another example, let $\mathcal{X} = [0,1]^n$, the n-dimensional unit cube, and consider the uncountable pattern space of all axis-aligned k-dimensional hyper-rectangles in this cube. In this case, each pattern h is a hyper-rectangle, such that $h(x)$ is true if x falls inside it. The choice of pattern space is an important consideration in the RPAD framework, since, in large part, this choice controls the semantic types of anomalies that will be detected.

Each pattern $h \in \mathcal{H}$ has a probability $P(h) = \Pr(\{x : h(x) = 1\})$ of being satisfied by data points generated according to $\mathcal{P}$. It will be useful to specify the set of all patterns in $\mathcal{H}$ that a point x satisfies, which we will denote by $\mathcal{H}[x] = \{h \in \mathcal{H} : h(x) = 1\}$. One approach to RPAD is to declare x to be anomalous if there is a pattern $h \in \mathcal{H}[x]$, such that $P(h) \leq \tau$. This approach is sensible when all patterns are approximately of the same "complexity". However, when $\mathcal{H}$ contains a mix of simple and complex patterns, this approach can be problematic. In particular, more complex patterns are inherently less likely to be satisfied by data points than simpler patterns, which makes choosing a single threshold τ difficult. For this reason, we introduced the *normalized pattern probability* $f(h) = P(h)/U(h)$, where $U(h)$ is the probability of h being satisfied according to a *reference density* U over $\mathcal{X}$. When $\mathcal{X}$ is bounded, we typically take U to be a uniform density function. Thus, a small value of $f(h)$ indicates that under $\mathcal{P}$, h is significantly more rare than it would be by chance, which provides a better-calibrated notion of rareness compared to only considering $\mathcal{P}(h)$. If $\mathcal{X}$ is unbounded, then an appropriate maximum entropy distribution (e.g., Gaussian) can be chosen.

We can now define the notion of anomaly under the RPAD framework. We say that a pattern h is *τ-rare* if $f(h) \leq \tau$, where τ is a detection threshold specified by the user. A data point x is a *τ-outlier* if there exists a τ-rare h in $\mathcal{H}[x]$ and otherwise x is said to be τ-common. Given τ and a stream of data drawn from $\mathcal{P}$, an optimal detector within the RPAD framework should detect all τ-outlier points and reject all τ-common points. That is, we want to detect any point that satisfies a τ-rare pattern and otherwise reject. An anomaly detector will make its decisions based on some finite amount of sampled data, and we expect that the performance should improve as the amount of data grows. Further, in analogy to supervised learning, we would expect that the amount of data required to achieve a certain level of performance should increase as the complexity of the pattern space increases. We now introduce a formal framework for making these intuitions more precise.

3 PROBABLY APPROXIMATELY CORRECT FRAMEWORK

To address the sample complexity of RPAD, we consider a learning protocol that makes the notion of training data explicit. The protocol first draws a training data set $\mathcal{D}$ of N i.i.d. data points from $\mathcal{P}$. An anomaly detector is provided with $\mathcal{D}$ along with a test instance x that may or may not be drawn from $\mathcal{P}$. The anomaly detector then outputs "detect" if the instance is considered to be an anomaly or "reject" otherwise. Note that the output of a detector is a random variable due to the randomness of $\mathcal{D}$ and any randomization in the algorithm itself. This protocol models a common use case in many applications of anomaly detection. For example, in a computer security application, data from normal system operation will typically be collected and provided to an anomaly detector before it is activated.

The *ideal* correctness criterion requires that the test instance x be detected if it is a τ-outlier and rejected otherwise. However, as we discussed above, this notion of correctness is too strict for the purpose of sample complexity analysis. In particular, such a criterion requires distinguishing between pattern probabilities that fall arbitrarily close to each side of the detection threshold τ, which can require arbitrarily large training samples. For this reason, we relax the correctness criterion by introducing a *tolerance parameter* $\epsilon > 0$. The detector is said to be approximately correct at level ϵ if it detects all τ-rare points and rejects all $(\tau+\epsilon)$-common points. For test points that are neither τ-rare nor $(\tau+\epsilon)$-common, the detector output can be arbitrary. The value of ϵ controls the false positive rate of the detector, where smaller values of ϵ will result in fewer false positives relative to the detection threshold.

We now define the PAC learning objective for RPAD. A detection algorithm will be considered PAC-RPAD if with high-probability over draws of the training data it produces an approximately correct output for any $x \in \mathcal{X}$.

Definition 1. *(PAC-RPAD) Let $\mathcal{A}$ be a detection algorithm over pattern space $\mathcal{H}$ with input parameters $0 < \delta < 1$, $0 < \tau$, $0 < \epsilon$, and the ability to draw a training set $\mathcal{D}$ of any size N from $\mathcal{P}$. $\mathcal{A}$ is a PAC-RPAD algorithm if for any $\mathcal{P}$ and any τ, with probability at least $1-\delta$ (over draws of $\mathcal{D}$), $\mathcal{A}$ detects all τ-outliers and rejects all $(\tau+\epsilon)$-commons.*

The *sample complexity* of a PAC-RPAD algorithm for $\mathcal{H}$ is a function of the inputs $N(\delta, \epsilon)$ that specifies the number of training examples to draw. We expect that the sample complexity will increase as the complexity of $\mathcal{H}$ increase, as the dimensionality d of points increases, and as the failure probability δ decreases. Further, we expect that the sample complexity will increase for smaller values of the

tolerance parameter ϵ, since this controls the difficultly of distinguishing between τ-rare and $(\tau+\epsilon)$-common data points. Accordingly we say that a PAC-RPAD algorithm is *sample efficient* if its sample complexity is polynomial in d, $\frac{1}{\delta}$, and $\frac{1}{\epsilon}$.

4 FINITE SAMPLE COMPLEXITY OF RPAD

We now consider a very simple algorithm, called RAREPATTERNDETECT, which will be shown to be a sample efficient PAC-RPAD algorithm for bounded complexity pattern spaces. The algorithm is given in Table 1 and first draws a training set $\mathcal{D}$ of size $N(\delta,\epsilon)$. Here $N(\delta,\epsilon)$ will depend on the pattern space complexity and will be specified later in this section. The training set is used to estimate the normalized pattern probabilities given by

$$\widehat{f}(h) = \frac{1}{|D|\cdot U(h)}|\{x\in\mathcal{D} : h(x)=1\}|.$$

Here, we assume that $U(h)$ can be computed analytically or at least closely approximated. For example, when U is uniform over a bounded space, $U(h)$ is proportional to the volume of h.

After drawing the training set, RAREPATTERNDETECT specifies a decision rule that detects any x as anomalous if and only if it satisfies a pattern with estimated frequency less than or equal $\tau+\epsilon/2$. This test is done using the subroutine HASRAREPATTERN$(x,\mathcal{D},\mathcal{H},\mu)$, which returns true if there exists a pattern h in $\mathcal{H}[x]$ such that $\widehat{f}(h)\leq\mu$. For the purposes of sample complexity analysis, we will assume an oracle for HASRAREPATTERN. For sufficiently complex pattern spaces, the problem addressed by HASRAREPATTERN will be computational hard. Thus, in practice, a heuristic approximation will be needed, for example, based on techniques developed in the rare pattern mining literature. In practice, we are often interested in having an anomaly detector return an anomaly ranking over multiple test data points. In this case, the algorithm can rank a data point x based on a score equal to the minimum normalized frequency of any pattern that it satisfies, that is, score$(x) = \min\{\widehat{f}(h) : h\in\mathcal{H}[x]\}$. It remains to specify $N(\delta,\epsilon)$ in order to ensure that RAREPATTERNDETECT is PAC-RPAD. Below we do this for two cases: 1) finite pattern spaces, and 2) pattern spaces with bounded VC-dimension. Later, in Section 5 we will instantiate these results for specific pattern spaces that underly several existing anomaly detection algorithms.

4.1 SAMPLE COMPLEXITY FOR FINITE $\mathcal{H}$

For finite pattern spaces, it is relatively straightforward to show that as long as $\log|\mathcal{H}|$ is polynomial in d then RAREPATTERNDETECT is a sample efficient PAC-RPAD algorithm.

Table 1: RAREPATTERNDETECT Algorithm

Input: δ, τ, ϵ

1. Draw a training set $\mathcal{D}$ of $N(\delta,\epsilon)$ instances from $\mathcal{P}$.
2. **Decision Rule for any x:**
   If HASRAREPATTERN$(x,\mathcal{D},\mathcal{H},\tau+\epsilon/2)$ then return "detect", otherwise return "reject".

HASRAREPATTERN$(x,\mathcal{D},\mathcal{H},\mu)$
$:= \{h\in\mathcal{H}[x] : \widehat{f}(h)\leq\mu\}\neq\emptyset$

Theorem 1. *For any finite pattern space $\mathcal{H}$,* RAREPATTERNDETECT *is PAC-RPAD with sample complexity* $N(\delta,\epsilon) = O\left(\frac{1}{\epsilon^2}\left(\log|\mathcal{H}| + \log\frac{1}{\delta}\right)\right)$.

Proof. Suppose, X is a Bernoulli random variable with parameter $P(h)$ for a pattern h, i.e., $E[X]=P(h)$. Let, $Y=\frac{X}{U(h)}$, hence, Y is a random variable with $E[Y]=\frac{E[X]}{U(h)}=\frac{P(h)}{U(h)}=f(h)$. We also observe that the maximum value of Y is $\frac{1}{U(h)}$. Given N samples $x_1,x_2,...,x_N$, each $x_i\sim\mathcal{P}$, we estimate $\widehat{f}(h)=\frac{1}{N}\sum_{i=1}^{N}\frac{\mathcal{I}[x_i\in h]}{U(h)}$. We seek a confidence interval $[L(h),R(h)]$ for $f(h)$ that is narrow enough that it does not simultaneously contain both τ and $\tau+\epsilon$. The reason is that if $L(h)>\tau$, then with probability $1-\delta$, $f(h)>\tau$, so h is not a τ-rare pattern. If $R(h)<\tau+\epsilon$, then with probability $1-\delta$, h is not a $\tau+\epsilon$-common pattern, so it is safe to treat it as τ-rare. Hence, the confidence interval should be $[\widehat{f}(h)-\epsilon/2, \widehat{f}(h)+\epsilon/2]$, and its "half width" is $\epsilon/2$. So, we want to bound (by δ) the probability that $\widehat{f}(h)$ is more than $\frac{\epsilon}{2}$ away from its true value $f(h)$. Now, using the Hoeffding bound we have

$$\begin{aligned}
&P\left(|E_{\mathcal{P}}[\widehat{f}(h)]-\widehat{f}(h)|>\frac{\epsilon}{2}\right)\\
\iff\ &P\left(\left|f(h)-\frac{1}{N}\sum_{i=1}^{N}\frac{\mathcal{I}[x_i\in h]}{U(h)}\right|>\frac{\epsilon}{2}\right)\\
&\leq 2\exp\left(-\frac{\epsilon^2}{2}U(h)^2N\right).
\end{aligned}$$

Since $\mathcal{H}$ is finite, we can bound the above probability for all $h\in\mathcal{H}$ using the union bound: $2|\mathcal{H}|\exp\left(-\frac{\epsilon^2}{2}U_{min}^2N\right)$, where, $U_{min}=\min_{h\in\mathcal{H}}U(h)$. We want this quantity to be less or equal to δ:

$$\begin{aligned}
&2|\mathcal{H}|\exp\left(-\frac{\epsilon^2}{2}U_{min}^2N\right)\leq\delta\\
\implies\ &N\geq\frac{2}{\epsilon^2}\frac{1}{U_{min}^2}\log\frac{2|\mathcal{H}|}{\delta}.
\end{aligned}$$

Hence, the sample complexity is $O\left(\frac{1}{\epsilon^2}\left(\log|\mathcal{H}|+\log\frac{1}{\delta}\right)\right)$. □

4.2 SAMPLE COMPLEXITY FOR INFINITE $\mathcal{H}$

When the sample space $\mathcal{X}$ is continuous, it is typically the case that the corresponding pattern space will be infinite and hence not covered by the above result. As is standard in supervised learning, we will characterize the complexity of infinite pattern spaces via the VC-dimension [17], which we denote by $\mathcal{V}_\mathcal{H}$. The VC-dimension of $\mathcal{H}$ is equal to the maximum number of points that can be shattered by patterns in $\mathcal{H}$. Here a set of points D is shattered by $\mathcal{H}$ if for any subset D' of D there is an $h \in \mathcal{H}$ such that $h(x) = 1$ for all $x \in D'$ and $h(x) = 0$ for all $x \in D - D'$. That is, patterns in $\mathcal{H}$ can be used to define all possible bi-partitions of D. For many interesting pattern spaces, the VC-dimension scales polynomially with the data dimension d. The following result exploits this property by showing that if a space has VC-dimension that is polynomial in d, then the space is sample-efficient learnable in the PAC-RPAD model.

Theorem 2. *For any pattern space $\mathcal{H}$ with finite VC-dimension $\mathcal{V}_\mathcal{H}$,* RAREPATTERNDETECT *is PAC-RPAD with sample complexity* $N(\delta, \epsilon) = O\left(\frac{1}{\epsilon^2}\left(\mathcal{V}_\mathcal{H} \log \frac{1}{\epsilon^2} + \log \frac{1}{\delta}\right)\right)$.

Proof. When the pattern space $\mathcal{H}$ is infinite, we want to bound the probability $P\left(\sup_{h\in\mathcal{H}} |\widehat{f}(h) - f(h)| > \frac{\epsilon}{2}\right)$, which can be achieved by bounding $P\left(\sup_{h\in\mathcal{H}} |\widehat{P}(h) - P(h)| > \frac{\epsilon}{2} U_{min}\right)$, where, $\widehat{P}(h)$ is an estimate of $P(h)$ based on sampled data. Let, $\epsilon_f = \frac{\epsilon}{2} U_{min}$. Using the VC uniform convergence bound on frequency estimates [6, Thm. 12.5] we have

$$P\left(\sup_{h\in\mathcal{H}} |\widehat{P}(h) - P(h)| > \epsilon_f\right) \leq 8\mathcal{S}_\mathcal{H}(N) e^{-N\epsilon_f^2/32}. \quad (1)$$

where, $\widehat{P}(h)$ is an estimate based on N i.i.d. samples from $\mathcal{P}$ and $\mathcal{S}_\mathcal{H}(N)$ is the Shatter Coefficient, which is the largest number of subsets that can be formed by intersecting some set of N points with patterns from $\mathcal{H}$.

Now, for any $N > 2\mathcal{V}_\mathcal{H}$, we can bound the Shatter Coefficient as: $\mathcal{S}_\mathcal{H}(N) < (\frac{eN}{\mathcal{V}_\mathcal{H}})^{\mathcal{V}_\mathcal{H}}$ [6, Thm. 13.3]. Hence, from Equation 1 we have

$$P\left(\sup_{h\in\mathcal{H}} |\widehat{P}(h) - P(h)| > \epsilon_f\right) < 8(\frac{eN}{\mathcal{V}_\mathcal{H}})^{\mathcal{V}_\mathcal{H}} e^{-N\epsilon_f^2/32}. \quad (2)$$

We want to bound this probability by δ, which yields

$$N \geq \frac{32}{\epsilon_f^2}\left(\mathcal{V}_\mathcal{H} \log(N) + \mathcal{V}_\mathcal{H} \log \frac{e}{\mathcal{V}_\mathcal{H}} + \log \frac{8}{\delta}\right). \quad (3)$$

Using the fact that $\log(N) \leq \alpha N - \log(\alpha) - 1$, where, $N, \alpha > 0$ and setting $\alpha = \frac{\epsilon_f^2}{64\mathcal{V}_\mathcal{H}}$, we get

$$\begin{aligned}\frac{32\mathcal{V}_\mathcal{H}}{\epsilon_f^2} \log(N) &\leq \frac{32\mathcal{V}_\mathcal{H}}{\epsilon_f^2}\left(\frac{\epsilon_f^2}{64\mathcal{V}_\mathcal{H}} N - \log \frac{\epsilon_f^2}{64\mathcal{V}_\mathcal{H}} - 1\right) \\ &= \frac{N}{2} + \frac{32\mathcal{V}_\mathcal{H}}{\epsilon_f^2} \log \frac{64\mathcal{V}_\mathcal{H}}{\epsilon_f^2 e}. \quad (4)\end{aligned}$$

Applying results from Equation 4 into Equation 3 and substituting the original value of ϵ_f we prove the Theorem 2:

$$N \geq \frac{256}{\epsilon^2} \frac{1}{U_{min}^2}\left(\mathcal{V}_\mathcal{H} \log\left(\frac{256}{\epsilon^2} \frac{1}{U_{min}^2}\right) + \log \frac{8}{\delta}\right).$$

□

5 APPLICATION TO SPECIFIC PATTERN SPACES

Most state-of-the-art anomaly detectors assign an anomaly score to data points and then detect points based on a score threshold or present a ranked list to the user. Further, while not usually explained explicitly, the scores are often based on frequency estimates of patterns in some space $\mathcal{H}$ with rare patterns leading to higher anomaly scores. While RAREPATTERNDETECT was designed as a pure implementation of this principle, it is reasonable to expect that its sample complexity is related qualitatively to the sample complexity of other algorithms grounded in pattern frequency estimation.

In this section, we consider a number of pattern spaces underlying existing algorithms and show that the sample complexity of those spaces is small. The spaces are thus all learnable in the PAC-RPAD framework, which offers some insight into why existing algorithms often show strong performance even in high-dimensional spaces.

5.1 CONJUNCTIONS

Consider a space $\mathcal{X}$ over d Boolean attributes and a pattern space $\mathcal{H}$ corresponding to conjunctions of those attributes. This setup is common in the data mining literature, where each boolean attribute corresponds to an "item" and a conjunction corresponds to an "item set", which indicates which items are in the set. Rare pattern mining has been studied for such spaces and applied to anomaly detection [1, 16]. In this case, the pattern space has a finite size 2^d and thus by Theorem 1 is efficiently PAC-RPAD learnable with sample complexity $O\left(\frac{1}{\epsilon^2}\left(d + \log \frac{1}{\delta}\right)\right)$. If we limit attention to conjunctions of at most k attributes, then the sample complexity drops to $O\left(\frac{1}{\epsilon^2}\left(k \log(d) + \log \frac{1}{\delta}\right)\right)$, which is sub-linear in d.

5.2 HALFSPACES

Given a continuous space $\mathcal{X} \subseteq \Re^d$, a *half space pattern* is an oriented d-dimensional hyperplane. A data point satisfies a half space pattern if it is on the positive side of the hyperplane. The half-space mass algorithm [5] for anomaly detection operates in this pattern space. Roughly speaking, the algorithm assigns a score to a point x based on the frequency estimates of random half spaces that contain x. The VC-dimension of d-dimensional half spaces is well known

to be $d+1$ and hence this space is sample-efficient learnable in the PAC-RPAD model.

5.3 AXIS ALIGNED HYPER RECTANGLES

For a continuous space $\mathcal{X} \subseteq \Re^d$, an axis-aligned hyper rectangle (bounded or unbounded) can be specified as a conjunction of threshold tests on a subset of the dimensions. The pattern space of axis-aligned rectangles are often implicit in decision tree algorithms, where each internal tree node specifies one threshold test.

The state-of-the-art anomaly detection algorithms, Isolation Forest [10] and RS-Forest [18] (among others), are based on this space. The core idea of these algorithms is to build a forest of T random decision trees, where each node specifies a random threshold test. The trees are grown until either a maximum depth is reached or a leaf node contains only a single data point. Each leaf corresponds to an axis-aligned hyper rectangle. Given a point x, the algorithm can compute the leaf node it reaches in each tree, yielding a set of T hyper-rectangle patterns. The score for x is then based on the average score assigned to each pattern, which is related to the pattern frequency, dimension, and volume.

The VC-dimension of the space of axis parallel hyper rectangles in $\Re^d$ is $2d$ [3]. Thus, the pattern space underlying Isolation Forest and RS-Forest is sample-efficient learnable in the PAC-RPAD model.

5.4 STRIPES

A stripe pattern in $\Re^d$ can be thought of as an intersection of two parallel halfspaces with opposite orientations and can be defined by the inequalities: $a \leq w^\top x \leq a + \Delta$, where, $w \in \Re^d$, a and $\Delta \in \Re$ and Δ represents the width of the stripe. The stripe pattern space consists of the set of all such stripes.

The very simple, but effective, anomaly detector, LODA [11], is based on the stripes pattern space. The main idea of LODA is to form a set of T sparse random projections along some random directions in the subspaces of $\Re^d$ and then estimate a discretized 1D histogram based on the projected values. Each bin of each histogram can be viewed as corresponding to a stripe in the original $\Re^d$ space with orientation defined by the direction of the random projection and location/width defined by the bin localtion/width.

To the best of our knowledge the VC-dimension of the stripes pattern space has not been previously derived. A loose bound can be found by noting that stripes are a special case of the more general pattern space of intersections of half spaces and then applying the general result for bounding the VC-dimension of intersections [3], which gives an upper bound on the VC-dimension of stripes of $4\log(6)(d+1) = O(d)$. Hence, stripes are PAC learnable in the RPAD model.

5.5 ELLIPSOIDS AND SHELLS

Anomaly detectors based on estimating "local densities" often form estimates based on frequencies observed in ellipsoids around query points. In particular, an ellipsoid pattern in a d dimensional space can be represented by $(x-\mu)^\top A\ (x-\mu) \leq t$, where $t \in \Re$, $\mu \in \Re^d$ and A is a $d \times d$ positive definite symmetric matrix. An upper bound for the VC-dimension of ellipsoids in $\Re^d$ is $(d^2+3d)/2$ [2]. Hence the ellipsoid pattern space is sample-efficient learnable in the PAC-RPAD model. However, we see that the complexity is quadratic in d rather than linear as we saw above for spaces based on hyperplane separators.

A related pattern space is the space of *ellipsoidal shells*, which is the analog of stripes for ellipsoidal patterns. An ellipsoidal shell in $\Re^d$ can be thought of as the subtraction of two ellipsoids with the same center and shape, but different volumes. That is, the shell is a region defined by $t \leq (x-\mu)^\top A(x-\mu) \leq t+\Delta$, where $\Delta \in \Re$ is the width. Shells naturally arise as the discretized level sets of multi-dimensional Gaussian density functions, which are perhaps the most widely-used densities in anomaly detection. We are unaware of previous results for the VC-dimensions of shells and show below that it is also $O(d^2)$.

Theorem 3. *The VC-dimension of the ellipsoidal shell pattern space in $\Re^d$ is upper bounded by* $2\log(6)(d^2+3d+2)$.

Proof. We can represent an ellipsoidal shell in $\Re^d$ as:

$$t \leq (x-\mu)^\top A\ (x-\mu)\ \leq t+\Delta. \tag{5}$$

Rewriting the equation of an ellipsoid in $\Re^d$:

$$\begin{aligned} & (x-\mu)^\top A\ (x-\mu)\ \leq t \\ \implies & x^\top A\, x - 2x^\top A\, \mu \leq t - \mu^\top A\, \mu \\ \implies & \sum_{i,j=1}^{d} A_{ij}x_i x_j - \sum_{i=1}^{d} 2(A\mu)_i x_i \leq t - \mu^\top A\mu \\ \implies & w^\top z \leq b. \end{aligned} \tag{6}$$

where, $w, z \in \Re^{d(d+1)/2+d}$. The vector w is a new parameter vector constructed from the original parameters. The matrix A gives $d(d+1)/2$ unique parameters, since A is symmetric, and the vector $A\mu$ gives another d parameters. The vector z is a new input constructed from the original input x, and $b = t - \mu^\top A\mu$.

Now, Applying result of Equation 6 to Equation 5 we get

$$\begin{aligned} & t - \mu^\top A\, \mu \leq w^\top z \leq t + \Delta - \mu^\top A\, \mu \\ \implies & t' \leq w^\top z \leq t' + \Delta. \end{aligned} \tag{7}$$

The Equation 7 is a representation of a stripe in $\Re^{d(d+1)/2+d}$. So, we apply the same approach from previous Section 5.4 i.e. the case of two halfspaces, which gives the upper bound of $4\log(6)(d(d+1)/2+d+1) = 2\log(6)(d^2+3d+2) = O(d^2)$. □

6 EXPERIMENTS

The above results suggest one reason for why state-of-the-art anomaly detectors often perform significantly better than random, even on high-dimensional data. However, existing empirical work does not go much further in terms of providing an understanding of learning curves for anomaly detection. To the best of our knowledge, there has not been a significant study of how the empirical performance of anomaly detectors varies as the amount of training/reference data increases. Typically empirical performance is reported for benchmark data sets without systematic variation of training set size, though other factors such as anomaly percentage are often varied. This is in contrast to empirical studies in supervised learning, where learning curves are regularly published, compared, and analyzed.

In this section, we present an initial investigation into empirical learning curves for anomaly detection. We are interested in the following experimental questions: 1) Will the empirical learning curves demonstrate the fast convergence predicted by the PAC-RPAD framework, and how is the convergence impacted by the data dimension and pattern space complexity? 2) How does the RPAD approach compare to a state-of-the-art detector based on the same pattern space on anomaly detection benchmarks? 3) In what ways do empirical learning curves for anomaly detection differ qualitatively from learning curves for supervised learning? While a complete empirical investigation is beyond the scope of this paper, below we provide experiments that shed light on each of these questions.

6.1 PATTERN SPACE AND ANOMALY DETECTOR SELECTION

A recent large scale evaluation [7] has shown that the Isolation Forest (IF) is among the top performing anomaly detectors across a wide range of benchmarks. This motivates us to focus our investigation on IF's pattern space of axis aligned hyper rectangles (see above). In order to allow for the complexity of this pattern space to be varied, we define *REC(k)* to be the space of all axis aligned hyper rectangles defined by at most k threshold tests on feature values.

The first step of IF is to construct a random forest of trees that are limited to a user-specified maximum leaf depth of k. Each tree leaf in the forest corresponds to a single pattern in REC(k). Thus, the first step of IF can be viewed as generating a random pattern space $\mathcal{H}_k \subseteq \text{REC}(k)$ that contains all leaf patterns in the forest. IF then operates by using training data to compute empirical frequencies $\widehat{P}(h)$ of patterns in $\mathcal{H}_k$ and then for any test point x computes an anomaly score based on those frequencies as follows (smaller is more anomalous):

$$\text{IF}(x) = \sum_{h \in \mathcal{H}_k[x]} d_h + c(\widehat{P}(h))$$

where, $d_h \leq k$ is the number of tests in pattern h and $c(h)$ is a function of the empirical frequency of h.[1]

In order to directly compare IF to our RPAD approach we will conduct multiple experiments, each one using a different randomly generated pattern space $\mathcal{H}_k$. We can then compute the scoring function corresponding to RAREPATTERNDETECT on those pattern spaces and compare to the performance of the IF scoring function. In particular, RAREPATTERNDETECT effectively assigns a score to x based on the minimum frequency pattern as follows:

$$\text{MIN}(x) = \min_{h \in \mathcal{H}_k[x]} \widehat{f}(h)$$

where the normalized frequency estimate $\widehat{f}(h)$ is normalized by a uniform density $U(h)$ over a region of bounded support defined by the training data. This normalizer is proportional to the volume of h and is easily computed. We see that compared to the IF scoring function with sums/averages over functions of each pattern in $\mathcal{H}_k[x]$, the MIN scoring function is only sensitive to the minimum frequency pattern. In order to provide a baseline in between these two, we also compare to the following alternative scoring function that averages normalized frequencies. This scoring function is given by

$$\text{AVE}(x) = \frac{1}{|\mathcal{H}_k[x]|} \sum_{h \in \mathcal{H}_k[x]} \widehat{f}(h).$$

AVE is included in order to observe whether averaging is a more robust approach to using normalized frequencies compared to MIN.

6.2 LEARNING CURVE GENERATION

We generate learning curves using three existing anomaly detection benchmarks:

Covertype [18]: $d = 10$ features, approximately 286k instances 0.9% anomalies.

Particle [7]: $d = 50$ features, approximately 130k instances with 5% anomalies.

Shuttle [7]: $d = 9$ features, approximately 58k instances with 5% anomalies.

These datasets were originally derived from UCI supervised learning benchmarks [9] by treating one or more classes as the anomaly classes and sub-sampling at an appropriate rate to produce benchmarks with certain percentages of anomalies. We have conducted experiments on a number of additional benchmarks, which are not included

[1] In particular, $c(h)$ is an estimate of the expected number of random tests required to completely isolate training data points that satisfy h, which is a function of the number of training points that satisfy h [10]. This score is motivated by attempting to estimate the "isolation depth" of x, which is the expected length of a random path required to isolate a point. Intuitively smaller isolation depths indicate a more anomalous point since it is easier to separate from other points.

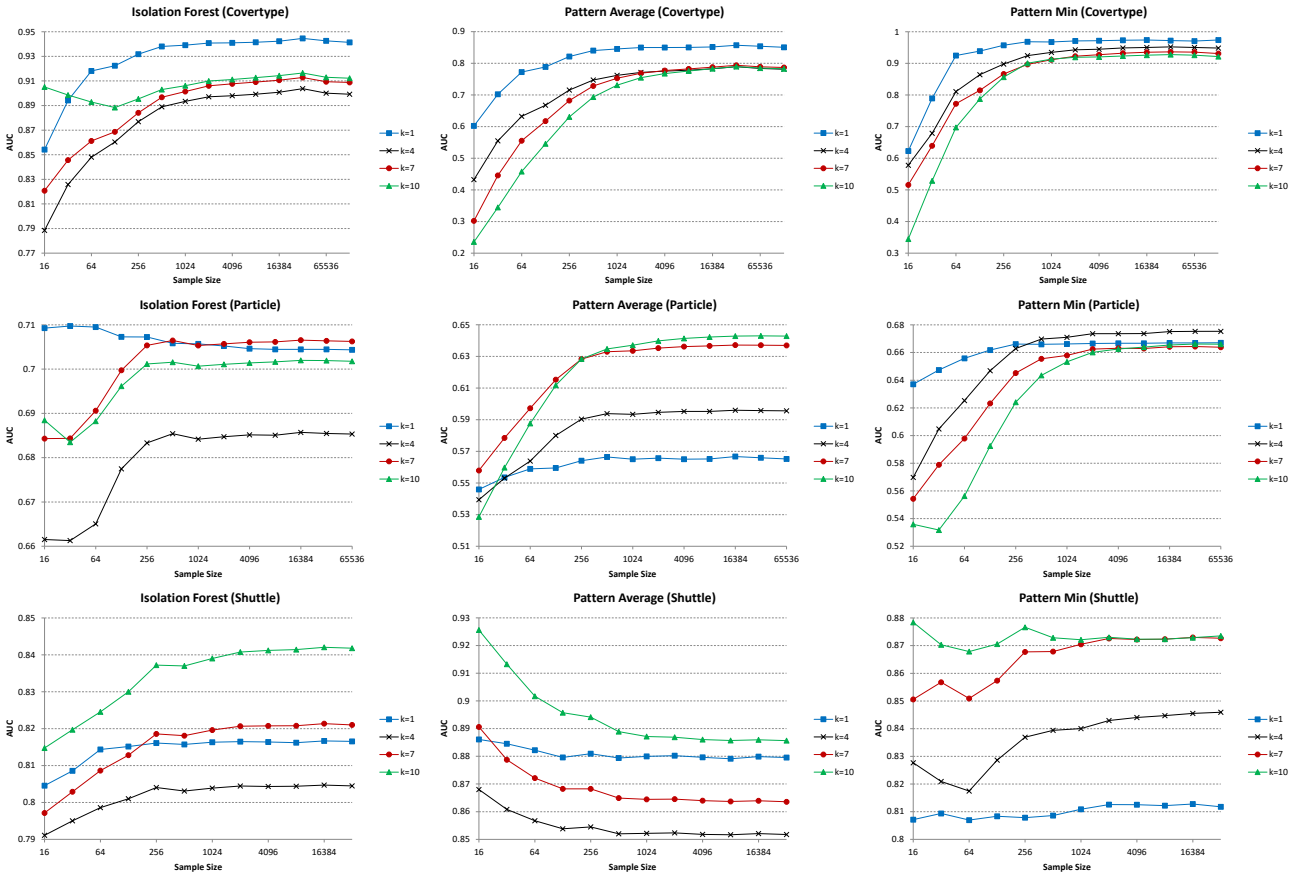

Figure 1: Learning Curves for the Three Scoring Methods (IF, AVE, MIN) with Varying Pattern Space Complexity k Over Three Benchmarks (Rows). MIN Represents the Main RPAD Approach Analyzed in this Paper.

for space reasons. These three data sets were selected as being representative of the qualitative learning curve types that we have observed. The data sets are divided into three sets of data: pattern generation data, training data, and test data for which we ensure that the fraction of anomaly points in each data set is approximately the same as for the full benchmark.

Given a benchmark and a specified pattern complexity k, we generate learning curves for each algorithm as follows. First, we use IF to generate a random pattern space $\mathcal{H}_k$, based on the pattern generation data using a forest of 250 random trees. Next for each desired training set size, we sample a training set of the appropriate size and use that data to estimate frequencies over $\mathcal{H}_k$, which can be done efficiently by passing each data point through each tree. Next, the scores defined above for IF, MIN, and AVE are computed for each test instance based on the frequency estimates and the *Area Under the Curve (AUC)* of those scores is computed relative to the ground truth anomalies. This process is repeated 50 times for each training set size and the resulting AUCs are averaged to produce a final learning curve.

6.3 RESULTS

Figure 1 gives learning curves for each benchmark (rows) and each of the anomaly detectors IF, MIN, and AVE (columns). Recall that MIN represents the main RPAD approach analyzed in this paper. In each case, four learning curves are shown for pattern space complexities $k = 1, 4, 7, 10$ and training instances range from 16 to 2^{15}.

Convergence rate: Each learning curve for each algorithm and benchmark follows a trajectory starting at 16 training instances to a converged performance at 2^{15} points. We see that in all cases, convergence to the final performance occurs very quickly, in particular around 1024 samples. This convergence rate is not significantly impacted by the dimensionality of the data, which can be seen by comparing the results for Particle with $d = 50$ to the other data sets with $d = 9$ and $d = 10$. Rather we see that the convergence rate visibly depends on the pattern space complexity k, though to a relatively small degree. In particular, we see that the convergence for the simplest space $k = 1$ tends to be faster than for $k = 10$ across our experiments. These observations agree with our analysis. The VC-dimension of REC(k), which controls worst case convergence, is dominated by the limiting effect of k. These observations are

consistent across additional benchmarks not shown here.

Relative Algorithm Performance: Here we focus on comparing the different detectors, or scoring functions, in terms of their converged performance. For the Cover and Shuttle data sets we see that the converged performance of MIN is better or competitive than the converged performance of IF for all values of k. For the Particle data set, the IF scoring function outperforms MIN consistently by a small margin. This shows that despite its simplicity the RPAD approach followed by MIN appears to be competitive with a state-of-the-art detector based on the same pattern space. Experiments on other benchmarks, not shown, further confirm this observation.

The converged performance of AVE tends to be worse than both IF and MIN for Covertype and Particle and is slightly better on Shuttle. It appears that for these data sets (and others not shown) that averaging is not significantly more robust than minimizing and can even hurt performance. One reason for degraded performance is that AVE can be influenced by the cumulative effect of a large number of non-rare patterns, which may sometimes overwhelm the signal provided by rare patterns.

An interesting observation is that for each data set, the best performing pattern space (i.e. value of k) is usually the same across the different learning algorithms. For example, for Covertype, $k = 1$ yields the best converged performance for all scoring functions. This observation, which we also frequently observed in other data sets, suggests that the choice of pattern space can have a performance impact that is as large or larger than the impact of the specific scoring function used. To understand this, note that the performance of an anomaly detector depends on both the convergence of its scoring function and the match between the scoring function and the semantic notion of anomaly for the application. The pattern space choice has a large influence on the this match since it controls the fundamental distinctions that can be made among data points.

Qualitative Properties: The qualitative behavior of the learning curves exhibits a couple of nonintuitive properties compared to supervised learning curves. First, in supervised learning, we typically expect and observe that more complex hypothesis spaces converge to a performance that is at least as good as simpler spaces, though more complex spaces may underperform at small sample sizes due to variance. This does not appear to be the case for anomaly detection learning curves in general. For example, the performance of the simplest pattern space ($k = 1$) on Covertype converges to better performance than the more complex spaces. This has also been observed in other data sets and does not appear to be due to premature termination of the learning curve. Rather, we hypothesize that this behavior is due to the mismatch between the anomaly detection scores and the semantic notion of anomaly in the benchmark. In particular, rare patterns in REC(1) are apparently a better indicator of the semantic notion of anomaly than some distracter rare patterns in REC(10). Indeed, it is straightforward to construct synthetic examples with such behavior.

Another nonintuitive aspect is that, in at least two cases, the learning curves consistently decrease in performance, while typically in supervised learning, ideal learning curves are non-decreasing. The most striking example is the performance of AVE on Shuttle, where all learning curves steadily decrease. After further analysis, this type of behavior again appears to be explained by the mismatch between the semantic notion of anomalies and the scoring function. In particular, the variance across different trials of the learning curve for large sample sizes is much smaller than for small sample sizes. It also turns out that the distribution of scoring functions generated for the small sample sizes is skewed toward solutions that better match the ground truth anomalies compared to the converged scoring function. Thus, the average performance for small sample sizes is better. We have observed this decreasing learning curve behavior in other data sets as well, though it is much more common for learning curves to increase.

7 SUMMARY

This work is motivated by the observation that many statistical anomaly detection methods perform much better than random in high dimensions using relatively small amounts of training data. Our PAC-RPAD framework attempts to explain these observations by quantifying the sample complexity in terms of the complexity of the pattern spaces underlying such anomaly detectors. Our results mirror those in supervised learning by showing that the VC-dimension of the pattern spaces is the dominating factor that controls sample complexity. We showed that for several state-of-the-art detectors, the underlying pattern spaces had well-behaved VC-dimensions with respect to the data dimensionality, which offers a partial explanation for their good performance. On the empirical side, we investigated for the first time, to the best of our knowledge, learning curves for anomaly detection. The experiments confirmed the fast convergence predicted by the theory. The results also suggest that our simple algorithm, which was shown to be PAC-RPAD, is competitive with the state-of-the-art algorithm Isolation Forest when using the same pattern space. Finally, the learning curves showed some interesting qualitative differences compared to supervised learning curves. In particular, the results highlight the importance of selecting a pattern space that is likely to be a good match to the semantic notion required for an application.

Abstract

Lossy compression fundamentally involves a decision about what is relevant and what is not. The information bottleneck (IB) by Tishby, Pereira, and Bialek formalized this notion as an information-theoretic optimization problem and proposed an optimal tradeoff between throwing away as many bits as possible, and selectively keeping those that are most important. Here, we introduce an alternative formulation, the deterministic information bottleneck (DIB), that we argue better captures this notion of compression. As suggested by its name, the solution to the DIB problem is a deterministic encoder, as opposed to the stochastic encoder that is optimal under the IB. We then compare the IB and DIB on synthetic data, showing that the IB and DIB perform similarly in terms of the IB cost function, but that the DIB vastly outperforms the IB in terms of the DIB cost function. Moreover, the DIB offered a 1-2 order of magnitude speedup over the IB in our experiments. Our derivation of the DIB also offers a method for continuously interpolating between the soft clustering of the IB and the hard clustering of the DIB.

1 INTRODUCTION

Compression is a ubiquitous task for humans and machines alike [Cover & Thomas (2006), MacKay (2002)]. For example, machines must turn the large pixel grids of color that form pictures into small files capable of being shared quickly on the web [Wallace (1991)], humans must compress the vast stream of ongoing sensory information they receive into small changes in the brain that form memories [Kandel et al (2000)], and data scientists must turn large amounts of high-dimensional and messy data into more manageable and interpretable clusters [MacKay (2002)].

Lossy compression involve an implicit decision about what is relevant and what is not [Cover & Thomas (2006), MacKay (2002)]. In the example of image compression, the algorithms we use deem some features essential to representing the subject matter well, and others are thrown away. In the example of human memory, our brains deem some details important enough to warrant attention, and others are forgotten. And in the example of data clustering, information about some features is preserved in the mapping from data point to cluster ID, while information about others is discarded.

In many cases, the criterion for "relevance" can be described as information about some other variable(s) of interest. Let's call X the signal we are compressing, T the compressed version, Y the other variable of interest, and $I(T;Y)$ the "information" that T has about Y (we will formally define this later). For human memory, X is past sensory input, T the brain's internal representation (e.g. the activity of a neural population, or the strengths of a set of synapses), and Y the features of the future environment that the brain is interested in predicting, such as extrapolating the position of a moving object. Thus, $I(T;Y)$ represents the predictive power of the memories formed [Palmer et al (2015)]. For data clustering, X is the original data, T is the cluster ID, and Y is the target for prediction, for example purchasing or ad-clicking behavior in a user segmentation problem. In summary, a good compression algorithm can be described as a tradeoff between the compression of a signal and the selective maintenance of the "relevant" bits that help predict another signal.

This problem was formalized as the "information bottleneck" (IB) by Tishby, Pereira, and Bialek [Tishby (1999)]. In their formulation, compression was measured by the mutual information $I(X;T)$. This compression metric has its origins in rate-distortion theory and channel coding, where $I(X;T)$ represents the maximal information transfer rate, or capacity, of the communication channel between X and T [Cover & Thomas (2006)]. While this approach has its applications, often one is more interested in directly restricting the amount of resources required to represent T, represented by the entropy $H(T)$. This latter notion comes

from the source coding literature and implies a restriction on the *representational cost* of T. In the case of human memory, for example, $H(T)$ would roughly correspond to the number of neurons or synapses required to represent or store a sensory signal X. In the case of data clustering, $H(T)$ is related to the number of clusters.

In the following paper, we introduce an alternative formulation of the IB, replacing the compression measure $I(X;T)$ with $H(T)$, thus emphasizing contraints on representation, rather than communication. We begin with a general introduction to the IB. Then, we introduce our alternative formulation, which we call the deterministic information bottleneck (DIB). Finally, we compare the IB and DIB solutions on synthetic data to help illustrate their differences.

2 THE ORIGINAL INFORMATION BOTTLENECK (IB)

Given the joint distribution $p(x,y)$, the encoding distribution $q(t \mid x)$ is obtained through the following "information bottleneck" (IB) optimization problem:

$$\min_{q(t|x)} L[q(t \mid x)] = I(X;T) - \beta I(T;Y)\,, \qquad (1)$$

subject to the Markov constraint $T \leftrightarrow X \leftrightarrow Y$. Here $I(X;T)$ denotes the mutual information between X and T, that is $I(X;T) \equiv H(T) - H(T \mid X) = \sum_{x,t} p(x,t) \log\left(\frac{p(x,t)}{p(x)p(t)}\right) = D_{KL}[p(x,t) \mid p(x)\,p(t)]$,[1] where D_{KL} denotes the Kullback-Leibler divergence.[2] The first term in the cost function is meant to encourage compression, while the second relevance. β is a non-negative free parameter representing the relative importance of compression and relevance, and our solution will be a function of it. The Markov constraint simply enforces the probabilistic graphical structure of the task; the compressed representation T is a (possibly stochastic) function of X and can only get information about Y through X. Note that we are using p to denote distributions that are given and fixed, and q to denote distributions that we are free to change and that are being updated throughout the optimization process.

Through a standard application of variational calculus (see Section 7 for a detailed derivation of the solution to a more general problem introduced below), one finds the formal solution:[3]

$$q(t \mid x) = \frac{q(t)}{Z(x,\beta)} \exp[-\beta D_{\mathrm{KL}}[p(y \mid x) \mid q(y \mid t)]] \qquad (2)$$

$$q(y \mid t) = \frac{1}{q(t)} \sum_x q(t \mid x)\, p(x,y)\,, \qquad (3)$$

where $Z(x,\beta) \equiv \exp\left[-\frac{\lambda(x)}{p(x)} - \beta \sum_y p(y \mid x) \log \frac{p(y|x)}{p(y)}\right]$ is a normalization factor, and $\lambda(x)$ is a Lagrange multiplier that enters enforcing normalization of $q(t \mid x)$.[4] To get an intuition for this solution, it is useful to take a clustering perspective - since we are compressing X into T, many X will be mapped to the same T and so we can think of the IB as "clustering" xs into their cluster labels t. The solution $q(t \mid x)$ is then likely to map x to t when $D_{\mathrm{KL}}[p(y \mid x) \mid q(y \mid t)]$ is small, or in other words, when the distributions $p(y \mid x)$ and $q(y \mid t)$ are similar. These distributions are similar to the extent that x and t provide similar information about y. In summary, inputs x get mapped to clusters t that maintain information about y, as was desired.

This solution is "formal" because the first equation depends on the second and vice versa. However, [Tishby (1999)] showed that an iterative approach can be built on the the above equations which provably converges to a local optimum of the IB cost function (eqn 1).

Starting with some initial distributions $q^{(0)}(t \mid x)$, $q^{(0)}(t)$, and $q^{(0)}(y \mid t)$, the n^{th} update is given by:

$$d^{(n-1)}(x,t) \equiv D_{\mathrm{KL}}\left[p(y \mid x) \mid q^{(n-1)}(y \mid t)\right] \qquad (4)$$

$$q^{(n)}(t \mid x) = \frac{q^{(n-1)}(t)}{Z(x,\beta)} \exp\left[-\beta d^{(n-1)}(x,t)\right] \qquad (5)$$

$$q^{(n)}(t) = \sum_x p(x)\, q^{(n)}(t \mid x) \qquad (6)$$

$$q^{(n)}(y \mid t) = \frac{1}{q^{(n)}(t)} \sum_x q^{(n)}(t \mid x)\, p(x,y)\,. \qquad (7)$$

[1] Implicit in the summation here, we have assumed that X, Y, and T are discrete. We will be keeping this assumption throughout for convenience of notation, but note that the IB generalizes naturally to X, Y, and T continuous by simply replacing the sums with integrals (see, for example, [Chechik et al (2005)]).

[2] For those unfamiliar with it, mutual information is a very general measure of how related two variables are. Classic correlation measures typically assume a certain form of the relationship between two variables, say linear, whereas mutual information is agnostic as to the details of the relationship. One intuitive picture comes from the entropy decomposition: $I(X;Y) \equiv H(X) - H(X \mid Y)$. Since entropy measures uncertainty, mutual information measures the *reduction in uncertainty* in one variable when observing the other. Moreover, it is symmetric ($I(X;Y) = I(Y;X)$), so the information is *mutual*. Another intuitive picture comes from the D_{KL} form: $I(X;Y) \equiv D_{KL}[p(x,y) \mid p(x)\,p(y)]$. Since D_{KL} measures the distance between two probability distributions, the mutual information quantifies how far the relationship between x and y is from a probabilistically independent one, that is how far the joint $p(x,y)$ is from the factorized $p(x)\,p(y)$.

[3] For the reader familiar with rate-distortion theory, eqn 2 can be viewed as the solution to a rate-distortion problem with distortion measure given by the KL-divergence term in the exponent.

[4] More explicitly, our cost function L also implicitly includes a term $\sum_x \lambda(x)\left[1 - \sum_t q(t|x)\right]$ and this is where $\lambda(x)$ comes in to the equation. See Section 7 for details.

Note that the first pair of equations is the only "meaty" bit; the rest are just there to enforce consistency with the laws of probability (e.g. that marginals are related to joints as they should be). In principle, with no proof of convergence to a global optimum, it might be possible for the solution obtained to vary with the initialization, but in practice, the cost function is "smooth enough" that this does not seem to happen. This algorithm is summarized in algorithm 1. Note that while the general solution is iterative, there is at least one known case in which an analytic solution is possible, name when X and Y are jointly Gaussian [Chechik et al (2005)].

Algorithm 1 - The information bottleneck (IB) method.

Given $p(x, y)$, $\beta \geq 0$
Initialize $q^{(0)}(t \mid x)$ and set $n = 0$
$q^{(0)}(t) = \sum_x p(x)\, q^{(0)}(t \mid x)$
$q^{(0)}(y \mid t) = \frac{1}{q^{(0)}(t)} \sum_x p(x, y)\, q^{(0)}(t \mid x)$
while not converged **do**
    $n = n + 1$
    $d^{(n-1)}(x, t) \equiv D_{\mathrm{KL}}\left[p(y \mid x) \mid q^{(n-1)}(y \mid t)\right]$
    $q^{(n)}(t \mid x) = \frac{q^{(n-1)}(t)}{Z(x,\beta)} \exp\left[-\beta d^{(n-1)}(x, t)\right]$
    $q^{(n)}(t) = \sum_x p(x)\, q^{(n)}(t \mid x)$
    $q^{(n)}(y \mid t) = \frac{1}{q^{(n)}(t)} \sum_x q^{(n)}(t \mid x)\, p(x, y)$
end while

In summary, given the joint distribution $p(x, y)$, the IB method extracts a compressive encoder $q(t \mid x)$ that selectively maintains the bits from X that are informative about Y. As the encoder is a function of the free parameter β, we can visualize the entire family of solutions on a curve (figure 1), showing the tradeoff between compression (on the x-axis) and relevance (on the y-axis). For small β, compression is more important than prediction and we find ourselves at the bottom left of the curve in the high compression, low prediction regime. As β increases, prediction becomes more important relative to compression, and we see that both $I(X;T)$ and $I(T;Y)$ increase. At some point, $I(T;Y)$ saturates, because there is no more information about Y that can be extracted from X (either because $I(T;Y)$ has reached $I(X;Y)$ or because T has too small cardinality). Note that the region below the curve is shaded because this area is feasible; for suboptimal $q(t \mid x)$, solutions will lie in this region. Optimal solutions will of course lie on the curve, and no solutions will lie above the curve.

Additional work on the IB has highlighted its relationship with maximum likelihood on a multinomial mixture model [Slonim & Weiss (2002)] and canonical correlation analysis [Creutzig et al (2009)] (and therefore linear Gaussian models [Bach & Jordan (2005)] and slow feature analysis [Turner & Sahani (2007)]). Applications have included speech recognition [Hecht & Tishby (2005), Hecht & Tishby (2008), Hecht et al (2009)], topic modeling [Slonim & Tishby (2000), Slonim & Tishby (2001), Bekkerman et al (2001), Bekkerman et al (2003)], and neural coding [Schneidman et al (2002), Palmer et al (2015)]. Most recently, the IB has even been proposed as a method for benchmarking the performance of deep neural networks [Tishby & Zaslavsky (2015)].

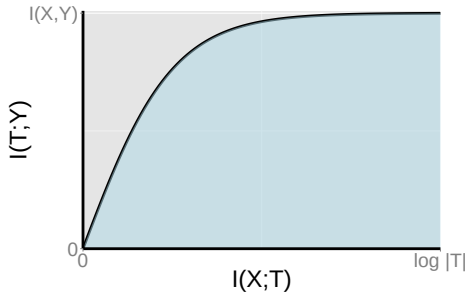

Figure 1: **An illustrative IB curve.** $I(T;Y)$ is the relevance term from eqn 1; $I(X;T)$ is the compression term. $I(X;Y)$ is an upper bound on $I(T;Y)$ since T only gets its information about Y via X. $\log(|T|)$, where $|T|$ is the cardinality of the compression variable, is a bound on $I(X;T)$ since $I(X;T) = H(T) - H(T \mid X) \leq H(T) \leq \log(|T|)$.

3 THE DETERMINISTIC INFORMATION BOTTLENECK (DIB)

Our motivation for introducing an alternative formulation of the information bottleneck is rooted in the "compression term" of the IB cost function; there, the minimization of the mutual information $I(X;T)$ represents compression. As discussed above, this measure of compression comes from the channel coding literature and implies a restriction on the *communication cost* between X and T. Here, we are interested in the source coding notion of compression, which implies a restriction on the *representational cost* of T. For example, in neuroscience, there is a long history of work on "redundancy reduction" in the brain in the form of minimizing $H(T)$ [Barlow (1981), Barlow (2001), Barlow (2001)].

Let us call the original IB cost function L_{IB}, that is $L_{\mathrm{IB}} \equiv I(X;T) - \beta I(T;Y)$. We now introduce the deterministic information bottleneck (DIB) cost function:

$$L_{\mathrm{DIB}}[q(t \mid x)] \equiv H(T) - \beta I(T;Y)\,, \tag{8}$$

which is to be minimized over $q(t \mid x)$ and subject to the same Markov constraint as the original formulation (eqn 1). The "deterministic" in its name will become clear below.

To see the distinction between the two cost functions, note that:

$$L_{\mathrm{IB}} - L_{\mathrm{DIB}} = I(X;T) - H(T) \tag{9}$$
$$= -H(T \mid X)\,, \tag{10}$$

where we have used the decomposition of the mutual information $I(X;T) = H(T) - H(T \mid X)$. $H(T \mid X)$ is sometimes called the "noise entropy" and measures the stochasticity in the mapping from X to T. Since we are minimizing these cost functions, this means that the IB cost function *encourages* stochasticity in the encoding distribution $q(t \mid x)$ relative to the DIB cost function. In fact, we will see that by removing this encouragement of stochasticity, the DIB problem actually produces a deterministic encoding distribution, i.e. an encoding *function*, hence the "deterministic" in its name.

Naively taking the same variational calculus approach as for the IB problem, one cannot solve the DIB problem.[5] To make this problem tractable, we are going to define a family of cost functions of which the IB and DIB cost functions are limiting cases. That family, indexed by α, is defined as:[6]

$$L_\alpha \equiv H(T) - \alpha H(T \mid X) - \beta I(T;Y)\,. \tag{11}$$

Clearly, $L_{\text{IB}} = L_1$. However, instead of looking at L_{DIB} as the $\alpha = 0$ case, we'll define the DIB solution $q_{\text{DIB}}(t \mid x)$ as the $\alpha \to 0$ limit of the solution to the generalized problem $q_\alpha(t \mid x)$:[7]

$$q_{\text{DIB}}(t \mid x) \equiv \lim_{\alpha \to 0} q_\alpha(t \mid x)\,. \tag{12}$$

Taking the variational calculus approach to minimizing L_α (under the Markov constraint), we get the following solution for the encoding distribution (see Section 7 for the derivation and explicit form of the normalization factor $Z(x, a, \beta)$):

$$d_\alpha(x,t) \equiv D_{\text{KL}}[p(y \mid x) \mid q_\alpha(y \mid t)] \tag{13}$$
$$\ell_{\alpha,\beta}(x,t) \equiv \log q_\alpha(t) - \beta d_\alpha(x,t) \tag{14}$$
$$q_\alpha(t \mid x) = \frac{1}{Z(x,\alpha,\beta)} \exp\left[\frac{1}{\alpha}\ell_{\alpha,\beta}(x,t)\right] \tag{15}$$
$$q_\alpha(y \mid t) = \frac{1}{q_\alpha(t)} \sum_x q_\alpha(t \mid x)\, p(x,y)\,. \tag{16}$$

[5] When you take the variational derivative of L_{DIB} + Lagrange multiplier term with respect to $q(t \mid x)$ and set it to zero, you get no explicit $q(t \mid x)$ term, and it is therefore not obvious how to solve these equations. We cannot rule that that approach is possible, of course; we have just here taken a different route.

[6] Note that for $\alpha < 1$, we cannot allow T to be continuous since $H(T)$ can become infinitely negative, and the optimal solution in that case will trivially be a delta function over a single value of T for all X, across all values of β. This is in constrast to the IB, which can handle continuous T. In any case, we continue to assume discrete X, Y, and T for convenience.

[7] Note a subtlety here that we cannot claim that the q_{DIB} is the solution to L_{DIB}, for although $L_{\text{DIB}} = \lim_{\alpha\to 0} L_\alpha$ and $q_{\text{DIB}} = \lim_{\alpha\to 0} q_\alpha$, the solution of the limit need not be equal to the limit of the solution. It would, however, be surprising if that were not the case.

Note that the last equation is just eqn 3, since this just follows from the Markov constraint. With $\alpha = 1$, we can see that the other three equations just become the IB solution from eqn 2, as should be the case.

Before we take the $\alpha \to 0$ limit, note that we can now write a generalized IB iterative algorithm (indexed by α) which includes the original as a special case ($\alpha = 1$):

$$d_\alpha^{(n-1)}(x,t) \equiv D_{\text{KL}}\left[p(y \mid x) \mid q_\alpha^{(n-1)}(y \mid t)\right] \tag{17}$$
$$\ell_{\alpha,\beta}^{(n-1)}(x,t) \equiv \log q_\alpha^{(n-1)}(t) - \beta d_\alpha^{(n-1)}(x,t) \tag{18}$$
$$q_\alpha^{(n)}(t \mid x) = \frac{1}{Z(x,\alpha,\beta)} \exp\left[\frac{1}{\alpha}\ell_{\alpha,\beta}^{(n-1)}(x,t)\right] \tag{19}$$
$$q_\alpha^{(n)}(t) = \sum_x p(x)\, q_\alpha^{(n)}(t \mid x) \tag{20}$$
$$q_\alpha^{(n)}(y \mid t) = \frac{1}{q_\alpha^{(n)}(t)} \sum_x q_\alpha^{(n)}(t \mid x)\, p(x,y)\,. \tag{21}$$

This generalized algorithm can be used in its own right, however we will not discuss that option further here.

For now, we take the limit $\alpha \to 0$ and see that something interesting happens with $q_\alpha(t \mid x)$ - the argument of the exponential begins to blow up. For a fixed x, this means that $q(t \mid x)$ will collapse into a delta function at the value of t which maximizes $\log q(t) - \beta D_{\text{KL}}[p(y \mid x) \mid q(y \mid t)]$. That is:

$$\lim_{\alpha\to 0} q_\alpha(t \mid x) = f : X \to T, \tag{22}$$

where:

$$f(x) \equiv t^* = \operatorname*{argmax}_t \ell(x,t) \tag{23}$$
$$\ell(x,t) \equiv \log q(t) - \beta D_{\text{KL}}[p(y \mid x) \mid q(y \mid t)]\,. \tag{24}$$

So, as anticipated, the solution to the DIB problem is a deterministic encoding distribution. The $\log q(t)$ above encourages that we use as few values of t as possible, via a "rich-get-richer" scheme that assigns each x preferentially to a t already with many xs assigned to it. The KL divergence term, as in the original IB problem, just makes sure we pick ts which retain as much information from x about y as possible. The parameter β, as in the original problem, controls the tradeoff between how much we value compression and prediction.

Also like in the original problem, the solution above is only a formal solution, since eqn 15 depends on eqn 16 and vice versa. So we will again need to take an iterative approach; in analogy to the IB case, we repeat the following updates to convergence (from some initialization):[8]

[8] Note that, if at step m no xs are assigned to a particular $t = t^*$, then $q_m(t^*) = 0$ and for all future steps $n > m$, no xs will

$$d^{(n-1)}(x,t) \equiv D_{\mathrm{KL}}\Big[p(y \mid x) \mid q^{(n-1)}(y \mid t)\Big] \tag{25}$$

$$\ell_\beta^{(n-1)}(x,t) \equiv \log q(t) - \beta d^{(n-1)}(x,t) \tag{26}$$

$$f^{(n)}(x) = \operatorname*{argmax}_t \ell_\beta^{(n-1)}(x,t) \tag{27}$$

$$q^{(n)}(t \mid x) = \delta\Big(t - f^{(n)}(x)\Big) \tag{28}$$

$$q^{(n)}(t) = \sum_x q^{(n)}(t \mid x)\, p(x) \tag{29}$$

$$= \sum_{x: f^{(n)}(x)=t} p(x) \tag{30}$$

$$q^{(n)}(y \mid t) = \frac{1}{q^{(n)}(t)} \sum_x q^{(n)}(t \mid x)\, p(x,y) \tag{31}$$

$$= \frac{\sum_{x: f^{(n)}(x)=t} p(x,y)}{\sum_{x: f^{(n)}(x)=t} p(x)}. \tag{32}$$

This process is summarized in algorithm 2.

Like with the IB, the DIB solutions can be plotted as a function of β. However, in this case, it is more natural to plot $I(T;Y)$ as a function of $H(T)$, rather than $I(X;T)$. That said, in order to compare the IB and DIB, they need to be plotted in the same plane. When plotting in the $I(X;T)$ plane, the DIB curve will of course lie below the IB curve, since in this plane, the IB curve is optimal; the opposite will be true when plotting in the $H(T)$ plane. Comparisons with experimental data can be performed in either plane.

Algorithm 2 - The deterministic information bottleneck (DIB) method.

Given $p(x,y)$, $\beta \geq 0$
Initialize $f^{(0)}(x)$ and set $n = 0$
$q^{(0)}(t) = \sum_{x: f^{(0)}(x)=t} p(x)$
$q^{(0)}(y \mid t) = \frac{\sum_{x: f^{(0)}(x)=t} p(x,y)}{\sum_{x: f^{(0)}(x)=t} p(x)}$
while not converged **do**
    $n = n + 1$
    $d^{(n-1)}(x,t) \equiv D_{\mathrm{KL}}\big[p(y \mid x) \mid q^{(n-1)}(y \mid t)\big]$
    $\ell_\beta^{(n-1)}(x,t) \equiv \log q(t) - \beta d^{(n-1)}(x,t)$
    $f^{(n)}(x) = \operatorname*{argmax}_t \ell_\beta^{(n-1)}(x,t)$
    $q^{(n)}(t) = \sum_{x: f^{(n)}(x)=t} p(x)$
    $q^{(n)}(y \mid t) = \frac{\sum_{x: f^{(n)}(x)=t} p(x,y)}{\sum_{x: f^{(n)}(x)=t} p(x)}$
end while

ever again be assigned to t^* since $\log q_n(t^*) = -\infty$. In other words, the number of ts "in use" can only decrease during the iterative algorithm above (or remain constant). Thus, it seems plausible that our solution will not depend on the cardinality of T, provided it is chosen to be large enough.

4 COMPARISON OF IB AND DIB

To get an idea of how the IB and DIB solutions differ in practice, we generated a series of random joint distributions $p(x,y)$, solved for the IB and DIB solutions for each, and compared them in both the IB and DIB plane. To generate the $p(x,y)$, we first sampled $p(x)$ from a symmetric Dirichlet distribution with concentration parameter α_x (so $p(x) \sim \mathrm{Dir}[\alpha_x]$), and then sampled each row of $p(y \mid x)$ from another symmetric Dirichlet distribution with concentration parameter α_y (so $p(y \mid x) \sim \mathrm{Dir}[\alpha_y], \forall x$). Since the number of clusters in use for both IB and DIB can only decrease from iteration to iteration (see footnote 8), we always initialized $|T| = |X|$.[9] For the DIB, we initialized the cluster assignments to be as even across the cluster as possible, i.e. each data points belonged to its own cluster. For IB, we initalized the cluster assignments to a normalized draw of a uniform random vector.

An illustrative pair of solutions is shown in figure 2. The key feature to note is that, while performance of the IB and DIB solutions are very similar in the IB plane, their behavior differs drastically in the DIB plane.

Perhaps most unintuitive is the behavior of the IB solution in the DIB plane. To understand this behavior, recall that the IB's compression term is the mutual information $I(X,T) = H(T) - H(T \mid X)$. This term is minimized by any $q(t \mid x)$ that maps ts independently of xs. Consider two extremes of such mappings. One is to map all values of X to a single value of T; this leads to $H(T) = H(T \mid X) = I(X,T) = 0$. The other is to map each value of X uniformly across all values of T; this leads to $H(T) = H(T \mid X) = \log |T|$ and $I(X,T) = 0$. In our initial studies, the IB consistently took the latter approach.[10] Since the DIB cost function favors the former approach (and indeed the DIB solution follows this approach), the IB consistently performs poorly by the DIB's standards. This difference is especially apparent at small β, where the compression term matters most, and as β increases, the DIB and IB solutions converge in the DIB plane.

To encourage the IB into more DIB-like behavior, we next altered our initialization scheme of $q(t \mid x)$. Originally, we used a normalized vector of uniform random numbers for each x. Next, we tried a series of delta-like functions, for which $q(t \mid x) = p_0$ for all x and one t, and the rest of the entries were uniform with a small amount of noise to break symmetry. The intended effect was to start the IB closer to solutions in which all data points were mapped to a single cluster. Results are shown in figure 3. While the different initialization schemes didn't change behavior in

[9] An even more efficient setting might be to set the cardinality of T based on the entropy of X, say $|T| = \mathrm{ceiling}(\exp(H(X)))$, but we didn't experiment with this.

[10] Intuitively, this approach is "more random" and is therefore easier to stumble upon during optimization.

the IB plane, we can see a gradual shift of the IB towards DIB-like behavior in the DIB plane as $p_0 \to 1$, i.e. the initialization scheme approaches a true delta. However, the IB still fails to reach the level of performance of the DIB, especially for large β, where the effect of the initialization washes out completely.

To summarize, the IB and DIB perform similarly by the IB standards, but the DIB tends to outperform the IB dramatically by the DIB's standards. Careful initialization of the IB can make up some of the difference, but not all.

It is also worth noting that, across all the datasets we tested, the DIB took 1-2 orders of magnitude fewer steps and time to converge, as illustrated in figure 4. About half of IB fits took at least an hour, while nearly a quarter took at least five hours. Contrast this with about half of DIB fits taking only five minutes, and more than 80% finishing within ten minutes. Put another way, about half of all DIB fits finished ten times faster than their IB counterpart, while about a quarter finished fifty times faster.

Note that the computational advantage of the DIB over the IB may vary by dataset and stopping criteria. In our case, we defined convergence for both algorithms as a change in cost function of less than 10^8 from one step to the next.

5 RELATED WORK

The DIB is not the first hard clustering version of IB.[11] Indeed, the agglomerative information bottleneck (AIB) [Slonim & Tishby (1999)] also produces hard clustering and was introduced soon after the IB. Thus, it is important to distinguish between the two approaches. AIB is a bottom-up, greedy method which starts with all data points belonging to their own clusters and iteratively merges clusters in a way which maximizes the gain in relevant information. It was explicitly designed to produce a hard clustering. DIB is a top-down method derived from a cost function that was not designed to produce a hard clustering. Our starting point was to alter the IB cost function to match the source coding notion of compression. The emergence of hard clustering in DIB is itself a result. Thus, while AIB does provide a hard clustering version of IB, DIB contributes the following in addition: 1) Our study emphasizes why a stochastic encoder is optimal for IB, namely due to the noise entropy term. The optimality of a stochastic encoder has been, for many, neither obvious nor necessarily desirable. 2) Our study provides a principled, top-down derivation of a hard clustering version of IB, based upon an intuitive change to the cost function. 3) Our non-trivial derivation also provides a cost-function and solution which interpolates between DIB and IB, by adding back the noise entropy continuously, i.e. with $0 < \alpha < 1$. This interpolation may be viewed as adding a regularization term to DIB. We are in fact currently exploring whether this type of regularization may be useful in dealing with finitely sampled data. Another interpretation of the cost function with intermediate α is as a penalty on *both* the mutual information between X and T as well as the entropy of the compression, $H(T)$. 4) It is likely that DIB offers a computational advantage to AIB. In the AIB paper, the authors say, "The main disadvantage of this method is computational, since it starts from the limit of a cluster per each member of the set X." In our experiments, we find that DIB is much more efficient than IB. Therefore, we expect that DIB will offer a considerable advantage in efficiency to AIB. However, we have not yet tested this.

The original IB also provides a deterministic encoding upon taking the limit $\beta \to \infty$ that corresponds to the causal-state partition of histories [Still et al (2010)]. However, this is the limit of no compression, whereas our approach allows for an entire family of deterministic encoders with varying degrees of compression.

[11] In fact, even the IB itself produces a hard clustering in the large β limit. However, it trivially assigns all data points to their own clusters.

6 DISCUSSION

Here we have introduced the deterministic information bottleneck (DIB) as an alternative to the information bottleneck (IB) for compression and clustering. We have argued that the DIB cost function better embodies the goal of lossy compression of relevant information, and shown that it leads to a non-trivial deterministic version of the IB. We have compared the DIB and IB solutions on synthetic data and found that, in our experiments, the DIB performs nearly identically to the IB in terms of the IB cost function, but far superior in terms of its own cost function. We also noted that the DIB achieved this performance at a computational efficiency 1-2 orders of magnitude better than the IB.

Of course, in addition to the studies with synthetic data here, it is important to compare the DIB and IB on real world datasets as well to see whether the DIB's apparent advantages hold. The linearity of the IB and DIB curves displayed above are indeed a signature of relatively simple data with not particularly complicated tradeoffs between compression and relevance.

One particular application of interest is maximally informative clustering. Previous work has, for example, offered a principled way of choosing the number of clusters based on the finiteness of the data [Still & Bialek (2004)]. Similarly interesting results may exist for the DIB, as well as relationships to other popular clustering algorithms such as k-means. More generally, there are learning theory results showing generalization bounds on IB for which an analog on DIB would be interesting as well [Shamir et al (2010)].

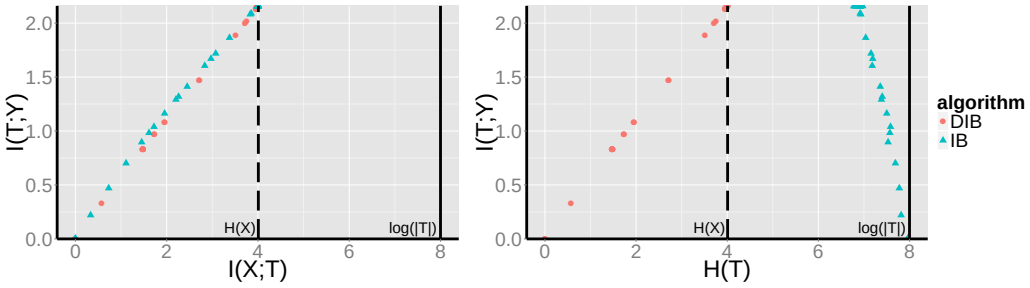

Figure 2: **Example IB and DIB solutions.** *Left*: IB plane. *Right*: DIB plane. Upper limit of the y-axes is $I(X, Y)$, since this is the maximal possible value of $I(T; Y)$. Solid vertical line marks $\log(|T|)$, since this is the maximal possible value of $H(T)$ and $I(X, T)$ (the latter being true since $I(X, T)$ is bounded above by both $H(T)$ and $H(X)$, and $|T| < |X|$). The dashed vertical line marks $H(X)$, which is both an upper bound for $I(X, T)$ and a natural comparison for $H(T)$ (since to place each data point in its own cluster, we need $H(T) = H(X)$). Here, $|X| = |Y| = 1024$ and $|T| = 256$.

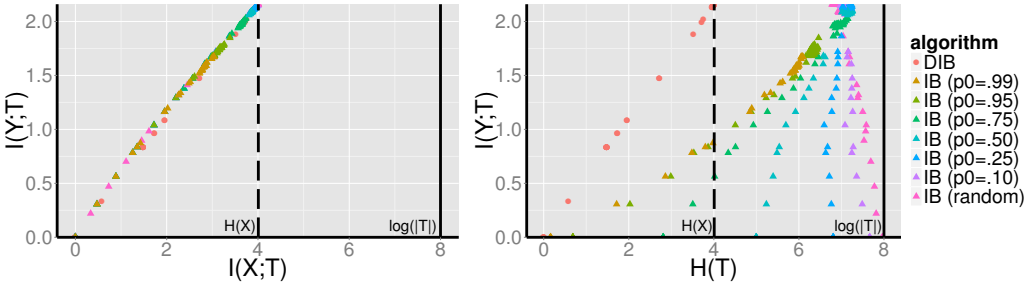

Figure 3: **Example IB and DIB solutions across different IB initializations.** Details identical to figure 2, except colors represent different initializations for the IB, as described in the text. "IB (random)" denotes the original initialization scheme of a normalized vector of uniform random numbers.

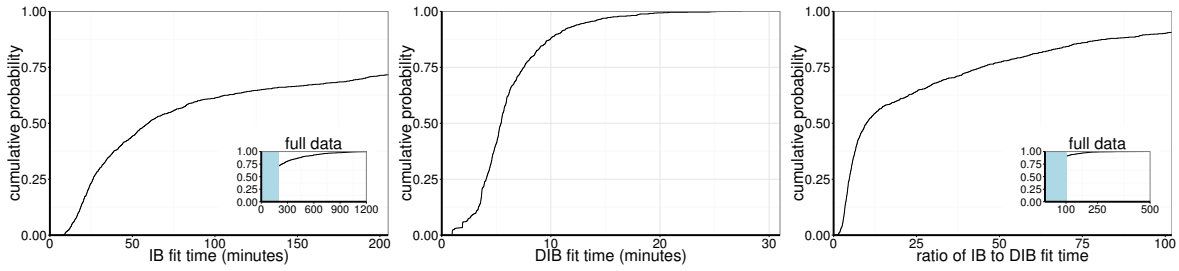

Figure 4: **Fit times for IB and DIB, as well as their ratios.** *Left*: cumulative distribution of IB fit times. Data shown here are for the original initialization of IB, though the delta-like initializations lead to nearly identical results. Mean fit time was 171 minutes. *Center*: cumulative distribution of DIB fit times. Mean fit time was 6 minutes. *Right*: cumultative distribution of ratios of IB to DIB fit times. Ratios are for the b^{th} value of β for DIB and the b^{th} value of β for IB, though those values of β are not necessarily the same. Both algorithms were fit to the same data. The IB fits are those resulting from the original random intialization, though the delta-like initializations lead to nearly identical results.

Another potential area of application is modeling the extraction of predictive information in the brain (which is one particular example in a long line of work on the exploitation of environmental statistics by the brain [Barlow (1981), Barlow (2001), Barlow (2001), Atick & Redlich (1992), Olshausen & Field (1996), Olshausen & Field (1997), Simoncelli & Olshausen (2001), Olshausen & Field (2004)]). There, X would be the stimulus at time t, Y the stimulus a short time in the future $t+\tau$, and T the activity of a population of sensory neurons. One could even consider neurons deeper in the brain by allowing X and Y to correspond not to an external stimulus, but to the activity of upstream neurons. An analysis of this nature using retinal data was recently performed with the IB [Palmer et al (2015)]. It would be interesting to see if the same data corresponds better to the behavior of the DIB, particularly in the DIB plane where the IB and DIB differ dramatically.

7 APPENDIX: DERIVATION OF GENERALIZED IB SOLUTION

Given $p(x, y)$ and subject to the Markov constraint $T \leftrightarrow X \leftrightarrow Y$, the generalized IB problem is:

$$\min_{q(t|x)} L[q(t \mid x)] = H(T) - \alpha H(T \mid X) - \beta I(T;Y) - \sum_{x,t} \lambda(x)\, q(t \mid x)\,, \tag{33}$$

where we have now included the Lagrange multiplier term (which enforces normalization of $q(t \mid x)$) explicitly. The Markov constraint implies the following factorizations:

$$q(t \mid y) = \sum_x q(t \mid x)\, p(x \mid y) \tag{34}$$

$$q(t) = \sum_x q(t \mid x)\, p(x)\,, \tag{35}$$

which give us the following useful derivatives:

$$\frac{\delta q(t \mid y)}{\delta q(t \mid x)} = p(x \mid y) \tag{36}$$

$$\frac{\delta q(t)}{\delta q(t \mid x)} = p(x)\,. \tag{37}$$

Now taking the derivative of the cost function with respect to the encoding distribution, we get:

$$\begin{aligned}
\frac{\delta L}{\delta q(t \mid x)} &= -\frac{\delta}{\delta q(t \mid x)} \sum_t q(t) \log q(t) && (38)\\
&\quad - \frac{\delta}{\delta q(t \mid x)} \sum_{x,t} \lambda(x)\, q(t \mid x) \\
&\quad + \alpha \frac{\delta}{\delta q(t \mid x)} \sum_{x,t} q(t \mid x)\, p(x) \log q(t \mid x) \\
&\quad - \beta \frac{\delta}{\delta q(t \mid x)} \sum_{y,t} q(t \mid y)\, p(y) \log \left[\frac{q(t \mid y)}{q(t)}\right] \\
&= -\log q(t)\, \frac{\delta q(t)}{\delta q(t \mid x)} - q(t)\, \frac{\delta \log q(t)}{\delta q(t \mid x)} && (39)\\
&\quad - \lambda(x)\, \frac{\delta q(t \mid x)}{\delta q(t \mid x)} \\
&\quad + \alpha \left[p(x) \log q(t \mid x)\, \frac{\delta q(t \mid x)}{\delta q(t \mid x)}\right. \\
&\quad \left. + q(t \mid x)\, p(x)\, \frac{\delta \log q(t \mid x)}{\delta q(t \mid x)}\right] \\
&\quad - \beta \sum_y \left[p(y) \log \left[\frac{q(t \mid y)}{q(t)}\right] \frac{\delta q(t \mid y)}{\delta q(t \mid x)}\right] \\
&\quad + \beta \sum_y \left[q(t \mid y)\, p(y)\, \frac{\delta \log q(t \mid y)}{\delta q(t \mid x)}\right. \\
&\quad \left. + q(t \mid y)\, p(y)\, \frac{\delta \log q(t)}{\delta q(t \mid x)}\right] \\
&= -p(x) \log q(t) - p(x) - \lambda(x) && (40)\\
&\quad + \alpha \left[p(x) \log q(t \mid x) + p(x)\right] \\
&\quad - \beta \sum_y \left[p(y) \log \left[\frac{q(t \mid y)}{q(t)}\right] p(x \mid y)\right. \\
&\quad \left. + p(y)\, p(x \mid y) - q(t \mid y)\, p(y)\, \frac{p(x)}{q(t)}\right] \\
&= -p(x) \log q(t) - p(x) - \lambda(x) && (41)\\
&\quad + \alpha \left[p(x) \log q(t \mid x) + p(x)\right] \\
&\quad - \beta p(x) \left[\sum_y p(y \mid x) \log \left[\frac{q(t \mid y)}{q(t)}\right]\right. \\
&\quad \left. + \sum_y p(y \mid x) - \sum_y q(y \mid t)\right] \\
&= p(x) \left[-1 - \log q(t) - \frac{\lambda(x)}{p(x)}\right. && (42)\\
&\quad + \alpha \log q(t \mid x) + \alpha \\
&\quad \left. - \beta \left[\sum_y p(y \mid x) \log \left[\frac{q(t \mid y)}{q(t)}\right]\right]\right]\,.
\end{aligned}$$

Setting this to zero implies that:

$$\alpha \log q(t \mid x) = 1 - \alpha + \log q(t) + \frac{\lambda(x)}{p(x)} + \beta \left[\sum_y p(y \mid x) \log \left[\frac{q(t \mid y)}{q(t)} \right] \right]. \tag{43}$$

We want to rewrite the β term as a KL divergence. First, we will need that $\log\left[\frac{q(t|y)}{q(t)}\right] = \log\left[\frac{q(t,y)}{q(t)p(y)}\right] = \log\left[\frac{q(y|t)}{p(y)}\right]$. Second, we will add and subtract $\beta \sum_y p(y \mid x) \log\left[\frac{p(y|x)}{p(y)}\right]$. This gives us:

$$\alpha \log q(t \mid x) = 1 - \alpha + \log q(t) + \frac{\lambda(x)}{p(x)} + \beta \sum_y p(y \mid x) \log \left[\frac{p(y \mid x)}{p(y)} \right] - \beta \left[\sum_y p(y \mid x) \log \left[\frac{p(y \mid x)}{q(y \mid t)} \right] \right]. \tag{44}$$

The second β term is now just $D_{\mathrm{KL}}[p(y \mid x) \mid q(y \mid t)]$. This leaves us with the equation:

$$\log q(t \mid x) = z(x, \alpha, \beta) + \frac{1}{\alpha} \log q(t) - \frac{\beta}{\alpha} D_{\mathrm{KL}}[p(y \mid x) \mid q(y \mid t)], \tag{45}$$

where we have divided both sides by α and absorbed all the terms that don't depend on t into the factor:

$$z(x, \alpha, \beta) \equiv \frac{1}{\alpha} - 1 + \frac{\lambda(x)}{\alpha p(x)} + \frac{\beta}{\alpha} \sum_y p(y \mid x) \log \left[\frac{p(y \mid x)}{p(y)} \right]. \tag{46}$$

Exponentiating both sides to solve for $q(t \mid x)$, we get:

$$d(x, t) \equiv D_{\mathrm{KL}}[p(y \mid x) \mid q(y \mid t)] \tag{47}$$

$$\ell_\beta(x, t) \equiv \log q(t) - \beta d(x, t) \tag{48}$$

$$q(t \mid x) = \frac{1}{Z} \exp\left[\frac{1}{\alpha} \ell_\beta(x, t) \right] \tag{49}$$

where:

$$Z(x, \alpha, \beta) \equiv \exp[-z] \tag{50}$$

is just a normalization factor. Now that we're done with the general derivation, let's add a subscript to the solution to distinguish it from the special cases of the IB and DIB.

$$q_\alpha(t \mid x) = \frac{1}{Z} \exp\left[\frac{1}{\alpha} \ell_\beta(x, t) \right]. \tag{51}$$

The IB solution is then:

$$q_{\mathrm{IB}}(t \mid x) = q_{\alpha=1}(t \mid x) \tag{52}$$

$$= \frac{q(t)}{Z} \exp[-\beta d(x, t)], \tag{53}$$

while the DIB solution is:

$$q_{\mathrm{DIB}}(t \mid x) = \lim_{\alpha \to 0} q_\alpha(t \mid x) \tag{54}$$

$$= \delta(t - t^*(x)), \tag{55}$$

with:

$$t^*(x) = \operatorname*{argmax}_t \ell_\beta(x, t). \tag{56}$$

Abstract

We present the Smoothing Machine (SMACH, pronounced "smash"), a dynamical system learning algorithm based on chain Conditional Random Fields (CRFs) with latent states. Unlike previous methods, SMACH is designed to optimize prediction performance when we have information from both past and future observations. By leveraging Predictive State Representations (PSRs), we model beliefs about latent states through *predictive states*—an alternative but equivalent representation that depends directly on observable quantities. Predictive states enable the use of well-developed supervised learning approaches in place of local-optimum-prone methods like EM: we learn regressors or classifiers that can approximate message passing and marginalization in the space of predictive states. We provide theoretical guarantees on smoothing performance and we empirically verify the efficacy of SMACH on several dynamical system benchmarks.

1 INTRODUCTION

In time series, smoothing is the process of inferring *a posteriori* latent state information given a model as well as past and future observations. Many applications leverage smoothing for inference, ranging from machine learning and robotics to biological science. For example, in a Linear Dynamical System (LDS), a Kalman smoother is frequently used to compute the posterior distribution of the system's states. Similarly, in Optical Character Recognition (OCR), smoothing is used to predict the word corresponding to a sequence of of handwritten characters.

Chain CRFs [Lafferty et al., 2001] are remarkably successful probabilistic graphical models for these applications. As a discriminative approach, CRFs can capture detailed structural properties of the observations and states with a reasonable number of parameters. (In this context, the states are often called *labels*.) Given a parametrization of the CRF, along with a training data set consisting of pairs of ground truth labels and observations, we can learn parameters for the CRF by maximizing the (log) conditional likelihood of the training labels given the training observations. For appropriate feature parametrizations, the log-likelihood objective is convex and one can achieve globally optimal solutions.

In this work, we are interested in *latent* chain CRFs, which generalize CRFs by adding a layer of latent variables between the labels and observations (Figure 1a). These latent variables increase the expressiveness of the underlying probabilistic model [Stratos et al., 2013], but also make the optimization problem more challenging: the log-likelihood objective becomes non-convex. Iterative approaches such as Expectation-Maximization (EM) can only compute locally optimal solutions, making the search for a globally optimal solution computationally infeasible. Though the global maximizer of the likelihood can promise good performance if we can find it, the locally optimal solutions that are found in practice typically do not have any performance guarantees.

To tackle the problem of local optima, we borrow ideas from spectral learning methods and Predictive State Representations (PSRs). In the last decade, these methods have been successfully used for learning and inference in latent state space models such as linear dynamical systems and hidden Markov models [Jaeger, 2000, Hsu et al., 2009, Boots, 2012, Boots et al., 2011, Song et al., 2010, Boots et al., 2013, Hefny et al., 2015]. The main idea is that, instead of tracking latent states directly, we track observable quantities such as expectations of features of future observations. If the features are selected to be sufficient statistics of the latent state distribution, knowing the predictive state is equivalent to knowing the underlying state of the system [Jaeger, 2000, Hefny et al., 2015, Sun et al., 2016]. Spectral learning algorithms provide theoretical guarantees: their estimating equations typically have a unique global solu-

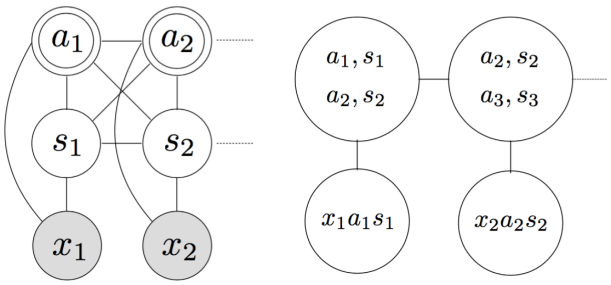
tion, which converges to the true model parameters under the assumption of realizability (no model mismatch). However, if there is model mismatch, no theoretical guarantees are available for the learned model or the associated inference tasks [Kulesza et al., 2014].

To gain the benefits of spectral learning methods even in the case of model mismatch, we propose a novel algorithm, the *Smoothing Machine* (SMACH). Our method builds on recent work on *Predictive State Inference Machines* (PSIMs) [Sun et al., 2016, Venkatraman et al., 2016]. Like a PSR, a PSIM uses predictive states to represent beliefs about latent states. But, unlike a PSR, a PSIM directly learns a closed-loop filter as an inference machine that propagates the predictive state forward in time. By focusing on inference in predictive state space rather than latent state space, a PSIM reduces the difficult problem of learning a latent state space model to supervised learning and achieves guaranteed performance for its inference task (filtering or forward belief propagation) even in the presence of model mismatch.

A PSIM learns a filter that uses past and current observations to predict current latent information. Recently, Venkatraman et al. [2016] applied PSIM to forward message passing in a graphical model with partially observable states. However, this approach is suboptimal for estimating latent states in an offline setting where future observations are also available. So, SMACH extends PSIMs by learning a smoother that takes account of both past *and* future observations. Similar to PSIMs and PSRs, SMACH replaces latent states by predictions of observable quantities. Different from classic messages in graphical models, predictive messages represent the distributions of the sufficient statistics of observable quantities (e.g., labels and observations).

SMACH treats message passing as a sequence of predictions. It directly learns three predictors for approximating message passing in the predictive state space: one for forward predictive state message passing, another for backward predictive state message passing, and a third for combining messages at a given time step. The first predictor learns to recursively compute forward messages that encode information about past events (all past observations up to now), while the second predictor learns to compute backward messages that encode information about future events (all future observations after now). The last predictor predicts the current label given the local observation and the corresponding forward and backward predictive states. At testing time, SMACH uses the first two predictors to compute the forward and backward predictive states along the chain, and then uses the last predictor to combine the forward and backward predictive states with the local observations to predict the labels.

The main advantages of SMACH are: (1) It leverages predictive states to reduce the problem of learning latent chain CRFs to a supervised setting. This reduction enables us to avoid local optima and use well developed theorems of supervised learning to quantify the smoothing performance of SMACH. (2) Similar to PSIM, SMACH combines the two phases of modeling and learning into a siingle task, to directly optimize the ultimate inference task of smoothing. Hence, no parametrization is needed for an explicit probabilistic graphical model (e.g., potential functions for cliques). (3) The learned predictors implicitly encode the information of the underlying probabilistic models. This enables the use of arbitrarily powerful regressors or classifiers as predictors for message passing and for the computation of marginal distributions and hence provides resistance to model mismatch. Finally, (4) as we will show, our formulation fully generalizes the special case of a *chain CRF* without latent states (i.e., removing s from Figure 1a).



(a) Latent chain CRF (b) Junction Tree

Figure 1: A form of latent chain CRF and its junction tree. The labels a (double circled) are observable in training but are latent and need to be inferred during testing. Latent state s is never observable and x (gray) is always observable. During testing, given all observations $x_{1:T}$, the inference task is to compute the posterior distribution $P(a_t \mid x_{1:T})$ for all t.

2 PRELIMINARIES

In this work we consider a general latent chain CRF structure, as shown in Figure 1a. The model consists of three different types of variables: (1) Labels a_t that can be either continuous (e.g, positions of a mobile robot) or discrete (e.g., labels of a hand-written character). We assume that the ground truth labels are available in the training data, while the labels are latent at test time and need to be predicted. (2) Latent states s_t (either continuous or discrete) that are hidden both at training and test time. (3) Observations x_t (either continuous or discrete), available both at training and test time. A sequence of labels and observations $\{a_1, x_1, ..., a_T, x_T\}$ defines a trajectory τ. In order to perform the *smoothing* inference process, we are interested in computing the posterior distribution of the label a_t, conditioned on all observations $\{x_1, ..., x_T\}$: $P(a_t \mid x_{1:T}), \forall t$.

To discuss message passing in the latent chain CRF of Figure 1a, we first need to generate the corresponding

junction tree representation, as shown in Figure 1b. The junction tree allows inference algorithms to avoid the inner loops in the original latent CRF model and perform message passing as follows [Koller and Friedman, 2009]. First, pick the node (a_1, s_1, a_2, s_2) as the root and perform backward message passing starting from each leaf (x_t, a_t, s_t). The message at the separation set (a_t, s_t) between the node $(a_t, s_t, a_{t+1}, s_{t+1})$ and the node (x_t, a_t, s_t) can be represented by $P(x_t \mid a_t, s_t)$, where x_t is the evidence. We define the backward message at the separation set (a_t, s_t), going from the node $(a_t, s_t, a_{t+1}, s_{t+1})$ to the node $(a_{t-1}, s_{t-1}, a_t, s_t)$, as $b_t \equiv P(a_t, s_t \mid x_{t:T})$, which we compute recursively as:

$$b_{t-1} \propto \sum_{a_t s_t} P(a_{t-1}, s_{t-1} \mid a_t, s_t) P(x_t \mid a_t, s_t) b_t. \quad (1)$$

We assume without loss of generality that the (forward) transition probability $P(a_{t+1}, s_{t+1} \mid a_t, s_t)$ is time-invariant, and we write $P(a_t, s_t \mid a_{t+1}, s_{t+1})$ for the corresponding backward transition probability. After all backward messages are computed, starting from the root, we pass messages forward. The forward message at the separation set (a_t, s_t) from the node $(a_{t-1}, s_{t-1}, a_t, s_t)$ to the node $(a_t, s_t, a_{t+1}, s_{t+1})$ is represented by $P(a_t, s_t \mid x_{1:t-1})$, which we denote $\tilde{b}_t$. The forward message is also computed recursively:

$$\tilde{b}_{t+1} \propto \sum_{s_t, a_t} P(a_{t+1}, s_{t+1} \mid a_t, s_t) P(x_t \mid a_t, s_t) \tilde{b}_t. \quad (2)$$

With forward and backward messages, at the node $(a_t, s_t, a_{t+1}, s_{t+1})$ the marginal message $P(a_t \mid x_{1:T})$, which we denote as $\hat{b}_t$, is computed as:

$$\hat{b}_t \propto \sum_{s_t, a_{t+1}, s_{t+1}} \frac{P(a_{t+1}, s_{t+1} \mid a_t, s_t) \tilde{b}_t P(x_t \mid a_t, s_t) b_{t+1}}{P(a_{t+1}, s_{t+1})}. \quad (3)$$

If we assume that $P(a, s)$ is time-invariant, the above equation can be regarded as a time-invariant, deterministic function that maps $\tilde{b}_t$, b_{t+1}, and the local observation x_t to $\hat{b}_t$.

3 OBSERVABILITY AND PREDICTIVE STATES

To perform message passing as described in Sec. 2, classic MLE-based approaches first parametrize latent CRFs and then learn the parametrization from training data. Learning the parameters of the transition models and the observations models is hard due to the latent states: the log likelihood of the observations and labels is non-convex. As a consequence, MLE-based approaches need to use iterative methods such EM, which can only promise local optimality and therefore lack performance guarantees.

Our approach leverages Predictive State Representations (PSRs) to overcome the difficulties of dealing with latent states. PSRs use *predictive states*, which consist of expectations of observable quantities, as an alternative, equivalent representation of latent belief states. Below, we first introduce the definition of *observability*, which extends the classic observability definition from latent state space models (e.g., LDS, HMM) to latent chain-CRFs.

