$$s_1, s_2 = -\frac{c_d}{2m_d} \pm \sqrt{\frac{c_d^2}{4m_d^2} - \frac{b_d}{m_d}},$$

are the roots of the polynomial obtained from the second-order ODE, and  $s_3 = j\lambda$  corresponds to the root induced by the excitation  $e^{j\lambda t}$ . Note that the coefficients  $A_1$  and  $A_2$  were calculated using (8). Furthermore, if  $c_d^2 > 4m_d b_d$  then the roots  $s_1$  and  $s_2$  are real, and the model’s response is known as “overdamped”. When  $c_d^2 < 4m_d b_d$  the roots are a pair of complex conjugates, and the response is known as “underdamped”.

Figure 2 shows the covariance matrices for a two-output LFM using the standard expression for the covariance function in Álvarez et al. [2009], and the kernel obtained by using the random Fourier response features for the ODE2,  $v_d^{(2)}(t, \theta_d, \lambda)$ , based on  $S = 100$  samples. In this example, we consider that the first output follows an overdamped response, while the second output has an underdamped response. Additionally, the input times comprises 100 values in the range from 0s to 3s for each output. Just to have a quantitative measure of the approximation obtained by the RFRF approach, the Frobenius norm between the covariance matrices shown in figure 2 is 239.1. However, for  $S = 10^5$  samples, the Frobenius norm is 5.8, which states that we are able to reduce the approximation error by the cost of increasing the number of samples. Note that the covariance values are similar,

Figure 2: Comparison of the covariance matrix evaluation using the standard LFM and the RFRF.

indicating that the correlation between the outputs and within each output is preserved and well approximated by the inner products of the random features  $v_d^{(2)}(t, \theta_d, \lambda)$ .

For the following experiments, we consider two motion capture (MOCAP) datasets,<sup>2</sup> which consist of measured joint angles from different types of motions. Additionally, the variational approach is configured with 25 inducing variables, six latent forces and the maximum number of iterations set to 500.

**MOCAP - Golf swing** In this experiment, we consider the movement “Golf swing” performed by subject 64 motion 01. From the 62 available channels, we selected 56 each having 448 samples, except for two outputs where 81 consecutive samples were considered for testing purposes. The complete dataset for training consists of 24926 data-points.

Table 3: Results for Golf Swing dataset.

Kernel	root-Ypos		lowerback-Yrot		Time [s]
	NMSE	NLPD	NMSE	NLPD	
ODE2+S10	0.39	-2.23	0.98	2.69	2.20
ODE2+S20	0.24	-2.35	1.49	4.30	3.02
ODE2+S50	0.17	-2.39	<b>0.27</b>	<b>1.17</b>	4.59
ODE2+S100	0.12	<b>-2.45</b>	0.32	1.34	9.31
ODE2	<b>0.11</b>	-2.39	3.19	7.26	28.96

Table 3 reports the predictive performance using the covariance functions built from the LFM and the proposed RFRF. In this experiment, the RFRF approximations fit better the testing data for output “lowerback-Yrot”, as shown in figure 3. In contrast, output “root-Ypos” testing data is best fitted by the standard LFM. In summary, the models learned using 50 and 100 samples not only performed better than the standard LFM, but also their cost time is reduced by a fraction of three and six, respectively.

**MOCAP - Walk** For this experiment, we consider the movement “walk” from subject 02 motion 01. From the 62 available channels, we selected 48 each having 343 samples, except for 121 and 105 consecutive samples of two outputs that were considered for testing purposes. The complete dataset for training consists of 16238 data-points.

Table 4 reports the predictive performance for the testing data used in “walk” experiment. Output “lowerback-Yrot” missing data is best fitted by the standard LFM. However, the testing data for output “lradius-Xrot” is best fitted by the proposed RFRF approach, as shown in figure 3. Interestingly, for this experiment, the observed data are smooth, which can be fitted with adequate accuracy using 10 or 20 samples using the RFRF approach.

<sup>2</sup>MOCAP datasets are available at <http://mocap.cs.cmu.edu/>.

Figure 3: Comparison of the predictive GPs, for the Golf swing experiment, using the standard LFM (first column) and the RFRF approximation for  $S = 100$  (second column) and  $S = 10$  samples (third column). Training data is represented using red dots and Test data using blue dots. The black line in the mean over the predictive GP function, and the shaded region denotes two times the standard deviation.

Figure 4: Comparison of the predictive GPs obtained for the the motion “Walk” using the standard LFM (first column) and the RFF approximation for  $S = 100$  (third column) and  $S = 10$  samples (third column). Training data is represented using red dots and Test data using blue dots. The black line in the mean over the predictive GP function, and the shaded region denotes two times the standard deviation.

We remark that the evaluation of the covariance function ODE2 is the most expensive one because it requires the evaluation of the Faddeeva function. Hence, the computation time per iteration is reduced using the inner product of  $v_d^{(2)}(t, \theta_d, \lambda)$ .

## 6 RANDOM FOURIER FEATURES FOR CONVOLVED MULTIPLE OUTPUT GAUSSIAN PROCESSES

Convolution processes can be used to build kernels for vector-valued functions, as reviewed in Álvarez and Lawrence [2011]. Following similar expressions to the ones in section 3, an output  $f_d(\mathbf{x})$ , with  $\mathbf{x} \in \mathbb{R}^p$ , can be modeled as a convolution integral of general smooth-

Table 4: Results for Walk Dataset.

Kernel	lowerback-Yrot		Iradius-Xrot		Time [s]
	NMSE	NLPD	NMSE	NLPD	
ODE2+S10	0.21	5.05	0.12	1.06	1.45
ODE2+S20	0.22	2.09	0.49	<b>0.87</b>	2.04
ODE2+S50	0.22	4.77	0.19	5.28	3.24
ODE2+S100	0.18	3.35	<b>0.09</b>	3.86	6.09
ODE2	<b>0.02</b>	<b>-0.10</b>	0.99	19.63	19.67

ing kernels  $\{G_{d,q}^i(\cdot)\}_{d=1,q=1,i=1}^{D,Q,R_q}$ , and latent processes  $\{u_q^i(\mathbf{x})\}_{q=1,i=1}^{Q,R_q}$

$$f_d(\mathbf{x}) = \sum_{q=1}^Q \sum_{i=1}^{R_q} \int_{\mathcal{X}} G_{d,q}^i(\mathbf{x} - \mathbf{z}) u_q^i(\mathbf{z}) d\mathbf{z},$$

where, according to Álvarez and Lawrence [2011], the variable  $R_q$  makes reference to the number of latent functions  $u_q$  that share the same covariance function  $k_q(x, x')$ , although are sampled independently. Granted that the  $u_q^i(\mathbf{x})$  are independent GPs with zero mean and covariance functions  $\text{cov}[u_q^i(\mathbf{x}), u_{q'}^j(\mathbf{x}')] = k_q(\mathbf{x}, \mathbf{x}') \delta_{q,q'} \delta_{i,j}$ , where  $\delta_{q,q'}$  and  $\delta_{i,j}$  are Kronecker deltas, the cross-covariance between  $f_d(\mathbf{x})$ , and  $f_{d'}(\mathbf{x}')$ ,  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$ , follows a familiar form

$$\sum_{q=1}^Q \sum_{i=1}^{R_q} \int_{\mathcal{X}} G_{d,q}^i(\mathbf{x} - \mathbf{z}) \int_{\mathcal{X}} G_{d',q}^i(\mathbf{x}' - \mathbf{z}') k_q(\mathbf{z}, \mathbf{z}') d\mathbf{z} d\mathbf{z}'.$$

This covariance function subsumes several other covariance functions proposed in the literature for multiple output GPs, including the linear model of coregionalization [Álvarez and Lawrence, 2011].

A general purpose expression for  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$  can be obtained by assuming that both  $G_{d,q}^i(\cdot)$  and  $k_q(\cdot, \cdot)$  follow Gaussian forms. The cross-covariance  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$  would then also follow a Gaussian form after solving the double integration for  $\mathcal{X} = \mathbb{R}^p$ . The authors in Álvarez and Lawrence [2011] provided a closed-form expression for  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$  for this case, when  $R_q = 1$ .

We can also use random Fourier features for  $k_q(\cdot, \cdot)$  in the expression above. For the Gaussian case, since the integrations are over  $\mathbb{R}^p$ , we use a Fourier transform instead of a Laplace transform as it was the case for the LFM. Let us assume that both  $G_{d,q}(\cdot)$  and  $k_q(\cdot, \cdot)$  follow Gaussian forms,

$$G_{d,q}(\boldsymbol{\tau}) = \exp \left[ -\frac{P_d}{2} \boldsymbol{\tau}^\top \boldsymbol{\tau} \right],$$

$$k_q(\mathbf{z}, \mathbf{z}') = \exp \left[ -\frac{1}{\ell_q^2} (\mathbf{z} - \mathbf{z}')^\top (\mathbf{z} - \mathbf{z}') \right],$$

where  $P_d$  is the inverse-width associated to the smoothing kernel for output  $d$ , and  $\ell_q$  is the length-scale for the kernel of the latent function. The cross-covariance  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$  follows as

$$\sum_{q=1}^Q S_{d,q} S_{d',q'} \int_{\mathcal{X}} \int_{\mathcal{X}} \exp \left[ -\frac{P_d}{2} (\mathbf{x} - \mathbf{z})^\top (\mathbf{x} - \mathbf{z}) \right] \times \exp \left[ -\frac{P_{d'}}{2} (\mathbf{x}' - \mathbf{z}')^\top (\mathbf{x}' - \mathbf{z}') \right] k_q(\mathbf{z}, \mathbf{z}') d\mathbf{z} d\mathbf{z}'.$$

Using again the Bochner's theorem for  $k_q(\mathbf{z}, \mathbf{z}')$ ,

$$k_q(\mathbf{z}, \mathbf{z}') = \int p(\boldsymbol{\lambda}) \exp(j\boldsymbol{\lambda}^\top (\mathbf{z} - \mathbf{z}')) d\boldsymbol{\lambda}.$$

Placing this form for  $k_q(\mathbf{z}, \mathbf{z}')$  inside the expression for  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$ , and solving the integral over  $\boldsymbol{\lambda}$  using Monte Carlo, we get that  $k_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$  follows

$$\sum_{q=1}^Q \frac{S_{d,q} S_{d',q'}}{S} \phi_d^\top(\mathbf{x}, P_d, \boldsymbol{\Lambda}_q) \phi_{d'}^*(\mathbf{x}', P_{d'}, \boldsymbol{\Lambda}_q),$$

where

$$\phi_d(\mathbf{x}, P_d, \boldsymbol{\Lambda}_q) = \exp \left[ -\frac{1}{2P_d} \mathbf{b}_q + j\boldsymbol{\Lambda}_q \mathbf{x} \right],$$

with  $\mathbf{b}_q = \sum_j (\boldsymbol{\Lambda}_q \odot \boldsymbol{\Lambda}_q)_{i,j} \in \mathbb{R}^{S \times 1}$ , being  $\odot$  the Hadamard product, and  $\boldsymbol{\Lambda}_q = \frac{1}{\ell_q} \mathbf{Z} \in \mathbb{R}^{S \times p}$ , where the entries of the matrix  $\mathbf{Z}$  are sampled from  $\mathcal{N}(0, 1)$ . Hyperparameters  $\theta_d$  and  $\ell_q$  can be estimated using similar procedures to the ones described in section 4.

**SARCOS** As an illustration of the use of the kernel above, we performed an experiment on a subset of the SARCOS dataset described in the book by Rasmussen and Williams [2006].<sup>3</sup> We use a subset of the data in the file `sarcos_inv.mat`. In particular, we randomly select 10000 data observations that include two outputs, corresponding to the first two joint torques, and the first seven inputs, corresponding to the joint positions. We then randomly select 1000 observations for the second output as the test data. We use the remaining 19000 for training, this is, for hyperparameter optimization. We compare the performance between the kernel proposed in Álvarez and Lawrence [2011] (CMOC) and the kernel obtained using the random Fourier response features for different values of  $S$ . For the CMOC we optimize the marginal likelihood as in Eq. (5), whereas for the RFRF, we use the marginal likelihood as in Eq. (6). Table 5 reports the NMSE and NLPD for the 1000 test observations for the second output. These experiments were carried out using a single core of an Intel Xeon E5-2630v3 @ 2.4 GHz.

<sup>3</sup>Available at <http://www.gaussianprocess.org/gpml/data/>

Table 5: Results for the Sarcos Experiment.

Kernel	NMSE	NLPD	Time [s]
RFF+GG+S50	0.34	3.58	10.14
RFF+GG+S100	0.30	3.52	18.47
RFF+GG+S200	0.26	3.44	38.55
RFF+GG+S500	0.24	3.41	64.62
RFF+GG+S1000	0.22	3.36	85.00
CMOC	<b>0.19</b>	<b>3.21</b>	353.00

We notice that the performance of the approximation increases with  $S$ , and approaches the performance of CMOC, keeping the computation time per iteration to a fraction of the original one. As it was also expected, in higher dimensions, we need a larger number of random features to approach the performance of the CMOC.

## 7 RELATED WORK

Random Fourier features have been used in the literature for Gaussian processes before. For example, in Bonilla et al. [2016], the authors use RFFs in order to propose a multi-task GP model that circumvents the scalability problem of the GPs. Their model for the multiple outputs uses an affine transformation of the random features, whereas we use a non-instantaneous transformation via the Green’s functions. Also in Yang et al. [2015], the authors use a faster approximation of random Fourier features via the FastFood kernels [Le et al., 2013], for approximating the kernel functions of a GP. Their method is not used for multiple outputs, nor does include dynamical systems.

Latent force models have been also studied using a state-space formulation [Hartikainen and Särkkä, 2011] and in that line of research, low-rank approximations for computing features have also been introduced [Solin and Särkkä, 2014]. Specifically, this work approximates the covariance function using the Laplace operator eigenvalues and eigenfunctions. This formulation has been used in Svensson et al. [2016] to approximate the GP priors that are placed over the functions that transform the state vector in the update state and observation equations. Thus, it has not been considered to approximate the GP model of the excitation function.

Brault et al. [2016] directly build random Fourier features for vector-valued kernels using an operator-valued version of Bochner’s theorem. The construction is applied to the decomposable kernel, the curl-free kernel and the div-free kernel. In our construction, rather than starting with a fixed form for the operator-valued kernel, we use a general mechanism used to build valid operator kernel functions and apply linear operators over the random Fourier features defined for single output kernels.

## 8 CONCLUSIONS AND FUTURE WORK

We have shown in this paper how to use random Fourier features for easing the computation of the kernel functions associated to LFM. As a by-product, we have also reduced the computational complexity of working in multiple-output GPs from  $\mathcal{O}(D^3N^3)$  to  $\mathcal{O}(DNQ^2S^2)$ . We showed experiments over datasets of different sizes for which results with LFM are slow to compute. Our random Fourier response features reduce computational time without compromising performance. Also, notice that by having decoupled the solution of the convolution integrals from the particular form for the kernel of the latent functions, we now can easily build kernels for latent force models with different kernel functions in the GPs of the latent functions, just by changing the distribution  $p(\lambda)$  from which we sample from.

These novel representations of latent force models open the path for different types of future work: the application of random Fourier response features for building more efficient versions of sequential LFM [Álvarez et al., 2011] and hierarchical LFM [Honkela and et al., 2010]; the use of physically inspired Fourier features in other Gaussian process models, particularly, deep models [Cutajar et al., 2017]; the use of more efficient sampling techniques for obtaining the Fourier features, e.g. Quasi-Monte Carlo sampling [Avron et al., 2016]. With a more efficient way to compute kernels for multiple-outputs, we can also use more expensive model selection approaches, for example, those based on automatic composition of kernel functions [Duvenaud and et al., 2013], for building more complex covariance functions, e.g. combinations of first order models and second order models, as sums of kernels or as products of kernels. For the case of convolved multiple outputs GPs where the input dimension is greater than three (compared to typical LFMs), the computation of dense Gaussian matrices can be replaced by the product between Hadamard matrices and diagonal Gaussian matrices, which are faster to compute [Le et al., 2013].

## Abstract

Imitation learning (IL) consists of a set of tools that leverage expert demonstrations to quickly learn policies. However, if the expert is suboptimal, IL can yield policies with inferior performance compared to reinforcement learning (RL). In this paper, we aim to provide an algorithm that combines the best aspects of RL and IL. We accomplish this by formulating several popular RL and IL algorithms in a common mirror descent framework, showing that these algorithms can be viewed as a variation on a single approach. We then propose LOKI, a strategy for policy learning that first performs a small but random number of IL iterations before switching to a policy gradient RL method. We show that if the switching time is properly randomized, LOKI can learn to outperform a suboptimal expert and converge faster than running policy gradient from scratch. Finally, we evaluate the performance of LOKI experimentally in several simulated environments.

## 1 INTRODUCTION

Reinforcement learning (RL) has emerged as a promising technique to tackle complex sequential decision problems. When empowered with deep neural networks, RL has demonstrated impressive performance in a range of synthetic domains (Mnih et al., 2013; Silver et al., 2017). However, one of the major drawbacks of RL is the enormous number of interactions required to learn a policy. This can lead to prohibitive cost and slow convergence when applied to real-world problems, such as those found in robotics (Pan et al., 2017).

Imitation learning (IL) has been proposed as an alternate strategy for faster policy learning that works by

leveraging additional information provided through expert demonstrations (Pomerleau, 1989; Schaal, 1999). However, despite significant recent breakthroughs in our understanding of imitation learning (Ross et al., 2011; Cheng and Boots, 2018), the performance of IL is still highly dependent on the quality of the expert policy. When only a suboptimal expert is available, policies learned with standard IL can be inferior to the policies learned by tackling the RL problem directly with approaches such as policy gradients.

Several recent attempts have endeavored to combine RL and IL (Ross and Bagnell, 2014; Chang et al., 2015; Nair et al., 2017; Rajeswaran et al., 2017; Sun et al., 2018). These approaches incorporate the cost information of the RL problem into the imitation process, so the learned policy can *both* improve faster than their RL-counterparts and outperform the suboptimal expert policy. Despite reports of improved empirical performance, the theoretical understanding of these combined algorithms are still fairly limited (Rajeswaran et al., 2017; Sun et al., 2018). Furthermore, some of these algorithms have requirements that can be difficult to satisfy in practice, such as state resetting (Ross and Bagnell, 2014; Chang et al., 2015).

In this paper, we aim to provide an algorithm that combines the best aspects of RL and IL. We accomplish this by first formulating first-order RL and IL algorithms in a common mirror descent framework, and show that these algorithms can be viewed as a single approach that only differs in the choice of first-order oracle. On the basis of this new insight, we address the difficulty of combining IL and RL with a simple, randomized algorithm, named LOKI (Locally Optimal search after  $K$ -step Imitation). As its name suggests, LOKI operates in two phases: picking  $K$  randomly, it first performs  $K$  steps of online IL and then improves the policy with a policy gradient method afterwards. Compared with previous methods that aim to combine RL and IL, LOKI is extremely straightforward to implement. Furthermore, it

has stronger theoretical guarantees: by properly randomizing  $K$ , LOKI performs as if directly running policy gradient steps with the expert policy as the initial condition. Thus, not only can LOKI improve faster than common RL methods, but it can also significantly outperform a suboptimal expert. This is in contrast to previous methods, such as AGGREGATE (Ross and Bagnell, 2014), which generally cannot learn a policy that is better than a one-step improvement over the expert policy. In addition to these theoretical contributions, we validate the performance of LOKI in multiple simulated environments. The empirical results corroborate our theoretical findings.

## 2 PROBLEM DEFINITION

We consider solving discrete-time  $\gamma$ -discounted infinite-horizon RL problems.<sup>1</sup> Let  $\mathbb{S}$  and  $\mathbb{A}$  be the state and the action spaces, and let  $\Pi$  be the policy class. The objective is to find a policy  $\pi \in \Pi$  that minimizes an accumulated cost  $J(\pi)$  defined as

$$\min_{\pi \in \Pi} J(\pi), \quad J(\pi) := \mathbb{E}_{\rho_\pi} [\sum_{t=0}^{\infty} \gamma^t c(s_t, a_t)], \quad (1)$$

in which  $s_t \in \mathbb{S}$ ,  $a_t \in \mathbb{A}$ ,  $c$  is the instantaneous cost, and  $\rho_\pi$  denotes the distribution of trajectories  $(s_0, a_0, s_1, \dots)$  generated by running the stationary policy  $\pi$  starting from  $s_0 \sim p_0(s_0)$ .

We denote  $Q_\pi(s, a)$  as the Q-function under policy  $\pi$  and  $V_\pi(s) = \mathbb{E}_{a \sim \pi_s} [Q_\pi(s, a)]$  as the associated value function, where  $\pi_s$  denotes the action distribution given state  $s$ . In addition, we denote  $d_{\pi,t}(s)$  as the state distribution at time  $t$  generated by running the policy  $\pi$  for the first  $t$  steps, and we define a joint distribution  $d_\pi(s, t) = (1 - \gamma)d_{\pi,t}(s)\gamma^t$  which has support  $\mathcal{S} \times [0, \infty)$ . Note that, while we use the notation  $\mathbb{E}_{a \sim \pi}$ , the policy class  $\Pi$  can be either deterministic or stochastic.

We generally will not deal with the objective function in (1) directly. Instead, we consider a surrogate problem

$$\min_{\pi \in \Pi} \mathbb{E}_{s,t \sim d_\pi} \mathbb{E}_{a \sim \pi_s} [A_{\pi'}(s, a)], \quad (2)$$

where  $A_{\pi'} = Q_{\pi'} - V_{\pi'}$  is the (dis)advantage function with respect to some fixed reference policy  $\pi'$ . For compactness of writing, we will often omit the random variable in expectation; e.g., the objective function in (2) will be written as  $\mathbb{E}_{d_\pi} \mathbb{E}_\pi [A_{\pi'}]$  for the remainder of paper.

By the performance difference lemma below, it is easy to see that solving (2) is equivalent to solving (1).

**Lemma 1.** (Kakade and Langford, 2002) *Let  $\pi$  and  $\pi'$  be two policies and  $A_{\pi'}(s, a) = Q_{\pi'}(s, a) - V_{\pi'}(s)$  be*

<sup>1</sup>LOKI can be easily adapted to finite-horizon problems.

the (dis)advantage function with respect to running  $\pi'$ . Then it holds that

$$J(\pi) = J(\pi') + \frac{1}{1 - \gamma} \mathbb{E}_{d_\pi} \mathbb{E}_\pi [A_{\pi'}]. \quad (3)$$

## 3 FIRST-ORDER RL AND IL

We formulate both first-order RL and IL methods within a single mirror descent framework (Nemirovski et al., 2009), which includes common update rules (Sutton et al., 2000; Kakade, 2002; Peters and Schaal, 2008; Peters et al., 2010; Rawlik et al., 2012; Silver et al., 2014; Schulman et al., 2015b; Ross et al., 2011; Sun et al., 2017). We show that policy updates based on RL and IL mainly differ in first-order stochastic oracles used, as summarized in Table 1.

### 3.1 MIRROR DESCENT

We begin by defining the iterative rule to update policies. We assume that the learner’s policy  $\pi$  is parametrized by some  $\theta \in \Theta$ , where  $\Theta$  is a closed and convex set, and that the learner has access to a family of strictly convex functions  $\mathcal{R}$ .

To update the policy, in the  $n$ th iteration, the learner receives a vector  $g_n$  from a first-order oracle, picks  $R_n \in \mathcal{R}$ , and then performs a mirror descent step:

$$\theta_{n+1} = P_{n,g_n}(\theta_n) \quad (4)$$

where  $P_{n,g_n}$  is a prox-map defined as

$$P_{n,g_n}(\theta_n) := \arg \min_{\theta \in \Theta} \langle g_n, \theta \rangle + \frac{1}{\eta_n} D_{R_n}(\theta || \theta_n). \quad (5)$$

$\eta_n$  is the step size, and  $D_{R_n}$  is the Bregman divergence associated with  $R_n$  (Bregman, 1967):  $D_{R_n}(\theta || \theta_n) := R_n(\theta) - R_n(\theta_n) - \langle \nabla R_n(\theta_n), \theta - \theta_n \rangle$ .

By choosing proper  $R_n$ , the mirror descent framework in (4) covers most RL and IL algorithms. Common choices of  $R_n$  include negative entropy (Peters et al., 2010; Rawlik et al., 2012),  $\frac{1}{2} \|\theta\|_2^2$  (Sutton et al., 2000; Silver et al., 2014), and  $\frac{1}{2} \theta^\top F(\theta_n) \theta$  with  $F(\theta_n)$  as the Fisher information matrix (Kakade, 2002; Peters and Schaal, 2008; Schulman et al., 2015a).

### 3.2 FIRST-ORDER ORACLES

While both first-order RL and IL methods can be viewed as performing mirror descent, they differ in the choice of the first-order oracle that returns the update direction  $g_n$ . Here we show the vector  $g_n$  of both approaches can be derived as a stochastic approximation of the (partial) derivative of  $\mathbb{E}_{d_\pi} \mathbb{E}_\pi [A_{\pi'}]$  with respect to policy  $\pi$ , but with a different reference policy  $\pi'$ .

Table 1: Comparison of First-Order Oracles

Method	First-Order Oracle
POLICY GRADIENT (Section 3.2.1)	$\mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}]$
DAGGERED (Section 3.2.2)	$\mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [\mathbb{E}_{\pi^*} [d]]$
AGGREGATED (Section 3.2.2)	$\mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi^*}]$
SOLS (Section 6)	$\mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [(1 - \lambda)A_{\pi_n} + \lambda A_{\pi^*}]$
THOR (Section 6)	$\mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n, t}^{H, \pi^*}]$

### 3.2.1 Policy Gradients

A standard approach to RL is to treat (1) as a stochastic nonconvex optimization problem. In this case,  $g_n$  in mirror descent (4) is an estimate of the policy gradient  $\nabla_{\theta} J(\pi)$  (Williams, 1992; Sutton et al., 2000).

To compute the policy gradient in the  $n$ th iteration, we set the current policy  $\pi_n$  as the reference policy in (3) (i.e.  $\pi' = \pi_n$ ), which is treated as constant in  $\theta$  in the following policy gradient computation. Because  $\mathbb{E}_{\pi_n} [A_{\pi_n}] = \mathbb{E}_{\pi_n} [Q_{\pi_n}] - V_{\pi_n} = 0$ , using (3), the policy gradient can be written as<sup>2</sup>

$$\begin{aligned}
& (1 - \gamma) \nabla_{\theta} J(\pi) |_{\pi=\pi_n} \\
&= \nabla_{\theta} \mathbb{E}_{d_{\pi}} \mathbb{E}_{\pi} [A_{\pi_n}] |_{\pi=\pi_n} \\
&= (\nabla_{\theta} \mathbb{E}_{d_{\pi}}) [0] + \mathbb{E}_{d_{\pi}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}] |_{\pi=\pi_n} \\
&= \mathbb{E}_{d_{\pi}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}] |_{\pi=\pi_n} \tag{6}
\end{aligned}$$

The above expression is unique up to a change of baselines:  $(\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}]$  is equivalent to  $(\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n} + b]$ , because  $(\nabla_{\theta} \mathbb{E}_{\pi}) [b(s)] = \nabla_{\theta} b(s) = 0$ , where  $b : \mathbb{S} \rightarrow \mathbb{R}$  is also called a control variate (Greensmith et al., 2004).

The exact formulation of  $(\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}]$  depends on whether the policy  $\pi$  is stochastic or deterministic. For stochastic policies,<sup>3</sup> we can compute it with the likelihood-ratio method and write

$$(\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}] = \mathbb{E}_{\pi} [A_{\pi_n} \nabla_{\theta} \log \pi] \tag{7}$$

For deterministic policies, we replace the expectation as evaluation (as it is the expectation over a Dirac delta function, i.e.  $a = \pi(s)$ ) and use the chain rule:

$$(\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}] = \nabla_{\theta} A_{\pi_n}(s, \pi) = \nabla_{\theta} \pi \nabla_a A_{\pi_n} \tag{8}$$

Substituting (7) or (8) back into (6), we get the equation for stochastic policy gradient (Sutton et al., 2000) or deterministic policy gradient (Silver et al., 2014). Note that the above equations require the exact knowledge, or

<sup>2</sup>We assume the cost is sufficiently regular so that the order of differentiation and expectation can exchange.

<sup>3</sup>A similar equation holds for reparametrization (Grathwohl et al., 2017).

an unbiased estimate, of  $A_{\pi}$ . In practice, these terms are further approximated using function approximators, leading to biased gradient estimators (Konda and Tsitsiklis, 2000; Schulman et al., 2015b; Mnih et al., 2016).

### 3.2.2 Imitation Gradients

An alternate strategy to RL is IL. In particular, we consider *online* IL, which interleaves data collection and policy updates to overcome the covariate shift problem of traditional batch IL (Ross et al., 2011). Online IL assumes that a (possibly suboptimal) expert policy  $\pi^*$  is available as a black-box oracle, from which demonstrations  $a^* \sim \pi_s^*$  can be queried for any given state  $s \in \mathbb{S}$ . Due to this requirement, the expert policy in online IL is often an *algorithm* (rather than a human demonstrator), which is hard-coded or based on additional computational resources, such as trajectory optimization (Pan et al., 2017). The goal of IL is to learn a policy that can perform similar to, or better than, the expert policy.

Rather than solving the stochastic nonconvex optimization directly, online IL solves an online learning problem with per-round cost in the  $n$ th iteration defined as

$$l_n(\pi) = \mathbb{E}_{d_{\pi_n}} \mathbb{E}_{\pi} [\tilde{c}] \tag{9}$$

where  $\tilde{c} : \mathbb{S} \times \mathbb{A} \rightarrow \mathbb{R}$  is a surrogate loss satisfying the following condition: For all  $s \in \mathbb{S}$  and  $\pi \in \Pi$ , there exists a constant  $C_{\pi^*} > 0$  such that

$$C_{\pi^*} \mathbb{E}_{\pi} [\tilde{c}] \geq \mathbb{E}_{\pi} [A_{\pi^*}]. \tag{10}$$

By Lemma 1, this implies  $J(\pi_n) \leq J(\pi^*) + \frac{C_{\pi^*}}{1-\gamma} l_n(\pi_n)$ . Namely, in the  $n$ th iteration, online IL attempts to minimize an online upper-bound of  $J(\pi_n)$ .

DAGGER (Ross et al., 2011) chooses  $\tilde{c}$  to be a strongly convex function  $\tilde{c}(s, a) = \mathbb{E}_{a^* \sim \pi_s^*} [d(a, a^*)]$  that penalizes the difference between the learner’s policy and the expert’s policy, where  $d$  is some metric of space  $\mathbb{A}$  (e.g., for a continuous action space Pan et al. (2017) choose  $d(a, a^*) = \|a - a^*\|^2$ ). More directly, AGGREGATE simply chooses  $\tilde{c}(s, a) = A_{\pi^*}(s, a)$  (Ross and Bagnell, 2014); in this case, the policy learned with online IL can potentially outperform the expert policy.

First-order online IL methods operate by updating policies with mirror descent (4) with  $g_n$  as an estimate of

$$\nabla_{\theta} l_n(\pi_n) = \mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi} [\tilde{c}])|_{\pi=\pi_n} \quad (11)$$

Similar to policy gradients, the implementation of (11) can be executed using either (7) or (8) (and with a control variate). One particular case of (11), with  $\tilde{c} = A_{\pi^*}$ , is known as AGGREGATED (Sun et al., 2017),

$$\nabla_{\theta} l_n(\pi_n) = \mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi} [A_{\pi^*}])|_{\pi=\pi_n}. \quad (12)$$

Similarly, we can turn DAGGER into a first-order method, which we call DAGGERED, by using  $g_n$  as an estimate of the first-order oracle

$$\nabla_{\theta} l_n(\pi_n) = \mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi} \mathbb{E}_{\pi^*} [d]). \quad (13)$$

A comparison is summarized in Table 1.

## 4 THEORETICAL COMPARISON

With the first-order oracles defined, we now compare the performance and properties of performing mirror descent with policy gradient or imitation gradient. We will see that while both approaches share the same update rule in (4), the generated policies have different behaviors: using policy gradient generates a *monotonically* improving policy sequence, whereas using imitation gradient generates a policy sequence that improves *on average*. Although the techniques used in this section are not completely new in the optimization literature, we specialize the results to compare performance and to motivate LOKI in the next section. The proofs of this section are included in Appendix B for completeness.

### 4.1 POLICY GRADIENTS

We analyze the performance of policy gradients with standard techniques from nonconvex analysis.

**Proposition 1.** *Let  $J$  be  $\beta$ -smooth and  $R_n$  be  $\alpha_n$ -strongly convex with respect to norm  $\|\cdot\|$ . Assume  $\mathbb{E}[g_n] = \nabla_{\theta} J(\pi_n)$ . For  $\eta_n \leq \frac{2\alpha_n}{\beta}$ , it satisfies*

$$\begin{aligned} \mathbb{E}[J(\pi_{n+1})] &\leq J(\pi_0) + \mathbb{E} \left[ \sum_{n=1}^N \frac{2\eta_n}{\alpha_n} \|\nabla_{\theta} J(\pi_n) - g_n\|_*^2 \right] \\ &\quad + \frac{1}{2} \mathbb{E} \left[ \sum_{n=1}^N \left( -\alpha_n \eta_n + \frac{\beta \eta_n^2}{2} \right) \|\hat{\nabla}_{\theta} J(\pi_n)\|^2 \right] \end{aligned}$$

where the expectation is due to randomness of sampling  $g_n$ , and  $\hat{\nabla}_{\theta} J(\pi_n) := \frac{1}{\eta_n} (\theta_n - P_{n, \nabla_{\theta} J(\pi_n)}(\theta_n))$  is a gradient surrogate.

Proposition 1 shows that monotonic improvement can be made under proper smoothness assumptions if the step

size is small and noise is comparably small with the gradient size. However, the final policy’s performance is sensitive to the initial condition  $J(\pi_0)$ , which can be poor for a randomly initialized policy.

Proposition 1 also suggests that the size of the gradient  $\|\hat{\nabla}_{\theta} J(\pi_n)\|^2$  does not converge to zero on average. Instead, it converges to a size proportional to the sampling noise of policy gradient estimates due to the linear dependency of  $\frac{2\eta_n}{\alpha_n} \|\nabla_{\theta} J(\pi_n) - g_n\|_*^2$  on  $\eta_n$ . This phenomenon is also mentioned by Ghadimi et al. (2016). We note that this pessimistic result is because the prox-map (5) is non-linear in  $g_n$  for general  $R_n$  and  $\Theta$ . However, when  $R_n$  is quadratic and  $\Theta$  is unconstrained, the convergence of  $\|\hat{\nabla}_{\theta} J(\pi_n)\|^2$  to zero on average can be guaranteed (see Appendix B.1 for a discussion).

### 4.2 IMITATION GRADIENTS

While applying mirror descent with a policy gradient can generate a monotonically improving policy sequence, applying the same algorithm with an imitation gradient yields a different behavior. The result is summarized below, which is a restatement of (Ross and Bagnell, 2014, Theorem 2.1), but is specialized for mirror descent.

**Proposition 2.** *Assume  $l_n$  is  $\sigma$ -strongly convex with respect to  $R_n$ .<sup>4</sup> Assume  $\mathbb{E}[g_n] = \nabla_{\theta} l_n(\pi_n)$  and  $\|g_n\|_* \leq G < \infty$  almost surely. For  $\eta_n = \frac{1}{\hat{\sigma} n}$  with  $\hat{\sigma} \leq \sigma$ , it holds*

$$\frac{1}{N} \mathbb{E} \left[ \sum_{n=1}^N J(\pi_n) \right] \leq J(\pi^*) + \frac{C_{\pi^*}}{1-\gamma} (\epsilon_{\text{class}} + \epsilon_{\text{regret}})$$

where the expectation is due to randomness of sampling  $g_n$ ,  $\epsilon_{\text{class}} = \sup_{\{\pi_n\}} \inf_{\pi \in \Pi} \frac{1}{N} \sum_{n=1}^N l_n(\pi)$  and  $\epsilon_{\text{regret}} = \frac{G^2(\log N + 1)}{2\hat{\sigma} N}$ .

Proposition 2 is based on the assumption that  $l_n$  is strongly convex, which can be verified for certain problems (Cheng and Boots, 2018). Consequently, Proposition 2 shows that the performance of the policy sequence on average can converge close to the expert’s performance  $J(\pi^*)$ , with additional error that is proportional to  $\epsilon_{\text{class}}$  and  $\epsilon_{\text{regret}}$ .

$\epsilon_{\text{regret}}$  is an upper bound of the average regret, which is less than  $\tilde{O}(\frac{1}{N})$  for a large enough step size.<sup>5</sup> This characteristic is in contrast to policy gradient, which requires small enough step sizes to guarantee local improvement.

$\epsilon_{\text{class}}$  measures the expressiveness of the policy class  $\Pi$ . It can be *negative* if there is a policy in  $\Pi$  that outper-

<sup>4</sup>A function  $f$  is said to be  $\sigma$ -strongly convex with respect to  $R$  on a set  $\mathcal{K}$  if for all  $x, y \in \mathcal{K}$ ,  $f(x) \geq f(y) + \langle \nabla f(y), x - y \rangle + \sigma D_R(x||y)$ .

<sup>5</sup>The step size should be large enough to guarantee  $\tilde{O}(\frac{1}{N})$  convergence, where  $\tilde{O}$  denotes Big-O but omitting log dependency. However, it should be bounded since  $\epsilon_{\text{regret}} = \Theta(\frac{1}{\hat{\sigma}})$ .

---

**Algorithm 1** LOKI

---

**Parameters:**  $d, N_m, N_M$ **Input:**  $\pi^*$ 

- 1: Sample  $K$  with probability in (15).
  - 2: **for**  $t = 1 \dots K$  **do** # Imitation Phase
  - 3:   Collect data  $\mathcal{D}_n$  by executing  $\pi_n$
  - 4:   Query  $g_n$  from (11) using  $\pi^*$
  - 5:   Update  $\pi_n$  by mirror descent (5) with  $g_n$
  - 6:   Update advantage function estimate  $\hat{A}_{\pi_n}$  by  $\mathcal{D}_n$
  - 7: **end for**
  - 8: **for**  $t = K + 1 \dots$  **do** # Reinforcement Phase
  - 9:   Collect data  $\mathcal{D}_n$  by executing  $\pi_n$ .
  - 10:   Query  $g_n$  from (6) f using  $\hat{A}_{\pi_n}$
  - 11:   Update  $\pi_n$  by mirror descent (5) with  $g_n$
  - 12:   Update advantage function estimate  $\hat{A}_{\pi_n}$  by  $\mathcal{D}_n$
  - 13: **end for**
- 

forms the expert policy  $\pi^*$  in terms of  $\tilde{c}$ . However, since online IL attempts to minimize an online upper bound of the accumulated cost through a surrogate loss  $\tilde{c}$ , the policy learned with imitation gradients in general cannot be better than performing one-step policy improvement from the expert policy (Ross and Bagnell, 2014; Cheng and Boots, 2018). Therefore, when the expert is suboptimal, the reduction from nonconvex optimization to online convex optimization can lead to suboptimal policies.

Finally, we note that updating policies with imitation gradients does not necessarily generate a monotonically improving policy sequence, even for deterministic problems; whether the policy improves monotonically is completely problem dependent (Cheng and Boots, 2018). Without going into details, we can see this by comparing policy gradient in (6) and the special case of imitation gradient in (12). By Lemma 3, we see that

$$\begin{aligned} & \mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi_n}] \\ &= (\nabla_{\theta} \mathbb{E}_{d_{\pi}}) \mathbb{E}_{\pi_n} [A_{\pi^*}] + \mathbb{E}_{d_{\pi_n}} (\nabla_{\theta} \mathbb{E}_{\pi}) [A_{\pi^*}]. \end{aligned}$$

Therefore, even with  $\tilde{c} = A_{\pi^*}$ , the negative of the direction in (12) is not necessarily a descent direction; namely applying (12) to update the policy is not guaranteed to improve the policy performance locally.

## 5 IMITATE-THEN-REINFORCE

To combine the benefits from RL and IL, we propose a simple randomized algorithm LOKI: first perform  $K$  steps of mirror descent with imitation gradient and then switch to policy gradient for the rest of the steps. Despite the algorithm’s simplicity, we show that, when  $K$  is appropriately randomized, running LOKI has similar performance to performing policy gradient steps directly from the expert policy.

## 5.1 ALGORITHM: LOKI

The algorithm LOKI is summarized in Algorithm 1. The algorithm is composed of two phases: an imitation phase and a reinforcement phase. In addition to learning rates, LOKI receives three hyperparameters ( $d, N_m, N_M$ ) which determine the probability of random switching at time  $K$ . As shown in the next section, these three hyperparameters can be selected fairly simply.

**Imitation Phase** Before learning, LOKI first randomly samples a number  $K \in [N_m, N_M]$  according to the prescribed probability distribution (15). Then it performs  $K$  steps of mirror descent with imitation gradient. In our implementation, we set the per-round loss as<sup>6</sup>

$$l_n(\pi) = \mathbb{E}_{d_{\pi_n}} [\text{KL}(\pi^* || \pi)], \quad (14)$$

which is the KL-divergence between the two policies. It can be easily shown that a proper constant  $C^*$  exists satisfying the requirement in (10) (Gibbs and Su, 2002). While using (14) does not guarantee learning a policy that outperforms the expert due to  $\epsilon_{\text{class}} \geq 0$ , with another reinforcement phase available, the imitation phase of LOKI is only designed to quickly bring the initial policy closer to the expert policy. Compared with choosing  $\tilde{c} = A_{\pi^*}$  as in AGGREGATED, one benefit of choosing  $\text{KL}(\pi^* || \pi)$  (or its variants, e.g.  $\mathbb{E}_{a \sim \pi} \mathbb{E}_{a^* \sim \pi^*} [\|a - a^*\|^2]$ ) is that it does not require learning a value function estimator. In addition, the imitation gradient can be calculated through *reparametrization* instead of a likelihood-ratio (Tucker et al., 2017), as now  $l_n$  is presented as a differentiable function. Consequently, the sampling variance of imitation gradient can be significantly reduced, for example, by using multiple samples of  $a \sim \pi_n$  (with a single query from the expert policy) and then performing averaging.

**Reinforcement Phase** After the imitation phase, LOKI switches to the reinforcement phase. At this point, the policy  $\pi_K$  is much closer to the expert policy than the initial policy  $\pi_0$ . In addition, an estimate of  $A_{\pi_K}$  is also available. Because the learner’s policies were applied to collect data in the previous *online* imitation phase,  $A_{\pi_n}$  can already be updated accordingly, for example, by minimizing TD error. Compared with other warm-start techniques, LOKI can learn *both* the policy and the advantage estimator in the imitation phase.

## 5.2 ANALYSIS

We now present the theoretical properties of LOKI. The analysis is composed of two steps. First, we show the

<sup>6</sup>While (14) does not conform with the classical choice  $\mathbb{E}_{\pi}[\tilde{c}]$  in (9), a bound similar to (10) can be derived.

performance of  $J(\pi_K)$  in Theorem 1, a generalization of Proposition 2 to consider the effects of non-uniform random sampling. Next, combining Theorem 1 and Proposition 1, we show the performance of LOKI in Theorem 2. The proofs are given in Appendix C.

**Theorem 1.** *Let  $d \geq 0$ ,  $N_m \geq 1$ , and  $N_M \geq 2N_m$ . Let  $K \in [N_m, N_M]$  be a discrete random variable such that*

$$P(K = n) = n^d / \sum_{m=N_m}^{N_M} m^d. \quad (15)$$

*Suppose  $l_n$  is  $\sigma$ -strongly convex with respect to  $R_n$ ,  $\mathbb{E}[g_n] = \nabla_{\theta} l_n(\pi_n)$ , and  $\|g_n\|_* \leq G < \infty$  almost surely. Let  $\{\pi_n\}$  be generated by running mirror descent with step size  $\eta_n = n^d / \hat{\sigma} \sum_{m=1}^n m^d$ . For  $\hat{\sigma} \leq \sigma$ , it holds that*

$$\mathbb{E}[J(\pi_K)] \leq J(\pi^*) + \Delta,$$

*where the expectation is due to sampling  $K$  and  $g_n$ ,  $\Delta = \frac{C_{\pi^*}}{1-\gamma} (\epsilon_{\text{class}}^w + 2^{-d} \hat{\sigma} D_{\mathcal{R}} + G^2 C_{N_M} / \hat{\sigma} N_M)$ ,  $D_{\mathcal{R}} = \sup_{R \in \mathcal{R}} \sup_{\pi, \pi' \in \Pi} D_R(\pi' || \pi)$ ,  $\epsilon_{\text{class}}^w := \sup_{\{w_n\}, \{\pi_n\}} \inf_{\pi \in \Pi} \frac{\sum_{n=1}^N w_n l_n(\pi)}{\sum_{n=1}^N w_n}$ , and*

$$C_{N_M} = \begin{cases} \log(N_M) + 1, & \text{if } d = 0 \\ \frac{8d}{3} \exp\left(\frac{d}{N_M}\right), & \text{if } d \geq 1 \end{cases}$$

Suppose  $N_M \gg d$ . Theorem 1 says that the performance of  $J(\pi_K)$  in expectation converges to  $J(\pi^*)$  in a rate of  $\tilde{O}(d/N_M)$  when a proper step size is selected. In addition to the convergence rate, we notice that the performance gap between  $J(\pi^*)$  and  $J(\pi_K)$  is bounded by  $O(\epsilon_{\text{class}}^w + 2^{-d} D_{\mathcal{R}})$ .  $\epsilon_{\text{class}}^w$  is a weighted version of the expressiveness measure of policy class  $\Pi$  in Proposition 2, which can be made small if  $\Pi$  is rich enough with respect to the *suboptimal* expert policy.  $D_{\mathcal{R}}$  measures the size of the decision space with respect to the class of regularization functions  $\mathcal{R}$  that the learner uses in mirror descent. The dependency on  $D_{\mathcal{R}}$  is because Theorem 1 performs a suffix random sampling with  $N_m > 0$ . While the presence of  $D_{\mathcal{R}}$  increases the gap, its influence can easily be made small with a slightly large  $d$  due to the factor  $2^{-d}$ .

In summary, due to the sublinear convergence rate of IL,  $N_M$  does not need to be large (say less than 100) as long as  $N_M \gg d$ ; on the other hand, due to the  $2^d$  factor,  $d$  is also small (say less than 5) as long as it is large enough to cancel out the effects of  $D_{\mathcal{R}}$ . Finally, we note that, like Proposition 2, Theorem 1 encourages using larger step sizes, which can further boost the convergence of the policy in the imitation phase of LOKI.

Given Proposition 1 and Theorem 1, now it is fairly easy to understand the performance of LOKI.

**Theorem 2.** *Running LOKI holds that*

$$\begin{aligned} \mathbb{E}[J(\pi_N)] &\leq J(\pi^*) + \Delta \\ &+ \mathbb{E} \left[ \sum_{n=K+1}^N \frac{2\eta_n}{\alpha_n} \|\nabla_{\theta} J(\pi_n) - g_n\|_*^2 \right] \\ &+ \frac{1}{2} \mathbb{E} \left[ \sum_{n=K+1}^N \left( -\alpha_n \eta_n + \frac{\beta \eta_n^2}{2} \right) \|\hat{\nabla}_{\theta} J(\pi_n)\|^2 \right], \end{aligned}$$

*where the expectation is due to sampling  $g_n$  and  $K$ .*

Firstly, Theorem 2 shows that  $\pi_N$  can perform better than the expert policy  $\pi^*$ , and, in fact, it converges to a locally optimal policy on average under the same assumption as in Proposition 1. Compare with to running policy gradient steps directly from the expert policy, running LOKI introduces an additional gap  $O(\Delta + K \|\hat{\nabla}_{\theta} J(\pi)\|^2)$ . However, as discussed previously,  $\Delta$  and  $K \leq N_M \ll N$  are reasonably small, for usual  $N$  in RL. Therefore, performing LOKI almost has the same effect as using the expert policy as the initial condition, which is the best we can hope for when having access to an expert policy.

We can also compare LOKI with performing usual policy gradient updates from a randomly initialized policy. The performance difference can be easily shown as  $O(J(\pi^*) - J(\pi_0) + \Delta + K \|\hat{\nabla}_{\theta} J(\pi)\|^2)$ . Therefore, if performing  $K$  steps of policy gradient from  $\pi_0$  gives a policy with performance worse than  $J(\pi^*) + \Delta$ , then LOKI is favorable.

## 6 RELATED WORK

We compare LOKI with some recent attempts to incorporate the loss information  $c$  of RL into IL so that it can learn a policy that outperforms the expert policy. As discussed in Section 4, when  $\tilde{c} = A_{\pi^*}$ , AGGREGATE(D) can potentially learn a policy that is better than the expert policy (Ross and Bagnell, 2014; Sun et al., 2017). However, implementing AGGREGATE(D) exactly as suggested by theory can be difficult and inefficient in practice. On the one hand, while  $A_{\pi^*}$  can be learned off-policy using samples collected by running the expert policy, usually the estimator quality is unsatisfactory due to covariate shift. On the other hand, if  $A_{\pi^*}$  is learned on-policy, it requires restarting the system from any state, or requires performing  $\frac{1}{1-\gamma}$ -times more iterations to achieve the same convergence rate as other choices of  $\tilde{c}$  such as  $\text{KL}(\pi^* || \pi)$  in LOKI; both of which are impractical for usual RL problems.

Recently, Sun et al. (2018) proposed THOR (Truncated HORizon policy search) which solves a truncated RL problem with the expert's value function as the terminal loss to alleviate the strong dependency of AGGREGATED on the quality of  $A_{\pi^*}$ . Their algorithm uses an  $H$ -step truncated advantage function

defined as  $A_{\pi_n, t}^{H, \pi^*} = \mathbb{E}_{\rho_{\pi_n}} [\sum_{\tau=t}^{t+H-1} \gamma^{\tau-t} c(s_\tau, a_\tau) + \gamma^H V_{\pi^*}(s_{t+H}) - V_{\pi^*}(s_t)]$ . While empirically the authors show that the learned policy can improve over the expert policy, the theoretical properties of THOR remain somewhat unclear.<sup>7</sup> In addition, THOR is more convoluted to implement and relies on multiple advantage function estimators. By contrast, LOKI has clearer theoretical properties, while being straightforward to implement with off-the-shelf learning algorithms.

Finally, we compare LOKI with LOLS (Locally Optimal Learning to Search), proposed by Chang et al. (2015). LOLS is an online IL algorithm which sets  $\tilde{c} = Q_{\hat{\pi}_n^\lambda}$ , where  $\lambda \in [0, 1]$  and  $\hat{\pi}_n^\lambda$  is a mixed policy that at each time step chooses to run the current policy  $\pi_n$  with probability  $1 - \lambda$  and the expert policy  $\pi^*$  with probability  $\lambda$ . Like AGGREGATED, LOLS suffers from the impractical requirement of estimating  $Q_{\hat{\pi}_n^\lambda}$ , which relies on the state resetting assumption.

Here we show that such difficulty can be addressed by using the mirror descent framework with  $g_n$  as an estimate of  $\nabla_{\theta} l_n^\lambda(\pi_n)$ , where  $l_n^\lambda(\pi) := \mathbb{E}_{d_{\pi_n}} \mathbb{E}_{\pi} [(1 - \lambda)A_{\pi_n} + \lambda A_{\pi^*}]$ . That is, the first-order oracle is simply a convex combination of policy gradient and AGGREGATED gradient. We call such linear combination SLOLS (simple LOLS) and we show it has the same performance guarantee as LOLS.

**Theorem 3.** *Under the same assumption in Proposition 2, running SLOLS generates a policy sequence, with randomness due to sampling  $g_n$ , satisfying*

$$\frac{1}{N} \mathbb{E} \left[ \sum_{n=1}^N J(\pi_n) - ((1 - \lambda)J_{\pi_n}^* + \lambda J(\pi^*)) \right] \leq \frac{\epsilon_{\text{class}}^\lambda + \epsilon_{\text{regret}}^\lambda}{1 - \gamma}$$

where  $(1 - \gamma)J_{\pi_n}^* = \min_{\pi \in \Pi} \mathbb{E}_{d_{\pi_n}} \mathbb{E}_{\pi} [Q_{\pi_n}] =: \mathbb{E}_{d_{\pi_n}} [V_{\pi_n}^*]$  and  $\epsilon_{\text{class}}^\lambda = \min_{\pi \in \Pi} \frac{1}{N} (\sum_{n=1}^N \mathbb{E}_{d_{\pi_n}} \mathbb{E}_{\pi} [(1 - \lambda)Q_{\pi_n} + \lambda Q_{\pi^*}]) - \frac{1}{N} (\sum_{n=1}^N \mathbb{E}_{d_{\pi_n}} [(1 - \lambda)V_{\pi_n}^* + \lambda V_{\pi^*}^*])$ .

In fact, the performance in Theorem 3 is actually a lower bound of Theorem 3 in (Chang et al., 2015).<sup>8</sup> Theorem 3 says that on average  $\pi_n$  has performance between the expert policy  $J(\pi^*)$  and the intermediate cost  $J_{\pi_n}^*$ , as long as  $\epsilon_{\text{class}}^\lambda$  is small (i.e., there exists a single policy in  $\Pi$  that is better than the expert policy or the local improvement from any policy in  $\Pi$ ). However, due to the presence of  $\epsilon_{\text{class}}^\lambda$ , despite  $J_{\pi_n}^* \leq J(\pi_n)$ , it is not guaranteed that  $J_{\pi_n}^* \leq J(\pi^*)$ . As in Chang et al. (2015), either LOLS or SLOLS can necessarily perform on average better than the expert policy  $\pi^*$ . Finally, we note that recently both Nair et al. (2017) and Rajeswaran et al.

<sup>7</sup>The algorithm actually implemented by Sun et al. (2018) does not solve precisely the same problem analyzed in theory.

<sup>8</sup>The main difference is due to technicalities. In Chang et al. (2015),  $\epsilon_{\text{class}}^\lambda$  is compared with a time-varying policy.

(2017) propose a scheme similar to SLOLS, but with the AGGREGATE(D) gradient computed using offline batch data collected by the expert policy. However, there is no theoretical analysis of this algorithm’s performance.

## 7 EXPERIMENTS

We evaluate LOKI on several robotic control tasks from OpenAI Gym (Brockman et al., 2016) with the DART physics engine (Lee et al., 2018)<sup>9</sup> and compare it with several baselines: TRPO (Schulman et al., 2015a), TRPO from expert, DAGGERED (the first-order version of DAGGER (Ross et al., 2011) in (13)), SLOLS (Section 6), and THOR (Sun et al., 2018).

### 7.1 TASKS

We consider the following tasks. In all tasks, the discount factor of the RL problem is set to  $\gamma = 0.99$ . The details of each task are specified in Table A in Appendix A.

**Inverted Pendulum** This is a classic control problem, and its goal is to swing up an pendulum and to keep it balanced in a upright posture. The difficulty of this task is that the pendulum cannot be swung up directly due to a torque limit.

**Locomotion** The goal of these tasks (Hopper, 2D Walker, and 3D Walker) is to control a walker to move forward as quickly as possible without falling down. In Hopper, the walker is a monopod, which is subjected to significant contact discontinuities, whereas the walkers in the other tasks are bipeds. In 2D Walker, the agent is constrained to a plane to simplify balancing.

**Robot Manipulator** In the Reacher task, a 5-DOF (degrees-of-freedom) arm is controlled to reach a random target position in 3D space. The reward consists of the negative distance to the target point from the finger tip plus a control magnitude penalty. The actions correspond to the torques applied to the 5 joints.

### 7.2 ALGORITHMS

We compare five algorithms (LOKI, TRPO, DAGGERED, THOR, SLOLS) and the idealistic setup of performing policy gradient steps directly from the expert policy (Ideal). To facilitate a fair comparison, all the algorithms are implemented based on a publicly available TRPO implementation (Dhariwal et al., 2017). Furthermore, they share the same parameters except for those

<sup>9</sup>The environments are defined in DartEnv, hosted at <https://github.com/DartEnv>.

that are unique to each algorithm as listed in Table A in Appendix A. The experimental results averaged across 25 random seeds are reported in Section 7.3.

**Policy and Value Networks** Feed-forward neural networks are used to construct the policy networks and the value networks in all the tasks (both have two hidden layers and 32 tanh units per layer). We consider Gaussian stochastic policies, i.e. for any state  $s \in \mathbb{S}$ ,  $\pi_s(a)$  is Gaussian distributed. The mean of the Gaussian  $\pi_s(a)$ , as a function of state, is modeled by the policy network, and the covariance matrix of Gaussian is restricted to be diagonal and independent of state. The policy networks and the value function networks are initialized randomly, except for the ideal setup (TRPO from expert), which is initialized as the expert.

**Expert Policy** The same sub-optimal expert is used by all algorithms (LOKI, DAGGERED, SLOLS, and THOR). It is obtained by running TRPO and stopping it before convergence. The estimate of the expert value function  $V_{\pi^*}$  (required by SLOLS and THOR) is learned by minimizing the sum of squared TD(0) error on a large separately collected set of demonstrations of this expert. The final explained variance for all the tasks is more than 0.97 (see Appendix A).

**First-Order Oracles** The on-policy advantage  $A_{\pi_n}$  in the first-order oracles for TRPO, SLOLS, and LOKI (in the reinforcement phase) is implemented using an on-policy value function estimator and Generalized Advantage Estimator (GAE) (Schulman et al., 2015b). For DAGGERED and the imitation phase of LOKI, the first-order oracle is calculated using (14). For SLOLS, we use the estimate  $A_{\pi^*}(s_t, a_t) \approx c(s_t, a_t) + \gamma \hat{V}_{\pi^*}(s_{t+1}) - \hat{V}_{\pi^*}(s_t)$ . And for THOR,  $A_{\pi_n, t}^{H, \pi^*}$  of the truncated-horizon problem is approximated by Monte-Carlo samples with an on-policy value function baseline estimated by regressing on these Monte-Carlo samples. Therefore, for *all* methods, an on-policy component is used in constructing the first-order oracle. The exponential weighting in GAE is 0.98; the mixing coefficient  $\lambda$  in SLOLS is 0.5;  $N_M$  in LOKI is reported in Table A in Appendix A, and  $N_m = \lfloor \frac{1}{2} N_M \rfloor$ , and  $d = 3$ .

**Mirror Descent** After receiving an update direction  $g_n$  from the first-order oracle, a KL-divergence-based trust region is specified. This is equivalent to setting the strictly convex function  $R_n$  in mirror descent to  $\frac{1}{2} \theta^\top F(\theta_n) \theta$  and choosing a proper learning rate. In our experiments, a larger KL-divergence limit (0.1) is selected for imitation gradient (14) (in DAGGERED and in the imitation phase of LOKI), and a smaller one (0.01) is set for all other algorithms. This decision follows

the guideline provided by the theoretical analysis in Section 3.2.2 and is because of the low variance in calculating the gradient of (14). Empirically, we observe using the larger KL-divergence limit with policy gradient led to high variance and instability.

### 7.3 EXPERIMENTAL RESULTS

We report the performance of these algorithms on various tasks in Figure 1. The performance is measured by the accumulated *rewards*, which are directly provided by OpenAI Gym.

We first establish the performance of two baselines, which represent standard RL (TRPO) and standard IL (DAGGERED). TRPO is able to achieve considerable and almost monotonic improvement from a randomly initialized policy. DAGGERED reaches the performance of the suboptimal policy in a relatively very small number of iterations, e.g. 15 iterations in 2D Walker, in which the suboptimal policy to imitate is TRPO at iteration 100. However, it fails to outperform the suboptimal expert.

Then, we evaluate the proposed algorithm LOKI and Ideal, the performance of which we wish to achieve in theory. LOKI consistently enjoys the best of both TRPO and DAGGERED: it improves as fast as DAGGERED at the beginning, keeps improving, and then finally matches the performance of Ideal after transitioning into the reinforcement phase. Interestingly, the on-policy value function learned, though not used, in the imitation phase helps LOKI transition from imitation phase to reinforcement phase smoothly.

Lastly, we compare LOKI to the two other baselines (SLOLS and THOR) that combine RL and IL. LOKI outperforms these two baselines by a considerably large margin in Hopper, 2D Walker, and 3D Walker; but surprisingly, the performance of SLOLS and THOR are inferior even to TRPO on these tasks. The main reason is that the first-order oracles of both methods is based on an estimated expert value function  $\hat{V}_{\pi^*}$ . As  $\hat{V}_{\pi^*}$  is only regressed on the data collected by running the expert policy, large covariate shift error could happen if the dimension of the state and action spaces are high, or if the uncontrolled system is complex or unstable. For example, in the low-dimensional Pendulum task and the simple Reacher task, the expert value function can generalize better. As a result, in these two cases, SLOLS and THOR achieve super-expert performance. However, in more complex tasks, where the effects of covariate shift amplifies exponentially with the dimension of the state space, THOR and SLOLS start to suffer from the inaccuracy of  $\hat{V}_{\pi^*}$ , as illustrated in the 2D Walker and 3D Walker tasks.

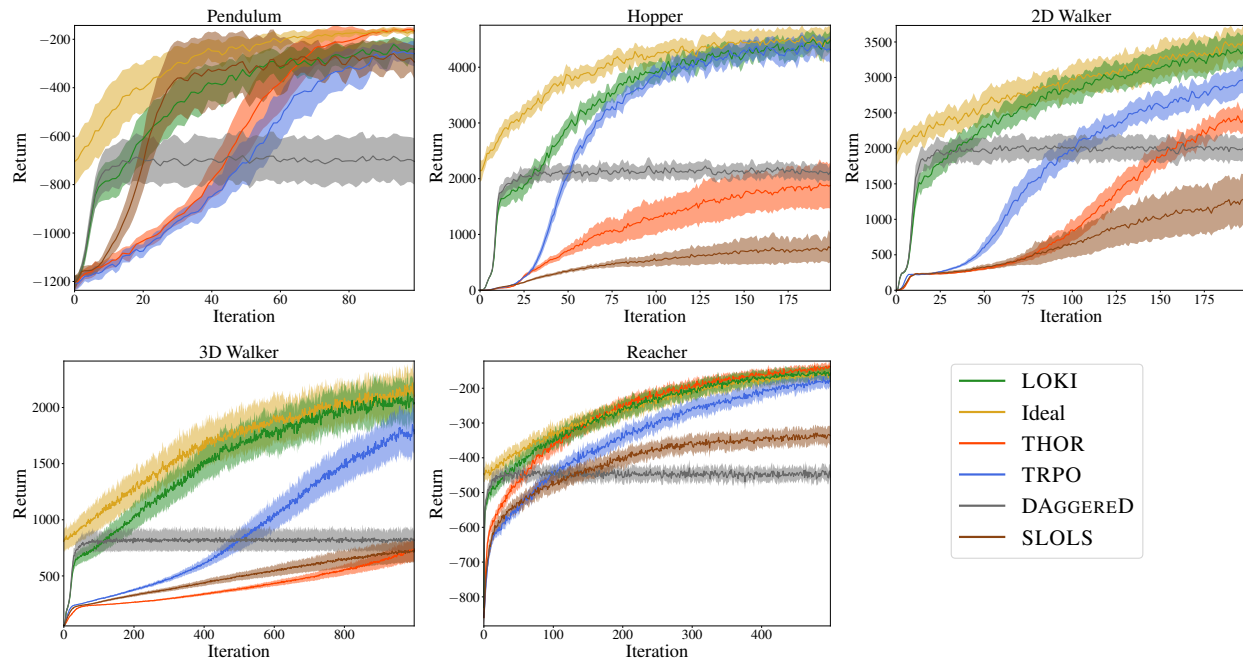

Figure 1: Learning curves. Shaded regions correspond to  $\pm \frac{1}{2}$ -standard deviation.

## 8 CONCLUSION

We present a simple, elegant algorithm, LOKI, that combines the best properties of RL and IL. Theoretically, we show that, by randomizing the switching time, LOKI can perform as if running policy gradient steps directly from the expert policy. Empirically, LOKI demonstrates superior performance compared with the expert policy and more complicated algorithms that attempt to combine RL and IL.

University of Amsterdam

## Abstract

The Variational Auto-Encoder (VAE) is one of the most used unsupervised machine learning models. But although the default choice of a Gaussian distribution for both the prior and posterior represents a mathematically convenient distribution often leading to competitive results, we show that this parameterization fails to model data with a latent hyperspherical structure. To address this issue we propose using a von Mises-Fisher (vMF) distribution instead, leading to a hyperspherical latent space. Through a series of experiments we show how such a hyperspherical VAE, or  $S$ -VAE, is more suitable for capturing data with a hyperspherical latent structure, while outperforming a normal,  $\mathcal{N}$ -VAE, in low dimensions on other data types.

## 1 INTRODUCTION

First introduced by Kingma and Welling (2013); Rezende et al. (2014), the Variational Auto-Encoder (VAE) is an unsupervised generative model that presents a principled fashion for performing variational inference using an auto-encoding architecture. Applying the non-centered parameterization of the variational posterior (Kingma and Welling, 2014), further simplifies sampling and allows to reduce bias in calculating gradients for training. Although the default choice of a Gaussian prior is mathematically convenient, we can show through a simple example that in some cases it breaks the assumption of an *uninformative* prior leading to unstable results. Imagine a dataset on the circle  $\mathcal{Z} \subset \mathcal{S}^1$ , that is subsequently embedded in  $\mathbb{R}^N$  using a transformation  $f$  to obtain  $f : \mathcal{Z} \rightarrow \mathcal{X} \subset \mathbb{R}^N$ . Given two hidden units, an autoencoder quickly discovers

the latent circle, while a normal VAE becomes highly unstable. This is to be expected as a Gaussian prior is concentrated around the origin, while the KL-divergence tries to reconcile the differences between  $\mathcal{S}^1$  and  $\mathbb{R}^2$ . A more detailed discussion of this ‘manifold mismatch’ problem will follow in subsection 2.3.

The fact that some data types like *directional data* are better explained through spherical representations is long known and well-documented (Mardia, 1975; Fisher et al., 1987), with examples spanning from protein structure, to observed wind directions. Moreover, for many modern problems such as text analysis or image classification, data is often first normalized in a preprocessing step to focus on the directional distribution. Yet, few machine learning methods explicitly account for the intrinsically spherical nature of some data in the modeling process. In this paper, we propose to use the *von Mises-Fisher* (vMF) distribution as an alternative to the Gaussian distribution. This replacement leads to a hyperspherical latent space as opposed to a hyperplanar one, where the Uniform distribution on the hypersphere is conveniently recovered as a special case of the vMF. Hence this approach allows for a truly uninformative prior, and has a clear advantage in the case of data with a hyperspherical interpretation. This was previously attempted by Hasnat et al. (2017), but crucially they do not learn the concentration parameter around the mean,  $\kappa$ .

In order to enable training of the concentration parameter, we extend the *reparameterization trick* for rejection sampling as recently outlined in Naesseth et al. (2017) to allow for  $n$  additional transformations. We then combine this with the rejection sampling procedure proposed by Ulrich (1984) to efficiently reparameterize the VAE <sup>1</sup>.

We demonstrate the utility of replacing the normal distribution with the von Mises-Fisher distribution for generating latent representations by conducting a range of experiments in three distinct settings. First, we show that

\* Equal contribution.

<sup>1</sup> <https://github.com/nicola-decao/s-vae>

our  $\mathcal{S}$ -VAEs outperform VAEs with the Gaussian variational posterior ( $\mathcal{N}$ -VAEs) in recovering a hyperspherical latent structure. Second, we conduct a thorough comparison with  $\mathcal{N}$ -VAEs on the MNIST dataset through an unsupervised learning task and a semi-supervised learning scenario. Finally, we show that  $\mathcal{S}$ -VAEs can significantly improve link prediction performance on citation network datasets in combination with a *Variational Graph Auto-Encoder* (VGAE) (Kipf and Welling, 2016).

## 2 VARIATIONAL AUTO-ENCODERS

### 2.1 FORMULATION

In the VAE setting, we have a latent variable model for data, where  $\mathbf{z} \in \mathbb{R}^M$  denotes latent variables,  $\mathbf{x}$  is a vector of  $D$  observed variables, and  $p_\phi(\mathbf{x}, \mathbf{z})$  is a parameterized model of the joint distribution. Our objective is to optimize the log-likelihood of the data,  $\log \int p_\phi(\mathbf{x}, \mathbf{z}) d\mathbf{z}$ . When  $p_\phi(\mathbf{x}, \mathbf{z})$  is parameterized by a neural network, marginalizing over the latent variables is generally intractable. One way of solving this issue is to maximize the Evidence Lower Bound (ELBO)

$$\log \int p_\phi(\mathbf{x}, \mathbf{z}) d\mathbf{z} \geq \mathbb{E}_{q(\mathbf{z})}[\log p_\phi(\mathbf{x}|\mathbf{z})] - KL(q(\mathbf{z})||p(\mathbf{z})), \quad (1)$$

where  $q(\mathbf{z})$  is the approximate posterior distribution, belonging to a family  $\mathcal{Q}$ . The bound is tight if  $q(\mathbf{z}) = p(\mathbf{z}|\mathbf{x})$ , meaning  $q(\mathbf{z})$  is optimized to approximate the true posterior. While in theory  $q(\mathbf{z})$  should be optimized for every data point  $\mathbf{x}$ , to make inference more scalable to larger datasets the VAE setting introduces an inference network  $q_\psi(\mathbf{z}|\mathbf{x}; \theta)$  parameterized by a neural network that outputs a probability distribution for each data point  $\mathbf{x}$ . The final objective is therefore to maximize

$$\mathcal{L}(\phi, \psi) = \mathbb{E}_{q_\psi(\mathbf{z}|\mathbf{x}; \theta)}[\log p_\phi(\mathbf{x}|\mathbf{z})] - KL(q_\psi(\mathbf{z}|\mathbf{x}; \theta)||p(\mathbf{z})), \quad (2)$$

In the original VAE both the prior and the posterior are defined as normal distributions. We can further efficiently approximate the ELBO by Monte Carlo estimates, using the *reparameterization trick* (Kingma and Welling, 2013; Rezende et al., 2014). This is done by expressing a sample of  $\mathbf{z} \sim q_\psi(\mathbf{z}|\mathbf{x}; \theta)$ , as  $\mathbf{z} = h(\theta, \varepsilon, \mathbf{x})$ , where  $h$  is a reparameterization transformation and  $\varepsilon \sim s(\varepsilon)$  is some noise random variable independent from  $\theta$ .

### 2.2 THE LIMITATIONS OF A GAUSSIAN DISTRIBUTION PRIOR

**Low dimensions: origin gravity** In low dimensions, the Gaussian density presents a concentrated probability

mass around the origin, encouraging points to cluster in the center. This is particularly problematic when the data is divided into multiple clusters. Although an ideal latent space should separate clusters for each class, the normal prior will encourage all the cluster centers towards the origin. An ideal prior would only stimulate the variance of the posterior without forcing its mean to be close to the center. A prior satisfying these properties is a uniform over the entire space. Such a uniform prior, however, is not well defined on the hyperplane.

**High dimensions: soap bubble effect** It is a well-known phenomenon that the standard Gaussian distribution in high dimensions tends to resemble a uniform distribution on the surface of a hypersphere, with the vast majority of its mass concentrated on the hyperspherical shell. Hence it would appear interesting to compare the behavior of a Gaussian approximate posterior with an approximate posterior already naturally defined on the hypersphere. This is also motivated from a theoretical point of view, since the Gaussian definition is based on the  $L_2$  norm that suffers from the curse of dimensionality.

### 2.3 BEYOND THE HYPERPLANE

Once we let go of the hyperplanar assumption, the possibility of a uniform prior on the hypersphere opens up. Mirroring our discussion in the previous subsection, such a prior would exhibit no pull towards the origin allowing clusters of data to evenly spread over the surface with no directional bias. Additionally, in higher dimensions, the cosine similarity is a more meaningful distance measure than the Euclidean norm.

**Manifold mapping** In general, exploring VAE models that allow a mapping to distributions in a latent space not homeomorphic to  $\mathbb{R}^D$  is of fundamental interest. Consider data lying in a small  $M$ -dimensional manifold  $\mathcal{M}$ , embedded in a much higher dimensional space  $\mathcal{X} = \mathbb{R}^N$ . For most real data, this manifold will likely not be homeomorphic to  $\mathbb{R}^M$ . An encoder can be considered as a smooth map  $enc : \mathcal{X} \rightarrow \mathcal{Z} = \mathbb{R}^D$  from the original space to  $\mathcal{Z}$ . The restriction of the encoder to  $\mathcal{M}$ ,  $enc|_{\mathcal{M}} : \mathcal{M} \rightarrow \mathcal{Z}$  will also be a smooth mapping. However since  $\mathcal{M}$  is not homeomorphic to  $\mathcal{Z}$  if  $D \leq M$ , then  $enc|_{\mathcal{M}}$  cannot be a homeomorphism. That is, there exists no invertible and globally continuous mapping between the coordinates of  $\mathcal{M}$  and the ones of  $\mathcal{Z}$ . Conversely if  $D > M$  then  $\mathcal{M}$  can be smoothly embedded in  $\mathcal{Z}$  for  $D$  sufficiently large <sup>2</sup>, such that  $enc|_{\mathcal{M}} : \mathcal{M} \rightarrow enc|_{\mathcal{M}}(\mathcal{M}) =: emb(\mathcal{M}) \subset \mathcal{Z}$  is a homeomorphism and  $emb(\mathcal{M})$  denotes the embedding of

<sup>2</sup>By the Whitney embedding theorem any smooth real  $M$ -dimensional manifold can be smoothly embedded in  $\mathbb{R}^{2M}$

Figure 1: Plots of the original latent space (a) and learned latent space representations in different settings, where  $\beta$  is a re-scaling factor for weighting the KL divergence. (Best viewed in color)

$\mathcal{M}$ . Yet, since  $D > M$ , when taking random points in the latent space they will most likely *not* be in  $emb(\mathcal{M})$  resulting in a poorly reconstructed sample.

The VAE tries to solve this problem by forcing  $\mathcal{M}$  to be mapped into an approximate posterior distribution that has support in the entire  $\mathcal{Z}$ . Clearly, this approach is bound to fail since the two spaces have a fundamentally different structure. This can likely produce two behaviors: first, the VAE could just smooth the original embedding  $emb(\mathcal{M})$  leaving most of the latent space empty, leading to bad samples. Second, if we increase the KL term the encoder will be pushed to occupy all the latent space, but this will create instability and discontinuity, affecting the convergence of the model. To validate our intuition we performed a small proof of concept experiment using  $\mathcal{M} = \mathcal{S}^1$ , which is visualized in Figure 1. Note that as expected the auto-encoder in Figure 1(b) mostly recovers the original latent space of Figure 1(a) as there are no distributional restrictions. In Figure 1(c) we clearly observe for the  $\mathcal{N}$ -VAE that points collapse around the origin due to the KL, which is much less pronounced in Figure 1(d) when its contribution is scaled down. Lastly, the  $\mathcal{S}$ -VAE almost perfectly recovers the original circular latent space. The observed behavior confirms our intuition.

To solve this problem the best option would be to directly specify a  $\mathcal{Z}$  homeomorphic to  $\mathcal{M}$  and distributions on  $\mathcal{M}$ . However, for real data discovering the structure of  $\mathcal{M}$  will often be a difficult inference task. Nevertheless, we believe this shows investigating VAE architectures that map to posterior distributions defined on manifolds different than the Euclidean space is a topic worth exploring.

### 3 REPLACING GAUSSIAN WITH VON MISES-FISHER

#### 3.1 VON MISES-FISHER DISTRIBUTION

The *von Mises-Fisher* (vMF) distribution is often seen

as the Normal Gaussian distribution on a hypersphere. Analogous to a Gaussian, it is parameterized by  $\mu \in \mathbb{R}^m$  indicating the mean direction, and  $\kappa \in \mathbb{R}_{\geq 0}$  the concentration around  $\mu$ . For the special case of  $\kappa = 0$ , the vMF represents a Uniform distribution. The probability density function of the vMF distribution for a random unit vector  $\mathbf{z} \in \mathbb{R}^m$  (or  $\mathbf{z} \in \mathcal{S}^{m-1}$ ) is then defined as

$$q(\mathbf{z}|\mu, \kappa) = \mathcal{C}_m(\kappa) \exp(\kappa \mu^T \mathbf{z}), \quad (3)$$

$$\mathcal{C}_m(\kappa) = \frac{\kappa^{m/2-1}}{(2\pi)^{m/2} \mathcal{I}_{m/2-1}(\kappa)}, \quad (4)$$

where  $\|\mu\|^2 = 1$ ,  $\mathcal{C}_m(\kappa)$  is the normalizing constant, and  $\mathcal{I}_v$  denotes the modified Bessel function of the first kind at order  $v$ .

#### 3.2 KL DIVERGENCE

As previously emphasized, one of the main advantages of using the vMF distribution as an approximate posterior is that we are able to place a uniform prior on the latent space. The KL divergence term  $KL(\text{vMF}(\mu, \kappa) || U(\mathcal{S}^{m-1}))$  to be optimized is:

$$\kappa \frac{\mathcal{I}_{m/2}(k)}{\mathcal{I}_{m/2-1}(k)} + \log \mathcal{C}_m(\kappa) - \log \left( \frac{2(\pi^{m/2})}{\Gamma(m/2)} \right)^{-1}, \quad (5)$$

see Appendix B for complete derivation. Notice that since the KL term does not depend on  $\mu$ , this parameter is only optimized in the reconstruction term. The above expression cannot be handled by automatic differentiation packages because of the modified Bessel function in  $\mathcal{C}_m(\kappa)$ . Thus, to optimize this term we derive the gradient with respect to the concentration parameter:

$$\nabla_{\kappa} KL(\text{vMF}(\mu, \kappa) || U(\mathcal{S}^{m-1})) = \frac{1}{2} k \left( \frac{\mathcal{I}_{m/2+1}(k)}{\mathcal{I}_{m/2-1}(k)} + \frac{\mathcal{I}_{m/2}(k) (\mathcal{I}_{m/2-2}(k) + \mathcal{I}_{m/2}(k))}{\mathcal{I}_{m/2-1}(k)^2} + 1 \right), \quad (6)$$

---

**Algorithm 1** vMF sampling

---

**Input:** dimension  $m$ , mean  $\mu$ , concentration  $\kappa$   
sample  $\mathbf{v} \sim U(\mathcal{S}^{m-2})$   
sample  $\omega \sim g(\omega|\kappa, m) \propto \exp(\omega\kappa)(1 - \omega^2)^{\frac{1}{2}(m-3)}$   
{acceptance-rejection sampling}  
 $\mathbf{z}' \leftarrow (\omega; (\sqrt{1 - \omega^2})\mathbf{v}^\top)^\top$   
 $U \leftarrow \text{Householder}(\mathbf{e}_1, \mu)$  {Householder transform}  
**Return:**  $U\mathbf{z}'$

---

where the modified Bessel functions can be computed without numerical instabilities using the exponentially scaled modified Bessel function.

### 3.3 SAMPLING PROCEDURE

To sample from the vMF we follow the procedure of Ulrich (1984), outlined in Algorithm 1. We first sample from a vMF  $q(\mathbf{z}|\mathbf{e}_1, \kappa)$  with modal vector  $\mathbf{e}_1 = (1, 0, \dots, 0)$ . Since the vMF density is uniform in all the  $m - 2$  dimensional sub-hyperspheres  $\{\mathbf{x} \in \mathcal{S}^{m-1} | \mathbf{e}_1^\top \mathbf{x} = \omega\}$ , the sampling technique reduces to sampling the value  $\omega$  from the univariate density  $g(\omega|\kappa, m) \propto \exp(\kappa\omega)(1 - \omega^2)^{(m-3)/2}$ ,  $\omega \in [-1, 1]$ , using an acceptance-rejection scheme. After getting a sample from  $q(\mathbf{z}|\mathbf{e}_1, \kappa)$  an orthogonal transformation  $U(\mu)$  is applied such that the transformed sample is distributed according to  $q(\mathbf{z}|\mu, \kappa)$ . This can be achieved using a Householder reflection such that  $U(\mu)\mathbf{e}_1 = \mu$ . A more in-depth explanation of the sampling technique can be found in Appendix A.

It is worth noting that the sampling technique does not suffer from the curse of dimensionality, as the acceptance-rejection procedure is only applied to a univariate distribution. Moreover in the case of  $\mathcal{S}^2$ , the density  $g(\omega|\kappa, 3)$  reduces to  $g(\omega|\kappa, 3) \propto \exp(k\omega)\mathbb{1}_{[-1, +1]}(\omega)$  which can be directly sampled without rejection.

### 3.4 N-TRANSFORMATION REPARAMETERIZATION TRICK

While the *reparameterization trick* is easily implementable in the normal case, unfortunately it can only be applied to a handful of distributions. However a recent technique introduced by Naesseth et al. (2017) allows to extend the reparameterization trick to the wide class of distributions that can be simulated using rejection sampling. Dropping the dependence from  $\mathbf{x}$  for simplicity, assume the approximate posterior is of the form  $g(\omega|\theta)$  and that it can be sampled by making proposals from  $r(\omega|\theta)$ . If *the proposal distribution can be reparameterized* we can still perform the reparameterization trick. Let  $\varepsilon \sim s(\varepsilon)$ , and  $\omega = h(\varepsilon, \theta)$ , a reparameterization of the proposal distribution,  $r(\omega|\theta)$ . Performing the reparameterization trick

for  $g(\omega|\theta)$  is made possible by the fundamental lemma proven in (Naesseth et al., 2017):

**Lemma 1.** *Let  $f$  be any measurable function and  $\varepsilon \sim \pi(\varepsilon|\theta) = s(\varepsilon)\frac{g(h(\varepsilon, \theta)|\theta)}{r(h(\varepsilon, \theta)|\theta)}$  the distribution of the accepted sample. Then:*

$$\begin{aligned} \mathbb{E}_{\pi(\varepsilon|\theta)}[f(h(\varepsilon, \theta))] &= \int f(h(\varepsilon, \theta))\pi(\varepsilon|\theta)d\varepsilon \\ &= \int f(\omega)g(\omega|\theta)d\omega = \mathbb{E}_{g(\omega|\theta)}[f(\omega)], \end{aligned} \quad (7)$$

Then the gradient can be taken using the log derivative trick:

$$\begin{aligned} \nabla_\theta \mathbb{E}_{g(\omega|\theta)}[f(\omega)] &= \nabla_\theta \mathbb{E}_{\pi(\varepsilon|\theta)}[f(h(\varepsilon, \theta))] = \\ &= \mathbb{E}_{\pi(\varepsilon|\theta)}[\nabla_\theta f(h(\varepsilon, \theta))] + \\ &+ \mathbb{E}_{\pi(\varepsilon|\theta)} \left[ f(h(\varepsilon, \theta)) \nabla_\theta \log \frac{g(h(\varepsilon, \theta)|\theta)}{r(h(\varepsilon, \theta)|\theta)} \right], \end{aligned} \quad (8)$$

However, in the case of the vMF a different procedure is required. After performing the transformation  $h(\varepsilon, \theta)$  and accepting/rejecting the sample, we sample *another* random variable  $\mathbf{v} \sim \pi_2(\mathbf{v})$ , and then apply a transformation  $\mathbf{z} = \mathcal{T}(h(\varepsilon, \theta), \mathbf{v}; \theta)$ , such that  $\mathbf{z} \sim q_\psi(\mathbf{z}|\theta)$  is distributed as the approximate posterior (in our case a vMF). Effectively this entails applying another reparameterization trick after the acceptance/rejection step. To still be able to perform the reparameterization we show that Lemma 1 fundamentally still holds in this case as well.

**Lemma 2.** *Let  $f$  be any measurable function and  $\varepsilon \sim \pi_1(\varepsilon|\theta) = s(\varepsilon)\frac{g(h(\varepsilon, \theta)|\theta)}{r(h(\varepsilon, \theta)|\theta)}$  the distribution of the accepted sample. Also let  $\mathbf{v} \sim \pi_2(\mathbf{v})$ , and  $\mathcal{T}$  a transformation that depends on the parameters such that if  $\mathbf{z} = \mathcal{T}(\omega, \mathbf{v}; \theta)$  with  $\omega \sim g(\omega|\theta)$ , then  $\mathbf{z} \sim q(\mathbf{z}|\theta)$ :*

$$\begin{aligned} \mathbb{E}_{(\varepsilon, \mathbf{v}) \sim \pi_1(\varepsilon|\theta)\pi_2(\mathbf{v})} [f(\mathcal{T}(h(\varepsilon, \theta), \mathbf{v}; \theta))] &= \\ \int f(\mathbf{z})q(\mathbf{z}|\theta)d\mathbf{z} &= \mathbb{E}_{q(\mathbf{z}|\theta)}[f(\mathbf{z})], \end{aligned} \quad (9)$$

*Proof.* See Appendix C.  $\square$

With this result we are able to derive a gradient expression similarly as done in equation 8. We refer to Appendix D for a complete derivation.

### 3.5 BEHAVIOR IN HIGH DIMENSIONS

The surface area of a hypersphere is defined as

$$S(m - 1) = r^m \frac{2(\pi^{m/2})}{\Gamma(m/2)}, \quad (10)$$

(a)  $\mathbb{R}^2$  latent space of the  $\mathcal{N}$ -VAE.

(b) Hammer projection of  $\mathcal{S}^2$  latent space of the  $\mathcal{S}$ -VAE.

Figure 2: Latent space visualization of the 10 MNIST digits in 2 dimensions of both  $\mathcal{N}$ -VAE (left) and  $\mathcal{S}$ -VAE (right). (Best viewed in color)

where  $m$  is the dimensionality and  $r$  the radius. Notice that  $S(m-1) \rightarrow 0$ , as  $m \rightarrow \infty$ . However, even for  $m > 20$  we observe a *vanishing surface problem* (see Figure 6 in Appendix E). This could thus lead to unstable behavior of hyperspherical models in high dimensions.

## 4 RELATED WORK

**Extending the VAE** The majority of VAE extensions focus on increasing the flexibility of the approximate posterior. This is usually achieved through *normalizing flows* (Rezende and Mohamed, 2015), a class of invertible transformations applied sequentially to an initial reparameterizable density  $q_0(\mathbf{z}_0)$ , allowing for more complex posteriors. Normalizing flows can be considered orthogonal to our approach. While allowing for a more flexible posterior, they do not modify the standard normal prior assumption. In (Gemici et al., 2016) a first attempt is made to extend normalizing flows to Riemannian manifolds. However, as the method relies on the existence of a diffeomorphism between  $\mathbb{R}^N$  and  $\mathcal{S}^N$ , it is unsuited for hyperspheres.

One approach to obtain a more flexible prior is to use a simple mixture of Gaussians (MoG) prior (Dilokthanakul et al., 2016). The recently introduced VampPrior model (Tomczak and Welling, 2018) outlines several advantages over the MoG and instead tries to learn a more flexible prior by expressing it as a mixture of approximate posteriors. A non-parametric prior is proposed in Nalisnick and Smyth (2017), utilizing a truncated stick-breaking process. Opposite to these approaches, we aim at using a non-informative prior to simplify the inference.

The closest approach to ours is a VAE with a vMF distribution in the latent space used for a sentence generation

task by (Guu et al., 2018). While formally this approach is cast as a variational approach, the proposed model does not reparameterize and learn the concentration parameter  $\kappa$ , treating it as a constant value that remains the same for every approximate posterior instead. Critically, as indicated in Equation 5, the KL divergence term only depends on  $\kappa$  therefore leaving  $\kappa$  constant means never explicitly optimizing the KL divergence term in the loss. The method then only optimizes the reconstruction error by adding vMF noise to the encoder output in the latent space to still allow generation. Moreover, using a fixed global  $\kappa$  for *all* the approximate posteriors severely limits the flexibility and the expressiveness of the model.

**Non-Euclidean Latent Space** In Liu and Zhu (2018), a general model to perform Bayesian inference in Riemannian Manifolds is proposed. Following other Stein-related approaches, the method does not explicitly define a posterior density but approximates it with a number of particles. Despite its generality and flexibility, it requires the choice of a kernel on the manifold and multiple particles to have a good approximation of the posterior distribution. The former is not necessarily straightforward, while the latter quickly becomes computationally unfeasible.

Another approach by Nickel and Kiela (2017), capitalizes on the hierarchical structure present in some data types. By learning the embeddings for a graph in a non-euclidean negative curvature hyperbolic space, they show this topology has clear advantages over embedding these objects in a Euclidean space. Although they did not use a VAE-based approach, that is, they did not build a probabilistic generative model of the data interpreting the embeddings as latent variables, this approach shows the merit of explicitly adjusting the choice of latent topology to the data used.

Table 1: Summary of results (mean and standard-deviation over 10 runs) of unsupervised model on MNIST. RE and KL correspond respectively to the reconstruction and the KL part of the ELBO. Best results are highlighted only if they passed a student t-test with  $p < 0.01$ .

**A Hyperspherical Perspective** As noted before, a distinction must be made between models dealing with the challenges of intrinsically hyperspherical data like omnidirectional video, and those attempting to exploit some latent hyperspherical manifold. A recent example of the first can be found in Cohen et al. (2018), where *spherical CNNs* are introduced. While flattening a spherical image produces unavoidable distortions, the newly defined convolutions take into account its geometrical properties.

The most general implementation of the second model type was proposed by Gopal and Yang (2014), who introduced a suite of models to improve cluster performance of high-dimensional data based on mixture of vMF distributions. They showed that reducing an object representation to its directional components increases clusterability over standard methods like  $K$ -Means or Latent Dirichlet Allocation (Blei et al., 2003).

Specific applications of the vMF can be further found ranging from computer vision, where it is used to infer structure from motion (Guan and Smith, 2017) in spherical video, or structure from texture (Wilson et al., 2014), to natural language processing, where it is utilized in text analysis (Banerjee et al., 2003, 2005) and topic modeling (Banerjee and Basu, 2007; Reisinger et al., 2010).

Additionally, modeling data by restricting it to a hypersphere provides some natural regularizing properties as noted in (Liu et al., 2017). Finally Aytekin et al. (2018) show on a variety of deep auto-encoder models that adding L2 normalization to the latent space during training, i.e. forcing the latent space on a hypersphere, improves clusterability.

## 5 EXPERIMENTS

In this section, we first perform a series of experiments to investigate the theoretical properties of the proposed  $\mathcal{S}$ -VAE compared to the  $\mathcal{N}$ -VAE. In a second experiment, we show how  $\mathcal{S}$ -VAEs can be used in semi-supervised

tasks to create a better separable latent representation to enhance classification. In the last experiment, we show that the  $\mathcal{S}$ -VAE indeed presents a promising alternative to  $\mathcal{N}$ -VAEs for data with a non-Euclidean latent representation of low dimensionality, on a link prediction task for three citation networks. All architecture and hyperparameter details are given in Appendix F.

### 5.1 RECOVERING HYPERSPHERICAL LATENT REPRESENTATIONS

In this first experiment we build on the motivation developed in Subsection 2.3, by confirming with a synthetic data example the difference in behavior of the  $\mathcal{N}$ -VAE and  $\mathcal{S}$ -VAE in recovering latent hyperspheres. We first generate samples from a mixture of three vMFs on the circle,  $\mathcal{S}^1$ , as shown in Figure 1(a), which subsequently are mapped into the higher dimensional  $\mathbb{R}^{100}$  by applying a noisy, non-linear transformation. After this, we in turn train an auto-encoder, a  $\mathcal{N}$ -VAE, and a  $\mathcal{S}$ -VAE. We further investigate the behavior of the  $\mathcal{N}$ -VAE, by training a model using a scaled down KL divergence.

**Results** The resulting latent spaces, displayed in Figure 1, clearly confirm the intuition built in Subsection 2.3. As expected, in Figure 1(b) the auto-encoder is perfectly capable to embed in low dimensions the original underlying data structure. However, most parts of the latent space are not occupied by points, critically affecting the ability to generate meaningful samples.

In the  $\mathcal{N}$ -VAE setting we observe two types of behaviours, summarized by Figures 1(c) and 1(d). In the first we observe that if the prior is too strong it will force the posterior to match the prior shape, concentrating the samples in the center. However, this prevents the  $\mathcal{N}$ -VAE to correctly represent the true shape of the data and creates instability problems for the decoder around the origin. On the contrary, if we scale down the KL term, we observe that the samples from the approximate posterior maintain

Table 2: Summary of results (mean accuracy and standard-deviation over 20 runs) of semi-supervised  $K$ -NN on MNIST. Best results are highlighted only if they passed a student t-test with  $p < 0.01$ .

$d = 20$	71.3 $\pm$ 1.9	<b>72.8</b> $\pm$ 1.6	88.3 $\pm$ 0.5	<b>89.1</b> $\pm$ 0.6	90.1 $\pm$ 0.4	<b>91.1</b> $\pm$ 0.3
$d = 40$	<b>72.3</b> $\pm$ 1.6	67.7 $\pm$ 2.3	88.0 $\pm$ 0.5	87.4 $\pm$ 0.7	90.3 $\pm$ 0.5	90.4 $\pm$ 0.4

a shape that reflects the  $\mathcal{S}^1$  structure smoothed with Gaussian noise. However, as the approximate posterior differs strongly from the prior, obtaining meaningful samples from the latent space again becomes problematic.

The  $\mathcal{S}$ -VAE on the other hand, almost perfectly recovers the original dataset structure, while the samples from the approximate posterior closely match the prior distribution. This simple experiment confirms the intuition that having a prior that matches the true latent structure of the data, is crucial in constructing a correct latent representation that preserves the ability to generate meaningful samples.

## 5.2 EVALUATION OF EXPRESSIVENESS

To compare the behavior of the  $\mathcal{N}$ -VAE and  $\mathcal{S}$ -VAE on a data set that does not have a clear hyperspherical latent structure, we evaluate both models on a reconstruction task using dynamically binarized MNIST (Salakhutdinov and Murray, 2008). We analyze the ELBO, KL, negative reconstruction error, and marginal log-likelihood (LL) for both models on the test set. The LL is estimated using importance sampling with 500 sample points (Burda et al., 2016).

**Results** Results are shown in Table 1. We first note that in terms of negative reconstruction error the  $\mathcal{S}$ -VAE outperforms the  $\mathcal{N}$ -VAE in all dimensions. Since the  $\mathcal{S}$ -VAE uses a uniform prior, the KL divergence increases more strongly with dimensionality, which results in a higher ELBO. However in terms of log-likelihood (LL) the  $\mathcal{S}$ -VAE clearly has an edge in low dimensions ( $d = 2, 5, 10$ ) and performs comparable to the  $\mathcal{N}$ -VAE in  $d = 20$ . This empirically confirms the hypothesis of Subsection 2.2, showing the positive effect of having a uniform prior in low dimensions. In the absence of any origin pull, the data is able to cluster naturally, utilizing the entire latent space which can be observed in Figure 2. Note that in Figure 2(a) all mass is concentrated around the center, since the prior mean is zero. Conversely, in Figure 2(b) all available space is evenly covered due to the uniform prior,

resulting in more separable clusters in  $\mathcal{S}^2$  compared to  $\mathbb{R}^2$ . However, as dimensionality increases, the Gaussian distribution starts to approximate a hypersphere, while its posterior becomes more expressive than the vMF due to the higher number of variance parameters. Simultaneously, as described in Subsection 3.5, the surface area of the vMF starts to collapse limiting the available space.

In Figure 7 and 8 of Appendix G, we present randomly generated samples from the  $\mathcal{N}$ -VAE and the  $\mathcal{S}$ -VAE, respectively. Moreover, in Figure 9 of Appendix G, we show 2-dimensional manifolds for the two models. Interestingly, the manifold given by the  $\mathcal{S}$ -VAE indeed results in a latent space where digits occupy the entire space and there is a sense of continuity from left to right.

## 5.3 SEMI-SUPERVISED LEARNING

Having observed the  $\mathcal{S}$ -VAE’s ability to increase clusterability of data points in the latent space, we wish to further investigate this property using a semi-supervised classification task. For this purpose we re-implemented the M1 and M1+M2 models as described in (Kingma et al., 2014), and evaluate the classification accuracy of the  $\mathcal{S}$ -VAE and the  $\mathcal{N}$ -VAE on dynamically binarized MNIST. In the M1 model, a classifier utilizes the latent features obtained using a VAE as in experiment 5.2. The M1+M2 model is constructed by stacking the M2 model on top of M1, where M2 is the result of augmenting the VAE by introducing a partially observed variable  $\mathbf{y}$ , and combining the ELBO and classification objective. This concatenated model is trained end-to-end<sup>3</sup>.

This last model also allows for a combination of the two topologies due to the presence of two distinct latent variables,  $\mathbf{z}_1$  and  $\mathbf{z}_2$ . Since in the M2 latent space the class assignment is expressed by the variable  $\mathbf{y}$ , while  $\mathbf{z}_2$  only needs to capture the style, it naturally follows that the

<sup>3</sup>It is worth noting that in the original implementation by Kingma et al. (2014) the stacked model did not converge well using end-to-end training, and used the extracted features of the M1 model as inputs for the M2 model instead.

Figure 3: Latent space of unsupervised  $\mathcal{N}$ -VGAE and  $\mathcal{S}$ -VGAE models trained on Cora citation network. Colors denote documents classes which are not provided during training. (Best viewed in color)

$\mathcal{N}$ -VAE is more suited for this objective due to its higher number of variance parameters. Hence, besides comparing the  $\mathcal{S}$ -VAE against the  $\mathcal{N}$ -VAE, we additionally run experiments for the M1+M2 model by modeling  $\mathbf{z}_1, \mathbf{z}_2$  respectively with a vMF and normal distribution.

**Results** As can be seen in Table 2, for M1 the  $\mathcal{S}$ -VAE outperforms the  $\mathcal{N}$ -VAE in all dimensions up to  $d = 40$ . This result is amplified for a low number of observed labels. Note that for both models absolute performance drops as the dimensionality increases, since  $K$ -NN used as the classifier suffers from the curse of dimensionality. Besides reconfirming superiority of the  $\mathcal{S}$ -VAE in  $d < 20$ , its better performance than the  $\mathcal{N}$ -VAE for  $d = 20$  was unexpected. This indicates that although the log-likelihood might be comparable (see Table 1) for higher dimensions, the  $\mathcal{S}$ -VAE latent space better captures the cluster structure.

In the concatenated model M1+M2, we first observe in Table 3 that either the pure  $\mathcal{S}$ -VAE or the  $\mathcal{S}+\mathcal{N}$ -VAE model yields the best results, where the  $\mathcal{S}$ -VAE almost always outperforms the  $\mathcal{N}$ -VAE. Our hypothesis regarding the merit of a  $\mathcal{S}+\mathcal{N}$ -VAE model is further confirmed, as displayed by the stable, strong performance across all different dimensions. Furthermore, the clear edge in clusterability of the  $\mathcal{S}$ -VAE in low dimensional  $\mathbf{z}_1$  as already observed in Table 2, is again evident. As the dimensionality of  $\mathbf{z}_1, \mathbf{z}_2$  increases, the accuracy of the  $\mathcal{N}$ -VAE improves, reducing the performance gap with the  $\mathcal{S}$ -VAE. As previously noticed the  $\mathcal{S}$ -VAE performance drops when  $\dim \mathbf{z}_2 = 50$ , with the best result being obtained for  $\dim \mathbf{z}_1 = \dim \mathbf{z}_2 = 10$ . In fact, it is worth noting that for this setting the  $\mathcal{S}$ -VAE obtains comparable results to the original settings of (Kingma et al., 2014), while needing a considerably smaller latent space. Finally, the end-to-end trained  $\mathcal{S}+\mathcal{N}$ -VAE model is able to reach

a significantly higher classification accuracy than the original results reported by Kingma et al. (2014),  $96.7 \pm 1$ .

The M1+M2 model allows for conditional generation. Similarly to (Kingma et al., 2014), we set the latent variable  $\mathbf{z}_2$  to the value inferred from the test image by the inference network, and then varied the class label  $\mathbf{y}$ . In Figure 10 of Appendix H we notice that the model is able to disentangle the style from the class.

#### 5.4 LINK PREDICTION ON GRAPHS

In this experiment, we aim at demonstrating the ability of the  $\mathcal{S}$ -VAE to learn meaningful embeddings of nodes in a graph, showing the advantages of embedding objects in a non-Euclidean space. We test hyperspherical reparameterization on the recently introduced Variational Graph Auto-Encoder (VGAE) (Kipf and Welling, 2016), a VAE model for graph-structured data. We perform training on

a link prediction task on three popular citation network datasets (Sen et al., 2008): Cora, Citeseer and Pubmed.

Dataset statistics and further experimental details are summarized in Appendix F.3. The models are trained in an unsupervised fashion on a masked version of these datasets where some of the links have been removed. All node features are provided and efficacy is measured in terms of average precision (AP) and area under the ROC curve (AUC) on a test set of previously removed links. We use the same training, validation, and test splits as in Kipf and Welling (2016), i.e. we assign 5% of links for validation and 10% of links for testing.

Table 4: Results for link prediction in citation networks.

Method		$\mathcal{N}$ -VGAE	$\mathcal{S}$ -VGAE
Cora	AUC	92.7 $\pm$ .2	<b>94.1</b> $\pm$ .1
	AP	93.2 $\pm$ .4	<b>94.1</b> $\pm$ .3
Citeseer	AUC	90.3 $\pm$ .5	<b>94.7</b> $\pm$ .2
	AP	91.5 $\pm$ .5	<b>95.2</b> $\pm$ .2
Pubmed	AUC	<b>97.1</b> $\pm$ .0	96.0 $\pm$ .1
	AP	<b>97.1</b> $\pm$ .0	96.0 $\pm$ .1

**Results** In Table 4, we show that our model outperforms the  $\mathcal{N}$ -VGAE baseline on two out of the three datasets by a significant margin. The log-probability of a link is computed as the dot product of two embeddings. In a hypersphere, this can be interpreted as the cosine similarity between vectors. Indeed we find that the choice of a dot product scoring function for link prediction is problematic in combination with the normal distribution on the latent space. If embeddings are close to the zero-center, noise during training can have a large destabilizing effect on the angle information between two embeddings. In practice, the model finds a solution where embeddings are "pushed" away from the zero-center, as demonstrated in Figure 3(a). This counteracts the pull towards the center arising from the standard prior and can overall lead to poor modeling performance. By constraining the embeddings to the surface of a hypersphere, this effect is mitigated, and the model can find a good separation of the latent clusters, as shown in Figure 3(b).

On Pubmed, we observe that the  $\mathcal{S}$ -VAE converges to a lower score than the  $\mathcal{N}$ -VAE. The Pubmed dataset is significantly larger than Cora and Citeseer, and hence more complex. The  $\mathcal{N}$ -VAE has a larger number of variance parameters for the posterior distribution, which might have played an important role in better modeling the relationships between nodes. We further hypothesize that not all graphs are necessarily better embedded in a hyperspher-

ical space and that this depends on some fundamental topological properties of the graph. For instance, the already mentioned work from Nickel and Kiela (2017) shows that hyperbolic space is better suited for graphs with a hierarchical, tree-like structure. These considerations prefigure an interesting research direction that will be explored in future work.

## 6 CONCLUSION

With the  $\mathcal{S}$ -VAE we set an important first step in the exploration of hyperspherical latent representations for variational auto-encoders. Through various experiments, we have shown that  $\mathcal{S}$ -VAEs have a clear advantage over  $\mathcal{N}$ -VAEs for data residing on a known hyperspherical manifold, and are competitive or surpass  $\mathcal{N}$ -VAEs for data with a non-obvious hyperspherical latent representation in lower dimensions. Specifically, we demonstrated  $\mathcal{S}$ -VAEs improve separability in semi-supervised classification and that they are able to improve results on state-of-the-art link prediction models on citation graphs, by merely changing the prior and posterior distributions as a simple drop-in replacement.

We believe that the presented research paves the way for various promising areas of future work, such as exploring more flexible approximate posterior distributions through normalizing flows on the hypersphere, or hierarchical mixture models combining hyperspherical and hyperplanar space. Further research should be done in increasing the performance of  $\mathcal{S}$ -VAEs in higher dimensions; one possible solution of which could be to dynamically learn the radius of the latent hypersphere in a full Bayesian setting.

## Abstract

We consider the weighted model counting task which includes important tasks in graphical models, such as computing the partition function and probability of evidence as special cases. We propose a novel partition-based bounding algorithm that exploits logical structure and gives rise to a set of inequalities from which upper (or lower) bounds can be derived efficiently. The bounds come with optimality guarantees under certain conditions and are oblivious in that they require only limited observations of the structure and parameters of the problem. We experimentally compare our bounds with the mini-bucket scheme (which is also oblivious) and show that our new bounds are often superior and never worse on a wide variety of benchmark networks.

## 1 INTRODUCTION

Logic and probability theory are formalisms employed for the task of automated reasoning. Logic facilitates deterministic representations and decisions, while probability theory accommodates situations where uncertainty arises. Propositional logic (Boolean satisfiability) is a prominent construct for performing deductive reasoning, particularly within a combinatorial setting. Extensive research efforts have resulted in state-of-the-art satisfiability solvers that have been successfully deployed in fields such as software/hardware model checking, planning and cybersecurity (Zhang and Malik, 2002). Graphical models (GM) have emerged as an effective scheme for modeling uncertainty. For example, Bayesian networks (Pearl, 1988) have been used in medical domains, while Markov networks are widely used in areas such as computer vision and natural language processing. However, in order to effectively

model problems in real-world domains, it is of great practical interest to solve the harder problem of developing models with the capacity to account for knowledge that is both deterministic and uncertain in a unified manner.

