Preface

The Conference on Uncertainty in Artificial Intelligence (UAI) is the premier international conference on research related to representation, inference, learning and decision making in the presence of uncertainty within the field of Artificial Intelligence. This volume contains all papers that were accepted for the 32nd UAI Conference, held in Jersey City, New Jersey, USA, from June 25 to 29, 2016. Papers appearing in this volume were subjected to a rigorous review process. 275 papers were submitted to the conference and each was peer-reviewed by 3 or more reviewers with the supervision of one Senior Program Committee member. A total of 85 papers were accepted, 26 for oral presentation and 59 for poster presentation, for an acceptance rate of 31%. We are very grateful to the program committee and senior program committee members for their diligent efforts. We are confident that the proceedings, like past UAI conference proceedings, will become an important archival reference for the field.

We are pleased to announce that the Microsoft Best Paper Award is awarded to Leonard Schulman and Piyush Srivastava for their paper, "Stability of Causal Inference". The Adobe Best Student Paper Award is awarded to Jan Leike (co-authored with Tor Lattimore, Laurent Orseau, and Marcus Hutter) for their paper, "Thompson Sampling is Asymptotically Optimal in General Environments".

In addition to the presentation of technical papers, we are very pleased to have four distinguished invited speakers at UAI 2016: Steven Low (Caltech), Andrew McCallum (University of Massachusetts Amherst), Steffen L. Lauritzen (University of Copenhagen) and, as Banquet Speaker, Farhan Feroz (Cambridge University). The UAI 2016 tutorials program, chaired by Jan Lemeire, consists of four tutorials: "Discrete Sampling and Integration in High Dimensional Spaces" by Supratik Chakraborty, Kuldeep S. Meel, and Moshe Y. Vardi, "Parallel and High-performance Computing for Speeding up Machine Learning Algorithms" by Anshul Gupta, "Integrative Logic-Based Causal Discovery" by Sofia Triantafillou and Ioannis Tsamardinos, and "Reasoning Under Uncertainty with Subjective Logic" by Audun Jøsang.

UAI 2016 also hosts three workshops, coordinated by workshops chair Melanie Zeilinger: "Causation: Foundation to Application" (Frederick Eberhardt, Ricardo Silva, Joris Mooij, Marloes Maathuis, Elias Bareinboim), "Bayesian Modeling Applications Workshop" (Rommel Carvalho, Kathryn Laskey), and "Machine Learning for Health" (Ke Yuan, Olivier Elemento, Edoardo Airoldi, Florian Markowetz).

Alexander Ihler and Dominik Janzing (Program Co-Chairs)
Marina Meila and Tom Heskes (General Co-Chairs)

Organizing Committee

General Chairs

Marina Meila, University of Washington, USA
Tom Heskes, Radboud University, Netherlands

Program Chairs

Alexander Ihler, University of California Irvine, USA
Dominik Janzing, Max Planck Institute for Intelligent Systems, Germany

Tutorials Chair

Jan Lemeire, Vrije Universiteit, Brussels

Workshops Chair

Melanie Zeilinger, ETH Zurich, Switzerland

Local Arrangements Chair

Changhe Yuan, City University of New York, USA

Acknowledgments

The success of a conference such as UAI depends greatly on the efforts of many individuals who volunteer their time to provide expert and detailed reviews of submitted papers. In particular, the Program Committee and Senior Program Committee for UAI 2016 were responsible for generating reviews and recommendations for the 275 submissions to the conference. Each submitted paper was reviewed by at least 3 members of the Program Committee. The Senior Program Committee then assessed the individual reviews for each paper, moderated discussion among Program Committee members if needed, and generated meta-reviews and recommendations for the program chairs. We are extremely grateful for the efforts of all of the individuals listed below.

Abstract

Stackelberg games are two-stage games in which the first player (called the leader) commits to a strategy, after which the other player (the follower) selects a best-response. These types of games have seen numerous practical application in security settings, where the leader (in this case, a defender) must allocate resources to protect various targets. Real world applications include the scheduling of US federal air marshals to international flights, and resource allocation at LAX airport. However, the best known algorithm for solving *general* Stackelberg games requires solving Integer Programs, and fails to scale beyond a few (significantly smaller than 100) number of leader actions, or follower types. In this paper, we present a new gradient-based approach for solving large Stackelberg games in security settings. Large-scale control problems are often solved by restricting the controller to a rich parameterized class of policies; the optimal control can then be computed using Monte Carlo gradient methods. We demonstrate that the same approach can be taken in a *strategic* setting. We evaluate our approach empirically, demonstrating that it can have negligible regret against the leader's true equilibrium strategy, while scaling to large games.

1 INTRODUCTION

Stackelberg games have received significant attention in the context of security applications, where a defender (the leader in the Stackelberg game) must deploy a limited number of security resources to protect a set of vulnerable targets to guard against an attacker (the follower in the Stackelberg game). Algorithms for these games have been deployed in real-world settings, e.g., to generate checkpoints and patrols at the Los Angeles International Airport [Pita et al., 2009], as well as to schedule US Federal Air Marshals (FAMS) to flights [Jain et al., 2010b, Tsai et al., 2009].

The best known solver for general Bayesian Stackelberg games is the DOBBS algorithm [Paruchuri et al., 2008], which was the first to formulate a Stackelberg game (given in normal form) as a Mixed Integer Linear Program (MILP). Since then, a great deal of research has been devoted to algorithms that scale to games of the size encountered in real settings. This has led to the development of a general class of Stackelberg Security Games (SSGs) [Korzhyk et al., 2011], which captures many of the key features of these real settings, along with algorithms including ORIGAMI, ERASER, ERASER-C [Kiekintveld et al., 2009], and ASPEN [Jain et al., 2010a], which can handle a large number of defender actions. With the exception of ASPEN, these algorithms work by assuming additional structure on the SSG, specifically on the pure strategy set of the defender. Similarly, the HBGS algorithm [Jain et al., 2011] scales to multiple attacker types by assuming hierarchical structure on the attacker types. Hence, these algorithms are able to solve MILPs more compact than would be generated from a game expressed in normal form.[1]

Among approximate methods, Monte-Carlo approaches have been used to solve games with infinite types [Kiekintveld et al., 2011], but also makes assumptions on what defender pure strategies are feasible. The HUNTER algorithm [Yin and Tambe, 2012], in contrast, can solve Stackelberg games with limited additional assumptions, but searches a game tree whose depth scales with the number of attacker types, and whose branching factor is the number of available targets. Approximate methods have also been utilized in recent work [Yang et al., 2012, 2013] considering attackers with bounded rationality, including attackers which behave according to the Quantal Response (QR) model [McKelvey and Palfrey, 1995]. This modeling assumption is made with limited loss of generality, as the degree of attacker rationally is specified by a parame-

[1] ORIGAMI makes the most restrictive assumptions on the game, and does not need to solve an MILP at all.

ter of the model. As we will see shortly, the algorithms in the present work can be seen as a refinement of the BRQR algorithm of Yang et al. [2013].

We introduce a different approach for finding good defender strategies in Stackelberg security games, which avoids imposing structure on the defender's *pure strategies*, the attackers' types, or the players' utilities. Instead, we propose restricting the search for defender strategies within a rich, but parameterized, class of mixed strategies. In a standard Stackelberg equilibrium the defender (who is the leader), plays an (unrestricted) mixed strategy, knowing that the attacker will select a best-response. In contrast, we will consider games where the defender's choice of mixed strategy must come from some fixed class of distributions.

This type of assumption is analogous to successful methods in AI and reinforcement learning such as policy gradient methods [Baxter and Bartlett, 2001], which avoid making assumptions about the dynamics of the environment, but rather, constrain the search for a good policy to within a parameterized family of policies. In this work, we will demonstrate how a similar approach can be applied to a *strategic* setting. We then apply Monte-Carlo gradient methods, a procedure we call STACKGRAD, to find solutions to the defender's optimization problem. In contrast to an ordinary optimal control problem, a unique feature of our derivation is that this gradient computation must pass through the attacker's response function. In order to maintain differentiability, we consider a smoothed version of the attacker's response function. We therefore consider an attacker in the QR model. While our primary motivation for this assumption is analytic, we reap the additional capability of modeling boundedly rational attackers.

Figure 1 provides a schematic of our approach. We begin with a Stackelberg game, consisting of the defender's set of mixed strategies, Δ, the attacker's response function g, and the defender's utility for playing $\mathcal{D} \in \Delta$, denoted $U(\mathcal{D}, g(\mathcal{D}))$. We then formulate an approximate Stackelberg game by restricting $\mathcal{D} \in \Delta(\Theta) \subset \Delta$ and smoothing $g \Rightarrow \tilde{g}$, where Θ denotes the parameterization of the defender strategy space. Finally, we solve for the defender's best strategy in the restricted game via gradient ascent.

Yang et al. [2013] propose finding approximate Stackelberg equilibria against QR attackers by finding local minima of the defender's expected utility function (over the unrestricted class of defender mixed strategies $\mathcal{D}$). This algorithm, called BRQR, relies on a black-box call to a procedure for finding such local minima. We can view our approach as an instantiation of BRQR where the restriction to defender strategies $\Delta(\Theta)$ bears fruit in two ways. First, we can explicitly find these local minima using gradient descent. In contrast, previous work relies on using black-box non-convex function optimization toolboxes. Secondly, we can scale to games with large pure strategy spaces in a principled manner, by designing $\Delta(\Theta)$ to have a compact parameterization.

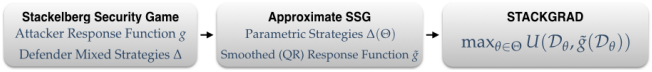

Figure 1: STACKGRAD optimizes the approximate game given considering a parametric class of leader (defender) strategies and by smoothing the follower's (attacker's) response function.

While any parameterized class of defender mixed strategies may be utilized, we propose two rich classes which yield heuristics with no computational dependence on the number of attacker types, and only mild dependencies on the size of the defender's pure strategy set. We then demonstrate empirically that STACKGRAD not only scales to large games, but also finds mixed strategies that are close to the defender's true Stackelberg optimal strategy.

Our primary contributions are in the derivation of a new algorithm for solving Stackelberg games approximately and in its empirical evaluation. Specifically, we define STACKGRAD, by deriving an approximate stochastic gradient of the defender's utility with respect to its strategy parameters through the (smoothed) best response function of the attacker. We argue analytically that STACKGRAD has no computational dependence on the number of attacker types in a Bayesian Stackelberg game, being able to handle any number (even infinite types). We then demonstrate empirically that, despite searching within a restricted class of mixed strategies, the solutions found by STACKGRAD have almost the same payoff to the defender as the true (unrestricted) Stackelberg optimum, computed directly using a solver for the unrestricted game. We also demonstrate the STACKGRAD has only a mild computational dependence on the number of pure strategies, by considering a game inspired by the Federal Air Marshal (FAMS) domain.

2 PRELIMINARIES

2.1 GENERAL SECURITY GAMES

We consider the *Stackelberg security game* introduced by Kiekintveld et al. [2009] (see Korzhyk et al. [2011] for a good overview).

An SSG is a two-player game between a defender and attacker. The attacker selects a target from a set $\mathcal{T} = \{t_1, \ldots, t_N\}$. The defender prevents attacks by guarding targets with various resources $\mathcal{R} = \{r_1, \ldots, r_K\}$. In the most general setting considered in previous work, resources may simultaneously cover a set of targets. For example, resources might be air marshals, and targets might be airline flights [Tsai et al., 2009]. An air marshal might protect a number of targets by flying a circuit which starts

and ends at the marshal's home city; each flight along the circuit is considered covered. This is modeled by having the defender assign resources to *schedules*, where a schedule $S \subset \mathcal{T}$ is just a subset of the possible targets. Assigning a resource r_k to schedule S corresponds to covering each $t \in S$ with resource r_k. The set of schedules to which a resource r_k may be assigned is denoted by $\mathcal{S}_k$. $\mathcal{S}_k$ specifies the constraints induced by the domain. For example, in the air marshal SSG, $\mathcal{S}_k$ comprises sets of flights that can form a circuit that starts and ends in the marshal's home city.

A defender's pure strategy is an assignment of resources to schedules, which we denote by $\mathbf{s} \in \mathcal{S} \triangleq \mathcal{S}_1 \times \cdots \times \mathcal{S}_K$. Strategy component $\mathbf{s}_k$ is the schedule to which resource r_k is assigned. Strategy $\mathbf{s}$ induces a coverage vector $\mathbf{c} \in \{0,1\}^N$ (sometimes denoted $\mathbf{c}(\mathbf{s})$ when we wish to emphasize the dependence on $\mathbf{s}$) indicating which targets are covered: $\mathbf{c}_n = 1$ if $t_n \in \mathbf{s}_k$ for some k. An attacker's pure strategy is simply a target $t_n \in \mathcal{T}$.

Our methods also allow for non-binary coverage. That is, we can take $\mathbf{c}(\mathbf{s})$ to be an arbitrary function from $\mathcal{S}$ to $[0,1]^K$ representing the assignment of varying resource quantities to achieve degrees of target coverage. However, to simplify our expressions, and to stay consistent with previous work, we assume binary $\mathbf{c}_n$ unless otherwise noted.

If the defender plays a mixed strategy—a distribution $\mathcal{D}$ over pure strategies—we use $\bar{\mathbf{c}} \in [0,1]^d$ to denote the probability that each target is covered. In other words, $\bar{\mathbf{c}}(\mathcal{D}) = \mathbb{E}_{\mathbf{s}\sim\mathcal{D}}[\mathbf{c}(\mathbf{s})]$.

The players' utilities are functions of which target is attacked, and whether that target is covered (by any resource). Attacker and defender utilities are denoted $U_a : \{0,1\} \times \mathcal{T} \to \mathbb{R}$ and $U_d : \{0,1\} \times \mathcal{T} \to \mathbb{R}$ respectively. $U_a(0, t_n)$, for example, specifies the utility to the attacker if t_n is attacked and uncovered. The expected payoffs for playing defender mixed strategy $\mathcal{D}$ and attacker pure strategy t_n are given by:

$$\mathbf{U}_a(\mathcal{D}, t_n) = \bar{\mathbf{c}}(\mathcal{D})U_a(1, t_n) + (1 - \bar{\mathbf{c}}(\mathcal{D}))U_a(0, t_n)$$
$$\mathbf{U}_d(\mathcal{D}, t_n) = \bar{\mathbf{c}}(\mathcal{D})U_d(1, t_n) + (1 - \bar{\mathbf{c}}(\mathcal{D}))U_d(0, t_n)$$

In a security game, it is assumed that for all n, $M_{a,n} \triangleq U_a(0, t_n) - U_a(1, t_n) \geq 0$ and $M_{d,n} \triangleq U_d(1, t_n) - U_a(0, t_n) \geq 0$. The attacker never prefers that its target is covered. Similarly, the defender never prefers that the attacker's target is uncovered.

2.2 STACKELBERG EQUILIBRIA

The solution concept typically applied to security games is that of a *Stackelberg Equilibrium*, as opposed to the more conventional *Nash Equilibrium*. In a two-player Stackelberg game, one player—termed *leader*—first commits to a strategy. The other player—termed *follower*—observes this commitment, and plays a best response to the leader's chosen strategy. In security games, the defender is the leader and the attacker follows. This leader-follower interaction is argued to be better suited than simultaneous moves for modeling security domains, since after the defender deploys its resources, that deployment is subject to scrutiny by a malicious agent, who can use this information when deciding on its point of attack.

Due to the two-stage nature of the game, it is convenient to think of the follower as selecting a *response function* which maps each of the leader's mixed strategies to a pure strategy. With Δ the set of defender mixed strategies, we denote a response function by $g : \Delta \to \mathcal{T}$. Upon observing leader mixed strategy $\mathcal{D}$, the follower plays pure strategy $g(\mathcal{D})$.

We say that $(\mathcal{D}, g)$ forms a *Strong Stackelberg Equilibrium* (SSE) if, informally: (1) given response function g, the leader maximizes its payoff by playing $\mathcal{D}$, (2) g is not just a response function, but always returns a follower *best* response, and (3) if there are multiple follower best-response functions, g selects the one most beneficial to the leader.

Condition (3) is what distinguishes a *Strong* Stackelberg Equilibrium from an ordinary Stackelberg Equilibrium. It can be argued that this is a reasonable solution concept if one believes that the leader can always force the attacker to break ties in its favor. For our purposes, it will be necessary only to observe that the payoff to the leader in a SSE is the most that a leader can hope to guarantee against a rational follower. Below we state the definition of an SSE formally in the context of a security game.

Definition 1 (Follower Best-Response)**.** *A follower response function $g : \Delta \to \mathcal{T}$ is a* best-response *function if for any other response function $g' : \Delta \to \mathcal{T}$ and leader strategy $\mathcal{D} \in \Delta$, $\mathbf{U}_a(\mathcal{D}, g(\mathcal{D})) \geq \mathbf{U}_a(\mathcal{D}, g'(\mathcal{D}))$.*

Definition 2 (Strong Stackelberg Equilibrium)**.** *$(\mathcal{D}, g)$ where $\mathcal{D} \in \Delta$ and $g : \Delta \to \mathcal{T}$ is a* Strong Stackelberg Equilibrium *iff:*

1. *For all $\mathcal{D}' \in \Delta$, $\mathbf{U}_d(\mathcal{D}, g(\mathcal{D})) \geq \mathbf{U}_d(\mathcal{D}', g(\mathcal{D}'))$*
2. *g is a best-response function.*
3. *For any $\mathcal{D}' \in \Delta$ and best-response function g', $\mathbf{U}_d(\mathcal{D}', g(\mathcal{D}')) \geq \mathbf{U}_d(\mathcal{D}', g'(\mathcal{D}'))$*

The definition of a SSE ensures that, although there may be multiple such equilibria, they all give the same payoff to the defender. Given an instance of a security game $\mathcal{G}$, let $V_{\mathcal{G}}$ denote the payoff to the defender in equilibrium.

2.3 BAYESIAN STACKELBERG GAMES

An extension of the game described in the previous section allows the defender to model uncertainty over the potential attackers by a prior q over a set of attacker *types* Λ. Letting

g_λ denote the best response of attacker λ, the defender's utility in the Bayesian setting is given by:

$$\mathbf{U}_d(\mathcal{D}, \{g_\lambda\}) = \sum_{\lambda \in \Lambda} q(\lambda) \mathbf{U}_d(\mathcal{D}, g_\lambda(\mathcal{D})). \quad (1)$$

As with a single attacker, if g_λ breaks ties in a consistent manner we can uniquely define $V_\mathcal{G}$ in the Bayesian setting. Given an arbitrary defender strategy $\mathcal{D}$, we define the competitive ratio of the defender's choice of strategy against the SSE solution. We assume that $\mathbf{U}_d(\mathcal{D}, \{g_\lambda\}) \geq 0$, and $V_\mathcal{G} > 0$.

Definition 3 (Competitive Ratio)**.** *Given an instance of a Bayesian Stackelberg game $\mathcal{G}$, and defender strategy $\mathcal{D}$, define* $\mathrm{R}(\mathcal{D}) = \mathbf{U}_d(\mathcal{D}, \{g_\lambda\})/V_\mathcal{G}$.

The defender would like to maximize equation (1), or short of doing so, find a strategy $\mathcal{D}$ which attains a large competitive ratio. In this work, we propose using gradient methods to search for such strategies. However, in order to do so $\mathbf{U}_d$ will have to be differentiable with respect to its argument. In the next section, we describe the approximations needed to ensure this.

3 GAME APPROXIMATION

We now consider an approximation to general Bayesian Stackelberg games. We (1) assume a probabilistic model for the attacker, and (2) restrict the set of strategies available to the defender.

Recall that the *softmax* function $\sigma_\eta : \mathbb{R}^N \times \{1, \ldots, N\} \to [0, 1]$ provides a probabilistic approximation to the maximum element of the set. Given a vector $\mathbf{x} \in \mathbb{R}^N$, we let $\sigma_\eta(\mathbf{x}, i) = \frac{\exp(\eta \mathbf{x}_i)}{\sum_{i=1}^N \exp(\eta \mathbf{x}_i)}$. The categorical distribution over the set $\{1, \ldots, N\}$, which selects element i with probability $\sigma_\eta(\mathbf{x}, i)$ is called the *softmax distribution*. As the inverse temperature $\eta \to \infty$, softmax concentrates mass on the indices belonging to the maximum elements of $\mathbf{x}$.

The first step to approximating the security game of Section 2 is to have the attacker select its target according to the softmax distribution over its utilities, often times called a *quantal response* attacker [Yang et al., 2012]. Let $\mathbf{U}_\lambda$ denote the utility function corresponding to attacker type λ. Let us also define

$$\mathbf{u}_\lambda(\mathcal{D}) = [\mathbf{U}_\lambda(\mathcal{D}, t_1), \ldots, \mathbf{U}_\lambda(\mathcal{D}, t_N)],$$

the vector of expected payoffs to the attacker for each choice of target, assuming the defender plays mixed strategy $\mathcal{D}$. In the security game approximation, we assume that conditioned on the defender's choice of $\mathcal{D}$, and a fixed choice of η (a parameter of the approximation), the attacker selects target t_n with probability $\sigma_\eta(\mathbf{u}_\lambda(\mathcal{D}), n)$.

Second, we restrict the defender to select distributions from a parameterized class $\Delta_\Theta \subset \Delta$, where Θ denotes a set of parameters, and for each $\theta \in \Theta$, there is a corresponding distribution $\mathcal{D}_\theta \in \Delta_\Theta$. We denote the probability mass function (over $\mathcal{S}$) of $\mathcal{D}_\theta$ by $p(\cdot \mid \theta)$.

Putting these approximations together gives us a stochastic optimization problem from the perspective of the defender (summarized in the model below). First nature draws attacker type λ according to q. Given λ, η, and $\theta \in \Theta$, an attacker's (now random) response t_n is determined by a draw from the categorical distribution defined by $\sigma_\eta(\mathbf{u}_\lambda(\mathcal{D}_\theta), \cdot)$, rather than an exact best-response function g_λ. Upon independently drawing $\mathbf{s} \sim \mathcal{D}_\theta$, the defender receives $U_d(\mathbf{c}_n(\mathbf{s}), t_n)$.

Security Game Approximation

Defender selects $\theta \in \Theta$.
Nature draws $\lambda \sim q$
$n \sim \sigma_\eta(\mathbf{u}_\lambda(\mathcal{D}_\theta), \cdot)$, $\mathbf{s} \sim \mathcal{D}_\theta$
Defender receives payoff $U_d(\mathbf{c}_n(\mathbf{s}), t_n)$.

The goal of the defender in the security game approximation is to maximize its expected payoff, which is given by the following function:

$$\tilde{\mathbf{U}}_d(\theta) = \mathbf{E}\left[U_d(\mathbf{c}_n(\mathbf{s}), t_n)\right], \quad (2)$$

The expectation here is taken according to the process just described.

If we take Δ_Θ identical to Δ and $\eta \to \infty$, then the logic of the model is that of a leader-follower game, and the defender strategy θ^* that maximizes $\tilde{\mathbf{U}}_d(\theta)$ is precisely its strategy in a Stackelberg equilibrium. However, maximizing $\tilde{\mathbf{U}}_d$ may not be tractable for larger games. If, on the other hand, Δ_Θ is restrictive ($\Delta_\Theta \neq \Delta$), the strategy $\mathcal{D}_{\theta^*}$ might suffer regret against an attacker best-response function g, but the parametric class may allow $\mathbf{U}_d$ to be efficiently maximized. Balancing these two effects is important. In the next section, we describe how given a fixed parametric class Θ, $\tilde{\mathbf{U}}_d$ can be maximized using gradient methods.

4 MONTE-CARLO GRADIENT ESTIMATE: STACKGRAD

If $\Theta \subset \mathbb{R}^d$ for some d, then gradient algorithms are natural candidates for maximizing Equation 2. However, to compute $\nabla \tilde{\mathbf{U}}_d(\theta)$ even at a single point θ, it might be necessary to sum over all of Λ, and the entire support of $\mathcal{D}_\theta$, which even for a parametric class of distributions might include all elements of $\mathcal{S}$. A more tractable approach is to take a Monte-Carlo estimate of $\nabla \tilde{\mathbf{U}}_d(\theta)$, which need not depend on the size of $\mathcal{S}$, and has *no* dependence on $|\Lambda|$.

The first step to producing such an estimate is to derive for any θ, an unbiased estimate $\tilde{\gamma}_\theta$ of $\nabla \tilde{\mathbf{U}}_d(\theta)$. Recall that given the defender's choice of parameter θ, the probability

of schedule $\mathbf{s} \in \mathcal{S}$ is given by $p(\mathbf{s} \mid \theta)$. Let us denote the probability that the defender selects pure strategy $\mathbf{s}$, and an attacker of type λ selects target t_n by $p(\mathbf{s}, t_n \mid \theta, \lambda)$.

Thus, with probability $q(\lambda)p(\mathbf{s}, t_n \mid \theta, \lambda)$, the defender receives $U_d(\mathbf{s}, t_n)$, and so the gradient is

$$\nabla \tilde{\mathbf{U}}_d(\theta) = \sum_{\lambda \in \Lambda} \sum_{\mathbf{s} \in \mathcal{S}, t_n \in \mathcal{T}} q(\lambda) U_d(\mathbf{c}_n(\mathbf{s}), t_n) \nabla p(\mathbf{s}, t_n \mid \theta, \lambda)$$

$$= \sum_{\lambda \in \Lambda} \sum_{\mathbf{s} \in \mathcal{S}, t_n \in \mathcal{T}} \frac{p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)} q(\lambda) U_d(\mathbf{c}_n(\mathbf{s}), t_n) \nabla p(\mathbf{s}, t_n \mid \theta, \lambda)$$

$$= \mathbb{E}\left[U_d(\mathbf{c}_n(\mathbf{s}), t_n) \frac{\nabla p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)} \right]. \quad (3)$$

We can estimate $\nabla \tilde{\mathbf{U}}_d(\theta)$ by drawing m random samples according to the model. The gradient estimate for sample i is given by

$$\tilde{\gamma}_\theta^{(i)} = U_d(\mathbf{c}_n(\mathbf{s}^{(i)}), t_n^{(i)}) \frac{\nabla p(\mathbf{s}^{(i)}, t_n^{(i)} \mid \theta, \lambda^{(i)})}{p(\mathbf{s}^{(i)}, t_n^{(i)} \mid \theta, \lambda^{(i)})},$$

and the overall gradient estimate by $\frac{1}{m} \sum_{i=1}^m \tilde{\gamma}_\theta^{(i)}$. This presumes that given realizations λ, $\mathbf{s}$ and t_n, the ratio $\frac{\nabla p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)}$ can be efficiently computed. We examine classes Θ where this holds in the following sections.

For gradient methods to converge in expectation any unbiased estimate of $\nabla \tilde{\mathbf{U}}_d$ suffices (even taking $m = 1$), although lower variance estimates perform better in practice. Furthermore, $\frac{\nabla p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)}$ depends on the realization $\lambda^{(i)}$, and not the entire set Λ. Thus, the computation required to estimate $\nabla \tilde{\mathbf{U}}_d$ is independent of $|\Lambda|$, and we expect such methods to scale to any number of attacker types (even infinitely many).

For completeness, we state the algorithm STACKGRAD, which is a projected stochastic gradient ascent, utilizing Monte-Carlo gradient estimates. Let $P_\Theta(x) = \min_{\theta \in \Theta} \|x - \theta\|_2$ denote the Euclidean projection of x onto Θ. We use the shorthand $\lambda, \mathbf{s}, t \sim M(\theta)$ to denote random variables sampled according to the stochastic approximation given defender parameter θ.

Algorithm STACKGRAD

Inputs: Class Θ, Horizon T, Sampling Parameter m
Initialize θ_0.
for $\tau = 1, \ldots, T$ **do**
  Sample $\lambda^{(i)}, \mathbf{s}^{(i)}, t_n^{(i)} \sim M(\theta_\tau)$ for $i = 1, \ldots, m$.
  Let $\tilde{\gamma}_\tau = \frac{1}{m} \sum_{i=1}^m U_d(\mathbf{c}_n(\mathbf{s}^{(i)}), t_n^{(i)}) \frac{\nabla p(\mathbf{s}^{(i)}, t_n^{(i)} \mid \theta_{\tau-1}, \lambda^{(i)})}{p(\mathbf{s}^{(i)}, t_n^{(i)} \mid \theta_{\tau-1}, \lambda^{(i)})}$
  $\theta_\tau = P_\Theta(\theta_{\tau-1} + \frac{1}{\sqrt{\tau}} \tilde{\gamma}_\tau)$
end for
return θ_T

Standard results (e.g. Boyd et al. [2003]) tell us that after T iterations, the expected value of $\tilde{\mathbf{U}}_d(\theta_T)$ will be within $O(\frac{1}{\sqrt{T}})$ of a local maximum of the function $\tilde{\mathbf{U}}_d$. Therefore, if the quality of the defender strategy found by STACKGRAD, $R(\mathcal{D}_{\theta_T})$, is poor, it must either be because: (1) good mixed strategies for the *true* game exist only in $\Delta \setminus \Delta_\Theta$ (i.e. $\max_{\theta \in \Theta} V_{\mathcal{G}} - \tilde{\mathbf{U}}_d(\theta) \gg 0$), or (2) good defender strategies exist in Δ_Θ, but STACKGRAD converged to a suboptimal local maximum.

In what follows, we will see that in empirical validations, STACKGRAD exhibits good behavior on standard security games. This leads us to two questions, which we leave open for future theoretical research. (1) Are there classes of Stackelberg games, and parameterized strategies Θ, where the best strategy for the approximate game is guaranteed to be a good strategy for the true game? (2) Are there classes of Stackelberg games where STACKGRAD is guaranteed to exhibit good convergence properties?

5 INDEPENDENT RESOURCE ALLOCATION : CATEGORICAL DISTRIBUTIONS

In this section we demonstrate how to compute the ratio $\frac{\nabla p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)}$ for a natural defender strategy class. We will then demonstrate how this parameterized class can be used to search for defender strategies in games with a large, even infinite number, of adversary types.

One simple, but rich class of defender strategies assumes that each defender resource is independently assigned to a schedule. For each resource k and schedule $s \in \mathcal{S}_k$, we assign resource k to s with some probability. This assignment is conducted independently across resources.

For each set of schedules $\mathcal{S}_k = \{s_{k,0}, \ldots, s_{k,d_k}\}$, we therefore introduce a parameter $\theta_{k,l}$ where for $l \geq 1$, $\theta_{k,l} \geq 0$ specifies the probability with which resource k is assigned to resource $s_{k,l}$. We require that $\sum_{l=1}^{d_k} \theta_{k,l} \leq 1$, and resource k is assigned to schedule $s_{k,0}$ with the remaining probability $\theta_{k,0} = 1 - \sum_{l=1}^{d_k} \theta_{k,l}$. Thus, this class of strategies is parameterized by $\Theta \subset \mathbb{R}^d$ where $d = \sum_{k=1}^K d_k$.

Notice that Δ_Θ is rich enough to describe any marginal distribution of an individual resource's assignment to schedules, including any pure strategy. However, Δ_Θ cannot capture mixed strategies which contain correlations between resource assignments.

In what follows, we derive $\frac{\nabla p(\mathbf{s}, t_n \mid \theta, \lambda)}{p(\mathbf{s}, t_n \mid \theta, \lambda)}$. We will need a helper lemma that characterizes the gradient of target coverage probabilities with respect to θ, the full proof of which is given in the supplemental material. In order to give the result, we will need some definitions. Given a joint assignment of resources to schedules $\mathbf{s}$, let $c_{-k,n}(\mathbf{s})$ indicate whether target n is covered by some resource other than resource k. In other words, $c_{-k,n}(\mathbf{s}) = \mathbf{1}[t_n \in \cup_{k' \neq k} \mathbf{s}_{k'}]$.

Also let $c_{k,l,n}$ indicate whether the lth schedule of resource k contains target t_n; $c_{k,l,n} = \mathbf{1}[t_n \in s_{k,l}]$.

Lemma 1. *For any target index n, resource index k, and schedule index $l \geq 1$,*

$$\frac{\partial}{\partial \theta_{k,l}} \bar{\mathbf{c}}_n(\mathcal{D}_\theta) = (c_{k,l,n} - c_{k,0,n})\, \mathbb{P}_{\mathbf{s}\sim\mathcal{D}_\theta}(c_{-k,n}(\mathbf{s}) = 0)$$

The ratio $\frac{\nabla p(\mathbf{s},t_n|\theta,\lambda)}{p(\mathbf{s},t_n|\theta,\lambda)}$ can be written in terms of the derivative in Lemma 1. Let $\mathbf{s} = [s_{1,l_1}, \ldots, s_{K,l_K}]$, so that the indices of the selected schedules are given by $l_1, \ldots, l_K$. Define $z(\mathbf{s}, k, l) \in \{-1, 0, 1\}$ by letting $z(\mathbf{s}, k, l) = \mathbf{1}[l_k = k] - \mathbf{1}[l_k = 0]$. In other words $z(\mathbf{s}, k, l)$ provides a sign of 1 if resource k is assigned to schedule l, a sign of -1 if it is assigned to schedule 0 and a sign of 0 otherwise.

Theorem 1. *For any target t_n, schedule assignment $\mathbf{s}$, as well as resource index k and schedule index $l \geq 1$, we have that:*

$$\frac{\frac{\partial}{\theta_{k,l}} p(\mathbf{s}, t_n \mid \theta)}{p(\mathbf{s}, t_n \mid \theta)} = \frac{z(\mathbf{s}, k, l)}{\theta_{k,l_k}} - \eta M_{a,n} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_n(\mathcal{D}_\theta) + \eta \sum_{n'=1}^{N} \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n') M_{a,n'} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_{n'}(\mathcal{D}_\theta)$$

Proof. Fix $\mathbf{s} = [s_{1,l_1}, ..., s_{K,l_K}]$. We have that $p(\mathbf{s} \mid \theta) = \prod_{k'=1}^{K} \theta_{k',l_{k'}}$. Now fix a resource index k and schedule index $l \geq 1$. We have that $\frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s} \mid \theta) = \prod_{k' \neq k} \theta_{k',l_{k'}}$ if $l_k = l$; $\frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s} \mid \theta) = -\prod_{k' \neq k} \theta_{k',l_{k'}}$ if $l_k = 0$; and $\frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s} \mid \theta) = 0$ otherwise. From the definition of z:

$$\frac{\frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s} \mid \theta)}{p(\mathbf{s} \mid \theta)} = \frac{z(\mathbf{s}, k, l)}{\theta_{k,l_k}} \tag{4}$$

Next fix a target index n, and note that $\frac{\partial}{\partial \theta_{k,l}} \exp(\eta \mathbf{u}_n(\mathcal{D}_\theta))) = \exp(\eta \mathbf{u}_n(\mathcal{D}_\theta)) \frac{\partial}{\partial \theta_{k,l}} \eta \mathbf{u}_n(\mathcal{D}_\theta) = -\eta \exp(\eta \mathbf{u}_n(\mathcal{D}_\theta)) M_{a,n} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_n(\mathcal{D}_\theta)$

This lets us differentiate $\sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n)$:

$$\begin{aligned}
\frac{\partial}{\partial \theta_{k,l}} \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n) &= \frac{\partial}{\partial \theta_{k,l}} \frac{\exp(\eta \mathbf{u}_n(\mathcal{D}_\theta)))}{\sum_{n'=1}^{N} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta)))} \\
&= \frac{1}{\sum_{n'=1}^{N} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta))} \frac{\partial}{\partial \theta_{k,l}} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta)) \\
&+ \exp(\eta \mathbf{u}_n(\mathcal{D}_\theta)) \frac{\partial}{\partial \theta_{k,l}} \frac{1}{\sum_{n'=1}^{N} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta))} \\
&= -\eta \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n) M_{a,n} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_n(\mathcal{D}_\theta) \\
&- \frac{\sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n)}{\sum_{n'=1}^{N} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta))} \frac{\partial}{\partial \theta_{k,l}} \sum_{n'=1}^{N} \exp(\eta \mathbf{u}_{n'}(\mathcal{D}_\theta)) \\
&= -\eta \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n) M_{a,n} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_n(\mathcal{D}_\theta) \\
&+ \eta \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n) \sum_{n'=1}^{N} \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n') M_{a,n'} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_{n'}(\mathcal{D}_\theta)
\end{aligned} \tag{5}$$

Using equations (4) and (5), we have:

$$\begin{aligned}
\frac{\frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s}, t_n \mid \theta)}{p(\mathbf{s}, t_n \mid \theta)} &= \frac{\sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n) \frac{\partial}{\partial \theta_{k,l}} p(\mathbf{s} \mid \theta)}{p(\mathbf{s} \mid \theta) \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n)} \\
&+ \frac{p(\mathbf{s} \mid \theta) \frac{\partial}{\partial \theta_{k,l}} \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n)}{p(\mathbf{s} \mid \theta) \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n)} \\
&= \frac{z(\mathbf{s}, k, l)}{\theta_{k,l_k}} - \eta M_{a,n} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_n(\mathcal{D}_\theta) \\
&+ \eta \sum_{n'=1}^{N} \sigma_\eta(\mathbf{u}(\mathcal{D}_\theta), n') M_{a,n'} \frac{\partial}{\partial \theta_{k,l}} \bar{c}_{n'}(\mathcal{D}_\theta)
\end{aligned}$$

□

6 EXPERIMENTS SCALING WITH ATTACKER TYPES

The derivation from the previous section allows us to implement the STACKGRAD algorithm for a particular class of defender mixed strategies, specifically those that assign resources to schedules independently. We call the resulting algorithm STACKGRAD-I (where I follows from the independence assumption).

We now demonstrate that STACKGRAD-I scales very well on games with a large numbers of attacker types. Specifically, we will see that for a fixed choice of parameters T and m, both the run-time and quality of the solution θ_T found by STACKGRAD-I are *constant* in the number of attacker types.

Experiments were conducted on the patrolling domain introduced by Paruchuri et al. [2007], (see Paruchuri et al. [2008]). The goal is to assign a single security resource (such as a UAV or robot) to a sequence of targets $[t_{i_1}, \ldots, t_{i_d}]$, called its patrol. Thus, for patrol length d, the set of defender pure strategies $\mathcal{S}$ consists of all length d permutations of the target set.

In the original game, the coverage induced by strategy $\mathbf{s} = [t_{n_1}, \ldots, t_{n_d}]$ is not binary, and depends on the location of a target t_n in $\mathbf{s}$. That is, there are parameters $p_1, \ldots, p_d$ where $\mathbf{c}_n(\mathbf{s}) = p_j$ if $n = n_j$ and $\mathbf{c}_n(\mathbf{s}) = 0$ if $n \neq \{n_1, \ldots, n_d\}$. Target t_n is covered with probability p_j if it appears jth in the patrol, otherwise it is not covered at all. x

We use this formulation, but note that for this (non-binary) coverage function Lemma 1 must re-derived. Using the categorical distribution, there is a single parameter θ_l for each permutation in $\mathcal{S}$, and it is not difficult to show that $\frac{\partial}{\partial \theta_l} \bar{\mathbf{c}}_n(\mathcal{D}_\theta) = \mathbf{c}_n(\mathbf{s}_l) - \mathbf{c}_n(\mathbf{s}_0)$. The result of Theorem 1 is unchanged. Secondly, we note that for this particular game, the categorical distribution completely characterizes the set of mixed defender strategies ($\Delta = \Delta_\Theta$). Thus,

for large enough inverse temperature in the softmax function ($\eta \to \infty$), maximizing $\tilde{U}_d(\theta)$ is equivalent to finding a Stackelberg equilibrium defender strategy.

Experiments where run on randomly generated instances of these games; $U_d(0, t_n)$, $M_{d,n}$, $U_\lambda(1, t_n)$ and $M_{\lambda,n}$ are chosen at random in $[0, 1]$. In all instances STACKGRAD-I is run with inverse temperature $\eta = 20$, and sampling parameter $m = 50$. Every data point is the average of 20 experiments. Experiments were run on a 2.5 GHz Intel Xeon E5-2680v3 processor, and Integer programs were solved using IBM CPLEX 12.4.

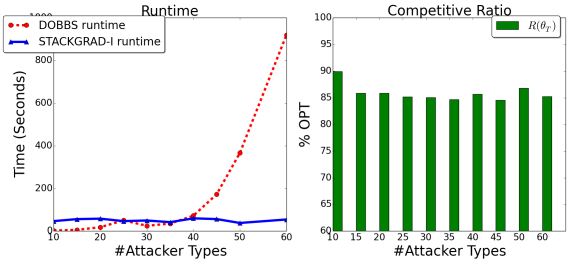

Figure 2: Patrol Game: STACKGRAD-I vs. DOBBS

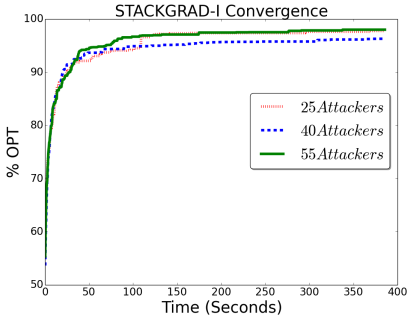

Figure 3: Competitive Ratio

In the left plot of Figure 2, we compare the running time of STACKGRAD-I and the DOBBS algorithm of Paruchuri et al. [2008], which is the fastest algorithm for general Stackelberg games, but must solve an integer program. Experiments were conducted on instances with 5 targets and patrol lengths of 2, for a total of 40 defender pure strategies. While the game is small enough to be tractable with a small number of defender pure strategies, as the number of attacker types is increased, the DOBBS algorithm begins to experience an exponential increase in its running time. In contrast, STACKGAD-I exhibits near constant average running time, with a range between 38 seconds and 59 seconds (against 55 attackers and 45 attackers respectively). Furthermore, as displayed on the right plot of Figure 2, scaling the game has no effect on the quality of the solution found by STACKGRAD-I. The competitive ratio of the solution θ^* found by STACKGRAD-I against the true optimum found by DOBBS ranges between 84.5% and 86.8%.

Of course both the running time and the quality of the solution found by STACKGRAD-I is a function of T, the number of iterations the gradient ascent is run. For the results in Figure 2, STACKGRAD-I was terminated after $T = 1000$ iterations.

In Figure 3, we show the results of running STACKGRAD-I for up to $T = 5000$ iterations, for $25, 40, 55$ attacker types. Here we see that the competitive ratio of the best solution found by STACKGRAD-I against the Stackelberg optimum quickly (displayed on the y axis) exceeds 90%. After 100 seconds (corresponding to about $T = 2500$), the average competitive ratio has reached above 94%.

STACKGRAD's constant running time, and performance, as the number of attackers is scaled up (but T is held constant), can be attributed to the fact that neither the parameterization nor the computation of the gradient depend on the size of Λ. Furthermore, the parameterization is complete, in the sense that all mixed strategies for the game are representable. The number of pure strategies, however, was kept small; with five targets and patrol of length two, there are a total of 20 defender pure strategies. In the next section, we demonstrate how STACKGRAD can be deployed to find solutions in games where the set of pure strategies is very large.

7 LARGE STRATEGY SETS

7.1 STRUCTURED PURE STRATEGIES

While the categorical distribution model of Section 5 demonstrates the power of gradient methods when the number of pure strategies are small, and the number of attacker types is large, most security games are concerned with settings in which there is a very large space of defender pure strategies. Recall that under the categorical model $\Theta \subset \mathbb{R}^d$, where $d = \sum_{k=1}^{K}(|\mathcal{S}_k| - 1)$. Thus, if $|\mathcal{S}_k|$ tends to be large, we would not expect STACKGRAD-I to perform very well. This is often the case in real security domains where the set of pure strategies exhibits a combinatorial explosion with the number of defender resources or potential targets.

In this Section, we introduce a new class of defender mixed strategies Θ which has a compact representation even as $|S_k|$ grows large. We consider a setting in which schedules can be iteratively constructed. In the FAMS domain, for example, an air marshal r_k is assigned a schedule consisting of a sequence of flights $\mathbf{s}_k = [t_{n_1}, \ldots, t_{n_L}]$ (which we take to be ordered). The length of the schedule is bounded (there is some upper bound $L \leq B$), and must land the marshal back to its origin airport. Although the set of feasible schedules for a marshal r_k can be exponentially large in B, it has a natural combinatorial structure. In particular, given a subsequence of flights $\mathbf{s}_{k,1:l} = [t_{n_1}, \ldots, t_{n_l}]$, $l < L$, the set of feasible "next flights" can be efficiently computed.

Specifically, the subsequence of flights specified by $\mathbf{s}_{k,1:l}$ lands the marshal at some airport A at some time τ. The viable choices for the $l+1$ flight are those flights leaving airport A after time τ, that can get the marshal back home in $B-l$ hops or fewer.[2]

More generally, we consider games where the schedules for some resource r_k is given by an ordered set of targets $\mathbf{s}_k$. We will further assume that given some subseqence $\mathbf{s}_{k,1:l}$, the set of feasible next targets $F(\mathbf{s}_{k,1:l})$ can be efficiently computed. Formally, t_n belongs to $F(\mathbf{s}_{k,1:l})$ if and only if there is some schedule $\mathbf{s}_k \in \mathcal{S}_k$, where $\mathbf{s}_k = [\mathbf{s}_{k,1:l}, t_n, \dots]$ ($\mathbf{s}_k$ begins with the prefix $\mathbf{s}_{k,1:l}$).

7.2 PARAMETRIC MODEL

Following the recipe outlined in Section 4, we introduce a new parametric model Θ for games that exhibit the sequential structure just described.

We will consider a simple logistic model. For each resource k we introduce a vector $\mathbf{w}_k$ of dimension N, where N is the number of targets. We denote the nth element of $\mathbf{w}_k$ by $\mathbf{w}_{k,n}$. A resource r_k is assigned to schedule $\mathbf{s}_k$ according to a sequential stochastic process. Given a subsequence of targets of length l, $\mathbf{s}_{k,1:l}$, the next target in resource r_k's schedule is selected with probability proportional to $\exp(\mathbf{w}_{k,n})$ when $t_n \in F(\mathbf{s}_{k,1:l})$ and with probability 0 otherwise. For $t_n \in F(\mathbf{s}_{k,1:l})$:

$$\mathbb{P}[\mathbf{s}_k(l+1) = t_n \mid \mathbf{s}_{k,1:l}] = \frac{\exp(\mathbf{w}_{k,n})}{\sum_{t_{n'} \in F(\mathbf{s}_{k,1:l})} \exp(\mathbf{w}_{k,n'})} \tag{6}$$

Thus, $\mathbf{w}_{k,n}$ indicates the propensity for target t_n to be covered whenever that target is available in the feasible set of next targets. As was the case with the model of Section 5, each resource will be independently assigned to a schedule. Therefore $\theta = \{\mathbf{w}_1, \dots, \mathbf{w}_K\}$, and $\Delta(\Theta)$ indicates the set of distributions over resource assignments where resources are independently assigned to schedules according to the aforementioned stochastic process. Notice that the dimension of θ is KN, where K is the number of resources and N is the number of targets. Therefore, the parameterization remains compact even if the size of $|\mathcal{S}|$ explodes.

We state $\frac{\nabla p(\mathbf{s}, t_n|\theta)}{p(\mathbf{s}, t_n|\theta)}$ for this new parametric class of strategies in the following Theorem. Due to space restrictions, the full proof is given in the supplemental material.

Theorem 2. *Let $t_{n_{k,l}}$ denote the lth target covered by the kth resource chosen by the defender. For any target t_{n^*} chosen by the attacker, schedule assignments $\mathbf{s}$ chosen by defender, and any parameter $\mathbf{w}_{k,n}$. $\frac{\partial}{\partial \mathbf{w}_{k,n}} p(\mathbf{s}, t_{n^*} \mid \theta)/p(\mathbf{s}, t_{n^*} \mid \theta)$ is given by the following equation:*

$$\sum_{l=1}^{L} \mathbf{1}[n = n_{k,l}] - \mathbb{P}[\mathbf{s}_k(l) = t_n \mid \mathbf{s}_{k,1:(l-1)}, \theta] - \eta \sum_{n'=1}^{N} \sigma_\eta(\mathbf{u}_\lambda(\mathcal{D}_\theta), n') M_{a,n'} \frac{\partial}{\partial \mathbf{w}_{k,n}} \bar{\mathbf{c}}_{n'}(\mathcal{D}_\theta) + \eta M_{a,n^*} \frac{\partial}{\partial \mathbf{w}_{k,n}} \bar{\mathbf{c}}_{n^*}(\mathcal{D}_\theta)$$

Unlike the categorical model of Section 5, the partial derivative of $\bar{\mathbf{c}}_n(\mathcal{D}_\theta)$ cannot be easily computed in closed form. Changing the value of parameter $\mathbf{w}_{k,n}$, might effect the coverage of targets $t_{n'} \neq t_n$. In the federal air marshal (FAMS) domain, $\mathbf{w}_{k,n}$ corresponds to the likelihood that marshal r_k takes flight t_n. Increasing $\mathbf{w}_{k,n}$, however, also changes the coverage probabilities of other flights; flights departing from the destination airport of t_n also become more likely, as the marshal needs to return home.

Therefore, instead of computing the derivative in closed form, we use numerical differentiation. Given a set of parameters $\theta = \{\mathbf{w}_1, \dots, \mathbf{w}_K\}$, let $\theta + \delta_{n,k}$ denote the set of parameters, where $\mathbf{w}_{k,n} = \mathbf{w}_{k,n} + \delta$, and all other parameters are unchanged. We estimate $\frac{\partial}{\partial \mathbf{w}_{k,n}} \bar{\mathbf{c}}_n(\theta)$ by sampling schedules $\mathbf{s}^{(i)}$ according to θ and schedules $\mathbf{s}^{(i)}_{n,k}$ according to $\theta + \delta^{(k)}_n$ for $i = 1, \dots, m$. We then estimate $\frac{\partial}{\partial \mathbf{w}_{k,n}} \bar{c}_n(\theta)$ using $\frac{1}{m} \sum_{i=1}^{m} \frac{\mathbf{c}_n(\mathbf{s}^{(i)}) - \mathbf{c}_n(\mathbf{s}^{(i)}_{k,n})}{\delta}$.

8 EXPERIMENTS: SCALING WITH LARGE STRATEGY SETS

The derivation of the gradient for the model in the previous section gives us another instantiation of STACKGRAD, which we call STACKGRAD-L (where L follows from the logistic model). We now demonstrate the scalability of STACKGRAD-L in domains with a large number of defender pure strategies.

Recall that the STACKGRAD-L was derived to have no dependency on $|\mathcal{S}_k|$, the number of schedules available for any resource k. We compare against the state-of-the-art ASPEN algorithm [Jain et al., 2010a]. We note that the ASPEN algorithm was designed to eliminate the combinatorial explosion in *joint* schedules. If all $|\mathcal{S}_k| = X$, then there are X^K possible joint schedules if the Stackelberg game were to be expressed in normal form. Nevertheless, ASPEN still has a computational dependency the size of an individual set of schedules $\mathcal{S}_k$. In particular, ASPEN uses a column generation technique, where selecting each new column requires solving a network flow problem with at least $\sum_k^K |\mathcal{S}_k|$ edges.

[2] This computation is via a modification of Djikstra's algorithm.

We conduct experiments on games inspired by the FAMS domain. We begin with a fixed weighted network G^*, representing actual air travel between the 500 US airports with the most traffic [Colizza et al., 2007]. Nodes represent airports and the weights in G^* represent how many tickets were available between two airports in a given year. Given a parameter N, we generate a game instance as follows. We create a new network G, where G is generated by sampling 30 airports from G^* where at least 5 of these airports are chosen to be "hub" airports. We then create N edges in G corresponding to flights, where a flight between aiports v_1 and v_2 is present in G with probability proportional the weight on (v_1, v_2) in G^*. The edges in G are meant to be representative of actual flights between 30 US airports on a given day. Each edge represents a flight, and therefore a target. In this game, we have only a single attacker type. In all our experiments there are 3 marshals, who can take a tour of length $L \leq 5$ before returning to their home city. The home city is selected uniformly from one of the hubs for each of the marshals. We allow any such tour on G. [3]

We conduct experiments for various values of $N \in \{500, 1000, 1500, 2000, 2500, 5000, 10000\}$. $\mathcal{S}_k$ for a single marshal k consists of all tours from a start vertex of length at most 5 in a network consisting of up to 10000 directed edges. Even simply enumerating $\mathcal{S}_k$ for our larger instances is impossible. However, running ASPEN requires $\{\mathcal{S}_k\}$ to be given as input. Therefore, in order to allow ASPEN to complete in a reasonable amount of time, we generate subsets $\hat{\mathcal{S}}_k \subset \mathcal{S}_k$ by randomly sampling $Y = 10,000$ tours for each marshal. As a result, the performance of STACKGRAD-L is not reported as a competitive ratio to the true Stackelberg optimum, since ASPEN is also solving a restricted game.

Nevertheless, we can compare the performance of STACKGRAD-L to that of ASPEN as the size of the game is increased. In Figure 4 we compare the runtime of ASPEN with STACKGRAD-L for various values of N. Once Y is fixed, the size of the pure strategy set of ASPEN is constant. ASPEN is unaware of any of the pure strategies outside the set $\hat{\mathcal{S}}_1 \times \hat{\mathcal{S}}_2 \times \hat{\mathcal{S}}_3$. Nevertheless ASPEN must still solve a mixed integer linear program where the number of constraints scale with N. The average runtime of STACKGRAD-L increases as N grows as well, as the parameterization of STACKGRAD-L is in $\mathbb{R}^N$, but remains bounded by that of ASPEN for large N.

In Figure 4 we also display the average performance of each algorithm. Performance is measured as the direct payoff to the defender in the unrestricted game, in contrast to the results in Section 6, where we computed competitive ratios directly. We see that for smaller number of targets ASPEN finds a higher quality solution than STACKGRAD-L on average. However, as N is increased the solution found by STACKGRAD-L overtakes. We suspect this is due to the fact that fixing Y in ASPEN eliminates pure strategies that might be necessary for the defender, while any pure strategy can be represented by STACKGRAD-L. For large N, $\hat{\mathcal{S}}_k$ is a very small subset of all the possible tours of length 5.

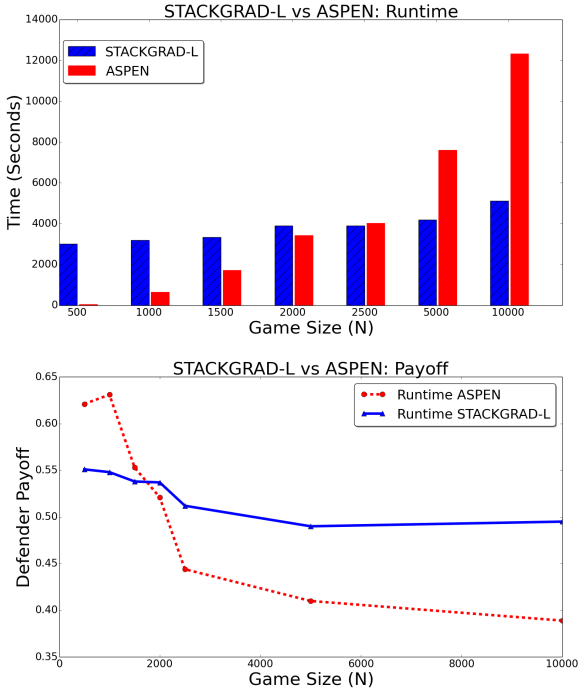

Figure 4: STACKGRAD-L vs ASPEN

9 CONCLUSIONS AND FUTURE WORK

We present a new algorithm, STACKGRAD, for solving Stackelberg security games, which works by performing a gradient ascent, rather than solving an integer program. We demonstrate a version of STACKGRAD with no computational dependence on the number of attacker types, and another version with a mild dependence on the number of defender pure strategies. Since the procedure restricts its search to within a parametric class of defender mixed strategies, and might find strategies bounded away from the true Stackelberg optimum, we also provide empirical evidence that the solutions found by STACKGRAD are of comparable quality to solutions in the unrestricted game. These empirical successes invite open questions for future research, chief among these being whether there are parametric classes of defender mixed strategies which are provably competitive with the true Stackelberg optimum.

[3] This permissiveness is somewhat artificial; in reality, a flight lands at its destination at a specified time, eliminating flights that leave sooner than that from consideration at the destination airport. This realism can be accounted for in the definition of F in the previous section. To keep the experiments simple, we allow any tour on G, and comment that this does not affect the scalability of STACKGRAD-L.

Abstract

Inferring the direction of causal dependence from observational data is a fundamental problem in many scientific fields. Significant progress has been made in inferring causal direction from data that are independent and identically distributed (i.i.d.), but little is understood about this problem in the more general relational setting with multiple types of interacting entities. This work examines the task of inferring the *causal direction of peer dependence* in relational data. We show that, in contrast to the i.i.d. setting, the direction of peer dependence can be inferred using simple procedures, regardless of the form of the underlying distribution, and we provide a theoretical characterization on the identifiability of direction. We then examine the conditions under which the presence of confounding can be detected. Finally, we demonstrate the efficacy of the proposed methods with synthetic experiments, and we provide an application on real-world data.[1]

1 INTRODUCTION

Inferring the direction of causal dependence between two random variables from observational data is a fundamental problem in statistical reasoning. There have been many advances in this area for data sets that are independent and identically distributed (i.i.d.) [Janzing et al., 2012, Stegle et al., 2010, Lopez-Paz et al., 2015]. For relational data, recent work has studied the problem of inferring the effects of peers via *experimentation* [Muchnik et al., 2013, Bakshy et al., 2012, Toulis and Kao, 2013]. However, the problem of identifying causal direction from *observational* relational data has yet to receive the same focus. In this work, we study the problem of inferring the causal direction of peer dependence from observational relational data. We provide theoretical and experimental results to show that the causal direction of peer dependence can be robustly inferred from observational data by comparing the magnitude of two similarity measures (one for each candidate direction).

For example, consider a study on the causes of personal debt. Data consist of the net worth and the average monthly discretionary spending of a large set of individuals, along with the position of each individual within a social network. One reasonable question is whether a person's friends influence his or her spending habits. If a person's spending and wealth are correlated with the wealth and spending of their friends, what can be inferred about the *causal* dependence among these quantities? A person's spending could be caused by their friends' wealth or vice versa (direct dependence), or both quantities could be caused by an unobserved variable (confounding).

This paper examines when and how it is possible to differentiate among these scenarios. Specifically, we:

1. Identify a set of conditions under which the causal direction of relational dependence can be consistently inferred.
2. Investigate the effect of unobserved confounding on this approach to causal inference, and provide a simple test of relational confounding.
3. Provide an extension of our method to the case of non-linear dependence via kernel embeddings.
4. Show that the proposed measures are robust to both the magnitude of the noise and the functional form of the true dependence, through a set of simulations under a variety of graph structures and functional forms.

The rest of the paper is structured as follows. Section 2 describes the problem setting. Section 3 presents a test of causal direction under deterministic linear dependence.

[1] A full version of this paper including supplementary material can be found at `http://kdl.cs.umass.edu/papers/arbour-et-al-uai2016.pdf`

Section 4 considers a relaxation of the assumptions by allowing for latent confounding and discusses the conditions under which latent confounding can be identified. Section 5 generalizes these results to the case where the similarity is measured by embedding the data in a reproducing kernel Hilbert space (RKHS). Section 6 presents experimental evaluation of these results using synthetic data and a variety of marginal and conditional distributions, as well as networks generated from the Erdős-Rényi, Watts-Strogatz, and Barabási-Albert models. Section 7 presents a demonstration of our method on Stack Overflow, a large online community where users ask and answer computer science related questions.

2 PROBLEM SETTING

Relational domains consist of multiple types of entities that interact with each other through multiple types of relationships. Consider, for example, the domain of academic publishing: authors write papers, papers cite other papers and so on. In this work, for clarity of exposition and without loss of generality, we focus on *networks*, a specific type of relational domains with a single type of entity (e.g., people) and a single type of relationship (e.g., friendship)[2].

An instantiation of a network consists of a set of people and a set of friendships among these people. This can be represented with an undirected graph $G = \langle V, E \rangle$ with n vertices. Nodes correspond to people and an edge denotes friendship between the nodes it connects. Every node of the graph $v_i \in V$ is associated with a pair of random variables, X_i and Y_i. These correspond to attributes of a person, for example wealth and spending habits. For every node, we can define a new random variable as a function of the random variables of its neighboring nodes. Specifically, in this section, we define a new random variable ${X_i}'$ as the sum of X_j over v_i's neighbors:

$$ {X_i}' = \sum_{\{v_j | \langle v_i, v_j \rangle \in E\}} X_j $$

Similarly,

$$ {Y_i}' = \sum_{\{v_j | \langle v_i, v_j \rangle \in E\}} Y_j. $$

For the remainder of the paper, we refer to functions of random variables of neighboring nodes, such as ${X_i}'$ and ${Y_i}'$, as *relational variables* and to random variables of the node, such as X_i and Y_i, as propositional variables. To avoid ambiguity, we refer to dependence between a relational variable and a propositional variable as *relational dependence*.

A very common assumption in relational domains is that of *templating*, i.e., random variables in different nodes follow the same distribution [Koller, 1999]. In our case, this would imply that the distribution of X_i is the same for all i (and the same for Y_i, ${X_i}'$, and ${Y_i}'$). This allows us to reason about four random variables on a model level: X, Y, X', and Y'. The task under consideration is determining the causal direction of relational dependence. Put in another way, we wish to determine whether $X' \to Y$ or $Y' \to X$ is the true generative process.

Since we are reasoning over random variables across all nodes of the network, it is convenient to represent them as vectors. Let $\mathbf{x} = \langle X_1, \ldots, X_n \rangle$ be a vector with the random variables X_i for every node and, similarly, $\mathbf{x}' = \langle {X_1}', \ldots, {X_n}' \rangle$. Let A denote the adjacency matrix of the graph defined as:

$$ A_{ij} = \begin{cases} 1, & \text{if } (v_i, v_j) \in E. \\ 0, & \text{otherwise.} \end{cases} $$

We note that A is a symmetric matrix since G is an undirected graph. We can write the vector of the sum of the friends (i.e., the vector $\mathbf{x}'$) as $\mathbf{x}' = A\mathbf{x}$. Similarly, $\mathbf{y}' = A\mathbf{y}$.

We use D to denote the degree matrix of the graph:

$$ D_{ij} = \begin{cases} d_i, & \text{if } i = j. \\ 0, & \text{otherwise.} \end{cases} $$

2.1 UNDERLYING ASSUMPTIONS

Throughout the paper, we make the following assumptions:

A1. *G is an undirected graph.*

A2. *Each node $v \in V$ has degree of at least 1.*

A3. *The distribution of X_i and Y_i is the same for all $v_i \in V$ (templating).*

A4. *There are no feedback cycles, i.e. $Y \to X \Rightarrow X \not\to Y$ for any two (relational or propositional) variables.*

Further, we initially assume (and later relax that assumption) that:

A5. *There are no confounding variables, i.e., unobserved variables that are common causes of the observed attributes.*

Section 4 is devoted to examining under which conditions this assumption can be loosened, while maintaining the ability to identify causal direction. Moreover, assumptions A4 and A5 mirror those found in the literature on determining causal direction between two propositional variables [Stegle et al., 2010, Janzing et al., 2012, Lopez-Paz et al., 2015].

[2]The extension to the more general multi-entity/multi-relationship case is straightforward. We provide the necessary details for this extension in the supplement.

3 DIRECTION UNDER LINEAR DEPENDENCE

In this section we show that, under the assumptions of linearity and a small amount of noise, peer dependence is asymmetric and the true causal direction can be consistently inferred. This is an inherent property of relational domains. The extension to non-linear dependencies is provided in Section 5.

To measure dependence between variables, we consider the square of Pearson's correlation, a common and widely employed measure of linear correlation between variables. Pearson's correlation between two variables X and Y can be computed from a sample $\mathbf{x}$, $\mathbf{y}$ as follows:

$$\rho(\mathbf{x},\mathbf{y}) = \frac{\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i-\bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i-\bar{y})^2}},$$

where $\bar{x}$ and $\bar{y}$ are the means of $\mathbf{x}$ and $\mathbf{y}$ respectively. We consider the square of the correlation to restrict the range of the metric to [0,1], rather than [-1,1].

Given a measure of dependence, a reasonable question is whether the measure is symmetric for relational data. Surprisingly, it is not. Given this, another reasonable question is what can be inferred by examining the dependence values in both directions. Surprisingly, the causal direction of dependence can be inferred from the resulting asymmetry.

We begin by handling a simplified case: Y is a deterministic function of the X values of related nodes. Specifically, we assume that Y_i is the scaled mean of the X_j variables of the related instances:

$$Y_i = \frac{\beta}{d_i}\sum_{i=1}^{d_i} X_j$$

Or, in matrix notation: $\mathbf{y} = \beta D^{-1}A\mathbf{x}$.

Under certain assumptions about the structure of the graph and the form of the dependence, the squared correlation in the causal direction will be greater that the squared correlation in the opposite direction.

Proposition 1. *Assume that G is a d-regular graph[3], the true generative process is $\mathbf{y} = \beta D^{-1}A\mathbf{x}$ for some constant β, and assumptions A1-A5 hold. Then, $\rho^2(\mathbf{x}',\mathbf{y}) > \rho^2(\mathbf{y}',\mathbf{x})$.*

Proof. The left-hand-side of the inequality, given that by definition $\mathbf{x}' = A\mathbf{x}$, can be written as:

$$\begin{aligned}\rho^2(\mathbf{x}',\mathbf{y}) &= \rho^2(A\mathbf{x}, \beta D^{-1}A\mathbf{x}) \\ &= \rho^2(A\mathbf{x}, \frac{\beta}{d}A\mathbf{x}) = 1\end{aligned}$$

[3]A graph is d-regular if every vertex has degree d.

It remains to show that $1 > \rho^2(\mathbf{y}',\mathbf{x})$ which holds, unless $\rho^2(\mathbf{y}',\mathbf{x}) = 1$. Equality holds only when $\mathbf{y}' = \beta AD^{-1}A\mathbf{x}$ is a linear combination of $\mathbf{x}$, or in words, when the values of a node's friends of friends are a linear combination of that node's value. For random values of X, that happens for a degenerate network structure where every node has one friend of a friend and is the exact same starting node. This would happen, for example, in the case of a regular graph with degree 1 (pairs of nodes). □

In the case where Y is a noisy function of X, a similar inequality holds.

Proposition 2. *Assume that the true generative process is $\mathbf{y} = \beta D^{-1}A\mathbf{x} + \epsilon$ for some constant β, where ϵ is a vector with the noise terms. Moreover, assume that assumptions A1-A5 hold and X and Y are scaled to mean 0. Then the following holds:*

$$\rho^2(\mathbf{x}',\mathbf{y}) > \rho^2(\mathbf{y}',\mathbf{x}) \Leftrightarrow$$
$$\frac{Var(AD^{-1}A\mathbf{x}) + Var(A\epsilon)}{Var(D^{-1}A\mathbf{x}) + Var(\epsilon)} > \frac{Var(A\mathbf{x})}{Var(\mathbf{x})}.$$

A full derivation can be found in the supplement. The implication of proposition 2 is that the causal direction can be accurately inferred, as long as the relative influence of the noise distribution is small in comparison to the relationship between $AD^{-1}\mathbf{x}$ and $\mathbf{y}$. As we show during our experimental evaluation in Section 6, the method is quite robust to the effect of noise in practice.

4 REASONING ABOUT CONFOUNDING

Throughout Section 2 we assumed the absence of confounding influences (assumption A5). However, in many real-world settings, this proves to be an unrealistic assumption. Within the relational setting, there are two distinct ways in which the relationship between variables can be confounded:

1. $\mathbf{x}$ and $\mathbf{y}$ may share a common relational cause, $A\mathbf{z}$, i.e., $A\mathbf{z} \rightarrow \mathbf{x}$ and $A\mathbf{z} \rightarrow \mathbf{y}$.
2. There is a variable $\mathbf{z}$ that is a non-relational cause of $\mathbf{x}$ and a relational cause of $\mathbf{y}$, i.e., $\mathbf{z} \rightarrow \mathbf{x}$ and $A\mathbf{z} \rightarrow \mathbf{y}$.

In what follows, we show that the first scenario is identifiable from data, while the second one is not.

Proposition 3. *If $Cov(A\mathbf{x}, A\mathbf{y}) \geq Cov(A\mathbf{x}, \mathbf{y})$ and $Cov(A\mathbf{x}, A\mathbf{y}) \geq Cov(A\mathbf{x}, \mathbf{y})$, then there exists a relational variable which is a common cause of x and y.*

The proof is deferred to the supplement. Proposition 3 implies a very simple procedure for ruling out the presence of mutual relational confounding between two variables.

First, the relative dependence is measured between $A\mathbf{x}, \mathbf{y}$ and $A\mathbf{y}, \mathbf{x}$ respectively. Then, these two values are compared against the measured dependence between $A\mathbf{y}, A\mathbf{x}$. If neither are larger than the between-relational variable dependence no determination of direction is made, since observed dependence is likely due to confounding.

We now turn to scenario two, which yields the following negative result:

Corollary 1. *Under confounding scenario 2, in the absence of noise, a false conclusion of dependence $A\mathbf{x} \to \mathbf{y}$ will be made.*

Proof. Assume the generative structure is given by:

$$\mathbf{x} \sim \mathbf{z}$$
$$\mathbf{y} \sim D^{-1}A\mathbf{z}$$

It can be immediately seen that the form of this dependence is identical to the form of proposition 1, where we substituted $\mathbf{z}$ for the $\mathbf{x}$. It follows that, in the no-noise setting, an incorrect determination of direct causation will be made. □

Note that this also applies in the case of a small amount of noise, as implied by proposition 2. This result shows that without the assumption of no-confounding a determination of non-causation can be reliably implied, but the converse is not necessarily true.

5 AN EXTENSION TO NON-LINEAR DEPENDENCE

In the previous section, we showcased the applicability of our method for detecting linear dependence in relational data using correlation. An extension to more complex variables and non-linear dependence functions can be achieved by applying the kernel trick.

Some background on kernel embeddings is useful. Let $\mathcal{X}$ be a non-empty set, $(\mathcal{X}, \mathcal{A})$ be a measurable space where $\mathcal{A}$ is a σ-algebra on $\mathcal{X}$, and let $\mathscr{P}$ be the set of all probability measures, P, on $\mathcal{X}$. $\mathcal{H}$ is the RKHS of the functions $f : \mathcal{X} \to \mathbb{R}$ with the reproducing kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. The *mean map* is a function $\mu : \mathscr{P} \to \mathcal{H}$ that defines a kernel embedding of a distribution into $\mathcal{H}$:

$$\mu_P = \mu(P) = \int_{\mathcal{X}} k(x, \cdot) dP(x)$$

If a characteristic kernel is used, then this mapping is unique, i.e., there is an injective function between a distribution and its kernel mean value. In this work, the purpose of kernel mean is twofold. For propositional variables, it is used to represent the underlying distribution and, as we shall see, can be used directly in a test for dependence. For relational variables, the mean embedding serves as an aggregation function for observations. The advantage of using the kernel mean embedding is that, under the assumption that the underlying distribution belongs to the exponential family, the underlying distributions are represented completely.

To reason over the distance between distributions, we define a second kernel, K, over the kernel means. Christmann and Steinwart [2010] showed that if the kernel inducing μ (k) is characteristic and K is the Gaussian kernel, then K is universal and thus, characteristic. This kernel is defined as:

$$K(\mu_x, \mu'_x) = e^{\frac{\|\mu_x - \mu'_x\|^2_{\mathcal{F}}}{2\theta}} \tag{1}$$

where $\sqrt{\theta}$ is the bandwidth of the kernel.

In addition to this measure of similarity between relational instances, we define a dependence measure. The centered *kernel target alignment* (KTA) is a normalized measure of dependence introduced by Cortes et al. [2012] within the context of multiple kernel learning. The measure is defined as:

$$\text{KTA}(\mathbf{x}, \mathbf{y}) = \frac{\langle K^c_{\mathbf{x}}, K^c_{\mathbf{y}} \rangle_{\mathcal{F}}}{\|K^c_{\mathbf{x}}\|_{\mathcal{F}} \|K^c_{\mathbf{y}}\|_{\mathcal{F}}} \tag{2}$$

Where $\|\cdot\|_{\mathcal{F}}$ is the Frobenius norm, $\langle K^c_{\mathbf{x}}, K^c_{\mathbf{y}} \rangle_{\mathcal{F}}$ is the Frobenius norm of the inner product between $K^c_{\mathbf{x}}$ and $K^c_{\mathbf{y}}$ which is calculated by taking the trace of the inner product. $K^c_{\mathbf{x}}$ is a centered kernel matrix, defined as:

$$K^c_{\mathbf{x}} = \left[\mathbf{I} - \frac{1}{m}\mathbf{1}\mathbf{1}^T\right] K_{\mathbf{x}} \left[\mathbf{I} - \frac{1}{m}\mathbf{1}\mathbf{1}^T\right]$$

where $\mathbf{I}$ is the identity matrix and $\mathbf{1}$ is a column vector of ones with length m. If a linear kernel is used, KTA reduces to squared Pearson's correlation, which has been our measure of focus thus far. Using this connection, the following corollary provides for consistent estimation of causal direction under the deterministic case with arbitrary functional dependence.

Corollary 2. *Under assumptions A1, A2, A3, A4, A5, and further assuming that the generative structure is given by $\mathbf{y} = D^{-1}A\phi(\mathbf{x})\beta$, then KTA$(A\mathbf{x}, \mathbf{y}) \geq$ KTA$(A\mathbf{y}, \mathbf{x})$.*

This follows as a straightforward extension of proposition 1. Because we are given by assumption that $KTA(A\mathbf{x}, \mathbf{y}) = 1$ and KTA is bounded from above by one, the inequality holds. Equality occurs only when the values of each node's friends of friends can be expressed as a sum of (feature-space embedded) values. For random values of X, this is reduced to the degenerate case of a graph of degree 1, as in proposition 1.

In practice, we note that the KTA based comparison relies on a number of hyper-parameters. The difficulty in

choosing these parameters can result in poorer empirical performance. This problem has also been observed for other kernel-based approaches for causal inference [Zhang et al., 2011]. We leave the investigation of hyper-parameter selection as future work.

6 EXPERIMENTS

Our theoretical results focus on regular graphs, linear dependence, and absence of noise. In this section, we examine the effect that the network structure, the functional form of the dependence, and the presence of noise have on the efficacy of the linear and kernel based methods. [4]

6.1 REGULAR NETWORKS

We first considered regular graphs with linear dependence—a setting that matches our theoretical analysis—and we examined the effect of noise. We considered networks with the total number of nodes ranging from 100 to 500 and varied the degree between 2 and 22 by increments of 5. For every graph structure, we generated data as follows:

$$\begin{aligned}\mathbf{x} &\sim \mathcal{N}(0,1)\\ \epsilon &\sim \mathcal{N}(0,1)\\ \mathbf{y} &\sim D^{-1}A\mathbf{x} + \beta\epsilon\end{aligned}$$

where β is the coefficient of the noise and was varied between 0 and 2.

Figure 1 shows the relationship between $D^{-1}A\mathbf{x}$ and $\mathbf{y}$ for varying values of β. In the noiseless case (Figure 1a), $D^{-1}A\mathbf{x}$ and $\mathbf{y}$ are perfectly linearly correlated, as expected from the generating process. However, as the noise increases, the correlation between $D^{-1}A\mathbf{x}$ and $\mathbf{y}$ decays very quickly, approaching an adversarial case by the time the noise coefficient is $\beta = 1.0$.

We then measured dependence in each direction ($\mathbf{x}$ and $A\mathbf{y}$, $\mathbf{y}$ and $A\mathbf{x}$). The direction that produced the higher value for dependence was recorded as the inferred causal direction. To measure dependence, we used (i) the square of Pearson's correlation, and (ii) KTA using RBF kernels with a fixed bandwidth of 1.0 for all kernel calculations. Figure 2c shows the accuracy of both methods for a graph with 500 nodes and degree 7, while varying β. As expected from the our earlier theoretical results, both methods perform perfectly in the noise-less case, and continue to do so through $\beta = 0.5$. The linear method is significantly more robust to noise, remaining nearly perfect until $\beta = 1.0$.

We also examined the interplay between the graph structure (degree and number of nodes) and and the performance of each method. Figure 2a shows the performance for the case of a 500-node graph with noise coefficient of 1.0 with the degree varied between 2 and 22. Both methods become systematically worse as the degree (and thus the density of the network) increases. This is expected behaviour since an increase in the degree results in a lower *effective sample size* [Jensen and Neville, 2002], which will reduce the expected efficacy of both methods. The converse of this effect can be seen in Figure 2b, where the accuracy of the linear based approach improves significantly as the size of the network increases while the degree is kept constant (and thus the density of the network decreases).

6.2 NON-REGULAR NETWORKS

We next compared the performance of both methods to a departure from the assumption of network regularity. We considered the three most common generative models of graphs. The Erdős-Rényi model creates networks where two nodes are connected with a given probability. Throughout the experiments, we considered a fixed connection probability equal to 0.2. The Watts-Strogatz model generates "small-world networks". It begins with a lattice with a given neighborhood size and randomly rewires edges according to a fixed probability. For our experiments, we used neighborhood size 5 and rewiring probability equal to 0.2. The final generative model we considered was the Barabási-Albert model. This model generates graphs that display preferential attachment. For our experiments the power of preferential attachment was set to 1.0. For each network we considered sizes between 100 and 1000, by increments of 100, with 20 graphs being drawn for each size.

We then considered the following data generation scenarios for all graph types:

$$\begin{aligned}\mathbf{x} &\sim \mathcal{N}(0,1)\\ \epsilon &\sim \mathcal{N}(0,1)\\ \mathbf{y} &\sim f(D^{-1}A\mathbf{x}) + \beta\epsilon\end{aligned}$$

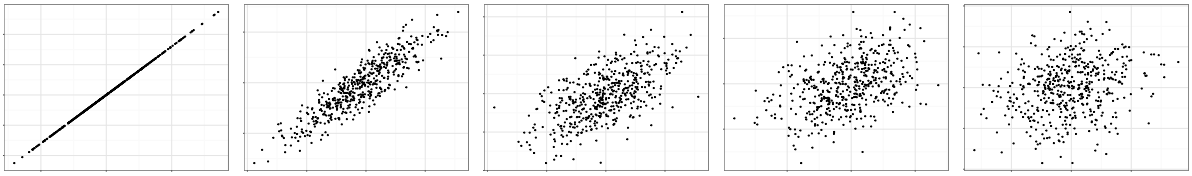
where $f(\cdot)$ is a function of $D^{-1}A\mathbf{x}$. We considered three functional forms:

- $f(\cdot)$ is a simple linear function (linear)
- $f(D^{-1}A\mathbf{x}) = \tan(D^{-1}A\mathbf{x})$ (nonlinear)
- $f(D^{-1}A\mathbf{x}) = \left(D^{-1}A\mathbf{x}\right)^4$ (quad)

For each setting, β was varied between 0 and 2 by increments of 0.25.

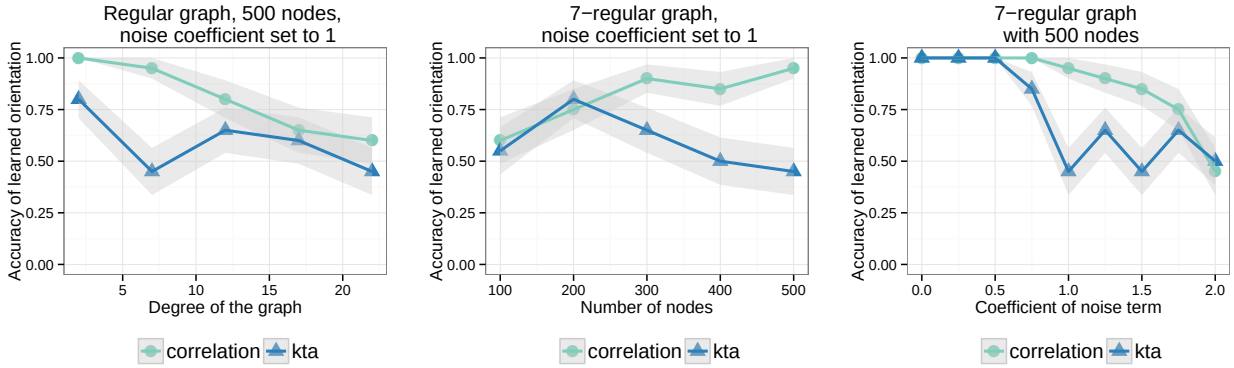
The performance of both the linear and KTA method for fixed network size of 1000 nodes with the magnitude of noise varied is shown in Figure 4. For the Barabási model under linear dependence, both the linear and kernel methods appear to be very robust up until a noise coefficient of

[4] Code is available at `https://github.com/darbour/RelationalCausalDirection.git`.



(a) $c_\epsilon = 0$ (b) $c_\epsilon = 0.25$ (c) $c_\epsilon = 0.5$ (d) $c_\epsilon = 1$ (e) $c_\epsilon = 2$

Figure 1: Scatterplots for the sum of X values of related nodes (x-axis) vs. the sum of X values of related nodes with additive Gaussian noise (y-axis). The noise coefficient (c_ϵ) varies from 0 to 2. The underlying network structure is a regular network of degree 10 with 500 nodes.



(a) (b) (c)

Figure 2: Orientation accuracy for regular graphs for varying degree (2a), size of network (2b), and noise coefficient (2c).

2.0. The KTA based method generally outperforms the linear dependence method for non-linear dependencies. This is to be expected, as Pearson's correlation is a measure of linear dependence.

The performance in the case where β is held to 0.5 and the size of the network is varied from 100 to 1000 can be seen in Figure 3. Here we can see that in both the Barabási-Albert and Watts-Strogatz graph models, Pearson's correlation and KTA achieve better performance under linear dependence as the size of the network increases. However, for in the case of the Erdős-Rényi models both methods perform poorly consistently as the size of the network increases. This is due to the nature of the graph-generation process. Both the Barabási-Albert and Watts-Strogatz models become increasingly sparse as the size of the network is increased. However, in the case of Erdős-Rényi, the probability connection is constant. As a result, the effective sample size remains low when the number of nodes increases. This likely accounts for the poor performance of the linear estimator. The opposite effect is seen in the case of the Barabási-Albert model. In nearly all cases the performance of the estimators is highest in the case of the Barabási-Albert networks.

6.3 A COMPARISON TO RELATIONAL BIVARIATE EDGE ORIENTATION

We also compared our results to the relational bivariate edge orientation (RBO) [Maier et al., 2013], the only other known method for testing causal direction in relational data. Maier et al. [2013] introduced the relational bivariate edge orientation (RBO) as an edge-orientation procedure within the context of learning causal models of relational domains. RBO is defined with respect to conditional independence properties of relational models. Specifically, rephrasing the definition of Maier et al. [2013] for single-entity/single-relationship networks, for a relational dependence between Y' and X, RBO checks if Y' is in the separating set of X and X'. If not, then Y' is effectively a "relational" collider and is oriented as such: $Y' \leftarrow X$. Otherwise, the only alternative model is $Y' \rightarrow X$, given that dependencies that induce feedback cycles (such as $X \rightarrow X'$) are excluded by assumption. The correctness of RBO is defined with respect to a conditional dependence oracle. In practice, Maier et al. [2013] follow the following procedure to infer causal direction between two relational variables:

1. Learn a linear model $\mathbf{x} \sim D^{-1}A\mathbf{x} + D^{-1}A\mathbf{y}$ to determine if $\mathbf{x} \perp\!\!\!\perp D^{-1}A\mathbf{x} \mid D^{-1}A\mathbf{y}$
2. If $\mathbf{x} \not\perp\!\!\!\perp D^{-1}A\mathbf{x} \mid D^{-1}A\mathbf{y}$, then return $D^{-1}A\mathbf{x} \rightarrow \mathbf{y}$,

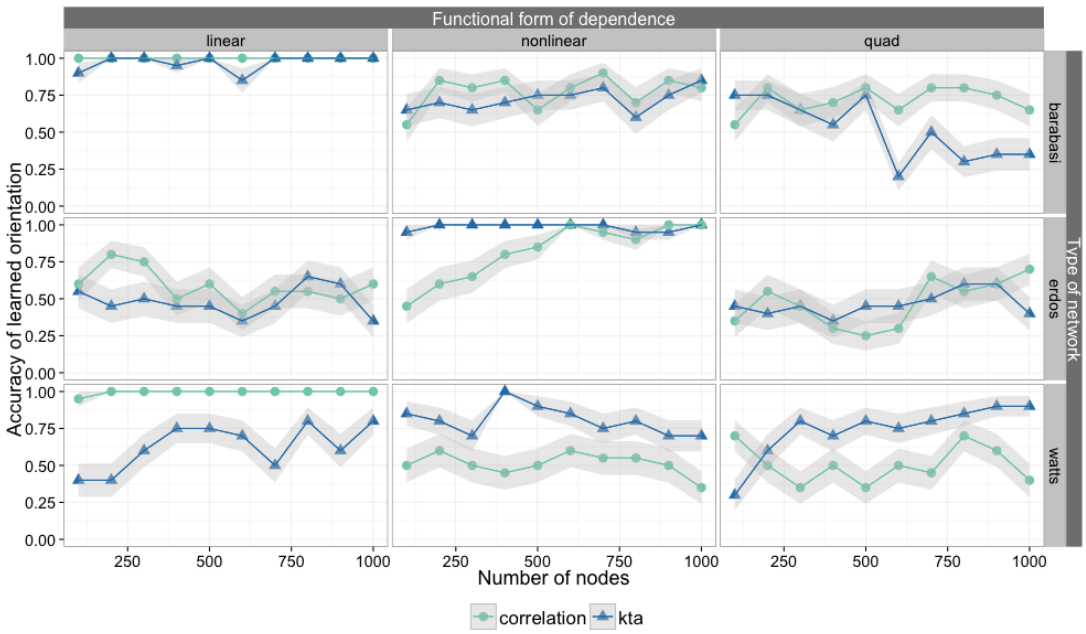


Figure 3: Orientation accuracy for various network types and functional forms, as the size of the graph increases. The noise coefficient is set to 0.5.

otherwise return $D^{-1}A\mathbf{y} \to \mathbf{x}$

We applied this procedure to the linear data-generating scenarios used in the previous two subsections, with one modification. Rather than testing a single perspective, we explicitly tested the conditional independence facts from the perspective of both $\mathbf{x}$ and $\mathbf{y}$. We found that between all scenarios, RBO failed to induce dependence in 80-90% of cases. This has important ramifications for the RCD algorithm of Maier et al. [2013]. As currently implemented, the RBO rule would have produced approximately $\%50$ error rate, since it does not explicitly check both directions. Using our more conservative method, RBO would fire less frequently. In contrast, by incorporating the findings of the more direct marginal comparison presented here, vast numbers of edges would be accurately oriented. We plan on examining further integration of our findings into joint causal structure learning algorithms in future work.

7 REAL WORLD DEMONSTRATION

In contrast to the propositional setting, where there is a number of labeled ground-truth data-sets for testing novel methods of causal inference (e.g. [Lichman, 2013]), to our knowledge, there are no known publicly available datasets which contain ground-truth relational causal relationships. In the absence of the ability to verify the relative efficacy of our findings on real-world datasets, we provide a demonstration of our method on a real-world dataset. Specifically, we considered Stack Overflow, an online community where users pose and answer questions regarding software development. A user can post a question, which can be answered by anyone else within the community. Other users can then up/down vote questions and the given answers. These votes are tracked and the accrual of achieved points is displayed as the "reputation" of a user on the site. Moreover, users can comment on a question. Comments receive votes as well, but do not affect the reputation of a user. The dataset consists of all users, questions, answers, comments, and votes from the inception of the site to 2014.

We tested three questions about user behavior on Stack Overflow. For every question we consider 100 sub-samples of 1000 data points. We computed KTA and Pearson's correlation in each direction. Significance of dependence was determined by performing permutation tests with 1000 permutations. For all tests we set the significance threshold to be 0.01. When dependence was determined to be statistically significant, we also recorded how many times each direction was chosen by comparing test statistics in both directions.

The first question was: "Is there a relationship between the quality of a question and the quality of its subsequent answers?" To answer this, we used the scores of the questions and answers as proxies for their quality. All methods determined significance in both directions across all trials. However, the normalized statistics consistently determined the direction of dependence to be Question Quality $\to$ Answer Quality, while both of the un-normalized statistics consistently determined the direction of dependence to be

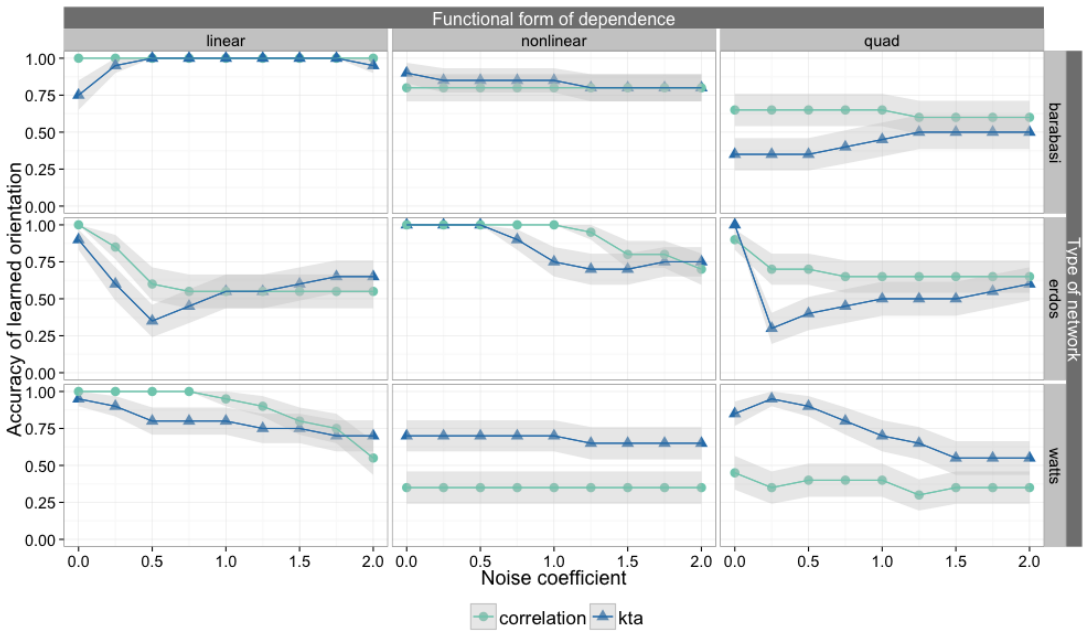

Figure 4: Orientation accuracy for various network types and functional forms, as the coefficient of the noise increases. The network size was kept constant at 1000 nodes.

Question Quality ← Answer Quality. Clearly, the former conclusion matches intuition and temporal ordering far better than the latter.

The second question we considered was whether users with high reputation receive higher quality answers. This was quantified by using the reputation of a user and the score of the answers as a proxy for quality. In this case, we found that KTA and Pearson both detected significance for both directions. For direction, we found that both KTA and Pearson determined direction to be Reputation → Answer Quality for over 90% of the cases. This indicates that there may be bias in the Stack Overflow community towards questions asked by high reputation users. We caution that this does not take into account the possible latent confounder of question quality, i.e., higher reputation users may simply ask higher quality questions.

Finally, we looked at the efficacy of comments as a quality improvement mechanism, i.e., whether allowing users to comment on a question causes the poster to improve or clarify her post. We constructed this test with the comments posted for a question and whether revisions were subsequently made to the question. In this case we found that all of the methods inferred that there was *not* a significant relationship between the score of the comments and subsequent revisions to posts. This negative result indicates that the commenting system provided by Stack Overflow is not an effective mechanism for improving the quality of questions on the site.

8 RELATED WORK

Relevant work to our investigation of methods for determining peer dependence in relational data falls into four basic categories. The most closely related work examines versions of this specific task with alternative methods. For example, Maier et al. [2013], Rattigan [2012], and Poole and Crowley [2013] provide scenarios in which an asymmetry may arise similar to that observed in our tests for direction. However, in contrast to prior work, we study the phenomenon of asymmetric dependence directly and provide a formal examination which provides guarantees to the circumstances under which this asymmetry can be reliably leveraged. Further, we provide extensive simulation experiments that further show conditions under which direction can be found by considering the difference in dependence in both directions.

A second category of related work focuses on measuring causal dependence in non-relational (i.i.d.) data. For example, Peters et al. [2014] examine the problem of determining the direction of dependence with i.i.d. data by either assuming non-Gaussian noise and linear dependence or non-linear dependence and Gaussian noise. The problem of identifying causal direction in the case of deterministic, i.e., non-noisy data, was studied by Daniusis et al. [2010]. The setting considered was propositional data, and the proposed solution leverages properties of information geometry in order to find asymmetries between the conditional distributions of the two variables. In contrast, the relational setting considered provides a much more direct

mechanism for determining direction.

A third thread of related work aims to detect non-causal dependence in relational data. This task has attracted attention in both statistical relational learning (SRL) community and in multiple areas of the social sciences. In SRL, Jensen and Neville [2002] use a χ^2 test to detect auto-correlation in relational data and show its effect for feature selection. Angin and Neville [2008] introduce a shrinkage estimator for auto-correlation in the presence of varying dependence strength. However, both of these rely on empirical evaluation as evidence of correctness. Dhurandhar and Dobra [2012] and London et al. [2013] provide theoretical analysis for the inductive error of classification and regression in the relational setting.

In the social sciences, relational dependence has been examined under the monikers of peer influence, spillover, and interference. In the experimental setting, Eckles et al. [2014] characterize the threat to validity arising from the bias induced by relational dependence and provide experimental designs to reduce these effects. Manski [2013], VanderWeele [2008], and Aronow and Samii [2013] examine methods for removing the bias associated with relational dependence, assuming discrete or linearly dependent data. Toulis and Kao [2013] provide conditions for experimental design with binary treatments to identify peer influence. Ogburn and VanderWeele [2014] characterize relational dependence in terms of graphical models, but do not present an explicit testing procedure. Work studying homophily and contagion (e.g., Christakis and Fowler [2009], La Fond and Neville [2010]) is related but distinct in the task setup, as we do not assume the availability of temporal information.

Finally, our work is strongly connected and can serve as a complement to existing work on causal learning of relational domains. Maier et al. [2013] and Marazopoulou et al. [2015] present constraint-based algorithms to learn the structure of relational models from data. However, for their experiments they either rely on a d-separation oracle (without actual data), or use linear regression with mean-aggregation on synthetically generated data. As we showed in our synthetic experiments, these choices can lead to a large number of type II errors. This is especially troublesome for constraint-based structure learning algorithms where type II errors can lead to large deviations from the true causal model [Cornia and Mooij, 2014]. Such algorithms could leverage our test in order to improve results reported on data. Additionally, the directionality results presented in this paper have implications for future work in constraint-based structure learning algorithms, since they imply a smaller Markov-equivalence class than what is commonly assumed.

9 CONCLUSIONS AND FUTURE WORK

Inferring relational dependence is a task of general interest in a wide number of fields, from statistical relational learning to the social sciences. In this work, we have studied the problem of inferring causal direction in relational data. We have shown that, in contrast to the propositional setting, causal direction can be accurately inferred in relational data under the simplest functional forms such as linear deterministic dependence, without additional assumptions on the distribution of the underlying data. We then studied the problem of identifying confounding, showing the conditions when the presence of a relational confounding variable can be identified. Our experimental evaluation shows that these measures are robust, providing accurate inference under model and network mis-specification.

There are several promising avenues for future research. For causal learning, the ability to detect the direction of dependence in relational data implies that a different Markov equivalence class [Spirtes et al., 2000] holds for the relational setting than what is commonly assumed. Integration of the findings of this work into a causal learning algorithm could substantially improve the efficacy of existing methods such as RCD [Maier et al., 2013]. Further analysis of the interaction between the network structure and inference may further strengthen the robustness of the methods discussed here. Finally, the asymmetries shown to be inherent to relational data here may result in significant bias of conditional independence testing procedures. Incorporating this additional information is a first step in developing robust measures of conditional dependence in relational data to help determine causation, a problem which has broad application in both the statistical learning and social science communities.

Abstract

Finding efficient and provable methods to solve non-convex optimization problems is an outstanding challenge in machine learning and optimization theory. A popular approach used to tackle non-convex problems is to use convex relaxation techniques to find a convex surrogate for the problem. Unfortunately, convex relaxations typically must be found on a problem-by-problem basis. Thus, providing a general-purpose strategy to estimate a convex relaxation would have a wide reaching impact. Here, we introduce *Convex Relaxation Regression* (CoRR), an approach for learning convex relaxations for a class of smooth functions. The idea behind our approach is to estimate the convex envelope of a function f by evaluating f at a set of T random points and then fitting a convex function to these function evaluations. We prove that with probability greater than $1-\delta$, the solution of our algorithm converges to the global optimizer of f with error $\mathcal{O}\big(\big(\frac{\log(1/\delta)}{T}\big)^{\alpha}\big)$ for some $\alpha > 0$. Our approach enables the use of convex optimization tools to solve non-convex optimization problems.

1 Introduction

Modern machine learning relies heavily on optimization techniques to extract information from large and noisy datasets (Friedman et al., 2001). Convex optimization methods are widely used in machine learning applications, due to fact that convex problems can be solved efficiently, often with a first order method such as gradient descent (Shalev-Shwartz and Ben-David, 2014; Sra et al., 2012; Boyd and Vandenberghe, 2004). A wide class of problems can be cast as convex optimization problems; however, many important learning problems, including binary classification with 0-1 loss, sparse and low-rank matrix recovery, and training multi-layer neural networks, are non-convex.

In many cases, non-convex optimization problems can be solved by first relaxing the problem: *convex relaxation* techniques find a convex function that approximates the original objective function (Tropp, 2006; Candès and Tao, 2010; Chandrasekaran et al., 2012). A convex relaxation is considered tight when it provides a tight lower bound to the original objective function. Examples of problems for which tight convex relaxations are known include binary classification (Cox, 1958), sparse and low-rank approximation (Tibshirani, 1996; Recht et al., 2010). The recent success of both sparse and low rank matrix recovery has demonstrated the power of convex relaxation for solving high-dimensional machine learning problems.

When a tight convex relaxation is known, then the underlying non-convex problem can often be solved by optimizing its convex surrogate in lieu of the non-convex problem. However, there are important classes of machine learning problems for which no such relaxation is known. These include a wide range of machine learning problems such as training deep neural nets, estimating latent variable models (mixture density models), optimal control, reinforcement learning, and hyper-parameter optimization. Thus, methods for finding convex relaxations of arbitrary non-convex functions would have wide reaching impacts throughout machine learning and the computational sciences.

Here we introduce a principled approach for black-box (zero-order) global optimization that is based on learning a convex relaxation to a non-convex function of interest (Sec. 3). To motivate our approach, consider the problem of estimating the convex envelope of the function f, i.e., the tightest convex lower bound of the function (Grotzinger, 1985; Falk, 1969; Kleibohm, 1967). In this case, we know that the envelope's minimum coincides with the minimum of the original non-convex function (Kleibohm, 1967). Unfortunately, finding the *exact* convex envelope of a non-convex function can be at least as hard as solving the original optimization problem. This is due to the fact that the problem of finding the convex envelope of a function is equiv-

alent to the problem of computing its Legendre-Fenchel bi-conjugate (Rockafellar, 1997; Falk, 1969), which is in general as hard as optimizing f. Despite this result, we show that for a class of smooth (non-convex) functions, it is possible to accurately and efficiently *estimate* the convex envelope from a set of function evaluations.

The main idea behind our approach, *Convex Relaxation Regression* (CoRR), is to estimate the convex envelope of f and then optimize the resulting empirical convex envelope. We do this by solving a constrained ℓ_1 regression problem which estimates the convex envelope by a linear combination of a set of convex functions (basis vectors). As our approach only requires samples from the function, it can be used to solve optimization problems where gradient information is unknown. Whereas most methods for global optimization rely on local search strategies which find a new search direction to explore, CoRR takes a global perspective: it aims to form a global estimate of the function to "fill in the gaps" between samples. Thus CoRR provides an efficient strategy for global minimization through the use of convex optimization tools.

One of the main theoretical contributions of this work is the development of guarantees that CoRR can find accurate convex relaxations for a broad class of non-convex functions (Sec. 4). We prove in Thm. 1 that with probability greater than $1-\delta$, we can approximate the global minimizer with error of $\mathcal{O}\Big(\big(\frac{\log(1/\delta)}{T}\big)^{\alpha}\Big)$, where T is the number of function evaluations and $\alpha > 0$ depends upon the exponent of the Hölder-continuity bound on $f(x) - f^*$. This result assumes that the true convex envelope lies in the function class used to form a convex approximation. In Thm. 2, we extend this result for the case where the convex envelope is in the proximity of this set of functions. Our results may also translated to a bound with polynomial dependence on the dimension (Sec. 4.2.4).

The main contributions of this work are as follows. We introduce CoRR, a method for black-box optimization that learns a convex relaxation of a function from a set of random function evaluations (Sec. 3). Following this, we provide performance guarantees which show that as the number of function evaluations T grows, the error decreases polynomially in T (Sec. 4). In Thm. 1 we provide a general result for the case where the true convex envelope f_c lies in the function class $\mathcal{H}$ and extend this result to the approximate setting where $f_c \notin \mathcal{H}$ in Thm. 2. Finally, we study the performance of CoRR on several multi-modal test functions and compare it with a number of widely used approaches for global optimization (Sec. 5). These results suggest that CoRR can accurately find a tight convex lower bound for a wide class of non-convex functions.

2 Problem Setup

We now introduce relevant notation, setup our problem, and then provide background on global optimization of non-convex functions.

2.1 Preliminaries

Let n be a positive integer. For every $x \in \mathbb{R}^n$, its ℓ_2-norm is denoted by $\|x\|$, where $\|x\|^2 := \langle x, x\rangle$ and $\langle x, y\rangle$ denotes the inner product between two vectors $x \in \mathbb{R}^n$ and $y \in \mathbb{R}^n$. We denote the ℓ_2 metric by d_2 and the set of ℓ_2-normed bounded vectors in $\mathbb{R}^n$ by $\mathcal{B}(\mathbb{R}^n)$, where for every $x \in \mathcal{B}(\mathbb{R}^n)$ we assume that there exists some finite scalar C such that $\|x\| < C$. Let $(\mathcal{X}, d)$ be a metric space, where $\mathcal{X} \in \mathcal{B}(\mathbb{R}^n)$ is a convex set of bounded vectors and $d(., x)$ is convex w.r.t. its first argument for every $x \in \mathcal{B}(\mathbb{R}^n)$.[1] We denote the set of all bounded functions on $\mathcal{X}$ by $\mathcal{B}(\mathcal{X}, \mathbb{R})$, such that for every $f \in \mathcal{B}(\mathcal{X}, \mathbb{R})$ and $x \in \mathcal{X}$ there exists some finite scalar $C > 0$ such that $|f(x)| \leq C$. Finally, we denote the set of all convex bounded functions on $\mathcal{X}$ by $\mathcal{C}(\mathcal{X}, \mathbb{R}) \subset \mathcal{B}(\mathcal{X}, \mathbb{R})$. Also for every $\mathcal{Y} \subseteq \mathcal{B}(\mathbb{R}^n)$, we denote the convex hull of $\mathcal{Y}$ by $\mathrm{conv}(\mathcal{Y})$. Let $\mathcal{B}(x_0, r)$ denote an open ball of radius r centered at x_0. Let $\mathbf{1}$ denote a vector of ones.

The convex envelope of function $f : \mathcal{X} \to \mathbb{R}$ is denoted by $f_c : \mathcal{X} \to \mathbb{R}$. Let $\widetilde{\mathcal{H}}$ be the set of all convex functions defined over $\mathcal{X}$ such that $h(x) \leq f(x)$ for all $x \in \mathcal{X}$. The function f_c is the convex envelope of f if for every $x \in \mathcal{X}$ **(a)** $f_c(x) \leq f(x)$, **(b)** for every $h \in \widetilde{\mathcal{H}}$ the inequality $h(x) \leq f_c(x)$ holds. Convex envelopes are also related to the concepts of the convex hull and the epigraph of a function. For every function $f : \mathcal{X} \to \mathbb{R}$ the epigraph is defined as $\mathrm{epi} f = \{(\xi, x) : \xi \geq f(x), x \in \mathcal{X}\}$. One can then show that the convex envelope of f is obtained by $f_c(x) = \inf\{\xi : (\xi, x) \in \mathrm{conv}(\mathrm{epi} f)\}$, $\forall x \in \mathcal{X}$.

In the sequel, we will generate a set of function evaluations from f by evaluating the function over i.i.d. samples from ρ, where ρ denotes a probability distribution on $\mathcal{X}$ such that $\rho(x) > 0$ for all $x \in \mathcal{X}$. In addition, we approximate the convex envelope using a function class $\mathcal{H}$ that contains a set of convex functions $h(\cdot; \theta) \in \mathcal{H}$ parametrized by $\theta \in \Theta \subseteq \mathcal{B}(\mathbb{R}^p)$. We also assume that every $h \in \mathcal{H}$ can be expressed as a linear combination of a set of basis $\phi : \mathcal{X} \to \mathcal{B}(\mathbb{R}^p)$, that is, $h(x; \theta) = \langle \theta, \phi(x)\rangle$ for every $h(\cdot; \theta) \in \mathcal{H}$ and $x \in \mathcal{X}$.

2.2 Black-box Global Optimization Setting

We consider a *black-box* (zero-order) global optimization setting, where we assume that we do not have access to

[1] This also implies that $d(x, .)$ is convex w.r.t. its second argument argument for every $x \in \mathcal{B}(\mathbb{R}^n)$ due to the fact that the metric d by definition is symmetric.

information about the gradient of the function that we want to optimize. More formally, let $\mathcal{F} \subseteq \mathcal{B}(\mathcal{X}, \mathbb{R})$ be a class of bounded functions, where the image of every $f \in \mathcal{F}$ is bounded by R and $\mathcal{X}$ is a convex set. We consider the problem of finding the global minimum of the function f,

$$f^* := \min_{x \in \mathcal{X}} f(x). \tag{1}$$

We denote the set of minimizers of f by $\mathcal{X}_f^* \subseteq \mathcal{X}$.

In the black-box setting, the optimizer has only access to the inputs and outputs of the function f. In this case, we assume that our optimization algorithm is provided with a set of input points $\widehat{\mathcal{X}} = \{x_1, x_2, \ldots, x_T\}$ in $\mathcal{X}$ and a sequence of outputs $[f]_{\widehat{\mathcal{X}}} = \{f(x_1), f(x_2), \ldots, f(x_T)\}$. Based upon this information, the goal is to find an estimate $\widehat{x} \in \mathcal{X}$, such that the error $f(\widehat{x}) - f^*$ becomes as small as possible.

2.3 Methods for Black-box Optimization

Standard tools that are used in convex optimization, cannot be readily applied to solve non-convex problems as they only converge to local minimizers of the function. Thus, effective global optimization approaches must have a mechanism to avoid getting trapped in local minima. In low-dimensional settings, performing an exhaustive grid search or drawing random samples from the function can be sufficient (Bergstra and Bengio, 2012). However, as the dimension grows, smarter methods for searching for the global minimizer are required.

Non-adaptive search strategies. A wide range of global optimization methods are build upon the idea of iteratively creating a deterministic set (pattern) of points at each iteration, evaluating the function over all points in the set, and selecting the point with the minimum value as the next seed for the following iteration (Hooke and Jeeves, 1961; Lewis and Torczon, 1999). Deterministic pattern search strategies can be extended by introducing some randomness into the pattern generation step. For instance, simulated annealing (Kirkpatrick et al., 1983) (SA) and genetic algorithms (Bäck, 1996) both use randomized search directions to determine the next place that they will search. The idea behind introducing some noise into the pattern, is that the method can jump out of local minima that deterministic pattern search methods can get stuck in. While many of these search methods work well in low dimensions, as the dimension of problem grows, these algorithms often become extremely slow due to the curse of dimensionality.

Adaptive and model-based search. In higher dimensions, adaptive and model-based search strategies can be used to further steer the optimizer in good search directions (Mockus et al., 1978; Hutter, 2009). For instance, recent results in Sequential Model-Based Global Optimization (SMBO) have shown that Gaussian processes are useful priors for global optimization (Mockus et al., 1978; Bergstra et al., 2011). In these settings, each search direction is driven by a model (Gaussian process) and updated based upon the local structure of the function. These techniques, while useful in low-dimension problems, become inefficient in high-dimensional settings.

Hierarchical search methods take a different approach in exploiting the structure of the data to find the global minimizer (Munos, 2014; Bubeck et al., 2011; Azar et al., 2014; Munos, 2011). The idea behind hierarchical search methods is to identify regions of the space with small function evaluations to sample further (exploitation), as well as generate new samples in unexplored regions (exploration). One can show that it is possible to find the global optimum with a finite number of function evaluations using hierarchical search; however, the number of samples needed to achieve a small error increases exponentially with the dimension. For this reason, hierarchical search methods are often not efficient for high-dimensional problems.

Graduated optimization. Graduated optimization methods (Blake and Zisserman, 1987; Yuille, 1989), are another class of methods for non-convex optimization which have received much attention in recent years (Chapelle and Wu, 2010; Dvijotham et al., 2014; Hazan et al., 2015; Mobahi and III, 2015). These methods work by locally smoothing the problem, descending along this smoothed objective, and then gradually sharpening the resolution to hone in on the true global minimizer. Recently Hazan et al. (2015) introduced a graduated optimization approach that can be applied in the black-box optimization setting. In this case, they prove that for a class of functions referred to as σ-nice functions, their approach is guaranteed to converge to an ε-accurate estimate of the global minimizer at a rate of $\mathcal{O}(n^2/\varepsilon^4)$. To the best of our knowledge, this result represents the state-of-the-art in terms of theoretical results for global black-box optimization.

3 Algorithm

In this section, we introduce *Convex Relaxation Regression* (CoRR), a black-box optimization approach for global minimization of a bounded function f.

3.1 Overview

The main idea behind our approach is to estimate the convex envelope f_c of a function and minimize this surrogate in place of our original function. The following result guarantees that the minimizer of f coincides with the minimizer of f_c.

Proposition 1 (Kleibohm 1967)**.** *Let f_c be the convex envelope of $f : \mathcal{X} \to \mathbb{R}$. Then (a)* $\min_{x \in \mathcal{X}} f_c(x) = f^*$ *and (b)* $\mathcal{X}_f^* \subseteq \mathcal{X}_{f_c}^*$.

This result suggests that one can find the minimizer of f by

optimizing its convex envelope. Unfortunately, finding the exact convex envelope of a function is difficult in general. However, we will show that, for a certain class of functions, it is possible to estimate the convex envelope accurately from a set of function evaluations. Our aim is to estimate the convex envelope by fitting a convex function to these function evaluations.

The idea of fitting a convex approximation to samples from f is quite simple and intuitive. However, the best unconstrained convex fit to f does not necessarily coincide with f_c. Determining whether there exists a set of convex constraints under which the best convex fit to f coincides with f_c is an open problem. The following lemma, which is key to efficient optimization of f with CoRR, provides a solution. This lemma transforms our original non-convex optimization problem to a least-absolute-error regression problem with a convex constraint, which can be solved using convex optimization tools.

Lemma 1. *Let every $h \in \mathcal{H}$ and f be λ-Lipschitz for some $\lambda > 0$. Let $L(\theta) = \mathbb{E}[|h(x;\theta) - f(x)|]$ be the expected loss, where the expectation is taken with respect to the distribution ρ. Assume that there exists $\Theta_c \subseteq \Theta$ such that for every $\theta \in \Theta_c$, $h(x;\theta) = f_c(x)$ for all $x \in \mathcal{X}$. Consider the following optimization problem:*

$$\theta_\mu = \arg\min_{\theta\in\Theta} \; L(\theta) \;\; \textit{s.t.} \;\; \mathbb{E}[h(x;\theta)] = \mu. \tag{2}$$

Then there exists a scalar $\mu \in [-R, R]$ for which $\theta_c \in \Theta_c$. In particular, $\theta_c \in \Theta_c$ when $\mu = \mathbb{E}(f_c(x))$.

The formal proof of this lemma is provided in the Supp. Materials. We prove this lemma by showing that for every $\theta \in \Theta$ where $\mathbb{E}[h(x;\theta)] = \mathbb{E}[f_c(x)]$, and for every $\theta_c \in \Theta_c$, the loss $L(\theta) \geq L(\theta_c)$. Equality is attained only when $\theta \in \Theta_c$. Thus, f_c is the only minimizer of $L(\theta)$ that satisfies the constraint $\mathbb{E}[h(x;\theta)] = \mathbb{E}[f_c(x)]$.

Optimizing μ. Lem. 1 implies that, for a certain choice of μ, Eqn. 2 provides us with the convex envelope f_c. However, finding the exact value of μ for which this result holds is difficult, as it requires knowledge of the envelope not available to the learner. Here we use an alternative approach to find μ which guarantees that the optimizer of $h(\cdot;\theta_\mu)$ lies in the set of true optimizers $\mathcal{X}_f^*$. Let x_μ denote the minimizer of $h(\cdot;\theta_\mu)$. We find a μ which minimizes $f(x_\mu)$:

$$\mu^* = \arg\min_{\mu\in[-R,R]} \; f(x_\mu). \tag{3}$$

Interestingly, one can show that x_{μ^*} lies in the set $\mathcal{X}_f^*$. To prove this, we use the fact that the minimizers of the convex envelope f_c and f coincide.This implies that $f(x_{\mu_c}) = f^*$, where $\mu_c := \mathbb{E}(f_c(x))$. It then follows that $f^* = f(x_{\mu_c}) \geq \min_{\mu\in[-R,R]} f(x_\mu) = f(x_{\mu^*})$. This combined with the fact that f^* is the minimizer of f implies that $f(x_{\mu^*}) = f^*$ and thus $x_{\mu^*} \in \mathcal{X}^*$.

3.2 Optimization Protocol

We now describe how we use the ideas presented in Sec. 3.1 to implement CoRR (see Alg. 1 for pseudocode). Our approach for black-box optimization requires two main ingredients: (1) samples from the function f and (2) a function class $\mathcal{H}$ from which we can form a convex approximation h. In practice, CoRR is initialized by first drawing two sets of T samples $\widehat{\mathcal{X}}_1$ and $\widehat{\mathcal{X}}_2$ from the domain $\mathcal{X} \subseteq \mathcal{B}(\mathbb{R}^n)$ and evaluating f over both of these sets. With these sets of function evaluations (samples) and a function class $\mathcal{H}$ in hand, our aim is to learn an approximation $h(x;\theta)$ to the convex envelope of f. Thus for a fixed value of μ, we solve the following constrained optimization problem (see the `OPT` procedure in Alg. 1):

$$\widehat{\theta}_c = \arg\min_{\theta\in\Theta} \; \widehat{\mathbb{E}}_1\big[|h(x;\theta) - f(x)|\big] \text{ s.t. } \widehat{\mathbb{E}}_2\big[h(x;\theta)\big] = \mu, \tag{4}$$

where the empirical expectation $\widehat{\mathbb{E}}_i[g(x)] := 1/T \sum_{x\in\widehat{\mathcal{X}}_i} g(x)$, for every $g \in \mathcal{B}(\mathcal{X}, \mathbb{R})$ and $i \in \{1, 2\}$. We provide pseudocode for optimizing Eqn. 4 in the `OPT` procedure of Alg. 1.

The optimization problem of Eqn. 4 is an empirical approximation of the optimization problem in Eqn. 2. However, unlike Eqn. 2, in which $L(\theta)$ is not easy to evaluate and optimize, the empirical loss can be optimized efficiently using standard convex optimization techniques. In addition, one can establish bounds on the error $|L(\widehat{\theta}_c) - L(\theta_c)|$ in terms of the sample size T using standard results from the literature on stochastic convex optimization (see, e.g., Thm. 1 in Shalev-Shwartz et al., 2009). Optimizing the empirical loss provides us with an accurate estimate of the convex envelope as the number of function evaluations increases.

The search for the best μ (Step 2 in Alg. 1) can be done by solving Eqn. 3. As μ is a scalar with known upper and lower bounds, we can employ a number of hyperparameter search algorithms (Munos, 2011; Bergstra et al., 2011) to solve this 1D optimization problem. These algorithms guarantee fast convergence to the global minimizer in low dimensions and thus can be used to efficiently search for the solution to Eqn. 3. Let $\widehat{\mu}$ denote the final estimate of μ obtained in Step 2 of Alg. 1 and let $h(\cdot;\theta_{\widehat{\mu}})$ denote our final convex approximation to f_c. The final solution $\widehat{x}_{\widehat{\mu}}$ is then obtained by optimizing $h(\cdot;\theta_{\widehat{\mu}})$ (Step 2 of `OPT`).

To provide further insight into how CoRR works, we point the reader to Fig. 1. Here, we show examples of the convex surrogate obtained by `OPT` for different values of μ. We observe that as we vary μ, the minimum error is attained for $\mu \approx 0.47$. However, when we analytically compute the empirical expectation of convex envelope ($\widehat{E}_2[f_c(x)] = 0.33$) and use this value for μ, this produces a larger function evaluation. This may seem surprising, as we know that if we set $\mu = \mathbb{E}(f_c(x))$, then the solution of Eqn. 2 should provide us the exact convex envelope with the same opti-

Algorithm 1 Convex Relaxation Regression (CoRR)

Input: A black-box function f which returns a sample $f(x)$ when evaluated at a point x. The number of samples N to draw from f. A class $\mathcal{H} \subseteq \mathcal{B}(\mathcal{X}, \mathbb{R})$ of convex functions in $\mathcal{X}$ (parametrized by θ), a scalar R for which $\|f\|_\infty \leq R$, a sampling distribution ρ supported over $\mathcal{X}$.

1: **Random function evaluations.** Draw $2N$ i.i.d. samples according to the distribution ρ and partition them into two sets, $\widehat{\mathcal{X}} = \{\widehat{\mathcal{X}}_1, \widehat{\mathcal{X}}_2\}$. Generate samples $[f]_{\widehat{\mathcal{X}}_1}$ and $[f]_{\widehat{\mathcal{X}}_2}$, where $[f]_{\widehat{\mathcal{X}}_i} = \{f(x) : x \in \widehat{\mathcal{X}}_i\}$, $i = \{1, 2\}\}$. Denote $[f]_{\widehat{\mathcal{X}}} = \{[f]_{\widehat{\mathcal{X}}_1}, [f]_{\widehat{\mathcal{X}}_2}\}$

2: **Optimize for μ.** Solve the 1D optimization problem

$$\widehat{\mu} = \underset{\mu \in [-R,R]}{\arg\min}\ f(\texttt{OPT}(\mu, [f]_{\widehat{\mathcal{X}}})),$$

Output: $\widehat{x}_{\widehat{\mu}} = \texttt{OPT}(\widehat{\mu}, [f]_{\widehat{\mathcal{X}}})$.

Procedure $\texttt{OPT}(\mu, [f]_{\widehat{\mathcal{X}}})$

1: **Estimate the convex envelope.** Estimate $\widehat{f}_c = h(\cdot; \widehat{\theta}_\mu)$ by solving Eqn. 4.

2: **Optimize the empirical convex envelope.** Find an optimizer $\widehat{x}_\mu$ for $\widehat{f}_c$ by solving

$$\widehat{x}_\mu = \min_{x \in \mathcal{X}} \widehat{f}_c(x),$$

return $\widehat{x}_\mu$

mizer as f. This discrepancy can be explained by the approximation error introduced through solving the empirical version of Eqn. 2. This figure also highlights the stability of our approach for different values of μ. Our results suggest that our method is robust to the choice of μ, as a wide range of values of μ produce minimizers close to the true global minimum. Thus CoRR provides an accurate and robust approach for finding the global optimizer of f.

4 Theoretical Results

In this section, we provide our main theoretical results. We show that as the number of function evaluations T grows, the solution of CoRR converges to the global minimum of f with a polynomial rate. We also discuss the scalability of our result to high-dimensional settings.

4.1 Assumptions

We begin by introducing the assumptions required to state our results. The first assumption provides the necessary constraint on the candidate function class $\mathcal{H}$ and the set of all points in $\mathcal{X}$ that are minimizers for the function f.

Assumption 1 (Convexity)**.** *Let $\mathcal{X}_f^*$ denote the set of minimizers of f. We assume that the following three convexity assumptions hold with regard to every $h(\cdot; \theta) \in \mathcal{H}$ and $\mathcal{X}_f^*$: (a) $h(x; \theta)$ is a convex function for all $x \in \mathcal{X}$, (b) h is a affine function of $\theta \in \Theta$ for all $x \in \mathcal{X}$, and (c) $\mathcal{X}_f^*$ is a convex set.*

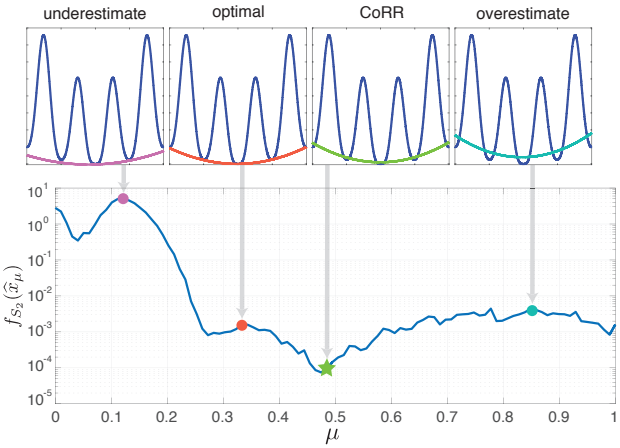

Figure 1: *Estimating the convex envelope of f with CoRR.* Here we demonstrate how CoRR learns a convex envelope by solving Eqn. 3. Along the top, we plot the test function f_{S_2} (see Sec. 5) and examples of the convex surrogates obtained for different values of μ. From left to right, we display the surrogate obtained for: an underestimate of μ, the empirical estimate of the convex envelope where $\mu \approx \widehat{\mathbb{E}}_2[f_c(x)]$, the result obtained by CoRR, and an overestimate of μ. Below, we display the value of the function f_{S_2} as we vary μ (solid blue).

Remark. Assumption 1c does not impose convexity on the function f. Rather, it requires that the set $\mathcal{X}_f^*$ is convex. This is needed to guarantee that both f_c and f have the same minimizers (see Prop. 1). Assumption 1c holds for a large class of non-convex functions. For instance, every continuous function with a unique minimizer satisfies this assumption (see, e.g., our example functions in Sect. 5).

Assumption 2 establishes the necessary smoothness assumption on the function f and the function class $\mathcal{H}$.

Assumption 2 (Lipschitz continuity)**.** *We assume that f and h are Lipschitz continuous. That is for every $(x_1, x_2) \in \mathcal{X}^2$ we have that $|f(x_1) - f(x_2)| \leq d(x_1, x_2)$. Also for every $x \in \mathcal{X}$ and $(\theta_1, \theta_2) \in \Theta^2$ we have that $|h(x; \theta_1) - h(x; \theta_2)| \leq U d_2(\theta_1, \theta_2)$. We also assume that every $h \in \mathcal{H}$ is λ-Lipschitz on $\mathcal{X}$ w.r.t. the metric d for some $\lambda > 0$.*

We show that the optimization problem of Eqn. 1 provides us with the convex envelope f_c when the candidate class $\mathcal{H}$ contains f_c (see Lem. 1). The following assumption formalizes this condition.

Assumption 3 (Capacity of $\mathcal{H}$)**.** *We assume that $f_c \in \mathcal{H}$, that is, there exist some $h \in \mathcal{H}$ and $\Theta \subseteq \Theta_c$ such that*

$h(x;\theta) = f_c(x)$ *for every* $x \in \mathcal{X}$ *and* $\theta \in \Theta_c$.

We also require that the following Hölder-type error bounds hold for the distances of our empirical estimates $\widehat{x}$ and $\widehat{\theta}$ from $\mathcal{X}_f^*$ and Θ_c, respectively.

Assumption 4 (Hölder-type error bounds)**.** *Let* $\Theta^e := \{\theta | \theta \in \Theta, \mathbb{E}(h(x;\theta)) = f_c(x)\}$. *Also denote* $L^* := \min_{\theta \in \Theta^e} L(\theta)$. *We assume that there exists some finite positive scalars* γ_1, γ_2, β_1 *and* β_2 *such that for every* $x \in \mathcal{X}$ *and* $\theta \in \Theta^e$*: (a)* $f(x) - f^* \geq \gamma_1 d(x, \mathcal{X}_f^*)^{1/\beta_1}$. *(b)* $L(\theta) - L^* \geq \gamma_2 d_2(\theta, \Theta_c)^{1/\beta_2}$.

Assumption 4 implies that whenever the error terms $f(x) - f^*$ and $L(\theta) - L^*$ are small, the distances $d(x, \mathcal{X}_f^*)$ and $d_2(\theta, \Theta_c)$ are small as well. To see why Assumption 4 is required for the analysis of CoRR, we note that the combination of Assumption 4 with Assumption 2 leads to the following *local* bi-Hölder inequalities for every $x \in \mathcal{X}$ and $\theta \in \Theta^e$:

$$\begin{aligned} \gamma_1 d(x, \mathcal{X}_f^*)^{1/\beta_1} \leq f(x) - f^* \leq d(x, \mathcal{X}_f^*) \\ \gamma_2 d_2(\theta, \Theta_c)^{1/\beta_2} \leq L(\theta) - L^* \leq U d_2(\theta, \Theta_c) \end{aligned} \tag{5}$$

These inequalities determine the behavior of function f and L around their minimums as they establish upper and lower bounds on the errors $f(x) - f^*$ and $L(\theta) - L^*$. Essentially, Eqn. 5 implies that there is a direct relationship between $d(x, \mathcal{X}_f^*)$ ($d_2(\theta, \Theta_c)$) and $f(x) - f^*$ ($L(\theta) - L(\Theta_c)$). Thus, bounds on $d(x, \mathcal{X}_f^*)$ and $d_2(\theta, \Theta_c)$, respectively, imply bounds on $f(x) - f^*$ and $L(\theta) - L(\Theta_c)$ and vice versa. These bi-directional bounds are needed due to the fact that CoRR doest not directly optimize the function. Instead it optimizes the surrogate loss $L(\theta)$ to find the convex envelope and then it optimizes this empirical convex envelope to estimate the global minima. This implies that the standard result of optimization theory can only be applied to bound the error $L(\widehat{\theta}) - L^*$. The inequalities of Eqn. 5 are then required to convert the bound on $L(\widehat{\theta}) - L^*$ to a bound on $f(\widehat{x}_{\widehat{\mu}}) - f^*$, which ensures that the solution of CoRR converges to a global minimum as $L(\widehat{\theta}) - L^* \to 0$.

It is noteworthy that global error bounds such as those in Assumption 4 have been extensively analyzed in the literature of approximation theory and variational analysis (see, e.g., Azé, 2003; Corvellec and Motreanu, 2008; Azé and Corvellec, 2004; Fabian et al., 2010). Much of this body of work can be applied to study convex functions such as $L(\theta)$, where one can make use of the basic properties of convex functions to prove lower bounds on $L(\theta) - L^*$ in terms of the distance between θ and Θ_c (see, e.g., Thm. 1.16 in Azé, 2003). While these results are useful to further study the class of functions that satisfy Assumption 4, providing a direct link between these results and the error bounds of Assumption 4 is outside the scope of this paper.

Assumptions 3-4 can not be applied directly when $f_c \notin \mathcal{H}$. When $f_c \notin \mathcal{H}$, we make use of the following generalized version of these assumptions. We first consider a relaxed version of Assumption 3, which assumes that f_c can be approximated by some $h \in \mathcal{H}$.

Assumption 5 (υ-approachability of f_c by $\mathcal{H}$)**.** *Let* υ *be a positive scalar. Define the distance between the function class* $\mathcal{H}$ *and* f_c *as* $\operatorname{dist}(f_c, \mathcal{H}) := \inf_{h \in \mathcal{H}} \mathbb{E}[|h(x;\theta) - f_c(x)|]$, *where the expectation is taken w.r.t. the distribution* ρ. *We then assume that the following inequality holds:* $\operatorname{dist}(f_c, \mathcal{H}) \leq \upsilon$.

The next assumption generalizes Assumption 4b to the case where $f_c \notin \mathcal{H}$:

Assumption 6. *Let* $\widetilde{p}$ *be a positive scalar. Assume that there exists a class of convex functions* $\widetilde{\mathcal{H}} \subseteq \mathcal{C}(\mathcal{X}, \mathbb{R})$ *parametrized by* $\theta \in \widetilde{\Theta} \subset \mathcal{B}(\mathbb{R}^{\widetilde{p}})$ *such that: (a)* $f_c \in \widetilde{\mathcal{H}}$, *(b) every* $h \in \widetilde{\mathcal{H}}$ *is linear in* θ *and (c)* $\mathcal{H} \subseteq \widetilde{\mathcal{H}}$. *Let* $\Theta_c \subseteq \widetilde{\Theta}$ *be the set of parameters for which* $h(x;\theta) = f_c(x)$ *for every* $x \in \mathcal{X}$ *and* $\theta \in \Theta_c$. *Also define* $\widetilde{\Theta}_e := \{\theta | \theta \in \widetilde{\Theta}, \mathbb{E}(h(x;\theta)) = f_c(x)\}$. *We assume that there exists some finite positive scalars* γ_2 *and* β_2 *such that for every* $x \in \mathcal{X}$ *and* $\theta \in \widetilde{\Theta}_e$

$$L(\theta) - L^* \geq \gamma_2 d_2(\theta, \widetilde{\Theta}_c)^{1/\beta_2}.$$

Intuitively speaking, Assumption 6 implies that the function class $\mathcal{H}$ is a subset of a larger unknown function class $\widetilde{\mathcal{H}}$ which satisfies the global error bound of Assumption 4b. Note that we do not require access to the class $\widetilde{\mathcal{H}}$, but we need that such a function class exists.

4.2 Performance Guarantees

We now present the two main theoretical results of our work and provide sketches of their proofs (the complete proofs of our results is provided in the Supp. Material).

4.2.1 Exact Setting

Our first result considers the case where the convex envelope $f_c \in \mathcal{H}$. In this case, we can guarantee that as the number of function evaluations grows, the solution of Alg. 1 converges to the optimal solution with a polynomial rate.

Theorem 1. *Let* δ *be a positive scalar. Let Assumptions 1, 2 ,3, and 4 hold. Then Alg. 1 returns* $\widehat{x}$ *such that with probability* $1 - \delta$

$$f(\widehat{x}) - f^* = \mathcal{O}\left[\xi_s \left(\frac{\log(1/\delta)}{T}\right)^{\beta_1\beta_2/2}\right],$$

where the smoothness coefficient $\xi_s := (\frac{1}{\gamma_1})^{\beta_2} (\frac{1}{\gamma_2})^{\beta_1\beta_2} U^{(1+\beta_2)\beta_1} (RB)^{\beta_2\beta_1}$.

Sketch of proof. To prove this result, we first prove bound on the error $L(\widehat{\theta}) - \min_{\theta \in \Theta_e} L(\theta)$ for which we rely on

standard results from stochastic convex optimization. This combined with the result of Lem. 1 leads to a bound on $L(\widehat{\theta}) - L^*$. The bound on $L(\widehat{\theta}) - L^*$ combined with Assumption 4 translates to a bound on $d(\widehat{x}, \mathcal{X}_f^*)$. The result then follows by applying the Lipschitz continuity assumption (Assumption 2). □

Thm. 1 guarantees that as the number of function evaluations T grows, the solution of CoRR converges to f^* with a polynomial rate. The order of polynomial depends on the constants β_1 and β_2. The following corollary, which is an immediate result of Thm. 1, quantifies the number of function evaluations T needed to achieve an ε-optimal solution.

Corollary 1. *Let Assumptions 1, 2, 3, and 4 hold. Let ε and δ be some positive scalars. Then Alg. 1 needs $T = (\frac{\xi_s}{\varepsilon})^{2/(\beta_1\beta_2)} \log(1/\delta)$ function evaluations to return $\widehat{x}$ such that with probability $1-\delta$, $f(\widehat{x}) - f^* \leq \varepsilon$.*

This result implies that one can achieve an ε-accurate approximation of the global optimizer with CoRR with a polynomial number of function evaluations.

4.2.2 Approximate Setting

Thm. 1 relies on the assumption that the convex envelope f_c lies in the function class $\mathcal{H}$. However, in general, there is no guarantee that f_c belongs to $\mathcal{H}$. When the convex envelope $f_c \notin \mathcal{H}$, the result of Thm. 1 cannot be applied. However, one may expect that Alg. 1 still may find a close approximation of the global minimum as long as the distance between f_c and $\mathcal{H}$ is small. To prove that CoRR finds a near optimal solution in this case, we must show that $f(\widehat{x}) - f^*$ remains small when the distance between f_c and $\mathcal{H}$ is small. We now generalize Thm. 1 to the setting where the convex envelope f_c does not lie in $\mathcal{H}$ but is close to it.

Theorem 2. *Let Assumptions 1, 2, 5, and 6 hold. Then Alg. 1 returns $\widehat{x}$ such that for every $\zeta > 0$ with probability (w.p.) $1-\delta$*

$$f(\widehat{x}) - f^* = \mathcal{O}\left[\xi_s \left(\sqrt{\frac{\log(1/\delta)}{T}} + \zeta + \upsilon\right)^{\beta_1\beta_2}\right].$$

Sketch of proof. To prove this result, we rely on standard results from stochastic convex optimization to first prove a bound on the error $L(\widehat{\theta}) - \min_{\theta\in\Theta^e} L(\theta)$ when we set μ the empirical mean of the convex envelope. We then make use of Assumption 5 as well as Lem. 1 to transform this bound to a bound on $L(\widehat{\theta}) - L^*$. The bound on $f(\widehat{x}) - f^*$ then follows by combining this result with Assumptions 2 and 6. □

4.2.3 Approximation Error υ vs. Complexity of $\mathcal{H}$

From function approximation theory, it is known that for a sufficiently smooth function g, one can achieve an υ-accurate approximation of g by a linear combination of $p = \mathcal{O}(n/\upsilon)$ bases (Mhaskar, 1996; Girosi and Anzellotti, 1992). These results imply that one can make the error υ in Thm. 2 arbitrary small by increasing the complexity of function class $\mathcal{H}$ (i.e., increasing the number of convex bases p). Similar *shape preserving* results have been established for the case when the function and bases are both convex (see, e.g., Gal, 2010; Konovalový et al., 2010; Shvedov, 1981) under some mild assumptions on g. In particular, Konovalový et al. (2010) have proven that for a rather general class of $\mathcal{H}$, the approximation error between a convex function g and class $\mathcal{H}$, can be bounded in terms of the approximation error between g and $\mathcal{H}$ when no convexity constraint is imposed on $\mathcal{H}$. This implies that existing results in the approximation theory literature can be used to bound the approximation error υ in terms of the complexity of function class $\mathcal{H}$.

4.2.4 Dependence on Dimension

The results of Thm. 1 and Thm. 2 have no explicit dependence on the dimension n. However, the Lipschitz constant U can, in the worst-case scenario, be of $\mathcal{O}(\sqrt{p})$ (due to the Cauchy-Schwarz inequality). On the other hand to achieve an approximation error of υ the number of bases p needs be of $\mathcal{O}(n/\upsilon)$ (see Sect. 4.2.3). When we plug this result in the bound of Thm. 2, this leads to a dependency of $\mathcal{O}(n^{(1+\beta_2)\beta_1/2})$ on the dimension n due to the Lipschitz constant U. In the special case where $\beta_2 = \beta_1 = 1$, i.e., when the error bounds of Assumption 4 are linear, the dependency on n becomes linear. The linear dependency on n in this case matches the results of the black-box (zero-order) convex optimization (see, e.g., Duchi et al., 2015).

5 Numerical Results

In this section, we evaluate the performance of CoRR on several multi-dimensional test functions used for benchmarking non-convex optimization methods (Jamil and Yang, 2013).

Evaluation setup. Here we study CoRR's effectiveness in finding the global minimizer of the following test functions (Fig. 2a). We assume that all functions are supported over $\mathcal{X} = \mathcal{B}(0,2) \subseteq \mathbb{R}^n$, and otherwise rescale them to lie within this set. **(S1)** Salomon function: $f_S(x) = 1 - \cos(2\pi\|x\|) + 0.5\|x\|$. **(S2)** Squared Salomon: $f_{S_2}(x) = 0.1 f_S(x)^2$. **(SL)** Salomon and Langerman combination: $f_{SL}(x) = f_S(x) + f_L(x)\ \forall x \in \mathcal{B}(0,10) \cap \mathcal{B}(0,0.2)$ and $f_{SL}(x) = 0$, otherwise (before rescaling the domain). **(L)** Langerman function: $f_L(x) = -\exp(\|x-\alpha\|_2^2/\pi)\cos(\pi\|x-\alpha\|_2^2) + 1,\ \forall x \in \mathcal{B}(0,5)$ (before rescaling the domain). **(G)** The Griewank function: $f_G(x) = 0.1\big[1 + \frac{1}{4000}\sum_{i=1}^N x(i)^2 - \prod_{i=1}^N \frac{\cos(x)}{\sqrt{i}}\big],\ \forall x \in \mathcal{B}(0,200)$ (before rescaling the domain). All of these functions have their minimum at the origin, except for the Langerman

function which has its minimum at $x^* = c\mathbf{1}$ for $c = 0.5$.

All of the aforementioned functions exhibit some amount of global structure for which the convex envelope can be approximated by a quadratic basis (Fig. 2a). We thus use a quadratic basis to construct our function class $\mathcal{H}$. The basis functions $h(x;\theta) \in \mathcal{H}$ are parameterized by a vector of coefficients $\theta = [\theta_1, \theta_2, \theta_3]$, and can be written as $h(x;\theta) = \langle \theta_1, x^2 \rangle + \langle \theta_2, x \rangle + \theta_3$. Thus, the number of parameters that we must estimate to find a convex approximation h equals $2n + 1$ (we drop the cross terms in our construction of the quadratic class). In practice, we impose a non-negativity constraint on all entries of the vector θ_1 to ensure that our approximation is convex.

Summary of results. To understand the difficulty of finding the minimizers for the test functions above, we compute the error $f(\widehat{x}) - f^*$ as we increase the number of function evaluations. Here, we show each of our five test functions (Fig. 2a) and their average scaling behavior in one dimension (Fig. 2b), where the error is averaged over 100 trials. We observe that CoRR quickly converges for all five test functions, with varying convergence rates. We observe the smallest initial error (for only 20 samples) for f_{SL} and the highest error for f_S. In addition, f_L achieves nearly perfect reconstruction of the global minimum after only 200 samples. The good scaling properties of f_L and f_{SL} is likely due the the fact that both of these functions have a wide basin around their global minimizer. This result provides nice insight into the scaling of CoRR in low dimensions.

Next, we study the approximation error as we vary the sample size and dimension for the Salomon function f_S (Fig. 2c-d). Just as our theory suggests, there is a clear dependence between the dimension and number of samples required to obtain small error. In Fig. 2c, we display the scaling behavior of CoRR as a function of both dimension and number of function evaluations T. In all of the tested dimensions, we obtain an error smaller than $1e^{-5}$ when we draw one million samples. In Fig. 2d, we compare the performance of CoRR (for fixed number of evaluations T) as we vary the dimension. In contrast, the quasi-Newton (QN) method and hybrid simulated annealing (SA) method (Hedar and Fukushima, 2004) recover the global minimizer for low dimensions but fail in dimensions greater than ten.[2] We posit that this is due to the fact the minimizer of the Salomon function lies at the center of its domain and as the dimension of the problem grows, drawing an initialization point (for QN) that is close to the global minimizer becomes extremely difficult.

[2]These methods are selected from a long list of candidates in MATLAB's global optimization toolbox. We report results for the methods that gave the best results for our test functions.

6 Discussion and Future Work

This paper introduced CoRR, an approach for learning a convex relaxation for a wide class of non-convex functions. The idea behind CoRR is to find an empirical estimate of the convex envelope of a function from a set of function evaluations. We demonstrate that CoRR is an efficient strategy for global optimization, both in theory and in practice. In particular, we provide theoretical results (Sec. 4) which show that CoRR is guaranteed to produce a convergent estimate of the convex envelope that exhibits polynomial dependence on the dimension. In numerical experiments (Sec. 5), we showed that CoRR provides accurate approximations to the global minimizer of multiple test functions and appears to scale well with dimension.

Our current instantiation of CoRR finds a convex surrogate for f based upon a set of samples that are drawn at random at the onset of the algorithm. In our evaluations, we draw i.i.d. samples from a uniform distribution over $\mathcal{X}$. However, the choice of the sampling distribution ρ has a significant impact on our estimation procedure. As such, selecting samples in an intelligent manner would significantly reduce the number of samples required to obtain an accurate estimate. A natural extension of CoRR is to the case where we can iteratively refine our distribution ρ based upon the output of the algorithm at previous steps.

An important factor in the success of our algorithm is the basis that we use to form our approximation. As discussed in Sec. 4.2.3, we know that a polynomial basis can be used to form a convex approximation to any convex function (Gal, 2010). However, finding a concise representation of the convex envelope using high-degree polynomials is not an easy task. Thus finding other well-suited bases for this approximation, such as the exponential basis, may improve the efficiency of CoRR by reducing the number of bases required. While outside the scope of this paper, exploring the use of constrained dictionary learning methods (Yaghoobi et al., 2009) for finding a good basis for our fitting procedure, is an interesting line for future work.

In our experiments, we observe that CoRR typically provides a good approximation to the global minimizer. However, in most cases, we do not obtain machine precision (like QN for low dimensions). Thus, we can combine CoRR with a local search method like QN by using the solution of CoRR as an initialization point for the local search. When using this hybrid approach, we obtain perfect reconstruction of the global minimum for the Salomon function for all of the dimensions we tested (Fig. 2d). This suggests that, as long the function does not fluctuate too rapidly around its global minimum (Asm. 2), CoRR can be coupled with other local search methods to quickly converge to the absolute global minimizer.

The key innovation behind CoRR is that one can efficiently

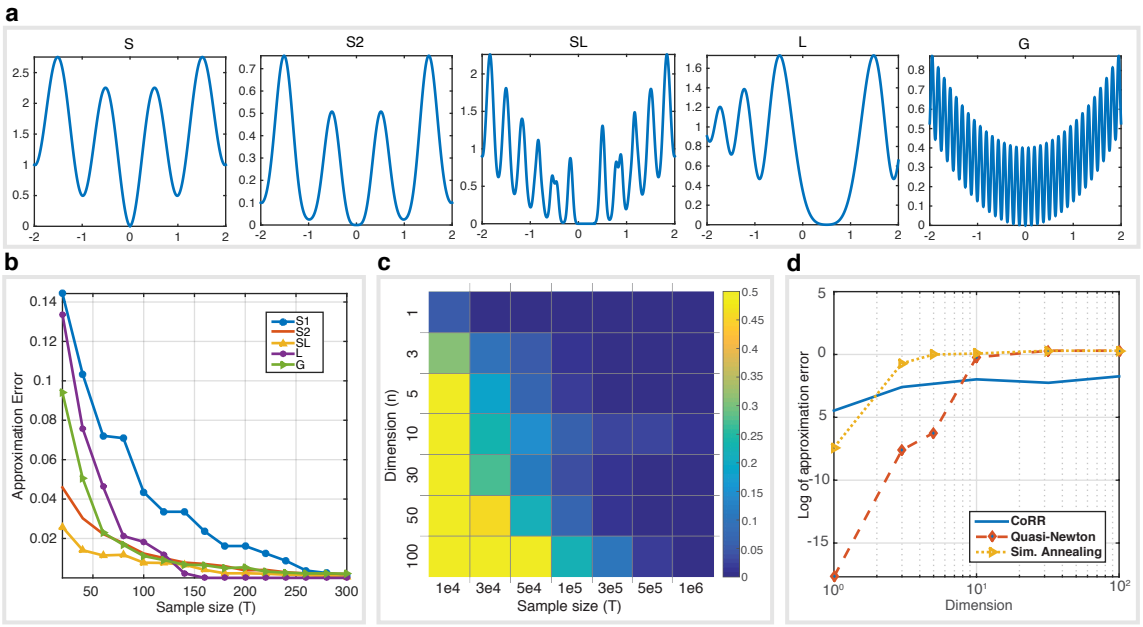

Figure 2: *Scaling behavior and performance of CoRR.* Along the top row in (a), we plot all five test functions studied in this paper. In (b), we display the mean approximation error between $f(\widehat{x}) - f^*$ as a function of the number of function evaluations T for all test functions in 1D. In (c), we display the mean approximation error as a function of the dimension and number of samples for the Salomon function. In (d), we compare CoRR's approximation error with other approaches for non-convex optimization, as we vary the dimension.

approximate the convex envelope of a non-convex function by solving a constrained regression problem which balances the approximation error with a constraint on the empirical expectation of the estimated convex surrogate. While our method could be improved by using a smart and adaptive sampling strategy, this paper provides a new way of thinking about how to relax non-convex problems. As such, our approach opens up the possibility of using the myriad of existing tools and solvers for convex optimization problems to efficiently solve non-convex problems.

Abstract

We introduce the Mondrian kernel, a fast *random feature* approximation to the Laplace kernel. It is suitable for both batch and online learning, and admits a fast kernel-width-selection procedure as the random features can be re-used efficiently for all kernel widths. The features are constructed by sampling trees via a Mondrian process [Roy and Teh, 2009], and we highlight the connection to Mondrian forests [Lakshminarayanan et al., 2014], where trees are also sampled via a Mondrian process, but fit independently. This link provides a new insight into the relationship between kernel methods and random forests.

1 INTRODUCTION

Kernel methods such as support vector machines and Gaussian processes are very popular in machine learning. While early work relied on dual optimization, recent large-scale kernel methods focus on the primal optimization problem where the input data are mapped to a finite-dimensional feature space and the weights are learned using fast linear optimization techniques, e.g., stochastic gradient descent. Rahimi and Recht [2007] proposed to approximate shift-invariant kernels by mapping the inputs to so-called *random features*, constructed so that the inner product of two mapped data points approximates the kernel evaluated at those two points (which is the inner product in the feature space corresponding to the kernel). Rahimi and Recht [2007] proposed two random feature construction schemes: *random Fourier features*, where data points are projected onto random vectors drawn from the Fourier transform of the kernel and then passed through suitable non-linearities; and *random binning*, where the input space is partitioned by a random regular grid into bins and data points are mapped to indicator vectors identifying which bins they end up in. Both of these approaches require specifying the kernel hyperparameters in advance, so that the appropriate distribution is used for sampling the random vectors or random grids, respectively. However, a suitable kernel width (length-scale) is often not known a priori and is found by cross-validation, or, where available, marginal likelihood optimization. In practice, this entails constructing a new feature space and training a linear learner from scratch for each kernel width, which is computationally expensive. Using a suitable kernel width is often more important than the choice of kernel type [Schölkopf and Smola, 2001], so a fast kernel width selection method is desirable.

We describe a connection between the Laplace kernel and the Mondrian process [Roy and Teh, 2009], and leverage it to develop a random feature approximation to the Laplace kernel that addresses the kernel width selection problem. This approximation, which we call the *Mondrian kernel*, involves random partitioning of data points using a Mondrian process, which can be efficiently reused for all kernel widths. The method preserves the nonparametric nature of kernel learning and is also suitable for online learning.

The Mondrian kernel reveals an interesting link between kernel methods and decision forests [Breiman, 2001, Criminisi et al., 2012], another popular class of nonparametric methods for black-box prediction tasks. The Mondrian kernel resembles *Mondrian forests*, a decision-forest variant introduced by Lakshminarayanan et al. [2014], where a Mondrian process is used as the randomization mechanism. The efficiently trainable Mondrian forests excel in the online setting, where their distribution is identical to the corresponding batch Mondrian forest, and have been successfully applied to both classification and regression [Lakshminarayanan et al., 2014, 2016]. Mondrian forests and the Mondrian kernel both lead to randomized, non-linear learning algorithms whose randomness stems from a Mondrian process. The former fits parameters corresponding to different Mondrian trees independently, while the latter fits them jointly. We compare these methods theoretically and thus establish a novel connection between the Laplace kernel and Mondrian forests via the Mondrian kernel.

[*]Also affiliated with Max-Planck Institute for Intelligent Systems, Tübingen, Germany.

The contributions of this paper are:

- a review of the Mondrian process using the simple notion of competing exponential clocks (Section 2);
- a novel connection between the Mondrian process and the Laplace kernel (Section 3), yielding a fast approximation to learning with the Laplace kernel;
- an efficient procedure for learning the kernel width from data (Section 4); and
- a comparison between Mondrian kernel and Mondrian forest that provides another connection between kernel learning and random forests (Section 6).

2 MONDRIAN PROCESS

For completeness, we review the Mondrian process [Roy and Teh, 2009, Roy, 2011, Chapter 5]. Although simple and perhaps well known to experts, our exposition through competing exponential clocks has not explicitly appeared in this form in the literature. Readers familiar with the Mondrian process may skip this section on first reading.

2.1 TERMINOLOGY

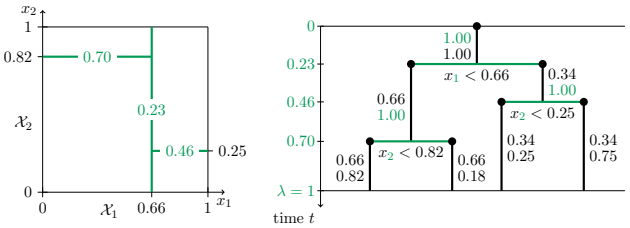
An *axis-aligned box* $\mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_D \subseteq \mathbb{R}^D$ is a Cartesian product of D bounded intervals $\mathcal{X}_d \subseteq \mathbb{R}$. Their total length $|\mathcal{X}_1| + \cdots + |\mathcal{X}_D|$ is the *linear dimension of* $\mathcal{X}$. A *guillotine partition* of $\mathcal{X}$ is a hierarchical partitioning of $\mathcal{X}$ using axis-aligned cuts. Such a partition can be naturally represented using a strictly binary tree.

An *exponential clock with rate* r takes a random time $T \sim \mathrm{Exp}(r)$ to ring after being started, where $\mathrm{Exp}(r)$ is the exponential distribution with rate (inverse mean) r. The notion of *competing exponential clocks* refers to D independent exponential clocks with rates $r_1, \ldots, r_D$, started at the same time. It can be shown that (1) the time until some clock rings has $\mathrm{Exp}(\sum r_d)$ distribution, (2) it is the d-th clock with probability proportional to r_d, and (3) once a clock rings, the remaining $D - 1$ clocks continue to run independently with their original distributions.

2.2 GENERATIVE PROCESS

The Mondrian process on an axis-aligned box $\mathcal{X} \subseteq \mathbb{R}^D$ is a time-indexed stochastic process taking values in guillotine-partitions of $\mathcal{X}$. It starts at time 0 with the trivial partition of $\mathcal{X}$ (no cuts) and as time progresses, new axis-aligned cuts randomly appear, hierarchically splitting $\mathcal{X}$ into more and more refined partitions. The process can be stopped at a lifetime $\lambda \in [0, \infty)$, which amounts to ignoring any cuts that would appear after time λ.

To describe the distribution of times and locations of new cuts as time progresses, we associate an independent exponential clock with rate $|\mathcal{X}_d|$ to each dimension d of $\mathcal{X}$. Let T be the first time when a clock rings and let d be the dimension of that clock. If $T > \lambda$ then this process terminates. Otherwise, a point a is chosen uniformly at random from $\mathcal{X}_d$ and $\mathcal{X}$ is split into $\mathcal{X}^< = \{\mathbf{x} \in \mathcal{X} \mid x_d < a\}$ and $\mathcal{X}^> = \{\mathbf{x} \in \mathcal{X} \mid x_d > a\}$ by a hyperplane in dimension d that is perpendicular to $\mathcal{X}_d$ at point a. After making this first cut, the remaining $D - 1$ clocks are discarded and the generative process restarts recursively and *independently* on $\mathcal{X}^<$ and $\mathcal{X}^>$. However, those processes start at time T rather than 0 and thus have less time left until the lifetime λ is reached.



(a) (b)

Figure 1: (a) Sample of a Mondrian process on the axis-aligned box $\mathcal{X} = [0, 1] \times [0, 1] \subseteq \mathbb{R}^2$ with lifetime $\lambda = 1.0$. Numbers on the cuts (shown in green) indicate the times when they appeared. The first cut appeared at time $T = 0.23$, in dimension $d = 1$, at location $a = 0.66 \in \mathcal{X}_1$. (b) Representing the Mondrian sample as a strictly binary tree, with new nodes (shown as circles) appearing as time (y-axis) progresses. The two numbers below each node show the rates of the two exponential clocks competing to split that node, with the winning clock's rate shown in green.

The specification of the generative process on $\mathcal{X}$ is now complete. Due to the properties of competing exponential clocks, the time until the first cut appears in $\mathcal{X}$ has exponential distribution with rate equal to the linear dimension of $\mathcal{X}$ and the dimension d in which the cut is made is chosen proportional to $|\mathcal{X}_d|$. This confirms equivalence of our generative process to the one proposed by Roy and Teh [2009]. Finally, we note that a.s. the Mondrian process does not explode, i.e., for every lifetime $\lambda \in [0, \infty)$, the process generates finitely many cuts with probability 1 [Roy, 2011].

2.3 PROJECTIVITY

If a Mondrian process runs on $\mathcal{X}$, what distribution of random partitions does it induce on an axis-aligned subbox $\mathcal{A} \subseteq \mathcal{X}$? (See Figure 2a for an illustration in $D = 2$ dimensions.) The Mondrian process was constructed so that the answer is the Mondrian process itself [Roy, 2011]. Here we explain this projectivity property using the notion of competing exponential clocks. To argue that the resulting process on $\mathcal{A}$ is indeed a Mondrian process, we show that the process running on $\mathcal{X}$ generates cuts in $\mathcal{A}$ in the same way as a Mondrian process running directly on $\mathcal{A}$ would.

Recall that each dimension d of $\mathcal{X}$ is associated with an exponential clock with rate $|\mathcal{X}_d|$ and if it rings first, the cut location is chosen uniformly at random from $\mathcal{X}_d$. This procedure can be equivalently represented using two competing clocks for each dimension (rather than just one):

- Clock $\mathcal{C}^d_{\mathcal{A}}$ with rate $|\mathcal{A}_d|$. If this clock rings first, the cut location is chosen uniformly at random from $\mathcal{A}_d$.
- Clock $\mathcal{C}^d_{\neg\mathcal{A}}$ with rate $|\mathcal{X}_d| - |\mathcal{A}_d|$. If it rings first, the cut location is sampled uniformly from $\mathcal{X}_d \setminus \mathcal{A}_d$.

(See Figure 2b.) Note that the clocks $\mathcal{C}^1_{\mathcal{A}}, \ldots, \mathcal{C}^D_{\mathcal{A}}$ represent the same cut distribution as a Mondrian process running on $\mathcal{A}$ would. If a clock $\mathcal{C}^d_{\neg\mathcal{A}}$ rings first, a cut is made outside of $\mathcal{A}$ and all of $\mathcal{A}$ remains on one side of this cut. None of the clocks $\mathcal{C}^d_{\mathcal{A}}$ have rung in that case and would usually be discarded and replaced with fresh clocks of identical rates, but by property (3) of competing exponential clocks, we can equivalently reuse these clocks (let them run) on the side of the cut containing $\mathcal{A}$. (Figure 2c shows a cut in dimension $d = 1$ that misses $\mathcal{A}$ and the reused clocks $\mathcal{C}^d_{\mathcal{A}}$). Hence, cuts outside $\mathcal{A}$ do not affect the distribution of the first cut crossing $\mathcal{A}$, and this distribution is the same as if a Mondrian process were running just on $\mathcal{A}$. When a cut is made within $\mathcal{A}$ (see Figure 2d), the process continues on both sides recursively and our argument proceeds inductively, confirming that the Mondrian process on $\mathcal{X}$ generates cuts in $\mathcal{A}$ in the same way as a Mondrian process on $\mathcal{A}$ would.

2.4 MONDRIAN PROCESS ON $\mathbb{R}^D$

The Mondrian process on $\mathbb{R}^D$ is defined implicitly as a time-indexed stochastic process such that its restriction to any axis-aligned box $\mathcal{X} \subseteq \mathbb{R}^D$ is a Mondrian process as defined in section 2.2. Fortunately, this infinite-dimensional object can be compactly represented by instantiating the Mondrian process only in regions where we have observed data. As we observe new data points, the Mondrian sample can be extended using the *conditional Mondrian* algorithm [Roy and Teh, 2009], a simple and fast sampling procedure for extending a Mondrian sample in an axis-aligned box $\mathcal{A}$ to a larger axis-aligned box $\mathcal{X} \supseteq \mathcal{A}$. The conditional Mondrian is useful for online learning and prediction, as it can be used to extend Mondrian samples to (yet) unobserved parts of the input space [Lakshminarayanan et al., 2014].

3 MONDRIAN KERNEL

For concreteness, our running example will be regression: the problem of learning a function $f : \mathbb{R}^D \to \mathbb{R}$ from a set of N training examples $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_N, y_N)$. However, the Mondrian kernel applies equally well to classification, or any other learning task.

Learning with kernels involves choosing a kernel function $k : \mathbb{R}^D \times \mathbb{R}^D \to \mathbb{R}$ to act as a similarity measure between input data points. Evaluating $k(\cdot, \cdot)$ on all pairs of N data

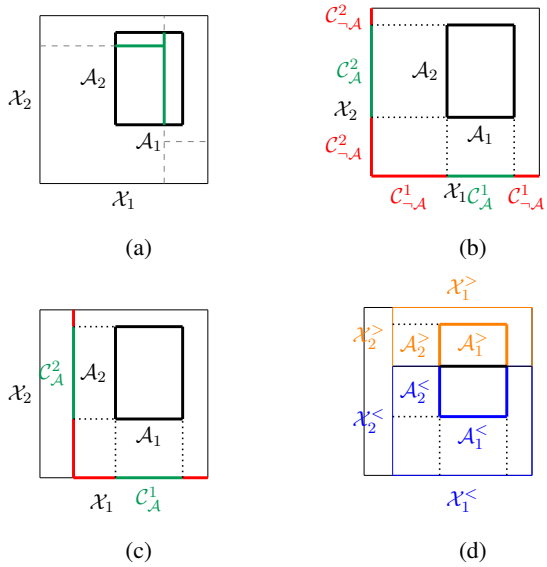


Figure 2: (a) A Mondrian process running on $\mathcal{X} = \mathcal{X}_1 \times \mathcal{X}_2$ generates cuts (dashed lines), some of which intersect $\mathcal{A} = \mathcal{A}_1 \times \mathcal{A}_2$ (green lines) and thus induces a random partition of $\mathcal{A}$. (b) Representing the first cut distribution using $2D = 4$ competing exponential clocks: in each dimension d, clock $\mathcal{C}^d_{\mathcal{A}}$ corresponds to the region where making a cut splits $\mathcal{A}$ (shown in green) and clock $\mathcal{C}^d_{\neg\mathcal{A}}$ to the (disconnected) region where making a cut misses $\mathcal{A}$ (shown in red). (c) Cut outside $\mathcal{A}$: reusing the clocks $\mathcal{C}^1_{\mathcal{A}}$, $\mathcal{C}^2_{\mathcal{A}}$ on the side of the cut containing $\mathcal{A}$. (d) Cut inside $\mathcal{A}$ (shown in black): the argument proceeds by induction on both sides.

points takes $\Omega(N^2)$ operations, with some models also requiring a $\Theta(N^3)$ operation on an $N \times N$ kernel matrix. This generally makes exact kernel methods unsuitable for large-scale learning. Rahimi and Recht [2007] proposed a fast approximation through a randomized construction of a low-dimensional feature map $\phi : \mathbb{R}^D \to \mathbb{R}^C$ such that

$$\forall \mathbf{x}, \mathbf{x}' \in \mathbb{R}^D \qquad k(\mathbf{x}, \mathbf{x}') \approx \phi(\mathbf{x})^T \phi(\mathbf{x}')$$

and then using a linear learning method in the feature space $\mathbb{R}^C$ implied by ϕ. For example, linear regression $\mathbf{y} \approx \mathbf{\Phi w}$, where $\mathbf{\Phi} \in \mathbb{R}^{N \times C}$ is the feature matrix with n-th row $\phi(\mathbf{x}_n)^T$, is solvable exactly in time linear in N. In general, the primal problem also lends itself naturally to stochastic gradient descent approaches for learning $\mathbf{w}$.

We use the Mondrian process to construct a randomized feature map for the (isotropic) *Laplace kernel*:

$$k(\mathbf{x}, \mathbf{x}') = \exp(-\lambda \|\mathbf{x} - \mathbf{x}'\|_1) = \exp(-\lambda \sum_{d=1}^{D} |x_d - x'_d|).$$

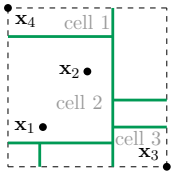
Here $\lambda \geq 0$ is the inverse kernel width (inverse length-scale), which we call the *lifetime* parameter of the kernel. We use a non-standard parametrization as this lifetime parameter will be linked to the Mondrian process lifetime.

3.1 MONDRIAN KERNEL

Consider the following randomized construction of a feature map $\phi : \mathbb{R}^D \to \mathbb{R}^C$:

1. Sample a partition of $\mathbb{R}^D$ via a Mondrian process on $\mathbb{R}^D$ with lifetime λ. Label the cells of the generated partition by $1, 2, \ldots$ in arbitrary order.
2. To encode a data point $\mathbf{x} \in \mathbb{R}^D$, look up the label c of the partion cell $\mathbf{x}$ falls into and set $\phi(\mathbf{x})$ to be the (column) indicator vector that has a single non-zero entry at position c, equal to 1.

The Mondrian process on $\mathbb{R}^D$ generates infinitely many partition cells and cannot be stored in memory, but projectivity comes to the rescue. As we only ever need to evaluate ϕ on finitely many data points, it suffices to run the Mondrian on the smallest axis-aligned box containing all these points. Also, we only label partition cells containing at least one data point, in effect removing features that would be 0 for all our data points. Then, the dimensionality C of ϕ equals the number of non-empty partiton cells and each data point has a single non-zero feature, equal to 1.



$\mathbf{x}$	$\phi(\mathbf{x})^T$
$\mathbf{x}_1$	[0 1 0]
$\mathbf{x}_2$	[0 1 0]
$\mathbf{x}_3$	[0 0 1]
$\mathbf{x}_4$	[1 0 0]

Figure 3: Feature expansions of 4 data points in $\mathbb{R}^2$.

However, note that the set of points on which the feature map ϕ is evaluated need not be known in advance and can even grow in an online fashion. Indeed, the conditional Mondrian algorithm discussed in section 2.4 allows us to extend Mondrian samples to larger boxes as necessary, and we can increase the dimensionality of ϕ whenever a data point is added to a previously empty partition cell.

This feature map ϕ induces a kernel

$$k_1(\mathbf{x}, \mathbf{x}') := \phi(\mathbf{x})^T \phi(\mathbf{x}') = \begin{cases} 1 & \text{if } \mathbf{x}, \mathbf{x}' \text{ in same partition cell} \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

which we call a *Mondrian kernel* of order 1.

Instead of using a single Mondrian sample (partition), we can use M independent samples and construct a feature map ϕ by concatenating and normalizing the feature maps $\phi^{(1)}, \ldots, \phi^{(M)}$ obtained from each individual sample as above:

$$\phi(\mathbf{x}) := \frac{1}{\sqrt{M}} \left[\phi^{(1)}(\mathbf{x})^T \quad \cdots \quad \phi^{(M)}(\mathbf{x})^T \right]^T. \tag{2}$$

This feature expansion is *sparse*: every data point has exactly M non-zero features. The corresponding kernel, which we call a *Mondrian kernel of order* M, is

$$k_M(\mathbf{x}, \mathbf{x}') := \phi(\mathbf{x})^T \phi(\mathbf{x}') = \frac{1}{M} \sum_{m=1}^{M} \phi^{(m)}(\mathbf{x})^T \phi^{(m)}(\mathbf{x}').$$

This is the empirical frequency with which points $\mathbf{x}$ and $\mathbf{x}'$ end up in the same partition cell of a Mondrian sample.

Algorithm 1 Mondrian kernel

1: **for** $m = 1$ **to** M **do**
2: construct feature map $\phi^{(m)}$ ▷ *section 3.1*
3: join and rescale $\phi^{(1)}, \ldots, \phi^{(M)}$ into ϕ ▷ *equation (2)*
4: map data $\mathbf{X}$ to feature representations $\mathbf{\Phi}$ using ϕ
5: use linear learning method on $\mathbf{\Phi}$

3.2 MONDRIAN–LAPLACE LINK

By independence of the M Mondrian samples, a.s.

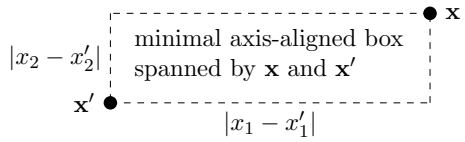
$$\lim_{M \to \infty} k_M(\mathbf{x}, \mathbf{x}') = \mathbb{E}\left[\phi^{(1)}(\mathbf{x})^T \phi^{(1)}(\mathbf{x}') \right] = \mathbb{E}\left[k_1(\mathbf{x}, \mathbf{x}') \right]$$

with convergence at the standard rate $\mathcal{O}_p(M^{-1/2})$. We thus define the *Mondrian kernel of order* ∞ as

$$k_\infty(\mathbf{x}, \mathbf{x}') := \mathbb{E}[k_1(\mathbf{x}, \mathbf{x}')].$$

Proposition 1 (Mondrian-Laplace link)**.** *The Mondrian kernel of order* ∞ *coincides with the Laplace kernel.*

Proof. As $k_1(\mathbf{x}, \mathbf{x}')$ (defined in (1)) is a binary random variable, $k_\infty(\mathbf{x}, \mathbf{x}')$ equals the probability that $\mathbf{x}$ and $\mathbf{x}'$ fall into the same partition cell of a Mondrian sample, which is equivalent to the sample having no cut in the minimal axis-aligned box spanned by $\mathbf{x}$ and $\mathbf{x}'$.



By projectivity, this probability is the same as the probability of not observing any cuts in a Mondrian process with lifetime λ running on just this minimal box. Noting that the linear dimension of this box is $\|\mathbf{x} - \mathbf{x}'\|_1$, we obtain

$$\begin{aligned} k_\infty(\mathbf{x}, \mathbf{x}') &= \mathbb{P}(\text{no cut between } \mathbf{x}, \mathbf{x}' \text{ until time } \lambda) \\ &= \mathbb{P}\left(T > \lambda\right) \text{ where } T \sim \text{Exp}\left(\|\mathbf{x} - \mathbf{x}'\|_1\right) \\ &= e^{-\lambda \|\mathbf{x} - \mathbf{x}'\|_1}. \end{aligned}$$

□

Note that the lifetime (inverse width) λ of the Laplace kernel corresponds to the lifetime of the Mondrian process used in the construction of the Mondrian kernel.

This link allows us to approximate the Laplace kernel with a Mondrian kernel k_M, which, unlike the Laplace kernel, admits a finite-dimensional feature expansion. The finite order M trades off kernel approximation error and computational costs (indirectly through the complexity of ϕ).

The following result confirms that the convergence of the Mondrian kernel approximation is exponentially fast in M *uniformly* on any fixed bounded input domain $\mathcal{X}$.

Proposition 2. *For any bounded input domain $\mathcal{X} \subseteq \mathbb{R}^D$ and $\delta > 0$, as $M \to \infty$,*

$$\mathbb{P}\left[\sup_{\mathbf{x},\mathbf{x}' \in \mathcal{X}} |k_M(\mathbf{x},\mathbf{x}') - k_\infty(\mathbf{x},\mathbf{x}')| > \delta\right] = \mathcal{O}\left(M^{2/3} e^{-M\delta^2/(12D+2)}\right).$$

Proof. Given in Supplement A. □

4 FAST KERNEL WIDTH LEARNING

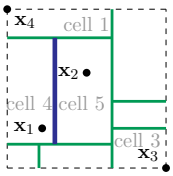
This section discusses the main advantage of our Mondrian approximation to the Laplace kernel: the efficient learning of kernel width from data. In particular, the approximation allows for efficient evaluation of all kernel lifetimes (inverse widths) $\lambda \in [0, \Lambda]$, where the terminal lifetime $\Lambda > 0$ need not be fixed a priori.

4.1 FEATURE SPACE REUSAL

We make the following recollections from earlier sections:

- the Mondrian process runs through time, starting at time 0 and only refining the generated partition as time progresses (cuts are never removed)
- the Mondrian process with lifetime λ is obtained by ignoring any cuts that would occur after time λ
- the lifetime λ of the Mondrian process used in constructing an explicit feature map ϕ for a Mondrian kernel corresponds to the lifetime (inverse width) of the Laplace kernel that it approximates

Running the Mondrian process from time 0 to some terminal lifetime Λ thus sweeps through feature spaces approximating all Laplace kernels with lifetimes $\lambda \in [0, \Lambda]$. More concretely, we start with $\lambda = 0$ and ϕ the feature map corresponding to M trivial partitions, i.e., for any data point $\mathbf{x}$, the vector $\phi(\mathbf{x})$ has length M and all entries set to the normalizer $M^{-1/2}$. As we increase λ, at discrete time points new cuts appear in the M Mondrian samples used in constructing ϕ. Suppose that at some time λ, the partition cell corresponding to the c-th feature in ϕ is split into two by a new cut that first appeared at this time λ. We update the feature map ϕ by removing the c-th feature and appending two new features, one for each partition cell created by the split. See Figure 4 for an example with $M = 1$.



$\mathbf{x}$	$\phi(\mathbf{x})^T$
$\mathbf{x}_1$	[0 *1* 0 **1** **0**]
$\mathbf{x}_2$	[0 *1* 0 **0** **1**]
$\mathbf{x}_3$	[0 *0* 1 **0** **0**]
$\mathbf{x}_4$	[1 *0* 0 **0** **0**]

Figure 4: A new cut (shown in thick blue) appeared, splitting cell $c = 2$ (cf. Figure 3) into two new cells $c = 4$ and $c = 5$. The table shows the update to ϕ, with the removed feature in gray italics and the two new features in bold blue.

This procedure allows us to approximate all Laplace kernels with lifetimes $\lambda \in [0, \Lambda]$ without having to resample new feature spaces for each lifetime. The total computational cost is the same (up to a multiplicative constant) as of constructing a single feature space just for the terminal lifetime Λ. This is because a strictly binary tree with $C^{(m)}$ leaves (partition cells in the m-th Mondrian sample at time Λ) contains at most $C^{(m)} - 1$ internal nodes (features that had to be removed at some time point $\lambda < \Lambda$).

4.2 LINEAR LEARNER RETRAINING

Evaluating suitability of a lifetime (inverse kernel width) λ requires training and evaluating a linear model in the feature space implied by ϕ. This can also be done more efficiently than retraining a new model from scratch every time a new cut is added and ϕ updated. We discuss the example of ridge regression with exact solutions, and a general case of models trainable using gradient descent methods.

4.2.1 Ridge regression

The MAP weights of the primal ridge regression problem are $\hat{\mathbf{w}} = \mathbf{A}^{-1}\mathbf{\Phi}^T\mathbf{y}$, where $\mathbf{A} := (\mathbf{\Phi}^T\mathbf{\Phi} + \delta^2\mathbf{I}_C)$ is the regularized feature covariance matrix and δ^2 is the regularization hyperparameter. Instead of inverting $\mathbf{A}$, it is numerically more stable to work with its Cholesky factor $\mathrm{chol}(\mathbf{A})$ [Seeger, 2003]. Phrasing the problem as Bayesian linear regression with, say, observation noise variance $\sigma_y^2 = \delta^2$ and prior weights variance $\sigma_w^2 = 1$, we can also obtain the log marginal likelihood $\mathcal{L}(\lambda)$ of the form

$$\mathcal{L}(\lambda) = -\frac{\|\mathbf{y} - \mathbf{\Phi}\hat{\mathbf{w}}\|_2^2}{2\delta^2} - \frac{\|\hat{\mathbf{w}}\|_2^2}{2} - \frac{1}{2}\ln\det\mathbf{A} + \text{const},$$

where the dependence on λ is implicit through ϕ.

When a new cut appears in one of the M Mondrian samples and ϕ is updated by deleting the c-th feature and appending two new ones, the corresponding update to the regularized feature covariance matrix $\mathbf{A}$ is to delete its c-th row and c-th column, and append two new rows and columns. Then both $\mathbf{A}^{-1}$ and $\mathrm{chol}(\mathbf{A})$ can be appropriately updated in $\mathcal{O}(C^2)$ time, faster than $\mathcal{O}(C^3)$ recomputation from scratch. Updating the Cholesky factor when the c-th row and column

are removed is slightly involved but can be achieved by first permuting the rows and columns so that the ones to be removed are the last ones [Seeger, 2004], after which the Cholesky factor is updated by deleting its last row and column. If C is the number of features at the terminal lifetime Λ, this $\mathcal{O}(C^2)$ update is performed $\mathcal{O}(C)$ times, for a total computational cost $\mathcal{O}(C^3)$. Note that performing the inversion or Cholesky factorization at just the terminal lifetime Λ would have the same time complexity.

After updating $\mathbf{A}^{-1}$ or $\mathrm{chol}(\mathbf{A})$, the optimal weights $\hat{\mathbf{w}}$ can be updated in $\mathcal{O}(C^2 + N)$ time and the determinant of $\mathbf{A}$ required for the marginal likelihood $\mathcal{L}(\lambda)$ can be obtained from $\mathrm{chol}(\mathbf{A})$ as the squared product of its diagonal elements in $\mathcal{O}(C)$ time. Exploiting sparsity of ϕ, evaluating the model on N_{test} data points takes $\mathcal{O}(N_{\text{test}}M)$ time.

Finally, we note that computing the marginal likelihood $\mathcal{L}(\lambda)$ for all $\lambda \in [0, \Lambda]$ and combining it with a prior $p(\lambda)$ supported on $[0, \Lambda]$ allows Bayesian inference over the kernel width λ^{-1}. We refer to Supplement B for more details.

4.2.2 Models trainable using gradient descent

Consider a linear model trained using a gradient descent method. If (an approximation to) the optimal weight vector $\mathbf{w}$ is available and then ϕ is updated by removing the c-th feature and appending two new features, a natural way of reinitializing the weights for subsequent gradient descent iterations is to remove the c-th entry of $\mathbf{w}$ and append two new entries, both set to the removed value (as points in the split cell are partitioned into the two new cells, this preserves all model predictions). Note that we have the freedom of choosing the number of gradient descent iterations after each cut is added, and we can opt to only evaluate the model (on a validation set, say) at several λ values on the first pass through $[0, \Lambda]$. One iteration of stochastic gradient descent takes $O(M)$ time thanks to sparsity of ϕ.

This efficient kernel width selection procedure can be especially useful with models where hyperparameters cannot be tweaked by marginal likelihood optimization (e.g., SVM).

5 ONLINE LEARNING

In this section, we describe how the Mondrian kernel can be used for online learning. When a new data point $\mathbf{x}_{N+1} \in \mathbb{R}^D$ arrives, incorporating it into M existing Mondrian samples (using the conditional Mondrian algorithm discussed in section 2.4) can create $0 \leq k \leq M$ new non-empty partition cells, increasing the dimensionality of the feature map ϕ. We set the new features to 0 for all previous data points $\mathbf{x}_1, \ldots, \mathbf{x}_N$.

In our running example of ridge regression, exact primal updates can again be carried out efficiently. The inverse $\mathbf{A}^{-1}$ or Cholesky factor $\mathrm{chol}(\mathbf{A})$ of the regularized feature covariance matrix $\mathbf{A}$ can be updated in two steps:

1. extend $\mathbf{A}^{-1}$ or $\mathrm{chol}(\mathbf{A})$ to incorporate the k new features (set to 0 for all existing data points) in $\mathcal{O}(C^2)$
2. incorporate the new data point $\mathbf{x}_{N+1}$, which is now a simple rank-1 update on $\mathbf{A}$, so $\mathbf{A}^{-1}$ or $\mathrm{chol}(\mathbf{A})$ can again be updated efficiently in $\mathcal{O}(C^2)$ time

We refer to Supplement C for more details.

With gradient descent trainable models, we maintain (an approximation to) the optimal weights $\mathbf{w}$ directly. When a new data point arrives, we expand the dimensionality of ϕ as described above. The previously optimal weights can be padded with 0's in any newly added dimensions, and then passed to the gradient descent method as initialization.

6 LINK TO MONDRIAN FOREST

We contrast Mondrian kernel with Mondrian forest [Lakshminarayanan et al., 2014, 2016], another non-linear learning method based on the Mondrian process. They both start by sampling M independent Mondrians on $\mathbb{R}^D$ to provide M independent partitions of the data. However, these partitions are then used differently in the two models:

- In a Mondrian forest, parameters of predictive distributions in each tree are fitted independently of all other trees. The prediction of the forest is the average prediction among the M trees.
- With Mondrian kernel, the weights of all random features are fitted jointly by a linear learning method.

Let $C^{(m)}$ count the leaves (non-empty partition cells) in the m-th Mondrian sample and let $C = \sum_{m=1}^{M} C^{(m)}$ be the total number of leaves. Let $\boldsymbol{\phi}_n^{(m)} := \phi^{(m)}(\mathbf{x}_n) \in \mathbb{R}^{C^{(m)}}$ be the indicator of the partition cell in the m-th sample into which the n-th data point falls (as in section 3.1). Also, as in equation (2), let $\boldsymbol{\phi}_n := \phi(\mathbf{x}_n) \in \mathbb{R}^C$ be the normalized concatenated feature encoding of the n-th data point. Recall that each vector $\boldsymbol{\phi}_n \in \mathbb{R}^C$ contains exactly M nonzero entries, all of which equal the normalizer $M^{-1/2}$.

For simplicity, we restrict our attention to ridge regression in this section and compare the learning objective functions of Mondrian kernel and Mondrian forest.

6.1 MONDRIAN KERNEL OBJECTIVE

The primal ridge regression problem in the feature space implied by ϕ is

$$\min_{\mathbf{w} \in \mathbb{R}^C} \sum_{n=1}^{N} (y_n - \mathbf{w}^T \boldsymbol{\phi}_n)^2 + \delta^2 \|\mathbf{w}\|_2^2.$$

Decomposing $\mathbf{w} = M^{-1/2}[\mathbf{w}^{(1)T} \cdots \mathbf{w}^{(M)T}]^T$, so that each (rescaled) subvector $\mathbf{w}^{(m)}$ corresponds to features from the m-th Mondrian, denoting by $\hat{y}_n^{(m)} := \mathbf{w}^{(m)T} \boldsymbol{\phi}_n^{(m)}$

the "contribution" of the m-th Mondrian to the prediction at the n-th data point, and writing $\text{loss}(y, \hat{y}) := (y - \hat{y})^2$, the Mondrian kernel objective function can be restated as

$$\min_{\mathbf{w}\in\mathbb{R}^C} \sum_{n=1}^{N} \text{loss}\left(y_n, \frac{1}{M}\sum_{m=1}^{M} \hat{y}_n^{(m)}\right) + \delta^2\|\mathbf{w}\|_2^2. \quad (3)$$

6.2 MONDRIAN FOREST OBJECTIVE

Assuming a factorizing Gaussian prior over the leaves in each Mondrian tree (i.e., without the hierarchical smoothing used by Lakshminarayanan et al. [2016]), the predictive mean parameters $\mathbf{w}^{(m)}$ in the leaves of the m-th Mondrian tree are fitted by minimizing

$$\min_{\mathbf{w}^{(m)}\in\mathbb{R}^{C^{(m)}}} \sum_{n=1}^{N} (y_n - \mathbf{w}^{(m)T}\boldsymbol{\phi}_n^{(m)})^2 + \gamma^2\|\mathbf{w}^{(m)}\|_2^2$$

where γ^2 is the ratio of noise and prior variance in the predictive model. The parameters $\mathbf{w}^{(m)}$ are disjoint for different trees, so these M independent optimization problems are equivalent to minimizing the average of the M individual objectives. Writing $\hat{y}_n^{(m)} := \mathbf{w}^{(m)T}\boldsymbol{\phi}_n^{(m)}$ for the m-th tree's prediction at the n-th data point and concatenating the parameters $\mathbf{w} := M^{-1/2}[\mathbf{w}^{(1)T} \cdots \mathbf{w}^{(M)T}]^T$, the Mondrian forest objective can be stated as

$$\min_{\mathbf{w}\in\mathbb{R}^C} \sum_{n=1}^{N} \frac{1}{M}\sum_{m=1}^{M} \text{loss}(y_n, \hat{y}_n^{(m)}) + \gamma^2\|\mathbf{w}\|_2^2. \quad (4)$$

6.3 DISCUSSION

Comparing (3) and (4), we see that subject to regularization parameters (priors) chosen compatibly, the two objectives only differ in the contribution of an individual data point n to the total loss:

$$\text{Mondrian kernel:} \quad \text{loss}\left(y_n, \frac{1}{M}\sum_{m=1}^{M} \hat{y}_n^{(m)}\right)$$

$$\text{Mondrian forest:} \quad \frac{1}{M}\sum_{m=1}^{M} \text{loss}(y_n, \hat{y}_n^{(m)})$$

Specifically, the difference is in the order in which the averaging $\frac{1}{M}\sum_{m=1}^{M}$ over Mondrian samples/trees and the nonlinear loss function are applied. In both models predictions are given by $\hat{y} = \frac{1}{M}\sum_{m=1}^{M} \hat{y}^{(m)}$, so the Mondrian kernel objective is consistent with the aim of minimizing empirical loss on the training data, while the forest objective minimizes average loss across trees, not the loss of the actual prediction (when $M > 1$) [Ren et al., 2015].

Ren et al. [2015] address this inconsistency between learning and prediction by proposing to extend random forests with a *global refinement* step that optimizes all tree parameters jointly, minimizing the empirical training loss. Our approximation of the Laplace kernel via the Mondrian kernel can be interpreted as implementing this joint parameter fitting step on top of Mondrian forest, revealing a new connection between random forests and kernel methods.

7 RELATED WORK

The idea of Rahimi and Recht [2007] to approximate shift-invariant kernels by constructing random features has been further developed by Le et al. [2013] and Yang et al. [2015], providing a faster method of constructing the random features when the input dimension D is high. The fast method of Dai et al. [2014] can adapt the number of random features, making it better-suited for streaming data. To the best of our knowledge, these methods require random features to be reconstructed from scratch for each new kernel width value; however, our solution allows us to efficiently learn this hyperparameter for the Laplace kernel.

Decision forests are popular for black-box classification and regression thanks to their competitive accuracy and computational efficiency. The most popular variants are Breiman's Random Forest [Breiman, 2001] and Extremely Randomized Trees [Geurts et al., 2006]. Breiman [2000] established a link between the Laplace kernel and random forests with an infinite number of trees, but unlike our work, made two additional strong assumptions, namely infinite data and a uniform distribution of features. From a computational perspective, Shen et al. [2006] approximated evaluation of an isotropic kernel using kd-trees, reducing computational complexity as well as memory requirements. Davies and Ghahramani [2014] constructed 'supervised' kernels using random forests and demonstrated that this can lead to linear-time inference. We refer to [Scornet, 2015] for a recent discussion on the connection between decision forests and kernel methods.

A key difference between decision forests and kernel methods is whether parameters are fit independently or jointly. In decision forests, the leaf node parameters for each tree are fit independently, whereas the weights of random features are fit jointly. Scornet [2015] shows that random forests can be interpreted as adaptive kernel estimates and discusses the theoretical properties of fitting parameters jointly. Ren et al. [2015] propose to extend random forests with a *global refinement* step, optimizing all tree parameters jointly to minimize empirical training loss.

The proposed Mondrian kernel establishes a link between Mondrian trees and Laplace kernel for finite data, without any assumptions on the distribution of the features. Unlike prior work, we exploit this connection to construct an adaptive random feature approximation and efficiently learn the kernel width.

8 EXPERIMENTS

We conducted three sets of experiments, with these goals:

1. verify that Mondrian kernel approximates the Laplace kernel, and compare to other random feature generation schemes (Section 8.1);
2. demonstrate usefulness of our efficient kernel width selection procedure, showing that it can quickly learn a suitable kernel width from data (Section 8.2); and
3. empirically compare the Mondrian kernel and Mondrian forests, supporting the insight into their relationship from Section 6 (Section 8.3).

With the exception of two experiments on synthetic data, we carried out our evaluation on the CPU dataset from [Rahimi and Recht, 2007], containing $N = 6554$ training and $N_{\text{test}} = 819$ test points with $D = 21$ attributes. Note that the CPU dataset is an adversarial choice here, as Rahimi and Recht [2007] report that random Fourier features perform better than binning schemes on this task. In all experiments, the ridge regularization constant was set to $\delta^2 = 10^{-4}$, the value used by Rahimi and Recht [2007], and the primal optimization problems were solved using stochastic gradient descent.

8.1 LAPLACE KERNEL APPROXIMATION

First we examined the absolute kernel approximation error $|k_\infty(\cdot,\cdot) - k_M(\cdot,\cdot)|$ directly. To this end, we sampled $N = 100$ data points uniformly at random in the unit square $[0,1]^2$ and computed the maximum absolute error over all N^2 pairs of points. The Laplace kernel k_∞ and Mondrian kernels k_M had a common lifetime (inverse width) $\lambda = 10$, so that several widths fit into the input domain $[0,1]^2$. We repeated the experiment 5 times for each value of M, showing the results in Figure 5. We plot the maximum error against the number M of non-zero features per data point, which is relevant for solvers such as Pegasos SVM [Shalev-Shwartz et al., 2007], whose running time scales with the number of non-zero features per data point. Under this metric, the Mondrian kernel and Random binning converged to the Laplace kernel faster than random Fourier features, showing that in some cases they can be a useful option. (The error of Random Fourier features would decrease faster when measured against the *total* number of features, as Mondrian kernel and Random binning generate sparse feature expansions.)

Second, we examined the approximation error indirectly via test set error on the CPU dataset. We repeated the experiment 5 times for each value of M and show the results in Figure 6. Even though Fourier features are better suited to this task, for a fast approximation with few ($M < 15$) non-zero features per data point, random binning and Mondrian kernel are still able to outperform the Fourier features.

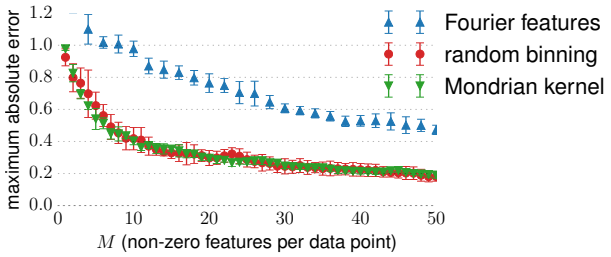


Figure 5: Maximum absolute kernel approximation error on all pairs of $N = 100$ data points in $[0,1]^2$.

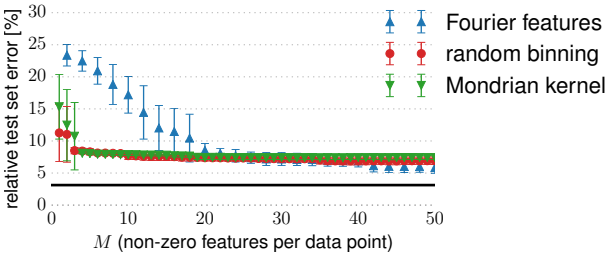

Figure 6: Test set error on the CPU dataset. The horizontal line at 3.1% indicates the error achieved with an exact, but expensive computation using the Laplace kernel.

8.2 FAST KERNEL WIDTH LEARNING

First, using a synthetic regression dataset generated from a Laplace kernel with known ground truth lifetime $\lambda_0 = 10$, we verified that the lifetime could be recovered using our kernel width selection procedure from Section 4. To this end, we let the procedure run until a terminal lifetime $\Lambda = 100$ and plotted the error on a held-out validation set as a function of the lifetime λ. The result in Figure 7 shows that the ground truth kernel lifetime $\lambda_0 = 10$ was recovered within an order of magnitude by selecting the lifetime $\hat{\lambda}$ minimizing validation set error. Moreover, this value of $\hat{\lambda}$ led to excellent performance on an independent test set.

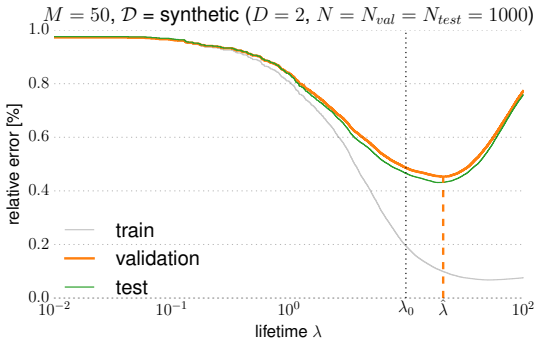

Figure 7: Recovering the ground truth lifetime $\lambda_0 = 10$ by selecting the value $\hat{\lambda} \approx 19$ minimizing validation set error.

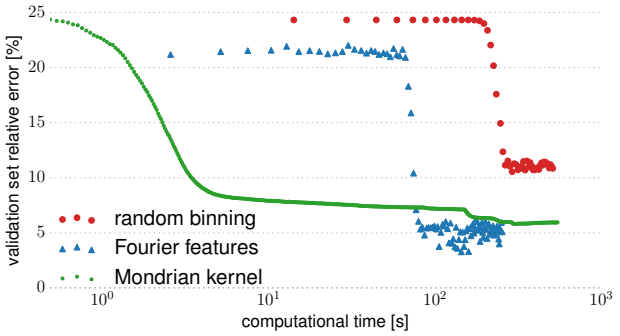

Figure 8: Validation set error as a function of computation time. Even though Fourier features are better suited to the CPU dataset [Rahimi and Recht, 2007] and eventually outperform the Mondrian kernel, the latter discovers suitable kernel widths at least an order of magnitude faster.

Second, we evaluated our kernel width selection procedure on the CPU dataset in order to demonstrate its practical usefulness. While the Mondrian kernel allows to efficiently sweep through lifetimes λ, Fourier features and random binning need to be reconstructed and retrained for each attempted lifetime value. We started the Fourier features and random binning at $\lambda = 1$, and in each step, we either doubled the maximum lifetime or halved the minimum lifetime considered so far, based on which direction seemed more promising. Once a good performing lifetime was found, we further optimized using a binary search procedure. All schemes were set to generate $M = 350$ non-zero features per datapoint. Figure 8 shows the performance of each scheme on a held-out validation set as a function of computation time. The result suggests that our kernel width learning procedure can be used to discover suitable lifetimes (inverse kernel widths) at least an order of magnitude faster than random Fourier features or random binning.

8.3 MONDRIAN KERNEL VS FOREST

We compared the performance of Mondrian kernel and "Mondrian forest" (quotes due to omission of hierarchical smoothing) based on the same $M = 50$ Mondrian samples, using the CPU dataset and varying the lifetime λ. Recall that higher values of λ lead to more refined Mondrian partitions, allowing more structure in the data to be modeled, but also increasing the risk of overfitting. Figure 9 shows that Mondrian kernel exploits the joint fitting of parameters corresponding to different trees and achieves a lower test error at lower lifetime values, thus producing a more compact solution based on simpler partitions. Figure 10 shows the parameter values learned by Mondrian kernel and Mondrian forest at the lifetime $\lambda = 2 \times 10^{-6}$. The distribution of weights learned by Mondrian kernel is more peaked around 0, as the joint fiting allows achieving more extreme predictions by adding together several smaller weights.

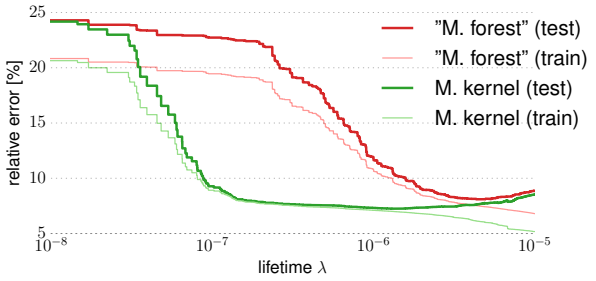

Figure 9: Comparison of Mondrian kernel and Mondrian forest models based on the same set of Mondrian samples.

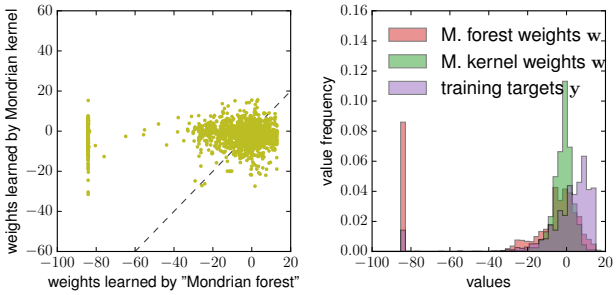

Figure 10: Weights learned by Mondrian forest and Mondrian kernel at the lifetime $\lambda = 2 \times 10^{-6}$ in Figure 9.

9 CONCLUSION

We presented the Mondrian kernel, a fast approximation to the Laplace kernel that admits efficient kernel width selection. When a different kernel or a different approximation is used, our procedure can provide a fast and simple way of initializing the kernel width for further optimization. While a Gaussian kernel is often considered a default choice, in many situations it imposes an inappropriately strong smoothness assumption on the modelled function and the Laplace kernel may in fact be a preferable option.

Our approach revealed a novel link between the Mondrian process and the Laplace kernel. We leave the discovery of similar links involving other kernels for future work.

Sequential Nonparametric Testing with the Law of the Iterated Logarithm

Akshay Balsubramani
University of California, San Diego

Aaditya Ramdas
University of California, Berkeley

Abstract

We propose a new algorithmic framework for sequential hypothesis testing with i.i.d. data, which includes A/B testing, nonparametric two-sample testing, and independence testing as special cases. It is novel in several ways: (a) it takes linear time and constant space to compute on the fly, (b) it has the same power guarantee (up to a small factor) as a non-sequential version of the test with the same computational constraints, and (c) it accesses only as many samples as are required – its stopping time adapts to the unknown difficulty of the problem. All our test statistics are constructed to be zero-mean martingales under the null hypothesis, and the rejection threshold is governed by a uniform non-asymptotic law of the iterated logarithm (LIL). For nonparametric two-sample mean testing, we also provide a finite-sample power analysis, and the first non-asymptotic stopping time analysis for this class of problems. We verify our predictions for type I and II errors and stopping times using simulations.

1 INTRODUCTION

Nonparametric statistical decision theory poses the problem of making a decision between a null (H_0) and alternate (H_1) hypothesis over a dataset with the aim of controlling both false positives and false negatives (in statistics terms, maximizing power while controlling type I error), all without making assumptions about the distribution of the data being analyzed. Such hypothesis testing is based on a "stochastic proof by contradiction" – the null hypothesis is thought of by default to be true, and is rejected only if the observed data are statistically very unlikely under the null.

There is increasing interest in solving such problems in a "big data" regime, in which the sample size N can be huge. We present a sequential testing framework for these problems that is particularly suitable for two related scenarios prevalent in many applications:

1) The dataset is extremely large and high-dimensional, so even a single pass through it is prohibitive.
2) The data is arriving as a stream, and decisions must be made with minimal storage.

Sequential tests have long been considered strong in such settings. Such a test accesses the data in an online/streaming fashion, assessing after every new datapoint whether it *then* has enough evidence to reject the null hypothesis. However, prior work tends to be univariate or parametric or asymptotic, while we are the first to provide non-asymptotic guarantees on multivariate nonparametric problems.

To elaborate on our motivations, suppose we have a gigantic amount of data from each of two unknown distributions, enough to detect even a minute difference in their means $\mu_1 - \mu_2$ if it exists. Further suppose that, unknown to us, deciding whether the means are equal is actually statistically easy ($|\mu_1 - \mu_2|$ is large), meaning that one can conclude $\mu_1 \neq \mu_2$ with high confidence by just considering a tiny fraction of the dataset. Can we take advantage of this, despite our ignorance of it?

A naive solution would be to discard most of the data and run a batch (offline) test on a small subset. However, we do not know how hard the problem is, and hence do not know how large a subset will suffice — sampling too little data might lead to incorrectly not rejecting the null, and sampling too much would unnecessarily waste computational resources. If we somehow knew $\mu_1 - \mu_2$, we would want to choose the fewest number of samples (say n^*) to reject the null while controlling type I error at some target level.

1.1 OVERVIEW OF OUR APPROACH

Our sequential test solves the problem by automatically stopping after seeing about n^* samples, while still controlling type I and II errors almost as well as the equivalent linear-time batch test. Without knowing the true problem difficulty, we are able to detect it with virtually no computational or statistical penalty. We devise and formally analyze a sequential algorithm for a variety of problems, starting with a basic test of the bias of a coin, and developing this to nonparametric two-sample mean testing, with further extensions to general nonparametric two-sample and independence testing.

Our proposed procedure only keeps track of a single scalar test statistic, which we construct to be a zero-mean random walk under the null hypothesis. It is used to test the null hypothesis each time a new data point is processed. A major statistical issue is dealing with the apparent multiple hypothesis testing problem – if our algorithm observes its first rejection of the null at time t, it might raise suspicions of being a false rejection, because $t-1$ hypothesis tests were already conducted and the t-th may have been rejected purely by chance. Applying some kind of multiple testing correction, like the Bonferroni or Benjamini-Hochberg procedure, is exceedingly conservative and produces very suboptimal results over a large number of tests. However, since the random walk moves only a relatively small amount every iteration, the tests are far from independent.

Formalizing this intuition requires adapting a classical probability result, the law of the iterated logarithm (LIL), with which we control for type I error (when H_0 is true). The LIL can be described as follows. Imagine tossing a fair coin, assigning $+1$ to heads and -1 to tails, and keeping track of the sum S_t of t coin flips. The LIL asserts that asymptotically, S_t always remains bounded between $\pm\sqrt{2t \ln \ln t}$ (and this "envelope" is tight).

When H_1 is true, we prove that the sequential algorithm does not need the whole dataset as a batch algorithm would, but automatically stops after processing just "enough" data points to detect H_1, depending on the unknown difficulty of the problem being solved. The near-optimal nature of this adaptive type II error control (when H_1 is true) is again due to the remarkable LIL.

As alluded to earlier, all of our test statistics can be thought of as random walks, which behave like S_t under H_0. The LIL then characterizes how such a random walk behaves under H_0 – our algorithm will keep observing new data since the random walk values will simply bounce around within the LIL envelope. Under H_1, the random walk is designed to have nonzero mean, and hence will eventually stray outside the LIL envelope, at which point the process stops and rejects the null hypothesis.

For practically applying this argument to finite samples and reasoning about type II error and stopping times, we cannot use the classical asymptotic form of the LIL typically stated in textbooks such as Feller (1950), instead adapting a finite-time extension of the LIL by Balsubramani (2015). As we will see, the technical contribution is necessary to investigate the stopping time, and control type I and II errors non-asymptotically *and* uniformly over all t.

In summary, our sequential testing framework has the following properties:

(A) Under H_0, it controls type I error, using a finite-time LIL computable in terms of empirical variance.
(B) Under H_1, and with type II error controlled at a target level, it automatically stops after seeing the same number of points as the corresponding computationally-constrained oracle batch algorithm.
(C) Each update takes $O(d)$ time and constant memory.

In later sections, we develop formal versions of these statements. The statistical observations, particularly the stopping time, follow from the finite-time LIL through simple concentration of measure arguments that extend to very general sequential testing settings, but have seemingly remained unobserved in the literature for decades because of the finite-time LIL necessary to make them.

We begin by describing a sequential test for the bias of a coin in Section 2. We then provide a sequential test for nonparametric two-sample *mean* testing in Section 3. We run extensive simulations in Section 4 to bear out predictions of our theory, followed by a comparison to the extensive existing literature on the subject. We also include extensions to general nonparametric two-sample and independence testing problems, in the appendices. All proofs (and code for experiments) are deferred to the full version (Balsubramani and Ramdas (2015)).

2 DETECTING THE BIAS OF A COIN

This section will illustrate how a simple sequential test can perform statistically as well as the best batch test in hindsight, while automatically stopping essentially as soon as possible. We will show that such early stopping can be viewed as quite a general consequence of concentration of measure. Just for this section, let K represent a constant that may take different values on each appearance, but is always absolute.

Consider observing i.i.d. binary flips $A_1, A_2, \cdots \in \{-1, +1\}$ of a coin, which may be fair or biased towards

1: Fix N and compute p_N
2: **if** $S_N > p_N$ **then**
3: Reject H_0
4: **else**
5: Fail to reject H_0

1: Fix N
2: **for** $n = 1$ **to** N **do**
3: Compute q_n
4: **if** $S_n > q_n$ **then**
5: Reject H_0 and return
6: Fail to reject H_0

Figure 1: Batch (left) and sequential (right) tests.

$+1$, with $P(A_i = +1) = \rho$. We want to test for fairness, detecting unfairness as soon as possible. Formulated as a hypothesis test, we wish to test, for $\delta \in (0, \frac{1}{2}]$:

$$H_0 : \ \rho = \frac{1}{2} \quad \text{vs.} \quad H_1(\delta) : \ \rho = \frac{1}{2} + \delta$$

For any sample size n, the natural test statistic for this problem is $S_n = \sum_{i=1}^{n} A_i$. S_n is a (scaled) simple mean-zero random walk under H_0. A standard hypothesis testing approach to our problem is a basic *batch* test involving S_N, which tests for deviations from the null for a fixed sample size N (Fig. 1, left). A basic Hoeffding bound shows that

$$S_N \leq \sqrt{\frac{N}{2} \ln \frac{1}{\alpha}} =: p_N$$

with probability $\geq 1 - \alpha$ under the null, so type I error is controlled at level α :

$$P_{H_0}(\text{reject } H_0) = P_{H_0}(S_N > p_N) \leq e^{-2p_N^2/N} = \alpha.$$

2.1 A SEQUENTIAL TEST

The main test we propose will be a sequential test as in Fig. 1. It sees examples as they arrive one at a time, up to a large time N, the maximum sample size we can afford. The sequential test is defined with a sequence of positive thresholds $\{q_n\}_{n\in[N]}$. We show how to set q_n to justify statements (A) and (B) in Section 1.1.

Type I Error. Just as the batch threshold p_N is determined by controlling the type I error with a concentration inequality, the sequential test also chooses $q_1, \ldots, q_N$ to control the type I error at α:

$$P_{H_0}(\text{reject } H_0) = P_{H_0}\left(\exists n \leq N : S_n > q_n\right) \leq \alpha \quad (1)$$

This inequality concerns the uniform concentration over infinite tails of S_n, but what $\{q_n\}_{n\in[N]}$ satisfies it? Asymptotically, the answer is governed by a foundational result, the LIL:

Theorem 1 (Law of the iterated logarithm (Khinchin (1924))). *With probability* 1, $\limsup_{n\to\infty} \frac{S_n}{\sqrt{n \ln \ln n}} = \sqrt{2}$.

The LIL says that q_n should have a $\sqrt{n \ln \ln n}$ asymptotic dependence on n, but does not specify its α dependence.

Our sequential testing insights rely on a stronger nonasymptotic LIL proved in (Balsubramani (2015), Theorem 2): with probability at least $1 - \alpha$, we have $|S_n| \leq \sqrt{Kn \ln\left(\frac{\ln n}{\alpha}\right)} =: q_n$ simultaneously for *all* $n \geq K \ln(\frac{4}{\alpha}) := n_0$. This choice of q_n satisfies (1) for $n_0 \leq n \leq N$, and specifies the sequential test as in Fig. 1. (Choosing q_n this way is unimprovable in all parameters up to absolute constants (Balsubramani (2015))).

Type II Error. For practical purposes, $\sqrt{\ln \ln n} \leq \sqrt{\ln \ln N}$ can be treated as a small constant (even when $N = 10^{20}, \sqrt{\ln \ln N} < 2$). Hence, $q_N \approx p_N$ (more discussion in the appendices), and the power is:

$$P_{H_1(\delta)}\left(\exists n \leq N : S_n > q_n\right) \geq P_{H_1(\delta)}\left(S_N > q_N\right) \quad (2)$$
$$\approx P_{H_1(\delta)}\left(S_N > p_N\right) \quad (3)$$

So the sequential test is essentially as powerful as a batch test with N samples (and similarly the n^{th} round of the sequential test is like an n-sample batch test).

Early Stopping. The standard motivation for using sequential tests is that they often require few samples to reject statistically distant alternatives. To investigate this with our working example, suppose N is large and the coin is actually biased, with a fixed unknown $\delta > 0$. Then, if we somehow had full knowledge of δ when using the batch test and wanted to ensure a desired type II error $\beta < 1$, we would use just enough samples $n^*_\beta(\delta)$ (written as n^* in context):

$$n^*_\beta(\delta) = \min\left\{n : P_{H_1(\delta)}\left(S_n \leq p_n\right) \leq \beta\right\} \quad (4)$$

so that for all $n \geq n^*_\beta(\delta)$, since $p_n = o(n)$,

$$\beta \geq P_{H_1(\delta)}\left(S_n \leq p_n\right) = P_{H_1(\delta)}\left(S_n - n\delta \leq p_n - n\delta\right)$$
$$\geq P_{H_1(\delta)}\left(S_n - n\delta \leq -Kn\delta\right) \quad (5)$$

Examining (5), note that $S_n - n\delta$ is a mean-zero random walk. Therefore, standard lower bounds for the binomial tail tell us that $n^*_\beta(\delta) \geq \frac{K \ln(1/\beta)}{\delta^2}$ suffices, and no test

can statistically use much less than $n^*_\beta(\delta)$ samples under $H_1(\delta)$ to control type II error at β.

How many samples does the sequential test use? The quantity of interest is the test's stopping time τ, which is $< N$ when it rejects H_0 and N otherwise. In fact, the expected stopping time is close to n^* under any alternate hypothesis:

Theorem 2. *For any δ and any $\beta > 0$, there exist absolute constants K_1, K_2 such that*

$$\mathbb{E}_{H_1}[\tau] \leq \left(1 + \frac{K_1 \beta^{K_2}}{\ln \frac{1}{\beta}}\right) n^*_\beta(\delta)$$

Theorem 2 shows that the sequential test stops roughly as soon as we could hope for, under any alternative δ, despite our ignorance of δ! We will revisit these ideas when presenting our two-sample sequential test later in Section 3.1.

2.2 DISCUSSION

Before moving to the two-sample testing setting, we note the generality of these ideas. Theorem 2 is proved for biased coin flips, but it uses only basic concentration of measure ideas: upper and lower bounds on the tails of a statistic that is a cumulative sum incremented each timestep. Many natural test statistics follow this scheme, particularly those that can be efficiently updated on the fly. Our main sequential two-sample test in the next section does also.

Theorem 2 is notable for its uniformity over δ and β. Note that q_n (and therefore the sequential test) are independent of both of these – we need only to set a target type I error bound α. Under any alternative $\delta > 0$, the theorem holds for all β simultaneously. As β decreases, $n^*_\beta(\delta)$ of course increases, but the leading multiplicative factor $\left(1 + \frac{K_1 \beta^{K_2}}{\ln \frac{1}{\beta}}\right)$ decreases. In fact, with an increasingly stringent $\beta \to 0$, we see that $\frac{\mathbb{E}_{H_1}[\tau]}{n^*} \to 1$; so the sequential test in fact stops closer to n^*, and hence τ is almost *deterministically* best possible. Indeed, the proof of Theorem 2 also shows that $P_{H_1}(\tau \geq n) \leq e^{-Kn\delta^2}$, so the probability of lasting n steps falls off exponentially in n, and is therefore quite sharply concentrated near the optimum $n^*_\beta(\delta)$.

We formalize this precise line of reasoning completely non-asymptotically in an even stronger high-dimensional setting, in the analysis of our main two-sample test in the next section.

3 TWO-SAMPLE MEAN TESTING

In this section, we present our main sequential two-sample test. Assume that we have samples $X_1, \ldots, X_n, \cdots \sim P$ and $Y_1, \ldots, Y_n, \cdots \sim Q$, with P, Q being unknown arbitrary continuous distributions on $\mathbb{R}^d$ with means $\mu_1 = \mathbb{E}_{X\sim P}[X], \mu_2 = \mathbb{E}_{Y\sim Q}[Y]$, and we need to test

$$H_0 : \mu_1 = \mu_2 \qquad \text{vs.} \qquad H_1 : \mu_1 \neq \mu_2 \tag{6}$$

Denote covariances of P, Q by Σ_1, Σ_2 and $\Sigma := \frac{1}{2}(\Sigma_1 + \Sigma_2)$. Define $\delta := \mu_1 - \mu_2$ so that $\delta = 0$ under H_0. Let $\Phi(\cdot)$ denote the standard Gaussian CDF, and $[\ln \ln]_+(x) := \ln \ln[\max(x, e^e)]$.

3.1 A LINEAR-TIME SEQUENTIAL TEST

Our sequential test follows the scheme in Fig. 1, so we only need to specify a sequence of rejection thresholds q_n. To do this, we denote

$$h_i = (X_{2i-1} - Y_{2i-1})^\top (X_{2i} - Y_{2i}).$$

and define our sequential test statistic as the following *stochastic process* evolving with n:

$$T_n = \sum_{i=1}^{n} h_i.$$

Under H_0, $\mathbb{E}[h_i] = 0$, and T_n is a zero-mean random walk.

Proposition 1. $\mathbb{E}[T_n] = \mathbb{E}[h] = n\|\delta\|^2$, *and*

$$\operatorname{var}(T_n) = n \operatorname{var}(h) = n(4 \operatorname{tr}(\Sigma^2) + 4\delta^\top \Sigma \delta) =: nV_0.$$

We assume – for now – that our data are bounded, i.e.

$$\|X\|, \|Y\| \leq 1/2,$$

so that by the Cauchy-Schwarz inequality, w.p. 1,

$$|T_n - T_{n-1}| = |(X_{2n-1} - Y_{2n-1})^\top (X_{2n} - Y_{2n})| \leq 1$$

Since T_n has bounded differences, it exhibits Gaussian-like concentration under the null. We examine the cumulative variance process of T_n under H_0,

$$\sum_{i=1}^{n} \mathbb{E}\left[(T_i - T_{i-1})^2 \mid h_{1:(i-1)}\right] = \sum_{i=1}^{n} \operatorname{var}(h_i) = nV_0$$

Using this, we can control the behavior of T_n under H_0.

Theorem 3 (Balsubramani (2015))**.** *Take any $\xi > 0$. Then with probability $\geq 1 - \xi$, for all n simultaneously,*

$$|T_n| < C_0(\xi) + \sqrt{2C_1 nV_0 [\ln \ln]_+(nV_0) + C_1 nV_0 \ln\left(\frac{4}{\xi}\right)}$$

where $C_0(\xi) = 3(e-2)e^2 + 2\left(1+\sqrt{\frac{1}{3}}\right)\ln\left(\frac{8}{\xi}\right)$, *and* $C_1 = 6(e-2)$.

Unfortunately, we cannot use the theorem directly to get computable deviation bounds for type I error control, because the covariance matrix Σ is unknown a priori. nV_0 must instead be estimated on the fly as part of the sequential test, and its estimate must be concentrated tightly and *uniformly over time*, so as not to present a statistical bottleneck if the test runs for a long time. We prove such a result, necessary for sequential testing, relating nV_0 to the empirical variance process $\widehat{V}_n = \sum_i h_i^2$.

Lemma 4. *With probability* $\geq 1-\xi$*, for all* n *simultaneously, there is an absolute constant* C_3 *such that*

$$nV_0 \leq C_3(\widehat{V}_n + C_0(\xi))$$

Its proof uses a self-bounding argument and is in the Appendix. Now, we can combine these to prove a novel uniform *empirical* Bernstein inequality to (practically) establish concentration of T_n under H_0.

Theorem 5 (Uniform Empirical Bernstein Inequality for Random Walks)**.** *Take any* $\xi > 0$*. Then with probability* $\geq 1-\xi$*, for all* n *simultaneously,*

$$|T_n| < C_0(\xi) + \sqrt{2\widehat{V}_n^*\left([\ln\ln]_+\widehat{V}_n^* + \ln\left(\frac{4}{\xi}\right)\right)}$$

where $\widehat{V}_n^* := C_3(\widehat{V}_n + C_0(\xi))$*,* $C_0(\xi) = 3(e-2)e^2 + 2\left(1+\sqrt{\frac{1}{3}}\right)\ln\left(\frac{8}{\xi}\right)$ *and* C_3 *is an absolute constant.*

Its proof follows immediately from a union bound on Thm. 3 and Lem. 4. Thm. 5 depends on $\widehat{V}_n$, which is easily calculated by the algorithm on the fly in constant time per iteration. Ignoring constants for clarity, Thm. 5 effectively implies that our sequential test from Figure 1 controls type I error at α by setting

$$q_n \propto \ln\left(\frac{1}{\alpha}\right) + \sqrt{2\widehat{V}_n \ln\left(\frac{\ln\widehat{V}_n}{\alpha}\right)} \tag{7}$$

Practically, we suggest using the above threshold with a constant of 1.1 to guarantee type-I error approximately α (this is all one often wants anyway, since any particular choice of $\alpha = 0.05$ is anyway arbitrary). This is what we do in our experiments, with excellent success in simulations. For exact or conservative control, consider using a small constant multiple of the above threshold, such as 2.

The above sequential threshold is remarkable, because within the practically useful and simple expression lies a deep mathematical result – the uniform Bernstein LIL effectively involves a union bound for the error probability over an infinite sequence of times. Any other naive attempt to union bound the error probabilities for a possibly infinite sequential testing procedure will be too loose and hence too conservative. Furthermore, the classical LIL is known to be asymptotically tight including constants, and our non-asymptotic LIL is also tight up to small constant factors.

This type-I error control with an implicit infinite union bound surprisingly does not lead to a loss in power. Indeed, our statistic possesses essentially the same power as the corresponding linear-time batch two sample test, and also stops early for easy problems. We make this precise in the following two subsections.

3.2 A LINEAR-TIME BATCH TEST

Here we study a simple linear-time batch two-sample mean test, following the template in Fig. 1. Consider the linear-time statistic $T_N = \sum_{i=1}^{N} h_i$, where, as before, $h_i = (x_{2i-1} - y_{2i-1})^\top (x_{2i} - y_{2i})$. Note that the h_is are also i.i.d., and T_N relies on $2N$ data points from each distribution.

Let V_{N0}, V_{N1} be $\mathrm{var}(T_N) = N\,\mathrm{var}(h)$ under H_0, H_1 respectively. Recalling Proposition 1:

$$V_{N0} := NV_0 := 4N\,\mathrm{tr}(\Sigma^2),$$
$$V_{N1} := NV_1 := N(4\,\mathrm{tr}(\Sigma^2) + 4\delta^\top\Sigma\delta).$$

Then since T_N is a sum of i.i.d. variables, the central limit theorem (CLT) implies that (where $\xrightarrow{d}$ is convergence in distribution)

$$\frac{T_N}{\sqrt{V_{N0}}} \xrightarrow{d}_{H_0} \mathcal{N}(0,1) \tag{8a}$$
$$\frac{T_N - N\|\delta\|^2}{\sqrt{V_{N1}}} \xrightarrow{d}_{H_1} \mathcal{N}(0,1) \tag{8b}$$

Based on this information, our test rejects the null hypothesis whenever

$$T_N > \sqrt{V_{N0}}\, z_\alpha, \tag{9}$$

where z_α is the $1-\alpha$ quantile of the standard normal distribution. So Eq. (8a) ensures that

$$P_{H_0}\left(\frac{T_N}{\sqrt{V_{N0}}} > z_\alpha\right) \leq \alpha,$$

giving us type I error control under H_0.

In practice, we may not know V_{N0}, so we standardize the statistic using the empirical variance – since we assume N is large, these scalar variance estimates do not

change the effective power analysis. For non-asymptotic type I error control, we can use an empirical Bernstein inequality (Maurer and Pontil, 2009, Thm. 11), based on an unbiased estimator of V_N. Specifically, the empirical variance of h_is ($\widehat{V}_N$) can be used to reject the null whenever

$$T_N > \sqrt{2\widehat{V}_N \ln(2/\alpha)} + \frac{7N\ln(2/\alpha)}{3(N-1)}. \tag{10}$$

Ignoring constants for clarity, the empirical Bernstein inequality effectively suggests that the batch test from Figure 1 will have type I error control of α on setting threshold

$$p_N \;\propto\; \ln\left(\frac{1}{\alpha}\right) + \sqrt{2\widehat{V}_N \ln\left(\frac{1}{\alpha}\right)} \tag{11}$$

For immediate comparison, we copy below the expression for q_n from Eq. (7):

$$q_n \;\propto\; \ln\left(\frac{1}{\alpha}\right) + \sqrt{2\widehat{V}_n \left(\ln\frac{\ln\widehat{V}_n}{\alpha}\right)}.$$

This similarity explains the optimal power and stopping time properties, detailed in the next subsection.

One might argue that if N is large, then $\widehat{V}_N \approx V_N$, and in this case we can simply derive the (asymptotic) power of the batch test given in Eq.(9) as

$$\begin{aligned} &P_{H_1}\left(\frac{T_N}{\sqrt{V_{N0}}} > z_\alpha\right) \qquad (12)\\ &= P_{H_1}\left(\frac{T_N - N\|\delta\|^2}{\sqrt{V_{N1}}} > z_\alpha\sqrt{\frac{V_{N0}}{V_{N1}}} - \frac{N\|\delta\|^2}{\sqrt{V_{N1}}}\right)\\ &= \Phi\left(\frac{\sqrt{N}\|\delta\|^2}{\sqrt{8\,\mathrm{tr}(\Sigma^2) + 8\delta^\top\Sigma\delta}} - z_\alpha\sqrt{\frac{\mathrm{tr}(\Sigma^2)}{\mathrm{tr}(\Sigma^2)+\delta^\top\Sigma\delta}}\right)\end{aligned}$$

Note that the second term is a constant less than z_α. As a concrete example, when $\Sigma = \sigma^2 I$, and we denote the signal-to-noise ratio as $\Psi := \frac{\|\delta\|}{\sigma}$, then the power of the linear-time batch test is at least $\Phi\left(\frac{\sqrt{N}\Psi^2}{\sqrt{8d+8\Psi^2}} - z_\alpha\right)$.

3.3 POWER AND STOPPING TIME OF SEQUENTIAL TEST

The striking similarity of Eq. (11) and Eq. (7), mentioned in the previous subsection, is not coincidental. Indeed, both of these arise out of non-asymptotic versions of CLT-like control and LIL-like control, and we know that in the asymptotic regime for Bernoulli coin-flips, CLT thresholds and LIL threshold differ by just $\propto \sqrt{\ln\ln n}$ factors. Hence, it is not surprising to see the empirical Bernstein LIL match empirical Bernstein thresholds up to $\propto \sqrt{\ln\ln\widehat{V}_n}$ factors. Since the power of the sequential test is *at least* the probability of rejection at the very last step, and since $\sqrt{\ln\ln n} < 2$ even for $n = 10^{20}$, the power of the linear-time sequential and batch tests is essentially the same. However, a sequential test that rejects at the last step is of little practical interest, bringing us to the issue of early stopping.

Early Stopping. The argument is again identical to that Section 2, proving that $\mathbb{E}_{H_1}[\tau]$ is nearly optimal, and arbitrarily close to optimal as β tends to zero. Once more note that the "optimal" above refers to the performance of the oracle linear-time batch algorithm that was informed about the right number of points to subsample and use for the one-time batch test. Formally, let $n^*_\beta(\delta)$ denote this minimum sample size for the two-sample mean testing *batch* problem to achieve a power β, the * indicating that this is an oracle value, unknown to the user of the batch test. From Eq. (12), it is clear that for $N \geq \frac{8Tr(\Sigma^2)+8\delta^T\Sigma\delta}{\|\delta\|^4}(z_\beta + z_\alpha)^2$, the power becomes at least β. In other words,

$$n^*_\beta(\delta) \leq \frac{Tr(\Sigma^2)+\delta^T\Sigma\delta}{\|\delta\|^4} 8(z_\beta + z_\alpha)^2 \tag{13}$$

Theorem 6. *Under H_1, the sequential algorithm of Fig. 1 using q_n from Eq.* (7) *has expected stopping time $\propto n^*_\beta(\delta)$.*

For clarity, we simplify (7) and (11) by dropping the initial $\ln\left(\frac{1}{\alpha}\right)$ additive term since it is soon dominated by the second term and does not qualitatively affect the conclusion.

3.4 DISCUSSION

This section's arguments have given an illustration of the flexibility and great generality of the ideas we used to test the bias of the coin. In the two-sample setting, we simply design the statistic $T_N = \sum_{i=1}^n h_i$ to be a mean-zero random walk under the null. As in the coin's case, the LIL controls type I error, and the remaining arguments are identical because of the common concentration properties of all random walks.

Our test statistic T_N is chosen with several considerations in mind. First, the batch test is linear-time in the sample complexity, so we are comparing algorithms with the *same computational budget*, on a fair footing. There exist batch tests using U-statistics that have higher power than ours (Reddi et al. (2015)) for a given N, but they use more computational resources ($O(N^2)$ rather than $O(N)$).

Also, the batch statistic is a sum of random increments, a common way to write many hypothesis tests, and one

that can be computed on the fly in the sequential setting. Note that T_N is a scalar, so our arguments do not change with d, and we inherit the favorable high-dimensional statistical performance of the statistic; Reddi et al. (2015) has more relevant discussion. The statistic also has been shown to have powerful generalizations in the recent statistics literature, which we discuss in the appendices.

Though we assume data scaled to have norm $\frac{1}{2}$ for convenience, this can be loosened. Any data with bounded norm $B > \frac{1}{2}$ can be rescaled by a factor $\frac{1}{B}$ just for the analysis, and then our results can be used. This results in an empirical Bernstein bound like Thm. 5, but of order $O\left(C_0(\xi) + \sqrt{\widehat{V}_n \ln\left(\frac{\ln(B\widehat{V}_n)}{\xi}\right)}\right)$. The dependence on B is very weak, and is negligible even when $B = \text{poly}(d)$.

In fact, we only require control of the higher moments (e.g. by Bernstein conditions, which generalize boundedness and sub-Gaussianity conditions) to prove the non-asymptotic Bernstein LIL in Balsubramani (2015), exactly as is the case for the usual Bernstein concentration inequalities for averages (Boucheron et al. (2013)). Therefore, our basic arguments hold for unbounded increments h_i as well. In fact, the LIL itself, as well as the non-asymptotic LIL bounds of Balsubramani (2015), apply to martingales – much more general versions of random walks capable of modeling dependence on the past history. Our ideas could conceivably be extended to this setting to devise more data-dependent tests, which would be interesting future work.

4 EMPIRICAL EVALUATION

In this section, we evaluate our proposed sequential test on synthetic data, to validate the predictions made by our theory concerning its type I/II errors and the stopping time.

We simulate data from two multivariate Gaussians ($d = 10$), motivated by our discussion at the end of Section 3.2: each Gaussian has covariance matrix $\Sigma = \sigma^2 I_d$, one has mean $\mu_1 = \mathbf{0}^d$ and the other has $\mu_2 = (\delta, 0, 0, \ldots, 0) \in \mathbb{R}^d$ for some $\delta \geq 0$. We keep $\sigma = 1$ here to keep the scale of the data roughly consistent with the biased-coin example, though we find the scaling of the data makes no practical difference, as we discussed.

4.1 RUNNING THE TEST AND TYPE I ERROR

Like typical hypothesis tests, ours is designed to control type I error. When implementing our algorithmic ideas, it suffices to set q_n as in (7), where the only unknown parameters are proportionality constants C, C_0: $q_n \propto C_0 + \sqrt{C\widehat{V}_n \left(\ln \frac{\ln \widehat{V}_n}{\alpha}\right)}$. The theory suggests that C, C_0 are absolute constants, and prescribes upper bounds for them, which can conceivably be loose because of the analytic techniques used (as Balsubramani (2015) discusses). On the other hand, in the asymptotic limit the bounds become tight; the empirical $\widehat{V}_n$ converges quickly to its mean V_n, and we know from second-moment versions of the LIL that $C = \sqrt{2}$ and $C_0 = 0$ are correct. However, as we consider smaller finite times, that bound must relax (at the extremely low $t = 1$ or 2 when flipping a fair coin, for instance).

Nevertheless, we find that in practice, for even moderate sample sizes like the ones we test here, the same reasonable constants suffice in all our experiments: $C = \sqrt{2}$ and $C_0 = \ln(\frac{1}{\alpha})$, with C_0 following Thm. 5 and similar fixed-sample Bennett bounds (Boucheron et al. (2013); Balsubramani (2015); also see the appendices). The situation is exactly analogous to how the Gaussian approximation is valid for even moderate sample sizes in batch testing, making possible a huge variety of common tests that are asymptotically and empirically correct with reasonable constants to boot.

To be more specific, consider the null hypothesis for the example of the coin bias testing given earlier; these fair coin flips are the most *anti*-concentrated possible bounded steps, and render our empirical Bernstein machinery ineffective, so they make a good test case. We choose C and C_0 as above, and plot the cumulative probability of type I violations $\Pr_{H_0}(\tau \leq n)$ up to time n for different α (where τ is the stopping time of the test), with the results in Fig. 2. To control type I error, the curves need to be asymptotically upper-bounded by the desired α levels (dotted lines). This does not appear true for our recommended settings of C, C_0, but the figure still indicates that type I error is controlled even for very high n with our settings. A slight further raise in C beyond $\sqrt{2}$ suffices to guarantee much stronger control.

Fig. 2 also seems to contain linear plots, which we cannot fully explain. We conjecture it is related to the standard proof of the classical LIL, which divides time into epochs of exponentially growing size (Feller (1950)). For more on provable correctness with low C, see the appendices.

4.2 TYPE II ERROR AND STOPPING TIME

Now we verify the results at the heart of the paper – uniformity over alternatives δ of the type II error and stopping time properties.

Fig. 3 plots the power of the sequential test $P_{H_1(\delta)}(\tau < N)$ against the maximum runtime N using the Gaussian

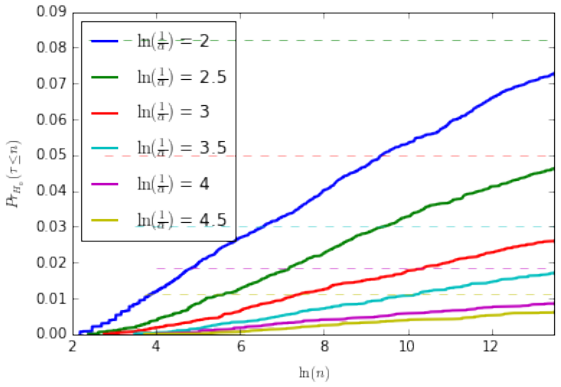

Figure 2: $\Pr_{H_0}(\tau \leq n)$ for different α, on biased coin. Dotted lines of corresponding colors are the target levels α.

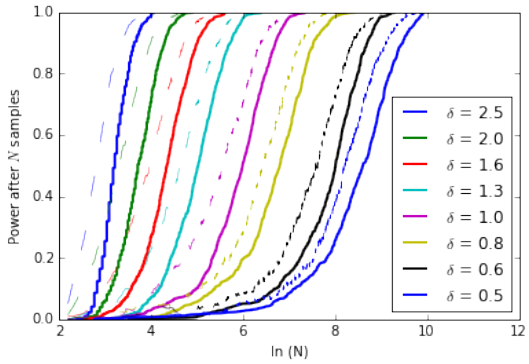

Figure 3: Power vs. $\ln(N)$ for different δ, on Gaussians. Dashed lines represent power of batch test with N samples.

data, at a range of different alternatives δ; the solid and dashed lines represent the power of the batch test (11) with N samples, and the sequential test with maximum runtime N. As we might expect, the batch test has somewhat higher power for a given sample size, but the sequential test consistently performs well compared to it. The role of N here is basically to set a desired tolerance for error; increasing N does not change the intermediate updates of the algorithm, but does increase the power by potentially running the test for longer. So each curve in Fig. 3 illustrates the statistical tradeoff inherent in hypothesis testing against a fixed simple alternative, but the great advantage of our sequential test is in achieving *all of them simultaneously with the same algorithm*.

To highlight this point, we examine the stopping time compared to the batch test for the Gaussian data, in Fig. 4. We see that the distributions of $\ln(\tau)$ are all quite concentrated, and that their medians (marked) fit well to a slope-4 line, showing the predicted $\frac{1}{\delta^4}$ dependence on δ. Some more experiments are in the appendices.

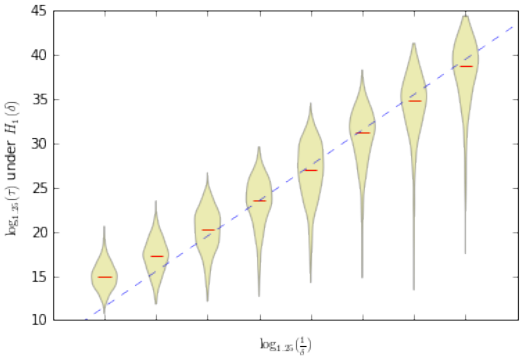

Figure 4: Distribution of $\log_{1.25}(\tau)$ for $\delta \in \{0.5(1.25)^c : c \in \{7, 6, \ldots, 0\}\}$, so that the abscissa values $\{\log_{1.25}(\frac{1}{\delta})\}$ are a unit length apart. Dashed line has slope 4.