3.1 OBSERVABILITY

Let us focus on a particular separation set (a_t, s_t) between the two nodes $(a_{t-1}, s_{t-1}, a_t, s_t)$ and $(a_t, s_t, a_{t+1}, s_{t+1})$ on the junction tree modelled in Figure 2. The forward belief in this separation set is represented as $P(a_t, s_t \mid x_{1:t-1})$. We define forward k-observability as follows:

Definition (Forward k-observability) There exists a constant $k \in \mathbb{N}^+$ such that the relationship between $P(a_t, s_t \mid x_{1:t-1})$ and $P(a_{t:t+k}, x_{t:t+k-1} \mid x_{1:t-1})$ is bijective.

Intuitively, forward k-observability means that the distribution of *future* observable quantities (labels a and observations x) uniquely determines the latent forward belief, conditioned on the previous observations. We define backward k-observability similarly:

Definition (Backward k-observability) There exists a constant $k \in \mathbb{N}^+$ such that the relationship between $P(a_t, s_t \mid x_{t:T})$ and $P(a_{t-k:t}, x_{t-k:t-1} \mid x_{t:T})$ is bijective.

Intuitively, backward k-observability means that the distribution of *past* observable quantities (labels a and observations x) uniquely determines the latent backward belief state, conditioned on future observations.[1]

In the Appendix, we conduct a case study of observability on one special form of latent chain-CRF—the Refinement Hidden Markov Model (RHMM) [Stratos et al., 2013]. Specifically, first we reduce the RHMM to a regular HMM, and then we leverage the well-defined concept of observability of HMMs to define the forward and backward observability of the original RHMM. In fact, when we set k big enough to cover the entire time windows of past and future, our definition is actually agrees with the *past* and *future* random variables defined by Stratos et al. [2013].

3.2 PREDICTIVE STATES

The definition of observability provides us with a different way to represent the beliefs containing latent states: we can use the joint distributions of future (past) labels

[1] In principle, the statistics could depend on the entire sequence of observations $x_{t:T}$ (or $x_{1:t}$). The restriction to a k-step window of visible variables simplifies the notation and is commonly used in practice.

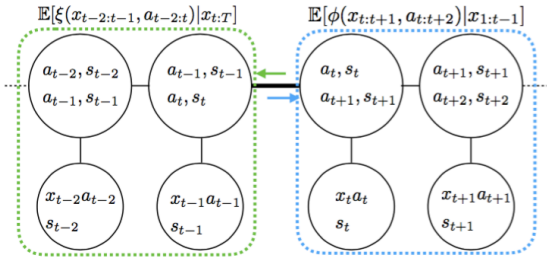


Figure 2: Illustration of the forward predictive state (blue) and backward predictive state (green) with $k = 2$.

and observations to represent the forward (backward) beliefs about latent states. Let us define a feature function ϕ that computes sufficient statistics of $a_{t:t+k}, x_{t:t+k-1}$, such that $P(a_{t:t+k}, x_{t:t+k-1} \mid x_{1:t-1})$ can be represented by $\mathbb{E}[\phi(a_{t:t+k}, x_{t:t+k-1}) \mid x_{1:t-1}]$. (In many cases, a good feature function is a kernel mean embedding, which is guaranteed to yield sufficient statistics for a wide range of distributions.) Similarly we define a feature function ξ that computes sufficient statistics of $a_{t-k:t}, x_{t-k:t-1}$, such that $P(a_{t-k:t}, x_{t-k:t-1} \mid x_{t:T})$ can be represented by $\mathbb{E}[\xi(a_{t-k:t}, x_{t-k:t-1}) \mid x_{t:T}]$. (In practice, ξ could be the same as ϕ.) Under the assumption that the system is forward k-observable and backward k-observable, we can now replace the beliefs about latent states $P(a_t, s_t \mid x_{1:t-1})$ and $P(a_t, s_t \mid x_{t:T})$ with the predictive messages $\mathbb{E}[\phi(a_{t:t+k}, x_{t:t+k-1}) \mid x_{1:t-1}]$ and $\mathbb{E}[\xi(a_{t-k:t}, x_{t-k:t-1}) \mid x_{t:T}]$ respectively. For notational simplicity, let us define $f_t = (a_{t:t+k}, x_{t:t+k-1})$ and $h_t = (a_{t-k:t}, x_{t-k:t-1})$. We define the *Forward Predictive State* (FPS) m_t at step t, and the *Backward Predictive State* (BPS) v_t at step t as:

$$m_t = \mathbb{E}[\phi(f_t) \mid x_{1:t-1}], \quad v_t = \mathbb{E}[\xi(h_t) \mid x_{t:T}]. \tag{4}$$

Note that our formulation fully generalizes the special case of a *chain CRF* without latent states (i.e., removing all s and edges connected to s from Figure 1a). In this case, by setting $k = 0$, the forward predictive state m_t becomes $\mathbb{E}[\phi(a_t) \mid x_{1:t-1}]$ and the backward predictive state v_t becomes $\mathbb{E}[\xi(a_t) \mid x_{t:T}]$. With sufficient feature functions ϕ and ξ, m_t and v_t are then equivalent to $P(a_t \mid x_{1:t-1})$ and $P(a_t \mid x_{t:T})$, which are the classic forward and backward beliefs on a chain CRF.

As we will show in the next section, we can use PSIM to compute forward and backward predictive states.

4 ALGORITHM

We now present the *Smoothing Machines* (SMACH) algorithm (Alg. 2). As introduced in the previous section, we first leverage PSIM to learn stationary filters for the generation of forward and backward predictive states. The final step of SMACH is to combine the forward and backward predictive states together with observations to learn a predictor for smoothing. Below we briefly introduce PSIM and how PSIM can be used for computing predictive states.

Algorithm 1 PSIM with DAgger (Forward Pass)

Input: M independent trajectories τ_i, $1 \leq i \leq M$;
Initialize $D_0 \leftarrow \emptyset$ and initialize $F_0 \in \mathcal{F}_1$;
Initialize $\hat{m}_1 = \frac{1}{M} \sum_{i=1}^{M} \phi(f_1^i)$
for n = 0 to N **do**
  Use F_n to perform belief propagation (Eq. 6) on trajectory τ_i, $1 \leq i \leq M$
  For each trajectory τ_i and each time step t, add the input $z_t^i = (m_t^{i,F_n}, x_t^i)$ encountered by F_n to D'_{n+1} as feature variables and the corresponding f_{t+1}^i to D'_{n+1} as the targets ;
  Aggregate dataset $D_{n+1} = D_n \cup D'_{n+1}$;
  Train a new hypothesis $F_{n+1} \in \mathcal{F}_1$ on D_{n+1} to minimize the loss $d(F(m, x), f)$;
end for
Return: the best hypothesis $F_f \in \{F_n\}_n$ on validation trajectories.

4.1 PREDICTIVE STATE INFERENCE MACHINES

We utilize *Predictive State Inference Machines* (PSIM) [Sun et al., 2016] to directly compute the predictive states m_t and v_t. PSIM is a discriminative learning approach that learns a filter (black box represented by any regressors or classifiers) to mimic the predictive message passing process: by taking the incoming predictive message and the local observation as inputs, it outputs the next predictive message. Specifically, for forward predictive message passing, given a trajectory $\tau = \{a_1, x_1, ..., a_T, x_T\}$ sampled from the distribution $\mathcal{D}$, PSIM aims at finding a hypothesis $F_f \in \mathcal{F}_1$ to optimize the following objective:

$$\min_{F_f \in \mathcal{F}_1} \mathbb{E}_\tau \sum_{t=1}^{T} \|\hat{m}_t^\tau - \phi(f_t^\tau)\|^2; \tag{5}$$

$$\text{s.t. } \hat{m}_{t+1}^\tau = F_f(\hat{m}_t^\tau, x_t^\tau). \tag{6}$$

Namely, PSIM finds a hypothesis that can mimic forward predictive message passing, and the quality of the computed predictive messages are measured by the loss $\|\hat{m}_t - \phi(f)_t\|^2$ (i.e., moment matching).

Similar to forward predictive message passing, we can use PSIM for backward predictive message passing. In this case, PSIM aims at finding a hypothesis $F_b \in \mathcal{F}_2$ ($\mathcal{F}_2$ and $\mathcal{F}_1$ could either be the same or different hypothesis classes)

to optimize the *backward* filtering performance as:

$$\min_{F_b \in \mathcal{F}_2} \mathbb{E}_\tau \sum_{t=1}^{T} \|\hat{v}_t^\tau - \xi(h_t^\tau)\|^2; \tag{7}$$

$$\text{s.t. } \hat{v}_t^\tau = F_b(\hat{v}_{t+1}^\tau, x_t^\tau). \tag{8}$$

In its original form [Sun et al., 2016], two optimization approaches are adopted for finding F_f or F_b: one uses Forward Training [Ross and Bagnell, 2010] to learn a non-stationary filter, while the other uses Data Aggregation [Ross et al., 2011b] to learn a stationary filter. However, as pointed out by the authors, even if the use of PSIM with Forward Training provably guarantees hypothesis consistency (i.e., the learned filters are equal to the true underlying filters), this solution is often impractical due to its data inefficiency. Conversely, PSIM with Data Aggregation is significantly more data efficient, both in the sample complexity analysis and in the empirical analysis [Sun et al., 2016]. Therefore, in this paper, we use PSIM with Data Aggregation to learn stationary filters for computing approximated predictive forward messages $\hat{m}$ and backward messages $\hat{v}$. The detailed description of the PSIM with DAgger for computing the hypothesis F_f for forward predictive message passing is provided in Alg. 1. The computation of backward predictive states will be similar, since we only need to reverse the belief propagation order (Line 5) using Eq. 7 and replace $f, \hat{m}, \mathcal{F}_1, F_f$ with $h, v, \mathcal{F}_2, F_b$ respectively.

Theoretically, PSIM ensures that the filtering errors resulting from the learned F_f and F_b are upper bounded as:[2]

$$\mathbb{E}_\tau \frac{1}{T} \sum_{t=1}^{T} [\|\hat{m}_t^\tau - \phi(f_t)\|^2] \leq \epsilon_m, \tag{9}$$

$$\mathbb{E}_\tau \frac{1}{T} \sum_{t=1}^{T} [\|\hat{v}_t^\tau - \xi(h_t)\|^2] \leq \epsilon_v, \tag{10}$$

where ϵ_m and ϵ_v are the regression or classification error on the aggregated dataset [Ross et al., 2011a, Sun et al., 2016]. In practice, both ϵ_m and ϵ_v can be small when we have an expressive hypothesis class and small noise (e.g., small Bayes error) [Ross et al., 2011c].

Therefore, by using PSIM, we can learn two operators F_f and F_b that mimic the forward and backward predictive state passing procedures. With these two operators, we can compute the approximated backward predictive state $\hat{v}_t$ and the forward predictive state $\hat{m}_t$ for the separation set (a_t, s_t) at any time step t (Figure 2).

[2]The original PSIM work by Sun et al. [2016] only provides theoretical bounds for forward message passing. However, for backward message passing, the same bounds directly apply if we reverse message passing direction.

Algorithm 2 Smoothing Machines (SMACH)

1: **Input:** M training trajectories $\tau_i = \{x_t^i, a_t^i\}_{t=1}^{T_i}$, $1 \leq i \leq M$; Hypothesis class $\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3$.
2: Run PSIM on $\{\tau_i\}_{t=1}^{M}$ to learn the forward model $F_f \in \mathcal{F}_1$.
3: Run PSIM on $\{\tau_i\}_{t=1}^{M}$ to learn the backward model $F_b \in \mathcal{F}_2$.
4: Initialize dataset $\mathcal{S} = \emptyset$.
5: **for** each τ_i, $1 \leq i \leq M$ **do**
6: Roll out F_f forward to generate forward predictive states $\{\hat{m}_t^{\tau_i}\}_{t=1}^{T_i}$.
7: Roll out F_b backward to generate backward predictive states $\{\hat{v}_t^{\tau_i}\}_{t=2}^{T_i+1}$.
8: Compose input feature $\hat{z}_t^{\tau_i} = (\hat{m}_t^{\tau_i}, \hat{v}_{t+1}^{\tau_i}, x_t^{\tau_i})$ for $1 \leq t \leq T_i$.
9: Add input and output pair $\{(\hat{z}_t^\tau, a_t^{\tau_i})\}_{t=1}^{T_i}$ into $\mathcal{S}$.
10: **end for**
11: Compute the marginal hypothesis:

$$\hat{G} = \arg\max_{G \in \mathcal{F}_3} \mathbb{E}_{(z,a)\sim\mathcal{S}}\, \ell(G(z), a). \tag{11}$$

12: **Return:** $F_f, F_b, \hat{G}$.

4.2 SMOOTHING MACHINES

The SMACH algorithm is presented in Alg. 2. SMACH first learns a stationary forward filter $F_f \in \mathcal{F}_1$ and a backward filter $F_b \in \mathcal{F}_2$: given training data, the SMACH algorithm uses PSIM to learn a hypothesis F_f that can compute and pass the forward predictive states $\hat{m}_t$ (Line 2) and, independently, uses PSIM to learn a hypothesis F_b that can compute and pass the backward predictive states $\hat{v}_t$ (Line 3). Due to their independence, learning F_f and F_b can be executed in parallel.

To learn the final message product and marginalization step, we first generate the predictive states by rolling out F_f and F_b on the training trajectories (Line 6 and 7). Next, the algorithm collects the pairs of forward messages $\hat{m}_t$ and backward messages $\hat{v}_{t+1}$, together with the local observation x_t, as the input feature, with the corresponding label a_t as the output. Finally, SMACH learns a classifier or regressor $\hat{G}$ as shown in Eq. 11 (Line 11) by minimizing a loss function ℓ that measures the prediction error. When a_t is discrete, ℓ can be a common classification loss, such as hinge loss, softmax, or cross entropy.

At test time, given a sequence τ, we only have access to the observations $\{x_t^\tau\}$ and need to predict $\{a_t^\tau\}$. With the learned $F_f, F_b, \hat{G}$, we simply roll F_f forward to compute $\{\hat{m}_t^\tau\}$ and roll F_b backward to compute $\{\hat{v}_t\}$, in parallel. With all the messages available, we then use $\hat{G}(\hat{m}_t^\tau, \hat{v}_{t+1}^\tau, x_t^\tau)$ to predict the label. This whole process uses all observations $\{x_t^\tau\}_t$ to predict a_t a posteriori.

4.3 DISCUSSION

Our learning algorithm shares some similarities with the well-known Baum-Welch algorithm for HMMs. Baum-Welch iterates between estimating the posterior distributions of latent states (using forward and backward pass), and optimizing the parameters. SMACH also performs a forward and backward pass to compute the messages represented by predictive states. The key difference is that we leverage predictive state representations (PSRs) to reduce the problem of learning latent chain-CRFs back to the supervised setting, where we can avoid local optimality issues and give strong theoretical guarantees (Sec. 5).

5 THEORETICAL ANALYSIS

Let us assume that we use PSIM to learn F_f to pass predictive states forward on any given sequences of observations $\{x_1, ..., x_T\}$ from τ as $\hat{m}^\tau_{t+1} = F_f(\hat{m}^\tau_t, x^\tau_t)$, and learn F_b to pass predictive states backward as $\hat{v}^\tau_t = F_b(\hat{v}^\tau_{t+1}, x^\tau_t)$. Let us define $\Delta_{m^\tau_t} = m^\tau_t - \hat{m}^\tau_t$, and $\Delta_{v^\tau_t} = v^\tau_t - \hat{v}^\tau_t$, as the difference between the underlying true predictive states (equivalent to the original beliefs $b_t, \tilde{b}_t$ due to the existence of the bijective map) and the predictive states computed from the learned F_f and F_b, respectively.

Eq. 9 and Eq. 10 quantify the filtering error from the approximated predictive states computed from the learned hypothesis F_f and F_b respectively. The ultimate goal of smoothing is to use both past and future information to compute the posterior distribution of a label more accurately. As one might expect, if we can exactly compute the forward and backward messages, namely $\hat{m}_t = m_t$ and $\hat{v}_{t+1} = v_{t+1}$ for any t and τ, then, in a realizable case, we can exactly learn a hypothesis that takes $\hat{m}_t$, $\hat{v}_t$ and the local observations as inputs and outputs the posterior distributions of the labels. However, one may wonder if we can still achieve strong prediction guarantees on the learned model even if we can only approximately compute m_t and v_t. Moreover, we may be interested in quantifying the performance of the learned model based on the accuracy of the approximated predictive states (e.g., using Δ_{m_t} and Δ_{v_t}). In order to perform this type of analysis, we first introduce some lemmas and notation.

The following lemma extends the results for PSIM shown in Eq. 9 and 10, by explicitly quantifying $\Delta_{\hat{m}_t}$ and $\Delta_{\hat{v}_t}$:

Lemma 5.1. *Given Eq. 9 and 10 from PSIM, for $\Delta_{\hat{m}_t}$ and $\Delta_{\hat{v}_t}$, we have:*

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[\|\Delta_{m^\tau_t}\|^2] \leq 2(\epsilon_m + \delta_m); \tag{12}$$

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[\|\Delta_{v^\tau_t}\|^2] \leq 2(\epsilon_v + \delta_v); \tag{13}$$

where $\delta_m = \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[\|m^\tau_t - \phi(f_t)\|^2]$ and $\delta_v = \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[\|v^\tau_t - \xi(h_t)\|^2]$.

Proof for this lemma and the lemmas/theorems in the remainder of this paper are all included in Appendix.

The above lemma states that the size of Δ_m (or Δ_v) is upper bounded by the sum of ϵ_m (or ϵ_v), which is the risk resulting from the predicted messages, and δ_m (or δ_v), which is the Bayes error resulting from the system itself. Note that the Bayes error is purely determined by the underlying systems and has nothing to do with the learning algorithms. In general, we cannot guarantee the elimination of the Bayes errors. This is because when aiming at learning a stationary F_f (or F_b) for forward (or backward) predictive message passing, the objective (Eq. 5) that PSIM tries to optimize is non-convex. Even ideally assuming that PSIM is *risk* consistent, i.e., it finds an F that has the same filtering error (risk) as the true underlying filter for predictive states, which is the best we can do for a general non-convex objective, we still cannot promise that the learned F is exactly the true underlying filter. Therefore, even if F is risk consistent with respect to the underlying true filter, we cannot promise that the approximated predictive state $\hat{m}_t$ generated from F would be exactly equal to the true underlying state m_t. More detailed explanation is included in Appendix. However, as shown in Lemma. 5.1, the smaller the filtering error from PSIM, the better approximation we get for the predictive states.

To analyze the performance of the learned marginalization hypothesis $\hat{G}$, we first assume that the loss function $\ell(\cdot, \cdot)$ that we are using for classification is Lipschitz continuous, with constant L_1 with respect to the first item ($G(z)$). Commonly used classification loss functions have this property (e.g., hinge loss, logistic loss). Additionally, we assume that $G(\cdot)$, for any $G \in \mathcal{F}_3$, is also Lipschitz continuous with constant L_2 with respect to z. This is also a reasonable assumption for common hypothesis classes such as linear, quadratic and, in fact, any differentiable hypotheses with bounded first derivatives.

Let us define G^* as the minimizer of the true risk measured under the true messages (m^τ_t, v^τ_t):

$$G^* = \arg\max_{G \in \mathcal{F}_3} \mathbb{E}_\tau[\ell(G(z^\tau_t), a^\tau_t)], \tag{14}$$

where z^τ_t is composed as $(m^\tau_t, v^\tau_{t+1}, x^\tau_t)$ with the true underlying predictive messages m^τ_t, v^τ_{t+1} on the sequence τ. With sufficient feature functions ϕ and ξ, m^τ_t and v^τ_t will be equivalent to b^τ_t and $\tilde{b}^\tau_t$ subject to a bijective map. Hence, in a realizable case, G^* encodes as much information as the true underlying marginalization step in the original latent chain-CRF, as shown in Eq. 3. Let us first analyze the learned model $\hat{G}$ under the assumption of infinite many training trajectories ($M \to \infty$):

Theorem 5.2. *Assuming F_f and F_b from PSIM generate the messages $\hat{m}_t$ and $\hat{v}_t$ satisfying Eq. 12 and 13, the*

marginalization hypothesis $\hat{G}$ obtained from Eq. 11 has the following property:

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_{\tau\sim\mathcal{D}}[\ell(\hat{G}(\hat{z}_t^\tau), a_t^\tau)]$$
$$\leq \frac{1}{T}\mathbb{E}_{\tau\sim\mathcal{D}}[\ell(G^*(z_t^\tau), a_t^\tau)] + O(\epsilon_m + \epsilon_v + \delta_m + \delta_v).$$

The above theorem shows that if PSIM learns good hypothesis F_f and F_b for estimating messages (e.g., ϵ_m and ϵ_m are small) and the underlying noise of the dynamical systems is not big, the learned hypothesis $\hat{G}$ can achieve competitive smoothing performance with respect to G^*—the global minimizer of the smoothing risk with access to the true messages (e.g., m_t^τ, v_t^τ).

For Theorem 5.2 we assumed an infinite number of training sequences, although in practice, we only have a finite number of sequences. To show the finite sample complexity of our algorithm, we additionally assume that the training sequences $\tau_1, ..., \tau_M$ are separated in two halves. We use the first half to learn F_f and F_b with PSIM, and the second half to generate messages $\hat{m}$ and $\hat{v}$ with F_f and F_b, and then train $\hat{G}$ for the marginalization step. This assumption ensures that, at every time step t, the generated messages $\{\hat{m}_t^{\tau_{M/2}}, \hat{m}_t^{\tau_{M/2+1}}, ..., \hat{m}_t^{\tau_M}\}$ are i.i.d sampled (note that F_f is independent with respect to $\tau_{M/2}, ..., \tau_M$, and each τ is i.i.d sampled). Let us define the distribution $\hat{d}_t$ as the distribution of $\hat{z}_t^\tau = (\hat{m}_t^\tau, \hat{v}_{t+1}^\tau, x_t^\tau)$. Note that $\{(\hat{m}_t^{\tau_i}, \hat{v}_{t+1}^{\tau_i}, x_t^{\tau_i})\}_{i=M/2}^{M}$ will be i.i.d sampled from $\hat{d}_t$. For convenience, we assume that we have $2M$ training sequences. We use the first M sequences for PSIM to learn F_f and F_b and the remaining M for learning $\hat{G}$.

Using the finite sample analysis for PSIM with Data Aggregation as the optimization tool,we first extend Lemma. 5.1 to the corresponding high probability bounds:

Lemma 5.3. *Using PSIM with Data Aggregation, with probability $1-\delta$, we have:*

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[(\Delta_{m_t^\tau})] \leq 2\hat{\gamma}_m + 2\hat{\epsilon}_m + 2\delta_m + O(\sqrt{\frac{\ln(1/\delta)}{MN}});$$
$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_\tau[(\Delta_{v_t^\tau})] \leq 2\hat{\gamma}_v + 2\hat{\epsilon}_v + 2\delta_v + O(\sqrt{\frac{\ln(1/\delta)}{MN}});$$

where N is number of iterations $PSIM$ used and $\hat{\gamma}_m$ and $\hat{\gamma}_v$ converge to zero as $N \to \infty$

We present the finite sample analysis using Rademacher complexity. We define $\mathcal{R}_t(\mathcal{F}_3)$ as the Rademacher number of the hypothesis class $\mathcal{F}_3$ under distribution $\hat{d}_t$, and $\bar{\mathcal{R}}(\mathcal{F}_3) = (\mathcal{R}_1(\mathcal{F}_3) + ... + \mathcal{R}_T(\mathcal{F}_3))/T$, as the average Rademacher number across T time steps. In our analysis, we assume we know T or the upper bound of T.

	KF	EKF	KS	iEKS	SMACH-0	Avg $\|a_t\|_2$

Theorem 5.4. *Given $2M$ training sequences for Alg. 2, as $N \to \infty$, with probability $1-\delta$, for any $G^* \in \mathcal{F}_3$, we have:*

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_{\tau\sim\mathcal{D}}[\ell(\hat{G}(\hat{z}_t^\tau), a_t^\tau)] \leq \frac{1}{T}\sum_{t=1}^{T}\mathbb{E}_{\tau\sim\mathcal{D}}[\ell(G^*(z_t^\tau), a_t^\tau)]$$
$$+ \tilde{O}(\sqrt{\frac{\ln(1/\delta)}{M}}) + O(\bar{\mathcal{R}}(\mathcal{F}_3) + \hat{\epsilon}_m + \hat{\epsilon}_v + \delta_v + \delta_m).$$

6 EXPERIMENTS

We test SMACH on two different types of datasets: (1) datasets with continuous labels a_t (SMACH needs to perform *regression*), which are collected from several simulated robotics dynamical systems, and (2) datasets whose labels a_t are discrete (SMACH needs to perform *classification*), which are from two domains: Optical Character Recognition, a sequential image recognition task, and questions and answers recognition [McCallum et al., 2000], a Natural Language Processing task.

6.1 REGRESSION TASKS

To show that our approach is able to deal with complicated, non-linear dynamical models of robotics systems, we test our approach on four classic simulated dynamics models: (1) Cart-Pole Balancing, (2) Bicycle Balancing [Ernst et al., 2005], (3) Helicopter Hover [Abbeel et al., 2005] and (4) Swimmer [Tassa et al., 2008]. The simulated models are available from RLPy [Geramifard et al., 2013].

We compare SMACH to classic physics-based algorithms: the Kalman Filter (KF), the Kalman Smoother (KS), the Extended Kalman Filter (EKF), and the iterated Extended Kalman Smoother (iEKS) [Bell, 1994]. We first consider the chain-CRF structure without latent states (no s_t in Fig. 1a). Hence, the label a_t represents the *full* state of the robot, and x_t is generated from a_t through a stochastic observation model. Since there are no latent states, we set $k = 0$. Here, we define the smoothing error as the average of the prediction errors $\|a - \hat{a}\|_2$.

In our setup, we allow KF, KS, EKF, iEKS to access the real underlying dynamical models and observation models. For KF and KS, we linearize the real dynamics and observation model around the balancing state. Note that directly comparing to KF, KS EKF, and iEKS is not fair since these approaches have access to the true stochastic dynamical models, while SMACH only has access to the data generated from the models. Nevertheless, as we can see from

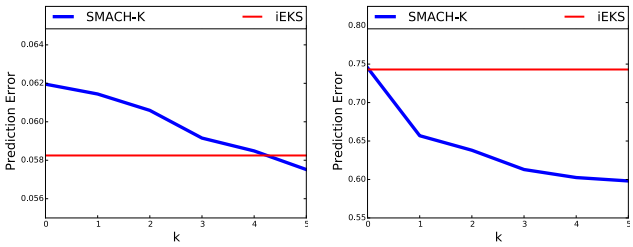
Tab. 1, by using Kernel Ridge regression (i.e., $\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_t$ are Reproducing Kernel Hilbert Spaces), SMACH outperforms these classic physics-based approaches on all four testbeds.[3] We only tested SMACH-0 here as we do not have latent states s_t in the setup here. As we expected, increasing k (using predictive states) does not give noticeable improvement on the prediction error.

To test the performances of SMACH with latent states, we separate the full state into two parts: labels a_t and latent states s_t (see Appendix for the detailed components of s_t and a_t). Under this setup, SMACH is never allowed to access s_t. Due to the existence of latent states, we set $k \geq 1$ (i.e. we use predictive states). Figure 3a and 3b show the performance of SMACH as k increases on the bicycle balancing and swimmer datasets. A similar trend is observed on the other two datasets. Overall, the smoothing performance improves as k increases, which illustrates that longer predictive states can potentially capture more information about latent states. Interestingly, SMACH outperforms iEKS (note that we still give iEKS full access to the latent states s_t in order to perform Kalman smoothing, but we only report smoothing prediction error with respect to label a_t). Since iEKS can be understood as applying the Gauss-Newton algorithm on the log likelihood, which could be non-convex due to non-linear dynamics and observation models, it is likely that iEKS will be stuck at locally optimal solutions.

Since KF, KS, EKF, and iEKS have access to the perfect stochastic models, this set of experiments also supports one of our main claims: separately learning the models and then using the learned models to perform inference may result in decreased performance. This can happen even if we can leverage powerful learning algorithms to learn the perfect models (e.g., using Gaussian Process [Deisenroth et al., 2012] or Hilbert space embeddings [Nishiyama et al., 2016] to model dynamics) due to the unavoidable approximations that one usually needs in order to make inference computationally tractable (e.g., linearize the real/learned dynamics and observations models as KF, KS, GP-EKF and GP-EKS [Ko and Fox, 2009] do). These approximations on the learned/real models may cancel out the benefits derived from the availability of perfect models. SMACH, instead, directly learns powerful predictors to optimize the smoothing performance. Since the predictors operate as black boxes to directly perform the smoothing operation, no further approximation is needed for inference.

6.2 CLASSIFICATION TASKS

We evaluate SMACH on classification tasks belonging to two different domains: Optical Character Recognition and



(a) Bicycle (b) Swimmer

Figure 3: Performance of SMACH with respect to k (length of predictive states) for models with latent states.

questions and answers recognition (FAQ) [McCallum et al., 2000]. In this case, for fair comparison to previous approaches, we use standard feature design. We compare SMACH to two families of algorithms: (1) search-based prediction algorithms such as SEARN [Daumé III et al., 2009], DAgger [Ross et al., 2011b], and PSIM [Sun et al., 2016], (2) CRF [Lafferty et al., 2001] and its extensions, such as Hidden-unit CRF [van der Maaten et al., 2011] and NeuroCRFs [Do et al., 2010].

Optical Character Recognition The OCR dataset contains 6877 handwritten words. Each word is represented as a series of handwritten characters and there are 52152 total characters. Each character is a binary 16×8 image, leading to 128-dimensional binary feature vectors. Each character is one of the 26 letters in the English alphabet. We define the binary vector for character at slot t as c_t. The task is to predict the identity of each character, given a sentence. In our experiments, we use a 7-step time window: we represent x_t as $[c_{t-3}, ..., c_t, ..., c_{t+3}]$ and we test SMACH with different k (SMACH-k).

We first test SMACH on a small experimental setting, where we separate the dataset into 10 folds and perform training on one fold while testing on the remaining 9 folds. Table 2 shows the comparison between SMACH and other closely related approaches.[4] SMACH outperforms SEARN, DAgger and PSIM, which are the state-of-art search-based prediction algorithms. Compared to probabilistic graphical model approaches, SMACH also has better performance than CRFs. From Table 2, we see that from DAgger (equivalent to PSIM-0) to PSIM-1 and PSIM-2 the prediction error decreases when we use, in the predictive messages, more steps of future/past labels and observations. This is consistent with the claim from Sun et al. [2016] that a larger k can lead to more accurate predictive states. As a result, SMACH-2 surpasses SMACH-1, since SMACH-2 uses more accurate predictive messages computed from PSIM-2. This evidence agrees with Theo-

[3]Note that, for iEKS, we use the solutions from EKF as initialization. Simply using random initialization, or the average of the training trajectories as initialization, does not perform well.

[4]The results of SVM^{struct}, SVM^{struct}, M^{3}N, CRF are from [Nguyen and Guo, 2007]; SVM^{struct2} and CRF^2 are from [Keerthi and Sundararajan, 2007]

SVM^{struct}	SVM^{struct2}	M^{3}N	SEARN
21.16	19.24	25.08	27.02
CRF	**CRF^2**	**Hidden unit CRF**	**DAgger**
32.30	19.97	18.36	30.02
PSIM-1	**PSIM-2**	**SMACH-1**	**SMACH-2**
26.11	23.89	18.41	16.21

Table 2: Comparison of SMACH with previous related approaches on the small OCR experimental setting.

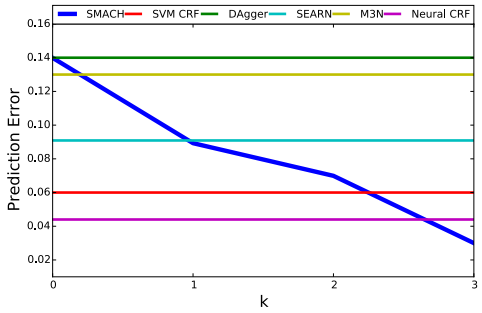


Figure 4: Performance of SMACH-k on large OCR task.

rem 5.4: when we have more accurate predictive messages for the marginal step (e.g., smaller ϵ), the marginal step has a smaller generalization error. We also ran SMACH on a larger setting (training on 9 folds and testing on the remaining one) with different k, reporting the results in Figure 4.[5] From the graph, we note that larger k can greatly improve smoothing performance. SMACH-3 achieves an average prediction error of 3.5%, while Hidden unit CRF achieves a 2.0% prediction error. Note, however, that SMACH-2 achieves a smaller error in the small experiment.

Recognizing questions and answers We also test SMACH on the FAQ dataset from McCallum et al. [2000]. We use the same feature representation from McCallum et al. [2000], where each sentence is described using a 24-dimensional binary vector. Each sentence in the FAQ data set is labeled by one of four labels: (1) question, (2) answer, (3) header, or (4) footer. We use linear SVM for PSIM for computing backward and forward predictive states. For the marginalization step, we use two classifiers: Linear SVM with Random Fourier feature (RFF-SVM) and Random Forest (RF) with 60 trees and maximum depth 30.

From Table 3, we see that both SMACH with RFF-SVM and SMACH with RF achieve performances which are comparable to Hidden-unit CRF [van der Maaten et al., 2011] with Stochastic Gradient Descent as the optimization (we note that SMACH performs slightly better than hidden-unit CRF with other optimizers like Perceptron and BFGS). SMACH with RF gives slightly better performance than SMACH with RFF-SVM. This indicates that using a powerful classifier for the marginal step can potentially enhance the performance. We also tested $k = 1$, leading to a slightly worse performance than $k = 0$. Since we are only allowed to use one file (one sequence) to train the model and test on all the remaining files in the same group [McCallum et al., 2000], when we increase k, we may not have enough training data, since the complexity of the hypothesis classes increases as k becomes larger.

[5]The result of SVM+CRF is from [Hoefel and Elkan, 2008].

Method	Error (%)
Linear SVM [Do et al., 2010]	9.87
Linear CRF [Maaten et al., 2011]	6.54
NeuroCRFs [Do et al., 2010]	6.05
Hidden-unit CRF [Maaten et al., 2011]	4.43
DAgger	7.47
SMACH-0 with RFF-SVM	5.10
SMACH-0 with RF	5.01

Table 3: Comparison of SMACH with related approaches on the FAQ dataset.

7 CONCLUSION

In this paper we present Smoothing Machines (SMACH), a data-driven approach that directly optimizes *smoothing* performance on time series with latent states. We use the concepts of predictive states and inference machines to directly learn functions that mimic forward and backward message passing in our system. Under this setting, we can achieve strong performance guarantees for the ultimate inference task (i.e., smoothing) in the agnostic setting. We show that SMACH outperforms classic physics-based smoothing algorithms on dynamical systems with complicated non-linear transition models. We also show that in the presence of latent states, using more features (i.e., a longer time window) can boost the algorithm's performance. Additionally, our experimental results on classification tasks are promising. We leave the application of SMACH on more complicated NLP tasks (e.g., Part of Speech Tagging) as future work.

Context-dependent feature analysis with random forests

Antonio Sutera[1] **Gilles Louppe**[2] **Vân Anh Huynh-Thu**[1] **Louis Wehenkel**[1] **Pierre Geurts**[1]
[1] Dept. of EE & CS, University of Liège, Belgium [2] New York University, USA

Abstract

In many cases, feature selection is often more complicated than identifying a single subset of input variables that would together explain the output. There may be interactions that depend on contextual information, i.e., variables that reveal to be relevant only in some specific circumstances. In this setting, the contribution of this paper is to extend the random forest variable importances framework in order (i) to identify variables whose relevance is context-dependent and (ii) to characterize as precisely as possible the effect of contextual information on these variables. The usage and the relevance of our framework for highlighting context-dependent variables is illustrated on both artificial and real datasets.

1 MOTIVATION

Supervised learning finds applications in many domains such as medicine, economics, computer vision, or bioinformatics. Given a sample of observations of several inputs and one output variable, the goal of supervised learning is to learn a model for predicting the value of the output variable given any values of the input variables. Another common side objective of supervised learning is to bring as much insight as possible about the relationship between the inputs and the output variable. One of the simplest ways to gain such insight is through the use of feature selection or ranking methods that identify the input variables that are the most decisive or relevant for predicting the output, either alone or in combination with other variables. Among feature selection/ranking methods, one finds variable importance scores derived from random forest models that stand out from the literature mainly because of their multivariate and non parametric nature and their reasonable computational cost. Although very useful, feature selection/ranking methods however only provide very limited information about the often very complex input-output relationships that can be modeled by supervised learning methods. There is thus a high interest in designing new techniques to extract more complete information about input-output relationships than a single global feature subset or feature ranking.

In this paper, we specifically address the problem of the identification of the input variables whose relevance or irrelevance for predicting the output only holds in specific circumstances, where these circumstances are assumed to be encoded by a specific context variable. This context variable can be for example a standard input variable, in which case, the goal of contextual analyses is to better understand how this variable interacts with the other inputs for predicting the output. The context can also be an external variable that does not belong to the original inputs but that may nevertheless affect their relevance with respect to the output. Practical applications of such contextual analyses are numerous. E.g., one may be interested in finding variables that are both relevant and independent of the context, as in medical studies (see, e.g., Geissler et al., 2000), where one is often interested in finding risk factors that are as independent as possible of external factors, such as the sex of the patients, their origins or their data cohort. By contrast, in some other cases, one may be interested in finding variables that are relevant but dependent in some way on the context. For example, in systems biology, differential analysis (Ideker and Krogan, 2012) aims at discovering genes or factors that are relevant only in some specific conditions, tissues, species or environments.

Our contribution in this paper is two-fold. First, starting from common definitions of feature relevance, we propose a formal definition of context-dependent variables and provide a complete characterization of these variables depending on how their relevance is affected by the context variable. Second, we extend the random forest variable importances framework in order to identify and characterize variables whose relevance is context-dependent or context-independent. Building on existing theoretical results for standard importance scores, we propose asymptotic guarantees for the resulting new measures.

The paper is structured as follows. In Section 2, we first lay out our formal framework defining context-dependent variables and describing how the context may change their relevance. We describe in Section 3 how random forest variable importances can be used for identifying context-dependent variables and how the effect of contextual information on these variables can be highlighted. Our results are then illustrated in Section 4 on representative problems. Finally, conclusions and directions of future works are discussed in Section 5.

2 CONTEXT-DEPENDENT FEATURE SELECTION AND CHARACTERIZATION

Context-dependence. Let us consider a set $V = \{X_1, \ldots, X_p\}$ of p input variables and an output Y and let us denote by V^{-m} the set $V \setminus \{X_m\}$. All input and output variables are assumed to be categorical, not necessarily binary[1]. The standard definitions of relevant, irrelevant, and marginally relevant variables based on their mutual information I are as follows (Kohavi and John, 1997; Guyon and Elisseeff, 2003):

- A variable X_m is *relevant to Y with respect to V* iff there exists a subset $B \subseteq V^{-m}$ (possibly empty) such that $I(Y; X_m|B) > 0$.
- A variable X_m is *irrelevant to Y with respect to V* iff, for all $B \subseteq V^{-m}$, $I(Y; X_m|B) = 0$.
- A variable is *marginally relevant to Y* iff $I(Y; X_m) > 0$.

Let us now assume the existence of an additional (observed) context variable $X_c \notin V$, also assumed to be categorical. Inspired by the notion of relevant and irrelevant variables, we propose to define context-dependent and context-independent variables as follows:

Definition 1. *A variable $X_m \in V$ is* context-dependent to Y with respect to X_c *iff there exists a subset $B \subseteq V^{-m}$ and some values x_c and b such that*[2]*:*

$$I(Y; X_m|B = b, X_c = x_c) \neq I(Y; X_m|B = b). \quad (1)$$

Definition 2. *A variable $X_m \in V$ is* context-independent to Y with respect to X_c *iff for all subsets $B \subseteq V^{-m}$ and for all values x_c and b, we have:*

$$I(Y; X_m|B = b, X_c = x_c) = I(Y; X_m|B = b). \quad (2)$$

[1]Non categorical outputs are discussed in Section 3.5.

[2]In this definition and all definitions that follow, we assume that the events on which we are conditioning have a non-zero probability and that if such event does not exist then the condition of the definition is not satisfied.

Context-dependent variables are thus the variables for which there exists a conditioning set B in which the information they bring about the output is modified by the context variable. Context-independent variables are the variables that, in all conditionings $B = b$, bring the same amount of information about the output whether the value of the context is known or not. This definition is meant to be as general as possible. Other more specific definitions of context-dependence are as follows:

$$\exists B \subseteq V^{-m}, b, x_c^1, x_c^2 : I(Y; X_m|X_c = x_c^1, B = b) \neq I(Y; X_m|X_c = x_c^2, B = b), \quad (3)$$

$$\exists B \subseteq V^{-m}, x_c : I(Y; X_m|X_c = x_c, B) \neq I(Y; X_m|B), \quad (4)$$

$$\exists B \subseteq V^{-m}, b : I(Y; X_m|X_c, B = b) \neq I(Y; X_m|B = b), \quad (5)$$

$$\exists B \subseteq V^{-m} : I(Y; X_m|X_c, B) \neq I(Y; X_m|B). \quad (6)$$

These definitions all imply context-dependence as defined in Definition 1 but the converse is in general not true. For example, Definition (3) misses problems where the context makes some otherwise irrelevant variable relevant but where the information brought by this variable about the output is exactly the same for all values of the context. A variable that satisfies Definition (1) but not Definition (4) is given in example 1. This example can be easily adapted to show that both Definitions (5) and (6) are more specific than Definition (1) (by swapping the roles of X_c and X_2).

Example 1. *This artificial problem is defined by two input variables X_1 and X_2, an output Y, and a context X_c. X_1, X_2, and X_c are binary variables taking their values in $\{0, 1\}$, while Y is a quaternary variable taking its values in $\{0, 1, 2, 3\}$. All combinations of values for X_1, X_2, and X_c have the same probability of occurrence 0.125 and the conditional probability $P(Y|X_1, X_2, X_C)$ is defined by the two following rules:*

- *If $X_2 = X_c$ then $Y = X_1$ with probability 1.*
- *If $X_2 \neq X_c$ then $Y = 2$ with probability 0.5 and $Y = 3$ with probability 0.5.*

The corresponding data table is given in Appendix A. For this problem, it is easy to show that $I(Y; X_1|X_2 = 0, X_c = 0) = 1$ and that $I(Y; X_1|X_2 = 0) = 0.5$, which means condition (1) is satisfied and X_1 is thus context-dependent to Y with respect to X_c according to our definition. On the other hand, we can show that:

$$I(Y; X_1|X_c = x_c) = I(Y; X_1) = 0.5$$
$$I(Y; X_1|X_2, X_c = x_c) = I(Y; X_1|X_2) = 0.5,$$

for any $x_c \in \{0, 1\}$, which means that condition (4) can not be satisfied for X_1.

To simplify the notations, the context variable was assumed to be a separate variable not belonging to the set of inputs V. It can however be considered as an input variable, whose own relevance to Y (with respect to $V \cup \{X_c\}$) can be assessed as for any other input. Let us examine the impact of the nature of this variable on context-dependence. First, it is interesting to note that the definition of context-dependence is not symmetric. A variable X_m being context-dependent to Y with respect to X_c does not imply that the variable X_c is context-dependent to Y with respect to X_m.[3] Second, the context variable does not need to be marginally relevant for some variable to be context-dependent, but it needs however to be relevant to Y with respect to V. Indeed, we have the following theorem (proven in Appendix B):

Theorem 1. *X_c is irrelevant to Y with respect to V iff all variables in V are context-independent to Y with respect to X_c (and V) and $I(Y; X_c) = 0$.*

As a consequence of this theorem, there is no interest in looking for context-dependent variables when the context itself is not relevant.

Characterizing context-dependent variables. Contextual analyses need to focus only on context-dependent variables since, by definition, context-independent variables are unaffected by the context: their relevance status (relevant or irrelevant), as well as the information they contain about the output, remain indeed unchanged whatever the context.

Context-dependent variables may be affected in several directions by the context, depending both on the conditioning subset B and on the value x_c of the context. Given a context-dependent variable X_m, a subset B and some values b and x_c such that $I(Y; X_m|B = b, X_c = x_c) \neq I(Y; X_m|B = b)$, the effect of the context can either be an increase of the information brought by X_m ($I(Y; X_m|B = b, X_c = x_c) > I(Y; X_m|B = b)$) or a decrease of this information ($I(Y; X_m|B = b, X_c = x_c) < I(Y; X_m|B = b)$). Furthermore, for a given variable X_m, the direction of the change can differ from one context value x_c to another (at fixed B and b) but also from one conditioning $B = b$ to another (for a fixed context x_c). Example 2 below illustrates this latter case. This observation makes a global characterization of the effect of the context on a given context-dependent variable difficult. Let us nevertheless mention two situations where such global characterization is possible:

Definition 3. *A context-dependent variable $X_m \in V$ is* context-complementary *(in a context x_c) iff for all $B \subseteq V^{-m}$ and b, we have $I(Y; X_m|B = b, X_c = x_c) \geq I(Y; X_m|B = b)$.*

Definition 4. *A context-dependent variable $X_m \in V$ is* context-redundant *(in a context x_c) iff for all $B \subseteq V^{-m}$ and b, we have $I(Y; X_m|B = b, X_c = x_c) \leq I(Y; X_m|B = b)$.*

Context-complementary and redundant variables are variables that always react in the same direction to the context and thus can be characterized globally without loss of information. Context-complementary variables are variables that bring complementary information about the output with respect to the context, while context-redundant variables are variables that are redundant with the context. Note that context-dependent variables that are also irrelevant to Y are always context-complementary, since the context can only increase the information they bring about the output. Context-dependent variables that are relevant to Y however can be either context-complementary, context-redundant, or uncharacterized. A context-redundant variable can furthermore become irrelevant to Y as soon as $I(Y; X_m|B = b, X_c = x_c) = 0$ for all B, b, and x_c.

Example 2. *As an illustration, in the problem of Example 1, X_1 and X_2 are both relevant and context-dependent variables. X_1 can not be characterized globally since we have simultaneously:*

$$\begin{aligned} I(Y; X_1|X_2 = 0, X_c = x_c) &> I(Y; X_1|X_2 = 0) \\ I(Y; X_1|X_2 = 1, X_c = x_c) &< I(Y; X_1|X_2 = 1), \end{aligned}$$

for both $x_c = 0$ and $x_c = 1$. X_2 is however context-complementary as the knowledge of X_c always increases the information it contains about Y.

Related works. Several authors have studied interactions between variables in the context of supervised learning. They have come up with various interaction definitions and measures, e.g., based on multivariate mutual information (McGill, 1954; Jakulin and Bratko, 2003), conditional mutual information (Jakulin, 2005; Van de Cruys, 2011), or variants thereof (Brown, 2009; Brown et al., 2012). There are several differences between these definitions and ours. In our case, the context variable has a special status and as a consequence, our definition is inherently asymmetric, while most existing variable interaction measures are symmetric. In addition, we are interested in detecting any information difference occurring in a given context (i.e., for a specific value of X_c) and for any conditioning subset B, while most interaction analyses are interested in average and/or unconditional effects. For example, (Jakulin and Bratko, 2003) propose as a measure of the interaction between two variables X_1 and X_2 with respect to an output Y the multivariate mutual information, which is defined as $I(Y; X_1; X_2) = I(Y; X_1) - I(Y; X_1|X_2)$. Unlike our definition, this measure can be shown to be symmetric with respect to its arguments. Adopting this measure to define context-dependence would actually amount at using condition (6) instead of condition (1), which would lead to a more specific definition as discussed earlier in this section.

[3] But this would be the case if we had adopted definition (6).

The closest work to ours in this literature is due to Turney (1996), who proposes a definition of context-sensitivity that is very similar to our definition of context-dependence. Using our notations, Turney (1996) defines a variable X_m as weakly context-sensitive to the variable X_c if there exist some subset $B \subseteq V^{-m}$ and some values y, x_m, b, and x_c such that these two conditions hold:

$$p(Y = y|X_m = x_m, X_c = x_c, B = b) \neq p(Y = y|X_m = x_m, B = b),$$
$$p(Y = y|X_m = x_m, X_c = x_c, B = b) \neq p(Y = y|X_c = x_c, B = b).$$

X_m is furthermore defined as strongly context-sensitive to X_c if X_m is weakly sensitive to X_c, X_m is marginally relevant,and X_c is not marginally relevant. These two definitions do not exactly coincide with ours and they have two drawbacks in our opinion. First, they do not consider that a perfect copy of the context is context-sensitive, which we think is counter-intuitive. Second, while strong context-sensitivity is asymmetric, the constraints about the marginal relevance of X_m and X_c seems also unnatural.

Our work is also somehow related to several works in the graphical model literature that are concerned with context-specific independences between random variables (see e.g. Boutilier et al., 1996; Zhang and Poole, 1999). Boutilier et al. (1996) define two variables Y and X_m as contextually independent given some $B \subseteq V^{-m}$ and a context value x_c as soon as $I(Y; X_m|B, X_c = x_c) = 0$. When $B \cup \{X_m, X_c\}$ are the parents of node Y in a Bayesian network, then such context-specific independences can be exploited to simplify the conditional probability tables of node Y and to speed up inferences. Boutilier et al. (1996)'s context-specific independences will be captured by our definition of context-dependence as soon as $I(Y; X_m|B) > 0$. However, our framework is more general as we want to detect any context dependencies, not only those that lead to perfect independences in some context.

3 CONTEXT ANALYSIS WITH RANDOM FORESTS

In this section, we show how to use variable importances derived from Random Forests first to identify context-dependent variables (Section 3.2) and then to characterize the effect of the context on the relevance of these variables (Section 3.3). Derivations in this section are based on the theoretical characterization of variable importances provided in (Louppe et al., 2013), which is briefly reminded in Section 3.1. Section 3.4 discusses practical considerations and Section 3.5 shows how to generalize our results to other impurity measures.

3.1 Variable importances

Within the random forest framework, Breiman (2001) proposed to evaluate the importance of a variable X_m for predicting Y by adding up the weighted impurity decreases for all nodes t where X_m is used, averaged over all N_T trees in the forest:

$$Imp(X_m) = \frac{1}{N_T} \sum_{T} \sum_{t \in T: v(s_t) = X_m} p(t) I(Y; X_m|t) \quad (7)$$

where $v(s_t)$ is the variable used in the split s_t at node t, $p(t)$ is the proportion of samples reaching t and I is the mutual information.

According to Louppe et al. (2013), for any ensemble of fully developed trees in asymptotic learning sample size conditions, the Mean Decrease Impurity (MDI) importance (7) can be shown to be equivalent to

$$Imp(X_m) = \sum_{k=0}^{p-1} \frac{1}{C_p^k} \frac{1}{p-k} \sum_{B \in \mathcal{P}_k(V^{-m})} I(Y; X_m|B), \quad (8)$$

where $\mathcal{P}_k(V^{-m})$ denotes the set of subsets of V^{-m} of size k. Most notably, it can be shown (Louppe et al., 2013) that this measure is zero for a variable X_m iff X_m is irrelevant to Y with respect to V. It is therefore well suited for identifying relevant features.

3.2 Identifying context-dependent variables

Theorem 1 shows that if the context variable X_c is irrelevant, then it can not interact with the input variables and thus modify their importances. This observation suggests to perform, as a preliminary test, a standard random forest variable importance analysis using all input variables and the context in order to check the relevance of the latter. If the context variable does not reveal to be relevant, then, there is no hope to find context-dependent variables.

Intuitively, identifying context-dependent variables seems similar to identifying the variables whose importance is globally modified when the context is known. Therefore, one first straightforward approach to identify context-dependent variables is to build a forest per value $X_c = x_c$ of the context variable, i.e., using only the data samples for which $X_c = x_c$, and also globally, i.e. using all samples and not including the context among the inputs. Then it consists in deriving from these models an importance score for each value of the context, as well as a global importance score. Context-dependent variables are then the variables whose global importance score differs from the contextual importance scores for at least one value of the context.

More precisely, let us denote by $Imp(X_m)$ the global score of a variable X_m computed using (7) from all samples and by $Imp(X_m|X_c = x_c)$ its importance score as computed according to (7) using only those samples such that $X_c = x_c$. With this approach, a variable would be declared as context-dependent as soon as there exists a value x_c such that $Imp(X_m) \neq Imp(X_m|X_c = x_c)$.

Although straightforward, this approach has several drawbacks. First, in the asymptotic setting of Section 3.1, it is not guaranteed to find all context-dependent variables. Indeed, asymptotically, it is easy to show from (8) that $Imp(X_m) - Imp(X_m|X_c = x_c)$ can be written as:

$$Imp^{x_c}(X_m) \triangleq Imp(X_m) - Imp(X_m|X_c = x_c) \quad (9)$$

$$= \sum_{k=0}^{p-1} \frac{1}{C_k^p} \frac{1}{p-k} \sum_{B \in \mathcal{P}_k(V^{-m})} \quad (10)$$
$$\hookrightarrow (I(Y; X_m|B) - I(Y; X_m|B, X_c = x_c)).$$

Example 1 shows that $I(Y; X_m|B)$ can be equal to $I(Y; X_m|B, X_c = x_c)$ for a context-dependent variable. Therefore we have the property that if there exists an x_c such that $Imp^{x_c}(X_m) \neq 0$, then the variable is context-dependent but the opposite is unfortunately not true. Another drawback of this approach is that in the finite case, we do not have the guarantee that the different forests will have explored the same conditioning sets B and therefore, even assuming that the learning sample is infinite (and therefore that all mutual informations are perfectly estimated), we lose the guarantee that $Imp^{x_c}(X_m) \neq 0$ for a given x_c implies context-dependence.

To overcome these issues, we propose the following new importance score to identify context-dependent variables:

$$Imp^{|x_c|}(X_m) \triangleq \frac{1}{N_T} \sum_T \sum_{t \in T: v(s_t) = X_m} p(t)$$
$$\hookrightarrow |I(Y; X_m|t) - I(Y; X_m|t, X_c = x_c)| \quad (11)$$

This score is meant to be computed from a forest of totally randomized trees built from all samples, not including the context variable among the inputs. At each node t where the variable X_m is used to split, one needs to compute the absolute value of the difference between the mutual information between Y and X_m estimated from all samples reaching that node and the mutual information between Y and X_m estimated only from the samples for which $X_c = x_c$. The same forest can then be used to compute $Imp^{|x_c|}(X_m)$ for all x_c. A variable X_m is then declared context-dependent as soon as there exists an x_c such that $Imp^{|x_c|}(X_m) > 0$.

Let us show that this measure is sound. In asymptotic conditions, i.e., with an infinite number of trees, one can show from (11) that $Imp^{|x_c|}(X_m)$ becomes:

$$Imp^{|x_c|}(X_m) = \sum_{k=0}^{p-1} \frac{1}{C_p^k} \frac{1}{p-k} \sum_{B \in \mathcal{P}_k(V^{-m})} \sum_{b \in \mathcal{B}} P(B = b)$$
$$\hookrightarrow |I(Y; X_m|B = b) - I(Y; X_m|B = b; X_c = x_c)|.$$

Asymptotically, this measure has now the very desirable property to not miss any context-dependent variable as formalized in the next theorem (the proof is in Appendix C).

Theorem 2. *A variable $X_m \in V$ is context-independent to Y with respect to X_c iff $Imp^{|x_c|}(X_m) = 0$ for all x_c.*

Given that the absolute differences are computed at each tree node, this measure also continues to imply context-dependence in the case of finite forests and infinite learning sample size. The only difference with the infinite forests is that only some conditionings B and values b will be tested and therefore one might miss the conditionings that are needed to detect some context-dependent variables.

3.3 Characterizing context-dependent variables

Besides identifying context-dependent variables, one would want to characterize their dependence with the context as precisely as possible. As discussed earlier, irrelevant variables (i.e, such that $Imp(X_m) = 0$) that are detected as context-dependent do not need much effort to be characterized since the context can only increase their importance. All these variables are therefore context-complementary.

Identifying the context-complementary and context-redundant variables among the relevant variables that are also context-dependent can in principle be done by simply comparing the absolute value of $Imp^{x_c}(X_m)$ with $Imp^{|x_c|}(X_m)$, as formalized in the following theorem (proven in Appendix D).

Theorem 3. *If $|Imp^{x_c}(X_m)| = Imp^{|x_c|}(X_m)$ for a context-dependent variable X_m, then X_m is context-complementary if $Imp^{x_c}(X_m) < 0$ and context-redundant if $Imp^{x_c}(X_m) > 0$.*

This result allows to identify easily the context-complementary and context-redundant variables. In addition, if, for a context-redundant variable X_m, we have $Imp^{|x_c|}(X_m) = Imp^{x_c}(X_m) = Imp(X_m)$, then this variable is irrelevant in the context x_c.

Then it remains to characterize the context-dependent variables that are neither context-complementary nor context-redundant. It would be interesting to be able to also characterize them according to some sort of average effect of the context on these variables. Similarly as the common use of importance $Imp(X_m)$ to rank variables from the most to the less important, we propose to use the importance $Imp^{x_c}(X_m)$ to characterize the average global effect of context x_c on the variable X_m. Given the asymptotic formulation of this importance in Equation (10), a negative value of $Imp^{x_c}(X_m)$ means that X_m is essentially complementary with the context: in average over all conditionings, it brings more information about Y in context x_c than when ignoring the context. Conversely, a positive value of $Imp^{x_c}(X_m)$ means that the variable is essentially redundant with the context: in average over all conditionings, it brings less information about Y than when ignoring the context. Ranking the context-dependent variables according to $Imp^{x_c}(X_m)$ would then give at the top the variables that are the most complementary with the context and at the bottom the variables that are the most redundant.

Note that, like $Imp^{|x_c|}(X_m)$, it is preferable to estimate $Imp^{x_c}(X_m)$ by using the following formula rather than to estimate it from two forests by subtracting $Imp(X_m)$ and $Imp(X_m|X_c = x_c)$:

$$Imp_s^{x_c}(X_m) = \frac{1}{N_T} \sum_T \sum_{t \in T: v(s_t)=X_m} p(t) \\ \hookrightarrow (I(Y; X_m|t) - I(Y; X_m|t, X_c = x_c)) \quad (12)$$

This estimation method has the same asymptotic form as $Imp(X_m) - Imp(X_m|X_c = x_c)$ given in Equation (10) but, in the finite case, it ensures that the same conditionings are used for both mutual information measures. Note that in some applications, it is interesting also to have a global measure of the effect of the context. A natural adaptation of (12) to obtain such global measure is as follows:

$$Imp^{X_c}(X_m) \triangleq \frac{1}{N_T} \sum_T \sum_{t \in T: v(s_t)=X_m} p(t) \\ \hookrightarrow (I(Y; X_m|t) - I(Y; X_m|t, X_c))$$

which, in asymptotic sample and ensemble of trees size conditions, gives the following formula:

$$Imp^{X_c}(X_m) = \sum_{k=0}^{p-1} \frac{1}{C_k^p} \frac{1}{p-k} \sum_{B \in \mathcal{P}_k(V^{-m})} \\ \hookrightarrow (I(Y; X_m|B) - I(Y; X_m|B, X_c)).$$

If $Imp^{X_c}(X_m)$ is negative then the context variable X_c makes variable X_m globally more informative (X_c and X_m are complementary with respect to Y and V). If $Imp^{X_c}(X_m)$ is positive, then the context variable X_c makes variable X_m globally less informative (X_c and X_m are redundant with respect to Y and V).

3.4 In practice

As a recipe when starting a context analysis, we suggest first to build a single forest using all input variables X_m (but not the context X_c) and then to compute from this forest all importances defined in the previous section: the global importances $Imp(X_m)$ and the different contextual importances, $Imp_s^{x_c}(X_m)$, $Imp^{|x_c|}(X_m)$, and $Imp^{X_c}(X_m)$, for all variables X_m and context values x_c.

Second, variables satisfying the context-dependence criterion, i.e., such that $Imp^{|x_c|}(X_m) > 0$ for at least one x_c, can be identified from the other variables. Among context-dependent variables, an equality between $|Imp_s^{x_c}(X_m)|$ and $Imp^{|x_c|}(X_m)$ highlights that the context-dependent variable X_m is either context-complementary or context-redundant (in x_c) depending on the sign of $Imp_s^{x_c}(X_m)$. Finally, the remaining context-dependent variables can be ranked according to $Imp_s^{x_c}(X_m)$ (or $Imp^{X_c}(X_m)$ for a more global analysis).

Note that, because mutual informations will be estimated from finite training sets, they will be generally non zero even for independent variables, leading to false positives in the identification of context-dependent variables. In practice, one could instead identify context-dependent variables by using a test $Imp^{|x_c|}(X_m) > \epsilon$ where ϵ is some cut-off value greater than 0. In practice, the determination of this cut-off can be very difficult. In our experiments, we propose to turn the importances $Imp^{|x_c|}(X_m)$ into p-values by using random permutations. More precisely, 1000 scores $Imp^{|x_c|}(X_m)$ will be estimated by randomly permuting the values of the context variable in the original data (so as to simulate the null hypothesis corresponding to a context variable fully independent of all other variables). A p-value will then be estimated by the proportion of these permutations leading to a score $Imp^{|x_c|}(X_m)$ greater than the score obtained on the original dataset.

Table 1: Problem 1: Values of X_c, X_1, X_2, X_3, Y.

X_c	X_1	X_2	X_3	Y
0	0	0	0	2

$Imp^{1}(X_m)$	0.0	0.125	-0.375
$Imp^{X_c}(X_m)$	0.0	-0.125	-0.125

3.5 Generalization to other impurity measures

All our developments so far have assumed a categorical output Y and the use of Shannon's entropy as the impurity measure. Our framework however can be carried over to other impurity measures and thus in particular also to a numerical output Y. Let us define a generic impurity measure $i(Y|t) \geq 0$ that assesses the impurity of the output Y at a tree node t. The corresponding impurity decrease at a tree node is defined as:

$$G(Y; X_m|t) = i(Y|t) - \sum_{x_m \in \mathcal{X}_m} p(t_{x_m}) i(Y|t_{x_m}) \quad (13)$$

Table 3: Problem 2: Variable importances as computed analytically using the asymptotic formulas for the different importance measures.

	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8

with t_{x_m} denoting the successor node of t corresponding to value x_m of X_m. By analogy with conditional entropy and mutual information, let us define the population based measures $i(Y|B)$ and $G(Y; X_m|B)$ for any subset of variables $B \subseteq V$ as follows:

$$\begin{aligned} i(Y|B) &= \sum_b P(B=b) i(Y|B=b) \\ G(Y; X_m|B) &= i(Y|B) - i(Y|B, X_m), \end{aligned}$$

where the first sum is over all possible combinations b of values for variables in B. Now, substituting mutual information I for the corresponding impurity decrease measure G, all our results above remain valid, including Theorems 1, 2, and 3 (proofs are omitted for the sake of space). It is important however to note that this substitution changes the notions of both variable relevance and context-dependence. Definition 1 indeed becomes:

Definition 5. *A variable $X_m \in V$ is* context-dependent to Y with respect to X_c *iff there exists a subset $B \subseteq V^{-m}$ and some values x_c and b such that*

$$G(Y; X_m|B=b, X_c=x_c) \neq G(Y; X_m|B=b).$$

When Y is numerical, a common impurity measure is variance, which defines $i(Y|t)$ as the empirical variance $\text{var}[Y|t]$ computed at node t. The corresponding $G(X_m; Y|B=b)$ and $G(X_m; Y|B=b, X_c=x_c)$ in Definition 5 are thus defined respectively as

$$\text{var}[Y|B=b] - \mathbb{E}_{X_m|B=b}[\text{var}[Y|X_m, B=b]] \text{ and}$$

$$\begin{aligned} &\text{var}[Y|B=b, X_c=x_c] \\ &\hookrightarrow -\mathbb{E}_{X_m|B=b, X_c=x_c}[\text{var}[Y|X_m, B=b, X_c=x_c]]. \end{aligned}$$

We will illustrate the use of our framework in a regression setting with this measure in the next section.

4 EXPERIMENTS

Problem 1. The purpose of this first problem is to illustrate the different measures introduced earlier. This artificial problem is defined by three binary input variables X_1, X_2, and X_3, a ternary output Y, and a binary context X_c. All samples are enumerated in Table 1 and are supposed to be equiprobable. By construction, the output Y is defined as $Y = 2$ if $X_1 = 0$, $Y = X_2$ if $X_c = 0$ and $X_1 = 1$, and $Y = X_3$ if $X_c = 1$ and $X_1 = 1$.

Table 2 reports all importance scores for the three inputs. These scores were computed analytically using the asymptotic formulas, not from actual experiments. Considering the global importances $Imp(X_m)$, it turns out that all variables are relevant, with X_1 clearly the most important variable and X_2 and X_3 of smaller and equal importances. According to $Imp^{|0|}(X_m)$ and $Imp^{|1|}(X_m)$, X_1 is a context-independent variable, while X_2 and X_3 are two context-dependent variables. This result is as expected given the way the output is defined. For X_2 and X_3, we have furthermore $Imp^{|x_c|}(X_m) = |Imp^{|x_c|}(X_m)|$ for both values of x_c. X_2 is therefore context-complementary when $X_c = 0$ and context-redundant when $X_c = 1$. Conversely, X_3 is context-redundant when $X_c = 0$ and context-

complementary when $X_c = 1$. X_2 is furthermore irrelevant when $X_c = 1$ (since $Imp^1(X_2) = Imp^{|1|}(X_2) = Imp(X_2)$) and X_3 is irrelevant when $X_c = 0$ (since $Imp^0(X_3) = Imp^{|0|}(X_3) = Imp(X_3)$). The values of $Imp^{X_c}(X_2)$ and $Imp^{X_c}(X_3)$ suggest that these two variables are in average complementary.

Problem 2. This second experiment is based on an adaptation of the digit recognition problem initially proposed in Breiman et al. (1984) and reused in Louppe et al. (2013). The original problem contains 7 binary variables (X_1,...,X_7) and the output Y takes its values in $\{0, 1, \ldots, 9\}$. Each input represents the on-off status of one lightning segment of a seven-segment indicator and is determined univocally from Y. To create an artificial (binary) context, we created two copies of this dataset, the first one corresponding to $X_c = 0$ and the second one to $X_c = 1$. The first dataset was unchanged, while in the second one variables X_5, X_6, and X_7 were turned into irrelevant variables. In addition, we included a new variable X_8, irrelevant by construction in both contexts. The final dataset contains 320 samples, 160 in each context.

Table 3 reports possible importance scores for all the inputs. Again, these scores were computed analytically using the asymptotic formulas. As expected, variable X_8 has zero importance in all cases. Also as expected, variables X_5, X_6, and X_7 are all context-dependent ($Imp^{|x_c|}(X_m) > 0$ for all of them). They are context-redundant (and even irrelevant) when $X_c = 1$ and complementary when $X_c = 0$. More surprisingly, variables X_1, X_2, X_3, and X_4 are also context-dependent, even if their distribution is independent from the context. This is due to the fact that these variables are complementary with variables X_5, X_6, and X_7 for predicting the output. Their context-dependence is thus a consequence of the context-dependence of X_5, X_6, X_7. X_1, X_2, X_3, and X_4 are all almost redundant when $X_c = 0$ and complementary when $X_c = 1$, which expresses the fact that they provide more information about the output when X_5, X_6 and X_7 are irrelevant ($X_c = 1$) and less when X_5, X_6, and X_7 are relevant ($X_c = 0$). Nevertheless, X_8 remains irrelevant in every situation.

Problem 3. We now consider bio-medical data from the *Primary tumor* dataset. The objective of the corresponding supervised learning problem is to predict the location of a primary tumor in patients with metastases. It was downloaded from the UCI repository (Lichman, 2013) and was collected by the University Medical Center in Ljubljana, Slovenia. We restrict our analysis to 132 samples without missing values. Patients are described by 17 discrete clinical variables (listed in the first column of Table 4) and the output is chosen among 22 possible locations. For this analysis, we use the patient gender as the context variable.

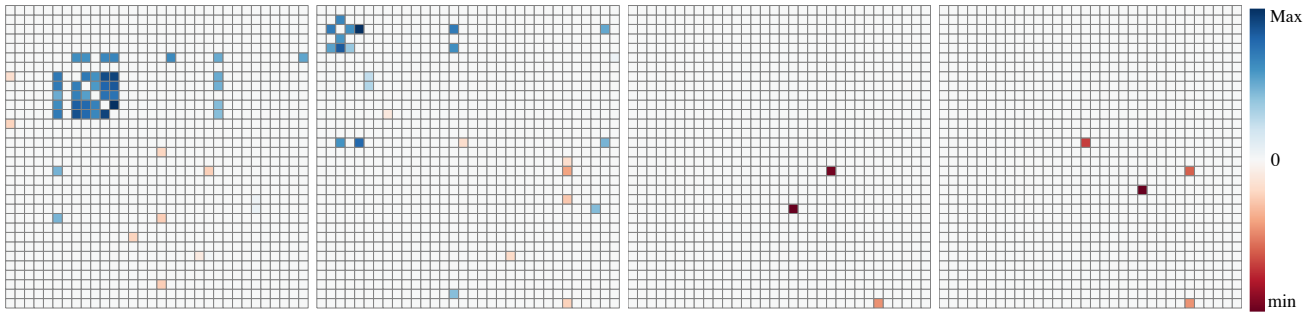
Table 4 reports variable importances computed with 1000 totally randomized trees and their corresponding p-values. According to the p-values of $Imp^{|x_c|}(X_m)$, two variables are clearly emphasized for each context: importances of *histologic-type* and *neck* both significantly decrease in the first context ($female$) and importances of *peritoneum* and *abdominal* both significantly decrease in the second context ($male$). While the biological relevance of these finding needs to be verified, such dependences could not have been highlighted from standard random forests importances.

Note that the same importances computed using the asymptotic formulas are provided in Appendix E. Importance values are very similar, highlighting that finite forests provide good enough estimates for this problem.

Problem 4. As a last experiment, we consider a publicly available brain cancer gene expression dataset (Verhaak et al., 2010). This dataset collects measurements of mRNA expression levels of 11861 genes in 220 tissue samples from patients suffering from glioblastoma multiforme (GBM), the most common form of malignant brain cancer in adults. Samples are classified into four GBM subtypes: Classical, Mesenchymal, Neural and Proneural. The interest of this dataset is to identify the genes that play a central role in the development and progression of the cancer and thus improve our understanding of this disease. In our experiment, our aim is to exploit importance scores to identify interactions between genes that are significantly affected by the cancer sub-type considered as our context variable. This dataset was previously exploited by Mohan et al. (2014), who used it to test a method based on Gaussian graphical models for detecting genes whose global interaction patterns with all the other genes vary significantly between the subtypes. This latter method can be considered as gene-based, while our approach is link-based.

Following (Mohan et al., 2014), we normalized the raw data using Multi-array Average (RMA) normalization. Then, the data was corrected for batch effects using the software ComBat (Johnson et al., 2007) and then $log2$ transformed. Following (Mohan et al., 2014), we focused our analysis on only two GBM sub-types, Proneural (57 tissue samples) and Mesenchymal (56 tissue samples), and on a particular set of 32 genes, which are all genes involved in the TCR signaling pathway as defined in the Reactome database (Matthews et al., 2009). The final dataset used in the experiments below thus contains 113 samples, 57 and 56 for both context values respectively, and 32 variables.

To identify gene-gene interactions affected by the context, we performed a contextual analysis as described in Section 3 for each gene in turn, considering each time a particular gene as the target variable Y and all other genes as the set of input variables V. This procedure is similar to the procedure adopted in the Random forests-based gene network inference method called GENIE3 (Huynh-Thu et al., 2010), that was the best performer in the DREAM5 network infer-



(a) $Imp^{|x_c=Mesenchymal|}$ **(b)** $Imp^{|x_c=Proneural|}$ **(c)** $Imp^{x_c=Mesenchymal}$ **(d)** $Imp^{x_c=Proneural}$

Figure 1: Results for Problem 4. Each matrix represents significant context-dependent gene-gene interactions as found using $Imp^{|x_c|}$ in (a)(b) and Imp^{x_c} in (c)(d), in GBM sub-type Mesenschymal in (a)(c) and Proneural in (b)(d). In (a) and (b), cells are colored according to $Imp_s^{x_c}$. In (c) and (d), cells are colored according to Imp^{x_c}. Positive (resp negative) values are in blue (resp. red) and highlight context-redundant (resp. context-complementary) interactions. Higher absolute values are darker.

ence challenge (Marbach et al., 2012). Since gene expressions are numerical targets, we used variance as the impurity measure (see Section 3.5) and we built ensembles of 1000 totally randomized trees in all experiments.

The matrices in Figure 1 highlight context-dependent interactions found using different importance measures (detailed below). A cell (i, j) of these matrices corresponds to the importance of gene j when gene i is the output (the diagonal is irrelevant). White cells correspond to non significant context-dependencies as determined by random permutations of the context variable, using a significance level of 0.05. Significant context-dependent interactions in Figures 1(a) and (b) were determined using the importance $Imp^{|x_c|}$ defined in (11), which is the measure we advocate in this paper. As a baseline for comparison, Figures 1(c) and (d) show significant interactions as found using the more straightforward score Imp^{x_c} defined in (10). In Figures 1(a) and (b) (resp. (c) and (d)), significant cells are colored according to the value of $Imp_s^{x_c}$ defined in (12). In Figures 1(c) and (d), they are colored according to the value of Imp^{x_c} in (10) instead. Blue (resp. red) cells correspond to positive (resp. negative) values of Imp^{x_c} or $Imp_s^{x_c}$ and thus highlight context-redundant (resp. context-complementary) interactions. The darker the color, the higher the absolute value of Imp^{x_c} or $Imp_s^{x_c}$.

Respectively 49 and 26 context-dependent interactions are found in Figures 1(a) and (b). In comparison, only 3 and 4 interactions are found respectively in Figures 1(c) and (d) using the more straightforward score Imp^{x_c}. Only 1 interaction is common between Figures 1(a) and (c), while 3 interactions are common between Figures 1(b) and (d). The much lower sensitivity of Imp^{x_c} with respect to $Imp^{|x_c|}$ was expected given the discussions in Section 3.2. Although more straightforward, the score $Imp^{x_c}(X_m)$, defined as the difference $Imp(X_m) - Imp(X_m|X_c = x_c)$, indeed suffers from the fact that $Imp(X_m)$ and $Imp(X_m|X_c = x_c)$ are estimated from different ensembles and thus do not explore the same conditionings in finite setting. Imp^{x_c} also does not have the same guarantee as $Imp^{|x_c|}$ to find all context-dependent variables.

5 Conclusions

In this work, our first contribution is a formal framework defining and characterizing the dependence to a context variable of the relationship between the input variables and the output (Section 2). As a second contribution, we have proposed several novel adaptations of random forests-based variable importance scores that implement these definitions and characterizations and we have derived performance guarantees for these scores in asymptotic settings (Section 3). The relevance of these measures was illustrated on several artificial and real datasets (Section 4).

There remain several limitations to our framework that we would like to address as future works. All theoretical derivations in Sections 2 and 3 concern categorical input variables. It would be interesting to adapt our framework to continuous input variables, and also, probably with more difficulty, to continuous context variables. Finally, all theoretical derivations are based on forests of totally randomized trees (for which we have an asymptotic characterization). It would be interesting to also investigate non totally randomized tree algorithms (e.g., Breiman (2001)'s standard Random Forests method) that could provide better trade-offs in finite settings.

Abstract

There has been growing interest in inferring implicit social structures using interaction data. This approach is motivated by the fact that entities organize themselves into groups having frequent interactions between each other. Unlike previous approaches that focused on subjectively declared relationships, the idea is to exploit the actual evidence at hand to reach conclusions about group formations, resulting in more objective data-driven inferences. To this end, [5] have employed Hawkes processes, and proposed a Hawkes IRM model to infer social structures from interaction data. A major factor that encourages the use of Hawkes processes is the capability to model reciprocity in the interaction between social entities. However, reciprocation is dynamically conditioned upon two key factors: the significance of each message sent by the sender, and the receptivity to each message received by the receiver. In the model proposed by [5], reciprocity is not affected by either of these factors, since the content of each message is not taken into account. In this paper, we extend the work of [5] by introducing Gaussian processes (GPs) into the Hawkes IRM model: based on the content of each message, GPs are used to model the message significance as well as receptivity. This allows us to more accurately capture the interactions among entities. The application of GPs also allows us to flexibly model the rates of reciprocal activities between two entities, allowing asymmetry in reciprocity to be captured more accurately. This leads to better cluster detection capability. Our model outperforms previous Hawkes and Poisson process-based models at predicting verbal, email, and citation activities.

1 INTRODUCTION

In the social sciences, group dynamics is the study of the content and dynamics of the complex interactions occurring within a social group or between social groups. The study of group dynamics helps understand decision making processes, disease epidemics and develop effective therapeutic/control techniques. Early approaches [12, 19, 4] have focused on declared relationships between individuals to infer latent group structures. For example, if three people declare they like each other but dislike others, it is reasonable to put them into one group. However, these declared relationships are not easily accessible, sometimes incorrect and usually highly subjective. Another limitation of previous models is their incapability to capture reciprocity in social interactions. Reciprocity is a common characteristic in group dynamics. It expresses the fact that social entities reciprocate in their interaction between each other. For example, if Alice has sent a message to Bob, it increases the likelihood of Bob replying back to Alice. Reciprocity is expected to be more prominent between entities within a group, and hence it can be used to infer social groups.

To address these issues, recently, there has been a trend to infer implicit social structures using interaction data. This approach is motivated by the fact that interactions between different groups varies in nature and frequency. Unlike approaches that focused on subjectively declared relationships, the idea is to exploit the actual evidence at hand to reach conclusions about group formations, making this approach is more objective in nature. Recently, [5] proposed a nonparametric Bayesian model that is built upon mutually-exciting point processes, known as Hawkes processes [9, 10], and the Infinite Relational Model (IRM) [19, 4] to infer social structures from continuous time interaction data. Pairs of mutually-exciting Hawkes processes are able to exploit reciprocity to infer social groups; here the processes excite one another through their actualized events.

However, reciprocation is dynamically conditioned upon two key factors: the significance of each message sent by

the sender, and the receptiveness of the receiver to each incoming message. In real communication, conveying an important message develops interest in the receiver. Then, if the receiver finds the message relevant, reciprocation takes place. Accordingly, reciprocal communication emerges from the interplay of these two factors. The model proposed by [5] does not take these factors into consideration, instead assuming that entities reciprocate simply because they received a message, and giving no consideration to the content of the message and its effects on the interaction.

In this paper, we extend the work of [5] by introducing Gaussian processes (GPs) into the Hawkes IRM model. We use these to account for the content of the messages, capturing the message significance as well as receptivity. This allows us to more accurately capture the interactions among entities. The interaction between a pair of clusters is modeled as the additive effect of the interactions between all pairs of nodes in the two clusters, allowing us to identify the contribution of each pair of nodes, where the actual communication is taking place, to the interaction between a pair of clusters. The introduction of GPs also allows us to flexibly model the rates of reciprocal activities between two entities, hence the asymmetry in reciprocity can be captured more accurately. We show how this leads to a better cluster detection capability. Since our proposed work is a natural extension of Hawkes IRM, it covers both Poisson processes and IRM as special cases.

The remainder of the paper is organized as follows: section 2 discusses Poisson and Hawkes processes, with and without IRM. Section 3 describes our extension of the Hawkes IRM model. Section 4 presents an inference algorithm for our model, section 5 discusses related work, and section 6 presents experimental results using our model on synthetic, verbal, email, and citation data.

2 BACKGROUND

We start with a brief description of Poisson processes, Hawkes processes, and Hawkes IRM model.

2.1 Poisson and Hawkes Processes

Point processes are stochastic processes, realizations of which are collections of points in time or space. The former are called temporal point processes, and the latter, spatial point processes. The homogeneous Poisson process is the simplest example of a point process, have a constant rate function, while the inhomogeneous Poisson process has rate function λ varying with, say, time. Both are examples of completely random measures, where events in disjoint sets are independent of each other. Hawkes processes, on the other hand, are mutually-exciting doubly point processes, whose rate function is itself a stochastic process, depending on events of its own and of other processes.

For both Poisson processes and Hawkes processes, with conditional rate function $\lambda(t)$ and event time history $\mathcal{H}_{(0,T]} = \{t_1, \cdots, t_n\}$, the likelihood function can be written as

$$\mathcal{L}(\lambda(t)|\mathcal{H}) = \exp\{-\Lambda(0,T)\} \prod_{i=1}^{n} \lambda(t_i) \tag{1}$$

where $\Lambda(0,T) = \int_0^T \lambda(t)dt$ is the cumulative conditional rate function. When the conditional rate function $\lambda(t) = \lambda$ is a constant, the Poisson process likelihood is simply:

$$\mathcal{L}(\lambda|\mathcal{H}) = \exp\{-\lambda T\} \lambda^n \tag{2}$$

For a Hawkes process, the rate function λ depends on earlier events. Let $N(\cdot)$ and $N'(\cdot)$ be a pair of mutually-exciting Hawkes processes. The conditional rate function $\lambda(t)$ of $N(\cdot)$, given the event time history $\mathcal{H}_{N'} = \{t'_1, \cdots, t'_n\}$ of N', has the form

$$\lambda(t) = \gamma + \int_{-\infty}^{t} g(t-s)dN'(s) \tag{3}$$

where γ is the base rate of $N(\cdot)$, and the triggering function $g(\cdot)$ is a non-negative function such that $\int_0^\infty g(s)ds < 1$, ensuring that $N(\cdot)$ is stationary.

If $g(\cdot) = 0$ then the process becomes a Poisson process with rate γ. If the counting measure $N'(\cdot)$ is $N(\cdot)$ itself, the process is self- exciting: its current rate only depends on its own past events. If the two counting measures are different, the rate is affected by the past events of each other.

2.2 Hawkes Processes with Infinite Relational Model (HP+IRM)

Amongst the models that use declared relationships to infer group information, the Infinite Relational Model (IRM) [12] is especially flexible and popular. [5] has combined the IRM idea with the concept of Hawkes Processes to model reciprocity in the interaction between entity groups. Let V denote the vertices of the graph, corresponding to individuals. Then the generative model for a Hawkes process is defined as follows:

$$\pi|\alpha \sim CRP(\alpha) \tag{4}$$

$$\lambda_{pq}(t)|\gamma_{pq}, \beta_{pq}, \tau_{pq} = \gamma_{pq} n_p n_q \quad + \int_{-\infty}^{t} g_{pq}(t-s)dN_{qp}(s) \;\; \forall p, q \in range(\pi) \tag{5}$$

$$N_{pq}(\cdot)|\lambda_{pq} \sim HawkesProcess(\lambda_{pq}) \tag{6}$$

$$N_{uv}(\cdot)|N_{\pi(u)\pi(v)}, \pi \sim Thin(N_{\pi(u)\pi(v)}) \;\; \forall u, v \in V \tag{7}$$

Here π is a partition of the vertices V , distributed according to the Chinese restaurant process (CRP) with concentration parameter α. We use p and q to index clusters

of π. We denote the cluster that vertex u belongs to as $\pi(u)$. The operator $Thin$ refers to thinning; this means distributing the atoms of $N_{pq}(\cdot)$ among each $N_{uv}(\cdot)$, such that $N_{pq} = \sum_{u,v} N_{u,v}(\cdot)$. Any thinning scheme may be used, such as a uniform thinning, which uniformly picks to elements of a cluster. The type of reciprocation (parameterized by g_{pq} and g_{qp}, respectively) differs with events from cluster p to cluster q and events from cluster q to cluster p. This difference in reciprocity is what the model exploits to learn about social groups.

3 HAWKES PROCESSES WITH IRM AND GAUSSIAN PROCESSES (HPGP + IRM)

We define the Hawkes process conditional rate function as:

$$\lambda_{uv}(t) = \gamma_{pq} + \int_0^t \beta_{uv} e^{-\frac{t-s}{\tau_{uv}}} dN_{vu}(s) \tag{8}$$

where $p = \pi^{-1}(u), q = \pi^{-1}(v)$ are the clusters individuals u and v belong to; and the triggering function $g_{uv}(\cdot)$ is defined as:

$$g_{uv}(\delta) = \beta_{uv} e^{-\frac{\delta}{\tau_{uv}}} \tag{9}$$

Geometrically, the excitation function β_{pq} is essentially the "jump size" of the rate function $\lambda_{uv}(t)$ whenever a new message is received. However, in the above definition, β_{uv} is not affected by the content of the message; its value does not change based on the significance and receptivity of the messages.

We would like to define β_{uv} in a way such that it measures the significance and receptivity of individual messages communicated between individuals u and v. The content measure x_{vu} can be suitably defined according to the application, for example, it can be a distribution of words, the length of the message, or the text entropy of the message, etc. The individual level excitation function $\beta_{uv}(x_{vu}(s)) = 0$ if no message was sent from v to u at time s, but can be otherwise any non-negative function.

We propose to use two sets of Gaussian Process (GP) priors to address sources of inhomogeneity of the excitation functions $\beta_{uv}(\cdot)$, one for the significance of the message and one for the receptivity of the message:

$$\beta_{uv}(s) = e^{r_u(x_{vu}(s)) + s_v(x_{vu}(s))} \tag{10}$$

where

$$r_u(\cdot) \sim \mathcal{GP}(0, k_r) \tag{11}$$

$$s_v(\cdot) \sim \mathcal{GP}(0, k_s) \tag{12}$$

k_r and k_s are radial basis function (RBF) kernels of the GPs. The exponential transformation is used to make sure that $\beta_{uv}(\cdot)$ is non-negative.

Larger values of r_u and s_v indicate that an important message has been sent by the sender, and receiver is receptive to the message, these result in larger values for β_{uv}. If either r_u or s_v is small, or both of them have smaller values, it leads to smaller values of β_{uv}. Application of GP functions also allows us to flexibly model the rates of reciprocal activities between two entities, allowing the asymmetry in reciprocity to be captured more accurately. This, as a by-product, leads to a better cluster detection capability.

The receptivity and significance functions r_u and s_v may have different behaviors and hence are designed to come from two different GPs. One subtle point is that although r_u and s_v seem exchangeable in the definition of β_{uv} and both use message content x_{vu} as input, they are evaluated from different perspectives: r_u evaluates x_{vu} from the receiver u's perspective, while s_v from the sender v's perspective. One alternative way is to model a single pair of GPs $s(\cdot)$ and $r(\cdot)$ for all users, instead of this per-user GP $s_u(\cdot)$ and $r_v(\cdot)$ framework. Experiments have shown that both the modeling schemes have good performances, however, we believe that the per-user GP setting can reveal more interesting user-specific details, and hence in the later sections, our results are based on the per-user GP framework.

The generative process of our model can be summarized as:

$$\pi|\alpha \sim CRP(\alpha) \tag{13}$$

$$\lambda_{uv}(t)|\gamma_{pq}, \beta_{uv}(\cdot), \tau_{uv} = \gamma_{pq} + \int_{-\infty}^t \beta_{uv}(\mathcal{X}_{vu}) e^{-\frac{t-s}{\tau_{uv}}} dN_{vu}(s) \tag{14}$$

$$N_{uv}(\cdot)|\lambda_{uv} \sim HawkesProcess(\lambda_{uv}) \tag{15}$$

where $\mathcal{X}_{vu} = \{x_{vu}(s)\}$ is the set of all messages sent from v to u, and the cluster level excitation function β_{pq} can be seen as an additive effect of β_{uv}:

$$\beta_{pq}(\mathcal{X}_{qp}) = \sum_{\pi(u)=p, \pi(v)=q} \beta_{uv}(x_{vu}(s)) \tag{16}$$

Now, the excitation function β_{pq} is no longer a constant, as in [5], but a function of the message content in the past events of the reciprocal process N_{qp}, taking into account both the significance and the receptivity of the messages. Our model is a generalization of the model described in [5], and if β_{uv} in equation 10 are constants, our model reduces to the model described in [5]. Therefore, all the basic features of the original model are inherited by our model. Also, in our modeling framework, the individual rate function λ_{uv} is affected by the group initial rate γ_{pq}, which, on the one hand, tends to put similarly behaving individuals into the same cluster; and on the other hand, if one member of a group is heavily influenced by a particular message, it is highly likely that other individuals in the same group will also be affected.

3.1 Stability Conditions of HPGP + IRM

For Hawkes processes with constant excitation functions β_{pq}, the sufficient condition of stationarity is $\beta_{pq}\tau_{pq} < 1$, derived from the condition $\int_0^\infty \beta(s)ds < 1$. By contrast, since our β_{pq} is a function of message contents, the expectation of $\lambda(t)$ cannot be time invariant. Therefore, the stationarity condition no longer holds. However, since β_{pq} is evaluated at finite locations (in the domain of message content x), we can define β_{pq}^{MAX} to be the maximum value of β_{pq} across all locations. For our model, we can still require that $\beta_{pq}^{MAX}\int_0^\infty e^{-\frac{u}{\tau_{pq}}}du < 1$. Since $\beta_{pq}^{MAX}\int_0^\infty e^{-\frac{u}{\tau_{pq}}}du = \beta_{pq}^{MAX}\tau_{pq}$, we just need to make sure that $\beta_{pq}^{MAX}\tau_{pq} < 1$.

4 HPGP + IRM INFERENCE

We perform posterior inference using Markov chain Monte Carlo method. In our model there is no conjugacy between prior and the likelihood, hence we can not marginalize out parameters and must sample all of them separately. To infer the partition of individuals π, the concentration parameter α, the parameters of each Hawkes process $\theta_{pq} = \{\gamma_{pq}, \tau_{pq}\}$, the training and test point projections of functions r_u and s_v, we use Algorithm 5 in [15] to draw samples from the posterior. We use elliptical slice sampling [14] for r_u and s_v, and standard slice sampling [16] for γ_{pq}, τ_{pq} and α. In case of τ_{pq} we set the upper bound of the slice sampler to $\frac{1}{\beta_{pq}^{MAX}}$, to ensure that $\beta_{pq}^{MAX}\tau_{pq} < 1$.

5 RELATED WORK

The interest of modeling relational data dates back to at least the work of [11], who introduced the Bayesian formulation of the stochastic block-model. This model was then extended by [12] to the Infinite Relational Model (IRM).

The IRM typically assumes that there is a fixed graph, describing the relationship between individuals, which is observed. This idea is used in many proposed works [12, 19]. Our model does not make this assumption, but learns the relationship among participants' interactions.

There have also been research works modeling relational events via latent classes [6]. They assume each event's sender, receiver, and action type are conditionally independent given the latent class for that event. This strong assumption greatly simplifies the model, but may not reflect real situations. Our model is not limited to any fixed number of action types.

Other works [17, 18, 7] are based on temporal Poisson-processes, where the rate of events on each edge is independent of every other edge. Although [18, 7] allow mutually exciting events to be modeled, they do not use content information to model dependencies between events. Our model uses Hawkes processes which are capable of dealing with interaction and reciprocal events, and also use message content information to capture the interactions more accurately. Our work is also closely related to [13]. They combine mutually exciting Hawkes process with random graph models by defining the excitation function, between a pair of nodes, as a product of a latent binary indicator variable, indicating the presence or absence of edge, and weight variable that determines the strength of interaction between the two nodes. However, unlike our model, their method does not use side information, such as information content, and simply relies on time interaction data to infer latent network structures. Lastly, our work extends the work of [5]. In their paper, the excitation function is not affected by the information content of the message. By introducing Gaussian processes, we are able to model non homogeneous excitation functions. In addition to that, since we use Gaussian processes to model the flexible rates of reciprocal activities between two entities, our model can capture the asymmetry in reciprocity more accurately. This, as a by-product, leads to a better cluster detection capability. The model in [8] does not have this leverage.

6 EXPERIMENTS

We compared our model (HPGP + IRM) to four methods: 1) Poisson Process Model (Poisson), 2) Hawkes Process Model (HP), 3) Poisson Processes with IRM (Poisson + IRM), and 4) Hawkes Processes with IRM (HP + IRM).

6.1 Synthetic Data Sets

We tested several synthetic data sets under various conditions to compare different model fittings to the rate functions, as well as their clustering behaviors.

A Simple Case Consists of Two Individuals. To generate synthetic data set, we need to set parameter values γ_{uv}, and τ_{uv}, as well as the functional form of $\beta_{uv}(\cdot)$ and message content measure x_{vu}. In figure 1, two mutually-exciting Hawkes processes are simulated during time interval $(0, 10]$, where $\gamma_{12} = \gamma_{21} = 0.1$, $\tau_{12} = \tau_{21} = 1$.

In part (a), case 1 used a constant message content $x_{12}(t_i) = x_{21}(t_i') = 1$ for all event times t_i and t_i', and a constant excitation function $\beta_{12}(x) = \beta_{21}(x) = x = 1$ for all messages. Since this synthetic data set has constant β values, it is essentially generated from a HP+IRM; we see that HP+IRM and our model, a generalization to HP+IRM, both perform well, and are better than other models, in terms of log-likelihood shown in table 1.