*Propositional model counting* is the generalization of the Boolean satisfiability problem. Extending the task of determining satisfiability, the objective is to count the number of distinct instances that result in satisfiability. This is also referred to as solution counting. Counting is a fundamental aspect to probabilistic computations (sum inference) and thus propositional model counting provides an intuitive connection between logic and uncertainty. In this paper, we address a further extension, namely the problem of *weighted model counting* (WMC). WMC allows for additional probabilistic interpretations of the variables in the model by associating a weight function either at the variable level or the clause level (Chavira and Darwiche, 2008; Gogate and Domingos, 2010; Sang et al., 2005).

It is well known that probabilistic inference in GM can be reduced to WMC (Chavira and Darwiche, 2008). The reduction has two main components: (1) encode the GM as a propositional knowledge base; and (2) leverage state-of-the-art propositional model counters to develop a WMC-based algorithm for solving the desired inference task. However, a major drawback of the aforementioned methods is that they are computationally intractable for most real-world problems. Therefore, developing fast, scalable approximate schemes is a subject of fundamental interest.

While there exists several approaches to propositional *approximate counting*, most of those are intrinsically stochastic (Ermon et al., 2013; Gogate and Dechter, 2007, 2011), and little attention has been given to deterministic methods that can bound estimates with correctness guarantees. In this paper we propose a *deterministic bounding scheme for WMC*. Our approach is partition-based (Dechter and Rish, 2003) and gives rise to a novel class of inequalities from which upper (or lower) bounds can be derived efficiently. In addition, the bounds are oblivious,

i.e. they require only limited observations of the structure and parameters of the problem, which yields fast methods.

Specifically, we extend the work of Gatterbauer and Suciú (Gatterbauer and Suciú, 2014, 2017), which is applicable to only monotone SAT formulas, to the task of WMC for arbitrary (*non-monotone*) formulas. Our method is related to the class of bounded complexity inference schemes such as mini-buckets (MB) (Dechter and Rish, 2003) and their extensions (Choi et al., 2007; Liu, 2014). MB relaxes the original problem by decomposing it into local sub-problems (by splitting/dissociating nodes) that are then solved exactly. The result is an approximate scheme that generates bounds for various inference tasks.

We make the following contributions. (1) We analyze the idea of dissociation based oblivious bounds (Gatterbauer and Suciú, 2014) using the framework of weighted model counting and extend it to the general non-monotone case; (2) we take advantage of logical structure and derive a novel set of inequalities for bounding methods that dissociate until the formula has a tree structure (namely the *i*-bound in MB is equal to 1); (3) we theoretically compare the idea of dissociation with MB and show that MB bounds are a special case of our bounds and can be quite inferior; and (4) we empirically demonstrate that dissociation based bounds are more accurate than MB on several synthetic and real-world datasets.

## 2 BACKGROUND

Let  $\mathbf{X}$ ,  $\mathbf{Y}$ , etc. be sets of propositional variables that take values (i.e., truth assignments) from the set  $\{\text{false}, \text{true}\}$  (or  $\{0, 1\}$ ). Given  $\mathbf{X} = \{X_1, \dots, X_n\}$ , let  $\Omega$  be the set of the  $2^n$  truth assignments to  $\mathbf{X}$ . Let  $\mathbf{x} = (x_1, \dots, x_n) \in \Omega$  be a truth assignment to all variables in  $\mathbf{X}$  s.t.  $X_i = x_i$ . We use the symbol ‘\*’ to denote the case when  $X_i$  can take either values, namely  $(0 \vee 1)$  or otherwise known as the *don’t care* condition. Let  $F$  be a propositional formula in conjunctive normal form (CNF) over  $\mathbf{X}$ , i.e.  $F$  is a conjunction of clauses, where a clause is a disjunction of literals, and each literal is defined as a variable  $X_i$  (positive literal, +) or its negation  $\bar{X}_i$  (negative literal, -). Let  $\mathbf{C}$  be the set of clauses of  $F$ . In this paper, we will focus on arbitrary (non-monotone) CNF.

**Definition 1.** (Monotonicity). A formula  $F$  is “monotone in variable  $X_i$ ” iff  $X_i$  appears in  $F$  as either positive or negative (but not both). A formula  $F$  is “monotone” iff it is monotone in all variables. Otherwise  $F$  is non-monotone.

### 2.1 WEIGHTED MODEL COUNTING

Given a propositional formula  $F$ , a satisfying assignment or *model* of  $F$  is a truth assignment to all variables in

$F$  such that  $F$  evaluates to *true* ( $\mathbf{x} \models F$ ). The problem of determining if there exists a satisfying assignment  $\mathbf{x}$  for  $F$  is called the *Boolean satisfiability problem* or SAT. *Propositional model counting* or #SAT is the task of computing the number of models of  $F$ . This is the canonical #P-complete problem that generalizes SAT.

Weighted model counting (WMC) (Chavira and Darwiche, 2008; Sang et al., 2005) extends model counting by associating the following probability distribution (weight function)  $\phi_i$  to each propositional variable  $X_i$ :

$$\phi_i(X_i) = \begin{cases} p_i & \text{if } X_i \text{ evaluates to } 1 \\ \bar{p}_i & \text{otherwise} \end{cases},$$

where  $p_i \in [0, 1]$  and  $\bar{p}_i \triangleq 1 - p_i$ .<sup>1</sup> The functions  $\phi_i$  yield a *weighted representation*  $\mathcal{F}$  of the CNF  $F$  and is called WCNF. Formally,  $\mathcal{F}$  is a triple  $\langle \mathbf{X}, \Phi, \mathbf{C} \rangle$ , where  $\mathbf{X}$  is a set of  $n$  Boolean variables in  $F$ ,  $\Phi$  is a set of weight functions  $\phi_i$  associated with each Boolean variable  $X_i \in \mathbf{X}$  and  $\mathbf{C}$  is a set of clauses of  $F$ .  $\mathcal{F}$  represents the following probability distribution

$$P_{\mathcal{F}}(\mathbf{x}) = \begin{cases} \frac{1}{Z_{\mathcal{F}}} \prod_{i=1}^n \phi_i(X_i = x_i) & \text{if } \mathbf{x} \models F \\ 0 & \text{otherwise} \end{cases},$$

where  $Z_{\mathcal{F}}$  is the *partition function*, also referred to as the *weighted model count* (WMC) of  $\mathcal{F}$ , and is given by

$$Z_{\mathcal{F}} = \sum_{(\mathbf{x} \in \Omega \wedge \mathbf{x} \models F)} \prod_{i=1}^n \phi_i(X_i = x_i).$$

When  $p_i = 1/2$  for all variables, the product  $2^n Z_{\mathcal{F}}$  equals the special case of (unweighted) model count of  $F$ .

### 2.2 GRAPHICAL MODELS

Graphical models (GM) provide a compact representation of joint probability distributions over a set of variables  $\mathbf{X}$ . For simplicity, we will focus on pairwise binary Markov networks since every GM can be converted to this form (cf. (Koller and Friedman, 2009)). Let  $\mathcal{I} \subseteq \mathcal{A}$  where  $\mathcal{A}$  denotes the set of all pairs  $(i, j)$  such that  $i < j$  and  $1 \leq i, j \leq n$ . In a pairwise graphical model, we associate a potential function  $\psi_{i,j}$  over each pair  $(i, j) \in \mathcal{I}$ . The probability distribution is given by

$$P(\mathbf{x}) = \frac{1}{Z} \prod_{(i,j) \in \mathcal{I}} \psi_{i,j}(x_i, x_j),$$

where  $Z$  is the normalization constant (partition function) and  $(x_i, x_j)$  is the projection of  $\mathbf{x}$  on  $\{X_i, X_j\}$ .

<sup>1</sup>WMC is typically defined by attaching weights to literals, and the corresponding potential function over each variable is constructed by exponentiating the weights. We consider an equivalent representation in which the potential function is normalized to yield a probability distribution.

Table 1: Clauses for w2CNF Encoding of a GM

$(\bar{X}_i \vee Y_{i,j,1})$	$(\bar{X}_j \vee Y_{i,j,1})$
$(\bar{X}_i \vee Y_{i,j,2})$	$(X_j \vee Y_{i,j,2})$
$(X_i \vee Y_{i,j,3})$	$(\bar{X}_j \vee Y_{i,j,3})$
$(X_i \vee Y_{i,j,4})$	$(X_j \vee Y_{i,j,4})$

### 2.3 WCNF ENCODING OF A GM

We describe here a possible translation from GM to WCNF. For more details see (Chavira and Darwiche, 2008; Gogate and Domingos, 2010, 2016). Since we focus on pairwise binary GMs, we can convert them to WCNFs in which each clause has at most two literals. We will refer to such WCNFs as w2CNF.

Given a GM, we can construct an equivalent w2CNF as follows. We start with a w2CNF  $\mathcal{F}$  defined over the variables  $\mathbf{X}$  of the GM such that the set of clauses  $\mathbf{C}$  of  $\mathcal{F}$  is empty and  $p_{X_i} = 0.5$  for each variable  $X_i \in \mathbf{X}$ . Then, for each pairwise binary potential  $\psi_{i,j}$  in the GM such that  $\psi_{ij} : X_i = 0, X_j = 0 \rightarrow w_{i,j,1}$ ,  $\psi_{ij} : X_i = 0, X_j = 1 \rightarrow w_{i,j,2}$ ,  $\psi_{ij} : X_i = 1, X_j = 0 \rightarrow w_{i,j,3}$ ,  $\psi_{ij} : X_i = 1, X_j = 1 \rightarrow w_{i,j,4}$ , we add a variable for each weight to  $\mathcal{F}$ . We will denote the variables associated with  $w_{i,j,1}$ ,  $w_{i,j,2}$ ,  $w_{i,j,3}$  and  $w_{i,j,4}$  by  $Y_{i,j,1}$ ,  $Y_{i,j,2}$ ,  $Y_{i,j,3}$  and  $Y_{i,j,4}$  respectively. Utilizing these weight variables, we add the the clauses given in Table 1 to  $\mathbf{C}$  for  $k = 1, \dots, 4$ . We also add the following probability distribution for each variable  $Y_{i,j,k}$

$$\phi(y_{i,j,k}) = \begin{cases} \frac{w_{i,j,k} - 1}{w_{i,j,k}} & \text{if } y_{i,j,k} \text{ is false or } 0 \\ \frac{1}{w_{i,j,k}} & \text{otherwise} \end{cases}$$

Note that when  $w_{i,j,k} < 1$ ,  $\phi(y_{i,j,k})$  will be negative. To avoid this condition, we can easily rescale the potentials of the GM by multiplying them with an appropriate constant. Also, zero weights can be handled by adding the corresponding negated assignment as a clause to  $\mathbf{C}$ . For example, if  $w_{i,j,1} = 0$ , we add the clause  $X_i \vee X_j$  to  $\mathbf{C}$ . Using previous work (Chavira and Darwiche, 2008; Gogate and Domingos, 2010), it is straight-forward to show that:

**Proposition 2.** w2CNF output by Encoding 1 represents the same probability distribution over  $\mathbf{X}$  as the input GM.

### 2.4 MINI-BUCKET ELIMINATION

We can utilize inference algorithms such as bucket or variable elimination (Dechter, 1996; Zhang and Poole, 1994) to compute the weighted model count of a w2CNF. However, since the complexity of using such algorithms is in general exponential in the treewidth, a more practical approach is to approximate the task by introducing

relaxations techniques that control model complexity (i.e., the induced width given a fixed elimination order). Mini-bucket (MB) (Dechter and Rish, 2003) is one such approximate scheme that builds on bucket elimination (BE) for generating upper (or lower) bounds on the partition function or weighted model count. We will use the following running example to illustrate BE and MB for WMC.

**Example 3.** Consider the w2CNF  $\mathcal{F}$  such that  $\mathbf{X} = \{X_1, Y_2, Y_3\}$ ,  $\mathbf{C} = \{(X_1 \vee Y_2), (X_1 \vee Y_3)\}$  and  $\Phi = \{\phi_1, \phi_2, \phi_3\}$ . For simplicity we denote  $\phi_1$  for  $\phi_1(X_1)$ , etc. We can convert the clauses and potentials of  $\mathcal{F}$  to the following two potentials yielding a more convenient form for BE.

$X_1$	$Y_2$	$\psi_{12}(X_1, Y_2)$	$X_1$	$Y_3$	$\psi_{13}(X_1, Y_3)$
0	0	0	0	0	0
0	1	$\bar{p}_1 p_2$	0	1	$p_3$
1	0	$p_1 \bar{p}_2$	1	0	$\bar{p}_3$
1	1	$p_1 p_2$	1	1	$p_3$

Without loss of generality, we assume the elimination ordering as  $[X_1, Y_2, Y_3]$  (although it is clearly not optimal, it will help us illustrate the main ideas). BE begins by creating  $|\mathbf{X}|$  number of buckets and groups the functions by placing each function involving some variable  $X_i$  (or  $Y_i$  in our example) in a bucket  $\mathbf{B}_{X_i}$  according to the position of  $X_i$  in the ordering. The resulting computation is  $Z_{\mathcal{F}}^{\text{BE}} = \sum_{Y_3} \sum_{Y_2} \sum_{X_1} \psi_{12} \psi_{13}$  where  $\mathbf{B}_{X_1} = \{\psi_{12}, \psi_{13}\}$  is first processed by taking the product of the two potentials and summing out variable  $X_1$ . The resulting new potential  $\psi'_{23}$  is placed in bucket  $\mathbf{B}_{Y_2}$  in which variable  $Y_2$  is summed out. Summing out  $Y_3$  from the subsequent function  $\psi'_3$  yields  $Z_{\mathcal{F}}^{\text{BE}}$ .

MB follows similarly. However, MB partitions each bucket into two or more so called mini-buckets according to an input parameter called the  $i$ -bound, which defines the maximum number ( $i$ -bound + 1) of variables in each mini-bucket. The mini-buckets are then processed independently. To obtain an upper bound, the sum-product operation is performed on one of the mini-buckets and the max-product for the remaining (min-product for lower bound). Using  $i$ -bound = 1,  $\mathbf{B}_{X_1}$  is split into two mini-buckets  $\mathbf{B}'_{X_1} = \{\psi_{12}\}$  and  $\mathbf{B}''_{X_1} = \{\psi_{13}\}$ . One possible resulting computation is

$$\underbrace{\sum_{Y_3 Y_2} \left( \sum_{X_1} \psi_{12} \right) \left( \min_{X_1} \psi_{13} \right)}_{Z_{\mathcal{F}}^{\text{MB}(L)}} \leq \sum_{Y_3} \sum_{Y_2} \sum_{X_1} \psi_{12} \psi_{13} \leq \underbrace{\sum_{Y_3 Y_2} \left( \sum_{X_1} \psi_{12} \right) \left( \max_{X_1} \psi_{13} \right)}_{Z_{\mathcal{F}}^{\text{MB}(U)}}$$

where the MB upper bound on the partition function,

$Z_{\mathcal{F}}^{\text{MB}(U)}$ , is computed by maxing out  $X_1$  from  $\psi_{13}$  independently from summing out  $X_1$  from  $\psi_{12}$ . Summing out  $Y_2$  and  $Y_3$  from the resulting two new potentials,  $\psi'_2, \psi'_3$ , and taking their product gives the upper bound. The lower bound,  $Z_{\mathcal{F}}^{\text{MB}(L)}$ , is computed similarly using min instead of max.

MB is a fast and simple algorithm for computing upper (or lower) bounds. The resulting complexity of inference is exponential in the  $i$ -bound. Lower  $i$ -bound values translates to simpler models and provides the trade-off between complexity and accuracy.

Next, we present the idea of dissociation based oblivious bounds for the case of monotone W2CNF and extend it to the non-monotone case by exploiting logical structure in Section 4. As mentioned earlier, in this paper, we focus on the case where variables are dissociated until the resulting formula is a tree. In other words, our scheme is comparable to the case when the  $i$ -bound in MB equals 1.

### 3 DISSOCIATION

Our task is to compute the WMC  $Z_{\mathcal{F}}$  of a given WCNF  $\mathcal{F}$ . Since the problem is computationally intractable in general (e.g., high treewidth), approximate methods are required. In this paper we use a *bounded inference* approach, where we approximate the original  $\mathcal{F}$  with  $\mathcal{F}'$  from which the upper (or lower) bounds on  $Z_{\mathcal{F}}$  can be computed efficiently. We build upon (Gatterbauer and Suciu, 2014, 2017) which presents a bounding scheme called *dissociation* that can be applied to WMC. The derived bounds are *oblivious* to the set of weight functions  $\phi_i$ , i.e. they can be calculated by only observing a limited subset of clauses. However, these bounds only apply to monotone formulas, whereas we are interested in extending the underlying ideas to more general non-monotone formulas (Section 4). Here, we first give a general intuition of prior results followed by the formal definition and then present optimal oblivious bounds for monotone formulas.

At a high level, dissociation is the process of replacing an existing variable  $X_i$  in  $\mathcal{F}$  with new variables  $X_{i,1}, \dots, X_{i,d}$  and assigning them new probability distributions. The technique is closely related to *variable or node splitting* (Choi et al., 2007) in which the new variables are referred to as clones. The partitioning of mini-buckets can also be classified under the general notion of variable splitting.

By creating new variables, we are implicitly ignoring (or relaxing) a set of equality constraints (Choi and Darwiche, 2009). However, we can recover the set by defining and incorporating the function  $\varphi(X_{i,1} = x_{i,1}, \dots, X_{i,n} = x_{i,d})$  which evaluates to 1 iff  $x_{i,1} = \dots = x_{i,d}$ , and 0 other-

wise, for the  $d$  copies  $X_{i,j}, j \in [d]$  of variable  $X_i$ , and  $x_{i,j}$  being the corresponding truth assignment. We can also incorporate equivalence clauses for each new pair of variables into a formula with the new clauses. For example, consider the formula  $F = (X_1 \vee Y_1)(X_1 \vee Y_2)$ . We can create the equivalent formula  $F' = (X_{1,1} \vee Y_1)(X_{1,2} \vee Y_2)(X_{1,1} \Leftrightarrow X_{1,2})$  using copies of  $X_1$  for the unweighted model counting case. We see two issues arising. First, for general 2-CNF formulas, we will require  $d - 1$  equality constraints (equivalence ( $\Leftrightarrow$ ) formulas). Second, it is not immediately clear on how to integrate the weight functions so that weighted model counts can be computed using this scheme.

Dissociation expands on the notion of variable duplication and provides an *algebraic framework* to analyze and approximate the aforementioned set of equality constraints. The result is a novel class of inequalities to construct upper (or lower) bounds on the WMC. We first give the formal definition of dissociation for W2CNF.

**Definition 4.** (Dissociation). *Let  $\mathcal{F} = \langle \mathbf{X}, \Phi, \mathbf{C} \rangle$ . Select a variable  $X_i \in \mathbf{X}$  and let  $C(X_i) \subseteq \mathbf{C}$  be the subset of all clauses that involve variable  $X_i$ . We say  $\mathcal{F}' = \langle \mathbf{X}', \Phi', \mathbf{C}' \rangle$  is a dissociation of  $\mathcal{F}$  on  $X_i$  iff*

- $\mathbf{X}' = \mathbf{X} \setminus X_i \cup X_{i,1} \cup \dots \cup X_{i,d}$  with  $d \leq |C(X_i)|$ ,
- $\Phi' = \Phi \setminus \phi_i \cup \phi_{i,1} \cup \dots \cup \phi_{i,d}$ , and
- $\mathbf{C}'[\theta_{X_i}(\mathbf{X}')] = \mathbf{C}[\mathbf{X}]$  with  $\theta_{X_i}$  being the substitution  $\theta_{X_i}[\{(X_{i,j}/X_i), j \in [d]\}]$ .

We say a dissociation is full if  $d = |C(X_i)|$ .

**Example 5.** (Dissociation). *Consider  $\mathcal{F}$  from example 3. Dissociating  $X_1$  results in adding two new variables,  $\mathbf{X}' = \mathbf{X} \setminus X_1 \cup X_{1,1} \cup X_{1,2}$ , and two new associated weight functions  $\Phi' = \Phi \setminus \phi_1 \cup \phi_{1,1} \cup \phi_{1,2}$ . Applying the substitution  $\theta_{X_1}[(X_{1,1}/X_1), (X_{1,2}/X_1)]$  on  $C(X_i)$  results in  $\mathbf{C}' = \mathbf{C} \setminus C(X_i) \cup (X_{1,1} \vee Y_2) \cup (X_{1,2} \vee Y_3)$ .*

Once we have defined the new weight functions (for dissociated variables), the question we are interested in is how to parameterize the new functions in order to obtain guaranteed upper (or lower) bounds. In particular, we are interested in *oblivious bounds*, i.e. when the *new probabilities are chosen independently of the probabilities of all other variables*. We achieve that by considering all possible valuations (or truth assignments) of the non-dissociated variables, The assignments give rise to a set of inequalities which are then evaluated to develop necessary and sufficient conditions for upper (or lower) bounds. We next illustrate with an example.

**Example 6.** (Oblivious bounds). *Consider the two sets of clauses,  $\{(X_1 \vee Y_2), (X_1 \vee Y_3)\}$  and  $\{(X_{1,1} \vee Y_2), (X_{1,2} \vee Y_3)\}$  from examples 3 and 5. We analyze the  $2^2 = 4$  possible truth assignments to the non-dissociated variables*

Table 2: Dissociation valuation analysis (example 6).

$Y_2$	$Y_3$	$X_1$	$X_{1;1}$	$X_{1;2}$	$\phi_1$	$\phi_{1;1}, \phi_{1;2}$
0	0	1	1	1	$p_1$	$p_{1;1}p_{1;2}$
0	1	1	1	*	$p_1$	$p_{1;1}$
1	0	1	*	1	$p_1$	$p_{1;2}$
1	1	*	*	*	1	1

$Y_2$  and  $Y_3$ . Table 2 shows each possible valuation of  $Y_2$  and  $Y_3$  and the corresponding assignments to  $X_1, X_{1;1}$  and  $X_{1;2}$  required to satisfy the clauses. We also show the weights (probabilities) of the original (column  $\phi_1$ ) and dissociated formulas (column  $\phi_{1;1}\phi_{1;2}$ ).

As example, consider the assignment,  $Y_2 = 0 \wedge Y_3 = 1$ : The assignment  $X_1 = 1$  is required to satisfy  $\mathcal{F}$ , resulting in the term  $p_1\bar{p}_2p_3$ . The assignments ( $X_{1;1} = 1 \wedge X_{1;2} = 0$ ) or ( $X_{1;1} = 1 \wedge X_{1;2} = 1$ ) are required to satisfy  $\mathcal{F}'$ , i.e.  $X_{1;2}$  can take any assignment (\*), resulting in the term  $p_{1;1}\bar{p}_2p_3$ . Utilizing the two terms, simplifying by removing the common terms ( $\bar{p}_2p_3$ ) and assuming that we are interested in computing lower bounds, we create the inequality  $p_1 \geq p_{1;1}$ . Repeating the same analysis for the three remaining cases results in the inequalities  $p_1 \geq p_{1;1}p_{1;2}$  and  $p_1 \geq p_{1;2}$ . The last case  $1 \geq 1$  is trivially satisfied. Combining the resulting inequalities, and doing a similar analysis for computing upper bounds (where we replace  $\geq$  by  $\leq$ ) gives rise to the following conditions for oblivious (U)pper and (L)ower bounds:

- $U: (p_1 \leq p_{1;1}p_{1;2}) \wedge (p_1 \leq p_{1;1}) \wedge (p_1 \leq p_{1;2})$ .
- $L: (p_1 \geq p_{1;1}p_{1;2}) \wedge (p_1 \geq p_{1;1}) \wedge (p_1 \geq p_{1;2})$ .

Notice the valuation process creates  $2^{|C(X_i)|}$  inequalities, one for each truth assignment. However, we can simplify the conditions by removing subsumed inequalities.

**Definition 7.** (Subsumed inequality). We say an inequality  $I_i$  subsumes inequality  $I_j$  ( $i \neq j$ ) iff  $I_i \Rightarrow I_j$ , i.e. satisfying  $I_i$  also satisfies  $I_j$ .

**Example 8.** Consider the upper and lower bound conditions in example 6. For the upper bound, clearly  $p_1 \leq p_{1;1}p_{1;2}$  subsumes the remaining inequalities since  $\forall p_1, p_{1;1}, p_{1;2} \in [0, 1] : (p_1 \leq p_{1;1}p_{1;2}) \Rightarrow (p_1 \leq p_{1;1}) \wedge (p_1 \leq p_{1;2})$ . For the lower bound, clearly  $(p_1 \geq p_{1;1}) \wedge (p_1 \geq p_{1;2})$  subsumes the remaining inequality since  $\forall p_1, p_{1;1}, p_{1;2} \in [0, 1] : ((p_1 \geq p_{1;1}) \wedge (p_1 \geq p_{1;2})) \Rightarrow (p_1 \geq p_{1;1}p_{1;2})$ . Therefore, we can reduce the required conditions for the oblivious bounds to:

- $U: p_1 \leq p_{1;1}p_{1;2}$ .
- $L: (p_1 \geq p_{1;1}) \wedge (p_1 \geq p_{1;2})$ .

Following the preceding analysis, we can now state the conditions for oblivious bounds for monotone w2CNF.

**Theorem 9.** (Gatterbauer and Suciu, 2014) (Oblivious bounds for monotone w2CNF). Let  $\mathcal{F}$  be a monotone w2CNF. Let  $\mathcal{F}'$  be the result of applying a series of dissociation steps on  $\mathcal{F}$ . For every set of weight functions defined for a dissociate variable, namely  $X_{i;1}, \dots, X_{i;d}$  and  $\{\phi_{i;1}, \dots, \phi_{i;d}\}$  with  $d > 1$ , we have the following oblivious bounds:

- $U: \prod_{j=1}^d p_{i;j} \geq p_i$ .
- $L: \forall j : p_{i;j} \leq p_i$ .

Optimal oblivious bounds are defined as those that are not dominated, i.e. they cannot be improved without knowledge of the probabilities of all other variables. They are obtained by replacing inequality with equality. Notice that optimal oblivious lower bounds are uniquely defined,  $\forall j : p_{i;j} = p_i$ , whereas there are infinitely many optimal oblivious upper bounds, e.g. symmetric ones:  $\forall j : p_{i;j} = \sqrt[d]{p_i}$ , and finding the best one requires access to all other probabilities (den Heuvel et al., 2018).

Note that optimal oblivious bounds are different from augmented mini-buckets (AMB) (Liu, 2014). For example, in AMB for computing upper bounds, the potential over each dissociated variable is initialized to  $\phi_{i;j}(X_{i;j} = 1) = \phi_i(X_i = 1)^{1/d}$  and  $\phi_{i;j}(X_{i;j} = 0) = \phi_i(X_i = 0)^{1/d}$  where we have  $d$  dissociations. A better initialization would be  $\phi_{i;j}(X_{i;j} = 1) = \phi_i(X_i = 1)^{1/d}$ , and  $\phi_{i;j}(X_{i;j} = 0) = 1 - \phi_i(X_i = 1)^{1/d}$ .

### 3.1 COMPARISON WITH MINI-BUCKET

We use example 3 to analyze the base case bounds for monotone dissociation ( $X_1$  to  $X_{1;1}$  and  $X_{1;2}$ ) and compare it with MB ( $i$ -bound = 1).

**Lower bound.** Dissociation results in the partition function  $Z_{\mathcal{F}'}^{\text{DIS}(U)} = p_2p_3 + p_{1;1}\bar{p}_2p_3 + p_{1;2}p_2\bar{p}_3 + p_{1;1}p_{1;2}\bar{p}_2\bar{p}_3$ . The two possible partition functions according to MB are (1)  $\sum_{X_1} \psi_1 \min_{X_1} \psi_2 \Rightarrow Z_{\mathcal{F}}^{\text{MB}(L1)} = p_2p_3 + p_{1;1}\bar{p}_2p_3$ ; (2)  $\min_{X_1} \psi_1 \sum_{X_1} \psi_2 \Rightarrow Z_{\mathcal{F}}^{\text{MB}(L2)} = p_2 \min(\bar{p}_1, p_1)(1 + p_3)$ . Clearly,  $Z_{\mathcal{F}'}^{\text{DIS}(L)} \geq Z_{\mathcal{F}}^{\text{MB}(L)} \forall p_1, p_{1;1}, p_{1;2}, p_2, p_3 \in [0, 1]$ .

**Upper bound.** Notice there exist an infinite number of settings to  $p_{1;1}$  and  $p_{1;2}$  that satisfy  $p_{1;1}p_{1;2} = p_1$  under dissociation. We analyze two possible cases. (1)  $(p_{1;1} = p_1) \wedge (p_{1;2} = 1) \Rightarrow Z_{\mathcal{F}'}^{\text{DIS}(U1)} = p_{1;1} + \bar{p}_{1;1}p_2$ ; (2)  $(p_{1;2} = p_1) \wedge (p_{1;1} = 1) \Rightarrow Z_{\mathcal{F}'}^{\text{DIS}(U2)} = p_{1;2} + \bar{p}_{1;2}p_3$ . The two possible partition functions according to MB are (1)  $\sum_{X_1} \psi_1 \max_{X_1} \psi_2 \Rightarrow Z_{\mathcal{F}}^{\text{MB}(U1)} = p_1 + \bar{p}_1p_1$ ; (2)  $\max_{X_1} \psi_1 \sum_{X_1} \psi_2 \Rightarrow Z_{\mathcal{F}}^{\text{MB}(U2)} = (1 + p_3)(p_2 \max(\bar{p}_1, p_1) + p_1\bar{p}_1)$ . We first observe the bounds are equivalent between dissociation and MB in setting

(1) and also for (2) if the functions are unweighted (e.g.,  $\forall i p_i = 1/2$ ). However, note there exist more degrees of freedom (solutions) for dissociation, and this example simply demonstrates one such setting for which we observe equivalency under certain conditions.

## 4 DISSOCIATION FOR NON-MONOTONE FORMULAS

In this section, we extend dissociation bounds from the monotone case to arbitrary non-monotone w2CNFs. Unlike monotone w2CNFs, we can apply logical inference techniques such as resolution and unit propagation to reduce non-monotone w2CNFs which in turn may improve our dissociation-based bounds. Moreover, logical propagation can be applied as a pre-processing step before dissociating a variable  $X_i$ .

### 4.1 PREPROCESSING

We say that a w2CNF  $\mathcal{F}$  is *minimal* if the following steps are applied to its set of clauses  $\mathbf{C}$  until convergence.

1. **(Binary) Resolution:** If  $\mathbf{C}$  contains two clauses of the form  $L_i \vee L_j$  and  $\bar{L}_i \vee L_k$ , where  $L_i, L_j$  and  $L_k$  are literals of variables  $X_i, X_j$  and  $X_k$  respectively, we add the clause  $L_j \vee L_k$  to  $\mathbf{C}$ .
2. **Unit Resolution:** If  $\mathbf{C}$  contains two clauses of the form  $L_i \vee L_j$  and  $\bar{L}_i \vee L_j$ , where  $L_i$  and  $L_j$  are literals of variables  $X_i$  and  $X_j$  respectively, we add the unit clause  $L_j$  to  $\mathbf{C}$ .
3. **Clause Deletion and Reduction:** If  $\mathbf{C}$  contains a unit clause  $L_i$  where  $L_i$  is a literal of  $X_i$  then we delete all clauses of the form  $L_i \vee L_j$  and remove  $\bar{L}_i$  from all clauses that mention  $\bar{L}_i$ . If  $\mathbf{C}$  contains both unit clauses  $L_i$  and  $\bar{L}_i$ ,  $\mathbf{C}$  is inconsistent and we return a lower/upper bound of 0.<sup>2</sup>

**Example 10 (Minimal formula).** Consider  $\mathbf{C} = \{(X_1 \vee \bar{X}_2), (X_1 \vee X_2), (\bar{X}_2 \vee Y_4), (X_1 \vee X_3), (X_3 \vee X_5)\}$ .  $\mathbf{C}$  is not minimal and we can make it minimal using the aforementioned steps. After applying Unit Resolution on the first two clauses, we get  $\mathbf{C} = \{(X_1), (X_1 \vee \bar{X}_2), (X_1 \vee X_2), (\bar{X}_2 \vee Y_4), (X_1 \vee X_3), (X_3 \vee X_5)\}$ . After applying Clause deletion and Reduction, we get  $\mathbf{C} = \{(X_1), (\bar{X}_2 \vee Y_4), (X_3 \vee X_5)\}$ , which is minimal.

### 4.2 TYPES OF NON-MONOTONE FORMULAS

In the sequel, we assume that the input w2CNF  $\mathcal{F}$  to our algorithm is minimal. To formulate oblivious bounds for non-monotone w2CNF, we first establish a *canonical*

<sup>2</sup>Note that our scheme will return an upper bound of 0 only when  $\mathbf{C}$  is inconsistent.

*representation* that helps us take advantage of symmetry and reduces the number of cases (inequalities) we need to consider for our proposed oblivious bounds. Specifically, given a candidate *dissociation variable*  $X_i$ , we convert the set of clauses  $\mathbf{C}$  into a canonical representation:

**Definition 11 (Canonical representation).** We say that  $\mathcal{F}$  is *canonical w.r.t. a variable  $X_i$*  if  $\mathcal{F}$  is minimal and all clauses in  $C(X_i)$  satisfy the following two properties:

1. If a variable  $Y_j$  appears only once in  $C(X_i)$  then it only appears positively, i.e. it appears in clauses of the form  $X_i \vee Y_j$  or  $\bar{X}_i \vee Y_j$  (but not of the form  $X_i \vee \bar{Y}_j$  or  $\bar{X}_i \vee \bar{Y}_j$ ).
2. If a variable  $Y_j$  appears twice in  $C(X_i)$ , then it appears in the following two clauses  $X_i \vee Y_j$  and  $\bar{X}_i \vee \bar{Y}_j$  (but not in the clauses  $\bar{X}_i \vee Y_j$  and  $X_i \vee \bar{Y}_j$ ).

Note that since  $\mathcal{F}$  is minimal,  $Y_j$  cannot appear more than twice in  $C(X_i)$ , nor twice with the same sign. If  $C(X_i)$  is not in canonical form, we can easily make it canonical by using the following procedure:

- If  $Y_j$  violates either condition (1) or (2) in definition 11, then replace  $Y_j$  by a new variable  $Y_k$  in all clauses of  $\mathcal{F}$  (where  $Y_j$  appears) such that  $Y_k = \bar{Y}_j$ , and set  $\phi(Y_k) = \phi(\bar{Y}_j)$  and  $\phi(\bar{Y}_k) = \phi(Y_j)$ .

**Example 12 (Canonical representation).** Consider  $\mathbf{C} = \{(X_1 \vee \bar{Y}_2), (\bar{X}_1 \vee Y_2), (X_1 \vee \bar{Y}_3)\}$ .  $\mathbf{C}$  is not in canonical form w.r.t.  $X_1$  because  $Y_2$  and  $Y_3$  violate the second and first property respectively in definition 11. To convert it to canonical form, set  $Y_4 = \bar{Y}_2, Y_5 = \bar{Y}_3, \phi(Y_4) = \phi(\bar{Y}_2), \phi(\bar{Y}_4) = \phi(Y_2), \phi(Y_5) = \phi(\bar{Y}_3)$  and  $\phi(\bar{Y}_5) = \phi(Y_3)$ . Thus, the canonical representation of  $\mathbf{C}$  is the set  $\{(X_1 \vee Y_4), (\bar{X}_1 \vee \bar{Y}_4), (X_1 \vee Y_5)\}$ .

We call variables  $Y_j$  which appear only once in  $C(X_i)$  *single-occurrence neighbors* of  $X_i$  and those which appear twice *two-occurrence neighbors*.

### 4.3 CHARACTERIZING OBLIVIOUS BOUNDS

We now derive oblivious bounds based on whether  $C(X_i)$  has two-occurrence neighbors or not. In the following, let  $\mathcal{F}$  denote a w2CNF that is canonical w.r.t.  $X_i$  and let  $\mathcal{F}'$  be the result of applying a series of dissociation steps on  $\mathcal{F}$ . Let  $Y_j$  be a single-occurrence neighbor of  $X_i$ . Let  $S^+$  and  $S^-$  denote the set of indices of the dissociated variables that appear in clauses  $(X_i \vee Y_j)$  and  $(\bar{X}_i \vee Y_j)$  respectively in  $C(X_i)$ . Let  $Y_k$  be a two-occurrence neighbor of  $X_i$ . Let  $T^+$  and  $T^-$  denote the set of indices of the dissociated variables in clauses  $X_i \vee Y_k$  and  $\bar{X}_i \vee \bar{Y}_k$  respectively in  $C(X_i)$ . (We use  $S$  and  $T$  to refer to “single-occurrence” and “two-occurrence” variables, respectively.)

**Example 13 (Indices).** Consider  $\mathbf{C} = \{(X_1 \vee Y_5), (X_1 \vee Y_8), (\bar{X}_1 \vee Y_6), (X_1 \vee Y_7), (\bar{X}_1 \vee \bar{Y}_7), (X_1 \vee$

$Y_9), (\overline{X_1 \vee Y_9})\}$ . After applying dissociation on  $X_1$ , we get  $C(X'_1) = \{(X_{1;1} \vee Y_5), (X_{1;2} \vee Y_8), (\overline{X_{1;3}} \vee Y_6), (X_{1;4} \vee Y_7), (\overline{X_{1;5}} \vee Y_7), (X_{1;6} \vee Y_9), (\overline{X_{1;7}} \vee Y_9)\}$ . Then  $S^+ = \{1, 2\}$ ,  $S^- = \{3\}$ ,  $T^+ = \{4, 6\}$ , and  $T^- = \{5, 7\}$ .

We next analyze the two possible non-monotone cases in Theorems 14 and 16. The proofs are presented in an extended version of the paper.

The first case is when  $C(X_i)$  has only single-occurrence neighbors (but no two-occurrence neighbors). This generalizes the monotone case, in which only one type of single-occurrence variables are present. In particular, in the monotone case either clauses of the form  $(X_i \vee Y_j)$  or  $(\overline{X_i} \vee Y_j)$  are present but not both while in the non-monotone case both clauses can be present in  $C(X_i)$ . Note that bounds given in Theorem 9 are a special case of the bounds in Theorem 14 presented next.

**Theorem 14.** (Oblivious bounds for w2CNFs having only single-occurrence neighbors w.r.t.  $X_i$ ). For a given variable  $X_i$ , if  $\mathcal{F}$  contains only single-occurrence neighbors but no two-occurrence neighbors then we have the following oblivious bounds for  $X_i$ :

- $U$ :  $\left( \prod_{j \in S^+} p_{i;j} \geq p_i \right) \wedge \left( \prod_{j \in S^-} \overline{p_{i;j}} \geq \overline{p_i} \right)$
- $L$ : Either of following two conditions hold:
  1.  $(\forall j \in S^+ : p_{i;j} \leq p_i) \wedge (\forall j \in S^- : \overline{p_{i;j}} = 0)$
  2.  $(\forall j \in S^- : \overline{p_{i;j}} \leq \overline{p_i}) \wedge (\forall j \in S^+ : p_{i;j} = 0)$

Optimal oblivious bounds are obtained by replacing inequality with equality in the bound conditions.

**Example 15.** Consider  $C(X'_1) = \{(X_{1;1} \vee Y_2), (\overline{X_{1;2}} \vee Y_3), (X_{1;3} \vee Y_4), (\overline{X_{1;4}} \vee Y_5)\}$ . Theorem 14 gives the conditions for upper and lower oblivious bounds as:

- $U$ :  $(p_{1;1} p_{1;3} \geq p_1) \wedge (\overline{p_{1;2}} \overline{p_{1;4}} \geq \overline{p_1})$ .
- $L$ : Either of following two conditions hold:
  1.  $(p_{1;1} \leq p_1) \wedge (p_{1;3} \leq p_1) \wedge (\overline{p_{1;2}} = \overline{p_{1;4}} = 0)$
  2.  $(\overline{p_{1;2}} \leq \overline{p_1}) \wedge (\overline{p_{1;4}} \leq \overline{p_1}) \wedge (p_{1;1} = p_{1;3} = 0)$

Our second non-monotone case is when  $\mathcal{F}$  has at least one two-occurrence neighbor. Intuitively, dissociated variables which form clauses with two-occurrence neighbors are more constrained than those that appear with single-occurrence neighbors. Thus, there are more constraints on probabilities associated with two-occurrence neighbors (indexed by  $T^+$  and  $T^-$ ) than those associated with single-occurrence neighbors (indexed by  $S^+$  and  $S^-$ ); see conditions 1. and 2. in Theorem 16.

**Theorem 16.** (Oblivious bounds for w2CNFs having two-occurrence neighbors w.r.t.  $X_i$ ). For a given variable  $X_i$ , if  $\mathcal{F}$  contains at least one two-occurrence neighbor then we have the following oblivious bounds for  $X_i$ :

---

**Algorithm 1:** (DIS) Dissociation Bounds for WMC

---

**Input:** w2CNF  $\mathcal{F} = \langle \mathbf{X}, \Phi, \mathbf{C} \rangle$ ,

Variable ordering  $o = [X_1, X_2, \dots, X_{|\mathbf{X}|}]$

**Output:** Lower (or upper) bound on the WMC

1. Initialize:  $Z_B = 1$  (Bound on the partition function)

2. for  $i = 1$  to  $|\mathbf{X}|$  do

    2a. Convert  $\mathcal{F}$  to a minimal  $\mathcal{F}$

    2b. Convert  $C(X_i)$  to canonical form

    2c. if  $\mathbf{C}$  is inconsistent then

        ⊥ return 0

    else if  $C(X_i) = \{X_i\}$  then

        ⊥  $Z_B = Z_B \times p_i$

    else if  $C(X_i) = \{\overline{X_i}\}$  then

        ⊥  $Z_B = Z_B \times \overline{p_i}$

    else if  $C(X_i)$  has two-occurrence neighbors then

        ⊥ Update  $Z_B$  using Theorem 16

    else if  $C(X_i)$  has single-occurrence neighbors then

        ⊥ Update  $Z_B$  using Theorem 14

return  $Z_B$

---

- $U$ :  $\left( \prod_{j \in (S^+ \cup T^+)} p_{i;j} \geq p_i \right) \wedge \left( \prod_{j \in (S^- \cup T^-)} \overline{p_{i;j}} \geq \overline{p_i} \right)$

•  $L$ : Either of following three conditions hold:

1.  $\left( \prod_{j \in T^+} p_{i;j} \leq p_i \right) \wedge (\forall j \in (S^- \cup T^-) : \overline{p_{i;j}} = 0)$
2.  $\left( \prod_{j \in T^-} \overline{p_{i;j}} \leq \overline{p_i} \right) \wedge (\forall j \in (S^+ \cup T^+) : p_{i;j} = 0)$
3. If  $|T^+| = |T^-| = 1$  and  $T^+ = \{a\} \wedge T^- = \{b\}$ :
  - $(p_{i;a} \leq p_i) \wedge (\forall j \in S^- : \overline{p_{i;j}} = 0) \wedge$
  - $(\overline{p_{i;b}} \leq \overline{p_i}) \wedge (\forall j \in S^+ : p_{i;j} = 0)$

Optimal oblivious bounds are obtained by replacing inequality with equality in the bound conditions.

**Example 17.** Consider  $C(X'_1) = \{(X_{1;1} \vee Y_3), (X_{1;2} \vee Y_4), (\overline{X_{1;3}} \vee Y_4), (X_{1;4} \vee Y_5), (\overline{X_{1;5}} \vee Y_6)\}$ . Theorem 16 gives the following conditions for upper and lower oblivious bounds:

- $U$ :  $(p_{1;1} p_{1;2} p_{1;4} \geq p_1) \wedge (\overline{p_{1;3}} \overline{p_{1;5}} \geq \overline{p_1})$

•  $L$ : Either of the following three conditions hold:

1.  $(p_{1;2} \leq p_1) \wedge (\overline{p_{1;3}} = \overline{p_{1;5}} = 0)$
2.  $(\overline{p_{1;3}} \leq \overline{p_1}) \wedge (p_{1;1} = p_{1;2} = p_{1;4} = 0)$
3.  $(p_{1;2} \leq p_1) \wedge (\overline{p_{1;3}} \leq \overline{p_1}) \wedge (p_{1;1} = p_{1;4} = \overline{p_{1;5}} = 0)$

Table 3 summarizes the oblivious bound conditions. Theorems 14 and 16 yield the algorithm given in Algorithm 1 for bounding the partition function of a given w2CNF.

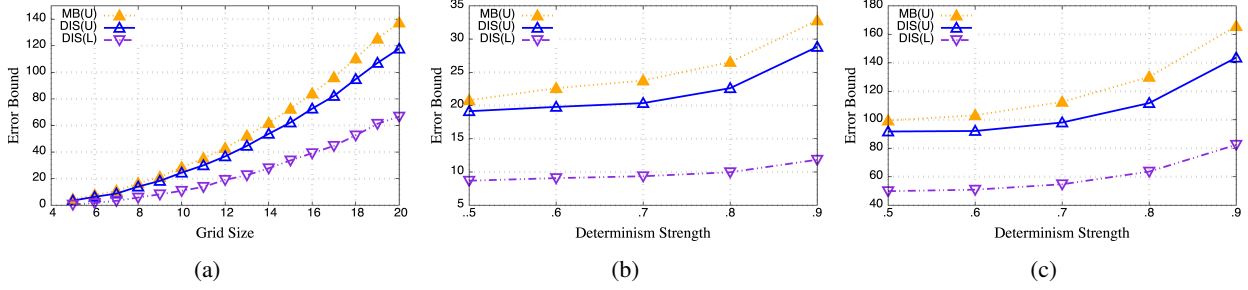

Figure 1: Upper bound estimates for dissociation DIS(U) and mini-bucket MB(U), and lower bound estimates for dissociation DIS(L). Error bound by varying (a) grid size (b) level of determinism for  $10 \times 10$  grid (c)  $20 \times 20$  grid. Lower value is better.

Table 3: Summary of oblivious bound conditions.  $T$ : whether  $C(X_i)$  has two-occurrence neighbors,  $S^+$  and  $S^-$ : whether  $C(X_i)$  has single-occurrence neighbors which appear in clauses  $(X_i \vee Y_j)$  and  $(\overline{X_i} \vee Y_j)$  respectively. An entry in a cell means that neighbors of the respective types are either present ( $\checkmark$ ), absent ( $\times$ ), or either present or absent ( $*$ ). ## 5 EXPERIMENTS

We evaluated the performance of DIS (see Algorithm 1) and compared it with MB on generated synthetic datasets and benchmark datasets from the UAI 2008 probabilistic inference competition repository (<http://graphmod.ics.uci.edu/uai08>) for the task of computing upper and lower bounds on the weighted model count (or partition function). All experiment were conducted on quad-core Intel i7 based machines with 24GB RAM running Ubuntu.

### 5.1 SYNTHETIC DATASETS

We generated non-monotone w2CNF formulas encoded as  $m \times m$  grid structure graphical models parameterized by univariate and pairwise binary potentials. We then compared error bound performance of DIS and MB ( $i$ -bound = 1) from the aspects of (1) varying grid sizes under random weight function settings; and (2) varying weight function settings according to determinism strength under fixed grid sizes. For each model, we computed the true weighted model count  $Z^*$ . We then compared each algorithm’s approximated bound  $Z^{\text{algo}}$  and calculated the error bound as  $\log(Z^*/Z^{\text{algo}})$  for the lower bound and the

same negated for the upper bound. A lower error bound value is better. For each setting, we generated 50 random problem instances and ran DIS and MB 100 times for each instance. From the 100 solutions, we selected the best, namely either the lowest upper bound or the highest lower bound. We then computed the average error bound across the 50 problem instances.

**Grid size.** We generated  $m \times m$  grids using values of  $m = \{5, 6, 7, \dots, 20\}$ . For the weight function values, we sampled from an uniform  $U(0, 1)$  distribution. We also uniformly generated the clauses. The results are shown in Figure 1a. For the upper bound, DIS noticeably begins to outperform MB starting at around grid size  $10 \times 10$  and the performance gap widens as the grid size increases. Since MB utilizes the max function, it has a higher tendency to overestimate the upper bound. This was accomplished only by setting the weight function values to the  $k$ -th root (e.g.,  $p_{X_{1,1}} = p_{X_{1,2}} = \sqrt[p_{X_1}]{|C(X_1)|} = 2$ ). We would expect the performance gap to be wider, favoring DIS, by optimizing the inequalities. For the lower bound, MB produced 0 for all problems and thus was not plotted. MB has a high tendency to converge to the so called degenerate solution (i.e., 0) due to the min function. The lower bound for DIS is tighter, as compared to the upper bounds, since the settings to the lower bound inequalities do not need to be optimized.

**Determinism strength.** We analyzed the performance of DIS and MB according to various levels of determinism, namely the distance from uniform .5 (unweighted) towards 0 and 1. To accomplish this, we set all weight functions to the same value  $p_X \in \{.5, .6, .7, .8, .9\}$ . The results are shown in Figures 1b and 1c. For the lower bound, MB produced 0 for all problems and thus was not plotted. The overall relative performance comparison is similar to that of varying grid size. Again, the lower bound performance for DIS is tighter and all bounds had higher bound error as the determinism strength increased. Intuitively, as the gap between  $p_{X_i}$  and  $\overline{p_{X_i}}$  widens, the tendency to overestimate (underestimate) the upper (lower) bound increases.

Table 4: The log relative upper bound between dissociation DIS(U) and mini-bucket MB(U) on UAI 2008 repository problem instances. Lower value is better for DIS.

Instance	$\log \frac{Z^{\text{DIS}(U)}}{Z^{\text{MB}(U)}}$	Instance	$\log \frac{Z^{\text{DIS}(U)}}{Z^{\text{MB}(U)}}$

orc42	407.9	orc225	499.7
orc45	747.8	orc139	576.6

## 5.2 UAI INFERENCE DATASETS

We also compared DIS to MB on the segmentation (sg), promedas (orc) and smokers (smk) dataset from the UAI 2008 repository. The variables in the models are binary and the number of variables range from  $\sim 100$  to 1000. We converted the non-pairwise models to pairwise models and then encoded them as W2CNF. We used  $i$ -bound = 1 for MB. We ran DIS and MB 100 times and similarly, we selected the best. For the upper bound, we evaluated using the log relative upper bound, namely  $\log(Z^{\text{DIS}(U)}/Z^{\text{MB}(U)})$ . Lower value is better for DIS. The results are shown in Table 4. DIS outperforms MB by a wide margin on the majority of the datasets. The solution quality of DIS for sg was quite consistent while for orc it had higher variance. For the lower bound, we evaluated dissociation’s lower bound against the ground truth, namely  $\log(Z^*/Z^{\text{DIS}(L)})$ . MB produced 0 for all problems and thus was not shown. The results are shown in Table 5 (orc62 was not tractable).

In summary, DIS performs consistently better than MB on harder WMC problems. In particular, the lower bounds

output by DIS are always better than MB.

## 6 CONCLUSION AND FUTURE WORK

We proposed an approximate, oblivious bounding scheme for WMC, extending the idea of dissociation to non-monotone formulas and exploiting logical structure. Dissociation yields a novel set of inequalities for which upper and lower bounds can be derived efficiently. Empirically, we showed that our method outperforms mini-buckets—a popular oblivious bounding scheme—on various datasets. The lower bounds are robust since they do not require optimization (in the monotone case). For upper bounds, we utilized naïve settings, namely the  $k$ -th root applied to the parameter of a dissociated variable.

For future work, we are interested in obtaining better (tighter) upper and lower bounds. To do so, we can leverage four powerful complementary techniques described in literature (cf. (Gogate and Domingos, 2011, 2013; Ihler et al., 2012; Lam et al., 2014; Liu and Ihler, 2011; Ping et al., 2015)): cost-shifting (or re-parameterization), higher  $i$ -bound, quantization and Hölder’s inequality. For instance, applying Hölder’s inequality to our running example (see Example 3) gives the optimization problem  $\min_{\omega} (p_{X_1}^{\omega} + (\overline{p_{X_1} p_{Y_2}})^{\omega})^{1/\omega} (1 + p_{Y_3}^{(1-\omega)})^{(1/1-\omega)}$  such that  $0 \leq \omega \leq 1$ . We can also apply Hölder’s inequality to dissociation which alternatively gives us the optimization problem  $\min_{p_{X_{1,1}}, p_{X_{1,2}}, \omega} (p_{X_{1,1}}^{\omega} + (\overline{p_{X_{1,1}} p_{Y_2}})^{\omega})^{1/\omega} (p_{X_{1,2}}^{(1-\omega)} + (\overline{p_{X_{1,2}} p_{Y_3}})^{(1-\omega)})^{(1/1-\omega)}$  such that  $p_{X_{1,1}} p_{X_{1,2}} = p_{X_1}$  and  $0 \leq \omega \leq 1$ . We are particularly interested in developing algorithms to optimize the latter problem and to determine which formulation will consistently yield tighter upper and lower bounds. Another line of future work is investigating the utility of our approach when applied to other inference tasks such as maximum a posteriori (MAP) estimation and marginal maximum a posteriori (MMAP) estimation.

## Abstract

Deep neural networks are typically trained by optimizing a loss function with an SGD variant, in conjunction with a decaying learning rate, until convergence. We show that simple averaging of multiple points along the trajectory of SGD, with a cyclical or constant learning rate, leads to better generalization than conventional training. We also show that this *Stochastic Weight Averaging* (SWA) procedure finds much broader optima than SGD, and approximates the recent *Fast Geometric Ensembling* (FGE) approach with a single model. Using SWA we achieve notable improvement in test accuracy over conventional SGD training on a range of state-of-the-art residual networks, PyramidNets, DenseNets, and Shake-Shake networks on CIFAR-10, CIFAR-100, and ImageNet. In short, SWA is extremely easy to implement, improves generalization, and has almost no computational overhead.

## 1 INTRODUCTION

With a better understanding of the loss surfaces for multilayer networks, we can accelerate the convergence, stability, and accuracy of training procedures in deep learning. Recent work [Garipov et al., 2018, Draxler et al., 2018] shows that local optima found by SGD can be connected by simple curves of near constant loss. Building upon this insight, Garipov et al. [2018] also developed *Fast Geometric Ensembling* (FGE) to sample multiple nearby points in weight space to create high performing ensembles in the time required to train a single DNN.

FGE uses a high frequency cyclical learning rate with SGD to select networks to ensemble. In Figure 1 (left)

we see that the weights of the networks ensembled by FGE are on the periphery of the most desirable solutions. This observation suggests it is promising to average these points in *weight space*, and use a network with these averaged weights, instead of forming an ensemble by averaging the outputs of networks in *model space*. Although the general idea of maintaining a running average of weights traversed by SGD dates back to Ruppert [1988], this procedure is not typically used to train neural networks. It is sometimes applied as an exponentially decaying running average in combination with a decaying learning rate (where it is called an exponential moving average), which smooths the trajectory of conventional SGD but does not perform very differently. However, we show that an equally weighted average of the points traversed by SGD with a cyclical or constant learning rate, which we refer to as *Stochastic Weight Averaging* (SWA), has many surprising and promising features for training deep neural networks, leading to a better understanding of the geometry of their loss surfaces. Indeed, SWA with cyclical or constant learning rates can be used as a drop-in replacement for standard SGD training of multilayer networks — but with improved generalization and essentially no overhead. In particular:

- We show that SGD with cyclical [e.g., Loshchilov and Hutter, 2017] and constant learning rates traverses regions of weight space corresponding to high-performing networks. We find that while these models are moving around this optimal set they never reach its central points. We show that we can move into this more desirable space of points by averaging the weights proposed over SGD iterations.
- While FGE ensembles [Garipov et al., 2018] can be trained in the same time as a single model, test predictions for an ensemble of  $k$  models requires  $k$  times more computation. We show that SWA can be interpreted as an approximation to FGE ensembles but with the test-time, convenience, and interpretability of a single model.

---

\*Equal contribution.

Figure 1: Illustrations of SWA and SGD with a Preactivation ResNet-164 on CIFAR-100<sup>1</sup>. **Left:** test error surface for three FGE samples and the corresponding SWA solution (averaging in weight space). **Middle and Right:** test error and train loss surfaces showing the weights proposed by SGD (at convergence) and SWA, starting from the same initialization of SGD after 125 training epochs.

- We demonstrate that SWA leads to solutions corresponding to wider optima than SGD. Keskar et al. [2017] and Hochreiter and Schmidhuber [1997] conjecture that the width of the optima is critically related to generalization. We illustrate that the loss on the train is shifted with respect to the test error (Figure 1, middle and right panels, and sections 3, 4). We show that SGD generally converges to a point near the boundary of the wide flat region of optimal points. SWA on the other hand is able to find a point centered in this region, often with slightly worse train loss but with substantially better test error.
- SWA achieves notable improvement for training a broad range of architectures over several consequential benchmarks. In particular, running SWA for just 10 epochs on ImageNet we are able to achieve 0.8% improvement for ResNet-50 and DenseNet-161, and 0.6% improvement for ResNet-150. We achieve improvement of over 1.3% on CIFAR-100 and of over 0.4% on CIFAR-10 with Preactivation ResNet-164, VGG-16 and Wide ResNet-28-10. We also achieve substantial improvement for the recent Shake-Shake Networks and PyramidNets.
- SWA is extremely easy to implement and has virtually no computational overhead compared to the conventional training schemes.
- We provide our implementation of SWA at <https://github.com/timgaripov/swa>.

## 2 RELATED WORK

This paper is fundamentally about better understanding the geometry of loss surfaces and generalization in deep learning. We follow the trajectory of weights traversed by SGD, leading to new geometric insights and the intuition that SWA will lead to better results than standard training. Empirically, we make the discovery that SWA

notably improves training of many state-of-the-art deep neural networks over a range of consequential benchmarks, with essentially no overhead.

The procedures for training neural networks are constantly being improved. New methods are being proposed for architecture design, regularization and optimization. The SWA approach is related to work in both optimization and regularization.

In optimization, there is great interest in how different types of local optima affect generalization in deep learning. Keskar et al. [2017] claim that SGD is more likely to converge to broad local optima than batch gradient methods, which tend to converge to sharp optima. Moreover, they argue that the broad optima found by SGD are more likely to have good test performance, even if the training loss is worse than for the sharp optima. On the other hand Dinh et al. [2017] argue that all the known definitions of sharpness are unsatisfactory and cannot on their own explain generalization. Chaudhari et al. [2017] propose the Entropy-SGD method that explicitly forces optimization towards wide valleys. They report that although the optima found by Entropy-SGD are wider than those found by conventional SGD, the generalization performance is still comparable.

The SWA method is based on averaging multiple points along the trajectory of SGD with cyclical or constant learning rates. The general idea of maintaining a running average of weights proposed by SGD was first considered in convex optimization by Ruppert [1988] and later by Polyak and Juditsky [1992]. However, this procedure is not typically used to train neural networks. Practi-

<sup>1</sup> Suppose we have three weight vectors  $w_1, w_2, w_3$ . We set  $u = (w_2 - w_1)$ ,  $v = (w_3 - w_1) - \langle w_3 - w_1, w_2 - w_1 \rangle / \|w_2 - w_1\|^2 \cdot (w_2 - w_1)$ . Then the normalized vectors  $\hat{u} = u / \|u\|$ ,  $\hat{v} = v / \|v\|$  form an orthonormal basis in the plane containing  $w_1, w_2, w_3$ . To visualize the loss in this plane, we define a Cartesian grid in the basis  $\hat{u}, \hat{v}$  and evaluate the networks corresponding to each of the points in the grid. A point  $P$  with coordinates  $(x, y)$  in the plane would then be given by  $P = w_1 + x \cdot \hat{u} + y \cdot \hat{v}$ .

tioners instead sometimes use an exponentially decaying running average of the weights found by SGD with a decaying learning rate, which smooths the trajectory of SGD but performs comparably.

SWA is making use of multiple samples gathered through exploration of the set of points corresponding to high performing networks. To enforce exploration we run SGD with constant or cyclical learning rates. Mandt et al. [2017] show that under several simplifying assumptions running SGD with a constant learning rate is equivalent to sampling from a Gaussian distribution centered at the minimum of the loss, and the covariance of this Gaussian is controlled by the learning rate. Following this explanation from [Mandt et al., 2017], we can interpret points proposed by SGD as being constrained to the surface of a sphere, since they come from a high dimensional Gaussian distribution. SWA effectively allows us to go inside the sphere to find higher density solutions.

In a procedure called Fast Geometric Ensembling (FGE), Garipov et al. [2018] showed that using a cyclical learning rate it is possible to gather models that are spatially close to each other but produce diverse predictions. They used the gathered models to train ensembles with no computational overhead compared to training a single DNN model. In recent work Neklyudov et al. [2018] also discuss an efficient approach for model averaging of Bayesian neural networks. SWA was inspired by following the trajectories of FGE proposals, in order to find a single model that would approximate an FGE ensemble, but provide greater interpretability, convenience, and test-time scalability.

Dropout [Srivastava et al., 2014] is an extremely popular approach to regularizing DNNs. Across each mini-batch used for SGD, a different architecture is created by randomly dropping out neurons. The authors make analogies between dropout, ensembling, and Bayesian model averaging. At test time, an ensemble approach is proposed, but then approximated with similar results by multiplying each connection by the dropout rate. At a high level, SWA and Dropout are both at once regularizers and training procedures, motivated to approximate an ensemble. Each approach implements these high level ideas quite differently, and as we show in our experiments, can be combined for improved performance.

### 3 STOCHASTIC WEIGHT AVERAGING

We present Stochastic Weight Averaging (SWA) and analyze its properties. In section 3.1, we consider trajectories of SGD with a constant and cyclical learning rate, which helps understand the geometry of SGD training for neural networks, and motivates the SWA procedure. Then in section 3.2 we present the SWA algorithm in

detail, in section 3.3 we derive its complexity, and in section 3.4 we analyze the width of optima found by SWA versus conventional SGD training. In section 3.5 we then examine the relationship between SWA and the recently proposed Fast Geometric Ensembling [Garipov et al., 2018]. Finally, in section 3.6 we consider SWA from the perspective of stochastic convex optimization.

We note the name SWA has two meanings: on the one hand, it is an average of SGD weights. On the other, with a cyclical or constant learning rate, SGD proposals are approximately sampling from the loss surface of the DNN, leading to stochastic weights.

#### 3.1 ANALYSIS OF SGD TRAJECTORIES

SWA is based on averaging the samples proposed by SGD using a learning rate schedule that allows exploration of the region of weight space corresponding to high-performing networks. In particular we consider cyclical and constant learning rate schedules.

The cyclical learning rate schedule that we adopt is inspired by Garipov et al. [2018] and Smith and Topin [2017]. In each cycle we linearly decrease the learning rate from  $\alpha_1$  to  $\alpha_2$ . The formula for the learning rate at iteration  $i$  is given by

$$\alpha(i) = (1 - t(i))\alpha_1 + t(i)\alpha_2,$$

$$t(i) = \frac{1}{c} (\text{mod}(i - 1, c) + 1).$$

The base learning rates  $\alpha_1 \geq \alpha_2$  and the cycle length  $c$  are the hyper-parameters of the method. Here by iteration we assume the processing of one batch of data. Figure 2 illustrates the cyclical learning rate schedule and the test error of the corresponding points. Note that unlike the cyclical learning rate schedule of Garipov et al. [2018] and Smith and Topin [2017], here we propose to use a discontinuous schedule that jumps directly from the minimum to maximum learning rates, and does *not* steadily increase the learning rate as part of the cycle. We use this more abrupt cycle because for our purposes exploration is more important than the accuracy of individual proposals. For even greater exploration, we also consider constant learning rates  $\alpha(i) = \alpha_1$ .

We run SGD with cyclical and constant learning rate schedules starting from a pretrained point for a Preactivation ResNet-164 on CIFAR-100. We then use the first, middle and last point of each of the trajectories to define a 2-dimensional plane in the weight space containing all affine combinations of these points. In Figure 3 we plot the loss on train and error on test for points in these planes. We then project the other points of the trajectory to the plane of the plot. Note that the trajectories do not generally lie in the plane of the plot, except for the

Figure 2: **Top:** cyclical learning rate as a function of iteration. **Bottom:** test error as a function of iteration for cyclical learning rate schedule with Preactivation-ResNet-164 on CIFAR-100. Circles indicate iterations corresponding to the minimum learning rates.

first, last and middle points, showed by black crosses in the figure. Therefore for other points of the trajectories it is not possible to tell the value of train loss and test error from the plots.

The key insight from Figure 3 is that both methods explore points close to the periphery of the set of high-performing networks. The visualizations suggest that both methods are doing exploration in the region of space corresponding to DNNs with high accuracy. The main difference between the two approaches is that the individual proposals of SGD with a cyclical learning rate schedule are in general much more accurate than the proposals of a fixed-learning rate SGD. After making a large step, SGD with a cyclical learning rate spends several epochs fine-tuning the resulting point with a decreasing learning rate. SGD with a fixed learning rate on the other hand is always making steps of relatively large sizes, exploring more efficiently than with a cyclical learning rate, but the individual proposals are worse.

Another important insight we can get from Figure 3 is that while the train loss and test error surfaces are qualitatively similar, they are not perfectly aligned. The shift between train and test suggests that more robust central points in the set of high-performing networks can lead to better generalization. Indeed, if we average several proposals from the optimization trajectories, we get a more robust point that has a substantially higher test performance than the individual proposals of SGD, and is essentially centered on the shifted mode for test error. We further discuss the reasons for this behaviour in sections 3.4, 3.5, 3.6.

### 3.2 SWA ALGORITHM

We now present the details of the Stochastic Weight Averaging algorithm, a simple but effective modification for training neural networks, motivated by our observations in section 3.1.

Following Garipov et al. [2018], we start with a pre-trained model  $\hat{w}$ . We will refer to the number of epochs required to train a given DNN with the conventional training procedure as its training budget and will denote it by  $B$ . The pretrained model  $\hat{w}$  can be trained with the conventional training procedure for full training budget or reduced number of epochs (e.g.  $0.75B$ ). In the latter case we just stop the training early without modifying the learning rate schedule. Starting from  $\hat{w}$  we continue training, using a cyclical or constant learning rate schedule. When using a cyclical learning rate we capture the models  $w_i$  that correspond to the minimum values of the learning rate (see Figure 2), following Garipov et al. [2018]. For constant learning rates we capture models at each epoch. Next, we average the weights of all the captured networks  $w_i$  to get our final model  $w_{\text{SWA}}$ .

Note that for cyclical learning rate schedule, the SWA algorithm is related to FGE [Garipov et al., 2018], except that instead of averaging the predictions of the models, we average their weights, and we use a different type of learning rate cycle. In section 3.5 we show how SWA can approximate FGE, but with a single model.

**Batch normalization.** If the DNN uses batch normalization [Ioffe and Szegedy, 2015], we run one additional pass over the data, as in Garipov et al. [2018], to compute the running mean and standard deviation of the activations for each layer of the network with  $w_{\text{SWA}}$  weights after the training is finished, since these statistics are not collected during training. For most deep learning libraries, such as PyTorch or Tensorflow, one can typically collect these statistics by making a forward pass over the data in training mode.

The SWA procedure is summarized in Algorithm 1.

### 3.3 COMPUTATIONAL COMPLEXITY

The time and memory overhead of SWA compared to conventional training is negligible. During training, we need to maintain a copy of the running average of DNN weights. Note however that the memory consumption in storing a DNN is dominated by its activations rather than its weights, and thus is only slightly increased by the SWA procedure, even for large DNNs (e.g., on the order of 10%). After the training is complete we only need to store the model that aggregates the average, leading to the same memory requirements as standard training.

Figure 3: The  $L_2$ -regularized cross-entropy train loss and test error surfaces of a Preactivation ResNet-164 on CIFAR-100 in the plane containing the first, middle and last points (indicated by black crosses) in the trajectories with **(left two)** cyclical and **(right two)** constant learning rate schedules.

---

### Algorithm 1 Stochastic Weight Averaging

---

**Require:**

weights  $\hat{w}$ , LR bounds  $\alpha_1, \alpha_2$ ,  
 cycle length  $c$  (for constant learning rate  $c = 1$ ), number of iterations  $n$

**Ensure:**  $w_{\text{SWA}}$

```

 $w \leftarrow \hat{w}$  {Initialize weights with  $\hat{w}$ }
 $w_{\text{SWA}} \leftarrow w$ 
for  $i \leftarrow 1, 2, \dots, n$  do
   $\alpha \leftarrow \alpha(i)$  {Calculate LR for the iteration}
   $w \leftarrow w - \alpha \nabla \mathcal{L}_i(w)$  {Stochastic gradient update}
  if  $\text{mod}(i, c) = 0$  then
     $n_{\text{models}} \leftarrow i/c$  {Number of models}
     $w_{\text{SWA}} \leftarrow \frac{w_{\text{SWA}} \cdot n_{\text{models}} + w}{n_{\text{models}} + 1}$  {Update average}
  end if
end for
{Compute BatchNorm statistics for  $w_{\text{SWA}}$  weights}

```

---

During training extra time is only spent to update the aggregated weight average. This operation is of the form

$$w_{\text{SWA}} \leftarrow \frac{w_{\text{SWA}} \cdot n_{\text{models}} + w}{n_{\text{models}} + 1},$$

and it only requires computing a weighted sum of the weights of two DNNs. As we apply this operation at most once per epoch, SWA and SGD require practically the same amount of computation. Indeed, a similar operation is performed as a part of each gradient step, and each epoch consists of hundreds of gradient steps.

### 3.4 OPTIMA WIDTH

Keskar et al. [2017] and Chaudhari et al. [2017] conjecture that the width of a local optimum is related to generalization. The general explanation for the importance of width is that the surfaces of train loss and test error are shifted with respect to each other and it is thus desirable to converge to the modes of broad optima, which stay approximately optimal under small perturbations. In this section we compare the solutions found by SWA and SGD and show that SWA generally leads to much wider optima.

Let  $w_{\text{SWA}}$  and  $w_{\text{SGD}}$  denote the weights of DNNs trained using SWA and conventional SGD, respectively. Consider the rays

$$w_{\text{SWA}}(t, d) = w_{\text{SWA}} + t \cdot d,$$

$$w_{\text{SGD}}(t, d) = w_{\text{SGD}} + t \cdot d,$$

which follow a direction vector  $d$  on the unit sphere, starting at  $w_{\text{SWA}}$  and  $w_{\text{SGD}}$ , respectively. In Figure 4 we plot train loss and test error of  $w_{\text{SWA}}(t, d_i)$  and  $w_{\text{SGD}}(t, d_i)$  as a function of  $t$  for 10 random directions  $d_i, i = 1, 2, \dots, 10$  drawn from a uniform distribution on the unit sphere. For this visualization we use a Preactivation ResNet-164 on CIFAR-100.

First, while the loss values on train for  $w_{\text{SGD}}$  and  $w_{\text{SWA}}$  are quite similar (and in fact  $w_{\text{SGD}}$  has a slightly lower train loss), the test error for  $w_{\text{SGD}}$  is lower by 1.5% (at the converged value corresponding to  $t = 0$ ). Further, the shapes of both train loss and test error curves are considerably wider for  $w_{\text{SWA}}$  than for  $w_{\text{SGD}}$ , suggesting that SWA indeed converges to a wider optimum: we have to step much further away from the solution found by  $w_{\text{SWA}}$  to increase error by a given amount. We even see the error curve for SGD has an inflection point that is not present for these distances with SWA.

Notice that in Figure 4 any of the random directions from  $w_{\text{SGD}}$  increase test error. However, we know that the direction from  $w_{\text{SGD}}$  to  $w_{\text{SWA}}$  would decrease test error, since  $w_{\text{SWA}}$  has considerably lower test error than  $w_{\text{SGD}}$ . In other words, the path from  $w_{\text{SGD}}$  to  $w_{\text{SWA}}$  is qualitatively different from all directions shown in Figure 4, because along this direction  $w_{\text{SGD}}$  is far from optimal. We therefore consider the line segment connecting  $w_{\text{SGD}}$  and  $w_{\text{SWA}}$ :

$$w(t) = t \cdot w_{\text{SGD}} + (1 - t) \cdot w_{\text{SWA}}.$$

In Figure 5 we plot the train loss and test error of  $w(t)$  as a function of signed distance from  $w_{\text{SWA}}$  for Preactivation ResNet-164 and VGG-16 on CIFAR-100.

We can extract several key insights about  $w_{\text{SWA}}$  and  $w_{\text{SGD}}$  from Figure 5. First, the train loss and test error plots are indeed substantially shifted, and the point obtained

Figure 4: **(Left)** Test error and **(Right)**  $L_2$ -regularized cross-entropy train loss as a function of a point on a random ray starting at SWA (blue) and SGD (green) solutions for Preactivation ResNet-164 on CIFAR-100. Each line corresponds to a different random ray.

Figure 5:  $L_2$ -regularized cross-entropy train loss and test error as a function of a point on the line connecting SWA and SGD solutions on CIFAR-100. **Left:** Preactivation ResNet-164. **Right:** VGG-16.

by minimizing the train loss is far from optimal on test. Second,  $w_{\text{SGD}}$  lies near the boundary of a wide flat region of the train loss. Further, the loss is very steep near  $w_{\text{SGD}}$ .

Keskar et al. [2017] argue that the loss near sharp optima found by SGD with very large batches are actually flat in most directions, but there exist directions in which the optima are extremely steep. They conjecture that because of this sharpness the generalization performance of large batch optimization is substantially worse than that of solutions found by small batch SGD. Remarkably, in our experiments in this section we observe that there exist directions of steep ascent even for small batch optima, and that SWA provides even wider solutions (at least along random directions) with better generalization.

### 3.5 CONNECTION TO ENSEMBLING

Garipov et al. [2018] proposed the Fast Geometric Ensembling (FGE) procedure for training ensembles in the time required to train a single model. Using a cyclical learning rate, FGE generates a sequence of points that are close to each other in the weight space, but produce diverse predictions. In SWA instead of averaging the predictions of the models we average their weights. However, the predictions proposed by FGE ensembles and SWA models have similar properties.

Let  $f(\cdot)$  denote the predictions of a neural network

parametrized by weights  $w$ . We will assume that  $f$  is a scalar (e.g. the probability for a particular class) twice continuously differentiable function with respect to  $w$ .

Consider points  $w_i$  proposed by FGE. These points are close in the weight space by design, and concentrated around their average  $w_{\text{SWA}} = \frac{1}{n} \sum_{i=1}^n w_i$ . We denote  $\Delta_i = w_i - w_{\text{SWA}}$ . Note  $\sum_{i=1}^n \Delta_i = 0$ . Ensembling the networks corresponds to averaging the function values

$$\bar{f} = \frac{1}{n} \sum_{i=1}^n f(w_i).$$

Consider the linearization of  $f$  at  $w_{\text{SWA}}$ .

$$f(w_j) = f(w_{\text{SWA}}) + \langle \nabla f(w_{\text{SWA}}), \Delta_j \rangle + O(\|\Delta_j\|^2),$$

where  $\langle \cdot, \cdot \rangle$  denotes the dot product. Thus, the difference between averaging the weights and averaging the predictions

$$\begin{aligned} \bar{f} - f(w_{\text{SWA}}) &= \frac{1}{n} \sum_{i=1}^n (\langle \nabla f(w_{\text{SWA}}), \Delta_i \rangle + O(\|\Delta_i\|^2)) \\ &= \left\langle \nabla f(w_{\text{SWA}}), \frac{1}{n} \sum_{i=1}^n \Delta_i \right\rangle + O(\Delta^2) = O(\Delta^2), \end{aligned}$$

where  $\Delta = \max_{i=1}^n \|\Delta_i\|$ . Note that the difference between the predictions of different perturbed networks is

$$f(w_i) - f(w_j) = \langle \nabla f(w_{\text{SWA}}), \Delta_i - \Delta_j \rangle + O(\Delta^2),$$

and is thus of the first order of smallness, while the difference between averaging predictions and averaging weights is of the second order of smallness. Note that for the points proposed by FGE the distances between proposals are relatively small by design, which justifies the local analysis.

To analyze the difference between ensembling and averaging the weights of FGE proposals in practice, we run FGE for 20 epochs and compare the predictions of different models on the test dataset with a Preactivation ResNet-164 [He et al., 2016] on CIFAR-100. The norm of the difference between the class probabilities of consecutive FGE proposals averaged over the test dataset is 0.126. We then average the weights of the proposals and compute the class probabilities on the test dataset. The norm of difference of the probabilities for the SWA model and the FGE ensemble is 0.079, which is substantially smaller than the difference between the probabilities of consecutive FGE proposals. Further, the fraction of objects for which consecutive FGE proposals output the same labels is not greater than 87.33%. For FGE and SWA the fraction of identically labeled objects is 95.26%.

The theoretical considerations and empirical results presented in this section suggest that SWA can approximate the FGE ensemble with a single model.

### 3.6 CONNECTION TO CONVEX MINIMIZATION

Mandt et al. [2017] showed that under strong simplifying assumptions SGD with a fixed learning rate approximately samples from a Gaussian distribution centered at the minimum of the loss. Suppose this is the case when we run SGD with a fixed learning rate for training a DNN.

Let us denote the dimensionality of the weight space of the neural network by  $d$ . Denote the samples produced by SGD by  $w_i$ ,  $i = 1, 2, \dots, k$ . Assume the points  $w_i$  are concentrated around the local optimum  $\hat{w}$ . The SWA solution is given by  $w_{\text{SWA}} = \frac{1}{n} \sum_{i=1}^k w_i$ . The points  $w_i$  are samples from a multidimensional Gaussian  $\mathcal{N}(\hat{w}, \Sigma)$  for some covariance matrix  $\Sigma$  defined by the curvature of the loss, batch size and the learning rate. Note that the samples from a multidimensional Gaussian are concentrated on the ellipsoid

$$\left\{ z \in \mathbb{R}^d \mid \|\Sigma^{-\frac{1}{2}}(z - \hat{w})\| = \sqrt{d} \right\},$$

and the probability mass for a sample to end up inside the ellipsoid near  $\hat{w}$  is negligible. On the other hand,  $w_{\text{SWA}}$  is guaranteed to converge to  $\hat{w}$  as  $k \rightarrow \infty$ .

Moreover, Polyak and Juditsky [1992] showed that averaging SGD proposals achieves the best possible conver-

gence rate among all stochastic gradient algorithms. The proof relies on the convexity of the underlying problem and in general there are no convergence guarantees if the loss function is non-convex [see e.g. Ghadimi and Lan, 2013]. While DNN loss functions are known to be non-convex [e.g. Choromanska et al., 2015], over the trajectory of SGD these loss surfaces are approximately convex [e.g. Goodfellow et al., 2015]. However, even when the loss is locally non-convex, SWA can improve *generalization*. For example, in Figure 5 we see that SWA converges to a central point of the training loss.

## 4 EXPERIMENTS

We compare SWA against conventional SGD training on CIFAR-10, CIFAR-100 and ImageNet ILSVRC-2012 [Russakovsky et al., 2012]. We also compare to Fast Geometric Ensembling (FGE) [Garipov et al., 2018], but we note that FGE is an ensemble whereas SWA corresponds to a single model. Conventional SGD training uses a standard decaying learning rate schedule (details in the Appendix) until convergence. We found an exponentially decaying average of SGD to perform comparably to conventional SGD at convergence. We release the code for reproducing the results in this paper at <https://github.com/timgaripov/swa>.

### 4.1 CIFAR DATASETS

For the experiments on CIFAR datasets we use VGG-16 [Simonyan and Zisserman, 2014], a 164-layer Preactivation-ResNet [He et al., 2016] and Wide ResNet-28-10 [Zagoruyko and Komodakis, 2016] models. Additionally, we experiment with the recent Shake-Shake-2x64d [Gastaldi, 2017] on CIFAR-10 and PyramidNet-272 (bottleneck,  $\alpha = 200$ ) [Han et al., 2016] on CIFAR-100. All models are trained using  $L_2$ -regularization, and VGG-16 also uses dropout.

For each model we define *budget* as the number of epochs required to train the model until convergence with conventional SGD training, such that we do not see improvement with SGD beyond this budget. We use the same budgets for VGG, Preactivation ResNet and Wide ResNet models as Garipov et al. [2018]. For Shake-Shake and PyramidNets we use the budgets indicated by the papers that proposed these models [Gastaldi, 2017, Han et al., 2016]. We report the results of SWA training within 1, 1.25 and 1.5 budgets of epochs.

For VGG, Wide ResNet and Preactivation-ResNet models we first run standard SGD training for  $\approx 75\%$  of the training budget, and then use the weights at the last epoch as an initialization for SWA with a fixed learning rate schedule. We ran SWA for 0.25, 0.5 and 0.75 budget to complete the training within 1, 1.25 and 1.5 budgets

Table 1: Accuracies (%) of SWA, SGD and FGE methods on CIFAR-100 and CIFAR-10 datasets for different training budgets. Accuracies for the FGE ensemble are from Garipov et al. [2018].

DNN (Budget)	SGD	FGE (1 Budget)	SWA		
			1 Budget	1.25 Budgets	1.5 Budgets
CIFAR-100					
VGG-16 (200)	72.55 ± 0.10	74.26	73.91 ± 0.12	74.17 ± 0.15	74.27 ± 0.25
ResNet-164 (150)	78.49 ± 0.36	79.84	79.77 ± 0.17	80.18 ± 0.23	80.35 ± 0.16
WRN-28-10 (200)	80.82 ± 0.23	82.27	81.46 ± 0.23	81.91 ± 0.27	82.15 ± 0.27
PyramidNet-272 (300)	83.41 ± 0.21	–	–	83.93 ± 0.18	84.16 ± 0.15
CIFAR-10					
VGG-16 (200)	93.25 ± 0.16	93.52	93.59 ± 0.16	93.70 ± 0.22	93.64 ± 0.18
ResNet-164 (150)	95.28 ± 0.10	95.45	95.56 ± 0.11	95.77 ± 0.04	95.83 ± 0.03
WRN-28-10 (200)	96.18 ± 0.11	96.36	96.45 ± 0.11	96.64 ± 0.08	96.79 ± 0.05
ShakeShake-2x64d (1800)	96.93 ± 0.10	–	–	97.16 ± 0.10	97.12 ± 0.06

respectively.

For Shake-Shake and PyramidNet architectures we do not report the results in one budget. For these models we use a full budget to get an initialization for the procedure, and then train with a cyclical learning rate schedule for 0.25 and 0.5 budgets. We used long cycles of small learning rates for Shake-Shake, because this architecture already involves many stochastic components.

We present the details of the learning rate schedules for each of these models in the Appendix.

For each model we also report the results of conventional SGD training, which we denote by **SGD**. For VGG, Preactivation ResNet and Wide ResNet we also provide the results of the **FGE** method with one budget reported in Garipov et al. [2018]. Note that for FGE we report the accuracy of an ensemble of 6 to 12 networks, while for SWA we report the accuracy of a single model.

We summarize the experimental results in Table 1. For all models we report the mean and standard deviation of test accuracy over 3 runs. In all conducted experiments SWA substantially outperforms SGD in one budget, and improves further, as we allow more training epochs. Across different architectures we see consistent improvement by  $\approx 0.5\%$  on CIFAR-10 (excluding Shake-Shake, for which SGD performance is already extremely high) and by 0.75-1.5% on CIFAR-100. Amazingly, SWA is able to achieve comparable or better performance than FGE ensembles with just one model. On CIFAR-100 SWA usually needs more than one budget to get results comparable with FGE ensembles, but on CIFAR-10 even with 1 budget SWA outperforms FGE.

## 4.2 IMAGENET

On ImageNet we experimented with ResNet-50, ResNet-152 [He et al., 2016] and DenseNet-161 [Huang et al.,

2017]. For these architectures we used pretrained models from `PyTorch.torchvision`. For each of the models we ran SWA for 10 epochs with a cyclical learning rate schedule with the same parameters for all models (the details can be found in the Appendix), and report the mean and standard deviation of test error averaged over 3 runs. The results are shown in Table 2.

Table 2: Accuracies (%) on ImageNet dataset for SWA and SGD with different architectures.

DNN	SGD	SWA	
		5 epochs	10 epochs
ResNet-50	76.15	76.83 ± 0.01	76.97 ± 0.05
ResNet-152	78.31	78.82 ± 0.01	78.94 ± 0.07
DenseNet-161	77.65	78.26 ± 0.09	78.44 ± 0.06

For all 3 architectures SWA provides consistent improvement by 0.6-0.9% over the pretrained models.

## 4.3 EFFECT OF THE LEARNING RATE SCHEDULE

In this section we explore how the learning rate schedule affects the performance of SWA. We run experiments on Preactivation ResNet-164 on CIFAR-100. For all schedules we use the same initialization from a model trained for 125 epochs using the conventional SGD training. As a baseline we use a fully-trained model trained with conventional SGD for 150 epochs.

We consider a range of constant and cyclical learning rate schedules. For cyclical learning rates we fix the cycle length to 5, and consider the pairs of base learning rate parameters  $(\alpha_1, \alpha_2) \in \{(10^{-1}, 10^{-3}), (5 \cdot 10^{-2}, 5 \cdot 10^{-4}), (10^{-2}, 10^{-4}), (5 \cdot 10^{-3}, 5 \cdot 10^{-5})\}$ . Among the constant learning rates we consider  $\alpha_1 \in \{10^{-1}, 5 \cdot 10^{-2}, 10^{-2}, 10^{-3}\}$ .

Figure 6: Test error as a function of training epoch for SWA with different learning rate schedules with a Pre-activation ResNet-164 on CIFAR-100.

We plot the test error of the SWA procedure for different learning rate schedules as a function of the number of training epochs in Figure 6.

We find that in general the more aggressive constant learning rate schedule leads to faster convergence of SWA. In our experiments we found that setting the learning rate to some intermediate value between the largest and the smallest learning rate used in the annealing scheme in conventional training usually gave us the best results. The approach is however universal and can work well with different learning rate schedules tailored for particular tasks.

#### 4.4 DNN TRAINING WITH A FIXED LEARNING RATE

Figure 7: Test error as a function of training epoch for constant (green) and decaying (blue) learning rate schedules for a Wide ResNet-28-10 on CIFAR-100. In red we average the points along the trajectory of SGD with constant learning rate starting at epoch 140.

In this section we show that it is possible to train DNNs from scratch with a fixed learning rate using SWA. We run SGD with a fixed learning rate of 0.05 on a Wide ResNet-28-10 [Zagoruyko and Komodakis, 2016] for 300 epochs from a random initialization on CIFAR-100.

We then averaged the weights at the end of each epoch from epoch 140 and until the end of training. The final test accuracy of this SWA model was 81.7.

Figure 7 illustrates the test error as a function of the number of training epochs for SWA and conventional training. The accuracy of the individual models with weights averaged by SWA stays at the level of  $\approx 65\%$  which is 16% less than the accuracy of the SWA model. These results correspond to our intuition presented in section 3.6 that SGD with a constant learning rate oscillates around the optimum, but SWA converges.

While being able to train a DNN with a fixed learning rate is a surprising property of SWA, for practical purposes we recommend initializing SWA from a model pre-trained with conventional training (possibly for a reduced number of epochs), as it leads to faster and more stable convergence than running SWA from scratch.

## 5 DISCUSSION

We have presented Stochastic Weight Averaging (SWA) for training neural networks. SWA is extremely easy to implement, architecture-agnostic, and improves generalization performance at virtually no additional cost over conventional training.

There are so many exciting directions for future research. SWA does not require each weight in its average to correspond to a good solution, due to the geometry of weights traversed by the algorithm. It therefore may be possible to develop SWA for much faster convergence than standard SGD. One may also be able to combine SWA with large batch sizes while preserving generalization performance, since SWA discovers much broader optima than conventional SGD training. Furthermore, a cyclic learning rate enables SWA to explore regions of high posterior density over neural network weights. Such learning rate schedules could be developed in conjunction with stochastic MCMC approaches, to encourage exploration while still providing high quality samples. One could also develop SWA to average whole regions of good solutions, using the high-accuracy curves discovered in Garipov et al. [2018].

A better understanding of the loss surfaces for multilayer networks will help continue to unlock the potential of these rich models. We hope that SWA will inspire further progress in this area.

## Abstract

One popular way for lifted inference in probabilistic graphical models is to first merge symmetric states into a single cluster (orbit) and then use these for downstream inference, via variations of orbital MCMC [Niepert, 2012]. These orbits are represented compactly using permutations over variables, and variable-value (VV) pairs, but they can miss several state symmetries in a domain.

We define the notion of permutations over block-value (BV) pairs, where a block is a set of variables. BV strictly generalizes VV symmetries, and can compute many more symmetries for increasing block sizes. To operationalize use of BV permutations in lifted inference, we describe 1) an algorithm to compute BV permutations given a block partition of the variables, 2) BV-MCMC, an extension of orbital MCMC that can sample from BV orbits, and 3) a heuristic to suggest good block partitions. Our experiments show that BV-MCMC can mix much faster compared to vanilla MCMC and orbital MCMC.

## 1 INTRODUCTION

A *lifted inference* algorithm for probabilistic graphical models (PGMs) performs inference on a smaller model, which is constructed by merging together states (or variables) of the original model [Poole, 2003; de Salvo Braz *et al.*, 2005; Kimmig *et al.*, 2015]. Two main kinds of lifted inference algorithms exist: those where lifting is tied to an existing inference procedure such as belief propagation [Singla and Domingos, 2008; Kersting *et al.*, 2009], Gibbs sampling [Venugopal and Gogate, 2012], weighted model counting [Gogate and Domingos, 2011],

variational inference [Bui *et al.*, 2013] and linear programming [Mladenov *et al.*, 2012]; and those that merge symmetric states/variables independent of the procedure [Niepert, 2012; Van den Broeck and Niepert, 2015; Anand *et al.*, 2016].

One approach for generating symmetries is by computing isomorphism over a graphical representation of the PGM. This merges symmetric states into a single cluster (orbit), which is compactly represented as permutations over a polynomial representation. Permutations over variables [Niepert, 2012] and over variable-value (VV) pairs [Anand *et al.*, 2017] have been studied, with latter being a generalization of the former, capturing many more state symmetries. While more general, VV permutations clearly do not capture all possible state symmetries in a domain. For example, state  $s_1 = (0, 0, 0, 0)$  is symmetric to  $s_2 = (0, 1, 1, 1)$  in Figure 1(b), but VV permutations cannot represent it.

A natural question arises: are there more general representations which can capture (a subset of) these larger set of symmetries? We note that the problem of computing all possible symmetries is intractable since there is an exponential number of permutations over an exponentially large state space, each of which could be a symmetry (or not). Nevertheless, we hope there are representations which can capture additional symmetries compared to current approaches in bounded polynomial time. More so, it would be interesting to come up with a representation that enables computation of larger and larger sets of symmetries, while paying additional costs, which could be controlled as a function of a parameter of the representation.

As a significant step toward this research question, we develop the novel notion of symmetries defined over *block-value (BV) pairs*. Here, a block is a set of variables, and its value is an assignment to these variables. Intuitively, BV pairs can capture all such VV pairs that are not permuted independently, instead, are

$X_1=0$	$X_2=1$	$\Phi$
0	0	a
0	1	b
1	0	c
1	1	c

(a)

$X_1=0$	$X_2=1$	$\Phi$	$X_3=0$	$X_4=1$	$\Phi$
0	0	a	0	0	b
0	1	b	0	1	d
1	0	c	1	0	c
1	1	d	1	1	a

(b)

Figure 1: Block-Value Symmetries (a) BV Symmetries within a block (b) BV Symmetries across blocks

permuted in subsets together. For example, it can capture symmetry of states  $s_1$  and  $s_2$  via a BV permutation which maps  $\{(X_1, 0), (X_2, 0)\} \leftrightarrow \{(X_3, 1), (X_4, 1)\}$  and  $\{(X_1, 0), (X_2, 1)\} \leftrightarrow \{(X_3, 0), (X_4, 0)\}$ .

Clearly, symmetries defined over BV pairs are a strict generalization of those over VV pairs, since each VV pair is a BV pair with a block of size 1. Our blocks can be of varying sizes and the size of each block essentially controls the set of symmetries that can be captured; larger the blocks, more the symmetries, coming at an additional cost (exponential in the max size of a block).

In this paper, we formally develop the notion of symmetries as permutations defined over a subset of BV pairs. Some of these permutations will be invalid (when blocks overlap with each other) and their application may lead to inconsistent state. In order to ensure valid permutations, we require that the blocks come from a disjoint set of blocks, referred to as a *block partition*. Given a block partition, we show how to compute the corresponding set of symmetries by reducing the problem to one of graph isomorphism. We also show that our BV symmetries can be thought of as VV symmetries, albeit over a transformed graphical model, where the new variables represent the blocks in the original graph.

Next, we show that jointly considering symmetries obtained from different block partitions can result in capturing symmetries not obtainable from any single one. Since, there is an exponential number of such block partitions, we provide an efficient heuristic for obtaining a promising partition of blocks, referred to as a *candidate set*.

Use of BV symmetries in an MCMC framework requires uniform sampling of a state from each orbit, i.e., a set of symmetric states. This turns out to be a non-trivial task when the orbits are defined over symmetries corresponding to different block partitions. In response, we design an aggregate Markov chain which samples from orbits corresponding to each (individual) candidate set in turn.

We prove that our aggregate Markov chain converges to the desired distribution. As a proof of the utility of our BV symmetries, we show that their usage results in significantly faster mixing times on two different domains.

The outline of this paper is as follows. We start with some background on variable and VV symmetries in Section 2. This is followed by the exposition of our symmetries defined over BV pairs (Section 3). Section 4 describes our algorithm for using BV symmetries in MCMC. This is followed by our heuristic to compute promising candidate sets in Section 5. We present our experimental evaluation (Section 6) and conclude the paper with directions for future work.

## 2 BACKGROUND

Let  $\mathcal{X} = \{X_1, X_2, \dots, X_n\}$  denote a set of discrete valued random variables. We will use the symbol  $x_i$  to denote the value taken by the variable  $X_i$ . We will assume that each of the variables comes from the same domain  $\mathcal{D}$ . A state  $s \in \mathcal{D}^n$  is an assignment to all the variables in the set  $\mathcal{X}$ . Further,  $s(X_i) = x_i$  gives the value of variable  $X_i$  in state  $s$ . We will use  $\mathcal{S}$  to denote the set of all possible states.

A Graphical Model [Koller and Friedman, 2009] is a set of pairs  $\{(f_j, w_j)\}_{j=1}^m$  where  $f_j$  is a feature function defined over the variables in the set  $\mathcal{X}$  and  $w_j$  is its associated weight.

**Definition 1.** Action of  $\theta$  on  $\mathcal{G}$  results in a new graphical model where the occurrence of  $X_i$  in each feature  $f_j$  in  $\mathcal{G}$  is replaced by  $\theta(X_i)$ . Given a graphical model  $\mathcal{G}$ , a permutation  $\theta$  of the variables in  $\mathcal{X}$  is said to be a **variable symmetry** of  $\mathcal{G}$  if the action of  $\theta$  on  $\mathcal{G}$  results back in  $\mathcal{G}$ .

Given a state  $s \in \mathcal{S}$ , the action of  $\theta$  on  $s$ , denoted by  $\theta(s)$ , results in a new state  $s'$  such that  $\forall X_i, X_j \in \mathcal{X}$  if  $\theta(X_i) = X_j$  and  $s(X_j) = x_j$  then  $s'(X_i) = x_j$ .

The set of all variable symmetries forms a group called *the variable automorphic group* of  $\mathcal{G}$  and is denoted by  $\Theta$ .  $\Theta$  partitions the states into equivalence classes or orbits which are as defined below.

**Definition 2.** Given a variable automorphic group  $\Theta$ , the **orbit** of a state  $s$  under the effect of  $\Theta$  is defined as  $\Gamma_{\Theta}(s) = \{\theta(s) | \theta \in \Theta\}$ .

Intuitively, the orbit of a state  $s$  is set of all states reachable from  $s$  under the action of any permutation in the automorphic group.

We note that variable symmetries are probability preserving transformations [Niepert, 2012]. Let  $\mathcal{P}$  denote the distribution defined by a graphical model  $\mathcal{G}$  where  $\mathcal{P}(s)$  is the probability of a state  $s$ .

**Theorem 1.** If  $\Theta$  is a variable automorphic group of  $\mathcal{G}$ , then  $\forall s \in \mathcal{S}, \forall \theta \in \Theta, \mathcal{P}(s) = \mathcal{P}(\theta(s))$ .

Anand et al. [2017] extend the notion of variable symmetries to those defined over variable value (VV) pairs. Let  $(X_i, x_i)$  denote a VV pair and let  $\mathcal{X}_V$  denote the set of all possible such pairs. Let  $\phi$  denote a permutation over the set  $\mathcal{X}_V$ . Action of  $\phi$  on state  $s$ , denoted by  $\phi(s)$ , results in a state  $s'$ , such that  $\forall X_i, X_j \in \mathcal{X}$ , if  $\phi(X_i, s(X_i)) = (X_j, x_j)$ , then  $s'(X_j) = x_j$ .

There are some VV permutations which when applied to a state  $s$  may result in an inconsistent state. For instance, let  $\phi(X_0, 0) = (X_0, 0)$ ,  $\phi(X_1, 1) = (X_0, 1)$  and  $s = (0, 1)$ , then  $\phi(s)$  results in an inconsistent state with multiple values being assigned to  $X_0$ . Therefore, the notion of valid VV permutation needs to be defined which when applied to any state  $s \in \mathcal{S}$  always results in a consistent state  $s'$  [Anand et al., 2017].

**Definition 3.** A VV permutation  $\phi$  over  $\mathcal{X}_V$  is said to be a **valid VV permutation** if whenever there exists a VV pair  $(X_i, x_i)$  such that  $\phi(X_i, x_i) = (X_j, x_j)$ , then for all the VV pairs of the form  $(X_i, x'_i)$  where  $x'_i \in \mathcal{D}_i$ ,  $\phi(X_i, x_i) = (X_j, x'_j)$  where  $x'_j \in \mathcal{D}_j$ .

**Definition 4.** Action of  $\phi$  on  $\mathcal{G}$  results in a new graphical model where the occurrence of  $(X_i, x_i)$  in each feature  $f_j$  in  $\mathcal{G}$  is replaced by  $\phi(X_i, x_i)$ . We say that  $\phi$  is a **VV symmetry** of  $\mathcal{G}$ , if action of  $\phi$  on  $\mathcal{G}$  results back in  $\mathcal{G}$ .

Similar to variable symmetries, the set of all VV symmetries form a group called the VV automorphic group of  $\mathcal{G}$  and is denoted by  $\Phi$ . Analogously,  $\Phi$  partitions the states into orbits defined as  $\Gamma_{\Phi}(s) = \{\phi(s) | \forall \phi \in \Phi\}$ .

In the following, we will often refer to the automorphic groups  $\Theta$  and  $\Phi$  as symmetry groups of  $\mathcal{G}$ . It can be easily seen that VV symmetries subsume variable symmetries and like variable symmetries, they are also probability preserving transformations.

**Theorem 2.** If  $\Phi$  is a VV automorphic group of  $\mathcal{G}$ , then  $\forall s \in \mathcal{S}, \forall \phi \in \Phi, \mathcal{P}(s) = \mathcal{P}(\phi(s))$

The orbits so obtained through variable (VV) symmetries can then be exploited for faster mixing by Markov Chain Monte Carlo (MCMC) based methods as described below.

## 2.1 Orbital-MCMC

Markov Chain Monte Carlo (MCMC) methods [Koller and Friedman, 2009] are one of the popular algorithms for approximate inference in Probabilistic Graphical Models. Starting with a random state, these methods set up a Markov chain over the state space whose stationary distribution is same as the desired distribution. Convergence is guaranteed in the limit of a large number of samples coming from the Markov chain.

Orbital MCMC and VV-MCMC improve MCMC methods by exploiting Variable and VV symmetries, respectively. Given a Markov chain  $\mathcal{M}$  and a symmetry group  $\Phi$ , starting from a sample  $s_t$ , any subsequent sample is obtained in 2 steps: a) An intermediate state  $s'$  is obtained according to  $\mathcal{M}$  b) The next sample  $s_{t+1}$  is obtained by sampling a state uniformly from the orbit (Variable or VV) of the intermediate state  $s'$ . Sampling a state from the orbit of the intermediate state is done using the Product Replacement Algorithm [Celler et al., 1995; Pak, 2000]. This two step chain so obtained converges to the true stationary distribution and has been shown to have better mixing both theoretically [Niepert, 2012] and empirically [Niepert, 2012; Anand et al., 2017]. The key insight exploited by these algorithms is the fact that all the states in any given orbit have the same probability.

## 3 BLOCK-VALUE SYMMETRIES

In this section, we will present symmetries defined over blocks of variables, referred to as *BV Symmetries* which strictly generalize the earlier notions of symmetries defined over VV pairs. As a motivating example, Figure 1 shows two Graphical Models  $\mathcal{G}_1$  and  $\mathcal{G}_2$ . For ease of explanation these have been represented in terms of potential tables. These can easily be converted to the weighted feature representation, as defined previously. In  $\mathcal{G}_1$ , state  $(1, 0)$  has the same joint probability as  $(1, 1)$  and in  $\mathcal{G}_2$ , state  $(0, 0, 0, 0)$  has the same joint probability as  $(0, 1, 1, 1)$ . However, none of these can be captured by Variable or VV symmetries. We start with some definitions.

**Definition 5.** Let  $B = \{X_1, X_2, \dots, X_r\}$  denote a set of variables ( $X_i \in \mathcal{X}$ ) which we will refer to as a **block**. Similarly, let  $b = \{x_1, x_2, \dots, x_r\}$  denote a set of (cor-

responding) assignments to the variables in the block  $B$ . Then, we refer to the pair  $(B, b)$  as a **Block-Value (BV) pair**.

**Definition 6.** A BV pair  $(B, b)$  is said to be **consistent** with a state  $s$  if  $\forall X_i \in B, s(X_i) = x_i$  where  $x_i$  is the value for variable  $X_i$  in block  $B$ .

Let  $\Delta_V^r$  denote some subset of all possible BV pairs defined over blocks of size less than equal to  $r$ . For ease of notation, we will drop superscript  $r$  and denote  $\Delta_V^r$  as  $\Delta_V$  where  $r$  is a pre-specified constant for maximum block size. Then, we are interested in defining permutations over the elements of the set  $\Delta_V$ . Considering any set of block-value pairs in  $\Delta_V$  and allowing permutation among them may lead to inconsistent states. Consider a graphical model defined over four variables:  $\{X_1, X_2, X_3, X_4\}$ . Let us consider all possible blocks of size  $\leq 2$ . Then, a BV permutation permuting the singleton block  $\{X_1\}$  to itself (with identity mapping on values) while at the same time, permuting the block  $\{X_1, X_3\}$  to the block  $\{X_2, X_4\}$  is clearly inconsistent since  $X_1$ 's value can not be determined uniquely. A natural way to avoid this inconsistency is to restrict each variable to be a part of single block while applying permutations. Therefore, we restrict our attention to sets of blocks which are non overlapping.

**Definition 7.** Let  $\Delta = \{B_1, B_2, \dots, B_L\}$  denote a set of blocks. We define  $\Delta$  to be a **partition** if each variable  $X_i \in \mathcal{X}$  appears in exactly one block in  $\Delta$ . For a partition  $\Delta$ , we define the **block value set**  $\Delta_V$  as a set of BV pairs where each block  $B_l \in \Delta$  is present with all of its possible assignments.

We would now like to define permutations over the block value set  $\Delta_V$ , which we refer to as *BV-permutations*. To begin, we define the action of a BV-permutation  $\psi : \Delta_V \rightarrow \Delta_V$  on a state  $s$ . The action of a BV-permutation  $\psi : \Delta_V \rightarrow \Delta_V$  on a state  $s$  results in a state  $s' = \psi(s)$  such that  $\forall (B, b) \in \Delta_V, (B, b)$  is consistent with  $s$  if and only if  $\psi(B, b)$  is consistent with  $s'$

However, similar to the case of VV symmetries, any bijection from  $\Delta_V \rightarrow \Delta_V$  may not always result in a consistent state. For instance, consider a graphical model with 4 variables. Let the partition  $\Delta = \{(X_1, X_2), (X_3, X_4)\}$ . Consider the state  $s = (0, 1, 1, 0)$ . In case  $\psi$  is defined as  $\psi(\{X_1, X_2\}, \{0, 1\}) = (\{X_1, X_2\}, \{1, 0\})$  and  $\psi(\{X_3, X_4\}, \{1, 0\}) = (\{X_1, X_2\}, \{1, 1\})$ , the action of  $\psi$  results in an inconsistent state, since the action of  $\psi$  would result in a state with  $X_2$  equal to both 0 and 1 simultaneously. To address this issue, we define a BV-permutation to be valid only under certain conditions.

**Definition 8.** A BV-permutation  $\psi : \Delta_V \rightarrow \Delta_V$  is said

to be **valid** if  $\forall (B_i, b_i) \in \Delta_V, \psi(B_i, b_i) = (B_j, b_j) \Rightarrow \forall b'_i, \exists b'_j$  such that  $\psi(B_i, b'_i) = (B_j, b'_j)$

Intuitively a BV-permutation  $\psi$  is valid if it maps all assignments of a block  $B$  to assignments of a fixed block  $B'$ .

Presently, it is tempting to define a new graphical model where each block is a multi valued variable, with domain of this variable describing all of the possible assignments. This would be useful in a lucid exposition of symmetries. To do this we must suitably transform the set of features as well to this new set of variables. Given a block partition  $\Delta$ , we transform the set of features  $f_j$  such that for each block either all the variables in this block appear in the feature or none of them appear in the feature, while keeping all features logically invariant. We denote the set of all variables over which feature  $f_j$  is defined as  $\mathcal{V}(f_j)$ . Further, for a block  $B_l$  and a feature  $f_j$ , let  $\bar{B}_l = B_l - \mathcal{V}(f_j)$  i.e  $\bar{B}_l$  contains the additional variables in the block which are not part of feature  $f_j$ .