5 RELATED WORK

Parametric or asymptotic methods. Our statements about the control of type I/II errors and stopping times are very general, following up on early sequential analysis work. Most sequential tests operate in the Wald's framework expounded in Wald (1945). In a seminal line of work, Robbins and colleagues delved into sequential hypothesis testing in an asymptotic sense Robbins (1985). Apart from being asymptotic, their tests were most often for simple hypotheses (point nulls and alternatives), were univariate, or parametric (assuming Gaussianity or known density). That said, two of their most relevant papers are Robbins (1970) and Darling and Robbins (1967), which discuss statistical methods related to the LIL. They give an asymptotic version of the argument of Section 2, using it to design sequential Kolmogorov-Smirnov tests with power one. Other classic works that mention using the LIL for testing various simple or univariate or parametric problems include Darling and Robbins (1968a,b); Lai (1977); Lerche (1986). These all operate in the asymptotic limit in which the classic LIL can be used to set q_N.

For testing a simple null against a simple alternative, the sequential probability ratio test (SPRT) was proved to be optimal by the seminal work of Wald and Wolfowitz (1948), but this applies when both the null and alternative have a known parametric form. The same authors also suggested a univariate nonparametric two-sample test in Wald and Wolfowitz (1940), but presumably found it unclear how to combine these two lines of work.

Bernstein-based methods. Finite-time uniform LIL-type concentration tools from Balsubramani (2015) are crucial to our analysis, and we adapt them in new ways; but novelty in this respect is not our primary focus here, because less recent concentration bounds can also be used to yield similar results. It is always possible to use a weighted union bound (allocating failure probability ξ over time as $\xi_n \propto \frac{\xi}{n^2}$) over fixed-$n$ Bernstein bounds, resulting in a deviation bound of $O\left(\sqrt{V_n \ln \frac{n}{\xi}}\right)$. A more advanced "peeling" argument, dividing time n into exponentially growing epochs, improves the bound to $O\left(\sqrt{V_n \ln \frac{\ln n}{\xi}}\right)$ (e.g. in Jamieson et al. (2014)). This suffices in many simple situations, but in general is still arbitrarily inferior to our bound of $O\left(\sqrt{V_n \ln \ln \frac{V_n}{\xi}}\right)$, precisely in the case $V_n \ll n$ in which we expect the second-moment Bernstein bounds to be most useful over Hoeffding bounds. A yet more intricate peeling argument, demarcating the epochs by exponential intervals in V_n rather than n, can be used to achieve our iterated-logarithm rate, in conjunction with the well-known second-order uniform martingale bound due to Freedman (1975). This serves as a sanity check on the non-asymptotic LIL bounds of Balsubramani (2015), where it is also shown that these bounds have the best possible dependence on all parameters. However, it can be verified that even a suboptimal uniform concentration rate like $O\left(\sqrt{V_n \ln \frac{V_n}{\xi}}\right)$ would suffice for the optimal stopping time properties of the sequential test to hold, with only a slight weakening of the power.

Bernstein inequalities that only depend on empirical variance have been used for stopping algorithms in Hoeffding races (Loh and Nowozin (2013)) and other even more general contexts (Mnih et al. (2008)). This line of work uses the empirical bounds very similarly to us, albeit in the nominally different context of direct estimation of a mean. As such, they too require uniform concentration over time, but achieve it with a crude union bound (failure probability $\xi_n \propto \frac{\xi}{n^2}$), resulting in a deviation bound of $O\left(\sqrt{\widehat{V}_n \ln \frac{n}{\xi}}\right)$. Applying the more advanced techniques above, it may be possible to get our optimal concentration rate, but to our knowledge ours is the first work to derive and use uniform LIL-type empirical Bernstein bounds.

Practical Usage. To our knowledge, implementing sequential testing in practice has previously invariably relied upon CLT-type results patched together with heuristic adjustments of the CLT threshold (e.g. the widely-used scheme for clinical trials of Peto et al. (1977) has an arbitrary conservative choice of $q_n = 0.001$ through the sequential process and $q_N = 0.05 = \alpha$ at the last datapoint). These perform as loose functional versions of our uniform finite-sample LIL upper bound, though without theoretical guarantees. In general, it is unsound to use an asymptotically normal distribution under the null at stopping time τ – the central limit theorem (CLT) applies to any *fixed* time t, but it may not apply to a *random* stopping time τ (see the random-sum CLT of Anscombe (1952), and Gut (2012) and references). This has caused myriad practical complications in implementing such tests (see Lai et al. (2008), Section 4). One of our contributions is to rigorously derive a directly usable finite-sample sequential test, in a way we believe can be extended to a large variety of testing problems.

We emphasize that there are several advantages to our proposed framework and analysis which, taken together, are unique in the literature. We tackle the multivariate nonparametric (possibly even high-dimensional) setting, with composite hypotheses. Moreover, we not only prove that the power is asymptotically one, but also derive finite-sample rates that illuminate dependence of other parameters on β, by considering non-asymptotic uniform concentration over finite times. The fact that it is not provable via purely asymptotic arguments is why our optimal stopping property has gone unobserved for a wide range of tests, even as basic as the biased coin. In our more refined analysis, it can be verified (Thm. 2) that the stopping time diverges to ∞ when the required type II error $\to 0$, i.e. power $\to 1$.

6 CONCLUSION

We have presented a sequential scheme for multivariate nonparametric hypothesis testing against composite alternatives, which comes with a full finite-sample analysis in terms of on-the-fly estimable quantities. Its desirable properties include type I error control by considering finite-time LIL concentration; near-optimal type II error compared to linear-time batch tests, due to the iterated-logarithm term in the LIL; and most importantly, essentially optimal early stopping, uniformly over a large class of alternatives. We presented some simple applications in learning and statistics, but our design and analysis techniques are general, and their extensions to other settings are of continuing future interest.

Abstract

We consider the problem of budget (or other resource) allocation in sequential decision problems involving a large number of concurrently running sub-processes, whose only interaction is through their consumption of budget. Our first contribution is the introduction of *budgeted MDPs (BMDPs)*, an MDP model in which policies/values are a *function of available budget*, (c.f. constrained MDPs which are solved given a *fixed* budget). BMDPs allow one to explicitly trade off allocated budget and expected value. We show that optimal value functions are concave, non-decreasing in budget, and piecewise-linear in the finite horizon case, and can be computed by dynamic programming (and support ready approximation). Our second contribution is a method that exploits BMDP solutions to allocate budget to a large number of independent BMDPs, coupled only by their common budget pool. The problem can be cast as a *multiple-choice knapsack problem*, which admits an efficient, optimal greedy algorithm. Empirical results in an online advertising domain confirm the efficacy of our methods.

1 INTRODUCTION

Markov decision processes (MDPs) [25, 7] are used widely throughout AI; but in many domains, actions consume limited resources and policies are subject to resource constraints, a problem often formulated using *constrained MDPs (CMDPs)* [2]. MDPs and CMDPs are even more complex when multiple independent MDPs, drawing from the same resources, must be controlled jointly, since the state and action spaces are formed by the cross-product of the individual subprocesses [23]. *Online advertising* is a domain with such properties: Archak et al. [4] propose a constrained MDP model for the optimal allocation of advertiser budget over an extended horizon that captures the sequential effect of multiple ads on a user's behavior.

Archak et al. [4] assume a fixed, predetermined budget for each user, and focus on optimally advertising to a user subject to this budget constraint. This formulation, however, does not determine a suitable budget, nor does it allow for making budget tradeoffs across different users, user types, or campaigns (e.g., different MDPs or different states of the same MDP). With this as motivation, we address these challenges by: (a) introducing *budgeted MDPs (BMDPs)*, which are solved as *a function of the (expected) budget available*; and (b) addressing budget tradeoffs across users using a *weakly coupled MDP* formulation [23] and optimally solving the allocation problem with a greedy algorithm that exploits local user BMDP solutions.

Our first contribution lies in the formulation and solution of BMDPs. The usual approach to resource constraints is CMDPs [2, 13]. While valuable models, CMDPs require *a priori* specification of fixed "budget" (e.g., a daily per-customer cap on ad spend). By contrast, BMDPs compute optimal policies and value functions (VFs) as a function of the budget made available. Effectively, we solve a CMDP *for all possible budget levels*, allowing one to explore the tradeoff between (optimal) expected value and allocated budget. Treating the budget b as a parameter, we show that, for any fixed state s of the BMDP, the optimal VF $V(s, b)$ is concave, non-decreasing in b; and for any finite horizon the VF is *piecewise-linear and concave (PWLC)*, defined by a finite set of *useful* resource levels. We derive a dynamic programming (DP) algorithm to compute this PWLC representation that supports approximation.

Our second contribution is a method for piecing together BMDP solutions to determine a joint policy over a set of BMDPs (e.g., for different users), subject to a global resource/budget constraint. Since the MDP is *weakly coupled* [23]—specifically, the individual customer BMDPs evolve independently, linked only through the consumption of shared budget—our aim is to determine an allocation of budget to each customer, which is turn dictates the optimal policy for that customer. We show that the budget allocation problem can be formulated as a *(multi-item variant of a) multiple-choice knapsack problem (MCKP)* [29], for which a straightforward greedy method can be used to construct the optimal budget allocation. We also discuss circumstances in which the dynamic, online *reallocation* of budget may be valuable, an approach rendered viable by the real-time nature of our method.

2 MDPS FOR BUDGET ALLOCATION

We describe an MDP model for engagement with users from a large, heterogeneous population. We use online advertising as our main motivation, though our techniques apply to the control of any large, distributed set of fully observable MDPs where actions consume limited resources. We abstract away a number of factors that arise in realistic ad domains to focus on budget allocation itself (e.g., partial observability and hidden state, control lag, incentives).

2.1 A WEAKLY COUPLED FORMULATION

We assume an advertiser has a fixed budget to spend on *advertising actions* for a target user population. Each action has a cost and is targeted to a specific user (e.g., a search, in-app or web page ad). Users respond stochastically in a way that may depend on their features (e.g., demographics), past actions (e.g., ad exposures) and past responses (e.g., click/purchase behavior).

Following Archak *et al.* [4], we model this as an MDP. We have a finite set of *users* $i \leq M$, who may be segmented into *types* reflecting static, observable characteristics that influence their responses. For ease of exposition, we assume all users have the same type; but the extension to multiple types is straightforward. We have a finite set S of *user states* $j \leq N$. At any time, user i is some state $s[i] \in S$. Let $\mathbf{S} = S^M$ be the *joint state space*, with the joint state denoted $\mathbf{s} = \langle s[1], \ldots, s[M] \rangle \in \mathbf{S}$. A user's state captures all relevant characteristics and history that influence her behavior. S may be small, or quite large in some contexts (e.g., the most recent search keyword on which the advertiser bid, or sufficient statistics summarizing historical interactions and user responses). A finite set A of *advertising actions* is available. At each stage, the advertiser selects an action $a[i]$ to apply to user i. Letting $\mathbf{A} = A^M$, a joint action is $\mathbf{a} = \langle a[1], \ldots, a[M] \rangle \in \mathbf{A}$.

Stochastic user response is captured by a *transition model* $P : S \times A \to \Delta(S)$, where $P(i, a, j) = p_{ij}^a$ is the probability that a user in state i moves to j when subjected to action a. *Reward* $R(i, a) = r_i^a$ reflects costs/payoffs when action a is applied to a user in state i. We decompose reward as $r_i^a = U(i) - C(i, a) = u_i - c_i^a$: *cost* C reflects action costs (e.g., cost of placing an ad, potential annoyance, etc.) and *utility function* U reflects benefits/payoffs (e.g., sales revenue, value of brand exposure, etc.).

The advertiser has a maximum *(global) budget* B that can be spent over the planning horizon. This global budget may be a hard limit in some settings; but we will require only that policies meet this constraint *in expectation*. We assume that the set of users is known, but our model easily handles new users who enter the system according to a known distribution over initial states. Different users will occupy many distinct states at any stage.

The optimal policy is defined w.r.t. the *joint constrained MDP*, with state space $\mathbf{S} = S^M$, action set $\mathbf{A} = A^M$, and a transition model, and cost, utility and reward functions defined as follows:

$$P(\mathbf{s}, \mathbf{a}, \mathbf{t}) = \prod_{i \leq M} P(s[i], a[i], t[i]); \quad U(\mathbf{s}) = \sum_{i \leq M} U(s[i]);$$
$$C(\mathbf{s}, \mathbf{a}) = \sum_{i \leq M} C(s[i], a[i]); \quad R(\mathbf{s}, \mathbf{a}) = U(\mathbf{s}) - C(\mathbf{s}, \mathbf{a}).$$

Joint transitions reflect the natural independence of user transitions. Costs and utilities are additive across users.

Our aim is to find a policy that maximizes expected discounted reward subject to the budget constraint: in expectation, the policy should spend no more than B. The optimal solution to this joint CMDP can be found by linear programming (LP) or DP. However, the exponential size of the state and action spaces (e.g., $O(N^M)$ states, or $\binom{M+N-1}{N-1}$ states if we use the "user count" for each state) makes this intractable. Fortunately, the MDP is *weakly coupled* [23]: users transitions are independent, with the local MDPs only coupled by their reliance on a single global budget. We take advantage of this below, solving the local MDPs such that their solutions can be effectively "pieced together" to form an approximate solution to the joint problem.

2.2 RELATED WORK

Budget Optimization. Allocation of advertising budgets is well-studied in marketing [19] with customer behavior and responses often modeled as a discrete or continuous Markov process [8, 24, 15]. Constrained budget optimization is of course critical to maximizing ROI in keyword auctions as well. [6, 16, 17, 12, 20].

Relatively little work has considered online budget optimization based on *sequential* user behavior. Markov models of web browsing and user response to online ads have been studied [10, 21]. Archak et al. [4] also assume Markovian user behavior in sponsored search—this is the behavioral model we adopt above. They propose a constrained MDP model and simple greedy algorithm that determines the optimal ad policy for a given user, assuming a fixed budget *for that user*. The same authors [5] demonstrate that user web search exhibits a "general to specific" behavior that is approximately Markovian. Other sequential work includes: budget optimization with advertiser response learning [3]; and reinforcement learning for optimal online ad strategies [27, 31] without budgets.

Constrained MDPs. We can extend the standard MDP model using *constrained MDPs (CMDPs)* [2, 13]: actions consume one or more resources (e.g., budget, energy) and policies must use no more than some set level of each resource in expectation. We outline a basic (one-dimensional) CMDP model.

Assume an underlying (local, not joint) MDP with states, actions, transitions, utilities and costs as above. Assuming a discounted infinite-horizon problem with discount factor

$0 \leq \gamma < 1$, our aim is to find an optimal (stationary, deterministic) policy that maximizes the expected sum of discounted rewards. The (unique) *optimal value function (VF)* $V^* : S \to \mathbb{R}$ satisfies the Bellman equation for all $i \in S$:

$$V^*(i) = \max_{a \in A} r_i^a + \gamma \sum_{j \in S} p_{ij}^a V^*(j),$$

while the optimal policy $\pi^*(i)$ selects the argmax of this expression. We will often use *Q-functions*, $Q(i,a) = r_i^a + \gamma \sum_{j \in S} p_{ij}^a V^*(j)$. The optimal VF and policy can be computed using DP algorithms (e.g., value/policy iteration) or LP methods [25, 7].

CMDPs extend this model by introducing constraints on the resources used by a policy [2]. We explicate the model using budgets (but it applies to any resource). A *budget constraint* B limits the cost of allowable policies, where the *expected discounted cost* of policy π at state i is:

$$C^\pi(i) = c_i^{\pi(i)} + \gamma \sum_{j \in S} p_{ij}^{\pi(i)} C^\pi(j).$$

An initial state (or distribution) is required for the constraint to be well-posed in general. The optimal solution (policy, VF) can be computed in poly-time using an LP [2]. There is always an optimal stationary policy for a CMDP, but unlike unconstrained MDPs, it may be stochastic.

Satisfying the budget constraint *in expectation* is suitable when a policy is executed many times, perhaps under different conditions, and budget is fungible over these instances, as in our ad domain. In other settings, the budget constraint may be *strict*—our model below easily accommodates strict budgets as well. We also allow costs in the budget constraint to be undiscounted (see below).

Weakly Coupled MDPs. The decomposition of MDPs into independent or semi-independent processes can often be used to mitigate the curse of dimensionality. Challenges lie in discovering a suitable decomposition structure and in determining how best to use the sub-process solutions to construct a (generally approximate) global solution. Many approaches have this flavor, in both standard MDPs and *decentralized (DEC)* MDPs and POMDPs [28, 1, 30, 22, 14]. The approach most related to ours is the decomposition method for *weakly-coupled MDPs* of [23]. There a joint MDP is comprised of a set of independent subprocesses, each itself a "local" MDP. Each local MDP reflects the task or objective of a specific agent, but the local policies require resources, both consumable and non-consumable. Their method: solves the local MDPs independently to produce local VFs parameterized by the resources available; uses the local VFs to assign resources to each local MDP; and reassigns unconsumed resources at each stage given the observed joint state. Our approach to budget decomposition is similar, but we use of the more standard *expected budget* constraint, and guarantee optimal composition. Our dynamic budget reallocation scheme is based on the reallocation mechanism of [23].

3 BUDGETED MDPS

We introduce *budgeted MDPs*, a variant of CMDPs in which budgets, or other resources, are (implicitly) treated as a part of the state, so that VFs/policies can vary with both the state *and available budget*. This allows budget-value tradeoffs to made quickly and easily.

3.1 THE BUDGETED MDP MODEL

A *(finite, one-dimensional) budgeted Markov decision process (BMDP)* $M = \langle S, A, P, U, C, B_{\max}, \gamma \rangle$ has the same components as a CMDP, but without a budget constraint. We allow an optional constant $B_{\max}$ that sets a plausible upper bound on useful or available budgets at any stage. We write $U(i) = u_i$ for the terminal utility at i if no action is taken (e.g., end of the planning horizon). We assume that, for each i, there is an a s.t. $c_i^a = 0$ (so a proper policy exists even with no budget).

We seek an optimal policy which maximizes expected reward over some horizon, but which consumes no more than some budget $b \leq B_{\max}$ in expectation. Unlike CMDPs, however, the policy should be a *function* of b.

3.2 DETERMINISTIC POLICIES

We begin by analyzing deterministic policies for finite-horizon problems, which develops useful intuitions. Define the *optimal deterministic t-stage-to-go VF* as follows. For all $i \in S, b \leq B_{\max}$, let $V_D^0(i,b) = u_i$, and define:

$$V_D^t(i,b) = \max_{\substack{a \in A \\ \mathbf{b} \in \mathbb{R}_+^n}} r_i^a + \gamma \sum_{j \leq n} p_{ij}^a V_D^{t-1}(j, b_j) \quad (1)$$

$$\text{subj. to } c_i^a + \gamma \sum_{j \leq n} p_{ij}^a b_j \leq b \quad (2)$$

The optimal policy $\pi_D^t(i,b)$ is obtained by taking the argmax. The VF reflects that doing a at i consumes c_i^a of the budget b, while optimal consumption at each reachable next state must be such that the *expected* budget used is no more than the remaining $b - c_i^a$. We discount the expected spend as is standard in CMDPs, but removing γ from Eq. 2 is also possible (we use undiscounted constraints below).

It is easy to see that $V_D^t(i,b)$ is monotone non-decreasing in b. While the optimal VF involves a continuous dimension b, it has a concise finite representation. For a fixed stage-to-go t and state i, define budget $0 \leq b \leq B_{\max}$ to be *(deterministically) useful* iff $V_D^t(i,b) > V_D^t(i, b-\varepsilon)$ for all $\varepsilon > 0$, and *useless* otherwise. We observe that:

Proposition 1. *For any finite t and state i, $V_D^t(i,\cdot)$ has a finite number of deterministically useful budget levels.*

We describe an algorithm to compute useful budgets (from which the proof of Prop. 1 follows).[1] Let $b_0^{i,t} = 0 < b_1^{i,t} < \ldots < b_M^{i,t}$ be the useful budget levels for (i,t). Prop. 1

[1] All proofs, and more detailed exposition, are available in a longer version of the paper, available at each author's web page.

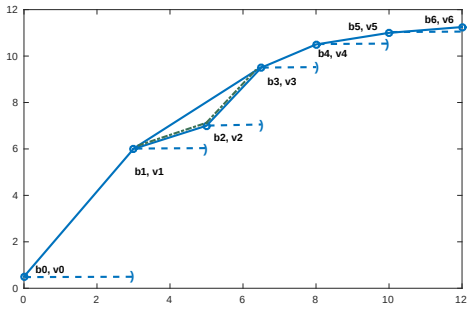

Fig. 1: An example VF $V_D(i,b)$. Useful budget levels are shown (the points (b,v)) along with: (a) the induced piecewise constant VF $V_D(i,b)$ (dashed line); and (b) the PWLC VF (solid line) for a randomized policy. Randomizing among b_0, b_1 for any expected spend $b \in (b_0, b_1)$ dominates deterministic spend b_0; and randomizing among b_1 and b_3 with expected spend b_2 dominates deterministic spend b_2 (dashed-dotted lines).

implies that $V_D^t(i,\cdot)$ is *piecewise constant* and monotone, with $V_D^t(i,b) = V_D^t(i,b_k^{i,t})$ for all $b \in [b_k^{i,t}, b_{k+1}^{i,t})$, for each $k < M$. We write $[\langle b_0^{i,t}, v_0^{i,t}\rangle, \ldots, \langle b_M^{i,t}, v_M^{i,t}\rangle]$ to denote this piecewise constant function (see Fig. 1).

Let the *reachable set* for state-action pair i,a be $S_i^a = \{j \in S | p_{ij}^a > 0\}$ and the *maximum out-degree* of an MDP be $d = \max_{i\in S, a\in A} |S_i^a|$. We compute the useful budgets for each state-stage pair—hence the optimal VF and policy—using a simple DP algorithm. Assume a piecewise constant representation of V_D^{t-1} (for V_D^0 this is trivial); and for ease of exposition, assume each i has $M+1$ useful levels $b_0^{i,t-1}, \ldots, b_M^{i,t-1}$. We compute $V_D^t(i,b)$ as follows:

- Let $\sigma : S_i^a \to [M]$ be an assignment of each reachable state $j \in S_i^a$ to a useful budget level $b_{\sigma(j)}^{j,t-1}$, $\sigma(j) \le M$, with $t-1$ stages-to-go. Let Σ be the set of such mappings. We view $b_\sigma^{j,t-1}(j)$ as the budget to be consumed if we reach j after doing a; implicitly, σ dictates the $t-1$-stage-to-go policy by selecting a budget level at each next state.
- Let the *potentially useful budget levels* for (i,t,a) be:

$$\widetilde{B}_a^{i,t} = \{c_i^a + \sum_{j\in S_i^a} p_{ij}^a b_{\sigma(j)}^{j,t-1} \mid \sigma \in \Sigma\} \cap \{b \le B_{\max}\}.$$

  Each $b_k^{i,t} \in \widetilde{B}_a^{i,t}$ is determined by some σ. The corresponding expected value is $v_k^{i,t} = r_i^a + \gamma \sum_j p_{ij}^a v_{\sigma(j)}^{j,t-1}$.
- Assume a reindexing of the entries in $\widetilde{B}_a^{i,t}$ so that the budget levels are ascending (ties broken arbitrarily). The *useful budget levels* for (i,t,a) are:

$$B_a^{i,t} = \{b_k^{i,t} \in \widetilde{B}_a^{i,t} : \nexists k' < k \text{ s.t. } v_{k'}^{i,t} \ge v_k^{i,t}\}.$$

  That is, any potentially useful budget that is weakly dominated by a smaller budget is discarded. The useful budgets and corresponding values give us $Q^t(i,a,b)$.
- Let the *potentially useful budget levels* for (i,t) be $\widetilde{B}^{i,t} = \cup_{a\in A} B_a^{i,t}$, and let $B^{i,t}$ be the *useful budget levels*, obtained by pruning $\widetilde{B}^{i,t}$ as above. The useful budget levels and corresponding values give the VF $V^t(i,b)$.

While finite, the number of useful budget levels can grow exponentially in the horizon:

Proposition 2. *For any finite t and state i, $V_D^t(i,\cdot)$ has at most $O((|A|^d)^t)$ useful budget levels, where d is the maximum out-degree of the underlying MDP.*

This motivates approximating this set, as we discuss below in the context of stochastic policies.

3.3 STOCHASTIC POLICIES

Stochastic policies can offer greater value than deterministic policies due to their inherent flexibility, and thus have a rather different structure. Suppose at state-stage pair (i,t) the available budget b lies strictly between two deterministically useful levels, $b_k^{i,t} < b < b_{k+1}^{i,t}$. A stochastic policy that spends $b_{k+1}^{i,t}$ (and takes the corresponding action) with probability $p = \frac{b - b_k^{i,t}}{b_{k+1}^{i,t} - b_k^{i,t}}$, and $b_k^{i,t}$ with $1-p$, provides greater expected value for (expected) spend b than the PW constant value offered by the optimal deterministic policy (see Fig. 1).

The optimal VF for such "single-stage randomized" policies is given by the *convex hull* of the useful budgets for (i,t) (see Fig. 1). Given useful budget set $B^{i,t} = \{0 = b_0^{i,t} < b_1^{i,t} < \ldots < b_M^{i,t}\}$, we say $b_k^{i,t}$ is *dominated* if there are two budgets $b_{k^-}^{i,t}, b_{k^+}^{i,t}$ $(k^- < k < k^+)$ s.t. $(1-p)v_{k^-}^{i,t} + pv_{k^+}^{i,t} > v_k^{i,t}$. The convex hull is *piecewise linear and concave (PWLC)* and monotone, comprising the PWL function formed by the *non-dominated* points.

This PWLC structure is preserved by Bellman backups, and can be computed effectively in two stages: first, a simple *greedy algorithm* assigns budget incrementally to reachable next states, giving a PWLC representation of the Q-functions for each a; second, we compute the backed up VF by taking the convex hull of the union of these Q-functions.

Computing Q-functions. Assume $V^{t-1}(j,\cdot)$ is PWLC for all $j \in S$, with points $[\langle b_0^{j,t-1}, v_0^{j,t-1}\rangle, \ldots, \langle b_M^{j,t-1}, v_M^{j,t-1}\rangle]$, where each $b_k^{j,t-1}$ is non-dominated (for ease of exposition, assume each j has $M+1$ non-dominated levels). Let $B(S_a^i) = \cup_{j\in S_a^i} B^{j,t-1}$, and re-index $B(S_a^i)$ in decreasing order of *bang-per-buck ratio (BpB)*:

$$BpB(b_k^{j,t-1}) = \frac{v_k^{j,t-1} - v_{k-1}^{j,t-1}}{b_k^{j,t-1} - b_{k-1}^{j,t-1}} = \frac{\Delta v_k^{j,t-1}}{\Delta b_k^{j,t-1}}.$$

(For $k=0$, we leave BpB undefined, since $b_0^{j,t-1} = 0$ for all j.) This BpB expresses the (per-unit budget) increase in value when increasing budget at $(j,t-1)$ from $b_{k-1}^{j,t-1}$ to $b_k^{j,t-1}$. Let $j(m), k(m), \Delta b(m), \Delta v(m)$ denote, resp., the state j, the useful budget index for j, the budget increment, and the value increment associated with the mth element of (sorted) $B(S_a^i)$. Let $M_i^* = |S_a^i|M$.

We define Q-functions as follows:

Definition 1. Let V^{t-1} be a VF such that, for all $j \in S$, $V^{t-1}(j,b)$ is bounded, monotone and PWLC in b with a

finite number of budget points. Define:

- the 0th useful budget for a at i to be $b^{i,t}_{a,0} = c^a_i$, which gives value $v^{i,t}_{a,0} = r^a_i + \gamma \sum_{j \in S^a_i} p^a_{ij} v_0^{j,t-1}$;
- the mth useful budget, for $0 < m \leq M^*_i$, to be $b^{i,t}_{a,m} = \sum_{\ell \leq m} p^a_{i,j(\ell)} \Delta b(\ell)$ which gives value $v^{i,t}_{a,m} = r^a_i + \gamma \sum_{\ell \leq m} p^a_{i,j(\ell)} \Delta v(\ell)$.

For any $0 < m \leq M^*_i$, and b s.t. $b^{i,t}_{a,m-1} < b < b^{i,t}_{a,m}$, let $p^{i,t,a}_b = \frac{b - b^{i,t}_{a,m-1}}{b^{i,t}_{a,m} - b^{i,t}_{a,m-1}}$. Define *the Q-function for action a at stage t* as follows:

$$Q^t(i,a,b) = \begin{cases} \text{undefined} & \text{if } b < b^{i,t}_{a,0} \\ v^{i,t}_{a,m} & \text{if } b = b^{i,t}_{a,m} \\ p^{i,t,a}_b v^{i,t}_{a,m} + (1 - p^{i,t,a}_b) v^{i,t}_{a,m-1} & \text{if } b^{i,t}_{a,m-1} < b < b^{i,t}_{a,m} \\ v^{i,t}_{a,M^*_i} & \text{if } b > b^{i,t}_{a,M^*_i}. \end{cases}$$

This Q-function is optimal:

Theorem 3. *$Q^t(i,a,b)$ in Defn. 1 is the maximum expected value achievable when taking action a at state i with budget b with future value given by V^{t-1}.*

Q-functions can thus be computed with a simple greedy algorithm that allocates budget to "next states" in BpB-order (i.e., using a simple sorted merge of the linear segments of all reachable-state VFs, with each segment scaled by its transition probability; see Fig. 2 for an illustration). The intuitions are straightforward: once taking a at i, cost c^a_i is incurred, and the remaining budget $b' = b - c^a_i$ must be "allocated" to states in S^a_i. The first units of b' are most effectively used by state $j(1)$—i.e., the first in $B(S^i_a)$—since it has the greatest initial BpB. Budget up to $\Delta b(1) = b^{j(1),t-1}_{k(1)}$ to $j(1)$ gives an expected (future) value improvement of $\Delta v(1) = \Delta v^{j(1),t-1}_{k(1)}$ with probability $p^a_{i,j(1)}$, and has an expected spend of $p^a_{i,j(1)} \Delta b(1)$. This is the greatest expected (future) value attainable at i for any $b' \leq p^a_{ij} b^{j(1),t-1}_{k(1)}$. Similarly, the next $\Delta b(2)$ units of b' should be allocated to $j(2)$, giving a return of $BpB(b^{j(2),t-1}_{k(2)})$ per unit, with expected spend and return occurring with probability $p^a_{i,j(2)}$. This continues until all useful budgets from states in S^a_i have been allocated (reaching the max useful budget for (i,t)).

Computing Value Functions. Given the PWLC representation of the Q-functions, we can construct a similar PWLC representation of $V^t(i,b) = \max_a Q^t(i,a,b)$. We simply take the union of the points that determine each Q-function, and remove any dominated points (analogous to the move from deterministic to stochastic policies). More precisely, assuming a fixed state-stage (i,t), let Q_a be the set of budget-value points in a's Q-function, and let $Q_* = \cup_a Q_a$ be the union of of these points—we annotate each point with the action from which it was derived, so each has the form (b,v,a). We say (b,v,a) is *dominated* in Q_* if there are two (different) points $(b_1,v_1,a_1), (b_2,v_2,a_2) \in Q_*$ such that $b_1 \leq b \leq b_2$ and $(1-\alpha)v_1 + \alpha v_2 > v$, where $\alpha = \frac{b - b_1}{b_2 - b_1}$. Removing all dominated points from Q_* leaves the set of points that form the useful budget levels in the PWLC representation of $V^t(i,\cdot)$. In other words, we form the convex hull of Q_*. Clearly no dominated point (b,v,a) is useful in a stochastic policy, since a greater value can be attained, using the same expected budget, by α-mixing between actions a_1 and a_2 (and the corresponding budgets).

The construction above shows:

Theorem 4. *For any finite t and state i, $V^t(i,b)$ is piecewise linear, concave and monotone in b.*

The PWLC representation of $V^t(i,\cdot)$ can be constructed using any convex hull method. A basic *Graham scan* [18] is appropriate here, since Q-budget points are maintained in sorted order, and has complexity $O(|Q_*| \log |Q_*|)$.

Again, the number of useful levels grows exponentially, but is no greater than the number of deterministically useful levels, i.e., $V^t(i,\cdot)$ has size at most $O((|A|^d)^t)$. For infinite horizon problems, we may not have finitely many useful budgets, but the VF remains concave:

Theorem 5. *For any state i, the optimal infinite-horizon VF $V(i,b)$ is concave and monotone in b.*

Standard bounds apply when using the finite-horizon V^t to approximate the infinite-horizon VF: if Bellman error of V^t is ε, $||V^* - V^t|| \leq \frac{\varepsilon}{1-\gamma}$.

Approximation. The complexity of VF computation depends on the number of useful budget points. The VF can be approximated by removing non-dominated points that are "close" to lying strictly inside the convex hull. For instance, in Fig. 2(c), deletion of the second and third points results in a simpler Q-function, with a single segment from $(pb_0 + p'b'_0, pv_0 + p'v'_0)$ to $(pb_2 + p'b'_1, pv_2 + p'v'_1)$ replacing three true segments. It closely approximates the true Q-function since the slopes (BpBs) of all deleted segments are nearly identical.

Several simple pruning criteria can be added to the insertion step of the Graham scan (i.e., when transforming Q-functions to VFs). When inserting (b_{new}, v_{new}) with BpB β_{new}, we can delete the previously inserted point, (b_k, v_k) with BpB β_k, if $\beta_{new} \geq \beta_k - \varepsilon$, for some tolerance ε. This introduces a max-norm error of at most $\varepsilon(b_k - b_{k-1})$. Recursively applying this rule gives additive accumulation: s consecutive pruning steps gives error at most $s\varepsilon(b_k - b_{k-s})$. Since error also depends on the length of the segments being pruned, we can use both *slope* pruning and *length* pruning, or pruning dictated by their product, i.e., terminated when this product bound reaches some threshold τ. Standard MDP approximation bounds can be derived.

Policy Execution. Given the optimal VF V^*, we can readily determine the ideal level of (expected) spend b_0 given initial state i_0 (see our discussion of sweet spots below). While one could then solve the corresponding CMDP with budget b_0, the BMDP solution, in fact, embeds an optimal

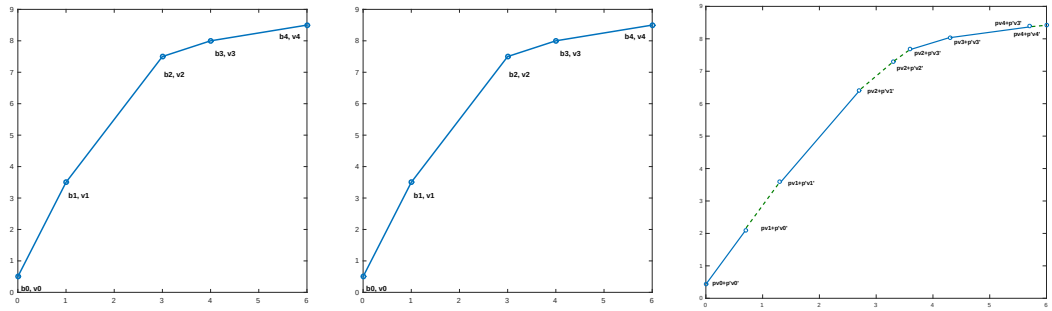

Fig. 2: (a) VF for state j; (b) VF for j'; (c) Q-function (future component) for a reaching j with prob. p and j' with $p' = 1 - p$.

Fig. 3: A synthetic ad MDP. "Begin" reflects the beginning of a customer search (transitions from it encode a prior over interest states). From an advertiser's perspective, the MDP for a specific customer can begin at any state of the process.

(non-stationary) CMDP solution for any budget level. The *execution* of the BMDP policy π^* is somewhat subtle, but straightforward. The optimization in Eqns. 1 and 2 generally assigns some future states a *greater* budget than what remains, $b_0 - c^a_{i_0}$, and some future states less—it is only *expected spend* that must not exceed the remaining budget. If state j's "assigned budget" b_j differs from $b_0 - c^a_{i_0}$, whether greater or less, then we must execute action $\pi^*(j, b_j)$ to ensure we achieve expected value $V^*(i_0, b_0)$. This requires that we record the optimal budget mapping σ at the final Bellman backup (assuming an infinite horizon problem) for each useful budget point at each state. When we reach any next state j, we "pass forward" its assigned budget $b_\sigma(j)$, at which point we take action $\pi^*(j, b_\sigma(j))$.

As in CMDPs, there can be substantial variance in actual spend when implementing the BMDP policy $\pi^*(i, b)$ (variance can be computed exactly during DP). We discuss strategies for mitigating the impact of variance below. A simple DP algorithm can be used to compute VFs with *strict* budgets [23], but allowing some variance in spend can improve expected value significantly.

3.4 EMPIRICAL EVALUATION

We evaluate the effectiveness of our DP method on several BMDPs, and measure the impact of approximation.

Synthetic Ad MDP. We begin with a small synthetic MDP that reflects the influence of ads on product search behavior. Its small size allows detailed examination of its optimal VF structure. The MDP (see Fig. 3) has 15 states reflecting various levels of customer interest in an advertiser's (or competitors') product, and five actions for different levels of ad intensity. Transitions for "nominal" (stochastic) progress through the search funnel are shown, with others omitted for clarity. More intense ad actions are more costly, but increase the odds of progressing in the funnel, and lower the odds of abandoning purchase intent.

We solve the BMDP ($\gamma = 0.975$, horizon 50) with four different degrees of approximation: exact (no pruning); mild pruning (slope/length pruning set to 0.01); aggressive pruning (both set to 0.05); and hybrid (mild pruning for 45 iterations, then exact computation for five). The following table shows the average (and min–max) number of segments in the PWLC VF over the 15 MDP states—the number of segments determines the complexity of the VFs—and computation time for each regime. For approximation schemes, we show the maximum absolute and relative errors (and the optimal value at which this error occurs).

	No prun.	Mild	Aggr.	Mild+No
Segments	3066 (0–5075)	18.3 (0–47)	10.4 (0–26)	480.8 (0–877)
Max Err	—	4.84 (26.61)	4.84 (26.61)	0.21 (58.77)
Max RelErr	—	40.9% (4.24)	48.7% (1.54)	2.3% (0.55)
CPU (s.)	1055.4	17.54	10.36	28.67

The optimal VF has a large number of segments per state but can be approximated quite well with very few segments. With mild/aggressive pruning, the VF is very compact, but has large maximum error (4.84, which is 18% rel. error at the point at which it occurs); the relative error is also significant, though it occurs at points with low value (hence gives small abs. error). The hybrid scheme works very well—by exploiting the contraction properties of the MDP, error associated with initial pruning is almost entirely overcome. It reduces the number of VF segments by an order of magnitude, and computation time by nearly two orders of magnitude, but gives very small max absolute (0.21, or 0.36%) and relative error (2.3%, or 0.0013).[2] Determining suitable pruning thresholds and schedules in general is an interesting open question.

Advertiser MDP. We next study two larger MDPs derived from the contact data of a large advertiser. The data consists of sequences of cross-channel touch points with users—each touch is labeled with a contact event (e.g., display ad, email, paid search ad, direct navigation to web site) or type of activity on the advertiser's web site (including transactions or "conversions"). There are 28 event types, and 3.6M trajectories comprising 10M events.

From this data, we learn (using MLE) several *variable-order Markov chain (VOMC) models* [9, 11] that predict

[2]CPU time using a simple Python prototype, on a 3.5GHz CPU with 32Gb of RAM.

transitions induced by the advertiser's policy. Predictions are based on a small sufficient history involving up to 10 preceding events. The histories comprising each VOMC form the state space of a Markov chain. From these we derive action-conditional transition models by substituting history end points with one of a small number of "controllable" events and using the VOMC model for these altered histories for transition predictions. We consider four actions (no-op, email, paid search, display ad), and two different models: the first is a VOMC model with a maximum state-order of 10 and an average state-order of five, giving an MDP with 451,582 states. The second is a two-component mixture of smaller VOMC models (maximum order of 3); we use the first component, with 1469 states.

We solve the BMDPs for both models (horizon 50, discount 0.975 as above). The table below shows pruning level, number of segments, and computation time for the 1469-state MDP using the same strategies as above.[3]

	No prun.	Mild	Aggr.	Mild+No
Segments	251.5 (74–359)	234.2 (77–342)	25.6 (5–39)	76.8 (18–321)
Max Err	—	5.13 (171.6)	28.9 (169.3)	3.9 (167.6)
Max RelErr	—	3.0% (171.6)	12.3% (169.3)	2.4% (167.6)
CPU (s.)	19918.9	10672.5	1451.8	2390.0

The 452K-state BMDP was solved only with aggressive pruning (slope 2.0, length 0.1), and averaged about 11.67 segments per state and 1168s. per DP iteration.

4 BUDGET ALLOCATED ACROSS MDPS

We now consider the problem facing an advertiser with a fixed maximum budget and a specific set of target customers, each of whom occupies the state of some underlying MDP. To solve the joint MDP above, we use the *weakly coupled* decomposition of [23], but merge the local solutions (and analyze this merge) in a different manner.

Offline Decomposition Our approach to decomposition is straightforward. We first solve each *single-user sub-MDP* as a BMDP with a some natural per-user maximum budget B_u. For ease of exposition, we assume just one user type, hence only one user MDP to solve (i.e., each user has the same dynamics). Users are distinguished only by their MDP state. The BMDP solution gives an optimal single-user policy π and VF V spanning all $s \in S, b \leq B_u$, indicating action choice and value *as a function of the budget available to be spent (in expectation) on that user alone*. We exploit this below. Indeed, this is why we do uses CMDPs, which do not indicate the value of allocating *varying* budgets to a user.

The Budget Allocation Problem Given initial (or current) joint state with M customers is $\mathbf{s} = \langle s[1], \cdots s[M] \rangle$, and budget B, a natural way to exploit the BMDP solution is to allocate some portion $b[i]$ of B to each customer $i \leq M$ s.t. we maximize the sum of expected values $v[i]$ assuming optimal engagement with i with budget $b[i]$. Specifically, the *budget allocation problem (BAP)* is :

$$\max_{b[i]:i\leq M} \sum_{i \leq M} V(s[i], b[i]) \text{ subj. to } \sum_{i \leq M} b[i] \leq B, \quad (3)$$

where V is the optimal VF for the underlying BMDP.

BAP determines an allocation $\mathbf{b}^* = \langle b^*[1], \ldots, b^*[M] \rangle$ that maximizes the expected value of *committing* a specific (expected) budget $b^*[i]$ to customer i. By simple linearity of expectation, we have:

Observation 6. *Let V be the optimal VF and π the optimal policy for the user MDP. Let $\mathbf{b}$ be the optimal solution to the budget allocation problem. Then the joint (non-stationary) policy $\overline{\pi}(\mathbf{s}) = \prod_i \pi(s[i], b[i])$ has expected value $\sum_i V(s[i], b[i])$ and expected spend $\sum_{i \leq M} b[i] \leq B$.*

We cannot guarantee this policy is truly optimal for the joint MDP, since this decomposed policy does not admit *recourse* in the execution of one user's MDP that depends on the realized outcome of some other user's MDP. However, we expect it to work well in practice (see below). For MDPs with large numbers of customers, or where the spend variance of the local BMDP policy is low, this form of suboptimality will be small. However, as we discuss below, *repeated online reallocation of budget* can sometimes overcome even this potential suboptimality in practice.

BAP (Eq. 3) can be viewed as a (multi-item variant of a) *multiple-choice knapsack problem (MCKP)* [29]. In the classic MCKP, we are given M classes of items, with each class i containing n_i items. To explain, we first begin with a restricted version of BAP, the *useful-budget assignment problem (UBAP)*. In UBAP, we require each user i be assigned a *useful* budget level from the discrete set $B^{s[i]}$. UBAP is exactly an MCKP: each user i is as an *item class* for whom exactly one budget must be chosen from the set of *items* $B^{s[i]}$ in that class. The *weight* of item $b \in B^{s[i]}$ is b (i.e., the amount of the budget it consumes); and the *profit* of assigning b to i is $V(s[i], b)$. The *capacity* is the global budget B, so total weight (budget assigned) cannot exceed B. We can view this as a *multi-item* variant of MCKP with multiple "copies" of the same class (namely, all users in a state j have the same items, weights and profits).

It is useful to consider an integer programming (IP) model of MCKP (where binary variable x_{ik} indicates that i is allocated the kth useful budget $\beta_{ik} = b_k^{s[i]}$):

$$\max_{x_{ik}} \quad \sum_{i \leq M} \sum_{k \in B^{s[i]}} V(s[i], \beta_{ik}) x_{ik} \quad (4)$$

$$\text{subject to} \quad \sum_{i \leq M} \sum_{k \in B^{s[i]}} \beta_{ik} x_{ik} \leq B \quad (5)$$

$$\sum_{k \in B^{s[i]}} x_{ik} = 1, \quad \forall i \leq M \quad (6)$$

$$x_{ik} \in \{0, 1\} \quad (7)$$

[3] The "no pruning" optimal benchmark uses slope/length pruning of $0.001/0.0001$ for 20 iterations and $0.01/0.001$ for 30. Aggressive is slope/length = $0.2/0.01$; mild is $0.02/0.001$.

We can collapse users in the same class using a counting (integer) variable as well.

Consider the LP relaxation of the IP Eq. 4—its optimal solution gives a (generally) fractional assignment of useful budget to any user i in state $s[i] = j$. Using a minor adaptation of the analysis of Sinha and Zoltners [29], we can show that the optimal allocation to any i is either integral (i.e., assigns a useful budget level to i), or is a mixture of two *consecutive* useful levels, in which case the expected budget $b^*[i]$ and induced expected value $v^*[i]$ in the LP corresponds to a point on the convex hull of the useful points. In other words, it lies on the PWLC VF $V(i, \cdot)$:

Proposition 7. *The optimal solution of the LP relaxation of UBAP IP Eq. 4 is such that, for each i: (a) $x_{ik} = 1$ for one value of k; or (b) there is some k such that only $x_{ik}, x_{i,k+1} > 0$ (i.e., only two budget levels are allocated, and they must be consecutive).*

We immediately obtain:

Corollary 8. *The optimal solution to the LP relaxation of UBAP is an optimal solution to BAP.*

The structure of the LP relaxation of MCKP is very valuable. Sinha and Zoltners [29] show that a simple greedy algorithm can be used to solve the relaxation. We adopt the same method, *greedy budget allocation (GBA)*, to solve BAP. For each state j, and each $1 \leq k \leq L$, define the *bang-for-buck ratio* as before:

$$BpB_{jk} = \frac{V(j, \beta_{jk}) - V(j, \beta_{jk-1})}{\beta_{jk} - \beta_{jk-1}}.$$

GBA assigns budget incrementally to each user in the order given by the BpB ratio. Initially each user i in state $s[i] = j$ is assigned a budget of $\beta_{j0} = 0$, and the unallocated budget is set to B (our budget constraint). At any stage of GBA, let b denote the unallocated budget, let β_{j,k_i} be i's current allocation and i's current ratio to be $BpB[i] = BpB_{jk_i+1}$. Let i be any *best user*, with maximum ratio $BpB[i]$. If sufficient budget remains, we increase i's allocation from β_{j,k_i} to β_{j,k_i+1}, then update i's ratio and the unallocated budget. We continue until the unallocated budget is less than $\beta_{j,k_i+1} - \beta_{j,k_i}$; then we allocate the remaining budget fractionally to the best i (β_{j,k_i} with probability p and β_{j,k_i+1} with $1 - p$, for $p = \frac{(\beta_{j,k_i+1} - \beta_{j,k_i}) - b}{(\beta_{j,k_i+1} - \beta_{j,k_i})}$).

We can show that GBA finds the optimal solution to our BAP (see [29]). GBA can be modified to aggregate all users that lie in the same state, and to account for the stochastic arrival of customers of various types, or at various states.

Dynamic Budget Reallocation The variance in the spend of an optimal policy $\pi(i, b)$ means there is some risk over overspending the global budget. This risk is, of course, greater with small numbers of users than with large numbers. One way to alleviate this risk *dynamic budget reallocation (DBRA)*. Rather than committing to the optimal policy for each user given their initial allocation, we reallocate any remaining budget at each stage. More precisely, given the current joint state $\mathbf{s} = \langle s[1], \ldots, s[M] \rangle$ and remaining budget B, we: (a) use GBA to determine allocation $b[i], i \leq M$ given $(\mathbf{s}, B)$; (b) execute action $\pi(s[i], b[i])$ for each i, incurring the cost c_i^a; and (c) observe the next state $\mathbf{s}'$ and remaining B' and repeat. This approach (virtually) guarantees that the global budget B will not be overspent (if the BMDP policy randomizes, a small chance of a small violation may exist). It also offers a form of recourse; e.g., if the budget for some user is no longer useful (e.g., transition to an unprofitable state), it budget can be reallocated to a more profitable user.

Empirical Evaluation We test the effectiveness of GBA on the BMDPs described in Sec. 3.4. We study expected spend and value of the "implied" joint policies, as well as spend variance.

We consider several ways of implementing the joint policies induced by the GBA solution of BAP. The first is the *BMDP policy*, where once GBA allocates $b[i]$ to each user i, we implement the corresponding BMDP policy starting at state $s[i]$. This ensures that *expected spend* does not exceed $b[i]$, but doesn't guarantee budget satisfaction for any specific user. The second is the *static user budget policy (SUB)*: given the GBA allocation $b[i]$, we implement the first action $a = \pi(s[i], b[i])$ in the BMDP policy at $s[i]$ for each i; but when reaching next state, we take the action as if we only had that user's *remaining* budget $b[i] - c^a_{s[i]}$, ignoring the next state budget mapping from the BMDP policy. SUB thus recalibrates the actual spend to minimize the odds of overspending $b[i]$ on a per-user basis. We also use the reallocation scheme DBRA, which reduces the overspending risk collectively (not per-user).

Solving BMDPs and using GBA to allocate budget allows one to assess budget tradeoffs across different users in different states. Without a BMDP model or our budget-dependent VF, these tradeoffs must be made heuristically. In this case, we can use *uniform budget allocation (UBA)*, which apportions budget equally across all users, and then solves the induced CMDPs (one per occupied state).

Synthetic Ad MDP. In the synthetic MDP, our initial setup has 1000 customers starting in s_0. The following table shows the expected value obtained by 3 different policies for 4 different global budgets:

Total Bud.	BMDP Val.	DBRA Val.	SUB Val.
1000	8210	8579 (830.5)	4106 (707)
2000	10,905	11,019 (964)	4429 (825)
5000	15,692	15,658 (1239)	5270 (830.5)
10,000	18,110	17,942 (—)	6329 (1159)

BMDP value is the true expected value of the optimal BMDP policy. SUB and DBRA values are averaged over 100 trials, which execute the relevant policies for all 1000 users (sample std. dev. also shown). The optimal BMDP policy has a considerable advantage over a static policy that forbids the per-user budget to be exceeded, yielding 2-3 times the return.[4] BMDP values also show a clear pat-

[4]Values are discounted, net of budget spent.

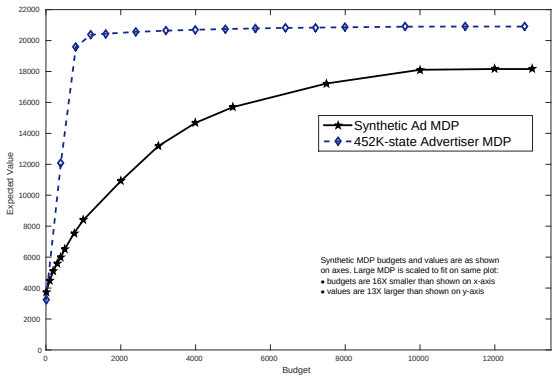

Fig. 4: Sweet spot curves: a plot of expected value vs. global budget for Synthetic and 452K-state MDPs (1000 users). The flat tails show that the maximal useful budget has been reached.

tern of diminishing return with increasing budget. Indeed, our MCKP-based GBA method allows one to *rapidly* assess the value of *optimally* using different global budgets to find the "sweet spot" in spend. Fig. 4 illustrates this *sweet spot curve*) for the joint MDP over 16 budget points.[5] The sweet spot curve is effectively the *Pareto frontier* expressing the tradeoff between two competing objectives, spend and expected return (for an in-depth survey of general multi-objective MDPs, please see [26]).

The optimal BMDP policy has considerable spend variance. In one run of 1000 customers (initial allocation 10 each), the sample average 10.012 is close to expected spend; but the sample std. dev. is 15.24. The empirical odds that a user exceeds the budget of 10 is 32.7%, and the odds of exceeding it by at least 50% is 28.7%. This alone explains the poor performance of the SUB allocation policy. Even with a large user base, overspending is possible: simulating the BMDP policy (1000 users) for 30 trials users, the global budget is exceeded in 13 of 30 trials, in 5 instances by over 3% (the largest overspend is by 11.7%). DBRA alleviates this risk—in all 100 trials the budget constraint is satisfied—while its average return matches or exceeds that of BMDP. With the very constrained budget (1000), DBRA also appears to offer the advantage of reallocating budget to more promising customers over time.

We also compare GBA to UBA on the same MDP, but with 1000 customers uniformly spread among the 12 non-terminal states (GBA and UBA are identical if all users start in the same state). The table below shows (exact) expected value of GBA and UBA for several global budgets.

Total Bud.	GBA Val.	UBA Val.
1000	39818.6	36997.2
2000	44559.5	40311.8
5000	53177.7	47142.4
10,000	58356.8	53773.8

The optimal BMDP solution allows GBA to make budget tradeoffs among customers in different states, giving greater value than a uniform scheme.

[5]The greedy algorithm averages 1.47ms. to compute the optimal allocation at each budget point.

Advertiser MDPs. We apply the same four methods to the advertiser-based MDPs. We first use GBA to derive "sweet spot" curves for the large MDP (results are similar for the 1469-state MDP). We assume 1000 customers, with 20 customers each entering the process in the 50 states with the largest "value spans" (i.e., difference in expected value given the minimal and maximal useful budget). Fig. 4 shows the budget-value tradeoff.

These MDPs model behavior that is quite random (i.e., not influenced very strongly by the actions). As a consequence, once the GBA algorithm is run, there is not a great difference between the BMDP and SUB policies. The table below shows results for the 452K-state BMDP for two fairly constrained budget levels (DBRA, SUB are averaged over 50 trials, BMDP and UBA values are exact).

Budg.	BMDP Val.	DBRA Val.	SUB Val.	UBA Val.
15	113358	99236 (3060)	112879 (1451)	106373
25	157228	142047 (3060)	157442 (2589)	149175

Neither BMDP nor SUB exhibit much variance in spend and both have similar expected values. SUB rarely overspends (e.g., maximum overspend for SUB with $B = 25$ is 0.16%). Variance tends to be greater when budgets are tighter. Among the 50 BMDP trials, 14 instances exceed the global budget, though only four instances exceed it by more than 4.0% (and one does so by 8.6%). DBRA eliminates the risk of overspending, but in this problem has a negative impact on expected value. GBA offers greater expected value than UBA (which is the only viable option if the BMDP has not been solved). GBA exceeds UBA by up to 6.5% over a range of constrained budgets.

5 CONCLUDING REMARKS

We have addressed the problem of budget (or other resource) allocation in MDPs so that budget-value tradeoffs can be addressed effectively. Our *budgeted MDP* model offers an alternative view of CMDPs that allows value to be derived as a function of available budget. We characterized the structure of optimal VFs and developed a DP algorithm that exploits the PWLC form of these VFs. Our second contribution was a method for exploiting BMDP solutions to allocate budget across independently operating BMDPs. We cast the problem as multi-item MCKP for which a simple greedy algorithm rapidly allocates budget optimally in a "committed" fashion. We also investigated dynamic reallocation of budget over time.

The extension of our methods to account for dynamic user populations is straightforward, but warrants empirical investigation. Future work includes the further study of and experimentation with our algorithms on richer models of user behavior. We are also interested in extending our models to partially observable settings (e.g., where user type estimation based on behavioral observations is needed).

Abstract

Large-scale kernel ridge regression (KRR) is limited by the need to store a large kernel matrix $\mathbf{K}_t$. To avoid storing the entire matrix $\mathbf{K}_t$, Nyström methods subsample a subset of columns of the kernel matrix, and efficiently find an approximate KRR solution on the reconstructed $\widetilde{\mathbf{K}}_t$. The chosen subsampling distribution in turn affects the statistical and computational tradeoffs. For KRR problems, [16, 1] show that a sampling distribution proportional to the *ridge leverage scores* (RLSs) provides strong reconstruction guarantees for $\widetilde{\mathbf{K}}_t$. While exact RLSs are as difficult to compute as a KRR solution, we may be able to approximate them well enough. In this paper, we study KRR problems in a sequential setting and introduce the INK-ESTIMATE algorithm, that *incrementally* computes the RLSs estimates. INK-ESTIMATE maintains a small *sketch* of $\mathbf{K}_t$, that at each step is used to compute an intermediate estimate of the RLSs. First, our sketch update does not require access to previously seen columns, and therefore a *single pass* over the kernel matrix is sufficient. Second, the algorithm requires a fixed, small space budget to run dependent only on the *effective dimension* of the kernel matrix. Finally, our sketch provides strong approximation guarantees on the distance $\|\mathbf{K}_t - \widetilde{\mathbf{K}}_t\|_2$, and on the statistical risk of the approximate KRR solution at *any time*, because all our guarantees hold at any intermediate step.

1 INTRODUCTION

Kernel ridge regression [17, 18] (KRR) is a common nonparametric regression method with well studied theoretical advantages. Its main drawback is that, for n samples, storing and manipulating the kernel regression matrix $\mathbf{K}_n$ requires $\mathcal{O}(n^2)$ space, and can become quickly intractable when n grows. This includes batch large scale KRR, and online KRR, where the size of the dataset t grows over time as new samples are added to the problem. For this purpose, many different methods [23, 4, 10, 14, 11, 24] attempt to reduce the memory required to store the kernel matrix, while still producing an accurate solution.

For the batch case, the Nyström family of algorithms randomly selects a subset of m columns from the kernel matrix $\mathbf{K}_n$ that are used to construct a low rank approximation $\widetilde{\mathbf{K}}_t$ that requires only $\mathcal{O}(nm)$ space to store. The low-rank matrix is then used to find an approximate solution to the KRR problem. The quality of the approximate solution is strongly affected by the sampling distribution and the number of columns selected [16]. For example, uniform sampling is an approach with little computational overhead, but does not work well for datasets with high coherence [7], where the columns are weakly correlated. In particular, Bach [2] shows that the number of columns m necessary for a good approximation when sampling uniformly scales linearly with the maximum degree of freedoms of the kernel matrix. In linear regression, the notion of coherence is strongly related to the definition of leverage points or *leverage scores* of the dataset [6], where points with high (statistical) leverage score are more influential in the regression problem. For KRR, Alaoui and Mahoney [1] introduce a similar concept of *ridge* leverage scores (RLSs) of a square matrix, and shows that Nyström approximations sampled according to RLS have strong reconstruction guarantees of the form $\|\mathbf{K}_n - \widetilde{\mathbf{K}}_n\|_2$, that translate into good guarantees for the approximate KRR solution [1, 16]. Compared to the uniform distribution, a distribution based on RLSs better captures non-uniformities in the data, and can achieve good approximations using only a number of columns m, proportional to the average degrees of freedom of the matrix, called the *effective dimension* of the problem. The disadvantage of RLSs compared to uniform sampling is the high computational cost of exact RLSs, which is comparable to solving KRR itself. Alaoui and Mahoney [1] reduces this problem by showing that a distribution based on approximate RLSs can also provide the same strong guarantees, if the RLSs are approximated up to a constant er-

ror factor. They provide a fast method to compute these RLSs, but, unlike our approach, requires multiple passes over data. Another disadvantage of their approach, that we address, is the *inverse dependence on the minimal eigenvalue* of the kernel matrix in the error bound of Alaoui and Mahoney [1], which can be significant.

While Nyström methods are a typical choice in a batch setting, *online kernel sparsification* (OKS) [4, 5] examines each sample in the dataset sequentially. OKS maintains a small *dictionary* of relevant samples. Whenever a new sample arrive, if the dictionary is not able to accurately represent the new sample as a combination of the samples already stored, the dictionary is updated. This dictionary can be used to approximate KRR incrementally. OKS decides whether to include a sample using the correlation between samples in the dictionary and the new sample. This can measured using approximate linear dependency (ALD) [5], coherence [15], or the surprise criterion [12].

Generalization properties of online kernel sparsification were studied by Engel et al. [5], but depend on the empirical error and are not compared with an exact KRR solution on the whole dataset. Online kernel regression with the ALD rule was analyzed by Sun et al. [19], under the assumption that, asymptotically in n, the eigenvalues of the kernel matrix decay exponentially fast. Sun et al. [19] show that in this case the size of the dictionary grows sublinearly in t, or in other words that, asymptotically in n, the dictionary size converge to a fraction of n that will be small whenever the eigenvalues decay fast enough. This space guarantee is weaker than the fixed space requirements of Nyström methods, one of the reasons is that these methods (unlike ours) cannot remove a sample from the dictionary after inclusion. Furthermore, Van Vaerenbergh et al. [22] studies variants of online kernel regression with a forgetting factor for time-varying series, but these methods are not well studied in the normal KRR setting. Unlike in the batch setting, in the sequential setting we often require the guarantees not only at the end but also *in the intermediate steps* and this is our objective. Inspired by the advances in the analyses of the Nyström methods, in this paper, we focus on finding a space efficient algorithm capable of solving KRR problems in the sequential setting but that would be also equipped with generalization guarantees.

Main contributions We propose the INK-ESTIMATE algorithm that processes a dataset $\mathcal{D}$ of size n in *a single pass*. It requires only a small, fixed space budget, $\overline{q}$ proportional to the effective dimension of the problem and on the accuracy required. The algorithm maintains a Nyström approximation $\widetilde{\mathbf{K}}_t$, of the kernel matrix at time t, $\mathbf{K}_t$, based on RLSs estimates. At each step, it uses only the approximation and the newly received sample to incrementally update the RLSs estimate, and to compute $\widetilde{\mathbf{K}}_{t+1}$. Unlike in the batch Nyström setting, our challenge is to track RLSs and an effective dimension that *changes over time*. Sampling distributions based on RLSs can become obsolete and biased, but we show how to update them over time *without necessity of accessing previously seen samples* outside of the ones contained in $\mathbf{K}_t$. Our space budget $\overline{q}$ scales with the average degree of freedom of the matrix, and not the larger maximum degree of freedom (as by Bach [2]), and does not imposes assumptions on the ridge regularization parameter, or on the smallest eigenvalue of the problem as the result of Alaoui and Mahoney [1]. However, we provide the same strong guarantees as batch RLSs based Nyström methods on $\|\mathbf{K}_n - \widetilde{\mathbf{K}}_n\|_2$ and on the risk of the approximate KRR solution. In addition to batch Nyström methods, all of these guarantees hold at any intermediate step t, and therefore the algorithm can output *accurate intermediate solutions*, or it can be interrupted at *any time* and return a solution with guarantees. Finally, it operates in a *sequential* setting, requiring only a single pass over the data.

If we compare INK-ESTIMATE to other online kernel regression methods (such as OKS), our algorithm provides generalization guarantees with respect to the exact KRR solution. Furthermore, it provides a new criteria for inclusion of a sample in the dictionary, in particular the ridge leverage scores. This criterion gives us a procedure that not only randomly includes samples in the dictionary, but that also randomly discards them to satisfy space constraints not only asymptotically, but at every step.

2 BACKGROUND

In this section we introduce the notation used through the paper and we introduce the kernel ridge regression problem [17] and Nyström approximation of the kernel matrix with ridge leverage scores.

Notation. We use curly capital letters $\mathcal{A}$ for collections. We use upper-case bold letters $\mathbf{A}$ for matrices, lower-case bold letters $\mathbf{a}$ for vectors, and lower-case letters a for scalars. We denote by $[\mathbf{A}]_{ij}$ and $[\mathbf{a}]_i$ the (i, j) element of a matrix and ith element of a vector respectively. We denote by $\mathbf{I}_n \in \mathbb{R}^{n\times n}$ the identity matrix of dimension n and by $\mathrm{Diag}(\mathbf{a}) \in \mathbb{R}^{n\times n}$ the diagonal matrix with the vector $\mathbf{a} \in \mathbb{R}^n$ on the diagonal. We use $\mathbf{e}_{i,n} \in \mathbb{R}^n$ to denote the indicator vector for element i of dimension n. When the dimensionality of $\mathbf{I}$ and $\mathbf{e}_i$ is clear from the context, we omit the n. We use $\mathbf{A} \succeq \mathbf{B}$ to indicate that $\mathbf{A} - \mathbf{B}$ is a PSD matrix. Finally, the set of integers between 1 and n is denoted by $[n] := \{1, \ldots, n\}$.

2.1 Exact Kernel Ridge Regression

Kernel regression. We consider a regression dataset $\mathcal{D} = \{(\mathbf{x}_t, y_t)\}_{t=1}^n$, with input $\mathbf{x}_t \in \mathcal{X} \subseteq \mathbb{R}^d$ and output $y_t \in \mathbb{R}$. We denote by $\mathcal{K} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ a positive definite kernel function and by $\varphi : \mathcal{X} \to \mathbb{R}^D$ the corresponding

feature map,[1] so that the kernel is obtained as $\mathcal{K}(\mathbf{x}, \mathbf{x}') = \varphi(\mathbf{x})^\mathsf{T}\varphi(\mathbf{x}')$. Given the dataset $\mathcal{D}$, we define the kernel matrix $\mathbf{K}_t \in \mathbb{R}^{t\times t}$ constructed on the first t samples as the application of the kernel function on all pairs of input values, i.e., $[\mathbf{K}_t]_{ij} = \mathcal{K}(\mathbf{x}_i, \mathbf{x}_j)$ for any $i, j \in [t]$ and we denote by $\mathbf{y}_t \in \mathbb{R}^t$ the vector with components y_i, $i \in [t]$. We also define the feature vectors $\boldsymbol{\phi}_t = \varphi(\mathbf{x}_t) \in \mathbb{R}^D$ and after introducing the feature matrix

$$\boldsymbol{\Phi}_t = \left[\ \boldsymbol{\phi}_1 \mid \boldsymbol{\phi}_2 \mid \dots \mid \boldsymbol{\phi}_t\ \right] \in \mathbb{R}^{D\times t},$$

we can rewrite the kernel matrix as $\mathbf{K}_t = \boldsymbol{\Phi}_t^\mathsf{T}\boldsymbol{\Phi}_t$. Whenever a new point $\mathbf{x}_{t+1}$ arrives, the kernel matrix $\mathbf{K}_{t+1} \in \mathbb{R}^{t+1\times t+1}$ is obtained by bordering $\mathbf{K}_t$ as

$$\mathbf{K}_{t+1} = \left[\begin{array}{c|c} \mathbf{K}_t & \overline{\mathbf{k}}_{t+1} \\ \hline \overline{\mathbf{k}}_{t+1}^\mathsf{T} & k_{t+1} \end{array}\right] \tag{1}$$

where $\overline{\mathbf{k}}_{t+1} \in \mathbb{R}^t$ is such that $[\overline{\mathbf{k}}_{t+1}]_i = \mathcal{K}(\mathbf{x}_{t+1}, \mathbf{x}_i)$ for any $i \in [t]$ and $k_{t+1} = \mathcal{K}(\mathbf{x}_{t+1}, \mathbf{x}_{t+1})$. According to the definition of the feature matrix $\boldsymbol{\Phi}_t$, we also have $\mathbf{k}_{t+1} = \boldsymbol{\Phi}_t^\mathsf{T}\boldsymbol{\phi}_{t+1}$.

At any time t, the objective of *sequential* kernel regression is to find the vector $\widehat{\mathbf{w}}_t \in \mathbb{R}^t$ that minimizes the regularized quadratic loss

$$\widehat{\mathbf{w}}_t = \arg\min_{\mathbf{w}} \|\mathbf{y}_t - \mathbf{K}_t\mathbf{w}\|^2 + \mu\|\mathbf{w}\|^2, \tag{2}$$

where $\mu \in \mathbb{R}$ is a regularization parameter. This objective admits the closed form solution

$$\widehat{\mathbf{w}}_t = (\mathbf{K}_t + \mu\mathbf{I})^{-1}\mathbf{y}_t. \tag{3}$$

In the following, we use $\mathbf{K}_t^\mu$ as a short-hand for $(\mathbf{K}_t + \mu\mathbf{I})$. In batch regression, $\widehat{\mathbf{w}}_n$ is computed only once when all the samples of $\mathcal{D}$ are available, solving the linear system in Eq. 3 with $\mathbf{K}_n$. In the *fixed-design* kernel regression, the accuracy of resulting solution $\widehat{\mathbf{w}}_n$ is measured by the prediction error on the input set from $\mathcal{D}$. More precisely, the prediction of the estimator $\widehat{\mathbf{w}}_n$ in each point is obtained as $[\mathbf{K}_n\widehat{\mathbf{w}}_n]_i$, while the outputs y_i in the dataset are assumed to be a noisy observation of an unknown target function $f^* : \mathcal{X} \to \mathbb{R}$, evaluated in x_i i.e., for any $i \in [n]$,

$$y_i = f^*(x_i) + \eta_i,$$

where η_i is a zero-mean i.i.d. noise with bounded variance σ^2. Let $\mathbf{f}^* \in \mathbb{R}^n$ be the vector with components $f^*(x_i)$, then the risk of $\widehat{\mathbf{w}}_n$ is measured as

$$\mathcal{R}(\widehat{\mathbf{w}}_n) = \mathbb{E}_\eta\big[||\mathbf{f}^* - \mathbf{K}_n\widehat{\mathbf{w}}_n||_2^2\big]. \tag{4}$$

If the regularization parameter μ is properly tuned, it is possible to show that $\widehat{\mathbf{w}}_n$ has near-optimal risk guarantees (in a minmax sense). Nonetheless, the computation of $\widehat{\mathbf{w}}_n$ requires $\mathcal{O}(n^3)$ time and $\mathcal{O}(n^2)$ space, which becomes rapidly unfeasible for large datasets.

[1] where D can be very large or infinite (e.g. gaussian kernel)

2.2 Nyström Approximation with Ridge Leverage Scores

A common approach to reduce the complexity of kernel regression is to (randomly) select a subset of m samples out of $\mathcal{D}$, and compute the kernel between two points only when one of them is in the selected subset. This is equivalent to selecting a subset of columns of the $\mathbf{K}_n$ matrix. More formally, given the n samples in $\mathcal{D}$, a probability distribution $\mathbf{p}_n = [p_{1,n}, \dots, p_{n,n}]$ is defined over all columns of $\mathbf{K}_n$ and $m \le n$ columns are randomly sampled with replacement according to $\mathbf{p}_n$. We define by $\mathcal{I}_n$ the sequence of m indices $i \in [n]$ selected by the sampling procedure. From $\mathcal{I}_n$, we construct the corresponding selection matrix $\mathbf{S}_n \in \mathbb{R}^{n\times m}$, where each column $[\mathbf{S}_n]_{:,t} \in \mathbb{R}^n$ is all-zero except from the entry corresponding to the t-th element in $\mathcal{I}_n$ (i.e., $[\mathbf{S}]_{ij}$ is non-zero if at trial j the element i is selected). Whenever the non-zero entries of $\mathbf{S}_n$ are set to 1, sampling m columns from matrix $\mathbf{K}_n$ is equivalent to computing $\mathbf{K}_n\mathbf{S}_n \in \mathbb{R}^{n\times m}$. More generally, the non-zero entries of $\mathbf{S}_n$ could be set to some arbitrary weight $[\mathbf{S}]_{ij} = b_{ij}$. The resulting regularized Nyström approximation of the original kernel $\mathbf{K}_n$ is defined as

$$\widetilde{\mathbf{K}}_n = \mathbf{K}_n\mathbf{S}_n(\mathbf{S}_n^\mathsf{T}\mathbf{K}_n\mathbf{S}_n + \gamma\mathbf{I}_m)^{-1}\mathbf{S}_n^\mathsf{T}\mathbf{K}_n, \tag{5}$$

where γ is a regularization term (possibly different from μ). At this point, $\widetilde{\mathbf{K}}_n$ can be used to solve Eq. 3. Let $\mathbf{W} = (\mathbf{S}_n^\mathsf{T}\mathbf{K}_n\mathbf{S}_n + \gamma\mathbf{I}_m)^{-1} \in \mathbb{R}^{m\times m}$ and $\mathbf{C} = \mathbf{K}_n\mathbf{S}_n\mathbf{W}^{1/2} \in \mathbb{R}^{n\times m}$, applying the Woodbury inversion formula [8] we have

$$\begin{aligned}\widetilde{\mathbf{w}}_n =& (\widetilde{\mathbf{K}}_n + \mu\mathbf{I}_n)^{-1}\mathbf{y}_n = (\mathbf{C}\mathbf{I}_m\mathbf{C}^\mathsf{T} + \mu\mathbf{I}_n)^{-1}\mathbf{y}_n \\ =& \left(\frac{1}{\mu}\mathbf{I}_n - \frac{1}{\mu^2}\mathbf{I}_n\mathbf{C}\left(\mathbf{I}_m + \frac{1}{\mu}\mathbf{C}^\mathsf{T}\mathbf{C}\right)^{-1}\mathbf{C}^\mathsf{T}\mathbf{I}_n\right)\mathbf{y}_n \\ =& \frac{1}{\mu}\left(\mathbf{y}_n - \mathbf{C}\left(\mathbf{C}^\mathsf{T}\mathbf{C} + \mu\mathbf{I}_m\right)^{-1}\mathbf{C}^\mathsf{T}\mathbf{y}_n\right).\end{aligned} \tag{6}$$

Computing $\mathbf{W}^{1/2}$ and $\mathbf{C}$ takes $\mathcal{O}(m^3)$ and $\mathcal{O}(nm^2)$ time using a singular value decomposition, and so does solving the linear system. All the operations require to store at most an $n \times m$ matrix. Therefore the final complexity is reduced from $\mathcal{O}(n^3)$ to $\mathcal{O}(nm^2 + m^3)$ time, and from $\mathcal{O}(n^2)$ to $\mathcal{O}(nm)$ space. Rudi et al. [16] recently showed that in random design, the risk of the resulting solution $\widetilde{\mathbf{w}}_n$ strongly depends on the choice of m and the column sampling distribution $\mathbf{p}_n$. Early methods sampled columns uniformly, and Bach [2] shows that the using this distribution can provide a good approximation when the maximum diagonal entry of $\mathbf{K}_n(\mathbf{K}_n + \mu\mathbf{I})^{-1}$ is small. Following on this approach, Alaoui and Mahoney [1] propose a distribution proportional to these diagonal entries and calls them γ-Ridge Leverage Scores. We now restate their definition of RLS, corresponding sampling distribution, and the effective dimension.

Definition 1. *Given a kernel matrix $\mathbf{K}_n \in \mathbb{R}^{n\times n}$, the γ-ridge leverage score (RLS) of column $i \in [n]$ is*

$$\tau_{i,n}(\gamma) = \mathbf{k}_{i,n}^{\mathsf{T}}(\mathbf{K}_n + \gamma\mathbf{I}_m)^{-1}\mathbf{e}_{i,n}, \tag{7}$$

where $\mathbf{k}_{i,n} = \mathbf{K}_n\mathbf{e}_{i,n}$. Furthermore, the effective dimension $d_{\mathit{eff}}(\gamma)_n$ of the kernel is defined as

$$d_{\mathit{eff}}(\gamma)_n = \sum_{i=1}^{n}\tau_{i,n}(\gamma) = \mathrm{Tr}\left(\mathbf{K}_n(\mathbf{K}_n + \gamma\mathbf{I}_n)^{-1}\right). \tag{8}$$

The corresponding sampling distribution $\mathbf{p}_n$ is defined as

$$[\mathbf{p}_n]_i = p_{i,n} = \frac{\tau_{i,n}(\gamma)}{\sum_{j=1}^{n}\tau_{i,n}(\gamma)} = \frac{\tau_{i,n}}{d_{\mathit{eff}}(\gamma)_n}. \tag{9}$$

The RLSs are directly related to the structure of the kernel matrix and the regularized regression. If we perform an eigendecomposition of the kernel matrix as $\mathbf{K}_n = \mathbf{U}_n\mathbf{\Lambda}_n\mathbf{U}_n^{\mathsf{T}}$, then the RLS of a column $i \in [n]$ is

$$\tau_{i,n}(\gamma) = \sum_{j=1}^{n}\frac{\lambda_j}{\lambda_j+\gamma}[\mathbf{U}]_{i,j}^2, \tag{10}$$

which shows how the RLS is a weighted version of the standard leverage scores (i.e., $\sum_j [U]_{i,j}^2$), where the weights depend on both the spectrum of $\mathbf{K}_n$ and the regularization γ, which plays the role of a soft threshold on the rank of $\mathbf{K}_n$. Similar to the standard leverage scores [3], the RLSs measure the relevance of each point $\mathbf{x}_i$ for the overall kernel regression problem. Another interesting property of the RLSs is that their sum is the effective dimension $d_{\text{eff}}(\gamma)_n$, which measures the intrinsic capacity of the kernel $\mathbf{K}_n$ when its spectrum is soft-thresholded by a regularization γ.[2] We refer to the overall Nyström method using RLS and sampling according to to $\mathbf{p}_n$ in Eq. 9 as BATCH-EXACT, which is illustrated in Alg. 1. We single out the DIRECT-SAMPLE subroutine (which simply draws m independent samples from the multinomial distribution $\mathbf{p}_n$) to ease the introduction of our incremental algorithm in the next section.

With the following claim, Alaoui and Mahoney [1] prove that the regularized Nyström approximation $\widetilde{\mathbf{K}}_n$ obtained from Eq. 5 guarantees an accurate reconstruction of the original kernel matrix $\mathbf{K}_n$, and the risk of the associated solution $\widetilde{\mathbf{w}}_n$ is close to the risk of the exact solution $\widehat{\mathbf{w}}_n$.

Proposition 1 (Alaoui and Mahoney [1], App. A, Lem. 1)**.** *Let $\gamma \geq 1$, let $\mathbf{K}_n$ be the full kernel matrix ($t = n$), and let $\tau_{i,n}$, $d_{\mathit{eff}}(\gamma)_n$, $p_{i,n}$ be defined according to Definition 1. For any $0 \leq \varepsilon \leq 1$, and $0 \leq \delta \leq 1$, if we run Alg. 1 using* DIRECT-SAMPLE *(Subroutine 1) with sampling budget m,*

$$m \geq \left(\frac{2d_{\mathit{eff}}(\gamma)}{\varepsilon^2}\right)\log\left(\frac{n}{\delta}\right),$$

[2]Notice that indeed we have $d_{\text{eff}}(\gamma)_n \leq \mathrm{Rank}(\mathbf{K}_n)$.

Algorithm 1 BATCH-EXACT algorithm

Input: $\mathcal{D}$, regularization parameter γ, sampling budget m and probabilities $\mathbf{p}_n$ (Eq. 9)
Output: Nyström approximation $\widetilde{\mathbf{K}}_n$, matrix $\mathbf{S}_n$

1: Compute $\mathcal{I}_n$ using DIRECT-SAMPLE$(\mathbf{p}_n, m)$
2: Compute $\mathbf{S}_n$ using $\mathcal{I}_n$ and weights $1/\sqrt{mp_{i,n}}$
3: Compute $\widetilde{\mathbf{K}}_n$ using $\mathbf{S}_n$ and Equation 5

Subroutine 1 DIRECT-SAMPLE$(\mathbf{p}_n, m) \to \mathcal{I}_n$

Input: probabilities $\mathbf{p}_n$, sampling budget m
Output: subsampled column indices $\mathcal{I}_n$

1: **for** $j = \{1, \ldots, m\}$ **do**
2: Sample $i \sim \mathcal{M}(p_{1,n}, \ldots, p_{n,n})$
3: Add i to $\mathcal{I}_n$
4: **end for**

to compute matrix $\mathbf{S}_n$, then with probability $1-\delta$ the corresponding Nyström approximation $\widetilde{\mathbf{K}}_n$ in Eq. 5 satisfies the condition

$$\mathbf{0} \preceq \mathbf{K}_n - \widetilde{\mathbf{K}}_n \preceq \frac{\gamma}{1-\varepsilon}\mathbf{K}_n(\mathbf{K}_n+\gamma\mathbf{I}_n)^{-1} \preceq \frac{\gamma}{1-\varepsilon}\mathbf{I}_n. \tag{11}$$

Furthermore, replacing $\mathbf{K}_n$ by $\widetilde{\mathbf{K}}_n$ in Eq. 3 gives an approximation solution $\widetilde{\mathbf{w}}_n$ such that

$$\mathcal{R}(\widetilde{\mathbf{w}}_n) \leq \left(1 + \frac{\gamma}{\mu}\frac{1}{1-\varepsilon}\right)^2\mathcal{R}(\widehat{\mathbf{w}}_n).$$

Discussion This result directly relates the number of columns selected m with the accuracy of the approximation of the kernel matrix. In particular, the inequalities in Eq. 11 show that the distance $\|\mathbf{K}_n - \widetilde{\mathbf{K}}_n\|_2$ is smaller than $\gamma/(1-\varepsilon)$. This level of accuracy is then sufficient to guarantee that, when γ is properly tuned, the prediction error of $\widetilde{\mathbf{w}}_n$ is only a factor $(1+2\varepsilon)^2$ away from the error of the exact solution $\widehat{\mathbf{w}}$. As it was shown in [1], using $\widetilde{\mathbf{K}}_n$ in place of $\mathbf{K}_n$ introduces a bias in the solution $\widetilde{\mathbf{w}}_n$ of order γ. For appropriate choices of γ this bias is dominated by the ridge regularization bias controlled by μ. As a result, $\widetilde{\mathbf{w}}_n$ can indeed achieve almost the same risk as $\widehat{\mathbf{w}}_n$ and, at the same time, ignore all directions that are whitened by the regularization and only approximate those that are more relevant for ridge regression, thus reducing both time and space complexity. The RLSs quantify how important each column is to approximate these relevant directions but computing exact RLSs $\tau_{i,n}(\gamma)$ using Eq. 7 is as hard as solving the regression problem itself. Fortunately, in many cases it is computationally feasible to find an approximation of the RLSs. Alaoui and Mahoney [1] explore this possibility, showing that the accuracy and space guarantees are robust to perturbations in the distribution $\mathbf{p}_n$, and provide a two-pass method to compute such approximations. Unfortunately, the accuracy of their RLSs approximation is proportional to the smallest eigenvalue $\lambda_{\min}(\mathbf{K}_n)$, which in

Algorithm 2 The INK-ORACLE algorithm

Input: Dataset $\mathcal{D}$, regularization γ, sampling budget $\overline{q}$ and (α, β)-ORACLE

Output: $\widetilde{\mathbf{K}}_n$, $\mathbf{S}_n$

Initialize $\mathcal{I}_0$ as empty, $\widetilde{p}_{1,0} = 1, b_{1,0} = 1$, budget $\overline{q}$
for $t = 0, \ldots, n-1$ **do**
  Receive new column $\overline{\mathbf{k}}_{t+1}$ and scalar k_{t+1}
  Receive α-leverage scores $\widetilde{\tau}_{i,t+1}$ for any $i \in \mathcal{I}_t \cup \{t+1\}$ from (α, β)-ORACLE
  Receive β-approximate $\widetilde{d}_{\text{eff}}(\gamma)_{t+1}$ from (α, β)-ORACLE
  Set $\widetilde{p}_{i,t+1} = \min\{\widetilde{\tau}_{i,t+1}/\widetilde{d}_{\text{eff}}(\gamma)_{t+1}, \widetilde{p}_{i,t}\}$
  $\mathcal{I}_{t+1}, \mathbf{b}_{t+1}$ = SHRINK-EXPAND$(\mathcal{I}_t, \widetilde{\mathbf{p}}_{t+1}, \mathbf{b}_t, \overline{q})$
  Compute $\mathbf{S}_{t+1}$ using $\mathcal{I}_{t+1}$ and weights $\sqrt{b_{i,t+1}}$
  Compute $\widetilde{\mathbf{K}}_{t+1}$ using $\mathbf{S}_{t+1}$ and Equation 5
end for
Return $\widetilde{\mathbf{K}}_n$ and $\mathbf{S}_n$

Subroutine 2 SHRINK-EXPAND$(\mathcal{I}_t, \widetilde{\mathbf{p}}_{t+1}, \mathbf{b}_t, \overline{q})$

Input: $\mathcal{I}_t$, app. pr. $\{(\widetilde{p}_{i,t+1}, b_{i,t}) : i \in \mathcal{I}_t\}$, $\widetilde{p}_{t+1,t+1}$, $\overline{q}$

Output: $\mathcal{I}_{t+1}$

for all $j \in \{1, \ldots, t\}$ **do** ▷SHRINK
  $b_{i,t+1} = b_{i,t}$
  while $b_{i,t+1}\widetilde{p}_{i,t+1} \leq 1/\overline{q}$ and $b_{i,t} \neq 0$ **do**
    Sample a random Bernoulli $\mathcal{B}\left(\frac{b_{i,t+1}}{b_{i,t+1}+1}\right)$
    On success set $b_{i,t+1} = b_{i,t+1} + 1$
    On failure set $b_{i,t+1} = 0$
  end while
end for
$b_{t+1,t+1} = 1$ ▷EXPAND
while $b_{t+1,t+1}\widetilde{p}_{t+1,t+1} \leq 1/\overline{q}$ and $b_{t+1,t+1} \neq 0$ **do**
  Sample a random Bernoulli $\mathcal{B}\left(\frac{b_{t+1,t+1}}{b_{t+1,t+1}+1}\right)$
  On success set $b_{t+1,t+1} = b_{t+1,t+1} + 1$
  On failure set $b_{t+1,t+1} = 0$
end while
Add to $\mathcal{I}_{t+1}$ all columns with $b_{i,t+1} \neq 0$

some cases can be very small. In the rest of the paper, we propose an *incremental* approach that requires only a *single pass* over the data and, at the same time, does not depend on $\lambda_{\min}(\mathbf{K}_n)$ to be large as in [1], or on $\max_i \tau_{i,n}$ to be small as in [2].

3 INCREMENTAL ORACLE KERNEL APPROXIMATION WITH SEQUENTIAL SAMPLING

Our main goal is to extend the known ridge leverage score sampling to the *sequential setting*. This comes with several challenges that needs to be addressed *simultaneously:*

1. The RLSs change when a new sample arrives. We not only need to estimate them, but to *update* this estimate over iterations.

2. The effective dimension $\widetilde{d}_{\text{eff}}(\gamma)_t$, necessary to normalize the leverage scores for the sampling distribution $\mathbf{p}_n$, depends on the interactions of all columns, including the ones that we decided *not* to keep.

3. Due to changes in RLSs, our sampling distribution $\widetilde{\mathbf{p}}_t$ *changes over time*. We need to update to dictionary to reflect these changes, or it will quickly become *biased*, but once we completely drop a column, we cannot sample it again.

In this section, we address the third challenge of incremental updates of the columns with an algorithm for the approximation of the kernel matrix $\mathbf{K}_n$, assuming that the first and second issue are addressed by an *oracle* giving *both* good approximations of leverage scores and the effective dimension.

Definition 2. *At any step t, an (α, β)-oracle returns an α-approximate ridge leverage scores $\widetilde{\tau}_{i,t}$ which satisfy*

$$\frac{1}{\alpha}\tau_{i,t}(\gamma) \leq \widetilde{\tau}_{i,t} \leq \tau_{i,t}(\gamma),$$

for any $i \in [t]$ and and a β-approximate effective dimension $\widetilde{d}_{\text{eff}}(\gamma)_t$ which satisfy

$$d_{\text{eff}}(\gamma)_t \leq \widetilde{d}_{\text{eff}}(\gamma)_t \leq \beta d_{\text{eff}}(\gamma)_t.$$

We address the first and second challenge in Sect. 4 with an efficient implementation and (α, β)-oracle. In the following we give the *incremental* INK-ORACLE algorithm equipped with an (α, β)-oracle that after n steps it returns a kernel approximation with the same properties as if an (α, β)-oracle was used directly at time n.

3.1 The INK-ORACLE Algorithm

Apart from an (α, β)-ORACLE and the dataset $\mathcal{D}$, INK-ORACLE (Alg. 2) receives as input the regularization parameter γ used in constructing the final Nyström approximation and a sampling budget $\overline{q}$. It initializes the index dictionary $\mathcal{I}_0$ of stored columns as empty, and the estimated probabilities as $\widetilde{p}_{i,0} = 1$. Finally it initializes a set of integer weights $b_{i,0} = 1$. These weights will represent a discretized approximation of $1/\widetilde{p}_{i,t}$ (the inverse of the probabilities). At each time step t, it receives a new column $\overline{\mathbf{k}}_{t+1}$ and k_{t+1}. This can be implemented either by hav-

ing a separate algorithm, constructing each column sequentially and stream it to INK-ORACLE, or by having INK-ORACLE store just the samples (for an additional $\mathcal{O}(td)$ space complexity) and independently compute the column once. The algorithm invokes the (α, β)-oracle to compute approximate probabilities $\widetilde{p}_{i,t+1} = \widetilde{\tau}_{i,t+1}/\widetilde{d}_{\text{eff}}(\gamma)_{t+1}$, and then takes the minimum $\min\{\widetilde{p}_{i,t+1}, \widetilde{p}_{i,t}\}$ for the sampling probability. As our analysis will reveal, this step is necessary to ensure that the SHRINK-EXPAND operation remains well defined, since the true probabilities $p_{i,t}$ decrease over time. It is important to notice that differently from the batch sampling setting, the approximate probabilities do not necessarily sum to one, but it is guaranteed that $\sum_{i=1}^{t} \widetilde{p}_{i,t} \leq 1$. The SHRINK-EXPAND procedure is composed of two steps. In the SHRINK step, we update the weights of the columns already in our dictionary. To decide whether a weight should be increased or not, the product of the weight at the preceding step $b_{i,t-1}$ and the new estimate $\widetilde{p}_{i,t}$ is compared to a threshold. If the product is above the threshold, it means the probability did not change much, and no action is necessary. If the product falls below the threshold, it means the decrease of $\widetilde{p}_{i,t}$ is significant, and the old weight is not representative anymore and should be increased. To increase the weight (e.g. from k to $k+1$), we draw a Bernoulli random variable $\mathcal{B}(\frac{k}{k+1})$, and if it succeeds we increase the weight to $k+1$, while if it fails we set the weight to 0. The more $\widetilde{p}_{i,t}$ decrease over time, the higher the chanches that $b_{i,t+1}$ is set to zero, and the index i (and the associated column $\mathbf{k}_{i,t+1}$) is completely dropped from the dictionary. Therefore, the SHRINK step randomly reduces the size of the dictionary to reflect the evolution of the probabilities. Conversely, the EXPAND step introduces the new column in the dictionary, and quickly updates its weight $b_{t,t}$ to reflect $\widetilde{p}_{t,t}$. Depending on the relevance (encoded by the RLS) of the new column, this means that it is possible that the new column is discarded at the same iteration as it is introduced. For a whole pass over the dataset, INK-ORACLE queries the oracle for each RLS at least once, but it *never* asks again for the RLS of a columns dropped from $\mathcal{I}_t$. As we will see in the next section, this greatly simplifies the construction of the oracle. Finally, after updating the dictionary, we use the updated weights $\sqrt{b_{i,t}}$ to update the approximation $\widetilde{\mathbf{K}}_t$, that can be used at any time and not only in the end.

3.2 Analysis of INK-ORACLE

The main result of this section is the lower bound on the number of columns required to be kept in order to guarantee a $\gamma/(1-\varepsilon)$ approximation of $\mathbf{K}_t$.

Theorem 1. *Let $\gamma > 1$. Given access to an (α, β)-oracle, for $0 \leq \varepsilon \leq 1$ and $0 \leq \delta \leq 1$, if we run Alg. 2 with parameter $\overline{q}$*

$$\overline{q} \geq \left(\frac{28\alpha\beta d_{\mathit{eff}}(\gamma)_t}{\varepsilon^2}\right)\log\left(\frac{4t}{\delta}\right),$$

to compute a sequence of random matrices $\mathbf{S}_t$ with a random number of columns Q_t, then with probability $1-\delta$, for all t the corresponding Nyström approximation $\widetilde{\mathbf{K}}_t$ (Eq. 5) satisfies condition in Eq. 11,

$$\mathbf{0} \preceq \mathbf{K}_t - \widetilde{\mathbf{K}}_t \preceq \frac{\gamma}{1-\varepsilon}\mathbf{K}_t(\mathbf{K}_t + \gamma\mathbf{I})^{-1} \preceq \frac{\gamma}{1-\varepsilon}\mathbf{I}.$$

and the number of columns selected Q_t is such that

$$Q_t \leq 8\overline{q}.$$

Discussion Unlike in the batch setting, where the sampling procedure always returned m samples, the number of columns Q_t selected by INK-ORACLE is a random variable, but with high probability it will be not much larger than $\overline{q}$. Comparing INK-ORACLE to online kernel sparsification methods [19], we see that the number of columns, and therefore the space requirement, is guaranteed to be small not only asymptotically but at each step, and that no assumption on the spectrum of the matrix is required. Instead, the space complexity naturally scales with the effective dimension of the problem, and old samples that become superfluous are automatically discarded. Comparing Thm. 1 to Prop.1, INK-ORACLE achieves the same performance as its batch counterpart, as long as the space budget $\overline{q}$ is large enough. This budget depends on several quantities that are difficult to estimate, such as the effective dimension of the full kernel matrix. In practice, this quantity can be interpreted as the maximum amount of space that the user can afford for the algorithm to run. If the actual complexity of the problem exceeds this budget, the user can choose to run it again with another parameter γ or a worse accuracy ε. It is important to notice that, as we show in the proof, the distribution induced by the sampling procedure of INK-ORACLE is not the same as the distribution obtained by the multinomial sampling of BATCH-EXACT. Nonetheless, in our analysis we show that the bias introduced by the different distribution is small, and this allows INK-ORACLE to match the approximation guarantees given by Alaoui and Mahoney [1].

We give a detailed proof of Thm. 1 in App. B. In the rest of this section we sketch the proof and give the intuition for the most relevant parts.

The SHRINK step uses the thresholding condition to guarantee that the weight $b_{i,t}$ are good approximations of the $\widetilde{p}_{i,t}$. To make the condition effective, we require that the approximate probabilities $\widetilde{p}_{j,t}$ are decreasing. Because the approximate probabilities follow the true probabilities $p_{i,t}$, we first show that this decrease happens for the exact case.

Lemma 1. *For any kernel matrix $\mathbf{K}_t$ at time t, and its bordering $\mathbf{K}_{t+1}$ at time $t+1$ we have that the probabilities $p_{i,t}$ are monotonically decreasing over time t,*

$$\frac{\tau_{i,t+1}}{d_{\mathit{eff}}(\gamma)_{t+1}} = p_{i,t+1} \leq p_{i,t} = \frac{\tau_{i,t+1}}{d_{\mathit{eff}}(\gamma)_t}.$$

Since ridge leverage scores represent the importance of a column, when a new column arrives, there are two cases that can happen. If the column is orthogonal to the existing matrix, none of the previous leverage scores changes. If the new column can explain part of the previous columns, the previous columns should be picked less often, and we expect $\tau_{i,t}$ to decrease. Contrary to RLS, the effective dimension increases when the new sample is orthogonal to the existing matrix, while it stays the same when the new sample is a linear combination of the existing ones. In addition, the presence of γ regularizes both cases. When the vector is nearly orthogonal, the presence of $\gamma\mathbf{I}$ in the inverse will still penalize it, while the γ term at the denominator of Δ will reduce the influence of linearly correlated samples. Because $\tau_{i,t}$ decreases over time and $d_{\text{eff}}(\gamma)_{i,t}$ increases, the probabilities $p_{i,t}$ will overall decrease over time. This result itself is not sufficient to guarantee a well defined SHRINK step. Due to the (α, β)-approximation, it is possible that $p_{i,t+1} \leq p_{i,t}$ but $\widetilde{p}_{i,t+1} \not\leq \widetilde{p}_{i,t}$. To exclude this possibility, we adapt the following idea from Kelner and Levin [9].

Proposition 2 (Kelner and Levin [9])**.** *Given the approximate probabilities $\widetilde{\mathbf{p}}_t$ returned by an (α, β)-oracle at time t, and the approximate probabilities $\widetilde{\mathbf{p}}_{t+1}$ returned by an (α, β)-oracle at time $\{t+1\}$, then the approximate probabilities $\min^3\{\widetilde{\mathbf{p}}_t, \widetilde{\mathbf{p}}_{t+1}\}$ are also (α, β)-approximate for $\{t+1\}$. Therefore, without loss of generality, we can assume that $\widetilde{p}_{i,t+1} \leq \widetilde{p}_{i,t}$.*

Combining Lemma 1 and Proposition 2, we can guarantee that at each step the $\widetilde{p}_{i,t}$-s decrease. Unlike in the batch setting [1], we have to take additional care to consider correlations between iterations, the fact that the inclusion probabilities of Algorithm 2 are different from the multinomial ones of DIRECT-SAMPLE, and that the number of columns kept at each iteration is a *random* quantity Q_t. We adapt the approach of Pachocki [13] to the KRR setting to analyse this process. The key aspect is that the reweighting and rejection rule on line 3 of Algorithm 2 will only happen when the probabilities are truly changing. Finally, using a concentration inequality, we show that the number Q_t of columns selected is with high probability only a constant factor away from the budget $\overline{q}$ given to the algorithm.

4 LEVERAGE SCORES AND EFFECTIVE DIMENSION ESTIMATION

In the previous section we showed that our incremental sampling strategy based on (estimated) RLSs has strong space and approximation guarantees for $\widetilde{\mathbf{K}}_n$. While the analysis reported in the previous section relied on the existence of an (α, β)-oracle returning accurate leverage scores and effective dimension estimates, in this section we show that such an oracle *exists and can be implemented efficiently.* This is obtained by *two separate estimators* for the RLSs and effective dimension that are updated incrementally and combined together to determine the sampling probabilities.

4.1 Leverage Scores

We start by constructing an estimator that at each time t, takes as input an approximate kernel matrix $\widetilde{\mathbf{K}}_t$, and returns α-approximate RLS $\widetilde{\tau}_{i,t+1}$. The incremental nature of the estimator lies in the fact that it exploits access to the columns already in $\mathbf{S}_t$ and the new (exact) column $\overline{\mathbf{k}}_{t+1}$. We give the following approximation guarantees.

Lemma 2. *We assume that $\widetilde{\mathbf{K}}_t$ satisfies Eq. (11), and define $\overline{\mathbf{K}}_{t+1}$ as the matrix bordered with the new row and column*

$$\overline{\mathbf{K}}_{t+1} = \left[\begin{array}{c|c} \widetilde{\mathbf{K}}_t & \overline{\mathbf{k}}_{t+1} \\ \hline \overline{\mathbf{k}}_{t+1}^\intercal & k_{t+1} \end{array}\right].$$

Then

$$\mathbf{0} \preceq \mathbf{K}_{t+1} - \overline{\mathbf{K}}_{t+1} \preceq \frac{\gamma}{1-\varepsilon}\mathbf{I}.$$

Moreover let $\alpha = \frac{2-\varepsilon}{1-\varepsilon}$ and

$$\widetilde{\tau}_{i,t+1} = \frac{1}{\alpha\gamma}\left(k_{i,i} - \mathbf{k}_{i,t+1}\left(\overline{\mathbf{K}}_{t+1} + \alpha\gamma\mathbf{I}\right)^{-1}\mathbf{k}_{i,t+1}\right). \tag{12}$$

Then, for all i such that $\mathbf{k}_{i,t+1} \in \mathcal{I}_t \cup \{t+1\}$,

$$\frac{1}{\alpha}\tau_{i,t+1}(\gamma) \leq \widetilde{\tau}_{i,t+1} \leq \tau_{i,t+1}(\gamma).$$

Remark There are two important details that are used in proof of Lem. 2 (App. C). First, notice that using $\widetilde{\mathbf{K}}_t$ to approximate RLSs directly, would not be accurate enough. RLSs are defined as $\tau_{i,t}(\gamma) = \mathbf{e}_i^\intercal \mathbf{K}_t(\mathbf{K}_t + \gamma\mathbf{I})^{-1}\mathbf{e}_i$ and while the product $(\mathbf{K}_t + \gamma\mathbf{I})^{-1}\mathbf{e}_i$ can be accurately reconstructed using $(\widetilde{\mathbf{K}}_t + \gamma\mathbf{I})^{-1}\mathbf{e}_i$, the multiplication $\mathbf{K}_t\mathbf{e}_i$ cannot be approximated well using $\widetilde{\mathbf{K}}_t$. Since the nullspace of $\widetilde{\mathbf{K}}_t$ can be larger than the one of $\mathbf{K}_t$, it is possible that $\mathbf{e}_i$ partially falls into it, thus compromising the accuracy of the approximation of the RLS. In our approach, we deal with this problem by using the *actual columns* $\mathbf{k}_{i,t}$ of $\mathbf{K}_t$ to compute the RLS. This way, we preserve as much as exact information of the matrix as possible, while the expensive inversion operation is performed on the smaller approximation $\widetilde{\mathbf{K}}_t$. Since we require access to the stored columns $\mathbf{k}_{i,t}$, our approach can approximate the RLSs only for columns present in the dictionary but this is enough, since we are only interested in accurate probabilities for columns in the dictionary and for the new column $\overline{\mathbf{k}}_{t+1}$ (which is available at time $t+1$). As a comparison, the

[3] element-wise mininum

two-pass approach of Alaoui and Mahoney [1] uses the first pass just to compute an approximation $\widetilde{\mathbf{K}}_n$, and then approximates all leverage scores with $\widetilde{\mathbf{K}}_n(\widetilde{\mathbf{K}}_n + \gamma\mathbf{I})^{-1}$. This has an impact on their approximation factor α, that is proportional to $(\lambda_{\min}(\mathbf{K}_n) - \gamma\varepsilon)$. Therefore to have $\alpha \approx (\lambda_{\min}(\mathbf{K}_n) - \gamma\varepsilon) > 0$, it is necessary that $\gamma\varepsilon$ is of the order of $\lambda_{\min}(\mathbf{K}_n)$, which in some cases can be very small, and strongly increase the space requirements of the algorithm. Using the actual columns of the matrix in Eq. 12 allows us to compute an α-approximation independent of the smallest eigenvalue.

4.2 Effective Dimension

Using Eq. 12, we can estimate all the RLSs that we need to update $\mathbf{S}_t$. Nonetheless, to prove that the number of columns selected is not too large, the proof of Thm. 1 in the appendix requires that the sum of the probabilities $\widetilde{p}_{i,t}$ is smaller than 1. Therefore we not only need to compute the RLSs, but also a normalization constant. Indeed, a naïve definition of the probability $\widetilde{p}_{i,t}$ could be $p_{i,t} = \frac{\widetilde{\tau}_{i,t}}{\sum_{j=1}^{t}\widetilde{\tau}_{i,t}}$. A major challenge in our setting is that we cannot compute the sum of the approximate RLSs, because we do not have access to all the columns. Fortunately, we know that $\sum_{j=1}^{t}\widetilde{\tau}_{i,t} \leq \sum_{j=1}^{t}\tau_{i,t}(\gamma) = d_{\text{eff}}(\gamma)_t$. Therefore, one of our technical contribution is an estimator $\widetilde{d}_{\text{eff}}(\gamma)_t$ that does not use the approximate RLSs for the the columns that we no longer have. We now define this estimator and state its approximation accuracy.

Lemma 3. *Assume $\widetilde{\mathbf{K}}_t$ satisfies Eq. 11. Let $\alpha = \left(\frac{2-\varepsilon}{1-\varepsilon}\right)$ and $\beta = \left(\frac{2-\varepsilon}{1-\varepsilon}\right)^2(1+\rho)$ with $\rho = \frac{\lambda_{\max}(\mathbf{K}_n)}{\gamma}$. Define*

$$\widetilde{d}_{\mathit{eff}}(\gamma)_{t+1} = \widetilde{d}_{\mathit{eff}}(\gamma)_t + \alpha\widetilde{\Delta}_t \tag{13}$$

with

$$\begin{aligned}\widetilde{\Delta}_t =& \frac{1}{k_{t+1} + \gamma - \overline{\mathbf{k}}_{t+1}^{\mathsf{T}}\left(\widetilde{\mathbf{K}}_t + \alpha\gamma\mathbf{I}\right)^{-1}\overline{\mathbf{k}}_{t+1}} \\ &\times \left(k_{t+1} - \overline{\mathbf{k}}_{t+1}^{\mathsf{T}}\left(\widetilde{\mathbf{K}}_t + \alpha\gamma\mathbf{I}\right)^{-1}\overline{\mathbf{k}}_{t+1}\right. \\ &\left. - \frac{(1-\varepsilon)^2}{4}\gamma\overline{\mathbf{k}}_{t+1}^{\mathsf{T}}(\widetilde{\mathbf{K}}_t + \gamma\mathbf{I})^{-2}\overline{\mathbf{k}}_{t+1}\right). \end{aligned} \tag{14}$$

Then

$$d_{\mathit{eff}}(\gamma)_{t+1} \leq \widetilde{d}_{\mathit{eff}}(\gamma)_{t+1} \leq \beta d_{\mathit{eff}}(\gamma)_{t+1}.$$

Discussion Since we cannot compute accurate RLSs for columns that are not present in the dictionary, we prefer to not estimate how each RLSs changes over time, but instead we directly estimate the increment of their sum. We do it by updating our estimate $\widetilde{d}_{\text{eff}}(\gamma)_{t+1}$ using our previous estimate $\widetilde{d}_{\text{eff}}(\gamma)_t$, and $\widetilde{\Delta}_t$. $\widetilde{\Delta}_t$ captures directly the interaction of the new sample with the *aggregate* of the previous samples, and allows us to estimate the increase in effective dimension using only the current matrix approximation $\widetilde{\mathbf{K}}_t$, the new column $\overline{\mathbf{k}}_{t+1}$ and the scalar k_{t+1}. Differently from the other terms we studied, the numerator of $\widetilde{\Delta}_t$ contains an additional $\gamma\overline{\mathbf{k}}_{t+1}^{\mathsf{T}}(\widetilde{\mathbf{K}}_t + \gamma\mathbf{I})^{-2}\overline{\mathbf{k}}_{t+1}$ second order term. The guarantees provided by Eq. 11 are not straightforward to extend because in general if $(\mathbf{K}_t + \gamma\mathbf{I})^{-1} \succeq (\widetilde{\mathbf{K}}_t + \alpha\gamma\mathbf{I})^{-1}$, it is not guaranteed that $(\mathbf{K}_t + \gamma\mathbf{I})^{-2} \succeq (\widetilde{\mathbf{K}}_t + \alpha\gamma\mathbf{I})^{-2}$. Nonetheless, we show that $\widetilde{\mathbf{K}}_t$ is still sufficient to estimate $\widetilde{\Delta}_t$, but, unlike α, the approximation error β is now dependent on the spectrum.

Algorithm 3 The INK-ESTIMATE algorithm

Input: Dataset $\mathcal{D}$, regularization γ, sampling budget $\overline{q}$
Output: $\widetilde{\mathbf{K}}_n$, $\mathbf{S}_n$

Initialize $\mathcal{I}_0$ as empty, $\widetilde{p}_{1,0} = 1, b_{1,0} = 1$, budget $\overline{q}$
for $t = 0, \ldots, n-1$ **do**
  Receive new column $\overline{\mathbf{k}}_{t+1}$ and scalar k_{t+1}
  Compute α-leverage scores $\{\widetilde{\tau}_{i,t+1} : i \in \mathcal{I}_t \cup \{t+1\}\}$, using $\overline{\mathbf{K}}_{t+1}$, $\mathbf{k}_i$, $k_{i,i}$, and Eq. (12)
  Compute β-approximate $\widetilde{d}_{\text{eff}}(\gamma)_{t+1}$ using $\widetilde{\mathbf{K}}_t$, $\overline{\mathbf{k}}_{t+1}$, k_{t+1}, and Eq. (13)
  Set $\widetilde{p}_{i,t+1} = \min\{\widetilde{\tau}_{i,t+1}/\widetilde{d}_{\text{eff}}(\gamma)_{t+1}, \widetilde{p}_{i,t}\}$
  $\mathcal{I}_{t+1}, \mathbf{b}_{t+1}$ = SHRINK-EXPAND$(\mathcal{I}_t, \widetilde{\mathbf{p}}_{t+1}, \mathbf{b}_t, \overline{q})$
  Compute $\mathbf{S}_{t+1}$ using $\mathcal{I}_{t+1}$ and weights $\sqrt{b_{i,t+1}}$
  Compute $\widetilde{\mathbf{K}}_{t+1}$ using $\mathbf{S}_{t+1}$ and Equation 5
end for
Return $\widetilde{\mathbf{K}}_n$ and $\mathbf{S}_n$

4.3 Analysis of INK-ESTIMATE

With the separate estimates for leverage scores (Sect. 4.1) and effective dimension (Sect. 4.2), we have the necessary ingredients for the (α, β)-oracle and we are ready to present the final algorithm INK-ESTIMATE (Alg. 3).

Using the approximation guarantees of Lem. 2 and Lem. 3, we are ready to state the final result, instantiating the generic α and β terms of Thm. 2 with the values obtained in this section.

Theorem 2. *Let $\rho = \lambda_{\max}(\mathbf{K}_t)/\gamma$, $\alpha = \left(\frac{2-\varepsilon}{1-\varepsilon}\right)$, $\beta = \left(\frac{2-\varepsilon}{1-\varepsilon}\right)^2(1+\rho)$, and $\gamma > 1$. For any $0 \leq \varepsilon \leq 1$, and $0 \leq \delta \leq 1$, if we run Alg. 3 with parameter $\overline{q}$, where*

$$\overline{q} \geq \left(\frac{28\alpha\beta d_{\mathit{eff}}(\gamma)_t}{\varepsilon^2}\right)\log\left(\frac{4t}{\delta}\right),$$

to compute a sequence of random matrices $\mathbf{S}_t$ with a random number of columns Q_t, then with probability $1-\delta$, for all t the corresponding Nyström approximation $\widetilde{\mathbf{K}}_t$ (Eq. 5)

satisfies condition 11

$$\mathbf{0} \preceq \mathbf{K}_t - \widetilde{\mathbf{K}}_t \preceq \frac{\gamma}{1-\varepsilon}\mathbf{K}_t(\mathbf{K}_t + \gamma\mathbf{I})^{-1} \preceq \frac{\gamma}{1-\varepsilon}\mathbf{I}.$$

With the same prob., INK-ESTIMATE *requires at most*

$$\begin{aligned}\mathcal{O}(n^2\overline{q}^2 + n\overline{q}^3) \\ &\leq \mathcal{O}\left(\alpha^2\beta^2 n^2 d_{\mathit{eff}}(\gamma)_n^2 + \alpha^3\beta^3 n d_{\mathit{eff}}(\gamma)_n^3\right) \\ &= \mathcal{O}\left(\alpha^4(1+\rho)^2 n^2 d_{\mathit{eff}}(\gamma)_n^2 + \alpha^6(1+\rho)^3 n d_{\mathit{eff}}(\gamma)_n^3\right)\end{aligned}$$

time and the space is bounded as

$$\mathcal{O}(n\overline{q}) \leq \mathcal{O}\left(\alpha\beta n d_{\mathit{eff}}(\gamma)_n\right) = \mathcal{O}\left(\alpha^2(1+\rho) n d_{\mathit{eff}}(\gamma)_n\right).$$

For the space complexity, from Theorem 1 we know we will not select more than $\mathcal{O}(\overline{q})$ columns in high probability. For the time complexity, at each iteration we need to solve linear systems involving $(\overline{\mathbf{K}}_{t+1} + \alpha\gamma\mathbf{I})^{-1}$ and $(\widetilde{\mathbf{K}}_t + \alpha\gamma\mathbf{I})^{-1}$. Approximating the inverse using transformations similar to Eq. (6) takes $\mathcal{O}(t\overline{q}^2 + \overline{q}^3)$ time, again using a singular value decomposition approach. To compute all leverage scores, we need to first compute an approximate inverse in $\mathcal{O}(t\overline{q}^2 + \overline{q}^3)$ time, and then solve Q_t systems, each using a multiplication costing $\mathcal{O}(tQ_t)$. With high probability, $Q_t \leq 8\overline{q}$, therefore computing all leverage scores costs $\mathcal{O}(t\overline{q}^2 + \overline{q}^3)$ for the first singular value decomposition, and $\mathcal{O}(t\overline{q})$ for each of the $\mathcal{O}(\overline{q})$ applications. To update the effective dimension estimate, we only have to compute another approximate inverse, and that costs $\mathcal{O}(t\overline{q}^2 + \overline{q}^3)$ as well. Finally, we have to sum the costs over n steps, and from $\sum_{t=1}^{n} t\overline{q}^2 \leq \overline{q}^2 n^2$, we obtain the final complexity. Even with a significantly different approach, INK-ESTIMATE achieves the same approximation guarantees as BATCH-EXACT. Consequently, it provides the same risk guarantees as the known batch version [1], stated in the following corollary.

Corollary 1. *For every $t \in \{1, \ldots, n\}$, let $\mathbf{K}_t$ be the kernel matrix at time t. Run Algorithm 3 with regularization parameter γ and space budget $\overline{q}$. Then, at any time t, the solution $\widetilde{\mathbf{w}}_t$ computed using the regularized Nyström approximation $\widetilde{\mathbf{K}}_t$ satisfies*

$$\begin{aligned}\mathcal{R}(\widetilde{\mathbf{w}}_t) &\leq \left(1 + \frac{\gamma}{\mu}\frac{1}{1-\varepsilon}\right)^2 \mathcal{R}(\widehat{\mathbf{w}}_t) \\ &= \left(1 + \frac{\lambda_{\max}(\mathbf{K}_t)}{\rho\mu}\frac{1}{1-\varepsilon}\right)^2 \mathcal{R}(\widehat{\mathbf{w}}_t).\end{aligned}$$

Discussion Thm. 2 combines the generic result of Thm. 1 with the actual implementation of an oracle that we developed in this section. All the guarantees that hold for INK-ORACLE are inherited by INK-ESTIMATE, but now we can quantify the impact of the errors α and β on the algorithm. As we saw, the α error does not depends on the time, the spectrum of the kernel matrix or other quantities that increase over time. On the other hand, estimating the effective dimension without having access to all the leverage scores is a much harder task, and the β factor depends on the spectrum through the ρ coefficient. The influence that this coefficient exerts on the space and time complexity can vary significantly as the relative magnitude of $\lambda_{\max}(\mathbf{K}_n)$, γ and μ changes. If the largest eigenvalue grows too large without a corresponding increase in γ, the space and time requirements of INK-ESTIMATE can grow, but the risk bound, depending on γ/μ remains small. On the other hand, increasing γ without increasing μ reduces the computational complexity, but makes the guarantees on the risk of the solution $\widetilde{\mathbf{w}}_t$ much weaker. As an example, [1, Thm. 3] chooses, $\mu \geq \lambda_{\max}(\mathbf{K}_n)$ and $\gamma \approxeq \mu$. If we do the same, we recover their bound.

5 CONCLUSION

We presented a space-efficient algorithm for sequential Nyström approximation that requires only a single pass over the dataset to construct a low-rank matrix $\widetilde{\mathbf{K}}_n$ that accurately approximates the kernel matrix $\mathbf{K}_n$, and compute an approximate KRR solution $\widetilde{\mathbf{w}}_n$ whose risk is close to the exact solution $\widehat{\mathbf{w}}_n$. All of these guarantees do not hold only for the final matrix, but are valid for all intermediate matrices $\widetilde{\mathbf{K}}_t$ constructed by the sequential algorithm.

To address the challenges coming from the sequential setup, we introduced two separate estimators for RLSs and effective dimension that provide multiplicative error approximations of these two quantities across iterations. While the approximation of the RLSs is only a constant factor away from the exact RLSs, the error of the approximate effective dimension scales with the spectrum of the matrix through the coefficient ρ. A more careful analysis, or a different estimator might improve this dependence, and they can be easily plugged to the general analysis.

Our generalization results apply to the fixed design setting. An important extension of our work would be to consider a random design, such as in the work of Rudi et al. [16]. This extension would need even more careful tuning of the regularization parameter γ, needing to satisfy requirements of both generalization and the approximation of the (α, β)-oracle. Finally, the runtime analysis of the algorithm does not fully exploit the sequential nature of the updates. An implementation based on decompositions more amenable to updates (e.g., Cholesky decomposition), or on low-rank solvers that can exploit hot-start might further improve the time complexity.

Abstract

We show that the climate phenomena of El Niño and La Niña arise naturally as states of macro-variables when our recent causal feature learning framework (Chalupka et al., 2015, 2016) is applied to micro-level measures of zonal wind (ZW) and sea surface temperatures (SST) taken over the equatorial band of the Pacific Ocean. The method identifies these unusual climate states on the basis of the relation between ZW and SST patterns without any input about past occurrences of El Niño or La Niña. The simpler alternatives of (i) clustering the SST fields while disregarding their relationship with ZW patterns, or (ii) clustering the joint ZW-SST patterns, do not discover El Niño. We discuss the degree to which our method supports a causal interpretation and use a low-dimensional toy example to explain its success over other clustering approaches. Finally, we propose a new robust and scalable alternative to our original algorithm (Chalupka et al., 2016), which circumvents the need for high-dimensional density learning.

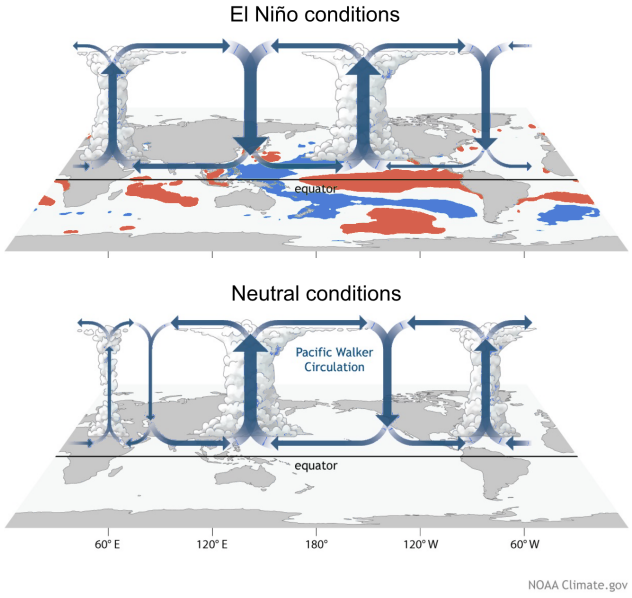

Figure 1: El Niño vs. neutral conditions from Di Liberto (2014). Top: An illustration of the state of the atmosphere and surface during typical El Niño conditions. Here, the colors indicate SST deviations from the neutral state with red being a positive and blue being a negative deviation. Bottom: Similar to the top panel but now showing neutral conditions of the Walker circulation (neither El Niño nor La Niña).

1 INTRODUCTION

The accurate characterization of macro-level climate phenomena is crucial to an understanding of climate dynamics, long term climate evolution and forecasting. Modern climate science models, despite their complexity, rely on an accurate and valid aggregation of micro-level measurements into macro-phenomena. While many aspects of the climate may indeed be subject fundamentally to chaotic dynamics, many large scale phenomena are deemed amenable to precise modeling. The El Niño–Southern Oscillation (ENSO) is arguably the most studied climate phenomenon at the inter-annual time scale, but much about its dynamics relating zonal winds (ZW) and sea surface temperatures (SST) remains poorly understood.

We apply our recent causal feature learning (CFL) framework (Chalupka et al., 2016) to learn causal macro-variables from the equatorial Pacific climate data. Our goal is threefold:

- apply CFL to real-world data, developing new practical algorithms as needed,
- test whether CFL can, without supervision, learn the ground truth that El Niño is an important macro-variable state in the ZW-SST system's dynamics,
- explore the theoretical and practical difference between CFL and clustering methods.

From the climate-science point of view, our research shows

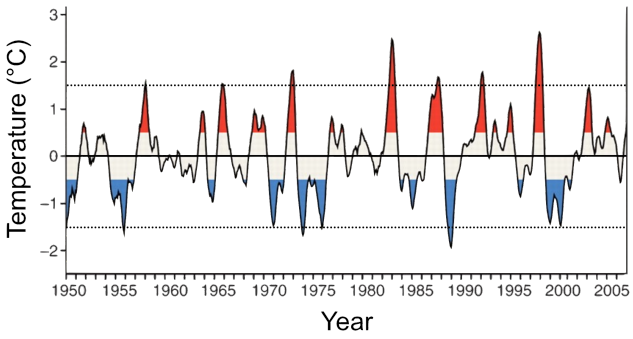

Figure 2: Niño 3.4 SST anomalies for the time period 1950–2005. The figure was adapted from McPhaden et al. (2006). Red shadings indicate El Niño years and blue shadings indicate La Niña years. The two dashed lines indicate the threshold for strong El Niño or La Niña events.

that CFL can be successfully used for an unbiased automated extraction of climate macro-variables, which would otherwise require tedious hand-crafting by domain experts. Moreover, the framework can directly suggest (computationally) expensive climate experiments (for example, through climate simulations) that could differentiate between true causes and mere correlations efficiently. Closer inspection of the output of CFL can also yield insights about new climate macro-phenomena (or important variants of existing ones) that inspire new physical models of the climate. Python code that reproduces our results and figures is available online at `http://vision.caltech.edu/~kchalupk/code.html`.

1.1 EL NIÑO–SOUTHERN OSCILLATION

El Niño is a weather pattern that is principally characterized by the state of eastern Pacific near-surface winds (ZW, zonal wind), sea surface temperature (SST) patterns, and the associated state of the atmospheric Walker circulation (see for example, Holton et al., 1989; Trenberth, 1997). The Walker circulation (see Fig. 1) is characterized by warm air rising over Indonesia and Papua New Guinea and cooler subsiding air over the eastern Pacific cold tongue region just west of equatorial South America (Lau and Yang, 2003). Near the surface, easterly winds (winds blowing from the east) drive water from east to west resulting in oceanic upwelling near the coast of equatorial South America (and downwelling east of Indonesia), that brings with it cold and nutrient rich waters from the deep oceans. During the ENSO warm phase, commonly referred to as El Niño (because it often occurs around and after Christmas), the Walker circulation weakens, ultimately resulting in weaker upwelling in the Eastern Pacific and thus in positive SST anomalies. Fig. 1 illustrates these phenomena.

ENSO-related weather in the tropics includes droughts, flooding, and may have direct impact on fisheries through reduced nutrient upwelling (e.g., Glantz, 2001). Atmospheric waves (ripples in wind, SST and rainfall patterns) generated by the change in circulation and SST anomalies in the tropics, make their way across the planet with dramatic impact (e.g, Ropelewski and Halpert, 1987; Changnon, 1999). Cashin et al. (2015) show that the economic impact of El Niño varies across regions. Economic activity may decline briefly in Australia, Chile, Indonesia, India, Japan, New Zealand, and South Africa after an El Niño event. Enhanced growth may be registered in other countries, such as the United States.

The ENSO cold phase, usually referred to as La Niña, is the opposing phase of El Niño with enhanced upwelling and colder SSTs in the eastern Pacific. Currently, predicting the strength of El Niño and La Niña events remains a difficult challenge for climate scientists as the period may vary between 3 and 7 years (see Fig. 2); as a consequence accurate forecasts are only possible less than a year in advance (e.g., Landsea and Knaff, 2000).

The National Oceanic and Atmospheric Administration (NOAA) defines El Niño as a positive three-month running mean SST anomaly of more than $0.5°$C from normal (for the 1971–2000 base period) in the Niño 3.4 region ($120°$W–$170°$W, $5°$N–$5°$S, see also Fig. 4). Similarly, La Niña conditions are defined as negative anomalies of more than $-0.5°$ C. Conditions in between $-0.5°$C and $0.5°$C are called neutral. This is illustrated using red and blue shadings in Fig. 2. Strong El Niño/La Niña events are defined as SST-anomalies greater than $1.5°$C. However, the definitions for El Niño and La Niña have evolved over time. For example, other regions than the Niño 3.4 region or other averaging conventions have been used in the specification of the SST anomalies.

1.2 CAUSAL FEATURES AND MACRO-VARIABLES

Climate experts view zonal winds as drivers of SST patterns. We take the view that if El Niño and La Niña are indeed genuine macro-level climate phenomena in their own right (and not just arbitrary quantities defined by convention) then they must consist of macro-level features of the relation between the high-dimensional micro-level ZT and SST patterns that can be detected by an unsupervised method. That is, it must be possible to identify El Niño and La Niña from a mass of air pressure and sea temperature readings, using a method that has no independent information about when such periods occurred.

In Chalupka et al. (2016) we developed a theoretically precise account of causal relations of macro-variables that supervene on micro-variables, and proposed an unsupervised method for their discovery, which we called Causal Feature Learning (CFL). We adopt the framework (summarized below) with a few interpretational adjustments for our climate setting. The method (originally inspired by

the neuroscience setting, only tested on synthetic data) was designed to establish claims such as *"The presence of faces (in an image) causes specific neural processes in the brain."*, where a neural process identifies a class of spike trains across a large number of neurons recorded by electrodes. An ability to characterize such neural processes would provide the basis to explain, for example, what constitutes face recognition in the brain. There we considered as input visual stimuli (in the form of still images) and as output electrode recordings of the neural response of 1000 neurons (in the form of spike trains).

Formally, let an input (micro-)variable X take values in a high-dimensional domain $\mathcal{X}$ (in Chalupka et al. (2016), the pixel space of an image, in our case here ZW maps) and the output (micro-)variable Y take values in the high-dimensional domain $\mathcal{Y}$ (the space of neural spike trains then, the SST patterns here). The basic idea underlying our set-up is that the causal macro-variable relation is defined in terms of the *coarsest* aggregation of the micro-level spaces that preserves the probabilistic relations under intervention (hence, causal) between the micro-level spaces. Conceptually, macro-level causal variables group together micro-level states that make no causal difference. In Chalupka et al. (2016) we started by defining a micro-level manipulation (similar to Pearl's $do()$-operator (Pearl, 2000)):

Definition 1 (Micro-level Manipulation)**.** *A* micro-level manipulation *is the operation* $man(X = x)$ *that changes the value of the micro-variable* X *to* $x \in \mathcal{X}$*, while not (directly) affecting any other variables. We write* $man(x)$ *if the manipulated variable* X *is clear from context.*

The micro-level manipulation is then used to define what we refer to as the *fundamental causal partition*:

Definition 2 (Fundamental Causal Partition, Causal Class)**.** *Given the pair* $(\mathcal{X}, \mathcal{Y})$*, the* fundamental causal partition of $\mathcal{X}$*, denoted by* $\Pi_c(\mathcal{X})$ *is the partition induced by the equivalence relation* $\overset{X}{\sim}$ *such that*

$$x_1 \overset{X}{\sim} x_2 \quad \Leftrightarrow \quad \forall_y \, P(y \mid man(x_1)) = P(y \mid man(x_2)).$$

Similarly, the fundamental causal partition of $\mathcal{Y}$*, denoted by* $\Pi_c(\mathcal{Y})$*, is the partition induced by the equivalence relation* $\overset{Y}{\sim}$ *such that*

$$y_1 \overset{Y}{\sim} y_2 \quad \Leftrightarrow \quad \forall_x \, P(y_1 \mid man(x)) = P(y_2 \mid man(x)).$$

A cell of a causal partition is a causal class *of* X *or* Y*.*

The fundamental causal partitions then naturally give rise to the macro-level cause variable C and effect variable E that stand in a bijective relation to the cells of $\Pi_c(\mathcal{X})$ and $\Pi_c(\mathcal{Y})$, respectively. Thus, the macro-variable cause C ignores all the micro-level changes in X that do not have an effect on the probabilities over Y, and the macro-level effect E ignores all the micro-level detail in Y, which occur with the same probability given a manipulation to any $X = x$.

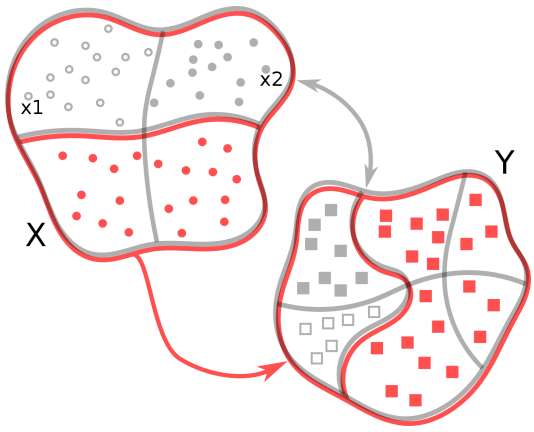

Figure 3: The Causal Coarsening Theorem, adapted from Chalupka et al. (2016). In this plot, the *observational* input macro-variable (top, gray) has four states, and has a well-defined joint with the observational output macro-variable (with six states). In each case, the *causal* macro-variable states are a coarsening of the observational states. For example, the input causal macro-variable merges the two top observational states. E.g. $P(Y \mid x_1) \neq P(Y \mid x_2)$, but $P(Y \mid man(x_1)) = P(Y \mid man(x_2))$.

With these definitions there is no reason *a priori* to think that macro-variables are common phenomena. In fact quite the opposite: The conditions that the probability distributions over X and Y must satisfy to give rise to non-trivial macro-variables C and E can easily be described as a measure-zero event when taken in their strict form. Consequently, our view is that to the extent that macro-variables are discussed in a scientific domain, there must be a presupposition that such strong conditions are satisfied at least approximately.

In the present context, our climate data consisting of ZW and SST measurements (we give a detailed description of the data in Section 1.3 below) is entirely observational. That is, the data is naturally sampled from $P(\text{SST},\ \text{ZW})$ and not created by a (hypothetical) experimentalist from $P(\text{SST} \mid man(\text{ZW} = z))$ for different values of z. Nevertheless, we can identify the *observational* macro-variables that characterize the probabilistic relation between ZW and SST by replacing the probabilities in Definition 1.2 with observational probabilities $P(y \mid x)$:

Definition 3 (Fundamental Observational Partition, Observational Class)**.** *Given the pair* $(\mathcal{X}, \mathcal{Y})$*, the* fundamental observational partition of $\mathcal{X}$*, denoted by* $\Pi_o(\mathcal{X})$ *is the partition induced by the equivalence relation* $\overset{X}{\sim}$ *such that*

$$x_1 \overset{X}{\sim} x_2 \quad \Leftrightarrow \quad \forall_y \, P(y \mid x_1) = P(y \mid x_2).$$

Similarly, the fundamental observational partition of $\mathcal{Y}$*, de-*

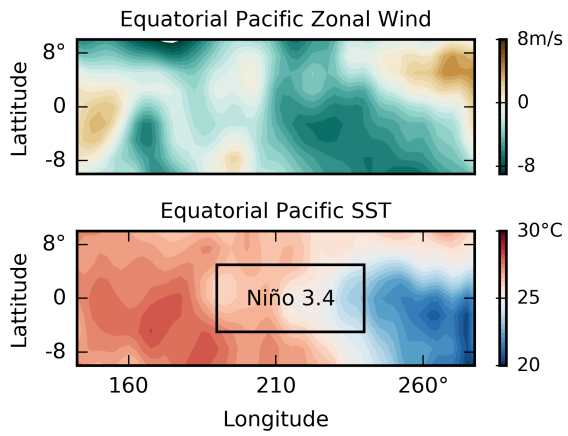

Figure 4: A micro-variable climate dataset. Top: A week's average ZW field. Bottom: A week's average SST field over the same region. In addition, the Niño 3.4 region is marked. Our dataset comprises 36 years' worth of overlapping weekly averages over the presented region.

noted by $\Pi_o(\mathcal{Y})$*, is the partition induced by the equivalence relation* $\overset{Y}{\sim}$ *such that*

$$y_1 \overset{Y}{\sim} y_2 \quad \Leftrightarrow \quad \forall_x \, P(y_1 \mid x) = P(y_2 \mid x).$$

A cell of an observational partition is an observational class *of* X *or* Y.

In Chalupka et al. (2016) we showed that the fundamental *causal* partition is almost always a *coarsening* of the corresponding fundamental *observational* partition, as illustrated in Fig. 3. We thus have some reason to expect that any macro-variables we do identify from our observational climate data will capture all the distinctions that are causal, but may in addition make some distinctions that do not support a causal inference. We return to this point in Section 6, where we discuss in more detail what causal insights can be drawn from this work. Our results should be seen as a step towards a characterization of macro-level causal variables for climate science, but we fully acknowledge that a complete causal characterization of the equatorial Pacific climate dynamics is beyond the scope of this paper.

1.3 DATASET

The data used for this study is based on the daily-averaged version of the NCEP-DOE Reanalysis 2 product for the time period 1979–2014 inclusive (Kanamitsu et al., 2002), a data product provided by the US National Centers for Environmental Protection (NCEP) and the Department of Energy (DOE). Reanalysis data sets are generated by fitting a complex climate model to all available data for a given period of time, thus generating estimates for times and locations that were not originally observed. In addition, we used the Geophysical Observational Analysis Tool (http://www.goat-geo.org) to interpolate the SST and zonal wind fields onto a $2.5^\circ \times 2.5^\circ$ spatial grid for easier analysis. We chose to focus on the (140°, 280°)E×(-10°, +10°)N equatorial band of the Pacific Ocean. From the raw dataset, we extracted the zonal (west-to-east) wind component and SST data in this region (specifically, we extracted the fields at the 1000 hPa level near the surface). Finally, we smoothed the data by computing a running weekly average in each domain. The resulting dataset contains 13140 zonal wind and 13140 corresponding SST maps, each a 9×55 matrix. Fig. 4 shows sample data points.

2 PACIFIC MACRO-VARIABLES

To apply CFL in practice, we adapted our unsupervised causal feature learning algorithm (Chalupka et al., 2016) to more realistic scenarios. The new solution (Sec. 3) is more robust and applicable to high-dimensional real-world data. We start with a description of the results.

Throughout the article, we will refer to zonal wind *macro-variables* as W, and to temperature *macro-variables* as T. We first chose to search for four-state macro-variables (though we experiment with varying this number in Sec. 4.1) and considered a zero-time delay[1] between W and T. In the CFL framework, each macro-variable state corresponds to a cell of a partition of the respective micro-variable input space. Fig. 5 visualizes the W and T we learned by plotting the difference between each macro-variable cell's mean and the ZW (SST) mean across the whole dataset. The visualized states are easy to describe: For example, when W=WEqt there is a larger-than-average westerly wind component in the west-equatorial region, a feature often associated with the causes of El Niño (see Fig. 1). Indeed, Table 1 shows that the El Niño cell of T only arises in connection with W=WEqt. In addition, WEqt is often positively correlated with the T=Warm. Throughout the rest of the article, we will mostly focus on the T macro-variable. Our first goal is to quantitatively justify calling T=1 "El Niño" and calling T=2 "La Niña". Qualitatively, the warm and cold water tongues that reach westward across the Pacific and that are often used to describe the two phenomena, are evident in the image.

Following the standard definition of El Niño (see Section 1.1), we use the SST anomaly in the Niño 3.4 region to detect its presence (Trenberth, 1997). The anomaly is computed with respect to the climatological mean, that is the

[1] A zero time delay implies that CFL will attempt to relate the weekly moving ZW average to the weekly moving SST average. The question of different time delays turns out to be a very subtle issue in the study of El Niño as El Niño is not a periodic event, nor does it have a fixed duration (see Fig. 2). A careful discussion of other delays is not feasible in a short article and the zero-time delay was deemed a reasonable starting point by domain experts we consulted.

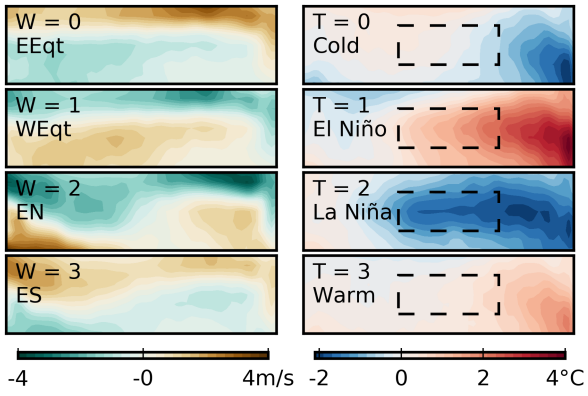

Figure 5: Macro-variables discovered by Alg. 1. For each state, the average difference from the dataset mean is shown. Left: Four states of W, the zonal wind macro-variable. We named the states "Easterly Equatorial" (EEqt),"Westerly Equatorial" (WEqt), "Easterly North of Equator" (EN) and "Easterly South of Equator" (ES). Right: Four states of T, the SST macro-variable. We named the states "Cold [American Coastal Waters]", "El Niño", "La Niña" and "Warm [American Coastal Waters]". The main text provides additional justification for calling T=1 and T=2 "El Niño" and "La Niña", respectively.

mean temperature *during the same week of the year* over all the weeks in our dataset. We will call a weekly average anomaly exceeding +.5°C a mild episode, and an anomaly exceeding +1.5°C a strong episode. The definition of La Niña is analogous, with negative thresholds. Fig. 6 shows that in the T=1 and T=2 cells, over 75% of all the points exceed the threshold for a mild (positive and negative, respectively) anomaly, and over 50% of the points exceed the strong threshold. The situation is different in the Warm and Cold cells, where almost no points exceed the strong threshold while the number of points falling in these non-anomalous cells is about 30% of the total. Since this macro-variable contains a state capturing a high proportion of El Niño-like patterns, we will say that this state has a "high precision" of detecting El Niño, while similarly, state T=2 has a high La Niña precision. Formally, we define the precision of a macro-variable state as follows:

Definition 4 (precision)**.** *Let $T = \{T_1, \cdots, T_K\}$ be a partition of the set of all the SST maps used in our experiments. Let $n34 : SST \rightarrow \mathbb{R}$ be the function that computes the Niño 3.4 anomaly for a given map. Then, let*

$$c_\theta(T_k) = \begin{cases} \frac{1}{|T_k|}|\{t \in T_k \; s.t. \; n34(t) > \theta\}| & \text{if } \theta > 0 \\ \\ \frac{1}{|T_k|}|\{t \in T_k \; s.t. \; n34(t) < \theta\}| & \text{if } \theta < 0 \end{cases}$$

be the function that computes for, a given cell T_k of the partition, the fraction of its members whose anomaly is greater than (if $\theta > 0$) or lesser than (if $\theta < 0$) a given threshold θ. Finally, call the four numbers $\max_k c_{.5}(T_k)$,

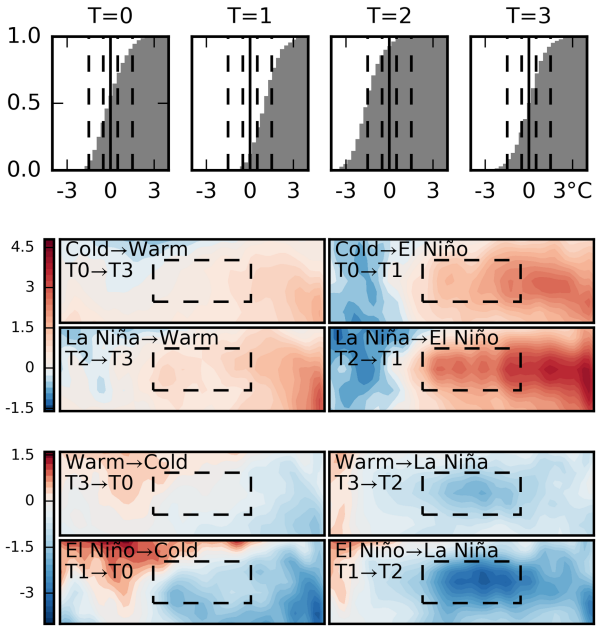

Figure 6: T=1 and T=2 are El Niño and La Niña. Top: Each plot shows the cumulative histogram of the Niño 3.4 anomalies, computed over all the weekly SST averages that belong to the given state of T. The dashed lines show the +/-0.5 and +/-1.5 "mild" and "strong" anomaly thresholds. Bottom: The minimal manipulations needed to transition from a given T-state into another (the exact procedure to obtain the plots is described in the text).

$\max_k c_{1.5}(T_k)$, $\max_k c_{(-.5)}(T_k)$, $\max_k c_{(-1.5)}(T_k)$ *the mild/strong-El Niño and mild/strong-La Niña precision of the macro-variable T.*

Together, the precisions indicate how well the partition T separates the mild and strong El Niño and La Niña anomalies from other structures in the data. In Fig. 6, for example, $c_{.5}(T) \approx .75$ and $c_{1.5}(T) \approx .25$ (both because of T=1), $c_{(-.5)}(T) \approx .85$ and $c_{(-1.5)}(T) \approx .5$ (both because of T=2). Thus, T has high mild-El Niño precision, and high mild-La Niña precision.

As further evidence that Alg. 1 recovered El Niño and La Niña, we show minimal state-to-state manipulations in Fig. 6. Take the La Niña→El Niño plot as an example. To compute it, we took all the SST maps for which T=La Niña, and for each found *the closest* (in the Euclidean space) map for which T=El Niño. We then averaged these differences. One of the insights the figure offers is that low SSTs in the Niño 3.4 region really are the distinguishing feature of T=La Niña. Similarly, an important difference between the T=Warm and T=El Niño is the characteristic tongue of warm water extending into the Niño 3.4 region. Adding this tongue is necessary to switch from T=Cold to T=El Niño, but not to switch from T=Cold or T=La Niña to T=Warm.

The CFL framework allows us to interpret W and T as stan-

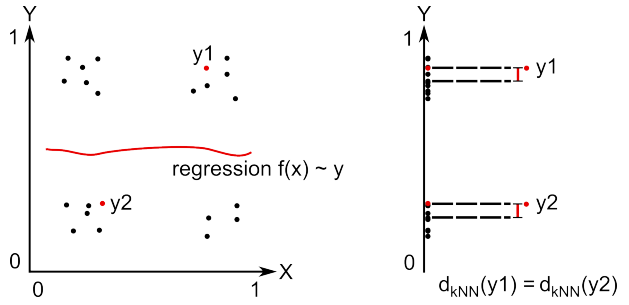

Figure 7: Alg. 1 vs. clustering. In this toy example, the data is sampled from the distribution $P(X) = U(\{1/5; 2/5)\} \cup \{3/5; 4/5\})$, $P(Y \mid X) = P(Y) = U(\{1/5; 2/5)\} \cup \{3/5; 4/5\})$. The clusters in the $\mathcal{X}$, $\mathcal{Y}$, and joint $\mathcal{X}, \mathcal{Y}$ space are evident. However, since X and Y are independent, we expect Alg. 1 to find only one macrolevel class of X. Indeed, (properly regularized) regression gives $f(x) = const\ \forall_x$, so $W(x) = 0\ \forall_x$. Incidentally, since the density of Y is similar in the neighborhood of each sample y (see data Y-projection on the right), $T(y) = 0\ \forall_y$.

dard probabilistic random variables with distribution we can estimate. Table 1 offers a probabilistic description of the system we learned. "When the equatorial zonal wind is unusually westerly, there is a 75% chance that the eastern Pacific is warm, and a 25% chance that El Niño arises." and "When the North-equatorial zonal wind is predominantly westerly, but the South-equatorial easterly, then the Eastern Pacific is most likely to be cold."—are example insights about the equatorial Pacific wind-SST system offered by CFL. We emphasize that both the macro-variables and the probabilities are learned from the data in an entirely unsupervised manner, without any a priori input about what constitutes ENSO events (except the fact that we restrict the SST and ZW fields to the equatorial Pacific region).

3 CFL: A ROBUST ALGORITHM

The practical bottleneck of the original CFL algorithm (Chalupka et al., 2016) is the need for joint density estimation of $p(X,\ Y)$. Density estimation is notoriously hard, especially in high dimensions. We modified the original algorithm to avoid explicit density estimation. An additional advantage of our approach (Alg. 1) is that it is very robust with respect to input space dimensionality: Input data is only used explicitly in regression, which can be implemented using any algorithm that easily handles high-dimensional inputs (we used neural nets).

Let $\mathcal{X}, \mathcal{Y}$ denote the micro-variable input and output space, respectively. Our algorithm is based on the insight that CFL only needs to detect the two equivalences

$$p(Y \mid x_1) = p(Y \mid x_2) \text{ for any } x_1, x_2 \in \mathcal{X} \text{ and} \quad (1)$$
$$p(y_1 \mid x) = p(y_2 \mid x) \text{ for any } y_1, y_2 \in \mathcal{Y}, x \in \mathcal{X}, \quad (2)$$

instead of actually computing the conditionals $p(Y \mid X)$.

Algorithm 1: Unsupervised Causal Feature Learning

input : $\mathcal{D} = \{(x_1, y_1), \cdots, (x_N, y_N)\}$
`Cluster` – a clustering algorithm
output: $W(x), T(y)$ – the causal class of each x, y.

1 Regress $f \leftarrow \text{argmin}_f \Sigma_i (f(x_i) - y_i)^2$;
2 Let $W(x_i) \leftarrow \texttt{Cluster}(f(x_1), \cdots, f(x_N))[x_i]$;
3 Let $\texttt{Range}(W) = \{0, \cdots, N\}$;
4 Let $\mathcal{Y}_w \leftarrow \{y \mid W(x) = w \text{ and } (x, y) \in \mathcal{D}\}$;
5 Let $g(y) \leftarrow [\texttt{kNN}(y, \mathcal{Y}_0), \cdots, \texttt{kNN}(y, \mathcal{Y}_N)]$;
6 Let $T(y_i) \leftarrow \texttt{Cluster}(g(y_1), \cdots, g(y_N))[y_i]$;

If Eq. (1) holds, we also have $\mathbb{E}[Y \mid x_1] = \mathbb{E}[Y \mid x_2]$. Computing conditional expectations is much easier than learning the full conditional: $f(X) = \mathbb{E}[Y \mid X]$ minimizes $\mathbb{E}[(Y - f(X))^2]$, so learning the conditional expectation amounts to regressing Y on X under the mean-squared error measure. Unfortunately, equal conditional expectations do not imply equal conditional distributions. However, arguably the practical risk of encountering differing conditionals with identical means is lower than the risk of failing at high-dimensional density learning. For this reason, we use $\mathbb{E}[Y \mid x_1] = \mathbb{E}[Y \mid x_2]$ as a heuristic indicator of the equivalence of the conditionals in Eq. (1) (see Line 2 in Alg. 1). For a more robust heuristic one could use more than just equal expectations to decide distribution equality. A promising direction would be to use a Mixture Density Network (Bishop, 1994) to approximate $P(Y \mid x)$ with a mixture of Gaussians for each x, and then cluster the mixtures.

Clustering the conditional expectations gives us the macro-variable class $W(x)$ of each input x. By construction (Chalupka et al., 2015), we have $p(Y \mid x) = P(Y \mid W(x))$ and by assumption the range of W is small. Instead of checking whether Eq. (2) holds for a given pair y_1, y_2 over all the $x \in \mathcal{X}$, it is thus enough to check whether $p(y_1 \mid W = w) = p(y_2 \mid W = w)$ for each value $w \in \texttt{Range}(W)$. For each given w we have a subset $\mathcal{Y}_w \subset \mathcal{Y}$ which consists of all the y's whose corresponding x's have causal class w. Consequently, Eq. (2) does not depend on the exact densities conditional on the micro-state, but only the densities conditional on the macro-level state. Thus, instead of trying to evaluate any given $p(y \mid w)$, Line 5 computes *the distance of y to the k-th nearest neighbor in $\mathcal{Y}_w$*. This idea is based on a principle that under-

	Cold	El Niño	La Niña	Warm
EEqt	2/3	0	1/3	0
WEqt	0	1/4	0	3/4
EN	∼1/10	0	1/4	∼2/3
ES	3/4	0	0	1/4

Table 1: Each row shows $P(T \mid W = w)$ for a given w.

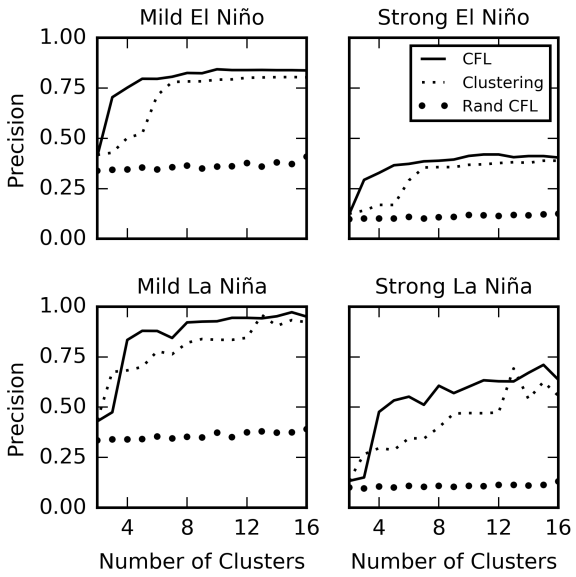

Figure 8: Changes in macro-variable precision as we vary the number of states in CFL, clustering, and CFL on reshuffled data ("Rand CFL"). With two states, it is impossible to differentiate El Niño and La Niña from other weather features, be it dynamic (CFL) or spatio-structural (clustering). Increasing the number of states reveals differences between the algorithms.

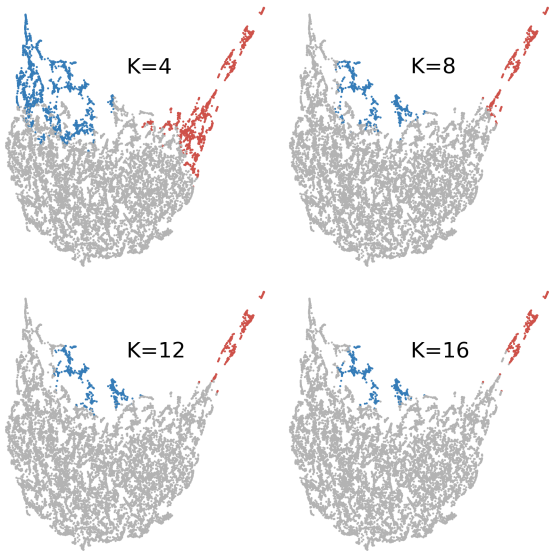

Figure 9: t-SNE (Van der Maaten and Hinton, 2008) embedding of the k-nn representation of SST data. The blue dots show, for varying K, the state of T with largest $c_{(-.5)}$ precision (see Def. 4). The red dots show the state with largest $c_{.5}$. Thus, the blue dots are "the" La Niña cluster for each K, and the red dots "the" El Niño cluster.

lies a whole class of nonparametric density estimation algorithms (Fukunaga and Hostetler, 1973; Mack and Rosenblatt, 1979): Where the density is high, samples from the distribution are closer to each other than where the density is low. This is illustrated in Fig 7. On the right, we plotted the projection of the data onto the y-space. In this projection, the distance of y_1 to its third-nearest neighbor is roughly the same as the distance of y_2 to its third-nearest neighbor. Indeed, this is the case for all the y's, because they are generated from a distribution that assigns equal density to all of them.

In Chalupka et al. (2016) we represented each y by an estimate of $[p(y \mid x_1), \cdots, p(y \mid x_N)]$, where N is the number of datapoints. The new approach represents each y sample by its 'k-nn representation', one scalar value for each $w \in \texttt{Range}(W)$ (Line 5). Clustering these representations gives us the causal state $T(y)$ for each y.

Algorithm 1 relies on a successful regression f that minimizes the mean squared error $\mathbb{E}[(f(x) - y)^2]$. In our experiments, we used the Theano (Bastien et al., 2012) and Lasagne packages to implement and train a three-hidden-layers, fully-connected neural network (Bishop, 1995) in Python. The data was sufficiently simple (compared to e.g. image datasets used to evaluate state-of-the-art neural nets in vision) that no regularization technique beyond simple weight decay and early stopping was necessary to minimize the validation error.

4 ROBUSTNESS OF THE RESULTS

In this section, we describe two additional studies we performed to ensure our algorithm behaves as expected, and that the results are robust with respect to changing the experimental parameters.

4.1 VARYING THE NUMBER OF STATES

Our choice of discovering four-state macro-variables was rather arbitrary. To check how varying the number of states changes the macro-variable precision (Def. 4), we repeated our experimental procedure, varying the number of states K from 2 to 16 (both in the ZW and SST space). Fig. 8 shows the precisions for each case. As expected, a low number of states (K=2, 3) doesn't allow the algorithm to precisely detect El Niño and La Niña. With K $>$ 4 however, a slowly growing trend persists at high precision values. El Niño and La Niña remain important features as K changes.

There are several possible behaviors of the algorithm given the slowly growing precision of the macro-variables with growing K: (1) The El Niño and La Niña states remain roughly constant, (2) CFL sub-divides the El Niño and La Niña states, (3) CFL finds better El Niño and La Niña regions, (3) A mix of the above. Fig. 9 suggests that (2) is true. As K grows, the clusters that most precisely detect the mild El Niño and mild La Niña phenomena form a chain of strict subsets.

	T1	T2	T3	T4
W1	.075	.40	.25	.27
W2	.083	.39	.25	.27
W3	.084	.39	.26	.27
W4	.080	.40	.24	.27

Table 2: Conditional probabilities $P(T \mid W)$ when Alg. 1 is applied to randomly (in time) reshuffled ZW and SST data.

4.2 RESHUFFLED DATA

As a sanity check, we ran Alg. 1 on randomly reshuffled (across the time dimension) ZW and SST data. We asked the algorithm to find K=4, ..., 16-state ZW and SST macro-variables. Table 2 shows $P(T \mid W)$, where W and T are the input and output macro-variables discovered in the randomized dataset with $K = 4$. Note that $P(T \mid W = W1)$, $P(T \mid W = W2)$, $P(T \mid W = W3)$ and $P(T \mid W = W4)$ are all equal. This is exactly as expected, since by reshuffling the data we removed any probabilistic dependence between the inputs and the outputs.

Applying Definition 2 to this data indicates that the algorithm implicitly only discovered one true input state, even though we explicitly asked it to look for a four-state macro-variable. The cardinality of the output macro-variable is three or four states, depending on whether .25 is close enough to .27 to apply Def. 2 to merge the last two columns. We performed the same reshuffled analysis for each K and computed as before the precision for the weak and strong El Niño and the weak and strong La Niña. Fig. 8, large dotted lines, shows that in each case none of the clusters contains a significant proportion of either El Niño or La Niña patterns. This experiment offers two insights:

- Alg. 1 passes the sanity check. When the inputs and outputs are independent, the input macro-variable is trivial, it has a single state.
- When SST patterns are clustered according to their probability of occurrence (e.g. as the W variable does in Table 2), El Niño and La Niña are not identified as macro-level climate states. We will return to this point in the Discussion.

5 WHY NOT NAIVE CLUSTERING?

It is instructive to compare our results with unsupervised clustering. Fig. 8 shows the precision coefficients for k-means clustering with k=4, ..., 16 (small dotted line), alongside our CFL results. Whereas CFL detects both El Niño and La Niña with high precision using only four states, k-means struggles to achieve a similar result even for larger K.

Barring particularities of the data (which we consider in the Discussion), there is in general no reason for CFL to give the same results as clustering. Consider the example in Fig. 7. Arguably, a reasonable clustering algorithm should find four linearly separable clusters in the joint $\mathcal{X}, \mathcal{Y}$ space, and two clusters in the $\mathcal{X}$ and $\mathcal{Y}$ space each. However, the variables are probabilistically independent. In contrast, CFL would only find a one-state input variable, since all values of X imply the same distribution over Y. Additionally, since $P(Y \mid X) = P(Y)$ is constant across all the samples, CFL would also only find a one-state output variable. The figure illustrates that Alg. 1 does precisely that (as should the original algorithm in Chalupka et al. (2016)).

6 DISCUSSION

The CFL framework we developed in Chalupka et al. (2015, 2016) aspires to solve an important problem in causal reasoning: how to automatically form macro-level variables from micro-level observations. In this work we have shown, for the first time, that these algorithms can be successfully applied to real-life data. We have recovered well-known, complex climate phenomena (El Niño, La Niña) as macro-variable states directly from climate data, in an entirely unsupervised manner. In order to do so, we developed a new, practical version of the original CFL algorithm.

We emphasize that our experiments use *observational* climate data, and we have to be cautious about causal conclusions. It is not even clear *a priori* whether the $ZW \rightarrow SST$ causal direction is a reasonable choice: it is known that wind patterns cause changes in SST and it in turn affects the wind by changing the atmospheric pressure. Feedback loops are commonplace in climate dynamics.

The Causal Coarsening Theorems in Chalupka et al. (2015, 2016) provide the basis for an efficient learning of causal relationships based on observational macro-variables – but some experiments are required. In addition, the theorems were only shown to hold for variables that are not subject to feedback. However, we are hopeful that an extension accounting for feedback can be proven. While real climate experiments are generally not feasible, such a theorem would provide the basis to perform large-scale climate experiments with detailed climate models, for example, to check whether *interventionally* shifting from the $W = 0$ zonal wind state to $W = 1$ in the climate model increases the likelihood of El Niño (i.e. of SST ending up in state T=1). Connecting the CFL framework with such experiments is an exciting future direction as it would also enable the possibility of using the macro-variables we have found to inform policy that aims to influence climate phenomena.

Our experiments that compare CFL with clustering showed that, as the number of clusters grows, k-means approaches never exceed CFL's precision in detecting El Niño and La Niña. One explanation for this finding is that while clustering looks for *spatial features* in the data, CFL looks

for *relational probabilistic features*. Fig. 8 suggests that when the number of clusters is small there are strong spatial features in the data that supersede El Niño and La Niña in their distinctiveness. In contrast, CFL already detects El Niño with high precision with only four clusters. This indicates that either (1) There is something unique about $P(\text{El Niño} \mid \text{W})$ and $P(\text{La Niña} \mid \text{W})$, or (2) There is something unique about $P(\text{El Niño})$ and $P(\text{La Niña})$. Since we disproved the second hypothesis in Sec. 4.2, our results overall indicate that the El Niño and La Niña phenomena do not only constitute interesting spatial features of the SST map, but are also crucially characterized by the dynamic aspect of the interplay between zonal winds and sea surface temperatures.

Even when working with purely observational data, CFL offers an important causal insight not revealed by clustering methods. It guards against learning variables with ambiguous manipulation effects (Spirtes and Scheines, 2004). An illustrative example of an ambiguous macro-variable is total cholesterol. Low density lipids (LDL, commonly called "bad cholesterol") and high density lipids (HDL, "good cholesterol") can be aggregated together to count total cholesterol (TC), but TC has an ambiguous effect on heart disease because effects of LDL and HDL differ. The Causal Coarsening Theorem guarantees that each state of the observational macro-variable is causally unambiguous: no mixing of HDL and LDL can occur. In case of our El Niño setup, this means that two ZW states within the same cell are guaranteed to have the same effect on the SST macro-variable.

Finally, we note that there still is significant debate among climate scientists about what exactly constitutes El Niño and what its causes are. For example, recent research has shown that there may be multiple different types of El Niño states (Kao and Yu, 2009; Johnson, 2013) that all fall under NOAA's definition. Our results suggest that the current definition described in Section 1.1 coincides well with states of the probabilistic macro-variable discovered by CFL. In addition, Sec. 4.1 indicates that finer-grained structure does exist within the El Niño and La Niña clusters when they are analyzed from the relational-probabilistic standpoint. We leave this line of research as an important future direction.

Abstract

Open agent systems are multiagent systems in which one or more agents may leave the system at any time possibly resuming after some interval and in which new agents may also join. Planning in such systems becomes challenging in the absence of inter-agent communication because agents must predict if others have left the system or new agents are now present to decide on possibly choosing a different line of action. In this paper, we prioritize open systems where agents of differing types may leave and possibly reenter but new agents do not join. With the help of a realistic domain – wildfire suppression – we motivate the need for individual planning in open environments and present a first approach for robust decision-theoretic planning in such multiagent systems. Evaluations in domain simulations clearly demonstrate the improved performance compared to previous methods that disregard the openness.

1 INTRODUCTION

The past year has been witness to one of the worst seasons of wildland fires, here onwards referred to as wildfires, on record in the United States. There were more than fifty thousand wildfires that burned more than nine million acres of wildland. Both ground and various types of aerial firefighting units are often deployed in suppressing these fires. Consider the decision-making task of a small ground unit of firefighters. As these fires are large, a unit needs to coordinate with others to focus their resources on the same area and make a difference. However, units may run out of suppressants (such as water and chemicals) or suffer from exhaustion causing them to temporarily leave. Consequently, wildfire fighting units form an *open* and *typed* multiagent system and a unit's decision making about its course of action becomes challenging if a leaving unit is unable to radio its intent to temporarily disengage.

Open agent systems such as the one described above are characterized by one or more interacting agents leaving the system at any time and possibly resuming after some interval, or new agents joining the system [1]. We refer to this characteristic as *agent openness*. A second form of openness is exhibited by a system when the types of agents alter at any time perhaps just briefly; we refer to this as *type openness*. The wildfire suppressing example presented above exhibits agent openness but not type openness.

In this paper, we prioritize systems exhibiting agent openness and further limit our attention to systems where agents may disengage at any time and possibly reenter the system but new agents do not enter the system. We are interested in how an individual agent, for example the ground firefighting unit, should plan its actions in such open and typed multiagent systems. A perspectivistic approach makes this investigation broadly applicable to cooperative, noncooperative and mixed settings all of which may exhibit agent openness.

Previous methods for individual decision-theoretic planning such as algorithms for the well-known interactive partially observable Markov decision process (I-POMDP) [2, 3] are well suited for typed systems but do not model agent openness so far. Similarly, algorithms for joint cooperative planning in frameworks such as the decentralized POMDP [4] are not easily amended for open agent systems. As such, there is a marked gap in the literature on principled planning for open systems. We present a first approach for modeling and planning in the context of agent openness when the physical state may not be perfectly observed. In keeping with our objective of individual planning and the presence of agents of various types, we generalize the I-POMDP-Lite framework [5] to allow for agent openness. This framework is more efficient than the general I-POMDP because it ascribes a nested MDP to model others rather than a belief hierarchy. We utilize a graph to model the interaction structure between various agents and extend the joint state to model the event that neighboring agents could have disengaged. In the absence of communication, we show how the

agent's unexpected observations allow it to correct its model of the other agent *post hoc* after the agent has left or has reentered. Alternately, a *proactive* approach that seeks to predict when agent may disengage or reenter should exhibit improved benefit. However, the subject agent may not know how factors relevant to others' decisions to leave or reenter evolve.

The generalized I-POMDP-Lite is utilized to model the problem domain of wildfire suppression exhibiting open and typed agent systems. We continue with Hoang and Low's [5] use of interactive point-based value iteration to scalably plan and extend it appropriately to the generalized I-POMDP-Lite. Evaluations in simulations of the domain clearly demonstrate not only the improved performance of the individual agent but also the performance of the entire open system at a macro level in comparison to planning that disregards agent openness.

2 RELATED WORK

Agent openness is a challenging property of realistic multiagent systems that has been identified at various points in the literature. Shehory [1] noted that the openness of an agent system refers to the ability of introducing additional agents into the system in excess to the agents that comprise it initially. Calmet et al. [6] also studied openness in societies of agents where an open society is one that is open to new agents either with no definite goal or with goals not exceedingly relevant to the society. Both definitions focused on the system and software architecture to support openness.

Recently, additional properties for agent openness have been reported. Jamroga et al. [7] defined the degree of openness of multi-agency as the complexity of the minimal transformation that the system must undergo in order to add a new agent to the system or remove an existing one from the system. Jumadinova et al. [8] and Chen et al. [9] extended the notion of openness to include both agent openness and task openness to model the dynamic nature of the agents and tasks in the environment. They considered fluctuations in the availability of agents needed to perform tasks, as well as dynamic changes in the type of tasks that appear over time. In both papers, the degree of openness is defined as the rate at which agents/tasks join and leave the environment.

Relevant to modeling individual agents in open environments, Huynh et al. [10] studied the problem of developing trust and reputation models in open agent systems to enable agents (owned by a variety of stakeholders) to assess the quality of their peers' likely performance. Similarly, Pinyol and Sabater-Mir [11] studied, for open environments where agents' intentions are unknown, how to control the interactions among the agents in order to protect good agents from fraudulent entities, or to help agents find trustworthy or reputable agents.

In this paper, we adopt the notion of dynamic agent openness defined by Shehory, extended in Jumadinova et al. and Chen et al. Similar to Huynh et al. and Pinyol and Sabater-Mir, we are also interested in developing a solution to enable an agent to model its transient neighbors in open environments. However, our problem and approach differ in that we are interested in modeling *how neighbors will behave over time* (i.e., predicting what actions they might take, as well as their future presence in the environment which directly impacts when and how they might work together with or against an agent), instead of determining how reliable a neighbor might be. Similar to Jumadinova et al. and Chen et al., we also seek to design agents capable of strategic, self-interested reasoning, but we do so from the decision-theoretic perspective grounded in the tradition of Markov decision problems with an added focus on modeling peer behavior in order to plan and perform actions as a best response to the expected behavior of peers.

Finally, we note that ad hoc cooperation – coming together of multiple agents on the fly to meet a goal [12] – is just one characteristic of an open agent system. As this paper's focus is instead on agents dynamically departing the system and reentering, we do not discuss the emerging literature on online planning for ad hoc teamwork.

3 BACKGROUND

I-POMDP-Lite mitigates the complexity of I-POMDPs by predicting other agent's actions using a nested MDP; this assumes that the other perfectly observes the physical state. A nested MDP [5] is a scalable framework for individual planning in multiagent systems where the physical state and others' models are perfectly observable to each agent. It is defined as a tuple for agent i:

$$\mathcal{M}_{i,l} \triangleq \langle S, A, T_i, R_i, \{\pi_{j,d}, \pi_{k,d}, \ldots, \pi_{z,d}\}_{d=0}^{l-1}, OC_i \rangle$$

where:

- S is the set of physical states of the interacting agent system. The space may be factored as, $S = X_1 \times X_2 \times \ldots \times X_k$, where $X_1, \ldots, X_k$ are $k > 0$ factors;
- $A = A_i \times A_j \times \ldots \times A_z$ is the set of joint actions of all interacting agents in the system;
- Transition of a state due to the joint actions to another state may be stochastic and the transition function is defined as, $T_i : S \times A \times S \rightarrow [0, 1]$. The transition probabilities may be conditionally factored based on the factorization of the state space;
- R_i is the reward function of agent i that depends on the state and joint actions, $R_i : S \times A \rightarrow \mathbb{R}$;
- $\{\pi_{j,d}, \pi_{k,d}, \ldots, \pi_{z,d}\}_{d=0}^{l-1}$ is the set of other agents j, k, …, z reasoning models at all levels from 0 to $l-1$. Each of these models is a policy which is a mapping from states

to distributions over actions and is obtained by solving a nested MDP for the agent at that level. However, a level-0 reasoning model is a uniform distribution over an agent's actions;

- OC_i is i's optimality criterion. In this paper, we utilize a finite horizon H with discount factor $\gamma \in (0, 1)$.

Analogous to MDPs, we may associate a horizon $0 < h \leq H$ value function with $\mathcal{M}_{i,l}$ that extends the standard Bellman equation. Let $A_{-i} = A_j \times A_k \times \ldots \times A_z$.

$$V^h_{i,l}(s) = \max_{a_i \in A_i} \sum_{\mathbf{a}_{-i} \in A_{-i}} \prod_{-i \in \{j,k,\ldots,z\}} \hat{\pi}_{-i,l-1}(s, a_{-i}) \times Q^h_{i,l}(s, a_i, \mathbf{a}_{-i}) \quad (1)$$

Here, $Q^h_{i,l}(s, a_i, \mathbf{a}_{-i})$ is defined recursively:

$$Q^h_{i,l}(s, a_i, \mathbf{a}_{-i}) = R_i(s, a_i, \mathbf{a}_{-i}) + \gamma \sum_{s' \in S} T_i(s, a_i, \mathbf{a}_{-i}, s') \times V^{h-1}_{i,l}(s') \quad (2)$$

Furthermore, $\hat{\pi}_{-i,l-1}$ in Eq. 1 is defined as a mixed strategy that has a distribution over reasoning models at all levels up to $l-1$. If $l-1=0$ in Eq. 1 then $\hat{\pi}_{-i,l-1}$ is a uniform distribution over the other agent's actions.

$$\hat{\pi}_{j,l}(s, a_j) \triangleq \begin{cases} \sum_{d=0}^{l} Pr(d)\, \pi_{j,d}(s, a_j) & l \geq 1 \\ \frac{1}{|A_j|} & l = 0 \end{cases} \quad (3)$$

Policy $\pi_{j,d}(s, a_j)$ is obtained by solving the nested MDP of agent j at level d, which involves optimizing the corresponding value function similar to Eq. 1. Let Opt_j be the set of j's actions that optimizes it. Then, $\pi_{j,d}(s, a_j) = \frac{1}{|Opt_j|}$ if $a_j \in |Opt_j|$ otherwise $\pi_{j,d}(s, a_j)$ is 0. Distribution $Pr(d)$ on the nesting depth up to l is typically uniform but may also be learned from data as well.

With all agents modeling each other, solution of a nested MDP proceeds bottom up. Level-0 models of all agents default to uniform distributions. These are utilized in solving level-1 nested MDPs, $\mathcal{M}_{i,1}, \mathcal{M}_{j,1}, \ldots, \mathcal{M}_{z,1}$. Both level-0 and -1 solutions are utilized in solving nested MDPs at level 2; and so on up to level l. Consequently, in an N-agent system we solve $N-1$ models of others at any level and a total of $(N-1)l$ models. This is *linear* in both the number of nesting levels l and the number of agents, and scales well with both. If all N agents plan using nested MDPs then a total of $\mathcal{O}(N^2 l)$ such models are solved.

For individual planning in situations where the physical state is not perfectly observable to the subject agent i although the reasoning models of other agents are known and are supposed to possess the capability to observe the state perfectly, Hoang and Low [5] present the I-POMDP-Lite framework.

$$\text{I-POMDP}^{\mathcal{L}}_{i,l} \triangleq \langle S, A, \Omega_i, T_i, O_i, R_i, \{\mathcal{M}_{j,l-1}, \mathcal{M}_{k,l-1}, \ldots, \mathcal{M}_{z,l-1}\}, OC_i \rangle$$

Parameters S, A, T_i and R_i are as defined previously in the nested MDP framework. Ω_i is the set of agent i's observations and O_i is the observation function, which models the level of noise in the observations: $O_i : S \times A_i \times \Omega_i \rightarrow [0, 1]$. Notice that the observation distribution is conditionally independent of other agents' actions. $\{\mathcal{M}_{j,l-1}, \mathcal{M}_{k,l-1}, \ldots, \mathcal{M}_{z,l-1}\}$ are the nested MDPs of various interacting agents, and OC_i is the optimality criterion that may include a discount factor and an initial belief, b^0_i, over the state space.

Analogous to POMDPs, an agent maintains a belief over the states and the planning method associates a value function with the belief:

$$V^h_{i,l}(b_i) = \max_{a_i \in A_i} \left(\rho_i(b_i, a_i) + \gamma \sum_{s' \in S, o_i \in \Omega_i} \mathcal{T}_i^{a_i, o_i}(s', o_i | b_i, a_i) \times V^{h-1}_{i,l}(b'_i) \right) \quad (4)$$

where,

$$\rho_i(b_i, a_i) = \sum_{s \in S} \sum_{\mathbf{a}_{-i} \in A_{-i}} \prod_{-i \in \{j,k,\ldots,z\}} \pi_{-i,l-1}(s, a_{-i}) \times R_i(s, a_i, \mathbf{a}_{-i})\, b_i(s)$$

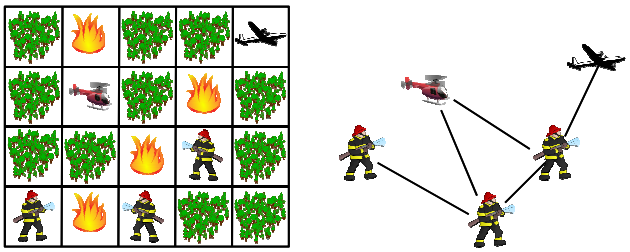
Policies $\pi_{-i,l-1}(s, a_{-i})$, $-i \in \{j, k, \ldots, z\}$ are solutions of the other agents' nested MDPs; and b'_i denotes the updated belief, $Pr(s'|o_i, a_i, \mathbf{a}_{-i}, b_i) \propto O_i(s', a_i, o_i) \times \sum_{s \in S} T_i(s, a_i, \mathbf{a}_{-i}, s')\, b_i(s)$.

Solution of I-POMDP$^{\mathcal{L}}_{i,l}$ requires solving the nested MDPs that are a part of its definition to obtain the policies. As we mentioned previously, this proceeds bottom up. At the top most level only, a POMDP is solved by decomposing the value function given in Eq. 4 into an inner product between a set of alpha vectors and the belief. While the total number of models that are solved remain linear in the nesting level and the number of agents, the computational complexity is higher because of the presence of a POMDP.

4 INDIVIDUAL PLANNING WITH AGENT OPENNESS

Planning that can assist fighting wildfires must deal with the event that units run out of suppressants – some types of units run out more quickly than others – due to which units temporarily leave the theater and thus the agent system. We seek to reason about the agent openness found in such environments as part of the individual planning in a principled way.

Systems of many agents in the real world often exhibit interaction structure. Specifically, not all agents interact with one another; rather, interactions often happen among small subgroups of agents.



(a) (b)

Figure 1: (a) An example wildfire scenario with 5 firefighting units of three types situated in a 4×5 grid of forestland. (b) Firefighting units must often coordinate on suppressing fires. This coordination overlays an interaction graph.

A well-known data structure that explicates the interaction structure is an *interaction graph*, which is an undirected graph whose nodes represent agents and the absence of an edge between two agents indicates that the reward of each of the two agents is not dependent on any action of the other agent. Interaction structure may be exploited during planning for computational scalability [13, 14, 15]. We motivate the interaction structure using an example:

Example 1. *Figure 1(a) illustrates an example wildfire suppressing scenario that consists of ground and two types of aerial firefighting units. Units must coordinate on adjacent or diagonally located fires to gradually suppress them and prevent them from spreading. This coordination overlays an interaction graph that is shown in Fig. 1(b). Notice that the graph is not a clique and thus exhibits structure.*

Each vertex in the graph denotes an agent i in the set $\mathcal{N}$ of agents and an edge between a pair of agents whose individual payoffs depend on each other's actions. Let $\nu(i)$ be the set of nodes that are directly linked by an edge to node i. We refer to $\nu(i)$ as the set of i's neighboring agents.

4.1 Post Hoc Reasoning

Let $\dot{\mathbf{X}}$ be the set of distinguished state factor(s) in S whose value determines whether other agent $j \in \nu(i)$ temporarily leaves the network. For example, this variable could reflect j's suppressant level. If i determines that j has left the network, i replaces j's predicted actions – using j's policy obtained by solving its nested MDP $\mathcal{M}_{j,l-1}$ – with a no op action from then onward during which the agent does not act. [1] Consequently, A_j is replaced with $A_j \cup \{\text{no op}\}$. This is beneficial because we need not change the definitions of agent i's transition, observation and reward functions when an agent leaves the network if no op is already in A_j. Otherwise, these are modified to model the implications of j's no operation to allow for agent openness.

[1] A caveat of this approach is that the agent's absence is observationally equivalent with the agent intentionally not acting.

However, the problem of predicting when an agent has left the network remains challenging because the state is partially observable – the amount of j's suppressant cannot be directly observed as we preclude communication between the separated units. Similarly, the problem of predicting if and when an agent has resumed its activities is also challenging.

Define joint probability $\mathcal{T}_i^{a_i,o_i}(s', o_i|a_i, b_i)$ as,

$$\mathcal{T}_i^{a_i,o_i}(s', o_i|a_i, b_i) = \sum_{s\in S} b_i(s) \sum_{\mathbf{a}_{-i}\in A_{-i}} T_i(s, a_i, \mathbf{a}_{-i}, s') \\ O_i(s', a_i, \mathbf{a}_{-i}, o_i) \prod_{-i\in\{j,k,\ldots,z\}} \pi_{-i,l-1}(s, a_{-i})$$

We make the following key observation that facilitates progress in this challenging task:

Observation 1. Post hoc $\mathcal{T}_i^{a_i,o_i}(s', o_i|a_i, b_i)$ *immediately after a neighboring agent has left the system will be small but will generally increase with time until the agent reenters.*

While agent j may abruptly leave the system at time step t, the planning agent continues to predict j's actions as if it were part of the system until the observation at time $t+1$ reveals that the state did not transition as expected. In other words, joint $\mathcal{T}_i^{a_i,o_i}(s', o_i|a_i, b_i)$ will be small because next state s' that is obtained by predicting j's action incorrectly will have low likelihood given observation o_i.

Nevertheless, observation o_i when used in the belief update to obtain b_i' will cause the probability mass in b_i to shift to states that make o_i more likely. These are likely to be states at which $\pi_{j,l-1}(s', \text{no op})$ is high; i.e., j is not performing any significant action because j has left the system. With more such observations that support the fact that j has left the system, more probability mass in the updated beliefs settles on states at which j is predicted to not perform any significant action. Therefore, joint $\mathcal{T}_i^{a_i,o_i}(s', o_i|a_i, b_i)$ will start rising until another such event occurs. We illustrate this observation:

Example 2. *Let firefighting unit j exit a team that consists of units i and j who are coordinating on suppressing a high intensity wildfire. Unit i expects the intensity of the fire to continue reducing in the next time step but instead observes that the intensity remained the same as before. This low probability observation makes i subsequently believe that perhaps j is not fighting the fire anymore (because it may have left the system); a belief that gets strengthened further as the fire continues to burn at the same intensity despite i fighting it. When its predictions of j performing* no ops *are sufficiently certain, i may choose to coordinate on a different wildfire with another unit.*

Observation 1 continues to hold when $\nu(i)$ has two or more agents but i may not be able to pinpoint which agent has exited.

Moving forward, let agent j reenter the system and resume its actions. Again, agent i may experience a phenomenon similar to that described in Observation 1 where *post hoc* $\mathcal{T}_i(s', o_i|a_i, b_i)$ drops because the observations do not support the next predicted state. This is because i is attributing no op to j despite j having reentered. However, persistent observations will shift the probability mass in i's belief to states at which j is predicted to be performing actions other than no op thereby modeling the fact that j is active again.

To illustrate, if unit i continued fighting the same wildfire as before, it may suddenly witness the intensity reducing significantly. This is indicative of the fact that unit j is active again and i's revised beliefs will emphasize those states at which j could also be suppressing the fire. On reentering, an agent can be expected to remain committed to fighting the fire if the intensity is steadily reducing, until the fire is suppressed or the agent's suppressant becomes low.

The observation below summarizes this subsection:

Observation 2. *Decision-theoretic planning that integrates modeling behaviors of other agents and a Bayesian belief update can reason about agent openness post hoc and plan accordingly with minimal extension.*

However, the limitation is that the adaptation of planning to the dynamic openness is delayed due to the *post hoc* reasoning.

4.2 Predicting Agent Openness

A better way to act in open agent systems would be to predict when a neighboring agent leaves or reenters the system. Presuming that the agent's departure is a policy-guided behavior and the agent's policy is known, we must predict changes in the distinguished state factors $\mathbf{X}$ that may cause the other agent to leave the system. However, the main challenge is that the subject agent is usually uninformed about how these factors evolve over time.

For example, the rate at which the other firefighting unit consumes its suppressant is typically not known and may not be observed due to the separation between the two units. Nevertheless, observations related to the unit leaving the system over time provide information from which the rate could be gradually learned and utilized in the prediction.

Let $\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')$ be the transition distribution for $\dot{\mathbf{X}}$ given i's action a_i, neighbors' joint actions $\mathbf{a}_{-i}$, and previous value of the factor $\dot{\mathbf{x}} \in \dot{\mathbf{X}}$. For notational convenience, we assume that $\dot{T}_i$ may be factored out from function T_i. Subsequently, predicting when neighboring agents $j \in \nu(i)$ are likely to leave the system is dependent on knowing $\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')$ for all pairs of state factors and joint actions.

Our approach is Bayesian; it involves explicitly modeling the uncertainty over the distribution, updating it over time based on expected next states and utilizing it in the offline planning.

We may model the uncertainty over the distribution $\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \cdot)$ as a Dirichlet process (DP), and the uncertainty over all such distributions as a system of Dirichlet processes. Formally, $\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \cdot) \sim DP(n, C)$, where n is a positive integer and C is a distribution over $\dot{\mathbf{X}}$. Let factor(s) $\dot{\mathbf{X}}$ assume values $\{\dot{\mathbf{x}}_1, \dot{\mathbf{x}}_2, \ldots, \dot{\mathbf{x}}_{|\dot{\mathbf{X}}|}\}$, then

$$\Big(\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_1), \dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_2), \ldots, \dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_{|\dot{\mathbf{X}}|})\Big) \sim Dir(n \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_1}}{n}, n \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_2}}{n}, \ldots, n \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_{|\dot{\mathbf{X}}|}}}{n}) \tag{5}$$

where $c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_1}$ is the number of samples where transition $(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_1)$ occurs, and analogously for others; $n \triangleq \sum_{q=1}^{|\dot{\mathbf{X}}|} c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_q}$ is the total number of samples. A Dirichlet process has the appealing property that the mean of its marginal, $E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_1)] = \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_1}}{n}$ and the concentration parameter n inversely impacts the variance.

Let us obtain a sequence of n' next states $\{\dot{\mathbf{x}}'_1, \ldots, \dot{\mathbf{x}}'_{n'}\}$ given the current state $\dot{\mathbf{x}}$ and actions $a_i, \mathbf{a}_{-i}$ in independent draws. Then the posterior distributions become,

$$\Big(\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_1), \dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_2), \ldots, \dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}_{|\dot{\mathbf{X}}|})\Big) \,|\dot{\mathbf{x}}'_1, \ldots, \dot{\mathbf{x}}'_{n'} \sim Dir\,(n + n' \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_1} + \sum_{q=1}^{n'} \delta_{\dot{\mathbf{x}}_1}(\dot{\mathbf{x}}_q)}{n + n'}, n + n' \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_2} + \sum_{q=1}^{n'} \delta_{\dot{\mathbf{x}}_2}(\dot{\mathbf{x}}_q)}{n + n'}, \ldots, n + n' \cdot \frac{c^{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_{|\dot{\mathbf{X}}|}} + \sum_{q=1}^{n'} \delta_{\dot{\mathbf{x}}_{|\dot{\mathbf{X}}|}}(\dot{\mathbf{x}}_q)}{n + n'}\Big) \tag{6}$$

where $\delta_{\dot{\mathbf{x}}'_1}(\dot{\mathbf{x}}_q)$ is a point mass located at $\dot{\mathbf{x}}_1$. As the posterior continues to be Dirichlet distributed, the posterior is also a Dirichlet process with concentration parameter that simply adds the count of new samples to the previous count and a base probability that is the proportion of the total number of samples in which say state $\dot{\mathbf{x}}_1$ occurs. As such, the Dirichlet process provides a conjugate family of priors over distributions.

By modeling the dynamic uncertainty over the transition function of distinguished state factors as a Dirichlet process, we may limit our attention to the counts of the different state samples. Let ϕ be the vector of counts of all transitions; its size is $|\dot{\mathbf{X}}|^2|A|$. Next, we show how to include the Dirichlet process in I-POMDP-Lite.

We augment the state space of I-POMDP$^{\mathcal{L}}_{i,l}$ to include this vector: $\mathcal{S} = S \times \Phi$ where Φ is the space of all such vectors and is of size $\mathbb{N}^{|\dot{\mathbf{X}}|^2|A|}$. Given the augmented state space, we redefine the transition, observation and reward functions

of I-POMDP$^{\mathcal{L}}_{i,l}$ as follows:

$$\mathcal{T}_i(\langle s,\phi\rangle, a_i, \mathbf{a}_{-i}, \langle s',\phi'\rangle) = \begin{cases} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}) & \text{if } \phi' = \phi + \delta_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}'} \\ \times E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')] & \\ 0 & \text{otherwise} \end{cases}$$

Here, $\delta_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}'}$ is a vector of size $|\dot{\mathbf{X}}|^2|A|$ with all 0s except for a 1 at the location indexed by $(\dot{\mathbf{x}}, \mathbf{a}, \dot{\mathbf{x}}')$ where $\dot{\mathbf{x}}$ is the distinguished factor of state s and $\dot{\mathbf{x}}'$ is a factor of s'. *The expected transition probability is obtained from the posterior Dirichlet process.* The observation function is now defined as,

$$\mathcal{O}_i(\langle s,\phi\rangle, a_i, \mathbf{a}_{-i}, \langle s',\phi'\rangle, o_i) = \begin{cases} O_i(s', a_i, \mathbf{a}_{-i}, o_i) & \text{if } \phi' = \phi + \delta_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}'} \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

The reward function is straightforward: $\mathcal{R}_i(\langle s,\phi\rangle, a_i, \mathbf{a}_{-i}) = R_i(s, a_i, \mathbf{a}_{-i})$. The optimality criteria remains the same as before.

Consequently, the *augmented* I-POMDP$^{\mathcal{L}}_{i,l}$ is defined by the tuple $\langle \mathcal{S}, A, \mathcal{T}_i, \Omega_i, \mathcal{O}_i, \mathcal{R}_i, \{\mathcal{M}_{j,l-1}, \mathcal{M}_{k,l-1}, \ldots, \mathcal{M}_{z,l-1}\}, OC_i\rangle$, where the new parameters are defined as above. It shares commonality with the Bayes-adaptive I-POMDP framework [16] though we are uncertain over partial transition distributions only and our framework differs by limiting attention to nested MDPs as models of others. Acting optimally in response to observations in this augmented framework entails the standard balance between exploring to learn the transition distributions of the distinguished state factor(s) with greater confidence and exploiting the learned distributions for reward. However, compared to traditional online methods for reinforcement learning, this balance is achieved offline as an integral part of the planning.

The exact solution of the augmented I-POMDP$^{\mathcal{L}}_{i,l}$ is challenged by the infinite state space because the count vector ϕ grows unboundedly. If the count vector somehow reflects the true transition probabilities, then $\mathcal{T}_i$ effectively collapses into the true transition function and we may obtain the exact solution of the planning problem. However, by the law of large numbers we can only approach the true distributions asymptotically using counts. Nevertheless, the following observation provides guidance on how we can move forward:

Observation 3. *With increasing numbers of samples, means of the posterior Dirichlet processes $DP(n, C)$ come arbitrarily close to the true transition probabilities. Consequently, values of the policies using the estimated transition functions may also come arbitrarily close to the value of the exact policy.*

Indeed, Ross et al. [17] exploit the above observation in the context of POMDPs and identify an ϵ-dependent finite space of counts of both transitions and observations whose consideration leads to policies with values that are within ϵ of the exact (obtained using the infinite space). We extend these results to our context where the uncertainty is over the partial transition function only but involving multiple agents; this allows solving the augmented I-POMDP$^{\mathcal{L}}_{i,l}$ with finite state spaces as bounded approximation of the exact.

Let $\alpha^t(s,\phi;\pi_{i,l})$ be i's expected value of following policy $\pi_{i,l}$ from augmented state (s,ϕ) at some time step t. Let $\mathcal{N}^{\dot{\mathbf{x}}\mathbf{a}}_{\phi} = \sum_{q=1}^{|\dot{X}|} \phi_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_q}$ where $\phi_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}_q}$ is the count for the transition $(\dot{\mathbf{x}}, \mathbf{a}, \dot{\mathbf{x}}_q)$ contained in the vector ϕ; and $\mathcal{N}^{\epsilon} = \max\left(\frac{|\dot{\mathbf{X}}|(1+\epsilon')}{\epsilon'}, \frac{1}{\epsilon''} - 1\right)$ where $\epsilon' = \frac{\epsilon(1-\gamma)^2}{8\gamma\mathcal{R}_{max}}$ and $\epsilon'' = \frac{\epsilon(1-\gamma)^2\, ln(\gamma^{-\epsilon})}{32\gamma\mathcal{R}_{max}}$. Here, $\mathcal{R}_{max}$ is the largest value in $\mathcal{R}$.

Proposition 1 shows that for transition counts that exceed $\mathcal{N}^{\epsilon}$, there exist counts less than or equal to $\mathcal{N}^{\epsilon}$ such that the negative impact of the reduced count on the expected value of following policy $\pi_{i,l}$ from the same state is bounded. More formally,

Proposition 1 (Bounded difference in value)**.** *Given $\epsilon > 0$ and for any (s,ϕ) such that $\mathcal{N}^{\dot{\mathbf{x}}\mathbf{a}}_{\phi} > \mathcal{N}^{\epsilon}$ for all $\dot{\mathbf{x}}, \mathbf{a}$, there exist ϕ' such that $\mathcal{N}^{\dot{\mathbf{x}}\mathbf{a}}_{\phi'} \leq \mathcal{N}^{\epsilon}$ for all $\dot{\mathbf{x}}, \mathbf{a}$, and $|\alpha^h(s,\phi;\pi_{i,l}) - \alpha^h(s,\phi';\pi_{i,l})| \leq \epsilon$.*

The proof of this proposition extends the proof of a similar proposition by Ross et al. [17] to the multiagent context of I-POMDP$^{\mathcal{L}}_{i,l}$ in a straightforward way. Let $\mathcal{S}^{\epsilon}$ be the set of augmented states of I-POMDP$^{\mathcal{L}}_{i,l}$ such that the count vectors are all limited to the following set, $\Phi^{\epsilon} = \{\phi \in \Phi : \mathcal{N}^{\dot{\mathbf{x}}\mathbf{a}}_{\phi} \leq \mathcal{N}^{\epsilon} \ \forall \dot{\mathbf{x}}, \mathbf{a}\}$; in other words, $\mathcal{S}^{\epsilon} = \mathcal{S} \times \Phi^{\epsilon}$. Then, define a new transition function over the augmented and bounded state space, $\mathcal{T}^{\epsilon}_i : \mathcal{S}^{\epsilon} \times A \times \mathcal{S}^{\epsilon} \to [0,1]$ such that

$$\mathcal{T}^{\epsilon}_i(\langle s,\phi\rangle, a_i, \mathbf{a}_{-i}, \langle s',\phi'\rangle) = \begin{cases} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}) & \text{if } \phi' = \zeta(\phi + \delta_{\dot{\mathbf{x}}\mathbf{a}\dot{\mathbf{x}}'}) \\ \times E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')] & \\ 0 & \text{otherwise} \end{cases}$$

Here, ζ is a function that projects those counts which cause $\mathcal{N}^{\dot{\mathbf{x}}\mathbf{a}}_{\phi}$ to exceed $\mathcal{N}^{\epsilon}$ back to values so that the latter is not exceeded. If $\phi + \delta_{\dot{\mathbf{x}}\mathbf{a}\cdot}$ does not exceed $\mathcal{N}^{\epsilon}$, then ζ is an identity function. Observation function with the bounded state space also applies the projection ζ to Eq. 7 similarly to its use above. Finally, the reward function $\mathcal{R}^{\epsilon}_i(\langle s,\phi\rangle, a_i, \mathbf{a}_{-i}) = R_i(s, a_i, \mathbf{a}_{-i})$.

Subsequently, the definition of I-POMDP$^{\mathcal{L}}_{i,l}$ modifies to be the tuple $\langle \mathcal{S}^{\epsilon}, A, \mathcal{T}^{\epsilon}_i, \Omega_i, O^{\epsilon}_i, \mathcal{R}_i, \{\mathcal{M}_{j,l-1}, \mathcal{M}_{k,l-1}, \ldots, \mathcal{M}_{z,l-1}\}, OC_i\rangle$. Let $\alpha^{h,\epsilon}(s,\phi;\pi_{i,l})$ be the expected value of following policy $\pi_{i,l}$ from state (s,ϕ) according to the modified framework with the bounded state space. Then, we may bound the negative impact on expected value due to using the new framework as follows:

Proposition 2 (Bounded difference in convergent value)**.** *Given $\epsilon > 0$ and the augmented I-POMDP$^{\mathcal{L},\epsilon}_{i,l}$ with the bounded state space $\mathcal{S}^{\epsilon}$, the following holds:*

$$|\alpha^{h}(s,\phi;\pi_{i,l}) - \alpha^{h,\epsilon}(s,\phi';\pi_{i,l})| \leq \frac{\epsilon}{1-\gamma}$$

for any $(s,\phi) \in \mathcal{S}$ and some $(s,\phi') \in \mathcal{S}^{\epsilon}$ where $\phi' = \zeta(\phi)$.

The proof of this proposition essentially generalizes Prop. 1 to the infinite horizon and is given in the Appendix. Consequently, Prop. 2 allows us to solve the augmented I-POMDP$^{\mathcal{L},\epsilon}_{i,l}$ while incurring a bounded loss.

In the context of open agent systems, the augmented framework provides a way to learn the transition probabilities of state factors that influence the other agents' decisions about whether they ought to leave the network, as a part of planning.

5 EXPERIMENTS

While the predictive method has the obvious advantage of potentially anticipating agent departures, it must first learn the transition probabilities accurately. Consequently, an empirical evaluation of the presented approaches on multiple configurations is needed.

5.1 Setup

We empirically evaluate our methods labeled **I-PBVI PostHoc** and **I-PBVI Predictive** using a realistic simulation of the complex wildfire domain (adapted from [18], similar to [19]). In the simulation, an agent obtains a reward of 1 each step and for each location that is not on fire, and a penalty of 100 for doing anything but a NOOP while recharging suppressant or trying to fight a nonexistent fire. Agents have three suppressant levels: empty and recharging, half full, and full with stochastic transitions between levels.

We measure the performance of agents employing both methods in two ways: (1) the average of discounted and cumulative rewards obtained by each agent; and (2) the average intensity of each fire over time (where intensity ranges from 0 for no fire to 4 for a burned-out location). The former evaluates the agent's planning method for maximizing rewards, whereas the latter evaluates the system-level performance of the team of agents in achieving their overall objective – suppressing the wildfire in the forest. Furthermore, we also include the performance of baselines that represent what would happen to the forest (1) if no agents were present (called **NOOP** as this situation is equivalent to all agents always taking NOOP actions), (2) if each agent randomly chooses between actions that put out fires or NOOP (labeled **Random**), representing a scenario where agents do not plan how or when to interact with their peers, and (3) if each agent carries out actions selected according to a heuristic-variant of Random (called **Heuristic**) – fight existing fires (chosen by random selection) only if the agent has available suppressant, else take a NOOP.

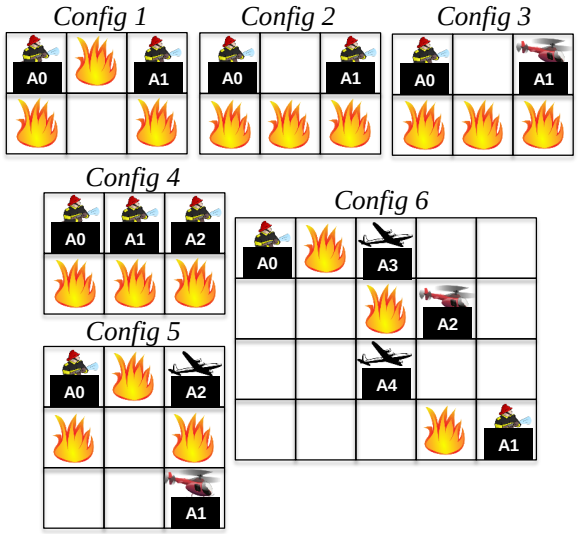


Figure 2: Illustration of experimental configurations.

To elicit different interactions between agents, we consider six configurations in our experiments, illustrated in Fig. 2: configurations C1, C2, and C3 where two agents are responsible for protecting the forest with three fires in each 2×3 grid, configuration C4 where three agents fight three fires in a 2×3 grid, configuration C5 where three agents fight three fires in a more spread out 3×3 grid, and configuration 6 where five agents fight 3 fires in a much larger 5×4 grid. In each of the six configurations, an agent can only put out a fire that is immediately adjacent – to its south, north, east, or west, or diagonal from the agent. In each configuration, I-PBVI PostHoc agents assume a uniform transition distribution for how peers' suppressant levels change, whereas I-PBVI Predictive agents perform random actions in simulation to learn the transition dynamics to better model openness and its impacts on joint behavior. After learning a transition model (i.e., after 100 steps and 30 trials), each agent in the predictive method will use this model for planning.

First configuration C1 contains two agents, each with an individual fire to fight (F0, F2, respectively) while also sharing a fire (F1). Each agent in C1 can lower the intensity of a fire by one. Configuration C2 represents an environment similar to C1, except all three fires are adjacent, and thus can spread to neighboring locations, increasing the pressure on agents to control the wildfires in the environment. Configuration C3, on the other hand, is the same as C2 except that agents are of differing types: A0 lowers the intensity of a fire by one, while A1 is more powerful and can accomplish twice as much reduction when it fights a fire. Together,

Table 1: Average team discounted rewards with 95% confidence intervals.

Configuration	I-PBVI Predictive	I-PBVI PostHoc	Heuristic	Random	NOOP

Table 2: Average fire intensities with 95% confidence intervals.

Configuration	I-PBVI Predictive	I-PBVI PostHoc	Heuristic	Random	NOOP
C1	$\mathbf{2.597 \pm 0.038}$	2.686 ± 0.038	3.063 ± 0.032	3.379 ± 0.027	3.948 ± 0.005
C2	2.683 ± 0.038	2.695 ± 0.038	3.053 ± 0.033	3.630 ± 0.021	3.953 ± 0.004
C3	$\mathbf{1.537 \pm 0.039}$	1.670 ± 0.039	2.806 ± 0.035	3.250 ± 0.030	3.953 ± 0.004
C4	$\mathbf{0.834 \pm 0.031}$	1.024 ± 0.034	2.068 ± 0.039	2.841 ± 0.035	3.954 ± 0.004
C5	$\mathbf{1.361 \pm 0.038}$	1.374 ± 0.038	1.929 ± 0.040	2.222 ± 0.040	3.953 ± 0.004
C6	$\mathbf{1.025 \pm 0.018}$	1.222 ± 0.019	1.684 ± 0.015	1.999 ± 0.017	3.958 ± 0.002

these configurations enable us to evaluate (1) how agents are able to *balance between fighting a shared fire and their own individual fires* in C1; (2) how agents *behave under a more pressing situation* in C2; and (3) how *different types of agents interact* in C3.

In configuration C4, we extend C2 to add a third agent, which simultaneously *makes others' actions more difficult to predict* since each agent has an extra neighbor that it can work together with, while at the same time *provides more firefighting ability* to control wildfires in the forest. Note that agent A1 in C4 can fight all 3 fires. Configuration C5 adds to the complexity – it not only represents a larger, more spread out forest but it also involves *more intricate relationships among three agents*, each of different types. Namely, the three agents A0, A1, and A2 can each reduce the intensity of a fire by 1, 2, and 3 with each firefighting action, respectively. Thus, A2 (who shares fires with both A0 and A1) is quite powerful and is able to put out fires entirely by itself. As a result, its neighbors face interesting decisions of predicting what A2 will do in order to choose their optimal best response (either fighting a different fire, or conserving suppressant to fight future fires). Configuration C6 further adds to the complexity of C5 – it represents a much larger forest involving five agents. Agents A0-4 in C6 can reduce the fire intensity by 1, 1, 2, 3, and 3 respectively. Comparing all six of these configurations, we note that the complexity of agent reasoning increases as the configuration number increases, because more fire locations are shared between agents, more agents interact with one another, and more types of agents are introduced in the environment. For each configuration, we conducted 30 runs of 100 steps, and we average the results of our performance measures.

5.2 Results and Analysis

Tables 1 and 2 present the average discounted, cumulative rewards earned (summed across the team of agents) and the average intensity across all fires per time step, respectively. From these results, we first observe that agents using the I-PBVI Predictive and PostHoc solutions earned greater cumulative rewards, as well as achieved lower average fire intensities than the baseline approaches. This indicates that our approaches to planning about the presence of peer agents in open environments is indeed beneficial toward both agent performance as measured by cumulative rewards, as well as desired system behavior due to reduction in wildfires.

Comparing between our two approaches, we make several additional important observations. First, I-PBVI Predictive performed better than I-PBVI PostHoc in all configurations in terms of average fire intensity (with statistical significance at the $p = 0.05$ level in configurations C1, C3, C4, C5 and C6). Thus, learning how to predict when peer agents will be available and when they might be absent from the environment is indeed beneficial to helping agents achieve system-level goals (i.e., minimizing fires in our domain). In terms of discounted rewards, I-PBVI Predictive also outperformed I-PBVI PostHoc in larger configurations but with only a slight (non-statistically significant) advantage in smaller ones.

To better understand the differences in agent behavior produced by I-PBVI Predictive and PostHoc, we further investigated the different types of interactions between agents. These interactions are based on the types of actions chosen by agents, including putting out individual fires, collaborating with another agent in fighting a fire, fighting alone a fire that is shared by multiple agents, performing a NOOP due to recharging the agent's suppressant, performing a NOOP because there was no fire to fight, and performing a NOOP to conserve suppressant instead of fighting an available fire.

We discovered that I-PBVI Predictive consistently carried out a higher percentage of NOOP actions in order to conserve suppressant than did I-PBVI PostHoc–1.23 to 1.56 times more in configurations C1, C2, and C3, 2.18 times more in configuration C4, 20.36 times more in configuration

C5 and 28.21 times more in C6. Thus, I-PBVI Predictive caused an agent to conserve its valuable, limited suppressant so that it would be able to contribute when its potential partner agent becomes available to jointly fight the shared fire (as indicated by the combination of more NOOPs when fires were present and lower overall average fire intensity). Further, this provides evidence that learning to predict the presence of neighbors in open environments (using I-PBVI Predictive) does lead to agents that better consider the impacts of interactions between their joint actions, which in turn results in better global behavior toward system goals.

We also discovered that I-PBVI Predictive caused agents to be 2.85 and 1.13 times more likely to fight their own individual fires in C1 and C3, respectively, when there were fewest agents available to fight fires and more individual behavior was necessary. In the similar C2 environment where fires spread faster than C1 and agents had less overall firefighting ability than in C3 (where one agent could reduce fires faster), and thus it was more difficult to fight individual fires than in C1 and C3, both I-PBVI Predictive and PostHoc focused solely on fighting the joint fire that they could feasibly extinguish together. These results further indicate that learning to predict the presence of peers also helps agents better balance individual-centered behavior vs. collaborative behavior in open environments, depending on the needs of the environment.

6 CONCLUSION

As a first paper on modeling open agent systems from a decision-theoretic perspective, the focus of this effort was to study the impact of agents leaving and reentering from the perspective of an individual agent and to point out areas where existing frameworks can be generalized to tackle this problem in a principled manner. As an immediate next step, we are looking into Monte-Carlo based approaches for better scalability during planning. Furthermore, we are currently exploring how *anonymity* – the problem structure that it doesn't matter who fights the fire, but how many agents fight it – can be featured into frameworks like I-POMDP-Lite. Anonymity coupled with better planners may help scale to real-world problems involving 1000+ agents.

Appendix

Proposition 1 (Bounded difference in convergent value)**.** *Given $\epsilon > 0$ and the augmented I-POMDP$^{\mathcal{L}}_{i,l}$ with the bounded state space $\mathcal{S}^{\epsilon}$, the following holds:*

$$|\alpha^{h,\epsilon}(s,\phi';\pi_{i,l}) - \alpha^{h}(s,\phi;\pi_{i,l})| \leq \frac{\epsilon}{1-\gamma}$$

for any $(s,\phi) \in \mathcal{S}$ and some $(s,\phi') \in \mathcal{S}^{\epsilon}$ where $\phi' = \zeta(\phi)$.

Proof. The proof of this proposition essentially generalizes Prop. 1 to the infinite horizon. Let $\mathcal{E}^h = \max_{\alpha^{h,\epsilon},\alpha^h,s,\phi} |\alpha^{h,\epsilon}(s,\phi';\pi_{i,l}) - \alpha^h(s,\phi;\pi_{i,l})|$. Omitting writing the $\max$ norm for brevity, we have,

$$\begin{aligned}
\mathcal{E} &= |\alpha^{h,\epsilon}(s,\phi';\pi_{i,l}) - \alpha^h(s,\phi';\pi_{i,l}) + \alpha^h(s,\phi';\pi_{i,l}) \\
&\quad - \alpha^h(s,\phi;\pi_{i,l})| \\
&\leq |\alpha^{h,\epsilon}(s,\phi';\pi_{i,l}) - \alpha^h(s,\phi';\pi_{i,l})| + |\alpha^h(s,\phi';\pi_{i,l}) \\
&\quad - \alpha^h(s,\phi;\pi_{i,l})| \text{(from the law of triangle inequality)} \\
&\leq |\alpha^{h,\epsilon}(s,\phi';\pi_{i,l}) - \alpha^h(s,\phi';\pi_{i,l})| + \epsilon \quad \text{(from Prop. 1)} \\
&= |\mathcal{R}_i^{\epsilon}(s,\phi',a_i,\mathbf{a}_{-i}) + \gamma \sum_{s'\in S, o_i\in\Omega_i} \mathcal{T}_i^{\epsilon}(\langle s,\phi'\rangle, a_i, \mathbf{a}_{-i}, \\
&\quad \langle s',\phi''\rangle) \times \mathcal{O}_i^{\epsilon}(\langle s',\phi''\rangle, a_i, \mathbf{a}_{-i}, o_i)\ \alpha_{o_i}^{h-1,\epsilon}(s',\phi';\pi_{i,l}) \\
&\quad - \mathcal{R}_i(s,\phi',a_i,\mathbf{a}_{-i}) + \gamma \sum_{s'\in S, o_i\in\Omega_i} \mathcal{T}_i(\langle s,\phi'\rangle, a_i, \mathbf{a}_{-i}, \langle s',\phi''\rangle) \\
&\quad \mathcal{O}_i(\langle s',\phi''\rangle, a_i, \mathbf{a}_{-i}, o_i) \times \alpha_{o_i}^{h-1}(s',\phi'';\pi_{i,l}1)| + \epsilon \\
&= |R_i(s,\phi' a_i,\mathbf{a}_{-i}) + \gamma \sum_{s'\in S, o_i\in\Omega_i} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}\rangle) \\
&\quad E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')]\ O_i(s', a_i, \mathbf{a}_{-i}, o_i)\ \alpha_{o_i}^{h-1,\epsilon}(s',\phi';\pi_{i,l}) \\
&\quad - R_i(s,\phi',a_i,\mathbf{a}_{-i}) + \gamma \sum_{s'\in S, o_i\in\Omega_i} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}) \\
&\quad E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')] \times O_i(s', a_i, \mathbf{a}_{-i}, o_i) \\
&\quad \alpha_{o_i}^{h-1}(s',\phi'';\pi_{i,l}1)| + \epsilon \\
&\leq \gamma \sum_{s'\in S, o_i\in\Omega_i} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}\rangle)\ E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')] \\
&\quad O_i(s', a_i, \mathbf{a}_{-i}, o_i)|\alpha_{o_i}^{h-1,\epsilon}(s',\phi'';\pi_{i,l}) - \alpha_{o_i}^{h-1}(s',\phi'';\pi_{i,l})| + \epsilon \\
&\leq \gamma \sum_{s'\in S, o_i\in\Omega_i} T_i(s_{/\dot{\mathbf{x}}}, a_i, \mathbf{a}_{-i}, s'_{/\dot{\mathbf{x}}}\rangle)\ E[\dot{T}_i(\dot{\mathbf{x}}, a_i, \mathbf{a}_{-i}, \dot{\mathbf{x}}')] \\
&\quad O_i(s', a_i, \mathbf{a}_{-i}, o_i) \max_{s',o_i,\phi''} |\alpha_{o_i}^{h+1,\epsilon}(s',\phi'';\pi_{i,l}) \\
&\quad - \alpha_{o_i}^{h+1}(s',\phi'';\pi_{i,l})| + \epsilon \\
&= \gamma \max_{s',o_i,\phi''} |\alpha^{h-1,\epsilon}(s',\phi'';\pi_{i,l}) - \alpha^{h-1}(s',\phi'';\pi_{i,l})| + \epsilon \\
&= \gamma\, \mathcal{E}^{h-1} + \epsilon
\end{aligned}$$

Notice that $|\alpha^{1,\epsilon}(s',\phi'';\pi_{i,l}) - \alpha^1(s',\phi'';\pi_{i,l})| = |\mathcal{R}_i^{\epsilon}(s',\phi'',a_i,\mathbf{a}_{-i}) - \mathcal{R}_i(s',\phi'',a_i,\mathbf{a}_{-i})| = |R_i(s',a_i,\mathbf{a}_{-i}) - R_i(s',a_i,\mathbf{a}_{-i})| = 0$. The above recursion is a geometric series with a base case of 0. Therefore, $\mathcal{E}^h \leq \frac{\epsilon}{1-\gamma}$. □

Abstract

An important source of high clustering coefficient in real-world networks is *transitivity*. However, existing algorithms which model transitivity suffer from at least one of the following problems: *i*) they produce graphs of a specific class like bipartite graphs, *ii*) they do not give an analytical argument for the high clustering coefficient of the model, and *iii*) their clustering coefficient is still significantly lower than real-world networks. In this paper, we propose a new model for complex networks which is based on adding transitivity to scale-free models. We theoretically analyze the model and provide analytical arguments for its different properties. In particular, we calculate a lower bound on the clustering coefficient of the model which is independent of the network size, as seen in real-world networks. More than theoretical analysis, the main properties of the model are evaluated empirically and it is shown that the model can precisely simulate real-world networks from different domains with and different specifications.

1 Introduction

Most of real-world networks such as World Wide Web, social networks, Internet and biological networks exhibit structural properties which are not in either entirely regular or purely random graphs. For example, graphs produced by the model of Paul Erdős and Alfréd Rényi (the ER model) [10], do not have the two important properties observed in many real-world networks. The first property is related to the *degree distribution*. In a network, the *degree distribution* is defined as the probability distribution of the degrees of vertices over the whole network. In many real-world networks a *power-law distribution* is observed. More formally, the probability that the degree of a vertex is k is proportional to $k^{-\gamma}$. Networks with this property are called *scale-free* networks. However, the degree distribution of the graphs produced by the ER model converges to a *Poisson distribution*.

The second property is related to the *clustering coefficient*. Clustering coefficient is used to measure how well vertices in a network tend to be clustered together. In most of real-world networks, vertices tend to create tight groups characterized by dense ties [28]. However, in the ER model, every two vertices are connected with a constant and independent probability and therefore, the model generates graphs with a low clustering coefficient.

The β model (the Watts-Strogatz model), proposed by Watts and Strogatz [28], produces graphs with the *small-world* property and high *clustering coefficient*. In small-world networks, the distance between each pair of vertices is proportional to the logarithm of the number of vertices in the network. However, the β model produces an unrealistic degree distribution. The Barabási-Albert (BA) model, proposed by Albert-László Barabási and Réka Albert produces *scale-free* graphs [3]. The model is based on two important concepts: *growth* and *preferential attachment*. *Growth* means that the number of vertices in the network increases over time. *Preferential attachment* means that vertices with higher degree are more likely to receive new edges. The degree distribution of a graph resulting from the BA model is a power-law in the form of $\Pr[k] \sim k^{-3}$. However, the clustering coefficient of the graphs produced by the BA model is significantly lower than the clustering coefficient of real-world networks. Takemoto and Oosawa [25] propose a model for evolving networks by merging complete graphs (cliques) as building blocks. The model shows power-law degree distribution, power-law clustering spectra and high average clustering coefficients independent of the size of network. However, in most cases, real-world networks are evolved in a different way: they usually *grow* during the time by obtaining new vertices, rather than by merging complete graphs.

An important source of high clustering coefficient in net-

* The authors contributed equally.

works is *transitivity*. Transitivity means if u is connected to v and v is connected to w, the probability of having a connection between u and w is higher than any other pair of vertices in the network. Most of edges in real-world networks are *local* and they are drawn between vertices which have a common neighbor [18]. The model of [22] incorporates transitivity and generates graphs with high clustering coefficient. However, it produces bipartite networks which are limited to situations like company directors and movie actors. Clustering coefficient in the graphs produced by the model of [19] is still significantly lower than clustering coefficient of real-world networks. Leskovec et.al. [18] propose several mechanisms for modeling transitivity in complex networks. However, they do not provide any theoretical argument for the clustering coefficient of the mechanisms. The importance of such a theoretical analysis is that it guarantees that the model will reflect important properties of real-world networks, since a high clustering coefficient, independent of the network size, is seen in many real-world networks. On the other hand, for most of network models, it is not easy to theoretically analyze the clustering coefficient. For example, up to now, clustering coefficient of BA networks has only been determined by numerical simulations[1], and it is known to be very difficult to theoretically analyze it. Therefore, it is interesting to develop a model for transitivity in complex networks such that its clustering coefficient can be verified by theoretical arguments.

In this paper, we present the η model for modeling transitivity in complex networks. At every time interval t, the network obtains a new vertex and the new vertex is connected to some existing vertices. This step is similar to the BA model. Then, each vertex is selected with a probability proportional to its *degree* . If it is selected, then a pair of its neighbors are chosen randomly and an edge is drawn between them. The model has two adjustment parameter η and m. We theoretically analyze the model and prove that it produces networks with power-law degree distribution, high clustering coefficient and the small-world property. Compared to the clustering coefficient of random graphs or graphs produced by existing scale-free models, the clustering coefficient of the η model is significantly higher. In particular, by theoretical arguments, we prove that it is independent of the network size and depends solely on parameters like η and m. We also empirically evaluate the model and show that it can precisely simulate networks from different domains (biology, technology, social and information networks) with different characteristics.

The rest of this paper is organized as follows. In Second 2 we present the model and theoretically analyze its important properties. In Section 3 we empirically evaluate the model and show that it produces graphs very close to real-world networks. An overview of related work is given in Section 4, and finally the paper is concluded in Section 5.

[1]Numerical simulations show that clustering coefficient of a BA network with n vertices is $n^{-0.75}$.

Table 1: Symbols and their definitions.

Symbol	Definition
γ	The power-law exponent of the degree distribution in a scale-free network
η	A parameter of the proposed model ($\eta > 0$)
$\mathbf{G}$	A network produced by the η model
$V_{\mathbf{G}}$	The set of vertices of $\mathbf{G}$
$V_{\mathbf{G}}(t)$	The set of vertices of $\mathbf{G}$ at time t
$\mathbf{G}_0$	The initial graph
d_v	The degree of a vertex v
$d_v(t)$	The degree of a vertex v at time t
t_v	The time of adding v to the network
N_v	The set of neighbors of v
$N_v(t)$	The set of neighbors of v at time t
n	The number of vertices of the network
e	The number of edges of the network
$e(t)$	The number of edges of the network at time t
m	The number of edges drawn between a new vertex and the existing vertices of the network
$\langle CC \rangle$	The clustering coefficient
α	$\frac{2\eta+m}{2(\eta+m)}$
K	$\frac{2\eta}{2\eta+m}$

2 The η model

In this section, we first present the η model and then we theoretically analyze its important properties like power-law degree distribution, high clustering coefficient and the small-world property. Before that, in Table 1 we summarize symbols and notations that we will use in the paper.

Algorithm 1 describes the high level pseudo code of the η model proposed for modeling transitivity in complex networks. First a small graph $\mathbf{G}_0$ is produced. We refer to it as the *initial graph*. Then, at every time interval $t \in \{1, \ldots, \mathbf{T}\}$, the following steps are performed:
I. *growth.* A new vertex v is added to the network $\mathbf{G}$. We denote by t_v the time of adding v to $\mathbf{G}$.
II. *preferential attachment.* The vertex v is connected to m existing vertices. Existing vertices are chosen based on their degree. While every model which produces scale-free networks can be used, for the sake of simplicity, we here use the basic BA model. Therefore, for m times, a vertex w with probability

$$\frac{d_w(t)}{2e(t)} \tag{1}$$

is chosen and connected to v. We denote by $d_w(t)$ the degree of w at time interval t and by $e(t)$ the number of edges of the graph at time interval t.
III. *transitivity.* At this step each vertex w of the graph is

selected with probability

$$\frac{\eta d_w(t)}{2e(t)} \tag{2}$$

where η is a non-negative real number. Then, if w is selected, among the neighbors of w, two vertices are chosen *uniformly at random* and are connected to each other.

Algorithm 1 High level pseudo code of the η model.

GRAPHGENERATOR

Require: A non-negative real number η, a non-negative integer $\mathbf{T}$, a non-negative integer m.
Ensure: A graph $\mathbf{G}$ generated by the η model.

```
initialize G by a small graph
for t = 1 to T do
    {growth:}
    add a new vertex v to G
    {preferential attachment:}
    connect v to m existing vertices {every existing vertex is selected proportional to its degree}
    {transitivity:}
    for every vertex w ∈ V_G do
        select w with probability η d_w(t) / 2e(t)
        if w is selected then
            select two neighbors x and y of w uniformly at random
            draw an edge between x and y
        end if
    end for
end for
return G
```

The authors of [18] investigated different cases of producing triangles in complex networks. In their scenario, a source vertex u decides to connect to some vertex w whose distance with u is two. u first selects a neighbor v and then v selects a neighbor $w \neq u$. u and v might use different policies to select v and w, e.g. uniform selection or selecting based on degree. Here we first select v proportional to its degree and then, u and w are selected uniformly at random. The main contribution of this work compared to [18] is that we precisely formulate the procedure, which gives us a possibility to analytically study the model. Particularly, we provide a lower bound on the clustering coefficient independent of the network size.

2.1 Expected number of edges

In this section, we calculate the expected number of edges of the network at every time interval t.

The number of edges at time interval t, i.e. $e(t)$, satisfies the following dynamical equation:

$$\frac{\partial e(t)}{\partial t} = \underbrace{m}_{\text{preferential attachment}} + \underbrace{\sum_{w \in V_{\mathbf{G}}(t)} \frac{\eta d_w(t)}{2e(t)}}_{\text{transitivity}} = m + \eta$$

where $V_{\mathbf{G}}(t)$ denotes vertices of $\mathbf{G}$ at time interval t. After solving this equation, we obtain

$$e(t) = (m + \eta)t + e(\mathbf{G}_0) \tag{3}$$

where $e(\mathbf{G}_0)$ denotes the number of edges in the initial graph. For large enough t, we sometimes discard $e(\mathbf{G}_0)$ and consider $e(t)$ as $(m + \eta)t$.

2.2 Power-law degree distribution

In this section, we show that in a graph produced by the η model, vertices (except those added at the very early time intervals) have a power-law degree distribution.

At every time interval $t \in \{1, \ldots, \mathbf{T}\}$, every vertex v in the network satisfies the following dynamical equation:

$$\begin{aligned}\frac{\partial d_v(t)}{\partial t} &\overset{(a)}{\approx} \underbrace{\sum_{u \in N_v(t)} \left(\frac{\eta d_u(t)}{2e(t)} \times \frac{2}{d_u(t)} \right)}_{\text{transitivity}} + \underbrace{\frac{m d_v(t)}{2e(t)}}_{\text{preferential attachment}} \\ &= \sum_{u \in N_v(t)} \left(\frac{\eta}{e(t)} \right) + \frac{m d_v(t)}{2e(t)} \\ &= \frac{\eta d_v(t)}{e(t)} + \frac{m d_v(t)}{2e(t)} \end{aligned} \tag{4}$$

where $N_v(t)$ refers to neighbors of vertex v at time interval t.

The approximation (a) is employed to make the computation of the dynamical equation $\frac{\partial d_v(t)}{\partial t}$ feasible, since, otherwise it would require taking the expectation of a function with a random variable at the denominator (i.e. the number of edges), which is computationally intractable. In principle, one could use the polynomial normal forms of such functions to eliminate the denominator. However, this transformation yields an exponential order in the number of conjunctions. Therefore, in mean-field theory, it is proposed to approximate the expectation via replacing the random denominator by its expectation, i.e. by $\mathbb{E}[f/g] \approx f/\mathbb{E}[g]$, where f is nonrandom [12, 13]. This approximation is exact in the thermodynamic limit, i.e. for large enough t, for example when $t > 20$. One can obtain higher order improvements of the approximation e.g. by a Taylor expansion around the expectation. The quality of such an approximation has been investigated in the context of mean-field theory by Markov Chain Monte Carlo (MCMC) simulations. Based on extensive experimental evidences, for example in [13, 23], the first-order approximation competes with more refined techniques such as the

TAP method [9]. Moreover, for large enough t, as mentioned earlier, the approximation becomes almost exact and the higher order approximation terms diminish. [2]

By replacing $e(t)$ with the value obtained in Equation 3, for large enough t, Equation 4 amounts to

$$\frac{\partial d_v(t)}{\partial t} = \frac{2\eta + m}{2(\eta + m)} \times \frac{d_v(t)}{t} = \frac{\alpha d_v(t)}{t} \tag{5}$$

where $\alpha = \frac{2\eta+m}{2(\eta+m)}$.

To solve Equation 5, we need to find the initial degree of vertex v, i.e. the number of edges v finds when it is added to the network at t_v. At time interval t_v, v finds m edges due to preferential attachment, and it expects to find $\frac{\eta m}{e(t_v)}$ edges due to transitivity. Therefore, its expected initial degree will be $m + \frac{\eta m}{(m+\eta)t_v}$.

Then, using the *continuum theory* [2], we obtain

$$d_v(t) = \left(m + \frac{\eta m}{(m+\eta)t_v}\right)\left(\frac{t}{t_v}\right)^{\alpha} \tag{6}$$

particularly

$$d_v(\mathbf{T}) = \left(m + \frac{\eta m}{(m+\eta)t_v}\right)\left(\frac{\mathbf{T}}{t_v}\right)^{\alpha} \tag{7}$$

If v is added to the network at a large enough time interval (i.e., t_v is larger than a lower bound L), Equations 6 and 7 can be written as

$$d_v(t) = m\left(\frac{t}{t_v}\right)^{\alpha} \tag{8}$$

and

$$d_v(\mathbf{T}) = m\left(\frac{\mathbf{T}}{t_v}\right)^{\alpha} \tag{9}$$

The probability that at time interval $\mathbf{T}$ a vertex v has a degree $d_v(\mathbf{T})$ smaller than k is

$$\Pr[d_v(\mathbf{T}) < k] = \Pr[m\left(\frac{\mathbf{T}}{t_v}\right)^{\alpha} < k] = \Pr[t_v > \frac{\mathbf{T} \times m^{\frac{1}{\alpha}}}{k^{\frac{1}{\alpha}}}] \tag{10}$$

and

$$\Pr[d_v(\mathbf{T}) < k] = 1 - \Pr[t_v \leq \frac{\mathbf{T} \times m^{\frac{1}{\alpha}}}{k^{\frac{1}{\alpha}}}] \tag{11}$$

We suppose that the vertices are added to the network at equal time intervals $\Pr[t_v] = \frac{1}{\mathbf{T}}$. Putting it into Equation 11, we get

$$\Pr[d_v(\mathbf{T}) < k] = 1 - \frac{\mathbf{T} \times m^{\frac{1}{\alpha}}}{\mathbf{T} \times k^{\frac{1}{\alpha}}} = 1 - \left(\frac{m}{k}\right)^{\frac{1}{\alpha}} \tag{12}$$

[2] In our MCMC simulations with $1,000$ runs, the approximation is unbiased, i.e. the difference between the mean of the empirical distribution and the approximated quantity is only 0.061 times the standard deviation.

Then, the degree distribution $\Pr[k]$ can be computed as

$$\Pr[k] = \frac{\partial \Pr[d_v(\mathbf{T}) < k]}{\partial k} = \frac{m^{\frac{1}{\alpha}}}{\alpha} \times k^{-(1+\frac{1}{\alpha})} \tag{13}$$

which means $\Pr[k] \sim k^{-(1+\frac{1}{\alpha})}$. Therefore, we have a power law degree distribution $\Pr[k] \sim k^{-\gamma}$, where

$$\gamma = 1 + \frac{1}{\alpha} = \frac{4\eta + 3m}{2\eta + m} = 2 + \frac{m}{2\eta + m} \tag{14}$$

2.3 The small world property

Reuven Cohen and Shlomo Havlin [8] showed that scale-free networks have a small diameter. In particular, they proved that the scale-free networks with $2 < \gamma < 3$ have a very small diameter which is proportional to $\mathbf{lnln}n$. They also showed that for $\gamma = 3$ the diameter is proportional to $\frac{\mathbf{ln}n}{\mathbf{lnln}n}$, and for $\gamma > 3$ it is proportional to $\mathbf{ln}n$. In all cases the scale-free network satisfies the small-world property. We note that here the diameter is the mean distance between vertices. As Equation 14 indicates, for the η model we have: $2 \leq \gamma \leq 3$. Particularly, for non-zero values of η and m, we have $2 < \gamma < 3$. This means that the η model satisfies the required conditions, i.e. it produces graphs with the small-world property where the diameter is proportional to $\mathbf{ln}n$.

2.4 Clustering coefficient

In this section, we provide a lower bound on the clustering coefficient of the networks produced by the η model, which is independent of the network size and depends only on the η and m parameters.

Watts and Strogatz [28] defined the clustering coefficient of a network as[3]

$$\langle CC \rangle = \frac{1}{n} \sum_{v \in V_{\mathbf{G}}} \langle CC_v \rangle \tag{15}$$

where n is the number of vertices of the network and

$$\langle CC_v \rangle = \frac{C_v}{\binom{d_v}{2}} \tag{16}$$

where C_v is the number of edges among the neighbors of v. $\langle CC_v \rangle$ is called the local clustering coefficient of v.

For a network produced by the η model, C_v can be written as

$$C_v = \sum_{t=t_v}^{\mathbf{T}} \left(\langle C_v \rangle_T (t) + \langle C_v \rangle_P (t)\right) \tag{17}$$

where

[3] An alternative definition of the clustering coefficient which is also widely used, was introduced by Barrat and Weigt [4]: $\frac{3 \times \text{number of triangles in the network}}{\text{number of connected triples of vertices}}$.

- $\langle C_v \rangle_P (t)$ is the number of edges between neighbors of v which are added to $\mathbf{G}$ during the *preferential attachment* step at time interval t, and
- $\langle C_v \rangle_T$ is the number of edges between neighbors of v which are added to $\mathbf{G}$ during the *transitivity* step at time interval t.

Then, for a vertex v, at every time interval $t \geq t_v$, we define $\tau_v(t)$ as

$$\tau_v(t) = \sum_{t'=t_v}^{t} \langle C_v \rangle_T (t') \tag{18}$$

We have

$$C_v \geq \tau_v(\mathbf{T}) \tag{19}$$

Therefore

$$\langle CC_v \rangle \geq \frac{\tau_v(\mathbf{T})}{\binom{d_v(\mathbf{T})}{2}} \tag{20}$$

Suppose that v is added to the network at a time interval greater than a lower bound L (i.e. $t_v \geq L$) such that we can use Equation 8 to describe its degree. In the following, we compute $\tau_v(\mathbf{T})$.

For $t \geq t_v$, τ_v satisfies the dynamical equation

$$\frac{\partial \tau_v(t)}{\partial t} = \frac{\eta d_v(t)}{2e(t)} = \frac{\eta m t^{\alpha-1}}{2(\eta+m){t_v}^{\alpha}} \tag{21}$$

Then, at time interval $\mathbf{T}$, we will have:

$$\tau_v(\mathbf{T}) - \tau_v(t_v) = \int_{t_v}^{\mathbf{T}} \frac{\eta m}{2(m+\eta){t_v}^{\alpha}} \times t^{\alpha-1} \partial t \tag{22}$$

To solve this dynamical equation, we need to find $\tau_v(t_v)$. Since at time interval t_v vertex v finds $m + \frac{\eta m}{(m+\eta)t_v}$ edges, $\tau_v(t_v)$ will be:

$$\tau_v(t_v) = \frac{\eta \times \left(m + \frac{\eta+m}{(m+\eta)t_v}\right)}{2(m+\eta)t_v} \geq \frac{\eta m}{2(m+\eta)t_v} \tag{23}$$

Therefore after solving the integral of Equation 22, we will have

$$\tau_v(\mathbf{T}) \geq mK \times \left(\frac{\mathbf{T}^{\alpha}}{2{t_v}^{\alpha}} - \frac{1}{2}\right) + \frac{\eta m}{2(m+\eta)t_v} \tag{24}$$

$$\geq \frac{mK\mathbf{T}^{\alpha}}{2{t_v}^{\alpha}} - \frac{mK}{2} \tag{25}$$

where $K = \frac{\eta}{\alpha \times (m+\eta)} = \frac{2\eta}{2\eta+m}$.

Now, we use Equation 20 to find a lower bound for $\langle CC_v \rangle$:

$$\langle CC_v \rangle \geq \frac{\tau_v(\mathbf{T})}{\binom{d_v(\mathbf{T})}{2}} \geq \frac{2\tau_v(\mathbf{T})}{d_v(\mathbf{T})^2} \geq \frac{K{t_v}^{\alpha}}{m\mathbf{T}^{\alpha}} - \frac{K{t_v}^{2\alpha}}{m\mathbf{T}^{2\alpha}} \tag{26}$$

Let v be a vertex such that $L \leq t_v \leq \mathbf{T}$. Up to now, we have computed a lower bound for $\langle CC_v \rangle$. Now, we want to compute a lower bound for the clustering coefficient of the network induced by the vertices added to the network at time intervals $t_L, t_{L+1}, \ldots, t_{\mathbf{T}}$. We refer to this quantity as $\langle CC \rangle$ since it is almost the clustering coefficient of the whole network (compared to $\mathbf{T}$, L is very small and only for few vertices we cannot use Equation 8 to express the degree).