In part (b), case 2 used the same settings as part (a), except for the introduction of variable message content, where both $x_{12}(t_i)$ and $x_{21}(t_i')$ follow an exponential distribution $\exp(0.5)$, which can be thought of as different message entropy values at different event times t_i and t_i'. We see that

the jump sizes of both processes are no longer constant. This cannot be modeled by a constant β model, but can only be handled by models like ours, which allow variable β. The effectiveness of our model in this case can be seen from the comparison of the log-likelihoods in table 1.

In part (c), case 3 further introduced non-constant $\beta_{uv}(\cdot)$, with all other settings being the same as in case 2, but $\beta_{12}(t_i) = e^{2sin(x_{21}(t_i))+1.5log(x_{21}(t_i))}$ and $\beta_{21}(t'_i) = e^{0.1cos(x_{12}(t'_i))+0.2\sqrt{x_{12}(t'_i)}}$, where $r_1(x_{21}(t_i)) = 2sin(x_{21}(t_i))$, $r_2(x_{12}(t'_i)) = 0.1cos(x_{12}(t'_i))$, $s_1(x_{12}(t'_i)) = 0.2\sqrt{x_{12}(t'_i)}$, and $s_2(x_{21}(t_i)) = 1.5log(x_{21}(t_i))$. Again, the jump sizes for both processes are not constant, and also note that $\beta_{21}(x) > \beta_{12}(x), \forall x \in (0, 10)$. This suggests that process 2 is excited to respond to any messages received from process 1, while process 1 is reluctant to respond to messages sent from process 2. In this case, the difference in log-likelihoods of different models is pronounced even more.

Table 1: Log likelihood comparison for the three-case synthetic data set

	CASE 1	CASE 2	CASE 3
HPGP+IRM	-21.88	-13.41	-10.86
HP+IRM	-22.97	-35.53	-82.78
POISSON + IRM	-72.31	-89.73	-126.33
HP	-129.37	-238.94	-192.78
POISSON	-127.83	-182.76	-187.23

Next, we will discuss our modeling preferences based on the three-case example used in figure 1.

GP Against Simple Parametric Functions. In order to demonstrate the effectiveness of using GP in our model, we compared its performances with simple parametric functions. In table 2, we summarize the log likelihood for the three-case synthetic data set mentioned earlier in figure 1, using GP and simple polynomials (up to order 3). The results clearly show the superior performance of GP over polynomial functions. The coefficients of polynomials are estimated by sampling from the posterior.

Table 2: Log likelihood comparison between GP and simple parametric functions

	GP	CUBIC	QUAD	LINEAR
CASE 1	-21.88	-38.67	-38.88	-39.18
CASE 2	-13.41	-61.27	-78.17	-89.28
CASE 3	-10.86	-71.26	-72.13	-76.73

Estimate Kernel Width From Data. In our experiment, we used the RBF (radial basis function) kernel, which has the form:

$$k(\delta) = \exp\left(-\frac{\delta^2}{2\sigma^2}\right) \tag{17}$$

where δ is the distance between two data points, and σ the kernel width. The estimation of the kernel width is crucial in our modeling framework as it controls the complexity of the underlying receptivity and significance functions. We applied 3 different approaches to estimate σ: Bayesian, heuristic, and fixed. The Bayesian approach introduces a prior on σ and obtains an estimate using MCMC; the heuristic way, bearing in mind that sigma largely depends on the maximum distance among the training data, estimates σ directly from sample data distances; and the fixed approach manually assigns a fixed value to the kernel width. It is evident from table 3 that the Bayesian approach is the best choice for our model in terms of log likelihood.

Table 3: Log likelihood comparison for kernel estimation

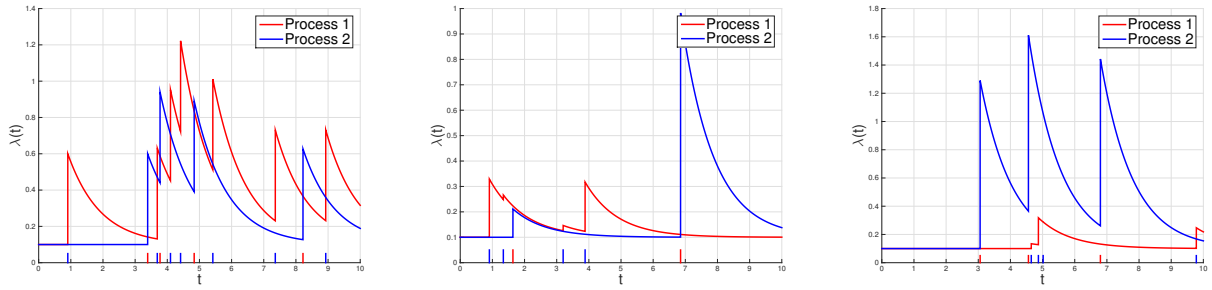
	BAYESIAN	HEURISTIC	FIXED
CASE 1	-21.88	-25.12	-39.78
CASE 2	-13.41	-17.16	-18.72
CASE 3	-10.86	-22.13	-24.67

Comparison Between Different Information Metrics. We compared four strategies to evaluate the information content of a message: KL divergence of word distribution, message length, TF-IDF, and message Shannon entropy. Using length as the measure of information may not be sufficient in practice; the importance of a message is simply determined by its longevity, without giving any consideration to the content. In case of Shannon entropy, however, the significance and receptivity of the message are better captured. TF-IDF has similar behavior and characteristics as those of message entropy. The best performance in our experiments were given by using KL divergence of word distribution and Shannon entropy, and we preferred KL divergence of word distribution over the other measures because it is more interpretable, and seemed to give consistent good performances in terms of log-likelihoods as shown in table 4. However, encoding content information efficiently is still an open question, and certainly a direction for future work.

Table 4: Log likelihood comparison for different information metrics

	WORD KL	ENTROPY	TF-IDF	LENGTH
CASE 1	-21.88	-21.98	-39.38	-128.76
CASE 2	-13.41	-12.78	-28.61	-87.21
CASE 3	-10.86	-12.63	-23.78	-72.13

Next, we will discuss a more detailed example consisting of three individuals.



(a) Case 1: x constant, β simple function $\beta = x$. The "jump sizes" are constant.

(b) Case 2: x random, β simple function $\beta = x$. The "jump sizes" are not constant.

(c) Case 3: x random, β non-trivial function. The "jump sizes" are not constant.

Figure 1: Simulated rate functions of two individuals

A Full Example Consists of Three Individuals. In this example, we put processes 1 and 2 in one cluster whereas process 3 is in another cluster, and we also intentionally made them behave differently to each other.

The settings we used were $m_{ij} \sim multinomial(p = [0.25, 0.25, 0.25, 0.25], n = 4), \forall i, j \in \{1, 2, 3\}$, which could represent a dialog consisting of only four words, and each m_{ij} can be thought of as the distribution of these four words in a message sent from j to i. We define the message content measure as $x_{ij} = KL(m_{ij}||\bar{m}_i)$, where $\bar{m}_i$ is the four-word distribution assigned to individual i ($\bar{m}_i = (1, 1, 1, 1), \forall i$ in our experiment). For the excitation functions we have: $\beta_{12} = \beta_{21} = 5\exp(1/x)$, $\beta_{23} = \beta_{31} = 0.1\exp(1/x)$, and $\beta_{13} = \beta_{32} = 10\exp(1/x)$. Note that $\beta_{12} = \beta_{21}$, $\beta_{31} < \beta_{13}$, and $\beta_{32} > \beta_{23}$.

Figure 2 (a) shows that processes 1 and 2 are frequently interacting in a similar way, while in part (b), process 3 is not excited to respond to messages from process 1 but tends to, suggested in part (c), reply to process 2's messages more actively. In figure 2 (g, h, and i), we see that only our model was able to correctly cluster processes 1 and 2 in the same cluster and put process 3 in a separate one. On the other hand, the other models generated redundant clusters. We have also shown in figure 2 (d, e, and f) that our model successfully recovered the underlying excitation functions.

6.2 Real Data Sets

We tested our model on various turn-taking data sets, which include public meetings, private conversations, email communications, and publication citations. Each data set has several lines of event records, indicated by a quadruplet (t_i, s_i, r_i, m_i), where t_i is the time when the event took place, s_i the index of the sender, r_i the index of the recipient, and m_i the message word distribution.

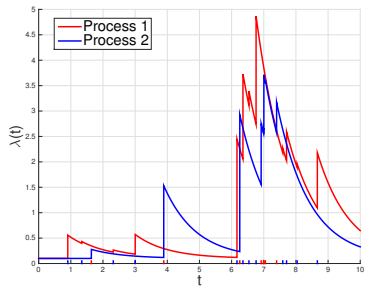
We divided the data set into two parts: the first part consists of the first 90% of the data lines, used as the training data set; and the second part contains the remaining 10% of the data lines, used as the testing data set. To compute the average log probability, we ran our code 10 times with different prior settings and computed the mean and standard deviation of the 10 values.

Enron email threads The Enron data set (ENRON) contains about half a million email messages sent or received by about 150 senior managers of the Enron corporation [2, 3]. We restricted ourselves to "true" conversation emails (e.g., auto-messages were ignored) sent and received only from the domain "@enron.com", and identified the threads by time, sender, receiver, and the subject line. The longest email communication was selected.

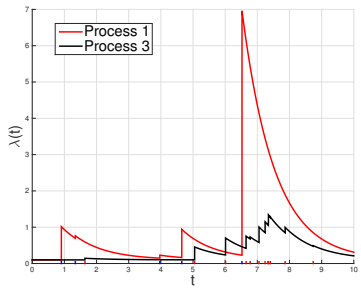
Santa Barbara Conversation Corpus The Santa Barbara Corpus [1] data set (SB) contains text and video recordings for various conversations. The data set used (#33) is a lively family argument/discussion recorded at a vacation home in Falmouth, Massachusetts. There are eight participants, all relatives or close friends. Discussion centers around a disagreement Jennifer (#2) is having with her mother Lisbeth (#5).

High-energy Physics Theory Citation Network The Arxiv HEP-TH (high energy physics theory) citation data set (CITATION) covers all 352807 citations of 27770 papers published during the time period January 1993 to April 2003 (124 months). We converted paper citation events to author citation events. For example, if a paper by authors A and B cited another paper by authors C, D, and E, we would record six events: A cited C, D, and E; and B cited C, D, and E. Only the most cited 17 authors and 97 citation events in the year 2003 were used from this data set.

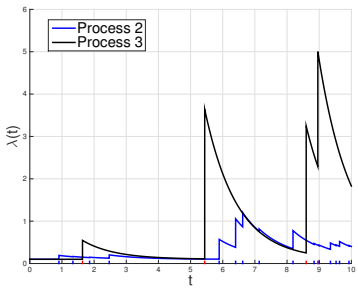
Results Table 5 and 6 show, for training and test data sets respectively, the predictive probability results as well as the most probable predictive number of clusters for competing methods. We used 10-fold cross-validation to prevent our model from being over-fitted to training data sets, and the performances on real data sets suggested a good generalization ability of our model.



(a) $\beta_{12} = 5\exp(1/x)$
$\beta_{21} = 5\exp(1/x)$



(b) $\beta_{13} = 10\exp(1/x)$
$\beta_{31} = 0.1\exp(1/x)$



(c) $\beta_{23} = 0.1\exp(1/x)$
$\beta_{32} = 10\exp(1/x)$

POISSON + IRM	46.21 ± 0.01	13.08 ± 0.00	97.00 ± 0.41

We also compared our model with HP+IRM in terms of cluster detection capability. Figure 3 shows the cluster configurations generated by our model and HP+IRM. This dataset is a record of a lively family argument/discussion. There were eight participants, all relatives or close friends, but the main communication was between Jennifer (#2) and her mother Lisbeth (#5). For our model, Jennifer and Lisbeth were put in one cluster, and rest in the other. This is more consistent with data evidence: Jennifer and Lisbeth reciprocate each other more frequently, and respond occasionally to others, despite receiving a lot of messages from them. Individuals other than #2 and #5 may be further decomposed into subgroups, but at this level, the best clustering would probably be the one given by our model. The contrast in the thicknesses of the arrows between the two clusters correctly reveals this aspect. On the other hand, the cluster configuration generated by HP+IRM model indicates a high level of reciprocity, indicated by comparable thicknesses of the two arrows, between clusters $\{2,5\}$ and $\{4,6,7,8\}$ which is inconsistent with data evidence. Additionally, the model creates an extra cluster,$\{1,3\}$, which is inconsistent with data evidence.

Figure 3: Diagram for data set *SB #33*. The thickness of the arrows are proportional to the expectation of the rate function.

7 CONCLUSION

In this paper, we have presented a non-parametric Bayesian model that uses Hawkes processes to model reciprocal relationships. Unlike previous approaches, our model utilizes the content of the messages to model reciprocity. Based on the content, our model captures the significance of the message sent by the sender, and receptivity to the message received by the receiver. This gives us the leverage to model reciprocity in a more realistic manner and more accurately. Empirical results suggest that our novel model formulation can yield improved predictive probability results, and can reveal clusters more accurately than alternative methods.

Abstract

A large body of algorithms have been proposed for multi-task learning. However, the effectiveness of many multi-task learning algorithms highly depends on the structural regularization, which incurs bias in the resulting estimators and leads to slower convergence rate. In this paper, we aim at developing a multi-task learning algorithm with faster convergence rate. In particular, we propose a general estimator for multi-task learning with row sparsity constraint on the parameter matrix, i.e., the number of nonzero rows in the parameter matrix being small. The proposed estimator is a nonconvex optimization problem. In order to solve it, we develop a forward backward greedy algorithm with provable guarantee. More specifically, we prove that the output of the greedy algorithm attains a sharper estimation error bound than many state-of-the-art multi-task learning methods. Moreover, our estimator enjoys model selection consistency under a mild condition. Thorough experiments on both synthetic and real-world data demonstrate the effectiveness of our method and back up our theory.

1 INTRODUCTION

Multi-task learning (MTL) (Caruana, 1997) has witnessed increasing attention in machine learning and statistics in the past decades. In multi-task learning, one deals with a number of related learning tasks simultaneously, with the goal to improve the generalization performance by utilizing the intrinsic relationship among these tasks. It has been successfully applied to a wide range of applications including object recognition (Caruana, 1997), speech recognition (Parameswaran and Weinberger, 2010), handwritten digits recognition (Quadrianto et al., 2010), and disease progression prediction (Zhou et al., 2011).

The fundamental problem in multi-task learning is how to characterize the relationship among tasks. Representative methods include learning hidden units in neural networks (Caruana, 1997; Baxter, 2000), sharing prior in hierarchical Bayesian models (Bakker and Heskes, 2003; Schwaighofer et al., 2004; Yu et al., 2005; Zhang et al., 2005) and Gaussian processes (Lawrence and Platt, 2004), learning a shared feature mapping matrix in multiple regression (Ando and Zhang, 2005; Evgeniou and Pontil, 2004). Some other works also proposed to learn the task relations (Zhang and Yeung, 2012, 2013; Han and Zhang, 2015), to mention a few. In this study, we focus on a large family of multi-task learning algorithms, which assume that all tasks share a common set of features (Obozinski et al., 2006; Argyriou et al., 2008; Negahban and Wainwright, 2008; Liu et al., 2009; Lounici et al., 2009; Yang et al., 2009; Zhang et al., 2010; Lounici et al., 2011), because they serve as the basis for many other sophisticated multi-task learning algorithms. Note that our method and theory can be extended to those sophisticated multi-task learning settings (Jacob et al., 2009; Kim and Xing, 2010; Kang et al., 2011; Zhang and Yeung, 2012; Gong et al., 2012; Zhang and Yeung, 2013; Han and Zhang, 2015) straightforwardly.

In detail, the multiple task learning setting (Obozinski et al., 2006; Argyriou et al., 2008; Negahban and Wainwright, 2008; Liu et al., 2009; Lounici et al., 2009; Yang et al., 2009; Zhang et al., 2010) considered in this paper is as follows: Given a set of observations $\{\mathbf{X}^{(i)}, \mathbf{y}^{(i)}\}, i = 1, \cdots, m$ from m tasks, where $\mathbf{X}^{(i)} = [\mathbf{x}_1^{(i)}, \ldots, \mathbf{x}_{n_i}^{(i)}]^\top \in \mathbb{R}^{n_i \times d}, i = 1, \cdots, m$ are the design matrices for each task, and $\mathbf{y}^{(i)} = [y_1^{(i)}, \ldots, y_{n_i}^{(i)}]^\top \in \mathbb{R}^{n_i}, i = 1, \cdots, m$ are corresponding vectors of response variables. It is often useful to represent the parameters in multiple tasks via a matrix, where each column corresponds to a task, and each row to a feature, i.e., $\boldsymbol{\Theta}^* = [\boldsymbol{\theta}_1^*, \cdots, \boldsymbol{\theta}_m^*] \in \mathbb{R}^{d \times m}$, where $\boldsymbol{\theta}_i^* \in \mathbb{R}^d$ is the parameter vector of the i-th task. We assume that, conditioned on the covariate (feature) vector $\mathbf{x}_j^{(i)}$, the response variable $y_j^{(i)}$ for each task depends on the same subset of features. In other words, $\boldsymbol{\theta}_i^*$'s are sparse and share the

same support. This corresponds to the matrix $\mathbf{\Theta}^*$ being " row-sparse": each row is either all zero or mostly nonzero, and the number of nonzero rows is relatively small. More specifically, the number of nonzero rows in $\mathbf{\Theta}^*$ is denoted by $s^* = \|\mathbf{\Theta}^*\|_{0,2}$. A lot of recent research in this setting used $\ell_{1,q}(q > 1)$ norm regularizations that encourage the parameter matrix to have such row-sparse structure. Particular examples include the $\ell_{1,\infty}$ norm regularization (Turlach et al., 2005; Zhang and Huang, 2008; Negahban and Wainwright, 2008), the $\ell_{1,2}$ norm regularization (Lounici et al., 2009; Obozinski et al., 2011), and the mixture of $\ell_{1,\infty}$ norm and $\ell_{1,1}$ norm regularizations (Jalali et al., 2013).

However, all the methods mentioned above for multi-task learning are based on convex regularization, i.e., $\ell_{1,q}, q > 1$ norm regularization. Recent studies (Fan and Li, 2001; Zhang, 2010) have shown that convex regularization based estimators suffer from the bias. To remedy this problem, one can choose nonconvex regularization alternatively such as the smoothly clipped absolute deviation (SCAD) penalty (Fan and Li, 2001) and the mimimax concave penalty (MCP) (Zhang, 2010). However, the empirical performance of nonconvex penalty regularized estimator highly relies on the parameters of the nonconvex penalty, which are difficult to tune in practice. One can also use the debiasing method proposed in Javanmard and Montanari (2014) to cancel the bias. However, the debiasing method will result in a non-sparse estimation result. In order to sparsify the result, a truncation step is needed, which introduces an extra tuning parameter. Moreover, the estimation error bound of debiased estimator is no better than that of convex relaxation based estimator.

In this paper, we aim at developing a new estimator which is able to get rid of the bias, attain faster convergence rate, and easy to implement in practice. In detail, we propose a general estimator for multi-task learning with row-sparsity constraint on the parameter matrix. Due to the nonconvex $\ell_{0,2}$ norm constraint, the estimator is a non-convex optimization problem and finding its global optimal solution is generally NP-hard. We propose a greedy algorithms to attain an approximate solution with provable guarantee. At the core of the proposed greedy algorithm is a forward backward feature selection strategy. We prove that the output of our algorithm attains a sharp statistical estimation error bound. As a special example of the proposed general estimator, we consider the multivariate linear regression model $\mathbf{y}^{(i)} = \mathbf{X}^{(i)}\boldsymbol{\theta}_i^* + \boldsymbol{\epsilon}$, where $\boldsymbol{\epsilon}$ is the zero mean noise vector. We show that its estimation error bound is $O(\sqrt{s^*m/n} + \sqrt{s^* \log s^*/n})$ in terms of the Frobenius norm with $n = \min_i\{n_i\}$, which is sharper than the state-of-the-art results Jalali et al. (2013); Gong et al. (2013). Furthermore, in order to achieve model selection consistency, most existing work for the square loss function (Jalali et al., 2013; Wainwright, 2009; Zhao and Yu, 2006) relies on the very stringent incoherence condition. In sharp contrast, our estimator enjoys model selection consistency under a mild condition on the ℓ_2 norms of the nonzero rows in $\mathbf{\Theta}^*$. Thorough experiments on both simulated data and real data show that the proposed method outperforms the state-of-the-art methods.

The remainder of this paper is organized as follows. In Section 2, we propose a general estimator for multi-task learning with row sparsity constraint, followed by a greedy algorithm with forward-backward feature selection strategy. In Section 3, we prove the convergence of the greedy algorithm, as well as the statistical estimation error bound for the output of the greedy algorithm. We report the experimental results in Section 4 and conclude our work in Section 5.

Notation We use bold capitals to denote matrices, bold lowercase letters for vectors, and lowercase letters for scalars. The j-th natural basis in $\mathbb{R}^d$ is denoted as $\mathbf{e}_j$. For matrices $\mathbf{A}$ and $\mathbf{B}$ with commensurate dimensions, we use $\langle \mathbf{A}, \mathbf{B} \rangle$ to denote their trace inner product, i.e. $\langle \mathbf{A}, \mathbf{B} \rangle = \mathrm{tr}(\mathbf{A}^\top \mathbf{B})$. Given a matrix $\mathbf{\Theta}$, its i-th row is denoted by $\mathbf{\Theta}_{i*}$ and its j-th column is denoted by $\mathbf{\Theta}_{*j}$. The $\ell_{p,q}$ norm of a matrix $\mathbf{\Theta}$ is defined as $\|\mathbf{\Theta}\|_{p,q} = \big\{ \sum_i [(\sum_j |\Theta_{ij}|^q)^{1/q}]^p \big\}^{1/p}$, and the Frobenius norm of $\mathbf{\Theta}$ is $\|\mathbf{\Theta}\|_F = \sqrt{\langle \mathbf{\Theta}, \mathbf{\Theta} \rangle} = \|\mathbf{\Theta}\|_{2,2}$. For a matrix $\mathbf{\Theta}$, we use $F(\mathbf{\Theta})$ to denote the index set of the non-zero rows in $\mathbf{\Theta}$. For a row index set F, we denote by $\mathbf{\Theta}_F$ to be the matrix that its i-th row is the same as the i-th row of $\mathbf{\Theta}$ if $i \in F$, and its i-th row is a zero vector if $i \notin F$.

2 THE PROPOSED METHOD

In this section, we first introduce the underlying model for multi-task learning, followed by a general estimator. Then we propose a greedy algorithm to solve the estimator.

2.1 THE MODEL AND ESTIMATOR

Suppose that we have observations $\{(\mathbf{X}^{(1)}, \mathbf{y}^{(1)}), \ldots, (\mathbf{X}^{(m)}, \mathbf{y}^{(m)})\}$ from m tasks, where $\mathbf{X}^{(i)} \in \mathbb{R}^{n_i \times d}$ is the design matrix of the i-th task, $\mathbf{y}_i \in \mathbb{R}^{n_i}$ is the vector of response variables for the i-th task. We assume that the observations in each task are generated from generalized linear models

$$\mathbb{P}(y_j^{(i)} | \mathbf{x}_j^{(i)}, \boldsymbol{\theta}_i^*, \sigma_i) = \exp\left\{ \frac{y_j^{(i)} \langle \boldsymbol{\theta}_i^*, \mathbf{x}_j^{(i)} \rangle - \Phi(\boldsymbol{\theta}_i^{*\top} \mathbf{x}_j^{(i)})}{c(\sigma_i)} \right\}, \quad i = 1, \ldots, m, j = 1, \ldots, n_i,$$

where $\Phi(\cdot) : \mathbb{R} \to \mathbb{R}$ is a link function, $\mathbf{x}_j^{(i)}$ is the j-th row of $\mathbf{X}^{(i)}$, $y_j^{(i)}$ is the j-th coordinate of $\mathbf{y}^{(i)}$, $\boldsymbol{\theta}_i^* \in \mathbb{R}^d$ is the parameter of i-th task, and $c(\sigma_i) \in \mathbb{R}$ is fixed and known scale parameter of the i-th task. A special example

of generalized linear model is the linear regression model where the distribution of the response variable conditioned on the covariates is a normal distribution. That is, when $c(\sigma)$ is chosen as σ^2 and $\Phi(t) = t^2$. Logistic regression is another special case of the generalized linear model, where $\Phi(t) = \log(1 + \exp(t)), c(\sigma) = 1$ and $y_j^{(i)} \in \{0, 1\}$.

Our goal is to recover the unknown $\boldsymbol{\theta}_i^*$'s given the observations from m tasks. A general estimator for multi-task learning is based on minimizing the negative log likelihood, under the $\ell_{0,2}$ constraint on the parameter matrix $\boldsymbol{\Theta}$. This gives rise to:

$$\min_{\boldsymbol{\Theta} \in \mathbb{R}^{d \times m}} \mathcal{L}(\boldsymbol{\Theta}) \quad \text{subject to } \|\boldsymbol{\Theta}\|_{0,2} \leq s, \tag{2.1}$$

where s is a tuning parameter which controls the row sparsity of $\boldsymbol{\Theta}$, $\mathcal{L}(\boldsymbol{\Theta})$ is the sum of the negative log likelihood over all the tasks, which is given by

$$\mathcal{L}(\boldsymbol{\Theta}) = -\sum_{i=1}^{m} \big[1/(2n_i) \sum_{j=1}^{n_i} y_j^{(i)} \boldsymbol{\Theta}_{*i}^\top \mathbf{x}_j^{(i)} + \Phi(\boldsymbol{\Theta}_{*i}^\top \mathbf{x}_j^{(i)})\big], \tag{2.2}$$

where $\boldsymbol{\Theta}_{*i}$ is the i-th column of $\boldsymbol{\Theta}$. In particular, when $c(\sigma) = \sigma^2$ and $\Phi(t) = t^2$, the negative log likelihood function of the exponential family distribution in (2.2) reduces to the square loss function, which is shown as follows:

$$\mathcal{L}(\boldsymbol{\Theta}) = \sum_{i=1}^{m} \frac{1}{2n_i} \|\mathbf{y}^{(i)} - \mathbf{X}^{(i)} \boldsymbol{\Theta}_{*i}\|_2^2. \tag{2.3}$$

Note that the square loss function has been used in Obozinski et al. (2006); Argyriou et al. (2008); Negahban and Wainwright (2008); Lounici et al. (2009); Zhang et al. (2010) for simplicity.

In addition, the optimization problem in (2.1) is nonconvex, because the constraint set $\|\boldsymbol{\Theta}\|_{0,2} \leq s$ is nonconvex. In fact, due to the combinatorial nature of this constraint, finding its global optimal solution is actually NP-hard. In the next subsection, we will propose a greedy algorithm to solve (2.1) approximately, yet with provable guarantee.

2.2 THE PROPOSED ALGORITHM

In order to get a good estimation of $\boldsymbol{\Theta}^*$, a vital problem is to get the row support of $\boldsymbol{\Theta}^*$. In order to get a good estimation of the row support of $\boldsymbol{\Theta}^*$, we designed the following algorithm. The formal description of the algorithm is summarized in Algorithm 1. In detail, we use the forward-backward strategy (Zhang, 2009) to select the feature set iteratively. In particular, we start from an empty feature set. The proposed algorithm adds the feature that will decrease the loss function most greatly into the current selected feature set in each iteration (The "Forward" strategy). Since the ℓ_2 norm of each row of the gradient characterize the decrease rate of the loss function, we use the row with largest ℓ_2 norm which is indexed by $i^{(t+1)}$ during the forward step (The seventh line of Algorithm 1).After each feature set updating, we also update the coefficients for each feature just as an ordinary regression problem. However, the forward strategy is too greedy because it only permits the entrance of new features but prohibits the deletion of irrelevant features. Hence we introduce the "Backward" mechanism to help the algorithm get rid of the bad local optima. That is, in each iteration, we not only add a new feature but also remove one or more irrelevant features from the feature set. The goodness of a feature is measured by the increase of the loss function when the feature is removed from the feature set. Similarly, the coefficient of each selected features is updated when there is a modification of feature set.

Algorithm 1 Forward Backward Greedy Algorithm for Multi-Task Learning (MultiFoBa)

1: **Require:** $\epsilon > 0$
2: **Initialize:** $\boldsymbol{\Theta}^{(0)} = 0, t = 0, F^{(0)} = \emptyset$
3: **while** TRUE **do**
4: **if** $\|\nabla \mathcal{L}(\boldsymbol{\Theta}^{(t)})\|_{\infty,2} < \epsilon$ **then**
5: break
6: **end if**
7: $i^{(t+1)} = \operatorname{argmax}_{i \notin F^{(t)}} \left\|\nabla \mathcal{L}(\boldsymbol{\Theta}^{(t)})_i\right\|_2$
8: $F^{(t+1)} = F^{(t)} \cup \{i^{(t+1)}\}$
9: $\boldsymbol{\Theta}^{(t+1)} = \operatorname{argmin}_{\boldsymbol{\Theta}_{i*}=\mathbf{0}, i \notin F^{(t+1)}} \mathcal{L}(\boldsymbol{\Theta})$
10: $\delta^{(t+1)} = \mathcal{L}(\boldsymbol{\Theta}^{(t)}) - \mathcal{L}(\boldsymbol{\Theta}^{(t+1)})$
11: $t = t + 1$
12: **while** TRUE **do**
13: **if** $\min_{i \in F^{(t)}} \mathcal{L}(\boldsymbol{\Theta}^{(t)} - \mathbf{e}_i \boldsymbol{\Theta}_{i*}^{(t)}) - \mathcal{L}(\boldsymbol{\Theta}^{(t)}) \geq \delta^{(t)}/2$ **then**
14: break
15: **end if**
16: $i^{(t)} = \operatorname{argmin}_{i \in F^{(t)}} \mathcal{L}(\boldsymbol{\Theta}^{(t)} - \mathbf{e}_i \boldsymbol{\Theta}_{i*}^{(t)})$
17: $F^{(t-1)} = F^{(t)} \setminus \{i^{(t)}\}$
18: $\boldsymbol{\Theta}^{(t-1)} = \operatorname{argmin}_{\boldsymbol{\Theta}_{i*}=\mathbf{0}, i \notin F^{(t-1)}} \mathcal{L}(\boldsymbol{\Theta})$
19: $t = t - 1$
20: **end while**
21: **end while**
22: **Output:** $\boldsymbol{\Theta}^{(t)}$

Note that we only delete those features which cause an increase of loss function by less than $\delta^{(t)}/2$, where $\delta^{(t)}$ is the decrease of the loss function when the last feature is added. This guarantees that the loss function will not increase when the cardinality of the feature set returns back. And this implies that the algorithm will not stuck in an infinite loop. In contrast to the forward feature selection algorithm, our algorithm employs a backward feature elimination step, which is able to help avoid the local optima. As we will show in the next section, the backward step is essential in achieving the model selection consistency under mild conditions.

We now analyze the time complexity of the algorithm.

The main computational overhead in the "forward" step is the 9-th line in Algorithm 1. For square loss, there exist a closed-form solution to the optimization problem in this line. In detail, for the i-th task, the solution is given by $\boldsymbol{\Theta}_{*i}^{(t)} = \left(\mathbf{X}_{F^{(t)}}^{(i)\top}\mathbf{X}_{F^{(t)}}^{(i)}\right)^{-1}\mathbf{X}_{F^{(t)}}^{(i)\top}\mathbf{y}^{(i)}$. The time complexity is $O(|F^{(t)}|^2\sum_{i=1}^m n_i)$ in the t-th iteration of the loop. Similarly, in the "backward" step, the main workload falls in the 18-th line and the time complexity is also $O(|F^{(t)}|^2\sum_{i=1}^m n_i)$. Since $|F^{(t)}|$ is much smaller than d, the computational cost is not expensive. Furthermore, we will prove in Section 3 that Algorithm 1 will terminate after finite steps. Therefore, the total time complexity of our algorithm is $O(|F^{(t)}|^2\sum_{i=1}^m n_i)$ times the number of steps. Overall, Algorithm 1 is efficient.

3 MAIN THEORETICAL RESULTS

In this section we will analyze the practicability of the algorithm and prove the finite-sample statistical rate of the proposed estimator. The detailed proofs of all the theory are deferred in the supplemental material.

For the ease of statistical analysis, we consider an oracle estimator $\widehat{\boldsymbol{\Theta}}_O$ which is obtained by restricting the row support of the estimator onto the row support of the unknown true parameter matrix $\boldsymbol{\Theta}^*$. More specifically, let $F(\boldsymbol{\Theta}) \subset \{1, 2, \ldots, d\}$ denote the index set of nonzero rows of $\boldsymbol{\Theta}$. Then $\widehat{\boldsymbol{\Theta}}_O$ is the optimal solution to the following problem:

$$\widehat{\boldsymbol{\Theta}}_O = \underset{\boldsymbol{\Theta}\in\mathbb{R}^{d\times m}}{\operatorname{argmin}} \mathcal{L}(\boldsymbol{\Theta}) \quad \text{subject to } F(\boldsymbol{\Theta}) = F(\boldsymbol{\Theta}^*). \tag{3.1}$$

Note that $\widehat{\boldsymbol{\Theta}}_O$ is not a practical estimator but a reference estimator used for theoretical analysis only. To simplify notation, let $F^* \equiv F(\boldsymbol{\Theta}^*) = F(\widehat{\boldsymbol{\Theta}}_O)$ and $F^{(t)} \equiv F(\boldsymbol{\Theta}^{(t)})$. We use $F^{(t)} - F^*$ to denote the set difference. For the matrix $\boldsymbol{\Theta}^{(t)}_{F^{(t)}-F^*} \in \mathbb{R}^{d\times m}$, its i-th row is the same as the i-th row of $\boldsymbol{\Theta}^{(t)}$ if $i \in F^{(t)} - F^*$. For $i \notin F^{(t)} - F^*$, the i-th row of $\boldsymbol{\Theta}^{(t)}_{F^{(t)}-F^*}$ is a zero vector. Note that according to this definition, $\boldsymbol{\Theta}^{(t)}_{F^{(t)}-F^*}$ is equal to $[\boldsymbol{\Theta}^{(t)} - \widehat{\boldsymbol{\Theta}}_O]_{F^{(t)}-F^*}$.

To concisely characterize the property of $\mathcal{L}(\boldsymbol{\Theta})$, we first introduce the definition of sparse eigenvalues, which is the extension of sparse eigenvalue for sparse regression (Zhang, 2009; Jalali et al., 2011; Liu et al., 2013; Rao et al., 2015). Similar extension has been used in Gong et al. (2013).

Definition 3.1 (Sparse Eigenvalues)**.** The smallest and largest s-sparse eigenvalues of $\nabla^2\mathcal{L}(\boldsymbol{\Theta})$ are

$$\rho_+(s) = \max_{1\le i\le m} \sup\big\{\mathbf{u}^\top\nabla^2_{\boldsymbol{\theta}_i}\mathcal{L}(\boldsymbol{\Theta})\mathbf{u} : \|\mathbf{u}\|_0 \le s, \|\mathbf{u}\|_2 = 1, \boldsymbol{\Theta}\in\mathbb{R}^{d\times m}\big\},$$
$$\rho_-(s) = \min_{1\le i\le m} \inf\big\{\mathbf{u}^\top\nabla^2_{\boldsymbol{\theta}_i}\mathcal{L}(\boldsymbol{\Theta})\mathbf{u} : \|\mathbf{u}\|_0 \le s, \|\mathbf{u}\|_2 = 1, \boldsymbol{\Theta}\in\mathbb{R}^{d\times m}\big\}.$$

Remark 3.2. The definition of $\rho_-(\cdot)$ is highly related to the definition of restricted strong convexity in Negahban et al. (2009). Previous studies (Zhang et al., 2009; Negahban et al., 2009) have shown that the assumption $\rho_-(s) > 0$ can be satisfied for different forms of $\mathcal{L}(\boldsymbol{\Theta})$. This is often referred to as sparse eigenvalue condition. For example, Zhang et al. (2009) proved that when the model is a linear regression model and $\mathcal{L}(\boldsymbol{\Theta})$ is a square loss, $\nabla^2_{\boldsymbol{\theta}_i}\mathcal{L}(\boldsymbol{\Theta})$ satisfies the sparse eigenvalue condition with high probability. Therefore, when we choose square loss in (2.3), it is easy to show that $\rho_-(s) > 0$ holds with high probability analogously. Another example is the generalized linear model. Negahban et al. (2009) proved that with high probability the loss function corresponding to generalized linear model satisfies the restricted strong convexity, which also implies that $\rho_-(s) > 0$.

Without loss of generality, we make the following assumption on the structure of the loss function $\mathcal{L}(\boldsymbol{\Theta})$.

Assumption 3.3 (Decomposable Loss Function)**.** The loss function can be decomposed into the sum of loss functions on different tasks. By formulation, we have

$$\mathcal{L}(\boldsymbol{\Theta}) = \sum_{i=1}^m \ell_i(\boldsymbol{\Theta}_{*i}),$$

where ℓ_i is the loss function defined on the i-th task.

Assumption 3.3 can be verified for many types of loss functions, including the loss functions in (2.2) and (2.3).

Combining Assumption 3.3 with the definition of sparse eigenvalues, it is easy to show that

$$\frac{\rho_-(s)}{2}\|\boldsymbol{\Delta}\|_F^2 \le \mathcal{L}(\boldsymbol{\Theta}+\boldsymbol{\Delta}) - \mathcal{L}(\boldsymbol{\Theta}) - \langle\nabla\mathcal{L}(\boldsymbol{\Theta}), \boldsymbol{\Delta}\rangle \le \frac{\rho_+(s)}{2}\|\boldsymbol{\Delta}\|_F^2, \quad \text{for all} \quad \|\boldsymbol{\Delta}\|_{0,2} \le s. \tag{3.2}$$

These two inequalities in (3.2) are frequently used in the proof in order to bound the difference between $\mathcal{L}(\boldsymbol{\Theta})$ and $\mathcal{L}(\boldsymbol{\Theta}+\boldsymbol{\Delta})$. In fact, it is highly related to the restricted strong convexity and smoothness condition proposed in Negahban et al. (2009). The key difference is here the inequality holds in the sparse subspace rather than a cone.

The first question we are going to address is whether and when Algorithm 1 will terminate. The following theorem guarantees that the proposed algorithm terminates in finite steps.

Theorem 3.4. Suppose that the loss function $\mathcal{L}(\mathbf{\Theta})$ satisfies Assumption 3.3. Let s be any integer satisfying $\rho_-(s) > 0$ and the following condition:

$$s \geq \big(s^* + 1\big)\bigg\{\bigg[\bigg(\sqrt{\frac{\rho_+(s)}{\rho_-(s)}} + 1\bigg)\frac{\sqrt{2}\rho_+(1)}{\rho_-(s)}\bigg]^2 + 1\bigg\}, \tag{3.3}$$

and take $\epsilon > 2\sqrt{2}\big\|\nabla\mathcal{L}(\widehat{\mathbf{\Theta}}_O)\big\|_{\infty,2}\ \rho_+(1)/\rho_-(s)$ in Algorithm 1. Then the algorithm terminates at some $t \leq s - s^*$.

Next we will introduce some theoretical results about the estimation error bounds of the output of Algorithm 1.

Theorem 3.5. Suppose that the loss function $\mathcal{L}(\mathbf{\Theta})$ satisfies Assumption 3.3. Let s be any integer satisfying (3.3) and $\rho_-(s) > 0$. Take

$$\epsilon > \frac{2\sqrt{2}\rho_+(1)}{\rho_-(s)}\ \|\nabla\mathcal{L}(\widehat{\mathbf{\Theta}}_O)\|_{\infty,2}, \tag{3.4}$$

then the output of Algorithm 1 satisfies

$$\big\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\big\|_F \leq \frac{2\sqrt{2}\epsilon}{\rho_-(s)}\sqrt{s_2^*} + \frac{2\sqrt{s^*}}{\rho_-(s^*)}\big\|[\nabla\mathcal{L}(\mathbf{\Theta}^*)]_{F^*}\big\|_{\infty,2}, \tag{3.5}$$

$$\frac{\rho_-(s)^2}{8\rho_+(1)^2}\big|F^{(t)} - F^*\big| \leq \big|F^* - F^{(t)}\big| \leq 2s_2^*, \tag{3.6}$$

where s_2^* is defined as

$$s_2^* := \big|\big\{i \in F^* - F^{(t)} : \big\|\mathbf{\Theta}_{i*}^*\big\|_2 < 2\sqrt{2}\epsilon/\rho_-(s) + \|[\widehat{\mathbf{\Theta}}_O - \mathbf{\Theta}^*]_{F^*}\|_{\infty,2}\big\}\big|. \tag{3.7}$$

Note in Theorem 3.5 that s_2^* denotes the number of nonzero rows in $\mathbf{\Theta}^*$ whose ℓ_2 norms are small. Those correspond to the rows which are difficult to recover. It is easy to verify that if $s_2^* = 0$, we have $|F^{(t)} - F^*| = |F^* - F^{(t)}| = 0$ by (3.6), which implies that $F^{(t)} = F^*$.

In the following corollary, we show that if the ℓ_2 norms of all the nonzero rows are sufficiently large, i.e., $s_2^* = 0$, we can achieve a sharper estimation error bound, together with model selection consistency.

Corollary 3.6. Under the same conditions as Theorem 3.5, if $s_2^* = 0$, i.e., the ℓ_2 norm of each row of $\widehat{\mathbf{\Theta}}_O$ is sufficiently large, then the estimation error of the output of Algorithm 1 is bounded by

$$\big\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\big\|_F \leq \frac{2\sqrt{s^*}}{\rho_-(s^*)}\big\|[\nabla\mathcal{L}(\mathbf{\Theta}^*)]_{F^*}\big\|_{\infty,2}, \tag{3.8}$$

and the model selection consistency can be obtained, i.e., $F^{(t)} = F^*$.

3.1 HIGH PROBABILITY RESULTS FOR SQUARE LOSS

In this subsection, we present the high probability result for a specific example, i.e., the square loss case. Similar high probability results can be proved for the general loss function in (2.2) with more involved arguments.

For the sake of simplicity, we assume that every task has the same number of observations, i.e., $n_1 = \ldots = n_m = n$. Then the square loss function in (2.3) can be further reduced to

$$\mathcal{L}(\mathbf{\Theta}) = \frac{1}{2n}\sum_{i=1}^{m}\|\mathbf{X}^{(i)}\boldsymbol{\theta}_i - \mathbf{y}^{(i)}\|_2^2. \tag{3.9}$$

Our analysis can be easily extended to the general square loss in (2.3) where different tasks may have different number of observations.

Without loss of generality, we make the following assumption on the design matrices $\mathbf{X}^{(i)}$'s.

Assumption 3.7. For all columns in $\mathbf{X}^{(i)}$, we have $\|\mathbf{X}_{*j}^{(i)}\|_2 \leq \sqrt{n}$, where $\mathbf{X}_{*j}^{(i)}$ is the j-th column of $\mathbf{X}^{(i)}$.

Note that Assumption 3.7 is often made in the analysis of Lasso estimator (Negahban et al., 2009; Zhang et al., 2009).

The estimation error bound of the output of Algorithm 1 is shown in the following theorem.

Theorem 3.8. Under the same conditions as Theorem 3.5, when the loss function is the square loss in (3.9) and satisfies Assumption 3.7, we have with probability at least $1 - 1/d - 2/s^*$ that

$$\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\|_F \leq \frac{10\rho_+(1)\sigma}{\rho_-^2(s)}\sqrt{\frac{s^*m}{n}} + \frac{16\rho_+(1)\sigma}{\rho_-^2(s)}\sqrt{\frac{s_2^*\log d}{n}} + \frac{4\sigma}{\rho_-(s^*)}\sqrt{\frac{s^*\log s^*}{n}}, \tag{3.10}$$

where s_2^* is defined as

$$s_2^* = \bigg|\bigg\{i \in F^* - F^{(t)} : \big\|\mathbf{\Theta}_{i*}^*\big\|_2 \leq \frac{9\rho_+(1)\sigma}{\rho_-^2(s)}\bigg(\sqrt{\frac{m}{n}} + 2\sqrt{\frac{\log d}{n}}\bigg)\bigg\}\bigg|.$$

Remark 3.9. Theorem 3.5 suggests that the statistical estimation rate of our algorithm is

$$O\bigg(\sqrt{\frac{s^*m}{n}} + \sqrt{\frac{s^*\log s^*}{n}} + \sqrt{\frac{s_2^*\log d}{n}}\bigg),$$

which is sharper than the statistical rate of convex relaxation based methods (Lounici et al., 2009; Obozinski et al., 2011), i.e., $O(\sqrt{s^*m/n} + \sqrt{s^*\log d/n})$, since s_2^* could be much smaller than s^*, and $\log s^*$ is much smaller than

$\log d$. From the sample complexity point of view, Theorem 3.5 implies the sample complexity of our algorithm is $O(s^*m + s^* \log s^* + s_2^* \log d)$. When s_2^* is sufficiently smaller than s^*, our sample complexity is tighter than the existing best sample complexity for group sparse signal recovery (Baraniuk et al., 2010; Rao et al., 2012), i.e., $O(s^* \log d + s^* m)$.

Corollary 3.10. Under the same conditions as Theorem 3.8, when $s_2^* = 0$, we have with probability at least $1 - 1/d - 2/s^*$ that

$$\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\|_F \leq \frac{10\rho_+(1)\sigma}{\rho_-^2(s)}\sqrt{\frac{s^*m}{n}} + \frac{4\sigma}{\rho_-(s^*)}\sqrt{\frac{s^* \log s^*}{n}},$$

and the model selection consistency can be obtained with probability at least $1 - 1/d - 2/s^*$, i.e., $F^{(t)} = F^*$.

Remark 3.11. From Corollary 3.10, we know that our algorithm can get a even faster convergence rate in terms of Frobenius norm as follows

$$O\bigg(\sqrt{\frac{s^*m}{n}} + \sqrt{\frac{s^* \log s^*}{n}}\bigg). \tag{3.11}$$

In addition, the sufficient condition for our algorithm to achieve model selection consistency is as follows

$$\big\|\mathbf{\Theta}^*_{i*}\big\|_2 \gtrsim \sqrt{\frac{m}{n}} + \sqrt{\frac{\log d}{n}} \quad \text{for all} \quad i \in F^* - F^{(t)}, \tag{3.12}$$

which is implied by $s_2^* = 0$. In other words, we need all non-zero rows of $\mathbf{\Theta}^*$ in the row index set $F^* - F^{(t)}$ are big enough in terms of ℓ_2 norm. This thanks to the $\ell_{0,2}$ constraint on the parameter matrix, which does not introduce bias when the nonzero rows of the parameter matrix are of large magnitude in terms of ℓ_2 norm. In fact, our analysis can be directly applied to the original forward backward algorithm in Zhang (2009), and delivers a sharper bound for single task sparse regression. This can be seen as a by-product of our technical contribution.

Remark 3.12. One may be curious that why our bound in (3.11) beats the minimax lower bound for group sparse recovery Lounici et al. (2011). Note that when $s_2^* = 0$, our algorithm fully recovers the support of $\mathbf{\Theta}^*$, and our estimator is identical to the multivariate regression estimator that is restricted on the true support F^* of the parameter matrix. In this case, our estimator reduces to a multivariate regression in the classical regime rather than in the high dimensional regime, i.e., the oracle estimator in (3.1). Therefore, the minimax lower bound that characterizes the information theoretic limit is no longer the one in the high dimensional regime Lounici et al. (2011), but the one for the multivariate regression in the classical regime, i.e., $O(\sqrt{s^*m/n})$. As we can see, the upper bound in (3.11) achieved by our algorithm matches the minimax lower bound of multivariate regression in the classical regime up to $\log(s^*)$. This is one of our major contributions in this paper and what we referred to as "faster rate".

Remark 3.13. It is interesting to compare our result in Corollary 3.10 with the main result in Gong et al. (2013). Gong et al. (2013) proposed multi-stage multi-task learning method and proved an estimation error bound as follows

$$\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\|_F \lesssim \sqrt{\frac{s^*m}{n}} + \sqrt{\frac{m \log d}{n}}. \tag{3.13}$$

The sufficient condition for their method to achieve model selection consistency is

$$\|\mathbf{\Theta}^*_{i*}\|_2 \gtrsim \sqrt{\frac{m(\log d + \log m)}{n}} \quad \text{for all} \quad i \in F^*. \tag{3.14}$$

By comparing (3.11) with (3.13), it is clear that our estimator attains a much shaper estimation error bound than Gong et al. (2013).

Furthermore, by comparing (3.12) with (3.14), we can see that the sufficient condition of model selection consistency for our algorithm is much milder than their method. In detail, our sufficient condition only takes into account those dimensions that fall in $F^* - F^{(t)}$ rather than the whole F^*. Moreover, the magnitude condition in (3.12) is also in a much smaller order than (3.14). This clearly demonstrates that the sufficient condition of the model selection consistency for our algorithm is substantially milder than Gong et al. (2013).

4 EXPERIMENTS

In this section, we conduct extensive empirical study on both synthetic and real-world datasets, to verify the effectiveness of the proposed method.

4.1 COMPARED ALGORITHMS

We present the empirical study by comparing the results of the following algorithms: **Lasso**: we apply Lasso (Tibshirani, 1996) to each task individually; **FoBa**: a forward backward algorithm for sparse regression (Zhang, 2009). Similar to Lasso, we apply FoBa to each task individually; **L1,2**: multi-task feature learning based on $\ell_{2,1}$-norm regularization (Liu et al., 2009); **MSMTFL**: the Multi-Stage Multi-Task learning method proposed by Gong et al. (2013); **DirtyMTL**: a dirty statistical model based multi-task learning algorithm with regularizer $\lambda_1\|\mathbf{P}\|_{1,1} + \lambda_2\|\mathbf{Q}\|_{1,\infty}$ ($\mathbf{\Theta} = \mathbf{P} + \mathbf{Q}$) (Jalali et al., 2013); **rRMTL**: a robust multi-task learning algorithm employing $\lambda_1\|\mathbf{P}\|_{2,1} + \lambda_2\|\mathbf{Q}^\top\|_{2,1}$ as the regularizer ($\mathbf{\Theta} = \mathbf{P} + \mathbf{Q}$) (Gong et al., 2012); **MultiFoBa**: This is our proposed algorithm, which employs the forward-backward strategy to select features under feature set cardinality constraint. We implement the proposed algorithm by MATLAB. For other algorithms, we use the implementation in

the software package MALSAR[1] In the experiments, the quadratic loss function in (3.9) is employed for all the compared algorithms. For MSMTFL, we use the capped-ℓ_1 regularizer. Note that the proposed algorithm has only one parameter ϵ, which controls the termination of the algorithm.

4.2 SYNTHETIC DATA

The synthetic data are generated by setting the number of tasks as m, where each task has n samples and of dimensionality d. Each sample is drawn from a multivariate normal distribution $N(0, \mathbf{I})$ where $\mathbf{I}$ is a $d \times d$ identity matrix. Then we normalize all columns of each data matrix $\mathbf{X}^{(i)} \in \mathbb{R}^{n\times d}$ to length one. Each entry of the underlying parameter matrix $\mathbf{\Theta}^*$ is sampled i.i.d. from the uniform distribution over the interval $[-10, 10]$. To simulate sparsity, we randomly set $d - s^*$ rows of $\mathbf{\Theta}^*$ to zero vectors. The response vector is generated by $\mathbf{y}^{(i)} = \mathbf{X}^{(i)}\boldsymbol{\theta}_i^* + \boldsymbol{\epsilon}^{(i)}$, where each entry of $\boldsymbol{\epsilon}^{(i)}$ is drawn i.i.d. from the normal distribution $N(0, \sigma_i^2)$. We choose $\sigma_i = 0.1$ for all i. In detail, we generate two synthetic datasets as follows. The parameter settings are $d = 256, m = 10, s^* = 5, n = 100$ for "Dataset 1"; and $d = 512, m = 10, s^* = 10, n = 100$ for "Dataset 2". In addition, we generate a more challenging synthetic dataset ("Dataset 3") to test the support recovery ability of different algorithms when there are nonzero rows with small ℓ_2 norm in $\mathbf{\Theta}^*$. "Dataset 3" is generated differently. Firstly, we generate a $d \times m$ matrix in which each element is sampled i.i.d. from the uniform distribution in the interval $[-10, 10]$. Then we randomly set $d - s^*$ rows as zero vectors. Among the other s^* nonzero rows, we randomly select s_w^* rows and divide each element in these rows by 20 to simulate the small norm. Other procedures of the data generation are the same as "Dataset 1" and "Dataset 2". We set $d = 512, m = 10, n = 100, s^* = 15, s_w^* = 5$ for "Dataset 3".

All algorithms in the comparative study are employed to estimate $\widehat{\mathbf{\Theta}}$ given $\mathbf{X}^{(i)}$'s and $\mathbf{y}^{(i)}$'s. Since all the algorithms have one or several parameters, we tune the parameters by 5-fold cross validation on each synthetic data. The estimation error of the parameter matrix in terms of Frobenius norm $\|\mathbf{\Theta}^{(t)} - \mathbf{\Theta}^*\|_F$ is reported in Table 1.

In order to evaluate the support recovery results of different algorithms, we use F_1 score defined as follows

$$F_1 = \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}},$$

where $\text{precision} = |\text{supp}(\mathbf{\Theta}^*) \cap \text{supp}(\widehat{\mathbf{\Theta}})|/|\text{supp}(\widehat{\mathbf{\Theta}})|$ and $\text{recall} = |\text{supp}(\mathbf{\Theta}^*) \cap \text{supp}(\widehat{\mathbf{\Theta}})|/|\text{supp}(\mathbf{\Theta}^*)|$. Note that for some algorithms (such as Dirty and rMTFL) they not only output the estimator $\widehat{\mathbf{\Theta}}$, but also output two intermediate estimators $\widehat{\mathbf{P}}$ and $\widehat{\mathbf{Q}}$, where $\widehat{\mathbf{\Theta}} = \widehat{\mathbf{P}} + \widehat{\mathbf{Q}}$. By empirical study, we found that the estimator $\widehat{\mathbf{P}}$ is more suitable for support recovery than the estimator $\widehat{\mathbf{\Theta}}$ (i.e., $\widehat{\mathbf{P}}$ achieves higher F_1 score than $\widehat{\mathbf{\Theta}}$), because in these algorithms $\widehat{\mathbf{P}}$ is a sparse or row-sparse matrix. Hence for Dirty and rMTFL algorithms, we use $\widehat{\mathbf{P}}$ to evaluate the feature selection (i.e., support recovery) performance. The F_1 score of support recovery is reported in Table 2.

From Tables 1 and 2, it can be seen that when all nonzero rows are with large ℓ_2 norms (Dataset 1 and 2), our algorithm can exactly recover the supports of $\mathbf{\Theta}^*$ and attain a small estimation error. While some other algorithms can also recover most supports (with a high F_1 score), they suffer from larger estimation error than ours. This is reasonable because our algorithm employs the support cardinality constraint, which is unbiased when the supports are recovered correctly. In contrast, many other algorithms employ some kinds of convex penalties, which lead to biased estimators. In order to recover the support correctly, they have to use a large penalty parameter λ, which makes the estimators more biased.

When there are nonzero rows with small ℓ_2 norm (Dataset 3), our algorithm can still recover the support of $\mathbf{\Theta}^*$ with high accuracy. This is consistent with our theory. In con-

trast, the other algorithms achieve even worse recovery results when nonzero rows with small ℓ_2 norms exist.

4.3 REAL DATA

We use the School data[2] and the SARCOS data[3] to verify the effectiveness of the proposed algorithm on real datasets.

The School dataset consists of information of students from 139 secondary schools, as well as their exam scores. Each student is described by their 27 attributes, such as gender and ethnic group. The student exam score predicting problem can be cast as a multi-task regression problem: each school is considered as a task, each task as different number of data points, the attributes of students are input variables and their scores are responses. We randomly choose 20% and 30% samples from each task to form the training set and the rest samples as the test set. We tune the parameters of all the algorithms by 5-fold cross validation on the training data. We use the normalized Mean Square Error (nMSE), i.e., the mean squared error divided by the variance of ground-truth output, to measure the performance of all algorithms. Experiment results averaged over 20 repetitions are reported in Table 3.

The SARCOS data is collected for an inverse dynamic prediction problem for a anthropomorphic arm with 7 degrees of freedom. The data contains the training part and the testing part. The training part consists of 44,484 samples and the testing part 4,449 samples. Each sample is described by 21 attributes such as joint positions and velocities. There are also 7 responses attached to each sample, representing 7 torques. Our goal is predicting the responses based on the attributes. This problem can be casted as a multi-task regression problem, where the prediction of each response is regarded as a task, and all tasks share the same design matrix. We randomly choose 50, 100 and 150 samples from the training data of the original dataset to form 3 training sets and accordingly select 2000 samples from the testing data of the original dataset to form 3 testing sets. The experiment results averaged over 20 repetitions are summarized in Table 4.

From both Table 3 and Table 4, we can observe that the proposed algorithm outperforms the other algorithms greatly under different training/test splits on both datasets. This is due to the unbiased property of our estimator under mild conditions, as well as the faster statistical rate of our proposed estimator.

5 CONCLUSIONS AND FUTURE WORK

In this paper, we proposed a general estimator for multi-task learning with row sparsity constraint on the parameter matrix. In order to solve it, we develop a forward backward greedy algorithm, whose output attains a sharper estimation error bound than many state-of-the-art multi-task learning methods. Moreover, the output of the proposed greedy algorithm enjoys model selection consistency under a mild condition. Thorough experiments on both synthetic and real-world data back up our theory.

We notice that the $\ell_{0,2}$ constrained nonconvex optimization problem in (2.1) can be potentially solved by the extensions of iterative hard thresholding (Jain et al., 2014) and Frank-Wolfe algorithms (Jaggi, 2013; Lacoste-Julien and Jaggi, 2013). We will investigate these algorithms in the future.

Abstract

MLNs utilize relational structures that are ubiquitous in real-world situations to represent large probabilistic graphical models compactly. However, as is now well-known, inference complexity is one of the main bottlenecks in MLNs. Recently, several approaches have been proposed that exploit approximate symmetries in the MLN to reduce inference complexity. These approaches approximate large domains containing many objects with much smaller domains of *meta-objects* (or cluster-centers), so that inference is considerably faster and more scalable. However, a drawback in most of these approaches is that it is typically very hard to tune the parameters (e.g., number of clusters) such that inference is both efficient and accurate. Here, we propose a novel non-parametric approach that trades-off solution quality with efficiency to automatically learn the optimal domain approximation. Further, we show how to perform Gibbs sampling effectively in a domain-approximated MLN by adapting the sampler according to the approximation. Our results on several benchmarks show that our approach is scalable, accurate and converges faster than existing methods.

1 INTRODUCTION

Markov Logic Networks (MLNs) offer a convenient way to express uncertain domain knowledge in the form of weighted first-order formulas. However, probabilistic inference in MLNs is well-known to be a notoriously challenging problem since the size of the Markov network underlying an MLN (*ground* Markov network) typically grows at an exponential rate as we increase the number of real-world objects that the MLN is defined over. Therefore, for MLNs to be practically applicable, controlling inference complexity in large domains is essential.

Efficient inference for MLNs and Statistical Relational Models, in general, has received a great deal of attention from the research community. In particular, the idea of *lifting* inference over the domain of the MLN such that we can perform inference over groups of objects instead of individual objects has been widely explored over the last few years. The main idea in lifted inference is to reduce complexity by taking advantage of exchangeable variables in the model. Several exact and approximate inference methods have been proposed over the past few years starting with the work by Poole [20], including, FOVE [4], WFOMC [26], Probabilistic Theorem Proving (PTP) [7] and lifted inference with soft evidence [3]. Popular approximate lifted inference methods include [16, 17, 22, 11, 8, 18, 29, 2, 1].

More recently, it has been understood that lifting even approximate inference techniques is typically insufficient to ensure scalability in MLNs. The key problem with most traditional lifting techniques is their over-reliance on exact symmetries which are either not present in real-world situations or are known to be broken fairly easily in the presence of evidence [27]. Therefore, a new class of methods that utilize approximate symmetries thereby forgoing strong theoretical guarantees in lieu of scalability have been proposed making MLNs much more attractive from a practical perspective. In this work, we develop one such novel approach by learning the lifting strategy automatically using non-parametric clustering and integrating a Gibbs sampler that adapts itself with the learned strategy.

The idea of grouping nodes in the input model to reduce inference complexity has been explored in previous work such as Kersting et al. [12] who progressively refine a model in the context of belief propagation and Broeck and Darwiche [27] who compute an over-symmetric low-rank boolean matrix approximation of the original MLN that is more amenable to lifted inference. More recently, Hadiji and Kersting [10] and Sarkhel et al. [21] apply grouping strategies in the context of MAP inference to sometimes obtain orders of magnitude reduction in the size of the

model. Venugopal and Gogate [30] formulate a clustering problem based on a distance measure computed with the help of evidence given to the MLN and use off-the-shelf clustering methods to approximately lift the MLN. Specifically, the key idea in their approach is to pre-process the original model and generate new, smaller domains consisting of meta-objects that implicitly represent a cluster of objects in the original MLN. However, the main problem with existing methods is that it is very hard to tune the parameters (e.g., number of clusters) such that we select the optimal clustering for an MLN balancing accuracy with complexity of inference. For example, consider a simple MLN with just one unit clause, $\mathtt{R}(x)\ w$, then, it turns out that given any evidence, the optimal number of clusters required to represent the complete domain of x accurately is equal to 3. Specifically, we form one cluster with all atoms for which the predicate R is known to be true, one cluster that contains all atoms for which R is known to be false and a third cluster of the remaining objects. On the other hand, for a more complex MLN, such as, $\mathtt{R}(x,\ y) \wedge \mathtt{R}(y,\ z) \Rightarrow \mathtt{R}(z,\ x)\ w$, choosing the correct number of clusters is not obvious. In this paper, we develop a novel method that automatically finds the clustering that is in some sense optimal. Specifically, we make the following contributions.

1. We develop a fully non-parametric approach to approximate the domain in an MLN with a new domain of meta-objects that correspond to the optimal clustering for that domain.
2. We integrate our clustering method with a Gibbs sampler that adapts itself based on the domain approximation in order to minimize sampling errors.

We perform an evaluation of our approach in terms of both accuracy and convergence on benchmarks chosen from Alchemy [13]. Our results clearly illustrate that our approach is scalable, yields accurate results and importantly converges quickly on large models.

2 BACKGROUND

2.1 FIRST-ORDER LOGIC

We assume a strict subset of first-order logic, called finite Herbrand logic. Thus, we assume that we have no function constants and finitely many object constants. A first-order knowledge base (KB) is a set of first-order formulas. A formula in first-order logic is made up of quantifiers ($\forall$ and $\exists$), logical variables, constants, predicates and logical connectives ($\vee$, $\wedge$, $\neg$, $\Rightarrow$, and $\Leftrightarrow$). We denote logical variables by lower case letters (e.g., x, y, z, etc.) and constants by strings that begin with an upper case letter (e.g., A, Ana, Bob, etc.). Constants model objects in the real-world domain. A predicate is a relation that takes a specific number of arguments (called its arity) as input and outputs either True (synonymous with 1) or False (synonymous with 0). A term is either a logical variable or a constant. We denote predicates by strings in typewriter font (e.g., R, S, Smokes, etc.) followed by a parenthesized list of terms.

A first-order formula is recursively defined as follows: (i) An atomic formula is a predicate; (ii) Negation of an atomic formula is a formula; (iii) If f and g are formulas then connecting them by binary connectives such as $\wedge$ and $\vee$ yields a formula; and (iv) If f is a formula and x is a logical variable then $\forall x f$ and $\exists x f$ are formulas. We assume that each argument of each predicate is typed and can only be assigned to a fixed subset of constants. We refer to a ground atom as an atom that contains no logical variables, i.e., all its variables have been substituted by constants. A possible world, denoted by ω, is a truth assignment to all possible ground atoms that can be formed from the constants and the predicates.

2.2 MARKOV LOGIC NETWORKS

Markov logic networks (MLNs) combine Markov networks and first-order logic. Formally, an MLN is a set of pairs (f_i, θ_i) where f_i is a formula in first-order logic and θ_i is a real number. Given a set of constants, an MLN represents a ground Markov network, defined as follows. We have one binary random variable in the Markov network for each possible ground atom. We have one propositional feature for each possible grounding of each first-order formula. The weight associated with the feature is the weight attached to the corresponding formula. The ground Markov network represents the following probability distribution:

$$\Pr(\omega) = \frac{1}{Z} \exp\left(\sum_i \theta_i N_{f_i}(\omega)\right) \tag{1}$$

where $N_{f_i}(\omega)$ is the number of groundings of f_i that evaluate to True given a world ω (assignment to every ground atom).

Important inference queries in MLNs are computing the partition function, finding the marginal probability of an atom given evidence (an assignment to a subset of variables) and finding the most probable assignment to all atoms given evidence (MAP inference). Here, we focus on the marginal inference problem.

2.3 GIBBS SAMPLING

Gibbs sampling [6] is one of the most widely used MCMC algorithms to date. Gibbs sampling changes one variable at a time by sampling that variable from its conditional distribution given all other variables as described below.

Given a set of n variables $X_1 \ \ldots \ X_n$, the Gibbs sampling algorithm begins with a random assignment $\overline{\mathbf{x}}^{(0)}$ to all variables. Then, for $t = 1, \ldots, T$, it performs the following steps (each step is called a Gibbs iteration). Let

$(X_1, \ldots, X_n)$ be an arbitrary ordering of variables in $\mathcal{M}$. Then, for $i = 1$ to n, it generates a new value $\overline{x}_i^{(t)}$ for X_i by sampling a value from the distribution $P(X_i|\overline{\mathbf{x}}_{-i}^{(t)})$ where $\overline{\mathbf{x}}_{-i}^{(t)} = (\overline{x}_1^t, \ldots, \overline{x}_{i-1}^t, \overline{x}_{i+1}^{(t-1)}, \ldots, \overline{x}_n^{(t-1)})$.

Gibbs sampling is typically used to estimate the marginal probabilities. Typically, the sampler is allowed to run for some time (called the *burn-in* time) to allow it to *mix* which ensures that it forgets its initialization, and after T samples from a mixed Gibbs sampler are generated, the 1-variable marginal probabilities can be estimated using the following equation.

$$\widehat{P}_T(\overline{x}_i) = \frac{1}{T}\sum_{t=1}^{T} P(\overline{x}_i|\overline{\mathbf{x}}_{-i}^{(t)}) \quad (2)$$

2.4 DP-MEANS

DP-Means [14] is a non-parametric clustering method that unifies K-means clustering with Bayesian non-parametric models. Specifically, Kullis and Jordan showed that modifying the K-means objective with a penalty term is asymptotically equivalent to performing Gibbs sampling in a Dirichlet-process Mixture Model to infer the right number of clusters. The modified objective is as follows:

$$\min_{\ell_c} \sum_{c=1}^{k} \sum_{x \in \ell_c} ||x - \mu_c||^2 + \lambda k \quad \text{where } \mu_c = \frac{1}{|\ell_c|}\sum_{x \in \ell_c} x \quad (3)$$

To solve the modified K-means objective, DP-Means creates new clusters only when points are sufficiently far off from existing clusters. For completeness sake, we restate the key aspects of the algorithm in Algorithm 1.

Input: $x_1, \ldots x_n; \lambda$
Output: clustering: $\ell_1 \ldots \ell_k$
while *converged=false* **do**
  for *each input point* x_i **do**
    m = Compute minimum distance of x_i w.r.t all current cluster centers
    if $m > \lambda$ **then**
      Create new cluster and assign x_i to new cluster
    end
    else
      Assign x_i to its closest cluster
    end
  end
end

Algorithm 1: DP-Means

Kulis and Jordan showed that Algorithm 1 converges to a local optimal solution. Depending on the value of λ, we would converge to solutions that place more (or less) emphasis on reducing the overall number of clusters.

Formulas:
$\mathtt{R}(x) \vee \mathtt{S}(x, y), w$
Original Domains:
$\Delta_x = \{A_1, B_1, C_1, D_1\}$
$\Delta_y = \{A_2, B_2, C_2, D_2\}$
Domain Approximation:
$\Delta'_x = \{\mu_1, \mu_2\}$
$\Delta'_y = \{\mu_3, \mu_\}$
(a)

Meta-Objects:
$\mu_1 = \{A_1, B_1\}$; $\mu_2 = \{C_1, D_1\}$
$\mu_3 = \{A_2, B_2\}$; and $\mu_4 = \{C_2, D_2\}$
(b)

Meta-Atoms:
$\mathtt{R}_1(\mu_1) = \{\mathtt{R}(A_1), \mathtt{R}(B_1)\}$
$\mathtt{R}_2(\mu_2) = \{\mathtt{R}(C_1), \mathtt{R}(D_1)\}$
$\mathtt{S}_1(\mu_1, \mu_2) = \{\mathtt{S}(A_1, C_1), \mathtt{S}(A_1, D_1),$
$\mathtt{S}(B_1, C_1), \mathtt{S}(B_1, D_1)\}$
...
(c)

Figure 1: (a) an example MLN $\mathcal{M}$ and a possible domain approximation for the original domain of $\mathcal{M}$. $\mathcal{M}'$ contains meta-objects and meta-atoms, i.e., objects that represent multiple objects in the original domain and atoms that represent multiple atoms in $\mathcal{M}$ as shown in (b) and (c)

3 NON-PARAMETRIC DOMAIN APPROXIMATION

It is now quite widely understood that in order to scale up inference in MLNs, one needs to perform *domain lifting* [25], i.e., take advantage of symmetries or exchangeability of variables in the MLN [19] to perform efficient inference over groups of objects in the MLN. Following a similar vein, the idea behind approximate domain lifting is to relax the notion of symmetries or exchangeable variables such that domain lifting is applicable to a much larger class of MLNs. One way to find such symmetries is to treat the problem of domain lifting as an unsupervised machine learning problem and use clustering algorithms to learn symmetries based on the structure of the MLN, the given inference query, and evidence. Specifically, for marginal inference, ideally, we would like to cluster together all ground atoms that have similar marginal probabilities. This would then allow us to treat all atoms in the cluster uniformly without having to explicitly compute the marginal probabilities separately for every atom in the cluster. However, it should be noted that clustering at the ground atom level is a non-trivial problem and one that is computationally expensive since the number of ground atoms may themselves be extremely large in MLNs that encode application domains such as Natural Language Understanding.

As an alternative to clustering at the level of ground atoms, Venugopal and Gogate [30], and Broeck and Darwiche [27] proposed clustering approaches at the object-level. That is, given a set of domains $\mathcal{D} = \{D_1, \ldots D_M\}$, where each D_j is a set of real-world objects that can be instantiated in $\mathcal{M}$, and evidence $\mathbf{E}$, we cluster each domain in $\mathcal{D}$ independently and replace the set of objects with *meta-objects*, i.e., the set of cluster-centers, to generate a new domain $\mathcal{D}' = \{D'_1, \ldots D'_k\}$, where each $|D'_j| << |D_j|$. Replacing the domain in $\mathcal{M}$ with $\mathcal{D}'$ yields a new MLN $\mathcal{M}'$ which we refer to as the *domain-approximated* version of $\mathcal{M}$. In $\mathcal{M}'$, each ground atom is now a *meta-atom* since it implicitly represents a set of ground atoms in $\mathcal{M}$. An example MLN and its domain approximation is shown in Fig 1.

Clearly, choosing the right domain approximation is crucial to ensuring the quality of inference results. Therefore, the key question that we wish to answer here is: Given $\mathcal{M}$, $\mathcal{D}$ and $\mathbf{E}$, how do we choose $D'_1, D'_2 \ldots D'_k$ to obtain $\mathcal{M}'$ that is in some sense optimal?

3.1 PROBLEM FORMULATION

We learn the approximate domains for an MLN using a non-parametric approach. Specifically, we use the DP-means algorithm to find the optimal clustering. Note that other notable alternatives for non-parametric clustering exist, such as Dirichlet Process Mixture Models, which uses the Bayesian non-parametric framework for learning clusters without fixing them apriori. However, it turns out that DP-means is a much simpler, more scalable approach and seamlessly integrates Bayesian non-parametrics with the classical and universally popular K-means clustering algorithm which makes it an ideal model for our problem.

Specifically, we formulate the non-parametric domain approximation problem for a given MLN as follows:

$$\min_{\{\ell_{cj}\}_{c=1;j=1}^{|D'_j|;M}} \sum_{j=1}^{M} \sum_{c=1}^{|D'_j|} \sum_{\mathbf{x} \in \ell_{cj}} ||\mathbf{x} - \mu_{cj}||^2 + \lambda |D'_j| \quad (4)$$

where $\mu_{cj} = \frac{1}{|\ell_{cj}|} \sum_{\mathbf{x} \in \ell_{cj}} \mathbf{x}$, λ is a parameter that controls the number of clusters created for each domain in $\mathcal{M}$. $||\mathbf{x} - \mu_{cj}||^2$ is the Euclidean distance between the cluster center μ_{cj} and $\mathbf{x}$.

Given a constant λ, it is easy to see that we can decompose Eq. (4) into M independent objective functions and optimize each objective independently. This will yield the approximate domains for the input MLN $\mathcal{M}$. However, the challenging task is to automatically tune the parameter λ such that $\mathcal{M}'$ is in some way a "good" approximation of $\mathcal{M}$. We next describe an approach to quantify the error made by $\mathcal{M}'$ in approximating $\mathcal{M}$ and incorporate this error to automatically tune λ in Eq. (4).

3.2 DOMAIN APPROXIMATION ERROR

Let $\mathcal{M}$ be the original MLN and $\mathcal{M}'$ be the MLN obtained after approximating each domain in $\mathcal{M}$. Clearly, the distributions $P_{\mathcal{M}}$ and $P_{\mathcal{M}'}$ are defined over spaces with different cardinalities since they have a different number of possible ground atoms. It turns out computing a valid distance metric that can directly compare such distributions is extremely challenging and is shown to be NP-hard [32]. Thus, we need to design approximations that can reasonably compare $P_{\mathcal{M}}$ and $P_{\mathcal{M}'}$.

Consider a single meta-atom in $\mathcal{M}'$, X, which corresponds to a set of ground atoms in $\mathcal{M}$ which we denote by $\mathbf{X}$. Thus, to map $P'_{\mathcal{M}}$ to $P_{\mathcal{M}}$, we need to map a 0/1 assignment of X to a vector of 0/1 assignments to $\mathbf{X}$. Clearly, there are $2^{|\mathbf{X}|}$ different ways to define this mapping. For each mapping, we will end up with a different approximation to $P_{\mathcal{M}}$. If we fix a specific mapping ρ, clearly, we can convert any sample $\mathbf{x}$ drawn from $P_{\mathcal{M}'}$ to a set of samples $\rho(\mathbf{x})$ in $P_{\mathcal{M}}$. In this case, the (un-normalized) probability $P_{\mathcal{M}'}(\mathbf{x})$ can be computed by summing over the (un-normalized) probabilities of $\rho(\mathbf{x})$ as follows:

$$P_{\mathcal{M}'}(\mathbf{x}) = \sum_{\mathbf{y} \in \rho(\mathbf{x})} P_{\mathcal{M}}(\mathbf{y})$$

However, computing the above probability is clearly infeasible since it involves a summation over the probabilities in the original space which can be very large and is precisely the reason to perform domain-approximation in the first place. Instead, if we choose ρ to be a one-to-one mapping, we map each sample in $P_{\mathcal{M}'}$ to exactly one sample in $P_{\mathcal{M}}$. In other words we assume that all other samples that $\mathbf{x}$ can be mapped to have negligible probabilities. Using this assumption, the above equation now reduces to

$$P_{\mathcal{M}'}(\mathbf{x}) \approx P_{\mathcal{M}}(\rho(\mathbf{x}))$$

Even with the above approximation of one-to-one mapping, computing $P_{\mathcal{M}'}(\mathbf{x})$ may be hard since we additionally require that $P_{\mathcal{M}}(\rho(\mathbf{x})$ should be sufficiently easy to compute. That is, given $\mathbf{x}$, we should be able to compute $P_{\mathcal{M}}(\rho(\mathbf{x})$ in bounded time/space. Unfortunately, for an arbitrary ρ, this problem requires computing the counts of satisfied formulas in a sample as its sub-step and is thus $\#P$-complete [24]. However, consider a special ρ, namely, given a sample from $\mathcal{M}'$ with meta-atom X assigned to x, we assign the same value x to all atoms in $\mathcal{M}$ that X corresponds to. We refer to such a mapping as a *uniform assignment* mapping and under this mapping, it turns out that marginal probabilities in $P_{\mathcal{M}}$ and $P'_{\mathcal{M}}$ have a direct relationship. Specifically,

Theorem 1. *Given an MLN $\mathcal{M}$ and its domain-reduced approximation $\mathcal{M}'$, under the assumption of uniform assignment mapping and no evidence atoms, for any ground atom X in $\mathcal{M}'$, $P_{\mathcal{M}'}(X) = P_{\mathcal{M}}(X')$, where $X' \in \mathbf{X}$.*

Proof. Let ω' be a world in $\mathcal{M}'$ and ω be a world in $\mathcal{M}$ obtained by the mapping function ρ.

$$P(\omega') \propto exp(\sum_i N_i(\omega')\theta_i)$$

$$P(\omega) \propto exp(\sum_i N_i(\omega)\theta_i)$$

Since we assume that ρ is a uniform assignment mapping, we have that for any formula f_i, $N_i(\omega') \propto N_i(\omega)$. Further, note that since there is no evidence in the model, $\forall\omega$, $P(\omega) > 0$. Therefore, $P(\omega') \propto P(\omega)$. Summing over all worlds, the partition function, $Z(\mathcal{M}') \propto Z(\mathcal{M})$. Since marginal probabilities are simply ratios of partition functions, the result of the theorem holds. □

The above theorem means that under the assumption of uniform assignment mapping, we can perform marginal inference as follows. We approximate the domains in $\mathcal{M}$ and without changing the weights or formulas in $\mathcal{M}$, we can simply replace the original domain by its domain-approximation to yield $\mathcal{M}'$. We then generate samples from $\mathcal{M}'$ and estimate the marginal probabilities from the generated samples for each meta-atom X. We can finally compute the marginal probabilities in $\mathcal{M}$ by using $P(X)$ for all atoms in $\mathcal{M}$ that meta-atom X represents.

3.3 ADAPTIVE GIBBS SAMPLING

In the presence of evidence, Theorem 1 no longer holds since we need to first translate the evidence $\mathbf{E}$ observed for $\mathcal{M}$ to $\mathcal{M}'$. Depending on this translation, $P_{\mathcal{M}}(\cdot|\mathbf{E})$ may be very different from $P_{\mathcal{M}'}(\cdot|\mathbf{E}')$ even under the assumption of uniform assignment mapping. Previous approaches such as [30] have proposed the transformation of evidence based on majority voting. Specifically, if X is a meta-atom in $\mathcal{M}'$ that corresponds to $\mathbf{X}$ in $\mathcal{M}$, X is assigned as true evidence in $\mathcal{M}'$ if the number of true evidence atoms in $\mathbf{X}$ outweighs the number of false or unknown atoms. However, consider sampling from $P_{\mathcal{M}'}(\cdot|\mathbf{E}')$, where $\mathbf{E}'$ has been generated by applying the aforementioned majority voting. Unless every meta-atom in $\mathcal{M}'$ represents a set of atoms that are all either evidence or all non-evidence atoms, each sample derived from $P_{\mathcal{M}'}(\cdot|\mathbf{E}')$ when mapped to $\mathcal{M}$ using a uniform assignment mapping, will have inconsistencies. For example, let X, Y, Z, U be the ground atoms in $\mathcal{M}$ and let $C1 = X, Y, Z$ and $C2 = U$ be the meta-atoms of $\mathcal{M}'$. If $X = 1$ is given as evidence to $\mathcal{M}$, then no evidence is set in $\mathcal{M}'$. Therefore, in every sample generated from $\mathcal{M}'$ is inconsistent with evidence $X = 1$. Similarly, if $Y = 1$ is added as evidence, then $C1 = 1$, and no samples with $Z = 0$ are generated. Our main idea is to reduce the expected number of inconsistencies when we generate samples from $\mathcal{M}'$ via Gibbs sampling.

In each iteration of Gibbs sampling, we pick a meta-atom, say X in $\mathcal{M}'$ and sample an assignment to this meta-atom from the conditional probability distribution $P_{\mathcal{M}'}(X|X_{-i})$, where X_{-i} is the set of all meta-atoms other than X. The choice of which meta-atom to sample in each iteration is according to a distribution of selection probabilities. Typically, in random-scan Gibbs sampling, this selection probability is a uniform distribution over the non-evidence atoms. However, in general, we can select the selection probabilities to be non-uniform, i.e. a probability α_i for atom X_i. It has also been shown that as long as the selection probabilities are not continuously updated (also called vanishing adaptation), we can show that the Markov chain remains ergodic (cf. [9])

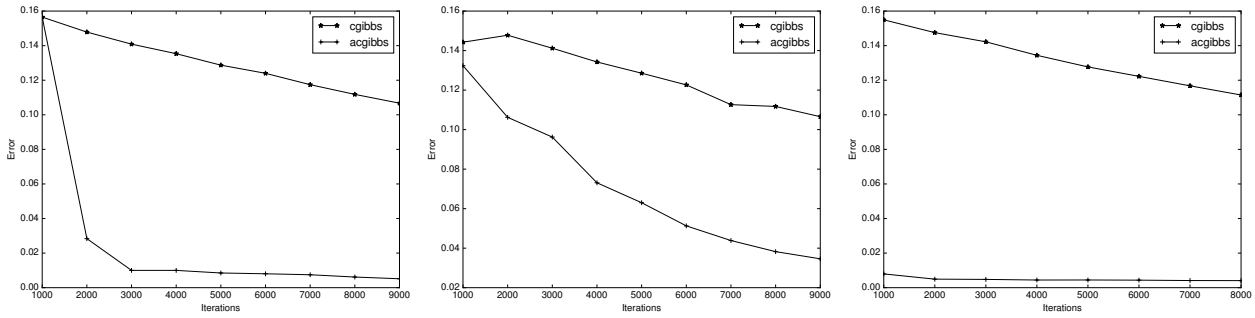
We now formalize the expected error in a sample drawn from the Gibbs sampler as follows. Let $X_1 \ldots X_K$ be the meta-atoms in $\mathcal{M}'$ and let $\mathbf{X}_1 \ldots \mathbf{X}_K$ be sets of ground atoms in $\mathcal{M}$ where X_i is a meta-atom for all the ground atoms in $\mathbf{X}_i$. If $\mathbf{X}_i$ consists of both evidence and non-evidence atoms and we sample X, clearly, the sample generated may be erroneous on every evidence atom in $\mathbf{X}_i$. But if we choose not sample X at all (i.e., treat it as hard evidence), then we will never sample the non-evidence atoms in $\mathbf{X}$. The expected error can be formulated as,

$$E_G = \sum_{i=1}^{K} \alpha_i \sum_{X' \in \mathbf{X}_i} \mathbb{I}(X') + (1 - \alpha_i) \\ (|\mathbf{X}_i| - \sum_{X' \in \mathbf{X}_i} \mathbb{I}(X')) \quad (5)$$

where $0 \leq \alpha_i \leq 1$ is the selection probability for meta-atom X_i and $\mathbb{I}(X') = 1$ if X' is an evidence atom and 0 otherwise.

Note that if the amount of evidence corresponding to X_i is large, E_G can be reduced by reducing α_i, while, if the amount of evidence corresponding to X_i is small, E_G can be reduced by increasing α_i. Therefore, we set $\alpha_i = 1 - \frac{\sum_{X' \in \mathbf{X}_i} \mathbb{I}(X')}{|\mathbf{X}_i|}$. At the extreme ends, if X_i corresponds to only evidence atoms, it is never sampled in the compressed model ($\alpha_i = 0$) while if X_i corresponds to only non-evidence atoms, it is always sampled in the compressed model ($\alpha_i = 1$).

Next, with the help of a simple example MLN, we illustrate that adapting the selection probabilities of meta-atoms based on the clustering is likely to yield more accurate estimates as opposed to randomly choosing a meta-atom to sample. Here, we considered a simple MLN with three formulas $w_1; \mathtt{R}(x) \vee \mathtt{S}(x)$, $w_2; \mathtt{R}(x)$ and $w_2; \mathtt{S}(x)$ where x has 10000 objects. We introduced 25% random evidence on the ground atoms of `R` and `S`. We then randomly divided the objects in x into K clusters to approximate its domain. Thus, there are $2K$ meta-atoms with each meta-atom representing a variable number of original atoms with varying evidence. We compared the performance of Gibbs sampling with random selection probabilities which we refer to as `cgibbs` and our approach where the selection



(a) $K = 1000$ (b) $K = 100$ (c) $K = 10$

Figure 2: Illustrating the effect of adapting the selection probabilities in Gibbs sampling based on the clustering. The results are shown for $w_1; \mathtt{R}(x) \vee \mathtt{S}(x)$, $w_2; \mathtt{R}(x)$ and $w_2; \mathtt{S}(x)$ with a domain of 10000 objects and randomly generated evidence. K signifies the number of clusters into which the domain objects were divided. `cgibbs` denotes Gibbs sampling without adapting the selection probability and `acgibbs` denotes Gibbs sampling with adapting the selection probability. The curves are shown as the average mean square error between the true marginal probabilities and the marginal probabilities computed by the samples.

probabilities are tied to the clustering, which we refer to as `acgibbs`. Specifically, we compared the average error between marginal probabilities output by `cgibbs` and `acgibbs` with the true marginal probabilities for the MLN (which we could easily compute due to our choice of the specific MLN structure). The results are shown in Fig. 2 for varying number of clusters (K). As seen in the figure, `acgibbs` generates much more accurate estimates of the marginal probability by reducing the number of inconsistent samples that were generated. The effect is even more pronounced when we have fewer but larger clusters, i.e., Fig. 2 (c), where since K is small, each meta-atom therefore represents a large number of atoms. Here, using random scan Gibbs is much worse since the number of inconsistencies in each sample is extremely large yielding to less accurate estimates of marginal probabilities.

3.4 GIBBS SAMPLING EFFICIENCY

If the Gibbs sampler contains N variables, since each variable is sampled one at a time, it roughly takes about N sampling steps to change the complete state of the sampler just once. Thus, suppose $\mathcal{M}$ has a million non-evidence atoms, we need to at least perform a million sampling operations to sample every variable in the model once which is prohibitively expensive. Further, the *mixing* time of the Gibbs sampler is roughly proportional to the number of variables in the model [15]. Thus, we would like our Gibbs sampler to have a bounded number of variables for efficiency and fast mixing. To specify this, given $\mathcal{M}'$ which is a domain-approximated version of $\mathcal{M}$, we define the sampling efficiency (S_G) of $\mathcal{M}'$ to be proportional the total number of meta-atoms in $\mathcal{M}'$.

Input: $\mathcal{M}$, β_1, β_2, ϵ
Output: $\mathcal{M}'$
$\lambda = 10000$
while *converged=false* **do**
  `// Find the clustering for a fixed` λ
  for *each domain* D_i *in* $\mathcal{M}$ **do**
    $D_i' =$ DP-Means(D_i)
  end
  $\mathcal{M}' =$ Replace-Domains($\mathcal{M}$, $D_1, \ldots$)
  $E_G(\lambda) =$ Evaluate Eq (5) for $\mathcal{M}'$
  $S_G(\lambda) =$ Number of meta-atoms in $\mathcal{M}'$
  if $E_G(\lambda) < \beta_1$ *and* $S_G(\lambda) < \beta_2$ **then**
    converged=true
    return $\mathcal{M}'$
  end
  else if $S_G(\lambda) > \beta_2$ **then**
    `// Could not find solution`
    return $\mathcal{M}'$
  end
  else
    `// Reduce` λ
    $\lambda = \epsilon\lambda$
  end
end

Algorithm 2: NP-Cluster

3.5 COMPUTING THE OPTIMAL CLUSTERS

We now re-formulate the minimization problem in Eq. (4) by incorporating the sampling error (E_G) and the sampling efficiency (S_G). That is, given constants β_1 and β_2, our clustering problem is defined as,

$$\min_{\{\ell_{cj}\}_{c=1;j=1}^{|D_j'|;M};\lambda} \sum_{j=1}^{M} \sum_{c=1}^{|D_j'|} \sum_{\mathbf{x} \in \ell_{cj}} ||\mathbf{x} - \mu_{cj}||^2 + \lambda |D_j'| \quad (6)$$

where $E_G(\lambda) < \beta_1$ and $S_G(\lambda) < \beta_2$

Note that both the sampling error and efficiency depend upon the parameter λ. That is, if λ is large, then we penalize the number of clusters a lot more, therefore, our solution will yield very few meta-atoms which results in a large $E_G(\lambda)$ but small $S_G(\lambda)$. Similarly, smaller λ will yield solutions that has small $E_G(\lambda)$ but large $S_G(\lambda)$. Jointly optimizing $\{\ell_{cj}\}_{c=1;j=1}^{|D'_j|;M}; \lambda$ is challenging because we need to consider every possible clustering with every possible parameter λ. Instead, we use a co-ordinate descent type of approach where we pick a λ and find the best clusters, and then fix the clustering and pick the next best λ.

The algorithm for non-parametric clustering of domains is shown in Algorithm 2. Algorithm 2 starts by fixing λ to a large constant and computes the optimal clustering for the domains of the input MLN, at this value of λ. The DP-Means algorithm is used a sub-step to compute optimal clustering for a given λ. Once, we compute the optimal clustering of the domains, we evaluate the sampling error and efficiency based on the new MLN generated from the clusters. If we satisfy the constraints on sampling error bound and efficiency, then the algorithm has reached a local optima and we output the domain-approximated MLN. However, if we fail to satisfy the constraints, we check if $S_G(\lambda)$ is greater than β_2 in which case, we cannot find a solution, else we reduce λ by ϵ to improve $E_G(\lambda)$ and $S_G(\lambda)$.

4 RELATED WORK

In recent years many methods have been proposed that use symmetries for improving the scalability both in exact inference [20, 4, 7, 26, 3] as well as approximate inference [22, 11, 8, 18, 29, 2]. Niepert and Broeck [19] recently showed that most of the earlier work on lifted inference can be connected to the concept of exploiting *finite partial exchangeability* in statistics that allows one to perform inference over groups of exchangeable variables efficiently. However, lifted inference that only looks for exact exchangeability tends to work with limited classes of MLNs as shown in [27]. Previous work that has addressed this issue in the context of belief propagation include Kersting et al. [12] and Singla et al [23], where scalability was achieved through message approximation. Broeck and Darwiche [27] proposed a general *over symmetric approximation* by adding symmetries to the MLN thereby making it liftable. Venugopal and Gogate [30] proposed the use of unsupervised machine learning methods to cluster similar domain objects together based on the evidence given to the MLN. Similar clustering ideas have been used in MAP inference algorithms and it has been shown that in some cases one can achieve orders of magnitude reduction in the size of the MLN network without sacrificing much accuracy [10, 21]. In the context of sampling based inference algorithms, Broeck and Niepert [28] introduced a Metropolis-Hastings sampler by utilizing over-symmetric approximations of MLNs in their proposal distribution, and Venugopal and Gogate [31] developed an importance sampler by constructing an tractable proposal from the clustered domain objects. However, unlike the aforementioned approaches which use parametric methods that can be difficult to tune, here, we propose a fully non-parametric approach integrated with Gibbs sampling that systematically trades-off sampling error with efficiency.

Dataset	#Clauses	#Atoms	#Parameters
WebKB	892 million	20 million	64
Protein	408 million	3.3 million	211
ER	1.7 trillion	5.5 million	15

Table 1: Dataset sizes.

5 EXPERIMENTS

We evaluate our approach, which we refer to as `acgibbs`, using three benchmark MLNs obtained from the Alchemy [13] website: Webkb MLN that models the relations between web-page links and topics in the webpage, Protein MLN that models the interaction between proteins, and the ER MLN that is used for entity resolution in NLP. The details of these benchmarks are shown in Table 1. For each MLN, we randomly set the weights of the individual formulas between 0 and 1. We evaluate our approach along two dimensions: accuracy in estimating the marginal probabilities and convergence of the Markov Chain. We compare our results with regular Gibbs sampling (`Gibbs`) and the approach proposed in Venugopal and Gogate [30] (`cgibbs`), where they use clustering algorithms such as KMeans to derive an approximate MLN and then sample this MLN using regular Gibbs sampling.