**Definition 9.** Given a variable  $X_i$ , which appears in a block  $B_l \in \Delta$  and a feature  $f_j$ , a **block consistent representation** of the feature, denoted by  $f'_j$ , is defined over the variables  $\mathcal{V}(f_j) \cup \bar{B}_l$ , such that,  $f'_j(\mathbf{x}_j, \bar{b}_l) = f_j(\mathbf{x}_j)$  where  $\mathbf{x}_j, \bar{b}_l$  denote an assignment to all the variables in  $\mathcal{V}(f_j)$  and  $\bar{B}_l$ , respectively.

For instance consider the feature  $f = (X_2)$ . Let the block  $B_l$  be  $\{(X_1, X_2)\}$ . Then the block consistent feature  $f'$  is given by  $f' = (X_1 \wedge X_2) \vee (\neg X_1 \wedge X_2)$ .

We extend the idea of block consistent representation to get a partition consistent representation  $\hat{f}_j$ .

**Definition 10.** A **partition consistent representation** of a feature  $f_j$ ,  $\hat{f}_j$  is defined by iteratively converting the feature  $f_j$  to its block consistent representation for each  $X_i \in \mathcal{V}(f_j)$ .

The set of partition consistent features  $\{(\hat{f}_j, w_j)\}_{j=1}^m$  has the property that for all  $B_l \in \Delta, B_l \subseteq \text{Var}(\hat{f}_j)$  or  $B_l \cap \text{Var}(\hat{f}_j) = \phi$ , i.e. all variables in each block either appear completely, or do not appear at all in any given feature. This property allows us to define a transformed graphical model  $\hat{\mathcal{G}}$  over a set of multi valued variables  $\mathcal{Y}$ , where each variable  $Y_l \in \mathcal{Y}$  represents a block  $B_l \in \Delta$ . The domain size of  $Y_l$  is the number of possible assignments of the variables in the block  $B_l$ . The set of features in this new model is simply the set of transformed features  $\{(\hat{f}_j, w_j)\}_{j=1}^m$ . As the blocks are non overlapping, such a transformation can always be carried out.

Since the transformation of features to partition consistent features always preserves logical equivalence, it seems natural to wonder about the relationship between

the graphical models  $\mathcal{G}$  and  $\hat{\mathcal{G}}$ . We first note that each state  $s$  in  $\mathcal{G}$  can be mapped to a unique state  $\hat{s}$  in  $\hat{\mathcal{G}}$  by simply iterating over all the blocks  $B_l \in \Delta$ , checking which BV pair  $(B_l, b_l)$  is consistent with the state  $s$  and assigning the appropriate value  $y_l$  to the corresponding variable  $Y_l$ . In a similar manner, each state  $\hat{s} \in \hat{\mathcal{G}}$  can be mapped to a unique state in  $s \in \mathcal{G}$ .

**Theorem 3.** *Let  $s$  denote a state in  $\mathcal{G}$  and let  $\hat{s}$  be the corresponding state in  $\hat{\mathcal{G}}$ . Then, this correspondence is probability preserving i.e.,  $\mathcal{P}(s) = \hat{\mathcal{P}}(\hat{s})$  where  $\mathcal{P}$  and  $\hat{\mathcal{P}}$  are the distributions defined by  $\mathcal{G}$  and  $\hat{\mathcal{G}}$ , respectively.*

Similar to the mapping between states, every BV-permutation  $\psi$  of  $\mathcal{G}$  corresponds to an equivalent VV-permutation  $\hat{\phi}$  of  $\hat{\mathcal{G}}$  obtained by replacing each BV pair in  $\mathcal{G}$  by the corresponding VV pair in  $\hat{\mathcal{G}}$  (and vice-versa). Since the distributions defined by the two graphical models are equivalent, we can define BV symmetries in  $\mathcal{G}$  as follows:

**Definition 11.** *Under a given partition  $\Delta$ , a BV-permutation  $\psi$  of a graphical model  $\mathcal{G}$  is a **BV-symmetry** of  $\mathcal{G}$  if the corresponding permutation  $\hat{\phi}$  under  $\hat{\mathcal{G}}$  is a VV-symmetry of  $\hat{\mathcal{G}}$ .*

We can now state the following results for BV-symmetries.

**Theorem 4.** *BV-symmetries are probability preserving transformations, i.e., for a BV-symmetry  $\psi$ ,  $\mathcal{P}(s) = \mathcal{P}(\psi(s))$  for all states  $s \in \mathcal{S}$ .*

It is easy to see that the set of all BV symmetries under a given partition  $\Delta$  form a group  $\Psi$ . Similar to the VV orbits, we define the BV orbit of a state  $s$  as  $\Gamma_\Psi(s) = \{\psi(s) | \psi \in \Psi\}$ .

When the partition  $\Delta$  is such that each variable appears in a block by itself, all the BV-symmetries are nothing but VV-symmetries.

**Theorem 5.** *Any VV-symmetry can be represented as a BV-symmetry for an appropriate choice of  $\Delta$ .*

### Computing BV Symmetries

Since BV symmetry on a graphical model  $\mathcal{G}$  is defined in terms of VV symmetry of a transformed graphical model  $\hat{\mathcal{G}}$ , BV symmetry can be trivially computed by constructing the transformed graphical model and then computing VV symmetry on  $\hat{\mathcal{G}}$  as described by Anand et al. [2017].

## 4 AGGREGATE ORBITAL MARKOV CHAINS

Given a block partition  $\Delta$ , BV symmetry group  $\Psi$  of  $\mathcal{G}$  can be found by computing VV symmetry group  $\Phi$  in the

auxiliary graphical model  $\hat{\mathcal{G}}$ . We further setup a Markov chain *BV-MCMC*( $\alpha$ ) over  $\Psi$  to exploit BV symmetries where  $\alpha \in [0, 1]$  is a parameter.

**Definition 12.** *Given a graphical model  $\mathcal{G}$ , a Markov chain  $\mathcal{M}$  and a BV symmetry group  $\Psi$ , one can define a **BV-MCMC**( $\alpha$ ) **Markov chain**  $\mathcal{M}'$  as follows: From the current sample  $s_t$*

- a) *Sample a state  $s'$  from original Markov chain  $\mathcal{M}$*
- b) i) *With probability  $\alpha$ , sample a state  $s_{t+1} = \Gamma_\Psi(s')$  uniformly from BV orbit of  $s'$  and return  $s_{t+1}$  as next sample.*
- ii) *With probability  $1 - \alpha$ , set state  $s_{t+1} = s'$  and return it as the next sample*

*BV-MCMC*( $\alpha$ ) Markov chain is defined similar to VV-MCMC except that it takes an orbital move only with probability  $\alpha$  instead of taking it always. For  $\alpha = 1$ , it is similar to VV-MCMC, and reduces to the original Markov chain  $\mathcal{M}$  for  $\alpha = 0$ . When  $\alpha = 1$ , sometimes, it is observed that the gain due to symmetries is overshadowed by the computational overhead of the orbital step. The parameter  $\alpha$  captures a compromise between these two contradictory effects.

**Theorem 6.** *Given a Graphical Model  $\mathcal{G}$ , if the original Markov chain  $\mathcal{M}$  is regular, then, *BV-MCMC*( $\alpha$ ) Markov chain  $\mathcal{M}'$ , constructed as above, is regular and converges to the unique stationary distribution of the original Markov chain  $\mathcal{M}$ .*

It should be noted that two different block partitions may capture different BV symmetries and hence may have different BV symmetry groups. In order to fully utilize all symmetries which may be present in multiple block partitions, we propose the idea of **Aggregate Orbital Markov Chain**.

Consider  $K$  different block partitions  $\Delta_1, \Delta_2, \dots, \Delta_K$ . We set up  $K$  independent *BV-MCMC*( $\alpha$ ) Markov chains, where each chain generates samples as per *BV-MCMC*( $\alpha$ ) corresponding to partition  $\Delta_k$ . Let these chains be  $\mathcal{M}'_1, \mathcal{M}'_2, \dots, \mathcal{M}'_K$ , and let the corresponding automorphism groups be  $\Psi_1, \Psi_2, \dots, \Psi_K$ . Given an intermediate state  $s'$ , we would like to sample uniformly from the union of orbits  $\bigcup_k \Psi_k(s')$ . Since these orbits may overlap with each other, sampling a state uniformly from the union of orbits is unclear. We circumvent this problem by setting up a new Markov chain, **Aggregate Orbital Markov Chain**. This Aggregate Orbital Markov Chain utilizes all available symmetries and converges to the true stationary distribution.

**Definition 13.** *Given  $K$  different *BV-MCMC*( $\alpha$ ) Markov chains,  $\mathcal{M}'_1, \mathcal{M}'_2, \dots, \mathcal{M}'_K$ , an **Aggregate Orbital Markov Chain**  $\mathcal{M}^*$  can be constructed in the following way: Starting from state  $s_t$  a) Sample a*

BV-MCMC( $\alpha$ ) Markov chain  $\mathcal{M}'_k$  uniformly from  $\mathcal{M}'_1, \mathcal{M}'_2, \dots, \mathcal{M}'_K$  b) Sample a state  $s_{t+1}$  according to  $\mathcal{M}'_k$ .

**Theorem 7.** *The aggregate orbital Markov chain  $\mathcal{M}^*$  constructed from  $K$  BV-MCMC( $\alpha$ ) Markov chains,  $\mathcal{M}'_1, \mathcal{M}'_2, \dots, \mathcal{M}'_K$ , all of which have stationary distribution  $\pi$ , is regular and converges to the same stationary distribution  $\pi$ .*

*Proof.* Given each of BV-MCMC( $\alpha$ ) Markov chains  $\mathcal{M}'_k$  are regular, firstly, we prove that the aggregate Markov chain is regular. In each step of aggregate chain, one of the BV-MCMC( $\alpha$ ) is applied and since, there is non-zero probability of returning to the same state in BV-MCMC( $\alpha$ ) chain, there is non-zero probability of returning to the same state in  $\mathcal{M}^*$ . Hence, aggregate chain so defined is regular and therefore, it converges to a unique stationary distribution. [Koller and Friedman, 2009].

The only fact that remains to be shown is that the stationary distribution of  $\mathcal{M}^*$  is  $\pi$ . Let  $T^*(s \rightarrow s')$  represent the transition probability of going from state  $s$  to  $s'$  in aggregate chain  $\mathcal{M}^*$ . We need to show that

$$\pi(s') = \sum_{s \in \mathcal{S}} \pi(s) * T^*(s \rightarrow s') \quad (1)$$

Let  $T_k(s \rightarrow s')$  represent the transition probability of going from state  $s$  to  $s'$  in  $\mathcal{M}'_k$

$$\sum_{s \in \mathcal{S}} \pi(s) * T^*(s \rightarrow s') = \sum_{s \in \mathcal{S}} \pi(s) * \frac{1}{K} * \sum_{k=1}^K T_k(s \rightarrow s') \quad (2)$$

$$= \frac{1}{K} \sum_{k=1}^K \sum_{s \in \mathcal{S}} \pi(s) * T_k(s \rightarrow s') = \frac{1}{K} \sum_{k=1}^K \pi(s') = \pi(s') \quad (3)$$

Equation 2 follows from the definition of aggregate chain while equation 3 holds since  $\mathcal{M}'_k$  converges to stationary distribution  $\pi$ .  $\square$

Aggregate Markov chain  $\mathcal{M}^*$  so obtained not only converges to the correct stationary distribution but also results in faster mixing since it can exploit the symmetries associated with each of the individual orbital Markov chains.

## 5 HEURISTICS FOR BLOCK PARTITIONS

We have so far computed BV symmetries given a specific block partition. We now discuss our heuristic that suggests candidate block partitions for downstream symme-

try computation (see supplementary material for pseudo-code). At a high level, our heuristic has the following two desiderata. Firstly, it ensures that there are no overlapping blocks, i.e., one variable is always in one block. Secondly, it guesses which blocks might exhibit BV-symmetries, and encourages such blocks in a partition.

The heuristic takes the hyperparameter  $r$ , the maximum size of a block, as an input. It considers only those blocks (upto size  $r$ ) in which for each variable in the block, there exists at least one other variable from the same block, such that some clause in  $\mathcal{G}$  contains both of them. This prunes away blocks in which variables do not directly interact with each other, and thus are unlikely to produce symmetries. Note that these candidate blocks can have overlapping variables and hence not all can be included in a block partition.

For these candidate blocks, for each block-value pair, the heuristic computes a weight signature. The weight signature is computed by multiplying weights of all the clauses that are made true by the specific block-value assignment. The heuristic then buckets all BV pairs of the same size based on their weight signatures. The cardinality of each bucket (i.e., the number of BV pairs of the same size that have the same weight signature) is calculated and stored.

The heuristic samples a block partition as follows. At each step it samples a bucket with probability proportional to its cardinality and once a bucket is selected, then it samples a block from that bucket uniformly at random, as long as the sampled block doesn't conflict with existing blocks in the current partition i.e., it has no variables in common with them. This process is repeated until all variables are included in the partition. In the degenerate case, if a variable can't be sampled from any block of size 2 or higher, then it gets sampled as an independent block of size 1. Once a partition is fully sampled, it is stored and the process is reset to generate another random block partition.

This heuristic encourages sampling of blocks that are part of a larger bucket in the hope that multiple blocks from the same bucket will likely yield BV symmetries in the downstream computation. At the same time, the non-conflicting condition and existence of single variable blocks jointly ensure that each sample is indeed a bona fide block partition.

## 6 EXPERIMENTS

Our experiments attempt to answer two key research questions. (1) Are there realistic domains where BV symmetries exist but VV symmetries do not? (2) For

Domain	Rules	Weights	Variables
Job Search	$\forall x \text{ TakesML}(x) \wedge \text{GetsJob}(x)$	$+w_1$	$\text{TakesML}(x),$ $\text{GetsJob}(x),$ $\text{Connected}(x,y)$
	$\forall x \neg \text{TakesML}(x) \wedge \text{GetsJob}(x)$	$+w_2$	
	$\forall (x,y) \text{ Connected}(x,y) \wedge \text{TakesML}(x) \Rightarrow \text{TakesML}(y)$	$w_3$	
Student Curriculum	$\forall x \text{ Maths}(x) \wedge \text{CS}(x)$	$+w_1$	$\text{Maths}(x)$ $\text{CS}(x)$
	$\forall x \text{ Maths}(x) \wedge \neg \text{CS}(x)$	$+w_2$	
	$\forall x \neg \text{Maths}(x) \wedge \text{CS}(x)$	$+w_3$	
	$\forall x \neg \text{Maths}(x) \wedge \neg \text{CS}(x)$	$+w_4$	
	$\forall (x,y) \in \text{Friends}, \text{Maths}(x) \Rightarrow \text{Maths}(y)$	$w$	
	$\forall (x,y) \in \text{Friends}, \text{CS}(x) \Rightarrow \text{CS}(y)$	$w$	

Table 1: Description of the two domains used in experiments. A weight of the form  $+w_1$  indicates that the weight is randomly sampled for each object.

such domains, how much faster can an MCMC chain mix when using BV symmetries compared to when using VV symmetries or not using any symmetries?

## 6.1 Domains

To answer the first question, we construct two domains. The first domain models the effect of an academic course on an individual’s employability, whereas the second domain models the choices a student makes in completing their course credits. Both domains additionally model the effect of one’s social network in these settings. Table 1 specifies the weighted first order formulas for both the domains.

**Job Search:** In this domain, there are  $N$  people on a social network, looking for a job. Given the AI hype these days, their employability is directly linked with whether they have learned machine learning (ML) or not. Each person  $x$  has an option of taking the ML course, which is denoted by  $\text{TakesML}(x)$ . Furthermore, the variable  $\text{Connected}(x,y)$  denotes whether two people  $x$  and  $y$  are connected in the social network or not. Finally, the variable  $\text{GetsJob}(x)$  denotes whether  $x$  gets employment or not.

In this Markov Logic Network (MLN) [Domingos and Lowd, 2009], each person  $x$  participates in three kinds of formulas. The first one with weight  $w_1$  indicates the (un-normalized) probability of the person getting a job and taking the ML course ( $\text{TakesML}(x) \wedge \text{GetsJob}(x)$ ). The second formula with weight  $w_2$  indicates the chance of the person getting a job while not taking the course ( $\neg \text{TakesML}(x) \wedge \text{GetsJob}(x)$ ). Our domain assigns different weights  $w_1$  and  $w_2$  for each person, modeling the fact that each person may have a different capacity to learn ML, and that other factors may also determine whether they get a job or not. Finally,  $x$  is more likely to take the course if their friends take the course. This is modeled by an additional formula for each pair  $(x,y)$ , with a fixed weight  $w_3$ .

In this domain, there are hardly any VV symmetries, since every  $x$  will likely have different weights. However there are *intra-block* BV symmetries for the block  $(\text{TakesML}(x), \text{GetsJob}(x))$  for every  $x$ . This is because within the potential table of this block the block values  $(0, 0)$  and  $(1, 0)$  are symmetric and can be permuted.

**Student Curriculum:** In this domain, there are  $N$  students who need to register for two courses, one from Mathematics and one from Computer Science to complete their course credits. There are two courses (basic or advanced) on offer in both disciplines. Variables  $\text{Math}(x)$  and  $\text{CS}(x)$  denote whether the student  $x$  would take the advanced course in each discipline. Since courses for Mathematics and CS could be related, each student needs to give a joint preference amongst the 4 available options. This is modeled as a potential table over  $(\text{Math}(x), \text{CS}(x))$  with weights chosen randomly from a fixed set of parameters. Further, some students may also be friends. Since students are more likely to register in courses with their friends, we model this as an additional formula, which increases the probability of registering for a course in case a friend registers for the same.

In this domain, VV pairs can only capture symmetries when the potential tables (over  $\text{Math}$  and  $\text{CS}$ ) for two students are exactly the same. However, there are a lot more *inter-block* BV symmetries since it is more likely to find pairs of students, whose potential tables use the same set of weights, but in a different order.

## 6.2 Comparison of MCMC Convergence

We now answer our second research question by comparing the convergence of three Markov chains – Vanilla-MCMC, VV-MCMC, and BV-MCMC( $\alpha$ ). All three use Gibbs sampling as the base MCMC chain. All experiments are done on Intel Core i7 machines. Following previous work, and for fair comparison, we implement

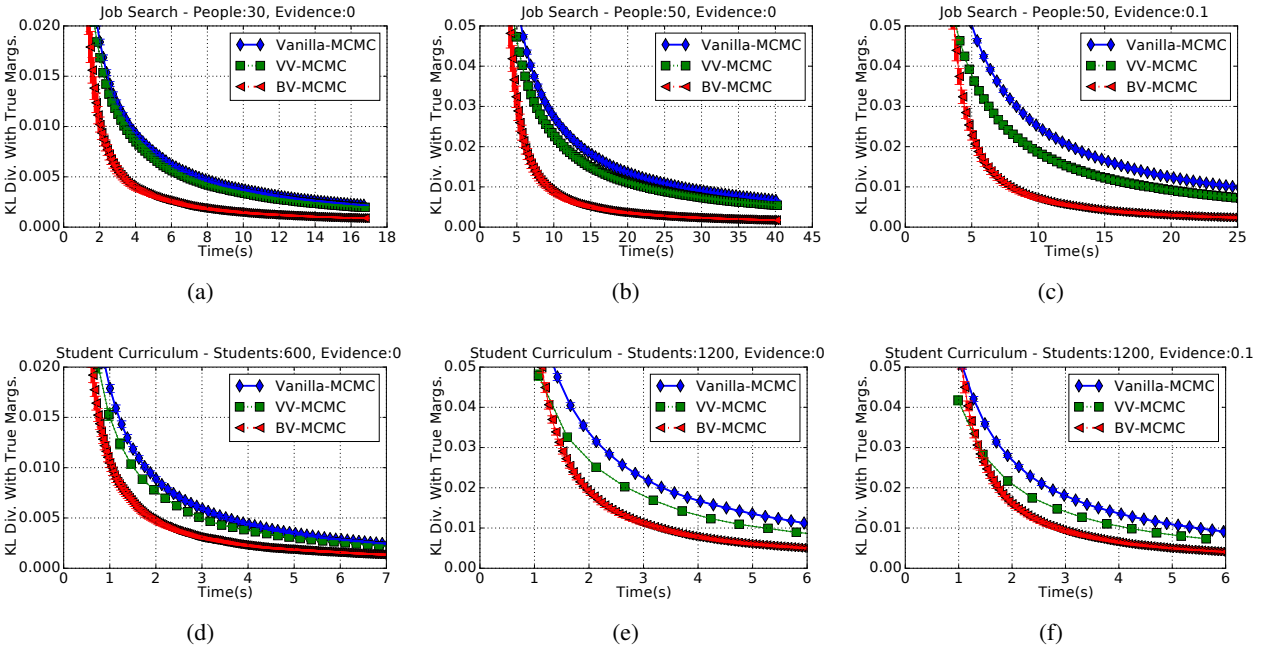

Figure 2: BV-MCMC( $\alpha = 1$ ) and BV-MCMC( $\alpha = 0.02$ ) outperforms VV-MCMC and Vanilla MCMC on Job Search and Student Curriculum domains respectively with different size and evidence variations

all the three Markov chains in group theoretic package - GAP [GAP, 2015]. This allows the use of off-the-shelf group theoretic operations. The code for generating candidate lists is written in C++. We solve graph isomorphism problems using the Saucy software [Darga *et al.*, 2008]. We release our implementation for future use by the community <sup>1</sup>.

In all experiments, we keep the maximum block size in a block partition to be two. For each chain we plot the KL divergence of true marginals and computed marginals for different runtimes. We estimate true marginals by running the Gibbs sampling algorithm for a sufficiently long period of time. Each algorithm is run 20 times to compute error bars indicating 95% confidence interval.

For VV-MCMC and BV-MCMC, the run time on x-axis includes the pre-processing time of computing symmetries as well. For BV-MCMC, this includes the time for generating candidate lists, running Saucy for each candidate list, and initializing the Product Replacement algorithm for each candidate lists. The total preprocessing time for Job Search domain is around 1.6 sec and for Student Curriculum domain is around 0.6 sec.

Figure 2 shows that BV-MCMC substantially outperforms VV-MCMC and Vanilla-MCMC in both the domains. The parameter  $\alpha$  is set to 1.0 for Job Search Do-

main and 0.02 for Student Curriculum Domain. Since these domains do not have many VV-Symmetries, VV-MCMC only marginally outperforms Vanilla MCMC. On the other hand BV-MCMC is able to exploit a considerably larger number of symmetries and leads to faster mixing. BV-MCMC scales well with domain size, significantly outperforming other algorithms as domain size is changed from 30 to 50 people in Job Search and 600 to 1200 in Student Curriculum domain. This is particularly due to more symmetries being captured by BV-MCMC for larger domain sizes. <sup>2</sup>

Figure 2(c) and 2(f) plot the variation with introduction of 10% evidence in each domain. BV MCMC still outperforms VV-MCMC and Vanilla-MCMC and is robust to presence of evidence.

Finally, we also test the sensitivity of BV-MCMC with the  $\alpha$  parameter. Figure 3 plots this variation on both these domains. We find that for Job Search, a high value  $\alpha = 1$  performs the best, whereas a lower value is better in Student Curriculum. This is because Job Search mostly has intra-block BV symmetries, which can be computed and applied efficiently. This makes sampling an orbital step rather efficient. On the other hand, for Student Curriculum, the inter-block symmetry between different pairs of people makes the orbital step costlier, and reducing the fraction of times an orbital move is taken

<sup>1</sup><https://github.com/dair-iitd/bv-mcmc>

<sup>2</sup>Most of the error-bars are negligible in size.

Figure 3: Variation on  $\alpha$   $\alpha < 1$  is significantly better than  $\alpha = 1$  in Student-Curriculum domain while  $\alpha = 1$  is best in Job-Search domains

improves the overall performance.

## 7 CONCLUSIONS

Permutations defined over variables or variable-value (VV) pairs miss a significant fraction of state symmetries. We define permutations over block-value (BV) pairs, which enable a subset of variables (block) and their assignment to jointly permute to another subset. This representation is exponential in the size of the maximum block  $r$ , but captures more and more state symmetries with increasing  $r$ .

Novel challenges arise when building the framework and algorithms for BV permutations. First, we recognize that all BV permutations do not lead to valid state symmetries. For soundness, we impose a sufficient condition that each BV permutation must be defined on blocks with non-overlapping variables. Second, to compute BV symmetries, we describe a graph-isomorphism based solution. But, this solution expects a block partition as an input, and we cannot run it over all possible block partitions as they are exponential in number. In response, we provide a heuristic that outputs candidate block partitions, which will likely lead to BV symmetries. Finally, since the orbits from different block partitions may have overlapping variables, they cannot be explicitly composed in compact form. This makes it difficult to uniformly sample from the aggregate orbit (aggregated over all block partitions). To solve this challenge, we modify the Orbital MCMC algorithm so that in the orbital step, it uniformly samples from the orbit from any one of the block partitions (BV-MCMC). We prove that this aggregate Markov chain also converges to the true posterior.

Our experiments show that there exist domains in which BV symmetries exist but VV symmetries may not. We find that BV-MCMC mixes much more rapidly than base

MCMC or VV-MCMC, due to the additional mixing from orbital BV moves. Overall, our work provides a unified representation for existing research on permutation groups for state symmetries. In the future, we wish to extend this notion to approximate symmetries, so that they can be helpful in many more realistic domains as done in earlier works [Habeeb *et al.*, 2017].

## Abstract

We propose a new way to answer probabilistic queries that span multiple datapoints. We formalize reasoning about the similarity of different datapoints as the evaluation of the Bayes Factor within a hierarchical deep generative model that enforces a separation between the latent variables used for representation learning and those used for reasoning. Under this model, we derive an intuitive estimator for the Bayes Factor that represents similarity as the amount of overlap in representation space shared by different points. The estimator we derive relies on a query-conditional latent reasoning network, that parameterizes a distribution over the latent space of the deep generative model. The latent reasoning network is trained to amortize the posterior-predictive distribution under a hierarchical model using supervised data and a max-margin learning algorithm. We explore how the model may be used to focus the data variations captured in the latent space of the deep generative model and how this may be used to build new algorithms for few-shot learning.

## 1 INTRODUCTION

How do we frame the problem of selecting, from a target set, an object most similar to a given query set? For example—given a red chair, a blue chair and a black chair, we would rank chairs in the target set highly. At the same time, given a red chair, a red car and a red shirt, we would rank red objects highly. Between the two tasks, our understanding of the *data* has not changed; what has changed is our understanding of the *task based on the context* given by the query. The query highlights the relevant property of the data that is needed for solving a specific task. Such

Figure 1: **Comparing objects in representational space:** On the left is a target set that will be ranked based on similarity to the query  $Q$  (right). The colour of each object is matched to a distribution in representation space. In orange is the output of the *latent reasoning network* – it represents the common factor of variation shared by  $Q$ . The black chair should rank higher than the black table; here its distribution (in representation space) overlaps more with the output of the latent reasoning network.

tasks appear in few-shot learning, where the goal is ranking objects according to their similarity to a given query set and in healthcare where a task may be finding similar patients to a given cohort.

To answer such queries, we could train discriminative models attuned to answering set-conditional queries at test time (e.g. Vinyals *et al.* (2016)). Or we could encode class separability in the structure of a generative model (Edwards & Storkey, 2017) and use inference for prediction. We take a different approach to the problem.

We learn a generic representation space (using unsupervised data) that is warped (using supervised data) for potentially different test-time problems. The task of scoring objects given a query is decomposed into two subtasks. The first determines the common property shared by items in the query set and represents the property as a region in representation space. In Figure 1, we visualize such

a hypothetical space. On the right is a query comprising chairs of different colors and (in orange) a region of space that characterizes the property (in this case, a likeness to a chair) common to items in the query. The second task is to score a target item based on how much it expresses the region of representation space shared by items in the query. For the two candidate target points in Figure 1 (left), the black chair would rank highly since its representation has more in common with the property encapsulated by the query.

Here, we will use the latent space of deep generative models (Rezende *et al.*, 2014; Kingma & Welling, 2014) as our representation space. In such models, one can do posterior inference to map from raw data to a distribution in latent space. Then, to find commonalities among query items, we introduce a *latent reasoning network* (LRN). The LRN takes a query as input and constructs a probability distribution over the latent space that *summarizes* the representations of the query points into a single distribution. Figure 1 (orange) depicts what the output of the LRN might look like. We design a neural architecture for the LRN based on Zaheer *et al.* (2017) so that it does not depend on the size of the query set. To score the latent space of a target item, we propose using the logarithm of the Bayes Factor (Jeffreys, 1998). The Bayes Factor measures how conditioning on the query alters the likelihood of a target point. Our approach is inspired by Bayesian Sets Ghahramani & Heller (2005) where data was assumed to be modeled by a hierarchical exponential family distribution and the likelihood ratio of the joint distribution and product of marginals was shown to be a useful measure of similarity.

The latent (representation) space of a deep generative models learned with unsupervised data is typically non-identifiable. i.e. there will exist multiple good (from the perspective of log-likelihood) representation spaces. Each corresponds to a different notion of similarity and a different way of grouping points. However, queries provide extra information: they reveal which points should be close together in latent space. We take advantage of this and propose a supervised max-margin learning algorithm for the LRN such that scores given to items in the query are larger than scores unrelated to the query.

We obtain a coupled set of models: in which one model is a deep generative model of the data whilst the other reshapes the latent space of the first and serves to answer queries about similarity judgements between datapoints. We study how the proposed approach can tune the latent space of deep generative models and be used to build new types of models for few-shot learning. We begin in Section 2 by motivating the Bayes Factor as a viable tool for computing similarity.

Figure 2: **Hypothesis testing with Deep Generative Models:** (a) The **Reasoning Model**, here, depicting the hypothesis that the set  $\{x_t, Q = \{x_1, x_2\}\}$  was generated jointly; (b) the two figures represent the hypothesis that  $x_t$  and  $Q$  were generated independently under different realizations of  $w$  (the random variable that captures the property shared across datapoints).

## 2 FROM REPRESENTATION LEARNING TO REASONING

Here, we consider the problem of scoring elements in a set based on how similar they are to a given query. Suppose we are given a dataset  $\mathcal{D} = \{x_1, \dots, x_N\}$ ,  $x_i \in \mathbb{R}^n$ ,  $x_i \in \mathcal{D}$ . Then for a query  $Q = \{x_1, \dots, x_Q\}$ ;  $|Q| = Q$ , we wish to assign to each  $x_t \in \mathcal{D}$  a score  $\text{score}(x_t, Q)$  that denotes how *similar*  $x_t$  is to elements of the query  $Q$ .

### 2.1 The Data Model

A simple way to quantify how similar objects are (here, between  $Q$  and  $x_t$ ) might be to take the pairwise Euclidian distance between them. For complex, high dimensional data that do not lie on a Euclidian manifold, such a metric may fail to capture interesting regularity between data.

Alternatively, we can use a latent variable model to construct a representation of data. The latent variable then becomes a low-dimensional sufficient statistic the raw data when quantifying similarity. The simplest latent variable model we will consider has the following generative process:  $z \sim p_{\text{dm}}(z)$ ;  $x \sim p_{\text{dm}}(x; f(z; \theta))$  where  $p_{\text{dm}}(z)$  is a simple distribution such as  $\mathcal{N}(0, I)$ . The use of MLPs in the conditional distributions allow the model to fit highly complex data despite the use of a simple prior. When  $f$  is parameterized by a Multi-Layer Perceptron (MLP), the resulting model is a deep generative model. We will refer to this model (Kingma & Welling, 2014; Rezende *et al.*, 2014) as the **Data Model** (with probabilities denoted with subscript  $\text{dm}$ ).

The generative process assumes datapoints are drawn independently. Using variational inference with an inference network (Hinton *et al.*, 1995) to approximate the posterior distribution,  $p_{\text{rm}}(z|x)$ , the model can be learned by maximizing a lower bound on the log-likelihood of the

data obtained using Jensen’s inequality:

$$\log p_{\text{dm}}(x; \theta) \geq \mathbb{E}_{q_{\text{dm}}(z|x; \phi)} [\log p_{\text{dm}}(x|z; \theta)] - \text{KL}(q_{\text{dm}}(z|x; \phi) || p_{\text{dm}}(z)) = \mathcal{L}(x; \theta, \phi), \quad (1)$$

With a Gaussian distribution as the variational approximation:  $q_{\text{dm}}(z|x; \phi) \sim \mathcal{N}(\mu_{\phi}(x), \Sigma_{\phi}(x))$  where  $\mu_{\phi}(x), \Sigma_{\phi}(x)$  are (differentiable, parametric, with parameters  $\phi$ ) functions of the observation  $x$ . Eq. 1 is differentiable in  $\theta, \phi$  (Kingma & Welling, 2014; Rezende *et al.*, 2014) and the model parameters  $(\theta, \phi)$  can be learned via gradient ascent on  $\mathcal{L}(x; \theta, \phi)$ .

With the variational approximation,  $q_{\text{dm}}(z|x; \phi)$ , to map from data to latent space, would computing overlap in the posterior distributions of points in  $\mathcal{Q}$  and  $x_t$  suffice to identify similar points? The answer is *sometimes*. While unsupervised learning will tend to put *similar* points together, the notion of similarity encoded in the latent space need not correspond to the notion of similarity required for a task at test time. We require a way to guide the structure of the latent space to be better suited for a task.

## 2.2 The Reasoning Model

Introducing hierarchy into the generative process is one way to guide the structure of latent variables. In Figure 2 (b) is a simple hierarchical model that makes explicit the insight that similar datapoints should have similar latent spaces. It defines the following generative process for a set of similar objects  $\mathcal{Q}$ :  $p_{\text{rm}}(\mathcal{Q}) = \int_w \int_z p_{\text{rm}}(w) \prod_{q=1}^Q p_{\text{rm}}(z_q|w) p_{\text{rm}}(x_q|z_q)$ . The random variable  $w$  defines the context of  $\mathcal{Q}$ . It may denote the label or class identity of points in  $\mathcal{Q}$  but more broadly is a representation of the properties that points in  $\mathcal{Q}$  satisfy. For notational convenience and because we can express reasoning about similarity as a probabilistic query in this model, we refer to it as the **Reasoning Model**.

The Neural Statistician (Edwards & Storkey, 2017) uses  $\text{KL}(p(w|x_t) || p(w|\mathcal{Q}))$  to quantify the similarity between  $x_t$  and  $\mathcal{Q}$  in a model similar to the one in Figure 2 (b). In this work, we pose the estimation of similarity between objects as hypothesis testing in a hierarchical deep generative model. The conditional independences in Figure 2 (b) enforce that  $x_t$  is independent of  $w$  given  $z_t$ , i.e. the per-data-point latent variables serve as a sufficient statistic to quantify comparisons between multiple datapoints. The conditional density  $p(x_t|z_t)$  is a map from the representation space to the data while  $p(z_t|w)$  dictates how the latent space of a datapoint behaves as a function of property encoded in  $w$ .

## 2.3 Bayes Factor

To score the similarity between two objects (in this case  $x_t$  and set  $\mathcal{Q}$ ) under the Reasoning Model, we turn to the likelihood ratio between the joint distribution of  $x_t$  and  $\mathcal{Q}$  and the product of their marginals. If  $x_t$  and  $\mathcal{Q}$  are drawn from the same joint distribution, then there exists a random variable  $w$  that governs the distribution of the *latent* spaces  $z_t, z_1, \dots, z_Q$ . With slight abuse of notation <sup>1</sup>, Figure 2 (a) depicts this scenario when  $\mathcal{Q} = \{x_1, x_2\}$ . If  $x_t$  and  $\mathcal{Q}$  are not similar, then their latent spaces will have different distributions, and they are children of different realizations of  $w$  (see Figure 2 (b)). With that in mind, the score function we use to measure similarity is given by (**Bayes Factor**):

$$\frac{p(x_t, \mathcal{Q})}{p(x_t)p(\mathcal{Q})} = \frac{p(x_t|\mathcal{Q})}{p(x_t)} = \text{score}(x_t, \mathcal{Q}) \quad (2)$$

The log-score is the pointwise mutual information (Fano, 1949), a measure of association that is frequently used in applications such as natural language processing (Church & Hanks, 1990). The Bayes Factor normalizes the posterior predictive density of the target point conditioned on the query by the target’s marginal likelihood under the model. It also has an information theoretic interpretation. Letting  $h(x) = -\log p(x)$  denote the self-information (or surprisal), then  $\log \text{score}(x_t, \mathcal{Q}) = h(x_t) - h(x_t|\mathcal{Q})$  intuitively denotes the surprise (quantified in nats or bits) from observing  $x_t$  when having already observed  $\mathcal{Q}$ .

**Similarity in Latent Space:** Equation 2 captures an intuitive notion of similarity but evaluating  $p(x_t)$ , the marginal density of the target, is typically intractable (except in hierarchical models that lie in the exponential family (Ghahramani & Heller, 2005)). Furthermore, an importance sampling based Monte-Carlo estimator for  $p(x_t)$  will involve a high-dimensional integral in the data  $x_t$ . We therefore propose the following decomposition of the score function that evaluates the Bayes Factor in the target datapoint’s (lower dimensional) latent space:

$$\begin{aligned} \frac{p_{\text{rm}}(x_t|\mathcal{Q})}{p_{\text{rm}}(x_t)} &= \frac{1}{p_{\text{rm}}(x_t)} \int_{z_t} p_{\text{rm}}(x_t, z_t|\mathcal{Q}) \\ &= \frac{1}{p_{\text{rm}}(x_t)} \int_{z_t} p_{\text{rm}}(x_t|z_t) p_{\text{rm}}(z_t|\mathcal{Q}) \\ &= \frac{1}{p_{\text{rm}}(x_t)} \int_{z_t} \frac{p_{\text{rm}}(z_t|x_t) p_{\text{rm}}(x_t)}{p_{\text{rm}}(z_t)} p_{\text{rm}}(z_t|\mathcal{Q}) \\ &= \int_{z_t} \underbrace{\frac{p_{\text{rm}}(z_t|x_t)}{p_{\text{rm}}(z_t)}}_{\text{Relative Posterior Likelihood}} \underbrace{p_{\text{rm}}(z_t|\mathcal{Q})}_{\text{Latent Reasoning Network}} \end{aligned} \quad (3)$$

<sup>1</sup>We re-use Figure 2 to denote both the instantiation of a hypothesis and the generative process

The estimator above formalizes the intuition for comparing points laid out in Section 1. The query-conditional posterior-predictive density over the latent space of the target datapoint,  $p_{\text{rm}}(z_t|\mathcal{Q})$ , reasons about points in the query and represents them as a density in latent space, The **Relative Posterior Likelihood**,  $\frac{p_{\text{rm}}(z_t|x_t)}{p_{\text{rm}}(z_t)}$  scores how likely the target point is to have come from the relevant part of latent space.

### 3 HIERARCHICAL MODELS WITH COMPOUND PRIORS

To compute the ratio  $\frac{p_{\text{rm}}(z_t|x_t)}{p_{\text{rm}}(z_t)}$ , we need to marginalize  $w_t$ . However, under certain assumptions about the conditional distributions in the **Reasoning Model**, we will see that approximating this ratio becomes simpler.

*Assumption 1.* Priors with Compound Distributions

$$\int_w p_{\text{rm}}(w)p_{\text{rm}}(z|w)dw = p_{\text{dm}}(z)$$

*Assumption 2.* Matching conditional likelihoods

$$p_{\text{rm}}(x|z) = p_{\text{dm}}(x|z)$$

**Lemma 1.** *Matching posterior marginals*

$$p_{\text{dm}}(z|x) = p_{\text{rm}}(z|x)$$

*Proof.* Follows from Bayes rule and Assumption 1, 2.  $\square$

**Lemma 2.** *Matching marginal likelihoods*

*Under Assumption 1 and 2:*

$$p_{\text{dm}}(x) = p_{\text{rm}}(x)$$

*Proof.*

$$\begin{aligned} p_{\text{rm}}(x) &= \int_w \int_z p_{\text{rm}}(w)p_{\text{rm}}(z|w)p_{\text{rm}}(x|z)]dzdw \\ &= \int_z p_{\text{dm}}(z)p_{\text{dm}}(x|z)dz = p_{\text{dm}}(x) \end{aligned}$$

$\square$

The conditions above state when we can take an instance of the **Data Model** discussed in Section 2.1 and transform it into an instance of the **Reasoning Model** in Section 2.2 while preserving the marginal likelihood of the data.

This transformation has a few implications. The first is when evaluating the Bayes Factor; if we work in a class of **Reasoning Models** that satisfy Assumption 1, then we can evaluate the **Relative Posterior Likelihood** using

the prior and posterior distribution of the associated **Data Model**. With Lemma 1 and Assumption 1:

$$\frac{p_{\text{rm}}(x_t|\mathcal{Q})}{p_{\text{rm}}(x_t)} = \int_{z_t} \underbrace{\frac{p_{\text{dm}}(z_t|x_t)}{p_{\text{dm}}(z_t)}}_{\text{Relative Posterior Likelihood}} \underbrace{p_{\text{rm}}(z_t|\mathcal{Q})}_{\text{Latent Reasoning Network}}$$

where  $p_{\text{dm}}(z_t)$  is typically fixed ahead of time (e.g.  $\mathcal{N}(0; \mathbb{I})$ ) and we can do inference for  $p_{\text{dm}}(z_t|x_t)$  (or approximate it using the inference network  $q_{\text{dm}}(z|x; \phi)$ ).

The second implication is that part of the **Reasoning Model**,  $p_{\text{rm}}(x|z)$ , can be learned ahead of time. This gives us the flexibility to *warm-start* the **Reasoning Model** using a *pre-trained Data Model* whose  $p_{\text{dm}}(z)$  can be expressed according to Assumption 1. In this way, even if we do not know which property will be used to organize datapoints into sets at test time, we can still learn a generic low-dimensional representation of the dataset. We will make use of this when we discuss the learning framework in Section 5. For now, what remains is how we can specify  $p_{\text{rm}}(w)$ ,  $p_{\text{rm}}(z|w)$  in order to evaluate  $p_{\text{rm}}(z_t|\mathcal{Q})$ .

### 4 LATENT REASONING NETWORKS

Although  $p_{\text{rm}}(z_t|\mathcal{Q}) = \int_w p_{\text{rm}}(z_t|w)p_{\text{rm}}(w|\mathcal{Q})dw$ , finding  $p_{\text{rm}}(w)$ ,  $p_{\text{rm}}(z|w)$  that satisfy Assumption 1 may prove challenging and so we will make use of another computational trick. To evaluate the Bayes Factor we only need a way to sample from  $p_{\text{rm}}(z_t|\mathcal{Q})$  i.e. the posterior predictive distribution given the query, of the target’s latent representation. Our strategy therefore, will instead be to parameterize and learn  $p_{\text{rm}}(z_t|\mathcal{Q})$  directly from data.

Without  $p_{\text{rm}}(w)$ ,  $p_{\text{rm}}(z|w)$ , we lose the ability to sample from the Reasoning Model but by amortizing  $p_{\text{rm}}(z_t|\mathcal{Q})$  we obtain a fast way to evaluate the Bayes Factor at test time.  $p_{\text{rm}}(z_t|\mathcal{Q})$  must *reason* about how the latent spaces of points in  $\mathcal{Q}$  are related and parameterize a distribution over the latent space of the target datapoint  $x_t$ ; this distribution must characterize the property represented by points in  $\mathcal{Q}$ . Therefore, we refer to this amortized, parameteric posterior-predictive distribution as a *Latent Reasoning Network*. Since we do not know the functional form of this distribution we will parameterize it as a non-linear function of the query  $\mathcal{Q}$ .

To construct the LRN, we require neural architectures capable of operating over sets. We make use of two primitives for such neural architectures proposed by Zaheer *et al.* (2017). These functions operate over sets of vectors  $\mathcal{Q} = \{x_1, \dots, x_Q\}$ ,  $x_q \in \mathbb{R}^n$ . We will use the notation  $\mathbb{R}^{n \times |\mathcal{Q}|}$  to denote a set of size  $|\mathcal{Q}|$  where each element is an  $n$ -dimensional vector. We design the LRN, with the following three properties:

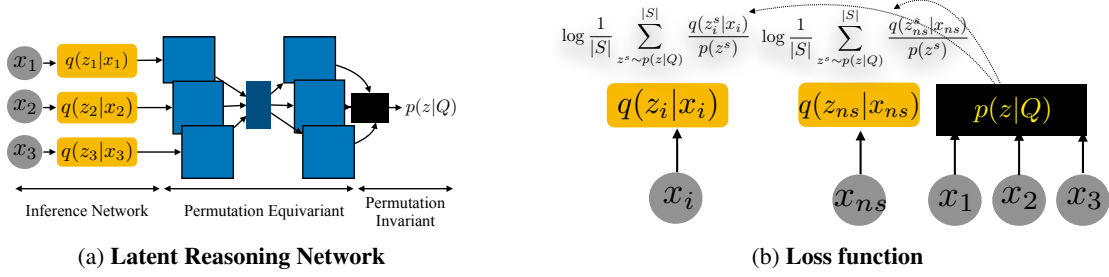

Figure 3: **Latent Reasoning Networks (LRN) and Loss function:** On the left is a diagrammatic representation of  $p_{\text{rm}}(z_t|\mathcal{Q})$ . On the right is a depiction of Monte-Carlo sampling (with samples from the LRN) to evaluate Bayes factor.  $x_i$  is a point similar to those in the query  $\mathcal{Q} = \{x_1, x_2, x_3\}$ , while  $x_{ns}$  is not. We suppress subscripts in the figure.

**A) Parameter Sharing:** We share parameters between the inference network of the Data Model and the LRN. A direct consequence of this choice is that the LRN now has the ability to change the way inference is done in the Data model. The first stage of the LRN uses the inference network of the Data Model to map from the set  $\mathcal{Q}$  to a set of each point’s variational parameters

**B) Exchangeability:** The output of the LRN must not depend on the order of elements in  $\mathcal{Q}$ . We achieve this by using the functions proposed by (Zaheer *et al.*, 2017):  $g : \mathbb{R}^{n \times |\mathcal{Q}|} \rightarrow \mathbb{R}^{m \times |\mathcal{Q}|}$  is a permutation equivariant function that maps from sets of  $n$  dimensional vectors to sets of  $m$  dimensional vectors while ensuring that if the input elements were permuted, then the output elements would also be permuted identically. The form of  $g$  is given by  $g(\mathcal{Q}) = \left[ \rho \left( W_1^{\text{eq}} x_q + W_2^{\text{eq}} (\sum_{q'} x_{q'}) \right) \right]_{q=1}^{|\mathcal{Q}|}$  where  $W_1^{\text{eq}} \in \mathbb{R}^{m \times n}$ ,  $W_2^{\text{eq}} \in \mathbb{R}^{m \times n}$  and  $\rho$  is an element-wise nonlinearity. We use compositions of the function  $g$  in the second stage of the LRN to *learn* about how the variational parameters between points in  $\mathcal{Q}$  relate to one-another and map to a set of intermediate representations.

**C) Distributions in latent space:** The network must parameterize a valid density in latent space; this is satisfied by construction. To go from the set of intermediate representations to the parameters of  $p(z_t|\mathcal{Q})$ , we leverage the following permutation invariant function:  $f(\mathcal{Q}) = \rho \left( \sum_q (W^{\text{inv}} x_q + b) \right)$ ,  $f : \mathbb{R}^{n \times |\mathcal{Q}|} \rightarrow \mathbb{R}^m$  where  $W^{\text{inv}} \in \mathbb{R}^{m \times n}$ ,  $b \in \mathbb{R}^m$  are linear operators and  $\rho$  is an elementwise non-linearity.

With  $\mu(\mathcal{Q}; \gamma, \phi)$ ,  $\Sigma(\mathcal{Q}; \gamma, \phi)$  as parametric functions of set  $\mathcal{Q}$ , we can write  $p_{\text{rm}}(z_t|\mathcal{Q}; \gamma, \phi) = \mathcal{N}(\mu(\mathcal{Q}; \gamma, \phi), \Sigma(\mathcal{Q}; \gamma, \phi))$ .  $\gamma$  denotes the parameters of the permutation equivariant and invariant layers while  $\phi$  represent the parameters shared with  $q_{\text{dm}}(z|x; \phi)$ . We visualize the LRN in Figure 3a.

## 5 LEARNING

The learning procedure we use is based on a combination of doing unsupervised learning to learn a good representation alongside a supervised max-margin loss to ground the representation for a specific task. We discuss each separately and then highlight how they are combined.

**Unsupervised Learning:** Since we use **Reasoning Models** that satisfy Assumption 1, 2, we make use of the transformation between the **Data Model** and **Reasoning Model** in Section 3. We maximize the likelihood of a given dataset using the lower-bound in Equation 1. A consequence of doing variational learning of the Data Model is that we can use  $q_{\text{dm}}(z|x; \phi)$  to approximate the Bayes Factor.

**Max-Margin Learning:** We expect that the Bayes Factor in Equation 3 takes a high value when the target point  $x_t$  is *similar* to  $\mathcal{Q}$  and a low value when  $x_t$  is dissimilar to  $\mathcal{Q}$ . But how do we know what points form  $\mathcal{Q}$ ? This will depend on the test-time task. We assume we are given labels that define the property encompassed in sets of datapoints.

*Assumption 3.* For  $L$  datapoints in  $\mathcal{D}$ , we have  $\mathcal{Y} = \{y_{x_1}, \dots, y_{x_L}\}$ ,  $y_l \in \{1, \dots, K\}$  where  $y_{x_i}$  is the label for  $x_i$  that takes one of  $K$  unique labels. We define  $\mathbb{N}_{x_i}^{\mathcal{Q}} = \{x_k \text{ s.t. } y_{x_k} \in \mathcal{Y} \ \& \ y_{x_k} = y_{x_i}\}$ ,  $\mathbb{N}_{x_i}^{\bar{\mathcal{Q}}} = \{x_k \text{ s.t. } y_{x_k} \in \mathcal{Y} \ \& \ y_{x_k} \neq y_{x_i}\}$  to be sets of datapoints that have the same label as  $x_i$  and those that do not.

We will assume that a point can only have a single label. Here, the labels characterize the property we want to base our similarity judgements on. Therefore, learn the parameters of  $p(z_t|\mathcal{Q}; \gamma, \phi)$  using the following (supervised) loss function:

$$\mathcal{L}_{\text{mm}}(x; \gamma, \phi) = \mathbb{E}_{\mathcal{Q} \sim \mathbb{N}_x^{\mathcal{Q}}} \mathbb{E}_{\mathcal{Q}_{ns} \sim \mathbb{N}_x^{\bar{\mathcal{Q}}}} \frac{1}{|\mathcal{Q}_{ns}|} \sum_{x_{ns} \in \mathcal{Q}_{ns}} \max(\log \text{score}(x_{ns}, \mathcal{Q}) - \log \text{score}(x, \mathcal{Q}) + \Delta, 0). \quad (4)$$

The loss function maximizes the difference between the log-Bayes Factor for points that lie within the set  $\mathcal{Q}$  and those that do not (they lie in  $\mathcal{Q}_{ns}$ ). The log score( $x, \mathcal{Q}$ ), in Equation 3, is evaluated via Monte-Carlo sampling and the log-sum-exp trick. The expectation is differentiable with respect to  $\gamma, \phi$  via the reparameterization trick (Kingma & Welling, 2014; Rezende *et al.*, 2014). For the margin  $\Delta$  we use the mean-squared-error between the the posterior means of  $x, x_{ns}$ . We provide a visual depiction of how the loss is evaluated using the LRN in Figure 3.

**Combined Loss:** With the unsupervised learning objective for the **Data Model** and the supervised max-margin loss function (Equation 4) for the LRN, we obtain the following loss to jointly learn  $\theta, \phi, \gamma$ :

$$\min_{\theta, \phi, \gamma} \frac{1}{N} \sum_{i=1}^N \frac{1}{C+1} [-\mathcal{L}(x_i; \theta, \phi)] + \frac{C}{C+1} \mathbb{I}[x_i \in \mathcal{Y}] \mathcal{L}_{\text{mm}}(x_i; \gamma, \phi) \quad (5)$$

where  $C$  is a regularization constant that trades off between the supervised and the unsupervised loss. The unsupervised loss learns a representation space constrained to lie close to the prior while explaining the data under the generative model. The max-margin loss modifies this representation space so that dissimilar points are kept apart. Note that Equation 5 is no longer a valid bound on the marginal likelihood of the training set (for  $C > 0$ ).

## 6 EVALUATION

The goal of this section is threefold: (1) to study whether  $p_{\text{rm}}(z|\mathcal{Q})$  is learnable from data using the max-margin learning objective—we expect this to be challenging since we learn the parameters of a model that is itself used to evaluate the the score function in the loss; (2) studying the role of parameter sharing between the inference network and the LRN – i.e. whether the latter can change the former in adversarial scenarios; and (3) studying the utility of the framework for few-shot learning.

We will release code in Keras (Chollet *et al.*, 2015). The supplementary material contains detailed information on the neural architectures of the deep generative models used in the evaluation. We learn parameters with a learning rate of 0.00005 and adaptive momentum updates given by ADAM (Kingma & Ba, 2015). We set the value  $C$  separately for each experiment. When there is a task to be solved,  $C$  can be set using the validation data. When using a pre-trained Data Model, we found it useful to anneal  $C$  from a higher to a lower value so that the task-specific supervised term can overcome (potentially)

suboptimal latent spaces learned from unsupervised data. We use the following datasets for our study:

**Synthetic Pinwheel:** A synthetic dataset of two-dimensional points arranged on a pinwheel taken from the work of Johnson *et al.* (2016). We depict the raw data in Figure 4a. The dataset is created with five labels.

**MNIST digits:** 50000 black and white images of handwritten digits (LeCun *et al.*, 1998).

**MiniImagenet:** A subsampled set of images taken from the Imagenet repository setup for the task of k-shot learning by Vinyals *et al.* (2016). We use the train-validate-test split kindly provided by Ravi & Larochelle (2016).

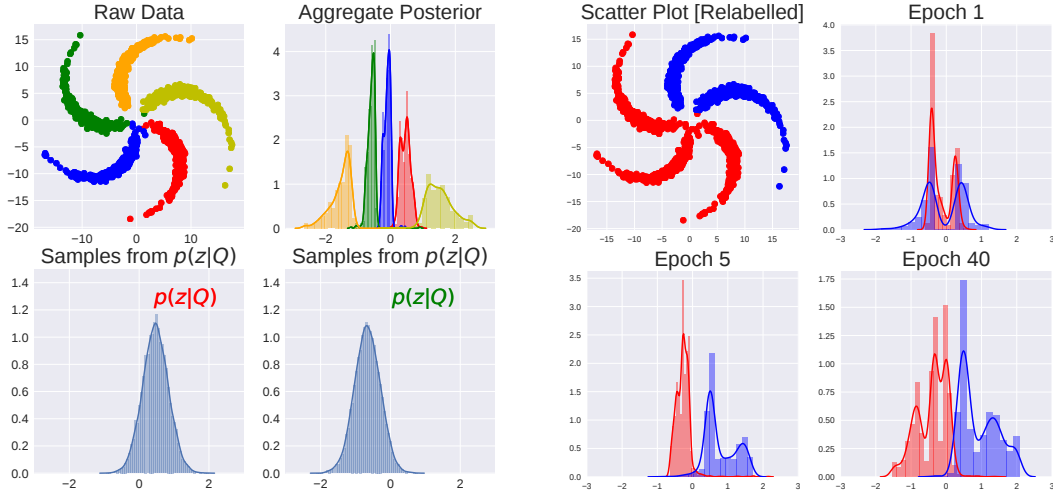

### 6.1 Learning $p(z|\mathcal{Q})$

As a sanity check, we begin by first training a deep generative model (without labels and using a one-dimensional latent space) on the Pinwheel dataset. We visualize the raw-data and learned aggregate posterior  $\sum_x q_{\text{dm}}(z|x; \phi)$  in Figure 4a (top row). We see that the unsupervised learning alone induces class separation in the aggregate posterior distribution. Using the learned model, we hold fixed parameters:  $\theta, \phi$  and learn the parameters  $\gamma$  of the LRN using the loss function in 4 with  $C = 2000$ . We form a kernel density estimate of samples from  $p_{\text{rm}}(z|\mathcal{Q})$  using randomly constructed sets of points derived from the red and green clusters. In Figure 4a (bottom row), we see that samples from the LRN correspond to regions of the latent space associated with  $\mathcal{Q}$ . On synthetic examples, the LRN finds regions of latent space corresponding to points from a query  $\mathcal{Q}$ .

### 6.2 Changing inductive biases at test-time

Previously, we worked with a model where the structure of the latent space (as seen in the aggregate posterior distribution) formed during unsupervised learning co-incident with how points were grouped into sets. Here, we study what happens where the notion of which points are similar changes at test time. We relabel the pinwheel dataset so that the yellow and orange points form one class while the green, red and blue form the other (see Figure 4b, top left). This corresponds to an *adversarial* labelling of the data since we use a deep generative model in which points in the same class are far apart in the learned latent space. If we keep  $\theta, \phi$  fixed then  $p_{\text{rm}}(z|\mathcal{Q})$  (whose output is parameterized as a unimodal Gaussian distribution) cannot capture the relevant subspace.

We have two choices here; we can either consider richer parameterizations for  $p_{\text{rm}}(z|\mathcal{Q})$  that are capable of capturing multi-modal structure in the latent space using techniques proposed by (Rezende & Mohamed, 2015), or we

(a) **Data and Aggregate Posterior:** (Top Left) Raw Pinwheel Data; (Top Right) Aggregate posterior density of a learned (unconditional) deep generative model coloured by class membership. (Bottom Row) Sampling from  $p_{\text{rm}}(z|Q)$  where the colour denotes the class membership of points in  $Q$ .

(b) **Learning dynamics:** (Top left) Visualization of *adversarially labelled data* (relative to the learned aggregate posterior in Figure 4a (top right)). The remaining plots are class coloured visualizations of the aggregate posterior (during training) while allowing the LRN to fine-tune the latent space of the DGM.

Figure 4: **Qualitative Evaluation on Pinwheel Data**

can instead allow the  $p_{\text{rm}}(z|Q)$  to *change* the underlying latent space of the generative model by back-propagating through the parameters of the inference network. Here, we opt for the latter though the former is an avenue for future work.

We minimize Equation 5 while annealing the constant  $C$  from  $1000 \rightarrow 1$  linearly through the course of training. To gain insight into the learning dynamics of the LRN during training, we visualize the aggregate posterior of the generative model (via the fine-tuned inference network) in Figure 4b through the course of training. The role of this adversarial scenario is to highlight two important points (1) unsupervised learning is typically unidentifiable and may not learn a representation appropriate to all tasks and (2) learning with the latent reasoning network can overcome a suboptimal (relative to the task at hand) representation and transform it to a more suitable one.

### 6.3 Modeling High Dimensional Data

**Inducing diversity in latent space:** Moving beyond low-dimensional data, we study learning LRNs on MNIST digits. We use a Data Model with a two-dimensional latent space for this experiment. We begin by training the model in a fully unsupervised manner and visualize the learned latent space in the form of the aggregate posterior (Figure 5a [left]). Although there is some class separability, we find that the unsupervised learning algorithm concentrates much of the probability mass together.

We re-learn the same model with the loss in Equation 5 where  $C$  is set to 3000 (and annealed to 1). We again visualize the new aggregate posterior distribution of the Data Model in Figure 5a (middle and right). When learning with Equation 5, the inference network uses more of the latent space in the model because the max-margin loss pushes points in different classes further apart.

**Qualitative Analysis of MNIST digits:** To validate our method, we provide visualizations on the MNIST dataset. We select a handful of labelled examples  $Q$  (Figure 5b, left) and visualize both their posterior means and samples from  $p(z|Q)$  (Figure 5b, middle). Then, for each sample from  $p_{\text{rm}}(z|Q)$ , we evaluate the fine-tuned  $p_{\text{dm}}(x|z)$  and visualize the images in Figure 5b (right). We see that the generative model fine-tuned with the learning algorithm retains its ability to generate meaningful samples.

### 6.4 Few-shot learning with the Bayes Factor

The task of k-shot learning is to identify the class an object came from given a single example from 5 other classes (1-shot, 5-way). In the 5-shot, 5-way task, there are 5 examples provided from each of the 5 potential classes. We use an LRN with a deep-discriminative model to obtain near state of the art performance in few-shot learning on the MiniImagenet dataset.

Following (Bauer *et al.*, 2017), who show that discriminative models alone form powerful baselines for this task

(a) **Training dynamics for MNIST:** Aggregate (two-dimensional) posterior of deep generative model of MNIST (coloured by label). The left corresponds to a model trained with unsupervised data only; the middle & right show the aggregate posteriors for a model fine-tuned using Equation 5.

(b) **Test-time evaluation of LRN on MNIST:** On the left are a set of query points  $\mathcal{Q}$  drawn from the same class, in the middle, we visualize samples from  $q_{\text{dm}}(z|x; \phi)$  for each of the points and  $p_{\text{rm}}(z|\mathcal{Q})$ . On the right is the output of the fine-tuned conditional density  $p_{\text{dm}}(x|z)$  for samples drawn from  $p_{\text{rm}}(z|\mathcal{Q})$ .

Figure 5: **Qualitative Evaluation on MNIST**

on this dataset, we pretrain an 18 layer Resnet (He *et al.*, 2016) convolutional neural network to predict class labels at training time. We use early stopping on a validation set based on the nearest neighbor performance of the learned embeddings (obtained from the final layer of the ResNet) to identify the best model. Building a good generative model of the images in MiniImagenet is difficult and so instead, we use the *fixed* embeddings as a 256 dimensional proxy for each image. We initialize  $q_{\text{dm}}(z|x; \phi)$  with the pretrained Resnet and set up a deep generative model to maximize the likelihood of the fixed embeddings (after discriminative pre-training).

For this task, when comparing to the many different approaches proposed, it is challenging to control for both the depth of the encoder that parameterizes the representation and the various algorithmic approach used to tackle the problem using the representation. Therefore, our two take-aways from Table 1 are: (1) on the 1 shot and 5 shot task, we outperform a strong nearest neighbors baseline created using fixed (but learned) embeddings suggesting that our algorithmic approach bears promise for this task and (2) the method is competitive with other state of the art approaches.

Table 1: Accuracy on the 5-way MiniImagenet task

MODEL	1-SHOT	5-SHOT
NEAREST NEIGHBOR	$51.4 \pm 0.08$	$67.5 \pm 0.08$

## 7 RELATED WORK

**Max Margin Learning:** Max margin parameter estimation has been widely used in machine learning (e.g. in structural SVMs (Yu & Joachims, 2009) and in discriminative Markov networks (Zhu & Xing, 2009)). (Li *et al.*, 2015) give a doubly stochastic subgradient algorithm for regularized maximum likelihood estimation when dealing with max-margin posterior constraints.

(Zaheer *et al.*, 2017) experiment with max-margin learning using a variant of the DeepSets model to predict a scalar score conditioned on a set. While (Zaheer *et al.*, 2017) cite the estimator in (Ghahramani & Heller, 2005) as motivation for their model, they do not explicitly use, parameterize, or differentiate through the Bayes Factor in a *generative* model of data.

**Inductive Transfer and Metric Learning:** Lake *et al.* (2013) use probabilistic inference in a hierarchical model to classify unseen examples by their probability of being in a new class. Instead of the Bayes Factor, they use the posterior predictive obtained via the use of a MCMC algorithm to score target points relative to a query. (Ghahramani & Heller, 2005) evaluate the Bayes factor analytically in exponential family distributions. What we gain in for sacrificing tractability is the ability to work within a richer class of models. Though not motivated within the context of a hierarchical model, (Engel *et al.*, 2018) use an adversarial loss to recognize regions of latent space that correspond to points with a specified class.

Vinyals *et al.* (2016) learn a parametric K-nearest neighbor classifiers to predict whether a target item is within the same class as  $k$ -others. (Snell *et al.*, 2017) associate a point with a prototype within a set and use it to answer whether an object is in the same class as others. The Neural Statistician (Edwards & Storkey, 2017) learns a model similar <sup>2</sup> to the **Reasoning Model** in Figure 2 (b) by maximizing the likelihood of sets  $\mathcal{Q}$ . Their method does not use the Bayes Factor to score items; it also does not permit easy initialization with pre-trained Data Models since the full model is trained with queries.

We tune the latent space of a deep generative model to enhance class separability for test time tasks. By contrast, meta learning algorithms learn to tune the parameters of an algorithm or a model. (Finn *et al.*, 2017) prime the parameters of a neural network to have high accuracy at test time using second order gradient information.

Our work has close parallels with metric-learning; here the metric learned lies in the latent space of a deep generative model. (Bar-Hillel *et al.*, 2005) proposed Relevant Component Analysis, an optimization problem that jointly performs (linear) dimensionality reduction and learns a Mahalanobis metric using queries.

## 8 DISCUSSION

We seek good, task-specific inductive biases to quantify how similar a point is to a set. We give new theoretical and practical constructs towards this goal. We break up

<sup>2</sup>Their model does not enforce the conditional independence statement  $x_t \perp\!\!\!\perp \mathcal{Q} | z_t$

the problem into two parts: learn a good representation and tune the learned representation for a specific notion of similarity. Using the latent space in a deep generative model as our representation, we use the Bayes Factor to quantify similarity.

We derive conditions under which there exists an equivalence between a generative model where data are generated independently to a hierarchical model that jointly generates sets of (similar) points. Using this insight, we derive an easy-to-evaluate estimator for the Bayes Factor; the estimator poses the comparison between a point and a set as overlap in latent space. With the Bayes Factor as a differentiable scoring mechanism, we give a max-margin learning algorithm capable of changing the inductive bias of a (potentially pre-trained) deep generative model. To evaluate the Bayes Factor, we propose a neural architecture for a *latent reasoning network*: a set conditional density that amortizes the posterior predictive distribution of a hierarchical model.

Our approach has limitations. By directly parameterizing the posterior predictive density, and not the prior  $p_{\text{rm}}(w)$  and conditional  $p_{\text{rm}}(z|w)$ , we lose the ability to sample points from the hierarchical generative model. Working with a set of models in which Assumption 1 holds may implicitly only find posterior predictive densities under relatively simple model families of  $p_{\text{rm}}(w)$  and  $p_{\text{rm}}(z|w)$ . Finally, enforcing that property identity in  $w$  is conditionally independent of the data  $x$ , given the representation  $z$ , may make for a challenging learning problem –  $z$  has to represent both the property and variability in the property conditional distribution of the data.

An avenue of future work is leveraging vast amounts of unlabeled data for representation learning informed by a small amount of supervision to guide either during learning, or after learning, the structured of the learned space. Yet another interesting direction would be to learn LRNs that parameterize distributions over multiple, per-data-point latent variables.

## ACKNOWLEDGEMENTS

The authors thank Uri Shalit, Fredrik Johansson, Adam Yala, and the anonymous reviewers for their comments that have improved the manuscript. RGK, AK, and DS are supported by a grant from SAP Corporation.

## Abstract

WTA (Winner Take All) hashing has been successfully applied in many large-scale vision applications. This hashing scheme was tailored to take advantage of the comparative reasoning (or order based information), which showed significant accuracy improvements. In this paper, we identify a subtle issue with WTA, which grows with the sparsity of the datasets. This issue limits the discriminative power of WTA. We then propose a solution to this problem based on the idea of Densification which makes use of 2-universal hash functions in a novel way. Our experiments show that Densified WTA Hashing outperforms Vanilla WTA Hashing both in image retrieval and classification tasks consistently and significantly.

## 1 INTRODUCTION

In many important applications like information retrieval and natural language processing, text documents, and images data are in high-dimensional representations. Such high-dimensionality is usually accompanied by extreme data sparsity due to either a large vocabulary or the use of large image window size. The major reason we find very sparse datasets almost everywhere results from the wide adoption of Bag of Words (BoW) representation for documents and images. In BoW representation, the presence or absence of specific features carries the most information [Chapelle et al., 1999, Jiang et al., 2007], especially with higher order shingles. The popularity of sparse machine learning [Caiafa et al., 2017, Liu and Tsang, 2017, Liu et al., 2017, Liu and Tsang, 2016] and sparse codes [Lee et al., 2006] for image data is another reason for the abundance of sparse datasets in modern applications. In order to get a sense of this extreme

sparsity, the datasets demonstrated in Google’s Machine Learning system SIBYL [Canini et al., 2012] have dimensions in billions and non-zeros in only a few thousands (even hundreds).

With the advent of the Internet and the explosion in volumes of data, almost all machine learning and data mining applications are constrained by their computational requirements. Learning with non-linear kernels, by materializing kernel matrices, which are quadratic in computation and memory, is infeasible [Rahimi and Recht, 2007, Li et al., 2011, Shrivastava, 2015]. Randomized algorithms, especially those based on Locality Sensitive Hashing (LSH) [Indyk and Motwani, 1998], have shown huge promise for reducing computational and memory requirement in these scenarios. These randomized algorithms lead to drastic gains in computation and memory for a small, insignificant, amount of approximations.

LSH-based algorithms are quite popular efficient sub-linear algorithms for near neighbor search [Indyk and Motwani, 1998]. This is because even a simple linear scan for near neighbor search, over massive datasets, becomes prohibitively expensive [Weber et al., 1998]. There are no options but to use hashing approaches for such scenarios. LSH algorithms can also be used as cheap random kernel features [Li et al., 2011] for training large-scale non-linear SVMs without materializing the expensive kernel matrix, leading to linear time algorithms. Besides, recently a line of work appears to use LSH as samplers in optimization [Chen et al., 2018] and deduplication [Chen et al., 2017] problems. They are embarrassingly parallel, simple and cheap. Owing to these unique advantages, they are heavily used by commercial search industries for truly large-scale data processing systems.

In the last decade, similarities based on relative (or comparative) attributes have gained huge popularity, especially in the vision literature [Parikh and Grauman, 2011]. For such similarities, a well-known hashing

scheme is *Winner Take All (or WTA) hashing* [Yagnik et al., 2011]. **It is one of the fastest known hashing scheme, which is much faster than signed random projection (SRP).** SRP requires one pass over the data vector for computing one hash value. This is expensive because in practice we need hundreds of hash values, which results in hundreds of passes over the data. Similarly, even random projections are significantly slow for many large-scale tasks. On the contrary, WTA can generate multiple hashes in one pass. It is widely known that hashing time is the major bottleneck, both in theory and practice, for the task of image retrieval. This is why Google [Dean et al., 2013] needed WTA for detecting 100,000 objects on a single machine in near-real time with very respectable accuracy.

Large-scale image retrieval, with low-latency constraints, is a reality. We cannot afford to have costly hash functions since even one pass over the data vector for hash computation is prohibitively expensive both for energy and latency. WTA hashing has been quite successfully applied to produce superior results on massive-scale object recognition and information retrieval. This randomized hashing scheme seems quite suitable for taking advantage of multiple partial order statistics rather than total orderings of the input vector’s feature dimensions to produce sparse embedding codes.

Deep Neural Networks are widely-used in vision and speech tasks. While the network architecture sizes grow exponentially larger to adapt data complexity, LSH algorithms are recently adopted to reduce the computation [Spring and Shrivastava, 2017, Vijayanarasimhan et al., 2014]. Moreover hashing cost and quality are the critical bottleneck in making such approaches practical. **Our Contributions:** In this work, we study the applicability of WTA hashing for very sparse datasets. We found that WTA hashes are not very informative for sparse datasets. We further provide a remedy based on the recent idea of *Densification* [Shrivastava and Li, 2014a]. In particular, our contributions can be summarized as follows:

1. We illustrate that the popular WTA hashing scheme starts losing information for very sparse datasets, i.e., most of the hash values for very sparse datasets do not have enough discriminative information.
2. We propose Densified WTA Hashing which combines traditional WTA hashing with the idea of Densification [Shrivastava, 2017]. We show that the idea of densification provably fixes the issue of WTA for sparse datasets. Our proposal makes novel use of 2-universal hashing, introduced in Section 4.1, and requires minimal modifications to the original WTA hashing. Furthermore, for dense

datasets, our proposal is equivalent to the original WTA hashes and thus a smooth generalization of WTA for sparse datasets.

3. We show for the first time that the idea of Densification actually leads to significant improvement in the quality of WTA hashing, informative hashes. Previously the idea of Densification was only known to speed up hash functions without losing quality. Furthermore, this is the first use of densification for non-binary data.
4. We demonstrate the benefits of our proposal by showing significant gains in accuracy compared to WTA on real-world sparse datasets for both retrieval and classification tasks.

## 2 REVIEW WTA HASHING

[Parikh and Grauman, 2011] pointed out the importance of relative attributes in the vision community. It suggested that for a given vector  $x$ , the information that the attribute  $x_i$  is dominant over some other attribute  $x_j$  has stronger discriminative powers compared to other features. It was further shown in [Yagnik et al., 2011] that comparative reasoning (or order information) among attributes is a very informative feature and similarities based on such comparisons lead to superior performances compared to widely adopted measures like  $L_2$  distances. However, kernel based (or similarity based) learning is computationally slow. To mitigate this problem, WTA (Winner Takes ALL) Hashing was proposed. The simplicity, scalability, and power of WTA hashing were quite appealing and it has been successfully used by commercial big-data companies to scale up the task of object detection significantly [Dean et al., 2013].

WTA hashing generates a set of random samples of  $K$  attributes, using a random permutation  $\Theta$ , and stores the index of the attribute with the maximum weight. It can be implemented in three lines with Matlab:

```
function [maxval, c] = wta(X, K)
theta = randperm(size(X, 2))
[maxval, c] = max(X(:, theta(1:K)), [], 2)
```

### 2.1 KEY WTA NOTATIONS

We denote  $\Theta(x)$  to be the  $K$  random samples from  $x$  sampled using permutation  $\Theta$ . For convenience, we drop the dependence on  $K$  as it will remain a fixed constant.  $\mathcal{H}_{wta}(\Theta(x))$  indicates the corresponding WTA hash. We will also drop  $\Theta$  and use  $\mathcal{H}_{wta}(x)$  when it is clear.

As illustrated in the example shown in Table 1, the original input vectors  $x_1, x_2, x_3, x_4$  are applied with random

Table 1: WTA Hashing Example with four input vectors  $x_1, x_2, x_3, x_4$ ,  $K = 3$  and one permutation  $\Theta = 4, 1, 2$

	$x_1$	$x_2$	$x_3$	$x_4$
$\mathbf{x}$	10, 12, 9, 23	8, 9, 1, 12	9, 2, 6, 1	3, 5, 1, 7
$\Theta(\mathbf{x})$	23, 10, 12	12, 8, 9	1, 9, 2	7, 3, 5
$\mathcal{H}_{\text{wta}}(\mathbf{x})$	1	1	2	1

permutation  $\Theta = (4, 1, 2, 3)$  and first  $K = 3$  attributes of the permuted vectors are selected (random sample of size 3), e.g. Vector (a) = [10, 12, 9, 23] will sample [23, 10, 12]. Then the index of the maximum attribute in every transformed vector is stored separately, e.g. 1 for (a), to contribute to the final WTA hash codes. If there are  $n$  such hashes codes for one input vector, **we define Bin  $i$  as the space to store the hash code generated from the  $i^{\text{th}}$  set of  $K$  samples.**

It was shown that WTA hashing scheme has locality sensitive hashing property. It implies that collision probability under this scheme, i.e. for given vectors  $x$  and  $y$ ,  $Pr(\mathcal{H}_{\text{wta}}(x) = \mathcal{H}_{\text{wta}}(y)) = \mathbb{E}[\mathbf{I}_{\mathcal{H}_{\text{wta}}(x)=\mathcal{H}_{\text{wta}}(y)}]$  is some desirable order based similarity measure. It was later shown that for  $K = 2$  this similarity is the well known Kendall Tau [Ziegler et al., 2012].

### 3 SPARSE DATASETS AND ISSUES WITH WTA HASHING

WTA hashing and the idea of comparative reasoning is quite appealing and intuitive. In this section, we delve deeper and show a critical issue with WTA hashing. We show that for very sparse datasets, which are common in practice [Li et al., 2011], WTA-based hashes are not very informative and deviate from the "relative attribute" intuition. We use the equivalence between hashing and the kernel view to illustrate this issue. With every hashing scheme  $\mathcal{H}$  is an associated positive definite kernel given by the collision probability  $Pr(\mathcal{H}(x) = \mathcal{H}(y)) = \mathbb{E}[\mathbf{I}_{\mathcal{H}(x)=\mathcal{H}(y)}]$ . For large-scale learning, as shown in [Yagnik et al., 2011], we can convert these hashes into random kernel features [Rahimi and Recht, 2007] by converting hash values to indicator vectors.

#### 3.1 SPARSITY MAKES WTA UNINFORMATIVE

Define the sparsity of a dataset  $X$  with  $n$  samples, with each sample of dimension  $d$ , as

$$S_x = \frac{\sum_{i=1}^n \sum_{j=1}^d [1\{X_{ij} = 0\}]}{n \times d} \quad (1)$$

Note that  $[1\{X_{ij} = 0\}]$  is an indicator for the event  $X_{ij} = 0$ .  $S_x$  is also the probability that  $Pr(X_{ij} = 0)$ . We will show that the kernel associated with WTA hashing becomes uninformative as the sparsity increases.

Consider the example that is shown in Table 2. Given very sparse input vectors  $x_1, x_2$ , we generate six WTA hashes with  $K = 3$ . In order to do this, we sample  $K = 3$  attributes six different times so that each different bin is generated using a different permutation. Due to sparsity, many of these bins contain all zeros. We can see that in all the bins except Bin 5,  $\mathcal{H}_{\text{wta}}(x_1)$  and  $\mathcal{H}_{\text{wta}}(x_2)$  collide and therefore the estimated collision probability, from the hashes, is roughly  $\frac{5}{6}$  indicating high similarity (1 is maximum). This seems misleading.

Due to sparsity, it is very likely that for a given  $x$ , all the sampled attributes  $\Theta(x)$  are zeros for some samples. We represent this situation by  $\Theta(x) = E$  (Empty). Consider Bin 1, 4 and 6, they collide only because they are all zeros. Note, WTA treats all empty bins as collisions and two empty bins will always lead to a hash collision. Sparse datasets are common with Bag-of-Words (or token-based) representation. Empty Bins (1, 4 and 6) indicate the absence of the randomly chosen  $K$  tokens which is not a strong indicator of similarity. In BoW analogy, if two documents concurrently lack the words "Hashing", "Winner" and "Take", it does not indicate strong similarity given the large vocabulary and the sparse nature of the dataset. In sparse BoW representation, the absence of features is not informative but only the presence of features is important. Thus, whenever the bins in both input vectors, under considerations for WTA, are empty, we observe undesirable collisions.

However, it is also problematic if we treat empty ones as mismatches. For two identical sparse vector, ideally they should always collide as they are identical. But if we treat zeros as mismatches, then even identical vectors would have low collision probability. If hashes do not collide, it is an indicator that the input vectors are not similar. Preventing empty bins from colliding will treat sparsity as dissimilarity, which is again undesirable. Thus, there is no straightforward fix to this problem.

If we further observe Bin 3, the collision is even worse because it is meaningless that an empty Bin of  $x_2$  collides with a non-empty bin of  $x_1$ , simply because the max value in  $x_1$  happens to be at index 1. This is actually a spurious collision and can be easily eliminated if we assign special values to all empty bins. Therefore, from the analysis, we ignore this easily fixable but spurious collision.

Table 2: WTA with input vectors  $x_1, x_2$  and six bins generated with six permutations. E denoted an empty sampling. WTA treats E and E as a match of hash values, which artificially inflates the similarity perceived by the hashes.

	$x_1$	<b>0, 0, 5, 0, 0, 7, 6, 0, 0</b>				
	$x_2$	<b>0, 0, 1, 0, 0, 0, 0, 0, 0</b>				
	<b>Bin 1</b>	<b>Bin 2</b>	<b>Bin 3</b>	<b>Bin 4</b>	<b>Bin 5</b>	<b>Bin 6</b>
$\Theta$	<b>2, 1, 8</b>	<b>5, 3, 9</b>	<b>6, 2, 4</b>	<b>8, 9, 1</b>	<b>1, 7, 3</b>	<b>2, 4, 5</b>
$\Theta(x_1)$	<b>0, 0, 0 (E)</b>	<b>0, 5, 0</b>	<b>7, 0, 0</b>	<b>0, 0, 0 (E)</b>	<b>0, 6, 5</b>	<b>0, 0, 0 (E)</b>
$\Theta(x_2)$	<b>0, 0, 0 (E)</b>	<b>0, 1, 0</b>	<b>0, 0, 0 (E)</b>	<b>0, 0, 0 (E)</b>	<b>0, 0, 1</b>	<b>0, 0, 0 (E)</b>
$\mathcal{H}_{wta}(x_1)$	<b>1 (E)</b>	<b>2</b>	<b>1</b>	<b>1 (E)</b>	<b>2</b>	<b>1 (E)</b>
$\mathcal{H}_{wta}(x_2)$	<b>1 (E)</b>	<b>2</b>	<b>1 (E)</b>	<b>1 (E)</b>	<b>3</b>	<b>1 (E)</b>

In Bin 2, neither  $\Theta(x_1)$  nor  $\Theta(x_2)$  are E, so those are informative collisions. This is in line with the original motivation of WTA. Owing to the presence of empty bins, sparsity dominates the hash representations of  $x_1, x_2$  and leads to high undesirable similarity. We can not simply ignore empty values because different vectors will have different occurrences of empty bins. Please refer [Shrivastava and Li, 2014a] to see in details why there is no way to ignore empty values in indexing.

Formally, given vectors  $x_1, x_2$  and a permutation  $\Theta$ , define the indicator vector for empty sampling of both  $x_1$  and  $x_2$ :

$$I_{empty} = \begin{cases} 1 & \Theta(x_1) = \Theta(x_2) = E \\ 0 & otherwise \end{cases} \quad (2)$$

Note if any of the  $\Theta(x_1)$  is not empty then  $I_{empty} = 0$ . Based on this indicator variable, we can define empty and non-empty collisions as:

$$\begin{aligned} k_{bad}(x_1, x_2) &= Pr(\mathcal{H}_{wta}(x_1) = \mathcal{H}_{wta}(x_2) | I_{empty} = 1) \\ k_{good}(x_1, x_2) &= Pr(\mathcal{H}_{wta}(x_1) = \mathcal{H}_{wta}(x_2) | I_{empty} = 0). \end{aligned}$$

As argued,  $k_{bad}(x_1, x_2)$  is not an informative kernel for very sparse datasets. Using these quantities we can formally write the WTA kernel as

$$\begin{aligned} k_{wta}(x_1, x_2) &= Pr(\mathcal{H}_{wta}(x_1) = \mathcal{H}_{wta}(x_2)) \\ &= ak_{bad}(x_1, x_2) + (1 - a)k_{good}(x_1, x_2), \end{aligned} \quad (3)$$

where  $a$  is the probability of  $I_{empty} = 1$ . Clearly, for very sparse datasets  $a$  will be high and hence  $k_{bad}(x_1, x_2)$  dominates the WTA kernel making it less discriminative.

## 4 OUR PROPOSAL: DENSIFIED WTA HASHING

### 4.1 2-UNIVERSAL HASHING

**Definition 1.** A randomized function  $h_u : [l] \rightarrow [k]$  is 2-universal if,  $\forall i, j \in [l]$  with  $i \neq j$ , we have the following

property for any  $z_1, z_2 \in [k]$

$$Pr(h_u(i) = z_1 \text{ and } h_u(j) = z_2) = \frac{1}{k^2}. \quad (4)$$

A simple universal hash function example would be, for random number  $a$  and  $b$  and a prime number  $p \leq k$ , compute:  $h_u(x) = (ax + b \bmod p) \bmod k$ .

### 4.2 PROPOSAL

In [Shrivastava and Li, 2014b] the authors proposed the idea of Densification of hashes for obtaining a one-pass hashing scheme which has the same collision probability as the traditional minwise hashing. The idea was to reassign empty bins, having all zero values, by borrowing values from nearest non-empty bins added with some constant offset. Furthermore, [Shrivastava, 2017] showed a better densification schema with optimal variance. Motivated by this idea, we propose a similar re-assignment of empty bins generated from WTA. We will show that the modified WTA, which we call "Densified WTA" (DWTA) hashing, produces the right kernel. This is little surprising because *Densification* was used in the literature to speed up the hashing scheme with the same old property. Here we rather show a first example where densification improves the hashing scheme by making it more informative. This is also the first use of densification over non-binary data.

Vanilla WTA assigns all empty bins a constant value of 1. Using densification, we assign new random values to all the empty bins. For a given data vector  $x$ , we first generate a set of WTA hashes and place them one after the other (See Table 3).

The overall procedure of Densification for reassigning the empty bins is shown in Algorithm 1. We do not touch non-empty bins, as we know that WTA hashes are informative enough. Thus, if a bin is non-empty, its WTA hash value is the DWTA hash value. The key idea in this algorithm is that when a bin  $i$  is empty, instead of assigning it with a constant 1 like what WTA does, it chose

Table 3: Example densification of WTA hashes shown in Table 2. All the hash values of empty bins are reassigned (shown in red) by the values of the mapped (using  $h_u(\cdot, \cdot)$ ) and lookup table in Table 4) non-empty bins with offset shown by the arrow. This unusual procedure actually is the right fix for WTA as shown by Theorem 1

$\mathcal{H}_{Dwta}(x_1)$	$1+3*C$	2	1	$2+1*C$	2	$2+2*C$
$\mathcal{H}_{Dwta}(x_2)$	$3+3*C$	2	$2+3*C$	$3+4*C$	3	$2+2*C$

Table 4: Results of empty bins re-assignment mapping in Table 2 running Algorithm 1.  $i$  and  $attempt$  are the two arguments for some 2-universal hash function and  $map$  represents the non-empty bin  $i$  is mapped to.

	$i$	$attempt$	$map$
$x_1$	1	3	3
	4	1	5
	6	2	2
$x_2$	1	3	5
	3	3	2
	4	4	5
	6	2	2

some non-empty bin randomly using a 2-universal hash function,  $h_u$  and use the value of the chosen non-empty bin with some appropriate offset that ensures no spurious collisions. The 2-universal hash function takes in two arguments: 1) the index of the current empty bin and 2) the number of attempts to reach the first non-empty bin. The first argument is to ensure that DWTA will produce good kernels defined in Section 3. Specifically, for instance, in Table 2, Bin 1s are both empty for  $x_1$  and  $x_2$ . The ideal collision probability of such empty bins should be the same as that of two non-empty bins, derived in Equation 3. The second argument,  $attempts$ , is to prevent infinite cycles during the process of reaching the non-empty bin. For instance, when we compute the non-empty bin mapping for Bin  $i$ , if  $h_u$  only takes in  $i$  as an argument and  $i = h_u(i)$ , then the algorithm would run into an infinite loop. However, with such monotonically increasing  $attempts$ , even under the same  $i$ , the sequence of hash values generated from  $h_u$  will not run into infinite cycles. Another scenario that can test the randomness of our algorithm is when  $j = h_u(i, attempt)$  and bin  $i$  and  $j$  are both empty. Under such circumstance, bin  $i$  and  $j$  are not guaranteed to be re-assigned with the value of the same bin because the re-assignments are independent due to 2-universality of  $h_u(\cdot, \cdot)$ .

For each empty bin  $i$ , we locate a random (but consistently chosen) non-empty bin  $j$  according to a 2-universal hash function, call it  $h_u$ . Formally,

$$\mathcal{H}_{Dwta}[i] = \mathcal{H}_{wta}[j] + attempt * C. \quad (5)$$

---

#### Algorithm 1 Densified WTA Hashing

---

**input**  $n$  hashes  $\mathcal{H}_{wta}[]$  generated from WTA Hashing  
**input**  $h_u(\cdot, \cdot)$ , constant  $C$   
Initialize  $\mathcal{H}_{Dwta}[] = 0$   
**for**  $i = 1$  to  $n$  **do do**  
  **if**  $\mathcal{H}_{wta}[i] \neq E$  **then**  
     $\mathcal{H}_{Dwta}[i] = \mathcal{H}_{wta}[i]$   
  **else**  
     $attempt = 1$   
     $next = h_u(i, attempt)$   
    **while**  $\mathcal{H}_{wta}[next] = E$  **do**  
       $attempt++$   
       $next = h_u(i, attempt)$   
    **end while**  
     $\mathcal{H}_{Dwta}[i] = \mathcal{H}_{wta}[next] + attempt * C$   
  **end if**  
**end for**  
**return**  $\mathcal{H}_{Dwta}[]$

---

Then the newly assigned value to the empty bin  $i$  is exactly the value of  $j$  with some appropriate offset. The offset is mainly the number of attempts such process make before termination, multiplying by some constant  $C > K$ . Table 3 gives a toy example of how Algorithm 1 works on table 2. For  $x_1$ , from Table 4, the mapped non-empty bin for Bin 1 with map function  $h_u$  is 3 and Bin 3's hash value is 1. The total attempts made for reaching Bin 2 is 3. Therefore, according to equation 5, the new hash value of Bin 1 would be  $1 + 3 * C$ . Similarly, Bin 4 is assigned with  $2 + 1 * C$  and Bin 6 is assigned with  $2 + 2 * C$ . Reassignments in the same manner happen to  $x_2$  but since it is more sparse than  $x_1$ , more bins are filled with new hash values. Recall in Issues with WTA Hashing Section, we discuss that the collisions between  $\mathcal{H}_{wta}(x_1)$  and  $\mathcal{H}_{wta}(x_2)$  happened in Bin 1, 4 and 6. After densification, there is no collision in Bin 1 and 4. Therefore after densification the hash collision similarity comes down to  $\frac{2}{6} = 0.33$ .

Formally, let us assume that we want to generate  $n$  hash values.  $\Theta_i(x)$  denote bin  $i$ . Let  $h_u(i, attempt)$  be the first number in the process described in Algorithm 1 such that  $\Theta_{h_u(i, attempt)}(x) \neq E$ . We can define the Densified

Table 5: Each entry displays the Sparsity of VOC2010, LabelMe-12-50k and MSRc datasets in 1000 BoW, 5000 BoW and 10000 BoW representation. Sparsity shows the Raw Data sparsity of original BoW vectors and Empty Codes shows the ratio of empty hash codes in resulting WTA Hashing encoding (empty codes means empty sampling). By increasing dictionary size, Sparsity naturally goes up in all three datasets.

	1000 BoW (%)		5000 BoW (%)		10000 BoW (%)	
	Sparsity	Empty Codes	Sparsity	Empty Codes	Sparsity	Empty Codes
<b>VOC2010</b>	68.63	23.84	88.18	61.39	92.87	74.81
<b>LabelMe-12-50k</b>	58.07	13.63	82.93	48.18	89.49	64.43
<b>MSRc</b>	69.46	24.66	86.83	56.60	91.54	70.07

WTA,  $\mathcal{H}_{Dwta}$ , as follows

$$\mathcal{H}_{Dwta}(\Theta_i(x)) = \begin{cases} \mathcal{H}_{wta}(\Theta_i(x)) & \text{if } \Theta_i(x) \neq E \\ \mathcal{H}_{wta}(\Theta_{h_u(i, attempt)}(x)) + attempt * C & \text{otherwise.} \end{cases}$$

Based on this definition, we now show our main result that  $\mathcal{H}_{wta}$  precisely fixes the issue of empty bins and get rid of the bad kernels. Since the result holds for any bin, we will drop the subscript  $i$ . Formally,

**Theorem 1.** *For any given  $x$  and  $y$ , the collision probability of "Densified WTA"  $\mathcal{H}_{Dwta}$  satisfies:*

$$\begin{aligned} Pr(\mathcal{H}_{Dwta}(x_1) = \mathcal{H}_{Dwta}(x_2)) &= k_{good}(x_1, x_2) \\ &= k_{Dwta}(x_1, x_2), \end{aligned} \quad (7)$$

**Proof:** See supplementary material.  $\square$

From Theorem 1, it is clear that the new kernel is precisely the good kernel  $k_{good}(x_1, x_2)$  with no contribution of  $k_{bad}(x_1, x_2)$  in  $k_{Dwta}(x_1, x_2)$ , irrespective of the sparsity.

### 4.3 COST OF DENSIFICATION

We can see that we incur an additional cost of densification over the generated WTA hashes. The cost comes from, as shown in Algorithm 1, if the bin is empty, it requires an additional while loop. Let  $n$  be the total number of bins in  $\mathcal{H}_{Dwta}(\Theta(x))$  and  $n_{NE}$  be the number of non-empty bins. The probability of terminating the while loop in one iteration is  $p = \frac{n_{NE}}{n}$ . Therefore the expected iterations each while loop need to run before termination will be  $\frac{1}{p}$ . The computation is negligible because it only involves  $\frac{1}{p}$  hash lookups for every empty bin. We will show in Section 5.4 that this negligible cost leads to huge performance gains in practice. This we believe is one of the many examples where a careful analysis and some mathematics goes a long way in designing simple and significantly better algorithms.

### 4.4 DEALING WITH LARGE HASH VALUES

It can be seen from Equation 6 that the value of  $\mathcal{H}_{Dwta}(\Theta_i(x))$  can become large due to the term  $attempt * C$ . It turns out that this is not a problem. There is a significant amount of literature to reduce the final range of hashing scheme [Li and König, 2011]. The idea is to randomly shrink the range at an insignificant cost of small constant random collisions. We found that if we want to constrain the final hash value to a range  $R$  simply taking mod  $R$  of the final hash value suffices in practice. This is what we use during evaluations.

## 5 EXPERIMENTS

In this section, we compare the performance of Densified WTA hashing with Vanilla WTA on two tasks: 1) Image retrieval and 2) classification. *The experiments do not compare with other hashing algorithms because the goal of this paper is solving the problem of WTA while maintaining its superiority over other methods mentioned in the introduction section.* They are important tasks of evaluating the performance of Hashing algorithms, because hashing has received increasing interests in efficient large-scale image retrieval with the rapid growth of web images and the classification accuracy can quantify the discriminative power in hashes.

### 5.1 DATASETS AND BASELINES

We use three popular publicly available image datasets, including VOC2010 [Everingham and Winn, 2010], LabelMe-12-50k [Russell et al., 2008] and MSRc [msr, 2004]:

- The VOC2010 database contains a total of 10103 annotated images of twenty classes, including people, animals, vehicles and indoors. The data has been split into 50% for training and 50% for testing. One image could belong to different classes.
- The LabelMe-12-50k dataset consists of 50,000

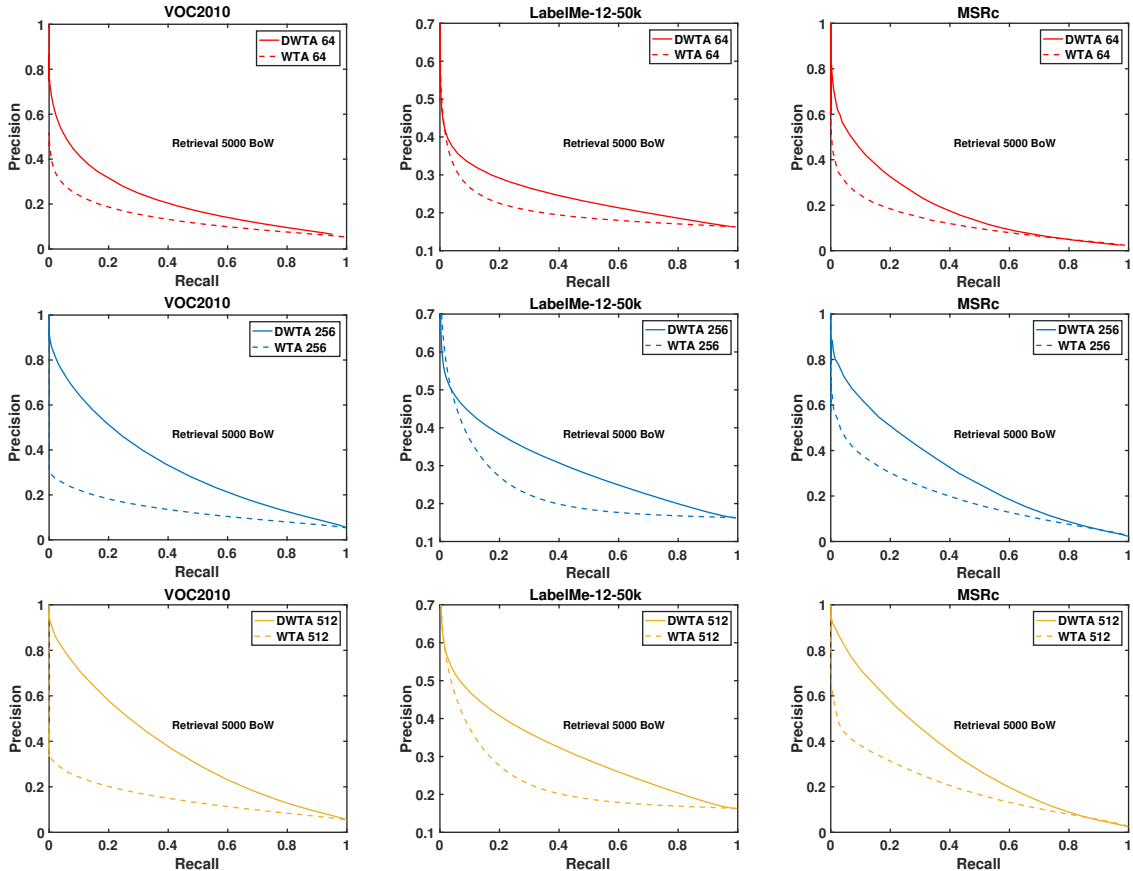

Figure 1: Precision and Recall curves comparing the retrieval performance of Densified WTA vs. WTA on VOC2010, LabelMe-12-50k and MSRC datasets for 1000, 5000 and 10000 BoW feature representations. The semi-dotted lines are the vanilla WTA hashes and bold lines are our proposed Densified WTA Hashes. Different colors represent different number of BoW. We only show 5000 BoW with 64, 256 and 512 hashes (number of hashes used for ranking). Densified WTA significantly outperforms the corresponding WTA consistently.

JPEG images of twelve classes, 80% for training and 20% for testing. They are  $256 \times 256$ -pixels pictures extracted from LabelMe.

- The MSRC is a database of thousands of labeled, high-resolution (680x480 pixels) images of eighteen classes.

The authors of WTA paper used LabelMe for retrieval tasks and VOC2010 datasets for classification tasks. We demonstrate both retrieval and classification on both of the datasets as well as a new MSRC dataset. As described in Section of Large Hash Values, to reduce the space of Densified WTA Hashing, we apply *mod* operation on hash values of all bins as a fix. Table 5 summarizes the sparsity of Raw Data, input Bag of Words, and the ratio of Empty Hash codes, the resulting codes after applying WTA Hashing to input Bag of Words vectors. We can see that when the number of BoW increases, sparsity, highest in 10000 BoW, also goes up in all three datasets.

Note here, we are doing the same tasks as WTA paper, but we do not apply exactly same settings and the sparsities of BoW would thereby be different (they did not reveal sparsity of their datasets as well). Therefore, we do not expect the same results on VOC2010 dataset due to the sparsity difference.

## 5.2 IMAGE RETRIEVAL

We now compare the performance of our Densified WTA codes with Vanilla WTA by replicating the retrieval experiments and studying the standard precision-recall curves. This is our main task of performance comparison because like we mentioned in the Introduction section, WTA is quite appealing for information retrieval. We re-stress that WTA (and our DTWA) are the fastest known hashing scheme, significantly faster than plain random projections. Furthermore hashing cost is a critical bottleneck in large-scale retrieval system.

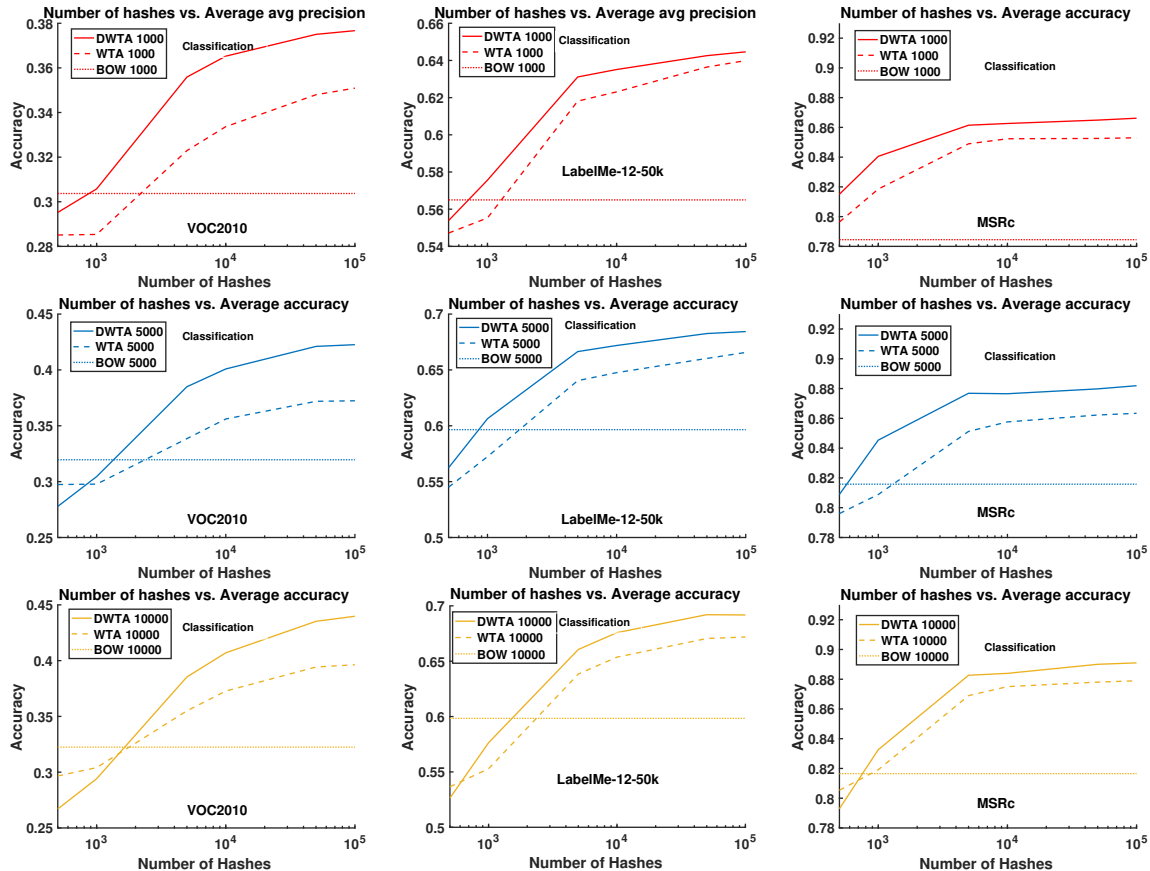

Figure 2: Densified WTA vs. WTA on the task of Image Classification on three different vision datasets. We used 1000, 5000 and 10000 BoW representation of the images. The y-axis is the mean accuracy and the x-axis is the number of hashes used as features. The horizontal lines (dotted) are classification based just on the BoW features. The semi-dotted lines are the vanilla WTA hashes and bold lines are our proposed Densified WTA Hashes. The colors represent which BoW was used as features. Densified WTA significantly outperforms the corresponding WTA consistently for all the choices.

For each query image, the nearest-neighbors of each test data were ranked among training data based on the Hamming distance of the hash codes. Since we had labeled datasets, all the images with the same label as the query were treated as the gold standard neighbors. Note, as mentioned in our proposal, WTA and Densified WTA leads to two different similarity measures (or kernel). Therefore, this experiment is comparing which among these two kernels agrees with the ground truth labels.

Replicating the setting of the original WTA paper, we first generated standard BoW of local descriptors, computed from the images, using the publicly available code [Vedaldi and Fulkerson, 2010]. BoW was generated by extracting local descriptors from the dense grid over each image and quantizing them using K-means. We used DSIFT [Kokkinos et al., 2012] as our descriptor measuring gradient at each key point pixel. The gradient was represented by a single 128-dimensional vector,

stacked by a three-dimensional ( $8 \times 4 \times 4$ ) elementary feature vector formed by the pixel location ( $4 \times 4$ ) and the gradient orientation (8). In this experiment, we consider BoW with 1000, 5000, and 10,000 bins to demonstrate the effect of sparsity. We then generated WTA and Densified WTA hashes from these images and produce feature vectors as suggested in the WTA paper. For the feature generation, we used the fixed recommended setting of  $K = 4$  for all the datasets which was picked using the same method described in [Yagnik et al., 2011] and best for WTA. The precision and recall curves for the rankings based on different hash codes are shown in Figure 1. We show plots for 64, 256 and 512 hash codes of 1000, 5000 and 10000 BoW representations (9 curves for each dataset per hashing scheme). To average out the randomness of both Densified and original WTA hashing, every curve on the graphs is averaged from 10 runs.

Densified WTA hashes lead to notably better precision-

recall compared to Vanilla WTA on all combinations irrespective of the choices of the dataset. As with classification, an increase in BoW leads to larger gap due to increases in sparsity. This again validates our claims. It is exciting to see that a small but principle modification to WTA Hashing can lead to drastic benefits.

### 5.3 CLASSIFICATION

Our motivation for comparing two Hashing algorithms using classification accuracy is to quantify the discriminative power in hashes. We use Densified WTA codes to do the classification task on the VOC2010, LabelMe-12-50k and MSRC datasets. We don't compare with those state-of-the-art methods like a particular type of nonlinear Mercer kernels, e.g. the intersection kernel or the Chi-square kernel [Yang et al., 2009] in classifying these datasets. Instead, we apply Densified WTA and original WTA hashes to a baseline method, sparse BoW of local descriptors and passing to linear SVM classifier, to show that the Densified WTA achieve superior improvement on classification tasks on sparse data.