Using Equations 15 and 26, we obtain

$$\langle CC \rangle \geq \frac{1}{\mathbf{T}-L+1} \sum_{t_v=L}^{\mathbf{T}} \left(\frac{K{t_v}^{\alpha}}{m\mathbf{T}^{\alpha}} - \frac{K{t_v}^{2\alpha}}{m\mathbf{T}^{2\alpha}}\right) \tag{27}$$

A simple form of the Riemann sum [26] says

$$\sum_{x=a}^{b} x^r \geq \int_{a-1}^{b} x^r \partial x$$

where $r, a, b > 0$.

This inequality and Equation 27 yield

$$\langle CC \rangle \geq \frac{1}{\mathbf{T}-L+1} \int_{L-1}^{\mathbf{T}} \left(\frac{K{t_v}^{\alpha}}{m\mathbf{T}^{\alpha}} - \frac{K{t_v}^{2\alpha}}{m\mathbf{T}^{2\alpha}}\right) \partial t_v \tag{28}$$

After solving the integral, we obtain

$$\langle CC \rangle \geq \frac{K}{m(\alpha+1)} - \frac{K}{m(2\alpha+1)} \tag{29}$$

$$= \frac{2\eta(\eta+m)}{m(4\eta+3m)(3\eta+2m)} \tag{30}$$

Therefore, a lower bound is provided for the clustering coefficient of a η network, which is independent of the network size and depends on the η and m parameters. We refer to Equation 30 as B.

3 Simulating real-world networks

In this section, we consider several real-world networks, with different specifications and from different domains including biology, technology, social and information networks, and aim to simulate them using the η model. Table 2 summarizes the characteristics of different real-world networks and the networks simulating them. Note that we only describe one way of simulating the real-world networks by the η model which is not unique and the only existing way. In all simulated networks, the initial graph simply consists of two vertices connected by an edge.

Table 2: Real-world networks and the equivalent networks produced by the η model. $\mathcal{C}$ and $\mathcal{C}_\eta$ are clustering coefficient of the real-world networks and clustering coefficient of the networks produced by the η model, respectively. $\mathcal{C}_{BA}$ is the clustering coefficient of the simulated network if transitivity is not used.

Real-world networks				**Simulated networks**				
Network	# vertices	# edges	$\mathcal{C}$	m	η	# edges	$\mathcal{C}_\eta$	$\mathcal{C}_{BA}$
electronic circuits	$24,097$	$53,248$	0.03	2	0.23	$53,121$	0.034	0.009
email address books	$16,881$	$57,029$	0.13	3	0.5	$58,041$	0.11	0.0047
marine food web	135	598	0.23	4	0.54	599	0.24	0.148
neural network	307	$2,359$	0.28	5	2.8	$2,341$	0.29	0.098
Roget's thesaurus	$1,022$	$5,103$	0.15	4	1.4	$5,389$	0.14	0.038

The first real-world network studied here is the *electronic circuits* network. In this network vertices are electronic components e.g., logic gates in digital circuits and resistors, capacitors and diodes in analogic circuits, and edges are the wires [5]. It has $24,097$ vertices and $53,248$ edges and its clustering coefficient is 0.030. In order to simulate this network, we produce an η graph with these parameters: $m = 2$ and $\eta = 0.23$ and it has the same number of vertices as the electronic circuits network. The graph produced by the η model has $53,121$ edges, its clustering coefficient is 0.034 and its degree distribution is depicted in Figure 1(a).

The second real-world network is the network of *email address books* [21]. In this network, vertices represent computer users and an edge is drawn from user A to user B if B's email address appears in A's address book. This network has $16,881$ vertices and $57,029$ edges and its clustering coefficient is 0.13. We simulate this network by the η model using the following parameters: $m = 3$ and $\eta = 0.5$ and the number of vertices in the produced graph is $16,881$. The clustering coefficient of the simulated network is 0.11. However, if we remove transitivity from the network (and produce a BA network), its clustering coefficient will be only 0.0047. Figure 1(b) presents degree distribution of the simulated network.

The next two real-world networks are biological networks. In the *marine food web* network, vertices represent species in an ecosystem and an edge from vertex A to vertex B indicates that A preys on B [14] and [7]. This network has 135 vertices and 598 edges and its clustering coefficient is 0.23. The following parameters are used by the η model to simulate this network: $m = 4$, $\eta = 0.54$, and number of vertices is 135. The produced graph has 599 edges and its clustering coefficient is 0.24. Figure 1(c) presents degree distribution of the networks simulated by the η model.

The other important class of biological networks are *neural networks*. The neural network of the nematode C. Elegans reconstructed by White et al. [29] has 307 vertices and $2,359$ edges and its clustering coefficient is 0.28. We simulate it by a η network with $m = 5$ and $\eta = 2.8$. The clustering coefficient of the produced graph is 0.29. Degree distribution of the simulated network is shown in Figure 1(d).

The last real-world network investigated in this paper is the *Roget's thesaurus* network [17]. Each vertex of the graph corresponds to one of the $1,022$ categories in the $1,879$ edition of Peter Mark Roget's Thesaurus of English Words and Phrases. An edge is drawn between two categories if Roget gave a reference to the latter among the words and phrases of the former, or if the two categories were related to each other by their positions in Roget's book. This network has $5,103$ edges and its clustering coefficient is 0.15. We simulate it by a η network with $m = 4$ and $\eta = 1.4$. The produced graph has $5,389$ edges and its clustering coefficient is 0.14. Figure 1(e) presents degree distribution of the simulated network.

Note that when the graph is dense, since m is large, the preferential attachment step has a significant effect on the clustering coefficient. However, the bound B does not consider the clustering coefficient resulted by preferential attachment and as a result, for dense graphs (e.g., the *neural network* graph) it is not tight. In summary, the bound B is always tight for the clustering coefficient resulted by transitivity, and it is tight for the clustering coefficient of a network that is not very dense.

3.1 Empirical evaluation of the η model

In this section, we empirically evaluate the different properties of the η model. In order to investigate the impact of η, we fix m to 2 and n to $10,000$, and produce networks with different η: $0.4, 0.8, 1.2, 1.6, 2$. Figure 2 illustrates the degree distributions of the produced networks. If η is set to 0, a BA network is obtained. As we see in the figure, the degree distributions follow a power-law. Furthermore, by increasing η, the exponent γ slowly increases which is consistent with Equation 14. Figure 3(a) compares the clustering coefficient of the networks and the bound B obtained in Equation 30. In the produced networks, m is 2, n is $10,000$ and η varies between 0.4 and 2. It shows that by increasing the clustering coefficient, B increases as well. Table 3 summarizes the characteristics of the simulated networks. In the produced networks, by increasing η, the clustering coefficient, average degree increase and the diameter de-

2	3.25	0.27	7.679

creases.

As depicted in Equations 6, 14 and 30, another parameter affecting the η networks is m. In order to evaluate the influence of m, we fix η to 1 and n to $10,000$, and produce networks with different values for m: 2, 3, 4 and 5. Figure 3 shows degree distributions of the produced networks. As depicted in the figure, the degree distributions follow a power-law. Similar to η, increasing m slightly increases the exponent γ, which is consistent with Equation 14. Figure 3(b) compares the clustering coefficient of the networks and the bound B obtained in Equation 30. In the produced networks, n is $10,000$ and η is 1 and m varies between 2 to 5. It shows that by decreasing B, the clustering coefficient decreases as well and as Equation 30 says, increasing m, reduces B. In Table 4, we describe the specifications of the networks. By increasing m, both the clustering coefficient and the diameter decrease but the average degree increases.

3	3.88	0.09	7.804
4	3.32	0.0638	9.91
5	3.47	0.05	11.928

4 Related work

In [1], a power-law model $P(\alpha, \beta)$ is proposed as follows: let y be the number of vertices with degree x. $P(\alpha, \beta)$ assigns uniform probability to all graphs with $y = e^{\alpha}/x^{\beta}$. The authors study the giant component and the evolution of random graphs in this model. The authors of [27] present a model to explain social network searchability. Their model defines a class of searchable networks and a method for searching them.

Chung and Lu [6] consider a family of random graphs with a given expected degree sequence. In this model each edge is selected independently with probability proportional to the product of the expected degrees of its endpoints. Eubank et al. [11] show that many basic characteristics of the social network of the city of Portland, Oregon, USA, are well-modeled by the random graph model of Chung and Lu. They also present approximation algorithms for computing basic structural properties such as clustering coefficients and shortest paths distribution.

(d) An η network with $m = 2$ and $\eta = 1.2$ (e) η model, $m = 2$, $\eta = 1.6$ (f) η model, $m = 2$, $\eta = 2$

Figure 2: Comparison of degree distributions of a BA network and five η networks having different values of η.

In [20], the authors formulate models of the time evolution of the networks that obtain and lose vertices over time. They show that the model generates networks with power-law degree distributions. In their models new vertices obtain edges by preferential attachment, but the number of added vertices is equal to the number of deleted vertices. In [32] and [33], the authors study and analyze different properties such as degree distribution, clustering coefficient, average path length and phase transition of an evolving email network model.

Takemoto and Oosawa [25] propose a model for evolving networks by merging complete graphs (cliques) as building blocks. The model shows power-law degree distribution, power-law clustering spectra and high average clustering coefficients independent of the size of network. However, most real-world networks are formed in a different way: they *grow* over time by obtaining new vertices, rather than by merging cliques.

Serrano, Krioukov and Boguna [24] show that a class of hidden variable models with underlying metric spaces are able to reproduce specific properties (such as topology) in real-world networks. Li and Maini [19] propose an evolving network model that produces community structures. The model is based on two mechanisms: the inner-community preferential attachment and inter-community preferential attachment. However, while their theoretical and numerical simulations show that this network model has community structure, they do not provide a theoretical analysis for the clustering coefficient of the model. Furthermore, their numerical simulations show that the clustering coefficient of their model is still significantly lower than the clustering coefficient of real-world networks.

Yang and Leskovec [30] model the global influence of a vertex on the rate of diffusion through the network. The same authors in [31] investigate several large scale social, collaboration and information networks and find out that the community overlaps are more densely connected than the non-overlapping parts. Kin and Leskovec [16] propose the Multiplicative Attribute Graphs (MAG) model that employs interactions between the vertex attributes and the network structure. In this model, the probability of having an edge between two vertices is proportional to the attribute link formation affinities. The same authors in [15] present a parameter estimation method for the MAG model which is based on variational expectation maximization.

5 Conclusions

In this paper, we proposed a new model, called the η model, for describing transitivity relations in complex networks. We theoretically analyzed the model and calculated a lower bound on the clustering coefficient of the model which is independent of the network size and depends only on the model's parameters (η and m). We proved that the model satisfies important properties such as power-law degree distribution and the small-world property. We also evaluated the model empirically and showed that it can precisely simulate real-world networks from different domains with dif-

Abstract

We develop a general framework for inverse optimal control that distinguishes between rationalizing demonstrated behavior and imitating inductively inferred behavior. This enables learning for more general imitative evaluation measures and differences between the capabilities of the demonstrator and those of the learner (i.e., differences in embodiment). Our formulation takes the form of a zero-sum game between a learner attempting to minimize an imitative loss measure, and an adversary attempting to maximize the loss by approximating the demonstrated examples in limited ways. We establish the consistency and generalization guarantees of this approach and illustrate its benefits on real and synthetic imitation learning tasks.

1 INTRODUCTION

Inverse optimal control (IOC) [Kalman, 1964, Rust, 1988, Boyd et al., 1994] and inverse reinforcement learning (IRL) [Ng and Russell, 2000, Abbeel and Ng, 2004] attempt to rationalize demonstrated sequential decision making by estimating a reward/cost function that makes observed decision sequences optimal. When the learned reward is defined over abstract properties of states and actions [Ng and Russell, 2000], it can generalize to new decision processes with states and actions that are similarly described. In contrast, methods that directly estimate a policy mapping from states to controls—also known as "behavioral cloning" [Pomerleau, 1989]—often generalize poorly when attempting to predict goal-directed sequential decisions when aspects of the decision process change.

Unfortunately, the basic IOC problem—selecting a reward function that makes demonstrated decision sequences optimal—is ill-posed, since degenerate solutions exist (e.g., setting all rewards to zero makes every decision sequence optimal) [Ng and Russell, 2000]. When demonstrated behavior is noisy, only degenerate solutions may remain as valid solutions to the basic IOC problem. Existing methods pose the problem in various ways to avoid degenerate solutions. Maximum margin planning (MMP) [Ratliff et al., 2006] seeks a reward function that makes demonstrated sequences have larger reward than all alternatives by a structured loss measure. Maximum (causal) entropy IRL [Ziebart et al., 2010], and its extensions [Boularias et al., 2011, Levine et al., 2011], seek an entropy-maximizing distribution over sequences/policies that matches the feature-based components of the reward function with demonstrated sequences. Each method is constructed around a specific loss function: MMP minimizes the the structured hinge loss, while MaxEnt IRL minimizes the (causal) log loss.

A typical assumption in IOC is that the demonstrator and the learner operate under identical decision processes. In other words, it is assumed that the demonstrator and imitator utilize the same action space, and have the same state transition dynamics. In such settings, imitation can be effectively accomplished by adequately predicting what a demonstrator would do in a new situation. We consider generalized imitation learning problems where the abilities of the demonstrator and the learner are different. This situation arises frequently in practice due to differences in embodiment between human demonstrators and robotic imitators [Nehaniv and Dautenhahn, 2002, Alissandrakis et al., 2002], and, more generally, when autonomously-controlled devices are more expensive and less capable than manually-controlled devices.

We propose a more general framework for inverse optimal control that is both consistent and computationally practical for a range of loss functions and situations where imitation learning across different embodiments is required. The key philosophy of our approach is that unknown properties of *how the demonstrator would behave in new situations* should be treated as pessimistically as possible, since any unwarranted assumptions could lead to substantial errors when behavior is evaluated under more general loss func-

tions or transferred across embodiments. Our formulation produces a zero-sum game between: the learner seeking a control policy to minimize loss; and an adversary seeking a control policy that adequately characterizes the demonstrations, but maximizes the learner's loss. We establish consistency and generalization guarantees, develop algorithms for inference and learning under this formulation, and illustrate the benefits of this approach on synthetic and real imitation learning tasks.

2 BACKGROUND & NOTATION

In this paper, we denote single variables with assigned values in lowercase (e.g., a, s), multivariates with values in bold (e.g., $\mathbf{s}_{1:T}$), and random variables using uppercase (e.g., A_t or $\mathbf{S}_{1:T}$). **Decision processes** are defined by state and action sets ($\mathcal{S}$ and $\mathcal{A}$) and the state transition dynamics τ, which describe the distribution of next states $s_{t+1} \in \mathcal{S}$ given current state $s_t \in \mathcal{S}$ and action $a_t \in \mathcal{A}$: $\tau(s_{t+1}|s_t, a_t)$. We make use of **causally conditioned probability distributions** [Kramer, 1998],

$$P(\mathbf{y}_{1:T}||\mathbf{x}_{1:T}) \triangleq \prod_{t=1}^{T} P(y_t|\mathbf{y}_{1:t-1}, \mathbf{x}_{1:t}),$$

to compactly represent a decision process's **state transition dynamics**,

$$\tau(\mathbf{s}_{1:T}||\mathbf{a}_{1:T-1}) \triangleq \prod_{t=1}^{T} \tau(s_t|\mathbf{s}_{1:t-1}, \mathbf{a}_{1:t-1}),$$

and **stochastic control policy**,

$$\pi(\mathbf{a}_{1:T}||\mathbf{s}_{1:T}) \triangleq \prod_{t=1}^{T} \pi(a_t|\mathbf{a}_{1:t-1}, \mathbf{s}_{1:t}).$$

Multiplied together, these produce a joint probability distribution over the states and actions:

$$P(\mathbf{a}_{1:T}, \mathbf{s}_{1:T}) = \pi(\mathbf{a}_{1:T}||\mathbf{s}_{1:T})\tau(\mathbf{s}_{1:T}||\mathbf{a}_{1:T-1}).$$

We denote **deterministic control policies** (a special case of stochastic control policies) mapping from states or state histories to actions as $\delta(s_t)$ or $\delta(\mathbf{s}_{1:t})$. In addition to denoting the demonstrator's full control policy, π, under dynamics, τ, we also consider distributions of trajectories sampled from the demonstrator's distribution as $\tilde{\pi}$, $\tilde{\tau}$, and a learner's control policy, $\hat{\pi}$, under a (possibly different) set of dynamics $\hat{\tau}$, and estimates of the demonstrator's policy, $\check{\pi}$. We similarly denote states, actions, and deterministic policies corresponds to these different sources as $\tilde{s}, \hat{s}, \check{s}, \tilde{a}, \hat{a}, \hat{\delta}$, etc.

3 PROBLEM DEFINITION

We begin by formally defining the supervised learning task of imitation learning with general loss measures in Definition 1. The learner's performance is measured by a loss function relating the expected state sequence of the learned control policy with the state sequence resulting from the demonstrator's control policy. The key inductive reasoning challenge is for the learner to produce a good control policy when demonstrations are unavailable by appropriately inferring the demonstrator's behaviors in such situations.

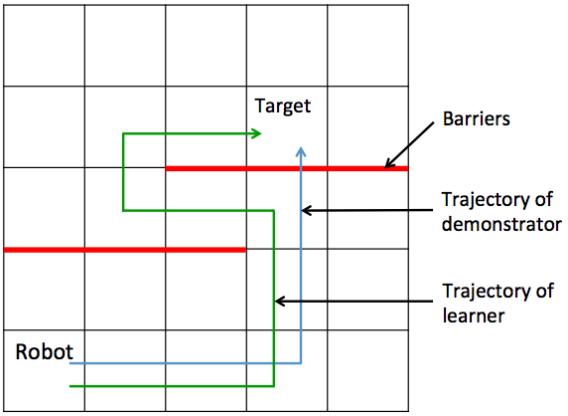

Figure 1: Learning to imitate a slower robot capable of walking over barriers.

Definition 1. *In the task of* **imitation learning with general losses and embodiments**, *at training time: demonstrated traces of behavior are available from distribution $\tilde{P}(\mathbf{A}_{1:T}, \mathbf{S}_{1:T})$ under a dynamical system with known dynamics, $\tau(\mathbf{S}_{1:T}||\mathbf{A}_{1:T})$, and unknown control policy $\pi(\mathbf{A}_{1:T}||\mathbf{S}_{1:T})$. The learner attempts to choose a control policy $\hat{\pi}(\hat{\mathbf{A}}_{1:T}||\hat{\mathbf{S}}_{1:T})$ for potentially different dynamics, $\hat{\tau}(\hat{\mathbf{S}}_{1:T}||\hat{\mathbf{A}}_{1:T})$, that, at testing time, minimizes a given loss function relating (unknown) demonstration policies and learned policies:* $\min_{\hat{\pi}} loss_{\tau,\hat{\tau}}(\pi, \hat{\pi})$.

When the demonstrator and the learner operate under different state-action transition dynamics, $\tau \neq \hat{\tau}$, we refer to this setting as the **imitation learning across embodiments** problem. We assume that a loss function expressing the undesirability of the imitator's differences from the demonstrator is available. The key challenge is that the learner must still estimate the control policy of the demonstrator to be able to generalize to new situations, while also constructing its own control policy to overcome its differences in embodiment. We show a simple illustrative example of this in Figure 1.

The ability to minimize the desired imitative loss function when provided enough demonstration data and a sufficiently expressive characterization of decision policies is desired in an imitation learning algorithm. This is formally known as Fisher consistency (Def. 2).

Definition 2. *An imitation learning algorithm producing policy π_{imit} is* **Fisher consistent** *if, given the demonstrator's control policy for any demonstrator/imitator decision*

processes, $(\tau, \hat{\tau})$, and a sufficiently expressive feature representation for policies, the policy π_{imit} is a loss minimizer:

$$\pi_{imit} \in \operatorname*{argmin}_{\hat{\pi}} \mathbb{E}\left[loss_{\tau,\hat{\tau}}(\pi, \hat{\pi})\right]. \quad (1)$$

We focus our attention in this work on loss functions that additively decompose over the state sequence[1]:

$$\mathbb{E}_{P(\mathbf{a}_{1:T}, \mathbf{s}_{1:T}, \hat{\mathbf{a}}_{1:T}, \hat{\mathbf{s}}_{1:T})}\left[\sum_{t=1}^{T} \text{loss}(S_t, \hat{S}_t) \middle| \pi, \tau, \hat{\pi}, \hat{\tau}\right],$$

where the state-action distribution is obtained by combining a stochastic control policy with a state-transition dynamics distribution: $P(\mathbf{a}_{1:T}, \mathbf{s}_{1:T}, \hat{\mathbf{a}}_{1:T}, \hat{\mathbf{s}}_{1:T}) = \tau(\mathbf{s}_{1:T}||\mathbf{a}_{1:T-1})\ \pi(\mathbf{a}_{1:T}||\mathbf{s}_{1:T})\ \hat{\tau}(\hat{\mathbf{s}}_{1:T}||\hat{\mathbf{a}}_{1:T-1})\ \hat{\pi}(\hat{\mathbf{a}}_{1:T}||\hat{\mathbf{s}}_{1:T})$. Important to this problem definition is the independence between the demonstrator and the learner: there is no direct influence of one's actions on the other's state or actions, as shown in the factorization of the joint distribution.

4 ADVERSARIAL APPROACH

We develop an adversarial approach to the problem of imitation learning with general losses and embodiments (Definition 1) by combining the idea of rationalizing demonstrated behaviors from inverse optimal control [Abbeel and Ng, 2004] with a game-theoretic perspective [Topsøe, 1979, Grünwald and Dawid, 2004] that incorporates different imitative losses. Our approach assumes that except for certain properties of the limited samples of available demonstrated behavior, the demonstrator's policy is the worst-case possible for the learner. This avoids generalizing from available demonstrations in a optimistic manner that may be unrealistic and ultimately detrimental to the learner. Using tools from convex optimization (Theorem 3) and constraint generation (Algorithm 1), this formulation can be solved efficiently (Algorithm 2). Though the demonstrator's true policy is unlikely to be maximally detrimental to the learner, considering it as such leads to Fisher consistency (Theorem 1), provides strong generalization guarantees (Theorem 2), and avoids making any unwarranted assumptions.

4.1 ADVERSARIAL FORMULATION AND PROPERTIES

Our approach employs a game-theoretic formulation of the prediction task for additive state-based losses. We introduce an adversarially-estimated policy, $\check{\pi}$, which must be similar to demonstrated training data traces, but is the worst-case for the learner otherwise, as formalized in Definition 3.

[1]Loss functions for state-action pairs can also be incorporated by defining new states that (partially) "remember" previous state-action histories.

Definition 3. *The* **adversarial inverse optimal control** *learner for the joint demonstrator/learner transition dynamics, $(\tau, \hat{\tau})$ is defined as a zero-sum game in which each player chooses a stochastic control policy, $\hat{\pi}$ or $\check{\pi}$, optimizing:*

$$\min_{\hat{\pi}} \max_{\check{\pi} \in \tilde{\Xi}} \mathbb{E}\left[\sum_{t=1}^{T} loss(\hat{S}_t, \check{S}_t) \middle| \check{\pi}, \tau, \hat{\pi}, \hat{\tau}\right], \quad (2)$$

where $\tilde{\Xi}$ represents a convex set of constraints measured from characteristics of the demonstrated data (e.g., the moment-matching constraints: $\check{\pi} \in \tilde{\Xi} \iff \mathbb{E}[\sum_{t=1}^{T} \phi(\check{S}_t)|\check{\pi}, \tau] = \tilde{\mathbf{c}} \triangleq \mathbb{E}[\sum_{t=1}^{T} \phi(S_t)|\tilde{\pi}, \tilde{\tau}]$ of inverse reinforcement learning [Abbeel and Ng, 2004]) and the joint state-action distributions are realized by combining control policy and state-transition dynamics: e.g., $P(\hat{\mathbf{a}}_{1:T}, \hat{\mathbf{s}}_{1:T}) = \hat{\pi}(\hat{\mathbf{a}}_{1:T}||\hat{\mathbf{s}}_{1:T})\hat{\tau}(\hat{\mathbf{s}}_{1:T}||\hat{\mathbf{a}}_{1:T-1})$.

Though maximum margin methods, such as MMP [Ratliff et al., 2006] in the imitation learning setting, can similarly incorporate arbitrary structured loss functions, they are not Fisher consistent (Def. 2) even for the relatively simple Hamming loss (i.e., number of state mismatches between two sequences).[2] We establish the consistency of the adversarial inverse optimal control approach in Theorem 1.

Theorem 1. *Given a sufficiently rich feature representation defining the constraint set Ξ, the adversarial inverse optimal control learner is a Fisher consistent loss function minimizer for all additive, state-based losses.*

Proof. A sufficiently rich feature representation is equivalent to the constraint set Ξ containing only the true policy π. Then, under $\check{\pi} = \pi$, Eq. (2) then reduces to:

$$\min_{\hat{\pi}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, \check{S}_t) \middle| \pi, \tau, \hat{\pi}, \hat{\tau}\right], \quad (3)$$

which is the loss function minimizer. □

An additional desirable property of this approach—even when the feature representation is not as expressive—is that if the set $\tilde{\Xi}$ can be defined to include the demonstrator's true policy, π, then generalization performance will be upper bounded by the expected adversarial training loss (Theorem 2).

Theorem 2. *The adversarial transfer IOC formulation (Definition 3) provides a useful generalization bound: if the true demonstrator policy π resides within the constraint set $\tilde{\Xi}$ with probability at least $1 - \alpha$, then the generalization*

[2]This follows directly from the Fisher inconsistency of multiclass classification [Liu, 2007, Tewari and Bartlett, 2007] using the Crammer-Singer multi-class generalization of the hinge loss [Crammer and Singer, 2002], which is a special case of the imitation learning setting with a single time step.

error will be worse than the training error (expected game value) with probability no more than α:

$$P(\pi \in \tilde{\Xi}) \geq 1-\alpha \implies P\left(\mathbb{E}\left[\sum_{t=1}^{T} \mathit{loss}(\hat{S}_t, S_t)|\pi,\tau,\hat{\pi},\hat{\tau}\right] \geq \mathbb{E}\left[\sum_{t=1}^{T} \mathit{loss}(\hat{S}_t, \check{S}_t)|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right]\right) \leq \alpha. \quad (4)$$

Proof. If $\pi \in \tilde{\Xi}$, then

$$\mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, S_t)|\pi,\tau,\hat{\pi},\hat{\tau}\right] \leq \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, \check{S}_t)|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right],$$

since replacing π with a worst case policy (maximizer of the set), $\check{\pi}$, only makes the expected loss worse. Thus, bounds on $P(\pi \in \tilde{\Xi})$ provide generalization guarantees with at least as much probability. □

4.2 LEARNING AND INFERENCE ALGORITHMS

Building on recently developed methods for tractably solving adversarial prediction problems for classification with cost-sensitive [Asif et al., 2015] and multivariate [Wang et al., 2015] performance measures, we employ the method of Lagrange multipliers to simplify from a game with one player's actions jointly constrained to a parameterized game with only probabilistic constraints on each player's policy (Theorem 3).

Theorem 3. *An equilibrium for the game of Definition 3 is obtained by solving an unconstrained zero-sum game parameterized by a vector of Lagrange multipliers:*

$$\min_{\mathbf{w}} \min_{\hat{\pi}} \max_{\check{\pi}} \mathbb{E}\left[\sum_{t=1}^{T} \mathit{loss}(\check{S}_t, \hat{S}_t) + \mathbf{w}\cdot\phi(\check{S}_t)\middle|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right] - \mathbf{w}\cdot\tilde{\mathbf{c}}.$$

Proof. The proof follows from applying the method of Lagrangian multipliers (a) to the constrained optimization problem of Eq. (2), and then employing strong Lagrangian duality and minimax duality (b):

$$\begin{aligned}
&\min_{\hat{\pi}} \max_{\check{\pi}\in\tilde{\Xi}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, \check{S}_t)\middle|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right] \\
&\overset{(a)}{=} \min_{\hat{\pi}} \max_{\check{\pi}} \min_{\mathbf{w}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, \check{S}_t) + \mathbf{w}\cdot\left(\sum_{t=1}^{T}\phi(\check{S}_t) - \tilde{\mathbf{c}}\right)\middle|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right] \\
&\overset{(b)}{=} \min_{\mathbf{w}} \min_{\hat{\pi}} \max_{\check{\pi}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\hat{S}_t, \check{S}_t) + \mathbf{w}\cdot\phi(\check{S}_t)\middle|\check{\pi},\tau,\hat{\pi},\hat{\tau}\right] - \mathbf{w}\cdot\tilde{\mathbf{c}}.
\end{aligned}$$

Note that we assume that the loss function is an expected loss over state predictions. The objective function of our optimization is therefore a bilinear function of the learner's strategy and the adversary's strategy, which provides the strong Lagrangian duality that we employ. No stronger assumption about the state-based loss function is needed so long as it takes this bilinear form. □

We form the stochastic policy of each player $\check{\pi}$, $\hat{\pi}$ as a mixture of deterministic policies: $\check{\delta}$ and $\hat{\delta}$. Conceptually, the payoff matrix of the zero-sum game can be constructed by specifying each combination of deterministic policies, $\check{\delta}$, $\hat{\delta}$, having payoff: $\mathbb{E}[\sum_{t=1}^{T} \text{loss}(\check{S}_t, \hat{S}_t) + \mathbf{w}\cdot\phi(\check{S}_t)|\check{\delta},\tau,\hat{\delta},\hat{\tau}]$. An example payoff matrix is shown in Table 1 with the adversary choosing a distribution over columns, and the learner choosing a distribution over rows.

Table 1: The payoff matrix for the adversarial IOC prediction game with $\ell(\check{\delta},\hat{\delta}) = \mathbb{E}[\sum_{t=1}^{T} \text{loss}(\check{S}_t, \hat{S}_t)|\check{\delta},\tau,\hat{\delta},\hat{\tau}]$ and $\psi(\check{\delta}) = \mathbf{w}\cdot\mathbb{E}[\sum_{t=1}^{T}\phi(\check{S}_t)|\check{\delta},\tau]$.

	$\check{\delta}_1$	$\check{\delta}_2$	$\cdots$	$\check{\delta}_k$
$\hat{\delta}_1$	$\ell(\check{\delta}_1,\hat{\delta}_1)$ $+\psi(\check{\delta}_1)$	$\ell(\check{\delta}_2,\hat{\delta}_1)$ $+\psi(\check{\delta}_2)$	$\cdots$	$\ell(\check{\delta}_k,\hat{\delta}_1)$ $+\psi(\check{\delta}_k)$
$\hat{\delta}_2$	$\ell(\check{\delta}_1,\hat{\delta}_2)$ $+\psi(\check{\delta}_1)$	$\ell(\check{\delta}_2,\hat{\delta}_2)$ $+\psi(\check{\delta}_2)$	$\cdots$	$\ell(\check{\delta}_k,\hat{\delta}_2)$ $+\psi(\check{\delta}_k)$
$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
$\hat{\delta}_j$	$\ell(\check{\delta}_1,\hat{\delta}_j)$ $+\psi(\check{\delta}_1)$	$\ell(\check{\delta}_2,\hat{\delta}_j)$ $+\psi(\check{\delta}_2)$	$\cdots$	$\ell(\check{\delta}_k,\hat{\delta}_j)$ $+\psi(\check{\delta}_k)$

Unfortunately, this leads to a payoff matrix with a size that is exponential in terms of the actions in the decision process. This cannot be explicitly constructed for practical problems of even modest size. We employ the double oracle method [McMahan et al., 2003] to construct a smaller sub-portion of the matrix that supports the Nash equilibrium strategy for the full game. The basic strategy, outlined in Algorithm 1, iteratively computes a Nash equilibrium for a payoff sub-matrix and augments the payoff matrix with an additional column and row that provide the most improvement for each player.

Finding the best response for each player:

$$\begin{aligned}
&\operatorname{argmin}_{\hat{\delta}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\check{S}_t, \hat{S}_t)\middle|\check{\pi},\tau,\hat{\delta},\hat{\tau}\right]; \text{ or} \quad (5)\\
&\operatorname{argmax}_{\check{\delta}} \mathbb{E}\left[\sum_{t=1}^{T} \text{loss}(\check{S}_t, \hat{S}_t) + \mathbf{w}\cdot\phi(\check{S}_t)\middle|\check{\delta},\tau,\hat{\pi},\hat{\tau}\right],
\end{aligned}$$

reduces to a time-varying optimal control problem. Consider finding the best demonstrator estimation policy $\check{\delta}^*$. The "expected loss" can be treated as a reward for state $s_t \in \mathcal{S}_D$ with a numerical value of:

$$\text{reward}(s_t) = \mathbb{E}[\text{loss}(s_t, \hat{S}_t)|\hat{\pi}] + \mathbf{w}\cdot\phi(s_t).$$

Algorithm 1 Double oracle method for adversarial IOC

Input: Demonstrator's state transition dynamics τ_D; learner's state transition dynamics, $\hat{\tau}$; loss function: $\text{loss}(s_t, \hat{s}_t)$; initial policy sets: $\check{\Pi}$ and $\hat{\Pi}$; feature function $\phi(s_t)$; and Lagrange multipliers $\mathbf{w}$.

Output: A Nash equilibrium $(\check{\pi}^*, \hat{\pi}^*)$.

repeat
  Compute Nash equilibrium $(\check{\pi}^*_D, \hat{\pi}^*)$ and its game value $\check{v}^*$ for sub-game $\check{\Pi}$, $\hat{\Pi}$, $\text{loss}(\cdot,\cdot)$, $\phi(\cdot)$, and $\mathbf{w}$
  Compute best response $\check{\delta}^*$ to $\hat{\pi}^*$ with value $\check{v}_{\check{\delta}^*}$
  if $\check{v}^* \neq v_{\check{\delta}^*}$ **then**
    Add action to set: $\check{\Pi} \leftarrow \check{\Pi} \cup \check{\delta}^*$
  end if
  Compute Nash equilibrium $(\check{\pi}^*, \hat{\pi}^*)$ and its game with value $\hat{v}^*$ for sub-game $\check{\Pi}$, $\hat{\Pi}$, $\text{loss}(\cdot,\cdot)$, $\phi(\cdot)$, and $\mathbf{w}$
  Compute best response $\hat{\delta}^*$ to $\check{\pi}$ value $\hat{v}_{\hat{\delta}^*}$
  if $\hat{v}^* \neq \hat{v}_{\hat{\delta}^*}$ **then**
    Add action to set: $\hat{\Pi} \leftarrow \hat{\Pi} \cup \hat{\delta}^*$
  end if
until $\check{v}_{\check{\delta}^*} = \hat{v}_{\hat{\delta}^*} = \check{v}^* = \hat{v}^*$
return $(\check{\pi}^*, \hat{\pi}^*)$

Once the reward function is constructed, this time-varying optimal control problem can be solved efficiently in $\mathcal{O}(|\mathcal{S}||\mathcal{A}|T)$ time using value iteration [Bellman, 1957]. We assume that the set of deterministic policies defining each player's stochastic policy is relatively small so that marginalizing to compute state rewards is dominated by the run time of solving the optimal control problem. Each player's best response can be constructed in this manner. Upon termination, neither player's (mixed) strategy can be improved with an additional game action (i.e., deterministic policy), and, thus, by definition $\check{\pi}^*$ and $\hat{\pi}^*$ must be an equilibrium pair [McMahan et al., 2003].

Algorithm 2 Learning algorithm for adversarial IOC

Input: Demonstration $\tilde{P}(\mathbf{A}_{1:T}, \mathbf{S}_{1:T})$ from given decision processes, $(\tau, \hat{\tau})$; loss function: $\text{loss}(\cdot,\cdot)$; and learning rate schedule λ_t

Output: Parameters $\mathbf{w}$ providing adversarial generalization

$\mathbf{w} \leftarrow \mathbf{0}$
while $\mathbf{w}$ not converged **do**
  Compute $\check{\pi}^*$ from parameters $\mathbf{w}$ using double oracle method (Alg. 1) given $\tau, \hat{\tau}$
  Gradient update of parameters: $\mathbf{w} \leftarrow \mathbf{w} - \lambda_t(\mathbb{E}_{P(\check{\mathbf{S}}_{1:T}, \check{\mathbf{A}}_{1:T})}[\sum_{t=1}^{T} \phi(\check{S}_t)|\check{\pi}^*, \tau] - \tilde{\mathbf{c}})$
end while

Model parameters $\mathbf{w}$ are estimated using a convex optimization routine described in Algorithm 2. We refer the reader to Asif et al. [Asif et al., 2015] for the proof of convexity for adversarial prediction learning problems of this form with payoff values that are constant with respect to the probability of each player's actions, but not the values themselves.

4.3 EXISTING METHOD RELATIONSHIPS

We conclude our development of the adversarial IOC method by highlighting its conceptual similarities to and differences from previous methods for imitating and predicting sequential decision making policies with the aid of Figure 2.

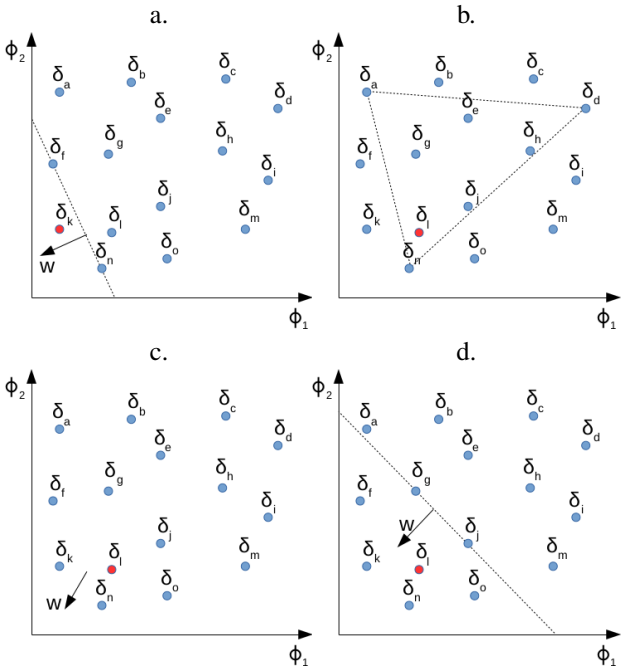

Figure 2: A set of deterministic policies, $\delta_a, \ldots, \delta_o$, represented as points in the two-dimensional feature space based on the expected sum of features under the policy, $\mathbb{E}[\sum_t \phi_k(S_t)|\delta]$. Maximum margin planning [Ratliff et al., 2006] chooses weight $\mathbf{w}$ to separate demonstration δ_k from δ_f and δ_n (top left); Abbeel & Ng's feature-matching algorithm [Abbeel and Ng, 2004] mixes between policies δ_a, δ_d, and δ_n (top right); maximum entropy IRL [Ziebart et al., 2010] chooses a weight direction and produces a probability distribution over all policies (bottom left); and our adversarial approach generates an equilibrium over deterministic policies, $\delta_f, \delta_g, \delta_j, \delta_k, \delta_l, \delta_n$, and δ_o, based on the learned weight $\mathbf{w}$ (bottom right).

When a single demonstrated trajectory resides on the convex hull of the expected feature space (e.g., δ_k in Figure 2a), Abbeel & Ng's feature-matching IRL algorithm [Abbeel and Ng, 2004], maximum margin planning [Ratliff et al., 2006], maximum causal entropy IRL [Ziebart et al., 2010] and our adversarial IOC approach will

produce weight estimates $\mathbf{w}$ that make the demonstrated policy (uniquely) optimal. They differ in that Abbeel & Ng's algorithm will be satisfied with any weight $\mathbf{w}$ that makes δ_k uniquely optimal, since this would match feature counts with the distribution of demonstrated sequences: $\frac{1}{n}\sum_{i=1}^{n}\mathbb{E}[\sum_{t=1}^{T}\phi(S_t^{(i)})|\pi,\tau] = \frac{1}{n}\sum_{i=1}^{n}\sum_{t=1}^{T}\phi(s_t^{(i)})$, guaranteeing equivalent expected reward under the assumption that the reward function is linear in the feature vector, ϕ [Abbeel and Ng, 2004]. As a refinement to this idea, maximum margin planning [Ratliff et al., 2006] seeks parameter weights that make a demonstrated policy on the convex hull "more optimal" than other policies by a structured margin (using a structured loss to penalize being "almost as optimal" from a policy that is very different from the demonstration policy), as shown in Figure 2a. Maximum (causal) entropy inverse reinforcement learning [Ziebart et al., 2010], which employs a Boltzmann distribution over actions for each state, similarly converges to allocate all of its probability to the actions of the demonstrated policy. Adversarial IOC's behavior is equivalent to that of maximum margin planning (when a small amount of regularization is included) in this situation: it obtains a weight vector $\mathbf{w}$ so that the demonstrated policy is better than all alternatives by the structured loss.

When demonstrated trajectories are on the interior of the convex hull, as shown in Figure 2b-d, the behaviors of the methods differ substantially. Abbeel & Ng's feature-matching algorithm [Abbeel and Ng, 2004] produces a mixture of deterministic policies (e.g., a mixture of δ_a, δ_d, and δ_n with probabilities of 10%, 10%, and 80%, as shown in Figure 2b) that match demonstrated feature counts. Unfortunately, many such mixtures exist and switching between the extremes of the convex hull often proves to imitate poorly in practice. Maximum (causal) entropy inverse reinforcement learning [Ziebart et al., 2010] provides a distribution that places some probability on each deterministic policy, with higher probabilities specified by the learned weight vector $\mathbf{w}$, as shown in Figure 2c. This avoids mixing between extremely different deterministic policies [Abbeel and Ng, 2004], but requires a computationally expensive integration over all policies instead of using an optimal MDP policy solver as a sub-routine for learning.

An additional limitation of maximum (causal) entropy inverse reinforcement learning [Ziebart et al., 2010] is due to its global normalization over control policies. This normalization imposes burdensome implicit constraints on learned cost functions[3] due to cycle sensitivity [Monfort et al., 2015, Ziebart, 2010], as defined below and illustrated in Figure 3. These cost function constraints can increase the loss of resulting maximum entropy IRL predictions in practice even when demonstrated behavior trajectories do not include the states of the cycles. Conversely, removing a completely irrelevant cycle from a Markov decision process can drastically change the estimated reward/cost function.

[3]These implicit cost function constraints are in contrast to explicit constraint, like cost function non-negativity to prevent negative cost cycles.

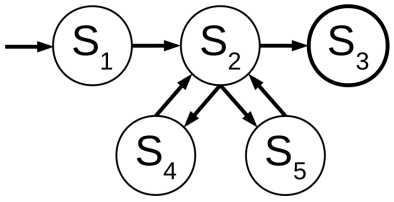

Figure 3: A deterministic Markov decision process with initial state s_1 and absorbing state s_3 in which we assume for simplicity that state two and four have identical features: $\phi(s_4) = \phi(s_5)$. Under maximum entropy inverse reinforcement learning [Ziebart et al., 2010], $P(s_{1:T}) \propto e^{-\mathbf{w}\cdot\sum_{t=1}^{T}\phi(s_t)}$ The number of paths terminating in the absorbing state of odd length $n \geq 3$ is $2^{\frac{n-3}{2}}$, each with cost of $C_0 + \frac{n-3}{2}C_1$, where $C_0 \triangleq \mathbf{w}\cdot(\phi(s_1)+\phi(s_2)+\phi(s_3))$ and $C_1 \triangleq \mathbf{w}\cdot(\phi(s_2)+\phi(s_4))$. The normalization constant under maximum entropy inverse optimal control is $\sum_{i=0}^{\infty}2^i e^{-C_0+iC_1} = e^{-C_0}\sum_{i=0}^{\infty}e^{i\ln 2-iC_1}$, and requires that $C_1 > \ln 2$ for it to be finite.

Definition 4. *An inverse optimal control method is characterized as being* **cycle sensitive** *when differences in a decision process's state representation and dynamics—independent from demonstrated trajectories through the decision process—can introduce arbitrary additional constraints on the estimated cost function.*

When provided with sub-optimal demonstration policies, our adversarial approach mixes together deterministic policies to match feature expectations with demonstrated policies. Unlike the extreme convex hull policies of the feature-matching algorithm [Abbeel and Ng, 2004], the deterministic policies mixed together by the adversarial IOC method are "competitive" with the demonstrated policy. They are specified by the learned weight vector $\mathbf{w}$, which determines thresholds for which deterministic policies need to be considered for mixing. For example, deterministic policies $\delta_k, \delta_n, \delta_o, \delta_l, \delta_j, \delta_g$ are included in the strategic game and appropriately mixed together when δ_l is demonstrated, as shown in Figure 2d. From this perspective, adversarial IOC can be viewed as combining the mixing behavior of Abbeel & Ng's feature-matching algorithm [Abbeel and Ng, 2004] with MMP's margin-like [Ratliff et al., 2006] selection of policies to mix, while avoiding the integration over all policies required by maximum (causal) entropy inverse reinforcement learning [Ziebart et al., 2010] and its sensitivity to irrelevant cycles in the MDP.

5 EXPERIMENTS

We demonstrate the benefits of our approach on synthetic and real imitation learning tasks with application-specific imitation losses and/or different embodiments.

5.1 NAVIGATION ACROSS A GRID

Our first experiment considers trajectories collected from simulated navigation across a discrete grid with various characteristics. For each task, a robot navigates through the environment to reach a target location. Each cell of the grid world is denoted by its horizontal and vertical positions, (x, y), where each is an integer value from 1 to N. The robot's goal is to reach the target location while minimizing the navigation cost within a fixed period of time. We define this fixed time horizon as the maximum number of steps needed to reach any cell of the grid world. The navigation task stops once the robot reaches the target, which is equivalent to representing that the robot stays in the cell where the target exists until the end of the final time step. We formulate the robot navigation problem to be an optimal sequential decision-making problem in a finite Markov decision process (MDP) in which the policy minimizes the expected cost of successful navigation.

Differing initial positions for the robot and the target location are sampled uniformly from the $N \times N$ cells. We generate the cost $C(s)$ for the demonstrator to traverse a particular grid cell (x, y position in the grid) in our simulations based on a linear function of feature vectors, $\phi(s)$, which characterize the state: $C(s) = \theta^T \phi(s) + \varepsilon(s)$, and a noise component, $\varepsilon(s)$. We employ a 7-element feature function vector, $\phi(s)$, in these grid experiments and choose each element of θ by sampling from the uniform distribution $U(0, 1)$. The noise component is similarly sampled from a uniform distribution, $U(0, \varepsilon)$, bounded by a scalar parameter ε that controls the amount of noise in the imitation learning task. We set $C(s) = 0$ when the robot reaches the cell where the target exists. Note that the cost is stationary; all values of $C(s)$ are sampled and fixed for each navigation task. The robot can attempt to move one step from its position in each of the cardinal directions (north, south, east and west), except it is unable to move beyond the boundaries of the grid. When the state transition dynamics are stochastic, the robot may accidentally move into another neighboring cell rather the intended one (e.g., north or south when attempting to move east). The state transition dynamics are formally then:

$$p(s_{t+1}|s_t, a_t) = \begin{cases} p_m & \text{matching the action} \\ \frac{1-p_m}{\text{number of neighbor cells}} & \text{neighbor cells} \end{cases}$$

where we call p_m the matching probability. The optimal policy from solving the finite MDP problem gives the robot's navigation strategy which then can generate a navigation trajectory for learning.

We establish a specific set of grid world navigation simulation characteristics as the base setting of our simulations:

- The size of the grid world is 9×9;
- The noise weight ε is 1; and
- The matching probability p_m is 0.7.

We repeat the simulation 200 times, yielding 200 navigation trajectories of which we use 100 as training data, and the remainder as testing data. We compare adversarial IOC to MMP [Ratliff et al., 2006] across various settings of the size of the grid, the amount of feature noise, the matching probability, and the number of training/testing datapoints. For our grid navigation experiments, we evaluate the loss as the Euclidean distance between the demonstrator's grid position (x, y) and the imitator's grid position $(\hat{x}, \hat{y})$, normalized by the maximum loss, m:

$$\frac{1}{N_{\text{test}}} \sum_{n=1}^{N_{\text{test}}} \mathbb{E}\left[\sum_{t=1}^{T} m^{-1} \sqrt{\left(X_t^{(n)} - \hat{X}_t^{(n)}\right)^2 + \left(Y_t^{(n)} - \hat{Y}_t^{(n)}\right)^2}\right],$$

where ($X_t^{(n)}$ and $Y_t^{(n)}$) are random variables under the demonstrator's control policy—the policy from solving the simulated finite MDP problem—and ($\hat{X}_t^{(n)}$ and $\hat{Y}_t^{(n)}$) are the ones with estimated policy. We employ this normalized Euclidean loss as the structured loss function for the margin in MMP and the game payoff in our adversarial method.

As shown in the first four plots of Figure 4, our adversarial IOC approach (Adv) provides significant improvements in reducing the imitation loss over the trajectory compared to maximum margin planning (MMP) under equivalent embodiment setting (i.e., standard imitation learning). Though the imitator's performance generally becomes worse as the imitation task becomes more difficult (less determinism in the state transition dynamics, increased amounts of noise influencing the demonstrator's optimal policy, and larger sizes of the grid), adversarial IOC consistently outperforms MMP across all of these settings. Very little dependence of the imitation performance on the number of training examples in the fourth plot reveals the general efficiency of training using IOC/IRL methods that estimate the motivating cost function.

We also compare the performance of our adversarial IOC imitation policy with the policy produced by MMP [Ratliff et al., 2006] when demonstrator and imitator have different embodiments. We assume that the demonstration robot's dynamics are noise free and more flexible. In our first experiment, the demonstrator has deterministic state transition dynamics with matching probability 1, and we evaluate the performance of the learner operating under stochastic dynamics with various matching probabilities from 0.9 to 0.5. In the second experiment, we set some obstacles in the grid world so that the imitating robot has to make a detour when it faces any of them, but the demonstrator does not. We evaluate the performance of learner on various number of obstacles from 20 to 60.

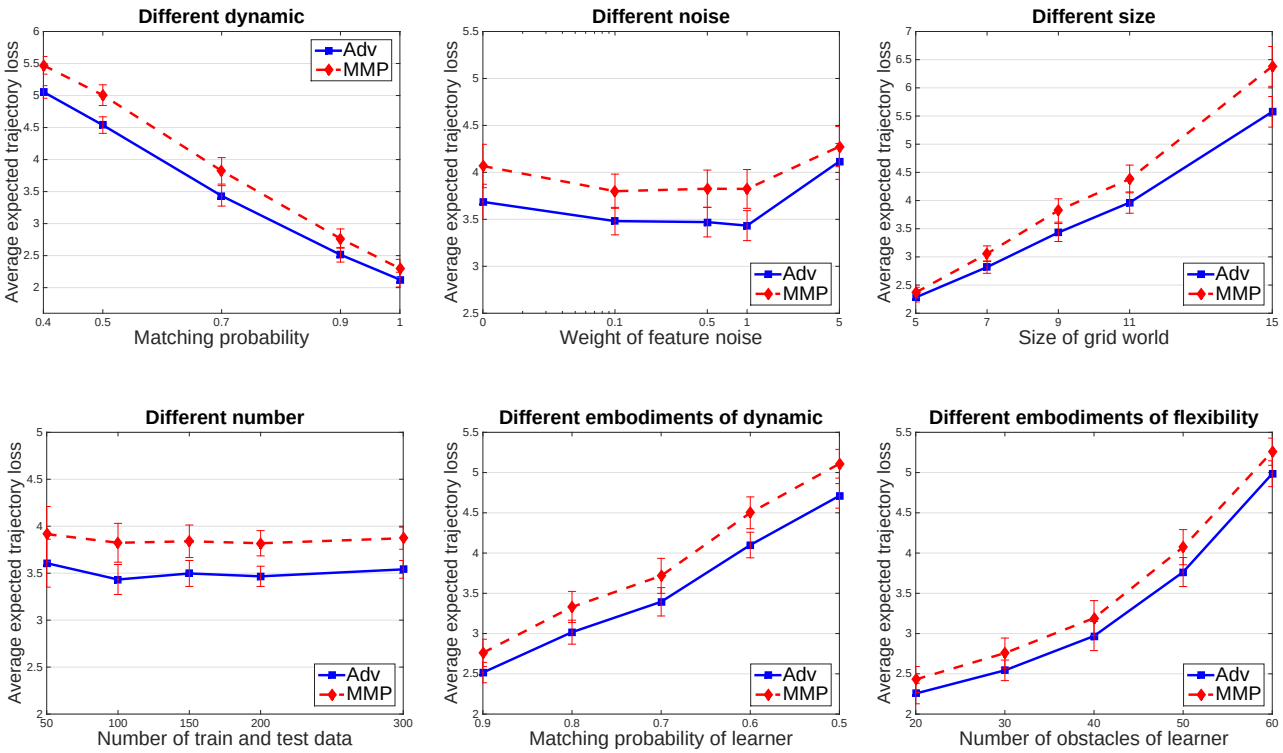

Figure 4: Experimental results with 95% confidence interval of various settings of the grid world's characteristics, including: the degree of stochasticity of the dynamics (top, left); varying amount of cost noise generating the demonstrator's trajectories (top, center); differences size of the grid world from 5x5 to 15x15 (top, right); different amount of training (test) data (bottom, left); the learner's dynamics differing from the demonstrator's (bottom, center); and the introduction of impassible obstacles for the learner (bottom, right).

The performance of the two methods under different embodiments is similarly evaluated according to the average expected trajectory loss of withheld test data, as shown in the final two plots of Figure 4. Our adversarial IOC method also outperforms MMP in these experimental settings.

5.2 LEARNING CAMERA CONTROL FROM DEMONSTRATION

We consider the task of learning to autonomously control a camera in a manner that appropriately captures the action of a basketball game based on human demonstrations of camera control [Chen and Carr, 2015]. The decision process characterizing camera control can be divided into a probabilistic model describing the state of the basketball game (the presence of players in different locations), and a dynamics model describing how camera movement controls effect the camera's state (quantized pan angle, θ, and quantize pan angle velocity, $\dot{\theta}$). As our focus is on the separation of rationalization and imitation evaluation measure, we assume that camera controls have no influence on the basketball game. Also based on this focus, we employ the empirical distribution of player locations rather than constructing a predictive model for those locations.

Our dataset is collected from high school basketball games. The camera recording the basketball game was operated by a human expert. The dataset consists of 46 sequences collected at 60Hz. The average number of frames for the sequences is 376. The output for each frame is the camera's horizontal pan angle, and the input is a 14 element vector that describes the state of the basketball game (the presence of players in different locations on the basketball court). The degree of the camera's pan angle in this dataset ranges from -30 degrees (left) to 30 degree (right), and we quantize the pan angle θ into discrete 61 levels. The pan angel velocity $\dot{\theta}$ of a particular frame is the difference between the current pan angle and the previous one, which is then mapped to 5 discrete levels $[-2, -1, 0, 1, 2]$ representing high speed of turning left to high speed of turning right. Overall, by combining the discrete pan angles and pan angle velocities, there are 305 total possible states for each frame. We use the first 23 sequences as our training dataset and the 23 remaining sequences as the testing dataset. We measure the performance of our adversarial IOC method and baseline methods using the average square

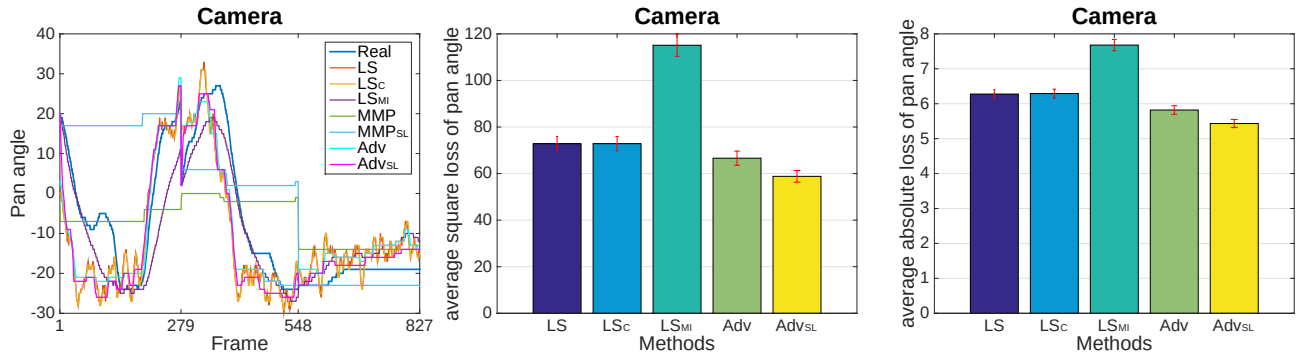

Figure 5: Imitating human camera operator's pan angle control (the Real trajectory on the left) using a regression approach, maximum margin planning, and our adversarial inverse optimal control method. Average squared loss and absolute loss of the imitator (with 95% mean confidence intervals estimates) are shown in the center and right plots, with maximum margin planning results suppressed due to being significantly worse and off of the presented scale.

loss per frame between pan angles:

$$\sum_{n=1}^{N}\sum_{t=1}^{T_n}(\theta_t^{(n)} - \hat{\theta}_t^{(n)})^2 / \sum_{n=1}^{N} T_n. \tag{6}$$

We compare our adversarial structured prediction method with a few forms of least squares linear regression models: one that is not constrained by the camera dynamics (**LS**); one that is constrained by the empirical dynamics of the camera (**LS$_\mathbf{C}$**); and one Markovian-based model that also conditions on the previous camera location (**LS$_\mathbf{MI}$**). Additionally, we consider two variants of maximum marginal planning methods: **MMP$_\mathbf{SL}$** is provided with the starting location of the human-operated camera, while **MMP** is not. Similarly, **Adv$_\mathbf{SL}$** is our adversarial IOC method provided with the starting location of the human-operated camera, while **Adv** is not. Let X_t denotes the 14 entry feature vector of the state of the basketball game at timestep t. The feature vector $\phi(S_t)$ of our adversarial method in Definition 3 is a 33 entry vector $[\theta, \theta^2, \dot{\theta}, \dot{\theta}^2, \theta X_t, \dot{\theta} X_t]$, which combines the basketball game state features and the camera angle and angle velocity state. For the regression models, the estimated sequence is a standard linear regression method $\hat{\theta}_t = \hat{a} X_t + \hat{b}$ where $\hat{a}$ and $\hat{b}$ are trained from the training dataset. For the constrained regression method, the predicted camera angle is projected to the closest angle for which transitioning is feasible.

The result of a test sequence of our experiment is shown in the left plot of Figure 5. The first two regression methods are generally very noisy as the predicted pan angle changes rapidly based on the rapid changes of the underlying inputs corresponding to the game state. The Markovian regression model performs well initially, but diverges from the demonstrated trajectory over time. Both of the MMP methods have much worse performance than the other methods presented. Our adversarial approaches tend to be similar to the regression model, but are much less noisy and provide a closer match to the demonstrated trajectory with significantly lower amounts of squared and absolute loss, as shown in the other plots of Figure 5.

6 CONCLUSION

In this paper, we introduced an adversarial framework for imitation learning using inverse optimal control. It takes the form of a game between an adversary seeking to maximize loss by approximating the training data, and a learner seeking to minimize the loss. Algorithmically, our approach possesses similarities with existing inverse optimal control methods, while resolving some of the deficiencies of those methods (e.g., lack of consistency, sensitivity to low cost cycles) in a principled manner. A key benefit of our approach is that it separates the rationalization of demonstrated decision sequences with the learner's optimization of an imitative loss function. We focused this added flexibility on the problem of learning to imitate under differences in embodiment. This is an underexplored, but important problem for imitation learning to be employed in practice. We established the consistency and useful generalization bounds for our adversarial inverse optimal control approach. We developed and presented efficient algorithms for inference and learning under this formulation. Finally, we demonstrated the benefits of adversarial inverse optimal control in a set of synthetic experiments and an autonomous camera control task where an autonomous camera is trained based on observations of human camera control. In the future, we plan to apply the developed framework to imitation learning settings for robotics applications for which we believe that generalizing across different embodiments will be especially useful.

Abstract

Probabilistic mixture models are among the most important clustering methods. These models assume that the feature vectors of the samples can be described by a mixture of several components. Each of these components follows a distribution of a certain form. In recent years, there has been an increasing amount of interest and work in similarity-matrix-based methods. Rather than considering the feature vectors, these methods learn patterns by observing the similarity matrix that describes the pairwise relative similarity between each pair of samples. However, there are limited works in probabilistic mixture model for clustering with input data in the form of a similarity matrix. Observing this, we propose a generative model for clustering that finds the block-diagonal structure of the similarity matrix to ensure that the samples within the same cluster (diagonal block) are similar while the samples from different clusters (off-diagonal block) are less similar. In this model, we assume the elements in the similarity matrix follow one of beta distributions, depending on whether the element belongs to one of the diagonal blocks or to off-diagonal blocks. The assignment of the element to a block is determined by the cluster indicators that follow categorical distributions. Experiments on both synthetic and real data show that the performance of the proposed method is comparable to the state-of-the-art methods.

1 INTRODUCTION

In many applications, we want to divide the data into a few groups. Clustering is a task of finding the structure and interesting patterns in data, by grouping objects in such a way that objects in the same group are similar to each other, but objects in different groups are different. Recently, much research has been focused on developing clustering techniques and on applying these techniques to different fields such as image segmentation and text mining [26].

Probabilistic mixture models [3, 8] are among the most important clustering methods. These models assume that the feature vectors of data can be described by a mixture of several components. Each of these components follows a distribution of a certain form. Although different probabilistic mixture models differ in the detailed assumptions, most of them try to fit the feature vectors with a mixture of distributions.

In recent years, there has been an increasing amount of interest and work in similarity-matrix-based methods. Rather than observing the feature vectors of the data, as existing probabilistic mixture models do, similarity-matrix-based methods learn patterns by observing the similarity matrix that describes the pairwise relative similarity between each pair of data samples. One example of these methods is spectral clustering [14, 20]. Similarity-matrix-based methods have been very successful in different applications, because it could be applied to data of any form, as long as we can compare the similarity between samples. However, there are limited works in generative models for clustering where the input is a similarity matrix.

In clustering problems, we want to ensure that the samples within the same cluster are similar while the samples from different clusters are less similar. Therefore, given a similarity matrix, if we sort the indices of the similarity matrix according to the cluster indicators, the elements in diagonal blocks usually have larger values, because these elements measure the similarity between samples in the same cluster; while the elements in the off-diagonal blocks usually have smaller values, because these elements measure the similarity between samples from different clusters. The block structure in a similarity matrix is illustrated in Figure 1. Observing this, we propose to cluster by finding the block-diagonal structure in the

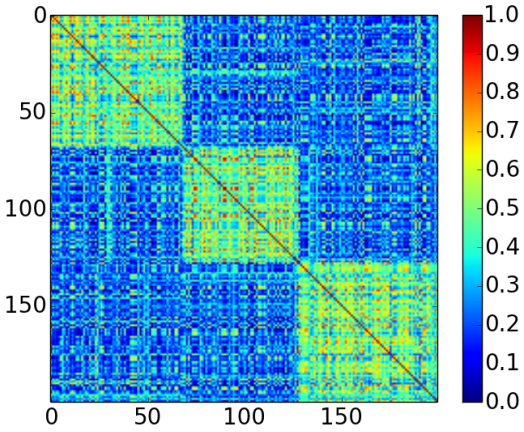

Figure 1: The block-diagonal structure in the similarity matrix. After we sort the indices of the similarity matrix according to the cluster indicators, elements in diagonal blocks have larger values, while elements in the off-diagonal blocks have smaller values.

similarity matrix.

Observing this, we propose a similarity-matrix-based probabilistic model for clustering, called *Block Mixture Model* (BMM). It is a generative model that discovers clusters by finding the block-diagonal structure in the similarity matrix. In BMM, we assume that the elements in the similarity matrix are drawn from a mixture of beta distributions, where the elements in the diagonal blocks are drawn from a beta distribution that is skewed towards one, and the elements in the off-diagonal blocks are drawn from a background beta distribution that is skewed towards zero. The assignment of each element to the blocks is determined by the cluster indicators for samples that follow categorical distributions. As a Bayesian method, BMM takes model uncertainty into consideration, allows us to provide an informative prior to the model, and safeguards against over-fitting [6].

Related Work Gaussian Mixture Model (GMM) [3] is the most well known generative model for clustering. GMM assumes data can be divided into several components and each component follows a Gaussian distribution. GMM usually has difficulty to cluster data with non-elliptical shape. To overcome this limitation, [8] proposes to warp a latent mixture of Gaussian distributions using Gaussian processes. This model can be applied when the clusters have more complex shapes. Although these generatives model methods differ in detailed assumptions, they all fit the real-valued feature vectors with a mixture of distributions. On the other hand, as a similarity-matrix-based method, BMM takes the similarity matrix as input. Therefore, it can be used to analyse any data types as long as the similarity between samples can be measured.

Spectral clustering [14, 20, 25, 21, 18] is a similarity-matrix-based clustering method. With this method, we first compute the eigenvectors of the Laplacian matrix that is derived from the similarity matrix. Then the clustering results are obtained by applying k-means [14, 20], or a probabilistic model [25, 21, 18] to analyse these eigenvectors. Unlike these methods, BMM is a generative model for the similarity matrix, which does not make use of the eigenvectors.

Stochastic blockmodels [24, 1, 10] are also generative models that find clusters. In these models, each sample belongs to a cluster and the connections between samples are determined by the corresponding pair of clusters. These methods are usually applied to an observed network, rather than similarity measures.

A generative clustering model for similarity matrices is proposed in [19]. It is assumed that the observed network is a noisy version of a latent network, where the latent network can be divided into several connected sub-networks. In contrast, BMM adopts a different strategy, where we try to find a block-diagonal structure in the similarity matrix. BMM tends to lead to better clustering results as demonstrated in the experiments (see Section 4).

The model proposed in [23] finds a block structure in Gaussian Graphical Models. Another related model is the orthogonal nonnegative matrix tri-factorization [4] that factorizes an observed matrix into 3 factors, which is equivalent to completing a non-negative matrix using a block structure. Both methods differ from BMM in that they are not probabilistic models and they are applied to the feature vectors directly but not on the similarity matrices.

Contributions of this work The contributions of this work can be summarized as follows:

1. We propose a new generative model for similarity-matrix-based clustering, we call *Block Mixture Model* (BMM), that searches for the diagonal-block structure in a similarity matrix.
2. We derive variational inference for BMM.
3. We test BMM on both synthetic and real data, and observe that the performance of BMM is comparable to the state-of-the-art methods.

2 MODEL FORMULATION

We propose a generative clustering model for the similarity matrix with a block-diagonal structure, we call *Block Mixture Model (BMM)*, to solve a clustering problem. To begin with, we construct a similarity matrix. Given a set of N data samples with C dimension $\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N\}$, where $\boldsymbol{x}_n \in \mathbb{R}^C$ for $n = 1, \ldots, N$. One possible way to construct a similarity matrix is to use the Gaussian kernel

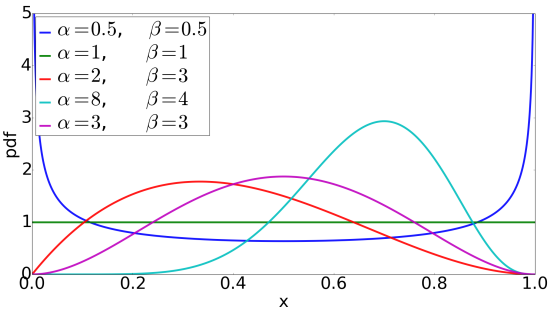

Figure 2: Beta distributions with different parameters

$\boldsymbol{W} \in \mathbb{R}^{N\times N}$ is defined as

$$\boldsymbol{W}_{ij} = \exp(-\frac{||\mathbf{x}_i - \mathbf{x}_j||^2}{2\sigma^2}),\ for\ i,j = 1,\ldots,N, \quad (1)$$

where σ is a positive real bandwidth parameter. In this paper, we focus our discussion on Gaussian kernel; but BMM can be applied to other similarity measures whose values range from 0 to 1 (e.g., cosine similarity).

In BMM, we assume that the data can be divided into K clusters, where K is a pre-defined integer. BMM can be easily extended to a nonparametric version, with Dirichlet process mixtures [7], such that the model can automatically find K. Since this is not the major focus of this paper, we introduce a simpler, more accessible version where K is pre-defined. We assign each sample $\boldsymbol{x}_n$ a K-element cluster indicator $\boldsymbol{z}_n = \{z_{nk}\}_{k=1}^K$ such that $z_{nk} = 1$ if and only if $\boldsymbol{x}_n$ belongs to the k-th cluster, and otherwise $z_{nk} = 0$. We let $\boldsymbol{z}_n$ follow a categorical distribution such that

$$\boldsymbol{z}_n \sim Categorical(\boldsymbol{\pi}), \quad (2)$$

where $\boldsymbol{\pi}$ is a K-element vector, representing the probability that each cluster is assigned. We let $\boldsymbol{\pi}$ be a sample from a symmetric Dirichlet distribution, with concentration parameter λ, i.e.

$$\boldsymbol{\pi} \sim Dirichlet(\lambda). \quad (3)$$

Note that in Gaussian kernel $\boldsymbol{W}$, all elements satisfying $0 < \boldsymbol{W}_{ij} \leq 1$, where a large $\boldsymbol{W}_{ij}$ indicates that the i-th and j-th samples are similar. Because of the range of $\boldsymbol{W}_{ij}$, we model it using beta distributions, which are distributions defined on the interval $(0, 1)$, parameterized by two positive shape parameters α and β. We choose beta distribution because it is a simple and flexible distribution that describes random variables between 0 and 1. We plot some probability density function (PDF) of beta distributions with different parameters in Figure 2.

If a random variable t follows a beta distribution such that $t \sim Beta(\alpha, \beta)$, then its expected value and variance are given by [9]

$$\mathbb{E}[x] = \frac{\alpha}{\alpha+\beta}, \quad (4)$$

$$\mathbf{Var}[x] = \frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)} = \frac{\mathbb{E}[x](1-\mathbb{E}[x])}{\alpha+\beta+1}. \quad (5)$$

Now we assume that the similarity matrix $\mathbf{W}$ can be separated into K clusters. Then if we sort the indices of the similarity matrix according to the cluster indicators, we can observe a block-diagonal structure as shown in Figure 1. If $\boldsymbol{W}_{ij}$ is in one of the diagonal blocks, then it tends to have a large value. In this case, we let $\boldsymbol{W}_{ij}$ be a sample from a beta distribution that is parameterized by $\boldsymbol{\Theta}_k = (\alpha_k, \beta_k)$, such that it is skewed towards one. We assign a different parameter $\boldsymbol{\Theta}_k$ for each diagonal block, because in some clusters, the within cluster similarity might be larger than others. If $\boldsymbol{W}_{ij}$ is in off-diagonal blocks, then we let $\boldsymbol{\Theta}_0 = (\alpha_0, \beta_0)$ be the parameters for the beta distribution, such that it is close to zero. Since whether the i-th and j-th elements are in the diagonal or off-diagonal blocks can be derived by observing the cluster indicators $\boldsymbol{z}_i$ and $\boldsymbol{z}_j$ respectively, the probability density function of $\boldsymbol{W}_{ij}$ can be expressed as

$$p(\boldsymbol{W}_{ij}|\{\boldsymbol{\Theta_k}\}_{k=1}^K, \boldsymbol{\Theta}_0, \boldsymbol{Z}) = Beta(\boldsymbol{W}_{ij}|\alpha_0, \beta_0)^{1-\sum_k^K z_{ik}z_{jk}} \prod_{k=1}^K Beta(\boldsymbol{W}_{ij}|\alpha_k, \beta_k)^{z_{ik}z_{jk}}. \quad (6)$$

Note that if both samples $\mathbf{x}_i$ and $\mathbf{x}_j$ belong to the same cluster k, then $z_{ik}z_{jk} = 1$ and W_{ij} belongs to the k-th diagonal block. Therefore, in the equation, the term $z_{ik}z_{jk}$ is an indicator that $\boldsymbol{W}_{ij}$ is in the k-th diagonal block and the term $1 - \sum_k^K z_{ik}z_{jk}$ is an indicator that the $\boldsymbol{W}_{ij}$ is in the off-diagonal blocks. With the equation, we let elements in the diagonal blocks and off-diagonal blocks follow the corresponding beta distributions, respectively. Note that, we do not care about the diagonal elements in the similarity matrix $\{\boldsymbol{W}_{ii}\}_{i=1}^N$, because these elements do not contain clustering information. Because $\boldsymbol{W}$ is a symmetric matrix; in the generative process, we only need to generate the upper triangle of this matrix.

If the data contain clustering structure, the elements in the diagonal blocks should have larger values than the off-diagonal blocks. Therefore, we assign different prior distributions to the beta distribution parameters $\{\boldsymbol{\Theta_k}\}_{k=1}^K$ and $\boldsymbol{\Theta}_0$. We let

$$p(\boldsymbol{\Theta}_k|\boldsymbol{\zeta}) \propto Beta(\frac{\alpha_k}{\alpha_k+\beta_k}|\alpha_\zeta, \beta_\zeta) Lognormal(\alpha_k+\beta_k|\mu_\zeta, \sigma_\zeta^2), \quad (7)$$

$$p(\boldsymbol{\Theta}_0|\boldsymbol{\eta}) \propto Beta(\frac{\alpha_0}{\alpha_0+\beta_0}|\alpha_\eta, \beta_\eta) Lognormal(\alpha_0+\beta_0|\mu_\eta, \sigma_\eta^2), \quad (8)$$

where $\boldsymbol{\zeta} = \{\mu_\zeta, \sigma_\zeta^2, \alpha_\zeta, \beta_\zeta\}$ and $\boldsymbol{\eta} = \{\mu_\eta, \sigma_\eta^2, \alpha_\eta, \beta_\eta\}$ are the hyper-parameters for $\{\boldsymbol{\Theta_k}\}_{k=1}^K$ and $\boldsymbol{\Theta}_0$ respectively. The expected value of a beta distribution, as described in Equation (4), has a value between 0 and 1. Therefore, we use another beta distribution to model this expected value, which is represented by the first factor in Equations (7) and (8). As shown in Equation (5) that given its expected value, the variance of the beta distribution is inversely proportional to the value of $\alpha + \beta + 1$; therefore, we let $\alpha + \beta$ follow a log-normal distribution, which is

represented by the second factor in Equations (7) and (8). Since we multiply two distributions to form the prior distributions in Equations (7) and (8), we need to introduce a normalization constant to make sure the integral of the new pdf over the entire space is equal to one. With the prior distributions in Equations (7) and (8), we can control the expected value and the variance of a beta distribution by adjusting the hyper-parameters $\boldsymbol{\zeta}$ and $\boldsymbol{\eta}$.

We assign the hyper-parameters $\boldsymbol{\zeta}$ and $\boldsymbol{\eta}$ to make sure that the similarity matrix demonstrates a diagonal-block structure as shown in Figure 1. We want the diagonal blocks to be relatively dense and distributed with smaller variance. Therefore, we let the value μ_ζ to be relatively large, and α_ζ larger than β_ζ. In practice, we let $\mu_\zeta = 15$, $\sigma_\zeta^2 = 1$, $\alpha_\zeta = 80,000$ and $\beta_\zeta = 20,000$. We also want to make sure the off-diagonal blocks are relatively sparse and distributed with larger variance. Therefore, we let the value μ_η to be relatively small and α_η smaller than β_η. In practice, we let $\mu_\eta = 0$, $\sigma_\eta^2 = 1$, $\alpha_\eta = 1,000$ and $\beta_\eta = 9,000$. The prior seems relatively strong. However, note that the number of observations for each beta distribution is proportional to N^2. Therefore, the posterior distributions may still be very different from the prior distributions because of the large number of observations. We analyse the sensitivity of these hyper-parameters in Section 4.3

The model is described using a directed graphical model in Figure 3. The generative process of BMM is summarized in Algorithm 1. In the generative process, due to symmetry of the similarity matrix, we only generate the upper triangular elements, $\boldsymbol{W}_{ij}$, $i \in 1, \ldots, N$ and $j \in 1, \ldots, i-1$.

3 INFERENCE

In this section, we introduce how the latent variables in BMM model can be learned via variational inference. The joint probability of the model is given by

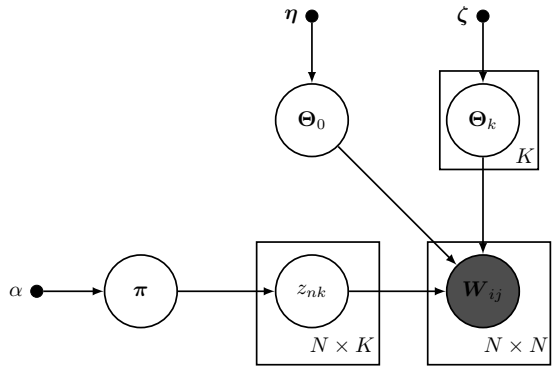

Figure 3: The graphical model. The dots represent the hyper-parameters. The regular circle represent latent random variables. The shaded circles represent observed random variables. The arrows represent the dependency between hyper-parameters and random variables. Each plate denotes that the structure inside the plate is repeated.

$$\begin{aligned} &p(\boldsymbol{W}, \boldsymbol{\pi}, \boldsymbol{Z}, \{\boldsymbol{\Theta}_k\}_{k=1}^K, \boldsymbol{\Theta}_0 | \boldsymbol{\zeta}, \boldsymbol{\eta}, \lambda) \\ =&p(\boldsymbol{\Theta}_0|\boldsymbol{\eta}) \prod_{k=1}^K p(\boldsymbol{\Theta}_k|\boldsymbol{\zeta}) p(\boldsymbol{\pi}|\lambda) \prod_{n=1}^N p(\boldsymbol{z}_n|\boldsymbol{\pi}) \\ &\prod_{i=1}^N \prod_{j=1}^{i-1} p(\boldsymbol{W}_{ij}|\{\boldsymbol{\Theta}_{\boldsymbol{k}}\}_{k=1}^K, \boldsymbol{\Theta}_0, \boldsymbol{Z}) \end{aligned} \tag{9}$$

We want to calculate the posterior distribution for the latent variables given the observed similarity matrix and the hyper-parameters, i.e. $p(\boldsymbol{\pi}, \boldsymbol{Z}, \{\boldsymbol{\Theta}_k\}_{k=1}^K, \boldsymbol{\Theta}_0 | \boldsymbol{W}, \boldsymbol{\zeta}, \boldsymbol{\eta}, \lambda)$. It is computationally intractable to directly calculate this posterior distribution. Therefore, we use a variational distribution $q(\boldsymbol{\pi}, \boldsymbol{Z}, \{\boldsymbol{\Theta}_k\}_{k=1}^K, \boldsymbol{\Theta}_0)$ to approximate the posterior distribution by minimizing the KL divergence $KL(q||p)$ [2]. As proven in [2], this is equivalent to maximizing a lower-bound $\mathcal{L}(q)$ that is defined as

$$\mathcal{L}(q) = \mathbb{E}_q[\log p(\boldsymbol{W}, \boldsymbol{\pi}, \boldsymbol{Z}, \{\boldsymbol{\Theta}_k\}_{k=1}^K, \boldsymbol{\Theta}_0) | \boldsymbol{\zeta}, \boldsymbol{\eta}, \lambda] + \mathcal{H}(q) \tag{10}$$

where $\mathbb{E}_q$ denotes that the expected value is taken with respect to the variational distribution q, and $\mathcal{H}(q)$ denotes the entropy of this variational distribution.

It is still impossible to directly calculate the variational distribution q. Therefore, we further assume that this distribution q can be factorized such that

$$q(\boldsymbol{\pi}, \boldsymbol{Z}, \{\boldsymbol{\Theta}_k\}_{k=1}^K, \boldsymbol{\Theta}_0) = q_{\boldsymbol{\pi}}(\boldsymbol{\pi}) \prod_{n=1}^N q_{\boldsymbol{z}_n}(\boldsymbol{z}_n) \prod_{k=1}^K q_{\boldsymbol{\Theta}_{\boldsymbol{k}}}(\boldsymbol{\Theta}_{\boldsymbol{k}}) q_{\boldsymbol{\Theta}_0}(\boldsymbol{\Theta}_0) \tag{11}$$

Because we do not use the conjugate prior distributions as the prior for the latent variables $\{\boldsymbol{\Theta}_{\boldsymbol{k}}\}_{k=1}^K$ and $\boldsymbol{\Theta}_0$, we cannot estimate the distributions $q_{\boldsymbol{\Theta}_{\boldsymbol{k}}}(\boldsymbol{\Theta}_{\boldsymbol{k}})$ and $q_{\boldsymbol{\Theta}_0}(\boldsymbol{\Theta}_0)$ in closed form. However, note that given the expected values $\mathbb{E}_{\boldsymbol{Z}}(\boldsymbol{Z})$, the distributions $q_{\boldsymbol{\Theta}_{\boldsymbol{k}}}(\boldsymbol{\Theta}_{\boldsymbol{k}})$ and $q_{\boldsymbol{\Theta}_0}(\boldsymbol{\Theta}_0)$ are independent in the lower-bound $\mathcal{L}(q)$ described in

Equation (10). Therefore, we can find point estimators for $\{\widehat{\boldsymbol{\Theta}}_k\}_{k=1}^K$ and $\widehat{\boldsymbol{\Theta}}_0$ that maximizes $\mathcal{L}(q)$, such that

$$\widehat{\boldsymbol{\Theta}}_k = \underset{(\alpha_k,\beta_k)}{\operatorname{argmax}}\, \mathcal{L}(q) \tag{12}$$

$$\widehat{\boldsymbol{\Theta}}_0 = \underset{(\alpha_0,\beta_0)}{\operatorname{argmax}}\, \mathcal{L}(q) \tag{13}$$

We find these point estimators using the Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm [17].

Given these point estimators, we calculate the optimal variational distributions $q^*_{\boldsymbol{\pi}}$ and $\{q^*_{\boldsymbol{z}_n}\}_{n=1}^N$. According to [2], with the factorization assumption introduced in Equation (11), the optimal factorized variational distribution $q^*_{\boldsymbol{Y}_j}(\boldsymbol{Y}_j)$ is given by

$$\log q^*_{\boldsymbol{Y}_j}(\boldsymbol{Y}_j) = \mathbb{E}_{i\neq j}[\log p(\boldsymbol{X},\boldsymbol{Y})] + const \tag{14}$$

where $\boldsymbol{X}$ represents the observed data, $\boldsymbol{Y} = \{\boldsymbol{Y}_i\}_{i=1}^M$ represents all M factorized latent variables and $\mathbb{E}_{i\neq j}$ represents that the expected value is taken with respect to $\{q_{\boldsymbol{Y}_i}\}_{i\neq j}$.

By applying Equation (14), the optimal variational distribution $\{q^*_{\boldsymbol{z}_n}\}_{n=1}^N$ is given by

$$\begin{aligned}\log q^*_{\boldsymbol{z}_n}(\boldsymbol{z}_n) = \sum_{k=1}^K z_{nk}\{&\mathbb{E}_{\boldsymbol{\pi}}[\log \boldsymbol{\pi}_k] \\ &+ \sum_{i\neq n}\mathbb{E}_{\boldsymbol{z}_i}[z_{ik}][\log \boldsymbol{B}(\hat{\alpha}_0,\hat{\beta}_0) - \log \boldsymbol{B}(\hat{\alpha}_k,\hat{\beta}_k) \\ &+(\hat{\alpha}_k-\hat{\alpha}_0)\log W_{in} + (\hat{\beta}_k-\hat{\beta}_0)\log(1-W_{in})]\} + const\end{aligned} \tag{15}$$

where $\boldsymbol{B}$ represents the beta function. By observing this equation, we conclude that

$$q^*_{\boldsymbol{z}_n}(\boldsymbol{z}_n) = Categorical(\boldsymbol{\omega}_n) \tag{16}$$

where $\boldsymbol{\omega}_n$ is a K-element vector such that

$$\begin{aligned}\boldsymbol{\omega}_{nk} \propto exp(&\mathbb{E}_{\boldsymbol{\pi}}[\log \boldsymbol{\pi}_k] + \sum_{i\neq n}\mathbb{E}_{\boldsymbol{z}_i}[z_{ik}]\{\log \boldsymbol{B}(\hat{\alpha}_0,\hat{\beta}_0) - \log \boldsymbol{B}(\hat{\alpha}_k,\hat{\beta}_k) \\ &+ (\hat{\alpha}_k-\hat{\alpha}_0)\log W_{in} + (\hat{\beta}_k-\hat{\beta}_0)\log(1-W_{in})\})\end{aligned} \tag{17}$$

and $\boldsymbol{\omega}_n$ is normalized such that $\sum_{k=1}^K \boldsymbol{\omega}_{nk} = 1$.

By applying Equation (14), the optimal variational distribution $q^*_{\boldsymbol{\pi}}$ is given by

$$\log q^*_{\boldsymbol{\pi}}(\boldsymbol{\pi}) = \sum_{k=1}^K \left(\lambda + \sum_{n=1}^N \mathbb{E}_{\boldsymbol{z}_n}[z_{nk}] - 1\right)\log \boldsymbol{\pi}_k + const \tag{18}$$

By observing this equation, we note that

$$q^*_{\boldsymbol{\pi}}(\boldsymbol{\pi}) = Dirichlet(\boldsymbol{\phi}) \tag{19}$$

where $\boldsymbol{\phi}$ is a K-element vector, whose k-th element is given by

$$\boldsymbol{\phi}_k = \lambda + \sum_{n=1}^N \mathbb{E}_{\boldsymbol{z}_n}[z_{nk}] \tag{20}$$

Algorithm 2 Variational Inference

```
Initialize {q*_{z_n}}_{n=1}^N
Initialize q*_π
repeat
  for k ← 1 to K do
    Calculate Θ̂_k according to Equation (12)
  end for
  Calculate Θ̂_0 according to Equation (13)
  for n ← 1 to N do
    Update q*_{z_n} according to Equation (16)
  end for
  Update q_{π*} according to Equation (19)
until Convergence
```

We iteratively update $\{\widehat{\boldsymbol{\Theta}}_k\}_{k=1}^K$, $\widehat{\boldsymbol{\Theta}}_0$, $\{q_{\boldsymbol{z}_n}(\boldsymbol{z}_n)^*\}_{n=1}^N$ and $q^*_{\boldsymbol{\pi}}(\boldsymbol{\pi})$ until convergence. The expected values involved in the updates are obtained by

$$\mathbb{E}_{\boldsymbol{z}_n}[z_{nk}] = \boldsymbol{\omega}_{nk} \tag{21}$$

$$\mathbb{E}_{\boldsymbol{\pi}}[\log \boldsymbol{\pi}_k] = \psi(\phi_k) - \psi\left(\sum_{i=1}^K \phi_i\right) \tag{22}$$

where ψ is the digamma function that is defined as the logarithmic derivative of the gamma function. The algorithm is summarized in Algorithm 2.

4 EXPERIMENTS

In this section, we test BMM using both synthetic and real data. We choose the bandwidth parameter of the Gaussian kernel σ in Equation (1) to be the median of the pairwise Euclidean distances. If not specified otherwise, the parameters for BMM are given as $\mu_\zeta = 15$, $\sigma^2_\zeta = 1$, $\alpha_\zeta = 80,000$, $\beta_\zeta = 20,000$, $\mu_\eta = 0$, $\sigma^2_\eta = 1$, $\alpha_\eta = 1,000$, $\beta_\eta = 9,000$ and $\lambda = 1$. We discuss the choice of the parameters in more details in Section 4.3. Because variational inference can only guarantee finding local minima, we run the algorithm with 10 different initial values, and select the solution with the maximum lower-bound value. We generate 5 of the initial values using random initialization, and generate the other 5 of the initial values using spectral clustering. Note that spectral clustering might give different results, because k-means is applied after embedding, and k-means only guarantees local optima.

4.1 SYNTHETIC 2D DATA

To demonstrate that BMM works when the clusters have complex shape , we test BMM using some 2-dimensional synthetic data. The clustering results of BMM , with each cluster shown in different color, are illustrated in Figure 4. We can observe that BMM is able to separate all of these

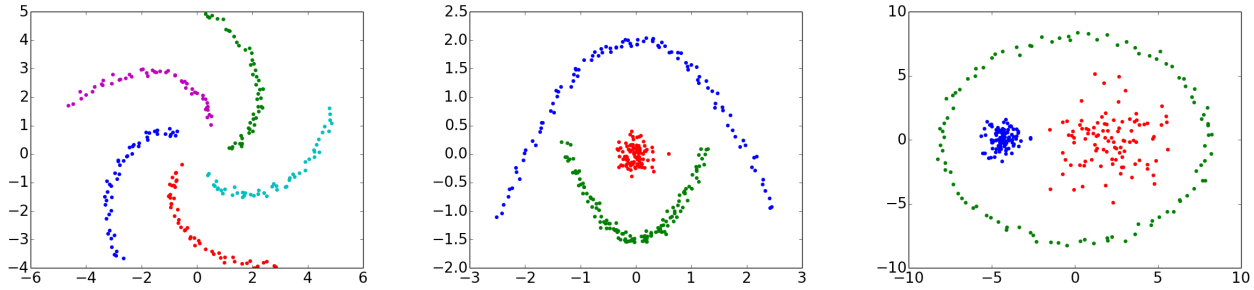

Figure 4: Clustering results for 2d synthetic data.

data perfectly. GMM fails to give similar results, because the cluster structure is complex shaped.

4.2 SYNTHETIC SIMILARITY MATRICES

In some applications, we are not directly given the feature vectors, but a similarity matrix. Similar to spectral clustering, BMM can also directly take a similarity matrix as an input. In this section, we test BMM using synthetic similarity matrices.

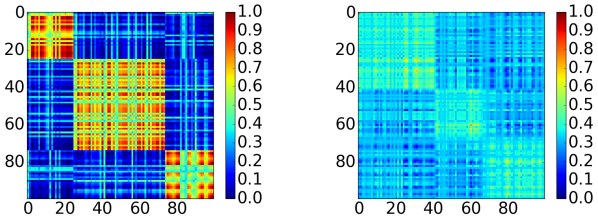
4.2.1 SIMILARITY MATRICES WITH A BLOCK-DIAGONAL STRUCTURE

To begin with, we test BMM using similarity matrices with different strength of block-diagonal structure. To generate a similarity matrix $\mathbf{W}$ with a block-diagonal structure, we let

$$\mathbf{W} = \mathbf{X}^T\mathbf{X}, \tag{23}$$

where $\boldsymbol{X}$ is a 100×3 matrix. Each row of $\boldsymbol{X}$ is a sample from a 3-element symmetric Dirichlet distribution with a positive concentration parameter α. We control the strength of the block-diagonal structure in the similarity matrix $\mathbf{W}$ by adjusting α. When α has a small value, the mass of the Dirichlet distribution tends to be concentrated in one of the three elements, and the similarly matrix has a strong block-diagonal structure, and vise versa. The ground-truth clustering label for each sample X_n is given by $L_n = \text{argmax}_{i=1,2,3} \boldsymbol{X}_{ni}$. To illustrate how α affects the block-diagonal structure, we plot $\boldsymbol{W}$ with different α in Figure 5, where indices of samples are sorted according to the ground-truth label $\mathbf{L} = \{L_n\}_{n=1}^{100}$. In the figure, we observe that when α is small (e.g., $\alpha = 0.25$), the block-diagonal structure is clear such that we can easily distinguish diagonal blocks from the off-diagonal blocks. However, when α is larger (e.g., $\alpha = 2$), the block structure is less clear.

We test BMM on $\mathbf{W}$ generated with different α between 0.06 to 4. For each α, we test BMM on 10 different random generated $\mathbf{W}$. We compare the clustering results of BMM against the results given by state-of-the-art methods that takes similarity matrices as input, including spectral



(a) $\alpha = 0.25$ (b) $\alpha = 2$

Figure 5: $\boldsymbol{W}$ with different α. The indices of samples are sorted according to the ground-truth labels L_n.

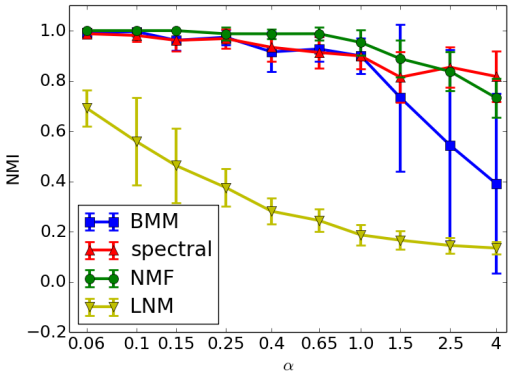


Figure 6: NMI on synthetic data $\mathbf{W}$ generated with different α. The line represents the mean value of the NMI, and the error bar demonstrates the standard deviation. The ticks on the horizontal axis are plotted with log scales.

clustering [14], Non-negative Matrix Factorization (NMF) [11] and Latent Network Model (LNM) [19]. We estimate the performance of the algorithms using Normalized Mutual Information (NMI) between the clustering results with respect to the labels $\mathbf{L}$. The NMI between two random variables X and Y is defined as [22]

$$\frac{\sum_{x\in X}\sum_{y\in Y} p(x,y)[\log p(x,y) - \log p(x)p(y)]}{\sqrt{\mathcal{H}(X)\mathcal{H}(Y)}} \tag{24}$$

where $\mathcal{H}(X)$ and $\mathcal{H}(Y)$ are the entropy for random variables X and Y respectively. The NMI ranges from 0 to 1, where a higher value indicates X and Y agree stronger with each other. We plot the mean values and standard

deviations of NMI for the clustering results with respect to the ground-truth label $\mathbf{L}$ in Figure 6. In this figure the lines represent the mean values of NMI, and the error bars denote the standard deviations.

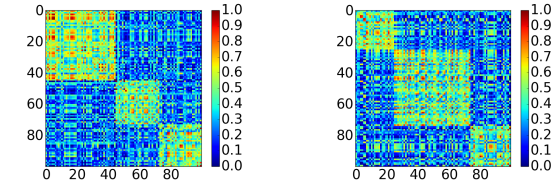
We can observe from the figure that NMF and spectral clustering outperform all other methods in this test. This is expected because $\mathbf{W}$ is generated based on non-negative matrix multiplication, which is consistent with the NMF assumption; and it is proved in [5] that there spectral clustering can be regarded as a relaxed version of NMF. We also observe from the figure that when $\alpha \leq 1$, the BMM results are comparable to the spectral clustering results. However, if $\alpha > 1$, the performance of BMM is worse. This is also expected since BMM gives clustering results based on the block-diagonal structure. When the similarity matrix contains a stronger block-diagonal structure, the performance of BMM is better. Note that in practice, we generate similarity matrices using Gaussian kernels that is described in Equation (1), with a bandwidth parameter σ set as the median value of the pairwise Euclidean distances. Therefore, the similarity matrix will be more similar to Figure 5(a) rather than Figure 5(b), because the pairwise similarity measures computed in this way usually differ significantly. LNM usually performs worse, because it only ensures samples in each cluster are well connected to their nearest neighbors respectively. LNM is more sensitive to the non-zero elements in the off-diagonal blocks.

4.2.2 SIMILARITY MATRICES WITH STRUCTURED NOISE

Now we consider the case when the similarity matrices contain structured noise. We generate two similarity matrices $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$ in the same way as described in Equation (23), with $\alpha = 0.25$ such that they contains clear block-diagonal structure. We denote the ground-truth labels samples represented by $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$ using $\mathbf{L}^{(1)}$ and $\mathbf{L}^{(2)}$, respectively.

Then we generate a similarity matrix $\boldsymbol{T} = \rho\, \boldsymbol{W}^{(1)} + (1 - \rho)\, \boldsymbol{W}^{(2)}$, where ρ is a real-value parameter between 0 and 1. By taking the weighted sum of matrices $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$, we introduce structured noise to the similarity matrix. After summation, $\boldsymbol{T}$ simultaneously have two block-diagonal structures, this is illustrated in Figures 7(a) and 7(b). Note that both figures show the same matrix $\boldsymbol{T}$, but we sort it according to the block-diagonal structure of $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$ respectively. Multiple possible block-diagonal structures indicate that there are more than one meaningful way to separate the data into clusters, which are common in real applications, because objects might be divided into groups by different criteria, or they can be interpreted in different ways [16, 15].

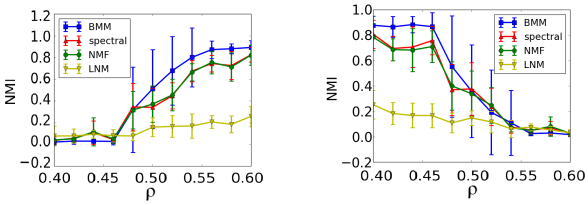
We vary the values of ρ between 0.4 to 0.6. For each ρ we generate 10 different matrices $\boldsymbol{W}$ and test BMM, spectral clustering, NMF and LNM using these matrices. The results are summarized in Figure 8.



(a) Plot of $\boldsymbol{T}$, with indices sorted according to the labels $\mathbf{L}^{(1)}$.

(b) Plot of $\boldsymbol{T}$, with indices sorted according to the labels $\mathbf{L}^{(2)}$.

Figure 7: $\boldsymbol{T}$ is constructed such that $\boldsymbol{T} = \rho \boldsymbol{W}^{(1)} + (1 - \rho)\boldsymbol{W}^{(2)}$, with $\rho = 0.45$. Both $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$ contain a block-diagonal structure.



(a) NMI between the clustering results and the labels $\mathbf{L}^{(1)}$

(b) NMI between the clustering results and the labels $\mathbf{L}^{(2)}$

Figure 8: NMI on synthetic data. The line represents the mean value of the NMI, and the error bar demonstrates the standard deviation.

In Figure 8, we observe that when $0.4 < \rho < 0.45$, the block-diagonal structure of $\boldsymbol{W}^{(2)}$ dominates the matrix $\boldsymbol{T}$, and we can consider $\mathbf{L}^{(2)}$ as the ground truth. As shown in Figure 8(b), BMM outperforms all other methods, since its results have a higher NMI with respect to $\mathbf{L}^{(2)}$. When $0.45 < \rho < 0.55$, the contribution of $\boldsymbol{W}^{(1)}$ or $\boldsymbol{W}^{(2)}$ becomes similar. We observed that BMM usually has a higher mean NMI value with respect to both $\mathbf{L}^{(1)}$ and $\mathbf{L}^{(2)}$ compared to other methods. In addition, BMM has a higher standard deviation. This indicates that BMM tends to reveal the block-diagonal structure of either $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$, but other methods usually find neither of them. When $\rho > 0.55$, the block-diagonal structure of $\boldsymbol{W}^{(1)}$ dominates the matrix $\boldsymbol{W}$, and we can consider $\mathbf{L}^{(1)}$ as the ground truth. As shown in 8(a), BMM also outperforms spectral clustering, since its results have a higher mean NMI with respect to $\mathbf{L}^{(1)}$.

From the observation above, we conclude that BMM outperforms other methods if such structured noise is present. This is because spectral clustering finds the clusters by observing the eigenvectors of the Laplacian matrix that is derived from the similarity matrix. Spectral

clustering can find the correct clusters for $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$ individually according to these eigenvectors respectively. However, when we take the weighted sum of $\boldsymbol{W}^{(1)}$ and $\boldsymbol{W}^{(2)}$, the eigenvectors will change in general, and therefore, the clustering results given by spectral clustering are different from either $\mathbf{L}^{(1)}$ or $\mathbf{L}^{(2)}$. Due to the equivalence between NMF and spectral clustering [5], NMF performs similarly compared to spectral clustering. BMM avoids making use of the eigenvectors and looks for the strongest block-diagonal structure. It is more robust against the structured noise and is able to find the clusters similar to either $\mathbf{L}^{(1)}$ or $\mathbf{L}^{(2)}$.

In summary, in this section, we test BMM on synthetic similarity matrices. We observe that when the similarity matrix contains clear diagonal structure, BMM is comparable to spectral clustering. BMM is more robust to structured noise compared to spectral clustering and NMF.

4.3 HYPER-PARAMETER SENSITIVITY ANALYSIS

In this section, we discuss how the hyper-parameters $\mu_\zeta, \sigma_\zeta^2, \alpha_\zeta, \beta_\zeta, \mu_\eta, \sigma_\eta^2, \alpha_\eta$, and β_η affect the performance of BMM. We generate 10 synthetic random similarity matrices according to Equation (23) with $\alpha = 1$. We test BMM on each of the similarity matrices. In each test, we change one pair of the hyper-parameters at a time and keep all other hyper-parameters using the default values. We summarize the means of the NMI between the clustering results and the ground-truth label across the 10 similarity matrices, with each of the hyper-parameter settings, in Figure 9.

In Figures 9(a) and 9(b), we observe that the choices of $\mu_\zeta, \sigma_\zeta^2, \mu_\eta$ and σ_η^2 influence the clustering results less significantly. The mean NMI values are above 0.85, no matter what values are chosen. We set $\mu_\zeta = 15, \sigma_\zeta^2 = 1, \mu_\eta = 0$ and $\sigma_\eta^2 = 1$, since these values are consistent with the heuristic that the variance of the similarity measures in the diagonal blocks is smaller than that in the off-diagonal blocks. Note that they also provide high mean NMI.

From Figures 9(c) and 9(d), we can conclude that the values of $\alpha_\zeta, \beta_\zeta, \alpha_\eta$ and β_ζ have more effect on the clustering results. As mentioned in Section 2, we need to make sure the diagonal blocks are more dense than the off-diagonal blocks, i.e., $\alpha_\zeta/(\alpha_\zeta + \beta_\zeta) > \alpha_\eta/(\alpha_\eta + \beta_\eta)$. Therefore, we choose $\alpha_\zeta = 80,000$, $\beta_\zeta = 20,000$, $\alpha_\eta = 1,000$ and $\beta_\eta = 9,000$. We set hyper-parameters to these values in all other experiments in Section 4.

4.4 REAL DATA

In this section, we test BMM on several real dataset, and compare it with the state-of-the-art methods. Similar to spectral clustering, instead of just starting from the Gaussian kernel $\mathbf{W}$ defined in Equation (1), we also utilize the normalized similarly matrix that is defined as

$$\widetilde{\boldsymbol{W}} = \boldsymbol{D}^{-1/2}\boldsymbol{W}\boldsymbol{D}^{-1/2}, \tag{25}$$

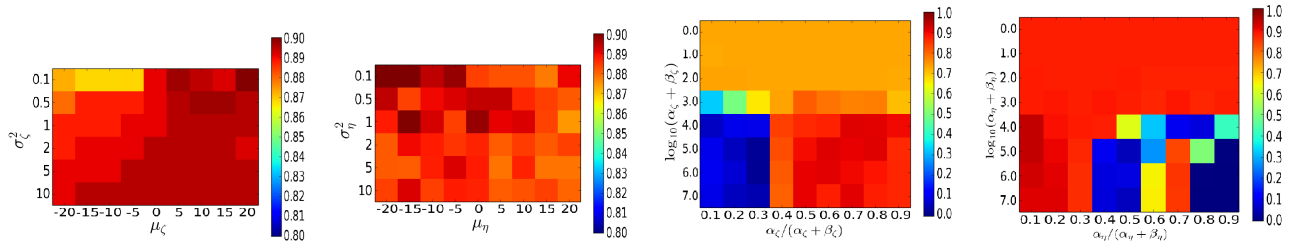
where $\boldsymbol{D}$ is a diagonal matrix such that $\boldsymbol{D}_{ii} = \sum_{j=1}^{N} \boldsymbol{W}_{ij}$. In this , we present the results using both un-normalized $\boldsymbol{W}$ and normalized $\widetilde{\boldsymbol{W}}$. In addition to the three similarity-matrix-based methods that are introduced in 4.2.1, we also compare BMM against k-means [13] and GMM [3].

First we introduce the experimental results on the Semeion handwritten digit dataset [12]. This dataset contains 1593 handwritten digits from 0 to 9 from 80 persons. The digits are stretched in a rectangular box 16x16 with $0/1$ values. We test the methods using different subsets of the dataset as different clustering tasks. In each task, we divide the dataset into 5 sets. We repeat the test 5 times, each time with one set taken out. The results are summarized in Table 1. The values in the table represent the means of the NMI. The values in the brackets represent the standard deviations. The values in bold is the largest mean NMI for each task.

We observe from Table 1 that BMM with the normalized similarity matrix $\widetilde{\boldsymbol{W}}$ is one of the best methods. In some tasks, this method outperforms all other methods by a relatively large margin. For example in the task of distinguishing 6 from 8, this outperforms the second best method by more than 0.1 in terms of mean NMI.

We also observe that making use of the normalized similarity matrix $\widetilde{\boldsymbol{W}}$ usually leads to better results, but in some tasks, such as the $\{0, 8\}$ and $\{4, 9\}$ tasks, utilizing the un-normalized similarity matrix $\boldsymbol{W}$ gives better results. However, in the $\{2, 3\}$ task, BMM with un-normalized similarity matrix $\boldsymbol{W}$ obtains a worse result compared to other methods. Although making the un-normalized similarity matrix might get better results in some of the tasks, we still recommend to use the normalized similarity matrix because its performance is better in general. In the $\{1, 7\}$ task, we observe that the performance of GMM is much better than all other methods. This might be due to that in the methods we compared, GMM is the only method that can scale the features. LNM usually performs worse, because it only ensures samples in each cluster are well connected to their nearest neighbors respectively, but do not guarantee that they are pairwise well connected. Note that BMM with normalized similarity matrix either performs comparably or outperforms spectral clustering and NMF in almost all tasks.

In addition to the Semeion data, we also compare BMM with the state-of-the-art methods using following UCI datasets [12]: iris dataset contains 150 samples from 3 classes of iris plants that are described using 4 features;



(a) μ_ζ vs. σ_ζ^2 (b) μ_η vs. σ_η^2 (c) α_ζ vs. β_ζ (d) α_η vs. β_η

Figure 9: Means NMI between the clustering results and the ground-truth label, with each hyper-parameter settings. We change a pair of hyper-parameters at a time.

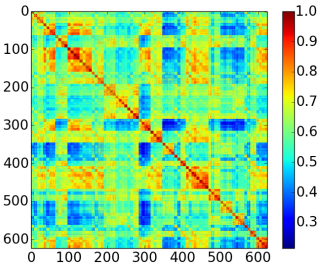

Figure 10: Similarity matrix for the CMU faces dataset.

synthetic control dataset contains 600 control charts that are synthetically generated from 6 classes; faults dataset contains $1,941$ samples from 7 types of steel plates faults; wine dataset contains chemical analysis results of 178 samples of wines that are derived from 3 different cultivars; CMU faces dataset consists of 640 face images of 20 people taken at varying poses.

The results are summarized in Table 2. In this table, we observe GMM performs well in the iris dataset because the iris clusters are elliptically shaped. BMM with normalized similarity $\widetilde{\boldsymbol{W}}$ is one of the best methods in most of the tasks. It outperforms all other methods in the synthetic control and faults datasets, while it has a comparable performance with most of the methods in iris and wine datasets. However, we observe that in the CMU faces dataset, BMM performs slightly worse than spectral clustering. To illustrate why BMM perform worse, we plot the similarity matrix for this dataset, with indices sorted using the ground-truth identity labels in Figure 10. We observe the elements in the off-diagonal blocks differ significantly in values. Note that, BMM uses only one background beta distribution to model all elements in off-diagonal blocks. The CMU faces dataset violates this assumptions of BMM, making BMM perform worse.

5 CONCLUSION

In this paper, we propose Block Mixture Model (BMM), a generative model for the similarity matrix with block-diagonal structure, to solve the clustering problem. In this model, we assume the elements in the similarity matrix follow one of beta distributions, depending on whether the element belongs to either one of the diagonal blocks or to the off-diagonal blocks. We derive variational inference to learn the latent variables in BMM. Experiments on synthetic data demonstrate that BMM performs at least comparably to spectral clustering if the similarity matrix contains a clear block-diagonal structure, and it is more robust to structured noise. We test BMM on real data and observe that the performance of BMM is comparable to the state-of-the-art methods.

Abstract

We consider stochastic strongly convex optimization with a complex inequality constraint. This complex inequality constraint may lead to computationally expensive projections in algorithmic iterations of the stochastic gradient descent (SGD) methods. To reduce the computation costs pertaining to the projections, we propose an Epoch-Projection Stochastic Gradient Descent (Epro-SGD) method. The proposed Epro-SGD method consists of a sequence of epochs; it applies SGD to an augmented objective function at each iteration within the epoch, and then performs a projection at the end of each epoch. Given a strongly convex optimization and for a total number of T iterations, Epro-SGD requires only $\log(T)$ projections, and meanwhile attains an optimal convergence rate of $O(1/T)$, both in expectation and with a high probability. To exploit the structure of the optimization problem, we propose a proximal variant of Epro-SGD, namely Epro-ORDA, based on the optimal regularized dual averaging method. We apply the proposed methods on real-world applications; the empirical results demonstrate the effectiveness of our methods.

1 INTRODUCTION

Recent years have witnessed an increased interest in adopting the stochastic (sub)gradient (SGD) methods [1, 3, 21] for solving large-scale machine learning problems. In each of the algorithmic iterations, SGD reduces the computation cost by sampling one (or a small number of) example for computing a stochastic (sub)gradient. Thus the computation cost in SGD is independent of the size of the data available for training; this property makes SGD appealing for large-scale optimization. However, when the optimization problems involve a complex domain (for example a positive definite constraint or a polyhedron one), the projection operation in each iteration of SGD, which is used to ensure the feasibility of the intermediate solutions, may become the computational bottleneck.

In this paper we consider to solve the following constrained optimization problem

$$\begin{aligned} \min_{\mathbf{x}\in\mathbb{R}^d} \quad & f(\mathbf{x}) \\ s.t. \quad & c(\mathbf{x}) \leq 0, \end{aligned} \tag{1}$$

where $f(\mathbf{x})$ is β-strongly convex [23] and $c(\mathbf{x})$ is convex. We assume a stochastic access model for $f(\cdot)$, in which the only access to $f(\cdot)$ is via a stochastic gradient oracle; in other words, given arbitrary $\mathbf{x}$, this stochastic gradient oracle produces a random vector $\mathbf{g}(\mathbf{x})$, whose expectation is a subgradient of $f(\cdot)$ at the point $\mathbf{x}$, i.e., $\mathrm{E}[\mathbf{g}(\mathbf{x})] \in \partial f(\mathbf{x})$, where $\partial f(\mathbf{x})$ denotes the subdifferential set of $f(\cdot)$ at $\mathbf{x}$. On the other hand we have the full access to the (sub)gradient of $c(\cdot)$.

The standard SGD method [5] solves Eq. (1) by iterating the updates in Eq. (2) with an appropriate step size η_t, e.g., $\eta_t = 1/(\beta t)$), as below

$$\mathbf{x}_{t+1} = \mathcal{P}_{\{\mathbf{x}\in\mathbb{R}^d : c(\mathbf{x})\leq 0\}}\left[\mathbf{x}_t - \eta_t \mathbf{g}(\mathbf{x}_t)\right], \tag{2}$$

and then returning $\widehat{\mathbf{x}}_T = \sum_{t=1}^{T} \mathbf{x}_t/T$ as the final solution for a total number of iterations T. Note that $\mathcal{P}_{\mathcal{D}}[\widehat{\mathbf{x}}]$ is a projection operator defined as

$$\mathcal{P}_{\mathcal{D}}[\widehat{\mathbf{x}}] = \arg\min_{\mathbf{x}\in\mathcal{D}} \|\mathbf{x} - \widehat{\mathbf{x}}\|_2^2. \tag{3}$$

If the involved constraint function $c(\mathbf{x})$ is complex (e.g., a polyhedral or a positive definite constraint), computing the associated projection may be computationally expensive; for example, a projection onto a positive definite cone over $\mathbb{R}^{d\times d}$ requires a full singular value decomposition (SVD) operation with time complexity of $O(d^3)$.

In this paper, we propose an epoch-based SGD method, called Epro-SGD, which requires only a logarithmic number of projections (onto the feasible set), and meanwhile achieves an optimal convergence rate for stochastic

strongly convex optimization. Specifically, the proposed Epro-SGD method consists of a sequence of epochs; within each of the epochs, the standard SGD is applied to optimize a composite objective function augmented by the complex constraint function, hence avoiding the expensive projections steps; at the end of every epoch, a projection operation is performed to ensure the feasibility of the intermediate solution. Our analysis shows that given a strongly convex optimization and for a total number of T iterations, Epro-SGD requires only $\log(T)$ projections, and meanwhile achieves an optimal rate of convergence at $O(1/T)$, both in expectation and with a high probability.

To exploit the structure (for example the sparisty) of the optimization problem, we propose a proximal variant of the Epro-SGD method, namely Epro-ORDA, which utilizes an existing optimal dual averaging method to solve the involved proximal mapping. Our analysis shows that Epro-ORDA similarly requires only a logarithmic number of projections while enjoys an optimal rate of convergence.

For illustration we apply the proposed Epro-SGD methods on two real-world applications, i.e., the constrained Lasso formulation and the large margin nearest neighbor (LMNN) classification. Our experimental results demonstrate the efficiency of the proposed methods, in comparison to the existing methods.

2 RELATED WORK

The present work is inspired from the break-through work in [20], which proposed two novel one-projection-based stochastic gradient descent (OneProj) methods for stochastic convex optimizations. Specifically the first OneProj method was developed for general convex optimization; it introduces a regularized Lagrangian function as

$$L(\mathbf{x}, \lambda) = f(\mathbf{x}) + \lambda c(\mathbf{x}) - \frac{\gamma}{2}\lambda^2, \quad \lambda \geq 0,$$

then applies SGD to the convex-concave problem $\min_{\mathbf{x}\in\mathcal{B}} \max_{\lambda\geq 0} L(\mathbf{x}, \lambda)$, and finally performs only one projection at the end of all iterations, where $\mathcal{B}$ is a bounded ball subsuming $\mathcal{F} = \{\mathbf{x} \in \mathbb{R}^d : c(\mathbf{x}) \leq 0\}$ as a subset.

The second OneProj method was developed for strongly convex optimization. The proposed method introduced an augmented objective function

$$F(\mathbf{x}) = f(\mathbf{x}) + \gamma \ln\left(1 + \exp\left(\frac{\lambda c(\mathbf{x})}{\gamma}\right)\right), \quad (4)$$

where γ is a parameter dependent on the total number of iterations T, and λ is a problem specific parameter [20]. OneProj applies SGD to the augmented objective function, specifically using a stochastic subgradient of $f(\mathbf{x})$ and a subgradient of $c(\mathbf{x})$, and then performs a projection step after all iterations. For a total number T iterations, the OneProj method achieves a rate of convergence at $O(\log T/(\beta T))$, which is suboptimal for stochastic strongly convex optimization.

Several recent works [15, 26] propose optimal methods with optimal rates of convergence at $O(1/T)$ for stochastic strongly convex optimization. In particular, the Epoch-SGD method [15] consists of a sequence of epochs, each of which has a geometrically decreasing step size and a geometrically increasing iteration number. This method however needs to project the intermediate solutions onto a feasible set at every algorithmic iteration; when the involved constraint is complex, the involved projection is usually computationally expensive. This limitation restricts the practical applications on large scale data analysis. Therefore we are motivated to develop an optimal stochastic algorithm for strongly convex optimization but with a constant number of projections.

Another closely related work is the logT-SGD [33] for stochastic strongly convex and smooth optimization. LogT-SGD achieves an optimal rate of convergence, while require to perform $O(\kappa \log_2 T)$ projections, where κ is the ratio of the smoothness parameter to the strong convexity parameter. There are several key differences between our proposed Epro-SGD method and logT-SGD: (i) logT-SGD and its analysis rely on both the smoothness and the strong convexity of the objective function; in contrast, Epro-SGD only assumes that the objective function is strongly convex; (ii) the number of the required projections in logT-SGD is $O(\kappa \log_2 T)$, where the conditional number κ can be very large in real applications; in contrast, Epro-SGD requires at most $\log_2 T$ projections.

Besides reducing the number of projections in SGD, another line of research is based on the conditional gradient algorithms [7, 14, 17, 18, 32]; this type of algorithms mostly build upon the Frank-Wolfe technique [11], which eschews the projection in favor of a linear optimization step; however in general, they require the smoothness assumption in the objective function. On the other hand, [12, 16] extended Frank-Wolfe techniques to stochastic or online setting for general and strongly convex optimizations. Specifically [16] presents an online/stochastic Frank-Wolfe (OFW) algorithm with a convergence rate $O(1/T^{1/3})$ for general convex optimization problems, which is slower than the optimal rate $O(1/\sqrt{T})$. [12] presents an algorithm for online strongly convex optimization with an $O(\log T)$ regret bound, implying an $O(\log T/T)$ convergence rate for stochastic stronlgy convex optimization. This algorithm requires the problem domain to be a polytope, instead of a convex inequality constraint used in this paper; it also hinges on an efficient local linear optimization oracle that amounts to approximately solve a linear optimization problem over an intersection of a ball and and the feasible domain; furthermore the convergence result only holds in expectation and is sub-optimal.

3 EPOCH-PROJECTION SGD ALGORITHM

In this section, we present an epoch-projection SGD method, called Epro-SGD, for solving Eq. (1) and discuss its convergence result. Based on a stochastic dual averaging algorithm, we then present a proximal variant of the proposed Epro-SGD method.

3.1 SETUP AND BACKGROUND

Denote the optimal solution to Eq. (1) by $\mathbf{x}_*$ and its domain set by $\mathcal{D} = \{\mathbf{x} \in \mathbb{R}^d : c(\mathbf{x}) \leq 0\}$. Since $f(\mathbf{x})$ is β-strongly convex [23] and $c(\mathbf{x})$ is convex, the optimization problem in Eq. (1) is strongly convex. Note that the strong convexity in $f(\cdot)$ implies that $f(\mathbf{x}) \geq f(\mathbf{x}_*) + (\beta/2)\|\mathbf{x} - \mathbf{x}_*\|^2$ for any $\mathbf{x}$. Our analysis is based on the following assumptions:

A1. The stochastic subgradient $\mathbf{g}(\mathbf{x})$ is uniformly bounded by G_1, i.e., $\|\mathbf{g}(\mathbf{x})\|_2 \leq G_1$.

A2. The subgradient $\partial c(\mathbf{x})$ is uniformly bounded by G_2, i.e., $\|\partial c(\mathbf{x})\|_2 \leq G_2$ for any $\mathbf{x}$.

A3. There exists a positive value $\rho > 0$ such that

$$\left[\min_{c(\mathbf{x})=0,\, \mathbf{v}\in\partial c(\mathbf{x}),\, \mathbf{v}\neq 0} \|\mathbf{v}\|_2\right] \geq \rho. \tag{5}$$

Remarks Assumptions A1 and A2 respectively impose an upper bound on the stochastic subgradient of the objective function $f(\cdot)$ and the constraint function $c(\cdot)$. Assumption A3 ensures that the projection of a point onto a feasible domain does not deviate too much from this intermediate point. Note that Assumption A1 is previously used in [15]; a condition similar to Assumption A3 is used in [20], which however simply assumes that $\min_{c(\mathbf{x})=0} \|\nabla c(\mathbf{x})\|_2 \geq \rho$, without considering possible non-differentiability in $c(\cdot)$.

A key consequence of Assumption A3 is presented in the following lemma.

Lemma 1. *For any $\widehat{\mathbf{x}}$, let $\widetilde{\mathbf{x}} = \arg\min_{c(\mathbf{x})\leq 0} \|\mathbf{x} - \widehat{\mathbf{x}}\|_2^2$. If Assumption A3 holds, then*

$$\|\widehat{\mathbf{x}} - \widetilde{\mathbf{x}}\|_2 \leq \frac{1}{\rho}[c(\widehat{\mathbf{x}})]_+, \quad \rho > 0, \tag{6}$$

where $[s]_+$ is a hinge operator defined as $[s]_+ = s$ if $s \geq 0$, and $[s]_+ = 0$ otherwise.

Proof. If $c(\widehat{\mathbf{x}}_T) \leq 0$, we have $\widehat{\mathbf{x}} = \widetilde{\mathbf{x}}$; the inequality in Eq. (6) trivially holds. If $c(\widehat{\mathbf{x}}_T) > 0$, we can verify that $c(\widetilde{\mathbf{x}}_T) = 0$, and there exists $s \geq 0$ and $\mathbf{v} \in \partial c(\widetilde{\mathbf{x}}_T)$ such that $\widetilde{\mathbf{x}}_T - \widehat{\mathbf{x}}_T + s\mathbf{v} = 0$ (using duality theory). It follows that $\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T = s\mathbf{v}$ ($\mathbf{v} \neq 0$), and thus $\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T$ is the same direction as $\mathbf{v}$. It follows that

$$\begin{aligned} c(\widehat{\mathbf{x}}_T) &= c(\widehat{\mathbf{x}}_T) - c(\widetilde{\mathbf{x}}_T) \geq (\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T)^\top \mathbf{v} \\ &= \|\mathbf{v}\|_2 \|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2 \geq \rho \|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2, \end{aligned}$$

where the last inequality uses Assumption A3. This completes the proof of this lemma. □

The result in Lemma 1 is closely related to *the polyhedral error bound condition* [13, 31]; this condition shows that the distance of a point to the optimal set of a convex optimization problem is bounded by the distance of the objective value at this point to the optimal objective value scaled by a constant. For illustration, we consider the optimization problem

$$\min_{\mathbf{x}\in\mathbb{R}^d} [c(\mathbf{x})]_+$$

with an optimal set as $\{\mathbf{x} \in \mathbb{R}^d : c(\mathbf{x}) = 0\}$. If $c(\widehat{\mathbf{x}}) > 0$, $\widetilde{\mathbf{x}} = \arg\min_{c(\mathbf{x})\leq 0} \|\mathbf{x} - \widehat{\mathbf{x}}\|_2^2 = \arg\min_{c(\mathbf{x})=0} \|\mathbf{x} - \widehat{\mathbf{x}}\|_2^2$ is the closest point in the optimal set to $\widehat{\mathbf{x}}$. Therefore, by *the polyhedral error bound condition* of a polyhedral convex optimization, if $c(\mathbf{x})$ is a polyhedral function, there exists a $\rho > 0$ such that

$$\|\widehat{\mathbf{x}} - \widetilde{\mathbf{x}}\|_2 \leq \frac{1}{\rho}\left([c(\widehat{\mathbf{x}})]_+ - \min_{\mathbf{x}}[c(\mathbf{x})]_+\right) = \frac{1}{\rho}[c(\widehat{\mathbf{x}})]_+.$$

Below we present three examples in which Assumption A3 or Lemma 1 is satisfied. Example 1: an affine function $c(\mathbf{x}) = \mathbf{c}^\top\mathbf{x} - b$ with $\rho = \|\mathbf{c}\|_2$. Example 2: the ℓ_1 norm constraint $\|\mathbf{x}\|_1 \leq B$ where $\rho = \min_{\mathbf{x}:\|\mathbf{x}\|_1=B} \|\partial\|\mathbf{x}\|_1\|_2 \geq 1$. Example 3: the maximum of a finite number of affine functions $c(\mathbf{x}) = \max_{1\leq i\leq m} \mathbf{c}_i^\top\mathbf{x} - b_i$ satisfying Lemma 1 as well as the polyhedral error bound condition [31].

3.2 MAIN ALGORITHM

To solve Eq. (1) (using Epro-SGD), we introduce an augmented objective function by incorporating the constraint function as

$$F(\mathbf{x}) = f(\mathbf{x}) + \lambda[c(\mathbf{x})]_+. \tag{7}$$

It is worth noting that the augmented function in Eq. (7) does not have any iteration-dependent parameter, for example the parameter γ in Eq. (4). λ is a prescribed parameter satisfying $\lambda > G_1/\rho$, as illustrated in Lemma 2.

The details of our proposed Epro-SGD algorithm is presented in Algorithm 1. Similar to Epoch-SGD [15], Epro-SGD consists of a sequence of epochs, each of which has a geometrically decreasing step size and a geometrically increasing iteration number (Line 9 in Algorithm 1). The updates in every intra-epoch (Line 5 - 6) are standard SGD steps applied to the augmented objective function $F(\mathbf{x})$ with $\mathbf{x} = \mathbf{x}_t^k$. Epro-SGD is different from Epoch-SGD in that the former computes a projection only at the end of each epoch, while the latter computes a projection at each iteration. Consequently, when the projection step is computationally expensive (e.g., projecting onto a positive definite constraint), Epro-SGD may require much less computation time than Epoch-SGD.

Algorithm 1 Epoch-projection SGD (Epro-SGD)

Input: an initial step size η_1, total number of iterations T, and number of iterations in the first epoch T_1, a Lagrangian multiplier λ ($\lambda > G_1/\rho$)
Initialization: $\mathbf{x}_1^1 \in \mathcal{D}$ and $k = 1$
while $\sum_{i=1}^{k} T_i \leq T$ **do**
  for $t = 1, \ldots, T_k$ **do**
    Compute a stochastic gradient $\mathbf{g}(\mathbf{x}_t^k)$
    Compute $\mathbf{x}_{t+1}^k = \mathbf{x}_t^k - \eta_k(\mathbf{g}(\mathbf{x}_t^k) + \lambda \partial [c(\mathbf{x}_t^k)]_+)$
  end for
  Compute $\widetilde{\mathbf{x}}_T^k = \mathcal{P}_{\mathcal{D}}[\widehat{\mathbf{x}}_T^k]$, where $\widehat{\mathbf{x}}_T^k = \sum_{t=1}^{T_k} \mathbf{x}_t^k / T_k$
  Update $\mathbf{x}_1^{k+1} = \widetilde{\mathbf{x}}_T^k$, $T_{k+1} = 2T_k, \eta_{k+1} = \eta_k/2$
  Set $k = k + 1$
end while

In Lemma 2, we present an important convergence analysis for the intra-epoch steps of Algorithm 1, which are key building blocks for deriving the main results in Theorem 1.

Lemma 2. *Under Assumptions A1∼A3, if we apply the update* $\mathbf{x}_{t+1} = \mathbf{x}_t - \eta(\widetilde{\nabla} f(\mathbf{x}_t; \varepsilon_t) + \lambda \nabla [c(\mathbf{x}_t)]_+)$ *for a number of* T *iterations, the following equality holds*

$$\mathrm{E}[f(\widetilde{\mathbf{x}}_T)] - f(\mathbf{x}_*) \leq \mu \left[\eta(G_1^2 + \lambda^2 G_2^2) + \frac{\mathrm{E}[\|\mathbf{x}_1 - \mathbf{x}_*\|_2^2]}{2\eta T} \right],$$

where $\mu = \rho/(\rho - G_1/\lambda)$.

Proof. Let $F(\mathbf{x}) = f(\mathbf{x}) + \lambda [c(\mathbf{x})]_+$ and denote by $\mathrm{E}_t[X]$ the expectation conditioned on the randomness until round $t-1$. It is easy to verify that $F(\mathbf{x}) \geq f(\mathbf{x})$, $F(\mathbf{x}) \geq f(\mathbf{x}) + \lambda c(\mathbf{x})$ and $F(\mathbf{x}_*) = f(\mathbf{x}_*)$. For any $\mathbf{x}$, we have

$$\begin{aligned}
(\mathbf{x}_t - \mathbf{x})^\top \nabla F(\mathbf{x}_t) &\leq \frac{1}{2\eta}\left(\|\mathbf{x} - \mathbf{x}_t\|_2^2 - \|\mathbf{x} - \mathbf{x}_{t+1}\|_2^2\right) + \\
&\quad \frac{\eta}{2}\|\widetilde{\nabla} f(\mathbf{x}_t, \xi_t) + \lambda \nabla [c(\mathbf{x}_t)]_+\|_2^2 + \\
&\quad (\mathbf{x} - \mathbf{x}_t)^\top (\mathbf{g}(\mathbf{x}_t) - \nabla f(\mathbf{x}_t)) \\
&\leq \frac{1}{2\eta}\left(\|\mathbf{x} - \mathbf{x}_t\|_2^2 - \|\mathbf{x} - \mathbf{x}_{t+1}\|_2^2\right) + \\
&\quad \eta\left(G_1^2 + \lambda^2 G_2^2\right) + \zeta_t(\mathbf{x}),
\end{aligned}$$

where $\zeta_t(\mathbf{x}) = (\mathbf{x} - \mathbf{x}_t)^\top (\mathbf{g}(\mathbf{x}_t) - \nabla f(\mathbf{x}_t))$. Furthermore by the convexity of $F(\mathbf{x})$, we have

$$\begin{aligned}
F(\mathbf{x}_t) - F(\mathbf{x}) &\leq \frac{1}{2\eta}\left(\|\mathbf{x} - \mathbf{x}_t\|_2^2 - \|\mathbf{x} - \mathbf{x}_{t+1}\|_2^2\right) + \\
&\quad \eta(G_1^2 + \lambda^2 G_2^2) + \zeta_t(\mathbf{x}).
\end{aligned}$$

Noting that $\mathrm{E}_t[\zeta_t(\mathbf{x})] = 0$, taking expectation over randomness and summation over $t = 1, \ldots, T$, we have

$$\begin{aligned}
\frac{1}{T}\mathrm{E}\left[\sum_{t=1}^{T}(F(\mathbf{x}_t) - F(\mathbf{x}))\right] &= \mathrm{E}\left[F(\widehat{\mathbf{x}}_t) - F(\mathbf{x})\right] \\
&\leq \frac{\mathrm{E}[\|\mathbf{x}_1 - \mathbf{x}\|_2^2]}{2\eta T} + \eta(G_1^2 + \lambda^2 G_2^2).
\end{aligned}$$

Let $B = \mathrm{E}[\|\mathbf{x}_1 - \mathbf{x}_*\|_2^2]/(2\eta T) + \eta(G_1^2 + \lambda^2 G_2^2)$. Since $\mathbf{x}_* \in \mathcal{D} \subseteq \mathcal{B}$, we have

$$\mathrm{E}\left[F(\widehat{\mathbf{x}}_t) - F(\mathbf{x}_*)\right] \leq B. \tag{8}$$

It follows that

$$\mathrm{E}[f(\widehat{\mathbf{x}}_T) + \lambda [c(\widehat{\mathbf{x}}_T)]_+] \leq f(\mathbf{x}_*) + B. \tag{9}$$

If $c(\widehat{\mathbf{x}}_T) \leq 0$, we have $\widetilde{\mathbf{x}}_T = \widehat{\mathbf{x}}_T$. Following from $F(\widetilde{\mathbf{x}}_T) \geq f(\widetilde{\mathbf{x}}_T)$ and $F(\mathbf{x}_*) = f(\mathbf{x}_*)$, we can verify that $\mathrm{E}[f(\widehat{\mathbf{x}}_T)] - f(\mathbf{x}_*) \leq B$ and also $\mathrm{E}[f(\widehat{\mathbf{x}}_T)] - f(\mathbf{x}_*) \leq \rho B/(\rho - G_1/\lambda)$ holds.

Next we show that $\mathrm{E}[f(\widehat{\mathbf{x}}_T)] - f(\mathbf{x}_*) \leq \rho B/(\rho - G_1/\lambda)$ holds when $c(\widehat{\mathbf{x}}_T) > 0$. From Lemma 1, we have

$$c(\widehat{\mathbf{x}}_T) \geq \rho \|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2. \tag{10}$$

Moreover it follows from $\|\partial f(\mathbf{x})\|_2 \leq G_1$ and $f(\mathbf{x}_*) \leq f(\widetilde{\mathbf{x}}_T)$ that the following inequality holds

$$\begin{aligned}
f(\mathbf{x}_*) - f(\widehat{\mathbf{x}}_T) &\leq f(\mathbf{x}_*) - f(\widetilde{\mathbf{x}}_T) + f(\widetilde{\mathbf{x}}_T) - f(\widehat{\mathbf{x}}_T) \\
&\leq G_1 \|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2.
\end{aligned} \tag{11}$$

Substituting Eqs. (10) and (11) into Eq. (9), we have

$$\begin{aligned}
\lambda\rho \mathrm{E}[\|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2] &\leq \mathrm{E}[f(\mathbf{x}_*) - f(\widehat{\mathbf{x}}_T)] + B \\
&\leq G_1 \mathrm{E}[\|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2] + B.
\end{aligned}$$

By some rearrangement, we have $\mathrm{E}[\|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2] \leq B/(\lambda\rho - G_1)$. Furthermore we have

$$\begin{aligned}
&\mathrm{E}[f(\widetilde{\mathbf{x}}_T)] - f(\mathbf{x}_*) \leq \mathrm{E}[f(\widetilde{\mathbf{x}}_T) - f(\widehat{\mathbf{x}}_T)] + \mathrm{E}[f(\widehat{\mathbf{x}}_T)] \\
&-f(\mathbf{x}_*) \leq \mathrm{E}[G_1 \|\widehat{\mathbf{x}}_T - \widetilde{\mathbf{x}}_T\|_2] + B \leq \frac{\lambda\rho}{\lambda\rho - G_1} B,
\end{aligned}$$

where the second inequality follows from $\|\nabla f(\mathbf{x})\|_2 \leq \mathrm{E}\|\nabla f(\mathbf{x}; \varepsilon)\| \leq G_1$, and $|f(\mathbf{x}) - f(\mathbf{y})| \leq G_1 \|\mathbf{x} - \mathbf{y}\|_2$ for any $\mathbf{x}, \mathbf{y}$. This completes the proof of the lemma. □

We present a main convergence result of the Epro-SGD algorithm in the following theorem.

Theorem 1. *Under Assumptions A1∼A3 and given that* $f(\mathbf{x})$ *is* β*-strongly convex, if we let* $\mu = \rho/(\rho - G_1/\lambda)$, $G^2 = G_1^2 + \lambda^2 G_2^2$, *and set* $T_1 = 8, \eta_1 = \mu/(2\beta)$, *the total number of epochs* $k^\dagger$ *in Algorithm 1 is given by*

$$k^\dagger = \left\lceil \log_2\left(\frac{T}{8} + 1\right)\right\rceil \leq \log_2\left(\frac{T}{4}\right), \tag{12}$$

the solution $\mathbf{x}_1^{k^\dagger + 1}$ *enjoys a convergence rate of*

$$\mathrm{E}[f(\mathbf{x}_1^{k^\dagger+1})] - f(\mathbf{x}_*) \leq \frac{32\mu^2 G^2}{\beta(T+8)}, \tag{13}$$

and $c(\mathbf{x}_1^{k^\dagger+1}) \leq 0$.

Proof. From the updating rule $T_{k+1} = 2T_k$, we can easily verify Eq. (12). Since $\mathbf{x}_1^{k^\dagger+1} = \widetilde{\mathbf{x}}_T^{k^\dagger} \in \mathcal{D}$, the inequality $c(\mathbf{x}_1^{k^\dagger+1}) \leq 0$ trivially holds.

Let $V_k = \mu^2 G^2 / \left(2^{k-2}\beta\right)$. It follows that $T_k = 2^{k+2} = 16\mu^2 G^2 / \left(V_k \beta\right)$ and $\eta_k = \mu / \left(2^k \beta\right) = V_k / \left(4\mu G^2\right)$. Next we show the inequality

$$\mathrm{E}[f(\mathbf{x}^k)] - f(\mathbf{x}_*) \leq V_k \tag{14}$$

holds by induction. Note that Eq. (14) implies $\mathrm{E}[f(\mathbf{x}_1^{k+1})] - f(\mathbf{x}_*) \leq 32\mu^2 G^2 / \left(\beta(T+8)\right)$, due to $V_k < 32\mu^2 G^2 / \left(\beta(T+8)\right)$. Let $\Delta_k = f(\mathbf{x}_1^k) - f(\mathbf{x}_*)$. It follows from Lemma 5 (detailed provided in Appendix), $\mu > 1$, and $G^2 > G_1^2$, the inequality in Eq. (14) holds when $k = 1$. Assuming that Eq. (14) holds for $k = k^\dagger$, we show that Eq. (14) holds for $k = k^\dagger{}_1 + 1$.

For a random variable X measurable with respect to the randomness up to epoch $k^\dagger + 1$. Let $\mathrm{E}_{k^\dagger}[X]$ denote the expectation conditioned on all the randomness up to epoch $k^\dagger$. Following Lemma 2, we have

$$\mathrm{E}_{k^\dagger}[\Delta_{k^\dagger+1}] \leq \mu \left[\eta_{k^\dagger} G^2 + \frac{\mathrm{E}[\|\mathbf{x}_1^{k^\dagger} - \mathbf{x}_*\|_2^2]}{2\eta_{k^\dagger} T_{k^\dagger}} \right].$$

Since $\Delta_{k^\dagger} = f(\mathbf{x}_1^{k^\dagger}) - f(\mathbf{x}_*) \geq \beta \|\mathbf{x}_1^{k^\dagger} - \mathbf{x}_*\|_2^2 / 2$ by the strong convexity in $f(\cdot)$, we have

$$\begin{aligned} \mathrm{E}[\Delta_{k^\dagger+1}] &\leq \mu \left[\eta_{k^\dagger} G^2 + \frac{\mathrm{E}[\Delta_{k^\dagger}]}{\eta_{k^\dagger} T_{k^\dagger} \beta} \right] \\ &= \mu \eta_{k^\dagger} G^2 + \frac{V_{k^\dagger} \mu}{\eta_{k^\dagger} T_{k^\dagger} \beta} = \frac{V_{k^\dagger}}{4} + \frac{V_{k^\dagger}}{4} = V_{k^\dagger+1}, \end{aligned}$$

which completes the proof of this theorem. □

Remark We compare the obtained main results in Theorem 1 with several existing works. Firstly Eq. (13) implies that Epro-SGD achieves an optimal bound $O(1/T)$, matching the lower bound for a strongly convex problem [15]. Secondly in contrast to the OneProj method [20] with a convergence rate $O(\log T / T)$, Epro-SGD uses no more than $\log_2(T/4)$ projections to obtain an $O(1/T)$ convergence rate. Epro-SGD thus has better control over the solution for not deviating (too much) from the feasibility domain in the intermediate iterations. Thirdly compared to Epoch-SGD with its convergence rate bounded by $O\left(8G_1^2 / \left(\beta T\right)\right)$, the convergence rate bound of Epro-SGD is only worse by a factor of constant $4\mu^2 G^2 / G_1^2$. Particularly consider a positive definite constraint with $\rho = 1$, $\mu = 2$, and $\lambda = 2G_1/\rho$, we have $G^2 = 5G_1^2$ and the bound of Epro-SGD is only worse by a factor of 80 than Epoch-SGD. Finally compared to the logT-SGD algorithm [33] which requires $O(\kappa \log_2 T)$ projections (κ is the conditional number), the number of projections in Epro-SGD is independent of the conditional number.

The main results in Lemma 2 and Theorem 1 are expected convergence bounds. In Theorem 2 (proof provided in Appendix) we show that Epro-SGD also enjoys a high probability bound under a boundedness assumption, i.e., $\|\mathbf{x}_* - \mathbf{x}_t\|_2 \leq D$ for all t. Note that the existing Epoch-SGD method [15] uses two different methods to derive its high probability bounds. Specifically the first method relies on an efficient function evaluator to select the best solutions among multiple trials of run; while the second one modifies the updating rule by projecting the solution onto the intersection of the domain and a center-shifted bounded ball with decaying radius. These two methods however may lead to additional computation steps, if being adopted for deriving high probability bounds for Epro-SGD.

Theorem 2. *Under Assumptions A1∼A3 and given $\|\mathbf{x}_t - \mathbf{x}_*\|_2 \leq D$ for all t. If we let $\mu = \rho/(\rho - G_1/\lambda)$, $G^2 = G_1^2 + \lambda^2 G_2^2$, $C = \left(8G_1^2/\beta + 2G_1 D\right)\ln(m/\epsilon) + 2G_1 D$, and set $T_1 \geq \max\left(3C\beta / \left(\mu G^2\right), 9\right)$, $\eta_1 = \mu/(3\beta)$, the total number of epochs $k^\dagger$ in Algorithm 1 is given by*

$$k^\dagger = \left\lfloor \log_2 \left(\frac{T}{T_1} + 1 \right) \right\rfloor \leq \log_2(T/4),$$

and the final solution $\mathbf{x}_1^{k^\dagger+1}$ enjoys a convergence rate of

$$f(\mathbf{x}_1^{k^\dagger+1}) - f(\mathbf{x}_*) \leq \frac{4T_1\mu^2 G^2}{\beta(T+T_1)}$$

with a probability at least $1 - \delta$, where $m = \lceil 2\log_2 T \rceil$.

Remark The assumption $\|\mathbf{x}_* - \mathbf{x}_t\|_2 \leq D$ can be satisfied practically, if we estimate the value of D such that $\|\mathbf{x}_*\|_2 \leq D/2$, and then project the intermediate solutions onto $\|\mathbf{x}\|_2 \leq D/2$ at every iteration. Note that Epoch-SGD [15] requires a total number of T projections, and its high probability bound of Epoch-SGD is denoted by $f(\mathbf{x}_1^{k^\dagger+1}) - f(\mathbf{x}_*) \leq 1200 G_1^2 \log(1/\widetilde{\delta}) / \left(\beta T\right)$ with a probability at lest $1 - \delta$, where $\widetilde{\delta} = \delta / \left(\lfloor \log_2(T/300 + 1) \rfloor\right)$.

3.3 A PROXIMAL VARIANT

We propose a proximal extension of Epro-SGD, by exploiting the structure of the objective function. Let the objective function in Eq. (1) be a sum of two components

$$\widehat{f}(\mathbf{x}) = f(\mathbf{x}) + g(\mathbf{x}),$$

where $g(\mathbf{x})$ is a relatively simple function, for example a squared ℓ_2-norm or ℓ_1-norm, such that the involved proximal mapping

$$\min_{\mathbf{x} \in \mathbb{R}^d} \quad g(\mathbf{x}) + \frac{1}{2}\|\mathbf{x} - \widehat{\mathbf{x}}\|_2^2$$

is easy to compute. The optimization problem in Eq. (1) can be rewritten as

$$\begin{aligned} &\min_{\mathbf{x} \in \mathbb{R}^d} \quad f(\mathbf{x}) + g(\mathbf{x}) \\ &s.t. \quad c(\mathbf{x}) \leq 0. \end{aligned} \tag{15}$$

Denote by $\mathbf{x}_*$ the optimal solution to Eq. (15). We similarly introduce an augmented objective function as

$$F(\mathbf{x}) = f(\mathbf{x}) + \lambda[c(\mathbf{x})]_+ + g(\mathbf{x}). \quad (16)$$

Subsequently the update of the proximal SGD method [9, 10, 22] is given by

$$\mathbf{x}_{t+1} = \arg\min_{\mathbf{x}\in\mathcal{D}} \frac{1}{2}\|\mathbf{x} - (\mathbf{x}_t - \eta\mathbf{g}(\mathbf{x}_t))\|_2^2 + \eta g(\mathbf{x}). \quad (17)$$

If $g(\mathbf{x})$ is a sparse regularizer, the proximal SGD can guarantee the sparsity in the intermediate solutions and usually yields better convergence than the standard SGD. However, given a complex constraint, solving the proximal mapping may be computational expensive. Therefore, we consider a proximal variant of Epro-SGD which involves only the proximal mapping of $g(\mathbf{x})$ without the constraint $\mathbf{x} \in \mathcal{D}$. An instinctive solution is to use the following update in place of step 6 in Algorithm 1:

$$\mathbf{x}_{t+1}^k = \arg\min_{\mathbf{x}\in\mathbb{R}^d} \frac{1}{2}\|\mathbf{x} - \left[\mathbf{x}_t^k - \eta_k(\mathbf{g}(\mathbf{x}_t^k) + \lambda\partial[c(\mathbf{x}_t^k)]_+)\right]\|_2^2 + \eta_k g(\mathbf{x}). \quad (18)$$

Based this update and using techniques in Lemma 2, we obtain similar convergence results (proof provided in Appendix), as presented in the following lemma [8].

Lemma 3. *Under Assumptions A1∼A3 and setting $\mu = \rho/(\rho - G_1/\lambda)$, by applying the update in Eq. (18) a number of T iterations, we have*

$$\mathrm{E}[\widehat{f}(\widetilde{\mathbf{x}}_T^k)] - \hat{f}(\mathbf{x}_*) \leq \mu\mathrm{E}\left[\eta G^2 + \frac{\|\mathbf{x}_1^k - \mathbf{x}_*\|_2^2}{2\eta T} + \frac{g(\mathbf{x}_1^k) - g(\mathbf{x}_{T+1}^k)}{T}\right], \quad (19)$$

where $G^2 = (G_1^2 + \lambda^2 G_2^2)$, and $\widetilde{\mathbf{x}}_T^k$ denotes the projected solution of the averaged solution $\widehat{\mathbf{x}}_T^k = \sum_{t=1}^T \mathbf{x}_t^k/T$.

Different from the main result in Lemma 2, Eq. (19) has an additional term $(g(\mathbf{x}_1^k) - g(\mathbf{x}_{T+1}^k))/T_k$; it makes the convergence analysis in Epro-SGD difficult. To overcome this difficulty, we adopt the optimal regularized dual averaging (ORDA) algorithm [6] for solving Eq. (16). The details of ORDA are presented in Algorithm 2. The main convergence results of ORDA are summarized in the following lemma (proof provided in Appendix).

Lemma 4. *Under Assumptions A1∼A3 and setting $\mu = \rho/(\rho - G_1/\lambda)$, by running ORDA a number of T iterations for solving the augmented objective (16), we have*

$$\mathrm{E}[F(\widehat{\mathbf{x}}_T) - F(\mathbf{x}_*)] \leq \frac{4\|\mathbf{x}_1 - \mathbf{x}_*\|_2^2}{\eta\sqrt{T}} + \frac{2\eta(3G_1 + 2\lambda G_2)^2}{\sqrt{T}},$$

and

$$\mathrm{E}[\widehat{f}(\widetilde{\mathbf{x}}_T)] - \widehat{f}(\mathbf{x}_*) \leq \mu\mathrm{E}\left[\frac{4\|\mathbf{x}_1 - \mathbf{x}_*\|_2^2}{\eta\sqrt{T}} + \frac{2\eta(3G_1 + 2\lambda G_2)^2}{\sqrt{T}}\right],$$

where $\widetilde{\mathbf{x}}_T$ denotes the projected solution of the final solution $\widehat{\mathbf{x}}_T$.

Algorithm 2 Optimal Regularized Dual Averaging (ORDA)

1: **Input**: a step size η, the number iterations T, and the initial solution $\mathbf{x}_1$,
2: Set $\theta_t = \frac{2}{t+1}$, $\nu_t = \frac{2}{t}$, $\gamma_t = \frac{t^{3/2}}{\eta}$ and $\mathbf{z}_1 = \mathbf{x}_1$
3: **for** $t = 1, \ldots, T+1$ **do**
4: compute $\mathbf{u}_t = (1-\theta_t)\mathbf{x}_t + \theta_t\mathbf{z}_t$
5: compute a stochastic subgradient $\mathbf{g}(\mathbf{x}_t)$ of $f(\mathbf{x})$ at $\mathbf{x}_t$ and a subgradient of $[c(\mathbf{x}_t)]_+$
6: let $\bar{\mathbf{g}}_t = \theta_t\nu_t\left(\sum_{\tau=1}^t \frac{\mathbf{g}(\mathbf{x}_\tau) + \lambda\partial[c(\mathbf{x}_\tau)]_+}{\nu_\tau}\right)$
7: compute $\mathbf{z}_{t+1} = \arg\min_{\mathbf{x}} \bar{\mathbf{g}}_t^\top\mathbf{x} + \frac{\theta_t\nu_t\gamma_{t+1}}{2}\|\mathbf{x} - \mathbf{x}_1\|_2^2 + g(\mathbf{x})$
8: compute $\mathbf{x}_{t+1} = \arg\min_{\mathbf{x}} \mathbf{x}^\top(\mathbf{g}(\mathbf{x}_t) + \lambda\partial[c(\mathbf{x}_t)]_+) + \frac{\gamma_t}{2}\|\mathbf{x} - \mathbf{u}_t\|_2^2 + g(\mathbf{x})$
9: **end for**
10: **Output**: $\widehat{\mathbf{x}}_T = \mathbf{x}_{T+2}$

Algorithm 3 Epoch-projection ORDA (Epro-ORDA)

1: **Input**: an initial step size η_1, total number of iterations T, and number of iterations in the first epoch T_1, a Lagrangian multiplier $\lambda > G_1/\rho$
2: **Initialization:** $\mathbf{x}_1^1 \in \mathcal{D}$ and $k = 1$.
3: **while** $\sum_{i=1}^k T_i \leq T$ **do**
4: Run ORDA to obtain $\widehat{\mathbf{x}}_T^k = \mathrm{ORDA}(\mathbf{x}_1^k, \eta_k, T_k)$
5: Compute $\widetilde{\mathbf{x}}_T^k = \mathcal{P}_{\mathcal{D}}[\widehat{\mathbf{x}}_T^k]$
6: Update $\mathbf{x}_1^{k+1} = \widetilde{\mathbf{x}}_T^k$, $T_{k+1} = 2T_k$, $\eta_{k+1} = \eta_k/\sqrt{2}$
7: Set $k = k + 1$
8: **end while**

We present a proximal variant of Epro-SGD, namely Epro-ORDA, in Algorithm 3, and summarize its convergence results in Theorem 3. Note that Algorithm 2 and the convergence analysis in Lemma 4 are independent of the strong convexity in $\widehat{f}(\mathbf{x})$; the strong convexity is however used for analyzing the convergence of Epro-ORDA in Theorem 3 (proof provided in Appendix).

Theorem 3. *Under Assumptions A1∼A3 and given that $\widehat{f}(\mathbf{x})$ is β-strongly convex, if we let $\mu = \rho/(\rho - G_1/\lambda)$ and $G = 3G_1 + 2\lambda G_2$, and set $T_1 = 16, \eta_1 = \mu/\beta$, then the total number of epochs $k^\dagger$ in Algorithm 3 is given by*

$$k^\dagger = \left\lfloor \log_2\left(\frac{T}{17} + 1\right)\right\rfloor \leq \log_2(T/8),$$

and the final solution $\mathbf{x}_1^{k^\dagger+1}$ enjoys a convergence rate of

$$\mathrm{E}[\widehat{f}(\mathbf{x}_1^{k^\dagger+1})] - \widehat{f}(\mathbf{x}_*) \leq \frac{68\mu^2G^2}{\beta(T+17)},$$

and $c(\mathbf{x}_1^{k^\dagger+1}) \leq 0$.

4 AN EXAMPLE OF SOLVING LMNN VIA EPRO-SGD

In this section, we discuss an application of applying the proposed Epro-SGD to solve a high dimensional distance metric learning (DML) with a large margin formulation, i.e., the large margin nearest neighbor (LMNN) classification method [30]. LMNN classification is one of the state-of-the-art methods for k-nearest neighbor classification. It learns a positive semi-definite distance metric, based on which the examples from the k-nearest neighbors always belong to the same class, while the examples from different classes are separated by a large margin.

To describe the LMNN method, we first present some notations. Let $(x_i, y_i), i = 1, 2, \cdots, \widehat{N}$, be a set of data points, where $x_i \in \mathbb{R}^d$ and $y \in \mathcal{Y}$ denote the feature representation and the class label, respectively. Let A be a positive definite matrix that defines a distance metric as $\text{dist}(x_1, x_2) = \|x_1 - x_2\|_A^2 = (x_1 - x_2)^\top A(x_1 - x_2)$. To learn a distance metric that separates the examples from different classes by a large margin, one needs to extract a set of similar examples (from the same class) and dissimilar examples (from a different class), denoted by $(x_1^j, x_2^j, x_3^j), j = 1, \ldots N$, where x_1^j shares the same class label to x_2^j and a different class from x_3^j. To this end, for each example $x_1^j = x_i$ one can form x_2^j by extracting the k nearest neighbors (defined by an Euclidean distance metric) that share the same class label to x_i, and form x_3^j by extracting a set of examples that have a different class label. Then an appropriate distance metric could be obtained from the following constrained optimization problem

$$\min_A \frac{c}{N}\sum_{j=1}^{N} \ell\left(A, x_1^j, x_2^j, x_3^j\right) + (1-c)tr(AL) + \frac{\mu_1}{2}\|A\|_F^2 \quad s.t.\ A \succeq \epsilon I, \tag{20}$$

where $\ell(A, x_1^j, x_2^j, x_3^j) = \max(0, \|x_1^j - x_2^j\|_A^2 - \|x_1^j - x_3^j\|_A^2 + 1)$ is a hinge loss and $c \in (0, 1)$ is a trade-off parameter. In Eq. (20), $A \succeq \epsilon I$ is used as the constraint to ensure that Assumption A3 holds. Minimizing the first term is equivalent to maximizing the margin between $\|x_1^j - x_3^j\|_A^2$ and $\|x_1^j - x_2^j\|_A^2$. The matrix L encodes certain prior knowledge about the distance metric; for example, the original LMNN work [30] defines L as $L = \sum_{l=1}^{m} \|x_1^l - x_2^l\|_A^2/m$, where (x_1^l, x_2^l) are all k-nearest neighbor pairs from the same class. Other works [19] have used a weighted summation of distances between all data pairs $L = \sum_{i \neq j}^{n} w_{ij}\|x_i - x_j\|_A^2/n(n-1)$ or intra-class covariance matrix [25]. The last term $\|A\|_F^2/2$ is used as a regularization term and also makes the objective function strongly convex.

For data sets of very high dimensionality, i.e., $d \gg n$, LMNN in Eq. (20) usually produces a sub-optimal solution [25], as this formulation does not capture the sparsity structure of the features. Therefore we add a sparse regularizer and express the formulation below

$$\begin{aligned} \min_A \quad & \frac{c}{N}\sum_{j=1}^{N} \ell\left(A, x_1^j, x_2^j, x_3^j\right) + (1-c)tr(AL) \\ & + \frac{\mu_1}{2}\|A\|_F^2 + \mu_2\|A\|_1^{\text{off}} \\ s.t. \quad & A \succeq \epsilon I, \end{aligned} \tag{21}$$

where $\|A\|_1^{\text{off}} = \sum_{i \neq j} |A_{ij}|$ is an elmenent-wise ℓ_1-norm excluding the diagonal entries. Note that this sparse regularizer $\|A\|_1^{\text{off}}$ have been previously used in [25] for a different purpose.

Many standard optimization solvers or algorithms may not be efficient for solving Eq. (21). Firstly, the optimization problem in Eq. (21) can be formulated as a semi-definite program (SDP); however, general SDP solvers usually scale poorly with the number of triplets and is not suitable for large scale data analysis. Secondly, the gradient decent method presented in [30] requires to project intermediate solutions onto a positive definite cone; this operation invokes expensive singular value decomposition (SVD) for a large matrix and this limitation restricts the real-world applications of the gradient descent method. Thirdly, [25] employs a block coordinate descent (BCD) method to solve an L1-penalized log-det optimization problem; the BCD method is not suitable for solving Eq. (21), as the loss function is not linear in the variable A.

We employ the proposed Epro-SGD algorithm to solve the LMNN formulation in Eq. (21). Let $f(A) = \frac{c}{N}\sum_{j=1}^{N} \ell(A, x_1^j, x_2^j, x_3^j) + (1-c)tr(AL)$ and $g(A) = \frac{\mu_1}{2}\|A\|_F^2 + \mu_2\|A\|_1^{\text{off}}$. The positive definite constraint can be rewritten into an inequality constraint as $c(A) = \epsilon - \lambda_{\min}(A) \leq 0$, where $\lambda_{\min}(\cdot)$ denotes the minimum eigenvalue of the matrix A. We also make the correspondences $\mathbb{R}^d \to \mathbb{R}^{d \times d}$, $\mathbf{x} \to A$, $\|\mathbf{x}\|_2 \to \|A\|_F$, and provide necessary details below in a question-answer form

- How to compute the stochastic gradient of $f(A)$? First sample one triplet (x_1^j, x_2^j, x_3^j) (or a small number of triplets) and then compute $\widetilde{\nabla} f(A; \varepsilon) = c[(x_1^j - x_2^j)(x_1^j - x_2^j)^\top - (x_1^j - x_3^j)(x_1^j - x_3^j)^\top] + (1-c)L$ if $\ell(\|x_1^j - x_2^j\|_A^2 - \|x_1^j - x_3^j\|_A^2 + 1) > 0$, $\widetilde{\nabla} f(A; \varepsilon) = (1-c)L$ otherwise.

- How to compute the gradient of $[c(A)]_+ = [\epsilon - \lambda_{\min}(A)]_+$? By the theory of matrix analysis, the subgradient of $[c(A)]_+$ can be computed by $\partial c(A) = -\mathbf{u}\mathbf{u}^\top$ if $c(A) > 0$, and zero otherwise, where $\mathbf{u}$ denotes the eigevector of A associated with its minimum eigenvalue.

- What is the solution to the following proximal gradi-

ent step?

$$\min_A \frac{1}{2}\|A - \bar{A}_{t+1}\|_F^2 + \eta\left(\frac{\mu_1}{2}\|A\|_F^2 + \mu_2\|A\|_1^{\text{off}}\right).$$

The solution can be obtained via a soft-thresholding algorithm [2].

- What are the appropriate values for β, ρ, r, λ, that are necessary for running the algorithm? The value of $\beta = \mu_1$. The value of ρ is $\min_{c(A)=0} \|\nabla c(A)\|_F = 1$. The value of r can be set to $\sqrt{2c/\mu_1}$. The value of $G_2 = 1$. The value of G_1 can be estimated as $8cR^2 + (1-c)\|L\|_F + \mu_1 r + \mu_2 d$ if we assume $\|x_i\|_2 \leq R, i = 1, \ldots, n$. The value of $\lambda > G_1$ is usually tuned among a set of prespecified values.

Finally, we discuss the impact of employing Epro-SGD and Epro-ORDA method on accelerating the computation for solving LMNN. Note that at each iteration to compute the gradient of $c(A)$, we need to compute the minimum eigenvalue and its eigen-vector. For a dense matrix, it usually involves a time complexity of $O(d^2)$. However, by employing a proximal projection, we can guarantee that the intermediate solution A_t is a element-wise sparse solution, for which the computation of the last eigen-pair can be substantially reduced to be linear to the number of non-zeros elements in A_t.

To analyze the running time compared to the Epoch-SGD method, let us assume we are interested in a ϵ-accurate solution. In the following discussion, we take a particular choice of $\lambda = 2G_1$ and suppress the dependence on constants and only consider dependence on T, G_1 and d. The number of iterations required by Epro-SGD is $\Omega\left(G_1^2/\epsilon\mu_1\right)$, and that by Epro-ORDA is $\Omega\left(G_1^2/\epsilon\mu_1\right)$. Taking into account the running time per iteration, the total running time of Epoch-SGD is $\Omega\left(G_1^2 d^3/\left(\epsilon\mu_1\right)\right)$ and that of Epro-ORDA is $\Omega\left(G_1^2 d^2/\left(\epsilon\mu_1\right)\right)$. When d is very large, the speed-up can be orders of magnitude.

5 EXPERIMENTS

In this section, we empirically demonstrate the efficiency and effectiveness of the proposed Epro-SGD algorithm. We compare the following four algorithms:

- Stochastic sub-Gradient Descent method (SGD) [27]: we set the step size $\eta_t = 1/(\lambda t)$ and SGD achieves a rate of convergence $O(logT/T)$, requiring $O(T)$ projections for a constrained convex optimization problem.
- One-Projection SGD method (OneProj) [20]: we set the step size $\eta_t = 1/(\lambda t)$ and OneProj achieves a rate of convergence $O(logT/T)$, requiring only one projection for a constrained strongly convex optimization problem.

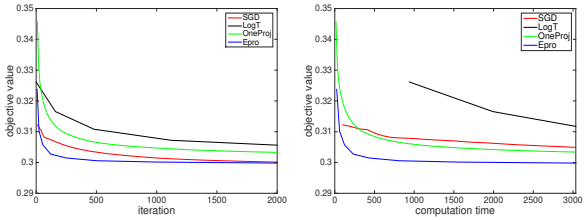

Figure 1: Empirical comparison of the four competing methods for solving Eq. (22). (1) Left plot: the change of the objective values with respect to the iteration number. (2) Right plot: the change of the objective values with respect to the computation time (in seconds).

- $O(logT)$-projections SGD method (logT) [33]: we set the step size $\eta_t = 1/(\sqrt{6}L)$ and logT achieves a rate of convergence $O(1/T)$, requiring $O(\log T)$ projections steps for a constrained strongly convex optimization problem.
- the proposed Epro-SGD with $O(logT)$ number of projections (Epro): we set the step size $\eta_t = 1/(\lambda t)$ and Epro archives a rate of convergence $O(1/T)$ with $O(\log T)$ projections steps for a constrained strongly convex optimization problem.

For illustration, we apply the competing algorithms for solving the constrained Lasso problem and the Large Margin Nearest Neighbor Classification (LMNN) in Eq. (21) respectively. We implement all algorithms using Matlab R2015a and conduct all simulations on an Intel(R) Xeon(R) CPU E5-2430 (15M Cache, 2.20 GHz).

5.1 EXPERIMENTS ON THE CONSTRAINED LASSO FORMULATION

We apply the proposed Epro-SGD algorithm and the other three competing algorithms to solve the L1-norm constrained least squares optimization problem

$$\begin{aligned} \min_w \quad & \frac{1}{2N}\sum_{i=1}^{N}\left(x_i^T w - y_i\right)^2 + \alpha\|w\|^2 \\ s.t. \quad & \|w\|_1 \leq \beta. \end{aligned} \tag{22}$$

Eq. (22) is an equivalent constrained counterpart of the well studied Lasso formation [29]. They aim at achieving entry-wise sparsity in the weight vector w while computing a linear predictor for regression.

We use the algebra data, a benchmark data from KDD Cup 2010 [28], for the following experiments. Specifically we use a preprocessed version of the algebra data[1] for our simulations. This preprocessed data set consists of $8,407,752$

[1] https://www.csie.ntu.edu.tw/ cjlin/libsvmtools/datasets/

samples from two classes, and each of the samples is represented as a feature feature of dimensionality $20,216,830$. In our experiments, we set $\alpha = 1$ and $\beta = 0.5$ for Eq. (22). We tune the initial step size respectively for each of the competing algorithms to get the (nearly) best performance; specifically in this experiments, we set $\eta_0 = 0.5$ for SGD, $\eta_0 = 0.3$ and $\lambda = 0.03$ for Epro, $\eta_0 = 0.1$ for OneProj, and $\eta_0 = 0.1$ for LogT.

In the experiments, we respectively run all competing algorithms for 2000 iterations; we then record the obtained objective values and the corresponding computation time. The experimental results are presented in Figure 1. The left plot shows how the objective value is changed with respect to the algorithm iteration. Note that for Eq. (22), the number of algorithm iterations is equal to the number of stochastic gradient computation (the access to the subgradient of the objective function). From this plot, we can observe that after running 2000 iterations, Epro and SGD attain smaller objective values, compared to OneProj and LogT; we can also observe that OneProj empirically converges slightly faster than logT. The right plot shows how the objective value is changed with respect to the computation time. For this experiment, we set the maximum computation time to 3035 seconds, which is the computation time required by running Epro for 2000 iterations. We can observe that Epro attain a smaller objective value, compared to the other three competing method; meanwhile, the standard SGD and OneProj attain similar objective values, given a fixed amount of computation time.

5.2 EXPERIMENTS ON THE LMNN FORMULATION

We apply the four competing algorithms to solve the LMNN formulation in Eq. (21). We use the Cora data [24] for the following experiments. Cora consists of 2708 scientific publications exclusively from 7 different categories. Each publication is represented by a normalized vector of length 1 and dimensionality 1433. From this data, we construct 5416 neighbor pairs (NP) by randomly selecting 2 publications of the same label; we then construct 16248 non-neighbor (NNT) by randomly selecting 3 non-neighbor publications (of a different label) for each of the NPs. Therefore, in each iteration of the SGD-type methods, we can use a NP and a NNT to construct a stochastic gradient for the optimization formulation. We set $c = 0.5$, $\mu_1 = 10^{-4}$, and $\mu_2 = 10^{-3}$ in Eq. (21). We terminate the algorithms when the iteration number is larger than $4,000$ or the relative change of the objective values in two iterations is smaller than 10^{-8}; we also record the obtained objective values, the required iteration number, and the computation time. Similarly we tune the initial step size respectively for the competing algorithms; specifically, we set $\eta_0 = 4 \times 10^{-8}$ for SGD, $\eta_0 = 10^{-5}$ and $\lambda = 0.1$ for Epro, $\eta_0 = 5 \times 10^{-7}$ for OneProj, and $\eta_0 = 10^{-6}$ for LogT.

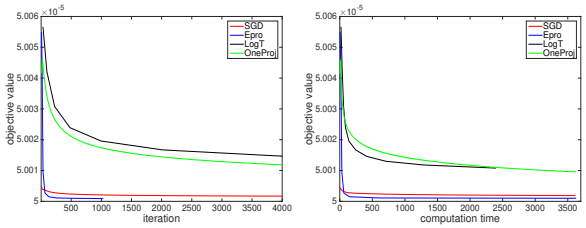

Figure 2: Empirical comparison of the four competing methods for solving Eq. (21). (1) Left plot: the change of the objective values with respect to the iteration number. (2) Right plot: the change of the objective value with respect to the computation time.

The experimental results are presented in Figure 2. Similarly in the left plot, we illustrate how the objective value changes with respect to the iteration number. For the LMNN formulation in Eq. (21), we can observe that Epro converges empirically much faster than all three competing algorithms; in particular, Epro converges after 1024 iterations, while the other 3 algorithms need more iterations. In the right plot, we illustrate how the objective value changes with respect to the computation time. We can observe that Epro converges using a smaller amount of computation time. specifically, in our experiment Epro converges with the computation time as 3622 seconds; while the other three competing algorithms need much more computation time.

6 CONCLUSIONS

We proposed an epoch-projection based SGD method, called Epro-SGD, for stochastic strongly convex optimization. The proposed Epro-SGD applies SGD on each iteration within its epochs and only performs a projection at the end of each epoch. Our analysis shows that Epro-SGD requires only a logarithmic number of projections, while achieves a guaranteed optimal rate of convergence both in expectation as well as with high probability. Additionally we proposed a variant of Epro-SGD based on an existing dual averaging method, called Epro-ORDA, which exploit structures of the optimization problems by incorporating an associated proximal mapping iteratively. For illustration, we applied the proposed Epro-SGD method for solving a large margin distance metric learning formulation and a constrained Lasso formulation respectively with a positive definite constraint. Our empirical results demonstrate the effectiveness of the proposed method.

Abstract

We propose an accelerated stochastic block coordinate descent algorithm for nonconvex optimization under sparsity constraint in the high dimensional regime. The core of our algorithm is leveraging both stochastic partial gradient and full partial gradient restricted to each coordinate block to accelerate the convergence. We prove that the algorithm converges to the unknown true parameter at a linear rate, up to the statistical error of the underlying model. Experiments on both synthetic and real datasets backup our theory.

1 INTRODUCTION

High-dimensional statistics (Bühlmann and Van De Geer, 2011) deals with models in which the number of parameters d is comparable to or even larger than the sample size n. Since it is usually impossible to obtain a consistent estimator when both d and n increase, various types of statistical models with structural assumptions including sparse vectors, sparse matrices, low-rank matrices have been proposed and widely studied. In such a high dimensional regime, a general approach is solving a regularized optimization problem, which consists of a loss function measuring how well the model fits the data and some penalty function that encourages the assumed structures. For an overview of high dimensional statistics, please refer to Bühlmann and Van De Geer (2011); Negahban et al. (2009).

In this paper, instead of considering regularized estimator, we focus on the following sparsity constrained optimization problem:

$$\min_{\boldsymbol{\beta}} F(\boldsymbol{\beta}) \quad \text{subject to} \quad \|\boldsymbol{\beta}\|_0 \leq s, \tag{1.1}$$

where $F(\boldsymbol{\beta}) = n^{-1}\sum_{i=1}^{n} f_i(\boldsymbol{\beta})$ is a sum of a finite number of convex and smooth functions, $\|\boldsymbol{\beta}\|_0$ is the number of nonzero elements in $\boldsymbol{\beta}$, and s is a tuning parameter that controls the sparsity of $\boldsymbol{\beta}$. The above problem is common in machine learning and statistics, such as the empirical risk minimization (ERM) and M-estimator, where $F(\boldsymbol{\beta})$ is the empirical loss function averaged over the training sample. For example, by choosing the squared loss $f_i(\boldsymbol{\beta}) = (\langle\boldsymbol{\beta}, \mathbf{x}_i\rangle - y_i)^2/2$, (1.1) becomes a sparsity constrained linear regression problem (Tropp and Gilbert, 2007).

Due to the nonconvexity of the sparsity constraint, the problem in (1.1) is in general NP hard. In order to obtain an approximate solution to (1.1), a variety of algorithms have been proposed. For example, when the objective function $F(\boldsymbol{\beta})$ is chosen to be the square loss function, it can be solved approximately by matching pursuit (Mallat and Zhang, 1993), orthogonal matching pursuit (Tropp and Gilbert, 2007), CoSaMP (Needell and Tropp, 2009), hard thresholding pursuit (Foucart, 2011), iterative hard thresholding (Blumensath and Davies, 2009) and forward backward feature selection algorithm (Zhang, 2011). For general loss functions, there also exists a set of algorithms such as forward feature selection (Shalev-Shwartz et al., 2010; Bahmani et al., 2013), forward backward feature selection algorithm (Jalali et al., 2011; Liu et al., 2013) and iterative gradient hard thresholding (Yuan et al., 2013; Jain et al., 2014). However, all the above algorithms are based on deterministic optimization such as gradient descent algorithm. In each iteration of gradient descent algorithm, it requires the evaluation of the full gradient over the n component functions, which is computationally very expensive, especially when n is large. In order to address this issue, Nguyen et al. (2014) proposed two stochastic iterative greedy algorithms. Yet neither of the algorithms attain linear rate of convergence for the objective function value. Li et al. (2016) proposed a stochastic variance reduced gradient hard thresholding algorithm. Nevertheless, it cannot leverage the coordinate block to accelerate the convergence.

In this paper, by leveraging the advantages of both stochastic gradient descent (Nemirovski et al., 2009; Lan, 2012) and randomized block coordinate descent (Shalev-Shwartz

and Tewari, 2011; Nesterov, 2012; Beck and Tetruashvili, 2013; Richtárik and Takáč, 2014; Lu and Xiao, 2015), we propose a stochastic block coordinate gradient descent algorithm to solve the nonconvex sparsity constrained optimization problem in (1.1). The core of our algorithm is to exploit both stochastic partial gradient and full partial gradient restricted to each coordinate block. In detail, our algorithm consists of two layers of loops. For each iteration of the outer loop, the full gradient is computed once; while in the follow-up inner loop, partial stochastic gradient is computed to adjust the full gradient. We also incorporate mini-batch gradient computation into our algorithm, to further accelerate the convergence. Replacing full gradients with stochastic gradients restricted on coordinate blocks essentially trades the number of iterations with a low computational cost per iteration. We prove that the algorithm is guaranteed converge to the unknown true parameter $\boldsymbol{\beta}^*$ at a linear rate up to statistical error. The gradient complexity[1] of our algorithm is

$$\mathcal{O}\Big(\big(n + \kappa_{\widetilde{s}}|\mathcal{B}|/k\big)\log(1/\epsilon)\Big),$$

where k is the number of coordinate blocks, $|\mathcal{B}|$ is the mini batch size, ϵ is the optimization error for the objective function value, and $\kappa_{\widetilde{s}}$ is the condition number of the Hessian matrix $\nabla^2 F(\boldsymbol{\beta})$ restricted on any $\widetilde{s} \times \widetilde{s}$ principal submatrix. When $k = 1$ and $|\mathcal{B}| = 1$, our algorithm is reduced to accelerated gradient descent for the sparsity constrained nonconvex optimization problem. It improves the gradient complexity for gradient hard thresholding algorithms (Yuan et al., 2013; Jain et al., 2014) from $\mathcal{O}(n\kappa_{\widetilde{s}}\log(1/\epsilon))$ to $\mathcal{O}[(n + \kappa_{\widetilde{s}})\log(1/\epsilon)]$. Furthermore, for both sparse linear regression and sparse generalized linear model estimation, we show that the estimator from our algorithm attains the minimax optimal statistical rate. Experiments on both synthetic and real datasets backup our theory.

The remainder of this paper is organized as follows. In Section 2, we briefly review some related work. In Section 3, we review two examples of the optimization problems. We present the algorithm in Section 4, and analyze it in Section 5. In addition, we apply our theory to two specific examples and illustrate the corresponding theory for the two examples. We compare the proposed algorithm with existing algorithms in Section 6. Finally, we conclude this paper in Section 7.

Notation Let $\mathbf{A} = [A_{ij}] \in \mathbb{R}^{d\times d}$ be a matrix and $\mathbf{x} = [x_1, \ldots, x_d]^\top \in \mathbb{R}^d$ be vector. For $0 < q < \infty$, we define the ℓ_0, ℓ_q and ℓ_∞ vector norms as $\|\mathbf{x}\|_0 = \sum_{i=1}^d \mathbb{1}(x_i \neq 0)$, $\|\mathbf{x}\|_q = \Big(\sum_{i=1}^d |x_i|^q\Big)^{\frac{1}{q}}$ and $\|\mathbf{x}\|_\infty = \max_{1\leq i\leq d}|x_i|$, where $\mathbb{1}(\cdot)$ represents the indicator function. For a vector $\mathbf{x}$, we define $\mathrm{supp}(\mathbf{x})$ as the index set of nonzero entries of $\mathbf{x}$, and $\mathrm{supp}(\mathbf{x}, s)$ as the index set of the top s entries of $\mathbf{x}$ in terms of magnitude. In addition, we denote by $\mathbf{x}_S$ the restriction of $\mathbf{x}$ onto a index set S, such that $[\mathbf{x}_S]_i = x_i$ if $i \in S$, and $[\mathbf{x}_S]_i = 0$ if $i \notin S$. In addition, we denote by $\mathbf{x}_s$ the restriction of $\mathbf{x}$ onto the top s entries in terms of magnitude, i.e., $[\mathbf{x}_s]_i = x_i$ if $i \in \mathrm{supp}(\mathbf{x}, s)$, and $[\mathbf{x}_s]_i = 0$ if $i \notin \mathrm{supp}(\mathbf{x}, s)$. For a set $\mathcal{B}$, we denote its cardinality by $|\mathcal{B}|$. For a matrix $\mathbf{X}$, its i-th row is denoted by $\mathbf{X}_{i*}$ and its j-th column is denoted by $\mathbf{X}_{*j}$.

[1]Gradient complexity is defined to be the iteration complexity times the number of gradient evaluation on each component function

2 RELATED WORK

In this section, we briefly review additional lines of research beyond the sparsity constrained nonconvex optimization, that are relevant to our work.

Gradient descent is computationally expensive at each iteration, hence stochastic gradient descent is often used when the data set is large. At each iteration, only one or a mini-batch of the n component functions f_i is sampled (Nemirovski et al., 2009; Lan, 2012). Due to the variance in estimating the gradient by stochastic sampling, stochastic gradient descent has a sublinear rate of convergence even when $F(\boldsymbol{\beta})$ is strongly convex and smooth. To accelerate stochastic gradient descent, various types of accelerated stochastic gradient descent algorithms (Schmidt et al., 2013; Johnson and Zhang, 2013; Konečnỳ and Richtárik, 2013; Defazio et al., 2014b; Mairal, 2014; Defazio et al., 2014a). The most relevant work to ours is stochastic variance reduced gradient (SVRG) (Johnson and Zhang, 2013) and its variants (Xiao and Zhang, 2014; Konečnỳ et al., 2014a).

In contrast to gradient descent, block coordinate descent (BCD) (Shalev-Shwartz and Tewari, 2011; Nesterov, 2012; Beck and Tetruashvili, 2013; Richtárik and Takáč, 2014; Lu and Xiao, 2015) only computes the full gradient of $F(\boldsymbol{\beta})$ restricted on a randomly selected coordinate block at each iteration. Compared with gradient descent, the per-iteration time complexity of RBCD is much lower. However, such algorithms still compute the partial full gradient based on all the n component functions per iteration.

Stochastic block coordinate gradient descent was proposed recently (Dang and Lan, 2015; Xu and Yin, 2015; Reddi et al., 2014), which integrates the advantages of stochastic gradient descent and block coordinate descent. Such algorithms compute the stochastic partial gradient restricted to one coordinate block with respect to one component function, rather than the full partial derivative with respect to all the component functions. These algorithms essentially employ sampling of both coordinates and data instances at each iteration. However, they can only achieve a sublinear rate of convergence. Recently, randomized block coordinate descent using mini-batches (Zhao et al., 2014; Wang and Banerjee, 2014; Konečnỳ et al., 2014b) are proposed

independently to accelerate the convergence of stochastic block coordinate gradient descent.

Our work departs from the above studies by considering a sparsity constrained nonconvex optimization problem instead of convex optimization. Due to the nonconvex nature of (1.1), our algorithm is no longer guaranteed to converge to the global optimum. Nevertheless, by taking into account the underlying statistical models, we illustrate that proposed algorithm is guaranteed to converge to the unknown true model parameters up to the statistical error.

3 ILLUSTRATIVE EXAMPLES OF SPARSITY CONSTRAINED OPTIMIZATION

In this section, we give two examples of the statistical estimation problems, which fall in the sparsity constrained optimization problem in (1.1). We return to demonstrate the implication of our general algorithm and theory to these examples in Section 5.

Example 3.1 (Sparse Linear Regression)**.** Consider the following linear regression model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta}^* + \boldsymbol{\epsilon}, \tag{3.1}$$

where $\mathbf{y} \in \mathbb{R}^n$ denotes a vector of the responses, and $\mathbf{X} \in \mathbb{R}^{n\times d}$ is the design matrix, $\boldsymbol{\beta}^* \in \mathbb{R}^d$ is the unknown regression coefficient vector such that $\|\boldsymbol{\beta}^*\|_0 \leq s^*$, and $\boldsymbol{\epsilon} \in \mathbb{R}^d$ is a noise vector. A commonly used estimator for the above sparse linear regression problem is the Lasso estimator (Tibshirani, 1996) with ℓ_1 norm penalty. An alternative estimator is the sparsity constrained estimator

$$\min_{\boldsymbol{\beta}\in\mathbb{R}^d} \frac{1}{2n}\|\mathbf{X}\boldsymbol{\beta} - \mathbf{y}\|_2^2 \quad \text{subject to} \quad \|\boldsymbol{\beta}\|_0 \leq s, \tag{3.2}$$

where s is a tuning parameter, which controls the sparsity of $\boldsymbol{\beta}$. This is indeed an example of the nonconvex optimization problem in (1.1) where $F(\boldsymbol{\beta}) = 1/(2n)\|\mathbf{X}\boldsymbol{\beta} - \mathbf{y}\|_2^2$, $f_i(\boldsymbol{\beta}) = 1/2(\mathbf{x}_i^\top\boldsymbol{\beta} - y_i)^2$ and $\mathbf{x}_i \in \mathbb{R}^d$ is the i-th row of $\mathbf{X}$. Similar estimator has been studied by Tropp and Gilbert (2007); Zhang (2011); Jain et al. (2014), to mention a few.

Example 3.2 (Sparse Generalized Linear Models)**.** We assume that the observations in each task are generated from generalized linear models

$$\mathbb{P}(y|\mathbf{x}, \boldsymbol{\beta}^*, \sigma) = \exp\left\{\frac{y\langle\boldsymbol{\beta}^*, \mathbf{x}\rangle - \Phi(\boldsymbol{\beta}^{*\top}\mathbf{x})}{c(\sigma)}\right\}, \tag{3.3}$$

where $\Phi(\cdot) : \mathbb{R} \to \mathbb{R}$ is a link function, $y \in \mathbb{R}$ is the response variable, $\mathbf{x} \in \mathbb{R}^d$ is the predictor vector, $\boldsymbol{\beta}^* \in \mathbb{R}^d$ is the parameter such that $\|\boldsymbol{\beta}^*\|_0 \leq s^*$, and $c(\sigma) \in \mathbb{R}$ is fixed and known scale parameter. A special example of generalized linear model is the linear regression model where the noise follows from a Gaussian distribution, which corresponds to $c(\sigma) = \sigma^2$ and $\Phi(t) = t^2$. Logistic regression is another special case of the generalized linear model, where $\Phi(t) = \log(1 + \exp(t)), c(\sigma) = 1$ and $y \in \{0, 1\}$.

Given $\{\mathbf{x}_i, y_i\}_{i=1}^n$, a widely used estimator for $\boldsymbol{\beta}^*$ is the ℓ_1 regularized maximum likelihood estimator (Negahban et al., 2009; Loh and Wainwright, 2013). An alternative estimator is the sparsity constrained maximum likelihood estimator as follows

$$\min_{\boldsymbol{\beta}} -\frac{1}{n}\sum_{i=1}^n \frac{1}{c(\sigma)}\big[y_i\langle\boldsymbol{\beta}, \mathbf{x}_i\rangle - \Phi(\boldsymbol{\beta}^{*\top}\mathbf{x})\big], \quad \text{subject to} \quad \|\boldsymbol{\beta}\|_0 \leq s. \tag{3.4}$$

The estimator in (3.4) has been investigated by Jalali et al. (2011); Yuan et al. (2013); Li et al. (2016).

For more examples, please refer to Yuan et al. (2013); Jain et al. (2014) and references therein.

4 THE PROPOSED ALGORITHM

In this section, we present an accelerated stochastic block coordinate descent algorithm based on nonconvex optimization for solving the proposed estimator in (1.1). The key motivation of the algorithm is using iterative hard thresholding to ensure cardinality constraint and mixed mini-batch partial gradient to reduce the variance of the stochastic gradient and accelerate the convergence. We display the algorithm in Algorithm 1.

Algorithm 1 Accelerated Stochastic Block Coordinate Gradient Descent with Hard Thresholding (ASBCDHT)

Initialization: $\widetilde{\boldsymbol{\beta}}^{(0)}$ **with** $\|\widetilde{\boldsymbol{\beta}}^{(0)}\|_0 \leq s$
for $\ell = 1, 2, \ldots$ **do**
  $\widetilde{\boldsymbol{\beta}} = \widetilde{\boldsymbol{\beta}}^{(\ell-1)}$
  $\widetilde{\boldsymbol{\mu}} = \frac{1}{n}\sum_{i=1}^n \nabla f_i(\widetilde{\boldsymbol{\beta}})$
  $\boldsymbol{\beta}^{(0)} = \widetilde{\boldsymbol{\beta}}$
  Randomly sample z **uniformly from** $\{0, \ldots, m-1\}$
  for $t = 0, 1, \ldots, z-1$ **do**
    Randomly sample a mini-batch $\mathcal{B}$ **from** $\{1, \ldots, n\}$ **uniformly**
    Randomly sample j **from** $\{1, \ldots, k\}$ **uniformly**
    $[\mathbf{v}]_{\mathcal{G}_j} = \frac{1}{|\mathcal{B}|}\sum_{i\in\mathcal{B}} \nabla_{\mathcal{G}_j} f_i(\boldsymbol{\beta}^{(t)}) - \nabla_{\mathcal{G}_j} f_i(\widetilde{\boldsymbol{\beta}}) + \widetilde{\boldsymbol{\mu}}_{\mathcal{G}_j}$
    $\boldsymbol{\beta}^{(t+0.5)} = \boldsymbol{\beta}^{(t)} - \eta[\mathbf{v}]_{\mathcal{G}_j}$
    $\boldsymbol{\beta}^{(t+1)} = \mathrm{HT}\big(\boldsymbol{\beta}^{(t+0.5)}, s\big)$
  end for
  Set $\widetilde{\boldsymbol{\beta}}^{(\ell)} = \boldsymbol{\beta}^{(z)}$
end for

Note that in Algorithm 1, we have two layers of loops. In the outer loop, $\widetilde{\boldsymbol{\beta}}^{(r-1)}$ denotes the estimated parameter from previous stage, and $\widetilde{\boldsymbol{\mu}}$ denotes the full gradient computed based on $\widetilde{\boldsymbol{\beta}}^{(r-1)}$.

In the inner loop, Algorithm 1 integrates the advantages of randomized block coordinate descent and stochastic gradient descent together. Let $\{\mathcal{G}_1, \ldots, \mathcal{G}_k\}$ be a partition of all the d coordinates where $\mathcal{G}_j$ is a block of coordinates. In step 7, it uniformly samples a mini batch of component functions. And in step 8, it uniformly samples a coordinate block. The random sampling significantly reduces the computational cost. Based on the mini batch of component functions, and the coordinate block, it calculates the mixed partial gradient $[\mathbf{v}]_{\mathcal{G}_j}$ restricted on the selected coordinate block, which is the combination of the partial stochastic gradient and the partial full gradient (See step 9). Note that similar mixed gradient has been originally introduced in Johnson and Zhang (2013) and later adopted by Xiao and Zhang (2014); Konečnỳ et al. (2014a); Zhao et al. (2014); Konečnỳ et al. (2014b) to reduce the variance introduced by random sampling. More specifically, we can show that the variance of $[\mathbf{v}]_{\mathcal{G}_j}$ i.e., $\mathbb{E}[\|\mathbf{v}_{\widetilde{\mathcal{S}}} - \nabla_{\widetilde{\mathcal{S}}} F(\boldsymbol{\beta}^{(t)})\|_2^2]$ diminishes when $\boldsymbol{\beta}^{(t)}$ approaches the unknown true model parameter vector $\boldsymbol{\beta}^*$. $\boldsymbol{\beta}^{(t+0.5)}$ is the output of coordinate gradient descent step. Since $\boldsymbol{\beta}^{(t+0.5)}$ is not necessarily sparse after the coordinate descent update, in order to make it sparse, we apply a hard thresholding procedure (Yuan et al., 2013; Jain et al., 2014) right after coordinate descent step. The hard thresholding operator is defined as follows:

$$[\mathrm{HT}(\boldsymbol{\beta}, s)]_i = \begin{cases} \beta_i, & \text{if } i \in \mathrm{supp}(\boldsymbol{\beta}, s), \\ 0, & \text{otherwise.} \end{cases} \tag{4.1}$$

The hard thresholding step preserves the entries of $\boldsymbol{\beta}^{(t+0.5)}$ with the top s large magnitudes and sets the rest to zero. This gives rise to $\boldsymbol{\beta}^{(t+1)}$. Recall that s is a tuning parameter that controls the sparsity level.

5 MAIN THEORY AND IMPLICATIONS

In this section, we will present the main theory that characterizes the performance of Algorithm 1, followed which we show the consequences of our theory when it is applied to the two examples in Section 3.

5.1 MAIN THEORETICAL RESULTS

We first layout a set of definition and assumptions, that are essential for our main theory.

Definition 5.1 (Sparse Eigenvalues)**.** Let $\widetilde{s}$ be a positive integer. The largest and smallest s-sparse eigenvalues of the Hessian matrix $\nabla^2 F(\boldsymbol{\beta})$ are

$$\rho_+(\widetilde{s}) = \sup_{\mathbf{v}} \Big\{ \mathbf{v}^\top \nabla^2 F(\boldsymbol{\beta}) \mathbf{v} : \|\mathbf{v}\|_0 \leq \widetilde{s}, \|\mathbf{v}\|_2 = 1, \boldsymbol{\beta} \in \mathbb{R}^d \Big\},$$
$$\rho_-(\widetilde{s}) = \inf_{\mathbf{v}} \Big\{ \mathbf{v}^\top \nabla^2 F(\boldsymbol{\beta}) \mathbf{v} : \|\mathbf{v}\|_0 \leq \widetilde{s}, \|\mathbf{v}\|_2 = 1, \boldsymbol{\beta} \in \mathbb{R}^d \Big\}.$$

Moreover, we define the restricted condition number $\kappa_{\widetilde{s}} = \rho_+(\widetilde{s})/\rho_-(\widetilde{s})$.

Based on the sparse eigenvalues, we make the following assumptions on $f_i(\boldsymbol{\beta})$ and $F(\boldsymbol{\beta})$ with respect to $\rho_+(\widetilde{s})$ and $\rho_-(\widetilde{s})$ mentioned above.

Assumption 5.2 (Restricted Strong Smoothness)**.** $f_i(\boldsymbol{\beta})$ satisfies restricted strong smoothness condition at sparsity level $\widetilde{s}$ with a constant $\rho_+(\widetilde{s}) > 0$: for all $\boldsymbol{\beta}, \boldsymbol{\beta}'$ such that $\|\boldsymbol{\beta} - \boldsymbol{\beta}'\|_0 \leq \widetilde{s}$, we have

$$f_i(\boldsymbol{\beta}) \leq f_i(\boldsymbol{\beta}') + \nabla f_i(\boldsymbol{\beta}')^\top (\boldsymbol{\beta} - \boldsymbol{\beta}') + \frac{\rho_+(\widetilde{s})}{2} \|\boldsymbol{\beta} - \boldsymbol{\beta}'\|_2^2.$$

Assumption 5.3 (Restricted Strong Convexity)**.** $F(\boldsymbol{\beta})$ satisfies restricted strong convexity condition at sparsity level $\widetilde{s}$ with a constant $\rho_-(\widetilde{s}) > 0$: for all $\boldsymbol{\beta}, \boldsymbol{\beta}'$ such that $\|\boldsymbol{\beta} - \boldsymbol{\beta}'\|_0 \leq \widetilde{s}$, we have

$$F(\boldsymbol{\beta}) \geq F(\boldsymbol{\beta}') + \nabla F(\boldsymbol{\beta}')^\top (\boldsymbol{\beta} - \boldsymbol{\beta}') + \frac{\rho_-(\widetilde{s})}{2} \|\boldsymbol{\beta} - \boldsymbol{\beta}'\|_2^2.$$

Assumptions 5.2 and 5.3 indicate that function $f_i(\boldsymbol{\beta})$ is smooth and function $F(\boldsymbol{\beta})$ is strongly convex when restricted on to a sparse subspace. These restricted strong smoothness and strong convexity conditions ensure that the standard convex optimization results for strongly convex and smooth objective functions (Nesterov, 2004) can be applied to our problem settings as well. It is worth noting that we do not require each $f_i(\boldsymbol{\beta})$ to be restricted strongly convex, we only require their summation $F(\boldsymbol{\beta})$ is restricted strongly convex. $f_i(\boldsymbol{\beta})$ typically does not satisfy restricted strong convexity for $\widetilde{s} > 1$. Recall that, in Example 3.1, $f_i(\boldsymbol{\beta}) = 1/2(\mathbf{x}_i^\top \boldsymbol{\beta} - y_i)^2$, which is obviously not restricted strongly convex unless $\widetilde{s} = 1$.

Now we are ready to present our main theorem.

Theorem 5.4. Suppose Assumptions 5.2 and 5.3 hold with $\widetilde{s} = 2s + s^*$. In addition, assume that $0 < \eta \leq 1/(18\rho_+(\widetilde{s}))$ and m, s are chosen such that,

$$\alpha = \frac{2k\tau^{m-1}(\tau - 1)}{\rho_-(\widetilde{s})\eta\gamma(\tau^m - 1)} + \frac{12\eta\rho_+(\widetilde{s})(n - |\mathcal{B}|)}{|\mathcal{B}|(n-1)\gamma} < 1,$$

where $\gamma = 1 - 12\eta\rho_+(\widetilde{s})(n - |\mathcal{B}|)/\big[|\mathcal{B}|(n-1)\big] - 6\eta\rho_+(\widetilde{s})$ and $\tau = 1 + 2\sqrt{s^*}/\sqrt{s - s^*}$. Then the estimator $\widetilde{\boldsymbol{\beta}}^{(\ell)}$ from Algorithm 1 satisfies

$$\mathbb{E}\big[F(\widetilde{\boldsymbol{\beta}}^{(\ell)}) - F(\boldsymbol{\beta}^*)\big] \leq \alpha^\ell \mathbb{E}\big[F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)\big] + \frac{3\eta}{2\gamma(1-\alpha)} \|\nabla_{\widetilde{s}} F(\boldsymbol{\beta}^*)\|_2^2. \tag{5.1}$$

We have the following remarks regarding the above theorem results:

Remark 5.5. Theorem 5.4 implies that in order to achieve linear rate of convergence, the learning rate η need to be set sufficiently small, the sparsity constraint s and the number of inner loop iterations m should be set sufficiently large such that $\alpha \leq 1$. Here we provide an example showing

Table 1: A comparison of gradient complexity for different algorithms.

Algorithms	Gradient Complexity
Nguyen et al. (2014)	$\mathcal{O}\big(1/\epsilon\big)$
Yuan et al. (2013)	$\mathcal{O}\big(n\kappa_{\widetilde{s}} \cdot \log(1/\epsilon)\big)$
Li et al. (2016)	$\mathcal{O}\big([n + \kappa_{\widetilde{s}}] \cdot \log(1/\epsilon)\big)$
Ours	$\mathcal{O}\big((n + \kappa_{\widetilde{s}}\lvert\mathcal{B}\rvert/k) \cdot \log(1/\epsilon)\big)$

this is absolutely achievable. Without loss of generality, we consider the simplified scenario where the batch size $|\mathcal{B}| = 1$ and coordinate block number $k = 1$. As stated in the theorem condition, suppose we choose $\eta = 1/(36\rho_+(\widetilde{s}))$, then we have $\gamma = 1/2$. This simplifies the expression of α to:

$$\alpha = 144\kappa_{\widetilde{s}} \cdot \frac{\tau^m}{\tau^m - 1}\Big(1 - \frac{1}{\tau}\Big) + \frac{2}{3},$$

Therefore, provided that s is chosen to be

$$s \geq \big(1 + 4(1728\kappa_{\widetilde{s}} - 1)^2\big)s^*,\ m \geq \log 2 \cdot (1728\kappa_{\widetilde{s}} - 1),$$

we have,

$$\frac{\tau^m}{\tau^m - 1} \leq 2,\ \Big(1 - \frac{1}{\tau}\Big) \leq \frac{1}{1728\kappa_{\widetilde{s}}},$$

which immediately verifies that $\alpha \leq \frac{5}{6} < 1$.

Remark 5.6. Theorem 5.4 illustrates the linear rate of convergence in objective function value gap. From (5.1), in order to ensure that the linear converging term satisfies $\alpha^\ell\big[F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)\big] \leq \epsilon$, the number of stages should satisfy

$$\ell \geq \log_{\alpha^{-1}} \frac{F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)}{\epsilon}.$$

Thus we need $\mathcal{O}(\log(1/\epsilon))$ outer iterations in Algorithm 1. Recall that from Remark 5.5, we have $m = \Omega(\kappa_{\widetilde{s}})$. Since in each outer iteration, we need to compute one full gradient and m mixed mini-batch gradient, the overall gradient complexity is $\mathcal{O}\big((n + \kappa_{\widetilde{s}} \cdot |\mathcal{B}|/k) \cdot \log(1/\epsilon)\big)$, where k is the number of coordinate blocks, $|\mathcal{B}|$ is the batch size, and $\kappa_{\widetilde{s}}$ is the restricted condition number of $\nabla^2 F(\boldsymbol{\beta}^*)$. For the ease of comparison, we summarize the gradient complexity of our algorithm as well as the other state of the art algorithms in Table 1. As we can see, our proposed algorithm improves gradient complexity over previous work. In particular, with $k > 1$ and $|\mathcal{B}| = 1$, the gradient complexity of our algorithm outperforms that of Li et al. (2016). In the special case that $k = 1$ and $|\mathcal{B}| = 1$, our algorithm has the same gradient complexity as Li et al. (2016). In general, our algorithm provides more flexibility than Li et al. (2016) by incorporating mini-batch technique.

Theorem 5.4 immediately implies the following results.

Corollary 5.7. Under the same conditions of Theorem 5.4, the estimator $\widetilde{\boldsymbol{\beta}}^{(\ell)}$ from Algorithm 1 satisfies

$$\mathbb{E}\|\widetilde{\boldsymbol{\beta}}^{(\ell)} - \boldsymbol{\beta}^*\|_2 \leq \underbrace{\alpha^{\ell/2}\sqrt{\frac{2\big[F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)\big]}{\rho_-(\widetilde{s})}}}_{\text{Optimization Error}} + \underbrace{\left(\frac{2}{\rho_-(\widetilde{s})} + \sqrt{\frac{3\eta}{\gamma\rho_-(\widetilde{s})(1-\alpha)}}\right)\sqrt{\widetilde{s}}\|\nabla F(\boldsymbol{\beta}^*)\|_\infty}_{\text{Statistical Error}}. \tag{5.2}$$

We have the following remark regarding the above result.

Remark 5.8. The right hand side of (5.2) consists of two terms. The first term is the optimization error, which goes to zero as ℓ increase, since $\alpha \in (0, 1)$. The second term corresponds to the statistical error, and is proportional to $\sqrt{\widetilde{s}}\|\nabla F(\boldsymbol{\beta}^*)\|_\infty$. Since $\widetilde{s} = s + s^*$ and $s = O(s^*)$, the statistical is actually in the order of $\sqrt{s^*}\|\nabla F(\boldsymbol{\beta}^*)\|_\infty$. Note that the statistical error of the regularized M estimators (Negahban et al., 2009; Loh and Wainwright, 2013) for sparse linear regression and generalized linear models, is also proportional to $\sqrt{s^*}\|\nabla F(\boldsymbol{\beta}^*)\|_\infty$. Theorem 5.7 suggests that our algorithm attains a linear rate of convergence to the true parameter, up to the statistical error. In other words, our algorithm linearly converges to a local optima, which enjoys good statistical property.

5.2 IMPLICATION FOR SPECIFIC STATISTICAL ESTIMATION PROBLEMS

We now turn to the consequences of our algorithm and general theory for specific statistical estimation problems that arise in applications. In particular, we show the theoretical results by applying our theory to the two examples introduced in Section 3.

We begin with a corollary for the problem of sparse linear regression, as introduced in Example 3.1. We assume that the noise vector $\boldsymbol{\epsilon}$ in (3.1) is zero-mean and has sub-Gaussian tails.

Assumption 5.9. $\boldsymbol{\epsilon}$ is a zero mean random vector, and there exists a constant $\sigma > 0$ such that for any fixed $\|\mathbf{v}\|_2 = 1$, we have

$$\mathbb{P}\big(|\mathbf{v}^\top\boldsymbol{\epsilon}| > \delta\big) \leq 2\exp\left(-\frac{\delta^2}{2\sigma^2}\right) \quad \text{for all} \quad \delta > 0.$$

In addition, without loss of generality, we make an additional assumption on the design matrices $\mathbf{X}$ in (3.1).

Assumption 5.10. For all columns in $\mathbf{X} \in \mathbb{R}^{n\times d}$, we have $\|\mathbf{X}_{*j}\|_2 \leq \sqrt{n}$, where $\mathbf{X}_{*j}$ is the j-th column of $\mathbf{X}$.

Note that Assumption 5.10 is often made in the analysis of Lasso estimator (Negahban et al., 2009; Zhang et al., 2009).

Corollary 5.11. Under the same conditions as Corollary 5.7, if Assumptions 5.9 and 5.10 hold, then with probability at least $1 - 1/d$, the estimator $\widetilde{\boldsymbol{\beta}}^{(\ell)}$ from Algorithm 1 for sparse linear regression in (3.2) satisfies

$$\mathbb{E}\|\widetilde{\boldsymbol{\beta}}^{(\ell)} - \boldsymbol{\beta}^*\|_2 \leq \underbrace{\alpha^{\ell/2}\sqrt{\frac{2\big[F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)\big]}{\rho_-(\widetilde{s})}}}_{\text{Optimization Error}} + \underbrace{C\left(\frac{2}{\rho_-(\widetilde{s})} + \sqrt{\frac{3\eta}{\gamma\rho_-(\widetilde{s})(1-\alpha)}}\right)\sigma\sqrt{\frac{s^*\log d}{n}}}_{\text{Statistical Error}}, \quad (5.3)$$

where σ is the variance proxy of the sub-Gaussian random vector $\boldsymbol{\epsilon}$.

Corollary 5.11 suggests that when applying our algorithm to sparse linear regression, it achieves $O(\sqrt{s^*\log d/n})$ statistical error. It matches the minimax optimal rate for sparse linear regression (Raskutti et al., 2011).

We then provide a corollary for the problem of sparse generalized linear model estimation, as introduced in Example 3.2. For generalized linear model, we need the following assumption on its link function $\Phi(t)$, which is introduced in (3.3).

Assumption 5.12. There exists one $\alpha_u > 0$ such that the second derivative of the link function satisfies $\Phi''(t) \leq \alpha_u$ for all $t \in \mathbb{R}$.

Similar assumption has been made in Loh and Wainwright (2013).

Corollary 5.13. Under the same conditions as Corollary 5.7, if Assumptions 5.10 and 5.12 hold, then with probability at least $1-1/d$, the estimator $\widetilde{\boldsymbol{\beta}}^{(\ell)}$ from Algorithm 1 for sparse generalized linear models in (3.4) satisfies

$$\mathbb{E}\|\widetilde{\boldsymbol{\beta}}^{(\ell)} - \boldsymbol{\beta}^*\|_2 \leq \underbrace{\alpha^{\ell/2}\sqrt{\frac{2\big[F(\widetilde{\boldsymbol{\beta}}^{(0)}) - F(\boldsymbol{\beta}^*)\big]}{\rho_-(\widetilde{s})}}}_{\text{Optimization Error}} + \underbrace{C\left(\frac{2}{\rho_-(\widetilde{s})} + \sqrt{\frac{3\eta}{\gamma\rho_-(\widetilde{s})(1-\alpha)}}\right)\alpha_u\sqrt{\frac{s^*\log d}{n}}}_{\text{Statistical Error}}, \quad (5.4)$$

where α_u is an upper bound on the second derivative of the link function $\Phi(t)$.

Corollary 5.13 demonstrates that when applying our algorithm to sparse generalized linear models, it achieves $O(\sqrt{s^*\log d/n})$ statistical error rate. It is also minimax rate-optimal.

6 EXPERIMENTS

In this section, we apply Algorithm 1 to the two examples discussed in Section 3, and present numerical results on both synthetic and large-scale real datasets to verify the performance of the proposed algorithm, and compare it with state-of-the-art sparsity cardinality constraint methods.

6.1 BASELINE METHODS

We compare our algorithm with several state-of-the-art baseline methods: (1) gradient descent with hard thresholding (GraHTP) by Yuan et al. (2013) ; (2) stochastic variance reduced gradient with hard thresholding by Li et al. (2016) (SVRGHT); (3) Our proposed accelerated stochastic block coordinate gradient descent with hard thresholding (ASBCDHT) with batch size $|\mathcal{B}| = 1$; and (4) Our proposed accelerated stochastic block coordinate descent with hard thresholding (ASBCDHT) with batch size $|\mathcal{B}| = 10$. Since our algorithm involves coordinate block, we set the block number as $k = 10$, where each block has (almost) the same number of coordinates. In addition, SVRGHT and ASBCDHT are based on mixed (partial) gradients, hence we need to specify the number of iterations for the inner loop. We simply choose $m = n$ since our theory demonstrates that m should be chosen as $\Omega(\kappa_{\widetilde{s}})$.

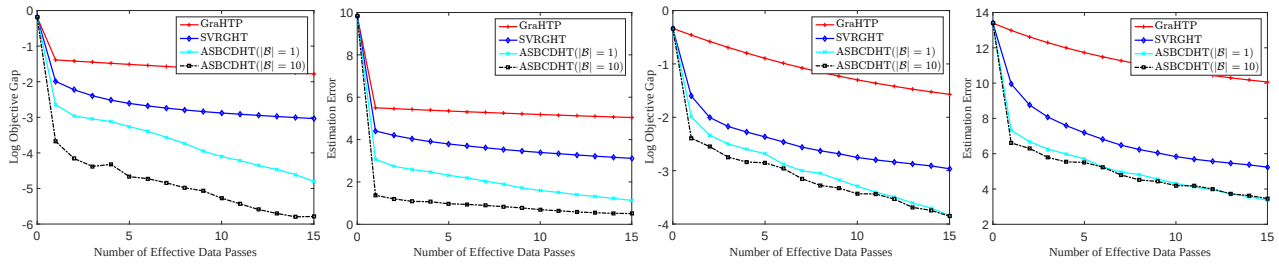
In order to fairly compare the above algorithms, we notice that at each iteration of GradHTP and SVRGHT, the gradient is updated with respect to all coordinates. When in our algorithm, at each iteration of Algorithm 1 the gradient is updated with respect to only a sampled coordinate block among all coordinates, so the computational cost is lower than that of gradient descent per iteration. Therefore, comparing algorithms that update the gradient with respect to different numbers of coordinates per iteration should be based on the same number of entire data passes (the least possible iterations for passing through the entire data set with respect to all coordinates).

6.2 SPARSE LINEAR REGRESSION

We first investigate the sparsity constrained linear regression problem in (3.2).

6.2.1 Synthetic Data

We generate an $n \times d$ design matrix $\mathbf{X}$ with rows drawn independently from a multivariate normal distribution $N(\mathbf{0}, \boldsymbol{\Sigma})$, where each element of $\boldsymbol{\Sigma}$ is defined by $\Sigma_{ij} = 0.6^{|i-j|}$. The true regression coefficient vector $\boldsymbol{\beta}^*$ has s^* nonzero entries that are drawn independently from the standard normal distribution. The response vector is generated by $\mathbf{y} = \mathbf{X}^\top\boldsymbol{\beta}^* + \boldsymbol{\epsilon}$, where each entry of $\boldsymbol{\epsilon}$ follows a normal distribution with zero mean and variance $\sigma^2 = 0.01$. In this part, we test our proposed algorithm



(a) (b) (c) (d)

Figure 1: Comparison of different algorithms for sparsity constrained sparse linear regression on the two synthetic datasets: (1) $n = 1000, d = 2000, s^* = 100$ (shown in (a) and (b)); (2) $n = 5000, d = 10000, s^* = 500$ (shown in (c) and (d)). (a) and (c) show the logarithm of the function value gap for the two datasets. (b) and (d) demonstrate the estimation error for the two datasets.

Table 2: Regression on E2006-TFIDF: MSE comparison of algorithms for the same entire effective data passes over 10 replications. The boldfaced results denote the lowest MSE among all the algorithms for the same entire effective data passes.

ASBCDHT($\lvert\mathcal{B}\rvert$ =10)	**0.7003**±0.1118	**0.6769**±0.0806	**0.6627**±0.0626	**0.6519**±0.0519	**0.6426**±0.0415

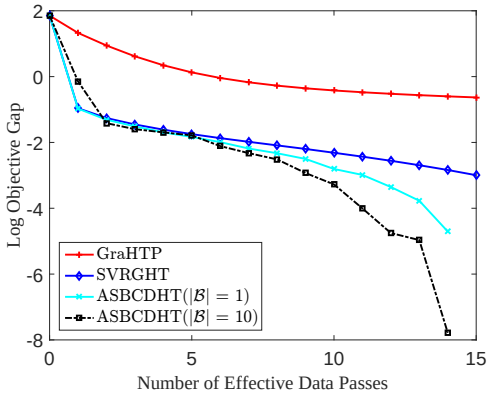

Figure 2: Comparison of different algorithms in terms of the logarithm of objective function value gap on E2006-TFIDF dataset.

along with with the state-of-the-art algorithms in two different settings: (1) $n = 1000, d = 2000, s^* = 100$; and (2) $n = 5000, d = 10000, s^* = 500$. Each experiment is repeated for 10 times. For each algorithm, we plot the logarithm of the objective function value gap and the estimation error $\|\boldsymbol{\beta}^{(t)} - \boldsymbol{\beta}^*\|_2$ for comparison. The sparsity parameter s is set to $s = 1.2s^*$ for all the algorithms according to the theory. The step size η of different algorithms is tuned by cross validation.

In Figure 1, we compare the logarithm of the function value gap and the estimation error in the above two datasets for all algorithms. Figure 1 (a) and (c) demonstrate that the optimization error decreases to zero at a linear rate while 1 (b) and (d) show that the estimation error of the estimator converges to certain level after some number of effective data passes. This is consistent with our theory in Corollary 5.11 that the estimation error of our algorithm consists of two terms: the optimization error that goes to zero, and the statistical error that depends on the problem parameters (d, n, s^* and so on). From Figure 1, it is obvious that our proposed algorithm outperforms other state-of-the-art algorithms in estimation error after the same number of effective data passes. Also note that when the data size is relatively small, our algorithm with batch size equals 10 performs better than the case when batch size equals 1, while this advantage decays as the data size grows. This is probably because the mini-batch sampling is more advantageous when the data are relatively small.

6.2.2 E2006-TFIDF Data

We use E2006-TFIDF dataset to test the sparsity constrained linear regression, which predicts risk from financial reports from thousands of publicly traded U.S. companies (Kogan et al., 2009). It contains $16,087$ training instances, $3,308$ testing instances and we randomly sample $50,000$ features for this experiment. In this section, we choose $s = 2000$ and compare all algorithms using mean square error (MSE) for 15 entire effective data passes over 10 replications. The step size η is chosen by cross validation on the training data.

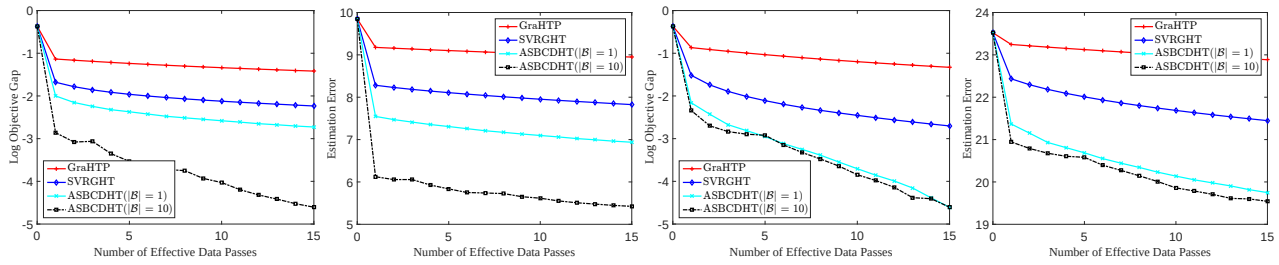

Figure 3: Comparison of different algorithms for sparsity constrained sparse logistic regression on the two synthetic datasets: (1) $n = 1000, d = 2000, s^* = 100$ (shown in (a) and (b)); (2) $n = 5000, d = 10000, s^* = 500$ (shown in (c) and (d)). (a) and (c) show the logarithm of the function value gap for the two datasets. (b) and (d) are the estimation error for the two datasets.

Table 3: Classification on RCV1: classification error comparison of algorithms for the same entire effective data passes over 10 replications. The boldfaced results denote the lowest classification error among all the algorithms for the same entire effective data passes.

Method	#Data Passes=3	#Data Passes=6	#Data Passes=9	#Data Passes=12	#Data Passes=15
GraHTP	0.0758	0.0748	0.0739	0.0733	0.0727
SVRGHT	0.0848±0.0043	0.0763±0.0034	0.0708±0.0029	0.0677±0.0025	0.0671±0.0020
ASBCDHT($\lvert\mathcal{B}\rvert$ =1)	0.0662±0.0044	0.0648±0.0025	0.0644±0.0019	0.0642±0.0021	0.0639±0.0021
ASBCDHT($\lvert\mathcal{B}\rvert$ =10)	**0.0550**±0.0043	**0.0542**±0.0034	**0.0539**±0.0029	**0.0534**±0.0025	**0.0527**±0.0020

Figure 2 illustrates the logarithm of the objective function value gap for all the baseline algorithms and ours. We can see that our algorithm converges faster than the other baselines and our algorithm converges to much smaller objective function value than the other algorithms. In addition, Table 2 shows the mean value as well as the standard error of MSE for all the algorithms with respect to the number of effective data passes. Since there is no randomness in GraHTP, its standard error is zero. We can see that our algorithm attains much smaller mean square error than the other baseline algorithms for the same entire effective data passes. In particular, when the number of data passes equals 3, 6, 9 and 12, our ASBCDHT with batch size $\mathcal{B} = 10$ achieves the lowest MSE; and when the number of data passes equals 15, our ASBCDHT with batch size $\mathcal{B} = 1$ achieves the best performance.

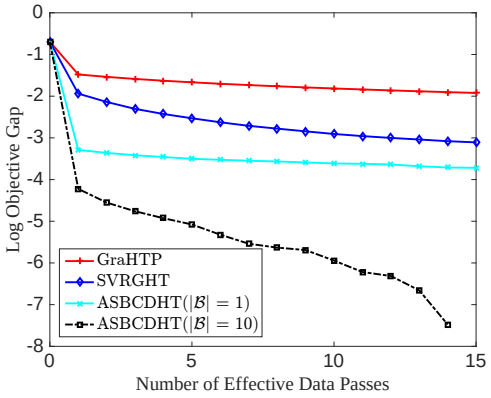

Figure 4: Comparison of different algorithms in terms of the logarithm of the objective function value gap on RCV1 dataset.

6.3 SPARSE LOGISTIC REGRESSION

We then evaluate the sparsity constrained generalized linear model, by considering a particular instance of sparse generalized linear model, i.e., sparse logistic regression. Its estimator is given by

$$\min_{\boldsymbol{\beta}\in\mathbb{R}^d} \frac{1}{n}\sum_{i=1}^{n}\left[-y_i\cdot\mathbf{x}_i^\top\boldsymbol{\beta}+\log\left(1+\exp(\mathbf{x}_i^\top\boldsymbol{\beta})\right)\right]$$
$$\text{subject to} \quad \|\boldsymbol{\beta}\|_0 \le s,$$

where $y_i \in \{0, 1\}$. Similar estimator has been studied by Yuan et al. (2013).

6.3.1 Synthetic Data

We generate an $n \times d$ design matrix $\mathbf{X}$ with rows drawn independently from a multivariate normal distribution $N(\mathbf{0}, \mathbf{I})$, where $\mathbf{I}$ is a $d \times d$ identity matrix. The true regression coefficient vector $\boldsymbol{\beta}^*$ has s^* nonzero entries that are drawn independently from the standard normal distribution. Each response variable is generated from the logistic distribution

$$y_i = \begin{cases} 1, & \text{with probability } 1/(1+\exp(\mathbf{x}_i^\top\boldsymbol{\beta}^*)), \\ 0, & \text{with probability } 1-1/(1+\exp(\mathbf{x}_i^\top\boldsymbol{\beta}^*)). \end{cases}$$

In this part, we test our proposed algorithm along with the baseline algorithms in two different datasets: (1) $n = 1000, d = 2000, s^* = 100$; and (2) $n = 5000, d = 10000, s^* = 500$. Each experiment is repeated for 10 times and for all algorithms we plot the logarithm of the objective function value gap and the estimation error $\|\boldsymbol{\beta}^{(t)} - \boldsymbol{\beta}^*\|_2$ for comparison. The sparsity parameter s is again set to $s = 1.2s^*$. And the step size η is chosen by cross validation.

Figure 3 illustrates the logarithm of the function value gap and the estimation error $\|\boldsymbol{\beta}^{(t)} - \boldsymbol{\beta}^*\|_2$. The four sub-figures in Figure 3 demonstrate the similar trends as in Figure 1. Our proposed algorithm outperforms the other baseline algorithms by a large margin.

6.3.2 RCV1 Data

In order to evaluate the sparsity constrained logistic regression, we use RCV1 dataset, which is a Reuters Corpus Volume I data set for text categorization research (Lewis et al., 2004). Reuters Corpus Volume I (RCV1) is an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. This dataset contains $20,242$ training instances, $677,399$ testing instances and $47,236$ features. We use the whole training set and a subset of the test set, which contains $20,000$ testing instances for our experiment. In detail, we choose $s = 500$ and compare all algorithms in terms of their classification error on the test set for 15 entire effective data passes over 10 replications. The step size η is chosen by cross validation on the training set.

Table 3 demonstrates the classification results for the four algorithms including ours. It is obvious that our proposed algorithm achieves the lowest test error on RCV1 dataset on all periods of effective data passes and beats the other state-of-the-art baseline algorithms. Figure 4 further illustrates the logarithm of the objective function value gap for both the baseline algorithms and ours. This clearly demonstrates the superiority of our algorithm.

7 CONCLUSIONS

We proposed an accelerated stochastic block coordinate descent algorithm for sparsity constrained nonconvex optimization problems. We show that the algorithm enjoys a linear rate of convergence to the unknown true parameter up to the statistical error. Experiments on both synthetic and real datasets verify the effectiveness of our algorithm.

Abstract

Bipartite ranking aims to maximize the area under the ROC curve (AUC) of a decision function. To tackle this problem when the data appears sequentially, existing online AUC maximization methods focus on seeking a point estimate of the decision function in a linear or predefined single kernel space, and cannot learn effective kernels automatically from the streaming data. In this paper, we first develop a Bayesian multiple kernel bipartite ranking model, which circumvents the kernel selection problem by estimating a posterior distribution over the model weights. To make our model applicable to streaming data, we then present a kernelized online Bayesian passive-aggressive learning framework by maintaining a variational approximation to the posterior based on data augmentation. Furthermore, to efficiently deal with large-scale data, we design a fixed budget strategy which can effectively control online model complexity. Extensive experimental studies confirm the superiority of our Bayesian multi-kernel approach.

1 INTRODUCTION

Aiming to learn a ranking decision function that is likely to place a positive instance before most negative ones, bipartite ranking [Agarwal and Roth, 2005; Clémençon *et al.*, 2008; Kotlowski *et al.*, 2011] is especially useful for imbalanced data sets, where the area under the ROC curve (AUC) [Hanley and McNeil, 1982; Bradley, 1997; Cortes and Mohri, 2004] is a commonly used evaluation metric. Recently, several online AUC maximization algorithms with pairwise loss functions were proposed to tackle this problem when the data appears sequentially [Zhao *et al.*, 2011a,b; Zhao and Hoi, 2012; Yang *et al.*, 2013; Gao *et al.*, 2013; Hu *et al.*, 2015; Ding *et al.*, 2015]. Furthermore, the generalization performance of online learning algorithms with pairwise loss functions have been investigated in [Wang *et al.*, 2012; Kar *et al.*, 2013].

Nevertheless, existing work only focus on seeking a point estimate of the decision function in a linear or predefined single kernel space, and cannot learn effective kernels automatically from the streaming data. As well known, choosing an appropriate kernel for real-world situations usually is not easy for users without enough domain knowledge. Multiple Kernel Learning (MKL) [Rakotomamonjy *et al.*, 2008; Gönen and Alpaydın, 2011] can circumvent such a problem by learning an optimal linear combination of a set of predefined kernels. However, conventional online MKL algorithms [Luo *et al.*, 2010; Hoi *et al.*, 2013; Sahoo *et al.*, 2014] are unsuitable for a direct use since AUC is a metric represented by the sum of pairwise losses between instances from different classes. More importantly, existing online MKL methods typically maintain a point estimate of their model weights, which can be affected seriously by online outliers and usually needs a tough tuning process for their penalty parameters.

Focusing on these problems, we first develop a Bayesian Bipartite Ranking model with Multiple Kernels (B^2RMK), which circumvents the kernel selection problem by estimating a posterior distribution over the model weights. Specifically, B^2RMK imposes global-local sparsity shrinkage priors on the weights of kernels and support vectors and adopts a margin-based ranking pseudo-likelihood function that mimics the pairwise hinge loss and can be expressed as a location-scale mixture of normals. Within the Bayesian formalism, the new model can automatically infer the weight penalty parameters and naturally alleviate overfitting to small training sets via model averaging over the posterior.

To make our model applicable to streaming data, we then present a kernelized online Bayesian Passive-Aggressive (PA) [Crammer *et al.*, 2006] learning framework. As far as we know, this is the first effort to perform online Bayesian learning with multiple kernels. The key of Bayesian PA

is to maintain a posterior distribution at each time step. Unfortunately, exact posterior inference of B^{2}RMK is intractable, so we devise an efficient data augmentation [Tanner and Wong, 1987] based variational method to approximate the posterior with mean-field assumption.

Unlike most existing online MKL methods [Jin *et al.*, 2010; Luo *et al.*, 2010; Hoi *et al.*, 2013], which don't bound their model complexity and require more and more memory and computation when the data arrives sequentially, online B^{2}RMK only maintains two fixed-size buffers (one for positive instances, and another for negative ones) to store the learned support vectors, thus are much more efficient for large-scale data sets. When a buffer is full, we propose a principled strategy to update it, which can guarantee that the most important support vectors won't be discarded. As in [Hu *et al.*, 2015], smooth updating and compensation schemes are employed to further boost performance when updating the buffer. Extensive experimental studies confirm the superiority of our online Bayesian multi-kernel approach.

2 PRELIMINARIES

To better motivate our work, we first introduce some preliminaries, including bipartite ranking, AUC optimization and MKL. Let $\mathcal{X} = \{x \in \mathbb{R}^d\}$ be the instance space, $\mathcal{Y} = \{+1, -1\}$ be the label set, and $\mathbf{S} = \mathbf{S}_+ \cup \mathbf{S}_-$ be a set of training instances, where $\mathbf{S}_+$ and $\mathbf{S}_-$ include N_+ positive instances and N_- negative instances, respectively. The goal of bipartite ranking is to learn a ranking decision function that is likely to place a positive instance before most negative ones. AUC is a commonly used evaluation metric for bipartite ranking. For a ranking decision function $f : \mathcal{X} \to \mathbb{R}$, its AUC measure on $\mathbf{S}$ is defined as:

$$\mathrm{AUC}(f) = 1 - \frac{\sum_{i=1}^{N_+}\sum_{j=1}^{N_-}\mathbb{I}\big(f(x_i^+)\le f(x_j^-)\big)}{N_+N_-}$$

where $\mathbb{I}(\pi)$ is the indicator function that equals 1 when π is true and 0 otherwise. Since directly maximizing $\mathrm{AUC}(f)$ leads to a difficult combinatorial optimization problem, in practice, the indicator function is usually replaced by its convex surrogate, e.g., pairwise hinge loss [Hu *et al.*, 2015; Zhao *et al.*, 2011a] and squared loss [Gao *et al.*, 2013], which leads to minimizing the following regularized pairwise learning task [Christmann and Zhou, 2015]:

$$\mathcal{L}(f) = \frac{c}{2}\|f\|_{\mathcal{H}}^2 + \sum_{i=1}^{N_+}\sum_{j=1}^{N_-}\ell\left(f; x_i^+, x_j^-\right)$$

where $\|\cdot\|_{\mathcal{H}}$ denotes the norm in Reproducing Kernel Hilbert Space (RKHS), $\ell(\cdot)$ is the convex surrogate loss function and c is the regularization parameter balancing the model complexity and training errors.

A kernelized ranking decision function $f : \mathcal{X} \to \mathbb{R}$ that is used to predict the ranking score of a test instance x_i can be written as

$$f(x_i) = \boldsymbol{a}^\top \boldsymbol{k}_i + b$$

where $\boldsymbol{a} = [a_1, \ldots, a_N]^\top$ denotes the vector of weights assigned to each training instance ($N = N_+ + N_-$); b is the bias; and $\boldsymbol{k}_i = [\mathfrak{K}(x_1, x_i), \ldots, \mathfrak{K}(x_N, x_i)]^\top$, where $\mathfrak{K} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a kernel function that measures the similarities between x_i and x_j, $j = 1, 2, \ldots, N$.

An important problem in single kernel learning is to prespecify the kernel parameters, which is often done in an empirical way. This problem can be circumvented by using the MKL framework [Rakotomamonjy *et al.*, 2008], which is a popular technique for learning an optimal linear combination of a set of predefined kernels. MKL algorithms basically use a weighted sum of P kernels $\{\mathfrak{K}_m : \mathcal{X}\times\mathcal{X} \to \mathbb{R}\}_{m=1}^P$ to get the following multi-kernel ranking decision function:

$$f(x_i) = \boldsymbol{a}^\top\left(\sum_{m=1}^{P} e_m \boldsymbol{k}_{m,i}\right) + b = \sum_{m=1}^{P} e_m \boldsymbol{a}^\top \boldsymbol{k}_{m,i} + b$$

where $\boldsymbol{k}_{m,i} = [\mathfrak{K}_m(x_1, x_i), \ldots, \mathfrak{K}_m(x_N, x_i)]^\top$, and e_m denotes the weight assigned to the m-th kernel.

In the sequel, the m-th $N \times N$ kernel matrix will be denoted by $\mathbf{K}_m$, and the vector of ranking scores of positive instances and negative instances will be denoted by $\mathbf{f}_+$ and $\mathbf{f}_-$, respectively, and $\mathbf{f} = \left[\mathbf{f}_+^\top \;\; \mathbf{f}_-^\top\right]^\top$.

3 BAYESIAN MULTIPLE KERNEL BIPARTITE RANKING

In this section, we formulate a probabilistic model for multi-kernel bipartite ranking. We impose a fairly general global-local shrinkage prior on the sample weights and kernel combination weights to keep the sparsity of them. Since pairwise hinge loss makes traditional Bayesian analysis hard, we then define a margin-based ranking pseudo-likelihood function to overcome this situation. After introducing a set of augmented variables and making the mean-field assumption, the intractable inference problem of our model can be transformed into a tractable one.

3.1 BAYESIAN SPARSITY SHRINKAGE PRIOR

Similar as in kernelized SVM, the sample weights $\boldsymbol{a}$ is often expected to be sparse for selecting support vectors actually needed in decision function. From the Bayesian perspective, a fairly general global-local shrinkage prior is the Three Parameter Beta Normal ($\mathcal{TPBN}$) [Armagan *et al.*, 2011], which favors strong shrinkage of small signals while having heavy tails to avoid over-shrinkage of the larger signals. Thus, concentrated at zero, $\mathcal{TPBN}$ can yield sparse model representations by suppressing unnecessary support vectors. In this paper, we select $\mathcal{TPBN}$ as the sparsity shrinkage prior due to its better mixing properties than

priors such as spike-slab and Laplace. Besides, $\mathcal{TPBN}$ works well for high-dimensional settings since it can specify global and local properties independently. Assuming $\boldsymbol{a} \sim \prod_{i=1}^{N} \mathcal{TPBN}(a_i|\alpha_a, \beta_a, \phi)$, we have the following hierarchical prior:

$$\begin{aligned} a_i|\lambda_i &\sim \mathcal{N}(a_i|0, \lambda_i), \\ \lambda_i|\xi_i &\sim \Gamma(\lambda_i|\alpha_a, \xi_i), \qquad \xi_i|\phi \sim \Gamma(\xi_i|\beta_a, \phi), \\ \phi|\eta &\sim \Gamma(\phi|1/2, \eta), \qquad \eta \sim \Gamma(\eta|1/2, 1), \end{aligned}$$

where $\Gamma(\cdot)$ is the Gamma distribution (with shape-rate parameterization). Note that sample-level sparsity can be tuned by assigning suitable values to the hyper-parameters (α_a, β_a). Setting $\alpha_a = \beta_a = 0.5$, a special case of $\mathcal{TPBN}$ corresponds to the horseshoe prior.

Similarly, sparsity on kernel combination weights $\boldsymbol{e} = [e_1, \ldots, e_P]^\top$ is also desirable for better interpretability. So, we assume $\boldsymbol{e} \sim \prod_{m=1}^{P} \mathcal{TPBN}(e_m|\alpha_e, \beta_e, \rho)$, involving latent variables ω_m, φ_m and τ. Kernel-level sparsity can also be tuned by changing (α_e, β_e).

With the above priors on model weights, we assume the ranking scores of our B^{2}RMK model have the following distributions,

$$\begin{aligned} \mathbf{G}|\boldsymbol{a}, \{\mathbf{K}_m\}_{m=1}^{P}, \upsilon &\sim \prod_{m=1}^{P}\prod_{i=1}^{N} \mathcal{N}\left(g_{mi}|\boldsymbol{a}^\top \boldsymbol{k}_{m,i}, \upsilon^{-1}\right), \\ \mathbf{f}_+|\boldsymbol{e}, \mathbf{G}, b, c &\sim \prod_{i=1}^{N_+} \mathcal{N}\left(f_i|\boldsymbol{e}^\top \boldsymbol{g}_{\cdot i} + b, c^{-1}\right), \\ \mathbf{f}_-|\boldsymbol{e}, \mathbf{G}, b, c &\sim \prod_{j=1}^{N_-} \mathcal{N}\left(f_j|\boldsymbol{e}^\top \boldsymbol{g}_{\cdot j} + b, c^{-1}\right), \end{aligned}$$

where $\upsilon \sim \Gamma(\upsilon|\alpha_\upsilon, \beta_\upsilon)$, $b|\gamma \sim \mathcal{N}\left(b|0, \gamma^{-1}\right)$, $\gamma \sim \Gamma(\gamma|\alpha_\gamma, \beta_\gamma)$, $c \sim \Gamma(c|\alpha_c, \beta_c)$. The intermediate variables g_{mi} $(m = 1, \ldots, P,\ i = 1, \ldots, N)$ are introduced to make the inference procedures efficient. The $P \times N$ matrix of intermediate variables is denoted by $\mathbf{G}$, and the m-th row and i-th column of $\mathbf{G}$ by $\boldsymbol{g}_{m\cdot}$ and $\boldsymbol{g}_{\cdot i}$, respectively. In the sequel, all hyper-parameters will be denoted by $\Upsilon = \{\alpha_a, \beta_a, \alpha_e, \beta_e, \alpha_\upsilon, \beta_\upsilon, \alpha_\gamma, \beta_\gamma, \alpha_c, \beta_c\}$, while the priors by $\Psi = \{\boldsymbol{\lambda}, \boldsymbol{\xi}, \phi, \eta, \boldsymbol{\omega}, \boldsymbol{\varphi}, \rho, \tau, \upsilon, \gamma, c\}$ and the remaining variables by $\Omega = \{\boldsymbol{a}, b, \boldsymbol{e}, \mathbf{G}, \mathbf{f}_+, \mathbf{f}_-\}$.