For `cgibbs`, since we explicitly need to set the number of clusters for each domain, we set this to be 10% of the original domain-size. Note that we set this size to be approximately the same size as the number of clusters that computed by our non-parametric methods. For `acgibbs`, for an approximate MLN, $\mathcal{M}'$, we set the threshold β_1 as 0.01% of the number of meta-atoms in $\mathcal{M}'$ and β_2 as 10K. For fairness, in both `cgibbs` and `acgibbs`, we used the same features as specified in [30] for computing the distances. Specifically, for each object in the MLN, the method proposed in Venugopal and Gogate partially grounds the MLN with that specific object and approximately counts the number of true groundings in each formula for the partially ground MLN given evidence. The approximate counting is performed by generating tractable SQL queries with a bounded number of joins. The feature vector for each object is computed with the counts obtained for each formula in the MLN.

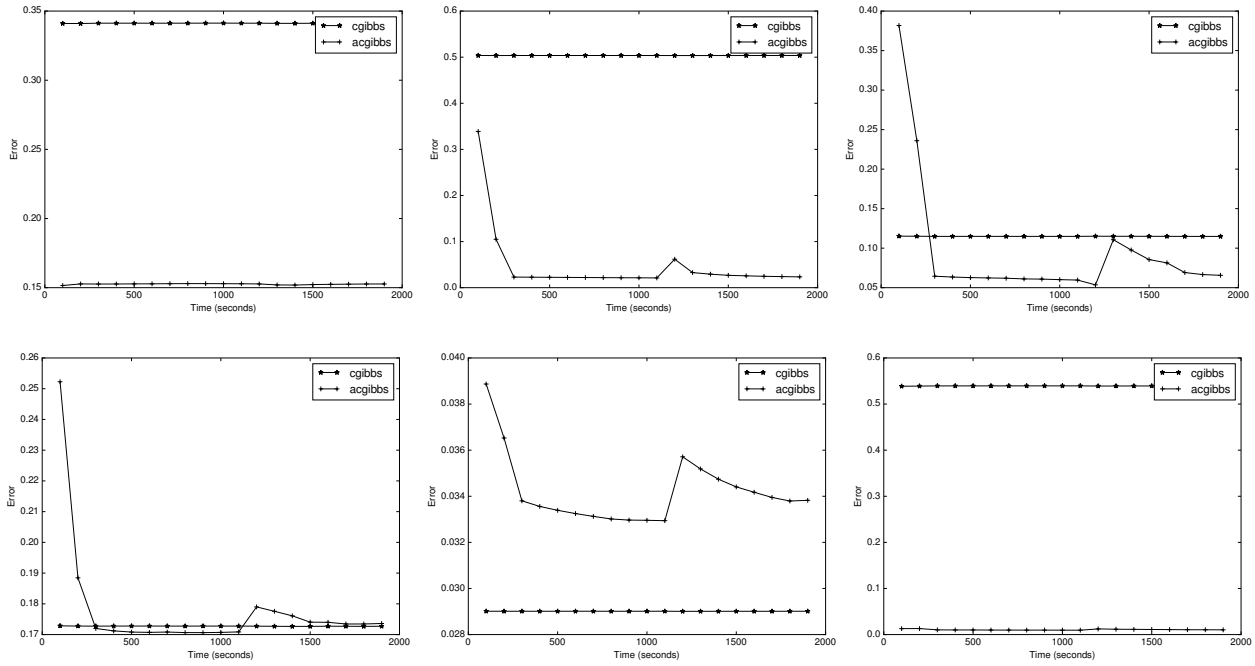


Figure 3: Accuracy Plots for various benchmarks. The domain size of each benchmark was reduced to 10% of its original size to ensure that we get better estimates with `gibbs`. The plots are shown for the average Hellinger distance between the marginal probabilities generated by `gibbs` and that generated by `cgibbs` and `acgibbs` respectively. (a) and (b) correspond to the Protein benchmark with 25% and 50% evidence respectively. Similarly (c) and (d) correspond to the Webkb benchmark, and (e), (f) correspond to the ER benchmark.

5.1 ACCURACY

We compare the accuracy of `cgibbs` and `acgibbs` using the following approach. We assume that the `gibbs` algorithm outputs the true marginal probabilities and compare the results of `cgibbs` and `acgibbs` with that of `gibbs`. We measure the average Hellinger distance between the marginal probabilities of the query atoms output by `gibbs` with the probabilities output by `acgibbs` and `cgibbs`. We considered all ground atoms not set as evidence to be the query atoms. We measured accuracy on small MLNs since for larger MLNs the output of `gibbs` is not reliable. Specifically, we subsampled the true domain of the benchmarks and derived smaller MLNs out of the original benchmarks. Further, we also evaluated the performance of the algorithms in the presence of low as well as high evidence. Fig. 3 shows the results that we obtained for our benchmarks. As seen here, for the protein benchmark, `acgibbs` performs much better than `cgibbs`. For the Webkb benchmark, the accuracy of `acgibbs` is again better than `cgibbs`. For the ER benchmark, for the low evidence case, `acgibbs` was slightly worse than `cgibbs` but for the high evidence case, `acgibbs` was much better than `cgibbs`. One hypothesis for this behavior is that perhaps `gibbs` is not very accurate on this benchmark as shown by the poor convergence property that it exhibits for this benchmark (see next section). Overall, `acgibbs` was seen to be more accurate than `cgibbs` in our evaluation.

5.2 CONVERGENCE

We compare the mixing time of `gibbs`, `cgibbs` and `acgibbs` based on the Gelman-Rubin (G-R) Statistic [5]. For a well-mixed sampler, the G-R statistic should ideally decrease over time illustrating that the MCMC chain has mixed. To compute the G-R statistics, we set up 5 Gibbs samplers from random initialization points and measure the within chain and across chain variances for the marginal probabilities for 1000 randomly chosen query ground atoms. We compute the G-R statistics for each of the 1000 query atoms and measure the mean G-R statistic. Fig. 4 shows our results on the benchmarks. Note that, here we consider larger sized MLNs, i.e., we evaluate on the full benchmark without subsampling the MLN domain. As seen here, for the protein benchmark `cgibbs` and `acgibbs` mix much faster than `gibbs` which has an upward trajectory for the G-R statistic indicating that it has not mixed at all. Among `cgibbs` and `acgibbs`, `acgibbs` mixes faster than `cgibbs` because the selection probability ensures that we spend more resources on sampling meta-atoms which are less deterministic (there is less evidence on the atoms that the meta-atom represents)

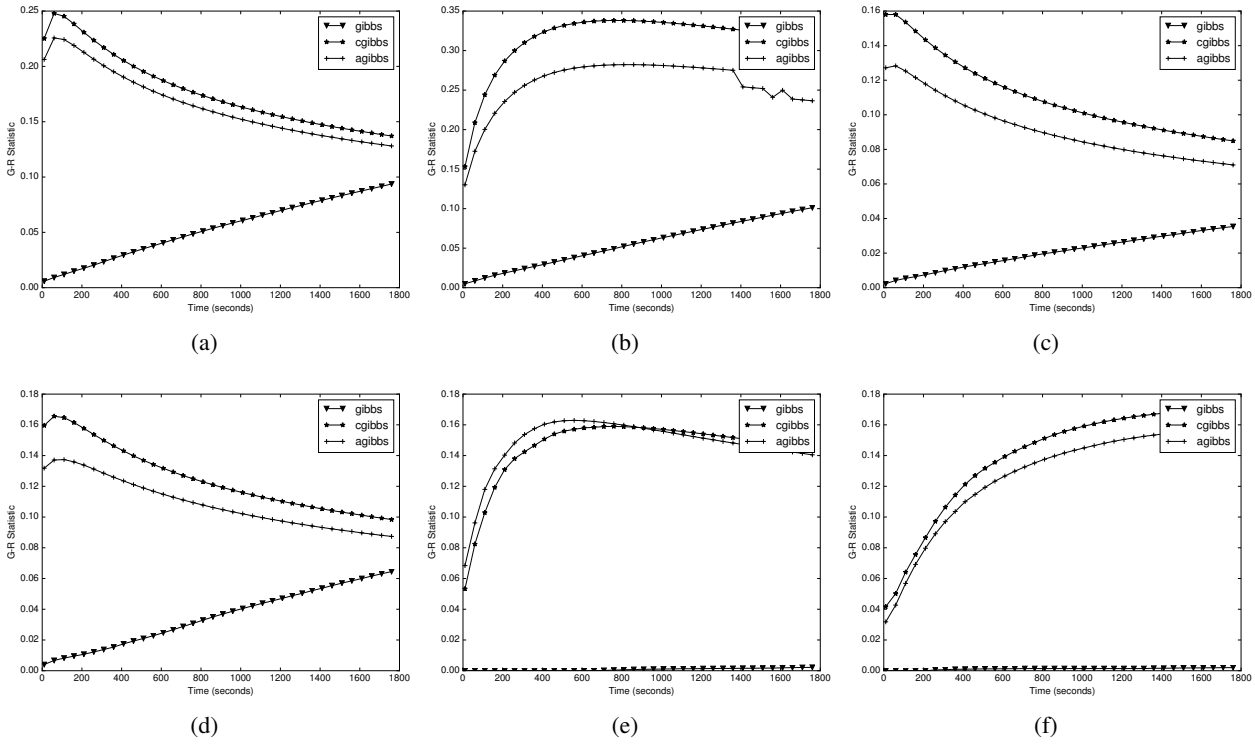

Figure 4: Convergence Plots for various benchmarks. The plots are shown for the average Gelman-Rubin statistic computed using 5 runs of the algorithms across 1000 randomly chosen estimates for the marginal probabilities. (a) and (b) correspond to the Protein benchmark with 25% and 50% evidence respectively. Similarly (c) and (d) correspond to the Webkb benchmark, and (e), (f) correspond to the ER benchmark.

as compared to meta-atoms which are more deterministic (more or less all the atoms represented by the meta-atom are evidence atoms). For the Webkb benchmark, the results look similar with `gibbs` not mixing and `acgibbs` mixing faster than `gibbs`. For the ER case, the curve for `gibbs` stays flat at almost 0. Due to the large size of the benchmark, `gibbs` is very slow in its iterations and most of the query atoms remain un-sampled and thus only retain their initialization values. Even `cgibbs` and `acgibbs` though clearly better than `gibbs`, have slower mixing times as compared to the other two benchmarks.

6 CONCLUSION

Exploiting approximate symmetries has been recognized as a practical approach to obtain scalable inference algorithms in MLNs. Several inference methods that take advantage of approximate symmetries have been proposed over the past few years. However, a major disadvantage of existing methods is that it is quite difficult to manually tune the parameters in these approaches to obtain accurate inference results. Here, we proposed a non-parametric approach that approximates the domains of an MLN and can systematically trade-off accuracy with efficiency. Further, we integrated our approach with a Gibbs sampling algorithm that adapts itself based on the domain-approximation to generate higher quality samples. Our results on benchmarks showed the promise of our approach in terms of scalability, accuracy and convergence.

In future, we would like to explore more complex mapping functions from meta-atoms to the original atoms, integrate our approach with variational distances and adapt our approach for MAP inference algorithms.

Abstract

Real-world data often includes rich relational information, which can be leveraged to help predict unknown variables using a small amount of observed variables via a propagation effect. We consider the problem of selecting the best subset of variables to observe to maximize the overall prediction accuracy. Under the Bayesian framework, the optimal subset should be chosen to minimize the Bayesian optimal error rate, which, unfortunately, is critically challenging to calculate when the variables follow complex and high dimensional probabilistic distributions such as graphical models. In this paper, we propose to use a class of Bayesian lower bounds, including Bayesian Cramér Rao bounds as well as a novel extension of it to discrete graphical models, as surrogate criteria for optimal subset selection, providing a set of computationally efficient algorithms. Extensive experiments are presented to demonstrate our algorithm on both simulated and real-world datasets.

1 INTRODUCTION

We consider the following optimal label selection problem: Given an unknown $\theta = [\theta_1, \dots, \theta_n]$ with posterior distribution $p(\theta \mid X)$ conditioning on observation X, select a best subset $C \subset [n]$ of size no larger than k on which the true values of θ_C are revealed, such that the prediction accuracy of $\theta_{\neg C}$ on the remaining set $\neg C = [n] \setminus C$ is maximized. We assume $p(\theta \mid X)$ to be a multivariate distribution with rich correlation structures, such as graphical models, so that the prediction of $\theta_{\neg C}$ can largely benefit from knowing θ_C via a "propagation effect".

Problems of this type appear widely in many important areas, including semi-supervised learning, experiment design, active learning, as well as application domains such as optimal sensor placement, and optimal budget allocation in crowdsourcing (e.g., Zhu et al., 2003; Krause & Guestrin, 2009; Settles, 2010; Bilgic et al., 2010; Liu et al., 2015).

The optimal subset C should be chosen to minimize certain uncertainty measures of the conditional model $p(\theta_{\neg C} \mid \theta_C\ ;\ X)$, and a natural choice is the conditional variance,

$$R_*(C) = \mathbb{E}_{\theta|X}\Big(\sum_{i\in\neg C} \mathrm{var}(\theta_i \mid \theta_C\ ;\ X)\Big),$$

which equals the mean squared error of the optimal Bayesian estimator of $\theta_{\neg C}$ given θ_C and X. Unfortunately, this objective is notoriously difficult to calculate in practice; Krause & Guestrin (2009) showed that it is #P-complete to calculate $R_*(C)$ for general discrete graphical models, even for simple tree structured models in many cases. Although practical approximations can be constructed using (approximate) posterior sampling via Markov chain Monte Carlo (MCMC), the estimation accuracy of the conditional variance can be poor when the size of C is large because each conditioning case only receives a small number of samples. Computationally, evaluating $R_*(C)$ requires both unconditioning sampling from $\theta \sim p(\theta \mid X)$, as well as conditional sampling from $\theta_{\neg C} \sim p(\theta_{\neg C} \mid \theta_C, X)$ for each value of θ_C that appears in the unconditioning sample; this makes it extremely difficult to optimize the conditional variance objective in practice, even when simple greedy search methods are used. Similar computational difficulty also appears in other uncertainty measures, such as conditional entropy and mutual information (Krause & Guestrin, 2009); what is worse, these information-theoretic objectives have the additional difficulty of depending on the normalization constant (known as the partition function) of $p(\theta \mid X)$, which is very challenging to calculate.

A special case when the computation can be largely simplified is when $p(\theta \mid X)$ is a multivariate Gaussian distribution; in this case, the conditional variance reduces a simple trace function of the inverse of the sub-matrix on $\neg C$, that is, $R_*(C) = \mathrm{tr}(Q[\neg C]^{-1})$, where Q is the inverse covariance (or the Fisher information) matrix of $p(\theta \mid X)$, and

$Q[\neg C]$ represents the sub-matrix of Q formed by the rows and columns in $\neg C$. This objective can be evaluated and optimized much more efficiently, because Q can be precalculated and the block-wise inversion can be calculated recursively using the block-wise matrix inversion formula (Horn & Johnson, 2012).

Contribution In this paper, we propose to solve the subset selection problem using information criteria of form $\mathrm{tr}(Q[\neg C]^{-1})$ for generic, non-Gaussian distribution $p(\theta \mid X)$, where Q is a generalized "information matrix" of $p(\theta \mid X)$ that we will define later; this is motivated by lower bounds of Bayesian risks of form

$$\mathbb{E}_{\theta|X}(\|\hat{\theta}_{\neg C} - \theta_{\neg C}\|_2^2) \geq \mathrm{tr}(Q[\neg C]^{-1}),$$

where $\hat{\theta}_{\neg C} = \hat{\theta}_{\neg C}(\theta_C, X)$ is any (deterministic or randomized) estimator of $\theta_{\neg C}$. Results of this type are the Bayesian version of the classical frequentist Cramér Rao bound, which, however, only works for unbiased estimators. For continuous θ with smooth densities, this bound is based on the van Trees inequality, or known as Bayesian Cramér Rao bound (Van Trees & Bell, 2007) and Q is a Bayesian version of the typical frequentist Fisher information matrix. For θ with discrete values, we derive a new form of Q based a new extension of van Trees inequality; our result appears to be the first bound of this type for discrete graphical models to the best of our knowledge.

Minimizing these Bayesian lower bounds provides new computationally efficient approaches for observation selection with complex $p(\theta \mid X)$. We provide extensive empirical results to demonstrate the advantage of our methods in two practical application settings, including selecting control questions in crowdsourcing and label propagation for graph-based semi-supervised learning.

Related Work Bayesian CR bounds have been widely used in signal processing and information fusion, but seem to be less well known in machine learning; we refer to Van Trees (2004); Van Trees & Bell (2007) for an overview of its theory and applications. Related to our work, Williams (2007) used the log-determinant (instead of the trace) of Bayesian Fisher information as the selection criterion, and studied its sub-modularity.

Outline This paper is organized as follows. Section 2 introduces backgrounds on the observation selection problem and Bayesian Cramér Rao (CR) bounds. We apply Bayesian CR bounds to solve the observation selection problem in Section 3 and propose the extension to discrete models in Section 4. We then discuss two examples of applications of our methods in Section 5, and present empirical results in Section 6. The paper is concluded in Section 7.

2 BACKGROUND

We introduce backgrounds on the observation selection problem in Section 2.1, and Bayesian Cramér-Rao bounds in Section 2.2. We restrict to the case when θ is a continuous variable in this section, and discuss the extension to discrete variables in Section 4.

2.1 OBSERVATION SELECTION

Assume $\theta = [\theta_1, \ldots, \theta_n] \in \mathbb{R}^n$ is a continuous random parameter of interest with posterior distribution $p(\theta \mid X) \propto p(X \mid \theta)p(\theta)$ conditioning on observed data X. We are interested in the setting when we have the option of revealing the true value θ_C of a subset $C \subset [n]$ of size no larger than k, such that we can get the best estimation on the unknown parameter $\theta_{\neg C}$ in the remaining set $\neg C = [n] \setminus C$. To be concrete, let $\hat{\theta}_{\neg C} = \hat{\theta}_{\neg C}(\theta_C, X)$ be an estimator of $\theta_{\neg C}$ based on θ_C and X, the optimal C should ideally minimize the mean squared Bayesian risk:

$$\min_{C:\,|C|\leq k} \left\{ R_{\hat{\theta}}(C) \equiv \mathbb{E}_{\theta|X}(\|\hat{\theta}_{\neg C} - \theta_{\neg C}\|_2^2) \right\}.$$

However, this objective depends on the choice of the estimator $\hat{\theta}_{\neg C}$ and is not easy to estimate in practice. Consider the Bayesian estimator $\hat{\theta}_{\neg C} = \mathbb{E}(\theta_{\neg C} \mid \theta_C,\ X)$, then $R_{\hat{\theta}}(C)$ reduces to the trace of the conditional variance:

$$R_*(C) = \mathrm{tr}(\mathbb{E}_{\theta|X}(\mathrm{cov}(\theta_{\neg C} \mid \theta_C, X))), \qquad (1)$$

which is also the minimum Bayesian risk one can possibly achieve. This objective function is called the A-optimality ("average" or trace) in the experiment design literature (e.g., Chaloner & Verdinelli, 1995).

There also exist other similar objective functions, but with less direct connection to the mean squared Bayesian risk; this includes the information-theoretic quantities such as the conditional entropy $H(\theta_{\neg C} \mid \theta_C,\ X)$ and the mutual information $I(\theta_{\neg C},\ \theta_C \mid X)$. The negative of these objective functions are often shown to be submodular and monotonic under certain conditions, for which an $(1-1/e)$ optimality approximation can be obtained using a simple greedy algorithm, that is, starting with an empty set $C = \emptyset$, and sequentially add the best item i so that $R(C \cup \{i\})$ is minimized (Nemhauser et al., 1978).

The major challenge in implementing the greedy algorithm for objectives like (1) is the computational cost of the objective. Although it is possible to draw approximate sample from $p(\theta \mid X)$ using MCMC, the estimation quality of the conditional variance $\mathrm{var}(\theta_{\neg C} \mid \theta_C)$ can be poor, especially when the size of C is large, because it requires samples from $\theta_{\neg C} \sim p(\theta_{\neg C} \mid \theta_C,\ X)$ for each value of θ_C that appears in the unconditioning sample of $p(\theta \mid X)$. Further, the Monte Carlo estimates are required for every candidate C considered, making the optimization algorithm very time consuming.

The information-theoretic objective functions, such as conditional entropy and mutual information, also suffer from the similar difficulty due to the need for estimating the conditional distribution $\log p(\theta_{\neg C} \mid \theta_C,\ X)$; in addition, they also involve calculating the normalization constant $Z = \int p(X \mid \theta)p(\theta)d\theta$, which is known to be critically difficult (e.g., Chen et al., 2012).

The computation can be largely simplified when $p(\theta \mid X)$ is a multivariate normal distribution, e.g., $\mathcal{N}(\mu, \Sigma)$, in which case the objective (1) reduces to a matrix function $\mathrm{tr}(Q[\neg C]^{-1})$, where $Q = \Sigma^{-1}$ is the inverse covariance matrix, and the greedy selection can be implemented efficiently based on the recursive relation,

$$R_*(C \cup \{i\}) = R_*(C) + \sum_{j \in \neg C} \frac{\sigma_{ij}^2}{\sigma_{ii}},$$

where $Q[\neg C]^{-1} = \{\sigma_{ij}\}$ and can also be calculated recursively using the block-wise matrix inversion formula (Horn & Johnson, 2012).

2.2 BAYESIAN CRAMÉR RAO LOWER BOUND

Bayesian Cramér Rao bounds (Van Trees, 2004), also known as van Trees inequalities, are lower bounds of Bayesian risks for any estimator $\hat{\theta}$ in terms of Fisher information matrix; it is the Bayesian version of the classical Cramér Rao bound, but does not restrict to unbiased estimators.

Let $\hat{\theta} = \hat{\theta}(X)$ be any (randomized or deterministic) estimator, then under mild regularity conditions (Van Trees & Bell, 2007, page 35), the Bayesian Cramér Rao bound guarantees

$$\mathbb{E}_{\theta|X}[\|\hat{\theta} - \theta\|^2] \geq \mathrm{tr}(H^{-1}), \tag{2}$$

where $H = -\mathbb{E}_{\theta|X}\left[\nabla_\theta^2 \log p(\theta \mid X)\right]$ and is called the *Bayesian Fisher information matrix*; compared to the classical Fisher information, Bayesian Fisher information takes expectation on the parameter θ and does not require a true value θ^*. We note that H can be rewritten into

$$H = -\mathbb{E}_\theta[\nabla_\theta^2 \log p(X \mid \theta)] - \mathbb{E}_\theta[\nabla_\theta^2 \log p(\theta)],$$

where the first term represents the information brought by the observed data, and the second term is the information from the prior knowledge.

Nuisance Parameter In many practical cases, there exist additional nuisance parameters $\eta \triangleq \{\eta_1, \cdots, \eta_{n'}\}$ of no direct interest. Ideally, this can be handled by applying Bayesian CR bound on the marginalized probability $p(\theta \mid X) = \int p(\theta, \eta \mid X)d\eta$. This, however, can be difficult to calculate because $\nabla_\theta^2 \log p(\theta \mid X)$ may have no closed form and require another Monte Carlo approximation. A weaker, but more computationally efficient, lower bound (Van Trees & Bell, 2007, Section 1.2.6) can be

$$\mathbb{E}_{\theta|X}[\|\hat{\theta} - \theta\|^2] \geq \mathrm{tr}([H^{-1}]_{\theta\theta}), \tag{3}$$

where $[H^{-1}]_{\theta\theta} = (H_{\theta\theta} - H_{\theta\eta}H_{\eta\eta}^{-1}H_{\eta\theta})^{-1}$ is the $\theta\theta$-submatrix of H^{-1}, with H being the joint Bayesian Fisher information matrix of $[\theta, \eta]$:

$$H = \begin{bmatrix} H_{\theta\theta} & H_{\theta\eta} \\ H_{\eta\theta} & H_{\eta\eta} \end{bmatrix} = \mathbb{E}_{\theta,\eta|X} \begin{bmatrix} \nabla_{\theta\theta}\ell & \nabla_{\theta\eta}\ell \\ \nabla_{\eta\theta}\ell & \nabla_{\eta\eta}\ell \end{bmatrix}, \tag{4}$$

where $\ell = -\log p(\theta, \eta \mid X)$.

3 BAYESIAN CR BOUND FOR LABEL SELECTION

We apply Bayesian CR bounds to define an objective function of form $\mathrm{tr}(Q[\neg C]^{-1})$ for the observation selection problems, allowing more efficient computation.

Proposition 1. *For any subset $C \subseteq [n]$ and estimator $\hat{\theta}_{\neg C} = \hat{\theta}_{\neg C}(\theta_C, X)$, assume the conditions for Bayesian Cramér Rao bound holds, we have*

$$\mathbb{E}_{\theta|X}[\|\hat{\theta}_{\neg C} - \theta_{\neg C}\|^2] \geq \mathrm{tr}(Q[\neg C]^{-1}),$$

where $Q[\neg C]$ is the submatrix of a matrix Q with rows and columns in $\neg C$ and Q can be one of the following two cases:

1. With no nuisance parameter, Q is the Bayesian Fisher information of θ, that is, $Q = -\mathbb{E}_{\theta|X}[\nabla_\theta^2 \log p(\theta \mid X)]$.

2. With a nuisance parameter η, we have $Q = H_{\theta\theta} - H_{\theta\eta}H_{\eta\eta}^{-1}H_{\eta\theta}$ and H is the joint Bayesian Fisher information of $[\theta, \eta]$ as defined in (4)*.*

Proof. Apply (2) and (3) by treating $[\theta_C, X]$ as the fixed observation and $\theta_{\neg C}$ as the random parameter to be estimated. □

Remark Because the conditional variance in (1) is the Bayesian risk obtained by the Bayesian estimator $\hat{\theta}_{\neg C} = \mathbb{E}(\theta_{\neg C} \mid \theta_C;\ X)$, it should also be lower bounded by the Bayesian CR bound, that is,

$$\mathrm{tr}(\mathbb{E}_{\theta|X}(\mathrm{cov}(\theta_{\neg C} \mid \theta_C;\ X))) \geq \mathrm{tr}(Q[\neg C]^{-1}).$$

The above result suggests a method for finding the optimal subset C by minimizing the lower bound in Proposition 1, reducing to the observation selection problem to a sub-matrix selection problem:

$$\max_{C:\ |C| \leq k} \left\{ f_Q(C) \equiv -\mathrm{tr}(Q[\neg C]^{-1}) \right\}, \tag{5}$$

where k is the maximum size of C that defines our budget.

We now introduce conditions under which the objective function $f_Q(C)$ is a monotonically non-increasing and submodular function, so that the simple greedy selection algorithm yields an $(1 - 1/e)$-approximation. See Algorithm 1.

Proposition 2. *(i). Assume Q is positive definite. For any $i \notin C$, we have*

$$f_Q(C \cup \{i\}) = f_Q(C) + \frac{\sum_{j \in \neg C} \sigma_{ij}^2}{\sigma_{ii}}.$$

where σ_{ij} is the ij-element of $Q[\neg C]^{-1}$, and hence we have $f_Q(C) \geq f_Q(C')$ for any $C' \subseteq C$.

(ii). If Q is positive definite and also satisfies $Q_{ij} \leq 0$ for $i \neq j$ (i.e.,it is a Stieltjes matrix, equivalently a symmetric M-matrix), then $\Sigma = Q^{-1}$ is element-wise nonnegative, and $f_Q(C)$ is a sub-modular function.

Proof. (1) is an elementary fact, and (2) is a special case of Friedland & Gaubert (2013, Theorem 3). □

Since $\Sigma = Q^{-1}$ corresponds to the covariance matrix in the Gaussian case, Proposition 2(ii) suggests that we need Σ to be element-wise nonnegative, that is, θ_i are positive related to each other (in a rough sense), to make $f_Q(C)$ a submodular function. We remark that this element-wise positive condition is necessary; see Friedland & Gaubert (2013, Example 18) for a counter example. Similar "suppressor-free" conditions also appear when considering the submodularity of conditional variance functions in other settings (e.g., Das & Kempe, 2008; Ma et al., 2013).

The greedy algorithm for optimizing (5) is shown in Algorithm 1, in which we use Proposition 2(i) to reduce the greedy update $i^* = \arg\max_i f_Q(C \cup \{i\})$ to a simpler form:

$$i^* = \arg\max_i \left\{ \sigma_{ii} + \frac{\sum_{j \in \neg C, j \neq i} \sigma_{ij}^2}{\sigma_{ii}} \right\}. \qquad (6)$$

Intuitively, the first term of the above selection criterion corresponds to a *local effect*, representing the uncertainty σ_{ii} of θ_i itself, while the second term corresponds to a *global effect*, representing how much knowing the true value of θ_i can help in estimating the remaining parameters. Note that Algorithm 1 also updates $Q[\neg C]^{-1} = \{\sigma_{ij}\}$ recursively using the sub-matrix inverse formula (Line 9).

We should point out that evaluating the expectation in $Q = -\mathbb{E}[\nabla_\theta^2 \log p(\theta \mid X)]$ still requires drawing samples from $p(\theta \mid X)$ (or $p(\theta, \eta \mid X)$), but this can be pre-calculated before the greedy search starts, and is much more efficient than optimizing the exact conditional variance objective function, which requires expensive Monte Carlo or MCMC sampling for each candidate C evaluated during the optimization process.

Algorithm 1 Greedy Subset Selection based on Bayesian CR bound

1: **Input:** Posterior distribution $p(\theta, \eta \mid X)$; budget size k.
2: Denote $H(\theta, \eta) = -\nabla^2_{[\theta,\eta]} \log p(\theta, \eta \mid X)$.
3: Draw sample $[\theta^\ell, \eta^\ell]_{\ell=1}^m \sim p(\theta, \eta \mid X)$.
4: $H = \frac{1}{m} \sum_\ell H(\theta^\ell, \eta^\ell)$ and $Q = H_{\theta\theta} - H_{\theta\eta} H_{\eta\eta}^{-1} H_{\eta\theta}$.
5: Initialize $C = \emptyset$. $\Sigma = Q^{-1}$.
6: **while** $|C| < k$ **do**
7: $\quad i^* \leftarrow \arg\max_{i \in \neg C} \sum_{j \in \neg C} \sigma_{ij}^2 / \sigma_{ii}$.
8: $\quad C \leftarrow C \cup \{i^*\}$.
9: $\quad \sigma_{ij} \leftarrow \sigma_{ij} - \sigma_{ii^*} \sigma_{i^* j} / \sigma_{i^* i^*}, \quad \forall i, j \in \neg C.$
10: **end while**

4 EXTENSION TO DISCRETE VARIABLES

The Bayesian CR bound above works only for continuous random parameters, since it requires to calculate the derivatives and Hessian matrices. In this section, we introduce a new class of lower bounds that apply to general discrete probabilistic graphical models.

Proposition 3. *(i). Assume $\theta = [\theta_1, \ldots, \theta_n]$ takes values in a discrete set $\theta \in \{a_1, \ldots, a_d\}^n$, and $p(\theta|X) > 0$ for any θ. Let a^* be the solution of $\sum_{k=1}^d \frac{1}{a_k - a^*} = 0$. Define*

$$s_i(\theta,\ X) = \frac{1}{d(\theta_i - a^*) p(\theta_i \mid \theta_{\neg i}\ ;\ X)},$$

and $Q = \mathbb{E}_{\theta|X}[ss^\top]$, then for any estimator $\hat{\theta}(X)$, we have

$$\mathbb{E}_{\theta|X}[\|\hat{\theta}(X) - \theta\|^2] \geq \mathrm{tr}(Q^{-1}).$$

(ii). For any subset $C \subseteq [n]$ and conditional estimator $\hat{\theta}_{\neg C} = \hat{\theta}_{\neg C}(\theta_C, X)$, we have

$$\mathbb{E}_{\theta|X}[\|\hat{\theta}_{\neg C} - \theta_{\neg C}\|^2] \geq \mathrm{tr}(Q[\neg C]^{-1}),$$

where $Q[\neg C]$ is the submatrix of Q with rows and columns in $\neg C = [n] \setminus C$.

Proof. (i). Denote by $\delta = \theta - \hat{\theta}$, we have by Cauchy's inequality,

$$\mathbb{E}_{\theta|X}[\delta\delta^\top] \succeq \mathbb{E}_{\theta|X}[\delta s^\top] \cdot [\mathbb{E}_{\theta|X}(ss^\top)]^{-1} \cdot \mathbb{E}_{\theta|X}[s\delta^\top].$$

Since $\|\hat{\theta}(X) - \theta\|^2 = \mathrm{tr}(\delta\delta^\top)$, we just need to show that $\mathbb{E}_{\theta|X}[\delta s^\top] = \mathbb{E}_{\theta|X}[(\theta - \hat{\theta}) s^\top] = I$ where I is the identity matrix. To see this, note that

$$\begin{aligned}\mathbb{E}_{\theta|X}[s_i] &= \sum_\theta \frac{p(\theta_{\neg i} \mid X)}{d(\theta_i - a^*)} \\ &= \sum_{\theta_i} \frac{1}{d(\theta_i - a^*)} \sum_{\theta_{\neg i}} p(\theta_{\neg i} \mid X) = 0,\end{aligned}$$

where the last step is because $\sum_{\theta_i} \frac{1}{\theta_i - a^*} = 0$ by the definition of a^*. Therefore, we have $\mathbb{E}_{\theta|X}[s] = 0$, and hence $\mathbb{E}_{\theta|X}[\delta s^\top] = \mathbb{E}_{\theta|X}[\theta s^\top]$. Further, note that

$$\mathbb{E}_{\theta|X}[\theta_i s_i] = \mathbb{E}_{\theta|X}[(\theta_i - a^*) s_i] = \frac{1}{d} \sum_\theta p(\theta_{\neg i} \mid X) = 1,$$

$$\begin{aligned}\mathbb{E}_{\theta|X}[\theta_j s_i] &= \sum_{\theta} \frac{\theta_j - a^*}{d(\theta_i - a^*)} p(\theta_{\neg i} \mid X) \\ &= \sum_{\theta_i} \frac{1}{d(\theta_i - a^*)} \sum_{\theta_{\neg i}} (\theta_j - a^*) p(\theta_{\neg i} \mid X) \\ &= 0 \quad \forall i \neq j.\end{aligned}$$

This gives $\mathbb{E}_{\theta|X}[\theta s^\top] = I$ and the result follows.

(ii). Apply the result in (ii) by treating $\theta_{\neg C}$ as the random parameter and (θ_C, X) as the observed data. □

Note that s_i depends on $p(\theta \mid X)$ only through the conditional distribution $p(\theta_i \mid \theta_{\neg i},\ X)$, which is often computationally tractable since it does not depend on the troublesome normalization constant $Z = \sum_\theta p(X|\theta)p(\theta)$.

Example Consider the case of binary parameter $\theta \in \{0,1\}^n$, then solving $\frac{1}{0-a^*} + \frac{1}{1-a^*} = 0$ gives $a^* = 1/2$. Therefore, we have $s_i(\theta,\ X) = \frac{1}{(2\theta_i - 1)p(\theta_i|\theta_{\neg i},\ X)}$ in this case.

We remark that there exist variants of Bayesian CR bounds that use finite differences to replace the derivatives, including Borrovsky-Zakai bound (Bobrovsky & Zakai, 1975) and Weiss-Weinstein bound (Weiss & Weinstein, 1985); these bounds can be naturally applied when θ takes values in the integer lattice $\mathbb{Z}^n$, but does not work well when θ takes values a finite set due to the boundary problem.

5 APPLICATIONS

The subset selection problem has wide applications in many important areas. In this section, we describe two examples of applications that involve continuous and discrete random variables, respectively; empirical results on real datasets are presented in Section 6.

5.1 CONTINUOUS LABEL SELECTION FOR CROWDSOURCING

Crowdsourcing has been widely used in data-driven applications for collecting large amounts of labeled data (Howe, 2006). A major challenge, however, is that the (often anonymous) crowd labelers tend to give unreliable, even strongly biased, answers. Probabilistic modeling has been widely used to estimate the workers' reliabilities and downweight or eliminate the unreliable workers (e.g., Raykar et al., 2010; Karger et al., 2011; Zhou et al., 2012; Liu et al., 2012). However, to correct the biases, it is often necessary to reveal a certain amount of true labels, raising the problem of deciding which questions should be chosen to reveal the true labels (e.g., Liu et al., 2013, 2015).

To set up the problem, we follow the setting in Liu et al. (2013, 2015). Assume we have a set of questions $\{i\}$, each relates to an unknown continuous quantity θ_i that we want to estimate (e.g., price, point spreads, GDP). Let $\{j\}$ be a set of crowd workers that we hire to estimate $\{\theta_i\}$, and each worker j is characterized by a parameter $\eta_j = [b_j, v_j]$, where b_j and v_j represent the bias and variance of worker j, respectively; we assume the crowd label $\{x_{ij}\}$ of question i given by worker j is generated by

$$x_{ij} = \theta_i + b_j + \sqrt{v_j}\xi_{ij}, \quad \xi_{ij} \sim \mathcal{N}(0,1). \tag{7}$$

Using a Bayesian approach, we assume Gaussian priors $p(\theta_i) = \mathcal{N}(0, \sigma_\theta^2)$, $p(b_j) = \mathcal{N}(0, \sigma_b^2)$ on θ_i and b_j, and an inverse Gamma prior $p(v_j) = \text{Inv-Gamma}(\alpha, \beta)$ on v_j. The posterior distribution of θ and η can be written as

$$p(\theta, \eta \mid X) \propto \prod_j \exp\left[-\frac{b_j^2}{2\sigma_b^2}\right] \prod_j v_j^{-\alpha - \frac{d_j}{2} + 1} \exp\left[-\frac{\beta}{v_j}\right] \prod_{i,j} \exp\left[-\frac{(X_{ij} - \theta_i - b_j)^2}{2v_j}\right] \prod_i \exp\left[-\frac{\theta_i^2}{2\sigma_\theta^2}\right].$$

However, the crowd labels X may not carry enough information for predicting θ, and we hence consider the option of acquiring the ground truth labels of a subset C of questions (called the *control questions*), which can be incorporated into Bayesian inference to help evaluate the bias and variance of the workers, and hence improve the prediction of the remaining questions.

We can use Algorithm 1 to select the optimal subset C, where the greedy update (6) strikes a balance between selecting the most uncertain questions to myopically improve the overall MSE, and the most "influential" questions (e.g., these labeled by a lot of workers) whose ground truth labels can significantly improve the estimation of the workers' bias and variance, and hence improve the prediction of the unlabeled questions via a *propagation effect*.

5.2 DISCRETE LABEL SELECTION ON GRAPHS

Numerous real-world applications produce networked data with rich relational structures, such as web data and communication networks, and these relational information can be used to improve the prediction accuracy of unlabeled data using a small amount of labeled data. Various methods have been developed to exploit this effect, including graph-based semi-supervised learning (e.g., Zhu et al., 2003; Zhou et al., 2004) and collective, or graph-based, classification (e.g., Lu & Getoor, 2003). A related important question is how to select the best labeling subset to enable the best prediction on the remaining data.

We set up the problem using undirected graphical models. Assume $G = (V, E)$ is an undirected graph, and θ_i is a discrete label associated with node $i \in V$. It is common to model the posterior distribution using a pairwise graphical model,

$$p(\theta) \propto \exp\big[\sum_{(i,j)\in E} J_{ij}\theta_i\theta_j + \sum_{i\in V} h_i\theta_i\big], \tag{8}$$

where J_{ij} represents the correlation between θ_i and θ_j and h_i the local information of θ_i. We are interested in the problem of selecting the best subset $C \subseteq V$ so that the prediction accuracy based $p(\theta_{\neg C} \mid \theta_C)$ is maximized. In the semi-supervised learning settings, θ_i is often assumed to be a continuous variable, and $p(\theta)$ reduces to a simple Gaussian Markov random field. We instead assume θ to be discrete labels (e.g., $\theta \in \{-1, +1\}$) which is much more challenging to deal with. Our bound in Section 4 and Algorithm 1 (but with Q defined in Proposition 3) provide a novel tool for solving this problem efficiently.

6 EXPERIMENTS

We present experiments to better understand the performance of our proposed observation selection methods based on Bayesian lower bounds. To achieve this, we first illustrate our method using a toy example based on Gaussian mixture, and then apply our method to the two application areas described in Section 5, including selecting optimal control questions in crowdsourcing, as well as discrete label selection in graph-based classification.

6.1 CONTINUOUS VARIABLES

We test our method in the case when θ is a continuous variable, first on a toy Gaussian mixture model, and then on the model for selecting control questions in crowdsourcing. We implement our method `BayesianCRB(Gibbs)` as shown in Algorithm 1 with the sample $[\theta^\ell, \eta^\ell]_{\ell=1}^m$ generated using Gibbs sampler. In addition, the following baseline selection methods are compared:

`Random`, in which a random set C of size k is selected uniformly.

`BayesianOpt(Gibbs)`, which greedily minimizes the trace of the conditional variance in (1); to estimate the conditional variance we draw $[\theta^\ell, \eta^\ell]_{\ell=1}^m \sim p(\theta, \eta, |X)$ using Gibbs sampler, and then for each candidate set C evaluated during the greedy search, we further draw $[\theta_{\neg C}^{\ell,r}, \eta^{\ell,r}]_{r=1}^{m'} \sim p(\theta_{\neg C}, \eta, |\theta_C^\ell, X)$ using another Gibbs sampler, and estimate the objective in (1) by

$$\frac{1}{m(m'-1)} \sum_{\ell=1}^{m} \sum_{r=1}^{m'} \sum_{i \in \neg C} (\theta_i^{\ell,r} - \bar{\theta}_i^\ell)^2,$$

where $\bar{\theta}_i^\ell = \frac{1}{m'} \sum_{r=1}^{m'} \theta_i^{\ell,r}$. This method aims to minimize the Bayesian optimal risk, but is obviously much more expensive than our `BayesianCRB(Gibbs)` because it needs a large size m' of MCMC sample to get a good approximation for evaluating each candidate C, while it tends to degenerate significantly when m' is small.

`MaxVar(Gibbs)`, which greedily finds a subset C with the largest uncertainty in the sense of maximizing the variance $\sum_{i \in C} \mathrm{var}(\theta_i | X)$, instead of minimizing the conditional variance. The variance is estimated by the empirical variance using the MCMC samples $[\theta^\ell, \eta^\ell]_{\ell=1}^m$. This algorithm is computationally as fast as our `BayesianCRB(Gibbs)`, but does not consider the "propagation effect" that the information in θ_C can help improve the inference on $\theta_{\neg C}$.

`Laplacian`, which uses a Laplacian approximation to approximate the posterior $p(\theta, \eta \mid X)$ with a multivariate normal distribution (Liu et al., 2015), under which the objective (1) reduces to the matrix form in (5). This algorithm is the same as our Algorithm 1, except that the H in Line 4 is instead estimated by $H = H(\theta^*, \eta^*)$, where $[\theta^*, \eta^*]$ is the mode of the posterior distribution $p(\theta, \eta \mid X)$. Obviously, `Laplacian` would perform similarly to `BayesianCRB(Gibbs)` when the posterior $p(\theta, \eta | X)$ is close to normal, but would otherwise perform poorly, especially when $p(\theta, \eta \mid X)$ is multimodal.

6.1.1 Gaussian Mixture Model

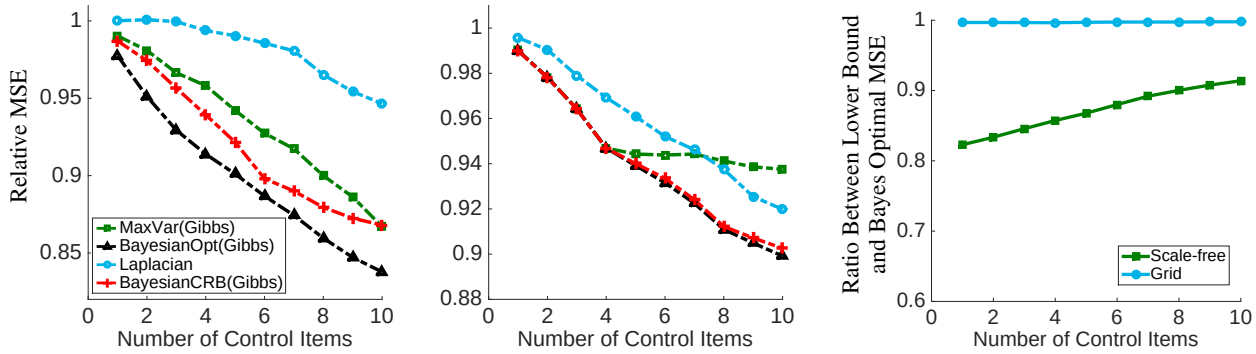
We start with the following toy example of Gaussian mixture model,

$$p(\theta) = \sum_{\kappa=1}^{2} \omega_\kappa \mathcal{N}(\theta \mid \mu_\kappa, \Sigma_\kappa),$$

where we ignore the dependence on observed data X. We draw μ_κ randomly from a zero-mean normal distribution with variance 0.1, and set $\Sigma_\kappa = 0.1(\alpha D_\kappa - W_\kappa)^{-1}$, where W_κ corresponds to an adjacency matrix of an undirected graph and D_κ is a diagonal matrix where $D_{\kappa,ii} = \sum_j W_{ij}$ and α is a constant larger than one to enforce L to be positive definite (we set $\alpha = 1.1$). We consider two different graph structures: (1) both W_1 and W_2 are the 30 by 30 2D grid graph, in which case we set $\omega = [1, 1]/2$; (2) W_1 and W_2 are scale-free networks of size 30 generated using the Barabási-Albert (BA) model (Barabási & Albert, 1999), with average degrees of 1 and 4, respectively, in which case we set $\omega = [0.9, 0.1]$. We simulate the ground truth of θ by drawing samples from $p(\theta \mid X)$, and plot the relative MSE of different algorithms compared to the random selection baseline in Figure 1(a)-(b); the results are averaged over 50 random trials.

As shown in Figure 1 (a)-(b), `BayesianOpt(Gibbs)` achieves the best performance, since it minimizes the conditional variance objective, which is the Bayesian optimal MSE. `Laplacian` performs the worst because $p(\theta)$ has multiple modes and the Laplacian approximation can only capture one of the mode. On the other hand, our `BayesianCRB(Gibbs)`, which takes the advantage of minimizing Bayesian CR bound, and is closer to `BayesianOpt(Gibbs)` than all the other methods.

It's also worth studying the tightness of the Bayesian CR bound. This is shown in Figure 1(c) where we plot the ratio



(a) *Relative MSE on scale-free graph* (b) *Relative MSE on grid graph* (c) *Tightness of the lower bounds*

Figure 1: (a-b) Results on the toy Gaussian mixture model; the y-axis are the MSE of different algorithms divided by the MSE of the random selection algorithm. (c) The ratio between the Bayesian CR lower bound and Bayesian optimal MSE (the trace of the conditional variance) on both the scale-free and grid graphs.

between the Bayesian optimal MSE (the trace of the conditional variance) and the Bayesian CR lower bound for both the scale-free and grid graphs; here the bounds are evaluated using the subsets C with different size k, selected by our `BayesianCRB(Gibbs)` method. We can see that the ratios are very close to one (≥ 0.8), suggesting that the bayesian CR bounds are very tight in these cases. In particular, we note that the bound is very tight for the grid graph example (ratio ≈ 1), explaining the good performances of `BayesianCRB(Gibbs)` in figure 1(b).

6.1.2 Application to Crowdsourcing

We further apply our method to the problem of selecting the optimal control questions in crowdsourcing as described in Section 5. We evaluate our selection algorithms on both simulated datasets and real-world datasets.

Toy dataset: We first generate a simulated dataset according to the Gaussian model described in (7), where θ_i and b_j are $i.i.d$ drawn from normal distribution with standard deviation of 4, and the labelers' variances v_j are generated from an inverse Gamma distribution Inv-Gamma$(1, 1)$. The dataset contains 30 questions and 30 labelers, and we assume the i-th question is answered only by the first i labelers; in this way, the first question is answered only by the first labeler and hence has the most *uncertain* result, and the last question is answered by all the 30 workers, and hence is the most *influential*, in that knowing its true value can help evaluate the bias and variance of all the 30 workers and hence improve the prediction on all the other items.

Figure 2(a) shows the average MSE given by the different methods. In this case, we can see that `BayesianOpt(Gibbs)`, `BayesianCRB(Gibbs)` and `Laplacian` tend to perform similarly, all of which significantly outperform `Random` and `MaxVar(Gibbs)`. Note that `MaxVar(Gibbs)` is even worse than `Random` at the beginning, since it myopically selects the most uncertain questions (the first few questions labeled by a small number of workers in this case), while much more significant improvements could be obtained by selecting the more influential items (these labeled by more workers). We find that `Laplacian` performs as well as `BayesianCRB(Gibbs)`, probably because the posterior distribution tends to be unimodal in this case. Figure 2 (b) shows the tightness of our lower bound as the size k of subset C increases, evaluated on the C given by `BayesianCRB(Gibbs)`, and we can see that the lower bound is again very tight in this case (ratio ≥ 0.93).

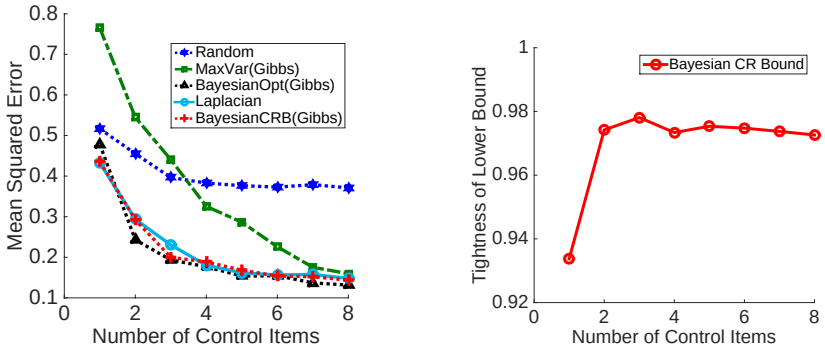
Real-world datasets: We also evaluate our approach on three real-world datasets:

The *PriceUCI* dataset (Liu et al., 2013). It consists of 80 household items collected from Internet, and whose prices are estimated by 155 UCI undergraduate students. As suggested in Liu et al. (2013), a log transform is performed on the prices before using the Gaussian models.

The national football league (*NFL*) forecasting dataset used in Massey et al. (2011). It consists predictions of point differences of 245 NFL games given by 386 participants; the point spreads determined by additional professional bookmakers are used as the ground truth.

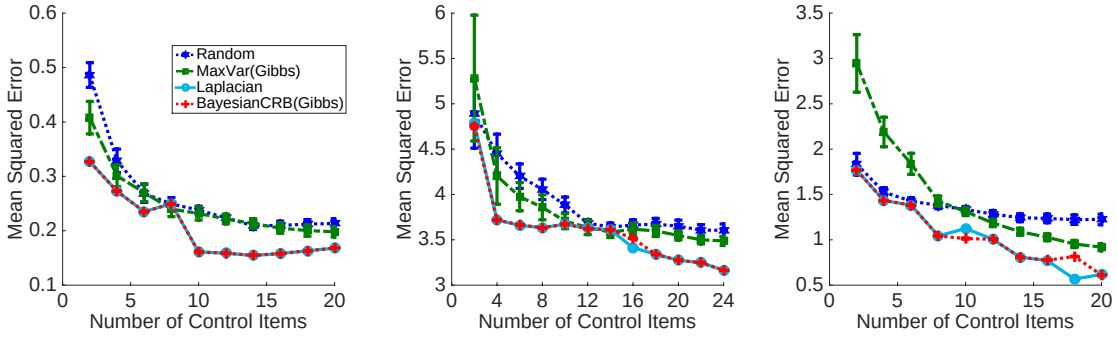
The *GDP Growth* dataset used in Budescu & Chen (2014). It contains the forecasts of GDP growth nine months ahead by professional forecasters surveyed by European Central Bank (ECB). A total of 98 forecasters made forecasts for 50 quarters of GDP growth.

The results on these three real-world datasets are shown in figure 3(a)-(c). `BayesianOpt(Gibbs)` is not evaluated because it is too slow on these real world datasets. We can see that both `BayesianCRB(Gibbs)` and `Laplacian` tend to outperform the other methods significantly. Again, `Laplacian` tends to perform as well as `BayesianCRB(Gibbs)` because the posteriors are very close to Gaussian distribution in these cases.



(a) *Average MSE on simulated dataset* (b) *Ratio between bounds and the Bayes optimal MSE*

Figure 2: Results on crowdsourcing with simulated data. (a) The MSE given by different selection algorithms as the budget k increases. (b) The ratio between the Bayesian lower bound and Bayesian optimal MSE. We can see that the lower bound is very close to the Bayesian optimal MSE (ratio ≥ 0.93), and the tightness tends to increase as the size k of C increases.



(a) *PriceUCI* (b) *NFL* (c) *GDP Growth*

Figure 3: (a)-(c) Results on three real datasets, *PriceUCI, NFL* and *GDP Growth*, respectively. The y-axes are the average MSE on the remaining items as the size of the subset C increases. The error bars show the standard deviation over the random trials.

6.2 DISCRETE VARIABLES

In this section, we use our algorithm to select optimal subsets on binary Ising graphical models defined in (8) with $\theta \in \{-1, +1\}$. We use `DiscreteLB(Gibbs)` to denote the greedy optimization algorithm on our discrete Bayesian lower bound (it is the same as Algorithm 1, except with Q defined in Proposition 3). We again compare our algorithm with several baselines, including:

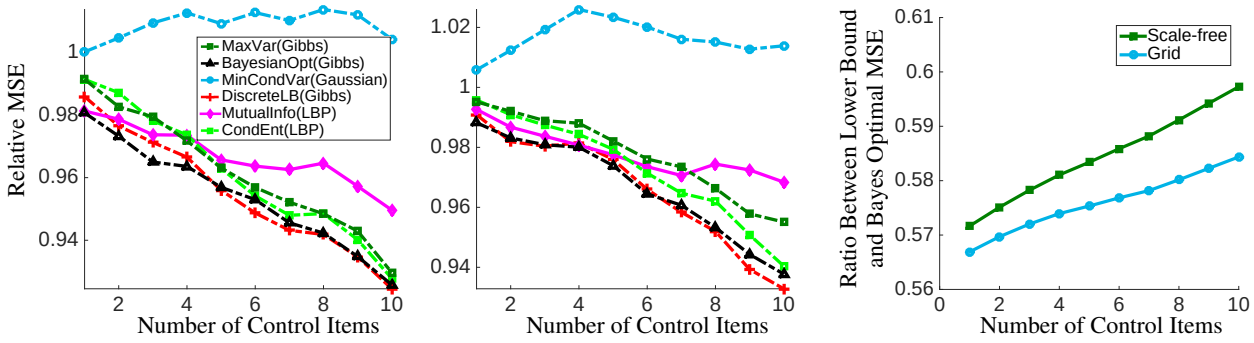
`CondEnt(LBP)`, which greedily selects a subset C to minimum the conditional entropy $H(\theta_{\neg C} \mid \theta_C, X)$; it is equivalent to maximizing the marginal entropy $H(\theta_C \mid X)$. The entropy is approximated using loopy belief propagation (LBP). This algorithm is similar to `MaxVar(Gibbs)` for continuous variables, in that both myopically find the subset with the largest uncertainty, ignoring the propagation effect that the added true labels can help predict the remaining unlabeled items (Krause et al., 2008).

`MutualInfo(LBP)`, which maximizes the mutual information $I(\theta_C; \theta_{\neg C} \mid X)$; this was proposed by Krause et al. (2008) to avoid the myopic property of the entropy objective. The mutual information is again approximated using loopy belief propagation (LBP).

`MinCondVar(Gaussian)`, which minimizes $\mathrm{tr}(L_{\neg C}^{-1})$ where $L = \Lambda - J$, where Λ is a diagonal matrix chosen to make L positive definite. This method is equivalent to treating θ as a continuous variable, and hence (8) a multivariate Gaussian distribution.

Comparisons are made on both simulated and real-world datasets:

Simulated data: We set $p(\theta \mid X)$ to be the binary graphical model in (8) (there is no actual observed data X in this case), with both J and h in (8) drawn from Gaussian distributions: we draw each element of h from $\mathcal{N}(0, 0.2)$, and set $J = 0.1W$, where W is an adjacency matrix of an undirected graph with values drawn from standard normal distribution. The graph structure is defined to be either a 30×30 2D grid, or a scale free network of size 30 generated using the Barabási-Albert (BA) model (Barabási & Albert, 1999) with the preferential attachment mechanism.



(a) *Relative error rate on scale-free graph* (b) *Relative error rate on grid graph* (c) *Tightness of the lower bounds*

Figure 4: Results on binary Ising models with simulated data. (a)-(b) The Relative MSE of different algorithms on the synthetic datasets simulated from the scale-free and the grid graph, respectively. (c) The ratio between our discrete Bayesian lower bound and the Bayesian optimal MSE on the simulated dataset; the bounds are evaluated on the subsets C selected by our `DiscreteLB(Gibbs)` method.

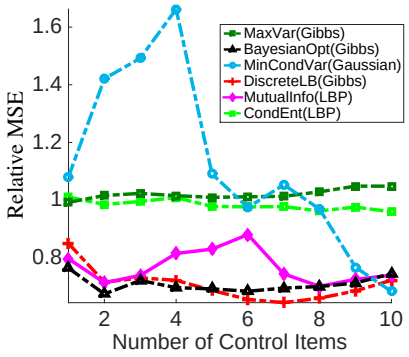


Figure 5: Comparison of the relative MSE of different methods on the PubMed Diabetes dataset. Our algorithm `DiscreteLB(Gibbs)` achieves similar results as `BayesianOpt(Gibbs)`, but with much lower computational cost.

We show the results of different algorithms in Figure 4, where we find that our `DiscreteLB(Gibbs)` is comparable with `BayesianOpt(Gibbs)` which minimizes the Bayesian optimal error rate, and outperforms all the other baselines. Both `MaxVar(Gibbs)` and `CondEnt(LBP)` tend to myopically select the most uncertain items first and hence have similar performance. Figure 4(c) shows the tightness of our Bayesian lower bound compared to the Bayesian optimal error; we can see that it is less tight (ratio $\geq$ 0.56) compared with the Bayesian CR bound for continuous variables, but the good performance of `DiscreteLB(Gibbs)` seems to suggest that the lower bound still represents a good surrogate for the Bayesian optimal error.

PubMed Diabetes:[1] This is a citation graph of scientific papers from the PubMed database (Sen et al., 2008), in which each paper is classified into one of three classes: "Diabetes Mellitus, Experimental", "Diabetes Mellitus Type 1", "Diabetes Mellitus Type 2". For our experiment, we select the top 100 nodes with the highest degrees from class Diabetes Mellitus Type 1 and Type 2, and then took the largest connected component, with 93 nodes in total and 376 edges; this gives 43 nodes from class Type 1 and 50 nodes from class Type 2, and a graph with an average degree of 4. In this case, since we don't have any prior knowledge, we set h to be a vector of small random numbers, and let $J = 0.05W$, where W denotes the adjacency matrix. The results is shown in Figure 5, in which we observe a similar trend as that in the simulated data.

7 CONCLUSION

The Bayesian optimal risk is the ideal objective function for optimal subset selection, which, however, is extremely difficult to calculate and optimize in practice. In this paper, we proposed to use Bayesian lower bounds as surrogate criteria, and derived a class of computationally more efficient algorithms for observation selection. We discussed both continuous and discrete scenarios: for continuous models, we based our bound on the classical Bayesian Cramér Rao bound; for discrete models, we derived a new form based on an novel extension of van Trees inequality. We presented a number of experiments for both continuous and discrete models in various practical settings, and showed that the selection algorithms based on the Bayesian lower bounds tend to outperform most baseline algorithms, and are comparable with the selection based on the Bayesian optimal risk.

Characterizing Tightness of LP Relaxations by Forbidding Signed Minors

Adrian Weller
University of Cambridge
aw665@cam.ac.uk

Abstract

We consider binary pairwise graphical models and provide an exact characterization (necessary and sufficient conditions observing signs of potentials) of tightness for the LP relaxation on the triplet-consistent polytope of the MAP inference problem, by forbidding an odd-K_5 (complete graph on 5 variables with all edges repulsive) as a signed minor in the signed suspension graph. This captures signs of both singleton and edge potentials in a compact and efficiently testable condition, and improves significantly on earlier results. We provide other results on tightness of LP relaxations by forbidding minors, draw connections and suggest paths for future research.

1 INTRODUCTION

Discrete undirected graphical models play a central role in machine learning, providing a powerful and compact way to model relationships between variables. A key challenge is the combinatorial search problem to identify a most likely configuration of variables, termed *maximum a posteriori* (MAP) or *most probable explanation* (MPE) inference. This has received a great deal of attention from various communities, where it is sometimes framed as energy minimization (Kappes et al., 2013) or as solving a valued constraint satisfaction problem (VCSP, Schiex et al., 1995).

Since the problem is NP-hard, much work has attempted to identify restricted settings where polynomial-time methods are feasible. Where possible, we call such settings *tractable* and the methods *efficient*. Two types of restriction have been considered separately, either: (i) structural constraints on the topology of connections between variables; or (ii) families of potential functions.

Exploring the first theme, Chandrasekaran et al. (2008) showed that, if no restriction is placed on types of potentials, then the structural constraint of *bounded treewidth* is needed for tractable inference.[1] See §2-4 for all definitions.

Recent work (Kolmogorov et al., 2015; Thapper and Živný, 2015) has examined the power of using a linear programming (LP) relaxation of the discrete optimization problem. An LP attains an optimum at a vertex of the feasible region; if this vertex is integral, then it provides an exact solution to the original problem and we say that the LP is *tight*. If the LP is performed over the *marginal polytope*, which enforces global consistency (Wainwright and Jordan, 2008), then this LP is always tight, but exponentially many constraints are required, hence the method is not efficient. The marginal polytope is typically relaxed to the *local polytope* LOC, which enforces only pairwise consistency, requiring a number of constraints linear in the number of edges. Thapper and Živný (2015) showed that, if no restriction is placed on topology, then for a given family of potentials, either LP+LOC is tight, and hence solves all such problems efficiently, or the problem set is NP-hard.

Here we consider *hybrid* conditions (Cooper and Živný, 2011), which combine constraints on both structure and potentials, an exciting field with little prior work. Focusing on the important class of binary pairwise models,[2] and considering each edge to be *signed* as either *attractive* or *repulsive*, we establish precise hybrid characterizations for when certain LP relaxations will be tight for all valid potentials. By valid, we mean potentials that observe the signs (attractive or repulsive) of the edges. We show that these characterizations may be achieved by forbidding particular signed *minors* of the signed graph topology, yielding compact and efficiently testable conditions.

In applications, LP relaxations are widely used for structured prediction but the most common form, LP+LOC, often yields a fractional solution, motivating constraints for

[1] This result makes mild assumptions, specifically the grid-minor hypothesis (Robertson et al., 1994), and that NP $\not\subseteq$P/poly. See also (Kwisthout et al., 2010).

[2] Eaton and Ghahramani (2013) showed that any discrete graphical model may be either exactly represented, or arbitrarily well approximated, by a binary pairwise model, though the number of variables may increase substantially.

higher order cluster consistency (Batra et al., 2011). Weller et al. (2016) considered the LP relaxation over the *triplet-consistent* polytope TRI, which is the next level up from LOC in the hierarchy given by Sherali and Adams (1990) and is still efficient. Whereas it is known that LP+LOC is tight for any model which is *balanced*, Weller et al. (2016) showed that LP+TRI is tight for any model which is *almost balanced*. Further they demonstrated that almost balanced models may be 'pasted' together in certain configurations, while still guaranteeing tightness of LP+TRI.

The results of Weller et al. (2016) and our stronger characterizations here are very relevant to many problems in computer vision, such as foreground-background image segmentation, where due to contiguity of real objects, learned edges are mostly attractive, leading to a model which is 'close to balanced'. For example, on the horses dataset considered by Domke (2013), LP+LOC is loose but LP+TRI is often tight. Our work helps to explain this phenomenon.

We consider a refinement by examining the signs not only of edge potentials, but also of singleton potentials. These can be neatly incorporated by considering the signed *suspension graph* of a model, which adds one extra node with edges to the other variable nodes, each new edge corresponding to a singleton of the original model; see §4.

1.1 MAIN RESULTS

Our strongest result is Theorem 14, which shows that LP+TRI is tight for all valid potentials, observing signs of both edge and singleton potentials, iff the signed suspension graph does not contain an *odd-*K_5 (the complete graph on 5 nodes with all edges odd/repulsive, see §3) as a signed minor. This is a more powerful, signed version of an unsigned result, Theorem 13, that follows from the work of Barahona and Mahjoub (1986), showing that LP+TRI is tight for all valid unsigned potentials iff the unsigned suspension graph does not contain K_5 as an unsigned minor; see §5. For a sense of the additional power of the signed version, Theorem 14 allows models with arbitrarily high treewidth, provided only that there is no odd-K_5 minor (*one particular* signing of a K_5 structure), whereas Theorem 12 prohibits a K_5 minor of *any* type; see Table 2.

A weaker corollary of Theorem 14, our Theorem 10 shows that if we are less observant and do not examine singleton potentials, then LP+TRI is tight for all valid potentials (respecting signs of edges only) iff the signed graph topology does not contain an *odd-*K_4 as a signed minor.[3] This may be directly compared to the sufficient conditions of Weller et al. (2016), which similarly do not examine singleton potentials. We show that Theorem 10 is a significant improvement: it covers a substantially larger set of models, provides a compact condition that is both necessary and sufficient, and is efficiently testable; see §4.3.

As another consequence of Theorem 14, we obtain a result that may be of significant practical interest. Theorem 16 shows that in some cases, the number of cycle constraints needed to enforce integrality for LP+TRI may be dramatically reduced to just the *signed cycle constraints*; see §5.

We also reframe earlier results on tightness of LP relaxations in terms of forbidden minors. This perspective elegantly captures conditions on both structure and potentials, and reveals fascinating connections which prompt natural directions to explore in future work. See Table 2 for a summary and §6 for discussion.

1.2 APPROACH AND RELATED WORK

Characterizing properties by forbidden minors has been a fruitful theme in graph theory since the fundamental work of Robertson and Seymour, which builds over more than 20 papers to the *graph minor theorem*, described by Diestel (2010) as "among the deepest theorems that mathematics has to offer." We describe elements of the approach in §2, its extension to signed graphs, signed minors and *odd* minors in §3, and its relevance to LP relaxations in §4.

Odd-minor-free graphs have received attention in theoretical computer science, for example (Demaine et al., 2010). However, aside from the characterization by Watanabe (2011) of when belief propagation has a unique fixed point in terms of signed minors, to our knowledge there has been little direct use of this perspective in machine learning.[4]

To show our results, we connect several earlier themes, for which we provide relevant background. A key result by Guenin (2001) showed that a signed graph is *weakly bipartite*, which characterizes integrality of the vertices of a particular polyhedron, iff it does not contain an odd-K_5 minor; see §3. We draw on connections between: the marginal polytope of a model, with its LOC and TRI relaxations; and the corresponding *cut polytope* of its suspension graph, with its *rooted semimetric* RMET and *semimetric* MET relaxations (De Simone, 1990; Deza and Laurent, 1997); see §5.1. We use a link between MET and the *cycle inequalities* (Barahona, 1993); see §5.2. We extend these ideas to signed graph topologies in §5.3. Some of these connections for the unsigned case were considered by Sontag (2010).

2 GRAPHS AND MINORS

We follow standard definitions and omit some familiar terms. For more background, see (Diestel, 2010), particularly §12 for a survey of treewidth and forbidden minors.

[3] Theorem 14 allows any odd-K_4 minor in G provided it is not part of an odd-K_5 in ∇G, a much stronger result; see Table 2.

[4] Junction trees (Cowell et al., 1999), treewidth and unsigned graph minors are closely related. Treewidth was discussed by Halin but gained popularity through use by Robertson and Seymour (see historical note by Seymour, 2014).

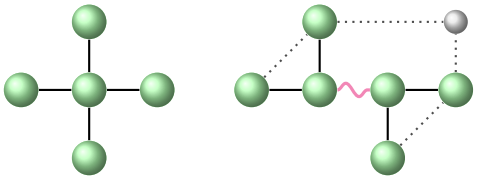

Figure 1: The left graph is a *minor* (unsigned) of the right graph, obtained by deleting the grey dotted edges and resulting isolated small grey vertex, and contracting the purple wavy edge. See §2.

2	K_4
3	K_5 and 3 others
4	K_6 and more than 70 others

Table 1: Characterization of low values of bounded treewidth by forbidding minors.

A *graph* $G(V, E)$ is a set of vertices V, and undirected edges E, where each edge $(i, j) \in E$ connects i and $j \in V$. The *complete* graph on n vertices, written K_n, has all $\binom{n}{2}$ edges. A pairwise graphical model topology is always assumed to be a *simple* graph, that is a vertex may not be adjacent to itself (no loops) and each pair of vertices may have at most one edge (no multiple edges). However, when we consider *minors*, we allow loops and multiple edges.

A *minor* of a graph G is obtained from G by deleting edges or isolated vertices (as may be done to form a subgraph), or also by *contracting* edges. To contract edge (i, j) means to remove the vertices i and j, and replace them by a new vertex with edges to all remaining vertices that were previously adjacent to i or j. See Figure 1 for an example.
For any property $\mathcal{P}$ of a graph, we say that $\mathcal{P}$ is *closed under taking minors* (or *minor-closed*) if whenever G has property $\mathcal{P}$ and H is a minor of G, then H has $\mathcal{P}$.

A consequence of the *graph minor theorem* of Robertson and Seymour is the following deep result.

Theorem 1 (Robertson and Seymour, 2004)**.** *If a graph property $\mathcal{P}$ is closed under taking minors then it can be characterized by a* finite *set of forbidden minors, i.e. G has $\mathcal{P}$ iff G has none of the finite forbidden set as a minor.*

There are important examples of graph properties closed under taking minors where this finite set has just a few members. Perhaps the best known is the early result of Wagner (1937) that a graph G is planar iff G does not contain K_5 or $K_{3,3}$ as a minor ($K_{3,3}$ is the complete bipartite graph where each partition has 3 vertices).

Another property closed under taking minors is bounded *treewidth*. A definition of treewidth of a graph G that may be familiar from the junction tree construction is that it is one less than the minimum possible size of a largest clique in a triangulation of G (Wainwright and Jordan, 2008). The

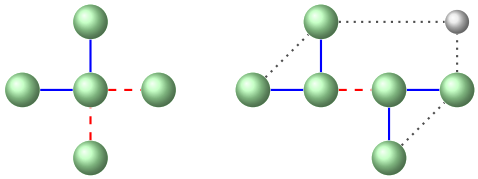

Figure 2: The left graph is a *signed minor* of the right signed graph, obtained similarly to Figure 1 except that before contracting the repulsive edge, first flip the vertex at its right end. Solid blue (dashed red) edges are attractive (repulsive). Grey dotted edges on the right are deleted and may be of any sign. See §3.2.

forbidden minors are known for low values of bounded treewidth, see Table 1. For example, a tree has treewidth 1 and cannot contain a K_3 minor.

Robertson and Seymour also showed that checking for any fixed minor may be performed efficiently.

Theorem 2 (Robertson and Seymour, 1995)**.** *For any fixed graph H and a given graph G with n vertices, there is an $O(n^3)$-time algorithm to determine if H is a minor of G.*[5]

Together, Theorems 1 and 2 show that any minor-closed graph property may be decided in polynomial-time.

3 SIGNED GRAPHS & SIGNED MINORS

A *signed graph* (Harary, 1953) is a graph (V, E) together with one of two possible signs for each edge. This is a natural structure when considering binary pairwise models, where we characterize edges as either *attractive* (or *even*) or *repulsive* (or *odd*), see §4. Where helpful for clarity, we refer to the standard graphs of §2 as *unsigned* graphs. We shall see that important concepts and results for minors of unsigned graphs have corresponding results for signed minors of signed graphs.

In a signed graph, a fundamental property of any cycle is whether or not it is a *frustrated cycle* (or *odd cycle*), i.e. if it is a cycle with an odd number of repulsive (or odd) edges. A signed graph is *balanced* if it contains no frustrated cycles. Following Weller (2015), a signed graph is *almost balanced* if it contains a vertex such that deleting it renders the remaining graph balanced.

3.1 FLIPPING/RESIGNING AND ODD GRAPHS

Given a signed graph, a subset of variables $S \subseteq V$ may be *flipped* (or *switched*). This flips the sign of any edge with exactly one end in S (i.e. flips the edge between attractive/even and repulsive/odd), and is called a *resigning*. It is easily seen that this operation does not change the nature (frustrated or not) of any cycle. For binary graphical models, this has a natural interpretation: if the original model has variables $\{X_i \in \{0, 1\} : i \in V\}$ then consider an

[5] Kawarabayashi et al. (2012) improved this to $O(n^2)$-time.

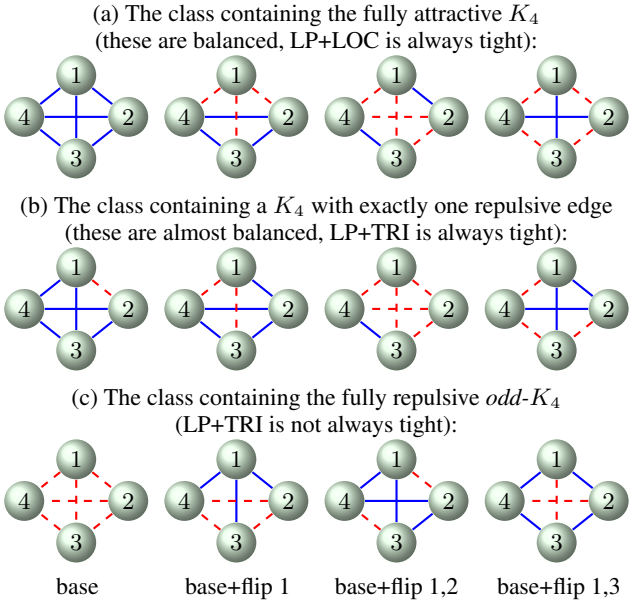

Figure 3: Examples of signed K_4 graphs. These are complete graphs on 4 vertices where each edge is either attractive/even (solid blue) or repulsive/odd (dashed red). Each row illustrates examples from one of the three signing equivalence classes. At bottom left is an *odd*-K_4. See §3.

equivalent model with variables $\{Y_i : i \in V\}$ given by $Y_i = 1 - X_i$ for $i \in S$, $Y_i = X_i$ for $i \in V \setminus S$, with new potentials set to match properties of the original model.[6]

Two signed graphs are *signing equivalent* (sometimes called *gauge equivalent*) if they are isomorphic up to a resigning (an equivalence relation). We are interested in signed graphs only up to signing equivalence; see §3.2.

For any unsigned graph G, the signed graph *odd*-G is the signed version of G where every edge is odd (or repulsive). Figure 3 shows examples of signed K_4 graphs, in their signing equivalence classes. The bottom row shows an *odd*-K_4 at the left, together with possible resignings.

3.2 SIGNED MINORS

A *signed minor* of a signed graph is obtained just as for an unsigned minor of an unsigned graph with the following modifications: any resigning operations are permitted (see §3.1); and contractions are allowed only for attractive/even edges. Note that a repulsive/odd edge may first be resigned to an attractive/even edge by flipping either end vertex (which will also affect its other incident edges) and then contracted. See Figure 2 for an example, which may be compared to the unsigned minor example of Figure 1.

A significant project is in progress to try to generalize all of Robertson and Seymour's graph minor theory to the much broader class of Γ-labeled graphs for any finite abelian group Γ (Geelen et al., 2014), which includes signed graphs by considering $\Gamma = \mathbb{Z}/2\mathbb{Z}$. An equivalent result to Theorem 1 is claimed, though the formal write-up is still to come. An equivalent result to Theorem 2 has been shown.

Theorem 3 (A special case of Theorem 1.1.10 of Huynh, 2009)**.** *For any fixed signed graph H, there is a polynomial-time algorithm which determines if an input signed graph G contains H as a signed minor.*

3.3 WEAKLY BIPARTITE SIGNED GRAPHS

If a signed graph is balanced, its vertices may be partitioned into two exhaustive groups s.t. all inter-group edges are odd and all intra-group edges are even (Harary, 1953); the resigning obtained by flipping either group renders all edges even. With this observation, a signed graph which is balanced is sometimes called *bipartite* (related, but different, to the standard meaning of bipartite for unsigned graphs).

Generalizing bipartite signed graphs, a signed graph $G(V, E)$ with edge signs is *weakly bipartite* if the following polyhedron Q has only integral vertices:

$$Q = \left\{ y \in \mathbb{R}_+^{|E|} : \sum_{e \in D} y_e \geq 1, \forall \text{ odd cycles } D \text{ of signed } G \right\} \quad (1)$$

Here, odd cycles D are in the signed sense, i.e. have an odd number of odd edges. We shall see in §5.3 that Q relates closely to the triplet-consistent polytope TRI of a graphical model, if we consider signs of all potentials. We make use of the following result, which proved a conjecture of Seymour (1977), earning Guenin a Fulkerson prize in 2003.

Theorem 4 (Guenin, 2001)**.** *A signed graph is weakly bipartite iff it does not contain an odd-K_5 as a signed minor.*[7]

4 GRAPHICAL MODELS AND LP RELAXATIONS

We consider a binary pairwise undirected model with n variables $X_1, \ldots, X_n \in \{0, 1\}$. Let $x = (x_1, \ldots, x_n) \in \{0, 1\}^n$ be one complete configuration. The probability distribution is specified by $p(x) \propto \exp[\text{score}(x)]$, where we choose a symmetric minimal reparameterization (Wainwright and Jordan, 2008) such that

$$\text{score}(x) = -\sum_{i \in V} \theta_i x_i - \sum_{(i,j) \in E} W_{ij} \mathbb{1}[x_i \neq x_j], \quad (2)$$

where $\mathbb{1}[\cdot]$ is the indicator function. The model's unsigned topology is the graph $G(V, E)$, with n variables $V = \{1, \ldots, n\}$ and $m = |E| \leq \binom{n}{2}$ edge relationships between the variables. The n singleton parameters $\{\theta_i : i \in V\}$ and m edge weights $\{W_{ij} : (i, j) \in E\}$

[6] Given the form of potentials (2) we choose in §4, this flips the signs of $\{\theta_i : i \in S\}$ and $\{W_{ij} : \text{exactly one of } i \text{ or } j \in S\}$.

[7] The original proof is long. A shorter proof was provided by Schrijver (2002). Both proofs rely on a result of Lehman (1990).

define the potentials, which we allow to take any rational value (to enable polynomial-time algorithms).

In addition to the unsigned graph G, we shall be interested in two more informative ways of considering a model's topology. The *signed graph* G assigns edge signs according to the signs of edge potentials. If $W_{ij} > 0$, the edge (i, j) tends to pull X_i and X_j toward the same value and is *attractive* (or *even*). If $W_{ij} < 0$, the edge is *repulsive* (or *odd*).

The *signed suspension graph* $\nabla G(V', E')$ of a model adds an extra node 0, that is $V' = V \cup \{0\}$. Edges to 0 encode singletons of the model, with $E' = E \cup \{(0, i) : \theta_i \neq 0\}$.

With ∇G in mind, we have chosen the form of (2) carefully, using negative signs so $W_{ij} > 0$ is attractive, and $\mathbb{1}[x_i \neq x_j]$ edge terms in order to facilitate later demonstration of the equivalence between the MAP problem and a max cut problem on the edge-weighted suspension graph; see §5.

In ∇G, it may be helpful to consider the added node 0 as being set to the value 0; then regarding (2), the singleton potential terms $\theta_i x_i$ may be viewed as $\theta_i \mathbb{1}[x_i \neq 0]$, and hence all singleton and edge potential terms follow the same sign convention. In particular, the sign of each new edge $(0, i)$ in ∇G matches that of θ_i: if $\theta_i > 0$ then the added edge is attractive, pulling X_i toward 0; if $\theta_i < 0$ then $(0, i)$ is repulsive (or odd).

4.1 LINEAR PROGRAMMING FOR MAP

The potential parameters may be concatenated to form a vector $w = (-\theta_1, \dots, -\theta_n, \dots, -W_{ij}, \dots) \in \mathbb{Q}^d$, where $d = n + m$. Let $y_{ij} = \mathbb{1}[x_i \neq x_j]$, and for any configuration x, similarly concatenate the n x_i and m $y_{ij}(x)$ terms into a vector $z = (x_1, \dots, x_n, \dots, y_{ij}, \dots) \in \{0, 1\}^d$. Now score$(x) = w \cdot z$, yielding the following integer linear programming formulation for MAP inference, to identify

$$z^* \in \operatorname*{arg\,max}_{z : x \in \{0,1\}^n} w \cdot z \tag{3}$$

The convex hull of the 2^n possible integer solutions in $[0, 1]^d$ is the *marginal polytope* $\mathbb{M}$ for our choice of singleton and edge terms.[8] Regarding the convex coefficients as a probability distribution p over all possible states, $\mathbb{M}$ may be considered the space of all singleton and pairwise mean marginals that are consistent with some global distribution p over the 2^n states, that is

$$\mathbb{M} = \{\mu = (\mu_1, \dots, \mu_n, \dots, \mu_{ij}, \dots) \in [0, 1]^d \text{ s.t.} \quad \exists p \colon \mu_i = \mathbb{E}_p(X_i)\ \forall i, \mu_{ij} = \mathbb{E}_p(\mathbb{1}[X_i \neq X_j])\ \forall (i, j) \in E\} \tag{4}$$

A standard approach is to relax (3) to a linear program (LP). Performing this over $\mathbb{M}$ remains intractable since the number of linear constraints required grows extremely rapidly with n (Deza and Laurent, 1997). Hence, a simpler, relaxed constraint set is typically employed, yielding an upper bound on the original optimum. This set is often chosen as the *local polytope* LOC, which enforces only pairwise consistency (Wainwright and Jordan, 2008). If an optimum vertex is achieved at an integer solution, then this must be an optimum of the original discrete problem (3), in which case we say that the relaxation LP+LOC is *tight*.

Sherali and Adams (1990) proposed a series of successively tighter relaxations by enforcing consistency over progressively larger clusters of variables. At order r, the $\mathcal{L}_r$ polytope enforces consistency over all clusters of variables of size $\leq r$. $\mathcal{L}_2$ is the local polytope LOC. Next, $\mathcal{L}_3$ is the triplet-consistent polytope TRI, and so on, with $\mathcal{L}_n = \mathbb{M} \subseteq \mathcal{L}_{n-1} \subseteq \cdots \subseteq \mathcal{L}_3 = \text{TRI} \subseteq \mathcal{L}_2 = \text{LOC}$. Clearly LP+$\mathcal{L}_n$ is always tight. The following result, derived using the junction tree theorem (Cowell et al., 1999), gives a sufficient condition for tightness at any order.

Theorem 5 (Wainwright and Jordan, 2004)**.** *If the graph of a model has treewidth $\leq r - 1$ then LP+$\mathcal{L}_r$ is tight.*

4.2 RELATION TO MINORS, NEW RESULTS

Theorem 5 provides a sufficient condition that considers only the treewidth of the unsigned graph G, without any regard to the potentials. As remarked in §2, the graph property of bounded treewidth is minor-closed, hence can be characterized by excluding a finite set of forbidden minors, see Table 1 for examples.

We now make the following observation, where "valid potentials" for a graph means any potentials that respect the graph structure (signed or unsigned accordingly).

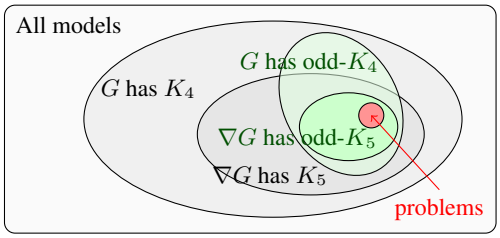
Theorem 6. *The property $\mathcal{P}$ of a graph G that "LP+$\mathcal{L}_r$ is tight for all valid potentials on G" is minor-closed, whether G is unsigned or signed (if signed then use signed minors).*

Proof. The property $\mathcal{P}$ is maintained under deletion, contraction and (for signed graphs) resigning. To see this for contraction: if an edge (i, j) of G is contracted to yield G', then for any valid model M' on G', consider the model M on G which has all the same potentials and in addition set the edge potential for (i, j) to be sufficiently high such that in M this forces X_i and X_j to take the same value. □

Hence, we should expect to be able to characterize LP tightness for all valid potentials, for both unsigned and signed topologies, by specifying a finite set of forbidden minors (signed minors in the signed case), see §2 and §3.

From Theorem 5 and Table 1: if we consider only the unsigned topology G, then LP+LOC (LP+TRI) is tight for all potentials if the graph G does not contain a K_3 (K_4, respectively) as a minor. To demonstrate the converse, and as a result of independent interest, we show the following.

[8] Our choice of edge term $\mathbb{1}[x_i \neq x_j]$ will facilitate later analysis of ∇G in §5. A common alternative choice for edges is to use $x_i x_j$, which leads to an equivalent polytope, sometimes called the *Boolean quadric polytope* QP^n (Padberg, 1989).



Sherali-Adams cluster size		Forbidden minors: Graph G Unsigned	Graph G Signed	Suspension graph ∇G Unsigned	Suspension graph ∇G Signed
LOC	$\mathcal{L}_2$	K_3	odd-K_3		
TRI	$\mathcal{L}_3$	K_4	odd-K_4	K_5	odd-K_5

	$\mathcal{L}_4$	K_5+?	odd-K_5+?	K_6+?	odd-K_6+?

Table 2: Summary of results characterizing tightness of LP relaxations by forbidden minors. All conditions may be checked efficiently. **Right:** The section for TRI (shaded blue) contains our main new results: Theorem 10 for signed G; and the stronger Theorem 14 for signed ∇G, which examines singleton and edge potentials. Theorem 14 implies Theorems 13, 10 and 8. Results for $\mathcal{L}_4$ are unknown. **Left:** Illustration of the model classes for LP+TRI, where *problems* are models for which LP+TRI is not tight. Theorem 14 is the most powerful result, showing that all problems lie within the set of models where ∇G contains an odd-K_5. See discussion in §4.3 and §6.

Theorem 7. *LP+$\mathcal{L}_r$ is not tight for the fully connected model on $n = r+1$ variables with all $\theta_i = W_{ij} = -1$ $\forall i \in V, (i,j) \in E$. Note that this model has signed G which is an odd-K_{r+1}, and signed ∇G which is an odd-K_{r+2}.*

Proof. The proof is from first principles. Consider the distribution for each r-cluster that is uniform over all configurations with $\lfloor \frac{r}{2} \rfloor$ 0s and $\lceil \frac{r}{2} \rceil$ 1s. This has higher score than the best integral configuration of $\lfloor \frac{n}{2} \rfloor$ 0s and $\lceil \frac{n}{2} \rceil$ 1s. □

Applying Theorem 7 for $r = 2$ and 3 yields the following result (since if a model contains a K_{r+1} minor, then we may assume potentials such that the model is the K_{r+1}).

Theorem 8. *Considering unsigned topologies: LP+LOC is tight for all valid potentials iff G does not contain a K_3 minor; LP+TRI is tight for all valid potentials iff G does not contain a K_4 minor.*

We next provide stronger results by considering the signs of edge potentials. Intriguingly, both for LOC and TRI, the forbidden signed minor is exactly the odd version of the forbidden unsigned minor in Theorem 8.

Theorem 9. *LP+LOC is tight for all valid potentials iff the signed graph G does not contain an odd-K_3 signed minor.*

Proof. It is easily seen that if the signed graph of a model does not contain an odd-K_3 signed minor, then it is balanced (see §3). Earlier work showed that LP+LOC is tight for any balanced model (Padberg, 1989; Weller et al., 2016). Necessity follows from Theorem 7. □

Theorem 10. *LP+TRI is tight for all valid potentials iff the signed graph G does not contain an odd-K_4 signed minor.*

Theorem 10 follows as a corollary of the stronger Theorem 14, which we shall show in §5, which also considers the signs of singleton potentials by examining the signed suspension graph ∇G (defined in §4 just before §4.1).

4.3 REMARKS, EARLIER WORK

Taken together, our results in §4.2 employ the framework of forbidden minors to characterize compactly the tightness of LP relaxations in an elegant and unifying way. See Table 2 for a summary, which includes later results from §5. Note the interesting relationships across conditions, all of which may be checked efficiently by Theorems 2 and 3.

Little was known theoretically about conditions for tightness of LP+TRI before Weller et al. (2016) showed that it was sufficient for a model to be almost balanced (defined in §3). They also demonstrated a composition result which allows almost balanced sub-models to be pasted together in particular ways, while maintaining tightness. The condition in Theorem 10 is substantially stronger: the new condition is both necessary and sufficient; it is compact to describe and it is efficient to check. Further, we next show that Theorem 10 covers a strict superset of models.

Observe that the property for a signed graph of being almost balanced is closed under taking signed minors. An odd-K_4 is clearly not almost balanced, see Figure 3. Hence almost balanced models $\subseteq$ models whose signed topology does not contain an odd-K_4 minor. Next consider the permitted pasting operation (Weller et al., 2016, Theorem 12), which allows sub-models to be pasted together either on a single variable or, in limited settings, on an edge. If each sub-model is odd-K_4-free, then so too is the pasted combination. Hence, Theorem 10 covers all the models covered by Weller et al. (2016); we next show that Theorem 10 covers a significant additional class of models.

Signed graphs that do not contain an odd-K_4 minor have been studied previously (Gerards, 1988; Truemper, 1998). An important class that is odd-K_4-minor-free but not almost balanced is planar signed graphs with two odd faces (i.e. all but exactly two faces have even bounding cycles). See Figure 4 for an example by J. Carmesin which is 3-connected, hence there is no way it could be constructed by pasting almost balanced sub-models on edges or vertices.

5 INCLUDING SINGLETONS, ∇G

In this Section, we extend the analysis of §4 to include singleton potentials, by now considering the suspension graph ∇G rather than just the base graph G. We build to §5.3,

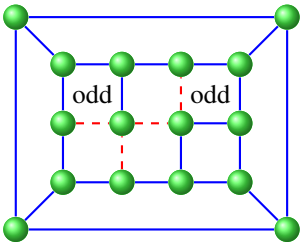

Figure 4: A 3-connected signed graph that is not almost balanced, hence the results of Weller et al. (2016) cannot be used to show that LP+TRI is tight for such a model; yet it is odd-K_4-minor-free, hence Theorem 10 proves that LP+TRI is tight for all valid potentials. This is a planar signed graph with two odd faces (Gerards, 1988, §3.2), with the odd faces indicated (others are even); see §4.3. Solid blue (dashed red) edges are even (odd).

Table 3: Relations between polytopes; see §5.

where we state and prove our strongest result, Theorem 14, which characterizes tightness of LP+TRI if we examine the signs of both edge and singleton potentials. We show that this result implies Theorem 10 from §4, which examines only edge signs. Our approach relies on Theorem 4 (Guenin's result), connecting to it by showing relations between various polytopes.

In §4, we introduced the marginal polytope $\mathbb{M}$, together with its relaxations TRI and LOC, with $\mathbb{M} \subseteq$ TRI $\subseteq$ LOC. Here, we first show equivalences to the *cut polytope* CUT of the suspension graph ∇G, together with its relaxations MET (the *semimetric polytope*) and RMET (the *rooted semimetric polytope*) with CUT $\subseteq$ MET $\subseteq$ RMET, see Table 3. In §5.2, we relate MET to the *cycle inequalities* (Barahona and Mahjoub, 1986; Barahona, 1993) and provide Theorem 13, which does not consider signs of potentials. For more background, see (Deza and Laurent, 1997).

In §5.3 we consider signed cycles, then by combining results, we prove Theorem 14, our strongest new result. In addition, we are able to show that many typically used cycle inequalities may be redundant for enforcing integrality.

5.1 MARGINAL AND CUT POLYTOPES, AND THEIR RELAXATIONS

Here we establish many of the equivalences of polytopes shown in Table 3. Recall the definition of the suspension graph $\nabla G(V', E')$ from §4.

Given a subset $S \subseteq V' = \{0, 1, \ldots, n\}$, let $\delta(S) \in \{0,1\}^{|E'|}$ be the *cut vector* of edges of ∇G that run between the vertex partitions S and $V' \setminus S$, defined by $\delta(S)_{ij} = 1$ iff i and j are in different partitions.