To compute the classification performance we ran a simple SVM on BoW features, WTA hashed features, and Densified WTA hashed features. We varied the number of hash features over a range of values:  $5 \times 10^2$ ,  $1 \times 10^3$ ,  $5 \times 10^3$ ,  $1 \times 10^4$ ,  $5 \times 10^4$ ,  $1 \times 10^5$ . We again choose  $K=4$ . The  $C$  parameter of SVM was tuned using cross-validation, for every individual run, to ensure the best possible performance on every combination of the number of features and the hashing scheme. This ensures fairness of the comparisons.

Figure 2 compares the mean average precision of classification tasks using Densified WTA codes, WTA codes and basic sparse BoW on three datasets. The baseline, mean average precision for the three BoWs with different bins is shown by dashed straight lines. The mean average precision for WTA feature vectors is shown by dot-dashed curves and for Densified WTA feature vectors is shown by dot-dashed curves. We observe that as stated in WTA paper, precision increases when original BoW bin number increases or the number of codes increases with WTA beating BoW in each case. These observations are in line with the original WTA paper. We followed the experiment pipeline from the WTA paper, while generating BoW using standard package [Vedaldi and Fulkerson, 2010]. It is not surprising to see exactly the same trends in classification results with a difference in relative values.

The Densified WTA consistently outperforms Vanilla WTA significantly on all the three datasets, irrespective of the choice of BoW or the number of hashes. More-

Table 6: Average running time comparison among DWTA, and Sparse Random Projection for three datasets with 10000 BoW representation and 512 hashes.

	SRP (ms)	DWTA (ms)
<b>VOC2010</b>	8.578	0.032
<b>LabelMe-12-50k</b>	8.62	0.046
<b>MSRC</b>	8.609	0.04

over, the performance gap increases with the number of BoW. The increase in BoW rises sparsity of the dataset and hence this trend validates our hypothesis and theory in this paper. The gains over WTA are significant and our results clearly push the boundary of classification performance with hashing-based kernels significantly outperforming BoW. Note that increasing BoW from 5000 to 10000 leads to no gains in accuracy. But with hashing, especially Densified WTA, the gains keep climbing.

### 5.4 RUNNING TIME OF DWTA HASHING

As mentioned in Section 4.3, DWTA hashing only induces negligible cost of densification. We implemented DWTA and another popular algorithm for sparse data, Sparse Random Projection [Achlioptas, 2001] (SRP) and empirically show the average running time comparison of both algorithms for each data point in Table 6. We used 10000 BoW representation for three datasets and 512 hashes. The results clearly exhibited the advantage of DWTA over FRP in running time which further proves the superiority and Practicality of DWTA in general.

## 6 CONCLUSIONS

In this work, we revisited the problem of WTA Hashing for very sparse datasets which are ubiquitous in large-scale applications. We found a particular issue with WTA hashing in this regime which makes them uninformative with an increase in sparsity. We provide a principled solution to this problem using the novel 2-universal hashing for "Densification". Our solutions leverage the theoretical benefits of rank correlation methods and at the same time successfully resolves the concern of uninformative hash values produced by WTA Hashing for data with high sparsity. Evaluation results shown confirm the superior performance of Densified WTA Hashing on both image retrieval and classification task.

## Abstract

Lifted inference reduces the complexity of inference in relational probabilistic models by identifying groups of constants (or atoms) which behave symmetric to each other. A number of techniques have been proposed in the literature for lifting marginal as well MAP inference. We present the first application of lifting rules for marginal-MAP (MMAP), an important inference problem in models having latent (random) variables. Our main contribution is two fold: (1) we define a new equivalence class of (logical) variables, called Single Occurrence for MAX (SOM), and show that solution lies at extreme with respect to the SOM variables, i.e., predicate groundings differing only in the instantiation of the SOM variables take the same truth value (2) we define a sub-class *SOM-R* (SOM Reduce) and exploit properties of extreme assignments to show that MMAP inference can be performed by reducing the domain of SOM-R variables to a single constant. We refer to our lifting technique as the *SOM-R* rule for lifted MMAP. Combined with existing rules such as decomposer and binomial, this results in a powerful framework for lifted MMAP. Experiments on three benchmark domains show significant gains in both time and memory compared to ground inference as well as lifted approaches not using SOM-R.

## 1 INTRODUCTION

Several real world applications such as those in NLP, vision and biology need to handle non-i.i.d. data as well as represent uncertainty. Relational Probabilistic models (Getoor and Taskar 2007) such as Markov logic networks (Domingos and Lowd 2009) combine the power

of relational representations with statistical models to achieve this objective. The naïve approach to inference in these domains grounds the relational network into a propositional one and then applies existing inference techniques. This can often result in sub-optimal performance for a large number of applications since inference is performed oblivious to the underlying network structure.

Lifted inference (Kimmig, Mihalkova, and Getoor 2015) overcomes this shortcoming by collectively reasoning about groups of constants (atoms) which are identical to each other. Starting with the work of Poole (Poole 2003), a number of lifting techniques which lift propositional inference to the first-order level have been proposed in literature. For instance, for marginal inference, exact algorithms such as variable elimination and AND/OR search and approximate algorithms such as belief propagation and MCMC sampling have been lifted to the first-order level (cf. (de Salvo Braz, Amir, and Roth 2005; Gogate and Domingos 2011; G. Van den Broeck et al. 2011; Kersting, Ahmadi, and Natarajan 2009; Singla and Domingos 2008; Niepert 2012; Venugopal and Gogate 2012)). More recently, there has been increasing interest in lifting MAP inference (both exact and approximate) (Sarkhel et al. 2014; Mittal et al. 2014; Mladenov, Kersting, and Globerson 2014). Some recent work has looked at the problem of approximate lifting i.e., combining together those constants (atoms) which are similar but not necessarily identical (Van den Broeck and Darwiche 2013; Singla, Nath, and Domingos 2014; Sarkhel, Singla, and Gogate 2015).

Despite a large body of work on lifted inference, to the best of our knowledge, there is no work on lifted algorithms for solving marginal maximum-a-posteriori (MMAP) queries. MMAP inference is ubiquitous in real-world domains, especially those having latent (random) variables. It is well known that in many real-world domains, the use of latent (random) variables significantly improves the prediction accuracy (Maaten, Welling, and

Saul 2011). Moreover, the problem also shows up in the context of SRL domains in tasks such as plan and activity recognition (Singla and Mooney 2011). Therefore, efficient lifted methods for solving the MMAP problem are quite desirable.

MMAP inference is much harder than marginal (sum) and MAP (max) inference because sum and max operators do not commute. In particular, latent (random) variables need to be marginalized out before MAP assignment can be computed over the query (random) variables and as a result MMAP is NP-hard even on tree graphical models (Park 2002). Popular approaches for solving MMAP include variational algorithms (Liu and Ihler 2013), AND/OR search (Marinescu, Dechter, and Ihler 2014) and parity solvers (Xue et al. 2016).

In this paper, we propose the first ever lifting algorithm for MMAP by extending the class of lifting rules (Jha et al. 2010; Gogate and Domingos 2011; Mittal et al. 2014). As our first contribution, we define a new equivalence class of (logical) variables called *Single Occurrence for MAX (SOM)*. We show that the MMAP solution lies at extreme with respect to the SOM variables, i.e., predicate groundings which differ only in the instantiation of the SOM variables take the same truth (true/false) value in the MMAP assignment. The proof is fairly involved due to the presence of both MAX and SUM operations in MMAP, and involves a series of problem transformations followed by exploiting the convexity of the resulting function.

As our second contribution, we define a sub-class of SOM, referred to as *SOM-R (SOM Reduce)*. Using the properties of extreme assignments, we show that the MMAP solution can be computed by reducing the domain of SOM-R variables to a single constant. We refer to this as *SOM-R rule for lifted MMAP*. SOM-R rule is often applicable when none of the other rules are, and can result in significant savings since inference complexity is exponential in the domain size in the worst case.

Finally, we show how to combine SOM-R rule along with other lifting rules e.g., binomial and decomposer, resulting in a powerful algorithmic framework for lifted MMAP inference. Our experiments on three different benchmark domains clearly demonstrate that our lifting technique can result in orders of magnitude savings in both time and memory compared to ground inference as well as vanilla lifting (not using the SOM-R rule).

## 2 BACKGROUND

**First-Order Logic:** The language of first-order logic (Russell and Norvig 2010) consists of *constant*, *variable*, *predicate*, and *function* symbols. A *term* is a variable, constant or is obtained by application of a func-

tion to a tuple of terms. Variables in first-order logic are often referred to as *logical variables*. We will simply refer to them as variables, henceforth. A *predicate* defines a relation over the set of its arguments. An *atom* is obtained by applying a predicate symbol to the corresponding arguments. A *ground atom* is an atom having no variables in it. Formulas are obtained by combining predicates using a set operators:  $\wedge$  (and),  $\vee$  (or) and  $\neg$  (not). Variables in a formula can be universally or existentially quantified using the operators  $\forall$  and  $\exists$ , respectively. A first-order theory (knowledge base) is a set of formulas. We will restrict our attention to function free finite first-order logic with Herbrand interpretation (Russell and Norvig 2010) and universally quantified variables. In the process of (partially) grounding a theory, we replace all (some) of the universally quantified variables with the possible constants in the domain. In the following, we will use capital letters (e.g.,  $X, Y$  etc.) to denote logical variables and small case letters to denote constants. We will use  $\Delta_X = \{x_1, x_2, \dots, x_m\}$  denotes the domain of variable  $X$ .

**Markov Logic:** A Markov logic network (Domingos and Lowd 2009) (MLN)  $M$  is defined as a set of pairs  $\{f_i, w_i\}_{i=1}^n$  where  $f_i$  is a formula in first-order logic and  $w_i$  is the weight of  $f_i$ . We will use  $F(M)$  to denote the set of all the formulas in MLN. Let  $\mathcal{X}$  denote the set of all the logical variables appearing in MLN. An MLN can be seen as a template for constructing ground Markov networks. Given the domain  $\Delta_X$  for every variable  $X \in \mathcal{X}$ , the ground network constructed by MLN has a node for every ground atom and a feature for every ground formula. Let  $\mathcal{T}$  denote the set of all the predicates appearing in  $M$ . We will use  $\mathcal{T}_g$  to denote all the ground atoms corresponding to the set  $\mathcal{T}$  and  $t$  to denote an assignment, i.e. a vector of true/false values, to  $\mathcal{T}_g$ . The distribution specified by an MLN is given as:

$$P(\mathcal{T}_g = t) = \frac{1}{Z} e^{\sum_{i=1}^n \sum_{j=1}^{m_i} w_i f_{ij}(t)} \quad (1)$$

where  $m_i$  denotes the number of groundings of the  $i^{th}$  formula.  $f_{ij}$  represents the feature corresponding to the  $j^{th}$  grounding of the  $i^{th}$  formula. The feature is on if the corresponding formula is satisfied under the assignment  $t$  off otherwise.  $Z$  is the normalization constant. Equivalently, in the potential function representation, the distribution can be written as:

$$P(t) = \frac{1}{Z} \prod_{i=1}^n \prod_{j=1}^{m_i} \phi_{ij}(t) \quad (2)$$

where there is a potential  $\phi_{ij}$  for each  $f_{ij}$  such that  $\phi_{ij}(t) = e^{w_i f_{ij}(t)}$ .

**Marginal MAP (MMAP):** Let the set of all predicates  $\mathcal{T}$  be divided into two disjoint subsets  $\mathcal{Q}$  and  $\mathcal{S}$ , referred

to as MAX and SUM predicates, respectively. Let  $q$  (resp.  $s$ ) denote an assignment to all the groundings of the predicates in  $\mathcal{Q}$  (resp.  $\mathcal{S}$ ). Note that  $\mathcal{T} = \mathcal{Q} \cup \mathcal{S}$ , and given assignment  $t$  to  $\mathcal{T}$ ,  $t = q \cup s$ . Then, the *marginal-MAP* (MMAP) problem for MLNs can be defined as:

$$\arg \max_q \sum_s \prod_{i=1}^n \prod_{j=1}^{m_i} \phi_{ij}(q, s) = \arg \max_q W_M(q) \quad (3)$$

$$\text{where, } W_M(q) = \sum_s \prod_{i=1}^n \prod_{j=1}^{m_i} \phi_{ij}(q, s)$$

$W_M(q)$  is referred to as the MMAP objective function for the MLN  $M$ , and its solution  $q^* = \arg \max_q W_M(q)$  is referred as the MMAP solution. Note that we can get rid of  $Z$  in equation 3, since we are only interested in finding the maximizing assignment and  $Z$  is a constant.

**Preliminaries:** We will assume that our MLN is in Normal Form (Mittal et al. 2014) i.e., (a) no constants appear in any of the formulae (b) if  $X$  and  $Y$  appear at the same predicate position in one or more formulae, then  $\Delta_X = \Delta_Y$ . Any MLN can be converted into normal form by a series of mechanical operations. We will also assume that formulas are standardized apart i.e., we rename the variables such that the sets of variables appearing in two different formulae are disjoint with each other. We define an equivalence relation  $\sim$  over the set of variables such that  $X \sim Y$  if (a)  $X$  and  $Y$  appear at the same predicate position OR (b)  $\exists Z$  such that  $X \sim Z$  and  $Y \sim Z$ . We will use  $\tilde{X}$  to denote the equivalence class corresponding to variable  $X$ . Variables in the same equivalence class must have the same domain due to the normal form assumption. We will use  $\Delta_{\tilde{X}}$  to refer to the domain of the variables belonging to  $\tilde{X}$ .

Finally, though our exposition in this work is in terms of MLNs, our ideas can easily be generalized to other representations such as weighted parfactors (de Salvo Braz, Amir, and Roth 2005) and probabilistic knowledge bases (Gogate and Domingos 2011).

### 3 SINGLE OCCURRENCE FOR MMAP

#### 3.1 Motivation

In this work, we are interested in lifting the marginal-MAP (MMAP) problem. Since MMAP is a problem harder than both marginal and MAP inference, a natural question to examine would be if existing lifting techniques for MAP and marginal inference can be extended to the case of MMAP. Or further still, if additional rules can be discovered for lifting the MMAP problem. Whereas many of the existing rules such as decomposer and binomial<sup>1</sup> (Jha et al. 2010; Mittal et al. 2015) extend

<sup>1</sup>applicable when the binomial predicate belongs to MAX

in a straightforward manner for MMAP, unfortunately the SO rule (Mittal et al. 2014), which is a powerful rule for MAP inference, is not directly applicable.

In response, we propose a new rule, referred to as Single Occurrence for MAX Reduce (SOM-R), which is applicable for MMAP inference. We first define a variable equivalence class, referred to as SOM, which requires that (1) no two variables in the class appear in the same formula (2) at least one of the variables in the class appears in a MAX predicate. We further define a sub-class of SOM, referred to as SOM-R, which imposes a third condition (3) either all the SUM predicates in the theory contain a SOM variable or none of them does. Our SOM-R rule states that domain of SOM-R variables can be reduced to a single constant for MMAP inference. Consider the following example MLN, henceforth referred to as  $M_1$ :

$$w_1 : Frnds(X, Y) \wedge Parent(Z, X) \Rightarrow Knows(Z, Y)$$

$$w_2 : Knows(U, V)$$

$$SUM : Parent \quad MAX : Frnds, Knows$$

The equivalence classes in this example are given by  $\{X\}$ ,  $\{Y, V\}$  and  $\{Z, U\}$ . It is easy to see that each of these equivalence classes satisfy the three conditions above and hence, SOM-R rule can be applied over them. This makes the MMAP inference problem independent of the size of the domain and hence, it can be solved in  $O(1)$  time. Ground inference has to deal with  $O(m^2)$  number of ground atoms resulting in  $O(\exp(cm^2))$  complexity in the worst case<sup>2</sup>, where  $c$  is a constant. Further, in the absence of the SOM-R rule, none of the existing lifting rules apply and one has to resort to partial grounding again resulting in worst case exponential complexity.

We note that conditions for identifying SOM and SOM-R specifically make use of the structure of the MMAP problem. Whereas condition 1 is same as Mittal et al.'s SO condition, condition 2 requires the variables in the SOM class to belong to a MAX predicate. Condition 3 (for SOM-R) further refines the SOM conditions so that domain reduction can be applied.

We prove the correctness of our result in two phases. First, we show that SOM equivalence class implies that MMAP solution lies at extreme, meaning that predicate groundings differing only in the instantiation of the SOM class take the same truth value. Second, for the sub-class SOM-R, we further show that domain can be reduced to a single constant for MMAP. Here, we rely on the properties of extreme assignments.

Our proof strategy makes use of a series of problem

<sup>2</sup>Inference complexity is exponential in the number of ground atoms. Here, we assume  $|\Delta_X| = |\Delta_Y| = |\Delta_Z| = m$

transformations followed by using the convexity of the resulting function. These algebraic manipulations are essential to prove the correctness of our result, and are some of the important contributions of our paper. Next, we describe each step in detail. The proofs of theorems (and lemmas) marked with (\*) are in the supplement.

### 3.2 SOM implies Extreme Solution

We introduce some important definitions. We will assume that we are given an MLN  $M$ . Further, we are interested in solving an MMAP problem over  $M$  where the set of MAX predicates is given by  $\mathcal{Q}$ .

**Definition 1.** (Single Occurrence for MAX) We say that a variable equivalence class  $\tilde{X}$  is Single Occurrence for MAX (SOM) if (a)  $\forall i, f_i \in F(M)$ , there is at most one variable from the set  $\tilde{X}$  occurring in  $f_i$  (b) there exists a variable  $X \in \tilde{X}$  and a predicate  $P \in \mathcal{Q}$ , such that  $X$  appears in  $P$ .

Next, we define the notion of an extreme assignment.

**Definition 2.** (Extreme Assignment) Let  $\tilde{X}$  be a variable equivalence class. An assignment  $q$  to MAX predicates  $\mathcal{Q}$  lies at extreme (with respect to  $\tilde{X}$ ), if  $\forall P \in \mathcal{Q}$ , all the groundings of  $P$  with the same instantiation to variables  $\mathcal{X} - \tilde{X}$ , take the same value in  $q$ .

In  $M_1$ , an extreme assignment with respect to variable equivalence class  $\{Y, V\}$  will assign the same truth value to the ground atoms  $Knows(z, y_1)$  and  $Knows(z, y_2)$ ,  $\forall z \in \Delta_Z$  and  $\forall y_1, y_2 \in \Delta_Y$ . We next define the notion of an MLN variablized with respect to a variable equivalence class.

**Definition 3.** (Variablized MLN) Let  $\tilde{X}$  be an equivalence class. Let  $M_{\tilde{X}}$  be the MLN obtained by instantiating (grounding) the variables in the set  $\mathcal{X} - \tilde{X}$ . We say that  $M_{\tilde{X}}$  is variablized (only) with respect to the set  $\tilde{X}$ .

For instance in  $M_1$ , variablizing with respect to the equivalence class  $\{Y, V\}$  results in MLN with formulas similar to:

$$\begin{aligned} w_1 &: Frnds(x, Y) \wedge Parent(z, x) \Rightarrow Knows(z, Y) \\ w_2 &: Knows(u, V) \end{aligned}$$

where  $x, z$  and  $u$  are constants belonging to respective domains.  $Frnds(x, Y)$ ,  $Knows(z, Y)$  and  $Knows(u, V)$  can be treated as unary predicates over the equivalence class  $\{Y, V\}$  since  $x, z$  and  $u$  are constants. Similarly,  $Parent(z, x)$  can be treated as a propositional predicate.

It is important to note that,  $M_{\tilde{X}}$  represents the same distribution as  $M$ . Further,  $M_{\tilde{X}}$  can be converted back into normal form by introducing a new predicate for every combination of constants appearing in a predicate. We now define one of the main theorems of this paper.

**Theorem 1.** Let  $M$  be an MLN and let  $\tilde{X}$  be a SOM equivalence class. Then, an MMAP solution for  $M$  lies at extreme with respect to  $\tilde{X}$ .

We will prove the above theorem by defining a series of problem transformations. In the following, we will work with MLN  $M$  and  $\tilde{X}$  as a SOM variable equivalence class. We will use  $\mathcal{Q}$  and  $\mathcal{S}$  to denote set of MAX and SUM predicates, respectively.  $q$  and  $s$  will denote the assignments to respective predicate groundings (see Background (section 2)).

#### 3.2.1 Problem Transformation (PT) 1

**Objective PT1:** Convert MMAP objective into a form which only has unary and propositional predicates.

**Lemma 1.** Let  $M_{\tilde{X}}$  denote the MLN variablized with respect to SOM equivalence class  $\tilde{X}$ . Then,  $M_{\tilde{X}}$  contains only unary and propositional predicates. Further, the MMAP objective can be written as:

$$\arg \max_q W_M(q) = \arg \max_q W_{M_{\tilde{X}}}(q)$$

The proof that  $M_{\tilde{X}}$  only has unary and propositional predicates follows immediately from the definition of  $M_{\tilde{X}}$  (defn. 3) and the fact that  $\tilde{X}$  is SOM. Further, since  $M$  and  $M_{\tilde{X}}$  define the same distribution, we have the equivalence of the MMAP objectives. Since,  $M_{\tilde{X}}$  only has unary and propositional predicates, we will split the assignment  $q$  to groundings of  $\mathcal{Q}$  into  $(q_u, q_p)$  where  $q_u$  and  $q_p$  denote the assignments to groundings of unary and propositional predicates, respectively. Similarly, for assignment  $s$  to groundings of  $\mathcal{S}$ , we split  $s$  as  $(s_u, s_p)$ .

#### 3.2.2 Problem Transformation 2

**Objective PT2:** In the MMAP objective, get rid of propositional MAX predicates.

**Lemma 2.\*** Consider the MMAP problem over  $M_{\tilde{X}}$ . Let  $q_p$  be some assignment to propositional MAX predicates. Let  $M'_{\tilde{X}}$  be an MLN obtained by substituting the truth value in  $q_p$  for propositional predicates. Then, if  $M'_{\tilde{X}}$  has a solution at extreme for all possible assignments of the form  $q_p$  then,  $M_{\tilde{X}}$  also has a solution at extreme.

Therefore, in order to prove the extrema property for  $M_{\tilde{X}}$ , it is sufficient to prove it for a generic MLN  $M'_{\tilde{X}}$ , i.e., without making any assumptions on the form of  $q_p$ .

For ease of notation, we will drop the prime in  $M'_{\tilde{X}}$  and simply refer to it as  $M_{\tilde{X}}$ . Therefore, we need to show that the solution to the following problem lies at extreme:

$$\arg \max_{q_u} W_{M_{\tilde{X}}}(q_u)$$

where the propositional MAX predicates have been gotten rid of in  $M_{\tilde{X}}$ .

### 3.2.3 Problem Transformation 3

**Objective PT3:** In the MMAP objective, get rid of unary SUM predicates using inversion elimination (de Salvo Braz, Amir, and Roth 2005).

First, we note that the MMAP objective:

$$W_{M_{\tilde{X}}}(q_u) = \sum_{s_p, s_u} \prod_{i=1}^n \prod_{j=1}^{m_i} \phi_{ij}(q_u, s_p, s_u)$$

can be equivalently written as:

$$W_{M_{\tilde{X}}}(q_u) = \sum_{s_p, s_u} \prod_{i=1}^n \prod_{j=1}^m \phi'_{ij}(q_u, s_p, s_u)$$

where  $m = |\Delta_{\tilde{X}}|$ .  $\phi'_{ij}(q_u, s_p, s_u) = \phi_{ij}(q_u, s_p, s_u)$  if  $f_i$  contains a variable from  $\tilde{X}$ , else  $\phi'_{ij}(q_u, s_p, s_u) = \phi_{ij}(q_u, s_p, s_u)^{\frac{1}{m}}$  otherwise. It is easy to see this equivalence since the only variables in the theory are from the class  $\tilde{X}$ . When  $f_i$  contains a variable from  $\tilde{X}$ , it has exactly  $m_i = m$  groundings since  $\tilde{X}$  is SOM. On the other hand, if  $f_i$  does not contain a variable from  $\tilde{X}$ , it only contains propositional predicates. Then we raise it to power  $\frac{1}{m}$ , and then multiply  $m$  times in the latter expression to get an equivalent form.

Next, we use inversion elimination (de Salvo Braz, Amir, and Roth 2005) to get rid of unary SUM predicates.

**Lemma 3.** *MMAP problem over  $M_{\tilde{X}}$  can be written as:*

$$\arg \max_{q_u} W_{M_{\tilde{X}}}(q_u) = \arg \max_{q_u} \sum_{s_p} \prod_{j=1}^m \Theta_j(q_u, s_p)$$

where  $\Theta_j$  is a function of unary MAX and propositional SUM predicates groundings  $q_u$  and  $s_p$ , respectively.

*Proof.* We can write the MMAP objective  $W_{M_{\tilde{X}}}(q_u)$  as:

$$\begin{aligned} &= \sum_{s_p, s_u} \prod_{i=1}^n \prod_{j=1}^m \phi'_{ij}(q_u, s_p, s_u) \\ &= \sum_{s_p, s_u} \prod_{j=1}^m \prod_{i=1}^n \phi'_{ij}(q_u, s_p, s_u) \\ &= \sum_{s_p, s_u} \prod_{j=1}^m \Phi_j(q_u, s_p, s_u) \\ &= \sum_{s_p} \sum_{s_{u_1}, s_{u_2}, \dots, s_{u_m}} \prod_{j=1}^m \Phi_j(q_u, s_p, s_{u_j}) \end{aligned}$$

(apply inversion elimination)

$$\begin{aligned} &= \sum_{s_p} \prod_{j=1}^m \sum_{s_{u_j}} \Phi_j(q_u, s_p, s_{u_j}) \\ &= \sum_{s_p} \prod_{j=1}^m \Theta_j(q_u, s_p) \end{aligned}$$

**Proof Explanation:** Second equality is obtained by interchanging the two products. Third equality is obtained by defining  $\prod_i \phi'_{ij}(q_u, s_p, s_u) = \Phi_j(q_u, s_p, s_u)$ . In fourth equality, we have made explicit the dependence of  $\Phi_j$  on  $s_{u_j}$  i.e. the groundings corresponding to the  $j^{\text{th}}$  constant.

**Inversion Elimination** (de Salvo Braz, Amir, and Roth 2006): Since  $\Phi_j$  only depends on  $s_{u_j}$  (among  $s_u$ ) groundings, we can use inversion elimination to invert the sum over  $s_{u_j}$  and product over  $j$  in the fifth equality.

**Final Expression:** We define  $\Theta_j(q_u, s_p) = \sum_{s_{u_j}} \Phi_j(q_u, s_p, s_u)$ .

Note that, at this point, we have only propositional SUM and unary MAX predicates in the transformed MMAP objective.

### 3.2.4 Problem Transformation 4

**Objective PT4:** Exploit symmetry of the potential functions in the MMAP objective.

We rename  $q_u$  to  $q$  and  $s_p$  to  $s$  for ease of notation in Lemma 3. The MMAP objective can be written as:

$$W_{M_{\tilde{X}}}(q) = \sum_s \prod_{j=1}^m \Theta_j(q_j, s) \quad (4)$$

Here,  $q = (q_1, q_2, \dots, q_m)$  and  $q_j$  represents the assignment to the unary MAX predicate groundings corresponding to constant  $j$ . In the expression above, we have made explicit the dependence of  $\Theta_j$  on  $q_j$ . We make the following two observations.

1) Due to the normal form assumption, all the groundings of a first-order logic formula behave identical to each other (up to renaming of constants). Hence, the resulting potential function  $\Theta_j$ 's are also identical to each other.

2) If there are  $r$  unary MAX predicates in  $M_{\tilde{X}}$ , then each  $q_j$  can take  $R = 2^r$  possible values<sup>3</sup>.

Therefore, the value of the product  $\prod_{j=1}^m \Theta_j(q, s)$  in the RHS of Equation 4 depends only on the number of different types of values  $q_j$ 's take in  $q$  (and not on which  $q_j$  takes which value). Let  $\{v_1, v_2, \dots, v_R\}$  denote the set of  $R$  different values that  $q_j$ 's can take. Given a value  $v_l$ , let  $N_l$  denote the number of times  $v_l$  appears in  $q$ . Next, we state the following lemma.

**Lemma 4.** *The MMAP problem can be written as:*

$$\arg \max_q W_{M_{\tilde{X}}}(q) = \arg \max_{N_1, N_2, \dots, N_R} \sum_s \prod_{l=1}^R f_l(s)^{N_l}$$

subject to the constraints that  $\forall l, N_l \geq 0, N_l \in \mathbb{Z}$  and  $\sum_l N_l = m$ . Here,  $f_l(s) = \Theta_j(v_l, s)$ .

<sup>3</sup>since there are  $r$  predicate groundings for each  $j$  and each is Boolean valued

*Proof.* Proof follows from the fact that  $\Theta_j$ 's are symmetric to each other and that the  $q_j$ 's take a total of  $m$  possible (non-unique) assignments since  $\Delta_{\tilde{X}} = m$ .

We say that an assignment  $N_1, N_2, \dots, N_R$  subject to the constraints:  $\forall l, N_l \geq 0$  and  $\sum_l N_l = m$  is at *extreme* if  $\exists l$  such that  $N_l = m$ . Note that for  $R \geq 2$ , extreme assignment also implies that  $\exists l, N_l = 0$ . We have the following lemma.

**Lemma 5.** \* The solution to the MMAP formulation  $\arg \max_q W_{M_{\tilde{X}}}(q)$  lies at extreme iff solution to its equivalent formulation:

$$\arg \max_{N_1, N_2, \dots, N_R} \sum_s \prod_{l=1}^R f_l(s)^{N_l}$$

subject to the constraints  $\forall l, N_l \geq 0, N_l \in \mathbb{Z}$  and  $\sum_l N_l = m$  lies at extreme.

### 3.2.5 Proving Extreme

**Lemma 6.** Consider the optimization problem:

$$\arg \max_{N_1, N_2, \dots, N_R} \sum_s g(s) \times \prod_{l=1}^R f_l(s)^{N_l}$$

subject to the constraints  $N_l \geq 0, \sum_l N_l = m$ .  $g(s)$  is an arbitrary real-valued function independent of  $l$ . The solution of this optimization problem lies at extreme.

*Proof.* Note that it suffices to prove this theorem assuming  $N_l$ 's are real-valued. If the solution is at extreme with real-valued  $N_l$ 's, it must also be at extreme when  $N_l$ 's are further constrained to be integer valued. We will use induction on  $R$  to prove the result. Consider base case of  $R = 2$ , the function becomes  $\arg \max_{N_1} \sum_s f_1(s)^{N_1} f_2(s)^{m-N_1} \times g(s)$ . This function is convex and has its maximum value at  $N_1 = m$  or  $N_1 = 0$  (see supplement for a proof).

Assuming that the induction hypothesis holds for  $R = k$ . We need to show for the case when  $R = k + 1$ . We will prove it by contradiction. Assume that the solution to this problem does not lie at extreme. Then, in this solution, it must be the case that  $N_l \neq 0, \forall l$ . If not, we can then reduce the problem to a  $k$  sized one and apply our induction hypothesis to get an extreme solution. Also, clearly  $N_l < m, \forall l$ . Let  $N_{k+1}$  has the optimal value of  $N_{k+1}^*$  in this solution. Then, substituting the optimal value of this component in the expression, we can get the optimal value for  $(N_1, N_2, \dots, N_k)$  by solving  $\arg \max_{N_1, N_2, \dots, N_k} \sum_s g'(s) \times \prod_{l=1}^k f_l(s)^{N_l}$ , subject to  $\sum_{l=1}^k N_l = m - N_{k+1}^*$ . Here,  $g'(s) = g(s) \times f_{k+1}(s)^{N_{k+1}^*}$ . Using the induction hypothesis, the solution for this must be at extreme, i.e.  $\exists l, N_l = 0$  since  $k \geq 2$ . This is a contradiction.

**Corollary 1.** The solution to the optimization problem

$$\arg \max_{N_1, N_2, \dots, N_R} \sum_s \prod_{l=1}^R f_l(s)^{N_l}$$

subject to the constraints  $\forall l, N_l \geq 0, N_l \in \mathbb{Z}$  and  $\sum_l N_l = m$  lies at extreme.

**Theorem 1 (Proof):** Corollary 1 combined with Lemma 5, Lemma 4, Lemma 3, Lemma 2 and Lemma 1 proves the theorem.

### 3.3 SOM-R Rule for lifted MMAP

We will first define the SOM-R (SOM Reduce) equivalence class which is a sub-class of SOM. Following our notation, we will use  $\mathcal{Q}$  and  $\mathcal{S}$  to denote the set of MAX and SUM predicates, respectively in the MMAP problem.

**Definition 4.** We say that an equivalence class of variables  $\tilde{X}$  is SOM-R if (a)  $\tilde{X}$  is SOM (b)  $\forall P \in \mathcal{S}, P$  contains a variable from  $\tilde{X}$  OR  $\forall P \in \mathcal{S}, P$  does not have a variable from  $\tilde{X}$ .

Note that if  $|\mathcal{S}| = 1$ , then any SOM equivalence class is also necessarily SOM-R. Next, we exploit the properties of extreme assignments to show that domain of SOM-R variables can be reduced to a single constant for MMAP inference. We start with the definition of a reduced MLN.

**Definition 5.** (Reduced MLN) Let  $\{(f_i, w_i)\}_{i=1}^n$  denote the set of (weighted) formulas in  $M$ . Let  $\tilde{X}$  be a SOM-R equivalence class with  $|\Delta_{\tilde{X}}| = m$ . We construct a reduced MLN  $M^r$  by considering the following 2 cases:

CASE 1:  $\forall P \in \mathcal{S}, P$  contains a variable from  $\tilde{X}$

- $\forall f_i \in F(M)$  containing a variable  $X \in \tilde{X}$ , add  $(f_i, w_i)$  to  $M^r$ .
- $\forall f_i \in F(M)$  not containing a variable  $X \in \tilde{X}$ , add  $(f_i, \frac{1}{m} \times w_i)$  to  $M^r$ .

CASE 2:  $\forall P \in \mathcal{S}, P$  does not contain a variable from  $\tilde{X}$

- $\forall f_i \in F(M)$  containing a variable  $X \in \tilde{X}$ , add  $(f_i, w_i \times m)$  to  $M^r$ .
- $\forall f_i \in F(M)$  not containing a variable  $X \in \tilde{X}$ , add  $(f_i, w_i)$  to  $M^r$ .

In each case, we reduce the domain of  $\tilde{X}$  to a single constant in  $M^r$ .

We are ready to state our SOM-R rule for lifted MMAP.

**Theorem 2.** (SOM-R Rule for MMAP) Let  $\tilde{X}$  be a SOM-R equivalence class. Let  $M^r$  be the reduced MLN in which domain of  $\tilde{X}$  has been reduced to single constant. Then, MMAP problem can be equivalently solved over  $M^r$ .

*Proof.* Let  $\mathcal{Q}$  denote the set of MAX predicates in the problem. We prove the above theorem in two parts. In Lemma 7 below, we show that for every extreme assignment (with respect to  $\tilde{X}$ )  $q$  to groundings of  $\mathcal{Q}$  in  $M$ , there is a corresponding extreme assignment  $q^r$  in  $M^r$  (and vice-versa). In Lemma 8, we show that given two extreme assignments,  $q$  and  $q^r$  for the respective MLNs, the MMAP value at  $q$  (in  $M_{\tilde{X}}$ ) is a monotonically increasing function of the MMAP value at  $q^r$  (in  $M_{\tilde{X}}^r$ ). These two facts combined with the fact that MMAP solution to the original problem is at extreme (using Theorem 1) prove the desired result. Next we prove each result in turn.

**Lemma 7.** *Let  $\mathbf{q}$  (resp.  $\mathbf{q}^r$ ) denote the sets of extreme assignments to the groundings of  $\mathcal{Q}$  in  $M$  (resp.  $M^r$ ). There exists a one to one to mapping between  $\mathbf{q}$  and  $\mathbf{q}^r$ .*

*Proof.* Instead of directly working with  $M$  and  $M^r$ , we will instead prove this lemma for the corresponding variablized MLNs  $M_{\tilde{X}}$  and  $M_{\tilde{X}}^r$ . This can be done since the process of variablization preserves the distribution as well as the set of extreme assignments. Let  $q$  denote an extreme assignment to MAX predicates in  $M_{\tilde{X}}$ . We will construct a corresponding assignment  $q^r$  for MAX predicate in  $M_{\tilde{X}}^r$ . Since  $\tilde{X}$  is SOM-R,  $M_{\tilde{X}}$  has only unary and propositional predicates, whereas  $M_{\tilde{X}}^r$  is full ground since the domain of  $\tilde{X}$  is reduced to a single constant.

First, let us consider a propositional MAX predicate  $P$  in  $M_{\tilde{X}}$ . Since  $P$  is ground both in  $M$  and  $M^r$ , we can assign the value of  $P$  in  $q^r$  to be same as  $q$ . Next, let us consider a unary predicate  $P$ . Let the assignments to the  $m$  groundings of  $P$  in  $q$  be given by the set  $\{q_{P_j}\}$  where  $1 \leq j \leq m$ . Since  $q$  is extreme, each element in the set  $\{q_{P_j}\}$  takes the same truth value. We can simply assign this value to the ground appearance of  $P$  in  $M_{\tilde{X}}$ . Hence, we get a mapping from  $q$  to  $q^r$ . It is easy to see that we can get a reverse mapping from  $q^r$  to  $q$  in a similar manner. Hence, proved.

Next, we state the relationship between the MMAP values obtained by the extreme assignments in  $M$  and  $M^r$ .

**Lemma 8.\*** *Let  $M$  be an MLN and  $M^r$  be the reduced MLN with respect to the SOM-R equivalence class  $\tilde{X}$ . Let  $q$  and  $q^r$  denote two corresponding extreme assignments in  $M$  and  $M^r$ , respectively. Then,  $\exists$  a monotonically increasing function  $g$  such that  $W_M(q) = g(W_{M^r}(q^r))$ .*

The proof of Lemma 8 exploits inversion elimination and symmetry of potential functions over a variablized MLN similar to their use in Section 3.2. These combined with Lemma 7 become our key insights for reducing the complexity of MMAP inference significantly compared to existing methods (see supplement for details).

**Corollary 2.** *SOM-R rule for MMAP problem subsumes SO rule for MAP problem given by Mittal et al. (2014).*

The corollary follows from the fact that MAP is a special case of MMAP when all the predicates are MAX.

## 4 ALGORITHMIC FRAMEWORK

SOM-R rule can be combined with existing lifted inference rules such as lifted decomposition and conditioning (Jha et al. 2010; Gogate and Domingos 2011) (with minor modifications) to yield a powerful algorithm for solving MMAP (see Algorithm 1). The algorithm takes as input an MLN  $M$ , the set of MAX predicates  $\mathcal{Q}$ , SUM predicates  $\mathcal{S}$  and a ground MMAP solver  $gSol$ . It has six steps. In the first step, the algorithm checks to see if the MLN, along with  $\mathcal{Q}$  and  $\mathcal{S}$  can be partitioned into disjoint MLNs that do not share any ground atoms. If this condition is satisfied, then the MMAP solution can be constructed by solving each component independently and simply concatenating the individual solutions. In the next three steps, we apply the decomposer (Jha et al. 2010), SOM-R (this work) and binomial rules (Jha et al. 2010; Gogate and Domingos 2011) in order. The former two reduce the domain of all logical variables in the equivalence class to a constant and thus yield exponential reductions in complexity. Therefore, they are applied before the binomial rule which creates  $O(m)$  ( $|\Delta_{\tilde{X}}| = m$ ) smaller sub-problems. In the algorithm,  $M^d$  refers to an MLN obtained from  $M$  by setting the domain of  $\tilde{X}$  to a single constant and we assume that  $|\Delta_{\tilde{X}}| = m$ . Similarly,  $M^r$  refers to the MLN obtained from  $M$  by applying the SOM-R rule (see Definition 5).

The binomial rule (steps 4a and 4b) efficiently conditions on the unary predicates and can be applied over the SUM as well as MAX predicates. However, care must be taken to ensure that all MAX predicates are instantiated before the SUM predicates. Therefore, the binomial rule is applied over the SUM predicates only when the MLN has no MAX predicates (Step 4b). In the algorithm,  $M_k$  refers to the MLN obtained from  $M$  by setting exactly  $k$  groundings of  $P$  to true and the remaining to false.

If none of the lifting rules are applicable and the MLN has only ground atom, we return the solution returned by the propositional solver  $gSol$ . Otherwise, if not all predicates are ground, we resort to partial grounding, namely we heuristically ground a logical variable and recurse on the corresponding MLN  $M'$ .

Finally, note that the algorithm returns the exponentiated weight of the MMAP assignment. The assignment can be recovered by tracing the recursion backwards.

**Heuristics:** (a) Binomial: In case of multiple possible binomial applications, we pick the one which results in

---

**Algorithm 1** Lifted MMAP

    //6. Partial Grounding
     $M' =$  Heuristically ground an equivalence class  $\tilde{X}$  in  $M$ 
    return liftedMMAP( $M', \mathcal{Q}, \mathcal{S}, gSol$ );
```

**End.**

---

the application of other lifting rules (in the priority order described above) using a one step look ahead. In case of a tie, we pick the one with maximum domain size.

(b) Partial Grounding: We pick the equivalence class which results in further application of lifting rules (in the priority order) using a one step look ahead. In case of a tie, we pick the one which has smallest domain size.

## 5 EXPERIMENTS

The goal of our experiments is two fold. First, we would like to examine the efficacy of lifting for MMAP. Second, we would like to analyze the contribution of SOM-R rule in lifting. Towards this end, we compare the following three algorithms: (1) Ground: ground inference with no lifting whatsoever (2) Lifted-Basic: lifted inference without use of the SOM-R rule<sup>4</sup> (3) Lifted-SOM-R: using all our lifting rules including SOM-R. For ground inference, we use a publicly available<sup>5</sup> base (exact) solver built on top of And/Or search developed by Marinescu et al. (2014).

We experiment with three benchmark MLNs: (1) Stu-

---

<sup>4</sup>We use the rules described in Algorithm 1. For Lifted-Basic, too many applications of the binomial rule led to blow up. So, we restricted the algorithm to a single binomial application and before any partial grounding. Lifted-SOM-R had no such issues.

<sup>5</sup><https://github.com/radum2275/merlin>

dent (Sarkhel et al. 2014) (2) IMDB (Mittal et al. 2016) (3) Friends & Smokers (FS) (Domingos and Lowd 2009). All the datasets are described in the lower part of Figure 1 along with the MAP predicates used in each case; the remaining predicates are treated as marginal predicates. Weights of the formulas were manually set.

We compare the performance of the three algorithms on two different metrics: (a) time taken for inference (b) memory used. We used a time-out of 30 minutes for each run. Memory was measured in terms of the number of formulas in the ground network in each case. We do not compare the solution quality since all the algorithms are guaranteed to produce MMAP assignments with same (optimal) probability. All the experiments were run on a 2.20 GHz Xeon(R) E5-2660 v2 server with 10 cores and 62 GB RAM.

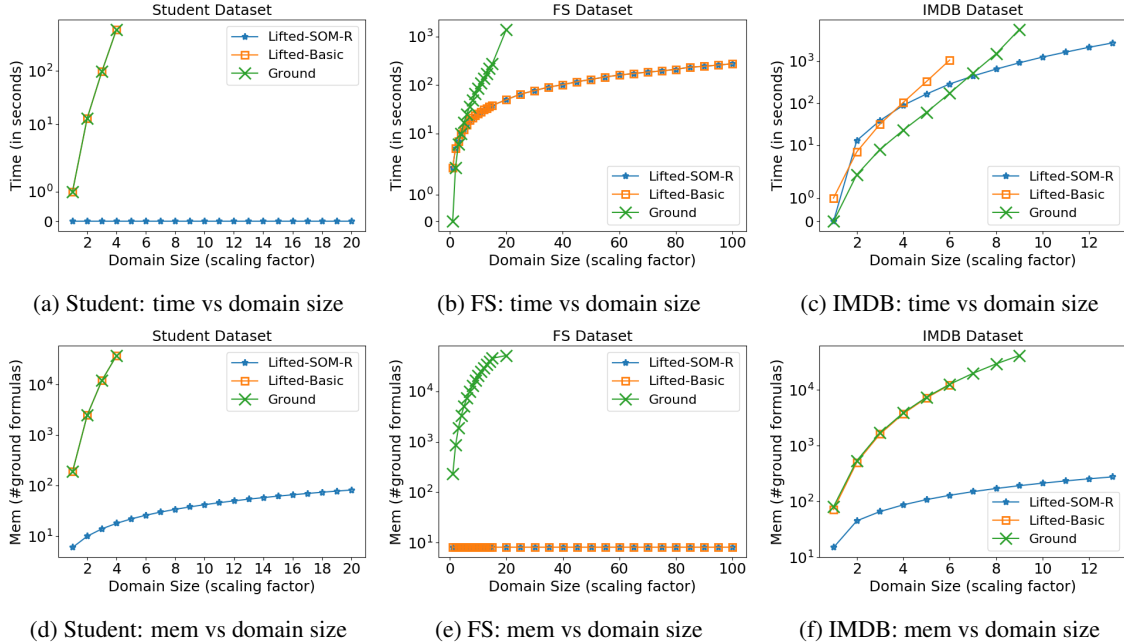

**Results:** For each of the graphs in Figure 1, we plot time (memory) on y-axis (log-scale) and domain size on x-axis. Time is measured in seconds. Since we are primarily concerned about the scaling behavior, we use the number of ground formulae as a proxy for the actual memory usage. Domain size is measured as a function of a scaling factor, which is the number by which (all of) the starting domain sizes are multiplied. We refer to domain descriptions (Figure 1) for the starting sizes.

Figures 1a and 1d compare the performance of the three algorithms on the Student dataset. None of the lifting rules apply for Lifted-Basic. Hence, its performance is identical to Ground. For Lifted-SOM-R, all the variables (except teacher(T)) can be reduced to a single constant, resulting in significant reduction in the size of the ground theory. Lifted-SOM-R is orders of magnitude better than Ground and Lifted-Basic for both time and memory.

Figures 1b and 1e compare the three algorithms on the FS dataset. Here, Lifted-Basic performs identical to Lifted-SOM-R. This is because binomial rule applies in the beginning on Smokes, following which theory decomposes. We never need to apply SOM-R rule on this domain. Both Lifted-SOM-R and Lifted-Basic perform significantly better than Ground on this domain (in both time and memory).

IMDB dataset (Figures 1c and 1f) presents a particularly interesting case of interspersed application of rules. For Lifted-SOM-R, SOM-R rule applies on movie(M) variables, simplifying the theory following which binomial rule can be applied on Mov, Dir and Act predicates. Theory decomposes after these binomial applications. For Lifted-Basic, though binomial rule can be applied on Dir, Act the movie variables still remain, eventually requiring for partial grounding. Surprisingly, Ground does slightly better than both the lifted approaches for

smaller domains for time. This is due to the overhead of solving multiple sub-problems in binomial without much gain since domains are quite small. Lifted-SOM-R has a much better scaling behavior for larger domains. It also needs significantly less memory compared to both other approaches.

In none of the above cases, Lifted-SOM-R has to ever partially ground the theory making a very strong case for using Lifted-SOM-R for MMAP inference in many practical applications. Overall, our experiments clearly demonstrate the utility of SOM-R in the scenarios where other lifting rules fail to scale.

## 6 CONCLUSION

We present the first lifting technique for MMAP. Our main contribution is the SOM-R rule, which states that the domain of a class of equivalence variables, referred to as SOM-R, can be reduced to a single constant for the purpose of MMAP inference. We prove the correctness of our rule through a series of problem transformations followed by the properties of what we refer to as extreme

assignments. Our experiments clearly demonstrate the efficacy of our approach on benchmark domains. Directions for future work include coming up with additional lifting rules, approximate lifting and lifting in presence of constraints (Mittal et al. 2015), all in the context of MMAP, and experimenting with a wider set of domains.

## Abstract

We consider the problem of predicting plausible missing facts in relational data, given a set of imperfect logical rules. In particular, our aim is to provide bounds on the (expected) number of incorrect inferences that are made in this way. Since for classical inference it is in general impossible to bound this number in a non-trivial way, we consider two inference relations that weaken, but remain close in spirit to classical inference.

## 1 INTRODUCTION

In this paper we study several forms of logical inference for predicting plausible missing facts in relational data. While a variety of approaches have already been studied for this task, ranging from (relational versions of) probabilistic graphical models [19, 4] to neural-network architectures [24, 20] and graph-based methods [15, 16], logic-based inference has several advantages over these other forms of inference. For example, logic-based inference is explainable: there is a proof for any derived statement, which can, in principle, be shown to a human user. It is also more transparent than most other methods, in the sense that a knowledge base as a whole can be understood and modified by domain experts. On the other hand, classic logical inference can be very brittle when some of the rules which are used are imperfect, or some of the initial facts may be incorrect.

Statistical relational learning approaches, such as Markov logic networks [19] or probabilistic logic programming [4], offer a solution to this latter problem, but they require learning a joint probability distribution over the set of possible worlds. This distribution is typically estimated from one or several large examples using maximum likelihood, which essentially corresponds to finding

a maximum-entropy distribution given by a set of sufficient statistics. However, there are usually no guarantees on the learned distributions beyond guarantees for the sufficient statistics (see, e.g., [12]), which means that we do not have much control over the quality of the predictions. Moreover, these models are not easy to modify, and are not always easy to explain because the way in which probabilities are computed can simply be too complex.

In this paper we focus on forms of inference that stay as close to classical logic as possible while not breaking completely when the given theory happens to be “mildly” inconsistent with the data. This problem of reasoning under inconsistency has a long tradition in the field of artificial intelligence, with common solutions including the use of paraconsistent logics [3, 18], belief revision [8] (and related inconsistency repair mechanisms [11]), and argumentation-based inference [7, 2]. In contrast to these approaches, however, our specific aim is to study forms of inference that can allow us to bound the (expected) number of mistakes that are made. To this end, we introduce two inference relations called *k-entailment* and *voting entailment*, both of which are close to classical logic, and in particular do not require rules to be weighted. We define them such that errors produced by imperfect rules would not necessarily propagate too much in the given relational data.

As our main contribution, we are able to show that in a relational learning scenario from [12], in which a (large) training example and a test example are sampled from a hidden relational structure, there are non-trivial PAC-type bounds on the number of errors that a theory learned on the training example produces on the test example. From this perspective, our work can also be seen as a relational-learning counterpart of PAC semantics [23].

**Technical contributions.** The results presented in this paper rest mainly on the following two technical contributions: (i) the introduction of bounds on the worst case behavior of the considered inference relations, and (ii)

new concentration inequalities for sampling from relational data without replacement that allow us to bound the (expected) test error as a function of the training error, in the spirit of classical PAC-learning results [22].

## 2 PRELIMINARIES

In this paper we consider a function-free first-order logic language  $\mathcal{L}$ , which is built from a set of constants  $Const$ , variables  $Var$ , and predicates  $Rel = \bigcup_i Rel_i$ , where  $Rel_i$  contains the predicates of arity  $i$ . We assume an untyped language. For  $a_1, \dots, a_k \in Const \cup Var$  and  $R \in Rel_k$ , we call  $R(a_1, \dots, a_k)$  an atom. If  $a_1, \dots, a_k \in Const$ , this atom is called ground. A literal is an atom or its negation. The formula  $\alpha_0$  is called a grounding of  $\alpha$  if  $\alpha_0$  can be obtained by replacing each variable in  $\alpha$  with a constant from  $Const$ . A formula is called closed if all variables are bound by a quantifier. A possible world  $\omega$  is defined as a set of ground atoms. The satisfaction relation  $\models$  is defined in the usual way. A substitution is a mapping from variables to terms.

## 3 PROBLEM SETTING

First we describe the learning setting considered in this paper. It follows the setting from [12], which was used to study the estimation of relational marginals.

An example is a pair  $(\mathcal{A}, \mathcal{C})$ , with  $\mathcal{C}$  a set of constants and  $\mathcal{A}$  a set of ground atoms which only use constants from  $\mathcal{C}$ . An example is intended to provide a complete description of the world, hence any ground atom over  $\mathcal{C}$  which is not contained in  $\mathcal{A}$  is implicitly assumed to be false. Note that this is why we have to explicitly specify  $\mathcal{C}$ , as opposed to simply considering the set of constants appearing in  $\mathcal{A}$ .

In practice, we usually only have partial information about some example of interest. The problems we consider in this paper relate to how we can then reason about the probability that a given ground atom is true (i.e. belongs to the example). To estimate such probabilities, we assume that we are given a fragment of the example, which we can use as training data. Specifically, let  $\Upsilon = (\mathcal{A}, \mathcal{C})$  be an example and  $\mathcal{S} \subseteq \mathcal{C}$ . The fragment  $\Upsilon\langle\mathcal{S}\rangle = (\mathcal{B}, \mathcal{S})$  is defined as the restriction of  $\Upsilon$  to the constants in  $\mathcal{S}$ , i.e.  $\mathcal{B}$  is the set of all atoms from  $\mathcal{A}$  which only contain constants from  $\mathcal{S}$ . In a given example, any closed formula  $\alpha$  is either true or false. To assign probabilities to formulas in a meaningful way, we consider how often the formula is satisfied in small fragments of the given example.

**Definition 1** (Probability of a formula [12]). *Let  $\Upsilon = (\mathcal{A}, \mathcal{C})$  be an example and  $k \in \mathbb{N}$ . For a closed formula  $\alpha$*

*without constants, we define its probability as follows<sup>1</sup>:*

$$Q_{\Upsilon,k}(\alpha) = P_{\mathcal{S} \sim \text{Unif}(\mathcal{C},k)} [\Upsilon\langle\mathcal{S}\rangle \models \alpha]$$

*where  $\text{Unif}(\mathcal{C}, k)$  denotes uniform distribution on size- $k$  subsets of  $\mathcal{C}$ .*

Clearly  $Q_{\Upsilon,k}(\alpha) = \frac{1}{|\mathcal{C}_k|} \cdot \sum_{\mathcal{S} \in \mathcal{C}_k} \mathbb{1}(\Upsilon\langle\mathcal{S}\rangle \models \alpha)$  where  $\mathcal{C}_k$  is the set of all size- $k$  subsets of  $\mathcal{C}$ .

The above definition is also extended straightforwardly to probabilities of sets of formulas (which we will also call *theories* interchangeably). If  $\Phi$  is a set of formulas, we set  $Q_{\Upsilon,k}(\Phi) = Q_{\Upsilon,k}(\bigwedge \Phi)$  where  $\bigwedge \Phi$  denotes the conjunction of all formulas in  $\Phi$ .

**Example 1.** *Let  $sm/1$  be a unary predicate denoting that someone is a smoker, e.g.  $sm(alice)$  means that  $alice$  is a smoker. Let us have an example  $\Upsilon = (\{fr(alice, bob), sm(alice), sm(eve)\}, \{alice, bob, eve\})$ , and formulas  $\alpha = \forall X : sm(X)$  and  $\beta = \exists X, Y : fr(X, Y)$ . Then, for instance,  $Q_{\Upsilon,1}(\alpha) = 2/3$ ,  $Q_{\Upsilon,2}(\alpha) = 1/3$  and  $Q_{\Upsilon,2}(\beta) = 1/3$ .*

**Definition 2** (Masking). *A masking process is a function  $\kappa$  from examples to ground conjunctions that assigns to any  $\Upsilon = (\mathcal{A}, \mathcal{C})$  a conjunction of ground literals  $\beta$  such that  $\Upsilon \models \beta$ . We also define  $\kappa(\Upsilon)\langle\mathcal{S}\rangle$  to be the conjunction consisting of all literals from  $\kappa(\Upsilon)$  that contain only constants from  $\mathcal{S}$ .*

Unlike examples, masked examples only encode partial information about the world. This is why they are encoded using conjunctions of literals, so we can explicitly encode which atoms we know to be false.

**Example 2.** *Let  $\Upsilon = \{sm(alice), fr(alice, bob), \{alice, bob\}\}$ . Then a masking process  $\kappa$  may, for instance, yield  $\kappa(\Upsilon) = \neg sm(bob) \wedge sm(alice)$ . In this case  $\kappa(\Upsilon)$  retains the information that  $alice$  is a smoker and  $bob$  is not, but it no longer contains any information about their friendship relation.*

Next we introduce the statistical setting considered in this paper.

**Definition 3** (Learning setting). *Let  $\aleph = (\mathcal{A}_{\aleph}, \mathcal{C}_{\aleph})$  be an example and  $\kappa$  be a masking function. Let  $\mathcal{C}_{\Upsilon} \subseteq \mathcal{C}_{\aleph}$  and  $\mathcal{C}_{\Gamma} \subseteq \mathcal{C}_{\aleph}$  be uniformly sampled subsets of size  $n$  and  $u$ , respectively. We call  $\Upsilon = \aleph\langle\mathcal{C}_{\Upsilon}\rangle$  the training example and  $\Gamma = \aleph\langle\mathcal{C}_{\Gamma}\rangle$  the test example. We assume that the learner receives  $\Upsilon$  in the training phase and  $\kappa(\Gamma)$  in the test phase.*

With slight abuse of terminology, we will sometimes say that  $\Upsilon$  and  $\Gamma$  are sampled from  $\aleph$ .

<sup>1</sup>We will use  $Q$  for probabilities of formulas as defined in this section, to avoid confusion with other ‘‘probabilities’’ we deal with in the text.

In addition to the training example  $\Upsilon$  and masked test example  $\kappa(\Gamma)$ , we will assume that we are given a set of formulas  $\Phi$  (which we will also refer to as rules). Our main focus will be on how these formulas can be used to recover as much of  $\Gamma$  as possible. Rather than specifying a loss function that should be minimized, we want to find a form of inference which allows us to provide bounds on the (expected) number of incorrect literals that can be inferred from  $\{\kappa(\Gamma)\} \cup \Phi$ . Note that in this case, the training example  $\Upsilon$  is used to estimate the accuracy of the set of formulas. We also analyze the case where the rules are learned from the training example  $\Upsilon$  (in the spirit of classical PAC-learning results).

Among others, the setting from Definition 3 is close to how Markov logic networks are typically used. For instance, when training Markov logic networks, one typically starts with a training example that contains all facts (i.e. nothing is unknown about the training set), on which a model is trained. This model is then used to predict unknown facts about a test example. However, unlike for Markov logic networks, we do not attempt to learn a probability distribution. It was shown in [14] that models based on classic logical inference, like those considered in this paper, work well in practice for relational inference from evidence sets containing a *small* number of constants (domain elements). Thus, such models are also of considerable practical interest.

## 4 REASONING WITH INACCURATE RULES

When reasoning with imperfect rules, using classical inference can have drastic consequences, as we will illustrate in Section 4.1. Even a single mistake can lead to many errors, since an incorrectly derived literal can be used as the basis for further inferences. This means that classical inference is not suitable for the considered setting, even in cases where the given rules have perfect accuracy on the training example. Intuitively, to allow for any meaningful bounds to be derived, we need to prevent arbitrarily long chains of inference. To this end, we propose and motivate the use of a restricted form of inference, called  $k$ -entailment, in Section 4.2. A further restriction on inferences, based on a form of voting, is subsequently discussed in Section 4.3. In Section 5 we will then show which bounds can be derived for these two restricted forms of inference.

### 4.1 WHEN CLASSICAL REASONING LEADS TO ERRORS

The next example, which is related to label propagation as studied e.g. in [26], shows that classic logical reasoning

on the obtained relational sample may produce *many* mistakes even when all the available rules are very *accurate*.

**Example 3.** Let  $k = 2$ ,  $\Gamma = \{\{rare(c_1)\}, \{c_1, c_2, \dots, c_{1000000}\}, \text{ and } \alpha = \forall X, Y : rare(X) \Rightarrow rare(Y)\}$ . While the rule does not intuitively make sense, its accuracy is actually very high  $Q_{\Gamma,k}(\alpha) = 1 - 999999/(0.5 \cdot 1000000 \cdot 999999) = 0.999998$ . When we apply this rule with the evidence  $rare(c_1)$ , we derive  $rare(c_2), \dots, rare(c_{1000000})$ , all of which are incorrect (i.e. not included in  $\Gamma$ ).

Note that in this paper, we are interested in worst-case behavior, in the sense that the masking process which is used may be seen as adversarial. The next example further illustrates how adversarial masking processes can lead to problems, even for rules with near-perfect accuracy.

**Example 4.** Let  $k = 2$ ,  $\Gamma = \{\{rare(c_1), e(c_1, c_2), e(c_2, c_3), \dots, e(c_{999999}, c_{1000000})\}, \{c_1, c_2, \dots, c_{1000000}\}, \text{ and } \alpha = \forall X, Y : rare(X) \wedge e(X, Y) \Rightarrow rare(Y)\}$ . In this case, there is only one size- $k$  subset of  $C_{\Gamma}$  where the formula  $\alpha$  does not hold, so the accuracy is even higher than in the previous example. Yet the adversarial masking process can select evidence consisting of all true positive literals from  $\Gamma$ , i.e. the evidence will consist of the  $rare(c_1)$  literal and all the  $e/2$  literals from  $\Gamma$ . Then the set of errors that are made when using the formula  $\alpha$  will be the same as in Example 3, despite the fact that the rule is almost perfect on  $\Gamma$ .

Note that in the examples above, we had perfect knowledge of the accuracy of the rule  $\alpha$  on the test example (i.e. we knew the value of  $Q_{\Gamma,k}(\alpha)$ ). In practice, this accuracy needs to be estimated from the training example. In such cases, it can thus happen that a rule  $\alpha$  has accuracy 1 on the training example  $\Upsilon$ , but still produces many errors on  $\kappa(\Gamma)$ . We will provide PAC-type bounds for this setting with estimated accuracies in Sections 5. First, however, in Section 4.2 and 4.3 we will look at how bounds can be provided on the number of incorrectly derived literals in the case where  $Q_{\Gamma,k}(\alpha)$  is known. As the above examples illustrate, to obtain reasonable bounds, we will need to consider forms of inference which are weaker than classical entailment.

### 4.2 BOUNDED REASONING USING $k$ -ENTAILMENT

We saw that even for formulas which hold for almost all subsets of  $\Gamma$ , the result of using them for inference can be quite disastrous. This was to a large extent due to the fact that we had inference chains involving a large number of domain elements (constants). This observation suggests a natural way to restrict the kinds of inferences that can be made when imperfect rules are involved.

**Definition 4** (*k*-entailment). *Let  $k$  be a non-negative integer,  $\Upsilon = (\mathcal{A}, \mathcal{C})$  be an example,  $\kappa$  be a masking process, and  $\Phi$  be a set of closed formulas. We say that a ground formula  $\varphi$  is *k*-entailed by  $\Phi$  and  $\kappa(\Upsilon)$ , denoted  $\{\kappa(\Upsilon)\} \cup \Phi \models_k \varphi$ , if there is a  $\mathcal{C}' \subseteq \mathcal{C}$  such that  $|\mathcal{C}'| \leq k$ ,  $\text{const}(\varphi) \subseteq \mathcal{C}'$ ,  $\{\kappa(\Upsilon)\langle \mathcal{C}' \rangle\} \cup \Phi$  is consistent and  $\{\kappa(\Upsilon)\langle \mathcal{C}' \rangle\} \cup \Phi \models \varphi$ .*

In other words, a formula  $\phi$  is *k*-entailed by  $\Upsilon$  and  $\Phi$  if it can be proved using  $\Phi$  together with a fragment of  $\kappa(\Upsilon)$  induced by no more than  $k$  constants, with the additional condition that  $\Phi$  and this fragment are not contradictory.

**Example 5.** *Let*

$$\begin{aligned} \Upsilon &= (\{fr(\text{alice}, \text{bob}), sm(\text{alice})\}, \{\text{alice}, \text{bob}, \text{eve}\}) \\ \kappa(\Upsilon) &= fr(\text{alice} \wedge \text{bob}) \wedge sm(\text{alice}) \\ \Phi &= \{\forall X, Y : fr(X, Y) \wedge sm(X) \Rightarrow sm(Y)\}. \end{aligned}$$

*Then  $\varphi = sm(\text{bob})$  is 2-entailed from  $\kappa(\Upsilon)$  and  $\Phi$  but not 1-entailed.*

Note that, in the setting of Example 4, *k*-entailment would make at most  $k - 1$  mistakes. However, 2-entailment would already produce many mistakes in the case of Example 3. So there are cases where *k*-entailment produces fewer errors than classical logic entailment but, quite naturally, also cases where both produce the same number of errors. Importantly, however, for *k*-entailment, we can obtain non-trivial bounds on the number of errors.

Next we state two lemmas that follow immediately from the respective definitions.

**Lemma 1.** *Let  $\Upsilon = (\mathcal{A}, \mathcal{C})$  be an example,  $\Phi$  be a set of constant-free formulas and  $\kappa$  be a masking function. Let  $\mathcal{C}_k$  be the set of all size- $k$  subsets of  $\mathcal{C}$ . Let  $\mathcal{H}_{\mathcal{X}}$  denote the set of all ground literals which can be derived using *k*-entailment from  $\{\kappa(\Upsilon)\} \cup \Phi$  and only contain constants from  $\mathcal{X}$ . Then  $\mathcal{H}_{\mathcal{C}} = \bigcup_{S \in \mathcal{C}_k} \mathcal{H}_S$ .*

**Lemma 2.** *When  $\Gamma \langle S \rangle \models \Phi$  then all ground literals that only contain constants from  $S$  and that are entailed by  $\{\kappa(\Gamma \langle S \rangle)\} \cup \Phi$  must be true in  $\Gamma \langle S \rangle$ .*

We now provide a bound on the number of ground literals wrongly *k*-entailed by a given  $\Phi$ , assuming that we know its accuracy  $Q_{\Gamma, k}(\Phi)$  on the example  $\Gamma$ .

**Proposition 6.** *Let  $\Gamma = (\mathcal{A}, \mathcal{C})$  be an example,  $\Phi$  be a set of constant-free formulas and  $\kappa$  be a masking process. Next let  $\mathcal{F}(\Gamma)$  be the set of all ground literals of a predicate  $p/a$ ,  $a \leq k$ , which are *k*-entailed by  $\{\kappa(\Gamma)\} \cup \Phi$  but are false in  $\Gamma$ . Then*

$$|\mathcal{F}(\Gamma)| \leq (1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k k^a.$$

*Proof.* First, we note that the number of size-*k* subsets is bounded by  $|\mathcal{C}|^k$  and the number of different ground

*p/a* atoms in each of these subsets is  $k^a$ . It follows from Lemma 2 and Lemma 1 that for any literal  $\delta \in \mathcal{F}$  there must be a size-*k* set  $S \subseteq \mathcal{C}$  such that  $\Gamma \langle S \rangle \not\models \delta$ . The number of all such  $S$ 's that satisfy  $\Gamma \langle S \rangle \not\models \delta$  is bounded by  $(1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k$ . Hence, we have  $|\mathcal{F}(\Gamma)| \leq (1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k k^a$ .  $\square$

We can notice that when we increase the domain size  $|\mathcal{C}|$ , keeping  $Q_{\Gamma, k}(\Phi)$  fixed and non-zero, the bound eventually becomes vacuous for predicates whose arity  $a$  is strictly smaller than  $k$ . This is because the number of all ground literals grows only as  $|\mathcal{C}|^a$  whereas the bound grows as  $|\mathcal{C}|^k$ . However, if  $a = k$ , the bound stays fixed when we increase the domain size. We will come back to consequences of this fact in Section 6.

### 4.3 BOUNDED REASONING USING VOTING

To further restrict the set of entailed ground literals, we next introduce *voting entailment*.

**Definition 5** (Voting Entailment). *Let  $k$  be an integer and  $\gamma \in [0; 1]$ . Let  $\Upsilon = (\mathcal{A}, \mathcal{C})$  be an example,  $\Phi$  be a set of constant-free formulas, and  $\kappa$  be a masking process. A ground literal  $l$  of arity  $a$ ,  $a \leq k$ , is said to be entailed from  $\Phi$  and  $\kappa(\Upsilon)$  by voting with parameters  $k$  and  $\gamma$  if there are at least  $\max\{1, \gamma \cdot |\mathcal{C}|^{k-a}\}$  size- $k$  sets  $S \subseteq \mathcal{C}$  such that  $l$  is *k*-entailed by  $\kappa(\Upsilon)\langle S \rangle$ .*

The next example illustrates the use of voting entailment.

**Example 7.** *Let  $\Upsilon = (\mathcal{A}, \mathcal{C})$ , where  $\mathcal{C} = \{\text{alice}, \text{bob}, \text{eve}\}$ , and let  $\kappa(\Upsilon) = fr(\text{alice}, \text{bob}) \wedge fr(\text{eve}, \text{bob}) \wedge sm(\text{eve})$ . Next, let  $\Phi = \{\forall X, Y : fr(X, Y) \wedge sm(X) \Rightarrow sm(Y)\}$ . Then  $sm(\text{bob})$  is entailed from  $\Phi$  and  $\kappa(\Upsilon)$  by voting with the parameters  $k = 2$  and  $\gamma = 2/3$ , as  $\gamma \cdot |\mathcal{C}|^{k-a} = 2/3 \cdot 3^{2-1} = 2$  and there are two size-2 subsets of  $\mathcal{C}$  that 2-entail  $sm(\text{bob})$ .*

We now show how the bound from Proposition 6 can be strengthened in the case of voting entailment.

**Proposition 8.** *Let  $k$  be an integer and  $\gamma \in [0; 1]$ . Let  $\Gamma = (\mathcal{A}, \mathcal{C})$  be an example,  $\Phi$  be a set of constant-free formulas, and  $\kappa$  be a masking process. Let  $\mathcal{F}(\Gamma)$  be the set of all ground literals of a predicate  $p/a$ ,  $a \leq k$ , that are entailed by voting from  $\{\kappa(\Gamma)\} \cup \Phi$  with parameters  $k$  and  $\gamma$  but are false in  $\Gamma$ . If  $\gamma \cdot |\mathcal{C}|^{k-a} \geq 1$  then*

$$|\mathcal{F}(\Gamma)| \leq (1 - Q_{\Gamma, k}(\Phi)) \frac{|\mathcal{C}|^a k^a}{\gamma}$$

*and otherwise*

$$|\mathcal{F}(\Gamma)| \leq (1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k k^a.$$

*Proof.* First we define the number of ‘‘votes’’ for a ground literal  $l$  as

$$\#\_{\kappa(\Gamma), \Phi}(l) = |\{S \subseteq \mathcal{C} \mid |S| = k, \{\kappa(\Gamma)\langle S \rangle\} \cup \Phi \models_k l\}|.$$

Let  $L$  be the set of all ground  $p/a$  literals  $l$  such that  $\Gamma \models \neg l$ . Then, since any size- $k$  subset of  $\mathcal{C}$  can only contribute  $k^a$  votes to literals based on the predicate  $p/a$ , we have

$$\sum_{l \in L} \#\kappa(\Gamma, \Phi)(l) \leq (1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k k^a.$$

Hence  $|\mathcal{F}(\Gamma)| \leq \frac{(1 - Q_{\Gamma, k}(\Phi)) |\mathcal{C}|^k k^a}{\max\{1, \gamma \cdot |\mathcal{C}|^{k-a}\}}$ . If  $\gamma \cdot |\mathcal{C}|^{k-a} \geq 1$  then  $|\mathcal{F}(\Gamma)| \leq (1 - Q_{\Gamma, k}(\Phi)) \frac{|\mathcal{C}|^a k^a}{\gamma}$ . The case when  $\gamma \cdot |\mathcal{C}|^{k-a} < 1$  follows from Theorem 6.  $\square$

Unlike for  $k$ -entailment, the fraction of “wrong” ground  $p/a$  literals entailed by voting entailment does not grow with an increasing domain size as long as  $\gamma \cdot |\mathcal{C}|^{k-a} \geq 1$ .

## 5 PROBABILISTIC BOUNDS

We now turn to the setting where the accuracy of the formulas needs to be estimated from a training example  $\Upsilon$ . More generally, we also cover the case where the formulas themselves are learned from the training example. In such cases, to account for over-fitting, we need to consider the (size of the) hypothesis class that was used for learning these formulas. Specifically, we prove probabilistic bounds for variants of the following learning problem. We are given a hypothesis set  $\mathcal{H}$  of constant-free theories, and we want to compute bounds on the number of incorrectly predicted literals which simultaneously hold for all  $\Phi \in \mathcal{H}$  (as a function of  $Q_{\Upsilon, k}(\Phi)$ ) with probability at least  $1 - \delta$ , where  $\delta$  is a confidence parameter. Note that the case where the theory  $\Phi$  is given, rather than learned, corresponds to  $\mathcal{H} = \{\Phi\}$ .

We start by proving general concentration inequalities in Section 5.1 which we then use to prove bounds for  $k$ -entailment. These bounds are studied for the realizable case in Section 5.2 and for the general case in Section 5.3. Bounds for voting entailment are studied in Section 5.4

### 5.1 CONCENTRATION INEQUALITIES

We will need to bound the difference between the “accuracy” of given sets of logic formulas  $\Phi$  on the training sample  $\Upsilon$  and their accuracy on a test sample  $\Gamma$  (i.e. the difference between  $Q_{\Upsilon, k}(\Phi)$  and  $Q_{\Gamma, k}(\Phi)$ ). To prove the concentration inequalities in this section, we will utilize the following lemma.

**Lemma 3** (Kuzelka et al. [12]). *Let  $\aleph = (\mathcal{A}_{\aleph}, \mathcal{C}_{\aleph})$  be an example. Let  $0 \leq n \leq |\mathcal{C}_{\aleph}|$  and  $0 \leq k \leq n$  be integers. Let  $\mathbf{X} = (\mathcal{S}_1, \mathcal{S}_2, \dots, \mathcal{S}_{\lfloor \frac{n}{k} \rfloor})$  be a vector of subsets of  $\mathcal{C}_{\aleph}$ , each sampled uniformly and independently of the others from all size- $k$  subsets of  $\mathcal{C}_{\aleph}$ . Next let  $\mathcal{C}_{\Upsilon}$  be sampled uniformly from all size- $n$  subsets of  $\mathcal{C}_{\aleph}$ . Finally,*

*let  $\mathcal{I}' = \{1, 2, \dots, |\mathcal{C}_{\aleph}|\}$  and let  $\mathbf{Y} = (\mathcal{S}'_1, \mathcal{S}'_2, \dots, \mathcal{S}'_{\lfloor \frac{n}{k} \rfloor})$  be a vector sampled by the following process:*

1. *Sample subsets  $\mathcal{I}'_1, \dots, \mathcal{I}'_{\lfloor \frac{n}{k} \rfloor}$  of size  $k$  from  $\mathcal{I}'$ .*
2. *Sample an injective function  $g : \bigcup_{i=1}^{\lfloor \frac{n}{k} \rfloor} \mathcal{I}'_i \rightarrow \mathcal{C}_{\Upsilon}$  uniformly from all such functions.*
3. *Define  $\mathcal{S}'_i = g(\mathcal{I}'_i)$  for all  $0 \leq i \leq \lfloor \frac{n}{k} \rfloor$ .*

*Then  $\mathbf{X}$  and  $\mathbf{Y}$  have the same distribution.*

The next example illustrates the intuition behind the proof of this lemma, which can be found in [12].

**Example 9.** *Let  $\mathcal{C}_{\aleph} = \{1, 2, \dots, 10^6\}$ . Let us sample  $\lfloor m/k \rfloor$  size- $k$  subsets of  $\mathcal{C}_{\aleph}$  uniformly. If this was the process that generates the data from which we estimate parameters, we could readily apply Hoeffding’s inequality to get the confidence bounds. However, in typical SRL settings (e.g. with MLNs), we are given a complete example on some set of constants (objects), rather than a set of small sampled fragments. So we instead need to assume that the whole training example is sampled at once, uniformly from all size- $m$  subsets of  $\mathcal{C}_{\aleph}$ . However, when we then estimate the probabilities of formulas from this example, we cannot use Hoeffding’s bound or any other bound expecting independent samples. What we can do<sup>2</sup> is to mimic sampling from  $\mathcal{C}_{\aleph}$  by sampling from an auxiliary set of constants of the same size as  $\mathcal{C}_{\aleph}$  and then specialising these constants to constants from a sampled size- $m$  subset. Hence the first  $\lfloor m/k \rfloor$  sampled sets will be distributed exactly as the first  $\lfloor m/k \rfloor$  subsets sampled i.i.d. directly from  $\mathcal{C}_{\aleph}$ .*

Lemma 3 was used in [12] to prove a bound on expected error. Here we extend that result and use Lemma 3 to prove the concentration inequalities stated in the next two theorems.

**Theorem 10.** *Let  $\aleph = (\mathcal{A}_{\aleph}, \mathcal{C}_{\aleph})$  be an example and let  $0 \leq n \leq |\mathcal{C}_{\aleph}|$  and  $0 \leq k \leq n$  be integers. Let  $\mathcal{C}_{\Upsilon}$  be sampled uniformly from all size- $n$  subsets of  $\mathcal{C}_{\aleph}$  and let  $\Upsilon = \aleph(\mathcal{C}_{\Upsilon})$ . Let  $\alpha$  be a closed and constant-free formula and let  $\mathcal{C}_k$  denote all size- $k$  subsets of  $\mathcal{C}_{\Upsilon}$ . Let  $\hat{A}_{\Upsilon} = Q_{\Upsilon, k}(\alpha)$  and let  $A_{\aleph} = Q_{\aleph, k}(\alpha)$ . Then we have  $P[\hat{A}_{\Upsilon} - A_{\aleph} \geq \varepsilon] \leq \exp(-2 \lfloor \frac{n}{k} \rfloor \varepsilon^2)$ ,  $P[A_{\aleph} - \hat{A}_{\Upsilon} \geq \varepsilon] \leq \exp(-2 \lfloor \frac{n}{k} \rfloor \varepsilon^2)$ , and  $P\left[|\hat{A}_{\Upsilon} - A_{\aleph}| \geq \varepsilon\right] \leq 2 \exp(-2 \lfloor \frac{n}{k} \rfloor \varepsilon^2)$ .*

*Proof.* First we define an auxiliary estimator  $\tilde{A}_{\Upsilon}^{(q)}$ . Let  $\mathbf{Y}^{(q)}$  be a vector of  $\lfloor n/k \rfloor \cdot q$  size- $k$  subsets of  $\mathcal{C}_{\Upsilon}$  where

<sup>2</sup>Note that we do not need to do this in practice which will follow from Theorem 10; we only need this mimicking process to prove that theorem.

the subsets of  $\mathcal{C}_\Upsilon$  in each of the  $q$  non-overlapping size- $\lfloor n/k \rfloor$  segments  $\mathbf{Y}_1^{(q)}, \mathbf{Y}_2^{(q)}, \dots, \mathbf{Y}_q^{(q)}$  of  $\mathbf{Y}^{(q)}$  are sampled in the same way as the elements of the vector  $\mathbf{Y}$  in Lemma 3, all with the same  $\mathcal{C}_\Upsilon$  (i.e.  $\mathbf{Y}^{(q)}$  is the concatenation of the vectors  $\mathbf{Y}_1^{(q)}, \mathbf{Y}_2^{(q)}, \dots, \mathbf{Y}_q^{(q)}$ ). Let us define  $\tilde{A}_\Upsilon^{(q)} = \frac{1}{q \cdot \lfloor n/k \rfloor} \sum_{\mathcal{S} \in \mathbf{Y}^{(q)}} \mathbb{1}(\Upsilon(\mathcal{S}) \models \alpha)$ . We can rewrite  $\tilde{A}_\Upsilon^{(q)}$  as  $\tilde{A}_\Upsilon^{(q)} = \frac{1}{q} \sum_{i=1}^q \frac{1}{\lfloor n/k \rfloor} \sum_{\mathcal{S} \in \mathbf{Y}_i^{(q)}} \mathbb{1}(\Upsilon(\mathcal{S}) \models \alpha)$ .

Then we can use the following trick (Hoeffding [9], Section 5) based on application of Jensen's inequality and Markov's inequality: If  $T = a_1 \cdot T_1 + a_2 \cdot T_2 + \dots + a_q \cdot T_n$ , where  $a_i \geq 0$  and  $\sum_{i=1}^q a_i = 1$ , then, for any  $h > 0$ ,  $P[T \geq \varepsilon] \leq \sum_{i=1}^q a_i \cdot \mathbb{E}[\exp(h(T_i - \varepsilon))]$ . Note that the  $T_i$ 's do not have to be independent. Next, using Hoeffding's lemma (Lemma 1 in [9]), if  $a_i = 1/q$  and each of the terms  $T_i$  is a sum of independent random zero-mean variables  $X_j^{(i)}$  such that  $P[a \leq X_j^{(i)} \leq b] = 1$  and  $b - a \leq 1$ , then we get:

$$\begin{aligned} P[T \geq \varepsilon] &\leq \sum_{i=1}^q \frac{1}{q} \cdot \mathbb{E}[\exp(h(T_i - \varepsilon))] \\ &\leq e^{-h\varepsilon} \exp\left(\frac{m \cdot h^2}{8}\right) = \exp\left(-h\varepsilon + \frac{m \cdot h^2}{8}\right) \end{aligned}$$

where  $m$  denotes the number of summands of  $T_i$  (which, in our case, is the same for all  $T_i$ 's). Note that this function achieves its minimum at  $h = \frac{4\varepsilon}{m}$ . We set  $T_i := \sum_{\mathcal{S} \in \mathbf{Y}_i^{(q)}} (\mathbb{1}(\Upsilon(\mathcal{S}) \models \alpha) - A_\aleph)$  (note that  $\mathbb{E}[T_i] = 0$  and  $m = \lfloor n/k \rfloor$ ). Thus, we get  $P[\lfloor \frac{n}{k} \rfloor \cdot (\tilde{A}_\Upsilon^{(q)} - A_\aleph) \geq \varepsilon] \leq \exp(-2\varepsilon^2 / \lfloor \frac{n}{k} \rfloor)$ , and finally

$$P[\tilde{A}_\Upsilon^{(q)} - A_\aleph \geq \varepsilon] \leq \exp\left(-2 \left\lfloor \frac{n}{k} \right\rfloor \varepsilon^2\right),$$

symmetrically also  $P[A_\aleph - \tilde{A}_\Upsilon^{(q)} \geq \varepsilon] \leq \exp(-2 \lfloor \frac{n}{k} \rfloor \varepsilon^2)$ , and, using union bound, we get

$$P[|\tilde{A}_\Upsilon^{(q)} - A_\aleph| \geq \varepsilon] \leq 2 \exp\left(-2 \left\lfloor \frac{n}{k} \right\rfloor \varepsilon^2\right).$$

It follows from the strong law of large numbers (which holds for any  $\Upsilon$ ) that  $P[\lim_{q \rightarrow \infty} \tilde{A}_\Upsilon^{(q)} = \hat{A}_\Upsilon] = 1$ . Since  $q$  was arbitrary, the statement of the proposition follows.  $\square$

As the next theorem shows, the above result can be generalized to the case where we need to bound the difference between the estimations obtained from two samples.

**Theorem 11.** *Let  $\aleph = (\mathcal{A}_\aleph, \mathcal{C}_\aleph)$  be an example and let  $0 \leq n, u \leq |\mathcal{C}_\aleph|$  and  $0 \leq k \leq n$  be integers. Let  $\mathcal{C}_\Upsilon$  and  $\mathcal{C}_\Gamma$  be sampled uniformly from all size- $n$  and size- $u$  subsets of  $\mathcal{C}_\aleph$  and let  $\Upsilon = \aleph(\mathcal{C}_\Upsilon), \Gamma = \aleph(\mathcal{C}_\Gamma)$ . Let  $\alpha$  be a closed and constant-free formula. Let  $\hat{A}_\Upsilon =$*

$Q_{\Upsilon, k}(\alpha), \hat{A}_\Gamma = Q_{\Gamma, k}(\alpha)$ , and let  $A_\aleph = Q_{\aleph, k}(\alpha)$ . Then we have  $P[|\hat{A}_\Upsilon - \hat{A}_\Gamma| \geq \varepsilon] \leq \exp\left(\frac{-2\varepsilon^2}{1/\lfloor n/k \rfloor + 1/\lfloor u/k \rfloor}\right)$ , and  $P[|\hat{A}_\Upsilon - \hat{A}_\Gamma| \geq \varepsilon] \leq 2 \exp\left(\frac{-2\varepsilon^2}{1/\lfloor n/k \rfloor + 1/\lfloor u/k \rfloor}\right)$ .

*Proof.* See the appendix.  $\square$

We note that the concentration inequality derived in Theorem 10 improves upon a concentration inequality derived in [17] (Chapter 10) that contains  $n/k^2$  (in our notation) instead of  $\lfloor n/k \rfloor$  in the exponential.<sup>3</sup>

Next we prove an inequality for the special case where the probability of a formula  $\alpha$  on  $\Upsilon$  is 0. Since we can also take negations of formulas, this theorem will be useful to prove bounds for formulas that are perfectly accurate on training data. As the following theorem shows, in this case we obtain stronger guarantees, where we have  $\varepsilon$  instead of  $\varepsilon^2$  in the exponential.

**Theorem 12.** *Let  $\aleph = (\mathcal{A}_\aleph, \mathcal{C}_\aleph)$  be an example and let  $0 \leq n \leq |\mathcal{C}_\aleph|$  and  $0 \leq k \leq n$  be integers. Let  $\mathcal{C}_\Upsilon$  be sampled uniformly from all size- $n$  subsets of  $\mathcal{C}_\aleph$  and let  $\Upsilon = \aleph(\mathcal{C}_\Upsilon)$ . Let  $\alpha$  be a closed and constant-free formula and let  $\mathcal{C}_k$  denote all size- $k$  subsets of  $\mathcal{C}_\Upsilon$ . Let  $\hat{A}_\Upsilon = Q_{\Upsilon, k}(\alpha)$  and let  $A_\aleph = Q_{\aleph, k}(\alpha) \geq \varepsilon$ . Then we have*

$$P[\hat{A}_\Upsilon = 0] \leq \exp(-\lfloor n/k \rfloor \varepsilon).$$

*Proof.* Let  $\mathbf{Y}$  be sampled as in Lemma 3 (i.e.  $\mathbf{Y}$  is sampled only using  $\Upsilon$  and not directly  $\aleph$ ). Then using Lemma 3 we know that the elements of  $\mathbf{Y}$  are distributed like  $\lfloor n/k \rfloor$  independent samples (size- $k$  subsets) from  $\mathcal{C}_\aleph$ . Hence we can bound the probability  $P[A_\Upsilon = 0] \leq (1 - \varepsilon)^{\lfloor n/k \rfloor} \leq \exp(-\lfloor n/k \rfloor \varepsilon)$ . Obviously, adding the rest of the information from size- $k$  subsets of  $\mathcal{C}_\Upsilon$  that are not contained in  $\mathbf{Y}$  cannot increase the bound.  $\square$

## 5.2 ZERO TRAINING ERROR CASE

We start by proving a bound for the realizable (i.e. zero training error) case.

**Theorem 13.** *Let  $\aleph, \Upsilon, \Gamma, n, u$  and  $\kappa$  be as in Definition 3 (i.e.  $\Upsilon$  and  $\Gamma$  are sampled from  $\aleph$  and  $n, u$  are sizes of  $\Upsilon$ 's and  $\Gamma$ 's domains). Let  $\mathcal{H}$  be a finite hypothesis class of constant-free formulas. Let  $\mathcal{F}(\Gamma, \Phi)$  denote the set of all ground literals of a predicate  $p/a$  that are  $k$ -entailed by  $\{\kappa(\Gamma)\} \cup \Phi$  but are false in  $\Gamma$ .<sup>4</sup> With probability at*

<sup>3</sup>This is essentially due to the fact that we use Hoeffding's decomposition whereas Lovasz relies on Azuma's inequality, leading to a looser bound compared to our bound.

<sup>4</sup>Note that here, as well as in the rest of the theorems in the paper,  $\mathcal{F}(\Gamma, \Phi)$  is a set-valued random variable.

least  $1 - \delta$ , the following holds for all  $\Phi \in \mathcal{H}$  that satisfy  $Q_{\Upsilon,k}(\Phi) = 1$ :

$$\mathbb{E}[|\mathcal{F}(\Gamma, \Phi)|] \leq \frac{\ln |\mathcal{H}| + \ln 1/\delta}{\lfloor n/k \rfloor} u^k k^a.$$

*Proof.* It follows from the linearity of expectation and from Proposition 6 that, for any  $\Phi$ ,  $\mathbb{E}[|\mathcal{F}(\Gamma, \Phi)|] \leq (1 - Q_{\aleph,k}(\Phi))u^k k^a$ . Next, it follows from Theorem 12 and from the union bound taken over all  $\Phi \in \mathcal{H}$  that the probability that there exists  $\Phi \in \mathcal{H}$  such that  $Q_{\Upsilon,k}(\Phi) = 1$  and  $\varepsilon \leq 1 - Q_{\aleph,k}(\Phi)$  is at most  $|\mathcal{H}| \cdot \exp(-\lfloor n/k \rfloor \varepsilon)$ . If  $\varepsilon \geq \frac{\ln |\mathcal{H}| + \ln 1/\delta}{\lfloor n/k \rfloor}$  then  $|\mathcal{H}| \cdot \exp(-\lfloor n/k \rfloor \varepsilon) \leq \delta$ . Hence, with probability at least  $1 - \delta$ , the following holds for all  $\Phi \in \mathcal{H}$  such that  $Q_{\Upsilon,k}(\Phi) = 1$ :  $\mathbb{E}[|\mathcal{F}(\Gamma, \Phi)|] \leq \frac{\ln |\mathcal{H}| + \ln 1/\delta}{\lfloor n/k \rfloor} u^k k^a$ .  $\square$

### 5.3 GENERAL CASE

Next we prove a bound for the general case when the training error is non-zero.

**Theorem 14.** *Let  $\aleph, \Upsilon, \Gamma, n, u$  and  $\kappa$  be as in Definition 3 (i.e.  $\Upsilon$  and  $\Gamma$  are sampled from  $\aleph$  and  $n, u$  are sizes of  $\Upsilon$ 's and  $\Gamma$ 's domains). Let  $\mathcal{H}$  be a finite hypothesis class of constant-free formulas. Let  $\mathcal{F}(\Gamma, \Phi)$  denote the set of all ground literals of a predicate  $p/a$  that are  $k$ -entailed by  $\{\kappa(\Gamma)\} \cup \Phi$  but are false in  $\Gamma$ . With probability at least  $1 - \delta$ , for all  $\Phi \in \mathcal{H}$ :*

$$\mathbb{E}[|\mathcal{F}(\Gamma, \Phi)|] \leq \left( 1 - Q_{\Upsilon,k}(\Phi) + \sqrt{\frac{\ln \left( \frac{|\mathcal{H}|}{\delta} \right)}{2\lfloor n/k \rfloor}} \right) u^k k^a.$$

*Proof.* First, as in the proof of Theorem 13, we find that, for any  $\Phi \in \mathcal{H}$ ,  $\mathbb{E}[|\mathcal{F}(\Gamma)|] \leq (1 - Q_{\aleph,k}(\Phi))u^k k^a$ . Next, it follows from Theorem 10 and from union bound that  $P[\exists \Phi \in \mathcal{H} : Q_{\Upsilon,k}(\Phi) - Q_{\aleph,k}(\Phi) \geq \varepsilon] \leq |\mathcal{H}| \exp(-2\lfloor n/k \rfloor \varepsilon^2)$ . It follows that

$$P\left[\exists \Phi \in \mathcal{H} : Q_{\Upsilon,k}(\Phi) \geq Q_{\aleph,k}(\alpha) + \sqrt{\frac{\ln (|\mathcal{H}|/\delta)}{2\lfloor n/k \rfloor}}\right] \leq \delta.$$

The theorem then follows straightforwardly from the above and from Proposition 6.  $\square$

The previous two theorems provided bounds on the expected number of errors on the sampled test examples. The next theorem is different in that it provides a bound on the actual number of errors.

**Theorem 15.** *Let  $\aleph, \Upsilon, \Gamma$ , and  $\kappa$  be as in Definition 3 (i.e.  $\Upsilon$  and  $\Gamma$  are sampled from  $\aleph$  and  $n, u$  are sizes of  $\Upsilon$ 's and  $\Gamma$ 's domains). Let  $\mathcal{H}$  be a finite hypothesis class of constant-free formulas. Let  $\mathcal{F}(\Gamma, \Phi)$  denote the set of*

*all ground literals of a predicate  $p/a$  that are  $k$ -entailed by  $\{\kappa(\Gamma)\} \cup \Phi$  but are false in  $\Gamma$ . With probability at least  $1 - \delta$ , for all  $\Phi \in \mathcal{H}$ :*

$$|\mathcal{F}(\Gamma, \Phi)| \leq \left( 1 - Q_{\Upsilon,k}(\Phi) + \sqrt{\frac{(\lfloor n/k \rfloor + \lfloor u/k \rfloor) \ln (2|\mathcal{H}|/\delta)}{2\lfloor n/k \rfloor \lfloor u/k \rfloor}} \right) u^k k^a \leq \left( 1 - Q_{\Upsilon,k}(\Phi) + \sqrt{\frac{\ln (2|\mathcal{H}|/\delta)}{\min\{\lfloor n/k \rfloor, \lfloor u/k \rfloor\}}} \right) u^k k^a.$$

*Proof.* Let us denote  $\hat{A} = Q_{\Upsilon,k}(\Phi)$ ,  $\hat{B} = Q_{\Gamma,k}(\Phi)$ . Using Theorem 11 and the union bound over  $\Phi \in \mathcal{H}$ , we get

$$P[\exists \Phi \in \mathcal{H} : |\hat{A} - \hat{B}| \geq \varepsilon] \leq 2|\mathcal{H}| \exp\left(\frac{-2\varepsilon^2 \lfloor n/k \rfloor \lfloor u/k \rfloor}{\lfloor n/k \rfloor + \lfloor u/k \rfloor}\right).$$

Solving the above for  $\varepsilon$  that achieves the  $1 - \delta$  bound, we obtain that, with probability at least  $1 - \delta$ , we have for all  $\Phi \in \mathcal{H}$ :  $|\hat{A} - \hat{B}| \leq \sqrt{\frac{(\lfloor n/k \rfloor + \lfloor u/k \rfloor) \ln (2|\mathcal{H}|/\delta)}{2\lfloor n/k \rfloor \lfloor u/k \rfloor}}$ . Hence, with probability at least  $1 - \delta$ , for all  $\Phi \in \mathcal{H}$  it holds  $1 - Q_{\Gamma,k}(\Phi) \leq 1 - Q_{\Upsilon,k}(\Phi) + \sqrt{\frac{(\lfloor n/k \rfloor + \lfloor u/k \rfloor) \ln (2|\mathcal{H}|/\delta)}{2\lfloor n/k \rfloor \lfloor u/k \rfloor}}$ . The validity of the theorem then follows from the above and from Proposition 6 and the fact that  $\frac{ab}{a+b} \geq \frac{\min(a,b)}{2}$  for any nonnegative  $a$  and  $b$ .  $\square$

### 5.4 BOUNDS FOR VOTING ENTAILMENT

Next we prove a bound for voting entailment, which, unsurprisingly, is tighter than the respective bound for  $k$ -entailment.

**Theorem 16.** *Let  $k$  be an integer and  $\gamma \in [0; 1]$ . Let further  $\aleph, \Upsilon, \Gamma$  and  $\kappa$  be as in Definition 3 (i.e.  $\Upsilon$  and  $\Gamma$  are sampled from  $\aleph$  and  $n, u$  are sizes of  $\Upsilon$ 's and  $\Gamma$ 's domains). Let  $\mathcal{H}$  be a finite hypothesis class of constant-free formulas. Let  $\mathcal{F}(\Gamma, \Phi)$  denote the set of all ground literals of a predicate  $p/a$  that are entailed by voting from  $\{\kappa(\Gamma)\} \cup \Phi$  with parameters  $k$  and  $\gamma$  but are false in  $\Gamma$ . Then, with probability at least  $1 - \delta$ , for all  $\Phi \in \mathcal{H}$ :*

$$|\mathcal{F}(\Gamma)| \leq \left( 1 - Q_{\Upsilon,k}(\Phi) + \sqrt{\frac{\ln (2|\mathcal{H}|/\delta)}{\min\{\lfloor u/k \rfloor, \lfloor n/k \rfloor\}}} \right) \frac{u^a k^a}{\gamma}.$$

*Proof.* This follows from the same reasoning as in the proof of Theorem 15, which gives us the bound on the difference of  $Q_{\Upsilon,k}(\Phi)$  and  $Q_{\Gamma,k}(\Phi)$ , combined with Theorem 8.  $\square$

**Remark 17.** *The fraction of “wrong” ground  $p/a$  literals does not grow with increasing test-set size ( $u$ ), since, by rewriting the bound from Theorem 16, we get, with probability at least  $1 - \delta$ , for all  $\Phi \in \mathcal{H}$ :*

$$\frac{|\mathcal{F}(\Gamma)|}{u^a} \leq \left( 1 - Q_{\Upsilon, k}(\Phi) + \sqrt{\frac{\ln(2|\mathcal{H}|/\delta)}{\min\{\lfloor u/k \rfloor, \lfloor n/k \rfloor\}}} \right) \frac{k^a}{\gamma}.$$

We note here that one can also easily obtain counterparts of Theorems 13 and 14 for voting entailment.

## 6 SUMMARY OF RESULTS

In this section we discuss positive and negative results that follow from the theorems presented in the preceding sections. Here, bounds are considered vacuous if they are not lower than the total number of ground literals. We first focus on  $k$ -entailment in Sections 6.1–6.3, and then discuss the results for voting entailment in Section 6.4. Finally, we also make a connection to MAP-entailment in Section 6.5.

### 6.1 SMALL TEST EXAMPLES

One case where we have non-vacuous bounds for the *expected* number of incorrectly predicted literals with  $k$ -entailment is when the domain of the test examples  $\Gamma$  is small. Naturally a necessary condition is also that the given (or learned) theory  $\Phi$  is sufficiently accurate. The only way to be confident that  $\Phi$  is indeed sufficiently accurate, given that this accuracy needs to be estimated, is by estimating it on a sufficiently large training example. This is essentially what Theorems 13 and 14 imply.

Interestingly, this finding agrees with some experimental observations in the literature. For instance, it has been observed in [14] that classical reasoning in a relational setting close to ours worked well for small-size test-set evidence but was not competitive with other methods for larger evidence sizes. The analysis in the present paper thus sheds light on experimental observations like these.

Note that the bounds from Theorems 13 and 14 are for the *expected* value of the number of errors. Bounds on the *actual* number of errors are provided in Theorem 15. In this case, to obtain non-vacuous bounds, we also need to require that the domain of the test example  $\Gamma$  be sufficiently large. This is not unexpected, however, as it is a known property of statistical bounds for transductive settings (see e.g., [21]) that the size of the test set affects confidence bounds, similarly to how the size of the  $\Gamma$ 's domain affects the bound in Theorem 15.

### 6.2 PREDICATES OF ARITY $k$

Another case where we have non-vacuous bounds for  $k$ -entailment is when the arity of the predicted literals is equal to the parameter  $k$ . In this case both the bounds for the expected error and for the actual error  $|\mathcal{F}(\Gamma, \Phi)|$  are non-vacuous. This means that our results cover important special cases. One such special case is classical attribute-value learning when  $k = 1$  and we represent attributes by unary predicates. Another case is link prediction when  $k = 2$  and higher-arity versions thereof. In link prediction, we have rules such as, for instance,  $\forall X, Y : \text{CoensFan}(X) \wedge \text{CoensFilm}(Y) \Rightarrow \text{likes}(X, Y)$ .

### 6.3 REALIZABLE SETTING

We can get stronger guarantees when the given (or learned) theory  $\Phi$  has zero training error. Keeping the fraction of the domain-sizes  $|\mathcal{C}_\Gamma|^{k-a}/|\mathcal{C}_\Upsilon|$  small, Theorem 13 implies non-vacuous bounds for predicates of arity  $a$  for any size of the domain of  $\Gamma$ . Intuitively, this means that we can use theories that are completely accurate on training data for inference using  $k$ -entailment. However, the required size of the domain of the training example  $\Upsilon$ , to guarantee that we will not produce too many errors, grows exponentially with  $k$  (for a fixed arity  $a$ ) and polynomially with  $|\mathcal{C}_\Gamma|$ .

### 6.4 VOTING

When using voting entailment, we can always obtain non-trivial bounds by making  $\gamma$  large; obviously this comes at the price of making the inferences more cautious. Voting entailment is a natural inference method in domains where one proof is not enough, i.e. where the support from several proofs is needed before we can be sufficiently confident in the conclusion; an example of such a domain is the well-known *smokers* domain, where knowing that one friend smokes does not provide enough evidence to conclude that somebody smokes; only if we have evidence of several smoker friends is the conclusion warranted that this person smokes.

### 6.5 RELATIONSHIP TO MAP INFERENCE

A popular approach to collective classification in relational domains is MAP-inference in Markov logic networks. Therefore a natural question is how this approach performs in our setting. Perhaps surprisingly, it might produce as many errors as classical logic reasoning in the examples from Section 4.1, if the Markov logic network contains the same rules, all with positive weights, as we had in these examples. This is because MAP-inference will predict the same literals as classical logical inference

when the rules from the Markov logic network are consistent with the given evidence. Thus, we can see that our guarantees for both  $k$ -entailment and voting entailment are better than guarantees one could get for MAP-inference. This is also in agreement with the well-known observations that, for instance, in the smokers domain, MAP inference often predicts everyone to be a smoker or everyone to be a non-smoker if there is only a small amount of evidence.

## 7 RELATED WORK

Our main inspiration comes from the works on PAC-semantics by Valiant [23] and Juba [10]. Our work differs mainly in the fact that we have one large relational structure  $\aleph$ , and a training example  $\Upsilon$  and a test example  $\Gamma$ , both sampled from  $\aleph$ , whereas it is assumed in these existing approaches that learning examples are sampled i.i.d. from some distribution. This has two important consequences. First, they could use statistical techniques developed for i.i.d. data whereas we had to first derive concentration inequalities for sampling without replacement in the relational setting. Second, since they only needed to bound the error on the independently sampled examples, they did not have to consider the number of incorrectly inferred facts. In contrast, in the relational setting that we considered here, the number of errors made on one relational example is the quantity that needs to be bounded. It follows that completely different techniques are needed in our case. Another difference is that, in their case, the training examples are also masked. In principle, we could modify our results to accommodate for masked examples by replacing “accurate” formulas by sufficiently-often “witnessed” formulas (see [10] for a definition).

Dhurandhar and Dobra [5] derived Hoeffding-type inequalities for classifiers trained with relational data, but these inequalities, which are based on the restriction on the independent interactions of data points, cannot be applied to solve the problems considered in the present paper. Certain other statistical properties of learning have also been studied for SRL models. For instance, Xiang and Neville [25] studied consistency of estimation. However, guaranteeing convergence to the correct distribution does not mean that the model would not generate many errors when used, e.g., for MAP-inference. In [26], they further studied errors in label propagation in collective classification. In their setting, however, the relational graph is fixed and one only predicts labels of vertices exploiting the relational structure for making the predictions. Here we also note that it is not always possible or desirable in practice to sample sets of domain elements uniformly as we assumed to be the case in our analysis.

Other sampling designs for relational data were studied, e.g. in [1]. A study of PAC guarantees for such other sampling designs is left as a topic for future work.

There have also been works studying restricted forms of inference in a purely logical context, e.g. [6]. It is an interesting question for future work to find out which existing restricted inference systems would lead to non-vacuous error bounds in the relational setting.

## 8 CONCLUSIONS

We have studied the problem of predicting plausible missing facts in relational data, given a set of imperfect logical rules, in a PAC reasoning setting. As for the considered inference methods, one of our main objectives was for the inference methods to stay close to classical logic. The first inference method,  $k$ -entailment, is a restricted form of classical logic inference and hence satisfies this objective. The second inference method, voting entailment, is based on a form of voting that combines results from inferences made by  $k$ -entailment on subsets of the relational data. Importantly, the voting is not weighted which makes voting entailment easier to understand. We were able to obtain non-trivial bounds for the number of literals incorrectly predicted by a learned (or given) theory for both  $k$ -entailment and voting entailment. Probably the most useful results of our analysis lie in the identification of cases where the bounds for learning and reasoning in relational data are non-vacuous, which we discussed in detail in Section 6.

There are many interesting directions in which one could extend the results presented in this paper. For instance, as practical means to improve the explainability of inferences made by voting entailment, we could first find representatives of isomorphism classes of “proofs” that are aggregated by voting entailment, and only show these to the user. Another direction is to extend the notion of implicit learning from [10] into the relational setting. It would also be interesting to exploit explicit sparsity constraints and to study other sampling designs, although that might also turn out to be analytically less tractable than the setting considered in the present paper. Finally, although all bounds presented in this paper assume finite hypothesis classes, we note that it is also possible to extend our results to infinite hypothesis classes [13].

## Abstract

Inspired by heavy-tailed distributions in practical scenarios, we investigate the problem on pure exploration of Multi-Armed Bandits (MAB) with heavy-tailed payoffs by breaking the assumption of payoffs with sub-Gaussian noises in MAB, and assuming that stochastic payoffs from bandits are with finite  $p$ -th moments, where  $p \in (1, +\infty)$ . The main contributions in this paper are three-fold. First, we technically analyze tail probabilities of empirical average and truncated empirical average (TEA) for estimating expected payoffs in sequential decisions with heavy-tailed noises via martingales. Second, we propose two effective bandit algorithms based on different prior information (i.e., fixed confidence or fixed budget) for pure exploration of MAB generating payoffs with finite  $p$ -th moments. Third, we derive theoretical guarantees for the proposed two bandit algorithms, and demonstrate the effectiveness of two algorithms in pure exploration of MAB with heavy-tailed payoffs in synthetic data and real-world financial data.

## 1 INTRODUCTION

The prevailing decision-making model named Multi-Armed Bandits (MAB) elegantly characterizes a wide class of practical problems on sequential learning with partial feedbacks, which was first formally proposed and investigated in (Robbins, 1952). In general, a predominant characteristic of MAB is a trade-off between exploration and exploitation for sequential decisions, which has been frequently encountered in scientific research and various industrial applications, e.g., resource allocation, online advertising and personalized recommendations (Auer et al., 2002; Bubeck et al., 2012; Chu et al., 2011; Lattimore et al., 2015; Wu et al., 2016).

Most algorithms in MAB are primarily developed to maximize cumulative payoffs during a number of rounds for sequential decisions. Recently, there have been interesting investigations on various variants of the traditional MAB model, such as linear bandits (Auer, 2002; Yu et al., 2017b; Zhao and King, 2016), pure exploration of MAB (Audibert and Bubeck, 2010), risk-averse MAB (Sani et al., 2012; Yu et al., 2017a), cascading bandits (Kveton et al., 2015) and clustering bandits (Korda et al., 2016; Li et al., 2016).

One non-trivial branch of MAB is pure exploration, where the goal is to find the optimal arm in a given decision-arm set at the end of exploration. In this case, there is no explicit trade-off between exploration and exploitation for sequential decisions, which means that the exploration phase and the exploitation phase are separated. The problem of pure exploration is motivated by real scenarios which prefer to identify an optimal arm instead of maximizing cumulative payoffs. Recent advances in pure exploration of MAB have found potential applications in many practical domains including communication networks and commercialized products (Audibert and Bubeck, 2010; Chen et al., 2014).

In previous studies on pure exploration of MAB, a common assumption is that noises in observed payoffs are sub-Gaussian. The sub-Gaussian assumption encompasses cases of all bounded payoffs and many unbounded payoffs in MAB, e.g., payoffs of an arm following a Gaussian distribution. However, there exist non-sub-Gaussian noises in observed payoffs for bandits, e.g., high-probability extreme payoffs in sequential decisions which are called heavy-tailed payoffs. A practical motivation example for MAB with heavy-tailed payoffs is the distribution of delays in end-to-end network routing (Liebeherr et al., 2012). Pure exploration of MAB with heavy-tailed payoffs is important, especially for identifications of the potential optimal investment target for practical financial applications. It is worth mentioning that the case of maximizing cumulative payoffs

of MAB with heavy tails has been extensively investigated in (Bubeck et al., 2013a; Carpentier and Valko, 2014; Lattimore, 2017; Medina and Yang, 2016; Vakili et al., 2013). In (Bubeck et al., 2013a), the setting of sequential payoffs with bounded  $p$ -th moments was investigated for regret minimization in MAB, where  $p \in (1, 2]$ . Vakili et al. (Vakili et al., 2013) introduced bounded  $p$ -th moments with the support over  $(1, +\infty)$ , and provided a complete regret guarantee in MAB. In (Medina and Yang, 2016), regret guarantee in linear bandits with heavy-tailed payoffs was investigated, which is still scaled by parameters of bounded moments. Recently, payoffs in bandits with bounded kurtosis were discussed in (Lattimore, 2017).

In this paper, we investigate the problem on pure exploration of MAB with heavy-tailed payoffs characterized by the bound of  $p$ -th moments. It is surprising to find that less effort has been devoted to pure exploration of MAB with heavy-tailed payoffs. Compared with previous work on pure exploration of MAB, the problem of best arm identification with heavy-tailed payoffs has three challenges. The first challenge is the estimate of expected payoffs of an arm in MAB. It might not be sufficient to adopt an empirical average (EA) of observed payoffs with heavy-tailed noises for estimating a true mean. The second challenge is the probability of error for the estimate of expected payoffs, which affects performance of bandit algorithms in pure exploration of MAB. The third challenge is to develop effective bandit algorithms with theoretical guarantees for pure exploration of MAB with heavy-tailed stochastic payoffs.

To solve the above three challenges, we need to introduce a general assumption that stochastic payoffs in MAB are with finite  $p$ -th moments, where  $p \in (1, +\infty)$ . Note that the case of  $p \in (1, 2]$  is weaker than the classic assumption of payoffs with sub-Gaussian noises in MAB. Then, under the assumption of finite  $p$ -th moments, we present theoretical behaviours of empirical average, and analyze the estimate of truncated empirical average (TEA). Based on different prior information, i.e., fixed confidence or fixed budget, we propose two bandit algorithms in pure exploration of bandits with heavy-tailed payoffs. Finally, based on synthetic data with noises from standard *Student's t-distribution* and real-world financial data, we demonstrate the effectiveness of the proposed bandit algorithms. To the best of our knowledge, this is the first systematic investigation on pure exploration of MAB with heavy-tailed payoffs. For reading convenience, we list contributions of this paper below.

- We technically analyze tail probabilities of EA and TEA to estimate true mean of arms in MAB with the general assumption of conditionally independent payoffs.

- We propose two bandit algorithms for pure exploration of MAB with heavy-tailed stochastic payoffs characterized by finite  $p$ -th moments, where  $p \in (1, +\infty)$ .
- We derive theoretical results of the proposed bandit algorithms, as well as demonstrating effectiveness of two algorithms via synthetic data and real-world financial data.

## 2 PRELIMINARIES

In this section, we first present related notations and definitions in this paper. Then, we present assumptions and the problem definition for pure exploration of MAB with heavy-tailed payoffs.

### 2.1 NOTATIONS

Let  $\mathcal{A}$  be a bandit algorithm for pure exploration of MAB, which contains  $K$  arms at the beginning of exploration. For pure exploration, let  $\text{Opt}$  be the true optimal arm among  $K$  arms, where  $\text{Opt} \in [K]$  with  $[K] \triangleq \{1, 2, \dots, K\}$ . The total number of sequential rounds for  $\mathcal{A}$  to play bandits is  $T$ , which is also called as sample complexity. The confidence parameter is denoted by  $\delta \in (0, 1)$ , which means that, with probability at least  $1 - \delta$ ,  $\mathcal{A}$  generates an output optimal arm  $\text{Out}$  equivalent to  $\text{Opt}$ , where  $\text{Out} \in [K]$ . In other words, it happens with a small probability  $\delta$  that  $\text{Opt} \neq \text{Out}$ , and  $\delta$  can be also called the probability of error.

There are two settings based on different prior information given at the beginning of exploration, i.e., fixed confidence or fixed budget. For the setting of fixed confidence,  $\mathcal{A}$  receives the information of  $\delta$  at the beginning, and  $\mathcal{A}$  generates  $\text{Out}$  when a certain condition related to  $\delta$  is satisfied. For the setting of fixed budget,  $\mathcal{A}$  receives the information of  $T$  at the beginning, and  $\mathcal{A}$  generates  $\text{Out}$  at the end of  $T$ .

We present the learning process on pure exploration of MAB as follows. For  $t = 1, 2, \dots, T$ ,  $\mathcal{A}$  decides to play an arm  $a_t \in [K]$  with historical information of  $\{a_1, \pi_1(a_1), \dots, a_{t-1}, \pi_{t-1}(a_{t-1})\}$ . Then,  $\mathcal{A}$  observes a stochastic payoff  $\pi_t(a_t) \in \mathbb{R}$  with respect to  $a_t$ , of which the expectation conditional on  $\mathcal{F}_{t-1}$  is  $\mu(a_t)$  with  $\mathcal{F}_{t-1} \triangleq \{a_1, \pi_1(a_1), \dots, a_{t-1}, \pi_{t-1}(a_{t-1}), a_t\}$  and  $\mathcal{F}_0$  being an empty set. Based on  $\pi_t(a_t)$ ,  $\mathcal{A}$  updates parameters to proceed with the exploration at  $t + 1$ . We store time index  $t$  of playing arm  $a_t$  in  $\Phi(a_t)$ , which is a set with increasing integers.

Given an event  $\mathcal{E}$  and a random variable  $\xi$ , let  $\mathbb{P}[\mathcal{E}]$  be the probability of  $\mathcal{E}$  and  $\mathbb{E}[\xi]$  be the expectation of  $\xi$ . For  $x \in \mathbb{R}$ , we denote by  $|x|$  the absolute value of  $x$ , and for a set  $S$ , we denote by  $|S|$  the cardinality of  $S$ . For an event  $\mathcal{E}$ , let  $\mathbf{1}_{[\mathcal{E}]}$  be the indicator function of  $\mathcal{E}$ .

**Definition 1.** (*Heavy-tailed payoffs in MAB*) Given MAB with  $K$  arms, let  $\pi(k)$  be a stochastic payoff drawn from any arm  $k \in [K]$ . For  $t = 1, \dots, T$ , conditional on  $\mathcal{F}_{t-1}$ , MAB has heavy-tailed payoffs with the  $p$ -th raw moment bounded by  $B$ , or the  $p$ -th central moment bounded by  $C$ , where  $p \in (1, +\infty)$ ,  $B, C \in (0, +\infty)$  and  $k \in [K]$ .

## 2.2 PROBLEM DEFINITION

It is general to assume that payoffs during sequential decisions contain noises in many practical scenarios. We list the assumptions in this paper for pure exploration of MAB with heavy-tailed payoffs as follows.

1. Assume that  $\text{Opt} \triangleq \arg \max_{k \in [K]} \mu(k)$  is unique for pure exploration of MAB with  $K$  arms.
2. Assume that MAB has heavy-tailed payoffs with the  $p$ -th raw or central moment conditional on  $\mathcal{F}_{t-1}$  bounded by  $B$  or  $C$ , for  $t = 1, \dots, T$ .
3. Assume that the sequence of stochastic payoffs from arm  $k \in [K]$  has noises with zero mean conditional on  $\mathcal{F}_{t-1}$  in pure exploration of MAB. For any time instant  $t \in [T]$  and the selected arm  $a_t$ , we define random noise of a true payoff as  $\xi_t(a_t) \triangleq \pi_t(a_t) - \mu(a_t)$ , and assume  $\mathbb{E}[\xi_t(a_t) | \mathcal{F}_{t-1}] = 0$ .

Now we present a problem definition for pure exploration of MAB as follows. Given  $K$  arms satisfying Assumptions 1–3, the problem in this paper is to develop a bandit algorithm  $\mathcal{A}$  generating an arm  $\text{Out}_T \in [K]$  after  $T$  pullings of bandits such that  $\mathbb{P}[\text{Out}_T \neq \text{Opt}] \leq \delta$ , where  $\delta \in (0, 1)$ .

We discuss theoretical guarantees in two settings for best arm identification of bandits. One is to derive the theoretical guarantee of  $T$  by fixing the value of  $\delta$ , which is called fixed confidence. The other is to derive the theoretical guarantee of  $\delta$  by fixing the value of  $T$ , which is called fixed budget.

For simplicity of notations, we enumerate the arms according to their expected payoffs as a sequence of  $\mu(1) > \mu(2) \geq \dots \geq \mu(K)$ . In the ranked sequence, we know that  $\text{Opt} = 1$ . Note that the ranking operation does not affect our theoretical guarantees. For any arm  $k \neq \text{Opt}$  and  $k \in [K]$ , we define the sub-optimality as  $\Delta_k \triangleq \mu(\text{Opt}) - \mu(k)$ , which leads to a sequence of sub-optimality as  $\{\Delta_k\}_{k=2}^K$ . To obtain  $K$  terms in sub-optimality, which helps theoretical analyses, we further define  $\Delta_1 \triangleq \Delta_2$ . Inspired by (Audibert and Bubeck, 2010), we define the hardness for pure exploration of MAB with heavy-tailed payoffs by quantities as

$$H_2^p \triangleq \max_{k \in [K]} k^{p-1} \Delta_k^{-p}. \quad (1)$$

## 3 RELATED WORK

Pure exploration in MAB, aiming at finding the optimal arm after exploration among a given decision-arm set, has become an attracting branch in the decision-making domain (Audibert and Bubeck, 2010; Bubeck et al., 2009; Chen et al., 2014; Gabillon et al., 2012, 2016; Jamieson and Nowak, 2014). It has been pointed out that pure exploration in MAB has many applications, such as communication networks and online advertising.

For pure exploration of MAB with payoffs under sub-Gaussian noises, theoretical guarantees have been well studied. Specifically, in the setting of fixed confidence, the first distribution-dependent lower bound of sample complexity was developed in (Mannor and Tsitsiklis, 2004), which is  $\sum_{k \in [K]} \Delta_k^{-2}$ . Even-Dar et al. (2002) originally proposed a bandit algorithm via successive elimination for bounded payoffs with an upper bound of sample complexity matching the lower bound up to a multiplicative logarithmic factor. Karnin et al. (2013) proposed an improved bandit algorithm, which achieves an upper bound of sample complexity matching the lower bound up to a multiplicative doubly-logarithmic factor. Jamieson et al. (2014) proved that it is necessary to have a multiplicative doubly-logarithmic factor in the distribution-dependent lower bound of sample complexity. Jamieson et al. also developed a bandit algorithm via the law of iterated logarithm for pure exploration of MAB, which achieved the optimal sample complexity of the problem.

In the setting of fixed budget with payoffs under sub-Gaussian noises, (Audibert and Bubeck, 2010) developed a distribution-dependent lower bound of probability of error, and provided two algorithms, which achieve optimal probability of error up to logarithmic factors. Gabillon et al. (2012) proposed a unified algorithm for fixed budget and fixed confidence, which discusses  $\epsilon$ -optimal learning in best arm identification of MAB. Karnin et al. (2013) proposed a bandit algorithm via sequential halving to improve probability of error by a multiplicative constant. It is worth mentioning that (Kaufmann et al., 2016) investigated best arm identification of MAB under Gaussian or Bernoulli assumption, and provided lower bounds in terms of Kullback-Leibler divergence. We also notice that there are extensions of best arm identification of MAB, which is multiple-arm identification (Bubeck et al., 2013b; Chen et al., 2014).

To the best of our knowledge, there is no investigation on pure exploration of MAB without the strict assumption of payoffs under sub-Gaussian noises. There are some potential reasons for this fact. One main reason can be that, without sub-Gaussian noises, the tail probabilities of estimates for expected payoffs can be heavy

Table 1: Comparisons on distributional assumptions and theoretical guarantees in pure exploration of MAB. Note we omit constant factors in the following inequalities, and  $H_1$ ,  $H_2$  and  $H_3$  can refer to the corresponding work.

because Chernoff-Hoeffding inequalities of estimates do not hold in general. The failure of Chernoff-Hoeffding inequalities of estimates is a big challenge in pure exploration of MAB. In this paper, we investigate theoretical performance of pure exploration of MAB with heavy-tailed stochastic payoffs characterized by finite  $p$ -th moments, where  $p \in (1, +\infty)$ . We will put more efforts on  $p \in (1, 2]$  because the case of  $p \in (2, +\infty)$  enjoys a similar format of  $p = 2$ . To compare our work with prior studies, we list the distributional assumptions and theoretical guarantees in pure exploration of MAB in Table 1. Finally, it is worth mentioning that the case of maximizing expected cumulative payoffs of MAB with heavy tails has been extensively investigated in (Bubeck et al., 2013a; Carpentier and Valko, 2014; Medina and Yang, 2016; Vakili et al., 2013).

## 4 ALGORITHMS AND ANALYSES

In this section, we first investigate two estimates, i.e., EA and TEA, for expected payoffs of bandits, and derive tail probabilities for EA and TEA under sequential payoffs. Then, we develop two bandit algorithms for best arm identification of MAB in the spirit of successive elimination (SE) and successive rejects (SR). In particular, SE is for the setting of fixed confidence and SR is for the setting of fixed budget. Finally, we derive theoretic

cal guarantees for each bandit algorithm, where we take advantage of EA or TEA.

### 4.1 EMPIRICAL ESTIMATES

In SE and SR, it is common for  $\mathcal{A}$  to maintain a subset of arms  $S_t \subseteq [K]$  at time  $t = 1, 2, \dots$  and  $\mathcal{A}$  will output an arm when a certain condition is satisfied, e.g.,  $|S_t| = 1$  in the setting of fixed confidence. Similar to the most frequently used estimates for expected payoffs in MAB, we consider the following EA to estimate expected payoffs for any arm  $k \in S_t$ :

$$\hat{\mu}_t(k) \triangleq \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} \pi_i(k), \quad (2)$$

where  $s_{t,k} \triangleq |\Phi(k)|$  at time  $t$ . Note that the number of elements in  $\Phi(k)$  will increase or hold with time evolution, and the elements in  $\Phi(k)$  may not successively increase. We also investigate the following estimator TEA for any arm  $k \in S_t$ :

$$\hat{\mu}_t^\dagger(k) \triangleq \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} \pi_i(k) \mathbb{1}_{[\pi_i(k) \leq b_i]}, \quad (3)$$

where  $b_i > 0$  is a truncating parameter, and  $b_i$  will be completely discussed in the ensuing theoretical analyses.

We do not discuss the estimator called median of means (MoM) shown in (Bubeck et al., 2013a), because theo-

retical guarantees of MoM enjoy similar formats to those of TEA. Before we prove concentration inequalities for estimates via martingales, we have results as below.

**Proposition 1.** (Dharmadhikari et al., 1968; von Bahr et al., 1965) Let  $\{\nu_i\}_{i=1}^t$  be random variables satisfying  $\mathbb{E}[|\nu_i|^p] \leq C$  and  $\mathbb{E}[\nu_i|\mathcal{F}_{i-1}] = 0$ . If  $p \in (1, 2]$ , then we have  $\mathbb{E}\left[\left|\sum_{i=1}^t \nu_i\right|^p\right] \leq 2tC$ . If  $p \in (2, +\infty)$ , then we have  $\mathbb{E}\left[\left|\sum_{i=1}^t \nu_i\right|^p\right] \leq C_p C t^{p/2}$ , where  $C_p \triangleq (8(p-1)\max(1, 2^{p-3}))^p$ .

**Proposition 2.** (Seldin et al., 2012) Let  $\{\nu_i\}_{i=1}^t$  be random variables satisfying  $|\nu_i| \leq b_i$  with  $\{b_i\}_{i=1}^t$  being a non-decreasing sequence,  $\mathbb{E}[\nu_i|\mathcal{F}_{i-1}] = 0$  and  $\mathbb{E}[\nu_i^2|\mathcal{F}_{i-1}]$  is bounded. Then, with probability  $1 - \delta$ , we have  $\left|\sum_{i=1}^t \nu_i\right| \leq b_t \log(2/\delta) + V_t/b_t$ , and  $V_t = \sum_{i=1}^t \mathbb{E}[\nu_i^2|\mathcal{F}_{i-1}]$ .

**Lemma 1.** In pure exploration of MAB with  $K$  arms, for any  $t \in [T]$  and any arm  $k \in S_t$ , with probability  $1 - \delta$

- for EA, we have

$$\begin{cases} |\hat{\mu}_t(k) - \mu(k)| \leq \left(\frac{2C}{s_{t,k}^{p-1}\delta}\right)^{\frac{1}{p}}, & 1 < p \leq 2, \\ |\hat{\mu}_t(k) - \mu(k)| \leq \left(\frac{C_p C}{s_{t,k}^{p/2}\delta}\right)^{\frac{1}{p}}, & p > 2; \end{cases}$$

- for TEA, we have

$$\begin{cases} |\hat{\mu}_t^\dagger(k) - \mu(k)| \leq 5B^{\frac{1}{p}} \left(\frac{\log(2/\delta)}{s_{t,k}}\right)^{\frac{p-1}{p}}, & 1 < p \leq 2, \\ |\hat{\mu}_t^\dagger(k) - \mu(k)| \leq 5B^{\frac{1}{p}} \left(\frac{\log(2/\delta)}{s_{t,k}}\right)^{\frac{1}{2}}, & p > 2. \end{cases}$$

*Proof.* We first prove the results with the estimator  $\hat{\mu}_t(k)$  with  $k \in S_t$ . By Chebyshev's inequality, we have

$$\begin{aligned} \mathbb{P}[|\hat{\mu}_t(k) - \mu(k)| \geq \delta] &\leq \frac{\mathbb{E}[|\hat{\mu}_t(k) - \mu(k)|^p]}{\delta^p} \\ &= \frac{\mathbb{E}\left[\left|\sum_{i \in \Phi(k)} \pi_i(k) - \mu(k)\right|^p\right]}{s_{t,k}^p \delta^p}, \end{aligned} \quad (4)$$

where  $\delta \in (0, 1)$  and  $s_{t,k}$  is fixed at time  $t$ .

Based on Assumption 2, we have  $\mathbb{E}[|\xi_i(k)|^p] \leq C$  and  $\mathbb{E}[\xi_i(k)|\mathcal{F}_{i-1}] = 0$  for any  $i \in \Phi(k)$  at  $t$ . For  $p \in (1, 2]$ ,

$$\mathbb{P}[|\hat{\mu}_t(k) - \mu(k)| \geq \delta] \leq \frac{\mathbb{E}\left[\left|\sum_{i \in \Phi(k)} \xi_i\right|^p\right]}{s_{t,k}^p \delta^p} \leq \frac{2C}{s_{t,k}^{p-1} \delta^p},$$

where we adopt Proposition 1. Thus, for any arm  $k \in S_t$ , with probability at least  $1 - \delta$

$$|\hat{\mu}_t(k) - \mu(k)| \leq \left(\frac{2C}{s_{t,k}^{p-1}\delta}\right)^{\frac{1}{p}}. \quad (5)$$

For  $p \in (2, +\infty)$ , we have

$$\mathbb{P}[|\hat{\mu}_t(k) - \mu(k)| \geq \delta] \leq \frac{C_p C}{s_{t,k}^{p/2} \delta^p}, \quad (6)$$

where we adopt Proposition 1. With probability  $1 - \delta$

$$|\hat{\mu}_t(k) - \mu(k)| \leq \left(\frac{C_p C}{s_{t,k}^{p/2} \delta}\right)^{\frac{1}{p}}. \quad (7)$$

Now we prove the results with the estimator  $\hat{\mu}_t^\dagger(k)$ , where  $k \in S_t$ . Considering  $b_i$  in Eq. (3), we define  $\mu_i^\dagger(k) \triangleq \mathbb{E}[\pi_i(k)\mathbb{1}_{[|\pi_i(k)| \leq b_i]}|\mathcal{F}_{i-1}]$ , and  $\zeta_i(k) \triangleq \mu_i^\dagger(k) - \pi_i(k)\mathbb{1}_{[|\pi_i(k)| \leq b_i]}$ , for any  $i \in \Phi(k)$ . We have  $|\zeta_i(k)| \leq 2b_i$ ,  $\mathbb{E}[\zeta_i(k)|\mathcal{F}_{i-1}] = 0$  and  $\mathbb{E}[\pi_i(k)\mathbb{1}_{[|\pi_i(k)| > b_i]}|\mathcal{F}_{i-1}] \leq B/b_i^{p-1}$ . Besides, we also have

$$\begin{aligned} \mu(k) - \hat{\mu}_t^\dagger(k) &= \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} [\mu(k) - \mu_i^\dagger(k)] \\ &\quad + \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} [\mu_i^\dagger(k) - \pi_i(k)\mathbb{1}_{[|\pi_i(k)| \leq b_i]}] \\ &= \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} (\mathbb{E}[\pi_i(k)\mathbb{1}_{[|\pi_i(k)| > b_i]}|\mathcal{F}_{i-1}] + \zeta_i(k)), \end{aligned}$$

which implies the inequality of  $\mu(k) - \hat{\mu}_t^\dagger(k) \leq \frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} \left(\frac{B}{b_i^{p-1}} + \zeta_i(k)\right)$ . For  $p \in (1, 2]$ , we have  $\mathbb{E}[\zeta_i^2(k)|\mathcal{F}_{i-1}] \leq \mathbb{E}[\pi_i^2(k)\mathbb{1}_{[|\pi_i(k)| \leq b_i]}|\mathcal{F}_{i-1}] \leq \frac{B}{b_i^{p-2}}$ .

Based on Proposition 2, with probability at least  $1 - \delta$

$$\begin{aligned} \left|\sum_{i \in \Phi(k)} \zeta_i(k)\right| &\leq 2b_t \log(2/\delta) + \frac{1}{2b_t} \sum_{i \in \Phi(k)} \mathbb{E}[\zeta_i^2(k)|\mathcal{F}_{i-1}] \\ &\leq 2b_t \log(2/\delta) + s_{t,k} \frac{B}{2b_t^{p-1}}, \end{aligned} \quad (8)$$

where we adopt the design of  $\{b_i\}_{i \in \Phi(k)}$  as a non-decreasing sequence, i.e.,  $b_1 \leq b_2 \leq \dots \leq b_t$ . Thus, by setting  $b_t = \left(\frac{B s_{t,k}}{\log(2/\delta)}\right)^{\frac{1}{p}}$ , with probability at least  $1 - \delta$ , we have

$$|\hat{\mu}_t^\dagger(k) - \mu(k)| \leq 5B^{\frac{1}{p}} \left(\frac{\log(2/\delta)}{s_{t,k}}\right)^{\frac{p-1}{p}}, \quad (9)$$

where we adopt the fact of

$$\frac{1}{s_{t,k}} \sum_{i \in \Phi(k)} \frac{B}{b_i^{p-1}} \leq 2B^{\frac{1}{p}} \left(\frac{\log(2/\delta)}{s_{t,k}}\right)^{\frac{p-1}{p}}. \quad (10)$$

For  $p \in (2, +\infty)$ , by Jensen's inequality, we have

$$\mathbb{E}[\zeta_t^2(k)|\mathcal{F}_{i-1}] \leq B^{\frac{2}{p}}. \quad (11)$$

By converting the condition in  $p \in (2, +\infty)$  to the condition in  $p = 2$  with Jensen's inequality and using Eq. (9), with probability at least  $1 - \delta$ , we have

$$|\hat{\mu}_t^\dagger(k) - \mu(k)| \leq 5B^{\frac{1}{p}} \left( \frac{\log(2/\delta)}{S_{t,k}} \right)^{\frac{1}{2}}, \quad (12)$$

which completes the proof.  $\square$

**Remark 1.** In (Bubeck et al., 2013a; Vakili et al., 2013), the Bernstein inequality without martingales is adopted with an implicit assumption of sampling payoffs of an arm being independent of sequential decisions, which is informal. By contrast, in Lemma 1, conditional on  $\mathcal{F}_{t-1}$ , the subset  $S_t$  is fixed, and we adopt Bernstein inequality with martingales. Thus, we break the assumption of independent payoffs in previous work, and prove formal theoretical results of tail probabilities of estimators EA and TEA. Note that the superiority of martingales in sequential decisions has been fully discussed in (Zhao et al., 2016).

**Remark 2.** The concentration results with martingales in Lemma 1 for  $p \in (1, +\infty)$  can also be applied into regret minimization of heavy-tailed payoffs and other applications in sequential decisions. In particular, we observe that the concentration inequality of  $p = 2$  recovers that of payoffs under sub-Gaussian noises. Besides, when  $p > 2$ , the concentration results indicate constant variations with respect to  $B$ . Note that, in Lemma 1, we analyze concentration results when  $p > 2$ , which has not been analyzed in (Bubeck et al., 2013a). Compared to (Vakili et al., 2013), the concentration result in our work for TEA when  $p > 2$  enjoys a constant improvement. Since the case of  $p \in (2, +\infty)$  can be resolved by  $p = 2$ , we will focus on  $p \in (1, 2]$  in bandit algorithms for pure exploration of MAB with heavy-tailed payoffs.

## 4.2 FIXED CONFIDENCE

In this subsection, we present a bandit algorithm for pure exploration of MAB with heavy-tailed payoffs under a fixed confidence. Then, we derive upper bounds of sample complexity of the bandit algorithms.

### 4.2.1 Description of SE- $\delta$

In fixed confidence, we design our bandit algorithm for pure exploration of MAB with heavy-tailed payoffs based on the idea of SE, which is inspired by (Even-Dar et al., 2002). For SE- $\delta$ (EA), the algorithmic procedures are almost the same as that in (Even-Dar et al., 2002), which are omitted here. For SE- $\delta$ (TEA),  $\mathcal{A}$  will output an arm **Out** when  $|S_t| = 1$  with computation details shown

---

### Algorithm 1 Successive Elimination- $\delta$ (SE- $\delta$ (TEA))

---