3.2 MARGIN-BASED RANKING LIKELIHOOD

Several loss functions are available for bipartite ranking. Among them, pairwise hinge loss is the tightest convex upper bound on the rank loss, which is beneficial for better performance and faster convergence. Specifically, the pairwise hinge loss on data set $\mathbf{S}$ can be written as

$$\ell(f; \mathbf{S}) = \sum_{i=1}^{N_+}\sum_{j=1}^{N_-} \max\left(0, 1 - f(x_i^+) + f(x_j^-)\right),$$

which does not lend itself to a convenient description of a likelihood function. To overcome this situation, we propose to define a margin-based ranking pseudo-likelihood

$$L(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^{N_+}\prod_{j=1}^{N_-} \exp\left(-2\max(0, 1 - f_i + f_j)\right),$$

where $\mathbf{y}$ is the label vector and has been divided out. With $\mathcal{TPBN}$ priors and the above margin-based ranking pseudo-likelihood, we can get the following pseudo posterior distribution using Bayes' rule

$$p(\Psi, \Omega|\mathbf{y}) = L(\mathbf{y}|\mathbf{f})p(\Omega|\Psi)p(\Psi)/p(\mathbf{y}|\Upsilon),$$

where $p(\mathbf{y}|\Upsilon)$ is the normalization constant. Note that it is hard to compute $p(\Psi, \Omega|\mathbf{y})$ analytically due to the max function in $L(\mathbf{y}|\mathbf{f})$. Fortunately, we can re-express $L(\mathbf{y}|\mathbf{f})$ as the product of $N_+ \cdot N_-$ location-scale mixtures of normals (see Supplement Section A) based on data augmentation idea [Tanner and Wong, 1987]

$$L(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^{N_+}\prod_{j=1}^{N_-} \int_0^\infty \frac{\exp\left(\frac{(\theta_{ij}+1-f_i+f_j)^2}{-2\theta_{ij}}\right)}{\sqrt{2\pi\theta_{ij}}}\, d\theta_{ij}, \quad (1)$$

where θ_{ij} is the augmented variable. In the following, the matrix of augmented variables will be denoted by $\boldsymbol{\theta}$, and the i-th row and j-th column of $\boldsymbol{\theta}$ by $\boldsymbol{\theta}_{i\cdot}$ and $\boldsymbol{\theta}_{\cdot j}$, respectively. (1) indicates that the posterior distribution $p(\Psi, \Omega|\mathbf{y})$ can be expressed as the marginal of a higher-dimensional distribution that includes the augmented variables. Therefore, the augmented posterior distribution has the form

$$p(\Psi, \Omega, \boldsymbol{\theta}|\mathbf{y}) = \frac{L(\mathbf{y}, \boldsymbol{\theta}|\mathbf{f})p(\Omega|\Psi)p(\Psi)}{p(\mathbf{y}|\Upsilon)}, \quad (2)$$

where the unnormalized joint distribution of $\mathbf{y}$ and $\boldsymbol{\theta}$ conditioned on $\mathbf{f}$ is

$$L(\mathbf{y}, \boldsymbol{\theta}|\mathbf{f}) = \prod_{i=1}^{N_+}\prod_{j=1}^{N_-} \frac{1}{\sqrt{2\pi\theta_{ij}}} \exp\left(\frac{(\theta_{ij} + 1 - f_i + f_j)^2}{-2\theta_{ij}}\right).$$

3.3 VARIATIONAL APPROXIMATE INFERENCE

Directly solving for the augmented posterior is intractable due to the normalization constant $p(\mathbf{y}|\Upsilon)$, thus we appeal to the mean-field variational approximate Bayesian inference method, which is generally much more efficient than the Markov Chain Monte Calo (MCMC) based sampling methods. Specifically, we assume there are a family of factorable and free-form variational distributions

$$\begin{aligned} q(\Psi, \Omega, \boldsymbol{\theta}) = q(\boldsymbol{\lambda})q(\boldsymbol{\xi})q(\phi)q(\eta)q(\boldsymbol{\omega})q(\boldsymbol{\varphi})q(\rho)q(\tau)q(\upsilon) \\ \cdot q(\gamma)q(c)q(\boldsymbol{a})q(b, \boldsymbol{e})q(\mathbf{G})q(\mathbf{f}_+)q(\mathbf{f}_-)q(\boldsymbol{\theta}), \end{aligned}$$

and the objective is to get the optimal one which minimizes the Kullback-Leibler (KL) divergence between the approximating distribution and the target posterior, i.e.,

$$\min_{q(\Psi,\Omega,\boldsymbol{\theta})\in\mathcal{P}} \mathrm{KL}\left(q(\Psi, \Omega, \boldsymbol{\theta})\|p(\Psi, \Omega, \boldsymbol{\theta}|\mathbf{y})\right),$$

where $\mathcal{P}$ is the space of probability distributions. To this end, we first initialize the moments of all factor distributions of $q(\Psi, \Omega, \boldsymbol{\theta})$ appropriately and then iteratively optimize each of the factors in turn using the current estimates for all of the other factors. It can be shown that when keeping all other factors fixed the optimal distribution $q^*(\boldsymbol{a})$ satisfies

$$q^*(\boldsymbol{a}) \propto \exp\{\mathbb{E}_{-\boldsymbol{a}}[\log p(\Psi, \Omega, \boldsymbol{\theta}, \{\mathbf{K}_m\}_{m=1}^P, \mathbf{y})]\}, \quad (3)$$

where $\mathbb{E}_{-\boldsymbol{a}}$ denotes the expectation with respect to $p(\Psi, \Omega, \boldsymbol{\theta})$ over all variables except for $\boldsymbol{a}$, and $p(\Psi, \Omega, \boldsymbol{\theta}, \{\mathbf{K}_m\}_{m=1}^P, \mathbf{y})$ is the joint distribution of data and all variables, which has the following form

$$\begin{aligned} &p(\Psi, \Omega, \boldsymbol{\theta}, \{\mathbf{K}_m\}_{m=1}^P, \mathbf{y}) = \\ &\quad L(\mathbf{y}, \boldsymbol{\theta}|\mathbf{f}) p(\mathbf{f}|\boldsymbol{e}, \mathbf{G}, b, c) p(\mathbf{G}|\boldsymbol{a}, \{\mathbf{K}_m\}_{m=1}^P, \upsilon) \\ &\quad \cdot p(\boldsymbol{a}|\boldsymbol{\lambda}) p(\boldsymbol{e}|\boldsymbol{\omega}) p(b|\gamma) p(\boldsymbol{\lambda}|\boldsymbol{\xi}) p(\boldsymbol{\xi}|\phi) p(\phi|\eta) p(\eta) \\ &\quad \cdot p(\boldsymbol{\omega}|\boldsymbol{\varphi}) p(\boldsymbol{\varphi}|\rho) p(\rho|\tau) p(\tau) p(\upsilon) p(\gamma) p(c). \end{aligned}$$

Expanding the right side of (3) and ignoring the terms unrelated to $\boldsymbol{a}$, we can further get[1]

$$\begin{aligned} q^*(\boldsymbol{a}) &\propto \exp\{\mathbb{E}_{-\boldsymbol{a}}[\log p(\mathbf{G}|\boldsymbol{a}, \{\mathbf{K}_m\}_{m=1}^P, \upsilon) + \log p(\boldsymbol{a}|\boldsymbol{\lambda})]\} \\ &= \mathcal{N}\left(\boldsymbol{\Sigma}_{\boldsymbol{a}} \left(\langle\upsilon\rangle \sum_{m=1}^P \mathbf{K}_m \langle \boldsymbol{g}_{m\cdot}^\top \rangle\right), \boldsymbol{\Sigma}_{\boldsymbol{a}}\right), \end{aligned}$$

where $\boldsymbol{\Sigma}_{\boldsymbol{a}} = \left(\langle\upsilon\rangle \sum_{m=1}^P \mathbf{K}_m \mathbf{K}_m^\top + \langle \Lambda_{\boldsymbol{\lambda}}^{-1} \rangle\right)^{-1}$ and $\Lambda_{\boldsymbol{\lambda}}^{-1} = \mathrm{diag}(\boldsymbol{\lambda})^{-1}$. Similarly, we can also get

$$q^*(b, \boldsymbol{e}) = \mathcal{N}\left(\Sigma_{(b,\boldsymbol{e})} \langle c \rangle \left[\mathbf{1}, \langle \mathbf{G} \rangle^\top\right]^\top \langle \mathbf{f} \rangle, \Sigma_{(b,\boldsymbol{e})}\right),$$

$$q^*(\mathbf{G}) = \prod_{i=1}^N \mathcal{N}\left(\mu_{\boldsymbol{g}_{\cdot i}}, \left(\langle c \rangle \langle \boldsymbol{e}\boldsymbol{e}^\top \rangle + \langle \upsilon \rangle \mathbf{I}\right)^{-1}\right),$$

$$q^*(\mathbf{f}_+) = \mathcal{N}\Big(\mu_{\mathbf{f}_+}, \Big(\sum_{j=1}^{N_-} \langle \Lambda_{\boldsymbol{\theta}_{\cdot j}}^{-1} \rangle + \langle c \rangle \mathbf{I}\Big)^{-1}\Big),$$

$$q^*(\mathbf{f}_-) = \mathcal{N}\Big(\mu_{\mathbf{f}_-}, \Big(\sum_{i=1}^{N_+} \langle \Lambda_{\boldsymbol{\theta}_{i\cdot}}^{-1} \rangle + \langle c \rangle \mathbf{I}\Big)^{-1}\Big),$$

$$q^*(\boldsymbol{\theta}) = \prod_{i=1}^{N_+} \prod_{j=1}^{N_-} \mathcal{GIG}\Big(\frac{1}{2}, 1, \langle (1 - f_i + f_j)^2 \rangle\Big),$$

where

$$\Sigma_{(b,\boldsymbol{e})} = \begin{bmatrix} \langle c \rangle N + \langle \gamma \rangle, & \langle c \rangle \mathbf{1}^\top \langle \mathbf{G}^\top \rangle \\ \langle c \rangle \langle \mathbf{G} \rangle \mathbf{1}, & \langle c \rangle \langle \mathbf{G}\mathbf{G}^\top \rangle + \langle \Lambda_{\boldsymbol{\omega}}^{-1} \rangle \end{bmatrix}^{-1},$$

$$\mu_{\boldsymbol{g}_{\cdot i}} = \Sigma_{\boldsymbol{g}_{\cdot i}} (\langle c \rangle (\langle f_i \rangle \langle \boldsymbol{e} \rangle - \langle b\boldsymbol{e} \rangle) + \langle \upsilon \rangle \mathbf{K}_i^\top \langle \boldsymbol{a} \rangle),$$

$$\mu_{\mathbf{f}_+} = \Sigma_{\mathbf{f}_+} (N_- \mathbf{1} + \langle \boldsymbol{\theta}^{-1} \rangle (\langle \mathbf{f}_- \rangle + \mathbf{1}) + \langle c \rangle (\langle \mathbf{G}_+^\top \rangle \langle \boldsymbol{e} \rangle + \langle b \rangle \mathbf{1})),$$

$$\mu_{\mathbf{f}_-} = \Sigma_{\mathbf{f}_-} (\langle \boldsymbol{\theta}^{-1} \rangle^\top (\langle \mathbf{f}_+ \rangle - \mathbf{1}) - N_+ \mathbf{1} + \langle c \rangle (\langle \mathbf{G}_-^\top \rangle \langle \boldsymbol{e} \rangle + \langle b \rangle \mathbf{1})).$$

[1]Here $\langle \cdot \rangle$ means the expectation operator, e.g., $\langle \upsilon \rangle$ means the expectation of υ over its current optimal variational distribution.

Note that, $\boldsymbol{\theta}^{-1}$ is the element-wise inversion of $\boldsymbol{\theta}$, and $\mathbf{G}_+$ ($\mathbf{G}_-$) denotes the part of $\mathbf{G}$ corresponding to positive (negative) instances. The detailed derivations of the above equations together with the equations for all other variables can be found in the Supplement Section B.

4 ONLINE B^{2}RMK LEARNING

The above batch B^{2}RMK model still suffers from efficiency problems, e.g., huge memory consumption in dealing with large data sets and time-consuming re-training when the data appears sequentially. Online Passive-Aggressive (PA) [Crammer *et al.*, 2006] learning is a principled way to solve such problems. However, it is less explored under the Bayesian framework. Here, we present a fixed budget strategy to conduct online multiple kernel PA learning in Bayesian manner. Our method can be seen as an extension of the linear framework in [Shi and Zhu, 2014], which studied online max-margin topic models.

In the online setting, what we truly care about is how to update the current model, on the arrival of a new data. So, assume we already have an existing B^{2}RMK model at the t-th trial. In the updating of the kernel-based ranking decision function, the main problem is to compute the Gram matrix of pairwise kernel evaluations between the historical instances and new arriving instance, and we have to store all the received historical instances, making it impractical for large-scale online learning tasks. We address this challenge by maintaining only a small number of received historical instances. Specifically, we define two buffers B_t^+ and B_t^- of size $|B_t^+|$ and $|B_t^-|$, for storing the learned important positive and negative support vectors at the t-th trial, respectively. These support vectors in B_t^+ and B_t^- are essential for constructing the ranking decision function at the $(t+1)$-th trial, thus are expected to keep track of the global information of the decision boundary. To this end, existing online MKL methods [Luo *et al.*, 2010; Hoi *et al.*, 2013] typically assume an infinite buffer. However, their naive treatment of storing all received historical instances, requires more and more memory and computation when the data arrives sequentially. On the contrary, we control the computational complexity of our Online B^{2}RMK (OB^{2}RMK) model by fixing the buffer size to an appropriate value, assuming that the performance of OB^{2}RMK increases gradually with the increase of the buffer and it will be saturated when the buffer is large enough. As will be seen in the experimental section, such assumptions are well validated. Overall, the proposed OB^{2}RMK consists of two key modules, i.e., buffer update and model update.

4.1 UPDATE BUFFER

How to maintain the buffers with the most informative support vectors to get better generalization performance is a

key challenge. Traditionally, First-In-First-Out (FIFO) and Reservoir Sampling (RS) are two typical stream oblivious policies to update the buffers and have demonstrated their effectiveness in online linear AUC maximization [Zhao *et al.*, 2011a]. However, FIFO and RS will cast off the important support vectors, thus will degrade the performance of the online learning algorithms. Compared with linear algorithms, this adverse impact will be more intense in the kernel-based algorithms which work with the Gram matrix of pairwise kernel evaluations [Yang *et al.*, 2013; Hu *et al.*, 2015]. In the following, we will propose a novel strategy to update the buffers for OB^{2}RMK, aiming to preserve the most important support vectors.

For the incoming new instance $(x_\star, y_\star)$, instead of counting its pairwise losses with all support vectors in the opposite buffer which is easily affected by outliers, we only count the pairwise losses with its k-nearest opposite support vectors X_k. This allows us to utilize the local information around $x_\star$ and improve the robustness of the ranking decision function [Hu *et al.*, 2015].

When the buffers B_t^+ and B_t^- are not full, the incoming new instance will be put into one of the buffers directly, thus the pairwise hinge loss at the $(t+1)$-th trial is

$$\ell(f; x_\star, X_k) = \begin{cases} \sum_{j=1}^{k} \max\left(0, 1 - f(x_\star) + f(x_j^-)\right), & y_\star = 1, \\ \sum_{i=1}^{k} \max\left(0, 1 - f(x_i^+) + f(x_\star)\right), & y_\star = -1. \end{cases}$$

When either buffer is full, one of the instances in this buffer should be discarded, to accommodate the incoming new instance. Recall that the $\mathcal{TPBN}$ prior concentrates at zero, thus a positive (negative) support vector x_i is likely to have a positive (negative) weight a_i to attain a discriminative decision function. Supposing B_t^+ (B_t^-) is full, we first search for a support vector x_r which has the smallest (largest) weight in the buffer. Instead of discarding x_r directly, we put x_r and $x_\star$ together to count the pairwise losses between them and X_k. This compensation scheme guarantees the useful information of x_r can be fully utilized before it is discarded. Hence, the pairwise hinge loss at the $(t+1)$-th trial is

$$\ell(f; x_\star, x_r, X_k) = \begin{cases} \sum_{j=1}^{k} \{\max(0, 1 - f(x_\star) + f(x_j^-)) \\ \qquad + \max(0, 1 - f(x_r) + f(x_j^-))\}, & y_\star = 1, \\ \sum_{i=1}^{k} \{\max(0, 1 - f(x_i^+) + f(x_\star)) \\ \qquad + \max(0, 1 - f(x_i^+) + f(x_r))\}, & y_\star = -1. \end{cases}$$

Concisely, the pairwise hinge loss at the $(t+1)$-th trial can be uniformly written as

$$\ell(f; x_\star, B_t) = \sum_{i=1}^{\tilde{N}_+} \sum_{j=1}^{\tilde{N}_-} \max\left(0, 1 - f(x_i^+) + f(x_j^-)\right),$$

where $B_t = B_t^+ \cup B_t^-$, and $\tilde{N}_+$ and $\tilde{N}_-$ are the number of positive and negative instances, respectively, in counting the pairwise hinge loss at the $(t+1)$-th trial. For example, we have $\tilde{N}_+ = 1, \tilde{N}_- = k$ when $y_\star = 1$ and B_t^+ was not full (i.e., without x_r), and $\tilde{N}_+ = 2, \tilde{N}_- = k$ when $y_\star = 1$ and B_t^+ was full (i.e., with x_r).

4.2 UPDATE MODEL

In online B^{2}RMK, the model parameters $\boldsymbol{a}$, b and $\boldsymbol{e}$ should vary with t, to update the ranking decision function. Note that the dimensionality of $\boldsymbol{a}$ will increase until the buffers are full, whereas b and $\boldsymbol{e}$ are always fixed-size.

4.2.1 Priors

Let $p_t(\boldsymbol{a}_t, b, \boldsymbol{e})$ denote the posterior distribution of $(\boldsymbol{a}, b, \boldsymbol{e})$ at the t-th trial, which will become a prior distribution at the $(t+1)$-th trial. Assuming $a_\star$ is the corresponding weight of $x_\star$ at the $(t+1)$-th trial. After imposing a $\mathcal{TPBN}$ prior on $a_\star$, i.e., $a_\star|\alpha_{a_\star}, \beta_{a_\star}, \phi_\star \sim \mathcal{TPBN}(a_\star|\alpha_{a_\star}, \beta_{a_\star}, \phi_\star)$, we have the hierarchical priors: $a_\star|\lambda_\star \sim \mathcal{N}(a_\star|0, \lambda_\star)$, $\lambda_\star|\xi_\star \sim \Gamma(\lambda_\star|\alpha_{a_\star}, \xi_\star), \xi_\star|\phi_\star \sim \Gamma(\xi_\star|\beta_{a_\star}, \phi_\star)$, $\phi_\star|\eta_\star \sim \Gamma(\phi_\star|1/2, \eta_\star)$ and $\eta_\star \sim \Gamma(\eta_\star|1/2, 1)$.

The prior distributions of $\mathbf{G}$, $\mathbf{f}_+$, $\mathbf{f}_-$, υ and c are omitted here as they are similar as in B^{2}RMK. Now let $\tilde{\Upsilon} = \{\alpha_{a_\star}, \beta_{a_\star}\}$, $\tilde{\Psi} = \{\lambda_\star, \xi_\star, \phi_\star, \eta_\star\}$ and $\tilde{\Omega} = \{\mathbf{f}_+, \mathbf{f}_-, \mathbf{G}, \upsilon, c\}$ for notational simplicity.

4.2.2 Posterior Updating

Since $\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}$ and $\tilde{\Omega}$ actually are random variables, we have to average the loss $\ell(f; x_\star, B_t)$ over their joint distribution. Let $\mathbb{E}_{p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega})}$ denote the expectation over $p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega})$, then we define the following expected pairwise hinge loss at the $(t+1)$-th trial:

$$\mathcal{R}(p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega})) = \sum_{i=1}^{\tilde{N}_+} \sum_{j=1}^{\tilde{N}_-} \mathbb{E}_{p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega})}[\max(0, 1 - f_i + f_j)].$$

Note that, expected pairwise hinge loss is an upper bound of the pairwise hinge loss of the expected bipartite ranking model by Jensen's inequality, and is more convenient for our inference as shown below.

Now we can infer the new posterior distribution $p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e})$ on the arrival of the new data $(x_\star, y_\star)$ by solving the following optimization problem:

$$\min_{p(\boldsymbol{a}, b, \boldsymbol{e}) \in \mathcal{P}} \mathrm{KL}\left(p(\boldsymbol{a}, b, \boldsymbol{e}) \| p_t(\boldsymbol{a}_t, b, \boldsymbol{e}) p(a_\star)\right) + 2C \cdot \mathcal{R}(p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega})), \tag{4}$$

where C is a positive regularization parameter, the constant 2 is just for convenience, and $\mathcal{R}(p(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}))$ is the expected pairwise hinge loss at the $(t+1)$-th trial. Intuitively,

we find a posterior distribution $p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e})$ in the feasible zone that is not only close to $p_t(\boldsymbol{a}_t, b, \boldsymbol{e})p(a_\star)$, but also has small loss at the new trial. Note that $\boldsymbol{a} = \left[\boldsymbol{a}_t^\top \ a_\star\right]^\top$ at the $(t+1)$-th trial, but if B_t^+ (B_t^-) is already full and $y_\star = 1$ ($y_\star = -1$), the weight vector $\boldsymbol{a}_t$ has been truncated one dimension before the optimization (4) to accommodate $a_\star$, which corresponds to an updating of the buffer.

Directly optimizing (4) with $\mathcal{R}$ is difficult and inefficient. Here we regard

$$L_{t+1}(\mathbf{y}|\boldsymbol{a}, b, \boldsymbol{e}) = \prod_{i=1}^{\tilde{N}_+}\prod_{j=1}^{\tilde{N}_-} \exp\left\{-2C \cdot \mathbb{E}_{p(\tilde{\Psi},\tilde{\Omega})}\left[\max(0, 1 - f_i + f_j)\right]\right\},$$

as the unnormalized pseudo-likelihood of label vector $\mathbf{y}$, then (4) can be rewritten as

$$\min_{p(\boldsymbol{a},b,\boldsymbol{e})\in\mathcal{P}} \mathrm{KL}\left(p(\boldsymbol{a}, b, \boldsymbol{e})\|p_t(\boldsymbol{a}_t, b, \boldsymbol{e})p(a_\star)\right) - \mathbb{E}_{p(\boldsymbol{a},b,\boldsymbol{e})}[\log(L_{t+1}(\mathbf{y}|\boldsymbol{a}, b, \boldsymbol{e}))].$$

It is straightforward to verify that the solution of this information theoretical optimization problem is

$$p(\boldsymbol{a}, b, \boldsymbol{e}) = \frac{p_t(\boldsymbol{a}_t, b, \boldsymbol{e})p(a_\star)L_{t+1}(\mathbf{y}|\boldsymbol{a}, b, \boldsymbol{e})}{p(\mathbf{y}|\tilde{\Upsilon})},$$

where $p(\mathbf{y}|\tilde{\Upsilon})$ is the normalization constant, and the posterior at the t-th trail $p_t(\boldsymbol{a}_t, b, \boldsymbol{e})$ becomes a prior. Since it is hard to compute the expectation with respect to $p(\tilde{\Psi}, \tilde{\Omega})$ in $L_{t+1}(\mathbf{y}|\boldsymbol{a}, b, \boldsymbol{e})$, we can regard the posterior distribution $p(\boldsymbol{a}, b, \boldsymbol{e})$ as the marginal of a higher-dimensional distribution that includes variables $\tilde{\Psi}$ and $\tilde{\Omega}$. Note that $\tilde{\Psi}$ and $\tilde{\Omega}$ will play only an auxiliary role in the inference procedure.

Therefore, the higher-dimensional distribution of $\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}$ and $\tilde{\Omega}$ at the $(t+1)$-th trial satisfies the following form:

$$p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}) = \frac{p_t(\boldsymbol{a}_t, b, \boldsymbol{e})p(a_\star)p(\tilde{\Psi}, \tilde{\Omega})L_{t+1}(\mathbf{y}|\mathbf{f})}{p(\mathbf{y}|\tilde{\Upsilon})},$$

$$L_{t+1}(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^{\tilde{N}_+}\prod_{j=1}^{\tilde{N}_-} \exp\left(-2C \cdot \max(0, 1 - f_i + f_j)\right),$$

which is intractable to compute analytically due to the max function in it. Similar as in B^{2}RMK, where data augmentation presents an elegant way to deal with the challenging posterior inference problem, we transform $L_{t+1}(\mathbf{y}|\mathbf{f})$ into the product of $\tilde{N}_+ \cdot \tilde{N}_-$ location-scale mixtures of normals:

$$L_{t+1}(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^{\tilde{N}_+}\prod_{j=1}^{\tilde{N}_-} \int_0^\infty \frac{\exp\left(\frac{(\theta_{ij}+C(1-f_i+f_j))^2}{-2\theta_{ij}}\right)}{\sqrt{2\pi\theta_{ij}}}\, d\theta_{ij}.$$

Now $L_{t+1}(\mathbf{y}|\mathbf{f})$ can also be seen as the marginal of the higher-dimensional distribution

$$L_{t+1}(\mathbf{y}, \boldsymbol{\theta}|\mathbf{f}) = \prod_{i=1}^{\tilde{N}_+}\prod_{j=1}^{\tilde{N}_-} \frac{\exp\left(\frac{(\theta_{ij}+C(1-f_i+f_j))^2}{-2\theta_{ij}}\right)}{\sqrt{2\pi\theta_{ij}}},$$

and the complete posterior distribution at the $(t+1)$-th trial can be expressed as

$$p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}, \boldsymbol{\theta}) = \frac{p_t(\boldsymbol{a}_t, b, \boldsymbol{e})p(a_\star)p(\tilde{\Psi}, \tilde{\Omega})L_{t+1}(\mathbf{y}, \boldsymbol{\theta}|\mathbf{f})}{p(\mathbf{y}|\tilde{\Upsilon})}.$$

4.2.3 Approximate Inference

We then make the variational approximate inference for $p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}, \boldsymbol{\theta})$. Specifically, assume there are a family of factorable and free-form variational distributions

$$q_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}, \boldsymbol{\theta}) = q_{t+1}(\boldsymbol{a})q_{t+1}(b, \boldsymbol{e})q_{t+1}(\lambda_\star)q_{t+1}(\xi_\star)q_{t+1}(\phi_\star)q_{t+1}(\eta_\star) \cdot q_{t+1}(\upsilon)q_{t+1}(c)q_{t+1}(\mathbf{G})q_{t+1}(\mathbf{f}_+)q_{t+1}(\mathbf{f}_-)q_{t+1}(\boldsymbol{\theta}),$$

and the goal is to get the optimal one which minimizes $\mathrm{KL}(q_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}, \boldsymbol{\theta})\|p_{t+1}(\boldsymbol{a}, b, \boldsymbol{e}, \tilde{\Psi}, \tilde{\Omega}, \boldsymbol{\theta}))$ between the approximating distribution and the target posterior. Following similar derivations as in B^{2}RMK model, we can infer the optimal distributions for all involved variables at the $(t+1)$-th trial, and the detailed descriptions are shown in Supplement Section C.

5 CONVERGENCE, COMPLEXITY AND PREDICTION

In both B^{2}RMK and OB^{2}RMK, the inference mechanism sequentially updates the approximate posterior distributions of the model parameters and the augmented parameters until convergence, which is guaranteed because the KL divergence is convex with respect to each of the factors.

Rather than addressing the high-dimensionality problem directly, our kernel-based approach always transforms the original data into kernel matrices whose sizes only depend on the number of instances. Meanwhile, our online algorithm can naturally overcome the memory consumption challenge posed by large training sets.

For B^{2}RMK, the computational complexity for transforming original data into kernel matrices $\{\mathbf{K}_m\}_{m=1}^P$ is $\mathrm{O}(N^2Pd)$, where d is the dimensionality of the original data. Note that $\sum_{m=1}^P \mathbf{K}_m\mathbf{K}_m^\top$ should be cached before starting inference to reduce the computation. The computational complexity for each iteration of the variational inference on training data is $\mathrm{O}(N^3 + P^3)$, where the matrix inversions for computing the covariances $\boldsymbol{\Sigma}_{\boldsymbol{a}}$ and $\boldsymbol{\Sigma}_{b,\boldsymbol{e}}$ consume $\mathrm{O}(N^3)$ and $\mathrm{O}(P^3)$ computation, respectively. Note that we can explore the symmetric positive semi-definite property to accelerate these matrix inversions.

For OB^{2}RMK, the computational complexity for the construction of P kernel matrices $\{\mathbf{K}_m\}_{m=1}^P$ at the t-th trial is $\mathrm{O}(|B_t|\tilde{N}Pd)$, where $|B_t| = |B_t^+| + |B_t^-|$ and $\tilde{N} = \tilde{N}_+ + \tilde{N}_-$. The computational complexity for each iteration of the variational inference during training is $\mathrm{O}(|B_t|^3 + P^3)$, which indicates that the computational complexity of OB^{2}RMK will be limited by the buffer size $|B_t|$ when P is given.

After obtaining the approximate posterior distributions $q^*(\boldsymbol{a})$ and $q^*(b, \boldsymbol{e})$, the ranking score for a new instance x_{new} can be calculated by:

$$f_{new} = \langle \boldsymbol{a} \rangle^\top \left(\sum_{m=1}^P \langle e_m \rangle \boldsymbol{k}_{m,new} \right) + \langle b \rangle.$$

6 EXPERIMENTS

In this section, we present extensive experimental results on real data sets to demonstrate the effectiveness of the proposed B^{2}RMK and OB^{2}RMK with fixed budgets. Specifically, we compare them with the following algorithms:

- Three batch learning algorithms, including SVM^{perf} for ordinal regression (SVM-OR) [Joachims, 2006], a bipartite ranking model with univariate logistic loss (Uni-Log) [Kotlowski *et al.*, 2011] and least square SVM (LS-SVM);
- Several state-of-the-art online AUC maximization algorithms, including one-pass AUC optimization (OPAUC) [Gao *et al.*, 2013], kernelized online imbalanced learning (KOIL) algorithm with fixed budgets [Hu *et al.*, 2015] and a bounded kernel-based online learning algorithm (Projectron++) [Orabona *et al.*, 2009];
- A latest online multiple kernel classification (OMKC) algorithm with infinite buffer size, which doesn't bound its model complexity, thus requires more and more computational resources when the data arrives sequentially [Hoi *et al.*, 2013].

6.1 EXPERIMENTAL TESTBED AND SETUP

We conduct experiments on a variety of data sets obtained from the UCI and the LIBSVM websites, as summarized in Table 1. To be consistent with previous studies [Gao *et al.*, 2013; Hu *et al.*, 2015], the features have been scaled to $[-1, 1]$ for all data sets, and multi-class data sets have been transformed into class-imbalanced binary ones. On each data set, we conduct four independent trials of 5-fold cross validation for all the algorithms, where four folds of the data are used for training while the rest for test in each trial. The averaged AUC value over these 20 runs is reported. For kernelized methods, we predefine a pool of 18 kernel functions on all features, including Gaussian kernels with 13 different widths $\{2^{-6}, 2^{-5}, \ldots, 2^6\}$ and polynomial kernels with 5 different degrees $\{1, 2, \ldots, 5\}$. Following [Gönen, 2012], all kernel matrices are normalized to have unit diagonal entries, i.e., spherical normalization, which can be done online. Note that our Bayesian multi-kernel approach infers model parameters automatically via posterior inference rather than time-consuming grid search. Though we still have to specify the hyper-parameters, they are fixed for all 15 data sets without re-adjustment on each data set.

Table 1: Details of the data sets used in our experiments.

6.2 PERFORMANCE EVALUATION

6.2.1 Batch Learning

Though we mainly focus on online learning, we also briefly compare the proposed B^{2}RMK with three batch methods. We force sparsity at both sample-level and kernel-level by imposing sparsity-inducing priors ($\mathcal{TPBN}$) on the sample weights and kernel weights, respectively. Specifically, the hyper-parameters of the proposed B^{2}RMK are set to $(\alpha_a, \beta_a) = (\alpha_e, \beta_e) = (0.5, 0.5)$, $(\alpha_v, \beta_v) = (\alpha_c, \beta_c) = (10^{+2}, 10^{-2})$ and $(\alpha_\gamma, \beta_\gamma) = (10^{-2}, 10^{-2})$ for all data sets, while 5-fold cross validation is conducted on training sets to choose a better regularization parameter from $2^{[-10:10]}$ for other methods. The averaged AUC values of these batch algorithms are listed in Table 2, which show that B^{2}RMK performs significantly better than the competitors on 3 out of 5 data sets. Figure 1 illustrates the kernel weights and sample weights obtained by B^{2}RMK on 'fourclass' data set, which show that our model can effectively identify the key kernels and support vectors that are actually needed.

6.2.2 Online Learning

In real world online learning problems, there is usually very few training data at the beginning, and it is required to maintain a dynamic model with the sequentially arriving data. Since revisiting historical data is expensive for online algorithms, we cannot do cross validation on the entire training set. As such, we assume a half of one fold in the training data is available in a batch manner, and all algorithms tune their parameters on them.

For KOIL updated by RS++ or FIFO++, we set the learning rate $\eta = 0.01$ and select the penalty parameter C from $2^{[-10:10]}$ as suggested in their paper. For OPAUC, we select the learning rate parameter η and the regularization parameter λ from $2^{[-12:10]}$ and $2^{[-10:2]}$, respectively. For Projectron++, we select the parameter of projection difference η from $2^{[-10:10]}$. For OMKC, we adopt the deterministic updating and combination strategy, and the discount weight parameter β and smoothing parameter δ are fixed to 0.8 and 0.01, respectively. For OB^{2}RMK, we initially conduct B^{2}RMK on the half fold of training data to get the posterior distribution $p(\boldsymbol{a}, b, \boldsymbol{e})$. Then the hyper-parameters of OB^{2}RMK are set to $(\alpha_{a_\star}, \beta_{a_\star}) = (\alpha_v, \beta_v) = (\alpha_c, \beta_c) = (1, 1)$. The parameter k is fixed to 3, and the regularization parameter C is chosen from $\{0.1, 1, 3\}$. Furthermore, to provide KOIL and Projectron++ with multiple kernel information, we also run them with an unweighted combination of all the kernels as well as the best kernel among the pool of kernels. The symbols u and $*$ marked on the upper right corner are used for denoting them, respectively. All buffer sizes for KOIL and OB^{2}RMK are set to 100.

Table 3 summarizes the average AUC values of the compared online algorithms. We also list the performance of the proposed batch B^{2}RMK in the last column for reference. Several observations can be drawn as follows. First, by comparing the proposed OB^{2}RMK algorithm against the other online algorithms, we can find that the OB^{2}RMK performs considerably better on most data sets. In particular, the AUC values of OB^{2}RMK significantly surpass the baseline algorithms on some data sets. For example, on 'bupaliver', the AUC values for the baseline algorithms are lower than 71%, while OB^{2}RMK is able to achieve 75.8%. Secondly, online multiple kernel learning algorithms show better AUC performance than the single kernel and linear online learning algorithms on most data sets. This demonstrates the power of multiple kernel learning methods in classifying real-world data sets. Thirdly, OPAUC achieves fairly comparable or even better results than kernel-based algorithms on the data sets of 'svmguide2' and 'german'. We attribute this to the fact that a linear algorithm is enough to achieve good performance on some data sets, while the kernel-based algorithms may be easily affected by outliers. Finally, by examining the proposed OB^{2}RMK algorithm against the online multiple kernel learning algorithm OMKC$_{(D,D)}$ with infinite buffers, we can find that the OB^{2}RMK algorithm tends to outperform the OMKC$_{(D,D)}$ algorithm on most data sets. This encouraging result shows that the OB^{2}RMK algorithm with fixed buffer size is able to maintain an accurate sketch of historical training examples by exploring the compensation scheme.

6.3 SENSITIVITY ANALYSIS

The default values of parameter C, the buffer size and the number of iterations for each online updating are 1, 100 and 30 respectively. When we study one of them through varying its values, the other two are fixed to their default values. First, from Figure 2 we observe that the performance of OB^{2}RMK increases gradually with the increase of the buffer size and it is saturated when the size is relatively large, which is consistent with the observations in [Zhao *et al.*, 2011a; Hu *et al.*, 2015]. Then, we can conclude from Figure 3 (a) that the regularization parameter C should not be too large, whereas there is a relatively broad range between $[10^{-3},\ 1]$ where OB^{2}RMK achieves good results. Finally, Figure 3 (b) shows that OB^{2}RMK converges rapidly, and typically stable results can be attained within 30 iterations.

anced Learning (KOIL) algorithm extended OAM to the nonlinear case with a predefined single kernel. Both of them provided regret bound based on pairwise hinge loss. [Ding *et al.*, 2015] extended OAM with adaptive gradient method which can exploit the knowledge of historical gradients. Besides, [Gao *et al.*, 2013] proposed a linear one-pass AUC optimization model which scans through the training data only once owing to the use of squared loss. A more recent squared loss based algorithm, named OPERA, was proposed in [Ying and Zhou, 2015], where a non-strongly convex objective was formulated in an unconstrained reproducing kernel Hilbert space. All the aforementioned methods seek point estimates of the decision function in a linear or single kernel space.

On the other hand, recent years witnessed the efforts on online extensions of multiple kernel learning due to its efficiency constrictions. Luo et al. [Luo *et al.*, 2010] first introduced an Online Multiclass Multi-kernel (OM2) classification algorithm with hinge loss. In [Hoi *et al.*, 2013], Hoi et al. proposed several Online Multiple Kernel Classification (OMKC) algorithms that aim to learn multiple kernelized classifiers and their linear combination simultaneously. In [Sahoo *et al.*, 2014], a family of Online Multiple Kernel Regression (OMKR) algorithms were proposed with sliding windows to address non-stationary times-series data. [Xia *et al.*, 2014] proposed an Online Multiple Kernel Similarity (OMKS) learning method, which learns a flexible nonlinear proximity function for visual search. These online MKL methods are effective for their specific applications, but generally involves several regularization parameters that are difficult to tune in real online scenario.

Bayesian learning is a principled way to infer the entire posterior distribution of various model parameters (e.g., kernel weights) from data automatically, providing the user a more simple way to accurately model data. In [Girolami and Rogers, 2005] and [Gönen, 2012], the authors studied Dirichlet and Gaussian priors for the kernel weights respectively. While both of them yield promising results, the former is difficult for inference. [Christoudias *et al.*, 2009] studied Bayesian localized MKL with Gaussian processes. So far, there is not only no online Bayesian MKL model but also no Bayesian multiple kernel AUC optimization model. Our margin-based model is the first combination of pairwise learning/AUC optimization with Bayesian MKL in the online setting.

8 CONCLUSION AND FUTURE WORK

We developed a Bayesian multi-kernel bipartite ranking model, which can circumvent the kernel selection problem by estimating a posterior distribution over the model weights. To make our model applicable to streaming data, we presented a kernelized online Bayesian PA learning framework by maintaining a variational approximation to the posterior. Furthermore, to efficiently deal with large-scale data, we maintained two fixed size buffers to control the number of support vectors while keeping track of the global information of the decision boundary. Extensive experimental studies confirmed the superiority of our Bayesian multi-kernel approach. In future, we plan to extend our model to deal with multi-source data with multi-task and transfer learning [Evgeniou *et al.*, 2005; Gönen and Margolin, 2014].

Pruning Rules for Learning Parsimonious Context Trees

Ralf Eggeling **Mikko Koivisto**

Abstract

We give a novel algorithm for finding a parsimonious context tree (PCT) that best fits a given data set. PCTs extend traditional context trees by allowing context-specific grouping of the states of a context variable, also enabling skipping the variable. However, they gain statistical efficiency at the cost of computational efficiency, as the search space of PCTs is of tremendous size. We propose pruning rules based on efficiently computable score upper bounds with the aim of reducing this search space significantly. While our concrete bounds exploit properties of the BIC score, the ideas apply also to other scoring functions. Empirical results show that our algorithm is typically an order-of-magnitude faster than a recently proposed memory-intensive algorithm, or alternatively, about equally fast but using dramatically less memory.

1 INTRODUCTION

The conditional distribution of a response variable y, given some explanatory variables $x_1, x_2, \ldots, x_d$, is a key ingredient in common probabilistic models. Often the modeler's interest is in distributions that admit a compact, structured representation, thereby facilitating statistically efficient learning and computationally efficient inference, as well as easy human interpretation.

Examples of general-purpose model classes include decision trees (Breiman et al., 1984; Friedman & Goldszmidt, 1996), decision graphs (Oliver, 1993; Chickering et al., 1997), multi-linear functions (Chavira & Darwiche, 2005), and conditional independence trees (Su & Zhang, 2005). These models allow for representing *context-specific independence* (Boutilier et al., 1996): given a *context*, i.e., an assignment for a *subset* of the explanatory variables x_i, the response y becomes independent of the rest.

When the explanatory variables are equipped with a natural linear ordering, more specialized models of context-specific independence are justified. In particular, *context trees* (CTs) of depth d over an alphabet Ω (Rissanen, 1983; Bühlmann & Wyner, 1999) model the distribution of the next symbol y after a sequence $x_d x_{d-1} \cdots x_1$ assuming each context is an assignment $a_\ell \cdots a_1$ for the $\ell \leq d$ immediate predecessors $x_\ell \cdots x_1$ of y, where the length ℓ may vary with the context. While context trees excel in computational efficiency, their statistical efficiency decays when there are long-range dependencies (requiring long contexts) and when the alphabet is non-binary.

To address the shortcoming of CTs, Bourguignon & Robelin (2004) proposed *parsimonious context trees* (PCTs), in which a context is a sequence $C_\ell \cdots C_1$ of *sets* of symbols $C_i \subseteq \Omega$. The idea is that the conditional distribution of y is the same of all assignments $a_d \cdots a_1$ that *match* the context, that is, $a_i \in C_i$ for $i = 1, \ldots, \ell$. In effect, PCTs allow for a compact representation and statistically efficient learning even in the presence of long-range dependencies. PCTs have found applications particularly within computational biology (Seifert et al., 2012; Eggeling et al., 2015b), where modeling sequential data over discrete alphabets constitutes a recurring challenge.

From a computational point of view, learning PCTs (i.e., maximizing a given scoring function) is, however, very challenging for larger depth d and alphabet size $|\Omega|$. The dynamic programming (DP) algorithm of Bourguignon & Robelin (2004) avoids explicit enumeration of all PCTs. Yet, it has to explore all possible contexts $C_\ell \cdots C_1$, with $\emptyset \subset C_i \subseteq \Omega$, each of which is a potential node of an optimal PCT and corresponds to a subproblem of optimizing the subtree rooted at it. Recently, Eggeling et al. (2015a) enhanced the DP algorithm by observing that two contexts of the same length are equivalent (i.e., have identical optimal subtrees) if they are matched by exactly the same set of data points; thus the respective subproblem needs to be solved only once. While this *memoization* variant is effective in reducing the time requirement of PCT optimization in practice, it has the disadvantage of increased memory consumption.

Here, we investigate a new idea to expedite PCT optimization in practice. We present pruning rules, which allow us to ignore subproblems that are guaranteed to not contribute to an optimal PCT. To obtain such guarantees, we derive upper bounds specifically for the BIC score, similar in spirit to the bounds on local scores by Tian (2000) and de Campos & Ji (2011) for structure learning in Bayesian networks. While for Bayesian networks also *global* bounds, useful in branch-and-bound search, can be derived by structural relaxations (de Campos & Ji, 2011; Yuan & Malone, 2013), with no assumptions on local scores, for PCTs a separate global view is absent and utilizing concrete properties of a particular score seems necessary.

As our subproblems form a so-called AND/OR search space (Dechter & Mateescu, 2007; Nilsson, 1980), we cannot prune a subproblem based solely on the associated bound, but we need to combine the bounds of a multitude of subproblems; in essence, we have to consider all alternative partitions of a subproblem into smaller subproblems, all of which need to be solved. To this end, we propose an efficient treatment, which resembles a simple pruning rule popular in structure learning in Bayesian networks (Teyssier & Koller, 2005); however, while the latter concerns the "is subset of" relation, our rule concerns the "refines" relation on set partitions. We note that our algorithm is an instantiation of so-called *General Branch and Bound* (Nau et al., 1984), but not of the more special A* algorithm for OR spaces.

Our pruning technique is orthogonal to the memoization technique of Eggeling et al. (2015a). In particular, our technique can be employed with or without memoization, resulting in high or low memory consumption, respectively. Because the effectiveness of our ideas is data-dependent, we evaluate the proposed algorithms empirically on a wide selection of real-world data sets.

2 PRELIMINARIES

In this section, we revisit the definition of PCTs, the basic structure learning algorithm, and a recently proposed memoization technique for improving it.

2.1 PARSIMONIOUS CONTEXT TREES

A *parsimonious context tree* (PCT) $\mathcal{T}$ of depth d over an alphabet Ω is a rooted, balanced, node-labeled tree of depth d with the following additional property: For each node of depth $\ell < d$ the labels of its children partition Ω, i.e., the labels of the children are pairwise disjoint nonempty subsets of Ω whose union is Ω.

We identify each node with the sequence of labels $V_\ell \cdots V_1$ of the nodes on the unique path from the node up to the root, denoted by $\mathbf{V}$ for short. We can also interpret the node $\mathbf{V}$ as the set of all sequences it represents. We say that a sequence $x_d \cdots x_1$ *matches* node $\mathbf{V}$, and denote it by $x_d \cdots x_1 \in \mathbf{V}$, if $x_i \in V_i$ for all positions $i = \ell, \ldots, 1$ (the remaining positions are ignored).

Given a PCT $\mathcal{T}$ and its node $\mathbf{V}$, we denote by $\mathcal{T}(\mathbf{V})$ the subtree of $\mathcal{T}$ rooted at $\mathbf{V}$. We say the subtree is *minimal* if it consists of a single chain of nodes down to a single leaf, thus all nodes labeled by Ω, and *maximal* if it consists only of nodes labeled with single symbols $a \in \Omega$, thus having $|\Omega|^{d-\ell(\mathbf{V})}$ leaves. Here, $\ell(\mathbf{V})$ denotes the depth of node $\mathbf{V}$.

To model the conditional distribution of the response variable y given a sequence $\mathbf{x}$, we equip each leaf $\mathbf{V}$ of a PCT with $|\Omega|$ parameters $\theta_{\mathbf{V}a}$, one parameter for each $a \in \Omega$. We interpret $\theta_{\mathbf{V}a}$ as the probability that y takes the value a given that $\mathbf{x}$ matches $\mathbf{V}$. In a data set $\mathbf{z} = (\mathbf{x}^t, y^t)_{t=1}^N$ we assume that, given $\mathbf{x}^t$, the response y^t is independent of the remainder of the data. Writing $\Theta_\mathcal{T}$ for the parameters of a PCT $\mathcal{T}$, we obtain the likelihood function

$$\mathcal{L}_\mathcal{T}(\Theta_\mathcal{T}) := \prod_{\text{leaf } \mathbf{V} \text{ of } \mathcal{T}} \prod_{a \in \Omega} \theta_{\mathbf{V}a}^{N_{\mathbf{V}a}}\,, \tag{1}$$

where $N_{\mathbf{V}a}$ denotes the count of the response a in data points where the explanatory variables match $\mathbf{V}$:

$$N_{\mathbf{V}a} := |\{t : \mathbf{x}^t \in \mathbf{V} \text{ and } y^t = a\}|\,. \tag{2}$$

We will further denote $N_\mathbf{V} := \sum_{a \in \Omega} N_{\mathbf{V}a}$.

2.2 BASIC STRUCTURE LEARNING

We consider a score-and-search approach to learn a PCT from a given data set. Suppose we are given a scoring function S that associates each PCT $\mathcal{T}$ with a real-valued score $S_\mathcal{T}$. The task is to find an optimal PCT,

$$\hat{\mathcal{T}} \in \operatorname*{argmax}_\mathcal{T} S_\mathcal{T}\,. \tag{3}$$

Aside from the fact that multiple PCTs may achieve the optimum, this task is practically equivalent to the task of finding the optimal score $S_{\hat{\mathcal{T}}}$. For convenience, we focus on the latter problem for the rest of the paper. An optimal tree $\hat{\mathcal{T}}$ can be constructed via, e.g., standard backtracking (see Section 2.3 for details).

Bourguignon & Robelin (2004) presented a dynamic programming algorithm for finding $S_{\hat{\mathcal{T}}}$. It relies on the mild assumption that the scoring function decomposes into a sum of leaf scores:

$$S_\mathcal{T} = \sum_{\text{leaf } \mathbf{V} \text{ of } \mathcal{T}} S(\mathbf{V})\,. \tag{4}$$

This property is fulfilled by the log-likelihood function (Eq. 1) and thus also by scoring functions that can be written as penalized maximum log-likelihood with a decomposable penalty term, such as AIC (Akaike, 1974), BIC (Schwarz, 1978), and the Bayesian marginal likelihood with a decomposable prior.

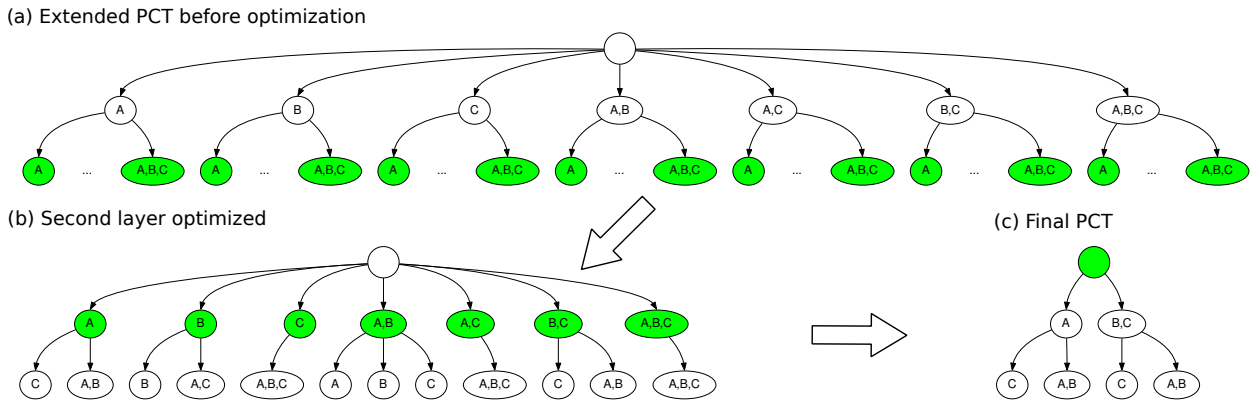

Figure 1: **Basic PCT optimization**. We show the bottom-up reduction of the extended PCT for a toy example of $d = 2$ and $\Omega = \{\mathsf{A}, \mathsf{B}, \mathsf{C}\}$. (a) Initially only the leaf scores of the extended PCT have an exact, optimal score assigned to them. (b) For each set of sibling leaves, the optimal valid selection of children is computed, the non-contributing siblings are discarded, and the winning score is propagated upwards to become the score of the parent. (c) The same principle is applied on the higher layer in order to select the optimal children of the root, obtaining a valid PCT with optimal score.

To describe the algorithm, we denote by $S_{\mathcal{T}(\mathbf{V})}(\mathbf{V})$ the sum of the leaf scores in the subtree $\mathcal{T}(\mathbf{V})$ rooted at an inner node $\mathbf{V}$ of $\mathcal{T}$; for a leaf $\mathbf{V}$, we put $S_{\mathcal{T}(\mathbf{V})}(\mathbf{V}) := S(\mathbf{V})$. We have the recurrence

$$S_{\mathcal{T}(\mathbf{V})}(\mathbf{V}) = \sum_{\text{child } \mathbf{C} \text{ of } \mathbf{V}} S_{\mathcal{T}(\mathbf{C})}(\mathbf{C}) \,, \tag{5}$$

and, in particular, $S_{\mathcal{T}} = S_{\mathcal{T}}(\Lambda)$, where Λ is the root node of $\mathcal{T}$. Exploiting this recurrence, the algorithm of Bourguignon & Robelin (2004) optimizes the score over the subtrees rooted at $\mathbf{C}$, independently for each possible child node $\mathbf{C}$, and then selects a set of children that form an optimal partition of the parent node $\mathbf{V}$. For the base case of each leaf, the algorithm sets the optimal score $S_*(\mathbf{V}) := S(\mathbf{V})$, and for each inner node it computes the optimal score defined by

$$S_*(\mathbf{V}) := \max_{\substack{\{C_1,\ldots,C_r\} \\ \text{partition of } \Omega}} \left\{ S_*(C_1\mathbf{V}) + \cdots + S_*(C_r\mathbf{V}) \right\}. \tag{6}$$

It follows that the maximum score over all PCTs of depth d is obtained as

$$\max_{\mathcal{T}} S_{\mathcal{T}} = S_*(\Lambda) \,. \tag{7}$$

The algorithm computes the leaf scores of $(2^{|\Omega|} - 1)^d$ possible leaves and, in addition, finds an optimal set of children in $O(3^{|\Omega|})$ time for each of slightly more than $(2^{|\Omega|} - 1)^{d-1}$ inner nodes. Since the complexitity is a product of two terms which are both exponential in $|\Omega|$, PCTs are to date limited to applications of small to moderate alphabet size (Eggeling et al., 2015a).

2.3 INTERPRETATION AS REDUCTION OF EXTENDED PCT

The inner workings of the algorithm of Bourguignon & Robelin (2004) and the construction of the optimal PCT itself can be viewed as bottom-up reduction of a data structure called *extended PCT*, as illustrated in Figure 1. In contrast to a PCT, the sibling nodes in an extended PCT do not partition their parent node, but are labeled by all nonempty subsets of Ω. An extended PCT thus contains all possible PCTs as subtrees, as illustrated in Figure 1a. We denote the set of all nodes of an extended PCT by $\mathcal{V}$, and treat a PCT $\mathcal{T}$ as its proper subset, i.e., $\mathcal{T} \subset \mathcal{V}$.

Given an extended PCT, the base case of the algorithm requires the computation of leaf scores, and the task is now to reduce the extended PCT so that a PCT with maximal score remains. For each inner node it then (i) computes an optimal selection of children with the constraint that the node labels must form a partition of Ω, and (ii) removes all children and subtrees below that do not belong to this optimal partition.

Since an inner node can be optimized only if all of its children have already a score attached to them and are thus roots of valid PCT subtrees, the recursion leads essentially to a bottom-up reduction of the extended PCT beginning at the deepest *layer*, which comprises all nodes of the same depth, as displayed in Figure 1b. The optimization terminates once an optimal selection of children of the root node are computed; a possible final result is shown in Figure 1c.

2.4 MEMOIZATION

Eggeling et al. (2015a) proposed a *memoization* technique for speeding up PCT learning by exploiting regularities in the observed explanatory variables.

The core idea is to implement the algorithm of Bourguignon & Robelin (2004) in a top-down fashion and to store the result of subtree optimization for node $\mathbf{V}$ with the depth

$\ell(\mathbf{V})$ and the index set $I(\mathbf{V}) := \{t : \mathbf{x}^t \in \mathbf{V}\}$ as key, e.g., in a hash table. When the algorithm needs an optimal subtree (or its score) for another node $\mathbf{V}'$, the algorithm checks whether the key $(\ell(\mathbf{V}'), I(\mathbf{V}'))$ exists in the storage already and the associated result can be re-used. To work correctly, memoization requires that the score $S_*(\mathbf{V})$ depends on $\mathbf{V}$ only through $I(\mathbf{V})$ and $\ell(\mathbf{V})$. This property holds for many relevant scoring functions such as penalized maximum log-likelihood scores, but not for the Bayesian marginal likelihood with context-dependent pseudo-counts.

While memoization has shown to be rather effective particularly on highly structured data sets, it increases memory consumption. The original DP algorithm of Bourguignon & Robelin (2004) is relatively memory-efficient as only a small fraction of nodes of the extended PCT needs to be stored in memory at a given time, provided that the extended PCT is constructed, traversed, and reduced top-down in a depth-first manner. Memoization, in contrast, requires storing the scores and the associated data subset indices for all visited inner nodes of the extended PCT.

3 PRUNING RULES

We derive pruning rules, which utilize score upper bounds to decide at any given node whether we can avoid the explicit optimization over possible subtrees.

3.1 SCORING FUNCTION: BIC

In order to obtain effective upper bounds, we focus on the BIC score, derived from be Bayesian Information Criterion (Schwarz, 1978). It is an approximation of the Bayesian marginal likelihood and has been empirically shown to be suitable for PCT learning on real-world data due to its harsh penalty term, which favors sparse trees (Eggeling et al., 2014). The score can also be given a two-part-MDL interpretation (Rissanen, 1978). For a PCT $\mathcal{T}$, the BIC score is given by

$$S_{\mathcal{T}}^{\text{BIC}} = \ln \mathcal{L}_{\mathcal{T}}(\hat{\Theta}_{\mathcal{T}}(\mathbf{z})) - \frac{k}{2} \ln N \,, \tag{8}$$

where $\hat{\Theta}_{\mathcal{T}}(\mathbf{z})$ denotes the maximum-likelihood parameter estimate on $\mathbf{z}$ and k denotes the number of free parameters. Since k is proportional to the number of leaves and since the likelihood (Eq. 1) is a product of leaf terms, the BIC score decomposes into a sum of

$$S^{\text{BIC}}(\mathbf{V}) := \overbrace{\sum_a N_{\mathbf{V}a} \ln \frac{N_{\mathbf{V}a}}{N_{\mathbf{V}}}}^{L(\mathbf{V})} - \overbrace{\frac{1}{2}\big(|\Omega| - 1\big) \ln N}^{K} \,. \tag{9}$$

Here, $L(\mathbf{V})$ is the maximized log-likelihood of leaf $\mathbf{V}$ and K is the BIC penalty contribution of a single leaf, involving $|\Omega| - 1$ free parameters and a global sample size of N. We observe that the score of a leaf $\mathbf{V}$ does actually not depend on all data points in $\mathbf{z}$, but only on those that match $\mathbf{V}$.

3.2 UPPER BOUNDING THE BIC SCORE

Consider an inner node $\mathbf{V} \in \mathcal{V}$. To upper bound the BIC score over all possible subtrees rooted at $\mathbf{V}$, we upper bound the largest possible gain in the maximum-likelihood term on one hand, and lower bound the inevitable penalty due to increased model complexity on the other hand.

Consider first the likelihood term. We make use of the observation that every PCT is *nested* in the maximal PCT, which has $|\Omega|^d$ leaves, each representing a single realization of the explanatory variables. The same holds also locally for any PCT subtree below a particular node $\mathbf{V}$. Hence, the likelihood term is maximized by the maximal model, which partitions all realizations perfectly. We obtain the upper bound

$$\tilde{L}(\mathbf{V}) := \sum_{\mathbf{a} \in \Omega^{d-\ell(\mathbf{V})}} L(\mathbf{aV}) \,, \tag{10}$$

that is, we have $L(\mathbf{V}) \leq \tilde{L}(\mathbf{V})$. Here, $\mathbf{aV}$ denotes the leaf node obtained by extending the context of node $\mathbf{V}$ with a single realization $\mathbf{a}$ of the remaining explanatory variables. Note that $\tilde{L}(\mathbf{V})$ can be computed fast by summing over the sequences $\mathbf{a}$ that occur in the data points that match $\mathbf{V}$. Now we distinguish:

Case 1 The minimal subtree is optimal. In this case, we can compute the exact score directly, without recursion.

Case 2 The minimal subtree is not optimal. Thus an optimal subtree makes at least one split, and therefore has at least two leaves. In this case, the likelihood term is upper bounded by $\tilde{L}(\mathbf{V})$ (Eq. 10), while the penalty term is at least $2K$.

Combining the two cases yields the following bound.

Proposition 1 (Score upper bound)**.** *For an arbitrary inner node $\mathbf{V} \in \mathcal{V}$ it holds that*

$$S_*^{BIC}(\mathbf{V}) \leq S_0^{BIC}(\mathbf{V}) \,,$$

with

$$S_0^{BIC}(\mathbf{V}) := \max\{L(\mathbf{V}) - K, \tilde{L}(\mathbf{V}) - 2K\} \,.$$

We will use this upper bound twice to device two pruning rules in the next two sections.

3.3 STOPPING RULE

First, we consider a simple rule for pruning, which is an immediate consequence of the aforementioned upper bound. The idea can be phrased as follows:

> *Stop optimizing the subtree below a node when context-specific independence can be declared already without even entering the recursion.*

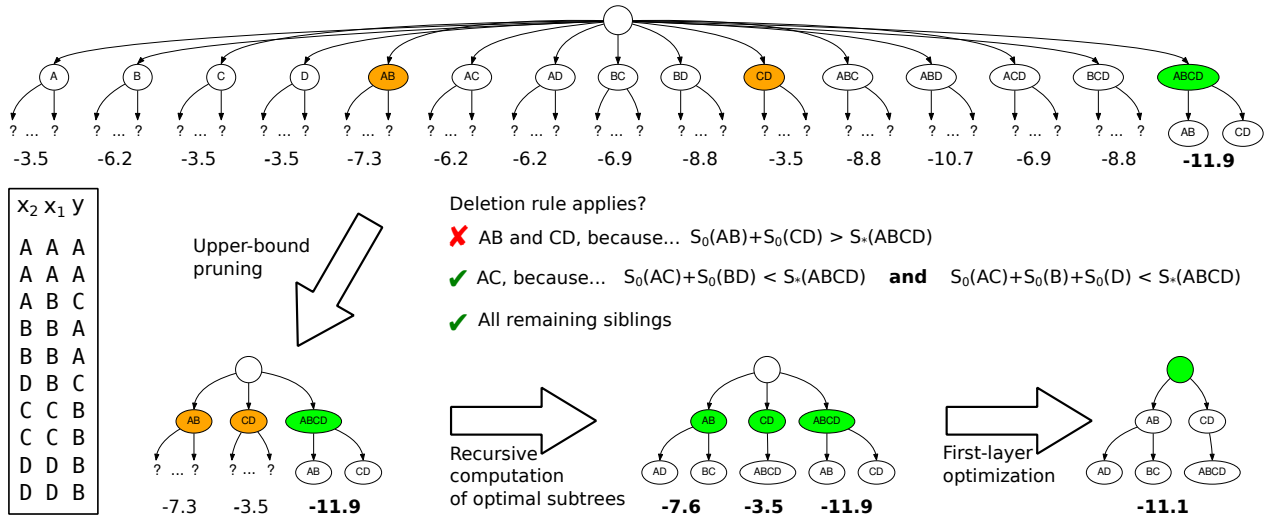

Figure 2: **Example of the deletion rule.** We consider a small data set of $N = 10$ for two explanatory variables over the alphabet $\Omega = \{\mathsf{A}, \mathsf{B}, \mathsf{C}, \mathsf{D}\}$ (bottom-left box). The root of each subtree for which exact BIC scores have been computed already is marked in green and corresponding score displayed in boldface below the subtree. The remaining other subtrees are associated with an upper bound on the BIC score. The root of a subtree which contributes to an upper-bounded partition score that is greater than the exact score of the maximal sibling node, and thus has to optimized explicitly, is displayed in orange.

Formally, we have the following.

Proposition 2 (Stopping rule)**.** *Let $\mathbf{V} \in \mathcal{V}$ with $\ell(\mathbf{V}) < d$, and let $\mathcal{T}'$ be the minimal subtree rooted at $\mathbf{V}$. If*

$$S_0^{BIC}(\mathbf{V}) = L(\mathbf{V}) - K\,,$$

then $S_*^{BIC}(\mathbf{V}) = S_{\mathcal{T}'}^{BIC}(\mathbf{V})$.

The correctness can be shown by contradiction. Assume $\mathcal{T}'$ does not yield the optimal score. Then $L(\mathbf{V}) - K < S_*^{\mathrm{BIC}}(\mathbf{V})$. But since $S_*^{\mathrm{BIC}}(\mathbf{V}) \leq S_0^{\mathrm{BIC}}(\mathbf{V})$, this violates the premise.

3.4 DELETION RULE

The idea of our second rule is to identify a node with so low a score that the node cannot appear in any optimal PCT. In an idealized form, the rule reads:

> *Delete a child node if the best set of children it belongs to is worse than some other set of children (to which the node does not belong).*

As we wish to delete as many potential child nodes as possible and not compute their optimal scores, we cannot assume the optimal scores of the sibling nodes are available. Thus, to make the rule concrete, we resort to upper bounds on the scores. Likewise, we need to lower bound the optimal score among the valid sets of children. While, in principle, various lower bounding schemes would be possible, we have chosen to use a particularly simple bound: the optimal score of the Ω-labeled child. We next describe the bounds and the rule more formally.

Consider a node $\mathbf{V}$. To efficiently check whether a child node $C\mathbf{V}$ can be deleted, we need an upper bound on the score obtained by a partition of $\mathbf{V}$ that includes $C\mathbf{V}$. To this end, we associate any set function $f : 2^\Omega \to \mathbb{R}$ with another function $f' : 2^\Omega \to \mathbb{R}$ defined by letting $f'(\emptyset) := 0$ and, for all $\emptyset \subset B \subseteq \Omega$,

$$f'(B) := \max_{\substack{\{C_1,\ldots,C_r\} \\ \text{partition of } B}} \left\{ f(C_1) + \cdots + f(C_r) \right\}. \qquad (11)$$

A folklore dynamic programming algorithm computes f' for a given f in $O(3^{|\Omega|})$ time, based on the recurrence

$$f'(B) = \max_{\emptyset \subset C \subseteq B} \left\{ f(C) + f'(B \setminus C) \right\}. \qquad (12)$$

Eggeling et al. (2015a) made use of this observation to compute the optimal score over all partitions of the alphabet, given by $f'(\Omega)$ with a suitable function f. Here, we apply it to score upper bounds, and we also use several of the values $f'(B)$ in order to stay within $O(3^{|\Omega|})$ for computing all upper bounds required:

Proposition 3 (Deletion rule)**.** *Let $\mathbf{V} \in \mathcal{V}$ with $\ell(\mathbf{V}) < d$, and let $\emptyset \subset C \subset \Omega$. Let $f(C') := S_0(C'\mathbf{V})$ for all $\emptyset \subset C' \subseteq \Omega$. If*

$$S_0(C\mathbf{V}) + f'(\Omega \setminus C) \;<\; S_*(\Omega\mathbf{V})\,,$$

then the node $C\mathbf{V}$ does not belong to any optimal PCT.

The correctness can be shown by contradiction. Suppose $C\mathbf{V}$ did belong to an optimal PCT even though the premise was fulfilled. Then $S_*(C\mathbf{V}) + f'(\Omega \setminus C) \geq S_*(\Omega\mathbf{V})$, leading to $S_0(C\mathbf{V}) < S_*(C\mathbf{V})$, which violates the property of S_0 being an an upper bound of S_*.

We illustrate the deletion rule by a small toy example in Figure 2. Here, we focus on the first layer, where only for the maximal node an optimal PCT subtree is computed and thus an exact score is available already, whereas for the other siblings only upper-bounded scores exist. Based on those scores, we compute the upper-bounded scores of every possible partition and observe and observe that only one partition, consisting of the two child nodes AB and CD, has an upper-bounded score that is greater than the exact score of the maximal sibling node ABCD. All other siblings can thus not contribute to an optimal partition of child nodes, as even the best partition they contribute to has an upper-bounded score smaller than what is already achieved. Hence, the corresponding subtrees do not need to be optimized explicitly and can be deleted.

The deletion rule does invest a certain amount of effort that the obtained savings need to compensate before the rule becomes effective: In the worst case, we need to compute the optimal partition of children twice for each inner node, once with the upper-bounded scores for excluding subtrees from further optimization, and once with the exact scores. As a positive side note, we observe that, while we focus on BIC upper bounds in this work, the deletion rule is in principle independent of the used scoring function, as long as an effective upper bound $S_0 \leq S_*$ can be specified.

3.5 LOOKAHEAD

The upper bound of Section 3.2 can be computed directly for a given node without entering the recursion. However, we can tighten the bound, if we do enter the recursion for one or more steps, in effect, performing a lookahead on the data. To this end, for all nodes $\mathbf{V}$ and number of steps $q = 1, \ldots, d - \ell(\mathbf{V})$, define

$$S_q(\mathbf{V}) := \max_{\substack{\{C_1,\ldots,C_r\} \\ \text{partition of } \Omega}} \sum_{i=1}^{r} S_{q-1}(C_i\mathbf{V})\,, \qquad (13)$$

with $S_0(\mathbf{V})$ being the base case of a flat upper bound.

Proposition 4 (Lookahead bound)**.** *For all $\mathbf{V} \in \mathcal{V}$ and $q = 1, \ldots, d - \ell(\mathbf{V})$, it holds that*

$$S_*(\mathbf{V}) \leq S_q(\mathbf{V}) \leq S_0(\mathbf{V})\,. \qquad (14)$$

Using the lookahead bound with large q does constitute a substantial computational effort. If $q = d - \ell(\mathbf{V})$, the bound matched the optimal score and, in essence, is obtained by traversing through all possible PCT subtrees. Hence, the choice of q is critical in order to obtain a trade-off between gained savings and additional invested effort in relation to the flat bound.

One possibility to cope with that issue is to dynamically increase q, i.e., to first test whether pruning on flat upper bounds S_0 is possible. If this is not the case, q is increased by one, up to the maximal value of $d - \ell(\mathbf{V})$. However, in this work we refrain from exploring this procedure in full, as in our preliminary studies one-step lookahead ($q = 1$) turned out to perform the best in the vast majority of cases.

3.6 FINAL ALGORITHM

We combine the presented ideas using pseudo code. Consider first the task of computing, for all nonempty subsets $B \subseteq \Omega$, the maximum total score over all partitions of B, in other words, the set function f' for a given set function f, as defined in Eq. 11. The procedure MAX-PART given below completes this task based on the recurrence in Eq. 12.

```
MAX-PART(f)
1  g[∅] ← 0
2  for each ∅ ⊂ B ⊆ Ω in quasi-lexicographical order
3       do g[B] ← −∞
4          for each ∅ ⊂ C ⊆ B
5               do g[B] ← max{g[B], f[C]+g[B\C]}
6  return g
```

The main algorithm, given below as procedure MAX-PCT, calls MAX-PART(f) both with exact scores and with upper bounds, as specified by the argument f. The call MAX-PCT($\mathbf{V}$) returns the optimal score $S_*(\mathbf{V})$. We thus obtain the maximum score over all PCTs of depth d by calling MAX-PCT(Λ).

```
MAX-PCT(V)
 1  score ← L(V) − K
 2  if ℓ(V) < d and score < S_0^BIC(V)
 3     then s[Ω] ← MAX-PCT(ΩV)
 4          for each ∅ ⊂ B ⊆ Ω
 5               do u[C] ← S_q^BIC(CV)
 6          u' ← MAX-PART(u)
 7          for each ∅ ⊂ B ⊆ Ω
 8               do s[C] ← −∞
 9                  if u[C] + u'[Ω \ C] > s[Ω]
10                    then s[C] ← MAX-PCT(CV)
11          s' ← MAX-PART(s)
12          score ← s'[Ω]
13  return score
```

3.7 INCORPORATING MEMOIZATION

While we omitted it for the sake of simplicity in the pseudocode, incorporating the memoization technique of Eggeling et al. (2015a) into the proposed algorithm is straightforward.

We can add a test that checks whether the index set $I(\mathbf{V})$ has already occurred with some other node at the same depth directly when entering the function. If the test is positive, the score is re-used and the rest of the function is skipped. If the test is negative, the score is stored in a hash data structure at the end of the function with the current data subset (index set) and the depth of the node as key.

4 CASE STUDIES

In the empirical part of this work, we evaluate the effect of the proposed pruning techniques using a Java-implemententation based on the Jstacs library (Grau et al., 2012). We focus on the metric of *visited nodes* in the extended PCT, which includes all created nodes, included those used only for look-ahead computations. In addition, we also measure the elapsed *running time*. We consider the problem of modeling DNA binding sites of regulatory proteins such as transcription factors, which constitutes one established application of PCTs.

4.1 DATA AND PREDICTION STUDY

A data set of DNA binding sites consists of short sequences of the same length over the alphabet $\Omega = \{\mathsf{A}, \mathsf{C}, \mathsf{G}, \mathsf{T}\}$ that are considered to be recognized by the same DNA-binding protein. We use 25 data sets, which all show at least some degree of statistical dependence among sequence positions, from the publicly available data base JASPAR (Mathelier et al., 2013). The data sets differ in sequence length L from 10 to 21 symbols, in the sample size N from 156 to 3629 sequences, and in the strength of the signal.

To exhibit the general properties of this data, we perform a prediction experiment based on the model class and learning framework of Eggeling et al. (2014), which makes a position-specific use of PCTs. We perform a leave-one-out cross-validation for different PCT depths $d \in \{0, \ldots, 6\}$ and compute the mean log predictive probability over the test sequences from all iterations. We aggregate the resulting 7×25 mean log predictive probabilities in two different ways and visualize the results in Figure 3. First, we check for each data set, which d yields the highest predictive probability, and in case that several depths share rank one (which can happen if all subtrees below a certain depth are minimal), we note the smallest d. Second, we average the mean log predictive probabilities for each d over all 25 data sets.

We observe that all data sets contain indeed statistical dependencies to some degree, since $d = 0$ is never the best choice, and increasing d yields – on average – an increased predictive performance, though the magnitude of improvement decreases gradually. This indicates that (i) the used BIC score for PCT optimization works reasonably well in order to avoid overfitting, and (ii) the data sets have a non-trivial structure so that the optimization problem is hard.

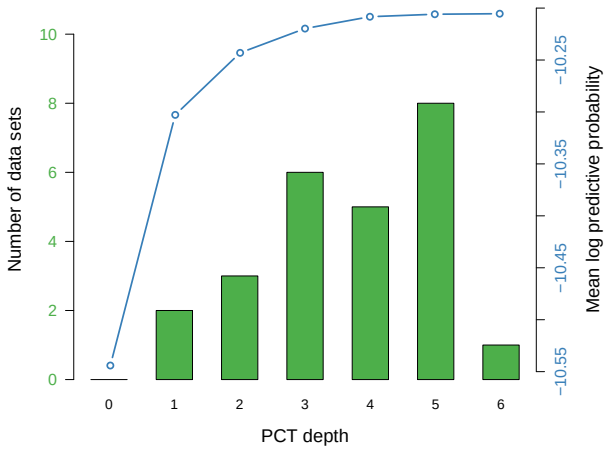

Figure 3: **Prediction study**. We show the results of a leave-one-out cross validation. Green bars indicate for how many data sets a certain PCT depth d is the smallest depth that yields an optimal prediction. The blue line shows the average predictive performance over all data sets as a function of d.

4.2 ONE DATA SET IN DETAIL

Next, we consider a single data set and investigate the effectiveness of the pruning rule in relation to the basic algorithm and to the memoization technique of Eggeling et al. (2015a). We focus on the DNA-binding protein CTCF (Kim et al., 2007), where the corresponding JASPAR data set consists of $N = 908$ sequences of length $L = 19$.

Figure 4a shows for this data set the *sequence logo* (Schneider & Stephens, 1990), which is a common visualization of the marginal distribution of the individual sequence positions. For each position, the four possible symbols are scaled relative to the marginal probability $\mathbf{p} = (p_\mathrm{A}, p_\mathrm{C}, p_\mathrm{G}, p_\mathrm{T})$ and the height of the symbol stack is scaled by $2 - \mathrm{H}(\mathbf{p})$ (which is often called *information content*), with H denoting the Shannon entropy in bits. Figure 4b shows the fraction of the visited nodes in the extended PCT of depth 5 for the pruning technique, the memoization technique, and the combination of both in relation to the basic algorithm.

We observe that pruning is effective in particular at positions where the marginal distribution of the response variable is far from uniform, with clear examples being position 10 and position 13. In fact, the correlation coefficient between the information content of the response variable and the common logarithm of fraction of visited nodes using the pruning rule in relation to the basic algorithm amounts -0.821. For memoization, a similar effect occurs, but here marginal distributions of the explanatory variables are the deciding factor: the largest saving occurs at position 14, where highly informative positions 10 and 13 are in the context.

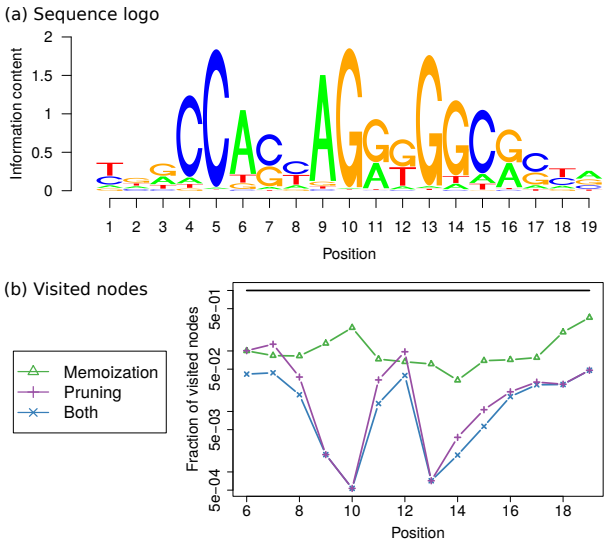

Figure 4: **Detailed result for CTCF data set.** Subfigure (a) shows the position-specific marginal nucleotide frequencies for each position in the sequence. Subfigure (b) shows the fraction of visited nodes required for PCT optimization ($d = 5$) for every sequence position $j = 6, \ldots, 19$, and for the three algorithmic variants in relation to the basic algorithm.

We summarize that the empirical performance does indeed satisfy the theoretical expectations: While memoization exploits regularities in the realizations of the explanatory variables, the pruning rules exploit regularity in the response variable, and the effect of the latter is often, though not always, greater. Combining both techniques generally resembles the sole application of pruning, albeit additional savings due to memoization do occur.

4.3 BROADER STUDY

We now take a broader view by considering all data sets. Given a PCT depth d, we (i) average the number of visited nodes and the absolute running times for each data set over all sequence positions, and (ii) take the median of average visited nodes and average running times over all data sets. The results are displayed for $d = 3, \ldots, 6$ in Figure 5, and confirm the observations made for a single data set in the previous section: Pruning outperforms memoization, yet the combination of both techniques yields the largest overall effect.

However, we observe a striking divergence between savings in terms of visited nodes in the extended PCT as displayed in Figure 5a and the improvements in terms of running times as displayed in Figure 5b. Whereas the savings in the first case are up to two orders of magnitude, the absolute running time yields a smaller improvement of roughly one order of magnitude for PCTs of $d = 5$.

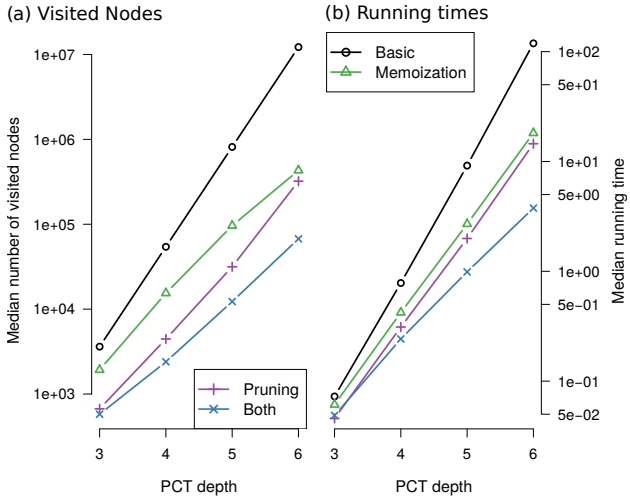

Figure 5: **Aggregated results for all four algorithmic variants.** For each data set, we average the visited nodes and running times over all sequence positions. We then plot (a) the median number of visited nodes and (b) median running times over all data sets.

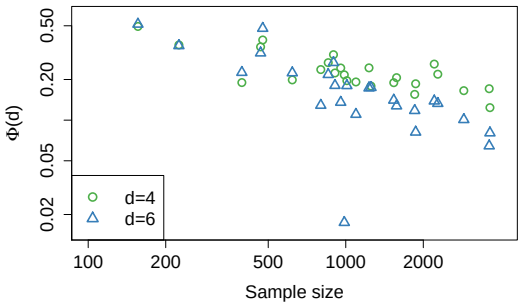

Figure 6: **Effect of sample size on savings ratio for pruning algorithm.** For all 25 data sets, for $d = \{4, 6\}$, we plot $\Phi(d)$ of Eq. 15 against the sample size N.

In order to investigate this issue further, we measure how strong the runtime reduction deviates from the reduction in terms of visited nodes. Let $\mathrm{VN}(d)$ denote the number of visited nodes in the extended PCT for finding an optimal PCT of depth d using the pruning technique, and let $\mathrm{RT}(d)$ denote the corresponding running time. Let further $\mathrm{VN}_{\mathrm{basic}}(d)$ and $\mathrm{RT}_{\mathrm{basic}}(d)$ denote the same quantities for the basic algorithm. We define

$$\Phi(d) = \frac{\mathrm{VN}(d) \times \mathrm{RT}_{\mathrm{basic}}(d)}{\mathrm{VN}_{\mathrm{basic}}(d) \times \mathrm{RT}(d)}, \tag{15}$$

which yields a value of 1, if the savings in visited nodes are translated one-to-one into savings in running times, and a value smaller than 1, if savings in terms of visited nodes are larger. Next, we plot $\Phi(4)$ and $\Phi(6)$ for each data set against the sample size (Figure 6).

We observe a correlation between Φ and sample size: for small data sets the discrepancy between running time and visited nodes is smaller than for larger data sets, which is beneficial since the statistical efficiency of PCTs is relevant in particular for small data settings. The one outlier in the plot at sample size close to 1000 where the $\Phi(6)$ is clearly off belongs to a highly-regular data set where pruning is so effective that reading the data and initializing all data structures becomes the dominating factor, albeit requiring only few milliseconds in absolute terms. Ignoring that outlier and extrapolating Φ in Figure 6 to a hypothetical sample size of zero, it appears that savings in running times and visited nodes could match.

To explain this behavior, we have to reconsider the theoretical expectations of the running time of the basic algorithm (Section 2.2). It assumes the work to be performed in each inner node to be dominated by the alphabet partitioning problem and thus constant for a fixed Ω. For small $|\Omega|$, however, data-management operations, such as determining $I(C\mathbf{V})$ given $I(\mathbf{V})$, become a significant factor. Unlike alphabet partitioning, data-management is not equally demanding within each node: Nodes close to the root match on average more data points than nodes close to the leaves. Moreover, assuming the siblings in the extended PCT are ordered quasi-lexicographically as in the example of Figure 1a, we observe that the right half of the extended PCT (or any subtree of it) matches on average more data points than the left half. However, the subtrees of the extended PCT not traversed explicitly due to the pruning or memoization technique are predominantly the subtrees that match comparably few data points, which explains why the savings in visited nodes do not directly translate into the same saving factors for running times.

5 CONCLUDING REMARKS

We have investigated a bound-and-prune approach to finding a maximum-score parsimonious context tree (PCT). Specifically, we derived local score upper bounds for the BIC score, with an option for a few-step lookahead, and we presented two pruning rules: a stopping rule and a deletion rule.

Empirical results on DNA binding site data showed that pruning alone, which essentially exploits regularities in the response variable, is slightly more effective than the memoization technique of Eggeling et al. (2015a), which exploits regularities in the explanatory variables. While the combination of pruning and memoization runs an about order-of-magnitude faster, it partially inherits the large memory requirements of memoization; however, pruning does reduce the memory requirement, too, as a smaller number of subproblems need to be solved explicitly. These finding suggest that pruning should always be included, and memoization can be added to gain further speedups provided that memory consumption is not an issue.

While we have restricted our attention to learning PCTs and to the BIC score, we believe many of the presented ideas are applicable more generally. First, the BIC score can, in principle, be replaced by any other scoring function for which good upper bounds similar to Proposition 1 can be established. Second, the techniques should easily extend to learning decision trees with many categorical explanatory variables. Third, the bound-and-prune approach might be effective also in expediting other algorithms that are based on recursive set partitioning, like the one by Kangas et al. (2014) for learning chordal Markov networks.

Abstract

Learning the influence structure of multiple time series data is of great interest to many disciplines. This paper studies the problem of recovering the causal structure in network of multivariate linear Hawkes processes. In such processes, the occurrence of an event in one process affects the probability of occurrence of new events in some other processes. Thus, a natural notion of causality exists between such processes captured by the support of the excitation matrix. We show that the resulting causal influence network is equivalent to the Directed Information graph (DIG) of the processes, which encodes the causal factorization of the joint distribution of the processes. Furthermore, we present an algorithm for learning the support of excitation matrix of a class of multivariate Hawkes processes with exponential exciting functions (or equivalently the DIG). The performance of the algorithm is evaluated on synthesized multivariate Hawkes networks as well as a stock market and MemeTracker real-world dataset.

1 INTRODUCTION

In many disciplines, including biology, economics, social sciences, and computer science, it is important to learn the structure of interacting networks of stochastic processes. In particular, succinct representation of the causal interactions in the network is of interest.

A lot of studies in the causality fields focus on causal discovery from time series. To find causal relations from time series, one may fit vector autoregressive models on the time series, or more generally, evaluate the causal influences with transfer entropy [22] or directed information [19]. This paper considers learning causal structure for a specific type of time series, multivariate linear Hawkes process [8]. Hawkes processes were originally motivated by the quest for good statistical models for earthquake occurrences. Since then, they have been successfully applied to seismology [15], biology [21], criminology [13], computational finance [5, 12, 14], etc. It is desirable to develop specific causal discovery methods for such processes and study the properties of existing methods in this particular scenario.

In multivariate or mutually exciting point processes, occurrence of an event (arrival) in one process affects the conditional probability of new occurrences, i.e., the *intensity* function of other processes in the network. Such interdependencies between the intensity functions of a linear Hawkes process are modeled as follows: the intensity function of processes j is assumed to be a linear combination of different terms, such that each term captures only the effects of one other process (See Section 2.1). Therefore, a natural notion of functional dependence (causality) exists among the processes in the sense that in linear mutually exciting processes, if the coefficient pertaining to the effects of process i is non-zero in the intensity function of process j, we know that process i is influencing process j. This dependency is captured by the support of the excitation matrix of the network. As a result, estimation of the excitation (kernel) matrix of multivariate processes is crucial both for learning the structure of their causal network and for other inference tasks and has been the focus of research. For instance, maximum likelihood estimators were proposed for estimating the parameters of excitation matrices with exponential and Laguerre decay in [16, 25]. These estimators depend on existence of i.i.d. samples. However, often we do not have access to i.i.d. samples when analyzing time series. Second-order statistics of the multivariate Hawkes processes were used to estimate the kernel matrix of a subclass of multivariate Hawkes processes called symmetric Hawkes processes [1]. Utilizing the branching property of the Hawkes processes, an expectation maximization algorithm was proposed to estimate the excitation matrix in [10].

We aim to investigate efficient approaches to estimation of excitation matrix of Hawkes processes from time series that

does not require i.i.d. samples and investigate how the concept of causality in such processes is related to other established approaches to analyze causal effects in time series.

1.1 SUMMARY OF RESULTS AND ORGANIZATION

Our contribution in this paper is two fold. First, we prove that for linear multivariate Hawkes processes, the causal relationships implied by the excitation matrix is equivalent to a specific factorization of the joint distribution of the system called *minimal generative model*. Minimal generative models encode causal dependencies based on a generalized notion of Granger causality, measured by causally conditioned directed information [20]. One significance of this result is that it provides a surrogate to directed information measure for capturing causal influences for Hawkes processes. Thus, instead of estimating the directed information, which often requires estimating a high dimensional joint distribution, it suffices to learn the support of the excitation matrix. Our second contribution is indeed providing an estimation method for learning the support of excitation matrices with exponential form using second-order statistics of the Hawkes processes.

Our proposed learning approach, in contrast with the previous work [1, 24], is not limited to symmetric Hawkes processes. In a symmetric Hawkes process, it is assumed that the Laplace transform of the excitation matrix can be factored into product of a diagonal matrix and a constant unitary matrix. Moreover, it is assumed that the expected values of all intensities are the same. A numerical method to approximate the excitation matrix from a set of coupled integral equations was recently proposed in [3]. Our approach is based on an exact analytical solution to find the excitation matrix. Interestingly, the exact approach turns out to be both more robust and less expensive in terms of complexity compared to the numerical method of [3].

The rest of this paper is organized as follows. Background material, some definitions, and the notation are presented in Section 2. Specifically, therein, we formally introduce multivariate Hawkes processes and directed information graphs. In Section 3, we establish the connection between the excitation matrix and the corresponding DIG. In Section 4, we propose an algorithm for learning the excitation matrix or equivalently the DIG of a class of stationary multivariate linear Hawkes processes. Section 5 illustrates the performance of the proposed algorithm in inferring the causal structure in a network of synthesized mutually exciting linear Hawkes processes and in stock market. Finally, we conclude our work in Section 6.

2 PRELIMINARY DEFINITIONS

In this Section we review some basic definitions and our notation. We denote random processes by capital letters and a collection of m random processes by $\underline{X}_{[m]} = \{X_1, ..., X_m\}$, where $[m] := \{1, ..., m\}$. We denote the ith random process at time t by $X_i(t)$, the random process X_i from time s up to time t by $X_{i,s}^t$, and a subset $\mathcal{K} \subseteq [m]$ of random process up to time t by $\underline{X}_{\mathcal{K}}^t$. The Laplace transform and Fourier Transform of X_i are denoted, respectively by

$$L[X_i](s) = \int_0^\infty X_i(t)e^{-st}dt, \tag{1}$$
$$\mathcal{F}[X_i](\omega) = \int_{-\infty}^\infty X_i(t)e^{-j\omega t}dt,$$

where $j = \sqrt{-1}$. The convolution between two functions f and g is defined as $f * g(t) := \int_{\mathbb{R}} f(x)g(t-x)dx$. The joint distribution of processes $\{X_1^n, ..., X_m^n\}$ is represented by $P_{\underline{X}}(n)$.

2.1 MULTIVARIATE HAWKES PROCESSES

Fix a complete probability space $(\Omega, \mathcal{F}, P)$. Let $N(t)$ denotes the counting process representing the cumulative number of events up to time t and let $\{\mathcal{F}^t\}_{t\geq 0}$ be a set of increasing σ-algebras such that $\mathcal{F}^t = \sigma\{N^t\}$. The non-negative, $\mathcal{F}^t$-measurable process $\lambda(t)$ is called the intensity of $N(t)$ if

$$P(N(t+dt) - N(t) = 1|\mathcal{F}^t) = \lambda(t)dt + o(dt).$$

A classical example of mutually exciting processes, a multivariate Hawkes process [8], is a multidimensional process $\underline{N}(t) = \{N_1, ..., N_m\}$ such that for each $i \in [m]$

$$P\left(dN_i(t) = 1|\underline{\mathcal{F}}^t\right) = \lambda_i(t)dt + o(dt), \tag{2}$$
$$P(dN_i(t) > 1|\underline{\mathcal{F}}^t) = o(dt),$$

where $\underline{\mathcal{F}}^t = \sigma\{\underline{N}^t\}$. The above equations imply that $\mathbb{E}[dN_i(t)/dt|\underline{\mathcal{F}}^t] = \lambda_i(t)$. Furthermore, the intensities are all positive and are given by

$$\lambda_i(t) = v_i + \sum_{k=1}^m \int_0^t \gamma_{i,k}(t-t')dN_k(t'). \tag{3}$$

The exciting functions $\gamma_{i,k}(\cdot)$s are in ℓ_1 such that $\lambda_i(t) \geq 0$ for all $t > 0$. Equivalently, in matrix representation:

$$\Lambda(t) = \mathbf{v} + \int_0^t \Gamma(t-t')d\underline{N}(t'), \tag{4}$$

where $\Gamma(\cdot)$ denotes an $m \times m$ matrix with entries $\gamma_{i,j}(\cdot)$; $d\underline{N}, \Lambda(\cdot)$, and $\mathbf{v}$ are $m \times 1$ arrays with entries $dN_i, \lambda_i(\cdot)$, and v_i, respectively. Matrix $\Gamma(\cdot)$ is called the excitation (kernel) matrix. Figure 1 illustrates the intensities of a multivariate Hawkes process comprised of two processes ($m = 2$) with the following parameters

$$\mathbf{v} = \begin{pmatrix} 0.5 \\ 0.4 \end{pmatrix}, \quad \Gamma(t) = \begin{pmatrix} 0.1e^{-t} & 0.3e^{-1.1t} \\ 0.5e^{-0.9t} & 0.3e^{-t} \end{pmatrix} u(t),$$

where $u(t)$ is the unit step function.

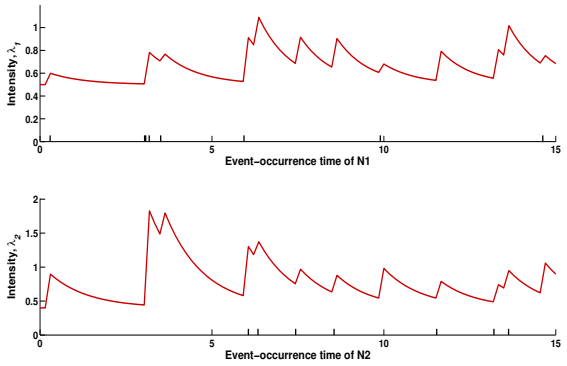

Figure 1: Intensities of the multivariate Hawkes process.

Assumption 1 *A joint distribution is called positive (non-degenerate), if there exists a reference measure ϕ such that $P_{\underline{X}} \ll \phi$ and $\frac{dP_{\underline{X}}}{d\phi} > 0$, where $P_{\underline{X}} \ll \phi$ denotes that $P_{\underline{X}}$ is absolutely continuous with respect to ϕ*[1].

Note that the Assumption 1 states that none of the processes is fully determined by the other processes.

2.2 CAUSAL STRUCTURE

A causal model allows the factorization of the joint distribution in some specific ways. *Generative model graphs* are a type of graphical model that similar to Bayesian networks [17] represent a causal factorization of the joint [19]. More precisely, it was shown in [19] that under Assumption 1, the joint distribution of a causal[2] discrete-time dynamical system with m processes can be factorized as follows,

$$P_{\underline{X}} = \prod_{i=1}^{m} P_{X_i||\underline{X}_{B_i}}, \tag{5}$$

where $B(i) \subseteq -\{i\}$ is the minimal[3] set of processes that causes process X_i, i.e., parent set of node i in the corresponding minimal generative model graph. Such factorization of the joint distribution is called minimal generative model. In Equation (5),

$$P_{X_i||\underline{X}_{B_i}} := \prod_{t=1}^{n} P_{X_i(t)|\underline{\mathcal{F}}^{t-1}_{B\cup\{i\}}},$$

and $\underline{\mathcal{F}}^{t-1}_{B\cup\{i\}} = \sigma\{\underline{X}^{t-1}_{B\cup\{i\}}\}$.

[1] A measure $P_{\underline{X}}$ on Borel subsets of the real line is absolutely continuous with respect to measure ϕ if for every measurable set B, $\phi(B) = 0$ implies $P_{\underline{X}}(B) = 0$.

[2] In causal systems, given the full past of the system, the present of the processes become independent.

[3] Minimal in terms of its cardinality.

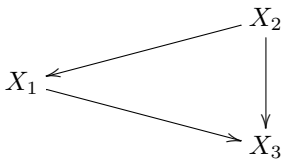

Figure 2: Minimal generative model graph of Example 1.

Extending the definition of generative model graphs to continuous-time systems requires some technicalities which are not necessary for the purpose of this paper. Hence we illustrate the general idea through an example.

The following example demonstrates the minimal generative model graph of a simple continuous-time system.

Example 1 *Consider a dynamical system in which the processes evolve over time horizon $[0, T]$ through the following coupled differential equations:*

$$\begin{aligned} dX_1 &= f(X_1, X_2)dt + dW, \\ dX_2 &= g(X_2)dt + dU, \\ dX_3 &= h(X_1, X_2, X_3)dt + dV, \end{aligned}$$

where W, U and V are independent exogenous noises. For small time dt, this becomes,

$$\begin{aligned} dX_1(t+dt) &\approx \Delta f(X_1(t), X_2(t)) + dW(t), \\ dX_2(t+dt) &\approx \Delta g(X_2(t)) + dU(t), \\ dX_3(t+dt) &\approx \Delta h(X_1(t), X_2(t), X_3(t)) + dV(t). \end{aligned} \tag{6}$$

In this example, since the system is causal, the corresponding joint distribution can be factorized as follows,

$$P_{\underline{X}} = \prod_{j=1}^{3} \prod_{k\geq 0} P_{X_j(T-kdt)|\underline{\mathcal{F}}^{T-(k+1)dt}}, \tag{7}$$

where $\underline{\mathcal{F}}^{T-(k+1)dt} = \sigma\{\underline{X}^{T-(k+1)dt}_{\{1,2,3\}}\}$. Due to (6), we can rewrite (7) as

$$P_{\underline{X}} = P_{X_1||X_2} P_{X_2} P_{X_3||X_1,X_2}. \tag{8}$$

Figure 2 demonstrates the corresponding generative model graph of the factorization in (8).

In general, the joint distribution of a causal dynamical system can be factorized as $P_{\underline{X}} = \prod_{i=1}^{m} P_{X_i||\underline{X}_{B_i}}$, where $B(i) \subseteq -\{i\}$ is the parent set of node i in the corresponding minimal generative model graph, and

$$P_{X_i||\underline{X}_{B_i}} = \prod_{k\geq 0} P_{X_i(T-kdt)|\underline{\mathcal{F}}^{T-(k+1)dt}_{B_i}}.$$

3 TWO EQUIVALENT NOTATIONS OF CAUSALITY FOR HAWKES PROCESSES

In linear multivariate Hawkes processes, a natural notion of causation exists in the following sense: if $\gamma_{i,j} \neq 0$, then

occurrence of an event in jth process will affect the likelihood of the arrivals in ith process. Next, we establish the relationship between the excitation matrix of multivariate Hawkes processes and their generative model graph. To do so, first, we discuss the equivalence of directed information graphs and generative models graphs which was established in [20].

3.1 DIRECTED INFORMATION GRAPHS (DIGs)

An alternative graphical model to encode statistical interdependencies in stochastic causal dynamical systems are *directed information graphs* (DIGs) [19]. Such graphs are defined based on an information-theoretic quantity, *directed information* (DI) that generalizes the Granger causality and it was shown in [20] that under some mild assumptions, they are equivalent to the minimal generative model graphs. Hence, DIGs also represent a minimal factorization of the joint distribution.

In a DIG, to determine whether X_j causes X_i over a time horizon $[0, T]$ in a network of m random processes, two conditional probabilities are compared in KL-divergence sense: one is the conditional probability of $X_i(t+dt)$ given full past, i.e., $\underline{\mathcal{F}}^t := \sigma\{\underline{X}^t\}$ and the other one is the conditional probability of $X_i(t+dt)$ given full past except the past of X_j, i.e., $\underline{\mathcal{F}}^t_{-\{j\}} := \sigma\{\underline{X}^t_{-\{j\}}\}$. It is declared that there is no influence from X_j on X_i, if the two conditional probabilities are the same. More precisely, there is an influence from X_j on X_i if and only if the following directed information measure is positive [19],

$$I_T(X_j \to X_i||\underline{X}_{-\{i,j\}}) := \inf_{\mathbf{t}\in\mathcal{T}(0,T)} \tilde{I}_{\mathbf{t}}(X_j \to X_i||\underline{X}_{-\{i,j\}}), \tag{9}$$

where $-\{i,j\} := [m]\backslash\{i,j\}$, $\mathcal{T}$ denotes the set of all finite partitions of the time interval $[0, T]$ [23], and

$$\tilde{I}_{\mathbf{t}}(X_j \to X_i||\underline{X}_{-\{i,j\}}) := \sum_{k=0}^{n} I\left(X^{t_k}_{i,t_{k-1}}; X^{t_k}_{j,0}|\mathcal{F}^{t_{k-1}}_{-\{j\}}\right),$$

where $\mathbf{t} := (0 = t_0, t_1, ..., t_n = T)$. Finally, $I(X;Y|Z)$ represents the conditional mutual information between X and X given Z and it is given by

$$I(X;Y|Z) := \mathbb{E}_{P_{X,Y,Z}}\left[\log \frac{dP_{X|Y,Z}}{dP_{X|Z}}\right].$$

3.2 EQUIVALENCE BETWEEN GENERATIVE MODEL GRAPHS AND SUPPORT OF EXCITATION MATRIX

As mentioned earlier, the corresponding minimal generative model graph and the DIG of a causal dynamical system are equivalent. Thus, to characterize the corresponding minimal generative model graphs of a multivariate Hawkes system, we study the properties of its corresponding DIG.

Proposition 1 *Consider a set of mutually exciting processes $\underline{N}$ with excitation matrix $\Gamma(t)$. Under Assumption 1, $I_T(N_j \to N_i||\underline{N}_{-\{i,j\}}) = 0$ if and only if $\gamma_{i,j} \equiv 0$ over time interval $[0, T]$.*

Proof: See Section 7.1. □

Proposition 1 signifies that the support of the excitation matrix $\Gamma(\cdot)$ determines the adjacency matrix of the DIG and vice versa. Therefore, learning DIG of a mutually exciting Hawkes processes satisfying Assumption 1 is equivalent to learning the excitation matrix given samples from each of the processes. In other word, in the presence of side information that the processes are Hawkes, it is more efficient to learn the causal structure through learning the excitation matrix rather than the directed information needed for learning the DIG in general.

4 LEARNING THE EXCIATIONA MATRIX

In this section, we present an approach for learning the causal structure of a stationary Hawkes network with exponential exciting functions through learning the excitation matrix. This method is based on second order statistic of the Hawkes processes and it is suitable for the case when no i.i.d. samples are available. Note that when i.i.d. samples are available, non-parametric methods for learning the excitation matrix such as MMEL algorithm [25] exist. In this approach the exciting functions are expressed as linear combination of a set of base kernels and a penalized likelihood is used to estimate the parameters of the model. As mentioned earlier, we focus on learning the excitation matrix of multivariate Hawkes processes with exponential exciting functions. This class of Hawkes processes has been widely applied in many areas such as seismology, criminology, and finance [15, 21, 13, 5].

Definition 2 *The excitation matrix of a multivariate Hawkes processes with exponential exciting functions is defined as follows*

$$\mathcal{E}_{xp}(m) := \{\sum_{d=1}^{D} A_d e^{-\beta_d t}u(t) : A_d \in \mathbb{R}^{m\times m}, \\ (\sum_{d=1}^{D} A_d e^{-\beta_d t})_{i,j} \geq 0, \rho(\sum_{d=1}^{D} \frac{A_d}{\beta_d}) < 1, D \in \mathbb{N}\}, \tag{10}$$

where $\{\beta_d\} > 0$ is called the set of exciting modes.

Example 2 *Consider a set of $m = 5$ mutually exciting processes with the following exponential excitation matrix*

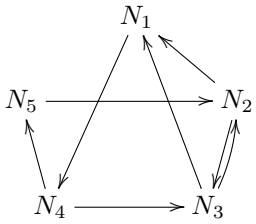

Figure 3: Corresponding DIG of the network in Example 2 with the excitation matrix given by (11)

$$\begin{pmatrix} 2 & 0 & 0 & 0 & 0 \\ 0 & 0 & .5 & 0 & 0 \\ 0 & 1.5 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1.3 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix} \frac{e^{-t}}{20} + \begin{pmatrix} 0 & 0 & .5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 \\ 0 & 1 & 0 & 2.5 & 0 \\ .1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix} \frac{e^{-1.4t}}{20}$$
$$+ \begin{pmatrix} 1 & 1.5 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 \\ 0 & 0 & 2 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \frac{e^{-2t}}{20} \tag{11}$$

In this example $D = 3$ and the exciting modes are $\{1, 1.4, 2\}$. By Proposition 1, the adjacency matrix of the corresponding DIG of this network is given by the support of its excitation matrix. Figure 3 depicts the corresponding DIG.

Before describing our algorithm, we need to derive some useful properties of moments of the process. A multivariate Hawkes process with the excitation matrix Γ has stationary increments, i.e., the intensity processes is stationary, if and only if the following assumption holds [8, 6]:

Assumption 2 *The spectral radius (the supremum of the absolute values of the eigenvalues) of the matrix $\overline{\Gamma}$, where $[\overline{\Gamma}]_{i,j} = ||\gamma_{i,j}||_1$ is strictly less than one, i.e., $\rho(\overline{\Gamma}) < 1$.*

In this case, from (4) and Equation (2):

$$\Lambda = \mathbb{E}[\Lambda(t)] = \mathbf{v} + \int_0^t \Gamma(t-t')\mathbb{E}[d\underline{N}(t')]$$
$$= \mathbf{v} + \int_0^t \Gamma(t-t')\Lambda dt' = \mathbf{v} + \overline{\Gamma}\Lambda. \tag{12}$$

By Assumption 2, $\sum_{i\geq 0} \overline{\Gamma}^i$ converges to $(I - \overline{\Gamma})^{-1}$, thus $\Lambda = (I - \overline{\Gamma})^{-1}\mathbf{v}$. The normalized covariance matrix of a stationary multivariate Hawkes process with lag τ and window size $z > 0$ is defined by

$$\Sigma_z(\tau) := \frac{1}{z}\mathbb{E}\left[\int_t^{t+z} d\underline{N}(x) \int_{t+\tau}^{t+\tau+z} (d\underline{N}(y))^T\right] - \Lambda\Lambda^T z, \tag{13}$$

where $\int_t^{t+t'} d\underline{N}(x)$ denotes the number of events in time interval $(t, t+t']$.

Theorem 3 *[1] The Fourier transform of the normalized covariance matrix of a stationary multivariate Hawkes process with lag τ and window size $z > 0$ is given by*

$$\mathcal{F}[\Sigma_z](-\omega) \tag{14}$$
$$= 4\frac{\sin^2 z\omega/2}{\omega^2 z} \left(I - \mathcal{F}[\Gamma](\omega)\right)^{-1} diag(\Lambda) \left(I - \mathcal{F}[\Gamma](\omega)\right)^{-\dagger},$$

where $A^\dagger$ denotes the Hermitian conjugate of matrix A, and $diag(\Lambda)$ is a diagonal matrix with vector Λ as the main diagonal.

In order to learn the excitation matrix with exponential exciting functions, we need to learn the exciting modes $\{\beta_d\}$, the number of components D, and coefficient matrices $\{A_d\}$. Next results establishes the relationship between the exciting modes and the number of components D with the normalized covariance matrix of the process.

Corollary 4 *Consider a network of a stationary multivariate Hawkes processes with excitation matrix $\Gamma(t)$ belonging to $\mathcal{E}xp(m)$. Then the exciting modes of $\Gamma(t)$ are the absolute values of the zeros of $1/\operatorname{Tr}\mathcal{F}[\Sigma_z]^{-1}(\omega)$.*

Proof: See Section 7.2. □

Next, we need to find the coefficient matrices $\{A_d\}$. To do so, we use the covariance density of the processes. The covariance density of a stationary multivariate Hawkes process for $\tau > 0$ is defined as [8]

$$\Omega(\tau) := \mathbb{E}\left[(d\underline{N}(t+\tau)/dt - \Lambda)(d\underline{N}(t)/dt - \Lambda)^T\right]. \tag{15}$$

Since the processes have stationary increments, we have $\Omega(-\tau) = \Omega^T(\tau)$.

Lemma 5 *[8]*

$$\Omega(\tau) = \Gamma(\tau)diag(\Lambda) + \Gamma * \Omega(\tau), \tau > 0. \tag{16}$$

It has been shown in [3] that the above equation admit a unique solution for $\Gamma(\tau)$. Next proposition provides a system of linear equations that allows us to learn the coefficient matrices.

Proposition 6 *Consider a network of a stationary multivariate Hawkes processes with excitation matrix $\Gamma(t) \in \mathcal{E}xp(m)$, and exciting modes $\{\beta_1, ..., \beta_D\}$. Then $\{A_d\}$ are a solution of the linear system of equations: $\boldsymbol{S} = \boldsymbol{AH}$, where $\boldsymbol{H}_{m^2\times m^2}$ is a block matrix with (i,j)th block given by*

$$\boldsymbol{H}_{i,j} = \frac{diag(\Lambda) + \mathcal{L}[\Omega](\beta_j) + \mathcal{L}[\Omega]^T(\beta_i)}{\beta_j + \beta_i},$$

and $\boldsymbol{A} = [A_1, ..., A_D]$ and $\boldsymbol{S} = [\mathcal{L}[\Omega](\beta_1), ..., \mathcal{L}[\Omega](\beta_D)]$.

Proof: See Section 7.3.□

Combining the results of Corollary 4 and Proposition 6 allows us to learn the excitation matrix of exponential multivariate Hawkes processes from the second order moments. Consequently applying Proposition 1, the causal structure of the network can be learned by drawing an arrow from node i to j, when $\sum_{d=1}^{D} |(A_d)_{j,i}| > 0$.

4.1 ESTIMATION AND ALGORITHM

This section discusses estimators for the second order moments, namely the normalized covariance matrix and the covariance density of a stationary multivariate Hawkes processes from data. Once such estimators are available, the approach of previous section maybe used to learn the network. The most intuitive estimator for Λ defined by Equation (12) is $\underline{N}(T)/T$. It turns out that this estimator converges almost surely to Λ as T goes to infinity [2]. Furthermore, [2] proposes an empirical estimator for the normalized covariance matrix as follows

$$\widehat{\Sigma}_{z,T}(\tau) := \frac{1}{T} \sum_{i=1}^{\lfloor T/z \rfloor} (X_{iz} - X_{(i-1)z})(X_{iz+\tau} - X_{(i-1)z+\tau})^T, \tag{17}$$

where $X_t := \underline{N}(t) - \Lambda t$. In the same paper, it has been shown that under Assumption 2, the above estimator converges in ℓ_2 to the normalized covariance matrix (13), i.e., $\widehat{\Sigma}_{z,T}(\tau) \underset{T\to\infty}{\longrightarrow} \Sigma_z(\tau)$. Notice that the normalized covariance matrix and the covariance density are related by $\Sigma_{dt}(\tau)/dt = \Omega^T(\tau)$. Therefore, we can estimate the covariance density matrix using Equation (17) by choosing small enough window size $z = \Delta$. Namely, $\widehat{\Omega}_{\Delta}^T(\tau) = \widehat{\Sigma}_{\Delta}(\tau)/\Delta$.

Algorithm 1

1: $Input:$ $\underline{N}^T$.
2: $Output:$ DIG.
3: $\widehat{\Lambda} \leftarrow \underline{N}(T)/T$
4: Choose $\sigma > 0$, $z > 0$, and small $\Delta > 0$.
5: Compute $\widehat{\Sigma}_{z,T}(\tau)$ and $\widehat{\Omega}_{\Delta}(\tau)$ using (17).
6: $\{\widehat{\beta}_d\}_{d=1}^{\widehat{D}} \leftarrow$ Zeros of $1/\operatorname{Tr} \mathcal{F}[\Sigma_z]^{-1}(\omega)$.
7: Compute $\mathcal{L}[\widehat{\Omega}_{\Delta}](\widehat{\beta}_d)$ for $d = 1, ..., \widehat{D}$.
8: Solve the set of equations arises from (20) for $\widehat{A}_d$.
9: Draw (j, i) if $\sum_{d=1}^{\widehat{D}} |(\widehat{A}_d)_{i,j}| \geq \sigma$.

Algorithm 1 summarizes the steps of our proposed approach for learning the excitation matrix and consequently the causal structure of an exponential multivariate Hawkes process.

5 EXPERIMENTAL RESULTS

In this section, we present our experimental results for both synthetic and real data.

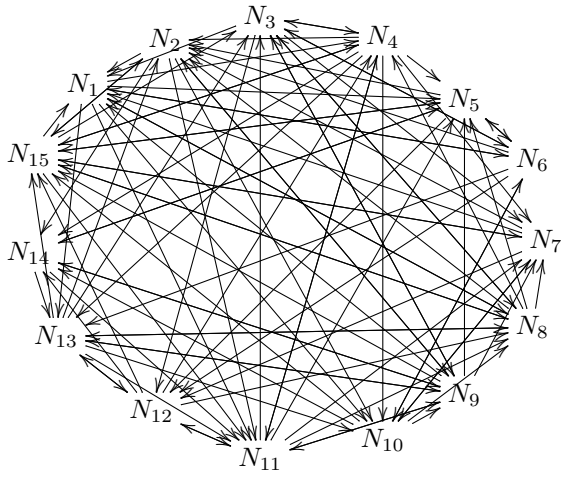

Figure 5: True causal structure of the synthesized example.

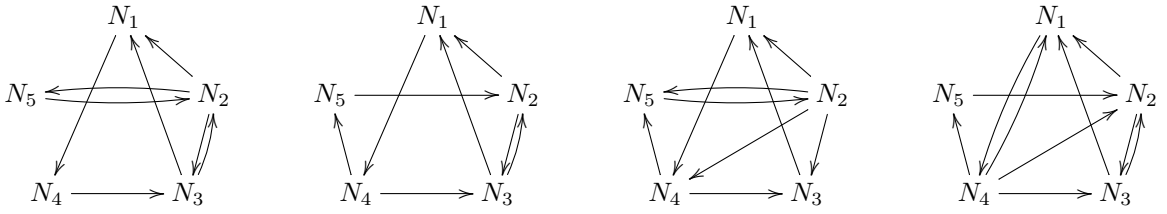
5.1 SYNTHETIC DATA

We apply the proposed algorithms to learn the causal structure of the multivariate Hawkes network of Example 2 with $\mathbf{v} = (0.5, 0.4, 0.5, 1, 0.3)^T$. This network satisfies Assumption 2, since $\rho(\overline{\Gamma}) \approx 0.16$. The exciting modes are $\{1, 1.4, 2\}$. We observed the arrivals of all processes during a time period T. Figure 4 depicts the outputs of algorithms 1 for $\Delta = 0.2$, $z = 2$, and observation lengths $T \in \{1000, 2100\}$. As illustrated in Figure 4, by increasing the length of observation T, the output graph converges the true DIG shown in Figure 3. As a comparison, we applied the MMEL algorithm proposed in [25] to learn the excitation matrix for this example and the numerical method based on Nystrom method proposed in [3] with $T = 2100$ and the number of quadrature $Q = 70$. Since MMEL requires i.i.d. samples, we generate 35 i.i.d. samples each of length 60 to obtain Figure 4(MMEL). Our proposed algorithm outperforms both MMEL and the numerical method of [3].

Furthermore, we conducted another experiment for a network of 15 processes with 102 edges illustrated in Figure 5. For a sample of length $T = 2500$, our algorithm was able to recover 70 edges correctly but identified 34 false arrows. MMEL could only recover 58 arrows correctly while detecting another 41 false arrows. The input for MMEL was 25 sequences each of length 100.

5.2 STOCK MARKET DATA

As an example of how our approach may discover causal structure in real-world data, we analyzed the causal relationship between stock prices of 12 technology companies of the New York Stock Exchange sourced from Google Finance. The prices were sampled every 2 minutes for twenty market days (03/03/2008 - 03/28/2008). Every time a stock price changed by $\pm 1\%$ of its current price an event was



(a) $T = 1000$ (b) $T = 2100$ (c) Numerical method (d) MMEL

Figure 4: Recovered DIG of the network in Example 2 with the excitation matrix given by (11), (a), (b) Algorithm 1 with $\Delta = 0.2$, $z = 2$, and $T \in \{1000, 2100\}$, (c) the numerical method of [3] with $Q = 70$ and $T = 2100$, and (d) MMEL with 35 i.i.d. samples each of length 60. Our approach learns the graph with $T = 2100$, while other approaches fail at the same sample size.

logged on the stock's process. In order to prevent the substantial changes in stock's prices due to the opening and closing of the market, we ignored the samples at the beginning and at the end of each working day. For this part, we have assumed that the jumps occurring in stock's prices are correlated through a multivariate Hawkes process. This model class was advocated in [11, 2]. Figure 6(a) illustrate the causal graph resulting from Algorithm 1, with $z = 30$ and $\Delta = 2$ minutes.

To compare our learning approach with other approaches, we applied the MMEL algorithm to learn the corresponding causal graph. For this scenario, we assumed that the data collected from each day is generated i.i.d. Hence, a total of 20 i.i.d. samples were used. Figure 6(c) illustrates the resulting graph. As one can see, Figures 6(a) and 6(c) convey pretty much a similar causal interactions in the dataset. For instance both of these graphs suggest that one of the most influential companies in that period of time was Hewlett-Packard (HP). Looking into the global PC market share during 2008, we find that this was indeed the case.[4]

To use another modality, we derive the corresponding DIG of this network applying Equation (9). For this part, we used the market based on the Black-Scholes model [4] in which the stock's prices are modeled via a set of coupled stochastic PDEs. We assumed that the logarithm of the stock's prices are jointly Gaussian and therefore the corresponding DIs were estimated using Equation (24) in [7]. The resulting DIG is shown in Figure 6(b). Note that this DIG is derived from the logarithm of prices and not the jump processes we used earlier. Still it shares a lot of similarities with the two other graphs. For instance, it also identifies HP as one of the most influential companies and Microsoft as one the most influenced companies in that time period.

	Alg. 1	DIG	MMEL
Alg. 1	33	25	26
DIG	25	30	24
MMEL	26	24	34

This table shows the number of edges that each of the above approaches recovers and the number of edges that they jointly recover. This demonstrates the power of exponential kernels even when data does not come from such a model class.

5.3 MEMETRACKER DATA

We also studied causal influences in a blogosphere. The causal flow of information between media sites may be captured by studying hyperlinks provided in one media site to others. Specifically, the time of such linking can be modeled using a linear multivariate Hawkes processes with exponential exciting functions [25, 18]. This model is also intuitive in the sense that after emerging a new hot topic, in the first several days, the blogs or websites are more likely feature that topics and it is also more likely that the topic would trigger further discussions and create more hyperlinks. Thus, exponential exciting functions are well suited to capture such phenomenon as the exiting functions should have relatively large values at first and decay fast as time elapses.

For this experiment, we used the MemeTracker[5] dataset. The data contains time-stamped phrase and hyperlink information for news media articles and blog posts from over a million different websites. We extracted the times that hyperlinks to 10 well-known websites listed in Table 1 are created during August 2008 to April 2009. When a hyperlink to a website is created at a certain time, an arrival events is recorded at that time. More precisely, in this experiment, we picked 30 different phrases that appeared on different websites at different times. If a website that published one of the phrases at time t also contained a hyperlink to one of the 10 listed websites, an arrival event was recorded at time t for that website in our list.

Figure 7(a) illustrates the resulting causal structure learned by Algorithm 1 for $z = 12$ hours and $\Delta = 1$ hour. In this graph, an arrow from a node to another, say node Ye to Yo, means creating a hyperlink to `yelp.com` triggers creation of further hyperlinks to `youtube.com`.

We also applied the MMEL algorithm with one exponential kernel function to learn the excitation matrix. For this experiment, the data corresponding to each phrase was treated as an i.i.d. realization of the system. The resulting causal structure is depicted in Figure 7(b).

As Figure 7(a) illustrates, the nodes can be clustered into two main groups: {Cr, Ye, Am, Yo} and {Bb, Cn, Gu, Hu, Sp, Wi}. The first group consists of mainly merchandise and reviewing websites and the second group contains the broadcasting websites. However, this is not as clear in Figure 7(b). This is because MMEL requires more i.i.d. samples (phrases) to be able to identify the correct arrows. Note that as we increase the number of phrases (110), Figure 7(c), both graphs become similar with two clearly visible main clusters.

6 CONCLUSION

Learning the causal structure (DIG) of a stochastic network of processes requires estimation of conditional directed information (9). Estimating this quantity in general has high complexity and requires a large number of samples. However, the complexity of the learning task could be significantly reduced, if side information about the underlying structure of system dynamics is available. As proved in 1, for multivariate Hawkes processes, estimating the support of the excitation matrix suffices to learn the associated DIG. Therefore, all approaches for learning the excitation matrix of the multivariate Hawkes processes such as ML estimation [16, 25], EM algorithm [10], non-parametric estimation techniques proposed in [2], and the proposed method in this paper may be used to learn the causal interactions in such networks. The previous estimation approaches either require i.i.d. samples such as MMEL or are limited to the class of symmetric Hawkes processes. The proposed algorithm in this work allows us to learn the support of the excitation matrix in a larger class of matrices in the absence of i.i.d. samples.

7 TECHNICAL PROOFS

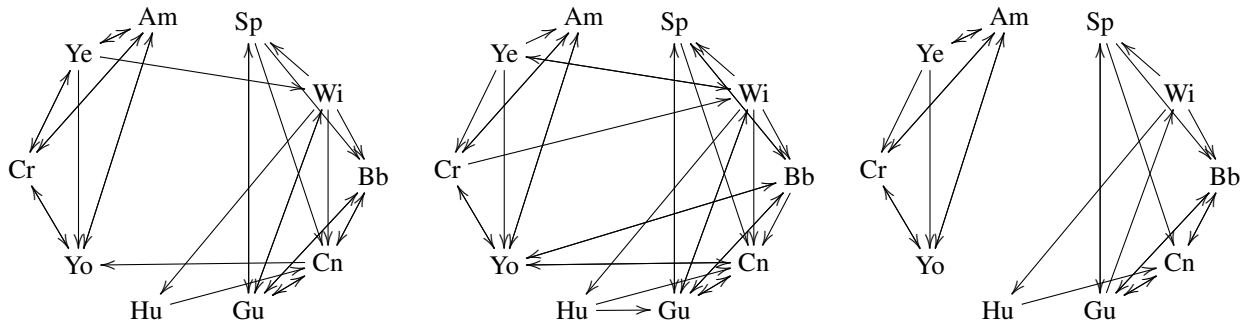
7.1 Proof of Proposition 1

Suppose $\gamma_{i,j} \equiv 0$. (3) implies that for every $t \leq T$, $\lambda_i(t)$ is $\underline{\mathcal{F}}^t_{-\{j\}} (= \sigma\{\underline{N}^t_{-\{j\}}\})$-measurable and from (2), we have

$$P\left(dN_i(t) = 1 | \underline{\mathcal{F}}^t\right) = P(dN_i(t) = 1 | \underline{\mathcal{F}}^t_{-\{j\}}).$$

Equivalently, for every $0 \leq t_{k-1} < t_k$,

$$I\left(N^{t_k}_{i,t_{k-1}}; N^{t_k}_{j,0} | \mathcal{F}^{t_{k-1}}_{-\{j\}}\right) = 0, \tag{18}$$



(a) Alg. 1 (30). (b) MMEL. (c) Both Alg. 1 & MMEL (110).

Figure 7: Recovered causal structure of the MemeTracker dataset using (a) Algorithm 1, (b) MMEL for 30 different phrases, and (c) both Algorithm 1 and MMEL for 110 different phrases.

and thus, $\tilde{I}_{\mathbf{t}}(N_j \to N_i || \underline{N}_{-\{i,j\}}) = 0$, for any finite partition $\mathbf{t} \in \mathcal{T}(0,T)$.

For the converse we use proof by contradiction. Suppose $I_T(N_j \to N_i || \underline{N}_{-\{i,j\}}) = 0$ and $\gamma_{i,j} \neq 0$. Using the definition in (9), it is straightforward to observe that for any $t < T$,

$$I_t(N_j \to N_i || \underline{N}_{-\{i,j\}}) = 0.$$

Similarly, $I_{t+dt}(N_j \to N_i || \underline{N}_{-\{i,j\}}) = 0$. Consequently,

$$0 = I_{t+dt}(N_j \to N_i || \underline{N}_{-\{i,j\}}) - I_t(N_j \to N_i || \underline{N}_{-\{i,j\}})$$

$$= I\left(dN_i(t); N_{j,0}^t | \underline{\mathcal{F}}_{-\{j\}}^t\right).$$

This implies $P(dN_i(t) = 1 | \underline{\mathcal{F}}_{-\{j\}}^t) = \lambda_i(t)dt + o(dt)$, or $\lambda_i(t)$ is $\underline{\mathcal{F}}_{-\{j\}}^t$-measurable. Since, we have assumed $\gamma_{i.j} \neq 0$, we obtain $N_j(t)$ is $\underline{\mathcal{F}}_{-\{j\}}^t$-measurable, for all $t \leq T$. In words, jth process is determined by other processes which contradicts with the Assumption 1 that states there is no deterministic relationships between processes.

7.2 Proof of Corollary 4

If the excitation matrix belongs to $\mathcal{E}xp(m)$, from Equation (14) we have

$$\left(I - \sum_{d=1}^{D} \frac{A_d^T}{j\omega + \beta_d}\right) diag(\Lambda)^{-1} \left(I - \sum_{d=1}^{D} \frac{A_d}{-j\omega + \beta_d}\right)$$
$$= \frac{4\sin^2 z\omega/2}{\omega^2 z} \mathcal{F}[\Sigma_z]^{-1}(\omega).$$

By evaluating the trace of the above equation, we obtain

$$\sum_{i=1}^{m} \frac{|1 - a_{i,i}|^2}{\lambda_i} + \sum_{i \neq j} \frac{|a_{i,j}|^2}{\lambda_i} = \frac{4\sin^2 z\omega/2}{\omega^2 z} \operatorname{Tr} \mathcal{F}[\Sigma_z]^{-1}(\omega), \tag{19}$$

where $a_{i,j} = \sum_{d=1}^{D} \frac{a_{i,j}^{(d)}}{-j\omega + \beta_d}$, and $A_d = [a_{i,j}^{(d)}]$. To learn the entire set $\{\pm j\beta_d\}$, we have to show that there are no pole zero cancellations in (19). That is, the nominator and denominator of (19) have no common roots. Let

$$g(\omega) := \left(\sum_{i=1}^{m} \frac{|1 - a_{i,i}|^2}{\lambda_i} + \sum_{i \neq j} \frac{|a_{i,j}|^2}{\lambda_i}\right) \prod_{d=1}^{D} |-j\omega + \beta_d|^2,$$

which is the nominator of Equation (19). It is straightforward to check that for $\omega = -j\beta_k$, the above quantity is non-zero, due to the fact that β_ds are distinct and $A_k \neq \mathbf{0}$. Since $g(\omega)$ is a polynomial with real coefficients, from complex conjugate root theorem [9], we have $g(j\beta_k) \neq 0$. Therefore, the set $\{\pm j\beta_d\}$ contains all the poles of (19).

7.3 Proof of Proposition 6

From Lemma 5, the Laplace transform of the covariance density can be written as

$$\mathcal{L}[\Omega](s) = \mathcal{L}[\Gamma](s) \left(diag(\Lambda) + \mathcal{L}[\Omega](s)\right)$$
$$+ \int_0^\infty \int_t^\infty \Gamma(t')\Omega^T(t) e^{-s(t'-t)} dt' dt.$$

When $\Gamma(t) \in \mathcal{E}xp(m)$, it can be shown that (1) becomes

$$\mathcal{L}[\Omega](s) = \sum_{d=1}^{D} \frac{A_d}{s + \beta_d} \left(diag(\Lambda) + \mathcal{L}[\Omega](s) + \mathcal{L}[\Omega]^T(\beta_d)\right). \tag{20}$$

If the set of exciting modes are given, we can insert $s = \beta_d$, for $d = 1, \ldots, D$ in the above equation and obtain the system of D equations.

Abstract

Markov Chain Monte Carlo techniques remain the gold standard for approximate Bayesian inference, but their practical issues — including onerous runtime and sensitivity to tuning parameters — often lead researchers to use faster but typically less accurate deterministic approximations. Here we couple the fast but biased deterministic approximation offered by expectation propagation with elliptical slice sampling, a state-of-the-art MCMC method. We extend our hybrid deterministic-MCMC method to include recycled samples and analytical slices, and we rigorously prove the validity of each enhancement. Taken together, we show that these advances provide an order of magnitude gain in efficiency beyond existing state-of-the-art sampling techniques in Bayesian classification and multivariate gaussian quadrature problems.

1 INTRODUCTION

Exact posterior inference in Bayesian models is rarely tractable, a fact which has prompted vast amounts of research into efficient approximate inference techniques. Deterministic methods such as the Laplace approximation, Variational Bayes, and Expectation Propagation offer fast and analytical posterior approximations, but introduce potentially significant bias due to their restricted form which can not capture important characteristics of the true posterior. Markov Chain Monte Carlo (MCMC) methods represent the target posterior with samples, which while asymptotically exact, can be slow, require substantial tuning, and perform poorly when variables are highly correlated.

Conceptually, these two techniques can be combined to great benefit: if a deterministic approximation can cover the true posterior mass accurately, then a subsequent MCMC sampler should be much faster and be less susceptible to inefficiency due to correlation (as the deterministic approximation would have captured this correlation). To do so, however, is practically quite difficult. First, both the Laplace and Variational Bayesian approximations fit local mass of a posterior (in Variational Bayes this is sometimes called the *exclusive* property of optimizing the Kullback-Liebler divergence from the approximation to the true posterior [Minka, 2005]). While excellent in many situations, this property is inappropriate for initializing an MCMC sampler, since it will be very difficult for that sampler to explore other areas of posterior mass (e.g., other modes). Expectation Propagation (EP, [Minka, 2001]), on the other hand, is typically derived as an inclusive approximation that, at least approximately, attempts to match the global sufficient statistics of the true posterior (most often the first and second moments, producing a Gaussian approximation). Such a choice is superior for an MCMC sampler.

Secondly, we require a sensible choice of MCMC sampler so as to leverage a deterministic approximation like EP. Given an unnormalized target distribution $p^*(\mathbf{x})$, we can write:

$$p^*(\mathbf{x}) \;=\; \hat{p}(\mathbf{x})\frac{p^*(\mathbf{x})}{\hat{p}(\mathbf{x})} \;\equiv\; \hat{p}(\mathbf{x})\hat{\mathcal{L}}(\mathbf{x}),$$

which allows us to treat the true posterior as the product of an effective prior $\hat{p}$ and likelihood $\hat{\mathcal{L}}$. We then have freedom to choose $\hat{p}$, which we will set to be the deterministic (Gaussian) posterior approximation from EP. Amongst all MCMC methods, Elliptical Slice Sampling (ESS, [Murray et al., 2010]) handles the above reformulations seamlessly. ESS has become an important and generic method for posterior inference with models that have a strong Gaussian prior. It inherits the attractive properties of slice sampling generally [Neal, 2003], and notably lacks tuning parameters that are often highly bur-

densome in other state-of-the-art methods like Hamiltonian Monte Carlo (HMC; Neal [2011]). The critical observation is that, if EP provides a quality posterior approximation $\hat{p} \approx p^*$, the likelihood term $\hat{\mathcal{L}}$ will typically be weak, which puts ESS in the regime where it is most efficient.

What results is a new MCMC sampler that combines EP and ESS, is faster than state-of-the-art samplers like HMC, and is able to explore the parameter space efficiently even in the presence of strong dependency among variables. Specifically, our contributions include:

1. In Section 2, we propose *Expectation Propagation based Elliptical Slice Sampling (EPESS)* where we justify the use of EP as the "prior" for ESS.

2. In Section 3, we investigate a method to improve the overall run time of ESS by sampling multiple points each iteration. It reduces the average number of shrinkage steps giving it a computational advantage. We call it *Recycled ESS* and integrate it with EPESS to further increase its efficiency.

3. We extend our method to *Analytic Elliptical Slice Sampling* in Section 4. As the name suggests, we can analytically find the region corresponding to a slice and sample uniformly from it. In addition to decorrelating samples, it offers the computational advantage of avoiding expensive shrinkage steps. It is applicable to only a few target distributions and we illustrate it, in the context of EPESS, for linear Truncated Multivariate Gaussian (TMG) quadrature.

4. We offer empirical evaluation of EPESS (Section 5), which show an order of magnitude improvement over the state-of-the art MCMC methods for TMG and probit models.

2 EXPECTATION PROPAGATION AND ELLIPTICAL SLICE SAMPLING

In this section we introduce our combined EP and ESS sampling method. We begin with background of the two building blocks of this method, to place them in context of current literature.

2.1 ELLIPTICAL SLICE SAMPLING

There are many problems where dependency between latent variables is induced through a Gaussian prior, for example in Gaussian Processes. Elliptical Slice Sampling (ESS, [Murray et al., 2010]) is specifically designed for efficiently sampling from such distributions and is considered state-of-the-art on these problems. ESS considers posteriors of the form

$$p^*(\mathbf{x}) = \frac{1}{Z}\mathcal{N}(\mathbf{x}; \mathbf{0}, \mathbf{\Sigma})\mathcal{L}(\mathbf{x}) \tag{1}$$

where $\mathcal{L}$ is a likelihood function, $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$ is a multivariate Gaussian prior and Z is the normalizing constant.

ESS is a variant of slice sampling [Neal, 2003] that takes advantage of the Gaussian prior to improve mixing time and eliminate parameter tuning. At the beginning of each iteration of ESS two random variables are sampled. The first is the slice height y which is uniformly distributed over $[0, \mathcal{L}(\mathbf{x})]$, where $\mathbf{x}$ is the current sample. The second variable $\boldsymbol{\nu}$ is sampled from the prior $\mathcal{N}(\mathbf{x}; \mathbf{0}, \mathbf{\Sigma})$ and, together with the current sample $\mathbf{x}$, defines an ellipse:

$$\mathbf{x}'(\theta) = \mathbf{x}\cos(\theta) + \boldsymbol{\nu}\sin(\theta). \tag{2}$$

Next, a one-dimensional angle bracket $[\theta_{\min}, \theta_{\max}]$ of length 2π is proposed containing the point $\theta = 0$ (corresponding to the current point $\mathbf{x}$). The bracket is then shrunk toward $\theta = 0$ until a point is found within the bracket that satisfies $\mathcal{L}(\mathbf{x}'(\theta)) > y$. This point is accepted as the next point in the Markov chain.

ESS is known to work well when the prior aligns with the posterior and the likelihood is weak [Murray et al., 2010, Section 2.5]. However, when this is not the case then ESS can perform poorly, as we demonstrate below.

Figure 1 illustrates the problem when the prior and the posterior do not align: here we have a $\mathcal{N}(\mathbf{0}, \mathbf{I})$ prior with an observed Bernoulli likelihood $\mathcal{L}(\mathbf{x}) = \mathbb{1}(\mathbf{x} \in A)$ for some rectangle A. The posterior is a truncated Gaussian within A. In this example we have placed A away from the origin, with the result that that most of the posterior density lies vertically on the left boundary of the box. Accordingly, a good sampler should be able to make large vertical moves to effectively explore the posterior mass.

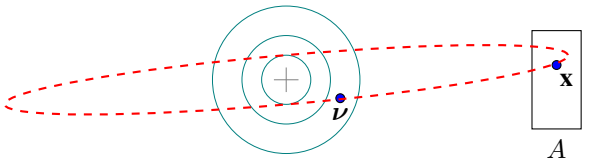

Figure 1: ESS ellipse shown in dashed red.

As the likelihood rectangle A moves further right, the posterior moves away from the prior. As a result most of the points proposed on the ellipse will not lie in A, so more shrinkage steps will be necessary until a point is accepted, leading to an inefficient algorithm. Moving A

further to the right also makes the ellipse more eccentric which prevents vertical movement, resulting in further inefficiency.

The other pathology afflicting ESS is that of strong likelihoods. This happens when $\mathcal{L}(\mathbf{x})$ is extremely large in regions of non-negligible posterior density. Once the sampler is in such a region, only with low probability will it be able to accept points proposed outside the region, hence it will get stuck. This will occur, for instance, when the prior underestimates the variance of the posterior and $\mathcal{L}(\mathbf{x})$ becomes large in the tails. We refer the reader to an extended explanation of this effect in [Nishihara et al., 2014]. Indeed, this motivates our choice of EP as a prior, since Variational Bayes and Laplace approximations are known to often underestimate posterior variance whereas EP does not [Minka, 2005].

We address both these problems by choosing an EP prior (Section 2.2) for ESS. How to incorporate EP into ESS is explained in Section 2.3.

2.2 EXPECTATION PROPAGATION

Expectation Propagation (EP) is a method for finding a Gaussian approximation q to a given distribution p^* by iteratively matching local moments and then updating the global approximation via a so-called 'tilted' distribution [Minka, 2001]. At termination the distribution q will optimize a global objective that approximates the Kullback-Liebler divergence $KL(p^*||q)$ [Wainwright and Jordan, 2008]. The resulting Gaussian approximation is an *inclusive* estimate of p^* that approximately matches its zeroth, first, and second moments.

Although EP has few theoretical guarantees [Dehaene and Barthelmé, 2015], it is known to be accurate for many models including truncated multivariate gaussian [Cunningham et al., 2011], probit and logistic regression [Nickisch and Rasmussen, 2008], log-Gaussian Cox processes [Ko and Seeger, 2015], and more [Minka, 2001]. It is also known to have superior performance compared to the Laplace approximation and Variational Bayes in terms of approximating marginal distributions accurately [Kuss and Rasmussen, 2005, Cseke and Heskes, 2011, Deisenroth and Mohamed, 2012].

2.3 ELLIPTICAL SLICE SAMPLING WITH EXPECTATION PROPAGATION

As outlined in Section 1, we incorporate a posterior approximation $\hat{p}$ as a proposal distribution for ESS. We do so by defining:

$$p^*(\mathbf{x}) \;=\; \hat{p}(\mathbf{x})\frac{p^*(\mathbf{x})}{\hat{p}(\mathbf{x})} \;=\; \hat{p}(\mathbf{x})\hat{\mathcal{L}}(\mathbf{x}) \qquad (3)$$

where p^* is the posterior distribution of interest from Equation (1), $\hat{p}$ is our new prior and $\hat{\mathcal{L}}$ is our new likelihood. As explained in Section 2.1, for ESS to work well, $\hat{p}$ should have two desirable properties: *(i)* It should approximate the posterior p^*. The most obvious candidates for $\hat{p}$ includes Laplace, Variational Bayes and EP approximations, *(ii)* It should ensure that the new likelihood $\hat{\mathcal{L}} = p^*/\hat{p}$ is weak, in the sense as described in Section 2.1. Using either Laplace or Variational Bayes may result in large values of $\hat{\mathcal{L}}$ in the tails due to variance underestimation, which could cause the sampler to get stuck. The more inclusive nature of the EP estimate, on the other hand, makes it a sensible choice to obtain a Gaussian posterior approximation $\hat{p}$.

To demonstrate the power of this approach we return to the problematic example given in Figure 1. Using the EP approximation we can shift our prior to align with the posterior density on the left side of the likelihood rectange A. The ellipses become short and vertical, allowing ESS to mix efficiently. This is illustrated in Figure 2. To demonstrate the difference in the sampling behavior between EPESS and ESS, Figure 2.3 plots 400 samples from both EPESS and ESS. EPESS is clearly superior and manages to explore the entire distribution whereas ESS moves consistently less.

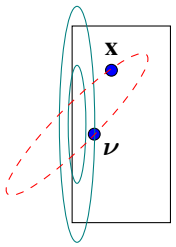

Figure 2: The EP approximation is in teal and an EPESS elliptical slice is in dashed red.

The idea of Equation (3) is not unique to this paper. Nishihara et al. [2014] use a similar construction where the Gaussian approximation is learned from samples. Although this has the advantage of not relying on EP to do moment matching, it requires parallelism and expensive moment calculations. EPESS will be simpler and more efficient when an accurate EP approximation is available. Braun and Bonfrer [2011] also have a similar method where they use the Laplace approximation, which as discussed, is a poor choice. We remark that using Power EP approximations is also a viable choice for a prior, a point that we will return to in Section 6.

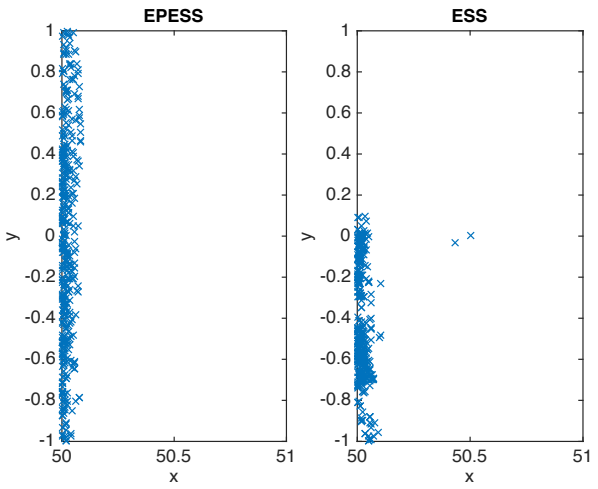

Figure 3: EPESS vs ESS: 400 samples of EPESS and ESS for a 2-d Gaussian $\mathcal{N}(\mathbf{0}, \mathbf{I})$ truncated in a rectangular box $\{50 \leq x \leq 51, -1 \leq y \leq 1\}$. EPESS explores the parameter space effectively whereas ESS does not.

Algorithm 1: `Recycled_ESS`

Input : Log-likelihood function $(\log \mathcal{L})$, initial point $\mathbf{x}_1^{(1)} \in \mathbb{R}^d$, prior $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$, number of iterations N, number of recycled points J

Output: Samples from Markov Chain $((\mathbf{x}_1^{(1)}, ..., \mathbf{x}_J^{(1)}), ..., (\mathbf{x}_1^{(N)}, ..., \mathbf{x}_J^{(N)}))$

      $(\log \mathcal{L}, \log y, \boldsymbol{\nu}, \mathbf{x}_1^{(i-1)}, \theta_{min}, \theta_{max})$
  end
  $(\mathbf{x}_1^{(i)}, ..., \mathbf{x}_J^{(i)}) \leftarrow$ `rand_perm`$(\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)})$
end
return $((\mathbf{x}_1^{(1)}, ..., \mathbf{x}_J^{(1)}), ..., (\mathbf{x}_1^{(N)}, ..., \mathbf{x}_J^{(N)}))$

3 RECYCLED ELLIPTICAL SLICE SAMPLING

In this section we show how to sample $J > 1$ points at every ESS iteration without a significant increase in computational complexity. This idea is inspired by the work of Nishimura and Dunson [2015] on HMC. In that work an HMC algorithm is devised which "recycles" the intermediate points as valid samples from the target distribution. We borrow the phrase "recycling" from them and call our method *Recycled Elliptical Slice Sampling*.

Recall that in every ESS iteration, we propose points along an ellipse within an angle bracket, which is iteratively shrunk, until a point is accepted. In Recycled ESS, we don't stop after accepting the first point but continue to propose points starting from the last angle bracket used. This procedure is continued until J points are accepted. One of the J points is randomly selected to propagate the Markov chain.

As we shrink the angle bracket $[\theta_{\min}, \theta_{\max}]$ towards $\theta = 0$ (corresponding to the current point), the probability of the next proposal point being accepted tends to increase. Hence the number of shrinkage steps required to accept latter points is typically smaller than that for first accepted point. Since the number of likelihood function evaluations is proportional to the number of shrinkage steps, Recycled ESS is able to sample more points with only a small increase in computational complexity, leading to improved run times per sample. This approach is formalized in Algorithm 1, where `ESS_inner_loop` function is the regular ESS inner loop and can be found in Figure 2 of [Murray et al., 2010].

It is clear from Algorithm 1 that we treat each sample $\mathbf{x}_j^{(i)}$ as an element in a large Markov chain with state space $(\mathbf{x}_1^{(i)}, ..., \mathbf{x}_J^{(i)})$. We prove in Theorem 3.2 that each element $\mathbf{x}_j^{(i)}$ has its stationary marginal distribution as p^*. In order to do so, we first show in Lemma 3.1 that the transition operator of accepting the j^{th} point is reversible.

Lemma 3.1. *Let T_j correspond to the transition operator from $\mathbf{x}_1^{(i-1)} \rightarrow \hat{\mathbf{x}}_j^{(i)}$. Then T_j is invariant to p^*.*

A detailed proof is given in the appendix. Theorem 3.2 easily follows:

Theorem 3.2. *Each element in the Recycled ESS Markov chain has marginal stationary distribution p^*.*

Proof. The sequence of points $\{\mathbf{x}_1^{(i)}\}$ follow a Markov Chain. At each step the transition operator is uniformly sampled from the set $\{T_j : j = 1, ..., J\}$, with each T_j being invariant to p^* (Lemma 3.1). Therefore we have that $\mathbf{x}_1^{(i)} \xrightarrow{dist.} \mathbf{x}^*$ where $\mathbf{x}^* \sim p^*$. Also, at any fixed iteration i, we have that all points in $\{\mathbf{x}_j^{(i)} : j = 1, ..., J\}$ are identically distributed. This follows from the random permutations:

$$\begin{aligned} p(\mathbf{x}_j^{(i)} | (\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)})) &= \text{Uniform}(\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)}) \\ &= p(\mathbf{x}_k^{(i)} | (\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)})). \end{aligned}$$

Integrating over $p(\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)})$ gives us that $p(\mathbf{x}_j^{(i)}) =$

$p(\mathbf{x}_1^{(i)})$ for any i, j. Since we have that $\mathbf{x}_1^{(i)} \xrightarrow{dist.} \mathbf{x}^*$, it follows that for all j: $\mathbf{x}_j^{(i)} \xrightarrow{dist.} \mathbf{x}^*$. □

The downside of Recycled ESS is that the latter accepted points (corresponding to $j \approx J$) are sampled from a very small angle bracket and so are highly correlated. On the other hand these points only require a small number of function evaluations. Overall the effect of recycling is a small increase in the effective number of samples, with a small increase in computational complexity. Whether or not this is beneficial is investigated empirically in Section 5.

4 ANALYTIC ELLIPTICAL SLICE SAMPLING

Consider the ellipse

$$\mathcal{E} = \{\mathbf{x}' : \mathbf{x}'(\theta) = \mathbf{x}\cos(\theta) + \boldsymbol{\nu}\sin(\theta)\}$$

as in an ESS iteration as defined by Equation (2). Let $\mathcal{S}(y; \mathcal{E})$ be the slice corresponding to the acceptable points in $\mathcal{E}$ for a given slice height y:

$$\mathcal{S}(y; \mathcal{E}) = \{\mathbf{x}' \in \mathcal{E} : \mathcal{L}(\mathbf{x}') > y\}.$$

If we can analytically characterize $\mathcal{S}(y; \mathcal{E})$ then we only need to sample a point uniformly from the slice to propagate the Markov Chain [Neal, 2003]. This has three advantages: *(i)* We eliminate expensive slice shrinkage steps which reduces the computational cost of our sampler; *(ii)* In standard slice sampling algorithms, shrinkage steps bias the next sample to be close to the current sample thereby introducing correlations. Since we uniformly sample over $\mathcal{S}(y; \mathcal{E})$, the resulting samples are less correlated as we are not biased towards the current point; *(iii)* We can easily incorporate the recycling idea here resulting in an extremely efficient algorithm, which we refer to as *Analytic Elliptical Slice Sampling*.

As in Recycled ESS, in Analytic ESS we sample $J > 1$ points from each ellipse $\mathcal{E}$. We first sample J different y values, which are evenly spaced in a Quasi Monte-Carlo way. Corresponding to each y value, we analytically solve for $\mathcal{S}(y; \mathcal{E})$ (which has only a small amortized computational cost). One point is then uniformly sampled from each slice $\mathcal{S}(y; \mathcal{E})$. The pseudocode for Analytic ESS is given in Algorithm 2 and in Theorem 4.1 we prove its validity.

Theorem 4.1. *Each element in the Analytic ESS Markov chain has marginal stationary distribution p^*.*

Proof. The proof follows exactly the same argument as in Theorem 3.2. □

Algorithm 2: `Analytic_Slice_Sampling`

Input : Likelihood $\hat{\mathcal{L}}$, prior $\hat{p}$, initial point $\mathbf{x}_1^{(0)}$, subroutine `Sample_Ellipse` to sample an ellipse, subroutine `Characterize_Slice` to analytically characterize $\mathcal{S}(\cdot; \mathcal{E})$, number of iterations N, number of slices per iteration J

Output: Samples from Markov Chain $((\mathbf{x}_1^{(1)}, ..., \mathbf{x}_J^{(1)}), ..., (\mathbf{x}_1^{(N)}, ..., \mathbf{x}_J^{(N)}))$

for $i = 1$ **to** N **do**
  $\mathcal{E} \leftarrow$ `Sample_Ellipse`$(\mathbf{x}_1^{(i-1)}, \hat{p})$
  $\mathcal{S}(\cdot; \mathcal{E}) \leftarrow$`Characterize_Slice`$(\mathcal{E})$
  $u \sim$ Uniform $[0, 1]$
  for $j = 1$ **to** J **do**
    $y \leftarrow (j - u)/J \cdot \hat{\mathcal{L}}(\mathbf{x}_1^{(i-1)})$
    $\mathbf{x}_j^{(i)} \leftarrow$ Uniform $\{\mathbf{x} : \mathbf{x} \in \mathcal{S}(y; \mathcal{E})\}$
  end
  $(\mathbf{x}_1^{(i)}, ..., \mathbf{x}_J^{(i)}) \leftarrow$ `rand_perm`$(\hat{\mathbf{x}}_1^{(i)}, ..., \hat{\mathbf{x}}_J^{(i)})$
end
return $((\mathbf{x}_1^{(1)}, ..., \mathbf{x}_J^{(1)}), ..., (\mathbf{x}_1^{(N)}, ..., \mathbf{x}_J^{(N)}))$

Unfortunately solving for $\mathcal{S}(y; \mathcal{E})$ in closed form is not possible in general, although it can be done for Truncated Multivariate Gaussian (TMG) quadrature as shown below.

4.1 ANALYTIC EPESS FOR TMG

The (linear) TMG distribution is defined as:

$$p^*(\mathbf{x}) = \frac{1}{Z}\mathcal{N}(\mathbf{x}; \mathbf{0}, \mathbf{I}) \prod_{j=1}^{M} \mathbb{1}(L_j^\top \mathbf{x} \geq 0).$$

Using the EP approximation $\mathcal{N}(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma})$ and Equation (3), we can rewrite the density p^* as:

$$\begin{aligned}
p^*(\mathbf{x}) &\propto \mathcal{N}(\mathbf{x}; \mathbf{0}, \mathbf{I}) \prod_{j=1}^{m} \mathbb{1}(L_j^\top \mathbf{x} \geq 0) \\
&\propto \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) \frac{\mathcal{N}(\mathbf{x}; \mathbf{0}, \mathbf{I})}{\mathcal{N}(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma})} \prod_{j=1}^{m} \mathbb{1}(L_j^\top \mathbf{x} \geq 0) \\
&= \mathcal{N}(\mathbf{z}; \mathbf{0}, \boldsymbol{\Sigma}) \frac{\mathcal{N}(\mathbf{z}; -\boldsymbol{\mu}, \mathbf{I})}{\mathcal{N}(\mathbf{z}; \mathbf{0}, \boldsymbol{\Sigma})} \prod_{j=1}^{m} \mathbb{1}(L_j^\top (\mathbf{z} + \mu) \geq 0) \\
&\equiv \mathcal{N}(\mathbf{z}; \mathbf{0}, \boldsymbol{\Sigma}) \hat{\mathcal{L}}(\mathbf{z}) \\
&\equiv \tilde{p}(\mathbf{z})
\end{aligned}$$

where $\mathbf{x} = \mathbf{z} + \boldsymbol{\mu}$ is a transformation with identity Jacobian. We are able to apply Analytic ESS to $\tilde{p}(\mathbf{z})$ and can then recover samples for $\mathbf{x}$ by reversing the transforma-

tion. First we analytically characterize the slice:

$$\begin{aligned}\mathcal{S}(y;\mathcal{E}) &= \{\theta \in [0,2\pi) : \mathcal{L}(\mathbf{z}'(\theta)) > y\} \\ &= \cap_{j=1}^{m}\{\theta \in [0,2\pi) : L_j^\top \mathbf{z}'(\theta) + L_j^\top \mu \geq 0\} \\ &\quad \cap \{\theta \in [0,2\pi) : \frac{\mathcal{N}(\mathbf{z}'(\theta); -\boldsymbol{\mu}, \mathbf{I})}{\mathcal{N}(\mathbf{z}'(\theta); \mathbf{0}, \boldsymbol{\Sigma})} > y\} \\ &\equiv \cap_{j=1}^{m}\Theta_j \cap \Theta_y,\end{aligned}$$

where $\mathbf{z}'(\theta) = \mathbf{z}\cos(\theta) + \boldsymbol{\nu}\sin(\theta)$. The region Θ_j is the part of the ellipse that lies in the halfspace defined by L_j. Since it is defined by a linear inequality of $\sin(\theta)$ and $\cos(\theta)$, it is easily characterized using basic trigonometry. The resulting region may be rewritten as $\Theta_j = [0, l_j] \cup [u_j, 2\pi]$ for some $l_j, u_j \in (0, 2\pi)$. Due to this nice structure, taking the intersection of all m regions can be computed in $\mathcal{O}(m)$. Region Θ_y can be simplified by taking logarithms on both sides of its inequality and reduces to the form:

$$a_0 + a_1\cos\theta + a_2\sin\theta + a_3\cos\theta\sin\theta + a_4\cos^2\theta > 0.$$

The roots of this inequality can be obtained by solving a quartic equation. This completes our analytic characterization of $\mathcal{S}(y;\mathcal{E})$.

The most expensive operations in Analytic ESS are generating $\mathcal{E}$ and characterizing $\mathcal{S}(y;\mathcal{E})$, as sampling from $\mathcal{S}(y;\mathcal{E})$ is relatively cheap. To see this, let d denote the dimension of $\mathbf{x}$ and m the number of linear truncations. To sample the ellipse $\mathcal{E}$ we must draw $\boldsymbol{\nu}$ from the Gaussian prior which costs $\mathcal{O}(d^2)$. Characterizing the slice $\mathcal{S}(y;\mathcal{E})$ involves m inner products of $\mathbf{x}$ and $\boldsymbol{\nu}$ with the linear truncations L_j and can be calculated in $\mathcal{O}(md)$. The total computational overhead is thus $\mathcal{O}(d^2 + md)$. Once this is done, sampling from $\mathcal{S}(y;\mathcal{E})$ is cheap. It involves sampling from an intersection of $\mathcal{O}(m)$ intervals which can be done in $\mathcal{O}(d+m)$ (here we have factored in the expense of storing each sample at a cost $\mathcal{O}(d)$).

Since the upfront cost of characterizing the slice $\mathcal{S}(y;\mathcal{E})$ is $\mathcal{O}(d^2 + md)$, we can sample $\mathcal{O}(d)$ points per ellipse $\mathcal{E}$ without significantly increasing the total computational complexity. This leads to a high effective sample size relative to the computational complexity.

The Exact-HMC algorithm for TMG [Pakman and Paninski, 2014] has an intimate relationship with Analytic ESS and inspired our analytic framework. We explain this connection in Section 5.2.

5 EXPERIMENTAL RESULTS

In this section we compare the empirical performance of the algorithms introduced in Sections 2.3–4 to other state-of-the-art MCMC methods. Comparisons are shown for the Probit regression and the TMG problem, both of which are often encountered in machine learning contexts, as well as the log-Gaussian Cox process. We quantify the mixing of MCMC samplers by comparing their effective number of samples. Effective sample size is estimated using the method as described in [Gelman et al., 2014] which is implemented in the MCMC Diagnostics Tool box for `Matlab` [Särkkä and Vehtari, 2014-02-34]. We compare the results in terms of effective sample size divided by the number of density function evaluations of p^*, which is the dominant computational expense of running the samplers.

5.1 PROBIT REGRESSION

Probit regression is one of the most common problems in machine learning and is often used as a benchmark for comparing Bayesian computation methods. A nice review of the state-of-the-art algorithms for probit can be found in [Chopin and Ridgway, 2015]. For our experiments, we choose 4 data sets of moderate size from UCI repository as listed in Table 1, with their dimension and number of datapoints. These are the Breast Cancer [Wolberg et al., 1995], Ionosphere [Sigillito, 1989], Sonar [Son] and Musk [AI Group at Arris Pharmaceutical Corporation, 1994] data sets. As is standard, each dataset is preprocessed to have zero mean and unit variance for each regressor, a unit intercept term has been included and the prior on each latent variable is $\mathcal{N}(0, 10)$.

Table 1: Datasets for probit: dimensions and number of data points.

DATASET	DIMENSION	DATA POINTS
Breast Cancer	31	569
Ionosphere	31	351
Sonar	61	97
Musk	165	419

We compare EPESS and Recycled EPESS (denoted by EPESS(J) where J is the number of recycled points per slice) against Metropolis-Hastings with an EP proposal (EPMH) and HMC using the No-U-Turn sampler as implemented in Stan [Carpenter et al., 2015]. EPMH is considered as state-of-the-art for Probit [Chopin and Ridgway, 2015] . The chains were initialized at the EP mean for all EPESS methods and the Stan implementation decides on its own initialization. We use the `R` package of Ridgway [2016] to find the EP approximation. Its CPU time is negligible compared to the time to run the samplers.

We run 100 chains with 20,000 samples per chain. For

EPMH we ran it until 20,000 unique samples (i.e., accepted proposed points) were collected to make it comparable with the other methods. The results are shown in the top three plots of Figure 4. EPESS outperforms HMC and EPMH by about a factor of 5 for effective sample size relative to number of function evaluations. As compared to EPMH, EPESS gives a slightly smaller effective number of samples but takes far fewer function evaluations. The number of function evaluations for Recycled EPESS is smaller than that of EPESS, however the effective number of samples are also proportionately small as the samples are highly correlated (this is expected: see Section 3). Overall Recycled EPESS does not improve the effective sample size relative to number of function evaluations above EPESS.

5.2 TRUNCATED MULTIVARIATE GAUSSIAN

The Truncated Multivariate Gaussian (TMG) is an important distribution which commonly arise in diverse models such as Probit/Tobit models, Neural models [Pillow et al., 2003], Bayesian bridge model in finance [Polson et al., 2014], True-skill model for competitions [Herbrich et al., 2006] and many others. There has been some recent work including [Lan and Shahbaba, 2015] focusing on sampling from TMG, but Exact-HMC algorithm [Pakman and Paninski, 2014] is considered to be state-of-the-art (see [Altmann et al., 2014] for a nice review). We treat it as the benchmark for comparisons in our experiments.

The equations of motion for Exact-HMC are the same as that of standard ESS,

$$\mathbf{x}'(t) = \mathbf{x}\cos(t) + \boldsymbol{\nu}\sin(t),$$

and so it suffers from the same problems as described in Section 2.1 and illustrated in Figure 1. The elliptical path enables *exact* calculation of where the HMC particle hits the truncations, hence the term *Exact*-HMC. These are the same calculations used to find the regions Θ_j in Analytic ESS, although being an HMC method, it does not have a slice height y with the corresponding region Θ_y. It also cannot incorporate an EP prior as this would destroy the elliptical path and render the calculations intractable. A tuning parameter T is required and for all our experiments we have fixed T to be $\pi/2$ as recommended by Pakman and Paninski [2014]. We only show comparative results for Analytic EPESS as it is faster than EPESS since it avoids slice shrinkages. We obtain an EP approximation for TMG using the method as described in [Cunningham et al., 2011] which is fast and scales well for high dimensions. It runs in negligible CPU time as compared to the running time of different sampling algorithms.

We run 100 chains with 20,000 samples per chain. The fourth plot in Figure 4 shows the results for a 2-d standard Gaussian where the truncated region is a rectangular box: $\{s \leq x \leq s+1, -1 \leq y \leq 1\}$. As we shift the box to the right, we see Analytic EPESS outperforming Exact-HMC by orders of magnitude. This trend carries over to higher dimensions as shown in the fifth plot in Figure 4. Results for $d = 500$ and $d = 1000$ have been omitted as Exact-HMC with $T = \pi/2$ takes prohibitively long to run.

5.3 LOG-GAUSSIAN COX PROCESS

We conducted experiments on a Log-Gaussian Cox Process (LGCP) applied to the coal mining disaster dataset as set up in the original ESS paper [Murray et al., 2010]. Although a convergent EP is available for the LGCP, it is not accurate with the EP mean substantially deviating from the true mean [Ko and Seeger, 2015]. Our experiments showed that EPESS fared no better than ESS on this problem, with the effective number of samples being about the same. This demonstrates the fact that EPESS will only perform well when EP is accurate.

6 DISCUSSION AND CONCLUSION

In this work we have shown how the ideas of ESS, EP and recycling can be combined to yield highly efficient MCMC methods. For both probit regression and Gaussian quadrature, performance exceeds state-of-the-art samplers by an order of magnitude. In the case of TMG, this can be multiple orders of magnitude.

We investigated two different types of recycling: sampling multiple points per slice (Recycled ESS), and sampling multiple points at different slice heights from the same ellipse (Analytic ESS). The benefit of Recycled ESS is questionable as it seems not to improve performance in probit, due to having highly correlated samples. It also introduces a tuning parameter which makes the algorithm more difficult to implement. Analytic EPESS for TMG does not have the above-mentioned issues of Recycled ESS. In this case recycling is of clear benefit as can be seen in the experimental results of Section 5.2. It is here where EPESS outperforms the state-of-the-art by the largest margin.

The example of the Log-Gaussian Cox process shows that EPESS will only offer an advantage over ESS when EP is accurate. This restricts the applicability of EPESS as a general method. Improving the accuracy of EP is a subject of active research and any developments made will be immediately be inherited by EPESS.

There are multiple directions of future work. Instead of

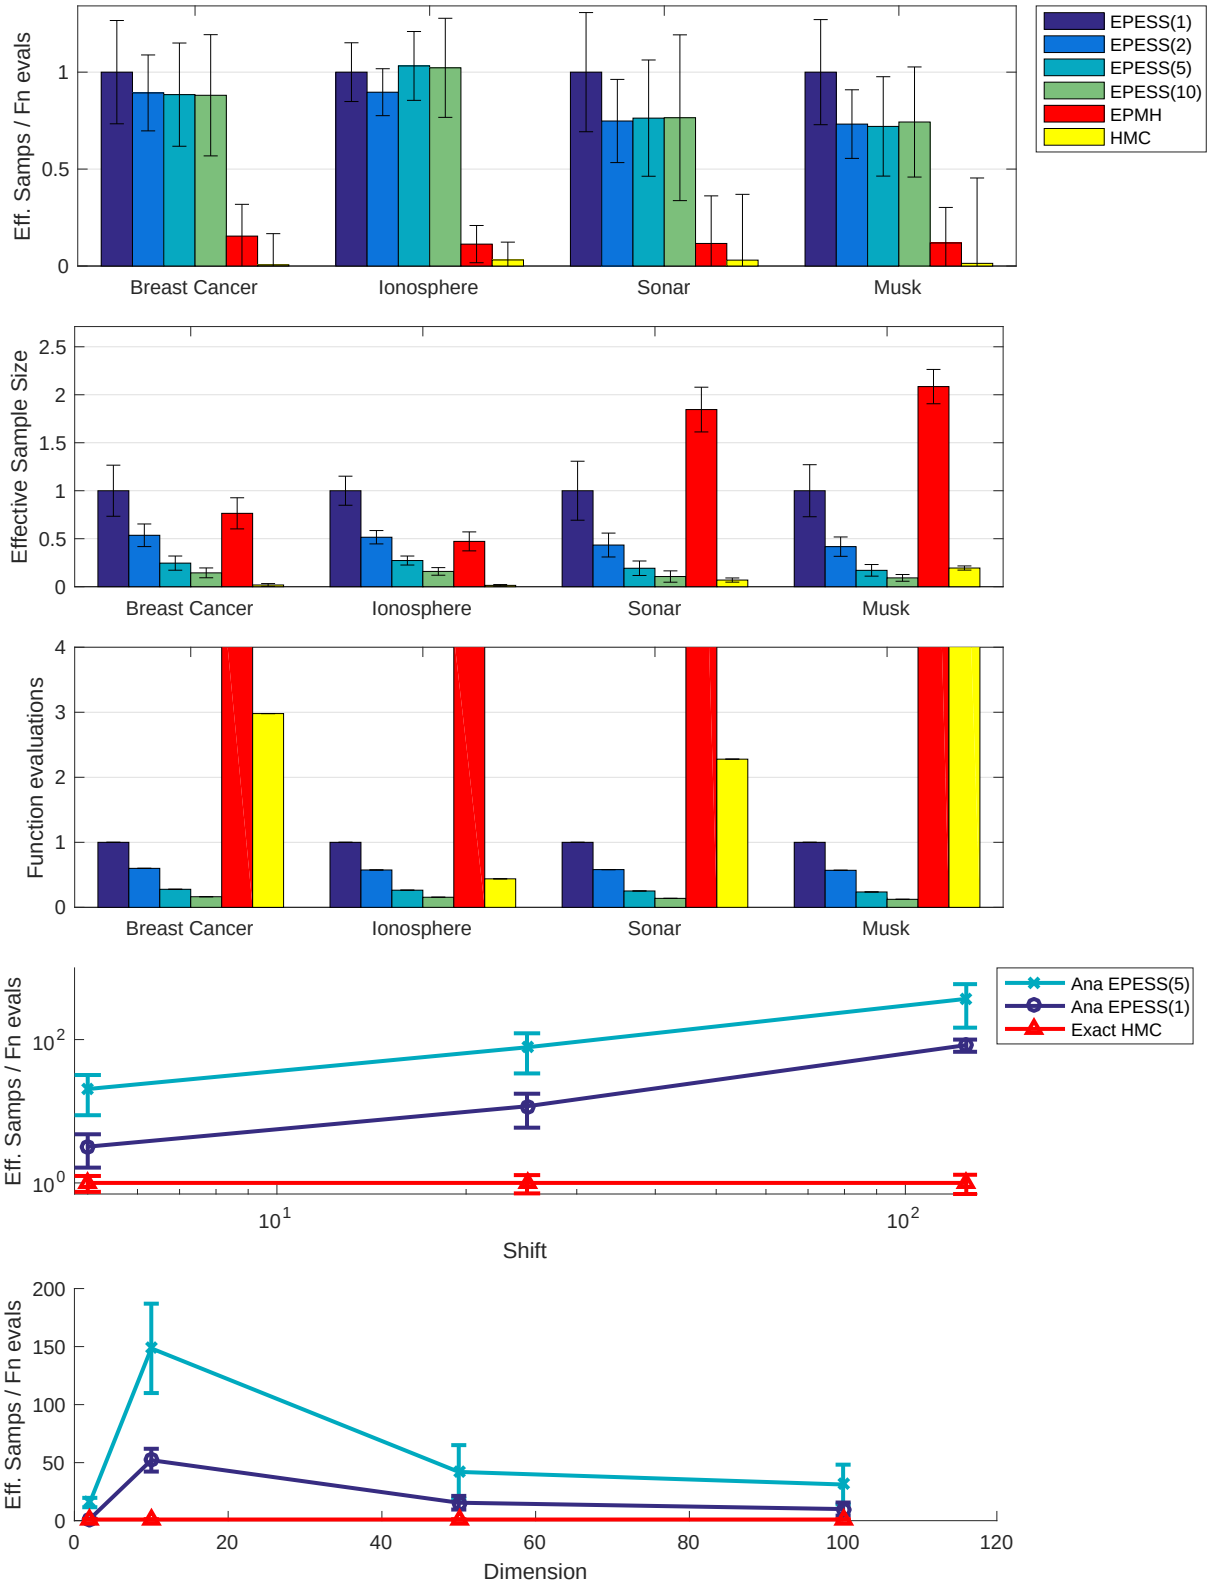

Figure 4: Plots of empirical results. In the top three plots all values are normalized so that EPESS(1) has value 1. In the bottom 2 plots all values are normalized so that Exact-HMC has value 1. The naming convention: EPESS(J) denotes Recycled EPESS with J points sampled per slice. EPESS(1) denotes EPESS without recycling. Ana EPESS(J) denotes Analytic EPESS with J threshold levels per iteration. Error bars in plot 3 for all algorithms are effectively zero.

choosing the prior that minimizes $\alpha = 1$ divergence, we could choose a prior corresponding to $\alpha > 1$ by replacing EP with Power-EP [Minka, 2004]. This might make the likelihood even weaker in EPESS and further improve performance.

Abstract

Kernel methods are one of the mainstays of machine learning, but the problem of kernel learning remains challenging, with only a few heuristics and very little theory. This is of particular importance in methods based on estimation of kernel mean embeddings of probability measures. For characteristic kernels, which include most commonly used ones, the kernel mean embedding uniquely determines its probability measure, so it can be used to design a powerful statistical testing framework, which includes nonparametric two-sample and independence tests. In practice, however, the performance of these tests can be very sensitive to the choice of kernel and its lengthscale parameters. To address this central issue, we propose a new probabilistic model for kernel mean embeddings, the Bayesian Kernel Embedding model, combining a Gaussian process prior over the Reproducing Kernel Hilbert Space containing the mean embedding with a conjugate likelihood function, thus yielding a closed form posterior over the mean embedding. The posterior mean of our model is closely related to recently proposed shrinkage estimators for kernel mean embeddings, while the posterior uncertainty is a new, interesting feature with various possible applications. Critically for the purposes of kernel learning, our model gives a simple, closed form marginal pseudolikelihood of the observed data given the kernel hyperparameters. This marginal pseudolikelihood can either be optimized to inform the hyperparameter choice or fully Bayesian inference can be used.

1 INTRODUCTION

A large class of popular and successful machine learning methods rely on kernels (positive semidefinite functions), including support vector machines, kernel ridge regression, kernel PCA (Schölkopf and Smola, 2002), Gaussian processes (Rasmussen and Williams, 2006), and kernel-based hypothesis testing (Gretton et al., 2005, 2008, 2012a). A key component for many of these methods is that of estimating kernel mean embeddings and covariance operators of probability measures based on data. The use of simple empirical estimators has been challenged recently (Muandet et al., 2016) and alternative, better-behaved frequentist shrinkage strategies have been proposed. In this article, we develop a Bayesian framework for estimation of kernel mean embeddings, recovering desirable shrinkage properties as well as allowing quantification of full posterior uncertainty. Moreover, the developed framework has an additional extremely useful feature. Namely, a persistent problem in kernel methods is that of kernel choice and hyperparameter selection, for which no general-purpose strategy exists. When a large dataset is available in a supervised setting, the standard approach is to use cross-validation. However, in unsupervised learning and kernel-based hypothesis testing, cross-validation is not straightforward to apply and yet the choice of kernel is critically important. Our framework gives a tractable closed-form marginal pseudolikelihood of the data allowing direct hyperparameter optimization as well as fully Bayesian posterior inference through integrating over the kernel hyperparameters. We emphasise that this approach is fully unsupervised: it is based solely on the modelling of kernel mean embeddings – going beyond marginal likelihood based approaches in, e.g., Gaussian process regression – and is thus broadly applicable in situations, such as kernel-based hypothesis testing, where the hyperparameter choice has thus far been mainly driven by heuristics.

In Section 2 we provide the necessary background on Reproducing Kernel Hilbert Spaces (RKHS) as well as describe some related works. In Section 3 we develop our Bayesian Kernel Embedding model, showing a rigorous Gaussian process prior formulation for an RKHS. In Section 4 we show how to perform kernel learning and posterior inference with our model. In Section 5 we empirically evaluate our model, arguing that our Bayesian Kernel Learning (BKL) objective should be considered as a "drop-in" replacement for heuristic methods of choosing kernel hyperparameters currently in use, especially in unsupervised settings such as kernel-based testing. We close in Section 6 with a discussion of various applications of our

approach and future work.

2 BACKGROUND AND RELATED WORK

2.1 KERNEL EMBEDDINGS OF PROBABILITY MEASURES

For any positive definite kernel function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, there exists a unique reproducing kernel Hilbert space (RKHS) $\mathcal{H}_k$. RKHS is an (often infinite-dimensional) space of functions $h : \mathcal{X} \to \mathbb{R}$ where evaluation can be written as an inner product, and in particular $h(x) = \langle h, k(\cdot, x)\rangle_{\mathcal{H}_k}$ for all $h \in \mathcal{H}_k, x \in \mathcal{X}$. Given a probability measure P on $\mathcal{X}$, its kernel embedding into $\mathcal{H}_k$ is defined as:

$$\mu_{\mathsf{P}} = \int k(\cdot, x)\, \mathsf{P}(dx). \tag{1}$$

Embedding μ_{P} is an element of $\mathcal{H}_k$ and serves as a representation of P akin to a characteristic function. It represents expectations of RKHS functions in the form of an inner product $\int h(x)\mathsf{P}(dx) = \langle h, \mu_{\mathsf{P}}\rangle_{\mathcal{H}_k}$. For a broad family of kernels termed *characteristic* (Sriperumbudur et al., 2011), every probability measure has a unique embedding – thus, such embeddings completely determine their probability measures and capture all of the moment information. This yields a framework for constructing nonparametric hypothesis tests for the two-sample problem and for independence, which are consistent against all alternatives (Gretton et al., 2008, 2012a) – we review this framework in the next section.

2.2 KERNEL MEAN EMBEDDING AND HYPOTHESIS TESTING

Given a kernel k and probability measures P and Q, the maximum mean discrepancy (MMD) between P and Q (Gretton et al., 2012a) is defined as the squared RKHS distance $\|\mu_{\mathsf{P}} - \mu_{\mathsf{Q}}\|^2_{\mathcal{H}_k}$ between their embeddings. A related quantity is the Hilbert Schmidt Independence Criterion (HSIC) (Gretton et al., 2005, 2008), a nonparametric dependence measure between random variables X and Y on domains $\mathcal{X}$ and $\mathcal{Y}$ respectively, defined as the squared RKHS distance $\|\mu_{\mathsf{P}_{XY}} - \mu_{\mathsf{P}_X\mathsf{P}_Y}\|^2_{\mathcal{H}_\kappa}$ between the embeddings of the joint distribution P_{XY} and of the product of the marginals $\mathsf{P}_X\mathsf{P}_Y$ with respect to a kernel $\kappa : (\mathcal{X} \times \mathcal{Y}) \times (\mathcal{X} \times \mathcal{Y}) \to \mathbb{R}$ on the product space. Typically, κ factorises, i.e. $\kappa((x, y), (x', y')) = k(x, x')l(y, y')$. The empirical versions of MMD and HSIC are used as test statistics for the two-sample ($\mathbf{H}_0 : \mathsf{P} = \mathsf{Q}$ vs. $\mathbf{H}_1 : \mathsf{P} \neq \mathsf{Q}$) and independence ($\mathbf{H}_0 : X \perp\!\!\!\perp Y$ vs. $\mathbf{H}_1 : X \not\perp\!\!\!\perp Y$) tests, respectively. With the help of the approximations to the asymptotic distribution under the null hypothesis, corresponding p-values can be computed (Gretton et al., 2012a). In addition, the so-called "witness function" which is proportional to $\mu_{\mathsf{P}} - \mu_{\mathsf{Q}}$ can be used to assess where the difference between the distributions arises.

2.3 KERNEL MEAN EMBEDDING ESTIMATORS

For a set of i.i.d. samples $x_1, \ldots, x_n$, the kernel mean embedding is typically estimated by its empirical version

$$\widehat{\mu_{\mathsf{P}}} = \mu_{\widehat{\mathsf{P}}} = \frac{1}{n}\sum_{i=1}^{n} k(\cdot, x_i), \tag{2}$$

from which various associated quantities, including the estimators of the squared RKHS distances between embeddings needed for kernel-based hypothesis tests, follow. As an empirical mean in an infinite-dimensional space, (2) is affected by Stein's phenomenon, as overviewed by Muandet et al. (2013) who also propose alternative shrinkage estimators similar to the well known James-Stein estimator. Improvements of test power using such shrinkage estimators are reported by Ramdas and Wehbe (2015). Connections between the James-Stein estimator and empirical Bayes procedures are classical (Efron and Morris, 1973), and thus a natural question to consider is whether a Bayesian formulation of the problem of kernel embedding estimation would yield similar shrinkage properties. In this paper, we will give a Bayesian perspective of the problem of kernel embedding estimation. In particular, we will construct a flexible model for underlying probability measures based on Gaussian measures in RKHSs which allows derivation of a full posterior distribution of μ_{P}, recovering similar shrinkage properties to Muandet et al. (2013), as discussed in Section 4.2. The model will give us a further advantage, however – as the marginal likelihood of the data given the kernel parameter can be derived leading to an informed choice of kernel parameters.

2.4 SELECTION OF KERNEL PARAMETERS

In supervised kernel methods like support vector machines, leave-one-out or k-fold crossvalidation is an effective and widely used method for kernel selection, and the myriad papers on multiple kernel learning (e.g. Bach et al. (2004); Sonnenburg et al. (2006); Gönen and Alpaydın (2011)) assume that some loss function is available and thus focus on effective ways of learning combinations of kernels. In the related but distinct world of smoothing kernels and kernel density estimation, there are a variety of long-standing approaches to bandwidth selection, again based on a loss function (in this case, mean integrated squared error is a popular choice (Bowman, 1985), and there is even a formula giving the optimal smoothing parameter asymptotically, see Rosenblatt (1956); Parzen (1962)) but we are not aware of work linking this literature to methods based on positive definite/RKHS kernels we study here. Separately,

Gaussian process learning can be undertaken by maximizing the marginal likelihood, which has a convenient closed form. This is noteworthy for its success and general applicability even for learning complicated combinations of kernels (Duvenaud et al., 2013) or rich kernel families (Wilson and Adams, 2013). Our approach has the same basic design as that of Gaussian process learning, yet it is applicable to learning kernel embeddings, which falls outside the realm of supervised learning.

As noted in Gretton et al. (2012b), the choice of the kernel k is critically important for the power of the tests presented in Section 2.2. However, no general, theoretically-grounded approaches for kernel selection in this context exist. The difficulty is that, unlike in supervised kernel methods, a simple cross-validation approach for the kernel parameter selection is not possible. What would be an ideal objective function – asymptotic test power – cannot be computed due to a complicated asymptotic null distribution. Moreover, even if we were able to estimate the power by performing tests on "training data" for each of the individual candidate kernels, in order to account for multiple comparisons, this training data would have to be disjoint from the one on which the hypothesis test is performed, which is clearly wasteful of power and appropriate only in the type of large-scale settings discussed in Gretton et al. (2012b). For these reasons, most users of kernel hypothesis tests in practice resort to using a parameterized kernel family such as squared exponential, and setting the length-scale parameter based on the "median heuristic."

The exact origins of the median heuristic are unclear (interestingly, it does not appear in the book that is most commonly cited as its source, Schölkopf and Smola (2002)) but it may have been derived from Takeuchi et al. (2006) and has precursors in classical work on bandwidth selection for kernel density estimation (Bowman, 1985). Note that there are two versions of the median heuristic in the literature: in both versions, given a set of observations $x_1, \ldots, x_n$ we calculate $\ell = \text{median}(\|x_i - x_j\|_2)$ and then one version (e.g. Mooij et al. (2015)) uses the Gaussian RBF / squared exponential kernel parameterized as $k(x, x') = \exp(-\frac{\|x-x'\|^2}{\ell^2})$ and the second version (e.g. Muandet et al. (2014)) uses the parameterization $k(x, x') = \exp(-\frac{\|x-x'\|^2}{2\ell^2})$. Some recent work has highlighted the situations in which the median heuristic can lead to poor performance (Gretton et al., 2012b). Cases in which the median heuristic performs quite well and also cases in which it performs quite poorly are discussed in (Reddi et al., 2015; Ramdas et al., 2015). We note that the median heuristic has also been used as a default value for supervised learning tasks (e.g. for the SVM implementation in R package `kernlab`) or when cross-validation is simply too expensive.

Outside of kernel methods, the same basic conundrum arises in spectral clustering in the choice of the parameters for the similarity graph (Von Luxburg, 2007, Section 8.1) and it is implicitly an issue in any unsupervised statistical method based on distances or dissimilarities, like the distance covariance (which is in fact equivalent to HSIC with a certain family of kernel functions (Sejdinovic et al., 2013)), or even the choice of the number of neighbors k in k-nearest neighbors algorithms.

3 OUR MODEL: BAYESIAN KERNEL EMBEDDING

Below, we will work with a parametric family of kernels $\{k_\theta(\cdot,\cdot)\}_{\theta\in\Theta}$. Given a dataset $\{x_i\}_{i=1}^n \sim \mathsf{P}$ of observations in $\mathbb{R}^D$ for an unknown probability distribution P, we wish to infer the kernel embedding $\mu_{\mathsf{P},\theta} = \int k_\theta(\cdot, x)\,\mathsf{P}(dx)$ for a given kernel k_θ in the parametric family. Moreover, we wish to construct a model that will allow inference of the kernel hyperparameter θ as well. Note that the two goals are related, since θ determines the space in which the embedding $\mu_{\mathsf{P},\theta}$ lies. When it is obvious from context, we suppress the dependence of the embeddings on the underlying measure P, writing μ_θ to emphasize the dependence on θ. Similarly, we will use $\widehat{\mu_\theta}$ to denote the simple empirical estimator from Eq. (2), which depends on a fixed sample $\{x_i\}_{i=1}^n$.

Our Bayesian Kernel Embedding (BKE) approach consists in specifying a prior on the kernel mean embedding μ_θ and a likelihood function linking it to the observations through the empirical estimator $\widehat{\mu_\theta}$. This will then allow us to infer the posterior distribution of the kernel mean embedding. The hyperparameter θ can itself have a prior, with the goal of learning a posterior distribution over the hyperparameter space.

3.1 PRIOR

A given hyperparameter θ (which can itself have a prior distribution), parameterizes a kernel k_θ and a corresponding RKHS $\mathcal{H}_{k_\theta}$. While it is tempting to define a $\mathcal{GP}(0, k_\theta(\cdot,\cdot))$ prior on μ_θ, this is problematic since draws from such prior would almost surely fall outside $\mathcal{H}_k$ (Wahba, 1990). Therefore, we define a GP prior over μ_θ as follows:

$$\mu_\theta \mid \theta \sim \mathcal{GP}(0, r_\theta(\cdot,\cdot))\,, \tag{3}$$

$$r_\theta(x, y) := \int k_\theta(x, u) k_\theta(u, y)\nu(du)\,. \tag{4}$$

where ν is any finite measure on $\mathcal{X}$. This choice of r_θ ensures that $\mu_\theta \in \mathcal{H}_{k_\theta}$ with probability 1 by the *nuclear dominance* (Lukić and Beder, 2001; Pillai et al., 2007) of k_θ over r_θ for any stationary kernel k_θ and more broadly whenever $\int k_\theta(x, x)\nu(dx) < \infty$. For completeness, we provide details of this construction in the Appendix in Section A.2. Since Eq. (4) is the convolution of a kernel with

itself with respect to ν, for typical kernels k_θ, the resulting kernel r_θ can be thought of as a smoother version of k_θ. A particularly convenient choice for $\mathcal{X} = \mathbb{R}^D$ is to take ν to be proportional to a Gaussian measure in which case r_θ can be computed analytically for a squared exponential kernel k_θ. The derivation is given in the Appendix in Section A.3, where we further show that if we set ν to be proportional to an isotropic Gaussian measure with a large variance parameter, r_θ becomes very similar to a squared exponential kernel with lengthscale $\theta\sqrt{2}$.

3.2 LIKELIHOOD

We need a likelihood linking the kernel mean embedding μ_θ to the observations $\{x_i\}_{i=1}^n$. We define the likelihood via the empirical mean embedding estimator of Eq. (2), $\widehat{\mu_\theta}$ which depends on $\{x_i\}_{i=1}^n$ and θ. Consider evaluating $\widehat{\mu_\theta}$ at some $x \in \mathbb{R}^D$ (which need not be one of our observations). The result is a real number giving an empirical estimate of $\mu_\theta(x)$ based on $\{x_i\}_{i=1}^n$ and θ. We link the empirical estimate, $\widehat{\mu_\theta}(x)$, to the corresponding modeled estimate, $\mu_\theta(x)$ using a Gaussian distribution with variance τ^2/n:

$$p(\widehat{\mu_\theta}(x)|\mu_\theta(x)) = \mathcal{N}(\widehat{\mu_\theta}(x); \mu_\theta(x), \tau^2/n), \quad x \in \mathcal{X}. \tag{5}$$

Our motivation for choosing this likelihood comes from the Central Limit Theorem. For a fixed location x, $\widehat{\mu_\theta}(x) = \frac{1}{n}\sum_{i=1}^n k_\theta(x_i, x)$ is an average of i.i.d. random variables so it satisfies:

$$\sqrt{n}(\widehat{\mu_\theta}(x) - \mu_\theta(x)) \xrightarrow{D} \mathcal{N}(0, \mathrm{Var}_{X\sim\mathsf{P}}[k_\theta(X, x)]). \tag{6}$$

We note that considering a heteroscedastic variance dependent on x in (5) would be a straightforward extension to our model, but we do not pursue this idea further here, i.e. while τ^2 can depend both on θ and x, we treat it as a single hyperparameter in the model.

3.3 JUSTIFICATION FOR THE MODEL

There are various ways to understand the construction of our hierarchical model. $\{x_i\}_{i=1}^n$ are drawn iid from P, which we do not have access to. We could estimate P directly (e.g. with a Gaussian mixture model) obtaining $\hat{\mathsf{P}}$, and then estimate $\mu_{\theta,\hat{\mathsf{P}}}$. But since density estimation is challenging in high dimensions, we posit a generative model for μ_θ directly.

Beginning at the top of the hierarchy, we have a fixed or random hyperparameter θ, which immediately defines k_θ and the corresponding RKHS $\mathcal{H}_{k_\theta}$. Then, we introduce a GP prior over μ_θ to ensure that $\mu_\theta \in \mathcal{H}_{k_\theta}$. A few realizations of μ_θ drawn from our prior are shown in Figure 1 (A), for an illustrative one-dimensional example where the prior is a Gaussian process with squared exponential kernel with lengthscale $\theta = 0.25$. Small values of θ yield rough functions and large values of θ yield smooth functions.

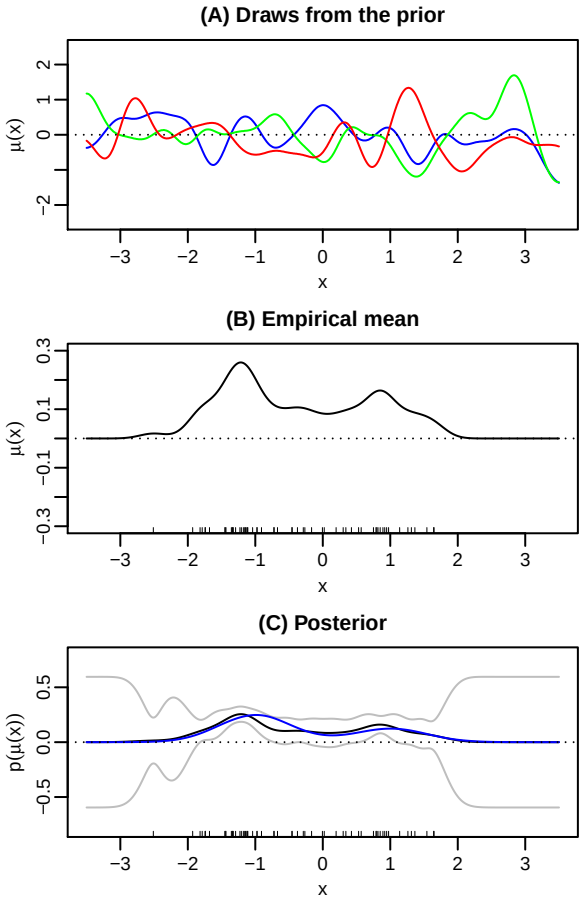

Figure 1: An illustration of the Bayesian Kernel Embedding model, where k_θ is a squared exponential kernel with lengthscale 0.1. Three draws of μ_θ from the prior are shown in (A). The empirical mean estimator $\widehat{\mu_\theta}$, which is the link function for the likelihood, is shown in (B) with the observations shown as a rug plot. In (C), the posterior mean embedding (black line) with uncertainty intervals (gray lines) is shown, as is the true mean embedding (blue line) based on the true data generating process (a mixture of Gaussians) and the same k_θ.

Next, we need to define the likelihood, which links these draws from the prior to the observations $\{x_i\}_{i=1}^n$. Since μ_θ is an infinite dimensional element in a Hilbert space and $\{x_i\}_{i=1}^n \in \mathcal{X}$ we need to transform the observations so that we can put a probability distribution over them. We use the empirical estimate of the mean embedding $\widehat{\mu_\theta}$ as our link function. Given a few observations, $\widehat{\mu_\theta}$ is shown in Figure 1 (B). Our likelihood links $\widehat{\mu_\theta}$ to μ_θ at the observation locations $\{x_i\}_{i=1}^n$ by assuming a squared loss function, i.e. Gaussian errors. As mentioned above, the motivation is the Central Limit Theorem, but also the convenient conjugate form that a Gaussian process with Gaussian likelihood yields. A plot of the posterior over the mean embedding

is shown in Figure 1 (C). A few points are worth noting: since the empirical estimator is already quite smooth (notice its similarity to a kernel density estimate), the posterior mean embedding is only slightly smoother than the empirical mean embedding. Notice that unlike kernel density estimation, there is no requirement that the kernel mean embedding be non-negative, thus explaining the posterior uncertainty intervals which are below zero.

Our original motivation for considering a Bayesian model for kernel mean embeddings was to see whether there was a coherent Bayesian formulation that corresponded to the shrinkage estimators in Muandet et al. (2013), while also enabling us to learn the hyperparameters. The first difficulty we faced was how to define a valid prior over the RKHS and a reasonable likelihood function. Our choices are by no means definitive, and we hope to see further development in this area in the future. The second difficulty was that of developing a method for inferring hyperparameters, to which we turn in the next section.

4 BAYESIAN KERNEL LEARNING

In this section we show how to perform learning and inference in the Bayesian Kernel Embedding model introduced in the previous section. Our model inherits various attractive properties from the Gaussian process framework (Rasmussen and Williams, 2006). First, we derive the posterior and posterior predictive distributions for the kernel mean embedding in closed form due to the conjugacy of our model, and show the relationship with previously proposed shrinkage estimators. We then derive the tractable marginal likelihood of the observations given the hyperparameters allowing for efficient MAP estimation or posterior inference for hyperparameters.

4.1 POSTERIOR AND POSTERIOR PREDICTIVE DISTRIBUTIONS

Similarly to GP models, the posterior mean of μ_θ is available in closed form due to the conjugacy of Gaussians. Perhaps given our data we wish to infer μ_θ at a new location $x^* \in \mathbb{R}^D$. Given a value of the hyperparameter θ we can calculate the posterior distribution of μ_θ as well as the posterior predictive distribution $p(\mu_\theta(x^*)|\widehat{\mu_\theta}, \theta)$.

Standard GP results (Rasmussen and Williams, 2006) yield the posterior distribution as:

$$\begin{aligned}[\mu_\theta(x_1), \ldots, \mu_\theta(x_n)]^\top \mid [\widehat{\mu_\theta}(x_1), \ldots, \widehat{\mu_\theta}(x_n)]^\top, \theta \\ \sim \mathcal{N}(R_\theta(R_\theta + (\tau^2/n)I_n)^{-1}[\widehat{\mu_\theta}(x_1), \ldots, \widehat{\mu_\theta}(x_n)]^\top, \\ R_\theta - R_\theta(R_\theta + (\tau^2/n)I_n)^{-1}R_\theta),\end{aligned} \tag{7}$$

where R_θ is the $n \times n$ matrix such that its (i, j)-th element is $r_\theta(x_i, x_j)$. The posterior predictive distribution at a new location x^* is:

$$\begin{aligned}\mu_\theta(x^*)^\top \mid [\widehat{\mu_\theta}(x_1), \ldots, \widehat{\mu_\theta}(x_n)]^\top, \theta \\ \sim \mathcal{N}(R_\theta^{*\top}(R_\theta + (\tau^2/n)I_n)^{-1}[\widehat{\mu_\theta}(x_1), \ldots, \widehat{\mu_\theta}(x_n)]^\top, \\ r_\theta^{**} - R_\theta^{*\top}(R_\theta + (\tau^2/n)I_n)^{-1}R_\theta^*)\end{aligned} \tag{8}$$

where $R_\theta^* = [r_\theta(x^*, x_1), \ldots r_\theta(x^*, x_n)]^\top$ and $r_\theta^{**} = r_\theta(x^*, x^*)$.

As in standard GP inference, the time complexity is $\mathcal{O}(n^3)$ due to the matrix inverses and the storage is $\mathcal{O}(n^2)$ to store the $n \times n$ matrix R_θ.

4.2 RELATION TO THE SHRINKAGE ESTIMATOR

The spectral kernel mean shrinkage estimator (S-KMSE) of Muandet et al. (2013) for a fixed kernel k is defined as:

$$\check{\mu}_\lambda = \hat{\Sigma}_{XX}(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\mu}, \tag{9}$$

where $\hat{\mu} = \sum_{i=1}^n k(\cdot, x_i)$ is the empirical embedding, $\hat{\Sigma}_{XX} = \frac{1}{n}\sum_{i=1}^n k(\cdot, x_i) \otimes k(\cdot, x_i)$ is the empirical covariance operator on $\mathcal{H}_k$, and λ is a regularization parameter. (Muandet et al., 2013, Proposition 12) shows that $\check{\mu}_\lambda$ can be expressed as a weighted kernel mean $\check{\mu}_\lambda = \sum_{i=1}^n \beta_i k(\cdot, x_i)$, where

$$\begin{aligned}\beta &= \frac{1}{n}(K + n\lambda I)^{-1}K\mathbf{1} \\ &= (K + n\lambda I)^{-1}[\widehat{\mu}(x_1), \ldots, \widehat{\mu}(x_n)]^\top.\end{aligned}$$

Now, evaluating S-KMSE at any point x^* gives

$$\begin{aligned}\check{\mu}_\lambda(x^*) &= \sum_{i=1}^n \beta_i k(x^*, x_i) \\ &= K_*^\top(K + n\lambda I)^{-1}[\widehat{\mu}(x_1), \ldots, \widehat{\mu}(x_n)]^\top,\end{aligned}$$

where $K_* = [k(x^*, x_1), \ldots, k(x^*, x_n)]^\top$. Thus, the posterior mean in Eq. (7) recovers the S-KMSE estimator (Muandet et al., 2013), where the regularization parameter is related to the variance in the likelihood model (5), with a difference that in our case the kernel k_θ used to compute the empirical embedding is not the same as the kernel r_θ used to compute the kernel matrices. We note that our method has various advantages over the frequentist estimator $\check{\mu}_\lambda$: we have a closed-form uncertainty estimate, while we are not aware of a principled way of calculating the standard error of the frequentist estimators of embeddings. Our model also leads to a method for learning the hyperparameters, which we discuss next.

4.3 INFERENCE OF THE KERNEL PARAMETERS

In this section we focus on hyperparameter learning in our model. For the purposes of hyperparameter learning, we

want to integrate out the kernel mean embedding μ_θ and consider the probability of our observations $\{x_i\}_{i=1}^n$ given the hyperparameters θ. In order to link our generative model directly to the observations, we use a pseudolikelihood approach as discussed in detail below.

We use the term pseudolikelihood because the model in this section will not correspond to the likelihood of the infinite dimensional empirical embedding; rather it will rely on the evaluations of the empirical embedding at a finite set of points. Let us fix a set of points $z_1, \ldots, z_m$ in $\mathcal{X} \subset \mathbb{R}^D$, with $m \geq D$. These points are not treated as random, and the inference method we develop does not require any specific choice of $\{z_j\}_{j=1}^m$. However, to ensure that there is a reasonable variability in the values of $k(x_i, z_j)$, these points should be placed in the high density regions of P. The simplest approach is to use a small held out portion of the data (with $m \ll n$ but $m \geq D$). Now, when we evaluate $\widehat{\mu_\theta}$ at these points, our modelling assumption from (5) on vector $\widehat{\mu_\theta}(\mathbf{z}) = [\widehat{\mu_\theta}(z_1), \ldots, \widehat{\mu_\theta}(z_m)]$ can be written as

$$\widehat{\mu_\theta}(\mathbf{z})|\mu_\theta \sim \mathcal{N}\left(\mu_\theta(\mathbf{z}), \frac{\tau^2}{n} I_m\right). \tag{10}$$

However, as $\widehat{\mu_\theta}(z_j) = \frac{1}{n}\sum_{i=1}^n k_\theta(X_i, z_j)$ and all the terms $k_\theta(X_i, z_j)$ are independent given μ_θ, by Cramér's decomposition theorem, this modelling assumption is for the mapping $\phi_\mathbf{z} : \mathbb{R}^D \mapsto \mathbb{R}^m$, given by

$$\phi_\mathbf{z}(x) := [k_\theta(x, z_1), \ldots, k_\theta(x, z_m)] \in \mathbb{R}^m,$$

equivalent to:

$$\phi_\mathbf{z}(X_i)|\mu_\theta \sim \mathcal{N}\left(\mu_\theta(\mathbf{z}), \tau^2 I_m\right). \tag{11}$$

Applying the change of variable $x \mapsto \phi_\mathbf{z}(x)$ and using the generalization of the change-of-variables formula to non-square Jacobian matrices as described in (Ben-Israel, 1999), we obtain a distribution for x conditionally on μ_θ and θ:

$$p(x|\mu_\theta, \theta) = p\left(\phi_\mathbf{z}(x)|\mu_\theta(\mathbf{z})\right) \mathrm{vol}\left[J_\theta(x)\right], \tag{12}$$

where $J_\theta(x) = \left[\frac{\partial k_\theta(x, z_i)}{\partial x^{(j)}}\right]_{ij}$ is an $m \times D$ matrix, and

$$\begin{aligned}
\mathrm{vol}\left[J_\theta(x)\right] &= \left(\det\left[J_\theta(x)^\top J_\theta(x)\right]\right)^{1/2} \\
&= \left(\det\left[\sum_{l=1}^m \frac{\partial k_\theta(x, z_l)}{\partial x^{(i)}} \frac{\partial k_\theta(x, z_l)}{\partial x^{(j)}}\right]_{ij}\right)^{1/2} \\
&=: \gamma_\theta(x)\,.
\end{aligned} \tag{13}$$

The notation $\gamma_\theta(x)$ highlights the dependence on both θ and x. An explicit calculation of $\gamma_\theta(x)$ for squared exponential kernels is described in Section 4.4.

By the conditional independence of $\{\phi_\mathbf{z}(X_i)\}_{i=1}^n$ given μ_θ, we obtain the pseudolikelihood of all n observations:

$$\begin{aligned}
p(x_1, \ldots, x_n|\mu_\theta, \theta) &= \prod_{i=1}^n \mathcal{N}\left(\phi_\mathbf{z}(x_i); \mu_\theta(\mathbf{z}), \tau^2 I_m\right) \gamma_\theta(x_i) \\
&= \mathcal{N}\left(\phi_\mathbf{z}(\mathbf{x}); \mathbf{m}_\theta(\mathbf{z}), \tau^2 I_{mn}\right) \prod_{i=1}^n \gamma_\theta(x_i),
\end{aligned} \tag{14}$$

where

$$\phi_\mathbf{z}(\mathbf{x}) = \left[\phi_\mathbf{z}(x_1)^\top \cdots \phi_\mathbf{z}(x_n)^\top\right]^\top = \mathrm{vec}\left\{K_{\theta,\mathbf{zx}}\right\} \in \mathbb{R}^{mn}$$

and in the mean vector $\mathbf{m}_\theta(\mathbf{z}) = \left[\mu_\theta(\mathbf{z})^\top \cdots \mu_\theta(\mathbf{z})^\top\right]^\top$, $\mu_\theta(\mathbf{z})$ repeats n times. Under the prior (3), this mean vector has mean $\mathbf{0}$ and covariance $\mathbf{1}_n\mathbf{1}_n^\top \otimes R_{\theta,\mathbf{zz}}$ where $R_{\theta,\mathbf{zz}}$ is the $m \times m$ matrix such that its (i, j)-th element is $r_\theta(z_i, z_j)$. Combining this prior and the pseudolikelihood in (14), we have the marginal pseudolikelihood:

$$\begin{aligned}
p(x_1, \ldots, x_n|\theta) &= \int p(x_1, \ldots, x_n|\mu_\theta, \theta) p(\mu_\theta|\theta) d\mu_\theta \\
&= \int \mathcal{N}\left(\phi_\mathbf{z}(\mathbf{x}); \mathbf{m}_\theta(\mathbf{z}), \tau^2 I_{mn}\right) \left[\prod_{i=1}^n \gamma_\theta(x_i)\right] p(\mu_\theta|\theta) d\mu_\theta \\
&= \mathcal{N}\left(\phi_\mathbf{z}(\mathbf{x}); \mathbf{0}, \mathbf{1}_n\mathbf{1}_n^\top \otimes R_{\theta,\mathbf{zz}} + \tau^2 I_{mn}\right) \prod_{i=1}^n \gamma_\theta(x_i).
\end{aligned} \tag{15}$$

While the marginal pseudolikelihood in Eq. (15) involves a computation of the likelihood for an mn-dimensional normal distribution, the Kronecker structure of the covariance matrix allows efficient computation as described in Appendix A.4. The complexity for calculating this likelihood is $\mathcal{O}(m^3 + mn)$ (dominated by the inversion of $R_{\theta,\mathbf{zz}} + (\tau^2/n)I_m$). The Jacobian term depends on the parametric form of k_θ, but a typical cost as shown in Section 4.4 for the squared exponential kernel is $\mathcal{O}(nD^3 + nmD^2)$. In this case, the computation of matrices $R_{\theta,\mathbf{zz}}$ and $\phi_\mathbf{z}(\mathbf{x}) = \mathrm{vec}\left\{K_{\theta,\mathbf{zx}}\right\}$ is $\mathcal{O}(m^2 D)$ and $\mathcal{O}(mnD)$ respectively.

Just as in GP modeling, the marginal pseudolikelihood can be maximized directly for maximum likelihood II (also known as empirical Bayes) estimation, in which we look for a single best $\hat{\theta}$, or it can be used to construct an efficient MCMC sampler from the posterior of θ.

4.4 EXPLICIT CALCULATIONS FOR SQUARED EXPONENTIAL (RBF) KERNEL

Consider the isotropic squared exponential kernel with lengthscale matrix $\theta^2 I_D$ defined by

$$k_\theta(x, y) = \exp(-.5(x - y)^\top \theta^{-2} I_D (x - y)). \tag{16}$$

In this case, we can analytically calculate $r_\theta(x, y)$, exact form is given in the Appendix in Section A.3.

The partial derivatives of $k_\theta(x, y)$ with respect to $x^{(i)}$ for $i = 1, \dots D$ can be easily derived as

$$\frac{\partial k_\theta(x, y)}{\partial x^{(i)}} = k_\theta(x, y) \frac{x^{(i)} - y^{(i)}}{\theta^2}$$

and therefore the Jacobian from Eq. (13) is equal to

$$\gamma_\theta(x) = \left(\det \left[\sum_{l=1}^{m} k_\theta(x, z_l)^2 \, \frac{(x^{(i)} - z_l^{(j)})^2}{\theta^4} \right]_{ij} \right)^{1/2}. \tag{17}$$

The computation of the matrix is $\mathcal{O}(mD^2)$ and the determinant is $\mathcal{O}(D^3)$. Since we must calculate $\gamma_\theta(x_i)$ for each x_i, the overall time complexity is $\mathcal{O}(nD^3 + nmD^2)$.

5 EXPERIMENTS

We demonstrate our approach on two synthetic datasets and one example on real data, focusing on two-sample testing with MMD and independence testing with HSIC. First, we use our Bayesian Kernel Embedding model and learn the kernel hyperparameters with maximum likelihood II, optimizing the marginal likelihood. Second, we take a fully Bayesian approach to inference and learning with our model. Finally, we apply the PC algorithm for causal structure discovery to a real dataset. The PC algorithm relies on a series of independence tests; we use HSIC with the lengthscales set with Bayesian Kernel Learning.

Choosing lengthscales with the median heuristic is often a very bad idea. In the case of two sample testing, Gretton et al. (2012b) showed that MMD with the median heuristic failed to reject the null hypothesis when comparing samples from a grid of isotropic Gaussians to samples from a grid of non-isotropic Gaussians. We repeated this experiment by considering a distribution P of a mixture of bivariate Gaussians centered on a grid with diagonal covariance and unit variance and a distribution Q of a mixture of bivariate Gaussians centered at the same locations but with rotated covariance matrices with a ratio ϵ of largest to smallest covariance eigenvalues.

As illustrated in Figures 2(A) and (B), for small values of ϵ both distributions are very similar whereas the distinction between P and Q becomes more apparent as ϵ increases. For different values of ϵ, we sample 100 observations from each mixture component, yielding 900 observations from P and 900 observations from Q and then perform a two-sample test ($\mathbf{H}_0 : \mathsf{P} = \mathsf{Q}$ vs. $\mathbf{H}_1 : \mathsf{P} \neq \mathsf{Q}$) using the MMD empirical estimate with an isotropic squared exponential kernel with one hyperparameter, the lengthscale. The type II error (i.e. probability that the test fails to reject the null hypothesis that $\mathsf{P} = \mathsf{Q}$ at $\alpha = 0.05$) is shown in Figure 2(C) for differently skewed covariances (ϵ from 0.5 to 15) when the median heuristic is chosen to select the kernel lengthscale or when using the Bayesian Kernel Learning. In this example, the median heuristic picks a kernel with a large lengthscale, since the median distance between points is large. With this large lengthscale MMD always fails to reject at $\alpha = 0.05$ even for simple cases where ϵ is large. When we use Bayesian Kernel Learning and optimize the marginal likelihood of Eq. (15) for $\tau^2 = 1$ (our results were not sensitive to the choice of this parameter, but in the fully Bayesian case below we show that we can learn it) we found the maximum marginal likelihood at a lengthscale of 0.85. With this choice of lengthscale, MMD correctly rejects the null hypothesis at $\alpha = 0.05$ even for very hard situations when $\epsilon = 2$. We observe that when ϵ is smaller than 2, the type II error of MMD is very high for both choices of lengthscale, because the two distributions P and Q are so similar that the test always retains the null hypothesis. In Figure 2(D) we illustrate the BKL marginal likelihood across a range of lengthscales. Interestingly, there are multiple local optima and the median heuristic lies between the two main modes. The plot indicates that multiple scales may be of interest for this dataset, which makes sense given that the true data generating process is a mixture model. This insight can be incorporated into the Bayesian Kernel Embedding framework by expanding our model, as discussed below. In Figure 2(E) we used the BKE posterior to estimate the witness function $\mu_{P,\theta} - \mu_{Q,\theta}$. This function is large in magnitude in the locations where the two distributions differ. For ease of visualization we do not try to include posterior uncertainty intervals, but these are readily available from our model, and we show them for a 1-dimensional case below.

Our model does not just provide a better way of choosing lengthscales. We can also use it in a fully Bayesian context, where we place priors over the hyperparameters θ and τ^2, and then integrate them out to learn a posterior distribution over the mean embedding. Switching to one dimension, we consider a distribution $\mathsf{P} = \mathcal{N}(0, 1)$ and a distribution $\mathsf{Q} = \text{Laplace}(0, \sqrt{.5})$. The densities are shown in Figure 3(A). Notice that the first two moments of these distributions are equal. To create a synthetic dataset we sampled n observations from each distribution, and then combined them together into a sample of size $2n$, following the strategy in the previous experiment to learn a single lengthscale and kernel mean embedding for the combined dataset. We ran a Hamiltonian Monte Carlo sampler (HMC) with NUTS (Stan source code is in the Appendix in Section B) for the Bayesian Kernel Embedding model with a squared exponential kernel, placing a Gamma$(1, 1)$ prior on the lengthscale θ of the kernel and a Gamma$(1, 1)$ prior on τ^2. We ran 4 chains for 400 iterations, discarding 200 iterations as warmup, with the chains starting at different random initial values. Standard convergence and mixing

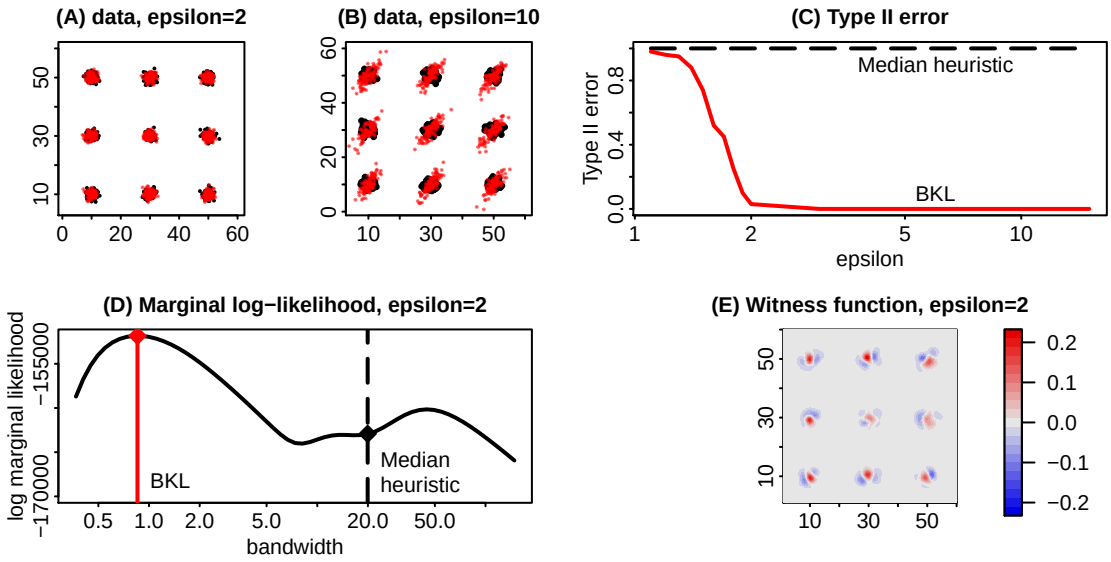

Figure 2: Two sample testing on a challenging simulated data set: comparing samples from a grid of isotropic Gaussians (black dots) to samples from a grid of non-isotropic Gaussians (red dots) with a ratio ϵ of largest to smallest covariance eigenvalues. Panels (A) and (B) illustrate such samples for two values of ϵ. (C) Type II error as a function of ϵ for significant level $\alpha = 0.05$ following the median heuristic or the BKL approach to choose the lengthscale. (D) BKL marginal log-likelihood across a range of lengthscales. It is maximised for a lengthscale of 0.85 whereas the median heuristic suggests a value of 20. (E) Witness function for the difficult case where $\epsilon = 2$ using the BKL lengthscale.

diagnostics were good ($\hat{R} \approx 1$), so we considered the result to be 800 draws from the posterior distribution. Recall that for fixed hyperparameters θ and τ^2 we can obtain a posterior distribution over $\mu_{P,\theta}$ and $\mu_{Q,\theta}$. For each of our 800 draws, we drew a sample from these two distributions and then calculated the witness function as the difference, thus obtaining a random function drawn from the posterior distribution over $\mu_{P,\theta} - \mu_{Q,\theta}$ (where in practice we evaluate this function at a fine grid for plotting purposes). We thus obtained the full posterior distribution over the witness function, integrating over the kernel hyperparameter. We followed this procedure twice to create a dataset with $n = 50$ and a dataset with $n = 400$. In Figure 3(B) we see that the witness function for the small dataset is not able to distinguish between the distributions as it rarely excludes 0. (Note that our model has the function 0 as its prior, which corresponds to the null hypothesis that the two distributions are equal. This could easily be changed to incorporate any relevant prior information.). As shown in Figure 3(C), with more data the witness function is able to distinguish between the two distributions, mostly excluding 0.

Finally, we consider the ozone dataset analyzed in Breiman and Friedman (1985), consisting of daily measurements of ozone concentration and eight related meteorological variables. Following the approach in Flaxman et al. (2015), we first pre-whiten the data to control for underlying temporal autocorrelation, then we use a combination of Gaussian process regression followed by HSIC to test for conditional independence. Each time we run HSIC, we set the kernel hyperparameters using Bayesian Kernel Learning. The graphical model that we learn is shown in Figure 4. The directed edge from the temperature variable to ozone is encouraging, as higher temperatures favor ozone formation through a variety of chemical processes which are not represented by variables in this dataset (Bloomer et al., 2009; Sillman, 1999). Note that this edge was not present in the graphical model in Flaxman et al. (2015) in which the median heuristic was used.

6 DISCUSSION

We developed a framework for Bayesian learning of kernel embeddings of probability measures. It is primarily designed for unsupervised settings, and in particular for kernel-based hypothesis testing. In these settings, one relies critically on a good choice of kernel and our framework yields a new method, termed Bayesian Kernel Learning, to inform this choice. We only explored learning the lengthscale of the squared exponential kernel, but our method extends to the case of richer kernels with more hyperparameters. We conceive of Bayesian Kernel Learning as a drop-in replacement for selecting the kernel hyperparameters in settings where cross-validation is unavailable. A sampling-based Bayesian approach is also demonstrated, enabling integration over kernel hyperparameters, and e.g., obtaining

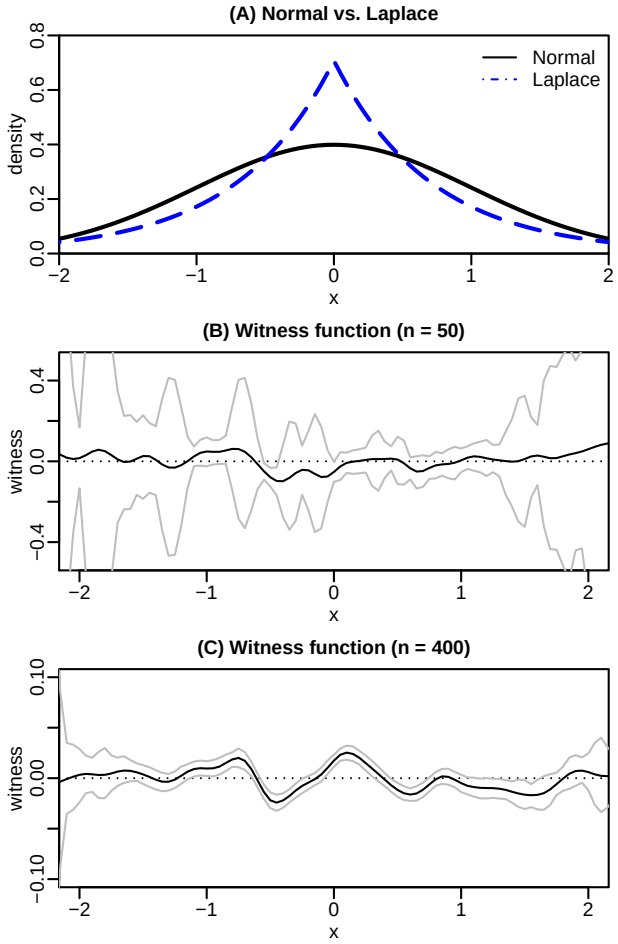

Figure 3: The true data generating process is shown in (A) where two samples of size n are drawn from distributions with equal means and variances. We then fit our Bayesian Kernel Embedding model, with priors over the hyperparameters θ and τ^2 to obtain a posterior over the witness function for two-sampling testing. The witness function indicates the model's posterior estimates of where the two distributions differ (when the witness function is zero, it indicates no difference between the distributions). Posterior means and 80% uncertainty intervals are shown. In (B) the small sample size means that the model does not effectively distinguish between samples from a normal and a Laplace distribution, while in (C) larger samples enable the model to find a clear difference, with much of the uncertainty envelope excluding 0.

the full posterior distribution over the witness function in two-sample testing.

While our method is designed for unsupervised settings, there are various reasons it might be helpful in supervised settings or in applied Bayesian modelling more generally. With the rise of large-scale kernel methods, it has become possible to apply, e.g. SVMs or GPs to very large datasets.

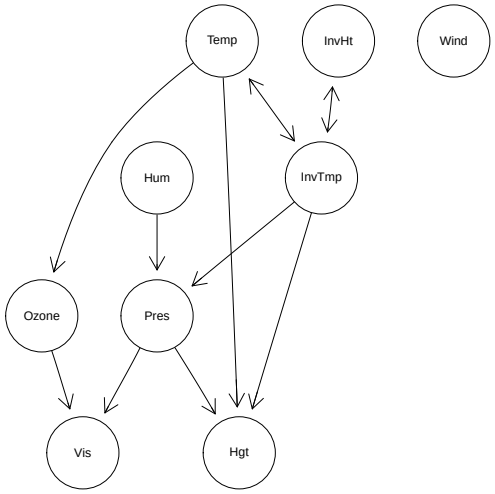

Figure 4: Graphical model representing an equivalence class of DAGs for the Ozone dataset from Breiman and Friedman (1985), learned using the PC algorithm following the approach in Flaxman et al. (2015) with HSIC to test for independence. We used BKL to set hyperparameters of HSIC. Singly directed edges represent causal links, while bidirected edges represent edges that the algorithm failed to orient. The causal edge from temperature to ozone accords with scientific understanding, and was not present in the graphical model learned in Flaxman et al. (2015) which employed the median heuristic.

But even with efficient methods, it can be very costly to run cross-validation over a large space of hyperparameters. In practice, when, e.g. large scale approximations based on random Fourier features (Rahimi and Recht, 2007) are used, we have not seen much attention paid to kernel learning – the features are often just one part of a complicated pipeline, so again the median heuristic is often employed. For these reasons, we think that the developed method for Bayesian Kernel Learning would be a judicious alternative. Moreover, it would be straightforward to develop scalable approximate versions of Bayesian Kernel Learning itself.

Abstract

Bayesian inference has great promise for the privacy-preserving analysis of sensitive data, as posterior sampling automatically preserves differential privacy, an algorithmic notion of data privacy, under certain conditions (Dimitrakakis et al., 2014; Wang et al., 2015b). While this *one posterior sample* (OPS) approach elegantly provides privacy "for free," it is data inefficient in the sense of asymptotic relative efficiency (ARE). We show that a simple alternative based on the Laplace mechanism, the workhorse of differential privacy, is as asymptotically efficient as non-private posterior inference, under general assumptions. This technique also has practical advantages including efficient use of the privacy budget for MCMC. We demonstrate the practicality of our approach on a time-series analysis of sensitive military records from the Afghanistan and Iraq wars disclosed by the Wikileaks organization.

1 INTRODUCTION

Probabilistic models trained via Bayesian inference are widely and successfully used in application domains where privacy is invaluable, from text analysis (Blei et al., 2003; Goldwater and Griffiths, 2007), to personalization (Salakhutdinov and Mnih, 2008), to medical informatics (Husmeier et al., 2006), to MOOCs (Piech et al., 2013). In these applications, data scientists must carefully balance the benefits and potential insights from data analysis against the privacy concerns of the individuals whose data are being studied (Daries et al., 2014).

Dwork et al. (2006) placed the notion of privacy-preserving data analysis on a solid foundation by introducing *differential privacy* (Dwork and Roth, 2013), an algorithmic formulation of privacy which is a gold standard for privacy-preserving data-driven algorithms. Differential privacy measures the privacy "cost" of an algorithm. When designing privacy-preserving methods, the goal is to achieve a good trade-off between privacy and utility, which ideally improves with the amount of available data.

As observed by Dimitrakakis et al. (2014) and Wang et al. (2015b), Bayesian posterior sampling behaves synergistically with differential privacy because it automatically provides a degree of differential privacy under certain conditions. However, there are substantial gaps between this elegant theory and the practical reality of Bayesian data analysis. Privacy-preserving posterior sampling is hampered by data inefficiency, as measured by asymptotic relative efficiency (ARE). In practice, it generally requires artificially selected constraints on the spaces of parameters as well as data points. Its privacy properties are also not typically guaranteed for approximate inference.

This paper identifies these gaps between theory and practice, and begins to mend them via an extremely simple alternative technique based on the workhorse of differential privacy, the Laplace mechanism (Dwork et al., 2006). Our approach is equivalent to a generalization of Zhang et al. (2016)'s recently and independently proposed algorithm for beta-Bernoulli systems. We provide a theoretical analysis and empirical validation of the advantages of the proposed method. We extend both our method and Dimitrakakis et al. (2014); Wang et al. (2015b)'s *one posterior sample (OPS)* method to the case of approximate inference with privacy-preserving MCMC. Finally, we demonstrate the practical applicability of this technique by showing how to use a privacy-preserving HMM model to analyze sensitive military records from the Iraq and Afghanistan wars leaked by the Wikileaks organization. Our primary contributions are as follows:

- We analyze the privacy cost of posterior sampling for exponential family posteriors via OPS.
- We explore a simple Laplace mechanism alternative to OPS for exponential families.

- Under weak conditions we establish the consistency of the Laplace mechanism approach and its data efficiency advantages over OPS.
- We extend the OPS and Laplace mechanism methods to approximate inference via MCMC.
- We demonstrate the practical implications with a case study on sensitive military records.

2 BACKGROUND

We begin by discussing preliminaries on differential privacy and its application to Bayesian inference. Our novel contributions will begin in Section 3.1.

2.1 DIFFERENTIAL PRIVACY

Differential privacy is a formal notion of the privacy of data-driven algorithms. For an algorithm to be differentially private the probabilities of the outputs of the algorithms may not change much when one individual's data point is modified, thereby revealing little information about any one individual's data. More precisely, a randomized algorithm $\mathcal{M}(\mathbf{X})$ is said to be (ϵ, δ)-differentially private if

$$Pr(\mathcal{M}(\mathbf{X}) \in \mathcal{S}) \leq \exp(\epsilon) Pr(\mathcal{M}(\mathbf{X}') \in \mathcal{S}) + \delta \quad (1)$$

for all measurable subsets $\mathcal{S}$ of the range of $\mathcal{M}$ and for all datasets $\mathbf{X}, \mathbf{X}'$ differing by a single entry (Dwork and Roth, 2013). If $\delta = 0$, the algorithm is said to be ϵ-differentially private.

2.1.1 The Laplace Mechanism

One straightforward method for obtaining ϵ-differential privacy, known as the *Laplace mechanism* (Dwork et al., 2006), adds Laplace noise to the revealed information, where the amount of noise depends on ϵ, and a quantifiable notion of the sensitivity to changes in the database. Specifically, the $L1$ sensitivity $\triangle h$ for function h is defined as

$$\triangle h = \max_{\mathbf{X}, \mathbf{X}'} \|h(\mathbf{X}) - h(\mathbf{X}')\|_1 \quad (2)$$

for all datasets $\mathbf{X}, \mathbf{X}'$ differing in at most one element. The Laplace mechanism adds noise via

$$\mathcal{M}_L(\mathbf{X}, h, \epsilon) = h(\mathbf{X}) + (Y_1, Y_2, \ldots, Y_d)\,, \quad (3)$$
$$Y_j \sim \text{Laplace}(\triangle h/\epsilon), \forall j \in \{1, 2, \ldots, d\}\,,$$

where d is the dimensionality of the range of h. The $\mathcal{M}_L(\mathbf{X}, h, \epsilon)$ mechanism is ϵ-differentially private.

2.1.2 The Exponential Mechanism

The exponential mechanism (McSherry and Talwar, 2007) aims to output responses of high utility while maintaining privacy. Given a utility function $u(\mathbf{X}, \mathbf{r})$ that maps database $\mathbf{X}$/output $\mathbf{r}$ pairs to a real-valued score, the exponential mechanism $\mathcal{M}_E(\mathbf{X}, u, \epsilon)$ produces random outputs via

$$Pr(\mathcal{M}_E(\mathbf{X}, u, \epsilon) = \mathbf{r}) \propto \exp\left(\frac{\epsilon u(\mathbf{X}, \mathbf{r})}{2\triangle u}\right), \quad (4)$$

where the sensitivity of the utility function is

$$\triangle u \triangleq \max_{r, (\mathbf{X}^{(1)}, \mathbf{X}^{(2)})} \|u(\mathbf{X}^{(1)}, r) - u(\mathbf{X}^{(2)}, r)\|_1\,, \quad (5)$$

in which $(\mathbf{X}^{(1)}, \mathbf{X}^{(2)})$ are pairs of databases that differ in only one element.

2.1.3 Composition Theorems

A key property of differential privacy is that it holds under composition, via an additive accumulation.

Theorem 1. *If $\mathcal{M}_1$ is (ϵ_1, δ_1)-differentially private, and $\mathcal{M}_2$ is (ϵ_2, δ_2)-differentially private, then $\mathcal{M}_{1,2}(\mathbf{X}) = (\mathcal{M}_1(\mathbf{X}), \mathcal{M}_2(\mathbf{X}))$ is $(\epsilon_1 + \epsilon_2, \delta_1 + \delta_2)$-differentially private.*

This allows us to view the total ϵ and δ of our procedure as a privacy "budget" that we spend across the operations of our analysis. There also exists an "advanced composition" theorem which provides privacy guarantees in an adversarial adaptive scenario called k-fold composition, and also allows an analyst to trade an increased δ for a smaller ϵ in this scenario (Dwork et al., 2010). Differential privacy is also immune to data-independent post-processing.

2.2 PRIVACY AND BAYESIAN INFERENCE

Suppose we would like a differentially private draw of parameters and latent variables of interest θ from the posterior $Pr(\theta|\mathbf{X})$, where $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ is the private dataset. We can accomplish this by interpreting posterior sampling as an instance of the exponential mechanism with utility function $u(\mathbf{X}, \theta) = \log Pr(\theta, \mathbf{X})$, i.e. the log joint probability of the chosen θ assignment and the dataset $\mathbf{X}$ (Wang et al., 2015b). We then draw θ via

$$f(\theta; \mathbf{X}, \epsilon) \propto \exp\left(\frac{\epsilon \log Pr(\theta, \mathbf{X})}{2\triangle \log Pr(\theta, \mathbf{X})}\right) = Pr(\theta, \mathbf{X})^{\frac{\epsilon}{2\triangle \log Pr(\theta, \mathbf{X})}} \quad (6)$$

where the sensitivity is $\triangle \log Pr(\theta, \mathbf{X}) \triangleq$

$$\max_{\theta, (\mathbf{X}^{(1)}, \mathbf{X}^{(2)})} \|\log Pr(\theta, \mathbf{X}^{(1)}) - \log Pr(\theta, \mathbf{X}^{(2)})\|_1 \quad (7)$$

in which $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ differ in one element. If the data points are conditionally independent given θ,

$$\log Pr(\theta, \mathbf{X}) = \log Pr(\theta) + \sum_{i=1}^{N} \log Pr(\mathbf{x}_i|\theta)\,, \quad (8)$$

where $Pr(\theta)$ is the prior and $Pr(\mathbf{x}_i|\theta)$ is the likelihood term for data point $\mathbf{x}_i$. Since the prior does not depend

on the data, and each data point is associated with a single log-likelihood term $\log Pr(\mathbf{x}_i|\theta)$ in $\log Pr(\theta, \mathbf{X})$, from the above two equations we have

$$\triangle \log Pr(\theta, \mathbf{X}) = \max_{\mathbf{x},\mathbf{x}',\theta} |\log Pr(\mathbf{x}'|\theta) - \log Pr(\mathbf{x}|\theta)| . \tag{9}$$

This gives us the privacy cost of posterior sampling:

Theorem 2. *If* $\max_{\mathbf{x},\mathbf{x}'\in\chi,\theta\in\Theta} |\log Pr(\mathbf{x}'|\theta) - \log Pr(\mathbf{x}|\theta)| \leq C$*, releasing one sample from the posterior distribution* $Pr(\theta|\mathbf{X})$ *with any prior is* $2C$*-differentially private.*

Wang et al. (2015b) derived this form of the result from first principles, while noting that the exponential mechanism can be used, as we do here. Although they do not explicitly state the theorem, they implicitly use it to show two noteworthy special cases, referred to as the *One Posterior Sample (OPS)* procedure. We state the first of these cases:

Theorem 3. *If* $\max_{\mathbf{x}\in\chi,\theta\in\Theta} |\log Pr(\mathbf{x}|\theta)| \leq B$*, releasing one sample from the posterior distribution* $Pr(\theta|\mathbf{X})$ *with any prior is* $4B$*-differentially private.*

This follows directly from Theorem 2, since if $|\log Pr(\mathbf{x}|\theta)| \leq B$, $C = \triangle \log Pr(\theta, \mathbf{X}) = 2B$.

Under the exponential mechanism, ϵ provides an adjustable knob trading between privacy and fidelity. When $\epsilon = 0$, the procedure samples from a uniform distribution, giving away no information about $\mathbf{X}$. When $\epsilon = 2\triangle \log Pr(\theta, \mathbf{X})$, the procedure reduces to sampling θ from the posterior $Pr(\theta|\mathbf{X}) \propto Pr(\theta, \mathbf{X})$. As ϵ approaches infinity the procedure becomes increasingly likely to sample the θ assignment with the highest posterior probability. Assuming that our goal is to sample rather than to find a mode, we would cap ϵ at $2\triangle \log Pr(\theta, \mathbf{X})$ in the above procedure in order to correctly sample from the true posterior. More generally, if our privacy budget is ϵ', and $\epsilon' \geq 2q\triangle \log Pr(\theta, \mathbf{X})$, for integer q, we can draw q posterior samples within our budget.

As observed by Huang and Kannan (2012), the exponential mechanism can be understood via statistical mechanics. We can write it as a Boltzmann distribution (a.k.a. a Gibbs measure)

$$f(\theta; \mathbf{x}, \epsilon) \propto \exp\Big(\frac{-E(\theta)}{T}\Big), T = \frac{2\triangle u(\mathbf{X}, \theta)}{\epsilon} , \tag{10}$$

where $E(\theta) = -u(\mathbf{X}, \theta) = -\log Pr(\theta, \mathbf{X})$ is the energy of state θ in a physical system, and T is the temperature of the system (in units such that Boltzmann's constant is one). Reducing ϵ corresponds to increasing the temperature, which can be understood as altering the distribution such that a Markov chain moves through the state space more rapidly.