The *cut polytope* (Barahona, 1983; Barahona and Mahjoub, 1986) of ∇G is the convex hull of all such cut vectors, that is CUT = conv $\{\delta(S) : S \subseteq V'\}$. Although there are 2^{n+1} choices of S, CUT has 2^n vertices since by definition $\delta(S) = \delta(V' \setminus S)$. In fact, there is a linear bijection between CUT and $\mathbb{M}$, which is particularly simple given the form we selected for edge marginals in (4).[9] Given $d \in$ CUT with entries d_{ij} for $(i,j) \in E'$, d maps to $\mu \in \mathbb{M}$ where $\mu_j = d_{0j}$ for $j \in V$, and $\mu_{ij} = d_{ij}$ for $(i,j) \in E$.

To see this, d_{ij} may be interpreted as the marginal probability that $i, j \in V'$ lie in different partitions. Similarly, $\mu_{ij} \in \mathbb{M}$ is the marginal probability that X_i and X_j take different values; and μ_i is the probability that $X_i \neq 0$ (corresponding in ∇G to i being in a different partition to 0).

MAP inference for the model on G is now clearly equivalent to the max cut problem for ∇G, i.e.[10]

$$\max_{\mu \in \mathbb{M}} w \cdot \mu = \max_{d \in \text{CUT}} w' \cdot d, \;\; w'_{ij} = \begin{cases} -\theta_j & i = 0 \\ -W_{ij} & (i,j) \in E. \end{cases} \quad (5)$$

The bijection between $\mathbb{M}$ and CUT may also be used to map the LOC and TRI relaxations of $\mathbb{M}$ to corresponding relaxations of CUT in $[0,1]^{|E'|}$, called the *rooted semimetric polytope* RMET and the *semimetric polytope* MET, respectively, as shown in Table 3. The constraints for the MET polytope (which corresponds to TRI) take the following form, sometimes described as unrooted triangle inequalities (Deza and Laurent, 1997, §27.1):

$$\text{MET} \quad \forall i,j,k \in V', \; \begin{array}{l} d(i,j) - d(i,k) - d(j,k) \leq 0 \\ d(i,j) + d(i,k) + d(j,k) \leq 2. \end{array} \quad (6)$$

Remarkably, the constraints for RMET, the *rooted* triangle inequalities, are exactly just those of (6) for which one of i, j, k is 0, the vertex that was added to yield ∇G. Hence, RMET may be regarded as MET *rooted* at 0. Correspondingly, we may consider TRI to be a version of LOC that is *universally rooted* (Weller, 2016). See discussion in §6.

5.2 CYCLE INEQUALITIES, CYC POLYTOPE

Here we define the cycle inequalities and provide background showing how they may be used to characterize tightness of LP+TRI by forbidding unsigned K_5 as a minor of the unsigned suspension graph $\nabla G(V', E')$.

For any edge set $F \subseteq E'$ and $x \in [0,1]^{|E'|}$, let $x(F) = \sum_{e \in F} x(e)$. Let $C \subseteq E'$ be the edge set of a cycle in ∇G.

[9] If instead, edge terms of the form $x_i x_j$ are used for the marginal polytope, as in the Boolean quadric polytope (see footnote 8), then the linear bijection required is slightly more complex and is called the *covariance mapping* (De Simone, 1990).

[10] The negative signs before θ_j and W_{ij} terms are because we followed the convention that $W_{ij} > 0$ is an attractive edge, and made the signs of singleton potentials consistent; see §4.

At any vertex of CUT, if we traverse C, we must change partitions an even number of times.

Hence, the following *cycle inequalities* hold $\forall x \in$ CUT: for any cycle C and any edge subset $F \subseteq C$ with $|F|$ odd,

$$x(F) - x(C \setminus F) \leq |F| - 1. \tag{7}$$

Let CYC be the polytope defined by these constraints, i.e. CYC $= \{x \in [0,1]^{|E'|} : x(F) - x(C \setminus F) \leq |F| - 1$ for any cycle C of ∇G and any $F \subseteq C, |F|$ odd$\}$. The triangle inequalities (6) are special cases of (7) with $|C| = 3$, though note that those apply in MET to any triplet $i, j, k \in V'$ without regard to the edges E', whereas cycle inequalities apply only to the cycles of $\nabla G(V', E')$. Nevertheless, in fact, the following result holds; see Table 3.

Theorem 11 (Barahona and Mahjoub, 1986; Barahona, 1993)**.** *MET = CYC.*

Barahona and Mahjoub (1986) established the following important characterization for when the cycle inequalities are sufficient for tightness by forbidding a K_5 minor.

Theorem 12 (Barahona and Mahjoub, 1986)**.** *CUT = CYC iff unsigned ∇G does not contain K_5 as a minor.*

Using the equivalences of §5.1 (see (5) and Table 3), Theorems 11 and 12 together show the following result, which characterizes when LP+TRI is tight if we examine only the *unsigned* suspension graph ∇G.

Theorem 13. *LP+TRI is tight for all valid potentials iff unsigned ∇G does not contain K_5 as a minor.*

Theorems 11 and 12 of Barahona and Mahjoub (1986) are often used to show only that LP+TRI is tight for a planar model with no singleton potentials (which excludes both K_5 and $K_{3,3}$, see §2), e.g. see Theorem 3.3.2 in (Sontag, 2010). However, Theorem 13 is stronger, and perhaps is more naturally viewed instead as extending the characterization of treewidth ≤ 2 as K_4-minor-free; see §6.

5.3 SIGNED CYCLES, MISS POLYTOPE

Here we shall prove Theorem 14, a stronger, signed version of Theorem 13. Theorem 10 will follow as a corollary. For cycles in ∇G, to avoid confusion, we write C for the edge set of an unsigned cycle, and D for the signed edge set of a signed odd cycle (which has an odd number of odd edges).

Given results in §5.1-5.2 (see (5) and Table 3), we have

$$\max_{\mu \in \text{TRI}} w \cdot \mu = \max_{x \in \text{CYC}} w' \cdot x, \, w'_{ij} = \begin{cases} -\theta_j & i = 0 \\ -W_{ij} & (i,j) \in E. \end{cases} \tag{8}$$

We shall relate this to Theorem 4 (Guenin's result on weakly bipartite graphs from §3.3) to prove the following.

Theorem 14. *LP+TRI is tight for all valid potentials, observing signs of both edge and singleton potentials, iff the signed suspension graph ∇G does not contain odd-K_5 as a signed minor.*

Proof. We first show sufficiency of the condition. Regarding (8), CYC is defined by the inequalities (7), which we rewrite as $|F| - x(F) + x(C \setminus F) \geq 1$, or

$$\sum_{e \in F} (1 - x_e) + \sum_{e \in C \setminus F} x_e \geq 1. \tag{9}$$

The unsigned cycle inequality (9) applies for every cycle C of ∇G and every $F \subseteq C$ with $|F|$ odd. Aiming to relate (9) to the definition of a weakly bipartite graph (1), we introduce the following MISS polytope, which is equivalent to CUT by a reflection that adjusts for the signs of edges of $\nabla G(V', E')$. Recall how these signs are set in §4, and regarding (8), observe that edge $e \in E'$ is odd iff $w'_e > 0$.

Given a configuration of variables $X_1, \ldots, X_n \in \{0,1\}^n$, the corresponding vertex $\in \{0,1\}^{|E'|}$ of the CUT polytope has a 1 for edge $(i,j) \in E'$ iff $X_i \neq X_j$, taking $X_0 = 0$.

For MISS, instead the corresponding vertex $m \in \{0,1\}^{|E'|}$ has a 1 for edge $(i,j) \in E'$ iff m_{ij} 'misses' the potential score benefit that the edge offers. That is, take $X_0 = 0$ as before, and now for all $(i,j) \in E'$, assign $m_{ij} = 1$ if $X_i \neq X_j$ and the edge is even (attractive), or if $X_i = X_j$ and the edge is odd (repulsive); otherwise $m_{ij} = 0$.

Each of CUT and MISS is formed as the convex hull of its 2^n vertices. MISS is the reflection of CUT across $\frac{1}{2}$ in exactly the dimensions for which edges of ∇G are odd. That is, $x \in$ CUT maps bijectively to $y \in$ MISS, where $y_e = x_e$ for even edges, and $y_e = 1 - x_e$ for odd edges.

Let D be the edge set of an odd cycle of signed ∇G (i.e. D has an odd number of odd edges). Given any configuration of variables, as we go round D, to return to the same value, we must 'miss' at least one edge. That is, for any vertex $m \in$ MISS, $\sum_{e \in D} m_e \geq 1$. Hence, what we call the *signed cycle inequalities* hold $\forall y \in$ MISS $\subseteq [0,1]^{|E'|}$:

$$\sum_{e \in D} y_e \geq 1, \quad \forall \text{ odd cycles } D \text{ of signed } \nabla G. \tag{10}$$

Note the direct correspondence between the signed cycle inequalities (10) and the inequalities defining the weakly bipartite polyhedron Q (1). Observe the following.

Lemma 15. *Each signed cycle inequality* (10) *corresponds to an unsigned cycle inequality* (9)*.*

Proof. Given a signed cycle inequality (10), let F be the odd edges of D, with $|F|$ odd. Let $C = D$. The equivalent reflected form of (10) for $x \in$ CUT is $\sum_{e \in F}(1 - x_e) + \sum_{e \in C \setminus F} x_e \geq 1$, which matches (9) as required. □

Let CYC^R be the polytope CYC reflected in the odd edge dimensions, just as MISS may be obtained from CUT, so

MISS $\subseteq$ CYC^R as CUT $\subseteq$ CYC. Consider (8), note edge e is odd $\Leftrightarrow w'_e > 0$, let $x \in$ CYC map to $y \in$ CYC^R, then

$$\max_{\mu \in \text{TRI}} w \cdot \mu = \max_{y \in \text{CYC}^R} \sum_{\text{odd } e \in E'} w'_e(1 - y_e) + \sum_{\text{even } e \in E'} w'_e y_e$$
$$= A + \max_{y \in \text{CYC}^R} w'' \cdot y, \quad (11)$$

where $A = \sum_{e:w'_e>0} w'_e$ is a constant, and $w''_e = -|w'_e| \; \forall e \in E'$.

We are now ready to apply Theorem 4. We have {all valid integer solutions} $\subseteq$ MISS $\subseteq$ CYC^R, while (by Lemma 15) CYC^R enforces all the signed cycle inequalities (10), which match the weakly bipartite conditions (1). Further, in (11) we are maximizing an objective with every coefficient negative, which is needed since Q is a polyhedron unbounded in the positive directions (1). Finally, no invalid integer solutions lie in CYC^R. Hence, by Theorem 4, if signed ∇G does not contain odd-K_5 as a signed minor, then LP+TRI is tight.

For necessity of the condition, if ∇G does contain an odd-K_5 minor, then by choice of potentials, we may assume signed $\nabla G(V', E')$ to be exactly odd-K_5. Then Theorem 7 with $r = 3$ provides an example where LP+TRI is not tight. This completes the proof of Theorem 14. □

Corollaries. Theorem 14 may be used to prove Theorem 10 as follows. First, if signed G does not contain an odd-K_4, then clearly signed ∇G cannot contain an odd-K_5, hence LP+TRI is tight by Theorem 14. Now, if signed G does contain an odd-K_4, then we may select all negative singleton potentials for those variables, then use the example above for odd-K_5 in signed ∇G.

In practice, LP+TRI is often implemented by enforcing the (unsigned) cycle constraints (9) rather than all triplet constraints (Sontag, 2010). Theorem 14 and Lemma 15 show the following, which may be useful by dramatically reducing the number of constraints required for integrality.[11]

Theorem 16. *If a model has signed ∇G that is odd-K_5-minor-free, then integrality of LP+TRI will be achieved by enforcing only the signed cycle inequalities* (10)*, with the other unsigned cycle inequalities* (9) *being redundant.*[12]

6 DISCUSSION, FUTURE WORK

We have drawn connections to powerful results from graph theory by showing how tightness of LP relaxations may be elegantly characterized by forbidding certain minors: either from the graph topology G, if singleton potentials are not examined; or, with more precision, from the suspension graph ∇G, if the topology of both edge and singleton potentials is considered. We significantly strengthen results by examining also the signs of the potentials and forbidding signed minors. All conditions can be tested efficiently (Theorems 2 and 3). Our strongest result, Theorem 14, shows that LP+TRI is tight for all valid potentials, observing the signed topology of the suspension graph ∇G, iff signed ∇G is odd-K_5-minor-free. Our results go substantially beyond earlier work (Weller et al., 2016) that provided only sufficient conditions for a smaller set of models, without an easy way to test.

Viewing our characterizations together in Table 2, fascinating patterns emerge. We make the following observations. (a) In all known cases, it is exactly just the *odd* versions of the forbidden unsigned minors which can cause lack of tightness of the LP relaxation. In future work, we would like to understand if this pattern extends to other cases. (b) For unsigned graphs G, given the treewidth result of Wainwright and Jordan (2004), we can expect that as cluster size increases, the number of forbidden minors could grow rapidly,[13] see Table 1. (c) For TRI, going from G to the suspension graph ∇G adds one universally connected vertex to the forbidden minor. Why does this not happen for LOC, and will it hold for higher cluster sizes? Recall the observations just before §5.2, where we saw that LOC has a *fixed root* whereas TRI is *universally rooted*. This is why results for TRI examine the suspension graph ∇G with complete symmetry for singleton and edge potentials, whereas for LOC, singleton potentials are different. This prompts further analysis and may lead to new algorithms for TRI. It also suggests viewing the forbidden K_5 minor in ∇G not as a strengthened form of planarity (which forbids K_5 and $K_{3,3}$), but rather as forbidding K_{4+1}, where K_4 is the treewidth constraint of the base graph G. Further, it explains why it is possible for LP+TRI to perform worse as singleton potentials rise within a range, see Appendix.

Theorem 7 shows that for any cluster size r, it is *necessary* to forbid K_{r+2} as a signed minor of ∇G in order to guarantee tightness of LP+$\mathcal{L}_r$. We have placed the appropriate entries in the $\mathcal{L}_4$ row of Table 2. Theorem 5 shows that it is *sufficient* to forbid all the treewidth minors in unsigned G. Must we forbid odd versions of all these in signed G? So far, we have not been able to find an example where LP+$\mathcal{L}_4$ is not tight other than where ∇G contains an odd-K_6.

Acknowledgements

The author thanks Standa Živný, Johannes Carmesin, Maria Chudnovsky, Mark Rowland, Tony Huynh, Tony Jebara, Amir Globerson, David Sontag, Nilesh Tripuraneni, Yarin Gal and Yingzhen Li for helpful comments.

[11] For implementations which successively add violated cutting planes, this result may be less useful, though it still dramatically reduces the search space of possible constraints to add.

[12] Consider that (9) has no access to edge signs, hence tests *all possible* frustrated/odd cycles (10).

[13] Ramachandramurthi (1997) showed that the number of forbidden minors for treewidth t is $\Omega(\exp(\sqrt{t}))$.

Subspace Clustering with a Twist

Abstract

Subspace segmentation or clustering can be defined as the process of assigning subspace labels to a set of data points assumed to lie on the union of multiple low-dimensional, linear subspaces. Given that each point can be efficiently expressed using a linear combination of other points from the same subspace, a variety of segmentation algorithms built upon ℓ_1, nuclear norm, and other convex penalties have recently shown state-of-the-art robustness on multiple benchmarks. However, what if instead of observing the original data points, we instead only have access to transformed, or 'twisted' so to speak, measurements? Here we consider underdetermined affine transformations that may arise in computer vision applications such as bidirectional reflectance distribution function (BRDF) estimation. Unfortunately most existing approaches, convex or otherwise, do not address this highly useful generalization. To fill this void, we proceed by deriving a probabilistic model that simultaneously estimates the latent data points and subspace memberships using simple EM update rules. Moreover, in certain restricted settings this approach is guaranteed to produce the correct clustering. Finally a wide range of corroborating empirical evidence, including a BRDF estimation task, speaks to the practical efficacy of this algorithm.

1 Introduction

As a data reduction or analysis tool, principal component analysis (PCA) is readily applicable whenever observable points lie on or near a low-dimensional linear subspace. Richer structures however may not conform to this model, and often we must consider ways of introducing additional complexity. For example, a natural extension of PCA is to consider that our data lie on a union of low-dimensional subspaces. In this expanded regime we may then consider the joint problem of estimating these subspaces and assigning each point to the closest one, a process commonly referred to as either subspace clustering or segmentation. Although unlike classical PCA a closed-form solution via the SVD is no longer possible, tractable approximations that succeed with high probability form a core component of numerous practical application domains. Examples include the analysis of social graphs (Jalali et al., 2011), network topology inference (Eriksson et al., 2012), user identification in movie rating systems Zhang et al. (2012), and a host of computer vision tasks such as image representation and compression, motion segmentation, and face clustering (Elhamifar & Vidal, 2013; Feng et al., 2014; Liu et al., 2013; Lu et al., 2012; Rao et al., 2010).

1.1 Problem Description

We define this problem more formally as follows. Let $\{\mathcal{S}_k\}_{k=1}^m$ denote a collection of m linear subspaces in $\mathbb{R}^d$, where $\dim[\mathcal{S}_k] = d_k < d \quad \forall k = 1, \ldots, m$. Moreover, suppose we have drawn n_k points from each subspace forming data matrices $\boldsymbol{X}_k \in \mathbb{R}^{d \times n_k}$. We then concatenate the points from each subspace, and the full arrangement of $n = \sum_{k=1}^m n_k$ points is reordered using an unknown permutation matrix $\boldsymbol{P} \in \mathbb{R}^{n \times n}$. Consequently, the entire data can be expressed as

$$\boldsymbol{X} \triangleq [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n] = [\boldsymbol{X}_1, \ldots, \boldsymbol{X}_m]\boldsymbol{P} \in \mathbb{R}^{d \times n}. \quad (1)$$

Subspace clustering can then be described as the process of estimating a basis for each $\mathcal{S}_k$ as well as the subspace membership of each point $\boldsymbol{x}_j$.

One of the most robust approaches to obtaining such accurate data segmentations exploits the so-called *self-expressiveness property* of $\boldsymbol{X}$ (Elhamifar & Vidal, 2013), namely that any $\boldsymbol{x}_j$ can be represented as a linear combination of other data points in $\boldsymbol{X}$ within the same subspace. Moreover, if we can find such a representation using *only* points from the same subspace, then we have extracted vital information pertaining to the true latent segmentation.

One way to favor such cluster-aligned decompositions is by solving

$$\min_{\boldsymbol{Z}} \|\boldsymbol{Z}\|_0 \text{ s.t. } \boldsymbol{X} = \boldsymbol{X}\boldsymbol{Z}, \text{ diag}[\boldsymbol{Z}] = 0, \tag{2}$$

where $\|\boldsymbol{Z}\|_0$ is the matrix ℓ_0 norm, or a count of the number of nonzero elements in $\boldsymbol{Z}$, a penalty function that strongly favors zero-valued elements or a canonically sparse $\boldsymbol{Z}$. The diagonal constraint is required to prevent each point from using itself in the representation (e.g., the degenerate solution $\boldsymbol{Z}^* = \boldsymbol{I}$), enforcing that we must rely only on others in the same subspace. If we assume that each individual subspace satisfies $d_k < d$ for all k, and that sampled points are sufficiently dense in general position, then the solution to (2) will be block diagonal and aligned with the true clusters up to the permutation matrix $\boldsymbol{P}$, revealing subspace memberships. A final spectral clustering, post-processing step can further solidify the labels and is adopted by most recent methods (Elhamifar & Vidal, 2013). Of course solving (2) is non-convex, discontinuous, and NP-hard, so following the typical compressive sensing recipe it is desirable to replace the troublesome $\|\boldsymbol{Z}\|_0$ penalty with the convex relaxation $\|\boldsymbol{Z}\|_1$. This substitution is supported by rigorous theoretical arguments detailing conditions whereby subspace-aligned block-diagonal structure is guaranteed when we minimize $\|\boldsymbol{Z}\|_1$ over the constraint set (Soltanolkotabi & Candès, 2012).

Proceeding further, suppose that we are unable to observe $\boldsymbol{X}$ directly, but instead are only granted access to a measurement matrix $\boldsymbol{Y} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n]$, where each column $\boldsymbol{y}_j$ is generated via the underdetermined system

$$\boldsymbol{y}_j = \boldsymbol{A}_j \boldsymbol{x}_j, \quad \forall j = 1, \ldots, n. \tag{3}$$

Here $\{\boldsymbol{A}_j\}$, with $\boldsymbol{A}_j \in \mathbb{R}^{p_j \times d}, p_j \leq d$ indicates a set of known, possibly overcomplete matrices with problem-dependent structure that can warp or *twist* each data point independently while mapping it onto the lower-dimensional observation space.[1] As described in depth later, such a situation commonly arises in computer vision applications such as bidirectional reflectance distribution function (BRDF) estimation, where each $\boldsymbol{A}_j$ is determined by lighting conditions and the surface geometry of an object with unknown BRDF we would like to obtain. Other possible scenarios include face clustering in subject-varying transform domains, or motion segmentation using approximations for perspective cameras. Additionally, if each $\boldsymbol{A}_j$ can be described as a matrix of zeroes with a single one in each row, then the resulting estimation problem is tantamount to subspace clustering with missing entries (Candès et al., 2014; Eriksson et al., 2012; Gruber & Weiss, 2004; Yang et al., 2015).

[1] We frequently use $\{\boldsymbol{M}_j\}$ to abbreviate a set of matrices $\{\boldsymbol{M}_j : j \in \mathcal{J}\}$, where the index set $\mathcal{J}$ should be clear from the context.

1.2 Naive Solutions

Clearly we can no longer directly rely on the original self-expressiveness property, because once we insert $\{\boldsymbol{A}_j\}$ into the pipeline, it no longer follows that each corresponding $\boldsymbol{y}_j$ can be compactly represented using only other points generated from the same subspace.[2] To compensate, several strategies immediately come to mind.

For example, suppose we somehow knew the number of clusters m. Then let the set $\{\Omega_k\}$, with each $\Omega_k \subset \{1, \ldots, n\}$, denote a partitioning such that $\bigcup_{k=1}^m \Omega_k = \{1, \ldots, n\}$ and $\Omega_k \cap \Omega_{k'} = \emptyset$ for all pairs $\{k, k'\}$. Also let $\boldsymbol{X}_{\Omega_k}$ represent the columns of matrix $\boldsymbol{X}$ indexed by Ω_k. Now consider the joint optimization over all possible segmentations and latent points

$$\min_{\boldsymbol{X}, \{\Omega_k\}} \sum_{k=1}^m |\Omega_k| \text{rank}(\boldsymbol{X}_{\Omega_k}) \text{ s.t. } \boldsymbol{y}_j = \boldsymbol{A}_j \boldsymbol{x}_j, \, \forall j = 1, \ldots, n. \tag{4}$$

Then assuming the true latent $\boldsymbol{X}$ is composed of sufficient samples per subspace in general position, and that $\boldsymbol{A}_j$ contains a sufficient number of non-degenerate measurements, the solution to (4) will be such that $\{\Omega_k\}$ reflects the correct segmentation and $\boldsymbol{X}$ will be recovered. Unfortunately however, minimizing (4) requires an infeasible, combinatorial search over every possible clustering pattern.

Perhaps the most natural way to circumvent this problem is to invoke a two-stage procedure inspired by traditional matrix completion (Candès & Recht, 2008). The basic idea is to first obtain an estimate of the latent $\boldsymbol{X}$ by solving

$$\min_{\boldsymbol{X}} \text{rank}[\boldsymbol{X}], \quad \text{s.t. } \boldsymbol{y}_j = \boldsymbol{A}_j \boldsymbol{x}_j, \, \forall j = 1, \ldots, n, \tag{5}$$

which excludes any combinatorial search over labels. This represents an affine rank minimization problem that can be approximately solved by replacing the non-convex rank$[\boldsymbol{X}]$ penalty with the convex nuclear norm relaxation $\|\boldsymbol{X}\|_*$, or the sum of the singular values of $\boldsymbol{X}$. Once this solution is in hand, we may deploy any traditional subspace clustering algorithm on the resulting $\hat{\boldsymbol{X}}$.

The difficulty with this strategy is two-fold. First, unlike the data from individual subspaces $\boldsymbol{X}_k$, the matrix $\boldsymbol{X}$ may be full rank given that it is quite common to have $\sum_k d_k \geq d$. So in this situation we have no chance of obtaining a meaningful segmentation. However, even if the global solution to (5) does produce the correct $\boldsymbol{X}$, the nuclear norm relaxation required by a tractable implementation will be highly sensitive to both the correlation structure and relative column norm scaling of $\{\boldsymbol{A}_j\}$.

[2] An exception to this occurs when $\boldsymbol{A}_j$ is equal to some fixed $\boldsymbol{A}$ across all j, in which case the self-expressiveness property still holds and natural adaptations already exist (Patel et al., 2013; Wang et al., 2015a).

In fact existing theoretical guarantees for rank-nuclear norm equivalence place extremely strong conditions on the structure of the measurement process, which are unlikely to hold in practice here since in the problem instances we consider, each $\boldsymbol{A}_j$ is determined by physical properties of the experimental design. Moreover, unlike typical compressive sensing designs, we cannot even normalize columns of $\{\boldsymbol{A}_j\}$, because if we were to do so then a low-rank solution will no longer satisfy the constraint set in (5). Therefore we are left with a challenging NP-hard rank minimization problem as a required preprocessing step, a clearly undesirable starting point.

As an alternative to the above two-stage procedure, we could append an additional data fitting constraints to the canonical sparse subspace clustering objective from above and solve

$$\min_{\boldsymbol{X},\boldsymbol{Z}} \|\boldsymbol{Z}\|_1 \text{ s.t. } \boldsymbol{X} = \boldsymbol{X}\boldsymbol{Z},\ \text{diag}[\boldsymbol{Z}] = 0, \boldsymbol{y}_j = \boldsymbol{A}_j\boldsymbol{x}_j\ \forall j. \tag{6}$$

Although the penalty is convex in $\boldsymbol{Z}$ and the constraints are individually convex in $\boldsymbol{X}$ and $\boldsymbol{Z}$, the overall problem remains highly non-convex and difficult to optimize. Moreover it is unclear whether the global solution, even if somehow attainable, would guarantee that the correct clustering could be found. Additionally, in practical environments with noisy data, relaxing the additional equality constraints would require the inclusion of an additional trade-off parameter and application-specific tuning.

1.3 Overview of Contributions

To address the conceptual limitations of naive adaptations of existing subspace clustering approaches, in Section 2 we derive an alternative Bayesian approach specifically tailored to the proposed latent variable setting and loosely motivate its effectiveness. Next Section 3 derives expectation maximization (EM) udpdate rules that accommodate practical deployment. We then proceed to theoretical analysis of the underlying objective function in Section 4, followed by empirical validation in Section 5, practical deployment in Section 6, and final contextualization in Section 7. Overall, our contributions can be summarized as follows:

- We delineate an important generalization of subspace clustering to accommodate an underdetermined affine measurement process and derive a Bayesian algorithm that explicitly circumvents limitations of natural alternatives. Unlike existing state-of-the-art segmentation pipelines, our algorithm does not require a final spectral clustering step.
- We thoroughly unpack the proposed objective function and its customized mechanism for favoring the true subspace labels. This includes the exposition of specific conditions, albeit somewhat idealized, whereby a unique minimizing solution (global or local) will produce the correct segmentation.
- Although not our original intention, we demonstrate that our model can achieve state-of-the-art performance in more specialized domains when $\boldsymbol{A}_j$ displays certain additional structure. This includes traditional subspace clustering when each $\boldsymbol{A}_j = \boldsymbol{I}$ for all j, or subspace clustering with missing entries when each $\boldsymbol{A}_j$ is an all-zero matrix with a single one in each row.
- We provide strong empirical validation on a practical BRDF estimation problem that requires the full generality of the proposed affine observation model.

2 Model Description

We begin by decomposing the latent unobserved data as

$$\boldsymbol{X} = \sum_{i=1}^{m} \widetilde{\boldsymbol{X}}^{(i)}, \tag{7}$$

where each $\widetilde{\boldsymbol{X}}^{(i)} \in \mathbb{R}^{d\times n}$ can be interpreted as our estimate of the overall signal generated from the i-th subspace. Although we will eventually arrive at an objective function that is independent of this decomposition, it nonetheless serves as a useful tool for constructing hidden data for the EM algorithm described in Section 3. We next adopt the Gaussian likelihood function

$$p\left(\boldsymbol{Y}|\{\widetilde{\boldsymbol{X}}^{(i)}\};\lambda\right) \propto \exp\left[-\sum_j \tfrac{1}{2\lambda}\|\boldsymbol{y}_j - \boldsymbol{A}_j\sum_i \widetilde{\boldsymbol{x}}_j^{(i)}\|_2^2\right], \tag{8}$$

where λ is a noise parameter.[3] Additionally, in the limit as $\lambda \to 0$ this will enforce the same constraint set as in (3). Next we define an independent, zero-mean Gaussian prior distribution for each column of $\widetilde{\boldsymbol{X}}^{(i)}$, parameterized as $p\left(\{\widetilde{\boldsymbol{X}}^{(i)}\};\{\boldsymbol{\Gamma}_i\},\boldsymbol{W}\right) =$

$$\prod_{i,j} p(\widetilde{\boldsymbol{x}}_j^{(i)};\boldsymbol{\Gamma}_i,w_{ij}) = \prod_{i,j}\mathcal{N}\left(\widetilde{\boldsymbol{x}}_j^{(i)};\boldsymbol{0},w_{ij}\boldsymbol{\Gamma}_i\right), \tag{9}$$

where each $\boldsymbol{\Gamma}_i$ represents a symmetric, positive semi-definite covariance basis matrix and the scalar coefficients w_{ij} constitute non-negative weighting factors that collectively form a parameter matrix $\boldsymbol{W}$.[4] Strictly speaking

[3] We could allow for a separate λ_j for each point which would ultimately allow us to learn outlier locations, but for space considerations we do not further pursue this direction here.

[4] Note that (Tipping & Bishop, 1999; Wang et al., 2015b) describe alternative probabilistic mixture models that can be applied to clustering; however, the parameterizations and underlying inference algorithms are completely different from ours, do not apply to the latent affine model we consider, and do not lead to any of the desired properties discussed herein.

we should require that each $w_{ij}\boldsymbol{\Gamma}_i$ factor be positive definite such that the implied matrix inverse included with this distribution is well-defined. However, we can adjust for the semi-definite case with a more refined definition of the prior. First, if some $w_{ij} = 0$, then we simply define that $\widetilde{\boldsymbol{x}}_j^{(i)} = \boldsymbol{0}$ with probability one. For the $w_{ij} > 0$ case, without loss of generality assume that $\boldsymbol{\Gamma}_i = \boldsymbol{R}_i\boldsymbol{R}_i^\top$ for some matrix $\boldsymbol{R}_j$. We then stipulate that $p\left(\widetilde{\boldsymbol{x}}_j^{(i)};\boldsymbol{\Gamma}_i,w_{ij}\right) = 0$ if $\widetilde{\boldsymbol{x}}_j^{(i)} \notin \text{span}[\boldsymbol{R}_j]$, and $p\left(\widetilde{\boldsymbol{x}}_j^{(i)};\boldsymbol{\Gamma}_i,w_{ij}\right) \propto \exp\left[-\frac{1}{2}(\widetilde{\boldsymbol{x}}_j^{(i)})^\top(\boldsymbol{R}_j^\top)^\dagger\boldsymbol{R}_j^\dagger\widetilde{\boldsymbol{x}}_j^{(i)}\right]$ otherwise. These refinements are tacitly assumed in many related Bayesian models, and can be viewed as a natural limiting case whereby a degenerate covariance enforces that all probability mass reside in a low-dimensional subspace of the full ambient space.

Given that both the likelihood function and prior distribution are Gaussians, the posterior distribution is also a Gaussian with closed-form moments. While expressing these moments in full is slightly cumbersome from a notational standpoint, the marginalized posterior of each $\widetilde{\boldsymbol{x}}_j^{(i)}$ is given by

$$p\left(\widetilde{\boldsymbol{x}}_j^{(i)}|\boldsymbol{y}_j;\boldsymbol{\Gamma}_i,w_{ij},\lambda\right) = \prod_j \mathcal{N}\left(\boldsymbol{x}_j^{(i)};\boldsymbol{\mu}_j^{(i)},\boldsymbol{\Sigma}_j^{(i)}\right) \quad (10)$$

with means and covariances defined by

$$\begin{aligned}\boldsymbol{\mu}_j^{(i)} &= w_{ij}\boldsymbol{\Gamma}_i\boldsymbol{A}_j^\top\left(\lambda\boldsymbol{I}+\boldsymbol{A}_j\boldsymbol{\Psi}_j\boldsymbol{A}_j^\top\right)^{-1}\boldsymbol{y}_j, \quad (11)\\ \boldsymbol{\Sigma}_j^{(i)} &= w_{ij}\boldsymbol{\Gamma}_i - w_{ij}^2\boldsymbol{\Gamma}_i\boldsymbol{A}_j^\top\left(\lambda\boldsymbol{I}+\boldsymbol{A}_j\boldsymbol{\Psi}_j\boldsymbol{A}_j^\top\right)^{-1}\boldsymbol{A}_j\boldsymbol{\Gamma}_i,\end{aligned}$$

where

$$\boldsymbol{\Psi}_j = \sum_i w_{ij}\boldsymbol{\Gamma}_i, \quad \forall j = 1,\ldots,n, \quad (12)$$

Although it is easily shown that each $\widetilde{\boldsymbol{x}}_j^{(i)}$ is independent across data points j, they may be highly correlated across the basis index i. However, for purposes of the EM algorithm derived in Section 3, only the moments from (11) will be required.

The rationale for the chosen parameterization of the prior $p\left(\{\widetilde{\boldsymbol{X}}^{(i)}\};\{\boldsymbol{\Gamma}_i\},\boldsymbol{W}\right)$ becomes partially evident upon inspection of the posterior mean expression from (11). Suppose each $\boldsymbol{\Gamma}_i$ spans the k-th unknown subspace we would like to recover. And moreover, suppose each $\boldsymbol{w}_j$ (the j-th column of $\boldsymbol{W}$) is a vector of zeros with a single nonzero in the position corresponding with the true subspace membership of $\boldsymbol{x}_j$. Then by virtue of the left multiplication in (11), $\boldsymbol{x}_j$ will have a posterior mean constrained to the correct subspace, with zero covariance (or posterior mass) leaking into other, errant subspaces. Hence under the stated conditions a posterior mean estimator will produce minimal reconstruction error.

Of course all of this is predicated on our ability to actually obtain a basis set $\{\boldsymbol{\Gamma}_i\}$ and weight matrix $\boldsymbol{W}$ fulfilling the stringent subspace-aware criterion described above. Hence we have merely shifted our original goal of estimating $\boldsymbol{X}$ and clustering its columns, to the task of learning subspace-aware covariances $\{\boldsymbol{\Gamma}_i\}$ and a column-sparse weight matrix $\boldsymbol{W}$ with support aligned with the true subspaces. While certainly not immediately obvious, the remainder of this paper will demonstrate that a standard marginalization strategy is quite effective for this purpose.

If we treat $\{\boldsymbol{\Gamma}_i\}$ and $\boldsymbol{W}$ as the key parameters of interest and $\{\widetilde{\boldsymbol{X}}^{(i)}\}$ as nuisance latent variables, then a common Bayesian inference strategy is to marginalize over $\{\widetilde{\boldsymbol{X}}^{(i)}\}$ and then maximize the resulting likelihood function with respect to remaining unknown parameters (Tipping, 2001; Wipf et al., 2011; Xin & Wipf, 2015). This involves solving

$$\max_{\boldsymbol{\Gamma}_i\in H^+\forall i,\boldsymbol{W}\geq 0}\int p(\boldsymbol{Y}|\boldsymbol{X};\lambda)p(\boldsymbol{X};\{\boldsymbol{\Psi}_j\})d\boldsymbol{X}, \quad (13)$$

where H^+ denotes the set of positive semi-definite and symmetric $d\times d$ matrices. After a $-2\log$ transformation and application of a standard convolution-of-Gaussians integration (Tipping, 2001), solving (13) is equivalent to minimizing the cost function

$$\mathcal{L}(\{\boldsymbol{\Gamma}_i\},\boldsymbol{W}) = \sum_j \boldsymbol{y}_j^\top\boldsymbol{\Sigma}_{y_j}^{-1}\boldsymbol{y}_j + \log\left|\boldsymbol{\Sigma}_{y_j}\right|, \quad (14)$$

where

$$\boldsymbol{\Sigma}_{y_j} = \sum_i w_{ij}\boldsymbol{A}_j\boldsymbol{\Gamma}_i\boldsymbol{A}_j^\top + \lambda\boldsymbol{I}. \quad (15)$$

The latter represents the covariance of $\boldsymbol{y}_j$ conditioned on $\{\boldsymbol{\Gamma}_i\}$ and $\boldsymbol{w}_j$.

3 Algorithm Derivation

To optimize $\mathcal{L}(\{\boldsymbol{\Gamma}_i\},\boldsymbol{W})$ we may treat $\{\widetilde{\boldsymbol{X}}^{(i)}\}$ as hidden data and execute a straightforward EM procedure (Dempster et al., 1977) similar to that proposed in (Tipping, 2001). For the E-step we need only compute the posterior moments given by (11). For the M-step we must solve

$$\min_{\{\boldsymbol{\Gamma}_i\},\boldsymbol{W}} \text{E}\left[-\log p\left(\{\widetilde{\boldsymbol{X}}^{(i)}\},\boldsymbol{Y};\{\boldsymbol{\Gamma}_i\},\boldsymbol{W},\lambda\right)\right], \quad (16)$$

where the expectation is with respect to $p\left(\{\widetilde{\boldsymbol{X}}^{(i)}\}|\boldsymbol{Y};\{\boldsymbol{\Gamma}_i'\},\boldsymbol{W}',\lambda\right)$, which represents the posterior distribution obtained using moments parameterized with fixed values $\{\boldsymbol{\Psi}_j'\}$ and $\boldsymbol{W}'$ computed from the previous iteration. After a few algebraic manipulations, this is equivalent to solving

$$\min_{\{\boldsymbol{\Gamma}_i\},\boldsymbol{W}} \sum_{i,j}\text{tr}\left[\text{E}\left[\widetilde{\boldsymbol{x}}_j^{(i)}(\widetilde{\boldsymbol{x}}_j^{(i)})^\top\right](w_{ij}\boldsymbol{\Gamma}_i)^{-1}\right] + \log|w_{ij}\boldsymbol{\Gamma}_i|, \quad (17)$$

where $\mathrm{E}\left[\widetilde{\boldsymbol{x}}_j^{(i)}(\widetilde{\boldsymbol{x}}_j^{(i)})^\top\right] = \boldsymbol{\mu}_j^{(i)}\left(\boldsymbol{\mu}_j^{(i)}\right)^\top + \boldsymbol{\Sigma}_j^{(i)}$. Unfortunately (17) has no closed-form solution. However, we can first optimize over $\{\boldsymbol{\Gamma}_i\}$ with $\boldsymbol{W}$ fixed, and then optimize over $\boldsymbol{W}$ with $\{\boldsymbol{\Gamma}_i\}$ fixed, both of which have closed-form solutions. Although these updates could be iterated until convergence, the EM algorithm does not actually require full completion of both E and M steps. In fact partial minimization, or incremental variants, are adequate to ensure cost function descent (Neal & Hinton, 1999).[5]

For the $\{\boldsymbol{\Gamma}_i\}$ update, we can solve for each $\boldsymbol{\Gamma}_i$ independently via

$$\boldsymbol{\Gamma}_i^* = \arg\min_{\boldsymbol{\Gamma}_i} \mathrm{tr}\left[\Theta_i \boldsymbol{\Gamma}_i^{-1}\right] + n\log|\boldsymbol{\Gamma}_i| \;=\; \tfrac{1}{n}\Theta_i \quad (18)$$

where

$$\Theta_i = \sum_j \tfrac{1}{w_{ij}} \mathrm{tr}\left[\left(\boldsymbol{\mu}_j^{(i)}\left(\boldsymbol{\mu}_j^{(i)}\right)^\top + \boldsymbol{\Sigma}_j^{(i)}\right)\right]. \quad (19)$$

Likewise for $\boldsymbol{W}$ we can solve independently for each element using

$$w_{ij}^* = \arg\min_{\boldsymbol{\Gamma}_i} \beta_{ij} w_{ij}^{-1} + d\log w_{ij} \;=\; \tfrac{1}{d}\beta_{ij}, \quad (20)$$

where

$$\beta_{ij} = \mathrm{tr}\left[\left(\boldsymbol{\mu}_j^{(i)}\left(\boldsymbol{\mu}_j^{(i)}\right)^\top + \boldsymbol{\Sigma}_j^{(i)}\right)\boldsymbol{\Gamma}_i^{-1}\right]. \quad (21)$$

To summarize then, we need only iterate (11), (18), and (20) to descend the objective function (14). With some attention to details, this can be accomplished with updates that are linear in n and m, the number of points and clusters respectively), and cubic in d (ambient space dimension).

A final point worth addressing is initialization. Assuming complete agnosticism regarding subspaces and labels, the selection $\boldsymbol{\Gamma}_i = \boldsymbol{I}$ and $w_{ij} = 1$ for all i and j seems like the most natural choice. However, we require some small degree of symmetry breaking randomness to initiate a non-degenerate descent. We simply use $w_{ij} \sim 1 + \mathrm{U}\left[0, 10^{-3}\right]$ for all initializations, although results are not sensitive to this choice.

4 Cost Function Analysis

While perhaps counterintuitive, the proposed objective function (14) has a number of desirable attributes that justify its usage for latent subspace clustering. As motivation for this claim, it is helpful to map the arguments of (14) to a criterion of subspace optimality. More formally, we say that $\{\{\boldsymbol{\Gamma}_i^*\}, \boldsymbol{W}^*\}$ is a *subspace optimal solution* iff

1. For all $i = 1, \ldots, m$, span$[\boldsymbol{\Gamma}_i^*]$ equals some true $\mathcal{S}_k$, and no two $\boldsymbol{\Gamma}_i^*$ span the same subspace.
2. For all $j = 1, \ldots, n$, $\|\boldsymbol{w}_j^*\|_0 = 1$, with nonzero element aligned with the correct subspace.

Such a solution guarantees that an accurate estimate of $\boldsymbol{X}$ can be obtained via (11), and that the correct subspace labels will be recovered. The remainder of this section will quantify how such solutions relate to minima of (14).

To begin, using duality arguments from (Wipf et al., 2011), there is a close association between global minima of (4) and (14) in terms of the recovered subspaces and labels. However, none of this is suggestive of why we might prefer dealing with the latter over say, brute force combinatorial optimization of the former. For this purpose we need to actually describe conditions whereby (14) is more likely to produce subspace optimal solutions without getting stuck at local optimal. While it is quite challenging to address this situation in sweeping terms for such a coupled, non-convex probabilistic model, we will nonetheless describe at least one scenario where bad local optimal can be fully eradicated, followed by more general conditions whereby optimal non-increasing solution paths exist.

For convenience, let $\{\Omega_k^*\}$ denote the true partitioning of $\boldsymbol{X}$, aligned with the presumed generative subspace labels. We then have the following:

Theorem 1. *Suppose that we have a data matrix $\boldsymbol{X}$ which follows the model from (1), we observe the affine measurements $\boldsymbol{y}_j = \boldsymbol{A}_j\boldsymbol{x}_j$ for all j, and that the true latent $\boldsymbol{X}$ is such that $d_k = 1$ for all subspaces. Furthermore assume that $\{\boldsymbol{A}_j\}$ satisfies $p_j > 1$ for all j and $\cap_{j\in\Omega_k^*}$null$[\boldsymbol{A}_j] = \emptyset$ for all k. Then any local or global minimizer $\{\{\boldsymbol{\Gamma}_i^*\}, \boldsymbol{W}^*\}$ of (14) in the limit $\lambda \to 0$ is subspace optimal.*

At least in low-noise/stylized conditions, this result specifies a relatively broad regime whereby no suboptimal minima exist, meaning any minimizer (local or global) will always return the correct clustering as well as a unique basis spanning each true subspace.[6] And this result is emblematic of a wider range of operating circumstances whereby subspace optimal solutions are closely aligned with minima of (14). Certainly our empirical evidence provided in Sections 5 and 6 suggests this to be the case.

Interestingly though, neither of the naive approaches discussed in Section 1 can satisfy something similar. In fact,

[5] While technically these updates are guaranteed to reduce or leave-unchanged the objective function until a fixed point is reached, to formally guarantee convergence of the EM algorithm to a local minima requires additional effort, such as the demonstration that the conditions of Zangwill's Global Convergence Theorem have been satisfied (Zangwill, 1969). We do not pursue a detailed theoretical investigation to this effect here, although it is possible to do so.

[6] In the context of affine rank minimization and a single subspace, i.e., $m = 1$, it has been shown that under similar conditions no bad local minima will exist with a probabilistic PCA-like model (Xin & Wipf, 2015); however, this is a much simpler problem and the same analysis/proof techniques do not apply.

under the stated conditions of Theorem 1, (4) can have numerous suboptimal local minima, while (6) can have both suboptimal local and global minima, both of which can return incorrect labels and cluster bases.

Likewise, if we replace the rank function with the nuclear norm in (5), then even with all other theorem specifications in place, it is still possible that we recover the wrong estimate for $\boldsymbol{X}$ such that no correct clustering is possible via any secondary step. As an example, it is a simple matter to design adversarial conditions on $\boldsymbol{A}_j$ via simple transformations such as $\boldsymbol{A}_j \rightarrow \boldsymbol{A}_j\boldsymbol{D}$, where $\boldsymbol{D}$ is a diagonal scaling matrix to which the nuclear norm solution will be highly sensitive. And as stated previously, we cannot negate the impact of $\boldsymbol{D}$ via normalization without destroying the low-rank assumption with which estimating $\boldsymbol{X}$ is predicated on to begin with. Moreover, it is also possible to have a full rank $\boldsymbol{X}$ consistent with the setting of Theorem 1 such that it is formally unidentifiable even with (5) unaltered.

Moving forward, it is considerably more difficult to guarantee that no bad local minima exist under broader conditions, e.g., when $d_k > 1$. However, we can still analyze non-increasing paths between a family of initializations (or intermediate points in some optimization trajectory) and subspace optimal solutions. This simplified analysis criteria yields the following:

Theorem 2. *Suppose* $\sum_i w_{ij}\boldsymbol{\Gamma}_i = \alpha_j\boldsymbol{U}\boldsymbol{U}^\top$ *for all* j*, where* $\boldsymbol{U}$ *represents any orthonormal basis spanning* $\bigoplus_{k=1}^m \mathcal{S}_k$ *and each* $\alpha_j > 0$ *is a scalar weighting factor. Then in the limit* $\lambda \rightarrow 0$*, if each* α_j *is suitably large there exists a non-increasing path from this point to some subspace optimal solution* $\{\{\boldsymbol{\Gamma}_i^*\}, \boldsymbol{W}^*\}$.

Corollary 1. *In the simplified scenario when* $\boldsymbol{A}_j = \boldsymbol{I}$ *for all* j *(i.e., canonical subspace clustering where the latent* $\boldsymbol{X} = \boldsymbol{Y}$ *are now fully observable), Theorem 2 holds without any size restrictions on each* $\alpha_j > 0$.

Because we can always choose to initialize with $\boldsymbol{\Gamma}_i = \boldsymbol{I}$ for all i, or more generally $\boldsymbol{\Gamma}_i$ equal to some suitable $\boldsymbol{U}\boldsymbol{U}^\top$, then a byproduct of Theorem 2 is the insurance that a path exists from a computable point to the correct clustering that is devoid of local minima even when $\boldsymbol{W}$ is initialized arbitrarily. And this result can be generalized with additional effort to quantify a broader class of locations such that such paths to optimal solutions exist. Of course obviously a result of this type is still quite limited in that it does not guarantee that such a path can be found, or rule out the existence of saddle points along the way. But it is nonetheless another indicator of the appropriateness of (14) in addressing even basic subspace clustering problems for which it was not initially designed. And similar to previous arguments, neither of the naive approaches, i.e., solving either (4) or (6), can satisfy something similar.

5 Simulation Experiments

We now present illustrative synthetic experiments tailored to showcase generic abilities, with designs and dimensions inspired by (Soltanolkotabi & Candès, 2012; Yang et al., 2015).

5.1 Fully Observable Model

We begin by investigating the original subspace clustering problem where $\boldsymbol{Y} = \boldsymbol{X}$. In particular, we examine challenging conditions where there exists a significant degree of subspace overlap similar to an experimental design from (Soltanolkotabi & Candès, 2012). Data are generated as follows. Three subspaces of dimension $d_1 = d_2 = d_3 = 20$ are embedded in $\mathbb{R}^{25}$, each containing 50 data points. This is accomplished for each subspace by generating $\boldsymbol{X}_k = \boldsymbol{U}_k\boldsymbol{V}_k^\top$, where $\boldsymbol{U}_k \in \mathbb{R}^{25\times 20}$ and $\boldsymbol{V} \in \mathbb{R}^{50\times 20}$ have iid $\mathcal{N}(0,1)$ elements. With probability one the resulting $\boldsymbol{X}$ will be full rank with significantly overlapping subspace magisteria. We then normalize each column to have unit ℓ_2 norm, and apply the state-of-the-art ℓ_1-norm based subspace clustering mentioned in Section 1, denoted ℓ_1-SSC, to sort out subspace labels. This algorithm involves solving (2) with $\|\boldsymbol{Z}\|_1$ replacing $\|\boldsymbol{Z}\|_0$, forming the symmetric affinity matrix $|\hat{\boldsymbol{Z}}| + |\hat{\boldsymbol{Z}}^\top|$ using the estimated $\hat{\boldsymbol{Z}}$, followed by a separate spectral clustering step with knowledge of the true number of clusters m (Elhamifar & Vidal, 2013). For our algorithm we assign cluster labels based on the index of the largest value of each estimated $\boldsymbol{w}_j$ (typically though there is only a single entry significantly larger than zero when the clustering is successful); no spectral clustering heuristic is required.

We note however that by drawing the data using such iid Gaussian isotropic sources (as is typically done for experimental purposes), the data within each subspace will lack any significant structure or correlation, to which the ℓ_1 norm solution can be highly sensitive. Hence to deviate from the relatively easier, isotropic situation, we gradually experiment with increasing the degree of intra-subspace correlation by adding a rank-one component $\alpha\|\boldsymbol{U}_k\boldsymbol{V}_k^\top\|_2\boldsymbol{a}_k\boldsymbol{b}_k^\top$ to each subspace, where vectors $\boldsymbol{a}_k \in \mathbb{R}^{25\times 1}$ and $\boldsymbol{b}_k \in \mathbb{R}^{50\times 1}$ are also iid $N(0,1)$ and α is a non-negative scalar that weights the contribution.

Figure 1 displays the clustering errors (percentage of mislabeled points) for both ℓ_1-SSC and our method averaged over 10 trials. We observe that when the correlation parameter $\alpha = 0$, both methods perform well, but as soon as α begins increasing, the quality of ℓ_1-SSC solutions degrades significantly, unlike our algorithm which is stable across all values. Hence even when no latent affine structure or the twist is present (the fully observable case with $\boldsymbol{A}_j = \boldsymbol{I}$), minimizing (14) represents a principled objective function for subspace clustering.

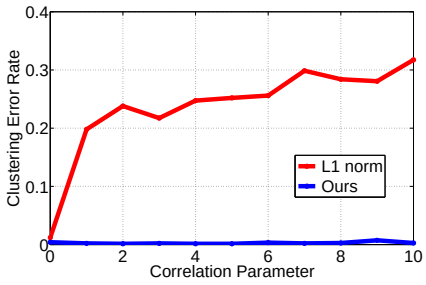

Figure 1: Comparisons using a fully-observable model as the within-subspace correlation is increased.

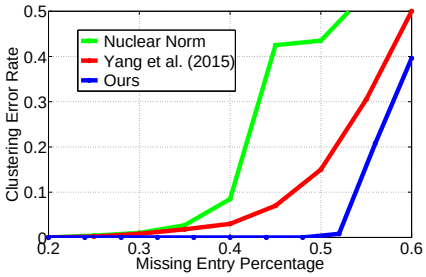

Figure 2: Comparisons using a partially-observable model as the number of missing entries is increased.

5.2 Missing Entries

Next we address the case were we have observed some $\boldsymbol{X}$ with a certain proportion of missing entries. As discussed in Section 1, this is equivalent to assuming that each $\boldsymbol{A}_j$ is a matrix of zeros with a single one per row. For this particular special case, (Yang et al., 2015) has proposed a modification of ℓ_1-SSC whereby missing entries are set to zero but partially compensated for using a special projection step.[7] Although this method cannot be extended to general $\{\boldsymbol{A}_j\}$, we can nonetheless evaluate our approach against this missing entry specialization. For this purpose, we select the most difficult clustering test from (Yang et al., 2015), whereby the latent $\boldsymbol{X}$ is full rank and the number of missing entries grows large.

Following (Yang et al., 2015), we generate $m = 5$ subspaces, each of dimension 5, embedded in $d = 25$ dimensional space. Next 50 points are drawn from each subspace using the same Gaussian factorization from above (and $\alpha = 0$). The fraction of missing entries is then gradually increased to test performance. Figure 2 displays the results, including a common baseline nuclear norm estimate of $\boldsymbol{X}$ followed by ℓ_1-SSC subspace clustering. Again we observe that, even without any spectral clustering step as used by others, our algorithm outperforms state-of-the-art existing approaches, including all variety of algorithms from (Yang et al., 2015) that were specifically designed for this problem.

5.3 General Affine Model

Finally, we consider our original motivating scenario where $\{\boldsymbol{A}_j\}$ can be arbitrary. To this end, we repeat the experiment from above, but with the binary sampling matrices replaced with elements of each $\boldsymbol{A}_j$ drawn iid from $\mathcal{N}(0,1)$. We also fix the number of measurements per point to $p_j = 15$ for each j; other dimensions remain unchanged.

[7] Actually (Yang et al., 2015) presents multiple approaches for handling missing entries, including another method from (Candès et al., 2014); however, we compare against the best performing variant among all of these.

Figure 3 explores the ability to recover the true latent $\boldsymbol{X}$ compared to the minimum nuclear norm solution, which represents the most viable existing alternative. We also tried minimizing (6); however, the results where quite poor (much worse than the nuclear norm solution) because of unavoidable convergence to local minima.

While the true number of clusters is $m = 5$, we vary the number of clusters assumed by our algorithm from $\hat{m} = 1, \ldots, 20$ and record the normalized MSE given by $\langle \|\boldsymbol{X} - \hat{\boldsymbol{X}}\|_{\mathcal{F}}^2 / \|\boldsymbol{X}\|_{\mathcal{F}}^2 \rangle$ averaged over 10 trials. Moreover, if we successfully recover $\boldsymbol{X}$ with $\hat{m} \neq m$, it is trivial to either fuse redundant clusters or split merged clusters using simple existing subspace clustering approaches to obtain labels if required.

Note that it is possible to exactly recover $\boldsymbol{X}$ with $\hat{m} \neq m$, provided $\hat{m}$ is sufficiently large such that $\boldsymbol{X}$ is identifiable. More specifically, to even have a chance of recovery for any possible algorithm, it must be the case that for all clusters k, the number of degrees-of-freedom in each associated low rank $\boldsymbol{X}_k$ (the points within cluster k) is less than the number of measurements of $\boldsymbol{X}_k$. For example, in the present case each $\boldsymbol{X}_k \in \mathbb{R}^{25 \times 50}$ has $5 \times (25 + 50) - 5^2 = 350$ degrees-of-freedom, and we have $\sum_{j \in \Omega_k} p_j = 15 \times 50 = 750$ measurements per subspace to work with (more than double the d.o.f.), which should be sufficient if $\hat{m} = 5$. However, when $\hat{m} < 5$, then two or more subspaces must be merged for estimation purposes leading to at least one $5 + 5 = 10$ dimensional subspace with $50 + 50 = 100$ points, and $10 \times (25 + 100) - 10^2 = 1150$ degrees-of-freedom, but only $15 \times 100 = 1500$ measurements. Even if we knew the true subspace labels, recovering $\boldsymbol{X}$ would still then be extremely challenging given how close the number of measurements are to the degrees-of-freedom.

But of course we still need to learn the labels as well, compounding the difficulty dramatically such that success by any possible algorithm is suspect. Therefore we should expect failure with $\hat{m} < 5$ on theoretical grounds, and indeed, from Figure 3 the error increases monotonically as $\hat{m}$ is decreased below 5. In contrast, for $\hat{m} > 5$, we observe that over-segmentation has minimal effect in disrupting the es-

timation of $\boldsymbol{X}$, and our algorithm has dramatically lower MSE than the nuclear norm solution; it only actually begins to rise appreciably for $\hat{m} > 17$. At this point presumably the large degree of superfluous over-segmentation may increase the risk of local minima as the parameter space becomes unnecessarily large.

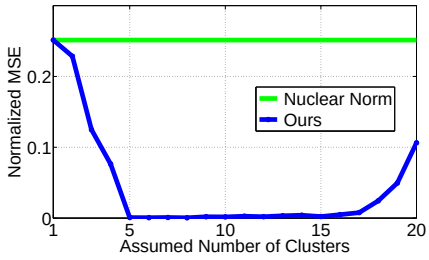

Figure 3: Comparisons using the general affine model as the number of assumed clusters is varied. Minimizing (6) led to a normalized MSE above 1.0 for all cases and initializations we tried (not shown).

6 Application Example: BRDF Estimation

One interesting application of the proposed method is surface reflectance reconstruction. Here surface reflectance simply refers to how a given surface reflects light. Moreover, if we have access to an accurate estimate, then we can compute exactly how a given object and material will appear under any lighting condition and viewing direction, which is extremely useful in many computer vision and graphics domains. From a technical standpoint, surface reflectance properties can be quantified by a spatially varying bi-directional reflectance distribution function (BRDF), which encodes the ratio between the *incoming* radiance from lighting direction θ_{in} and the *outgoing* radiance to the viewing direction θ_{out}, at each surface point j on some object or scene of interest. Although the BRDF represents an inherent property of the underlying materials, it is quite difficult to acquire since what we actually perceive from an object is jointly dependent on lighting conditions, viewing direction, and the BRDF itself.

More concretely, the observed outgoing radiance $y_j(\theta_{out})$ at direction θ_{out} can be expressed as the product of the surface BRDF $\rho_j(\theta_{out}, \theta_{in})$ at point j and the incoming radiance $r(\theta_{in})$ from direction θ_{in} integrated over all lighting directions $\mathcal{D}$, giving

$$y_j(\theta_{out}) = \int_{\mathcal{D}} \rho_j(\theta_{out}, \theta_{in}) r(\theta_{in}) d\theta_{in}. \quad (22)$$

Moreover, the surface reflectance of each surface pixel can be expressed, to close approximation, as a linear combination of basis functions via

$$\rho_j(\theta_{out}, \theta_{in}) = \sum_{i=1}^{21} x_{ij} \rho_i(\theta_{out}, \theta_{in}), \quad (23)$$

where $\boldsymbol{x}_j = [x_{1j}, \ldots, x_{21j}]^\top$ are weights and each $\rho_i(\theta_{out}, \theta_{in})$ represents a Cook-Torrance BRDF basis function for $i \in \{1, \ldots, 20\}$ and a Lambertian reflectance function for $i = 21$ (Lawrence et al., 2006; Dong et al., 2010; Chen et al., 2014). Combining with (22) this yields

$$y_j(\theta_{out}) = \sum_{i=1}^{21} x_{ij} \int_{\mathcal{D}} \rho_i(\theta_{out}, \theta_{in}) r(\theta_{in}) d\theta_{in}. \quad (24)$$

With known lighting conditions and incoming radiance $r(\theta_{in})$, and the fixed known basis $\rho_i(\theta_{out}, \theta_{in})$, the integral components of (24) can be pre-computed. Additionally, measurements from multiple viewing directions can be packed into the vector $\boldsymbol{y}_j = [y_j(\theta_{out_1}), \ldots, y_j(\theta_{out_p})]^\top$ for each point j, and the corresponding integrals of the basis function can also be packed similarly in to a matrix $\boldsymbol{A}_j$ with $(A_j)_{ti} = \int_{\mathcal{D}} \rho_i(\theta_{out_t}, \theta_{in}) r(\theta_{in}) d\theta_{in}$, producing the affine model $\boldsymbol{y}_j = \boldsymbol{A}_j \boldsymbol{x}_j$, which is of course equivalent to (3). Note that both the viewing and lighting directions are defined in local coordinates of the surface point j, and therefore the transformation $\boldsymbol{A}_j$ will necessarily change with pixel position.

The estimation goal is to recover each latent weight vector $\boldsymbol{x}_j$ for all j, from which we can compute the BRDF using (23). Here we make the reasonable assumption that at any given location, the number of unknown materials is limited to a small number, consistent with many real-world objects (in fact, it is quite common that only a single material may be present in many object regions). Moreover, given that the BRDF of each unknown base material can be closely approximated using (23) with a fixed weight vector for each material, it follows that the corresponding unknown weights $\boldsymbol{x}_j$ will each lie in a union of low-dimensional subspaces, conforming with the proposed subspace clustering model (Lawrence et al., 2006; Dong et al., 2010; Chen et al., 2014).

We test our algorithm as follows. Data acquisition is accomplished using physically-based path-tracing (Wenzel, 2010; Pharr & Humphreys, 2010), which accurately reproduces the physical capturing process. Importantly, this gains us access to the ground-truth such that quantitative comparisons are possible. We prepare two datasets to evaluate the performance of the proposed algorithm, one *checker* dataset, which consists of four different materials positioned in a checker-board pattern, and one *blend* dataset, that has four representative materials and each surface point represents a blending between two of the four possible materials. In both cases we mapped the materials onto a sphere with known geometry comprised of a total of $n = 104074$ points. The lighting was produced using the *Grace Cathedral* environment map (Debevec & Malik, 1997). Finally, we capture images of the object under 5 different view directions, resulting in 5 observations per visible surface point for a total of $5 \times n = 520370$ measurements. We compare our algorithm against a similar frame-

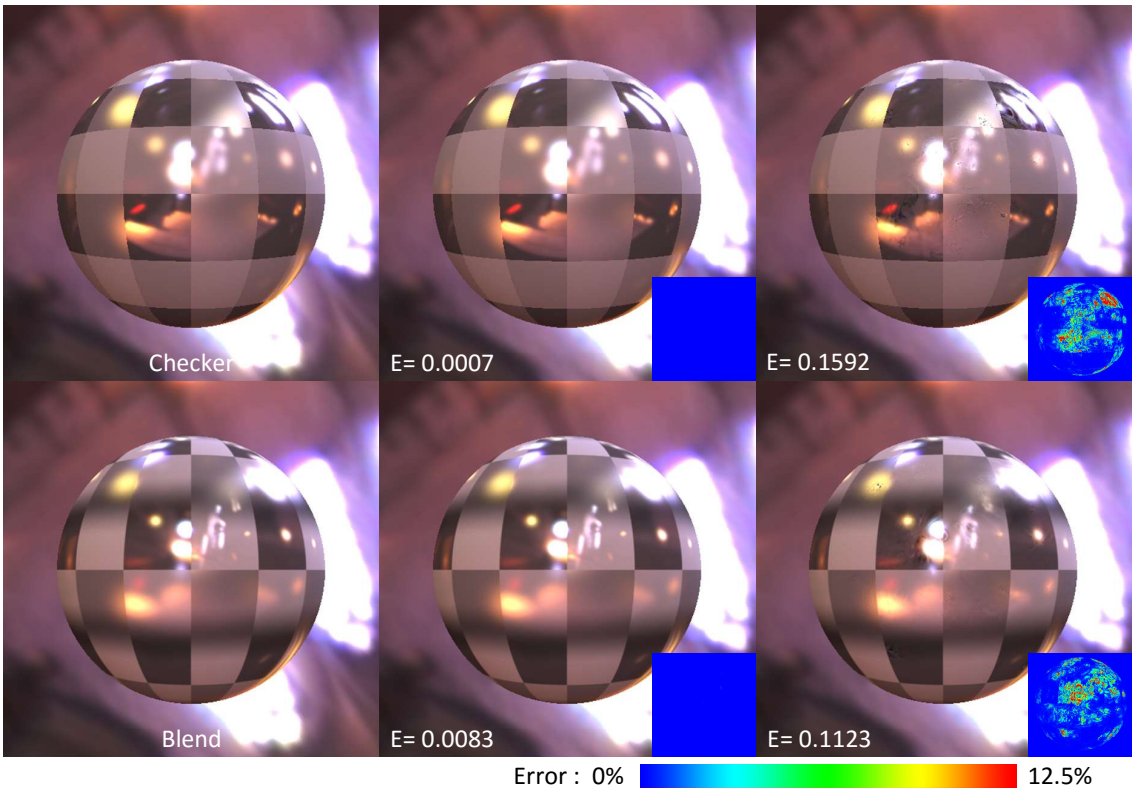

Figure 4: Spatially-varying BRDF reconstruction results. *Left column:* Ground truth reference under novel environmental lighting. *Middle column:* Rendering using our model. *Right column:* Rendering using the nuclear norm. Normalized MSE and difference maps are also included as an insert for both algorithms. Rendering errors best viewed by zooming.

work built upon the nuclear norm (Chen et al., 2014).

Figure 4 compares the renderings based on the reconstructed BRDFs under novel environmental lighting conditions (not those used to actually learn the BRDFs). We observe that with only 5 measurements per surface point, we can accurately reconstruct the BRDF without producing any visual artifacts. On the contrary, when using the nuclear norm Chen et al. (2014), the limited measurements cannot produce an accurate reconstruction and visual artifacts are clearly evident (zoom in for better viewing). The problem is compounded by the fact that the measurement matrices $\{\boldsymbol{A}_j\}$ are highly ill-conditioned as indicated by Figure 5, which displays the singular values of each $\boldsymbol{A}_j$ averaged across all j as compared to those from ideal matrices sampled iid from $\mathcal{N}(0,1)$. The nuclear norm is quite sensitive to this distinction which likely accounts, at least in part, for its poor performance. Note that accurate reconstruction from few measurements is a crucial ingredient of practical, inexpensive systems because it implies that fewer cameras are needed and/or a shorter acquisition time.

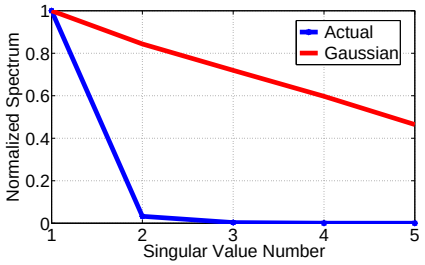

Figure 5: Singular values averaged across all $\boldsymbol{A}_j$ used in the BRDF estimation experiments. Ideal Gaussian data of equivalent dimensions is included for comparison. A fast singular value decay can be highly disruptive to nuclear-norm-based recovery algorithms.

7 Conclusions

In this paper we have introduced a practically-relevant, affine twist into the standard subspace clustering pipeline. We then derived a new, Bayesian-inspired algorithm that accounts for this added confound when necessary, while still defaulting to a principled state-of-the-art approach when deployed on existing segmentation problems with fully observable data, or when missing entries are present. Our framework, which does not require the typical spectral clustering post-processing step, is supported both by theoretical arguments and a large-scale, real-world application involving BRDF estimation and subsequent rendering.

Bayesian Estimators As Voting Rules

Lirong Xia
Rensselaer Polytechnic Institute
Troy, NY, USA
xial@cs.rpi.edu

Abstract

We investigate the fairness of Bayesian estimators (BEs) by viewing them as (irresolute) voting rules and evaluating them by satisfaction of desirable social choice axioms. We characterize the class of BEs that satisfy *neutrality* by the class of BEs with neutral structures. We prove that a BE with a neutral structure is a minimax rule if it further satisfies *parameter connectivity*. We prove that no BE satisfies *strict Condorcet criterion*. We also propose three new BEs of natural frameworks and investigate their computational complexity and satisfaction of *monotonicity* and *Condorcet criterion*.

1 INTRODUCTION

Bayesian estimators have been widely applied in rank aggregation. For example, IMDb uses Bayesian estimators to aggregate users' votes to create the top-250 movie list [2]. However, users have complaint that such mechanisms are "unfair" because the rank of a seemingly good film is not high [1]. While this particular complaint may not be hard to address, ideally we would like to use a fair rank aggregation method with high statistical efficiency. This raises the following important questions.

Q1. How can we measure fairness in rank aggregation?

Q2. How can we design fair Bayesian estimators?

Same questions arise in many other rank aggregation situations, especially those where the voting agents are human beings. For example, in political domains, important public decisions are made by aggregating citizens' votes; in low-stakes voting scenarios, friends vote to decide the place for dinner; in crowdsourcing, online workers' noisy answers are aggregated to estimate the correct answer [22].

Q1 has been partially answered by social choice theory. Following Arrow's celebrated impossibility theorem [4], various kinds of measures on fairness, called *axioms*, have been formulated and used to evaluate voting rules in political elections. For example, the *anonymity* axiom states that the voting rule is insensitive to permutations over agents' votes, which can be seen as fairness for voters; *neutrality* is a fairness condition for the alternatives; and *Condorcet criterion* (informally) states that an obviously socially strong alternative should win, which is similar in spirit to the complaint by the IMDb user. The axiomatic approach has gone beyond political elections to e.g. ranking systems [3], recommender systems [25], and community detection [9].

While there has been a growing literature on statistical properties of commonly studied voting rules, there is little work in the reverse direction, i.e. studying the satisfaction of social choice axioms for commonly studied statistical estimators, especially Bayesian estimators. Recently Azari Soufiani et al. [7] proposed a statistical decision-theoretic framework (framework for short) to obtain new voting rules as Bayesian estimators, and investigated the satisfaction of some axioms for two Bayesian estimators. To the best of our knowledge, there is no general characterizations of social choice axioms for Bayesian estimators.

Our Contributions. We study the satisfaction of axioms for Bayesian estimators (BEs) under the framework proposed by Azari Soufiani et al. [7]. We answer Q2 for two well-studied axioms: *neutrality* and *strict Condorcet criterion*. We characterize BEs that satisfy neutrality by the BEs of *neutral* frameworks. Therefore, to design neutral BEs we only need to focus on neutral frameworks. We also prove that no BE satisfies strict Condorcet criterion.

In addition, we prove that if a neutral framework satisfies *parameter connectivity*, then its BE is a minimax rule, which means that the BE is optimal w.r.t. the worst-case frequentist expected loss. We believe that this result is of independent interest.

We also analyze the satisfaction of *Condorcet criterion*, *monotonicity*, and computational complexity for four classes of BEs. Each BE in each class is identified by a

	Anonymity	Strict Condorcet	Neutrality	Minimax	Condorcet	Monotonicity	Comp.
BEs	Y (trivial)	N (Thm. 4)	Y/N	Y/N	Y/N	Y/N	P/NP-hard
$f^{\text{Top}}_{\text{Ma},\varphi}$			Y (Thm. 2)	Y (Thm. 1)	Y iff $\frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \leq 1$ (Thm. 5)	Y [5]	NP-hard [25]
$f^{\text{Borda}}_{\text{Co},\varphi}$					Y iff $\varphi \leq \frac{1}{m-1}$ (Thm. 7)	Y (Prop. 1)	P (Thm. 6)
$f^{1}_{\text{Pair},\varphi}$					Y iff $\varphi \leq \frac{1}{m-1}$ (Thm. 10)	Y (Prop. 2)	P (Thm. 9)
$f^{2}_{\text{Pair},\varphi}$					N (Thm. 10)		

Table 1: Main results. m is the number of alternatives.

dispersion value $0 < \varphi < 1$. The first class has been studied [30, 27, 7] while the remaining three classes are new. The four classes are (1) $f^{\text{Top}}_{\text{Ma},\varphi}$ is the BE of Mallows' model with the top loss function. Condorcet criterion has been studied for $f^{\text{Top}}_{\text{Ma},\varphi}$ for $\varphi > \frac{1}{\sqrt{2}}$ but the remaining cases are open [7][1]. (2) $f^{\text{Borda}}_{\text{Co},\varphi}$ is the BE of Condorcet's model with the Borda loss function. (3) $f^{1}_{\text{Pair},\varphi}$ and (4) $f^{2}_{\text{Pair},\varphi}$ are the BEs of a new model with different loss functions, where a parameter can be interpreted as the "strongest pairwise comparison". Our results are summarized in Table 1.

The second row in Table 1 are results for general BEs. A "Y/N" means that some Bayesian estimators satisfy the axiom and some do not. For $f^{\text{Top}}_{\text{Ma},\varphi}$, we prove a dichotomy theorem on its satisfaction of Condorcet criterion: it satisfies the Condorcet criterion if and only if $\frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \leq 1$, where m is the number of alternatives (Theorem 5). We also proved similar dichotomy theorems for $f^{\text{Borda}}_{\text{Co},\varphi}$ and $f^{1}_{\text{Pair},\varphi}$, where the threshold is $\frac{1}{m-1}$ (Theorem 7 and 10). We would like to highlight two new classes of BEs: $f^{\text{Borda}}_{\text{Co},\varphi}$ and $f^{1}_{\text{Pair},\varphi}$, because they can satisfy all axioms studied in this paper (except strict Condorcet criterion, which is not satisfied by any BE) and can be computed in polynomial time.

In addition to satisfaction of axioms, we also study the limiting cases of the three new BEs as $\varphi \to 0$ and $\varphi \to 1$. While all classes converge to refinements of the Borda rule as $\varphi \to 1$, they converge to refinements of different rules as $\varphi \to 0$. Interestingly, $f^{\text{Borda}}_{\text{Co},\varphi}$ converges to a refinement of Copeland$_{0.5}$ (Theorem 8) and for any $\varphi \leq \frac{1}{m-1}$, $f^{1}_{\text{Pair},\varphi}$ is a refinement of maximin (Theorem 11).

Related Work and Discussions. As discussed above our theorems on neutrality and strict Condorcet criterion answer Q2 for the two axioms. We are not aware of other general results on satisfaction of axioms for Bayesian estimators. In particular, Azari Soufiani et al. [7] studied the satisfaction of some axioms for two classes of BEs but did not obtain general results for BEs.

[1]The original paper has a typo on the direction of the inequality.

Most previous work at the intersection of social choice and statistics focused on computational aspects of the *maximum likelihood estimators (MLEs)* of various ranking models [14, 10, 15, 17, 29, 20, 24, 27, 5, 6, 16, 19]. The focuses of our work are different. We focus on Bayesian estimators, which are more general than MLEs, and we focus on the satisfaction of axioms rather than computation.

Minimax rules for various statistical models with continuous parameter spaces have been characterized by Berger [8]. Choirat and Seri [12] provided a sufficient condition on discrete-parameter models for MLEs to be minimax. In the social choice context, Caragiannis et al. [11] proved that the uniformly randomized MLE has the least sample complexity w.r.t. Mallows' model, which is equivalent to minimaxity. Our minimaxity proof can be seen as an application of techniques by Berger [8] to social choice frameworks. As we will see in Corollary 1, our results can be easily applied to Mallows' model and other models.

Our work is also related to statistical justification of commonly studied voting rules. Conitzer and Sandholm [14] studied whether some commonly studied voting rules can be rationalized as MLEs of some statistical models. They showed that if a voting rule does not satisfy *consistency*, then it cannot be an MLE. Pivato [26] further investigated voting rules that can be viewed as MLEs, maximum a posteriori estimators, and Bayesian estimators. Our impossibility theorem on strict Condorcet criterion can be used to prove that a voting rule *cannot* be justified a Bayesian estimator. In Corollary 2, we show that a number of voting rules including Copeland$_1$ and maximin are not Bayesian estimators. On the other hand, we prove that as $\varphi \to 0$, $f^{\text{Borda}}_{\text{Co},\varphi}$ converges to a refinement of Copeland$_{0.5}$ (Theorem 8), and for all for any $\varphi < \frac{1}{m-1}$, $f^{1}_{\text{Pair},\varphi}$ is a refinement of maximin (Theorem 11). Therefore, $f^{1}_{\text{Pair},\varphi}$ for $\varphi < \frac{1}{m-1}$ are desirable refinements of maximin because they can be justified as BEs. Previously it was only known that a refinement of Kemeny is a BE [27] and a refinement of Tideman's rule is a BE [16].

2 PRELIMINARIES

Let $\mathcal{A} = \{a_1, \ldots, a_m\}$ denote a set of m *alternatives* and let $\mathcal{L}(\mathcal{A})$ denote the set of all linear orders over $\mathcal{A}$. Let n denote the number of agents. Each agent's vote is a linear order in $\mathcal{L}(\mathcal{A})$. The collection P of all agents' votes is called a *profile*. An *irresolute voting rule* r maps each profile to a non-empty set of winning alternatives. That is, $r : \bigcup_{n=1}^{\infty} \mathcal{L}(\mathcal{A})^n \to (2^{\mathcal{A}} \setminus \{\emptyset\})$.

For example, an irresolute *positional scoring rule* is characterized by a scoring vector $\vec{s} = (s_1, \ldots, s_m)$ with $s_1 \geq s_2 \geq \cdots \geq s_m$. For any alternative a and any linear order V, we let $\vec{s}(V, a) = s_j$, where j is the rank of a in V. Given a profile P, an irresolute positional scoring rule chooses all alternatives a with maximum $\sum_{V \in P} \vec{s}(V, a)$, where P is viewed as a multi-set of votes. The Borda rule is a positional scoring rule with $\vec{s} = (m-1, m-2, \ldots, 1)$.

For any profile P and any pair of alternatives a, b, we let $P(a \succ b)$ denote the number of votes in P where a is preferred to b. The *weighted majority graph* of P, denoted by $\mathrm{WMG}(P)$ is a directed weighted graph where the weight $w_P(a, b)$ on any edge $a \to b$ is $w_P(a, b) = P(a \succ b) - P(b \succ a)$. Clearly $w_P(a, b) = -w_P(b, a)$.

Given $0 \leq \alpha \leq 1$, the Copeland$_\alpha$ score of an alternative a in a profile P is the number of alternatives beaten by a in head-to-head competitions plus α times the alternatives tied with a. Copeland$_\alpha$ chooses all alternatives with the maximum Copeland$_\alpha$ score as the winners. The *maximin* rule chooses all alternatives a with the maximum *min-score*. The min-score of a is $\min_b w_P(a, b)$.

We will focus on the following axioms in this paper. An irresolute r satisfies

• *anonymity*, if r is insensitive to permutations over agents;

• *neutrality*, if r is insensitive to permutations over alternatives;

• *monotonicity*, if for any P, any $a \in r(P)$, and any P' that is obtained from P by only raising the positions of a, we have $a \in r(P')$;

• *Condorcet criterion*, if for any profile P, whenever a *Condorcet winner* a exists, it must be the unique winner. That is, $r(P) = \{a\}$. A Condorcet winner is an alternative that beats all other alternatives in their head-to-head competitions;

• *strict Condorcet criterion [18]*, if for any profile P, whenever the set of *weak Condorcet winners* is non-empty, it must be the output of r. A weak Condorcet winner is an alternative that never loses to any other alternative in their head-to-head competition.

Azari Soufiani et al. [7] defined a *statistical decision-theoretic framework for social choice* (*framework* for short) to be a tuple $\mathcal{F} = (\mathcal{M}_{\mathcal{A}}, \mathcal{D}, L)$, where $\mathcal{A}$ is the set of alternatives, $\mathcal{M}_{\mathcal{A}} = (\Theta, \vec{\pi})$ is a parametric ranking model, $\mathcal{D}$ is the decision space, and $L : \Theta \times \mathcal{D} \to \mathbb{R}$ is a loss function. $\mathcal{M}_{\mathcal{A}} = (\Theta, \vec{\pi})$ has two parts: a *parameter space* Θ and a set of probability distributions $\vec{\pi} = \{\pi_\theta : \theta \in \Theta\}$ over $\mathcal{L}(\mathcal{A})$. Agents' votes are generated i.i.d. according to $\mathcal{M}_{\mathcal{A}}$, which means that the sample space is $\mathcal{L}(\mathcal{A})^n$ and is omitted for simplicity. In this paper we focus on frameworks with finite parameter spaces and finite decision spaces.

We now recall two popular parametric ranking models. For any pair of linear orders V, W in $\mathcal{L}(\mathcal{A})$, let $\mathrm{Kd}(V, W)$ denote the *Kendall-tau distance* between V and W, which is the total number of pairwise disagreements between V and W.

Definition 1 (Mallows' model with fixed dispersion [21])**.** *Given $0 < \varphi < 1$, the* Mallows model with fixed dispersion φ *is denoted by $\mathcal{M}_{Ma,\varphi} = (\mathcal{L}(\mathcal{A}), \vec{\pi})$, where the parameter space is $\mathcal{L}(\mathcal{A})$ and for any $V, W \in \mathcal{L}(\mathcal{A})$, $\pi_W(V) = \frac{1}{Z}\varphi^{Kd(V,W)}$, where Z is the normalization factor with $Z = \sum_{V \in \mathcal{L}(\mathcal{A})} \varphi^{Kd(V,W)}$.*

Let $\mathcal{B}(\mathcal{A})$ denote the set of all irreflexive, antisymmetric, and total binary relations over $\mathcal{A}$. We have $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{B}(\mathcal{A})$ and the Kendall-tau distance can be easily extended to $\mathcal{B}(\mathcal{A})$ by counting the number of pairwise disagreements.

Definition 2 (Condorcet's model [13, 30])**.** *Given $0 < \varphi < 1$, the* Condorcet model *is denoted by $\mathcal{M}_{Co,\varphi} = (\mathcal{B}(\mathcal{A}), \vec{\pi})$, where the parameter space is $\mathcal{B}(\mathcal{A})$ and for any $W \in \mathcal{B}(\mathcal{A})$ and $V \in \mathcal{L}(\mathcal{A})$, $\pi_W(V) = \frac{1}{Z}\varphi^{Kd(V,W)}$, where Z is the normalization factor.*

Next, we give three examples of loss functions. When $\Theta = \mathcal{D}$, the 0-1 *loss function*, denoted by $L_{0\text{-}1}(\theta, d)$, outputs 0 if $\theta = d$, otherwise it outputs 1. When $\mathcal{D} = \mathcal{A}$ and Θ is $\mathcal{L}(\mathcal{A})$ or $\mathcal{B}(\mathcal{A})$, the *top loss function*, denoted by $L_{\text{top}}(\theta, d)$, outputs 0 if for all other alternatives $c \in \mathcal{A}$, $d \succ c$ in θ, otherwise it outputs 1. The *Borda loss function*, denoted by $L_{\text{Borda}}(\theta, d)$, outputs the number of alternatives that are preferred to d in θ, that is, $L_{\text{Borda}}(\theta, d) = \#\{c \in \mathcal{A} : c \succ_\theta d\}$. All loss functions can be naturally generalized to evaluate a subset D of $\mathcal{D}$ by computing the average loss of the decisions in D. More precisely, for any $D \subseteq \mathcal{D}$ and any $\theta \in \Theta$, we let $L(\theta, D) = \sum_{d \in D} L(\theta, d)/|D|$.

Given a framework $\mathcal{F}$, the *Bayesian expected loss* of $d \in \mathcal{D}$ given a profile P is $\mathrm{EL}_{\mathcal{F}}(d|P) = \sum_{\theta \in \Theta} \Pr(\theta|P) L(\theta, d)$. The subscript $\mathcal{F}$ is often omitted without introducing confusions. In this paper we focus on the uniform prior. The *Bayesian estimator* of $\mathcal{F}$, denoted by $\mathrm{BE}_{\mathcal{F}}$, takes a profile P as input and outputs all decisions with minimum expected Bayesian loss. That is, $\mathrm{BE}_{\mathcal{F}}(P) = \arg\min_{d \in \mathcal{D}} \mathrm{EL}(d|P)$.

Let $f^{\text{Top}}_{\text{Ma},\varphi}$ denote the Bayesian estimator of the framework $(\mathcal{M}_{\text{Ma},\varphi}, L_{\text{top}})$. It was proved by Azari Soufiani et al. [7] that $f^{\text{Top}}_{\text{Ma},\varphi}$ satisfy anonymity, neutrality, monotonicity, but fails to satisfy the Condorcet criterion for some φ. Let $f^{\text{Borda}}_{\text{Co},\varphi}$ denote the Bayesian estimator of the framework $(\mathcal{M}_{\text{Co},\varphi}, L_{\text{Borda}})$. We will study the satisfaction of axioms

for $f^{\text{Borda}}_{\text{Co},\varphi}$.

Given a framework $\mathcal{F}$, a parameter $\theta \in \Theta$, $n \in \mathbb{N}$, and a voting rule r, the *frequentist loss* $\text{FL}_n(\theta, r)$ is the expected loss of the output of r against θ for randomly generated profiles of n votes. More precisely,

$$\text{FL}_n(\theta, r) = \sum_{P_n \in \mathcal{L}(\mathcal{A})^n} \pi_\theta(P_n) L(\theta, r(P_n))$$

Definition 3 ([8])**.** *Given a framework $\mathcal{F} = (\mathcal{M}_\mathcal{A}, \mathcal{D}, L)$, a voting rule r is* minimax*, if $r \in \arg\min_{r^*} \max_{\theta \in \Theta} FL_n(\theta, r^*)$.*

That is, a minimax rule minimizes the worst-case frequentist loss among all deterministic or randomized rules. Minimaxity is an important statistical criteria for decision functions—a minimax rule is the most robust rule against the adversarial nature who controls the true state of the world (the parameter). A minimax rule can be seen as having the minimum *sample complexity* [11].

3 NEUTRAL FRAMEWORKS AND MINIMAXITY

We first define the neutrality of a framework for general decision spaces. Intuitively, a framework $\mathcal{F} = (\mathcal{M}_\mathcal{A}, \mathcal{D}, L)$ is neutral if and only all of its three components are neutral w.r.t. permutations σ over $\mathcal{A}$. Because σ may not be well-defined for the parameter space and the decision space, we require the existence of homomorphisms from the permutation group over $\mathcal{A}$ to the permutation groups over Θ and $\mathcal{D}$, respectively. Formally, we have the following definition.

Definition 4. *A framework $\mathcal{F} = (\mathcal{M}_\mathcal{A}, \mathcal{D}, L)$ where $\mathcal{M}_\mathcal{A} = (\Theta, \vec{\pi})$ is* neutral*, if each permutation σ over $\mathcal{A}$ is mapped to a permutation σ_Θ over Θ and a permutation $\sigma_\mathcal{D}$ over $\mathcal{D}$ that satisfy the following conditions.*

(i) Homomorphism. *For any pair of permutations γ and β over $\mathcal{A}$, $(\gamma \circ \beta)_\Theta = \gamma_\Theta \circ \beta_\Theta$ and $(\gamma \circ \beta)_\mathcal{D} = \gamma_\mathcal{D} \circ \beta_\mathcal{D}$.*

(ii) Model neutrality. *For any $\theta \in \Theta$, any $V \in \mathcal{L}(\mathcal{A})$, and any permutation σ over $\mathcal{A}$, we have $\pi_\theta(V) = \pi_{\sigma_\Theta(\theta)}(\sigma(V))$.*

(iii) Loss function neutrality. *For any $\theta \in \Theta$, any $d \in \mathcal{D}$, and any permutation σ over $\mathcal{A}$, we have $L(\theta, d) = L(\sigma_\Theta(\theta), \sigma_\mathcal{D}(d))$.*

Example 1. *For any $0 < \varphi < 1$, $(\mathcal{M}_{Ma,\varphi}, \mathcal{A}, L_{top})$, $(\mathcal{M}_{Ma,\varphi}, \mathcal{A}, L_{Borda})$, $(\mathcal{M}_{Co,\varphi}, \mathcal{A}, L_{top})$, $(\mathcal{M}_{Co,\varphi}, \mathcal{A}, L_{Borda})$ are neutral, where $\sigma_\Theta = \sigma_\mathcal{D} = \sigma$.*

The main theorem of this section states that if a neutral framework further satisfies the following connectivity condition, then its Bayesian estimator is a minimax rule.

(iv) Parameter connectivity. For any pair $\theta_1, \theta_2 \in \Theta$, there exists a permutation σ over $\mathcal{A}$ such that $\sigma_\Theta(\theta_1) = \theta_2$.

Theorem 1. *For any neutral framework $\mathcal{F}$ that satisfies parameter connectivity and any $n \in \mathbb{N}$, $BE_\mathcal{F}$ is a minimax rule.*[2]

Proof: Any deterministic Bayesian estimator $\text{BE}_\mathcal{F}$ can be seen as a randomized rule that chooses a single decision uniformly at random from the output of $\text{BE}_\mathcal{F}$. Our proof is based on the following lemma.

Lemma 1 (Section 5.3.2 III in [8])**.** *Given a framework $\mathcal{F}$. Let r_{π^*} denote a Bayesian estimator for prior π^*. If $FL_n(\theta, r_{\pi^*})$ are equal for all $\theta \in \Theta$, then r_{π^*} is minimax.*

Let r_U denote the randomized decision rule that outputs all decisions with the minimum Bayesian expected loss uniformly at random. By Lemma 1, it suffices to show that for all $\theta \in \Theta$, $\text{FL}_n(\theta, r_U)$ are equal. For any pair of parameters $\theta_1, \theta_2 \in \Theta$, we let $\sigma^{(\theta_1,\theta_2)}$ denote a permutation over $\mathcal{A}$ such $\sigma_\Theta^{(\theta_1,\theta_2)}(\theta_1) = \theta_2$, which is guaranteed by Condition (iv).

Claim 1. *For any profile P of n votes and any $d^* \in \mathcal{D}$, $r_U(P)(d^*) > 0$ if and only if $r_U(\sigma^{(\theta_1,\theta_2)}(P))(\sigma_\mathcal{D}^{(\theta_1,\theta_2)}(d^*)) > 0$.*

Proof: To simplify the notation, in this proof we let σ^* denote $\sigma^{(\theta_1,\theta_2)}$. $r_U(P)$ has positive probability on d^* if and only if d^* minimizes the Bayesian loss at P under uniform prior, which is equivalent to requiring that for all $d' \in \mathcal{D}$, $\sum_\theta L(\theta, d^*) \Pr(\theta|P) \leq \sum_\theta L(\theta, d') \Pr(\theta|P)$. We have the following calculation, where $\Pr(P|\theta) = \pi_\theta(P)$.

$$\begin{aligned}
&\sum_\theta L(\theta, d^*) \Pr(\theta|P) \leq \sum_\theta L(\theta, d') \Pr(\theta|P) \\
\Leftrightarrow\ &\sum_\theta L(\theta, d^*) \Pr(P|\theta) \leq \sum_\theta L(\theta, d') \Pr(P|\theta) \quad (1) \\
\Leftrightarrow\ &\sum_\theta L(\sigma^*_\Theta(\theta), \sigma^*_\mathcal{D}(d^*)) \Pr(\sigma^*(P)|\sigma^*_\Theta(\theta)) \\
&\quad \leq \sum_\theta L(\sigma^*_\Theta(\theta), \sigma^*_\mathcal{D}(d')) \Pr(\sigma^*(P)|\sigma^*_\Theta(\theta)) \quad (2) \\
\Leftrightarrow\ &\sum_\theta L(\theta, \sigma^*_\mathcal{D}(d^*)) \Pr(\sigma^*(P)|\theta) \\
&\quad \leq \sum_\theta L(\theta, \sigma^*_\mathcal{D}(d')) \Pr(\sigma^*(P)|\theta) \quad (3) \\
\Leftrightarrow\ &\sum_\theta L(\theta, \sigma^*_\mathcal{D}(d^*)) \Pr(\theta|\sigma^*(P)) \\
&\quad \leq \sum_\theta L(\theta, \sigma^*_\mathcal{D}(d')) \Pr(\theta|\sigma^*(P)) \quad (4)
\end{aligned}$$

Therefore, d^* minimizes the Bayesian loss for P if and only if $\sigma^*_\mathcal{D}(d^*)$ minimizes the Bayesian loss for $\sigma^*(P)$, which means that $r_U(\sigma^*(P))$ has positive probability on $(\sigma^*_\mathcal{D}(d^*))$. (1) and (4) are due to Bayes' rule and the uniform prior assumption. (2) is obtained from applying σ^*, σ^*_Θ, and $\sigma^*_\mathcal{D}$ on both sides of the inequality and then considering the neutrality of the framework. (3) is a change of

[2] A similar result was presented at COMSOC-14 workshop [28].

variable names, which is possible because for any pair of parameters $\theta \neq \theta'$ and any permutation σ over $\mathcal{A}$, we must have $\sigma_\Theta(\theta) \neq \sigma_\Theta(\theta')$, because σ_Θ is a permutation over Θ. □

We note that r_U chooses a decisions d with $r_U(P)(d) > 0$ uniformly at random. Therefore, by Claim 1, for any $\theta_1 \neq \theta_2$ and any profile P, we have $r_U(\sigma^{(\theta_1,\theta_2)}(P)) = \sigma_{\mathcal{D}}^{(\theta_1,\theta_2)}(r_U(P))$. By neutrality of $\mathcal{F}$, we have $L(\theta_1, r_U(P)) = L(\sigma_\Theta^{(\theta_1,\theta_2)}(\theta_1), \sigma_{\mathcal{D}}^{(\theta_1,\theta_2)}(r_U(P))) = L(\theta_2, r_U(\sigma^{(\theta_1,\theta_2)}(P)))$.