```

1: input:  $\delta, K, p, B$ 
2: initialization:  $\hat{\mu}_1^\dagger(k) \leftarrow 0$  for any arm  $k \in [K]$ ,  $S_1 \leftarrow [K]$ , and  $b_1 \leftarrow 0$ 
3:  $t \leftarrow 1$   $\triangleright$  begin to explore arms in  $[K]$ 
4: while  $|S_t| > 1$  do
5:    $c_t \leftarrow 5B^{\frac{1}{p}} \left( \frac{\log(2K/\delta)}{t} \right)^{\frac{p-1}{p}}$   $\triangleright$  update confidence bound
6:    $b_t \leftarrow \left( \frac{Bt}{\log(2K/\delta)} \right)^{\frac{1}{p}}$   $\triangleright$  update truncating parameter
7:   for  $k \in S_t$  do
8:     play arm  $k$  and observe a payoff  $\pi_t(k)$ 
9:      $\hat{\mu}_t^\dagger(k) \leftarrow \frac{1}{t} \sum_{i=1}^t \pi_i(k) \mathbb{1}_{\{|\pi_i(k)| \leq b_i\}}$   $\triangleright$  calculate TEA
10:  end for
11:   $a_t \leftarrow \arg \max_{k \in [K]} \hat{\mu}_t^\dagger(k)$   $\triangleright$  choose the best arm at  $t$ 
12:   $S_{t+1} \leftarrow \emptyset$   $\triangleright$  create a new arm set for  $t+1$ 
13:  for  $k \in S_t$  do
14:    if  $\hat{\mu}_t^\dagger(a_t) - \hat{\mu}_t^\dagger(k) \leq 2c_t$  then
15:       $S_{t+1} \leftarrow S_{t+1} + \{k\}$   $\triangleright$  add arm  $k$  to  $S_{t+1}$ 
16:    end if
17:  end for
18:   $t \leftarrow t+1$   $\triangleright$  update time index
19: end while
20: Out  $\leftarrow S_t[0]$   $\triangleright$  assign the first entry of  $S_t$  to Out
21: return: Out

```

---

in Algorithm 1, where  $\delta$  is a given parameter. The idea is to eliminate the arm which has the farthest deviation compared with the empirical best arm in  $S_t$ .

### 4.2.2 Theoretical Guarantee of SE- $\delta$

We derive upper bounds of sample complexity of SE- $\delta$  with estimators of EA and TEA. Note that  $T$  is the time complexity of SE- $\delta$ .

**Theorem 1.** For pure exploration in MAB with  $K$  arms, with probability at least  $1 - \delta$ , Algorithm SE- $\delta$  identifies the optimal arm  $Opt$  with sample complexity as

- for SE- $\delta$ (EA)

$$T \leq \sum_{k=1}^K \left( \frac{2^{2p+1} K C}{\Delta_k^p \delta} \right)^{\frac{1}{p-1}};$$

- for SE- $\delta$ (TEA)

$$T \leq \sum_{k=1}^K \left( \frac{20B^{\frac{1}{p}}}{\Delta_k} \right)^{\frac{p}{p-1}} \log \left( \frac{2K}{\delta} \right),$$

where  $p \in (1, 2]$ .

*Proof.* We first consider EA in Eq. (2) for estimating the expected payoffs in MAB. For  $p \in (1, 2]$ , for any arm  $k \in S_t$ , we have

$$\mathbb{P}[|\hat{\mu}_t(k) - \mu(k)| \geq \delta] \leq \frac{2C}{t^{p-1} \delta^p}, \quad (13)$$

where we adopt  $s_{t,k} = t$  in SE- $\delta$ (EA). We notice the inherent characteristic of SE that, for any arm  $k \in S_t$ , we have  $\Phi(k) = \{1, 2, \dots, t\}$ .

Based on Lemma 1, for  $t = 1, 2, \dots$ , with probability at least  $1 - \delta/K$ , the following event holds

$$\mathcal{E}_t \triangleq \{k \in S_t, |\hat{\mu}_t(k) - \mu(k)| \leq c_{t_k}\},$$

where  $c_{t_k} = \left(2KC/(t_k^{p-1}\delta)\right)^{\frac{1}{p}}$  is a confidence interval. To eliminate a sub-optimal arm  $k$ , we need to play any arm  $k \in [K] \setminus \text{Opt}$  with  $t_k$  times such that

$$\hat{\Delta}_k \triangleq \hat{\mu}_{t_k}(\text{Opt}) - \hat{\mu}_{t_k}(k) \geq 2c_{t_k}. \quad (14)$$

Based on Lemma 1, with a high probability, we have

$$\hat{\Delta}_k \geq \mu(\text{Opt}) - c_{t_k} - (\mu(k) + c_{t_k}) = \Delta_k - 2c_{t_k},$$

where  $c_{t_k}$  is a confidence interval. To satisfy Eq. (14), we are ready to set

$$\Delta_k - 2c_{t_k} \geq 2c_{t_k}. \quad (15)$$

To solve the above inequality, we are ready to have that  $t_k = \left(\frac{2^{2p+1}KC}{\Delta_k^p \delta}\right)^{\frac{1}{p-1}}$  is sufficient. The total sample complexity is  $T = t_2 + \sum_{k=2}^K t_k$ , because the number of pulling the optimal arm  $t_1 = t_2$ . This implies, with probability at least  $1 - \delta$ , we have

$$T \leq \sum_{k=1}^K \left(\frac{2^{2p+1}KC}{\Delta_k^p \delta}\right)^{\frac{1}{p-1}}. \quad (16)$$

Now we consider TEA in Eq. (3) for estimating the expected payoffs in MAB. Similarly, for  $p \in (1, 2]$ , with probability at least  $1 - \delta$ , we have

$$T \leq \sum_{k=1}^K \left(\frac{20B^{\frac{1}{p}}}{\Delta_k}\right)^{\frac{p}{p-1}} \log\left(\frac{2K}{\delta}\right), \quad (17)$$

which completes the proof.  $\square$

### 4.3 FIXED BUDGET

In this subsection, we present a bandit algorithm for pure exploration of MAB with heavy-tailed payoffs under a fixed budget. Then, we derive upper bounds of probability of error for the bandit algorithms.

#### 4.3.1 Description of SR- $T$

For SR- $T$ (EA), we omit the algorithm because it is almost the same as that in (Audibert and Bubeck, 2010). For SR- $T$ (TEA), we design a bandit algorithm for pure exploration of MAB with heavy-tailed payoffs based on the idea of SR, with computation details shown in Algorithm 2, where  $T$  is a given parameter. The high-level

---

#### Algorithm 2 Successive Rejects- $T$ (SR- $T$ (TEA))

---

```

1: input  $T, K, p, B, \underline{\Delta} > 0$ 
2: initialization:  $\hat{\mu}^\dagger(k) \leftarrow 0$  for any arm  $k \in [K]$ ,  $S_1 \leftarrow [K]$ ,  $n_0 \leftarrow 0$ ,  $b \leftarrow 0$  and  $\bar{K} \leftarrow \sum_{i=1}^K \frac{1}{i}$ 
3:  $b \leftarrow \left(\frac{3Bp}{\underline{\Delta}}\right)^{\frac{1}{p-1}}$   $\triangleright$  calculate truncating parameter
4: for  $k \in S_1$  do
5:    $\Phi(k) \leftarrow \emptyset$   $\triangleright$  construct sets to store time index
6: end for
7: for  $k \in [K-1]$  do
8:    $n_k \leftarrow \lceil \frac{T-K}{K(K+1-k)} \rceil$   $\triangleright$  calculate  $n_k$  at stage  $k$ 
9:    $n \leftarrow n_k - n_{k-1}$   $\triangleright$  calculate the number of times to pull arms
10:  for  $y \in S_k$  do
11:    for  $i \in [n]$  do
12:       $t \leftarrow t + 1$ 
13:      play arm  $y$ , and observe a payoff  $\pi_t(y)$ 
14:       $\Phi(y) \leftarrow \Phi(y) + \{t\}$   $\triangleright$  store time index for arm  $y$ 
15:    end for
16:     $\hat{\mu}_k^\dagger(y) \leftarrow \frac{1}{|\Phi(y)|} \sum_{i \in \Phi(y)} \pi_i(y) \mathbb{1}_{|\pi_i(y)| \leq b}$ 
17:  end for
18:   $a_k \leftarrow \arg \min_{y \in S_k} \hat{\mu}_k^\dagger(y)$   $\triangleright$  choose the worst arm at  $k$ 
19:   $S_{k+1} \leftarrow S_k - \{a_k\}$   $\triangleright$  successively reject arm  $a_k$ 
20: end for
21:  $\text{Out} \leftarrow S_K[0]$   $\triangleright$  assign the first entry of  $S_K$  to  $\text{Out}$ 
22: return:  $\text{Out}$ 

```

---

idea is to conduct non-uniform pulling of arms by  $K-1$  phases, and SR- $T$  rejects a worst empirical arm for each phase. The reject operation is based on EA or TEA, and we distinguish the two cases by SR- $T$ (EA) and SR- $T$ (TEA).

For simplicity, we show SR- $T$ (TEA) in Algorithm 2, where  $\underline{\Delta} > 0$  is a design parameter for the estimator of TEA. The design parameter  $\underline{\Delta}$  helps to calculate the truncating parameter  $b$  in SR- $T$ (TEA). Usually, we set  $\underline{\Delta} \leq \Delta_k$  for any  $k \in [K]$ .

#### 4.3.2 Theoretical Guarantee of SR- $T$

We derive upper bounds of probability of error for SR- $T$  with estimators of EA and TEA. We have the following theorem for SR- $T$ .

**Theorem 2.** *For pure exploration in MAB with  $K$  arms, if Algorithm SR- $T$  is run with a fixed budget  $T$ , we have probability of error for  $p \in (1, 2]$  as*

- for SR- $T$ (EA)

$$\mathbb{P}[\text{Out} \neq \text{Opt}] \leq 2^{p+1}CK(K-1)H_2^p \left(\frac{\bar{K}}{T-K}\right)^{p-1};$$

- for SR- $T$ (TEA)

$$\mathbb{P}[\text{Out} \neq \text{Opt}] \leq 2K(K-1) \exp\left(-\frac{(T-K)\bar{B}_1}{\bar{K}K\underline{\Delta}^{p/(1-p)}}\right),$$

$$\text{where } \bar{B}_1 = \frac{p-1}{4(2^p 3Bp^p)^{\frac{1}{p-1}}}.$$

*Proof.* We first consider EA in Eq. (2) for estimating the expected payoffs in MAB. For  $p \in (1, 2]$ , we have

$$\begin{aligned} \mathbb{P}[\text{Out} \neq \text{Opt}] &\leq \sum_{k=1}^{K-1} \sum_{i=K+1-k}^K \mathbb{P}[\hat{\mu}_k(\text{Opt}) \leq \hat{\mu}_k(i)] \\ &\leq \sum_{k=1}^{K-1} \sum_{i=K+1-k}^K \mathbb{P}[\hat{\mu}_k(i) - \mu(i) + \mu(\text{Opt}) - \hat{\mu}_k(\text{Opt}) \geq \Delta_i] \\ &\leq \sum_{k=1}^{K-1} \sum_{i=K+1-k}^K \frac{4C}{n_i^{p-1} \left(\frac{\Delta_i}{2}\right)^p} \\ &\leq \sum_{k=1}^{K-1} \frac{2^{p+2} C_k}{n_k^{p-1} \Delta_{K+1-k}^p}, \end{aligned} \quad (18)$$

where the inequality of Eq. (18) is due to the results in Lemma 1 by setting  $s_{t,k} = n_k$ . Besides, we notice that

$$n_k^{p-1} \Delta_{K+1-k}^p \geq \frac{1}{H_2^p} \left( \frac{T-K}{\bar{K}} \right)^{p-1},$$

which implies that

$$\mathbb{P}[\text{Out} \neq \text{Opt}] \leq 2^{p+1} C K (K-1) H_2^p \left( \frac{\bar{K}}{T-K} \right)^{p-1}.$$

Now we consider TEA in Eq. (3) for estimating the expected payoffs in MAB. By considering the design of  $b$  in SR- $T$ (TEA), we have a similar result of Lemma 1. Then, for  $p \in (1, 2]$ , we have probability of error as

$$\begin{aligned} \mathbb{P}[\text{Out} \neq \text{Opt}] &\leq \sum_{k=1}^{K-1} \sum_{i=K+1-k}^K \mathbb{P}[\hat{\mu}_k^\dagger(\text{Opt}) \leq \hat{\mu}_k^\dagger(i)] \\ &\leq \sum_{k=1}^{K-1} \sum_{i=K+1-k}^K \mathbb{P}[\hat{\mu}_k^\dagger(i) - \mu(i) + \mu(\text{Opt}) - \hat{\mu}_k^\dagger(\text{Opt}) \geq \Delta] \\ &\leq 2K(K-1) \exp\left(-\frac{(T-K)\bar{B}_1}{\bar{K} K \underline{\Delta}^{p/(1-p)}}\right), \end{aligned} \quad (20)$$

which completes the proof.  $\square$

## 5 EXPERIMENTS

In this section, we conduct experiments via synthetic and real-world data to evaluate the performance of the proposed bandit algorithms. We run experiments in a personal computer with Intel CPU@3.70GHz and 16GB memory. For the setting of fixed confidence, we compare the sample complexities of SE- $\delta$ (EA) and SE- $\delta$ (TEA). For the setting of fixed budget, we compare the error probabilities of SR- $T$ (EA) and SR- $T$ (TEA).

### 5.1 SYNTHETIC DATA AND RESULTS

For verifications, we adopt two synthetic data (named as S1-S2) in the experiments, of which statistics are shown in Table 2. The data are generated from *Student's t-distribution* with 3 degrees of freedom. In experiments, we run multiple epochs for each dataset, with each epoch containing ten independent experiments for

Table 2: Statistics of used synthetic data.

dataset	#arms	$\{\mu(k)\}$	heavy-tailed $\{p, B, C\}$
S1	10	one arm is 2.0 and nine arms are over [0.7, 1.5] with a uniform gap	{2, 7, 3}
S2	10	one arm is 2.0 and nine arms are over [1.0, 1.8] with a uniform gap	{2, 7, 3}

Figure 1: Sample complexity for SE- $\delta$  in pure exploration of MAB with heavy-tailed payoffs.

Figure 2: Probability of error for SR- $T$  in pure exploration of MAB with heavy-tailed payoffs.

best arm identification of MAB. Besides, we set the value of fixed confidence from 0.005 to 0.040 with a uniform gap of 0.005. We set the value of fixed budget from 400 to 1100 with a uniform gap of 100.

We show experimental results in Figures 1 and 2, where both proposed algorithms are effective for pure exploration of MAB with heavy-tailed payoffs. In particular, in fixed-confidence setting, sample complexity decreases with increasing value of  $\delta$ . In fixed-budget setting, probability of error converges to zero with increasing value of  $T$ . Besides, for fixed-confidence setting, SE- $\delta$ (TEA) beats SE- $\delta$ (EA) in both datasets with small  $\delta$  due to a better control of confidence interval. The experimental results also reflect that the concentration properties of EA are much weaker than those of TEA. For fixed-budget setting, SR- $T$ (TEA) is comparable to SR- $T$ (EA) due to the selection of truncating parameter.

### 5.2 FINANCIAL DATA AND RESULTS

It has been pointed out that financial data show the inherent characteristic of heavy tails (Panahi, 2016). We choose a financial application of identifying the most profitable cryptocurrency in a given pool of digital cur-

rencies. The identification for the most profitable cryptocurrency among the top ten cryptocurrency in terms of market value is motivated by the practical scenario that an investor would like to invest a fixed budget of money in a cryptocurrency and get return as much as possible.

For experiments, we get hourly price data of the ten selected cryptocurrencies<sup>1</sup>, and show the statistics of real data in Table 3. In the table, we conduct a statistical analysis in hindsight with hourly returns of cryptocurrency from February 3rd, 2018 to April 27th, 2018. From the table, we find that the optimal option in hindsight is EOS in terms of the maximal empirical mean of hourly payoffs. Besides, we conduct Kolmogrov-Smirnov (KS) test to fit real data of a cryptocurrency to a distribution. In particular, via KS test, we know that the null hypothesis of real data following a Gaussian distribution is rejected, because  $\bar{p}$ -value is smaller than a significant level of 0.05. We observe that real data of cryptocurrency are likely to follow a *Student’s t-distribution* via KS test in Table 3.

<sup>1</sup><https://www.cryptocompare.com/>

Figure 3: Pure exploration of cryptocurrency.

With the above statistical analyses, we can fit real data of cryptocurrency to a *Student’s t-distribution*, and obtain distribution parameters shown in Table 4. Based on the property of *Student’s t-distribution*, we can set  $p = 2$ , and estimate  $B$  and  $C$  as shown in the table.

Via a similar setting to that of synthetic data, we show the results on pure exploration of top ten cryptocurrencies in Figure 3. Note that, due to limitation of data points in the setting of fixed confidence, we generate payoffs from *Student’s t-distributions* fitting to real data. But in the setting of fixed budget, we adopt exactly real financial data. We have similar observations as those in synthetic data. It is worth mentioning that, TEA algorithm outperforms EA algorithm in fixed-confidence setting when the value of  $\delta$  is small. Besides, TEA is comparable to EA in fixed-budget setting because the truncating parameter in Algorithm 2 only has budget information and does not increase with the number of samples. Overall, with synthetic and real-world data, we have verified the effectiveness of our two algorithms.

## 6 CONCLUSION

In this paper, we broke the assumption of payoffs under sub-Gaussian noises in pure exploration of MAB, and investigated best arm identification of MAB with a general assumption that the  $p$ -th moments of stochastic payoffs are bounded, where  $p \in (1, +\infty)$ . We have technically analyzed tail probabilities of empirical average and truncated empirical average for estimating expected payoffs in sequential decisions. Besides, we proposed two bandit algorithms for pure exploration of MAB with heavy-tailed payoffs based on SE and SR. Finally, we derived theoretical guarantees of the proposed bandit algorithms, and demonstrated the effectiveness of bandit algorithms in pure exploration of MAB with heavy-tailed payoffs.

## Abstract

Predictive models can fail to generalize from training to deployment environments because of dataset shift, posing a threat to model reliability in practice. As opposed to previous methods which use samples from the target distribution to reactively correct dataset shift, we propose using graphical knowledge of the causal mechanisms relating variables in a prediction problem to proactively remove variables that participate in spurious associations with the prediction target, allowing models to generalize across datasets. To accomplish this, we augment the causal graph with latent counterfactual variables that account for the underlying causal mechanisms, and show how we can estimate these variables. In our experiments we demonstrate that models using good estimates of the latent variables instead of the observed variables transfer better from training to target domains with minimal accuracy loss in the training domain.

## 1 INTRODUCTION

Supervised machine learning is concerned with predicting a target output label  $T$  from input features  $\mathbf{X}$ . Classical learning frameworks assume that training and test data are independently and identically distributed from a fixed distribution  $p(\mathbf{X}, T)$ . When this assumption does not hold, training with classical frameworks can yield models with unreliable and, in the case of safety-critical applications like medicine, dangerous predictions (Dyagilev and Saria, 2015; Caruana et al., 2015; Schulam and Saria, 2017). For example, prediction systems are often deployed in dynamic environments that systematically differ from the one in which the historical training data was collected—a problem known as *dataset shift* which results in poor

generalization. Methods for addressing dataset shift are typically reactive: they use unlabeled data from the target deployment environment during the learning process (see Quionero-Candela et al. (2009) for an overview). However, when the differences in environments are unknown prior to model deployment (e.g., no available data from the target environment or target environments that have not yet been conceived), it is important to understand what aspects of the prediction problem can change and how we can train models that will be robust to these changes. We consider this problem of *proactively addressing dataset shift* in this work.

In particular, we will guard against *spurious associations* between predictors and the target—non-causal marginal relationships that often do not generalize due to shifts in training and test distributions. To illustrate, consider an example prediction problem of medical screening. The features ( $\mathbf{X}$ ) are blood pressure (BP)  $Y$  and congestive heart failure  $C$ . The label we want to predict is whether or not a patient has meningitis  $T$ . Underlying every prediction problem is a directed acyclic graph (DAG), such as the one in Figure 1a, which describes the *causal mechanisms* (general directional knowledge of causes and effects, e.g.,  $C \rightarrow Y$ : heart failure causes low BP) between the variables that hold in all environments. In this graph,  $T$  and  $C$  are not *causally related* to each other:  $C$  is neither a causal ancestor nor a causal descendant of  $T$ . By *d*-separation (Koller and Friedman, 2009), unless we condition on  $Y$ , the two are statistically independent:  $T \perp\!\!\!\perp C$ . However, *selection bias* (Figure 1b) or domain-dependent *confounding by indication* (Figure 1c) can introduce a spurious association:  $T \not\perp\!\!\!\perp C$ . We now define these cases of dataset shift and show how they threaten model reliability.

Selection bias occurs when certain subpopulations (with respect to  $T$  and  $C$ ) are underrepresented in the training data ( $S=1$ ) which can result in inaccurate predictions in the deployment population. For example, suppose patients with heart failure but without meningitis ( $C = 1, T = 0$ ) are underrepresented because they rarely

Figure 1: (a) The DAG capturing causal mechanisms for the medical screening example. The features are blood pressure  $Y$  and heart failure  $C$ . The target label  $T$  is meningitis. (b) Selection bias  $S$  is included. (c) Domain-dependent confounding is shown.  $C$  represents narcotics and  $D$  a latent risk factor, brain surgery. Shaded nodes denote observed variables.

visit this hospital since they manage their chronic condition using a high quality local chronic care clinic. This results in a spurious positive association between  $T$  and  $C$ , with the strength of the association depending on the degree of selection bias. Further, the distribution  $p(T|\mathbf{X})$  (i.e.,  $p(T|C, Y)$  in our example) in the deployment population can differ from the distribution in the training population  $p(T|C, Y, S = 1)$ . For the case of the under-represented ( $C = 1, T = 0$ ) subpopulation, the screening model will be poorly calibrated and overestimate the risk of meningitis in patients with the chronic condition (i.e.,  $p(T = 1|C = 1, Y)$  predictions will be too high). These systematic errors on a subpopulation pose a threat to model reliability.

Domain-dependent confounding, shown in Figure 1c, also threatens model reliability. Suppose  $C$  were instead an indicator for narcotic pain medications which lower BP. Doctors sometimes prescribe narcotics after brain surgery ( $D$  in Figure 1c), a risk factor for meningitis that may not be recorded in the data. The policy  $p(C|D)$  doctors use to prescribe narcotics varies between domains (i.e., doctors and hospitals) which also causes  $p(T|Y, C)$  to vary. For example, one hospital may freely prescribe narcotics (resulting in a positive association between  $T$  and  $C$ ) while another hospital may carefully restrict the number of painkiller prescriptions. A model trained on data from the first hospital will overestimate the risk of meningitis in patients treated with narcotics at the second hospital. However, when confounders are observed and differences in policies are known beforehand, adjustments can be made by discounting the policies during learning (e.g., Swaminathan and Joachims (2015); Schulam and Saria (2017)). Otherwise, instead of learning to predict using a domain-specific association between the target and the treatment that will not generalize, we can remove the treatment information from the model or, as we propose, retain relevant information by accounting for the effects of the medication.

In both cases of dataset shift, due to either the *collider*  $S$  (Figure 1b) or the confounder  $D$  (Figure 1c), the graphs contain the spurious marginal association  $T \not\perp C$  that does not generalize across datasets. When we do not have data from the target distribution or the differences in policies across domains are unknown, we propose modifying the graph to contain latent *counterfactual* variables which, when estimated, allow us to remove the variables that participate in spurious associations with  $T$  (such as  $C$  in Figure 1) from the problem. Specifically, if we somehow knew an adjusted value of  $Y$ , denoted  $Y(C = \emptyset)$ —the value of  $Y$  for which the effects of  $C$  were removed (e.g., the blood pressure had the patient not had heart failure or not been given narcotics)—then  $C$  would no longer be causally relevant for predicting  $T$ . This concept is inspired by *potential outcomes* (Neyman, 1923; Rubin, 1974) in causal inference. However, we do not need to assume full knowledge of the causal DAG (which also includes latent factors and intermediate variables), required for the assumptions of causal inference methods. Instead, we only use knowledge of the causal mechanisms between the variables in a prediction problem.

In this paper we make the following contributions. First, we identify variables in a DAG capturing causal mechanisms which make a statistical model *vulnerable* to learning spurious associations that do not generalize across datasets. Second, we define a *node-splitting* operation which modifies the DAG to contain interpretable latent counterfactual variables which render the vulnerable variables irrelevant in the prediction problem. Third, we provide conditions for estimating the latent variables as adjustments of observed features. Fourth, we explain how the proposed method can make a classification problem measurably simpler due to reduced variance of the latent features. On simulated data we evaluate the quality of model predictions when the accuracy of the latent variable estimates changes. Then, on a real world medical classification task, we demonstrate that the proposed method allows us to remove vulnerable variables while preserving relevant information.

## 2 RELATED WORK

**Spurious Associations:** Predictive modeling methods for accounting for spurious associations in data typically require representative unlabeled samples from the test distribution. For example, the classic selection bias paradigm is to detect and correct bias in the training distribution by using unlabeled test samples to estimate the probability of selection in the training data so the training examples can be discounted during learning (see e.g., Heckman (1977); Zadrozny (2004); Huang et al. (2007); Storkey (2009)).

Beyond predictive modeling, previous work has consid-

ered estimation of causal models in the presence of selection bias and confounding. For example, Spirtes et al. (1995) learn the structure of the causal DAG from data affected by selection bias. Others have studied methods and conditions for *identification* of causal effects under spurious associations due to selection bias and confounding (e.g., Bareinboim and Pearl (2012); Bareinboim and Tian (2015); Correa et al. (2018)). Most relevantly, Correa and Bareinboim (2017) determine conditions under which interventional distributions are identified without using external data. Our work is concerned with statistical prediction under selection bias or domain-dependent confounding without external data.

**Transportability:** The goal of an experiment is for the findings to generalize beyond a single study, a concept known as *external validity* (Campbell and Stanley, 1963). Similarly, in causal inference *transportability*, formalized in Pearl and Bareinboim (2011), transfers causal effect estimates from one environment to another. Bareinboim and Pearl (2013) further generalize this to transfer causal knowledge from multiple source domains to a single target domain. Like these works, we assume the structure of the causal mechanism DAG is the same in the source and any relevant target domains. However, rather than transfer causal estimates from source to target, the proposed method learns a single statistical model whose predictions should perform well on the source domain while also generalizing well to new domains.

**Graphical Representations of Counterfactuals:** The node-splitting operation we introduce in Section 3.2.2 is similar to the node-splitting operation in Single World Intervention Graphs (SWIGs) (Richardson and Robins, 2013). However, intervening in a SWIG results in a causal generative graph for a potential outcome with the factual outcome removed from the graph. By contrast, the node-splitting operation of the proposed method results in a modified causal generative graph of the factual outcomes, with new intermediate counterfactual variables. Other graphical representations such as twin networks (Pearl, 2009) and counterfactual graphs (Shpitser and Pearl, 2007) simultaneously represent factual and counterfactual outcomes, rather than the intermediate counterfactuals exploited in this work.

### 3 METHODS

Counterfactual Normalization consists of three steps: identification of variables that are vulnerable to participating in spurious associations with the target that do not generalize across datasets, a node-splitting operation to place latent counterfactual variables onto the causal DAG such that they  $d$ -separate the target from the vulnerable variables, and estimation of the relevant latent variables.

We will first review necessary background about potential outcomes and structural equation models before introducing the method.

#### 3.1 BACKGROUND

##### 3.1.1 Potential Outcomes

The proposed method involves the estimation of counterfactuals, which can be formalized using the Neyman-Rubin potential outcomes framework (Neyman, 1923; Rubin, 1974). For outcome variable  $Y$  and intervention  $A$ , we denote the potential outcome by  $Y(a)$ : the value  $Y$  would have if  $A$  were observed to be  $a$ .

In general, the distributions  $p(Y(a))$  and  $p(Y|A = a)$  are not equal. For this reason, estimation of the distribution of the potential outcomes relies on two assumptions:

**Consistency:** The distribution of the potential outcome under the observed intervention is the same as the distribution of the observed outcome. This implies  $p(Y(a)|A = a) = p(Y|A = a)$ .

**Conditional Ignorability:**  $Y(a) \perp\!\!\!\perp A|X, \forall a \in A$ . There are no unobserved confounders. This implies  $p(Y(a)|X, A = a') = p(Y(a)|X, A = a)$ .

##### 3.1.2 Counterfactuals and SEMs

Shpitser and Pearl (2008) develop a causal hierarchy consisting of three layers of increasing complexity: association, intervention, and counterfactual. Many works in causal inference are concerned with estimating average treatment effects—a task at the intervention layer because it uses information about the interventional distribution  $p(Y(a)|X)$ . In contrast, the proposed method requires counterfactual queries which use the distribution  $p(Y(a)|Y, a', X)$  s.t.  $a \neq a'$ <sup>1</sup>. That is, given that we observed an individual’s outcome to be  $Y$  under intervention  $a'$ , what would the distribution of their outcome have been under a different intervention  $a$ ?

In addition to the assumptions for estimating potential outcomes, computing counterfactual queries requires functional or structural knowledge (Pearl, 2009). We can represent this knowledge using causal structural equation models (SEMs). These models assume variables  $X_i$  are functions of their immediate parents in the generative causal DAG and exogenous noise  $u_i$ :  $X_i = f_i(pa(X_i), u_i)$ . Reasoning counterfactually at the level of an individual unit requires assumptions on the form of the functions  $f_i$  and independence of the  $u_i$ , because typically we are inter-

<sup>1</sup>The distinction is that  $p(Y(a)|X)$  reasons about the effects of causes while  $p(Y(a)|Y, a', X)$  reasons about the causes of effects (see, e.g., Pearl (2015)).

Figure 2: (a) The DAG of causal mechanisms for the medical screening example. (b) The modified DAG after node-splitting yielding the latent signal value under no different treatment  $Y(a)$ . (c) The modified DAG after node-splitting yielding the latent signal value under no treatment and no chronic condition  $Y(a, c)$ .

ested in reasoning about interventions in which the exogenous noise variables remain fixed. We build on this to estimate the latent counterfactual variables.

### 3.2 COUNTERFACTUAL NORMALIZATION

Counterfactual Normalization uses a DAG,  $\mathcal{G}$ , that leverages any prior knowledge of the causal mechanisms relating variables in a prediction problem with target variable  $T$ , assumed to be binary for the purposes of explanation. We further assume that the predictors form a Markov blanket<sup>2</sup> of  $T$  in  $\mathcal{G}$ . To sketch the method, recall that in the example in Figure 1a we identified that  $C$  is vulnerable to participating in a spurious association with  $T$ . To retain generalizable information about  $C$  we will estimate  $Y(C = \emptyset)$ , the counterfactual blood pressure if a patient did not have heart failure or did not receive narcotics. Instead of predicting  $T$  by modeling  $p(T|Y, C)$  which likely will not generalize, we will instead model  $p(T|Y(\emptyset))$  which notably does not contain  $C$  as a feature. To explain the method’s steps in complete detail, we will consider an expanded version of the meningitis example. In Figure 2a we have added a variable  $A$  to represent medications given to the patient, and a variable  $X$  to represent demographic factors (e.g., age).

#### 3.2.1 Identification of Vulnerable Variables

Spurious associations are marginal non-causal associations with  $T$  in the training data. Since we are using the Markov blanket of  $T$  for prediction, a variable  $v \in \mathcal{G}$  makes a model *vulnerable* to learning a spurious association if it is neither an ancestor nor a descendant of the target variable  $T$  while being a member of the Markov

<sup>2</sup>The Markov blanket of a target variable is a set of variables such that, conditioned on the set, the target is independent of all other variables not in the set (Koller and Friedman, 2009). Graphically, these are the target’s parents, children, and other parents of its children.

---

#### Algorithm 1: Node-splitting Operation

---

**Input:** Graph  $\mathcal{G}$ , child of target node  $Y$ , observed parents of  $Y$  to intervene upon  $\mathbf{P}$

**Output:** Modified graph  $\mathcal{G}^*$

1. Insert counterfactual node  $Y(\mathbf{P} = \emptyset)$
  2. Delete edges  $\{x \rightarrow Y : x \in pa(Y) \setminus \mathbf{P}\}$
  3. Insert edges  $\{x \rightarrow Y(\mathbf{P} = \emptyset) : x \in pa(Y) \setminus \mathbf{P}\}$
  4. Insert edge  $Y(\mathbf{P} = \emptyset) \rightarrow Y$
- 

blanket of  $T$ . Thus, vulnerable variables are parents of children of  $T$  that are non-causally associated with the target variable.

In Figure 2(a), the vulnerable variables are  $C$  and  $A$  because they are parents of  $Y$  (a child of  $T$ ) without being descendants or ancestors of  $T$ .

#### 3.2.2 Node-Splitting

To remove vulnerable variables from the Markov blanket of  $T$  we need to create a modified graph  $\mathcal{G}^*$  by adding latent nodes to  $\mathcal{G}$  such that the new nodes and the existing non-vulnerable nodes  $d$ -separate the vulnerable variables from  $T$ . We term the process (shown in Algorithm 1) of generating  $\mathcal{G}^*$  node-splitting.

Consider intervening on treatment ( $A$ ) in Figure 2a. We assume variables are interventionally set to a “null” value (e.g.,  $A = \emptyset$  representing the absence of treatment or  $C = \emptyset$  representing the absence of the chronic condition).  $A$  is a vulnerable variable because it is not causally associated with  $T$  and it is a parent of a child of  $T$ , namely blood pressure ( $Y$ ). The structural equation of blood pressure is  $Y = f_y(T, X, C, A, u_y)$ . Intervening on  $A$  results in the latent variable  $Y(\emptyset) = f_y(T, X, C, A = \emptyset, u_y)$  representing the untreated blood pressure value. Unlike traditional SEM interventions, we retain the factual version of the variables we intervene on in the graph. We visualize this in Figure 2b by placing the resulting latent outcome variable  $Y(a)$  onto the causal graph as a parent of its factual version  $Y$ . The latent version subsumes the parents (in the original graph  $\mathcal{G}$ ) of its factual version that were not intervened upon (e.g.,  $X$  and  $C$ ). Thus, the new latent variable represents the value before the observed effects of the interventional variables occurred. We further assume that the factual outcome can be recovered as some invertible function of the counterfactual outcome and the observed value of the parent, subject to the same values of the exogenous noise variables:  $Y = g_y(Y(\emptyset), A, u_y)$ . As a result, the new graph  $\mathcal{G}^*$  is still a model of the observed data generating process.

The node-splitting operation naturally extends to simultaneous interventions on multiple variables. Figure 2c

shows the modified DAG when  $A$  and  $C$  are simultaneously intervened upon. Importantly, because we intervened on all vulnerable variables, this graph yields the conditional independence:  $T \perp\!\!\!\perp Y, A, C | Y (A = \emptyset, C = \emptyset), X$  in which the vulnerable variables  $A$  and  $C$  are now irrelevant for predicting  $T$  conditioned on the new Markov blanket which contains the latent variable. Thus, to  $d$ -separate the target from the vulnerable variables  $\mathbf{V}$ , we need to compute the latent versions of the shared children of  $T$  and  $\mathbf{V}$  in which we intervene and set  $\mathbf{V} = \emptyset$ .

### 3.2.3 Estimating Latent Variables

Under what conditions can we estimate the latent variables so that we  $d$ -separate the vulnerable variables from the target? First, we need adjusted versions of the assumptions required to estimate the distributions of potential outcomes, namely the previously mentioned conditional ignorability assumption. We assume we can accurately fit SEMs with respect to the available features in  $\mathcal{G}$ . In addition to no unobserved confounders, we also ideally have no unobserved exogenous variables. Enumerating more parents of a variable in its SEM allows us to better fit the equation and reduce the influence of  $u_i$ , the exogenous noise. Additionally, there are structural requirements for the models used to estimate the latent variables because of the underlying prediction problem, which results in an unobserved target variable for test units.

**No Interaction with the Target:** *In the structural equations, the effects of vulnerable variables  $\mathbf{V}$  on children  $Y$  shared with the  $T$  cannot depend on  $T$ .* If this were not the case, then estimating the latent outcome would require knowing the value of  $T$ , defeating the purpose of the prediction problem.

To compute the hypothetical latent variables, we first pick arbitrary forms for the generative structural equations of the children of  $T$  satisfying the invertibility and no interaction requirements and fit them to the factual outcomes data (e.g., using maximum likelihood estimation). Then, we can compute the latent outcome values by performing the interventions on the fitted structural equations. In our experiments in Section 5 we demonstrate how to do this for additive structural equations.

### 3.2.4 Non-Vulnerable Interventions

As we will explain in Section 4, the proposed method can result in a measurably simpler classification problem when the target is binary by decreasing variance in the children of  $T$  due to removing the effects of the vulnerable variables. A natural question is: are we limited to intervening only on the vulnerable variables?

We can intervene on any parent of a child of  $T$  (except

Figure 3: The modified DAG after intervening on  $C$ ,  $A$ , and  $X$ .

for  $T$  itself). However, unless the parent is a vulnerable variable, the parent will still be relevant for predicting  $T$ . This is because we cannot change the value of a parent of  $T$  in the structural equation for  $T$ , because in evaluation data  $T$  is unobserved. In the meningitis example of Figure 2, suppose we intervene on  $X$  (a parent of  $T$  and a parent of a child of  $T$ ) in addition to  $C$  and  $A$ . The resulting DAG after node-splitting is shown in Figure 3. Note that the only parent of  $Y(a, c, x)$  is  $T$  since it is the only parent of  $Y$  in the original DAG that is not intervened upon. Since the edge  $X \rightarrow T$  remains unchanged by the node-splitting operation,  $X$  is still a member of the Markov blanket of  $T$ . Thus, we would predict  $T$  using  $p(T|Y(\emptyset, \emptyset, \emptyset), X)$ . While not pictured, we can also intervene on children of  $T$  that are parents of other children of  $T$ . For example, if we added a variable  $Z$  to Figure 2a with edges  $T \rightarrow Z \rightarrow Y$ , we could intervene on  $Z$ . We would not, however, be able to remove  $Z$  from the Markov blanket of  $T$  because the edge  $T \rightarrow Z$  remains.

Even though these variables remain relevant for predicting  $T$  after intervening on them, there are still potential benefits to removing their effects on the children of  $T$  because it can measurably lower variance in these variables as we now discuss.

## 4 COMPLEXITY METRICS

Beyond guarding against vulnerabilities, what are other benefits of the proposed method? For binary prediction problems, the geometric complexity (on the basis of euclidean distance) of the class boundary of a dataset can decrease when using the latent variables instead of the factual outcome and vulnerable variables. This is similar to the work of Alaa and van der Schaar (2017) who use the smoothness of the treated and untreated response surfaces to quantify the difficulty of a causal inference problem. To measure classifier-independent geometric complexity we will use two types of metrics developed by Ho and Basu (2000, 2002): measures of overlap of individual features and measures of separability of classes.

For measuring feature overlap, we use the maximum

Fisher’s discriminant ratio of the features. For a single feature, this measures the spread of the means for each class ( $\mu_1$  and  $\mu_2$ ) relative to their variances ( $\sigma_1^2$  and  $\sigma_2^2$ ):  $\frac{(\mu_1 - \mu_2)^2}{\sigma_1^2 + \sigma_2^2}$ . Since the proposed method uses latent variables in which we have adjusted for the effects of the vulnerable variables (and any other variables we intervene on), this also removes sources of variance in the outcome. Thus, we expect the variances of each class to reduce resulting in increased feature separability and a corresponding increased Fisher’s discriminant ratio.

One measure of separability of classes is based off of a test (Friedman and Rafsky, 1979) for determining if two samples are from the same distribution. First, compute a minimum spanning tree (MST) that connects all the data points regardless of class. Then, the proportion of nodes which are connected to nodes of a different class is an approximate measure of the proportion of examples on the class boundary. Higher values of this proportion generally indicate a more complex boundary, and thus a more difficult classification problem.

However, this metric is only sensitive to which class neighbors are closer, and not the relative magnitudes of intra-class and interclass distances. Another measure of class separability is the ratio between the average intraclass nearest neighbor distance and the average interclass nearest neighbor distance. This measures the relative magnitudes of the dispersion within classes and the gap between classes. While we do not necessarily expect Counterfactual Normalization to increase the gap between classes, we do expect intraclass distances to decrease because the data units are transformed to have the same value of the vulnerable variables, reducing sources of variance (e.g., less variance in counterfactual untreated BP than in factual BP). While the MST metric may not decrease, we expect the intraclass-interclass distance ratio to decrease.

We can now state more specifically the benefits of the proposed method. Based on the assumptions in Section 3, we know that the vulnerable variables are not causally related to the target variable and that their effects on the outcome variables are not dependent on the target variable. These variables add variance to the prediction problem and, given that we can account for their effects on the children of  $T$ , are irrelevant to it. Thus, the proposed method can directly increase the signal-to-noise ratio of the classification problem. With respect to the geometric complexity of the class boundary, this manifests itself through reductions in the variance within a class, as we will demonstrate in our simulated experiments.

Table 1: Simulated Experiment Results

CFN	0.96	0.96
CFN (vuln)	0.97	0.95

## 5 EXPERIMENTS

The proposed method allows us to learn accurate prediction models that generalize across datasets. We first consider simulated experiments in which we know the true counterfactual outcomes to illustrate how the quality of predictions depends on the accuracy of the counterfactual estimates. Then we apply the method to a real medical classification task and demonstrate how we can use the proposed method to train a model that does not rely on vulnerable variables while retaining relevant information. In all experiments we train models using only source data and evaluate on test data from both the the source and target domains.

### 5.1 SIMULATED EXPERIMENTS

#### 5.1.1 Cross Hospital Transfer

We consider a simulated version of the medical screening problem in Figure 2(a), but remove  $X$  from the graph. We let  $A$  represent the time since treatment and simulate the exponentially decaying effects of the treatment as  $f(A) = 2 \exp(-0.08A)$  where the treatment policy depends on  $C$ . In this example,  $C$  and  $A$  are vulnerable variables.

We simulate data for patients from two hospitals. In the source hospital, we directly introduce a spurious association between  $C$  and  $T$ , which leads to an association between  $A$  and  $T$ . At this hospital shorter times since treatment are correlated with having the target condition. For this hospital the data are generated as follows:

$$\begin{aligned}
 T &\sim \text{Bernoulli}(0.4) \\
 C|T = 1 &\sim \text{Bernoulli}(0.8) \\
 C|T = 0 &\sim \text{Bernoulli}(0.3) \\
 A|C = 1 &\sim 24 * \text{Beta}(0.5, 2.1) \\
 A|C = 0 &\sim 24 * \text{Beta}(0.7, 0.2) \\
 Y &\sim \mathcal{N}(-0.5T + -0.3C + f(A), 0.2^2) \\
 f(A) &= 2 \exp(-0.08A)
 \end{aligned}$$

We remove the spurious correlation between  $T$  and  $C$  in the target hospital:  $p(C = 1|T) = p(C = 1) = 0.75$ . We also change the after-treatment measurement policy parameters to 1.7 and 1.1 such that  $p(A|C) = p(A)$ .

We assume that the  $T$  and  $C$  coefficients (in the struc-

Table 2: Simulated Classification Complexity Metrics

Method	Fisher's	Distance	MST
Baseline (vuln)	0.86	0.11	0.54
CFN	3.51	0.02	0.19

tural equation for  $Y$ ), the treatment response amplitude and timescale parameters, and noise scale parameter are unknown and need to be learned through maximum likelihood estimation, optimized using BFGS (Chong and Zak, 2013). We generate 800 patients from the source hospital, using 600 to learn the parameters and holding out 200 to evaluate performance on the source hospital. We evaluate cross hospital transfer on 600 patients generated from the second hospital.

As we identified in Section 2, the target latent variable is  $Y(A = \emptyset, C = \emptyset)$ : the patient’s blood pressure value if they had not been treated and did not have heart failure. Once the model parameters are learned, computing the latent variable is straightforward due to the additive structural equation of  $Y$ :  $Y_i(A = \emptyset, C = \emptyset) = Y_i - \hat{\beta}C_i - \hat{f}(s_i)^3$  which can be computed for every individual  $i$  at both hospitals without observing  $T$ . We consider counterfactual (CFN)  $p(T|Y(\emptyset, \emptyset))$  and baseline factual models  $p(T|Y)$  and corresponding versions with the vulnerable variables ( $p(T|Y(\emptyset, \emptyset), A, C)$  and  $p(T|Y, A, C)$ ) using logistic regression and measure predictive accuracy with the area under the Receiver Operating Characteristic curve (AUROC).

The results of evaluation on the patients from the source and target are shown in Table 1. The accuracy of the baseline model using the vulnerable variables does not transfer across hospitals. However, simply discarding the vulnerable features results in consistently poor performance at both hospitals. Instead, the counterfactually normalized models both transfer well while maintaining high performance. The latent features also capture most of the relevant information from the vulnerable variables, since adding the vulnerable variables results in marginal improvements at the source hospital.

The increased separability in the latent variables is shown in Figure 4, in which the factual blood pressure distributions (solid lines) contain significant overlap. However, once we normalize the blood pressures for treatment and chronic condition, the separability by class is increased. We also measure the increase through the classification complexity metrics in Table 2, computed using the source hospital training data. The feature with the maximum Fisher’s Discriminant Ratio in the baseline model is  $C$ , but this is much smaller than the ratio for the latent fea-

<sup>3</sup> denotes an estimated value.

Figure 4: The distribution of factual (solid line) and estimated counterfactual (dashed line) blood pressures at the source hospital in the simulated experiment. It is easier to discriminate  $T$  from counterfactual BP than from observed BP due to decreased overlap in the distributions.

Figure 5: Performance as the accuracy of counterfactual estimates decreases. Secondary y-axis measures correlation between predictions using vulnerable variables and predictions without using them. The error bars denote the standard error of 50 runs.

ture. The large decrease in the MST metric indicates fewer examples lies on the class boundary in the normalized problem, and the decrease in intraclass-interclass is due to a combination of increased separability and reduced intraclass variance of the latent variables visible in the reduced spread of the distributions in Figure 4.

### 5.1.2 Accuracy of Counterfactual Estimates

In this experiment, we examine how the accuracy of counterfactual estimates affects the quality of model predictions. If the counterfactual estimates are accurate, then we expect the conditional independence of the vulnerable variables in the modified DAG to hold. We measure the degree of independence using the correlation between the predictions with ( $p(T|Y(\emptyset, \emptyset))$ ) and without

Figure 6: Real data experiment DAG of causal mechanisms. The outcome  $Y$  is INR and the target  $T$  is sepsis.

$(p(T|Y(\emptyset, \emptyset), C, A))$  using vulnerable variables.

We bias the true counterfactual values by adding normally distributed noise of increasing scale. Then, we train the counterfactual logistic regressions (with and without vulnerable variables) to predict  $T$  and evaluate the AUROC on the source and target hospital patients. We vary the standard deviation of the perturbations from 0.05 to 1 in increments of 0.05, repeating the process 50 times for each perturbation.

The results, shown in Figure 5, demonstrate what we expect: as the mean squared error (MSE) of the estimated latent variables increases, predictive performance on both populations worsens and the correlations of the predictions with and without vulnerable variables decreases. Since the model using vulnerable variables is biased by a spurious association that does not transfer (since the noisy adjustment is not capturing the relevant information), that model consistently underperforms at the target hospital. The counterfactual model without the vulnerable variables performs equally well at both hospitals, but the noise removes both the information captured by the adjustment and the information contained in  $Y$  itself.

## 5.2 REAL DATA: SEPSIS CLASSIFICATION

### 5.2.1 Problem and Data Description

We apply the proposed method to the task of detecting sepsis, a deadly response to infection that leads to organ failure. Early detection and intervention has been shown to result in improved mortality outcomes (Kumar et al., 2006) which has resulted in recent applications of machine learning to build predictive models for sepsis (e.g., Henry et al. (2015); Soleimani et al. (2017); Futoma et al. (2017)).

We consider a simple cross-sectional version of the sepsis detection task as follows using electronic health record (EHR) data from our institution’s hospital. Working with a domain expert, we determined the primary factors in the causal mechanism DAG (Figure 6) for the effects of sepsis on a single physiologic signal  $Y$ : the interna-

tional normalized ratio (INR), a measure of the clotting tendency of blood. The target variable  $T$  is whether or not the patient has sepsis due to hematologic dysfunction. We use chronic liver disease and sickle cell disease as conditions  $C$  affecting INR that are risk factors for sepsis (Goyette et al., 2004; Booth et al., 2010). We consider five types of relevant treatments  $A$ : anticoagulants, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), plasma transfusions, and platelet transfusions, where  $A_{ij} = 1$  means patient  $i$  has received treatment  $j$  in the last 24 hours. Finally, we include a demographic risk factor, age  $X$ . For each patient, we take the last recorded measurements while only considering data up until the time sepsis is recorded in the EHR for patients with  $T = 1$ .

27,633 patients had at least one INR measurement, 388 of whom had sepsis due to hematologic dysfunction. We introduced spurious correlation through selection bias as follows. First, we took one third of the data as a sample from the original target population for evaluation. Second, we subsample the remaining data such that it only contains patients who are flagged in the EHR for having high INR. Third, we split the subsampled data into a random two thirds/one third train/test splits for training on biased data and evaluating on both the biased and unbiased data to measure transferability. We repeated the three steps 50 times. We normalize INR in all experiments.

### 5.2.2 Experimental Setup

We apply the proposed method by fitting an additive structural equation for  $Y$  using the Bayesian calibration form of Kennedy and O’Hagan (2001):

$$\begin{aligned}
 Y_i &= \beta_0 + \beta_1 T_i + \beta_2^T \mathbf{A}_i + \beta_3^T \mathbf{C}_i + \beta_4 X_i \\
 &\quad + \delta(T_i, \mathbf{A}_i, \mathbf{C}_i, X_i) + \varepsilon \\
 \delta(\cdot) &\sim \mathcal{GP}(0, \gamma^2 K_{rbf}) \\
 \varepsilon &\sim \mathcal{N}(0, \sigma^2)
 \end{aligned}$$

where  $\delta(\cdot)$  is a Gaussian process (GP) prior (with RBF kernel) on the *discrepancy function* since our linear regression model is likely misspecified.

Due to the selection bias in the training data, all patients have high INR making it difficult to calibrate the regression parameters. For this reason we place informative priors on  $\beta_1, \beta_2$ , and  $\beta_3$  using  $\mathcal{N}(1, 0.1)$  for features that increase INR (e.g.,  $T$  and anticoagulants) and  $\mathcal{N}(-1, 0.1)$  for features that decrease INR (e.g., sickle cell disease and plasma transfusions). For full specification of the other priors please consult the supplement. We compute point estimates for the parameters using MAP estimation and the FITC sparse GP (Snelson and Ghahramani, 2006) implementation in PyMC3 (Salvatier et al., 2016).

While the counterfactual  $Y(\mathbf{A} = \emptyset)$  is sufficient for  $d$ -

Figure 7: Results for models trained and tested on the selection biased data. In order the average AUROCs are 0.71, 0.75, and 0.78 and the average AUPRCs are 0.34, 0.36, and 0.39. Error bars denote 50 run 95% intervals.

Figure 8: Results for models trained on biased data and tested on unbiased data. In order the average AUROCs are 0.96, 0.94, and 0.88 and the average AUPRCs are 0.26, 0.29, and 0.28. Error bars denote 50 run 95% intervals.

separating  $\mathbf{A}$  from  $T$  in Figure 6 after node splitting, we additionally normalize the effects of  $\mathbf{C}$  and  $X$ :

$$Y_i(\emptyset, \emptyset, \emptyset) = Y_i - \hat{\beta}_2^T \mathbf{A}_i - \hat{\beta}_3^T \mathbf{C}_i - \hat{\beta}_4 X_i \quad (1)$$

We consider three logistic regression models trained on the biased data for predicting  $T$ : a baseline that does not use the vulnerable variables  $p(T|\mathbf{C}, Y, X)$ , a baseline that uses the vulnerable variables  $p(T|\mathbf{A}, \mathbf{C}, Y, X)$ , and a counterfactually normalized model  $p(T|\mathbf{C}, Y(\emptyset, \emptyset, \emptyset), X)$ . We evaluate prediction accuracy on biased and unbiased data using AUROC and the area under the precision-recall curve (AUPRC).

### 5.2.3 Results

The resulting AUCs when predicting on biased data are shown in Figure 7. The counterfactually normalized model (CFN) outperforms the baseline model in which the

vulnerable variables are removed, but performs slightly worse than the normalized model which includes the vulnerable variables. This indicates that the latent variable estimates have captured some, but not all, of the relevant information in the vulnerable variables.

The results when predicting on unbiased data are shown in Figure 8. Since most of the examples in the unbiased data are negative (only 1.4% are positive), the AUPRC is a more interesting measurement because it is sensitive to false positives. As we expect, the baseline model without vulnerable variables has the lowest AUPRC because it has less statistically relevant information to use. Somewhat surprisingly, despite being trained on finite samples of biased data, the model with the vulnerable variables is able to learn a conditional distribution with the vulnerable variables that carries over to the unbiased population. Additionally, the counterfactual model without non-vulnerable variables has similar performance to the vulnerable model with respect to AUPRC indicating that it also captured a relationship of the vulnerable variables that generalizes. These results are encouraging because we were able to learn a counterfactually normalized model that transfers while clearly retaining non-spurious information about the vulnerable variables.

## 6 CONCLUSION

Using properties of DAGs encoding causal mechanisms, we have identified variables in prediction problems that are vulnerable to participating in spurious associations that can cause models to fail to generalize from training to deployment settings. As opposed to previous approaches which rely on unlabeled samples from the target distribution, we proposed a solution which allows us to identify latent variables that, when estimated, can allow a model to generalize by removing the vulnerable variables from the prediction problem. Because of their causal interpretations, we believe these latent variables are more intelligible for human experts than existing adjustment-based methods. For example, we think it is easier to reason about “the blood pressure if the patient had not been treated” than interaction features or kernel embeddings—we would like to test this in a future user study. In our experiments we demonstrated that we can successfully remove vulnerable variables at prediction time with minimal accuracy loss.

## Abstract

Decentralized planning under uncertainty for agent teams is a problem of interest in many domains including (but not limited to) disaster rescue, sensor networks and security patrolling. Decentralized MDPs, Dec-MDPs have traditionally been used to represent such decentralized planning under uncertainty problems. However, in many domains, agents may not be dedicated to the team for the entire time horizon. For instance, due to limited availability of resources, it is quite common for police personnel leaving patrolling teams to attend to accidents. Such non-dedication can arise due to the emergence of higher priority tasks or damage to existing agents. However, there is very limited literature dealing with handling of non-dedication in decentralized settings. To that end, we provide a general model to represent problems dealing with cooperative and decentralized planning for non-dedicated agent teams. We also provide two greedy approaches (an offline one and an offline-online one) that are able to deal with agents leaving the team in an effective and efficient way by exploiting the submodularity property. Finally, we demonstrate that our approaches are able to obtain more than 90% of optimal solution quality on benchmark problems from the literature.

## 1 INTRODUCTION

Decentralized planning for a team of agents is required in a wide variety of problems such as target tracking by a team of sensors [Nair *et al.*, 2005; Kumar and Zilberstein, 2011; Chapman and Varakantham, 2014], securing targets from unknown attackers using a team of defenders [Brown *et al.*, 2014; Shieh *et al.*, 2014; Varakantham

*et al.*, 2013], rescuing of victims by a team of robots during disaster [Melo and Veloso, 2011; Varakantham *et al.*, 2009, 2014; Velagapudi *et al.*, 2011] and analysing underwater samples using a team of underwater vehicles [Yin and Tambe, 2011], etc.

These domains have the following common characteristics: (a) A decentralized team of agents (sensors, ambulances, fire-trucks, etc.) that coordinate plans to achieve a goal; (b) There is transition uncertainty in planning problems of individual agents, either due to travelling on roads (due to traffic) or due to physical constraints (sensors, robots, etc.) (c) The agents are independent and collaborate through a global reward (save victims, prevent attacks, etc.); and most importantly (d) The individual agents have a chance of leaving the team at any time step to address a higher priority task. For example, in the case of patrolling, agents (e.g., coast guard boats, traffic police) can be forced to leave their assignment to attend to an accident or incident (e.g., incursion, smuggling, accident).

We are interested in application problems with the above mentioned characteristics and specifically teams in which agents are non-dedicated and may leave the team due to higher priority tasks or damage to agents. Non-dedication has been explored by Agrawal and Varakantham [2017] for centralized planning. Further, Shieh *et al.* [2014] considered non-dedicated teams in decentralized settings, but they provide an exhaustive offline approach that is not scalable. Our contributions differ in providing quick solutions by exploiting reward submodularity for decentralized planning such that remaining agents can reconfigure their policies to attend to tasks of leaving agents.

Submodularity has been exploited by Kumar and Zilberstein [2009]; Satsangi *et al.* [2015] for centralized planning model while Kumar *et al.* [2017] focus on decentralized planning in cooperative teams. Our contributions differ from this line of work in considering non dedicated agent teams with multiple agent exits from the team while still considering joint submodular reward functions for

decentralized planning. Another closely related thread of research is on adaptive submodularity [Golovin and Krause, 2011], where a sequence of decisions are taken by accounting for the observations of past decisions. Our work differs from this thread because we consider a multi-stage submodular problem (which introduces a partition matroid constraint) where at every decision epoch, we have a new submodular problem<sup>1</sup> with fewer number of agents.

To that end, we provide a general model to represent the class of problems dealing with a team of independently collaborating non-dedicated agents. A key contribution of our work lies in establishing connections between non-dedicated agent teams and submodularity. We show that with monotone submodular reward functions subject to the matroid constraint, greedy solutions computed at every decision epoch are still submodular with fewer number of agents and provide an a priori guarantee of at least 50% from the optimal and much better posterior guarantees. Another main contribution includes our two greedy approaches to efficiently deal with agent exits before the end of horizon. In our first approach, we exploit lazy greedy to obtain a unique offline policy for every agent irrespective of the agent exits from the team. The second approach is an offline-online approach where the offline phase creates a fixed number of joint policies to be used in the online phase. Finally, our experiments demonstrate the improved performance of our approaches on benchmark problems from literature.

## 2 BACKGROUND

### 2.1 Monotone Submodularity and Matroids

**Definition 1** Given a finite set,  $\Pi$ , a **submodular function** is a set function,  $g : 2^\Pi \rightarrow \mathbb{R}$ , where  $2^\Pi$  is the power set corresponding to  $\Pi$ . More importantly,  $\forall X, Y \subseteq \Pi$  with  $X \subseteq Y$  and for every  $i \in \Pi \setminus Y$ , we have:

$$g(X \cup i) - g(X) \geq g(Y \cup i) - g(Y)$$

A submodular function  $g$  is **monotone** if  $g(Y) \geq g(X)$  for  $X \subseteq Y$ .

Monotone submodular functions are interesting because maximizing a submodular function to pick a fixed number of elements (say  $k$ ) from the finite set ( $\Pi$ ) while difficult can be approximated efficiently with a strong quality guarantee. Specifically, a greedy algorithm that incrementally generates the solution set by maximizing marginal utility provides solutions that are at least 63% ( $1 - \frac{1}{e}$ ) of the optimal solution.

<sup>1</sup>This is unlike in adaptive submodularity, where there is one submodular problem with updated information on sensor state.

If we have a submodular function under a specific constraint on the finite set ( $\Pi$ ) and the elements that are picked, the constraint is specified using a partition matroid. In this paper, we are also interested in maximizing a submodular function, however, under a specific constraint on the finite set ( $\Pi$ ) and the elements that are picked. Specifically, the constraint is specified using a partition matroid. We provide the formal definitions below:

**Definition 2** For a finite ground set  $\Pi$ , let  $\mathcal{P}$  be a non-empty collection of subsets of  $\Pi$ . The system  $\Gamma = (\Pi, \mathcal{P})$  is a matroid if it satisfies the following two properties:

- *The hereditary property:*  $\mathcal{P}_1 \in \mathcal{P} \wedge \mathcal{P}_2 \subset \mathcal{P}_1 \implies \mathcal{P}_2 \in \mathcal{P}$ . In other words, all the subsets of  $\mathcal{P}_1$  must be in  $\mathcal{P}$ .
- *The exchange property:*  $\forall \mathcal{P}_1, \mathcal{P}_2 \in \mathcal{P} : |\mathcal{P}_1| < |\mathcal{P}_2| \implies \exists x \in \mathcal{P}_2 \setminus \mathcal{P}_1; \mathcal{P}_1 \cup x \in \mathcal{P}$ .

We are specifically interested in a ground set that is partitioned as  $\Pi = \Pi_1 \cup \Pi_2 \cup \dots \cup \Pi_k$ . The family of subsets,  $\mathcal{P} = \{P \subseteq \Pi : \forall i, |P \cap \Pi_i| \leq 1\}$  forms a matroid called a partition matroid. This family of subsets denotes that any solution can include at most one element from each ground set partition where the ground set partitions represent the policy space of each agent and exactly one policy must be picked for each agent.

### 2.2 Submodular TI-Dec-MDP

Submodular Transition Independent Decentralized Markov Decision Process (TI-Dec-MDP) model [Kumar *et al.*, 2017] is characterized by the tuple:  $\langle \mathcal{A}g, S, A, \{P_i\}_{i \in \mathcal{A}g}, R, H, \alpha \rangle$ , where

- $\mathcal{A}g$  is the set of agents.
- $S$  is the factored joint state space.  $S = S_1 \times S_2 \dots S_{|\mathcal{A}g|}$ , where  $S_i$  is the state space corresponding to each individual agent  $i$ . We can also have a global unaffected state feature  $S_u$ .
- $A$  is the joint action space.  $A = \times_{i \in \mathcal{A}g} A_i$ , where  $A_i$  is the action space corresponding to each agent  $i$ .
- $P_i$  is the individual agent transition function.  $P_i(s'_i | s_i, a_i)$  indicates the transition probability of moving from  $s_i$  to  $s'_i$  on taking action  $a_i$ .
- $R$  is the monotone submodular joint reward, with  $R(s, a)$  representing the reward for taking joint action  $a$  in joint state  $s$ . In security domains [Shieh *et al.*, 2014], reward is both monotonically increasing and submodular. It is defined as follows:

$$R(s, a) = \sum_{\tau} y_{\tau} \cdot f_{\tau}(\sigma(s, a, \tau)) \quad (1)$$

$y_{\tau}$  indicates the value of target  $\tau$  and hence is a non-

negative number.  $f_\tau(\cdot)$  is a monotone submodular function referred to as the effectiveness of patrolling a target  $\tau$ . Effectiveness of patrols at a target  $\tau$  depends on the number of agents patrolling the target.  $\sigma(s, a, \tau)$  counts the number of agents at target  $\tau$  if the current joint state is  $s$  and joint action is  $a$ . Let  $\epsilon$  ( $0 < \epsilon \leq 1$ ) represent the effectiveness of one agent visiting a target. Then, the effectiveness of  $\sigma$  agents visiting the same target  $\tau$  in the joint state  $s$  is given by the usual definition of  $f(\cdot)$  for effectiveness parameter  $\epsilon$  is  $f(\sigma) = 1 - (1 - \epsilon)^\sigma$ .

- $H$  is the time horizon and  $\alpha$  is the starting state distribution.

The goal is to obtain a joint policy  $\pi^* = \langle \pi_1, \pi_2, \dots \rangle$  (with one policy,  $\pi_i$  for each agent  $i$ ) that maximizes expected reward or value defined as follows:

$$V(\pi) = \sum_s \alpha(s) \cdot V^H(s, \pi) \quad (2)$$

$$V^t(s, \pi) = R\left(s, \langle \pi_1^t(s_1), \dots, \pi_{|\mathcal{A}g|}^t(s_{|\mathcal{A}g|}) \rangle\right) + \sum_{s'} \left[ \prod_{i \in \mathcal{A}g} P_i\left(s'_i | \pi_i^t(s_i), s_i\right) \right] \cdot V^{t-1}(s', \pi) \quad (3)$$

### 3 SUBMODULAR ND-TI-Dec-MDP

We extend Submodular TI-Dec-MDPs to Non-Dedicated TI-Dec-MDPs (ND-TI-Dec-MDPs) in order to model non-dedicated teams. The model is characterised by the following tuple:

$$\langle \mathcal{A}g, \{\Delta_i\}_{i \in \mathcal{A}g}, S, A, \{P_i\}_{i \in \mathcal{A}g}, R, H, \alpha \rangle$$

The main change to the Submodular TI-Dec-MDP is  $\Delta_i$ .  $\Delta_i$  is the vector of probabilities for agent  $i$  leaving the system at different times. Specifically,  $\Delta_i^t$  represents the probability of agent  $i$  leaving the team at time  $t$  and  $\sum_t \Delta_i^t = 1$ . We use the global state  $S_u$  to represent the dead state (i.e., the state that agents enter when they move out of the system). The individual agent transition function  $P_i^t(s'_i | s_i, a_i)$  is modified to  $P_i^t(s'_i | s_i, a_i, \Delta_i)$  and is described as following:

$$P_i^t(s'_i | s_i, a_i, \Delta_i) = P_i^t(s'_i | s_i, a_i) \cdot (1 - \Delta_i^t) \quad (4)$$

$$P_i^t(S_u | s_i, a_i, \Delta_i) = \Delta_i^t \quad (5)$$

If  $\Delta_i^t = 0$ , it implies that the agent transitions to the expected state according to its transition probability  $P_i^t(s'_i | s_i, a_i)$ . Otherwise, if  $\Delta_i^t \neq 0$ , the transitions depend on the agent's probability of staying in the system (i.e.,  $1 - \Delta_i^t$ ). Furthermore, an agent transitions to the dead state from any other state with probability  $\Delta_i^t$ . Note that once an agent transitions to the dead state  $S_u$ , it stays there

until the end of horizon (i.e.,  $P_i^t(S_u | S_u, a_i, \Delta_i) = 1$ ) irrespective of the action taken. The joint reward function  $R(s, a)$  however remains unchanged since the computation of reward only requires the count of agents present in the joint state  $s$ . In addition, there is no reward associated with agents present in  $S_u$  and we simply have  $R(S_u, a) = 0$ . The goal of submodular ND-TI-Dec-MDP is to obtain a joint policy  $\pi$  that maximizes the expected value  $V^t(s, \pi)$  over all agents with an additional constraint that the agents may leave the team.

#### 3.1 Properties of ND-TI-Dec-MDP

We now describe the important properties of ND-TI-Dec-MDPs with a joint reward function that is monotonically increasing and submodular. Let us first consider the case of a dedicated team where no agent leaves the system (represented as  $\Delta_i^H = 1$  for all agents). In this case, the state of the system is fixed (i.e., no agents leaving) and already known to the decision maker, and hence, the policy of every agent can be determined in advance. However, in a non-dedicated agent team, agents may leave the team midway requiring reconfiguration of the remaining agent policies. The timestep at which an agent leaves the team is referred to as observation timestep,  $t'$  and the set of agents leaving the system at  $t'$  represent the observation  $\psi$ . All the agents that have left until  $t'$  constitute the observation set  $\psi_{t'}$ . The joint policy for a ND-TI-Dec-MDP is a concatenated policy which is formally defined for one observation timestep as following.

**Definition 3** *Policy Concatenation:* Let  $\pi_{\psi_0}$  be the joint policy over all agents until the first observation at time  $t'$  and  $\pi_{\psi_{t'}}$  be the joint policy with observation set  $\psi_{t'}$ . The concatenated policy  $\hat{\pi}$  is represented as:

$$\hat{\pi} = [\pi_{\psi_0}]_{t=0}^{t < t'} + [\pi_{\psi_{t'}}]_{t=t'}^{t=H}$$

**Proposition 1** [Kumar et al., 2017]: For a TI-Dec-MDP,  $V^H(s, \pi)$  is monotonically increasing and submodular if the joint reward,  $R$  is monotonically increasing and submodular.

At  $t = 0$ , ND-TI-Dec-MDP is similar to TI-Dec-MDP and is solved for  $|\mathcal{A}g|$  agents and  $H$  timesteps. The value function,  $V^H(s, \pi)$  is a monotone and submodular being the case of dedicated agent team. Similarly, for every observation timestep  $t'$ , ND-TI-Dec-MDP is solved as a new TI-Dec-MDP problem with  $\mathcal{A}g \setminus \psi_{t'}$  agents and  $H - t'$  timesteps where  $\psi_{t'}$  represents the set of agents that have left until  $t'$ . The value function,  $V^{H-t'}(s, \pi)$  at  $t'$  is also monotonically increasing and submodular. Hence, for a single observation  $\psi_{t'}$ , the joint policy comprises of two components (as per definition 3) where the second

component is guaranteed to be submodular but not the first component. This is because submodularity of the value function  $V^H(\pi)$  holds for  $[t]_0^H$  but for ND-TI-Dec-MDP, we consider only timesteps  $[t]_0^{t'}$  for the first component. Hence, the value function  $V^H(\hat{\pi})$  for ND-TI-Dec-MDP is not guaranteed to be submodular for  $\hat{\pi}$ , however, it is submodular for every TI-Dec-MDP sub-problem.

The goal in ND-TI-Dec-MDPs is to maximize the expected value by obtaining a correct joint policy (i.e., exactly one policy per agent). Formally, the goal is to maximize  $V^H(\pi)$  for every individual TI-Dec-MDP problem given the partition matroid  $\Gamma = (\Pi, I)$  where  $I = \{X \subseteq \Pi : |X \cap \Pi_i| = 1\}$ . Intuitively, the partition matroid enforces that we can only have one policy for each agent.

**Proposition 2** [Fisher et al., 1978]: *Greedy algorithm for maximizing a monotone submodular function subject to a partition matroid yields solutions that are at least 50% of the optimal solution.*

For a non-dedicated agent team, the a priori bounds for every TI-Dec-MDP sub-problem at any  $t'$  is guaranteed to be at least 50% of optimal in the worst case. However, these bounds are quite loose since the solution provided by greedy is much better in most cases. Therefore, we compute online bounds by adding the marginal value of the best policy for every agent in the solution set to provide a tighter upper bound on the optimum. The online bound for a monotonically increasing and submodular value function is represented as below:

**Proposition 3** [Kumar et al., 2017]: *For any joint policy,  $\pi$ :*

$$V(\pi^*) \leq V(\pi) + \sum_{i \in \mathcal{A}g} \delta_i(\pi)$$

where  $\delta_i(\pi) = \max_{\pi_i \in \Pi_i} V(\pi \cup \pi_i) - V(\pi)$

Here,  $\pi^*$  is the optimal joint policy with optimal individual policies for every agent. For any joint policy  $\pi$ , we get an upper bound on the value of the optimal policy by adding the individual policies,  $\pi_i$  that yield best marginal values for each agent. In the context of ND-TI-Dec-MDP, at every observation timestep  $t'$ , we solve a new TI-Dec-MDP problem with  $\mathcal{A}g \setminus \psi_{t'}$  agents and  $H - t'$  timesteps where any policy  $\pi_{\psi_{t'}}$  provides an upper bound on the optimal policy  $\pi_{\psi_{t'}}^*$ . However, any concatenated policy  $\hat{\pi}$  is not guaranteed to provide an upper bound on the optimal concatenated policy  $\hat{\pi}^*$  since submodularity may not hold for  $\pi_{\psi_0}$ . We still compute the online bound for the concatenated policy as following.

$$V(\hat{\pi}^*) \leq \left[ V(\pi_{\psi_0}) + \sum_{i \in \mathcal{A}g} \delta_i(\pi_{\psi_0}) \right]_{t=0}^{t < t'} + \left[ V(\pi_{\psi_{t'}}) + \sum_{i \in \mathcal{A}g \setminus \psi_{t'}} \delta_i(\pi_{\psi_{t'}}) \right]_{t=t'}^{t=H} \quad (6)$$

---

**Algorithm 1** ND-GREEDY ( $\mathcal{A}g, S, A, P, R, H - t', \alpha, \psi_{t'}$ )

---

```

1:  $Z \leftarrow \emptyset$ 
2:  $\pi_i^* \leftarrow \emptyset, \forall i \in \mathcal{A}g \setminus \psi_{t'}$ 
3: repeat
4:   for all  $i \in \mathcal{A}g \setminus \{\psi_{t'} \cup Z\}$  do
5:      $\pi_i^* \leftarrow \max_{\pi_i} V_i(\pi_i, \alpha_i^{t'} | \pi_Z^*)$ 
6:    $\langle i^*, V_{i^*} \rangle \leftarrow \max_{i \in \mathcal{A}g \setminus \psi_{t'} \cup Z} V_i(\pi_i^*, \alpha_i^{t'} | \pi_Z^*)$ 
7:    $Z \leftarrow Z \cup \{i^*\}$ 
8: until  $\mathcal{A}g \setminus \{\psi_{t'} \cup Z\} = \emptyset$ 
9: return  $\{Z, \pi^* \leftarrow \{\pi_i^*\}_{i \in \mathcal{A}g \setminus \psi_{t'}}\}$ 

```

---

where  $\delta_i(\pi_{\psi_t}) = \max_{\pi_i \in \Pi_i} V(\pi_{\psi_t} \cup \pi_i) - V(\pi_{\psi_t})$ ,  $t \in \{0, t'\}$

The expression in the first square bracket bounds the value of the optimal concatenated policy  $V^H(\hat{\pi}^*)$  from  $t = 0$  to  $t \leq t'$  for the policy  $\pi_{\psi_0}$  (however, it is not a guaranteed online bound), while the second expression provides a guaranteed online bound on the value of the optimal concatenated policy from  $t \geq t'$  to  $t = H$ . For our experiments, we compute online bounds for ND-TI-Dec-MDP using Equation 6.

## 4 APPROACHES

In this section, we provide enhancements to the existing approaches in literature along with an offline and an offline-online approach for solving ND-TI-Dec-MDPs. We extend the existing lazy greedy algorithm for TI-Dec-MDPs to provide solutions for non-dedicated agent teams. We further provide a lazy greedy extension for the benchmark heuristics in non-dedicated teams [Agrawal and Varakantham, 2017] to provide bounds on the solution quality of ND-TI-Dec-MDPs.

### 4.1 Greedy and Lazy Greedy

For dedicated agent teams, greedy has been well explored in the context of Dec-MDPs [Shieh et al., 2014; Agrawal et al., 2016; Kumar et al., 2017] while for non-dedicated agent teams, it has been explored only in centralized settings [Agrawal and Varakantham, 2017]. Therefore, we extend the previous work by [Kumar et al., 2017] to provide a lazy greedy extension for non-dedicated teams in decentralized settings.

Algorithm 1 provides the pseudocode for a non-dedicated greedy algorithm that is solved at every observation timestep,  $t'$  where  $|\psi_{t'}|$  agents leave the team and  $H - t'$  timesteps are remaining. The algorithm is initially invoked at the starting timestep (i.e.,  $t = t' = 0$  and  $\psi_{t'=0} = \emptyset$ ) after which it is invoked only for timesteps where  $\psi_{t'} \neq \emptyset$ . ND-Greedy builds the solution set by incrementally adding a policy for every agent that has not

been assigned a policy. Initially, we start with an empty solution set  $Z$  (line 1). At every iteration, for each agent in the set of remaining agents,  $\mathcal{A}_g \setminus \psi_{t'}$  that has not been assigned a policy (line 4), we compute a policy with the highest marginal value given the current solution set (line 5) by constructing and solving an MDP (similar to the TI-Dec-MDP. Among those highest marginal value policies, we choose the one with the highest value and add it to the solution set (lines 6-7). This process is repeated until all  $\mathcal{A}_g \setminus \psi_{t'}$  agents have been assigned a policy to collectively provide the joint policy  $\pi^*$  (Every agent is assigned exactly one policy with the help of partition matroid constraint). Finally, the agents in  $Z$  are present in decreasing order of their marginal values. We refer this solution set  $Z$  as **selection order** of the agents.

ND-Greedy evaluates the marginal value for all the agents at every iteration, thereby affecting the scalability of the algorithm with increasing agents. Interestingly, submodularity of the value function  $V^H(\cdot)$  can be exploited to implement an accelerated version of classical greedy algorithm, otherwise known as Lazy Greedy [Minoux, 1978]. Instead of computing the marginal gain for all agents, lazy greedy allows a lazy evaluation of marginal benefits by storing the upper bounds  $\mu(i)$  on the marginal gain for all agents  $i \in \mathcal{A}_g$  sorted in descending order. This reduces the marginal gain computation as the submodularity of value/objective function guarantees that the marginal gain for an agent is always equal to or lower than the previous iteration. Intuitively, for each iteration, lazy greedy evaluates the agent on the top of the list, say  $i$ , and updates its upper bound,  $\mu(i)$ . If  $\mu(i) \geq \mu(i'), \forall i' \neq i$ , submodularity guarantees that agent  $i$  has the highest marginal gain. Therefore, lazy greedy leads to significant reduction in running times compared to the classical greedy.

**Why is the new policy recomputation needed:** The recomputation of a new joint policy at every observation timestep  $t'$  is important because the contribution of rewards by agents at every timestep may vary. This means that an agent may have higher rewards at earlier timesteps compared to later timesteps. In security games, if the remaining agents continue with their initial policies even after few agents leave, the coverage of important targets may be missed, making the system vulnerable to attacks. This creates an urgency for policy recomputation and therefore, we use lazy greedy to obtain a new selection order for agents by considering the reward contributions from the current timestep to the end of planning horizon. For example, let the selection order of agents at  $t = 0$  be  $[A_2(555), A_3(545), A_1(500), A_4(490)]$  with the reward values for agents specified alongside. Let  $a_1$  leave the system at  $t = 1$ . The total value for agents at  $t = 1$  could be  $[A_2(500), A_3(505), A_4(490)]$  on recomputation of reward for the remaining agents. This creates a change

in order of selection of the agents because the contribution at  $t = 0$  dominated the contribution over remaining timesteps for agents  $A_2$  and  $A_3$ . Hence, the change in order contributes to the change in marginal gain, and therefore, agents must rearrange their policies to adapt to the change in system.

## 4.2 Benchmarking Heuristics

The existing benchmark heuristics for non dedicated agent teams [Agrawal and Varakantham, 2017] are centralized approaches and incapable of computing joint policy and joint reward for the agent team. Hence, we provide a lazy greedy extension for the existing benchmarks to be able to solve ND-TI-Dec-MDPs.

**Ignore the leaving agent, Dec-ILA:** We start with a lazy greedy solution for the dedicated team and whenever agents leave the team, the remaining agents continue with the execution of their existing policies. However, due to the presence of joint reward for the system, we recompute the joint reward over the remaining agents whenever agents leave. This provides a good lower bound on solution quality that has to be achieved. For example, in security games domain, ignoring the targets covered by leaving defender agent is not the best choice since the leaving agent may be protecting a target of high importance. Hence, it is important for the remaining agents to modify their policies to provide an improved coverage to the targets that would become vulnerable to attacks. Similarly, in sensor domain, the sensors in the vicinity of a spoilt sensor should be able to change their policies and sense the target locations assigned to the spoilt sensor for better observation of any spatial phenomenon.

**Offline Optimal, Dec-OPT:** This heuristic assumes that the sample information (details of agents leaving the system) is received beforehand. Mixed integer program provides an optimal solution, but is not a suitable approach for finding the joint policy and the joint reward computation for a decentralized team of heterogeneous agents. Hence, we use lazy greedy for finding the agent policies where the agents are selected sequentially in the decreasing order of their values. Since the agents leaving the system have a shorter timespan compared to non-leaving agents, the marginal gain for such agents will be lowest. Hence, non-leaving agents are provided least preference in the selection process by greedy. Although not an exactly optimal approach, this heuristic provides a good upper bound on the solution quality.

**Online Revamp, Dec-O-Rev:** Similar to Dec-ILA, for this heuristic, we start with the initial lazy greedy solution until one or more agents leave the system. At the observation timestep  $t'$ , the problem is solved again for

---

---