3 PRIVACY FOR EXPONENTIAL FAMILIES: EXPONENTIAL VS LAPLACE

By analyzing the privacy cost of sampling from exponential family posteriors in the general case we can recover the privacy properties of many standard distributions. These results can be applied to full posterior sampling, when feasible, or to Gibbs sampling updates, as we discuss in Section 4. In this section we analyze the privacy cost of sampling from exponential family posterior distributions exactly (or at an appropriate temperature) via the exponential mechanism, following Dimitrakakis et al. (2014) and Wang et al. (2015b), and via a method based on the Laplace mechanism, which is a generalization of Zhang et al. (2016). The properties of the two methods are compared in Table 1.

3.1 THE EXPONENTIAL MECHANISM

Consider exponential family models with likelihood

$$Pr(\mathbf{x}|\theta) = h(\mathbf{x})g(\theta)\exp\Big(\theta^\intercal S(\mathbf{x})\Big) ,$$

where $S(\mathbf{x})$ is a vector of sufficient statistics for data point $\mathbf{x}$, and θ is a vector of natural parameters. For N i.i.d. data points, we have

$$Pr(\mathbf{X}|\theta) = \Big(\prod_{i=1}^{N} h(\mathbf{x}^{(i)})\Big) g(\theta)^N \exp\Big(\theta^\intercal \sum_{i=1}^{N} S(\mathbf{x}^{(i)})\Big) .$$

Further suppose that we have a conjugate prior which is also an exponential family distribution,

$$Pr(\theta|\chi, \alpha) = f(\chi, \alpha)g(\theta)^\alpha \exp\Big(\alpha\theta^\intercal \chi\Big) ,$$

where α is a scalar, the number of prior "pseudo-counts," and χ is a parameter vector. The posterior is proportional to the prior times the likelihood,

$$Pr(\theta|\mathbf{X}, \chi, \alpha) \propto g(\theta)^{N+\alpha} \exp\Big(\theta^\intercal \big(\sum_{i=1}^{N} S(\mathbf{x}^{(i)}) + \alpha\chi\big)\Big). \tag{11}$$

To compute the sensitivity of the posterior, we have

$$\begin{aligned} &|\log Pr(\mathbf{x}'|\theta) - \log Pr(\mathbf{x}|\theta)| \qquad (12)\\ &\quad = |\theta^\intercal \Big(S(\mathbf{x}') - S(\mathbf{x})\Big) + \log h(\mathbf{x}') - \log h(\mathbf{x})| . \end{aligned}$$

From Equation 9, we obtain $\triangle \log Pr(\theta, \mathbf{X}) =$

$$\sup_{\mathbf{x},\mathbf{x}'\in\chi,\theta\in\Theta} |\theta^\intercal \Big(S(\mathbf{x}') - S(\mathbf{x})\Big) + \log h(\mathbf{x}') - \log h(\mathbf{x})| . \tag{13}$$

A posterior sample at temperature T,

$$Pr_T(\theta|\mathbf{X}, \chi, \alpha) \propto g(\theta)^{\frac{N+\alpha}{T}} \exp\Big(\theta^\intercal \frac{\sum_{i=1}^{N} S(\mathbf{x}^{(i)}) + \alpha\chi}{T}\Big) ,$$
$$T = \frac{2\triangle \log p(\theta, X)}{\epsilon} , \tag{14}$$

Mechanism	Sensitivity	$S(\mathbf{X})$ is	Release	ARE	Pay Gibbs cost
Laplace	$\sup_{\mathbf{X},\mathbf{X}'} \| \sum_{i=1}^{N} S(\mathbf{x}'^{(i)}) - \sum_{i=1}^{N} S(\mathbf{x}^{(i)}) \|_1$	Noised	Statistics	1	Once
Exponential (OPS)	$\sup_{\mathbf{x},\mathbf{x}' \in \chi, \theta \in \Theta} \lvert \theta^\intercal \Big(S(\mathbf{x}') - S(\mathbf{x}) \Big) + \log h(\mathbf{x}') - \log h(\mathbf{x}) \rvert$	Rescaled	One Sample	$1 + T$	Per update (unless converged)

Table 1: Comparison of the properties of the two methods for private Bayesian inference.

has privacy cost ϵ, by the exponential mechanism. As an example, consider a beta-Bernoulli model,

$$\begin{aligned} Pr(p|\alpha,\beta) &= \frac{1}{B(\alpha,\beta)} p^{\alpha-1}(1-p)^{\beta-1} \\ &= \frac{1}{B(\alpha,\beta)} \exp\big((\alpha-1)\log p + (\beta-1)\log(1-p)\big) \\ Pr(x|p) &= p^x(1-p)^{1-x} = \exp(x\log p + (1-x)\log(1-p) \end{aligned}$$

where $B(\alpha,\beta)$ is the beta function. Given N binary-valued data points $\mathbf{X} = x^{(1)}, \ldots, x^{(N)}$ from the Bernoulli distribution, the posterior is

$$\begin{aligned} &Pr(p|\mathbf{X},\alpha,\beta) \propto \\ &\quad \exp\Big(\big(n_+ + \alpha - 1\big)\log p + \big(n_- + \beta - 1\big)\log(1-p)\Big) \\ &n_+ = \sum_{i=1}^{N} x^{(i)}, \qquad n_- = \sum_{i=1}^{N} (1 - x^{(i)}) \,. \end{aligned}$$

The sufficient statistics for each data point are $S(x) = [x, 1-x]^\intercal$. The natural parameters for the posterior are $\theta = [\log p, \log(1-p)]^\intercal$, and $h(x) = 0$. The exponential mechanism sensitivity for a *truncated* version of this model, where $a_0 \le p \le 1 - a_0$, can be computed from Equation 13, $\triangle \log Pr(\theta, \mathbf{X}) =$

$$\begin{aligned} \sup_{x,x' \in \{0,1\}, p \in [a_0, 1-a_0]} & \lvert x \log p + (1-x)\log(1-p) \\ & - \big(x' \log p + (1-x')\log(1-p)\big) \rvert \\ &= -\log a_0 + \log(1-a_0) \,. \end{aligned} \tag{15}$$

Note that if $a_0 = 0$, corresponding to a standard untruncated beta distribution, the sensitivity is unbounded. This makes intuitive sense because some datasets are impossible if $p = 0$ or $p = 1$, which violates differential privacy.

3.2 THE LAPLACE MECHANISM

One limitation of the exponential mechanism / OPS approach to private Bayesian inference is that the temperature T of the approximate posterior is fixed for any ϵ that we are willing to pay, regardless of the number of data points N (Equation 10). While the posterior becomes more accurate as N increases, and the OPS approximation becomes more accurate by proxy, the OPS approximation remains a factor of T flatter than the posterior at N data points. This is not simply a limitation of the analysis. An adversary can choose data such that the dataset-specific privacy cost of posterior sampling approaches the worst case given by the exponential mechanism as N increases, by causing the posterior to concentrate on the worst-case θ (see the supplement for an example).

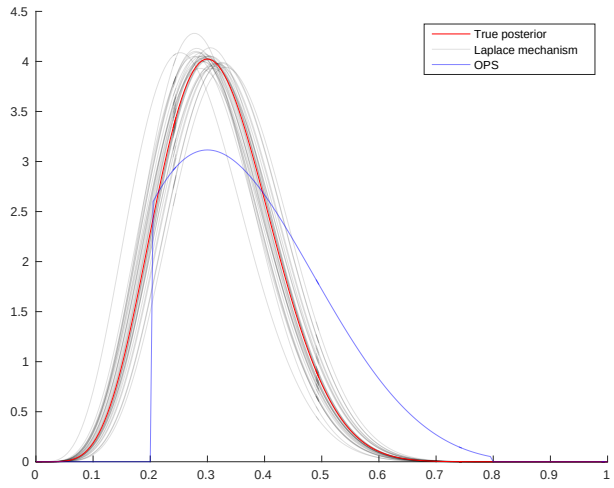

Figure 1: Privacy-preserving approximate posteriors for a beta-Bernoulli model ($\epsilon = 1$, the true parameter $p = 0.3$, OPS truncation point $a_0 = 0.2$, and number of observations $N = 20$). For the Laplace mechanism, 30 privatizing draws are rendered.

Here, we provide a simple Laplace mechanism alternative for exponential family posteriors, which becomes increasingly faithful to the true posterior with N data points, as N increases, for any fixed privacy cost ϵ, under general assumptions. The approach is based on the observation that for exponential family posteriors, as in Equation 11, the data interacts with the distribution only through the aggregate sufficient statistics, $S(\mathbf{X}) = \sum_{i=1}^{N} S(\mathbf{x}^{(i)})$. If we release privatized versions of these statistics we can use them to perform any further operations that we'd like, including drawing samples, computing moments and quantiles, and so on. This can straightforwardly be accomplished via the Laplace mechanism:

$$\begin{aligned} \hat{S}(\mathbf{X}) &= \text{proj}(S(\mathbf{X}) + (Y_1, Y_2, \ldots, Y_d)) \,, \\ Y_j &\sim \text{Laplace}(\triangle S(\mathbf{X})/\epsilon), \forall j \in \{1, 2, \ldots, d\} \,, \end{aligned} \tag{16}$$

where $\text{proj}(\cdot)$ is a projection onto the space of sufficient statistics, if the Laplace noise takes it out of this region.

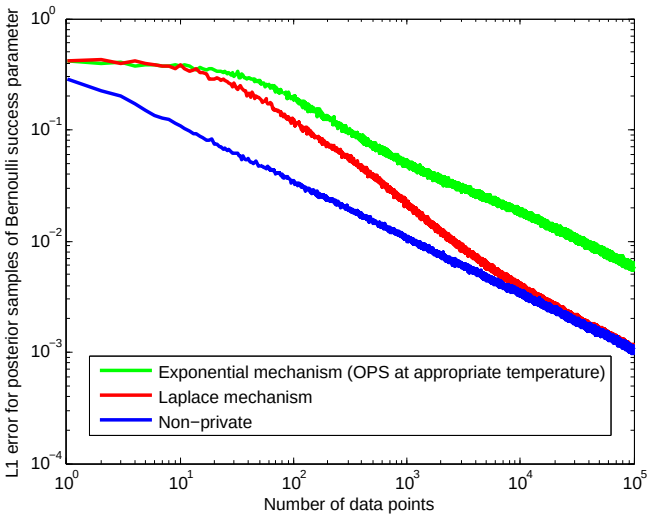

Figure 2: L1 error for private approximate samples from a beta posterior over a Bernoulli success parameter p, as a function of the number of Bernoulli(p) observations, averaged over 1000 repeats. The true parameter was $p = 0.1$, the exponential mechanism posterior was truncated at $a_0 = 0.05$, and $\epsilon = 0.1$.

For example, if the statistics are counts, the projection ensures that they are non-negative. The L_1 sensitivity of the aggregate statistics is

$$\begin{aligned} \triangle S(\mathbf{X}) &= \sup_{\mathbf{X},\mathbf{X}'} \| \sum_{i=1}^{N} S(\mathbf{x}'^{(i)}) - \sum_{i=1}^{N} S(\mathbf{x}^{(i)}) \|_1 \qquad (17) \\ &= \sup_{\mathbf{x},\mathbf{x}'} \|S(\mathbf{x}') - S(\mathbf{x})\|_1 \,, \end{aligned}$$

where $\mathbf{X}$, $\mathbf{X}'$ differ in at most one element. Note that perturbing the sufficient statistics is equivalent to perturbing the parameters, which was recently and independently proposed by Zhang et al. (2016) for beta-Bernoulli models such as Bernoulli naive Bayes.

A comparison of Equations 17 and 13 reveals that the L1 sensitivity and exponential mechanism sensitivities are closely related. The L1 sensitivity is generally easier to control as it does not involve θ or $h(\mathbf{x})$ but otherwise involves similar terms to the exponential mechanism sensitivity. For example, in the beta posterior case, where $S(\mathbf{x}) = [x, 1-x]$ is a binary indicator vector, the L1 sensitivity is 2. This should be contrasted to the exponential mechanism sensitivity of Equation 15, which depends heavily on the truncation point, and is unbounded for a standard untruncated beta distribution. The L1 sensitivity is fixed regardless of the number of data points N, and so the amount of Laplace noise to add becomes smaller relative to the total $S(\mathbf{X})$ as N increases.

Figure 1 illustrates the differences in behavior between the two privacy-preserving Bayesian inference algorithms for a beta distribution posterior with Bernoulli observations. The OPS estimator requires the distribution be truncated, here at $a_0 = 0.2$. This controls the exponential mechanism sensitivity, which determines the temperature T of the distribution, i.e. the extent to which the distribution is flattened, for a given ϵ. Here, $T = 2.7$. In contrast, the Laplace mechanism achieves privacy by adding noise to the sufficient statistics, which in this case are the pseudo-counts of successes and failures for the posterior distribution. In Figure 2 we illustrate the fidelity benefits of posterior sampling based on the Laplace mechanism instead of the exponential mechanism as the amount of data increases. In this case the exponential mechanism performs better than the Laplace mechanism only when the number of data points is very small (approximately $N = 10$), and is quickly overtaken by the Laplace mechanism sampling procedure. As N increases the accuracy of sampling from the Laplace mechanism's approximate posterior converges to the performance of samples from the true posterior at the current number of observations N, while the exponential mechanism behaves similarly to the posterior with fewer than N observations. We show this formally in the next subsection.

3.3 THEORETICAL RESULTS

First, we show that the Laplace mechanism approximation of exponential family posteriors approaches the true posterior distribution *evaluated at N data points*. Proofs are given in the supplementary.

Lemma 1. *For a minimal exponential family given a conjugate prior, where the posterior takes the form* $Pr(\theta|\mathbf{X}, \chi, \alpha) \propto g(\theta)^{n+\alpha} \exp\Big(\theta^\intercal \big(\sum_{i=1}^{n} S(\mathbf{x}^{(i)}) + \alpha\chi\big)\Big)$*, where $p(\theta|\eta)$ denotes this posterior with a natural parameter vector η, if there exists a $\delta > 0$ such that these assumptions are met:*

1. *The data $\mathbf{X}$ comes i.i.d. from a minimal exponential family distribution with natural parameter $\theta_0 \in \Theta$*
2. *θ_0 is in the interior of Θ*
3. *The function $A(\theta)$ has all derivatives for θ in the interior of Θ*
4. *$cov_{Pr(\mathbf{x}|\theta)}(S(\mathbf{x})))$ is finite for $\theta \in \mathcal{B}(\theta_0, \delta)$*
5. *$\exists w > 0$ s.t. $\det(cov_{Pr(\mathbf{x}|\theta)}(S(\mathbf{x})))) > w$ for $\theta \in \mathcal{B}(\theta_0, \delta)$*
6. *The prior $Pr(\theta|\chi, \alpha)$ is integrable and has support on a neighborhood of θ^**

then for any mechanism generating a perturbed posterior $\tilde{p}_N = p(\theta|\eta_N + \gamma)$ against a noiseless posterior $p_N = p(\theta|\eta_N)$ where γ comes from a distribution that does not

depend on the number of data observations N and has finite covariance, this limit holds:

$\lim_{N\to\infty} E[KL(\tilde{p}_N||p_N)] = 0\,.$

Corollary 2. *The Laplace mechanism on an exponential family satisfies the noise distribution requirements of Lemma 1 when the sensitivity of the sufficient statistics is finite and either the exponential family is minimal, or if the exponential family parameters θ are identifiable.*

These assumptions correspond to the data coming from a distribution where the Laplace regularity assumptions hold and the posterior satisfies the asymptotic normality given by the Bernstein-von Mises theorem. For example, in the beta-Bernoulli setting, these assumptions hold as long as the success parameter p is in the open interval $(0, 1)$. For $p = 0$ or 1, the relevant parameter is not in the interior of Θ, and the result does not apply. In the setting of learning a normal distribution's mean μ where the variance $\sigma^2 > 0$ is known, the assumptions of Lemma 1 always hold, as the natural parameter space is an open set. However, Corollary 2 does not apply in this setting because the sensitivity is infinite (unless bounds are placed on the data). Our efficiency result, in Theorem 4, follows from Lemma 1 and the Bernstein-von Mises theorem.

Theorem 4. *Under the assumptions of Lemma 1, the Laplace mechanism has an asymptotic posterior of $\mathcal{N}(\theta_0, 2\mathbb{I}^{-1}/N)$ from which drawing a single sample has an asymptotic relative efficiency of 2 in estimating θ_0, where $\mathbb{I}$ is the Fisher information at θ_0.*

Above, the asymptotic posterior refers to the normal distribution, whose variance depends on N, that the posterior distribution approaches as N increases. This ARE result should be contrasted to that of the exponential mechanism (Wang et al., 2015b).

Theorem 5. *The exponential mechanism applied to the exponential family with temperature parameter $T \geq 1$ has an asymptotic posterior of $\mathcal{N}(\theta^*, (1+T)\mathbb{I}^{-1}/N)$ and a single sample has an asymptotic relative efficiency of $(1 + T)$ in estimating θ^*, where $\mathbb{I}$ is the Fisher information at θ^*.*

Here, the ARE represents the ratio between the variance of the estimator and the optimal variance $\mathbb{I}^{-1}/N$ achieved by the posterior mean in the limit. Sampling from the posterior itself has an ARE of 2, due to the stochasticity of sampling, which the Laplace mechanism approach matches. These theoretical results provide an explanation for the difference in the behavior of these two methods as N increases seen in Figure 2. The Laplace mechanism will eventually approach the true posterior and the impact of privacy on accuracy will diminish when the data size increases. However, for the exponential mechanism with $T > 1$, the ratio of variances between the sampled posterior and the true posterior given N data points approaches $(1 + T)/2$, making the sampled posterior more spread out than the true posterior even as N grows large.

So far we have compared the ARE values for *sampling*, as an apples-to-apples comparison. In reality, the Laplace mechanism has a further advantage as it releases a full posterior with privatized parameters, while the exponential mechanism can only release a finite number of samples with a finite ϵ, which we discuss in Remark 1.

Remark 1. *Under the the assumptions of Lemma 1, by using the full privatized posterior instead of just a sample from it, the Laplace mechanism can release the privatized posterior's mean, which has an asymptotic relative efficiency of 1 in estimating θ^*.*

4 PRIVATE GIBBS SAMPLING

We now shift our discussion to the case of approximate Bayesian inference. While the analysis of Dimitrakakis et al. (2014) and Wang et al. (2015b) shows that posterior sampling is differentially private under certain conditions, exact sampling is not in general tractable. It does not directly follow that approximate sampling algorithms such as MCMC are also differentially private, or private at the same privacy level. Wang et al. (2015b) give two results towards understanding the privacy properties of approximate sampling algorithms. First, they show that if the approximate sampler is "close" to the true distribution in a certain sense, then the privacy cost will be close to that of a true posterior sample:

Proposition 3. *If procedure $\mathcal{A}$ which produces samples from distribution $P_{\mathbf{X}}$ is ϵ-differentially private, then any approximate sampling procedures $\mathcal{A}'$ that produces a sample from $P'_{\mathbf{X}}$ such that $\|P_{\mathbf{X}} - P'_{\mathbf{X}}\|_1 \leq \delta$ for any $\mathbf{X}$ is $(\epsilon, (1 + \exp(\epsilon)\delta)$-differentially private.*

Unfortunately, it is not in general feasible to verify the convergence of an MCMC algorithm, and so this criterion is not generally verifiable in practice. In their second result, Wang et al. study the privacy properties of stochastic gradient MCMC algorithms, including stochastic gradient Langevin dynamics (SGLD) (Welling and Teh, 2011) and its extensions. SGLD is a stochastic gradient method with noise injected in the gradient updates which converges in distribution to the target posterior.

In this section we study the privacy cost of MCMC, allowing us to quantify the privacy of many real-world MCMC-based Bayesian analyses. We focus on the case of Gibbs sampling, under exponential mechanism and Laplace mechanism approaches. By reinterpreting Gibbs sampling as an instance of the exponential mechanism, we obtain the "privacy for free" cost of Gibbs sampling. Metropolis-Hastings and annealed importance sampling also have privacy guarantees, which we show in the supplementary materials.

4.1 EXPONENTIAL MECHANISM

We consider the privacy cost of a Gibbs sampler, where data $\mathbf{X}$ are behind the privacy wall, current sampled values of parameters and latent variables $\theta = [\theta_1, \ldots, \theta_D]$ are publicly known, and a Gibbs update is a randomized algorithm which queries our private data in order to randomly select a new value θ'_l for the current variable θ_l. The transition kernel for a Gibbs update of θ_l is

$$T^{(Gibbs,l)}(\theta, \theta') = Pr(\theta'_l | \theta_{\neg l}, \mathbf{X}) \,, \tag{18}$$

where $\theta_{\neg l}$ refers to all entries of θ except l, which are held fixed, i.e. $\theta'_{\neg l} = \theta_{\neg l}$. This update can be understood via the exponential mechanism:

$$T^{(Gibbs,l,\epsilon)}(\theta, \theta') \propto Pr(\theta'_l, \theta_{\neg l}, \mathbf{X})^{\frac{\epsilon}{2\triangle \log Pr(\theta'_l, \theta_{\neg l}, \mathbf{X})}} \,, \tag{19}$$

with utility function $u(\mathbf{X}, \theta'_l; \theta_{\neg l}) = \log Pr(\theta'_l, \theta_{\neg l}, \mathbf{X})$, over the space of possible assignments to θ_l, holding $\theta_{\neg l}$ fixed. A Gibbs update is therefore ϵ-differentially private, with $\epsilon = 2\triangle \log Pr(\theta'_l, \theta_{\neg l}, \mathbf{X})$. This update corresponds to Equation 6 except that the set of responses for the exponential mechanism is restricted to those where $\theta'_{\neg l} = \theta_{\neg l}$. Note that

$$\triangle \log Pr(\theta'_l, \theta_{\neg l}, \mathbf{X}) \leq \triangle \log Pr(\theta, \mathbf{X}) \tag{20}$$

as the worst case is computed over a strictly smaller set of outcomes. In many cases each parameter and latent variable θ_l is associated with only the lth data point $\mathbf{x}_l$, in which case the privacy cost of a Gibbs scan can be improved over simple additive composition. In this case a random sequence scan Gibbs pass, which updates all N θ_l's exactly once, is $2\triangle \log Pr(\theta, \mathbf{X})$-differentially private by parallel composition (Song et al., 2013). Alternatively, a random scan Gibbs sampler, which updates a random Q out of N θ_l's, is $4\triangle \log Pr(\theta, \mathbf{X})\frac{Q}{N}$-differentially private from the *privacy amplification* benefit of subsampling data (Li et al., 2012).

4.2 LAPLACE MECHANISM

Suppose that the conditional posterior distribution for a Gibbs update is in the exponential family. Having privatized the sufficient statistics arising from the data for the likelihoods involved in each update, via Equation 16, and publicly released them with privacy cost ϵ, we may now perform the update by drawing a sample from the approximate conditional posterior, i.e. Equation 11 but with $S(\mathbf{X}) = \sum_{i=1}^{N}(\mathbf{x}^{(i)})$ replaced by $\hat{S}(\mathbf{X})$. Since the privatized statistics can be made public, we can also subsequently draw from an approximate posterior based on $\hat{S}(\mathbf{X})$ with any other prior (selected based on public information only), without paying any further privacy cost. This is especially valuable in a Gibbs sampling context, where the "prior" for a Gibbs update often consists of factors from other variables and parameters to be sampled, which are updated during the course of the algorithm.

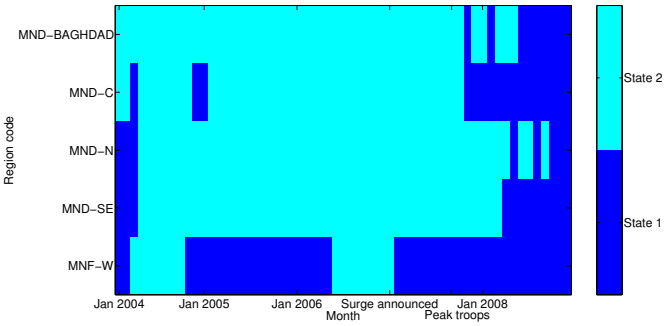

Figure 3: State assignments of privacy-preserving HMM on Iraq (Laplace mechanism, $\epsilon = 5$).

In particular, consider a Bayesian model where a Gibbs sampler interacts with data only via conditional posteriors and their corresponding likelihoods that are exponential family distributions. We can privatize the sufficient statistics of the likelihood just once at the beginning of the MCMC algorithm via the Laplace mechanism with privacy cost ϵ, and then approximately sample from the posterior by running the entire MCMC algorithm based on these privatized statistics without paying any further privacy cost. This is typically much cheaper in the privacy budget than exponential mechanism MCMC which pays a privacy cost for every Gibbs update, as we shall see in our case study in Section 5. The MCMC algorithm does not need to converge to obtain privacy guarantees, unlike the OPS method. This approach applies to a very broad class of models, including Bayesian parameter learning for fully-observed MRF and Bayesian network models. Of course, for this technique to be useful in practice, the aggregate sufficient statistics for each Gibbs update must be large relative to the Laplace noise. For latent variable models, this typically corresponds to a setting with many data points per latent variable, such as the HMM model with multiple emissions per timestep which we study in the next section.

5 CASE STUDY: WIKILEAKS IRAQ & AFGHANISTAN WAR LOGS

A primary goal of this work is to establish the practical feasibility of privacy-preserving Bayesian data analysis using complex models on real-world datasets. In this section we investigate the performance of the methods studied in this paper for the analysis of sensitive military data. In July and October 2010, the Wikileaks organization disclosed collections of internal U.S. military field reports from the wars in Afghanistan and Iraq, respectively. Both disclosures contained data from between January 2004 to December 2009, with ~75,000 entries from the war in Afghanistan, and ~390,000 entries from Iraq. Hillary Clinton, at that time

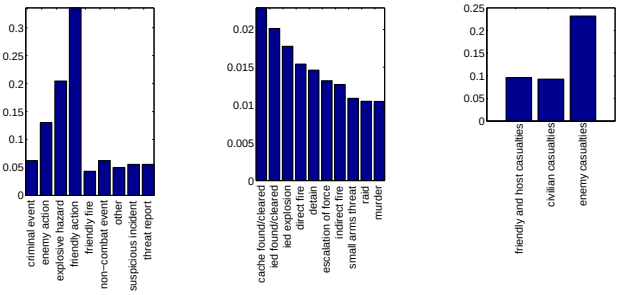

Figure 4: State 1 for Iraq (*type*, *category*, *casualties*).

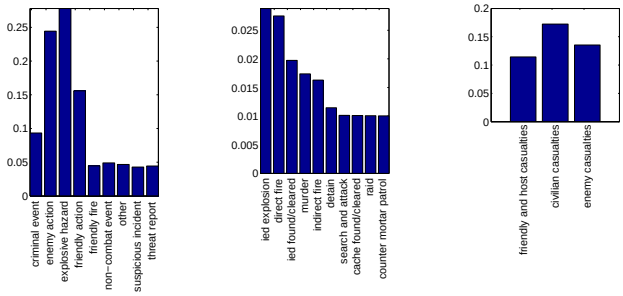

Figure 5: State 2 for Iraq (*type*, *category*, *casualties*).

the U.S. Secretary of State, criticized the disclosure, stating that it "puts the lives of United States and its partners' service members and civilians at risk."[1] These risks, and the motivations for the leak, could potentially have been mitigated by releasing a differentially private analysis of the data, which protects the contents of each individual log entry while revealing high-level trends. Note that since the data are publicly available, although our *models* were differentially private, other aspects of this manuscript such as the evaluation may reveal certain information, as in other works such as Wang et al. (2015a,b).

The disclosed war logs each correspond to an individual event, and contain textual reports, as well as fields such as coarse-grained *types* (*friendly action*, *explosive hazard*, ...), fine-grained *categories* (*mine found/cleared*, *show of force*, ...), and casualty counts (*wounded/killed/detained*) for the different factions (*Friendly*, *HostNation* (i.e. Iraqi and Afghani forces), *Civilian*, and *Enemy*, where the names are relative to the U.S. military's perspective). We use the techniques discussed in this paper to privately infer a hidden Markov model on the log entries. The HMM was fit to the non-textual fields listed above, with one timestep per month, and one HMM chain per region code. A naive Bayes conditional independence assumption was used in the emission probabilities for simplicity and parameter-count parsimony. Each field was modeled via a discrete distribution per latent state, with casualty counts binarized (0 versus > 0), and with *wounded/killed/detained* and *Friendly/HostNation* features combined, respectively, via disjunction of the binary values. This decreased the number of features to privatize, while slightly increasing the size of the counts per field to protect and simplifying the model for visualization purposes. After preprocessing to remove empty timesteps and near-empty region codes (see the supplementary), the median number of log entries per region/timestep pair was 972 for Iraq, and 58 for Afghanistan. The number of log entries per timestep was highly skewed for Afghanistan, due to an increase in density over time.

The models were trained via Gibbs sampling, with the transition probabilities collapsed out, following Goldwater and Griffiths (2007). We did not collapse out the naive Bayes parameters in order to keep the conditional likelihood in the exponential family. The details of the model and inference algorithm are given in the supplementary material. We trained the models for 200 Gibbs iterations, with the first 100 used for burn-in. Both privatization methods have the same overall computational complexity as the non-private sampler. The Laplace mechanism's computational overhead is paid once up-front, and did not greatly affect the runtime, while OPS roughly doubled the runtime. For visualization purposes we recovered parameter estimates via the posterior mean based on the latent variable assignments of the final iteration, and we reported the most frequent latent variable assignments over the non-burn-in iterations. We trained a 2-state model on the Iraq data, and a 3-state model for the Afghanistan data, using the Laplace approach with total $\epsilon = 5$ ($\epsilon = 1$ for each of 5 features).

Interestingly, when given 10 states, the privacy-preserving model only assigned substantial numbers of data points to these 2-3 states, while a non-private HMM happily fit a 10-state model to the data. The Laplace noise therefore appears to play the role of a regularizer, consistent with the noise being interpreted as a "random prior," and along the lines of noise-based regularization techniques such as (Srivastava et al., 2014; van der Maaten et al., 2013), although of course it may correspond to more regularization than we would typically like. This phenomenon potentially merits further study, beyond the scope of this paper.

We visualized the output of the Laplace HMM for Iraq in Figures 3–5. State 1 shows the U.S. military performing well, with the most frequent outcomes for each feature being *friendly action*, *cache found/cleared*, and *enemy casualties*, while the U.S. military performed poorly in State 2 (*explosive hazard*, *IED explosion*, *civilian casualties*). State 2 was prevalent in most regions until the situation improved to State 1 after the troop surge strategy of 2007. This transition typically occurred after troops peaked in Sept.–Nov. 2007. The results for Afghanistan, in the supplementary, provide a critical lens on the US military's performance, with enemy casualty rates (including

[1]Fallon, Amy (2010). "Iraq war logs: disclosure condemned by Hillary Clinton and Nato." The Guardian. Retrieved on 2/22/2016.

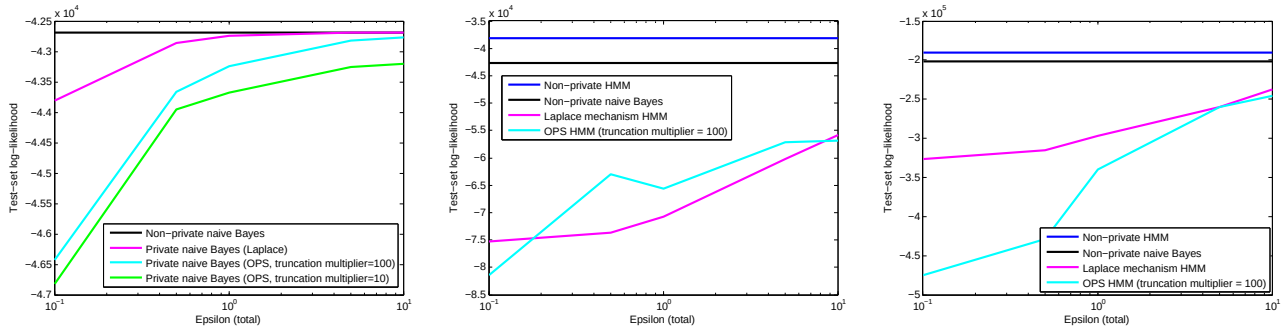

Figure 6: Log-likelihood results. **Left:** Naive Bayes (Afghanistan). **Middle**: Afghanistan. **Right**: Iraq. For OPS, Dirichlets were truncated at $a_0 = \frac{1}{MK_d}$, $M = 10$ or 100, where $K_d =$ feature d's dimensionality.

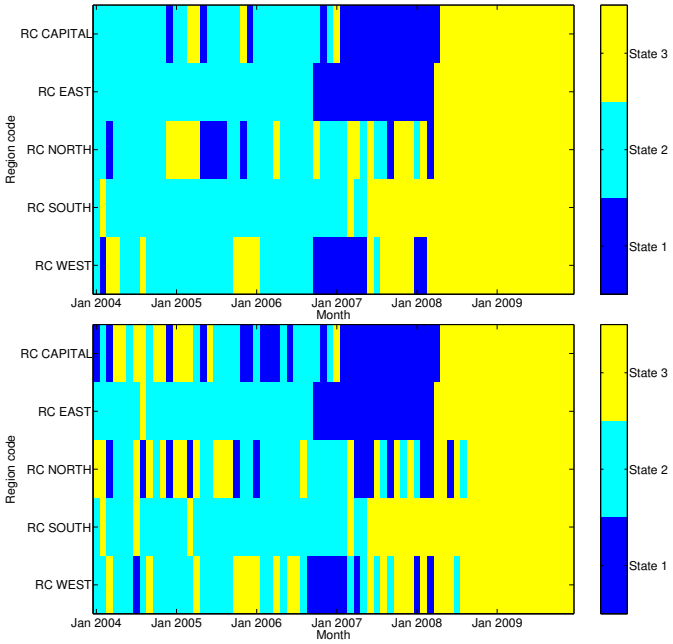

Figure 7: State assignments for OPS privacy-preserving HMM on Afghanistan. ($\epsilon = 5$, truncation point $a_0 = \frac{1}{100K_d}$). **Top**: Estimate from last 100 samples. **Bottom**: Estimate from last one sample.

detainments) lower than friendly/host casualties for all latent states, and lower than civilian casualties in 2 of 3 states.

We also evaluated the methods at prediction. A uniform random 10% of the timestep/region pairs were held out for 10 train/test splits, and we reported average test likelihoods over the splits. We estimated test log-likelihood for each split by averaging the test likelihood over the burned-in samples (Laplace mechanism), or using the final sample (OPS). All methods were given 10 latent states, and ϵ was varied between 0.1 and 10. We also considered a naive Bayes model, equivalent to a 1-state HMM. The Laplace mechanism was superior to OPS for the naive Bayes model, for which the statistics are corpus-wide counts, corresponding to a high-data regime in which our asymptotic analysis was applicable. OPS was competitive with the Laplace mechanism for the HMM on Afghanistan, where the amount of data was relatively low. For the Iraq dataset, where there was more data per timestep, the Laplace mechanism outperformed OPS, particularly in the high-privacy regime. For OPS, privacy at ϵ is only guaranteed if MCMC has converged. Otherwise, from Section 4.1, the worst case is an impractical $\epsilon^{(Gibbs)} \leq 400\epsilon$ (200 iterations of latent variable and parameter updates with worst-case cost ϵ). OPS only releases one sample, which harmed the coherency of the visualization for Afghanistan, as latent states of the final sample were noisy relative to an estimate based on all 100 post burn-in samples (Figure 7). Privatizing the Gibbs chain at a privacy cost of $\epsilon^{(Gibbs)}$ would avoid this.

6 CONCLUSION

This paper studied the practical limitations of using posterior sampling to obtain privacy "for free." We explored an alternative based on the Laplace mechanism, and analyzed it both theoretically and empirically. We illustrated the benefits of the Laplace mechanism for privacy-preserving Bayesian inference to analyze sensitive war records. The study of privacy-preserving Bayesian inference is only just beginning. We envision extensions of these techniques to other approximate inference algorithms, as well as their practical application to sensitive real-world data sets. Finally, we have argued that asymptotic efficiency is important in a privacy context, leading to an open question: how large is the class of private methods that are asymptotically efficient?

Taming the Noise in Reinforcement Learning via Soft Updates

Roy Fox[*] Hebrew University

Abstract

Model-free reinforcement learning algorithms, such as Q-learning, perform poorly in the early stages of learning in noisy environments, because much effort is spent unlearning biased estimates of the state-action value function. The bias results from selecting, among several noisy estimates, the apparent optimum, which may actually be suboptimal. We propose G-learning, a new off-policy learning algorithm that regularizes the value estimates by penalizing deterministic policies in the beginning of the learning process. We show that this method reduces the bias of the value-function estimation, leading to faster convergence to the optimal value and the optimal policy. Moreover, G-learning enables the natural incorporation of prior domain knowledge, when available. The stochastic nature of G-learning also makes it avoid some exploration costs, a property usually attributed only to on-policy algorithms. We illustrate these ideas in several examples, where G-learning results in significant improvements of the convergence rate and the cost of the learning process.

1 INTRODUCTION

The need to separate signals from noise stands at the center of any learning task in a noisy environment. While a rich set of tools to regularize learned parameters has been developed for supervised and unsupervised learning problems, in areas such as reinforcement learning there still exists a vital need for techniques that tame the noise and avoid overfitting and local minima.

One of the central algorithms in reinforcement learning is Q-learning [1], a model-free off-policy algorithm, which attempts to estimate the optimal value function Q, the cost-to-go of the optimal policy. To enable this estimation, a stochastic exploration policy is used by the learning agent to interact with its environment and explore the model. This approach is very successful and popular, and despite several alternative approaches developed in recent years [2, 3, 4], it is still being applied successfully in complex domains for which explicit models are lacking [5].

However, in noisy domains, in early stages of the learning process, the min (or max) operator in Q-learning brings about a bias in the estimates. This problem is akin to the "winner's curse" in auctions [6, 7, 8, 9]. With too little evidence, the biased estimates may lead to wrong decisions, which slow down the convergence of the learning process, and require subsequent unlearning of these suboptimal behaviors.

In this paper we present G-learning, a new off-policy information-theoretic approach to regularizing the state-action value function learned by an agent interacting with its environment in model-free settings.

This is achieved by adding to the cost-to-go a term that penalizes deterministic policies which diverge from a simple stochastic prior policy [10]. With only a small sample to go by, G-learning prefers a more randomized policy, and as samples accumulate, it gradually shifts to a more deterministic and exploiting policy. This transition is managed by appropriately scheduling the coefficient of the penalty term as learning proceeds.

In Section 4 we discuss the theoretical and practical aspects of scheduling this coefficient, and suggest that a simple linear schedule can perform well. We show that G-learning with this schedule reduces the value estimation bias by avoiding overfitting in its selection of the update policy. We further establish empirically the link between bias reduction and learning performance, that has been the underlying assumption in many approaches to reinforcement learning [11, 12, 13, 14]. The examples in Section 6 demonstrate the significant improvement thus obtained.

Furthermore, in domains where exploration incurs significantly higher costs than exploitation, such as the classic

[*]These authors contributed equally to this work.

cliff domain [2], G-learning with an ϵ-greedy exploration policy is exploration-aware, and chooses a less costly exploration policy, thus reducing the costs incurred during the learning process. Such awareness to the cost of exploration is usually attributed to on-policy algorithms, such as SARSA [2, 4] and Expected-SARSA [15, 16]. The remarkable finding that G-learning exhibits on-policy-like properties is illustrated in the example of Section 6.2.

In Section 2 we discuss the problem of learning in noisy environments. In Section 3 we introduce the penalty term, derive G-learning and prove its convergence. In Section 4 we determine a schedule for the coefficient of the information penalty term. In Section 5 we discuss related work. In Section 6 we illustrate the strengths of the algorithm through several examples.

2 LEARNING IN NOISY ENVIRONMENTS

2.1 NOTATION AND BACKGROUND

We consider the usual setting of a Markov Decision Process (MDP), in which an agent interacts with its environment by repeatedly observing its state $s \in S$, taking an action $a \in A$, with A and S finite, and incurring cost $c \in \mathbb{R}$. This induces a stochastic process $s_0, a_0, c_0, s_1, \ldots$, where s_0 is fixed, and where for $t \geq 0$ we have the Markov properties indicated by the conditional distributions $a_t \sim \pi_t(a_t|s_t)$, $c_t \sim \theta(c_t|s_t, a_t)$ and $s_{t+1} \sim p(s_{t+1}|s_t, a_t)$.

The objective of the agent is to find a time-invariant policy π that minimizes the total discounted expected cost

$$V^\pi(s) = \sum_{t \geq 0} \gamma^t \, \mathrm{E}[c_t|s_0 = s], \tag{1}$$

simultaneously for any $s \in S$, for a given discount factor $0 \leq \gamma < 1$. For each t, the expectation above is over all trajectories of length t starting at $s_0 = s$. A related quantity is the state-action value function

$$\begin{aligned} Q^\pi(s, a) &= \sum_{t \geq 0} \gamma^t \, \mathrm{E}[c_t|s_0 = s, a_0 = a] \\ &= \mathrm{E}_\theta[c|s, a] + \gamma \, \mathrm{E}_p[V^\pi(s')|s, a], \end{aligned} \tag{2}$$

which equals the total discounted expected cost that follows from choosing action a in state s, and then following the policy π.

If we know the distributions p and θ (or at least $\mathrm{E}_\theta[c|s, a]$), then it is easy to find the optimal state-action value function

$$Q^*(s, a) = \min_\pi Q^\pi(s, a) \tag{3}$$

using standard techniques, such as Value Iteration [17]. Our interest is in model-free learning, where the model parameters are unknown. Instead, the agent obtains samples from $p(s_{t+1}|s_t, a_t)$ and $\theta(c_t|s_t, a_t)$ through its interaction with the environment. In this setting, the Q-learning algorithm [1] provides a method for estimating Q^*. It starts with an arbitrary Q, and in step t upon observing s_t, a_t, c_t and s_{t+1}, performs the update

$$\begin{aligned} Q(s_t, a_t) \leftarrow (1 - \alpha_t) Q(s_t, a_t) \\ + \alpha_t \left(c_t + \gamma \sum_{a'} \pi(a'|s_{t+1}) Q(s_{t+1}, a') \right), \end{aligned} \tag{4}$$

with some learning rate $0 \leq \alpha_t \leq 1$, and the greedy policy for Q having

$$\pi(a|s) = \delta_{a, a^*(s)}; \qquad a^*(s) = \arg\min_a Q(s, a). \tag{5}$$

$Q(s, a)$ is unchanged for any $(s, a) \neq (s_t, a_t)$. If the learning rate satisfies

$$\sum_t \alpha_t = \infty; \qquad \sum_t \alpha_t^2 < \infty, \tag{6}$$

and the interaction itself uses an exploration policy that returns to each state-action pair infinitely many times, then Q is a consistent estimator, converging to Q^* with probability 1 [1, 17]. Similarly, if the update rule (4) uses a fixed update policy $\pi = \rho$, we call this algorithm Q$^\rho$-learning, because Q converges to Q^ρ with probability 1.

2.2 BIAS AND EARLY COMMITMENT

Despite the success of Q-learning in many situations, learning can proceed extremely slowly when there is noise in the distribution, given s_t and a_t, of either of the terms of (2), namely the cost c_t and the value of the next state s_{t+1}. The source of this problem is a negative bias introduced by the min operator in the estimator $\min_{a'} Q(s_{t+1}, a')$, when (5) is plugged into (4).

To illustrate this bias, assume that $Q(s, a)$ is an unbiased but noisy estimate of the optimal $Q^*(s, a)$. Then Jensen's inequality for the concave min operator implies that

$$\mathrm{E}[\min_a Q(s, a)] \leq \min_a Q^*(s, a), \tag{7}$$

with equality only when Q already reveals the optimal policy by having $\arg\min_a Q(s, a) = \arg\min_a Q^*(s, a)$ with probability 1, so that no further learning is needed. The expectation in (7) is with respect to the learning process, including any randomness in state transition, cost, exploration and internal update, given the domain.

This is an optimistic bias, causing the cost-to-go to appear lower than it is (or the reward-to-go higher). It is the well known "winner's curse" problem in economics and decision theory [6, 7, 8, 9], and in the context of Q-learning it was studied before in [3, 11, 12, 13]. A similar problem occurs when a function approximation scheme is used

for Q instead of a table, even in the absence of transition or cost noise, because the approximation itself introduces noise [18].

As the sample size increases, the variance in $Q(s,a)$ decreases, which in turn reduces the bias in (7). This makes the update policy (5) more optimal, and the update increasingly similar to Value Iteration.

2.3 THE INTERPLAY OF VALUE BIAS AND POLICY SUBOPTIMALITY

It is insightful to consider the effect of the bias not only on the estimated value function, but also on the real value V^π of the greedy policy (5), since in many cases the latter is the actual output of the learning process. The central quantity of interest here is the gap $Q^*(s,a')-V^*(s)$, in a given state s, between the value of a non-optimal action a' and that of the optimal action.

Consider first the case in which the gap is large compared to the noise in the estimation of the $Q(s,a)$ values. In this case, a' indeed appears suboptimal with high probability, as desired. Interestingly, when the gap is very small relative to the noise, the learning agent should not worry, either. Confusing such a' for the optimal action has a limited effect on the value of the greedy policy, since choosing a' is near-optimal.

We conclude that the real value V^π of the greedy policy (5) is suboptimal only in the intermediate regime, when the gap is of the order of the noise, and neither is small. The effect of the noise can be made even worse by the propagation of bias between states, through updates. Such propagation can cause large-gap suboptimal actions to nevertheless appear optimal, if they lead to a region of state-space that is highly biased.

2.4 A DYNAMIC OPTIMISM-UNCERTAINTY LOOP

The above considerations were agnostic to the exploration policy, but the bias reduction can be accelerated by an exploration policy that is close to being greedy. In this case, high-variance estimation is self-correcting: an estimated state value with optimistic bias draws exploration towards that state, leading to a decrease in the variance, which in turn reduces the optimistic bias. This is a dynamic form of optimism under uncertainty. While in the usual case the optimism is externally imposed as an initial condition [19], here it is spontaneously generated by the noise and self-corrected through exploration.

The approach we propose below to reduce the variance is motivated by electing to represent the uncertainty explicitly, and not indirectly through an optimistic bias. We notice that although *in the end* of the learning process one obtains the deterministic greedy policy from $Q(a,s)$ as in (5), *during* the learning itself the bias in Q can be ameliorated by avoiding the hard min operator, and refraining from committing to a deterministic greedy policy. This can be achieved by adding to Q, at the early learning stage, a term that penalizes deterministic policies, which we consider next.

3 LEARNING WITH SOFT UPDATES

3.1 THE FREE-ENERGY FUNCTION G AND G-LEARNING

Let us adopt, before any interaction with the environment, a simple stochastic prior policy $\rho(a|s)$. For example, we can take the uniform distribution over the possible actions. The *information cost* of a learned policy $\pi(a|s)$ is defined as

$$g^\pi(s,a) = \log \tfrac{\pi(a|s)}{\rho(a|s)}, \tag{8}$$

and its expectation over the policy π is the Kullback-Leibler (KL) divergence of $\pi_s = \pi(\cdot|s)$ from $\rho_s = \rho(\cdot|s)$,

$$\mathrm{E}_\pi[g^\pi(s,a)|s] = \mathrm{D}_{\mathrm{KL}}[\pi_s \| \rho_s]. \tag{9}$$

The term (8) penalizes deviations from the prior policy and serves to regularize the optimal policy away from a deterministic action. In the context of the MDP dynamics $p(s_{t+1}|s_t,a_t)$, similarly to (1), we consider the total discounted expected information cost

$$I^\pi(s) = \sum_{t\geq 0} \gamma^t \,\mathrm{E}[g^\pi(s_t,a_t)|s_0 = s]. \tag{10}$$

The discounting in (1) and (10) is justified by imagining a horizon $T \sim \mathrm{Geom}(1-\gamma)$, distributed geometrically with parameter $1-\gamma$. Then the cost-to-go V^π in (1) and the information-to-go I^π in (10) are the total (undiscounted) expected T-step costs.

Adding the penalty term (10) to the cost function (1) gives

$$\begin{aligned} F^\pi(s) &= V^\pi(s) + \tfrac{1}{\beta} I^\pi(s), \\ &= \sum_{t\geq 0} \gamma^t \,\mathrm{E}[\tfrac{1}{\beta} g^\pi(s_t,a_t) + c_t | s_0 = s], \end{aligned} \tag{11}$$

called the *free-energy function* by analogy with a similar quantity in statistical mechanics [10].

Here β is a parameter that sets the relative weight between the two costs. For the moment, we assume that β is fixed. In following sections, we let β grow as the learning proceeds.

In analogy with the Q^π function (2), let us define the *state-action free-energy function* $G^\pi(s,a)$ as

$$\begin{aligned} G^\pi(s,a) &= \mathrm{E}_\theta[c|s,a] + \gamma \,\mathrm{E}_p[F^\pi(s')|s,a] \\ &= \sum_{t\geq 0} \gamma^t \,\mathrm{E}[c_t + \tfrac{\gamma}{\beta} g^\pi(s_{t+1},a_{t+1}))|s_0 = s, a_0 = a], \end{aligned} \tag{12}$$

and note that it does not involve the information term at time $t = 0$, since the action $a_0 = a$ is already known. From the definitions (11) and (12) it follows that

$$F^\pi(s) = \sum_a \pi(a|s) \left[\tfrac{1}{\beta} \log \tfrac{\pi(a|s)}{\rho(a|s)} + G^\pi(s,a) \right]. \quad (13)$$

It is easy to verify that, given the G function, the above expression for F^π has gradient 0 at

$$\pi(a|s) = \frac{\rho(a|s) e^{-\beta G(s,a)}}{\sum_{a'} \rho(a'|s) e^{-\beta G(s,a')}}, \quad (14)$$

which is therefore the optimal policy.

The policy (14) is the soft-min operator applied to G, with inverse-temperature β. When β is small, the information cost is dominant, and π approaches the prior ρ. When β is large, we are willing to diverge much from the prior to reduce the external cost, and π approaches the deterministic greedy policy for G.

Evaluated at the soft-greedy policy (14), the free energy (13) is

$$F^\pi(s) = -\tfrac{1}{\beta} \log \sum_a \rho(a|s) e^{-\beta G^\pi(s,a)}, \quad (15)$$

and plugging this expression into (12), we get that the optimal G^* is a fixed point of the equation

$$\begin{aligned} G^*(s,a) = {} & \mathrm{E}_\theta[c|s,a] \quad (16) \\ & - \tfrac{\gamma}{\beta} \mathrm{E}_p \left[\log \sum_{a'} \rho(a'|s') e^{-\beta G^*(s',a')} \right] \\ \equiv {} & \mathbf{B}^*[G^*]_{(s,a)}. \quad (17) \end{aligned}$$

Based on the above expression, we introduce G-learning as an off-policy TD-learning algorithm [2], that learns the optimal G^* from the interaction with the environment by applying the update rule

$$\begin{aligned} G(s_t,a_t) \leftarrow {} & (1-\alpha_t) G(s_t,a_t) \quad (18) \\ & + \alpha_t \left(c_t - \tfrac{\gamma}{\beta} \log \left(\sum_{a'} \rho(a'|s_{t+1}) e^{-\beta G(s_{t+1},a')} \right) \right). \end{aligned}$$

3.2 THE ROLE OF THE PRIOR

Clearly the choice of the prior policy ρ is significant in the performance of the algorithm. The prior policy can encode any prior knowledge that we have about the domain, and this can improve the convergence if done correctly. However an incorrect prior policy can hinder learning. We should therefore choose a prior policy that represents all of our prior knowledge, but nothing more. This prior policy has maximal entropy given the prior knowledge [20].

In our examples in Section 6, we use the uniform prior policy, representing no prior knowledge. Both in Q-learning and in G-learning, we could utilize the prior knowledge that moving into a wall is never a good action, by eliminating those actions. One advantage of G-learning is that it can utilize softer prior knowledge. For example, a prior policy that gives lower probability for moving into a wall represent the prior knowledge that such an action is usually (but not always) harmful, a type of knowledge that cannot be utilized in Q-learning.

We have presented G-learning in a fully parameterized formulation, where the function G is stored in a lookup table. Practical applications of Q-learning often resort to approximating the function Q through function approximations, such as linear expansions or neural networks [2, 3, 4, 21, 5]. Such an approximation generates inductive bias, which is another form of implicit prior knowledge. While G-learning is introduced here in its table form, preliminary results indicate that its benefits carry over to function approximations, despite the challenges posed by this extension.

3.3 CONVERGENCE

In this section we study the convergence of G under the update rule (18). Recall that the supremum norm is defined as $|x|_\infty = \max_i |x_i|$. We need the following Lemma, proved in the Supplementary Material.

Lemma 1. *The operator* $\mathbf{B}^*[G]_{(s,a)}$ *defined in* (17) *is a contraction in the supremum norm,*

$$\left| \mathbf{B}^*[G_1] - \mathbf{B}^*[G_2] \right|_\infty \le \gamma \left| G_1 - G_2 \right|_\infty. \quad (19)$$

The update equation (18) of the algorithm can be written as a stochastic iteration equation

$$\begin{aligned} G_{t+1}(s_t,a_t) = {} & (1-\alpha_t) G_t(s_t,a_t) \quad (20) \\ & + \alpha_t (\mathbf{B}^*[G_t]_{(s_t,a_t)} + z_t(c_t, s_{t+1})) \end{aligned}$$

where the random variable z_t is

$$\begin{aligned} z_t(c_t,s_{t+1}) = {} & -\mathbf{B}^*[G_t]_{(s_t,a_t)} \quad (21) \\ & + c_t - \tfrac{\gamma}{\beta} \log \sum_{a'} \rho(a'|s_{t+1}) e^{-\beta G_t(s_{t+1},a')}. \end{aligned}$$

Note that z_t has expectation 0. Many results exist for iterative equations of the type (20). In particular, given conditions (6) for α_t, the contractive nature of $\mathbf{B}^*$, infinite visits to each pair (s_t, a_t) and assuming that $|z_t| < \infty$, G_t is guaranteed to converge to the optimal G^* with probability 1 [17, 22].

4 SCHEDULING β

In the previous section, we showed that running G-learning with a fixed β converges, with probability 1, to the optimal G^* for that β, given by the recursion in (12)–(14).

When $\beta = \infty$, the equations for G^* and F^* degenerate into the equations for Q^* and V^*, and G-learning becomes Q-learning. When $\beta = 0$, the update policy π in (14) is equal to the prior ρ. This case, denoted Q^ρ-learning, converges to Q^ρ.

In an early stage of learning, Q^ρ-learning has an advantage over Q-learning, because it avoids committing to a deterministic policy based on a noisy Q function. In a later stage of learning, when Q is a more precise estimate of Q^*, Q-learning gains the advantage by updating with a better policy than the prior. This is demonstrated in section 6.1.

We would therefore like to schedule β so that G-learning makes a smooth transition from Q^ρ-learning to Q-learning, just at the right pace to enjoy the early advantage of the former and the late advantage of the latter. As we argue below, such a β always exists.

4.1 ORACLE SCHEDULING

To consider the effect of the β scheduling on the correction of the bias (7), suppose that during learning we reach some G that is an unbiased estimate of G^*. $G(s_t, a_t)$ would remain unbiased if we update it towards

$$c_t + \gamma G(s_{t+1}, a^*) \tag{22}$$

with

$$a^* = \arg\min_{a'} G^*(s_{t+1}, a'), \tag{23}$$

but we do not have access to this optimal action. If we use the update rule (18) with $\beta = 0$, we update $G(s_t, a_t)$ towards

$$c_t + \gamma \sum_{a'} \rho(a'|s_{t+1}) G(s_{t+1}, a'), \tag{24}$$

which is always at least as large as (22), creating a positive bias. If we use $\beta = \infty$, we update $G(s_t, a_t)$ towards

$$c_t + \gamma \min_{a'} G(s_{t+1}, a'), \tag{25}$$

which creates a negative bias, as explained in Section 2.2. Since the right-hand side of (18) is continuous and monotonic in β, there must be some β for which this update rule is unbiased.

This is a non-constructive proof for the existence of a β schedule that keeps the value estimators unbiased (or at least does not accumulate additional bias). We can imagine a scheduling oracle, and a protocol for the agent by which to consult the oracle and obtain the β for its soft updates. At the very least, the oracle must be told the iteration index t, but it can also be useful to let β depend on any other aspect of the learning process, particularly the current world state s_t.

4.2 PRACTICAL SCHEDULING

A good schedule should increase β as learning proceeds, because as more samples are gathered the variance of G decreases, allowing more deterministic policies. In the examples of Section 6 we adopted the linear schedule

$$\beta_t = kt, \tag{26}$$

with some constant $k > 0$. Another possibility that we explored was to make β inversely proportional to a running average of the Bellman error, which decreases as learning progresses. The results were similar to the linear schedule.

The optimal parameter k can be obtained by performing initial runs with different values of k and picking the value whose learned policy gives empirically the lower cost-to-go. Although this exploration would seem costly compared to other algorithms for which no parameter tuning is needed, these initial runs do not need to be carried for many iterations. Moreover, in many situations the agent is confronted with a class of similar domains, and tuning k in a few initial domains leads to an improved learning for the whole class. This is the case in the domain-generator example in Section 6.1.

5 RELATED WORK

The connection between domain noise or function approximation, and the statistical bias in the Q function, was first discussed in [18, 3]. An interesting modification of Q-learning to address this problem is Double-Q-learning [11, 14], which uses two estimators for the Q function to alleviate the bias. Other modifications of Q-learning that attempt to reduce or correct the bias are suggested in [12, 13].

An early approach to Q-learning in continuous noisy domains was to learn, instead of the value function, the advantage function $A(s, a) = Q(s, a) - V(s)$ [23]. The algorithm represents A and V separately, and the optimal action is determined from $A(s, a)$ as $a^*(s) = \arg\min_a A(s, a)$. In noisy environments, learning A is shown in some examples to be faster than learning Q [23, 24].

More recently, it was shown that the advantage learning algorithm is a gap-increasing operator [25]. As discussed in Section 2.2, the action gap is a central factor in the generation of bias, and increasing the gap should also help reduce the bias. In Section 6.1 we compare our algorithm to the consistent Bellman operator $\mathcal{T}_C$, one of the gap-increasing algorithms introduced in [25].

For other works that study the effect of noise in Q-learning, although without identifying the bias (7), see [26, 27, 28].

Information considerations have received attention in recent years in various machine learning settings, with the free energy F^π and similar quantities used as a design

principle for policies in known MDPs [10, 29, 30]. Other works have used related methods for reinforcement learning [31, 32, 33, 34, 35]. A KL penalty similar to ours is used in [35], in settings with known reward and transition functions, to encourage "curiosity".

Soft-greedy policies have been used before for exploration [2, 36], but to our knowledge G-learning is the first TD-learning algorithm to explicitly use soft-greedy policies in its updates.

Particularly relevant to our work is the approach studied in [32]. There the policy is iteratively improved by optimizing it in each iteration under the constraint that it only diverges slightly, in terms of KL-divergence, from the empirical distribution generated by the previous policy. In contrast, in G-learning we measure the KL-divergence from a fixed prior policy, and in each iteration allow the divergence to grow larger by increasing β. Thus the two methods follow different information-geodesics from the stochastic prior policy to more and more deterministic policies.

This distinction is best demonstrated by considering the Ψ-learning algorithm presented in [33, 34], based on the same approach as [32]. It employs the update rule

$$\Psi(s_t, a_t) \leftarrow \Psi(s_t, a_t) + \alpha_t(c_t + \gamma\bar{\Psi}(s_{t+1}) - \bar{\Psi}(s_t)), \tag{27}$$

with

$$\bar{\Psi}(s) = -\log \sum_a \rho(a|s) e^{-\Psi(s,a)}, \tag{28}$$

which is closely related to our update of G in (18).

Apart from lacking a β parameter, the most important difference is that the update of Ψ involves subtracting $\alpha_t\bar{\Psi}(s_t)$, whereas the update of G involves subtracting $\alpha_t G(s_t, a_t)$. This seemingly minor modification has a large impact on the behavior of the two algorithms. The update of G is designed to pull it towards the optimal state-action free energy G^*, for all state-action pairs. In contrast, subtracting the log-partition $\bar{\Psi}(s_t)$, in the long run pulls only $\Psi(s_t, a^*)$, with a^* the optimal action, towards its true value, while for the other actions the values grow to infinity. In this sense, the Ψ-learning update (27) is an information-theoretic gap-increasing Bellman operator [25].

The growth to infinity of suboptimal values separates them from the optimal value, and drives the algorithm to convergence. In G-learning, this parallels the increase in β with the accumulation of samples. However, there is a major benefit to keeping G reliable in all its parameters, and controlling it with a separate β parameter. In Ψ-learning, the Ψ function penalizes actions it deems suboptimal. If early noise causes an error in this penalty, the algorithm needs to unlearn it - a similar drawback to that of Q-learning. In Section 6, we demonstrate the improvement offered by G-learning.

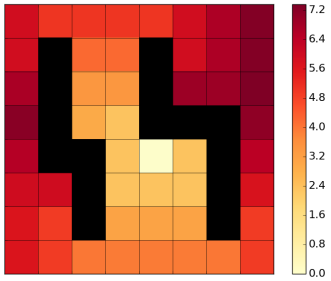

Figure 1: Gridworld domain. The agent can choose an adjacent square as the target to move to, and then may end up stochastically in a square adjacent to that target. The color scale indicates the optimal values V^* with a fixed cost of 1 per step.

6 EXAMPLES

This section illustrates how G-learning improves on existing model-free learning algorithms in several settings. The domains we use are clean and simple, to demonstrate that the advantages of G-learning are inherent to the algorithm itself.

We schedule the learning rate α_t as

$$\alpha_t = n_t(s_t, a_t)^{-\omega}, \tag{29}$$

where $n_t(s_t, a_t)$ is the number of times the pair (s_t, a_t) was visited. This scheme is widely used, and is consistent with (6) for $\omega \in (1/2, 1]$. We choose $\omega = 0.8$, which is within the range suggested in [37].

We schedule β linearly, as discussed in Section 4.2. In each case, we start with 5 preliminary runs of G-learning with various linear coefficients, and pick the coefficient with the lowest empirical cost. This coefficient is used in the subsequent test runs, whose results are plotted in Figure 2.

In all cases, we use a uniform prior policy ρ, a discount factor $\gamma = 0.95$, and 0 for the initial values ($Q_0 = 0$ in Q-learning, and similarly in the other algorithms). Except when mentioned otherwise, we employ random exploration, where s_t and a_t are chosen uniformly at the beginning of each time step, independently of any previous sample. This exploration technique is useful when comparing update rules, while controlling for the exploration process.

6.1 GRIDWORLD

Our first set of examples occurs in a gridworld of 8×8 squares, with some unavailable squares occupied by walls shown in black (Figure 1). The lightest square is the goal, and reaching it ends the episode.

At each time step, the agent can choose to move one square in any of the 8 directions (including diagonally), or stay in place. If the move is blocked by a wall or the edge of the

board, it effectively attempts to stay in place. With some probability, the action performed by the agent is further followed by an additional random slide: with probability 0.15 to each vertically or horizontally adjacent available position, and with probability 0.05 to each diagonally adjacent available position.

The noise associated with these random transitions can be enhanced further by the possible variability in the costs incurred along the way. We consider three cases. In the first case, the cost in each step is fixed at 1. In the second case, the cost in each step is distributed normally i.i.d, with mean 1 and standard deviation 2. In the third case we define a distribution over domains, such that at the time of domain-generation the mean cost for each state-action is distributed uniformly i.i.d over $[1, 3]$. Once the domain has been generated and interaction begins, the cost itself in each step is again distributed normally i.i.d, with the generated mean and standard deviation 4.

We attempt to learn these domains using various algorithms. Figure 2 summarizes the results for Q-learning, G-learning, Double-Q-learning [11], Ψ-learning [33, 34] and the consistent Bellman operator $\mathcal{T}_C$ of [25]. We also include Q$^\rho$-learning, which performs updates as in (4) towards the prior policy ρ. Comparison with Speedy-Q-learning [12] is omitted, since it showed no improvement over vanilla Q-learning in these settings. In our experiments, these algorithms had comparable running times.

The β scheduling used in G-learning is linear, with the coefficient k equal to 10^{-3}, 10^{-4}, $5 \cdot 10^{-5}$ and 10^{-6}, respectively for the fixed-cost, noisy-cost, domain-generator and cliff domains (see Section 6.2).

For each case, Figure 2 shows the evolution over 250,000 algorithm iterations of the following three measures, averaged over $N = 100$ runs:

1. Empirical bias, defined as

$$\frac{1}{Nn} \sum_{i=1}^{N} \sum_{s=1}^{n} (V_{i,t}(s) - V_i^*(s)), \tag{30}$$

   where i indexes the N runs and s the n states. Here $V_{i,t}$ is the greedy value based on the estimate obtained by each algorithm (Q, G, etc.), in iteration t of run i. The optimal value V_i^*, computed via Value Iteration, varies between runs in the domain-generator case.

2. Mean absolute error in V

$$\frac{1}{Nn} \sum_{i=1}^{N} \sum_{s=1}^{n} |V_{i,t}(s) - V_i^*(s)|. \tag{31}$$

   A low bias could result from the cancellation of terms with high positive and negative biases. A convergence in the absolute error is more indicative of the actual convergence of the value estimates.

3. Increase in cost-to-go, relative to the optimal policy

$$\frac{1}{Nn} \sum_{i=1}^{N} \sum_{s=1}^{n} (V^{\pi_{i,t}}(s) - V_i^*(s)). \tag{32}$$

   This measures the quality of the learned policy. Here $\pi_{i,t}$ is the greedy policy based on the state-action value estimates, and $V^{\pi_{i,t}}$ is its value in the model, computed via Value Iteration.

An algorithm is better when these measures reach zero faster. As is clear in Figure 2, in the domains with noisy cost (Rows 2 and 3), G-learning dominates over all the other competing algorithms by the three measures. The results are statistically significant, but plotting confidence intervals would clutter the figure.

An important and surprising point of Figure 2 is that Q$^\rho$-learning always outperforms Q-learning initially, before degrading. The reason is that the Q-learning updates initially rely on very few samples, so these harmful updates need to be undone by later updates. Q$^\rho$-learning, on the other hand, updates in the direction of a uniform prior. This gives an early advantage in mapping out the local topology of the problem, before long-range effects start pulling the learning towards the suboptimal Q^ρ.

The power of G-learning is that it enjoys the early advantage of Q$^\rho$-learning, and smoothly transitions to the convergence advantage of Q-learning. When β is small, the information cost g_t (8) outweighs the external costs c_t, and we update towards ρ. As samples keep coming in, and our estimates improve, β increases, and the updates gradually lean more towards a cost-optimizing policy. Unlike early stages in Q-learning, at this point G_t is already a good estimate, and we avoid overfitting. As mentioned above, Figure 2 shows that this effect is more manifest in noisier scenarios.

Finally, Figure 3 shows running averages of the Bellman error for the different algorithms considered. The Bellman error in G-learning is the coefficient multiplying α_t in (18),

$$\Delta G_t \equiv c_t - \frac{\gamma}{\beta} \log \left(\sum_{a'} \rho(a'|s_{t+1}) e^{-\beta G_t(s_{t+1}, a')} \right) - G_t(s_t, a). \tag{33}$$

When learning ends and $G = G^*$, the expectation of ΔG_t is zero (see (16)). Similar definitions hold for the other learning algorithms we compare with. As is clear from Figure 3, G-learning reaches zero average Bellman error faster than the competing methods, even while β is still increasing in order to make G^* converge to Q^*.

6.2 CLIFF WALKING

Cliff walking is a standard example in reinforcement learning [2], that demonstrates an advantage of on-policy algorithms such as SARSA [2, 4] and Expected-SARSA [15,

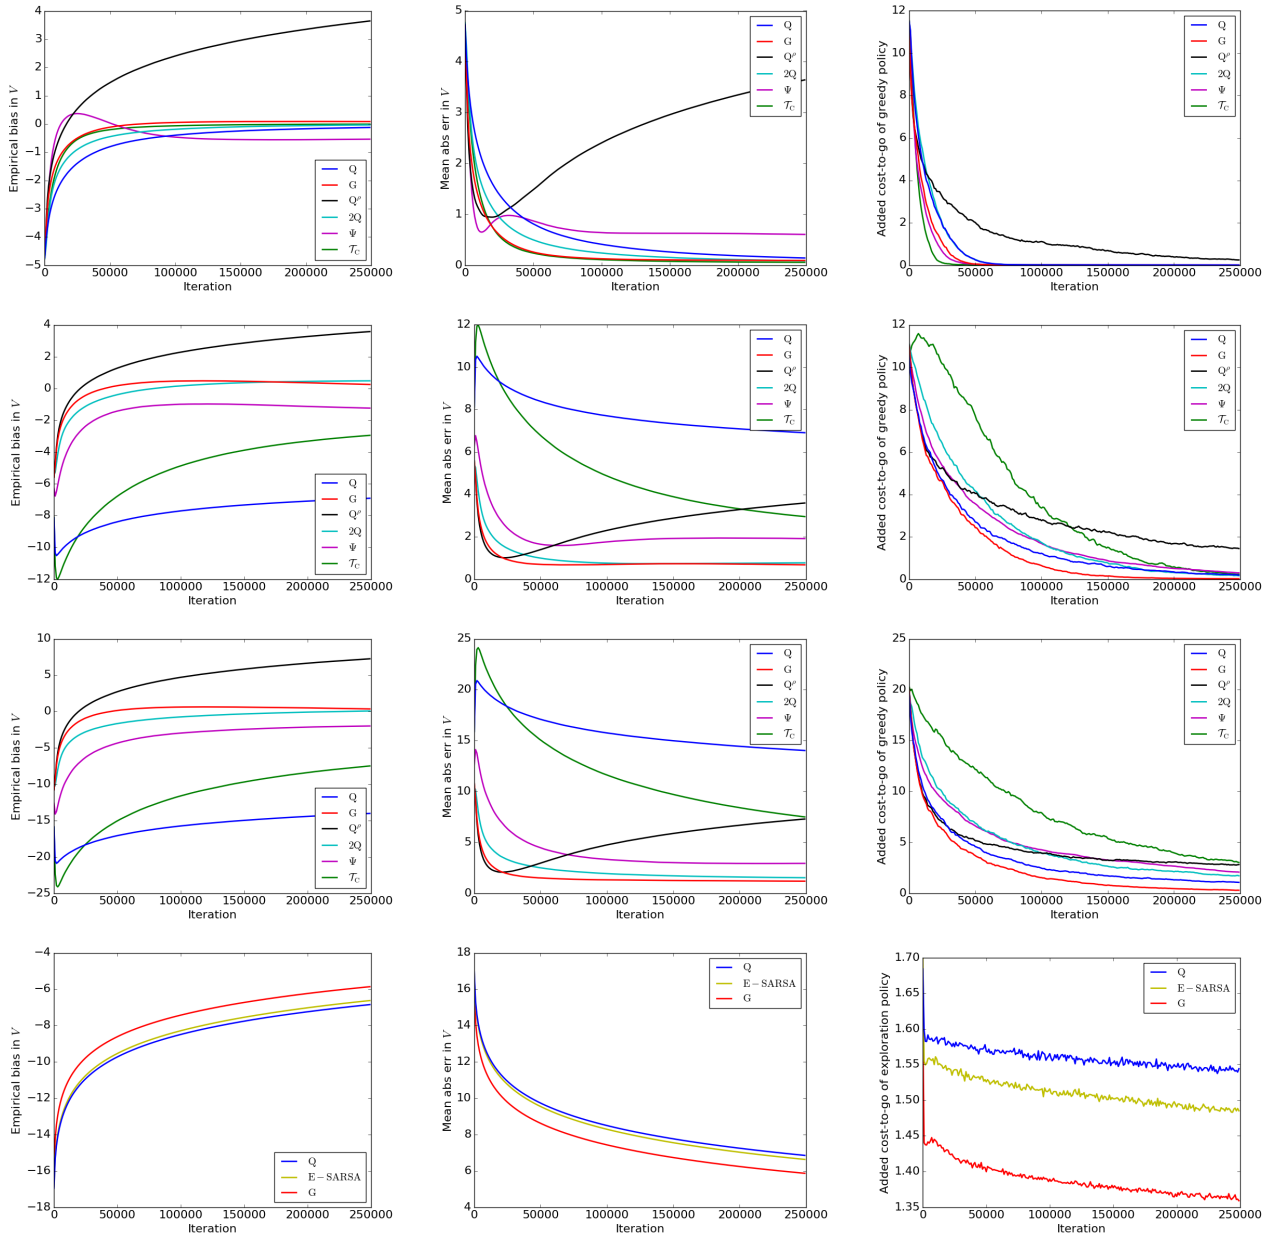

Figure 2: **Gridworld (Rows 1-3):** Comparison of Q-, G-, Q^ρ-, Double-Q-, Ψ- and $\mathcal{T}_C$-learning. **Row 1:** The cost in each step is fixed at 1. **Row 2:** The cost in each step is distributed as $\mathcal{N}(1, 2^2)$. **Row 3:** In each run, the domain is generated by drawing each $\mathrm{E}[c|s,a]$ uniformly over $[1,3]$. The cost in each step is distributed as $\mathcal{N}(\mathrm{E}[c|s,a], 4^2)$. Note that in the noisy domains (Rows 2 and 3), G-learning dominates over all the other algorithms by the three measures. **Cliff (Row 4):** Comparison of Q- and G-learning, and Expected-SARSA. The cost in each step is 1, and falling off the cliff costs 5. **Left:** Empirical bias of V, relative to V^* (30). **Middle:** Mean absolute error between V and V^* (31). **Right:** Value of greedy policy, with the baseline V^* subtracted (32); except in Row 4, which shows the value of the exploration policy.

16] over off-policy learning approaches such as Q-learning. We use it to show another interesting strength of G-learning.

In this example, the agent can walk on the grid in Figure 4 horizontally or vertically, with deterministic transitions. Each step costs 1, except when the agent walks off the cliff (the bottom row), which costs 5, or reaches the goal (lower right corner), which costs 0. In either of these cases, the position resets to the lower left corner.

Exploration is now on-line, with s_t taken from the end of the previous step. The exploration policy in our simulations is ϵ-greedy with $\epsilon = 0.1$, i.e. with probability ϵ the agent

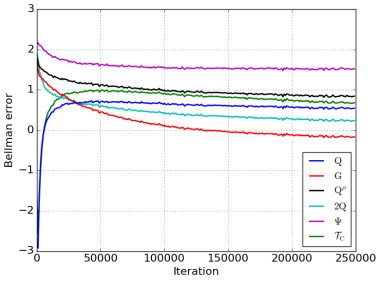

Figure 3: Running average of the Bellman error in the grid-world domain-generator example for Q-, G-, Q^ρ-, Double-Q-, Ψ- and $\mathcal{T}_C$-learning. The results for the other two grid-worlds of Figure 2 are similar.

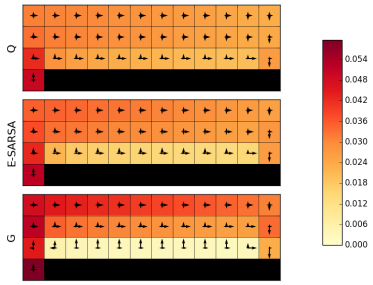

Figure 4: Cliff domain. The agent can choose a horizontally or vertically adjacent square, and moves there deterministically. The color scale and the arrow lengths indicate, respectively, the frequency of visiting each state and of making each transition, in the first 250,000 iterations of Q-learning, Expected-SARSA and G-learning. The near-greedy exploration policy of Q-learning has higher chance of taking the shortest path near the edge of the cliff at the bottom, than that of G-learning. As an off-policy algorithm, Q-learning fails to optimize for the exploration policy, whereas G-learning succeeds.

chooses a random action, and otherwise it takes deterministically the one that seems optimal. In practice, ϵ can be decreased after the learning phase, however it is also common to keep ϵ fixed for continued exploration [2].

In this setting, as shown in the bottom row of Figure 2, an off-policy algorithm like Q-learning performs poorly in terms of the value of its exploration policy, and the empirical cost it incurs. It learns a rough estimate of Q^* quickly, and then tends to use it and walk on the edge of the cliff. This leads to the agent occasionally exploring the possibility of falling off the cliff. In contrast, an on-policy algorithm like Expected-SARSA [15, 16] learns the value of its exploration policy, and quickly manages to avoid the cliff.

Figure 4 compares Q-learning, G-learning and Expected-SARSA in this domain, and shows that G-learning learns to avoid the cliff even better than an on-policy algorithm, although for a different reason. As an off-policy algorithm, G-learning does learn the value of the update policy, which prefers trajectories far from the cliff in the early stages of learning. This occurs because near the cliff, avoiding the cost of falling requires ruling out downward moves, which has a high information cost. On the other hand, trajectories far from the cliff, while paying a higher cost in overall distance to the goal, enjoy lower information cost because acting randomly is not costly for them.

As shown in the bottom row of Figure 2, by using a greedy policy for G as the basis of the ϵ-greedy exploration, we enjoy the benefits of being aware of the value of the exploration policy during the learning stage. At the same time, G-learning converges faster than either Q-learning or Expected-SARSA to the correct value function. In this case the "noise" that G-learning mitigates is related to the variability associated with the exploration.

7 CONCLUSIONS

The algorithm we have introduced successfully mitigates the slow learning problem of early stage Q-learning in noisy environments, that is caused by the bias generated by the hard optimization of the policy.

Although we have focused on Q-learning as a baseline, we believe that early-stage information penalties can also be applied to advantage in more sophisticated model-free settings, such as TD(λ), and combined with other incremental learning techniques, such as function approximation, experience replay and actor-critic methods.

G-learning takes a Frequentist approach to estimating the optimal Q function. This is in contrast to Bayesian Q-learning [38], which explicitly models the uncertainty about the Q function as a posterior distribution. It would be interesting to study the bias that hard optimization causes in the mean of this posterior, and to consider its reduction using methods similar to G-learning.

An important next step is to apply G-learning to more challenging domains, where an approximation of the G function is necessary. The simplicity of our linear β schedule (26) should facilitate such extensions, and allow G-learning to be combined with other schemes and algorithms. Further study should also address the optimal schedule for β. We leave these important questions for future work.

Abstract

The Hamiltonian Monte Carlo (HMC) method has become significantly popular in recent years. It is the state-of-the-art MCMC sampler due to its more efficient exploration to the parameter space than the standard random-walk based proposal. The key idea behind HMC is that it makes use of first-order gradient information about the target distribution. In this paper, we propose a novel dynamics using second-order geometric information about the desired distribution. The second-order information is estimated by using a quasi-Newton method (say, the BFGS method), so it does not bring heavy computational burden. Moreover, our theoretical analysis guarantees that this dynamics remains the target distribution invariant. As a result, the proposed quasi-Newton Hamiltonian Monte Carlo (QNHMC) algorithm traverses the parameter space more efficiently than the standard HMC and produces a less correlated series of samples. Finally, empirical evaluation on simulated data verifies the effectiveness and efficiency of our approach. We also conduct applications of QNHMC in Bayesian logistic regression and online Bayesian matrix factorization problems.

1 Introduction

Hamiltonian Monte Carlo (HMC) (Neal, 2011) is the state-of-the-art MCMC sampling algorithm. It defines a Hamiltonian function in terms of a potential energy—the negative logarithm of the target distribution and a kinetic energy parameterized by an auxiliary variable called momentum. By simulating from such a dynamical system, the proposal of distant states can be achieved. The attractive property of HMC is its rapid exploration to the state space. The main reason is that HMC makes use of the first-order gradient about the target distribution so that random-walk behaviors are suppressed to a great extent.

Along the idea of HMC, stochastic gradient MCMC algorithms have received great attention (Welling and Teh, 2011; Ahn, Korattikara, and Welling, 2012; Patterson and Teh, 2013; Chen, Fox, and Guestrin, 2014; Ding et al., 2014). Recently, Ma, Chen, and Fox (2015) proposed a general framework for this kind of stochastic gradient MCMC algorithms, which is built on a skew-symmetry structure. This structure represents determining traversing effect in HMC procedure and becomes one motivation of our new dynamics.

On the other hand, it is well established that the Newton or quasi-Newton methods using second-order information are more advanced than first-order gradient methods in the numerical optimization community (Nocedal and Wright, 2006). Since the Newton method is deemed to be computationally intensive, the quasi-Newton method is widely used in practice. In this paper, we explore the possibility of marrying the second-order gradient with HMC. Intuitively, a naive approach is to replace the first-order gradient in HMC with the second-order gradient about the negative logarithm of the target distribution using the quasi-Newton method. However, we will see that the resulting dynamics leads to an incorrect stationary distribution. Thus, it is challenging to incorporate second-order gradient into HMC.

Motivated by the work of Ma, Chen, and Fox (2015), we construct a skew-symmetry structure in our dynamics via adding the approximation of the inverse Hessian matrix to the standard Hamiltonian dynamics. We theoretically prove that this new dynamics keeps the target distribution invariant. Accordingly, we develop a quasi-Newton Hamiltonian Monte Carlo (QNHMC) algorithm. In QNHMC, both momentum and position variables are rescaled into a better condition using the geometric information estimated via a quasi-Newton method. Such an algorithm would produce a better proposal, take a large movement in the extended Hamiltonian dynamical system and enable a faster convergence rate to the desired distribution, which is verified by empirical results.

The remainder of the paper is organized as follows. Basic quasi-Newton and HMC methods are introduced in Section 2. We then describe our approach QNHMC in Section 3. Related studies are briefly reviewed in Section 4 while empirical results are shown in Section 5. Finally, we conclude our work in Section 6. All the proofs of theoretical results are given in Appendix.

2 Background

In this section we describe backgrounds on both quasi-Newton Approximation and Hamiltonian Monte Carlo.

2.1 Quasi-Newton Approximation

It is well-known that the Hessian matrix describes second-order curvature of the objective function $f\colon \mathbb{R}^d \to \mathbb{R}$. The time complexity and space complexity for exactly computing the Hessian matrix are both $O(d^2)$, which is computationally prohibitive for high-dimensional problems. Alternatively, quasi-Newton methods, including the BFGS method and its variant limited-memory BFGS(L-BFGS), are widely used (Nocedal and Wright, 2006).

In particular, let $\boldsymbol{\theta} \in \mathbb{R}^d$ be the parameter that needs to be estimated. Given the previous m estimates $\{\boldsymbol{\theta}_{k-m+1}, \boldsymbol{\theta}_{k-m+2}, \ldots, \boldsymbol{\theta}_k\}$ of $\boldsymbol{\theta}$ and the k-th estimate $\mathbf{B}_k$ of the inverse Hessian matrix, the BFGS updates $\mathbf{B}_{k+1}$ in the following way:

$$\mathbf{B}_{k+1} = (\mathbf{I} - \frac{\mathbf{s}_k \mathbf{y}_k^T}{\mathbf{y}_k^T \mathbf{s}_k})\mathbf{B}_k(\mathbf{I} - \frac{\mathbf{y}_k \mathbf{s}_k^T}{\mathbf{y}_k^T \mathbf{s}_k}) + \frac{\mathbf{s}_k \mathbf{s}_k^T}{\mathbf{s}_k^T \mathbf{y}_k}, \quad (1)$$

where $\mathbf{I}$ is the identity matrix, $\mathbf{s}_k = \boldsymbol{\theta}_{k+1} - \boldsymbol{\theta}_k$, and $\mathbf{y}_k = \nabla f(\boldsymbol{\theta}_{k+1}) - \nabla f(\boldsymbol{\theta}_k)$. It is implemented by storing the full $d \times d$ matrix $\mathbf{B}_k$. However, in the high-dimensional scenario (i.e., d is very large), the limited-memory BFGS is much more efficient. Specifically, in L-BFGS, $\mathbf{B}_{k-m+1}$ is set as $\gamma\mathbf{I}$ for some $\gamma > 0$, and $\{\mathbf{s}_{k-m+1}, \ldots, \mathbf{s}_{k-1}\}$ and $\{\mathbf{y}_{k-m+1}, \ldots, \mathbf{y}_{k-1}\}$ are stored. The involved matrix-vector product can be computed in linear time $O(md)$ by using a specially-designed recursive algorithm (Nocedal and Wright, 2006).

2.2 Hamiltonian Monte Carlo

We now briefly review the Hamiltonian Monte Carlo (Neal, 2011). HMC lies in Metropolis-Hastings (MH) framework. It can traverse long distances in the parameter space during a single transition. The proposals are generated from a Hamiltonian system by extending the state space via adding an auxiliary variable called momentum variable, and then simulating Hamiltonian dynamics to move long distances along the iso-probability contours in the extended parameter space.

Formally, suppose that $\boldsymbol{\theta} \in \mathbb{R}^d$ is the parameter of interest and $\pi(\boldsymbol{\theta})$ is the desired posterior distribution. Let $\mathbf{p}$ be the auxiliary variable which is independent of $\boldsymbol{\theta}$. For simplicity and generality, $\mathbf{p} \in \mathbb{R}^d$ is always assumed to be a zero-mean Gaussian with covariance $\mathbf{M}$.

Then a Hamiltonian is defined as the negative log-probability of the joint distribution $p(\boldsymbol{\theta}, \mathbf{p})$ as follows:

$$\begin{aligned} H(\boldsymbol{\theta}, \mathbf{p}) &= -\log p(\boldsymbol{\theta}, \mathbf{p}) \\ &= -\log \pi(\boldsymbol{\theta}) - \log p(\mathbf{p}) \\ &= U(\boldsymbol{\theta}) + \frac{1}{2}\mathbf{p}^T \mathbf{M}^{-1} \mathbf{p} + \text{const}, \end{aligned} \quad (2)$$

where $U(\boldsymbol{\theta}) = -\log \pi(\boldsymbol{\theta})$ is called the potential function. In the Hamiltonian system $\mathbf{M}$ is called a preconditioning mass matrix, $\boldsymbol{\theta}$ is regarded as a position variable, and $\mathbf{p}$ is called a momentum variable.

Given an initial state $(\boldsymbol{\theta}_0, \mathbf{p}_0)$, the state $(\boldsymbol{\theta}, \mathbf{p})$ is generated by deterministic simulation of Hamiltonian dynamics based on the following ordinary differential equation (ODE):

$$\begin{aligned} \dot{\boldsymbol{\theta}} &= \mathbf{M}^{-1}\mathbf{p}, \\ \dot{\mathbf{p}} &= -\nabla U(\boldsymbol{\theta}), \end{aligned} \quad (3)$$

where the dots denote the derivatives in time. In this paper we will also use $\mathbf{z} = (\boldsymbol{\theta}, \mathbf{p}) \in \mathbb{R}^{2d}$ to denote the joint variable of the position and momentum variables.

The trajectories of $\boldsymbol{\theta}$ and $\mathbf{p}$ produce proposals to the Metropolis-Hastings procedure. In particular, given the k-th estimate of the position variable $\boldsymbol{\theta}_k$, the standard HMC runs in the following steps: (i) draw $\mathbf{p}_k \sim \mathcal{N}(\mathbf{0}, \mathbf{M})$; (ii) compute the proposal$(\boldsymbol{\theta}^\star, \mathbf{p}^\star)$ by simulation from Eq. (3) using ϵ-discretization; (iii) compute the error caused by discretization $\nabla H = H(\boldsymbol{\theta}_k, \mathbf{p}_k) - H(\boldsymbol{\theta}^\star, \mathbf{p}^\star)$; (iv) accept new proposal $\boldsymbol{\theta}^\star$ with probability at $\min(\exp(\nabla H), 1)$.

It is worth mentioning that the error is only caused from the discretization and highly related to the step size ϵ. If the discretization error vanishes, that is to say, Eq. (3) is solved exactly, then Hamiltonian $H(\boldsymbol{\theta}, \mathbf{p})$ is conserved exactly and new proposal is always accepted. The details of HMC can be found in Neal (2011).

In practice, the mainstream integrator is the well-known leapfrog method in Algorithm 1, which is symplectic and time-reversible. The error is second-order in the step size ϵ, keeping acceptance rate a reasonable value. However, when the ODE described in Eq. (2) is stiff, the step size ϵ is required to be small to maintain a reasonable acceptance rate. This will cause the high-correlated series and reduce the effective sample size. A main reason is that only first-order gradient is not enough. That is, HMC fails to make sufficient use of the local geometric information, as shown by Girolami and Calderhead (2011); Zhang and Sut-

Algorithm 1 Standard Hamiltonian Monte Carlo(HMC)

Input: target posterior distribution $\pi(\boldsymbol{\theta})$ and potential function $U(\boldsymbol{\theta}) = -\log \pi(\boldsymbol{\theta})$, step size ϵ, number of leapfrog L, total number of sample N, burn-in samples K, start point $\boldsymbol{\theta}_0$, mass matrix $\mathbf{M}$

Output: $\{\boldsymbol{\theta}_{K+1}, \boldsymbol{\theta}_{K+2}, \ldots, \boldsymbol{\theta}_N\}$

Iteration counter $t = 1$.
while $t < N$ **do**
  Let $\mathbf{q} = \boldsymbol{\theta}_t$.

    end if
  end for
  Last half step: $\mathbf{p} = \mathbf{p} - \epsilon \nabla U(\mathbf{q})/2$
  Compute the proposed energy E_1 using Eq. (2).
  Draw $u \sim \text{Uniform}(0, 1)$
  if $u < \min\{1, \exp(E_1 - E_0)\}$ **then**
    Accept the proposal $\mathbf{q}$, i.e., $\boldsymbol{\theta}_{t+1} = \mathbf{q}$.
  else
    Reject, $\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t$.
  end if
  $t = t + 1$.
end while

ton (2011). We also demonstrate this problem empirically in Section 5.

3 Methodology

In this section, we first discuss the condition for variants of Hamiltonian dynamics to reach the correct stationary distribution and then propose a novel dynamics satisfying the condition. Accordingly, we develop a quasi-Newton Hamiltonian Monte Carlo (QNHMC) algorithm.

3.1 A Naive Replacement

Intuitively, the most straightforward approach to apply the quasi-Newton method on Hamiltonian Monte Carlo is simply to replace $\nabla U(\boldsymbol{\theta})$ in Algorithm 1 by $\mathbf{B}\nabla U(\boldsymbol{\theta})$, where $\mathbf{B}$ is the approximation to the inverse Hessian matrix. The resulting discrete time system can be viewed as an ϵ-discretization of the following continuous ODE:

$$\begin{aligned} \dot{\boldsymbol{\theta}} &= \mathbf{M}^{-1}\mathbf{p}, \\ \dot{\mathbf{p}} &= -\mathbf{B}(t)\nabla U(\boldsymbol{\theta}), \end{aligned} \tag{4}$$

where $\mathbf{B}(t) \in \mathbb{R}^{d\times d}$ is positive definite and varies with time t. For simplicity, we always ignore the time t and assume that $\mathbf{B}$ is not the identity matrix, i.e., $\mathbf{B} = \mathbf{B}(t) \neq \mathbf{I}$. Now we show that, as given by Corollary 1 below, $p(\boldsymbol{\theta}, \mathbf{p}) \propto \exp(-H(\boldsymbol{\theta}, \mathbf{p}))$ is no longer the stationary distribution of the dynamics described in Eq. (4). The following theorem shows a stronger result, a necessary condition for the invariance property, i.e., the dynamics governed by Eq. (4) can not conserve the entropy of p_t with time.

Theorem 1. *Let $p_t(\boldsymbol{\theta}, \mathbf{p})$ be the distribution of $(\boldsymbol{\theta}, \mathbf{p})$ at time t with dynamics described in Eq.* (4)*. Define the entropy of $p_t(\boldsymbol{\theta}, \mathbf{p})$ as $h(p_t) = -\int_{\boldsymbol{\theta},\mathbf{p}} f(p_t(\boldsymbol{\theta}, \mathbf{p}))d\boldsymbol{\theta}d\mathbf{p}$, where $f(x) = x \ln x$ is defined for measuring entropy. Assume p_t is a distribution with density and gradient vanishing at infinity and the gradient vanishes faster than $\frac{1}{\ln p_t}$. Then, the entropy of p_t varies over time.*

Intuitively, Theorem 1 is true because the standard Hamiltonian dynamics strictly preserve the entropy (Qian, 2012). The additional $\mathbf{B}$ can be seen as a noise, destroying the entropy preservation. This hints the fact that the distribution $p_t(z)$ tends toward far from the target distribution.

Based on Theorem 1, we conclude that the naive modification to Hamiltonian dynamics can not keep the target distribution invariant. That is,

Corollary 1. *The distribution of extended system $p(\boldsymbol{\theta}, \mathbf{p}) \propto exp(-H(\boldsymbol{\theta}, \mathbf{p}))$ is no longer invariant under the dynamics described by Eq.* (4)*.*

This corollary claims the failure of dynamics governed by Eq. (4). In what follows, we will consider a general framework which builds the necessary and sufficient condition for variants of Hamiltonian dynamics to satisfy the invariance of the target distribution. Accordingly, this leads us to a new dynamics.

3.2 Motivation: A general recipe

In this section, we introduce a general framework for stochastic gradient MCMC algorithms proposed recently by Ma, Chen, and Fox (2015). It provides the sufficient and necessary condition for Hamiltonian systems to reach the invariant distribution.

Consider the following Stochastic Differential Equation (SDE) for continuous Markov processes for sampling:

$$d\mathbf{z} = f(\mathbf{z})dt + \sqrt{2D(\mathbf{z})}dW(t), \tag{5}$$

where $f(\cdot) : \mathbb{R}^{2d} \to \mathbb{R}^{2d}$ denotes the deterministic drift and is often related to the gradients of Hamiltonian $\nabla H(\mathbf{z})$, $W(t)$ is a $2d$-dimensional Wiener process, and $D(\mathbf{z}) \in \mathbb{R}^{2d\times 2d}$ is a positive semi-definite diffusion matrix. Obviously, not all choices of $f(\mathbf{z})$ and $D(\mathbf{z})$ can yield the stationary distribution $p(\boldsymbol{\theta}, \mathbf{q}) = p(\mathbf{z}) \propto \exp(-H(\mathbf{z}))$.

Ma, Chen, and Fox (2015) devised a recipe for constructing SDEs with the correct stationary distributions. They

defined $f(\mathbf{z})$ directly in terms of the target distribution:

$$f(\mathbf{z}) = -[D(\mathbf{z}) + Q(\mathbf{z})]\nabla H(\mathbf{z}) + \Xi(\mathbf{z}),$$
$$\Xi_i(\mathbf{z}) = \sum_{j=1}^{d} \frac{\partial}{\partial \mathbf{z}_j}(D_{ij}(\mathbf{z}) + Q_{ij}(\mathbf{z})). \tag{6}$$

Here $\Xi_i(\cdot)$ is the i-th entry of the vector-valued function $\Xi(\cdot) : \mathbb{R}^{2d} \to \mathbb{R}^{2d}$, and $Q(\mathbf{z}) \in \mathbb{R}^{2d\times 2d}$ is a skew-symmetric curl matrix representing the determining traversing effects seen in the HMC procedure. It was proved that under certain conditions $p(\mathbf{z})$ is the unique stationary distribution of the dynamics governed by Eq. (5) (Ma, Chen, and Fox, 2015).

Theorem 2. *$p(\mathbf{z}) \propto \exp(-H(\mathbf{z}))$ is a stationary distribution of the dynamics described in Eq.* (5) *if f is restricted to the form of Eq.* (6)*, with $D(\mathbf{z})$ positive semidefinite and $Q(\mathbf{z})$ skew-symmetric.*

Since in this paper we restrict our attention to the deterministic dynamics, we can omit the term related to diffusion part $D(\mathbf{z})$. In this case, the SDE is reduced to an ODE. The skew-symmetry of $Q(\mathbf{z})$ inspires us to add $\mathbf{B}$ into update of the position variable $\boldsymbol{\theta}$ in the dynamics in Eq. (4).

In the next section we will consider skew-symmetric modification to the Hamiltonian dynamics that achieves the desired $p(\boldsymbol{\theta}, \mathbf{p})$ as the invariant distribution of the continuous Hamiltonian dynamical system.

3.3 Novel Dynamics in skew-symmetric structure

In this section, inspired by the skew-symmetric structure, we consider a variant on Hamiltonian dynamics as follows:

$$\dot{\boldsymbol{\theta}} = \mathbf{C}\mathbf{M}^{-1}\mathbf{p},$$
$$\dot{\mathbf{p}} = -\mathbf{C}\nabla U(\boldsymbol{\theta}), \tag{7}$$

where $\mathbf{C} \in \mathbb{R}^{d\times d}$ is a symmetric positive definite matrix, independent of $\boldsymbol{\theta}$ and $\mathbf{p}$.

Now we show that the new dynamics maintains the desired distribution as the invariant distribution.

Theorem 3. *$p(\boldsymbol{\theta}, \mathbf{p}) \propto exp(-H(\boldsymbol{\theta}, \mathbf{p}))$ is the unique stationary distribution of the dynamics governed by Eq.* (7)*.*

Then it is easy to prove the entropy preservation of proposed dynamics directly using the intermediate results in Theorem 3.

Corollary 2. *Let $p_t(\boldsymbol{\theta}, \mathbf{p})$ be the distribution of $(\boldsymbol{\theta}, \mathbf{p})$ at time t with dynamics described in Eq.* (7)*. Under almost the same condition with Theorem 1, i.e., the entropy of $p_t(\boldsymbol{\theta}, \mathbf{p})$ is defined as $h(p_t) = -\int_{\boldsymbol{\theta},\mathbf{p}} f(p_t(\boldsymbol{\theta}, \mathbf{p}))d\theta d\mathbf{p}$, where $f(x) = x \ln x$. Assume p_t is an arbitrary distribution with density and gradient vanishing at infinity. Then, the entropy of p_t is strictly conserved with time.*

Algorithm 2 Quasi-Newton HMC (QNHMC)

Input: target distribution $\pi(\boldsymbol{\theta})$ and potential function $U(\boldsymbol{\theta}) = -\log \pi(\boldsymbol{\theta})$, step size ϵ, number of Leapfrog L, total number of sample N, burn-in samples K, start point $\boldsymbol{\theta}_0$, mass matrix $\mathbf{M}$, approximation of Hessian Matrix $\mathbf{B} = \mathbf{I}$.
Output: $\boldsymbol{\theta}_{K+1}, \boldsymbol{\theta}_{K+2}, \cdots, \boldsymbol{\theta}_N$.

1: Iteration counter $t = 1$.
2: **while** $t < N$ **do**
3: Let $\mathbf{q} = \boldsymbol{\theta}_t$ and $\mathbf{C} = \mathbf{B}$.
4: Draw $\mathbf{p} \sim \mathcal{N}(\mathbf{0}, \mathbf{M})$.
5: Compute the current energy E_0 using Eq. (2).
6: First half step: $\mathbf{p} = \mathbf{p} - \epsilon\mathbf{C}\nabla U(\mathbf{q})/2$.
7: Update $\mathbf{B}$ using Eq. (1).
8: **for** $i = 1 : L$ **do**
9: $\mathbf{q} = \mathbf{q} + \epsilon\mathbf{C}\mathbf{M}^{-1}p$.
10: **if** $i \neq L$ **then**
11: $\mathbf{p} = \mathbf{p} - \epsilon\mathbf{C}\nabla U(\mathbf{q})$.
12: Update $\mathbf{B}$ using Eq. (1).
13: **end if**
14: **end for**
15: Last half step: $\mathbf{p} = \mathbf{p} - \epsilon\mathbf{C}\nabla U(\mathbf{q})/2$
16: Update $\mathbf{B}$ using Eq. (1).
17: Compute the proposed energy E_1 using Eq. (2).
18: Draw $u \sim$ Uniform$(0, 1)$.
19: **if** $u < \min\{1, \exp(E_1 - E_0)\}$ **then**
20: Accept the proposal $\mathbf{q}$, i.e., $\boldsymbol{\theta}_{t+1} = \mathbf{q}$.
21: **else**
22: Reject, $\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t$. $\mathbf{B} = \mathbf{C}$.
23: **end if**
24: $t = t + 1$.
25: **end while**

In summary, we have shown that the dynamics given by Eq. (7) owns the invariance property. Furthermore, it is concise. When $\mathbf{C} = \mathbf{I}$, it reduces to Hamiltonian dynamics.

3.4 Quasi-Newton Hamiltonian Monte Carlo

In the previous section we mainly focus on the invariance property of the proposed dynamics given in Eq. (7), which in essence is a continuous ODE. However, in practice, we need a numerical solution to the continuous ODE in Eq. (7). Here, the discretization step employ leapfrog methods, inheriting from the standard HMC (Neal, 2011). In particular, the resulting Quasi-Newton Hamiltonian Monte Carlo (**QNHMC**) algorithm is shown in Algorithm 2.

It is worth noting that in Algorithm 2 the approximation $\mathbf{B}$ varies with iteration counter. In contrast, to keep the invariance property of the dynamics in Eq. (7), in each proposal (Step 3-15), $\mathbf{B}$ is kept as a constant $\mathbf{C}$. The update to $\mathbf{B}$ is only done when the proposal procedure ends and the proposal is accepted. The following theorem shows the correctness of Algorithm 2.

Theorem 4. *$\pi(\boldsymbol{\theta})$ is maintained as an invariant distribution for the whole chain produced by Algorithm 2.*

To gain some intuitions about the proposed QNHMC algorithm in physical interpretation, consider the well-known hockey puck instance widely used in the Hamiltonian dynamical system (Leimkuhler and Reich, 2004), where we can imagine the puck on an uneven surface. Here, $\mathbf{B}$ represents the approximation to the local geometric information. In HMC, when the local geometry is stiff, movements controlled by momentum $\mathbf{p}$ are always useless. By multiplying the matrix $\mathbf{B}$ ($\mathbf{C}$), the momentum variable and position variable are rescaled into the case where each dimension has a similar scale. This makes the movement in the extended Hamiltonian system more efficient. Empirically, it can traverse a large step in the state space. In the Bayesian scenario, this new dynamics produces a better proposal and less-autocorrelated series.

3.5 Computational Complexity

Two strategies (BFGS/L-BFGS) are used in estimating the matrix $\mathbf{B}$ according to the dimension of the parameter. When the dimension of the parameter d is high, the L-BFGS is adopted. In this case, $O(md)$ space complexity is needed. Moreover, since only matrix-vector product is required, the product $\mathbf{Bv}$ ($\mathbf{Cv}$) can be computed in linear time $O(md)$. It is worth noting that unlike in Algorithm 2, no need to update $\mathbf{B}$ in each leapfrog step when adopting L-BFGS. Instead, we choose to store $2m$ d-dimensional vectors as mentioned in Section 2. Only when the proposal is accepted, it is required to update $\mathbf{B}$.

On the other hand, when d is not high, BFGS is chosen. A $d \times d$ matrix needs to be stored so the complexity is $O(d^2)$. Each updating step requires $O(d)$ time without matrix-vector or matrix-matrix product.

In this paper, we mainly compare our QNHMC approach with the standard HMC (Neal, 2011). The gradient computation of the negative log-posterior $\nabla U(\boldsymbol{\theta})$ has already been done in the standard HMC in each leapfrog step. And, in practice, the gradient computation always contains expensive computations such as matrix-matrix/matrix-vector product. The size of matrix depends on both the dimension of the parameter and the number of the training instances. Our QNHMC algorithm can make use of the byproduct of leapfrog step, e.g., $\mathbf{s}_k$ and $\mathbf{y}_k$ in Eq. (1). Thus, the gradient computation is always dominant in computational time, which means that HMC and QNHMC cost the same order of magnitude running time in each proposal. Considering the larger step that QNHMC takes owing to more sufficient use of geometric information, QNHMC converges to the desired distribution faster than the standard HMC, which will be further validated by our empirical results.

4 Related Studies

In recent years, many approaches have been proposed to scale up Bayesian methods in machine learning community. As is well-known, gradient information of log-posterior distribution is widely used in Langevin/Hamiltonian dynamics. Among these methods, one large category is stochastic gradient Markov Chain Monte Carlo methods. The framework is to estimate the gradient from small mini-batches of observations instead of the whole dataset to cut the computational budget. The landmark of this kind of approaches is proposed by Welling and Teh (2011), which applied stochastic gradient on Langevin dynamics. Subsequently, a series of algorithms are developed to complete this framework (Ahn, Korattikara, and Welling, 2012; Patterson and Teh, 2013; Ahn, Shahbaba, and Welling, 2014; Chen, Fox, and Guestrin, 2014; Ding et al., 2014; Ma, Chen, and Fox, 2015). For instance, Chen, Fox, and Guestrin (2014) adapted stochastic gradient on Hamiltonian Monte Carlo (SGHMC) while Ding et al. (2014) devised a SGNHT algorithm by introducing a thermostat variable to make SGHMC more robust. Ma, Chen, and Fox (2015) developed a complete recipe for all stochastic gradient based MCMC approaches. There are some recent works (Bardenet, Doucet, and Holmes, 2014; Korattikara, Chen, and Welling, 2013; Maclaurin and Adams, 2015), attempting to perform Metropolis-Hastings rejection procedure using partial observations instead of whole dataset. These approaches mainly accelerate sampling procedure via a stochastic method applied on likelihood of data observations.

Another class of methods aim at sampler itself (Girolami and Calderhead, 2011; Zhang and Sutton, 2011; Calderhead and Sustik, 2012; Patterson and Teh, 2013; Wang, Mohamed, and Nando, 2013; Chao et al., 2015). Most of them are closely related to geometry. Concretely, they aim at finding the local geometric structure of posterior so that the random-walk behaviour in proposal can be significantly suppressed. Such algorithms allow a larger step size without loss of acceptance rate and make the sampling efficient. The representative work is Riemann Manifold Hamiltonian Monte Carlo proposed by Girolami and Calderhead (2011), which employed the high-order of geometric information about the local point. Chao et al. (2015) proposed an exponential integration to solve the high-oscillatory component of posterior more accurately than the integration used in the standard HMC method.

It is worth noting that Zhang and Sutton (2011) also proposed a quasi-Newton based Hamiltonian Monte Carlo method called HMC-BFGS. Different from our QNHMC, HMC-BFGS uses the geometric information in covariance of zero-mean proposal. In contrast, our QNHMC makes use of second-order information in scaling both momentum and position variables. Furthermore, HMC-BFGS devises

an extended chain. The specially-designed structure may sacrifice the convergence rate and leads to a poor estimate of Hessian, validated by our empirical evaluations.

5 Empirical Evaluation

In this section, we empirically analyze the quasi-Newton HMC. We mainly compare our quasi-Newton HMC (QNHMC) with the standard HMC (Neal, 2011) and HMC-BFGS (Zhang and Sutton, 2011) in both efficiency and effectiveness. In all cases, QNHMC outperforms HMC and HMC-BFGS under the same settings of hyperparameters in both burn-in time and effective sample size.

5.1 Simulated data

First, we evaluate the scalability of our model on a high-dimensional zero-mean Gaussian distribution. The target distribution is high-dimensional Gaussian distribution $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$. The covariance matrix is $\mathbf{\Sigma} = \mathbf{1}\mathbf{1}^T + 4\mathbf{I} \in \mathbb{R}^{d\times d}$, where $\mathbf{1}$ and $\mathbf{0}$ are the all-1 and all-0 vectors of d-dimension, respectively. This d-dimensional distribution is highly correlated in one direction. Hence, it is a challenging task for random-walk based sampler, such as MCMC.

The main evaluating metrics are as follows:

- Autocorrelation. Since the desired distribution is highly correlated, when computing the autocorrelation of samples, the samples are projected onto the direction of its largest eigenvalue ($\mathbf{x} = \mathbf{1}$). And the max number of lag m is set to 500. ρ_k is the autocorrelation at lag k.

- Effective sample size (ESS) is the common measurement, which summaries the amount of autocorrelation across different lags over all dimensions. ESS is formally defined as follows

$$\text{ESS} = \frac{n}{1 + 2\sum_{k=1}^{m} \rho_k},$$

  where n is the original sample size, m is the maximal number of lag and determined empirically. In this scenario, $m = 500$. Notice that ESS per second is also a metric to measure the efficiency of sampler.

- Convergence diagnostics. To compare the convergence rate fairly, we choose the starting position far away from the mode of the target distribution. Notice that the starting positions are same for all the samplers. Thus the chain should be run long enough to "forget" the starting position. This is the so-called burn-in period. Determining the length of burn-in period is critical. In this paper, we choose to monitor the probability of the samples, a mainstream method in convergence diagnostics (Gilks, Richardson, and Spiegelhalter, 1996). In particular, by observing the negative log-probability of samples $\mathbf{x}$ (i.e., $(\mathbf{x}-\mu)^T\mathbf{\Sigma}(\mathbf{x}-\mu)$, ignoring the normalizing constant), we can easily find that how long steps the chain takes to reach the highest posterior density (HPD) region and ends the burn-in period.

In this experiment, for fair comparison among these three methods, we adopt the same setting of the hyperparameters involved. In particular, we use the step size $\epsilon = 0.01$ and the number of leaps $L = 10$, the dimension of the problem $d = 100$. We draw 100K samples for each sampler. For HMC-BFGS, we need to choose an ensemble of K chains. If K is too large, there will be numerical unstability about the BFGS methods and the performance will degrade drastically. Here, K is chosen to be 5, following the setting of Zhang and Sutton (2011). The starting positions for these methods are the same, a randomly-generated point distant from the HPD region.

As illustrated in Figure 1, the chain of QNHMC only requires hundreds of samplings to end the burn-in period and reach the HPD region while the rest two algorithms need far more samplings. Hence, one advantage of QNHMC is that it can converge to the HDP region quicker than the other two algorithms.

Though QNHMC only requires hundreds of burn-in samples here, for fair comparison, when computing ESS and autocorrelation, we only use the last 50K samples for all the methods. The results are shown in Table 1. We observe that QNHMC can not only produce more "independent" series than the other methods, but also obtain the most effective sample size among the three methods under the same setting and draw samples from the desired distribution most efficiently.

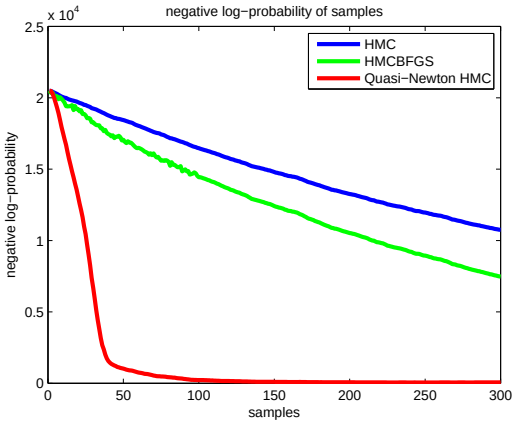

Figure 1: Performance of different samplers on simulated data: monitoring the convergence to HPD: negative log-probability of samples ($(\mathbf{x} - \mu)^T\mathbf{\Sigma}(\mathbf{x} - \mu)$) v.s. iteration

Table 1: Performance of different samplers on artificial data, as measured by sum of autocorrelation coefficient, burn-in time, Effective Sampler Size(ESS) and ESS per second. For the first two metric, lower is better while for the other two metric, higher is better.

Method	$\sum_{k=1}^{m} \lvert\rho_k\rvert$	burn-in time(second)	ESS	ESS per second
HMC	98.27	81	253	7.22
HMC-BFGS	49.74	47	497	9.65
QN-HMC	2.65	0.93	7936	93.36

Table 2: Performance of different methods on Bayesian Logistic Regression, as measured by sum of autocorrelation coefficient, burn-in time(in seconds) for sampling based methods, Effective Sampler Size(ESS) and ESS per second. GD is the abbreviation for gradient descent.

Method	burn-in time	ESS per second	Error
HMC	64	0.286	0.0493
HMC-BFGS	36	0.418	0.0501
QN-HMC	17	1.30	0.0496
GD	–	–	0.0578

5.2 Bayesian Logistic Regression

Next, we evaluate our method on a well-known handwritten digits classification task using the MNIST dataset[1]. In this task, we aim at discriminate digits "7" and "9". The number of training instances are 6265 and 5949 for "7" and "9", respectively while the number of test instances are 1028 and 1009 for "7" and "9", respectively.

We test four methods: gradient descent (GD), HMC, HMCBFGS and our QNHMC. For GD, we employ an ℓ_2 regularizer trial several time to choose the near-optimal hyperparameter. And in each iteration, we use all the training instances. For the sampling-based approaches, we take a fully Bayesian approach and place a weakly informative Gaussian prior on the weight, following Zhang and Sutton (2011); Girolami and Calderhead (2011).

The results for the sampling methods are shown in Table 2. The result with GD is provided as a baseline. We set the number of leapfrog L to 5 for all sampling based approaches. The step size ϵ is set to 0.1. Dimension $d = 784$ here, and L-BFGS method are used, where m is set to be 7. We can see that the Bayesian approaches are superior to the optimization based methods. Among the Bayesian approaches, QNHMC requires less burn-in time than the others and converges to a low test error faster. This shows its advantage over the other two HMC-related methods.

[1]http://yann.lecun.com/exdb/mnist/

5.3 Online Bayesian Matrix Factorization

Collaborative filtering is a popular theme. The target is to predict users' preference over a set of items, e.g., movies, music and produce recommendation. Owing to the sparsity in the ratings matrix (users versus items) in recommendation systems, over-fitting is a severe issue. Hence Bayesian approaches provide a natural solution. The most famous Bayesian algorithm for collaborative filtering is the online probabilistic matrix factorization proposed in Salakhutdinov and Mnih (2008).

In the experiment, the Root-Mean-Square Error (RMSE) is used to evaluate the performance of the three algorithms. It is defined as

$$\text{RMSE} = \|P_{\Omega_{\text{test}}}(\mathbf{X}) - P_{\Omega_{\text{test}}}(\mathbf{T})\|_F, \tag{8}$$

where Ω_{test} represents the index of all testing entries and $|\Omega_{test}|$ is the cardinality of Ω_{test}, and $\mathbf{X}$ is the solution from the algorithms and $P_{\Omega_{\text{test}}}(\mathbf{T})$ is corresponding partially observed labels, $\|\mathbf{X}\|_F$ represents the Frobenius norm of the matrix $\mathbf{X}$. $P_\Omega(\mathbf{X})$ represent the entry-wise projection of $\mathbf{X}$ onto Ω, defined by:

$$\{P_\Omega(\mathbf{X})\}_{ij} = \begin{cases} \mathbf{X}_{ij}, & (i,j) \in \Omega \\ 0, & \text{otherwise.} \end{cases}$$

We conduct the experiment in online Bayesian PMF on the Movielens-1M datasets[2]. The dataset contains about 1 million ratings of 3,952 movies by 6,040 users. The number of latent dimensions is set to 10. Other settings follow from the demo code given by Salakhutdinov and Mnih (2008). For HMC-related methods, step size ϵ is set to 0.01, length of leapfrog $L = 10$.

Performances of the different methods are shown in Table 3. The sampling-based methods (standard HMC, QNHMC and HMC-BFGS) provide better prediction results than the optimization-based methods (MAP), showing an advantage of Bayesian inference in this scenario, thus validating the need for scalable and efficient Bayesian algorithm such as QNHMC. In this experiment, prediction results for QNHMC, HMC and HMCBFGS are comparable. This experiment shows that QNHMC converges faster than the

[2]http://grouplens.org/datasets/movielens/

Table 3: Performance of different methods on Online Bayesian Matrix Factorization in terms of RMSE and running time. For RMSE, lower is better.

Method	RMSE	Running time(second)
MAP	0.8701	27.67
HMC	0.8607	202.5
QNHMC	0.8628	108.34
HMC-BFGS	0.8618	179.23

other two HMC-related approaches and can be seen as an effective choice for online Bayesian PMF.

6 Conclusion

In this paper we have proposed a novel quasi-Newton Hamiltonian Monte Carlo (QNHMC) algorithm to accelerate the Hamiltonian Monte Carlo sampler. Our theoretical analysis has guaranteed that the desired distribution is the unique stationary distribution under the proposed dynamics. The empirical results have verified the efficiency and effectiveness of our QNHMC on both simulated and practical datasets. A natural next step is to explore marrying stochastic gradient with QNHMC. More broadly, we believe that the unification of efficient optimization and sampling techniques, such as those described herein, will enable a significant scaling of Bayesian approaches.

Appendix

A: Proof of Theorem 1

Proof. Define

$$d\mathbf{z} = d\begin{pmatrix} \boldsymbol{\theta} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} \mathbf{M}^{-1}\mathbf{p} \\ -\mathbf{B}\nabla U(\boldsymbol{\theta}) \end{pmatrix} dt = G(\mathbf{z})dt \quad (9)$$

where $G(\cdot) : \mathbb{R}^{2d} \to \mathbb{R}^{2d}$ is a function and the i-th component of $G(\mathbf{z})$ is denoted by $G_i(\mathbf{z})$. According to the definition of FPE (Fokker-Planck Equation) (Kadanoff, 2000), the corresponding FPE is given by

$$\partial_t p_t(\boldsymbol{\theta}, \mathbf{p}) = \nabla^T[G(\mathbf{z})p_t(\boldsymbol{\theta}, \mathbf{p})] \quad (10)$$

The entropy at time t is defined by integrating out the joint variable $\mathbf{z}$, as follows:

$$h(p_t) = -\int_{\mathbf{z}} f(p_t(\mathbf{z}))d\mathbf{z} \quad (11)$$

The evolution of the entropy is governed by

$$\begin{aligned} \partial_t h(p_t(\mathbf{z})) &= -\partial_t \int_{\mathbf{z}} f(p_t(z))d\mathbf{z} \\ &= -\int_{\mathbf{z}} f'(p_t(\mathbf{z}))\partial_t p_t(\mathbf{z})d\mathbf{z} \\ &= -\int_{\mathbf{z}} f'(p_t(\mathbf{z}))\nabla^T[G(\mathbf{z})p_t(\mathbf{z})]d\mathbf{z} \\ &= -\int_{\mathbf{z}} f'(p_t(\mathbf{z}))\nabla^T[G(z)]p_t(\mathbf{z})d\mathbf{z} \\ &\quad -\int_{\mathbf{z}} f'(p_t(\mathbf{z}))(\nabla p_t(\mathbf{z}))^T[G(\mathbf{z})]d\mathbf{z} \end{aligned} \quad (12)$$

where the last equality uses the fact that

$$\begin{aligned} &\nabla^T[G(\mathbf{z})p_t(\boldsymbol{\theta}, \mathbf{p})] \\ &= p_t(\theta, \mathbf{p})\nabla^T[G(\mathbf{z})] + (\nabla p_t(\boldsymbol{\theta}, \mathbf{p}))^T[G(\mathbf{z})] \end{aligned} \quad (13)$$

The second term on the RHS of Equation 12 can be simplified into following form:

$$\begin{aligned} &-\int_{\mathbf{z}} f'(p_t(\mathbf{z}))(\nabla p_t(\mathbf{z}))^T[G(\mathbf{z})]d\mathbf{z} \\ &= -\int_{\mathbf{z}} (\nabla f(p_t(\mathbf{z})))^T[G(\mathbf{z})]d\mathbf{z} \\ &= \int_{\mathbf{z}} f(p_t(\mathbf{z}))\nabla^T[G(\mathbf{z})]d\mathbf{z} = 0 \end{aligned} \quad (14)$$

where the second equality is given by integrations by parts, using the fact that

$$\int_{\mathbf{z}} \nabla^T[f(p_t(\mathbf{z}))G(\mathbf{z})]d\mathbf{z} = 0 \quad (15)$$

which is based on the assumption that the probability density vanishes at infinity and $f(x) \to 0$ as $x \to 0$ such that $f(p_t(\mathbf{z}))[G(\mathbf{z})] \to 0$ as $\mathbf{z} \to \infty$.

Hence the entropy of p_t varies with rate of

$$\begin{aligned} \partial_t h(p_t(\mathbf{z})) &= -\int_{\mathbf{z}} f^{'}(p_t(\mathbf{z}))\nabla^T[G(\mathbf{z})]p_t(\mathbf{z})d\mathbf{z} \\ &= -\int_{\mathbf{z}} f^{'}(p_t(\mathbf{z}))(\mathbf{p}^T\mathbf{M}^{-T}(\mathbf{B}-\mathbf{I})\nabla U(\theta))p_t(\mathbf{z})d\mathbf{z} \end{aligned} \quad (16)$$

This is not equal to zero for $\mathbf{B}$ obviously. □

B: Proof of Theorem 3

Proof. Using FPE (Kadanoff, 2000), Eq. (7) can be written in the following decomposed form:

$$\begin{aligned} d\mathbf{z} &= d\begin{pmatrix} \boldsymbol{\theta} \\ \mathbf{p} \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{0} & -\mathbf{C} \\ \mathbf{C} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \nabla U(\boldsymbol{\theta}) \\ \mathbf{M}^{-1}\mathbf{p} \end{pmatrix} dt \\ &= \begin{pmatrix} -\mathbf{C}\mathbf{M}^{-1}\mathbf{p} \\ \mathbf{C}\nabla U(\boldsymbol{\theta}) \end{pmatrix} dt \\ &= \mathbf{F}(\mathbf{z})dt. \end{aligned} \quad (17)$$

The distribution evolution under this dynamical system is governed by a Fokker-Planck Equation as following:

$$\begin{aligned}
&\partial_t p_t(\mathbf{z}) \\
&= -\nabla^T[F(\mathbf{z})p_t(\mathbf{z})] \\
&= \sum_{i=1}^{2d} \partial_{\mathbf{z}_i}[\mathbf{F}_i(\mathbf{z})p_t(\mathbf{z})] \\
&= \sum_{i=1}^{d} \partial_{\theta_i}[\mathbf{f}_i(\mathbf{z})p(\mathbf{z})] + \sum_{j=1}^{d} \partial_{\mathbf{p}_j}[\mathbf{g}_j(\mathbf{z})p(\mathbf{z})] \\
&= \sum_{i=1}^{d} [\partial_{\theta_i} p(\mathbf{z})]\mathbf{f}_i(\mathbf{z}) + \sum_{j=1}^{d} [\partial_{\mathbf{p}_j} p(\mathbf{z})]\mathbf{g}_j(\mathbf{z}) \\
&= \sum_{i=1}^{d} p(\mathbf{z})[-\nabla U(\theta)]_i \mathbf{f}_i(\mathbf{z}) + \sum_{j=1}^{d} p(\mathbf{z})[\mathbf{M}^{-1}\mathbf{p}]_j \mathbf{g}_j(\mathbf{z}) \\
&= p(\mathbf{z})(\nabla U(\theta))^T(-\mathbf{C}\mathbf{M}^{-1}\mathbf{p}) + p(\mathbf{z})(\mathbf{M}^{-1}\mathbf{p})^T(\mathbf{C}\nabla U(\theta)) \\
&= p(\mathbf{z})[(\nabla U(\theta))^T(-\mathbf{C}\mathbf{M}^{-1}\mathbf{p}) + (\nabla U(\theta))^T\mathbf{C}^T(\mathbf{M}^{-1}\mathbf{p})] \\
&= 0
\end{aligned} \tag{18}$$

where $f(\cdot)$ and $g(\cdot)$ are functions defined as: $f(\cdot) : \mathbb{R}^{2d} \to \mathbb{R}^d$, $g(\cdot) : \mathbb{R}^{2d} \to \mathbb{R}^d$. $\mathbf{f}(\mathbf{z}) = \mathbf{f}(\mathbf{p}, \boldsymbol{\theta}) = -\mathbf{C}\mathbf{M}^{-1}\mathbf{p}$ and $\mathbf{g}(\mathbf{z}) = \mathbf{g}(\mathbf{p}, \boldsymbol{\theta}) = C\nabla U(\boldsymbol{\theta})$. It satisfy that

$$F(\mathbf{z}) = \begin{pmatrix} -\mathbf{C}\mathbf{M}^{-1}\mathbf{p} \\ \mathbf{C}\nabla U(\boldsymbol{\theta}) \end{pmatrix} = \begin{pmatrix} f(\mathbf{z}) \\ g(\mathbf{z}) \end{pmatrix} \tag{19}$$

$\mathbf{f}_i(\mathbf{z})$ and $\mathbf{g}_j(\mathbf{z})$ are the i-th entry and j-th entry of $\mathbf{f}(\mathbf{z})$ and $\mathbf{g}(\mathbf{z})$ respectively.

The fourth equality follows from the fact that function $f(\mathbf{z})$ only depend on $\mathbf{p}$ while function $g(\mathbf{z})$ only depend on $\boldsymbol{\theta}$. Hence, following happens.

$$\begin{aligned}
\partial_{\boldsymbol{\theta}_i} f_i &= 0 \\
\partial_{\mathbf{p}_i} g_i &= 0
\end{aligned} \tag{20}$$

Since $p(\mathbf{z}) = \pi(\boldsymbol{\theta}, \mathbf{p}) = \exp(-U(\boldsymbol{\theta}) - 1/2\mathbf{p}^T\mathbf{M}^{-1}\mathbf{p})$, we expand the partial derivation as following:

$$\begin{aligned}
\partial_{\boldsymbol{\theta}_i} p(\mathbf{z}) &= p(\mathbf{z})[-\nabla U(\boldsymbol{\theta})]_i \\
\partial_{\mathbf{p}_i} p(\mathbf{z}) &= p(\mathbf{z})[\mathbf{M}^{-1}\mathbf{p}]_i
\end{aligned} \tag{21}$$

Hence the fifth equality satisfies.

The last equality is given by the fact that $\mathbf{C}$ is symmetric, i.e., $\mathbf{C}^T = \mathbf{C}$. By calculating $\partial_t p_t(\mathbf{z}) = 0$, we show that the distribution p_t does not vary with time, i.e., $p(\mathbf{z}) = \pi(\boldsymbol{\theta}, \mathbf{p})$ is invariant under the dynamics described in Equation 7. □

C: Proof of Corollary 2

Proof. With the entropy defined in Eq. (11) and compact form of dynamics defined in Eq. (17), The evolution of the entropy is governed by

$$\begin{aligned}
\partial_t h(p_t(\mathbf{z})) &= \partial_t \int_{\mathbf{z}} f(p_t(\mathbf{z}))d\mathbf{z} \\
&= -\int_{\mathbf{z}} f^{'}(p_t(\mathbf{z}))\partial_t p_t(\mathbf{z})d\mathbf{z} \\
&= -\int_{\mathbf{z}} f^{'}(p_t(\mathbf{z}))\nabla^T[F(\mathbf{z})p_t(\mathbf{z})]d\mathbf{z} \\
&= 0,
\end{aligned} \tag{22}$$

where the first two equalities can be referred from part of Eq. (12) and the last equality follows from the conclusion in Eq. (18). □

D: Proof of Theorem 4

The idea behind the correctness of Algorithm 2 is that Theorem 3 guarantees the detailed balance condition for any neighboring samples (e.g., $\boldsymbol{\theta}_{i-1}$ and $\boldsymbol{\theta}_i$) while Theorem 4 strengthen this results on the whole chain.

Proof. Firstly, we define $\{\boldsymbol{\theta}_i\}_{i=1}^n$, the chain generated by Algorithm 2. At i-th iteration, $\mathbf{B}$ is denoted by $\mathbf{B}_i$. For every i, the approximation to inverse Hessian $\mathbf{B}_i$ is symmetric positive definite (Nocedal and Wright, 2006). As seen from Algorithm 2, in i-th proposal (Step 3-15), $\mathbf{B}_i$ is fixed. Moreover, according to Theorem 3 and ϵ-discretization, we obtain that the detailed balance condition hold for any neighboring samples $\boldsymbol{\theta}_{i-1}$ and $\boldsymbol{\theta}_i$, i.e.,

$$\pi(\boldsymbol{\theta}_{i-1})\mathcal{T}_i(\boldsymbol{\theta}_{i-1} \to \boldsymbol{\theta}_i) = \pi(\boldsymbol{\theta}_i)\mathcal{T}_i(\boldsymbol{\theta}_i \to \boldsymbol{\theta}_{i-1}) \tag{23}$$

where $\mathcal{T}_i(\cdot \to \cdot)$ is the transition kernel at i-th proposal.

Integrating out $\boldsymbol{\theta}_{i-1}$ on both sides, we obtain that

$$\begin{aligned}
\pi(\boldsymbol{\theta}_i) &= \int \pi(\boldsymbol{\theta}_i)\mathcal{T}_i(\boldsymbol{\theta}_i \to \boldsymbol{\theta}_{i-1})d\boldsymbol{\theta}_{i-1} \\
&= \int \pi(\boldsymbol{\theta}_{i-1})\mathcal{T}_i(\boldsymbol{\theta}_{i-1} \to \boldsymbol{\theta}_i)d\boldsymbol{\theta}_{i-1}
\end{aligned} \tag{24}$$

That is, distribution π is a stationary distribution with a single transition kernel $\mathcal{T}_i$, i.e.,

$$\mathcal{T}_i(\pi) = \pi \tag{25}$$

holds for every i.

Thus,

$$\mathcal{T}_n\mathcal{T}_{n-1}...\mathcal{T}_1(\pi) = \pi \tag{26}$$

Proved. □

Abstract

A major goal in personalized medicine is the ability to provide individualized predictions about the future trajectory of a disease. Moreover, for many complex chronic diseases, patients simultaneously have additional comorbid conditions. Accurate determination of the risk of developing serious complications associated with a disease or its comorbidities may be more clinically useful than prediction of future disease trajectory in such cases. We propose a novel probabilistic generative model that can provide individualized predictions of future disease progression while jointly modeling the pattern of related recurrent adverse events. We fit our model using a scalable variational inference algorithm and apply our method to a large dataset of longitudinal electronic patient health records. Our model gives superior performance in terms of both prediction of future disease trajectories and of future serious events when compared to non-joint models. Our predictions are currently being utilized by our local accountable care organization during chart reviews of high risk patients.

1 INTRODUCTION

With the dawn of precision medicine and accountable care, it will become increasingly important for healthcare organizations to make accurate predictions about individual patients' future health risks to improve quality and contain costs. Accountable care organizations (ACOs) are organizations that bear financial responsibility for the quality and total cost of healthcare services provided to a defined population of patients. In order to deliver the right care at the right time in the right setting, ACOs need personalized prediction tools that identify individual patients in their populations at greatest risk of having poor clinical outcomes [Parikh et al., 2016, Bates et al., 2014]. Most ACOs currently lack these capabilities.[1] With the widespread adoption of electronic health records (EHRs), much of the data necessary to build such tools are already being collected during the course of routine medical care. In order to be clinically useful, such tools should be flexible enough (1) to accommodate the limitations inherent to operational EHR data [Hersh et al., 2014]; (2) to update predictions dynamically as new information becomes available; and (3) to scale to the massive size of modern health records.

We collaborated with Duke Connected Care, the ACO affiliated with the Duke University Health System, to develop predictive tools for chronic kidney disease (CKD). CKD is characterized by a gradual and generally symptomless loss of kidney function over time. CKD and its complications cause poor health, premature death, increased health service utilization, and excess economic costs. CKD is defined and staged by the degree to which a person's estimated glomerular filtration rate (eGFR) is impaired. eGFR is an approximation of overall kidney function and is calculated using a routinely obtained clinical laboratory test (serum creatinine) and demographic information (age, sex and race) [Levey et al., 2009; KDIGO, 2013]. Most clinical laboratories report eGFR automatically with every serum creatinine measurement.

Healthcare providers struggle at many levels to provide optimal care for patients with CKD. First, the majority of healthcare providers fail to recognize the presence of CKD, despite the fact that CKD can be readily identified using simple, eGFR-based laboratory criteria [Szcech et al., 2013; Tuot et al., 2011; Allen et al., 2011]. Second, among those patients with recognized CKD, both primary care providers and kidney specialists struggle to predict which patients will progress to kidney failure (requiring dialysis or kidney transplantation to survive) or suffer from other complications caused by CKD, such as early death from heart attack or stroke [Mendehlsson et al., 2011]. Third, providers often fail to prescribe appropriate preventive treatment to slow disease progression or address com-

[1] http://www.healthcare-informatics.com/article/survey-acos-still-cite-lack-interoperability-biggest-barrier

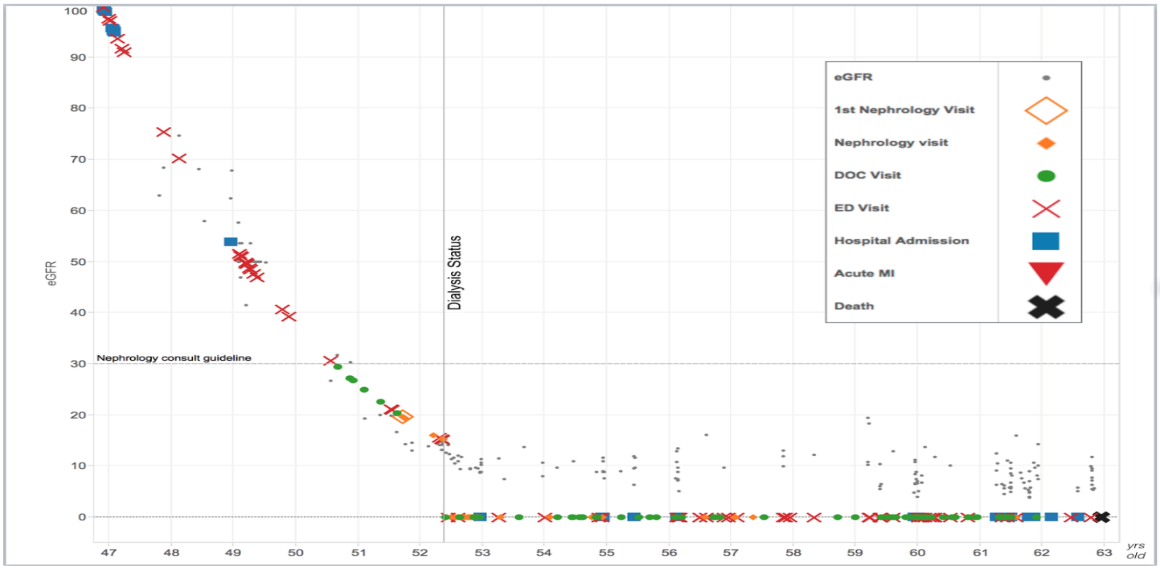

Figure 1: 15-year clinical course of an example patient who experienced both a rapid progression of CKD and a number of other serious health events. Y-axis indicates estimated glomerular filtration rate (eGFR), an estimate of overall kidney function (60-100 is normal, <60 indicates clinically significant kidney disease). X-axis indicates patient age in years. Markers indicate health service use and adverse events. Our model allows us to jointly model progression of CKD, as well as the association between the disease progression and risk for adverse events.

plications [Smart et al., 2014]. Medications such as RAAS drugs can slow progression of CKD if used early enough, while patient counseling and advanced planning can reduce the physical and psychological trauma when kidney failure is imminent.

From a population health management perspective, these characteristics make CKD an ideal condition to model and to develop high-impact care management programs. The challenges surrounding CKD care are best articulated with a representative clinical case, illustrated in Figure 1. A 47 year-old man makes first contact with our health system for emergency treatment of a stroke. His kidney function at this point is normal, although he possesses several risk factors for future CKD. Over the next 5 years, he receives sufficient medical care to detect that his kidney function is deteriorating rapidly (the normal annual rate of kidney function loss at his age is only about 1-2%). His kidney disease goes unnoticed by his healthcare providers, and he does not receive any treatment aimed at slowing progression to total kidney failure. At age 52, he is eventually referred to a kidney specialist, more than a year after his kidney function has fallen below the recommended threshold for such a referral. By this point, kidney failure is inevitable and there is too little time to make advanced preparations for kidney failure, such as pre-emptive kidney transplantation or at-home dialysis. Within 90 days of that first kidney specialist appointment, he develops symptoms of kidney failure and requires hospitalization for emergency dialysis initiation, which is both extremely traumatic and makes him among the most expensive type of patient to treat [Johnson et al., 2015]. He survives on dialysis for about a decade, suffering multiple cardiovascular complications from kidney failure, and ultimately dies at age 63. This patient's story is one of missed opportunities–opportunities that could have been acted upon with accurate predictions using machine learning methods and care management programs.

Our goal is to develop statistical methods that model both the risks of future loss of kidney function and the risks of future complications or adverse health events. The predictions from these models can then be used by healthcare organizations to connect high-risk patients to appropriately targeted interventions. Since the broad aim is to predict which patients will worsen in the near future, we need to model associations between CKD and the multitude of various health outcomes that could occur. CKD frequently coexists with and contributes to cardiovascular disease. In fact, most patients with advanced CKD pass away from cardiovascular complications before the onset of kidney failure. In this article, we choose to focus on two common types of adverse cardiovascular events: heart attacks (acute myocardial infarctions [AMIs]) and strokes (cerebrovascular accidents [CVAs]).

To this end, we develop a joint model that flexibly captures the eGFR trajectory of CKD progression, while simultaneously learning the association between disease trajectory and cardiovascular events. We formulate our approach as a hierarchical latent variable model. Each patient is represented by a set of latent variables characterizing both their disease trajectory and risk of having events. This approach

captures dependencies between the disease trajectory and event risk.

Using our model, we study a large cohort of patients with CKD from the Duke University Health System and make predictions about the trajectory of their disease, as well as their risk of cardiovascular events. Our inference algorithm scales well to the large dataset, and makes accurate predictions that outperform several baselines.

2 PROPOSED JOINT MODEL FOR ELECTRONIC HEALTH RECORDS

In this section, we first describe the structure of electronic health records before introducing our proposed joint model for longitudinal and point process data.

Electronic Health Records

The Duke University Health System's electronic health record (Epic Systems, Madison, WI) stores nearly all available information captured about patients during their encounters within the health system. The EHR contains a large quantity of longitudinal patient data. The vast majority of the data are unstructured, contained within free-text notes and reports. Structured data include demographics, diagnosis and procedural codes, orders, laboratory results, and objective clinical observations (such as vital signs and various nursing assessments). Of particular interest to our work in modeling CKD patients are structured diagnosis codes and laboratory results.

The EHR stores granular information about medical diagnoses using structured, hierarchical codes conforming to ICD-9 (International Classification of Disease, 9th revision), a standardized taxonomy that is used principally for medical billing. For each medical encounter (such as a clinic or emergency department visit), a set of codes is assigned to document the primary problems or diseases that were addressed. In total, there are about 9,000 unique ICD-9 codes. Each clinical diagnosis may have multiple corresponding ICD-9 diagnosis codes. The Agency for Healthcare Research and Quality publishes the Clinical Classifications Software[2], a categorization tool that collapses the thousands of original codes into a few hundred clinically meaningful concepts. We use this mechanism to identify and aggregate codes for CVAs and AMIs, where we use the mean date among all relevant codes within monthly bins to account for multiple codes in a short time period that refer to the same clinical event.

In contrast to diagnosis codes, which capture clinicians' subjective diagnostic impressions, laboratory tests provide objective clinical data. A single medical encounter may include dozens, hundreds or (in the case of hospitalizations) thousands of discrete laboratory test results. Identifying and grouping relevant laboratory test results can be difficult due to lack of standardization and changing conventions over time. For example, serum creatinine, which is a lab test used to calculate eGFR, has more than 18 different names in our EHR that refer to the same value (e.g. "CREA", "Creatinine", "DUAP CREA"). Harmonizing and grouping these lab results required an exhaustive review of laboratory metadata by a subject matter expert.

There are numerous ongoing efforts to develop improved algorithms to identify chronic medical conditions and incident clinical events using a wide assortment of clinical data. Our model is agnostic to the particular algorithm used to identify clinical events. After cleaning and transforming the raw EHR data, we obtained a longitudinal set of eGFRs for each patient, and dates of CVA and AMI diagnoses.

Proposed Model

Our proposed hierarchical latent variable model jointly models longitudinal and point process data by creating different submodels for each type of data, with shared latent variables for each patient inducing dependencies between their two data types. Assume there are N patients, let $\vec{y_i} = \{y_{ij}\}_{j=1}^{N_i}$ denote the N_i observed readings of eGFR for patient i at times $\vec{t_i} = \{t_{ij}\}_{j=1}^{N_i}$, and let $\vec{u_i} = \{u_{ik}\}_{k=1}^{K_i}$ denote the K_i cardiac events patient i experiences (note that K_i may be 0). Let T_i^- be the time patient i is first seen in our sample of their health record, and T_i^+ the final time they are observed. Let z_i, b_i, f_i and v_i be a set of shared hierarchical latent variables for each patient i, to be defined subsequently. Conditioned on these latent variables, to be learned during inference, we make a common conditional independence assumption that the conditional likelihood for patient i factorizes:

$$\begin{aligned} p(\vec{y_i}, \vec{u_i} | z_i, b_i, f_i, v_i; x_i) = p(\vec{y_i} | z_i, b_i, f_i; x_i) \\ p(\vec{u_i} | z_i, b_i, f_i, v_i; x_i). \end{aligned} \tag{1}$$

Longitudinal Submodel

We use a recently proposed model for disease trajectories for our longitudinal submodel [Schulam and Saria, 2015], that was shown to be extremely flexible and accurate at modeling continuous functions of disease progression. Given the set of latent variables for patient i, the longitudinal variables are conditionally independent, i.e. $p(\vec{y_i} | z_i, b_i, f_i) = \prod_{j=1}^{N_i} p(y_{ij} | z_i, b_i, f_i)$. The model assumes each observed longitudinal value is a normally distributed random variable containing a population component, a subpopulation component, an individual component, and a structured noise component:

$$y_i(t) = m_i(t) + \epsilon_i(t),\ \epsilon_i(t) \overset{iid}{\sim} N(0, \sigma_\epsilon^2) \tag{2}$$

$$m_i(t) = \Phi_p(t)^\top \Lambda x_{ip} + \Phi_z(t)^\top \beta_{z_i} + \Phi_l(t)^\top b_i + f_i(t). \tag{3}$$

[2] http://www.hcup-us.ahrq.gov/toolssoftware/ccs/ccs.jsp

The first term in (3) is the population component, where $\Phi_p(t) \in \mathbb{R}^{d_p}$ is a fixed basis expansion of time, $\Lambda \in \mathbb{R}^{d_p \times q_p}$ is a coefficient matrix, and $x_{ip} \in \mathbb{R}^{q_p}$ is a vector of baseline covariates.

The second term in (3) is the subpopulation component, where it is assumed person i belongs to latent subpopulation $z_i \in \{1, \ldots, G\}$. Each subpopulation is associated with a unique disease trajectory represented using B-splines, in particular, $\Phi_z(t) \in \mathbb{R}^{d_z}$ is a fixed B-spline basis expansion of time with $\beta_g \in \mathbb{R}^{d_z}$ the coefficient vector for group g. We assign z_i a multinomial logistic regression prior that depends on baseline covariates $x_{iz} \in \mathbb{R}^{q_z}$: $p(z_i = g) \propto \exp\{w_g^\top x_{iz}\}$, where $\{w_g\}_{g=1}^G$ are regression coefficients with $w_1 \equiv 0$ for identifiability.

The third term is the individual component, allowing for individual-specific long-term deviations in trajectory that are learned dynamically as more data is available. $\Phi_l(t) \in \mathbb{R}^{d_l}$ is a fixed basis expansion of time, and $b_i \in \mathbb{R}^{d_l}$ is a random effect for patient i, with prior $b_i \sim N(0, \Sigma_b)$.

Finally, $f_i(t)$ is the structured noise process that captures transient trends in disease trajectory. This is modeled using a zero-mean Gaussian process with Ornstein-Uhlenbeck covariance function $K_{OU}(t_1, t_2) = \sigma_f^2 \exp\{-\frac{|t_1 - t_2|}{l}\}$. This kernel is well-suited for this task, as it is mean-reverting and has no long-range dependence between deviations [Schulam and Saria, 2015].

Point Process Submodel

We choose to model the times $\vec{u_i} = \{u_{ik}\}_{k=1}^{K_i}$ that a person has an adverse event as a Poisson process. A common choice for the rate function from related literature in survival analysis corresponds to the hazard function from the Cox proportional hazards model. We make this choice in this work, for reasons both of simplicity and also computational efficiency as we discuss later. The conditional likelihood for the Poisson process for patient i on the interval $[T_i^-, T_i^+]$, with events at times $\{u_{ik}\}_{k=1}^{K_i}$, is given by:

$$p(\vec{u_i} | z_i, b_i, f_i, v_i) = \prod_{k=1}^{K_i} r_i(u_{ik}) \exp\{-\int_{T_i^-}^{T_i^+} r_i(t) dt\}, \tag{4}$$

where we specify the rate function for patient i as:

$$r_i(t) = r_0(t) \exp\{\gamma^\top x_{ir} + \alpha m_i(t) + \delta m_i'(t) + v_i\}. \tag{5}$$

We assume that $r_0(t)$ is a piecewise constant function with jumps at fixed quantiles of the event times, and heights $\{a_l\}_{l=1}^{N_r}$. The parameter $\gamma \in \mathbb{R}^{q_r}$ specifies the association between baseline covariates $x_{ir} \in \mathbb{R}^{q_r}$ and the risk for an event, while parameters α and δ specify the association between the risk for an event and the expected mean and expected slope of the longitudinal variable at that time, respectively.[3] Finally, the latent variable v_i, with prior $v_i \sim N(0, \sigma_v^2)$, represents an additional random effect (called a frailty term in survival analysis), multiplicatively adjusting an individual's overall risk for events. In order to compute the likelihood, we must compute the definite integral in (4) numerically. We find that the trapezoid rule works fine, although other options such as Gaussian quadrature are also possible.

3 RELATED WORK

There is a rich literature, mostly from biostatistics, on joint models typically for longitudinal data and time-to-event data with right censoring. See [Rizopoulos, 2012] for a thorough introduction to these types of joint models. A slightly different flavor of joint models is presented in [Proust-Lima et al., 2014]. These models differ in that instead of the longitudinal value directly influencing the event rate, they consider latent subpopulations of individuals within which it is assumed there is a different average profile of both the longitudinal value and risk of the event.

Most directly relevant to our work are several methods for modeling longitudinal data and recurrent event data [Liu and Huang, 2009; Kim et al., 2012; Han et al., 2007]. However, these methods share several notable weaknesses. First, the form for their longitudinal models are simplistic, all being mixed effects models. Such models are inflexible and will fail to capture the types of trajectories that our model can, through its mixture model and both long and short-term individual-specific deviations. In addition, these works as well as most of the literature on joint models rely on computationally expensive inference algorithms, thereby limiting their use to small datasets. Typically EM or gradient methods are employed for Maximum Likelihood Estimation, or MCMC in Bayesian settings. It is extremely uncommon to find a published joint model applied to a dataset of over 1000 individuals. However, our scalable variational inference algorithm, developed in the next section, is much more efficient, facilitating use in large-scale applications where there can be tens or even hundreds of thousands of patients.

Within the medical literature, there have been numerous studies on predicting adverse events such as kidney failure, death, or cardiac events in patients with CKD; for instance, [Tangri et al., 2011] is a common reference. In almost every case, the models developed are Cox proportional hazards models for time-to-event data, or logistic regression models for occurrence of an event in a specified time window. As such, these models are all static and use only a single snapshot of patient data to make predictions, which precludes the ability to generate dynamic predictions.

[3] Since $f_i(t)$ with an OU kernel is not differentiable, we let $m_i'(t)$ be the sum of the slopes of the first three terms in (3).

In recent years there has been much interest in machine learning in modeling electronic health records and other forms of healthcare data. For instance, [Lian et al., 2015] use hierarchical point processes to predict hospital admissions, and [Ranganath et al., 2015] develop a dynamic factor model to learn relationships between diseases and predict future diagnosis codes. Closest to our work in the application is [Perotte et al., 2015], who explore using time-series models to predict a time-to-event (progression from CKD stage 3 to stage 4) in CKD patients.

4 INFERENCE

As with most complex probabilistic generative models, the computational problem associated with fitting the model is estimation of the posterior distribution of latent variables and model parameters given the observed data. Exact computation of the posterior is intractable, and requires approximation to compute. To this end, we develop a mean field variational inference [Jordan et al., 1999] algorithm to approximate the posterior distribution of interest.

Variational methods transform the task of posterior inference into an optimization problem. The optimization problem posed by variational inference is to find a distribution q in some approximating family of distributions that is close in KL divergence to the true posterior. Equivalently, the problem can be viewed as maximizing what is known as the evidence lower bound (ELBO) [Bishop, 2006]:

$$\mathcal{L}(q) = E_q[\log p(y, u, z, b, f, v, \Theta) - \log q(z, b, f, v, \Theta)], \tag{6}$$

which forms a lower bound on the marginal likelihood $p(y, u)$ of our model.

Variational Approximation

Recall for our model that the model parameters are $\Theta = \{\Lambda, W, \beta, a, \gamma, \alpha, \delta\}$, and the local latent variables specific to each person are their subpopulation assignment z_i, random effects b_i and v_i, and structured noise function f_i. The joint distribution for our model can be expressed as:

$$\begin{aligned} p(y, u, z, b, f, v, \Theta) = p(\Theta) \prod_{i=1}^{N} \prod_{j=i}^{N_i} p(y_{ij}|z_i, b_i, f_i(t_{ij}), \Theta) \\ p(\vec{u_i}|z_i, b_i, f_i, v_i, \Theta) p(z_i) p(b_i) p(f_i) p(v_i) \end{aligned} \tag{7}$$

We make the mean field assumption for the variational distribution, which assumes that in the approximate posterior q, all the latent variables are independent. This implies that $q(z, b, f, v, \Theta) = q(\Theta) \prod_{i=1}^{N} q_i(z_i, b_i, f_i, v_i)$, where:

$$\begin{aligned} q_i(z_i, b_i, f_i, v_i) = q_i(z_i|\nu_{z_i}) q_i(b_i|\mu_{b_i}, \Sigma_{b_i}) \\ q_i(v_i|\mu_{v_i}, \sigma^2_{v_i}) q_i(f_i). \end{aligned} \tag{8}$$

The assumed variational distributions for z_i, b_i, and v_i are the same family as their prior distribution, i.e. multinomial, multivariate normal, and univariate normal. For the variational form for f_i, we adapt ideas from the variational learning for sparse GPs literature [Lloyd et al., 2014; Titsias, 2009] to approximate the true posterior over f_i. In order to evaluate the ELBO in (6), we will need to evaluate $E_{q_i}[f_i]$ at times $\vec{t_i}$ for the longitudinal likelihood, as well as at $\vec{u_i}$ and at a grid of times t_i^{grid} for the point process likelihood (the grid is for the numerical integration). We choose to treat the observed observation times $\vec{t_i}$ as pseudo-inputs; this helps reduce overfitting and reduces the number of variational parameters to learn. In particular:

$$\begin{aligned} q_i(f_i(\vec{t_i}), f_i(\vec{u_i}), f_i(t_i^{\text{grid}})) = p(f_i(\vec{u_i}), f_i(t_i^{\text{grid}})|f_i(\vec{t_i})) \\ q(f_i(\vec{t_i})|\mu_{f_i}, \Sigma_{f_i}). \end{aligned} \tag{9}$$

We allow a free-form multivariate Gaussian distribution for f_i at the longitudinal observation times, and use a so-called conditional Gaussian process for the distribution at $\vec{u_i}, t_i^{\text{grid}}$, i.e. the true conditional distribution of the joint multivariate normal, $f_i|f_i(\vec{t_i}) \sim \mathcal{GP}(\mu(t), \Sigma(t, t'))$:

$$\mu(t) = K_{t,\vec{t_i}} K^{-1}_{\vec{t_i},\vec{t_i}} f_i(\vec{t_i}) \tag{10}$$

$$\Sigma(t, t') = K_{t,t'} - K_{t,\vec{t_i}} K^{-1}_{\vec{t_i},\vec{t_i}} K_{\vec{t_i},t'} \tag{11}$$

where $K_{t,\vec{t_i}}, K_{\vec{t_i},\vec{t_i}}, K_{t,t'}$ are matrices evaluated at t, t', and $\vec{t_i}$ using the OU covariance kernel from Section 2.

Although priors on the model parameters Θ may be imposed, i.e. log-normal on a and normal on the rest, in our work we learn their maximum likelihood estimate (MLE) instead, and let $q(\Theta)$ be a delta function. Thus, the goal of our variational algorithm is to learn optimal variational parameters $\lambda_i = \{\nu_{z_i}, \mu_{b_i}, \Sigma_{b_i}, \mu_{v_i}, \sigma^2_{v_i}, \mu_{f_i}, \Sigma_{f_i}\}$ for each individual i, as well as a point estimate $\hat{\Theta}$ for the model parameters. In practice, we optimize the Cholesky decompositions L_{b_i}, L_{f_i} for the covariance matrices $\Sigma_{b_i}, \Sigma_{f_i}$.

Solving the Optimization Problem

In traditional settings for variational inference, the objective function is iteratively optimized by maximizing the variational parameters associated with each latent variable or parameter, holding the rest fixed. In models where the log complete conditional distributions (log of the conditional distribution of each latent variable given everything else) have analytic expectations with respect to the variational approximation, closed form EM-style updates are available for the variational parameters. This convenient property is typically observed in conditionally conjugate models, where each log complete conditional will be in the exponential family [Ghahramani and Beal, 2001].

Recently there has been much interest in applying variational methods to more complex models that do not ex-

hibit conjugacy. In many cases, it is intractable to even evaluate the ELBO analytically, since one or both of the expectations in (6) have no closed form. In these cases, variational algorithms have been developed that rely on sampling from the variational approximation [Ranganath et al.,2014; Rezende et al., 2014]. However, because of the form we chose for r_i, it is possible to calculate a closed form approximation to the ELBO for our model (approximate due to the numerical integration; see Appendix for details). As such, we use the automatic differentiation package *autograd* [4] in Python to compute analytic gradients in order to optimize the bound. At each iteration of the algorithm, we optimize the local variational parameters in parallel using exact gradients. To optimize the global parameters, we turn to stochastic optimization.

Stochastic optimization has become a commonly used tool in variational inference. Rather than using every single observation to compute the gradient of the ELBO with respect to Θ, we can compute a noisy gradient based on a sampled batch of observations [Hoffman et al., 2013]. As long as the noisy gradient is unbiased and the learning rate ρ_t at each iteration satisfies the Robbins Monro conditions ($\sum_{t=1}^{\infty} \rho_t = \infty,\ \sum_{t=1}^{\infty} \rho_t^2 < \infty$), the stochastic optimization procedure will converge to a local maximum. To set the learning rate we use the AdaGrad algorithm, which adaptively allows for a different learning rate for each parameter. The learning rate for each parameter is scaled by the square root of a running sum of the squares of historical gradients [Duchi et al., 2011].

Algorithm

Algorithm 1 summarizes the procedure to learn an approximate posterior for the local latent variables and a point estimate for the model parameters.

Data: data y, u; hyperparameters.
Result: point estimate $\hat{\Theta}$, approximate posteriors q_i.
Initialize global parameters Θ.
repeat
  Randomly sample data for S patients, $\{y_s, u_s\}_{s=1}^{S}$.
  for *s = 1:S in parallel* **do**
    Optimize local variational parameters for q_s via gradient ascent.
  end
  Compute the noisy gradient for Θ.
  Update Θ using AdaGrad.
until *convergence of the ELBO*;

5 EMPIRICAL STUDY

In this section we describe our experimental setup and results on our real dataset.

Dataset

Our dataset comprises longitudinal and cardiac event data from 23,450 patients with stage 3 CKD or higher within our university health system. IRB approval (#Pro00066690) was obtained for this work. We first created an initial cohort of roughly 600,000 patients that had at least one encounter in the health system in the year prior to Feb. 1, 2015. This includes all types of encounters within the health system, including inpatient, outpatient, and emergency department visits. From this, we filtered to patients who had at least ten recorded values for serum creatinine, the laboratory value required to calculate eGFR. We next filtered to patients that had Stage 3 CKD or higher, indicative of moderate to severe kidney damage, defined as two eGFR measurements less than 60 mL/min separated by at least 90 days. Finally, since the recorded eGFR values are extremely noisy and eGFR is only a valid estimate of kidney function at steady state, we take the mean of eGFR readings in monthly time bins for each patient. Rapid fluctuations in acute illness are related to long term risk, but we have not yet explicitly incorporated this into our modeling.

After this preprocessing, on average each patient has 22.9 eGFR readings (std dev 13.6; median 19.0). In order to align the patients on a common time axis, for each patient we fix $t = 0$ to be their first recorded eGFR reading below 60 mL/min. The adverse events of interest in our experiments are AMIs and CVAs, and these were identified using ICD-9 codes as detailed in Section 2. 13.4% of patients had at least one code for AMI (among those with at least one: mean 4.1, std dev 7.1, median 2.0), and likewise 17.4% of patients had at least one code for CVA (mean 6.4, std dev 13.3, median 3.0). We use the same set of baseline covariates for x_{ip}, x_{iz}, x_{ir}: baseline age, race and gender, and indicator variables for hypertension and diabetes. Note that x_{ip}, x_{iz} include an intercept while x_{ir} does not.

For the experiments, we used ten fold cross validation with training sets of 21,105 patient records and test sets of 2,345 records. We fit separate joint models for CVA events and AMI events.

Evaluation Metrics

After learning a point estimate for the global model parameters during training, they are held fixed. Then, an approximate posterior is fit to each patient in the test set, where we allow the learning algorithm to see the first 60% of a patient's eGFR trajectory (and any events before then) and hold out the remaining 40% (and future events). Predictions about future disease trajectory and adverse events are

made by drawing samples from the approximate posterior predictive distribution.

We evaluate our model on two tasks to asses predictive performance of each submodel. For the longitudinal submodel, we compute the mean squared error (MSE) and mean absolute error (MAE) for predictions about held-out eGFR values. For the point process submodel, we view the problem of predicting whether any event will occur in a given future time window (in our experiments, 1-5 years) as a binary classification problem. We report the area under the ROC curve (AUROC) and area under the precision-recall curve (AUPR) as evaluation metrics for each binary classification task. Calculating the probability of an event in a future time window $[T_i, T_i + c]$ for person i is easily computed as $1 - \exp\{-\int_{T_i}^{T_i+c} r_i(t)dt\}$.

Baselines

For the longitudinal submodel, we compare against the model in [Schulam and Saria, 2015], since we use their model as our longitudinal submodel. However, because our model was trained jointly with the point process submodel we do not in general learn the same model parameters, since the parameters for the learned trajectories are also influenced by the event data.

For the point process submodel, we compare against two standard baselines. The first is a simple Cox proportional hazards model from survival analysis, where we use the same set of time independent covariates x_{ir} as in our model. The likelihood is the same as (4), but now $r_i(t) = r_0(t) \exp\{\gamma^\top x_{ir}\}$. We also compare against a Cox model with time-dependent covariates, where $r_i(t) = r_0(t) \exp\{\gamma^\top x_{ir} + \alpha y_i(t)\}$, with $y_i(t)$ a step function denoting the most recent observed eGFR up until time t. Due to the lack of scalable inference algorithms for related works from the joint modeling literature, we were unable to compare against them on our large patient cohort.

Hyperparameters

We learn point estimates for hyperparameters $\sigma_\epsilon, \Sigma_b, \sigma_v, \sigma_f, l$ by maximizing the ELBO with respect to them. Additional hyperparameters include G, N_r, and the choice of basis expansions Φ_p, Φ_z, Φ_l in the longitudinal submodels. We let Φ_p and Φ_l be linear basis functions of time, thus allowing for population covariates and individual heterogeneity to shift the intercept and slope of eGFR trajectory. We let Φ_z be a B-spline expansion of time with degree two and twelve knots at equally spaced quantiles of eGFR observation times. We fix $G = 15$ and $N_r = 9$. Finally, we set the global scale parameter for AdaGrad to 0.1, and subsample 250 observations at a time. We experimented with other values for these fixed hyperparameters without major changes in performance.

Results

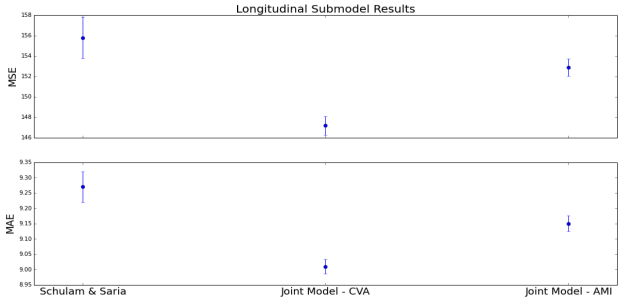

Figure 2: Mean MSE and MAE from longitudinal submodels. Error bars are one standard error.

Figure 2 highlights the results from the longitudinal submodel, where we present the mean MSEs and MAEs across the test sets. The longitudinal submodel from our joint model performs slightly better than the method of [Schulam and Saria, 2015] fit independently to the eGFR values. Figure 3 highlight the results from the point process submodel. Our proposed joint model performs substantially better than the two baselines at predicting future events, in terms of both AUROC and AUPR.

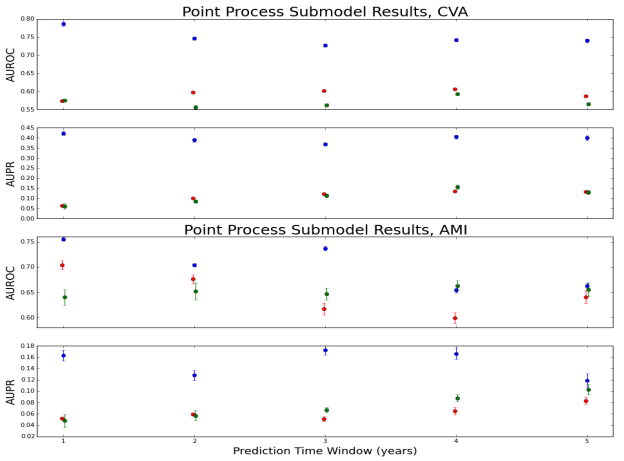

Figure 3: Mean AUROC and AUPR for CVA and AMI events. Blue is proposed Joint Model, red is Cox, green is time-varying Cox. Error bars are one standard error.

In addition, in this dataset it appears that prediction of CVA events is slightly easier than prediction of AMIs. For the CVA joint model, we estimate that $\alpha = -0.063$ and $\delta = -0.061$ while for the AMI joint model, $\alpha = -0.158$ and $\delta = -0.069$ (standard errors for all four estimates < 0.01, from the cross validation). The signs of these parameters agree with clinical intuition that patients with lower overall eGFR values and more rapid eGFR declines should be at higher risk for adverse events. It appears there is a slightly stronger association between eGFR trajectory and risk for AMIs compared to CVAs.

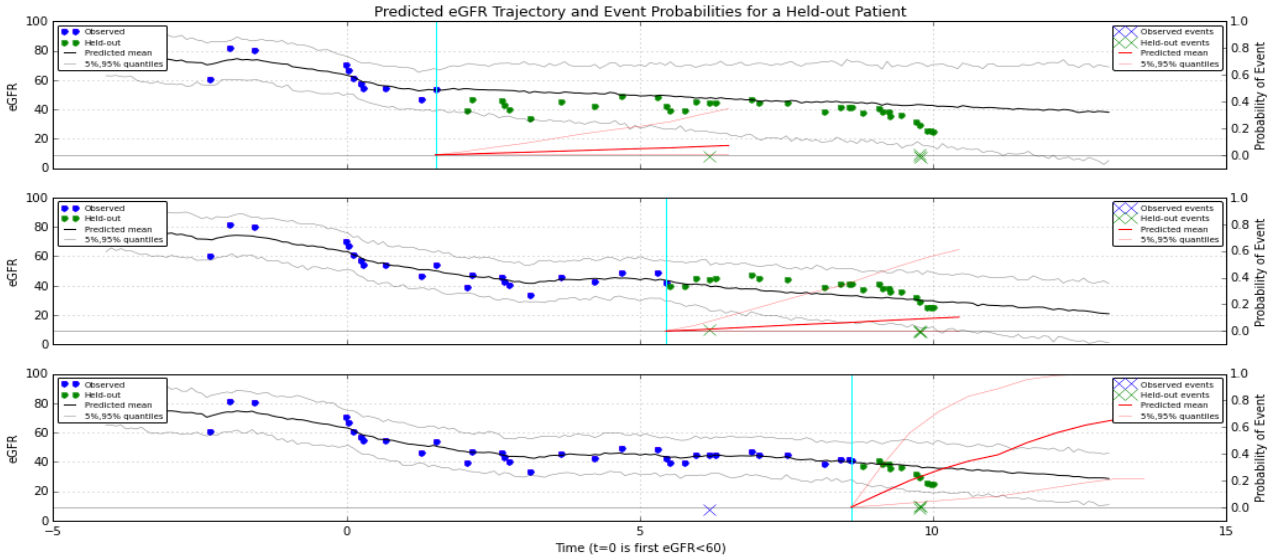

Figure 4: Dynamic predictions from our joint model. In each row, the parameters for this individual are refit as more data is made available (information to the left of the light blue lines is used to refit parameters). Blue circles and x's correspond to observed eGFR readings and CVA events, while green correspond to yet-unseen data.

Figure 4 shows an example of dynamic predictions over time for a test patient. In the three rows of the figure, we make predictions about the test patient after observing the first 25%, 50% and 75% of their disease trajectory and adverse events (in this example, CVAs). For each row we relearn the patient's parameters using information to the left of the vertical light blue line. As we observe more data, the longitudinal model updates its prediction about future disease trajectory and provides a reasonable forecast for the steady decline of this patient's eGFR. In the second row, as the model sees that the patient's trajectory is decreasing faster than in the first row, it correspondingly increases the probability of a future event. In the third row, after the model sees the patient's first CVA event, it further increases the probability of a future event.

6 DISCUSSION

In this paper, we have proposed a new joint model for longitudinal and point process data, and applied it to disease trajectory modeling and prediction of adverse events in patients with chronic kidney disease. We developed the first variational inference algorithm for this class of models, allowing us to fit our model to a large set of longitudinal patient data that is over an order of magnitude the size of datasets used by related methods. We find that our model yields good performance on the tasks of predicting future kidney function and predicting cardiovascular events.

Although our work is a promising first step for developing predictive models from EHR data and applying them to real clinical tasks, there are numerous inherent limitations to EHR data [Hersh et al., 2014]. Data quality is often poor, complicated by inaccurate, inconsistent or missing information. The EHR at a single organization may fail to capture the full patient story and all relevant outcomes of interest, as is the case when patients receive care from multiple, non-interoperable healthcare systems over time. Relevant patient reported outcomes, such as perceived quality of life, are rarely captured by EHRs. Events such as death may not be registered, particularly when patients die outside of the hospital. Data may be biased; certain laboratory tests may be performed only when a clinician suspects an abnormality. Furthermore, many clinical data are collected for billing purposes rather than patient care or research, distorting the relative importance of certain elements.

There are many directions in which we plan to extend this work. Future models will be multivariate in both longitudinal markers and in event processes. Inclusion of additional longitudinal variables such as blood pressure, albuminuria, and hemoglobin A1c will be important, since these are well known to be clinically important for monitoring cardiovascular and kidney health. Jointly modeling multiple event processes will allow us to learn correlations between different types of events. More flexible models, particularly for the event processes, should improve model performance, for instance using Gaussian Process modulated Poisson processes or Hawkes processes instead of employing the proportional hazards assumption as we do in this work. By further refining and deploying a flexible, scalable model such as ours, ACOs around the country can intervene on high-risk patients and realize the potential benefits of precision medicine.

7 APPENDIX

We present the full derivation of the ELBO for our model. We can rewrite the expression for the ELBO in (6) as:

$$\mathcal{L}(q) = \sum_{i=1}^{N} \mathcal{L}(q_i), \tag{12}$$

$$\begin{aligned}\mathcal{L}(q_i) = &E_{q_i}[\log p(\vec{y_i}|z_i, b_i, f_i, \Theta) + \log p(\vec{u_i}|z_i, b_i, f_i, v_i, \Theta)] \\ &- KL(q_i(b_i)||p(b_i)) - KL(q_i(v_i)||p(v_i)) \\ &- KL(q_i(z_i)||p(z_i)) - KL(q_i(f_i(\vec{t_i}))||p(f_i(\vec{t_i}))).\end{aligned} \tag{13}$$

Computation of the KL divergence terms are standard. We focus our attention on the first two terms in (13).

The first term in (13) is the variational expectation of the log likelihood for the longitudinal submodel. To compute this, we need to calculate $E_{q_i}[(\vec{y_i} - m_i(\vec{t_i}))^\top(\vec{y_i} - m_i(\vec{t_i}))]$. It is straightforward to expand this product and calculate the expectation of each term. The relevant expectations are:

$$E_{q_i(z_i)}[\beta_{z_i}] = \sum_{g=1}^{G} \nu_{z_i,g}\beta_g \tag{14}$$

$$E_{q_i(b_i)}[b_i] = \mu_{b_i} \tag{15}$$

$$E_{q_i(f_i)}[f_i(\vec{t_i})] = \mu_{f_i} \tag{16}$$

$$\begin{aligned}&E_{q_i(z_i)}[(\Phi_z(\vec{t_i})\beta_{z_i})^\top(\Phi_z(\vec{t_i})\beta_{z_i})] = \\ &\sum_{g=1}^{G} \nu_{z_i,g}(\Phi_z(\vec{t_i})\beta_g)^\top(\Phi_z(\vec{t_i})\beta_g)\end{aligned} \tag{17}$$

$$\begin{aligned}&E_{q_i(b_i)}[(\Phi_l(\vec{t_i})b_i)^\top(\Phi_l(\vec{t_i})b_i)] = \\ &\text{Tr}(\Phi_l(\vec{t_i})\Sigma_{b_i}\Phi_l(\vec{t_i})^\top) + \mu_{b_i}^\top\Phi_l(\vec{t_i})^\top\Phi_l(\vec{t_i})\mu_{b_i}\end{aligned} \tag{18}$$

$$E_{q_i(f_i(\vec{t_i}))}[f_i(\vec{t_i})^\top f_i(\vec{t_i})] = \text{Tr}(\Sigma_{f_i}) + \mu_{f_i}^\top\mu_{f_i} \tag{19}$$

The second term in (13) is the variational expectation of the log likelihood for the point process submodel:

$$\begin{aligned}&E_{q_i}[\log p(\vec{u_i}|z_i, b_i, f_i, v_i, \Theta)] = \\ &E_{q_i}[\sum_{k=1}^{K} \log r_i(u_{ik}) - \int_{T_i^-}^{T_i^+} r_i(t)dt].\end{aligned} \tag{20}$$

Each term in the summation in (20) is given by:

$$\begin{aligned}E_{q_i}[\log r_i(u_{ik})] = &\log r_0(u_{ik}) + \gamma^\top x_{ir} + \alpha E_{q_i}[m_i(u_{ik})] \\ &+ \delta E_{q_i}[m_i'(u_{ik})] + E_{q_i}[v_i],\end{aligned} \tag{21}$$

where $E_{q_i}[v_i] = \mu_{v_i}$ and $E_{q_i}[m_i(u_{ik})], E_{q_i}[m_i'(u_{ik})]$ are simple to compute using (14) and (15), where we use the time derivatives of the bases $\Phi_p', \Phi_z', \Phi_l'$ in place of the actual bases for the latter. The only nontrivial term in $E_{q_i}[m_i(u_{ik})]$ is $E_{q_i}[f_i(u_{ik})]$. However, due to conjugacy, we have that for arbitrary t:

$$\begin{aligned}q_i(f_i(t)) &= \int p(f_i(t)|f_i(\vec{t_i}))q_i(f_i(\vec{t_i})) \\ &\equiv \mathcal{GP}(f_i; \mu(t), \Sigma(t, t'))\end{aligned} \tag{22}$$

$$\mu(t) = K_{t,\vec{t_i}}K_{\vec{t_i},\vec{t_i}}^{-1}\mu_{f_i} \tag{23}$$

$$\begin{aligned}\Sigma(t, t') = &K_{t,t'} - K_{t,\vec{t_i}}K_{\vec{t_i},\vec{t_i}}^{-1}K_{\vec{t_i},t'} \\ &+ K_{t,\vec{t_i}}K_{\vec{t_i},\vec{t_i}}^{-1}\Sigma_{f_i}K_{\vec{t_i},\vec{t_i}}^{-1}K_{\vec{t_i},t'},\end{aligned} \tag{24}$$

so we can use (23) to compute $E_{q_i}[f_i(u_{ik})]$; the K matrices are the OU kernel evaluated at the relevant times.

The final term to compute is the integral in (20). Since we approximate it numerically, we need to evaluate $E_{q_i}[r_i(t)]$ for arbitrary times t:

$$E_{q_i}[r_i(t)] = r_0(t)e^{\gamma^\top x_{ir}}E_{q_i}[e^{\alpha m_i(t) + \delta m_i'(t) + v_i}]. \tag{25}$$

Using the mean field assumption, this expectation of products factorizes into products of expectations. There are no local latent variables corresponding to the population term in $m_i(t)$, so that term can be brought outside the expectation. Since $q_i(v_i) \sim N(\mu_{v_i}, \sigma_{v_i}^2)$ we have that e^{v_i} is log-normal, hence $E_{q_i}[e^{v_i}] = e^{\mu_{v_i} + \frac{\sigma_{v_i}^2}{2}}$. Expanding $m_i(t)$ and $m_i'(t)$ in (25) leads to three final expectations to compute. The first is:

$$E_{q_i(z_i)}[e^{(\alpha\Phi_z(t) + \delta\Phi_z'(t))^\top\beta_{z_i}}] = \sum_{g=1}^{G} \nu_{z_i,g}e^{(\alpha\Phi_z(t) + \delta\Phi_z'(t))^\top\beta_g} \tag{26}$$

The last two are $E_{q_i}[e^{(\alpha\Phi_l(t)^\top + \delta\Phi_l'(t)^\top)b_i}]$ and $E_{q_i}[e^{\alpha f_i(t)}]$. Since the variational distributions for b_i and $f_i(t)$ are multivariate normal (from (8) and (22)-(24)), the exponential of an affine transformation of them will be multivariate log-normal. We can use this with the fact that if $X \sim N(\mu, \Sigma)$ is multivariate normal, then $Y = e^X$ is multivariate log-normal with mean $E[Y]_i = e^{\mu_i + \frac{\Sigma_{ii}}{2}}$ to compute the desired variational expectations.

To compute noisy gradients of the ELBO with respect to Θ, we randomly sample S observations $\{y_s, u_s\}_{s=1}^S$ at each iteration, and compute the gradient of $\hat{\mathcal{L}}(q) \equiv \frac{N}{S}\sum_{s=1}^S \mathcal{L}(q_s)$, which equals $\mathcal{L}(q)$ in expectation.

Abstract

In this paper, we explore degrees of freedom in deep sigmoidal neural networks. We show that the degrees of freedom in these models are related to the expected *optimism*, which is the expected difference between test error and training error. We provide an efficient Monte-Carlo method to estimate the degrees of freedom for multi-class classification methods. We show that the degrees of freedom is less than the parameter count in a simple XOR network. We extend these results to neural nets trained on synthetic and real data and investigate the impact of network's architecture and different regularization choices. The degrees of freedom in deep networks is dramatically less than the number of parameters. In some real datasets, the number of parameters is several orders of magnitude larger than the degrees of freedom. Further, we observe that for fixed number of parameters, deeper networks have less degrees of freedom exhibiting a regularization-by-depth. Finally, we show that the degrees of freedom of deep neural networks can be used in a model selection criterion. This criterion has comparable performance to cross-validation with lower computational cost.

1 INTRODUCTION

Model selection is one of the key tasks in machine learning, as method's performance on training data is an optimistic estimate of its general performance. Efron [2004] provided an estimate of optimism, difference of error on test and training data, and related it to a measure of model's complexity deemed effective degrees of freedom. This result reflects Occam's razor since models with higher degrees of freedom tends to have higher optimism. Degrees of freedom, defined as parameter counts, have been frequently used in model selection. However, even in linear models, the number of parameters are not a good indicator of model's complexity. Straightforward examples of this behavior are models fit using sparsity penalties. In that context, degrees of freedom are related to the number of non-zero parameters instead of total parameter count.

Ye [1998] introduced the concept of Generalized Degrees of freedom (GDF) for complex modeling procedures with Gaussian distributed outputs. GDF is defined based on the sensitivity of the fitted values to the perturbations in observed values. Efron [2004] provided a framework for estimating degrees of freedom for modeling procedures with output in exponential family distribution. In order to estimate degrees of freedom in deep neural networks for classification problems, where the outputs can be regarded as a categorical distribution, we extend Efron's results to the context of multinomial logistic regression. Similar to Ye's GDF, the computation of the degrees of freedom involves assessing network's changes in output as a result of perturbation of the training data. The more sensitive the network's output to the perturbation, the more degrees of freedom it has.

We provide a straightforward algorithm for evaluating the degrees of freedom for any modeling procedure with outputs in categorical distribution form. This algorithm requires an additional run of the modeling procedure on the perturbed data. In the worst case, this amounts to doubling the running time of the procedure. Using this algorithm we first analyze the complexity of XOR network. This simple example highlights the fact that the degrees of freedom in a neural net is not simply equal to the total number of parameters in the network.

In our experiments, we aim to answer following questions:

1. How does the network's complexity (DoF) vary with its architecture? Specifically, how do the degrees of freedom grow with the depth of a neural network?

2. How does regularization affect network's complexity? Specifically, what is the impact of dropout, weight decay, adding noise on the degrees of freedom?

We answer these questions in the context of feed-forward sigmoidal networks employed on classification tasks on both synthetic and real datasets.

The prior work on the model complexity is rich, and we briefly review some key contributions. Bayesian Information Criterion (BIC) [Schwarz et al., 1978] and Akaike Information Criterions (AIC) [Akaike, 1974] are most commonly used techniques for model selection. Both aim to construct an estimate of the test log-likelihood by correcting the training set log likelihood with terms dependent on the number of parameters in the model in order to produce a score that is a less biased estimate of test log-likelihood. The weighting of the parameter count is different, BIC depends on the sample size, and AIC uses a constant. BIC applied to the family of models that contain the true model is consistent in the limit of the data. AIC, with some mild constraints, guarantees the selection of model with least square error, among models that do not include the true model. Crucial to the practical application of these methods is the correct count of parameters. Bayesian model selection elegantly avoids the need to specify the complexity of the network by evaluating evidence, a marginal probability of the data given the model. This approach marginalizes over all of the parameters, making models of different parameterizations comparable. The size of the parameter space directly impacts the evidence through this integration, as the prior on parameters gets spread thinly across high dimensional spaces. Unfortunately, the cost of computing such integrals is often prohibitive, but the models selected using these techniques have been shown to be very competitive. [MacKay, 2003, Neal, 1996, Guyon et al., 2004]. Kolmogorov-Chaitin complexity [Kolmogorov, 1965] describes dataset complexity in terms of a program that recapitulates the data. Generation of task-specific neural networks using algorithmically simple programs was explored by Schmidhuber [1997]. Networks whose parameters could not be captured by a simple program were avoided. A related method of Minimal Description Length reflects the desire for compact representation of the data. Its application [Hinton and Zemel, 1994] shows how the trade-off between the data and parameter compression can lead to an objective for training auto-encoders. Degrees of freedom of linear models fit with Lasso-type penalties have been analyzed, e.g. Lasso [Zou et al., 2007], Fused Lasso [Tibshirani et al., 2005] and Group Lasso [Vaiter et al., 2012]. The number of predictors and the number of degrees of freedom greatly differ due to the imposed sparsity and weight tying. Recent results on degrees of freedom for non-continuous procedures such as best subset regression and forward stagewise regression [Janson et al., 2015] highlight challenges in determining the complexity of these procedures as the estimators can be discontinuous. Research on Stein's Unbiased Risk Estimate has yielded model selection techniques [Stein, 1981] as well as algorithms for their estimation [Ye, 1998, Ramani et al., 2008]. Generalization of SURE to exponential families has been proposed by Eldar [2009]. However, its focus is on estimating parameter risk instead of prediction error. In linear models, the two neatly coincide. But this does not carry over to logistic regression and more broadly sigmoidal neural networks.

2 DEGREES OF FREEDOM FOR CATEGORICAL DISTRIBUTION

In this section, we derive the definition of degrees of freedom for categorical distribution from the optimism according to Efron [2004]. Then, we introduce an efficient Monte-Carlo sampling based method [Ramani et al., 2008] to estimate degrees of freedom.

2.1 DEFINITIONS

We focus on models aimed at multi-class classification task. The data is assumed to be composed of features $\mathbf{X} \in \mathbb{R}^{n \times p}$, and output labels $\mathbf{y}$ range over k categories. We will denote categorical distribution with $\mathcal{C}(\cdot)$. Categorical distribution over k categories can be parameterized using a vector of non-negative values with a sum of 1. We treat sample label y_i as realization of categorical random variables for a specific parameter vector $\boldsymbol{\mu}_i$. Hence $y_i \sim \mathcal{C}(\boldsymbol{\mu}_i)$, where $\boldsymbol{\mu}_i = [\mu_{i1}, \mu_{i2}, \ldots, \mu_{ik}]$ is the **true probability** of sample y_i being in each class. $\mu_{ic} \in [0, 1]$ and $\sum_{c=1}^{k} \mu_{ic} = 1$. Members of exponential family follow form:

$$f(\mathbf{p}_i|\boldsymbol{\mu}_i) = r(\mathbf{p}_i) \exp\{\boldsymbol{\theta}(\boldsymbol{\mu}_i)^T \mathbf{p}_i - A(\boldsymbol{\mu}_i)\}$$

where $\mathbf{p}_i$ is the vector of sufficient statistics for sample i, $\boldsymbol{\theta}(\boldsymbol{\mu}_i)$ is the vector of natural parameters, $r(\mathbf{p}_i)$ is the base measure, $A(\boldsymbol{\mu}_i)$ is the log-partition function.

For categorical distribution with parameter $\boldsymbol{\mu}_i$, we have $\mathbf{p}_i = h(y_i) = [\delta(y_i - 1), \ldots, \delta(y_i - k - 1)]^T$, where $\delta(\cdot)$ is the Kronecker delta function, $\delta(a) = 1$ if $a = 0$, $\delta(a) = 0$ if $a \neq 0$. In other words, $\mathbf{p}_i$ is a vector of the **observations** of sample i being in each class. Base measure is $r(\mathbf{p}_i) = 1$; natural parameters are $\theta_c(\boldsymbol{\mu}_i) = \ln \mu_{ic} - \ln(1 - \sum_{l=1}^{k-1} \mu_{il})$, and log partition function $A(\boldsymbol{\mu}_i) = \ln(1 + \sum_{c=1}^{k-1} e^{\theta_c(\boldsymbol{\mu}_i)})$. Note that both $\boldsymbol{\mu}_i$ and $\mathbf{p}_i$ are of dimension $k - 1$. Let $\mathbf{P} = [\mathbf{p}_1, \ldots, \mathbf{p}_n]^T$ be the matrix of observations for all sample labels $y_1, \ldots, y_n$.

2.2 OPTIMISM IN MODELS WITH CATEGORICAL DISTRIBUTION

Optimism is the difference between expected test log deviance error and training log deviance error for a model fitting procedure. It is related to the complexity of the model and degrees of freedom is derived from optimism. If the optimism for a modeling procedure can be estimated, we

can use it for model selection. Efron [2004] provides the derivations of expected optimism for the single parameter exponential family. We follow Efron's approach to derive the definition of degrees of freedom for modeling procedure with output in categorical distribution form.

Given sample input $\mathbf{x}_i$, we assume that the output label $y_i \sim \mathcal{C}(\boldsymbol{\mu}_i)$. Let $\hat{\boldsymbol{\mu}}_i = \mathcal{L}(\mathbf{p}_i)$ be the **estimated probability** for sample i from observations $\mathbf{p}_i$. The log deviance error for $\hat{\boldsymbol{\mu}}_i$ and $\mathbf{p}_i$ is:

$$\begin{aligned} \text{err}_i &= -2\log f(\mathbf{p}_i|\hat{\boldsymbol{\mu}}_i^T) \\ &= -2[\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i)^T\mathbf{p}_i - A(\hat{\boldsymbol{\mu}}_i)] \end{aligned}$$

Suppose we have another sample y_i^0 drawn from the same distribution as y_i, $y_i^0 \sim \mathcal{C}(\mu_i)$. Let $\mathbf{q}_i = h(y_i^0)$ be the vector of its observations. The expected log deviance error of $\mathbf{q}_i$ using $\hat{\boldsymbol{\mu}}_i$ is:

$$\begin{aligned} \text{Err}_i &= E_{y_i^0}\{-2\log f(\mathbf{q}_i|\hat{\boldsymbol{\mu}}_i)\} \\ &= -2[\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i)^T\boldsymbol{\mu}_i + A(\hat{\boldsymbol{\mu}}_i)] \end{aligned}$$

The definition of optimism is:

$$\begin{aligned} O_i &= \text{Err}_i - \text{err}_i \\ &= 2\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i)^T(\mathbf{p}_i - \boldsymbol{\mu}_i) \end{aligned}$$

Hence, optimism is the difference between log deviance error on the training set and expected log deviance error with respect to the true distribution.

The expected optimism over $y_i \sim \mathcal{C}(\boldsymbol{\mu}_i)$ for the estimated probability $\hat{\boldsymbol{\mu}}_i$ and true probability $\boldsymbol{\mu}_i$ is:

$$\Omega_i = 2E_{y_i}\{\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i)^T(\mathbf{p}_i - \boldsymbol{\mu}_i).\}$$

As we do not know the true probability $\boldsymbol{\mu}_i$, we cannot compute the expected optimism. However, we can get an approximate measurement using Taylor series expansion. We can approximate $\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i)$ by taking the Taylor series expansion at $\mathbf{p}_i = \boldsymbol{\mu}_i$ to obtain:

$$\boldsymbol{\theta}(\hat{\boldsymbol{\mu}}_i) \approx \boldsymbol{\theta}(\mathcal{L}(\boldsymbol{\mu}_i)) + \mathbf{D}^{(i)}(\mathbf{p}_i - \boldsymbol{\mu}_i).$$

$\mathbf{D}^{(i)}$ is the first derivative matrix where each entry $D_{jc}^{(i)} = \frac{\partial\theta_j(\mathcal{L}(\mathbf{v}))}{\partial v_c}|_{\mathbf{v}=\boldsymbol{\mu}_i}$.

Therefore, we can approximate expected optimism as:

$$\begin{aligned} \tilde{\Omega}_i &= 2E_{y_i}\{[\boldsymbol{\theta}(\mathcal{L}(\boldsymbol{\mu}_i)) + \mathbf{D}^{(i)}(\mathbf{p}_i - \boldsymbol{\mu}_i)]^T(\mathbf{p}_i - \boldsymbol{\mu}_i)\} \\ &= 2E_{y_i}\{\sum_{j=1}^{k-1}\sum_{l=1}^{k-1}(p_{ij} - \mu_{ij})(p_{il} - \mu_{il})D_{jl}^{(i)}\} \\ &= 2\sum_{j=1}^{k-1}\sum_{l=1}^{k-1}\text{cov}(p_{ij}, p_{il})\frac{\partial\theta_j(\mathcal{L}(\mathbf{v}))}{\partial v_l}|_{\mathbf{v}=\boldsymbol{\mu}_i} \end{aligned}$$

We can estimate the expected optimism by assuming $p_i \sim \mathcal{C}(\hat{\boldsymbol{\mu}}_i)$, so:

$$\hat{\Omega}_i = 2\sum_{j=1}^{k-1}\sum_{l=1}^{k-1}\text{cov}(p_{ij}, p_{il})\frac{\partial\theta_j(\mathcal{L}(\mathbf{v}))}{\partial v_l}|_{\mathbf{v}=\hat{\boldsymbol{\mu}}_i}. \quad (1)$$

In categorical distribution, $\text{cov}(p_{ij}, p_{il}) = -\hat{\mu}_{ij}\hat{\mu}_{il}$, if $i \neq j$. $\text{var}(p_{ij}) = \hat{\mu}_{ij}(1 - \hat{\mu}_{ij})$. Therefore, Equation (1) can be reduced to:

$$\hat{\Omega}_i = 2\sum_{j=1}^{k-1}\frac{\partial\mathcal{L}_j(\mathbf{v})}{\partial v_j}|_{\mathbf{v}=\hat{\boldsymbol{\mu}}_i}. \quad (2)$$

The proof is given in the supplementary material.

Equation (2) for $k = 2$ is exactly the result for Bernoulli distribution derived in [Efron, 2004]. Efron also showed that Eqn (2) gives the correct degrees of freedom for maximum likelihood estimation [Efron, 1975]. In a p-parameter curved exponential family, we have:

$$\sum_{i=1}^{n}\frac{\partial\mathcal{L}(\mathbf{v})}{\partial v_i}|_{\mathbf{v}=\hat{\boldsymbol{\mu}}_i} = p.$$

Here, we define the degrees of freedom for a classification model estimator $\hat{\boldsymbol{\mu}}_i = \mathcal{L}_i(\mathbf{P})$ on all the data samples $\mathbf{P}$ to be:

$$\text{df} = \sum_{i=1}^{n}\sum_{c=1}^{k-1}\frac{\partial\mathcal{L}_{ic}(\mathbf{P})}{\partial p_{ic}}. \quad (3)$$

This definition tells that the degrees of freedom is the sum of each sample's sensitivity of its estimated probability to the perturbations in its observation for all categories.

2.3 DEGREES OF FREEDOM FOR MODEL SELECTION

As degrees of freedom is related to the expected optimism, we can use degrees of freedom for model selection. According to Equation (2) and (3), the relationship between expected test and training log deviance errors is:

$$\sum_{i=1}^{n}E_{y_i}\{\text{Err}_i\} = \sum_{i=1}^{n}E_{y_i}\{\text{err}_i\} + 2\text{df}. \quad (4)$$

Euqation (4) is very similar to Akaike Information Criterions (AIC) Akaike [1974]:

$$\text{AIC} = \sum_{i=1}^{n}\text{err}_i + 2k, \quad (5)$$

where k is the number of parameters. We refer to 2df in Equation (4) and $2k$ in Equation (5) as "complexity correction" for training log deviance error. In simple linear

regression models, df $= k$, and the complexity corrections are the same. However, in complex models such as deep neural networks, simply counting number of parameters can result in overestimate of the expected test log deviance error. Therefore, we introduce DoFAIC for model selection:

$$\text{DoFAIC} = \sum_{i=1}^{n} \text{err}_i + 2\text{df}. \tag{6}$$

DoFAIC uses degrees of freedom instead of the number of parameters for complexity correction. We assume that DoFAIC can produce a better criterion for model selection than Naïve AIC.

2.4 MONTE-CARLO ESTIMATE FOR DEGREES OF FREEDOM

For most practical estimators of the model's predictions with respect to the data derivatives, $\frac{\partial \mathcal{L}_{ic}(\mathbf{P})}{\partial p_{ic}}$ are not available in closed form. For example, fitting multinomial logistic regression using stochastic gradient descent with adaptive learning rates requires a fairly sophisticated derivation which accounts for changes in step-sizes as a result of data perturbation. For deep neural networks, this difficulty grows due to the use of back-propagation. In this paper, we used a sampling based method to efficiently estimate

Monte-Carlo estimation A theoretical result for a stochastic estimate of the degrees of freedom of nonlinear estimators has been proposed by Ramani et al. [2008]. We restate the key result from that paper here.

Theorem 1. *Let* $\mathbf{b}$ *be a zero mean i.i.d. random vector (that is independent of* $\mathbf{y}$*) with unit variance and bounded higher moments. Then*

$$\sum_i \frac{\partial f(\mathbf{y})}{\partial y_i} = \lim_{\epsilon \to 0} E_{\mathbf{b}} \left[\mathbf{b}^T \left(\frac{f(\mathbf{y} + \epsilon \mathbf{b}) - f(\mathbf{y})}{\epsilon} \right) \right]$$

provided that f *admits a well-defined second-order Taylor expansion.*

We sketch out a proof that the prediction in a neural net via forward pass is a smooth function of the observations of training labels. We will abbreviate "differentiable with respect to observations" as d.w.r.t.o. Sigmoid and soft-max are smooth functions of their inputs. The cross-entropy loss is a multivariate function that depends on data and weights, and all of its partial derivatives exist. For simplicity, we assume that the network is trained using gradient descent. Each update of the network's parameters is a linear combination of previous weights and a gradient of the loss. Assuming that the initial weights d.w.r.t.o. and loss is smooth then the update yields weights that are d.w.r.t.o. Random initialization and pre-training both yield initializations that are independent of observations, hence the partial derivatives of the initial weights with respect to observations are 0. By induction, gradient descent, at any iteration, yields weights that are d.w.r.t.o. Forward pass through sigmoidal network yields estimated probabilities which are smooth with respect to observations. Thus, the Taylor expansion required by the above theorem exists.

Algorithm 1 Monte Carlo algorithm for computing degrees of freedom of a multi-class classifier

Input: training data $\mathbf{X} \in \mathbf{R}^{n \times p}$, $\mathbf{y} \in \{1, 2, .., k\}^n$

1: Compute observations matrix $\mathbf{P} = h(\mathbf{y})$
2: Train model on $\mathbf{X}$ and $\mathbf{P}$
3: Compute estimated probabilities for each sample $\mathcal{L}(\mathbf{P})$
4: Sample entries of $\mathbf{B}^{(t)} \in \mathbf{R}^{p \times k}$ from zero-mean, unit variance normal distribution
5: Train model on $\mathbf{X}$ and $\mathbf{P}^{(t)} = \mathbf{P} + \epsilon \mathbf{B}^{(t)}$
6: Using trained model compute estimated probabilities for each sample $\mathcal{L}(\mathbf{P}^{(t)})$;
7: Repeat 4-6 for T times;
8: Calculate df from Equation (7)

Using this theorem, we can evaluate the derivative of a function $\frac{\partial f(x)}{\partial x}$ by perturbing the inputs. We applied a modified version of the method [Ramani et al., 2008] for categorical distribution. We applied random perturbation to the observations to estimate the degrees of freedom:

$$\begin{aligned} \text{df} &= \textstyle\sum_{i=1}^{n} \sum_{c=1}^{k-1} \frac{\partial \mathcal{L}_{ic}(\mathbf{P})}{\partial p_{ic}} \\ &= \lim_{\epsilon \to 0} \left\{ E_{\mathbf{B}} \left[\textstyle\sum_i \sum_c b_{ic} \left(\frac{\mathcal{L}_{ic}(\mathbf{P} + \epsilon \mathbf{B}) - \mathcal{L}_{ic}(\mathbf{P})}{\epsilon} \right) \right] \right\}, \end{aligned}$$

where $\mathbf{B}$ is a zero-mean i.i.d. random matrix with unit variance and bounded higher order moments. Therefore, we can approximate df with T independent samplings of $\mathbf{B}^{(t)}$:

$$df \approx \frac{1}{T} \sum_{t=1}^{T} \sum_{i=1}^{n} \sum_{c=1}^{k-1} b_{ic}^{(t)} \left(\frac{\mathcal{L}_{ic}(\mathbf{P} + \epsilon \mathbf{B}^{(t)}) - \mathcal{L}_{ic}(\mathbf{P})}{\epsilon} \right), \tag{7}$$

where ϵ is a small value. In our experiments, we choose $\epsilon = 10^{-5}$. To better estimate the sensitivity, we can use the average of multiple runs as the final estimation. The algorithm for estimating degrees of freedom is summarized in Algorithm 1.

Note that training on original and perturbed observations matrix can be performed in parallel. Finally, we also derived analytical derivatives for stochastic gradient descent learning which yields the same degrees of freedom as the algorithm presented above. However, this method requires maintenance of partial derivatives of each parameter with respect to each sample's observations. Such storage requirements make this method impractical for real world applications.

Variance reduction For deep neural networks, training takes a considerable amount of time. In order to estimate

degrees of freedom in a reasonable computational time, we used a variance reduction technique – common random numbers – during Monte-Carlo sampling. When comparing the degrees of freedom on a specific data, fixed $\mathbf{P}$, for several different fitting procedures, we used the same perturbation matrix $\mathbf{B}$ for all the models. We used the same random seed for all models throughout the training. For example, in deep neural network training, we use the same random seed to initialize weights and bias; during pre-training with denoising-autoencoders, we use the same random seed for drop-out and input corruptions. For stochastic gradient descent methods, we use the same mini-batches splittings during training. In our experiment, we found that we can estimate degrees of freedom well enough using just one perturbed copy of the data when using these variance reduction techniques.

2.5 DEGREES OF FREEDOM IN MULTINOMIAL LOGISTIC REGRESSION

In order to validate the above algorithm in a setting with known degrees of freedom, we perform an empirical analysis of the degrees of freedom in different multinomial logistic regression models.

We generate an i.i.d. zero mean unit variance random design matrix $\mathbf{X}$ with $n = 100$ samples and $p = 20$ features. We represent each sample with $\mathbf{x}_i = [x_{i1}, x_{i2}, \ldots, x_{ip}]$. With $k = 4$ class, we generated a random weight matrix $\mathbf{W} \in \mathbb{R}^{p\times k}$, where each entry $w_{ic} \sim \mathcal{N}(0, 1)$. We generate each label from $y_i = \text{argmax}_j\, \mu_{ij}$, where $\boldsymbol{\mu}_i = e^{\mathbf{x}_i\mathbf{W}}$.

We fit 5 models using multinomial logistic regression. In ith model, we only use first $2i$ features in $\mathbf{X}$ to fit. Therefore, ith model only contains $2(i + 1)(k - 1)$ parameters and the degrees of freedom are equal to the number of parameters. We perform 5 Monte-Carlo degrees of freedom estimates for each model.

We plot degrees of freedom in Figure 1(a). We observed that degrees of freedom are very close to the number of parameters we used in the model. The standard error for Monte-Carlo estimate is small.

We also randomly generated 1000 samples for testing. Optimism is calculated by the difference between average testing log deviance error and training log deviance error. We plot the degrees of freedom and optimisms for all 5 models in Figure 1(b). It shows that the optimism has a linear relationship with degrees of freedom, as expected.

2.6 DEGREES OF FREEDOM OF A XOR NETWORK

We generated a small synthetic example using exclusive-or (XOR) operator, where $\text{XOR}(a, b) = 0$ if $a = b$, and $\text{XOR}(a, b) = 1$ if $a \neq b$. Given an input $x_1, x_2 \in \{0, 1\}$, the output $y = XOR(x_1, x_2)$, we hope to learn a model of

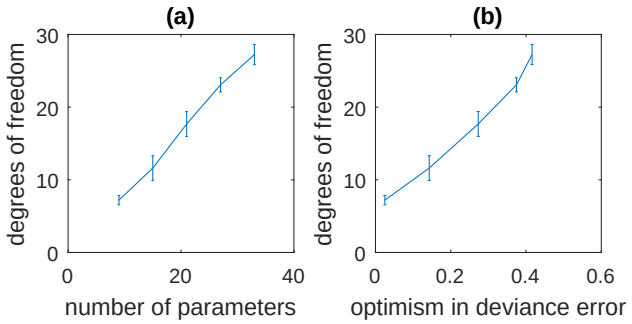

Figure 1: **(a)** Comparison between degrees of freedom estimates in multinomial logsitic regression and the true number of parameters used in the model. **(a)** Comparison between degrees of freedom estimates in multinomial logsitic regression and the optimism in log deviance error. In each plot, blue line is the mean of the five Monte-Carlo estimates. Error bar represents the standard error.

XOR operator. In general, we can build a neural network with two hidden nodes as shown in Figure 2 and weights in Table 1 to learn a perfect XOR classifier.

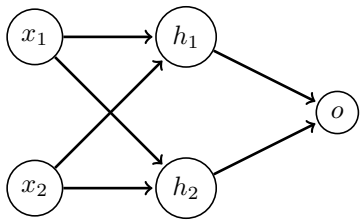

Figure 2: A Neural Network with 2 Hidden Nodes

Table 1: An XOR Network

x_1	0	1	0	1
x_2	0	0	1	1
$h_1 = \sigma(F(-0.5 + x_1 - x_2))$	0	1	0	0
$h_2 = \sigma(F(-0.5 - x_1 + x_2))$	0	0	1	0
$y = \sigma(K(-0.5 + h_1 + h_2))$	0	1	1	0

A network that trained properly should have weight matrix with form in Table 1. If x contains no noise, F, a multiplier, can be infinitely large to achieve perfect estimation. Therefore, we set y to be 0.9 instead of 1.

We train networks with different structures on XOR data using back-propagation and estimate their degrees of freedom using Monte-Carlo method. Even though there are 9 parameters in the network, we found that the degrees of freedom for all learned models is 4. We note that the symmetry in weights of the inputs to the two hidden nodes, eliminates degrees of freedom, as does implicit tying of the weights of inputs to the output node. To give an intuition

why this tying occurs, we note that the predominantly correctly labeled data drives the network to keep the weights close to each other. Hence, a small perturbation in the labels can affect multiple weights simultaneously, but does not disturb their balance. This observation encourages us to investigate deeper models.

3 DEGREES OF FREEDOM IN DEEP NEURAL NETWORKS

In this section, we investigate degrees of freedom in deep neural network models. From the XOR example, we know that the degrees of freedom in a network is not equal the number of parameters in the model. The structure of the network and different regularization techniques will impact degrees of freedom.

3.1 TERMINOLOGIES AND SETTINGS

In the following experiments, we explore deep networks trained to solve larger classification problems. Each of the networks takes real value vector $\mathbf{x}_i \in \mathbb{R}^{p\times 1}$ as input and outputs the probability $\hat{\boldsymbol{\mu}}_i$ for this sample being in one of k categories. We use sigmoid activation function for all the hidden nodes and a soft-max in the last layer. The number of hidden layers is called "**depth**" of the network. We only consider networks with an equal number of units in each hidden layer, and we call this number "**width**" of the network. Next, we investigate degrees of freedom in networks with different width and depth.

Stacked-Auto-Encoder (SdA) pre-training We used SdA [Vincent et al., 2010] to pre-train the neural network with input dataset, as unsupervised pre-training helps the network to achieve a better generalization from the training data on supervised tasks [Erhan et al., 2010]. In denoising auto-encoder, **corruption** is used in layer-wised pre-training. The corruption is introduced by zeroing out input to the auto-encoder with a certain probability. The chosen probability of corruption is called **corruption rate**. **Dropout** [Srivastava et al., 2014] is also used during the pre-training of SdA, where output of hidden units are randomly zeroed with probability, which is called **dropout rate**. We assume that increasing in corruption rate or dropout rate will reduce degrees of freedom as they provide more regularization to the network.

Weight-decay We used a weight decay penalty on the sum of the squares of all the weights in the network during both pre-training and fine-tuning stage. Adding this penalty prevents the network from over-fitting. We refer to the multiplier associated with the sum of squares as **weight decay rate**. We expect to see that the degrees of freedom drops with increasing weight decay rate.

Implementation All our code are based on Theano [Bastien et al., 2012, Bergstra et al., 2010] and we ran experiments on a cluster of machines with NVIDIA Tesla compute cards.

3.2 DATA SETS

We prepared a synthetic dataset and two real datasets MNIST and CIFAR-10 to estimate degrees of freedom.

Synthetic We build a synthetic dataset from a randomly generated network with 30 input nodes, 2 hidden layers with 30 hidden nodes in each, and 4 output nodes. We generated $n = 5000$ random zero-mean unit variance inputs with 30 dimensions. Each layer was fully connected to the previous layer, and we generated weights $w \sim \mathcal{N}(0, 5)$. We used sigmoid activation function for each layer and a soft-max on top of the network. The output sample labels y are then sampled according to the probabilities from the soft-max layer. To get the optimism, we also generated another 5000 samples for test.

MNIST [1] [LeCun et al., 1998] is a benchmark dataset that contains handwritten digit images. Each sample is a 28×28 image from 10 classes. We used 50000 samples for training.

CIFAR-10 [2] [Krizhevsky and Hinton, 2009] is a dataset contains 32×32 tiny color images from 10 classes. Each sample has 3072 features. We used 50000 samples for training.

3.3 DEGREES OF FREEDOM AND THE STRUCTURE OF THE NETWORK

To investigate the degrees of freedom for networks with different structures, we estimated the degrees of freedom for networks with width $[10, 20, \ldots, 100]$ and depth with 1,2,3 and 4, where all the hidden layers have equal widths. We used SdA to pre-train with 0.1 dropout rate and 0.1 corruption rate. We use weight decay penalty $1e-5$ for both pre-training and fine-tuning. The estimated degrees of freedom is shown in Figure 3.

From the results, we found that networks with more width have more degrees of freedom. This is reasonable as increasing width leads to more independence between parameters. However, the degrees of freedom in deep networks is generally much less than the number of parameters it used. We see that the ratio of the parameters to degrees of freedom is on the order of 10^2. Loosely, one degree of freedom is acquired for 100 parameters. Among the models with the same number of parameters, deeper networks have

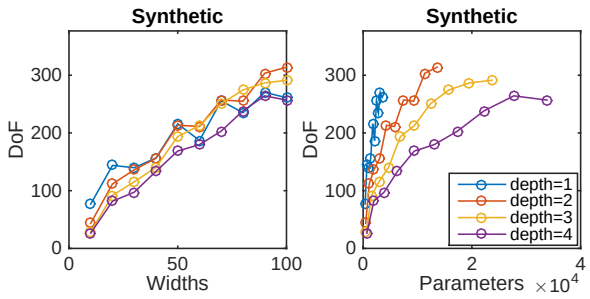

Figure 3: Degrees of freedom estimates for different models trained on synthetic data. Left: degrees of freedom vs network width. Right: degrees of freedom vs number of parameters in the network, which is linearly related to the network depth and quadratically related to the number of width. The line represent the degrees of freedom estimate from 1 Monte-Carlo run, and the color of each indicates the depth of the models.

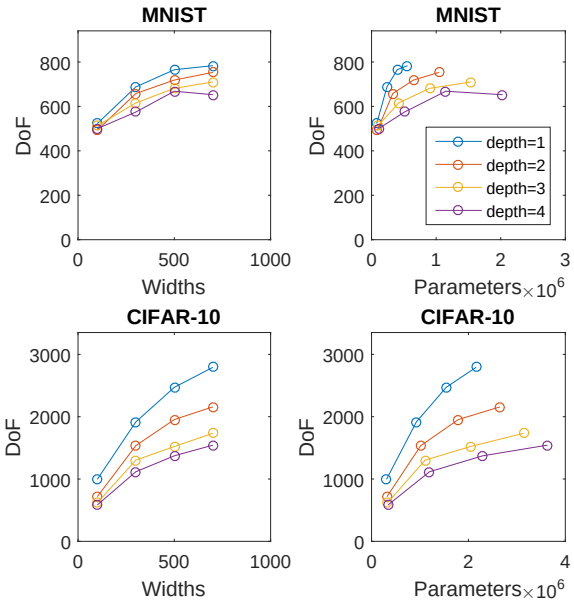

Figure 4: Degrees of freedom estimates for different models trained on MNIST and CIFAR-10. Left: degrees of freedom vs network width. Right: degrees of freedom vs the number of parameters in the network, which is linearly related to the network depth and quadratically related to the number of widths. The lines represent the degrees of freedom estimate from single Monte-Carlo sample and the color of each indicates the depth of that model.

less degrees of freedom. This observation indicates that the depth of the network has regularization on the complexity.

To further validate our assumption that deeper networks have less degrees of freedom, we also estimated degrees of freedom on MNIST and CIFAR-10 dataset. We tested networks with width $[100, 300, 500, 700]$, all other settings are the same as in the above synthetic experiment. The results are shown in Figure 4.

We observe that we can make the same conclusions hold for MNIST and CIFAR-10 as we did for synthetic data. The only difference is increasing depth results in more degrees of freedom than models trained with synthetic data. We attribute this to the differences of input data size and complexity between the real datasets, MNIST and CIFAR-10, and the much simpler synthetic datasets.

3.4 DEGREES OF FREEDOM AND REGULARIZATION TECHNIQUES

When training a deep neural network, many practical methods can be used for regularization. We investigate how the different techniques affect the degrees of freedom in the model.

We train networks using the same settings as in Section 3.3. In this experiment, we separately trained networks with different settings of penalty rates: corruption rate, dropout rate, and weight decay rate. We changed one rate at a time while keeping rest fixed.

tested the corruption rate, dropout rate, and weight decay penalty by keeping all others fixed and only changing one at a time.

For all three datasets, we trained network using corruption rate and dropout rate from $[0, 0.1, 0.2, \ldots, 0.9]$, and weight decay rate from 10^{-6} to 10^{-3}. For each setting of regularization parameters, we trained a 3 layer network $[30, 30, 30]$ for synthetic data and $[300, 300, 300]$ on MNIST and CIFAR-10 data. We used one Monte Carlo sample to estimate degrees of freedom in each model. The result is shown in Figure 5.

We found that neither corruption rate nor dropout rate affected degrees of freedom drastically for synthetic data. This is because the input of the synthetic data is generated randomly. Hence, pre-training cannot learn higher level features for synthetic data. For MNIST and CIFAR-10, we found that both corruption rate and dropout rate have an impact on degrees of freedom . In CIFAR-10, the regularization effect is much larger. These results suggest that the regularization strength from dropout and corruption can be data-specific.

Weight decay penalty has a very strong effect on the degrees of freedom for all three datasets. Further, the weight decay exhibited a highly non-linear impact on the degrees of freedom, in dramatic contrast to its effect in ridge regression.[3]

[3]Ridge regression degrees of freedom scale with $\frac{1}{1+\lambda}$ which is non-linear but much tamer multiplier than in neural networks

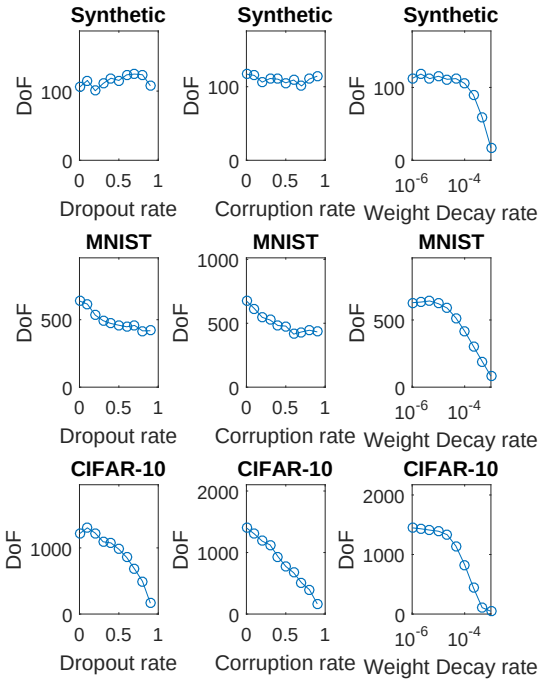

Figure 5: Degrees of freedom estimates for models trained on Synthetic data, MNIST and CIFAR-10 under different regularizations. The lines represent the degrees of freedom estimate.

3.5 MODEL SELECTION USING DEGREES OF FREEDOM

To validate that DoFAIC is a useful criterion for model selection, we compare it against model selection based on error estimates using cross validation. For brevity, we refer to the cross validation estimate of error as cross validation error. We performed a 5-fold cross-validation experiment for Synthetic, MNIST and CIFAR data on models with different network structures learned in Section 3.3. We calculated DoFAICs for all the models we trained using Equation (6) with the estimated degrees of freedom. We also calculated Naïve AIC using Equation (5) with the number of parameters in the network. We compared these estimates against cross-validation errors. The result is shown in Figure 6.

Further, we calculate the Spearman rank correlation between cross-validation log deviance errors and DoFAIC/Naïve AIC estimates for each dataset. The result is shown in Table 2.

We find that DoFAIC is very consistent with cross-validation error. Naïve AIC, on the other hand, exhibits negative correlation with cross validation error due to highly non-linear behavior. This is because Naïve AIC

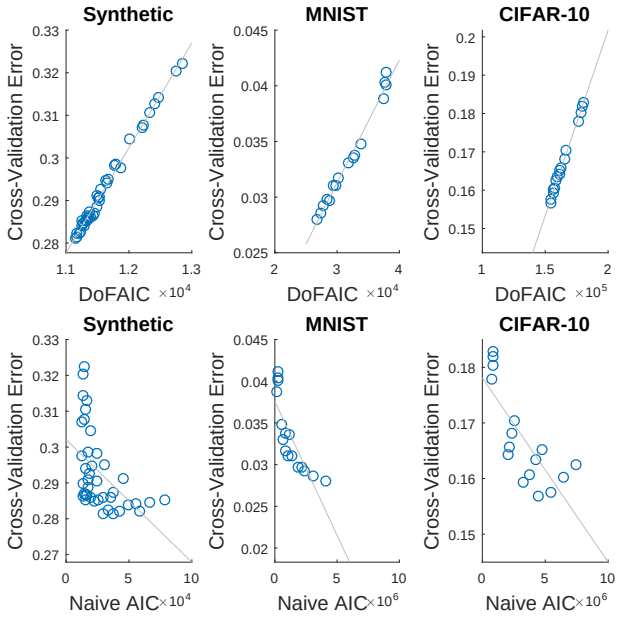

Figure 6: Comparison between DoFAIC (first row) / Naïve AIC (second row) and 5-fold cross validation. Each circle in the plot represents a model with a specific structure. The x-axis is the mean cross-validation log deviance error across 5 folds.

Table 2: Spearman Rank Correlation between Cross-validation error and DoFAIC/Naïve AIC

Dataset	DoFAIC ρ	Naïve AIC ρ
Synthetic	0.9865	-0.6711
MNIST	0.9853	-0.9471
CIFAR-10	0.9941	-0.7824

overestimates the complexity of the model by using the large number of parameters in the network. The actual complexity in deeper and larger networks are much less than the number of parameters.

For all three datasets, both DoFAIC and cross-validation chose the same model. This indicates that DoFAIC can be used for model selection. We note that k-fold cross-validation, which needs at most k rounds of training, while DoFAIC only requires at most 2 rounds of training. This makes DoFAIC an efficient model selection criterion.

4 DISCUSSION

In this paper, we investigated the degrees of freedom for classification models and presented an efficient method to estimate their degrees of freedom. We showed that for simple classification models, degrees of freedom is equal to the number of parameters in the model. In deep networks, the

degrees of freedom is generally much less than the number of parameters in the model, and deeper networks tend to have less degrees of freedom. We also theoretically and empirically showed we can use DoFAIC as an efficient criterion for model selection, which has comparable performance to cross-validation.

Future work It would be interesting to investigate degrees of freedom in other deep architectures, such as Convolution Neural Network (CNN), Recurrent Neural Networks (RNN), denoising auto-encoders and contractive auto-encoders.

Training Deep Neural Nets to Aggregate Crowdsourced Responses

Abstract

We propose a new method for aggregating crowdsourced responses, based on a deep neural network. Once trained, the aggregator network gets as input the responses of multiple participants to the same set of questions, and outputs its prediction for the correct response to each question. We empirically evaluate our approach on a dataset of responses to a standard IQ questionnaire, and show it outperforms existing state-of-the-art methods.

1 INTRODUCTION

Crowdsourcing platforms such as Amazon's Mechanical Turk are marketplaces which bring together participants who wish to take part in small micro-tasks in return for a fee and businesses or individuals who want to employ people for such tasks. A common use-case is data annotation and labelling, such as determining whether a caption correctly describes an image, or deciding whether the sentiment expressed in a text is positive, neutral or negative. Annotators may not always produce the correct responses to the questions posed to them. This might happen for several reasons: they may lack the sufficient knowledge to accurately answer every question or they might not be exerting the required effort to do well on a task. As annotators are not completely reliable in producing the correct responses to the posed questions, the resulting set of annotations would include errors, which results in an *inherent uncertainty* regarding which answers are correct. One instrument that can reduce the number of such errors is using *redundancy*: rather than asking a single participant to answer a question, the same question is posed to multiple participants; the multiple responses to the same question can then be *aggregated* into a single response to the question.

A commonly used aggregator is "majority vote", in which the chosen answer to each question is the one given most frequently by the participants. [1] This form of collective decision making has been heavily investigated. A result from the 18th century by the Marquis de Condorcet [5] states that the probability of majority vote to reach the correct conclusion to a question with two possible answers approaches 1 as the number of aggregated participants approaches infinity, assuming that participants are independent and each has a probability $p > \frac{1}{2}$ to provide the correct answer. [2]

Using crowdsourcing marketplaces it is possible to gather the responses of many participants to many questions in a very short time frame. Thus, such services make it easy to harness the collective intelligence of many participants. Given a set of responses of multiple participants to the same questions, one can use majority vote to get the aggregate responses to all the questions. However, this simple aggregator may be suboptimal, as some annotators produce higher quality results than others. For instance, if we know that the annotator Alice is more reliable than Bob, we might give her responses more weight when computing the aggregate solution. One way to determine the ability of annotators to provide correct responses is to evaluate each participant on a "gold-set" of questions, for which the correct answer is known. Given information about the ability of annotators evaluated on the gold-set, one can better aggregate the responses to a set of questions for which the correct answer is not known. However, what can be done to better aggregate responses in the absence of such a gold-set?

Earlier work has uncovered aggregation algorithms that outperform the majority vote aggregator, and that do not use external information such as a gold-set. Many such techniques are based on Bayesian models, that jointly infer information about the relative abilities and biases of participants, the difficulty levels of questions and the correct answer to each question [23, 2, 21]. As these techniques are Bayesian, they rely on a statistical model of the process through which the data was generated, reflecting model-

[1] The field of social choice refers to this aggregator as "plurality voting".

[2] The majority aggregator has also been shown to perform well in practice in multiple domains [22, 1, 10].

ing assumptions regarding the domain. Such assumptions are captured as random variables and the relation between them, consisting of the observed data and a set of assumed latent (unobserved) variables, along with a joint probability model tying the variables. While such techniques have been shown to be powerful tools for aggregating crowdsourced responses, their performance can be hindered when the modeling assumptions are incorrect or inaccurate – especially in the absence of large amounts of data.

Our contribution:

We propose a novel approach for aggregating crowdsourced responses. As opposed to existing Bayesian algorithms, at the heart of our approach lies a deep neural network, rather than a carefully engineered statistical model encoding an assumed relation between observed variables and possible latent factors. The network is trained by taking a small **seed dataset** of responses of participants to questions to which the correct answers are known. However, as opposed to the gold-set approach, we *only use the seed dataset to train the aggregator network*. Once the network is trained, we evaluate its ability to aggregate responses on a *completely separate* dataset, of both participants and questions the aggregator *has not encountered in the past*. Our training procedure involves using the small seed dataset to synthetically create a large training dataset, reflecting certain desiderata for aggregator functions.

We empirically evaluate our approach on a dataset of responses to a standard IQ questionnaire, and show it has a superior performance over existing methods. We examine the relation between the quantity of data available to our aggregator and its performance. Finally, we explore ways in which the network can infer not only the correct answers but also who the strong annotators are.

2 RELATED WORK

Earlier work in machine learning and artificial intelligence examined methods for merging the opinions of multiple people or agents, covering various aspects such as prediction markets [12] for predicting a future random event, aggregation of information in semantic web platforms [9], hybrid probabilistic relational frameworks [7] which combine logic based representations and probabilistic inference, and information aggregation in peer assessment systems [13].

A domain of particular interest is collective decision making and voting over candidate alternatives. Social choice theory focused on a set of rational agents, each of which has a preference order over the same set of candidates, and examined voting schemes which aggregate these preferences into a single aggregate decision [20] (such as who is the chosen candidate who wins the elections). Social choice theory shows how voting mechanisms allow reaching good group decisions [11], but has also uncovered ways in which voting rules are susceptible to manipulations by voters, who may lie about their true preferences so that the voting rule chooses an alternative their prefer [8]. We assume that the participants' responses reflect their true opinion and focus on the inference problem.

Our work focuses on aggregating crowdsourced opinions. A recent survey examines the implications of label noise in classification [6], and discusses label noise cleaning methods. One approach proposed for this problem is using EM [24], and another approach relies on modeling task difficulty [17]. Further, some algebraic bounds were provided for the binary rating case [4]. Other aggregation methods rely on probabilistic graphical models [23, 14, 18] including the state-of-the-art method of Bachrach et al. [2] (our empirical analysis shows we outperform this method).

3 PRELIMINARIES

We consider a set Q of $|Q| = q$ multiple choice questions, where each question has several possible answers. For simplicity, we denote the possible answers for each question as $[a] = \{1, 2, 3, \ldots, a\}$. For each question $j \in Q$, there is exactly one correct answer $g_j \in [a]$ and we denote the set of correct answers to all the questions as the vector $g = (g_1, g_2, \ldots, g_q) \in [a]^q$. The questions are posed to a set P of $|P| = p$ participants. Each participant $i \in P$ selects a response to each question j, reflecting which of the a possible answers they believe to be the correct one. We denote the response of participant $i \in P$ to question $j \in Q$ as $r_{i,j} \in [a]$. We collect the responses of all participants to all questions in a response matrix $M \in M_{p\times q}$ (where $M_{p\times q}$ denotes the set of all matrices with p rows and q columns) as follows: the element in the i'th row and j'th column in the matrix is the response of participant $i \in P$ to question $j \in Q$ (i.e. $M_{i,j} = r_{i,j} \in [a]$). Thus, each row in M represents a single participant's responses to each question and similarly, each column in M encodes the responses given by all the participants to a particular question.

Our goal is to use the response matrix M to uncover the correct answers g. This can be achieved if the responses of the participants to a question are correlated with the correct answer, though we do not make any specific model assumptions regarding the nature of this correlation. An aggregator is a function $f : M_{p\times q} \to [a]^q$ that takes a response matrix, produced by a set of participants for a set of questions, and outputs a proposed vector of correct answers – one for each of the considered questions. Given an input matrix $M \in M_{p\times q}$ and the vector of correct answers $g = (g_1, \ldots, g_q) \in [a]^q$ for the considered q questions, we can measure the performance of the aggregator as the proportion of questions for which the inferred answers match the correct answers: $\frac{|Q_c|}{q}$ where Q_c denotes the set of questions for which the aggregator infers the correct responses $Q_c = \{j \in Q | f(M)_j = g_j\}$.

3.1 Desiderata for Aggreators

We now describe several properties of aggregator functions that intuitively characterize minimal requirements we expect fair aggregators to fulfill.

3.1.1 Participant ordering invariance

First, we have no a priori knowledge about the relative ability of the participants. In other words, the order of the participants whose opinions we aggregate is arbitrary, thus we expect a good aggregator to show no prejudice in favour or against a participant based on their position in the response matrix. We denote by $M^{r(x\leftrightarrow y)}$ the matrix M where the rows x and y are swapped,

$$M_{i,j}^{r(x\leftrightarrow y)} = \begin{cases} M_{y,j}, & i = x \\ M_{x,j}, & i = y \\ M_{i,j}, & otherwise \end{cases} \quad (1)$$

We say an aggregator $f : M_{p\times q} \rightarrow [a]^q$ is *participant location indifferent* if for any response matrix M and x, y we have $f(M^{r(x\leftrightarrow y)}) = f(M)$.

3.1.2 Question ordering invariance

Similarly, we may not attribute special meaning to the order in which the questions were posed to the participants. In other words, the choice of a specific column in the response matrix, where a certain question is placed reflects no knowledge we have regarding the question. We denote by $M_{i,j}^{c(x\leftrightarrow y)}$ the matrix M with columns x and y swapped:

$$M_{i,j}^{c(x\leftrightarrow y)} = \begin{cases} M_{i,y}, & j = x \\ M_{i,x}, & j = y \\ M_{i,j}, & otherwise \end{cases} \quad (2)$$

Given a vector $g \in [a]^q$ (representing either the true correct answers or a suggestion made by an aggregator regarding the correct answers), we denote by $g^{x\leftrightarrow y}$ the vector with the coordinates x and y swapped. We say an aggregator $f : M_{p\times q} \rightarrow [a]^q$ is *question location indifferent* if by swapping the order of two questions x, y, we obtain the same aggregated result, except the output differs in the order of answers, for the swapped questions, i.e. the required property is: $\forall M, x, y : f(M^{c(x\leftrightarrow y)}) = (f(M))^{x\leftrightarrow y}$.

3.1.3 Answer ordering invariance

Finally, we consider assigning meaning to the identities of the possible answers. The identities of answers are the set $[a] = 1, 2, \ldots, a$. In some cases, these identities reflect no knowledge we posses regarding the dataset. For instance, in an IQ questionnaire such as the one our empirical evaluation is based on. The unique correct answer has an equal probability of being placed in any location in the answer set. In contrast, in other datasets, the order in which the answers are shown is not arbitrary. For instance, consider the case of relevance judgement queries, where users are shown the current results of a search engine for a given query and are asked which is the most relevant. The search engine ranks results from best to worst, so if it is functioning well, the best match should be placed in the first place (or at least in one of the first few places). In this case, unless answers are deliberately shuffled, the correct response is far more likely to be one of the first responses than one of the last responses.

If we know the identities of answers are chosen arbitrarily, we may want to reflect this invariance. We denote by Π_a the set of all possible permutations over the set $[a]$ (i.e. any $\pi \in \Pi_a$ is a bijection $\pi : [a] \rightarrow [a]$). Consider a given $\pi_j \in \Pi_a$, and the column vector $r_{:,j}^T = (r_{1,j}, r_{2,j}, \ldots, r_{p,j})^T$ of given responses by p participants to a certain question j. We denote by $(r_{:,j}^{\pi})^T$ the column vector consisting of the answers by the p participants where the answer identities are shuffled through π, so $\pi(r_{:,j})^T = (\pi(r_{1,j}), \pi(r_{2,j}), \ldots, \pi(r_{p,j}))^T$. Given a response matrix $M \in M_{p\times q}$, we consider the case of permuting the answer identities for each question. Given a set of permutations $h = (\pi_1, \pi_2, \ldots, \pi_q)$ (where $\pi_j \in \Pi_a$), we consider shuffling the responses with these permutations for each of the questions. We denote by M^h the matrix where the responses of the participants where shuffled through the appropriate permutation, i.e. the j'th column of M^h is $\pi_j(r_{:,j})$. Similarly, given a vector $v \in [a]^q$ and a permutation sequence $h = (\pi_1, \pi_2, \ldots, \pi_q)$, we denote the vector where each element was shuffled by the respective permutation as $h(v) = (\pi_1(v_1), \pi_2(v_2), \ldots, \pi_q(v_q))$. We say an aggregator is *answer identity indifferent* if for any response matrix M and $h = (\pi_1, \pi_2, \ldots, \pi_p)$ we have $(f \circ h)(M) = (h \circ f)(M)$.

4 DeepAgg - TRAINING A NEURAL NETWORK AS AN AGGREGATOR

Our goal is to train a neural network as an aggregator $f_n : M_{p\times q} \rightarrow [a]^q$, following the desiderata of Section 3.1. We thus aim to generate an aggragtor that is participant location indifferent, question location indifferent and answer identity indifferent. This is a supervised learning problem, where the input is a response matrix $M \in M_{p\times q}$ and the desired output is the set of correct answers.

4.1 Constructing a Synthetic Training Set

The desired aggregator function is a complex mapping, so training a neural network requires a large training set. Given an infinite supply of participants and questions (along with their correct answers), we could repeatedly source q questions and p participants from the infinite sup-

ply source, pose the questions to the participants, collect the answers and thus obtain a large training set. However, in real-world settings we have a very limited supply of participants and questions.

Our solution relies on *synthetic data generation* through subsampling. We first take an original dataset, consisting of the responses of $p' > p$ participants to a set of $q' > q$ questions. We then select q questions at random from the q' available questions, and p participants of the p' available participants, and use only their responses. A single choice of q questions, $\mathcal{I}_q \in C(q', q)$ [3], and p participants, $\mathcal{I}_p \in C(p', p)$, results in a subsampled input matrix $M_{\mathcal{I}_p,\mathcal{I}_q} \in M_{p\times q}$. We repeat this process many times to generate a training dataset $D = \{(M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q})\}_{\mathcal{I}_q\in C(q',q),\mathcal{I}_p\in C(p',p)}$ where $g_{\mathcal{I}_q}$ denoted the correct responses for the subset of questions $\mathcal{I}_q$. In total we will have $\binom{q'}{q} \cdot \binom{p'}{p}$ choices of training instances. This augmented dataset enables us to transform a moderately small original dataset into one containing enough sub-sampled training examples to successfully train a neural net.

4.2 Adhering to Desiderata

Training a neural network involves optimizing the network's weight parameters based on the training set. The network could thus overfit the parameters to various properties of the training set that fail to generalize to the test set. For instance, if one answer is more common then others in the training set, a trained network might reflect this and select weights leading to this answer being chosen more often than others. When such trends are specific to the training data and do not occur on the test set, this overfitting is likely to lead to reduced performance. The Desiderata in Section 3.1 reflect assumptions regarding how the data was generated and the expected behavior of a good aggregator. Adhering to these properties avoids certain forms of overfitting. How should we design and train a neural network so it would achieve these properties and avoid overfitting?

One possibility is relying on the synthetic data generation process, and applying various *synthetic dataset perturbations*. Note that out of the three invariance properties identified in Section 3.1, the constructed dataset D encodes the first two. Thus in order to enforced the third invariance, we can permute the answer identities for each question in every subsampled data, by taking a set of random answer identity permutations $h = (\pi_1, \pi_2, \ldots, \pi_q)$ (where $\pi_j \in \Pi_a$), and shuffling the responses with these permutations for each of the questions. During the synthetic dataset construction, we generate a subsampled matrix $(M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q}) \in D$. Now we can expand this dataset by shuffling the answer identities via a random permutation h: $(h\circ(M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q})) = (h\circ(M_{\mathcal{I}_p,\mathcal{I}_q}), h\circ(g_{\mathcal{I}_q}))$. [4] As the answers identities are randomly shuffled, even if one answer identity is more frequently the correct answer in the original dataset, in the synthetic dataset any answer has an equal probability of being the correct answer. Hence, training on the synthetic dataset should result in an answer identity indifferent aggregator. Thus we get a large training dataset $\mathcal{D} = \{(h \circ (M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q}))|h \sim \Pi_a^q, (M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q}) \in D\}$.