Finally, we have:

$$\begin{aligned}&\mathrm{FL}_n(\theta_1, r_U) = \sum_P L(\theta_1, r_U(P)) \Pr(P|\theta_1)\\ =&\sum_P L(\theta_2, r_U(\sigma^{(\theta_1,\theta_2)}(P))) \Pr(\sigma^{(\theta_1,\theta_2)}(P)|\theta_2)\\ =&\mathrm{FL}_n(\theta_2, r_U)\end{aligned}$$

By Lemma 1, r_U is a minimax rule. We note that for any θ and any profile P, $L(\theta, r_U(P)) = L(\theta, \mathrm{BE}_{\mathcal{F}}(P))$. This means that $\mathrm{BE}_{\mathcal{F}}$ is a minimax rule. □

It is not hard to verify that all models mentioned in Example 1 satisfy parameter connectivity. Therefore, their Bayesian estimators are minimax rules. In particular, $f^{\text{Top}}_{\text{Ma},\varphi}$ is a minimax rule for $(\mathcal{M}_{\text{Ma},\varphi}, L_{\text{Top}})$. When the 0-1 loss function is used, the Bayesian estimator becomes *maximum likelihood estimator (MLE)*. Therefore, Theorem 1 immediately implies that MLE is minimax.

Corollary 1. *For any neutral framework $\mathcal{F} = (\mathcal{M}_\mathcal{A}, \mathcal{A}, L_{0\text{-}1})$, its MLE (that outputs all alternatives with the maximum likelihood) is a minimax rule.*

The special case of Corollary 1 for $\mathcal{M}_{\text{Ma},\varphi}$ was proved by Caragiannis et al. [11]. We note that in Appendix A of [11], an example was shown to illustrate that MLE is not minimax w.r.t. $L_{0\text{-}1}$. This does not contradict Theorem 1 and Corollary 1 because the framework in the example is not neutral.

As shown in the following example, not all Bayesian estimators of neutral frameworks satisfy minimaxity.

Example 2. *Let $\mathcal{A} = \{a, b\}$. Consider a framework $(\mathcal{M}, L)$ for two alternatives where $\mathcal{M} = (\Theta, \vec{\pi})$ combines two Mallows' models with dispersion parameter 0.6 and 0.7 respectively. Formally, let $\Theta = \{0.6, 0.7\} \times \{a \succ b, b \succ a\}$. For each $(\varphi, W) \in \Theta$, $\pi_{(\varphi,W)}$ is the same as π_W in Mallows' model with dispersion φ. For any $W \in \mathcal{L}(\mathcal{A})$ and $c \in \mathcal{A}$, we let $L((0.6, W), c) = L_{top}(W, c)$ and $L((0.7, W), c) = 1 - L_{top}(W, c)$.*

It can be verified that $\mathcal{F}$ is neutral by letting γ_Θ be a permutation that only applies to the second component of the parameter (the ranking). Let $n = 1$. When the vote is $a \succ b$, the posterior distribution is the following.

Parameter	$(0.6, a \succ b)$	$(0.6, b \succ a)$	$(0.7, a \succ b)$	$(0.7, b \succ a)$
Post. Prob.	$\frac{1}{3.2}$	$\frac{0.6}{3.2}$	$\frac{1}{3.4}$	$\frac{0.7}{3.4}$
Loss for a	0	1	1	0

Therefore, $EL(a|\{a \succ b\}) = \frac{0.6}{3.2} < \frac{0.7}{3.4} = EL(b|\{a \succ b\})$. Therefore, $BE_\mathcal{F}(a \succ b) = a$. Similarly $BE_\mathcal{F}(b \succ a) = b$.

When the ground truth parameter is $(0.7, a \succ b)$, the frequentist expected loss of $BE_\mathcal{F}$ is $\frac{1}{1.7} > \frac{1}{2}$. We note that the worst-case frequentist loss of the voting rule that always output $\mathcal{A}$ is $\frac{1}{2}$, which means that $BE_\mathcal{F}$ is not a minimax rule. □

4 GENERAL RESULTS ON SATISFACTION OF AXIOMS

To analyze the satisfaction of axioms of Bayesian estimators, in the rest of this paper we focus on a special class of frameworks where the decision space is $\mathcal{A}$. We let $\mathcal{F} = (\mathcal{M}_\mathcal{A}, L)$ denote such a framework where the decision space is omitted. For neutral frameworks, we further require that $\sigma_\mathcal{A} = \sigma$, where $\sigma_\mathcal{A}$ is the corresponding permutation over the decision space, which is $\mathcal{A}$ in this section.

Theorem 2. *The Bayesian estimator of any neutral framework satisfies neutrality.*

Proof: Let $S(\mathcal{A})$ denote the set of all permutations over $\mathcal{A}$. It suffices to prove that the expected loss function is insensitive to permutations. For any neutral framework $\mathcal{F}$, any profile P, any alternative a, and any $\gamma \in S(\mathcal{A})$, we have

$$\begin{aligned}&\mathrm{EL}(a|P) = \sum_{\theta\in\Theta} \Pr(\theta|P) L(\theta, a) \propto \sum_{\theta\in\Theta} \Pr(P|\theta) L(\theta, a)\\ =&\sum_{\theta\in\Theta} \Pr(\gamma(P)|\gamma_\Theta(\theta)) L(\gamma_\Theta(\theta), \gamma(a))\\ \propto&\sum_{\theta\in\Theta} \Pr(\gamma_\Theta(\theta)|\gamma(P)) L(\gamma_\Theta(\theta), \gamma(a)) = \mathrm{EL}(\gamma(a)|\gamma(P))\end{aligned}$$

□

Theorem 3. *If the Bayesian estimator $BE_\mathcal{F}$ of a framework $\mathcal{F}$ satisfies neutrality then there exists a neutral framework $\mathcal{F}^*$ such that $BE_{\mathcal{F}^*} = BE_\mathcal{F}$.*

All missing proofs can be found in the full version on arXiv.

Theorem 4. *No Bayesian estimator satisfies strict Condorcet criterion.*

Proof: For the sake of contradiction suppose a Bayesian estimator r of $\mathcal{F} = (\mathcal{M}_\mathcal{A}, L)$ satisfies strict Condorcet criterion where $\mathcal{M}_\mathcal{A} = (\Theta, \vec{\pi})$.

We first prove that for any profile P, if alternatives a and b are tied in their head-to-head competition, then expected loss for a must be the same as the expected loss for b.

Lemma 2. *Suppose $r = BE_{\mathcal{F}}$ satisfies strict Condorcet criterion. For any profile P and any pair of alternatives (a, b), if $w_P(a, b) = 0$ then $EL(a|P) = EL(b|P)$.*

Proof: For any distribution π over Θ, let $\mathcal{S}_\pi = \{S_1, \ldots, S_p\}$ denote the partition of Θ into equivalent classes according to π, where p is the number of equivalent classes. That is, for any $S \in \mathcal{S}_\pi$ and any $\theta_1, \theta_2 \in S$, we have $\pi(\theta_1) = \pi(\theta_2)$. Let $\mathcal{T}_\pi$ denote the total order over $\mathcal{S}_\pi$ such that for any pair $S, S' \in \mathcal{S}_\pi$, we have $S \succ_{\mathcal{T}_\pi} S'$ if and only if the π value of parameters in S is strictly larger than the π value of parameters in S'.

For any profile P, let $\mathcal{S}_P$ denote $\mathcal{S}_{\Pr(\cdot|P)}$. That is, $\mathcal{S}_P$ is the partition of Θ according to the posterior distribution over Θ given P. $\mathcal{T}_P$ is defined similarly. The next lemma states that for any profile P and any pair of co-winners (a, b), the total loss of a and b within each equivalent class in $\mathcal{S}_P$ must be the same. For any $S \subseteq \Theta$, we let $L(S, a) = \sum_{\theta \in S} L(\theta, a)$.

Lemma 3. *Suppose $r = BE_{\mathcal{F}}$ satisfies strict Condorcet criterion. For any profile P and any $S \in \mathcal{S}_P$, if there are at least two weak Condorcet winners $\{a, b\}$ in P, then $L(S, a) = L(S, b)$.*

Proof: For the sake of contradiction suppose the lemma does not hold for a profile P where $\{a, b\}$ are two weak Condorcet winners. Let $\mathcal{T}_P = S_1 \succ S_2 \succ \cdots \succ S_p$. Let S_i denote the highest-ranked equivalent class in $\mathcal{T}_P$ such that the total loss of a and the total loss of b on S_i are different. W.l.o.g. suppose $L(S_i, a) > L(S_i, b)$. For any natural number k, it follows that a and b are also weak Condorcet winners in kP, whose weighted majority graph is exactly $\text{WMG}(P)$ times k. We next show that when k is sufficiently large, $EL(a|kP) > EL(b|kP)$. For any $i \leq p$, let $\theta_i \in S_i$ be an arbitrary parameter in S_i.

$$EL(a|kP) = \sum_{\theta \in \Theta} \Pr(\theta|kP) L(\theta, a)$$

$$\propto \sum_{\theta \in \Theta} \Pr(\theta|P)^k L(\theta, a) = \sum_{i=1}^{p} \sum_{\theta \in S_i} \Pr(\theta|P)^k L(\theta, a)$$

$$= \sum_{i=1}^{p} \Pr(\theta_i|P)^k L(S_i, a)$$

Because for any $i' > i$ we have $\Pr(\theta_i|P) > \Pr(\theta_{i'}|P)$, there exists $k \in \mathbb{N}$ such that $(\frac{\Pr(\theta_i|P)}{\Pr(\theta_{i+1}|P)})^k > \frac{\sum_{l=i+1}^{p}(L(S_l,a)-L(S_l,b))}{L(S_i,a)-L(S_i,b)}$. Therefore, for such k we have $\sum_{i=1}^{p} \Pr(\theta_i|P)^k L(S_i, a) > \sum_{i=1}^{p} \Pr(\theta_i|P)^k L(S_i, b) \propto EL(b|kP)$. This means that b cannot be a co-winner in $r(kP)$, which contradicts the assumption that r satisfies strict Condorcet criterion. □

For any pair of partitions $\mathcal{S}_1$ and $\mathcal{S}_2$ of Θ, we let $\mathcal{S}_1 \oplus \mathcal{S}_2$ denote the coarsest partition of Θ that refines both $\mathcal{S}_1$ and $\mathcal{S}_2$. That is,

$$\mathcal{S}_1 \oplus \mathcal{S}_2 = \{S_1 \cap S_2 : S_1 \in \mathcal{S}_1, S_2 \in \mathcal{S}_2\} \setminus \{\emptyset\}$$

Lemma 4. *For any statistical model and any pair of profiles P_1, P_2, there exists $k \in \mathbb{N}$ such that $\mathcal{S}_{kP_1 \cup P_2} = \mathcal{S}_{P_1} \oplus \mathcal{S}_{P_2}$.*

Proof: We let $P^* = kP_1 \cup P_2$ for a sufficiently large k such that the "gap" between two equivalent classes in kP is large enough that the only effect of P_2 is to refine the equivalent classes in kP. More formally, we choose $k \in \mathbb{N}$ such that for any $\theta_1, \theta_2 \in \Theta$, $\Pr(\theta_1|P_1)^k \Pr(\theta_1|P_2) > \Pr(\theta_2|P_1)^k \Pr(\theta_2|P_2)$ if and only if one of the following two conditions hold: (1) $\Pr(\theta_1|P_1) > \Pr(\theta_2|P_1)$, or (2) $\Pr(\theta_1|P_1) = \Pr(\theta_1|P_2)$ and $\Pr(\theta_1|P_2) > \Pr(\theta_2|P_2)$. □

For any $a, b \in \mathcal{A}$, let $\mathcal{L}_{ab}$ denote the set of all rankings where $a \succ b$. Let $\mathcal{P}_{ab}$ denote the set of all two-agent profiles where one vote comes from $\mathcal{L}_{ab}$ and the other vote comes from $\mathcal{L}_{ba}$. That is,

$$\mathcal{P}_{ab} = \{\{V_1, V_2\} : V_1 \in \mathcal{L}_{ab}, V_2 \in \mathcal{L}_{ba}\}$$

Let $\mathcal{S}_{ab}$ denote the finest partition of Θ that refines all partitions induced by profiles in $\mathcal{P}_{ab}$. That is, $\mathcal{S}_{ab} = \oplus \mathcal{P}_{ab}$. By Lemma 4, there exists a profile P_{ab} such that $\mathcal{S}_{P_{ab}} = \mathcal{S}_{ab}$.

Lemma 5. *Suppose $r = BE_{\mathcal{F}}$ satisfies strict Condorcet criterion. For any $a, b \in \mathcal{A}$ and any $S \in \mathcal{S}_{ab}$, we have $L(S, a) = L(S, b)$.*

Proof: Let P^* be an arbitrary profile with the following conditions. (1) $w_{P^*}(a, b) = w_{P^*}(b, a) = 0$. (2) For any $c \notin \{a, b\}$, we have $w_{P^*}(a, c) > 0$ and $w_{P^*}(b, c) > 0$. By Lemma 4, there exists a sufficiently large $k \in \mathbb{N}$ such that both conditions still hold for $kP^* \cup P_{ab}$, and $S_{kP^* \cup P_{ab}} = S_{ab}$. The latter is because P^* can be seen as the union of $|P^*|/2$ profiles in $\mathcal{P}_{ab}$, which means that S_{ab} is a refinement of S_{kP^*}. The lemma follows after Lemma 3. □

We note that for any $a, b \in \mathcal{A}$, any profile P where $w_P(a, b) = 0$ can be seen as the union of $|P|/2$ profiles in $\mathcal{P}_{ab}$. This means that S_{ab} is a refinement of S_P. Therefore, any $S \in S_P$ must be the union of some equivalent classes in S_{ab}. By Lemma 5 we have that $L(S, a) = L(S, b)$. We have $EL(a|P) = \sum_{S \in \mathcal{S}_P} \Pr(\theta_S|P) L(S, a) = \sum_{S \in \mathcal{S}_P} \Pr(\theta_S|P) L(S, b) = EL(b|P)$, where θ_S denote an arbitrary element in S. This proves Lemma 2. □

Consider any profile P where $w_P(a, b) = w_P(b, c) = 0$, $w_P(a, c) = 2$, a and b are the only two weak Condorcet winners, and c loses to all other alternatives in head-to-head competitions. Such a profile exists due to McGarvey's theorem [23]. By Lemma 2, $EL(a|P) = EL(b|P) = EL(c|P)$. However, because r satisfies strict Condorcet criterion, $c \notin r(P)$, which is a contradiction. □

A direct corollary is that any voting rule that satisfies strict Condorcet criterion cannot be the BE of any framework.

Corollary 2. *Copeland$_1$, maximin, Black's function,*[3] *Dodgson's function, Young's function, Condorcet's function, and Fishburn's function cannot be the Bayesian estimator of any framework.*

5 NEW BAYESIAN ESTIMATORS AS VOTING RULES

The following theorem solves the open question about the satisfaction of Condorcet criterion for $f^{\text{Top}}_{\text{Ma},\varphi}$ [7].

Theorem 5. *$f^{Top}_{Ma,\varphi}$ satisfies the Condorcet criterion if and only if $\frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \leq 1$.*

Proof: The "if part": suppose $\frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \leq 1$. Let P be a profile where a is the Condorcet winner. For any $c, d \in \mathcal{A}$, we let $\mathcal{A}_{-c} = \mathcal{A} \setminus \{c\}$ and $\mathcal{A}_{-cd} = \mathcal{A} \setminus \{c, d\}$. For any $c \in \mathcal{A}$, let $\mathcal{L}_c$ denote the set of all rankings where c is ranked at the top. For any profile P, let $P|_{-a}$ denote its restriction on $\mathcal{A}_{-a}$.

$$1 - \text{EL}(c|P) = \sum_{V \in \mathcal{L}_c} \Pr(V|P)$$
$$\propto \sum_{V \in \mathcal{L}_c} \Pr(P|V) \propto \sum_{V \in \mathcal{L}_c} \varphi^{\text{Kd}(P,V)}$$

Fix $b \neq a$. For any ranking $V_{-ab} \in \mathcal{L}(\mathcal{A}_{-ab})$, we let $Q(V_{-ab})$ denote the set of $m-1$ rankings over $\mathcal{A} \setminus \{a\}$ obtained by inserting b to V_{-ab} without changing the relative positions of other alternatives. Let $J(V_{-ab}) \in \mathcal{L}(\mathcal{A}_{-a})$ be the ranking in $Q(V_{-ab})$ with the minimum Kentall-tau distance from $P|_{-a}$. If there are multiple such rankings, let $J(V_{-ab})$ be the one where b is ranked at the highest position.

Let $H : \mathcal{L}_b \to \mathcal{L}_a$ denote the following mapping. For any $b \succ V_{-b} \in \mathcal{L}_b$ we first look at V_{-ab} and decide the best position to insert b, then put a at the top, where V_{-ab} is obtained from V_{-b} by removing a. Formally, $H(b \succ A_{-b}) = a \succ J(V_{-ab})$.

It follows that for any pair of rankings $V, W \in \mathcal{L}_b$, where the only difference is the position of a, we have $H(V) = H(W)$. Therefore, for any $V \in H(\mathcal{L}_b)$, $H^{-1}(V)$ contains exactly $m-1$ rankings in $\mathcal{L}_b$ that correspond to the $m-1$ positions of a (from the second position to the m-th position—the first position is occupied by b). For each $2 \leq i \leq m$, let $W_i \in H^{-1}(V)$ denote the ranking where a is ranked at the i-th position.

$$\begin{aligned}
&\text{Kd}(P, W_i) \\
=&\text{Kd}(P|_{-a}, (W_i)_{-a}) + \sum_{d \succ_{W_i} a} P(a \succ d) \\
&+ \sum_{a \succ_{W_i} d} P(d \succ a) \\
\geq&\text{Kd}(P|_{-a}, J((W_i)_{-ab})) + \sum_{d \neq a} P(d \succ a) + i - 1 \quad (5) \\
=&\text{Kd}(P, V) + i - 1
\end{aligned}$$

Inequality (5) is because a is the Condorcet winner, which means that for any $d \neq a$ we have $\#_P(a \succ d) \geq \#_P(d \succ a) + 1$. Therefore, for each $V \in H(\mathcal{L}_b)$ we have

$$\sum_{W \in H^{-1}(V)} \varphi^{\text{Kd}(P,W)} \leq (\varphi + \cdots + \varphi^{m-1}) \varphi^{\text{Kd}(P,V)}$$
$$= \frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \varphi^{\text{Kd}(P,V)}$$

Therefore,

$$\sum_{W \in \mathcal{L}_b} \varphi^{\text{Kd}(P,W)} \leq \frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \sum_{V \in H(\mathcal{L}_b)} \varphi^{\text{Kd}(P,V)}$$
$$< \frac{\varphi(1-\varphi^{m-1})}{1-\varphi} \sum_{V \in \mathcal{L}_a} \varphi^{\text{Kd}(P,V)} \leq \sum_{V \in \mathcal{L}_a} \varphi^{\text{Kd}(P,V)}$$

Therefore, we have $1 - \text{EL}(a|P) > 1 - \text{EL}(b|P)$, which means that $\text{EL}(a|P) < \text{EL}(b|P)$ and a is the unique winner.

The "only if part": suppose $\frac{\varphi(1-\varphi^{m-1})}{1-\varphi} > 1$. For any odd number $k \in \mathbb{N}$ we consider the a profile P_k whose weighted majority graph is the same as in Figure 1. The existence of P^* is guaranteed by McGarvey's theorem [23]. More precisely, in Figure 1 the weight on the edges from a to all other alternatives is 1; the weight on the edges from b to all other alternatives (except a) is k; for any $3 \leq i_1 < i_2 < m$, the weight on $a_{i_1} \to a_{i_2}$ is k.

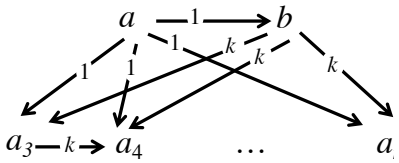

Figure 1: The WMG of P_k for odd k.

Let $V_a = a \succ b \succ a_3 \succ \cdots \succ a_m$ and for each $2 \leq i \leq m$, let V_b^i be the ranking obtained from V_a by moving a to the i-th position. It is not hard to check that $\lim_{k \to \infty} \frac{\sum_{V \in \mathcal{L}_a} \varphi^{\text{Kd}(P_k,V)}}{\varphi^{\text{Kd}(P_k,V_a)}} = 1$ and

[3] Definitions of these rules except Copeland and maximin can be found in [18], where it was proved that they satisfy strict Condorcet criterion.

$\lim_{k\to\infty} \frac{\sum_{V\in\mathcal{L}_b} \varphi^{\text{Kd}(P_k,V)}}{\sum_{i=2}^{m} \varphi^{\text{Kd}(P_k,V_b^i)}} = 1$. We note that for each $2 \le i \le m$, $\text{Kd}(P_k, V_b^i) = \text{Kd}(P_k, V_a) + i - 1$. This means that

$$\lim_{k\to\infty} \frac{\sum_{V\in\mathcal{L}_b} \varphi^{\text{Kd}(P_k,V)}}{\sum_{V\in\mathcal{L}_a} \varphi^{\text{Kd}(P_k,V)}} = \lim_{k\to\infty} \frac{\sum_{i=2}^{m} \varphi^{\text{Kd}(P_k,V_b^i)}}{\varphi^{\text{Kd}(P_k,V_a)}}$$

$$= \varphi + \varphi^2 + \cdots \varphi^{m-1} = \frac{\varphi(1-\varphi^{m-1})}{1-\varphi} > 1$$

Therefore, there exists odd $k \in \mathbb{N}$ such that $\text{EL}(b|P_k) < \text{EL}(a|P_k)$, which means that a cannot be the winner. Because a is the Condorcet winner in P_k, $f^{\text{Top}}_{\text{Ma},\varphi}$ does not satisfy Condorcet criterion. □

Theorem 6. *For any profile P, $f^{Borda}_{Co,\varphi}(P) = \arg\max_{a\in\mathcal{A}} \sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}}$.*

Proof: For any $W \in \mathcal{B}(\mathcal{A})$ and any pair of alternatives a, b, let $I_W(a \succ b) = 1$ if $a \succ_W b$; otherwise $I_W(a \succ b) = 0$. It follows that $m - 1 - L_{\text{Borda}}(W, a) = \sum_{b\neq a} I_W(a \succ b)$. Let $\mathcal{B}_{a\succ b}$ denote the set of all rankings over $\mathcal{A}$ where $a \succ b$.

$$\begin{aligned} & m - 1 - \text{EL}(a|P) \\ =& \sum_{W\in\mathcal{B}(\mathcal{A})} \Pr(W|P)(m - 1 - L_{\text{Borda}}(W, a)) \\ =& \sum_{W\in\mathcal{B}(\mathcal{A})} \Pr(W|P) \sum_{c\neq a} I_W(a \succ c) \\ =& \sum_{c\neq a} \sum_{W\in\mathcal{B}_{a\succ c}} \Pr(W|P) \end{aligned}$$

Following similar calculations as in [16, 7], we have

$$\begin{aligned} & \sum_{c\neq a} \sum_{W\in\mathcal{B}_{a\succ c}} \Pr(W|P) \\ \propto & \sum_{c\neq a} \varphi^{P(c\succ a)} \prod_{\{b,d\}:\{b,d\}\neq\{a,c\}} (\varphi^{P(b\succ d)} + \varphi^{P(d\succ b)}) \\ \propto & \sum_{c\neq a} \frac{\varphi^{P(c\succ a)}}{\varphi^{P(c\succ a)} + \varphi^{P(a\succ c)}} = \sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} \end{aligned}$$

Therefore, for any pair of alternatives (a, b), $\text{EL}(a|P) \le \text{EL}(b|P)$ if and only if $\sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} \ge \sum_{c\neq b} \frac{1}{1+\varphi^{w_P(b,c)}}$. This proves the theorem. □

Proposition 1. *For all $0 < \varphi < 1$, $f^{Borda}_{Co,\varphi}$ satisfies monotonicity.*

Proof: For any profile P, any $a \in f^{\text{Borda}}_{\text{Co},\varphi}(P)$ and any profile P' obtained from P by raising the positions of a without changing relative positions of other alternatives. It is not hard to check that for any $b \neq a$, $w_{P'}(a, b) > w_P(a, b)$, and the weights of edges not involving a do not change. Therefore, for any $b \neq a$, $\sum_{c\neq a} \frac{1}{1+\varphi^{w_{P'}(a,c)}} > \sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} \ge \sum_{c\neq b} \frac{1}{1+\varphi^{w_P(b,c)}} > \sum_{c\neq b} \frac{1}{1+\varphi^{w_{P'}(b,c)}}$. It follows from Theorem 6 that $a \in f^{\text{Borda}}_{\text{Co},\varphi}(P')$. □

Theorem 7. *$f^{Borda}_{Co,\varphi}$ satisfies the Condorcet criterion if and only if $\varphi \le \frac{1}{m-1}$.*

Proof: The "if" part. Let P be any profile where a is the Condorcet winner. This means that for any $c \neq a$, $w_P(a, c) \ge 1$. By Theorem 6 we have $\sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} \ge \frac{m-1}{1+\varphi}$. For any $b \neq a$, we have $\sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} < \frac{1}{1+\varphi^{-1}} + m - 2$. When $\varphi \le \frac{1}{m-1}$, we have $\frac{1}{1+\varphi^{-1}} + m - 2 \le \frac{m-1}{1+\varphi}$. Therefore, a is the unique winner.

The "only if" part is proved by considering the profile P_k whose WMG is in Figure 1 and let $k \to \infty$. □

Theorem 8. *As $\varphi \to 0$, $f^{Borda}_{Co,\varphi}$ converges to a refinement of Copeland$_{0.5}$. As $\varphi \to 1$, $f^{Borda}_{Co,\varphi}$ converges to a refinement of Borda.*

Proof: For any profile P any pair of alternatives a, b we have

$$\lim_{\varphi\to 0} \frac{1}{1+\varphi^{w_P(a,b)}} = \begin{cases} 1 & \text{if } w_P(a,b) > 0 \\ 0.5 & \text{if } w_P(a,b) = 0 \\ 0 & \text{otherwise} \end{cases}$$

Therefore, for any alternative a, $\lim_{\varphi\to 0} \sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}}$ is its Copeland$_{0.5}$ score, which means that the winners must also be winners under Copeland$_{0.5}$.

For any $k > 0$, when $\epsilon \to 0$, we have $\frac{1}{1+(1-\epsilon)^k} = \frac{1}{2}(1 + \frac{k\epsilon}{2} + o(\epsilon))$ and $\frac{1}{1+(1-\epsilon)^{-k}} = \frac{1}{2}(1 - \frac{k\epsilon}{2} + o(\epsilon))$. Therefore, for any alternative a, $\sum_{c\neq a} \frac{1}{1+\varphi^{w_P(a,c)}} = \frac{m-1}{2} + \frac{1}{4}(\sum_{c\neq a} w_P(a, c))(1 - \varphi) + o(1 - \varphi)$. We note that $\sum_{c\neq a} w_P(a, c)$ equals to twice the Borda score of a in P minus $n(m - 1)$. Therefore, as $\varphi \to 1$, all $f^{\text{Borda}}_{\text{Co},\varphi}$ winners must be Borda winners. □

We propose a new class of ranking model and framework as follows.

Definition 5. *For any $0 < \varphi < 1$ we define $\mathcal{M}_{Pair,\varphi}$ as follows. The parameter space $\Theta = \{\theta_{bc} : b \neq c \in \mathcal{A}\}$. For any $V \in \mathcal{L}(\mathcal{A})$ we let $\pi_{\theta_{bc}}(V) \propto \begin{cases} 1 & \text{if } b \succ_V c \\ \varphi & \text{otherwise} \end{cases}$.*

Let $L_1(\theta_{bc}, a) = \begin{cases} 1 & \text{if } a = c \\ 0 & \text{otherwise} \end{cases}$ and

$L_2(\theta_{bc}, a) = \begin{cases} 0 & \text{if } a = b \\ 1 & \text{otherwise} \end{cases}$.

Let $\mathcal{F}^1_{Pair,\varphi} = (\mathcal{M}_{Pair,\varphi}, L_1)$ and $\mathcal{F}^2_{Pair,\varphi} = (\mathcal{M}_{Pair,\varphi}, L_2)$.

That is, the parameters in $\mathcal{M}_{\text{Pair},\varphi}$ correspond to pairwise comparisons between alternatives. A parameter θ_{bc} can be interpreted as "$b \succ c$ is the strongest pairwise comparison". The first loss function states that the loss of a is 1 if and only if a is the less preferred alternative in the parameter. The second loss function states that the loss of a is 0 if and only if a is the preferred alternative in the parameter.

$\mathcal{M}_{\text{Pair},\varphi}$ might be of independent interest. In this paper we

focus on the satisfaction of axioms for the two Bayesian estimators and leave further exploration of the model for future work. We note that given φ, the normalization factor for all θ_{bc} are the same.

Theorem 9. *The Bayesian estimator $f^1_{Pair,\varphi}$ of $\mathcal{F}^1_{Pair,\varphi}$ is $\arg\min_{a\in\Theta} \sum_{b\neq a} \varphi^{w_P(a,b)/2}$. The Bayesian estimator $f^2_{Pair,\varphi}$ of $\mathcal{F}^2_{Pair,\varphi}$ is $\arg\max_{a\in\Theta} \sum_{b\neq a} \varphi^{w_P(b,a)/2}$.*

It is easy to check that both $\mathcal{F}^1_{\text{Pair},\varphi}$ and $\mathcal{F}^2_{\text{Pair},\varphi}$ satisfy neutrality and parameter connectivity. Therefore, their Bayesian estimators satisfy neutrality and minimaxity.

Corollary 3. *$f^1_{Pair,\varphi}$ and $f^2_{Pair,\varphi}$ satisfy neutrality and minimaxity (w.r.t. to $\mathcal{F}^1_{Pair,\varphi}$ and $\mathcal{F}^2_{Pair,\varphi}$, respectively).*

Proposition 2. *$f^1_{Pair,\varphi}$ and $f^2_{Pair,\varphi}$ satisfy monotonicity.*

Proof: The proof is similar to the proof of Theorem 1. We note that raising the position of a will increase the weight on some edges $a \to b$. Weights on other edges do not change. Monotonicity of both rules can be verified by applying Theorem 9. □

Theorem 10. *$f^1_{Pair,\varphi}$ satisfies the Condorcet criterion if and only if $\varphi \leq \frac{1}{m-1}$. For all $0 < \varphi < 1$, $f^2_{Pair,\varphi}$ does not satisfy Concorcet criterion.*

Proof: The "if" part for $f^1_{\text{Pair},\varphi}$ follows after Theorem 11 because when $\varphi < \frac{1}{m-1}$, $f^1_{\text{Pair},\varphi}$ is a refinement of maximin and any refinement of maximin satisfies the Condorcet criterion.

The "only if" part for $f^1_{\text{Pair},\varphi}$ and the non-satisfaction for $f^2_{\text{Pair},\varphi}$ are proved by considering the profile P_k whose weighted majority graph is in Figure 1 and let $k \to \infty$. □

For any profile P, the *maximax* rule to chooses all alternatives with the maximum weight on at least one outgoing edge in the weighted majority graph. That is, the rule is $\arg\max_a \max_b w_P(a,b)$.

Theorem 11. *For any $\varphi \leq \frac{1}{m-1}$, $f^1_{Pair,\varphi}$ is a refinement of maximin, and $f^2_{Pair,\varphi}$ is a refinement of maximax. As $\varphi \to 1$, both rules converge to refinements of Borda.*

Proof: By Theorem 9, for any $\varphi \leq \frac{1}{m-1}$, for any alternative a, $\sum_{b\neq a} \varphi^{w_P(a,b)/2}$ is mainly determined by $\min_{b\neq a} w_P(a,b)/2$, which is half of a's minscore. It follows that all winners under $f^1_{\text{Pair},\varphi}$ must be maximin winners. Similarly, $\sum_{b\neq a} \varphi^{w_P(b,a)/2}$ is determined by $\min_{b\neq a} w_P(b,a)/2$, which corresponds to $\max_{b\neq a} w_P(a,b)/2$. It follows that the winner under $f^2_{\text{Pair},\varphi}$ must be maximax winners.

For any $\epsilon > 0$, we have $\sum_{b\neq a}(1-\epsilon)^{w_P(a,b)/2} = m - 1 - \sum_{b\neq a} \frac{w_P(a,b)}{2}\epsilon + o(\epsilon)$. Similar to the proof of Theorem 8, the minimizers of this function as $\epsilon \to 0$, which is $f^1_{\text{Pair},\varphi}$ as $\varphi \to 1$, must be Borda winners. The proof for $f^2_{\text{Pair},\varphi}$ is similar. □

6 SUMMARY AND FUTURE WORK

We characterized neutrality and proved an impossibility theorem about strict Condorcet criterion for Bayesian estimators. We also proposed new frameworks to obtain new BEs and showed that some of them satisfy many desirable axioms and can be computed in polynomial time.

There are many directions for future work. Can we answer Q2 in the Introduction for other desirable axioms such as homogeneity? How about axioms for other types preferences such as ratings? Are there any BEs that are refinements of other commonly studied rules, especially Copeland$_\alpha$ for $\alpha \notin \{0.5, 1\}$, STV, and ranked pairs? What are other natural frameworks and which axioms do their BEs satisfy?

Abstract

Matrix-parametrized models (MPMs) are widely used in machine learning (ML) applications. In large-scale ML problems, the parameter matrix of a MPM can grow at an unexpected rate, resulting in high communication and parameter synchronization costs. To address this issue, we offer two contributions: first, we develop a computation model for a large family of MPMs, which share the following property: the parameter update computed on each data sample is a rank-1 matrix, *i.e*. the outer product of two "sufficient factors" (SFs). Second, we implement a decentralized, peer-to-peer system, Sufficient Factor Broadcasting (SFB), which broadcasts the SFs among worker machines, and reconstructs the update matrices locally at each worker. SFB takes advantage of small rank-1 matrix updates and efficient partial broadcasting strategies to dramatically improve communication efficiency. We propose a graph optimization based partial broadcasting scheme, which minimizes the delay of information dissemination under the constraint that each machine only communicates with a subset rather than all of machines. Furthermore, we provide theoretical analysis to show that SFB guarantees convergence of algorithms (under full broadcasting) without requiring a centralized synchronization mechanism. Experiments corroborate SFB's efficiency on four MPMs.

1 INTRODUCTION

Machine Learning (ML) provides a principled and effective mechanism for extracting latent structure and patterns from raw data and making automatic predictions and decisions. The growing prevalence of *big data*, such as billions of text pages in the web, hundreds of hours of video uploaded to video-sharing sites every minute[1], accompanied by an increasing need of *big model*, such as neural networks (Dean et al., 2012) and topic models (Yuan et al., 2015) with billions of parameters, has inspired the design and development of distributed machine learning systems (Dean and Ghemawat, 2008; Gonzalez et al., 2012; Zaharia et al., 2012; Li et al., 2014; Xing et al., 2015) running on research clusters, data center and cloud platforms with 10s-1000s machines.

For many machine learning (ML) models, such as multiclass logistic regression (MLR), neural networks (NN) (Chilimbi et al., 2014), distance metric learning (DML) (Xing et al., 2002) and sparse coding (SC) (Olshausen and Field, 1997), their parameters can be represented by a matrix $\mathbf{W}$. For example, in MLR, rows of $\mathbf{W}$ represent the classification coefficient vectors corresponding to different classes; whereas in SC rows of $\mathbf{W}$ correspond to the basis vectors used for reconstructing the observed data. A learning algorithm, such as stochastic gradient descent (SGD), would iteratively compute an update $\Delta\mathbf{W}$ from data, to be aggregated with the current version of $\mathbf{W}$. We call such models *matrix-parameterized models* (MPMs).

Learning MPMs in large scale ML problems is challenging: ML application scales have risen dramatically, a good example being the ImageNet (Deng et al., 2009) compendium with millions of images grouped into tens of thousands of classes. To ensure fast running times when scaling up MPMs to such large problems, it is desirable to turn to distributed computation; however, a unique challenge to MPMs is that the parameter matrix grows rapidly with problem size, causing straightforward parallelization strategies to perform less ideally. Consider a data-parallel algorithm, in which every worker uses a subset of the data to update the parameters — a common paradigm is to synchronize the full parameter matrix and update matrices amongst all workers (Dean and Ghemawat, 2008; Dean et al., 2012; Li et al., 2015; Chilimbi et al., 2014; Sindhwani and Ghoting, 2012; Gopal and Yang, 2013). However, this synchronization can quickly become a bottle-

[1] https://www.youtube.com/yt/press/statistics.html

neck: take MLR for example, in which the parameter matrix $\mathbf{W}$ is of size $J \times D$, where J is the number of classes and D is the feature dimensionality. In one application of MLR to Wikipedia (Partalas et al., 2015), $J = 325$k and $D > 10,000$, thus $\mathbf{W}$ contains several billion entries (tens of GBs of memory). Because typical computer cluster networks can only transfer a few GBs per second at the most, inter-machine synchronization of $\mathbf{W}$ can dominate and bottleneck the actual algorithmic computation. In recent years, many distributed frameworks have been developed for large scale machine learning, including Bulk Synchronous Parallel (BSP) systems such as Hadoop (Dean and Ghemawat, 2008) and Spark (Zaharia et al., 2012), graph computation frameworks such as GraphLab (Gonzalez et al., 2012), and bounded-asynchronous key-value stores such as DistBelief(Dean et al., 2012), Petuum-PS (Ho et al., 2013), Project Adam (Chilimbi et al., 2014) and (Li et al., 2014). When using these systems to learn MPMs, it is common to transmit the full parameter matrices $\mathbf{W}$ and/or matrix updates $\Delta\mathbf{W}$ between machines, usually in a server-client style (Dean and Ghemawat, 2008; Dean et al., 2012; Sindhwani and Ghoting, 2012; Gopal and Yang, 2013; Chilimbi et al., 2014; Li et al., 2015). As the matrices become larger due to increasing problem sizes, so do communication costs and synchronization delays — hence, reducing such costs is a key priority when using these frameworks.

We begin by investigating the structure of matrix parameterized models, in order to design efficient communication strategies. We focus on models with a common property: when the parameter matrix $\mathbf{W}$ of these models is optimized with stochastic gradient descent (SGD) (Dean et al., 2012; Ho et al., 2013; Chilimbi et al., 2014) or stochastic dual coordinate ascent (SDCA) (Hsieh et al., 2008; Shalev-Shwartz and Zhang, 2013), the update $\triangle\mathbf{W}$ computed over one (or a few) data sample(s) is of low-rank, *e.g.* it can be written as the outer product of two vectors $\mathbf{u}$ and $\mathbf{v}$: $\triangle\mathbf{W} = \mathbf{u}\mathbf{v}^\top$. The vectors $\mathbf{u}$ and $\mathbf{v}$ are *sufficient factors* (SF, meaning that they are sufficient to reconstruct the update matrix $\triangle\mathbf{W}$). A rich set of models (Olshausen and Field, 1997; Lee and Seung, 1999; Xing et al., 2002; Chilimbi et al., 2014) fall into this family: for instance, when solving an MLR problem using SGD, the stochastic gradient is $\triangle\mathbf{W} = \mathbf{u}\mathbf{v}^\top$, where $\mathbf{u}$ is the prediction probability vector and $\mathbf{v}$ is the feature vector. Similarly, when solving an ℓ_2 regularized MLR problem using SDCA, the update matrix $\triangle\mathbf{W}$ also admits such as a structure, where $\mathbf{u}$ is the update vector of a dual variable and $\mathbf{v}$ is the feature vector. Other models include neural networks (Chilimbi et al., 2014), distance metric learning (Xing et al., 2002), sparse coding (Olshausen and Field, 1997), non-negative matrix factorization (Lee and Seung, 1999) and principal component analysis, to name a few.

Leveraging this property, we propose a system called Sufficient Factor Broadcasting (SFB), whose basic idea is to send sufficient factors (SFs) between workers, which then reconstruct matrix updates $\triangle\mathbf{W}$ locally, thus greatly reducing inter-machine parameter communication. This stands in contrast to the well-established parameter server idiom (Chilimbi et al., 2014; Li et al., 2014), a centralized design where workers maintain a "local" image of the parameters $\mathbf{W}$, which are synchronized with a central parameter image $\mathbf{W}$ (stored on the "parameter servers"). In existing parameter server designs, the (small, low-rank) updates $\triangle\mathbf{W}$ are accumulated into the central parameter server's $\mathbf{W}$, and the low-rank structure of each update $\triangle\mathbf{W}$ is lost in the process. Thus, the parameter server can only transmit the (large, full-rank) matrix $\mathbf{W}$ to the workers, inducing extra communication that could be avoided. We address this issue by designing SFB as a *decentralized, peer-to-peer system*, where each worker keeps its own image of the parameters $\mathbf{W}$ (either in memory or on local disk), and sends sufficient factors to only a subset of other workers, via "partial broadcasting" strategies that avoid the usual $O(P^2)$ peer-to-peer broadcast communication over P machines. SFB also exploits ML algorithm tolerance to bounded-asynchronous execution (Ho et al., 2013), as supported by both our experiments and a theoretical proof. SFB is highly communication-efficient; transmission costs are linear in the dimensions of the parameter matrix, and the resulting faster communication greatly reduces waiting time in synchronous systems (e.g. Hadoop and Spark), or improves parameter freshness in (bounded) asynchronous systems (e.g. GraphLab, Petuum-PS and (Li et al., 2014)). SFs have been used to speed up some (but not all) network communication in deep learning (Chilimbi et al., 2014); our work differs primarily in that we always transmit SFs, never full matrices.

The major contributions of this paper are as follows:

- We identify the *sufficient factor property* of a large family of matrix-parametrized models when solved with two popular algorithms: stochastic gradient descent and stochastic dual coordinate ascent.
- In light of the sufficient factor property, we propose a *sufficient factor broadcasting* (SFB) model of computation. Through a decentralized, peer-to-peer architecture with bounded-asynchronous partial broadcasting, SFB greatly reduces communication complexity while maintaining excellent empirical performance.
- To further reduce communication cost, we investigate a partial broadcasting scheme and propose a graph-optimization based approach to determine the topology of the communication network.
- We analyze the communication and computation costs of SFB and provide a convergence guarantee of SFB based minibatch SGD algorithm, under bulk synchronous and bounded asynchronous executions.

- We empirically evaluate SFB on four popular models, and confirm the efficiency and low communication complexity of SFB.

The rest of the paper is organized as follows. In Section 2 and 3, we introduce the sufficient factor property of matrix-parametrized models and propose the sufficient factor broadcasting computation model, respectively. Section 4 analyzes the costs and convergence behavior of SFB. Section 5 gives experimental results. Section 6 reviews related works and Section 7 concludes the paper.

2 SUFFICIENT FACTOR PROPERTY OF MATRIX-PARAMETRIZED MODELS

The core goal of Sufficient Factor Broadcasting (SFB) is to reduce network communication costs for matrix-parametrized models; specifically, those that follow an optimization formulation

$$\textbf{(P)} \quad \min_{\mathbf{W}} \quad \frac{1}{N}\sum_{i=1}^{N} f_i(\mathbf{W}\mathbf{a}_i) + h(\mathbf{W}) \tag{1}$$

where the model is parametrized by a matrix $\mathbf{W} \in \mathbb{R}^{J\times D}$. The loss function $f_i(\cdot)$ is typically defined over a set of training samples $\{(\mathbf{a}_i, \mathbf{b}_i)\}_{i=1}^N$, with the dependence on $\mathbf{b}_i$ being suppressed. We allow $f_i(\cdot)$ to be either convex or nonconvex, smooth or nonsmooth (with subgradient everywhere); examples include ℓ_2 loss and multiclass logistic loss, amongst others. The regularizer $h(\mathbf{W})$ is assumed to admit an efficient proximal operator $\text{prox}_h(\cdot)$. For example, $h(\cdot)$ could be an indicator function of convex constraints, ℓ_1-, ℓ_2-, trace-norm, to name a few. The vectors $\mathbf{a}_i$ and $\mathbf{b}_i$ can represent observed features, supervised information (e.g., class labels in classification, response values in regression), or even unobserved auxiliary information (such as sparse codes in sparse coding (Olshausen and Field, 1997)) associated with data sample i. The key property we exploit below ranges from the matrix-vector multiplication $\mathbf{W}\mathbf{a}_i$. This optimization problem **(P)** can be used to represent a rich set of ML models (Olshausen and Field, 1997; Lee and Seung, 1999; Xing et al., 2002; Chilimbi et al., 2014), such as the following:

Distance Metric Learning (DML) (Xing et al., 2002) improves the performance of other ML algorithms, by learning a new distance function that correctly represents similar and dissimilar pairs of data samples; this distance function is a matrix $\mathbf{W}$ that can have billions of parameters or more, depending on the data sample dimensionality. The vector $\mathbf{a}_i$ is the difference of the feature vectors in the ith data pair and $f_i(\cdot)$ can be either a quadratic function or a hinge loss function, depending on the similarity/dissimilarity label $\mathbf{b}_i$ of the data pair. In both cases, $h(\cdot)$ can be an ℓ_1-, ℓ_2-, trace-norm regularizer or simply $h(\cdot) = 0$ (no regularization).

Sparse Coding (SC) (Olshausen and Field, 1997) learns a dictionary of basis from data, so that the data can be represented sparsely (and thus efficiently) in terms of the dictionary. In SC, $\mathbf{W}$ is the dictionary matrix, $\mathbf{a}_i$ are the sparse codes, $\mathbf{b}_i$ is the input feature vector and $f_i(\cdot)$ is a quadratic function (Olshausen and Field, 1997). To prevent the entries in $\mathbf{W}$ from becoming too large, each column $\mathbf{W}_k$ must satisfy $\|\mathbf{W}_k\|_2 \leq 1$. In this case, $h(\mathbf{W})$ is an indicator function which equals 0 if $\mathbf{W}$ satisfies the constraints and equals ∞ otherwise.

2.1 OPTIMIZATION VIA PROXIMAL SGD, SDCA

To solve the optimization problem **(P)**, it is common to employ either (proximal) stochastic gradient descent (SGD) (Dean et al., 2012; Ho et al., 2013; Chilimbi et al., 2014; Li et al., 2015) or stochastic dual coordinate ascent (SDCA) (Hsieh et al., 2008; Shalev-Shwartz and Zhang, 2013), both of which are popular and well-established parallel optimization techniques.

Proximal SGD: In proximal SGD, a stochastic estimate of the gradient, $\triangle\mathbf{W}$, is first computed over one data sample (or a mini-batch of samples), in order to update $\mathbf{W}$ via $\mathbf{W} \leftarrow \mathbf{W} - \eta \triangle \mathbf{W}$ (where η is the learning rate). Following this, the proximal operator $\text{prox}_{\eta h}(\cdot)$ is applied to $\mathbf{W}$. Notably, the stochastic gradient $\triangle\mathbf{W}$ in **(P)** can be written as the outer product of two vectors $\triangle\mathbf{W} = \mathbf{u}\mathbf{v}^\top$, where $\mathbf{u} = \frac{\partial f(\mathbf{W}\mathbf{a}_i, \mathbf{b}_i)}{\partial(\mathbf{W}\mathbf{a}_i)}$, $\mathbf{v} = \mathbf{a}_i$, according to the chain rule. Later, we will show that this low rank structure of $\triangle\mathbf{W}$ can greatly reduce inter-worker communication.

Stochastic DCA: SDCA applies to problems **(P)** where $f_i(\cdot)$ is convex and $h(\cdot)$ is strongly convex (*e.g.* when $h(\cdot)$ contains the squared ℓ_2 norm); it solves the dual problem of **(P)**, via stochastic coordinate ascent on the dual variables. Introducing the dual matrix $\mathbf{U} = [\mathbf{u}_1, \ldots, \mathbf{u}_N] \in \mathbb{R}^{J\times N}$ and the data matrix $\mathbf{A} = [\mathbf{a}_1, \ldots, \mathbf{a}_N] \in \mathbb{R}^{D\times N}$, the dual problem of **(P)** can be written as

$$\textbf{(D)} \quad \min_{\mathbf{U}} \quad \frac{1}{N}\sum_{i=1}^{N} f_i^*(-\mathbf{u}_i) + h^*(\tfrac{1}{N}\mathbf{U}\mathbf{A}^\top) \tag{2}$$

where $f_i^*(\cdot)$ and $h^*(\cdot)$ are the Fenchel conjugate functions of $f_i(\cdot)$ and $h(\cdot)$, respectively. The primal-dual matrices $\mathbf{W}$ and $\mathbf{U}$ are connected by[2] $\mathbf{W} = \nabla h^*(\mathbf{Z})$, where the auxiliary matrix $\mathbf{Z} := \frac{1}{N}\mathbf{U}\mathbf{A}^\top$. Algorithmically, we need to update the dual matrix $\mathbf{U}$, the primal matrix $\mathbf{W}$, and the auxiliary matrix $\mathbf{Z}$: every iteration, we pick a random data sample i, and compute the stochastic update $\triangle\mathbf{u}_i$ by minimizing **(D)** while holding $\{\mathbf{u}_j\}_{j\neq i}$ fixed. The dual variable is updated via $\mathbf{u}_i \leftarrow \mathbf{u}_i - \triangle\mathbf{u}_i$, the auxiliary variable via $\mathbf{Z} \leftarrow \mathbf{Z} - \triangle\mathbf{u}_i\mathbf{a}_i^\top$, and the primal variable via $\mathbf{W} \leftarrow \nabla h^*(\mathbf{Z})$. Similar to SGD, the update of $\mathbf{Z}$ is also the outer product of two vectors: $\triangle\mathbf{u}_i$ and $\mathbf{a}_i$, which can be exploited to reduce communication cost.

[2]The strong convexity of h is equivalent to the smoothness of the conjugate function h^*.

Sufficient Factor Property in SGD and SDCA: In both SGD and SDCA, the parameter matrix update can be computed as the outer product of two vectors — we call these sufficient factors (SFs). This property can be leveraged to improve the communication efficiency of distributed ML systems: instead of communicating parameter/update matrices among machines, we can communicate the SFs and reconstruct the update matrices locally at each machine. Because the SFs are much smaller in size, synchronization costs can be dramatically reduced. See Section 4 below for a detailed analysis.

Low-rank Extensions: More generally, the update matrix $\triangle\mathbf{W}$ may not be exactly rank-1, but still of very low rank. For example, when each machine uses a mini-batch of size K, $\triangle\mathbf{W}$ is of rank at most K; in Restricted Boltzmann Machines, the update of the weight matrix is computed from four vectors $\mathbf{u}_1, \mathbf{v}_1, \mathbf{u}_2, \mathbf{v}_2$ as $\mathbf{u}_1\mathbf{v}_1^\top - \mathbf{u}_2\mathbf{v}_2^\top$, *i.e.* rank-2; for the BFGS algorithm (Bertsekas, 1999), the update of the inverse Hessian is computed from two vectors $\mathbf{u}, \mathbf{v}$ as $\alpha\mathbf{u}\mathbf{u}^\top - \beta(\mathbf{u}\mathbf{v}^\top + \mathbf{v}\mathbf{u}^\top)$, *i.e.* rank-3. Even when the update matrix $\triangle\mathbf{W}$ is not genuinely low-rank, to reduce communication cost, it might still make sense to send only a certain low-rank *approximation*. We intend to investigate these possibilities in future work.

3 SUFFICIENT FACTOR BROADCASTING

Leveraging the SF property of the update matrix in problems **(P)** and **(D)**, we propose a *Sufficient Factor Broadcasting* (SFB) system that supports efficient (low-communication) distributed learning of the parameter matrix $\mathbf{W}$. We assume a setting with P workers, each of which holds a data shard and a copy of the parameter matrix[3] $\mathbf{W}$. Stochastic updates to $\mathbf{W}$ are generated via proximal SGD or SDCA, and communicated between machines to ensure parameter consistency. In proximal SGD, on every iteration, each worker p computes SFs $(\mathbf{u}_p, \mathbf{v}_p)$, based on one data sample $\mathbf{x}_i = (\mathbf{a}_i, \mathbf{b}_i)$ in the worker's data shard. The worker then broadcasts $(\mathbf{u}_p, \mathbf{v}_p)$ to all other workers; once all P workers have performed their broadcast (and have thus received all SFs), they re-construct the P update matrices (one per data sample) from the P SFs, and apply them to update their local copy of $\mathbf{W}$. Finally, each worker applies the proximal operator $\text{prox}_h(\cdot)$. When using SDCA, the above procedure is instead used to broadcast SFs for the auxiliary matrix $\mathbf{Z}$, which is then used to obtain the primal matrix $\mathbf{W} = \nabla h^*(\mathbf{Z})$. Figure 1 illustrates SFB operation: 4 workers compute their respective SFs $(\mathbf{u}_1, \mathbf{v}_1)$, ..., $(\mathbf{u}_4, \mathbf{v}_4)$, which are then broadcast to the other 3 workers. Each worker p uses all 4 SFs $(\mathbf{u}_1, \mathbf{v}_1), \ldots, (\mathbf{u}_4, \mathbf{v}_4)$ to exactly reconstruct the update matrices $\triangle\mathbf{W}_p = \mathbf{u}_p\mathbf{v}_p^\top$, and update their local copy of the parameter matrix: $\mathbf{W}_p \leftarrow \mathbf{W}_p - \sum_{q=1}^4 \mathbf{u}_q\mathbf{v}_q^\top$. While the above description reflects synchronous execution, it is easy to extend to (bounded) asynchronous execution.

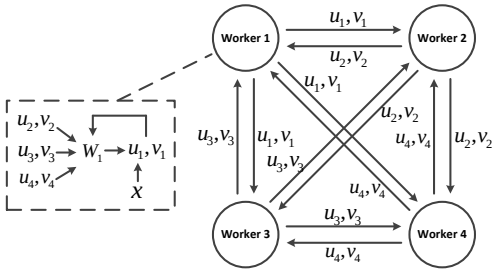

Figure 1: Sufficient Factor Broadcasting (SFB).

SFB vs Client-Server Architectures: The SFB peer-to-peer topology can be contrasted with a "full-matrix" client-server architecture for parameter synchronization, e.g. as used by Project Adam (Chilimbi et al., 2014) to learn neural networks: there, a centralized server maintains the global parameter matrix, and each client keeps a local copy. Clients compute sufficient factors and send them to the server, which uses the SFs to update the global parameter matrix; the server then sends the full, updated parameter matrix back to clients. Although client-to-server costs are reduced (by sending SFs), server-to-client costs are still expensive because full parameter matrices need to be sent. In contrast, the peer-to-peer SFB topology never sends full matrices; only SFs are sent over the network. We also note that under SFB, the update matrices are reconstructed at each of the P machines, rather than once at a central server (for full-matrix architectures). Our experiments show that the time taken for update reconstruction is empirically negligible compared to communication and SF computation.

Partial Broadcasting A naive peer-to-peer topology incurs a communication cost of $O(P^2)$ (where P is the number of worker machines), which inhibits scalability to data center scale clusters where P can reach several thousand (Dean et al., 2012; Li et al., 2014). Hence, SFB adopts an (optional) partial broadcasting scheme where each machine connects with and sends messages to a subset of Q machines (rather than all other machines), thus reducing communication costs from $O(P^2)$ to $O(PQ)$. Figure 2 presents an example. In partial broadcasting, an update U_p^t generated by machine p at iteration t is sent only to machines that are directly connected with p (and the update U_p^t takes effect at iteration $t+1$). The effect of U_p^t is *indirectly and eventually* transmitted to every other machine q, via the updates generated by machines sitting between p and q in the topology. This happens at iteration $t+\tau$, for some delay $\tau > 1$ that depends on Q and the location of p and q in the network topology. Consequently, the

[3]For simplicity, we assume each worker has enough memory to hold a full copy of the parameter matrix $\mathbf{W}$. If $\mathbf{W}$ is too large, one can either partition it across multiple machines (Dean et al., 2012; Li et al., 2014), or use local disk storage (*i.e.* out of core operation). We plan to investigate these strategies as future work.

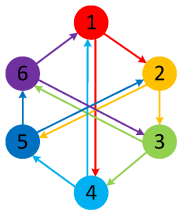

Figure 2: An Example of Partial Broadcasting.

P machines will not have the exact same parameter image $\mathbf{W}$, even under bulk synchronous parallel execution — yet surprisingly, this does not empirically (Section 5) compromise algorithm accuracy as long as Q is not too small. We hypothesize that this property is related to the tolerance of ML algorithms to bounded-asynchronous execution and random error, and we defer a formal proof to future work.

Determining the "best" topology of partial broadcasting, i.e., which subset of machines each machine should send message to, is a challenging issue. Previous studies (Li et al., 2015) are mostly based on heuristics. While empirically effective, these heuristics lack a mathematically formalizable objective. To address this issue, we propose an optimization-oriented solution, with the goal to achieve fast dissemination of information: the effect of updates generated at each machine should be "seen" by all other machines as quickly as possible. Formally, we aim to reduce the delay τ. Consider a directed network with P nodes, where $e_{pq} = 1$ denotes that node p sends message to node q and $e_{pq} = 0$ otherwise. Let c_{pq} denote the shortest directed path from node p to q. It is easy to see that $\tau = |c_{pq}|$, where $|c_{pq}|$ is the length of c_{pq}. Letting $E = \{e_{pq}\}_{p=1,q\neq p}^{P}$ we can find a network topology that minimizes τ by solving this optimization problem:

$$\begin{array}{ll} \min_E & \sum_{p=1}^{P} \sum_{q\neq p}^{P} |c_{pq}| \\ s.t. & \sum_{q\neq p}^{P} e_{pq} = Q, \forall p \end{array} \quad (3)$$

which can be efficiently solved by using a Branch and Bound (Land and Doig, 1960) searching of the graph structure, in conjunction with an algorithm (Williams, 2014) finding all-pairs shortest path in directed graphs.

Mini-batch Proximal SGD/SDCA: SFB can also be used in mini-batch proximal SGD/SDCA; every iteration, each worker samples a mini-batch of K data points, and computes K pairs of sufficient factors $\{(\mathbf{u}_i, \mathbf{v}_i)\}_{i=1}^{K}$. These K pairs are broadcast to all other workers, which reconstruct the originating worker's update matrix as $\triangle\mathbf{W} = \frac{1}{K}\sum_{i=1}^{K} \mathbf{u}_i\mathbf{v}_i^{\mathsf{T}}$.

Consistency Models SFB supports two consistency models: Bulk Synchronous Parallel (BSP-SFB) and Stale Synchronous Parallel (SSP-SFB), and we provide theoretical convergence guarantees in the next section.

- **BSP-SFB:** Under BSP (Dean and Ghemawat, 2008; Zaharia et al., 2012), an end-of-iteration global barrier ensures all workers have completed their work, and synchronized their parameter copies, before proceeding to the next iteration. BSP is a strong consistency model, that guarantees the same computational outcome (and thus algorithm convergence) each time.

```
sfb_app mlr ( int J, int D, int staleness )
//SF computation function
function compute_sv ( sfb_app mlr ):
  while ( ! converged ):
    X = sample_minibatch ()
    foreach x_i in X:
      //sufficient factor u_i
      pred = predict ( mlr.para_mat, x_i )
      mlr.sv_list[i].write_u ( pred )
      //sufficient factor v_i
      mlr.sv_list[i].write_v ( x_i )
    commit()
```

Figure 3: Multiclass LR Pseudocode.

- **SSP-SFB:** BSP can be sensitive to stragglers (slow workers) (Ho et al., 2013), limiting the distributed system to the speed of the slowest worker. Stale Synchronous Parallel (SSP) (Bertsekas and Tsitsiklis, 1989; Ho et al., 2013) communication model addresses this issue, by allowing workers to advance at different rates, provided that the difference in iteration number between the slowest and fastest workers is no more than a user-provided staleness s. SSP alleviates the straggler issue while guaranteeing algorithm convergence (Ho et al., 2013). Under SSP-SFB, each worker p tracks the number of SF pairs computed by itself, t_p, versus the number $\tau_p^q(t_p)$ of SF pairs received from each worker q. If there exists a worker q such that $t_p - \tau_p^q(t_p) > s$ (*i.e.* some worker q is likely more than s iterations behind worker p), then worker p pauses until q is no longer s iterations or more behind.

Programming Interface The SFB programming interface is simple; users need to provide a SF computation function to specify how to compute the sufficient factors. To send out SF pairs $(\mathbf{u}, \mathbf{v})$, the user adds them to a buffer object sv_list, via: $write\_u(vec\_u)$, $write\_v(vec\_v)$, which set i-th SF $\mathbf{u}$ or $\mathbf{v}$ to vec_u or vec_v. All SF pairs are sent out at the end of an iteration, which is signaled by $commit()$. Finally, in order to choose between BSP and SSP consistency, users simply set $staleness$ to an appropriate value (0 for BSP, > 0 for SSP). SFB automatically updates workers' local parameter matrix using all SF pairs — including both locally computed SF pairs added to sv_list, as well as SF pairs received from other workers. Figure 3 shows SFB pseudocode for multiclass logis-

tic regression. For proximal SGD/SDCA algorithms, SFB requires users to write an additional function, $prox(mat)$, which applies the proximal operator $\text{prox}_h(\cdot)$ (or the SDCA dual operator $h^*(\cdot)$) to the parameter matrix mat.

4 COST ANALYSIS AND THEORY

We now examine the costs and convergence behavior of SFB under synchronous and bounded-async (e.g. SSP (Bertsekas and Tsitsiklis, 1989; Ho et al., 2013)) consistency, and show that SFB can be preferable to full-matrix synchronization/communication schemes.

4.1 COST ANALYSIS

Figure 4 compares the communications, space and time (to apply updates to $\mathbf{W}$) costs of peer-to-peer SFB, against full matrix synchronization (FMS) under a client-server architecture (Chilimbi et al., 2014). For SFB with a full broadcasting scheme, in each minibatch, every worker broadcasts K SF pairs $(\mathbf{u}, \mathbf{v})$ to $P-1$ other workers, i.e. $O(P^2K(J+D))$ values are sent per iteration — linear in matrix dimensions J, D, and quadratic in P. For SFB with a partial broadcasting scheme, every worker communicates SF pairs with $Q < P$ peers, hence the communication cost is reduced to $O(PQK(J+D))$. Because SF pairs cannot be aggregated before transmission, the cost has a dependency on K. In contrast, the communication cost in FMS is $O(PJD)$, linear in P, quadratic in matrix dimensions, and independent of K. For both SFB and FMS, the cost of storing $\mathbf{W}$ is $O(JD)$ on every machine. As for the time taken to update $\mathbf{W}$ per iteration, FMS costs $O(PJD)$ at the server (to aggregate P client update matrices) and $O(PKJD)$ at the P clients (to aggregate K updates into one update matrix). By comparison, SFB bears a cost of $O(P^2KJD)$ under full broadcasting and $O(PQKJD)$ under partial broadcasting due to the additional overhead of reconstructing each update matrix P or Q times.

Compared with FMS, SFB achieves communication savings by paying an extra computation cost. In a number of practical scenarios, such a tradeoff is worthwhile. Consider large problem scales where $\min(J, D) \geq 10000$, and moderate minibatch sizes $1 \leq K \leq 100$ (as studied in this paper); when using a moderate number of machines (around 10-100), the $O(P^2K(J+D))$ communications cost of SFB is lower than the $O(PJD)$ cost for FMS, and the relative benefit of SFB improves as the dimensions J, D of $\mathbf{W}$ grow. In data center scale computing environments with thousands of machines, we can adopt the partial broadcasting scheme. As for the time needed to apply updates to $\mathbf{W}$, it turns out that the additional cost of reconstructing each update matrix P or Q times in SFB is negligible in practice — we have observed in our experiments that the time spent computing SFs, as well as communicating SFs over the network, greatly dominates the cost of reconstructing update matrices using SFs. Overall, the communication savings dominate the added computational overhead, which we validated in experiments.

4.2 CONVERGENCE ANALYSIS

We study the convergence of minibatch SGD under full broadcasting SFB (with extensions to proximal-SGD, SDCA being a topic for future study). Since SFB is a peer-to-peer decentralized computation model, we need to show that parameter copies on different workers converge to the same limiting point without a centralized coordination, even under delays in communication due to bounded asynchronous execution. In this respect, we differ from analyses of centralized parameter server systems (Ho et al., 2013), which instead show convergence of global parameters on the central server.

We wish to solve the optimization problem $\min_{\mathbf{W}} \sum_{m=1}^{M} f_m(\mathbf{W})$, where M is the number of training data minibatches, and f_m corresponds to the loss function on the m-th minibatch. Assume the training data minibatches $\{1, ..., M\}$ are divided into P disjoint subsets $\{S_1, ..., S_P\}$ with $|S_p|$ denoting the number of minibatches in S_p. Denote $F = \sum_{m=1}^{M} f_m$ as the total loss, and for $p = 1, \ldots, P$, $F_p := \sum_{j \in S_p} f_j$ is the loss on S_p (on the p-th machine).

Consider a distributed system with P machines. Each machine p keeps a local variable $\mathbf{W}_p$ and the training data in S_p. At each iteration, machine p draws one minibatch I_p uniformly at random from partition S_p, and computes the partial gradient $\sum_{j \in I_p} \nabla f_j(\mathbf{W}_p)$. Each machine updates its local variable by accumulating partial updates from all machines. Denote η_c as the learning rate at c-th iteration on every machine. The partial update generated by machine p at its c-th iteration is denoted as $U_p(\mathbf{W}_p^c, I_p^c) = -\eta_c |S_p| \sum_{j \in I_p^c} \nabla f_j(\mathbf{W}_p^c)$. Note that I_p^c is random and the factor $|S_p|$ is to restore unbiasedness in expectation. Then the local update rule of machine p is

$$\begin{aligned} &\mathbf{W}_p^c = \mathbf{W}^{\mathbf{0}} + \sum_{q=1}^{P} \sum_{t=0}^{\tau_p^q(c)} U_q(\mathbf{W}_q^t, I_q^t) \\ &0 \leq (c-1) - \tau_p^q(c) \leq s \end{aligned} \tag{4}$$

where $\mathbf{W}^0$ is the common initializer for all P machines, and $\tau_p^q(c)$ is the number of iterations machine q has transmitted to machine p when machine p conducts its c-th iteration. Clearly, $\tau_p^p(c) = c$. Note that we also require $\tau_p^q(c) \leq c-1$, *i.e.*, machine p will not use any partial updates of machine q that are too fast forward. This is to avoid correlation in the theoretical analysis. Hence, machine p (at its c-th iteration) accumulates updates generated by machine q up to iteration $\tau_p^q(c)$, which is restricted to be at most s iterations behind. This formulation, in which s is the maximum "staleness" allowed between any update and any worker, covers bulk synchronous parallel (BSP) full broadcasting ($s = 0$) and bounded-asynchronous full broadcasting ($s > 0$). The following standard assumptions are needed for our analysis:

Computational Model	Total comms, per iter	$\mathbf{W}$ storage per machine	$\mathbf{W}$ update time, per iter
SFB (peer-to-peer, full broadcasting)	$O(P^2K(J+D))$	$O(JD)$	$O(P^2KJD)$
SFB (peer-to-peer, partial broadcasting)	$O(PQK(J+D))$	$O(JD)$	$O(PQKJD)$
FMS (client-server (Chilimbi et al., 2014))	$O(PJD)$	$O(JD)$	$O(PJD)$ at server, $O(PKJD)$ at clients

Figure 4: Cost of using SFB versus FMS. K is minibatch size, J, D are dimensions of $\mathbf{W}$, and P is the number of workers.

Assumption 1. *(1) For all j, f_j is continuously differentiable and F is bounded from below; (2) ∇F, ∇F_p are Lipschitz continuous with constants L_F and L_p, respectively, and let $L = \sum_{p=1}^{P} L_p$; (3) There exists B, σ^2 such that for all p and c, we have (almost surely) $\|\mathbf{W}_p^c\| \leq B$ and $\mathbb{E}\| \, |S_p| \sum_{j \in I_p} \nabla f_j(\mathbf{W}) - \nabla F_p(\mathbf{W}) \, \|_2^2 \leq \sigma^2$.*

Our analysis is based on the following auxiliary update

$$\mathbf{W}^c = \mathbf{W}^0 + \sum_{q=1}^{P} \sum_{t=0}^{c-1} U_q(\mathbf{W}_q^t, I_q^t), \qquad (5)$$

Compare to the local update (4) on machine p, essentially this auxiliary update accumulates all $c-1$ updates generated by all machines, instead of the $\tau_p^q(c)$ updates that machine p has access to. We show that all local machine parameter sequences are asymptotically consistent with this auxiliary sequence:

Theorem 1. *Let $\{\mathbf{W}_p^c\}$, $p = 1, \ldots, P$, and $\{\mathbf{W}^c\}$ be the local sequences and the auxiliary sequence generated by SFB for problem **(P)** (with $h \equiv 0$), respectively. Under Assumption 1 and set the learning rate $\eta_c = O(\sqrt{\frac{1}{L\sigma^2 Psc}})$, then we have*

- $\liminf_{c \to \infty} \mathbb{E}\|\nabla F(\mathbf{W}^c)\| = 0$, *hence there exists a subsequence of $\nabla F(\mathbf{W}^c)$ that almost surely vanishes;*
- $\lim_{c \to \infty} \max_p \|\mathbf{W}^c - \mathbf{W}_p^c\| = 0$, i.e. *the maximal disagreement between all local sequences and the auxiliary sequence converges to 0 (almost surely);*
- *There exists a common subsequence of $\{\mathbf{W}_p^c\}$ and $\{\mathbf{W}^c\}$ that converges almost surely to a stationary point of F, with the rate* $\min_{c \leq C} \mathbb{E}\| \sum_{p=1}^{P} \nabla F_p(\mathbf{W}_p^c)\|_2^2 \leq O\left(\sqrt{\frac{L\sigma^2 Ps}{C}}\right)$

Intuitively, Theorem 1 says that, given a properly-chosen learning rate, all local worker parameters $\{\mathbf{W}_p^c\}$ eventually converge to stationary points (i.e. local minima) of the objective function F, despite the fact that SF transmission can be delayed by up to s iterations. Thus, SFB learning is robust even under bounded-asynchronous communication (such as SSP). Our analysis differs from (Bertsekas and Tsitsiklis, 1989) in two ways: (1) Bertsekas and Tsitsiklis (1989) explicitly maintains a consensus model which would require transmitting the parameter matrix among worker machines — a communication bottleneck that we were able to avoid; (2) we allow subsampling in each worker machine. Accordingly, our theoretical guarantee is probabilistic, instead of the deterministic one in (Bertsekas and Tsitsiklis, 1989). In future work, we intend to extend the analysis to partial broadcasting under BSP and bounded-asynchronous execution. Partial broadcasting presents additional challenges, because updates are only sent to a subset of machines (rather than every machine).

5 EXPERIMENTS

We demonstrate how four popular models can be efficiently learnt using SFB: (1) multiclass logistic regression (MLR) and distance metric learning (DML)[4] based on SGD; (2) sparse coding (SC) based on proximal SGD; (3) ℓ_2 regularized multiclass logistic regression (L2-MLR) based on SDCA. For baselines, we compared with (a) Spark (Zaharia et al., 2012) for MLR and L2-MLR, and (b) full matrix synchronization (FMS) implemented on open-source parameter servers (Ho et al., 2013; Li et al., 2014) for all four models. In certain experiments, we made a comparison with the distributed (L2-)MLR system proposed in (Gopal and Yang, 2013). In FMS, workers send update matrices to the central server, which then sends up-to-date parameter matrices to workers[5]. Due to data sparsity, both the update matrices and sufficient factors are sparse; we use this fact to reduce communication and computation costs. The experiments were performed on a cluster where each machine has 64 2.1GHz AMD cores, 128G memory, and a 10Gbps network interface. Unless otherwise noted, 12 machines were used. Some experiments were conducted on 28 machines.

Datasets and Experimental Setup We used two datasets for our experiments: (1) ImageNet (Deng et al., 2009) ILSFRC2012 dataset, which contains 1.2 million images from 1000 categories; the images are represented with LLC features (Wang et al., 2010), whose dimensionality is 172k. (2) Wikipedia (Partalas et al., 2015) dataset, which contains 2.4 million documents from 325k categories; documents are represented with *term frequency, inverse document frequency* (tf-idf), with a dimensionality of 20k. We ran MLR, DML, SC, L2-MLR on the Wikipedia, Ima-

[4]For DML, we use the parametrization proposed in (Weinberger et al., 2005), which is a linear projection matrix $\mathbf{L} \in \mathrm{R}^{d \times k}$, where d is the feature dimension and k is the latent dimension.

[5]This has the same communication complexity as (Chilimbi et al., 2014), which sends SFs from workers to servers, but sends matrices from servers to workers; the latter matrix transmission dominates the total cost.

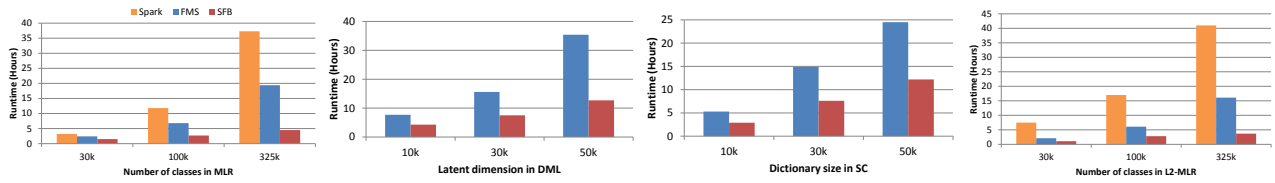

Figure 5: Convergence time versus model size for MLR, DML, SC, L2-MLR (left to right), under BSP.

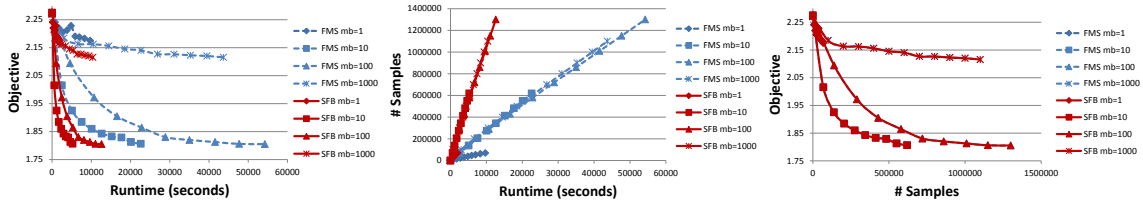

Figure 6: MLR objective vs runtime (left), #samples vs runtime (middle), objective vs #samples (right).

geNet, ImageNet, Wikipedia datasets respectively, and the parameter matrices contained up to 6.5b, 8.6b, 8.6b, 6.5b entries (the largest latent dimension for DML and largest dictionary size for SC were both 50k). The tradeoff parameters in SC and L2-MLR were set to 0.001 and 0.1. We tuned the minibatch size, and found that $K = 100$ was near-ideal for all experiments. All experiments used the same constant learning rate (tuned in the range $[10^{-5}, 1]$). Unless otherwise stated, a full broadcasting scheme is used for most experiments.

Convergence Speed and Quality Figure 5 shows the time taken to reach a fixed objective value, for different model sizes, using BSP consistency (SSP results are in the supplement), on 12 machines. SFB converges faster than FMS, as well as Spark v1.3.1[6]. This is because SFB has lower communication costs, hence a greater proportion of running time gets spent on computation rather than network waiting. This is shown in Figure 6, which plots data samples processed per second[7] (throughput) and algorithm progress per sample for MLR, under BSP consistency (SSP results are in the supplement) and varying minibatch sizes. The middle graph shows that SFB processes far more samples per second than FMS, while the rightmost graph shows that SFB and FMS produce exactly the same algorithm progress per sample under BSP. For this experiment, minibatch sizes between $K = 10$ and 100 performed the best as indicated by the leftmost graph. We point out that larger model sizes should further improve SFB's advantage over FMS, because SFB has linear communications cost in the matrix dimensions, whereas FMS has quadratic costs. Under a large model size (e.g., 325k classes in MLR), the communication cost becomes the bottleneck in FMS and causes prolonged network waiting time and parameter synchronization delays, while the cost is moderate in SFB.

We also evaluated SFB on 28 machines, under BSP and full broadcasting (Q=27). On MLR (325k classes), SFB took 2.46 hours to converge while FMS took 10.77 hours. On L2-MLR (325k classes), the convergence time of SFB is 2.14 hours while that of FMS is 9.31 hours.

We made a comparison with the distributed (L2-)MLR system proposed by (Gopal and Yang, 2013) on 12 machines. On MLR (325k classes), Gopal and Yang (2013) took 31.7 hours to converge while SFB took 4.5 hours. To converge on L2-MLR (325k classes), Gopal and Yang (2013) took 28.3 hours while SFB took 3.7 hours.

Scalability In all experiments that follow, we set the number of (L2-)MLR classes, DML latent dimension, SC dictionary size to 325k, 50k, 50k. Figure 7 shows SFB scalability with varying machines under BSP (SSP results are in the supplement), for MLR, DML, SC, L2-MLR, on 12 machines. In general, we observed close to linear (ideal) speedup, with a slight drop at 12 machines. On 28 machines, for MLR and L2-MLR, SFB achieved 17.4x and 15.7x speedup over one machine respectively.

Computation Time vs Network Waiting Time Figure 8 shows the *total* computation and network time required for SFB and FMS to converge, across a range of SSP staleness values[8] — in general, higher communication cost and lower staleness induce more network waiting. For all staleness values, SFB requires far less network waiting (because SFs are much smaller than full matrices in FMS). Computation time for SFB is slightly longer than FMS because (1) update matrices must be reconstructed on each SFB worker, and (2) SFB requires a few more iterations for convergence, because peer-to-peer communication causes a slightly more parameter inconsistency under staleness. Overall, the SFB reduction in network waiting time remains far greater than the added computation time, and outperforms FMS in total time. For both FMS and SFB,

[6]Spark is about 2x slower than PS (Ho et al., 2013) based C++ implementation of FMS, due to JVM and RDD overheads.

[7]We use samples per second instead of iterations, so different minibatch sizes can be compared.

[8]The Spark implementation does not easily permit this time breakdown, so we omit it.

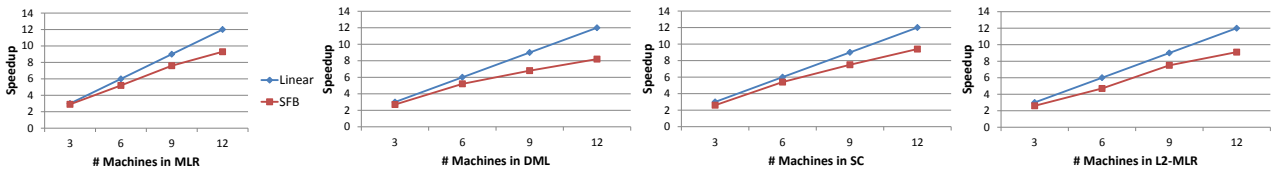

Figure 7: SFB scalability with varying machines under BSP, for MLR, DML, SC, L2-MLR (left to right).

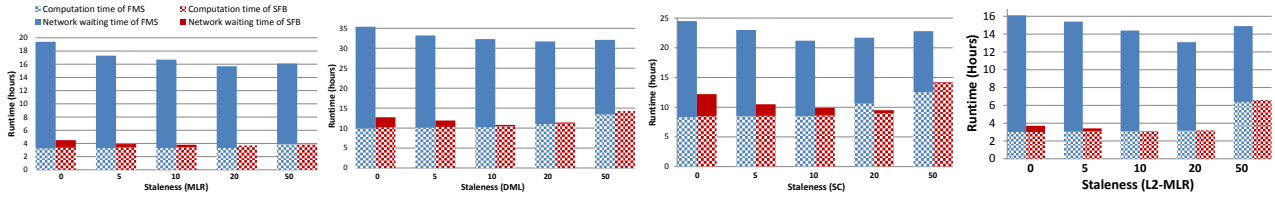

Figure 8: Computation vs network waiting time for MLR, DML, SC, L2-MLR (left to right).

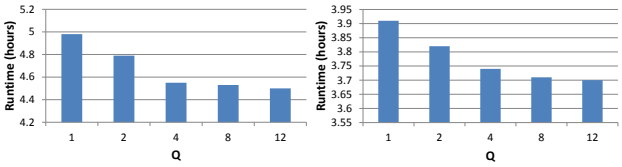

Figure 9: Convergence time versus Q in partial broadcasting for MLR (left) and L2-MLR (right), under BSP.

the shortest convergence times are achieved at moderate staleness values, confirming the importance of bounded-asynchronous communication.

Partial Broadcasting On 12 machines, we studied in partial broadcasting how the parameter Q, which is the number of peers to which each machine sends messages, affects the convergence speed of SFB. Figure 9 shows the convergence time of SFB on MLR and L2-MLR versus varying Q, under BSP (SSP results are given in supplements). First, we observed that SFB under partial broadcasting (PB) with $Q < 11$ converges to the same objective value as under full broadcasting (FB) where $Q = 11$. This provides empirical justification that PB preserves correctness and convergence of algorithms. Second, we noted that the convergence time of PB is affected by Q. As observed in this figure, a smaller Q incurs longer convergence time. This is because a smaller Q is more likely to cause the parameter copies on different workers to be out of synchronization and degrade iteration quality. However, as long as Q is not too small, the convergence speed of PB is comparable with FB. As shown in the figure, for $Q \geq 4$, the convergence time of PB is very close to FB. This demonstrates that using PB, we can reduce the communication cost from $O(P^2)$ to $O(PQ)$ with slight sacrifice of the convergence speed.

6 RELATED WORKS

A number of system and algorithmic solutions have been proposed to reduce communication cost in distributed ML. On the system side, Dean et al. (2012) proposed to reduce communication overhead by reducing the frequency of parameter/gradient exchanges between workers and the server. Li et al. (2014) used filters to select "important" parameters/updates for transmission to reduce the number of data entries to be communicated. On the algorithm side, Tsianos et al. (2012) studied the tradeoffs between communication and computation in distributed dual averaging and distributed stochastic dual coordinate ascent respectively. Shamir et al. (2014) proposed an approximate Newton-type method to achieve communication efficiency in distributed optimization. SFB is orthogonal to these existing approaches and be potentially combined with them to further reduce communication cost.

Peer-to-peer, decentralized architectures have been investigated in other distributed ML frameworks (Li et al., 2015). Our SFB system also adopts such an architecture, but with the specific purpose of supporting the SFB computation model, which is not explored by existing peer-to-peer ML frameworks.

7 CONCLUSIONS

In this paper, we identify the sufficient factor property of a large set of matrix-parametrized models: when these models are optimized with stochastic gradient descent or stochastic dual coordinate ascent, the update matrices are of low-rank. Leveraging this property, we propose a sufficient factor broadcasting strategy to efficiently handle the learning of these models with low communication cost. A partial broadcasting scheme is investigated to alleviate the overhead of full broadcasting. We analyze the cost and convergence property of SFB, whose communication efficiency is demonstrated in empirical evaluations.

Abstract

A graph-based multi-class classification problem is typically converted into a collection of binary classification tasks via the one-vs.-all strategy, and then tackled by applying proper binary classification algorithms. Unlike the one-vs.-all strategy, we suggest a unified framework which operates directly on the multi-class problem without reducing it to a collection of binary tasks. Moreover, this framework makes active learning practically feasible for multi-class problems, while the one-vs.-all strategy cannot. Specifically, we employ a novel randomized query technique to prioritize the informative instances. This query technique based on the hybrid criterion of "margin" and "uncertainty" can achieve a comparable mistake bound with its fully supervised counterpart. To take full advantage of correctly predicted labels discarded in traditional conservative algorithms, we propose an aggressive selective sampling algorithm that can update the model even if no error occurs. Thanks to the aggressive updating strategy, the aggressive algorithm attains a lower mistake bound than its conservative competitors in expectation. Encouraging experimental results on real-world graph databases show that the proposed technique by querying an extremely small ratio of labels is able to accomplish better classification accuracy.

I. INTRODUCTION

Graphs, as a family of ubiquitous structures to model different types of networks, such as social networks (*e.g.*, Facebook, Twitter), biological networks [19], [20], and citation networks [21], have been widely applied in diverse applications. Particularly, one important task is to classify graph vertices into multiple classes, *e.g.*, authors in a citation network can be classified into different domains/classes, such as computer science, biology, physics, mathematics, economics, *etc*. To build a classifier, the desired classification model can be learnt from a set of vertex-label pairs in both offline [7] and online settings [16]. Offline algorithms can access the labels of all the stored vertices in a pool, which increases the storage requirement. Online learning, on the other hand, obtains the instances in a sequential order. It allows to access the label of the current vertex; after updating the model, the current input will be discarded [18]. Therefore, online learning is scalable to deal with massive datasets.

Although online classification on graphs has been well studied, it still remains as a challenging research subject, which is primarily due to three reasons. First, most online techniques focus on binary classification problems. Some approaches [14], [22] address multi-class problems by using output coding [12]. Such a setting may be ineffective and ill-defined since it generalizes multiple binary classifiers and each classifier is maintained and updated *independently* of the others [1]. Second, online learning assumes that the labels of all vertices are provided already. It is impractical as labeling every sample is expensive and time-consuming in many real-world applications. Third, in social networks, data usually arrives in a sequential order and the network scale can be very large, which brings a critical challenge to develop efficient and scalable algorithms for graph classification.

To address the aforementioned challenges, we present a unified framework to cope with multi-class online classification on graphs. Specifically, we adapt the graph Laplacian Regularized Least Squares (LapRLS) model to the multi-class setting, in which updating one class model has a global impact on the other classes. However, such an approach assumes that all labels are available, which obviously limits its usage to many domains. To minimize the labeling cost, we propose a new query technique based on both the "margin" [9] and "uncertainty" criteria, to only query the labels of the most informative instances. We

[1]Refer to the comparison between the binary and multi-class settings in the supplementary material.

theoretically analyze an online algorithm running on the selected labels by our query technique, which achieves a comparable mistake bound with the one that queries all labels. In addition, to take full advantage of correctly predicted labels that are discarded in conservative algorithms, we introduce an aggressive version of selective sampling. It hybrids the conservative update with the aggressive sampling scheme, which updates the model even if no error occurs. The theoretical results show that our aggressive selective sampling algorithm can achieve better performance than its conservative competitors. Extensive experiments carried out on several real-world graph datasets further validate the empirical performance of the proposed algorithms.

The rest of this paper is organized as follows. Section 2 presents the problem setting of graph classification. The proposed multi-class online learning and selective sampling algorithms are described in Section 3 and Section 4, respectively. Section 5 discusses the experimental results. Section 6 concludes our work.

II. GRAPH CLASSIFICATION

In this section, we first present the notations. Then we introduce a graph Laplacian regularization that can derive a linear model for multi-class classification.

A. Notation

In this paper, we will use lower case letters as scalars (e.g. x), lower case bold letters as vectors (e.g. $\mathbf{f}$), upper case letters as elements of a matrix (e.g. S_{ij}) and boldface upper letters as matrices (e.g. $\mathbf{S}$). With an appropriate size, an identity matrix is defined as $\mathbf{I}$ and a vector of all zeros as $\mathbf{0}$. The transpose of a vector $\mathbf{m}$ is denoted as $\mathbf{m}^\top$, the inverse of a matrix $\mathbf{A}$ as $\mathbf{A}^{-1}$, and the pseudo inverse of $\mathbf{A}$ as $\mathbf{A}^\dagger$. A diagonal matrix is denoted as $\text{diag}(\sigma_1, \ldots, \sigma_n)$ with diagonal elements $\sigma_i, i \in [1, n]$. In addition, Euclidean norms are denoted as $\|\cdot\|_2$, Frobenius norm as $\|\cdot\|_F$ and the trace of square matrix as $tr(\cdot)$. When function $f(W)$ is differentiable, we denote its gradient by $\nabla f(W)$.

We consider the problem of classification in probabilistic setting: n i.i.d. pais are generated by a probability distribution on $\mathcal{X} \times \mathcal{Y}$, where y_i in a pair of (x_i, y_i) is the $class$ of instance x_i. We define $|\mathcal{Y}| = 2$ as binary-class setting, and $|\mathcal{Y}| > 2$ as a multi-class problem.

B. Graph Laplacian Regularization

$G = (V, E)$ is defined as a graph with an vertex set $V = \{v_1, \ldots, v_n\}$, an edge set $E = \{(v_i, v_j) | v_i, v_j \in V\}$ and an adjacency matrix $\mathbf{S} \in \mathbb{R}^{n \times n}$, where the element $S_{ij} \in \mathbb{R}_0^+$ is measured by the affinity of edge (v_i, v_j). We assume graph G is connected and undirected in this work. Given D is the diagonal matrix with $D_{ii} = \sum_j S_{ij}$, graph Laplacian is defined as $L = D - S$ with its eigenvector $\mathbb{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_n] (\mathbf{v}_i \in \mathbb{R}^n)$ and eigenvalue $\Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n)$ where $0 = \lambda_1 \leq \ldots \leq \lambda_n$. Intuitively, the objective function incurs a heavy penalty, if neighboring vertices v_i and v_j are mapped far apart. The graph regularization [17] assumes a label smoothness over the graph,

$$\frac{1}{2} \sum_{i,j=1}^{n} S_{ij} \|\mathbf{f}_i - \mathbf{f}_j\|^2 = tr\left(F^\top (D - S) F\right) = tr\left(F^\top L F\right),$$

where $F = [\mathbf{f}_1, \ldots, \mathbf{f}_n]^\top$ and $\mathbf{f}_i \in \mathbb{R}^K$ is the prediction scores of node i on K classes.

In the setting of graph classification, the real-valued function satisfies: 1) the values of function F for labeled vertices should be close to the given labels for that vertices; 2) vertices should satisfy label smoothness on the whole graph, that is, the points nearby in graph should have similar labels. In the multi-class scenario, the generalized LapRLS solves the following function,

$$\min_F \|F - Y\|_F^2 + \gamma tr\left(F^\top L F\right), \tag{1}$$

where $Y = [\mathbf{y}_1, \ldots, \mathbf{y}_n]^\top \in \mathbb{R}^{n \times K}$, $\mathbf{y}_i \in \mathbb{R}^K$ is the true label of node i on K classes, and $\gamma > 0$ is a regularized parameter for graph Laplacian. To solve the problem (1) with a linear model, we consider its dual form. Using the definition of graph kernel [17], the function F can be defined, $F = L^\dagger \Phi$, where $L^\dagger$ is the pseudo inverse of L and $\Phi \in \mathbb{R}^{n \times K}$ is a parameter matrix. Assuming that $L^\dagger = M^\top M = \sum_i \frac{1}{\lambda_i} \mathbf{v}_i \mathbf{v}_i^\top$, where $M = [\frac{1}{\sqrt{\lambda_1}} \mathbf{v}_1, \ldots, \frac{1}{\sqrt{\lambda_n}} \mathbf{v}_n]^\top \in \mathbb{R}^{n \times n}$ and $W = M\Phi \in \mathbb{R}^{n \times K}$, the kernel function F can be reformatted in a linear model form,

$$F = M^\top W, \tag{2}$$

where $\mathbf{f}_i = W^\top \mathbf{m}_i$ is essentially a linear regression model. In the multi-class setting, our linear model and its prediction margin are defined as follows.

Definition 1. *We define a multi-class linear model that consists of label score of an input $\mathbf{m}_i$ over the K classes,*

$$\mathbf{f}_i = \left[P_W^{\mathbf{m}_i}(1), \ldots, P_W^{\mathbf{m}_i}(K)\right]^\top. \tag{3}$$

Given the node-label pair $(\mathbf{m}_i, y_i)$, we define the prediction margin of $\mathbf{f}_i$,

$$P_W^{\mathbf{m}_i}(y_i) - \max_{j \neq y_i} P_W^{\mathbf{m}_i}(j) = \mathbf{f}_i \cdot \mathbf{y}_i, \tag{4}$$

where $\mathbf{y}_i \in \mathbb{R}^K$ is a label vector of node i with an entry of $+1$ for true class y_i, -1 for the class $j = \text{argmax}_{j \neq y_i} P_W^{\mathbf{m}_i}(j)$ and 0 otherwise.