```
1:  $Z \leftarrow \emptyset, O \leftarrow \emptyset$ 
2:  $V_i \leftarrow 0, \forall i \in \mathcal{A}g$ 
3: for all  $\xi^k \in \xi$  do
4:    $V^k \leftarrow \text{Dec-OPT}(\mathcal{A}g, S, A, P, R, H, \alpha, \xi^k)$ 
5:    $V_i \leftarrow V_i + W^k \cdot V_i^k$ 
6: for all  $i \in \mathcal{A}g$  do
7:    $V_{i^*} \leftarrow \max_{i \in \mathcal{A}g \setminus O} V_i$ 
8:    $O \leftarrow O \cup i^*$ 
9: for all  $o \in O$  do
10:   $\langle \pi_o^*, V_o^* \rangle \leftarrow V_o(\pi_o^*, \alpha_o^0 | \pi_Z^*)$ 
11:   $Z \leftarrow Z \cup \{o\}$ 
12:  $\pi^* \leftarrow \{\pi_o^*\}_{o \in O}$ 
13: return  $\langle \pi^*, O \rangle$ 
```

---

the remaining agents  $\mathcal{A}g \setminus \psi_{t'}$  and remaining timesteps  $H - t'$ . The starting distribution of the remaining agents is recomputed at  $t'$  and is input to the lazy greedy algorithm along with the information of leaving agents,  $\psi_{t'}$ . The new joint policy obtained for the remaining agents is executed by the agent team until there is a change in the system (i.e., an agent leaves the system). Dec-O-Rev provides a good upper bound on the desired performance for our proposed approaches but suffers from some limitations. Although the running time reduction due to lazy greedy is significant compared to classical greedy, the total number of function evaluations with lazy greedy cannot be predicted beforehand to provide the exact running cost. This makes the complete recomputation of selection order at observation timesteps time consuming and difficult to be evaluated on the fly. Secondly, if there is a requirement of recomputation at every timestep  $t$ , revamp would become infeasible since at least  $\mathcal{A}g \setminus \psi_t$  rounds of sequential computation for agents will be required.

### 4.3 Offline-Greedy Approach

Offline-Greedy is a sampling-based approach that computes an offline selection order,  $O$  and a single joint policy  $\pi^*$  over multiple scenarios of agent availability. Since it is impossible to consider all the samples of agent availability on larger problems, we choose a smaller training set for the joint policy computation. The sample set is represented as  $\xi$  and has  $|K|$  samples. Due to repetition of samples, we assign frequency-specific weights  $W^k, \forall k \in K$  and select 20 best samples in decreasing order of weights. Every sample of agent availability,  $\xi^k$  is generated by sampling from a biased coin with probability  $p_i$  independently for every agent  $i$ . At every timestep  $t$ , the coin is tossed to decide whether agent  $i$  leaves or stays in the team depending on the value of associated probability in  $\Delta_i$ . Hence, for every sample  $\xi^k$ , we know the available horizon  $\xi^k(i)$  for every agent  $i$ .

Algorithm 2 provides the pseudocode for Offline-Greedy

---

**Algorithm 3** OFFLINE-ONLINE ( $\mathcal{A}g, N$ )

---

```
1: for all  $n \in N$  do
2:    $Z \leftarrow \emptyset$ 
3:    $\pi_i^n \leftarrow \emptyset, \forall i \in \mathcal{A}g$ 
4:   repeat
5:      $r_i \leftarrow \text{Random}(\mathcal{A}g \setminus Z)$ 
6:      $\pi_{r_i}^n \leftarrow V_{r_i}^n(\pi_{r_i}, \alpha_{r_i}^0 | \pi_Z^n)$ 
7:      $Z \leftarrow Z \cup \{r_i\}$ 
8:   until  $\mathcal{A}g \setminus Z = \emptyset$ 
9:    $\pi^n \leftarrow \{\pi_i^n\}_{i \in \mathcal{A}g}$ 
10:  $\Pi \leftarrow \Pi \cup \{\pi^n\}$ 
11: return  $\Pi$ 
```

---

with the training set  $\xi$ , the agent set  $\mathcal{A}g$  and the vector of frequency weights over all samples  $W$  as inputs. The agent selection set,  $Z$  and the selection order  $O$  are initialized as empty sets and the total value of every agent over all samples  $V_i$  is set to 0 (line 1-2). For every sample  $\xi^k$  in the training set, the available horizon of every agent is already known, and therefore, we use Dec-OPT heuristic to obtain the total value,  $V^k$  for every  $\xi^k \in \xi$  (line 4). The total value for every agent  $V_i$  is computed as the weighted sum of values over the sample set (i.e.,  $W^k \cdot V_i^k$ ) (line 5). The selection order  $O$  is computed by sorting the agents in decreasing order of their values  $V_i$  (line 6-9) such that the agents with higher probability of staying in the system are added before the agents with higher probability of leaving. For all the agents in the selection order, highest marginal value policy for an agent given the current solution set (line 10) is computed by constructing and solving an MDP (similar to TI-Dec-MDP) and the computed agent is then added to the solution set (line 11). Finally, we return the best selection order  $O$  and the offline joint policy  $\pi^*$  over all agents and all training samples.

For every test sample, the agents are assigned their individual policies from the offline joint policy  $\pi^*$ . However, irrespective of the observations obtained at different observation timesteps, the agents continue with their pre-assigned policies while the joint reward is recomputed for the remaining agents. This approach saves the online recomputation of policy at observation timesteps but with a compromise in the solution quality.

### 4.4 Offline-Online Approach

In this section, we present our Offline-Online algorithm which is a randomized greedy algorithm with an offline and an online phase. The offline phase focuses on the generation of multiple agent(s) selection orders to handle the different possibilities of scenarios, while the online phase focuses on choosing the best selection order for remaining agents depending on the current observation (availability of agents). We note that having multiple selection orders is better than having one fixed selection

order for all scenarios (as present in Offline-Greedy) because the total value of a selection order can change at different observation timesteps due to the dominance of rewards in previous timesteps (explained in details in section 4.1). We generate a fixed number of selection orders for the agent set since the total number of orderings possible with  $|\mathcal{A}g|$  agents is  $|\mathcal{A}g|!$  orders which is difficult to maintain with increasing agents. At every decision stage, we choose the best/closest selection order such that the position of the leaving agent is towards the end of the selection order, thereby, avoiding the recomputations. The time complexity of the offline phase is linear in the number of agents (or  $O(|\mathcal{A}g|)$ ) while it takes constant time for the online phase. The main difference with respect to lazy greedy (used in all the above approaches) is that instead of choosing the agent with highest marginal gain at every iteration, we randomly pick an agent and add it to the selection set. However, due to the joint reward computation and the presence of submodular rewards, the total utility always improves with addition of agents iteratively.

Algorithm 3 shows the offline phase of Offline-Online algorithm where the input to the algorithm is the agent count  $|\mathcal{A}g|$ , and the number of selection orders to be generated ( $N$ ). For computing every order  $n$ , we start with an empty agent selection set  $Z$  and add one agent at a time by randomly selecting agents from the set of remaining agents  $\mathcal{A}g \setminus Z$ . The policy and value of every agent is obtained by solving an MDP and is stored in  $\pi^n$ . Finally, we return  $\Pi$  that represents the set of policies for all the  $N$  selection orders.

The online phase of our algorithm does not require any computation and only reacts to a situation by choosing the best order from the set of offline orders for the remaining agents and providing a new policy for every agent from the observation timestep  $t'$  until the end of horizon. The selection criteria for choosing the best order for the defender team whenever any agent leaves the team depends on the number of exact matching and closest matching selection orders. For example, let us assume that there are 4 agents in the system  $\{a_1, a_2, a_3, a_4\}$  and the available set of selection order contains three orders,  $O_1 = \{3, 2, 1, 4\}$ ,  $O_2 = \{4, 2, 3, 1\}$  and  $O_3 = \{3, 2, 4, 1\}$  with total utility of  $\{200, 150, 100\}$  for the orders respectively. Let us consider two case studies:

- **Agent  $a_1$  leaves the system:** In this case,  $O_2$  and  $O_3$  are the best suitable orders since they require no re-evaluation but the order with highest utility is given preference and hence,  $O_2$  is chosen.
- **Agent  $a_3$  leaves the system:** In this case, none of the matches are exact and therefore, we find the closest match. We choose  $O_2$  to assign policies to the remain-

(a)  $\tau = 40, H = 20, \epsilon = 0.7$  (b)  $|\mathcal{A}g| = 20, H = 20, \epsilon = 0.7$

Figure 1: Quality Comparison w.r.t. (a) Agents and (b) Targets

ing agents since it requires minimal updates to agent policies. At the observation timestep, the previous policy of  $a_1$  is replaced by the existing policy of  $a_3$ , but after considering the change in state distribution of the agents since  $a_1$  and  $a_3$  are not guaranteed to be in the same state at the considered timestep. However, due to the replacement of agent policies,  $a_1$  would now become the third agent in the system, assuming the presence of two agents. Policy recomputation is not required because the offline joint policy (of every selection order) computes the  $V^t(s, \pi)$  values for all states at all intermediate timesteps (i.e., joint value after selection of every agent in the selection order). Furthermore, no reward recomputation is required since the joint reward considers only the count of agents (and not the identity of agents) at any state due to the monotone submodular reward structure for the joint reward.

In this manner, the online phase improves the value of solution roughly the same as Dec-O-Rev, but very quickly.

## 5 EXPERIMENTS

We evaluate<sup>2</sup> the performance of our greedy approaches and compare them with the benchmark approaches mentioned in section 4.2 on the security games domain provided by Shieh *et al.* [2014] and the sensor network domain provided by Kumar *et al.* [2017]. The performance is evaluated on the following metrics: (a) solution quality; (b) runtime; (c) quality of online bounds. We generate 1500 samples of agent availability (defenders in security domain and sensors in sensor domain) and divide it into training and testing sets of 1000 and 500 samples, respectively. To obtain a fair comparison over all approaches, we compare the solutions on the same test set.

### 5.1 Security Games Domain

In this domain, there are a set of targets (train stations) on the metro rail network which must be defended by a set of decentralized (yet cooperative) defenders in the presence

<sup>2</sup>All our optimization problems are run on CPLEX v12.7

Figure 2: Comparison of Online Bound w.r.t. Effectiveness

of transition uncertainty. We constructed the metro rail graphs by connecting the stations together in lines of length 5 and then randomly adding  $|\tau|/2$  edges between targets, to resemble train systems in the real world with complex loops. The reward is a joint reward which is a function of the number of active defenders and the targets for a joint state  $s$  (see Section 2.2 for details). The test results were averaged over 15 randomly generated metro-based graph networks and the rewards were generated randomly in the range of  $[0,100]$ . We run the scenarios with a probability delay of .2 and a maximum of 5 agents (varies from 10% to 25% across scenarios) with an ability to leave the system, defined by probability vector  $\Delta$ . The defender agents are homogeneous (due to same reward and transition function) but differ from each other in their starting states (generated randomly for every agent) and their capability to leave the system.

**Solution Quality:** We compare different approaches with respect to average team utility in Figure 1(a) as the number of defenders  $|\mathcal{A}g|$  is increased. Specifically, we consider a metro network with targets  $\tau = 40$ , horizon  $H = 20$  and effectiveness parameter  $\epsilon = 0.7$ . Similarly, in Figure 1(b), we vary the targets,  $\tau$  for a fixed number of agents  $|\mathcal{A}g| = 20$ , horizon  $H = 10$  and effectiveness parameter  $\epsilon = 0.7$ . The key observations are summarized as following:

- (1) The average team utility increases with increasing defenders for a fixed number of targets and planning horizon due to the submodular reward structure. Similarly, the team utility increases with increasing targets due to increased number of choices for obtaining better rewards.
- (2) Dec-ILA provides low team utility solutions since the remaining agents continue with existing policies even after agents leave. This impacts the scope of improvement in rewards and is a cause of serious concern in security domain since it allows easy access to an adversary to plan an attack in unprotected areas.
- (3) Offline-Greedy provides similar or better solutions than Dec-ILA. We observe that with fewer agents and targets, and smaller planning horizon, Offline-Greedy performs almost similar to Dec-O-Rev as agent exits are given due importance during the offline policy design but

the performance degrades quickly with increasing count of agents and the planning horizon. In the worst case, the solution quality was seen to be even lower than Dec-ILA. (4) Offline-Online provides a steady performance, almost at par with the upper bound benchmarks (Dec-O-Rev and Dec-OPT) even with increasing problem sizes. Due to the random selection of agents at different observation times and the presence of submodular reward function, in the best case, Offline-Online could provide better team utility than Dec-O-Rev (uses lazy Greedy).

(5) Dec-OPT provides a good upper bound but is not always guaranteed to provide better utility compared to Dec-O-Rev due to the dominance of rewards in earlier timesteps explained in the section 4.1. However, on average, Dec-OPT provides slightly better solution quality compared to Dec-O-Rev after having the knowledge of samples before-hand.

**Solution Runtime:** With respect to runtime, we compare only online runtime since the offline runtimes do not matter. Due to decentralized planning of agents, individual agent planning time varies from 100 ms to 5000 ms from the smallest problem instance (20 targets and 10 timesteps) to the largest instance (40 targets and 20 timesteps). For Dec-O-Rev, due to the use of lazy greedy approach at every timestep of revamp, the revamp time varies from 15 seconds to 1700 seconds depending on the number of defenders and the problem size per defender. Further, there can be multiple revamps for one planning scenario making Dec-O-Rev infeasible for providing new policies quickly. However, our Offline-Online approach uses a proactive offline planning which reduces the online execution time to milliseconds, even in the worst case (although it requires offline training time). Similarly, the online runtime is minimal for Dec-ILA, Dec-OPT and Offline-Greedy.

**Online Bound Comparison:** For the online bound comparison, we use a consistent reward structure for every randomly generated metro network. For every metro network, we generate various scenarios of agents availabilities for different number of defenders and varying effectiveness of defenders. We compute the online bound for every scenario using Equation 6 and average the online

Grid-Size	Sensors,Targets Global States	$\epsilon$		
		.3	.5	.7
5 × 5	5, 1, 10	58.3	64.5	71.5
5 × 5	5, 2, 6*6	58.6	65	71.5

10 × 10	10, 5, 5*5*5*5*5	55.5	61.2	67.3

Table 1: Online Bound Comparison for Sensor Domain

bounds over all test samples and all randomly generated graphs. This leads to the inference that the online guarantees are significantly better than the a priori guarantees (of 50% from optimal), with the best case of at least 90% from optimal for different values of effectiveness parameter. Figure 2 compares the online (or posterior) quality guarantees obtained by Dec-O-Rev for different values of agents ( $A_g$ ), targets ( $\tau$ ) and effectiveness parameter ( $\epsilon$ ). It shows that the online guarantees improve with increasing agents and decreasing targets over varying effectiveness, with highest guarantee being reported for 10 targets and 40 agents. Further, with increasing effectiveness of agents, the optimal bound increases with highest quality guarantees (up to 99%) observed for  $\epsilon = 0.9$ . To avoid clutter, we do not plot the quality guarantees provided by policies generated using Offline-Online in the same graph. However, Offline-Online fared slightly lower than Dec-O-Rev in terms of guarantees and provided a guarantee that was 0.7% lower than Dec-O-Rev in the best case, while in the worst case, it was 2% lower than Dec-O-Rev.

## 5.2 Sensor Network Domain

We use the similar settings as Kumar *et al.* [2017] for this domain. The environment is modelled as a grid and a submodular reward function with n-ary interactions (any number of sensors can track a target) is used where the reward of tracking a target is dependent on the number of sensors tracking it. The sensors are randomly placed at junctions of cells on the grid and can track four target cells surrounding the sensor. However, due to wear and tear or due to unforeseen conditions, some sensors may get spoilt and the neighbouring sensors must track the targets of damaged sensors to maximize the reward. Therefore, reconfiguration of sensors after one or more sensors are spoilt is important. The targets move stochastically (according to some fixed distribution) in the grid and follow a path of fixed length for movement. The product of path

lengths of all available targets defines the total number of global states for the sensor domain.

**Online Bound Comparison:** Table 1 shows the online guarantees obtained for offline-online by varying the grid-size, number of sensors and their effectiveness, number of targets and the number of global states. We vary the effectiveness parameter from 0.3 to 0.7 and observe that the online bounds vary from 55% to 73% for Offline-Online, while the guarantees provided by Dec-O-Rev were 4% and 1.8% better than Offline-Online in the worst case and best case, respectively. An important observation is that with increasing targets, the number of global states increases exponentially, leading to memory issues. We note that 5 targets for a 10 × 10 grid with every target having a path-length of 5 was very difficult instance to solve with  $5^5$  or 3125 global states. However, increasing the number of sensors with a fixed number of targets was comparatively easier to solve since every sensor agent problem was solved independent of other agents due to the decentralized settings. With respect to runtime, the time taken by any sensor agent for individual planning varies from few milliseconds to 10 seconds with increasing number of targets and the global states. Due to lazy greedy evaluations for Dec-O-Rev, every revamp may take time ranging from less than a minute to 40 minutes depending on the complexity of the problem being solved. This makes the usage of Dec-O-Rev infeasible in online settings. Further, there can be multiple revamps for every scenario to worsen the situation. Similar to the security domain, the performance of Offline-Greedy is very similar to Dec-ILA while Dec-OPT provides results similar to Dec-O-Rev. More interestingly, our Offline-Online approach continues to perform gracefully with increasing number of sensors, targets and the grid size, while taking minimal time (in milliseconds) for solving the largest problem. Finally, we conclude from the experiments that Offline-Online is the best choice considering the trade-off of running time and compromise in solution quality.

## 6 CONCLUSION

In this work, we focussed on cooperative decentralized stochastic planning for non-dedicated agent teams. We provided a general model for decentralized non dedicated agent teams. Our offline greedy based approach provided good results in small instances while our Offline-Online approach provided the best results even in large instances in an effective manner. Finally, our extensive experiments on benchmark problems demonstrate that our Offline-Online approach provides the best solutions that are on par with benchmarks that provide an upper bound on the performance while taking negligible online runtime making it effective even for taking decisions at every step.

# A Forest Mixture Bound for Block-Free Parallel Inference

---

Neal G. Lawton and Greg Ver Steeg and Aram Galstyan

Information Sciences Institute  
University of Southern California  
Marina del Rey, CA 90292

## Abstract

Coordinate ascent variational inference is an important algorithm for inference in probabilistic models, but it is slow because it updates only a single variable at a time. Block coordinate methods perform inference faster by updating blocks of variables in parallel. However, the speed and convergence of these algorithms depends on how the variables are partitioned into blocks. In this paper, we give a convergent parallel algorithm for inference in deep exponential families that doesn't require the variables to be partitioned into blocks. We achieve this by lower bounding the ELBO by a new objective we call the *forest mixture bound* (FM bound) that separates the inference problem for variables within a hidden layer. We apply this to the simple case when all random variables are Gaussian and show empirically that the algorithm converges faster for models that are inherently more forest-like.

## 1 INTRODUCTION

Inference in directed models like deep exponential families (DEF's) [Ranganath et al., 2015] is complicated by the “explaining away effect”: for a directed model with observed variables  $\mathbf{x} \in \mathbb{R}^n$  and latent variables  $\mathbf{y} \in \mathbb{R}^m$ , independent “causes”  $y_j$  become dependent given an observed “effect”  $x_i$ . To handle this, the coordinate ascent variational inference (CAVI) algorithm iteratively updates the variational distribution for a single latent variable  $y_j$  while holding the variational distribution for all other latent variables fixed [Blei et al., 2017].

Though the  $y_j$ 's are not conditionally independent given  $\mathbf{x}$  except in exceedingly simple models, in many cases the  $y_j$ 's are *nearly* conditionally independent. Is there a

way to perform parallel inference in such models, or do we have to resort to the serial coordinate algorithm?

Block methods provide one avenue for parallel inference. These algorithms work by first partitioning the latent variables into a collection of blocks, and then iteratively updating a variable from each block in parallel. However, the speed (as in MCMC methods [Terenin et al., 2015]) or convergence (as in Hogwild methods [Recht et al., 2011]) of the resulting algorithm will depend on how the variables are blocked, and finding a good choice of blocking for an arbitrary model can be difficult.

The main contribution of this paper is a novel lower bound on log-likelihood we call the forest mixture bound (FM bound) that separates the problem of inference for each variable in a hidden layer. This allows all the variables in a layer to be updated in parallel, without the use of blocks. We call the resulting parallel inference algorithm the forest mixture algorithm (FM algorithm).

We study in detail the case when all the random variables in the DEF are Gaussian. We then demonstrate on both synthetic and real-world data the proposed method achieves faster convergence compared to existing methods.

## 2 RELATED WORK

**Hogwild Block Methods** There are two types of block methods for inference. The first is Hogwild-type algorithms [Recht et al., 2011][Sa et al., 2016] [Wang and Banerjee, 2014] [Zhao et al., 2014]. After partitioning the variables into blocks, these algorithms iteratively choose a single variable from each block and update as in CAVI, but in parallel [Sa et al., 2016]. These algorithms are guaranteed to converge only in certain cases, e.g., when the blocks are conditionally independent [Johnson et al., 2013].

**Convergent Block Methods** Instead of making CAVI updates in parallel, block algorithms may achieve convergence by making small parallel updates [Sontag and Jaakkola, 2009]. For example, “exact” asynchronous Gibbs sampling randomly rejects each block update according to an MCMC rejection ratio [Terenin et al., 2015]. If the blocks are chosen poorly, the rejection rate will increase and the rate of convergence will decrease [Singh et al., 2017].

In either type of block method, the performance of the algorithm depends on how the variables are blocked. In a distributed computation setting, blocking is necessary since each worker can only store a fraction of all variables in local memory. In this case, the FM bound provides a method for updating variables within a block or worker in parallel, instead of updating only a single variable in each block at a time.

**Amortized Inference** Instead of treating inference as an inverse problem that has to be solved for each observation, VAE’s train inference network (encoder) so the cost of inference is amortized over many observations [Kingma and Welling, 2013]. Once the encoder is trained, inference for any observation can be performed quickly with a single pass through the inference network. Encoder-free methods like ours may still be useful in the case when we have a trained generative model (decoder) but no trained encoder and want to perform inference for only a few samples or, more likely, for when we want to improve the solution produced by the encoder at test time.

**Undirected Models** Besides directed models, there is a wide literature for fast inference in undirected models [Baqué et al., 2016] [Singh et al., 2010]. Note that inference in undirected models like Deep Restricted Boltzmann Machines [Salakhutdinov and Hinton, 2009] can already be parallelized: non-consecutive layers can be updated in parallel in red-black fashion. In fact, the same degree of parallelization can be achieved in a directed model using our technique. While there is also a wide literature on bounding the log-partition function of an *undirected* model [Wainwright et al., 2005], we derive the FM bound by lower bounding the log-partition function of a *directed* model. The technique we use may be applicable to undirected models, but that is not explored in this paper.

**Structure Learning** The FM bound we derive is closely related to an interesting family of models called *forest mixture models*. These models may be applicable to the problem of structure learning, where the task is to infer the graphical structure of the underlying model

from data [Chow and Liu, 1968]. However, in this paper we narrowly focus on the problem of inference in a *given* generative model, not on training a new one.

### 3 PRELIMINARIES

Vector-valued variables are written in bold. The component-wise product of two vectors  $\mathbf{u}$  and  $\mathbf{v}$  is denoted  $\mathbf{u} \odot \mathbf{v}$ . Unless stated otherwise, all expectations, including the variance  $\text{Var}[\cdot]$ , standard deviation  $\text{Std}[\cdot]$ , and conditional entropy  $H(\mathbf{y}|\mathbf{x})$ , are taken with respect to the variational distribution  $q(\mathbf{y}|\mathbf{x})$ , though we sometimes write this explicitly for emphasis.

An *exponential family* of distributions is a family of distributions of the form

$$p(x) = \exp\{g(x) + t(x) \cdot \eta - a(\eta)\} \quad (1)$$

Where  $g$  is the log-base measure,  $t$  are the sufficient statistics,  $\eta$  are the natural parameters, and  $a$  is the log-partition function. When  $\eta$  is a function of another random variable  $\mathbf{y}$ , e.g.,  $\eta = b + \mathbf{w} \cdot \mathbf{y}$ , we will sometimes write  $\eta = \eta(\mathbf{y})$  for emphasis.

We denote the Gaussian probability density function with mean  $\mu$  and variance  $\sigma^2$  as  $\mathcal{N}(\mu, \sigma^2)$ . When we write  $\log p(x) \propto f(x)$ , we mean  $\log p(x) = f(x) + \text{constant}$ .

#### 3.1 FOREST MIXTURE MODELS

Consider a general directed model with a single layer of observed variables  $\mathbf{x} \in \mathbb{R}^n$  and latent variables  $\mathbf{y} \in \mathbb{R}^m$ . The joint distribution  $p(\mathbf{x}, \mathbf{y})$  takes the form

$$p(\mathbf{x}, \mathbf{y}) = \left[ \prod_{j=1}^m p(y_j) \right] \left[ \prod_{i=1}^n p(x_i | \mathbf{y}) \right] \quad (2)$$

A directed model is a *forest model* if each  $x_i$  has exactly one parent in the model’s directed dependency graph; they are so-named because the resulting graphical model is a forest with one tree per latent variable  $y_j$ . These models are particularly simple because the  $y_j$ ’s are conditionally independent given  $\mathbf{x}$ . Let  $\mathbf{e}_i \in I^m$  be the one-hot vector indicating the parent of  $x_i$ , so  $e_{ij} = 1$  if and only if  $y_j$  is the parent of  $x_i$ . Then we can write

$$p(x_i | \mathbf{y}) = \prod_{j=1}^m p(x_i | y_j)^{e_{ij}} \quad (3)$$

Suppose we want to fit a forest model to data, but we don’t know which  $x_i$ ’s should be the children of which  $y_j$ ’s. One way to handle this uncertainty is to treat the  $\mathbf{e}_i$ ’s as independent latent random variable that have to

Figure 1: Visualization of sampling from a forest mixture model. (a) In a forest mixture model, the edges between  $\mathbf{x}$  and  $\mathbf{y}$  are unknown random variables. (b) To sample from the model, first the parent of each  $x_i$  is chosen independently at random according to  $p(e_i)$ . In this visualization, each  $p(e_i)$  is uniform over the latent variables. (c) After sampling a forest structure from  $p(e)$ ,  $\mathbf{x}$  and  $\mathbf{y}$  are sampled according to the resulting forest model.

be inferred, just like  $\mathbf{y}$ . To do this, we must first define a prior  $p(e_i)$  for each  $i$ . Given such a prior, the joint distribution over  $\mathbf{x}$ ,  $\mathbf{y}$ , and  $\mathbf{e} \equiv \{e_i\}_{i=1}^n$  is

$$p(\mathbf{x}, \mathbf{y}, \mathbf{e}) = \left[ \prod_{i=1}^n p(e_i) \right] \left[ \prod_{j=1}^m p(y_j) \right] \left[ \prod_{i=1}^n p(x_i | \mathbf{y}, e_i) \right] \quad (4)$$

The resulting model is a *forest mixture model* (FMM): to sample from this model, we first draw a random forest structure by sampling from the prior  $p(e)$ ; then,  $\mathbf{x}$  and  $\mathbf{y}$  are sampled from the selected forest model.

Though the  $y_j$ 's are no longer conditionally independent given  $\mathbf{x}$ , they are independent given  $\mathbf{x}$  and  $\mathbf{e}$ . Similarly, the  $e_i$ 's are conditionally independent given  $\mathbf{x}$  and  $\mathbf{y}$ . To see this, define  $\hat{p}(x_i | y_j) \equiv p(x_i | y_j, e_{ij} = 1)$ . Then the joint distribution can be written

$$p(\mathbf{x}, \mathbf{y}, \mathbf{e}) = \left[ \prod_{i=1}^n p(e_i) \right] \left[ \prod_{j=1}^m p(y_j) \right] \prod_{i=1}^n \prod_{j=1}^m \hat{p}(x_i | y_j)^{e_{ij}} \quad (5)$$

In the next section, we will use the mean-field variational ELBO for this model, which for a given variational distribution  $q(\mathbf{y}, \mathbf{e} | \mathbf{x})$  is

$$\begin{aligned} \log p(\mathbf{x}) &\geq \mathbb{E}[\log p(\mathbf{x} | \mathbf{y}, \mathbf{e})] - D_{KL}(q(\mathbf{y}, \mathbf{e} | \mathbf{x}) \| p(\mathbf{y}, \mathbf{e})) \\ &= \sum_{i=1}^n \sum_{j=1}^m \mathbb{E}[e_{ij}] \mathbb{E}[\log \hat{p}(x_i | y_j)] \\ &\quad - \sum_{j=1}^m D_{KL}(q(y_j | \mathbf{x}) \| p(y_j)) \\ &\quad - \sum_{i=1}^n D_{KL}(q(e_i | \mathbf{x}) \| p(e_i)) \end{aligned} \quad (6)$$

## 4 THE FOREST MIXTURE BOUND

For simplicity, we only consider shallow models in this section. The extension to deep models is straightforward (see Appendix C).

A single-layer *deep exponential family* (DEF) model is a directed model with a single layer of observed variables  $\mathbf{x} \in \mathbb{R}^n$  and hidden variables  $\mathbf{y} \in \mathbb{R}^m$ , where the conditional distribution is in an exponential family. The joint distribution  $p(\mathbf{x}, \mathbf{y})$  takes the form

$$p(\mathbf{x}, \mathbf{y}) = \left[ \prod_{j=1}^m p(y_j) \right] \left[ \prod_{i=1}^n p(x_i | \mathbf{y}) \right] \quad (7)$$

$$p(x_i | \mathbf{y}) = \exp \{g(x_i) + t(x_i)\eta_i(\mathbf{y}) - a(\eta_i(\mathbf{y}))\} \quad (8)$$

Suppose we are given an observation  $\mathbf{x}$  and want to approximately infer the posterior  $p(\mathbf{y} | \mathbf{x})$  by maximizing the variational ELBO, and suppose the  $y_j$ 's are conditionally independent given  $\mathbf{x}$ , so  $p(\mathbf{x}, \mathbf{y}) = p(\mathbf{x}) \prod_{j=1}^m p(y_j | \mathbf{x})$ . Then the mean-field variational ELBO is

$$\log p(\mathbf{x}) \geq \max_{q(\mathbf{y} | \mathbf{x})} \mathbb{E}[\log p(\mathbf{x}, \mathbf{y})] + H(\mathbf{y} | \mathbf{x}) \quad (9)$$

$$\equiv \max_{q(\mathbf{y} | \mathbf{x})} \sum_{j=1}^m \mathbb{E}[\log p(y_j | \mathbf{x})] + H(y_j | \mathbf{x}) \quad (10)$$

$$= \sum_{j=1}^m \max_{q(y_j | \mathbf{x})} \mathbb{E}[\log p(y_j | \mathbf{x})] + H(y_j | \mathbf{x}) \quad (11)$$

In the second line,  $\log p(\mathbf{x})$  is constant with respect to  $q(\mathbf{y} | \mathbf{x})$  and can be removed without changing the optimization problem. In this case, the ELBO separates into a sum of terms, each of which involves only a single  $y_j$ . This allows us to optimize the ELBO by updating each  $q(y_j | \mathbf{x})$  independently and in parallel.

In a general DEF, the  $y_j$ 's are not conditionally independent and the objective does not separate. However, without much manipulation, much of the ELBO does separate: for a single-layer DEF, the ELBO can be written

$$\log p(\mathbf{x}) \geq \mathbb{E}[\log p(\mathbf{x}, \mathbf{y})] + H(\mathbf{y}|\mathbf{x}) \quad (12)$$

$$= \sum_{i=1}^n \mathbb{E}[\log p(x_i|\mathbf{y})] + \sum_{j=1}^m \mathbb{E}[\log p(y_j)] + H(y_j|\mathbf{x}) \quad (13)$$

So only the  $\mathbb{E}[\log p(x_i|\mathbf{y})]$  terms aren't separable. However, if  $\eta_i$  is an affine function of  $\mathbf{y}$ , so  $\eta_i \equiv b_i + \mathbf{w}_i \cdot \mathbf{y}$  for some  $b_i \in \mathbb{R}$  and  $\mathbf{w}_i \in \mathbb{R}^m$ , then each  $\mathbb{E}[\log p(x_i|\mathbf{y})]$  term can be expanded

$$\mathbb{E}[\log p(x_i|\mathbf{y})] = g(x_i) + t(x_i)\mathbb{E}[\eta_i] - \mathbb{E}[a(\eta_i)] \quad (14)$$

$$= g(x_i) + t(x_i)(b_i + \mathbf{w}_i \cdot \mathbb{E}[\mathbf{y}]) - \mathbb{E}[a(b_i + \mathbf{w}_i \cdot \mathbf{y})] \quad (15)$$

From this we can see the only term left preventing the entire ELBO from separating is  $\mathbb{E}_{q(\mathbf{y}|\mathbf{x})}[-a(\eta_i(\mathbf{y}))]$ , a high-dimensional expectation of the non-linear log-partition function. The one thing we know about the log-partition function in exponential families is that it's convex. This suggests we use Jensen's inequality to bound  $\mathbb{E}[-a(\eta_i)]$ . Note that using Jensen's to bring the expectation over  $q$  inside  $a$  gives an inequality in the wrong direction because  $-a(\eta_i)$  is concave; to get a lower bound, we need to pull an expectation out from the inside of  $a$ . The derivation of the ELBO gives a hint on how to do this: recall

$$\log p(x) = \log \int p(x, y) dy \quad (16)$$

$$= \log \int \frac{q(y|x)}{q(y|x)} p(x, y) dy \quad (17)$$

$$= \log \mathbb{E}_{q(y|x)} \left[ \frac{p(x, y)}{q(y|x)} \right] \quad (18)$$

$$\geq \mathbb{E}_{q(y|x)} \left[ \log \frac{p(x, y)}{q(y|x)} \right] \quad (19)$$

In the same way, we will introduce a variational or auxiliary distribution inside the concave function  $-a(\eta)$ , then use Jensen's to pull it out. For each  $i$ , introduce an auxiliary discrete distribution over  $m$  categories  $\varepsilon_i \in \Delta^{m-1}$ , so

$$\sum_{j=1}^m \varepsilon_{ij} = 1 \quad \varepsilon_{ij} \geq 0 \quad \forall j \in [m] \quad (20)$$

Injecting this inside the log-partition function gives

$$\mathbb{E}[-a(b_i + \mathbf{w}_i \cdot \mathbf{y})] = \mathbb{E} \left[ -a \left( b_i + \sum_{j=1}^m \varepsilon_{ij} \frac{w_{ij} y_j}{\varepsilon_{ij}} \right) \right] \quad (21)$$

To use Jensen's inequality, we first need to bring  $b_i$  inside the sum, which we can do using  $b_i = \sum_{j=1}^m \varepsilon_{ij} b_i$ . This partitions the bias  $b_i$  into  $m$  parts according to  $\varepsilon_i$ . However, to get a sufficiently tight bound, we'll need to consider more general splittings: introduce another set of auxiliary parameters  $\hat{b}_i \in \mathbb{R}^m$  with the constraint  $b_i = \sum_{j=1}^m \varepsilon_{ij} \hat{b}_{ij}$ . Then

$$\begin{aligned} \mathbb{E}[-a(b_i + \mathbf{w}_i \cdot \mathbf{y})] &= \mathbb{E} \left[ -a \left( \sum_{j=1}^m \varepsilon_{ij} \left( \hat{b}_{ij} + \frac{w_{ij} y_j}{\varepsilon_{ij}} \right) \right) \right] \\ &\geq \sum_{j=1}^m \varepsilon_{ij} \mathbb{E} \left[ -a \left( \hat{b}_{ij} + \frac{w_{ij} y_j}{\varepsilon_{ij}} \right) \right] \end{aligned} \quad (22)$$

Bounding this term for each  $i$  separates the entire ELBO into a sum of terms, each of which involves only a single  $y_j$ . Plugging this in directly to get a final bound on log-likelihood results in an unwieldy expression, so first we will introduce new notation to simplify the bound.

#### 4.1 CONNECTION WITH FMM

To demonstrate the relation of the above bound and forest mixture models, let us define

$$\hat{\eta}_{ij} \equiv \hat{b}_{ij} + \frac{w_{ij} y_j}{\varepsilon_{ij}} \quad (23)$$

$$\hat{p}(x_i|y_j) \equiv \exp \{g(x_i) + t(x_i)\hat{\eta}_{ij} - a(\hat{\eta}_{ij})\} \quad (24)$$

Then  $\eta_i = \sum_{j=1}^m \varepsilon_{ij} \hat{\eta}_{ij}$  and the bound can be rewritten as follows:

$$\mathbb{E}[-a(\eta_i)] \geq \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[-a(\hat{\eta}_{ij})] \quad (25)$$

This expression can be used to impose bounds on each  $\mathbb{E}[\log p(x_i|\mathbf{y})]$ :

$$\mathbb{E}[\log p(x_i|\mathbf{y})] = g(x_i) + t(x_i)\mathbb{E}[\eta_i] - \mathbb{E}[a(\eta_i)] \quad (26)$$

$$\geq g(x_i) + t(x_i)\mathbb{E}[\eta_i] - \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[a(\hat{\eta}_{ij})] \quad (27)$$

$$= \sum_{j=1}^m \varepsilon_{ij} (g(x_i) + t(x_i)\mathbb{E}[\hat{\eta}_{ij}] - \mathbb{E}[a(\hat{\eta}_{ij})]) \quad (28)$$

$$= \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[\log \hat{p}(x_i|y_j)] \quad (29)$$

**input** : An observation  $\mathbf{x} \in \mathbb{R}^n$  and model parameters

$W \in \mathbb{R}^{n \times m}$ ,  $\mathbf{b} \in \mathbb{R}^n$ ,  $\sigma_y^2 \in \mathbb{R}$  and  $\sigma_x^2 \in \mathbb{R}$ .

**output**: The mean-field variational distribution

$$q(\mathbf{y}|\mathbf{x}) \equiv \prod_{j=1}^m q(y_j|\mathbf{x})$$

initialize  $(\mu_0)_j$  and  $(\sigma_0)_j^2$  for each  $j \in [m]$

**for**  $t = 0$  **to**  $T - 1$  **do**

**for**  $i = 1$  **to**  $n$  **do**

**for**  $j = 1$  **to**  $m$  **do**

$$(\varepsilon_t)_{ij} = \frac{|w_{ij}|(\sigma_t)_j}{\sum_{j'=1}^m |w_{ij'}|(\sigma_t)_{j'}^2}$$

$$(\hat{\mathbf{b}}_t)_{ij} = (b_i + \sum_{j=1}^m w_{ij}(\mu_t)_j) - \frac{w_{ij}(\mu_t)_j}{(\varepsilon_t)_{ij}}$$

**end**

**end**

**for**  $j = 1$  **to**  $m$  **do**

$$(\mu_{t+1})_j \equiv \frac{\sum_{i=1}^n w_{ij}(x_i - (\hat{\mathbf{b}}_t)_{ij})}{\frac{\sigma_x^2}{\sigma_y^2} + \sum_{i=1}^n \frac{w_{ij}^2}{(\varepsilon_t)_{ij}}}$$

$$(\sigma_{t+1})_j^2 \equiv \frac{1}{\frac{1}{\sigma_y^2} + \frac{1}{\sigma_x^2} \sum_{i=1}^n \frac{w_{ij}^2}{(\varepsilon_t)_{ij}}}$$

**end**

**end**

**return**  $q(y_j|\mathbf{x}) = \mathcal{N}((\mu_T)_j, (\sigma_T)_j^2)$  for  $j \in [m]$

**Algorithm 1**: The FM algorithm in the Gaussian case.

Finally, plugging the above expression into the ELBO gives

$$\begin{aligned} \log p(x) &\geq \mathbb{E}[\log p(\mathbf{x}, \mathbf{y})] + H(\mathbf{y}|\mathbf{x}) \\ &\geq \sum_{i=1}^n \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[\log \hat{p}(x_i|y_j)] \\ &\quad - \sum_{j=1}^m D_{KL}(q(\mathbf{y}|\mathbf{x}) \| p(\mathbf{y})) \end{aligned} \quad (30)$$

Comparing (30) with (6) confirms that this bound is *identical* to the ELBO of a forest mixture model with the same  $\hat{p}(x_i, y_j)$  and  $q(y_j|\mathbf{x})$ , with  $q(e_{ij} = 1|\mathbf{x}) = \varepsilon_{ij}$  (so that  $\mathbb{E}[e_{ij}] = \varepsilon_{ij}$ ) and  $p(e_i) = q(e_i|\mathbf{x})$  (so that the second  $KL$  term of the FMM ELBO is zero and disappears entirely). For this reason, we call this bound the *forest mixture bound* (FM bound). Note this bounds the DEF ELBO by the ELBO of each FMM in a large family of FMM's parameterized by  $\varepsilon \equiv \{\varepsilon_i\}_{i=1}^n$  and  $\hat{\mathbf{b}} \equiv \{\hat{\mathbf{b}}_i\}_{i=1}^n$ .

## 5 ALGORITHM

To optimize the FM bound, we propose an alternating maximization algorithm: in the first step, update all  $q(y_j|\mathbf{x})$  in parallel while holding all  $\varepsilon_{ij}$  and  $\hat{\mathbf{b}}_{ij}$  fixed; in the second step, update all  $\varepsilon_{ij}$  and  $\hat{\mathbf{b}}_{ij}$  in parallel while holding all  $q(y_j|\mathbf{x})$  fixed. In this section, we will derive the optimal updates for  $q(y_j|\mathbf{x})$ ,  $\varepsilon_{ij}$ , and  $\hat{\mathbf{b}}_{ij}$  in the case when each  $x_i$  and  $y_j$  are Gaussian with known variance:

$$p(y_j) = \mathcal{N}(0, \sigma_y^2) \quad p(x_i|\mathbf{y}) = \mathcal{N}(\eta_i(\mathbf{y}), \sigma_x^2) \quad (31)$$

We will derive the updates for the auxiliary parameters first since this will help simplify the update for the variational distribution later.

### 5.1 AUXILIARY PARAMETER UPDATES

Maximizing the FM bound over  $\varepsilon$  and  $\hat{\mathbf{b}}$  is equivalent to maximizing  $\mathcal{L}_i \equiv \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[-a(\hat{\eta}_{ij})]$  over  $\varepsilon_i$  and  $\hat{\mathbf{b}}_i$  for each  $i$ , since these are the only terms in the FM bound that depend on  $\varepsilon$  and  $\hat{\mathbf{b}}$ . In the Gaussian case,  $-a(\hat{\eta}_{ij}) = -\frac{1}{2\sigma_x^2} \hat{\eta}_{ij}^2$  and

$$\mathcal{L}_i = \sum_{j=1}^m \varepsilon_{ij} \mathbb{E} \left[ -\frac{1}{2\sigma_x^2} \hat{\eta}_{ij}^2 \right] \quad (32)$$

$$= -\frac{1}{2\sigma_x^2} \sum_{j=1}^m \varepsilon_{ij} \left( \text{Var}[\hat{\eta}_{ij}] + \mathbb{E}[\hat{\eta}_{ij}]^2 \right) \quad (33)$$

$$= -\frac{1}{2\sigma_x^2} \sum_{j=1}^m \frac{w_{ij}^2 \text{Var}[y_j]}{\varepsilon_{ij}} + \varepsilon_{ij} \left( \hat{\mathbf{b}}_{ij} + \frac{w_{ij} \mathbb{E}[y_j]}{\varepsilon_{ij}} \right)^2 \quad (34)$$

**Theorem 1** Holding  $q(y_j|\mathbf{x})$  constant, the choice of  $\hat{\mathbf{b}}_i$  and  $\varepsilon_i$  that maximizes  $\mathcal{L}_i$  is  $\hat{\mathbf{b}}_i = \hat{\mathbf{b}}_i^*$  and  $\varepsilon_i = \varepsilon_i^*$ , where

$$\hat{\mathbf{b}}_{ij}^* = \mathbb{E}[\eta_i] - \frac{w_{ij} \mathbb{E}[y_j]}{\varepsilon_{ij}^*} \quad \varepsilon_{ij}^* = \frac{|w_{ij}| \text{Std}[y_j]}{\sum_{j'=1}^m |w_{ij'}| \text{Std}[y_{j'}]} \quad (35)$$

For a proof, see Appendix A. Note that these computations can be parallelized across  $i$  and  $j$ .

### 5.2 VARIATIONAL UPDATES

Holding the auxiliary parameters fixed, each variational distribution  $q(y_j|\mathbf{x})$  can be updated in parallel:

**Theorem 2** For a fixed  $\varepsilon$  and  $\hat{\mathbf{b}}$ , the choice for the next variational distribution  $q_{t+1}(y_j|\mathbf{x})$  that maximizes the FM bound is  $q_{t+1}(y_j|\mathbf{x}) = \mathcal{N}((\mu_{t+1}^*)_j, (\sigma_{t+1}^*)_j^2)$ , where

$$(\mu_{t+1}^*)_j \equiv \frac{(\mathbf{x} - \mathbb{E}_{q_t}[\boldsymbol{\eta}]) \cdot \mathbf{w}_j + \mathbb{E}_{q_t}[y_j] \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}}}{\frac{\sigma_x^2}{\sigma_y^2} + \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}}} \quad (36)$$

$$(\sigma_{t+1}^*)_j^2 \equiv \frac{1}{\frac{1}{\sigma_y^2} + \frac{1}{\sigma_x^2} \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}}} \quad (37)$$

For a proof, see Appendix B.

## 6 DISCUSSION

**Tightness** We derived the FM bound by using Jensen’s inequality to lower bound the ELBO. For a given variational distribution  $q$ , the gap between the two bounds is

$$\text{GAP} \equiv \sum_{i=1}^n \mathbb{E}[-a(\eta_i)] - \sum_{i=1}^n \sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[-a(\hat{\eta}_{ij})] \quad (38)$$

In the Gaussian case, for an optimal choice of auxiliary parameters (see Appendix A),

$$\sum_{j=1}^m \varepsilon_{ij} \mathbb{E}[-a(\hat{\eta}_{ij})] = -\frac{1}{2\sigma_x^2} \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_1^2 - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (39)$$

$$\mathbb{E}[-a(\eta_i)] = -\frac{1}{2\sigma_x^2} \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_2^2 - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (40)$$

$$\text{GAP} = \frac{1}{2\sigma_x^2} \sum_{i=1}^n \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_1^2 - \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_2^2 \quad (41)$$

Since  $\sum_{i=1}^n \|\mathbf{w}_i\|_1^2 \geq \sum_{i=1}^n \|\mathbf{w}_i\|_2^2$ , the FM bound imposes a stronger regularization on the variance of the variational distribution compared to the variational ELBO. For this reason, the variational distribution  $q$  that maximizes the FM bound generally has a smaller variance compared to the variational distribution that maximizes the ELBO.

The FM bound tightly bounds the ELBO when  $p$  is a forest model, so that  $w_{ij}$  has exactly one non-zero element in the component  $j(i)$  corresponding to the parent of  $x_i$ . In this case,

$$\|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_1^2 = w_{ij(i)}^2 \text{Var}[y_{j(i)}] = \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_2^2 \quad (42)$$

The bound is also tight when  $\text{Var}[\mathbf{y}] = 0$ , but in this case both the ELBO and the FM bound yield  $-\infty$  because of the conditional entropy term  $H(\mathbf{y}|\mathbf{x})$ .

**Speed of Convergence** Let’s examine the role of  $\varepsilon$  in the update for  $q(y_j|\mathbf{x})$ . If  $\sum_{j=1}^m \frac{w_{ij}}{\varepsilon_{ij}}$  is large, then  $\mathbb{E}_{q_{t+1}} \approx \mathbb{E}_{q_t}[y_j]$ , and so the FM algorithm makes a small update for  $y_j$ . If  $\sum_{j=1}^m \frac{w_{ij}}{\varepsilon_{ij}}$  is small, then  $\mathbb{E}_{q_{t+1}}[y_j]$  makes a large step in the direction of the residual  $\mathbf{x} - \mathbb{E}[\boldsymbol{\eta}]$ . In fact, if for some  $j$ ,  $\varepsilon_{ij} = 1$  for all  $i$  where  $w_{ij}$  is non-zero, then the FM algorithm updates

$q(y_j|\mathbf{x})$  exactly as CAVI would. In this sense,  $\varepsilon$  acts like an attention parameter that selects which  $q(y_j|\mathbf{x})$  to change and by how much.

If  $p$  is a forest model, then the FM algorithm chooses  $\varepsilon_i$  to be the one-hot vector indicating the parent of  $x_i$ . In this case, the FM algorithm makes coordinate updates for all  $j$  in parallel and converges in one iteration. If  $p$  is forest-like, i.e.,  $|\mathbf{w}_j| \cdot |\mathbf{w}_{j'}|$  is small for  $j \neq j'$ , then  $\varepsilon_i$  is close to one-hot and the FM algorithm makes damped, nearly-CAVI updates in parallel. In this sense, the speed at which the FM algorithm converges depends on how inherently forest-like the model  $p$  is.

## 7 EXPERIMENTS

Recall that we derived the FM bound by lower bounding the ELBO. Algorithms that optimize the ELBO like CAVI will generally provide a superior lower bound on log-likelihood compared to the FM algorithm. For a more fair comparison, we can instead measure how quickly these algorithms converge to the optimal mean. In the Gaussian case, optimizing the mean of the mean-field variational distribution is equivalent to minimizing a ridge regression objective:

$$\frac{1}{2\sigma_x^2} \sum_{i=1}^n (x_i - (b_i + \mathbf{w}_i \cdot \mathbb{E}[\mathbf{y}]))^2 + \frac{1}{2\sigma_y^2} \sum_{j=1}^m \mathbb{E}[y_j]^2 \quad (43)$$

To evaluate each algorithm on the ridge regression problem, we must first choose a  $\mathbf{x}$ ,  $\mathbf{b}$ , and a set of  $w_{ij}$ . All the algorithms we consider in this section are guaranteed to converge to the optimal solution, so we are only interested in comparing how quickly each algorithm converges to that optimal solution. This is measured by recording the objective value achieved by the mean of the variational distribution  $\mathbb{E}_{q_t}[\mathbf{y}]$  in the ridge regression problem across 200 iterations.

In the first experiment, we choose  $\mathbf{x}$  to be a vectorized sample from the MNIST dataset, with pixel values scaled to lie in the interval  $[-1, 1]$ ; we choose  $\mathbf{b}$  to be the average of 1000 randomly chosen MNIST samples; and we construct a synthetic  $w_{ij}$  as follows: given an integer window side length  $s$ , we construct all possible square  $s \times s$  windows of pixels. For windows that overlap the border of the  $28 \times 28$  MNIST image region, we clip the window so that it lies entirely inside the image region, resulting in a rectangular window. For each window, we add a latent variable  $y_j$  to the model and a corresponding  $\mathbf{w}_j$ , where  $w_{ij} = 1$  if pixel  $i$  lies in window  $j$ , and  $w_{ij} = 0$  otherwise. The resulting model is more forest-like for smaller choices of  $s$ : if  $s = 1$ , the windows are

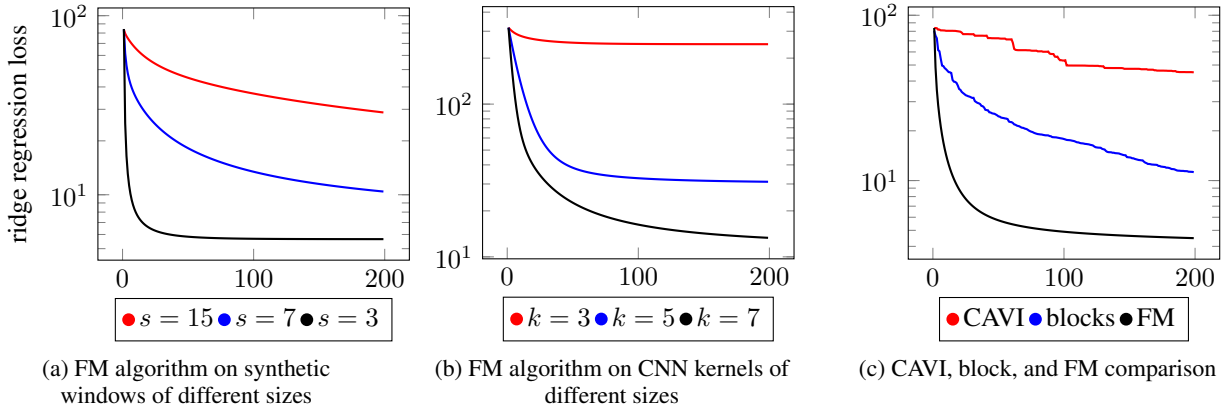

Figure 2: The ridge regression objective over 200 iterations.

disjoint and the graphical model is exactly a forest. Figure 2a demonstrates the rate of convergence of the FM algorithm for various choices of  $s$ . As we expect, the FM algorithm converges faster for more forest-like models, i.e., smaller  $s$ . Note that the objective value achieved by the optimal solution to the ridge regression problem changes as  $w_{ij}$  changes.

The second experiment is similar to the first, except it uses  $\mathbf{x}$  from the CIFAR-10 dataset,  $\mathbf{b} = 0$ , and instead of uniform windows, uses the first layer kernels from a convolutional neural net trained several times changing only the width of the first layer kernels. Figure 2b demonstrates the FM algorithm converges faster for more forest-like models even using real-world data.

Our last experiment compares the convergence of the FM algorithm with CAVI and block coordinate ascent. Here we choose  $\mathbf{x}$  and  $\mathbf{b}$  the same as in the first experiment, but we choose  $w_{ij}$  differently to make blocking the latent variables easy: first we partition the  $28 \times 28$  MNIST image region into 16 regions, each of size  $7 \times 7$ . Then, we construct all possible  $7 \times 7$  windows (as in the first experiment with  $s = 7$ ), then clip them to fit in the first region. This is repeated for each region. If we block the latent variables according to which region the corresponding windows were clipped to, then the blocks will be conditionally independent, since windows clipped to different regions must be disjoint. Blocking in this way guarantees that the block coordinate algorithm will converge to the optimal solution. Figure 2c compares the rate of convergence for CAVI, block coordinate ascent, and the FM algorithm. The figure shows our block-free method can outperform the block coordinate method, even when the blocking is quite good.

## 8 CONCLUSION

In this paper we derived a forest mixture bound on the log-likelihood of deep exponential families. This bound gets around the “explaining away effect” by using a set of auxiliary parameters to separate the problem of inference for each latent variable in the same layer, allowing us to make parallel updates. We then made a deep dive into the simple case where all variables are Gaussian: we derived the exact variable updates, then tested the algorithm on both synthetic and real-world data. Our promising results show that fast, parallel inference in deep exponential families is possible without the use of blocks.

## A AUXILIARY PARAMETER UPDATES

**Proof of Theorem 1:** First, we will find the optimal choice of  $\hat{\mathbf{b}}_i$  for any given  $\varepsilon_i$ . Since  $\hat{\mathbf{b}}_i$  is constrained by  $\sum_{j=1}^m \varepsilon_{ij} \hat{b}_{ij} = b_i$ , let’s first parameterize  $\hat{\mathbf{b}}_i$  by a set of unconstrained parameters: let  $\gamma_i \in \mathbb{R}^m$  and write

$$\hat{b}_{ij} = b_i - \gamma_{ij} + \varepsilon_i \cdot \gamma_i \quad (44)$$

So for any choice of  $\gamma_i$ , the constraint  $b_i = \sum_{j=1}^m \varepsilon_{ij} \hat{b}_{ij}$  is satisfied. Now we can differentiate the bound with respect to  $\gamma_{ij}$ , set to zero and solve. We will need the following partial derivatives:

$$\frac{\partial \hat{b}_{ij}}{\partial \gamma_{ij}} = -1 + \varepsilon_{ij} \quad \frac{\partial \hat{b}_{ij'}}{\partial \gamma_{ij}} = \varepsilon_{ij} \quad \forall j' \neq j \quad (45)$$

Now setting the partial derivative of  $\mathcal{L}_i$  with respect to  $\gamma_{ij}$  to zero,

$$0 = \frac{\partial}{\partial \gamma_{ij}} \mathcal{L}_i = -\frac{1}{\sigma_x^2} \sum_{j'=1}^m \varepsilon_{ij'} \mathbb{E}[\hat{\eta}_{ij'}] \frac{\partial \hat{b}_{ij'}}{\partial \gamma_{ij}} \quad (46)$$

$$= \frac{\varepsilon_{ij}}{\sigma_x^2} \left( \mathbb{E}[\hat{\eta}_{ij}] - \sum_{j'=1}^m \varepsilon_{ij'} \mathbb{E}[\hat{\eta}_{ij'}] \right) \quad (47)$$

The derivative is zero for all  $j$  in particular when the choice of  $\hat{b}_{ij}$  makes  $\mathbb{E}[\hat{\eta}_{ij}]$  constant across  $j$ . We can verify this is satisfied by the choice  $\gamma_{ij} = \frac{w_{ij}}{\varepsilon_{ij}} \mathbb{E}[y_j]$ , which makes  $\hat{b}_{ij} = \hat{b}_{ij}^*$ :

$$\mathbb{E}[\hat{\eta}_{ij}] = \mathbb{E} \left[ \hat{b}_{ij} + \frac{w_{ij}}{\varepsilon_{ij}} y_j \right] \quad (48)$$

$$= \mathbb{E} \left[ \mathbb{E}[\eta_i] - \frac{w_{ij}}{\varepsilon_{ij}} \mathbb{E}[y_j] + \frac{w_{ij}}{\varepsilon_{ij}} y_j \right] \quad (49)$$

$$= \mathbb{E}[\eta_i] \quad (50)$$

Plugging this choice into  $\mathcal{L}_i$  yields

$$\mathcal{L}_i = -\frac{1}{2\sigma_x^2} \sum_{j=1}^m \left( \frac{w_{ij}^2 \text{Var}[y_j]}{\varepsilon_{ij}} + \varepsilon_{ij} \mathbb{E}[\eta_i]^2 \right) \quad (51)$$

$$= -\frac{1}{2\sigma_x^2} \left( \sum_{j=1}^m \frac{w_{ij}^2 \text{Var}[y_j]}{\varepsilon_{ij}} \right) - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (52)$$

Now let's try to find the optimal choice of  $\varepsilon_{ij}$ . Since  $\varepsilon_{ij}$  is constrained by  $\varepsilon_i \in \Delta^{m-1}$ , we'll also parameterize  $\varepsilon_{ij}$  by a set of unconstrained parameters  $\tau_i \in \mathbb{R}^m$ :

$$\varepsilon_{ij} = \exp\{\tau_{ij}\} / \sum_{j'=1}^m \exp\{\tau_{ij'}\} \quad (53)$$

We will need the following partial derivatives:

$$\frac{\partial \varepsilon_{ij}}{\partial \tau_{ij}} = \varepsilon_{ij}(1 - \varepsilon_{ij}) \quad \frac{\partial \varepsilon_{ij'}}{\partial \tau_{ij}} = -\varepsilon_{ij} \varepsilon_{ij'} \quad \forall j' \neq j \quad (54)$$

Now setting the partial derivative of  $\mathcal{L}_i$  with respect to  $\tau_{ij}$  to zero,

$$0 = \frac{\partial}{\partial \tau_{ij}} \mathcal{L}_i = \frac{1}{2\sigma_x^2} \sum_{j'=1}^m \frac{w_{ij'}^2 \text{Var}[y_{j'}]}{\varepsilon_{ij'}^2} \frac{\partial \varepsilon_{ij'}}{\partial \tau_{ij}} \quad (55)$$

$$= \frac{1}{2\sigma_x^2} \sum_{j'=1}^m \text{Var}[\hat{\eta}_{ij'}] \frac{\partial \varepsilon_{ij'}}{\partial \tau_{ij}} \quad (56)$$

$$= \frac{\varepsilon_{ij}}{2\sigma_x^2} \left( \text{Var}[\hat{\eta}_{ij}] - \sum_{j'=1}^m \varepsilon_{ij'} \text{Var}[\hat{\eta}_{ij'}] \right) \quad (57)$$

The derivative is zero for all  $j$  in particular when the choice of  $\varepsilon_{ij}$  makes  $\text{Var}[\hat{\eta}_{ij}]$  constant across  $j$ . We can verify this is satisfied by the choice  $\tau_{ij} = \log |w_{ij} \text{Std}[y_j]|$ , which makes  $\varepsilon_{ij} = \varepsilon_{ij}^*$ :

$$\text{Var}[\hat{\eta}_{ij}] = \frac{w_{ij}^2 \text{Var}[y_j]}{\varepsilon_{ij}^2} \quad (58)$$

$$= \frac{w_{ij}^2 \text{Var}[y_j]}{w_{ij}^2 \text{Var}[y_j] / \left( \sum_{j'=1}^m |w_{ij'}| \text{Std}[y_{j'}] \right)^2} \quad (59)$$

$$= \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_1^2 \quad (60)$$

Plugging this choice into  $\mathcal{L}_i$  yields

$$\mathcal{L}_i = -\frac{1}{2\sigma_x^2} \sum_{j=1}^m |w_{ij}| \text{Std}[y_j] \left( \sum_{j'=1}^m |w_{ij'}| \text{Std}[y_{j'}] \right) - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (61)$$

$$= -\frac{1}{2\sigma_x^2} \left( \sum_{j=1}^m |w_{ij}| \text{Std}[y_j] \right)^2 - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (62)$$

$$= -\frac{1}{2\sigma_x^2} \|\mathbf{w}_i \odot \text{Std}[\mathbf{y}]\|_1^2 - \frac{1}{2\sigma_x^2} \mathbb{E}[\eta_i]^2 \quad (63)$$

## B VARIATIONAL UPDATES

Proof of **Theorem 2**: First, note that for any DEF, the optimal update equation is as follows:

$$\log q_{t+1}(y_j | \mathbf{x}) \propto \log p(y_j) + \sum_{i=1}^n \varepsilon_{ij} \log \hat{p}_t(x_i | y_j) \quad (64)$$

In the Gaussian case, we have

$$\log p(y_j) \propto -\frac{1}{2\sigma_y^2} y_j^2 \quad (65)$$

$$\log \hat{p}(x_i|y_j) \propto -\frac{1}{2\sigma_x^2} (x_i - \hat{\eta}_{ij})^2 \quad (66)$$

$$\propto -\frac{1}{2\sigma_x^2} \left( x_i - \left( \hat{b}_{ij} + \frac{w_{ij}}{\varepsilon_{ij}} y_j \right) \right)^2 \quad (67)$$

$$\propto \frac{1}{\sigma_x^2} \frac{(x_i - \hat{b}_{ij})w_{ij}}{\varepsilon_{ij}} y_j - \frac{1}{2\sigma_x^2} \frac{w_{ij}^2}{\varepsilon_{ij}^2} y_j^2 \quad (68)$$

Plugging this in yields

$$\log q(y_j|\mathbf{x}) \propto \frac{1}{\sigma_x^2} \left( (\mathbf{x} - \hat{\mathbf{b}}_j) \cdot \mathbf{w}_j \right) y_j - \frac{1}{2} y_j^2 \left( \frac{1}{\sigma_y^2} + \frac{1}{\sigma_x^2} \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}} \right) \quad (69)$$

$$\propto -\frac{1}{\sigma_x^2} \left( (\mathbf{x} - \hat{\mathbf{b}}_j) \cdot \mathbf{w}_j \right) y_j - \frac{1}{2(\sigma_{t+1}^*)^2} y_j^2 \quad (70)$$

$$\propto -\frac{1}{2(\sigma_{t+1}^*)^2} \left( y_j - \frac{\frac{1}{\sigma_x^2} (\mathbf{x} - \hat{\mathbf{b}}_j) \cdot \mathbf{w}_j}{\frac{1}{\sigma_y^2} + \frac{1}{\sigma_x^2} \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}}} \right)^2 \quad (71)$$

$$\propto -\frac{1}{2(\sigma_{t+1}^*)^2} \left( y_j - \frac{(\mathbf{x} - \hat{\mathbf{b}}_j) \cdot \mathbf{w}_j}{\frac{\sigma_x^2}{\sigma_y^2} + \sum_{i=1}^n \frac{w_{ij}^2}{\varepsilon_{ij}}} \right)^2 \quad (72)$$

After substituting  $\hat{b}_{ij} = \mathbb{E}[\eta_i] - \frac{w_{ij}}{\varepsilon_{ij}} \mathbb{E}_{q_t}[y_j]$  and rearranging, we get  $\log q_{t+1}(y_j|\mathbf{x}) \propto \mathcal{N}((\mu_{t+1}^*)_{ij}, (\sigma_{t+1}^*)_{ij}^2)$ .

## C EXTENSION TO DEEP MODELS

A DEF model with observed variables  $\mathbf{y}^{(0)} \in \mathbb{R}^{m_0}$  and  $L$  layers of latent variables  $\{\mathbf{y}^{(\ell)}\}_{\ell=1}^L$  with  $\mathbf{y}^{(\ell)} \in \mathbb{R}^{m_\ell}$  has joint distribution

$$p(\{\mathbf{y}^{(\ell)}\}_{\ell=0}^L) = \left[ \prod_{\ell=0}^{L-1} \prod_{i=1}^{m_\ell} p(y_i^{(\ell)}|\mathbf{y}^{(\ell+1)}) \right] \left[ \prod_{i=1}^{m_L} p(y_i^{(L)}) \right] \quad (73)$$

$$p(y_i^{(\ell)}|\mathbf{y}^{(\ell+1)}) = \exp \left\{ g(y_i^{(\ell)}) + t(y_i^{(\ell)})\eta_i^{(\ell)} - a(\eta_i^{(\ell)}) \right\} \quad (74)$$

$$\eta_i^{(\ell)} \equiv b_i^{(\ell)} + \mathbf{w}_i^{(\ell)} \cdot \mathbf{y}^{(\ell+1)} \quad (75)$$

The ELBO for this model is

$$\log p(\mathbf{y}^{(0)}) \geq \sum_{i=1}^{m_0} \mathbb{E}[\log p(y_i^{(0)}|\mathbf{y}^{(1)})] \quad (76)$$

$$+ \sum_{\ell=1}^{L-1} \sum_{i=1}^{m_\ell} \mathbb{E}[\log p(y_i^{(\ell)}|\mathbf{y}^{(\ell+1)})] + H_q(\mathbf{y}_i^{(\ell)}|\mathbf{y}^{(0)}) \quad (77)$$

$$+ \sum_{i=1}^{m_L} p(y_i^{(L)}) + H_q(\mathbf{y}_i^{(L)}|\mathbf{y}^{(0)}) \quad (78)$$

For each  $\ell \in \{0, \dots, L-1\}$ , introduce the auxiliary parameters  $\{\varepsilon_i^{(\ell)}\}_{i=1}^{m_\ell}$  and  $\{\hat{\mathbf{b}}_i^{(\ell)}\}_{i=1}^{m_\ell}$ , with  $\varepsilon_i^{(\ell)} \in \Delta^{m_{\ell+1}-1}$  and  $\hat{\mathbf{b}}_i^{(\ell)} \in \mathbb{R}^{m_{\ell+1}}$  constrained by  $b_i^{(\ell)} = \sum_{j=1}^{m_{\ell+1}} \varepsilon_{ij}^{(\ell)} \hat{b}_{ij}^{(\ell)}$ . For all  $\ell \in \{0, \dots, L-1\}$ ,  $i \in [m_\ell]$ , and  $j \in [m_{\ell+1}]$ , define

$$\hat{\eta}_{ij}^{(\ell)} \equiv \hat{b}_{ij}^{(\ell)} + \frac{w_{ij}^{(\ell)}}{\varepsilon_{ij}^{(\ell)}} y_j^{(\ell+1)} \quad (79)$$

$$\hat{p}(y_i^{(\ell)}|\mathbf{y}_j^{(\ell+1)}) \equiv \exp\{g(y_i^{(\ell)}) + t(y_i^{(\ell)})\hat{\eta}_{ij}^{(\ell)} - a(\hat{\eta}_{ij}^{(\ell)})\} \quad (80)$$

Then by (25),

$$\mathbb{E}[\log p(y_i^{(\ell)}|\mathbf{y}^{(\ell+1)})] \geq \sum_{j=1}^{m_{\ell+1}} \varepsilon_{ij}^{(\ell)} \mathbb{E}[\log \hat{p}(y_i^{(\ell)}|\mathbf{y}_j^{(\ell+1)})] \quad (81)$$

Plugging this into the ELBO yields

$$\log p(\mathbf{y}^{(0)}) \geq \sum_{i=1}^{m_0} \sum_{j=1}^{m_1} \varepsilon_{ij}^{(0)} \mathbb{E}[\log \hat{p}(y_i^{(0)}|\mathbf{y}_j^{(1)})] \quad (82)$$

$$+ \sum_{\ell=1}^{L-1} \sum_{i=1}^{m_\ell} \sum_{j=1}^{m_{\ell+1}} \varepsilon_{ij}^{(\ell)} \mathbb{E}[\log \hat{p}(y_i^{(\ell)}|\mathbf{y}_j^{(\ell+1)})] + H_q(\mathbf{y}_i^{(\ell)}|\mathbf{y}^{(0)}) \quad (83)$$

$$+ \sum_{i=1}^{m_L} p(y_i^{(L)}) + H_q(\mathbf{y}_i^{(L)}|\mathbf{y}^{(0)}) \quad (84)$$

This objective separates as a sum of terms, each of which involves no more than one latent variable in the same layer. This allows any group of variables forming an independent set in the model graph to be updated in parallel, the same as for undirected models.

## Abstract

Assessing the magnitude of cause-and-effect relations is one of the central challenges found throughout the empirical sciences. The problem of identification of causal effects is concerned with determining whether a causal effect can be computed from a combination of observational data and substantive knowledge about the domain under investigation, which is formally expressed in the form of a causal graph. In many practical settings, however, the knowledge available for the researcher is not strong enough so as to specify a unique causal graph. Another line of investigation attempts to use observational data to learn a qualitative description of the domain called a Markov equivalence class, which is the collection of causal graphs that share the same set of observed features. In this paper, we marry both approaches and study the problem of causal identification from an equivalence class, represented by a partial ancestral graph (PAG). We start by deriving a set of graphical properties of PAGs that are carried over to its induced subgraphs. We then develop an algorithm to compute the effect of an arbitrary set of variables on an arbitrary outcome set. We show that the algorithm is strictly more powerful than the current state of the art found in the literature.

## 1 INTRODUCTION

Science is about explaining the mechanisms underlying a phenomenon that is being investigated. One of the marks imprinted by these mechanisms in reality is cause and effect relationships. Systematically discovering the existence, and magnitude, of causal relations constitutes,

therefore, a central task in scientific domains. The value of inferring causal relationships is also tremendous in other, more practical domains, including, for example, engineering and business, where it is often crucial to understand how to bring about a specific change when a constrained amount of controllability is in place. If our goal is to build AI systems that can act and learn autonomously, formalizing the principles behind causal inference, so that these systems can leverage them, is a fundamental requirement (Pearl and Mackenzie, 2018).

One prominent approach to infer causal relations leverages a combination of substantive knowledge about the domain under investigation, usually encoded in the form of a causal graph, with observational (non-experimental) data (Pearl, 2000; Spirtes et al., 2001; Bareinboim and Pearl, 2016). A sample causal graph is shown in Fig. 1a such that the nodes represent variables, directed edges represent direct causal relation from tails to heads, and bi-directed arcs represent the presence of unobserved (latent) variables that generate a spurious association between the variables, also known as *confounding bias* (Pearl, 1993). The task of determining whether an interventional (experimental) distribution can be computed from a combination of observational and experimental data together with the causal graph is known as the problem of identification of causal effects (identification, for short). For instance, a possible task in this case is to identify the effect of  $do(X=x)$  on  $V_4=v_4$ , i.e.  $P_x(v_4)$ , given the causal graph in Fig. 1a and data from the observational distribution  $P(x, v_1, \dots, v_4)$ .

The problem of identification has been extensively studied in the literature, and a number of criteria have been established (Pearl, 1993; Galles and Pearl, 1995; Kuroki and Miyakawa, 1999; Tian and Pearl, 2002; Huang and Valtorta, 2006; Shpitser and Pearl, 2006; Bareinboim and Pearl, 2012), which include the celebrated back-door criterion and the do-calculus (Pearl, 1995). Despite their power, these techniques require a fully specified causal graph, which is not always available in practical settings.

Another line of investigation attempts to learn a qualitative description of the system, which in the ideal case would lead to the “true” data-generating model, the blueprint underlying the phenomenon being investigated. These efforts could certainly be deemed more “data-driven” and aligned with the zeitgeist in machine learning. In practice, however, it is common that only an equivalence class of causal models can be consistently inferred from observational data (Verma, 1993; Spirtes et al., 2001; Zhang, 2008b). One useful characterization of such an equivalence class comes under the rubric of *partial ancestral graphs (PAGs)*, which will be critical to our work. Fig. 1 shows the PAG (right) that can be inferred from observational data that is consistent with the true causal model (left). The directed edges in a PAG signify ancestral relations (not necessarily direct) and circle marks stand for structural uncertainty.

In this paper, we analyze the marriage of these two lines of investigation, where the structural invariance learned in the equivalence class will be used as input to identify the strength of causal effect relationships, if possible. Identification from an equivalence class is considerably more challenging than from a single diagram due to the structural uncertainty regarding both the direct causal relations among the variables and the presence of latent variables that confounds causal relations between observed variables. Still, there is a growing interest in identifiability results in this setting (Maathuis et al., 2010). Zhang (2007) extended the do-calculus to PAGs. In practice, however, it is in general computationally hard to decide whether there exists (and, if so, find) a sequence of applications of the rules of the generalized calculus to identify the interventional distribution. Perković et al. (2015) generalized the back-door criterion to PAGs, and provided a sound and complete algorithm to find a back-door admissible set, should such a set exist. However, in practice, the back-door criterion is not as powerful as the do-calculus, since no adjustment set exists for many identifiable causal effects. Jaber et al. (2018b) generalized the work of (Tian and Pearl, 2002) and devised a graphical criterion to identify causal effects with singleton interventions in PAGs.<sup>1</sup>

Building on this work, we develop here a decomposition strategy akin to the one introduced in (Tian, 2002) to identify causal effects given a PAG. Our proposed approach is computationally more attractive than the do-calculus as it provides a systematic procedure to identify

<sup>1</sup>Another possible approach is based on SAT (boolean constraint satisfaction) solvers (Hyttinen et al., 2015). Given its somewhat distinct nature, a closer comparison lies outside the scope of this paper. We note, however, that an open research direction would be to translate our systematic approach into logical rules so as to help improving the solver’s scalability.

Figure 1: A causal model (left) and the inferred PAG (right).

a causal effect, if identifiable. It is also more powerful than the generalized adjustment criterion, as we show later. More specifically, our main contributions are:

1. We study some critical properties of PAGs and show that they also hold in induced subgraphs of a PAG over an arbitrary subset of nodes. We further study Tian’s *c*-component decomposition and relax it to PAGs (when only partial knowledge about the ancestral relations and *c*-components is available).
2. We formulate a systematic procedure to compute the effect of an arbitrary set of intervention variables on an arbitrary outcome set from a PAG and observational data. We show that this algorithm is strictly more powerful than the adjustment criterion.

## 2 PRELIMINARIES

In this section, we introduce the basic notation and machinery used throughout the paper. Bold capital letters denote sets of variables, while bold lowercase letters stand for particular assignments to those variables.

**Structural Causal Models.** We use the language of Structural Causal Models (SCM) (Pearl, 2000, pp. 204–207) as our basic semantic framework. Formally, an SCM  $M$  is a 4-tuple  $\langle U, V, F, P(u) \rangle$ , where  $U$  is a set of exogenous (latent) variables and  $V$  is a set of endogenous (measured) variables.  $F$  represents a collection of functions  $F = \{f_i\}$  such that each endogenous variable  $V_i \in V$  is determined by a function  $f_i \in F$ , where  $f_i$  is a mapping from the respective domain of  $U_i \cup Pa_i$  to  $V_i$ ,  $U_i \subseteq U$ ,  $Pa_i \subseteq V \setminus V_i$ . The uncertainty is encoded through a probability distribution over the exogenous variables,  $P(u)$ . A causal diagram associated with an SCM encodes the structural relations among  $V \cup U$ , in which an arrow is drawn from each member of  $U_i \cup Pa_i$  to  $V_i$ . We constraint our results to recursive systems, which means that the corresponding diagram will be acyclic. The marginal distribution over the endogenous variables  $P(v)$  is called observational, and factorizes according to the causal diagram, i.e.:

$$P(v) = \sum_u \prod_i P(v_i | pa_i, u_i) P(u)$$

Within the structural semantics, performing an action  $X=x$  is represented through the do-operator,  $do(X=x)$ , which encodes the operation of replacing the original equation for  $X$  by the constant  $x$  and induces a submodel  $M_x$ . The resulting distribution is denoted by  $P_x$ , which is the main target for identification in this paper. For details on structural models, we refer readers to (Pearl, 2000).

**Ancestral Graphs.** We now introduce a graphical representation of equivalence classes of causal diagrams. A *mixed* graph can contain directed ( $\rightarrow$ ) and bi-directed edges ( $\leftrightarrow$ ).  $A$  is a *spouse* of  $B$  if  $A \leftrightarrow B$  is present. An *almost directed cycle* happens when  $A$  is both a spouse and an ancestor of  $B$ . An *inducing path relative to  $\mathbf{L}$*  is a path on which every node  $V \notin \mathbf{L}$  (except for the endpoints) is a collider on the path (i.e., both edges incident to  $V$  are into  $V$ ) and every collider is an ancestor of an endpoint of the path. A mixed graph is *ancestral* if it doesn't contain a directed or almost directed cycle. It is *maximal* if there is no inducing path (relative to the empty set) between any two non-adjacent nodes. A *Maximal Ancestral Graph* (MAG) is a graph that is both ancestral and maximal. MAG models are closed under marginalization (Richardson and Spirtes, 2002).

In general, a causal MAG represents a set of causal models with the same set of observed variables that entail the same independence and ancestral relations among the observed variables. Different MAGs may be Markov equivalent in that they entail the exact same independence model. A partial ancestral graph (PAG) represents an equivalence class of MAGs  $[\mathcal{M}]$ , which shares the same adjacencies as every MAG in  $[\mathcal{M}]$  and displays all and only the invariant edge marks.

**Definition 1 (PAG).** Let  $[\mathcal{M}]$  be the Markov equivalence class of an arbitrary MAG  $\mathcal{M}$ . The PAG for  $[\mathcal{M}]$ ,  $\mathcal{P}$ , is a partial mixed graph such that:

- i.  $\mathcal{P}$  has the same adjacencies as  $\mathcal{M}$  (and hence any member of  $[\mathcal{M}]$ ) does.
- ii. An arrowhead is in  $\mathcal{P}$  iff shared by all MAGs in  $[\mathcal{M}]$ .
- iii. A tail is in  $\mathcal{P}$  iff shared by all MAGs in  $[\mathcal{M}]$ .
- iv. A mark that is neither an arrowhead nor a tail is recorded as a circle.

A PAG is learnable from the conditional independence and dependence relations among the observed variables and the FCI algorithm is a standard method to learn such an object (Zhang, 2008b). In short, a PAG represents an equivalence class of causal models with the same observed variables and independence model.

**Graphical Notions.** Given a DAG, MAG, or PAG, a path between  $X$  and  $Y$  is *potentially directed* (causal)

from  $X$  to  $Y$  if there is no arrowhead on the path pointing towards  $X$ .  $Y$  is called a *possible descendant* of  $X$  and  $X$  a *possible ancestor* of  $Y$  if there is a potentially directed path from  $X$  to  $Y$ . A set  $\mathbf{A}$  is (*descendant*) *ancestral* if no node outside  $\mathbf{A}$  is a possible (descendant) ancestor of any node in  $\mathbf{A}$ .  $Y$  is called a *possible child* of  $X$ , i.e.  $Y \in \text{Ch}(X)$ , and  $X$  a *possible parent* of  $Y$ , i.e.  $X \in \text{Pa}(Y)$ , if they are adjacent and the edge is not into  $X$ . For a set of nodes  $\mathbf{X}$ , we have  $\text{Pa}(\mathbf{X}) = \cup_{X \in \mathbf{X}} \text{Pa}(X)$  and  $\text{Ch}(\mathbf{X}) = \cup_{X \in \mathbf{X}} \text{Ch}(X)$ . Given two sets of nodes  $\mathbf{X}$  and  $\mathbf{Y}$ , a path between them is called *proper* if one of the endpoints is in  $\mathbf{X}$  and the other is in  $\mathbf{Y}$ , and no other node on the path is in  $\mathbf{X}$  or  $\mathbf{Y}$ . For convenience, we use an asterisk (\*) to denote any possible mark of a PAG ( $\circ, >, -$ ) or a MAG ( $>, -$ ). If the edge marks on a path between  $X$  and  $Y$  are all circles, we call the path a *circle path*.

A directed edge  $X \rightarrow Y$  in a MAG or PAG is *visible* if there exists no DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  in the corresponding equivalence class where there is an inducing path between  $X$  and  $Y$  that is into  $X$  relative to  $\mathbf{L}$ . This implies that a visible edge is not confounded ( $X \leftarrow U_i \rightarrow Y$  doesn't exist). Which directed edges are visible is easily decidable by a graphical condition (Zhang, 2008a), so we simply mark visible edges by  $v$ . For brevity, we refer to any edge that is not a visible directed edge as *invisible*.

**Identification Given a Causal DAG.** Tian and Pearl (2002) presented an identification algorithm based on a decomposition strategy of the DAG into a set of so-called *c-components* (confounded components).

**Definition 2 (C-Component).** In a causal DAG, two observed variables are said to be in the same *c-component* if and only if they are connected by a bi-directed path, i.e. a path composed solely of such bi-directed treks as  $V_i \leftarrow U_{ij} \rightarrow V_j$ , where  $U_{ij}$  is an exogenous variable.

For convenience, we often refer to a bi-directed trek like  $V_i \leftarrow U_{ij} \rightarrow V_j$  as a bi-directed edge between  $V_i$  and  $V_j$  (and  $U_{ij}$  is often left implicit). For any set  $\mathbf{C} \subseteq \mathbf{V}$ , we define the quantity  $Q[\mathbf{C}]$  to denote the post-intervention distribution of  $\mathbf{C}$  under an intervention on  $\mathbf{V} \setminus \mathbf{C}$ :

$$Q[\mathbf{C}] = P_{\mathbf{v} \setminus \mathbf{c}}(\mathbf{c}) = \sum_u \prod_{\{i|V_i \in \mathbf{C}\}} P(v_i | pa_i, u_i) P(u)$$

The significance of c-components and their decomposition is evident from (Tian, 2002, Lemmas 10, 11), which are the basis of Tian's identification algorithm.

### 3 REVISIT IDENTIFICATION IN DAGS

We revisit the identification results in DAGs, focusing on Tian's algorithm (Tian, 2002). Our goal here is to have an amenable algorithm that allows the incorporation of the structural uncertainties arising in the equivalence class.

Let  $\mathcal{D}_A$  denote the (induced) subgraph of a DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  over  $\mathbf{A} \subseteq \mathbf{V}$  and the latent parents of  $\mathbf{A}$  (i.e.  $\text{Pa}(\mathbf{A}) \cap \mathbf{L}$ ). The original algorithm (Alg. 5 in (Tian, 2002)) alternately applies Lemmas 10 and 11 in (Tian, 2002) until a solution is derived or a failure condition is triggered. We rewrite this algorithm with a more local, atomic criterion based on the following results.

**Definition 3** (Composite C-Component). *Given a DAG that decomposes into c-components  $S_1, \dots, S_k$ ,  $k \geq 1$ , a composite c-component is the union of one or more of these c-components.*

**Lemma 1.** *Given a DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$ ,  $\mathbf{X} \subset \mathbf{T} \subseteq \mathbf{V}$ , and  $P_{\mathbf{V} \setminus \mathbf{T}}$  the interventional distribution of  $\mathbf{V} \setminus \mathbf{T}$  on  $\mathbf{T}$ . Let  $S^{\mathbf{X}}$  denote a composite c-component containing  $\mathbf{X}$  in  $\mathcal{D}_{\mathbf{T}}$ . If  $\mathbf{X}$  is a descendant set in  $\mathcal{D}_{S^{\mathbf{X}}}$ , then  $Q[\mathbf{T} \setminus \mathbf{X}]$  is identifiable and given by*

$$Q[\mathbf{T} \setminus \mathbf{X}] = \frac{P_{\mathbf{V} \setminus \mathbf{T}}}{Q[S^{\mathbf{X}}]} \times \sum_{\mathbf{x}} Q[S^{\mathbf{X}}] \quad (1)$$

*Proof.* By (Tian, 2002, Lemma 11),  $Q[\mathbf{T}]$  decomposes as follows.

$$Q[\mathbf{T}] = Q[\mathbf{T} \setminus S^{\mathbf{X}}] \times Q[S^{\mathbf{X}}] = \frac{Q[\mathbf{T}]}{Q[S^{\mathbf{X}}]} \times Q[S^{\mathbf{X}}]$$

$Q[S^{\mathbf{X}}]$  is computable from  $P_{\mathbf{V} \setminus \mathbf{T}}$  using Lemma 11 in (Tian, 2002), and  $Q[S^{\mathbf{X}} \setminus \mathbf{X}]$  is computable from  $Q[S^{\mathbf{X}}]$  using (Tian, 2002, Lemma 10) as  $\mathbf{X}$  is a descendant set in  $\mathcal{D}_{S^{\mathbf{X}}}$ . Therefore,

$$Q[\mathbf{T} \setminus \mathbf{X}] = \frac{P_{\mathbf{V} \setminus \mathbf{T}}}{Q[S^{\mathbf{X}}]} \cdot Q[S^{\mathbf{X}} \setminus \mathbf{X}] = \frac{P_{\mathbf{V} \setminus \mathbf{T}}}{Q[S^{\mathbf{X}}]} \cdot \sum_{\mathbf{x}} Q[S^{\mathbf{X}}] \quad \square$$

The next result follows directly when  $\mathbf{X}$  is a singleton.

**Corollary 1.** *Given a DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$ ,  $X \in \mathbf{T} \subseteq \mathbf{V}$ , and  $P_{\mathbf{V} \setminus \mathbf{T}}$ . If  $X$  is not in the same c-component with a child in  $\mathcal{D}_{\mathbf{T}}$ , then  $Q[\mathbf{T} \setminus \{X\}]$  is identifiable and given by*

$$Q[\mathbf{T} \setminus \{X\}] = \frac{P_{\mathbf{V} \setminus \mathbf{T}}}{Q[S^X]} \times \sum_x Q[S^X] \quad (2)$$

where  $S^X$  is the c-component of  $X$  in  $\mathcal{D}_{\mathbf{T}}$ .

The significance of Corol. 1 stems from the fact that it can be used to rewrite the identification algorithm in a step-wise fashion, which is shown in Algorithm 1. The same is equivalent to the original algorithm since neither one of Lemmas 10 nor 11 in (Tian, 2002) is applicable whenever Corol. 1 is not applicable, which is shown by Lemmas 2 and 3. This result may not be surprising since Corol. 1 follows from the application of these lemmas.

---

**Algorithm 1:** ID( $\mathbf{x}, \mathbf{y}$ ) given DAG  $\mathcal{G}$

---

**input** : two disjoint sets  $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$

**output:** Expression for  $P_{\mathbf{x}}(\mathbf{y})$  or FAIL

1. Let  $\mathbf{D} = \text{An}(\mathbf{Y})_{\mathcal{G}_{\mathbf{V} \setminus \mathbf{X}}}$
2. Let the c-components of  $\mathcal{G}_{\mathbf{D}}$  be  $\mathbf{D}_i, i = 1, \dots, k$
3.  $P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{d} \setminus \mathbf{y}} \prod_i \text{Identify}(\mathbf{D}_i, \mathbf{V}, P)$

**Function** Identify ( $\mathbf{C}, \mathbf{T}, Q = Q[\mathbf{T}]$ ) :

```

if  $\mathbf{C} = \mathbf{T}$  then
  | return  $Q[\mathbf{T}]$ ;
end
/* Let  $S^B$  be the c-component of  $\{B\}$  in  $\mathcal{G}_{\mathbf{T}}$  */
if  $\exists B \in \mathbf{T} \setminus \mathbf{C}$  such that  $S^B \cap \text{Ch}(B) = \emptyset$  then
  | Compute  $Q[\mathbf{T} \setminus \{B\}]$  from  $Q$ ; // Corollary 1
  | return Identify( $\mathbf{C}, \mathbf{T} \setminus \{B\}, Q[\mathbf{T} \setminus \{B\}]$ );
else
  | throw FAIL;
end

```

---

**Lemma 2.** *Given a DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$ ,  $\mathbf{C} \subset \mathbf{T} \subseteq \mathbf{V}$ . If  $\mathbf{A} = \text{An}(\mathbf{C})_{\mathcal{D}_{\mathbf{T}}} \neq \mathbf{T}$ , then there exist some node  $X \in \mathbf{T} \setminus \mathbf{A}$  such that  $X$  is not in the same c-component with any child in  $\mathcal{D}_{\mathbf{T}}$ .*

*Proof.* If  $\mathbf{A} \neq \mathbf{T}$ , then  $\mathbf{T} \setminus \mathbf{A}$  is a non-empty set where none of the nodes is an ancestor of  $\mathbf{A}$ . Since the graph is acyclic, then at least one node of  $\mathbf{T} \setminus \mathbf{A}$  is with no children. Hence, the above conclusion follows.  $\square$

**Lemma 3.** *Given a DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$ ,  $\mathbf{C} \subset \mathbf{T} \subseteq \mathbf{V}$ , and assume  $\mathcal{D}_{\mathbf{C}}$  is a single c-component. If  $\mathcal{D}_{\mathbf{T}}$  partitions into c-components  $\mathbf{S}_1 \dots \mathbf{S}_k$ , where  $k > 1$ , then there exists some node  $X \in \mathbf{S}_i$  such that  $\mathbf{C} \not\subseteq \mathbf{S}_i$  and  $X$  is not in the same c-component with any child in  $\mathcal{D}_{\mathbf{T}}$ .*

*Proof.* Subgraph  $\mathcal{D}_{\mathbf{S}_i}$  is acyclic, so there must exist some node ( $X$ ) that doesn't have any children in  $\mathcal{D}_{\mathbf{S}_i}$ . Since  $\mathbf{S}_i$  is one of the c-components in  $\mathcal{D}_{\mathbf{T}}$ , then  $X$  is not in the same c-component with any of its children in  $\mathcal{D}_{\mathbf{T}}$ .  $\square$

The revised algorithm requires checking an atomic criterion at every instance of the recursive routine Identify. This might not be crucial when the precise causal diagram is known and induced subgraphs preserve a complete graphical characterization of the c-components and the ancestral relations between the nodes. The latter, unfortunately, doesn't hold when the model is an equivalence class represented by a PAG.<sup>2</sup>

<sup>2</sup>We thank a reviewer for bringing to our attention a similar formulation of Alg. 1 (Richardson et al., 2017, Thm. 60).

Figure 2: Example for properties discussed in Section 4

## 4 PAG-SUBGRAPH PROPERTIES

Evidently, induced subgraphs of the original causal model play a critical role in identification (cf Alg. 1). It is natural to expect that in the generalized setting we study here, induced subgraphs of the given PAG will also play an important role. An immediate challenge, however, is that a subgraph of a PAG  $\mathcal{P}$  over  $\mathbf{V}$  induced by  $\mathbf{A} \subseteq \mathbf{V}$  is, in general, not a PAG that represents a full Markov equivalence class. In particular, if  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  is a DAG in the equivalence class represented by  $\mathcal{P}$ ,  $\mathcal{P}_{\mathbf{A}}$  is in general not the PAG that represents the equivalence class of  $\mathcal{D}_{\mathbf{A}}$ . To witness, let  $\mathcal{D}$  and  $\mathcal{P}$  denote the DAG and the corresponding PAG in Figure 1, respectively, and let  $\mathbf{A} = \{V_1, V_2, X, V_4\}$ . The induced subgraph of  $\mathcal{P}$  over  $\mathbf{A}$  (Fig. 2a) does not represent the equivalence class of the corresponding induced subgraph of  $\mathcal{D}$  (Fig. 2b). Despite this subtlety, we establish a few facts below showing that for any  $\mathbf{A} \subseteq \mathbf{V}$  and any DAG  $\mathcal{D}$  in the equivalence class represented by  $\mathcal{P}$ , some information about  $\mathcal{D}_{\mathbf{A}}$ , which is particularly relevant to identification, can be read off from  $\mathcal{P}_{\mathbf{A}}$ .

**Proposition 1.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ , and  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  be any DAG in the equivalence class represented by  $\mathcal{P}$ . Let  $X \neq Y$  be two nodes in  $\mathbf{A} \subseteq \mathbf{V}$ . If  $X$  is an ancestor of  $Y$  in  $\mathcal{D}_{\mathbf{A}}$ , then  $X$  is a possible ancestor of  $Y$  in  $\mathcal{P}_{\mathbf{A}}$ .*

*Proof.* If  $X$  is an ancestor of  $Y$  in  $\mathcal{D}_{\mathbf{A}}$ , then there is a path  $p$  in  $\mathcal{D}_{\mathbf{A}}$  composed of nodes  $\langle X = V_0, \dots, Y = V_m \rangle$ ,  $m \geq 1$  such that  $V_i \in \mathbf{A}$  and  $V_i \rightarrow V_{i+1}$ ,  $0 \leq i < m$ . Path  $p$  is obviously also present in  $\mathcal{D}$ , and consequently the corresponding MAG  $\mathcal{M}$ . Hence,  $p$  corresponds to a possibly directed path in  $\mathcal{P}$ . Since all the nodes along  $p$  are in  $\mathbf{A}$ , then  $p$  is present in  $\mathcal{P}_{\mathbf{A}}$  and so  $X$  is a possible ancestor of  $Y$  in  $\mathcal{P}_{\mathbf{A}}$ .  $\square$

This simple proposition guarantees that possible-ancestral relationship in  $\mathcal{P}_{\mathbf{A}}$  subsumes ancestral relationship in  $\mathcal{D}_{\mathbf{A}}$  for every  $\mathcal{D}$  in the class represented by  $\mathcal{P}$ . This is illustrated by  $\mathcal{D}_{\mathbf{A}}$  and  $\mathcal{P}_{\mathbf{A}}$  in Figures 2a and 2b.

Given an induced subgraph of a PAG,  $\mathcal{P}_{\mathbf{A}}$ , a directed edge  $X \rightarrow Y$  in  $\mathcal{P}_{\mathbf{A}}$  is said to be *visible* if for every DAG  $\mathcal{D}$  in the class represented by  $\mathcal{P}$ , there is no inducing path in  $\mathcal{D}_{\mathbf{A}}$  between  $X$  and  $Y$  relative to the latent nodes in  $\mathcal{D}_{\mathbf{A}}$  that is into  $X$ .

**Lemma 4.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ , and  $\mathcal{P}_{\mathbf{A}}$  be an induced subgraph of  $\mathcal{P}$  over  $\mathbf{A} \subseteq \mathbf{V}$ . For every  $X \rightarrow Y$  in  $\mathcal{P}_{\mathbf{A}}$ , if it is visible in  $\mathcal{P}$ , then it remains visible in  $\mathcal{P}_{\mathbf{A}}$ .*

*Proof.* Let  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  be any causal model in the equivalence class represented by  $\mathcal{P}$ , and let  $X \rightarrow Y$  be a visible edge in  $\mathcal{P}$ ,  $X, Y \in \mathbf{A}$ . Then, there is no inducing path between  $X$  and  $Y$  relative to  $\mathbf{L}$  that is into  $X$  in  $\mathcal{D}$ . It follows that no such inducing path (relative to the latent nodes in  $\mathcal{D}_{\mathbf{A}}$ ) exists in the subgraph  $\mathcal{D}_{\mathbf{A}}$ .  $\square$

Visibility is relevant for identification because it implies absence of confounding, which is the major obstacle to identification. Lemma 4 shows that an edge in an induced subgraph that is visible in the original PAG also implies absence of confounding in the induced subgraphs. Interestingly, note that a directed edge  $X \rightarrow Y$  in  $\mathcal{P}_{\mathbf{A}}$ , visible or not, does not imply that  $X$  is an ancestor of  $Y$  in  $\mathcal{D}_{\mathbf{A}}$  for every  $\mathcal{D}$  in the class represented by  $\mathcal{P}$ . For example,  $X$  is not an ancestor of  $V_4$  in Fig. 2b, even though  $X \rightarrow V_4$  is a visible edge in Fig. 2a.

**Definition 4 (PC-Component).** *In a MAG, a PAG, or any of its induced subgraphs, two nodes  $X$  and  $Y$  are in the same possible c-component (pc-component) if there is a path between the two nodes such that (1) all non-endpoint nodes along the path are colliders, and (2) none of the edges is visible.*

As alluded earlier, a c-component in a causal graph plays a central role in identification. The following proposition establishes a graphical condition in an induced subgraph  $\mathcal{P}_{\mathbf{A}}$  that is necessary for two nodes being in the same c-component in  $\mathcal{D}_{\mathbf{A}}$  for some DAG  $\mathcal{D}$  represented by  $\mathcal{P}$ .

**Proposition 2.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ , and  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  be any DAG in the equivalence class represented by  $\mathcal{P}$ . For any  $X, Y \in \mathbf{A} \subseteq \mathbf{V}$ , if  $X$  and  $Y$  are in the same c-component in  $\mathcal{D}_{\mathbf{A}}$ , then  $X$  and  $Y$  are in the same pc-component in  $\mathcal{P}_{\mathbf{A}}$ .*

*Proof Sketch.* If  $X$  and  $Y$  are in the same c-component in  $\mathcal{D}_{\mathbf{A}}$ , then there is a path  $p$  in  $\mathcal{D}_{\mathbf{A}}$  composed of nodes  $\langle X = V_0, \dots, Y = V_m \rangle$ ,  $m \geq 1$ , such that  $V_i \in \mathbf{A}$  and  $V_i \leftarrow L_{i,i+1} \rightarrow V_{i+1}$ ,  $0 \leq i < m$ . We prove that  $X$  and  $Y$  are in the same pc-component in  $\mathcal{M}$ , the MAG of  $\mathcal{D}$  over  $\mathbf{V}$ , due to a path  $p'$  over a subsequence of  $p$ . We then

show that  $X$  and  $Y$  are in the same pc-component in  $\mathcal{P}$ , the PAG of  $\mathcal{M}$ , due to a path  $p^*$  over a subsequence of  $p'$ . Since all the nodes along  $p^*$  are in  $\mathbf{A}$ , then  $p^*$  is present in  $\mathcal{P}_{\mathbf{A}}$ , and so  $X$  and  $Y$  are in the same pc-component in  $\mathcal{P}_{\mathbf{A}}$ . Due to space constraints, the complete proofs are provided in (Jaber et al., 2018a).  $\square$

This result provides a sufficient condition for *not* belonging to the same c-component in any of the relevant causal graphs. In Fig. 2a, for example,  $V_1$  and  $V_4$  or  $X$  and  $V_4$  are not in the same pc-component, which implies by Prop. 2 that they are not in the same c-component in  $\mathcal{D}_{\mathbf{A}}$  for any DAG  $\mathcal{D}$  in the equivalence class represented by the PAG in Fig. 1b.

As a special case of Def. 4, we define the following notion, which will prove useful later on.

**Definition 5** (DC-Component). *In a MAG, a PAG, or any of its induced subgraphs, two nodes  $X$  and  $Y$  are in the same definite c-component (dc-component) if they are connected with a bi-directed path, i.e. a path composed solely of bi-directed edges.*

One challenge with the notion of *pc-component* is that it is not transitive as *c-component* is. Consider the PAG  $V_1 \circ\text{---}\circ V_2 \circ\text{---}\circ V_3$ . Here,  $V_1$  and  $V_2$  are in the same pc-component,  $V_2$  and  $V_3$  are in the same pc-component, however,  $V_1$  and  $V_3$  are not in the same pc-component. Hence, we define a notion that is a transitive closure of the notion of pc-component, which will prove instrumental to our goal.

**Definition 6** (CPC-Component). *Let  $\mathcal{P}$  denote a PAG or a corresponding induced subgraph. Nodes  $X$  and  $Y$  are in the same composite pc-component in  $\mathcal{P}$ , denoted *cpc-component*, if there exist a sequence of nodes  $\langle X = V_0, \dots, Y = V_m \rangle$ ,  $m \geq 1$ , such that  $V_i$  and  $V_{i+1}$  are in the same pc-component,  $0 \leq i < m$ .*

It follows from the above definition that a PAG or an induced subgraph  $\mathcal{P}$  can be decomposed into unique sets of cpc-components. For instance, the cpc-components in Fig. 2a are  $\mathbf{S}_1 = \{V_1, V_2, X\}$  and  $\mathbf{S}_2 = \{V_4\}$ . The significance of a *cpc-component* is that it corresponds to a composite c-component in the relevant causal graphs as shown in the following proposition.

**Proposition 3.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ ,  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  be any DAG in the equivalence class represented by  $\mathcal{P}$ , and  $\mathbf{A} \subseteq \mathbf{V}$ . If  $\mathbf{C} \subseteq \mathbf{A}$  is a cpc-component in  $\mathcal{P}_{\mathbf{A}}$ , then  $\mathbf{C}$  is a composite c-component in  $\mathcal{D}_{\mathbf{A}}$ .*

*Proof.* According to Definition 6,  $\mathbf{C}$  includes all the nodes that are in the same pc-component with some node in  $\mathbf{C}$  in  $\mathcal{P}_{\mathbf{A}}$ . It follows from the contrapositive of Prop. 2 that no node outside  $\mathbf{C}$  is in the same c-component with

---

### Algorithm 2: PTO Algorithm

---

**input** : PAG  $\mathcal{P}$  over  $\mathbf{V}$

**output**: PTO over  $\mathcal{P}$

1- Create singleton buckets  $\mathbf{B}_i$  each containing  $V_i \in \mathbf{V}$ .

2- Merge buckets  $\mathbf{B}_i$  and  $\mathbf{B}_j$  if there is a circle edge between them ( $\mathbf{B}_i \ni X \circ\text{---}\circ Y \in \mathbf{B}_j$ ).

3- **while** set of buckets ( $\mathbf{B}$ ) is not empty **do**

    (i) Extract  $\mathbf{B}_i$  with only arrowheads incident on it.

    (ii) Remove edges between  $\mathbf{B}_i$  and other buckets.

**end**

4- The partial order is  $\mathbf{B}_1 < \mathbf{B}_2 < \dots < \mathbf{B}_m$  in reverse order of the bucket extraction. Hence,  $\mathbf{B}_1$  is the last bucket extracted and  $\mathbf{B}_m$  is the first bucket extracted.

---

any node in  $\mathbf{C}$  in  $\mathcal{D}_{\mathbf{A}}$ . Hence, set  $\mathbf{C}$  represents a composite c-component in  $\mathcal{D}_{\mathbf{A}}$  by Definition 3.  $\square$

Recall that the algorithm for identification given a DAG uses a topological order over the nodes. Similarly, the algorithm we design for PAGs will depend on some (partial) topological order. Thanks to the possible presence of circle edges ( $\circ\text{---}\circ$ ) in a PAG, in general, there may be no complete topological order that is valid for all DAGs in the equivalence class. Algorithm 2 presents a procedure to derive a *partial topological order* over the nodes in a PAG, using buckets of nodes that are connected with circle paths (Jaber et al., 2018b). This algorithm remains valid over an induced subgraph of a PAG. To show this, the following lemma is crucial:

**Lemma 5.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ , and  $\mathcal{P}_{\mathbf{A}}$  be the induced subgraph over  $\mathbf{A} \subseteq \mathbf{V}$ . For any three nodes  $A, B, C$ , if  $A \ast \rightarrow B \circ\text{---}\ast C$ , then there is an edge between  $A$  and  $C$  with an arrowhead at  $C$ , namely,  $A \ast \rightarrow C$ . Furthermore, if the edge between  $A$  and  $B$  is  $A \rightarrow B$ , then the edge between  $A$  and  $C$  is either  $A \rightarrow C$  or  $A \circ\text{---}\rightarrow C$  (i.e., it is not  $A \leftrightarrow C$ ).*

*Proof.* Lemma 3.3.1 of (Zhang, 2006) establishes the above property for every PAG. By the definition of an induced subgraph, the property is preserved in  $\mathcal{P}_{\mathbf{A}}$ .  $\square$

Thus, a characteristic feature of PAGs carries over to their induced subgraphs. It follows that Algorithm 2 is sound for induced subgraphs as well.

**Proposition 4.** *Let  $\mathcal{P}$  be a PAG over  $\mathbf{V}$ , and let  $\mathcal{P}_{\mathbf{A}}$  be the subgraph of  $\mathcal{P}$  induced by  $\mathbf{A} \subseteq \mathbf{V}$ . Then, Algorithm 2 is sound over  $\mathcal{P}_{\mathbf{A}}$ , in the sense that the partial order is valid with respect to  $\mathcal{D}_{\mathbf{A}}$ , for every DAG  $\mathcal{D}$  in the equivalence class represented by  $\mathcal{P}$ .*

*Proof.* Let  $D$  be any DAG in the equivalence class represented by  $\mathcal{P}$ . By Prop. 1, the possible-ancestral relations in  $\mathcal{P}_A$  subsume those present in  $\mathcal{D}_A$ . Hence, a partial topological order that is valid with respect to  $\mathcal{P}_A$  is valid with respect to  $\mathcal{D}_A$ . The correctness of Alg. 2 with respect to a PAG in (Jaber et al., 2018b) depends only on the property in Lemma 5, a proof of which is given in the Supplementary Materials for completeness. Therefore, thanks to Lemma 5, the algorithm is also sound with respect to an induced subgraph  $\mathcal{P}_A$ .  $\square$

For example, for  $\mathcal{P}_A$  in Fig. 2a, a partial topological order over the nodes is  $V_1 < V_2 < X < V_4$ , which is valid for all the relevant DAGs.

With these results about induced subgraphs of a PAG, we are ready to develop a recursive approach for identification given a PAG, to which we now turn.

## 5 IDENTIFICATION IN PAGS

We start by formally defining the notion of identification given a PAG, which generalizes the model-specific notion (Pearl, 2000, pp. 70).

**Definition 7.** Given a PAG  $\mathcal{P}$  over  $\mathbf{V}$  and a query  $P_{\mathbf{x}}(\mathbf{y})$  where  $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$ ,  $P_{\mathbf{x}}(\mathbf{y})$  is identifiable given  $\mathcal{P}$  if and only if  $P_{\mathbf{x}}(\mathbf{y})$  is identifiable given every DAG  $\mathcal{D}(\mathbf{V}, \mathbf{L})$  in the Markov equivalence class represented by  $\mathcal{P}$ , and with the same expression.

We first derive an atomic identification criterion analogous to Corollary 1. As seen in the algorithm for constructing a partial order (Alg. 2), a bucket or circle component in a PAG is for our purpose analogous to a single node in a DAG. Therefore, the following criterion targets a bucket  $\mathbf{X}$  rather than a single node.

**Theorem 1.** Given a PAG  $\mathcal{P}$  over  $\mathbf{V}$ , a partial topological order  $\mathbf{B}_1 < \dots < \mathbf{B}_m$  with respect to  $\mathcal{P}$ , a bucket  $\mathbf{X} = \mathbf{B}_j \subset \mathbf{T} \subseteq \mathbf{V}$ , for some  $1 \leq j \leq m$ , and  $P_{\mathbf{v} \setminus \mathbf{t}}$  (i.e.  $Q[\mathbf{T}]$ ),  $Q[\mathbf{T} \setminus \mathbf{X}]$  is identifiable if and only if there does not exist  $X \in \mathbf{X}$  such that  $X$  has a possible child  $C \notin \mathbf{X}$  that is in the same pc-component as  $X$  in  $\mathcal{P}_T$ . If identifiable, then the expression is given by

$$Q[\mathbf{T} \setminus \mathbf{X}] = \frac{P_{\mathbf{v} \setminus \mathbf{t}}}{\prod_{\{i | \mathbf{B}_i \subseteq S^{\mathbf{X}}\}} P_{\mathbf{v} \setminus \mathbf{t}}(\mathbf{B}_i | \mathbf{B}^{(i-1)})} \times \sum_{\mathbf{x}} \prod_{\{i | \mathbf{B}_i \subseteq S^{\mathbf{X}}\}} P_{\mathbf{v} \setminus \mathbf{t}}(\mathbf{B}_i | \mathbf{B}^{(i-1)}), \quad (3)$$

where  $S^{\mathbf{X}} = \bigcup_{X \in \mathbf{X}} S^X$ ,  $S^X$  being the dc-component of  $X$  in  $\mathcal{P}_T$ , and  $\mathbf{B}^{(i-1)}$  denoting the set of nodes preceding bucket  $\mathbf{B}_i$  in the partial order.

*Proof Sketch.* (if) Let  $D$  be any DAG in the equivalence class represented by  $\mathcal{P}$ ,  $\mathcal{D}_T$  be the induced subgraph over  $\mathbf{T}$ , and  $S'$  be the smallest composite c-component containing  $\mathbf{X}$  in  $\mathcal{D}_T$ . We show that  $\mathbf{X}$  is a descendant set in  $\mathcal{D}_{S'}$ . Suppose otherwise for the sake of contradiction. Then, there is a node  $C \in S' \setminus \mathbf{X}$  such that  $C$  is a child of  $X_i$  and is in the same c-component with  $X_j$ , where  $X_i, X_j \in \mathbf{X}$  and possibly  $i = j$ . By Prop. 2,  $X_j$  is in the same pc-component with  $C$  in  $\mathcal{P}_T$ . Let  $T_i$  be the node closest to  $X_j$  along the collider path in  $\mathcal{P}_T$  between  $X_j$  and  $C$  consistent with Def. 4. If the edge between  $X_j$  and  $T_i$  in  $\mathcal{P}_T$  is not into  $X_j$ , then  $X_j$  is in the same pc-component with a possible child as the edge is not visible. This violates the criterion stated in the theorem. Otherwise, the edge is  $X_j \leftrightarrow T_i$  and there exist a bi-directed edge between  $T_i$  and every node in  $\mathbf{X}$  (which follows from Lemma 5). Hence,  $X_i$  is in the same pc-component with a possible child  $C$  in  $\mathcal{P}_T$  (Prop. 1), and the criterion stated in the theorem is violated again. Therefore,  $\mathbf{X}$  is a descendant set in  $\mathcal{D}_{S'}$  and  $Q[\mathbf{T} \setminus \mathbf{X}]$  is identifiable from  $Q[\mathbf{T}]$  by Lemma 1. It remains to show that Eq. 3 is equivalent to Eq. 1 for  $\mathcal{D}$ . The details for this step are left to the Supplementary Material.

(only if) Suppose the criterion in question is not satisfied. Then some  $X_i \in \mathbf{X}$  is in the pc-component with a possible child  $C \notin \mathbf{X}$  in  $\mathcal{P}_T$ . The edge between  $X_i$  and  $C$  is  $X_i \ast \rightarrow C$  as  $C$  is outside of  $\mathbf{X}$ . If the edge is not visible in  $\mathcal{P}_T$ , then this edge is not visible in  $\mathcal{P}$  (Lemma 4). Hence, we can construct a DAG  $\mathcal{D}$  in the equivalence class of  $\mathcal{P}$  where  $C$  is a child of  $X_i$  and the two nodes share a latent variable. The pair of sets  $\mathbf{F} = \{X_i, C\}$  and  $\mathbf{F}' = \{C\}$  form a so-called hedge for  $Q[\mathbf{T} \setminus \mathbf{X}]$  and the effect is not identifiable in  $\mathcal{D}$  (Shpitser and Pearl, 2006, Theorem 4), and hence not identifiable given  $\mathcal{P}$ .

Otherwise,  $X_i \rightarrow C$  is visible in  $\mathcal{P}_T$ . So, there is a collider path between  $X_i$  and  $C$  consistent with Def. 4 such that the two nodes are in the same pc-component. Let  $p = \langle X_i = T_0, T_1, \dots, T_m = C \rangle$  denote the shortest such path in  $\mathcal{P}_T$ . If the edge between  $X_i$  and  $T_1$  is not into  $X_i$ , then  $T_1$  is a child of  $X_i$  and the proof follows as in the previous case. Otherwise, we have  $X_i \leftrightarrow T_1$  and we can show that  $X_i$  is the only node along  $p$  that belongs to  $\mathbf{X}$  (details in the Supplementary Material). In  $\mathcal{P}$ , path  $p$  is present with  $X_i \rightarrow C$  visible. Hence, we can construct a DAG  $\mathcal{D}$  in the equivalence class of  $\mathcal{P}$  such that  $C$  is a child of  $X_i$  and both are in the same c-component through a sequence of bi-directed edges along the corresponding nodes of  $p$ . The pair of sets  $\mathbf{F} = \{X_i, T_1, \dots, T_m = C\}$  and  $\mathbf{F}' = \{T_1, \dots, T_m = C\}$  form a hedge for  $Q[\mathbf{T} \setminus \mathbf{X}]$  and the effect is not identifiable in  $\mathcal{D}$ , and hence it is not identifiable given  $\mathcal{P}$ .  $\square$

Note that the above result simplifies into computing the

Figure 3: Sample PAG  $\mathcal{P}$  (left) and induced subgraphs used to identify  $Q[\{Y_1, Y_2\}]$ .

interventional distribution  $P_{\mathbf{x}}$  whenever the input distribution is the observational distribution, i.e.  $\mathbf{T} = \mathbf{V}$ . Consider the query  $P_{\mathbf{x}}(\mathbf{v} \setminus \{x\})$  over the PAG in Fig. 1b. The intervention node  $X$  is not in the same pc-component with any of its possible children ( $V_3$  and  $V_4$ ), hence the effect is identifiable and given by

$$\begin{aligned} P_{\mathbf{x}}(\mathbf{v} \setminus \{x\}) &= \frac{P(\mathbf{v})}{P(x|v_1, v_2)} \times \sum_{x'} P(x'|v_1, v_2) \\ &= P(v_1, v_2)P(v_4, v_5|v_1, v_2, x) \end{aligned}$$

Putting these observations together leads to the procedure we call **IDP**, which is shown in Alg. 3. In words, the main idea of **IDP** goes as follows. After receiving the sets  $\mathbf{X}, \mathbf{Y}$ , and a PAG  $\mathcal{P}$ , the algorithm starts the pre-processing steps: First, it computes  $\mathbf{D}$ , the set of possible ancestors of  $\mathbf{Y}$  in  $\mathcal{P}_{\mathbf{V} \setminus \mathbf{X}}$ . Second, it uses  $\mathcal{P}_{\mathbf{D}}$  to partition set  $\mathbf{D}$  into cpc-components. Following the pre-processing stage, the procedure calls the subroutine **Identify** over each cpc-component  $\mathbf{D}_i$  to compute  $Q[\mathbf{D}_i]$  from the observational distribution  $P(\mathbf{V})$ . The recursive routine basically checks for the presence of a bucket  $\mathbf{B}$  in  $\mathcal{P}_{\mathbf{T}}$  that is a subset of the intervention nodes, i.e.  $\mathbf{B} \subseteq \mathbf{T} \setminus \mathbf{C}$ , and satisfies the conditions of Thm. 1. If found, it is able to successfully compute  $Q[\mathbf{T} \setminus \mathbf{B}]$  using Eq. 3, and proceed with a recursive call. Alternatively, if such a bucket doesn't exist in  $\mathcal{P}_{\mathbf{T}}$ , then **IDP** throws a failure condition, since it's unable to identify the query. We show next that this procedure is, indeed, correct.

**Theorem 2.** *Algorithm IDP (Alg.3) is sound.*

*Proof.* Let  $\mathcal{G}(\mathbf{V}, \mathbf{L})$  be any causal graph in the equivalence class of PAG  $\mathcal{P}$  over  $\mathbf{V}$ , and let  $\mathbf{V}' = \mathbf{V} \setminus \mathbf{X}$ . We have

$$P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{v}' \setminus \mathbf{y}} P_{\mathbf{x}}(\mathbf{v}') = \sum_{\mathbf{v}' \setminus \mathbf{y}} Q[\mathbf{V}'] = \sum_{\mathbf{v}' \setminus \mathbf{d}} \sum_{\mathbf{d} \setminus \mathbf{y}} Q[\mathbf{V}']$$

By definition,  $\mathbf{D}$  is an ancestral set in  $\mathcal{P}_{\mathbf{V}'}$ , and hence it is ancestral in  $\mathcal{G}_{\mathbf{V}'}$  by Prop. 1. So, we have the following by (Tian, 2002, Lemma 10):

$$P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{d} \setminus \mathbf{y}} \sum_{\mathbf{v}' \setminus \mathbf{d}} Q[\mathbf{V}'] = \sum_{\mathbf{d} \setminus \mathbf{y}} Q[\mathbf{D}] \quad (4)$$

---

**Algorithm 3: IDP**( $\mathbf{x}, \mathbf{y}$ ) given PAG  $\mathcal{P}$

---

**input** : two disjoint sets  $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$

**output**: Expression for  $P_{\mathbf{x}}(\mathbf{y})$  or FAIL

1. Let  $\mathbf{D} = \text{An}(\mathbf{Y})_{\mathcal{P}_{\mathbf{V} \setminus \mathbf{X}}}$
2. Let the cpc-components of  $\mathcal{P}_{\mathbf{D}}$  be  $\mathbf{D}_i, i = 1, \dots, k$
3.  $P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{d} \setminus \mathbf{y}} \prod_i \text{Identify}(\mathbf{D}_i, \mathbf{V}, P)$

**Function Identify**( $\mathbf{C}, \mathbf{T}, Q = Q[\mathbf{T}]$ ):