An alternative approach to synthetic dataset perturbations is relying on the *chosen features* to achieve the desiderata: we simply create features that *abstract away* the irrelevant information. Under this approach we first construct the synthetic dataset D. We then take a training instance $(M_{\mathcal{I}_p,\mathcal{I}_q}, g_{\mathcal{I}_q}) \in D$, construct features representing this instance, denoted as $\phi(M_{\mathcal{I}_p,\mathcal{I}_q})$. Rather than training a neural network on the "raw" input $M \in D$, we train it on the feature representation, $\phi(M)$. Although any neural network must receive some *representation* of the training instance in some form, we will construct the feature representation in a way that eliminates information about participant locations, question locations or answer identities. More formally, we say a feature representation ϕ is participant location indifferent if changing the location of a participant in the matrix has no influence on the generated representation, so $\phi(M^{r(x\leftrightarrow y)}) = \phi(M)$ (for any $M \in D; x, y \in \mathcal{I}_p$). Similarly, we say a feature representation is question location indifferent if $\phi(M^{c(x\leftrightarrow y)}) = \phi(M), \forall M \in D; x, y \in \mathcal{I}_q$, and say that it is answer identity indifferent if $\phi(h \circ M) = \phi(M), \forall M \in D$,$h = (\pi_1, \pi_2, \ldots, \pi_p)$. [5]

4.3 An Overview of Our Approach

Our approach is indeed based on choosing a feature representation that adheres to our desiderata. Earlier work shows that while stronger aggregators do exist, majority vote is already powerful in aggregating crowdsourced responses [2]. Our architecture thus begins by using the majority vote rule to determine an initial answer sheet, and constructing features that describe participants and questions based on this initial chosen answer set; we then *gradually refine* this answer sheet, using two building blocks.

The first block is a neural network that predicts the probability that a participant would respond correctly to a specific question. We refer to these probabilities as "success probabilities". The input to the block is a proposed answer sheet, reflecting the "best guess" of the correct answer for each question. Given this answer sheet, the block constructs our feature representation of the participants and

[3] We denote by $C(n, k)$ the set of k-combinations that can be form using n elements

[4] See the definitions of these operators in Section 3.1.

[5] These properties of a *feature representation* are similar to those of an aggregator function, except in the case of a feature representation we refer to an *encoding* of the important bits of the input matrix that allow determining how to best aggregate the data, rather than to the end result consisting of the chosen answer for each question.

questions, and applies the neural network to compute the success probabilities.

The second building block focuses on a single question, and receives as input these success probabilities of the participants as well as the answer chosen by each participant, and outputs the chosen answer for the question. We propose two alternatives for constructing the second block, which both work by computing the total support for each possible answer, then outputting the answer with the strongest support. One alternative is using a neural network, and the other is a deterministic formula that weighs the success probabilities using a simplistic probabilistic model of the behavior of participants. [6]

Combining the two building blocks, we obtain a method for refining an answer sheet. The first block takes the current answer sheet and the responses of the participants, and computes the success probabilities; the second block uses these success probabilities to output an improved answer sheet. We call the application of the two building blocks a *refinement step*. We initialize the system with an answer sheet computed by majority vote, and perform multiple refinement steps to generate our final answer sheet. [7]

We now describe the features used to represent the participants and questions, then describe the building blocks and the overall network architecture in more detail.

4.4 Feature Representation of the Input

Consider an input matrix $M \in M_{p\times q}$ consisting of the responses of p participants to a set of q questions, and a proposed set of answers to these questions $g' \in [a]^n$. An element g'_i can be thought of as the current best guess for the answer to question i (our algorithms initialize g'_i as the majority vote to question i in the subsampled matrix). We refer to the vector g' of proposed responses as an answer sheet. A rough estimate for the success or ability of a participant i is the proportion of questions to which they responded correctly, assuming that the answer sheet g' is indeed correct: $a_i = \frac{|\{j\in[q]|M_{i,j}=g'_j\}|}{q}$. Similarly, a rough estimate for a difficulty of a question is the proportion of students who failed to provide the correct response to it: $d_j = 1 - \frac{|\{i\in[s]|M_{i,j}=g'_j\}|}{s}$. Clearly, the quality of the features a_i (for a participant i) and d_j (for a question j) depend on the answer sheet g': the higher the quality of g', the less noisy these features are.

The above features allow predicting whether a participant is likely to correctly answer a question, and can also be used to rank participants based on their ability or questions by their difficulty. Consider sorting the questions by their estimated difficulty, d_j, and partitioning this set into k parts, $D_1, \ldots, D_k$ by the estimated difficulty. For example, for $k = 2$ we partition the questions into two parts by estimated difficulty:the easiest half of the questions are D_1 (with the lower difficulty estimate d_j), and the hardest half of the questions are D_2 (with the highest difficulty estimate d_j). We can estimate the ability of a participant using only the questions in one part of the partition. For instance, for $k = 2$ the performance of participant i on the easiest questions D_1 is $a_i^1 = \frac{|\{j\in D_1|M_{i,j}=g'_j\}|}{|D_1|}$, and their performance on the hardest questions is $a_i^2 = \frac{|\{j\in D_2|M_{i,j}=g'_j\}|}{|D_2|}$. More generally, we choose a number of parts (the "width" k), and denote $a_i^t = \frac{|\{j\in D_t|M_{i,j}=g'_j\}|}{|D_t|}$ (where $t \in \{1, 2, \ldots, k\}$, and $|D_t| = \frac{q}{k}$, assuming that k divides q).

Consider partitioning the questions into two parts, the easy questions D_1 and hard questions D_2 (with difficulty estimated using the current answer sheet g'). We'd expect a student i to do better on the easy questions than on the hard questions, so a_i^1 is higher and a_i^2 is lower. If we have a student where a_i^1 is lower than a_i^2, we might infer that their success on the harder questions is due to luck rather than skill (and predict him to be less successful than a student v of identical average skill but where a_v^1 is higher than a_v^2). Thus $a_i^1, \ldots, a_i^k$ can serve as additional features providing further useful information, beyond just the average skill.

Similarly to partitioning the questions by their difficulty to build a more fine-grained representation of students, we can partition the students by ability to generate a better representation for questions. We sort the students by their estimated ability, a_i, and partition this set into k' parts, $E_1, \ldots, E'_k$. We estimate the difficulty of a question using only the students in one part of the partition (e.g. the difficulty of a question for the strong and weak students). We denote $d_j^t = 1 - \frac{|\{i\in E_t|M_{i,j}=g'_j\}|}{|E_t|}$ (where $t \in \{1, 2, \ldots, k'\}$, and $|E_t| = \frac{s}{k'}$, assuming that k' divides s).

The goal of our first building block is to take an input subsampled matrix M and a proposed answer sheet g' and determine the probability of a student i to correctly answer question j. We represent the students and questions using the above features: $\phi_{i,j}(M) = (a_i, a_i^1, \ldots, a_i^k, d_j, d_j^1, \ldots, d_j^{k'})$ (where the features are computed using g' as the answer sheet). We note that the representation ϕ is answer identity indifferent, participant location indifferent and question location indifferent.

4.5 Predicting Whether a Participant Will Answer a Question Correctly

We use a neural network which takes a representation of a single user and a single questions, and predicts the prob-

[6] In the empirical analysis in Section 5 we show both perform well on our dataset (with no significant performance difference between the two).

[7] If a refinement step does not change the answer sheet, we have reached a fixed point of the refinement function, and can terminate the process early.

ability that the user would correctly answer the question. The input to the network is $\phi_{i,j}(M)$ (where $i \in [p]$ and $j \in [q]$), as defined in Section 4.4. We have used the dimensions $k = k' = 3$, so both a user and a question are represented as 4 real numbers, meaning each input is a vector $\phi_{i,j}(M) \in \mathbb{R}^8$. Our network consists of three fully connected layers, each performing a linear transformation then a $\tanh$ operation. The first linear transformation maps the input to a hidden layer with a hidden state of size $h = 10$ neurons, and the following layers maintain this hidden state size. Following these layers, our network linearly maps the final layer into a single neuron.

Given a single subsampled matrix M and given the correct answer sheet g (consisting of the known correct answers to the subsampled questions), we use $y_{i,j}$ as an indicator variable denoting whether the participant i answered question j correctly, so $y_{i,j} = 1$ if $M_{i,j} = g_j$ and $y_{i,j} = 0$ otherwise. [8] Each subsampled matrix results in $p \cdot q$ representations for participant-question pairs, $\phi_{i,j}(M)$, and in $p \cdot q$ indicator variables $y_{i,j}$. Applying the network on all the representations of participant-question pairs, we obtain $p \cdot q$ activations of the final layer, denoted as $\hat{y}_{i,j}$. We use the cross entropy loss:

$$\mathcal{L} = \sum_{i=1}^{p}\sum_{j=1}^{q}[y_{i,j}\log\hat{y}_{i,j} + (1-\hat{y}_{i,j})\log(1-\hat{y}_{i,j})]$$

We train the network by randomly subsampling $n = 10,000$ matrices along with the correct responses to the questions. Once the network is trained, it can receive a representation $\phi_{i,j}$ of a participant i and a question j, and its output $\hat{y}_{i,j}$ can be interpreted as the probability that the participant would answer the question correctly. Figure 1 illustrates the structure of this neural network.

4.6 Computing Support for a Given Answer

The second building block in our approach considers a single question and the responses of p participants to that question. The goal of the block is to provide a score for each answer, such that the correct answer would receive the highest score. We refer to this as computing the aggregate support in favor of an answer. The output of the block is thus a vector of scores $s = (s_1, s_2, \ldots, s_a)$ where s_t is the score of answer t. We propose two alternatives for the construction of this building block.

The first alternative we propose is a neural network. Given the probability of a participant i to correctly answer the question, denoted b_i for brevity [9] and the responses of each participant to the question, denoted $m_i = r_{i,j}$ for the question j, we construct a $a \times p$ matrix U representing a probability distribution over the a possible answers.

$$U_{i,k} = \begin{cases} b_i, & k = m_i \text{ (participant's chosen answer)} \\ \frac{1-b_i}{a-1}, & otherwise \end{cases} \quad (3)$$

This is an alternative to a "one-hot" encoding of $\{b_i\}_{i=1:p}$, reflecting the probability of a participant to choose each answer, assuming that the correct answer is indeed the one they chose, and that each incorrect answer is equally likely (the remaining mass $1 - b_i$ spread evenly across them).

The input to the network are the rows in matrix $U = (u_1^T, \cdots, u_a^T)$ – one for each possible answer. As the identity of each answer does not matter, we train a function f that takes a answer probability vector u and produces a score, s, for this answer vector. To learn the function we use a network of 3 fully connected layers, each consisting of a linear transformation followed by a $\tanh$ non-linearity, and a hidden size of $h = 15$, followed by another linear layer mapping the h neurons to a score s. We use the same mapping f to produce scores for all a possible answers, leading to $(s_1, \ldots, s_a) = (f(u_1), \ldots, f(u_a))$.

Each subsampled matrix used to train this network consists of q questions, where each question has an encoding, U, of size $p \cdot a$ representing the responses of the participants. Further, each subsampled matrix is considered along the vector of correct responses to each question $(g_1, \ldots, g_q)$. As we wish to optimize the network parameters so that the correct answer g_j to question j would receive the highest score s_j, the final layer of our network is a softmax operator: $\frac{\exp(s_i)}{\sum_{i=1}^{a}\exp(s_i)}$, and we use the cross-entropy loss. Figure 2 illustrates the structure of this neural network.

The second alternative we propose is a deterministic scor-

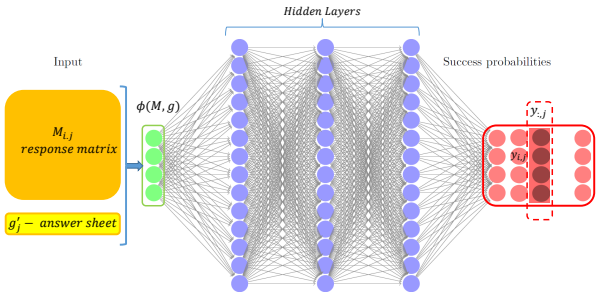

Figure 1: Visualization of the first building block: predicting success probabilities $y_{i,j}$, given a response matrix $M \in D$ and current answer sheet $g' = (g'_1, \cdots, g'_q)$

[8] Note that while training the network we use the ground truth correct answers. However, once the neural network is trained, it does not require this information, and can be used for any dataset. In our empirical analysis we train the network using one dataset, and use it on a completely separate dataset (both participants and questions that were not shown during training).

[9] Replacing the notation $\hat{y}_{i,j}$ as the question index is redundant

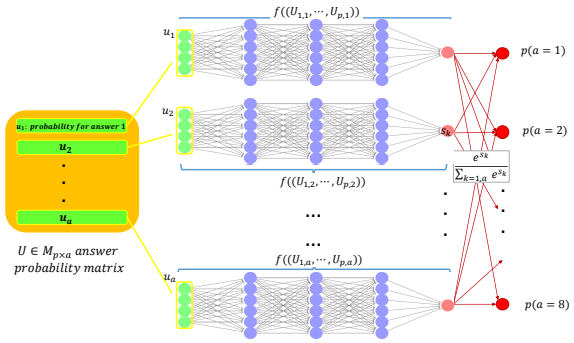

Figure 2: Visualization of the second building block: predicting the answer for a particular question j. Given the participants responses $M_{:,j}$ and the inferred probabilities of participants to be right or wrong $y_{:,j}$, we construct an answer probability matrix U as described in Eq. 3. Then for each possible answer k, we compute a score based on the participants' answer probabilities u_k: $s_k = f(u_k)$. These scores go through a `softmax` operator and finally we choose the answer with the highest probability.

ing function, based on a simple probabilistic model for the way in which the responses are chosen by the participant. Suppose that a priori each answer is equally likely to be the correct answer (reflecting answer identity invariance). Thus the correct answer is a random variable A, with a uniform distribution over the support $\{1,\ldots,a\}$. Assume that the probability of a participant i to choose the right answer to the question is b_i (given as the block's input), and that if i fails to choose the correct answer, they choose an answer uniformly at random from the remaining $a-1$ answers. Finally, we assume that the participants are independent of one another. The responses of the participants are thus an observed random variable R over the support $[a]^p$.

Consider the case where the correct answer to the question as $r \in [a]$. Given the observed responses R, we can partition the participants into two sets: the participants who responded with the answer r as X_r (the correct participants), and those who responded with some other answer X_o (the incorrect participants). To obtain the observed responses R, each of the correct participants must have chosen the correct answer (with probability b_i), and each of the incorrect participant must have failed to chose the correct answer (with probability $1-b_i$), and then choose exactly the incorrect answer they chose (there are $a-1$ incorrect responses and each is equally probable). Thus, under our model, the probability of obtaining the observed responses R is:

$$P(R|A=r) = \prod_{f\in X_r} b_f \cdot \prod_{g\in X_o} \frac{1-b_g}{a-1} \qquad (4)$$

The goal of the second building block is choosing the best response for a question given the input parameters $b1,\ldots,b_p$ and the observed responses R. By Bayes' theorem we have $P(A|R) = \frac{P(R|A)\cdot P(A)}{P(R)}$. Given the observed responses R and our assumed model, we seek the most probable answer $\arg\max_a P(A=a|R) = \frac{P(R|A=a)\cdot P(A=a)}{P(R)}$. As $P(R)$ is a normalizing constant and as we assumed that for any a we have $P(A=a)=\frac{1}{a}$, we have $\arg\max_a P(A=a|R) = \arg\max_a P(R|A=a)$. We can thus simply apply Equation 4 to compute the score $P(R|A=r)$ for each possible response $r \in [a]$, and return the answer with the maximal score.

4.7 Iterative Refinement

Section 4.4 discusses how we take a subsampled matrix M and a proposed answer sheet g'_0, and output a feature representation $\phi(M,g')$ for each user and question. Section 4.5 discusses how we take the feature representation and apply a neural network to predict $y_{i,j}$, the probability of each participant i to answer any question j. We call this step $cor(\phi(M,g'))$. Finally, section 4.6 discusses how we take the success probabilities $y = (y_{1,1}, y_{1,2}, \ldots, y_{1,q}, y_{2,1}, \ldots, y_{p,q})$ and the subsampled response matrix M and generate and refined answer sheet g' (either using a trained neural network, or through the formula on equation 4). We call this step $ref(y,M)$.

Our method, called DeepAgg, simply involves applying multiple such iterations (the number of iterations is the parameter $nIter$). Algorithm 1 describes this process.

Data: Reponse matrix $M \in M_{p\times q}$
Result: Aggregated responses $g' \in [a]^q$
$g' \leftarrow \text{Maj}(M)$ // Majority vote initialization ;
for $i \leftarrow 1$, *nIter* **do**
  $y \leftarrow cor(\phi(M,g'))$;
  $g' \leftarrow ref(y,M)$;
end
return g' ;

Algorithm 1: DeepAgg: Iterative Refinement

5 EMPIRICAL ANALYSIS

We empirically examine the DeepAgg method of Section 4, and evaluate its performance against both the majority vote aggregator and the DARE Bayesian aggregator of Bachrach et al. [2], using the same dataset described in that paper. This dataset consists of the responses of participants to the Raven's Standard Progressive Matrices (SPM) IQ test [15], an intelligence screening test. This test is a multiple choice questionnaire, consisting of $q' = 46$ questions, each with eight possible answers. [10] SPM is a popular intelligence

[10] The full test has 4 parts in increasing difficulty. We removed the easiest questions to focus on the more interesting cases where there is not a consensus between participants. Note that including all questions does not alter the qualitative conclusions of this paper.

test, that has been used for research purposes, clinical assessment and even military personnel screening [16]. The dataset contains the responses of $p' = 746$ participants, who took the test in the 2006, in the process of establishing the ability norms for the British market [15]. [11]

To conduct our experiments, we partitioned the dataset's questions into two parts, Q_a and Q_b, each with half (23) of the dataset's questions (where $Q_a \cup Q_b = \emptyset$). Similarly, we partitioned the participants into two parts, P_a and P_b, each with half (373) of the dataset's participants (with $Q_a \cup Q_b = \emptyset$). We trained DeepAgg using subsampled data from the responses of the participants in P_a to the questions in Q_a, and evaluated the performance using subsampled data from the responses of the participants in P_b to the questions in Q_b. This guarantees that the training and testing are done on separate datasets: not only are the training instances different from the test instances, effectively we are testing the aggregator on a completely unseen dataset.

5.1 Aggregation Quality

DeepAgg aggregates the responses of multiple participants and outputs the predicted correct answer for each question, similarly to majority vote or the DARE aggregator of Bachrach et al. [2]. We now compare the performance of these approaches. Our quality metric for an aggregator is simple. Given a response matrix $M^i \in M_{p \times q}$, an aggregator returns a vector $g'^i \in [a]^q$. Given the the set of actual correct responses $g^i \in [a]^q$, we denote the number of questions where the aggregator was correct as $c(g') = |\{j | g'^i_j = g^i_j\}|$. We denote the proportion of questions that were aggregated successfully as $s^i(g') = \frac{c^i(g'^i)}{q}$.

Figure 3 shows the quality of majority vote, DARE and our DeepAgg, as a function of the available date. When an aggregator has more available responses for each question, we expect it to achieve a better performance as it has more available data. The x-axis of Figure 3 shows the number of responses per question (the number of participants in the subsampled response matrix), and the y-axis shows the aggregation quality $\frac{1}{k}\sum_{i=1}^{k} s^i(g'^i)$, across $k = 10,000$ runs (each of which is a random subsampled response matrix).

Figure 3 shows that all methods achieve a better result as more data is available, but that the returns diminish as the number of participants increases (in agreement with the results reported in the work of Bachrach et al. [2]). For all data regimes, DeepAgg outperforms DARE.

The plot in Figure 3 was created with DeepAgg using equation 4 as the second building block. We have also run DeepAgg with the neural net implementation for the second block, with an almost identical performance, indicating that both are reasonable choices for that block.

[11] We thank the Psychometrics Centre of the University of Cambridge for making this dataset available for this research.

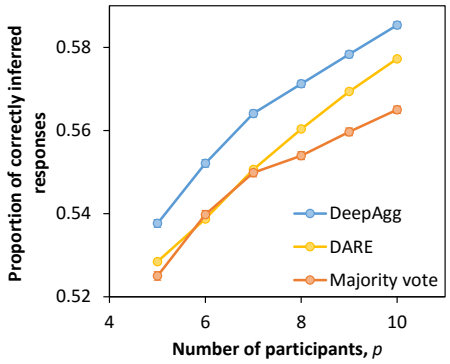

Figure 3: The performance of DeepAgg and alternative aggregators as a function of the size of the data

DeepAgg performs multiple iterations of improving the answer sheet, as described in Algorithm 1. Figure 4 shows the effect of the number of iterations on the quality of aggregation. The x-axis is the number of iterations ($nIter$ in Algorithm 1) and the y-axis is the average aggregation quality $\frac{1}{k}\sum_{i=1}^{k} s^i(g'^i)$ across $k = 10,000$ runs (with random subsampled response matrices). We find that performing multiple iterations improves the quality of aggregation, but that this improvement diminishes as the number of iterations increases. One possible cause for these diminishing returns is that if the answer sheet g' does not change following an iterations, we have reached a fixed point of this function, so there is no point in performing additional iterations.

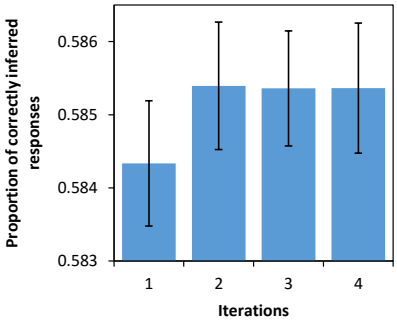

Figure 4: The effect of the number of DeepAgg iterations on aggregation quality

5.2 Evaluating the ability of participants

While the main stated goal of the DeepAgg aggregator is inferring the set of correct answers g, a common use-case in crowdsourcing settings is deciding which of the participants are good at the task and which are not.

One possible measure of the ability of a participant i given a response matrix M and a set of correct answers $g \in [a]^q$, is the proportion of questions which i answered correctly: $a_i = \frac{|\{j \in [q] | M_{i,j} = g_j\}|}{q}$. If we are not given the ground truth

set of responses, g, we could use an approximate answer sheet g', and use $a'_i = \frac{|\{j \in [q] | M_{i,j} = g'_j\}|}{q}$ as an approximation. Clearly, the quality of this estimator depends on how well g' approximates g. As DeepAgg allows inferring an answer sheet g' given the response matrix M, one could thus use it as a tool for inferring the ability of participants.

Figure 5 investigates how well DeepAgg performs in inferring the ability of participants. This is a density plot which was generated by examining many data points, each describing a single random participant in a run of DeepAgg on a random subsampled matrix. The x-axis of each point represents the true ability of the participant, a_i, and the y-axis is the estimated ability of the participant, a'_i (using an answer sheet g' inferred using DeepAgg). The figure shows the density of the sampled points in each area on the chart.

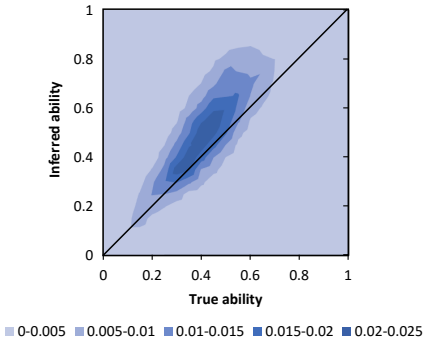

Figure 5: Using DeepAgg to infer the ability of participants

A perfect aggregator would result in a figure where points rest on the $y = x$ axis, and a Pearson correlation of 1. Figure 5 shows a very strong correlation between the inferred and true ability of each participant, even with few iterations. The Pearson correlation between the true ability of a participant and the inferred ability of that participant is $r = 0.79$, which is high considering the limited amount of data available to DeepAgg. This indicates that DeepAgg is a powerful tool not only in aggregating responses, but also for identifying skilled and less-skilled participants.

5.3 The Need for Computing Features

A major advantage of deep learning is its ability to learn feature representations without resorting to hand-crafted features [3, 19]. One might ask why we have used a method that relies on the features discussed in Section 4.4. A simpler architecture could use a deep neural net which simply operates on the input subsampled matrix M (for instance using a "one-hot" encoding for the chosen response of each participant on each question). We have indeed tested such an architecture, showing the performance it achieves to only match majority vote. A very deep network is theoretically capable of performing the overall computation we have done using DeepAgg. However, as this requires a very deep network, training the network using stochastic gradient descent (or similar variants) must search through an extremely large and complicated parameter space. The fact that a direct architecture does not achieve the high performance of DeepAgg indicates that the current optimization methods are incapable of finding this solution.

The computation in DeepAgg is quite deep: we apply a 3 layer deep network twice for each iteration (each building block is a network), so with even as few as 3 iterations this is a 18 layer deep architecture. Further, our computation relies on computing the desired features once in each iterations. Our ability to successfully train the network stems from the *constant supervision* we apply: a loss can be computed after every building block using the ground truth. In other words, once every basic building block, we apply a loss using the ground truth answer sheet g, allowing us to find excellent optimized parameters for each block.

6 LIMITATIONS AND CONCLUSIONS

We presented DeepAgg, an approach for aggregating crowdsourced responses, based on a deep neural network. Our empirical analysis shows that DeepAgg has a superior performance over the majority aggregator and a more sophisticated Bayesian approach. Our approach has some **inherent limitations**. Training the network requires taking an initial dataset and repeatedly sub-sampling parts of it to generate synthetic training examples. This training procedure is a computationally expensive calculation, which yields an aggregator taking the responses of p participants to q questions. Once the aggregator is trained, applying it to a new training instance is has a relatively low runtime complexity. However, if the input dimensions p or q are changed, the training process needs to be repeated to create a new aggregator. Further, we used a simple network architecture. A more elaborate structure could potentially improve performance. Finally, our method is desigend for the **complete data case**. It is difficult to adapting our method to the case of incomplete data, where some of the participants have only answered some of the questions. [12]

Several issues remain open for future research. How can our procedure be modified to handle the case of missing responses, where some participants may only provide responses to a subset of the questions? While it is easy to encode this in the input to the network, this may have a large impact of the quality of the aggregator. Second, is it possible to extend our approach to an active learning scenario, where we have control over the next question to ask a participant? Finally, could we take an aggregator training for certain input dimensions and convert it into an aggregator for other input sizes, without retraining a network?

[12] In contrast, Bayesian approaches are usually robust to missing data (for instance, in approaches based on graphical models, these can simply be treated as unobserved random variables).

Abstract

In reinforcement learning, policies are typically evaluated according to the expectation of cumulated rewards. Researchers in decision theory have argued that more sophisticated decision criteria can better model the preferences of a decision maker. In particular, Skew-Symmetric Bilinear (SSB) utility functions generalize von Neumann and Morgenstern's expected utility (EU) theory to encompass rational decision behaviors that EU cannot accommodate. In this paper, we adopt an SSB utility function to compare policies in the reinforcement learning setting. We provide a model-free SSB reinforcement learning algorithm, *SSB Q-learning*, and prove its convergence towards a policy that is ϵ-optimal according to SSB. The proposed algorithm is an adaptation of fictitious play [Brown, 1951] combined with techniques from stochastic approximation [Borkar, 1997]. We also present some experimental results which evaluate our approach in a variety of settings.

1 INTRODUCTION

In problems of sequential decision-making under uncertainty (often represented as Markov Decision Problems—MDPs [Puterman, 1994]), an agent has to repeatedly choose according to her current state an action whose consequences are uncertain, in order to maximize a certain criterion in the long run. In most cases, the criterion chosen is the expectation of cumulated rewards, but it is not risk sensitive and fails to explain widely observed violations of axioms such as transitivity or von Neumann's independence axiom. One of the aims of decision theory is to provide criteria able to account for such behaviors.

Interestingly, the Skew-Symmetric Bilinear (SSB) utility theory [Fishburn, 1984] defines a family of decision criteria able to represent risk-averse and risk-seeking behaviors, intransitive choices and violations of the independence axiom. In particular it encompasses the expected utility (EU) model [von Neumann and Morgenstern, 1947], which is the most popular risk sensitive criterion in decision theory. In SSB theory a binary functional φ over probability distributions is given, where the sign of $\varphi(\mathbf{p}, \mathbf{q})$ gives the preference between two distributions $\mathbf{p}$ and $\mathbf{q}$. Furthermore, particular choices of φ allow decision criteria that only rely on ordinal pieces of information such as "this trajectory is preferred to this other trajectory" to be used. This property is of interest for MDPs as the optimal policy can be highly sensitive to the reward function, but specifying such a reward function is often difficult even for an expert user.

Such preference-based approaches have received much attention lately [Akrour *et al.*, 2012, Furnkranz *et al.*, 2012, Busa-fekete *et al.*, 2014, Wilson *et al.*, 2012, Wirth and Fürnkranz, 2013, Wirth and Neumann, 2015], and a special case of SSB utility function which optimizes the probability of yielding a preferred outcome has been investigated in various domains [Busa-fekete *et al.*, 2014, Dudík *et al.*, 2015, Rivest and Shen, 2010]. In reinforcement learning (RL), Busa-Fekete *et al.* [2014] provided a meta-heuristic algorithm using evolutionary strategies to compute a "good" policy. Designing a learning scheme for an RL problem using an SSB utility function would therefore enable RL problems to be solved for a large class of criteria including "preference-based" criteria.

The possibility of intransitive preferences in SSB utility theory could be seen as a significant barrier to its use in automated decision making. However, the seminal work of Gilbert *et al.* [2015a] shows that an SSB-optimal strategy always exists as a mixture of policies, and furthermore, that in a finite horizon MDP where the model is known, such an SSB-optimal strategy can be computed using a double oracle approach. Unfortunately, this approach suffers two drawbacks: its time and space requirements might become prohibitive if the optimal mixture of policies is composed of too many policies, and it does not generalize to the case where the model is unknown, and thus cannot be used to derive a model-free RL algorithm.

We remedy this by providing a new algorithm which behaves optimally in an MDP with an SSB utility function, from which we derive a model-free RL algorithm in order to learn an SSB-optimal policy when the model is unknown. While the approach is still based on game-theoretic arguments, the algorithm differs in spirit and resembles an adaptation of a fictitious play algorithm [Brown, 1951] combined with Q-learning [Watkins and Dayan, 1992] using stochastic approximation techniques with two timescales [Borkar, 2008]. Kalathil *et al.* [2014] recently exploited a similar two-timescale technique in MDPs, but in a different context; using the average expected reward criterion with vector rewards, their goal is to learn a policy whose vectorial value approaches a fixed set.

The paper is organized as follows. In Section 2, we give the background elements and introduce our notations. In Section 3, we give a game theoretic view of the resolution of an RL problem with an SSB utility function and present a fictitious play approach to solve it. Lastly, in Section 4, we present some experimental results.

2 SSB MARKOV DECISION PROCESSES

We study in this paper episodic MDPs with finite state and action spaces. An MDP $\mathcal{M}$ is formally defined by a tuple $(\mathcal{S}, \mathcal{F}, \mathcal{A}, \mathcal{P}, s_0)$ where: $\mathcal{S}$ is a finite collection of states; $\mathcal{F} = \{f_1, f_2, \ldots, f_{|\mathcal{F}|}\} \subset \mathcal{S}$ is a finite set of final states; $\mathcal{A} = \{\mathcal{A}_s | s \in \mathcal{S}\}$ is a collection of finite sets of possible actions, one for each state; $\mathcal{P}$ is the transition function where $\mathcal{P}(s'|s,a)$ is the probability that the state at time step $t+1$ is s', given that the state at time step t was s and that the agent performed action a; $s_0 \in \mathcal{S} \setminus \mathcal{F}$ is the initial state in which all episodes start.[1]

Whereas preferences over state-action pairs are typically modeled with numerical rewards, in our framework we assume that the final states summarize the preference information. More precisely, we assume that the decision maker has a preference relation $\succeq$ over possible final states, where $f \succeq f'$ means that ending in final state f is at least as good as ending in f'. Note that *we do not assume $\succeq$ to be total or even transitive*, thus accommodating a wide variety of preference behaviors, including those deviating from normative decision theory. A "standard" MDP (with rewards obtained at each time step) could still be represented in our setting with the notion of an *augmented MDP* [Gilbert *et al.*, 2015a] at the cost of introducing additional states.

We assume (as standard in RL) that $\mathcal{S}$, $\mathcal{A}$, s_0 and $\mathcal{F}$ are known, that $\mathcal{P}$ is unknown and that at each step the agent knows exactly which state she occupies.

We call *episode* a succession of state-action pairs $(s_0, a_0, s_1, \ldots, s_{t-1}, a_{t-1}, s_t)$, starting in s_0 and ending in a final state $s_t \in \mathcal{F}$. When the current episode ends, a new episode starts in state s_0. We further assume that the length of an episode is upper-bounded by a constant $T_{max} \in \mathbb{N}$.

Table 1: Probabilities for Each Gardner Die

	1	2	3	4	5	6
$\mathbf{p}_A$	1/6	0	0	5/6	0	0
$\mathbf{p}_B$	0	0	5/6	0	0	1/6
$\mathbf{p}_C$	0	1/2	0	0	1/2	0

A *policy* π at horizon T indicates which action to perform in each nonfinal state for each time step $t < T$. A policy is *Markovian* if the action depends only on the current state and timestep (otherwise it may depend on all state-action pairs encoutered so far); *deterministic* if it prescribes exactly one action, or *randomized* if it prescribes a probability distribution over actions; *stationary* if the action prescribed does not depend on the timestep. We write Π_s for the set of Markovian stationary deterministic policies.

Importantly, given a set $\Pi = \{\pi^1, \pi^2, \ldots\}$ of policies, we define an enlarged set $\widetilde{\Pi}$ of policies, that denotes the set consisting of *mixtures* of policies, i.e., $\widetilde{\Pi} = \{\tilde{\pi} = (\pi^1|\alpha_1, \pi^2|\alpha_2, \ldots) : \sum_i \alpha_i = 1,\ \alpha_i \geq 0\}$, where $\tilde{\pi}$ is the *mixed policy*[2] that randomly selects policy π^i with probability α_i at the beginning of each episode.

Example 1. *As a running example, we consider a variant of the classical "Gardner dice" two-player game. Each player has three six-sided dice, written A, B, C and biased as shown in Table 1. Players simultaneously choose a die to throw, and whoever rolls the highest number wins.*

It is easy to see that die A rolls higher than B most of the time, so die A should be preferred to B, but B mostly beats C, and C mostly beats A, hence the relation "more likely to win" is cyclic. The optimal policy for this problem is to play dice A, B and C with probabilities $3/13$, $3/13$ and $7/13$, respectively [Gilbert et al.*, 2015a].*

For illustrative purposes, we consider a variant where each player makes sequential decisions: she must first choose whether to throw die A (action a_A) or not (a_{BC}). If she chooses a_{BC}, then she can choose to throw B (action a_B) or C (a_C). Clearly, this does not change the probabilities with which to throw each die in an optimal policy.

This problem can be represented as an MDP where T_{max} is 2, with an initial state s_0 where $\mathcal{A}_{s_0} = \{a_A, a_{BC}\}$; a state s_{BC} (reached by choosing action a_{BC} in s_0); and six final states $\{f_1, \ldots, f_6\}$ representing the numbers rolled. An example transition probability is $\mathcal{P}(f_3|s_{BC}, a_B) = 5/6$, and an example episode is $(s_0, a_{BC}, s_{BC}, a_C, f_5)$. An example (Markovian stationary deterministic) policy is $\pi_B(s_0) = a_{BC}, \pi_B(s_{BC}) = a_B$.

Using similar notation for A and C, the optimal policy is

[1] A probability distribution $\mathcal{P}_0$ over initial states can easily be accommodated by using a dummy state s_0 with one dummy action whose transitions to all the other states are governed by $\mathcal{P}_0$.

[2] Not to be confused with the notion of randomized policies.

the mixed policy $\tilde{\pi}^*$=($\pi_A|3/13$,$\pi_B|3/13$,$\pi_C|7/13$), which dictates that the player draws one of π_A,π_B,π_C at the start of an episode, following it for the whole episode. [3]

Our aim is to find an optimal (defined in the next subsection) policy. Recall that the decision maker has a preference relation $\succeq$ over possible final states; we want to compare policies by considering this preference relation. In other words, we want to lift the preference relation $\succeq$ defined on final states to a preference relation defined on policies.

2.1 COMPARING POLICIES WITH AN SSB UTILITY FUNCTION

We assume throughout the paper that the agent's preferences between probability distributions are described by the SSB model as presented and axiomatized by Fishburn [1984]. In this model, an agent is endowed with a binary functional φ over ordered pairs $(f, f') \in \mathcal{F}^2$ of final states, indicating the intensity with which she prefers f to f', with $f \succeq f' \Leftrightarrow \varphi(f, f') \geq 0$. Functional φ is assumed to be skew-symmetric, i.e., $\varphi(f, f') = -\varphi(f', f)$ and is extended to the space of probability distributions over $\mathcal{F}$ by bilinearity (wrt the mixture operation on distributions). The SSB criterion for comparing $\mathbf{p}$ and $\mathbf{q}$ is then written:

$$\varphi(\mathbf{p}, \mathbf{q}) = \sum_{f, f' \in \mathcal{F}} p(f) q(f') \varphi(f, f') \tag{1}$$

where $p(f)$ (resp. $q(f')$) denotes the probability of reaching the final state f (resp. f') in distribution $\mathbf{p}$ (resp. $\mathbf{q}$). We have $\mathbf{p} \succ \mathbf{q}$ if $\varphi(\mathbf{p}, \mathbf{q}) > 0$ (strict preference), and $\mathbf{p} \sim \mathbf{q}$ if $\varphi(\mathbf{p}, \mathbf{q}) = 0$ (indifference).

Any policy π in an MDP induces a probability distribution $\mathbf{p}^\pi$ over final states (reached after at most T_{max} time steps); $\mathbf{p}^\pi$ is referred to as the *final state distribution* of π. As comparing policies amounts to comparing their induced distributions, we write $\varphi(\pi, \pi')$ for $\varphi(\mathbf{p}^\pi, \mathbf{p}^{\pi'})$ to simplify notation and define the preference relation $\succsim$ over policies:

$$\pi \succsim \pi' \equiv \varphi(\pi, \pi') \geq 0 \tag{2}$$

Example 2 (continued)**.** *The goal of beating the opponent's roll can be expressed as $\varphi(f_m, f_n) = 1$ for $m > n$, -1 for $m < n$, and 0 for $m = n$. The deterministic policies π_A, π_B, π_C amount to rolling the corresponding die, inducing the final state distributions $\mathbf{p}_A, \mathbf{p}_B, \mathbf{p}_C$ of Table 1 over final states. We have (zero entries are irrelevant):*

$$\begin{aligned}
&\varphi(\mathbf{p}_A, \mathbf{p}_B) \\
&= \mathbf{p}_A(f_1)\mathbf{p}_B(f_3)\varphi(f_1, f_3) + \mathbf{p}_A(f_1)\mathbf{p}_B(f_6)\varphi(f_1, f_6) \\
&\quad + \mathbf{p}_A(f_4)\mathbf{p}_B(f_3)\varphi(f_4, f_3) + \mathbf{p}_A(f_4)\mathbf{p}_B(f_6)\varphi(f_4, f_6) \\
&= \frac{1}{6} \cdot \frac{5}{6} \cdot (-1) + \frac{1}{6} \cdot \frac{1}{6} \cdot (-1) + \frac{5}{6} \cdot \frac{5}{6} \cdot 1 + \frac{5}{6} \cdot \frac{1}{6} \cdot (-1) \\
&= 14/36 > 0,
\end{aligned}$$

showing that die A should be preferred to die B.

If we were to define φ by $\varphi(f_m, f_n) = m - n$, the strength of a victory (or defeat) would be taken into account. The policies in this case would be compared wrt the expectation of the roll (as explained below).

The SSB model is very general, as it can take into account choice intransitivity, which is widely observed in practice [Fishburn, 1991]. Moreover, the SSB model can represent different risk attitudes via an adequate choice of φ. For example, it represents risk-averse behavior (in the weak sense) if the certainty equivalent of a distribution $\mathbf{p}$ is less than or equal to its expected value, where the certainty equivalent of a distribution $\mathbf{p}$ is the element f such that $\varphi(\mathbf{p}, f) = 0$ (*i.e.*, $\mathbf{p} \sim f$). Nakamura [1989] shows how to design risk averse and risk seeking SSB utility functions.

The SSB model also encompasses many decision criteria, such as the expectation criterion $\varphi(f, f') = c(f) - c(f')$ (where c denotes a utility/cost function); the probability threshold criterion [Yu *et al.*, 1998] $\varphi(f, f') = 1_{c(f) \geq \tau} - 1_{c(f') \geq \tau}$, which states that $\mathbf{p} \succ \mathbf{q}$ if $\sum_{c(f) \geq \tau} p(f) > \sum_{c(f) \geq \tau} q(f)$ for a threshold $\tau \in \mathbb{R}$; and the dominance relation $\varphi(f, f') = 1$ (resp. 0, -1) if $f \succ f'$ (resp. $f \sim f'$, $f \prec f'$), which states that $\mathbf{p} \succ \mathbf{q}$ if $\sum_{f \succ f'} p(f)q(f') > \sum_{f' \succ f} p(f)q(f')$ (as in Example 2). In other words $\mathbf{p}$ is preferred to $\mathbf{q}$ if a final state generated according to $\mathbf{p}$ is more likely to be preferred to a final state generated according to $\mathbf{q}$ than the converse. This is called *probabilistic dominance* in the following.

Probabilistic Dominance (PD) is interesting as it only relies on ordinal pieces of information. Its axiomatic characterization was given by Blavatskyy [2006] and it has been explored lately in various domains such as RL [Busa-fekete *et al.*, 2014], voting systems [Rivest and Shen, 2010] and dueling bandits [Dudík *et al.*, 2015]. In the latter work, the authors adopt the name of *von Neumann solution* for the PD optimal solution. Indeed, as will be discussed in the next section, finding an SSB-optimal policy (and in particular, finding an optimal policy according to PD) is equivalent to finding a Nash equilibrium in a finite zero-sum two-player game. Thus the existence of a von Neumann solution is implied by von Neumann's minimax theorem.

In standard MDPs, the optimal policy can be highly sensitive to the reward function used, and yet designing a numerical reward function is often cognitively difficult, even

[3] Note the difference with the *randomized* (stationary) policy π which draws a_A with probability $3/13$ in s_0, and, *independently of this*, draws a_B (resp. a_C) with probability $3/10$ (resp. $7/10$) in s_{BC}. The expectation of reaching each final state is nonetheless the same in π and $\tilde{\pi}^*$ (hence π is also optimal).

for an expert user. This issue is tackled in preference-based approaches [Akrour *et al.*, 2012, Weng and Zanuttini., 2013, Gilbert *et al.*, 2015b, Weng *et al.*, 2013, Busa-fekete *et al.*, 2014, Furnkranz *et al.*, 2012, Wilson *et al.*, 2012, Wirth and Fürnkranz, 2013, Wirth and Neumann, 2015] by only considering ordinal pieces of information, such as feedbacks of the type "this trajectory is preferable to that one". We can distinguish two types of approach. The first [Wirth and Fürnkranz, 2013, Wirth and Neumann, 2015, Weng *et al.*, 2013] aims to recover a numerical reward function that explains most of the expressed preferences of the user and can be used with classic criteria. The second [Busa-fekete *et al.*, 2014, Furnkranz *et al.*, 2012] deals with purely ordinal criteria, *e.g.*, Busa-Fekete *et al.* [2014] find a good policy (wrt to PD) using a meta-heuristic algorithm based on evolutionary strategies in finite horizon continuous MDPs.

Example 3. *Consider a car racing against the clock. The driver aims to complete the race in the shortest time possible, but must find the right compromise between speed and the risk of being eliminated; driving too fast can cause the car to run off the track and be eliminated from the competition; the relation between the car's speed and going off track is stochastic (the faster, the more likely). This is easily modeled as an MDP where policies induce a distribution over the race's possible outcomes. The preference $\succ$ over final states is determined by two conditions: (i) race completion is always strictly preferred to an elimination, and (ii) a trajectory completing the race in time t_1 is strictly preferred to completion in time $t_2 > t_1$.*

In this model, adopting SSB with probabilistic dominance finds the "best" policy for a driver who wants to maximize her chance of winning a race (against other drivers facing the same MDP). In contrast, traditional approaches would solve this problem by setting a (large) negative reward r_{elim} for an elimination and a small negative reward for each time step before completing the race, and then maximize expectation of rewards using, for example, Q-learning or any other classic algorithm. Different values of r_{elim} would result in very different policies, and while it might be possible to find a good compromise value allowing for a competitive behavior, manually tuning the reward function would be difficult in more complex scenarios.

Consequently, designing and implementing an algorithm for solving MDPs in an RL setting with an SSB utility function also gives us a tool to compute optimal policies for a large class of criteria, including "preference based" ones. A first step towards the design of this algorithm is to give a game-theoretic view of the problem.

2.2 A GAME ON POLICIES

When an MDP is fixed, Equations 1 and 2 induce a zero-sum two-player symmetric game where the set of strategies coincides with the set of possible policies. The players $i \in \{1, 2\}$ simultaneously choose a strategy $\tilde{\pi}_i$ (pure or mixed). The resulting payoff is then given by $\varphi(\tilde{\pi}_1, \tilde{\pi}_2)$. As emphasized by Gilbert *et al.* [2015a], an SSB optimal policy can be found by computing a Nash equilibrium of this game. Indeed, Nash equilibria $(\tilde{\pi}^*, \tilde{\pi}^*)$ are characterized by $\forall \tilde{\pi}, \varphi(\tilde{\pi}^*, \tilde{\pi}) \geq 0$.

Gilbert *et al.* [2015a] also showed that in this game, a best response to a strategy $\tilde{\pi}$ is given by a policy maximizing the expectation of cumulated rewards with reward function:

$$\mathcal{R}_{\mathbf{p}^{\tilde{\pi}}}(s) = \begin{cases} \mathbf{1}_i^\top \Phi \mathbf{p}^{\tilde{\pi}} & \text{if } s = f_i \in \mathcal{F} \\ 0 & \text{otherwise} \end{cases}$$

where $\mathbf{1}_i$ is the i^{th} canonical vector, $^\top$ is the transpose operator and Φ is the SSB matrix (i.e., $\Phi_{i,j} = \varphi(f_i, f_j)$). Put another way, the reward obtained when arriving in the i^{th} final state is given by the i^{th} element of the vector $\Phi \mathbf{p}^{\pi}$ (the reward is 0 for nonfinal states). Since this defines a standard MDP, there is always a stationary, Markovian and deterministic optimal policy (i.e., the best response to $\tilde{\pi}$). Thus we can restrict ourselves to the finite game with Π_s as the set of pure strategies. To summarize, a Nash equilibrium of this game will give an SSB-optimal policy, in the form of a mixed policy $\tilde{\pi}^* \in \tilde{\Pi}_s$.

Example 4 (continued)**.** *The game induced by our running example has pure strategies π_A, π_B, π_C for both players, with payoff, e.g., $\varphi(\pi_A, \pi_B) = 14/36$ (Example 2). Consider the mixed policy $\tilde{\pi}_{AAB} = (\pi_A|2/3, \pi_B|1/3)$; Table 1 gives its final state distribution $\mathbf{p}^{\tilde{\pi}_{AAB}} = (2/18, 0, 5/18, 10/18, 0, 1/18)$. The value of response π_A to $\tilde{\pi}_{AAB}$ is given by*

$$\mathbf{p}^{\pi_A} \cdot \Phi \cdot \mathbf{p}^{\tilde{\pi}_{AAB}}$$
$$= (\frac{1}{6}, 0, 0, \frac{5}{6}, 0, 0)^\top (-\frac{16}{18}, -\frac{14}{18}, -\frac{9}{18}, \frac{6}{18}, \frac{16}{18}, \frac{17}{18}) = \frac{7}{54}$$

Similarly, the values of π_B, π_C are $-7/27$ and $1/18$ respectively, so a best response to $\tilde{\pi}_{AAB}$ is π_A. The second component of vector $\Phi \cdot \mathbf{p}^{\tilde{\pi}_{AAB}}$ can be computed as follows. We know that rolling 2 is worse than $16/18$ and better than $2/18$ of the outcomes of $\mathbf{p}^{\tilde{\pi}_{AAB}}$, and $\varphi(f_i, f_j)$ is always 1 for $i > j$. Therefore this component is $-1 \cdot 16/18 + 1 \cdot 2/18 = -14/18$.

In a finite zero-sum symmetric game, it is well-known that there exists a symmetric Nash Equilibrium (NE). We aim to compute this NE on policies characterized by payoff function φ (*solving the game*).

3 SOLVING THE GAME

Games in strategic forms can be solved by linear programming [Chvátal, 1983], unfortunately, here, the game is too large to be solved directly (we remind the reader that the number of pure strategies of the game is equal to the number of deterministic stationary policies of the MDP, which

is exponential in the number of states).[4] If the model was known, one could rely on the double oracle algorithm of Gilbert *et al.* [2015a]. Unfortunately, that approach suffers some drawbacks. Firstly, if the optimal mixture of policies $\tilde{\pi}^*$ is composed of too many policies, its time and space requirements might become prohibitive, as the double oracle algorithm would have to compute and store all polices that are in the support of $\tilde{\pi}^*$. Secondly, this approach does not generalize to the case where the model is unknown. Thus it can not be used to derive a model-free RL algorithm. We therefore turn to a different approach, based on fictitious play and on a double timescale technique.

3.1 LEARNING SETTING

In RL, one typically expects convergence to playing an optimal policy at each step. Since in our case the optimal policy is mixed, this cannot be evaluated at each time step independently. Rather, after any number n of episodes, we consider the *final state distribution*, defined as $(f_1|\alpha_1, \ldots, f_{|\mathcal{F}|}|\alpha_{|\mathcal{F}|})$, where for all i, α_i is the fraction of episodes so far in which the final state was f_i.

We define the *loss* $L(\mathbf{p})$ of a distribution over final states to be the value of its best response against it:

$$L(\mathbf{p}) \stackrel{def}{=} \varphi(\mathbf{p}^{BR}, \mathbf{p})$$

where $\mathbf{p}^{BR}$ is the vector of final state frequencies of a policy which maximizes the expectation of cumulated rewards with respect to reward funtion $\mathcal{R}_{\mathbf{p}}$ (hence a best response to $\mathbf{p}$). Since $L(\mathbf{p}^{\tilde{\pi}^*}) = 0$ characterizes SSB-optimal policies $\tilde{\pi}^*$, it is natural to measure the quality of learning by the decrease in loss of the final state distribution so far $\mathbf{p}_n$, as n increases. Convergence to an SSB-optimal policy then amounts to $L(\mathbf{p}_n) \to 0$ with $n \to \infty$.

Rephrasing, we expect that, considering the final states reached from the beginning, in retrospect their frequencies are approximately equivalent to those we would have obtained had we played a mixed optimal policy from the start (and more and more exactly as n increases). This corresponds to the standard "on-line" setting of RL, in which success is measured from the start.

3.2 FICTITIOUS PLAY

Fictitious Play is an algorithm that only needs a best response procedure to solve a game. The algorithm maintains for each player her mixed policy so far $\tilde{\pi}_n$, defined as $(\pi^1|\alpha_1, \ldots, \pi^k|\alpha_k)$, where for all i, α_i is the fraction of episodes so far in which the stationary, deterministic policy π^i has been played. At each time step, each player considers that $\tilde{\pi}_n$ perfectly represents the mixed strategy that is used by the adversary and plays a best response to it. The algorithm converges to a Nash equilibrium of the game (in the sense that $L(\mathbf{p}_n)$ converges to 0) when the game is a finite zero-sum game. Fictitious play is represented in Algorithm 1 for a symmetric two-player zero-sum game. As the game is symmetric, we only need to consider the mixed policy so far, $\tilde{\pi}_n$, of a player playing against herself.

Algorithm 1: Fictitious Play

Data: Game $\mathcal{G}$, arbitrary pure strategy π_0

1 **while** *True* **do**

2 Play π_n

3 # update current mixed policy

4 $\tilde{\pi}_{n+1} = (\pi^1|\alpha_1, \ldots, \pi^k|\alpha_k)$ with

5 $\begin{cases} \alpha_i = n \cdot \alpha_i/(n+1) + 1/(n+1) & \text{for } \pi^i = \pi_n \\ \alpha_i = n \cdot \alpha_i/(n+1) & \text{for } \pi^i \neq \pi_n \end{cases}$

6 $\pi_{n+1} = BestResponseTo(\tilde{\pi}_{n+1})$

Example 5 (continued)**.** *Assume the agent chooses initial strategy $\pi_0 = \pi_B$, then after one episode/game we have $\tilde{\pi}_1 = (\pi_B|1)$. Now π_A is a best response to $\tilde{\pi}_1$ (Example 2), hence $\pi_1 = \pi_A$. So the agent plays π_A during the second episode, and we get $\tilde{\pi}_2 = (\pi_A|1/2, \pi_B|1/2)$. Now it is easy to see that π_A is a best response to $\tilde{\pi}_2$, so the agent again plays π_A and gets $\tilde{\pi}_3 = (\pi_A|2/3, \pi_B|1/3)$. From Example 4 we get that π_A is a best response to $\tilde{\pi}_3$, and that the loss of $\tilde{\pi}_3$ is $L(\mathbf{p}^{\tilde{\pi}_3}) = \varphi(\pi_A, \tilde{\pi}_3) = 7/54$.*

3.3 SSB Q-LEARNING

This subsection makes a first step towards the adaptation of fictitious play to solve the game induced by an MDP and an SSB utility function. Recall from Section 2.2 that the best responses to the mixed strategy so far, $\tilde{\pi}_n$, are exactly the optimal policies in the (standard) MDP with reward function $\mathcal{R}_{\mathbf{p}^{\tilde{\pi}_n}}$. In other words, best responses can be computed as a function of $\mathbf{p}^{\tilde{\pi}_n}$ only. Accordingly, instead of recording $\tilde{\pi}_n$ as such, which involves an exponential number k of pure policies π^i in the worst case, as in Algorithm 1, it is enough to record the vector $\mathbf{p}_n = \mathbf{p}^{\tilde{\pi}_n}$. Then we can rewrite Lines 4–6 of Algorithm 1 as:

$$\begin{aligned} \mathbf{p}_{n+1} &= n \cdot \mathbf{p}_n/(n+1) + \mathbf{p}^{\pi_n}/(n+1) \\ \pi_{n+1} &= BestResponseTo(\mathbf{p}_{n+1}) \end{aligned}$$

However, in practice, when policy π_n is played, one observes only one drawing from $\mathbf{p}^{\pi_n}$, and not the distribution itself. Hence our first adaptation of fictitious play is as given in Algorithm 2. Note that we do not know the model of the MDP, so we use $BestResponseTo$ as an oracle. We find a better solution later in this section.

Example 6 (continued)**.** *Let $\pi_0 = \pi_B$ again. Hence the agent plays π_B during one complete episode. If the die rolls 3, we get $\mathbf{p}_1 = (f_3|1)$. Then the best response is computed as one to a strategy which always yields f_3, and we get $\pi_1 = \pi_A$. The agent therefore plays π_A during one episode,*

[4] Our running example does not illustrate this combinatorial explosion, but it clearly arises, e.g., in the "intransitive grid" and the "race against the clock" (see Section 4).

Algorithm 2: Approximate Fictitious Play

Data: MDP $\mathcal{M}$, SSB function φ, arbitrary policy $\pi_0 \in \Pi_s$

while *True* **do**
- Play π_n for one episode
- $f_i =$ final state reached
- $\mathbf{p}_{n+1} = n \cdot \mathbf{p}_n/(n+1) + \mathbf{1}_i/(n+1)$
- $\pi_{n+1} = BestResponseTo(\mathbf{p}_{n+1})$

and if the die rolls 4*, we get* $\mathbf{p}_2 = (f_3|1/2, f_4|1/2)$*, to which a best response is* $\pi_2 = \pi_A$*. If the die then rolls* 1*, we get* $\mathbf{p}_3 = (f_1|1/3, f_3|1/3, f_4|1/3)$*. In this case the best response is* π_A*, just as in Example 4, but note that it has an estimated value* $\mathbf{p}_A \cdot \Phi \cdot \mathbf{p}_3 = 5/6 \cdot 2/3 - 1/6 \cdot 2/3 = 4/9$*, instead of* $\varphi(\pi_A, \tilde{\pi}_{AAB}) = 7/54$ *if* $\mathbf{p}^{\tilde{\pi}_{AAB}}$ *were directly observed.*

The following theorem proves that observing only realizations of $\mathbf{p}^{\pi_n}$ does not prevent the convergence of $(\mathbf{p}_n)_{n\in\mathbb{N}}$ to the distribution of an SSB-optimal policy.

Theorem 1. *In Algorithm 2,* $L(\mathbf{p}_n)$ *tends to* 0 *as* $n \to \infty$*.*

Proof. Assume an optimal policy π_n with respect to $\mathcal{R}_{\mathbf{p}_n}$ is played during the (n+1)-th episode. At the end of the episode, a final state f_i is reached and $\mathbf{p}_{n+1}$ is defined by:

$$\mathbf{p}_{n+1} = \frac{n \cdot \mathbf{p}_n}{n+1} + \frac{\mathbf{1}_i}{n+1} = \mathbf{p}_n + \frac{1}{n+1}(\mathbf{1}_i - \mathbf{p}_n)$$

We rewrite this equation in the following way :

$$\mathbf{p}_{n+1} = \mathbf{p}_n + \frac{1}{n+1}(\mathbf{p}^{\pi_n} - \mathbf{p}_n + \boldsymbol{M}_{n+1}) \qquad (3)$$

where $\boldsymbol{M}_{n+1} = \mathbf{1}_i - \mathbf{p}^{\pi_n}$ is a square integrable martingale difference sequence. Equation 3 is a standard single timescale process with continuous differential inclusion:

$$\dot{\mathbf{p}}(t) \in \{\mathbf{p}^{\pi} - \mathbf{p}(t) : \pi \in \Pi(\mathbf{p}(t))\} \qquad (4)$$

where $\Pi(\mathbf{p})$ denotes the set of optimal policies with respect to reward $\mathcal{R}_{\mathbf{p}}$. A similar differential inclusion can be obtained for the standard fictitious play. However, here, as $\mathbf{p}_n$ is a distribution over final states (not over strategies) and as only a realization of $\mathbf{p}^{\pi}$ is observed, we need to invoke a stochastic approximation argument.

Indeed, the best response correspondence is upper-semicontinuous, with closed and convex values. Hence the existence of at least one solution $\mathbf{p}(t)$ through each initial value $\mathbf{p}(0)$, which is Lipschitz continuous and defined for all positive times, is guaranteed [Hofbauer, 1995]. Let $\mathbf{p}(t)$ be a solution of inclusion 4 and $\boldsymbol{\zeta}(t) = \mathbf{p}(t) + \dot{\mathbf{p}}(t) = \mathbf{p}^{\pi}$ for a best response $\pi \in \Pi(\mathbf{p}(t))$. By definition of L, we have $L(\mathbf{p}(t)) = \varphi(\boldsymbol{\zeta}(t), \mathbf{p}(t))$, and by the envelope theorem:

$$\frac{d}{dt}L(\mathbf{p}(t)) = \frac{\partial\varphi(\boldsymbol{\zeta}(t), \mathbf{p}(t))}{\partial\boldsymbol{\zeta}}\dot{\boldsymbol{\zeta}}(t) + \frac{\partial\varphi(\boldsymbol{\zeta}(t), \mathbf{p}(t))}{\partial\mathbf{p}}\dot{\mathbf{p}}(t)$$

As $\boldsymbol{\zeta}(t)$ maximizes $\varphi(., \mathbf{p}(t))$, the first term is null [Mas-Colell *et al.*, 1995, pp. 964–965], and by linearity:

$$\begin{aligned}\frac{d}{dt}L(\mathbf{p}(t)) &= \varphi(\boldsymbol{\zeta}(t), \dot{\mathbf{p}}(t)) \\ &= \varphi(\mathbf{p}(t), \dot{\mathbf{p}}(t)) + \underbrace{\varphi(\dot{\mathbf{p}}(t), \dot{\mathbf{p}}(t))}_{=0} \\ &= \varphi(\mathbf{p}(t), \dot{\mathbf{p}}(t)) + \underbrace{\varphi(\mathbf{p}(t), \mathbf{p}(t))}_{=0} \\ &= \varphi(\mathbf{p}(t), \boldsymbol{\zeta}(t)) = -\varphi(\boldsymbol{\zeta}(t), \mathbf{p}(t))\end{aligned}$$

as Φ is skew-symmetric (hence $\varphi(\mathbf{p}(t), \mathbf{p}(t)) = \varphi(\dot{\mathbf{p}}(t), \dot{\mathbf{p}}(t)) = 0$, and $\varphi(\mathbf{p}(t), \boldsymbol{\zeta}(t)) = -\varphi(\boldsymbol{\zeta}(t), \mathbf{p}(t))$). Thus, $\frac{d}{dt}L(\mathbf{p}(t)) = -L(\mathbf{p}(t))$, $L(\mathbf{p}(t)) = L(\mathbf{p}(0))e^{-t}$, and hence $L(\mathbf{p}(t))$ tends to 0 with $t \to \infty$. Thus, the set of final state distributions of the optimal strategies is globally attracting for the best response dynamic, which implies the convergence of the discrete stochastic approximation (3) [Benaïm *et al.*, 2006, Properties 1, 2]. □

If the model was known, one could use Algorithm 2. At each iteration of the **while** loop, the corresponding MDP would be solved using dynamic or linear programming to find the best response policy π_{n+1}. Unfortunately, as the model is unknown, this policy can not be computed directly and has to be learned. The "$\pi_{n+1} = BestResponseTo(\mathbf{p}_{n+1})$" line should therefore be replaced by, say, a Q-learning phase which converges asymptotically to the desired policy.

Recall that an agent using Q-learning (in a standard MDP) maintains an estimate of Q-values $Q(s, a)$ using:

$$\begin{aligned}&Q_{n+1}(s_n, a_n) = Q_n(s_n, a_n) \\ &+ \alpha_n(s_n, a_n)(r_{n+1} + \max_b\{Q_n(s_{n+1}, b)\} - Q_n(s_n, a_n))\end{aligned}$$

after taking action a_n in state s_n, ending up in state s_{n+1}, and observing the (numerical) reward r_{n+1}, and where $\alpha_n(s_n, a_n)$ is the value of the learning rate for (s_n, a_n) at timestep n. Note that from now on, for simplicity, we use n to denote the number of time steps (while previously it denoted the number of episodes). Exploitation is realized by choosing $a_n = \arg\max_a Q_n(s_n, a)$ at state s_n. Q-learning is known to converge to an optimal policy in the limit, provided the reward function is stationary [Watkins and Dayan, 1992].

Hence the idea is to adapt Algorithm 2 to run Q-learning while keeping its target reward function fixed to $\mathcal{R}_{\mathbf{p}_n}$ as when it started, and when it has converged (to an approximate best response to $\mathbf{p}_n$), to update $\mathbf{p}_n$ using what has been observed in this phase and start a new Q-learning phase. Unfortunately, the number of learning episodes required to learn an optimal or ϵ-optimal policy is unknown. Therefore, we want to avoid alternating the Q-learning phase and the reward update phase by using a technique from Borkar [1997] which interleaves both phases successfully using a two-timescale approach. In this approach, the

following iterative equations are used concurrently:

$$\mathbf{p}_{n+1} = \mathbf{p}_n + \beta_n(\mathbf{1}_i - \mathbf{p}_n) \text{ when } f_i \in \mathcal{F} \text{ is reached} \quad (5)$$

$$Q_{n+1}(s_n, a_n) = Q_n(s_n, a_n) + \alpha_n(s_n, a_n)\Delta_{n+1} \quad (6)$$

$$\Delta_{n+1} = \mathcal{R}_{\mathbf{p}_n}(s_{n+1}) + \max_b\{Q_n(s_{n+1}, b)\} - Q_n(s_n, a_n)$$

$$\forall s, a, \left\{ \begin{array}{l} \sum_{n=0}^{\infty} \alpha_n(s,a) = \infty \text{ and } \sum_{n=0}^{\infty} \beta_n = \infty \\ \beta_n/\alpha_n(s,a) \to 0 \\ \sum_{n=0}^{\infty} \alpha_n(s,a)^2 + \beta_n^2 < \infty \end{array} \right\} \quad (7)$$

The intuition is that Q_n evolves more quickly than $\mathbf{p}_n$, giving time for Q_n, and hence the best response, to adapt to changes in the target reward $\mathcal{R}_{\mathbf{p}_n}$.

Write $\eta_{\mathbf{p}}$ (resp. $\eta_{s,a}$) for the number of times vector $\mathbf{p}_n$ (resp. state action-pair (s,a)) has been updated (resp. experienced). In our case, β_n is $1/(\eta_{\mathbf{p}}+1)$ since Equation 5 tracks the final state distribution so far, so we can set α_n to $1/(\eta_{s,a}+1)^{2/3}$ for instance. Note that this example works because $\mathbf{p}_n$ is updated after at most T_{max} steps, bounding the number of updates of α_n (for any (s,a)) between two consecutive updates of β_n. With these conditions, the two recursive equations on $\mathbf{p}_n$ and Q_n form a two-timescale stochastic approximation iteration, where $\mathbf{p}_n$ is on a slower timescale than Q_n. The following example gives the intuition behind the two time-scale technique; the convergence proof under Condition (7) is given in Theorem 2.

Example 7. *Suppose that at some point the Q-values of a_A and a_{BC} in s_0 are 0.1 and 0.2, respectively, and that those of a_B,a_C in s_{BC} are 0.3,-0.7. Assume moreover $\mathbf{p}_n$=$(1/5, 0, 1/5, 1/5, 1/5, 1/5)$, $n = 80$ (with 20 episodes of length 1 and 30 of length 2, hence $\eta_{\mathbf{p}} \simeq 0.02$) $\eta_{s_0,a_{BC}} = 30$ ($\alpha_n(s_0, a_{BC}) \simeq 0.1$) and $\eta_{s_{BC},a_B} = 20$ ($\alpha_n(s_{BC}, a_B) \simeq 0.13$).*

Hence the agent will choose a_{BC} in s_0, reach s_{BC} and update $Q(s_0, a_{BC})$ to $\simeq 0.2 + 0.1 \cdot (0 + 0.3 - 0.2) = 0.21$. In s_{BC} she will choose a_B and, if she rolls 3, update $Q(s_{BC}, a_B)$ to $\simeq 0.3 + 0.13 \cdot (\mathbf{1}_3 \cdot \Phi \cdot \mathbf{p}_n + 0 - 0.3) = 0.3 + 0.13 \cdot (-2/5 - 0.3) \simeq 0.2$, and $\mathbf{p}_n$ to $(10/51, 0, 11/51, 10/51, 10/51, 10/51)$.

Note that Q-values have evolved significantly more than $\mathbf{p}_n$ (and hence than the target numerical reward $\mathcal{R}_{\mathbf{p}_n}$).

3.4 HANDLING EXPLORATION

In order for Q-learning to converge, one needs to ensure that all state-action pairs are performed infinitely often. Usually, this exploration is guaranteed through some randomization, using an ϵ-greedy strategy, for instance. We present in this subsection an exploration strategy called *Episodic-ϵ-Greedy (EG for short)* that guarantees that we converge to an ϵ-optimal SSB strategy using the algorithm described by Equations 5 and 6. During learning, an episode will be generated using either the current best policy (defined by the Q-values), with probability $(1-\epsilon)$, or the uniformly random policy, which we denote by π_U, with probability ϵ. If an episode is generated using π_U (i.e., the agent is exploring), then the update of Equation 5 is not performed at the end of the episode. This guarantees that the convergence of $\mathbf{p}_n$ is not biased by the exploration strategy. The final proposed algorithm is presented in Algorithm 3.

Algorithm 3: SSB Q-learning

Data: MDP $\mathcal{M}$, SSB function φ

while *True* **do**
- Choose a_n using the EG exploration strategy
- Play a_n, observe s_{n+1}, and let $r_{n+1} = \mathcal{R}_{\mathbf{p}_n}(s_{n+1})$
- $Q_{n+1}(s_n, a_n) = Q_n(s_n, a_n) + \alpha_n(s_n, a_n)(r_{n+1} + \max_b\{Q_n(s_{n+1}, b)\} - Q_n(s_n, a_n))$
- **if** $s_{n+1} = f_i \in \mathcal{F}$ *and exploration is off* **then**
  - $\mathbf{p}_{n+1} = \mathbf{p}_n + \frac{1}{\eta_{\mathbf{p}}+1}(\mathbf{1}_i - \mathbf{p}_n)$

We are now ready to prove the convergence of SSB Q-learning to an ϵ-optimal policy through two theorems.

Theorem 2. *Under Conditions (7) with $\beta_n = 1/(\eta_{\mathbf{p}}+1)$, in Algorithm 3, $L(\mathbf{p}_n)$ tends to 0 almost surely as $n \to \infty$.*

Proof. The idea is that $\mathbf{p}_n$ can be viewed as quasi-static compared to Q_n. Indeed, let π_n be the greedy policy given by Q_n. We can rewrite the equations as:

$$\mathbf{p}_{n+1} = \mathbf{p}_n + \alpha_n(\epsilon_n + \mathbf{M}'_n) \quad (8)$$

$$Q_{n+1}(s_n, a_n) = Q_n(s_n, a_n) + \alpha_n(s_n, a_n)(T(Q_n)(s_n, a_n) - Q_n(s_n, a_n) + \mathbf{M}''_{n+1})$$

where $\epsilon_n = \frac{\beta_n}{\alpha_n}(\mathbf{p}^{\pi_n} - \mathbf{p}_n)$ and $\mathbf{M}'_n = \frac{\beta_n}{\alpha_n}(\mathbf{1}_i - \mathbf{p}^{\pi_n})$

$$T(Q_n)(s,a) = \sum_{s'} \mathcal{P}(s'|s,a)(\mathcal{R}_{\mathbf{p}_n}(s') + \max_b\{Q_n(s',b)\})$$

$$\mathbf{M}''_{n+1} = \mathcal{R}_{\mathbf{p}_n}(s_{n+1}) + \max_b\{Q_n(s_{n+1}, b)\} - T(Q_n)(s_n, a_n)$$

Clearly $\epsilon_n \to 0$ almost surely ($||\mathbf{p}^{\pi_n}||$ and $||\mathbf{p}_n||$ are bounded). Then $(\mathbf{p}_n, Q_n)$ will converge to the internally chain transitive invariant set of the ODE [Borkar, 2008]:

$$\dot{\mathbf{p}}(t) = 0 \qquad \dot{Q}(t) = T(Q(t)) - Q(t)$$

Let $Q^*(\mathbf{p}_n)$ denote the optimal Q-value function for reward function $\mathcal{R}_{\mathbf{p}_n}$. Therefore $Q_n - Q^*(\mathbf{p}_n) \to 0$ almost surely, which entails that $(\mathbf{p}_n, \pi_n)$ converges to the set $(\mathbf{p}, \pi^*(\mathbf{p}))$ with $\pi^*(\mathbf{p})$ a best response to $\mathbf{p}$. We then rewrite (5) to:

$$\mathbf{p}_{n+1} = \mathbf{p}_n + \beta_n(\mathbf{p}^{\pi^*(\mathbf{p}_n)} - \mathbf{p}_n + (\mathbf{p}^{\pi_n} - \mathbf{p}^{\pi^*(\mathbf{p}_n)}) + (\mathbf{1}_i - \mathbf{p}^{\pi_n}))$$

As $\mathbf{p}^{\pi_n} - \mathbf{p}^{\pi^*(\mathbf{p}_n)} \to 0$ almost surely, the asymptotic behavior is the same as in Theorem 1. Thus the loss of $\mathbf{p}_n$ converges to 0 with $n \to \infty$. □

The result of Theorem 2 uses the fact that with the EG exploration strategy, exploration has no impact on $\mathbf{p}_n$. The drawback of this strategy is that $\mathbf{p}_n$ does not truly represent the frequencies with which each final state has been obtained. If we let $\mathbf{p}_n^{real}$ represent the vector of true frequencies with which each final state has been obtained, then following theorem proves that $\mathbf{p}_n^{real}$ converges to the final state frequencies of an ϵ- optimal SSB-policy.

Theorem 3. *Under Conditions (7) with $\beta_n = 1/(\eta_{\mathbf{p}} + 1)$, when Algorithm 3 is run, $\mathbf{p}_n^{real}$ converges to the final state distribution of an ϵ-optimal SSB-policy almost surely.*

Proof. Let ϵ' denote the parameter of EG exploration and let $\mathbf{p}^{real} = \lim_{n\to\infty} \mathbf{p}_n^{real}$. Then asymptotically we have

$$\mathbf{p}^{real} = (1-\epsilon')\mathbf{p}^* + \epsilon'\mathbf{p}^{\pi_U}$$

where $\mathbf{p}^*$ is the final state distribution of an optimal SSB-policy. Thus for any policy π:

$$\varphi(\mathbf{p}^{real}, \mathbf{p}^\pi) = (1-\epsilon')\underbrace{\varphi(\mathbf{p}^*, \mathbf{p}^\pi)}_{\geq 0} + \epsilon'\underbrace{\varphi(\mathbf{p}^{\pi_U}, \mathbf{p}^\pi)}_{\geq -\varphi_{\max}}$$
$$\geq -\epsilon'\varphi_{\max}$$

with $\varphi_{\max} = \max_{f,f'} \varphi(f, f')$. Hence, with $\epsilon' = \epsilon/\varphi_{\max}$, Algorithm 3 converges to an ϵ-optimal SSB strategy. □

4 PROOF OF CONCEPT

Although SSB encompasses many different criteria, we focus here on the probabilistic dominance criterion as it is an important case for which no model-free algorithm that is provably correct has been proposed. We plot here the results of four experiments: "sequential Gardner dice", "who wants to be a millionaire", "intransitive grid" and "race against the clock" using the probabilistic dominance criterion (hence values are all in $[-1, 1]$). For all runs, $10,000,000$ steps were performed in the MDP, ϵ was set to 0.1, and α_n was set to $1/(\eta_{s,a}+1)^{11/20}$.

Gardner Dice. We first present the results on Gardner's dice problem as formalized in Example 1. Figure 1(a) shows the evolution of the frequencies (f_A, f_B, f_C) with which each die has been played for a representative run. The optimal frequency vector $\mathbf{p}^* = (3/13, 3/13, 7/13)$ is shown as a green dot and the same vector biased by exploration $\mathbf{p}_\epsilon^* = (1-\epsilon) * \mathbf{p}^* + \epsilon * \mathbf{p}^{\pi_\mathcal{U}}$ by a red dot; the vector (f_A, f_B, f_C) tends towards $\mathbf{p}_\epsilon^*$, drawing triangles of decreasing surface around $\mathbf{p}_\epsilon^*$. Figure 1(b) presents the evolution of the Q-values of the three actions, a_A, a_B and a_C. One can see that the best die alternates between the three dice and that $\max\{Q_A, Q_B, Q_C\}$ tends towards 0. (The best response is always deterministic and so must be one of π_A, π_B, π_C. However at convergence its value has to be 0.)

Who wants to be a millionaire. In this popular television game show, a contestant answers 15 multiple-choice questions (with four possible answers) of increasing difficulty, for increasingly large sums, roughly doubling the pot each question. At each time step, the contestant may decide to walk away with the money currently won. If she answers incorrectly, then all winnings are lost except what has been earned at a "guarantee point" (questions 5 and 10). The player is allowed 3 lifelines (50:50, removing two of the choices, ask the audience and call a friend for suggestions); each can only be used once. We used the first model of the Spanish 2003 version of the game presented by Perea and Puerto [2007]. The probability of answering correctly is a function of the question's number and increased by the lifelines used (if any).

Intransitive grid. In this domain we study an episodic grid MDP containing 9 states. The agent always starts an episode in the bottom-right corner of the grid. Three terminal states, f_1, f_2 and f_3 can be attained at the three other corners of the grid. The agent can only go left and up. With a probability of 0.2, the agent makes a mistake and goes in the wrong direction. The preference relation between the final states is the following: $f_1 \succ f_2 \succ f_3 \succ f_1$.

Race against the clock. Lastly, we discuss the domain discussed in Example 3.[5] The racing circuit is represented by 6 physical positions $\{p_1, \ldots, p_6\}$ plus one, p_{el}, representing elimination. A state of the MDP is a triple (p, s, t) giving the current position $p \in \{p_1, \ldots, p_6, p_{el}\}$, the current speed of the car $s \in \{Slow, Medium, Fast\}$ and the current time $t \in \mathbf{N}$. In each state the agent can decide between 3 actions: accelerating, decelerating or keeping the same speed. At each time step t, the probability of running off the track is a function of s_t, p_t and a_t, taking into account both the speed of the car and the difficulty of the current part of the circuit. Finally, the time spent between two positions decreases stochastically with the current speed.

Results. Figure 1(c)-(f) shows the evolution of $L(\mathbf{p}_n^{real})$ and $L(\mathbf{p}_n)$ (i.e., the values of the optimal policies regarding reward functions defined by $\Phi\mathbf{p}_n^{real}$, $\Phi\mathbf{p}_n$) for each domain. The results are averaged over 20 runs. As expected the value of $L(\mathbf{p}_n)$ tends towards 0 as the number of learning steps increase. The value of $L(\mathbf{p}_n^{real})$ decreases and is much lower than ϵ ($= 0.1$ in the experiments) on all figures.

Finally, in Table 2, we compare the "race against the clock" results obtained by our SSB Q-learning algorithm to the results obtained by a standard Q-learning algorithm launched with three different reward functions $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$. For each reward function, a penalty of value $-t$ is received by the agent each time the circuit is completed in time t. For reward function $\mathbf{R}_i$, an elimination results in a penalty of value $r_{elem}^i \in \{-10, -25, -40\}$. For each algorithm we give the frequency of elimination f_{elem} and the average time T_{cc} of circuit completion. The final columns show the probabilities with which the SSB Q-learning agent would

[5]The complete description is given as supplementary material at hugogilbert.pythonanywhere.com.

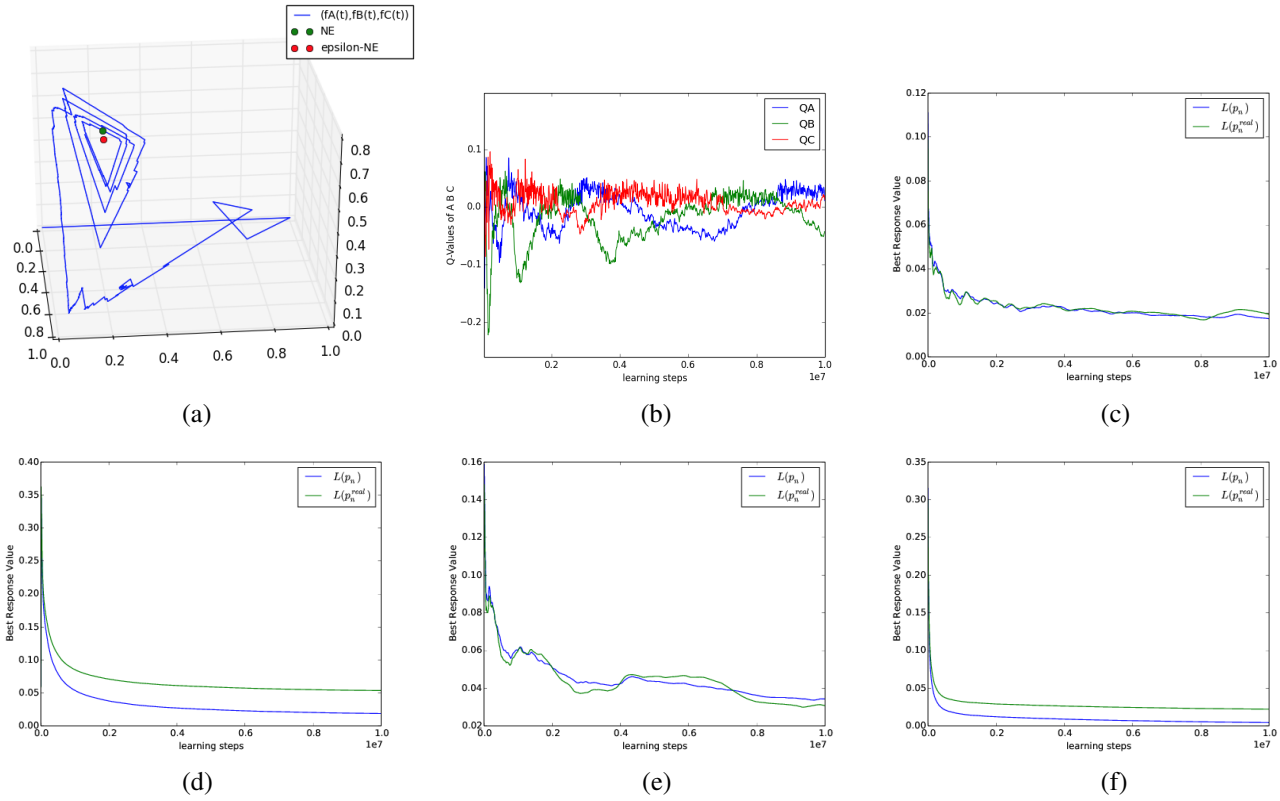

Figure 1: For the Gardner dice domain, **(a)** convergence of the policy in the space of die frequencies, **(b)** evolution of Q-values, **(c)** evolution of loss; For **(d)** Who wants to be a millionnaire, **(e)** Intransitive grid and **(f)** Race against the clock, evolution of loss.

beat ($\mathbf{P}_{\succ}$) and at least tie with ($\mathbf{P}_{\succeq}$) each Q-learning agent. As expected, f_{elem} decreases and T_{cc} increases with the penalty value of an elimination. For a Q-learning agent, this penalty would have to be tuned to give the best compromise. The SSB Q-learning agent does not face this problem and the last two columns show that this agent is more likely to produce a preferred episode.

5 Conclusion

Skew-Symmetric Bilinear (SSB) utility is a useful general decision model that encompasses many decision criteria (e.g., EU, threshold probability, probabilistic dominance, etc.). We designed a model-free reinforcement learning algorithm to compute an epsilon SSB-optimal policy and provided experimental results.

Table 2: Comparisons of SSB Q-Learning with Three Q-Learning Algorithms (Results Averaged Over 20 Runs).

	f_{elem}	T_{cc}	$\mathbf{P}_{\succ}$	$\mathbf{P}_{\succeq}$
SSB Q-learning	0.41	5.29	–	–
Q-learning with $\mathbf{R}_1$	0.48	4.34	0.37	0.64
Q-learning with $\mathbf{R}_2$	0.31	7.14	0.48	0.66
Q-learning with $\mathbf{R}_3$	0.26	9.09	0.54	0.66

Our current work can be extended in several natural ways. For instance, it would be interesting to tackle non-episodic problems. Another direction is to use more elaborate RL algorithms than Q-learning for computing best responses.

Our work is currently being applied in an industrial context with good results. An automated information extraction (IE) treatment chain is modelled as an MDP, and improved using a reward function balancing extraction quality and treatment time. SSB utility theory is used to formalise qualitative preferences expressed by human operators on the output of the treatments.

Bridging Heterogeneous Domains With Parallel Transport For Vision and Multimedia Applications

San Francisco, CA 94108

Abstract

Accounting for different feature types across datasets is a relatively under-studied problem in domain adaptation. We address this heterogeneous adaptation setting using principles from parallel transport and hierarchical sparse coding. By learning generative subspaces from each domain, we first perform label-independent cross-domain feature mapping using parallel transport, and obtain a collection of paths (bridges) that could compensate domain shifts. We encode the information contained in these bridges into an expanded prior, and then integrate the prior into a hierarchical sparse coding framework to learn a selective subset of codes representing holistic data properties that are robust to domain change and feature type variations. We then utilize label information on the sparse codes to perform classification, or in the absence of labels perform clustering, and obtain improved results on several previously studied heterogeneous adaptation datasets. We highlight the flexibility of our approach by accounting for multiple heterogeneous domains in training as well as in testing, and by considering the zero-shot domain transfer scenario where there are data categories in testing which are not seen during training. In that process we also empirically show how existing heterogeneous adaptation solutions can benefit from the findings of our study.

1 INTRODUCTION

Domain adaptation, which addresses the problem of change in data characteristics across training (source domain) and testing (target domain) datasets, has received substantial attention over the last few years [Daume III and Marcu, 2006, Gopalan et al., 2015]. Its utility for visual recognition problems has been adequately demonstrated by several efforts that have utilized principles from distance transforms [Saenko et al., 2010], max-margin methods [Duan et al., 2009], manifolds [Gong et al., 2012], dictionary learning [Qiu et al., 2012] among others. Many of these approaches have addressed settings where the source domain is labeled and the target domain is unlabeled (unsupervised adaptation), when the target domain also has partial labels (semi-supervised adaptation) and when there is more than one domain in the source and/or target (multiple domain adaptation). However they assume that data, across domains, is represented by same type of features with same dimensions. This is not always possible in practice, given the prevalence of multi-modal sensors, and there have been relatively few efforts in the literature addressing the heterogeneous domain adaptation (HDA) setting which allows different feature types across domains.

One of the earliest efforts is by [Dai et al., 2008] that proposed a translated learning framework using risk minimization principles to bridge data across different feature types. [Prettenhofer and Stein, 2010] utilized structural correspondence learning by identifying pivot features that share similarities across domains. While such models have restrictions on the type of applications where they can be deployed, [Shi et al., 2010] proposed a more generic heterogeneous spectral mapping framework that learns an embedding to obtain a common domain-invariant feature subspace that optimally represents data from each domain. Along similar lines, [Wang and Mahadevan, 2011] proposed a manifold alignment approach that bridges source and target domain manifolds through a latent space that in addition to preserving topology of each domain, maximizes the intra-class similarities and inter-class dis-similarities across domains. [Kulis et al., 2011] approached this problem by learning asymmetric kernel transformations that perform cross-domain data mapping using semantic similarity. More recently, [Li et al., 2014] proposed a feature augmentation strategy coupled with max-margin classifiers, whose formulation resembles multiple kernel learning that in turn guarantees global optimal solution, and [Yeh et al., 2014] studied the utility of canonical correlation subspaces to this problem. Most of these methods either

address the HDA problem by learning projections for each domain onto a common latent space where certain properties are satisfied, or by learning feature mapping from one domain onto another directly.

We take a rather different approach which, instead of learning a *few complex transformations* to map domains, learns *several simpler transformations* that explain how data from different domains can be bridged. In learning such transformations we bring the domains to a common dimension using simpler generative information, instead of more complex objectives tied to the domain structure and data similarities. What we gain by doing so is a richer 'expanded' set of prior information which could be harnessed by hierarchical learning methodologies to perform inference. More specifically, given N domains, with each domain representing the data with different feature type (thus having different dimension), we group the data from each domain into k clusters based on their feature similarity and obtain generative subspaces corresponding to each cluster by doing principal component analysis (PCA). We fix all subspaces to have the same dimension p using a heuristic tied to the amount of energy preserved in doing the dimensionality reduction. We then perform parallel transport [Edelman et al., 1998] between subspaces in every domain pair and obtain several intermediate representations that describe how data across domains can be bridged. We subsequently project the data from each domain onto all these intermediate representations to obtain an expanded prior, and integrate it with hierarchical sparse coding [Jenatton et al., 2011] to obtain compact codes on which we use label information, if any, to perform cross-domain inference. More details are provided in Section 2. The construction of our approach has the following benefits.

Accommodating Unlabeled Data: In many practical situations, with the widespread availability of multi-modal data on the web, we have very few (or at times no) labeled data and lots of unlabeled data. Our approach can readily utilize such big unlabeled data as we rely on generative modeling in addressing the heterogeneous domain shift. By doing so, when the source and target domains contain the same categories/classes, our final inference can range from the classification scenario where we have labels for all categories in source domain and the target domain may or may not have partial labels, to the clustering scenario where both the source and target domains are unlabeled. The label information is utilized while training a discriminative classifier such as support vector machines (SVM) on the learnt sparse codes, and if no labels are available we perform clustering on the sparse codes using methods such as k-means.

Zero-Shot Domain Transfer: We can also address the zero-shot scenario in which there are categories in the target domain that are not present in the source domain. This is somewhat different from the scenarios discussed above where we at least had unlabeled data in source domain for all target categories to support inference models. We could handle such a zero-shot scenario as our model is generative and therefore the learned domain shift would have pertinent information for reasoning out new categories.

Multiple Heterogeneous Domains: Finally we can easily accommodate multiple heterogeneous domains in the source as well as in target since we obtain the expanded prior by doing parallel transport between each domain pair. This does not pose a computational bottleneck as we are eventually learning sparse codes in a hierarchical learning setting that could handle big data.

To the best of our knowledge, our proposed approach is the first to handle these varied aspects of the HDA problem, and while some existing methods could handle a subset of these in principle, we make explicit discussions on these practically relevant requirements. We tested our approach on existing heterogeneous adaptation datasets and obtained good performance improvement over previous results for diverse tasks such as object recognition, event classification, text categorization and sentiment analysis. Detailed experimental analysis is provided in Section 3, and concluding remarks are given in Section 4.

2 APPROACH

Problem Setting: We assume there are N heterogeneous domains $D = \{D_i\}_{i=1}^{N}$, where each domain $D_i = \{x_i^j, y_i^j\}_{j=1}^{n_i}$ contains n_i data samples with $x_i^j \in \mathbb{R}^{d_i}$ denoting the feature vector of dimension d_i and y_i^j denoting the corresponding label information (if any) belonging to one of M different categories. These domains could be partitioned into source and target domains depending on the problem situation. With this information, the goal of this work is to account for heterogeneous domain shift in inferring the labels of the unlabeled target domain data.

2.1 PRELIMINARIES

Before we proceed, we will first review relevant details about the tools we use in our approach.

Parallel Transport: We will be working on subspaces derived from the data, and we will generally have multiple subspaces extracted from each domain. In domain adaptation literature, the notion of geodesic on the Grassmann manifold has been used as a bridge to connect a pair of subspaces [Gopalan et al., 2011]. When we need to bridge two 'sets' of subspaces instead, parallel transport [Edelman et al., 1998] provides a way by learning multiple paths by which subspace sets can be bridged. More specifically, let $S_1 = \{S_1^i\}_i$ and $S_2 = \{S_2^i\}_i$ denote two sets of p-dimensional subspaces in $\mathbb{R}^d$ corresponding to domains D_1 and D_2 respectively, where each subspace say S_1^1 is a point

on the Grassmannian $\mathcal{G}_{d,p}$. Let $g_A(t)$ denote the geodesic with the initial direction $A \in \mathbb{R}^{(d-p)\times p}$ connecting the means of S_1 and S_2, and $\bar{S}_1^1$ denote the tangent space representation of S_1^1 obtained using inverse exponential mapping computed at the mean of S_1. The parallel transport of $\bar{S}_1^1$ is then given as

$$\gamma\bar{S}_1^1(t) = Q_{S_1^1} \exp\left(t \begin{bmatrix} 0 & A^T \\ -A & 0 \end{bmatrix}\right) \begin{bmatrix} 0 \\ B \end{bmatrix} \quad (1)$$

where exp is the matrix exponential, $Q_{S_1^1} \in SO(d)$ is the orthogonal completion of S_1^1, and $B \in \mathbb{R}^{(d-p)\times p}$ is the initial direction to reach from S_1^1 to the exponential map of $\bar{S}_1^1$. Similar directions can be obtained for all subspaces in the sets S_1 and S_2 using the above tangent space approximation. Please refer to [Edelman et al., 1998] for more details. We will discuss how to utilize these directions (bridges) for HDA in Section 2.2.

Hierarchical Sparse Coding: In sparse coding [Yang et al., 2009] the goal is to represent each input vector $x \in \mathbb{R}^p$ as a sparse linear combination of basis vectors. Given a stacked input data matrix $X \in \mathbb{R}^{p\times n}$, where n is the number of data, it seeks to minimize:

$$\underset{Z\in\mathcal{Z},C}{\arg\min} ||X - ZC||_2^2 + \lambda\Omega(C) \quad (2)$$

where $Z \in \mathbb{R}^{p\times r}$ is the dictionary of basis vectors, $\mathcal{Z}$ is the set of matrices whose columns have small ℓ_2 norm and $C \in \mathbb{R}^{r\times n}$ is the code matrix, λ is a regularization hyperparameter, and Ω is the regularizer. In hierarchical sparse coding, such a scheme is extended in a layered fashion using a combination of coding and pooling steps and we pursue the schema presented in [Jenatton et al., 2011]. Our modification comes in the way in which the dictionary is initialized and we present the details in Section 2.2.

While there has been an attempt in using parallel transport for unsupervised homogeneous domain adaptation [Shrivastava et al., 2014], our construction vastly differs from that work as we handle multiple heterogeneous domains without using label information to bridge the domain shift. Moreover, ours is the first approach to integrate parallel transport information with hierarchical sparse coding for adaptation problems.

2.2 PROPOSED HETEROGENEOUS ADAPTATION ALGORITHM

Step 1: We first bring data from all N domains, $D = \{D_i\}_{i=1}^N$, onto a common dimension d by performing PCA on each D_i and choosing the resultant subspace dimension as the largest dimension required among all N subspaces such that 90% of the signal energy is preserved for that decomposition. Then we project data from each domain onto its corresponding subspace. We now have d-dimensional data across all domains, say $\bar{X} = \{\bar{x}_i^j\}_{i,j}$, where i ranges from 1 to N and j ranges from 1 to n_i.

Step 2: From each domain D_i, we then derive k generative subspaces by partitioning $\{\bar{x}_i^j\}_{j=1}^{n_i}$ into k clusters using the k-means algorithm based on the similarity of the d dimensional features, and performing PCA on each cluster. We ensure all the subspaces are of dimension p, by choosing p as the largest dimension required for a subspace, amongst all subspaces obtained by doing k-means in each of the N domains, such that 90% of the signal energy is preserved by that decomposition[1]. Thus from every domain D_i we have a set of p-dimensional subspaces in $\mathbb{R}^d$ denoted by $S_i = \{S_i^j\}_{j=1}^k$. Each subspace in this set is a point on the Grassmann manifold, $\mathcal{G}_{d,p}$. Let $X \in \mathbb{R}^{p\times n}, n = \sum_{i=1}^{N} n_i$ denote the matrix containing the projections of each data in $\bar{X}$ onto its appropriate subspace in $S = \{S_i\}_{i=1}^N$. This is our input data matrix for sparse coding.

Step 3: We then perform parallel transport between S_i's using the method described in Section 2.1, and obtain a collection of directions between each pair of (S_i, S_j), i=1,..N-1, $j = i$+1,..,N. We uniformly sample points along these directions using exponential mapping, which results in new subspaces that have information on how domain shift information flows between domains. We project each data in $\bar{X}$ onto these subspaces to get the expanded prior $\mathcal{P} \in \mathbb{R}^{p\times r}$, which we in turn use to initialize the dictionary Z.

Step 4: Finally we perform hierarchical sparse coding [Jenatton et al., 2011] with the input data matrix X from Step 2 and the initial dictionary Z obtained from Step 3. At the output of each layer of hierarchical sparse coding, we apply Steps 2 and 3 obtain another set of expanded prior which is then used to complement the dictionary of the following layer. Let the final output (from the last layer) of hierarchical sparse coding corresponding to the original data X be denoted by $\hat{X} = \{\hat{x}_i^j\}_{i,j}$, and their corresponding label information (if any) is denoted as before by $Y = \{y_i^j\}_{i,j}$. Note that we have not used any label information thus far.

2.3 INFERENCE

We now perform cross-domain inference using the information contained in $W = (\hat{X}, Y)$. Note that W contains data from both source and target domains, and depending on the dataset we may have one or more domains in the source and target.

Classification: For the classification scenarios widely studied in HDA, source domain contains labeled data for all M categories, and the target domain may or may not have partial labels, and both the source and target domains

[1]While this is a simple heuristic in addressing variations in feature dimensions, we show that it works well empirically. As stated in the introduction, our main proposal for HDA is by generating an expanded prior on how these domains interact, rather than addressing domain shift 'during' the process of bringing domains to a common dimension as done by most existing methods.

have the same M categories. So we consider labeled data present in W to train a multi-class SVM [Crammer and Singer, 2002] with default parameters for linear kernel, and then use the SVM similarity score to classify the unlabeled target domain data into one of M categories. Classification accuracy is computed as the percentage of unlabeled target data that were correctly assigned their category label (using ground truth). Note that while we could have used the label information in any of the previous stages, be it during parallel transport or in sparse coding, we did not because we would like the learned cross-domain representations $\hat{X}$ to be generic to support other inference scenarios discussed next. Nevertheless, we make some observations regarding this later in Section 3.6.

Clustering: We also address the clustering scenario where both source and target domain data are unlabeled, and they have the same M categories. In this case we cluster all the data in $\hat{X}$ into M groups using k-means, and compute the clustering accuracy using a standard method of labeling each of the resulting clusters with the majority class label according to the ground truth, and measuring the number of mis-classifications made by each cluster grouping.

Zero-shot Learning: We finally account for the zero-shot learning scenario where the target domain has some categories that are not a part of the M source domain categories. For this case, we use labels for M categories in the source domain and (if available) in the target domain to train the SVM as discussed for the classification scenario. We then threshold the SVM similiarity score for the unlabeled target data, with the hope that if such data comes outside of the M source categories, the similarity score will be less. We then cluster such data using k-means to obtain groupings, with the number of clusters set to the number of new target categories known apriori, and evaluate the accuracy as discussed above for the clustering scenario. If we do not even know the number of new target categories, then it becomes difficult to quantify clustering accuracy.

3 EXPERIMENTS

We first discuss the classification scenario and experiment with the setup used by [Li et al., 2014] for the problems of heterogeneous object recognition, text categorization and sentiment analysis. These experiments have only one domain each in the source and target. We then consider the event classification experiment designed by [Chen et al., 2013] which consists of multiple source domains and a single target domain. We then provide a detailed analysis of the findings from our study.

3.1 OBJECT RECOGNITION

We work with the Office dataset [Saenko et al., 2010] that contains a total of 4106 images from 31 categories collected from three sources: amazon (object images downloaded from Amazon), dslr (high-resolution images taken from a digital SLR camera) and webcam (low-resolution images taken from a web camera). SURF features are extracted for all the images. The images from amazon and webcam are clustered into 800 visual words by using k-means. After vector quantization, each image is represented as a 800 dimensional histogram feature. Similarly, we represent each image from dslr as a 600-dimensional histogram feature. In the experiments, dslr is used as the target domain, while amazon and webcam are considered as two individual source domains. For training the SVM, we randomly select 20 labeled images per category for the source domain amazon, and 8 labeled images per category for webcam as source domain. For the target domain dslr, 3 labeled images are randomly selected from each category. The remaining target domain data is used for testing. We present results of our HDA approach in Table 1 along with other methods studied in [Li et al., 2014].

Methods	Source Domain

Ours	62.1±1.7	61.5±2.1

Table 1: Mean and std. deviation of classification accuracy (%) on Object Recognition Dataset with target domain dslr.

3.2 TEXT CATEGORIZATION

We use the Reuters multilingual dataset [Amini et al., 2009] which contains about 11K newswire articles from 6 categories in 5 languages namely, English, French, German, Italian and Spanish. All documents are represented by using the TF-IDF feature. We perform PCA based on the TF-IDF features from each domain with 60% energy preserved and thus the features for each language have the following dimensions respectively, 1131, 1230, 1417, 1041 and 807. We consider Spanish as the target domain in the experiments and use each of the other four languages as individual source domains. For each category, we randomly sample 100 labeled documents from the source domain and either 10 or 20 labeled documents from the target domain to train the SVM. The remaining documents in the target domain are used as the test data. We report classification results of our HDA approach in Table 2 along with the results of the other approaches discussed in [Li et al., 2014].

3.3 SENTIMENT ANALYSIS

We use the Cross-Lingual Sentiment (CLS) dataset [Prettenhofer and Stein, 2010], which is an extended version of the Multi-Domain Sentiment Dataset [Blitzer et al., 2007] widely used for domain adaptation. It is collected from

Amazon and contains about 800,000 reviews of three product categories: Books, DVDs and Music, and written in four languages: English, German, French, and Japanese. The English reviews were sampled from the Multi-Domain Sentiment Dataset and reviews in other languages are crawled from Amazon. For each category and each language, the dataset is partitioned into a training set, a test set consisting of 2,000 reviews each. We take English as the source domain and each of the other three languages as an individual target domain in the experiment. We randomly sample 500 reviews from the training set of the source domain and 100 reviews from the training set of the target domain as the labeled data to train the SVM. The test set is the official test set for each category and each language. As with text categorization experiment, we extracted the TF-IDF features and performed PCA with 60% energy preserved to result in dimensions 715, 929, 964 and 874 respectively for the four languages discussed above. Results on this dataset are presented in Table 3.

3.4 EVENT CLASSIFICATION

We then worked on the event classification dataset of [Chen et al., 2013] that accounts for multiple heterogeneous source domains and a single target domain. The events pertain to six classes namely, birthday, picnic, parade, show, sports and wedding. Three source domains correspond to Google and Bing image search, and Youtube video search corresponding to these events. Kodak and CCV dataset serve as the individual target domain. The Google and Bing domains are represented by a 4000 dimensional bag-of-words codebooks learnt on SIFT features, while YouTube, Kodak and CCV datasets are represented by 6000 dimensional spatio-temporal features corresponding to histogram of oriented gradient, histogram of optical flow and motion boundary histogram. By considering the source domains to be labeled and target domain completely unlabeled we trained the SVM on the source domain samples to perform separate inference on CCV and Kodak datasets as the target domain. The cross-domain event classification results are presented in Table 4.

3.5 DISCUSSION

Clustering and Zero-shot Learning: We see that our HDA approach outperforms existing methods on diverse heterogeneous classification tasks. We also performed these experiments for the clustering scenario by not considering any labeled data from the source and target domains using the approach discussed in Section 2.3. The performance decreased by around 15% on average from the classification results. While this is reasonable since label information always helps in performing class-specific inference, it also shows that our generative heterogeneous model outputs $\hat{X}$ contain information agnostic to domain and feature variations and thus is relevant in grouping data categories. We verified this by performing a baseline using k-means after Step 1 (i.e. without the adaptation procedure) and the results dropped further by around 18% on average.

We then considered the zero-shot learning scenario, by considering the classification experiments and holding out 10%, 20% and 30% of the categories as being exclusive to the target which the source domain has not seen. As per the discussion in Section 2.3, we first thresholded the SVM similarity scores for data from these new categories. With the similarity score ranging from 0 (low) to 1(high), we tried three thresholds namely 0.3, 0.2 and 0.1. Ideally these new categories should have lower similarities since they are not part of the trained model. On average we obtained a 95% filtering accuracy with these thresholds, across all

datasets discussed before, and then we grouped the filtered data to get an accuracy of 85% on average. Note that these results are only for the new data categories, which are much less in number than those considered for classification scenario and hence can not be compared with those results. As a sanity check we tested the unlabeled data from the target categories that are present in the source, and observed that their SVM similarity scores were always greater than 0.3 for all datasets. These results convey that our model outputs are quite useful in reasoning out never seen before categories, which is very important in practice.

Parameter Tuning: For all the results discussed thus far, we used $k = 10$ clusters within each domain, and uniformly sampled 10 points on the parallel transport directions. We tried other values 8 and 12 for both clusters and sampling on directions, and PCA energy of 80% and 85% in learning the generative subspaces from the domains, and found the results decreased at the most by 2%. We used default parameters for other tools we have employed in the approach. This sheds light on the robustness of our approach. It takes about 5 to 10 seconds on a single 2GHz machine to perform inference over the range of scenarios discussed here.

Design Choice Analysis: We now analyze the rationale behind some choices we made in the approach. Firstly, we tested whether hierarchical sparse coding is necessary, or will a single layer sparse coding be sufficient. We also tested how many layers are necessary by experimenting up to five layers. The results reported in the paper are with three layers, and when we used four and five layers, the results reduced by 2.5% and 3% on average, using two layers saw average performance reduction of around 8% and using one layer saw a reduction of 17%. This suggests that hierarchical feature learning is useful, and the results reach a plateau around three layers for our experiments.

Then we inspect whether learning multiple bridges across domains using parallel transport is necessary, or just a single bridge using the geodesic will suffice. Results using only the geodesic was inferior by around 21% which highlights the utility of parallel transport to the HDA problem. We also test whether we need to do parallel transport to obtain expanded prior on the outputs of each layer of hierarchical sparse coding, by just initializing the first layer with the prior and doing hierarchical feature learning on it. That resulted in a performance drop of about 12% on average.

Multiple Source and Multiple Target Domains: Our experiments so far contained single source and single target domain, or multiple source domains and single target domain. We now pursue multiple source domains and multiple target domains on these datasets, where possible. Given N domains, we try all possible combinations across source and target domains. For example, if we have four domains, we consider 1 to 3 source domains that are accompanied by 3 to 1 target domains respectively. Our results for such a setting improves the results discussed in Sec 3.1 to 3.4 by at least 3% and up to 12%. This explains the utility of our method for HDA with increasing availability of domains.

3.6 EXTENSIONS

In this section we discuss some extensions of our approach, by relaxing certain assumptions that were made to facilitate its generalizability to different adaptation settings.

Using Label Information In Modeling Stage: Till now the labels were used only in the classification stage (Sec 2.3) and not in the modeling stage (Sec 2.2) as we wanted the model to handle classification, clustering and zero-shot learning. But in cases where say, the goal is just classification and there are labels available for training the model, it makes sense to use them in the model building stage itself. To support such a scenario, we modify our approach (in Step 4) by performing discriminative hierarchical sparse coding. We use the method of [Ji et al., 2011] and feed it with data labels contained in Y. Thus, we obtain the sparse codes output $\hat{X}$ which in addition to minimizing the reconstruction error of the data samples, also separates samples belonging to one class from other classes. Let us call this Case A. With this modification, the performance for classification experiments reported in Section 3.1 to 3.4 improved by at least 3% and up to 15% on average.

Another way to utilize label information is in forming the clusters within each domain (Step 2). Instead of using the similarity of the d dimensional features to group the data into k clusters, we group the data using their labels into M clusters and then perform the remaining steps as outlined in Section 2.2. So in this case the parallel transport information will have a notion of class discrimination in traversing the domain shift. Let us call this Case B. This resulted in an average performance improvement of at least 1.8% and up to 9% for the classification experiments reported in Section 3.1 to 3.4. We then used Case A and Case B together, and this improved the results by at least 5% and up to 20% on average.

Integrating With Other Heterogeneous Adaptation Strategies: As mentioned in the introduction, one of the goals of our study was to see how a large number of simple transformations would fare against few complex transformations to handle heterogeneous domain shift, which was the reason to map all domains to a common dimension using simpler generative information (Step 1). This strategy was shown to be successful through detailed experiments. Now we study how to get the best of both approaches. For this, instead of Step 1, we use outputs from existing heterogeneous adaptation techniques which map different dimensions onto a common one using more involved objectives related to domain structure. We tried two such techniques, one based on spectral mapping [Shi et al., 2010] and the

Domain		Classification accuracy (in %), mean±std. deviation

other based on manifold alignment [Wang and Mahadevan, 2011]. The mapped output of these techniques, where the data from all domains $\{D_i\}_{i=1}^{N}$ will have the transformed to the same dimension d, signifies $\bar{X}$ which is then fed into Step 2, and the remaining steps from Sec 2.2 and 2.3 are followed. This resulted in a performance improvement of at least 5% and up to 18%, and at least 4.2% and up to 16.5% while using [Shi et al., 2010] and [Wang and Mahadevan, 2011] respectively, for classification, clustering, and zero-shot learning experiments reported in Section 3.1 to 3.5. These results hold promise on the utility of our approach to existing adaptation solutions.

Heterogeneous View Of Homogeneous Adaptation: Encouraged by these observations, we considered homogeneous adaptation problems that have been extensively studied in the literature [Saenko et al., 2010], which assumes the data is represented by same features (same dimensions) in both source and target domains. The goal of our study here is to represent such data with many different features, with each feature forming a separate domain, and empirically investigate whether multiple features can make adaptation problems easier to handle. We experiment with different combinations of heterogeneous features in the source and target and at the same time making sure that the same feature type is not used for both source and target. The results presented below are averaged over such combinations.

We first consider the Office-Caltech dataset [Gong et al., 2012] for adaptive object recognition that contains 10 objects with four domains namely, amazon, dslr, webcam, and Caltech. The data is represented by bag-of-words codebooks learnt from SURF features. We additionally extracted histogram of oriented gradients, local binary patterns, local phase quantization, and GIST descriptors. Thus we have five domains each in the source and target domain. We then followed the adaptation protocol of [Gong et al., 2012] that first considered labeled data from source domain and no labels from target domain, and then allows few labeled samples from target as well. Our results are provided in Table 5.

We then worked on adaptive face recognition and considered the following facial features, image intensities in RGB and HSV color spaces, edge magnitudes and gradient direction, multi-scale block LBP, self-quotient image and Gabor wavelets. We first followed the protocol of [Shekhar et al., 2013] that used the Multi-PIE dataset [Gross et al., 2010] with images of 129 subjects in frontal pose as the source domain, and five other off-frontal poses as the target domain. Images under five illumination conditions across source and target domains were used for training with which images from remaining 15 illumination conditions in the target domain were recognized. Face recognition accuracy for this experiment is given in Table 6. We also performed an experiment on the PIE dataset [Sim et al., 2002] using the protocol of [Ni et al., 2013], where the domain change is caused by illumination and blur. Frontal pose faces of 34 subjects under 11 different illumination conditions formed the source domain, while the unlabeled target domain consisted of frontal images of the same subjects under 10 other lighting conditions that were also blurred using four kernels, a Gaussian with standard deviation of 3 and 4 and motion blur with length 9, angle 135° and length 11, angle 45°. The results are provided in Table 7.

Method	Mean classification accuracy (%) Target domain pose				
	15°	30°	45°	60°	75°
[Sharma and Jacobs, 2011]	92.1	89.7	88.0	86.1	83.0
[Sharma et al., 2012]	99.7	99.2	98.6	94.9	95.4
[Yang et al., 2011]	96.8	90.6	94.4	91.4	90.5
[Shekhar et al., 2013]	98.4	98.2	98.9	99.1	98.8
Ours	99.5	99.3	99.1	99.4	98.9

Table 6: Comparison with homogeneous adaptation methods on CMU Multi-PIE dataset for face recognition across pose and lighting variations with few labeled target data.

Finally we performed adaptation experiments for action recognition on the IXMAS multi-view action dataset [Weinland et al., 2007] that contains eleven action categories including walk, kick and throw. Each action was performed three times by twelve actors taken from five different views, which include four side views and one top view. From each action video we extracted the following features, histograms of oriented gradients and optical flow (HOG/HOF), 3DHOG that is based on 3D gradi-

Method	Mean classification accuracy (%)			
	$\sigma = 3$	$\sigma = 4$	$len = 9$	$len = 11$
[Ahonen et al., 2008]	66.5	32.9	73.8	62.1
[Gopalan et al., 2011]	70.9	60.3	72.4	67.9
[Gong et al., 2012]	78.5	77.7	82.4	77.7
[Ni et al., 2013]	80.3	77.9	85.9	81.2
Ours	86.3	85.2	87.9	87.2

Table 7: Comparing homogeneous adaptation methods on CMU PIE dataset for face recognition across blur and lighting variations with no labeled target data. σ: std. deviation of the Gaussian blur, and len: length of linear motion blur.

ent orientations, and extended SURF descriptor for videos. The experiment was to recognize actions with the source and target domain pertaining to different views, thereby making 20 source-target combinations. The average cross-view recognition accuracy results for all these view combinations are given in Table 8. The correspondence mode contains matched instances across source and target domains, partial labels mode having fewer target labels and the non-discriminative virtual views (NDVV) comprising of partially-labeled and unlabeled target data, as studied in [Li and Zickler, 2012].

All these results show our method outperforming other homogeneous adaptation approaches, which suggests that such approaches could, in some form, benefit by expanding the type of features used to represent the data. The features we have used are only somewhat representative of the vast literature and more of them can be used with our approach.

4 CONCLUSION

We have approached the problem of bridging heterogeneous domains by learning a large set of intermediate representations, born out of simpler generative information, and integrated them with hierarchical feature learning mechanisms to perform inference pertaining to classification, clustering and zero-shot learning. We demonstrated superior empirical performance over existing methods on a wide range of problems involving different data modalities such as images, videos and natural language. We also discussed the utility of our design choices, and the robustness of the approach in dealing with multiple domains, feature types, unlabeled data and new unseen data categories. While our approach offers an alternative to many existing heterogeneous solutions that address domain shift through a latent space modeling, it also opens up opportunities for harnessing the benefits of the two strategies, which we highlighted through some initial studies. Such a mechanism could eventually pave way for establishing error bounds on the nature of heterogeneous shifts an approach can handle, within a reasonable set of domain shift assumptions reflecting practical data acquisition constraints.

Abstract

Margin-based structured prediction commonly uses a maximum loss over all possible structured outputs (Altun & Hofmann, 2003; Collins, 2004; Taskar et al., 2003). In natural language processing, recent work (Zhang et al., 2014; Zhang et al., 2015) has proposed the use of the maximum loss over random structured outputs sampled independently from some proposal distribution. This method is linear-time in the number of random structured outputs and trivially parallelizable. We study this family of loss functions in the PAC-Bayes framework under Gaussian perturbations (McAllester, 2007). Under some technical conditions and up to statistical accuracy, we show that this family of loss functions produces a tighter upper bound of the Gibbs decoder distortion than commonly used methods. Thus, using the maximum loss over random structured outputs is a principled way of learning the parameter of structured prediction models. Besides explaining the experimental success of (Zhang et al., 2014; Zhang et al., 2015), our theoretical results show that more general techniques are possible.

1 INTRODUCTION

Structured prediction has been shown to be useful in many diverse domains. Application areas include natural language processing (e.g., named entity recognition, part-of-speech tagging, dependency parsing), computer vision (e.g., image segmentation, multiple object tracking), speech (e.g., text-to-speech mapping) and computational biology (e.g., protein structure prediction).

In dependency parsing, for instance, the observed input is a sentence and the desired structured output is a parse tree for the given sentence.

In general, structured prediction can be viewed as a kind of decoding. A *decoder* is a machine for predicting the structured output y given the observed input x. Such a decoder, depends on a parameter w. Given a fixed w, the task performed by the decoder is called *inference*. In this paper, we focus on the problem of learning the parameter w. Next, we introduce the problem and our main contributions.

We assume a distribution D on pairs (x, y) where $x \in \mathcal{X}$ is the observed input and $y \in \mathcal{Y}$ is the latent structured output, i.e., $(x, y) \sim D$. We also assume that we have a training set S of n i.i.d. samples drawn from the distribution D, i.e., $S \sim D^n$, and thus $|S| = n$.

We let $\mathcal{Y}(x) \neq \emptyset$ denote the countable set of feasible *decodings* of x. In general, $|\mathcal{Y}(x)|$ is exponential with respect to the input size.

We assume a fixed mapping ϕ from pairs to feature vectors, i.e., for any pair (x, y) we have the feature vector $\phi(x, y) \in \mathbb{R}^k \setminus \{0\}$. For a parameter $w \in \mathcal{W} \subseteq \mathbb{R}^k \setminus \{0\}$, we consider linear decoders of the form:

$$f_w(x) \equiv \arg\max_{y \in \mathcal{Y}(x)} \phi(x, y) \cdot w \tag{1}$$

In practice, very few cases of the above general *inference* problem are tractable, while most are NP-hard and also hard to approximate within a fixed factor. (We defer the details in theory of computation to Section 6.)

We also introduce the *distortion* function $d : \mathcal{Y} \times \mathcal{Y} \to [0, 1]$. The value $d(y, y')$ measures the amount of difference between two structured outputs y and y'. Disregarding the computational and statistical aspects, the ultimate goal is to set the parameter w in order to minimize the decoder distortion. That is:

$$\min_{w \in \mathcal{W}} \mathop{\mathbb{E}}_{(x,y) \sim D} [d(y, f_w(x))] \tag{2}$$

Computationally speaking, the above procedure is inefficient since $d(y, f_w(x))$ is a discontinuous function with respect to w and thus, it is in general an exponential-time optimization problem. Statistically speaking, the problem in

eq.(2) requires access to the data distribution D and thus, in general it would require an infinite amount of data. In practice, we only have access to a small amount of training data.

Additionally, eq.(2) would potentially favor parameters w with low distortion, but that could be in a neighborhood of parameters with high distortion. In order to avoid this issue, we could optimize a more "robust" objective under Gaussian perturbations. More formally, let $\alpha > 0$ and let $Q(w)$ be a unit-variance Gaussian distribution centered at $w\alpha$ of parameters $w' \in \mathcal{W}$. The Gibbs decoder distortion of the perturbation distribution $Q(w)$ and data distribution D, is defined as:

$$L(Q(w), D) = \mathop{\mathbb{E}}_{(x,y)\sim D}\left[\mathop{\mathbb{E}}_{w'\sim Q(w)}[d(y, f_{w'}(x))]\right] \quad (3)$$

The minimization of the Gibbs decoder distortion can be expressed as:

$$\min_{w\in\mathcal{W}} L(Q(w), D)$$

The focus of our analysis will be to propose upper bounds of the Gibbs decoder distortion, with good computational and statistical properties. That is, we will propose upper bounds that can be computed in polynomial-time, and that require a small amount of training data.

For our analysis, we follow the same set of assumptions as in (McAllester, 2007). We define the margin $m(x, y, y', w)$ as the amount by which y is preferable to y' under the parameter w. More formally:

$$m(x, y, y', w) \equiv \phi(x, y) \cdot w - \phi(x, y') \cdot w$$

Let $c(p, x, y)$ be a nonnegative integer that gives the number of times that the part $p \in \mathcal{P}$ appears in the pair (x, y). For a part $p \in \mathcal{P}$, we define the feature p as follows:

$$\phi_p(x, y) \equiv c(p, x, y)$$

We let $\mathcal{P}(x) \neq \emptyset$ denote the set of $p \in \mathcal{P}$ such that there exists $y \in \mathcal{Y}(x)$ with $c(p, x, y) > 0$. We define the Hamming distance H as follows:

$$H(x, y, y') \equiv \sum_{p\in\mathcal{P}(x)} |c(p, x, y) - c(p, x, y')|$$

The commonly applied margin-based approach to learning w uses the maximum loss over all possible structured outputs (Altun & Hofmann, 2003; Collins, 2004; Taskar et al., 2003). That is:[1]

$$\min_{w\in\mathcal{W}} \frac{1}{n} \sum_{(x,y)\in S} \max_{\hat{y}\in\mathcal{Y}(x)} d(y, \hat{y})\, 1\begin{pmatrix} H(x, y, \hat{y}) \\ -m(x, y, \hat{y}, w) \geq 0 \end{pmatrix} + \lambda\|w\|_2^2 \quad (4)$$

[1]For computational convenience, the *convex* hinge loss $\max(0, 1 + z)$ is used in practice instead of the *discontinuous* 0/1 loss $1(z \geq 0)$.

In Section 2, we reproduce the results in (McAllester, 2007) and show that the above objective is related to an upper bound of the Gibbs decoder distortion in eq.(3). Note that evaluating the objective function in eq.(4) is as hard as the inference problem in eq.(1), since both perform maximization over the set $\mathcal{Y}(x)$.

Our main contributions are presented in Sections 3 and 4. Inspired by recent work in natural language processing (Zhang et al., 2014; Zhang et al., 2015), we show a tighter upper bound of the Gibbs decoder distortion in eq.(3), which is related to the following objective:[1]

$$\min_{w\in\mathcal{W}} \frac{1}{n} \sum_{(x,y)\in S} \max_{\hat{y}\in T(w,x)} d(y, \hat{y})\, 1\begin{pmatrix} H(x, y, \hat{y}) \\ -m(x, y, \hat{y}, w) \geq 0 \end{pmatrix} + \lambda\|w\|_2^2 \quad (5)$$

where $T(w, x)$ is a set of random structured outputs sampled i.i.d. from some proposal distribution with support on $\mathcal{Y}(x)$. Note that evaluating the objective function in eq.(5) is linear-time in the number of random structured outputs in $T(w, x)$.

2 FROM PAC-BAYES TO THE MAXIMUM LOSS OVER ALL POSSIBLE STRUCTURED OUTPUTS

In this section, we show the relationship between PAC-Bayes bounds and the commonly used maximum loss over all possible structured outputs.

As reported in (McAllester, 2007), by using the PAC-Bayes framework under Gaussian perturbations, we show that the commonly used maximum loss over all possible structured outputs is an upper bound of the Gibbs decoder distortion up to statistical accuracy ($\mathcal{O}(\sqrt{\log n/n})$ for n training samples).

Theorem 1 (McAllester, 2007)**.** *Assume that there exists a finite integer value ℓ such that $|\cup_{(x,y)\in S} \mathcal{P}(x)| \leq \ell$. Fix $\delta \in (0, 1)$. With probability at least $1 - \delta/2$ over the choice of n training samples, simultaneously for all parameters $w \in \mathcal{W}$ and unit-variance Gaussian perturbation distributions $Q(w)$ centered at $w\sqrt{2\log(2n\ell/\|w\|_2^2)}$, we have:*

$$L(Q(w), D) \leq \frac{1}{n} \sum_{(x,y)\in S} \max_{\hat{y}\in\mathcal{Y}(x)} d(y, \hat{y})\, 1\begin{pmatrix} H(x, y, \hat{y}) \\ -m(x, y, \hat{y}, w) \geq 0 \end{pmatrix} + \frac{\|w\|_2^2}{n} + \sqrt{\frac{\|w\|_2^2 \log(2n\ell/\|w\|_2^2) + \log(2n/\delta)}{2(n-1)}}$$

(See Appendix A for detailed proofs.)

The proof of the above is based on the PAC-Bayes theorem and well-known Gaussian concentration inequalities.

As it is customary in generalization results, a *deterministic* expectation with respect to the data distribution D is upper-bounded by a *stochastic* quantity with respect to the training set S. This takes into account the statistical aspects of the problem.

Note that the upper bound uses maximization with respect to $\mathcal{Y}(x)$ and that in general, $|\mathcal{Y}(x)|$ is exponential with respect to the input size. Thus, the computational aspects of the problem have not been fully addressed yet. In the next section, we solve this issue by introducing randomness.

3 FROM PAC-BAYES TO THE MAXIMUM LOSS OVER RANDOM STRUCTURED OUTPUTS

In this section, we analyze the relationship between PAC-Bayes bounds and the maximum loss over random structured outputs sampled independently from some proposal distribution.

First, we will focus on the computational aspects. Instead of using maximization with respect to $\mathcal{Y}(x)$, we will perform maximization with respect to a set $T(w,x)$ of random structured outputs sampled i.i.d. from some proposal distribution $R(w,x)$ with support on $\mathcal{Y}(x)$. In order for this approach to be computationally appealing, $|T(w,x)|$ should be polynomial, even when $|\mathcal{Y}(x)|$ is exponential with respect to the input size.

Assumptions A and B will allow us to attain $|T(w,x)| = \mathcal{O}\left(\max\left(\frac{1}{\log(1/\beta)}, \|w\|_2^2\right)\right)$. The constant $\beta \in [0,1)$ is properly introduced on Assumption A. It can be easily observed that β plays an important role in the number of random structured outputs that we need to draw from the proposal distribution $R(w,x)$. Next, we present our first assumption.

Assumption A (Maximal distortion)**.** *The proposal distribution $R(w,x)$ fulfills the following condition. There exists a value $\beta \in [0,1)$ such that for all $(x,y) \in S$ and $w \in \mathcal{W}$:*

$$\mathop{\mathbb{P}}_{y' \sim R(w,x)}[d(y,y') = 1] \geq 1 - \beta$$

In Section 4 we show examples that fulfill the above assumption, which include a *binary* distortion function for *any* type of structured output, as well as a distortion function that returns the number of different edges/elements for directed spanning trees, directed acyclic graphs and cardinality-constrained sets.

Next, we present our second assumption that allows obtaining $|T(w,x)| = \mathcal{O}\left(\max\left(\frac{1}{\log(1/\beta)}, \|w\|_2^2\right)\right)$. While Assumption A contributes with the term $\frac{1}{\log(1/\beta)}$ in $|T(w,x)|$, the following assumption contributes with the term $\|w\|_2^2$ in $|T(w,x)|$.

Assumption B (Low norm)**.** *For any vector $z \in \mathbb{R}^k$, define:*

$$\mu(z) = \begin{cases} z/\|z\|_1 & \text{if } z \neq 0 \\ 0 & \text{if } z = 0 \end{cases}$$

The proposal distribution $R(w,x)$ fulfills the following condition for all $(x,y) \in S$ and $w \in \mathcal{W}$:[2]

$$\left\| \mathop{\mathbb{E}}_{y' \sim R(w,x)} [\mu(\phi(x,y) - \phi(x,y'))] \right\|_2 \leq \frac{1}{2\sqrt{n}} \leq \frac{1}{2\|w\|_2}$$

It is natural to ask whether there are instances that fulfill the above assumption. In Section 4 we provide two extreme cases: one example of a *sparse* mapping and a uniform proposal, and one example of a *dense* mapping and an *arbitrary* proposal distribution.

We will now focus on the statistical aspects. Note that randomness does not only stem from data, but also from sampling structured outputs. That is, in Theorem 1, randomness only stems from the training set S. We now need to produce generalization results that hold for all the sets $T(w,x)$ of random structured outputs. In addition, the uniform convergence of Theorem 1 holds for all parameters w. We now need to produce a generalization result that also holds for all possible proposal distributions $R(w,x)$. Therefore, we need a method for upper-bounding the number of possible proposal distributions $R(w,x)$. Assumption C will allow us to upper-bound this number.

Assumption C (Linearly inducible ordering)**.** *The proposal distribution $R(w,x)$ depends solely on the linear ordering induced by the parameter $w \in \mathcal{W}$ and the mapping $\phi(x,\cdot)$. More formally, let $r(x) \equiv |\mathcal{Y}(x)|$ and thus $\mathcal{Y}(x) \equiv \{y_1 \dots y_{r(x)}\}$. Let $w, w' \in \mathcal{W}$ be any two arbitrary parameters. Let $\pi(x) = (\pi_1 \dots \pi_{r(x)})$ be a permutation of $\{1 \dots r(x)\}$ such that $\phi(x, y_{\pi_1}) \cdot w < \dots < \phi(x, y_{\pi_{r(x)}}) \cdot w$. Let $\pi'(x) = (\pi'_1 \dots \pi'_{r(x)})$ be a permutation of $\{1 \dots r(x)\}$ such that $\phi(x, y_{\pi'_1}) \cdot w' < \dots < \phi(x, y_{\pi'_{r(x)}}) \cdot w'$. For all $w, w' \in \mathcal{W}$ and $x \in \mathcal{X}$, if $\pi(x) = \pi'(x)$ then $KL(R(w,x) \| R(w',x)) = 0$. In this case, we say that the proposal distribution fulfills $R(\pi(x), x) \equiv R(w,x)$.*

Assumption C states that two proposal distributions $R(w,x)$ and $R(w',x)$ are the same provided that for the same permutation $\pi(x)$ we have $\phi(x, y_{\pi_1}) \cdot w < \dots < \phi(x, y_{\pi_{r(x)}}) \cdot w$ and $\phi(x, y_{\pi_1}) \cdot w' < \dots < \phi(x, y_{\pi_{r(x)}}) \cdot w'$. Geometrically speaking, for a fixed x we first project the feature vectors $\phi(x,y)$ of all the structured outputs $y \in \mathcal{Y}(x)$ onto

[2] The second inequality follows from an implicit assumption made in Theorem 1, i.e., $\|w\|_2^2/n \leq 1$. Note that if $\|w\|_2^2/n > 1$ then Theorem 1 provides an upper bound greater than 1, which is meaningless since the distortion function d is at most 1.

the lines w and w'. Let $\pi(x)$ and $\pi'(x)$ be the resulting ordering of the structured outputs after projecting them onto w and w' respectively. Two proposal distributions $R(w,x)$ and $R(w',x)$ are the same provided that $\pi(x) = \pi'(x)$. That is, the specific values of $\phi(x,y)\cdot w$ and $\phi(x,y)\cdot w'$ are irrelevant, and only their ordering matters.

In Section 4 we show examples that fulfill the above assumption, which include the algorithm proposed in (Zhang et al., 2014; Zhang et al., 2015) for directed spanning trees, and our proposed generalization to any type of data structure with computationally efficient local changes.

In what follows, by using the PAC-Bayes framework under Gaussian perturbations, we show that the maximum loss over random structured outputs sampled independently from some proposal distribution provides an upper bound of the Gibbs decoder distortion up to statistical accuracy ($\mathcal{O}(\log^{3/2} n/\sqrt{n})$ for n training samples).

Theorem 2. *Assume that there exist finite integer values ℓ and r such that $|\cup_{(x,y)\in S}\mathcal{P}(x)| \leq \ell$ and $|\mathcal{Y}(x)| \leq r$ for all $(x,y)\in S$. Assume that the proposal distribution $R(w,x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption A with value β, as well as Assumptions B and C. Fix $\delta\in(0,1)$ and an integer $\mathfrak{s}$ such that $3\leq\mathfrak{s}\leq\frac{9}{20}\sqrt{\ell+1}$. With probability at least $1-\delta$ over the choice of both n training samples and n sets of random structured outputs, simultaneously for all parameters $w\in\mathcal{W}$ with $\|w\|_0\leq\mathfrak{s}$, unit-variance Gaussian perturbation distributions $Q(w)$ centered at $w\sqrt{2\log(2n\ell/\|w\|_2^2)}$, and for sets of random structured outputs $T(w,x)$ sampled i.i.d. from the proposal distribution $R(w,x)$ for each training sample $(x,y)\in S$, such that $|T(w,x)| = \left\lceil \frac{1}{2}\max\left(\frac{1}{\log(1/\beta)}, 32\|w\|_2^2\right)\log n\right\rceil$, we have:*

$$
\begin{aligned}
&L(Q(w),D)\\
&\leq \frac{1}{n}\sum_{(x,y)\in S}\max_{\hat{y}\in T(w,x)} d(y,\hat{y})\,1\begin{pmatrix}H(x,y,\hat{y})\\ -m(x,y,\hat{y},w)\geq 0\end{pmatrix}\\
&+\frac{\|w\|_2^2}{n}+\sqrt{\frac{\|w\|_2^2\log(2n\ell/\|w\|_2^2)+\log(2n/\delta)}{2(n-1)}}+\sqrt{\frac{1}{n}}\\
&+\max\Big(\tfrac{1}{\log(1/\beta)},32\|w\|_2^2\Big)\sqrt{\frac{\mathfrak{s}\log(\ell+1)\log^3(n+1)}{n}}\\
&+3\sqrt{\frac{\mathfrak{s}(\log\ell+2\log(nr))+\log(4/\delta)}{n}}
\end{aligned}
$$

(See Appendix A for detailed proofs.)

The proof of the above is based on Theorem 1 as a starting point. In order to account for the computational aspect of requiring sets $T(w,x)$ of polynomial size, we use Assumptions A and B for bounding a *deterministic* expectation. In order to account for the statistical aspects, we use Assumption C and Rademacher complexity arguments for bounding a *stochastic* quantity for all sets $T(w,x)$ of random structured outputs and all possible proposal distributions $R(w,x)$. The assumption of sparsity (i.e., $\|w\|_0\leq\mathfrak{s}$) is pivotal for obtaining terms of order $\mathcal{O}(\sqrt{\mathfrak{s}\log\ell/n})$. Without sparsity, the terms would be of order $\mathcal{O}(\sqrt{\ell/n})$ which is not suited for high-dimensional settings.

3.1 Inference on Test Data

Note that the upper bound in Theorem 2 holds simultaneously for all parameters $w\in\mathcal{W}$. Therefore, our result implies that after learning the optimal parameter $\widehat{w}\in\mathcal{W}$ in eq.(5) from *training* data, we can bound the decoder distortion when performing *exact* inference on *test* data. More formally, Theorem 2 can be additionally invoked for a *test* set S', also with probability at least $1-\delta$. Thus, under the same setting as of Theorem 2, the Gibbs decoder distortion is upper-bounded with probability at least $1-2\delta$ over the choice of S and S'. In this paper, we focus on learning the parameter of structured prediction models. We leave the analysis of *approximate* inference on test data for future work.

4 EXAMPLES

In this section, we provide several examples that fulfill the three main assumptions of our theoretical result.

4.1 Examples for the Maximal Distortion Assumption

In what follows, we present some examples that fulfill our Assumption A. For a *binary* distortion function, we show that *any* type of structured output fulfills the above assumption. For a distortion function that returns the number of different edges/elements, we show that directed spanning trees, directed acyclic graphs and cardinality-constrained sets, fulfill the assumption as well.

For simplicity of analysis, most proofs in this part will assume a uniform proposal distribution $R(w,x) = R(x)$ with support on $\mathcal{Y}(x)$. In the following claim, we argue that we can perform a change of measure between different proposal distributions. Thus, allowing us to focus on uniform proposals afterwards.

Claim i (Change of measure)**.** *Let $R(w,x)$ and $R'(w,x)$ two proposal distributions, both with support on $\mathcal{Y}(x)$. Assume that the proposal distribution $R(w,x)$ fulfills Assumption A with value β_1. Let $r_{w,x}(\cdot)$ and $r'_{w,x}(\cdot)$ be the probability mass functions of $R(w,x)$ and $R'(w,x)$ respectively. Assume that the total variation distance between $R(w,x)$ and $R'(w,x)$ is bounded as follows for all $(x,y)\in S$ and $w\in\mathcal{W}$:*

$$
\begin{aligned}
TV(R(w,x)\|R'(w,x)) &\equiv \frac{1}{2}\sum_{y\in\mathcal{Y}(x)}|r_{w,x}(y)-r'_{w,x}(y)|\\
&\leq \beta_2
\end{aligned}
$$

The proposal distribution $R'(w, x)$ fulfills Assumption A with $\beta = \beta_1 + \beta_2$ provided that $\beta_1 + \beta_2 \in [0, 1)$.

Next, we provide a result for *any* type of structured output, but for a *binary* distortion function.

Claim ii (Any type of structured output)**.** *Let $\mathcal{Y}(x)$ be an arbitrary countable set of feasible decodings of x, such that $|\mathcal{Y}(x)| \geq 2$ for all $(x, y) \in S$. Let $d(y, y') = 1\,(y \neq y')$. The uniform proposal distribution $R(w, x) = R(x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption A with $\beta = 1/2$.*

The following claim pertains to directed spanning trees and for a distortion function that returns the number of different edges.

Claim iii (Directed spanning trees)**.** *Let $\mathcal{Y}(x)$ be the set of directed spanning trees of v nodes. Let $A(y)$ be the adjacency matrix of $y \in \mathcal{Y}(x)$. Let $d(y, y') = \frac{1}{2(v-1)} \sum_{ij} |A(y)_{ij} - A(y')_{ij}|$. The uniform proposal distribution $R(w, x) = R(x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption A with $\beta = \frac{v-2}{v-1}$.*

The next result is for directed acyclic graphs and for a distortion function that returns the number of different edges.

Claim iv (Directed acyclic graphs)**.** *Let $\mathcal{Y}(x)$ be the set of directed acyclic graphs of v nodes and b parents per node, such that $2 \leq b \leq v - 2$. Let $A(y)$ be the adjacency matrix of $y \in \mathcal{Y}(x)$. Let $d(y, y') = \frac{1}{b(2v-b-1)} \sum_{ij} |A(y)_{ij} - A(y')_{ij}|$. The uniform proposal distribution $R(w, x) = R(x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption A with $\beta = \frac{b^2+2b+2}{b^2+3b+2}$.*

The final example is for cardinality-constrained sets and for a distortion function that returns the number of different elements.

Claim v (Cardinality-constrained sets)**.** *Let $\mathcal{Y}(x)$ be the set of sets of b elements chosen from v possible elements, such that $b \leq v/2$. Let $d(y, y') = \frac{1}{2b}(|y - y'| + |y' - y|)$. The uniform proposal distribution $R(w, x) = R(x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption A with $\beta = 1/2$.*

4.2 Examples for the Low Norm Assumption

Next, we present some examples that fulfill our Assumption B. We provide two extreme cases: one example for *sparse* mappings, and one example for *dense* mappings.

Next, we provide a result for a particular instance of a sparse mapping and a uniform proposal distribution.

Claim vi (Sparse mapping)**.** *Let $b > 0$ be an arbitrary integer value. For all $(x, y) \in S$, let $\mathcal{Y}(x) = \cup_{p \in \mathcal{P}(x)} \mathcal{Y}_p(x)$, where the partition $\mathcal{Y}_p(x)$ is defined as follows:*

$$(\forall p \in \mathcal{P}(x))\ \mathcal{Y}_p(x) \equiv \{y' \mid |\phi_p(x, y) - \phi_p(x, y')| = b \wedge (\forall q \neq p)\ \phi_q(x, y) = \phi_q(x, y')\}$$

If $n \leq |\mathcal{P}(x)|/4$ for all $(x, y) \in S$, then the uniform proposal distribution $R(w, x) = R(x)$ with support on $\mathcal{Y}(x)$ fulfills Assumption B.

The following claim pertains to a particular instance of a dense mapping and an *arbitrary* proposal distribution.

Claim vii (Dense mapping)**.** *Let $b > 0$ be an arbitrary integer value. Let $|\phi_p(x, y) - \phi_p(x, y')| = b$ for all $(x, y) \in S$, $y' \in \mathcal{Y}(x)$ and $p \in \mathcal{P}(x)$. If $n \leq |\mathcal{P}(x)|/4$ for all $(x, y) \in S$, then any arbitrary proposal distribution $R(w, x)$ fulfills Assumption B.*

4.3 Examples for the Linearly Inducible Ordering Assumption

In what follows, we present some examples that fulfill our Assumption C. We show that the algorithm proposed in (Zhang et al., 2014; Zhang et al., 2015) for directed spanning trees, fulfills the above assumption. We also generalize the algorithm in (Zhang et al., 2014; Zhang et al., 2015) to any type of data structure with computationally efficient local changes, and show that this generalization fulfills the assumption as well.

Next, we present the algorithm proposed in (Zhang et al., 2014; Zhang et al., 2015) for dependency parsing in natural language processing. Here, x is a sentence of v words and $\mathcal{Y}(x)$ is the set of directed spanning trees of v nodes.

Algorithm 1 Procedure for sampling a directed spanning tree $y' \in \mathcal{Y}(x)$ from a greedy local proposal distribution $R(w, x)$

Input: parameter $w \in \mathcal{W}$, sentence $x \in \mathcal{X}$
Draw uniformly at random a directed spanning tree $\hat{y} \in \mathcal{Y}(x)$
repeat
  $s \leftarrow$ post-order traversal of $\hat{y}$
  for each node t in the list s **do**
    for each node u before t in the list s **do**
      $y \leftarrow$ change the parent of node t to u in $\hat{y}$
      if $\phi(x, y) \cdot w > \phi(x, \hat{y}) \cdot w$ **then**
        $\hat{y} \leftarrow y$
      end if
    end for
  end for
until no refinement in last iteration
Output: directed spanning tree $y' \leftarrow \hat{y}$

The above algorithm has the following property:

Claim viii (Sampling for directed spanning trees)**.** *Algorithm 1 fulfills Assumption C.*

Note that Algorithm 1 proposed in (Zhang et al., 2014; Zhang et al., 2015) uses the fact that we can perform local

changes to a directed spanning tree in a computationally efficient manner. That is, changing parents of nodes in a post-order traversal will produce directed spanning trees. We can extend the above algorithm to any type of data structure where we can perform computationally efficient local changes. For instance, we can easily extend the method for directed acyclic graphs (traversed in post-order as well) and for sets with up to some prespecified number of elements.

Next, we generalize Algorithm 1 to any type of structured output.

Algorithm 2 Procedure for sampling a structured output $y' \in \mathcal{Y}(x)$ from a greedy local proposal distribution $R(w, x)$

Input: parameter $w \in \mathcal{W}$, observed input $x \in \mathcal{X}$
Draw uniformly at random a structured output $\hat{y} \in \mathcal{Y}(x)$
repeat
  Make a local change to $\hat{y}$ in order to increase $\phi(x, \hat{y}) \cdot w$
until no refinement in last iteration
Output: structured output $y' \leftarrow \hat{y}$

The above algorithm has the following property:

Claim ix (Sampling for any type of structured output)**.** *Algorithm 2 fulfills Assumption C.*

5 EXPERIMENTAL RESULTS

In this section, we provide experimental evidence on synthetic data. Note that the work of (Zhang et al., 2014; Zhang et al., 2015) has provided extensive experimental evidence on real-world datasets, for part-of-speech tagging and dependency parsing in the context of natural language processing. Our experimental results are not only for directed spanning trees (Zhang et al., 2014; Zhang et al., 2015) but also for directed acyclic graphs and cardinality-constrained sets.

We performed 30 repetitions of the following procedure. We generated a ground truth parameter w^* with independent zero-mean and unit-variance Gaussian entries. Then, we generated a training set S of $n = 100$ samples. The fixed mapping ϕ from pairs (x, y) to feature vectors $\phi(x, y)$ is as follows. For every pair of possible edges/elements i and j, we define $\phi_{ij}(x, y) = 1\,(x_{ij} = 1 \wedge i \in y \wedge j \in y)$. For instance, for directed spanning trees of v nodes, we have $x \in \{0, 1\}^{\binom{v}{2}}$ and $\phi(x, y) \in \mathbb{R}^{\binom{v}{2}}$. In order to generate each training sample $(x, y) \in S$, we generated a random vector x with independent Bernoulli entries, each with equal probability of being 1 or 0. After generating x, we set $y = f_{w^*}(x)$. That is, we solved eq.(1) in order to produce the latent structured output y from the observed input x and the parameter w^*.

We compared two training methods: the maximum loss over all possible structured outputs as in eq.(4), and the maximum loss over random structured outputs as in eq.(5). For both minimization problems, we replaced the *discontinuous* 0/1 loss $1\,(z \geq 0)$ with the *convex* hinge loss $\max(0, 1 + z)$, as it is customary. For both problems, we used $\lambda = 1/n$ as suggested by Theorems 1 and 2, and we performed 20 iterations of the subgradient descent method with a decaying step size $1/\sqrt{t}$ for iteration t. For sampling random structured outputs in eq.(5), we implemented Algorithm 2 for directed spanning trees, directed acyclic graphs and cardinality-constrained sets. We considered directed spanning trees of 6 nodes, directed acyclic graphs of 5 nodes and 2 parents per node, and sets of 4 elements chosen from 15 possible elements. We used $\beta = 0.8$ for directed spanning trees, $\beta = 0.85$ for directed acyclic graphs, and $\beta = 0.5$ for cardinality-constrained sets, as prescribed by Claims iii, iv and v. After training, for inference on an independent test set, we used eq.(1) for the maximum loss over all possible structured outputs. For the maximum loss over random structured outputs, we use the following *approximate* inference approach:

$$\widetilde{f}_w(x) \equiv \arg\max_{y \in T(w,x)} \phi(x, y) \cdot w \tag{6}$$

Table 1 shows the average over 30 repetitions, and the standard error at 95% confidence level of the following measurements. We report the runtime, the training distortion as well as the test distortion in an independently generated set of 100 samples. We also report the normalized distance of the learnt $\widehat{w}$ to the ground truth w^*, i.e., $\|\widehat{w} - w^*\|_2 / \sqrt{\ell}$. Additionally, we report the angle of the learnt $\widehat{w}$ with respect to the ground truth w^*, i.e. $\arccos(\widehat{w} \cdot w^* / (\|\widehat{w}\|_2 \|w^*\|_2))$. In the different study cases (directed spanning trees, directed acyclic graphs and cardinality-constrained sets), the maximum loss over random structured outputs outperforms the maximum loss over all possible structured outputs.

6 DISCUSSION

In this section, we provide more details regarding the computational complexity of the inference problem. We also present a brief review of the previous work and provide ideas for extending our theoretical result.

6.1 Computational Complexity of the Inference Problem

Very few cases of the general *inference* problem in eq.(1) are tractable. For instance, if $\mathcal{Y}(x)$ is the set of directed spanning trees, and w is a vector of edge weights (i.e., linear with respect to y), then eq.(1) is equivalent to the maximum directed spanning tree problem, which is polynomial-time. In general, the inference problem in eq.(1) is not

Table 1: Average over 30 repetitions, and standard error at 95% confidence level of several methods and measurements. For the maximum loss over all possible structured outputs (All) we used eq.(4) for training, and eq.(1) for inference on a test set. For the maximum loss over random structured outputs (Random and Random/All) we used eq.(5) for training. For inference, Random used eq.(6) while Random/All used eq.(1). Random outperforms All in the different study cases (directed spanning trees, directed acyclic graphs and cardinality-constrained sets). The difference between Random and Random/All is not statistically significant.

Problem	**Method**	**Training runtime**	**Training distortion**	**Test runtime**	**Test distortion**	**Distance to ground truth**	**Angle with ground truth**

only NP-hard but also hard to approximate. For instance, if $\mathcal{Y}(x)$ is the set of directed acyclic graphs, and w is a vector of edge weights (i.e., linear with respect to y), then eq.(1) is equivalent to the maximum acyclic subgraph problem, which approximating within a factor better than $1/2$ is unique-games hard (Guruswami et al., 2008). As an additional example, consider the case where $\mathcal{Y}(x)$ is the set of sets with up to some prespecified number of elements (i.e., $\mathcal{Y}(x)$ is a cardinality constraint), and the objective $\phi(x, y) \cdot w$ is submodular with respect to y. In this case, eq.(1) cannot be approximated within a factor better than $1 - 1/e$ unless P=NP (Nemhauser et al., 1978).

These negative results made us to avoid interpreting the maximum loss over random structured outputs in eq.(5) as an approximate optimization algorithm for the maximum loss over all possible structured outputs in eq.(4).

6.2 Previous Work

Approximate inference was proposed in (Kulesza & Pereira, 2007), with an adaptation of the proof techniques in (McAllester, 2007). More specifically, (Kulesza & Pereira, 2007) performs maximization of the loss over a *superset* of feasible decodings of x, i.e., over $y \in \mathcal{Y}'(x) \supseteq \mathcal{Y}(x)$. Note that our upper bound of the Gibbs decoder distortion dominates the maximum loss over $y \in \mathcal{Y}(x)$, and the latter dominates the upper bound of (Kulesza & Pereira, 2007). One could potentially use a similar argument with respect to a *subset* of feasible decodings of x, i.e., with respect to $y \in \mathcal{Y}'(x) \subseteq \mathcal{Y}(x)$. Unfortunately, this approach does not obtain an upper bound of the Gibbs decoder distortion.

Tangential to our work, previous analyses have exclusively focused either on sample complexity or convergence. Sample complexity analyses include margin bounds (Taskar et al., 2003), Rademacher complexity (London et al., 2013) and PAC-Bayes bounds (McAllester, 2007; McAllester & Keshet, 2011). Convergence have been analyzed for specific algorithms for the separable (Collins & Roark, 2004) and nonseparable (Crammer et al., 2006) cases.

6.3 Concluding Remarks

The work of (Zhang et al., 2014; Zhang et al., 2015) has shown extensive experimental evidence for part-of-speech tagging and dependency parsing in the context of natural language processing. In this paper, we present a theoretical analysis that explains the experimental success of (Zhang et al., 2014; Zhang et al., 2015) for directed spanning trees. Our analysis was provided for a far more general setup, which allowed proposing algorithms for other types of structured outputs, such as directed acyclic graphs and cardinality-constrained sets. We hope that our theoretical work will motivate experimental validation on many other real-world structured prediction problems.

There are several ways of extending this research. While we focused on Gaussian perturbations, it would be interesting to analyze other distributions from the computational as well as statistical viewpoints. We analyzed a general class of proposal distributions that depend on the induced linear orderings. Algorithms that make greedy local changes, traverse the set of feasible decodings in a constrained fashion, by following allowed moves defined by some prespecified graph. The addition of these graph-theoretical constraints would enable obtaining tighter upper bounds. From a broader perspective, extensions of our work to latent models (Ping et al., 2014; Yu & Joachims, 2009) as well as maximum a-posteriori perturbation models (Gane et al., 2014; Papandreou & Yuille, 2011) would be of great

interest. Finally, while we focused on learning the parameter of structured prediction models, it would be interesting to analyze *approximate* inference for prediction on an independent test set.

Abstract

We consider *anytime* linear prediction in the common machine learning setting, where features are in groups that have costs. We achieve anytime (or interruptible) predictions by sequencing the computation of feature groups and reporting results using the computed features at interruption. We extend Orthogonal Matching Pursuit (OMP) and Forward Regression (FR) to learn the sequencing greedily under this group setting with costs. We theoretically guarantee that our algorithms achieve near-optimal linear predictions at each budget when a feature group is chosen. With a novel analysis of OMP, we improve its theoretical bound to the same strength as that of FR. In addition, we develop a novel algorithm that consumes cost $4B$ to approximate the optimal performance of *any* cost B, and prove that with cost less than $4B$, such an approximation is impossible. To our knowledge, these are the first anytime bounds at *all* budgets. We test our algorithms on two real-world data-sets and evaluate them in terms of anytime linear prediction performance against cost-weighted Group Lasso and alternative greedy algorithms.

1 INTRODUCTION AND BACKGROUND

First defined by Grass and Zilberstein [1996], anytime predictors output valid results even if they are interrupted at any point in time. The results improve with resources spent. In this work, we propose an anytime linear prediction algorithm under the common machine learning setting, where features are computed in groups with associated costs. We further assume that the cost of prediction is dominated by feature computation. Hence, we can achieve anytime predictions by computing feature groups in a specific order and outputting linear predictions using only computed features at interruption.

Formally, we are given n samples (x^i, y^i) from a feature matrix $X \in \mathbb{R}^{n \times D}$ and a response vector $Y \in \mathbb{R}^n$. We also have a partition of the D feature dimensions into J feature groups, $\mathcal{G}_1, \mathcal{G}_2, ..., \mathcal{G}_J$, and an associated cost of each group $c(\mathcal{G}_j)$. Our anytime prediction approach learns a sequencing of the feature groups, $G = g_1, g_2, ..., g_J$. For each budget limit B, the computed groups at cost B is a prefix of the sequencing, $G_{\langle B \rangle} = g_1, g_2, .., g_{J_{\langle B \rangle}}$, where $J_{\langle B \rangle} = \max\{j \leq J | \sum_{i \leq j} c(g_i) \leq B\}$ indexes the last group within the budget B. An ideal anytime algorithm seeks a sequencing G to minimize risk at all budgets B:

$$R(G_{\langle B \rangle}) := \min_w \frac{1}{2n} \|Y - X_{G_{\langle B \rangle}} w\|_2^2 + \frac{\lambda}{2} \|w\|_2^2, \quad (1)$$

where $X_{G_{\langle B \rangle}}$ contains features in $G_{\langle B \rangle}$, w is the associated linear predictor coefficient, and λ is a regularizing constant. Equivalently, if we assume that the y^i's have unit variance and zero mean by normalization, we can maximize the explained variance, $F(G_{\langle B \rangle}) := \frac{1}{2n} Y^T Y - R(G_{\langle B \rangle})$.

The above optimization problem is closest to the problem of subset selection for regression [Das and Kempe, 2011], which selects at most k features to optimize a linear regression. The problem is also similar to that of sparse model recovery [Tibshirani, 1994], which recovers coefficients of a true linear model. One common approach to these two problems is to select the features greedily via Forward Regression (FR) [Miller, 1984] or Orthogonal Matching Pursuit (OMP) [Pati et al., 1993]. Forward Regression greedily selects features that maximize the marginal increase in explained variance at each step. Orthogonal Matching Pursuit selects features as follows. The linear model coefficients of the unselected features are set to zero. At each step, the feature whose model coefficient has the largest gradient of the risk is selected. In this work, we extend FR and OMP to the setting where features are in groups that have costs. The extension to FR is intuitive: we only need to select feature groups using their marginal gain in objective per unit cost instead of using just the marginal gain. However, we have two notes about the extension to OMP. First, to incorporate

feature costs, we need to evaluate a feature based on the squared norm of the associated weight vector gradient per unit cost instead of just the gradient norm. Second, when we compute the gradient norm for a feature group, ∇_g, we have to use the norm $\nabla_g^T (X_g^T X_g)^{-1} \nabla_g$, which is $\|\nabla_g\|_2^2$ if and only if each feature group g is whitened, which is an assumption in group OMP analysis by Lozano et al. [2009, 2011]. Our analysis sheds light on why this assumption is important in a group setting. Like previous analyses of greedy algorithms by Streeter and Golovin [2008], our analysis guarantees that our methods produce near-optimal linear predictions, measured by explained variance, at budgets where feature groups are selected. Thus, they exhibit the desired anytime behavior at those budgets. Finally, we extend our algorithm to account for *all* budgets and show a novel anytime result: for any budget B, if *OPT* is the optimal explained variance of cost B, then our proposed sequencing can approximate within a factor of *OPT* with cost at most $4B$. Furthermore, with a cost less than $4B$, a fixed sequence of predictors cannot approximate *OPT* in general. To our knowledge, these are the first anytime performance bounds at all budgets.

In previous works, both FR and OMP are theoretically analyzed for both the problem of subset selection and model recovery. Das and Kempe [2011] cast the subset selection problem as a submodular maximization that selects a set S with $|S| \leq k$ to maximize the explained variance and prove that FR and OMP achieve $(1 - e^{-\lambda^*})$ and $(1 - e^{-\lambda^{*2}})$ near-optimal explained variance, where λ^* is the minimum eigenvalue of the sample covariance, $\frac{1}{n} X^T X$. We can adopt these previous analyses to our extensions to FR and OMP under the group setting with costs and produce the same near-optimal results. We also present a novel analysis of OMP that leads to the same near-optimal factor $(1 - e^{-\lambda^*})$ as that of FR. Works on model recovery have also analyzed FR and OMP. Zhang [2009] proves that OMP discovers the true linear model coefficients, if they exist. This result was then extended by [Lozano et al., 2009, 2011] to the setting of feature groups using generalized linear models. However, we note that these theoretical analyses of model recovery assume that a true model exists. They focus on recovering model coefficients rather than directly analyzing prediction performance.

Besides greedy selection, another family of approaches to find the optimal subset S that minimizes $R(S)$ is to relax the NP-hard selection problem as a convex optimization. Lasso [Tibshirani, 1994], a well-known method, uses L_1 regularization to force sparsity in the linear model. To get an ordering of the features, compute the Lasso solution path by varying the L_1 regularization constant. Group Lasso [Yuan and Lin, 2006] extends Lasso to the group setting, replacing the L_1 norm with the sum of L_2 norms of feature groups. Group Lasso can also incorporate feature costs by scaling the L_2 norms of feature groups. Lasso-based methods are generally analyzed for model recovery, not prediction performance. We demonstrate experimentally that our greedy methods achieve better prediction performance than cost-weighted Group Lasso.

Various works have addressed anytime prediction previously. The most well-known family of approaches use *cascades* [Viola and Jones, 2001], which achieve anytime prediction by filtering out samples with a sequence of classifiers of increasing complexity and feature costs. At each stage, cascade methods [Sochman and Matas, 2005, Brubaker et al., 2008, Lefakis and Fleuret, 2010, Xu et al., 2014, Cai et al., 2015] typically achieve a target accuracy and assign a portion of samples with their final predictions. While this design frees up computation for the more difficult samples, it prevents recovery from early mistakes. Most cascade methods select features of each stage before being trained. Although the more recent works start to learn feature sequencing, the learned sequences are the same as those of cost-weighted Group Lasso [Chen et al., 2012] and greedy methods [Cai et al., 2015] when they are restricted to linear prediction. Hence our study of anytime linear prediction can help cascade methods choose features and learn cascades. Another branch of anytime prediction methods uses boosting. It outputs as results partial sums of the ensemble [Grubb and Bagnell, 2012] or averages of randomly sampled weak learners [Reyzin, 2011]. Our greedy methods can be viewed as a gradient boosting scheme by treating each feature as a weak learner. Some works approach anytime prediction with feature transformations [Xu et al., 2012, 2013] and learn cost-sensitive, non-linear transformation of features for linear classification. Similarly, Weinberger et al. [2009] hashes high dimensional features to low dimensional subspaces. These approaches operate on readily-computed features, which is orthogonal to our problem setting. Karayev et al. [2012] models the anytime prediction as a Markov Decision Process and learns a policy of applying intermediate learners and computing features through reinforcement learning.

Contributions

- We cast the problem of anytime linear prediction as a feature group sequencing problem and propose extensions to FR and OMP under the setting where features are in groups that have costs.

- We theoretically analyze our extensions to FR and OMP and show that they both achieve $(1-e^{-\lambda^*})$ near-optimal explained variance with linear predictions at budgets when they choose feature groups.

- We develop the first anytime algorithm that provably approximates the optimal performance of *all* budgets B with cost of $4B$; we also prove it impossible to achieve a constant-factor approximation with cost less than $4B$.

2 COST-SENSITIVE GREEDY METHOD

This section formally introduces our extensions to FR and OMP to the group setting with costs. We assume that all feature dimensions and responses are normalized to have zero mean and unit variance. We define the regularized feature covariance matrix as $C := \frac{1}{n}X^TX + \lambda I_D$. Let C_{st} be the sub-matrix that selects rows from s and columns from t. Let C_S be short for C_{SS}. Given a non-empty union of selected feature groups S, the maximum explained variance $F(S)$ is achieved with the regularized optimal coefficient $w(S) = \frac{1}{n}(\frac{1}{n}X_S^TX_S + \lambda I)^{-1}(X_S^TY) = \frac{1}{n}C_S^{-1}X_S^TY$. When we take gradient of $F(S)$ with respect to the coefficient of a feature group g, if $g \subseteq S$ then the gradient is $\nabla_g F(S) = \frac{1}{n}X_g^T(Y - X_S w(S)) - \lambda w(S)_g$; if $g \cap S = \emptyset$ then we can extend $w(S)$ to dimensions of g, setting $w(S)_g = 0$, and then take the gradient to have $\nabla_g F(S) = \frac{1}{n}X_g^T(Y - X_S w(S))$. In both cases, we have $\nabla_g F(S) = \frac{1}{n}X_g^TY - C_{gS}w(S)$. We further shorten the notations by defining $b_g^S = \nabla_g F(S)$. If S is empty, we assume that coefficient $w(\emptyset)$ has zero for all features so that $F(\emptyset) = 0$. When $S = s_1, s_2, ...,$ is a sequence of feature groups, we define S_j to be the prefix sequence $s_1, s_2, ..., s_j$. We overload notations of a sequence S so that S also represents the union of its groups in notations such as $F(S)$, $w(S)$, C_S and b_S^S.

Algorithm 1: Cost Sensitive Group Orthogonal Matching Pursuit (CS-G-OMP)

input : The normalized feature matrix $X \in \mathbb{R}^{n\times D}$. The normalized response vector $Y \in \mathbb{R}^n$, which has a zero mean and unit variance. Feature groups $\mathcal{G}_1, ...\mathcal{G}_J$ that partition $\{1, .., D\}$, and group costs $c(\mathcal{G}_j)$. Regularization constant λ.

output: A sequence $G = g_1, g_2, ..., g_J$ of feature groups. For each $j \le J$, a coefficient $w(G_j)$ for the prefix sequence $G_j = g_1, ..., g_j$.

1 $G_0 = \emptyset$;
2 **for** $j = 1, 2, ..., J$ **do**
  `// Learn linear model`
3 compute $w(G_{j-1}) = \frac{1}{n}C_{G_{j-1}}^{-1}X_{G_{j-1}}^TY$;
  `// Selection step (*)`
4 For each $g \notin G_{j-1}$, compute $b_g = \nabla_g F(G_{j-1}) = \frac{1}{n}X_g^T(Y - X_{G_{j-1}}w)$;
5 $g_j = \underset{g=\mathcal{G}_1,...,\mathcal{G}_J, g\notin G_{j-1}}{\operatorname{argmax}} \frac{b_g^T(X_g^TX_g)^{-1}b_g}{c(g)}$;
6 $G_j = G_{j-1} \oplus g_j$;
7 compute $w(G_J)$;

In Algorithm 1, we present Cost-Sensitive Group Orthogonal Matching Pursuit (CS-G-OMP), which learns a near-optimal sequencing of the feature groups for anytime linear predictions. The feature groups are selected greedily. At the j^{th} selection step $(*)$, we have chosen $j-1$ groups, $G_{j-1} = g_1, g_2, ..., g_{j-1}$, and have computed the best model using G_{j-1}, $w(G_{j-1})$. To evaluate a feature group g, we first compute the gradient $b_g = \nabla_g F(G_{j-1})$ of the explained variance F with respect to the coefficients of g. Then, we evaluate it with the whitened gradient L_2-norm square per unit cost, $\frac{b_g^T(X_g^TX_g)^{-1}b_g}{c(g)}$. We select the group g that maximizes this value as g_j, and continue until all groups are depleted. At test time, our proposed anytime prediction algorithm computes the feature groups in the order of $G = g_1, g_2, ..., g_J$. After each feature group g_j is available, we can compute and store prediction $\hat{y} = x^Tw(G_j)$ because we assumed that the costs of feature generation dominate the computations of linear predictions. At interruption, we can then report the latest prediction $\hat{y}$.

The learning procedure extending from Forward Regression is similar to Algorithm 1: we compute the linear models $w(G_{j-1} \oplus g)$ at line 4 instead of the gradients b_g and replace the selection criterion $\frac{b_g^T(X_g^TX_g)^{-1}b_g}{c(g)}$ at line 5 with the marginal gain in explained variance per unit cost, $\frac{F(G_{j-1}\oplus g) - F(G_{j-1})}{c(g)}$. We call this cost-sensitive FR extension as CS-G-FR.

Before we theoretically analyze our greedy methods in the next section, we provide an argument why **group whitening** at line 5 of Algorithm 1 is natural. OMP greedily selects features whose coefficients have the largest gradients of the objective function. In linear regression, the gradient for a feature g is the inner-product of X_g and the prediction residual $Y - \hat{Y}$. Hence OMP selects features that best reconstruct the residual. From this perspective, OMP under group setting should seek the feature group whose span contains the largest projection of the residual. Let the projection to feature group g be $P_g = X_g(X_g^TX_g)^{-1}X_g^T$ and recall projection matrices are idempotent. We observe that the criterion for CS-G-OMP selection step is $\frac{\|P_g(Y-\hat{Y})\|_2^2}{c(g)}$, i.e, a cost-weighted norm square of the projection of the residual onto a feature group. The name group whitening is chosen because the criterion is $\frac{\|b_g\|_2^2}{c(g)}$ if and only if feature groups are whitened. We assume *feature groups are whitened* in our formal analysis to make the criterion easier to analyze.

Besides the above greedy criterion, one may suggest other approaches to evaluate gradient vectors b_g for group g. For example, L_2 norm and L_∞ norm can be used to achieve greedy criteria $\frac{\|b_g\|_2^2}{c(g)}$ and $\frac{\|b_g\|_\infty^2}{c(g)}$, respectively. The former criterion forgoes group whitening, so we call it *no-whiten*. Thus, it overestimates a feature group that has correlated but effective features, an extreme example of which is a feature group of identical but effective features. The latter criterion evaluates only the best feature of each feature

group, so we call it *single*. Thus, it underestimates a feature group that has a descriptive feature span but no top-performing individual feature dimensions. We will show in experiments that no-whiten and single are indeed inferior to our CS-G-OMP choice.

3 THEORETICAL ANALYSIS

This section proves that CS-G-FR and CS-G-OMP produce near-optimal explained variance F at budgets where features are selected. The main challenge of our analysis is to prove Lemma 3.1, which is a common stepping stone in submodular maximization analysis, e.g., Equation 8 in [Krause and Golovin, 2012]. The main Theorem 3.2 follows from the lemma by standard techniques, which we defer to the appendix.

Lemma 3.1 (main)**.** *Let G_j be the first j feature groups selected by our greedy algorithm. There exists a constant $\gamma = \frac{\lambda^*+\lambda}{1+\lambda} > 0$ such that for any sequence S, total cost K, and indices $j = 1, 2, ..., J$, $F(S_{\langle K\rangle}) - F(G_{j-1}) \leq \frac{K}{\gamma}[\frac{F(G_j)-F(G_{j-1})}{c(g_j)}]$.*

Theorem 3.2. *Let $B = \sum_{i=1}^{L} c(g_i)$ for some L. There exists a constant $\gamma = \frac{\lambda^*+\lambda}{1+\lambda}$, such that for any sequence S and total cost K, $F(G_{\langle B\rangle}) > (1 - e^{-\gamma\frac{B}{K}})F(S_{\langle K\rangle})$.*

Before delving into the proof of Lemma 3.1, we first discuss some implications of Theorem 3.2, which argues that the explained variance of greedily selected features of cost B is within $(1 - e^{\gamma\frac{B}{K}})$-factor of that of any competing feature sequence of cost K. If we apply minimum regularization ($\lambda \to 0$), then the constant γ approaches λ^*. The resulting bound factor $(1 - e^{-\lambda^*\frac{B}{K}})$ is the bound for FR by Das and Kempe [2011]. However, we achieve the same bound for OMP, improving theoretical guarantees of OMP. We also note that less-correlated features lead to a higher λ^* and a stronger bound.

Lemma 3.1 for CS-G-FR is standard if we follow proofs in [Streeter and Golovin, 2008] and [Das and Kempe, 2011] because the objective F is γ-approximately submodular. However, we present a proof of Lemma 3.1 for CS-G-OMP without approximate submodularity to achieve the same constant γ. This proof in turn uses Lemma 3.3 and Lemma 3.4, whose proofs are based on the Taylor expansions of the regularized risk $\mathcal{R}[f_S] = R(S)$, a M-strongly smooth and m-strongly convex loss functional of predictors $f(x) = w^T x$. We defer these two proofs to the appendix and note that $M = m$ with our choice of R.

Lemma 3.3 (Using Smoothness)**.** *Let S and G be some fixed sequences. Then $F(S) - F(G) \leq \frac{1}{2m}\langle b^G_{G\oplus S}, C^{-1}_{G\oplus S} b^G_{G\oplus S}\rangle$.*

Lemma 3.4 (Using Convexity)**.** *For $j = 1, 2, ..., J$, $F(G_j) - F(G_{j-1}) \geq \frac{1}{2M}\langle b^{G_{j-1}}_{g_j}, C^{-1}_{g_j} b^{G_{j-1}}_{g_j}\rangle$.*

Note that in Lemma 3.4, since we assume feature groups are whitened, then $C_{g_j} = (1 + \lambda)I$. The bound of the lemma becomes $F(G_j) - F(G_{j-1}) \geq \frac{1}{2M(1+\lambda)}\langle b^{G_{j-1}}_{g_j}, b^{G_{j-1}}_{g_j}\rangle$. If feature groups are not whitened, the constant $(1+\lambda)$ can be scaled up to $(|\mathcal{G}_j|+\lambda)$, which detriments the strength of Theorem 3.2 especially when feature groups are large.

Proof. (of Lemma 3.1, using Lemma 3.3 and Lemma 3.4) Using Lemma 3.3, on $S_{\langle K\rangle}$ and G_{j-1}, we have:

$$F(S_{\langle K\rangle}) - F(G_{j-1}) \leq \frac{1}{2m}\langle b^{G_{j-1}}_{G_{j-1}\oplus S_{\langle K\rangle}}, C^G_{G_{j-1}\oplus S_{\langle K\rangle}} b^{G_{j-1}}_{G_{j-1}\oplus S_{\langle K\rangle}}\rangle \quad (2)$$

Note that the gradient $b^{G_{j-1}}_{G_{j-1}}$ equals 0, because $F(G_{j-1})$ is achieved by the linear model $w(G_{j-1})$. Then, using block matrix inverse formula, we have:

$$F(S_{\langle K\rangle}) - F(G_{j-1}) \leq \frac{1}{2m}\langle b^{G_{j-1}}_{S_{\langle K\rangle}}, C^G_{S_{\langle K\rangle}} b^{G_{j-1}}_{S_{\langle K\rangle}}\rangle \quad (3)$$

where $C^G_{S_{\langle K\rangle}} = C_{S_{\langle K\rangle}} - C_{S_{\langle K\rangle}G} C^{-1}_{S_{\langle K\rangle}} C_{GS_{\langle K\rangle}}$. Using spectral techniques in Lemmas 2.5 and 2.6 in [Das and Kempe, 2011] and noting that the minimum eigenvalue of C, $\lambda_{min}(C)$, is $\lambda^* + \lambda$, we have

$$\frac{1}{2m}\langle b^{G_{j-1}}_{S_{\langle K\rangle}}, C^G_{S_{\langle K\rangle}} b^{G_{j-1}}_{S_{\langle K\rangle}}\rangle \leq \frac{1}{2m(\lambda^*+\lambda)}\langle b^{G_{j-1}}_{S_{\langle K\rangle}}, b^{G_{j-1}}_{S_{\langle K\rangle}}\rangle. \quad (4)$$

Expanding $S_{\langle K\rangle}$ into individual groups s_i, we continue:

$$= \frac{1}{2m(\lambda^*+\lambda)} \sum_{s_i \in S_{\langle K\rangle}} \langle b^{G_{j-1}}_{s_i}, b^{G_{j-1}}_{s_i}\rangle \quad (5)$$

$$\leq \frac{1}{2m(\lambda^*+\lambda)} \sum_{s_i \in S_{\langle K\rangle}} c(s_i) \max_g \frac{\langle b^{G_{j-1}}_g, b^{G_{j-1}}_g\rangle}{c(g)} \quad (6)$$

$$= \frac{1}{2m(\lambda^*+\lambda)} \sum_{s_i \in S_{\langle K\rangle}} c(s_i) \frac{\langle b^{G_{j-1}}_{g_j}, b^{G_{j-1}}_{g_j}\rangle}{c(g_j)} \quad (7)$$

$$\leq \frac{M(1+\lambda)}{m(\lambda^*+\lambda)} \sum_{s_i \in S_{\langle K\rangle}} c(s_i) \frac{F(G_j) - F(G_{j-1})}{c(g_j)}. \quad (8)$$

The last equality follows from the greedy selection step of Algorithm 1 when feature groups are whitened. The last inequality is given by Lemma 3.4. The theorem then follows from $\gamma = (\frac{m}{M})\frac{\lambda^*+\lambda}{1+\lambda} = \frac{\lambda^*+\lambda}{1+\lambda}$. □

4 BI-CRITERIA APPROXIMATION AT ALL BUDGETS

Our analysis so far only bounds algorithm performance at budgets when new items are selected. However, an ideal analysis should apply to all budgets. As illustrated in Figure 1a, previous methods may choose expensive features

early; until they are computed, we have no bounds. Figure 1b illustrates our proposed fix: each new item g_{j+1} cannot be more costly than the current sequence G_j.

This section proves two theorems of anytime prediction at *any* budget. Theorem 4.1 shows that to approximate the optimal explained variance of cost B within a constant factor, an anytime algorithm must cost at least $4B$. We then motivate and formalize our fix in Algorithm 2, which is shown in Theorem 4.3 to achieve this *bi-criteria approximation* bound for both budget and objective with the form: $F(G_{\langle B \rangle}) > (1 - e^{-\frac{\gamma^2}{1+\gamma}}) F(S_{\langle \frac{B}{4} \rangle})$, where γ is the approximate submodular ratio, i.e., the maximum constant $\gamma \leq 1$ such that for all sets $A' \subseteq A$ and all element x,

$$\gamma(F(A \cup \{x\}) - F(A)) \leq F(A' \cup \{x\}) - F(A'). \quad (9)$$

We first illustrate the inherent difficulty in generating single sequences that are competitive at arbitrary budgets B by using the following budgeted maximization problem:

$$X = \{1, 2, \ldots\}, \;\; c(x) = x, \;\; F(S) = \sum_{x \in S} e^x. \quad (10)$$

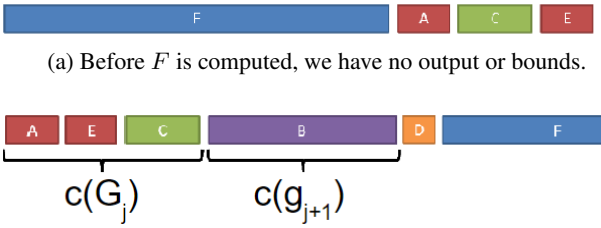
The above problem originates from fitting the linear model $Y = \sum_{i=1}^{D} e^i X_i$, where X_i's are i.i.d. and X_i costs i.

Theorem 4.1. *Let $\mathcal{A}$ be any algorithm for selecting sequences $A = (a_1, \ldots)$. The best bi-criteria approximation that $\mathcal{A}$ can satisfy must be at least a 4-approximation in cost for the sequence described in Equation (10). That is, there does not exist a $C < 4$, and a $c_1 \in [0, 1)$, such that for any budget B and any sequence S,*

$$F(A_{\langle B \rangle}) > (1 - c_1) F(S_{\langle \frac{B}{C} \rangle}).$$

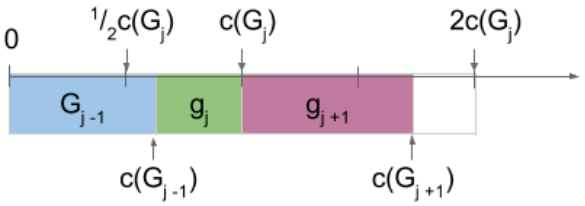
Proof. For any budget B, it is clear that the optimal selection contains a single item, B, whose value is e^B. For any budget B, let $m(B)$ denote the item of the maximum cost that is selected by the algorithm. If the bi-criteria bound holds, then $\sum_{k=1}^{m(B)} e^k \geq F(A_{\langle B \rangle}) > (1 - c_1) F(S_{\langle \frac{B}{C} \rangle})$. Taking the log of both sides and rearranging terms, we have $m(B) \geq \lfloor \frac{B}{C} \rfloor + \ln(1 - c_1) + \ln(e - 1) - 2$. Since $3 - \ln(1 - c_1) - \ln(e - 1) > 0$, we have for B large enough: $C \geq \frac{B}{m(B)}$. Hence, we need to minimize $\frac{B}{m(B)}$ for all B to minimize C. We can assume a_j to be increasing because otherwise we could remove the violating a_j from the sequence and decrease the ratio $\frac{B}{m(B)}$ for all subsequent j.

Let $b_j := c(A_j)$ and $\alpha_j := \frac{c(a_j)}{b_{j-1}}$. Then immediately before a_j is available, $\frac{B}{m(B)} \to \frac{c(A_j)}{c(a_{j-1})} \geq \frac{(1+\alpha_j) b_{j-1}}{b_{j-1}} = 1 + \alpha_j$. If we can bound $\frac{B}{m(B)} \leq C$ for all B, then there exists α_{max} such that $\alpha_j < \alpha_{max}$ for all j large enough. Immediately after a new a_j is selected, $\frac{B}{m(B)} = \frac{c(A_j)}{c(a_j)} = \frac{1+\alpha_j}{\alpha_j}$. For $\frac{B}{m(B)}$ to be bounded, there must exist some $\alpha_{min} > 0$ such



(a) Before F is computed, we have no output or bounds.

(b) Our constraint $c(g_{j+1}) \leq c(G_j)$ induces a smoother cost increase.



(c) Illustration of Doubling Algorithm Cost Constraint

Figure 1: Doubling Algorithm (b) has better anytime behaviors than greedy algorithm with no cost constraints (a).

that $\alpha_j > \alpha_{min}$ for large enough j. Now we consider the ratio $\frac{B}{m(B)}$ right before a_{j+1} is selected:

$$\frac{c(A_{j+1})}{c(a_j)} = \frac{b_j(1 + \alpha_{j+1})}{b_j \frac{\alpha_j}{1+\alpha_j}} = 1 + \frac{\alpha_{j+1}}{\alpha_j} + \alpha_{j+1} + \frac{1}{\alpha_j}. \quad (11)$$

Assume for seek of contradiction that $\frac{c(A_{j+1})}{c(a_j)}$ is bounded above by z for some $z \in (1, 4)$. Let $y := \frac{\alpha_{j+1}}{\alpha_j}$. Then we have: $z \geq 1 + y + y\alpha_j + \frac{1}{\alpha_j} \geq 1 + y + 2\sqrt{y} = (\sqrt{y} + 1)^2$. Hence $y \leq (\sqrt{z} - 1)^2 < 1$. So $a_{j+1} \leq (\sqrt{z} - 1)^2 a_j$, which implies that a_j converges to 0 and we have a contradiction. So $C \geq \frac{B}{m(B)} \to \frac{c(A_{j+1})}{c(a_j)} \geq 4$ for large j. □

The above proof lower bounds the cost approximation ratio C by Eq. 11, which is shown to be at least 4 for $C < \infty$. We note that $Eq.$ 11 equals 4 if $\forall j, \alpha_j = 1$, which means the sequence total cost is doubled at each selection step. This observation leads to *Doubling Algorithm* (Alg. 2): we perform greedy selection in the same way as CS-G-FR, except that the total cost can be at most doubled at each step (illustrated in Figure 1c). The advantage of Doubling Algorithm over CS-G-FR is that the former prevents early computation of expensive features and induces a smoother increase of total cost; in most real-world data-sets, the two are identical after few steps because feature costs are often in a narrow range. We will analyze Doubling Algorithm with the following assumption, called *doubling capable*.

Definition 4.2. Let $G = (g_1, \ldots)$ be the sequence selected by the doubling algorithm. The set X and function F are *doubling capable* if, at every iteration j, the following set is non-empty: $\{x \mid x \in X \setminus G_{j-1}, \; c(x) \leq c(G_{j-1})\}$

Algorithm 2: Doubling Algorithm

input: objective function F, elements X, minimum cost $c_{\min}$

Let $g_1 = \underset{x \in X,\ c(x) \le c_{\min}}{\operatorname{argmax}} \frac{F(\{x\})}{c(x)}$; Let $G_1 = g_1$;

for $j = 2, \ldots$ **do**

  Let $g_j = \underset{x \in X \setminus G_{j-1},\ c(x) \le c(G_{j-1})}{\operatorname{argmax}} \frac{F(G_{j-1} \oplus \{x\}) - F(G_{j-1})}{c(x)}$;

  Let $G_j = G_{j-1} \oplus \{g_j\}$;

Theorem 4.3. *Let $G = (g_1, \ldots)$ be the sequence selected by the doubling algorithm (Algorithm 2). Fix some $B > c_{min}$. Let F be γ-approximately submodular as in Definition 9. For any sequence S,*

$$F(G_{\langle B \rangle}) > \left(1 - e^{-\frac{\gamma^2}{1+\gamma}}\right) F(S_{\langle \frac{B}{4} \rangle}).$$

Proof. Doubling capable easily leads to the observation that for all budgets B, there exists an index j such that $\frac{B}{2} \le c(G_j) < B$. Choose K and k to be the largest integers such that $\frac{B}{2} \le c(G_K) < B$ and $\frac{B}{8} \le c(G_k) < \frac{B}{4}$. Since at each step we at most double the total cost and $4c(G_k) < B$, we observe $K \ge k + 2$. For each j, define $s_j = \frac{F(G_{j+1}) - F(G_j)}{c(g_{j+1})}$ as the best rate of improvement among the items Doubling Algorithm is allowed to consider after choosing G_j. Consider the item x in sequence $S_{\langle \frac{B}{4} \rangle}$ of the maximum cost.

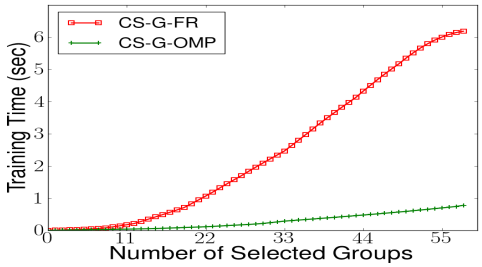
(Case 1) If $c(x) \le c(G_k)$, then every item in $S_{\langle \frac{B}{4} \rangle}$ was a candidate for g_j for all $j = k+1, ..., K$. So by approximate submodularity from Equation 9, we have

$$F(S_{\langle \frac{B}{4} \rangle}) \le F(S_{\langle \frac{B}{4} \rangle} \cup G_j) \le F(G_j) + \frac{B s_j}{4\gamma}. \quad (12)$$

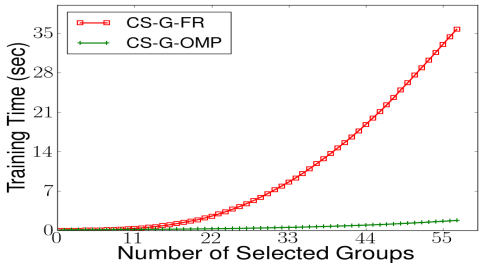
Then using the standard submodular maximization proof technique, we define $\Delta_j = F(S_{\langle \frac{B}{4} \rangle}) - F(G_j)$. Applying $s_j = \frac{\Delta_j - \Delta_{j+1}}{c(g_{j+1})}$ in the above inequality, we have $\Delta_{k+j} \le \Delta_k \prod_{j=k+1}^{k+j} (1 - \gamma \frac{4c(g_j)}{B})$. Maximizing the inequality by setting $c(g_j) = \frac{B}{K-k} \le \frac{c(G_K) - c(G_k)}{4(K-k)}$, and using $(1 - z/l)^l < e^{-z}$, we have $F(G_K) > (1 - e^{-\gamma}) F(S_{\langle \frac{B}{4} \rangle})$.

From now on, we assume that $c(x) > c(G_k)$ and consider two cases by comparing $c(g_{k+2})$ and $c(G_k)$.

(Case 2.1) If $c(g_{k+2}) \ge c(G_k)$, then $c(G_K) - c(G_{k+1}) \ge c(g_{k+2}) \ge c(G_k)$. Since $c(G_{k+1}) \le 2c(G_k)$ and $c(x) > c(G_k)$, we have $c(G_K) - c(G_{k+1}) \ge \frac{B}{2} - 2c(G_k)$. So $c(G_K) - c(G_{k+1}) \ge \max(c(G_k), \frac{B}{2} - 2c(G_k)) \ge \frac{B}{6}$. Thus, using the same proof techniques as in case 1, we can analyze the ratio between Δ_{k+1} and Δ_K, and have: $F(G_K) > (1 - e^{-\frac{2}{3}\gamma}) F(S_{\langle \frac{B}{4} \rangle})$.



(a) Training Time OMP vs. FR (AGRICULTURAL)



(b) Training Time OMP vs. FR (YAHOO! LTR)

Figure 2: The training time vs. the number of feature groups selected with two algorithms: CS-G-FR and CS-G-OMP. CS-G-OMP achieves a 8x and 20x overall training time speed-up on AGRICULTURAL and YAHOO! LTR.

(Case 2.2) Finally, if $c(g_{k+2}) < c(G_k) < c(x) < c(G_{k+1})$, g_{k+2} was a candidate for g_{k+1}, and x was a candidate for g_{k+2}. For an item y, let $r(y^j) = \frac{F(G_j \cup \{y\}) - F(G_j)}{c(y)}$ be the improvement rate of item y at G_j. Then we have $r(g_{k+1}^k) > r(g_{k+2}^k)$ and $r(g_{k+2}^{k+1}) > r(x^{k+1})$. Since the objective function is increasing, we have $r(x^k)c(x) \le r(x^{k+1})c(x) + r(g_{k+1}^k)c(g_{k+1})$, so that $r(x^k) \le r(x^{k+1}) + r(g_{k+1}^k)\frac{c(g_{k+1})}{c(x)}$. Then by the definition of γ in Equation 9, we have $\gamma r(g_{k+2}^{k+1}) \le r(g_{k+2}^k)$. Hence we have $\gamma r(x^{k+1}) \le r(g_{k+1}^k)$, which leads to $r(x^k) \le r(g_{k+1}^k)(\frac{1}{\gamma} + \frac{c(g_{k+1})}{c(x)}) \le r(g_{k+1}^k)(1 + \frac{1}{\gamma})$. Then inequality (12) holds with a coefficient adjustment and becomes $F(S_{\langle \frac{B}{4} \rangle}) \le F(G_k) + \frac{B s_k (1+\gamma)}{4\gamma^2}$. Noting that the above inequality holds for all $j = k+1, ..., K$, we can replace the constant γ in the proof of case 1 with $\frac{\gamma^2}{1+\gamma}$ and have the following bound: $F(G_K) > (1 - e^{-\frac{\gamma^2}{1+\gamma}}) F(S_{\langle \frac{B}{4} \rangle})$.

□

5 EXPERIMENTS

5.1 DATA-SETS AND SET-UP

We experiment our methods for anytime linear prediction on two real-world data-sets, each of which has a significant number of feature groups with associated costs.

Table 1: Test time 0.97-Timeliness measurement of different methods on AGRICULTURAL. We break the methods into OMP, FR and Oracle family: e.g., "Single" in the G-CS-OMP family means G-CS-OMP-Single, and "FR" in the Oracle family means the oracle curve derived from G-FR.

CS-G-OMP-Variants				CS-G-FR	Oracles		Sparse
CS-G-OMP	Single	No-Whiten	G-OMP		FR Oracle	OMP Oracle	
0.4406	0.4086	0.4340	0.4073	**0.4525**	**0.4551**	0.4508	0.3997

Table 2: Test time 0.99-Timeliness measurement of different methods on YAHOO! LTR.

- **Yahoo! Learning to Rank Challenge** [Chapelle and Chang, 2011] contains 883k web documents, each of which has a relevance score in $\{0, 1, 2, 3, 4\}$. Each of the 501 document features has an associated computational cost in $\{1, 5, 20, 50, 100, 150, 200\}$; the total feature cost is around 17K. The original data-set has no feature group structures, so we generated random group structures by grouping features of the same cost into groups of a given size s.[1]

- **Agriculture** is a proprietary data-set that contains 510k data samples, 328 features, and 57 feature groups. Each sample has a binary label in $\{1, 2\}$. Each feature group has an associated cost measured in its average computation time.[2]

5.2 EVALUATION METRIC, BASELINE AND ORACLE

Following the practice of Karayev et al. [2012], we use the area under the maximization objective F (explained variance) vs. cost curve normalized by the total area as the *timeliness* measurement of the anytime performance of an algorithm. In our data-sets, the performance of linear predictors plateaus much before all features are used, e.g., Figure 3a demonstrates this effect in YAHOO! LTR, where the last one percent of total improvement is bought by half of the total feature cost. Hence the majority of the timeliness measurement is from the plateau performance of linear predictors. The difference between timeliness of different anytime algorithms diminishes due to the plateau effect. Furthermore, the difference vanishes as we include additional redundant high cost features. To account for this effect, we stop the curve when it reaches the plateau. We define an α-*stopping cost* for parameter α in $[0, 1]$ as the cost at which our CS-G-OMP achieves α of the final objective value in training and ignore the objective vs. cost curve after the α-stopping cost. We call the timeliness measure on the shortened curve as α-*timeliness*; 1-timeliness equals the normalized area under the full curve and 0-timeliness is zero. If a curve does not pick a group at α-stopping cost, we linearly interpolate the objective value at the stopping cost to computr timeliness. We say an objective vs. cost curve has reached its final plateau if at least 95% of the total objective has been achieved and the next 1% requires more than 20% feature costs. (If the plateau does not exist, we use $\alpha = 1$.) Following this rule, we choose $\alpha = 0.97$ for AGRICULTURAL and $\alpha = 0.99$ for YAHOO! LTR.

Since an exhaustive search for the best feature sequencing is intractable, we approximate with the **Oracle** anytime performance following the approach of Karayev et al. [2012]. Given an objective vs. cost curve of a sequencing, we reorder the feature groups in descending order of their marginal benefit per unit cost, assuming that the marginal benefits stay the same after reordering. We specify which sequencing is used for creating **Oracle** in Section 5.5. For baseline performance, we use cost-weighted Group Lasso [Yuan and Lin, 2006], which scales the regularization constant of each group with the cost of the group. We note that the cascade design by Chen et al. [2012] can be reduced to this baseline if we enforce linear prediction. More specifically, the baseline solves the following minimization prob-

[1]We experiment on group sizes $s \in \{5, 10, 15, 20\}$. We choose regularizer $\lambda = 10^{-5}$ based on validation. We use $s = 10$ for qualitative results such as plots and illustrations, but we report quantitative results for all group size s. For our quantitative results, we report the average test performance. The initial risk is $R(\emptyset) = 0.85$.

[2] There are 6 groups of size 32; the other groups have sizes between 1 and 6. The cost of each group is its expected computation time in seconds, ranging between 0.0005 and 0.0088; the total feature cost is 0.111. We choose regularizer $\lambda = 10^{-7}$. The data-set is split into five 100k sets, and the remaining 10k are used for validation. We report the cross validation results on the five 100K sets as the test results. The initial risk is $R(\emptyset) = 0.091$.

[2]Karayev et al. [2012] define *timeliness* as the area under the average precision vs. time curve

lem: $\min_{w \in \mathbb{R}^D} \|Y - Xw\|_2^2 + \lambda \sum_{j=1}^{J} c(\mathcal{G}_j) \|w_{\mathcal{G}_j}\|_2$, and we vary value of regularization constant λ to obtain lasso paths. We call this baseline algorithm **Sparse**[3].

5.3 FEATURE COST

Our proposed CS-G-OMP differs from Group Orthogonal Matching Pursuit (G-OMP) [Lozano et al., 2009] in that G-OMP does not consider feature costs when evaluating features. We show that this difference is crucial for anytime linear prediction. In Figure 3b, we compare the objective vs. costs curves of CS-G-OMP and G-OMP that are stopped at 0.97-stopping cost on YAHOO! LTR. As expected, CS-G-OMP achieves a better overall prediction at every budget, qualitatively demonstrating the importance of incorporating feature costs. Table 1 and Table 2 quantify this effect, showing that CS-G-OMP achieves a better timeliness measure than regular G-OMP.

5.4 GROUP WHITENING

We provide experimental evidence that Group whitening, i.e., $X_g^T X_g = I_{D_g}$ for each group g, is a key assumption of both this work and previous feature group selection literature by Lozano et al. [2009, 2011]. In Figure 4, we compare anytime prediction performances using group whitened data against those using the common normalization scheme where each feature dimension is individually normalized to have zero mean and unit variance. The objective vs. cost curve qualitatively shows that group whitening consistently results in the better predictions. This behavior is expected from data-sets whose feature groups contain correlated features, e.g., group whitening effectively prevents selection step $(*)$ from overestimating the predictive power of feature groups of repeated good features. Table 1 and Table 2 demonstrate quantitatively the consistent better timeliness performance of CS-G-OMP over that of CS-G-OMP-no-whiten.

5.5 SELECTION CRITERION VARIANTS

This section compares CS-G-OMP and CS-G-FR, along with variants of these two methods and the baseline, Sparse. We formulated the variant of CS-G-OMP, *single*, in Section 2 and it intuitively chooses feature groups of the best single feature dimension per group cost. Our experiments show that this modification degrades prediction performance of CS-G-OMP. Since FR directly optimizes the objective at each step, we expect CS-G-FR to perform the best and use its curve to compute the **Oracle** curve as an approximate to the best achievable performance.

[3]We use an off-the-shelf software, SPAMS (SPArse Modeling Software [Jenatton et al., 2010]), to solve the optimization.

In Figure 5, we evaluate CS-G-FR, CS-G-OMP and CS-G-OMP-single based on the objective in Theorem 3.2, i.e., explained variance vs. feature cost curves. CS-G-FR, as expected, outperforms all other methods. CS-G-OMP outperforms the baseline method, Sparse, and the CS-G-OMP-Single variant. The performance advantage of CS-G-OMP over CS-G-OMP-Single is much clearer in the AGRICULTURAL data-set than in the YAHOO! LTR data-set. AGRICULTURAL has a natural group structure which may contain correlated features in each group. YAHOO! LTR has a randomly generated group structure whose features were filtered by feature selection before the data-set was published [Chapelle and Chang, 2011]. CS-G-FR and CS-G-OMP outperform the baseline algorithm, Sparse. We speculate that linearly scaling group regularization constants by group costs did not enforce Group-Lasso to choose the most cost-efficient features early. The test-time timeliness measures of each of the methods are recorded in Table 1 and Table 2, and quantitatively confirm the analysis above. Since AGRICULTURAL and YAHOO! LTR are originally a classification and a ranking data-set, respectively, we also report in Figure 5 the performance using classification accuracy and NDCG@5. This demonstrates the same qualitatively results as using explained variants.

As expected, when compared against CS-G-OMP, CS-G-FR consistently chooses more cost-efficient features at the cost of a longer training time. In the context of linear regression, let us assume that the group sizes are bounded by a constant when we are to select the number K feature group. We can then compute a new model of K groups in $O(K^2N)$ using Woodbury's matrix inversion lemma, evaluate it in $O(KN)$, and compute the gradients with respect to the weights of unselected groups in $O(N(J-K))$. Thus, CS-G-OMP requires $O(K^2N + JN)$ at step $K = 1, 2, 3, ..., J$ and CS-G-FR requires $O((J-K)K^2N)$, so the total training complexities for CS-G-OMP and CS-G-FR are $O(J^3N)$ and $O(J^4N)$, using $\sum_{K=1}^{J} K^2 = \frac{1}{6}J(J+1)(2J+1)$ and $\sum_{K=1}^{J} K^3 = \frac{1}{4}J^2(J+1)^2$. We also show this training complexity gap empirically in Figure 2, which plots the curves of training time vs. number of feature groups selected. When all feature groups are selected, CS-G-OMP achieves a 8x speed-up in AGRICULTURAL over CS-G-FR. In YAHOO! LTR, CS-G-OMP achieves a speed-up factor between 10 and 20; the smaller the sizes of the groups, the larger speed-up due to the increase in the number of groups. Both greedy methods are much faster than the Lasso path computation using SPAMS, however.

This work was conducted in part through collaborative participation in the Robotics Consortium sponsored by the U.S Army Research Laboratory under the Collaborative Technology Alliance Program, Cooperative Agreement W911NF-10-2-0016.

Abstract

Multilevel clustering problems where the content and contextual information are jointly clustered are ubiquitous in modern datasets. Existing works on this problem are limited to small datasets due to the use of the Gibbs sampler. We address the problem of scaling up multilevel clustering under a Bayesian nonparametric setting, extending the MC2 model proposed in (Nguyen *et al.*, 2014). We ground our approach in structured mean-field and stochastic variational inference (SVI) and develop a tree-structured SVI algorithm that exploits the interplay between content and context modeling. Our new algorithm avoids the need to repeatedly go through the corpus as in Gibbs sampler. More crucially, our method is immediately amendable to parallelization, facilitating a scalable distributed implementation on the Apache Spark platform. We conduct extensive experiments in a variety of domains including text, images, and real-world user application activities. Direct comparison with the Gibbs-sampler demonstrates that our method is an order-of-magnitude faster without loss of model quality. Our Spark-based implementation gains another order-of-magnitude speedup and can scale to large real-world datasets containing millions of documents and groups.

1 INTRODUCTION

A prominent feature in numerous modern datasets tackled in machine learning is how the data are naturally layered into groups in a hierarchical representation: text corpus as collection of documents, which are subdivided into words, user's activities are organized by users, whose sessions divided into actions, electronic medical records (EMR) organized as sets of ICD[1] codes diagnosed for the patient. Probabilistic modeling techniques for grouped data have become a standard tool in machine learning, including topic modeling (Blei *et al.*, 2003; Teh *et al.*, 2006) and multilevel data analysis (Hox, 2010; Diez-Roux, 2000). Another important feature in such datasets is the availability of rich sources of additional information known as contexts and group-specific meta-data (Phung *et al.*, 2012; Nguyen *et al.*, 2014). These include information about authorships, timestamps, various tags associated with texts and images, user's demographics, etc. For consistency, we shall refer to the content groups (e.g., text documents, images, user's activity session) broadly as *documents*, and its associated context as document-specific *context*.

The rich and interwoven nature of raw document contents and their contextual information provides an excellent opportunity for joint modeling and, in particular, clustering the content-units (e.g., forming topics from words) and the content-groups (e.g., forming cluster of documents) — a problem known as *multilevel clustering with context* (Nguyen *et al.*, 2014). There have been several attempts of multilevel clustering in the probabilistic topic modeling literature. A simple approach is to subdivide this task into two phases: first learn a topic model and then perform document clustering using the topic-induced representation of the documents (Lu *et al.*, 2011; Nguyen *et al.*, 2013; Phung *et al.*, 2014). An elegant approach is to unify these two steps into a single framework (Nguyen *et al.*, 2014; Xie & Xing, 2013; Rodriguez *et al.*, 2008; Wulsin *et al.*, 2012). Among these work, the Bayesian nonparametric approach to multilevel clustering with group-level contexts (MC2) (Nguyen *et al.*, 2014) offers a powerful method capable of jointly modeling both content and context in a flexible and nonparametric manner, generalizing on several previous modeling techniques. The key idea of the MC2 model is a special Dirichlet Process (DP) whose base-measure is a product between a context-generating measure and a content-generating DP. This construct enables both clustering of documents associating with their

[1] Stands for International Classification of Disease.

contexts and clustering of words into topics. Nguyen *et al.* (2014) have shown that their MC2 integrates the nested DP (Rodriguez *et al.*, 2008) and DP mixture (DPM) (Antoniak, 1974) into one single unified model wherein marginalizing out the documents' contents results in a DP mixture, and marginalizing out document-specific contexts results in a nested DP mixture.

The need for jointly accounting for both context and content data in a flexible Bayesian nonparametric fashion also underlies a formidable computational challenge for model fitting. In fact, the MC2 model of Nguyen *et al.* (2014) was originally equipped with a Gibbs sampler for inference; hence the usefulness of the model could only be demonstrated on relatively small datasets. This seriously hinders the usefulness and applicability of MC2 in tackling big real world datasets which can contain millions of documents or more, along with it the millions of useful pieces of contextual information.

Our goal in this work is to address the multilevel clustering with contexts problem at scale, by developing effective posterior inference algorithms for the MC2 using techniques from stochastic variational inference. A challenging aspect about inference for MC2 is the computational treatment in the clustering of discrete distributions of contents jointly with the context variables. Unlike either the Dirichlet process or HDP mixtures, the context-content linkage present in the MC2 model makes the model more expressive, while necessitating the inference of the joint context and content atoms. These are mathematically rich objects — while the context atoms take on usual contextual values, the content atoms represent probability distributions over words. To maintain an accurate approximation of the joint context and content atoms, we employ a *tree-structured mean-field* decomposition that explicitly links the model context and content atoms.

The result is a scalable stochastic variational inference (SVI) algorithm for MC2 (SVI-MC2) that, unlike Gibbs sampling, avoids the need to go through the corpus multiple times. Moreover, the SVI computation within each mini-batch can be easily parallelizable. To fully exploit this advantage of the SVI formulation, we further implement our proposed SVI for the MC2 algorithm on the Apache Spark platform. We demonstrate that even a sequential implementation of SVI-MC2 is several times faster than Nguyen *et al.* (2014)'s Gibbs sampler while yielding the same model perplexity. A parallel implementation can gain another order of magnitude improvement in speed; our Spark implementation can simultaneously find topics and clustering millions of documents and their context. Our contributions then can be summarized as: (a) a new theoretical development of stochastic variational inference for an important family of models to address the problem of multilevel clustering with contexts. We note this class of models (MC2) include nested DP, DPM, and HDP as the special cases; (b) a scalable implementation of the proposed SVI-MC2 on Apache Spark; and (c) the demonstration that our new algorithm can scale up to very large corpora.

2 RELATED WORK

Models for clustering documents

Two of the most well-known probabilistic models for learning from grouped data are Latent Dirichlet Allocation (LDA) (Blei *et al.*, 2003) and its nonparametric counterpart, Hierarchical Dirichlet process (HDP) (Teh *et al.*, 2006). These models allow us to exploit the group structure for word clustering but not to cluster the groups of data. To clustering documents, some authors employed a two-step process. In the first step, each document is represented by the feature of its topic proportion using topic models, e.g. LDA or HDP. Now each document is considered as an input data point for some clustering algorithm. Elango & Jayaraman (2005) used LDA combined with K-means to cluster images while Nguyen *et al.* (2013) exploited features by HDP and used Affinity Propagation for clustering human activities.

Incorporating topic modeling and clustering in one unique model is a more elegant approach. Nested DP (nDP) (Rodriguez *et al.*, 2008) is the first attempt to handle this challenge in the context of Bayesian nonparametric. The model by Rodriguez *et al.* (2008) has tried to group documents into clusters each of which shares the same distribution over the topics. However, in the original nDP, the documents do not share topics. An extension to nDP, the MLC-HDP model with 3-level clustering, has been done by Wulsin *et al.* (2012). This model can cluster words, documents and document-corpora with shared topic atoms throughout the group hierarchy with this model. Later, Multi-Grain Clustering Topic Model which allows mixing between global topics and document-cluster topics has been introduced by Xie & Xing (2013). The most recent work, the Bayesian nonparametric multilevel clustering with group-level contexts (MC2) (Nguyen *et al.*, 2014), offers a theoretically elegant joint model for both content and context. To our best of knowledge, this model is the current state-of-the-art for this problem.

However, authors in (Nguyen *et al.*, 2014) only provide a Gibbs sampling method for inference. This seriously hinder the usefulness and applicability of MC2 in tackling modern datasets which can contain millions of documents.

Stochastic Variational Inference

Between two main inference approaches for graphical model including MCMC and deterministic variational methods, variational inference is usually preferred due to its predictable convergence. In variational inference scheme, the problem of computing intractable posterior distribution is transformed into an optimization problem by

introducing tractable variational distribution. One of the most popular approximation is mean-field which assumes that the variational distribution is fully factorized. The objective function called Evidence Lower BOund (ELBO) is defined as KL divergence between approximated distribution and the posterior distribution plus a constant. To solve this optimization problem, coordinate descent can be used. However, this optimization method is not suitable for modern datasets with millions of documents since all document are visited in each iteration. To circumvent this challenge, the earliest, but very recent, attempt can be traced back to (Hoffman *et al.*, 2010) where SVI framework for Bayesian nonparametric inference was proposed by combining mean-field approximation and stochastic optimization. SVI for the hierarchical Dirichlet process (HDP) was also presented in (Wang *et al.*, 2011).

Instead of using coordinate descent, stochastic variational inference (SVI) (Hoffman *et al.*, 2013) using stochastic gradient descent to optimize the ELBO. In order to keep optimization process converge faster, SVI uses the coordinate descent for the local update which is related to each data point and update global variables involving multiple data points with stochastic gradient. Moreover, as suggested by Amari (1998), learning with natural gradient may lead to faster convergence. In the SVI framework with exponential family distributions, the natural gradient updates are not only more likely to improve optimization speed but also produces simpler update equations.

We ground our methodology on (Hoffman *et al.*, 2013) and develop the SVI updates for MC2. However, we note at the outset that, unlike HDP, our model is not completely factorized, hence our solution does not simply follow a naive mean field, but rather a variant of structured mean field approximation of Bayesian nonparametric models.

3 MULTILEVEL CLUSTERING WITH CONTEXTS (MC2)

We first describe the MC2 model of (Nguyen *et al.*, 2014). The generative process for MC2 model (see Fig. 1a) is as follows

$$U \sim \text{DP}\left(\gamma\left(H \times \text{DP}\left(\upsilon Q_0\right)\right)\right) \text{ where } Q_0 \sim \text{DP}\left(\eta S\right),$$
$$(\theta_j, Q_j) \sim U \text{ for each group } j$$
$$x_j \sim F\left(\cdot \mid \theta_j\right), \quad \varphi_{ji} \sim Q_j, \quad w_{ji} \sim Y\left(\cdot \mid \varphi_{ji}\right).$$

In the above, U is a DP realization, hence a discrete measure with probability 1, and therefore enforces the clustering of documents. The sample pair $(\theta_j, Q_j) \sim U$ represents the context parameter and content-generating measures of the j-th document. Distinct measures Q_j are effectively drawn from $\text{DP}(\upsilon Q_0)$ where $Q_0 \sim \text{DP}\left(\eta S\right)$, so the samples φ_{ji} share atoms just like in a hierarchical DP (HDP). $F(.|\theta_j)$ and $Y(.|\varphi_{ji})$ are the likelihoods for context and content with parameters θ_j and φ_{ji}. Their base-measures H and S are assumed to be conjugate with the respective likelihoods.

The stick-breaking representation for the MC2 model is given Fig. 1b. When integrated out the random stick length, the model has an intuitive Polya-Urn view known as the Chinese Restaurant Franchise Bus (CRF-Bus) (Nguyen *et al.*, 2014). Each word in a document is viewed as a customer in a bus. The buses deliver customers randomly to a set of restaurants following a Chinese Restaurant Process (CRP). After getting off the buses, the customers in the restaurants behave as in the HDP - Chinese Restaurant Franchise (CRF). The MC2 model thus inherits the metaphor of tables at restaurants and global dishes from the CRF. The detailed stick-breaking representations are

- Stick length for *content* generation $\epsilon = \{\epsilon_m\}_{m=1}^{\infty}$ and *content* shared atoms $\{\psi_m\}_{m=1}^{\infty}$

$$\epsilon \sim \text{GEM}\left(1, \gamma\right), \qquad \psi_m \sim S, \qquad Q_0 = \sum_{m=1}^{\infty} \epsilon_m \delta_{\psi_m}.$$

- Stick length for *context* generation $\beta = \{\beta_k\}_{k=1}^{\infty}$ and *context* shared atoms $\{\phi_k\}_{k=1}^{\infty}$

$$\beta \sim \text{GEM}\left(1, \eta\right), \qquad \phi_k \sim H, \qquad G = \sum_{t=1}^{\infty} \beta_k \delta_{\phi_k}.$$

- Choosing document group (restaurant) for document $j = 1, \ldots, J$ and generating *context observation*

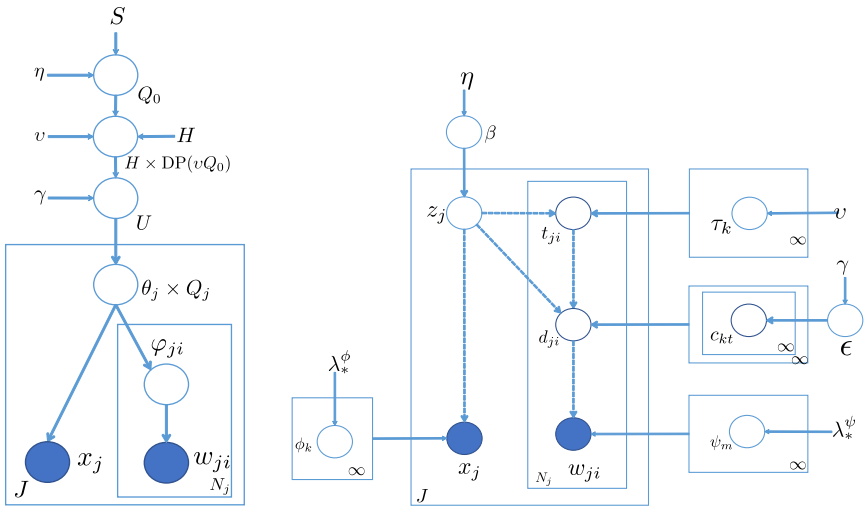
$$z_j \sim \text{Cat}\left(\beta_{1:\infty}\right), \qquad x_j \sim F\left(\cdot \mid \phi_{z_i}\right).$$

- Stick length for each document group $k = 1, \ldots, \infty$, $\{\tau_{kt}\}_{t=1}^{\infty}$, choosing tables t, dishes c and generating *content word,* $j = 1, \ldots, J$ and $i = 1, \ldots, n_j$

$$\tau_k \sim \text{GEM}\left(1, \upsilon\right), \qquad t_{ji} \sim \text{Cat}\left(\tau_{z_j}\right),$$
$$c_{kt} \sim \text{Cat}\left(\epsilon\right), \qquad w_{ji} \sim Y\left(\cdot \mid \psi_{c_{z_j t_{ji}}}\right).$$

We consider general exponential family forms for the likelihoods[2] $Y\left(w \mid \psi\right) = \exp\left(\left\langle T\left(w\right), \psi\right\rangle - A\left(\psi\right)\right)$ and $F\left(x \mid \phi\right) = \exp\left(\left\langle T\left(x\right), \psi\right\rangle - A\left(\phi\right)\right)$. The prior $S\left(\psi \mid \cdot\right)$ and $H\left(\phi \mid \cdot\right)$ have the conjugate forms $p\left(\psi \mid \lambda_*^{\psi}\right) \propto \exp\left(\left\langle \lambda_*^{\psi}, [\psi; -A\left(\psi\right)]\right\rangle\right)$ and $p\left(\phi \mid \lambda_*^{\phi}\right) \propto \exp\left(\left\langle \lambda_*^{\phi}, [\phi; -A\left(\phi\right)]\right\rangle\right)$. The notation $[v; c]$ represents the stacking of two column vectors.

[2]Note that $T\left(w\right)$ and $T\left(x\right)$ may have different forms.



(a) Generative view. (b) Stick-breaking view.

Figure 1: Graphical presentation for Multilevel clustering with contexts models.

4 SVI FOR MC2

4.1 TRUNCATED STICK-BREAKING REPRESENTATIONS

The approximation of DP by truncated stick-breaking representation has been introduced by (Ishwaran & James, 2001) and later used by (Blei & Jordan, 2006) for variational inference in DP mixtures model. In this work, we also use the truncated stick-breaking approximation for all three stick-breaking length variables of the model which are β, ϵ, and τ. As pointed by Ishwaran & James (2001), the truncated stick-breaking is equivalent to the generalized Dirichlet distribution (Connor & Mosiman, 1969; Wong, 1998) which is a distribution on $K-1$ simplex with $2(K-1)$-parameter $\lambda = \left(\lambda_{11}, \ldots \lambda_{(K-1)1},, \lambda_{12}, \lambda_{(K-1)2}\right)$. Each pair of parameters $(\lambda_{k1}, \lambda_{k2})$ corresponds to the parameters for a Beta distribution in stick-breaking process. Generalized Dirichlet (GD) distribution is a member of the exponential family and is conjugate to Multinomial distributions (for more details, see the Appendix). For this reason, the mean-field update of a GD-distributed stick length also has a GD form. We used this conjugacy to compute the variational updates for stick-breaking variables.

4.2 MEAN-FIELD VARIATIONAL APPROXIMATION

The objective of inference problem with the model is to estimate the posterior distribution $p(\Theta \mid x, w)$ where Θ is the collection of parameter variable of the model, $\Theta \triangleq \{\beta, \epsilon, \tau, c, z, t, \psi, \phi\}$. In variational Bayes inference, this intractable posterior will be approximated with a tractable distribution called variational distribution, $q(\Theta)$. In order to ensure that $q(\Theta)$ is tractable, one usually uses mean-field assumption which assumes that all variational variables in Θ are independent. However, because of the nature of the MC2 model, two group of variables z_i (restaurant) and $t_{j1}, \ldots, t_{jn_j}$(tables) are highly correlated. We will maintain the joint distribution of these variables in as a collection of tree-structure graphical model. Thus, the variational distribution q is factorized as

$$q(\Theta) = q(\beta)\, q(\epsilon)\, q(\tau)\, q(c)\, q(z,t)\, q(\psi)\, q(\phi)\,.$$

All the factorized q's have exponential family form and for convenience we shall use either the natural or mean parameterization when appropriate. We use the following convention in naming the variational parameters: λ denotes a natural parameter, μ denotes a mean parameter, superscript denotes the collection of random variables of being parameterized and subscript denotes the index of variables. For instance, under this convention, λ^{ϕ}_{k} is the natural parameter for $q(\phi_k)$. The actual parameterization of q's are

- For the group of stick-breaking variables $q(\beta) = \mathrm{GD}\left(\beta \mid \lambda^{\beta}\right)$, $q(\epsilon) = \mathrm{GD}\left(\epsilon \mid \lambda^{\epsilon}\right)$, and $q(\tau) = \prod_{k=1}^{K} \mathrm{GD}\left(\tau_k \mid \lambda^{\tau}_{k}\right)$ where λ^{β}, λ^{ϵ}, and λ^{τ}_{k} are $2K-2$, $2M-2$, and $2T-2$ dimension vector, respectively. K, M and T are the truncated levels for restaurants, dishes and tables in the CRF-Bus process respectively.
- For the group of content and context atoms $q(\psi) = \prod_{m=1}^{M} q\left(\psi_m \mid \lambda^{\psi}_{m}\right)$ and $q(\phi) = \prod_{k=1}^{K} q\left(\phi_k \mid \lambda^{\phi}_{k}\right)$.
- For the group of indicator variables $q(c) = \prod_{k=1}^{K}\prod_{t=1}^{T} \mathrm{Mult}\left(c_{kt} \mid \mu^{c}_{kt}\right)$ and $q(z,t) = \prod_{j}\left[\mathrm{Mult}\left(z_j \mid \mu^{z}_{j}\right)\prod_{i=1}^{n_j}\mathrm{Mult}\left(t_{ji} \mid \mu^{t}_{jiz_j}\right)\right]$ where μ^{z}_{j}, μ^{c}_{kt}, and μ^{t}_{jik} are K, M, T-dimension vectors,

correspondingly. Note that two groups of variables z and t are not fully factorized but form a forest of trees, with each tree rooted at z_j.

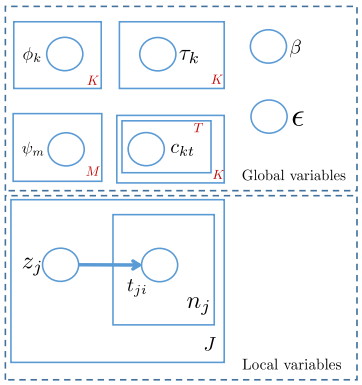


Figure 2: Variational factorization and global vs. local variables for SVI.

4.3 MEAN-FIELD UPDATES

All the individual q's in our model are in the exponential family and are locally conjugate. Thus, standard naive mean-field updates (Bishop *et al.*, 2006; Blei & Jordan, 2006), can be derived for all the variational parameters in a straight-forward manner. We provide more details on the update for the variational parameters of z and t since these are coupled and structured mean-field is needed (Wainwright & Jordan, 2008). At a high-level, for each tree rooted at z_j, exact inference needs to be done to convert from natural to mean parameters. The actual updates equation for these parameters are

$$\mu^t_{jikl} \propto \tilde{\mu}^t_{jikl}, \tag{1}$$

$$\mu^z_{jk} \propto \exp(\mathbb{E}\left[\ln \beta_k p(x_j \mid \phi_k)\right] + \sum_i \ln(\sum_{l=1}^{T} \tilde{\mu}^t_{jikl})),$$

where $\tilde{\mu}^t_{jikl}$ is the unnormalized value of μ^t_{jikl} and is $\exp\left(\sum_{m=1}^{M} \mu^c_{klm}\mathbb{E}\left[\ln p\left(w_{ji} \mid \psi_m\right)\right] + \mathbb{E}\left[\ln \tau_{kl}\right]\right)$.

The update for the rest of the parameters uses naive mean-field.

Two groups of variables, stick-breaking and atoms, contain similar variables. One variable in each group will be presented, the others have a similar forms and can be found in the appendix. The following equations includes updates for the content side of the stick-breaking and atom variables.

For the stick-breaking variational distribution $q(\epsilon)$

$$\lambda^\epsilon_{m1} = 1 + \sum_{k,t} \mu^c_{ktm} \quad \lambda^\epsilon_{m2} = \gamma + \sum_{k,t} \sum_{l=m+1}^{M} \mu^c_{ktl}. \tag{2}$$

For the content-atom variational distribution $q(\psi)$

$$\lambda^\psi_m = \lambda^\psi_* + \sum_{j=1}^{J}\sum_{i=1}^{n_j}\left(\sum_{k=1}^{K}\mu^z_{jk}\sum_{l=1}^{T}\mu^c_{ktm}\mu^t_{jikl}\right)\left[T\left(w_{ji}\right);1\right].$$

4.4 STOCHASTIC VARIATIONAL INFERENCE

We follow the SVI framework (Hoffman *et al.*, 2013) and divide the set of variables Θ in the posterior into the set of *local* variables $\{z, t\}$ with the rest as *global* variables (see Fig. 2). The variational Evidence Lower BOund (ELBO) function is

where $\Theta^g \triangleq \Theta \backslash \{z, t\}$ is the global parameters of the model.

We will reuse the coordinate descent updates for local variational parameters μ^z_j and μ^t_{jik} given in section 4.2. To derive the stochastic gradient descent update for the global parameters, instead of taking the gradient of $\mathcal{L}$ which would result in messages being passed from all the documents, we take the gradient of $\mathcal{L}_j$ which is sufficient to yield a stochastic gradient of $\mathcal{L}$. The gradients are multiplied with the inverse Fisher information matrix to obtain the natural gradients (denoted as $\frac{\partial^{(\text{ng})}}{\partial}$). The gradient with respect to the content atom and stick breaking variational parameters λ^ψ_m and $\lambda^\epsilon_{m1,2}$ are

$$\frac{\partial^{(\text{ng})}\mathcal{L}_j}{\partial\lambda^\psi_m} = \frac{-\lambda^\psi_m + \lambda^\psi_*}{J} + \sum_{i=1}^{n_j}(\sum_{k,l}\mu^z_{jk}\mu^c_{klm}\mu^t_{jikl})\left[T\left\langle w_{ji}\right\rangle;1\right]. \tag{3}$$

$$\frac{\partial^{(\text{ng})}\mathcal{L}_j}{\partial\lambda^\epsilon_{m1}} = \frac{-\lambda^\epsilon_{m1} + 1}{J} + \sum_{k,t}\mu^c_{ktm}, \tag{4}$$

$$\frac{\partial^{(\text{ng})}\mathcal{L}_j}{\partial\lambda^\epsilon_{m2}} = \frac{-\lambda^\epsilon_{m2} + \gamma}{J} + \sum_{k,t}\sum_{r=m+1}^{M}\mu^c_{ktr}$$

Computing the gradient w.r.t. $q(c_{kt})$ is easier using the minimal natural parameterization of the multinomial. Let λ^c_{kt} be the minimal natural parameter corresponding to the mean parameter μ^c_{kt}, the gradient w.r.t λ^c_{kt} is

$$\frac{\partial^{(\text{ng})}\mathcal{L}_j}{\partial\lambda^c_{ktm}} = \frac{-\lambda^c_{ktm} + \mathbb{E}\left[\ln\frac{\epsilon_m}{\epsilon_M}\right]}{J} + (a_{ktm} - a_{ktM}) \tag{5}$$

where $a_{ktm} = \mu^z_{jk}\sum_{i=1}^{n_j}\mu^t_{jikl}\mathbb{E}\left[\ln p\left(w_{ji} \mid \psi_m\right)\right]$ for $m = 1 \ldots M$. Conversion from natural to mean parameters for the multinomials are standard

$$\mu^c_{ktm} = \frac{\exp\left(\lambda^c_{ktm}\right)}{1 + \sum_{m=1}^{M-1}\exp\left(\lambda^c_{ktm}\right)}, m = 1, \ldots, M-1$$

and $\mu^c_{ktM} = 1 - \sum_{m=1}^{M-1}\mu_{ktm}$.

With above derivations, we can summarize the procedure of stochastic variational inference for MC2 model in Algorithm 1.

In the above, the stochastic gradient is obtained for each document. In practice, mini-batch of documents are used

Algorithm 1 Stochastic variational inference for MC2

Require: forgetting rate ι and delay ϱ
Initialize $\lambda_m^{\psi(0)}, \lambda_k^{\phi(0)}$ and set $t = 1$;
repeat
Choose uniformly document j from data
Compute μ_{jik}^t and μ_j^z with Eq. (1)
Set $\varpi_t = (t + \varrho)^{-\iota}$
Update stick-breaking variable hyperparameters $\lambda^\beta, \lambda^\epsilon, \lambda_k^\tau$ using corresponding gradient similar to Eq. (4) as follows $\lambda^{(t+1)} = \lambda^{(t)} + J\varpi_t \frac{\partial^{(\text{ng})} \mathcal{L}_j}{\partial \lambda}$
Update content and context atom hyperparameters $\lambda^\psi, \lambda^\phi$ using corresponding gradient similar to Eq. (3) as follows $\lambda^{(t+1)} = \lambda^{(t)} + J\varpi_t \frac{\partial^{(\text{ng})} \mathcal{L}_j}{\partial \lambda}$
Update "dish-table" indicator variable hyperparameters μ_{ktm}^c using gradient in Eq. (5).
until convergence

in each update to reduce the variance (Hoffman *et al.*, 2010, 2013). In this case, the gradients with a single document in are replaced by the average gradients of all the documents in a mini-batch.

5 EXPERIMENTS

We evaluate our inference algorithm on real datasets with two different scale settings: small datasets with thousands of documents which can also be run using Gibbs sampler; large-scale data with millions of documents which can not be practically run with sampling methods. For small-scale settings, we illustrate competitive perplexity of our inference methods compare to Gibbs sampler but with much less computation time. We also report the running time and performance of our model for large-scale data sets.

5.1 DATASETS

As aforementioned, we use two groups of different scales of datasets. For the *small scale setting*, in order to compare with Gibbs sampler, we use the same datasets in (Nguyen *et al.*, 2014): a text dataset, NIPS, and image dataset, NUS-WIDE.

- NIPS[3] consists of 1740 document with the vocabulary size 13,649. To evaluate predictive performance, we randomly split into 90% training and 10% held-out for computing perplexity.
- NUS-WIDE (Chua *et al.*, 2009) contains a subset of 13 animal classes which totally include 3411 images. Held-out data includes 1357 images and the rest is used for training the model. For the image features, we use bag-of-word SIFT vector with dimension 500. For the context observations, we use the tags for each image which are 1000-dimension spare vectors.

[3]http://www.cs.nyu.edu/~roweis/data.html

For the *large-scale setting,* we use three different datasets including *Wikipedia*, *Pubmed*, and *Application Usage Activity (AUA).*

- *Wikipedia* includes about 1.1 million documents downloaded from wikipedia.com. We pre-process data using a vocabulary list taken from the top 10,000 words in Project Gutenberg and remove all words less than three characters (Hoffman *et al.*, 2013). For the context features we use the (first) writer of the articles and the (top level) categories inferred from tagged categories in each article as described in (De Vries *et al.*, 2010).
- *PubMed* comprises 1.4 million abstracts acquired from pubmed.gov. These documents are filtered with the published year from 2000 onward. Similar to *Wikipedia,* we also extracted the vocabulary from the whole dataset and only kept words with more than 2 characters. A top list of 10.000 words is used as vocabulary list for computing bag-of-word. We further extract the Medical Subject Headings (MeSH) and consider as the context.
- *Application Usage Activity (AUA)*: This dataset contains the usage behavior from more than one million users of a popular software application. Each user is treated as a document in which a word refers to a specific functionality of the application and word frequency refers to the number of times the user interact with the corresponding functionality. The total number of functionalities (vocabulary size) is roughly 10,000. In addition to the current application, each user also uses a host of other related software products which can be used as the context of the user. Applying MC2 to this data effectively cluster the set of users into different segments. To measure the clustering quality, we simply use a ground-truth of two clusters of paid and free users. Note that this information is not present in the context or the word content.

5.2 EXPERIMENT SETUPS

Since our observed data are discrete, we assume that they are generated from either Categorical or Multinomial distributions endowed with Dirichlet priors. The learning rate for stochastic learning at iteration t is $\varpi_t = (t + \varrho)^{-\iota}$where $\varrho \geq 0$ is the delay parameter, and $\iota \in (.5, 1]$ is the forgetting rate which controls how quickly previous statistics is forgotten. In the experiment for computing perplexity, we fixed $\varrho = 1$ and $\iota = 0.8$. The hyperparameters for Dirichlet distributions are set to 0.01 and 0.1 for content and context, respectively.

Small-scale setting

The experiments for NIPS and NUSWIDE datasets are carried out on an Intel Xeon 2.6GHz machine with 16 cores, 16GB RAM using a C# implementation running on Windows 7. SVI method can be parallelized when computing local updates. We run the experiment using both datasets in serial and parallel modes. The parallel implementation is accomplished using the Task Parallel Library (TPL) in .NET framework.

Large-scale setting

In order to handle big datasets, we implement our algorithms on Apache Spark platform[4]. The experiments for *Wikipedia*, *Pubmed*, *AUA* are run in two main settings with no context observations, and with full context observations for each corresponding context. Since HDP implementation is not available on Spark, we use the LDA implementation provided by Spark machine learning library (MLLIB) to compare perplexity with our algorithm. We set the number of topics for LDA equal to the number of topic truncated in the MC2 model.

5.3 EVALUATION METRICS

Perplexity. We use perplexity as the evaluation metric to compare the modelling performance between inference algorithms (Gibbs vs. SVI) or between model (our model vs. LDA). The perplexity is defined as perplexity $(w^{\text{test}}) = \exp\left\{-\frac{\sum_j \ln p(w_{j.}|\mathcal{D})}{\sum_j n_j}\right\}$ where w^{test} is the content words in the test set and $\mathcal{D}$ is the training data. Since we wish to compare our SVI algorithm with Gibbs sampler, we implemented importance sampling (Wallach *et al.*, 2009) to computed $\ln p\left(w_{j.} \mid \mathcal{D}\right)$ in both cases. In Spark MLLIB, there is no implementation for computing perplexity with importance sampling, we instead used the code given by Wallach *et al.* (2009).

Clustering performance. Since our model can carry out clustering for documents, we wish to compare clustering performance. However, documents usually do not have a "strong" ground truth and most of them are with multiple-cluster. For instance, with PubMed data, we use MeSH for each article as ground truth cluster but each article usually associates with several MeSH terms. Some popular clustering performance metrics including purity, Random Index(RI), Normalized Mutual Information (NMI), Fscore (Manning *et al.*, 2008, Chap16) are designed for single cluster ground truth. Whenever there is single cluster ground truth, for example, in the *AUA* dataset, we use the above four metrics. In other cases, we use the extended Normalized Mutual Information (eNMI) which is defined as follows. Let suppose that we have N objects each of which is belong to one of K clusters. A clustering algorithm will assign this object to one of T clusters. With N objects, we denote W as an $N \times K$ ground truth matrix where each row of this matrix represent a (transposed) one-hot vector encoding of the cluster it belongs. Similarly, we have $N \times T$ matrix as a result matrix. The joint probability when an object has the ground truth cluster k and is assigned to cluster t is $p(w, c) = W^{\mathsf{T}}C$. The mutual information between discovered clusters and ground truth cluster is $\text{MI}(W, C) = \sum_{k,t} p(w = k, c = t) \ln \frac{p(w=k,c=t)}{p(c=t)p(w=k)}$. The normalized mutual information is $\text{NMI}(W, C) = \frac{2\text{MI}(W,C)}{H(C)H(W)}$ where $H(\cdot)$ is the entropy of histogram of clusters. In the case of multiple clustering, we have the matrix W and C where each row is not one-hot vector but a vector with the sum as 1. We use some equations above for computing extended NMI (eNMI).

5.4 EXPERIMENTAL RESULT

Results on small -scale setting

First, we demonstrate the performance of our proposed methods (SVI) compared with Gibbs sampler of (Nguyen *et al.*, 2014). For Gibbs samplers, we ran 1500 iterations and SVI with 50 documents in each mini-batch and compute perplexity. The Fig. 3 showed the predictive performance of them over running time. In both datasets, SVI can approach the performance of Gibbs sampler within one epoch[5]; after the first epoch, the perplexity only improved a little. To obtain the competitive performance with Gibbs sampler, our algorithm needs only one-fourth of the amount of running time. Furthermore, SVI algorithm is parallelizable. As shown in Table 1, running time with parallelized version on a single machine with 16 cores is further reduced significantly, 8 and 12 times for NIPS and NUS-WIDE, respectively. Note that our parallel SVI-MC2 only parallelize the local updates, hence, the per-core speedup also depends on the fraction of parallelizable local updates and the global update. In the case of NIPS data set, the dimension of the (global) content and context topic are 13,649 and 2037, respectively, while those of NUS-WIDE are 500 and 1000 which could explain why parallelization is more effective for NUS-WIDE.

[5]Each epoch is an iteration in which algorithm visited all data points.

	Context availability	
	1%	0%
eNMI	**0.084**	0.065

Table 3: Extended Normalized mutual information (NMI) for Pubmed data

Results on large-scale setting

In this setting, we validate the robustness of our algorithm with large-scale datasets. We ran our inference algorithm with *Wikipedia, PubMed*, and *AUA* datasets together with the LDA baseline on an 8-node Spark cluster. We used writer, MeSH, and other products used as contexts for *Wikipedia*, *PubMed*, and *AUA,* respectively. For each dataset, we ran data with full observations of context and without context. Table 2 depict the perplexity for these datasets with and without context compared with LDA. The predictive performance of SVI-MC2 improved remarkably compared to LDA.

For *PubMed* dataset, we used MeSH as the ground truth for clustering evaluation. As each document contains several MeSH terms, we use extended NMI (eNMI) for computing clustering performance. For each mini-batch, we compute eNMI of this mini-batch with its ground truth. The table 3 depict the average eNMI for all mini-batches in an epoch. With a very little availability of the ground truth as context, our algorithm can considerably improve clustering performance.