Substituting Eq. (2) into Eq. (1), we obtain,

$$\min_W \|M^\top W - Y\|_F^2 + \gamma tr\left(W^\top W\right).$$

In this way, we derive a formulation, similar to ridge-regression, with an additional regularization to shrink the prediction. It helps us to derive a multi-class online model with a new data representation for graph vertex.

C. Low-rank Approximation

Given $M = [\frac{1}{\sqrt{\lambda_1}}\mathbf{v}_1, \ldots, \frac{1}{\sqrt{\lambda_n}}\mathbf{v}_n]^\top$, the matrix W is updated with the time complexity $O(n^2)$, that is computationally expensive in large graph datasets. To make our algorithm scalable to big graphs, we propose a low-rank approximation $\hat{M}$ as follows,

$$\hat{M} = [\frac{1}{\sqrt{\lambda_1}}\mathbf{v}_1, \ldots, \frac{1}{\sqrt{\lambda_d}}\mathbf{v}_d]^\top \in \mathbb{R}^{d\times n},\ \hat{W} = \hat{M}\Phi \in \mathbb{R}^{d\times K},$$

where $d \ll n$ and the time complexity of our algorithm becomes $O(d^2) \ll O(n^2)$. We analyze the impact of such low-rank approximation on the function $\hat{F} = \hat{M}^\top\hat{W}$. We have $\hat{F} = \hat{L}^\dagger\Phi$, where $\hat{L}^\dagger = \hat{M}^\top\hat{M} = \sum_{i=1}^{d}\frac{1}{\lambda_i}\mathbf{v}_i\mathbf{v}_i^\top$. Given that $\frac{1}{\lambda_1} \geq \ldots \geq \frac{1}{\lambda_n}$, $\hat{L}^\dagger$ holds the d largest eigenvalues of $L^\dagger$. In this case, $\hat{L}^\dagger$ is the best rank-d approximation of $L^\dagger$ [13], and thus $\hat{F}$ is the best rank-d approximation of F. Equipped with $\hat{M}$ and $\hat{W}$ a low-rank objective function for multi-class online classification can be rewritten as follows,

$$\arg\min_{\hat{W}} \sum_{t=1}^{T} \|\hat{W}^\top\hat{\mathbf{m}}_t - \mathbf{y}_t\|_2^2 + \gamma tr(\hat{W}^\top\hat{W}).$$

III. ONLINE LEARNING

Now we are ready to derive a multi-class online model on graph. We first present the problem setting of online learning. Then we derive the online classifier and its mistake bound.

A. Problem Setting

The purpose of online learning is to minimize the cumulative loss over the sequential nodes. Let $(\mathbf{m}_1, \mathbf{y}_1), \ldots, (\mathbf{m}_T, \mathbf{y}_T)$ $(T \leq n)$ be a sequence of vertices, where $\mathbf{m}_t \in \mathbb{R}^n$ is one column of matrix M and $\mathbf{y}_t \in \mathbb{R}^K$ is its label vector, an online version of LapRLS in multi-class setting is derived,

$$G_T(W) = \sum_{t=1}^{T} \|W^\top\mathbf{m}_t - \mathbf{y}_t\|_2^2 + \gamma tr\left(W^\top W\right). \quad (5)$$

At round t, online algorithm receives an input vertex $\mathbf{m}_t$, and predicts its label with the maximal score among the K classes, $\hat{y}_t = \underset{i\in[K]}{\operatorname{argmin}} P_{W_t}^{\mathbf{m}_t}(i)$. After prediction, its actual label y_t is revealed, and the algorithm uses it to update model and then proceeds to the next round. At each iteration, the performance of the online model is evaluated by a squared loss, $\ell_t(W) = \ell(y_t, \hat{y}_t) = \|\mathbf{y}_t - W^\top\mathbf{m}_t\|_2^2$ with cumulative loss over T iterations, $L_T(W) = \sum_{t=1}^{T}\ell_t(W)$. Similar, for any $U \in \mathbb{R}^{n\times K}$, let $\ell_t(U) = \|U^\top\mathbf{m}_t - \mathbf{y}_t\|_2^2$ be the instantaneous loss and $L_T(U) = \sum_{t=1}^{T}\ell_t(U)$ be the cumulative loss. The goal of online learning is to achieve low regret compared with the best linear function,

$$R_T = \sum_{t=1}^{T} g_t(W) - \inf_U \sum_{t=1}^{T} g_t(U),$$

where $G_T(W) = \sum_{t=1}^{T} g_t(W)$ and $g_t(W) = \ell_t(W) + \gamma tr\left(W^\top W\right)$ is regularized instantaneous loss on round t.

B. Online Learning on Graph

To minimize the regret, we have to minimize the cumulative loss $G_T(W)$ in the following lemma. We start with the notations,

$$A_T = \gamma I + \sum_{t=1}^{T}\mathbf{m}_t\mathbf{m}_t^\top, \quad B_T = \sum_{t=1}^{T}\mathbf{m}_t\mathbf{y}_t^\top. \quad (6)$$

Lemma 1. *For all $T \geq 1$, $G_T(W) = L_T(W) + \gamma tr(W^\top W)$ is minimal at an unique point W_T for all $T \geq 1$, given by*

$$W_T = A_T^{-1}B_T,\ G(W_T) = \sum_{t=1}^{T}\|\mathbf{y}_t\|^2 - tr\left(B_T^\top A_T^{-1}B_T\right).$$

We leave the proof in supplementary file. In Lemma 1, we obtain an optimal linear solution W_T. Inspired by [2], we exploit current input to predict its label with $\mathbf{f}_t = B_{t-1}^\top A_t^{-1}\mathbf{m}_t$ where $A_t = A_{t-1} + \mathbf{m}_t\mathbf{m}_t^\top$. However, it is not efficient to perform update in each iteration. To make it scalable on big graphs, we adopt a conservative strategy [4] to update model whenever an error occurs ($y_t \neq \hat{y}_t$). Note that our algorithm is different from [4], since the solution is a matrix for multi-class classification. We call our algorithm CMOG, a Conservative Multi-class Online learning on Graph, and summarize it in algorithm 1.

Although the CMOG is simple, it is the first work of online learning for solving graph-based multi-class problem. Below gives theoretical analysis of the CMOG and we begin with a lemma that facilitates the proof. With this lemma, we could then derive the mistake bound for the CMOG. For convenience, we introduce an additional notation:

$$r_t = \mathbf{m}_t^\top A_{t-1}^{-1}\mathbf{m}_t. \quad (7)$$

Then the following notation can be derived using Woodbury formula [3],

$$\begin{aligned}\mathbf{m}_t^\top A_t^{-1}\mathbf{m}_t &\overset{(6)}{=} \mathbf{m}_t^\top\left(A_{t-1} + \mathbf{m}_t\mathbf{m}_t^\top\right)^{-1}\mathbf{m}_t \\ &= \mathbf{m}_t^\top(A_{t-1}^{-1} - \frac{A_{t-1}^{-1}\mathbf{m}_t\mathbf{m}_t^\top A_{t-1}^{-1}}{1+\mathbf{m}_t^\top A_{t-1}^{-1}\mathbf{m}_t})\mathbf{m}_t = \frac{r_t}{1+r_t}.\end{aligned}$$

Lemma 2. *For all $t \geq 1$, $G_t(U)$ is the online LapRLS with any $U \in \mathbb{R}^{n\times K}$. Let $(\mathbf{m}_1, \mathbf{y}_1), \ldots, (\mathbf{m}_T, \mathbf{y}_T)$ be a sequence of input vertices, where $\mathbf{m}_t \in \mathbb{R}^n$ and $\mathbf{y}_t \in \mathbb{R}^K$, an online algorithm predicts with $\mathbf{f}_t = B_{t-1}^\top A_t^{-1}\mathbf{m}_t$. Then the following equality holds,*

$$\inf_U G_t(U) - \inf_U G_{t-1}(U) = \|\mathbf{y}_t - \mathbf{f}_t\|_2^2 - \frac{2r_t}{1+r_t} + r_t\|\mathbf{f}_t\|_2^2$$

We leave the proof in supplementary file. Based on the above lemma, we prove the following theorem that bounds the expected mistakes of CMOG. We denote

$\mathcal{M} = \{t|y_t \neq \hat{y}_t\}$ as the set of mistake trials with $|\mathcal{M}| = M$. For any model $U \in \mathbb{R}^{n\times K}$, let $\mathcal{U}_T$ be the set of its update trial, and $A_{\mathcal{U}_T} = \gamma I + \sum_{t\in\mathcal{U}_T} \mathbf{m}_t\mathbf{m}_t^\top$. Its hinge loss on round t is defined,

$$\mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t) = [1 - (P_U^{\mathbf{m}_t}(y_t) - \max_{j\neq y_t} P_U^{\mathbf{m}_t}(j))]_+.$$

Theorem 1. *Let $(\mathbf{m}_1, \mathbf{y}_1), \ldots, (\mathbf{m}_T, \mathbf{y}_T)$ be a sequence of inputs, where $\mathbf{m}_t \in \mathbb{R}^n$ and $\mathbf{y}_t \in \mathbb{R}^K$. Then for any model $U \in \mathbb{R}^{n\times K}$ and $h > 0$, the expected mistakes of CMOG (Alg. 1) on these sequential nodes is bounded by,*

$$\begin{aligned}\mathbb{E}[M] \leq & \mathbb{E}[\sum_t \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t)] + \frac{h}{2} tr(U^\top \mathbb{E}[A_{\mathcal{U}_T}]U) \\ & + \frac{1}{h}\mathbb{E}[\sum_t \frac{r_t}{1+r_t}].\end{aligned}$$

Remark 2. *$\sum_t \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t)$ is the cumulative hinge loss made by U. Besides, for each class prototype $\mathbf{u}_i (i \in [K])$, $\mathbf{u}_i^\top A_{\mathcal{U}_T}\mathbf{u}_i$ lines between $\min_j \lambda_j$ and $\max_j \lambda_j$ where λ_j is an eigenvalue of the matrix $A_{\mathcal{U}_T}$. Thus, $tr(U^\top \mathbb{E}[A_{U_T}]U) \leq K \max_j \lambda_j$. Finally, $\sum_t \frac{r_t}{1+r_t} \leq \log \frac{\det(A_T)}{\det(A_0)} \leq n\log(R^2T+1)$ given $\|\mathbf{m}\|_2 \leq R$.*

Proof. The CMOG is a conservative algorithm that updates model whenever an error occurs. If there is no update, $U_t = U_{t-1}$ yields $\inf_U G_t(U) = \inf_U G_{t-1}(U)$. According to lemma 2, we have,

$$\begin{aligned}&\inf_U G_t(U) - \inf_U G_{t-1}(U) \\ =&\mathbb{I}\{y_t \neq \hat{y}_t\}(\|\mathbf{y}_t - \mathbf{f}_t\|_2^2 - \frac{2r_t}{1+r_t} + r_t\|\mathbf{f}_t\|_2^2)\end{aligned}$$

holds for all trial t. Summing over $t = 1, \ldots, T$, we obtain via expanding the squares and some manipulations,

$$\begin{aligned}&\sum_{t\in\mathcal{M}}(\|\mathbf{y}_t\|_2^2 - 2\mathbf{y}_t\cdot\mathbf{f}_t + \|\mathbf{f}_t\|_2^2 - \frac{2r_t}{1+r_t} + r_t\|\mathbf{f}_t\|_2^2) \\ =&\inf_U G_T(U) - \inf_U G_0(U) \\ \leq&\sum_{t\in\mathcal{M}}(\|\mathbf{y}_t\|_2^2 - 2\mathbf{y}_t\cdot U^\top\mathbf{m}_t) + tr(U^\top(\gamma I + \sum_{t\in\mathcal{U}_T}\mathbf{m}_t\mathbf{m}_t^\top)U)\end{aligned}$$

holding for any $U \in \mathbb{R}^{n\times K}$. We ignore $r_t\|\mathbf{f}_t\|_2^2$ as it does not affect upper bound. Given that $\hat{y} = \operatorname{argmax}_{j\neq y_t} P_{W_T}^{\mathbf{m}_t}(j)$,

$$\begin{aligned}1 - &\mathbf{y}_t\cdot U^\top\mathbf{m}_t \leq [1 - (P_U^{\mathbf{m}_t}(y_t) - P_U^{\mathbf{m}_t}(\hat{y}))]_+ \\ &\leq [1 - (P_U^{\mathbf{m}_t}(y_t) - \max_{j\neq y_i} P_U^{\mathbf{m}_t}(j))]_+ = \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t).\end{aligned}$$

Since U is a random variable, we use hU ($h > 0$) to replace U. We add $\sum_t 2h$ on both sides of inequality and simplify inequality with A_t and $\mathcal{L}(\cdot)$,

$$\begin{aligned}&\sum_{t\in\mathcal{M}}(\|\mathbf{f}_t\|_2^2 - 2\mathbf{y}_t\cdot\mathbf{f}_t - \frac{2r_t}{1+r_t} + 2h) \\ \leq&2h\sum_{t\in\mathcal{M}}\mathcal{L}(\mathbf{y}_t^\top U^\top\mathbf{m}_t) + h^2 tr(U^\top A_{\mathcal{U}_T}U).\end{aligned} \tag{8}$$

Algorithm 1 CMOG: Conservative Multi-class Online model on Graph

Input: Adjacency matrix $\mathbf{S}$, and regularization parameter γ.
Output: W_T
Compute $\mathbf{L} = \mathbf{D} - \mathbf{S}$ and $\mathbf{M}$ from $\mathbf{L}$;
Initialize: $\mathbf{A}_0 = \gamma I$, $\mathbf{B}_0 = \mathbf{0}$, $W_0 = \mathbf{0}$;
for $t = 1, \ldots, T$ **do**
  Receive $\mathbf{m}_t \in R^n$;
  Compute $A_t^{-1} = (A_{t-1} + \mathbf{m}_t\mathbf{m}_t^\top)^{-1}$;
  Predict $\mathbf{f}_t = B_{t-1}^\top A_t^{-1}\mathbf{m}_t$;
  $\hat{y}_t = \arg\max_{j=1,..,K} \mathbf{f}_t(j)$;
  Query the actual label y_t;
  if $\hat{y}_t \neq y_t$ **then**
    Update $A_t = A_{t-1} + \mathbf{m}_t\mathbf{m}_t^\top$;
    Update $B_t = B_{t-1} + \mathbf{m}_t\mathbf{y}_t^\top$;
  else
    $A_t = A_{t-1}, B_t = B_{t-1}$;
  end if
end for
$W_T = A_T^{-1}B_T$;

When an error occurs (i.e., $y_t \neq \hat{y}_t$), we have that $P_{W_t}^{\mathbf{m}_t}(y_t) \leq P_{W_t}^{\mathbf{m}_t}(\hat{y}_t)$ yields $-\mathbf{y}_t\cdot\mathbf{f}_t = P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t) \geq 0$. With the expectation of the inequality, we bound given by $\|\mathbf{f}_t\|_2 > 0$,

$$\begin{aligned}&\sum_{t\in\mathcal{M}}\mathbb{E}[\|\mathbf{f}_t\|_2^2 - 2\mathbf{y}_t\cdot\mathbf{f}_t - \frac{2r_t}{1+r_t} + 2h] \\ \geq&2h\mathbb{E}[M] - \mathbb{E}[\sum_t \frac{2r_t}{1+r_t}].\end{aligned} \tag{9}$$

Taking the expectation of Eq. (8) to upper bound the left-side of Eq. (9), we complete the proof. □

IV. SELECTIVE SAMPLING

In this section, we first introduce the setting of selective sampling. Next, we propose a novel randomized query approach to select labels and then introduce an aggressive algorithm that can use correctly predicted labels to optimize the model. We theoretically analyze mistake bound and query ratio of the proposed techniques. Finally, a low rank approximation is introduced in our framework.

A. Problem Setting

Unlike online algorithm that queries all labels, selective sampling has to decide whether to query label or not for each vertex $\mathbf{m}_t$. If a label $\mathbf{y}_t$ is queried of, the algorithm can update learner with $\mathbf{y}_t$; otherwise, no action is performed and the learner proceeds next one. Query and update decisions in trial t are denoted as binary variables Q_t and Z_t, respectively. When $Q_t = 1$ iif label $\mathbf{y}_t$ is queried of; $Q_t = 0$, no action performed. Update

decision Z_t is under similar setting. Generally, selective sampling is a semi-supervised online learning algorithm. Thus, its optimal solution can be derived in a form of online learning with query/update decision in each trial, i.e., $W_t = A_t^{-1}B_t$, where A_t and B_t can turn to be a recursive form,

$$A_t = A_{t-1} + Q_t Z_t \mathbf{m}_t \mathbf{m}_t^\top, \quad B_t = B_{t-1} + Q_t Z_t \mathbf{m}_t \mathbf{y}_t^\top.$$

Since A_t^{-1} is computationally expensive, we derive a non-inverted recursive form with time complexity $O(n^2)$ using Woodbury formula as in (8).

B. Label Query

The CMOG assumes that all labels are provided, which is not efficient in many real-world applications. To save the labeling cost, we propose a novel randomized query approach in multi-class setting. We begin with additional quantities of interest:

$$y_t^* = \underset{i=1,\ldots,K}{\operatorname{argmax}} P_{U^*}^{\mathbf{m}_t}(i), \quad y_t^{'} = \underset{i \neq y_t^*}{\operatorname{argmax}} P_{U^*}^{\mathbf{m}_t}(i);$$
$$\hat{y}_t = \underset{i=1,\ldots,K}{\operatorname{argmax}} P_{W_t}^{\mathbf{m}_t}(i), \quad y_t^{''} = \underset{i \neq \hat{y}_t}{\operatorname{argmax}} P_{W_t}^{\mathbf{m}_t}(i).$$

In words, y_t^* and $y_t^{'}$ are the optimal and second-best classes with respect to U^* (i.e., the best model in hindsight), while $\hat{y}_t$ and $y_t^{''}$ are the estimates of these classes based on our online learner W_t.

Definition 2. *Given an input $\mathbf{m}_t (t \in [T])$ and the weight $W_t = A_t^{-1}B_{t-1}$, an algorithm predicts its label with $\mathbf{f}_t = W_t^\top \mathbf{m}_t$, and queries the true label with a probability $\frac{2h}{2h+\max(0,\Theta_t)}$ ($h > 0$), where Θ_t is a confidence score towards current prediction,*

$$\Theta_t = \Theta(\mathbf{f}_t, r_t) = \frac{1}{2}\Delta_t^2 + 2\Delta_t - \frac{Kr_t}{1+r_t}, \qquad (10)$$

where $\Delta_t = P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t^{''})$.

This query is tuned by a confidence score Θ_t: a coin with bias $\frac{h}{h+\max(0,\Theta_t)}$ is flipped; if the coin turns up heads, then actual label $\mathbf{y}_t$ is queried; otherwise $Q_t = 0$ and no query performed. The randomized query has been studied in previous selective samplings under binary classification setting [6], [10]. Unlike these methods, we present a new confidence Θ_t based on the margin and uncertainty of the multi-class classification problems.

Intuitively, a query method is effective if it can control the probability of making a mistake whenever this label is not queried of. In the following theorem, we prove that an online algorithm on these selected labels $\{t|Q_t = 1, Q_t \sim \frac{2h}{2h+\max(0,\Theta_t)}\}$ can achieve a comparable mistake bound with one that queries all labels. Under randomized query, the mistake trials can be partitioned into two disjoint sets, $\mathcal{S} = \{t|\frac{2h}{2h+\max(0,\Theta_t)} < 1\}$ includes trials on which a stochastic query is conduct, while $\mathcal{D} = \{t|\frac{2h}{2h+\max(0,\Theta_t)} = 1\}$ includes trials when a deterministic query is issued.

Theorem 3. *For all $t \geq 1$, the CMOG runs over an arbitrary node-label sequence $(\mathbf{m}_1, \mathbf{y}_1), \ldots, (\mathbf{m}_T, \mathbf{y}_T)$ ($\mathbf{m}_t \in \mathbb{R}^n$ and $\mathbf{y}_t \in \mathbb{R}^K$) with a query probability of $\frac{2h}{2h+\max(0,\Theta_t)} (h > 0)$ on round t, then the following inequality holds for any $U \in \mathbb{R}^{n\times K}$,*

$$\begin{aligned}\mathbb{E}[\mathcal{M}] \leq & \mathbb{E}[\sum_t \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t)] + \frac{h}{2} tr(U^\top \mathbb{E}[A_{\mathcal{U}_T}] U) \\ & + \frac{1}{2h}\mathbb{E}[\sum_{t\in\mathcal{M}\cap\mathcal{D}} \frac{Kr_t}{1+r_t}].\end{aligned}$$

The expectation of queried number is upper bounded by $\mathbb{E}[|\mathcal{D}| + \sum_{t\in\mathcal{S}} \frac{2h}{2h+\Theta_t}]$.

Note that labels are selected randomly. Thus, the expectation occurring in this theorem is w.r.t this randomization.

Proof. In the setting of selective sampling, a model is updated whenever $Q_t Z_t = 1$. Given that $K > 2$ in multi-class setting, we bound as in Eq. (8),

$$\begin{aligned}&\sum_t Q_t Z_t (\|\mathbf{f}_t\|_2^2 - 2\mathbf{y}_t \cdot \mathbf{f}_t - \frac{Kr_t}{1+r_t} + 2h) \\ \leq & 2h \sum_t Q_t Z_t \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t) + h^2 tr(U^\top A_{\mathcal{U}_T} U).\end{aligned} \qquad (11)$$

If an error occurs ($y_t \neq \hat{y}_t$), $P_{W_t}^{\mathbf{m}_t}(y_t) \leq P_{W_t}^{\mathbf{m}_t}(y_t^{''})$. Thus,

$$-\mathbf{y}_t \cdot \mathbf{f}_t \overset{(4)}{=} P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t) \geq P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t^{''}).$$

Since $\|\mathbf{f}_t\|_2^2 \geq \frac{1}{2}\Delta_t^2$ and $P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t^{''}) = \Delta_t$, we bound,

$$\begin{aligned}&\sum_t Q_t Z_t (\|\mathbf{f}_t\|_2^2 - 2\mathbf{y}_t \cdot \mathbf{f}_t - \frac{Kr_t}{1+r_t} + 2h) \\ \geq & \sum_t Q_t Z_t (\frac{1}{2}\Delta_t^2 + 2\Delta_t - \frac{Kr_t}{1+r_t} + 2h) \\ \overset{(10)}{=} & \sum_t Q_t Z_t (\Theta_t + 2h).\end{aligned}$$

When an error occurs at trial $t \in \mathcal{M}$, the Θ_t can be positive ($\mathcal{M} \cap \mathcal{S}$) or negative ($\mathcal{M} \cap \mathcal{D}$). In the former case, $\mathbb{E}[Q_t] = \frac{2h}{2h+\Theta_t}$ is a random variable and we bound,

$$\mathbb{E}[Q_t Z_t (\Theta_t + 2h)] = \mathbb{E}[Z_t]\mathbb{E}[Q_t(\Theta_t + 2h)] = 2h\mathbb{E}[Z_t];$$

In the later case, $\mathbb{E}[Q_t] = 1$. Given $\frac{1}{2}\Delta_t^2 \geq 0$ and $\Delta_t \geq 0$, we have,

$$\begin{aligned}&\mathbb{E}[\sum_t Q_t Z_t (\frac{1}{2}\Delta_t^2 + 2\Delta_t - \frac{Kr_t}{1+r_t} + 2h)] \\ \geq & 2h\mathbb{E}[Z_t] - \mathbb{E}[\sum_{t\in\mathcal{M}\cap\mathcal{D}} \frac{Kr_t}{1+r_t}]\end{aligned}$$

In summary,

$$\begin{aligned}&\sum_t Q_t Z_t (\Theta_t + 2h) \\ \geq & 2h(\sum_{t\in\mathcal{M}\cap\mathcal{S}} \mathbb{E}[Z_t] + \sum_{t\in\mathcal{M}\cap\mathcal{D}} \mathbb{E}[Z_t]) - \mathbb{E}[\sum_{t\in\mathcal{M}\cap\mathcal{D}} \frac{Kr_t}{1+r_t}]\end{aligned}$$

With $\sum_{t\in\mathcal{M}} Z_t = |\mathcal{M}|$ and upper bound (11), we complete our proof. □

Remark 4. *The mistake bound of the CMOG on randomly selected labels is comparable with the bound of CMOG that learns all the labels. Similar to Theorem 1, the CMOG run on selected labels is bounded by the cumulative hinge loss suffered by U, $\log(T)$ (upper bound of $\sum_t \frac{r_t}{1+r_t}$) and $K\max_j \lambda_j$ (upper bound of $tr(U^\top A_{\mathcal{U}_T} U)$). Note that we use $\frac{Kr_t}{1+r_t}$ to let data "uncertainty" regularized by the class number. In addition, the CMOG run on selected labels can achieve a comparable mistake bound with the online algorithm OLLGC (i.e. Corollary 5, [14]) in binary classification, since $tr(U^\top A_{\mathcal{U}_T} U) \le \sum_{t\in\mathcal{M}} \|U^\top \mathbf{m}_t\|_2^2 \le \alpha tr(U^\top U) = \alpha tr(F^\top L F)$, where $\alpha = |\mathcal{M}|R^2$. Noted that this bound is incomparable with that in [6] since the Θ_t is different in two methods. In summary, the theoretical results present that an online algorithm learning on these selected labels could perform no worse than its fully-supervised counterpart. Thus above results theoretically demonstrate the efficacy of the proposed query method.*

C. Aggressive Learning

The CMOG is conservative, i.e., it will only update the model when an error occurs. To take advantage of the correctly predicted instances, we propose an aggressive version of selective sampling. We call our algorithm MSG, the Multi-class Selective Sampling on Graph, present in Algorithm 2. After observing a vertex $\mathbf{m}_t$ at round t, the MSG predicts its label with $W_t = A_t^{-1} B_{t-1}$ and then queries true label $\mathbf{y}_t$ with a probability of $\frac{2h}{2h+\max(0,\Theta_t)}$. It yields to stochastic query and deterministic query. When stochastic query (i.e. $\frac{2h}{2h+\max(0,\Theta_t)} < 1$) is issued, it is conservative to update model when an error occurs ($\hat{y}_t \neq y_t$). While a deterministic query is issued (i.e. $\frac{2h}{2h+\max(0,\Theta_t)} = 1$), we adopt an aggressive learning strategy, that is, we update even if no error occurs. Note that our model is different from [8], [1], since we perform a randomized query based on the predicted results of multiple classes.

The theoretical results below show the superiority of the aggressive algorithm compared to its conservative and fully-supervised counterpart CMOG (i.e. Algorithm 1). Besides the stochastic query trials $\mathcal{S}$ and deterministic query trials $\mathcal{D}$, we denote by $\mathcal{V}$ the set of trials for which there is an aggressive update but not a mistake (i.e., $y_t = \hat{y}_t$ and $\Theta_t < 0$) and let $V = |\mathcal{V}|$.

Theorem 5. *The algorithm MSG (Algorithm 2) runs on an arbitrary sequential nodes, then given $h > 0$, the following inequality holds for any $U \in \mathbb{R}^{n\times K}$,*

$$\mathbb{E}[M] \le \mathbb{E}[\sum_t Q_t Z_t \mathcal{L}(\mathbf{y}_t^\top U^\top \mathbf{m}_t)] + \frac{h}{2} tr(U^\top \mathbb{E}[A_{\mathcal{U}_T}] U) + \frac{1}{h}\mathbb{E}[\sum_{t\in D} \frac{Kr_t}{1+r_t}] - \mathbb{E}[V].$$

Algorithm 2 MSG: Multiclass Selective Sampling on Graph

Input: sequences of instance-label pair $(\mathbf{m}_t, \mathbf{y}_t), t = 1,\dots,T$, the parameters $\gamma > 0$ and $h > 0$.
Output: W_T
Initialize: $W_0 = 0$, $A_0 = \gamma I$ and $B_0 = \mathbf{0}$.
for $t = 1,\dots,T$ **do**
  Receive an input $\mathbf{m}_t$;
  Compute $A_t^{-1} = (A_{t-1} + \mathbf{m}_t\mathbf{m}_t^\top)^{-1}$;
  $\mathbf{f}_t = B_{t-1}^\top A_t^{-1}\mathbf{m}_t$;
  Predict $\hat{y}_t = \arg\max_{j\in[K]} P_{W_t}^{\mathbf{m}_t}(j)$;
  if $\Theta_t < 0$ (Definition 2) **then**
    Set $Q_t = Z_t = 1$ (i.e. deterministic query) and Query actual label $\mathbf{y}_t$;
  else
    Draw a Bernoulli random variable $Q_t \in \{0,1\} \sim \frac{2h}{2h+\max(0,\Theta_t)}$;
    if $Q_t = 1$ **then**
      Query actual label $\mathbf{y}_t$;
      Set $Z_t = 1$ if $\hat{y}_t \neq y_t$ ($Z_t = 0$, otherwise);
    end if
  end if
  $A_t = A_{t-1} + Q_t Z_t \mathbf{m}_t\mathbf{m}_t^\top$,
  $B_t = B_{t-1} + Q_t Z_t \mathbf{m}_t\mathbf{y}_t^\top$;
end for
$W_T = A_T^{-1} B_T$;

In addition, the expected number of queries is upper bounded by $\mathbb{E}[|\mathcal{D}| + \sum_{t\in\mathcal{S}} \frac{2h}{2h+\Theta_t}]$.

Proof. The update trials in algorithm 2 could be categorized into three groups,

$$\sum_t Z_t = |\mathcal{S}\cap\mathcal{M}| + |\mathcal{D}\cap\mathcal{M}| + |\mathcal{D}\cap\mathcal{V}|.$$

In the first case where an error occurs in randomized query with $\mathbb{E}[Q_t] = \frac{2h}{2h+\Theta_t}$ (i.e. $\mathcal{S}\cap\mathcal{M}$). Similar as Theorem 3,

$$\mathbb{E}[Q_t Z_t(\Theta_t + 2h)] = \mathbb{E}[Z_t]\mathbb{E}[Q_t(\Theta_t + 2h)] = \mathbb{E}[Z_t];$$

If an error incurs in a deterministic query (i.e. $t \in \mathcal{D}\cap\mathcal{M}$) with $\mathbb{E}[Q_t] = 1$, we bound,

$$\mathbb{E}[Q_t Z_t(\frac{1}{2}\Delta_t^2 + 2\Delta_t - \frac{Kr_t}{1+r_t} + 2h)] \ge 2h\mathbb{E}[Z_t] - \frac{Kr_t}{1+r_t};$$

Now we consider the third case where the updates were performed with no mistake, i.e., $\Theta_t \le 0$, and by definition,

$$\Theta_t \le 0 \Rightarrow 0 \le \Delta_t \le 2\sqrt{1 + \frac{Kr_t}{2(1+r_t)}} - 2. \qquad (12)$$

If no mistake incurs ($y_t = \hat{y}_t$), we have $\mathbf{y}_t\cdot\mathbf{f}_t = P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - \max_{j\neq\hat{y}_t} P_{W_t}^{\mathbf{m}_t}(j) = P_{W_t}^{\mathbf{m}_t}(\hat{y}_t) - P_{W_t}^{\mathbf{m}_t}(y_t'') = \Delta_t$. Thus,

$$\mathbb{E}[Q_t Z_t(\frac{1}{2}\Delta_t^2 - 2\Delta_t - \frac{Kr_t}{1+r_t} + 2h)]$$
$$= \mathbb{E}[Z_t(\frac{1}{2}\Delta_t^2 - 2\Delta_t + \frac{Kr_t}{1+r_t} - \frac{2Kr_t}{1+r_t} + 2h)]$$

Let $C(\Delta_t, r_t) = \frac{1}{2}\Delta_t^2 - 2\Delta_t + \frac{Kr_t}{1+r_t}$. Whenever $\frac{Kr_t}{1+r_t} \geq 2$, $C(\Delta_t, r_t) \geq 0 (\forall \Delta_t \geq 0)$. If $\frac{Kr_t}{1+r_t} < 2$, let $C(\Delta_t, r_t)$ be a quadratic equation with two non-negative roots and a minima, $2 - 2\sqrt{1 - \frac{Kr_t}{2(1+r_t)}}$. We observe this smaller root is higher than the upper bound in (12), that makes $C(\Delta_t, r_t) \geq 0$ in the trials $\mathcal{D} \cap \mathcal{V}$. Thus, we bound,

$$\mathbb{E}[Q_t Z_t (\frac{1}{2}\Delta_t^2 - 2\Delta_t - \frac{Kr_t}{1+r_t} + 2h)] \geq 2h\mathbb{E}[Z_t] - \frac{2Kr_t}{1+r_t}.$$

To summarize,

$$\mathbb{E}[\sum_t Q_t Z_t (\Delta_t^2 - 2\mathbf{f}_t \cdot \mathbf{y}_t - \frac{Kr_t}{1+r_t} + 2h)]$$

$$\geq 2h \sum_{t \in \mathcal{M}} \mathbb{E}[Z_t] + 2h \sum_{t \in \mathcal{D} \cap \mathcal{V}} \mathbb{E}[Z_t] - \sum_{t \in \mathcal{D}} \mathbb{E}[\frac{2Kr_t}{1+r_t}].$$

Equipped with upper bound as Eq. (11), we complete the proof. □

Remark 6. *The upper bound of the aggressive algorithm MSG is expected to be lower than CMOG that learns on all the labels (Theorem 1) and CMOG on the selected labels (Theorem 3), due to the deduction of $\mathbb{E}[\mathcal{V}]$ from the bound. In summary, the theoretical analysis demonstrate that the MSG, in expectation, can achieve a better performance than its conservative and fully-supervised counterparts, which can be regarded as a theoretical support for the aggressive method.*

Discussion: To further understand the aggressive algorithm, we analyze under what condition an aggressive query will be conducted. An aggressive query is issued when $\Theta_t \leq 0$ (i.e.,$\Theta_t \leq 0 \Rightarrow \Delta_t \leq \theta(K, r_t) = 2\sqrt{1 + \frac{Kr_t}{2(1+r_t)}} - 2$). If the margin Δ_t is less than $\theta(K, r_t)$, a deterministic query is issued, while Δ_t is above $\theta(K, r_t)$, a label is queried randomly with a probability less than 1. We observe that the upper bound of $\theta(K, r_t)$ increases with r_t. When $r_t = 0$, that is, current instance is observed before, the label would be queried deterministically in case its margin is 0 ($\Delta_t \leq \theta(K, r_t = 0) = 0$, i.e., an extreme case that the current model is unable to predict its label). However, if $r_t = 1$ (i.e., little knowledge to current input), the learner would query aggressively whenever its margin does not exceed $\theta(K, r_t = 1) = \sqrt{4 + K} - 2$, a threshold far from the boundary.

V. EXPERIMENTAL RESULTS

In this section, we first introduce experimental dataset and evaluation metrics. Then we present the empirical results to validate the proposed algorithms. Our experiments are designed to answer two questions: (i) if the proposed randomized query is effective to reducing the amount of labeled data significantly while maintain comparable performance? (ii) if the aggressive strategy achieves a better predictive performance at the cost of more queried number?

A. Data Sets and Evaluation Metrics

Data Sets: Four real-world graph data sets are used in the experiment to evaluate the approaches.
(a) Coauthor[2] extracted from *DBLP* database is an undirected co-author graph in which 1711 authors are denoted as vertices while their co-authored relationship are treated as the edges. The authors are classified in four classes in terms of research topic: "data mining", "machine learning", "information retrieval" and "databases". **(b)** Cora[3] is a citation network including 2485 scientific publications and 5429 citation links. The publications as vertices are related to seven domains: "Case based", "Genetic Algorithms", "Rule Learning", "Probabilistic Methods", "Neural Networks", "Reinforcement Learning", et al. **(c)** IMDB[4] is a movie organization that presses up-to-date movie information. The IMDB links total 17046 movies with their co-actor associations. The movies as vertices in graph are categorized into four genres: "Action", "Romance", "Animation" and "Thriller". **(d)** PubMed[5] is also a citation graph related to diabetes research. The PubMed collects 44338 publication citations among 19717 scientific publications and labels the publications with one of three types of diabetes.
The graph data is supposed to be undirected and connected. If the edges are directed, we transform them into undirected graphs via $\mathbf{S} \leftarrow \max(\mathbf{S}, \mathbf{S}^\top)$. If the graphs are disconnected, the biggest connected subgraph is chosen for study.

Evaluation Measures: We evaluate the performance of baselines and our algorithms with two measurements:
i) *cumulative error rate*, reflecting the prediction accuracy of online algorithm; **ii)** *number of queried labels*, reflecting the label efficiency of query method. Note that a small value of above measures indicates a better performance of a method. In order to compare these algorithms fairly, we randomly shuffle the ordering of samples for each dataset. We repeat each experiment 20 times and calculate the average results.

Baselines and Parameter Setting: We compare the proposed algorithms with state-of-the-art baselines. The algorithms we study and their parameter settings are summarized as follows. **(1)** GPA: a first order nonparametric online learning algorithm on graph [15]. Note that the perceptron algorithm is not affected by the step-size. **(2)** BBQ/BBQ$_\epsilon$: The two algorithms are the BBQ query criterion [5] and its modification version [1]. The intuition behind this rule is that at the rounds where the label is not queried, it guaranteed that the regret bound is at most ϵ. The parameter ϵ is tuned with grid $\{10^{-5}, \ldots, 10\}$ in our experiment. **(3)** DGS: This query

criterion is a nonparametric rule for binary classification [11] and adapts into multi-class setting in [1]. It takes both previous covariances and the observed labels into account. The intuition behind this rule is that on rounds where the label y_t is not queried, it guaranteed that either $\hat{y}_t = y_t^*$, or the regret is small. **(4)** CMOG and MSG: two second-order algorithm in multi-class setting. CMOG is a conservative online algorithm while MSG is an aggressive algorithm that queries label with a randomized method. We set $\gamma = 1$ to avoid overfiiting and tune the parameter h with grid $\{10^{-4}, \ldots, 1\}$ on a held-out random shuffle.

B. Comparison Evaluation

The experimental results are present in Table I. We found that MSG outperforms all baselines consistently across all data sets. We also show the results in terms of learning epoches in Figure 1. In all subfigures, the cumulative error rate and queried number along the learning epochs are both averaging over 20 times of shuffling order.

First of all, we observe that the improvement of the CMOG over GPA are always significant on all data sets. This is consistent with previous observations in online learning: second-order algorithms are generally better than first-order algorithm . The reason is due to the covariance matrix A_t which has a spectral structure to correlate with a best estimator for observed instances [4]. MSG always enjoys smaller or comparable error rates than BBQ_ϵ and DGS with much fewer queried number. The good performance generally is due to two reasons. First, the proposed randomized query approach improves the efficiency of the labeling. Second, thanks to the aggressive learning, the MSG achieves a convergence stage quickly with informative labels, thus the query rate is reduced further when learner has sufficient knowledge of data. The results in figure 1 indicate the MSG queries a small number of labels while maintains the quality of classification model.

C. Evaluation on Varied Ratios of Queries

We study the impact of h with respect to query ratio of the MSG. Basically, the smaller *h* is, the fewer the number of queries is. Specifically, we set *h* to $\{10^{-4}, 10^{-3}, \ldots, 1\}$, and run MSG for 20 times under each h. We calculate the average ratio of queried nodes under different values of *h*. The comparison results in Figure 2 show that MSG achieves better or comparable performance consistently under different ratios of queried labels. This validates the label-efficiency of our proposed confidence score Θ_t that can adaptively prioritize informative labels to optimize the model. We also observe that the MSG outperforms BBQ significantly over all query ratios. The reason is that MSG considering "Δ_t" will query the vertices close to current boundary, while these labels are omitted in BBQ. The better results in figure 2 demonstrate that these "small-margin" instances are useful to optimize the multi-class classifier.

D. Evaluation on Low-rank Approximation

The low-rank vertex representation $\mathbf{m} \in \mathbb{R}^d$ is used to build a scalable online model in our experiments. To study the impact of low-rank approximation on the proposed algorithms, we tune the rank d in the grid {10, 100, 250, 500, 750, 1000}. We use Coauthor and Cora as a case study since similar observations are obtained on other data sets. The results in Figure 3 present that MSG achieves a better or comparable performance than other baselines consistently under different rank approximation. Obviously with a higher rank, the performance becomes better in terms of error rate. However, to achieve a better prediction accuracy, algorithms need a high number of queries and high-rank inputs, which demands a more labeling and computational cost. It motivates us to select a proper rank d to achieve a balance. Therefore, we chose $d = 100$ in the rest of experiments, since in this setting

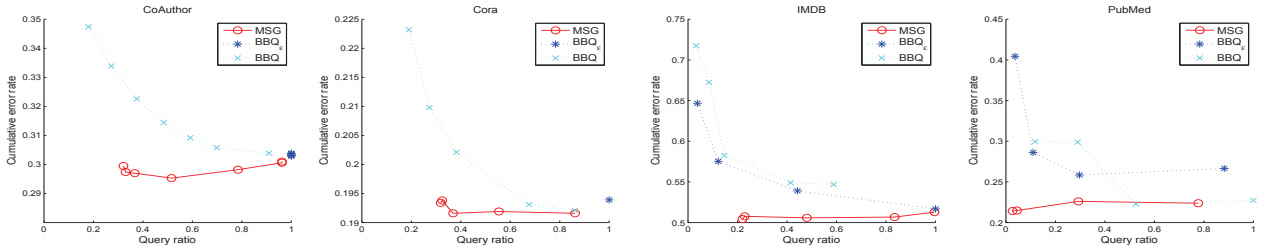

Fig. 2. A comparison among BBQ, BBQ$_\epsilon$ and MSG with respect to different ratios of queried nodes.

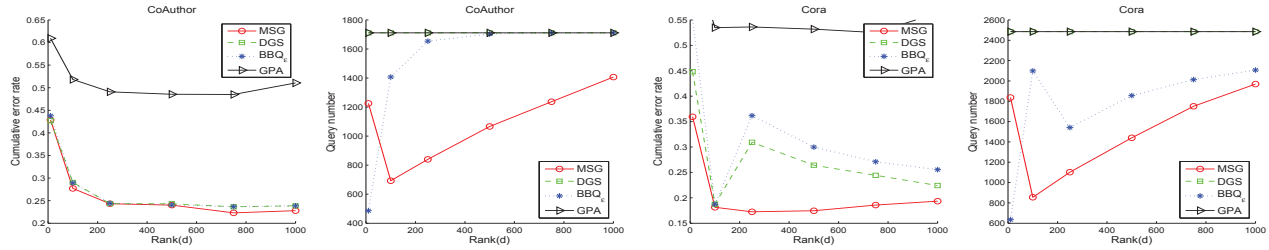

Fig. 3. A case study of low rank impact on performance.

the algorithms perform well while number of queries is small.

VI. CONCLUSIONS

In this paper, we proposed a new framework for multi-class online learning, leading to a scalable algorithm to tackle multi-class classification on graphs. To save the labeling cost, we presented a novel randomized query technique to prioritize the labels. Besides, we introduced an aggressive selective sampling algorithm to take full advantage of these wasted labels in existing conservative algorithms. The theoretical results demonstrated the efficacy of the proposed algorithms in terms of the expected mistake bound and query ratio.

The encouraging empirical results on several real-world datasets also indicated that 1) the MSG is able to achieve comparable or better predictive performance by querying a significantly small amount of labeled data; and that 2) the aggressive selective sampling scheme can further reduce the query rate, achieving a convergence stage rapidly.

Abstract

We present adaptive algorithms with strong data-dependent regret guarantees for the problem of bandit convex optimization. In the process, we develop a general framework from which the main previous results in this setting can be recovered. The key method is the introduction of adaptive regularization. By appropriately adapting the exploration scheme, we show that one can derive regret guarantees that can be significantly more favorable than those previously known. Moreover, our analysis also modularizes the problematic quantities in achieving the conjectured minimax optimal rates in the most general setting of the problem.

1 INTRODUCTION

Bandit convex optimization (BCO) is a general scenario for sequential decision making under uncertainty. In contrast to the standard full information setting of online convex optimization, in the BCO scenario, at each round, the learner only receives only the value of the loss function and no other feedback, in particular no information about the function derivatives.

BCO extends the well-known multi-armed bandit scenario and is an instance of the exploration-exploitation dilemma inherent in many online machine learning problems: at each round, the learner must decide between exploring new actions and exploiting the best actions determined thus far.

The partial information assumption also captures many real-world problems where the exact form of the loss function is not readily available at each step. These include settings such as ad prediction and medical diagnosis. In these problems, the learner is typically able to see only the value returned from the current action, as the exact loss function and its gradients are often quite abstract and complex.

From a theoretical vantage point, bandit convex optimization also remains an area of online learning in which existing regret guarantees in several regimes are known to be sub-optimal and where optimal methods have still yet to be discovered.

We now formalize the setting that we consider. Let $\mathcal{K} \subset \mathbb{R}^n$ be a compact convex set, and let $\{f_t\}_{t=1}^{\infty}$ be a sequence of convex functions. At each round $t = 1, 2, \ldots, T$, the learner selects a point $x_t \in \mathcal{K}$ and incurs loss $f_t(x_t)$. The learner's objective is to minimize his regret, defined by:

$$\mathrm{Reg}_T := \max_{x \in \mathcal{K}} \sum_{t=1}^{T} f_t(x_t) - f_t(x),$$

that is the difference between his cumulative loss and that of the best fixed point $x^* \in \mathcal{K}$ in hindsight. In contrast to the standard online learning or online convex optimization scenarios, in bandit convex optimization, the learner has access only to the value $f_t(x_t)$ and not any higher-order information. This scenario was first studied by Flaxman et al. (2005), where they proved that for sequences of Lipschitz functions, one can achieve a regret that is in $\mathcal{O}(T^{3/4})$. The seminal work of Abernethy et al. (2008) showed that, for linear functions, one can attain a regret in $\mathcal{O}(\sqrt{T})$. Agarwal et al. (2010) showed that one can improve upon Flaxman's bound and attain $\mathcal{O}(T^{2/3})$ in the strongly convex setting, and Saha and Tewari (2011) showed that one can achieve $\mathcal{O}(T^{2/3})$ in the strongly smooth setting. Hazan and Levy (2014) showed that when the functions are guaranteed to be both strongly smooth and strongly convex, one can attain $\mathcal{O}(\sqrt{T})$ regret. Most recently, Bubeck and Eldan (2015) presented a non-constructive proof demonstrating that a $\mathcal{O}(\sqrt{T})$ bound is also theoretically attainable in the general setting, albeit with a much heavier dependence on the dimension of the domain $\mathcal{O}(n^{11})$ than in the other references mentioned above.

It still remains an open question whether one can efficiently obtain the desired $\mathcal{O}(\sqrt{T})$ regret in the purely strongly convex, purely strongly smooth, or purely Lipschitz settings. To make progress in this direction, we will build upon recent advances in other areas of the online convex

optimization literature. Specifically, we will draw from the techniques in adaptive regularization presented in (Bartlett et al., 2007; Duchi et al., 2010; McMahan and Streeter, 2010) as well as ideas from the "learning faster from easy data" paradigm studied in (Even-Dar et al., 2007; Bubeck and Slivkins, 2012; Sani et al., 2014; de Rooij et al., 2014) to derive two efficient adaptive algorithms with minimal assumptions on the function's loss sequence.

Our algorithms will provide strong data-dependent guarantees, so that while their regret will never be worse than that of previous algorithms in the same setting, they can also be much better depending on how favorable and "easy" the actual data is. Moreover, the algorithms we present are anytime and automatically adjust to the data, so that they can run without any a priori tuning or unreasonable parameter specification. Perhaps most importantly, analyzing the resulting bounds provides insight into both whether the conjectured optimal bounds are truly achievable as well as how they might viably be attained.

We will start off by introducing some mathematical notation for the rest of our paper. Then, in Section 3, we will describe the general methodology of BCO, and in the process, introduce several key concepts and tools as well as our intuition and contribution to this framework. This will be formalized in Sections 4, 5, and 6, where we introduce concrete algorithms and guarantees. Finally, we will highlight the main implications of our results in Section 7, both in terms of new regret guarantees as well as added insight for the general bandit convex optimization setting with only the Lipschitz loss assumption.

2 NOTATION

In what follows, we will denote by $\mathcal{B}^n$ the n-dimensional unit ball under the Euclidean norm, and $\mathcal{S}^n = \partial\mathcal{B}^n$ the $(n-1)$-dimensional unit sphere. For any sequence of functions $\{c_t\}_{t=1}^{\infty}$, we will write $c_{1:t} = \sum_{s=1}^{t} c_t$. Given a function f_t and a point x_t, we will denote by $g_t \in \partial f_t(x_t)$ an element of the subgradient of f_t at x_t, such that for any y, $f_t(y) \geq f_t(x_t) + g_t^\top(y - x_t)$. Given any norm $\|\cdot\|$, we will denote its dual by $\|\cdot\|_*$, so that $\|x\|_* = \sup_{\|y\|\leq 1} x^\top y$. Moreover, given any symmetric positive semi-definite (SPSD) matrix A, we define the semi-norm $\|x\|_A = \sqrt{x^\top A x}$, and we denote the j-th eigenvalue of A by $\lambda_j(A)$ (in decreasing order).

Definition 1 (Strongly Smooth and Strongly Convex)**.** *Let A be an SPSD matrix. A function f is said to be*

- *A-strongly smooth if $f(x) \leq f(y) + \nabla f(y)^\top(x-y) + \frac{1}{2}\|x-y\|_A^2$;*
- *A-strongly convex if $f(x) \geq f(y) + \nabla f(y)^\top(x-y) + \frac{1}{2}\|x-y\|_A^2$.*

For a scalar $\beta \in \mathbb{R}_+$, f is said to be β-strongly smooth (β-strongly convex) if it is βI-strongly smooth (respectively strongly convex). For functions that are not C^1, we replace the gradients by subgradients in these definitions.

3 OVERVIEW OF BANDIT CONVEX OPTIMIZATION

Bandit convex optimization, and bandit problems in general, can be viewed as online learning problems with partial information. In this context, the natural approach is to estimate the missing data from the full information setting, and to then apply online learning methods to the problem.

One online learning method that is commonly used in bandit convex optimization is the Follow-the-Regularized-Leader (FTRL) (Kalai and Vempala, 2005) algorithm, which is based on the update:

$$x_{t+1} = \operatorname*{argmin}_{x\in\mathcal{K}} \eta g_{1:t}^\top x + \mathcal{R}(x),$$

where $\mathcal{R}$ is some regularization function.

However, in bandit convex optimization, the missing data at each round is the gradient. Since the learner only knows the value of the loss function at each round, the FTRL algorithm cannot be readily applied (nor can most other online learning algorithms, which also typically use gradient information). This is what makes bandit convex optimization significantly more difficult than standard online onvex optimization.

A key step toward addressing this issue has been the insight that by playing an action randomly near the intended one, it is possible to estimate the gradient of a smoothed version of the loss function. More formally, given any $f\colon \mathbb{R}^n \to \mathbb{R}$ and $A \in \mathbb{R}^{n\times n}$ an SPSD matrix, we define $\widehat{f}(x) = \mathbb{E}_{v\in\mathcal{B}^n}[f(x+Av)]$, the average of f at x over the ellipsoid generated by A, and $\widehat{g}_t = nf(x+Au)A^{-1}u$, its one-point gradient estimate. Then the following result holds:

Lemma 1 (Saha and Tewari (2011))**.** $\mathbb{E}_{u\sim\mathcal{S}^n}[\widehat{g}_t] = \nabla\widehat{f}(x)$.

For completeness, we provide a proof of this result in Appendix A.

This implies that by sampling a point $x+Av$ in an ellipsoid around the intended action, we can estimate the gradient of a smoothed version of our loss function even if we are only able to play a single action. Moreover, by playing these gradient estimates, our regret will be the regret of this smoothed loss up to the approximation error of smoothing.

In practice, the smoothing ellipsoid is defined by scaling the inverse Hessian of the regularization function $\mathcal{R}$, i.e. $A = \delta\nabla^2\mathcal{R}(x)^{-1/2}v$. Thus, the choice of regularization becomes crucial towards determining how much to explore and how much approximation error to incur. The

key work along this direction has been (Abernethy et al., 2008), which showed that one can use the notion of self-concordant barrier to find a good tradeoff.

For completeness, we briefly introduce this concept and summarize the key results that we will use in our analysis.

3.1 BACKGROUND ON SELF-CONCORDANT FUNCTIONS

The use of self-concordant functions can be traced back to Nesterov's work on Newton's method (see (Nesterov, 2004) for a comprehensive treatment).

Definition 2 (Self-concordant barrier)**.** *A C^3 function $\mathcal{R}\colon \operatorname{int}(K) \to \mathbb{R}$ is a ν-self concordant barrier if for any $h \in \mathbb{R}^n$:*

1. *$\mathcal{R}$ approaches infinity for any sequence of points approaching the boundary of $\mathcal{K}$.*
2. *$\left|\nabla^3 \mathcal{R}(x)[h,h,h]\right| \leq 2(\nabla^2 \mathcal{R}(x)[h,h])^{3/2}$.*
3. *$|\nabla \mathcal{R}(x)h| \leq (\nu \nabla^2 \mathcal{R}(x)[h,h])^{1/2}$.*

Definition 3 (Dikin Ellipsoid)**.** *Let $\mathcal{R}$ be a self-concordant function and $x \in \operatorname{int}(K)$. Then, the Dikin Ellipsoid $W_1(x)$ is the ellipsoid induced by the Hessian of $\mathcal{R}$ at x:*

$$W_1(x) = \{z \in \mathbb{R}^n | \|z - x\|_{\nabla^2 \mathcal{R}(x)} \leq 1\} \subset \mathcal{K}.$$

Definition 4 (Newton Decrement)**.** *Given any C^2 function $\mathcal{R}$ whose Hessian is invertible at a point x, the Newton decrement of $\mathcal{R}$ at x is defined to be $\lambda(x, \mathcal{R}) = \|\nabla \mathcal{R}(x)\|_{\nabla^2 \mathcal{R}(x)^{-1}}$.*

The following two results can be found in (Nemirovski and Todd, 2008) and will be the most important properties for our analysis.

Lemma 2. *Let $\mathcal{R}$ be a self concordant function and $x \in \operatorname{int}(\mathcal{K})$ a point such that $\lambda(x, \mathcal{R}) \leq \frac{1}{2}$. Then, $\|x - \operatorname{argmin}_u \mathcal{R}(u)\|_{\nabla^2 \mathcal{R}(x)} \leq 2\lambda(x, \mathcal{R})$.*

Given $x, y \in \operatorname{int}(\mathcal{K})$, the Minkowsky function is defined as $\pi_x(y) = \inf\left\{t \geq 0 \mid x + \frac{1}{t}(y - x)\right\}$.

Lemma 3. *Let $\mathcal{R}$ be a ν-self concordant barrier. Then for any $x, y \in \operatorname{int}(\mathcal{K})$: $\mathcal{R}(y) - \mathcal{R}(x) \leq \nu \log\left(\frac{1}{1 - \pi_x(y)}\right)$.*

Thus, the current state-of-the-art approach to bandit convex optimization problem has been to play a FTRL-type algorithm with the update:

$$x_{t+1} = \operatorname*{argmin}_{x \in \mathcal{K}} \eta \widehat{g}_{1:t}^{\top} x + \mathcal{R}(x),$$

where $\widehat{g} = \widehat{g}(\delta, \nabla^2 \mathcal{R})$, and $\mathcal{R}$ is a self-concordant barrier.

For global σ-strongly convex loss functions, one can also add an associated quadratic term to the optimization problem and a σ-ball to the sampling ellipsoid.

In this paper, we extend the above framework with the concept of adapting to the data. Specifically, we will tune the learning rate and sampling ellipsoid at each step of the algorithm according to the local data that we see. The goal of this approach is two-fold. On the one hand, we want to design any-time algorithms with general regret bounds that recover all existing approaches in a unified manner. Previous algorithms assumed various levels of global regularity information, had different sampling schemes for each, and had to be tuned with a posteriori knowledge. On the other hand, and perhaps more importantly, we also want to derive data-dependent guarantees that can reveal new insight into the difficulties of the problem.

4 ADAPTIVE BANDIT CONVEX OPTIMIZATION

Using the motivation above, we now present AdaBCO, an adaptive procedure for bandit convex optimization. AdaBCO is a skeleton algorithm that we will use as a *launching point* for our two data-dependent algorithms. As such, it is not meant to be implemented on its own, and some of its parameters, such as η_t and δ_t, are not specified precisely. These will be selected carefully in Algorithms 2 and 3.

Unlike previous algorithms in the literature, AdaBCO does not need the learner to specify a priori a fixed level of global convexity for the entire sequence of loss functions encountered during learning. This is often an unreasonable requirement, particularly in a truly online setting, and so instead, AdaBCO allows the learner to specify the convexity of functions as it sees them. The algorithm is designed such that the regret bound will automatically adapt to this data. This is achieved via dynamic tuning of the sampling ellipsoids and learning rates, which will be prescribed more explicitly in Algorithms 2 and 3, when we also take into account the level of function smoothness.

Moreover, it is important to realize that computing parameters in real-time is never more difficult than computing bounds that hold uniformly over all rounds at the start in a truly online scenario. Thus, AdaBCO is never more difficult to implement than previous algorithms.

AdaBCO also differs from previous work in that it treats strong convexity as a matrix parameter instead of a scalar parameter. This is based on the insight that, for minimizing regret, convexity of the loss function is closely tied to convexity of the self-concordant barrier's Hessian, and that one can bound regret in terms of the average eigenvalue of the sum of these matrices as opposed to the minimal eigenvalue. Essentially, the algorithm can "borrow" convexity from the self-concordant barrier if the convexity of the loss function is not strong enough to achieve the desired regret. This becomes particularly useful when the learner is querying points near the decision set's boundary, and the Hessian

of $\mathcal{R}$ has large eigenvalues in the direction of the boundary (often the case because $\mathcal{R} \nearrow \infty$ at $\partial\mathcal{K}$). This will become more clear with the data-dependent guarantees and discussion in Sections 5, 6, and 7.

We will first show that AdaBCO yields a strong data-dependent regret bound on the sequence of smoothed loss functions. The proof technique is based on a few key steps. We first use convexity of the loss function to change the problem into bounding the regret of quadratic functions. Then we use the fact that our original algorithm can be seen as a Follow-the-Regularized-Leader algorithm played on this sequence of surrogate loss functions to bound the regret. From here, we leverage the fact that part of our loss function is proximal, along with the properties of self-concordant barriers that we stated, to show that in the local norm, the incremental update can be bounded by the gradient of the (smoothed) loss function. Then we can estimate the gradient in the local norm in terms of the quantities that we have prescribed. Finally, we use more properties about self-concordant barriers to bound their growth near the center of the domain.

In the process, we will require a few technical lemmas about the properties of smoothed functions as well as some results from the general online learning literature. For completeness, all proofs are provided in Appendix A.

4.1 TECHNICAL LEMMAS

The following result is a mild generalization of Lemma 7 in (Hazan and Levy, 2014) and states that a smoothed loss function retains the same strong convexity properties as the original.

Lemma 4. *Let A be an SPSD matrix, and let $f : \mathbb{R}^n \to \mathbb{R}$ be A-strongly convex. Then $\widehat{f}$ is also A-strongly convex.*

Next we state a lemma by Zinkevich (2003), which shows that we can bound the regret of any sequence of loss functions by a lower barrier. This will be useful for switching between our loss functions and the quadratic lower bounds induced by their strong convexity.

Lemma 5. *Let $\{f_t\}_{t=1}^{\infty}$ be a sequence of functions and $\{x_t\}_{t=1}^{\infty} \subset \mathcal{K}$. Suppose there exists a sequence of lower barrier functions $\{h_t\}_{t=1}^{\infty}$ such that $h_t(x_t) = f_t(x_t)$ and $h_t \le f_t$. Then, the following inequality holds:*

$$\max_{x\in\mathcal{K}} \sum_{t=1}^{T} f_t(x_t) - f_t(x) \le \max_{x\in\mathcal{K}} \sum_{t=1}^{T} h_t(x_t) - h_t(x).$$

The final technical lemma in this section extends the well-known "be-the-leader"-based result of follow-the-regularized-leader type algorithms (originally from (Kalai and Vempala, 2005), to algorithms with adaptive regularization.

Algorithm 1 AdaBCO

Input: $\eta_0 = \frac{1}{2nC}$, ν-self concordant barrier $\mathcal{R}$.
Initialize: $x_1 = \operatorname{argmin}_{x\in\mathcal{K}} \mathcal{R}(x)$.
for $t = 1, \dots, T$: **do**
  Choose matrix $Q_t \succcurlyeq 0$ such that $f_t(x) \ge f_t(x_t) + g_t^\top (x - x_t) + \frac{1}{2}\|x - x_t\|_{Q_t}^2$.
  Define $\eta_t \le \eta_{t-1}$.
  Set $B_t = \left[\nabla^2\mathcal{R}(x_t) + \eta_t Q_{1:t}\right]^{-1/2}$.
  Sample $u \sim \mathcal{S}^n$ uniformly.
  Define δ_t and set $y_t = x_t + \delta_t B_t u \in W_1(x_t) \subset \mathcal{K}$.
  Play y_t and incur loss $f_t(y_t)$.
  Compute the estimate $\widehat{g}_t = n f_t(y_t)(\delta_t B_t)^{-1} u$.
  Update $x_{t+1} = \operatorname{argmin}_{x\in\mathcal{K}} \widehat{g}_{1:t}^\top x + \frac{1}{2}\sum_{s=1}^{t} \|(x - x_s)\|_{Q_s}^2 + \frac{1}{\eta_t}\mathcal{R}(x)$.
end for

Lemma 6. *Let $\{f_t\}_{t=1}^{\infty}$ be a sequence of convex functions defined on a closed convex set $\mathcal{K}$, and let $\{x_t\}_{t=1}^{\infty}$ be a sequence of points in $\mathcal{K}$ such that the subgradient of f_t at x_t is denoted as g_t. Let $\{r_t\}_{t=1}^{\infty}$ be a sequence of non-negative convex functions. Then the update $x_{t+1} = \operatorname{argmin}_x g_{1:t}^\top x + r_{0:t}(x)$ incurs regret at most*

$$\sum_{t=1}^{T} f_t(x_t) - f_t(x) \le r_{0:T}(x) + \sum_{t=1}^{T} g_t^\top (x_t - x_{t+1}).$$

We are now able to present the regret guarantee for Algorithm 1:

Theorem 1 (AdaBCO)**.** *Let $\mathcal{K}$ be a convex set with diameter $\mathcal{D}_{\mathcal{K}}$, and $\mathcal{R}$ a ν-self-concordant barrier over $\mathcal{K}$. Assume that $|f| \le C$. Then, for $0 < \eta_t \le \frac{1}{2nC}$, the following regret bound holds for Algorithm 1:*

$$\max_{w\in\mathcal{K}} \sum_{t=1}^{T} \mathbb{E}[\widehat{f}_t(y_t) - \widehat{f}_t(w)] \le \sum_{t=1}^{T} \frac{\eta_t}{\delta_t^2}\mathbb{E}\left[(n f_t(x_t + \delta_t B_t u))^2 + \frac{1}{\eta_T}\nu\log(T)\right].$$

Proof. We will refer back to the series of lemmas presented in the prior sections in our analysis.

Let r_0 and r_t be defined as follows:

$$r_0(x) = \frac{1}{\eta}\mathcal{R}(x), \quad r_t(x) = \frac{1}{2}\|x - x_t\|_{Q_t}^2.$$

Let $h_0 = r_0$, and for $t \ge 1$, let $h_t(x) = \widehat{g}_t^\top x + r_t(x)$. Then, $h_{0:t}(x) = \widehat{g}_{1:t}^\top x + r_{0:t}(x)$, and the update in Algorithm 1 can be written as $x_{t+1} = \operatorname{argmin} h_{0:t}(x)$.

Now, define $b_t(x) = \widehat{g}_t^\top (x - x_t) + r_t(x)$. By our choice of Q_t and the fact that smoothed functions preserve strong convexity (Lemma 4), it follows that $\widehat{f}_t(x) \ge b_t(x) + \widehat{f}_t(x_t)$ for all $x \in \mathcal{K}$, with equality at x_t. Thus, if we define

$\tilde{f}_t(x) = \widehat{g}_t^\top x + r_t(x)$, we can apply Lemma 5 to obtain $\max_x \sum_{t=1}^T \widehat{f}_t(x_t) - \widehat{f}_t(x) \le \max_x \sum_{t=1}^T \tilde{f}_t(x_t) - \tilde{f}_t(x)$. This helps us reduce upper bounding the regret of our theorem by the regret of quadratic functions plus a self-concordant barrier.

Note that $x_{t+1} = \operatorname{argmin} \tilde{f}_{1:t}(x) + \frac{1}{\eta_t}\mathcal{R}(x)$ is a FTRL-style update. Thus, by Lemma 6, the following holds:

$$\sum_{t=1}^T \mathbb{E}\left[\tilde{f}_t(x_t) - \tilde{f}_t(x)\right] \le \sum_{t=1}^T \mathbb{E}\left[\nabla \tilde{f}_t(x_t)^\top (x_t - x_{t+1}) + \frac{1}{\eta_T}\mathcal{R}(x)\right].$$

The first term can be bounded by

$$\begin{aligned}&\sum_{t=1}^T \mathbb{E}\left[\nabla \tilde{f}_t(x_t)^\top (x_t - x)\right] \\ &= \sum_{t=1}^T \mathbb{E}\left[\widehat{g}_t^\top (x_t - x)\right] \\ &\le \sum_{t=1}^T \|\widehat{g}_t\|_{\nabla^2 \eta_t h_{0:t}(x_t),*} \|x_t - x_{t+1}\|_{\nabla^2 \eta_t h_{0:t}(x_t)}.\end{aligned}$$

Since $x_{t+1} = \operatorname{argmin}_x \eta_t h_{0:t}(x)$, Lemma 2 tells us that if the Newton decrement $\lambda(x_t, \eta_t h_{0:t}) = \|\nabla \eta_t h_{0:t}(x_t)\|_{(\nabla^2 \eta_t h_{0:t}(x_t))^{-1}} \le \frac{1}{2}$, then $\|x_t - x_{t+1}\|_{\nabla^2 \eta_t h_{0:t}(x_t)} \le 2\lambda(x_t, \eta_t h_{0:t})$. This implies that $\sum_{t=1}^T \nabla \tilde{f}_t(x_t)^\top (x_t - x) \le \sum_{t=1}^T 2\eta_t \|\widehat{g}_t\|_{\nabla^2 \eta h_{0:t}(x_t),*} \|\nabla h_{0:t}(x_t)\|_{\nabla^2 \eta_t h_{0:t}(x_t),*}$.

At the same time, since

$$\begin{aligned}x_t &= \operatorname*{argmin}_x h_{0:t-1}(x), \\ h_{0:t-1}(x) + r_t(x) &= h_{0:t}(x) - \widehat{g}_t^\top x,\end{aligned}$$

and x_t also minimizes r_t, it follows that $0 = \nabla(h_{0:t-1} + r_t)(x_t) = \nabla h_{0:t}(x_t) - \widehat{g}_t$. Thus, the following holds: $\sum_{t=1}^T \nabla \tilde{f}_t(x_t)^\top (x_t - x) \le \sum_{t=1}^T 2\eta_t \|\widehat{g}_t\|^2_{\nabla^2 \eta_t h_{0:t}(x_t),*}$.

Putting everything together yields:

$$\sum_{t=1}^T \mathbb{E}\left[\widehat{f}_t(x_t) - \widehat{f}_t(x)\right] \le \left(\sum_{t=1}^T \mathbb{E}\left[2\eta_t \|\widehat{g}_t\|^2_{\nabla^2 \eta_t h_{0:t}(x_t),*}\right]\right) + \mathbb{E}\left[\frac{1}{\eta_T}\mathcal{R}(x)\right].$$

In addition, we know that

$$\begin{aligned}&\mathbb{E}\left[\|\widehat{g}_t\|^2_{\nabla^2 \eta_t h_{0:t}(x_t),*}\right] \\ &= \mathbb{E}\left[\|n f_t(y_t)(\delta_t B_t)^{-1} u\|^2_{\nabla^2 \eta_t h_{0:t}(x_t),*}\right] \\ &= \mathbb{E}[(n f_t(y_t)(\delta_t B_t)^{-1} u)^\top \nabla^2 \eta_t h_{0:t}(x_t)^{-1} \\ &\qquad (n f_t(y_t)(\delta_t B_t)^{-1} u)] \\ &\le \mathbb{E}\left[\frac{1}{\delta_t^2}(n f_t(x_t + \delta_t B_t u))^2\right].\end{aligned}$$

To bound the self-concordant function, Lemma 3 shows that if $\mathcal{R}$ is any ν-self concordant function over $\mathcal{K}$, then

$$\mathcal{R}(y) - \mathcal{R}(x) \le \nu \log\left(\frac{1}{1 - \pi_x(y)}\right), \quad \forall x, y \in \operatorname{int}(\mathcal{K})$$

where $\pi_{\mathcal{K},x}(y) = \inf\{t \ge 0 \colon x + \frac{1}{t}(y - x) \in \mathcal{K}\}$ is the Minkowsky functional over $\mathcal{K}$ at x.

By definition, $x_1 = \operatorname{argmin}_{x \in \mathcal{K}} \mathcal{R}(x)$. Now, any point $y \in \mathcal{K}$ satisfying $\pi_{\mathcal{K},x_1}(w) \le 1 - \frac{1}{T}$ must satisfy $\mathcal{R}(w) - \mathcal{R}(x_1) \le \nu \log(T)$. Since $\mathcal{R} \ge 0$ on $\mathcal{K}$ by assumption, this also means that $\mathcal{R}(w) \le \nu \log(T)$.

On the other hand, if $\pi_{\mathcal{K},x_1}(w) > 1 - \frac{1}{T}$, then the fact that $\pi_{\mathcal{K},x_1}(w) \le 1$ implies that there exists $0 < \epsilon \le \frac{1}{T}$ such that $\pi_{\mathcal{K},x_1}(w) \le 1 - \frac{1}{T} + \epsilon$. Defining $z = x_1 + (w - x_1)\frac{1 - \frac{1}{T}}{1 - \frac{1}{T} + \epsilon} \in \mathcal{K}$ yields that $\|w - z\| = \|\frac{\epsilon}{1 - \frac{1}{T}} x_1 - w\| \le \mathcal{O}\left(\frac{1}{T}\right)$ and $\pi_{\mathcal{K},x_1}(z) \le 1 - \frac{1}{T}$. But $\mathcal{R}$ is Lipschitz on any compact subset of $\operatorname{int}(\mathcal{K})$, so we get that $\mathcal{R}(w) \le \nu \log(T) + \mathcal{O}\left(\frac{1}{T}\right)$. Since the last term does not grow as a function of T, we will ignore it in the regret bound.

Combining the above estimates shows that if $\eta_t \|\widehat{g}_t\|_{\nabla^2 \mathcal{R}(x_t) + \eta_t Q_t,*} \le \frac{1}{2}$ (i.e. if $\eta_t \le \frac{1}{2nC}$), then

$$\sum_{t=1}^T \mathbb{E}[\widehat{f}_t(y_t) - \widehat{f}_t(w)] \le \sum_{t=1}^T \mathbb{E}\left[\frac{\eta_t}{\delta_t^2}(n f_t(x_t + \delta_t B_t u))^2 + \frac{1}{\eta_T}\nu \log(T)\right].$$

□

The extrapolation of the regret bound in Theorem 1 for smoothed loss functions to a regret bound on the original loss requires taking into account some local regularity assumptions. Factoring in local second-order regularity yields Algorithm 2.

5 AdaBCO FOR SMOOTH FUNCTIONS

The major differences between Algorithm 2 with the previous algorithm are that we now account for the local smoothness parameter β_t and that we also specify precisely the

Algorithm 2 AdaBCO-Smooth

Input: $\eta_0 = \frac{1}{2nC}$, ν-self concordant barrier $\mathcal{R}$, $C > 0$ constant.
Initialize: $x_1 = \text{argmin}_{x \in \mathcal{K}} \mathcal{R}(x)$.
for $t = 1, \ldots, T$: **do**
  Choose a constant $\beta_t > 0$ such that $f_t(x) \leq f_t(y) + \nabla f_t(y)^\top (x - y) + \frac{\beta_t}{2} \|x - y\|_2^2$.
  Choose matrix $Q_t \succcurlyeq 0$ such that $f_t(x) \geq f_t(x_t) + g_t^\top (x - x_t) + \frac{1}{2} \|x - x_t\|_{Q_t}^2$.
  Define $\tilde{B}_{t,s} = \left(\nabla^2 R(x_s) + \eta_s 1_{\{s<t\}} Q_{1:s}\right)^{-1/2}$ and

$$\eta_t = \left(\sum_{s=1}^{t} \sqrt{4\beta_s \frac{1}{n} \sum_{j=1}^{n} \lambda_j(\tilde{B}_{t,s}^2) n^2 C^2} \right)^{-2/3} (\nu \log(T))^{2/3}.$$

  Let $B_t = \left[\nabla^2 \mathcal{R}(x_t) + \eta_t Q_{1:t}\right]^{-1/2}$.
  Define $\delta_t = \left(\frac{n^3 C^2 \eta_t}{\beta_t \sum_{j=1}^{n} \lambda_j(B_t^2)} \right)^{1/4}$.
  Sample $u \sim \mathcal{S}^n$ uniformly.
  Set $y_t = x_t + \delta_t B_t u \in W_1(x_t) \subset \mathcal{K}$.
  Play y_t and incur loss $f_t(y_t)$.
  Compute the estimate $\widehat{g}_t = n f_t(y_t)(\delta_t B_t)^{-1} u$.
  Update $x_{t+1} = \text{argmin}_{x \in \mathcal{K}} g_{1:t}^\top x + \frac{1}{2} \sum_{s=1}^{t} \|(x - x_s)\|_{Q_s}^2 + \frac{1}{\eta_t} \mathcal{R}(x)$.
end for

dynamic learning rate η_t and sampling radius δ_t. Thus, Algorithm 2 is also an upgrade from previous algorithms in the literature in the sense that it does not require a priori assumptions on the global convexity or smoothness of the loss functions. One can adjust these parameters online, and the algorithm's regret will adapt.

The proof of the regret bound relies first on comparing the true loss function with the smoothed one by using the regularity parameters at each step. In contrast to previous algorithms which used global regularity parameters in a coarse manner (e.g. (Saha and Tewari, 2011)), we analyze the random sampling of the ellipsoid in greater depth in order to produce data-dependent estimates that we can leverage. This requires some general results about random variables and sampling that we present in Lemmas 8 and 9. After analyzing the approximation error, we use the result of Theorem 1 to derive a tight data-dependent bound in terms of all the relevant controllable quantities. From here, the sampling ellipsoid and learning rate at each iteration are adjusted dynamically to achieve a tight bound on the regret.

The choice of these ellipsoids and learning rates is fairly subtle and cannot be done directly due to their interdependence. The optimal a posteriori learning rate depends on the sampling ellipsoid, and the radius of the sampling ellipsoid depends on the learning rate. To get around this chicken-and-egg type of phenomenon, we force the learner to first hallucinate a different set of sampling ellipsoids based on history from which the learner can determine good learning rates. From here, the learner is then able to define an efficient true sampling ellipsoid. Deriving a tight on-line approximation to the a posteriori optimal parameters also involves an abstract calculation on normalized sums, which we present in Lemma 7.

We first formerly state the technical lemmas that we will need in this section. Their proofs are provided in Appendix A.

5.1 TECHNICAL LEMMAS

Lemma 7. *Let $\alpha_t \geq 0$, $\gamma > 0$, $\beta > 1$, and $\eta_t = \beta^{\frac{1}{1+\gamma}} (\alpha_{1:t})^{\frac{-1}{1+\gamma}}$. Then*

$$\left(\sum_{t=1}^{T} \eta_t^\gamma \alpha_t \right) + \frac{\beta}{\eta_T} \leq (2 + \gamma) \beta^{\frac{\gamma}{1+\gamma}} (\alpha_{1:T})^{\frac{1}{1+\gamma}}.$$

To derive finer estimates on the approximation error, we will use the following facts about quadratic forms of random variables and the statistical properties of sampling from the unit sphere.

Lemma 8. *Let $x \sim \mathcal{D}$ be a random vector and A be a symmetric matrix. Then, the following identity holds:*

$$\mathbb{E}_{x \sim \mathcal{D}}[x^\top A x] = \textit{trace}(A\textit{cov}(x)) + \mathbb{E}[x]^\top A \mathbb{E}[x],$$

where $\textit{cov}(x) = \mathbb{E}[x x^\top] - \mathbb{E}[x]\mathbb{E}[x]^\top$ is the covariance matrix associated to x.

Lemma 9. *Let $u \sim \mathcal{S}^n$. Then $\textit{cov}(u) = \frac{1}{n} I$ and $\mathbb{E}[u] = 0$.*

We are now ready to present the regret guarantee of Algorithm 2:

Theorem 2 (AdaBCO using dynamic smoothness bounds)**.** *Let $\mathcal{K}$ be a convex set and $\mathcal{R}$ a ν-self-concordant barrier over $\mathcal{K}$. Assume that $|f| \leq C$. Then the following regret bound holds for Algorithm 2:*

$$\max_{x \in \mathcal{K}} \sum_{t=1}^{T} \mathbb{E}[f_t(y_t) - f_t(x)] \leq \mathbb{E}\left[\frac{5}{2} (\nu \log(T))^{\frac{1}{3}} \left(\sum_{t=1}^{T} \sqrt{4\beta_t n C^2 \sum_{j=1}^{n} \lambda_j(B_t^2)} \right)^{\frac{2}{3}} \right]$$

Proof. We will show first that Algorithm 2 yields regret of

at most:

$$\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(x)]$$
$$\le \sum_{t=1}^{T}\mathbb{E}\left[\delta_t^2\beta_t\frac{1}{n}\sum_{j=1}^{n}\lambda_j(B_t^2)\right]$$
$$+\mathbb{E}\left[\left(\sum_{t=1}^{T}\frac{\eta_t}{\delta_t^2}(nf_t(x_t+B_tu))^2\right)+\frac{1}{\eta_T}\nu\log(T)\right]$$

for any schedule of $\{\delta_t\}_{t=1}^T$ and $\{\eta_t\}_{t=1}^T$.

The expected regret can be decomposed as follows:

$$\mathbb{E}[\mathrm{Reg}_T(w)]$$
$$=\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(w)]$$
$$=\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(x_t)]+\mathbb{E}[f_t(x_t)-\widehat{f}_t(x_t)]$$
$$+\mathbb{E}[\widehat{f}_t(w)-f_t(w)]+\mathbb{E}[\widehat{f}_t(x_t)-\widehat{f}_t(w)].$$

The first three terms reflect the approximation error from running our algorithm against the true loss functions versus the smoothed out versions, and the last term can be bounded via Theorem 1. To bound the first three, we use the β_t-strongly smooth property.

For the first term, we can use the smooothness constant of the particular loss function along with the results on random sampling to derive the following bound:

$$\mathbb{E}[f_t(y_t)-f_t(x_t)]$$
$$=\mathbb{E}\Big[\mathbb{E}_{u\sim\mathcal{S}^n}[f_t(x_t+\delta_tB_tu)-f_t(x_t)|x_t]\Big]$$
$$\le\mathbb{E}\Big[\mathbb{E}_{u\sim\mathcal{S}^n}[\nabla f_t(x_t)\delta_tB_tu+\tfrac{\beta_t}{2}\|\delta_tB_tu\|_2^2|x_t]\Big]$$
$$=\mathbb{E}\Big[\mathbb{E}\Big[\tfrac{\beta_t}{2}\|\delta_tB_tu\|_2^2|x_t\Big]\Big]$$
$$=\mathbb{E}\left[\frac{\beta_t}{2}\,\mathrm{trace}\left(\delta_t^2B_t^2\frac{1}{n}I\right)\right]\ \text{(by Lemmas 8 and 9)}$$
$$=\mathbb{E}\left[\frac{\beta_t}{2}\delta_t^2\frac{1}{n}\sum_{j=1}^{n}\lambda_j(B_t^2)\right].$$

The second term can be bounded using Jensen's inequality:

$$\mathbb{E}[f_t(x_t)-\widehat{f}_t(x_t)]$$
$$=\mathbb{E}\left[f_t(x_t)-\mathbb{E}_{v\sim\mathcal{B}^n}\left[f_t(x_t+\delta_tB_tv)\right]\right]$$
$$\le\mathbb{E}\left[f_t(x_t)-f_t\left(\mathbb{E}_{v\sim\mathcal{B}^n}\left[x_t+\delta_tB_tv\right]\right)\right]$$
$$=0.$$

The third term can be analyzed in a way similar to the first term, using the smoothness constant of the particular loss function as well as the results on random sampling:

$$\mathbb{E}[\widehat{f}_t(w)-f_t(w)]$$
$$=\mathbb{E}[\mathbb{E}_{v\sim\mathcal{B}^n}[f_t(w+\delta_tB_tv)]-f_t(w)]$$
$$\le\mathbb{E}\left[\mathbb{E}_{v\sim\mathcal{B}^n}\left[\nabla f_t(w)\delta_tB_tv+\frac{\beta_t}{2}\|\delta_tB_tv\|_2^2\right]\right]$$
$$=\mathbb{E}\left[\frac{\beta_t}{2}\delta_t^2\mathbb{E}_{v\sim\mathcal{B}^n}\left[\|B_tv\|_2^2\right]\right]$$
$$\le\mathbb{E}\left[\frac{\beta_t}{2}\delta_t^2\frac{1}{n}\sum_{j=1}^{n}\lambda_j(B_t^2)\right]\ \text{(by Lemmas 8 and 9)}.$$

By putting together all of the estimates above, we can arrive at the following intermediate inequality:

$$\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(x)]$$
$$\le\sum_{t=1}^{T}\mathbb{E}\left[\delta_t^2\beta_t\frac{1}{n}\sum_{j=1}^{n}\lambda_j(B_t^2)\right]$$
$$+\mathbb{E}\left[\left(\sum_{t=1}^{T}\frac{\eta_t}{\delta_t^2}(nf_t(x_t+B_tu))^2\right)+\frac{1}{\eta_T}\nu\log(T)\right]$$
$$\le\sum_{t=1}^{T}\mathbb{E}\left[\delta_t^2\beta_t\frac{1}{n}\sum_{j=1}^{n}\lambda_j(B_t^2)\right]$$
$$+\mathbb{E}\left[\left(\sum_{t=1}^{T}\frac{\eta_t}{\delta_t^2}n^2C^2\right)+\frac{1}{\eta_T}\nu\log(T)\right],$$

and by our choice of δ_t, it follows that

$$\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(x)]$$
$$\le\mathbb{E}\left[\sum_{t=1}^{T}2\sqrt{\beta_t\eta_tnC^2\sum_{j=1}^{n}\lambda_j(B_t^2)}+\frac{1}{\eta_T}\nu\log(T)\right].$$

Finally, our choice of η_t, the fact that $\eta_t\le\eta_{t-1}$, and Lemma 7 with $\gamma=\frac{1}{2}$, $\alpha_t=2\sqrt{\beta_tnC^2\sum_{j=1}^{n}\lambda_j(B_t^2)}$, $\beta=\nu\log(T)$ yield:

$$\sum_{t=1}^{T}\mathbb{E}[f_t(y_t)-f_t(x)]$$
$$\le\mathbb{E}\left[\frac{5}{2}(\nu\log(T))^{\frac{1}{3}}\left(\sum_{t=1}^{T}\sqrt{4\beta_tnC^2\sum_{j=1}^{n}\lambda_j(B_t^2)}\right)^{\frac{2}{3}}\right].$$

6 AdaBCO FOR LIPSCHITZ FUNCTIONS

Using first-order regularity instead of second motivates the design of Algorithm 3. Like Algorithm 2, the major difference here is that we factor in the local Lipschitz constant L_t and that we specify precisely η_t and δ_t. In the process, we also need to hallucinate a separate set of ellipsoids to circumvent the chicken-and-egg phenomenon.

Using similar techniques as in Theorem 2, one can derive the following regret bound:

Theorem 3 (AdaBCO using dynamic Lipschitz bounds)**.** *Let $\mathcal{K}$ be a convex set and $\mathcal{R}$ a ν-self-concordant barrier over $\mathcal{K}$. Assume that $|f| \leq C$. Then Algorithm 2 provides the regret bound:*

$$\max_{x \in \mathcal{K}} \sum_{t=1}^{T} \mathbb{E}[f_t(y_t) - f_t(x)] \leq \mathbb{E}\left[5(\nu \log(T))^{\frac{1}{4}} \left(\sum_{t=1}^{T} \left(L_t n C^2 \sum_{j=1}^{n} \lambda_j(\tilde{B}_t) \right)^{\frac{1}{3}} \right)^{\frac{3}{4}} \right]$$

The proof of this result is similar to that of Theorem 2, and is provided in Appendix B.

7 APPLICATIONS AND COMPARISON WITH PREVIOUS RESULTS

The data-dependent nature of Algorithms 2 and 3 provide two important implications.

The first is that they allow us to easily produce regret bounds in a variety of new situations, where the learner experiences loss functions with various levels of local smoothness and convexity. In particular, we can identify new scenarios where the optimal $\tilde{\mathcal{O}}(\sqrt{T})$ regret is achievable by navigating the relationship between smoothnesss and convexity.

The second is that these algorithms also automatically adapt to the smoothness and convexity of these scenarios. These new cases do not require any a priori insight or tuning. The algorithms presented in this paper adaptively determine optimal sampling ellipsoids and learning rates, which lead to strong guarantees.

In particular, they allow the learner to recover existing regret bounds without modifying the algorithms. Properties such as strong convexity or smoothness are processed adaptively and online, so that if, e.g., a sequence of loss functions is found to be approximately strongly convex (which will become clear in the following results), then the strongly convex guarantee will apply. If the sequence of loss functions is better than strongly convex, then the algorithm will give an even better guarantee. Thus, these algorithms are prime examples of algorithms that "learn faster from easy data".

We present first the results for Algorithm 2.

Corollary 1 (Power law asymptotics for the dynamically smooth and strongly convex scenario)**.** *Assume that there exists $\alpha \in \mathbb{R}$ such that*

$$\beta_t n C^2 \sum_{j=1}^{n} \lambda_j((\nabla^2 \mathcal{R}(x_t) + \eta_t Q_{1:t})^{-1}) = \mathcal{O}(t^\alpha).$$

Then the inequality $\sum_{t=1}^{T} \mathbb{E}[f_t(y_t) - f_t(x)] \leq \tilde{\mathcal{O}}(T^{\frac{2+\alpha}{3}})$ holds.

In particular, $\tilde{\mathcal{O}}(\sqrt{T})$ regret is attainable for $\alpha \leq \frac{-1}{2}$.

Moreover, $\tilde{\mathcal{O}}(T^{1/2})$ regret is adaptively attained for smooth and strongly convex functions, while $\tilde{\mathcal{O}}(T^{2/3})$ regret is adaptively attained for smooth functions.

For purely strongly smooth and strongly convex functions, $\beta_t \equiv \beta > 0$, and $Q_t \equiv Q \succ 0$, such that $Q_{1:t} = tQ$. Algorithm 2 then implies that $\eta_t = \tilde{\mathcal{O}}(t^{-1/2})$ (provable via induction), so that the corollary above applies with $\alpha \leq \frac{-1}{2}$. Thus, we adaptively attain the bound of $\tilde{\mathcal{O}}(\sqrt{T})$ in

(Hazan and Levy, 2014) without a priori knowledge of the function's regularity or any extra tuning.

For purely strongly smooth functions, $\beta_t \equiv \beta$ and in the worst case $Q_t \equiv 0$. This implies that the expression above reduces to $\beta n C^2 \sum_{j=1}^n \lambda_j(\nabla^2 \mathcal{R}(x_t)^{-1})$, so that the regret in t depends entirely on the average eigenvalue of the inverse Hessian, $\sum_{j=1}^n \lambda_j(\mathcal{R}(x_t)^{-1})$. In the worst case, this expression is $\mathcal{O}(1)$, which gives us the bound of $\tilde{\mathcal{O}}(T^{2/3})$ in (Saha and Tewari, 2011).

From another perspective, the corollary can be interpreted as saying that as long as $\beta_t \asymp \frac{1}{t \sum_{j=1}^n \lambda_j(Q_{1:t}^{-1})} \asymp t^\gamma$ for any $\gamma \in \mathbb{R}$, then $\eta_t = \tilde{\mathcal{O}}(\frac{1}{\sqrt{t}})$, and a regret of at most $\tilde{\mathcal{O}}(\sqrt{T})$ regret is guaranteed. In other words, we can extend the result of (Hazan and Levy, 2014) to not just the case where the smoothness and strong convexity are fixed and local, but in fact to any setting where the smoothness and average strong convexity parameters are locally changing at the same rate.

Moreover, we would like to stress that the above reductions are worst-case guarantees. The data-dependent nature of the regret bound above implies that it can do much better on easier data. We also do not need to know about these optimistic settings in advance of running the algorithms, as they will be adaptively and automatically obtained.

In particular, our algorithms factor in and leverage the convexity of the self-concordant barrier, so that the algorithm's bounds are much stronger when the algorithm plays points at which the Hessian of the barrier has large average eigenvalues. For common self-concordant barriers such as the log-barrier function, this corresponds to being closer to the boundary of the action set. This insight is actually somewhat surprising, because being further from the boundary generally implies that the learner will use a wider sampling ellipsoid and be able to explore more. This suggests that the self-concordant barrier regularization introduced by Abernethy et al. (2008) might not ellicit the best tradeoff between exploration and exploitation for general convex functions as it does for linear functions. Previous algorithms in bandit convex optimization did not reveal this phenomenon because they were not adaptive and did not provide data-dependent guarantees.

We now present the accompanying results for Algorithm 3.

Corollary 2 (Power law asymptotics for the dynamically Lipschitz and strongly convex scenario)**.** *Assume that there exists $\alpha \in \mathbb{R}$ such that*

$$L_t n C^2 \sum_{j=1}^n \lambda_j((\nabla^2 \mathcal{R}(x_t) + \eta_t Q_{1:t})^{-1/2}) = \mathcal{O}(t^\alpha).$$

Then the inequality $\sum_{t=1}^T \mathbb{E}[f_t(y_t) - f_t(x)] \leq \tilde{\mathcal{O}}(T^{\frac{3+\alpha}{4}})$ holds.

In particular, $\tilde{\mathcal{O}}(\sqrt{T})$ regret is attainable for $\alpha \leq -1$.

Moreover, $\tilde{\mathcal{O}}(T^{2/3})$ regret is adaptively attained for strongly convex functions, and $\tilde{\mathcal{O}}(T^{3/4})$ regret is adaptively attained for Lipschitz functions.

For purely Lipschitz and strongly convex functions, $L_t \equiv L > 0$, and $Q_t \equiv Q \succ 0$, such that $Q_{1:t} = tQ$. Algorithm 2 then implies that $\eta_t = \tilde{\mathcal{O}}(t^{-1/3})$, so that the corollary above applies with $\alpha = \frac{-1}{3}$. Thus, we adaptively attain the bound of $\tilde{\mathcal{O}}(T^{2/3})$ of (Agarwal et al., 2010) without a priori knowledge of the regularity or any extra tuning.

For purely Lipschitz functions, $L_t \equiv L$ and in the worst case $Q_t \equiv 0$. This implies that the expression above reduces to $L n C^2 \sum_{j=1}^n \lambda_j(\nabla^2 \mathcal{R}(x_t)^{-1/2})$, so that the regret now depends entirely on the average eigenvalue of the square root of the inverse Hessian, $\sum_{j=1}^n \lambda_j(\mathcal{R}(x_t)^{-1/2})$. In the worst case, this expression is $\mathcal{O}(1)$, which gives us the bound of $\tilde{\mathcal{O}}(T^{3/4})$ in (Flaxman et al., 2005).

Moreover, as long as $L_t \asymp \frac{1}{t \sum_{j=1}^n \lambda_j(Q_{1:t}^{-1/2})} \asymp t^\gamma$ for $\gamma \in \mathbb{R}$, it follows that $\eta_t = \tilde{\mathcal{O}}(t^{-1/3})$ and will attain a regret of at least $\tilde{\mathcal{O}}(T^{2/3})$.

However, as we mentioned before, these bounds can be more favorable in optimistic settings with easier data, and our algorithm will automatically adapt to these scenarios.

8 CONCLUSION

We presented two efficient and adaptive algorithms for bandit convex optimization. Unlike previous algorithms, ours do not require a priori assumptions of global strong convexity or smoothness. Instead, they can process these parameters locally and online, which is much more suitable for the setting of online convex optimization.