```

if  $\mathbf{C} = \mathbf{T}$  then
  | return  $Q[\mathbf{T}]$ ;
end
/* In  $\mathcal{P}_{\mathbf{T}}$ , let  $\mathbf{B}$  be a bucket, and  $\mathbf{C}^{\mathbf{B}}$  be the
pc-component of  $\mathbf{B}$  */
if  $\exists \mathbf{B} \subseteq \mathbf{T} \setminus \mathbf{C}$  such that  $\mathbf{C}^{\mathbf{B}} \cap \text{Ch}(\mathbf{B}) \subseteq \mathbf{B}$  then
  | Compute  $Q[\mathbf{T} \setminus \mathbf{B}]$  from  $Q$ ; // Theorem 1
  | return  $\text{Identify}(\mathbf{C}, \mathbf{T} \setminus \mathbf{B}, Q[\mathbf{T} \setminus \mathbf{B}])$ ;
else
  | throw FAIL;
end

```

---

Using Prop. 3, each cpc-component in  $\mathcal{P}_{\mathbf{D}}$  corresponds to a composite c-component in  $\mathcal{G}_{\mathbf{D}}$ . Hence, Eq. 4 can be decomposed as follows by (Tian, 2002, Lemma 11).

$$P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{d} \setminus \mathbf{y}} Q[\mathbf{D}] = \sum_{\mathbf{d} \setminus \mathbf{y}} \prod_i Q[\mathbf{D}_i] \quad (5)$$

Eq. 5 is equivalent to the decomposition we have in step 3 of Alg. 3, where we attempt to compute each  $Q[\mathbf{D}_i]$  from  $P$ . Finally, the correctness of the recursive routine **Identify** follows from that of Theorem 1.  $\square$

## 5.1 ILLUSTRATIVE EXAMPLE

Consider the query  $P_{x_1, x_2}(y_1, y_2, y_3)$  given  $\mathcal{P}$  in Fig. 3a. We have  $\mathbf{D} = \{Y_1, Y_2, Y_3\}$ , and the cpc-components in  $\mathcal{P}_{\mathbf{D}}$  are  $\mathbf{D}_1 = \{Y_1, Y_2\}$  and  $\mathbf{D}_2 = \{Y_3\}$ . Hence, the problem reduces to computing  $Q[\{Y_1, Y_2\}] \cdot Q[\{Y_3\}]$ .

We start with the call **Identify**( $\mathbf{D}_1, \mathbf{V}, P$ ). Consider the singleton bucket  $Y_3$  the pc-component of which includes all the nodes in  $\mathcal{P}$ . This node satisfies the condition in **Identify** as it has no children, and we compute

$Q[\mathbf{V} \setminus \{Y_3\}]$  using Theorem 1.

$$\begin{aligned} Q[\mathbf{V} \setminus \{Y_3\}] &= \frac{P(\mathbf{v})}{P(y_1, y_2, y_3, x_1, x_2 | v_1, v_2)} \times \\ &\quad \sum_{y_3} P(y_1, y_2, y_3, x_1, x_2 | v_1, v_2) \\ &= P(v_1, v_2) \cdot P(y_1, y_2, x_1, x_2 | v_1, v_2) \\ &= P(y_1, y_2, x_1, x_2, v_1, v_2) \end{aligned} \quad (6)$$

In the next recursive call,  $\mathbf{T}_1 = \mathbf{V} \setminus \{Y_3\}$ ,  $P_{y_3}$  corresponds to Eq. 6, and the induced subgraph  $\mathcal{P}_{\mathbf{T}_1}$  is shown in Fig. 3b. Now,  $X_2$  satisfies the criterion and we can compute  $Q[\mathbf{T}_1 \setminus \{X_2\}]$  from  $P_{y_3} = Q[\mathbf{T}_1]$ , i.e.,

$$\begin{aligned} Q[\mathbf{T}_1 \setminus \{X_2\}] &= \frac{P_{y_3}}{P_{y_3}(y_1, y_2, x_1, x_2 | v_1, v_2)} \times \\ &\quad \sum_{x_2} P_{y_3}(y_1, y_2, x_1, x_2 | v_1, v_2) \\ &= P(y_1, y_2, x_1, v_1, v_2) \end{aligned} \quad (7)$$

Let  $\mathbf{T}_2 = \mathbf{T}_1 \setminus \{X_2\}$ , where the induced subgraph  $\mathcal{P}_{\mathbf{T}_2}$  is shown in Fig. 3c. Now,  $X_1$  satisfies the criterion and we can compute  $Q[\mathbf{T}_2 \setminus \{X_1\}]$  from Eq. 7,

$$\begin{aligned} Q[\mathbf{T}_2 \setminus \{X_1\}] &= \frac{P_{y_3, x_2}}{P_{y_3, x_2}(x_1 | v_1, v_2)} \times \\ &\quad \sum_{x_1} P_{y_3, x_2}(x_1 | v_1, v_2) \\ &= \frac{P(v_1, v_2) \cdot P(y_1, y_2, x_1, v_1, v_2)}{P(x_1, v_1, v_2)} \\ &= P(v_1, v_2) \cdot P(y_1, y_2 | x_1, v_1, v_2) \end{aligned}$$

Choosing  $V_1$  and  $V_2$  in the next two recursive calls, we finally obtain the simplified expression:

$$Q[\{Y_1, Y_2\}] = P(y_1, y_2 | x_1)$$

Next, we solve for  $Q[\mathbf{D}_2]$  and we get an expression analogous to that of  $Q[\mathbf{D}_1]$ . Hence, the final solution is:

$$P_{x_1, x_2}(y_1, y_2, y_3) = P(y_1, y_2 | x_1) \times P(y_3 | x_2)$$

## 5.2 COMPARISON TO STATE OF THE ART

In the previous section, we formulated an identification algorithm in PAGs for causal queries of the form  $P_{\mathbf{x}}(\mathbf{y})$ ,  $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$ . A natural question arises about the expressiveness of the **IDP** in comparison with the state-of-the-art methods. One of the well established results in the literature is the adjustment method (Perković et al., 2015), which is complete whenever an adjustment set exists.

In the sequel, we formally show that the proposed algorithm subsumes the adjustment method.

Figure 4: Query  $P_{\mathbf{x}}(\mathbf{y})$  is identifiable by **IDP**.

**Theorem 3.** Let  $\mathcal{P}$  be a PAG over set  $\mathbf{V}$  and let  $P_{\mathbf{x}}(\mathbf{y})$  be a causal query where  $\mathbf{X}, \mathbf{Y} \subset \mathbf{V}$ . If the distribution  $P_{\mathbf{x}}(\mathbf{y})$  is not identifiable using **IDP** (Alg. 3), then the effect is not identifiable using the generalized adjustment criterion in (Perković et al., 2015).

*Proof Sketch.* Whenever **IDP** fails to identify some query, it is due to one of the recursive calls to `Identify`. We use the failing condition inside this call to systematically identify a proper definite status non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  in  $\mathcal{P}$  that is m-connecting given set  $\text{Adjust}(\mathbf{X}, \mathbf{Y}, \mathcal{P})$  (Perković et al., 2016, Def. 4.1). As this set fails to satisfy the adjustment criterion, then there exist no adjustment set relative to the pair  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$  (Perković et al., 2016, Cor. 4.4). The details of the proof are left to the Supplementary Material.  $\square$

Based on this result, one may wonder whether these algorithms are, after all, just equivalent. In reality, **IDP** captures strictly more identifiable effects than the adjustment criterion. To witness, consider the PAG in Fig. 4 and note that the causal distribution  $P_{\mathbf{x}}(\mathbf{y})$  is identifiable by **IDP** but not by adjustment in this case.

## 6 CONCLUSION

We studied the problem of identification of interventional distributions in Markov equivalence classes represented by PAGs. We first investigated graphical properties for induced subgraphs of PAGs over an arbitrary subset of nodes with respect to induced subgraphs of DAGs that are in the equivalence class. We believe that these results can be useful to general tasks related to causal inference from equivalence classes. We further developed an identification algorithm in PAGs and proved it to subsume the state-of-the-art adjustment method.

## Abstract

Hierarchical Bayesian methods can unify many related tasks (e.g.  $k$ -shot classification, conditional and unconditional generation) as inference within a single generative model. However, when this generative model is expressed as a powerful neural network such as a PixelCNN, we show that existing learning techniques typically fail to effectively use latent variables. To address this, we develop a modification of the Variational Autoencoder in which encoded observations are decoded to new elements from the same class. This technique, which we call a *Variational Homoencoder* (VHE), produces a hierarchical latent variable model which better utilises latent variables. We use the VHE framework to learn a hierarchical PixelCNN on the Omniglot dataset, which outperforms all existing models on test set likelihood and achieves strong performance on one-shot generation and classification tasks. We additionally validate the VHE on natural images from the YouTube Faces database. Finally, we develop extensions of the model that apply to richer dataset structures such as factorial and hierarchical categories.

## 1 INTRODUCTION

Learning from few examples is possible only with strong inductive biases. In machine learning these biases can be hand designed, such as a model’s parametrisation, or can be the result of a meta-learning algorithm. Furthermore they may be task-specific, as in discriminative modelling, or may describe the world causally so as to be naturally

reused across many tasks. Recent work has approached one- and few-shot learning from all of these perspectives.

Much research has focused on developing neural architectures for few-shot classification (Koch, 2015; Vinyals et al., 2016; Snell et al., 2017; Santoro et al., 2016). These discriminatively-trained networks take as input a test example and a ‘support set’ of examples from several novel classes, and determine the most likely classification of the test example within the novel classes. A second approach, as explored in Ravi & Larochelle (2016); Finn et al. (2017), is to use only a standard classification network but adapt its parameters to the support examples with a learned initialisation and update rule. In either case, such discriminative models can achieve state-of-the-art few-shot classification performance, although they provide no principled means for transferring knowledge to other tasks.

An alternative approach centers on few-shot learning of *generative* models, from which good classification ought to come for free. Much recent work on meta-learning aims to take one or a few observations from a set  $D$  as input, and produce a distribution over new elements  $p(x|D)$  by some learning procedure, expressed either as a neural network (Rezende et al., 2016; Bartunov & Vetrov, 2016; Reed et al., 2017) or by adapting the parameters of an unconditional model (Reed et al., 2017).

A promising route to learning generative models is hierarchical Bayesian inference, which aims to capture shared structure between instances through *shared* latent variables. A recent example is developed in Lake et al. (2015): a compositional, causal generative model of handwritten characters which achieves state-of-the-art results at few-shot character classification, alphabet classification, and both conditional and unconditional generation. However, this model was hand engineered for the Omniglot domain, and so leaves open the challenge of how to learn such hierarchical Bayesian models using only a generic architecture. The recently proposed *Neu-*

---

A PyTorch implementation of the Variational Homoencoder can be found at [github.com/insperatum/vhe](https://github.com/insperatum/vhe).

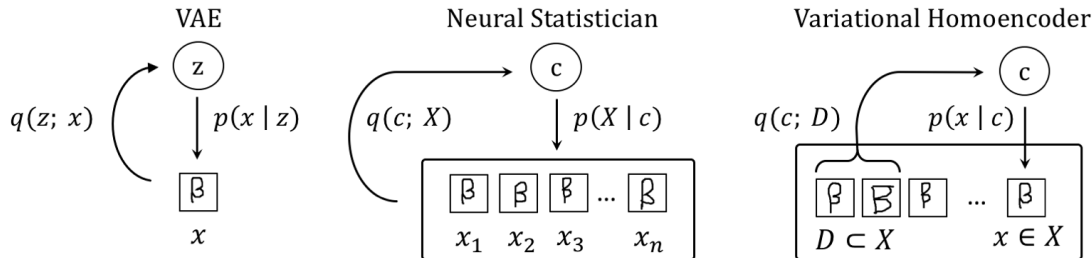

Figure 1: Single step of gradient training in various models. A VAE treats all datapoints as independent, so only a single random element need be encoded (with  $q(z; x)$ ) and decoded (with  $p(x|z)$ ) each step. A Neural Statistician instead feeds a full set of elements  $X$  through both encoder ( $q(c; X)$ ) and decoder ( $p(X|c)$ ) networks, in order to share a latent variable  $c$ . In a VHE, we bound the full likelihood  $p(X)$  using only random subsamples  $D$  and  $x$  for encoding/decoding. Optionally, the decoder  $p(x|c)$  may be defined through a local latent variable  $z$ .

*ral Statistician* (Edwards & Storkey, 2016) offers one means towards this, using amortised variational inference to support learning in a deep hierarchical generative model.

In this work we aim to learn generative models, expressed using high capacity neural network architectures, from just a few examples of a concept. To this end we propose the *Variational Homoencoder* (VHE), combining several advantages of the models described above:

1. Like conditional generative approaches (e.g. Rezende et al. (2016)), we train on a few-shot generation objective which matches how our model may be used at test time. However, by introducing an encoding cost, we simultaneously optimise a likelihood lower bound for a hierarchical generative model, in which structure shared across elements is made explicit by shared latent variables.
2. Edwards & Storkey (2016) has learned hierarchical Bayesian models by applying Variational Autoencoders to sets, such as classes of images. However, their approach requires feeding a full set through the model per gradient step (Figure 1), rendering it intractable to train on very large sets. In practice, they avoid computational limits by training on smaller, random subsets. In a VHE, we instead optimise a likelihood bound for the complete dataset, while *constructing this bound* by subsampling. This approach can not only improve generalisation, but also departs from previous work by extending to models with richer latent structure, for which the joint likelihood cannot be factorised.
3. As with a VAE, the VHE objective includes both an *encoding-* and *reconstruction-* cost. However, by sharing latent variables across a large set of elements, the *encoding cost* per element is reduced

significantly. This facilitates use of powerful autoregressive decoders, which otherwise often suffer from ignoring latent variables (Chen et al., 2016). We demonstrate the significance of this by applying a VHE to the Omniglot dataset. Using a PixelCNN decoder (Oord et al., 2016), our generative model is arguably the first with a general purpose architecture to both attain near state-of-the-art one-shot classification performance and produce high quality samples in one-shot generation.

## 2 BACKGROUND

### 2.1 VARIATIONAL AUTOENCODERS

When dealing with latent variable models of the form  $p(x) = \int_z p(z)p(x|z)dz$ , the integration is necessary for both learning and inference but is often intractable to compute in closed form. *Variational Autoencoders* (VAEs, Kingma & Welling (2013)) provide a method for learning such models by utilising neural-network based approximate posterior inference. Specifically, a VAE comprises a generative network  $p_\theta(z)p_\theta(x|z)$  alongside a separate inference network  $q_\phi(z; x)$ . These are trained jointly to maximise a single objective:

$$\begin{aligned} \mathcal{L}_X(\theta, \phi) = & \sum_{x \in X} \left[ \log p_\theta(x) - \mathbf{D}_{KL}(q_\phi(z; x) \parallel p_\theta(z|x)) \right] \quad (1) \\ = & \sum_{x \in X} \left[ \mathbb{E}_{q_\phi(z; x)} \log p_\theta(x|z) - \mathbf{D}_{KL}(q_\phi(z; x) \parallel p_\theta(z)) \right] \quad (2) \end{aligned}$$

As can be seen from Equation 1, this objective  $\mathcal{L}_X$  is a lower bound on the total log likelihood of the dataset

---

**Algorithm 1:** Minibatch training for the *Variational Homoencoder*. Minibatches are of size  $M$ . Stochastic inference network  $q$  uses subsets of size  $N$ .

---

initialize $(\theta, \phi)$ <b>repeat</b> sample $(x_k, i_k)$ for $k = 1, \dots, M$ sample $D_k \subseteq X_{i_k}$ for $k = 1, \dots, M$ sample $c_k \sim q_\phi(c; D_k)$ for $k = 1, \dots, M$ (optional) sample $z_k \sim q_\phi(z; c_k, x_k)$ for $k = 1, \dots, M$ $\mathbf{g} \approx \frac{1}{M} \sum_k \nabla \mathcal{L}_{\theta, \phi}(x_k; D_k,  X_{i_k} )$ $(\theta, \phi) \leftarrow (\theta, \phi) + \lambda \mathbf{g}$ <b>until</b> convergence of $(\theta, \phi)$	<i>Parameters for decoder <math>p</math> and encoder <math>q</math></i>  <i>Minibatch of elements with corresponding class labels where <math> D_k  = N</math></i>  <i>Reparametrization gradient estimate using <math>\mathbf{c}, \mathbf{z}</math></i> <i>Gradient step, e.g. SGD</i>
--	--

---

$\sum_{x \in X} \log p_\theta(x)$ , while  $q_\phi(z; x)$  is trained to approximate the true posterior  $p_\theta(z|x)$  as accurately as possible. If it could match this distribution exactly then the bound would be tight so that the VAE objective equals the true log likelihood of the data. In practice, the resulting model is typically a compromise between two goals: pulling  $p_\theta$  towards a distribution that assigns high likelihood to the data, but also towards one which allows accurate inference by  $q_\phi$ . Equation 2 provides a formulation for the same objective which can be optimised stochastically, using Monte-Carlo integration to approximate the expectation. For brevity, we will omit subscripts  $\theta, \phi$  for the remainder of this paper.

## 2.2 VARIATIONAL AUTOENCODERS OVER SETS

The *Neural Statistician* (Edwards & Storkey, 2016) is a Variational Autoencoder in which each item to be encoded is itself a set, such as the set  $X^{(i)}$  of all images with a particular class label  $i$ :

$$X^{(i)} = \{x_1^{(i)}, x_2^{(i)}, \dots, x_n^{(i)}\} \quad (3)$$

The generative model for sets,  $p(X)$ , is described by introduction of a corresponding latent variable  $c$ . Given  $c$ , individual  $x \in X$  are conditionally independent:

$$p(X) = \int_c p(c) \prod_{x \in X} p(x|c) dc \quad (4)$$

The likelihood is again intractable to compute, but it can be bounded below via:

$$\log p(X) \geq \mathcal{L}_X = \mathbb{E}_{q(c; X)} \left[ \sum_{x \in X} \log p(x|c) \right] - \mathbf{D}_{KL}(q(c; X) \| p(c)) \quad (5)$$

Unfortunately, calculating the variational lower bound for each set  $X$  requires evaluating both  $q(c; X)$  and  $p(X|c)$ , meaning that the entire set must be passed

through both networks for each gradient update. This can become computationally challenging for classes with hundreds of examples. Instead, previous work (Edwards & Storkey, 2016) ensures that sets used for training are always of small size by maximising a log-likelihood bound for randomly sampled subsets  $D \subset X$ :

$$\mathbb{E}_{D \subset X} \left[ \mathbb{E}_{q(c; D)} \left[ \sum_{x \in D} \log p(x|c) \right] - \mathbf{D}_{KL}(q(c; D) \| p(c)) \right] \quad (6)$$

As we demonstrate in section 4, this subsampling decreases the model’s incentive to capture correlations within a class, reducing utilisation of the latent variables. This poses a significant challenge when scaling up to more powerful generative networks, which require a greater incentive to avoid simply memorising the global distribution. Our work addresses this by replacing the variational lower-bound in Equation 6 with a new objective, which better incentivises the use of latent variables, leading to improved generalisation.

## 3 VARIATIONAL HOMOENCODERS

Rather than bound the likelihood of subsamples  $D$  from a set, as in Edwards & Storkey (2016), we instead use subsampling to construct a lower bound on the complete set  $X$ . We use a constrained variational distribution  $q(c; D), D \subseteq X$  for posterior inference and an unbiased stochastic approximation  $\log p(x|c), x \in X$  for the likelihood. This bound will typically be loose due to stochasticity in sampling  $D$ , and we view this as a regularization strategy: we aim to learn latent representations that are quickly inferable from a small number of instances, and the VHE objective is tailored for this purpose.

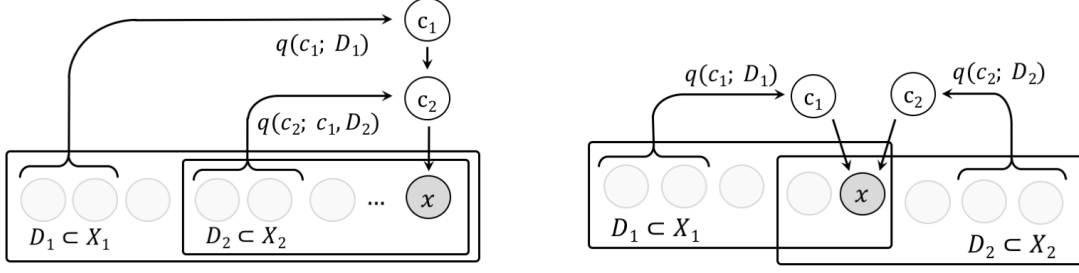

Figure 2: Application of VHE framework to hierarchical (*left*) and factorial (*right*) models. Given an element  $x$  such that  $x \in X_1$  and  $x \in X_2$ , an approximate posterior is constructed for the corresponding shared latent variables  $c_1, c_2$  using subsampled sets  $D_1 \subset X_1, D_2 \subset X_2$ .

### 3.1 STOCHASTIC LOWER BOUND

We would like to learn a generative model for sets  $X$  of the form

$$p(X) = \int p(c) \prod_{x \in X} p(x|c) dc \quad (7)$$

We will refer our full dataset as a union of disjoint sets  $\mathcal{X} = X_1 \sqcup X_2 \sqcup \dots \sqcup X_n$ , and use  $X_{(x)}$  to refer to the set  $X_i \ni x$ . Using the standard consequent of Jensen's inequality, we can lower bound the log-likelihood of each set  $X$  using an arbitrary distribution  $q$ . In particular, we give  $q$  as a fixed function of arbitrary data.

$$\log p(X) \geq \mathbb{E}_{q(c;D)} \log p(X|c) - \mathbf{D}_{KL}[q(c;D) \| p(c)], \quad \forall D \subset X \quad (8)$$

Splitting up individual likelihoods, we may rewrite

$$\log p(X) \geq \mathbb{E}_{q(c;D)} \left[ \sum_{x \in X} \log p(x|c) \right] - \mathbf{D}_{KL}[q(c;D) \| p(c)], \quad \forall D \subset X \quad (9)$$

$$= \sum_{x \in X} \left[ \mathbb{E}_{q(c;D)} \log p(x|c) - \frac{1}{|X|} \mathbf{D}_{KL}[q(c;D) \| p(c)] \right], \quad \forall D \subset X \quad (10)$$

$$\stackrel{\text{def}}{=} \sum_{x \in X} \mathcal{L}(x; D, |X|), \quad \forall D \subset X \quad (11)$$

Finally, we can replace the universal quantification with an expectation under any distribution of  $D$  (e.g. uniform

sampling from  $X$  without replacement):

$$\log p(X) \geq \mathbb{E}_{D \subset X} \sum_{x \in X} \mathcal{L}(x; D, |X|) \quad (12)$$

$$= \sum_{x \in X} \mathbb{E}_{D \subset X} \mathcal{L}(x; D, |X|) \quad (13)$$

$$\log p(\mathcal{X}) \geq \sum_{x \in \mathcal{X}} \mathbb{E}_{D \subset X_{(x)}} \mathcal{L}(x; D, |X_{(x)}|) \quad (14)$$

This formulation suggests a simple modification to the VAE training procedure, as shown in Algorithm 1. At each iteration we select an element  $x$ , use resampled elements  $D \subset X_{(x)}$  to construct the approximate posterior  $q(c; D)$ , and rescale the encoding cost appropriately.

*VHE objective:*

$$\mathbb{E}_{\substack{x \in \mathcal{X} \\ D \subset X_{(x)}}} \left[ \mathbb{E}_{q(c;D)} \log p(x|c) - \frac{1}{|X_{(x)}|} \mathbf{D}_{KL}[q(c;D) \| p(c)] \right] \quad (15)$$

If the generative model  $p(x|c)$  also describes a separate latent variable  $z$  for each element, we may simply introduce a second inference network  $q(z; c, x)$  in order to further bound the reconstruction error of Equation 15:

*VHE objective with per-element latent variables:*

$$\mathbb{E}_{\substack{x \in \mathcal{X} \\ D \subset X_{(x)}}} \left[ \mathbb{E}_{q(c;D)} \left[ \mathbb{E}_{q(z;c,x)} \log p(x|c,z) - \mathbf{D}_{KL}[q(z;c,x) \| p(z|c)] \right] - \frac{1}{|X_{(x)}|} \mathbf{D}_{KL}[q(c;D) \| p(c)] \right] \quad (16)$$

### 3.2 APPLICATION TO STRUCTURED DATASETS

The above derivation applies to a dataset partitioned into *disjoint* subsets  $\mathcal{X} = X_1 \sqcup X_2 \sqcup \dots \sqcup X_n$ , each with a corresponding latent variable  $c_i$ . However, many datasets

offer a richer organisational structure, such as the hierarchical grouping of characters into alphabets (Lake et al., 2015) or the factorial categorisation of rendered faces by identity, pose and lighting (Kulkarni et al., 2015).

Provided that such organisational structure is known in advance, we may generalise the training objective in Equation 14 to include a separate latent variable  $c_i$  for each group  $X_i$  within the dataset, even when these groups overlap. To do this we first rewrite this bound in its most general form, where  $\mathbf{c}$  collects all latent variables:

$$\log p(\mathcal{X}) \geq \mathbb{E}_{Q(\mathbf{c}; \mathbf{D})} \left[ \sum_{x \in X} \log p(x|\mathbf{c}) \right] - D_{KL}[Q(\mathbf{c}; \mathbf{D}) \| P(\mathbf{c})] \quad (17)$$

As shown in Figure 2, a separate  $D_i \subset X_i$  may be subsampled for inference of each latent variable  $c_i$ , so that  $Q(\mathbf{c}) = \prod_i q_i(c_i; D_i)$ . This leads to an analogous training objective (Equation 18), which may be applied to data with factorial or hierarchical category structure. For the hierarchical case, this objective may be further modified to infer layers sequentially, derived in Supplementary Material.

$$\log p(\mathcal{X}) \geq \sum_{x \in \mathcal{X}} \mathbb{E}_{\substack{D_i \subset X_i \\ \text{for each} \\ i: x \in X_i}} \left[ \mathbb{E}_{\substack{q_i(c_i; D_i) \\ \text{for each} \\ i: x \in X_i}} \log p(x|\mathbf{c}) - \sum_{i: x \in X_i} \frac{1}{|X_i|} D_{KL}(q_i(c_i; D_i) \| p(c_i)) \right] \quad (18)$$

### 3.3 POWERFUL DECODER MODELS

As evident in Equation 10, the VHE objective provides a formal motivation for KL rescaling in the variational objective (a common technique to increase use of latent variables in VAEs) by sharing these variables across many elements. This is of particular importance when using autoregressive decoder models, for which a common failure mode is to learn a decoder  $p(x|z)$  with no dependence on the latent space, thus avoiding the encoding cost. In the context of VAEs, this particular issue has been discussed by Chen et al. (2016) who suggest crippling the decoder as a potential remedy.

The same failure mode can occur when training a VAE for sets, particularly when the sets  $D$  are of small size and thus have low total correlation. *Variational Homocoders* suggest a potential remedy to this, encouraging use of the latent space by reusing the same latent variables across a large set  $X$ . This allows a VHE to learn useful representations even with  $|D| = 1$ , while at the

Figure 3: PixelCNN VHE architecture used for Omniglot and Youtube Faces. A spatial transformer network  $q(c; D)$  encodes a subset  $D$  of a character class into a class latent variable  $c$  with the same width and height as the input image. A separate encoder  $q(z; x)$ , parametrized by a convolutional network, encodes position information in the target image into a latent variable  $z$ . A PixelCNN prior is used for  $c$ , and a Gaussian prior for  $z$ . During decoding,  $c$  and  $z$  are combined by a spatial transformer and used to condition a PixelCNN decoder network  $p(x|\text{STN}(c, z))$ .

same time utilising a powerful decoder to achieve highly accurate density estimation. In our experiments, we exploit the VHE’s ability to use powerful decoders: specifically, we learn a generative model with a PixelCNN decoder, which is not possible with previous frameworks.

## 4 EXPERIMENTAL RESULTS

### 4.1 HANDWRITTEN CHARACTER CLASSES

To demonstrate that the VHE objective can facilitate learning with more expressive generative networks, we trained a variety of models on the Omniglot dataset exploring the interaction between model architecture and training objective. We consider two model architectures: a standard deconvolutional network based on Edwards & Storkey (2016), and a hierarchical PixelCNN architecture inspired by the PixelVAE (Gulrajani et al., 2016). For each, we compare models trained with the VHE objective against three alternative objectives.

For our hierarchical PixelCNN architecture (Figure 3) each character class is associated with a spatial latent variable  $c$  (a character ‘template’) with a PixelCNN prior, and each image  $x$  is associated with its own latent variable  $z$  (its ‘position’) with a Gaussian prior. To generate  $x$ , a Spatial Transformer Network (STN) (Jaderberg

Table 1: Comparison of VHE, Neural Statistician, and intermediate objectives with both deconvolutional and PixelCNN architectures. Rescaling encourages use of the latent space, while resampling encourages generalisation from the support set. The VHE is able to utilise the PixelCNN to achieve the highest classification accuracy.

	KL / nats*	Accuracy (5-shot)
<b>Deconvolutional Architecture</b>		
Neural Statistician [3]	31.34	95.6%
Resample (Eq 19)	25.74	94.0%
Rescale (Eq 20)	477.65	95.3%
VHE (resample + rescale, Eq 16)	452.47	95.6%
<b>PixelCNN Architecture</b>		
Neural Statistician	14.90	66.0%
Resample	0.22	4.9%
Rescale	506.48	62.8%
VHE (resample + rescale)	268.37	<b>98.8%</b>

\* $D_{KL}(q(c; D) \parallel p(c))$ , train set

et al., 2015) applies  $z$  to the class template  $c$ , and the result is input to a Gated PixelCNN  $p(x|\text{STN}(c, z))$  (Oord et al., 2016). The position encoder  $q(z; x)$  is given by a CNN, and the class encoder  $q(c; D)$  by an STN averaged over  $D$ . Both produce diagonal Gaussian distributions.

Using both PixelCNN and deconvolutional architectures, we trained models by several objectives. We compare a VHE model against a Neural Statistician baseline, with each trained on sampled subsets  $D \subset X$  with  $|D| = 5$  (as in Edwards & Storkey (2016)). Secondly, since the VHE introduces both data-resampling and KL-rescaling as modifications to this baseline, we separate the contributions of each using two intermediate objectives:

Resample only:

$$\underbrace{\mathbb{E}_{\substack{D \subset X \\ x \in X}}}_{\text{resample decoded element}} \left[ \mathbb{E}_{q(c; D)} \log p(x|c) - \frac{1}{|D|} D_{KL}[q(c; D) \parallel p(c)] \right] \quad (19)$$

Rescale only:

$$\mathbb{E}_{\substack{D \subset X \\ x \in D}} \left[ \mathbb{E}_{q(c; D)} \log p(x|c) - \underbrace{\frac{1}{|X|}}_{\text{rescale KL}} D_{KL}[q(c; D) \parallel p(c)] \right] \quad (20)$$

Table 2: Comparison of classification accuracy with previous work. The VHE objective allows us to use a powerful decoder network, yielding state-of-the-art few-shot classification amongst deep generative models.

	Classification Accuracy (20-way)	
	1-shot	5-shot
<b>Generative models, <math>\log p(X)</math></b>		
Generative Matching Networks [1]	77.0%	91.0%
Neural Statistician [3]	93.2%	98.1%
VHE	<b>95.2%</b>	<b>98.8%</b>
<b>Discriminative models, <math>\log q(y; x, X, Y)</math></b>		
Matching Networks [21]	93.8%	98.7%
Convnet with memory module [9]	95.0%	98.6%

Model-Agnostic Meta-learning [4]	95.8%	<b>98.9%</b>
Prototypical Networks [19]	<b>96.0%</b>	<b>98.9%</b>
(VHE, within-alphabet <sup>1</sup> )	81.3%	90.3%

All models were trained on a random sample of 1200 Omniglot classes using images scaled to 28x28 pixels, dynamically binarised, and augmented by 8 rotations/reflections to produce new classes. We additionally used 20 small random affine transformations to create new instances within each class. Models were optimised using Adam (Kingma & Welling, 2013), and we used training error to select the best parameters from 5 independent training runs. We also implemented the ‘sample dropout’ trick of Edwards & Storkey (2016), but found that this had no effect on performance. At test time we classify an example  $x$  by Monte Carlo estimation of the expected conditional likelihood under the variational posterior  $E_{q(c; D)} p(x|c)$ , with 20 samples from  $q(c; D)$ .  $x$  is then classified to class with support set  $D$  that maximises this expected conditional likelihood.

Table 1 collects classification results of models trained using each of the four alternative training objectives, for both architectures. For a deconvolutional architecture, we find little difference in classification performance between all four training objectives, with the Neural Statistician and VHE models achieving equally high accuracy.

<sup>1</sup>The few-shot classification task defined by Lake et al. (2015) is to identify an image to one of 20 character classes, where *all 20 classes belong to the same (unseen) alphabet*. However, most work since has evaluated on an easier one-shot classification task, in which the 20 support characters are drawn from the entire test set (so are typically more dissimilar). We find that our model performs significantly worse on the within-alphabet variant, and so include results to facilitate future comparison on this more challenging task. Attaining near-human classification accuracy on this variant remains an open challenge for neural network models.

Figure 4: 5-shot samples generated by each model (more in Supplement). With a PixelCNN architecture, both Neural Statistician and Resample objectives lead to underutilisation of the latent space, producing unfaithful samples.

For the hierarchical PixelCNN architecture, however, significant differences arise between training objectives. In this case, a Neural Statistician learns a strong global distribution over images but makes only minimal use of latent variables  $c$ . This means that, despite the use of a higher capacity model, classification accuracy is much poorer (66%) than that achieved using a deconvolutional architecture. For the same reason, conditional samples display an improved sharpness but are no longer identifiable to the cue images on which they were conditioned (Figure 4). Our careful training suggests that this is not an optimisation difficulty but is core to the objective, as discussed in Chen et al. (2016).

By contrast, a VHE is able to gain a large benefit from the hierarchical PixelCNN architecture, with a 3-fold reduction in classification error (5-shot accuracy 98.8%) and conditional samples which are simultaneously sharp and identifiable (Figure 4). This improvement is in part achieved by increased utilisation of the latent space, due to rescaling of the KL divergence term in the objective. However, our results show that this common technique is insufficient when used alone, leading to overfitting to cue images with an equally severe impairment of classification performance (accuracy 62.8%). Rather, we find that KL-rescaling and data resampling must be used together in order for the benefit of the powerful PixelCNN architecture to be realised.

Table 2 lists the classification accuracy achieved by VHEs with both  $|D| = 1$  and  $|D| = 5$ , as compared to existing deep learning approaches. We find that both networks are not only state-of-the-art amongst deep generative models, but also competitive against the best discriminative models trained directly for few-shot classification. Unlike these discriminative models, a VHE is also able to generate new images of a character in one shot, producing samples which are both realistic and faithful to the class of the cue image (Figure 5).

As our goal is to model shared structure across images, we evaluate generative performance using joint log like-

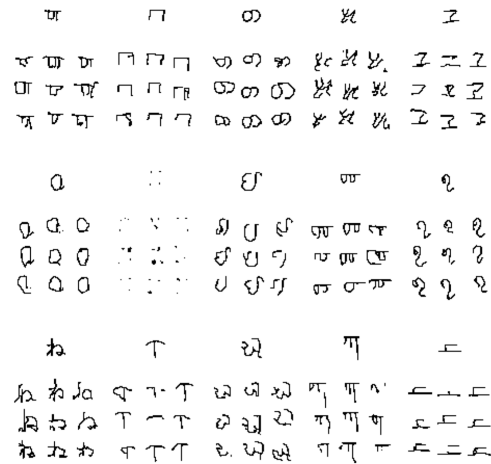

Figure 5: One-shot same-class samples generated by our model. Cue images were sampled from previously unseen classes.

lihood of the entire Omniglot test set (rather than separately across images). From this perspective, a single element VAE will perform poorly as it treats all datapoints as independent, optimising a sum over log likelihoods for each element. By sharing latents across elements of the same class, a VHE can improve upon this considerably.

For likelihood evaluation, our most appropriate comparison is with Generative Matching Networks (Bartunov & Vetrov, 2016) as they also model dependencies within a class. Thus, we trained models under the same train/test split as them, with no data augmentation. We evaluate the joint log likelihood of full character classes from the test set, normalised by the number of elements, using importance weighting with  $k=500$  samples from  $q(c; X)$ . As can be seen in Tables 3 and 4, our hierarchical PixelCNN architecture is able to achieve state-of-the-art log likelihood results only when trained using the VHE objective.

Table 3: Joint NLL of Omniglot test set, compared across architectures and objectives.

Test NLL per image

## 4.2 YOUTUBE FACES

To confirm that our approach can be used to produce naturalistic images, we compare VHE and Neural Statistician models trained on images from the YouTube Faces Database (Wolf et al., 2011), comprising 3,425 videos of 1,595 celebrities downloaded from YouTube. For our experiments, we use the aligned and cropped to face version, additionally cropping each image by 50% in both height and width, and rescale to 40x40 pixels. Our training, validation, and test sets consist of one video per person and 48 images per video. We use 954 videos for the training set and 641 videos for the test set.

We consider two architectures: the hierarchical PixelCNN network used for Omniglot experiments, and the deconvolution network used to model faces in Edwards & Storkey (2016). As above, we train each model using both VHE and NS objectives with  $|D| = 5$ .

Table 5: Classification results for YouTube faces dataset. The VHE PixelCNN utilises the latent space most effectively, and therefore achieves the highest few-shot classification accuracy and test image NLL.

	Test NLL per image	Accuracy (200-way)	
		1-shot	5-shot
<b>Deconvolutional</b>			
Neural Statistician	12512.4	39.2%	49.0%
<i>VHE</i>	12717.6	37.2%	44.8%
<b>PixelCNN</b>			
Neural Statistician	4229.8	92.1%	98.5%
<i>VHE</i>	<b>4091.3</b>	<b>92.5%</b>	<b>98.9%</b>

<sup>2</sup>We thank the authors of Bartunov & Vetrov (2016) for providing us with this comparison.

Table 4: Comparison of deep generative models by joint NLL of Omniglot test set.

Test NLL per image	
<b>Independent models</b>	$\frac{1}{n} \log \prod_i p(x_i)$
DRAW [5]	< 96.5 nats
Conv DRAW [6]	< 91.0 nats
VLAE [2]	89.83 nats
<b>Conditional models</b>	$\frac{1}{n} \log \prod_i p(x_i   x_{1:i-1})$
Generative Matching Networks [1]	62.42 nats <sup>2</sup>
<b>Shared-latent models</b>	$\frac{1}{n} \log \mathbb{E}_{p(c)} \prod_i p(x_i   c)$
<i>Variational Homoencoder</i>	<b>61.22 nats</b>

Classification results for trained models are shown in Table 5, and conditionally generated samples in Figure 6. As with Omniglot experiments, we find that the VHE objective improves use of the hidden layer  $c$ , leading to more accurate classification and conditional generation than the Neural Statistician. While the deconvolutional architecture is capable of producing realistic images (see Edwards & Storkey (2016)), our results show that it is not powerful enough to perform accurate few-shot classification. On the other hand, the PixelCNN architecture trained using the Neural Statistician objective achieves accurate few-shot classification, but generates poor images. The only network able to produce realistic images *and* perform accurate classification is the PixelCNN trained using our VHE objective.

## 4.3 MODELLING RICH CATEGORY STRUCTURE

To demonstrate how the VHE framework may apply to models with richer category structure, we built both a hierarchical and a factorial VHE (Figure 2) using simple modifications to the above architectures. For the hierarchical VHE, we extended the deconvolutional model with an extra latent layer  $a$  using the same encoder and decoder architecture as  $c$ . This was used to encode alphabet level structure for the Omniglot dataset, learning a generative model for alphabets of the form

$$p(\mathcal{A}) = \int p(a) \prod_{X_i \in \mathcal{A}} \int p(c_i | a) \prod_{x_{ij} \in X_i} p(x_{ij} | c_i, a) dc_i da \quad (21)$$

Again, we trained this model using a single objective, using separately resampled subsets  $D^a$  and  $D^c$  to infer each latent variable (see Supplement). We then tested

Figure 6: 5-shot samples of YouTube faces generated using both PixelCNN and deconvolutional architectures. Note that, for accurate comparison, we *sample* images from the decoder rather than taking the conditional mode as is common. For the deconvolutional models, this leads to images which appear more noisy than shown in previous work.

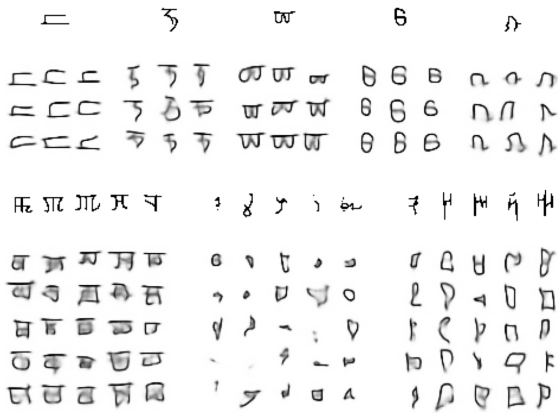

Figure 7: Conditional samples from character (top) and alphabet (bottom) levels of the same hierarchical model.

our model at both one-shot character generation and 5-shot alphabet generation, using samples from previously unseen alphabets. Our single trained model is able to learn structure at both layers of abstraction (Figure 7)

For the factorial VHE, we extended the Omniglot dataset by assigning each image to one of 30 randomly generated styles (independent of its character class), modifying both the colour and pen stroke characteristics of each image. We then extended the PixelCNN model to include a 6-dimensional latent variable  $s$  to represent the *style* of an image, alongside the existing  $c$  to represent the *character*. We used a CNN for style encoder  $q(s; D^s)$ , and for each image location we condition the PixelCNN decoder using the outer product  $s \otimes c_{ij}$ .

We then test this model on a *style transfer* task by feeding separate images into the character encoder  $q(c; D^c)$  and style encoder  $q(s; D^s)$ , then rendering a new image from the inferred  $(c, s)$  pair. We find that synthesised samples are faithful to the respective character and style of both support images (Figure 8), demonstrating the ability of a

Figure 8: Previously unseen characters redrawn with both the colour and stroke width of a second character. For each group, the top two images denote the content (left) and style (right).

factorial VHE to successfully disentangle these two image factors using separate latent variables.

## 5 CONCLUSION

We introduce the *Variational Homoencoder*: a hierarchical Bayesian approach to learning expressive generative models from few examples. We test the VHE by training a hierarchical PixelCNN on the Omniglot dataset, and achieve state-of-the-art results: our model is arguably the first which uses a general purpose architecture to both produce high quality samples and attain near state-of-the-art one-shot classification performance. We further validate our approach on a dataset of face images, and find that the VHE significantly improves the visual quality and classification accuracy achievable with a PixelCNN decoder. Finally, we show that the VHE framework extends naturally to models with richer latent structure, which we see as a promising direction for future work.

## Abstract

We present Probabilistic Collaborative Representation Learning (PCRL), a new generative model of user preferences and item contexts. The latter builds on the assumption that relationships among items within contexts (e.g., browsing session, shopping cart, etc.) may underlie various aspects that guide the choices people make. Intuitively, PCRL seeks representations of items reflecting various regularities between them that might be useful at explaining user preferences. Formally, it relies on Bayesian Poisson Factorization to model user-item interactions, and uses a multilayered latent variable architecture to learn representations of items from their contexts. PCRL seamlessly integrates both tasks within a joint framework. However, inference and learning under the proposed model are challenging due to several sources of intractability. Relying on the recent advances in approximate inference/learning, we derive an efficient variational algorithm to estimate our model from observations. We further conduct experiments on several real-world datasets to showcase the benefits of the proposed model.

## 1 INTRODUCTION

With pervasive digitization of marketplaces and services, we now make most of our consumption choices online. Relieved from the inventory limitation of a physical storefront, online providers are able to offer a mind-boggling array of choices numbering in the thousands to millions. To help users in navigating this sea of choices, modern applications rely heavily on recommender systems to deliver a personalized ranking or selection of items to each user according to her preferences.

There are various approaches to recommender systems, including memory-based and model-based approaches (Sarwar et al., 2001). At the heart of the more prevalent model-based approach is learning a latent representation for every user and every item. Such a latent representation places a user or an item in the “feature” space of preferences, such that when two related items share similar representations or “features”, a user who prefers one likely also prefers the other. Further recommendation predictions are based on these latent representations.

Much of the previous work seek to learn these representations from historical behavioral data, such as ratings, clicks, purchases, etc. (usually organized into a user-item interaction or preference matrix). For instance, the widespread Matrix Factorization (MF) (Mnih and Salakhutdinov, 2008; Hu et al., 2008; Koren et al., 2009) derives user and item latent representations in the form of low dimensional vectors by decomposing the preference matrix. The bilinear combination of user and item’s latent factors can be used to predict unknown preferences.

The limitation of learning these representations from historical behaviors is the sparsity of such data. The long-tail effect (Park and Tuzhilin, 2008) means that most items have been adopted by few users. Moreover, given the rapid expansion of catalogues, there are continually new items with scant record of historical consumption. One consequence of this sparsity is that closely related items may not be mapped to the same direction in the latent space, as they might not have been rated by the same users. As such, historical consumption data alone may not suffice for learning effective item representations.

In some real-world scenarios, there may be known some auxiliary information on how items are likely related to one another. For example, a user interested in a particular shirt may also be interested in a matching pair of jeans. Moreover, such relatedness among items may not have to be explicitly stated, and could be implicitly inferred from such indicative events as whether items are placed

within the same shopping carts, are browsed within the same session, etc. Such item-item relationships constitute valuable information that would otherwise not easily be derivable from similarities in product attributes alone. We thus seek to enrich the learned item representation to also incorporate such item-item relationships, to supplement the sparse user-item interactions.

Representation learning (Bengio et al., 2013) is of interest to learn features or representations from different data, such as images, text, etc. Recent techniques rely on deep neural networks to learn compositional representations. While inspired by this promising approach, our work is set apart in that we are interested not only on extracting objective features of items, but more importantly also those that could help describe user preferences effectively. Therefore, instead of relying on representation learning solely or separately, given the efficacy of probabilistic models for collaborative filtering, we propose to conjoin the representation learning from item-item contextual relationships, and collaborative filtering from user-item interactions, within a unified model.

In this paper, we develop Probabilistic Collaborative Representation Learning (PCRL), which seeks to learn item representations both *contextually* based on their relatedness with other items, as well as *collaboratively* based on their interactions/adoptions by users. For the former, PCRL uses a multilayered (hierarchical) latent variable structure, with a Poisson likelihood and Gamma distributed layers, to model the item’s context (e.g., shopping cart, session). For the latter, PCRL relies on Poisson Factorization (PF) for decomposing users’ interactions with items. As shown in (Gopalan et al., 2015), PF realistically models user preferences, fits well to sparse data thanks to the Poisson’s mathematical form, and it substantially outperforms previous state-of-the-art Gaussian likelihoods-based MF models (Mnih and Salakhutdinov, 2008; Shan and Banerjee, 2010; Koren et al., 2009) for item recommendation.

PCRL joins both sources of data through a shared item latent space within a probabilistic generative model. Intuitively, the collaborative PF component can guide the contextual representation learning process to focus on extracting features that are relevant for predicting the preference information. The contextual representation learning component in turn will encourage the PF part to rely on items’ contexts to explain user preferences, which would supplement the lack of user-item interactions.

Exact inference under the PCRL model is very challenging due to various sources of intractability. To overcome this difficulty we rely on recent innovations in approximate inference/learning and derive an efficient variational algorithm to estimate PCRL from observed user

preferences and item contexts. Empirical results on several real-world datasets reflect the benefits of PCRL in terms of both personalized recommendation and item representation learning.

## 2 RELATED WORK

The sparsity of preference data has driven many to extend Matrix Factorization (MF) models (Mnih and Salakhutdinov, 2008; Hu et al., 2008; Koren et al., 2009) beyond user-item interactions, and leverage auxiliary information, such as social networks (Ma et al., 2008; Zhou et al., 2012; Rao et al., 2015), product taxonomy (Koenigstein et al., 2011), item content (Wang and Blei, 2011), etc. However, these are mostly still within the framework of MF. For instance, Collective Matrix Factorization (Singh and Gordon, 2008), which co-factorized multiple data matrices, is a popular approach in the recommendation literature to jointly model several sources of information.

Yet other approaches, similarly to ours, use graphical models to join different modalities. Wang and Blei (2011) developed Collaborative Topic Regression (CTR), which composes a topic model, Latent Dirichlet Allocation (LDA), with probabilistic matrix factorization to model texts (articles) and user (reader) preferences. Along the same line, Wang et al. (2015); Li and She (2017) proposed alternatives to CTR where probabilistic auto-encoder, is substituted for LDA for modeling text.

We focus on incorporating item relatedness, a modality mostly neglected by previous personalized recommendation models. Notable exceptions include CoFactor (Liang et al., 2016) and Matrix Co-Factorization (MCF) (Park et al., 2017), which used the principle of collective MF based on Gaussian likelihoods. In contrast, we build on Bayesian Poisson Factorization (PF), and we further investigate another architecture for leveraging the item’s contexts with new modeling perspectives. In experiments, we compare to the more recent MCF that learns from item network as a baseline. CoFactor learns not from an external auxiliary source, but rather from item-item relations induced from the user-item interactions.

Since (Gopalan et al., 2015), there is a growing body of work on applying PF (Canny, 2004; Cemgil, 2009) to recommender systems. Gopalan et al. (2014a) developed non-parametric PF. Chaney et al. (2015) incorporated social interactions. Charlin et al. (2015) accounted for user and item evolution over time. Notably, Gopalan et al. (2014b) proposed Collaborative Topic Poisson Factorization (CTPF) to model both article contents and reader preferences. In contrast to CTPF that uses PF to model both the user preferences and auxiliary item information (text), we adopt PF for the user-item interactions only,

and we use a multilayered latent variable structure to learn item representations from auxiliary data (item contexts). The benefits of our modeling architecture would be reflected in the experiments with CTPF as a baseline.

### 3 PROBABILISTIC COLLABORATIVE REPRESENTATION LEARNING

The observed data that we would learn from are user preferences and item contexts respectively. The former are organized into a user-item preference matrix of size  $U \times I$ , denoted  $\mathbf{X} = (x_{ui})$ , where  $x_{ui}$  is the integer rating<sup>1</sup> that user  $u$  gave to item  $i$ , or zero if no preference was expressed. The contextual interactions among items are encoded in an item-context matrix  $\mathbf{C} = (c_{ij})$ , of size  $I \times J$ , where  $c_{ij} = 1$  if item  $j$  belongs to the context<sup>2</sup> of  $i$ , and  $c_{ij} = 0$  otherwise. The  $i^{\text{th}}$  row of this matrix is represented by a vector  $\mathbf{c}_i = (c_{i1}, \dots, c_{iJ})^\top$ , where  $\top$  denotes the transpose. We will refer to the set of items  $j$  such that  $c_{ij} > 0$  as the context of item  $i$ .

We now describe *Probabilistic Collaborative Representation Learning* or PCRL, a new probabilistic latent variable model for jointly modeling user preferences and item contexts. The intuition is to learn item representations reflecting various contextual relationships between them that are useful for explaining user preferences. Figure 1 depicts PCRL in plate notation.

**Contextual Representation Learning.** To model representations due to the item contexts (refer to the left portion of Figure 1) we use a multilayer structure similar to Deep Exponential Families (Ranganath et al., 2015). More precisely, PCRL assumes  $L$  layers of hidden variables per item:  $\mathcal{Z}_i = \{\mathbf{z}_{i,1}, \dots, \mathbf{z}_{i,L}\}$ , such that  $\mathbf{z}_{i,\ell} \in \mathbb{R}_+^{K_\ell}$ . For a reason that will be clear shortly, we denote  $\mathbf{z}_{i,L+1} = \beta_i$ . Along with these variables, PCRL has  $L + 1$  layers of latent weights shared across items,  $\mathcal{W} = \{\mathbf{W}_0, \dots, \mathbf{W}_L\}$ , where  $\mathbf{W}_\ell$  is a matrix of size  $K_{\ell+1} \times K_\ell$ , with  $K_0 = J$ , and its  $k^{\text{th}}$  column is denoted by  $\mathbf{w}_{\ell,k}$ . Effectively, each hidden layer models representations for items based on their contexts. Intuitively, a higher layer encodes a higher level of representational abstraction;  $\beta_i$  is the most abstract representation.

The components  $z_{i,\ell,k}$  at each hidden layer are Gamma distributed. Note that this choice is not a limitation of our modeling framework. Depending on specific requirements, other types of  $z_{i,\ell,k}$  are possible, e.g., Gaussian, and these might differ across layers.

<sup>1</sup>Other user-item interactions indicative of preferences are also possible, e.g., number of clicks.

<sup>2</sup>The definition of ‘‘context’’ is scenario-dependent, e.g., another item  $j$  is found in the same shopping cart as item  $i$ .

Figure 1: The proposed model PCRL in plate representation,  $\xi$  and  $\lambda = (\lambda^s, \lambda^r)$  stand for Gaussian and Gamma parameters.

To capture various correlations across layers, including negative ones, we let the weights  $\mathbf{W}_\ell$  be real valued with Gaussian priors. These latent variables interact with each other to explain the contextual relationships among items. While several interaction schemes are possible, we mimic neural networks (multilayer perceptron or MLP), and let the mean of the local variable at the current layer to be driven by the current weights and the previous layer as follows:

$$\mathbb{E}(\mathbf{z}_{i,\ell} | \mathbf{W}_\ell, \mathbf{z}_{i,\ell+1}) = a_\ell(\mathbf{z}_{i,\ell+1}^\top \mathbf{W}_\ell) \quad (1)$$

where  $a_\ell(x)$  is a function that maps  $x$  into the right mean space. Following the nomenclature in the neural network literature, we call it the *activation function*.

Conditional on the lowest layer,  $\mathbf{z}_{i,1}$ , the components of the item-context vector  $\mathbf{c}_i$  are independent Poisson variables, i.e.,  $\mathbf{c}_i \sim p(\mathbf{c}_i | \mathbf{z}_{i,1}, \mathcal{W}) = \prod_j p(c_{ij} | \mathbf{z}_{i,1}, \mathcal{W})$ , and

$$p(c_{ij} | \mathcal{Z}, \mathcal{W}, \beta) = \text{Poisson}(\mathbf{z}_{i,1}^\top \mathbf{w}_{0,j}) \quad (2)$$

where  $\mathbf{w}_{0,j}$  denotes the  $j^{\text{th}}$  column of the matrix  $\mathbf{W}_0$ .

**Collaborative Poisson Factorization.** To model user preferences (refer to the right portion of Figure 1), PCRL relies on Poisson factorization, i.e.,

$$x_{ui} | \theta, \beta \sim \text{Poisson}(\theta_u^\top \beta_i), \quad (3)$$

where  $\theta_u^\top \in \mathbb{R}_+^K$  and  $\beta_i^\top \in \mathbb{R}_+^K$  are latent variables referred to as the vectors of user preferences and item attributes respectively. Similar to the original Bayesian Poisson factorization, we let the user preferences  $\theta_{uk}$  and item attributes  $\beta_{ik}$  be Gamma random variables—throughout the paper, we use the shape and rate parameterization of the Gamma distribution.

**Unified Generative Model.** The intuition behind this multilayer architecture and sharing  $\beta$  between the collaborative and contextual parts, is to let the latent variables  $\mathcal{Z}$  and  $\mathcal{W}$ , at the intermediate layers, absorb various item-context patterns encoded in  $\mathbf{C}$ , while encouraging the item latent attributes  $\beta$  to capture only those patterns

which are useful for explaining user preferences. The corresponding generative process is as follows:

1. Draw user preferences:  $\theta_{uk} \sim \text{Gamma}(\lambda_\theta^s, \lambda_\theta^r)$ .
2. For each item  $i$ 
  - (a) Draw its attributes:  $\beta_{ik} \sim \text{Gamma}(\lambda_\beta^s, \lambda_\beta^r)$
  - (b) For each layer  $\ell$ , for  $k \in \{1, \dots, K_\ell\}$ :
    - i. Draw  $\mathbf{w}_{\ell,k} \sim \mathcal{N}(\boldsymbol{\mu}_\ell, \boldsymbol{\sigma}_\ell^2 \mathbf{I}_{K_{\ell+1}})$
    - ii. Draw  $z_{i,\ell,k} \sim \text{Gamma}(\lambda_z^s, \frac{\lambda_z^s}{a_\ell(\mathbf{z}_{\ell+1}^\top \mathbf{w}_{\ell,k})})$
  - (c) For  $j \in \{1, \dots, J\}$ ,
    - i. Draw  $\mathbf{w}_{0,j} \sim \mathcal{N}(\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0^2 \mathbf{I}_{K_1})$
    - ii. Draw  $c_{ij} \sim \text{Poisson}(a_0(\mathbf{z}_{i,1}^\top \mathbf{w}_{0,j}))$
3. For each user-item pair  $(u, i)$  sample a preference:  $x_{ui} \sim \text{Poisson}(\boldsymbol{\theta}_u^\top \boldsymbol{\beta}_i)$ ,

where  $\mathbf{I}_K$  stands for the identity matrix of size  $K$ . In practice, we use the standard multivariate isotropic Gaussian as the prior over each variable  $\mathbf{w}_{\ell,k}$ . Further, for efficiency purposes, we will make the latent variables  $\mathbf{z}_{i,\ell}$  for  $\ell \in \{1, \dots, L\}$  deterministic by taking  $\lambda_z^s$  to infinity.

In principle PCRL should place high probability on item factors  $\boldsymbol{\beta}$  reflecting various item relationship patterns that are useful at explaining user preferences.

**Connections to Existing Models.** In unifying item contexts and user-item preferences, PCRL effectively generalizes and subsumes other more restricted formulations.

For one, as evident from the construction of PCRL, if we remove the context-specific components,  $\mathcal{Z}$ ,  $\mathcal{W}$  and  $\mathbf{C}$ , then PCRL collapses to the original Bayesian Poisson factorization (Cemgil, 2009; Gopalan et al., 2015) that would learn from user-item preferences alone.

For another, if we drop the collaborative filtering components, namely  $\mathbf{X}$  and  $\boldsymbol{\theta}$ , then we would recover an instance of Deep Exponential Families (DEFs) (Ranganath et al., 2015) for unsupervised feature learning. However it should be noted that our composition of Gamma distributed layers and Gaussian weights has not been investigated previously in (Ranganath et al., 2015). The PCRL’s representation learning component is also related to the Poisson Gamma Belief Network (PGBN) (Zhou et al., 2016). The key differences are: PGBN uses Dirichlet weights, it factorizes and chains the Gamma shape instead of the rate parameters.

If we further take the shape parameter  $\lambda_z^s$  to infinity, than PCRL is reduced to a Bayesian deep “decoder” neural network, with a stochastic Gamma top layer  $\boldsymbol{\beta}$ . Furthermore, starting from PCRL we can derive a Bayesian Gamma-Poisson variant of the variational auto-encoder

(Kingma and Welling, 2014). To our knowledge, such neural networks with Gamma stochastic layers have not been studied in prior literature.

## 4 INFERENCE & LEARNING

So far we describe PCRL as a generative model. In practice, we are given  $\mathbf{X}$  and  $\mathbf{C}$ , and we are interested in reversing the above generative process to infer the posterior distribution of the latent variables, i.e.,  $p(\boldsymbol{\theta}, \boldsymbol{\beta}, \mathcal{W} | \mathbf{X}, \mathbf{C})$  that would be the most likely to generate the observations. This allows us to explore data in different ways as well as predict unknown ratings for recommendations. Note that by taking  $\lambda_z^s$  to infinity the intermediate latent variables  $\mathcal{Z}$  become deterministic; this is why they are not considered in the above posterior.

As in many Bayesian models, the above posterior is intractable. We therefore resort to approximate inference. In particular, we rely on Variational Inference (VI) (Bishop, 2006; Blei et al., 2017), which is widely used in statistical learning to fit complex Bayesian models.

### 4.1 THE VARIATIONAL FAMILY

The key to variational inference is to introduce a tractable family of distributions  $q$ , governed by a set of *variational parameters*  $\nu$ . The objective is then to find the closest, typically in terms of the Kullback-Leibler (KL) divergence, member of this family to the true posterior.

We can ease inference in the collaborative part of PCRL by introducing an additional layer of auxiliary latent variables, leaving the original model intact when marginalized out. As in (Cemgil, 2009), we add  $K$  variables  $s_{uik} \sim \text{Poisson}(\theta_{uk}\beta_{ik})$  for each observed rating  $x_{ui}$ , such that  $x_{ui} = \sum_k s_{uik}$ . The marginal distribution of  $x_{ui}$  is preserved thanks to the additive property of Poisson random variables (Kingman, 1993). As the  $s_{uik}$ ’s are not random when  $x_{ui}$  is zero, we need to consider these variables for the non-zero elements in  $\mathbf{X}$  only.

One main source of intractability in our model is the coupling between the different latent variables. To overcome this difficulty, we adopt a *mean-field* variational family (Jordan et al., 1999),  $q(\cdot | \nu) = q(\boldsymbol{\theta}, \boldsymbol{\beta}, \mathbf{s}, \mathcal{W} | \nu)$ , which factorizes with respect to the latent variables:

$$q(\cdot | \nu, \mathbf{C}) = \prod_u q(\boldsymbol{\theta}_u | \tilde{\boldsymbol{\lambda}}_u^\theta) \prod_i q(\boldsymbol{\beta}_i | \tilde{\boldsymbol{\lambda}}_i^\beta) \prod_{u,i} q(s_{ui} | \tilde{\phi}_{ui}) \prod_{\ell=0}^L q(\mathbf{W}_\ell | \tilde{\boldsymbol{\xi}}_\ell) \quad (4)$$

where  $\nu = \{\tilde{\boldsymbol{\lambda}}, \tilde{\boldsymbol{\xi}}, \tilde{\boldsymbol{\phi}}\}$ . Note that the variational distributions in the above equation are fully factorized, e.g.,  $q(\boldsymbol{\theta}_u | \tilde{\boldsymbol{\lambda}}_u^\theta) = \prod_k q(\theta_{uk} | \tilde{\lambda}_{uk}^\theta)$ . Each variational distribution is in the same family as the model distribution.

That is, the factors over the Gamma variables,  $\theta$  and  $\beta$ , are also Gamma distributions variational parameters  $\lambda$ , e.g.,  $\tilde{\lambda}_{uk}^\theta = (\tilde{\lambda}_{uk}^{\theta,s}, \tilde{\lambda}_{uk}^{\theta,r})$ . For the item attributes, we further amortize computations by using an inference network. More precisely, we let  $\tilde{\lambda}_i^\beta = (\tilde{\lambda}_i^{\beta,s}, \tilde{\lambda}_i^{\beta,r}) = \mathbf{f}_\omega(\mathbf{c}_i)$ , where  $\mathbf{f}_\omega(\mathbf{c}_i)$  is a deep ‘‘encoder’’ neural network (MLP), parameterized by  $\omega$ , whose input is  $\mathbf{c}_i$ ,  $\tilde{\lambda}_i^{\beta,s} = (\tilde{\lambda}_{ik}^{\beta,s}, \dots, \tilde{\lambda}_{iK}^{\beta,s})$  and  $\tilde{\lambda}_i^{\beta,r} = (\tilde{\lambda}_{ik}^{\beta,r}, \dots, \tilde{\lambda}_{iK}^{\beta,r})$ . Note that, the variational parameters over the item factors  $q(\beta)$  become  $\omega$ .

The factors over  $\mathbf{s}_{ui}$  are Multinomial distributions with free parameters  $\tilde{\phi}$ . This follows from the fact that the conditional distribution of a set of Poisson variables given their sum is a Multinomial (Cemgil, 2009).

The variational factor over  $\mathbf{W}_\ell$  takes this form:  $q(\mathbf{W}_\ell | \tilde{\xi}_\ell) = \prod_{k=1}^{K_\ell} q(\mathbf{w}_{\ell,k} | \tilde{\xi}_\ell^k)$ , where  $\tilde{\xi}_\ell^k = \{\tilde{\boldsymbol{\mu}}_\ell^k, (\tilde{\boldsymbol{\sigma}}_\ell^k)^2 \mathbf{I}_{K_{\ell+1}}\}$  indexes a multivariate Gaussian with a diagonal covariance structure.

Fitting the variational parameters  $\nu$  by minimizing the KL divergence between  $q$  and the true posterior is akin to maximizing the Evidence Lower Bound (ELBO), i.e.,

$$\mathcal{L} = \mathbb{E}_q[\log p(\mathbf{X}, \mathbf{C}, \mathcal{W}, \beta, \theta, \mathbf{s}) - \log(q(\cdot | \nu))] \quad (5)$$

Next we derive an algorithm to maximize (5).

## 4.2 COORDINATE ASCENT LEARNING

We now derive a variational algorithm to estimate PCRL from data. The principle is to alternate the update of each variational parameter while holding the others fixed.

**Updates for  $\tilde{\lambda}^\theta$  and  $\tilde{\phi}$ .** Thanks to the auxiliary variables  $\mathbf{s}$ ,  $\tilde{\lambda}^\theta$  and  $\tilde{\phi}$  have the following closed-form updates,

$$\tilde{\lambda}_{uk}^\theta = \left( \lambda_\theta^s + \sum_i x_{ui} \tilde{\phi}_{uik}, \lambda_\theta^r + \sum_i \frac{\tilde{\lambda}_{ik}^{\beta,s}}{\tilde{\lambda}_{ik}^{\beta,r}} \right), \quad (6)$$

$$\tilde{\phi}_{uik} \propto \exp \left( \psi(\tilde{\lambda}_{uk}^{\theta,s}) - \log \tilde{\lambda}_{uk}^{\theta,r} + \psi(\tilde{\lambda}_{ik}^{\beta,s}) - \log \tilde{\lambda}_{ik}^{\beta,r} \right) \quad (7)$$

where  $\psi(\cdot)$  denotes the digamma function. These updates are identical to those of Bayesian PF (Cemgil, 2009; Gopalan et al., 2015). For more details, please refer to the supplementary material (A.1).

**Parameter update for  $q(\beta)$  and  $q(\mathcal{W})$ .** The remaining variational parameters do not admit closed-form updates. We therefore rely on stochastic steepest gradient ascent to optimize the ELBO according to these parameters.

Keeping only terms which are function of  $\mathcal{W}$  or  $\beta$ , the ELBO can be rewritten, for each item  $i$ , as follows

$$\begin{aligned} \mathcal{L}_i &= \mathbb{E}_q[\log p(\mathbf{s} | \theta, \beta_i)] + \mathbb{E}_q[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] \\ &\quad - \text{KL}(q(\beta_i) || p(\beta_i)) - \text{KL}(q(\mathcal{W}) || p(\mathcal{W})) + \text{const} \quad (8) \end{aligned}$$

with  $\mathcal{L} = \sum_i \mathcal{L}_i$ . While the first expectation and KL terms in (8) are available analytically, the second expectation over  $\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)$  is intractable for general PCRL with respect to both  $\mathcal{W}$  and  $\beta_i$ . We cannot always push the expectations inward non-linear activation functions  $a_\ell$ . This makes the direct evaluation of the gradient of  $\mathcal{L}_i$  problematic. To overcome this difficulty we build a Monte Carlo estimator of the gradient of  $\mathbb{E}_q[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)]$ . To this end, we rely on the recent Rejection Sampling Variational Inference (RSVI) method (Naesseth et al., 2017), which generalizes the *reparameterization trick* (Kingma and Welling, 2014; Rezende et al., 2014).

RSVI requires continuous latent variables, and its applicability depends on whether we can sample from the variational distribution  $q(\beta; \omega)$  using the following reparameterization: (i) draw  $\epsilon \sim \pi(\epsilon; \omega)$ , (ii)  $\beta = \mathcal{G}(\epsilon, \omega)$ , where  $\mathcal{G}$  is a deterministic function (mapping) that must be differentiable with respect to  $\omega$ , and the distribution  $\pi(\epsilon; \omega)$ , defined by a rejection sampling algorithm, takes the following form,

$$\pi(\epsilon; \omega) = t(\epsilon) \frac{q(\mathcal{G}(\epsilon, \omega); \omega)}{r(\mathcal{G}(\epsilon, \omega); \omega)}, \quad (9)$$

where  $r$  and  $t$  are respectively the *proposal* and original distributions of  $\epsilon$  used in rejection sampling. In this procedure, some samples from  $t$  are not valid (and therefore rejected), here we are interested in the distribution of the accepted samples  $\pi(\epsilon; \omega)$ . For more details, please refer to the supplementary material (A.2.1) where we provide a brief review of the reparameterized acceptance-rejection algorithm in our notations.

Assuming that we have a reparameterized acceptance-rejection sampling procedure to simulate from  $q(\beta_{ik}; \omega)$ , the next step is to rewrite  $\mathbb{E}_{q(\beta_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)]$  as an expectation with respect to  $\pi(\epsilon_i; \omega)$  as follows

$$\begin{aligned} \mathbb{E}_{q(\beta_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] \\ = \mathbb{E}_{\pi(\epsilon_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \mathcal{G}(\epsilon_i, \omega))] \quad (10) \end{aligned}$$

where,  $\epsilon_i = \{\epsilon_{i1}, \dots, \epsilon_{iK}\}$ , and  $\pi$  fully factorizes over the components of  $\epsilon_i$ . The form of  $\mathcal{G}(\epsilon_i, \omega)$  will be given shortly. Based on (10) the gradient of  $\mathbb{E}_{q(\beta_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)]$  is

$$\begin{aligned} \nabla_\omega \mathbb{E}_{q(\beta_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] \\ = \mathbb{E}_{\pi(\epsilon_i; \omega)}[\log p(\mathbf{c}_i | \mathcal{W}, \mathcal{G}(\epsilon_i, \omega)) \nabla_\omega \log \pi(\epsilon_i; \omega)] \\ + \mathbb{E}_{\pi(\epsilon_i; \omega)}[\nabla_\omega \log p(\mathbf{c}_i | \mathcal{W}, \mathcal{G}(\epsilon_i, \omega))] \quad (11) \end{aligned}$$

where we have pushed the gradient into the integral, used the log derivative-trick or REINFORCE (Glynn, 1990; Williams, 1992), and expressed integrals as expectations. All the derivations details of equations (11) and (10) are given in the supplementary material (A.2.2).

We can now form an unbiased Monte Carlo estimate of the above gradient as follows:

$$\begin{aligned} & \nabla_{\omega} \mathbb{E}_{q(\beta_i; \omega)} [\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] \\ & \simeq \frac{1}{M} \sum_{m=1}^M \log p(\mathbf{c}_i | \mathcal{W}, \beta_i^m) \nabla_{\omega} \log \frac{q(\mathcal{G}(\epsilon_i^m, \omega); \omega)}{r(\mathcal{G}(\epsilon_i^m, \omega); \omega)} \\ & + \frac{1}{M} \sum_{m=1}^M \nabla_{\omega} \log p(\mathbf{c}_i | \mathcal{W}, \beta_i^m) \end{aligned} \quad (12)$$

where  $\beta_i^m = \{\beta_{i1}^m, \dots, \beta_{iK}^m\}$ , and  $\beta_{ik}^m = \mathcal{G}(\epsilon_{ik}^m, \omega)$ , with  $\epsilon_{ik}^m \sim \pi(\epsilon_{ik}, \omega)$ . In practice we set  $M = 1$ .

Following Naesseth et al. (2017), for the Gamma random variables, we use the reparameterization proposed by Marsaglia and Tsang (2000). For a  $\text{Gamma}(\lambda_{\omega}^s, \lambda_{\omega}^r)$ , such that  $\lambda_{\omega}^s \geq 1$ , we use:

$$\mathcal{G}(\epsilon, \omega) = \frac{1}{\lambda_{\omega}^r} \left( \lambda_{\omega}^s - \frac{1}{3} \right) \left( 1 + \frac{\epsilon}{\sqrt{9\lambda_{\omega}^s - 3}} \right) \quad (13)$$

with  $\epsilon \sim t(\epsilon) = \mathcal{N}(0, 1)$ . When the shape parameter is less than 1,  $\lambda_{\omega}^s < 1$ , we use the shape augmentation technique (Marsaglia and Tsang, 2000). That is, if  $\beta \sim \text{Gamma}(\lambda^s + 1, \lambda^r)$ , and  $\beta = u^{\frac{1}{\lambda^s}} \tilde{\beta}$  with  $u \sim \mathcal{U}[0, 1]$ , then  $\beta \sim \text{Gamma}(\lambda^s, \lambda^r)$ .

Approximating the gradient of the ELBO with respect to  $\xi$  is simpler since the Gaussian satisfies the requirements of the original reparameterization trick (Kingma and Welling, 2014; Rezende et al., 2014). Roughly, the second expectation in (11) vanishes since the marginal distribution of the samples  $\epsilon$  is independent of the variational parameters  $\xi$ . Hence, the Monte Carlo estimator of  $\nabla_{\xi} \mathbb{E}_{q(\mathcal{W})} [\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)]$  takes this form:

$$\begin{aligned} & \nabla_{\xi} \mathbb{E}_{q(\mathcal{W}; \xi)} [\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] \\ & \simeq \frac{1}{M} \sum_{m=1}^M \nabla_{\xi} \log p(\mathbf{c}_i | \mathcal{W}^m, \beta_i) \end{aligned} \quad (14)$$

where  $\mathcal{W}^m = \{\mathbf{W}_1^m, \dots, \mathbf{W}_L^m\}$ ,  $\mathbf{w}_{\ell, k}^m = \mathcal{T}(\boldsymbol{\eta}^m, \tilde{\xi}_{\ell}^k) = \tilde{\boldsymbol{\mu}}_{\ell}^k + \tilde{\boldsymbol{\sigma}}_{\ell}^k \odot \boldsymbol{\eta}^m$ , and  $\boldsymbol{\eta}^m \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ , the notation  $\odot$  refers to the Hadamard product.

Putting it all together, our Monte Carlo estimator for the gradient of the ELBO, is given by:

$$\begin{aligned} & \nabla_{\omega, \xi} \mathcal{L}_i \simeq I \nabla_{\omega} (\mathbb{E}_q [\log p(\mathbf{s} | \boldsymbol{\theta}, \beta_i)] - \text{KL}(q(\beta_i) || p(\beta_i))) \\ & + \frac{I}{M} \sum_{m=1}^M \nabla_{\omega, \xi} \log p(\mathbf{c}_i | \mathcal{W}^m, \beta_i^m) \\ & + \frac{I}{M} \sum_{m=1}^M \log p(\mathbf{c}_i | \mathcal{W}^m, \beta_i^m) \nabla_{\omega} \log \frac{q(\mathcal{G}(\epsilon_i^m, \omega); \omega)}{r(\mathcal{G}(\epsilon_i^m, \omega); \omega)} \\ & - \nabla_{\xi} \text{KL}(q(\mathcal{W}) || p(\mathcal{W})) \end{aligned} \quad (15)$$

With the estimator (15) in place, we perform stochastic gradient ascent over the parameters  $\omega$  and  $\xi$ . We use backpropagation to evaluate the gradients over the weights of the inference network  $\omega$ . In particular, we use RMSProp to scale the gradients before applying them. In practice, we take several stochastic gradient steps to nearly optimize the ELBO with respect to  $\omega$  and  $\xi$ , before to perform coordinate ascent step to update  $\tilde{\lambda}^{\theta}$  and  $\tilde{\phi}$ . More precisely, after each epoch of stochastic gradient ascent we update  $\tilde{\lambda}^{\theta}$  and  $\tilde{\phi}$ .

### 4.3 MISSING RATINGS ESTIMATION

Once PCRL is fit to the observations, we can estimate the unknown ratings for each user  $u$  and item  $i$  as follows

$$\hat{x}_{ui} = \mathbb{E}_q(\boldsymbol{\theta}_u^{\top} \beta_i) = \mathbb{E}_q(\boldsymbol{\theta}_u)^{\top} \mathbb{E}_q(\beta_i), \quad (16)$$

Note that this expectation is intractable with respect to the true posterior. These predicted values are then used to rank unrated items for each user so as to provide her with a recommendation list.

### 4.4 DESIRABLE PROPERTIES

The variational PCRL enjoys several desirable properties. In terms of efficiency, the operations involving user-item and item-context interactions need to be carried out only for the non-zero entries in  $\mathbf{X}$  and  $\mathbf{C}$ . It can be shown that the computational time complexity of the variational PCRL algorithm (its batch version) is linear in the number of non-zeros entries in  $\mathbf{X}$  and  $\mathbf{C}$ .

The main intuition behind PCRL is to learn item representations encoding various contextual regularities among items that are good at explaining the user behaviour. Interestingly, this intuition is reflected theoretically, as seen in the proposition below. Note that this result arises naturally from our formulation.

**Proposition 1** *Let  $q(\beta_i; \omega)$  be the variational distribution over the item factor in PCRL. Then, for fixed  $\tilde{\lambda}^{\theta}$ ,  $\tilde{\phi}$  and  $\tilde{\xi}$ , maximizing the ELBO (5) with respect to  $\omega$  is equivalent to maximizing the following criterion:*

$$\sum_i \mathbb{E}_q [\log p(\mathbf{c}_i | \mathcal{W}, \beta_i)] - \text{KL}(q(\beta_i; \omega) || \tilde{q}(\beta_i)). \quad (17)$$

where  $\tilde{q}(\beta_i)$  denotes the optimal mean-field variational distribution over the item attributes in Bayesian Poisson factorization. That is,  $\tilde{q}(\beta_i) = \prod_k \tilde{q}(\beta_{ik})$ , and  $\tilde{q}(\beta_{ik}) = \text{Gamma}(\lambda_{\beta}^s + \sum_u x_{ui} \tilde{\phi}_{uik}, \lambda_{\beta}^r + \sum_u \frac{\tilde{\lambda}_{uk}^s}{\lambda_{uk}^r})$ .

The proof is given below. The KL term in the above proposition can be viewed as a regularizer which encourages PCRL's variational factor over the items,  $q(\beta_i; \omega)$  to look like its optimal mean-field counterpart in Bayesian

Poisson factorization  $\tilde{q}(\beta_i)$ . Recall that  $\tilde{q}(\beta_i)$  is independent of the item context  $\mathbf{C}$ , and puts high probability on configurations of  $\beta_i$  that explain user preferences. This makes it clear how the collaborative PF component in PCRL guides or encourages the representation learning part to focus on extracting contextual features that might be useful for explaining user preferences. From this perspective, PCRL can be interpreted as regularizing a deep generative model with Bayesian Poisson Factorization.

**Proof.** If we fix all the variational parameters except  $\omega$ , then maximizing the ELBO with respect to the latter is equivalent to maximizing

$$\begin{aligned} \mathcal{L}_i = & \mathbb{E}_q[\log p(\mathbf{s}|\boldsymbol{\theta}, \beta_i) + \log p(\beta_i)] \\ & + \mathbb{E}_q[\log p(\mathbf{c}_i|\mathcal{W}, \beta_i) - \log q(\beta_i; \omega)] + \text{const.} \end{aligned} \quad (18)$$

In particular, we have

$$\log p(\beta_{ik}) \propto (\lambda_\beta^s - 1) \log(\beta_{ik}) - \lambda_\beta^r \beta_{ik}, \text{ and,}$$

$$\log p(s_{uik}|\theta_{uk}, \beta_{ik}) \propto s_{uik} \log(\beta_{ik}) - \theta_{uk} \beta_{ik}.$$

Therefore we get

$$\begin{aligned} \mathbb{E}_{q(\theta, s)}[\log p(\mathbf{s}|\boldsymbol{\theta}, \beta_i) + \log p(\beta_i)] = & -(\lambda_\beta^r + \sum_u \frac{\tilde{\lambda}_{uk}^s}{\tilde{\lambda}_{uk}^r}) \beta_{ik} \\ & + (\lambda_\beta^s + \sum_u x_{ui} \tilde{\phi}_{uik} - 1) \log \beta_{ik} + \text{const,} \end{aligned} \quad (19)$$

where we recognize the log (up to the normalizing constant) of the following Gamma( $\lambda_\beta^s + \sum_u x_{ui} \tilde{\phi}_{uik}$ ,  $\lambda_\beta^r + \sum_u \frac{\tilde{\lambda}_{uk}^s}{\tilde{\lambda}_{uk}^r}$ ) distribution. Adding the normalizing constant (which is independent of  $\omega$ ) and plugin (19) into (18), completes the proof. ■

## 5 EXPERIMENTS

In this section, we study the impact of item context, and our modeling assumptions, on personalized item recommendation as well as item representation learning.

**Datasets.** We use five datasets from `Amazon.com`<sup>3</sup>, provided by McAuley et al. (2015b,a). They include both user-item interactions and the ‘‘Also Viewed’’ lists that we treat as item contexts. We preprocess all datasets so that each user (resp. item) has at least ten (resp. two) ratings, and the sets of row and column items in  $\mathbf{C}$  are identical. Table 1 reports the resulting statistics.

**Comparative Models.** We benchmark PCRL<sup>4</sup> against strong comparable generative factorization models.

- MCF: Matrix Co-Factorization (Park et al., 2017) incorporates item-item relationships into Gaussian MF.

Table 1: Statistics of the Datasets.

- PF: Bayesian Poisson Factorization (Gopalan et al., 2015) arises as a special case of our model without the context-specific components. Comparison to PF allows us to assess the impact of item contexts.
- CTPF: Collaborative Topic Poisson Factorization (Gopalan et al., 2014b) was developed for content-based recommendation, but can serve as baseline by substituting item-word matrix with item-context  $\mathbf{C}$ .
- CoCTPF: Content-only CTPF (Gopalan et al., 2014b) is a variant of CTPF without the document topic offsets; please refer to (Gopalan et al., 2014b) for details. Comparison to CoCTPF allows us to assess the impact of our modeling choice of multilayered representation learning, as opposed to PF, for item context.
- RL+PF: Representation Learning + PF is a two-stage pipelined approach, which models item context independently from user preferences. First, it infers  $q(\beta)$  from  $\mathbf{C}$  using PCRL’s representation learning-specific part. Second, it performs PF on  $\mathbf{X}$  to infer  $q(\theta)$  while holding the item factors fixed. Comparison to RL+PF allows us to assess the benefit of our unified modeling.

**Experimental Setup.** For each dataset, we randomly select 80% of the ratings as training data and the remaining 20% as test data. Random selection is carried out three times independently on each dataset. The reported result is the average performance over the three samples.

Following previous works (Gopalan et al., 2014a, 2015), we set the number of latent dimensions for user preferences  $\theta$  and item attributes  $\beta$  to 100. In all experiments, we use a two-layer PCRL ( $\mathbf{z}_1, \beta$ ) with dimensions (100, 300) in the item representation learning component. The activation functions at the layers ( $\mathbf{c}, \mathbf{z}_1$ ) are set to (sigmoid, relu). Similarly, we use a two-layer inference network (encoder) with dimensions (300, 100 + 100)—recall that this network outputs Gamma variational parameters, a total of 100 (shape) + 100 (rate) parameters—and activation functions (relu, sofplus). When necessary we add a small offset to ensure strict positivity, e.g., the rate of the Poisson, the shape and rate of the Gamma, all must be positive. To encourage sparse latent representations, we set Gamma prior parameters ( $\lambda^s, \lambda^r$ ) to (0.3, 0.3)—resulting in exponen-

tially shaped Gamma distributions with mean equal to 1. For an illustration, please refer to Figure 2 in (Cemgil, 2009). We follow the same strategy, grid search, as in (Park et al., 2017) to set the different hyperparameters of MCF. In order for the comparisons to be fair, we use the same random parameters to initialize all PF-based models, where it is possible.

**Item Recommendation.** Here we look into the quality of item recommendation, and discuss item representation later. We assess the recommendation accuracy on a set of held-out items—the test set. We retain four widely used measures for top- $M$  recommendation, namely the Normalized Discount Cumulative Gain (nDCG), Mean Reciprocal Rank (MRR), Precision@ $M$  ( $P@M$ ) and Recall@ $M$  ( $R@M$ ), where  $M$  is the number of items in the recommendation list (Bobadilla et al., 2013). Intuitively, nDCG and MRR measures the ranking quality of a model, while Precision@ $M$  and Recall@ $M$  assess the quality of a user’s top- $M$  recommendation list. These measures vary from 0.0 to 1.0 (higher is better).

Table 2 depicts the average performances<sup>5</sup> of the competing models in terms of different metrics, over all datasets. For the sake of completeness we also report, in Table 3, the average log-likelihood values for the Poisson models, i.e.,  $\log p(\mathbf{X}|\boldsymbol{\theta}, \boldsymbol{\beta})$ , where we set  $\boldsymbol{\theta}$  and  $\boldsymbol{\beta}$  to their mean values under the corresponding variational distribution.

<sup>5</sup>Most of the standard deviation values are of order  $1e-3/1e-4$ , we do not report them to fit Table 2 into one column.

Table 3: Comparison of Poisson log-likelihood.

The main points from these results are as follows.

*Item context is useful for personalized recommendation.*

The proposed PCRL substantially outperforms the other competing models in virtually all cases. In particular, the major difference between the original PF and our proposed PCRL as well as CTPF or CoCTPF is that the latter models incorporate item context. We can therefore attribute the performance improvements reached by those over PF to the modeling of the item context.

*Poisson Factorization performs better than its Gaussian counterpart.* Effectively CoCTPF is the closest Poisson alternative to the Gaussian MCF. The former outperforms the latter in all cases. Even when augmented with contextual item information, the Poisson remains a better alternative than the Gaussian for modeling user preferences, which is in line with the findings of previous work on PF.

*The hierarchical (multilayered) structure in PCRL is useful.* The model PCRL can be viewed as an alternative to CoCTPF, where a multilayered generative model is substituted for PF to model item contexts. From Tables 2 and 3, we note that PCRL substantially outperforms CoCTPF on almost all datasets and across all metrics, except in terms of recall on Automotive. Since the main difference between the two approaches lies in how they model item context, these results suggest that our multilayered architecture does a better job than PF in extracting latent features from item’s contexts.

*Joint modeling or learning is beneficial.* A key point to PCRL is to model user preferences and item contexts jointly. As Tables 2 and 3 show, PCRL outperforms the two-stage pipelined model RL+PF. Quite surprisingly, the latter performs even worse than PF on almost all datasets. This demonstrates the importance of joint modeling, and suggests that the PCRL’s collaborative component plays an important role in guiding item representation learning towards extracting contextual features that are relevant for explaining user preferences. Whereas modeling the item context independently yields item representations that capture other item aspects, which are not necessarily as good for predicting user preferences.

To gain further insight into the results, especially the latter two points above, we conduct another series of experiments where we compare the quality of the item representations produced by the different models.

Figure 2: Average NMI over different datasets.

Figure 3: Average Recall@50 over different datasets.

**Item Representations.** Evaluating the quality of item representations is a challenging task. Here, we propose to make such an evaluation in terms of clustering. We seek to assess how well the representations produced by each model are good at organizing items into meaningful clusters. As evaluation measure, we use Normalized Mutual Information (NMI) (Strehl and Ghosh, 2002). Intuitively, NMI quantifies how much the estimated clustering is informative about the true clustering. As the “true” clustering, we retain the ten most frequent item categories (classes) in each dataset; these categories per dataset are listed in the supplementary material (B). We do not consider Grocery in this experiment, since its category labels are not available.

To form clusters based on learned item representations, we use the spherical k-means (*Skmeans*) (Dhillon and Modha, 2001). We perform fifty runs of (*Skmeans*), with different initial random points, and report the average NMI of the ten best runs—in terms of the *Skmeans*’ criterion—as the final results. The fifty random starting points used by *Skmeans* are the same across all models.

Figure 2 reports the clustering results. For reference, Figure 3 reproduces the Recall@50 (the results are consistent across all metrics) on the item recommendation task.

PF that relies solely on user-item interactions obtains the worst clustering results. Such sparse information is not rich enough to allow PF infer relationships among items. The other models that use contextual information perform better. In particular, we note that PCRL produces representations that are better suited to organize items into categories than the CoCTPF models. This provides additional empirical support for the importance of our hierarchical architecture to model items’ contexts.

Interestingly, RL+PF performs relatively well on clustering (Figure 2) even as it performs rather poorly on recommendation (Figure 3). One possible explanation of

this phenomenon is that RL+PF focuses on item similarity. While this is beneficial for clustering, this might not always be useful for recommendation. Hypothetically, two similar items may be alternatives. Instead of recommending alternatives to an item that a user has purchased, it may be useful to recommend complementary items (which may not belong to the same category).

## 6 DISCUSSION

PCRL composes Bayesian Poisson factorization with a multilayered latent variable model to join both sources of data: user preferences and item contexts. Empirical results provide strong support for the benefits of our modeling framework and reflect the underlying assumption in PCRL, namely: the collaborative component guides the item representation learning towards extracting contextual features that are useful for the recommendation task, whereas the representation learning encourages the collaborative part to rely on item’s contexts to explain recommendations, alleviating data sparsity.

While our focus here has been on item context, PCRL could potentially be extended to learn item representations from other modalities, e.g., text, images, etc. Another interesting direction of future work, is to investigate deeper variants of PCRL which would improve the feature learning.

We make PCRL’s implementation publicly available as part of the CORNAC<sup>6</sup> recommendation library.

## Abstract

Generative models, while not new, have taken the deep learning field by storm. However, the widely used training methods have not exploited the substantial statistical literature concerning parametric distributional testing. Having sound theoretical foundations, these goodness-of-fit tests enable parts of the black box to be stripped away. In this paper we use the Shapiro-Wilk and propose a new multivariate generalization of Shapiro-Wilk to respectively test for univariate and multivariate normality of the code layer of a generative autoencoder. By replacing the discriminator in traditional deep models with the hypothesis tests, we gain several advantages: objectively evaluate whether the encoder is actually embedding data onto a normal manifold, accurately define when convergence happens, explicitly balance between reconstruction and encoding training. Not only does our method produce competitive results, but it does so in a fraction of the time. We highlight the fact that the hypothesis tests used in our model asymptotically lead to the same solution of the  $L_2$ -Wasserstein distance metrics used by several generative models today.

## 1 INTRODUCTION

Recently a large variety of generative models have been proposed such as generative adversarial networks and generative autoencoders. A widely-used way to construct such a network requires training of a generator and a discriminator. There are great needs to understand the statistical foundation of these generative models. On the other hand, there exists substantial statistical literature

concerning parametric distributional hypothesis testing with a solid theoretical base. One particular group of deep generative models which, we show in this study, can benefit from hypothesis testing is the generative autoencoder (GAE). The objective of these models is to reconstruct the input as accurately as possible, while constraining the code layer to a specified distribution, usually normal. Often times once training has ended, this code layer distribution does not in fact match the required distribution. The spirit of these models is to embed data into a distribution that matches the prior to enable sampling, and thus it is of utmost importance we have ways to assess the quality of the fit. In other words, if the embedded distribution does not match the prior that is used to sample and generate instances, the method does not work in theory.

In this paper we propose to use goodness-of-fit hypothesis tests of normality on the code layer of an autoencoder as a new type of critic in both the univariate and multivariate case. Doing so leads to an adversary-free optimization problem. These hypothesis tests provide a more direct way to measure if the data representation, the latent code layer, matches a pre-specified distribution. More specifically, we test for normality using a composite test:

$$H_0 : \mathbf{X} \in \mathcal{G} \quad \text{vs} \quad H_1 : \mathbf{X} \notin \mathcal{G} \quad (1)$$

where  $\mathcal{G} = \{\pi : \pi = \mathcal{N}(\mu, \Sigma), -\infty < \mu < \infty, \Sigma \text{ is positive semi-definite (p.s.d)}\}$ . Many tests for comparing two distributions can be used in our model<sup>1</sup>. We specifically focus on the well studied univariate Shapiro-Wilk test (Shapiro and Wilk, 1965) and propose a new multivariate generalization of the Shapiro-Wilk test to demonstrate the effectiveness of the new method. We further highlight a link between these methods and those based on the Wasserstein distance by drawing attention to the fact that the Shapiro-Wilk test and the  $L_2$ -Wasserstein distance lead to the same asymptotic solution.

The remainder of the paper follows as such. Section 2 covers existing work that is most closely related to our method. In section 3 we present the basics of hypothe-

sis testing followed by a recap of the Shapiro-Wilk test and propose its multivariate generalization. Section 4 describes the new method in detail, followed by theoretical analysis in Section 5 where we explore the linkage between the hypothesis tests and several distance-based methods of training. Section 6 discusses the empirical results. Section 7 presents a discussion of the new method, followed by a conclusion section 8.

**Notation.** Boldface capital letters, e.g.,  $\mathbf{Y}$ , denote matrices while boldface lower case, e.g.,  $\mathbf{y}$ , denote vectors. Scalar values are denoted by lower case letters and no font change, such as  $y_i$ . Upper case without font change denote test statistics. Calligraphic capital letters, e.g.,  $\mathcal{Y}$ , denote sets. Probability density functions (PDF) are represented as  $p(\mathbf{z})$ , while cumulative distribution functions are the upper case version  $P(\mathbf{z})$ . Any modifications to this are explained in their respective context.

## 2 RELATED WORK

The original generative adversarial network (GAN) (Goodfellow et al., 2014) sparked a surge in generative models, parameterized by neural networks, that has yet to abate. As this paper is focused on autoencoders, GAN can be thought of as just the decoder part of a regular autoencoder. This decoder,  $G(\cdot)$ , endeavors to learn a mapping from the sampled prior,  $p(\mathbf{z})$ , to the data distribution  $p(\mathbf{x})$ . An auxiliary network called the discriminator,  $D(\cdot)$ , serves to discern how close the generated data distribution,  $p_g(\mathbf{z})$ , is to the true data distribution  $p(\mathbf{x})$ . Training a GAN amounts to the widely known two-player minimax game  $\min_G \max_D V(D, G) = \mathbb{E}_{\mathbf{x} \sim p_d(\mathbf{x})} [\log D(\mathbf{x})] + \mathbb{E}_{\mathbf{z} \sim p(\mathbf{z})} [\log(1 - D(G(\mathbf{z})))]$ .