For *AUA* dataset, three different levels of context availability are used including no context, 1%, and full context. Since the ground truth clusters do not overlap, we can use the conventional metrics for clustering evaluation such as NMI, RI, purity, and Fscore. We also compute the average of the above indices for all mini-batches in an epoch. The clustering results are are shown in table 4. All clustering metrics showed the advantage of context observation (very small percentage is needed) to improve the clustering performance.

It is not possible to run the Gibbs sampler for these large datasets; even the serial version of SVI took too much time, hence we only reported running time for Spark SVI-MC2. With the mini-batch size of 500, the best running times are achieved using an 8-node cluster: Wikipedia: 17 hours; Pubmed: 18.5 hours; AUA: 18 hours. However, using a single-node (with 16-core) could also suffice with running time roughly 1.5 times slower than on a full 8-node cluster. We note that the size of the mini-batch (500) in this case strongly affects the effectiveness of the distributed-cluster setting. For example, with a mini-batch size of 1000, the speed-up factor on an 8-node cluster (compared to single-node) increases from 1.5 to 1.8.

6 CONCLUSION

We have presented a scalable method for Bayesian nonparametric multilevel clustering with contextual side information. We proposed a tree-structured SVI approximation for an efficient approximation of the model's posterior. The approach can be directly parallelizable, and we provide parallelized implementations that work both on a single machine and on a distributed Apache Spark cluster. The experimental results demonstrate that our method is several orders of magnitude faster than existing the Gibb-sampler while yield the same model quality. Most importantly, our work enables the applicability of multilevel clustering to modern real-world datasets which can contain millions of documents.

Abstract

The counting grid is a grid of *microtopics*, sparse word/feature distributions. The generative model associated with the grid does not use these microtopics individually, but in predefined groups which can only be (ad)mixed as such. Each allowed group corresponds to one of all possible overlapping rectangular windows into the grid. The capacity of the model is controlled by the ratio of the grid size and the window size. This paper builds upon the basic counting grid model and it shows that hierarchical reasoning helps avoid bad local minima, produces better classification accuracy and, most interestingly, allows for extraction of large numbers of coherent microtopics even from small datasets. We evaluate this in terms of consistency, diversity and clarity of the indexed content, as well as in a user study on word intrusion tasks. We demonstrate that these models work well as a technique for embedding raw images and discuss interesting parallels between hierarchical CG models and other deep architectures.

1 INTRODUCTION

Recently, a new breed of topic models, dubbed counting grids (CG) [1, 2], has been shown to have advantages in unsupervised learning over previous topic models, while at the same time providing a natural representation for visualization and user interface design [3]. CG models are *generative* models based on a grid of word distributions, which can best be thought of as the grounds for a massive Venn diagram of documents. The intersections among multiple documents (bags of words) create little intersection units with a very small number of words in them (or rather, a very sparse distribution of the words). The grid arrangement of these sparse distributions, which we will refer to here as *microtopics*, facilitates fast cumulative sum based inference and learning algorithms that chop up the documents into much smaller constitutive pieces than what traditional topic models typically do. For example, Fig. 1 shows a small part of such a grid with a few representative words with greatest probability from each microtopic. Each of the Science magazine abstracts used to train this grid is assumed to have been generated from a group of microtopics found in a single 4×4 window with equal weight given to all component microtopics. Thus, each microtopic can be 16 times sparser than the set of documents grouped into the window.

A document may share a window with another very similar document, but it is also mapped so that it only partially overlaps with a window that is the source for a set of slightly less related documents. The varying window overlap literally results in a varying overlap in document themes. This modeling assumption results in a trained grid where nearby microtopics tend to be related to each other as they are often used together to generate a document. Consider, e.g., the lower right 4×4 window in Fig. 1. The word distributions in these 16 cells are such that a variety of Science papers on evidence of ancient life on Earth could be generated by sampling words from there. (Note that each cell, though of very low entropy, contains a distribution over the entire vocabulary.) In the posterior distribution, this window is by far the most likely source for an article on a bizarre microorganism that produced nitrogen in cretaceous oceans. In the 4×4 window two cells to the left of this example we find mapped a variety of articles on even more ancient events on Earth, e.g. on how sulfur isotopes reveal a deep mantle storage of ancient crust. But there we also start to see words which increase the fit for articles that describe similar events on other planets. Further movement to the left gets us away from the Earth and into astronomy.

To demonstrate the refinement of the microtopics compared to topics from a typical topic model, the color labeling of the grid was created so as to reflect the Kullback-Leibler (KL) divergence of the individual microtopics to the topics trained on the same data through latent Dirichlet allocation (LDA). The LDA topics, hand-labeled after unsu-

pervised training, correspond to fairly broad topics, while the CG represents the data as a group of slowly evolving microtopics. For example, all the yellow coded microtopics map to the "Physics" LDA topic, but they occupy a contiguous area in which from left to right the focus slowly shifts from electromagnetism and particle physics to material science. Furthermore, it is interesting to see the microtopics that occupy the boundaries between coarser topics that LDA model found, capturing the links among astronomy, physics and biology. It is immediately evident that the 2D CGs can have great use in data visualization, though the model can be trained for arbitrary dimensionality [1]. These models combine topic modeling and data embedding ideas in a way that facilitates intuitive regularization controls and allows creation of much larger sets of organized sparse topics. Furthermore, they lend them selves to elegant visualization and browsing strategies, and we encourage the reader to see the example `http://research.microsoft.com/en-us/um/people/jojic/CGbrowser.zip`.

However, the existing EM algorithm for CG learning is prone to local minima problems which occasionally lead to under performance [4, 5]. In addition, no direct testing of the microtopic coherence has been performed to date, which makes it unclear if they are meaningful outside their windowed grouping. After all, a variety of sophisticated topic models have been developed and tested by the research community, but LDA seems to still beat them often in practice. E.g., [16,17] raise doubts that various reported perplexity improvements over the basic LDA model are meaningful as they are sensitive to smoothing constants in the model, and also fail to translate to improvements in human judgement of topic quality. In fact, LDA usually outperforms more complex models on tasks that involve human judgement, which may be the main reason why practitioners of data science prefer this basic model to others [6]. Here we develop hierarchical versions of CG models, which in our experiments produced embeddings of considerably higher quality. We show that layering into deeper architectures primarily aids in avoiding bad local minima, rather than increasing representational capacity: The trained hierarchical model can be collapsed into an original counting grid form but with a much higher likelihood compared to the grids fit to the same data using EM with random restarts. The better data fit then translates into quantitatively better summaries of the data, as shown in numerical experiments as well as human evaluations of microtopics obtained through crowdsourcing.

2 HIERARCHICAL LEARNING OF GRIDS OF MICROTOPICS

The (C)CG grids [1, 2]: The basic counting grid $\pi_{\mathbf{k}}$ [1] is a set of distributions on the d-dimensional toroidal discrete grid $\mathbf{E}$ indexed by $\mathbf{k}$. The grids in this paper are bi-dimensional and typically from $(E_x = 32) \times (E_y = 32)$ to

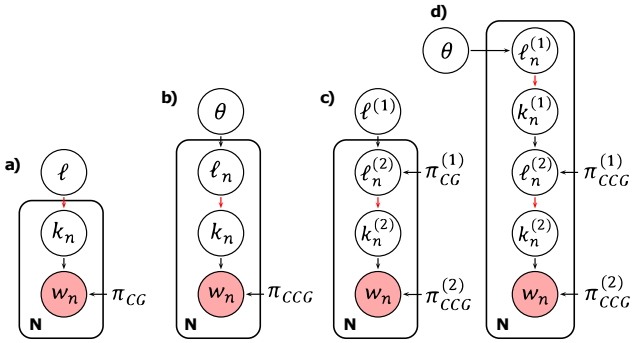

Figure 2: **a)** The basic counting grid, **b)** the componential counting grid, **c)** the hierarchical counting grid model (HCG) obtained by stacking a componential counting grid and a counting grid, and **d)** the hierarchical componential counting grid model (HCCG). Dotted circles represent the parameters of the models. Red links represents known conditional distributions $P(k_n|\ell_n) = U_\ell^W$ - Eq. 5. They are distributions over the grid locations, uniformly equal to $1/|\mathbf{W}|$ in the window of size $\mathbf{W}_\ell$ unequivocally identified by ℓ.

$(E_x = 64) \times (E_y = 64)$ in size. The index z indexes a particular word in the vocabulary $z = [1 \dots Z]$. Thus, $\pi_{\mathbf{i}}(z)$ is the probability of the word z at the d-dimensional discrete location $\mathbf{i}$, and $\sum_z \pi_{\mathbf{i}}(z) = 1$ at every location on the grid. The model generates bags of words, each represented by a list of words $\mathbf{w} = \{w_n\}_{n=1}^N$ with each word w_n taking an integer value between 1 and Z. The modeling assumption in the basic CG model is that each bag is generated from the distributions in a single window $\mathbf{W}$ of a preset size, e.g., $W_x = 5 \times W_y = 5$. A bag can be generated by first picking a window at a d-dimensional location ℓ, denoted as W_ℓ, then generating each of the N words by sampling a location $\mathbf{k}_n$ for a particular microtopic $\pi_{\mathbf{k}_n}$ uniformly within the window, and finally by sampling from that microtopic. Because the conditional distribution $p(\mathbf{k}_n|\ell)$ is a preset uniform distribution over the grid locations inside the window placed at location ℓ, the variable $\mathbf{k}_n$ can be summed out[1], and the generation can directly use the grouped histograms

$$h_\ell(z) = \frac{1}{|\mathbf{W}|} \sum_{\mathbf{j} \in W_\ell} \pi_{\mathbf{j}}(z), \quad (1)$$

where $|\mathbf{W}|$ is the area of the window, e.g. 25 when 5×5 windows are used. In other words, the position of the window ℓ in the grid is a latent variable given which we can write the probability of the bag as

$$P(\mathbf{w}|\ell) = \prod_{w_n \in \mathbf{w}} h_\ell(w_n) = \prod_{w_n \in \mathbf{w}} \Big(\frac{1}{|\mathbf{W}|} \cdot \sum_{\mathbf{j} \in W_\ell} \pi_{\mathbf{j}}(w_n)\Big) \quad (2)$$

As the grid is toroidal, a window can start at any position and there is as many h distributions as there are π distributions. The former will have a considerably higher entropy as they are averages of many π distributions. Although the basic CG model is essentially a simple mixture assuming the existence of a single source (one window) for all the features in one bag, it can have a very large number of (highly related) choices h to choose from. Topic models [7, 8], on the other hand, are admixtures that capture word

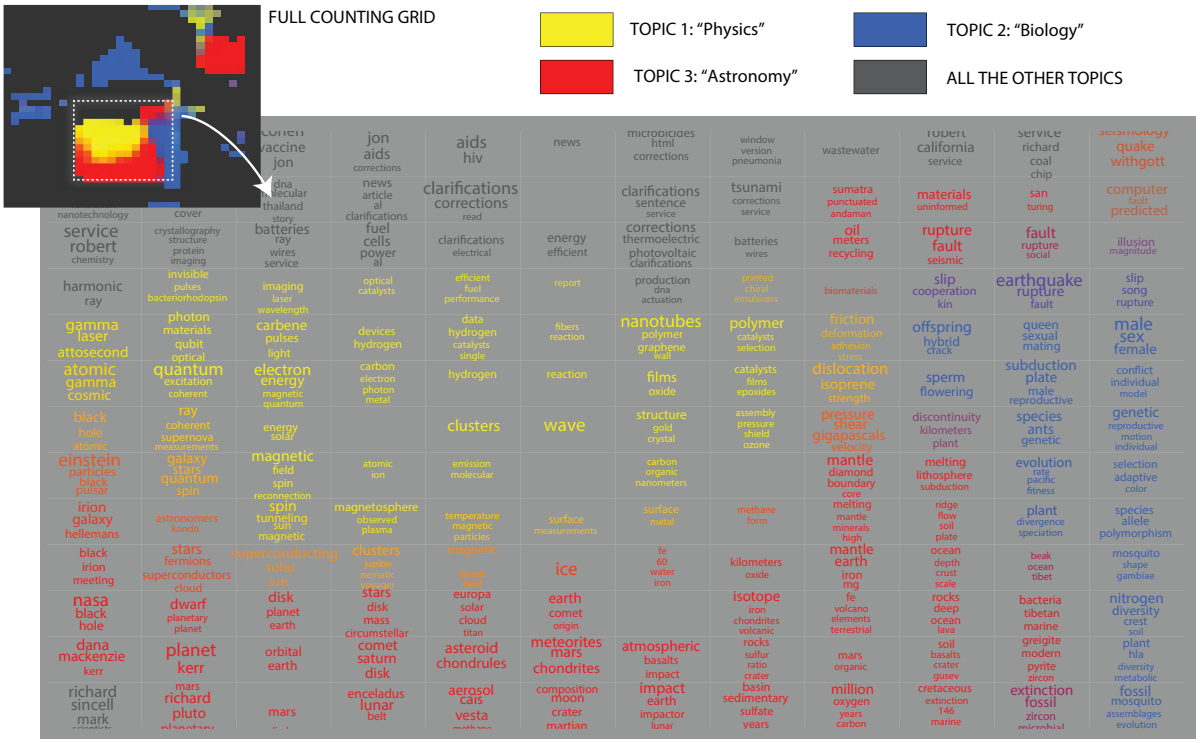

Figure 1: Clash of topics: LDA topics are mapped onto a counting grid. As shown in the top left panel, LDA's topics cluster in contiguous areas on the grid. In the enlarged part of the grid, for each microtopic we show the most likely words if they exceed a threshold.

co-occurrence statistics by using a much smaller number of topics that can be more freely combined to explain a single document. Componential Counting Grids (CCG) [2] combine these ideas, allowing multiple groups of broader topics h to be mixed to explain a single document. The entropic h distributions are still made of sparse microtopics π in the same way as in CG so that the CCG model can have a much larger number of topics than an LDA model without overtraining. More precisely, each word w_n can be generated from a different window, placed at location ℓ_n, but the choice of the window follows the same prior distributions θ_ℓ for all words. Within the window at location ℓ_n the word comes from a particular grid location k_n, and from that grid distribution the word is assumed to have been generated. The probability of a bag is now

$$P(\mathbf{w}|\pi) = \prod_{w_n \in \mathbf{w}} \sum_{\ell \in \mathbf{E}} \left(\theta_\ell \cdot \left(\frac{1}{|\mathbf{W}|} \sum_{\mathbf{j} \in W_\ell} \cdot \pi_{\mathbf{j}}(w_n) \right) \right) \quad (3)$$

In a well-fit CCG model, each data point has an inferred θ_ℓ distribution that usually hits multiple places in the grid, while in a CG, each data point tends to have a rather peaky posterior location distribution because the model is a mixture. Both models can be learned efficiently using the EM algorithm because the inference of the hidden variables, as well as updates of π and h can be performed using summed area tables [9], and are thus considerably faster than most of the sophisticated sampling procedures used to train other topic models. An intriguing property of these models is that even on a 32×32 grid with 1024 microtopics π and just as many grouped topics h, there is no room for too many independent groups. With a window size 8×8, for example, we can place only 16 windows without overlap, and the remaining windows are overlapping the pieces of these 16. The ratio between grid and window size is referred to as the *capacity* of the model, and the training set size necessary to avoid overtraining the model only needs to be 1-2 orders of magnitude above the capacity number. Thus a grid of 1024 microtopics may very well be trainable with thousands of data points, rather than 100s of thousands that traditional topic models usually require for that many topics.

Raw image embedding using (C)CGs: In previous applications of CG models to computer vision, images were represented as spatially disordered bags of features. We experimented with embedding raw images with full spatial information preserved, and we present this here as we feel that the image data helps in illuminating the benefits of hierarchical learning. An image described by a full intensity function $I(x, y)$ could be considered as a set of words, each word being an image location $z = (x, y)$. For a $N \times M$ image, we have a vocabulary of size $M \cdot N$. The number of repetitions of word (x, y) is then set to be proportional to the intensity I(x,y). (In case of color images, the number of features is simply tripled with each color channel treated in this way). In other words, an unwrapped image

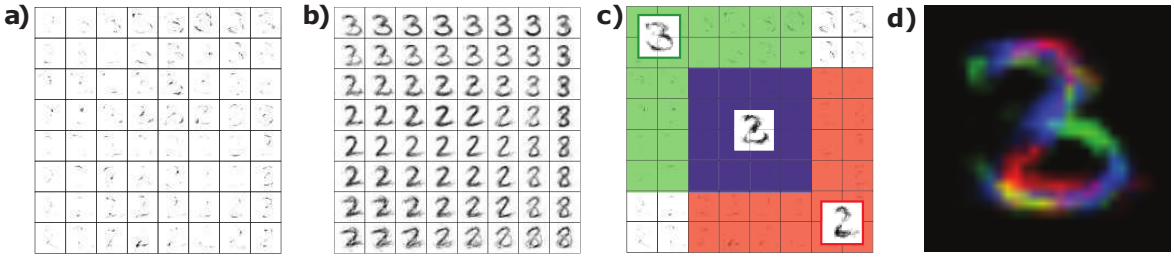

Figure 3: Intersecting digits on a grid of strokes. Each digit image is represented by counts (intensity) associated with image locations. **a)** π-distributions **b)** h-distributions **c-d)** Intersecting digits

is considered to be a word (location) histogram. π and h distributions can then also be seen as images, as they provide weights for different image locations. If we tile the image representations of these distributions we get additional insight into CGs as an embedding method. Fig. 3 shows a portion of a 48×48 grid trained on 2000 MNIST digits assuming a 6×6 window averaging. To illustrate the generative model, in c) we show the partial window sums for two overlapping windows over π. The green and blue areas form a window that generates a version of digit 3, which can be seen at the top left of this portion of the h grid (panel b)). The blue and red, on the other hand, combine into a window that represent a digit 2 at the position (3,3) in panel b). Partial sums for green, blue and red areas are shown in c) and these partial sums, color coded and overlapped are also illustrated in d). Careful observation of b) or the full grid in the appendix, demonstrates the slow deformation of digits from one to another in the h distributions. The appendix has additional examples of image dataset embedding, including rendered 3D head models and images of bold eagles retrieved by internet search. The CG π distributions shown here look like little strokes, while h distributions are full digits. The CCG model, on the other hand, combines multiple h distributions to represent a single image, and so h looks like a grid of strokes Fig. 4a, while π distributions are even sparser.

Hierarchical grids: By learning a model in which microtopics join forces with their neighbors to explain the data, (C-)CG models tend to exhibit high degrees of relatedness of nearby topics. As we slowly move away from one microtopic, the meaning of the topics we go over gradually shifts to related narrowly defined topics as illustrated by Fig. 1; this makes these grids attractive to HCI applications. But this also means that simple learning algorithms can be prone to local minima, as random initializations of the EM learning sometimes result in grouping certain related topics into large chunks, and sometime breaking these same chunks into multiple ones with more potential for suboptimal microtopics along boundaries. To illustrate this, in Fig. 4a we show a 48×48 grid of strokes h (Eq. 1) learned from 2000 MNIST digits using a CCG model assuming a 5×5 window averaging. Nearby features h are highly related to each other as they are the result of adding up features in overlapping windows over π (which is not shown). CCG is an admixture model, and so each digit indexed by t has a relatively rich posterior distribution θ^t over the locations in the grid that point to different strokes h. In Fig. 4, we show one of the main principal components of variation in θ as an image of the size of the grid. For three peaks there, we also show h-features at those locations. The combination of these three sparse features creates a longer contiguous stroke, which indicates that this longer stroke is often found in the data. Thus, the separation of these features across three distant parts of the map is likely a result of a local minimum in basic EM training. To transfer this reasoning to text models, consider the 5th cell in the first row in Fig. 1 with words HIV, AIDS, and the blue cell in the middle of the last column with words SELECTION, ADAPTIVE. The separation of these two things in faraway locations may very well be a result of a local minimum, which could be detected if location posteriors exhibit correlation. This illustration points to an idea on how to build better models. The distribution over locations ℓ that a data point t maps to (a posteriori) could be considered a new representation of the data point (digit in this case), with the mapped grid locations considered as features, and the posterior probabilities for these locations considered as feature counts. Thus another layer of a generative model can be added to generate the locations in the grid below, Fig. 2c-d. It is particularly useful to use another microtopic grid model as this added layer, because of the inherent relatedness of the nearby locations in the grid. The layer above can thus be either another admixture grid model (Componential Counting Grid - CCG), or a mixture (CG), and this layering can be continued to create a deep model. As CG is a mixture model, it terminates the layering: Its posterior distributions are peaky and thus uncorrelated. However, an arbitrary number of CCGs can be stacked on top of each other in this manner, terminating on top with a CG layer to form a hierarchical CG (HCG) model, or terminating in a CCG layer to form a hierarchical CCG (HCCG) model. In each layer, the pointers to features below are grouped, which should result in creating a contiguous longer stroke as discussed above in a grid cell that contains a combination of pointers to the lower layers.

For the sake of brevity, we only derive the HCG learning

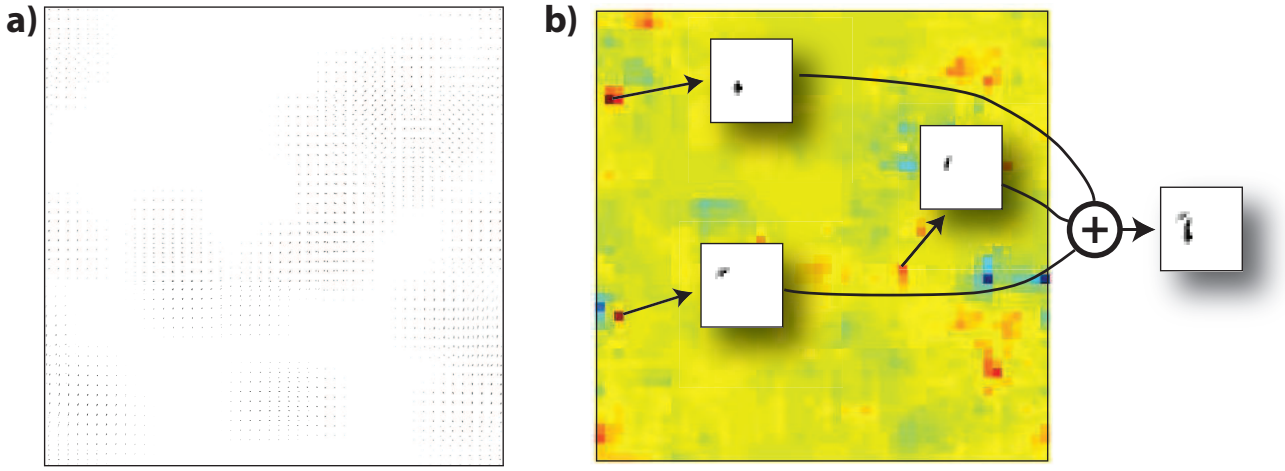

Figure 4: The benefits of hierarchical learning: **a)** h_{CCG} - a bigger higher resolution version in the appendix. **b)** Principal components of θ and three peaks put together.

algorithm with a single intermediate CCG layer. The extension to HCCG and higher order hierarchies is reported in the appendix. Variational inference and learning procedure for counting grid-based models utilizes cumulative sums and is only slower than training an individual (C)CG layer by a factor proportional to the number of layers. The graphical model for HCG is shown in Fig. 2c, where location variables pointing to grids in different layers have the same name, ℓ but carry a disambiguating superscript. *To avoid superscripts in the equations below, we renamed the CG's location variable from $\ell^{(1)}$ to m and dropped the superscript "$^{(2)}$' in the layer above*. The bottom CCG layer follows

$$P(w_n|k_n, \pi_{CCG}) = \pi_{CCG,k_n}(w_n) \tag{4}$$

$$P(k_n|\ell_n) = U^W_{\ell_n}(k_n) = \begin{cases} \frac{1}{|\mathbf{W}|} & \text{if } k_n \in \mathbf{W}_{\ell_n} \\ 0 & \text{Otherwise} \end{cases} \tag{5}$$

The latter is a pre-set distribution over the grid locations, uniform inside W_{ℓ_n}. Instead of the prior θ_ℓ the locations are generated from a top layer CG, indexed by m ($\ell^{(2)}$ in the figure),

$$P(\ell_n|m, \pi_{CG}) = \frac{1}{|\mathbf{W}|} \cdot \sum_{\mathbf{k} \in W_m} \pi_{CG,\mathbf{k}}(\ell_n) \tag{6}$$

This equation also shows that the lower-levels' grid locations act as observations in the higher level. We use the fully factorized variational posterior $q^t(\{k_n\}, \{\ell_n\}, m) = q^t(m) \cdot \prod_n \left(q^t(k_n) \cdot q^t(\ell_n)\right)$ to write the negative free energy $\mathcal{F}$ bounding the non-constant part of the loglikelihood of the data as

$$\begin{aligned} \mathcal{F} &= \sum_{t,n,k_n} q^t(k_n) \log \pi_{CCG,k_n}(w^t_n) \\ &+ \sum_{t,n,k_n,\ell_n} q^t(k_n) q^t(\ell_n) \log U^W_{\ell_n}(k_n) \\ &+ \sum_{t,m,\ell_n} q^t(m) q^t(\ell_n) \log \pi_{CG,m}(\ell_n) \\ &- \mathbb{H}\big(q(m, \{k_n\}, \{\ell_n\})\big) \end{aligned}$$

We maximize $\mathcal{F}$ with the EM algorithm which iterates E- and M-steps until convergence. E:

$$\begin{aligned} q^t(k_n = \mathbf{i}) &\propto \left(e^{\sum_{\ell_n} q^t(\ell_n) \log U^W_{\ell_n}(\mathbf{i})}\right) \cdot \pi_{CCG,\mathbf{i}}(w_n) \\ q^t(\ell_n = \mathbf{i}) &\propto \left(e^{\sum_{k_n} q^t(k_n) \log U^W_{\mathbf{i}}(k_n)}\right) \\ &\cdot \left(e^{\sum_m q^t(m) \log \pi_{CG,m}(\mathbf{i})}\right) \\ q^t(m = \mathbf{i}) &\propto e^{\sum_n \sum_{\ell_n} q^t(\ell_n) \cdot \log h_{CG,\mathbf{i}}(\ell_n)} \end{aligned}$$

The M step re-estimates the model parameters using these updatedposteriors:

$$\pi_{CCG,\mathbf{i}}(z) \propto \sum_t \sum_n q^t(k_n = \mathbf{i}) \cdot [w^t_n = z]$$

$$\pi_{CG,\mathbf{i}}(\mathbf{l}) \propto \hat{\pi}_{CG,\mathbf{i}}(\mathbf{l}) \cdot \sum_{t,n} q^t(\ell_n = \mathbf{l}) \cdot \sum_{\mathbf{k}|\mathbf{i} \in W_\mathbf{k}} \frac{q^t(k_n = \mathbf{i})}{\hat{h}_{CG,\mathbf{i}}(\mathbf{l})}$$

where the last (CG) update is performed analogous with [1]. Interestingly, training these hierarchical models stage by stage, reminiscent of deep models where such incremental learning was practically useful [10].

Although it has been shown that a deep neural network can be compressed into a shallow broader one through post training [11], the stacked (C-)CG models can be collapsed mathematically. In this sense we can view HCG and HCCG as *hierarchical learning algorithms* for CG and CCG, which are easier to visualize than deeper models. For example, for HCG in Fig. 2c-d, it is straightforward to see that the following grid defined over the original features $\{w_n\}$,

$$\pi_\ell(w_n) = \sum_{\mathbf{i}} \pi^{(1)}_{\cdot,\ell}(\mathbf{i}) \cdot h^{(2)}_{CCG,\mathbf{i}}(w_n) \tag{7}$$

can be used as a single layer grid that describes the same data distribution as the two-layer model[1]. However, the grids estimated from the hierarchical models should be more compact as the scattered groups of features are progressively merged in each new layer. *Learning in hierarchical models is thus more gradual and results in better*

[1] $h_\mathbf{i}$ are the grouped microtopics in the window $\mathbf{W_i}$ - Eq. 1

local maxima, and we show below that the results are far superior to regular EM learning of the collapsed CG or CCG models.

3 EXPERIMENTS

In all the experiments we used models with two extra layers, although, in some experiments, we found that three levels worked slightly better. In general, the optimal number of layers will depend on the particular application.

Likelihood comparison: In the first experiment we compared the local maxima on models learned using the (full) MNIST data set. The two layer HCG model was first pretrained stage-wise as, e.g., [10], by training the higher level on the posterior distribution from the lower level as the input. Then, the model was refined by further variational EM training. The procedure is repeated 20 times with different random initializations to produce twenty hierarchical models. As discussed above, these models can be collapsed to a CG model by integrating out intermediate layers (7). These models were then compared with twenty models learned by directly learning CG models through previously published standard EM learning algorithm starting from twenty random initializations. Despite being collapsible to the same mathematical form, the HCG models consistently produced higher likelihood than the CG models directly learned using the standard method. *In fact, each CG model created by collapsing one of the learned HCG models had log likelihood at least two standard deviations above the highest log likelihood learned by basic EM (p-value* $< 10^{-20}$*).* Both learning approaches used the computation time equivalent to 1000 iterations of standard EM, which was more than enough for convergence.

Document classification: Next we ran test to see if the increased likelihood obtainable with a better learning algorithm translates into increased quality of representation when posterior distributions for individual text documents are considered as features in classification tasks. We considered the 20-newsgroup dataset[2] (20N) and the Mastercook dataset[3] (MC) composed by 4000 recipes divided in 15 classes. Previous work [12, 13] reduced 20-Newsgroup dataset into subsets with varying similarities and we considered the hardest subset composed by posts from the very similar newsgroups `comp.os.ms-windows`, `comp.windows.x` and `comp.graphics`. We considered the same complexities as in [2], using 10-fold cross validation and classified test document using maximum likelihood. Results for both datasets are shown in Tab. 1.

	CG	**HCG**	CCG	**HCCG**	linSVM
20N	82,3%	**83,5**%	83,4%	**85,0**%	77.5%
MC	38,7%	38,9%	76,2%	**78,9**%	71.3%

Table 1: Document classification. When bold, hierarchical grids outperformed the basic grids with statistical significance (HCG p-value =2.01e-4, HCCG p-values $<$ 1e-3). "linSVM" stands for linear support vector machines which we reported as baseline.

Evaluation of microtopic quality using quantitative measures related to the use in visualization and indexing: We evaluated the coherence and the clarity of the microtopics comparing the collapsed (2 layers) hierarchical grids - HCG and HCCG with regular grids [1, 2], latent Dirichlet allocation (LDA) [7], the correlated topic model (CTM) [8] which allows to learn a large set of correlated topics and few non-parametric topic models [14, 15].
Generative models are often evaluated in terms of perplexity. However different models, even different learning algorithms applied to the same model, are very difficult to compare [16] and better perplexity does not always indicate better quality of topics as judged by human evaluators [17]. On the other hand, the subjective evaluation of topic quality is highly related to measures that have to do with data indexing, e.g. quality of word combinations when used for information retrieval. Thus we start with a novel evaluation procedure for topic models which is strongly related to information indexing and then show that we obtain similar evaluation results when we use human judgement. In the following experiments, we considered a corpus $\mathcal{D}$ composed of Science Magazine reports and scientific articles from the last 20 years. This is a very diverse corpus similar to the one used in [8]. As preprocessing step, we removed stop-words and applied the Porters' stemmer algorithm [18]. We considered grids of size $16 \times 16, 24 \times 24, 32 \times 32, 40 \times 40$ and 48×48 fixing the window size to 5×5. (Previous literature showed that counting grids are only sensitive to the ratio between grid and window area, as long as windows are sufficiently big.) We varied number of topics for LDA and CTM in $\{10, 15, \ldots, 100, 125, 150, \ldots, 1000\}$. For each complexity we trained 5 models starting with different random initializations and we averaged the results. In each repetition, we considered a random third of this corpus, for total of roughly $|\mathcal{D}| = 12K$ documents, $Z = 20K$ different words and more than $600K$ tokens.

To evaluate (micro)topics, we repetitively sampled *k*-tuples of words and checked for consistency, diversity and clarity of the indexed content. In the following, we describe the procedure used for evaluating grids. An equivalent procedure was used to evaluate other topic models for comparison.
To pick a tuple $\mathcal{T}$ of n words, we sampled a grid location $\hat{\ell}$. Then, we repetitively sampled the microtopic $\pi_{\hat{\ell}}$ to obtain the words in the tuple $\mathcal{T} = \{w_1, \ldots w_n\}$. We did not allow repetitions of words in the tuple. We considered 5000 dif-

[3] [2]

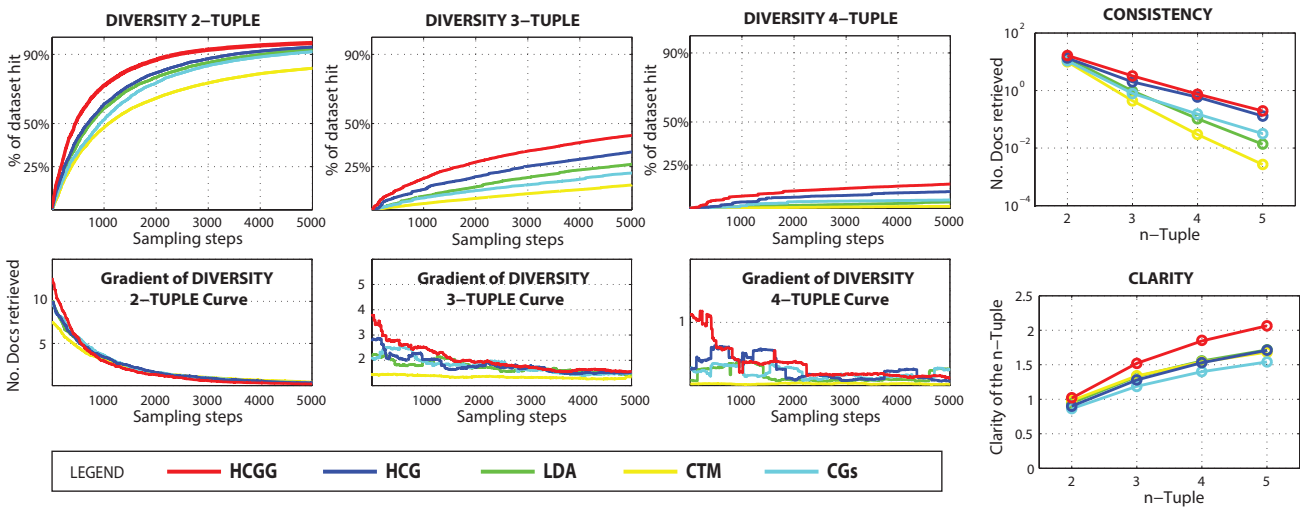

Figure 5: Microtopic evaluations. We compared 32×32 grids with the *best* result obtained by LDA and CTM. To avoid cluttering the graph, we did not report CCG results which were found inferior to the proposed hierarchical models. We also reported the gradient of the diversity curves to show that new samples steadily continue to contribute new tuples.

ferent $n = 2, 3, 4, 5$-tuples, not allowing repeated tuples.
Then we checked for consistency, diversity and clarity of content indexed by each tuple. The **consistency** is quantified in terms of the average number of documents from the dataset that contained *all* words in $\mathcal{T}$. The **diversity** of indexed content is illustrated through the cumulative graph of acquired unique documents as more and more n-tuples are sampled and used to retrieve documents containing them. As this last curve depends on the sample order, we further repeated the process 5 times for a total of 25K different samples. Finally the **clarity** [19], measures the ambiguity of a query with respect to a collection of documents and it has been used to identify ineffective queries, on average, without relevance information.

Formally, the query clarity is measured as the entropy between the n-tuple and the language model $P(w)$ (unigram distributions) as $\sum_w P(w|T) \cdot \log_2 \frac{P(w|T)}{P(W)}$ where $P(w|T) = \sum_{d \in \mathcal{D}} P(w|\mathcal{D}) \cdot P(\mathcal{D}|T)$. We estimated the likelihood of an individual document model generating the tuple $P(T|\mathcal{D}) = \prod_{w_t \in T} P(w_t|\mathcal{D})$ and obtain $P(\mathcal{D}|T)$ using uniform prior probabilities for documents that contains a word in the tuple, and a zero prior for the rest. Finally, to estimate $P(w|T)$ we employed MonteCarlo sampling.
Results are illustrated in Fig.5 and should be appreciated by looking at all three measures together, as some can be over-optimized at the expense of others. The diversity curve that consistently grows as more tuples are sampled indicates that the sampled tuples belong to different subsets of the data, and are thus discriminative in segmenting the data into different clusters. The average tuple consistency, on the other hand, demonstrates that the sampled tuples do occur in large chunks of the data, demonstrating that the induced clusters are of significant size. The clarity measure shows that the clusters made of texts retrieved using different tuples have clear differentiation from the rest of the dataset in usage of all the words in the dictionary. We report results for the 32×32 grids and the best result of LDA and CTM which peaked respectively at 80 and 60 topics. Results for other grid sizes can be found in the additional material; they are stable across complexities with slightly better performances for larger grids.
All grid models show good consistency of words selected as they are optimized so that documents' words map into overlapping windows. Through positioning and intersection of many related documents the words end up being arranged in a fine-grained manner so as to reflect their higher-order co-occurrence statistics. Hierarchical learning greatly improved the results despite the fact that HCCG and HCG can be reduced to (C)CGs through marginalization (7).
Overall HCCG strongly outperformed all the methods, especially with a total gain of 0.5 bits on clarity, which is around third of the score for LDA/CTM. Despite allowing for correlated topics that enable CTM to learn larger topic models, CTM trails LDA in these graphs as topics were over expanded. We also considered non-parametric topic models such as "Dilan" [14] and the hierarchical Dirichlet process [15] but their best results were poor and we did not reported them in the figure. To get an idea, both models only indexed 25% of the content after 5000 2-Tuples samples and had a clarity lower of 0.7-1.2 bits than other topic models.

Human judgments of topic coherence: We next tested the quality of the inferred topics. Topic coherence is often measured based on co-occurrence of the top $k = 10$ words per topic. While good as a quick sanity check of a

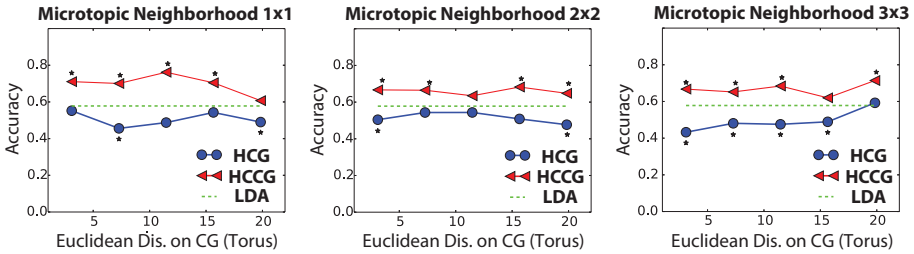

Figure 6: Result of word intrusion task. Statistical significance is denoted by *. *p-values and further details on the test are reported in the appendix*

single learned model, when this measure is used to compare models, it will favor models that lock onto top themes and distribute the rest of the words in the tails of the topic distributions. The LDA models usually have a large drop off in topic coherence when the number of topics is increased to force the model to address more correlations in the data. Indeed, using this measure, LDA topics outperform CG topics in case of small models. But as the number of topics grows, the microtopics trained by HCG significantly outperform both LDA and CG (see the appendix). A more interesting measure of topic quality, which not only depends on individual topic coherence but also on meaningful separation of different topics, requires human evaluation of *word intrusions*. In a word intrusion task [17], six randomly ordered words are presented to a human subject who then guesses which word is an outlier. In the original procedure a target topic is randomly selected and then the five words with *highest* probability are picked. Then, an intruder is added to this set. It is selected at random from the low probability words of the target topic that have high probability in some other topic. Finally the six words are shuffled and presented to the subject. If the target topic shows a lack of coherence or distinction from the intruding topic, the subject will often fail to correctly identify the intruder. This task is again geared towards only getting the top words right in a topic model and ignoring the rest of the distribution, which makes it unsuitable to comparison with microtopic models which attempt to extract much more correlation from the data. Thus instead of picking the top words from each topic, we sampled the words from the target topic to create the in-group. After sampling the location of a microtopic from the grid $\hat{\ell}$, we picked three randomly chosen words from $\pi_{\hat{\ell}}$ or from the small groups of microtopics in the window of size 2×2, and 3×3 around $\hat{\ell}$ (The latter is equivalent to computing the window distributions h using windows of smaller size than the ones used in training and should give us the indication if the granularity assumed in the window size was exaggerated: If it is then averaging of nearby topics should significantly reduce the noise due to forced topic splitting). For each of these groups we choose the intruder word using the standard procedure. If in this harder task humans can identify intruders better for microtopic models than for LDA models, this would indicate that the microtopics are not simply random subsamples of broader topics captured in h and similar in entropy to LDA topics. They would be a meaningful breakup of broad topics into finer ones. We compared LDA (known to performed better than CTM on intrusion tasks [17]), HCG, and HCCG, on randomly crawled 10K Wikipedia articles and used Amazon Mechanical Turk (24000 completed tasks from 345 different people). The trained grids were of size 32×32 and the windows 5×5. The optimal LDA size was chosen using likelihood cross-validation over the range of complexities as in the previous experiments (The peak performance there was at 80 topics). Results are shown in Fig.6 as a function of the Euclidean distance on the grid of the intruder word from the topic. HCCG outperformed LDA (p-values for the 3 tasks 1.20e-11, 1.88e-5, 2.97e-05) and HCG (p-values for the 3 tasks 3.97e-18, 1.01e-11, 3.14e-19) indicating that learning microtopics is possible with a good algorithm. Overall, *users were able to solve correctly 71% of HCCG problems and only 58% of LDA problems*. Interestingly, the performance of HCCG and HCG does not seem to depend on the distance of the intruder word: Even picking intruder word from a very close location rather than from a far away one lead to no additional confusion for the user. This shows that HCCG chops up the data into meaningful microtopics which are then combined into a large number of groups h that do not over broaden the scope. HCCG and HCG also outperformed respectively CG and CCG (see the appendix).

Learning to separate mixed digits. Finally, we show that an HCCG model can be used to perform a task that eludes most unsupervised *and* supervised models. We created a set of 10000 28×28 images, each containing two different MNIST digits overlapped, Fig. 7. We trained an HCCG model consisting of five 32×32 layers on this data stagewise by feeding $L^t(\ell) = \sum_n q^t(\ell_n = \ell)$ from one layer to the next. Windows of size 5×5 were used in all layers. From layer to layer, the new representations of the image consist of growing combinations of low level features h from the bottom layer (sparseness of which is similar to Fig. 4a). The hierarchical grouping is further encouraged by simply smoothing $L^t(\ell)$ with a 5×5 Gaussian kernel with deviation of 0.75, before feeding it to the next layer (This is motivated by the fact that nearby features in h are related and so if two distant locations should be grouped, so should those locations' neighbors). Once the model is

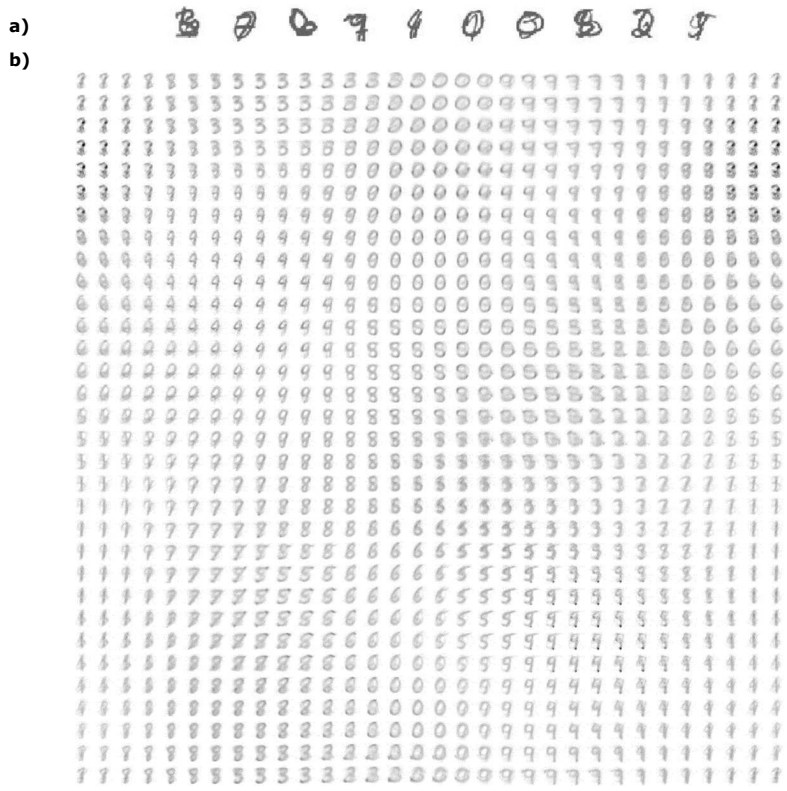

Figure 7: Unsupervised learning on mixed digits

collapsed to a single HCCG grid the components no longer look like short strokes but like whole digits, mostly free of overlap: The model has learned to approximately separate the images into constitutive digits. Reasoning on overlapping digits even eludes deep neural networks trained in a supervised manner, but here we did not use the information about which two digits are present in each of the training images.

4 CONCLUSIONS

We show that with new learning algorithms based on a hierarchy of CCG models, possibly terminated on the top with a CG, it is possible to learn large grids of sparse related microtopics from relatively small datasets. These microtopics correspond to intersections of multiple documents, and are considerably narrower than what traditional topic models can achieve without overtraining on the same data. Yet, these microtopics are well formed, as both the numerical measures of consistency, diversity and clarity and the user study on 345 mechanical turkers show. Another approach to capturing sparse intersections of broader topics is through product of expert models, e.g. RBMs [20], which consist of relatively broad topics but model the data through intersections rather than admixing. RBMs are also often stacked into deep structures. In future work it would be interesting to compare these models, though the tasks we used here would have to be somewhat changed to focus on the intersection modeling, rather than the topic coherence (as this is not what RBM topics are optimized for). HCCG and HCG models have a clear advantage in that it is easy to visualize how the data is represented, which is useful both to end users in HCI applications, and to machine learning experts during model development and debugging. Another parallel between the stacks of CCGs and other deep models is that the uniform connectivity of units is directly enforced through window constraints, rather than encouraged by dropout. Finally, in this specific context we illustrate a broader phenomenon that requires more methodical and broader treatment by the machine learning community. A more complex (deeper) model showed here large advantages in terms of training likelihood, but these advantages were *not* due to the expanded parameter space, because the resulting model is equivalent to a collapsed single layer model. Rather than being a reflection of increased representational abilities of the model, better likelihoods were thus the result of better fitting algorithm that consists of training a deep model (and then collapsing it into a simpler but equivalent parameterization). Similar phenomena are likely regularly encountered elsewhere in machine learning, but not always recognized as such, as in the absence of the full knowledge of the extrema of the fitting criterion, an increase in performance is often inappropriately ascribed to better modeling rather than better model fitting.

Active Uncertainty Calibration in Bayesian ODE Solvers

Hans Kersting and Philipp Hennig

Spemannstraße, 72076 Tübingen, Germany
[hkersting|phennig]@tue.mpg.de

Abstract

There is resurging interest, in statistics and machine learning, in solvers for ordinary differential equations (ODEs) that return probability measures instead of point estimates. Recently, Conrad et al. introduced a sampling-based class of methods that are 'well-calibrated' in a specific sense. But the computational cost of these methods is significantly above that of classic methods. On the other hand, Schober et al. pointed out a precise connection between classic Runge-Kutta ODE solvers and Gaussian filters, which gives only a rough probabilistic calibration, but at negligible cost overhead. By formulating the solution of ODEs as approximate inference in linear Gaussian SDEs, we investigate a range of probabilistic ODE solvers, that bridge the trade-off between computational cost and probabilistic calibration, and identify the inaccurate gradient measurement as the crucial source of uncertainty. We propose the novel filtering-based method Bayesian Quadrature filtering (BQF) which uses Bayesian quadrature to actively learn the imprecision in the gradient measurement by collecting multiple gradient evaluations.

1 INTRODUCTION

The numerical solution of an initial value problem (IVP) based on an *ordinary differential equation* (ODE)

$$u^{(n)} = f(t, u(t), u'(t), \dots, u^{(n-1)}(t)),\ u(0) = u_0 \in \mathbb{R}^D \tag{1}$$

of order $n \in \mathbb{N}$, with $u : \mathbb{R} \to \mathbb{R}^D$, $f : [0, T] \times \mathbb{R}^{nD} \to \mathbb{R}^D$, $T > 0$, is an essential topic of numerical mathematics, because ODEs are the standard model for dynamical systems. Solving ODEs with initial values is an exceedingly well-studied problem (see Hairer et al., 1987, for a comprehensive presentation) and modern solvers are designed very efficiently. Usually, the original ODE (1) of order n is reduced to a system of n ODEs of first order

$$u'(t) = f(t, u(t)),\ u(0) = u_0 \in \mathbb{R}^D, \tag{2}$$

which are solved individually. The most popular solvers in practice are based on some form of Runge-Kutta (RK) method (as first introduced in Runge (1895) and Kutta (1901)) which employ a weighted sum of a fixed amount of gradients in order to iteratively extrapolate a discretized solution. That is, these methods iteratively collect 'observations' of approximate gradients of the solved ODE, by evaluating the dynamics f at an estimated solution, which is a linear combination of previously collected 'observations':

$$y_i = f\left(t_i, u_0 + \sum_{j<i} w_{ij} y_j\right). \tag{3}$$

The weights of s-stage RK methods of p-th order are carefully chosen so that the numerical approximation $\hat{u}$ and the Taylor series of the true solution u coincide up to the p-th term, thereby yielding a local truncation error of high order, $\|u(t_0 + h) - \hat{u}(t_0 + h)\| = \mathcal{O}(h^{p+1})$, for $h \to 0$. One can prove that $s \geq p$ in general, but for $p \leq 4$ there are RK methods with $p = s$. Hence, allowing for more function evaluations can drastically improve the speed of convergence to the true solution.

The polynomial convergence is impressive and helpful; but it does not actually quantify the true epistemic uncertainty about the accuracy of the approximate solution $\hat{u}$ for a concrete non-vanishing step-size h. One reason one may be concerned about this in machine learning is that ODEs are often one link of a chain of algorithms performing some statistical analysis. When employing classic ODE solvers and just plugging in the solution of the numerical methods in subsequent steps, the resulting uncertainty of the whole computation is ill-founded, resulting in overconfidence in a possibly wrong solution. It is thus desirable to model the epistemic uncertainty. Probability theory provides the framework to do so. Meaningful probability measures of the uncertainty about the result of determin-

istic computations (such as ODE solvers) can then be combined with probability measures modeling other sources of uncertainty, including 'real' aleatoric randomness (from e.g. sampling). Apart from quantifying our certainty over a computation, pinning down the main sources of uncertainty could furthermore improve the numerical solution and facilitate a more efficient allocation of the limited computational budget.

A closed framework to measure uncertainty over numerical computations was proposed by Skilling (1991) who pointed out that numerical methods can be recast as statistical inference of the latent true solution based on the observable results of tractable computations. Applying this idea to ordinary differential equations, Hennig & Hauberg (2014) phrased this notion more formally, as Gaussian process (GP) regression. Their algorithm class, however, could not guarantee the high polynomial convergence orders of Runge-Kutta methods. In parallel development, Chkrebtii et al. (2013) also introduced a probabilistic ODE solver of similar structure (i.e. based on a GP model), but using a Monte Carlo updating scheme. These authors showed a linear convergence rate of their solver, but again not the high-order convergence of classic solvers.

Recently, Schober et al. (2014) solved this problem by finding prior covariance functions which produce GP ODE solvers whose posterior means *exactly* match those of the optimal Runge-Kutta families of first, second and third order. While producing only a slight computational overhead compared to classic Runge-Kutta, this algorithm — as any GP-based algorithm — only returns Gaussian measures over the solution space.

In contrast, Conrad et al. (2015) recently provided a novel sampling-based class of ODE solvers which returns asymptotically non-parametric measures over the solution space, but creates significant computational overhead by running the whole classic ODE solvers multiple times over the whole time interval $[0, T]$ in order to obtain meaningful approximations for the desired non-parametric measure.

For practitioners, there is a trade-off between the desire for quantified uncertainty on the one hand, and low computational cost on the other. The currently available probabilistic solvers for ODEs either provide only a roughly calibrated uncertainty (Schober et al., 2014) at negligible overhead or a more fine-grained uncertainty supported by theoretical analysis (Conrad et al., 2015), at a computational cost increase so high that it rules out most practical applications. In an attempt to remedy this problem, we propose an algorithm enhancing the method of Schober et al. (2014) by improving the gradient measurement using modern probabilistic integration methods. By modeling the uncertainty where it arises, i.e. the imprecise prediction of where to evaluate f, we hope to gain better knowledge of the propagated uncertainty and arrive at well-calibrated posterior variances as uncertainty measures.

2 BACKGROUND

2.1 SAMPLING-BASED ODE SOLVERS

The probabilistic ODE solver by Conrad et al. (2015) modifies a classic deterministic one-step numerical integrator Ψ_h (e.g. Runge-Kutta or Taylor methods, cf. Hairer et al. (1987)) and models the discretization error of Ψ_h by adding suitably scaled i.i.d. Gaussian random variables $\{\xi_k\}_{k=0,\dots,K}$ after every step. Hence, it returns a discrete solution $\{U_k\}_{k=0,\dots,K}$ on a mesh $\{t_k = kh\}_{k=0,\dots,K}$ according to the rule

$$U_{k+1} = \Psi_h(U_k) + \xi_k. \tag{4}$$

This discrete solution can be extended into a continuous time approximation of the ODE, which is random by construction and can therefore be interpreted as a draw from a non-parametric probability measure Q_h on the solution space $C([0, T], \mathbb{R}^n)$, the Banach space of continuous functions. This probability measure can then be interpreted as a notion of epistemic uncertainty about the solution. This is correct in so far as, under suitable assumptions, including a bound on the variance of the Gaussian noise, the method converges to the true solution, in the sense that Q_h contracts to the Dirac measure on the true solution δ_u with the *same* convergence rate as the original numerical integrator Ψ_h, for $h \to 0$. This is a significant step towards a well-founded notion of uncertainty calibration for ODE solvers: It provides a probabilistic extension to classic method which does not break the convergence rate of these methods.

In practice, however, the precise shape of Q_h is *not* known and Q_h can only be interrogated by sampling, i.e. repeatedly running the entire probabilistic solver. After S samples, Q_h can be approximated by an empirical measure $Q_h(S)$. In particular, the estimated solution and uncertainty can only be expressed in terms of statistics of $Q_h(S)$, e.g. by the usual choices of the empirical mean and empirical variance respectively or alternatively by confidence intervals. For $S \to \infty$, $Q_h(S)$ converges in distribution to Q_h which again converges in distribution to δ_u for $h \to 0$:

$$Q_h(S) \overset{S\to\infty}{\to} Q_h \overset{h\to 0}{\to} \delta_u. \tag{5}$$

The theoretical analysis in Conrad et al. (2015) only concerns the convergence of the latent probability measures $\{Q_h\}_{h>0}$. Only the empirical measures $\{Q_h(S)\}_{S\in\mathbb{N}}$, however, can be observed. Consequently, it remains unclear whether the empirical mean of $Q_h(S)$ for a fixed step-size $h > 0$ converges to the true solution as $S \to \infty$ and whether the empirical variance of $Q_h(S)$ is directly related, in an analytical sense, to the approximation error. In order to extend the given convergence results to the practically observable measures $\{Q_h(S)\}_{S\in\mathbb{N}}$ an analysis of the first convergence in (5) remains missing. The deterministic algorithm proposed below avoids this problem, by instead

constructing a (locally parametric) measure from prior assumptions.

The computational cost of this method also seems to mainly depend on the rate of convergence of $Q_h(S) \to Q_h$ which determines how many (possibly expensive) runs of the numerical integrator Ψ_h over $[0,T]$ have to be computed and how many samples have to be stored for a sufficient approximation of Q_h. Furthermore, we expect that in practice the mean of Q_h, as approximated by $Q_h(S)$ might not be the best possible approximation, since in one step the random perturbation of the predicted solution by Gaussian noise ξ_k worsens our solution estimate with a probability of more than $1/2$, since - due to the full support of Gaussian distributions - the numerical sample solution is as likely to be perturbed away from as towards the true solution and - due to the tails of Gaussian distributions - it can also be perturbed way past the true solution with positive probability.

2.2 A FRAMEWORK FOR GAUSSIAN FILTERING FOR ODES

Describing the solution of ODEs as inference in a joint Gaussian model leverages state-space structure to achieve efficient inference. Therefore, we employ a Gauss-Markov prior on the state-space: *A priori* we model the solution function and $(q-1)$ derivatives $(u, \dot{u}, u^{(2)}, \dots, u^{(q-1)}) : [0,T] \to \mathbb{R}^{qD}$ as a draw from a q-times integrated Wiener process $X = (X_t)_{t\in[0,T]} = (X_t^{(1)}, \dots, X_t^{(q)})_{t\in[0,T]}^T$, i.e. the dynamics of X_t are given by the linear Itô stochastic differential equation (Karatzas & Shreve, 1991; Øksendal, 2003):

$$dX_t = F \cdot X_t dt + Q \cdot dW_t, \tag{6}$$
$$X_0 = \xi, \quad \xi \sim \mathcal{N}(m(0), P(0)), \tag{7}$$

with constant drift $F \in \mathbb{R}^{q\times q}$ and diffusion $Q \in \mathbb{R}^q$ given by

$$F = \begin{pmatrix} 0 & f_1 & 0 & \dots & 0 \\ 0 & 0 & f_2 & \dots & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & & \dots & 0 & f_{q-1} \\ 0 & & \dots & 0 & 0 \end{pmatrix}, Q = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ \sigma^2 \end{pmatrix} \tag{8}$$

for all $t \in [0,T]$ and some $f_1, \dots, f_{q-1} \in \mathbb{R}$, where W_t denotes a q-dimensional Wiener process ($q \geq n$). Hence, we are a priori expecting that $u^{(q)}$ behaves like a Brownian motion with variance σ^2 and that $u^{(i)}$ is modeled by $(q-1-i)$-times integrating this Brownian motion. The fact that the $(i+1)$-th component is the derivative of the i-th component in our state space is captured by a drift matrix with non-zero entries only on the first off-diagonal. The entries $f_1, \dots, f_{q-1}$ are damping factors. A standard choice is e.g. $f_i = i$. Without additional information, it seems natural to put white noise on the q-th derivative as the first derivative which is not captured in the state space. This gives rise to Brownian noise on the $(q-1)$-th derivative which is encoded in the diffusion matrix scaled by variance σ^2. Hence, we consider the integrated Wiener process a natural prior. For notational simplicity, only the case of scalar-valued functions, i.e. $D = 1$, is presented in the following. The framework can be extended to $D \geq 2$ in a straightforward way by modeling the output dimensions of f as independent stochastic processes.

Since X is the strong solution of a linear equation (6) with normally distributed initial value X_0, it follows from the theory of linear SDEs (Karatzas & Shreve, 1991) that X is a uniquely-determined Gauss-Markov process. This enables Bayesian inference in a highly efficient way by Gaussian filtering (Saatci, 2011)). For time invariant linear SDEs like (6), the fixed matrices for Gaussian filtering can be precomputed analytically (Särkkä, 2006).

In addition, Schober et al. (2014) showed that for $q \leq 3$ inference in this linear SDE yields Runge-Kutta steps.

Equipped with this advantageous prior we can perform Bayesian inference. The linearity and time-invariance of the underlying SDE permits to formulate the computation of the posterior as a Kalman filter (KF) (cf. (Särkkä, 2013) for a comprehensive introduction) with step size $h > 0$. The prediction step of the KF is given by

$$m_{t+h}^- = A(h) m_t, \tag{9}$$
$$P_{t+h}^- = A(h) P_t A(h)^T + Q(h), \tag{10}$$

with matrices $A(h), Q(h) \in \mathbb{R}^{q\times q}$ with entries

$$A(h)_{i,j} = \exp(h \cdot F)_{i,j} = \chi_{j\geq i} \frac{h^{j-i}}{(j-i)!} \left(\prod_{k=0}^{j-i-1} f_{i+k} \right), \tag{11}$$

$$Q(h)_{i,j} = \sigma^2 \cdot \left(\prod_{k_1=0}^{q-1+i} f_{i+k_1} \right) \cdot \left(\prod_{k_2=0}^{q-1+j} f_{j+k_2} \right) \cdot \tag{12}$$
$$\frac{h^{2q+1-i-j}}{(q-i)!(q-j)!(2q+1-i-j)}, \tag{13}$$

and followed by the update step

$$z = y - H m_{t+h}^-, \tag{14}$$
$$S = H P_{t+h}^- H^T + R, \tag{15}$$
$$K = P_{t+h}^- H^T S^{-1}, \tag{16}$$
$$m_{t+h} = m_{t+h}^- + Kz, \tag{17}$$
$$P_{t+h} = P_{t+h}^- - K H P_{t+h}^-, \tag{18}$$

where $H = e_n^T \in \mathbb{R}^{1\times q}$ is the n-th unit vector.

Between the prediction and update step the n-th derivative of the true solution $\frac{\partial^n u}{\partial x^n}$ at time $t+h$ as a measurement for the n-th derivative and the noise of this measurement

are estimated by the variable y and R. In order to derive precise values of y and R from the Gaussian prediction $\mathcal{N}(m_{t+h}, P_{t+h})$, we would have to compute the integrals

$$y = \int f(t+h, m^-_{t+h} + x) \cdot \mathcal{N}(x; 0, P^-_{t+h}) dx \quad (19)$$

and

$$R = \int f(t+h, m^-_{t+h} + x) \cdot f(t+h, m^-_{t+h} + x)^T \cdot \mathcal{N}(x; 0, P^-_{t+h}) dx - yy^T, \quad (20)$$

which are intractable for most choices of f. Below we investigate different ways to address the challenge of computing these integrals precisely while not creating too much computational overhead.

2.3 MEASUREMENT GENERATION OPTIONS FOR GAUSSIAN FILTERING

Schober et al. (2014) as, to the best of our knowledge, the first ones to point out the connection between Gaussian filtering and probabilistic ODE solvers, presents an algorithm which simply evaluates the gradient at the predicted mean, which is equivalent to setting y to be equal to its maximum likelihood estimator:

$$y = f(t+h, m^-_{t+h}),\ R = 0. \quad (21)$$

While ensuring maximum speed, this is clearly not an ideal measurement. In our atomless predicted probability measure $\mathcal{N}(m^-_{t+h}, P^-_{t+h})$ the mean predictor m^-_{t+h} is different from its true value $(u^{(0)}(t+h), \ldots, u^{(n)}(t+h))^T$ almost surely. Hence, for a non-constant f the estimate will be inaccurate most of the times. In particular this method deals poorly with 'skewed' gradient fields (a problem that leads to a phenomenon known as 'Lady Windermeres fan' (Hairer et al., 1987)). To get a better estimate of the true value of y, more evaluations of f seem necessary.

Therefore, we want to find numerical integration methods which capture y and R with sufficient precision, while using a minimal number of evaluations of f. Possible choices are:

(i) *Monte Carlo integration by sampling*:

$$y = \frac{1}{N} \sum_{i=1}^{N} f(t+h, x_i), \quad (22)$$

$$R = \frac{1}{N} \sum_{i=1}^{N} f(t+h, x_i) \cdot f(t+h, x_i)^T - y \cdot y^T, \quad (23)$$

$$x_i \sim \mathcal{N}(m^-_{t+h}, P^-_{t+h}), \quad (24)$$

(which is *not* the same as the sampling over the whole time axis in (Conrad et al., 2015)).

(ii) *Approximation by a first-order Taylor series expansion:*

$$f(t+h, m^-_{t+h} + x) \simeq f(t+h, m^-_{t+h}) + \nabla f(t+h, m^-_{t+h} + x) \cdot x \quad (25)$$

and thereby deriving moments of the linear transform of Gaussian distributions:

$$y = f(t+h, m^-_{t+h}), \quad (26)$$

$$R = \nabla f(t+h, m^-_{t+h}) P^-_{t+h} \nabla f(t+h, m^-_{t+h})^T. \quad (27)$$

(iii) Integration by *Bayesian quadrature* with Gaussian weight function:

$$y = \alpha^T \cdot K^{-1} \cdot \big(f(x_1), \ldots, f(x_n)\big)^T, \quad (28)$$

$$R = \int \int k(x, x') w(x) w(x') dx dx' - \alpha^T K^{-1} \alpha. \quad (29)$$

with $w(x) = \mathcal{N}(x; m^-_{t+h}, P^-_{t+h})$, kernel matrix $K \in \mathbb{R}^{N \times N}$ with $K_{i,j} = k(x_i, x_j)$ and $\alpha = (\alpha(1), \ldots, \alpha(N))^T \in \mathbb{R}^N$ with $\alpha(i) = \int k(x, x_i) w(x) dx$ for a predefined covariance function k and evaluation points $(x_i)_{i=1,\ldots,N}$ (cf. section 2.4).

Our experiments, presented in Section 3, suggest that BQ is the most useful option.

Monte Carlo integration by sampling behaves poorly if the trajectory of the numerical solution passes through domain areas (as e.g. in the spikes of oscillators governed by non-stiff ODEs) where f takes highly volatile values since the random spread of samples from the domain are likely to return a skewed spread of values resulting in bad predictions of y with huge uncertainty R. Hence, the posterior variance explodes and the mean drifts back to its zero prior mean, i.e. $m_t \to 0$ and $\|P_t\| \to \infty$, for $t \to \infty$. Thus, we consider this method practically useless.

One may consider it a serious downside of Taylor-approximation based methods that the gradient only approximates the shape of f and thereby its mapping of the error on an 'infinitesimally small neighborhood' of m^-_{t+h}. Hence, it might ignore the true value of y completely, if the mean prediction is far off. However, for a highly regular f (e.g. Lipschitz-continuous in the space variable) this gradient approximation is very good.

Moreover, the approximation by a first-order Taylor series expansion needs an approximation of the gradient, which explicit ODE solvers usually do not receive as an input. However, in many numerical algorithms (e.g. optimization) the gradient is provided anyway. Therefore the gradient

might already be known in real-world applications. While we find this method promising when the gradient is known or can be efficiently computed, we exclude it from our experiments because the necessity of a gradient estimate breaks the usual framework of ODE solvers.

In contrast, Bayesian quadrature avoids the risk of a skewed distortion of the samples for Monte Carlo integration by actively spreading a grid of deterministic sigma-points. It does not need the gradient of f and still can encode prior knowledge over f by the choice of the covariance function if more is known (Briol et al., 2015). The potential of using Bayesian quadrature as a part of a filter was further explored by Prüher & Simandl (2015), however in the less structured setting of nonlinear filtering where additional inaccuracy from the linear approximation in the prediction step arises. Moreover, Särkkä et al. (2015) recently pointed out that GPQ can be seen as sigma-point methods and gave covariance functions and evaluation points which reproduce numerical integration methods known for their favorable behavior (for example Gauss-Hermite quadrature, which is used for a Gaussian weight function).

Due to these advantages, we propose a new class of BQ-based probabilistic ODE filters named BQ Filtering.

2.4 BAYESIAN QUADRATURE FILTERING (BQF)

The crucial source of error for filtering-based ODE solvers is the calculation of the gradient measurement y and its variance R (c.f. Section 2.2). We propose the novel approach to use BQ to account for the uncertainty of the input and thereby estimate y and R. This gives rise a novel class of filtering-based solvers named *BQ Filter* (BQF). As a filtering-based method, one BQF-step consists of the KF prediction step (9) – (10), the calculation of y and R by BQ and the KF update step (14) – (18).

The KF prediction step outputs a Gaussian belief $\mathcal{N}(m^-_{t+h}, P^-_{t+h})$ over the true solution $u(t+h)$. This input value is propagated through f yielding a distribution over the gradient at time $t+h$. In other words, our belief over $\nabla f(t+h, u(t+h))$ is equal to the distribution of $Y := f(t, X)$, with uncertain input $X \sim \mathcal{N}(m^-_{t+h}, P^-_{t+h})$. For general f the distribution of Y will be neither Gaussian nor unimodal (as e.g. in Figure 1). But it is possible to compute the moments of this distribution under Gaussian assumptions on the input and the uncertainty over f (see for example Deisenroth (2009)). The equivalent formulation of prediction under uncertainty clarifies as numerical integration clarifies the connection to sigma-point methods, i.e. quadrature rules (Särkkä et al., 2015). Quadrature is as extensively studied and well-understood as the solution of ODEs. A basic overview can be found in Press et al. (2007). Marginalizing over X yields an integral with Gaussian weight function

$$\mathbb{E}[Y] = \int f(t+h, x) \cdot \underbrace{\mathcal{N}(x; m^-_{t+h}, P^-_{t+h})}_{=:w(x)} dx, \quad (30)$$

which is classically solved by quadrature, i.e. evaluating f at a number of evaluation points $(x_i)_{i=1,\dots,N}$ and calculating a weighted sum of these evaluations. BQ can be interpreted as a probabilistic extension of these quadrature rules in the sense that their posterior mean estimate of the integral coincides with classic quadrature rules, while adding a posterior variance estimate at low cost (Särkkä et al., 2015).

By choosing a kernel k over the input space of f and evaluation points $(x_i)_{i=1,\dots,N}$, the function f is approximated by a GP regression (Rasmussen & Williams, 2006) with respect to the function evaluations $(f(x_i))_{i=1,\dots,N}$, yielding a GP posterior over f with mean m_f and covariance k_f denoted by $\mathcal{GP}(f)$. The integral is then approximated by integrating the GP approximation, yielding the predictive distribution for $\mathcal{I}[f]$:

$$\mathcal{I}[f] \sim \int \mathcal{GP}(f)(x) \cdot \mathcal{N}(x; m^-_{t+h}, P^-_{t+h}) dx. \quad (31)$$

The uncertainty arising from the probability measure over the input is now split up in two parts: the uncertainty over the input value $x \sim \mathcal{N}(0, I)$ and the uncertainty over the precise value at this uncertain input, which can only be approximately inferred by its covariance with the evaluation points $(x_i)_{i=1,\dots,N}$, i.e. by $\mathcal{GP}(f)$. These two kinds of uncertainty are depicted in Figure 1. From the predictive distribution in (31), we can now compute a posterior mean and variance of $\mathcal{I}[f]$ which results in a weighted sum for the mean

$$y := \mathbb{E}[\mathcal{I}[f]|] = \alpha^T K^{-1} \big(f(x_1), \dots, f(x_n)\big)^T \quad (32)$$

with

$$\alpha(i) = \int k(x, x_i) \mathcal{N}(x; 0, I) dx \quad (33)$$

and variance

$$R := \mathrm{Var}[\mathcal{I}(f)] \quad (34)$$

$$= \int\int k(x, x') w(x) w(x') dx dx' - \alpha^T K^{-1} \alpha, \quad (35)$$

where $K \in \mathbb{R}^{N \times N}$ denotes the kernel matrix, i.e. $K_{i,j} = k(x_i, x_j)$.

The measurement generation in BQF is hence completely defined by the two free choices of BQ: the kernel k and the evaluation points $(x_i)_{i=1,\dots,n}$. By these choices, BQ and thereby the measurement generation in BQF is completely defined. For the squared exponential kernel (Rasmussen & Williams, 2006)

$$k(x, x') = \theta^2 \exp\left(-\frac{1}{2\lambda^2} \|x - x'\|^2\right), \quad (36)$$

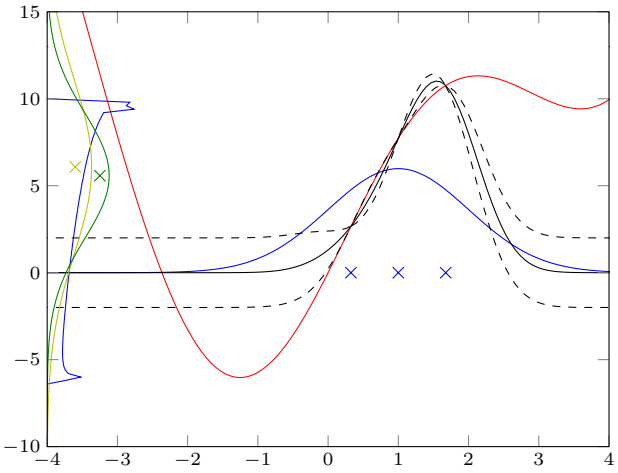

Figure 1: Prediction of function $f(x) = 8\sin(x) + x^2$ (red) under uncertain input $x \sim \mathcal{N}(x; 1, 1)$ (density in blue). $\mathcal{GP}(f)$ (black) derived from Gaussian grid evaluation points with $N = 3$ (blue crosses) as mean $\pm$ 2 standard deviation. True distribution of prediction in blue. Gaussian fit to true distribution in yellow and predicted distribution by BQ in green with crosses at means.

with lengthscale $\lambda > 0$ and output variance $\theta^2 > 0$, it turns out that y and R can be computed in closed form and that many classic quadrature methods which are known for their favorable properties can be computed in closed form (Särkkä et al., 2015), significantly speeding up computations. For the scalar case $nD = 1$, we obtain for (33) by straightforward computations:

$$\alpha(i) = \frac{\lambda\theta^2}{\sqrt{\lambda^2 + \sigma^2}} \exp\left(-\frac{(x_i - \mu)^2}{2(\lambda^2 + \sigma^2)}\right), \tag{37}$$

and

$$\int\int k(x, x')w(x)w(x')dxdx' = \frac{\theta^2}{\sqrt{1 + 2\sigma^2/\lambda^2}} \tag{38}$$

Hence, our BQ estimate for y is given by the sigma-point rule

$$y \approx \sum_{i=1}^{N} W_i f(t + h, x_i) \tag{39}$$

with easily computable weights

$$W_i = [\alpha \cdot K]_i. \tag{40}$$

Also the variance R takes a convenient shape

$$R = \frac{\theta^2}{\sqrt{1 + 2\sigma^2/\lambda^2}} - \alpha^T K^{-1}\alpha. \tag{41}$$

For $nD > 1$, we get slightly more complicated formulas which are given in Deisenroth (2009).

The other free choice in BQ, the evaluation points $(x_i)_{i=1,\ldots,n}$, can also be chosen freely in every step of BQF. Usually, the nodes of BQ chosen are chosen so that the variance of the integral estimate is minimized (cf. Briol et al. (2015)). For this algorithm, the uncertainty has to be measured, not minimized though. Hence, we propose just to take a uniform grid scaled by $\mathcal{N}(m^-_{t+h}, P^-_{t+h})$ to measure the uncertainty in a comprehensive way.

Another promising choice is given by the roots of the physicists' version of the Hermite polynomials, since they yield Gauss-Hermite quadrature (GHQ), the standard numerical quadrature against Gaussian measures, as a posterior mean for a suitable covariance function (Särkkä et al., 2015). For GHQ, efficient algorithms to compute the roots and the weights are readily available (Press et al., 2007).

2.5 COMPUTATIONAL COST

All of the presented algorithms buy their probabilistic extension to classic ODE solvers by adding computational cost, sometimes more sometimes less. In most cases, evaluation of the dynamic function f forms the computational bottleneck, so we will focus on it here. Of course, the internal computations of the solver adds cost as well. Since all the models discussed here have linear inference cost, though, this additional overhead is manageable.

The ML-algorithm by Schober et al. (2014) is the fastest algorithm. By simply recasting a Runge-Kutta step as Gaussian filtering, rough probabilistic uncertainty is achieved with negligible computational overhead.

For the sampling method, the calculation of one individual sample of Q_h amounts to running the entire underlying ODE solver once, hence the overall cost is S times the original cost.

In contrast, the BQ-algorithm only has to run through $[0, T]$ once, but has to invert a $ND \times ND$ covariance matrix to perform Bayesian quadrature with N evaluation points. Usually, N will be small, since BQ performs well for a relatively small number of function evaluations (as e.g. illustrated by the experiments below). However, if the output dimension D is very large, Bayesian quadrature—like all quadrature methods—is not practical. BQ thus tends to be faster for small D, while MC tends to be faster for large D.

When considering these computational overheads, there is a nuanced point to be made about the value-to-cost tradeoff of constructing a posterior uncertainty measure. If a classic numerical solver of order p is allotted a budget of M times its original one, it can use it to reduce its step-size by a factor of M, and thus reduce its approximation error by an order M^p. It may thus seem pointless to invest even such a linear cost increase into constructing an uncertainty measure around the classic estimate. But, in some practical settings, it may be more helpful to have a notion of uncertainty on a slightly less precise estimate than to produce a

more precise estimate without a notion of error. In addition, classic solvers are by nature sequential algorithms, while the probabilistic extensions (both the sampling-based and Gaussian-filtering based ones) can be easily parallelized. Where parallel hardware is available, the effective time cost of probabilistic functionality may thus be quite limited (although we do not investigate this possibility in our present experiments).

With regards to memory requirements, the MC-method needs significantly more storage, since it requires saving all sample paths, in order to statistically approximate the entire non-parametric measure Q_h on $C([0,T],\mathbb{R})$. The BQ-algorithm only has to save the posterior GP, i.e. a mean and a covariance function, which is arguably the minimal amount to provide a notion of uncertainty. If MC reduces the approximation of Q_h to its mean and variance, it only requires this minimal storage as well.

3 EXPERIMENTS

This section explores applications of the probabilistic ODE solvers discussed in Section 2. The sampling-based algorithm by (Conrad et al., 2015) will be abbreviated as MC, the maximum-likelihood Gaussian filter ((Schober et al., 2014)) as ML and our novel BQ-based filter (BQF) as BQ. In particular, we assess how the performance of the purely deterministic class of Gaussian filtering based solvers compares to the inherently random class of sampling-based solvers.

We experiment on the Van der Pol oscillator (Hairer et al., 1987), a non-conservative oscillator with non-linear damping, which is a standard example for a non-stiff dynamical system. It is governed by the equation

$$\frac{\partial^2 u}{\partial t^2} = \mu(1-u^2)\frac{\partial u}{\partial t} - u, \tag{42}$$

where the parameter $\mu \in \mathbb{R}$ indicates the non-linearity and the strength of the damping. We set $\mu = 5$ on a time axis $[10, 60]$, with initial values $(u(10), \dot{u}(10)) = (2, 10)$.

All compared methods use a model of order $q = 3$, and a step size $h = 0.01$. This induces a state-space model given by a twice-integrated Wiener process prior (cf. (6)) which yields a version of ML close to second-order Runge-Kutta (Schober et al., 2014). The same solver is used as the underlying numerical solver Ψ_h in MC. For the noise parameter, which scales the deviation of the evaluation point of f from the numerical extrapolation (i.e. the variance of the driving Wiener process for ML and BQ, and the variance of ξ_k for MC), we choose $\sigma^2 = 0.1$. The drift matrix F of the underlying integrated Wiener process is set to the default values $f_i = i$ for $i = 1, \ldots, q-1$. The covariance function used in BQ is the widely popular squared exponential (36), with lengthscale $\lambda = 1$ and output variance $\theta^2 = 1$. (Since all methods use the same model, this tuning does not favor one algorithm over the other. In practice all these parameters should of course be set by statistical estimation.).

For a fair comparison in all experiments, we allow MC and BQ to make the same amount of function evaluations per time step. If MC draws N samples, BQ uses N evaluation points. The first experiment presents the solutions of the presented algorithms on the van der Pol oscillator (42) on the whole time axis in one plot, when we allow BQ and MC to make five function evaluations. Then, we examine more closely how the error of each methods changes as a function of the number of evaluations of f in Figure 3 and Figure 4.

3.1 SOLUTION MEASURES ON VAN DER POL OSCILLATOR

Figure 3 shows the solution estimates constructed by the three solvers across the time domain. In all cases, the mean estimates roughly follow the true solution (which e.g. Gaussian filtering with Monte Carlo integration by sampling (22) – (24) does not achieve). A fundamental difference between the filtering-based methods (ML and BQ) and the sampling-based MC algorithm is evident in both the mean and the uncertainty estimate.

While the filtering-based methods output a trajectory quite similar to the true solution with a small time lag, the MC algorithm produces a trajectory of a more varying shape. Characteristic points of the MC mean estimate (such as local extrema) are placed further away from the true value than for filtering-based methods.

The uncertainty estimation of MC appears more flexible as well. ML and BQ produce an uncertainty estimate which runs parallel to the mean estimate and appears to be strictly increasing. It appears to increase slightly in every step, resulting in an uncertainty estimate, which only changes very slowly. The solver accordingly appears overconfident in the spikes and underconfident in the valleys of the trajectory. The uncertainty of MC varies more, scaling up at the steep parts of the oscillator and decreasing again at the flat parts, which is a desirable feature.

Among the class of filtering-based solvers, the more refined BQ method outputs a better mean estimate with more confidence than ML.

3.2 QUALITY OF ESTIMATE AS A FUNCTION OF ALLOWED EVALUATIONS

Figure 3 and Figure 4 depict the value of the error of the mean approximation as a function of the allowed function evaluations N (i.e. N evaluation points for BQ and N samples for MC) at time points $t_1 = 18$ and $t_2 = 54$. Since the desired solution measure Q_h for MC can only be statistically approximated by the N samples, the mean estimate of MC is random. For comparison, the average of five MC-

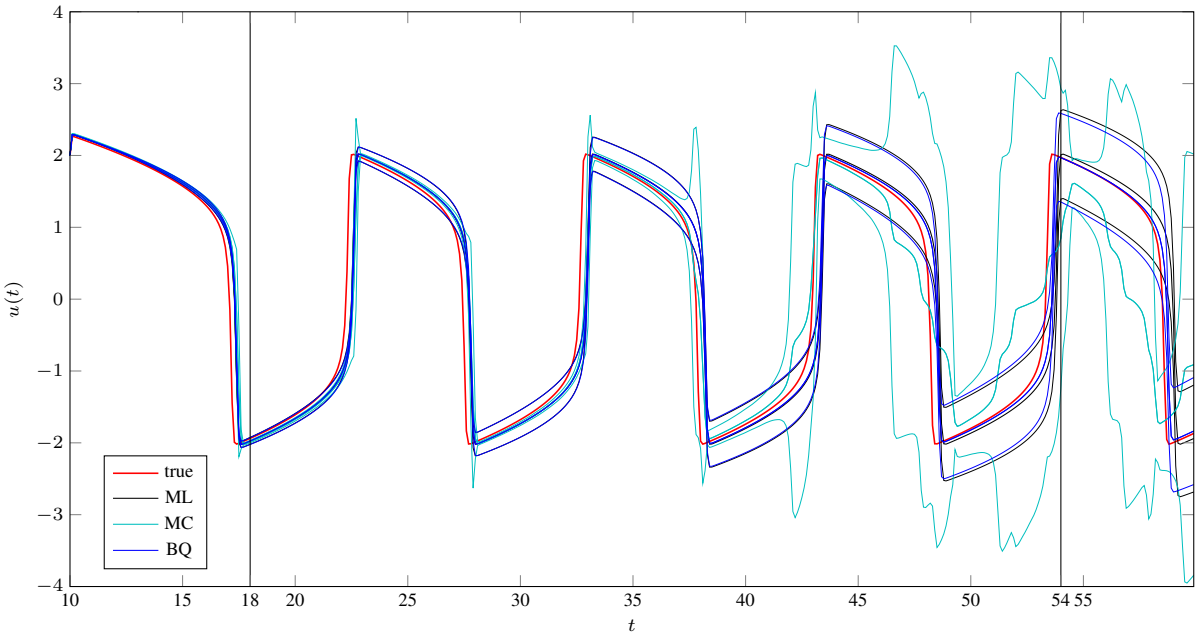

Figure 2: Solution estimates constructed on the Van der Pol oscillator (42). True solution in red. Mean estimates of ML, MC and BQ in black, green, blue, respectively. Uncertainty measures (drawn at two times standard deviation) as thin lines of the same color.

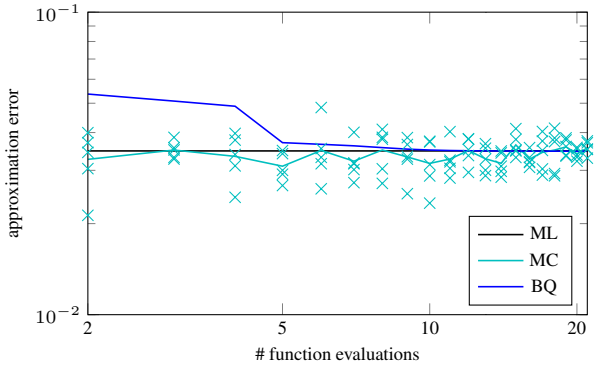

Figure 3: Plot of errors of the mean estimates at $t = 18$ of the methods MC (green) and BQ (blue) as a function of the allowed function evaluations. Maximum likelihood error in black. Single runs of the probabilistic MC solver as green crosses. Average over all runs as green line.

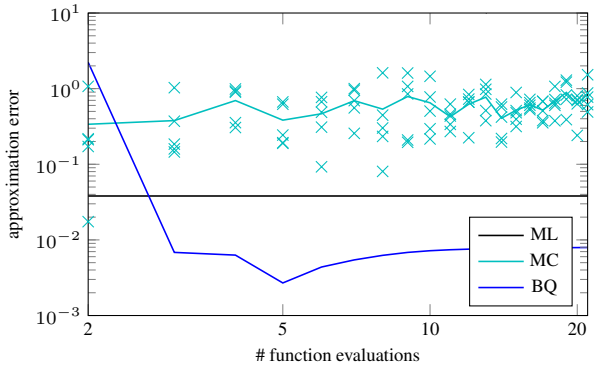

Figure 4: Plot of errors of the mean estimates at $t = 54$ of the methods MC (green) and BQ (blue) as a function of the allowed function evaluations. Maximum likelihood error in black. Single runs of the probabilistic MC solver as green crosses. Average over all runs as green line.

runs is computed.

At the early time point $t_1 = 18$, all trajectories are still close together and the methods perform roughly the same, as we allow more evaluations. There is a slight improvement for BQ with more evaluations, but the error remains above the one of ML error.

At the later time $t_2 = 54$, BQ improves drastically when at least five evaluations are allowed, dropping much below the ML error.

The average error by MC appears to be not affected by the number of samples. The ML error is constant, because it always evaluates only once.

4 DISCUSSION

The conducted experiments provide an interesting basis to discuss the differences between filtering-based methods (ML and BQ) and the sampling-based MC algorithm. We make the following observations:

(i) *Additional samples do not improve the random mean estimate of MC in expectation:*
Since the samples of MC are independent and identically distributed, the expectation of the random mean estimate of MC is the same, regardless of the amounts of samples. This property is reflected in Figure 3 and Figure 4, by the constant green line (up to random fluctuation). Additional samples are therefore only useful to improve the uncertainty calibration.

(ii) *The uncertainty calibration of MC appears more adaptive than of ML and BQ:*
Figure 3 suggests that MC captures the uncertainty more flexibly: It appropriately scales up in the steep parts of the oscillator, while expressing high confidence in the flat parts of the oscillator. The true trajectory is inside the interval between mean $\pm$ 2 standard deviations, which is not the case for BQ and ML. Moreover, MC produces a more versatile measure. The filtering-based methods appear to produce a strictly increasing uncertainty measure by adding to the posterior uncertainty in every step. MC avoids this problem by sampling multiple time over the whole time interval. We deem the resulting flexibility a highly desirable feature. BQ also outputs a meaningful uncertainty measure and we expect that adding Bayesian smoothing (Särkkä, 2013) would enable filtering-based methods to produce more adaptive measures as well.

(iii) *The expected error of MC-samples (and their mean) is higher than the error of ML:*
In the experiments, MC produced a higher error for the mean estimate, compared to both ML and BQ. We expect that this happens on all dynamical systems *by construction*: Given U_k, the next value U_{k+1} of a MC-sample is calculated by adding Gaussian noise ψ_k to the ML-extrapolation starting in U_k (cf. equation (4)). Due to the symmetry and full support of Gaussian distributions, the perturbed solution has a higher error than the unperturbed prediction, which coincides with the ML solution. Hence, every MC-sample accumulates with every step a positive expected error increment compared to the ML estimate. By the linearity of the average, the mean over all samples inherits the same higher error than the ML mean (and thereby also than the error of the more refined BQ mean).

Summing up, we argue that — at their current state — filtering-based methods appear to produce a 'better' mean estimate, while sampling-based methods produce in some sense a 'better' uncertainty estimate. Many applications might put emphasis on a good mean estimate, while needing a still well-calibrated uncertainty quantification. Our method BQF provides a way of combining a precise mean estimate with a meaningful uncertainty calibration. Sampling-based methods might not be able to provide this due to their less accurate mean estimate. For future work (which is beyond the scope of this paper), it could be possible to combine the advantages of both approaches in a unified method.

5 CONCLUSION

We have presented theory and methods for the probabilistic solution of ODEs which provide uncertainty measures over the solution of the ODE, contrasting the classes of (deterministic) filtering-based and (random) sampling-based solvers. We have provided a theoretical framework for Gaussian filtering as state space inference in linear Gaussian SDEs, highlighting the prediction of the gradient as the primary source of uncertainty. Of all investigated approximations of the gradient, Bayesian Quadrature (BQ) produces the best results, by actively learning the shape of the dynamic function f through deterministic evaluations. Hence, we propose a novel filtering-based method named *Bayesian Quadrature Filtering* (BQF), which employs BQ for the gradient measurement.

For the same amount of allowed gradient evaluations, the mean estimate of BQF appears to outperform the mean estimate of state-of-the-art sampling-based solvers on the Van der Pol oscillator, while outputting a better calibrated uncertainty than other filtering-based methods.

Abstract

Several recent works have explored stochastic gradient methods for variational inference that exploit the geometry of the variational-parameter space. However, the theoretical properties of these methods are not well-understood and these methods typically only apply to conditionally-conjugate models. We present a new stochastic method for variational inference which exploits the geometry of the variational-parameter space and also yields simple closed-form updates even for non-conjugate models. We also give a convergence-rate analysis of our method and many other previous methods which exploit the geometry of the space. Our analysis generalizes existing convergence results for stochastic mirror-descent on non-convex objectives by using a more general class of divergence functions. Beyond giving a theoretical justification for a variety of recent methods, our experiments show that new algorithms derived in this framework lead to state of the art results on a variety of problems. Further, due to its generality, we expect that our theoretical analysis could also apply to other applications.

1 INTRODUCTION

Variational inference methods are one of the most widely-used computational tools to deal with the intractability of Bayesian inference, while stochastic gradient (SG) methods are one of the most widely-used tools for solving optimization problems on huge datasets. The last three years have seen an explosion of work exploring SG methods for variational inference (Hoffman et al., 2013; Salimans et al., 2013; Ranganath et al., 2013; Titsias & Lázaro-Gredilla, 2014; Mnih & Gregor, 2014; Kucukelbir et al., 2014). In many settings, these methods can yield simple updates and scale to huge datasets.

A challenge that has been addressed in many of the recent works on this topic is that the "black-box" SG method ignores the geometry of the variational-parameter space. This has lead to methods like the stochastic variational inference (SVI) method of Hoffman et al. (2013), that uses *natural gradients* to exploit the geometry. This leads to better performance in practice, but this approach only applies to conditionally-conjugate models. In addition, it is not clear how using natural gradients for variational inference affects the theoretical convergence rate of SG methods.

In this work we consider a general framework that (i) can be stochastic to allow huge datasets, (ii) can exploit the geometry of the variational-parameter space to improve performance, and (iii) can yield a closed-form update even for non-conjugate models. The new framework can be viewed as a stochastic generalization of the proximal-gradient method of Khan et al. (2015), which splits the objective into conjugate and non-conjugate terms. By linearizing the non-conjugate terms, this previous method as well as our new method yield simple closed-form proximal-gradient updates even for non-conjugate models.

While proximal-gradient methods have been well-studied in the optimization community (Beck & Teboulle, 2009), like SVI there is nothing known about the convergence rate of the method of Khan et al. (2015) because it uses "divergence" functions which do not satisfy standard assumptions. Our second contribution is to *analyze the convergence rate* of the proposed method. In particular, we generalize an existing result on the convergence rate of stochastic mirror descent in non-convex settings (Ghadimi et al., 2014) to allow a general class of divergence functions that includes the cases above (in both deterministic and stochas-

tic settings). While it has been observed empirically that including an appropriate divergence function enables larger steps than basic SG methods, this work gives the first theoretical result justifying the use of these more-general divergence functions. It in particular reveals how different factors affect the convergence rate such as the Lipschitz-continuity of the lower bound, the information geometry of the divergence functions, and the variance of the stochastic approximation. Our results also suggest conditions under which the proximal-gradient steps of Khan et al. (2015) can make more progress than (non-split) gradient steps, and sheds light on the choice of step-size for these methods. A notable aspect of our results is that, for the stochastic case and a fixed accuracy, there is always a sufficiently-small *fixed* step-size that leads to a solution with this accuracy or higher. Our experimental results indicate that the new method leads to improvements in performance on a variety of problems, and we note that the algorithm and theory might be useful beyond the variational inference scenarios we have considered in this work.

2 VARIATIONAL INFERENCE

Consider a general latent variable model where we have a data vector $\mathbf{y}$ of length N and a latent vector $\mathbf{z}$ of length D. In Bayesian inference, we are interested in computing the marginal likelihood $p(\mathbf{y})$, which can be written as the integral of the joint distribution $p(\mathbf{y}, \mathbf{z})$ over all values of $\mathbf{z}$. This integral is often intractable, and in variational inference we typically approximate it with the evidence lower-bound optimization (ELBO) approximation $\underline{\mathcal{L}}$. This approximation introduces a distribution $q(\mathbf{z}|\boldsymbol{\lambda})$ and chooses the variational parameters $\boldsymbol{\lambda}$ to maximize the following lower bound on the marginal likelihood:

$$\begin{aligned} \log p(\mathbf{y}) &= \log \int q(\mathbf{z}|\boldsymbol{\lambda}) \frac{p(\mathbf{y}, \mathbf{z})}{q(\mathbf{z}|\boldsymbol{\lambda})} \, d\mathbf{z}, \\ &\geq \max_{\boldsymbol{\lambda} \in \mathcal{S}} \underline{\mathcal{L}}(\boldsymbol{\lambda}) := \mathbb{E}_{q(\mathbf{z}|\boldsymbol{\lambda})} \left[\log \frac{p(\mathbf{y}, \mathbf{z})}{q(\mathbf{z}|\boldsymbol{\lambda})} \right]. \end{aligned} \tag{1}$$

The inequality follows from concavity of the logarithm function. The set $\mathcal{S}$ is the set of valid parameters $\boldsymbol{\lambda}$.

To optimize $\boldsymbol{\lambda}$, one of the seemingly-simplest approaches is gradient descent: $\boldsymbol{\lambda}_{k+1} = \boldsymbol{\lambda}_k + \beta_k \nabla \underline{\mathcal{L}}(\boldsymbol{\lambda}_k)$, which can be viewed as optimizing a quadratic approximation of $\underline{\mathcal{L}}$,

$$\boldsymbol{\lambda}_{k+1} = \operatorname*{argmin}_{\boldsymbol{\lambda} \in \mathcal{S}} \left[-\boldsymbol{\lambda}^T \nabla \underline{\mathcal{L}}(\boldsymbol{\lambda}_k) + \frac{1}{2\beta_k} \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_k\|_2^2 \right]. \tag{2}$$

While we can often choose the family q so that it has convenient computational properties, it might be impractical to apply gradient descent in this context when we have a very large dataset or when some terms in the lower bound are intractable. Recently, SG methods have been proposed to deal with these issues (Ranganath et al., 2013; Titsias & Lázaro-Gredilla, 2014): they allow large datasets by using random subsets (mini-batches) and can approximate intractable integrals using Monte Carlo methods that draw samples from $q(\mathbf{z}|\boldsymbol{\lambda})$.

A second drawback of applying gradient descent to variational inference is that it uses the Euclidean distance and thus ignores the *geometry of the variational-parameter space*, which often results in slow convergence. Intuitively, (2) implies that we should move in the direction of the gradient, but not move $\boldsymbol{\lambda}_{k+1}$ too far away from $\boldsymbol{\lambda}_k$ in terms of the Euclidean distance. However, the Euclidean distance is not appropriate for variational inference because $\boldsymbol{\lambda}$ is the parameter vector of a distribution; the Euclidean distance is often a poor measure of dissimilarity between distributions. The following example from Hoffman et al. (2013) illustrates this point: the two normal distributions $\mathcal{N}(0, 10000)$ and $\mathcal{N}(10, 10000)$ are almost indistinguishable, yet the Euclidean distance between their parameter vectors is 10, whereas the distributions $\mathcal{N}(0, 0.01)$ and $\mathcal{N}(0.1, 0.01)$ barely overlap, but their Euclidean distance between parameters is only 0.1.

Natural-Gradient Methods: The canonical way to address the problem above is by replacing the Euclidean distance in (2) with another divergence function. For example, the *natural gradient* method defines the iteration by using the symmetric Kullback-Leibler (KL) divergence (Hoffman et al., 2013; Pascanu & Bengio, 2013; Amari, 1998),

$$\boldsymbol{\lambda}_{k+1} = \operatorname*{argmin}_{\boldsymbol{\lambda} \in \mathcal{S}} \left[-\boldsymbol{\lambda}^T \nabla \underline{\mathcal{L}}(\boldsymbol{\lambda}_k) + \frac{1}{\beta_k} \mathbb{D}_{KL}^{sym}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)] \right]. \tag{3}$$

This leads to the update

$$\boldsymbol{\lambda}_{k+1} = \boldsymbol{\lambda}_k + \beta_k \left[\nabla^2 \mathbf{G}(\boldsymbol{\lambda}_k) \right]^{-1} \nabla \underline{\mathcal{L}}(\boldsymbol{\lambda}_k), \tag{4}$$

where $\mathbf{G}(\boldsymbol{\lambda})$ is the Fisher information-matrix,

$$\mathbf{G}(\boldsymbol{\lambda}) := \mathbb{E}_{q(\mathbf{z}|\boldsymbol{\lambda})} \left\{ [\nabla \log q(\mathbf{z}|\boldsymbol{\lambda})] \, [\nabla \log q(\mathbf{z}|\boldsymbol{\lambda})]^T \right\}.$$

Hoffman et al. (2013) show that the natural-gradient update can be computationally simpler than gradient descent for conditionally-conjugate exponential family models. In this family, we assume that the distribution of $\mathbf{z}$ factorizes as $\prod_i p(\mathbf{z}^i|\text{pa}^i)$ where $\mathbf{z}^i$ are disjoint subsets of $\mathbf{z}$ and pa^i are the parents of the $\mathbf{z}^i$ in a directed acyclic graph. This family also assumes that each conditional distribution is in the exponential family,

$$p(\mathbf{z}^i|\text{pa}^i) := h^i(\mathbf{z}^i) \exp\left[[\boldsymbol{\eta}^i(\text{pa}^i)]^T \mathbf{T}^i(\mathbf{z}^i) - A^i(\boldsymbol{\eta}^i) \right],$$

where $\boldsymbol{\eta}^i$ are the natural parameters, $\mathbf{T}^i(\mathbf{z}^i)$ are the sufficient statistics, $A^i(\boldsymbol{\eta}^i)$ is the partition function, and $h^i(\mathbf{z}^i)$ is the base measure. Hoffman et al. (2013) consider a mean-field approximation $q(\mathbf{z}|\boldsymbol{\lambda}) = \prod_i q^i(\mathbf{z}^i|\boldsymbol{\lambda}^i)$ where

each q^i belongs to the same exponential-family distribution as the joint distribution,

$$q^i(\mathbf{z}^i) := h^i(\mathbf{z}^i) \exp\left[(\boldsymbol{\lambda}^i)^T \mathbf{T}^i(\mathbf{z}^i) - A^i(\boldsymbol{\lambda}^i)\right].$$

The parameters of this distribution are denoted by $\boldsymbol{\lambda}^i$ to differentiate them from the joint-distribution parameters $\boldsymbol{\eta}^i$.

As shown by Hoffman et al. (2013), the Fisher matrix for this problem is equal to $\nabla^2 A^i(\boldsymbol{\lambda}^i)$ and the gradient of the lower bound with respect to $\boldsymbol{\lambda}^i$ is equal to $\nabla^2 A^i(\boldsymbol{\lambda}^i)(\boldsymbol{\lambda}^i - \boldsymbol{\lambda}^i_*)$ where $\boldsymbol{\lambda}^i_*$ are the mean-field parameters (see Paquet, 2014). Therefore, when computing the natural-gradient, the $\nabla^2 A^i(\boldsymbol{\lambda}^i)$ terms cancel out and the natural-gradient is simply $\boldsymbol{\lambda}^i - \boldsymbol{\lambda}^i_*$ which is much easier to compute than the actual gradient. Unfortunately, for non-conjugate models this cancellation does not happen and the simplicity of the update is lost. The Riemannian conjugate-gradient method of Honkela et al. (2011) has similar issues, in that computing $\nabla^2 A(\boldsymbol{\lambda})$ is typically very costly.

KL-Divergence Based Methods: Rather than using the symmetric-KL, Theis & Hoffman (2015) consider using the KL divergence $\mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)]$ within a stochastic proximal-point method:

$$\boldsymbol{\lambda}_{k+1} = \underset{\boldsymbol{\lambda}\in\mathcal{S}}{\operatorname{argmin}} \left[-\underline{\mathcal{L}}(\boldsymbol{\lambda}) + \frac{1}{\beta_k}\mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)]\right]. \tag{5}$$

This method yields better convergence properties, but requires numerical optimization to implement the update even for conditionally-conjugate models. Khan et al. (2015) considers a deterministic proximal-gradient variant of this method by splitting the lower bound into $-\underline{\mathcal{L}} := f + h$, where f contains all the "easy" terms and h contains all the "difficult" terms. By linearizing the "difficult" terms, this leads to a closed-form update even for non-conjugate models. The update is given by:

$$\boldsymbol{\lambda}_{k+1} = \underset{\boldsymbol{\lambda}\in\mathcal{S}}{\operatorname{argmin}} \Big[\boldsymbol{\lambda}^T[\nabla f(\boldsymbol{\lambda}_k)] + h(\boldsymbol{\lambda}) + \frac{1}{\beta_k}\mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)]\Big]. \tag{6}$$

However, this method requires the exact gradients which is usually not feasible for large dataset and/or complex models.

Mirror Descent Methods: In the optimization literature, *mirror descent* (and stochastic mirror descent) algorithms are a generalization of (2) where the squared-Euclidean distance can be replaced by any Bregman divergence $\mathbb{D}_F(\boldsymbol{\lambda}\|\boldsymbol{\lambda}_k)$ generated from a strongly-convex function $F(\boldsymbol{\lambda})$ (Beck & Teboulle, 2003),

$$\boldsymbol{\lambda}_{k+1} = \underset{\boldsymbol{\lambda}\in\mathcal{S}}{\operatorname{argmin}} \left\{-\boldsymbol{\lambda}^T\nabla\underline{\mathcal{L}}(\boldsymbol{\lambda}_k) + \frac{1}{\beta_k}\mathbb{D}_F(\boldsymbol{\lambda}\|\boldsymbol{\lambda}_k)\right\}. \tag{7}$$

The convergence rate of mirror descent algorithm has been analyzed in convex (Duchi et al., 2010) and more recently in non-convex (Ghadimi et al., 2014) settings. However, mirror descent does not cover the cases described above in (5) and (6) when a KL divergence between two exponential-family distributions is used with $\boldsymbol{\lambda}$ as the natural-parameter. For such cases, the Bregman divergence corresponds to a KL divergence with swapped parameters (see Nielsen & Garcia, 2009, Equation 29),

$$\begin{aligned}\mathbb{D}_A(\boldsymbol{\lambda}\|\boldsymbol{\lambda}_k) &:= A(\boldsymbol{\lambda}) - A(\boldsymbol{\lambda}_k) - [\bigtriangledown A(\boldsymbol{\lambda}_k)]^T(\boldsymbol{\lambda} - \boldsymbol{\lambda}_k) \\ &= \mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}_k) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda})].\end{aligned} \tag{8}$$

where $A(\boldsymbol{\lambda})$ is the partition function of q. Because (5) and (6) both use a KL divergence where the second argument is fixed to $\boldsymbol{\lambda}_k$, instead of the first argument, they are not covered under the mirror-descent framework. In addition, even though mirror-descent has been used for variational inference (Ravikumar et al., 2010), Bregman divergences do not yield an efficient update in many scenarios.

3 PROXIMAL-GRADIENT SVI

Our proximal-gradient stochastic variational inference (PG-SVI) method extends (6) to allow stochastic gradients $\widehat{\nabla} f(\boldsymbol{\lambda}_k)$ and general divergence functions $\mathbb{D}(\boldsymbol{\lambda}\|\boldsymbol{\lambda}_k)$ by using the iteration

$$\boldsymbol{\lambda}_{k+1} = \underset{\boldsymbol{\lambda}\in\mathcal{S}}{\operatorname{argmin}} \left\{\boldsymbol{\lambda}^T\left[\widehat{\bigtriangledown} f(\boldsymbol{\lambda}_k)\right] + h(\boldsymbol{\lambda}) + \frac{1}{\beta_k}\mathbb{D}(\boldsymbol{\lambda} \,\|\, \boldsymbol{\lambda}_k)\right\}. \tag{9}$$

This unifies a variety of existing approaches since it allows:

1. Splitting of $\underline{\mathcal{L}}$ into a difficult term f and a simple term h, similar to the method of Khan et al. (2015).
2. A stochastic approximation $\widehat{\nabla} f$ of the gradient of the difficult term, similar to SG methods.
3. Divergence functions $\mathbb{D}$ that incorporate the geometry of the parameter space, similar to methods discussed in Section 2 (see (3), (5), (6), and (7)).

Below, we describe each feature in detail, along with the precise assumptions used in our analysis.

3.1 SPLITTING

Following Khan et al. (2015), we split the lower bound into a sum of a "difficult" term f and an "easy" term h, enabling a closed-form solution for (9). Specifically, we split using $p(\mathbf{y}, \mathbf{z})/q(\mathbf{z}|\boldsymbol{\lambda}) = c\,\tilde{p}_d(\mathbf{z}|\boldsymbol{\lambda})\tilde{p}_e(\mathbf{z}|\boldsymbol{\lambda})$, where $\tilde{p}_d$ contains all factors that make the optimization difficult, and $\tilde{p}_e$ contains the rest (while c is a constant). By substituting in (1), we

get the following split of the lower bound:

$$\underline{\mathcal{L}}(\boldsymbol{\lambda}) = \underbrace{\mathbb{E}_q[\log \tilde{p}_d(\mathbf{z}|\boldsymbol{\lambda})]}_{-f(\boldsymbol{\lambda})} + \underbrace{\mathbb{E}_q[\log \tilde{p}_e(\mathbf{z}|\boldsymbol{\lambda})]}_{-h(\boldsymbol{\lambda})} + \log c.$$

Note that $\tilde{p}_d$ and $\tilde{p}_e$ need not be probability distributions.

We make the following assumptions about f and h:

(A1) The function f is differentiable and its gradient is $L-$Lipschitz-continuous, i.e. $\forall \boldsymbol{\lambda}$ and $\boldsymbol{\lambda}' \in \mathcal{S}$ we have

$$\|\nabla f(\boldsymbol{\lambda}) - \nabla f(\boldsymbol{\lambda}')\| \leq L\|\boldsymbol{\lambda} - \boldsymbol{\lambda}'\|.$$

(A2) The function h can be a general convex function.

These assumptions are very weak. The function f can be non-convex and the Lipschitz-continuity assumption is typically satisfied in practice (and indeed the analysis can be generalized to only require this assumption on a smaller set containing the iterations). The assumption that h is convex seems strong, but note that we can always take $h = 0$ in the split if the function has no "nice" convex part. Below, we give several illustrative examples of such splits for variational-Gaussian inference with $q(\mathbf{z}|\boldsymbol{\lambda}) := \mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V})$, so that $\boldsymbol{\lambda} = \{\mathbf{m}, \mathbf{V}\}$ with $\mathbf{m}$ being the mean and $\mathbf{V}$ being the covariance matrix.

Gaussian Process (GP) Models: Consider GP models (Kuss & Rasmussen, 2005) for N input-output pairs $\{y_n, \mathbf{x}_n\}$ indexed by n. Let $z_n := f(\mathbf{x}_n)$ be the latent function drawn from a GP with mean 0 and covariance $\mathbf{K}$. We use a non-Gaussian likelihood $p(y_n|z_n)$ to model the output. We can then use the following split, where the non-Gaussian terms are in $\tilde{p}_d$ and the Gaussian terms are in $\tilde{p}_e$:

$$\frac{p(\mathbf{y}, \mathbf{z})}{q(\mathbf{z}|\boldsymbol{\lambda})} = \underbrace{\prod_{n=1}^{N} p(y_n|z_n)}_{\tilde{p}_d(\mathbf{z}|\boldsymbol{\lambda})} \underbrace{\frac{\mathcal{N}(\mathbf{z}|0, \mathbf{K})}{\mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V})}}_{\tilde{p}_e(\mathbf{z}|\boldsymbol{\lambda})}. \tag{10}$$

The detailed derivation is in the appendix. By substituting in (1), we obtain the lower bound $\underline{\mathcal{L}}(\boldsymbol{\lambda})$ shown below along with its split:

$$\underbrace{\sum_n \mathbb{E}_q[\log p(y_n|z_n)]}_{-f(\boldsymbol{\lambda})} - \underbrace{\mathbb{D}_{KL}[\mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V}) \,\|\, \mathcal{N}(\mathbf{z}|0, \mathbf{K})]}_{h(\boldsymbol{\lambda})}. \tag{11}$$

A1 is satisfied for common likelihoods, while it is easy to establish that h is convex. We show in Section 6 that this split leads to a closed-form update for iteration (9).

Generalized Linear Models (GLMs): A similar split can be obtained for GLMs (Nelder & Baker, 1972), where the non-conjugate terms are in $\tilde{p}_d$ and the rest are in $\tilde{p}_e$. Denoting the weights by $\mathbf{z}$ and assuming a standard Gaussian prior over it, we can use the following split:

$$\frac{p(\mathbf{y}, \mathbf{z})}{q(\mathbf{z}|\boldsymbol{\lambda})} = \underbrace{\prod_{n=1}^{N} p(y_n|\mathbf{x}_n^T\mathbf{z})}_{\tilde{p}_d(\mathbf{z}|\boldsymbol{\lambda})} \underbrace{\frac{\mathcal{N}(\mathbf{z}|0, \mathbf{I})}{\mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V})}}_{\tilde{p}_e(\mathbf{z}|\boldsymbol{\lambda})}.$$

We give further details about the bound for this case in the appendix.

Correlated Topic Model (CTM): Given a text document with a vocabulary of N words, denote its word-count vector by $\mathbf{y}$. Let K be the number of topics and $\mathbf{z}$ be the vector of topic-proportions. We can then use the following split:

$$\frac{p(\mathbf{y}, \mathbf{z})}{q(\mathbf{z}|\boldsymbol{\lambda})} = \underbrace{\prod_{n=1}^{N} \left[\sum_{k=1}^{K} \beta_{n,k} \frac{e^{z_k}}{\sum_j e^{z_j}}\right]^{y_n}}_{\tilde{p}_d(\mathbf{z}|\boldsymbol{\lambda})} \underbrace{\frac{\mathcal{N}(\mathbf{z}|\boldsymbol{\mu}, \boldsymbol{\Sigma})}{\mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V})}}_{\tilde{p}_e(\mathbf{z}|\boldsymbol{\lambda})},$$

where $\boldsymbol{\mu}, \boldsymbol{\Sigma}$ are parameters of the Gaussian prior and $\beta_{n,k}$ are parameters of K multinomials. We give further details about the bound in the appendix.

3.2 STOCHASTIC-APPROXIMATION

The approach of Khan et al. (2015) considers (9) in the special case of (6) where we use the exact gradient $\nabla f(\boldsymbol{\lambda}_k)$ in the first term. But in practice this gradient is often difficult to compute. In our framework, we allow a stochastic approximation of $\nabla f(\boldsymbol{\lambda})$ which we denote by $\widehat{\nabla} f(\boldsymbol{\lambda}_k)$.

As shown in the previous section, f might take a form $f(\boldsymbol{\lambda}) := \Sigma_{n=1}^{N} \mathbb{E}_q[\tilde{f}_n(\mathbf{z})]$ for a set of functions $\tilde{f}_n$ as in the GP model (11). In some situations, $\mathbb{E}_q[\tilde{f}_n(\mathbf{z})]$ is computationally expensive or intractable. For example, in GP models the expectation is equal to $\mathbb{E}_q[\log p(y_n|z_n)]$, which is intractable for most non-Gaussian likelihoods. In such cases, we can form a stochastic approximation by using a few samples $\mathbf{z}^{(s)}$ from $q(\mathbf{z}|\boldsymbol{\lambda})$, as shown below:

$$\nabla \mathbb{E}_q[\tilde{f}_n(\mathbf{z})] \approx \widehat{\mathbf{g}}(\boldsymbol{\lambda}, \boldsymbol{\xi}_n) := \frac{1}{S} \sum_{s=1}^{S} \tilde{f}_n(\mathbf{z}^{(s)}) \nabla [\log q(\mathbf{z}^{(s)}|\boldsymbol{\lambda})]$$

where $\boldsymbol{\xi}_n$ represents the noise in the stochastic approximation $\widehat{\mathbf{g}}$ and we use the identity $\nabla q(\mathbf{z}|\boldsymbol{\lambda}) = q(\mathbf{z}|\boldsymbol{\lambda}) \nabla [\log q(\mathbf{z}|\boldsymbol{\lambda})]$ to derive the expression (Ranganath et al., 2013). We can then form a stochastic-gradient by randomly selecting a mini-batch of M functions $\tilde{f}_{n_i}(\mathbf{z})$ and employing the estimate

$$\widehat{\nabla} f(\boldsymbol{\lambda}) = \frac{N}{M} \sum_{i=1}^{M} \widehat{\mathbf{g}}(\boldsymbol{\lambda}, \boldsymbol{\xi}_{n_i}). \tag{12}$$

In our analysis we make the following two assumptions regarding the stochastic approximation of the gradient:

(A3) The estimate is unbiased: $\mathbb{E}[\widehat{\mathbf{g}}(\boldsymbol{\lambda}, \boldsymbol{\xi}_n)] = \bigtriangledown f(\boldsymbol{\lambda})$.

(A4) Its variance is upper bounded: $\text{Var}[\widehat{\mathbf{g}}(\boldsymbol{\lambda}, \boldsymbol{\xi}_n)] \leq \sigma^2$.

In both the assumptions, the expectation is taken with respect to the noise $\boldsymbol{\xi}_n$. The first assumption is true for the stochastic approximations of (12). The second assumption is stronger, but only needs to hold for all $\boldsymbol{\lambda}_k$ so is almost always satisfied in practice.

3.3 DIVERGENCE FUNCTIONS

To incorporate the geometry of q we incorporate a divergence function $\mathbb{D}$ between $\boldsymbol{\lambda}$ and $\boldsymbol{\lambda}_k$. The set of divergence functions need to satisfy two assumptions:

(A5) $\mathbb{D}(\boldsymbol{\lambda} \,\|\, \boldsymbol{\lambda}') > 0$, for all $\boldsymbol{\lambda} \neq \boldsymbol{\lambda}'$.

(A6) There exist an $\alpha > 0$ such that for all $\boldsymbol{\lambda}, \boldsymbol{\lambda}'$ generated by (9) we have:

$$(\boldsymbol{\lambda} - \boldsymbol{\lambda}')^T \nabla_{\boldsymbol{\lambda}} \mathbb{D}(\boldsymbol{\lambda} \,\|\, \boldsymbol{\lambda}') \geq \alpha \|\boldsymbol{\lambda} - \boldsymbol{\lambda}'\|^2. \qquad (13)$$

The first assumption is reasonable and is satisfied by typical divergence functions like the squared Euclidean distance and variants of the KL divergence. In the next section we show that, whenever the iteration (9) is defined and all $\boldsymbol{\lambda}_k$ stay within a compact set, the second assumption is satisfied for all divergence functions considered in Section 2.

4 SPECIAL CASES

Most methods discussed in Section 2 are special cases of the proposed iteration (9). We obtain gradient descent if $h = 0$, $f = -\underline{\mathcal{L}}$, $\widehat{\nabla} f = \nabla f$, and $\mathbb{D}(\boldsymbol{\lambda} \| \boldsymbol{\lambda}_k) = (1/2)\|\boldsymbol{\lambda} - \boldsymbol{\lambda}_k\|^2$ (in this case A6 is satisfied with $\alpha = 1$). From here, there are three standard generalizations in the optimization literature: SG methods do not require that $\widehat{\nabla} f = \nabla f$, proximal-gradient methods do not require that $h = 0$, and mirror descent allows $\mathbb{D}$ to be a different Bregman divergence generated by a strongly-convex function. Our analysis applies to all these variations on existing optimization algorithms because A1 to A5 are standard assumptions (Ghadimi et al., 2014) and, as we now show, A6 is satisfied for this class of Bregman divergences. In particular, consider the generic Bregman divergence shown in the left side of (8) for some strongly-convex function $A(\boldsymbol{\lambda})$. By taking the gradient with respect to $\boldsymbol{\lambda}$ and substituting in (13), we obtain that A6 is equivalent to

$$(\boldsymbol{\lambda} - \boldsymbol{\lambda}_k)^T [\bigtriangledown A(\boldsymbol{\lambda}) - \bigtriangledown A(\boldsymbol{\lambda}_k)] \geq \alpha \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_k\|^2,$$

which is equivalent to strong-convexity of the function $A(\boldsymbol{\lambda})$ (Nesterov, 2004, Theorem 2.1.9).

The method of Theis & Hoffman (2015) corresponds to choosing $h = -\underline{\mathcal{L}}$, $f = 0$, and $\mathbb{D}(\boldsymbol{\lambda} || \boldsymbol{\lambda}_k) := \mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)]$ where q is an exponential family distribution with natural parameters $\boldsymbol{\lambda}$. Since we assume h to be convex, only limited cases of their approach are covered under our framework. The method of Khan et al. (2015) also uses the KL divergence and focuses on the deterministic case where $\widehat{\nabla} f(\boldsymbol{\lambda}) = \nabla f(\boldsymbol{\lambda})$, but uses the split $-\underline{\mathcal{L}} = f + h$ to allow for non-conjugate models. In both of these models, A6 is satisfied when the Fisher matrix $\bigtriangledown^2 A(\boldsymbol{\lambda})$ is positive-definite. This can be shown by using the definition of the KL divergence for exponential families (Nielsen & Garcia, 2009):

$$\begin{aligned} &\mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)] \\ &\quad := A(\boldsymbol{\lambda}_k) - A(\boldsymbol{\lambda}) - [\bigtriangledown A(\boldsymbol{\lambda})]^T (\boldsymbol{\lambda}_k - \boldsymbol{\lambda}). \end{aligned} \qquad (14)$$

Taking the derivative with respect to $\boldsymbol{\lambda}$ and substituting in (13) with $\boldsymbol{\lambda}' = \boldsymbol{\lambda}_k$, we get the condition

$$(\boldsymbol{\lambda} - \boldsymbol{\lambda}_k)^T [\bigtriangledown^2 A(\boldsymbol{\lambda})](\boldsymbol{\lambda} - \boldsymbol{\lambda}_k) \geq \alpha \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_k\|^2,$$

which is satisfied when $\bigtriangledown^2 A(\boldsymbol{\lambda})$ is positive-definite over a compact set for α equal to its lowest eigenvalue on the set.

Methods based on natural-gradient using iteration (3) (like SVI) correspond to using $h = 0$, $f = -\underline{\mathcal{L}}$, and the symmetric KL divergence. Assumption A1 to A5 are usually assumed for these methods and, as we show next, A6 is also satisfied. In particular, when q is an exponential family distribution the symmetric KL divergence can be written as the sum of the Bregman divergence shown in (8) and the KL divergence shown in (14),

$$\begin{aligned} &\mathbb{D}^{sym}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)] \\ &:= \mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}_k) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda})] + \mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)] \\ &= \mathbb{D}_A(\boldsymbol{\lambda} \| \boldsymbol{\lambda}_k) + \mathbb{D}_{KL}[q(\mathbf{z}|\boldsymbol{\lambda}) \,\|\, q(\mathbf{z}|\boldsymbol{\lambda}_k)] \end{aligned}$$

where the first equality follows from the definition of the symmetric KL divergence and the second one follows from (8). Since the two divergences in the sum satisfy A6, the symmetric KL divergence also satisfies the assumption.

5 CONVERGENCE OF PG-SVI

We first analyze the convergence rate of deterministic methods where the gradient is exact, $\widehat{\nabla} f(\boldsymbol{\lambda}) = \nabla f(\boldsymbol{\lambda})$. This yields a simplified result that applies to a wide variety of existing variational methods. Subsequently, we consider the more general case where a stochastic approximation of the gradient is used.

5.1 DETERMINISTIC METHODS

The following theorem establishes the convergence under a fixed step-size. We use $C_0 = \underline{\mathcal{L}}^* - \underline{\mathcal{L}}(\boldsymbol{\lambda}_0)$ as the initial (constant) sub-optimality, and express our result in terms of the quantity $\|\boldsymbol{\lambda}_{k+1} - \boldsymbol{\lambda}_k\|$.

Proposition 1. *Let A1, A2, A5, and A6 be satisfied. If we run t iterations of (9) with a fixed step-size $\beta_k = \alpha/L$ for all k and an exact gradient $\nabla f(\boldsymbol{\lambda})$, then we have*

$$\min_{k\in\{0,1,\ldots,t-1\}} \|\boldsymbol{\lambda}_{k+1} - \boldsymbol{\lambda}_k\|^2 \leq \frac{2C_0}{\alpha t} \tag{15}$$

We give a proof in the appendix. Roughly, the theorem states that the minimum distance moved across all iterations must be in $O(1/t)$. If the objective is bounded below (C_0 is finite), then this result implies that the algorithm converges to a stationary point and also gives a rate of convergence.

Stating the result in terms of $\|\boldsymbol{\lambda}_{k+1} - \boldsymbol{\lambda}_k\|$ may appear to be unconventional, but this quantity is useful since it characterizes a fixed point of the algorithm. For example, consider the special case of gradient descent where $h = 0$ and $\mathbb{D}(\boldsymbol{\lambda}, \boldsymbol{\lambda}_k) = \frac{1}{2}\|\boldsymbol{\lambda} - \boldsymbol{\lambda}_k\|^2$. In this case, $\alpha = 1$ and $\beta_k = 1/L$, therefore we have $\|\boldsymbol{\lambda}_{k+1} - \boldsymbol{\lambda}_k\| = \|\nabla f(\boldsymbol{\lambda}_k)\|^2/L$ and Proposition 1 implies that $\min_k \|\nabla f(\boldsymbol{\lambda}_k)\|^2$ has a convergence rate of $O(1/t)$. This in turn shows that the method converges at a sublinear rate to an approximate stationary point, which would be a global minimum in the special case where f is convex.

If we use a divergence with $\alpha > 1$ then we can use a step-size larger than $1/L$ and the error will decrease faster than gradient-descent. To our knowledge, this is the first result that formally shows that natural-gradient methods can achieve faster convergence rates. The splitting of the objective into f and h functions is also likely to improve the step-size. Since L only depends on f, sometimes it might be possible to reduce the Lipschitz constant by choosing an appropriate split.

We next give a more general result that allows a per-iteration step size.

Proposition 2. *If we choose the step-sizes β_k to be such that $0 < \beta_k \leq 2\alpha/L$ with $\beta_k < 2\alpha/L$ for at least one k, then,*

$$\min_{k\in\{0,1\ldots t-1\}} \frac{1}{\beta_k}\|\boldsymbol{\lambda}_{k+1} - \boldsymbol{\lambda}_k\|^2 \leq \frac{C_0}{\sum_{k=0}^{t-1}(\alpha\beta_k - L\beta_k^2/2)} \tag{16}$$

We give a proof in the appendix. For gradient-descent, the above result implies that we can use any step-size less than $2/L$, which agrees with the classical step-size choices for gradient and proximal-gradient methods.

5.2 STOCHASTIC METHODS

We now give a bound for the more general case where we use a stochastic approximation of the gradient.

Proposition 3. *Let A1-A6 be satisfied. If we run t iterations of (9) for a fixed step-size $\beta_k = \gamma\alpha_*/L$ (where $0 < \gamma < 2$ is a scalar) and fixed batch-size $M_k = M$ for all k with a stochastic gradient $\widehat{\nabla} f(\boldsymbol{\lambda})$, then we have*

$$\mathbb{E}_{R,\boldsymbol{\xi}}(\|\boldsymbol{\lambda}_{R+1} - \boldsymbol{\lambda}_R\|^2) \leq \frac{1}{2-\gamma}\left[\frac{2C_0}{\alpha_* t} + \frac{\gamma c\sigma^2}{ML}\right].$$

where c is a constant such that $c > 1/(2\alpha)$ and $\alpha_* := \alpha - 1/(2c)$. The expectation is taken with respect to the noise $\boldsymbol{\xi} := \{\boldsymbol{\xi}_0, \boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_{t-1}\}$, and a random variable R which follows the uniform distribution $Prob(R = k) = 1/t, \forall k \in \{0, 1, 2, \ldots, t-1\}$.

Unlike the bound of Proposition 1, this bound depends on the noise variance σ^2 as well the mini-batch size M. In particular, as we would expect, the bound gets tighter as the variance gets smaller and as the size of our mini-batch grows. Notice that we can also make the second term smaller by decreasing the value of γ and the first term smaller by increasing the number of iterations. Therefore, this bound indicates that a small enough constant step-size γ (or a sufficiently-large batch-size M) can be used to reach any target level of accuracy. In the appendix, we give a more general result that allows a per-iteration step-size which can used to give an "anytime" algorithm that is able to converge to an arbitrary level of accuracy by using a decreasing sequence of step sizes (but we found that constant step-sizes work better empirically). Note that while stating the result in terms of a randomized iteration might seem strange, in practice we typically just take the last iteration as the minimizer.

6 CLOSED-FORM UPDATES FOR NON-CONJUGATE MODELS

We now give an example where iteration (9) attains a closed-form solution. We expect such closed-form solution to exist for a large class of problems, including models where q is an exponential-family distribution, but here we focus on the GP model discussed in Section 3.1.

For the GP model, we rewrite the lower bound (11) as

$$-\underline{\mathcal{L}}(\mathbf{m}, \mathbf{V}) := \underbrace{\sum_{n=1}^{N} f_n(m_n, v_n)}_{f(\boldsymbol{m},\boldsymbol{V})} + \underbrace{\mathbb{D}_{KL}[q\,\|\,p]}_{h(\boldsymbol{m},\boldsymbol{V})} \tag{17}$$

where we've used $q := \mathcal{N}(\mathbf{z}|\mathbf{m}, \mathbf{V})$, $p := \mathcal{N}(\mathbf{z}|0, \mathbf{K})$, and $f_n(m_n, v_n) := -\mathbb{E}_q[\log p(y_n|z_n)]$ with m_n being the entry n of $\mathbf{m}$ and v_n being the diagonal entry n of $\mathbf{V}$. We can compute a stochastic approximation of f using (12) by randomly selecting an example n_k (choosing $M = 1$) and using a Monte Carlo gradient approximation of f_{n_k}. Using this approximation, the linearized term in (9) can be

simplified to the following:

$$\boldsymbol{\lambda}^T \left[\widehat{\nabla} f(\boldsymbol{\lambda}_k)\right] = m_n \underbrace{N[\nabla_{m_n} f_{n_k}(m_{n_k,k}, v_{n_k,k})]}_{:=\alpha_{n_k,k}} + v_n \underbrace{N[\nabla_{v_n} f_{n_k}(m_{n_k,k}, v_{n_k,k})]}_{:=2\,\gamma_{n_k,k}} = m_n \alpha_{n_k,k} + \tfrac{1}{2} v_n \gamma_{n_k,k} \quad (18)$$

where $m_{n_k,k}$ and $v_{n_k,k}$ denote the value of m_n and v_n in the k'th iteration for $n = n_k$. By using the KL divergence as our divergence function in iteration (9), and by denoting $\mathcal{N}(\mathbf{z}|\mathbf{m}_k, \mathbf{V}_k)$ by q_k, we can express the two last two terms in (9) as a single KL divergence function as shown below:

$$\begin{aligned}
&\boldsymbol{\lambda}^T \left[\widehat{\nabla} f(\boldsymbol{\lambda}_k)\right] + h(\boldsymbol{\lambda}) + \frac{1}{\beta_k}\mathbb{D}(\boldsymbol{\lambda}\|\boldsymbol{\lambda}_k),\\
&= (m_n \alpha_{n,k} + \tfrac{1}{2} v_n \gamma_{n,k}) + \mathbb{D}_{KL}[q \,\|\, p] + \frac{1}{\beta_k}\mathbb{D}_{KL}[q \,\|\, q_k],\\
&= (m_n \alpha_{n,k} + \tfrac{1}{2} v_n \gamma_{n,k}) + \frac{1}{1-r_k}\mathbb{D}_{KL}[q \,\|\, p^{1-r_k} q_k^{r_k}],
\end{aligned}$$

where $r_k := 1/(1+\beta_k)$. Comparing this to (17), we see that this objective is similar to that of a GP model with a Gaussian prior[1] $p^{1-r_k} q_k^{r_k}$ and a linear Gaussian-like log-likelihood. Therefore, we can obtain closed-form updates for its minimization.

The updates are shown below and a detailed derivation is given in the appendix.

$$\begin{aligned}
\widetilde{\boldsymbol{\gamma}}_k &= r_k \widetilde{\boldsymbol{\gamma}}_{k-1} + (1-r_k)\gamma_{n_k,k}\mathbf{1}_{n_k},\\
\mathbf{m}_{k+1} &= \mathbf{m}_k - (1-r_k)(\mathbf{I} - \mathbf{K}\mathbf{A}_k^{-1})(\mathbf{m}_k + \alpha_{n_k,k}\boldsymbol{\kappa}_{n_k}),\\
v_{n_{k+1},k+1} &= \kappa_{n_{k+1},n_{k+1}} - \boldsymbol{\kappa}_{n_{k+1}}^T \mathbf{A}_k^{-1} \boldsymbol{\kappa}_{n_{k+1}}, \qquad (19)
\end{aligned}$$

where $\widetilde{\boldsymbol{\gamma}}_0$ is initialized to a small positive constant to avoid numerical issues, $\mathbf{1}_{n_k}$ is a vector with all zero entries except n_k'th entry which is equal to 1, $\boldsymbol{\kappa}_k$ is n_k'th column of $\mathbf{K}$, and $\mathbf{A}_k := \mathbf{K} + [\text{diag}(\widetilde{\boldsymbol{\gamma}}_k)]^{-1}$. For iteration $k+1$, we use $m_{n_{k+1},k+1}$ and $v_{n_{k+1},k+1}$ to compute the gradients $\alpha_{n_{k+1},k+1}$ and $\gamma_{n_{k+1},k+1}$, and run the above updates again. We continue until a convergence criteria is reached.

There are numerous advantages of these updates. First, We do not need to store the full covariance matrix $\mathbf{V}$. The updates avoid forming the matrix and only update $\mathbf{m}$. This works because we only need one diagonal element in each iteration to compute the stochastic gradient $\gamma_{n_k,k}$. For large N this is a clear advantage since the memory cost is $O(N)$ rather than $O(N^2)$. Second, computation of the mean vector $\mathbf{m}$ and a diagonal entry of $\mathbf{V}$ only require solving two linear equations, as shown in the second and third line of (19). In general, for a mini-batch of size M, we need a total of $2M$ linear equations, which is a lot cheaper than an explicit inversion. Finally, the linear equations at iteration $k+1$ are very similar to those at iteration k, since $\mathbf{A}_k$ differ only at one entry from $\mathbf{A}_{k+1}$. Therefore, we can reuse computations from the previous iteration to improve the computational efficiency of the updates.

[1] Since p and q are Gaussian, the product is a Gaussian.

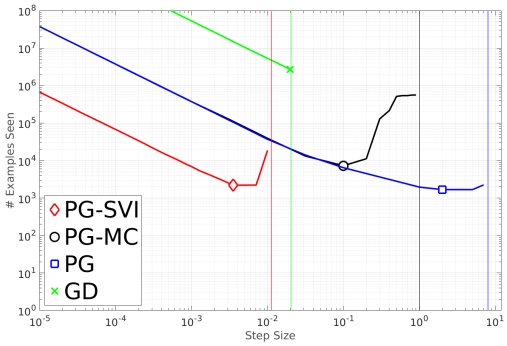

Figure 1: We show the number of examples required for convergence versus fixed step-sizes for binary GP classification. Methods based on proximal-gradient require fewer number of examples compared to gradient descent (GD). Step-size is upper bounded for all methods (upper bound shown with vertical lines). PG-SVI surprisingly converges at the same rate as PG.

7 EXPERIMENTAL RESULTS

In this section, we compare our method to many existing approaches such as SGD and four adaptive gradient-methods (ADAGRAD, ADADELTA, RMSprop, ADAM), as well as two variational inference methods for non-conjugate models (the Delta method and Laplace method). We show results on Gaussian process classification (Kuss & Rasmussen, 2005) and correlated topic models (Blei & Lafferty, 2007). The code to reproduce these experiments can be found at this link[2].

7.1 GAUSSIAN PROCESS CLASSIFICATION

We consider binary classification by using a GP model with Bernoulli-logit likelihood on three datasets: Sonar, Ionosphere, and USPS-3vs5. These datasets can be found at the UCI data repository[3] and their details are discussed in Kuss & Rasmussen (2005). For the GP prior, we use the zero mean-function, and a squared-exponential covariance function with hyperparameters σ and l as defined in Kuss & Rasmussen (2005) (see Eq. 33). We set the values of the hyperparameters using cross-validation. For the three datasets, the hyperparameters $(\log l, \log \sigma)$ are set to $(-1, 6)$, $(1, 2.5)$, and $(2.5, 5)$, respectively.

[2] https://github.com/emtiyaz/prox-grad-svi

[3] https://archive.ics.uci.edu/ml/datasets.html

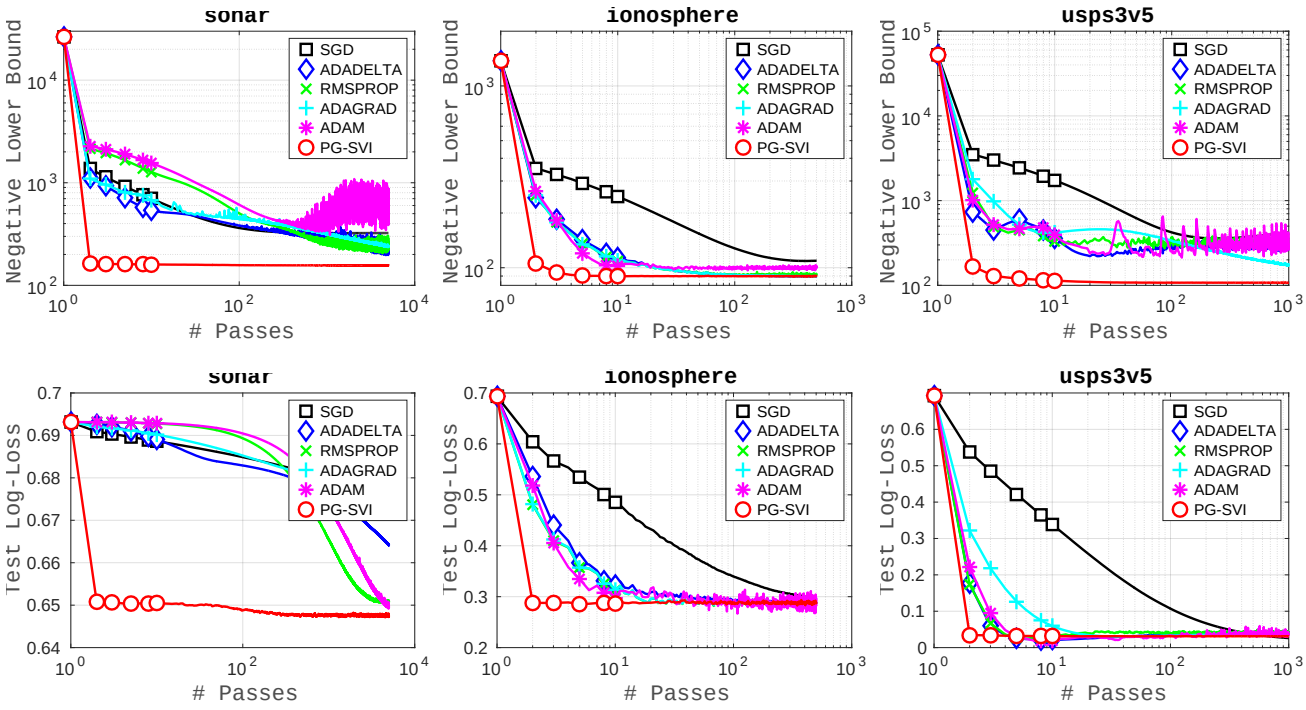

Figure 2: Comparison with adaptive gradient methods for binary classification using GP. We compare PG-SVI to SGD, ADADELTA, RMSprop, ADAGRAD, and ADAM on three datasets. Each column shows results for a dataset. Top row shows the negative of the lower bound, while the bottom row shows the test log-loss. In each plot, the X-axis shows the number of passes made through the data. Markers are shown at 0, 1, 2, 4, 7, and 9 passes through the data. Our method always converges within 10 passes through the data, while other methods more than 100 passes.

7.1.1 Performance Under a Fixed Step-Size

In our first experiment, we compare the performance under a fixed step-size. These results demonstrate that the step-size required for convergence is upper-bounded, as shown in our convergence analysis. The results also demonstrate the faster convergence of our method compared to gradient-descent methods. We compare the following four algorithms on the Ionosphere dataset: (1) batch gradient-descent (referred to as 'GD'), (2) batch proximal-gradient algorithm (referred to as 'PG'), (3) batch version of proximal-gradient algorithm with gradients approximated by using Monte-Carlo (referred to as 'PG-MC'), and (4) proposed proximal-gradient stochastic variational-inference (referred to as 'PG-SVI') where stochastic gradients are obtained using (12) with $M = 5$. For Monte Carlo approximation, we use $S = 500$ samples.

Figure 1 shows the number of examples required for convergence versus the step-size. A lower number implies faster convergence. The vertical lines show the step-size above which a method diverges. Convergence is assessed by monitoring the lower bound, and when the change in consecutive iterations do not exceed a certain threshold, we stop the algorithm.

We clearly see that GD requires many more passes through the data, and methods based on proximal-gradient method converge faster than GD. In addition, the upper bound on the step-size for PG is much larger than GD. This implies that PG can potentially take larger steps than the GD method. PG-SVI is surprisingly as fast as PG which shows the advantage of our approach over the approach of Khan et al. (2015).

7.1.2 Comparison with Adaptive Gradient Methods

We also compare PG-SVI to SGD and four adaptive methods, namely ADADELTA (Zeiler, 2012), RMSprop (Tieleman & Hinton, 2012), ADAGRAD (Duchi et al., 2011), and ADAM (Kingma & Ba, 2014). The implementation details of these algorithms are given in the appendix. We compare the value of the lower bound versus number of passes through the data. We also compare the average log-loss on the test data: $-\sum_n \log \hat{p}_n / N_*$ where $\hat{p}_n = p(y_n|\sigma, l, \mathcal{D}_t)$ is the predictive probabilities of the test point y_n given training data $\mathcal{D}_t$ and N_* is the total number of test-pairs. A lower value is better for the log-loss, and a value of 1 is equal to the performance of random coin-flipping.

Figure 2 summarizes the results. Each column shows results for a dataset. The top row shows the negative of the lower bound, while the bottom row shows the test log-loss.

Lower values are better for both. In all plots, the X-axis shows the number of passes made through the data. Markers are shown at 0, 1, 2, 4, 7, and 9 passes through the data (one pass means the number of randomly selected examples is equal to the total number of examples). Our method is much faster to converge than other methods, and it always converges within 10 passes through the data, while other methods requires more than 100 passes.

7.2 CORRELATED TOPIC MODEL

We now show results for correlated topic model on two collections of documents, namely NIPS dataset and Associated Press (AP) dataset. The NIPS[4] dataset contains 1500 documents from the NIPS conferences held between 1987 and 1999 (a vocabulary-size of 12,419 words and a total of around 1.9M words). The AP[5] collection contains 2,246 documents from the Associated Press (a vocabulary-size of 10,473 words and a total of 436K observed words). We use 50% of the documents for training and 50% for testing.

We compare to the Delta method and the Laplace method discussed in Wang & Blei (2013), and also to the original mean-field (MF) method of Blei & Lafferty (2007). For these methods, we use the implementation available at this link[6]. All of these methods approximate the lower bound by using approximations to the expectation of log-sum-exp functions (see Appendix for details). We compare these methods to the two versions of our algorithm which do not use such approximations, rather use a stochastic gradient as explain in Section 3.2. Specifically, we use the following two versions: one with full covariance (referred to as PG-SVI), and the other with diagonal covariance (referred to as PG-SVI-MF). For both of these algorithms, we use a fixed step-size of 0.001, and a mini-batch size of 2 documents.

Following Wang & Blei (2013), we compare the held-out log-likelihood, which is computed as follows: a new test document $\mathbf{y}$ is split into two halves $(\mathbf{y}^1, \mathbf{y}^2)$, then we compute the approximate posterior $q(\mathbf{z})$ to the posterior $p(\mathbf{z}|\mathbf{y}^1)$ using which we compute the held-out log-likelihood for each $y_n \in \mathbf{y}^2$ as follows:

$$\log p(y_n) \approx \log \int_z \left[\sum_{k=1}^{K} \beta_{n,k} \frac{e^{z_k}}{\sum_j e^{z_j}}\right]^{y_n} q(\mathbf{z}) d\mathbf{z} \quad (20)$$

We use Monte Carlo to approximate this quantity by using a large number of samples from q (unlike Wang & Blei (2013) who approximate it by using the Delta method). We report the average of this quantity over all words in $\mathbf{y}^2$.

Figure 3 shows the negative of the average held-out log-likelihood versus time for 10 topics. Lower values are better. Markers are shown at iterations after second and fifth passes through the data. We see that methods based on proximal-gradient algorithm converge a little bit faster than the existing methods. More importantly, they achieves better performance. This could be due to the fact that we do not approximate the expectation of the log-sum-exp function, unlike the Delta and Laplace method. We obtained similar results for different number of topics.

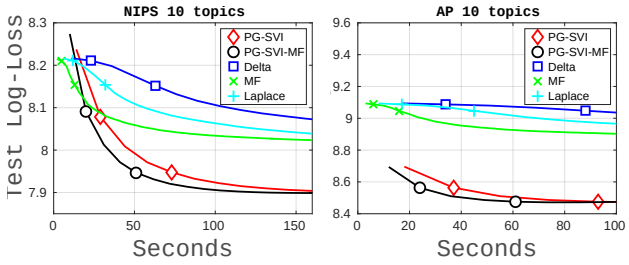

Figure 3: Results on NIPS (left) and AP (right) datasets using correlated topic model with 10 topics. We plot the negative of the average held-out log-likelihood versus time. Lower values are better. Methods based on proximal-gradient algorithm perform better.

8 DISCUSSION

This work has made two contributions. First, we proposed a new variational inference method that combines variable splitting, stochastic gradients, and general divergence functions. This method is well-suited for a huge variety of the variational inference problems that arise in practice, and we anticipate that it may improve over state of the art methods in a variety of settings. Our second contribution is a theoretical analysis of the convergence rate of this general method. Our analysis generalizes existing results for the mirror descent algorithm in optimization, and resolves the convergences of a variety of existing variational inference methods. Due to its generality we expect that this analysis could be useful to establish convergence of other algorithms that we have not thought of, perhaps beyond the variational inference settings we consider in this work.

One issue that we have not satisfactorily resolved is giving a theoretically-justified way to set the step-size in practice; our analysis only indicates that it must be sufficiently small. However, this problem is common in many methods in the literature and our analysis at least suggests the factors that should be taken into account. Another open issue is the applicability our method to many other latent variable models; in this paper we have shown applications to variational-Gaussian inference, but we expect that our method should result in simple updates for a larger class of latent variable models such as non-conjugate exponential family distribution models. Additional work on these issues will improve usability of our method.

Abstract

Microclustering refers to clustering models that produce small clusters or, equivalently, to models where the size of the clusters grows sublinearly with the number of samples. We formulate probabilistic microclustering models by assigning a prior distribution on the size of the clusters, and in particular consider microclustering models with explicit bounds on the size of the clusters. The combinatorial constraints make full Bayesian inference complicated, but we manage to develop a Gibbs sampling algorithm that can efficiently sample from the joint cluster allocation of all data points. We empirically demonstrate the computational efficiency of the algorithm for problem instances of varying difficulty.

1 INTRODUCTION

Clustering is classically identified as the task of grouping similar objects into a number of clusters. Typical probabilistic formulations are based on mixture models [McLachlan and Peel, 2004], following the intuitive idea that each data point independently chooses a cluster by considering the product of some mixture weights and the likelihood of that cluster producing the data point. Because of these independent decisions, these models have very limited means for controlling the sizes of the clusters. Parametric mixture models are effectively agnostic of the cluster size; they can be tuned to a degree with the prior distribution of the weights, but in the end the likelihood overrides even the strongest priors for large sample sizes. Nonparametric mixture models such as Dirichlet process (DP) mixtures [Antoniak, 1974], Pitman-Yor mixtures [Dubey et al., 2014], and uniform process mixtures [Wallach et al., 2010] in turn induce some characteristic behavior for the size distribution. For example, DP mixtures assume that the number of clusters for a sample size of N grows proportionally to $\log(N)$ and the biggest clusters hold a large proportion of the data points due to the rich-get-richer property, which is not always consistent with reasonable clustering assumptions [Miller and Harrison, 2013]. The uniform process by Wallach et al. [2010] eliminates the rich-get-richer property, but in expectation produces clusters of all sizes with equal probability, resulting in total number of clusters proportional to $\sqrt{N}$.

Both being agnostic about the sizes of the clusters and explicitly assuming the rich-get-richer property are reasonable assumptions for a wide range of clustering tasks, as clearly demonstrated by the wide-spread usage of mixture models. For some clustering tasks, however, it would be useful to have finer control over the possible sizes of the clusters. For example, if the clustering model is used for creating teams of similar individuals [Kim et al., 2015] we would want to find clusters that are approximately of the same size, even as small as two to create working pairs. Another practical example is to use clustering to split a collection of items for further processing for distributed set of workers with limited capacity. We can expect the worker to perform the task more accurately and faster if the items are similar, and the clusters should contain at most a certain pre-given number of instances.

In this work, we consider probabilistic clustering models with explicit constraints on the sizes to address the illustrative scenarios above. Our model that assumes constant maximum size is a specific instance of the more general concept of *microclustering*, defined as clustering models for which the size of the clusters grows sublinearly with respect to the sample size [Miller et al., 2015] – here the size is explicitly forced to be constant, to guarantee small clusters even for extremely large data collections. Our microclustering model builds on standard parametric mixture models, but replaces the independent cluster assignments of individual data points with a joint assignment of all points that needs to satisfy the constraints.

Specifying the model for size-constrained microclustering is straightforward, requiring only a simple change in the prior distribution, and in fact similar models have earlier been discussed outside the probabilistic framework.

Banerjee [2006] considered distance-based clustering models that produce clusters of approximatively the same size, and Zhu et al. [2010] added explicit constraints to K-means to utilize prior knowledge on the cluster sizes. Their solutions correspond effectively to maximum likelihood estimation, which is easy given access to standard constrained optimization tools, whereas the core challenge in our case is in conducting full Bayesian inference over the model.

In this work we discuss the challenge of jointly sampling the cluster assignments of all data points in our microclustering model and present two alternative algorithms for that purpose, a dynamic programming algorithm based on depth-first branch-and-bound, and a simple rejection sampler. We empirically demonstrate that these two alternatives dominate in different conditions, the former being efficient for highly constrained cases and the latter being optimal for loose constraints. We then construct a final sampling algorithm that utilizes both parts to produce a Gibbs sampler that is a direct generalization of the corresponding algorithm for regular mixture models: In the absence of constraints it draws the samples independently with no computational overhead, whereas with increasingly tight constraints it starts using the dynamic programming algorithm for improved efficiency.

Besides introducing the size-constrained clustering model, the main message of this article is to highlight that full Bayesian inference is also feasible for models with combinatorial constraints, encouraging people to explore the opportunities outside independent samples. Even though probabilistic reasoning under combinatorial constraints is generally hard [Roth, 1996], many practical probabilistic models result in sufficiently small problem instances that can today be solved efficiently. Explicit constraints can hence be effective in constraining the model and often the computational overhead needed for finding the solution is small compared to the gain in overall performance. We are currently aware of only limited existing literature in this direction; Chen et al. [2005] and Dobra et al. [2006] presented MCMC algorithms for sampling contingency tables with constrained marginals, Klami [2012, 2013] considered posterior inference over permutations to solve cross-domain object matching problems, and Wang et al. [2015] presented an MCMC algorithm for combinatorial problems related to phylogenetic trees.

2 MICROCLUSTERING

Miller et al. [2015] define microclustering as any clustering model where the size of the clusters grow sublinearly with the total number of data points. Even though their formulation considers non-parametric models, the concept itself is useful also for parametric models where the number or size of the clusters is chosen via other means during the modeling process.

The core requirement for building probabilistic microclustering models is to have control over the sizes of the clusters. Regular mixture models have no control over the size distribution besides the prior weights (that can be dominated by the likelihood) because their independent data point assignment prior

$$p(\{z_n\}_{n=1}^N|\theta) = \prod_{n=1}^{N} p(z_n|\theta) \quad (1)$$

implies that the conditional posterior $p(z_n|\{z_n\}_{-n},\theta) = p(z_n|\theta)$ is independent of the other assignments. Hence the sizes of the clusters cannot influence the decision of the individual sample. Marginalizing the parameters θ out introduces such a dependency, but its nature is completely determined by the prior used on θ and cannot be controlled easily. See Wallach et al. [2010] for both theoretical and empirical analysis of the resulting cluster size distributions for various non-parametric prior processes.

Explicit control over the cluster sizes is conceptually easy to obtain, by replacing the prior in (1) with one that factorizes over the clusters and not the samples:

$$p(\{z_n\}_{n=1}^N|\theta) = \prod_{k=1}^{K} p(s_k|\theta),$$

where s_k is the number of data points assigned to the kth cluster. It is linked to the assignments as $s_k = \sum_{n=1}^N \mathbb{I}(z_n = k)$ where $\mathbb{I}(\cdot)$ evaluates to one if its argument is true and otherwise to zero. In other words, we assume that all joint assignments that result in cluster sizes $\{s_k\}_{k=1}^K$ are equally probable, and their number does not directly influence the probability.

This general formulation leaves open the specific prior given for the sizes. Miller et al. [2015] introduced a non-parametric microclustering model that assumes the cluster sizes follow a negative binomial distribution, whereas we will be using constant priors over a set of legal cluster sizes. One might also imagine other practical choices, such as constant probability for some favoured cluster size with exponential decay for violations from that size. In general, this choice will be application-specific and hence the priors should be subjective, rather unconventionally for mixture modeling in general.

2.1 SIZE-CONSTRAINED MICROCLUSTERING

In this work, we consider microclustering models with explicit hard constraints on the cluster sizes, applicable for scenarios where the (typically maximum) size of a clusters is determined by external channel constraints. These clustering models clearly belong to the family of microclustering models, since the size of the clusters is constant with respect to the total number of data points and hence sublinear. The explicit constraints are easy to formulate but require constrained optimization techniques for inference.

Our model that restricts the sizes between L and U is

$$p(\{x_n\}|\phi,\{z_n\}) = \prod_{n=1}^{N} p(x_n|\phi,z_n) = \prod_{n=1}^{N} g(x_n,\phi_{z_n}),$$
$$p(\{z_n\}) = \prod_{k=1}^{K} p(s_k), \tag{2}$$
$$p(s_k) = \frac{1}{U-L+1}\delta(L \le s_k \le U),$$

where $g(x_n,\phi_{z_n})$ is some likelihood function and the model is coupled with a suitable prior $p(\phi)$ on its parameters. In our experiments, we will use the Gaussian likelihood $\log g(x_n,\phi_k) = C - \frac{1}{2}(x_n-\mu_k)^T\tau(x_n-\mu_k)$ with diagonal precision τ and priors $\mu \sim N(\mu_0,\Sigma_0)$ and $\tau_d \sim \text{Gamma}(\alpha_0,\beta_0)$, but the core inference algorithms for $\{z\}$ works identically for any likelihood that factorizes over the samples. Here the constraints U and L are constant over the clusters, but all of the inference details apply also for cluster-specific constraints if such prior information is available.

3 INFERENCE

We now discuss the full Bayesian inference for the proposed model. The practical algorithmic details are given for a Gibbs sampler that samples the parameters ϕ of the clusters given the assignments and the assignments $\{z_n\}$ given the cluster parameters. The sampling equations for the cluster parameters are exactly as in any standard mixture model, and are not discussed here in any more detail.

The challenging part is sampling the assignments, which needs to be done jointly for all data points due to the prior distribution and constraints (2) defined for the whole collection instead of individual points. We will first briefly explain how the maximum likelihood solution is easy to find, and then proceed to present two alternatives algorithms for producing samples from the posterior distribution.

As a side remark, the microclustering model of Miller et al. [2015] sidesteps the issue of joint sampling by sampling the allocations of individual samples conditional on all others allocations, from $p(z_n|z_{-n})$. This is feasible in their model that does not have hard constraints, but results in long auto-correlation time due to aggressive conditioning. For our model such a sampler would be catastrophic if the constraints are tight; in the extreme case where the cluster sizes are forced to exact values it could never change the allocation since all clusters except the one where this data point was previously allocated at would be full.

3.1 THE MOST LIKELY ASSIGNMENT(S)

An important initial observation is that we can efficiently find the most likely assignment by solving the integer programming problem

$$\max \sum_{n=1}^{N}\sum_{k=1}^{K} \log g(x_n,z_k)\pi_{k,n}, \tag{3}$$
$$s_k = \sum_n \pi_{k,n} \ge L \quad \forall k,$$
$$s_k = \sum_n \pi_{k,n} \le U \quad \forall k,$$
$$\sum_k \pi_{k,n} = 1 \quad \forall n,$$

where π is a binary matrix whose element $\pi_{k,n}$ indicates whether the nth sample is assigned to the kth cluster. Any off-the-shelf linear programming solver will find the optimal solution in reasonable time for problems of practical size. By alternating between assignments obtained by solving (3) and maximum a posteriori choice for the cluster parameters ϕ_k, we would get a probabilistic variant of the size-constrained K-means model by Zhu et al. [2010].

Typical branch-and-bound algorithms used for solving (3) retain a list of solution candidates that are pruned away by comparing upper bounds for their value against a lower bound for the best candidate. They can be easily modified to retain a list of all possible solutions that are close enough to the optimal, to explicitly enumerate all solutions that are sufficiently likely. Given such a list of solutions $\{\pi^i\}$ and their associated log-probabilities $\{c^i\}$ we could easily sample a solution from $p(\pi=\pi^i) = \frac{\exp(c^i)}{\sum_i \exp(c^i)}$.

Unfortunately, explicitly enumerating all of the good solutions is infeasible for all but the smallest problems because their number becomes inordinately large. In the unconstrained case there are N^K possible allocations, all of which would need to be enumerated if the probabilities fall off of too slowly. We do not discuss this approach further since the cases for which it would be efficient are easy to solve by other means as well, but the optimization problem (3) is still important; we will use it for quickly creating an upper bound in our actual sampler, as well as for initializing the sampling chain.

3.2 CLUSTER SIZE ASSIGNMENT SAMPLER

3.2.1 Motivation

A more practical solution to the problem is a dynamic programming algorithm that operates in the space of possible cluster sizes, enumerating only the possible cluster size allocation vectors $r \in [L,U]^K$ instead of the sample allocation vectors $z \in [1,K]^N$. Even in the unconstrained case the maximum number of solutions to be enumerated in the end goes down from N^K to $\binom{N+K-1}{K-1}$, and for the constrained case with uniform maximum size U we have at most $\sum_{q=0}^{\min(K,\lfloor N/(U+1)\rfloor)}(-1)^q\binom{K}{q}\binom{N-q*(U+1)+K-1}{K-1}$ solutions. As a case in point, already for $N=20$, $K=8$ and

$U = 4$ these three numbers would be 2.6×10^{10}, 888.030 and 23.940. With minimum size $L = 2$ the number of possible solutions would further decrease to just 266. Enumerating 2.6×10^{10} solutions would be clearly infeasible, whereas the result set of at most 266 solutions would cause no trouble.

Operating in the space of cluster size allocations does come with a drawback as well, in the form of more difficult bounding of the solution candidates. Furthermore, the number of solution candidates in the intermediate stages is typically considerably higher than the size of the final set, but still orders of magnitude smaller than the number of individual solutions. We will next show how a reasonably efficient dynamic programming algorithm operating in the space of the cluster sizes can be designed.

3.2.2 Basic Concept

The algorithm operates on solution sets $A_a = (R_a, q_a)$, where each set contains a collection of solution candidates $R_a = \{r_a^i, p_a^i\}$ and the total probability of the set $q_a = \sum_i p_a^i$. Each solution i is characterized by a vector of cluster sizes $r_a^i \in \mathbb{N}^K$ and the associated probability p_a^i of that particular solution. Throughout the description of the algorithm, subscripts refer to the sets and superscripts to the individual solution candidates within the set, so that p_a^i means the probability of the ith solution candidate in set A_a.[1]

We build a forward-backward sampling algorithm based on dynamic programming reminiscent of the algorithm used for sampling the state sequence of Bayesian hidden Markov models [Scott, 2002]. Similar to that algorithm we make a forward pass to accumulate total probabilities of solutions and a backward pass to sample given the accumulated probabilities after each sample. For HMMs this algorithm can cover all possibilities since it only needs to keep track of K probabilities at each stage, but since we are keeping track of all possible cluster size allocations we also need to prune out solution candidates that will have negligible probability in the final set.

The overall algorithm is illustrated in Figure 1, which also demonstrates how the practical computations are performed.

3.2.3 Forward Pass

The forward pass starts by constructing N initial sets A_n, each storing the K possible cluster allocations for one sample. The probability of each solution is given by $p_n^k = g(x_n, z_k)$, and the total probability is $q_n = \sum_k p_n^k$.

[1] In practice we naturally store the values in the logarithmic domain for numerical stability, but the presentation below uses actual probabilities to avoid needing to write $\log \sum \exp(\cdot)$ for all cases where we sum up probabilities.

The first iteration of the forward pass picks two of these sets (denoted by i and j) and joins them to create a solution set $A_{i,j}$, containing all possible allocations of the two samples, stored still as the possible cluster size allocation vectors $r_{i,j}^i$ and their probabilities $p_{i,j}^i$. This join is performed by a collection of four basic operations described soon and illustrated in Figure 1.

After joining the two sets we proceed to join the resulting set with another of the initial N sets, denoted by l, this time producing the set $A_{i,j,l}$ that stores the joint allocations of all three samples. The process continues this way for $N - 1$ iterations, until all samples have been joined to the final set $A_{1:N}$. It stores the probabilities of all possible cluster size allocations that satisfy the constraints. Together with all of the intermediate sets it enables drawing a sample from the posterior using the backward pass described in Section 3.2.5.

3.2.4 Set operations

For manipulating the sets the algorithm requires four basic operations:

1. MERGE(A_a,A_b): Takes as input two sets and combines them, to produce a new set that contains all possible combinations of the solutions in the two sets: each solution in A_a is paired with each solution in A_b, so that the cluster size vectors are summed up and the probabilities are multiplied together. Note that this typically results in duplicate solution candidates, since the same sum $r_a^i + r_b^j$ can be reached in multiple ways.

2. COLLAPSE(A_a): Takes as input a solution set A_a with possible duplicates for the cluster size vectors r_a^i and returns the set so that each unique vector is represented only once. The probability of that set is obtained by summing over the probabilities associated with each duplicate: $p_a^i = \sum_j p_a^j \quad \forall r_a^j = r_a^i$.

3. CHECKCONSTRAINTS(A_a, U_a, L_a): Takes as input a solution set and returns a set that excludes all solutions that violate the constraints. That is, we keep only solutions for which $L_a \leq r_a^i \leq U_a$ holds for all K elements.

4. BOUND(A_a, b): Takes as input a solution set and returns a set that excludes all solutions for which the probability is below the bound, $p_a^i < b$.

A single iteration of the forward pass is simply a concatenation of all of the above operations: The initial sets are passed to MERGE, the result of that to COLLAPSE, and then to CHECKCONSTRAINTS and BOUND in either order. Without bounding or checking for the constraints the algorithm would simply proceed to enumerate all possible cluster size allocations, so the efficiency of the algorithm

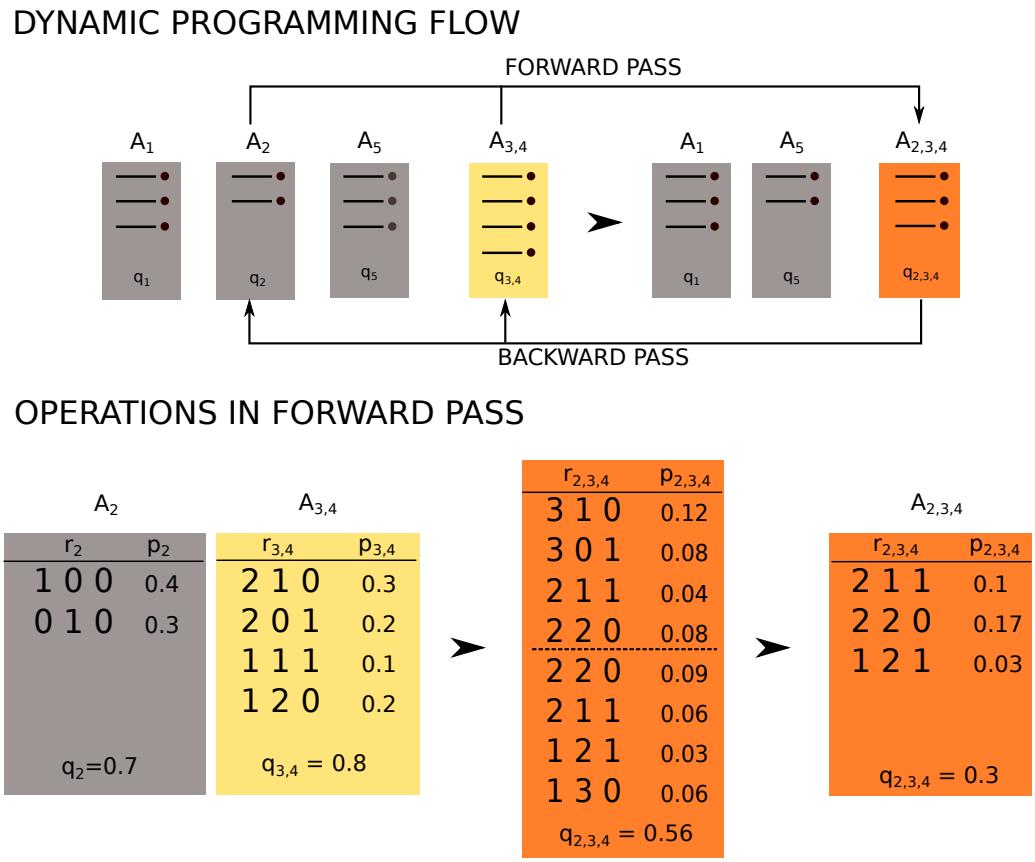

Figure 1: **Top:** Schematic overview of the dynamic programming algorithm. The forward pass computes the probabilities of possible cluster size allocation vectors by joining one sample at a time to the current overall solution set marked in yellow, producing the next overall solution set marked in orange. The backwards step then draws a sample by considering the probabilities in the intermediate sets created during the forward pass. **Bottom:** Example of an individual join. Each set stores all possible cluster size vectors r^i for the samples in that set with the associated probabilities p^i, as well as the total probability q that is their sum. The MERGE operation produces all possible combinations of the cluster size vectors of the two sets, here ordered so that the solutions above the dashed line correspond to r_2^1, and multiplies the probabilities. The COLLAPSE operation then sums up the probabilities for each unique solution, and CHECKCONSTRAINTS cuts out solutions that exceed the constraints; here solutions with cluster sizes above $U = 2$ were pruned out. Note that the total probability in the intermediate stage is simply the product of the probabilities for the incoming sets, but the probability of the final result is often considerably smaller. This allows pruning the other sets again since their upper bounds have decreased, here by $0.56 - 0.3 = 0.26$, resulting in A_5 now having only two valid solutions instead of three.

depends on how well we can cut out solution candidates based on the constraints and the bound on probabilities.

To efficiently bound the solutions in A_a we need to know an upper bound for the probability of still unprocessed samples, denoted by β_a^i, and a global lower bound for the probability of the most likely final solution, denoted by $G = \max_i p_{1:N}^i$. We can then prune out all solution candidates i in set A_a for which

$$p_a^i + \beta_a^i \leq G/\Delta,$$

where Δ is a threshold chosen sufficiently large; we use $\Delta = \exp(12)$ in our experiment, to indicate that we only prune out solutions that are guaranteed to be at least five orders of magnitude less likely than the optimal one. The bound β_a^i is obtained by inspecting the other sets A_m. Since we store with each set the total probability of all possible allocations as q_m, we obtain the bound $\beta_a^i = \sum_{m \neq a} q_m$ that is independent of the solution candidate itself. Note that the quantity G is in general unknown but we can use any lower bound for that instead and retain the validity (at the expense of longer computation time); we will return to the choice of G in Section 3.2.6.

The constraints used for CHECKCONSTRAINTS are not the original constraints, but instead we need to here look at what the remaining feasible solutions for this set are. For each set we can compute the minimum and maxi-

mum sizes of the clusters, denoted by $r_a^l = \min_i r_a^i$ and $r_a^u = \max_i r_a^i$, where the minimum and maximum are taken separately for each dimension. Then the constraints for the set A_a are given by

$$U_a = U - \sum_{m \neq a} r_m^l,$$

$$L_a = \max\left(L - \sum_{m \neq a} r_m^u, 0\right).$$

In other words, we can subtract from the global bound all the counts that we know for sure will be allocated in some future set, and we need to allocate in this set the counts that cannot be anymore allocated in the future sets.

3.2.5 Backward pass

The actual sample is produced by traversing the partial solution sets backwards, starting from the final set $A_{1:N}$. We normalize the probabilities of the possible solutions in that set and randomly sample one of those, denoting it by $r_{1:N}^l$. We then find all possible combinations of the last joined set m and its counterpart A_{-m}, that stores the solutions for all other samples, for which

$$r_m^i + r_{-m}^j = r_{1:N}^l.$$

That is, we find the possible solutions in each set that could have been paired up to create the final solution. For each of these we compute the probability $p_m^i \times p_{-m}^j$ and draw a categorical sample to indicate the cluster assignment for sample m. We then proceed backwards in the table repeating this same procedure, now using r_{-m}^j for the chosen allocation as the target vector, until at the very end we simply pick the only possible allocation for the first sample. This is guaranteed to produce a valid sample, the only error source coming from partial solution sets pruned away because of the upper bound being smaller than G/Δ.

3.2.6 Implementation Remarks

The efficiency of the algorithm depends on the order of the samples being merged into the final set. We use a simple heuristic that attempts to keep the size of the intermediate sets minimal, which proved efficient in our preliminary experiments: we keep track of the expected cluster size vector (obtained by summing simple matrix products for all remaining sets), and always join the sample that is expected to violate the maximum constraints most. If no such samples exist, we merge with the set having the smallest number of remaining solutions.

Another key element is keeping the total probabilities q_a associated with the unprocessed sets updated. Right after the initialization, we can typically exclude considerable number of solution candidates in the singleton sets because already that single assignment would make the full solution too unlikely. Since the bounding is based on the sum over all other sets, including the one that has already accumulated more samples, we should apply BOUND and CHECK-CONSTRAINTS again for all sets after each join.

Finally, we stated earlier that for bounding the candidates we need to know the probability G of the best final solution, so that we can prune out solutions for which the bounded probability is sufficiently smaller than that. Since we are operating in a depth-first manner we do not obtain such a bound with the algorithm itself. Instead, we find a lower bound for it by the following procedure: we first find the most likely individual solution by solving (3) and compute the cluster sizes $\hat{r}$ of that solution. We then solve the forward pass with constraints $L_k = U_k = \hat{r}_k$ and global bound G_0 corresponding to the total probability of all possible assignments without any constraints. This either produces a lower bound for the probability of the solution candidate corresponding to cluster sizes $\hat{r}$ or, if G_0 is too large, fails by producing an empty set. If the process failed we repeat the procedure using smaller G_0, until a valid lower bound is obtained. While this procedure is somewhat inefficient it generally still takes only a fraction of the total computation time, especially for hard instances. In our experiments, the resulting lower bound for G was also typically very close to the actual true maximum probability (seen after running the full forward pass).

Finally, for well-separated clusters it is typically not necessary to solve the whole problem in one go. Instead, we can partition the data set into disjoint subsets of data points that do not compete for the same clusters, using a simple greedy procedure. Then we can apply the algorithm for each subset separately, while still guaranteeing to produce an independent sample. In the empirical experiments we skip this step to keep the results as clear as possible (how often the problem splits into disjoint sets depends heavily on the data), but in practice it should be done since finding the disjoint sets is very light operation.

3.3 REJECTION SAMPLER

A considerably simpler algorithm for solving the same problem can be obtained by a rejection principle. Despite the simplicity, the rejection sampler presented next will still be a practical solution for some problem instances.

Given N samples to be allocated to K clusters, the rejection sampler simply allocates all samples independently, drawing the assignment for each from the normalized likelihoods $p(z_n = k) = \frac{g(x_n, z_k)}{Z}$, where Z sums over the probabilities for the different clusters k. Afterwards, the sampler checks whether the constraints on the cluster sizes are violated. If there are no violations we keep the sample. Otherwise we create another sample and check for the constraints again, continuing until a valid sample is produced.

This sampler is obviously inefficient for cases where the constraints rule out the most likely solutions, but for cases with loose constraints it is a practical tool. Often the very first sample will be accepted and the sampler is so fast that we can typically afford to re-sample quite many times.

4 EVALUATING THE ASSIGNMENT SAMPLERS

In the following we demonstrate the samplers on artificial problems. At this stage we do not consider the sampler as part of a full clustering model, but instead merely look at the process of sampling the cluster assignments given some log-probabilities for the individual assignments. In other words, we simply consider the constrained optimization task of finding all possible solutions to the maximization problem (3) that exceed a certain threshold and drawing a sample from that set.

4.1 PROBLEM INSTANCES

The difficulty of a problem instance can be described crudely along two axes: the optimality gap indicating how close the best individual solution is to the unconstrained optimal allocation, and how quickly the probabilities decay when forced to pick sub-optimal allocations. The former is tightly connected with the tightness of the constraints, whereas the latter related to the tightness and separation of the clusters.

Intuitively, the instances with small (or zero) optimality gap are good for the rejection sampler: Almost all samples produced are within the constraints and hence the sampler is almost as efficient as an unconstrained sampler would be. For the dynamic programming algorithm these instances are the worst possible ones, especially if the probabilities decay slowly; we need to enumerate an excessively large set of solutions. The other extreme of problems with tight constraints and large optimality gap is difficult for the rejection sampler, but easy for the dynamic programming variant as long as the probabilities decay quickly enough.

To study the behavior of the samplers under these characteristics we create random problem instances by sampling the log-probabilities from standard distributions and by controlling the tightness of the constraints. We do this instead of considering actual cluster assignment setups since it allows finer control over the characteristics; for real clustering instances the optimality gap and rate of decay are often correlated in a complicated manner. We return to actual clustering problems in Section 6.

4.2 RESULTS

We created random solution instances with $K \in [6, 15]$ and $N \in [36, 225]$, drawing the entries from normal distribution with zero mean and standard deviation $\sigma \in [4, 40]$. We then solved the problems with varying degree of constraints, so that each cluster size was allowed to differ from the mean by $[0, 3]$ samples. For each problem, we ran both of the above algorithms and stored the running time until a valid solution was found, terminating the samplers if it took more than 20 seconds.

We summarize the results in Figure 2, where we present the computation times as a function of the problem instance characteristics discussed above. The optimality gap is determined by simply comparing the solution of (3) to the unconstrained optimum, and for measuring the probability decay we use a simple proxy: we count for each sample the number of cluster assignments that have probability above $1/\Delta$ of the highest probability, excluding the top candidate itself, and sum them up. This approximates the number of free variables to be considered outside the best allocation, but need not correlate with the original problem size. For producing these plots we always grouped all problem instances satisfying specific conditions into one pool, reporting the quantiles of the computation time for that pool. For studying the effect of the optimality gap we only used instances for which the number of free variables is below 50, and for studying the effect of the free variables we considered cases with logarithmic optimality gap below 7.

The experiment confirms the intuitive expectations of the previous section: for small optimality gap the rejection sampler is optimal but it quickly becomes infeasible when the gap grows. The rejection sampler, meanwhile, is efficient for fast enough probability decay (or, equivalently, small enough effective problem size), but becomes extremely slow if the probabilities do not decay quickly enough. A notable observation is that the running time curves of both algorithms have a sharp curve with respect to one of the measures: The running time is reasonably constant and always manageable until some threshold in gap or probability decay, and after that the running time becomes quickly excessive. In other words, the instances with large optimality gap and small decay of probabilities are problematic for both samplers.

5 HYBRID SAMPLER

In light of the above experiments, we propose as the final sampling solution a hybrid algorithm that uses both the rejection sampler and the dynamic programming algorithm while avoiding the cases that are too slow for both of them.

For a given task of assigning N samples, we first try out with the rejection sampler for some number of tries; if we produce a valid sample we keep it and the process terminates. If we fail to produce a valid sample we proceed to evaluate the difficulty of the problem. If the problem is considered easy enough, we apply the dynamic programming algorithm to produce the sample.

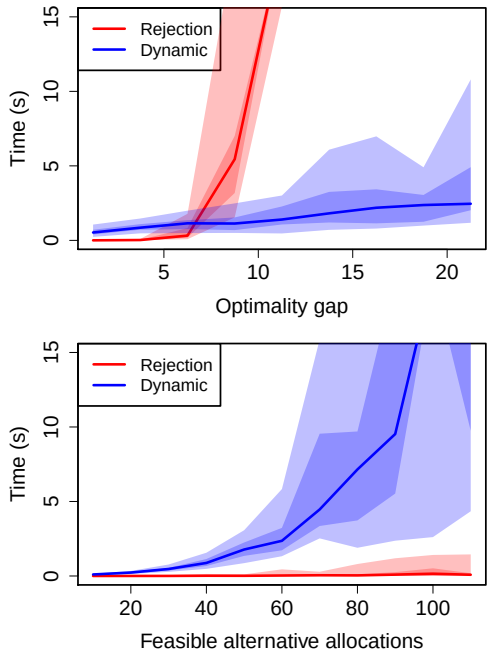

Figure 2: Comparison of running times of the two alternative sampling algorithms in producing a sample from posterior distributions $p(\{z_n\}|\{x_n\}, \phi)$ of varying difficulty. For both figures the dark shaded area indicates times between the 35% and 65% quantiles and the light shaded area between the 20% and 80% quantiles, and the times refer to single-core implementations. **Top:** The rejection sampler breaks down for logarithmic optimality gaps of roughly 7, meaning that the optimal allocation is roughly 1000 times more likely than the best feasible solution, but before that has effectively constant running time. The dynamic programming algorithm is largely insensitive to the optimality gap, but slightly slows down for the harder problems and occasionally takes longer time. **Bottom:** The dynamic programming sampler breaks down when the probabilities decay off too slowly. Here the horizontal axis denotes the count of non-optimal sample allocations with log-probabilities within 6 points of the most likely allocation for that sampler, and we see the algorithm becomes excessively slow around count 60.

If the problem is considered too challenging for the dynamic programming algorithm we split the problem into smaller chunks. We randomly divide the data point into two sets of $N/2$ instances each, and draw the assignments for each half conditional on the current assignments for the other half. For each half we again first try the rejection sampler and then consider the dynamic programming sampler or proceed to further subdivide the problem recursively. Assigning only a subset of the data points at a time naturally introduces auto-correlation in the overall sampling chain, but the time saved in not attempting to solve an overly difficult instance at once allows repeating the process enough times to produce an independent sample.

The exact criteria for when to split the problem into two halves should depend on the cost of sampling the cluster parameters ϕ given the assignments. For models where this stage is efficient, like our Gaussian likelihoods, the increased auto-correlation in sampling the assignments is not an issue and we can sample fairly small sets at once. In the other extreme, such as mixture models where approximative Bayesian computation [Csillery et al., 2010] is needed for sampling the cluster parameters, it pays off to solve the whole problem at once even if it takes a long time.

A full-blown analysis stage should inspect the rate of decline for the probabilities, the optimality gap, the number of solutions within the constraints, and possibly other statistics. In practice, however, we resort to a simpler heuristic to avoid the computation needed for the analysis (finding the optimality gap requires solving (3)); we simply use the same measure of effective problem size used in Section 4.2 and use the dynamic programming algorithm for cases where this number is small enough.

6 EVALUATING THE MICROCLUSTERING MODEL

Next we evaluate the final hybrid algorithm as part of a whole microclustering model to illustrate the balance between the two alternative solutions. As explained above, the algorithm has two parameters: The number of times the rejection sampler is tried before giving up, and the maximum complexity of the problem instance solved with the dynamic programming solver. Both parameters control how many samples can be jointly allocated; bigger values make it more likely that the sampler can allocate large number of data points at once, but at the same time increases the computational time per posterior sample. The relative ratio of these two parameters, in turn, controls how often each of the algorithms is in practice used; high number of tries and small complexity threshold imply that the rejection sampler allocates most samples, and vice versa.

Figure 3 illustrates the effect of the two parameters for an example clustering problem where the input data is uniformly distributed in a two-dimensional rectangle; the data has no natural cluster structure and hence the constraints are crucial in guaranteeing balanced cluster sizes. We show results for both 64 data points being clustered into $K = 8$ clusters and 256 data points being clustered into $K = 16$ clusters, constraining the clusters to be exactly identical in size. For both cases the results are similar: The rejection sampler takes care of the assignments of majority of the samples unless the maximum number of trials is very low, but using the dynamic sampler to solve harder problem instances helps assign more data points at a time. Both indi-

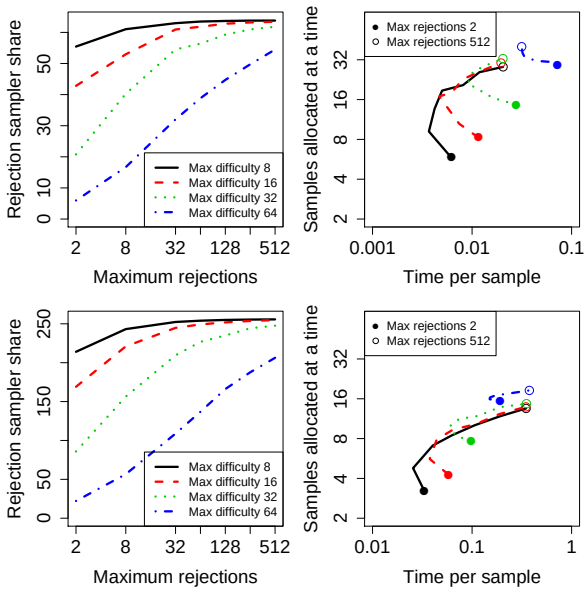

Figure 3: Illustration of the hybrid algorithm on two clustering problems. The top row corresponds to clustering $N = 64$ data points into $K = 8$ clusters and bottom row to clustering $N = 256$ samples into $K = 16$ clusters. For both cases the data points are uniformly distributed on a two-dimensional space, the clusters are forced to be of equal size, and the results are averaged over five randomly created data sets. **The left plots** show how many data points are on average assigned by the rejection sampler; the ratio naturally goes up if we try several times before giving up and down if we solve harder problems using the dynamic programming algorithm. The colored lines corresponding to different maximum difficulty scores, corresponding to the number of free variables in the problem instance as defined in Section 4.2. **The right plots** characterize the overall efficiency of the algorithm, plotting the average number of data points assigned jointly (by either algorithm) versus the computational time required for producing the whole posterior sample. Points closer to the top left corner are here the best, quickly allocating several data points at once, and we see that comparable results are obtained with several combinations for the two parameters as long as the extreme values are avoided. The color-codes in the right plot match the left one; for example, the red line shows how the behavior of the sampler evolves for maximum problem difficulty of 16 when the number of allowed rejections grows from 2 to 512.

vidual algorithms are hence useful for the overall solution. Importantly, a wide range of parameter values gives satisfactory results, suggesting that the overall algorithm is not very sensitive to the choice of the thresholds.

7 DISCUSSION

In this work we introduced a new microclustering model [Miller et al., 2015] for solving clustering tasks with predefined constraints on the sizes of the clusters, motivated by scenarios where the clusters are used, for example, in creating teams of fixed sizes [Kim et al., 2015] or for allocating items for further processing of (manual or automated) workers with limited capacity. To control the sizes we introduced a cluster assignment prior that does not factorize over the samples but instead over the clusters; this formulation is more general and can be used also for models without hard constraints. One straightforward extension would consider priors where the log-probability of the cluster decays linearly when moving away from some preferred size; for such a prior we can still find the most likely assignment easily and hence can generalize the whole sampler.

The model requires the cluster assignments to be drawn jointly for all data points, which increases the computational cost compared to standard mixture models. We discussed two alternative samplers and showed that each is efficient for a subclass of problems, and then proceeded to present a practical algorithm that can draw samples also for large data collections with the possible expense of increased auto-correlation for overly complex problem instances. The algorithm attempts to assign all samples jointly, but in case the problem instance is too difficult it recursively splits the problem into two parts and assigns the samples conditional on the assignments for the other part. Probabilistic treatment of clustering is most useful for fairly small cluster sizes that necessitate explicitly treating the full posterior, and we showed that for such setups we can draw posterior samples in a fraction of a second.

Finally, we want to encourage Bayesian practitioners to consider combinatorial constraints in their models. Even though the problem of finding all solutions that exceed a certain threshold is considerably harder than finding the best one, it is still feasible for problems of moderate size. Sampling-based probabilistic inference also comes with natural solution for splitting the problem into easier and smaller sub-problems, in form of conditioning based on a subset of the assignments. Consequently, we believe that several types of combinatorial constraints can be incorporated into typical latent-variable models and other probabilistic models with fairly low additional overhead. The auto-correlation of the sampling chain increases and the individual sampler steps typically take longer time, but one should not shy away from introducing the constraints if they are important for the model itself.

Abstract

We consider adversarial multi-armed bandit problems where the learner is allowed to observe losses of a number of arms beside the arm that it actually chose. We study the case where all non-chosen arms reveal their loss with an *unknown* probability r_t, independently of each other and the action of the learner. Moreover, we allow r_t to change in every round t, which rules out the possibility of estimating r_t by a well-concentrated sample average. We propose an algorithm which operates under the assumption that r_t is large enough to warrant at least one side observation with high probability. We show that after T rounds in a bandit problem with N arms, the expected regret of our algorithm is of order $\mathcal{O}\left(\sqrt{\sum_{t=1}^{T}(1/r_t)\log N}\right)$, given that $r_t \geq \log T/(2N-2)$ for all t. All our bounds are within logarithmic factors of the best achievable performance of any algorithm that is even allowed to know exact values of r_t.

1 INTRODUCTION

In sequential learning, a learner is repeatedly asked to choose an action for which it obtains a loss and receives a feedback from the environment (Cesa-Bianchi and Lugosi, 2006). We typically study two feedback settings: the learner either observes the losses for all the potential actions (full information) or it observes only the loss of the action it chose. This latter feedback scheme is known as the *bandit* setting (cf. Auer et al., 2002a). In this paper, instead of considering these two limit cases, we study a more refined feedback model, known as *bandit with side observations* (Mannor and Shamir, 2011; Alon et al., 2013; Kocák et al., 2014, 2016), that generalizes both of them. Typical examples for learning with full information and bandit feedback are sequential trading on a stock market (where all stock prices are fully observable after each trading period), and electronic advertising (where the learner can only observe the clicks on actually shown ads), respectively. However, advertising in a social network offers a more intricate user feedback than captured by the basic bandit model: when proposing an item to a user in a social network, the advertiser can often learn about the preferences of the user's connections as well. Naturally, the advertiser would want to improve its recommendation strategy by incorporating these side observations.

Besides advertising and recommender systems, side observations can also arise in sensor networks, where the action of the learner amounts to probing a particular sensor. In this setting, each sensor can reveal readings of some other sensors that are in its range. When our goal is to sequentially select a sensor maximizing a property of interest, a good learning strategy should be able to leverage these side readings.

In this paper, we follow the formalism of Mannor and Shamir (2011) who model side observations with a graph structure over the actions: two actions mutually reveal their losses if they are connected by an edge in the graph in question. In a realistic scenario this graph is *time dependent* and *unknown* to the learner (e.g., the advertiser or the algorithm scheduling sensor readings). All previous algorithms for the studied setting (Mannor and Shamir, 2011; Alon et al., 2013; Kocák et al., 2014, 2016) require the environment to reveal a substantial part of a graph, at least after the side observations have been revealed. Specifically, these algorithms require the knowledge of the *second neighborhood* (the set of neighbors of the neighbors) of the chosen action in order to update their internal loss estimates. On the other hand, they are able to handle arbitrary graph structures, potentially chosen by an adversary and prove performance guarantees using graph properties based on cliques or independence sets.

The main contribution of our work is a learning algorithm that, unlike previous solutions, does *not require the knowledge of the exact graph* underlying the observations, beyond knowing from which nodes the side observations

came from. Relaxing this assumption, however, has to come with a price: As the very recent results of Cohen et al. (2016) show, achieving nontrivial advantages from side observations may be impossible without perfectly known side-observation graphs when an adversary is allowed to pick *both* the losses and the side-observation graphs. On the positive side, Cohen et al. offer efficient algorithms achieving strong improvements over the standard regret guarantees under the assumption that the losses are generated in an i.i.d. fashion and the graphs may be generated adversarially. Complementing these results, we consider the case of adversarial losses and make the assumption that the side-observation graph in round t is generated from an *Erdős–Rényi* model with an *unknown* and *time-dependent* parameter r_t. The main challenge for the learner is then the necessity to exploit the side observations despite not knowing the sequence (r_t). It is easy to see that this model can be equivalently understood as each non-chosen arm revealing its loss with probability r_t, independently of all other observations. That said, we still find it useful to think of the side observations as being generated from an Erdős–Rényi model, as it allows direct comparisons with the related literature. In particular, the case of learning with Erdős–Rényi side-observation graphs was considered before by Alon et al. (2013): Given *full access* to the underlying graph structure, their algorithm `Exp3-SET` can be shown to guarantee a regret bound of $\mathcal{O}\big(\sqrt{\sum_t (1/r_t)(1-(1-r_t)^N)\log N}\big)$. While the assumption of having full access to the graph be dropped relatively easily in this particular case, exact knowledge of r_t seems to be crucial for constructing reliable loss estimates and use them to guide the choice of action in each round.

It turns out that the problem of estimating r_t while striving to perform efficiently is in fact a major difficulty in our setting. Indeed, as we allow r_t to change arbitrarily between each round, we cannot rely on any past observations to construct well-concentrated estimates of these parameters. That is, the main challenge is estimating r_t from only a handful of samples. The core technical tool underlying our approach is a direct estimation procedure for the losses that does not estimate r_t explicitly.

Armed with this estimation procedure, we propose a learning algorithm called `Exp3-Res` that guarantees a regret of $\mathcal{O}(\sqrt{\sum_t (1/r_t)\log N})$, provided that $r_t \geq \log T/(2N-2)$ holds for all rounds t. This assumption essentially corresponds to requiring that, with high probability, at least 1 side observation is produced in every round, or, in other words, the side-observation graphs encountered are all *non-empty*. Notice that for the assumed range of r_t's, our regret bound improves upon the standard regret bound of `Exp3`, which is of $\mathcal{O}(\sqrt{NT\log N})$. It is easy to see that when r_t becomes smaller than $1/N$, side observations become unreliable and the bound of `Exp3` cannot be improved. That is, if our assumption cannot be verified a priori, then ignoring all side observations and using the `Exp3` algorithm of Auer et al. (2002a) instead can yield a better performance. On the other hand, given that our assumption holds, our bounds cannot be significantly improved as suggested by the lower-bound of $\Omega(\sqrt{T/r})$ proved for a static r by Alon et al. 2013.

Many other partial-information settings have been studied in previous work. One of the simplest of these settings is the label-efficient prediction game considered by Cesa-Bianchi et al. (2005), where the learner can observe either losses of all the actions or none of them, not even the loss of the chosen action. This observation can be queried by the learner at most an $\varepsilon < 1$ fraction of the total number of rounds, which means no losses are observed in the remaining rounds. An even more restricted information setting, label efficient bandit feedback was considered by Allenberg et al. (2006), where the learner can only query the loss of the chosen action, instead of all losses (see also Audibert and Bubeck, 2010). Algorithms for these two settings have regret of $\widetilde{\mathcal{O}}(\sqrt{T/\varepsilon})$ and $\widetilde{\mathcal{O}}(\sqrt{NT/\varepsilon})$, respectively. While these bounds may appear very similar to ours, notice that our setting offers a more intricate (and, for some problems, more realistic) feedback scheme, which also turns out to be much more challenging to exploit. In another related setting, Seldin et al. (2014) consider M side observations that the learner can proactively choose in each round without limitations. Seldin et al. deliver an algorithm with regret of $\widetilde{\mathcal{O}}(\sqrt{(N/M)T})$, also proving that choosing M observations uniformly at random is minimax optimal; given this sampling scheme, it is not even necessary to observe the loss of the chosen action. Their result is comparable to ours and the result by Alon et al. (2013) for Erdős–Rényi observation graphs with parameter $r = M/N$. However, Seldin et al. also assume that M is known, which obviates the need for estimating r. We provide a more technical discussion on the related work in Section 6.

In our paper, we assume that, just like the observation probabilities, the losses are *adversarial*, that is, they can change at each time step without restrictions. Learning with side observations and stochastic losses was studied by Caron et al. (2012) and Buccapatnam et al. (2014). While this is an easier setting that the adversarial one, the authors assumed, in both cases, that the graphs have to be known in advance. Recently, Carpentier and Valko (2016) studied another stochastic setting where the graph is also not known in advance, however their setting considers different feedback and loss structure (influence maximization) which differs from the side-observation setting.

Furthermore, Alon et al. (2015) considered a strictly more difficult setting than ours, where the loss of the chosen action may not be a part of the received feedback.

2 PROBLEM DEFINITION

We now formalize our learning problem. We consider a sequential interaction scheme between a learner and an environment, where the following steps are repeated in every round $t = 1, 2, \ldots, T$:

1. The environment chooses $r_t \in [0, 1]$ and a loss function over the arms, with $\ell_{t,i}$ being the loss associated with arm $i \in [N] \stackrel{\text{def}}{=} \{1, 2, \ldots, N\}$ at time t.
2. Based on its previous observations (and possibly some randomness), the learner draws an arm $I_t \in [N]$.
3. The learner suffers loss ℓ_{t,I_t}.
4. For all $i \neq I_t$, $O_{t,i}$ is independently drawn from a Bernoulli distribution with mean r_t. Furthermore, O_{t,I_t} is set as 1.
5. For all $i \in [N]$ such that $O_{t,i} = 1$, the learner observes the loss $\ell_{t,i}$.

The goal of the learner is to minimize its total expected losses, or, equivalently, to minimize the *total expected regret* (or, in short, regret) defined as

$$R_T = \max_{i \in [N]} \mathbb{E}\left[\sum_{t=1}^{T} \left(\ell_{t,I_t} - \ell_{t,i}\right)\right].$$

We will denote the interaction history between the learner and the environment up to the beginning of round t by $\mathcal{F}_{t-1}$. We also define $p_{t,i} = \mathbb{P}\left[I_t = i \middle| \mathcal{F}_{t-1}\right]$.

The main challenge in our setting is leveraging side observations *without knowing* r_t. Had we had access to the exact value of r_t, we would be able to define the following estimate of $\ell_{t,i}$:

$$\widehat{\ell}^{\star}_{t,i} = \frac{O_{t,i}\ell_{t,i}}{p_{t,i} + (1 - p_{t,i})r_t} \tag{1}$$

It is easy to see that the loss estimates defined this way are unbiased in the sense that $\mathbb{E}\left[\widehat{\ell}_{t,i} \middle| \mathcal{F}_{t-1}\right] = \ell_{t,i}$ for all t and i. It is also straightforward to show that an appropriately tuned instance of the Exp3 algorithm of Auer et al. (2002a) fed with these loss estimates is guaranteed to achieve a regret of $\mathcal{O}(\sqrt{\sum_t (1/r_t) \log N})$ (see also Seldin et al. 2014).

Then, one might consider a simple algorithm that devotes a number of observations to obtain an estimate $\widehat{r}_t$ of r_t and plug this estimate into (1). However, notice that since r_t is allowed to change arbitrarily over time, we can only work with a severely limited sample budget for estimating r_t: only $N - 1$ independent observations! Thus, we can obtain only very loose confidence intervals around r_t which translate to even more useless confidence intervals around $\widehat{\ell}^{\star}_{t,i}$.

Below, we describe a simple trick for obtaining loss estimates that have similar properties to the ones defined in (1) without requiring exact knowledge or even explicit estimation of r_t. Our procedure is based on the geometric resampling method of Neu and Bartók (2013). To get an intuition of the method, let us assume that we have access to the independent geometrically distributed random variable $G^{\star}_{t,i}$ with parameter $o_{t,i} = p_{t,i} + (1 - p_{t,i})r_t$. Then, replacing $1/o_{t,i}$ by $G^{\star}_{t,i}$ in the definition of $\widehat{\ell}^{\star}_t$ and ensuring that $G^{\star}_{t,i}$ is independent of $O_{t,i}$, we can obtain an unbiased loss estimate essentially equivalent to $\widehat{\ell}^{\star}_t$.

The challenge posed by this approach is that in our setting, we do not have exact sample access to the geometric random variable $G^{\star}_{t,i}$. In the next section, we describe our algorithm that is based on replacing $G^{\star}_{t,i}$ in the above definition by an appropriate surrogate.

3 ALGORITHM

Our algorithm is called `Exp3-Res` and displayed as Algorithm 1. It is based on the `Exp3` algorithm of Auer et al. (2002a) and crucially relies on the construction of a surrogate $G_{t,i}$ of $G^{\star}_{t,i}$. Throughout this section, we will assume that $r_t \geq \frac{\log T}{2N-2}$, which implies that the probability of having no side observations in round t is of order $1/\sqrt{T}$.

The algorithm is initialized by setting $w_{1,i} = 1/N$ for all $i \in [N]$, and then performing the updates

$$w_{t+1,i} = \frac{1}{N} \exp\left(-\eta_{t+1} \widehat{L}_{t,i}\right) \tag{2}$$

after each round t, where $\eta_{t+1} > 0$ is a parameter of the algorithm called the *learning rate* in round t and $\widehat{L}_{t,i}$ is cumulative sum of the loss estimates $\widehat{\ell}_{s,i}$ up to (and including) time t. In round t, the learner draws its action I_t such that $I_t = i$ holds with probability $p_{t,i} \propto w_{t,i}$. To simplify some of the notation below, we introduce the shorthand notations $\mathbb{P}_t[\cdot] = \mathbb{P}\left[\cdot \middle| \mathcal{F}_{t-1}\right]$ and $\mathbb{E}_t[\cdot] = \mathbb{E}\left[\cdot \middle| \mathcal{F}_{t-1}\right]$.

For any fixed t, i, we now describe an efficiently computable surrogate $G_{t,i}$ for the geometrically distributed random variable $G^{\star}_{t,i}$ with parameter $o_{t,i}$ that will be used for constructing our loss estimates. In particular, our strategy will be to construct several independent copies $\{O'_{t,i}(k)\}$ of $O_{t,i}$ and choosing $G_{t,i}$ as the index k of the first copy with $O'_{t,i}(k) = 1$. It is easy to see that with infinitely many copies, we could exactly recover $G^{\star}_{t,i}$; our actual surrogate is going to be weaker thanks to the smaller sample size. For clarity of notation, we will omit most explicit references to t and i, with the understanding that all calculations need to be independently executed for all pairs t, i.

Let us now describe our mechanism for constructing the copies $\{O'(k)\}$. Since we need independence of $G_{t,i}$ and $O_{t,i}$ for our estimates, we use only side observations from

actions $[N] \setminus \{I_t, i\}$. First, let's define σ as a uniform random permutation of $[N] \setminus \{I_t, i\}$. For all $k \in [N-2]$, we define $R(k) = O_{t,\sigma(k)}$. Note that due to the construction, $\{R(k)\}_{k=1}^{N-2}$ are pairwise independent Bernoulli random variables with parameter r_t, independent of $O_{t,i}$. Furthermore, knowing $p_{t,i}$ we can define $P(1), \ldots, P(N-2)$ as pairwise independent Bernoulli random variables with parameter $p_{t,i}$. Using $P(k)$ and $R(k)$ we define the random variable $O'(k)$ as

$$O'(k) = P(k) + (1 - P(k))R(k)$$

for all $k \in [N-2]$. Using independence of all previously defined random variables, it is easy to check that the variables $\{O'(k)\}_{k=1}^{N-2}$ are pairwise independent Bernoulli random variables with expectation $o_{t,i} = p_{t,i} + (1-p_{t,i})r_t$. Now we are ready to define $G_{t,i}$ as

$$G_{t,i} = \min\left\{k \in [N-2] : O(k)' = 1\right\} \cup \{N-1\}. \quad (3)$$

The following lemma states some properties of $G_{t,i}$.

Lemma 1. *For any value of g we have*

$$\mathbb{E}\left[G_{t,i}\right] = \frac{1}{o_{t,i}} - \frac{1}{o_{t,i}}(1-o_{t,i})^{N-1}$$
$$\mathbb{E}\left[G_{t,i}^2\right] = \frac{2-o_{t,i}}{o_{t,i}^2} + \frac{1}{o_{t,i}^2}(1-o_{t,i})^{N-2} \times$$
$$\times \left(o_{t,i}^2 + o_{t,i} - 2 + 2o_{t,i}(N-2)(o_{t,i}-1)\right)$$

Proof. The proof follows directly from using the definition of $G_{t,i}$ and simplifying the sums

$$\mathbb{E}\left[G_{t,i}\right] = \sum_{k=1}^{N-2}\left[k o_{t,i}(1-o_{t,i})^{k-1}\right] + \\ + (N-1)\left(1-o_{t,i}\right)^{N-2},$$
$$\mathbb{E}\left[G_{t,i}^2\right] = \sum_{k=1}^{N-2}\left[k^2 o_{t,i}(1-o_{t,i})^{k-1}\right] + \\ + (N-1)^2\left(1-o_{t,i}\right)^{N-2}.$$

□

Using Lemma 1, it is easy to see that $G_{t,i}$ follows a truncated geometric law in the sense that

$$\mathbb{P}\left[G_{t,i} = m\right] = \mathbb{P}\left[\min\left\{G_{t,i}^\star, N-1\right\} = m\right]$$

holds for all $m \in [N-1]$. Using all this notation, we construct an estimate of $\ell_{t,i}$ as

$$\widehat{\ell}_{t,i} = G_{t,i} O_{t,i} \ell_{t,i}. \quad (4)$$

The rationale underlying this definition of $G_{t,i}$ is rather delicate. First, note that $p_{t,i}$ is deterministic given the history $\mathcal{F}_{t-1}$ and therefore, does not depend on $O_{t,i}$. Second,

Algorithm 1 `Exp3-Res`

Input:
Set of actions $[N]$.
Initialization:
$\widehat{L}_{0,i} \leftarrow 0$ for $i \in [N]$.
Run:
for $t = 1$ **to** T **do**
  $\eta_t \leftarrow \sqrt{\log N \Big/ \left(N^2 + \sum_{s=1}^{t-1}\sum_{i=1}^{N} p_{s,i}(\widehat{\ell}_{s,i})^2\right)}$.
  $w_{t,i} \leftarrow (1/N)\exp(-\eta_t \widehat{L}_{t-1,i})$ for $i \in [N]$.
  $W_t \leftarrow \sum_{i=1}^{N} w_{t,i}$.
  $p_{t,i} \leftarrow w_{t,i}/W_t$.
  Choose $I_t \sim p_t = (p_{t,1}, \ldots, p_{t,N})$.
  Receive the observation set O_t.
  Receive the pairs $\{i, \ell_{t,i}\}$ for all i s.t. $O_{t,i} = 1$.
  Compute $G_{t,i}$ for all $i \in [N]$ using (3).
  $\widehat{\ell}_{t,i} \leftarrow \ell_{t,i} O_{t,i} G_{t,i}$ for all $i \in [N]$.
  $\widehat{L}_{t,i} = \widehat{L}_{t-1,i} + \widehat{\ell}_{t,i}$ for all $i \in [N]$.
end for

$O_{t,i}$ is also independent of $O_{t,j}$ for $j \notin \{i, I_t\}$. As a result, $G_{t,i}$ is independent of $O_{t,i}$, and we can use the identity $\mathbb{E}_t\left[G_{t,i}O_{t,i}\right] = \mathbb{E}_t\left[G_{t,i}\right]\mathbb{E}_t\left[O_{t,i}\right]$. The next lemma relates the loss estimates (4) to the true losses, relying on the observations above and the assumption $r_t \geq \frac{\log T}{2N-2}$.

Lemma 2. *Assume $r_t \geq \frac{\log T}{2N-2}$. Then, for all t and i,*

$$0 \leq \ell_{t,i} - \mathbb{E}_t\left[\widehat{\ell}_{t,i}\right] \leq \frac{1}{\sqrt{T}}.$$

Proof. Fix an arbitrary t and i. Using Lemma 1 along with $\mathbb{E}_t\left[O_{t,i}\right] = o_{t,i}$ and the independence of $G_{t,i}$ and $O_{t,i}$, we get

$$\mathbb{E}_t\left[\widehat{\ell}_{t,i}\right] = \mathbb{E}_t\left[G_{t,i}O_{t,i}\ell_{t,i}\right] = \ell_{t,i} - \ell_{t,i}(1-o_{t,i})^{N-1},$$

which immediately implies the lower bound on $\ell_{t,i} - \mathbb{E}_t\left[\widehat{\ell}_{t,i}\right]$. For proving the upper bound, observe that

$$\ell_{t,i}(1-o_{t,i})^{N-1} \leq (1-r_t)^{N-1} \leq e^{-r_t(N-1)} \leq \frac{1}{\sqrt{T}}$$

holds by our assumption on r_t, where we used the elementary inequality $1 - x \leq e^x$ that holds for all $x \in \mathbb{R}$. □

The next theorem states our main result concerning `Exp3-Res` with an adaptive learning rate.

Theorem 1. *Assume that $r_t \geq \frac{\log T}{2N-2}$ holds for all t and set*

$$\eta_t = \sqrt{\frac{\log N}{N^2 + \sum_{s=1}^{t-1}\sum_{i=1}^{N} p_{s,i}(\widehat{\ell}_{s,i})^2}}.$$

Then, the expected regret of `Exp3-Res` *satisfies*

$$R_T \leq 2\sqrt{\left(N^2 + \sum_{t=1}^{T} \frac{1}{r_t}\right) \log N} + \sqrt{T}.$$

4 PROOF OF THEOREM 1

In this section, we present details of the proof of Theorem 1 but first, we state an auxiliary lemma.

Lemma 3 (Lemma 3.5 of Auer et al., 2002b)**.** *Let* b_1, b_2, $\ldots$, b_T *be non-negative real numbers. Then*

$$\sum_{t=1}^{T} \frac{b_t}{\sqrt{\sum_{s=1}^{t} b_t}} \leq 2\sqrt{\sum_{t=1}^{T} b_t}.$$

Proof. The proof is based on the inequality $x/2 \leq 1 - \sqrt{1-x}$ for $x \leq 1$. Setting $x = b_t / \sum_{s=1}^{t} b_s$ and multiplying both sides of the inequality by $\sqrt{\sum_{s=1}^{t} b_s}$ we get

$$\frac{b_t}{\sqrt{\sum_{s=1}^{t} b_t}} \leq \sqrt{\sum_{s=1}^{t} b_s} - \sqrt{\sum_{s=1}^{t} b_s - b_t}.$$

The proof is concluded by summing over t. □

The first part of the analysis follows the proof of Lemma 1 by Györfi and Ottucsák (2007). Defining $W'_t = \frac{1}{N}\sum_{i=1}^{N} e^{-\eta_{t-1}\widehat{L}_{t-1,i}}$, we get

$$\begin{aligned}
\frac{1}{\eta_t}\log\frac{W'_{t+1}}{W_t} &= \frac{1}{\eta_t}\log\sum_{i=1}^{N}\frac{\frac{1}{N}e^{-\eta_t\widehat{L}_{t-1,i}}e^{-\eta_t\widehat{\ell}_{t,i}}}{W_t} \\
&= \frac{1}{\eta_t}\log\sum_{i=1}^{N} p_{t,i}e^{-\eta_t\widehat{\ell}_{t,i}} \\
&\leq \frac{1}{\eta_t}\log\sum_{i=1}^{N} p_{t,i}\left(1 - \eta_t\widehat{\ell}_{t,i} + (\eta_t\widehat{\ell}_{t,i})^2\right) \qquad (5) \\
&= \frac{1}{\eta_t}\log\left(1 - \eta_t\sum_{i=1}^{N} p_{t,i}\widehat{\ell}_{t,i} + \eta_t^2\sum_{i=1}^{N} p_{t,i}(\widehat{\ell}_{t,i})^2\right),
\end{aligned}$$

where in (5), we used the inequality $\exp(-x) \leq 1 - x + x^2$ that holds for $x \geq -1$. Further, we used the inequality $\log(1-x) \leq -x$, which holds for all $x \leq 1$, to upper bound last term.

Using $\eta_{t+1} \leq \eta_t$ and Jensen's inequality, we get

$$\begin{aligned}
W_{t+1} &= \sum_{i=1}^{N}\frac{1}{N}e^{-\eta_{t+1}\widehat{L}_{t,i}} = \sum_{i=1}^{N}\frac{1}{N}\left(e^{-\eta_t\widehat{L}_{t,i}}\right)^{\frac{\eta_{t+1}}{\eta_t}} \\
&\leq \left(\sum_{i=1}^{N}\frac{1}{N}e^{-\eta_t\widehat{L}_{t,i}}\right)^{\frac{\eta_{t+1}}{\eta_t}} = (W'_{t+1})^{\frac{\eta_{t+1}}{\eta_t}},
\end{aligned}$$

which, together with the last inequality, gives us

$$\sum_{i=1}^{N} p_{t,i}\widehat{\ell}_{t,i} \leq \frac{\eta_t}{2}\sum_{i=1}^{N} p_{t,i}\left(\widehat{\ell}_{t,i}\right)^2 + \left[\frac{\log W_t}{\eta_t} - \frac{\log W_{t+1}}{\eta_{t+1}}\right]$$

for every $t \in [T]$. Taking expectations and summing over time, we get

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i=1}^{N} p_{t,i}\widehat{\ell}_{t,i}\right] &\leq \mathbb{E}\left[\sum_{t=1}^{T}\frac{\eta_t}{2}\sum_{i=1}^{N} p_{t,i}\left(\widehat{\ell}_{t,i}\right)^2\right] \\
&\quad + \mathbb{E}\left[\sum_{t=1}^{T}\left(\frac{\log W_t}{\eta_t} - \frac{\log W_{t+1}}{\eta_{t+1}}\right)\right].
\end{aligned}$$

The goal of the second part of the analysis is to construct bounds for each of the three expectations in the previous inequality. For the term on the left-hand side, we use Lemma 2 to get the lower-bound

$$\mathbb{E}\left[\sum_{t=1}^{T}\sum_{i=1}^{N} p_{t,i}\widehat{\ell}_{t,i}\right] \geq \sum_{t=1}^{T}\sum_{i=1}^{N} p_{t,i}\ell_{t,i} + \sqrt{T}.$$

Note that is the only step in the analysis where the actual magnitude (and not just the sign) of the bias of the loss estimates shows up. Anything bigger than $\sqrt{T}$ would degrade our final regret bound.

We are left with bounding the two terms on the right-hand side. To simplify some notation below, let us define $b_t = \sum_{i=1}^{N} p_{t,i}(\widehat{\ell}_{t,i})^2$. By our definition of η_t and the help of Lemma 3, we can bound the first term on the right hand side as

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=1}^{T}\frac{\eta_t b_t}{2}\right] &= \mathbb{E}\left[\sum_{t=1}^{T}\frac{b_t\sqrt{\log N}}{2\sqrt{N^2 + \sum_{s=1}^{t-1} b_s}}\right] \\
&\leq \mathbb{E}\left[\sqrt{\left(N^2 + \sum_{t=1}^{T} b_t\right)\log N}\right] \\
&\leq \sqrt{\left(N^2 + \sum_{t=1}^{T}\mathbb{E}\left[b_t\right]\right)\log N},
\end{aligned}$$

where we also used the fact that $N^2 \geq b_t$ and Jensen's inequality in the last line. We continue by bounding $\mathbb{E}[b_t]$:

$$\begin{aligned}
\mathbb{E}_t\left[\sum_{i=1}^{N} p_{t,i}(\widehat{\ell}_{t,i})^2\right] &= \sum_{i=1}^{N} p_{t,i}\ell_{t,i}^2\mathbb{E}_t\left[O_{t,i}G_{t,i}^2\right] \\
&\leq \sum_{i=1}^{N} p_{t,i}o_{t,i}\frac{2 - o_{t,i}}{o_{t,i}^2} \leq \frac{2}{r_t}, \qquad (6)
\end{aligned}$$

where we used $o_{t,i} \geq r_t$ together with the second part of Lemma 1 which gives us

$$\mathbb{E}_t\left[G_{t,i}^2\right] = \frac{2-o_{t,i}}{o_{t,i}^2} + \frac{1}{o_{t,i}^2}(1-o_{t,i})^{N-2}\times$$
$$\times\left(o_{t,i}^2 + o_{t,i} - 2 + 2o_{t,i}(N-2)(o-1)\right)$$
$$\leq \frac{2-o_{t,i}}{o_{t,i}^2},$$

since both $o_{t,i}^2 + o_{t,i} - 2$ and $2o_{t,i}(N-2)(o-1)$ are non-positive. Thus, we obtain

$$\mathbb{E}\left[\sum_{t=1}^{T}\frac{\eta_t b_t}{2}\right] \leq \sqrt{\left(\sum_{t=1}^{T}\frac{1}{r_t} + N^2\right)\log N}. \qquad (7)$$

Finally, using $W_1 = 1$, the sum in the last expectation telescopes to

$$\mathbb{E}\left[\sum_{t=1}^{T}\left(\frac{\log W_t}{\eta_t} - \frac{\log W_{t+1}}{\eta_{t+1}}\right)\right] = \mathbb{E}\left[-\frac{\log W_{T+1}}{\eta_{T+1}}\right].$$

Using the definition of W_t, we get that

$$\mathbb{E}\left[-\frac{\log W_{T+1}}{\eta_{T+1}}\right] \leq \mathbb{E}\left[-\frac{\log w_{T+1,j}}{\eta_{T+1}}\right]$$
$$\leq \mathbb{E}\left[\frac{\log N}{\eta_{T+1}}\right] + \mathbb{E}\left[\widehat{L}_{T,j}\right]$$

holds for any arm $j \in [N]$. Now note that the first term can be bounded by using the defintion of η_{T+1} with the help of (6) and Jensen's inequality. Using $\mathbb{E}_t\left[\widehat{\ell}_{t,i}\right] \leq \ell_{t,i}$ from Lemma 2 and combining everything together, we obtain the regret bound

$$R_T = \mathbb{E}\left[\sum_{t=1}^{T} p_{t,i}\ell_{t,i}\right] - \min_{j\in[N]}\mathbb{E}\left[\sum_{t\in T_k}\ell_{t,j}\right]$$
$$\leq 2\sqrt{\left(N^2 + \sum_{t=1}^{T}\frac{1}{r_t}\right)\log N} + \sqrt{T}.$$

5 EXPERIMENTS

In this section, we study the empirical performance of Exp3-Res compared to three other algorithms:

- Exp3 – a basic adversarial multi-armed bandit algorithm which uses only loss observations of chosen arms and discards all side observations.
- Oracle – full-information algorithm with access to losses of every action in every time step, regardless of the value of r_t. Our particular choice is Hedge (Littlestone and Warmuth, 1994; Freund and Schapire, 1997).
- Exp3-R – a variant of the Exp3-Res algorithm with access to the sequence $(r_t)_t^T$, using (1) to construct unbiased loss estimate instead of using geometric resampling.

The most interesting parameter of our experiment is the sequence (r_t), since it controls amount of side observation presented to the learner. In order to show that Exp3-Res can effectively make use of the additional information provided by the environment, we designed several sequences (r_t) with different amounts of side observation provided to the learner. In the case of small r_t-s, the problem is almost as difficult as the multi-armed bandit problem. On the other hand, in the case of large r_t-s, the problem is almost as easy as the full-information problem. Therefore, we expect that the performance of Exp3-Res will interpolate between the performance of the Exp3-R and Oracle algorithms depending on the values of the r_t-s. In the next section, we validate this claim empirically.

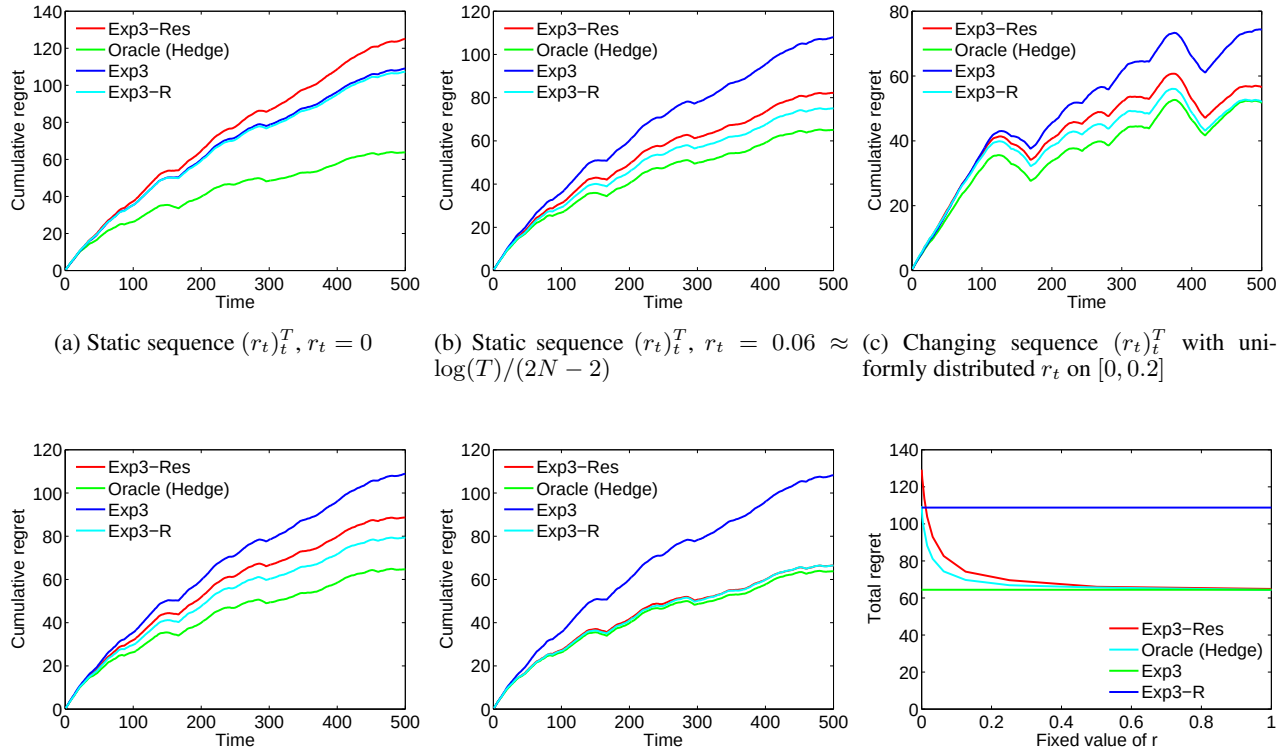
5.1 EXPERIMENT DETAILS

To ensure sufficient challenge for the algorithms, we have generated a sequence of losses as a random walk for each arm with independent increments uniformly distributed on $[-0.1, 0.1]$ while enforcing the random walks to stay within $[0, 1]$ by setting the value of a random walk to 0 or 1, respectively, if the random walk gets outside the boundaries. The loss sequence is fixed through all of the experiments to demonstrate the impact of the sequence $(r_t)_t^T$ on the regret of algorithms. We have observed qualitatively similar behavior for other loss sequences.

We fix the number of arms in all of the experiments as 50, and the time horizon as 500. Every curve represents an average of 100 runs.

5.2 RESULT OF THE EXPERIMENTS

We performed experiments on many different loss sequences and sequences of r_t-s. Since the results are essentially the same for all the different sequences, we included in the present paper just the results for one loss sequence with different sequences of r_t-s. In the case of $r_t \geq \log(T)/(2N-2)$, the case of high probability of having some side observation, the performance of the algorithm Exp3-Res proposed in the present paper is comparable to the performance of the idealistic Exp3-R which knows exact value of r_t in every time step. Moreover, if the average r_t is close to 1, the performance of the proposed algorithm is close to the performance of Oracle which observes all the losses. If the average r_t is close to zero, the performance of the algorithm is a little bit worse that the performance of basic Exp3. This is also supported by the theory, since our algorithm is not able to construct reliable estimates in the case of small r_t-s.



(a) Static sequence $(r_t)_t^T$, $r_t = 0$

(b) Static sequence $(r_t)_t^T$, $r_t = 0.06 \approx \log(T)/(2N-2)$

(c) Changing sequence $(r_t)_t^T$ with uniformly distributed r_t on $[0, 0.2]$

(d) Sequence $(r_t)_t^T$ generated as a random walk on $[0, 0.1]$

(e) Sequence $(r_t)_t^T$ generated as a random walk on $[0, 1]$

(f) Total regret for different values of static $(r_t)_t^T$

Figure 1: Comparison of algorithm for different amount of side information sequences (different sequences $(r_t)_t^T$)

6 CONCLUSION & FUTURE WORK

In this paper, we considered multi-armed bandit problems with stochastic side observations modeled by Erdős–Rényi graphs. Our contribution is a computationally efficient algorithm that operates under the assumption $r_t \geq \log T/(2N-2)$, which essentially guarantees that at least one piece of side observation is generated in every round, with high probability. In this case, our algorithm guarantees a regret bound of $\mathcal{O}\left(\sqrt{\log N \sum_{t=1}^{T} \frac{1}{r_t}}\right)$ (Theorem 1). In this section, we discuss several open questions regarding this result.

The most obvious question is whether it is possible to remove our assumptions on the values of r_t. We can only give a definite answer in the simple case when all r_t's are identical: In this case, one can think of simply computing the empirical frequency $\widehat{r}_t$ of all previous side observations in round t to estimate the constant r, plug the result into (1), and then use the resulting loss estimates in an exponential-weighting scheme. It is relatively straightforward (but also rather tedious) to show that the resulting algorithm satisfies a regret bound of $\widetilde{\mathcal{O}}\left(\sqrt{T/r}\right)$ for all possible values of r, thanks to the fact that $\hat{r}_t$ quickly concentrates around the true value of r. Notice however that this approach clearly breaks down if the r_t's change over time.

In the case of changing r_t's, the number of observations we can use to estimate r_t is severely limited, so much that we cannot expect any direct estimate of r_t to concentrate around the true value. Our algorithm proposed in Section 3 gets around this problem by directly estimating the importance weights $1/o_{t,i}$ instead of r_t, which enables us to construct reliable loss estimates, although only at the price of our assumption on the range of r_t. While we acknowledge that this assumption can be difficult to confirm a priori in practice, we remark that we find it quite surprising that *any algorithm whatsoever* can take advantage of such limited observations, even under such a restriction. We also point out that for values of r_t that are consistently below our bound, it is not possible to substantially improve the regret bounds of `Exp3` which are of $\widetilde{\mathcal{O}}\left(\sqrt{TN}\right)$, as shown by the lower bounds of Alon et al. (2013). We expect that in several practical applications, one can verify whether the r_t's satisfy our assumption or not, and decide to use `Exp3-Res` or `Exp3` accordingly. In fact, our experiments suggest that our algorithm performs well even if neither of these two assumptions are verified: we have seen that the empirical performance of `Exp3-Res` is only slightly worse than that

of Exp3 even when the values of r_t are very small (Section 5). Still, finding out whether our restriction on r_t can be relaxed in general is a very important and interesting question left for future study.

An important corollary of our results is that, under some assumptions, it is possible to leverage side observations in a non-trivial way without having access to the second neighborhoods in the side-observation graphs as defined by Mannor and Shamir (2011). This complements the recent results of Cohen et al. (2016), who show that non-stochastic side-observations may provide non-trivial advantage over bandit feedback when the losses are stochastic even when the side-observation graphs are unobserved, but learning with unobserved feedback graphs can be as hard as learning with bandit feedback when both the losses and the graphs are generated by an adversary. A natural question that our work leads to is whether it is possible to efficiently leverage side-observations under significantly weaker assumptions on the observation model.

Abstract

Binary classification (rain or shine, disease or not, increase or decrease) is a fundamental problem in machine learning. We present an algorithm that can take any standard online binary classification algorithm and provably improve its performance under very weak assumptions, given the right to refuse to make predictions in certain cases. The extent of improvement will depend on the data size, stability of the algorithm, and room for improvement in the algorithms performance. Our experiments on standard machine learning data sets and standard algorithms (k-nearest neighbors and random forests) show the effectiveness of our approach, even beyond what is possible using previous work on conformal predictors upon which our approach is based. Though we focus on binary classification, our theory could be extended to multiway classification. Our code and data are available upon request.

1 INTRODUCTION

Reacting intelligently to incoming data lies at the heart of forecasting, trading, and many other applications. The simplest decision one has to make is binary (go/stop, buy/sell). However, in many cases one needs to assess the risk of a decision and refuse to make a decision at all if one is not confident enough. One of the well known methodologies for this task is using confidence predictors and declining to make a decision on ambiguous data points (Vovk, Gammerman, & Shafer, 2005). Intuitively, conformal predictors look at how previous predictions worked out for similar input data and let those results shape first whether to make a prediction at all and if so, which one to make. We extend existing conformal prediction approaches by permitting the use of multidimensional test statistics to provide more flexibility while keeping the theoretical guarantees of the original predictors. We apply this extended framework to the binary classification problem and show that our methods improve the performance of previous conformal predictors.

1.1 Related Work

Forecasting the upcoming data point in a data stream has been studied in econometrics, meteorology, finance, computer science, and many other disciplines (Box, Jenkins, Reinsel, & Ljung, 2015). In confidence predictors, the goal is to create a set of possible candidate outcomes such that the probability that the real outcome is not one of these candidates is less than a predetermined tolerance level. Some examples for the uses of confidence predictions include signal denoising (Ryabko & Ryabko, 2013), growth estimation for planning (Meade & Islam, 1995), among many similar forecast problems that requires bounds for the predicted values (Chatfield, 1993). Though most of the confidence prediction literature considers either parametric models or asymptotic results, Vovk, Gammerman and Shaffer (Vovk et al., 2005) introduced the conformal prediction framework, which provides exact finite-sample guarantees for exchangeable data sequences.

Binary classification problems where the classifier is allowed to decline making a decision has been studied both in online and offline settings. Optimal error-rejection tradeoffs are investigated under the names *selective classification* (El-Yaniv & Wiener, 2010, 2012), (Chaudhuri & Zhang, 2013) and *classification with reject option* (Denis & Hebiri, 2015), (Chow, 1970), (Herbei & Wegkamp, 2006).

Following this work, we focus on the conformal prediction approach to the online binary classification with reject option, and propose an extended framework to decrease the number of rejects while guaranteeing a small probability of error on the classified points.

1.2 Outline & Contributions

In Section 2, we describe our problem formally and provide some background information on online confidence

prediction and conformal prediction. In Section 3, we extend the conformal prediction framework to multiple dimensions and then show how to preserve the theoretical error guarantees provided by the conformal framework, while rejecting less often.

The flexibility provided by this multidimensional framework is demonstrated in Section 4, where we introduce the notion of *conjugate conformal prediction*. Formally, a *conjugate conformal predictor* is a two dimensional conformal predictor derived from any given traditional conformal predictor. Intuitively, conjugate predictors not only compare the test point with the previous ones, but also compare the test point with its conjugate, i.e. the same point with its label flipped, to be able to make more aggressive predictions - not only when we have high confidence to accept the test point but also when we have high confidence to reject the conjugate point.

In Section 4.1, we define conjugate conformal predictors formally and prove their efficiency under mild stability assumptions on the set statistics used in the original predictor. Lastly, in Section 4.2. we present experimental results for classical conformal and conjugate conformal predictors on standard machine learning data sets from UCI ML Repository (Lichman, 2013) and standard machine learning algorithms (k nearest neighbors and random forests).

Finally, in Section 5 we conclude with a brief discussion of our results and planned future work.

2 PROBLEM SETUP & CONFORMAL PREDICTION

2.1 Data Model & Notation

In this work, we assume data points are revealed to the algorithm, one data point at a time. A data point generated at time t, consists of a feature vector x_t, which takes values from a feature space $\mathcal{X}$, and a label y_t, which takes values from a label space $\mathcal{Y}$. For the sake of brevity, we represent a data point with $z_t = (x_t, y_t) \in \mathcal{X} \times \mathcal{Y}$. We refer to the space $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$ as the data space.

The only statistical assumption about the data generating process is the *exchangeability* of the data points, that is: for any positive integer N, the probability of observing a data sequence $z_1, \ldots, z_N$ is invariant under any permutation of the data points, π, i.e.

$$Pr\left(z_1, \ldots, z_N\right) \quad = \quad Pr\left(z_{\pi(1)}, \ldots, z_{\pi(N)}\right).$$

Many processes (or variants of these processes) satisfy this assumption. For example, stock price histories are not exchangeable, but stock price returns (percentage up or down over a given time period) are. Echangeability can be considered as a generalization of the more common i.i.d assumption. We refer the reader to (Schervish, 2012) and (Kallenberg, 2006) for a thorough discussion of this assumption.

In addition, we also make use of a source of randomness: uniform random variables $\tau_1, \tau_2, \ldots$ on the unit interval, which are independent of the data. This will be used to randomize the prediction algorithms in such a way as to achieve validity guarantees.

Lastly, we use multi-sets throughout the paper. In other words, each set may contain the same element multiple times, in particular, we denote the (multi-)set of the first t data points as $\sigma_t = \{z_1, \ldots, z_t\}$ and we don't require the data points to be distinct. In addition, we use the following variations of σ_t for the sake of brevity of exposition:

- $\sigma_t^{(i)} = \{z_1, \ldots, z_{i-1}, z_{i+1}, \ldots, z_t\}$ stands for the set of first t data points except the i^{th} one for any $i = 1, \ldots, t$.
- $\sigma_{t/y} = \{z_1, \ldots, z_{t-1}, (x_t, y)\}$ represents the set of first t data points assuming the t^{th} label is equal to y, for any $y \in \mathcal{Y}$.
- $\sigma_{t/y}^{(i)}$ is the set of data points in $\sigma_{t/y}$ with the exception of the i^{th} one, for $i = 1, \ldots, t$ and $y \in \mathcal{Y}$.

2.2 Online Prediction of Confidence

For the confidence prediction task, we assume the feature vector x_t is revealed at time t, but the corresponding label y_t is revealed only after the prediction is made and before the next feature vector x_{t+1} is revealed.

The task of the predictor is to predict a subset of the label space that contains the unseen label y_t with probability at least $1 - \epsilon$, for a given error tolerance level $\epsilon \in (0, 1)$. We denote the prediction set generated at time t as Γ_t^ϵ. Because Γ_t^ϵ is a set, we may be making a prediction of the form "the answer may be 1, 4, or 5". Formally:

Workflow for Online Confidence Prediction The fewer the errors, the more valid; the smaller the prediction set, the more efficient.

1: **for** $t = 1, 2, \ldots$ and given $\epsilon \in (0, 1)$ **do**
2: Nature reveals x_t.
3: Predictor calculates a prediction set $\Gamma_t^\epsilon \subseteq \mathcal{Y}$.
4: Nature reveals y_t and declares an error if $y_t \notin \Gamma_t^\epsilon$.

There are two main properties one expects from a good confidence predictor. The first is that the predictor should be *valid* (intuitively, the label value falls within the prediction set Γ_t^ϵ, fraction $1 - \epsilon$ of the time) and the other is that it is *efficient* (intuitively, $|\Gamma_t^\epsilon|$ is at least one but small).

The literature contains various ways of defining efficiency and validity measures, see (Vovk et al., 2014) for a detailed list. We use the following definitions:

- We call a confidence predictor *exactly valid* if the error events associated with its predictions occurs independently with probability ϵ. Additionally, we say a predictor is *conservatively valid* or simply *valid*, if it makes errors only on the data points on which some other exactly valid predictor makes errors. For further implications of this definition, see (Vovk et al., 2005).