They also provide data-dependent guarantees, so that on "easier data", the algorithms learn faster and the bounds become tighter. In particular, we present and characterize many new data-dependent scenarios under which one can obtain the desired $\tilde{\mathcal{O}}(\sqrt{T})$ regret, including in the purely Lipschitz and purely smooth settings.

Moreover, our algorithms characterize easy data to be situations where the local smoothness and convexity of our loss functions grow at the same rate as well as when the loss function guides the learner to play points closer to the boundary. This bias in optimal exploration suggests that the self-concordant barrier may be a sub-optimal regularizer in the case of general Lipschitz convex functions.

On the Identifiability and Estimation of Functional Causal Models in the Presence of Outcome-Dependent Selection

Abstract

We study the identifiability and estimation of functional causal models under selection bias, with a focus on the situation where the selection depends solely on the effect variable, which is known as outcome-dependent selection. We address two questions of identifiability: the identifiability of the causal direction between two variables in the presence of selection bias, and, given the causal direction, the identifiability of the model with outcome-dependent selection. Regarding the first, we show that in the framework of post-nonlinear causal models, once outcome-dependent selection is properly modeled, the causal direction between two variables is generically identifiable; regarding the second, we identify some mild conditions under which an additive noise causal model with outcome-dependent selection is to a large extent identifiable. We also propose two methods for estimating an additive noise model from data that are generated with outcome-dependent selection.

1 Introduction

Selection bias is an important issue in statistical inference. Ideally, samples should be drawn randomly from the population of interest. In reality, however, it is commonplace that the probability of including a unit in the sample depends on some attributes of the unit. Such selection bias, if not corrected, often distorts the results of statistical analysis. For example, it is well known that in a regression analysis, if there is selection on the dependent variable, the ordinary least squares estimation of the regression coefficients will be biased and inconsistent (Heckman, 1979). The challenge is even bigger in causal inference; both the task of learning causal structures from data and the task of estimating causal mechanisms or parameters given a causal structure are usually rendered more difficult by the presence of selection bias.

In this paper, we are concerned with the approach to causal inference based on (restricted) functional causal models (Shimizu et al., 2006; Hoyer et al., 2009; Zhang & Hyvärinen, 2009), and aim to investigate the extent to which selection bias can be handled within this approach. Specifically, we mainly focus on the outcome-dependent selection bias, where the selection mechanism depends only on the effect, and are interested in the following two questions:

- Is the causal direction between two random variables identifiable in the presence of selection bias?
- Is the causal mechanism as represented by a functional causal model identifiable in the presence of selection bias?

These two questions have to do with the two main aspects of causal inference, respectively. The former question is about the inference of causal structure. In the traditional conditional-independence-constraint-based approach to learning causal structures (Spirtes et al., 2001; Pearl, 2000), some methods have been developed to handle selection bias (Spirtes et al., 1999; Zhang, 2008; Borboudakis & Tsamardinos, 2015). However, the structural information that can be learned via the constraint-based approach is typically limited to a Markov equivalence class. In particular, the approach cannot distinguish cause from effect with just two variables. In contrast, a distinctive virtue of the approach based on functional causal models is that Markov equivalent causal structures can usually be distinguished. In particular, the direction between two random variables is generically identifiable. Whether this virtue survives the challenge posed by selection bias is therefore worth investigating.

The latter question is related to the inference of causal parameters (i.e., parameters or quantities that have

causal interpretations), including intervention effects. In addition to the work on various selection models in econometrics and social science (Heckman, 1979; Winship & Mare, 1992), recent literature has seen interesting work on the recoverability of causal parameters based on graphical models (Didelez et al., 2010; Bareinboim & Pearl, 2012; Bareinboim et al., 2014; Evans & Didelez, 2015). Much of this work, however, deals with linear models or discrete variables, whereas we are concerned in this paper with continuous variables that may bear a nonlinear relationship.

We will proceed as follows. In Section 2, we introduce the general setup and briefly discuss several types of selection, before focusing our attention on the situation where the selection depends on the effect variable, known as outcome-dependent selection. In Section 3, we show that in the framework of post-nonlinear causal models, once outcome-dependent selection is properly modeled, the causal direction between two variables is generically identifiable. In Section 4, we identify some mild conditions under which an additive noise causal model with outcome-dependent selection is to a large extent identifiable. We then propose, in Section 5, two methods for estimating an additive noise model from data that are generated with outcome-dependent selection. Some experiments are reported in Section 6.

2 Outcome-Dependent Selection Bias

A common way to represent selection bias is to use a binary selection variable S encoding whether or not a unit is included in the sample. Suppose we are interested in the relationship between X and Y, where X has a causal influence on Y. Let p_{XY} denote the joint distribution of X and Y in the population. The selected sample follows $p_{XY|S=1}$ instead of p_{XY}. In general, $p_{XY|S=1} \neq p_{XY}$, and that is how selection may distort statistical and causal inference. However, different kinds of selection engender different levels of difficulty. In general, S may depend on any number of substantive variables, as illustrated in Figure 1, where $X = (X_1, X_2)$. [1]

[1] In this paper, we assume that we only know which variables the selection variable S depends on, but the selection mechanism is unknown, i.e., the probability of $S = 1$ given those variables is unknown. Notice that we do not have access to the data points that were not selected. This is very different from Heckman's framework to correct the bias caused by a censored sample (Heckman, 1979), which assumes access to an i.i.d. sample from the whole population, on which the Y values are observable only for the data points that satisfy the selection criterion (implied by the selection equation), but other attributes of the "censored" points are still available, enabling one to directly identify the selection mechanism.

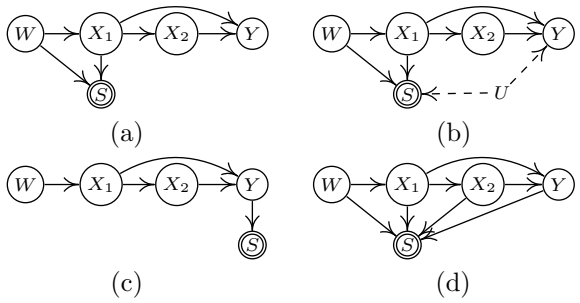

Figure 1: Illustration of different situations with sample selection bias. (a) S depends on $X = (X_1, X_2)$ but not on Y. (b) S depends on X and is also statistically dependent on Y given X due to a confounder U. (c) S directly depends solely on Y (outcome-dependent selection). (d) S depends on both X and Y.

Selection Bias on the Cause For the purpose of causal inference, the least problematic kind of situation is depicted in Figure 1(a), in which S is independent of the effect variable Y given the cause variable X. It follows that $p_{Y|X,S=1} = p_{Y|X}$. That is, the selection bias does not distort the conditional distribution of the effect Y given the cause X or the structural equation model for the causal process. In such a situation, causal inference can essentially proceed as usual. However, if there is a (latent) confounder for Y and S, as illustrated in Figure 1(b), S and Y are not conditionally independent given X any more, that is, $p_{Y|X,S=1} \neq p_{Y|X}$. Such a distortion may be corrected under rather restrictive assumptions; see, e.g., Heckman's correction (Heckman, 1979).

Selection Bias on the Effect If the selection depends solely on the effect, as depicted in Figure 1(c), then $p_{Y|X,S=1} \neq p_{Y|X}$, and the selection bias, if not corrected, will mislead inference. Consider, for example, a standard assumption in functional causal modeling that the effect Y is a function of the cause variable X and an noise variable E that is independent of X. Suppose this assumption holds in the population. With the outcome-dependent selection, X and E are typically not independent in the selected sample, as they are typically not independent conditional on S (which is a descendant of a collider between X and E, i.e., Y). Furthermore, even if one fits a regression model on selected sample, the estimated residual (which is usually different from the true noise term in the causal process) is usually not independent from X; we will get back to this issue in Section 4.1.

This kind of selection is known as *outcome-dependent selection bias* (OSB) (Didelez et al., 2010; Bareinboim et al., 2014), and will be our focus in this paper. We will show that although outcome-dependent selection seriously complicates analysis, it can be handled in the identification and estimation of functional causal

models. Note that in the case of outcome-dependent selection, X is independent of S given Y, and so we can model the distribution of the observed sample as:

$$p^{\beta}_{XY} \triangleq p_{XY|S=1} = \frac{p_{X,Y,S=1}}{P(S=1)} = p_{XY} \cdot \frac{P(S=1|X,Y)}{P(S=1)}$$
$$= p_{XY} \cdot \frac{P(S=1|Y)}{P(S=1)} = \beta(y) p_{XY}, \quad (1)$$

where the nonnegative function $\beta(y) \triangleq P(S = 1|Y)/P(S = 1)$ is a density ratio for biased sampling that only depends on Y. We will adopt this representation of outcome-dependent selection in what follows.

Selection Bias on Both the Cause and the Effect An even more general situation is depicted in Figure 1(d), where the selection depends on both X and Y (and probably others). In such a situation, the density ratio function β will depend on both X and Y. The selected sample follows the distribution $p^{\beta}_{XY} \propto p_{XY}\beta(x, y, w)$. Roughly speaking, the selection procedure is so flexible that without further constraints on $\beta(x, y, w)$, we cannot see much information about the population p_{XY}: if p_{XY} is positive on $(-\infty, +\infty)$, the same p^{β}_{XY} can be generated from a large class of distributions p_{XY} with a suitably chosen $\beta(x, y, w)$. Moreover, the causal direction is generally not identifiable, for with a sufficiently flexible $\beta(x, y, w)$, either direction can be made compatible with whatever distribution. Interestingly, when β depends only on Y, as is the case under outcome-dependent selection, the causal direction according to a restricted functional causal model is still generically identifiable, without any substantial restriction on β. To this result we now turn.

3 Identifiability of Causal Direction

In this section we investigate whether it is possible to successfully recover the causal direction between two variables when the data are generated according to a functional causal model, but with outcome-dependent selection. Here we assume that both X and Y are scalar variables.

3.1 Identifiability Without Selection Bias

The traditional approaches to inferring causal structure from data, such as the constraint-based approach (Spirtes et al., 2001; Pearl, 2000) and the score-based approach (Chickering, 2002; Heckerman et al., 1995) cannot distinguish Markov equivalent causal structures without background knowledge. In particular, with only two variables, those methods cannot distinguish cause from effect. The more recent approach based on restricted functional causal models is usually more powerful in this respect. In a functional causal model, the effect is taken to be a function of the direct causes together with an noise term that is independent of the direct causes (Pearl, 2000). When the class of functions is constrained, the causal direction is usually identifiable in that only one direction can satisfy the model assumptions, such as the assumed independence between the noise term and the direct causes. Available identifiability results include those on linear, non-Gaussian, acyclic Model (LiNGAM) (Shimizu et al., 2006)), additive noise model (ANM) (Hoyer et al., 2009), and post-nonlinear (PNL) causal model (Zhang & Hyvärinen, 2009). In this section, we will establish a main result for the PNL causal model. The result also applies to linear models and additive noise models, as they are special cases of PNL models.

A PNL model for $X \to Y$ is specified as follows:

$$Y = f_2(f_1(X) + E), \quad (2)$$

where X and E are statistically independent, f_1 is a non-constant smooth function, f_2 is an invertible smooth function, and $f_2' \neq 0$. This model is sufficiently flexible to represent or approximate many causal processes in reality (Zhang & Hyvärinen, 2009).

Similarly, for the reverse direction $Y \to X$, a PNL model would take the following form:

$$X = g_2(g_1(Y) + \tilde{E}), \quad (3)$$

where Y and $\tilde{E}$ are independent, g_1 is non-constant and smooth, g_2 is invertible and smooth, and $g_2' \neq 0$.

As shown in (Zhang & Hyvärinen, 2009), (2) and (3) can generate the same distribution of X and Y only for very special configurations of the functions and distributions. In generic cases, if data are generated according to a model of form (2), there is no model of form (3) that generates the same distribution. Hence the causal direction is generically identifiable.

3.2 Identifiability of Causal Direction in PNL-OSB

We now show that the generic identifiability of causal direction based on PNL models still holds even if we allow the possibilty of outcome-dependent selection.

Suppose the data distribution is generated by a PNL causal model from X to Y in the form of (2), denoted by $\mathcal{F}_{\to}$, followed by an outcome-dependent selection with an density ratio $\beta(y)$, as in (1). Call $(\mathcal{F}_{\to}, \beta(y))$ a PNL-OSB model, and let $p^{\rightarrow}_{XY}$ denote the joint density of X and Y resulting from $(\mathcal{F}_{\to}, \beta(y))$. We are interested in whether there is a PNL-OSB model in the reverse direction that can generate the same data distribution. That is, consider $(\mathcal{F}_{\leftarrow}, v(x))$, where $\mathcal{F}_{\leftarrow}$

is a PNL causal model from Y to X in the form of (3), and $v(x)$ is an density ratio function that depends on X. Let $p^{\leftarrow}_{XY}$ denote the joint density of X and Y resulting from $(\mathcal{F}_{\leftarrow}, v(x))$. When is it the case that $p^{\rightarrow}_{XY} = p^{\leftarrow}_{XY}$?

To simplify the presentation, we define random variables $T \triangleq g_2^{-1}(X)$, $Z \triangleq f_2^{-1}(Y)$, and function $h \triangleq f_1 \circ g_2$. That is, $h(t) = f_1(g_2(t)) = f_1(x)$. Similarly, $h_1 \triangleq g_1 \circ f_2$ is a function of Z. Moreover, we let $\eta_1(t) \triangleq \log p_T(t) = \log p_X(x) + \log |g_2'(t)|$, and $\eta_2(e) \triangleq \log p_E(e)$.

Note that T and E are independent (for X and E are assumed to be independent), and Z and $\tilde{E}$ are independent (for Y and $\tilde{E}$ are assumed to be independent). It follows that

$$p^{\rightarrow}_{XY} = \beta(y) p^{\mathcal{F}_{\rightarrow}}_{XY} = \beta(y) p_{XE}/|f_2'| = \beta_{f_2}(z) p_T p_E/|f_2' g_2'|,$$
$$p^{\leftarrow}_{XY} = v(x) p^{\mathcal{F}_{\leftarrow}}_{XY} = v(x) p_{Y\tilde{E}}/|g_2'| = v_{g_2}(t) p_{Z\tilde{E}}/|f_2' g_2'|,$$

where $\beta_{f_2} = \beta \circ f_2$, and $v_{g_2} = v \circ g_2$.

Now suppose

$$p^{\rightarrow}_{XY} = p^{\leftarrow}_{XY} \tag{4}$$

This implies

$$p_{Z\tilde{E}} = \frac{\beta_{f_2}(z)}{v_{g_2}(t)} p_T p_E,$$

or equivalently

$$\begin{aligned} \log p_{Z\tilde{E}} &= \log \beta_{f_2}(z) - \log v_{g_2}(t) + \log p_T + \log p_E \\ &= \log \beta_{f_2}(z) + \tilde{\eta}_1(t) + \eta_2(e), \end{aligned} \tag{5}$$

where $\tilde{\eta}_1(t) \triangleq \log p_T - \log v_{g_2}(t) = \eta_1(t) - \log v_{g_2}(t)$. Since Z and $\tilde{E}$ are independent, we have

$$\frac{\partial^2 \log p_{Z\tilde{E}}}{\partial z \partial \tilde{e}} \equiv 0. \tag{6}$$

(5) and (6) entail very strong constraints on the distribution of E, as stated in the following theorem.

Theorem 1 *Suppose that the densities of E and T and the functions f_1, f_2, g_1, g_2, and $v(x)$ are third-order differentiable and that p_E is positive on $(-\infty, +\infty)$. The condition (4) implies that for every point of (X, Y) satisfying $\eta_2'' h' \neq 0$:*

$$\begin{aligned} \tilde{\eta}_1''' - \frac{\tilde{\eta}_1'' h''}{h'} \quad = \quad & \Big(\frac{\eta_2' \eta_2'''}{\eta_2''} - 2\eta_2''\Big) \cdot h' h'' - \frac{\eta_2'''}{\eta_2''} \cdot h' \tilde{\eta}_1'' \\ & + \eta_2' \cdot \Big(h''' - \frac{h''^2}{h'}\Big), \end{aligned} \tag{7}$$

and h_1 depends on $\tilde{\eta}_1$, η_2, and h in the following way:

$$\frac{1}{h_1'} = \frac{\tilde{\eta}_1'' + \eta_2'' h'^2 - \eta_2' h''}{\eta_2'' h'}. \tag{8}$$

Further assume that $\eta_2'' h' \neq 0$ almost everywhere. Then in order for (7) to hold, p_E and h must satisfy one of the five conditions listed in Table 1.

Table 1: All situations in which the causal direction implied by the PNL-OSB model may be unidentifiable.

	p_E	$h = f_1 \circ g_2$
1	Gaussian	linear
2	log-mix-lin-exp	linear
3	log-mix-lin-exp	h strictly monotonic, and $h' \to 0$, as $t_1 \to +\infty$ or as $t_1 \to -\infty$
4	generalized mixture of two exponentials	Same as above

All proofs are given in the Supplementary material. In the five situations given in Table 1, the causal direction may not be identifiable according to the PNL-OSB model, and the involved distribution p_E is very specific. For the definition of distributions of the form `log-mix-lin-exp` or `generalized mixture of two exponentials`, see (Zhang & Hyvärinen, 2009). As a consequence, generally speaking, the causal direction implied by PNL-OSB is identifiable.

This identifiability result regarding the causal direction implied by PNL-OSB is similar to the original result on PNL, which was given in (Zhang & Hyvärinen, 2009). The difference is that $\eta_1(t) = \log p_T(t)$ in the original identifiability result on PNL is replaced by $\tilde{\eta}_1(t) = \log \frac{p_T(t)}{v_{g_2}(t)}$. Recall that $v_{g_2}(t)$ can be any valid density ratio; if $p_T(t)$ is positive on $(-\infty, +\infty)$, one can always adjust $v_{g_2}(t)$ so that $\frac{p_T(t)}{v_{g_2}(t)}$ meets the constraint on η_1 in (Zhang & Hyvärinen, 2009). That is, in our result any $p_T(t)$ that is positive on $(-\infty, +\infty)$ is allowed. Therefore, our non-identifiable situations (Table 1) do not contain any constraints on p_T, but still have very strong constraints on P_E and $h = f_1 \circ g_2$.

4 Identifiability of ANM-OSB Model

Given the causal direction, a further important question is whether the causal mechanism, represented by the functional causal model, and the selection procedure, represented by $\beta(y)$, can be recovered from data.

For simplicity of the derivation and presentation, we shall consider the ANM for the causal mechanism (not a PNL one in this section):

$$Y = f^{AN}(X) + E, \tag{9}$$

where $E \perp\!\!\!\perp X$. Here we further assume that f^{AN} is smooth. The observed data are generated by applying the selection bias on Y, i.e., they were drawn from the distribution

$$p^{\beta}_{XY} = \beta(y) p^{\mathcal{F}}_X p^{\mathcal{F}}_{Y|X}, \tag{10}$$

where $p^{\mathcal{F}}_{Y|X}$ is specified by the causal model (9) and $p^{\mathcal{F}}_X$ denotes the distribution of X before applying the

selection procedure. Note that generally speaking, $p_X^{\mathcal{F}}$ is not identical to p_X^{β}. Call the model $(\mathcal{F}, \beta(y))$ an ANM-OSB model.

Suppose that the observed data are generated from an ANM-OSB $(\mathcal{F}_1, \beta_1(y))$. We are interested in whether another ANM-OSB $(\mathcal{F}_2, \beta_2(y))$ can generate the same data distribution. Suppose it does. The observed data distribution is then

$$p_{XY}^{\beta} = p_{XY}^{\mathcal{F}_1}\beta_1(y) = p_{XY}^{\mathcal{F}_2}\beta_2(y). \tag{11}$$

Let $\beta_r(y) \triangleq \frac{\beta_2(y)}{\beta_1(y)}$. Bear in mind that $p_{XY}^{\mathcal{F}_1} = p_X^{(1)} p_{E_1}(Y - f^{(1)}(X))$ and $p_{XY}^{\mathcal{F}_2} = p_X^{(2)} p_{E_2}(Y - f^{(2)}(X))$. If (11) holds, we have

$$\beta_r^{-1}(y) p_X^{(1)}(x) p_{E_1}(e_1) = p_X^{(2)}(x) p_{E_2}(e_2). \tag{12}$$

Taking the logarithm of both sides gives

$$-\log \beta_r(y) + \log p_X^{(1)} + \log p_{E_1}(e_1) = \log p_X^{(2)} + \log p_{E_2}(e_2). \tag{13}$$

Now let us see whether it is possible for (13) to hold and, if yes, what constraints the functions $\beta_r(y)$, $\log p_X^{(1)}$, and $\log p_{E_1}(e_1)$ must satisfy. Denote by $J_{AN} \triangleq \log p_X^{(2)} + \log p_{E_2}(e_2)$. As seen from the RHS, (13) implies

$$\frac{\partial^2 J_{AN}}{\partial x \partial e_2} \equiv 0. \tag{14}$$

Let $l_\beta(y) = \log \beta_r(y)$, $\eta_{X_1}(x) \triangleq \log p_X^{(1)}$ and $\eta_{E_1}(e_1) \triangleq \log p_{E_1}(e_1)$. By solving (14), we can establish the relationship between the two ANM-OSB models.

4.1 General Results

Interestingly, as stated in the following theorem, if the noise E_1 is non-Gaussian, then $f^{(2)}(x)$ must be a shifted version of $f^{(1)}(x)$; in other words, the underlying function f^{AN} is identifiable up to a constant. Furthermore, if E_1 is non-Gaussian, the selection weight $\beta(y)$ can be recovered up to a factor which is an exponential function of y, i.e., $\beta_2(y) \propto \beta_2(y) \cdot e^{c_2 y}$, where c_2 is a constant; accordingly, $p_{E_2} \propto p_{E_1} \cdot e^{-c_2 e_1}$.

Theorem 2 *Let Assumptions A_1 and A_2 hold true:*
A_1. $p_X^{(1)}$ and p_{E_1} are positive on $(-\infty, +\infty)$.
A_2. $\eta''_{E_1}(e_1) f^{(1)'}(x) = 0$ only at finite points.[2]
Then if (11) is true, the following statements hold.

a) If E_1 is not Gaussian, then $f^{(2)}(x) = f^{(1)}(x) + c_1$, and $\beta_2(y) = \beta_1(y)\beta_r(y)$, where $\beta_r(y) = e^{c_2 y + d_1} = e^{d_1} \cdot e^{c_2 f^{(1)}(x)} \cdot e^{c_2 e_1}$. Accordingly, $p_X^{(2)} \propto p_X^{(1)} \cdot e^{-c_2 f_1(x)}$, and $p_{E_2} \propto p_{E_1} \cdot e^{-c_2 e_1}$. Here c_1, c_2, and d_1 are constants, and d_1 guarantees that $\beta_2(y)$ is a valid density ratio.

That is, $f^{(2)}(x)$ is equal to $f^{(1)}(x)$ (up to a constant), and with proper scaling, $\beta_2(y)$ equals $\beta_1(y)$ times an exponential function of y.

b) If E_1 is Gaussian, then $\beta_2(y) = \beta_1(y)\beta_r(y)$, where $\beta_r(y) = e^{\frac{-ab}{2}y^2 + c_4 y + d_4}$, and $f^{(2)}(x) = \frac{1}{1+b} f^{(1)}(x) + d_3$. Here a, b, c_4, d_3, and d_4 are constants, d_4 guarantees that $\beta_2(y)$ is a valid density ratio, and $a \neq 0$.

That is, with proper scaling, $\beta_2(y)$ equals $\beta_1(y)$ times a Gaussian function of y (which includes the exponential function of y as a special case by setting $b = 0$).

An interesting implication of Theorem 2 is that generally speaking, fitting an ordinary ANM on the data that were generated by an ANM-OSB will not produce an independent error term. That is, under mild assumptions, if one sets $\beta_2(y) \equiv 1$, $(\mathcal{F}_2, \beta_2(y))$ cannot produce the same distribution over (X, Y) as $(\mathcal{F}_1, \beta_1(y))$ does, as is given in the following corollary.

Corollary 3 *Let Assumptions A1 and A2 hold. Then under either of the following conditions, there does not exist an ANM, specified by (9), to generate the same distribution over (X, Y) as $(\mathcal{F}_1, \beta_1(y))$ does.*

a) E_1 is not Gaussian and $\beta_1(y)$ is not proportional to $e^{c'y}$ for any c'.

b) E_1 is Gaussian and $\beta_1(y)$ is not proportional to $e^{a'y^2 + c'y}$ for any a' and c' (i.e., $\beta_1(y)$ is not proportional to an exponential function of any polynomial of y of degree 1 or 2).

4.2 When the Noise is Gaussian

When p_{E_1} is Gaussian, as stated in b) of Theorem 2, the function f^{AN} is not identifiable any more: $f^{(2)}(x)$ and $f^{(1)}(x)$can differ by an affine transformation (not simply a shift). Accordingly, $\beta_2(y)$ can differ from $\beta_1(y)$ in a Gaussian function of y. Compared to the case where E_1 is non-Gaussian, the Gaussian case suffers from more indeterminacies because the product of two Gaussian functions is still a Gaussian function. In particular, since $\beta_r^{-1}(y)$ and $p_{E_1}(y - f^{(1)}(x))$ (or $p_{Y|X}^{\mathcal{F}_1}(y|x)$) are both Gaussian functions in y, their product is still a Gaussian function in y. Accordingly, (12) will hold true, by setting p_{E_2} to another appropriate Gaussian density; in other words, in this case two additive noise models $\mathcal{F}_1$ and $\mathcal{F}_2$ can both generate

[2]This excludes the special case where $f^{(1)'} \equiv 0$, i.e., where X and Y are independent; in this case clearly the selection procedure is not identifiable.

the same observed data, by applying the bias selection procedures $\beta_1(y)$ and $\beta_2(y) = \beta_1(y)\beta_r(y)$, respectively.

More specifically, we can derive the function $f^{(2)(x)}$ and noise distribution $p_{E_2}(e_2)$ for the model $\mathcal{F}_2$. As shown above, $f^{(2)(x)} = \frac{1}{1+b} f^{(1)}(x) + d_3$. Eq. 12, combined with (25) and (26), implies that $p_{E_2}(e_2) \propto e^{\frac{a}{2}e_2^2 + \frac{ab}{2}e_2^2} = e^{\frac{a(1+b)}{2}e_2^2}$, while $p_{E_1}(e_1) \propto e^{\frac{a}{2}e_1^2}$.

Figure 2 gives an illustration of this result. Notice that the identifiability results imply some constraints on $\beta_r(y) = \beta_2(y)/\beta_1(y)$, not on $\beta_1(y)$, so without loss of generality, we set $\beta_1(y) \equiv 1$, leading to $\beta_2(y) = \beta_r(y)$. The circles denote the data points generated by applying the density ratio $\beta_1(y) \equiv 1$ on additive noise model $\mathcal{F}_1$: the dash line shows the nonlinear function $f^{(1)}(x)$, and the red solid line shows the shape of p_{E_1}. In contrast, additive noise model $\mathcal{F}_2$ uses nonlinear function $f^{(2)}(x)$, which is different from $f^{(1)}(x)$, and its noise variance is slightly larger than that in $\mathcal{F}_1$. The crosses denote the data points generated by $\mathcal{F}_2$. Although $\mathcal{F}_1$ and $\mathcal{F}_2$ are not the same in this case, applying the density ratio function $\beta_r(y)$ on $p_{XY}^{\mathcal{F}_2}$ gives the same joint distribution as $p_{XY}^{\mathcal{F}_1}$, i.e., $\beta_1(y)p_{XY}^{\mathcal{F}_1} = p_{XY}^{\mathcal{F}_1} = \beta_r(y)p_{XY}^{\mathcal{F}_2} = \beta_2(y)p_{XY}^{\mathcal{F}_2}$.

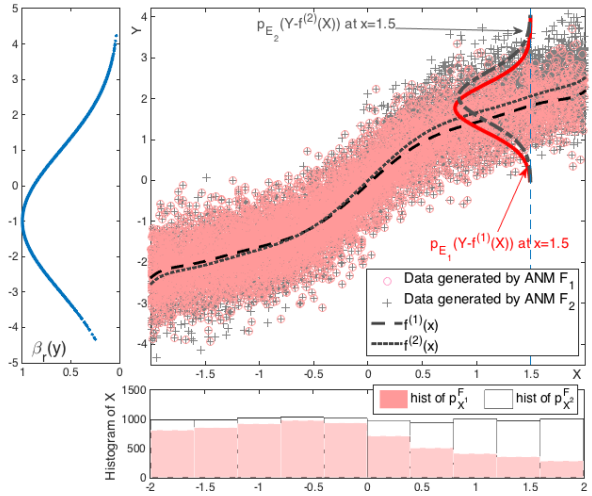

Figure 2: Illustration of the non-identifiability of the additive noise model, especially f^{AN}, when the noise is Gaussian. Red circles denote data points generated by the ANM $\mathcal{F}_1$, or by the ANM-OSB $(\mathcal{F}_1, \beta_1(y) \equiv 1)$. The gray crosses denote data generated by the ANM $\mathcal{F}_2$. The two ANM-OSB models, $(\mathcal{F}_2, \beta_r(y))$ and $(\mathcal{F}_1, 1)$, produce the same distribution of (X, Y).

4.3 With Further Constraints

Not surprisingly, if we have more knowledge about the noise distribution p_E or the density ratio function $\beta(y)$, the ANM model, including the function, the noise distribution, and the density ratio, can be fully identifiable. Below is an example showing that this is the case if we know that p_E is symmetric and non-Gaussian.

Corollary 4 *Let the assumptions made in Theorem 2 A_1 and A_2 hold. Suppose E_1 is not Gaussian. Then If both p_{E_1} and p_{E_2} are symmetric about the origin, then $f^{(2)}(x) = f^{(1)}(x)$, $E_1 = E_2$, $p_{E_1}(e_1) = p_{E_2}(e_2)$, and $\beta_r(y) \equiv 1$, i.e., $\beta_1(y) = \beta_2(y)$.*

5 Estimation of ANM-OSB

Eq. 10 gives the distribution for the observed data. In theory, we can then estimate the parameters involved in $\beta(y)$, $p_{Y|X}^{\mathcal{F}}$, as well as p_X, by maximum likelihood. However, when using maximum likelihood, we have to guarantee that the quantity on the right hand side of (10) is a valid density. This constraint is notoriously difficult to enforce in the optimization procedure. Below we propose two methods to estimate the underlying additive noise model and $\beta(y)$; one is maximum likelihood with the above constraint enforced approximately, and the other makes use of the score matching technique.

5.1 Maximum Likelihood Estimation with a Sample Approximation Constraint

To estimate the involved functions $\beta(y)$, $p_X^{\mathcal{F}}$, and $p_{Y|X}^{\mathcal{F}}$, we can maximize the data likelihood:

$$\begin{aligned}\mathcal{L} &= \sum_{k=1}^{n} \log p_{XY}^{\beta}(x_k, y_k) \\ &= \sum_{k=1}^{n} \big[\log \beta(y_k) + \log p_X^{\mathcal{F}}(x_k) + \log p_{Y|X}^{\mathcal{F}}(y_k|x_k)\big]. \quad (15)\end{aligned}$$

According to the theory shown in Section 4, the solution to βy, $p_X^{\mathcal{F}}$, and $p_{Y|X}^{\mathcal{F}}$ suffers from some indeterminacies, e.g., the solution to βy may differ from the true one by an exponential transformation. To find the solution for which the biased selection procedure is as weak as possible, we regularize the likelihood function with the constraint that $\log \beta(y)$ is close to 0. That is, we maximize

$$\mathcal{L}^r = \mathcal{L} - \lambda_r \sum_{k=1}^{n} \sqrt{(\log \beta(y_k))^2 + r}, \quad (16)$$

where the regularization parameter λ_r was set to 10^{-3} in our experiments, and r is a small positive number and was set to 0.02.

Now we have two issues to consider. One is how to parameterize the involved functions. The other is how to enforce that p_{XY}^{β}, specified in (10), corresponds to

a valid density. More specifically, the constraint is

$$\beta(y)p^{\mathcal{F}}_X p^{\mathcal{F}}_{Y|X} > 0, \text{ or equivalently } \beta(y) > 0, \text{ and} \quad (17)$$

$$\int \beta(y)p^{\mathcal{F}}_X p^{\mathcal{F}}_{Y|X} dxdy = 1. \quad (18)$$

Without constraint (18), the scale of p^{β}_{XY} will go to infinity during the process of maximizing (15).

Parameterization The additive noise model for the data-generating process, (9), implies that $p^{\mathcal{F}}_{Y|X} = p_E(y - f^{AN}(x))$. We parameterize $\beta(y)$ as the exponential transformation of a nonlinear function represented by MLP's (with the tanh activation function); this automatically guarantees the nonnegativity constraint of $\beta(y)$, as required in (17). Furthermore, we represent $p^{\mathcal{F}}_X$ with a mixture of Gaussians, the nonlinear function f^{AN} with MLP's (with the tanh activation function), and p_E with another mixture of Gaussians.

Enforcing p^{β}_{XY} to Be a Valid Density We present a sample-average approximation scheme to approximately enforce the condition that the right hand side of (10) corresponds to a valid distribution, or more specifically, to impose the constraint (18). Notice that the given data points $\{x_k, y_k\}_{k=1}^n$ were drawn from p^{β}_{XY}. As a matter of fact, we have

$$\int \beta(y)p^{\mathcal{F}}_X p^{\mathcal{F}}_{Y|X} = \int p^o_{XY} \frac{\beta(y)p^{\mathcal{F}}_X p^{\mathcal{F}}_{Y|X}}{p^o_{XY}} dxdy \quad (19)$$

$$\approx \frac{1}{n}\sum_{k=1}^{n} \frac{\beta(y_k)p^{\mathcal{F}}_X(x_k)p^{\mathcal{F}}_{Y|X}(y_k|x_k)}{p^o_{XY}(x_k, y_k)} \quad (20)$$

$$\approx \frac{1}{n}\sum_{k=1}^{n} \frac{\beta(y_k)p^{\mathcal{F}}_X(x_k)p^{\mathcal{F}}_{Y|X}(y_k|x_k)}{\hat{p}^o_{XY}(x_k, y_k)}, \quad (21)$$

where p^o_{XY} denotes the data distribution of (X, Y), and $\hat{p}^o_{XY}(x_k, y_k)$ denotes its estimate at point (x_k, y_k). Here the expression in (20) is an empirical estimate of (19) on the sample drawn from the distribution p^o_{XY}; furthermore, (20) replaces the density $p^o_{XY}(x_k, y_k)$ with its empirical estimate $\hat{p}^o_{XY}(x_k, y_k)$. As a consequence, the constraint (18) can be (approximately) achieved by enforcing

$$\frac{1}{n}\sum_{k=1}^{n} \frac{\beta(y_k)p^{\mathcal{F}}_X(x_k)p^{\mathcal{F}}_{Y|X}(y_k|x_k)}{\hat{p}^o_{XY}(x_k, y_k)} = 1. \quad (22)$$

In our experiments, we used kernel density estimation with a Gaussian kernel for $\hat{p}^o_{XY}(x_k, y_k)$; for each dimension, we set the kernel width to the median distance between points in the sample, as in (Gretton et al., 2007).

Under the parameterization given in (27) and with the above approach to guarantee that p^o_{XY} is (approximately) a valid density, one can then maximize the likelihood function given in (15) to estimate the function f^{AN}, the noise distribution, and $\beta(y)$.

5.2 With Score Matching

Alternatively, we can estimate the parameters by score matching (Hyvärinen, 2005), i.e., by minimizing the expected squared distance between the gradient of the log-density given by the model and the gradient of the log-density of the observed data. This procedure aims to match the *shape* of the density given by the model and that of the empirical density of the observed data, and is invariant to the scaling factor of the model density. As a clear advantage, in the optimization procedure one does not need to guarantee that p^{β}_{XY} is a valid density.

Given any model density $p_Z(z;\theta)$ of a m-dimensional random vector Z, the score function is the gradient of the log-density w.r.t. the data vector, i.e., $\psi(z;\theta) = (\psi_1(z;\theta), ..., \psi_m(z;\theta))^\intercal = (\frac{\partial \log p_Z(z;\theta)}{\partial z_1}, ..., \frac{\partial \log p_Z(z;\theta)}{\partial z_m})^\intercal$. Note that the score function is invariant to scale transformations in $p_Z(z)$, i.e., it is invariant to the normalization constant for a valid density. One can then estimate model parameters by minimize the expected squared distance between the model score function $\psi(\cdot;\theta)$ and the data score function $\psi_Z(\cdot;\theta)$, i.e., minimize $\frac{1}{2}\int_{z\in\mathbb{R}^m} p_Z(z)||\psi(z;\theta) - \psi_Z(z)||^2 dz$. It has been shown in (Hyvärinen, 2005) that minimizing the above squared distance is equivalent to minimizing

$$J^{SM}(\theta) = \int_{z\in\mathbb{R}^m} p_Z(z) \sum_{i=1}^{m} \big[\tilde{\psi}_i(z;\theta) + \frac{1}{2}\psi_i^2(z;\theta)\big] dz,$$

where $\tilde{\psi}_i(z;\theta) = \frac{\partial \psi_i(z;\theta)}{\partial z_i}$. The sample version of $J^{SM}(\theta)$ over the sample $\mathbf{z}_1, ..., \mathbf{z}_n$ is

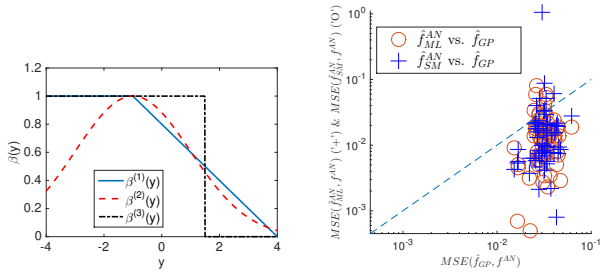
$$\hat{J}^{SM}(\theta) = \frac{1}{n}\sum_{k=1}^{n}\sum_{i=1}^{m} \big[\tilde{\psi}_i(\mathbf{z}_k;\theta) + \frac{1}{2}\psi_i^2(\mathbf{z}_k;\theta)\big]. \quad (23)$$

In particular, here we have $\psi_1 = \psi_X$ and $\psi_2 = \psi_Y$; noting that $p^{\mathcal{F}}_{Y|X} = p_E(y - f^{AN}(x))$, we can write down the involved derivatives involved in (28), and then minimize the regularized score function (with the same regularization term as in Eq. 16) to estimate the involved parameter.

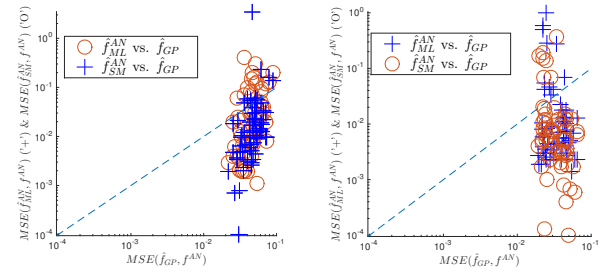
6 Experiments

Simulations The simulated data are generated by applying the biased selection procedure on the data generated by a additive noise model with function f^{AN}, i.e., by (9) and (10). As shown in Section 4, the function f^{AN} is identifiable up to some shift when

the noise is non-Gaussian. We shall study the estimation quality of the regression function f^{AN} under different settings.



(a) $\beta(y)$ used in simulations. (b) Results in settings 1∼4.



(c) Results in settings 5∼8. (d) Results in settings 9∼12.

Figure 3: Simulation settings and results. (a) shows the density ratio functions for OSB, $\beta_1(y)$, $\beta_2(y)$, and $\beta_3(y)$, which are used in settings 1-4, 5-8, and 9-12, respectively. (b), (c), and (d) show the pairwise MSE of the estimated function for the proposed methods against GP regression on the given sample, in settings 1-4, 5-8, and 9-12, respectively. The dashed line marks the threshold where the proposed methods and GP regression on the given sample perform equally well.

We consider three settings for OSB, by setting $\beta(y)$ (see Eq. 10) to different functions. As shown in Figure 3(a), $\beta^{(1)}(y)$ is a piecewise linear function, $\beta^{(2)}(y)$ is a (scaled) Gaussian function with mean -1 and standard deviation 2, and $\beta^{(3)}(y)$ corresponding to a hard biased selection procedure: it drops all data points corresponding to the 10% largest values of Y.

We use two ways to generate the distributions of X and E; one is the uniform distribution, and the other the mixture of three Gaussians with random coefficients. The function f^{AN} is a mixture of the linear, tanh, and cubic function with random coefficients (the coefficient for the cubic function is constrained to be small to avoid extreme values in Y).

In total there are $2 \times 2 \times 3$ simulation settings. For each setting we repeat the experiment with 15 random replications. We use the methods proposed in Section 5 to recover this function. Denote by $\hat{f}^{AN}_{ML}$ the estimate given by the (approximate) maximum likelihood method, and by $\hat{f}^{AN}_{SM}$ that given by the score matching method. The estimation performance is evaluated by the mean square error (MSE) between the estimate and the true function, $\frac{1}{n}\sum_{i=1}^{n}(\hat{f}^{AN}(x_i) - f^{AN}(x_i))^2$. We compare the estimates produced by our methods with that estimated by Gaussian process (GP) regression on the given sample, denoted by $\hat{f}_{GP}$. Figure 3(b-d) compares the estimation quality of $\hat{f}^{AN}_{ML}$ and $\hat{f}^{AN}_{SM}$ against $\hat{f}_{GP}$; note that they are plotted on a log scale.

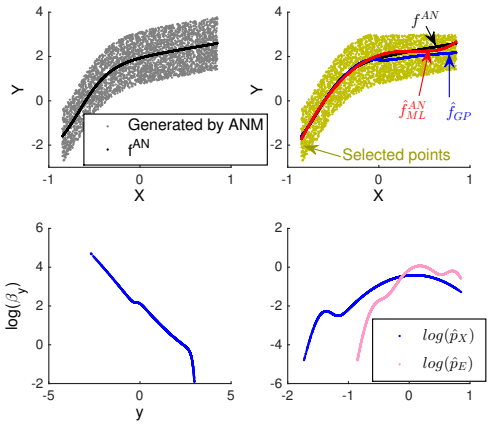


Figure 4: Results of a typical run estimated by the maximum likelihood approach. The four subfigures show the data produced by the ANM, the selected sample and the estimates of f^{AN}, the estimate of $\beta(y)$, and the estimates of p_X and p_E, respectively.

As one can see from Figure 3(b-d), the proposed methods may converge to unwanted solutions, as shown by the few points above the dashed lines. However, in most cases the proposed method provides a better estimate of the function f^{AN}. As suggested by (Demšar, 2006), we use the Wilcoxon signed ranks test to check whether $MSE(\hat{f}^{AN}, f^{AN})$ is significantly better than $MSE(\hat{f}_{GP}, f^{AN})$ under all the three settings for $\beta(y)$. It is a nonparametric test to detect shifts in populations given a number of paired samples. Under the null hypothesis the distribution of differences between the two populations is symmetric about 0. We find that under all the three sets of settings, for the score matching method, the null hypothesis is always rejected at the 0.01 level (the p-values are 6×10^{-7}, 2×10^{-6}, and 8×10^{-5}, respectively). For the maximum likelihood method, the null is rejected in settings 1-4 and 5-9 (the p-values are 2×10^{-7}, and 8×10^{-5}, respectively); we fail to reject the null in settings 5-8 (with the p-value 0.22): this seems to be caused by local optima, which will be discussed below. This means that the proposed method outperforms the method that fits GP regression on the observed data, in terms of the estimation quality of the true function.

Figure 4 gives the result of a typical run (with $\beta_3(y)$) produced by maximum likelihood. Interestingly, one

can see that compared to the true $\beta(t)$, which is $\beta_3(y)$ in Figure 3(a), $\hat{\beta}(y)$ contains an additional factor of the form $e^{c_2 y}$ with some constant c_2. The estimates of p_X and p_E are also skewed accordingly. This verifies the statements given in Theorem 2(a).

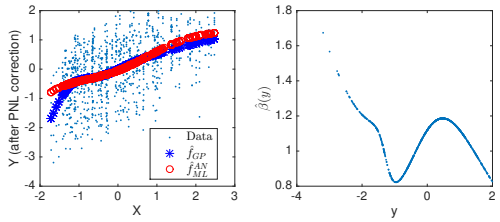
As seen from Figure 3, both algorithms may get stuck in local optima. Let us have a closer look at the results given by maximum likelihood. We found that for each simulation setting, in all runs where the function f^{AN} was not accurately recovered, or more specifically, where $MSE(\hat{f}^{AN}_{ML}, f^{AN}) > MSE(\hat{f}_{GP}, f^{AN})$, the corresponding likelihood values are among the lowest across all 15 runs. That is, the attained likelihood value suggests whether the algorithm converges to a local optimum. Therefore, in practice one may run the algorithms multiple times with random initializations and choose the one which gives the best model fit (e.g., the highest likelihood). However, this is not the case for the score matching-based approach: we did not find that the unwanted solutions always correspond to relatively large score distances. The precise reason for this phenomenon is still under investigation. Hence, below we only report the results given by the (approximate) maximum likelihood approach.

Experiments on Real Data We went through the cause-effect pairs (`http://webdav.tuebingen.mpg.de/cause-effect/`) to find data sets which are likely to suffer the OSB issue according to *commonsense or background knowledge*. We selected Pairs 25, 40, and 41. Here to save space, we only report the results on Pair 25; it is about the relationship between the age (X) and the concrete compressive strength (Y) of different samples of concrete.

The empirical distribution of the data in Pair 25 suggests that it is very likely for the effect to suffer from a PNL distortion. We use a rough way to take into account both the PNL distortion in the causal process and the OSB. We first fit the PNL causal model (Zhang & Hyvärinen, 2009) on the data and correct the data with the estimated PNL transformation on Y. We then fit the ANM-OSB procedure on the corrected data. To avoid local optima, we run the (approximate) maximum likelihood algorithm presented in Section 5.1 five times with random initializations and choose the one with the highest likelihood. Figure 7 shows the result on Pair 25. As seen from $\hat{\beta}(y)$, it seems for some reason, the samples whose compressive strength is very high were not selected. The estimated function $\hat{f}^{GP}_{ML}$ seems to address this issue.

7 Conclusion and Discussions

As we have shown, in the presence of outcome-dependent selection, the causal direction is still generically identifiable if the causal relationship can be modeled by a post-nonlinear causal model. Moreover, in the case of an additive noise model, the causal mechanism as represented by the function in the model is identifiable up to a constant if the noise term is non-Gaussian (and completely identified if the noise term follows a symmetric, non-Gaussian distribution). However, due to the selection bias, the estimation requires more care than standard methods for fitting such models, and we developed two estimation procedures in this paper.



(a) Data & estimated functions. (b) $\hat{\beta}(y)$.

Figure 5: Results on pair 25 of the cause-effect pairs. (a) The scatterplot of the data (after correcting the nonlinear distortion in Y with the PNL causal model), the nonlinear regression function $\hat{f}_{GP}$ on the data, and the estimated function $\hat{f}^{AN}_{ML}$ by the maximum likelihood approach. (b) The estimated density ratio $\beta(y)$.

This is a first step towards a better understanding of the bearing of selection bias on the identifiability and estimation of functional causal models. There are several interesting problems for future work. First, the identifiability result on additive noise models can be generalized to post-nonlinear models, but it will take more work to put the more general result in a sufficiently simple form. Second, our positive results here are confined to outcome-dependent selection. Thanks to this restriction, our results do not rely on any substantial assumption on the selection mechanism. For more complex structures of selection, such as when the selection depends on both cause and effect, identifiability will require more specifications of the selection model. Third, our result on the identification of causal direction is confined to the two-variable case without latent confounders; how to handle selection in multi-variable structural learning, with or without latent confounders, remains an open problem.

Abstract

Most recommender systems recommend a list of items. The user examines the list, from the first item to the last, and often chooses the first attractive item and does not examine the rest. This type of user behavior can be modeled by the *cascade model*. In this work, we study *cascading bandits*, an online learning variant of the cascade model where the goal is to recommend K most attractive items from a large set of L candidate items. We propose two algorithms for solving this problem, which are based on the idea of linear generalization. The key idea in our solutions is that we learn a predictor of the attraction probabilities of items from their features, as opposing to learning the attraction probability of each item independently as in the existing work. This results in practical learning algorithms whose regret does not depend on the number of items L. We bound the regret of one algorithm and comprehensively evaluate the other on a range of recommendation problems. The algorithm performs well and outperforms all baselines.

1 INTRODUCTION

Most recommender systems recommended a list of K items, such as restaurants, songs, or movies. The user *examines* the recommended list from the first item to the last, and typically clicks on the first item that *attracts* the user. The *cascade model* [10] is a popular model to formulate this kind of user behavior. The items before the first clicked item are *not attractive*, because the user examines these items but does not click on them. The items after the first attractive item are *unobserved*, because the user never examines these items. The key assumption in the cascade model is that each item attracts the user independently of the other items. Under this assumption, the optimal solution in the cascade model, the list of K items that maximizes the probability that the user finds an attractive item, are K most attractive items. The cascade model is simple, intuitive, and surprisingly effective in explaining user behavior [7].

In this paper, we study on an online learning variant of the cascade model, which is known as *cascading bandits* [15]. In this model, the learning agent does not know the preferences of the user over recommended items and the goal is to learn them by interacting with the user. At time t, the agent recommends to the user a list of K items out of L candidate items and observes the click of the user. If the user clicks on an item, the agent receives a reward of one. If the user does not click on any item, the agent receives a reward of zero. The performance of the learning agent is evaluated by its cumulative reward in n steps, which is the total number of clicks in n steps. The goal of the agent is to maximize it.

Kveton *et al.* [15] proposed two computationally and sample efficient algorithms for cascading bandits. They also proved a $\Omega(L - K)$ lower bound on the regret in cascading bandits, which shows that the regret grows linearly with the

number of candidate items L. Therefore, cascading bandits are impractical for learning when L is large. Unfortunately, this setting is common practice. For instance, consider the problem of learning a personalized recommender system for $K = 10$ movies from the ground set of $L = 100$k movies. In this setting, each movie would have to be shown to the user at least once, which means at least 10k interactions with the recommender system, before the system starts behaving intelligently. Such a system would clearly be impractical. The main contribution of our work is that we propose *linear cascading bandits*, an online learning framework that makes learning in cascading bandits practical at scale. The key step in our approach is that we assume that the attraction probabilities of items can be predicted from the features of items. Features are often available in practice or can be easily derived.

To the best of our knowledge, this is the first work that studies a top-K recommender problem in the bandit setting with cascading feedback and context. Specifically, we make four contributions. First, we propose linear cascading bandits, a variant of cascading bandits where we make an additional assumption that the attraction probabilities of items are a linear function of the features of items. This assumption is the key step in designing a sample efficient learning algorithm for our problem. Second, we propose two computationally efficient learning algorithms, `CascadeLinTS` and `CascadeLinUCB`, which are motivated by *Thompson sampling (TS)* [23, 3] and *linear UCB* [1, 24], We believe this is the first application of linear generalization in the cascade model under partial monitoring feedback. Third, we derive an upper bound on the regret of `CascadeLinUCB` and discuss why a similar upper bound should hold for `CascadeLinTS`. Finally, we evaluate `CascadeLinTS` on a range of recommendation problems; in the domains of restaurant, music, and movie recommendations; and demonstrate that it performs well even when our modeling assumptions are violated.

Our paper is organized as follows. In Section 2, we review the cascade model and cascading bandits. In Section 3, we present linear cascading bandits; propose `CascadeLinTS` and `CascadeLinUCB`; and bound the regret of `CascadeLinUCB`. In Section 4, we evaluate `CascadeLinTS` on several recommendation problems. We review related work in Section 5 and conclude in Section 6.

To simplify exposition, we denote random variables by boldface letter. We define $[n] = \{1, \ldots, n\}$ and denote the cardinality of set A by $|A|$.

2 BACKGROUND

In this section, we review the cascade model [10] and cascading bandits [15].

2.1 Cascade Model

The *cascade model* [10] is a popular model of user behavior. In this model, the user is recommended a list of K items $A = (a_1, \ldots, a_K) \in \Pi_K(E)$, where $\Pi_K(E)$ is the set of all K*-permutations* of some *ground set* $E = [L]$, which is the set of all possibly recommended items. The model is parameterized by L *attraction probabilities* $\bar{w} \in [0, 1]^E$ and the user scans the list A sequentially from the first item a_1 to the last a_K. After the user examines item a_k, the item attracts the user with probability $\bar{w}(a_k)$, *independently* of the other items. If the user is attracted by item a_k, the user clicks on it and stop examining the remaining items. If the user is not attracted by item a_k, the user examines the next recommended item a_{k+1}. It is easy to see that the probability that item a_k is examined is $\prod_{i=1}^{k-1}(1 - \bar{w}(a_i))$, and that the probability that at least one item in A is attractive is $1 - \prod_{i=1}^{K}(1 - \bar{w}(a_i))$. This objective is maximized by K most attractive items.

The cascade model is surprising effective in explaining how users scan lists of items [7]. The reason is that lower ranked items typically do not get clicked because the user is attracted by higher ranked items, and never examines the rest of the recommended list.

2.2 Cascading Bandits

Kveton *et al.* [15] proposed a learning variant of the cascading model, which is known as a cascading bandit. Formally, a *cascading bandit* is a tuple $B = (E, P, K)$, where $E = [L]$ is a *ground set* of L items, P is a probability distribution over a binary hypercube $\{0, 1\}^E$, and $K \leq L$ is the number of recommended items.

The learning agent interacts with our problem as follows. Let $(\mathbf{w}_t)_{t=1}^n$ be an i.i.d. sequence of n *weights* drawn from P, where $\mathbf{w}_t \in \{0, 1\}^E$ and $\mathbf{w}_t(e)$ is the preference of the user for item e at time t. More precisely, $\mathbf{w}_t(e) = 1$ if and only if item e attracts the user at time t. At time t, the agent recommends a list of K items $\mathbf{A}_t = (\mathbf{a}_1^t, \ldots, \mathbf{a}_K^t) \in \Pi_K(E)$. The list is a function of the observations of the agent up to time t. The user examines the list, from the first item $\mathbf{a}_1^t$ to the last $\mathbf{a}_K^t$, and clicks on the first attractive item. If the user is not attracted by any item, the user does not click on any item. Then time increases to $t + 1$.

The reward of the agent at time t is one if and only if the user is attracted by at least one item in $\mathbf{A}_t$. Formally, the reward at time t can be expressed as $\mathbf{r}_t = f(\mathbf{A}_t, \mathbf{w}_t)$, where $f : \Pi_K(E) \times [0, 1]^E \to [0, 1]$ is a *reward function* and we define it as:

$$f(A, w) = 1 - \prod_{k=1}^{K} (1 - w(a_k))$$

for any $A = (a_1, \ldots, a_K) \in \Pi_K(E)$ and $w \in [0, 1]^E$. The

agent at time t receives feedback:

$$\mathbf{C}_t = \min\left\{k \in [K] : \mathbf{w}_t(\mathbf{a}_k^t) = 1\right\} ,$$

where we assume that $\min \emptyset = \infty$. The feedback $\mathbf{C}_t$ is the click of the user. If $\mathbf{C}_t \leq K$, the user clicks on item $\mathbf{C}_t$. If $\mathbf{C}_t = \infty$, the user does not click on any item. Since the user clicks on the first attractive item in the list, the observed weights of all recommended items at time t can be expressed as a function of $\mathbf{C}_t$:

$$\mathbf{w}_t(\mathbf{a}_k^t) = \mathbb{1}\{\mathbf{C}_t = k\} \quad k = 1, \ldots, \min\{\mathbf{C}_t, K\} . \quad (1)$$

Accordingly, we say that item e is *observed* at time t if $e = \mathbf{a}_k^t$ for some $k \in [\min\{\mathbf{C}_t, K\}]$.

Let the attraction weights of items in the ground set E be distributed independently as:

$$P(w) = \prod_{e \in E} \mathrm{Ber}(w(e); \bar{w}(e)) ,$$

where $\mathrm{Ber}(\cdot; \theta)$ is a Bernoulli distribution with mean θ. Then the expected reward for list $A \in \Pi_K(E)$, the probability that at least one item in A is satisfactory, can be expressed as $\mathbb{E}[f(A, \mathbf{w})] = f(A, \bar{w})$, and depends only on the attraction probabilities of individual items in A. Therefore, it is sufficient to learn a good approximation to $\bar{w}$ to act optimally.

The agent's policy is evaluated by its *expected cumulative regret*:

$$R(n) = \mathbb{E}\left[\sum_{t=1}^{n} R(\mathbf{A}_t, \mathbf{w}_t)\right] , \quad (2)$$

where $R(\mathbf{A}_t, \mathbf{w}_t) = f(A^*, \mathbf{w}_t) - f(\mathbf{A}_t, \mathbf{w}_t)$ is the *instantaneous stochastic regret* of the agent at time t and:

$$A^* = \operatorname*{arg\,max}_{A \in \Pi_K(E)} f(A, \bar{w})$$

is the *optimal list* of items, the list that maximizes the reward at any time t. For simplicity of exposition, we assume that the optimal solution, as a set, is unique.

2.3 Algorithm `CascadeUCB1`

Kveton *et al.* [15] proposed and analyzed two learning algorithms for cascading bandits, `CascadeUCB1` and `CascadeKL-UCB`. In this section, we review `CascadeUCB1`.

`CascadeUCB1` belongs to the family of UCB algorithms. The algorithm operates in three stages. First, it computes the *upper confidence bounds (UCBs)* $\mathbf{U}_t \in [0, 1]^E$ on the attraction probabilities of all items in E. The UCB of item e at time t is:

$$\mathbf{U}_t(e) = \hat{\mathbf{w}}_{\mathbf{T}_{t-1}(e)}(e) + c_{t-1, \mathbf{T}_{t-1}(e)} , \quad (3)$$

where $\hat{\mathbf{w}}_s(e)$ is the average of s observed attraction weights of item e, $\mathbf{T}_t(e)$ is the number of times that item e is observed in t steps, and:

$$c_{t,s} = \sqrt{(1.5 \log t)/s}$$

is the radius of a confidence interval around $\hat{\mathbf{w}}_s(e)$ after t steps such that $\bar{w}(e) \in [\hat{\mathbf{w}}_s(e) - c_{t,s}, \hat{\mathbf{w}}_s(e) + c_{t,s}]$ holds with high probability. Second, `CascadeUCB1` recommends a list of K items with largest UCBs:

$$\mathbf{A}_t = \operatorname*{arg\,max}_{A \in \Pi_K(E)} f(A, \mathbf{U}_t) .$$

Finally, after the user provides feedback $\mathbf{C}_t$, the algorithm updates its estimates of the attraction probabilities $\bar{w}(e)$ based on the observed weights of items, which are defined in (1) for all $e = \mathbf{a}_k^t$ such that $k \leq \mathbf{C}_t$.

3 LINEAR CASCADING BANDITS

Kveton *et al.* [15] showed that the n-step regret of `CascadeUCB1` is $O((L - K)(1/\Delta) \log n)$, where L is the number of items in ground set E; K is the number of recommended items; and Δ is the gap, which measures the sample complexity. This means that the regret increases linearly with the number of items L. As a result, `CascadeUCB1` is not practical when L is large. Unfortunately, this setting is common practice. For instance, consider the problem of learning a personalized recommender for 10 movies from the ground set of 100k movies. To learn, `CascadeUCB1` would need to show each movie to the user at least once, which means that the algorithm would require at least 10k interactions with the user to start behaving intelligently. This is clearly impractical.

In this work, we propose *practical algorithms* for large-scale cascading bandits, in the setting where L is large. The key assumption, which allows us to learn efficiently, is that we assume that the attraction probability of each item e, $\bar{w}(e)$, can be approximated by a linear combination of some known d-dimensional feature vector $x_e \in \mathbb{R}^{d \times 1}$ and an unknown d-dimensional parameter vector of $\theta^* \in \mathbb{R}^{d \times 1}$, which is shared among all items. More precisely, we assume that there exists $\theta^* \in \Theta$ such that:

$$\bar{w}(e) \approx x_e^\top \theta^* \quad (4)$$

for any $e \in E$. The features are problem specific and we discuss how to construct them in Section 4.3. We propose two learning algorithms, which we call *cascading linear Thompson sampling* (`CascadeLinTS`) and *cascading linear UCB* (`CascadeLinUCB`). We prove that when the above linear generalization is perfect, the regret of `CascadeLinUCB` is independent of L and sublinear in n. Therefore, `CascadeLinUCB` is suitable for learning to recommend from large ground sets E. We also discuss why a similar regret bound should hold for `CascadeLinTS`, though we do not prove this bound formally.

Algorithm 1 `CascadeLinTS`

Inputs: Variance σ^2

// Initialization
$\mathbf{M}_0 \leftarrow I_d$ and $\mathbf{B}_0 \leftarrow \mathbf{0}$

for all $t = 1, \ldots, n$ **do**
  $\bar{\theta}_{t-1} \leftarrow \sigma^{-2}\mathbf{M}_{t-1}^{-1}\mathbf{B}_{t-1}$
  $\theta_t \sim \mathcal{N}(\bar{\theta}_{t-1}, \mathbf{M}_{t-1}^{-1})$

  // Recommend a list of K items and get feedback
  for all $k = 1, \ldots, K$ **do**
    $\mathbf{a}_k^t \leftarrow \arg\max_{e \in [L] - \{\mathbf{a}_1^t, \ldots, \mathbf{a}_{k-1}^t\}} x_e^\intercal \theta_t$
  $\mathbf{A}_t \leftarrow (\mathbf{a}_1^t, \ldots, \mathbf{a}_K^t)$
  Observe click $\mathbf{C}_t \in \{1, \ldots, K, \infty\}$
  Update statistics using Algorithm 3

Algorithm 2 `CascadeLinUCB`

Inputs: Variance σ^2, constant c (Section 3.2)

// Initialization
$\mathbf{M}_0 \leftarrow I_d$ and $\mathbf{B}_0 \leftarrow \mathbf{0}$

for all $t = 1, \ldots, n$ **do**
  $\bar{\theta}_{t-1} \leftarrow \sigma^{-2}\mathbf{M}_{t-1}^{-1}\mathbf{B}_{t-1}$
  for all $e \in E$ **do**
    $\mathbf{U}_t(e) \leftarrow \min\left\{x_e^\intercal \bar{\theta}_{t-1} + c\sqrt{x_e^\intercal \mathbf{M}_{t-1}^{-1} x_e}, 1\right\}$

  // Recommend a list of K items and get feedback
  for all $k = 1, \ldots, K$ **do**
    $\mathbf{a}_k^t \leftarrow \arg\max_{e \in [L] - \{\mathbf{a}_1^t, \ldots, \mathbf{a}_{k-1}^t\}} \mathbf{U}_t(e)$
  $\mathbf{A}_t \leftarrow (\mathbf{a}_1^t, \ldots, \mathbf{a}_K^t)$
  Observe click $\mathbf{C}_t \in \{1, \ldots, K, \infty\}$
  Update statistics using Algorithm 3

Algorithm 3 Update of statistics in Algorithms 1 and 2

$\mathbf{M}_t \leftarrow \mathbf{M}_{t-1}$
$\mathbf{B}_t \leftarrow \mathbf{B}_{t-1}$
for all $k = 1, \ldots, \min\{\mathbf{C}_t, K\}$ **do**
  $e \leftarrow \mathbf{a}_k^t$
  $\mathbf{M}_t \leftarrow \mathbf{M}_t + \sigma^{-2} x_e x_e^\intercal$
  $\mathbf{B}_t \leftarrow \mathbf{B}_t + x_e \mathbb{1}\{\mathbf{C}_t = k\}$

3.1 Algorithms

Our learning algorithms are based on the ideas of Thompson sampling [23, 3] and linear UCB [1], and motivated by the recent work of Wen *et al.* [24], which proposes computationally and sample efficient algorithms for large-scale stochastic combinatorial semi-bandits. The pseudocode of both algorithms is in Algorithms 1 and 2, and we outline them below.

Both `CascadeLinTS` and `CascadeLinUCB` represent their past observations as a positive-definite matrix $\mathbf{M}_t \in \mathbb{R}^{d \times d}$ and a vector $\mathbf{B}_t \in \mathbb{R}^{d \times 1}$. Specifically, let $\mathbf{X}_t$ be a matrix whose rows are the feature vectors of all observed items in t steps and $\mathbf{Y}_t$ be a column vector of all observed attraction weights in t steps. Then:

$$\mathbf{M}_t = \sigma^{-2}\mathbf{X}_t^\intercal \mathbf{X}_t + I_d$$

is the *gram matrix* in t steps and:

$$\mathbf{B}_t = \mathbf{X}_t^\intercal \mathbf{Y}_t\,,$$

where I_d is a $d \times d$ identity matrix and $\sigma > 0$ is parameter that controls the learning rate.[1]

Both `CascadeLinTS` and `CascadeLinUCB` operate in three stages. First, they estimated the expected weight of each item e based on their model of the world. `CascadeLinTS` randomly samples parameter vector θ_t from a normal distribution, which approximates its posterior on θ^*, and then estimates the expected weight as $x_e^\intercal \theta_t$. `CascadeLinUCB` computes an upper confidence bound $\mathbf{U}_t(e)$ for each item e. Second, both algorithms choose the optimal list $\mathbf{A}_t$ with respect to their estimates. Finally, they receive feedback, and update $\mathbf{M}_t$ and $\mathbf{B}_t$ using Algorithm 3.

[1] Ideally, σ^2 should be the variance of the observation noises. However, based on recent literature [24], we believe that both algorithms will perform well for a wide range of σ^2.

We would like to emphasize that both `CascadeLinTS` and `CascadeLinUCB` are computationally efficient. In practice, we would update $\mathbf{M}_t^{-1}$ instead of $\mathbf{M}_t$. In particular, note that:

$$\mathbf{M}_t \leftarrow \mathbf{M}_t + \sigma^{-2} x_e x_e^\intercal$$

can be equivalently updated as:

$$\mathbf{M}_t^{-1} \leftarrow \mathbf{M}_t^{-1} - \frac{\mathbf{M}_t^{-1} x_e x_e^\intercal \mathbf{M}_t^{-1}}{x_e^\intercal \mathbf{M}_t^{-1} x_e + \sigma^2}\,,$$

and hence $\mathbf{M}_t^{-1}$ can be updated incrementally and computationally efficiently in $O(d^2)$ time. It is easy to to see that the per-step time complexities of both `CascadeLinTS` and `CascadeLinUCB` are $O(L(d^2 + K))$.

3.2 Analysis and Discussion

We first derive a regret bound on `CascadeLinUCB`, under the assumptions that (1) $\bar{w}(e) = x_e^\intercal \theta^*$ for all $e \in E$ and (2) $\|x_e\|_2 \le 1$ for all $e \in E$. Note that condition (2) can be always ensured by rescaling feature vectors. The regret bound is detailed below.

Theorem 1. *Under the above assumptions, for any $\sigma > 0$ and any*

$$c \ge \frac{1}{\sigma}\sqrt{d \log\left(1 + \frac{nK}{d\sigma^2}\right) + 2\log(nK)} + \|\theta^*\|_2,$$

if we run `CascadeLinUCB` *with parameters* σ *and* c*, then*

$$R(n) \leq 2cK\sqrt{\frac{dn\log\left[1+\frac{nK}{d\sigma^2}\right]}{\log\left(1+\frac{1}{\sigma^2}\right)}}+1.$$

Note that if we choose $\sigma = 1$ and

$$c = \sqrt{d\log\left(1+\frac{nK}{d}\right)+2\log\left(nK\right)}+\eta,$$

for some constant $\eta \geq \|\theta^*\|_2$, then $R(n) \leq \tilde{O}\left(Kd\sqrt{n}\right)$ where the $\tilde{O}$ notation hides logarithmic factors.

The proof is in Appendix and we outline it below. First, we define event $\mathcal{G}_{t,k} = \{\text{item } \mathbf{a}_k^t \text{ is examined in step } t\}$ for any time t and $k \in [K]$, and bound the n-step regret as

$$R(n) \leq \mathbb{E}\left[\sum_{t=1}^{n}\sum_{k=1}^{K}\mathbb{1}\{\mathcal{G}_{t,k}\}\left[\bar{w}(\mathbf{a}_k^{*,t})-\bar{w}(\mathbf{a}_k^t)\right]\right],$$

where $\mathbf{a}_k^{*,t}$ is an optimal item in A^* matched to item $\mathbf{a}_k^t$ in step t. Second, we define an event

$$\mathcal{E} = \left\{\left|x_e^T(\bar{\theta}_{t-1}-\theta^*)\right| \leq c\|x_e\|_{\mathbf{M}_{t-1}^{-1}}\ \forall t \leq n,\ \forall e \in E\right\},$$

where $\|x_e\|_{\mathbf{M}_{t-1}^{-1}} = \sqrt{x_e^\intercal \mathbf{M}_{t-1}^{-1} x_e}$. Then we prove a high-probability bound $P(\mathcal{E}) \geq 1-1/nK$ for any c that satisfies the condition of Theorem 1. Finally, we show that by conditioning on $\mathcal{E}$, we have

$$\begin{aligned}
&\sum_{t=1}^{n}\sum_{k=1}^{K}\mathbb{1}\{\mathcal{G}_{t,k}\}\left[\bar{w}(\mathbf{a}_k^{*,t})-\bar{w}(\mathbf{a}_k^t)\right] \\
&\quad\leq 2c\sum_{t=1}^{n}\sum_{k=1}^{K}\mathbb{1}\{\mathcal{G}_{t,k}\}\left\|x_{\mathbf{a}_k^t}\right\|_{\mathbf{M}_{t-1}^{-1}} \\
&\quad\leq 2cK\sqrt{\frac{dn\log\left[1+\frac{nK}{d\sigma^2}\right]}{\log\left(1+\frac{1}{\sigma^2}\right)}},
\end{aligned}$$

where the first inequality follows from the definition of $\mathcal{E}$ and the second inequality follows from a worst-case bound. The bound in Theorem 1 follows from putting the above results together.

Recent work [21, 24] demonstrated close relationships between UCB-like algorithms and Thompson sampling algorithms in related bandit problems. Therefore, we believe that a similar regret bound to that in Theorem 1 also holds for `CascadeLinTS`. However, it is highly non-trivial to derive a regret bound for `CascadeLinTS`. Unlike in [24], `CascadeLinTS` cannot be analyzed from the Bayesian perspective because the Gaussian posterior is inconsistent with the fact that $\bar{w}(e)$ is bounded in $[0, 1]$. Moreover, a subtle statistical dependence between partial monitoring and Thompson sampling prevents a frequentist analysis similar to that in [4]. Therefore, we leave the formal analysis of `CascadeLinTS` for future work. It is well known that Thompson sampling tends to outperform UCB-like algorithms in practice [3]. Therefore, we only empirically evaluate `CascadeLinTS`.

4 EXPERIMENTS

We validate `CascadeLinTS` on several problems of various sizes and from various domains. In each problem, we conduct several experiments that demonstrate that our approach is scalable and stable with respect to its tunable parameters, the number of recommended items K and the number of features d.

Our experimental section is organized as follows. In Section 4.1, we outline the experiments that are conducted on each dataset. In Section 4.2, we introduce our metrics and baselines. In Section 4.3, we describe how we construct the features of items E. We present our empirical results in the rest of the section.

4.1 Experimental Setting

All of our learning problems can be viewed as follows. The feedback of users is a matrix $W \in \{0,1\}^{m\times L}$, where row i corresponds to user $i \in [m]$ and column j corresponds to item $j \in E$. Entry (i, j) of W, $W_{i,j} \in \{0, 1\}$, indicates that user i is attracted by item j. The user at time t, the row of W, is chosen at random from the pool of all users. Our goal is to learn the list of items A^*, the columns of W, that maximizes the probability that the user at time t is attracted by at least one recommended item.

In each of our problems, we conduct a set of experiments. In the first experiment, we compare `CascadeLinTS` to baselines (Section 4.2) and also evaluate its scalability. We experiment with three variants of our problems: $L = 16$ items, $L = 256$ items, and the maximum possible value of L in a given experiment. The number of recommended items is $K = 4$ and the number of features is $d = 20$.

In the second experiment, we show that the performance of `CascadeLinTS` is robust with respect to the number of features d, in the sense that d affects the performance but `CascadeLinTS` performs reasonably well for all settings of d. We experiment with three settings for the number of features: $d = 10$, $d = 20$, and $d = 40$. The ground set contains $L = 256$ items and the number of recommended items is $K = 4$.

In the third experiment, we evaluate `CascadeLinTS` on an interesting subset of each dataset, such as *Rock Songs*. The setting of this experiment is identical to the second experiment. This experiment validates that `CascadeLinTS` can also learn to recommend items in the context, of a subset of the dataset.

In the last experiment, we evaluate how the performance of

CascadeLinTS varies with the number of recommended items K. We experiment with three settings for the number of recommended items: $K = 4$, $K = 8$, and $K = 12$. The ground set contains $L = 256$ items and the number of features is $d = 20$.

All experiments are conducted for $n = 100$k steps and averaged over 10 randomly initialized runs. The tunable parameter σ in CascadeLinTS is set to 1.

4.2 Metrics and Baselines

The performance of CascadeLinTS is evaluated by its expected cumulative regret, which is defined in (2). In most of our experiments, our modeling assumptions are violated. In particular, the items are not guaranteed to attract users independently because the attraction indicators $\mathbf{w}_t(e)$ are correlated across items e. The result is that:

$$A^* = \arg\max_{A \in \Pi_K(E)} \mathbb{E}\left[f(A, \mathbf{w})\right] > \arg\max_{A \in \Pi_K(E)} f(A, \bar{w}) \,.$$

It is NP-hard to find A^*, because $\mathbb{E}\left[f(A, \mathbf{w})\right]$ does not decompose into the product of expectations as we assume in our model (Section 2.2). However, since $\mathbb{E}\left[f(A, \mathbf{w})\right]$ is submodular and monotone in A, a $(1 - 1/e)$ approximation to A^* can be computed greedily, by iteratively adding items that attract most users that are not attracted by any previously added item. We denote this approximation by A^* and use it instead of the optimal solution.

We compare CascadeLinTS to two baselines. The first baseline is CascadeUCB1 (Section 2.3). This baseline does not leverage the structure of our problem and learns the attraction probability of each item e independently. The second baseline is RankedLinTS (Algorithm 4). This baseline is a variant of ranked bandits (Section 5), where the base bandit algorithm is LinTS. This base algorithm is the same as in CascadeLinTS. Therefore, any observed difference in the performance of cascading and ranked bandits must be due to the efficiency of using the base algorithm, and not the algorithm itself. In this sense, our comparison of CascadeLinTS and RankedLinTS is fair. The tunable parameter σ in RankedLinTS is also set to 1.

4.3 Features

In most recommender problems, good features of items are rarely available. Thus, they are typically learned from data [14]. As an example, in movie recommendations, all state of the art approaches are based on collaborative filtering rather than on the features of movies, such as movie genres.

Motivated by the successes of collaborative filtering in recommender systems, we derive the features of our items using low-rank matrix factorization. In particular, let $W \in \{0,1\}^{m \times L}$ be our feedback matrix for m users and L items. We randomly divide the rows of W into two matrices, training matrix $W_{\text{train}} \in \{0,1\}^{(m/2) \times L}$ and test matrix

Algorithm 4 Ranked bandits with linear TS.

Inputs: Variance σ^2

// Initialization
$\forall k \in [K] : \mathbf{M}_0^k \leftarrow I_d$ and $\mathbf{B}_0^k \leftarrow \mathbf{0}$

for all $t = 1, \ldots, n$ **do**
  for all $k = 1, \ldots, K$ **do**
    $\bar{\theta}_{t-1}^k \leftarrow \sigma^{-2} (\mathbf{M}_{t-1}^k)^{-1} \mathbf{B}_{t-1}^k$
    $\theta_t^k \sim \mathcal{N}(\bar{\theta}_{t-1}^k, (\mathbf{M}_{t-1}^k)^{-1})$
    $\mathbf{a}_k^t \leftarrow \arg\max_{e \in [L] - \{\mathbf{a}_1^t, \ldots, \mathbf{a}_{k-1}^t\}} x_e^\intercal \theta_t^k$

  // Recommend a list of K items and get feedback
  $\mathbf{A}_t \leftarrow (\mathbf{a}_1^t, \ldots, \mathbf{a}_K^t)$
  Observe click $\mathbf{C}_t \in \{1, \ldots, K, \infty\}$

  // Update statistics
  $\forall k \in [K] : \mathbf{M}_t^k \leftarrow \mathbf{M}_{t-1}^k$
  $\forall k \in [K] : \mathbf{B}_t^k \leftarrow \mathbf{B}_{t-1}^k$
  for all $k = 1, \ldots, \min\{\mathbf{C}_t, K\}$ **do**
    $e \leftarrow \mathbf{a}_k^t$
    $\mathbf{M}_t^k \leftarrow \mathbf{M}_t^k + \sigma^{-2} x_e x_e^\intercal$
    $\mathbf{B}_t^k \leftarrow \mathbf{B}_t^k + x_e \mathbb{1}\{\mathbf{C}_t = k\}$

$W_{\text{test}} \in \{0,1\}^{(m/2) \times L}$. We use W_{train} to learn the features of items and W_{test} in place of W to evaluate our learning algorithms. Most existing real-world recommender systems already have some data about their users. Such data can be used to construct W_{train}.

Let $W_{\text{train}} \approx U \Sigma V^\intercal$ be rank-d truncated SVD of W_{train}, where $U \in \mathbb{R}^{(m/2) \times d}$, $\Sigma \in \mathbb{R}^{d \times d}$, and $V \in \mathbb{R}^{L \times d}$. Then the features of items are the rows of $V\Sigma$. Specifically, for each item $e \in E$ and feature $i \in [d]$, $x_e(i) = V_{e,i} \Sigma_{i,i}$.

4.4 Restaurant Recommendations

Our dataset is from Yelp Dataset Challenge[2]. This dataset has five parts, including business information, checkin information, review information, tip information, and user information. We only consider the business and review information. The dataset contains 78k businesses, out of which 11k are restaurants; and 2.2M reviews written by 550k users. We extract $L = 3$k most reviewed restaurants and $m = 20$k most reviewing users.

Our objective is to maximize the probability that the user is attracted by at least one recommended restaurant. We build the model of users from past review data and assume that the user is attracted by the restaurant if the user reviewed this restaurant before. This indicates that the user visited the restaurant at some point in time, likely because the restaurant attracted the user at that time.

[2] https://www.yelp.com/dataset_challenge

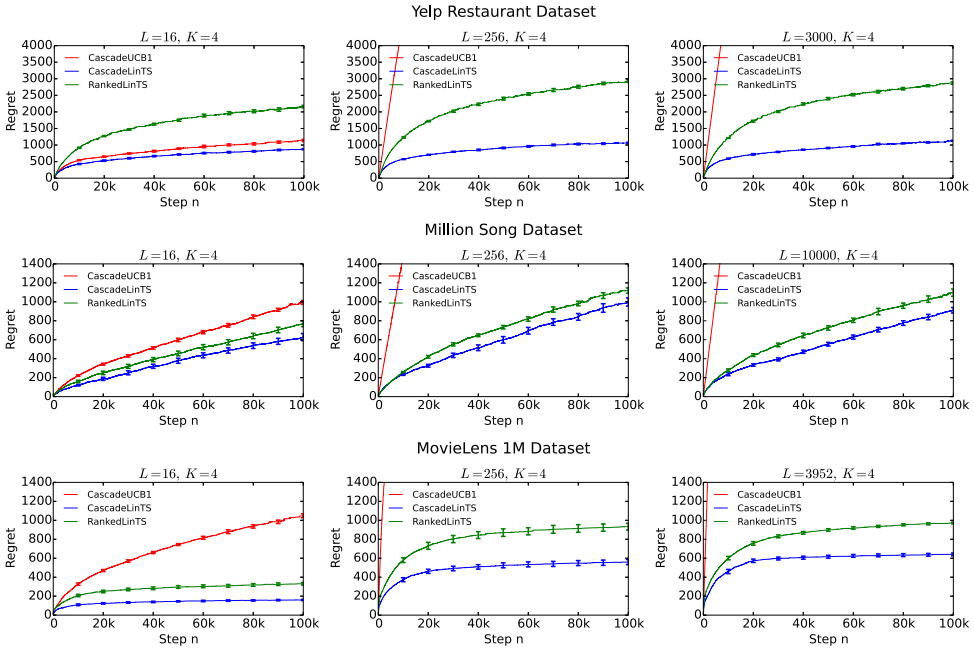

Figure 1: The n-step regret of `CascadeUCB1`, `CascadeLinTS` and `RankedLinTS` on three problems. We vary the number of items in the ground set E, from $L = 16$ to the maximum value in each problem.

4.4.1 Results

The results of our first experiment are reported in Fig. 1. When the ground set is small, $L = 16$, all compared methods perform similarly. In particular, the regret of `CascadeLinTS` is similar to that of `RankedLinTS`. The regret of `CascadeUCB1` is about two times larger than that of `CascadeLinTS`. As the size of the ground set increases, the gap between `CascadeLinTS` and the other methods increases. In particular, when $L = 3$k, the regret of `CascadeUCB1` is orders of magnitude larger than that of `CascadeLinTS`, and the regret of `RankedLinTS` is almost three times larger.

In the second experiment (Fig. 2a), we observe that `CascadeLinTS` performs well for all settings of d. When the number of features doubles to $d = 40$, the regret roughly doubles. When the number of features is halved to $d = 10$, the regret improves and is roughly halved.

In the third experiment (Fig. 2b), `CascadeLinTS` is evaluated on the subset of *American Restaurants*. This is the largest restaurant category in our dataset. We observe that `CascadeLinTS` can learn for any number of features d, similarly to Fig. 2a.

In the last experiment (Fig. 2c), we observe that the regret of `CascadeLinTS` increases with the number of recommended items, from $K = 4$ to $K = 8$. This result is surprising and seems to contradict to Kveton *et al.* [15], who find both theoretically and empirically that the regret in cascading bandits decreases with the number of recommended items K. We investigate this further and plot the cumulative reward of `CascadeLinTS` in Fig. 2d. The reward increases with K, which is expected and validates that `CascadeLinTS` learns better policies for larger K. Therefore, the increase in the regret in Fig. 2c must be due to the fact that the expected reward of the optimal solution, $f(A^*, \bar{w})$, increases faster with K than that of the learned policies. We believe that the optimal solutions for larger K are harder to learn because our modeling assumptions are violated. In particular, the linear generalization in (4) is imperfect and the items in E are not guaranteed to attract users independently.

4.5 Million Song Recommendation

Million Song Dataset[3] is a collection of audio features and metadata for a million contemporary pop songs. Instead of storing any audio, the dataset consists of features derived from the audio, user-song profile data, and genres of songs. We extract $L = 10$k most popular songs from this dataset, as measured by the number of song-listening events; and $m = 400$k most active users, as measured by the number of song-listening events.

Our objective is to maximize the probability that the user is attracted with at least one recommended song and plays it. We build the model of users from their past listening patterns and assume that the user is attracted by the song if the user listened to this song before. This indicates that the

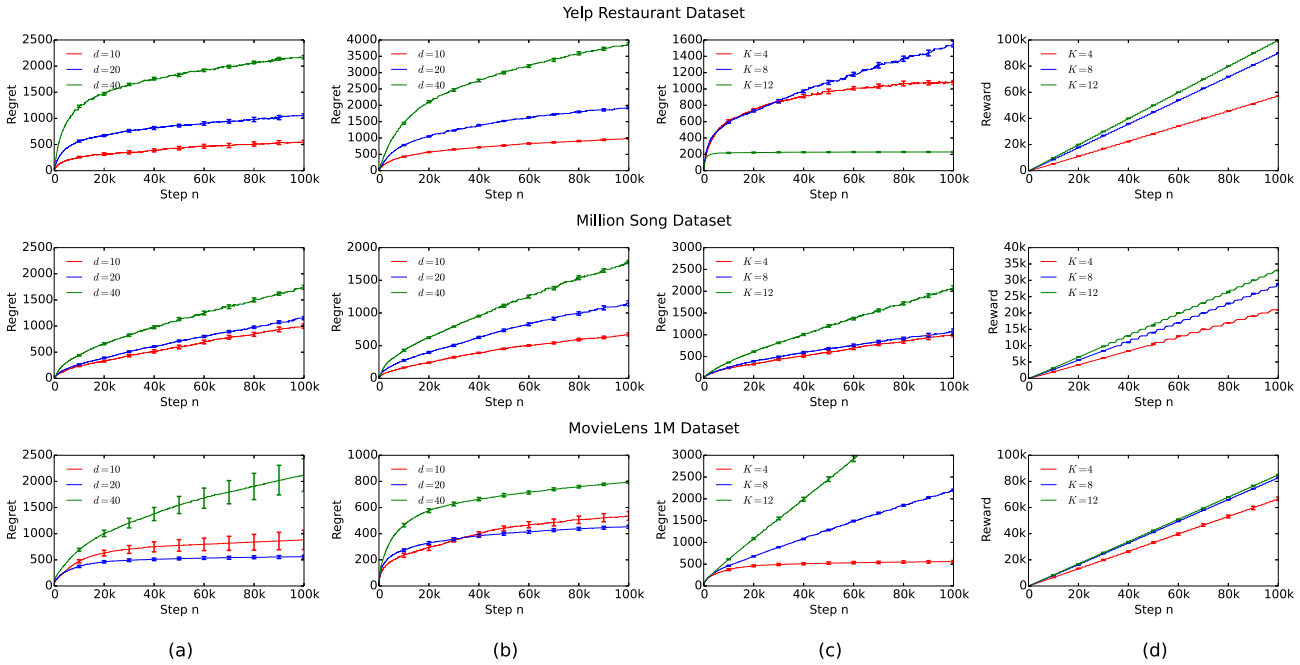

Figure 2: **a**. The n-step regret of `CascadeLinTS` for varying number of features d. **b**. The n-step regret of `CascadeLinTS` in a subset of each dataset for varying number of features d. **c**. The n-step regret of `CascadeLinTS` for varying number of recommended items K. **d**. The n-step reward of `CascadeLinTS` for varying number of recommended items K.

user was attracted by the song at some point in time.

4.5.1 Results

The results of our first experiment are reported in Fig. 1. Similarly to Section 4.4, we observe that when the ground set is small, $L = 16$, the regret of all compared methods is similar. As the size of the ground set increases, the gap between `CascadeUCB1` and the rest of the methods increases, and the regret of `CascadeUCB1` is orders of magnitude larger than that of `CascadeLinTS`. The regret of `CascadeLinTS` is similar to that of `RankedLinTS` for all settings of L.

We report the regret of `CascadeLinTS` for various numbers of features d, on the whole dataset and its subset of *Rock Songs*, in Fig. 2a and 2b, respectively. Similarly to Section 4.4, we observe that `CascadeLinTS` performs well for all settings of d. The lowest regret in both experiments is achieved at $d = 10$.

In the last experiment (Fig. 2c), we observe that the regret of `CascadeLinTS` increases with the number of recommended items K. As in Section 4.4, we observe that the cumulative reward of our learned policies increases with K. Therefore, the increase in the regret must be due to the fact that the expected reward of the optimal solution, $f(A^*, \bar{w})$, increases faster with K than that of the learned policies. This is due to the mismatch between our model and real-world data.

4.6 Movie Recommendation

MovieLens datasets[4] contain the ratings of users for movies from the MovieLens website. The datasets come in different sizes and we choose MovieLens 1M for our experiments. This dataset contains 1M anonymous ratings of 4k movies by 6k users who joined MovieLens in 2000.

We build the model of users from their historical ratings. The ratings are on a 5-star scale and we assume the user is attracted by a movie if the user rates it with more than 3 stars. Thus, the feedback matrix is defined as $W_{i,j} = \mathbb{1}\{\text{user } i \text{ rates movie } j \text{ with more than 3 stars}\}$. Our goal is to maximize the probability of recommending at least one attractive movie.

4.6.1 Results

The results of our first experiment are reported in Fig. 1. Similarly to Section 4.4, we observe that the regret of all compared methods is similar when the ground set is small, L = 16. The gap between `CascadeUCB1` and the rest of the methods increases when the size of the ground set increases. In particular, the regret of `CascadeUCB1` is orders of magnitude larger than that of `CascadeLinTS`. The regret of `CascadeLinTS` is always lower than that of `RankedLinTS` for all settings of L.

We report the regret of `CascadeLinTS` for various num-

[4] http://grouplens.org/datasets/movielens/

bers of features d, on the whole dataset and its subset of *Adventures*, in Fig. 2a and 2b, respectively. Similarly to Sections 4.4 and 4.5, we observe that `CascadeLinTS` performs well for all settings of d. The lowest regret in both experiments is achieved at $d = 20$.

In the last experiment (Fig. 2c), we observe that the regret of `CascadeLinTS` increases with the number of recommended items K. As in Sections 4.4 and 4.5, the cumulative reward of our learned policies increases with K. Therefore, the increase in the regret must be due to the fact that the expected reward of the optimal solution, $f(A^*, \bar{w})$, increases faster with K than that of the learned policies.

5 RELATED WORK

Our work is closely related to *cascading bandits* [15, 8], which are learning variants of the cascade model of user behavior [10]. The key difference is that we assume that the attraction weights of items are a linear function of known feature vectors, which are associated with each item; and an unknown parameter vector, which is learned. This leads to very efficient learning algorithms whose regret is sublinear in the number of items L. We compare `CascadeLinTS` to `CascadeUCB1`, one of the proposed algorithms by Kveton *et al.* [15], in Section 4.

Ranked bandits [20] are a popular approach in learning to rank. The key idea in ranked bandits is to model each position in the recommended list as an independent bandit problem, which is then solved by a *base bandit algorithm*. The solutions in ranked bandits are $(1 - 1/e)$ approximate and their regret grows linearly with the number of recommended items K. On the other hand, ranked bandits do not assume that items attract the user independently. Slivkins *et al.* [22] proposed contextual ranked bandits. We compare `CascadeLinTS` to contextual ranked bandits with linear generalization in Section 4.

Our learning problem is a partial monitoring problem where we do not observe the attraction weights of all recommended items. Bartok *et al.* [5] studied general partial monitoring problems. The algorithm of Bartok *et al.* [5] scales at least linearly with the number of actions, which is $\binom{L}{K}$ in our setting. Therefore, the algorithm is impractical for large L and moderate K. Agrawal *et al.* [2] studied a variant of partial monitoring where the reward is observed. The algorithm of Agrawal *et al.* [2] cannot be applied to our problem because the algorithm assumes a finite parameter set. Lin *et al.* [19] and Kveton *et al.* [17] studied combinatorial partial monitoring. Our feedback model is similar to that of Kveton *et al.* [17]. Therefore, we believe that our algorithm and analysis can be relatively easily generalized to combinatorial action sets.

Our learning problem is combinatorial as we learn K most attractive items out of L candidate items. In this sense, our work is related to stochastic combinatorial bandits, which are frequently studied with a linear reward function and semi-bandit feedback [11, 6, 16, 18, 24, 9]. Our work differs from these approaches in both the reward function and feedback. Our reward function is a non-linear function of unknown parameters. Our feedback model is less than semi-bandit, because the learning agent does not observe the attraction weights of all recommended items.

6 CONCLUSIONS

In this work, we propose linear cascading bandits, a framework for learning to recommend in the cascade model at scale. The key assumption in linear cascading bandits is that the attraction probabilities of items are a linear function of the features of items, which are known; and an unknown parameter vector, which is unknown and we learn it. We design two algorithms for solving our problem, `CascadeLinTS` and `CascadeLinUCB`. We bound the regret of `CascadeLinUCB` and suggest that a similar regret bound can be proved for `CascadeLinTS`. We comprehensively evaluate `CascadeLinTS` on a range of recommendation problems and compare it to several baselines. We report orders of magnitude improvements over learning algorithms that do not leverage the structure of our problem, the features of items. We observe empirically that `CascadeLinTS` performs very well.

We leave open several questions of interest. For instance, we only bound the regret of `CascadeLinUCB`. Based on the existing work [24], we believe that a similar regret bound can be proved for `CascadeLinTS`. Moreover, note that our analysis of `CascadeLinUCB` is under the assumption that items attract the user independently and that the linear generalization is perfect. Both of these assumptions tend to be violated in practice. Our current analysis cannot explain this behavior and we leave it for future work.

The main limitation of the cascade model [10] is that the user clicks on at most one item. This assumption is often violated in practice. Recently, Katariya *et al.* [13] proposed a generalization of cascading bandits to multiple clicks, by proposing a learning variant of the dependent click model [12]. We strongly believe that our results can be generalized to this setting and leave this for future work.