- Since our results in Section 4 are focused on binary predictions, we use the cardinality of the predicted set, $|\Gamma_t^\epsilon|$, as a measure of efficiency. Particularly, we say the prediction at time t is *efficient* if $|\Gamma_t^\epsilon| = 1$. In binary classification setup, as in Section 4, an inefficient prediction at time t implies that the predictor chooses both possible values or none, effectively refusing to make a decision at t.

  Furthermore, we say a first predictor is more efficient than a second predictor at time t, if the first refuses to make a decision only if the second also refuses to make a decision at time t. Note that, such a comparison makes sense when both of the predictors are valid and have the same tolerance parameter, ϵ.

  For continuous label spaces, one can refer to the volume or size of the the prediction sets as a measure of efficiency (Lei, Robbins, & Wasserman, 2011).

2.3 Conformal Prediction

The main idea behind conformal predictors is to define a *nonconformity score* at time t between a candidate point $z = (x_t, y)$ for a candidate label $y \in \mathcal{Y}$ and the rest of the data $z_1, \ldots, z_{t-1}$, and to use it as a test statistic to decide whether a particular candidate label y will be included in the prediction set (candidate outcomes) or not. Intuitively, if data points similar to x_t have often mapped to y in the past, then y should belong to the prediction set for x_t.

The test statistic should take on smaller values the more probable the y is. One can create a non-conformity score based on a machine learning algorithm. Say that we employ the given algorithm, f, train it on the set σ_{t-1} and predict $\hat{y}_t = f_{\sigma_{t-1}}(x_t)$ as an estimate of y_t. Then we can derive a non-conformity score (also called the test statistic) to use at time t as $A_t(\sigma_{t-1}, z_t) = \phi\left(f_{\sigma_{t-1}}(x_t), y_t\right)$, where ϕ is any properly chosen loss function.

Because of the exchangeability assumption on the data, the conformity scores should be invariant to the order of data points in the training set σ_{t-1}. Therefore, the set of first t data points, σ_t, constitutes a complete sufficient statistic on the test statistic $A_t(\sigma_{t-1}, z_t)$. In our context, this means we can compute the exact probability distribution of the test statistic conditioned on σ_t. For a more detailed analysis of test statistics and how to compute their distribution under exchangeability, see Chapters 3.2 and 6.2 of (Cox & Hinkley, 1974).

Exploiting this idea leads to the following algorithm: calculate the non-conformity scores for each data point z_i that precedes t, based on the rest of the data preceding t plus the assumption that $y_t = y$ (the algorithm will do this one at a time for each label y for time t). We then calculate a confidence value, p_t^y, for the candidate label y as the fraction of the data points with greater non-conformity scores than the score of the last one (x_t, y). We will accept y into the confidence set provided this confidence value is greater than or equal to ϵ. Vovk (2005) has shown that, after some smoothing (using the additional source of randomness mentioned in section 2.1, the uniform random variable τ_t), this confidence value has a uniform distribution on $[0, 1]$ if the label y_t is really equal to y. The uniformity implies therefore that refusing to include y as a candidate point if its confidence value is less than ϵ would cause an error only with probability ϵ. The pseudocode is given in Algorithm 1, and further details are given in (Vovk et al., 2005).

Algorithm 1 (Smoothed) Conformal Prediction: The goal is to create a set of predicted values Γ_t^ϵ which covers the true label with probability $1 - \epsilon$, based on a confidence value p_t^y calculated from a given non-conformity measure A_t. In particular, p_t^y computes the fraction of data points with a larger non-conformity score than α_t^y, where τ_t is used to break the ties. The detailed definitions are in the text.

for $t = 1, 2, \ldots$ **do**
  $\Gamma_t^\epsilon \leftarrow \emptyset$
  for $y \in \mathcal{Y}$ **do**
    $y_t \leftarrow y$
    for $i = 1, \ldots, t$ **do**
      $\alpha_i^y \leftarrow A_t\left(\sigma_{t/y}^{(i)}, z_i\right)$
    $p_t^y = \left(|\{i : \alpha_i^y > \alpha_t^y, \}| + \tau_t |\{i : \alpha_i^y = \alpha_t^y\}|\right)/t$
    if $p_t^y \geq \epsilon$ **then**
      $\Gamma_t^\epsilon \leftarrow \Gamma_t^\epsilon \bigcup \{y\}$.

To appreciate the strength of the conformal predictors one can refer to the following results (Schafer & Vovk, 2008):

i. All (smoothed) conformal predictors are exactly valid (i.e. the error event at any time point is independent from others and occurs with probability ϵ) under the exchangeability assumption.

ii. If the data space is a Borel space, any given valid confidence predictor which is invariant to the order of the previous data points, there exists a conformal predictor that generates prediction sets not larger than the prediction sets generated by the given confidence predictor.

3 MULTIDIMENSIONAL CONFORMAL PREDICTION

In this section we will generalize the conformal prediction framework to multidimensional statistics and propose a principled extension to the algorithm presented above. This generalization is both simple and improves the efficiency of the formal prediction framework thus achieving practical improvements to standard algorithms.

The idea of the extension is to use non-conformity scores that take vector values instead of scalar ones, i.e. the range of A_t is $\mathbb{R}^d$ for some positive integer d. Such an approach may be helpful when we have several possible sets of data that may bear on a prediction. In such a scenario, one can use the non-conformity score of the candidate point to each of the several sets as components of a *non-conformity vector*.

The approach also helps in the application described in the next section, in which we focus on the case where the label space is binary, i.e. $\mathcal{Y} = \{0, 1\}$. In that setting, a one-dimensional non-conformity score $A_t(\sigma_{t-1}, (x_t, y))$ and its conjugate $A_t(\sigma_{t-1}, (x_t, 1-y))$ together provide a substantial improvement to the performance of the prediction compared to using just one score.

Just as in the one dimensional case, we assume that data points come from an exchangeable process and each component of the conformity vectors is invariant to the order of the points in the history, thus making the multi-dimensional conformity vectors exchangeable. Therefore, we can build a test statistic from them. However, in contrast to the scalar case, we don't have a linear order on these vectors, which complicates the decision of whether to include or exclude a label in the prediction set.

Instead of calculating a confidence value p^y for each $y \in \mathcal{Y}$ as before, we propose to select some subset of the d dimensional Euclidean space, which we call the *acceptance set* and denote it with S_t^y, for each y. We add the label y to the prediction set Γ_t^ϵ only if the corresponding nonconformity vector falls into the acceptance set, i.e. $y \in S_t^y$. Also, just as in the calculation of the one dimensional conformal prediction, we apply random smoothing on the boundary points of the acceptance set to guarantee exact validity. Specifically, we add y into the prediction set if the corresponding non-conformity vector is an interior point of the acceptance set, but if it is a boundary point of the set we include y iff τ_t is less than a specific value that is calibrated to the targeted error level. In Theorem 3.1 and the following Corollary 3.1.1, we provide some sufficient conditions on the acceptance sets to guarantee the validity of the associated predictor.

As an example, for the binary case, we propose to construct acceptance sets that include the points with smaller non-conformity scores than their conjugate scores in addition to some points with small non-conformity scores. This will satisfy the conditions given in Corollary 3.1.1 (See Figure 1). Such proposed acceptance sets will be investigated in detail in the next section.

The pseudocode for the described algorithm is given in Algorithm 2 below for generic acceptance sets. The following notation is used in the presentation of the algorithm to denote the acceptance sets:

- S_t^y: The acceptance set at time t for the prospective label y.
- $int(S_t^y)$: Interior points of the acceptance set.
- $\overline{int}(S_t^y)$: The set of points in the acceptance set, but not in the interior of it, i.e. $S_t^y / int(S_t^y)$.
- $\mathbf{v}_i^y$: The non-conformity vector for data point z_i, assuming $y_t = y$.
- Δ_t^y: Set of first t non-conformity vectors for $y_t = y$, i.e. $\{\mathbf{v}_1^y, \ldots, \mathbf{v}_t^y\}$.

Algorithm 2 Multidimensional Conformal Prediction: The goal is create a set of predicted outcomes Γ_t^ϵ based on d-dimensional statistics. See the definitions just above.

for $t = 1, 2, \ldots$ **do**
  $\Gamma_t^\epsilon \leftarrow \emptyset$
  for $y \in \mathcal{Y}$ **do**
    $y_t \leftarrow y$
    for $i = 1, \ldots, t$ **do**
      $\mathbf{v}_i^y \leftarrow A_t\left(\sigma_{t/y}^{(i)}, z_i\right)$
    Calculate $S_t^y \subseteq \mathbb{R}^d$ from $\sigma_{t/y}$
    if $\mathbf{v}_t^y \in int(S_t^y)$ **then**
      $\Gamma_t^\epsilon \leftarrow \Gamma_t^\epsilon \bigcup \{y\}$.
    if $\mathbf{v}_t^y \in \overline{int}(S_t^y)$ & $\tau_t \geq \frac{|S_t^y \cap \Delta_t^y| - (1-\epsilon)t}{|\overline{int}(S_t^y) \cap \Delta_t^y|}$ **then**
      $\Gamma_t^\epsilon \leftarrow \Gamma_t^\epsilon \bigcup \{y\}$.

The following theorem provides sufficient conditions for a sequence of acceptance sets using the above algorithm to guarantee that they lead to valid predictions. These conditions have the following intuitive interpretations: (i) S_t^y should not depend on the order of data points to preserve the exchangeability of the non-conformity vectors, and (ii) fraction $1-\epsilon$ of the non-conformity vectors should fall into the acceptance set, i.e $|S_t^y \cap \Delta_t^y| \simeq (1-\epsilon)\, t$, to make sure the probability of error is kept at ϵ. These requirements provide a guideline to design acceptance sets. In the next section, we will see that each conformal predictor can be represented in terms of acceptance sets satisfying this conditions. Also we will see an example of acceptance sets tailored for the binary classification problem.

Theorem 3.1 *For a given sequence of d dimensional conformity scores A_t, acceptance sets S_t^y, and smoothing parameters τ_t; if for all $t = 1, 2, \ldots$ and $y \in \mathcal{Y}$:*

i. S_t^y *is measurable conditioned on* $\sigma_{t/y}$,

ii. $|int\left(S_t^y\right) \cap \Delta_t^y| \leq (1-\epsilon)\, t \leq |S_t^y \cap \Delta_t^y|$,

then the multidimensional conformal predictor associated with these as described in Algorithm 2 *is exactly valid.*

The proof is based on the fact that any smoothed conformal predictor is exactly valid (Appendix of (Shafer & Vovk, 2008)). We simply construct a classical non-conformity score based on a given multidimensional predictor that satisfies the conditions of the theorem, and show that the associated predictors generate exactly the same prediction sets.

Proof: First, consider the acceptance set for label y and time t, S_t^y, and assume it satisfies both of the conditions given in the theorem statement. Then, define the non-conformity score

$$B_t\left(\sigma_{t/y}^{(i)}, z_i\right) \;=\; \begin{cases} 2 & \text{if } \mathbf{v}_i^y \notin S_t^y \\ 1 & \text{if } \mathbf{v}_i^y \in \overline{int}\left(S_t^y\right) \\ i/\left(t+1\right) & \text{if } \mathbf{v}_i^y \in int\left(S_t^y\right). \end{cases}$$

Next, we consider three exclusive and exhaustive scenarios to demonstrate the equivalence of the conformal predictor associated with B_t and the multidimensional one. Assuming, $z_t = (x_t, y)$, we calculate the p_t^y values for the conformal predictor associated with B_t in each scenario:

- If $\mathbf{v}_t^y \in int\left(S_t^y\right)$, then y is included in the prediction set for the multidimensional predictor. Also note that the first inequality of the second condition of the theorem implies:

$$p_t^y \;=\; \frac{\tau_t + t - |int\left(S_t^y\right) \cap \Delta_t^y|}{t} \;\geq\; \epsilon.$$

  Thus y is included for both of the predictors.

- If $\mathbf{v}_t^y \notin S_t^y$, the multidimensional predictor will reject y at time t, and also if we calculate the confidence value of y for the conformal predictor, by the second half of condition ii:

$$p_t^y \;=\; \frac{\tau_t\left(t - |S_t^y \cap \Delta_t^y|\right)}{t} \;<\; \frac{t - |S_t^y \cap \Delta_t^y|}{t} \;\leq\; \epsilon.$$

- Lastly, if $\mathbf{v}_t^y \in boun\left(S_t^y\right)$, the corresponding confidence value becomes:

$$p_t^y \;=\; \frac{t - |S_t^y \cap \Delta_t^y| + \tau_t |\overline{int}\left(S_t^y\right) \cap \Delta_t^y|}{t},$$

  and this value is greater or equal to ϵ if and only if the second condition on the Line 10 of the Algorithm 2 holds.

Since both predictors behave exactly the same for all of these scenarios, we can declare they are equivalent and since the conformal predictor is valid, the multidimensional one also has to be valid. ■

In addition, we can omit the first half of the second assumed condition, i.e. $|int\left(S_t^y\right) \cap \Delta_t^y| \leq (1-\epsilon)\, t$, at the cost of achieving conservative validity instead of exact validity.

This follows from the fact that the inequality $|int\left(S_t^y\right) \cap \Delta_t^y| \leq (1-\epsilon)\, t$ is used only in the first scenario of the proof. In that scenario, the multi-dimensional predictor does not cause an error since the label y is included in the predicted set. However, the conformal predictor may cause an error if the inequality is violated. Thus the multidimensional predictor preserves its (conservative) validity. This argument is summarized in Corollary 3.1.1.

Corollary 3.1.1 *The multidimensional conformal predictor described in Algorithm 2 is valid, if* S_t^y *is* σ_t*-measurable and* $|S_t^y \cap \Delta_t^y| \geq (1-\epsilon)\, t$.

This section has extended the conformal prediction framework to multiple dimensional non-conformity scores and has provided some sufficient conditions to achieve the validity guarantees. However, we haven't touched the issue of "How one should choose acceptance sets to obtain efficient predictions?". The answer to this question depends on the choice of the non-conformity scores which will entail a specific design of acceptance sets. In the next section, we will present a simple choice of acceptance sets for 2-dimensional non-conformity vectors in the binary classification setup that achieves more efficient predictions than the traditional one dimensional conformal predictors under some stability assumptions.

4 CONJUGATE PREDICTION FOR BINARY CLASSIFICATION WITH REJECT OPTION

In this section, we focus on a special case of the confidence prediction problem, where the label space consists of only two elements $\mathcal{Y} = \{0, 1\}$. We propose a simple and effective way of choosing acceptance sets for two dimensional conformal predictors based on any given classical conformal predictor.

As mentioned in the introduction, this problem is equivalent to the scenario of *binary classification with reject option* (Denis & Hebiri, 2015), where at each time point t the predictor either makes a point prediction, i.e. 0 or 1, for y_t or refuses (rejects) to make one, i.e. $\Gamma_t^\epsilon = \{0, 1\}$.In this interpretation, validity implies the probability of error for each prediction is equal to or less than ϵ and efficiency implies the reject option is not used frequently. An asymptotic analysis of error and reject options for this scenario when the traditional conformal prediction is employed can be found at Chapter 3 of (Vovk et al., 2005).

The intuitive idea behind conformal prediction is that a prediction y should be taken if its non-conformity score (monotonic with the probability of error) takes on small values with respect to the non-conformity scores of the other data points. The proposed scheme, which we call *conjugate prediction*, says to make a prediction y if its non-conformity score takes a smaller value than the non-conformity score of the alternative prediction, namely $1-y$.

This approach in some sense tries to find a compromise between the maximum likelihood and conformal prediction. Specifically, it will usually choose the most conforming label, thus enhancing efficiency, while preserving validity by requiring the acceptance set to be large enough to cover at least $1-\epsilon$ fraction of the data points. In the next section, we define conjugate predictors rigorously and show their efficiency. In Section 4.2. we will present the comparison of conjugate and conformal predictors on standard machine learning data sets.

4.1 Conjugate Conformal Prediction

Formally, a conjugate predictor associated with a given one dimensional non-conformity score A_t is a two-dimensional conformal predictor with the non-conformity vectors

$$\mathbf{v}_i^y \quad = \quad \begin{pmatrix} \alpha_i^y \\ \beta_i^y \end{pmatrix} \quad = \quad \begin{pmatrix} A_t\left(\sigma_{t/y}^{(i)}, (x_i, y_i)\right) \\ A_t\left(\sigma_{t/y}^{(i)}, (x_i, 1-y_i)\right) \end{pmatrix},$$

and the acceptance sets

$$S_t^y \quad = \quad \{(\alpha,\beta) : \alpha < \beta \text{ or } \alpha \leq \sup \mathcal{L}_t^y\},$$

where $\mathcal{L}_t^y = \{\gamma : |\{i : \alpha_i^y \leq \gamma \text{ or } \alpha_i < \beta_i^y\}| \leq (1-\epsilon)\,t\}$ and $\sup \emptyset = -\infty$.

For a more intuitive interpretation of the acceptance sets S_t^y, one can imagine to start with the set of points above the $\alpha = \beta$ line (see Figure 1) and combine it with the region $\alpha \leq \gamma$ where γ starts from $-\infty$ and increase the acceptance set until the total number of points in the set equals $(1-\epsilon)\,t$, i.e. $\alpha \leq \sup \mathcal{L}_t^y$, to make sure it satisfies the conditions given in Corollary 3.1.1.

Similarly, the traditional conformal predictor associated with A_t can also be represented as a two dimensional conformal predictor with the same non-conformity vectors $\mathbf{v}_i^y$ and acceptance sets:

$$\tilde{S}_t^y \quad = \quad \{\alpha : \alpha \leq \sup \mathcal{E}_t^y\}$$

where, $\mathcal{E}_t^y = \{\gamma : |\{i : \alpha_i^y \leq \gamma\}| \leq (1-\epsilon)\,t\}$.

As you can see in Figure 1, the traditional conformal predictor satisfies the same intuition as the conjugate predictor: start from $\gamma = -\infty$ and include points in the acceptance set until the number of non-conformity vectors that satisfy $\alpha \leq \gamma$ inequality become equal to $(1-\epsilon)\,t$. Note that this final γ value becomes equal to $\sup \mathcal{E}_t^y$.

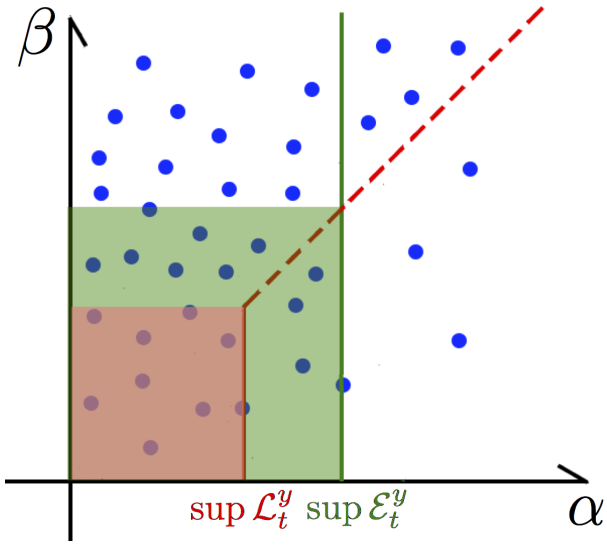

Figure 1: *(A Pictorial View of Conjugate Prediction)* In the figure α-β plane is sketched to illustrate the difference between the conformal and confidence prediction frameworks. For representative purposes, we choose $t = 40$ and $\epsilon = 0.2$. Each non-conformity vector is presented by a blue point assuming $y_t = y$, the acceptance set for conjugate prediction is on the right side of the red line, and the acceptance set for the conformal predictor is on the left of the green line. Assuming the green and red lines are approximately stable (i.e. they do not change based on an individual label value y), the conformal predictor declines to make a prediction if the test point, (x_t, y), falls into either green or red regions, however the conjugate predictor declines only on the red region.

In the following theorem, we argue that a conjugate conformal predictor is more efficient than the conformal predictor associated with the same non-conformity score, if the scoring functions are stable in the following sense. We say a scoring function A_t is stable if it changes little when any single label in the training set flips, i.e. $A_t\left(\sigma_{t/y}^{(i)}, z_i\right) \simeq A_t\left(\sigma_{t/1-y}^{(i)}, z_i\right)$ for any $i < t$. The notion of stability is studied thoroughly in statistical learning theory in the context of necessary conditions for learnability (Shalev-Shwartz, Shamir, Srebro, & Sridharan, 2010) (Bousquet & Elisseeff, 2002). In fact, many of the well-known learning algorithms, as well as the non-conformity scores derived from them, are stable to differing degrees, especially as the number of data points in the training sets increases, i.e. as t increases (Shave-Taylor & Cristianini, 2004), (Bousquet & Elisseeff, 2002), (Shalev-Shwartz & Ben-David, 2002).

In the following theorem, we first present a set of conditions in terms of the auxilary sets $\mathcal{L}_t^y$ and $\mathcal{E}_t^y$ for relative efficiency of the conjugate predictors and then intuitively discuss why the stability of the scoring functions imply these

conditions.

Theorem 4.1 *Let scoring functions A_t and tolerance level $\epsilon \in [0,1]$ be given. Also assume the auxilary sets $\mathcal{L}_t^y$ and $\mathcal{E}_t^y$ are defined as:*

$$\begin{aligned}\mathcal{E}_t^y &= \{\gamma : |\{i : \alpha_i^y \leq \gamma\}| \leq (1-\epsilon)\, t\} \text{ and} \\ \mathcal{L}_t^y &= \{\gamma : |\{i : \alpha_i^y \leq \gamma \text{ or } \alpha_i^y < \beta_i^y\}| \leq (1-\epsilon)\, t\}.\end{aligned}$$

If $\sup \mathcal{L}_t^y \leq \sup \mathcal{E}_t^{1-y}$ for both $y \in \{0,1\}$, then the conjugate predictor associated with A_t is more efficient than the conformal predictor associated with the same non-conformity score at time t.

Proof: In the proof, we ignore the tie-breaking issues for the sake of brevity, but one can show, with a similar analysis, that the result holds as long as both the conjugate and conformal predictors use the same smoothing value, τ_t.

We start by assuming that the conjugate predictor declines to make a decision at time t, i.e. $|\Gamma_t^\epsilon| = 2$, which implies the non-conformity vector corresponding to the t^{th} data point is included in the acceptance set regardless of the value of y, i.e. $\mathbf{v}_t^y \in S_t^y$ for both $y \in \{0,1\}$.

The definition of the non-conformity vector $\mathbf{v}_t^y = (\alpha_t^y, \beta_t^y)$, implies the equality $\alpha_t^y = \beta_t^{1-y}$ for all $y \in \{0,1\}$. Hence, the conditions for the rejection at time t can be written for any y as:

$$\begin{aligned}\mathbf{v}_t^y &\in \{(\alpha,\beta) : (\alpha < \beta \text{ or } \alpha \leq \sup \mathcal{L}_t^y) \\ &\qquad \text{and } (\alpha < \beta \text{ or } \alpha \leq \sup \mathcal{L}_t^{1-y})\} \\ &\subseteq \{(\alpha,\beta) : \max\{\alpha,\beta\} \leq \max_{y\in\{0,1\}} \sup \mathcal{L}_t^y\}.\end{aligned}$$

To simplify this last statement further, note $\sup \mathcal{L}_t^y \leq \sup \mathcal{E}_t^y$ from the definitions of the auxiliary sets $\mathcal{L}_t^y$ and $\mathcal{E}_t^y$. Combining this inequality with the hypothesis of the theorem, i.e. $\sup \mathcal{L}_t^y \leq \sup \mathcal{E}_t^{1-y}$, we obtain:

$$\max_{y\in\{0,1\}} \sup \mathcal{L}_t^y \leq \min_{y\in\{0,1\}} \sup \mathcal{E}_t^y.$$

Plugging this inequality in the previous statement:

$$\mathbf{v}_t^y \in \{(\alpha,\beta) : \max\{\alpha,\beta\} \leq \min_{y\in\{0,1\}} \sup \mathcal{E}_t^y\},$$

which implies $\mathbf{v}_t^y \in \tilde{S}_t^y$ and $\mathbf{v}_t^y \in \tilde{S}_t^{1-y}$. Therefore, the conformal predictor associated with A_t also declines to make a prediction.

Because the conformal predictor will decline to predict whenever the conjugate predictor will, the conjugate predictor is at least as efficient as the conformal predictor. Further, there are many cases where the conjugate predictor might predict even though the conformal predictor doesn't, for example if the test point fall into the green region in Figure 1. ∎

Intuitively, the conditions given in the theorem hold for stable enough non-conformity scores, since stability implies $\sup \mathcal{E}_t^y \simeq \sup \mathcal{E}_t^{1-y}$, and as mentioned before $\sup \mathcal{L}_t^y \leq \sup \mathcal{E}_t^y$ follows directly from the definition of these sets.

The theorem says the conjugate predictor performs at least as efficiently as the original conformal predictor under these stability conditions. The validity of the conjugate predictors follows from Corollary 3.1.1.

In the next subsection, we investigate the relative performance of the conformal and conjugate predictors by comparing the error and rejection rates for different choices of non-conformity scores and datasets. Our main observation is that the conjugate predictors provide two type of gains. First, it reduces the rejection rate due to the extra information provided by the conjugate scores. Second, even if the conjugate score does not provide any extra information (i.e. the β_t^y can be calculated as a function of α_t^y), it reduces the error rate for a given rejection rate, by being more decisive about its choices on easy samples.

4.2 Empirical Results

In this section, we show the results of applying our algorithm and corresponding conformal predictor on some real data-sets from UCI Machine Learning Repository (Lichman, 2013). The details of the used non-conformity scores and the datasets are given in the following two subsections and the numerical results are given at the last subsection.

4.2.1 Experiments

Our experiments use two different non-conformity scores: one based on random forests and the other is based on nearest neighbor classifiers. The reason to choose these two example scores is to illustrate the effect of the conjugate predictor when the conjugate score providing new information about the data (as in the nearest neighbor case), or not (as in the random forests).

1. *Out-of-bag Score in Random Forests:* At each time t, we train a random forest consist of 100 randomized decision trees on $\sigma_{t/y}$. Randomization entails taking a bootstrap of the samples for training and restricting the optimization at the decision nodes to random subsets of the features as described in (Breiman, 2001). We used the Statistics and Machine Learning Toolbox's (MATLAB, 2013) under the default settings, which are the settings suggested by Breiman originally.

   The non-conformity score α_i^y of point z_i is calculated as the fraction of trees (using a training set that doesn't include z_i) that miss-classify the sample x_i, i.e. give the output $1 - y_i$. Note that this choice of non-conformity score implies $\beta_i^y = 1 - \alpha_i^y$, and thus

the conjugate score does not provide any new information about the data. Nevertheless, conjugate prediction will still be useful for larger error tolerances.

2. *In-Class Distance in k-Nearest-Neighbor:* As the second scoring function, we built a non-conformity score based on the well-known k nearest neighbor algorithm. For each point z_i, we calculated the closest k data points with the same label y_i from the set $\sigma_{t/y}^{(i)}$ and used the arithmetic average of these k distances as the non-conformity score of α_i^y.

   In the implementation, we tried k values in the range 3 to 10, and we report the results for $k = 5$, which performed the best in all five data sets. Note that while larger values imply better stability, choosing k too large weakens the classifier's predictive power. We used Euclidean distance to measure the closeness of the data points after centering and scaling each feature to unit variance.

   Note that, in contrast to the non-conformity score used with random forests, this non-conformity score provides new information about the data, and as we see in Section 4.2.3, the advantage of using conjugate predictors is greater in this case.

4.2.2 Data Sets

We used the following data sets from UCI ML Repository (Lichman, 2013):

- Breast Cancer Wisconsin (Original) Data Set (Mangasarian & Wolberg, 1990): This data set consists of 699 data points, where each data point is collected from a patient that contains 10 integer valued features of a breast tumor and a binary label for its type (benign/malignant).
- Haberman's Survival Data Set: This data set contains 5 year survival information 306 patients after surgery for breast cancer. The data contain 3 integer features and 1 binary label (survived/died in 5 year.)
- Parkinson's Data Set (Little, McSharry, Hunter, & Ramig, 2008): This dataset contains data about 195 vocal recordings, where each record is represented by a 23 dimensional real vector and the goal is to predict if the subject has Parkinson's disease or not.
- Musk (v1) Data Set: This data set contains 476 data points on 92 types of molecules, each of which is represented by 166 features classifying them as musks and non-musks. The goal is to determine whether a new molecule will be a musk or not.
- Statlog (Australian Credit Approval) Data Set: This data set contains 690 data points on anonymized credit card applications described by 14 features, and classifying them as approved or rejected.

4.2.3 Results

In this part, we tested the above five data sets with both of the described non-conformity scores using error tolerance values of 0.03, 0.10, and 0.18. Because we assume exchangeability, we randomly permute the data before each experiment. Each experiment is repeated 10 times. The means are reported in Table 1,2,3, and 4.

In Tables 1 and 2, we report the cumulative error rate, i.e. fraction of mis-classified samples, for both conjugate and conformal predictors for each score, data, tolerance level combinations. Tables 3 and 4 give the cumulative rejection rates, i.e. the ratio of samples where the classifier declined to predict/classify.

Table 1: *Conjugate Conformal Predictors:* Mean Cumulative Error Rates. KNN means k nearest neighbor, and RF means random forest. B.C. means the breast cancer data set, Surv means survival, and Park. means Parkinson's.

	$\epsilon = 0.03$	$\epsilon = 0.10$	$\epsilon = 0.18$
KNN/B.C.	0.0284	0.0329	0.0335

RF/Statlog	0.3962	0.0929	0.0148

samples that corresponding conjugate predictors refused to make a prediction or not.

We observe that conjugate predictors always preserve validity (see Table 1), since they reach an error rate equal or less than the target tolerance level (up to statistical fluctuations). However, when the data is relatively easy to classify as in the breast cancer data (see Table 5), conjugate predictors are more decisive while also reducing the error rate by preserving the original validity guarantees.

Furthermore, the decisiveness of conjugate predictors reduces the rejection rates in our simulations (see Table 3 and 4). The gain is more pronounced when the data is relatively less noisy, i.e. easy to classify as in the breast cancer data, and the conjugate score of the base algorithm provides extra information about the data, as when using the k nearest neighbor algorithm.

Table 5: *Baseline:* Depending on the error tolerance ϵ, the conjugate algorithm refuses to predict on certain data points. For each box having format x/y, the table shows the error rate (x) of the underlying algorithm on the refused data points and the error rate (y) on the data points upon which the conjugate algorithm makes prediction. Note that, the error rate is significantly higher on the refused data points whenever the target error level ϵ is low, i.e. refusals are inevitable to preserve the validity.

5 DISCUSSION & CONCLUSION

Extending conformal predictors to multiple dimensions is both technically reasonable and practically beneficial. This paper has shown that the extension almost always increases the efficiency and always preserves the validity of machine learning algorithms compared with standard conformal predictors.

Other applications of this extension include scenarios where one may want to combine a set of conformal predictions to make better predictions even when there are breaks in exchangeability. For example, consider the problem of prediction under seasonal changes or other sources of concept drift.

Our conjugate prediction framework is an iterative method for finding hybrid non-conformity scores. As noted in the proof of Theorem 3.1, each multidimensional predictor can be equivalently represented as a conformal predictor. Thus, if one starts with a conformal predictor and can improve upon it by extending it to higher dimensions, as in the case of conjugate predictors, one will obtain a more effective conformal predictor.

The next steps in this work are to demonstrate the benefits of this extension to these other applications, to incorporate the resulting methods into standard machine learning software, and to explore further generalizations of conformal (and multi-dimensional/conjugate conformal) predictors.

Online Forest Density Estimation

Frédéric Koriche

Abstract

Online density estimation is the problem of predicting a sequence of outcomes, revealed one at a time, almost as well as the best expert chosen from a reference class of probabilistic models. The performance of each expert is measured with the log-likelihood loss. The class of experts examined in this paper is the family of discrete, acyclic graphical models, also known as *Markov forests*. By coupling Bayesian mixtures with symmetric Dirichlet priors for parameter learning, and a variant of "Follow the Perturbed Leader" strategy for structure learning, we derive an online forest density estimation algorithm that achieves a regret of $\tilde{O}(\sqrt{T})$, with a per-round time complexity that is quasi-quadratic in the input dimension. Using simple and flexible update rules, this algorithm can be easily adapted to predict with Markov trees or mixtures of Markov forests. Empirical results indicate that our online algorithm is a practical alternative to the state-of-the-art batch algorithms for learning tree-structured graphical models.

1 INTRODUCTION

Graphical models have attracted considerable interest in AI, computational statistics, and machine learning (Wainwright and Jordan, 2008; Koller and Friedman, 2009). One of the key virtues of these models is to allow a separation between qualitative, structural aspects of uncertain knowledge, and quantitative, parametric aspects of uncertainty. As such, graphical models are able to represent, in a compact and intelligible way, high-dimensional probability distributions, using local interactions between variables. For *undirected* graphical models, also known as *Markov networks*, the structure is an undirected graph G, and the parameters are grouped into a set $\boldsymbol{\theta}$ of factors associated with the cliques of G. The probability $\mathbb{P}_M(\boldsymbol{x})$ assigned to an outcome $\boldsymbol{x}$ by a model $M = (G, \boldsymbol{\theta})$ is given by the product of factors in $\boldsymbol{\theta}$ which are activated by $\boldsymbol{x}$, divided by a normalization constant, known as the *partition function*.

A fundamental problem in graphical models is to extract from a series of observed outcomes, the structure and the parameters of a model that accurately predicts future, unseen, outcomes. This learning problem, which can be generalized to arbitrary probabilistic models, is often referred to as *density estimation* in the literature (Grünwald, 2007; Rissanen, 2012). In the *batch* density estimation setting, it is assumed that outcomes are sampled independently from a fixed (but unknown) target distribution. The data samples, available ahead of time, are separated into a training set for learning the model, and a test set for evaluating its performance. Contrastingly, in the *online* density estimation setting, there are no statistical assumptions about the series of outcomes (Merhav and Feder, 1998; Cesa-Bianchi and Lugosi, 2006). The learner receives inputs sequentially, and its performance is measured over all the observed sequence. The absence of statistical assumption makes online algorithms applicable in adaptive or "dynamic" environments, where the target distribution is allowed to arbitrarily change in response to various events, including the learner's decisions. Even in "static" environments, online algorithms can provide a practical alternative to batch algorithms, by processing only one outcome at a time. They are indeed particularly suited to handle streaming applications, where all the data is not available in advance, or large-scale domains with massive amounts of data.

Conceptually, online density estimation with graphical models can be viewed as a repeated game between the learner and its environment. The parameters of the game are an outcome space $\mathcal{X}$ and a class $\mathcal{M}$ of graphical models over $\mathcal{X}$, called *experts*. During each trial t of the game, the learner selects (possibly at random) a model $M^t \in \mathcal{M}$, the environment responds by an outcome $\boldsymbol{x}^t \in \mathcal{X}$, and the learner incurs the log-likelihood loss (or *log-loss*, for short) $\ell(M^t, \boldsymbol{x}^t) = -\ln \mathbb{P}_{M^t}(\boldsymbol{x}^t)$. The quality of an online learning algorithm is measured according to two standard metrics. The first, called *regret*, measures the difference in cumulative loss between the algorithm and the best expert in $\mathcal{M}$. Borrowing the terminology of game theory, an online learning algorithm is called *Hannan-consistent* if its regret over any possible sequence of T outcomes is only sublinear in T. The second metric is computational complexity, i.e. the amount of resources required to compute M^t at each round t, given the sequence of outcomes observed so far.

In this paper, we examine the problem of online density estimation for the class of *(discrete) Markov forests*, which represent discrete multivariate probability distributions where interdependencies are restricted to an acyclic graph. Markov forests are endowed with two remarkable properties, namely, (i) they can be factorized into a *closed form* which does not involve a partition function, and (ii) the space of all acyclic graphs upon which a Markov forest can be constructed is a *matroid*. As observed in (Pearl, 1988; Lauritzen, 1996), the closed-form expression of the probability distribution $\mathbb{P}_M$ associated with an n-dimensional Markov forest $M = (F, \boldsymbol{\theta})$ is given by

$$\mathbb{P}_M(\boldsymbol{x}) = \prod_{i=1}^{n} \theta_i(x_i) \prod_{(i,j)\in F} \frac{\theta_{ij}(x_i, x_j)}{\theta_i(x_i)\theta_j(x_j)} \qquad (1)$$

where $\theta_i(x_i)$ and $\theta_{ij}(x_i, x_j)$ are the marginal densities of the node i and the edge (i, j), respectively. Based on (1), probabilistic inference in Markov forests can be performed in linear time. Moreover, the matroid associated with the structure space of Markov forests allows linear optimization to be performed in low-polynomial time, using the greedy matroid algorithm.

Based on these properties, the "batch" forest density estimation problem can be solved in quasi-quadratic time (in the input dimension n), by finding a maximum weight spanning tree in the complete graph of order n, whose edges are weighted according to the empirical bivariate marginals measured on the training set. This simple and elegant strategy, due to Chow and Liu (1968), is the blueprint of more sophisticated algorithms for learning other tree-structured graphical models, such as constrained Markov forests (Liu et al., 2011; Tan et al., 2011), and mixtures of Markov trees (Meila and Jordan, 2000; Kumar and Koller, 2009). Beyond Markov forests and their variants, the problem of finding the structure and the parameters of a maximum likelihood graphical model is, in general, NP-hard (Chickering, 1995), even for the restricted classes of Bayesian polytrees (Dasgupta, 1999) and Markov networks of bounded treewidth (Srebro, 2003).

Our Results. The challenge of the "online" forest density estimation problem lies in the fact that outcomes are revealed only one at a time, thus forcing the learner to iteratively update both the structure and the parameters of a Markov forest, so as to minimize the cumulative log-loss over the sequence of outcomes observed so far. This difficulty naturally raises the question of whether there exist Hannan-consistent forest density estimation algorithms with a total runtime complexity comparable to that of batch learning algorithms. By exploiting the closed form of Markov forests and the matroid of their structure space, we answer this question in the affirmative using easily implementable update strategies.

The key point of our online learning algorithm and its regret analysis lies in the fact that the parameters and the structure of a forest can be updated in an *independent* way. Indeed, in light of the closed-form expression (1), the log-likelihood loss of a Markov forest can be additively decomposed to the nodes and the edges of a forest, in such a way that the contribution of the local components are independent of the forest structure. Thus, the regret of any algorithm producing the sequence $M^1, \cdots, M^T$ of Markov forests can be decomposed into a telescopic sum of two regret expressions, namely, a "parametric" part defined over the forest parameters $\boldsymbol{\theta}^1, \cdots, \boldsymbol{\theta}^T$, and a "structural" part defined over the forest structures $F^1, \cdots, F^T$.

By exploiting the additive decomposition of the log-loss, the parametric part can, in turn, be decomposed into a sum of "local" regrets defined over node and edge parameters. This observation naturally suggests the use of Bayesian mixtures under Dirichlet priors for estimating univariate marginals and bivariate marginals. Such mixtures, which have been extensively studied in the literature of density estimation (see e.g. Cesa-Bianchi and Lugosi (2006); Grünwald (2007)), can be implemented using very simple update rules. Namely, by selecting Jeffreys mixtures for univariate and bivariate marginal estimators, our strategy achieves a regret that is logarithmic in the number T of rounds, with a per-round time complexity that is quadratic in the input dimension n.

Concerning the structural part of the regret, the log-loss is an affine function of the forest structure. This, together with the matroid property of forest structures, opens up the possibility of using various online combinatorial optimization algorithms (see e.g. Koolen et al. (2010); Audibert et al. (2011)). Here, our structure-update strategy is based on the well-known *Follow the Perturbed Leader* (FPL) algorithm (Hannan, 1957; Kalai and Vempala, 2005), which essentially adds a random perturbation to the total loss observed so far, and selects the forest structure that minimizes the resulting cost function. In order to attenuate the possibly unstable effects of perturbations, our strategy uses a convex combination of forest structures, coupled with a swap-rounding method (Chekuri et al., 2010) for generating, at each iteration, a forest that is consistent with the current convex mixture. By ignoring logarithmic factors, this strategy achieves a regret of $\tilde{O}(\sqrt{T})$, with a quadratic per-round time complexity.

In a nutshell, our online forest density estimation algorithm achieves Hannan-consistency with a cumulative runtime complexity that is comparable to that of the Chow-Liu algorithm. Furthermore, our algorithm can be easily adapted to predict with Markov trees, and mixtures of Markov forests (with shared parameters). Experiments conducted on several real-world datasets support our theoretical approach. Notably, our online learning algorithm rapidly converges to the estimations of the state-of-the-art batch algorithms for Markov trees (Chow and Liu, 1968), and thresholded Markov forests (Tan et al., 2011).

Paper Structure. After introducing the necessary background in forest polytopes (Section 2) and Markov forests (Section 3), we present our online forest density estimation algorithm in Section 4. Its regret analysis is detailed in Section 5, and its experimental validation is presented in Section 6. Finally, Section 7 concludes with some related work in online learning, together with several perspectives of further research.

2 FOREST POLYTOPES

We start with some notations and definitions which will be used throughout the paper. Let $[n]$ denote the set $\{1, \cdots, n\}$, and $\binom{[n]}{2}$ denote the set $\{(i,j) \in [n] \times [n], i < j\}$. To simplify notation, we use the abbreviation $\boldsymbol{x}^{1:t}$ to designate any sequence of vectors $\boldsymbol{x}^1, \cdots, \boldsymbol{x}^t$. For $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^n$ and $p \in [1, \infty]$, we use $\|\boldsymbol{x}\|_p$ to denote the L_p norm of $\boldsymbol{x}$, and we use $\langle \boldsymbol{x}, \boldsymbol{y} \rangle$ to denote the scalar product of $\boldsymbol{x}$ and $\boldsymbol{y}$. For a subset $\boldsymbol{X} \subseteq \mathbb{R}^n$, we denote by $\operatorname{conv} \boldsymbol{X}$ the convex hull of $\boldsymbol{X}$.

In what follows, we shall adopt set and vector notations interchangeably for describing graphs over the node set $[n]$; in the set notation, G is a subset of $\binom{[n]}{2}$, and in the vector notation $\boldsymbol{g}$ is a vector in $\{0,1\}^{\binom{n}{2}}$, such that $g_{ij} = 1$ if and only if $(i,j) \in G$. As usual, a *forest* is an acyclic graph, and a *spanning tree* is an acyclic, connected graph that spans $[n]$. The spaces of all forests and all spanning trees of order n are denoted $\mathbf{F}_n$ and $\mathbf{T}_n$, respectively. It is well-known that the set of all forests of order n defines a *matroid* over the ground set $\binom{[n]}{2}$, where $\mathbf{F}_n$ is the collection of independent sets, and $\mathbf{T}_n$ is the collection of bases. The rank of this matroid is $n-1$, which corresponds to the size of any spanning tree over $[n]$.

The convex hull of $\mathbf{F}_n$, where elements are viewed in vector notation, is called the *forest polytope*. This polyhedron of dimension $n-1$ is characterized by the system of inequalities:

$$\operatorname{conv} \mathbf{F}_n = \left\{ \boldsymbol{p} \in \mathbb{R}_+^{\binom{n}{2}} : \langle \boldsymbol{p}, \boldsymbol{g} \rangle \leq n-1, \text{ for all } \boldsymbol{g} \in \{0,1\}^{\binom{n}{2}} \right\}$$

Such inequalities are often referred to as *acyclicity constraints* in the literature (Shrijver, 2003). The convex hull of $\mathbf{T}_n$, called the *spanning tree polytope*, is the subset of $\operatorname{conv} \mathbf{F}_n$ formed by the points $\boldsymbol{p}$ satisfying the equality $\langle \boldsymbol{p}, \mathbf{1} \rangle = n-1$, where $\mathbf{1}$ is the all-ones vector in $\mathbb{R}^n$. By Carathéodory's theorem, any point $\boldsymbol{p} \in \operatorname{conv} \mathbf{F}_n$ (resp. $\boldsymbol{p} \in \operatorname{conv} \mathbf{T}_n$) can be represented as a convex combination of $t \leq n-1$ forests (resp. spanning trees), i.e. $\boldsymbol{p} = \sum_{\tau=1}^t \alpha_\tau \, \boldsymbol{f}^\tau$, where $\boldsymbol{\alpha} \in \mathbb{R}_+^t$ and $\|\boldsymbol{\alpha}\|_1 = 1$.

Although the forest polytope and the spanning tree polytope are characterized by an exponential number N of acyclicity constraints, linear optimization under these combinatorial structures can be performed in low polynomial time. Indeed, by Edmond's theorem (1970), both $\operatorname{conv} \mathbf{F}_n$ and $\operatorname{conv} \mathbf{T}_n$ are totally dual-integral, and hence, any minimizer $\boldsymbol{p}^*$ of a linear objective $\langle \boldsymbol{w}, \boldsymbol{p} \rangle$ subject to $\boldsymbol{p} \in \operatorname{conv} \mathbf{F}_n$ (resp. $\boldsymbol{p} \in \operatorname{conv} \mathbf{T}_n$) is an extreme point in $\mathbf{F}_n$ (resp. $\mathbf{T}_n$). This point $\boldsymbol{p}^*$ can be found in $O(n^2 \log n)$ time, using the greedy matroid algorithm. Specifically, for the forest polytope, the greedy algorithm first sorts the $\binom{n}{2}$ edges in decreasing order according to the linear objective $\boldsymbol{w}$, next keeps the first m edges with non-positive weight, and then iteratively finds a minimum cost forest F over these m ordered edges. For the spanning tree polytope, the greedy algorithm coincides with Kruskal's method, which also sorts the edges according to $\boldsymbol{w}$, but uses (in the worst case) all the $\binom{n}{2}$ ordered edges for generating a minimum cost spanning tree.

Finally, in order to round fractional points in matroid polytopes, we shall focus on SWAP method proposed by Chekuri et al. (2010). This algorithm takes as input a fractional point $\boldsymbol{p} \in \operatorname{conv} \mathbf{F}_n$ (resp. $\boldsymbol{p} \in \operatorname{conv} \mathbf{T}_n$), given as a convex combination $\boldsymbol{p} = \sum_{\tau=1}^t \alpha_\tau \boldsymbol{f}^\tau$ of forests (resp. spanning trees), and iteratively generates the sequence of points $\boldsymbol{p}^1, \cdots, \boldsymbol{p}^t$, such that $\boldsymbol{p}^1 = \boldsymbol{p}$, $\boldsymbol{p}^t$ is an extreme point in $\mathbf{F}_n$ (resp. $\mathbf{T}_n$), and $\mathbb{E}[\boldsymbol{p}^\tau] = \boldsymbol{p}$ for all $\tau \in [t]$. Each point $\boldsymbol{p}^{\tau+1}$ is obtained from $\boldsymbol{p}^\tau$ by arbitrarily choosing two components $\alpha_i \boldsymbol{f}^i$ and $\alpha_j \boldsymbol{f}^j$ in $\boldsymbol{p}^\tau$, and by replacing them with a new component $(\alpha_i + \alpha_j)\boldsymbol{f}'$. Here, $\boldsymbol{f}'$ is generated in $O(n^2)$ time using random base exchanges. So, $\boldsymbol{p}$ can be rounded using $t-1$ quadratic-time operations. Importantly, SWAP can be interrupted at any iteration τ to give a convex combination $\boldsymbol{p}^\tau$ of $t+1-\tau$ graphical structures. In what follows, we use $\text{SWAP}_k(\boldsymbol{p})$ to denote the application of at most $\tau = t+1-k$ iterations of the SWAP algorithm, which returns a convex combination including at most k components.

3 MARKOV FORESTS

The graphical models examined in this paper are defined over a set $\{X_1, \cdots, X_n\}$ of multinomial random variables, each taking values over a finite alphabet $\{1, \cdots, m\}$, with $m \geq 2$.

A *probability table* for a random variable X_i, is a vector $\boldsymbol{\theta}_i$ in the m-dimensional probability simplex, where $\theta_i(u)$ denotes the probability that $X_i = u$. Similarly, a probability table for a pair of random variables (X_i, X_j) is a vector $\boldsymbol{\theta}_{ij}$ in the m^2-dimensional probability simplex, where $\theta_{ij}(u,v)$ indicates the probability that $X_i = u$ and $X_j = v$. By $\boldsymbol{\Theta}_{m,n}$, we denote the set of all mappings $\boldsymbol{\theta}$ that assign a probability table $\boldsymbol{\theta}_i$ to each $i \in [n]$, and a probability table $\boldsymbol{\theta}_{ij}$ to each $(i,j) \in \binom{[n]}{2}$, while satisfying the *marginalization constraints*:

$$\sum_{u=1}^m \theta_{ij}(u,v) = \theta_j(v) \text{ and } \sum_{v=1}^m \theta_{ij}(u,v) = \theta_i(u) \qquad (2)$$

Note that the dimension of $\boldsymbol{\theta}$ is $d = mn + m^2\binom{n}{2}$. The class of *m-ary n-dimensional Markov forests* is defined as $\mathcal{F}_{m,n} = \mathbf{F}_n \times \boldsymbol{\Theta}_{m,n}$, and the class of *$m$-ary n-dimensional Markov trees* is given by $\mathcal{T}_{m,n} = \mathbf{T}_n \times \boldsymbol{\Theta}_{m,n}$. For a class $\mathcal{M} \in \{\mathcal{F}_{m,n}, \mathcal{T}_{m,n}\}$, we denote by $\boldsymbol{P}(\mathcal{M})$ the matroid polytope associated with the structure space of $\mathcal{M}$, i.e. $\boldsymbol{P}(\mathcal{M}) = \operatorname{conv} \mathbf{F}_n$ if $\mathcal{M} = \mathcal{F}_{m,n}$, and $\boldsymbol{P}(\mathcal{M}) = \operatorname{conv} \mathbf{T}_n$ if $\mathcal{M} = \mathcal{T}_{m,n}$.

By taking into account the acyclicity constraints of $\mathbf{F}_n$ and the marginalization constraints of $\boldsymbol{\Theta}_{m,n}$, the probability distribution $\mathbb{P}_M$ over $\mathcal{X} = [m]^n$ represented by a Markov forest $M = (\boldsymbol{f}, \boldsymbol{\theta})$ is given by the closed-form expression (1). More generally, if $(\boldsymbol{p}, \boldsymbol{\theta})$ is a pair of vectors in $\boldsymbol{P}(\mathcal{M}) \times \boldsymbol{\Theta}_{m,n}$, then the corresponding distribution is given by

$$\mathbb{P}_{\boldsymbol{p},\boldsymbol{\theta}}(\boldsymbol{x}) = \prod_{i \in [n]} \theta_i(x_i) \prod_{(i,j) \in \binom{[n]}{2}} \left(\frac{\theta_{ij}(x_i, x_j)}{\theta_i(x_i)\theta_j(x_j)} \right)^{p_{ij}} \qquad (3)$$

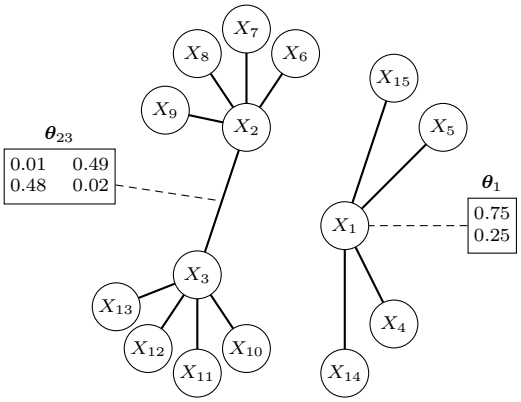

Figure 1: A binary Markov forest.

When $\boldsymbol{p}$ is described as a convex combination of forests (resp. trees), the pair $(\boldsymbol{p}, \boldsymbol{\theta})$ can be viewed as a *mixture* of Markov forests (resp. Markov trees) sharing the same parameters.

4 ONLINE MARKOV FORESTS

Recall that online learning can be viewed as a repeated game between a learning algorithm $\mathcal{A}$ and its environment. During each trial $t \in [T]$, the learner $\mathcal{A}$ starts by choosing (possibly at random) a model $M^t \in \mathcal{M}$, where $\mathcal{M}$ is a class of graphical models. Next, the environment responds by supplying an outcome $\boldsymbol{x}^t \in \mathcal{X}$, and then, $\mathcal{A}$ incurs the log-loss $\ell(M^t, \boldsymbol{x}^t) = -\ln \mathbb{P}_{M^t}(\boldsymbol{x}^t)$. The *(expected) regret* of the learning algorithm $\mathcal{A}$ with respect to the sequence of outcomes $\boldsymbol{x}^{1:T} = (\boldsymbol{x}^1, \cdots, \boldsymbol{x}^T)$ is given by

$$R_{\boldsymbol{x}^{1:T}}(\mathcal{A}) = \sum_{t=1}^{T} \mathbb{E}\left[\ell(M^t, \boldsymbol{x}^t)\right] - \min_{M \in \mathcal{M}} \sum_{t=1}^{T} \ell(M, \boldsymbol{x}^t) \quad (4)$$

where the expectation is taken with respect to the learner's internal randomization. By extension, the *minimax regret* of $\mathcal{A}$ at horizon T, denoted $R_T(\mathcal{A})$, is the maximum of $R_{\boldsymbol{x}^{1:T}}(\mathcal{A})$ over any sequence $\boldsymbol{x}^{1:T}$ in $\mathcal{X}^T$. $\mathcal{A}$ is called *Hannan-consistent* if its minimax regret is sublinear in T, or equivalently, if its average minimax regret $R_T(\mathcal{A})/T$ vanishes as $T \to \infty$.

The classes of experts investigated in this study are Markov forests and Markov trees, that is, $\mathcal{M} \in \{\mathcal{F}_{m,n}, \mathcal{T}_{m,n}\}$. The log-loss can be extended to $\boldsymbol{P}(\mathcal{M}) \times \boldsymbol{\Theta}_{m,n} \times \mathcal{X} \to \mathbb{R}$, using $\ell(\boldsymbol{p}, \boldsymbol{\theta}, \boldsymbol{x}) = -\ln \mathbb{P}_{\boldsymbol{p},\boldsymbol{\theta}}(\boldsymbol{x})$, where $\mathbb{P}_{\boldsymbol{p},\boldsymbol{\theta}}$ is defined according to the closed-form expression (3). Interestingly, we can observe that ℓ is an affine function of $\boldsymbol{p}$, given by

$$\ell(\boldsymbol{p}, \boldsymbol{\theta}, \boldsymbol{x}) = \psi(\boldsymbol{x}) + \langle \boldsymbol{p}, \boldsymbol{\phi}(\boldsymbol{x}) \rangle \quad (5)$$

where

$$\psi(\boldsymbol{x}) = \sum_{i \in [n]} \ln \frac{1}{\theta_i(x_i)} \text{ and } \phi_{ij}(x_i, x_j) = \ln \left(\frac{\theta_i(x_i)\theta_j(x_j)}{\theta_{ij}(x_i, x_j)} \right)$$

It is important to keep in mind that the sign of the components in the vector $\boldsymbol{\phi}(\boldsymbol{x}) \in \mathbb{R}^{\binom{n}{2}}$ can be positive or negative. A negative weight $\phi_{ij}(x_i, x_j)$ can be interpreted as a positive contribution (or gain) in favor of using the edge (i, j) in the graphical structure. Contrarily, a positive weight $\phi_{ij}(x_i, x_j)$ provides a negative contribution to the candidate edge (i, j).

With these notions in hand, we are now in position to examine the online forest density estimation (OFDE) algorithm. As specified in Algorithm 1, OFDE takes as input a class of experts $\mathcal{M} \in \{\mathcal{F}_{m,n}, \mathcal{T}_{m,n}\}$, and an upper bound k on the number of candidate structures maintained by its mixture. During each trial t, the learner maintains a pair $(\boldsymbol{p}^t, \boldsymbol{\theta}^t) \in \boldsymbol{P}(\mathcal{M}) \times \boldsymbol{\Theta}_{m,n}$, where $\boldsymbol{p}^t$ is a convex combination of at most k structures. The model $M^t = (\boldsymbol{f}^t, \boldsymbol{\theta}^t)$ used to predict the outcome $\boldsymbol{x}^t$ is obtained by generating $\boldsymbol{f}^t$ at random according to $\boldsymbol{p}^t$ (Line 4). After observing $\boldsymbol{x}^t$ (Line 5), the learner updates its parameters and its structure according to Lines 6-7 and Lines 8-12, respectively.

The vector of parameters $\boldsymbol{\theta}^t$ is updated by applying the Jeffreys (1946) rule to the probability table of each node $i \in [n]$ and each candidate edge $(i, j) \in \binom{[n]}{2}$. Here, t_u (resp. t_v) is the number of u's (resp. v's) in the sequence $x_i^1, \cdots, x_i^t$, and t_{uv} is the number of occurrences of (u, v) in $(x_i, x_j)^1, \cdots, (x_i, x_j)^t$.

The mixture $\boldsymbol{p}^t$ is updated using the following operations: first, apply the FPL strategy to produce an intermediate structure $\boldsymbol{f}^{t+\frac{1}{2}}$ (Lines 9-10); next, combine this structure with $\boldsymbol{p}^t$ to yield a new intermediate mixture $\boldsymbol{p}^{t+\frac{1}{2}}$ (Line 11), and then use SWAP$_k$ to build a new mixture with at most k components (Line 12). The values of the hyperparameters α_t and β_t, used to generate mixtures and perturbations, will be derived from regret analysis. Note that the same algorithmic scheme is used to learn with Markov forests and Markov trees. The key difference lies in the behavior of the greedy matroid algorithm; as mentioned above, the greedy algorithm uses only non-positive weights in $\phi^t(\boldsymbol{x}^t)$ to find an optimal point in $\operatorname{conv} \mathbf{F}_n$ for the linear objective $\boldsymbol{w}^t$, while it uses all weights in $\phi^t(\boldsymbol{x}^t)$ to produce an optimal point in $\operatorname{conv} \mathbf{T}_n$ for $\boldsymbol{w}^t$.

Theorem 1. The per-round time complexity of the OFDE algorithm is in $O\big(n^2m^2 + n^2 \log n + kn^2\big)$.

Proof. Based on the Jeffreys rule, the parameters $\boldsymbol{\theta}^{t+1}$ are computed in $O(d)$ time, where $d = mn + m^2\binom{n}{2}$. Furthermore, $\boldsymbol{f}^{t+\frac{1}{2}}$ is obtained in $O(n^2 \log n)$ time by applying the greedy matroid algorithm, and by exploiting the fact that the objective $\boldsymbol{w}^t$ can be maintained in $O(n^2)$ time per trial using $\boldsymbol{w}^0 = \mathbf{0}$ and $\boldsymbol{w}^t = \boldsymbol{w}^{t-1} + \phi^t(\boldsymbol{x}^t)$. Since $\boldsymbol{p}^{t+\frac{1}{2}}$ includes at most $k+1$ components, the updated mixture $\boldsymbol{p}^{t+1}$ and the updated forest $\boldsymbol{f}^{t+1}$ are obtained using SWAP in $O(n^2)$ time and $O(kn^2)$ time, respectively. □

Note that the time complexity of the Chow-Liu algorithm for a training set of size T is in $O(Tm^2n^2 + n^2 \log n)$. So, if k is constant or logarithmic in n, then the overall complexity of OFDE at horizon T is comparable to that of the Chow-Liu algorithm.

Algorithm 1: Online Forest Density Estimation (OFDE)

Input:
a class of experts $\mathcal{M} \in \{\mathcal{F}_{m,n}, \mathcal{T}_{m,n}\}$, and mixture size k

Initialization step

1 $\theta_i^1(u) \leftarrow \frac{1}{m}$ for all $i \in [n], u \in [m]$

2 $\theta_{ij}^1(u,v) \leftarrow \frac{1}{m^2}$ for all $(i,j) \in \binom{[n]}{2}, u,v \in [m]$

3 $\boldsymbol{p}^1 \leftarrow \mathbf{0}$

Trials

foreach $t \leftarrow 1, \dots$ **do**

4 Play $M^t \leftarrow (\boldsymbol{f}^t, \boldsymbol{\theta}^t)$ where $\boldsymbol{f}^t = \textsc{Swap}_1(\boldsymbol{p}^t)$

5 Receive $\boldsymbol{x}^t$

Parameter update

6 $\theta_i^{t+1}(u) \leftarrow \dfrac{t_u + \frac{1}{2}}{t + \frac{m}{2}}$ for all $i \in [n], u \in [m]$

7 $\theta_{ij}^{t+1}(u,v) \leftarrow \dfrac{t_{uv} + \frac{1}{2}}{t + \frac{m^2}{2}}$ for all $(i,j) \in \binom{[n]}{2}, u,v \in [m]$

Structure update

8 Choose α_t and β_t in $(0,1)$

9 Draw $\boldsymbol{r}^t$ in $\left[0, \frac{1}{\beta_t}\right]^{\binom{n}{2}}$ uniformly at random

10 $\boldsymbol{f}^{t+\frac{1}{2}} \leftarrow \operatorname{argmin}_{\boldsymbol{p} \in \boldsymbol{P}}(\boldsymbol{w}^t)$ where $\boldsymbol{w}^t \leftarrow \boldsymbol{r}^t + \sum_{\tau=1}^t \phi^\tau(\boldsymbol{x}^\tau)$

11 $\boldsymbol{p}^{t+\frac{1}{2}} \leftarrow \alpha_t \boldsymbol{p}^t + (1-\alpha_t)\boldsymbol{f}^{t+\frac{1}{2}}$

12 $\boldsymbol{p}^{t+1} \leftarrow \textsc{Swap}_k(\boldsymbol{p}^{t+\frac{1}{2}})$

5 REGRET ANALYSIS

Based on the decomposable form of the log-loss (5), the regret of the OFDE algorithm can be expressed as a telescopic sum of two separate components, namely, a "parametric" regret with fixed structure and varying parameters, and a "structural" regret, with fixed parameters and varying structure. Formally, let $(\boldsymbol{p}, \boldsymbol{\theta})^{1:T} = ((\boldsymbol{p}^1, \boldsymbol{\theta}^1), \cdots, (\boldsymbol{p}^T, \boldsymbol{\theta}^T))$ be the sequence generated by the algorithm during T rounds. Then,

$$R_{\boldsymbol{x}^{1:T}}[(\boldsymbol{p}, \boldsymbol{\theta})^{1:T}] = R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T}) + R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T})$$

where

$$R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T}) = \sum_{t=1}^T \ell(\boldsymbol{p}^t, \boldsymbol{\theta}^t, \boldsymbol{x}^t) - \ell(\boldsymbol{p}^*, \boldsymbol{\theta}^t, \boldsymbol{x}^t), \quad (6)$$

$$R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T}) = \sum_{t=1}^T \ell(\boldsymbol{p}^*, \boldsymbol{\theta}^t, \boldsymbol{x}^t) - \ell(\boldsymbol{p}^*, \boldsymbol{\theta}^*, \boldsymbol{x}^t) \quad (7)$$

and where $(\boldsymbol{p}^*, \boldsymbol{\theta}^*)$ is any minimizer in $\boldsymbol{P}(\mathcal{M}) \times \boldsymbol{\Theta}_{m,n}$ of the cumulative log-loss $\sum_{t=1}^T \ell(\boldsymbol{p}, \boldsymbol{\theta}, \boldsymbol{x}^t)$. The rest of this section is devoted to the analysis of each separate part (7) and (6), and the unification of our results.

5.1 PARAMETRIC REGRET

For the analysis of the parametric regret $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T})$, we consider the problem of online density estimation problem with the class of experts $(\{\boldsymbol{p}\}, \boldsymbol{\Theta}_{m,n})$, where $\boldsymbol{p}$ is an arbitrary point in $\boldsymbol{P}$. As mentioned above, $\boldsymbol{p}$ can be viewed as a convex combination $\boldsymbol{p} = \mathbb{E}[\boldsymbol{f}]$ of graphical structures $\boldsymbol{f} \in \mathcal{M}$. Using the additive decomposition (5) and the linearity of expectations, we have

$$\begin{aligned} R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T}) &= \mathbb{E}\left[\sum_{t=1}^T \ell(\boldsymbol{f}, \boldsymbol{\theta}^t, \boldsymbol{x}^t) - \ell(\boldsymbol{f}, \boldsymbol{\theta}^*, \boldsymbol{x}^t)\right] \\ &= \mathbb{E}\left[\ln \prod_{t=1}^T \frac{\mathbb{P}_{\boldsymbol{f},\boldsymbol{\theta}^*}(\boldsymbol{x}^t)}{\mathbb{P}_{\boldsymbol{f},\boldsymbol{\theta}^t}(\boldsymbol{x}^t)}\right] \end{aligned} \quad (8)$$

In light of the closed-form expression (1), the logarithmic term inside the expectation in (8) can be reformulated as

$$\begin{aligned} \ln \prod_{t=1}^T \frac{\mathbb{P}_{\boldsymbol{f},\boldsymbol{\theta}^*}(\boldsymbol{x}^t)}{\mathbb{P}_{\boldsymbol{f},\boldsymbol{\theta}_t}(\boldsymbol{x}^t)} &= \sum_{i=1}^n \ln \frac{\theta_i^*(x_i^{1:T})}{\theta_i^{1:T}(x_i^{1:T})} + \\ \sum_{(i,j)\in F} \ln \frac{\theta_{ij}^*(x_{ij}^{1:T})}{\theta_{ij}^{1:T}(x_{ij}^{1:T})} &+ \sum_{(i,j)\in F} \ln \frac{\theta_i^{1:T}(x_i^{1:T})}{\theta_i^*(x_i^{1:T})} \frac{\theta_j^{1:T}(x_j^{1:T})}{\theta_j^*(x_j^{1:T})} \end{aligned} \quad (9)$$

where

$$\theta_i^*(x_i^{1:t}) = \prod_{\tau=1}^t \theta_i^*(x_i^\tau), \qquad \theta_i^{1:t}(x_i^{1:t}) = \prod_{\tau=1}^t \theta_i^\tau(x_i^\tau)$$

$$\theta_{ij}^*(x_{ij}^{1:t}) = \prod_{\tau=1}^t \theta_{ij}^*(x_i^\tau, x_j^\tau), \quad \theta_{ij}^{1:t}(x_{ij}^{1:t}) = \prod_{\tau=1}^t \theta_{ij}^\tau(x_i^\tau, x_j^\tau)$$

We may observe that (9) is essentially a composition of local regrets defined over univariate density estimators $\theta_i^{1:T}(x_i^{1:T})$ and bivariate density estimators $\theta_{ij}^{1:T}(x_{ij}^{1:T})$. Notably, for each edge $(i,j) \in F$, the regret of the bivariate estimator $\theta_{ij}^{1:T}(x_{ij}^{1:T})$ is compensated by the relative gains of the univariate estimators $\theta_i^{1:T}(x_i^{1:T})$ and $\theta_j^{1:T}(x_j^{1:T})$. Such a decomposition motivates the use of well-known Bayesian mixtures with Dirichlet priors for specifying the estimators. We focus here on *symmetric* Dirichlet priors, given by

$$p_\mu(\boldsymbol{\lambda}) = \frac{\Gamma(m\mu)}{\Gamma(\mu)^m} \prod_{v=1}^m (\lambda(v))^{\mu-1}$$

where $\boldsymbol{\lambda}$ is a vector in the m-dimensional probability simplex, $\Gamma(z) = \int_0^\infty t^{z-1}e^{-t}dt$ is the gamma function, and $\mu \in [0,1]$ is a hyperparameter. The corresponding Bayesian mixture $\lambda(x^{1:t})$ for the sequence $x^{1:t} = (x^1, \cdots, x^t)$ is given by

$$\int \prod_{\tau=1}^t \mathbb{P}_{\boldsymbol{\lambda}}(x^\tau) p_\mu(\boldsymbol{\lambda}) d\boldsymbol{\lambda} = \frac{\Gamma(m\mu)}{\Gamma(\mu)^m} \frac{\prod_{v=1}^m \Gamma(t_v + \mu)}{\Gamma(t + m\mu)} \quad (10)$$

where t_v is the number of v's in $x^{1:t}$. Thus, by applying (10) with $\mu = 1/2$ to the estimators $\theta_i^t(x_i^{1:t})$ and $\theta_{ij}^{1:t}(x_{ij}^{1:t})$, we derive the update rules specified by Lines 6-7 of the OFDE algorithm.

Before deriving a bound for the parametric regret (7), we present two useful double inequalities for log-gamma functions, summarized in the next lemma.

Lemma 1. Let m be a positive integer. Then for any $t > 0$,

$$-\ln\sqrt{2} \leq \ln\Gamma\left(t+\frac{1}{2}\right) - t\ln t + t - \ln\sqrt{2\pi} \leq 0 \quad (11)$$

$$0 \leq \ln\Gamma\left(t+\frac{m}{2}\right) - \ln\Gamma\left(t+\frac{1}{2}\right) - \frac{m-1}{2}\ln t \leq o(1) \quad (12)$$

Proof. (11) is a reformulation of Lemma 1 in (Watanabe and Roos, 2015), and the right-hand inequality of (12) follows from the classical asymptotic relation (see e.g. Qi and Luo (2013)):

$$\lim_{t\to\infty}\left[t^{b-a}\frac{\Gamma(t+a)}{\Gamma(t+b)}\right] = 1$$

using $a = m/2$ and $b = 1/2$. For the left-hand inequality of (12), we can observe that

$$\ln\frac{\Gamma\left(t+\frac{m}{2}\right)}{\Gamma\left(t+\frac{1}{2}\right)} = \ln\frac{\Gamma\left(z+\frac{m-1}{2}\right)}{\Gamma\left(z+k\right)} + \ln\frac{\Gamma\left(z+k\right)}{\Gamma\left(z\right)} \quad (13)$$

where $z = t + 1/2$ and $k = \lfloor\frac{m-1}{2}\rfloor$. Based on the identity $\ln\Gamma(z+k) = \ln\Gamma(z) + \sum_{i=0}^{k-1}\ln(z+i)$, the second term in the right-hand side of (13) is lower bounded by $k\ln z$. So, if m is odd, then $k = \frac{m-1}{2}$, and hence, (13) is lower bounded by $\frac{m-1}{2}\ln t$, as desired. Now, if m is even, then using $z' = t + k$, we can observe that the first term in the right-hand side of (13) can be rewritten as the log-ratio of $\Gamma(z'+1)$ to $\Gamma(z'+\frac{1}{2})$. Thus, by Wendel's inequality (1948), we have

$$\frac{1}{2}\ln z' \leq \ln\frac{\Gamma(z'+1)}{\Gamma(z'+\frac{1}{2})} \leq \frac{1}{2}\ln\left(z'+\frac{1}{2}\right)$$

By combining the lower bounds $k\ln z$ and $\frac{1}{2}\ln z'$, it follows that (13) is lower bounded by $(k+\frac{1}{2})\ln t = \frac{m-1}{2}\ln t$, which again yields the desired result. □

With these inequalities in hand, we can derive "sandwiching" bounds for the regret of the Jeffreys mixture. Specifically, using the Bayes mixture (10) with $\mu = 1/2$, the regret expression $\ln\theta^*(x^{1:T}) - \ln\theta^{1:T}(x^{1:T})$ is equal to

$$\ln\left[\prod_{u=1}^{m}\left(\frac{t_u}{T}\right)^{t_u}\right] + \ln\frac{\Gamma\left(T+\frac{m}{2}\right)}{\prod_{u=1}^{m}\Gamma\left(t_u+\frac{1}{2}\right)} + C_m \quad (14)$$

where $C_m = m\ln\Gamma(\frac{1}{2}) - \ln\Gamma(\frac{m}{2})$. By coupling the double inequalities (11) and (12), we can deduce that

$$-\ln\sqrt{2} \leq \ln\Gamma\left(T+\frac{m}{2}\right) + T - T\ln T - \frac{m-1}{2}\ln T - \ln\sqrt{2\pi} \leq o(1)$$

Similarly, using the double inequality (11) and summing over m values, we can infer that

$$-m\ln\sqrt{2} \leq \ln\prod_{u=1}^{m}\Gamma\left(t_u+\frac{1}{2}\right) - \sum_{u=1}^{m}t_u\ln t_u + T - m\ln\sqrt{2\pi} \leq 0$$

Now, using the fact that the first term in (14) is equal to $\sum_{u=1}^{m}t_u\ln t_u - T\ln T$, we can combine the above two double inequalities to derive the sandwiching bounds:

$$-\ln\sqrt{2} \leq \ln\frac{\theta^*(x^{1:T})}{\theta^{1:T}(x^{1:T})} - \frac{m-1}{2}\ln\frac{T}{2\pi} - C_m \leq m\ln\sqrt{2} + o(1) \quad (15)$$

Unsurprisingly, the right-hand inequality of (15) coincides with the regret bound of the Jeffreys mixture established by Xie and Barron (2000). As shown below, the left-hand inequality of (15) will also prove useful for bounding the regret expression (9).

Lemma 2. The parametric regret $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T})$ of the OFDE algorithm is upper bounded by

$$\frac{n(m-1)+(n-1)(m-1)^2}{2}\ln\frac{T}{2\pi} + C_{m,n} + o(m^2n)$$

where $C_{m,n} = nC_m + (n-1)(C_{m^2} - 2C_m)$.

Proof. As specified by Equality (8), any upper bound on the minimax regret of (9) is an upper bound on $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T})$. Based on this observation, consider the first term of (9), given by $\sum_{i=1}^{n}\ln[\theta_i^*(x_i^{1:T})/\theta_i^{1:T}(x_i^{1:T})]$. Using the right-hand inequality of (15) and summing over n nodes, this term is upper bounded by

$$\frac{n(m-1)}{2}\ln\frac{T}{2\pi} + nC_m + mn\ln\sqrt{2} + o(n)$$

Clearly, a similar strategy can be applied to the second term $\sum_{(i,j)\in F}\ln[\theta_{ij}^*(x_{ij}^{1:T})/\theta_{ij}^{1:T}(x_{ij}^{1:T})]$ of (9). Since $|F| \leq n-1$, this term is upper bounded by

$$\frac{(n-1)(m^2-1)}{2}\ln\frac{T}{2\pi} + (n-1)C_{m^2} + (n-1)m^2\ln\sqrt{2} + o(n)$$

Finally, the third term of (9) can be reformulated as a sum over each $(i,j) \in F$ of two components: $\ln[\theta_i^{1:T}(x_i^{1:T})/\theta_i^*(x_i^{1:T})]$ and $\ln[\theta_j^{1:T}(x_j^{1:T})/\theta_j^*(x_j^{1:T})]$. By applying the left-hand side inequality of (15) to each component, and summing over at most $n-1$ edges, this term is upper bounded by

$$-(n-1)(m-1)\ln\frac{T}{2\pi} - 2(n-1)C_m + 2(n-1)\ln\sqrt{2}$$

By combining the above three bounds, rearranging terms, and taking into account the fact that $[(n-1)(m^2+2)+mn]\ln\sqrt{2}$ is in $o(m^2n)$ (for $m \geq 2$), we get the desired result. □

In the binomial case ($m = 2$), it is easy to check that $C_{2,n} = n \ln \pi$. By reporting this result into Lemma 2, we may derive for binary Markov forests a parametric regret bound of the form:

$$R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T}) \leq \left(n - \frac{1}{2}\right) \ln T + o(n) \tag{16}$$

5.2 STRUCTURAL REGRET

Before deriving a bound for the structural part of the regret, we first examine some analytic properties of the loss function (5), specified as an affine function of the predicted structure.

Lemma 3. Given a class of models $\mathcal{M} \in \{\mathcal{F}_{m,n}, \mathcal{T}_{m,n}\}$, let $\boldsymbol{\theta}^{1:T}$ be the sequence of parameters in $\boldsymbol{\Theta}_{m,n}$ generated by the OFDE algorithm on the sequence of outcomes $\boldsymbol{x}^{1:T}$. Then, for any $t \in [T]$, any $\boldsymbol{p}, \boldsymbol{q} \in \boldsymbol{P}(\mathcal{M})$, and any $\boldsymbol{x} \in \mathcal{X}$,

$$\left\|\boldsymbol{\phi}^t(\boldsymbol{x})\right\|_\infty \leq \ln\left(\frac{T}{2} + \frac{m^2}{4}\right)$$
$$\|\boldsymbol{p} - \boldsymbol{q}\|_1 \leq 2(n-1)$$

Proof. For the first property, consider two values $u, v \in [m]$. We may observe that $\phi^1_{ij}(u,v) = 0 < \ln(T/2 + m^2/4)$, for $m \geq 2$. Furthermore, using the Jeffreys update rule, we have

$$\begin{aligned}\phi^{t+1}_{ij}(u,v) &= \ln \frac{(t_u + 1/2)(t_v + 1/2)}{(t + m/2)^2} + \ln \frac{t + m^2/2}{t_{uv} + 1/2} \\ &\leq \ln \frac{1}{4} + \ln \frac{t + m^2/2}{t_{uv} + 1/2} \leq \ln\left(\frac{T}{2} + \frac{m^2}{4}\right)\end{aligned}$$

where the first inequality follows from the fact that the maximizer of $(t_u + 1/2)(t_v + 1/2)$ subject to the constraint $t_u + t_v \leq t$ is given by $t_u = t_v = \frac{t}{2}$. Concerning the second property, recall that the dimension of $\boldsymbol{P}(\mathcal{M})$ is $n-1$, which implies that $\|\boldsymbol{p}\|_1 \leq n-1$ for all $\boldsymbol{p} \in \boldsymbol{P}(\mathcal{M})$. This, together with the fact that $\|\boldsymbol{p} - \boldsymbol{q}\|_1 \leq \|\boldsymbol{p}\|_1 + \|\boldsymbol{q}\|_1$, implies the result. □

Based on these properties, we derive a regret bound for the structural part of the OFDE algorithm by analyzing the update rules in Lines 10-12. Specifically, the expression (6) is decomposed into the telescopic sum:

$$R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T}) \leq \sum_{t=1}^{T} \langle \boldsymbol{p}^t, \boldsymbol{\ell}^t \rangle - \langle \boldsymbol{p}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle \tag{17}$$
$$+ \sum_{t=1}^{T} \langle \boldsymbol{p}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle - \langle \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle \tag{18}$$
$$+ \sum_{t=1}^{T} \langle \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle - \langle \boldsymbol{p}^*, \boldsymbol{\ell}^t \rangle \tag{19}$$

where $\boldsymbol{\ell}^t$ is used here as a shorthand of $\boldsymbol{\phi}^t(\boldsymbol{x}^t)$. Recall that each point $\boldsymbol{p}^t$ in the sequence $\boldsymbol{p}^{1:T}$ includes at most k forests. So, the difference (17) captures the regret of the OFDE algorithm with respect to its *unbounded* version, where the swap rounding step at Line 12 is omitted.

Lemma 4. The OFDE algorithm has no regret with respect to its unbounded version: $\sum_{t=1}^{T} \langle \boldsymbol{p}^t, \boldsymbol{\ell}^t \rangle - \langle \boldsymbol{p}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle = 0$.

Proof. Let $\tilde{\boldsymbol{p}}^{1:T}$ be the sequence of points given by the unbounded version of OFDE, that is, $\tilde{\boldsymbol{p}}^1 = \boldsymbol{p}^1$ and $\tilde{\boldsymbol{p}}^{t+1} = \alpha_t \tilde{\boldsymbol{p}}^t + (1 - \alpha_t)\boldsymbol{f}^{t+\frac{1}{2}}$ for each $t \in [T]$. We prove that $\mathbb{E}[\boldsymbol{p}^t] = \boldsymbol{p}^{t+\frac{1}{2}}$ by induction on $t \in [T]$. The case $t = 1$ follows from $\boldsymbol{p}^1 = \tilde{\boldsymbol{p}}^1$. Suppose by induction hypothesis that $\mathbb{E}[\boldsymbol{p}^t] = \tilde{\boldsymbol{p}}^t$. Using the SWAP algorithm, $\mathbb{E}[\boldsymbol{p}^{t+1}] = \alpha_t \boldsymbol{p}^t + (1 - \alpha_t)\boldsymbol{f}^{t+\frac{1}{2}}$. Furthermore, by induction hypothesis, we also know that $\mathbb{E}[\alpha_t \boldsymbol{p}^t + (1 - \alpha_t)\boldsymbol{f}^{t+\frac{1}{2}}] = \alpha_t \mathbb{E}[\boldsymbol{p}^t] + (1 - \alpha_t)\boldsymbol{f}^{t+\frac{1}{2}} = \tilde{\boldsymbol{p}}^{t+1}$. Since $\mathbb{E}[\mathbb{E}[\boldsymbol{p}^{t+1}]] = \mathbb{E}[\boldsymbol{p}^{t+1}]$, it follows that $\mathbb{E}[\boldsymbol{p}^{t+1}] = \tilde{\boldsymbol{p}}^{t+1}$, as desired. Based on this invariant, the result follows from the linearity of expectations: $\sum_{t=1}^{T} \langle \mathbb{E}[\boldsymbol{p}^t], \boldsymbol{\ell}^t \rangle - \langle \boldsymbol{p}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle = \sum_{t=1}^{T} \mathbb{E}\langle \boldsymbol{p}^{t+\frac{1}{2}} - \boldsymbol{p}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle = 0$. □

With this result in hand, the structural regret of the OFDE algorithm is reduced to the sum of (18) and (19). Using appropriate choices for the hyperparameters α_t and β_t we can derive sublinear regret bounds in both the horizon-dependent setting (where T is known) and the horizon-independent setting.

Lemma 5. Let $\gamma = \ln(T/2 + m^2/4)$. The structural regret $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T})$ of the OFDE algorithm is bounded by

- $n^2\gamma\sqrt{2T}$ in the horizon-dependent case, using $0 < \alpha_t \leq \frac{1}{2\sqrt{2t}}$ and $\beta_t = \frac{1}{\gamma n}\sqrt{2/t}$;
- $n^2(\gamma+1)^2\sqrt{2T}$ in the horizon-independent case, using $0 < \alpha_t \leq \frac{1}{4\sqrt{2t}}$ and $\beta_t = \frac{1}{n}\sqrt{2/t}$.

Proof. Consider the regret expression (18), and let $\alpha_t = \alpha'/\sqrt{t}$. Using the specification of $\boldsymbol{p}^{t+\frac{1}{2}}$ given at Line 11, we get

$$\begin{aligned}\sum_{t=1}^{T} \langle \boldsymbol{p}^{t+\frac{1}{2}} - \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle &= \sum_{t=1}^{T} \alpha_t \langle \boldsymbol{p}^t - \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle \\ &\leq 2(n-1)\gamma \sum_{t=1}^{T} \alpha_t \leq 4(n-1)\gamma\alpha'\sqrt{T}\end{aligned}$$

where the first inequality follows from Hölder's inequality $\langle \boldsymbol{p}^t - \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle \leq \|\boldsymbol{p}^t - \boldsymbol{f}^{t+\frac{1}{2}}\|_1 \|\boldsymbol{\ell}^t\|_\infty$, and the application of Lemma 3. The last inequality follows from $\sum_{t=1}^{T} 1/\sqrt{t} \leq 2\sqrt{T}$. Now, observe that (19) is the regret of the FPL strategy. Let $\beta_t = \beta'/\sqrt{t}$. By applying Theorem 3.3 in (Kalai and Vempala, 2005), we can derive that

$$\begin{aligned}\sum_{t=1}^{T} \langle \boldsymbol{f}^{t+\frac{1}{2}} - \boldsymbol{p}^*, \boldsymbol{\ell}^t \rangle &\leq 2\beta' RA\sqrt{T} + \tfrac{D}{\beta'}\sqrt{T} \\ &\leq (n-1)n^2\gamma^2\beta'\sqrt{T} + \tfrac{2(n-1)}{\beta'}\sqrt{T}\end{aligned}$$

using the facts that $R = \max_{t \in [T]} \langle \boldsymbol{f}^{t+\frac{1}{2}}, \boldsymbol{\ell}^t \rangle \leq 2(n-1)\gamma$ from Hölder inequality, $A = \max_{t \in [T]} \|\boldsymbol{\ell}^t\|_1 \leq \gamma n^2/2$, and

$D = \max_{t\in[T]} \|\boldsymbol{f}^{t+\frac{1}{2}} - \boldsymbol{f}^{t-\frac{1}{2}}\|_1 \leq 2(n-1)$. Combining the derived bounds for (18) and (19), and rearranging, yields

$$R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T}) \leq (n-1)\sqrt{T}\left(4\gamma\alpha' + n^2\gamma^2\beta' + \frac{2}{\beta'}\right)$$

In the horizon-dependent case, we can take $\beta' = \sqrt{2}/\gamma n$ to derive that $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T}) \leq \gamma(n-1)(4\alpha' + n\sqrt{2})\sqrt{T}$, which is bounded by $n^2\gamma\sqrt{2T}$ for $\alpha' \leq 1/2\sqrt{2}$. In the horizon-independent case, γ is unknown. So, using $\beta' = \sqrt{2}/n$, we get that $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{p}^{1:T}) \leq (n-1)[4\gamma\alpha' + (n/\sqrt{2})(\gamma^2+1)]\sqrt{T}$, which is bounded by $n^2(\gamma+1)^2\sqrt{2T}$ for $\alpha' \leq 1/4\sqrt{2}$. □

5.3 MAIN RESULTS

We have now all ingredients in hand to prove the Hannan-consistency of our online learning algorithm. The next theorem is obtained by coupling Lemma 2 with Lemma 5. The corollary is simply derived by replacing the bound in Lemma 2 with (16).

Theorem 2. For the classes of Markov forests $\mathcal{F}_{m,n}$ and Markov trees $\mathcal{T}_{m,n}$, there exists an online density estimation algorithm achieving a minimax regret in $O(m^2 n \ln T + n^2 \ln T\sqrt{T})$ in the horizon-dependent case, and $O(m^2 n \ln T + n^2 (\ln T)^2\sqrt{T})$ in the horizon-independent case.

Corollary 1. For the classes of binary Markov forests $\mathcal{F}_{2,n}$ and Markov trees $\mathcal{T}_{2,n}$, there exists an online density estimation algorithm that attains (in the horizon-dependent case) a minimax regret of $n^2 \ln(\frac{T}{2}+1)\sqrt{2T} + (n-\frac{1}{2})\ln T + o(n)$.

To conclude the theoretical part of this study, recall that the competitor used in both parts (6) and (7) of the regret analysis is an expert in $(\boldsymbol{P}(\mathcal{M}), \boldsymbol{\Theta}_{m,n})$. As mentioned above, such experts are tree-structured mixtures sharing the same parameters, which predict according to the probability distribution (3). As stated in Lemma 2, the parametric regret $R_{\boldsymbol{x}^{1:T}}(\boldsymbol{\theta}^{1:T})$ of the OFDE algorithm with respect to these experts is in $O(m^2 n \ln T)$. Since the regret bounds in Lemma 5 also hold for these competitors, it follows that OFDE is Hannan-consistent with respect to tree-structured mixtures.

6 EXPERIMENTS

In order to empirically evaluate our algorithm, we performed simulations on 4 publicly available datasets[1], listed in Table 1. Though all these datasets are binary-valued, they differ in the number of variables and the number of instances.

Our experimental objective was to compare the OFDE algorithm with respect to batch learning algorithms which have the benefit of hindsight for the train set. To this end, we used the Chow-Liu (CL) algorithm (Chow and Liu, 1968) that learns a Markov tree, and the Chow-Liu with Thresholding (CLT) algorithm (Tan et al., 2011), that learns a Markov forest by pruning the Chow-Liu tree. The CL and OFDE algorithms were trained without using the tune set. As CLT relies on a user-supplied threshold parameter $\epsilon \in (0,1)$, we performed experiments using several values $\{1/4, 1/2, 3/4\}$ for this parameter and kept in our results the best choice of ϵ measured on the tune set. In our implementation of CLT, we used a slight refinement of the original pruning rule: any edge (i,j) for which the empirical mutual information is lower than $n^{-\epsilon}$ is removed from the tree. Our OFDE algorithm was trained with both reference classes $\mathcal{F}_{2,n}$ and $\mathcal{T}_{2,n}$. Here, we denote by OFDE_F (resp. OFDE_T) the instantiation of OFDE with Markov forests (resp. Markov trees). Both instances of OFDE were trained under the horizon-independent setting, using $k = \ln n$, $\alpha_t = \frac{1}{4\sqrt{2t}}$, and $\beta_t = \frac{1}{n}\sqrt{2/t}$.

Dataset	Train set	Tune set	Test set	Vars (n)
Abalone	3,134	417	626	31
Covertype	30,000	4,000	6,000	84
KDDCup 2000	180,092	19,907	34,955	64
MSNBC	291,326	38,843	58,265	17

Table 1: Dataset Characteristics.

The batch algorithms CL and CLT were trained on the whole train set, and their generalization performance was measured using the average log-loss evaluated on the test set. For the online learners OFDE_F and OFDE_T, the instances were revealed only one at a time and, at the end of each iteration, the performance was measured by evaluating the average log-loss on the test set. The sequence of observations was generated by simply listing the instances of the train set.

The results, averaged over 10 experiments per dataset, are reported in Figure 2. Unsurprisingly, the performance of OFDE_T is generally better than OFDE_F, since the batch tree learner CL outperforms its forest variant CLT. Yet, it is apparent that OFDE_T and OFDE_F respectively converge to the estimations of CL and CLT. The convergence rates are particularly remarkable for the datasets Covertype, KDDCup 2000, and MSNBC, where a logarithmic scale is used for the number of iterations.

Concerning runtimes, the three algorithms were implemented in C++ and tested on a Quad-core Intel XEON X5550. For all datasets, the per-round runtime of OFDE (using forests or trees) is less than 3 ms. This indicates that OFDE can be used as practical alternative to CL(T) for handling streaming applications.

7 DISCUSSION

As a fundamental result in universal prediction, it is known that the optimal solution achieving minimax regret for any class $\mathcal{M}$ of discrete probabilistic models is obtained by the *normalized maximum likelihood* strategy (Shtarkov, 1987). Unfortunately, for this optimal strategy, the time horizon T must be known in advance, and the computation of the log-loss at each round $t \in [T]$ requires the evaluation of exponentially many marginalization terms. Thus, one of the key challenges in online density estimation is to devise horizon-independent strategies that pro-

[1] alchemy.cs.washington.edu/papers/davis10a/

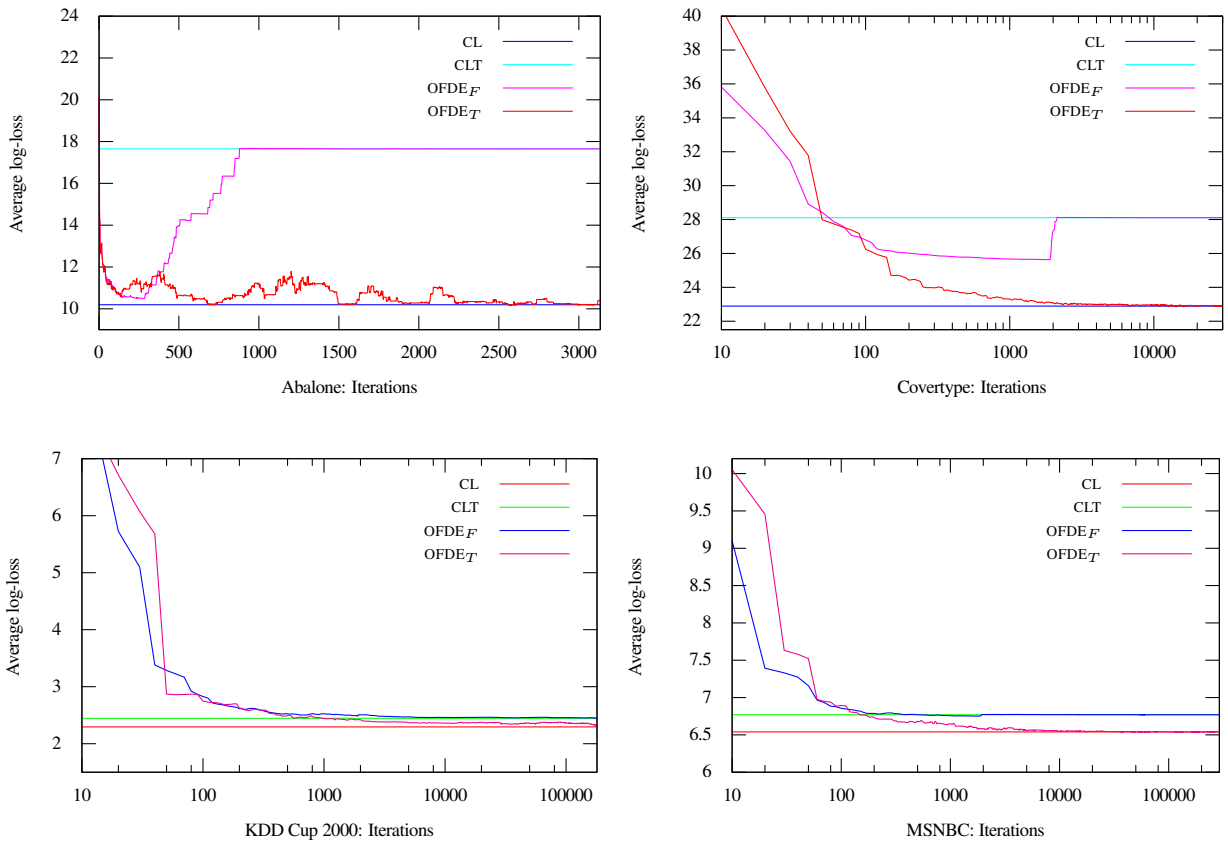

Figure 2: Comparison of OFDE$_T$ and OFDE$_F$ with CL and CLT on the four datasets.

vide a good compromise between minimax optimality and computational complexity. Several easily implementable nearly optimal strategies have been proposed for unidimensional probabilistic models, including binomial and multinomial families (Freund, 1996; Xie and Barron, 2000; Watanabe and Roos, 2015), and, more generally, univariate exponential families (Takimoto and Warmuth, 2000; Azoury and Warmuth, 2001; Kotłowski and Grünwald, 2011). Much less is known, however, about multidimensional families, especially the classes of graphical models characterized by multiple interdependencies between variables. A notable exception is the work by Bauer et al. (1997) for sequentially predicting the parameters of a Bayesian network. Yet, the target network structure is known in advance. To our knowledge, the present paper is one of the first studies that investigates both structural and parametric aspects of graphical models in online density estimation.

By considering classes of experts defined over varying structures, our study has intimate connections with *online combinatorial optimization*, a topic of online learning where the reference classes are combinatorial spaces. Several Hannan-consistent algorithms have been proposed in this setting, including the *Follow the Perturbed Leader* (FPL) strategy (Hannan, 1957; Kalai and Vempala, 2005), and the *Online Mirror Descent* (OMD) strategy (Koolen et al., 2010; Audibert et al., 2011; Rajkumar and Agarwal, 2014). Though OMD is known to achieve better regret bounds than FPL, it relies on a projection step performed at each iteration, in order to maintain the current estimate in the convex hull of the combinatorial space. The computational complexity of this projection step is typically much worse than the cost of linear optimization, especially when the combinatorial space is a matroid. The FPL strategy, advocated in this study, provides a reasonable compromise between optimality and computational complexity. Yet, alternative strategies can be devised in our setting such as, for example, online Franck-Wolfe optimization methods (Hazan and Kale, 2012).

A natural perspective of research that emerges from our study is to devise *lower bounds* for the minimax regret of forest density estimators. In a related setting, Kveton et al. (2014) have recently shown that such lower bounds are essentially logarithmic in T for the reference class of partition matroids. We conjecture that similar bounds holds for graphical matroids, and more generally for the classes $\mathcal{F}_{m,n}$ and $\mathcal{T}_{m,n}$. Finally, our work is also related to mixtures of trees (Meila and Jordan, 2000; Kumar and Koller, 2009). To this point, we have shown that OFDE is Hannan-consistent with mixtures of forests (or trees) sharing the *same* parameters. An interesting open question is to determine whether *arbitrary* mixtures of trees are learnable in the online density estimation setting.

Abstract

Collective matrix factorization (CMF) is a popular technique to improve the overall factorization quality of multiple matrices presuming they share the same latent factor. However, it suffers from performance degeneration when this assumption fails, an effect called *negative transfer (n.t.)*. Although the effect is widely admitted, its theoretical nature remains a mystery to date.

This paper presents a first theoretical understanding of $n.t.$ in theory. Under the statistical minimax framework, we derive lower bounds for the CMF estimator and gain two insights. First, the $n.t.$ effect can be explained as the rise of a bias term in the standard lower bound, which depends only on the structure of factor space but neither the estimator nor samples. Second, the $n.t.$ effect can be explained as the rise of an d_{th}-root function on the learning rate, where d is the dimension of a Grassmannian containing the subspaces spanned by latent factors. These discoveries are also supported in simulation, and suggest $n.t.$ may be more effectively addressed via model construction other than model selection.

1 INTRODUCTION

Collective matrix factorization (CMF) is a popular technique to factorize multiple matrices in hope of improving their overall factorization quality (e.g. [7, 23, 17, 11, 16, 2, 12, 3, 21, 26]). The key assumption of CMF is that all matrices share the same low-rank factor, under which its estimator proves to be consistent [5]. However, when this assumption fails, CMF is known to suffer from performance degeneration – an effect called *negative transfer*. Several algorithmic solutions have been proposed, which alternatively assume different matrix factors are drawn from the same distribution [24, 1] or partially shared [10].

Although negative transfer has been long accused for causing the performance degeneration, the theoretical understanding on its nature appears surprisingly scarce, i.e. no study was done to justify its existence or how it may hurt CMF. *What can we say about negative transfer in theory?* This is the question we aim to address in the paper.

Our investigation is performed under the mini-max framework in statistical decision theory. We first cast CMF into this framework and design a collective hypothesis testing problem that captures the negative transfer effect. By reducing the CMF estimation problem to this testing problem, we manage to derive a lower bound of the CMF estimator, through which a new bias term is discovered that worsens the standard bound. In particular, the bias only depends on the structure of the factor space, but neither the choice of estimator nor training samples. This suggests negative transfer is an intrinsic difficulty of learning, which may only be resolved at the model construction phase but neither model selection nor data collection. This is also supported from another observation that negative transfer down-weights the contribution of estimation accuracy in the lower bound.

For better interpretability, we further refine the lower bound by capturing more problem characteristics. In particular, we derive a learning rate of $\Omega(1/|\omega|^{\frac{1}{d}})$, where $\vec{\omega}$ is the index set of all matrix observations and d is the dimension of a Grassmannian containing the subspaces spanned by latent factors. Pessimistically, this rate is d_{th}-root slower than the standard rate $\Omega(1/|\omega|)$ where negative transfer does not exist. This discovery is also supported in our simulation.

The rest of this paper is organized as follows: the notations are introduced in section two; our primary lower bound is presented in section three, and the refined bound is presented in section four; proofs and remarks are given in section five, followed by simulation in section six and conclusions in section seven.

2 PRELIMINARIES

In this section we introduce the major notations, concepts and assumptions used in analysis. For the ease of presentation, we focus on two matrix factorization, but all discussions are readily generalizable.

Matrix Notations. For a matrix M, let M_{ij} be its entry at row i and column j, let $[M]$ be its column space, $||M||$ be its Frobenius norm [1] and M^T be its transpose. Given two matrices M, M' of the same column size, let $\vec{M} = [M, M']$ be their column concatenation. Let I be an identify matrix properly sized by the context.

Sets. Let $\mathbb{M}_k^{n\cdot}$ be a set of rank-k matrices with row dimension n and arbitrary column dimension, and $\mathbb{M}_k^{n,p} \subseteq \mathbb{M}_k^{n\cdot}$ be its subset with column dimension p. Let $\mathbb{G}_k^n$ be the Grassmannian defined as the set of k-dimensional subspaces in $\mathbb{R}^n$ (a metric will be equipped later). Note each element in $\mathbb{G}_k^n$ is a subspace. Let $\mathbb{S}_k^n$ be the set of orthonormal matrices in $\mathbb{R}^{k\times n}$.

Metrics. Let d be the metric on $\mathbb{M}_k^{n,p}$ such that

$$d(M, M') = ||M - M'||, \tag{1}$$

for all $M, M' \in \mathbb{M}_k^{n,p}$. It will be used for any choice of p. Let ρ be the metric on $\mathbb{G}_k^n$ such that for any $\mathcal{G}, \mathcal{G}' \in \mathbb{G}_k^n$,

$$\rho(\mathcal{G}, \mathcal{G}') = ||\mathrm{P}_{\mathcal{G}} - \mathrm{P}_{\mathcal{G}'}||, \tag{2}$$

where $\mathrm{P}_{\mathcal{G}}$ is the orthogonal projection matrix onto $\mathcal{G}$. It is defined as $\mathrm{P}_{\mathcal{G}} = DD^T$ for any basis $D \in \mathbb{S}_k^n$ of $\mathcal{G}$. See [4, Section 2.5] for more explanations.

Factorization Model. We focus on full-rank matrix factorization, which is typically assumed in CMF (e.g. [17, 5]). The factorization model is generally denoted as $M = DA$, where D is called the *factor* and A is called the *loading*. For the ease of presentation, we assume $D \in \mathbb{S}_k^n$ but all discussions are generalizable. (See Remark 11 for a justification.) In general the loading will not be specified in analysis, as long as it is a properly sized full rank matrix. All matrices are assumed bounded.

The Shared-Factor Assumption of CMF. The CMF assumption can be stated as: *any input $M, M' \in \mathbb{M}_k^{n\cdot}$ admit factorization $M = DA$ and $M' = D'A'$ such that $[D] = [D']$*. Note although CMF assumes $D = D'$, in essence it only requires $[D] = [D']$. Also note $[D] \in \mathbb{G}_k^n$.

Probability Notations. We mainly use two styles of probability notations with different focuses: 1) notation $\Pr\{\cdot\}$ focuses on the uncertainty over random samples, e.g. in section 3 where we prove the mini-max bound randomized over samples; 2) notation $\mathbb{P}$ focuses on treating the probability as a subject of interest, e.g. in section 4 where we pick a finite set of probabilities for testing which one generates the random sample.

Sampling Model. In many applications M is not fully observed (e.g. matrix completion [17]). Let ω be the index set of observed entries and M_ω be the input matrix. Assume ω is randomly sampled. Given a concatenated matrix $\vec{M}$, we use $\vec{\omega}$ to denote its index set of observations (induced from the observations of each matrix).

Generative Model. The matrix generative model is needed for refining the mini-max bound, but not for modeling negative transfer. In our analysis, only one generative model needs to be defined on the concatenated matrix $\vec{M}$.

Suppose $\vec{M} \in \mathbb{M}_k^{n,\vec{p}}$. Let $\mathcal{P}$ be a set of probabilities defined on $\mathbb{M}_k^{n,\vec{p}}$ such that each $\mathbb{P} \in \mathcal{P}$ is a matrix-variate normal distribution (e.g. [6, Chapter 2]),

$$\mathbb{P}_{\bar{M}}(\vec{M}) = \mathcal{N}(\bar{M}, \sigma^2\mathrm{I}, \sigma^2\mathrm{I}'), \tag{3}$$

with mean matrix $\bar{M}$ and covariance matrices $\sigma^2\mathrm{I}$ (among rows) and $\sigma^2\mathrm{I}'$ (among columns). It follows

$$\mathbb{P}_{\bar{M}}(\vec{M}) = \prod\nolimits_{(i,j)} \tilde{\mathbb{P}}_{\bar{M}}(\vec{M}_{ij}), \tag{4}$$

where $\tilde{\mathbb{P}}_{\bar{M}}(\vec{M}_{ij}) = \tilde{\mathcal{N}}(\bar{M}_{ij}, \sigma^2)$ is a univariate normal distribution and the product is taken over all indices of $\vec{M}$. We note in passing $\mathbb{P}_{\bar{M}}$ is similar to the probabilistic matrix factorization model assumed in [15, Equation 1]. Define

$$\mathbb{P}_{\bar{M}}(\vec{M}_{\vec{\omega}}) = \prod\nolimits_{(i,j)\in\vec{\omega}} \tilde{\mathbb{P}}_{\bar{M}}(\vec{M}_{ij}). \tag{5}$$

Mapping. Since each M admits a unique $[D]$ in factorization $M{=}DA$ (Remark 12), we have a mapping $\theta : \mathbb{M}_k^{n\cdot} \to \mathbb{G}_k^n$ such that $\theta(M) = [D]$. This is the mapping from a rank-k matrix with n rows to its column space in $\mathbb{R}^n$. Note θ applies to any column dimension.

CMF Estimator. Recall $\vec{M}_{\vec{\omega}}$ is the random observation of two matrices. Define CMF estimator as $\hat{\theta} : \{\vec{M}_{\vec{\omega}}\} \to \mathbb{G}_k^n$. Note it realizes the shared-factor assumption by mapping two matrix observations into a single subspace. Write $\hat{\theta}_{\vec{\omega}}$ for $\hat{\theta}(\vec{M}_{\vec{\omega}})$. The quality of $\hat{\theta}$ is evaluated by

$$\ell_{\vec{\omega}}(\hat{\theta}|\vec{M}) = \frac{1}{2}\left[\rho(\hat{\theta}_{\vec{\omega}}, \theta(M)) + \rho(\hat{\theta}_{\vec{\omega}}, \theta(M'))\right]. \tag{6}$$

Define the maximum risk of any CMF estimator as

$$\mathfrak{M}(\hat{\theta}) = \sup_{\vec{M}} \mathbb{E}_{\vec{\omega}} \ell_{\vec{\omega}}(\hat{\theta}|\vec{M}), \tag{7}$$

where expectation $\mathbb{E}_\omega$ is taken over the randomness of $\vec{M}_{\vec{\omega}}$.

It was noted when the shared-factor assumption is satisfied, CMF is equivalent to factorizing on a single matrix $\vec{M}$ [10].

Packing. This notion is used to define the following hypothesis testing problem and widely used in proof. For any

[1] This notation should not cause confusion since we only consider Frobenius norm in this paper.

set $\mathcal{X}$ equipped with a metric $\rho_{\mathcal{X}}$, let $\{x_v\}_{v\in\mathcal{V}}$ be an arbitrary subset of $\mathcal{X}$ indexed by a set $\mathcal{V}$. For any $\delta > 0$, we say this subset is a δ-packing of $\mathcal{X}$ with respect to $\rho_{\mathcal{X}}$ if $\rho_{\mathcal{X}}(x_v, x_{v'}) \geq \delta$ whenever $v \neq v'$.

Collective Hypothesis Testing. To lower bound $\mathfrak{M}(\hat{\theta})$, we employ the classic estimation-to-testing reduction method (e.g. [22]). To capture the negative transfer effect, we additionally design a *collective hypothesis testing* problem.

Let $\{\mathcal{G}_v\}_{v\in\mathcal{V}}$ be a 2δ-packing of $\mathbb{G}_k^n$ indexed by a finite set $\mathcal{V}$, and V, V' be two random variables taking values $v, v' \in \mathcal{V}$ respectively. Our testing problem is stated as follows:

Step 1: choose V, V' (with replacement) from $\mathcal{V}$ independently and uniformly at random.

Step 2: conditioned on $(V = v, V' = v')$, randomly choose $(D, D') \in \mathbb{S}_k^n \times \mathbb{S}_k^n$ satisfying $([D], [D']) = (\mathcal{G}_v, \mathcal{G}_{v'})$.

Step 3: generate $(M, M') = (DA, D'A')$ with some random A, A'; then generate observation $\vec{M}_{\vec{\omega}}$ from $\vec{M}$.

Step 4: apply a collective testing function $\hat{V} : \{\vec{M}_{\vec{\omega}}\} \to \mathcal{V}$ defined as [2]

$$\hat{V}(\vec{M}_{\vec{\omega}}) := \arg\min_{v\in\mathcal{V}} \rho(\hat{\theta}(\vec{M}_{\vec{\omega}}), \mathcal{G}_v). \tag{8}$$

To our knowledge, the collective hypothesis testing problem, albeit simple, is the first attempt to theoretically model the negative transfer effect in CMF. It also allows incorporation of richer information such as prior distribution, and can be applied to other problems besides CMF, as will be exemplified in later discussions.

3 A PRIMARY LOWER BOUND

The following proposition presents a primary lower bound, which reveals our main idea and insights.

Proposition 1. *Suppose $\mathbb{G}_k^n$ admits a 2δ-packing indexed by a finite set $\mathcal{V}$, and V is a uniform random variable on $\mathcal{V}$. Then, any CMF estimator $\hat{\theta}$ satisfies*

$$\mathfrak{M}(\hat{\theta}) \geq \frac{\delta}{2} \cdot \left(C_\delta + \frac{1}{|\mathcal{V}|} \Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\} \right), \tag{9}$$

where $C_\delta = 1 - |\mathcal{V}|^{-1}$ and the probability is defined over the random choice of V and $\vec{M}_{\vec{\omega}}$ [3].

Our main idea of proving the proposition is to first reduce the estimation problem into the collective hypothesis testing problem. Then, if two matrices are generated from different subspaces (i.e. $\theta(M) \neq \theta(M')$), $\hat{V}$ is guaranteed to make mistake on at least one matrix by a geometrical argument in Figure 1. This inevitable mistake gives rise to bias C_δ in the lower bound, which does not depend on the choice of estimator nor observations. On the other hand, the testing error $\Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\}$ is obtained by standard arguments, conditioned on the case when two matrices are indeed generated from the same subspace.

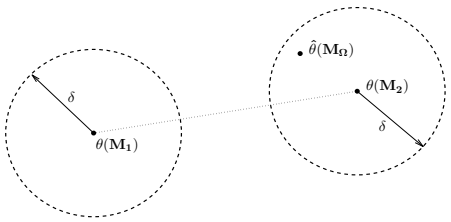

Figure 1: When two matrices are generated from different subspaces, no CMF estimator $\hat{\theta}$ can simultaneously fall into the two δ-balls centered at $\theta(M_2)$ and $\theta(M_2)$ respectively. As a result, the testing function $\hat{V}$ is guaranteed to make a mistake on at least one matrix.

Next, we discuss the implications of Proposition 1. For comparison, consider the case when negative transfer does not exist (i.e. $V = V'$). In this case, by Remark 13 we have

$$\mathfrak{M}(\hat{\theta}) \geq \delta \cdot \Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\}. \tag{10}$$

Comparing the lower bounds in (9) and (10), we see negative transfer has caused two changes: 1) introduce a bias term C_δ; 2) down-weight the testing error by $1/(2|\mathcal{V}|)$. In particular, the bias term depends merely on the structure of $\mathbb{G}_k^n$, pessimistically suggesting that CMF may never succeed in a mini-max sense, disregarding the choice of estimator $\hat{\theta}$ or observation $\vec{M}_{\vec{\omega}}$. Combining both aspects, it seems finding a good factor space may be more important than finding a good estimator or sample for mitigating the negative transfer effect.

When negative transfer does not exist, we may obtain another indirect implication by comparing CMF with independent matrix factorization (IMF) [4]. To elaborate the latter, let $\hat{\theta}_s : \{M_\omega\} \to \mathbb{G}_k^n$ be an IMF estimator and define its maximum risk as

$$\mathfrak{M}_s(\hat{\theta}_s) = \sup_M \mathbb{E}\, \rho(\hat{\theta}_s(M_\omega), \theta(M)), \tag{11}$$

where the expectation is taken over the randomness of ω. Let $\hat{V}_s : \{M_\omega\} \to \mathcal{V}$ be any testing function on a single matrix, which possibly induces $\hat{V}$. By standard mini-max arguments it is easy to verify that

$$\mathfrak{M}_s(\hat{\theta}_s) \geq \delta \cdot \Pr\{\hat{V}_s(M_\omega) \neq V\}. \tag{12}$$

A comparison between the lower bounds in (10) and (12) suggests CMF estimator performs *no worse* than IMF estimator on at least one matrix. The reason is $\hat{V}(\vec{M}_{\vec{\omega}}) \neq V$ implies inclusively either $\hat{V}_s(M_\omega) \neq V$ or $\hat{V}_s(M'_{\omega'}) \neq V$.

[2] Note $\vec{M}_{\vec{\omega}}$ depends on v, v' in Steps 3 and 4.

[3] Both V and $\hat{V}(\vec{M}_{\vec{\omega}})$ are random variables on $\mathcal{V}$.

[4] This is the technique that separately factorizes each matrix based on its own observations.

(Otherwise, $\hat{V}$ would not make the mistake if, say, it is simply defined as the random choice of one $\hat{V}_s$.) Taking M_w for instance, we thus have

$$\Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\} \leq \Pr\{\hat{V}_s(M_\omega) \neq V\}. \quad (13)$$

Further detailing (13) is beyond the scope of this paper. Nevertheless, it is not difficult to conjecture the inequality holds typically when M has insufficient observation (thus CMF improves over IMF on at least one matrix) and the equality holds otherwise. It should be noted even without negative transfer, our lower bound does not suggest CMF always improves over IMF. We note this is neither concluded from the upper bound analysis of CMF assuming no negative transfer [5].

Next we present two extensions of the proposition.

3.1 A BOUND WITH PRIOR

In [16], authors assumed a prior distribution over the factor space. A natural question for us is how such intrinsic prior may affect the negative transfer effect. For simplicity assume all sets are measurable.

Let ν be a probability measure defined on the factor space $\mathbb{S}_k^n$, as assumed in [16]. It naturally induces a probability measure μ over $\mathbb{G}_k^n$ such that for any $\mathcal{G} \in \mathbb{G}_k^n$,

$$\mu(\mathcal{G}) := \int_{[D]=\mathcal{G}} 1 \, d\nu(D). \quad (14)$$

Define $\tilde{\mu} := \mu/N$ as a normalized probability measure with proper choice of N. We can replace *Step 1* in the collective hypothesis testing problem with

Step 1^**: choose both* V, V' *(with replacement) by* $\tilde{\mu}(\mathcal{G}_V)$.

By the same arguments for Proposition 1, and now

$$\Pr\{V = V'\} = \sum\nolimits_{v \in \mathcal{V}} \tilde{\mu}^2(\mathcal{G}_v), \quad (15)$$

it is easy to verify the following result.

Corollary 2. *Suppose* $\mathbb{G}_k^n$ *admits a* 2δ*-packing indexed by a finite set* $\mathcal{V}$*. Let* V *be a uniform random variable on* $\mathcal{V}$*. Replace Step* 1 *in collective hypothesis testing with Step* 1^**. Then, any CMF estimator* $\hat{\theta}$ *satisfies*

$$\mathfrak{M}(\hat{\theta}) \geq \frac{\delta}{2} \cdot \left(\tilde{C}_\delta + \tilde{N}_\delta \Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\} \right), \quad (16)$$

where $\tilde{N}_\delta = \sum_{v \in \mathcal{V}} \tilde{\mu}^2(\mathcal{G}_v)$*,* $\tilde{C}_\delta = 1 - \tilde{N}_\delta$*, and the probability is defined over the random choice of* $\vec{M}_{\vec{\omega}}$ *and* V*.*

The implication of Corollary 2 is clear: since $\tilde{N}_\delta$ reaches its minimum when $\tilde{\mu}(\mathcal{G}_V)$ is the same for all choices of V (by Chebyshev's sum inequality), resulting in the maximum bias $\tilde{C}_\delta$, we see CMF suffers most negative transfer when nature chooses V uniformly.

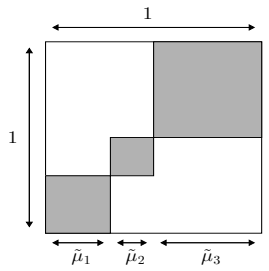

Figure 2: A packing of three points, each indexing a gray square in the figure with its prior $\mu_i := \mu(\mathcal{G}_i)$, $i = 1, 2, 3$. The total area of three squares equals to $\tilde{N}_\delta$. Clearly, this area reaches its maximum value 1 when $\mu_i = 1$ for any i. This corresponds to the most concentrated prior μ.

On the other hand, a simple geometric argument in Figure 2 shows the more concentrated $\tilde{\mu}$ nature uses, the less negative transfer CMF suffers.

3.2 A BOUND FOR MATRIX RECOVERY

A major use of CMF is for recovering the missing values of incomplete matrices (e.g. [17]). This section presents a technique to extend Proposition 1 for the recovery task under mild conditions. The main strategy is to convert the recovery error back to $\rho(\hat{\mathcal{G}}, \mathcal{G})$ using the following variant of [18, Theorem 2.3].

Lemma 3. *Let* $\mathcal{G}, \mathcal{G}'$ *respectively be the column spaces of any* $M, M' \in \mathbb{M}_k^{n,p}$*. Let* $s_k(M)$ *be the smallest non-zero singular value of* M*. Then*

$$\rho(\mathcal{G}, \mathcal{G}') \leq \sqrt{2}||M - M'||/s_k(M). \quad (17)$$

For simplicity, we focus on a set $\tilde{\mathbb{M}}_k^{n\cdot} \subseteq \mathbb{M}_k^{n\cdot}$ whose matrices have their smallest non-zero singular values bounded away from zero. A similar assumption was made for matrix recovery in [9, Theorem I.2.].

Let $\tilde{\mathbb{G}}_k^n \subseteq \mathbb{G}_k^n$ be the set induced from $\tilde{\mathbb{M}}_k^{n\cdot}$ such that for every $\mathcal{G} \in \tilde{\mathbb{G}}_k^n$ there is an $M \in \tilde{\mathbb{M}}_k^{n\cdot}$ satisfying $\theta(M) = \mathcal{G}$. For a matrix M and a factor $\hat{D}$ estimated from its observation M_ω, define the recovery error as

$$er_M(\hat{D}) = \min_A ||M - \hat{D}A||^2. \quad (18)$$

This is similar to the reconstructive error in [13, page 1]. Define the recovery loss as

$$\ell_{\mathfrak{r}|\vec{\omega}}(\hat{\theta}|\vec{M}) = \frac{1}{2}\left[er_M(\hat{\theta}(\vec{M}_{\vec{\omega}})) + er_{M'}(\hat{\theta}(\vec{M}_{\vec{\omega}})) \right], \quad (19)$$

and the maximum risk of any CMF estimator as

$$\tilde{\mathfrak{M}}_{\mathfrak{r}}(\hat{\theta}) = \sup_{\vec{M} \in \tilde{\mathbb{M}}_k^{n\cdot} \times \tilde{\mathbb{M}}_k^{n\cdot}} \mathbb{E}_{\vec{\omega}} \ell_{\mathfrak{r}|\vec{\omega}}(\hat{\theta}|\vec{M}). \quad (20)$$

Our recovery bound is stated as follows.

Corollary 4. *Given a $\tilde{\mathbb{M}}_k^{n\cdot}$ and its induced $\tilde{\mathbb{G}}_k^n$ that admits a 2δ-packing indexed by a finite set $\mathcal{V}$. Let V be a uniform random variable on $\mathcal{V}$. Then, there is a $c > 0$ (depending on $\tilde{\mathbb{M}}_k^{n\cdot}$) bounded away from zero such that every CMF estimator $\hat{\theta}$ satisfies*

$$\tilde{\mathfrak{M}}_{\mathfrak{r}}(\hat{\theta}) \geq \frac{\delta \cdot c}{2\sqrt{2}} \left(C_\delta + \frac{1}{|\mathcal{V}|} \Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\} \right), \quad (21)$$

where $C_\delta = 1 - |\mathcal{V}|^{-1}$ and the probability is defined over the random choice of $\vec{M}_{\vec{\omega}}$ and V.

Corollary 4 shows a recovery error bound that maintains the same order as the estimation error bound.

4 A FINER LOWER BOUND

In this section, we first introduce a few more machinery used to refine the lower bound in Proposition 1, and then present the refined bound.

Generalized Fano Method for CMF. The first piece of information is related to the generalized Fano method in [22, Lemma 3], which will be the starting point of our proof.

Let $I(;)$ denote the mutual information between two variables. The following lemma is our extension of the generalized Fano method for the CMF problem.

Lemma 5. *Let $\{M_v \in \mathbb{M}_k^{n\cdot}\}_{v\in\mathcal{V}} \subseteq \mathcal{P}$ be a collection of matrices indexed by $\mathcal{V}$ such that for any $v \neq v'$,*

$$\rho(\theta(M_v), \theta(M_{v'})) \geq 2\delta. \quad (22)$$

Further, suppose

$$I(V; \vec{M}_{\vec{\omega}}) \leq \beta, \quad (23)$$

where V is a uniform random variable on $\mathcal{V}$. Then

$$\max_{v,v'\in\mathcal{V}} \mathbb{E}_\omega \frac{1}{2} \left(d(\hat{\theta}, \theta(M_v)) + d(\hat{\theta}, \theta(M_{v'})) \right) \geq \frac{\delta}{2} \left(1 - \frac{\beta + \log 2}{|\mathcal{V}| \log |\mathcal{V}|} \right). \quad (24)$$

Comparing (24) with the standard bound [22, Lemma 3] [5]

$$\frac{\delta}{2} \left(1 - \frac{\beta + \log 2}{\log |\mathcal{V}|} \right), \quad (25)$$

our generalization introduces an additional $|\mathcal{V}|$ in the denominator, which significantly speeds up the growth of the lower bound as $|\mathcal{V}|$ increases. This coincides with with our discovery in Proposition 1, and provides a finer implication of the negative transfer effect. In result we retain the mutual information (instead of relaxing it to KL divergence) to facilitate later application.

A few things should be clarified about the lemma. First, it does not require M_v's to have the same column dimension. Second, $I(V; \vec{M}_{\vec{\omega}})$ is derived from $\Pr\{\hat{v}(\vec{M}_{\vec{\omega}}) \neq V\}$ in Proposition 1 and thus inherits the condition that two matrices share the same latent factor.

Packing Number. The second piece of information is related to the packing number on Grassmannian $\mathbb{G}_k^n$, which will be used to bound $|\mathcal{V}|$ in Lemma 5.

Let $M(\mathbb{G}_k^n, \rho, \delta)$ be the packing number on $\mathbb{G}_k^n$ with respect to metric ρ and radius δ. It is the largest size of $\mathcal{V}$ that indexes an admitted δ-packing on $\mathbb{G}_k^n$. Let $\tau(\mathbb{G}_k^n)$ and d be the diameter and dimension of $\mathbb{G}_k^n$, respectively. The following result is a variant of [19, Proposition 8].

Lemma 6. *There exist universal constants $c_1, c_2 > 0$ such that for any $\delta \in (0, \tau(\mathbb{G}_k^n)]$,*

$$(c_1 \tau(\mathbb{G}_k^n)/\delta)^d \leq M(\mathbb{G}_k^n, \rho, \delta) \leq (c_2 \tau(\mathbb{G}_k^n)/\delta)^d. \quad (26)$$

Mutual Information. The third piece of information is related to the mutual information $I(V; \vec{M}_{\vec{\omega}})$ appeared in Lemma 5, which will be used for deriving its upper bound.

Let $D_{k\ell}$ denote KL divergence. Recall the probability notation $\mathbb{P}$ introduced in section 2. A classic approach (e.g. [22, page 428]) to bound $I(V; \vec{M}_{\vec{\omega}})$ is by

$$I(V; \vec{M}_{\vec{\omega}}) \leq \frac{1}{|\mathcal{V}|^2} \sum_{v,v'} D_{k\ell}(\mathbb{P}_v || \mathbb{P}_{v'}). \quad (27)$$

However, this does not directly apply to our setting since $\mathbb{P}_v$ is not easy to specify. The following technique is from [8, Equation 110], which addresses the problem.

Lemma 7. *Let $T(\vec{M}_{\vec{\omega}})$ be any side information. Then*

$$I(V; \vec{M}_{\vec{\omega}}) \leq I(V; \vec{M}_{\vec{\omega}} | T(\vec{M}_{\vec{\omega}})). \quad (28)$$

Write $\vec{T}$ for $T(\vec{M}_{\vec{\omega}})$. We notice

$$I(V; \vec{M}_{\vec{\omega}} | \vec{T}) \leq \frac{\sum_{v,v'} \mathbb{E} D_{k\ell}(\mathbb{P}_v(\cdot|\vec{T}) || \mathbb{P}_{v'}(\cdot|\vec{T}))}{|\mathcal{V}|^2}, \quad (29)$$

where expectation $\mathbb{E}$ is taken over the randomness of $\vec{T}$.

KL Divergence. The last piece of information is related to KL divergence, which is used to specify the bound in (29).

Recall the generative model introduced in section 2. For a matrix $\vec{M}$ and its observation index $\vec{\omega}$, let W_ω be a matrix of the same size as $\vec{M}$ such that $W_{ij|\vec{\omega}} = 1$ if $(i,j) \in \vec{\omega}$ and $W_{ij|\vec{\omega}} = 0$ otherwise. Let $\circ$ denote the Hadamard product between matrices. We remark the following result.

Lemma 8. *For any $\bar{M}, \bar{M}' \in \mathbb{M}_k^{n,\vec{p}}$ and $\vec{\omega}$,*

$$D_{k\ell}(\mathbb{P}_{\bar{M}|\vec{\omega}} || \mathbb{P}_{\bar{M}'|\vec{\omega}}) = \frac{1}{2\sigma^4} ||W_{\vec{\omega}} \circ (\bar{M} - \bar{M}')||^2. \quad (30)$$

[5] While [22] focused on probability set, we focus on matrix set to facilitate later application. Nevertheless, our extension is also applicable on probability set and will give result similar to (24).

4.1 THE FINER BOUND

Recall the factorization model $M = DA$ and A is randomly generated. Let $\Sigma_A = \mathbb{E}||A||^2$. Our finer bound is based on the setting of Proposition 1 and stated as follows.

Theorem 9. *Every CMF estimator $\hat{\theta}$ satisfies*

$$\mathfrak{M}(\hat{\theta}) \geq c \cdot \tau(\mathbb{G}_k^n)^{1-1/d}(|\vec{\omega}|\Sigma_A/\sigma^4)^{-1/d}, \tag{31}$$

where $c > 0$ depends on the nature of $\mathbb{G}_k^n$ and absorbs lower order terms.

The new lower bound can be interpreted as follows.

- $|\vec{\omega}|$: larger observation number $|\vec{\omega}|$ leads to smaller lower bound. This makes sense, as more observations improve the accuracy of testing. However, we see its impact is significantly restricted by d, resulting in a learning rate $\Omega(|\vec{\omega}|^{-1/d})$. Based on (25) and our arguments for the theorem, one can easily derive a learning rate without negative transfer as $\Omega(|\vec{\omega}|^{-1})$. Thus we see negative transfer significantly slows down learning. This shall not be too surprising, however, since in Lemma 5 the lower bound has already become linearly dependent on $|\mathcal{V}|$ (instead of logarithmically) due to the negative transfer effect.

- d: for simplicity, assume $\tau(\mathbb{G}_k^n)|\vec{\omega}|\Sigma_A/\sigma^4 \geq 1$. Then, larger d leads to larger lower bound. In particular, a very large d significantly weakens the impact of other parameters (except $\tau(\mathbb{G}_k^n)$) on the lower bound. This coincides with our discovery in Proposition 1, where the impact of estimation quality (and now its related parameters) is down-weighted.

  We notice the dimension $d = k(n-k)$ is quadratic to matrix rank k and reaches its maximum at $k = n/2$ (and thus the worst bound). It is unclear how to explain such role of k, but we have another consistent observation based mainly on combinatoric arguments: Assume $\mathbb{M}_k^{n\cdot}$ is defined on a finite field of order q (which is common in problems such as recommendation system). Then the number of its column spaces (thus factor spaces) is the q-binomial coefficient $\binom{n}{k}_q$ based on [14]. Clearly, the more subspaces $\mathbb{M}_k^{n\cdot}$ induces, the more difficult estimation/testing will be. In particular, we notice $\binom{n}{k}_q$ is also a quadratic-style function of k and reaches its maximum at $k = n/2$.

- $\tau(\mathbb{G}_k^n)$: larger diameter of $\mathbb{G}_k^n$ leads to larger lower bound. This makes sense, since a larger hypothesis set admits a larger packing (see Lemma 6), resulting in a more challenging testing problem. In addition, we see the impact of diameter is slightly restricted by the dimension d of $\mathbb{G}_k^n$. Specifically, a large diameter hurts more when the dimension is high.

- Σ_A and σ: we are not particularly interested in these two terms, but note in passing that larger Σ_A or smaller σ leads to smaller lower bound.

- c : this coefficient arises from the universal constants in Lemma 6 that depend on the nature of $\mathbb{G}_k^n$. Then it absorbs lower order terms through derivation, but this shall not affect the order of interested parameters.

5 PROOFS AND REMARKS

Proof of Proposition 1.

Write $\hat{\theta}$ for $\hat{\theta}(\vec{M}_{\vec{\omega}})$, $\vec{V}$ for (V, V') and $\vec{v}$ for (v, v'). Let notation $\vee$ denote the logical disjunction. Following standard mini-max arguments, we first have

$$\begin{aligned}
&\sup_{\vec{M}} \mathbb{E}_{\vec{\omega}} \left[\rho(\hat{\theta}, \theta(M)) + \rho(\hat{\theta}, \theta(M'))\right] \\
&\geq \sup_{\vec{M}} \mathbb{E}\left[\delta \, \mathbf{1}\{\rho(\hat{\theta}, \theta(M)) \geq \delta \vee \rho(\hat{\theta}, \theta(M')) \geq \delta\}\right] \\
&= \delta \cdot \sup_{\vec{M}} \Pr\{\rho(\hat{\theta}, \theta(M)) \geq \delta \vee \rho(\hat{\theta}, \theta(M')) \geq \delta\},
\end{aligned} \tag{32}$$

where the inequality is based on the fact that total distance is greater than δ if any one distance is greater than δ.

Reducing the above estimation problem into the collective hypothesis testing problem (with a 2δ-packing $\{\theta_v\}_{v\in\mathcal{V}}$), we have

$$\begin{aligned}
&\sup_{\vec{M}} \Pr\{\rho(\hat{\theta}, \theta(M)) \geq \delta \vee \rho(\hat{\theta}, \theta(M')) \geq \delta\} \\
&\geq \frac{1}{|\mathcal{V}|^2} \sum_{\vec{v}} \Pr\{\rho(\hat{\theta}, \theta_v) \geq \delta \vee \rho(\hat{\theta}, \theta_{v'}) \geq \delta \mid \vec{V} = \vec{v}\},
\end{aligned} \tag{33}$$

where the coefficient is based on the uniform sampling assumption on $\mathcal{V}$ so that $\Pr\{\vec{V} = \vec{v}\} = 1/|\mathcal{V}|^2$.

Now we introduce the negative transfer effect. Consider two cases $v = v'$ and $v \neq v'$. Clearly the second one captures the violation of the shared-factor assumption. Then

$$\begin{aligned}
&\Pr\{\rho(\hat{\theta}, \theta_v) \geq \delta \vee \rho(\hat{\theta}, \theta_{v'}) \geq \delta \mid \vec{V} = \vec{v}\} \\
&= \Pr\{\rho(\hat{\theta}, \theta_v) \geq \delta \vee \rho(\hat{\theta}, \theta_{v'}) \geq \delta \mid v \neq v', \vec{V} = \vec{v}\} \\
&\quad \cdot \Pr\{v \neq v' \mid \vec{V} = \vec{v}\} \\
&\quad + \Pr\{\rho(\hat{\theta}, \theta_v) \geq \delta \vee \rho(\hat{\theta}, \theta_{v'}) \geq \delta \mid v = v', \vec{V} = \vec{v}\} \\
&\quad \cdot \Pr\{v = v' \mid \vec{V} = \vec{v}\} \\
&= 1 \cdot \Pr\{v \neq v' \mid \vec{V} = \vec{v}\} \\
&\quad + \Pr\{\rho(\hat{\theta}, \theta_v) \geq \delta \vee \rho(\hat{\theta}, \theta_{v'}) \geq \delta \mid v = v', \vec{V} = \vec{v}\} \\
&\quad \cdot \Pr\{v = v' \mid \vec{V} = \vec{v}\},
\end{aligned} \tag{34}$$

where the second equality is based on the geometric argument illustrated in Figure 1, i.e. if $v \neq v'$, then no $\hat{\theta}$ can be

simultaneously δ-close to both θ_v and $\theta_{v'}$, which implies $\Pr\{\rho(\hat{\theta},\theta_v)\geq\delta\vee\rho(\hat{\theta},\theta_{v'})\geq\delta\}=1$.

Putting all above arguments together and in addition: 1) $\rho(\hat{\theta},\theta_{v_t})\geq\delta$ as implied by $\hat{V}(\vec{M}_{\vec{\omega}})\neq v_t$ (by the definition of $\hat{V}$); 2) average over all possible $\vec{v}$, we have

$$\begin{aligned}&\sup_{\vec{M}}\mathbb{E}\left[\rho(\hat{\theta},\theta(M))+\rho(\hat{\theta},\theta(M'))\right]\\&\geq\delta\left(\Pr\{V\neq V'\}+\frac{1}{|\mathcal{V}|}\Pr\{\hat{V}(\vec{M}_{\vec{\omega}})\neq V|V=V'\}\right).\end{aligned}\tag{35}$$

It remains to simplify the above lower bound. First, by uniform sampling $\Pr\{V\neq V'\}=1-|\mathcal{V}|^{-1}$. Second, $\Pr\{\hat{V}\neq V|V=V'\}=\Pr\{\hat{v}\neq V\}$, where the left side probability is over the randomness of both V,V', while the right side probability is merely over the randomness of V. Putting all together proves the proposition.

Proof of Corollary 4.

Recall $s_k(M)$ is the smallest non-zero singular value of matrix M. By our assumption $c=\inf_{M\in\tilde{\mathbb{M}}_k^{n\cdot}}s_k(M)$ is positive and bounded away from zero. Combining with Lemma 3, this implies any $M,M'\in\tilde{\mathbb{M}}_k^{n\cdot}$ satisfy

$$\rho(\mathcal{G},\mathcal{G}')\leq\sqrt{2}||M-M'||/c.\tag{36}$$

Writing $\hat{\theta}:=\hat{\theta}(\vec{M}_\omega)$, this further implies

$$er_M(\hat{\theta})\geq c\cdot\rho(\hat{\theta},\theta(M))/\sqrt{2}.\tag{37}$$

Hence over all $\vec{M}\in\tilde{\mathbb{M}}_k^{n\cdot}\times\tilde{\mathbb{M}}_k^{n\cdot}$, we have

$$\begin{aligned}&\sup_{\vec{M}}\mathbb{E}_{\vec{\omega}}\left[er_M(\hat{\theta})+er_{M'}(\hat{\theta})\right]\\&\geq\frac{c}{\sqrt{2}}\sup_{\vec{M}}\mathbb{E}_{\vec{\omega}}\left[\rho(\hat{\theta},\theta(M))+\rho(\hat{\theta},\theta(M'))\right].\end{aligned}\tag{38}$$

Applying Proposition 1 yields the corollary.

Proof of Lemma 5.

The proof is similar to [22, Lemma 3], with the main difference that we study a joint estimation problem (instead of a single one) and apply our own reduction technique.

By assumption $\{\phi(\mathbb{P}_v)\}_{v\in\mathcal{V}}$ is a 2δ-packing on $\mathbb{G}_k^n$. Applying the arguments in Proposition 1 gives a lower bound

$$\frac{\delta}{2}\left(C_\alpha+\frac{1}{|\mathcal{V}|}\Pr\{\hat{V}(\vec{M}_{\vec{\omega}})\neq V\}\right),\tag{39}$$

where $C_\alpha=1-|\mathcal{V}|^{-1}$.

Further, following the same arguments in the generalized Fano method [22, Lemma 3] (in particular, the Fano's inequality and data processing inequality), we have

$$\Pr\{\hat{V}(\vec{M}_{\vec{\omega}})\neq V\}\geq1-\frac{I(V;\vec{M}_{\vec{\omega}})+\log 2}{\log|\mathcal{V}|}.\tag{40}$$

Combining both with $I(V;\vec{M}_{\vec{\omega}})\leq\beta$ proves the lemma.

Proof of Lemma 6.

Let $N(\mathbb{G}_k^n,\rho,\delta)$ be the covering number of $\mathbb{G}_k^n$ with respect to metric ρ and covering radius δ. It is defined as

$$\min\{|\mathcal{V}|:\mathbb{G}_k^n\text{ admits a }\delta\text{-cover indexed by }\mathcal{V}\},\tag{41}$$

where a *δ-cover* is a set of points in $\mathbb{G}_k^n$ such that the union of their δ-balls contains $\mathbb{G}_k^n$. It is stated [19, Proposition 8] there are universal constants $s_1,s_2>0$ such that

$$(s_1\cdot D_g/\delta)^d\leq N(\mathbb{G}_k^n,\rho,\delta)\leq(s_2\cdot D_g/\delta)^d.\tag{42}$$

In addition, it is well-known that (e.g. [25, Equation 1.5]).

$$N(\mathbb{G}_k^n,\rho,\delta)\leq M(\mathbb{G}_k^n,\rho,\delta)\leq N(\mathbb{G}_k^n,\rho,\delta/2).\tag{43}$$

Putting two together we have

$$(s_1\cdot D_g/\delta)^d\leq M(\mathbb{G}_k^n,\rho,\delta)\leq(2s_2\cdot D_g/\delta)^d.\tag{44}$$

Setting $c_1=s_1$ and $c_2=2s_2$ proves the lemma.

Proof of Lemma 8.

Recall the generative model in section 2, where $\mathcal{P}=\{\mathbb{P}\}$ is a set of probabilities defined on $\mathbb{M}_k^{n,\vec{p}}$. For clarity we first derive the case when $\vec{M}$ is complete, and its generalization for $\vec{M}_{\vec{\omega}}$ naturally follows. Remark the following result.

Remark 10. *For any $\bar{M},\bar{M}'\in\mathbb{M}_k^{n,\vec{p}}$,*

$$D_{k\ell}(\mathbb{P}_{\bar{M}}(M)||\mathbb{P}_{\bar{M}'}(M))=\frac{1}{2\sigma^4}||\bar{M}-\bar{M}'||^2.\tag{45}$$

Proof. By the definition of KL divergence,

$$D_{k\ell}(\mathbb{P}_{\bar{M}}||\mathbb{P}_{\bar{M}'})=\mathbb{E}_{\mathbb{P}_{\bar{M}}}\log\left(\mathbb{P}_{\bar{M}}/\mathbb{P}_{\bar{M}'}\right),\tag{46}$$

where expectation $\mathbb{E}_{\mathbb{P}_{\bar{M}}}$ is taken over $\mathbb{P}_{\bar{M}}$. Further, by the definition of matrix-variate normal distribution (e.g. [6]),

$$\mathbb{P}_{\bar{M}}(\vec{M})=\exp\left(-||(\vec{M}-\bar{M}||^2/2\sigma^4\right)/\sqrt{(2\pi)^{np}}.\tag{47}$$

This implies

$$\log\frac{\mathbb{P}_{\bar{M}}}{\mathbb{P}_{\bar{M}'}}=-\frac{1}{2\sigma^4}(||\vec{M}-\bar{M}||^2-||\vec{M}-\bar{M}'||^2).\tag{48}$$

In addition,

$$\begin{aligned}&\mathbb{E}_{\mathbb{P}_M}\,||\vec{M}-\bar{M}||^2-||\vec{M}-\bar{M}'||^2\\&=\mathbb{E}\sum_{i,j}(\vec{M}_{ij}-\bar{M}_{ij})^2-(\vec{M}_{ij}-\bar{M}'_{ij})^2\\&=\mathbb{E}\sum_{i,j}2\vec{M}_{ij}(\bar{M}'_{ij}-\bar{M}_{ij})+\bar{M}_{ij}^2-(\bar{M}'_{ij})^2\\&=\sum_{i,j}2\bar{M}_{ij}(\bar{M}'_{ij}-\bar{M}_{ij})+\bar{M}_{ij}^2-(\bar{M}'_{ij})^2\\&=\sum_{i,j}(\bar{M}'_{ij}-\bar{M}_{ij})^2=||\bar{M}'-\bar{M}||^2.\end{aligned}\tag{49}$$

Putting all together completes the proof. □

The arguments for Lemma 8 is almost the same as those for Remark 10, except now we have

$$\mathbb{P}_{\bar{M}|\vec{\omega}}(\vec{M}) = \prod\nolimits_{(i,j)\in\vec{\omega}} \tilde{\mathbb{P}}_{\bar{M}}(\vec{M}_{ij}), \tag{50}$$

which admits a matrix form (can be easily verified)

$$\mathbb{P}_{\bar{M}|\vec{\omega}}(\vec{M}) = \frac{\exp\left(-\frac{1}{2\sigma^4}||W_{\vec{\omega}} \circ (\vec{M} - \bar{M})||^2\right)}{\sqrt{(2\pi)^{|\vec{\omega}|}}}. \tag{51}$$

Keeping $W_{\vec{\omega}}$ through the derivation proves the lemma.

Proof of Theorem 9.

The first step is to apply the extended generalized Fano method (Lemma 5) to derive a lower bound. To do so, we need to fulfill its two conditions (22) and (23) respectively.

Let $\{\vec{M}_v \in \mathbb{M}_k^{n,\vec{p}}\}_{v\in\mathcal{V}}$ be a set inducing a 2δ-packing on $\mathbb{G}_k^n$, i.e. $\rho(\theta(\vec{M}_v), \theta(\vec{M}_{v'})) \geq 2\delta$ for any $v \neq v'$. This set fulfills (22). Note we have chosen all matrices from $\mathbb{M}_k^{n,\vec{p}}$, which does not weaken the analysis since this set can induce the entire $\mathbb{G}_k^n$ through θ.

It takes more effort to fulfill (23). Recall $I(V; \vec{M}_{\vec{\omega}})$ is based on the condition that input matrices share the same factor. Then our problem is equivalent to testing V using a single matrix $\vec{M}$ randomly drawn from $\mathbb{M}_k^{n,\vec{p}}$. This allows us to apply the generative model on $\mathbb{M}_k^{n,\vec{p}}$ in section 2.

For any $\vec{M} \in \mathbb{M}_k^{n,\vec{p}}$, let $\vec{A} \in \mathbb{R}^{k\times\vec{p}}$ be a loading in its factorization and $\vec{W} \in \mathbb{R}^{n\times\vec{p}}$ be its mask such that $\vec{W}_{ij} = 1$ if $\vec{M}_{ij}$ is observed and $\vec{W}_{ij} = 0$ otherwise. We have

$$\begin{aligned}
&I(V; \vec{M}_{\vec{\omega}}) \\
&\leq I(V; \vec{M}_{\vec{\omega}}|\vec{A}) \\
&\leq \mathbb{E}_{\vec{A}} \frac{1}{|\mathcal{V}|^2} \sum_{v,v'\in\mathcal{V}} D_{k\ell}(\mathbb{P}_v(\vec{M}|\vec{A})||\mathbb{P}_{v'}(\vec{M}|\vec{A})) \\
&\leq \frac{1}{|\mathcal{V}|^2} \sum_{v,v'} \mathbb{E} D_{k\ell}(\mathbb{P}_v(\vec{M}|\vec{A})||\mathbb{P}_{v'}(\vec{M}|\vec{A})) \\
&= \frac{1}{|\mathcal{V}|^2} \sum_{v,v'} \mathbb{E} \frac{1}{2\sigma^4} ||\vec{W} \circ (D_{\mathcal{G}_v} - D_{\mathcal{G}_{v'}})\vec{A}||^2 \qquad (52) \\
&\leq \frac{1}{|\mathcal{V}|^2} \sum_{v,v'} \frac{||\vec{W}||^2}{2\sigma^4} ||D_{\mathcal{G}_v} - D_{\mathcal{G}_{v'}}||^2 \cdot \mathbb{E}||\vec{A}||^2 \\
&\leq \frac{1}{|\mathcal{V}|^2} \sum_{v,v'} \frac{|\vec{\omega}|}{2\sigma^4} \cdot \rho(\mathcal{G}_v, \mathcal{G}_{v'}) \cdot \Sigma_{\vec{A}} \\
&\leq \frac{1}{2\sigma^4} |\vec{\omega}| \cdot \tau(\mathbb{G}_k^n) \cdot \Sigma_{\vec{A}},
\end{aligned}$$

where the first inequality is based on Lemma 7 where we condition both probabilities on a loading A; the second inequality is based on (29); the third inequality is due to the convexity of $\mathbb{E}_{\vec{A}}$; the first equality is based on Lemma 8; the fourth inequality is based on simple algebra argument (see Remark 14), and the fifth inequality is based on an extended argument of [20, Lemma A.1.2.] (see Remark 15); the last inequality is by the fact that $\rho(\mathcal{G}_v, \mathcal{G}_{v'}) \leq \tau(\mathbb{G}_k^n)$.

Till now we have fulfilled both conditions in the generalized Fano method described in Lemma 5. Together with Lemma 6 that bounds $|\mathcal{V}|$, this implies a lower bound

$$\frac{\delta}{2}\left(1 - \frac{|\vec{\omega}|\tau(\mathbb{G}_k^n)\Sigma_A/2\sigma^4 + \log 2}{d\left(\tau(\mathbb{G}_k^n)c/\delta\right)^d \log\left(\tau(\mathbb{G}_k^n)c/\delta\right)}\right). \tag{53}$$

As a standard strategy, it remains to choose a proper δ so that the 'big' fraction in (53) is upper bounded by $1/2$.

We are mainly interested in the order of parameters. First relax the lower order term $\log\left(\tau(\mathbb{G}_k^n)c/\delta\right) \geq \log(2c)$ since $\tau(\mathbb{G}_k^n) \geq 2\delta$ and the constant $\log 2 \geq \log 1 = 0$. Rearranging terms, we wish to choose a δ satisfying

$$\delta \geq \left(\frac{c^d \cdot d \cdot \log 2c \cdot \tau(\mathbb{G}_k^n)^d \cdot 2\sigma^4}{2|\vec{\omega}|\tau(\mathbb{G}_k^n)\Sigma_A}\right)^{1/d}. \tag{54}$$

Further, since $d = k(n-k)$ is a positive integer, it is easy to verify $d^{1/d} \leq 1.45$ and $(\log(2c))^{1/d} \leq \log(2c)$. Plugging both in the above lower bound and merging constants and terms depending on c into c', we have

$$\delta \geq c' \cdot \tau(\mathbb{G}_k^n)^{1-1/d} \cdot \left(|\vec{\omega}|\Sigma_A/\sigma^4\right)^{-1/d}. \tag{55}$$

Plugging this back to the lower bound (53) and merging constants again proves the theorem.

5.1 REMARKS

Remark 11. *Any $M, M' \in \mathbb{M}_k^{n\cdot}$ admit a joint full-rank factorization $M = QA$ and $M' = QA'$ for some $Q \in \mathbb{R}^{n\times k}$ if and only if they admit a joint factorization $M = DB$ and $M' = DB'$ for some $D \in \mathbb{S}_k^n$.*

Proof. A well known fact is that that every subspace of $\mathbb{R}^n$ admits an orthonormal basis (by Gram-Schmidt process). Thus for one direction, any Q induces a subspace $span(Q)$, which admits an orthonormal basis $D \in \mathbb{S}_k^n$. This means $Q = DL$ for some expressive coefficient matrix L and thus $M = QA = D(LA)$. The other direction is trivial. □

Remark 12. *Every $M \in \mathbb{M}_k^{n\cdot}$ admits exactly one $\mathcal{S} \in \mathbb{G}_k^n$ such that $\mathcal{S} = [D]$ for any $D \in \mathbb{S}_k^n$ satisfying $M = DA$.*

Proof. Given any two factorizations $M = DA = D'A'$ with $D, D' \in \mathbb{S}_k^n$, to justify the remark it suffices to show $span(D) \subseteq span(D')$ and $span(D) \supseteq span(D')$.

For the first direction, it suffices to find a $W \in \mathbb{R}^{k\times k}$ such that $D'W = D$. This is easy as $(D')^T D'$ is invertible since $D' \in \mathbb{S}_k^n$. (In fact, we only need D' to have full column rank.) Thus one can set $W = ((D')^T D')^{-1}(D')^T D$. Similar arguments apply for the other direction. □

Remark 13. *In Proposition 1, if one always has* $\theta(M) = \theta(M')$*, then* $\mathfrak{M}(\hat{\theta}) \geq \delta \cdot \Pr\{\hat{V}(\vec{M}_{\vec{\omega}}) \neq V\}$.

Proof. Condition $\theta(M) = \theta(M')$ implies we can fix $V = V'$ while designing the collective hypothesis testing problem. This means $\Pr\{V \neq V'\} = 0$ and $\Pr\{V = V'\} = 1$. Plugging both into the proof of Proposition 1 (last inequality) justifies the remark. □

Remark 14. *For any same sized matrices* A *and* B*, we have* $||A \circ B||^2 \leq ||A||^2 \cdot ||B||^2$.

Proof. For all sums taken over all matrix indices, it follows $||A \circ B||^2 = \sum (A_{ij}B_{ij})^2 = \sum (A_{ij})^2 (B_{ij})^2 \leq \sum (A_{ij})^2 \sum (B_{i'j'})^2 = ||A||^2 ||B||^2$, where the inequality is by the fact that $(B_{ij})^2 \leq \sum (B_{i'j'})^2$ for any (i, j). □

Remark 15. *For any* $D, D' \in \mathbb{S}_k^n$,

$$||D - D'||^2 \leq ||DD^T - D'(D')^T||^2. \tag{56}$$

Proof. This remark is a matrix extension of [20, Lemma A.1.2]. Let $D_{:j}$ denote the column j of D. We have

$$\begin{aligned} &||DD^T - D'(D')^T||^2 \\ &= \sum_j ||D_{:j} D_{:j}^T - D'_{:j}(D'_{:j})^T||^2 \\ &\leq \sum_j ||D_{:j} - D'_{:j}||^2 = ||D - D'||^2, \end{aligned} \tag{57}$$

where the inequality is based on [20, Lemma A.1.2] and the fact that $||D_{:j} - D'_{:j}|| \leq \sqrt{2}$ since $D, D' \in \mathbb{S}_k^n$. □

6 SIMULATION

In this section we empirically evaluate the learning rate of CMF under two settings, one without negative transfer and the other with negative transfer (NT):

NT-Free: in this case, we randomly generate a factor $D \in \mathbb{S}_k^n$ and two loadings $A \in \mathbb{R}^{n \times p}$ and $A' \in \mathbb{R}^{n \times p'}$ to construct matrices $M = DA$ and $M' = D'A'$. By this means, M, M' are guaranteed to share the same factor and negative transfer does not exist.

NT-Likely: in this case, we randomly and independently generate two factors $D, D' \in \mathbb{S}_k^n$ and two loadings A, A' same sized as in the NT-Free case. The two matrices are constructed by $M = DA$ and $M' = D'A'$. By this means, it is likely $[D] \neq [D']$ and thus negative transfer exists.

In evaluation we simply set n, p, p' to 50 and set k to 10. To examine the learning rate, the ratio of observations, denoted by r, is varied from 0.1, 0.3, 0.5, 0.7 to 0.9. At each choice of r, we randomly select $r \cdot np$ number of entries in each matrix to form the observation $\vec{M}_{\vec{\omega}}$. The CMF algorithm in [17] is implemented with no use of prediction link function. After performing CMF on $\vec{M}$, the loss function in the proposition is evaluated. Rewrite its notation as

$$Loss_{\omega}(\hat{\theta}) = \frac{1}{2}\left[\rho(\hat{\theta}, \theta(M)) + \rho(\hat{\theta}, \theta(M'))\right]. \tag{58}$$

In addition, fpr each r we repeat the random choice of $\vec{M}_{\vec{\omega}}$ for 10 times and report the averaged loss in Figure 3.

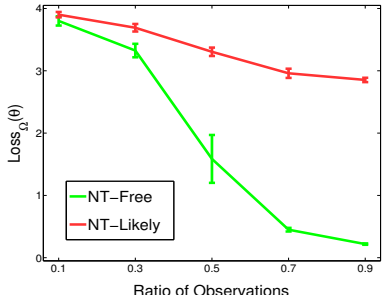

Figure 3: Performance simulation.

From Figure 3 it is clear that CMF converges much slower when negative transfer exists, as compared with the case when negative transfer does not exist. The bias is also quite obvious. These coincide with our theoretical discoveries.

7 CONCLUSION AND DISCUSSION

This paper presents a first theoretical explanation of negative transfer in collective matrix factorization. We present a min-max lower bound of the CMF estimator and show negative transfer gives rise to an additional bias term that depends only on the structure of the factor space. We further present a finer lower bound and show negative transfer slows the learning rate from $\Omega(|\vec{\omega}|^{-1})$ to $\Omega(|\vec{\omega}|^{-1/d})$, where d is the dimension of Grassmannian containing the subspaces spanned by matrix factors.

A limitation of this study is we assumed full-rank factorization. As suggested by the theory, increasing k may mitigate negative transfer, but clearly at the cost of increasing estimation variance. How these two aspects trade with each other remains unclear, even though our analysis may be naively extended for a larger k' (by simply basing everything on $\mathbb{G}_{k'}^n$). In addition, in reality two matrices may have different ranks and their induced subspaces may partly overlap [10]. This partial overlapping is merely implicitly captured in our analysis (thorough the choice of δ) and stronger results may be obtained by explicitly modeling it.

Abstract

Due to the prevalence of unlabeled data, semi-supervised learning has drawn significant attention and has been found applicable in many real-world applications. In this paper, we present the so-called Budgeted Semi-supervised Support Vector Machine (BS3VM), a method that leverages the excellent generalization capacity of kernel-based method with the adjacent and distributive information carried in a spectral graph for semi-supervised learning purpose. The fact that the optimization problem of BS3VM can be solved directly in the primal form makes it fast and efficient in memory usage. We validate the proposed method on several benchmark datasets to demonstrate its accuracy and efficiency. The experimental results show that BS3VM can scale up efficiently to the large-scale datasets where it yields a comparable classification accuracy while simultaneously achieving a significant computational speed-up compared with the baselines.

1 Introduction

Supervised learning constitutes one of the most fundamental problems in machine learning. While in no doubt this theory has been applied successfully to many real-world applications, a key limitation of this theory lies in the requirement of annotated labels during training. However, manual labeling process for large-scale data is labor intensive and error-prone. Consequently, the collected datasets frequently consist of a collection of labeled data jointly with a larger collection of unlabeled data. Semi-supervised learning (SSL) involves utilizing the intrinsic information carried in unlabeled data to enhance the generalization capacity of the learning algorithms. During the past decade, SSL has attracted significant attention and has been found applicable in a variety of problems including text categorization [Joachims, 1999], and bioinformatics [Kasabov et al., 2005] to name a few.

A notable approach to semi-supervised learning paradigm is to employ a spectral graph for representing the adjacent and distributive information in data. Several existing works have leveraged on the expressiveness of spectral graphs for SSL, including mincut [Blum et al., 2004], graph random walk [Azran, 2007], manifold regularization [Belkin et al., 2006], and spectral graph [Duong et al., 2015].

Inspired from the seminal work of [Joachims, 1999], a large body of works has attempted to advance kernel methods such as Support Vector Machine (SVM) [Cortes and Vapnik, 1995] within the semi-supervised learning paradigm. The underlying idea is to *solve standard SVM problem while treating the unknown labels as optimization variables* [Chapelle et al., 2008]. This leads to a non-convex optimization problem with a combinatorial explosion of label assignments. A wide spectrum of techniques have been proposed to solve this optimization problem including local combination search [Joachims, 1999], gradient descent [Chapelle and Zien, 2005], convex-concave procedures [Collobert et al., 2006], and deterministic annealing [Sindhwani et al., 2006, Le et al., 2013, Nguyen et al., 2014]. Although these approaches can somehow deal with the combinatorial intractability, their requirement of repeated retraining the model renders them impractical for many real-world problems.

At the intersection between kernel method and the spectral graph theory, several existing works have attempted to incorporate information carried in a spectral graph to build a better kernel function [Smola and Kondor, 2003, Zhu et al., 2004]. These works basically employed the Laplacian matrix induced from the spectral graph to construct the kernel function which can capture the features of ambient space. Manifold regularization framework [Belkin et al., 2006] exploited the geometry property of the probability distribution that generates data and incorporated it as an additional regularization term. Two regularization terms

[*]This work was carried out when the first author was supported and visiting the Centre for Pattern Recognition and Data Analytics, Deakin University, Australia in 2015.

were introduced to control the complexity of the classifier in the ambient space and to control the complexity measured by the geometry property of the data distribution. However, the computational complexity for manifold regularization approach is cubical in the training size. Hence, other approaches have been proposed to scale it up [Tsang and Kwok, 2006, Melacci and Belkin, 2011]. In particular, the work of [Melacci and Belkin, 2011] (the Laplacian Support Vector Machine or LapSVM) made use of preconditioned conjugate gradient to solve the optimization problem of manifold regularization approach in the primal form. This allows the computational complexity to be scaled up to quadratic. However, this approach was to solve the corresponding optimization problem in the first dual layer instead of in the primal form, hence renders the solution infeasible for online setting. Furthermore, LapSVM requires storing a full Hessian matrix of the training size in the memory, resulting in a quadratic memory complexity.

Recently, stochastic gradient descent (SGD) method [Shalev-Shwartz and Singer, 2007, Kakade and Shalev-Shwartz, 2008, Lacoste-Julien et al., 2012, Rakhlin et al., 2012, Hazan and Kale, 2014] has emerged as a promising framework to scale up fast and online learning algorithms. SGD possesses three key advantages: i) very fast; ii) capacity to run in online mode; and iii) economic memory usage. However, SGD-based methods are vulnerable to the *curse of kernelization* [Wang et al., 2012], that is, the model size linearly grows up with the training size accumulated over time. To bound the model size, budget-based algorithms limit the model size to a predefined budget B. When the model size exceeds the budget, a budget maintenance procedure is invoked to decrease the model size by one. Three widely-used budget maintenance strategies are removal, projection, and merging. In the removal strategy, the most redundant support vector is simply discarded [Crammer et al., 2004, Cavallanti et al., 2007, Wang and Vucetic, 2010, Le et al., 2016]. In the projection strategy, the information of the most redundant support vector is partly preserved through its projection onto the linear span of the remaining support vectors [Wang and Vucetic, 2010, Wang et al., 2012, Le et al., 2016]. The merging strategy first selects two vectors, and then merges them into one before discarding them [Wang et al., 2012].

Leveraging on the advantages of kernel method, spectral graph theory and stochastic gradient descent, we propose in this paper a novel approach to semi-supervised learning, termed as *Budgeted Semi-supervised Support Vector Machine* (BS3VM). To devise BS3VM, we first conjoin the theory of kernel method with the framework of spectral-graph-based semi-supervised learning. This allows us to form a specific optimization problem which involves the core optimization problem of kernel method and simultaneously enables the label propagation. We then apply SGD method to solve the incurred optimization problem directly in the primal form. To avoid the curse of kernelization, we employ two budgets B_l and B_u for the labeled and unlabeled portions. When either the labeled or unlabeled portion in the model exceeds its budget, the corresponding budget maintenance strategy will be invoked accordingly. We also establish a rigorous convergence analysis for BS3VM. The theoretical result shows that there exists a gap between the proposed and optimal solutions. This gap can be explicitly quantified and crucially depends on the budget maintenance rates and the coefficients accompanied with the removed vectors. We further establish the extensive experiments on several real-world datasets. The experimental results show that our proposed BS3VM can offer a comparable predictive performance while simultaneously achieving a significant computational speed-up comparing with the state-of-the-art baselines.

2 Spectral-graph-based Semi-supervised Learning

2.1 Spectral Graph

Spectral graph is a useful tool to capture the geometrical and distributive information carried in data. It is usually an undirected graph whose vertices are data instances. In the context of semi-supervised learning, we are given a training set $X = X_l \cup X_u$ where $X_l = \{(x_i, y_i)\}_{i=1}^{l}$ specifies labeled data and $X_u = \{x_i\}_{i=l+1}^{l+u}$ identifies unlabeled data. We can start constructing the spectral graph $\mathscr{G} = (\mathscr{V}, \mathscr{E})$ with the vertex set $\mathscr{V}$ including all labeled and unlabeled instances (i.e., $\mathscr{V} = \{x_i\}_{i=1}^{l+u}$). An edge $e_{ij} = \overline{x_i x_j} \in \mathscr{E}$ between two vertices x_i, x_j represents the similarity of these two instances. Let μ_{ij} be the weight of this edge. The principle is that if μ_{ij} is sufficiently large then two labels y_i, y_j are expected to be the same. The set of edges $\mathscr{G}$ and its weighs can be established using the following ways:

- *Fully connected graph*: every pair of vertices x_i, x_j is connected by an edge. The edge weight decreases when the distance $\|x_i - x_j\|$ increases. The Gaussian kernel weight function widely used is given by

$$\mu_{ij} = e^{-\|x_i - x_j\|^2/(2\sigma^2)}$$

  where σ is known as the bandwidth parameter and controls how quickly the weight decreases.

- *k-NN*: each vertex x_i defines its k nearest neighbors (k-NN) and makes an edge with one of its k-NN. The Gaussian kernel weight function can be used for the edge weight. Empirically, k-NN graphs with small k tend to perform well.

- *ε-NN*: we connect x_i and x_j if $\|x_i - x_j\| \leq \varepsilon$. Again the Gaussian kernel weight function can be used to weight the connected edges. In practice, ε-NN graphs are easier to construct than k-NN graphs.

It is noteworthy that when constructing the spectral graph, we avoid connecting the edge of two labeled instances since we do not need to propagate the label between them.

2.2 Label Propagation

After constructing the spectral graph, a semi-supervised learning problem is cast to assign labels to the unlabeled vertices. To this end, we need a mechanism to rationally propagate labels from the labeled vertices to the unlabeled ones. The key idea is that if μ_{ij} is large, then the two labels y_i, y_j are expected to be the same.

To assign labels to the unlabeled instances, it is desirable to learn a map $f: \mathscr{X} \longrightarrow \mathscr{Y}$ where $\mathscr{X}$ and $\mathscr{Y}$ are domains of data and label, respectively such that

- $f(x_i)$ is as closest to its label y_i as possible for all labeled instances x_i $(1 \leq i \leq l)$.
- f should be smooth on the whole graph $\mathscr{G}$, i.e., if x_i is very close to x_j (i.e., x_i, x_j are very similar or μ_{ij} is large), the discrepancy between f_i and f_j (i.e., $|f_i - f_j|$) is small.

Therefore, the following optimization problem is proposed to solve

$$\min_f \left(\infty . \sum_{i=1}^{l} (f_i - y_i)^2 + \sum_{(i,j)\in\mathscr{E}} \mu_{ij} \left| f_i - f_j \right| \right) \qquad (1)$$

where by convention we define $\infty.0 = 0$ and $f_i = f(x_i)$.

The optimization problem in Eq. (1) peaks its minimum as the first term is exactly 0 and the second term is as smallest as possible. It is therefore rewritten as follows

$$\min_f \left(\sum_{(i,j)\in\mathscr{E}} \mu_{ij} \left| f_i - f_j \right| \right) \qquad (2)$$
$$\text{s.t.}: \forall_{i=1}^{l} : f_i = y_i$$

To extend the representation ability of the prediction function f, we relax the discrete function f to be a real-valued. The drawback of the relaxation is that in the solution, $f(x)$ is now real-valued, hence does not directly correspond to a label. This can however be addressed by thresholding $f(x)$ at zero to produce discrete label predictions, i.e., if $f(x) \geq 0$, predict $y = 1$, and if $f(x) < 0$, predict $y = -1$.

3 Budgeted Semi-supervised Support Vector Machine

In this section, we present our proposed Budgeted Semi-supervised Support Vector Machine (BS3VM). We start this section with the introduction of the optimization problem of BS3VM. We then propose SGD-based solution for BS3VM with two budgets for the labeled and unlabeled portions, followed by the convergence analysis.

3.1 BS3VM Optimization Problem

Let $\Phi: \mathscr{X} \longrightarrow \mathscr{H}$ be a transformation from the input space $\mathscr{X}$ to a Reproducing Hilbert Kernel Space (RHKS) $\mathscr{H}$. We use the function $f(x) = \mathbf{w}^\mathsf{T}\Phi(x) - \rho = \sum_{i=1}^{l+u} \alpha_i K(x_i, x) - \rho$, where $\mathbf{w} = \sum_{i=1}^{l+u} \alpha_i \Phi(x_i)$ and $K(.,.)$ is kernel function, to predict label. Inspired from the optimization problem in Eq. (2), the following optimization problem is proposed

$$\min_{\mathbf{w}} \left(\frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{l}\sum_{i=1}^{l}\xi_i + \frac{C'}{|\mathscr{E}|}\sum_{(i,j)\in\mathscr{E}} \mu_{ij}\left|f_i - f_j\right| \right) \qquad (3)$$
$$\text{s.t.}: \forall_{i=1}^{l} : y_i\left(\mathbf{w}^\mathsf{T}\Phi(x_i) - \rho\right) \geq 1 - \xi_i$$
$$\forall_{i=1}^{l} : \xi_i \geq 0$$

where $f_i = \mathbf{w}^\mathsf{T}\Phi(x_i) - \rho$.

In the optimization formulation of Eq. (3), we minimize $\frac{1}{2}\|\mathbf{w}\|^2$ to maximize the margin for motivating the generalization capacity. At the same time, we minimize $\sum_{(i,j)\in\mathscr{E}} \mu_{ij}\left|f_i - f_j\right|$ to make the prediction function smoother on the spectral graph.

We rewrite the optimization problem in Eq. (3) in the primal form as follows[1]

$$\min_{\mathbf{w}} \left(\frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{l}\sum_{i=1}^{l} l(\mathbf{w}; z_i) + \frac{C'}{|\mathscr{E}|}\sum_{(i,j)\in\mathscr{E}} \mu_{ij} l_1\left(\mathbf{w}^\mathsf{T}\Phi_{ij}\right) \right) \qquad (4)$$

where $z_i = (x_i, y_i)$, $l(\mathbf{w}; x, y) = \max\left\{0, 1 - y\mathbf{w}^\mathsf{T}\Phi(x)\right\}$, $\Phi_{ij} = \Phi(x_i) - \Phi(x_j)$, $l_p(t) = |t|^p$ with $t \in \mathbb{R}$, and $p \geq 1$.

3.2 Budgeted SGD-based Solution for BS3VM

We now present the SGD-based solution for the optimization problem in Eq. (4). To resolve the curse of kernelization, we employ two budgets for the labeled and unlabeled portions whose budget sizes are B_l and B_u, respectively. When either the size of labeled or unlabeled portion in the current model exceeds its budget, the corresponding budget maintenance strategy is executed to maintain the model.

Let us denote the objective function in Eq. (4) by $J(\mathbf{w})$. At the iteration t, we construct the instantaneous objective function $J_t(\mathbf{w})$ which is defined as

$$J_t(\mathbf{w}) = \frac{1}{2}\|\mathbf{w}\|^2 + Cl(\mathbf{w}; x_{i_t}, y_{i_t}) + C'\mu_{u_t v_t} l_1\left(\mathbf{w}^\mathsf{T}\Phi_{u_t v_t}\right)$$

where i_t is uniformly sampled from $\{1, ..., l\} = [l]$ and the edge (u_t, v_t) connected x_{u_t} and x_{v_t} is uniformly sampled from the set of edges $\mathscr{E}$.

[1] We can eliminate the bias ρ by simply adjusting the kernel.

Inspired from the SGD method, we update $\mathbf{w}_t$ as

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t g_t = \mathbf{w}_t - \frac{1}{t} J'(\mathbf{w}_t) = \frac{t-1}{t}\mathbf{w}_t + \frac{C\alpha_t y_{i_t} \Phi(x_{i_t})}{t} + C' \frac{\mu_{u_t v_t} \beta_t (\Phi(x_{u_t}) - \Phi(x_{v_t}))}{t} \quad (5)$$

where $\alpha_t = -l'_o(\mathbf{w}_t; x_{i_t}, y_{i_t})$, $\beta_t = -\text{sign}\left(\mathbf{w}_t^{\mathsf{T}} \Phi_{u_t v_t}\right)$, the learning rate $\eta_t = \frac{1}{t}$, and $g_t = J'(\mathbf{w}_t)$.

It is noteworthy that we denote $o = \mathbf{w}^{\mathsf{T}}\Phi(x)$ which implies $l(\mathbf{w}; x, y)$ is now a function of o, and $l'_o(\mathbf{w}; x, y)$ is the derivative of the loss function w.r.t the variable o.

The update formula shown in Eq. (5) is vulnerable to the curse of kernelization, that is, the model size linearly grows with the data size accumulated over time. To address this issue, we propose to use two budgets for the labeled and unlabeled portions whose sizes are B_l and B_u, respectively.

Algorithm 1 Algorithm for training BS3VM.

Input: $B_l, B_u, K(.,.), C, C', \sigma$

1: $\mathbf{w}_1 = \mathbf{0}$
2: $b_l = 0$
3: $b_u = 0$
4: **for** $t = 1$ **to** T **do**
5: Uniformly sample i_t from $[l]$
6: Uniformly sample the edge (u_t, v_t) from $\mathscr{E}$
7: Update

$$\mathbf{w}_{t+1} = \frac{t-1}{t}\mathbf{w}_t + \frac{C}{t}\alpha_t y_{i_t}\Phi(x_{i_t}) + \frac{C'}{t}\mu_{u_t v_t}\beta_t(\Phi(x_{u_t}) - \Phi(x_{v_t}))$$

8: $b_l = b_l + 1 + \mathbb{I}_{u_t \le l} + \mathbb{I}_{v_t \le l}$
9: $b_u = b_u + \mathbb{I}_{u_t > l} + \mathbb{I}_{v_t > l}$
10: **if** $b_l > B_l$ **then**
11: $BM(\mathbf{w}_{t+1}, 'l')$ // *labeled portion*
12: $b_l = B_l$
13: **end if**
14: **if** $b_u > B_u$ **then**
15: $BM(\mathbf{w}_{t+1}, 'u')$ // *unlabeled portion*
16: $b_u = B_u$
17: **end if**
18: **end for**

Output: $\overline{\mathbf{w}}_T = \frac{1}{T}\sum_{t=1}^{T}\mathbf{w}_t$ or $\mathbf{w}_{T+1}$

Algorithm 1 presents the pseudocode of BS3VM. The model of BS3VM is represented through the labeled and unlabeled portions whose current sizes are b_l and b_u, respectively. When either b_l or b_u exceeds its budget, a budget maintenance procedure is triggered to maintain the model size (cf. lines 11 and 15 in Algorithm 1). We have two kinds of budget maintenance (BM) which involve the labeled and unlabeled portions, respectively. To differentiate these two kinds of BM, we employ the second argument in BM procedure wherein $'l'$ involves BM for the labeled portion and $'u'$ involves BM for the unlabeled portion. In addition, two options (i.e., $'l'$ or $'u'$) involve the same functional activity. The only difference is that they refer to either labeled or unlabeled portions. In addition, we utilize the fully connected spectral graph wherein the edge weights are computed on the fly as necessary.

3.3 Budget Maintenance Strategy

In this section, we present the BM strategies used in this paper which are removal and projection. The original projection strategy can partly preserve the information of the removed vectors and hence, usually offers better predictive performance than removal strategy. However, it requires a costly computation of the inverse of a matrix whose dimension is either B_l or B_u. To resolve this computational burden, we propose two special projection strategies which are nearest-neighbor projection (NNP) and random-neighbor projection (RNP). At the outset of this section, we define the index sets of the labeled and unlabeled portions at the iteration t as $I_t^l \subset [l]$[2] and $I_t^u \subset [l+1 : l+u]$[3], respectively. Hence, the current model $\mathbf{w}_t$ can be written as

$$\mathbf{w}_t = \sum_{i \in I_t^l} \delta_i \Phi(x_i) + \sum_{i \in I_t^u} \delta_i \Phi(x_i)$$

Both the removal and projection strategies involve the vectors whose coefficients have smallest absolute values in the labeled and unlabeled portions. We now define

$$l_t = \underset{i \in I_t^l}{\text{argmin}} \ |\delta_i| \text{ and } u_t = \underset{i \in I_t^u}{\text{argmin}} \ |\delta_i|$$

3.3.1 Removal

In the removal strategy, we simply remove $\Phi(x_{l_t})$ or $\Phi(x_{u_t})$. This strategy is efficient, but the information of the removed vectors are completely vanished.

3.3.2 Projection

To keep the information of the removed vector, the original projection strategy performs a projection of this vector onto the linear span of the remaining vectors. Although this full projection can efficiently preserve the information of the removed vector, it requires a costly computation of the inverse of B_l (or B_u) by B_l (or B_u) matrix which costs cubically over the budget sizes. Furthermore, decreasing the budget sizes to reduce the computational cost may significantly compromise the learning performance. To speed up the computation and omit the computational dependence of the projection on the budget sizes, we propose two variations of the projection which are nearest-neighbor projec-

[2] We denote $[l] = \{1, 2, \ldots, l\}$.
[3] We denote $[l+1 : l+u] = \{l+1, l+2, \ldots, l+u\}$.

tion (NNP) and random-neighbor projection (RNP) strategies. For brevity in presentation, we denote

$$x_{r_t} = \begin{cases} x_{l_t} & \text{for the option 'l' of BM} \\ x_{u_t} & \text{for the option 'u' of BM} \end{cases}$$

Nearest-Neighbor Projection (NNP). To efficiently preserve the information of x_{r_t}, before removing it, we find k-NN of x_{r_t} and do projection of x_{r_t} onto the linear span of this set. Our intuition is that if the vector x falls into the k-NN of x_{r_t} then x is close to x_{r_t}; consequently the induced dot product $K(x, x_{r_t}) = \Phi(x)^{\mathsf{T}} \Phi(x_{r_t})$ is high and hence, $\Phi(x)$ can largely keep the information of $\Phi(x_{r_t})$.

Random-Neighbor Projection (RNP). To further speed up the NNP strategy, we propose random-neighbor projection (NNP) wherein we first randomly choose k vectors from the support set and then project $\Phi(x_{r_t})$ onto the linear span of these vectors to preserve its information.

3.4 Convergence Analysis

In what follows we present the convergence analysis for BS3VM. Given an instance x, in a BM procedure, we replace this instance by its approximation $A(x)$ which incurs the difference vector $D(x) = \Phi(x) - A(x)$. In particular, with the removal strategy, $A(x) = 0, \forall x$, with the full projection strategy, $A(x) = \mathbb{P}_L(x), \forall x$ where $\mathbb{P}_L(x)$ specifies the linear span of the remaining vectors in the support set, and with NNP or RNP strategy, $A(x) = \mathbb{P}_L(x), \forall x$ where $\mathbb{P}_L(x)$ specifies the linear span of k corresponding vectors. We further define $\mathbf{w}^* = \underset{\mathbf{w}}{\operatorname{argmin}} J(\mathbf{w})$. For simplification, we assume that $\|\Phi(x)\| = K(x,x)^{1/2} = 1, \forall x$.

Let us denote two Bernoulli random variables which indicate whether the budget maintenances for the labeled portion (i.e., the option 'l') and for the unlabeled portion (i.e., the option 'u') are performed by Z_t^l, Z_t^u. The update rule is

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t g_t - Z_t^l \delta_{l_t} D(x_{l_t}) - Z_t^u \delta_{u_t} D(x_{u_t}) \quad (6)$$

It is noteworthy that the update rule in Eq. (6) covers all BM strategies. In addition, our convergence analysis can be applied to all aforementioned BM strategies but for comprehensibility, we present the theoretical results for the removal strategy.

Lemma 1 establishes an upper bound on $\|\mathbf{w}_t\|$, followed by Lemma 2 which establishes an upper bound on $\|g_t\|$.

Lemma 1. *The following statement holds*

$$\|\mathbf{w}_t\| \leq C + 2C', \forall t$$

Lemma 2. *The following statement holds*

$$\|g_t\| \leq G = 2\left(C + 2C'\right), \forall t$$

In Algorithm 1, the labeled-vertex sampling (cf. line 5) updates the coefficient of one labeled support vector while the edge sampling (cf. line 6) updates two coefficients of two support vectors. To proceed the convergence analysis, we assume that before removed, the coefficient of the labeled vector $\Phi(x_{l_t})$ is updated at most m times via the labeled-vertex sampling and n times via the edge sampling and the coefficient of the unlabeled vector $\Phi(x_{u_t})$ is updated at most p times via the edge sampling. Particularly, in the context of online learning, the labeled vector $\Phi(x_{l_t})$ might be sampled from a continuous distribution and so might be the edge. It follows that $m = n = p = 1$ and the assumption is naturally valid.

Lemma 3. *Given two positive integer numbers m, n, assume that before removed, the coefficient of $\Phi(x_{l_t})$ is updated at most m times via the labeled-vertex sampling and n times via the edge sampling. We then have*

$$|\delta_{l_t}| \leq \left(mC + nC'\right)/t, \forall t$$

Lemma 4. *Given a positive integer number p, assume that before removed, the coefficient of $\Phi(x_{u_t})$ is updated at most p times via the edge sampling. We then have*

$$|\delta_{u_t}| \leq pC'/t, \forall t$$

Lemma 5 establishes an upper bound on $\|h_t\|$, followed by Lemma 6 establishing an upper bound on $\mathbb{E}\left[\|\mathbf{w}_t - \mathbf{w}^*\|^2\right]^{1/2}$.

Lemma 5. *We define $\rho_i = \frac{\delta_i}{\eta_t} = t\delta_i$ and $h_t = Z_t^l \rho_{l_t} D(x_{l_t}) + Z_t^u \rho_{u_t} D(x_{u_t})$. Then we have*

$$\|h_t\| \leq H = mC + (n+p)C', \forall t$$

Lemma 6. *The following statement holds*

$$\mathbb{E}\left[\|\mathbf{w}_t - \mathbf{w}^*\|^2\right]^{1/2} \leq W = H + \sqrt{H^2 + (G+H)^2}, \forall t$$

We can now state Theorem 7 which establishes an upper bound on the regret. This theorem also reveals that there exists a gap between the rendered and optimal solutions. This gap crucially depends on the budget maintenance rates for the labeled and unlabeled portions.

Theorem 7. *Let us consider the running of Algorithm 1. The following statement holds*

$$\begin{aligned} \mathbb{E}\left[J(\overline{\mathbf{w}}_t)\right] - J(\mathbf{w}^*) &\leq \frac{1}{T}\sum_{t=1}^{T} \mathbb{E}\left[J(\mathbf{w}_t)\right] - J(\mathbf{w}^*) \\ &\leq \frac{(G+H)^2(\log T + 1)}{2T} \\ &+ \frac{W}{T}\sum_{t=1}^{T} \mathbb{P}\left(Z_t^l = 1\right) \mathbb{E}\left[\rho_{l_t}^2\right]^{1/2} \\ &+ \frac{W}{T}\sum_{t=1}^{T} \mathbb{P}\left(Z_t^u = 1\right) \mathbb{E}\left[\rho_{u_t}^2\right]^{1/2} \end{aligned}$$

where $\rho_{l_t} = \delta_{l_t}/\eta_t$ *and* $\rho_{u_t} = \delta_{u_t}/\eta_t$.

Remark 8. The theoretical result gained in Theorem 7 also encompasses the standard analysis. In particular, if the BM procedures never happen (i.e., $\mathbb{P}\left(Z_t^l = 1\right) = \mathbb{P}\left(Z_t^u = 1\right) = 0, \forall t$), we achieve the logarithm regret bound $\frac{(G+H)^2(\log T+1)}{T}$. Furthermore, to minimize the gap, we should choose to remove the vectors with the smallest absolute coefficients (since $\rho_{l_t} = \frac{\delta_{l_t}}{\eta_t}$ and $\rho_{u_t} = \frac{\delta_{u_t}}{\eta_t}$).

4 Experiments

We establish quantitative experiments to investigate the influence of the budget sizes (i.e., B_l and B_u) to the accuracy and training time, and to prove the accuracy and efficiency of our proposed BS3VM on several benchmark datasets. The data statistics is given in Table 1. To simulate the semi-supervised learning context, we randomly remove 80% and 90% data labels in each dataset. We create three versions of our approach: BS3VM with the removal strategy (BS3VM-R), BS3VM with the nearest-neighbor projection strategy (BS3VM-NNP), and BS3VM with the random-neighbor projection strategy (BS3VM-RNP).

Baselines. In order to investigate the efficiency and accuracy of BS3VM, we compare with the following baselines:

- LapSVM [Melacci and Belkin, 2011]: Laplacian Support Vector Machine is a state-of-the-art method in semi-supervised classification based on manifold regularization framework. It can reduce the computational complexity from $\mathrm{O}\left(n^3\right)$ to $\mathrm{O}\left(n^2\right)$ where n is the training size using the preconditioned conjugate gradient and an early stopping strategy.
- CCCP-TSVM [Collobert et al., 2006]: A kernel-based semi-supervised method was proposed to solve the optimization problem using convex-concave procedures.

All codes of the baselines are achieved from the corresponding authors. All compared methods run on a Windows machine with the configuration of 24-vcore CPU Xeon 3.47 GHz and 96GB RAM.

Hyperparameter Setting. The standard RBF kernel, given by $K\left(x,x^{'}\right) = e^{-\gamma\left\|x-x^{'}\right\|^2}$, is used in the experiments. For LapSVM, we use the parameter settings proposed in [Melacci and Belkin, 2011], wherein the parameters γ_A and γ_I are searched in the range $\left\{10^{-6}, 10^{-4}, 10^{-2}, 10^{-1}, 1, 10, 100\right\}$. In all experiments with LapSVM, we utilize the preconditioned conjugate gradient version, which is more suitable for the LapSVM optimization problem [Melacci and Belkin, 2011]. For CCCP-TSVM, we use the setting CCCP-TSVM$|^{s=0}_{UC*=LC}$. The trade-off parameter C is tuned in the range $\left\{2^{-5}, 2^{-3}, \ldots, 2^3, 2^5\right\}$ and the width of kernel δ is varied in the range $\left\{2^{-5}, 2^{-3}, \ldots, 2^3, 2^5\right\}$. Regarding our proposed BS3VM, the bandwidth σ of Gaussian kernel weight function is set as to $\frac{1}{2\sigma^2} = \gamma$, and the second trade-off parameter $C^{'}$ is set to be equal the first trade-off parameter C. We employ the standard training-testing split with 90% of data for training and 10% of data for testing. We run 5-fold cross-validation, and then select the parameter set that yields the highest classification accuracy. We set the number of iterations T in BS3VM to $\lceil 0.01 \times (l+u) \rceil$ for the large-scale datasets such as MUSHROOMS, W5A, W8A, COD-RNA, and COVTYPE, and to $\lceil 0.1 \times (l+u) \rceil$ for the remaining datasets. Each experiment is carried out five times to compute the average of the reported measures.

COVTYPE	54	100,945

Table 1: The statistics of the experimental datasets.

Experimental Results. The experimental results are reported in Tables 2 and 3. For readability, we emphasize in boldface the highest accuracy and in italics the shortest training time. Regarding the classification accuracy, our proposed BS3VMs are comparable with other baselines and CCCP-TSVM is slightly better than others. However, our BS3VMs scale impressively with the large-scale datasets whilst CCCP-TSVM scale unsatisfactorily. The version BS3VM-R wins the shortest training time over all experimental datasets, except for the dataset W5A under 80%-unlabeled setting. Besides, two other versions BS3VM-NNP and BS3VM-RNP also scale efficiently with the training size, and their training times only slightly exceed those of BS3VM-R on all datasets. This implies that the simplified projection strategies (i.e., NNP and RNP) do not incur a significant computational burden. Interestingly, BS3VM-R always offers comparable accuracies comparing with BS3VM-NNP and BS3VM-RNP, which indicates that the information loss occurring in the removal of vector in BS3VM-R is tolerant. It is noteworthy that although we only set small budgets for all datasets (i.e., 50 or 100), the classification accuracies attained by three versions on all datasets are still remarkable. This fact confirms the effectiveness of our proposed budget maintenance strategies in eliminating the redundant vectors and in keeping the core vectors which sufficiently characterize the training set.

Influence of Budget Sizes to Learning Performance. We investigate the influence of the budget sizes (i.e., B_l and B_u) to the learning performance. We choose to conduct a simulation study on 4 datasets AUSTRALIAN, COIL20, G50C, and SVMGUIDE3. For each dataset, we simultaneously vary the labeled budget size B_l and the unlabeled budget size B_u to measure the classification accuracy and the training time. We visualize the classification accuracies and the training times using heat maps shown in Figures 1, 2, 3, and 4. It can be observed that when increasing the budget sizes (i.e., B_l and B_u), the classification accuracy tends to increase and the training time tends to decrease or fluctuate. The reason is that large budget sizes enrich the expressiveness of the model, and hence boost the accuracy. In the meanwhile, when increasing the budget sizes, there appears a trade-off between the computational cost in each iteration and the budget maintenance rate which fluctuates the training time depending on which factor dominates. In practice, using these heat maps, one can conveniently find the optimal pair (B_l, B_u) that balances the classification accuracy and the training time for example $(50, 300)$ for AUSTRALIAN, $(50, 50)$ for COIL20, $(40, 320)$ for G50C, and $(60, 300)$ for SVMGUIDE3. Another observation is that the increases of B_l and B_u fairly equally affect the classification accuracy while increasing B_u strongly affects to the training time than increasing B_l. Finally, the training time becomes worst if we set one budget size to a small value and gradually increase another.

5 Conclusion

In this paper, we have proposed Budgeted Semi-supervised Support Vector Machine (BS3VM) for semi-supervised learning purpose. We first leverage the theory of kernel method with the framework of spectral-graph-based semi-supervised learning to form a specific optimization problem, which involves the core optimization problem of kernel method for learning on labeled data and simultaneously allows the label propagation. We then apply the SGD method to directly solve such optimization problem in the primal form. To resolve the curse of kernelization, we employ two budgets for the labeled and unlabeled portions in the model. We further establish a rigorous convergence analysis for BS3VM. The theoretical results reveal that there exists a gap between the rendered and optimal solutions. This gap crucially depends on the budget maintenance rates and the coefficients accompanied with the removed vectors. Finally, we conduct extensive experiments on several benchmark datasets. The experimental results show that BS3VM yields a comparable classification accuracy while simultaneously achieving a significant computational speed-up comparing with the state-of-the-art baselines.

Abstract

Relational Causal Models (RCM) generalize Causal Bayesian Networks so as to extend causal discovery to relational domains. We provide a novel and elegant characterization of the Markov equivalence of RCMs under *path semantics*. We introduce a novel representation of unshielded triples that allows us to efficiently determine whether an RCM is Markov equivalent to another. Under path semantics, we provide a sound and complete algorithm for recovering the structure of an RCM from conditional independence queries. Our analysis also suggests ways to improve the orientation recall of algorithms for learning the structure of RCM under *bridge burning semantics* as well.

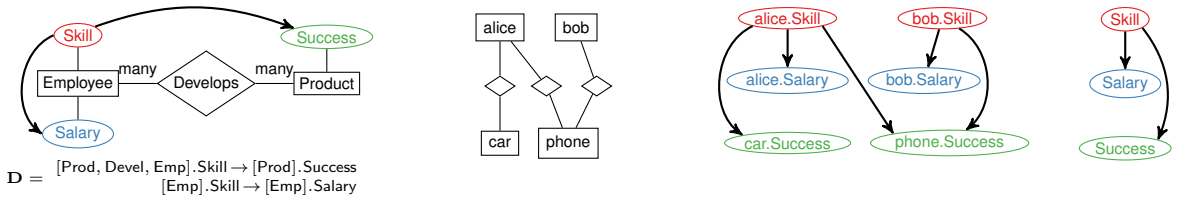
1 INTRODUCTION

The discovery of causal relationships from observational and, when available, experimental data is a central problem in artificial intelligence. Of particular interest is causal discovery in real-world settings consist of inherently interrelated entities and the resulting data exhibit a rich *relational* (Chen, 1976) structure. The past three decades have seen major advances in causal discovery (Pearl, 2000; Spirtes et al., 2000). However, the vast majority of this work has focused on Causal Bayesian Networks (CBN), directed graphical models that model causal relationships between a set of random variables of interest. Such models lack the expressive power to model causal relationships in relational domains.

Maier et al. (2010) showed that the Directed Acyclic Probabilistic Entity-Relationship model (DAPER) (Heckerman et al., 2007) which generalizes both Probabilistic Relational Models (PRM) (Friedman et al., 1999) and plate models (Buntine, 1994) is sufficient to represent causality in relational domains. Maier et al. (2010) proposed Relational PC (RPC), a relational extension of the PC algorithm (Spirtes et al., 2000) for learning the structure of Relational Causal Model (RCM), which is a particular class of DAPER, under *bridge burning semantics* (BBS). However, RPC is not complete, and is prone to erroneous orientation of edges (Maier et al., 2013a). To overcome the limitations of RPC, Maier et al. (2013a) introduced the Relational Causal Discovery (RCD) algorithm which reduces learning the structure of an RCM to learning the structure of Abstract Ground Graph (AGG, Maier et al., 2013b), a directed acyclic graph that is intended to correctly abstract the *ground instances* of the RCM, and Lee and Honavar (2016) proposed RCD-Light, a more efficient alternative to RCD. However, all of existing algorithms for learning RCM are provably *not complete* (Lee and Honavar, 2016).

Against this background, we characterize the *Markov equivalence* of RCMs, an essential step in specifying a provably complete constraint-based algorithms for learning the structure of RCM under *path semantics*, a more elegant alternative to BBS. The key idea is to show that two RCMs are Markov equivalent *if and only if* their corresponding sets of ground instances are Markov equivalent. We introduce *canonical unshielded triples,* a novel graphical construct that can be used to test the Markov equivalence of two RCMs. We provide an efficient algorithm to enumerate a subset of canonical unshielded triples of an RCM that suffice for testing whether an RCM is Markov equivalent to another. Finally, we provide an algorithm to construct a *completed partially-directed RCM*, a unique compact representation of the Markov equivalence class of an RCM.

The main contributions of this paper are: (i) a novel characterization of Markov equivalence of RCMs, using a novel representation of the relational counterparts of unshielded triples and efficient identification thereof; (ii) revelation of problematic behaviors of BBS (Maier et al., 2013a,b; Lee and Honavar, 2015, 2016), and proposal of a viable alternative, namely, *path semantics*, which is more intuitive and retains the desirable properties of BBS while avoiding its drawbacks; and (iii) the first sound and complete algorithm for learning the structure of an RCM under path semantics.



(a) RCM $\mathcal{M} = (\mathcal{S}, \mathbf{D})$ (b) relational skeleton $\sigma \in \Sigma_{\mathcal{S}}$ (c) ground graph $\mathcal{G}_{\sigma}^{\mathcal{M}}$ (d) CDG $\mathcal{G}_{\mathcal{A}}^{\mathcal{M}}$

2 PRELIMINARIES

We follow the notational conventions for Causal Bayesian Networks (Pearl, 2000; Spirtes et al., 2000) and the literature on RCM (Maier et al., 2013a; Lee and Honavar, 2015). A graph is specified by a set of vertices and the edges that connect them. An edge may be directed ($\rightarrow$) or undirected ($-$), but not both. A partially directed acyclic graph (PDAG) includes undirected as well as directed edges but no directed cycles. A directed acyclic graph (DAG) is a PDAG with no undirected edges. Let $\mathcal{G}$ be a PDAG and X be a vertex in $\mathcal{G}$, i.e., $X \in \mathbb{V}(\mathcal{G})$. Then, parents of X, $pa(\mathcal{G}, X)$, are vertices that have a direct edge towards X. Children (ch) are analogously defined. Neighbors (ne) of X are vertices connected to X via an undirected edge while adjacencies (adj) of X are those connected to X via an edge either directed or undirected. A *walk* on a graph is an ordered sequence of vertices where consecutive vertices in the sequence are adjacent to each other in the graph, and a *path* is a walk in which every vertex is distinct.

Relational Domain A relational domain comprises of entities that are interdependent through relationships. The specification of such relational domain is called a relational schema (schema for short). A schema, denoted by $\mathcal{S}$, is a tuple of entity classes, relationship classes, attribute classes, and cardinality constraints, denoted by $\mathcal{E}$, $\mathcal{R}$, $\mathcal{A}$, and $card$, respectively. For example, *Employee* and *Product* are entity classes in a business domain (Figure 1). *Develops* is a relationship class between them. *Employee* has *Salary* as an attribute class. Each employee may develop *multiple* products; and each product may be developed by *multiple* employees. We collectively call $\mathcal{E}$ and $\mathcal{R}$ item classes. Every item class is associated with a set of attribute classes. We denote $\mathcal{A}(I)$ a set of attribute classes associate with an item class I. A relationship class consists of participating entity classes. We denote $E \in R$ if E is a participating entity class of a relationship class R. For simplicity, we drop role indicators (as in other literature on RCM), which allow participation of an entity class in a relationship class in multiple ways. A cardinality constraint defines how many relationships an entity can participate in. Following RCM literature, $card$ is a partial function from $\mathcal{R} \times \mathcal{E}$ to $\{one, many\}$.

A relational skeleton (skeleton for short) is a particular realization of a schema, which is an undirected graph where vertices are items (i.e., instances of item classes). An edge is defined between a relationship and an entity if the entity participates in the relationship. We denote a skeleton by σ, a member of all possible skeletons $\Sigma_{\mathcal{S}}$. We denote by $\sigma(I)$ the set of items of item class I.

2.1 RELATIONAL CAUSAL MODEL

A relational causal model (RCM) (Maier et al., 2010, 2013a) consists of a set of cause-effect relationships and parameters where the cause and the effect are related in the given relational schema. For example, "the success of a product depends on the skills of employees who develop the product" is encoded as a *relational dependency*, "[Product, Develops, Employee].Skill→[Product].Success". We elaborate on each component of an RCM more precisely in what follows.

A *relational path* is an alternating sequence of entity and relationship classes. The relational path corresponds to a *walk* (with some restrictions) in the given schema where item classes are vertices and the participation of an entity class to a relationship class is an undirected edge between them. A relational path is similar to a slot chain in PRM (Friedman et al., 1999) and a first-order constraint in DAPER (Heckerman et al., 2007). The first and the last item class of a relational path is called *base* and *terminal* item class, respectively. The path explains the relation of the terminal item class from the *perspective* of the base item class. Hence the base item class is also called the *perspective*. A relational path is *canonical* if it is of unit length. A *relational variable* is a pair of a relational path and an attribute class, which belongs to the terminal item class of the path. For example, a relational variable $P.X$ consists of a path P and an attribute class X where X is an attribute class associated with the terminal item class of P. Then, an RCM $\mathcal{M} = (\mathcal{S}, \mathbf{D}, \mathbf{\Theta})$ is a set of relational dependencies $\mathbf{D}$ along with parameters $\mathbf{\Theta}$ given a schema $\mathcal{S}$. A relational dependency $P.Y \rightarrow Q.X$ consists of two relational variables as an effect and its cause where the effect relational variable is canonical, $Q = [I]$ where $X \in \mathcal{A}(I)$, and the base of P is I. To emphasize the use of canonical relational

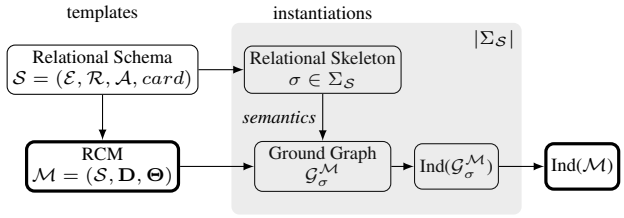

Figure 2: Schematic showing a relational schema, an RCM, and their respective instantiations, i.e., relational skeleton, and ground graphs and the independence relations of the RCM entailed from the independence relations admitted by the ground graphs.

variable, we denote a canonical relational variable with an attribute class X by $\mathcal{V}_X$.

An RCM is said to be acyclic if its *class dependency graph* $\mathcal{G}^{\mathcal{M}}_{\mathcal{A}} \triangleq (\mathcal{A}, \{Y \to X \mid P.Y \to \mathcal{V}_X \in \mathbf{D}\})$ is a DAG (see Figure 1(d)). Hence, $\mathcal{A}$ is a partially-ordered set where we denote $Z \prec_{\mathcal{A}} X$ if there exists a directed path from Z to X in $\mathcal{G}^{\mathcal{M}}_{\mathcal{A}}$. This implies that dependencies of the same pair of attribute classes must have the same orientation (i.e., it is impossible to have both $P.Y \to \mathcal{V}_X$ and $Q.X \to \mathcal{V}_Y$).

An RCM (or its partially directed variant) is *not* a traditional graphical model defined over relational variables: edges (i.e., relational dependencies) are only well-defined between a pair of relational variables where one of them is canonical. Hence, graphical relation (i.e., adj, ch, pa, and ne) is well-defined only if its argument is a canonical relational variable. For example, if $P.Y \to \mathcal{V}_X \in \mathcal{M}$, then $pa(\mathcal{M}, \mathcal{V}_X) = \{P.Y\}$ but $ch(\mathcal{M}, P.Y)$ is undefined if P is not canonical.

Relational d-separation An RCM defines a set of dependencies at the schema level. Given a skeleton σ, the RCM $\mathcal{M}$ is realized as a ground graph $\mathcal{G}^{\mathcal{M}}_{\sigma}$ (see Figure 1(c)), which is a DAG where vertices are attributes of items in the skeleton (e.g., $i.X$ for $X \in \mathcal{A}(I)$ of an item $i \in \sigma(I)$) and each directed edge is interpreted as a direct cause (e.g., $j.Y \to i.X$). If the RCM is an actual model of given relational data, then the ground graph will correspond to the underlying causal process that governs the attribute values of the items in the skeleton (i.e., relational data). An edge $j.Y \to i.X$ exists if there exists a dependency $P.Y \to \mathcal{V}_X \in \mathbf{D}$ such that j is *reachable* (which we will formally define in Section 3) from i along P in the skeleton. We denote by $P|^{\sigma}_i$ a *terminal set*, a set of reachable items from i along P in σ, which is determined according to the chosen semantics, e.g., BBS (Maier et al., 2013a; Maier, 2014). For simplicity, we drop σ if it is either unnecessary or can be inferred without ambiguity.

In RCM, we are especially interested in conditional independence between relational variables. We might ask, for example, is the success of a product independent of its developers' salaries given their skills? This conditional independence query can be represented as [Product].Success $\perp\!\!\!\perp$ [Product, Develops, Employee].Salary | [Product, Develops, Employee].Skill. If true, this implies that each product's success is independent of its developers' salary given their skills (in every company). Formally, an independence query is of the form $U \perp\!\!\!\perp V \mid \mathbf{W}$ where $\{U, V\} \cup \mathbf{W}$ is a set of relational variables of the same perspective, say $B \in \mathcal{E} \cup \mathcal{R}$. Then, the query is equivalent to checking

$$\forall_{\sigma \in \Sigma_{\mathcal{S}}} \forall_{i \in \sigma(B)} \; U|^{\sigma}_i \perp\!\!\!\perp V|^{\sigma}_i \mid \mathbf{W}|^{\sigma}_i, \tag{1}$$

in all of the instantiations of the RCM (Maier et al., 2013b) (see Figure 2). In other words, the existence of a relational skeleton $\sigma \in \Sigma_{\mathcal{S}}$ and a base item $i \in \sigma(B)$ such that $U|^{\sigma}_i \not\perp\!\!\!\perp V|^{\sigma}_i \mid \mathbf{W}|^{\sigma}_i$ in a ground graph $\mathcal{G}^{\mathcal{M}}_{\sigma}$ is the necessary and sufficient condition for $U \not\perp\!\!\!\perp V \mid \mathbf{W}$.

3 RCM SEMANTICS

We proceed to describe two alternative semantics for interpreting relational paths, and hence translating relational dependencies of an RCM into causal relationships on attributes of items of a skeleton. Let P be a relational path of n item classes. We denote the length of P by $|P|$, the reverse of the path P by $\tilde{P}$, the ℓth item class of P by P^{ℓ}, and the subpath of P from ℓ to m (inclusive) by $P^{\ell:m}$. We might omit the beginning or ending index if the subpath is from the beginning (i.e., prefix) or to the end of the path (i.e., suffix). i.e., $P^{:m} = P^{1:m}$ and $P^{\ell:} = P^{\ell:n}$.

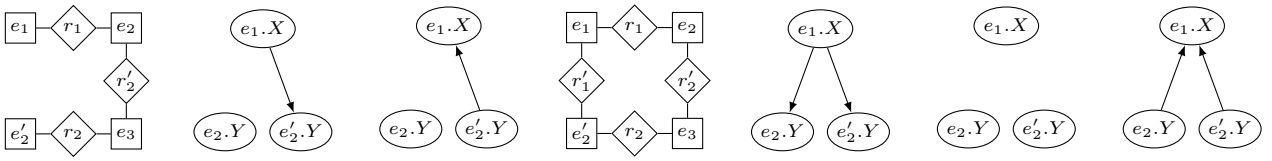
We first introduce *path semantics*, where the term path exactly means what path is defined in graph theory. Let $i \overset{P,\sigma}{\rightsquigarrow} j$ denote the fact that items i and j are connected by a path of items $\mathbf{p}$ from i to j in the given skeleton σ, where the item class of ℓth item of $\mathbf{p}$ is the ℓth item class of P for $1 \leq \ell \leq |P|$. Then, under path semantics, the terminal set $P|^{\sigma}_i$ is simply defined as,

$$P|^{\sigma}_i \triangleq \{j \mid i \overset{P,\sigma}{\rightsquigarrow} j\}.$$

Bridge burning semantics (BBS) (Maier et al., 2013b; Maier, 2014) computes $P|^{\sigma}_i$ as the set of leaves of the tree obtained by traversing the given skeleton σ along P in breadth-first order starting at i. Formally, BBS defines $P|^{\sigma}_i$ iteratively as $P^{:1}|^{\sigma}_i \triangleq \{i\}$ and

$$P^{:m}|^{\sigma}_i \triangleq \{k \in \sigma(P^m) \cap ne(\sigma, j) \mid j \in P^{:m-1}|^{\sigma}_i\} \setminus \bigcup_{\ell < m} P^{:\ell}|^{\sigma}_i$$

The choice of BBS has following implications, which are not fully considered in the existing RCM literature. First, given a more complex relational skeleton, BBS may yield, counterintuitively, a sparser ground graph because, as we can clearly see in the definition, if P' is a proper prefix of P and $j \in P'|_i$, then $j \notin P|_i$ even though there exists a path of items from i to j along P. Compare Figure 3(f) with 3(c). The addition of two edges e_1–r'_1–e'_2



(a) skeleton σ (b) $\mathcal{G}_{\sigma}^{(\mathcal{S},\{D\})}$ (c) $\mathcal{G}_{\sigma}^{(\mathcal{S},\{\tilde{D}\})}$ (d) skeleton σ' (e) $\mathcal{G}_{\sigma'}^{(\mathcal{S},\{D\})}$ (f) $\mathcal{G}_{\sigma'}^{(\mathcal{S},\{\tilde{D}\})}$ BBS (g) $\mathcal{G}_{\sigma'}^{(\mathcal{S},\{\tilde{D}\})}$ PS

Figure 3: Comparison of ground graphs under bridge burning semantics and path semantics. Let $\mathcal{S}$ be a schema with $\mathcal{E} = \{E_1, E_2, E_3\}$, $X \in \mathcal{A}(E_1)$, $Y \in \mathcal{A}(E_2)$, and $\mathcal{R} = \{R_1, R_2\}$ where $E_1, E_2 \in R_1$ and $E_2, E_3 \in R_2$ with cardinality greater than 1. $D = [E_2, R_2, E_3, R_2, E_2, R_1, E_1].X \rightarrow [E_2].Y$. Both semantics yield the same ground graphs (b), (c), and (e) for the relational skeleton σ. However, the two semantics yield different ground graphs (f,), (g) for $\mathcal{M} = (\mathcal{S}, \{\tilde{D}\})$ for relational skeleton σ'.

in σ' compared to σ make $e_2' \in [E_1, R_1, E_2]|_{e_1}^{\sigma'}$ and, hence, $e_2' \notin [E_1, R_1, E_2, R_2, E_3, R_2, E_2]|_{e_1}^{\sigma'}$. Second, the two RCMs that differ only with respect to the directionality of their dependencies may have different (undirected) adjacencies in their ground graphs (compare Figure 3(f) with 3(e)). This is because $j \in P|_i$ does not entail $i \in \tilde{P}|_j$ under BBS since the fact that Q is a prefix of P does not necessarily imply that $\tilde{Q}$ is a prefix of $\tilde{P}$.

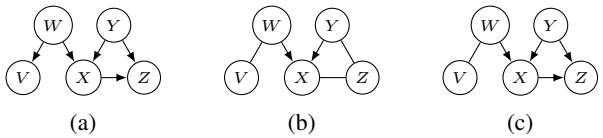
In this paper, we consider RCMs under path semantics, which is an elegant and more intuitive alternative to BBS. Further, path semantics shares the desirable properties of BBS (Maier, 2014): both semantics do not permit revisiting the base item. However, path semantics does not suffer from the counter-intuitive consequences of BBS and easier to analyze as we will see in the rest of paper.

4 MARKOV EQUIVALENCE OF RCMS UNDER PATH SEMANTICS

Recall that, in general, there can be Markov equivalent CBNs that represent a given set of independence relations (Pearl, 2000). Because RCMs are essentially relational counterparts of CBNs, it follows that there can be multiple RCMs that encode a given set of independence relations in relational domains.

Definition 1 (Markov Equivalence of RCMs)**.** Two RCMs are *Markov equivalent* if they entail the same set of relational *d*-separation conditions.

The previous attempts to characterize the Markov equivalence of RCMs under BBS (Maier et al., 2013a; Marazopoulou et al., 2015) had relied on analyses of the Abstract Ground Graph (AGG) representation of an RCM. However, Lee and Honavar (2015) have shown that AGGs cannot faithfully represent the independence relations encoded by RCMs under BBS. Consequently, the RCD algorithm (Maier et al., 2013a), which relies on AGGs to learn the structure of an RCM under BBS is *not* complete Lee and Honavar (2016). Hence, we proceed to characterize the Markov equivalence of RCMs under path semantics.



(a) (b) (c)

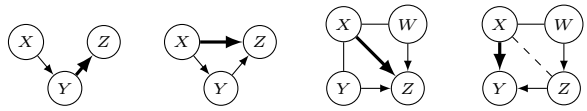
Figure 4: An example of a DAG, its pattern, and its CPDAG where (W, X, Y) is an unshielded collider and (V, W, X) and (W, X, Z) are unshielded non-colliders.

Recall that the relational d-separation $U \perp\!\!\!\perp V \mid \mathbf{W}$ in an RCM is equivalent to $U|_i \perp\!\!\!\perp V|_i \mid \mathbf{W}|_i$ for every base item i in *every* ground graph of the RCM. Hence, a sufficient condition for two RCMs to be Markov equivalent is that, for *every* relational skeleton, the corresponding sets of ground graphs of the two RCMs be Markov equivalent:

$$\forall_{\sigma \in \Sigma_{\mathcal{S}}} [\mathcal{G}_{\sigma}^{\mathcal{M}}] = [\mathcal{G}_{\sigma}^{\mathcal{M}'}] \Rightarrow [\mathcal{M}] = [\mathcal{M}'] \tag{2}$$

where $[\mathcal{M}]$ and $[\mathcal{G}]$ denote the Markov equivalence class of an RCM and a DAG $\mathcal{G}$, respectively. In Section 4.1, we will demonstrate that the converse of Equation 2 holds as well, thereby establishing a necessary and sufficient condition for two RCMs to be Markov equivalent.

Markov equivalence of DAG First, we recall the characterization of Markov equivalence of DAG (see Figure 4, Verma and Pearl, 1990; Andersson et al., 1997). Let $\mathcal{G}$ be a DAG with random variables $\mathbf{V}$ as vertices. Let X, Y, and Z be in $\mathbf{V}$. A triple (X, Y, Z) is an *unshielded triple* if both X and Z are adjacent to Y but X and Z are not adjacent. It is an *unshielded collider* if they are oriented as $X \rightarrow Y \leftarrow Z$ in the given DAG. Let $\mathcal{G}'$ be a DAG that share the same vertices of $\mathcal{G}$. Then, $\mathcal{G}$ and $\mathcal{G}'$ are said to be *Markov equivalent* if they entail identical independence relations among $\mathbf{V}$. Two DAGs are Markov equivalent if and only if their *patterns* are the same (Verma and Pearl, 1990). The *pattern* of a DAG is a PDAG where all *unshielded colliders* are oriented and the only oriented edges are unshielded colliders. A Markov equivalence class is represented by a *completed PDAG* (CPDAG or *essential graph*), a PDAG in which a directed edge $X \rightarrow Y$ implies that every DAG in the class shares the edge $X \rightarrow Y$ (*compelled edge*) while an undi-



(a) R1 (b) R2 (c) R3 (d) R4

Figure 5: Orientation rules to construct a CPDAG from a pattern and background knowledge where the orientation of a thick edge is determined by the other given edges. The edge between X and Z in R4 might be undirected or directed in any direction.

rected edge $X - Y$ implies that there exist two DAGs in the class where one has $X \to Y$ and the other has $X \leftarrow Y$ (*reversible edge*).

There are at least two systematic methods to discover the CPDAG from a pattern: The first method uses orientation rules (Meek, 1995) (Figure 5). The three rules (R1–R3) are sufficient to discover CPDAG from a pattern, and an additional rule R4 can deal with background knowledge (i.e., known orientations other than those implied by the pattern), if available. The second method exploits an algorithm for *extensibility* of a PDAG (Dor and Tarsi, 1992), which examines whether there exists a DAG which is a *consistent extension* of the PDAG, that is, the DAG shares the same sets of adjacencies, unshielded colliders, and oriented edges (if any) of the PDAG. We proceed to characterize Markov equivalence of RCM by generalizing the notions of unshielded triples, pattern, and CPDAG from the setting of CBNs to the (relational) setting of RCMs.

4.1 THE PATTERN OF AN RCM

We consider unshielded triples in ground graphs of an RCM and relate them to the RCM under path semantics. Let $i.X$, $j.Y$, and $k.Z$ be three different vertices in the ground graph $\mathcal{G}_\sigma^\mathcal{M}$ of an RCM $\mathcal{M}$ for an arbitrary skeleton $\sigma \in \Sigma_\mathcal{S}$. Then, $(i.X, j.Y, k.Z)$ is an unshielded triple in $\mathcal{G}_\sigma^\mathcal{M}$ only if $P.Y \in adj\,(\mathcal{M}, \mathcal{V}_X)$ and $Q.Z \in adj\,(\mathcal{M}, \mathcal{V}_Y)$ where $j \in P|_i^\sigma$ and $k \in Q|_j^\sigma$ for $i.X$ and $k.Z$ to be connected to $j.Y$. Furthermore, $R.Z$ must not be in $adj\,(\mathcal{M}, \mathcal{V}_X)$ for every path R such that $k \in R|_i^\sigma$ for $i.X$ and $k.Z$ to be disconnected in $\mathcal{G}_\sigma^\mathcal{M}$. Then, we define a *canonical unshielded triple* as follows:

Definition 2 (Canonical Unshielded Triple)**.** Let $\mathcal{M}$ be an RCM defined on a relational schema $\mathcal{S}$. Suppose $(i.X, j.Y, k.Z)$ is an unshielded triple (UT) in the ground graph $\mathcal{G}_\sigma^\mathcal{M}$ for some $\sigma \in \Sigma_\mathcal{S}$. There must be two (not necessarily distinct) dependencies $P.Y - \mathcal{V}_X$ and $Q.Z - \mathcal{V}_Y$ of $\mathcal{M}$ (ignoring directions) such that $j \in P|_i^\sigma$ and $k \in Q|_j^\sigma$. Then, we say that $(\mathcal{V}_X, \mathbf{P}.Y, R.Z)$ is a *canonical unshielded triple* (CUT) of $\mathcal{M}$ for every $R \in \{T \mid k \in T|_i^\sigma\}$ where $\mathbf{P} = \{T \mid j \in T|_i^\sigma\}$.

Since whenever $(i.X, j.Y, k.Z)$ is a UT in $\mathcal{G}_\sigma^\mathcal{M}$, so is $(k.Z, j.Y, i.X)$, it follows that whenever $(\mathcal{V}_X, \mathbf{P}.Y, R.Z)$ is a CUT of $\mathcal{M}$, there exists a CUT $(\mathcal{V}_Z, \mathbf{Q}.Y, \tilde{R}.X)$ for some relational paths $\mathbf{Q}$.

Theorem 3. *Two RCMs defined over the same relational schema are Markov equivalent if and only if their ground graphs are Markov equivalent for every relational skeleton of the relational schema:*

$$[\mathcal{M}] = [\mathcal{M}'] \Leftrightarrow \forall_{\sigma \in \Sigma_\mathcal{S}} [\mathcal{G}_\sigma^\mathcal{M}] = [\mathcal{G}_\sigma^{\mathcal{M}'}].$$

Proof. (If part) By the definition of relational d-separation.
(Only if part) Let $[\mathcal{G}_\sigma^\mathcal{M}] \neq [\mathcal{G}_\sigma^{\mathcal{M}'}]$ for some $\sigma \in \Sigma_\mathcal{S}$. Then, the two ground graphs $\mathcal{G}_\sigma^\mathcal{M}$and $\mathcal{G}_\sigma^{\mathcal{M}'}$ differ either in their (i) adjacencies or in their (ii) unshielded colliders.
Case (i): There must exist a relational dependency $P.Y \to \mathcal{V}_X$ in $\mathcal{M}$ while both $P.Y \to \mathcal{V}_X$ and $\tilde{P}.X \to \mathcal{V}_Y$ are not in $\mathcal{M}'$ (or vice versa). Then, either $P.Y \perp\!\!\!\perp \mathcal{V}_X \mid pa(\mathcal{M}', \mathcal{V}_X)$ or $\tilde{P}.X \perp\!\!\!\perp \mathcal{V}_Y \mid pa(\mathcal{M}', \mathcal{V}_Y)$ hold in $\mathcal{M}'$ by causal Markov condition. However, both tests will be false in $\mathcal{M}$ since there exists a relational skeleton σ yielding $i.X \to j.Y$ in $\mathcal{G}_\sigma^\mathcal{M}$ where $\{P\} = \{T \mid i \in T|_j^\sigma\}$ while $P.Y \notin pa(\mathcal{M}', \mathcal{V}_X)$ and $\tilde{P}.X \notin pa(\mathcal{M}', \mathcal{V}_Y)$.
Case (ii): There must exist a CUT $(\mathcal{V}_X, \mathbf{P}.Y, R.Z)$ corresponding to an unshielded triple $(i.X, j.Y, k.Z)$, which is an unshielded collider in $\mathcal{G}_\sigma^\mathcal{M}$ and unshielded non-collider in $\mathcal{G}_\sigma^{\mathcal{M}'}$ (or vice versa). Because $R.Z \notin adj\,(\mathcal{M}, \mathcal{V}_X)$ for every $R \in \{T \mid k \in T|_i^\sigma\}$, there must exist a separating set $\mathbf{S} \subseteq adj(\mathcal{M}, \mathcal{V}_X)$ such that $\mathcal{V}_X \perp\!\!\!\perp R.Z \mid \mathbf{S}$ in $\mathcal{M}$ assuming $X \not\prec_\mathcal{A} Z$ without loss of generality.[1] By the definition of relational d-separation, $\mathbf{S}$ must be disjoint with $\mathbf{P}.Y$. However, in $\mathcal{M}'$, $\mathcal{V}_X \not\perp\!\!\!\perp R.Z \mid \mathbf{S}$ since $\mathbf{S}$ is disjoint from $\mathbf{P}.Y$, and $i.X$ and $k.Z$ are d-connected with $j.Y$ unblocked. □

We derive the definition of the *pattern* of an RCM taking into account the fact that acyclicity of an RCM is defined at an attribute class level.

Definition 4 (Pattern of RCM)**.** Let $\mathcal{M} = (\mathcal{S}, \mathbf{D})$ be an RCM and $\mathfrak{C}^\mathcal{M}$ be all canonical unshielded colliders of $\mathcal{M}$. We define the set of *attribute class level colliders* as

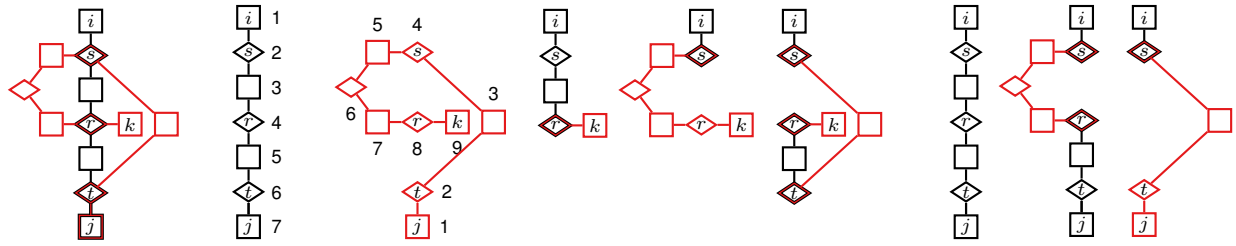
$$\mathfrak{C}_\mathcal{A}^\mathcal{M} \triangleq \{(X, Y, Z) \mid (\mathcal{V}_X, \mathbf{P}.Y, R.Z) \in \mathfrak{C}^\mathcal{M}\}.$$

Then, the *pattern* of $\mathcal{M}$, $pattern\,(\mathcal{M})$, is a partially-directed RCM $(\mathcal{S}, \mathbf{D}' \cup \mathbf{D}'')$ where $\mathbf{D}' = \{Q.X \to \mathcal{V}_Y \in \mathbf{D} \mid (X, Y, Z) \in \mathfrak{C}_\mathcal{A}^\mathcal{M}\}$ and $\mathbf{D}'' = \{P.Y - \mathcal{V}_X \mid P.Y \to \mathcal{V}_X \in \mathbf{D} \setminus \mathbf{D}'\}$.

Lemma 5. $[\mathcal{M}] = [\mathcal{M}'] \Leftrightarrow pattern(\mathcal{M}) = pattern(\mathcal{M}')$.

Proof. The proof follows from Theorem 3. □

[1] Otherwise, the proof can be obtained using $(\mathcal{V}_Z, \tilde{\mathbf{Q}}.Y, \tilde{R}.X)$.



(a) σ (b) $\mathbf{p}$ (c) $\mathbf{q}$ (d) paths of items for R_r, R_s, and R_t (e) paths of items for $\mathbf{P}$

Figure 6: Illustration of key concepts used to characterize CUTs for a hypothetical RCM $\mathcal{M}$ with $P.Y \in adj\,(\mathcal{M}, \mathcal{V}_X)$ and $Q.Z \in adj\,(\mathcal{M}, \mathcal{V}_Y)$ yielding a UT $(i.X, j.Y, k.Z)$ in $\mathcal{G}_\sigma^{\mathcal{M}}$ where P and Q correspond to item classes of $\mathbf{p}$ and $\mathbf{q}$, respectively.

Unlike in the case of DAGs, it is not immediately obvious how to identify all CUTs of an RCM. Fortunately, to discover the pattern of an RCM, it suffices to identify only one CUT from the set of CUTs for each triple of attribute classes if exists.

4.1.1 Characterization of Canonical Unshielded Triples for Pattern of RCM

How can we identify a subset of CUTs of an RCM that is sufficient to identify the pattern of the RCM? One approach is to enumerate all relational skeletons, identify the UTs in the corresponding ground graphs, and the corresponding CUTs. Because such an approach is not computationally tractable, we consider the following alternative: enumerate the skeletons that are just large enough to include a UT in the corresponding ground graph, and the corresponding CUT. We first investigate conditions under which a relational skeleton includes a UT in the corresponding ground graph, and then provide a characterization of CUTs in terms of such UTs, which leads to an efficient CUT enumeration algorithm whose time complexity is polynomial in the number of dependencies, $|\mathbf{D}|$, and $\max\{|P| \mid P.X \to \mathcal{V}_Y \in \mathbf{D}\}$ (the maximum length of dependencies, which is typically bounded by a small constant).

Relational Skeleton of an Unshielded Triple Each shielded or unshielded triple of item-attributes associates with two dependencies non-exclusively. Consider a triple $(i.X, j.Y, k.Z)$ in some skeleton $\sigma \in \Sigma_{\mathcal{S}}$. Let $P.Y \in adj\,(\mathcal{M}, \mathcal{V}_X)$ and $Q.Z \in adj\,(\mathcal{M}, \mathcal{V}_Y)$ (the two are the same if $Q.Z = \tilde{P}.X$) that admit the triple, that is, $j \in P|_i^\sigma$ and $k \in Q|_j^\sigma$. Let $\mathbf{p} = [i, \ldots, j]$ and $\mathbf{q} = [j, \ldots, k]$ be paths of items from i to j along P and j to k along Q, respectively. Since $\mathbf{p}$ and $\mathbf{q}$ must share at least one item j, there must be a non-empty set of items shared by $\mathbf{p}$ and $\mathbf{q}$. We define *anchors*, denoted by $\mathbf{J}_{\mathbf{p},\mathbf{q}}$, to be the set of pairs of indices of items shared by $\mathbf{p}$ and $\mathbf{q}$:

$$\mathbf{J}_{\mathbf{p},\mathbf{q}} \triangleq \{(a, b) \mid \mathbf{p}_a = \mathbf{q}_b\}.$$

For example, $\mathbf{J}_{\mathbf{p},\mathbf{q}} = \{(2,4), (4,8), (6,2), (7,1)\}$ in Figure 6. Anchors permit us to construct a small relational skeleton made of items for P and Q. Thus, we can enumerate the candidate anchors and verify if they are indeed anchors by constructing a relational skeleton that conforms to the equalities implied by $\mathbf{J}_{\mathbf{p},\mathbf{q}}$.

Characteristic Anchors We consider anchors that allow us to efficiently enumerate a subset of CUTs that suffice to identify the pattern of an RCM $\mathcal{M}$. We identify three special anchors (a_r, b_r), (a_s, b_s), and (a_t, b_t) among the anchors in $\mathbf{J}_{\mathbf{p},\mathbf{q}}$, and derive three relational paths R_r, R_s, and R_t from the special anchors.

Consider the item j that is the last shared item of $\mathbf{p}$ and the first shared item of $\mathbf{q}$such that $(|P|, 1) \in \mathbf{J}_{\mathbf{p},\mathbf{q}}$. Since $\mathbf{J}_{\mathbf{p},\mathbf{q}}$ is not empty, there must be a last shared item for $\mathbf{q}$ at the following anchor:

$$(a_r, b_r) \triangleq \arg\max_{(a,b) \in \mathbf{J}_{\mathbf{p},\mathbf{q}}} b.$$

No item in $\mathbf{p}_{:a_r}$ and $\mathbf{q}_{b_r:}$ is shared other than the item at the anchor (a_r, b_r) and, hence, there exists a path of items from i to k. We define $R_r \triangleq P^{:a_r} \bowtie Q^{b_r:}$ where the symbol "$\bowtie$" is a path concatenation operator (e.g., $[E_1, R_1, E_2] \bowtie [E_2, R_2] = [E_1, R_1, E_2, R_2]$). We can infer that $R_r.Z \notin adj\,(\mathcal{M}, \mathcal{V}_X)$ since $i.X$ and $k.Z$ are disconnected. Next, we define an anchor for the first shared item of $\mathbf{p}$:

$$(a_s, b_s) \triangleq \arg\min_{(a,b) \in \mathbf{J}_{\mathbf{p},\mathbf{q}}} a.$$

We characterize the given unshielded triple by considering following two cases where (a_s, b_s) is identical to (a_r, b_r) and where it is not.

Case $(a_r, b_r) = (a_s, b_s)$: A path of items corresponding to R_r is the *only* path from i to k that consists of items only in $\mathbf{p}$ and $\mathbf{q}$, and $\{R_r\} \subseteq \{T \mid k \in T|_i^\sigma\}$.

Case $(a_r, b_r) \neq (a_s, b_s)$: In a similar manner we define R_r with (a_r, b_r), we define $R_s \triangleq P^{:a_s} \bowtie Q^{b_s:}$, which satisfies $k \in R_s|_i^\sigma$. Note that $R_r = R_s$ if $P^{a_s:a_r} = Q^{b_s:b_r}$. Observing that $a_s < a_r \leq |P|$ and $1 \leq b_s < b_r$, we infer that $(|P|, 1)$ can be neither (a_r, b_r) nor (a_s, b_s).

Hence, there must exist at least three distinct anchors in $\mathbf{J}_{\mathbf{p},\mathbf{q}}$: $\{(|P|,1),(a_r,b_r),(a_s,b_s)\} \subseteq \mathbf{J}_{\mathbf{p},\mathbf{q}}$. The existence of characteristic anchors further implies that there must be an anchor (a,b) such that $a_r < a \leq |P|$ and $1 \leq b < b_s$. Among such anchors, if $\mathbf{p}_{a_r:a:-1}$ and $\mathbf{q}_{b:b_s:-1}$ do not share any items except the item at (a,b), then there exists a path of items from i to k, $\mathbf{p}_{:a_s} \bowtie \mathbf{q}_{b:b_s:-1} \bowtie \mathbf{p}_{a_r:a:-1} \bowtie \mathbf{q}_{b_r:}$, where the subpath with ": -1" represents the reverse of the subpath. There do exist such anchors:

$$(a_t, b_t) \triangleq \arg\max_{(a,b)\in\mathbf{J}_{\mathbf{p},\mathbf{q}}, a_r<a, b<b_s} b,$$

and we likewise define $R_t \triangleq P^{:a_s} \bowtie Q^{b_t:b_s:-1} \bowtie P^{a_r:a_t:-1} \bowtie Q^{b_r:}$. We call such a set of anchors, *characteristic anchors*. Given the characteristic anchors $\{(a_r,b_r),(a_s,b_s),(a_t,b_t)\} \subseteq \mathbf{J}_{\mathbf{p},\mathbf{q}}$, we retrieve three relational paths, R_r, R_s, and R_t, such that $\{R_r,R_s,R_t\} \subseteq \{T \mid k \in T|_i^\sigma\}$. See Figure 6(d) for characteristic anchors $(a_s,b_s)=(2,4)$, $(a_r,b_r)=(4,8)$, and $(a_t,b_t)=(6,2)$, and for paths of items corresponding to R_r, R_s, and R_t.

Construction of CUTs with Characteristic Anchors The characteristic anchors permit the construction of a relational skeleton σ such that the corresponding ground graph $\mathcal{G}_\sigma^\mathcal{M}$ includes a UT. First, since all triples characterized by a given characteristic anchor share common relational path(s) from i to k, the existence of a dependency $R_r.Z - \mathcal{V}_X$ (ignoring its direction) makes the triple "shielded" if $(a_r,b_r) = (a_s,b_s)$. Similarly, we can test "shieldedness" in the case of $(a_r,b_r) \neq (a_s,b_s)$ by checking $adj\,(\mathcal{M},\mathcal{V}_X) \cap \{R_r,R_s,R_t\}.Z$ is non-empty. Second, we can devise an efficient and complete procedure that (virtually) constructs a relational skeleton σ that includes an unshielded triple in $\mathcal{G}_\sigma^\mathcal{M}$. Hence, characteristic anchors can be used to identify the CUTs of an RCM without enumerating the entire set of anchors $\mathbf{J}_{\mathbf{p},\mathbf{q}}$.

We proceed to outline an algorithm (see supplementary material for details) that, given a pair of dependencies of an RCM, constructs a CUT. The algorithm initialize candidate anchors $\mathbf{J}_{\mathbf{p},\mathbf{q}}$ by checking pairs of indices (a,b) where $P^a = Q^b$. Then, the algorithm picks an anchor as (a_r,b_r), checks whether (a_r,b_r) can be (a_s,b_s) and yields a UT. Then, it outputs a CUT $(\mathcal{V}_X, \{P.Y, (P^{:a_r} \bowtie Q^{:b_r:-1}).Y\}, R_r.Z)$ where the (virtually constructed) relational skeleton σ' satisfies $\{R_r\} = \{T \mid k \in T|_i^{\sigma'}\}$ and $\{P,\, P^{:a_r} \bowtie Q^{:b_r:-1}\} = \{T \mid j \in T|_i^{\sigma'}\}$. If (a_r,b_r) must differ from (a_s,b_s), then the algorithm explores valid candidates for (a_s,b_s) and (a_t,b_t). If all necessary conditions are passed, then it yields a CUT from among the following: $(\mathcal{V}_X,\mathbf{P}.Y,R_r.Z)$, $(\mathcal{V}_X,\mathbf{P}.Y,R_s.Z)$, and $(\mathcal{V}_X,\mathbf{P}.Y,R_t.Z)$ where σ' satisfies $\{R_r,R_s,R_t\} = \{T \mid k \in T|_i^{\sigma'}\}$ and $\mathbf{P} = \{T \mid j \in T|_i^{\sigma'}\}$, which consists of at most six relational paths[2]. For example, paths of items in Figure 6(e) correspond to three distinct relational paths of $\mathbf{P}$.

[2] P, $P^{:a_w} \bowtie Q^{:b_w:-1}$, $P^{:a_s} \bowtie Q^{:b_s:-1}$, $P^{:a_s} \bowtie Q^{b_t:b_s:-1} \bowtie P^{a_t:}$, $P^{:a_s} \bowtie Q^{b_s:b_r} \bowtie P^{a_r:}$, and $P^{:a_s} \bowtie Q^{b_s:b_r} \bowtie P^{a_r:a_w} \bowtie Q^{:b_w:-1}$ with $a_w \triangleq a_t - \gamma + 1$ and $b_w \triangleq b_t - \gamma + 1$ where $\gamma = LLRSP(P^{a_r:a_t:-1}, Q^{:b_t:-1})$ (see Lee and Honavar, 2015).