Using an autoencoder styled network to train a generative model is not new; the main goal being to understand the code layer distribution given data,  $q(\mathbf{z}|\mathbf{x})$ , while minimizing a reconstruction error. These GAEs tend to fall into several classes dictated by their training and generating mechanisms, and include adversarial methods, variational methods, MCMC based procedures, and the most closely related to our work, statistical hypothesis tests.

The adversarial autoencoder (AAE) (Makhzani et al., 2015) is a modification of the original GAN in which an encoder network is included, and where the discriminator is shifted from the decoder network to the latent code space. The encoder creates the encoding distribution  $q(\mathbf{z}|\mathbf{x})$  which defines an aggregated posterior distribution  $q(\mathbf{z}) = \int_{\mathbf{x}} q(\mathbf{z}|\mathbf{x}) p_{data}(\mathbf{x}) d\mathbf{x}$  where  $p_{data}(\mathbf{x})$  is the input data distribution. As in GAN, training the AAE, in part, amounts to a minimax game between a generator network,  $G(\cdot)$ , and a discriminator network,  $D(\cdot)$  where the objective is to have  $q(\mathbf{z})$  match  $p(\mathbf{z})$ , the specified

prior distribution defined over the latent space  $\mathcal{Z}$ . The decoder maps back to data space  $\mathcal{X}$  giving  $p(\mathbf{x}|\mathbf{z})$ . A reconstruction loss is minimized as usual.

However, aside from possible mode collapse issues, there are questions regarding how the generator and discriminator should be balanced during training, the issue of when to stop still has not been satisfactorily addressed. Within the adversarially trained autoencoders it is possible to vary the loss function used in the discriminator. One possible change is to use a Wasserstein loss (Arjovsky et al., 2017) (WGAN) which alleviates the vanishing gradient problem. Improvements to the WGAN include the addition of a gradient penalty (Gulrajani et al., 2017). In (Tolstikhin et al., 2017) the authors modify the AAE to use a Wasserstein distance between the target distribution and the model distribution.

Variational autoencoder (VAE) methods include the work of (Kingma and Welling, 2013; Rezende et al., 2014; Mnih and Gregor, 2014). Despite being some of the most successful methods for generation, they have been found to produce unrealistic or blurry samples (Dosovitskiy and Brox, 2016). The VAE model makes use of a random decoder mapping  $p(\mathbf{x}|\mathbf{z})$ . Moreover, there is no auxiliary network needed for discrimination. A third line of thought comes from modification of the traditional autoencoder paradigm so as to recover the density using MCMC. These include (Rifai et al., 2012; Bengio et al., 2013b, 2014) and attempt to use contraction operators, or denoising criteria in order to generate a Markov chain by repeated perturbations during the encoding phase. However, it has been a challenge to ensure adequate mixing in that process (Bengio et al., 2013a).

To the best of our knowledge there is only one method, aside from our work, that falls into the class of statistical hypothesis tests for training generative networks. It is based on the maximum mean discrepancy (MMD) (Gretton et al., 2007, 2012). Two works utilizing the MMD for training came out simultaneously (Li et al., 2015) and (Dziugaite et al., 2015), each taking a different approach. Li et al. used the MMD on features learned from the autoencoder to shape the distribution of the output layer of the network to create a generative moment matching network (GMMN). On the other hand, Dziugaite et al. applied the MMD to directly compare the generated against true data. This latter method is the closest to our work. When using the MMD, the bandwidth parameter in the kernel plays a crucial role in determining the statistical efficiency of MMD, and it is still an open problem how to find its optimal value. Moreover, using kernels in MMD requires that the computation of the objective function scales quadratically with the amount of data. This is due to the requirement of a linear increase in sample size as

dimensionality increases, and is necessary to ensure the power, covered next, goes to 1 as  $n \rightarrow \infty$ . In (Li et al., 2017) the authors propose to mitigate the bandwidth problem by using adversarial kernel learning to replace the fixed Gaussian kernel in the GMMN, while in (Sutherland et al., 2016) the authors propose to maximize the power of the statistical test based on the MMD.

### 3 STATISTICAL HYPOTHESIS TESTS

Distinguishing between two distributions is often carried out in the form of a hypothesis test. Suppose  $\theta$  is a quantity of interest, the format of a hypothesis test between the null,  $H_0$ , and the alternative,  $H_1$ , is:  $H_0 : \theta \in \Theta_0$  vs  $H_1 : \theta \in \Theta_0^c$ . To understand a hypothesis test the concept of statistical power is required. Two types of errors associated with hypothesis testing exist: type I, and type II. A type I error occurs when the null is rejected when it is true; the rate of this is called  $\alpha$ . A type II error occurs when the null is not rejected when the alternative is true, its rate defined as  $\beta$ . Power is defined to be  $1 - \beta$ . It is not possible to control both type I and type II errors; therefore it is necessary to pre-specify the  $\alpha$  one is willing to tolerate. The more powerful the test, the better. By utilizing information about the null distribution, a test statistic can be computed such that, for a given  $\alpha$ , if its value is unlikely to be observed, then  $H_0$  is rejected in favor of the alternative hypothesis' conclusion. This discerning threshold is called the critical value, and comes from the null distribution of the test statistic. When this distribution is known, a p-value, which is the observed significance level of the test, can be calculated. The p-value is bounded between 0 and 1, and can be interpreted as the probability the test statistic being at least as extreme as the test statistic calculated on the sample under  $H_0$ . The p-value affords the ability for different users to judge whether to reject or fail to reject  $H_0$ .

Testing for goodness-of-fit takes up the task of testing whether the underlying data distribution belongs to some given family of distribution functions. One such example is determining if a sample  $x_1, \dots, x_n$  is normally distributed or not, for which the hypothesis test is denoted in Eq.(1). For a more thorough discussion of hypothesis testing and goodness-of-fit see (Casella and Berger, 2002; Lehmann and Romano, 2006).

Hypothesis testing techniques fall into several sub-categories. (Seier, 2002) describes these sub-categories as those tests belonging to: skewness and kurtosis tests, empirical distribution function tests, regression and correlation tests, and others. Hypothesis tests can also be split into parametric vs non-parametric. Parametric hypothesis tests make assumptions about the underlying distribution while non-parametric hypothesis tests (also

called distribution-free tests) do not. In this paper we focus on a test containing a parametric null hypothesis.

#### 3.1 UNIVARIATE: SHAPIRO-WILK TEST

A goodness-of-fit test for normality is the Shapiro-Wilk (SW) test. In a Monte Carlo simulation by (Razali et al., 2011) the authors compared the power of the SW test to several non-parametric tests on various alternative distributions concluding it was the most powerful. The SW test is a composite parametric test to determine if a univariate data sample comes from a normal distribution. The original SW test was limited to a sample size between 3 and 50, but (Royston, 1982) extended the approach to use up to 2000 samples. The SW original test statistic,  $W$ , is calculated as

$$W = \frac{(\sum_{i=1}^n a_i x_{(i)})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}. \quad (2)$$

In the Eq.(2)  $x_{(i)}$  represents the  $i^{th}$  ordered statistic of the sample. The constants  $a_i$  are given by  $(a_1, a_2, \dots, a_n) = \frac{\mathbf{m}^T \mathbf{V}^{-1}}{(\mathbf{m}^T \mathbf{V}^{-1} \mathbf{V}^{-1} \mathbf{m})^{1/2}}$ , where  $\mathbf{m}$  is a vector consisting of the  $n$  expected values of the order statistics of independent and identically distributed random variables samples from the standard normal distribution.  $\mathbf{V}$  is the covariance matrix of those order statistics. The most extreme order statistics are weighted the largest, and decrease when approaching the median. This property of the SW test will be important in later sections. Calculation of the constants  $a_i$  can be computationally demanding, prompting Royston in (Royston, 1992) to approximate these coefficients. He found that for  $12 \leq n \leq 2000$  a two-parameter log-normal distribution fitted the upper half of the empirical distribution of  $1 - W$ . The associated p-value for  $W$  is referred to the upper tail of  $\mathcal{N}(0, 1)$ . Using the hypothesis test defined in Eq.(1), the SW test fails to reject  $H_0$  if  $W > W_\alpha$ , or the p-value is larger than  $\alpha$ , where  $W_\alpha$  is the critical value based on the chosen confidence level. Three analytical properties that will become useful in the later sections, originally presented as lemmas in (Shapiro and Wilk, 1965), are cited as follows:

**Lemma 3.1.**  $W$  is scale and origin invariant.

**Lemma 3.2.**  $W$  has a maximum value of 1

**Lemma 3.3.** The minimum value of  $W$  is  $\frac{na_1^2}{(n-1)}$

As our approach makes use of this test as a new loss function, one must be cognizant of its computational complexity. Enjoying the benefits of a strong test at the cost of long run time may not be appealing. However, the  $a_i$  are calculated a single time prior to training and are stored. The actual time complexity of the SW test during training is  $O(n \log(n))$ .

### 3.2 A NEW MULTIVARIATE GENERALIZATION OF SHAPIRO-WILK

**Definition 3.1.** (Multivariate Normal (Rao et al., 1973)) A  $d$ -dimensional random variable  $\mathbf{u}$ , that is, a random variable  $\mathbf{u}$  taking values in  $E_d$  (Euclidean space of  $d$ -dimensions) is said to have a  $d$ -variate normal distribution  $\mathcal{N}_d$  if and only if every linear function of  $\mathbf{u}$  has a univariate normal distribution.

In a review by (Mecklin and Mundfrom, 2005) the authors noted more than 50 methods for testing multivariate normality. However, finding a multivariate test that is both powerful, and has low time complexity proved challenging. This necessitated the creation of a new multivariate hypothesis test that was able to make use of the strengths of SW, and relies on a well-known characterization of the multivariate normal (MVN) distribution.

**Proposition 3.4.**  $\mathbf{x} \sim \mathcal{N}_d(\mu, \Sigma)$  if and only if  $\mathbf{z} = \Sigma^{-\frac{1}{2}}(\mathbf{x} - \mu) \sim \mathcal{N}_d(\mathbf{0}, \mathbf{I})$ .

Letting  $\bar{\mathbf{x}}$  and  $\mathbf{S}$  be respectively the sample mean and covariance matrix, define  $\mathbf{S}^{-\frac{1}{2}}$  as the symmetric positive definite square root of the inverse of  $\mathbf{S}$ . Therefore, when  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n \sim \mathcal{N}_d(\mu, \Sigma)$ , then  $\mathbf{z}_i = \mathbf{S}^{-\frac{1}{2}}(\mathbf{x}_i - \bar{\mathbf{x}}) \quad \forall i = 1, \dots, n$  should be approximately  $\mathcal{N}_d(\mathbf{0}, \mathbf{I})$ . Under the assumption that observations are independent, and writing  $\mathbf{z}_i = (z_{i1}, z_{i2}, \dots, z_{id})^T$ , then  $z_{ij} \sim \mathcal{N}(0, 1)$  approximately for each  $j = 1, \dots, d$  and  $i = 1, \dots, n$ .

To test the null hypothesis that the sample  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$  is from  $\mathcal{N}_d(\mu, \Sigma)$  where  $\mu$  and  $\Sigma$  are unknown we propose to vectorize the entire  $\mathbf{Z}$  matrix as  $\mathbf{z}_{vec} = \text{vec}(\mathbf{Z}) = (z_{11}, z_{12}, \dots, z_{nd})^T$ , and then use the SW test statistic of Eq.(2) on  $\mathbf{z}_{vec}$ . Under  $H_0$ ,  $W$  is expected to be close to 1. This multivariate generalization of the Shapiro-Wilk test (MSW) does not require any corrections for multiple testing, nor any simulation to calculate new critical values. Furthermore, it inherits the same good power properties while keeping the test complexity at  $O(nd \log(nd))$ .

### 3.3 SHAPIRO-WILK ASYMPTOTICS

For years after the original (Shapiro and Wilk, 1965) paper, the distribution of  $W$  remained unknown. While variations of the original  $W$  statistic were proposed, it was the modification by (De Wet et al., 1972) that produced the first correlation normality test with known asymptotic distribution. The de Wet-Venter statistic  $W^*$  is defined as

$$W^* = \sum_i \left( \frac{x_{(i)} - \bar{x}}{s_n} - \Phi^{-1} \left[ \frac{i}{(n+1)} \right] \right)^2, \quad (3)$$

where  $\Phi^{-1}(\cdot)$  is the inverse normal cumulative density function. In their paper it was shown that  $W^*$  converges

in distribution to

$$2n(1 - W^{*\frac{1}{2}}) - a_n \xrightarrow{\mathcal{D}} \xi, \quad (4)$$

where  $\xi = \sum_3^\infty \frac{y_i^2 - 1}{i}$ ,  $\{y_i, i \geq 1\}$  is a sequence of independent and identically distributed  $\mathcal{N}(0, 1)$  random variables, and with  $a_n = \frac{1}{n+1} \left\{ \sum_{i=1}^n \frac{j(1-j)}{(\phi\{\Phi^{-1}(j)\})^2} - \frac{3}{2} \right\}$ ,

where  $j = \frac{i}{n+1}$ , and  $\phi(\cdot)$  is the standard normal density. (Verrill and Johnson, 1983; Fotopolous et al., 1984) showed that the Shapiro-Francia (Shapiro and Francia, 1972) statistic  $W^\dagger$  and the de Wet-Venter statistic  $W^*$  were asymptotically equivalent via convergence in probability  $n(W^{*\frac{1}{2}} - W^{\dagger\frac{1}{2}}) \xrightarrow{\mathcal{P}} 0$ . (Leslie et al., 1986) produced the final result connecting Shapiro-Wilk to Shapiro-Francia showing that  $n(W^{\frac{1}{2}} - W^{\dagger\frac{1}{2}}) \xrightarrow{\mathcal{P}} 0$ .

## 4 PROPOSED GENERATIVE MODEL

We propose to replace the discriminator neural network with a goodness-of-fit hypothesis test; specifically the Shapiro-Wilk hypothesis test, and its multivariate generalization. As the main idea here, maximizing the associated test statistic forces the encoder to encode data to a distribution (from which the decoder learns to generate data) so that the null hypothesis is not rejected, hence allowing  $q(\mathbf{z})$  to be indistinguishable from the true distribution  $p(\mathbf{z})$ . Lemma 3.2 gives a target value for maximization, and from lemma 3.1 it can be seen that maximizing  $W$  to  $W \geq W_\alpha$  results in the encoding distribution  $q(\mathbf{z}|\mathbf{x})$  indistinguishable from the family  $\mathcal{G} = \{\pi : \pi = \mathcal{N}(\mu, \Sigma)\}$ .

Constraining the network to map  $q(\mathbf{z}|\mathbf{x})$  to a specific distribution in the Gaussian class, for instance  $\mathcal{N}(\mathbf{0}, \mathbf{I})$ , as is often done, is not necessary. It may present challenges when generating data if the decoder is not robust to deviations from the prior,  $p(\mathbf{z})$ . Our new model allows the network to find the right  $q(\mathbf{z}) = \pi^* \in \mathcal{G} = \{\pi : \pi = \mathcal{N}(\mu, \Sigma)\}$  that minimizes the reconstruction loss without requiring a specific prior as long as it is in the class. In the univariate case, SW is directly applied to the encoded data, and the decoder works off of this code layer. When training is complete,  $(\hat{\mu}, \hat{\Sigma})$  are estimated using all data and the decoder generates data from  $\mathcal{N}(\hat{\mu}, \hat{\Sigma})$ . In the multivariate case, however, we include a whitening step in the code layer, which is necessary in order to use the proposed multivariate SW. In other words, let  $\mathbf{y}$  be the encoded data of  $k$  samples, and  $(\bar{\mathbf{y}}, \mathbf{S})$  be the respective sample mean and covariance, we whiten the encoded data as  $\mathbf{S}^{-\frac{1}{2}}(\mathbf{y} - \bar{\mathbf{y}})$ . Then, Prop.3.4 allows the decoder to work off samples coming from  $\mathcal{N}(\mathbf{0}, \mathbf{I})$ . In our empirical evaluation, we found that this whitening step also helped when other hypothesis tests were used in the proposed approach (see the supplement).

Now the presence of normality for  $q(\mathbf{z})$  can be directly tested, i.e., cannot be rejected if  $W$  passes a critical value  $W_\alpha$ . The overall optimization problem that our neural network solves is formulated as

$$\min \|\mathbf{X} - F_\psi(G_\theta(\mathbf{X}))\|_2^2 \text{ s.t. } W(G_\theta(\mathbf{X})) > W_\alpha, \quad (5)$$

where  $G_\theta(\cdot)$  is the encoder, and  $F_\psi(\cdot)$  is the decoder, respectively parameterized by  $\theta$  and  $\psi$ . Using the mathematically equivalent multi-objective loss, we can also find the solution  $G_\theta^*, F_\psi^* = \arg \min_{G_\theta, F_\psi} \|\mathbf{X} - F_\psi(G_\theta(\mathbf{X}))\|_2^2 - \lambda W(G_\theta(\mathbf{X}))$  for some proper value of  $\lambda > 0$  although we propose an algorithm that directly solves Eq.(5).

#### 4.1 OPTIMIZATION OF W

Eq.(5) is commonly optimized using a flavor of gradient descent with mini-batches, e.g., Adam (Kingma and Ba, 2014) which is used in Alg.1. The following proposition characterizes how to compute the gradient of  $W$ .

**Proposition 4.1.** *Let  $k$  be the size of the mini-batch. For any layer  $\ell$ , denote  $\mathbf{Y}^\ell = \Theta^\ell \mathbf{Y}^{(\ell-1)}$ , where  $\mathbf{Y}^{(\ell-1)}$  is an  $(n \times k)$  matrix of arbitrary activation from layer  $(\ell - 1)$ ,  $\mathbf{Y}^\ell$  is an  $(m \times k)$  matrix of linear activation for layer  $\ell$ , and  $\Theta^\ell$  is the  $(m \times n)$  matrix of parameters connecting the layers. Let  $\mathbf{y}$  be the  $(mk \times 1)$  ascendingly sorted vectorization of  $\mathbf{Y}^\ell$ . Then,  $\mathbf{y}$  can be computed by  $\mathbf{A}\theta$  where  $\mathbf{A}$  and  $\theta$  are the re-organized  $\mathbf{Y}^{\ell-1}$  and the vectorization of  $\Theta^\ell$ . Specifically,  $\mathbf{A}$  is an  $(mk \times mn)$  matrix with each row containing the relevant  $\mathbf{Y}^{(\ell-1)}$  data for a particular node’s activation. The gradient of  $W$  can be computed by*

$$\nabla_\theta W = \frac{2\mathbf{a}^T \mathbf{A} \theta}{\theta^T \mathbf{Z} \theta} \mathbf{a}^T \mathbf{A} \left[ \mathbf{I} - \frac{\theta \theta^T \mathbf{Z}}{\theta^T \mathbf{Z} \theta} \right], \quad (6)$$

where  $\mathbf{Z} = \mathbf{A}(\mathbf{I} - \frac{\mathbf{J}}{mk})\mathbf{A}^T$ ,  $\mathbf{I}$  is  $mk$ -dimensional identity matrix, and  $\mathbf{J}$  is a  $(mk \times mk)$  matrix of ones.

Unlike the adversarial framework the hypothesis testing model is straightforward to train. As shown in the pseudocode for this method in Alg.1, only the encoder part of the GAE updates when  $H_0$  is rejected (by re-optimizing  $G_\theta$  to reach  $W > W_\alpha$  or a p-value if available). When whitening is used, and if  $W > W_\alpha$ , the decoder can generate new data by sampling with respect to  $\mathcal{N}(\mathbf{0}, \mathbf{I})$ . It must be reiterated that failure to reject does *not* imply normality, however in practice this procedure works well.

#### 4.2 INNER LOOP TERMINATION

Alg.1 follows a conditional alternating optimization procedure, or can also be referred to as a feasible direction method. The outer loop seeks to minimize the reconstruction loss, whereas the inner loop evaluates the hypothesis testing and identifies the updates of  $\theta$  that satisfy:

---

#### Algorithm 1 Hypothesis Testing Autoencoder

---

**Require:**  $\mathbf{X}$ =training data,  $N$ =number of iterations,  $W_\alpha$ =critical value,  $\lambda$ =regularization coefficient,  $m$ =size of mini-batch  $> d$  = dimension of latent code layer to be tested

- 1: **Initialize:**  $\theta, \psi$
  - 2: **for**  $i = 0$  to  $N$  **do**
  - 3:   Sample next mini-batch from training data  $\mathbf{X}_m$

$W > W_\alpha$ , a constraint that implies failure to reject  $H_0$ . Note that the inner loop is activated only when the condition is *not* already met. A fundamental question is whether this “while” loop will terminate given we solve a highly non-convex optimization problem (ultimately, whether we can find a  $\theta$  such that the  $q(\mathbf{z})$  stays within the Gaussian class). In (Bottou, 1991a) results were given for a general non-convex setting and show that under specific conditions the computation will converge. The following theorem is cited from that paper for which the proof can be found in (Bottou, 1991b).

**Theorem 4.2.** *For any measure  $dP(\mathbf{z})$ , if the cost  $C(\theta) = \mathbb{E}(J(\mathbf{z}, \theta))$  is differentiable up to the third derivatives where  $J$  is an objective function to be optimized, with bounded second and third derivatives, and if the following assertions are true,*

- (i)  $\forall \theta, E(H(\theta)) = \nabla_\theta C(\theta)$
- (ii)  $\sum_{t=1}^\infty \epsilon_t = \infty, \quad \sum_{t=1}^\infty \epsilon_t^2 < \infty$
- (iii)  $\exists A, B, \quad \forall \theta, \quad \mathbb{E}(H(\theta)^2) < A + BC(\theta)$
- (iv)  $\exists C_{min}, \quad \forall \theta, \quad C_{min} < C(\theta)$

*then  $C(\theta_t)$  converges with probability 1 and  $\nabla_\theta C(\theta_t)$  converges to 0 with probability 1.*

In our case,  $W(\theta)$  is  $C$ , thus  $H(\theta) \equiv \nabla_\theta W(\theta)$ , and  $\epsilon_t$  is the learning rate. The inner loop terminates according to Thm.4.2 if its conditions are all satisfied (the detailed proof is given in a supplement). Using the same argument of (Bottou, 1991b) regarding the similarity of simulated annealing, denoting  $q_t(\theta)$  the density of probability that  $\theta_t$  follows, by Thm.4.2 the support of  $q_t(\theta)$  converges to the set of extrema of  $W(\theta)$ , i.e.,  $\theta_t \rightarrow \{\theta | W(\theta) = 1\}$

thus  $W(\theta_t) \rightarrow 1$ . In fact, it is not necessary to train until  $W(\theta) = 1$ , so the procedure exits once  $W > W_\alpha$ .

## 5 THEORETICAL EQUIVALENCY

There exists a link between a distance based method for comparing the goodness-of-fit of two distributions and hypothesis testing discovered in (del Barrio et al., 1999). The general class of Wasserstein distances is studied in (Villani, 2008). We recite the definition here.

**Definition 5.1.** (Wasserstein Distances) Let  $(\chi, d)$  be a Polish metric space, and let  $p \in [1, \infty)$ . For any two probability measures  $\mu, \nu$  on  $\chi$ , the Wasserstein distance of order  $p$  between  $\mu$  and  $\nu$  is defined by

$$W_p(\mu, \nu) = \left( \inf_{\pi \in \Pi(\mu, \nu)} \int_{\chi} d(x, y)^p d\pi(x, y) \right)^{\frac{1}{p}}$$

$$= \inf \left\{ \left[ \mathbb{E}d(X, Y)^p \right]^{\frac{1}{p}}, \text{ law}(X) = \mu, \text{ law}(Y) = \nu \right\},$$

where  $\Pi(\mu, \nu)$  is the set of all joint probability measures. When the Polish metric space under consideration is the one-dimensional Euclidean space,  $W(\mu, \nu) = W_2(\mu, \nu)$ .

Of primary interest is the  $L_2$ -Wasserstein distance. It is possible to consider the distance between distributions  $P_1$  and  $P_2$ , defined by  $\mathcal{W}(P_1, P_2) = \left[ \int_0^1 (F_1^{-1}(t) - F_2^{-1}(t))^2 dt \right]^{\frac{1}{2}}$ , where  $F_1^{-1}$  and  $F_2^{-1}$  are the quantile functions of  $P_1$  and  $P_2$  defined to be  $F_i^{-1}(t) = \inf\{s : F_i(s) \geq t\}$  for  $i = 1, 2$ . The distance between a distribution with cumulative distribution function (CDF)  $F$ , mean  $\mu_0$  and standard deviation  $\sigma_0$ , and the class of all normal distributions can be written as  $\mathcal{W}^2(F, \mathcal{G}') = \inf\{\mathcal{W}^2(F, \pi), \pi \in \mathcal{G}'\}$ , where  $\mathcal{G}' = \{\pi : \pi = \Phi\left(\frac{x-\mu}{\sigma}\right), -\infty < \mu < \infty, \sigma > 0\}$ .

By expressing a normal random variable with mean  $\mu$  and variance  $\sigma^2$  as  $F^{-1}(p) = \mu + \sigma\Phi^{-1}(p)$ , it can be shown that  $\frac{\mathcal{W}^2(F, \mathcal{G}')}{\sigma_0^2} = 1 - \frac{\left( \int_0^1 (F^{-1}(t))\Phi^{-1}(t) dt \right)^2}{\sigma_0^2}$ . With a random sample of data,  $x_1, x_2, \dots, x_n$ , with underlying CDF  $F$ , define  $\mathcal{R}_n = \frac{\mathcal{W}^2(F_n, \mathcal{G}')}{S_n^2} = 1 - \frac{\hat{\sigma}_n^2}{S_n^2}$ , where  $\hat{\sigma}_n = \int_0^1 F_n^{-1}(t)\Phi^{-1}(t) dt$  and  $S_n^2$  is the sample variance.  $\mathcal{R}_n$  can be utilized as a test statistic for testing the composite null hypothesis that the data are normally distributed, and it belongs to the class of minimum distance tests.

### 5.1 $L_2$ -WASSERSTEIN ASYMPTOTICS

To study the null asymptotics of  $\mathcal{R}_n$ , assuming normality, (del Barrio et al., 1999) used approximations of quantile processes by Brownian bridges,  $B(t)$ . Under normal-

ity del Barrio et al. show that there exist constants  $a_n$  such that  $n\mathcal{R}_n - a_n \xrightarrow{\mathcal{D}} \int_0^1 \hat{B}^2(t) - E\hat{B}^2(t) dt$  where  $\hat{B} = \frac{(B - \langle B, 1 \rangle)1 - \langle B, \Phi^{-1} \rangle \Phi^{-1}}{\phi(\Phi^{-1})}$ . By applying principle component decomposition, (del Barrio et al., 1999) obtains the final result and is repeated here for clarity.

**Theorem 5.1.** Let  $\{X_n\}_n$  be a sequence of i.i.d normal random variables. Then

$$\mathcal{R}_n - a_n \xrightarrow{\mathcal{D}} -\frac{3}{2} + \sum_{j=3}^{\infty} \frac{Y_j^2 - 1}{j},$$

where  $\{Y_n\}_n$  is a sequence of i.i.d  $\mathcal{N}(0, 1)$  random variables with  $a_n = \int \frac{\frac{t}{(n+1)}}{\left(\phi(\Phi^{-1}(t))\right)^2} dt$

Cross referencing the asymptotics in Section 3.3, we find the  $L_2$ -Wasserstein normality test to be equivalent to the Shapiro-Wilk test, thus attaining similar power properties.

## 6 EMPIRICAL EVALUATION

We evaluated our method, the hypothesis testing based autoencoder using univariate Shapiro-Wilk (HTAE-SW), and its multivariate generalization (HTAE-MSW) on the standard MNIST digits dataset (LeCun et al., 1998), comparing it against the models believed to be the most closely related: the adversarial autoencoder (Makhzani et al., 2015) (AAE), the adversarial autoencoder with Wasserstein discriminator loss (WAAE), and autoencoder with maximum mean discrepancy loss for the critic (MMDAE as the model is not adversarial). We note that MMD constitutes a true hypothesis test where an  $\alpha$ -level test may be performed by way of permutation or approximation tests. Using it as such would lead to the HTAE-MMD model, a variant of our model. However, we used it as others did by simply optimizing it for comparison against the HTAE. To further evaluate the proposed approach, four additional goodness-of-fit tests were used to replace the (M)SW test. A supplementary material provided more results and discussion on Royston's H (Royston, 1983) (HTAE-R), Mardia's Skewness (Mardia, 1970) (HTAE-M), Malkovich-Afifi (Malkovich and Afifi, 1973) (HTAE-MA), and Henze-Zirkler (Henze and Zirkler, 1990) (HTAE-HZ). All models used  $\|x - \hat{x}\|_2^2$  for the reconstruction loss.

The network architecture was a fully connected class conditional autoencoder with conditioning done at the code layer. Two hidden layers are used between the input and code layer, each consisting of 784 nodes. The decoder contained the same structure. For AAE and WAAE, discriminators contained 2 layers each of 784 nodes with their respective losses. Models requiring sampling from  $p(\mathbf{z})$  used Gaussian priors of appropriate dimension  $p(\mathbf{z}) = \mathcal{N}_d(0, I)$ . Dropout (Srivastava

et al., 2014) was used with a “keep” probability equal to 0.9. The Adam optimizer was used with  $\beta_1 = 0.9$ ,  $\beta_2 = 0.999$ ,  $\epsilon = 10^{-8}$ , and  $\eta = 0.001$ . The hypothesis test was computed at the mini-batch level consisting of 100 samples. The hypothesis tests require an  $\alpha$  to be set. While technically a hyperparameter, it is the level of the test with a clear meaning that training proceeds with respect to this level of confidence. A more stringent  $\alpha$ -level tends to increase inner loop iterations. We found the commonly used  $\alpha = 0.05$  to work well. Two experiments were conducted to gauge the efficacy of the hypothesis testing method: a univariate and multivariate test.

Several criteria were used to assess each model: reconstruction loss, generative quality, normality constraints, prior matching (where applicable), and run-time. We generated images of hand-written digits, and monitored the reconstruction loss during training. By considering the hypothesis test statistic as an objective measure for rejecting normality, the test statistic was monitored for each iteration, and its corresponding p-value was plotted, during training for all models. In particular, the null hypothesis was rejected when the p-value was less than 0.05; larger p-values were preferred. Q-Q plots were also provided. By plotting the theoretical quantiles of the normal distribution against the empirical quantiles of the data in a Q-Q plot, any departure from the straight line provides evidence against normality. This can be used as a diagnostic measure after training has completed. The run times are included in Table 1.

### 6.1 UNIVARIATE: SHAPIRO-WILK

There was only a single node in the latent code layer in the univariate case. Results from the univariate case can be seen in Fig.1. Along with the plots mentioned above, the univariate case presented an opportunity to monitor the trajectory of  $(\hat{\mu}, \hat{\sigma})$ . Initial  $(\hat{\mu}, \hat{\sigma})$  were calculated using the initialized network weights. By monitoring the p-values, it appeared that the  $q(\mathbf{z})$  distributions from many other methods were not in fact normal. Of the Q-Q plots, only HTAE-SW maintained close enough proximity to the straight line. Based on the final batch, WAAE and MMDAE were able to match the prior distribution  $(\mu, \sigma)$  parameters fairly closely, however neither maintained normality. AAE could neither match parameters nor maintain normality. As HTAE-SW was not restricted to a specific normal, it had the opportunity to explore the normal class for an optimal distribution for the given data.

### 6.2 MULTIVARIATE GENERALIZATION OF SHAPIRO-WILK

For the multivariate methods a latent code dimension of 8 was used. By employing the new multivariate gener-

alization of the SW test (MSW) it was possible to use Q-Q plots to lend visual support to the p-value outcome, however trajectory plots were no longer an option. Each model was run for 100,000 iterations with plots shown in Fig.2, and run time shown in Table 1 when the code layer had 8 nodes. The generated images seemed to get visually better the higher the simple moving average of the p-values was. Q-Q plots for the last mini-batch show improper tail behaviors, for normality, in all models but HTAE-MSW. As before, the p-value should be greater than  $\alpha = 0.05$  to fail to reject the null; again the higher the p-value the better. For models that failed to reject  $H_0$  but had poor generative quality, this suggested several possibilities: training time needed to be increased, more focus should be given to reconstruction, or the network size should be increased. As can be seen in Table 1 HTAE methods were substantially faster in all cases.

Table 1: Run time in seconds for  $10^5$  iterations in the 1-D and 8-D cases using an NVIDIA GTX 1080Ti GPU.

Method	1-D	8-D
AAE	765.39	982.61
WAAE	904.95	1092.19
MMDAE	597.67	756.69
HTAE-(M)SW	346.16	548.08

## 7 DISCUSSION

Our empirical results suggest that substituting a hypothesis test, notably  $W$  and its the new multivariate generalization, which do not require pre-specifying a mean and covariance, may be a competitive alternative to other members of the GAE class. Allowing  $q(\mathbf{z})$  to deviate in the feasible space,  $\mathcal{G}$ , during training means sampling is done with respect to  $q(\mathbf{z}) = \hat{\pi} = \mathcal{N}(\hat{\mu}, \hat{\Sigma}) \in \mathcal{G}$  where  $(\hat{\mu}, \hat{\Sigma})$  are estimated (or when whitening is used in the multivariate case, with respect to  $\mathcal{N}(\mathbf{0}, \mathbf{I})$ ). Consequently, there is less need to worry about discrepancy between the distribution we *want* to sample from, and the distribution we *are* sampling from, as we tacitly interpret failure to reject as within the class of normals. This need *not* be the case in the other models. However, as HTAE-MSW does make use of whitening, ensuring enough samples to adequately estimate  $\hat{\Sigma}^{-\frac{1}{2}}$  and  $\hat{\mu}$  is a necessity.

The AAE and WAAE both require training of a discriminator network. This network, with size on the order of the encoder or decoder, increases training time. Moreover, training of the discriminator needs to be scheduled in balance with that of the generator, and how exactly this should be done is still an open problem. On the other hand, using the hypothesis test abolishes this problem

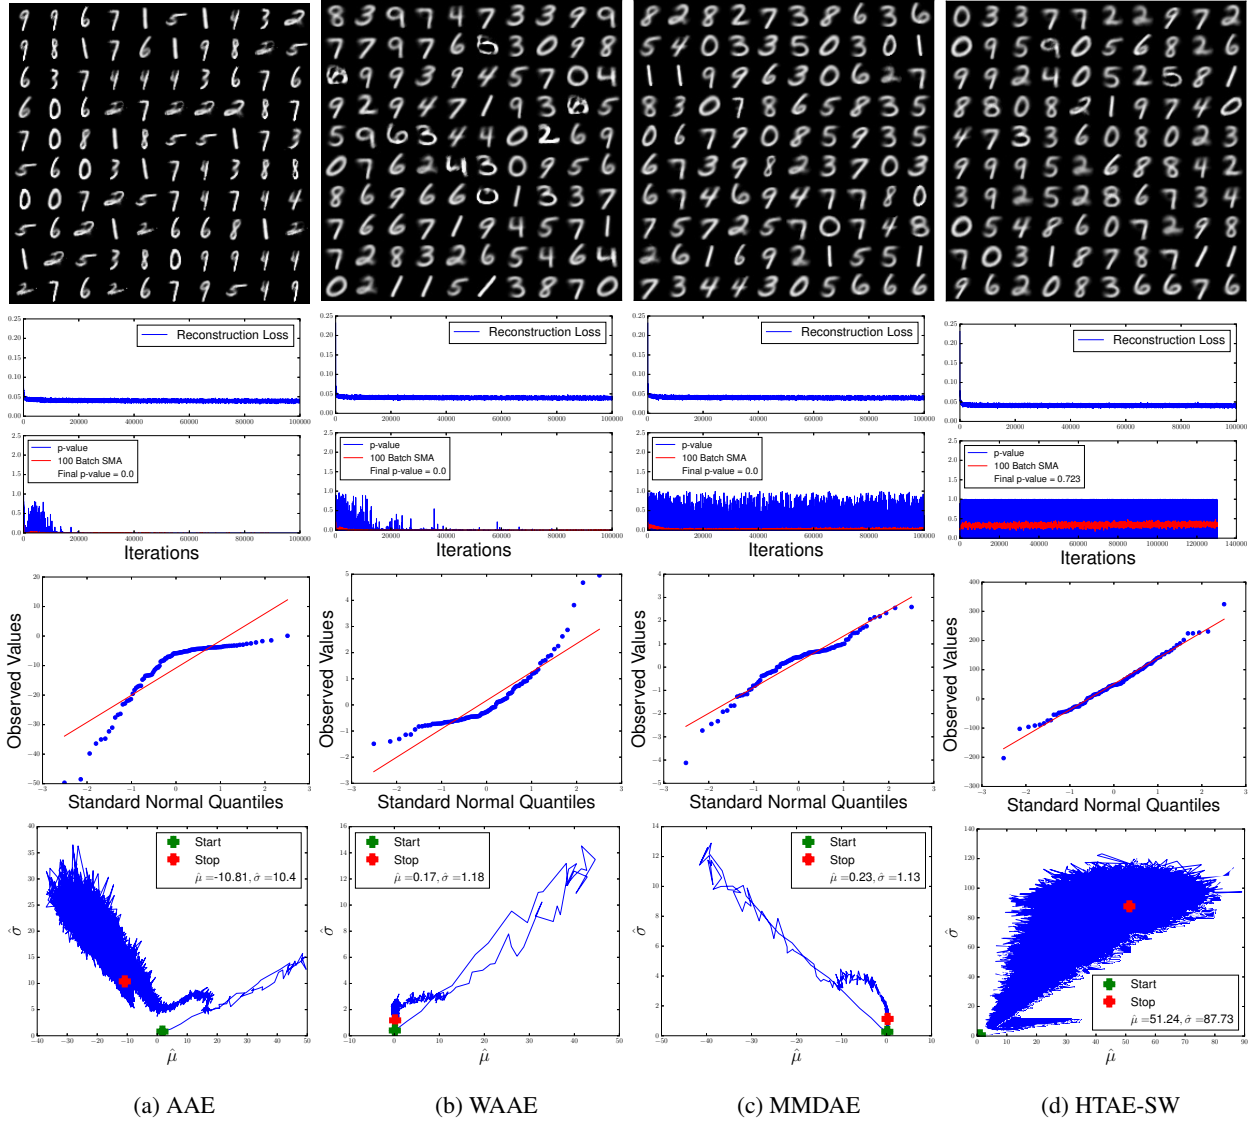

Figure 1: Row one illustrates sample digits generated by each model. Row two shows the reconstruction loss, and the simple moving average (SMA) of the p-value for a batch size of 100, along with the final mini-batch terminating p-value. Row three contains the Q-Q plots, and row four plots the trajectory of  $(\hat{\mu}, \hat{\sigma})$  over the course of training.

completely. By utilizing the critical values (or p-values) for the test statistic it is now possible to know *precisely* when to alternate between enforcing prior constraints, and minimizing the reconstruction loss. In our empirical evaluation, we also observed that using a parametric hypothesis test could improve gradient updates by utilizing information about the null distribution. A full exploration into this mechanism is left for future investigation.

A concern may be raised that Thm.4.2 merely guarantees the “while” loop will terminate, yet provides no indication of when it terminates. In all experiments, the speed never proved to be an issue. The inner loop was able to ensure  $q(\mathbf{z}) \in \mathcal{G}$  in a very small number of iterations as can be

seen in Fig.3 in supplementary materials. We attempt to understand why this is the case in the near future.

We experimented with four other goodness-of-fit tests (see the supplement please), but none provided the benefits that the Shapiro-Wilk and its generalization did. Issues included longer run times, and weaker power. The search for greater power motivates the following conjecture.

*Conjecture 1.* The more powerful the hypothesis test, the more precise the null distribution information contained within the test statistic that can be transmitted to the encoder to update  $\theta$  via the gradient.

A trade-off between the power of the test, time complex-

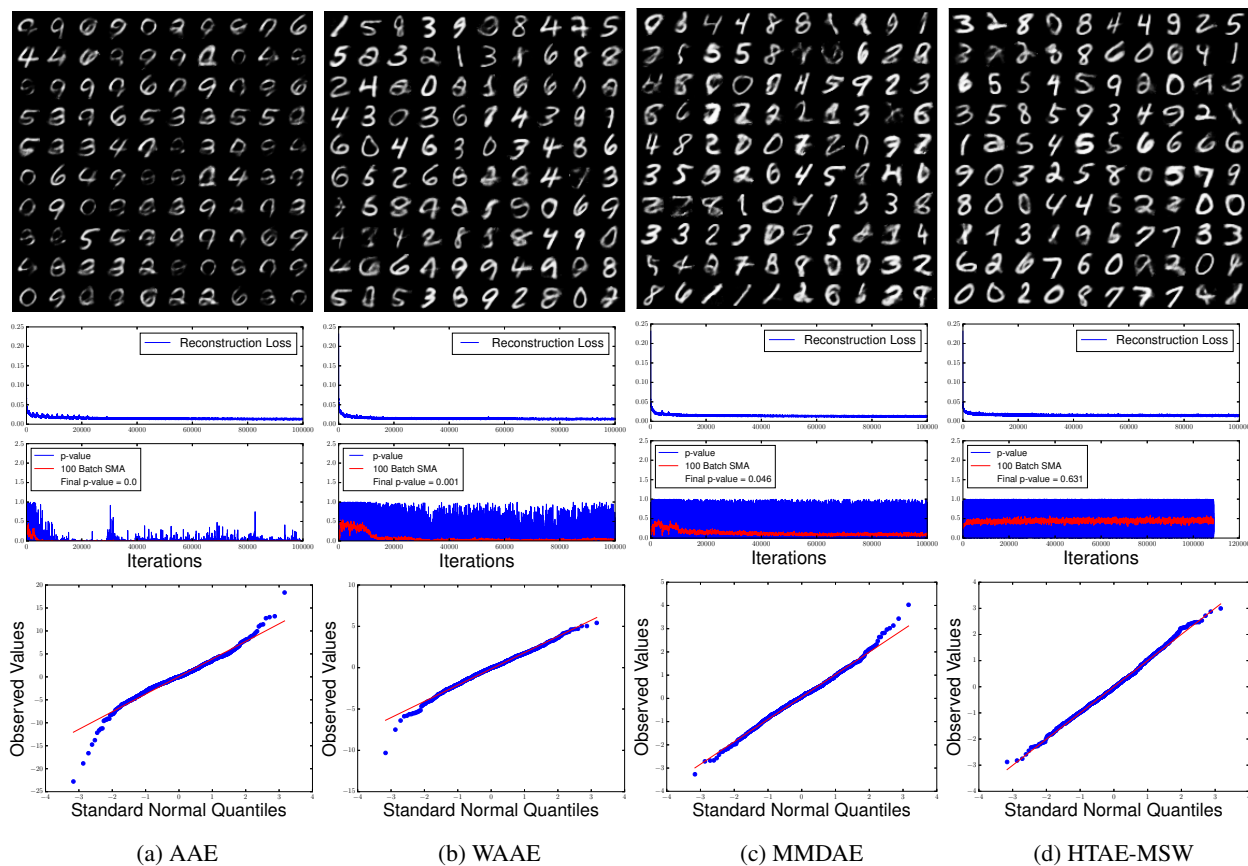

Figure 2: Similar to Fig.1, the top row plots random samples generated from each model. Row two contains the p-values with a 100 batch SMA. Row three are Q-Q plots associated with MSW.

ity and reconstruction quality likely exists. What is the cheapest computational complexity of a hypothesis test available for a given power? We expect that future research will reveal more on these questions.

## 8 CONCLUSION AND FUTURE WORK

In this paper we have proposed a new method for training generative autoencoders by explicitly testing the distribution of the code layer output via univariate and multivariate parametric hypothesis tests. We have shown a number of benefits to using such an approach including: objectively verifying if training has indeed pushed  $q(\mathbf{z}) \in \mathcal{G}$ , the ability to utilize the critical value of a hypothesis test as a threshold for determining when to switch between reconstruction and encoding iterations. Our method produces competitive results while showing computational efficiency. Moreover, we explored the link between the Shapiro-Wilk hypothesis test and the  $L_2$ -Wasserstein distance between two distributions.

Given the large numbers of univariate and multivariate

parametric hypothesis tests available, it remains to be seen how others compare when used in a generative autoencoder. In fact, any distribution for which a hypothesis test can be derived can be used for training a latent code layer. Furthermore, the proposed method of training can be applied to any of the models that takes a generative autoencoder style network. This initial work brings up additional interesting problems, so our future work will dive into the questions raised. It is also worth asking how other hypothesis testing methods can be included into neural network training.

## Acknowledgments

We thank Vladamir Pozdnyakov for insightful discussions, especially regarding the multivariate test. ## Abstract

Whereas optimizing deep neural networks using stochastic gradient descent has shown great performances in practice, the rule for setting step size (i.e. learning rate) of gradient descent is not well studied. Although it appears that some intriguing learning rate rules such as ADAM (Kingma and Ba, 2014) have since been developed, they concentrated on improving convergence, not on improving generalization capabilities. Recently, the improved generalization property of the flat minima was revisited, and this research guides us towards promising solutions to many current optimization problems. In this paper, we analyze the flatness of loss surfaces through the lens of robustness to input perturbations and advocate that gradient descent should be guided to reach flatter region of loss surfaces to achieve generalization. Finally, we suggest a learning rate rule for escaping sharp regions of loss surfaces, and we demonstrate the capacity of our approach by performing numerous experiments.

## 1 INTRODUCTION

Overfitting is a core issue in the domain of machine learning. When it comes to deep learning, it becomes even more important, because of its high dimensionality. Owing to the huge number of parameters, deep learning models show some strange behaviors. For example, deep models easily fit random labeling of training data and furthermore training data replaced with random noise input (Zhang et al., 2016). A peculiar phenomenon called “fooling deep neural networks (DNNs)” was also reported in (Nguyen et al., 2015; Szegedy et al., 2013). These kinds of unexpected behavior might be a potential

risk when adopting DNNs for applications which require high precision. Classic DNN regularization methods include placing a Gaussian or Laplacian prior on parameters, called weight decays (Figueiredo, 2003; Bishop, 2006). A weight decay assumes that the desirable solutions of the parameters are placed near zero, and therefore does not consider solutions which may lie a bit far from zero but possibly show better test performance. Numerous interesting works are still being proposed, including Stochastic Gradient Langevin Dynamics (SGLD) (Raginsky et al., 2017), parametrization method for reducing overfitting for genomics (Romero et al., 2016), employing stochastic effects; randomly dropping features (Hinton et al., 2012) or using stochastic depth (Huang et al., 2016). Some interesting works analyzed these stochastic effects in the view of a  $L_2$ -regularization (Wager et al., 2013) or an ensemble method (Singh et al., 2016).

The concept of generalization via achieving flat minima was first proposed in (Hochreiter et al., 1995), and its importance has recently been revisited in the domain of deep learning optimization (Chaudhari et al., 2016), (Keskar et al., 2016). This another viewpoint of thinking generalization may become a promising direction for investigating the weight space property of DNNs; moreover, DNN loss surface property analysis has become a popular issue (Sagun et al., 2016; Swirszcz et al., 2016; Littwin and Wolf, 2016; Im et al., 2016). Recently, achieving generalization via flat minima is investigated in terms of optimizing PAC-Bayes bound (Dziugaite and Roy, 2017a,b; Neyshabur et al., 2017).

A stochastic gradient descent (SGD) walks around loss surfaces in DNNs, and its behavior can be controlled by learning rates. It leads us to an interesting question: “Is it possible to seek flatter valleys of loss surfaces by controlling learning rate schedules?”. We show the relation of learning rates and flatness of the loss surface, then show that a nonmonotonic scheduling of learning rates with an intermediate large learning rate stages are

beneficial to discover flat minima and therefore leads to improved generalization. On the scheduling of learning rates, recent studies achieve great convergence rates on training data, but they are prone to overfit, showing some degradation of test performance. Therefore, even state-of-the-art DNN models (Simonyan and Zisserman, 2014; Szegedy et al., 2014; He et al., 2016) have continued to use simple step or exponentially-decaying learning step sizes. Thus, our work has great implications on improving the theory of learning rates. To the best of our knowledge, this is the first work that pays substantial attention to learning rates with regard to generalization and overfitting of deep neural networks. We cite selected noteworthy work on learning rates; however, again note that none of the work concerns what we consider throughout the paper. Regarding fast convergence of given training data: RMSprop (Tieleman and Hinton, 2012), Adagrad (Duchi et al., 2011), Adadelata (Zeiler, 2012), Adam (Kingma and Ba, 2014), and an interesting work that searches for optimal adaptive learning rates without manual tuning (Schaul et al., 2012).

In this paper, we begin with robustness in the input space, which is a traditional way of explaining generalization. Then, we find the relation of robustness in the input perturbation and that in weight perturbation to show why flat minima work better (Section 2). Next, we explain how large learning rates can guide gradient descent to flatter losses (Section 3). Then, a simple nonmonotonic learning rate scheduling technique is introduced for adopting larger learning rates. Finally, our claims are demonstrated by performing numerous experiments.

## 2 THE RELATION OF ROBUSTNESS IN INPUT SPACE AND WEIGHT SPACE

In this section, we show that generalization can be achieved through robustness with respect to input perturbations, input perturbations can be equivalently transferred to weight perturbations, and therefore generalization can be achieved through robustness with respect to weight perturbations.

Generalization can be stated as the uniformity of the loss function with respect to input change (See Supplementary Material A). Denote  $\mathbf{x} \in \mathbb{R}^{n \times 1}$  as input,  $\mathbf{w} \in \mathbb{R}^d$  as the vectorized weight of the model and  $\mathcal{L}(\mathbf{w}; \mathbf{x})$  as the loss function of the neural network. Then, input perturbations  $\delta^{\mathbf{x}} \in \mathbb{R}^{n \times 1}$  should result in a small change in the loss function:

$$|\mathcal{L}(\mathbf{w}; \mathbf{x} + \delta^{\mathbf{x}}) - \mathcal{L}(\mathbf{w}; \mathbf{x})| < \epsilon,$$

A similar interpretation of generalization in DNNs can be found in (Rifai et al., 2011), where the authors attempted to reduce  $|f(\mathbf{w}; \mathbf{x} + \delta^{\mathbf{x}}) - f(\mathbf{w}; \mathbf{x})|$  for  $f$ , which is an auto-encoder.

Now, the generalization capability of the model is evaluated for the change of the loss function with respect to perturbations on the weight vector  $\delta^{\mathbf{w}}$ .

**Lemma 1.** *Let  $\delta^{\mathbf{x}}$  and  $\delta^{\mathbf{w}}$  be input and weight perturbations, respectively. For a single-layer neural network, the input perturbations  $\delta^{\mathbf{x}}$  can be transferred to the weight perturbations  $\delta^{\mathbf{w}}$ . More formally, suppose we have weight matrix  $\mathbf{W} \in \mathbb{R}^{m \times n}$  and weight perturbations  $\delta^{\mathbf{W}} \in \mathbb{R}^{m \times n}$ . Then for any  $\mathbf{W}$  and  $\mathbf{x}$  that satisfy  $\mathbf{x} \neq \mathbf{0}$  and  $\mathbf{W} \neq \mathbf{0}$ , there exists  $\delta^{\mathbf{W}}$  such that  $(\mathbf{W} + \delta^{\mathbf{W}})\mathbf{x} = \mathbf{W}(\mathbf{x} + \delta^{\mathbf{x}})$ . Consequently,  $|\mathcal{L}(\mathbf{W} + \delta^{\mathbf{W}}; \mathbf{x}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| = |\mathcal{L}(\mathbf{W}; \mathbf{x} + \delta^{\mathbf{x}}) - \mathcal{L}(\mathbf{W}; \mathbf{x})|$ .*

*Proof.* The proof can be accomplished by finding  $\delta^{\mathbf{W}}$  which satisfies

$$\delta^{\mathbf{W}}\mathbf{x} = \mathbf{W}\delta^{\mathbf{x}} \quad (1)$$

The following choice of  $\delta^{\mathbf{W}}$  satisfies (1):

$$\delta^{\mathbf{W}} = \frac{\mathbf{W}\delta^{\mathbf{x}}}{\mathbf{x}^{\top}\mathbf{x}}\mathbf{x}^{\top} = \frac{\mathbf{W}\delta^{\mathbf{x}}}{\|\mathbf{x}\|^2}\mathbf{x}^{\top} \quad (2)$$

□

**Proposition 1.** *Suppose  $|\mathcal{L}(\mathbf{W} + \delta^{\mathbf{W}}; \mathbf{x}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| < \epsilon$  holds for any  $\delta^{\mathbf{W}}$  such that  $\|\delta^{\mathbf{W}}\|_F < \delta$ ,  $\delta > 0$  and  $\epsilon > 0$ . Then  $|\mathcal{L}(\mathbf{W}; \mathbf{x} + \delta^{\mathbf{x}}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| < \epsilon$  holds for any  $\delta^{\mathbf{x}}$  such that  $\frac{\|\delta^{\mathbf{x}}\|}{\|\mathbf{x}\|} < \frac{\delta}{\sigma_{max}(\mathbf{W})}$ , where  $\sigma_{max}(\mathbf{W})$  is the maximum singular value of  $\mathbf{W}$ .*

*Proof.* For any  $\delta^{\mathbf{x}}$  such that  $\frac{\|\delta^{\mathbf{x}}\|}{\|\mathbf{x}\|} < \frac{\delta}{\sigma_{max}(\mathbf{W})}$ , if we choose  $\delta^{\mathbf{W}}$  as in (2), then from the result of Lemma 1, we have

$$\begin{aligned} & |\mathcal{L}(\mathbf{W}; \mathbf{x} + \delta^{\mathbf{x}}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| \\ &= |\mathcal{L}(\mathbf{W} + \delta^{\mathbf{W}}; \mathbf{x}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| \quad (3) \end{aligned}$$

Then, corresponding bound on  $\|\delta^{\mathbf{W}}\|_F$  can be derived by

$$\|\delta^{\mathbf{W}}\|_F^2 = \frac{\|\mathbf{W}\delta^{\mathbf{x}}\|^2 \|\mathbf{x}^{\top}\|^2}{(\mathbf{x}^{\top}\mathbf{x})^2} \leq \frac{\sigma_{max}^2(\mathbf{W}) \|\delta^{\mathbf{x}}\|^2}{\|\mathbf{x}\|^2} < \delta^2, \quad (4)$$

where we used  $\|\mathbf{a}\mathbf{b}^{\top}\|_F^2 = \|\mathbf{a}\|^2 \|\mathbf{b}\|^2$  and  $\|\mathbf{W}\delta^{\mathbf{x}}\| \leq \sigma_{max}(\mathbf{W}) \|\delta^{\mathbf{x}}\|$ .

Figure 1: Conjectured illustration showing the relation of learning rate to loss surface. (a) A nonmonotonic scheduling of learning rates with an intermediate large learning rate stages lets the model escape from the steep valleys with high curvature. (b) Concept of what we call ‘wide valleys’. The scale of perturbation should be large enough so that the loss surface can effectively cope with proper perturbations.

Therefore, we have

$$\begin{aligned}
 & |\mathcal{L}(\mathbf{W}; \mathbf{x} + \delta^{\mathbf{x}}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| \\
 &= |\mathcal{L}(\mathbf{W} + \delta^{\mathbf{W}}; \mathbf{x}) - \mathcal{L}(\mathbf{W}; \mathbf{x})| < \epsilon \quad (5)
 \end{aligned}$$

□

According to Lemma 1, for an arbitrary input perturbation, the first layer’s weight matrix can be perturbed so that  $\mathbf{W}(\mathbf{x} + \delta^{\mathbf{x}}) = (\mathbf{W} + \delta^{\mathbf{W}})\mathbf{x}$ , i.e. the first layer’s responses are the same for the two cases. Thus, the remaining layer’s responses are also the same throughout, and the results in Lemma 1 and Proposition 1 are applicable to general DNNs. In Supplementary Material B, we provide additional analysis that shows how to distribute weight perturbations to all DNN layers to match the input perturbations.

Now that we can transfer the perturbations of input to those of weight, generalization can be interpreted on the loss surface. Reduction of the effects on the loss function with respect to perturbations on the input, requires us to reduce the effects with respect to perturbations on the weight vector. Finally, we propose the relation of the loss surface and a measure for generalization as follows:

**Conjecture 1.** *Given the same cost value, if the loss surface is flatter, then it is more likely for neural networks to be more generalized.*

### 3 THE RELATION OF LEARNING RATES AND GENERALIZATION

High-dimensional loss surfaces are regarded as non-convex and extremely difficult to visualize. Let us consider the SGD algorithm, which corresponds well to current large-scale problems. Not only are there abundant pathways that the SGD can follow, but the pathways are

also highly dependent on learning rates. We can expect the loss surface of the model to have many locally convex areas and the learning rates to largely affect the outcome achieved by the algorithm. We justify this situation by evaluating the stationary characteristic of the stochastic gradients as the mean of the given values as follows:

$$\bar{\mathcal{L}}(\mathbf{w}; \mathbf{x}) := \mathbb{E}_{\mathbf{x}_i \sim \mathcal{D}}[\mathcal{L}(\mathbf{w}; \mathbf{x}_i)], \quad (6)$$

where the training data  $\mathbf{x}_i \in \mathbb{R}^{n \times 1}$  are drawn from a distribution  $\mathcal{D}$ . We can fit a quadratic approximation of the entire loss surface surrounding the local optimum  $\mathbf{w}^*$  using the positive definite Hessian matrix

$$\bar{\mathcal{L}}(\mathbf{w}; \mathbf{x}) \approx \bar{\mathcal{L}}(\mathbf{w}^*; \mathbf{x}) + \frac{1}{2}(\mathbf{w} - \mathbf{w}^*)^\top \mathbf{H}^*(\mathbf{w} - \mathbf{w}^*), \quad (7)$$

where  $\mathbf{H}^*$  is the mean (over  $\mathcal{D}$ ) of the Hessian of the loss function at  $\mathbf{w}^*$ . Let us denote  $\gamma_t$  as the learning rate at the iteration  $t$ . Then, the gradient descent can be calculated as follows:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \gamma_t \nabla \bar{\mathcal{L}}(\mathbf{w}; \mathbf{x}) \quad (8)$$

$$\approx \mathbf{w}_t - \gamma_t \mathbf{H}^*(\mathbf{w}_t - \mathbf{w}^*). \quad (9)$$

$$\mathbf{w}_{t+1} - \mathbf{w}^* \approx (I - \gamma_t \mathbf{H}^*)(\mathbf{w}_t - \mathbf{w}^*). \quad (10)$$

If we assume small and smooth changes of the learning rate during some epochs (equivalently,  $t_s \leq t \leq t_f$  where  $|\gamma_t - \gamma_{t_s}| < \epsilon_\gamma$ ), providing constant  $\gamma_{t_s}$ , the weight vector can be measured by both the optimal and the initial points:

$$\mathbf{w}_t \approx \mathbf{w}^* + (I - \gamma_{t_s} \mathbf{H}^*)^{t-t_s} (\mathbf{w}_{t_s} - \mathbf{w}^*) \quad (11)$$

Then, we can strictly obtain the range of the learning rate capable of enforcing the convergence. If  $\mathbf{H}^*$  is diagonal as (Schaul et al., 2012), and  $h_{max}$  is the maximum value

amongst the second-order gradients, the convergence criteria are expressed by the condition<sup>1</sup>

$$|1 - \gamma_{t_s} h_{max}| < 1, \quad (12)$$

which is equivalent to

$$0 < h_{max} < \frac{2}{\gamma_{t_s}}, \quad (13)$$

which provides the relationship of the learning rate and the curvature of the surface necessary to converge. A large learning rate has the critical requirement that the curvature of the surface should be sufficiently low to avoid diverging. Therefore, we anticipate that the SGD having a large learning rate allows for locating a smooth area.

Our remarks on the relationship between learning rates and generalization address “which local minimum should be chosen” as conceptually illustrated in Figure 1. Recent studies on loss surfaces, such as (Dauphin et al., 2014) and (Choromanska et al., 2015), both theoretically and empirically discovered that local minima are more likely to be located only where train losses are very close to those of the global minimum. Based on these results, we consider that the loss surface has basins of local minima that occur only at the bottom of the loss surface, i.e.,  $|\mathcal{L}(\mathbf{w}^*; \mathbf{x}) - \mathcal{L}_{gmin}| \approx \epsilon$  where  $\mathcal{L}_{gmin}$  is the global minimum. When such a basin has a high curvature  $h_{max}$  violating (13),  $w$  keeps drifting from  $w^*$  because of (11) until it reaches another basin with a smaller curvature, a flatter region satisfying (13).

Additionally, once it reaches the entrance of a basin of smaller curvature, it is more likely to converge to a flatter local minimum. This is discussed in Section 6.3 implying that the average slope of the loss surface depends on the width of the basin’s entrance. Finally, we propose the following chain of effects showing how generalization can be achieved via nonmonotonic learning rates scheduling:

**High learning rate  $\Rightarrow$  escape from high curvature valleys in weight space  $\Rightarrow$  smooth region in weight space  $\Rightarrow$  smooth region in input space  $\Rightarrow$  improved generalization.**

## 4 LEARNING RATES AND STOCHASTIC VARIANCE

The major claim of our work is that learning rates should be set large to escape sharp loss surface valleys. For setting large learning rates, curvature of loss surfaces is the

<sup>1</sup>(12) is still a valid condition for a non-diagonal  $\mathbf{H}^*$  with the maximum eigenvalue  $h_{max}$

Figure 2: An illustration of the occurrence of maximum gradients. As the loss at random initial weights is significantly large, maximum gradients are most likely to occur near initial weights.

only constraint in plain gradient descent cases. However, stochastic variance (Reddi et al., 2016) further interferes with convergence in SGD cases. Stochastic variance is an inherent variance of gradients caused by minibatch selection in SGD. When stochastic variance is large, learning rates should be set smaller to prevent divergence. Therefore, the maximum learning rate can be achieved when the stochastic variance is small.

Stochastic variance is relatively large when the gradients are large (Johnson and Zhang, 2013). Therefore, learning rates should be set large after the occurrence of the maximum gradients. As in Figure 2, suppose the randomly initialized weights are  $\mathbf{w}_{init}$  for which  $\bar{\mathcal{L}}(\mathbf{w}_{init}; \mathbf{x})$  will be large (e.g. around  $\log(n_{class})$  in the case of cross-entropy loss where  $n_{class}$  is the number of classes).  $\mathbf{w}_{opt}$  is a local minimum that is closest to  $\mathbf{w}_{init}$  and  $\mathbf{w}_{peak}$  is a weights of local maximum which is the closest to  $\mathbf{w}_{opt}$  and under the condition  $\bar{\mathcal{L}}(\mathbf{w}_{init}; \mathbf{x}) \gg \bar{\mathcal{L}}(\mathbf{w}_{peak}; \mathbf{x})$ . We constrain our claims under

$$\frac{|\bar{\mathcal{L}}(\mathbf{w}_{init}; \mathbf{x}) - \bar{\mathcal{L}}(\mathbf{w}_{opt}; \mathbf{x})|}{|\bar{\mathcal{L}}(\mathbf{w}_{peak}; \mathbf{x}) - \bar{\mathcal{L}}(\mathbf{w}_{opt}; \mathbf{x})|} \gg \frac{\|\mathbf{w}_{init} - \mathbf{w}_{opt}\|}{\|\mathbf{w}_{peak} - \mathbf{w}_{opt}\|} \quad (14)$$

and consider other cases to be beyond the scope of this paper. In practice,  $\bar{\mathcal{L}}(\mathbf{w}_{init}; \mathbf{x}) \gg \bar{\mathcal{L}}(\mathbf{w}_{peak}; \mathbf{x})$ . Therefore (14) is a probable condition. If we divide the loss surfaces into subspaces of basins and assume Lipschitz continuity, then we get the lower bound of maximum gradients during the optimization  $g_{LB}$  as follows.

$$g_{LB} = \frac{|\bar{\mathcal{L}}(\mathbf{w}_{init}; \mathbf{x}) - \bar{\mathcal{L}}(\mathbf{w}_{opt}; \mathbf{x})|}{\|\mathbf{w}_{init} - \mathbf{w}_{opt}\|} \quad (15)$$

which makes maximum gradients mostly occur near the initial weights.

## 5 PEAK LEARNING STAGE : NONMONOTONIC LEARNING RATES SCHEDULING

To experimentally show that high learning rates are beneficial to discovering flatter loss surfaces, we propose non-monotonic learning rate schedules to utilize larger learning rates. Adopting larger learning rates presents the risk of learning to diverge because of (13) and Section 4. Rather than placing the maximum learning rate at the start of the learning, we place maximum learning rate in the middle, so the initial stage can stabilize learning (i.e. reduce stochastic variance) and prepare for the consecutive large learning rates. This learning rate schedule is motivated by the neurological phenomenon called *critical period* or *sensitive period*—a period in which learning plasticity reaches its peak (Wiesel et al., 1963; Ge et al., 2007). The plasticity gradually increases if biological systems are prepared to learn, after which plasticity is reduced over time. Considering the stabilization of learning, it is not surprising that plasticity *gradually* and *slowly* grows to a certain degree once it is switched on. We tried two nonmonotonic learning rate schedules,  $\gamma_t$  at normalized iteration  $t$ , as follows<sup>2</sup>:

- Gaussian Shape:  $\gamma_t = \gamma_{max} * \exp\left(\frac{-(t-0.5)^2}{\sigma^2}\right)$ .
- Laplacian Shape:  $\gamma_t = \gamma_{max} * \exp\left(-\frac{|t-0.5|}{\lambda}\right)$ .

Here,  $\gamma_{max}$  is the peak or maximum learning rate;  $\gamma_{min}$  is the final or minimum learning rate; and  $\gamma_{start}$  is the starting learning rate. Also,  $\sigma^2$  for the Gaussian-shaped schedule and  $\lambda$  for the Laplacian-shaped schedule is defined as  $-0.25 * \frac{1}{\ln(\gamma_{min}/\gamma_{max})}$  and  $-0.5 * \frac{1}{\ln(\gamma_{min}/\gamma_{max})}$ , respectively. Because the function starts with a value that is too small, we use a truncated function that is cut at the appropriate offset,  $t_{offset}$ , for faster convergence. The offset  $t_{offset}$  is  $0.5 - \sqrt{-\sigma^2 \ln(\gamma_{start}/\gamma_{max})}$  in the Gaussian schedules and  $0.5 + \lambda \ln(\gamma_{start}/\gamma_{max})$  in the Laplacian schedules.

The total number of iterations determines not only the total number of weight updates but also the sampling frequency from the continuous peak-shaped function. The sampling frequency controls the smoothness of the change in learning rate. By setting  $\gamma_{max}$  larger than the maximum learning rate of the classical learning rate schedule within convergence, the local optimum can be found in the flatter basin. We found both two peak shaped learning rates worked well, but the Gaussian-shaped learning rates worked slightly better than the

<sup>2</sup>For notation simplicity, the iteration  $t$  is normalized between 0 and 1.

Laplacian-shaped ones as shown in Figure 6. Therefore, we used Gaussian-shaped scheduling for most of the experiments. Note that a Gaussian-shaped curve is not the only way but just one way to implement the proposed peak learning stages.

**SLOW START** Because of (13) and stochastic variance of the SGD, learning rates that are too large cause the learning to diverge. If we start with a too large learning rate, the learning either diverges or finds a poor critical point. Therefore, considering the stability of optimization, learning should commence with a small learning rate. However, we verified experimentally that starting with a learning rate that is too small does not lead to success. Thus, adopting  $t_{offset}$  in the learning rate rules is required to eliminate the redundant initial phase.

**DECAYING LEARNING RATES** The peak learning stage induces some divergence to escape from the sharp minima. Thus, the learning rate must be decayed for the final convergence. Considering conventional methods, this stage is intuitively acceptable. It is noteworthy that most DNNs are optimized using SGD, which implies loss surfaces are substantially fluctuating for each minibatch. Therefore decaying stages are necessary for achieving stability of optimization results.

## 6 EVALUATING THE FLATNESS OF LOSS SURFACES

Evaluation of the effect of the learning rate inevitably requires its behavior on the loss surface to be analyzed. However, in neural networks, the loss surface is high-dimensional so that optimization trajectory on the loss function becomes difficult to visualize. First, we tracked the local property of high-dimensional loss surfaces by measuring the magnitude of the gradient. Throughout this paper, the magnitude of the gradient refers to the 2-norm of the gradient vector which represents the local steepness of loss surfaces.

However, because the gradient (or Hessian) of the loss is computed at a specified location in the weight space, its application is limited to a local area of the loss surface. Therefore, we visualize large-scale properties of loss surfaces by adopting the linear path experiments introduced by (Goodfellow and Vinyals, 2014). The linear path experiments measure the loss surface by sweeping the trajectory between two points in high-dimensional spaces. By visualizing a single cross section of the loss surface, we indirectly measure its large-scale flatness.

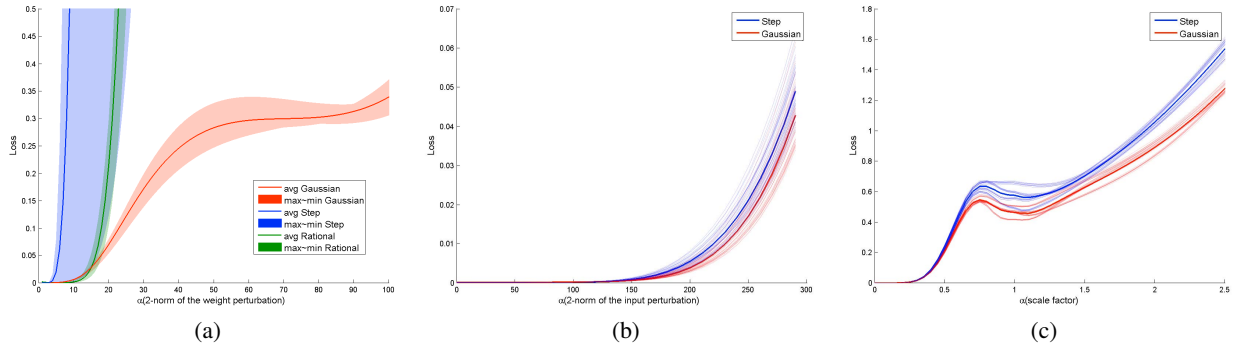

Figure 3: Linear path experiments in Section 6. (a) Loss versus weight perturbation along the line path, which follows the trajectory between the final state weight and peak stage weight. The model trained using the proposed learning rate clearly shows flatter loss surface. Each color represents different learning rates. Maximum and minimum losses are also presented from different models trained by random initialization. (b) Loss versus randomly generated input perturbation. Each transparent line represents different random noise directions, and the bold line indicates the ensemble average of these transparent lines. The model trained using the proposed learning rate shows smaller loss for the same perturbation, indicating that our method is more robust to input perturbations. (c) Loss versus input perturbations in the directions of training to validation data. Each transparent line represents different perturbation decided by the selection of nearby validation data. The bold line indicates the ensemble average of the transparent lines. This also shows that the loss surface determined by our method is flatter with respect to input perturbations.

## 6.1 LOSS WITH RESPECT TO WEIGHT PERTURBATIONS

Because our learning rate rule has a peak stage that is not considered in existing methods, we analyzed its effects by performing linear path experiments which follow the trajectory between the final state weight,  $\mathbf{w}_{\text{final}}$ , and peak stage weight,  $\mathbf{w}_{\text{peak}}$ . That is, we calculated  $\mathcal{L}(\mathbf{w}; \mathbf{x})$ , where  $\mathbf{w} = \mathbf{w}_{\text{final}} + \alpha \frac{\mathbf{w}_{\text{peak}} - \mathbf{w}_{\text{final}}}{\|\mathbf{w}_{\text{peak}} - \mathbf{w}_{\text{final}}\|}$  and  $\alpha > 0$ . We reported the flatness over a training set  $S$ . Thus, the average of losses,  $\frac{1}{|S|} \sum_{\mathbf{x} \in S} \mathcal{L}(\mathbf{w}; \mathbf{x})$ , was calculated. We also tested weight perturbations in random directions and fooling directions (Szegedy et al., 2013).

## 6.2 LOSS WITH RESPECT TO INPUT PERTURBATIONS

We also applied the linear path experiments to input spaces. Flatter loss surfaces can be easily expected to be robust, regarding random perturbations. Thus, we calculated  $\mathcal{L}(\mathbf{w}; \mathbf{x})$ , where  $\mathbf{x} = \mathbf{x}_{\text{train}} + \alpha \mathbf{x}_{\text{noise}}$ , given that  $\mathbf{x}_{\text{noise}}$  is randomly generated from the Normal distribution and then normalized to  $\|\mathbf{x}_{\text{noise}}\| = 1$ . Moreover, what the generalization tries to achieve is higher accuracy on the validation data. Therefore, we performed further experiments generating perturbations in the direction of validation data from training data. Thus, we calculated  $\mathcal{L}(\mathbf{w}; \mathbf{x})$ , where  $\mathbf{x} = \mathbf{x}_{\text{train}} + \alpha(\mathbf{x}_{\text{val}} - \mathbf{x}_{\text{train}})$ . In this case,  $\mathbf{x}_{\text{val}}$  was randomly selected from the ten closest validation candidates placed near  $\mathbf{x}_{\text{train}}$  for each trial. Finally, the average of losses over training set is

calculated.

## 6.3 THE FLATNESS OF LOSS SURFACES

The notion of flatness of a loss surface can be defined as follows. Let us consider a basin of a loss surface with local minimum  $\mathbf{w}_i^*$ , and define level set  $\mathbf{S}_{\mathcal{L}_i} = \{\mathbf{w} | \mathcal{L}(\mathbf{w}; \mathbf{x}) = c\}$  where  $c$  is the loss at the entrance of the basin. Choose any  $\mathbf{w}_0 \in \mathbf{S}_{\mathcal{L}_i}$ , and then the average slope of the surface along the line from  $\mathbf{w}_i^*$  to  $\mathbf{w}_0$  can be determined as  $\frac{c - \epsilon}{\|\mathbf{w}_i^* - \mathbf{w}_0\|}$ , where  $\epsilon$  is the loss at  $\mathbf{w}_i^*$ . If this slope is small, then we call the loss surface is flat.

## 7 EXPERIMENTS

Here, we verify the roles of these peak-shaped learning rates on baseline convolutional neural networks (Krizhevsky et al., 2012), which we call “small model”, and (Springenberg et al., 2014), which we call “large model” with the CIFAR-10 dataset. Hereinafter, all the experimental results are based on these settings, except for those in Section 7.2. We compared step decay, rational decay ( $\gamma_t = \gamma_0(1 + \lambda t)^{-1}$ ), and RMSprop (Tieleman and Hinton, 2012) as adaptive step size schedules and Gaussian-shaped schedules. For the “small model”, the best validation error was 18.79 % with the baseline step decaying learning rates. This result was reduced to 16.48% after adding our learning rate method. For the “large model”, the validation error, 9.53%, of the baseline method was reduced to 8.68%. We tried numerous random settings of hyperparameters (e.g., total number

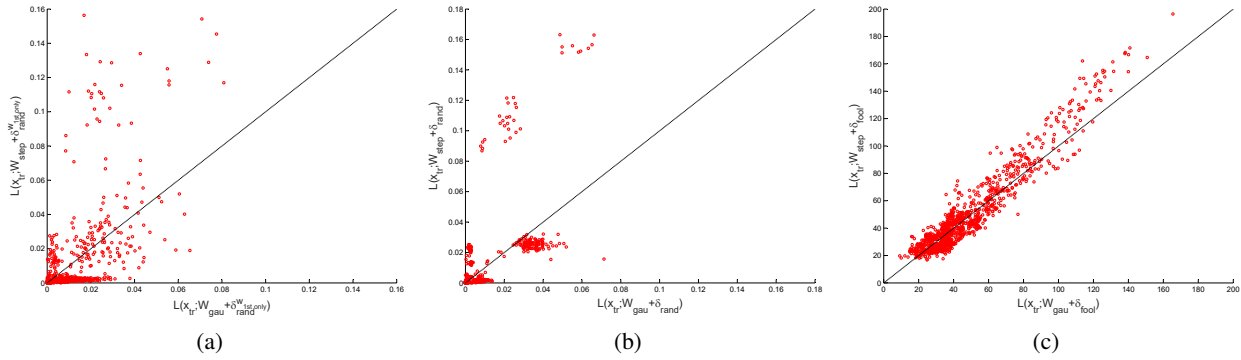

Figure 4: Measuring effects of various weight perturbations (at  $t = 1$ ) was introduced in Section 6. The x and y axes indicate the loss of the model trained by Gaussian and stepped learning rates, respectively. Because all graphs are tilted toward the y-axis, we can see that the nonmonotonic learning rate technique leads to flatter region of loss surfaces with less loss for weight perturbation. (a) Random weight perturbations are added to the first layer. (b) Random weight perturbations are added to the entire layers. (c) Weight perturbations along the fooling direction are added to the entire layers.

Figure 5: Examples of learning process of each learning rate schedule. (a), (b) and (c) :“small model” results, (d), (e) and (f) :“large model” results. (a), (b) and (c), or (d), (e) and (f) show learning rates, gradient magnitude, train and validation errors of each learning rate schedule (step, rational and Gaussian learning rates), respectively. All given values are calculated after each epoch. For the Gaussian learning case, the magnitude of the gradient peaks at the initial phase. Afterwards, it gradually decreases until the learning rate peaks. Other plots are provided for comparison.

of iterations, weight decay, momentum, and initial or peak learning rate) on the “small model” and confirmed that our methods are robust to selection of those settings (see Figure 7). However, we would like to clarify some experimental details on hyperparameters.

**STARTING OFFSET** This parameter can be ignored if the training time does not matter. It is safe to set  $t_{offset} = 0$ . However, going through all these extremely small learning rates is not necessary for achieving good performance.  $t_{offset}$  is controlled by  $\gamma_{start}$  and setting this value as maximum learning rate from the step decay-

Figure 6: Comparisons of Gaussian-shaped and Laplacian-shaped learning rates, in terms of final validation error at  $s = 1$ . Horizontal axis is the total number of epochs. “Continuous” refers to learning rates that are updated at each iteration, whereas “Discrete” refers learning rates that are only updated at the beginning of each epoch.

ing scheduling is predominantly a good choice.

**MAXIMUM LEARNING RATE** Because we are claiming that a large learning rate increases the generalization capability of the model, it is necessary to increase the peak learning rate more than three times of the original maximum learning rate reported in the baseline model. Three times the conventional maximum learning rate is most often safe. However, one can further increase  $\gamma_{max}$  if enough epochs are taken.

**MINIMUM LEARNING RATE** Generally, using learning rates that are too small presents the risk of overfitting. However, because we regularize for the smooth loss surface in the peak learning stages, setting  $\gamma_{min}$  smaller than the conventional value does not harm the performance. It sometimes results in further performance improvement during trials. We experimentally found that setting  $\gamma_{min} = \gamma_{max}/10000$  works well.

**THE NUMBER OF EPOCHS** Our method spends times on peak learning rate, which does not reduce training loss. Therefore, we were required to take more epochs than the conventional schedule to get the best performance. However, even with the same number of epochs, our method can surpass other learning rate schedules, as reported in Section 7.2. Furthermore, we compared the performance of our method to the step-decaying learning rate using the model ensemble in Table 1. To reproduce the same performance as our method, the step decaying learning rate rule needs five model ensembles. Therefore, whereas Gaussian learning rate requires more epochs, our method is still practically efficient.

Figure 7: Prediction on test error with cost and  $\ell_2$ -norm of gradients.

## ROBUSTNESS TO HYPERPARAMETER TUNING

We reported the experimental results with several values for the peak learning rate,  $\gamma_{max}$ , and the total number of iterations in Figure 7. This clearly shows our method is robust to variations in the hyperparameter. For a wide range of  $\gamma_{max}$ , from 0.002 to 0.015, the worst validation error was 18.15%, which is still better than the baseline error (18.79%).

## 7.1 EVALUATING FLATNESS OF THE LOSS GUIDED BY PEAK LEARNING STAGES

Using the techniques presented in Section 6, we evaluated the flatness of the loss trained by peak learning stages. Peak learning stage showed robustness with respect to random input perturbations (Figure 3(b)) and flatness in the direction of train to validation data (Figure 3(c)). In terms of weight perturbations, our method showed flatness in the direction of  $\mathbf{w}^{final}$  to  $\mathbf{w}^{peak}$  (Figure 3(a)). It also showed flatness along random directions (Figure 4(a), (b)) and even with fooling directions (Figure 4(c)). Thus, our theory of flattening loss surface using peak learning stages is well supported by numerous experimental results.

Method	Error (%)	
	Step learning rate	Gaussian learning rate
1 CNN	18.79(360 epochs)	16.91(360 epochs)
2 CNNs	17.49	15.98
3 CNNs	17.13	15.37
4 CNNs	17.09	14.88
5 CNNs	16.75	14.89

Table 1: Model Ensemble.

## 7.2 PERFORMANCE EVALUATION

In what follows, all test error rates are evaluated at the last epoch, not at the best validation epoch. The per-

formance of our learning rate schedule(Gaussian-shaped learning rates) is compared to the state-of-the-art models (Zeiler and Fergus, 2013; Lin et al., 2013; Goodfellow et al., 2013; Lee et al., 2014; He et al., 2016).

**MNIST** For MNIST, we set the  $\gamma_{max} = 0.3$ ,  $\sigma^2 = 2*0.08^2$  (this value makes Gaussian-shape visually looks good) of the Gaussian shaped-learning schedule with total 167 epochs. We considered that the training time is not the issue in case of MNIST because training time is significantly short. Throughout our proposed learning rate policy, without any modification of loss functions and architectures, the accuracy already surpasses the previous works. Table 2 summarizes the result.

METHOD	ERROR (%)
CNN	0.53
STOCHASTIC POOLING	0.47
NIN	0.47
MAXOUT NETWORKS	0.45
DEEPLY SUPERVISED NET	0.39
<b>NIN + ours</b>	<b>0.34</b>

Table 2: Test error rates for the MNIST dataset (without data augmentation).

**CIFAR-10 and CIFAR-100** On the hyperparameter tuning, we followed same settings as in MNIST, except 720 total epochs for NIN (Lin et al., 2013), 270 epochs for ResNet (He et al., 2016). We preprocess the images similar to (Lin et al., 2013; Zeiler and Fergus, 2013; Goodfellow et al., 2013). Color jittering is also added in the ResNet experiment. For CIFAR-100, experiments on DenseNet (Huang et al., 2017) and Wide ResNet (Zagoruyko and Komodakis, 2016) are also performed. In case of Wide ResNet, we exceptionally set the peak learning rate twice as large as the start learning rate (this model adopts large dropout rate 0.3 and exceptionally small number of epochs, which interfere with convergence). Table 3 summarizes the result.

**ImageNet** Because ImageNet classification requires huge computational cost, we reduced shape of the Gaussian-shaped learning rate scheduling by adopting  $t_{offset}$ . We tested with the model of (Krizhevsky et al., 2012) and (Szegedy et al., 2014), which is well-reported and widely used as baseline model. First, we tried learning rate schedules with  $t_{offset} = 0$ ,  $\sigma^2 = 0.0128$  and total 270 epochs (Naive version). Then, to make training efficient, we adopt  $\gamma_{start} = 0.01$ ,  $\gamma_{max} = 0.03$  and  $\gamma_{min} = 0.000003$ , as suggested in the section 7. Finally, we report validation errors in Table 4.

## 8 CONCLUSION

We showed why a flatter loss generalizes better in the view of robustness. Then we presented the relationship of flat losses and learning rates. Inspired by neuroscience, we further proposed peak learning stages for improving high-dimensional DNNs. We thoroughly analyzed how such learning rates affect conventional deep networks. To the best of our knowledge, the work presented in this paper is the first work in this line of research bridging the gap between the learning rate scheduling and the regularization theory of deep learning.

## Abstract

A large number of objectives have been proposed to train latent variable generative models. We show that many of them are Lagrangian dual functions of the same primal optimization problem. The primal problem optimizes the mutual information between latent and visible variables, subject to the constraints of accurately modeling the data distribution and performing correct amortized inference. By choosing to maximize or minimize mutual information, and choosing different Lagrange multipliers, we obtain different objectives including InfoGAN, ALI/BiGAN, ALICE, CycleGAN, beta-VAE, adversarial autoencoders, AVB, AS-VAE and InfoVAE. Based on this observation, we provide an exhaustive characterization of the statistical and computational trade-offs made by all the training objectives in this class of Lagrangian duals. Next, we propose a dual optimization method where we optimize model parameters as well as the Lagrange multipliers. This method achieves Pareto optimal solutions in terms of optimizing information and satisfying the constraints.

## 1 INTRODUCTION

Latent variable generative models are designed to accomplish a wide variety of tasks in computer vision (Radford et al., 2015; Kuleshov & Ermon, 2017), natural language processing (Yang et al., 2017), reinforcement learning (Li et al., 2017b), compressed sensing Dhar et al. (2018), etc. Prominent examples include Variational Autoencoders (VAE, Kingma & Welling (2013); Rezende et al. (2014)), with extensions such as  $\beta$ -VAE (Higgins et al., 2016), Adversarial Autoencoders (Makhzani et al., 2015), and InfoVAE (Zhao et al., 2017); Generative Adversarial Networks (Goodfellow et al., 2014), with extensions such as ALI/BiGAN (Dumoulin et al., 2016a; Don-

ahue et al., 2016), InfoGAN (Chen et al., 2016a) and ALICE (Li et al., 2017a); hybrid objectives such as CycleGAN (Zhu et al., 2017), DiscoGAN (Kim et al., 2017), AVB (Mescheder et al., 2017) and AS-VAE (Pu et al., 2017). All these models attempt to fit an empirical data distribution, but differ in multiple ways: how they measure the similarity between distributions; whether or not they allow for efficient (amortized) inference; whether the latent variables should retain or discard information about the data; and how the model is optimized, which can be likelihood-based or likelihood-free (Mohamed & Lakshminarayanan, 2016; Grover et al., 2018).

In this paper, we generalize existing training objectives for latent variable generative models. We show that all the above training objectives can be viewed as *Lagrangian dual functions* of a constrained optimization problem (primal problem). The primal problem optimizes over the parameters of a generative model and an (amortized) inference distribution. The optimization objective is to maximize or minimize mutual information between latent and observed variables; the constraints (which we term “*consistency constraints*”) are to accurately model the data distribution and to perform correct amortized inference. By considering the Lagrangian dual function and different settings of the Lagrange multipliers, we can obtain all the aforementioned generative modeling training objectives. Surprisingly, under mild assumptions, the aforementioned objectives can be linearly combined to produce every possible primal objective/multipliers in this model family.

In Lagrangian dual optimization, the dual function is maximized with respect to the Lagrange multipliers, and minimized with respect to the primal parameters. Under strong duality, the optimal parameters found by this procedure also solve the original primal problem. However, the aforementioned objectives use fixed (rather than maximized) multipliers. As a consequence, strong duality does not generally hold.

To overcome this problem, we propose a new learning approach where the Lagrange multipliers are also optimized. We show that strong duality holds in distribution space,

so this optimization procedure is guaranteed to optimize the primal objective while satisfying the consistency constraints. As an application of this approach, we propose *Lagrangian VAE*, a Lagrangian optimization algorithm for the InfoVAE (Zhao et al., 2017) objective. Lagrangian VAE can explicitly trade-off optimization of the primal objective and consistency constraint satisfaction. In addition, both theoretical properties (of Lagrangian optimization) and empirical experiments show that solutions obtained by Lagrangian VAE *Pareto dominate* solutions obtained with InfoVAE: Lagrangian VAE either obtains better mutual information or better constraint satisfaction, regardless of the hyper-parameters used by either method.

## 2 BACKGROUND

We consider two groups of variables: observed variables  $\mathbf{x} \in \mathcal{X}$  and latent variables  $\mathbf{z} \in \mathcal{Z}$ . Our algorithm receives input distributions  $q(\mathbf{x}), p(\mathbf{z})$  over  $\mathbf{x}$  and  $\mathbf{z}$  respectively. Each distribution is either specified *explicitly* through a tractable analytical expression such as  $\mathcal{N}(0, I)$ , or *implicitly* through a set of samples. For example, in latent variable generative modeling of images (Kingma & Welling, 2013; Goodfellow et al., 2014),  $\mathcal{X}$  is the space of images, and  $\mathcal{Z}$  is the space of latent features.  $q(\mathbf{x})$  is a dataset of sample images, and  $p(\mathbf{z})$  is a simple “prior” distribution, e.g., a Gaussian; in unsupervised image translation (Zhu et al., 2017),  $\mathcal{X}$  and  $\mathcal{Z}$  are both image spaces and  $q(\mathbf{x}), p(\mathbf{z})$  are sample images from two different domains (e.g., pictures of horses and zebras).

The underlying joint distribution on  $(\mathbf{x}, \mathbf{z})$  is not known, and we are not given any sample from it. Our goal is to nonetheless learn some model of the joint distribution  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  with the following desiderata:

**Desideratum 1. Matching Marginal** The marginals of  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  over  $\mathbf{x}, \mathbf{z}$  respectively match the provided distributions  $q(\mathbf{x}), p(\mathbf{z})$ .

**Desideratum 2. Meaningful Relationship**  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  captures a meaningful relationship between  $\mathbf{x}$  and  $\mathbf{z}$ . For example, in latent variable modeling of images, the latent variables  $\mathbf{z}$  should correspond to semantically meaningful features describing the image  $\mathbf{x}$ . In unsupervised image translation,  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  should capture the “correct” pairing between  $\mathbf{x}$  and  $\mathbf{z}$ .

We address desideratum 1 in this section, and desideratum 2 in section 3. The joint distribution  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  can be represented in factorized form by chain rule. To do so, we define conditional distribution families  $\{p_{\theta^p}(\mathbf{x}|\mathbf{z}), \theta^p \in \Theta^p\}$  and  $\{q_{\theta^q}(\mathbf{z}|\mathbf{x}), \theta^q \in \Theta^q\}$ . We require that for any  $\mathbf{z}$  we can both efficiently sample from  $p_{\theta^p}(\mathbf{x}|\mathbf{z})$  and compute  $\log p_{\theta^p}(\mathbf{x}|\mathbf{z})$ , and similarly for  $q_{\theta^q}(\mathbf{z}|\mathbf{x})$ . For compactness we use  $\theta = (\theta^p, \theta^q)$  to denote the parameters of both distributions  $p_{\theta}$  and  $q_{\theta}$ . We define the joint distribu-

tion  $r_{\text{model}}(\mathbf{x}, \mathbf{z})$  in two ways:

$$r_{\text{model}}(\mathbf{x}, \mathbf{z}) \stackrel{\text{def}}{=} p_{\theta}(\mathbf{x}, \mathbf{z}) \stackrel{\text{def}}{=} p(\mathbf{z})p_{\theta}(\mathbf{x}|\mathbf{z}) \quad (1)$$

and symmetrically

$$r_{\text{model}}(\mathbf{x}, \mathbf{z}) \stackrel{\text{def}}{=} q_{\theta}(\mathbf{x}, \mathbf{z}) \stackrel{\text{def}}{=} q(\mathbf{x})q_{\theta}(\mathbf{z}|\mathbf{x}) \quad (2)$$

Defining the model in two (redundant) ways seem unusual but has significant computational advantages: given  $\mathbf{x}$  we can tractably sample  $\mathbf{z}$ , and vice versa. For example, in latent variable models, given observed data  $\mathbf{x}$  we can sample latent features from  $\mathbf{z} \sim q_{\theta}(\mathbf{z}|\mathbf{x})$  (amortized inference), and given latent feature  $\mathbf{z}$  we can generate novel samples from  $\mathbf{x} \sim p_{\theta}(\mathbf{x}|\mathbf{z})$  (ancestral sampling).

If the two definitions (1), (2) are **consistent**, which we define as  $p_{\theta}(\mathbf{x}, \mathbf{z}) = q_{\theta}(\mathbf{x}, \mathbf{z})$ , we automatically satisfy desideratum 1:

$$\begin{aligned} r_{\text{model}}(\mathbf{x}) &= \int_{\mathbf{z}} r_{\text{model}}(\mathbf{x}, \mathbf{z}) d\mathbf{z} = \int_{\mathbf{z}} q_{\theta}(\mathbf{x}, \mathbf{z}) d\mathbf{z} = q(\mathbf{x}) \\ r_{\text{model}}(\mathbf{z}) &= \int_{\mathbf{x}} r_{\text{model}}(\mathbf{x}, \mathbf{z}) d\mathbf{x} = \int_{\mathbf{x}} p_{\theta}(\mathbf{x}, \mathbf{z}) d\mathbf{x} = p(\mathbf{z}) \end{aligned}$$

Based on this observation, we can design objectives that encourage consistency. Many latent variable generative models fit into this framework. For example, variational autoencoders (VAE, Kingma & Welling (2013)) enforce consistency by minimizing the KL divergence:

$$\min_{\theta} D_{\text{KL}}(q_{\theta}(\mathbf{x}, \mathbf{z}) \| p_{\theta}(\mathbf{x}, \mathbf{z}))$$

This minimization is equivalent to maximizing the evidence lower bound ( $\mathcal{L}_{\text{ELBO}}$ ) (Kingma & Welling, 2013):

$$\begin{aligned} &\max_{\theta} -D_{\text{KL}}(q_{\theta}(\mathbf{x}, \mathbf{z}) \| p_{\theta}(\mathbf{x}, \mathbf{z})) \quad (3) \\ &= -\mathbb{E}_{q_{\theta}(\mathbf{x}, \mathbf{z})} [\log(q_{\theta}(\mathbf{z}|\mathbf{x})q(\mathbf{x})) - \log(p_{\theta}(\mathbf{x}|\mathbf{z})p(\mathbf{z}))] \\ &= \mathbb{E}_{q_{\theta}(\mathbf{x}, \mathbf{z})} [\log p_{\theta}(\mathbf{x}|\mathbf{z})] + H_q(\mathbf{x}) \\ &\quad - \mathbb{E}_{q(\mathbf{x})} [D_{\text{KL}}(q_{\theta}(\mathbf{z}|\mathbf{x}) \| p(\mathbf{z}))] \\ &\equiv \mathbb{E}_{q_{\theta}(\mathbf{x}, \mathbf{z})} [\log p_{\theta}(\mathbf{x}|\mathbf{z})] \\ &\quad - \mathbb{E}_{q(\mathbf{x})} [D_{\text{KL}}(q_{\theta}(\mathbf{z}|\mathbf{x}) \| p(\mathbf{z}))] \quad \Big\} \mathcal{L}_{\text{ELBO}} \quad (4) \end{aligned}$$

where  $H_q(\mathbf{x})$  is the entropy of  $q(\mathbf{x})$  and is a constant that can be ignored for the purposes of optimization over model parameters  $\theta$  (denoted  $\equiv$ ).

As another example, BiGAN/ALI (Donahue et al., 2016; Dumoulin et al., 2016b) use an adversarial discriminator to approximately minimize the Jensen-Shannon divergence

$$\min_{\theta} D_{\text{JS}}(q_{\theta}(\mathbf{x}, \mathbf{z}) \| p_{\theta}(\mathbf{x}, \mathbf{z}))$$

Many other ways of enforcing consistency are possible. Most generally, we can enforce consistency with a vector of divergences  $\mathcal{D} = [D_1, \dots, D_m]$ , where each  $D_i$  takes two

probability measures as input, and outputs a non-negative value which is zero if and only if the two input measures are the same. Examples of possible divergences include Maximum Mean Discrepancy (MMD, Gretton et al. (2007)), denoted  $D_{\text{MMD}}$ ; Wasserstein distance (Arjovsky et al., 2017), denoted  $D_{\text{W}}$ ;  $f$ -divergences (Nowozin et al., 2016), denoted  $D_f$ ; and Jensen-Shannon divergence (Goodfellow et al., 2014), denoted  $D_{\text{JS}}$ .

Each  $D_i$  can be any divergence applied to a pair of probability measures. The pair of probability measures can be defined over either both variables  $(\mathbf{x}, \mathbf{z})$ , a single variable  $\mathbf{x}, \mathbf{z}$ , or conditional  $\mathbf{x}|\mathbf{z}, \mathbf{z}|\mathbf{x}$ . If the probability measure is defined over a conditional  $\mathbf{x}|\mathbf{z}, \mathbf{z}|\mathbf{x}$ , we also take expectation over the conditioning variable with respect to  $p_\theta$  or  $q_\theta$ . Some examples of  $D_i$  are:

$$\begin{aligned} & \mathbb{E}_{q_\theta(\mathbf{z})}[D_{\text{KL}}(q_\theta(\mathbf{x}|\mathbf{z})\|p_\theta(\mathbf{x}|\mathbf{z}))] \\ & D_{\text{MMD}}(q_\theta(\mathbf{z})\|p(\mathbf{z})) \\ & D_{\text{W}}(p_\theta(\mathbf{x}, \mathbf{z})\|q_\theta(\mathbf{x}, \mathbf{z})) \\ & \mathbb{E}_{q(\mathbf{x})}[D_f(q_\theta(\mathbf{z}|\mathbf{x})\|p_\theta(\mathbf{z}|\mathbf{x}))] \\ & D_{\text{JS}}(q(\mathbf{x})\|p_\theta(\mathbf{x})) \end{aligned}$$

We only require that

$$D_i = 0, \forall i \in \{1, \dots, m\} \iff p_\theta(\mathbf{x}, \mathbf{z}) = q_\theta(\mathbf{x}, \mathbf{z})$$

so  $\mathcal{D} = \mathbf{0}$  implies consistency. Note that each  $D_i$  implicitly depends on the parameters  $\theta$  through  $p_\theta$  and  $q_\theta$ , but notationally we neglect this for simplicity.

Enforcing consistency  $p_\theta(\mathbf{x}, \mathbf{z}) = q_\theta(\mathbf{x}, \mathbf{z})$  by  $\mathcal{D} = \mathbf{0}$  satisfies desideratum 1 (matching marginal), but does not directly address desideratum 2 (meaningful relationship). A large number of joint distributions can have the same marginal distributions  $p(\mathbf{z})$  and  $q(\mathbf{x})$  (including ones where  $\mathbf{z}$  and  $\mathbf{x}$  are independent), and only a small fraction of them encode meaningful models.

### 3 GENERATIVE MODELING AS CONSTRAINT OPTIMIZATION

To address desideratum 2, we modify the training objective and specify additional preferences among consistent  $p_\theta(\mathbf{x}, \mathbf{z})$  and  $q_\theta(\mathbf{x}, \mathbf{z})$ . Formally we solve the following primal optimization problem

$$\min_{\theta} f(\theta) \quad \text{subject to } \mathcal{D} = \mathbf{0} \quad (5)$$

where  $f(\theta)$  encodes our preferences over consistent distributions, and depends on  $\theta$  through  $p_\theta(\mathbf{x}|\mathbf{z})$  and  $q_\theta(\mathbf{x}|\mathbf{z})$ .

An important preference is the mutual information between  $\mathbf{x}$  and  $\mathbf{z}$ . Depending on the downstream application, we may maximize mutual information (Chen et al., 2016b; Zhao et al., 2017; Li et al., 2017a; Chen et al., 2016a) so that the features (latent variables)  $\mathbf{z}$  can capture as much

information as possible about  $\mathbf{x}$ , or minimize mutual information (Zhao et al., 2017; Higgins et al., 2016; Tishby & Zaslavsky, 2015; Shamir et al., 2010) to achieve compression. To implement mutual information preference we consider the following objective

$$f_I(\theta; \alpha_1, \alpha_2) = \alpha_1 I_{q_\theta}(\mathbf{x}; \mathbf{z}) + \alpha_2 I_{p_\theta}(\mathbf{x}; \mathbf{z}) \quad (6)$$

where  $I_{p_\theta}(\mathbf{x}; \mathbf{z}) = \mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}, \mathbf{z}) - \log p_\theta(\mathbf{x})p(\mathbf{z})]$  is the mutual information under  $p_\theta(\mathbf{x}, \mathbf{z})$ , and  $I_{q_\theta}(\mathbf{x}; \mathbf{z})$  is their mutual information under  $q_\theta(\mathbf{x}, \mathbf{z})$ .

The optimization problem in Eq.(5) with mutual information  $f(\theta)$  in Eq.(6) has the following Lagrangian dual function:

$$\alpha_1 I_{q_\theta}(\mathbf{x}; \mathbf{z}) + \alpha_2 I_{p_\theta}(\mathbf{x}; \mathbf{z}) + \boldsymbol{\lambda}^\top \mathcal{D} \quad (7)$$

where  $\boldsymbol{\lambda} = [\lambda_1, \dots, \lambda_m]$  is a vector of Lagrange multipliers, one for each of the  $m$  consistency constraints in  $\mathcal{D} = [D_1, \dots, D_m]$ .

In the next section, we will show that many existing training objectives for generative models minimize the Lagrangian dual in Equation 7 for some *fixed*  $\alpha_1, \alpha_2, \mathcal{D}$  and  $\boldsymbol{\lambda}$ . However, dual optimization requires maximization over the dual parameters  $\boldsymbol{\lambda}$ , which should *not* be kept fixed. We discuss dual optimization in Section 5.

## 4 GENERALIZING OBJECTIVES WITH FIXED MULTIPLIERS

Several existing objectives for latent variable generative models can be rewritten in the dual form of Equation 7 with *fixed* Lagrange multipliers. We provide several examples here and provide more in Appendix A.

**VAE (Kingma & Welling, 2013)** Per our discussion in Section 2, the VAE training objective commonly written as ELBO maximization in Eq.(4) is actually equivalent to Equation 3. This is a dual form where we set  $\mathcal{D} = [D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z})\|p_\theta(\mathbf{x}, \mathbf{z}))]$ ,  $\alpha_1 = \alpha_2 = 0$  and  $\boldsymbol{\lambda} = 1$ . Because  $\alpha_1 = \alpha_2 = 0$ , this objective has no information preference, confirming previous observations that the learned distribution can have high, low or zero mutual information between  $x$  and  $z$ . Chen et al. (2016b); Zhao et al. (2017).

**$\beta$ -VAE (Higgins et al., 2016)** The following objective  $\mathcal{L}_{\beta\text{-VAE}}$  is proposed to learn disentangled features  $\mathbf{z}$ :

$$-\mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}|\mathbf{z})] + \beta \mathbb{E}_{q(\mathbf{x})}[D_{\text{KL}}(q_\theta(\mathbf{z}|\mathbf{x})\|p(\mathbf{z}))]$$

This is equivalent to the following dual form:

$$\begin{aligned} & \mathcal{L}_{\beta\text{-VAE}} \\ & \equiv \mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})} \left[ \log \frac{q_\theta(\mathbf{x}|\mathbf{z})q(\mathbf{x})}{p_\theta(\mathbf{x}|\mathbf{z})q_\theta(\mathbf{x}|\mathbf{z})} + \beta \log \frac{q_\theta(\mathbf{z}|\mathbf{x})q_\theta(\mathbf{z})}{q_\theta(\mathbf{z})p(\mathbf{z})} \right] \\ & \equiv (\beta - 1) I_{q_\theta}(\mathbf{x}; \mathbf{z}) \quad (\text{primal}) \\ & \quad + \beta D_{\text{KL}}(q_\theta(\mathbf{z})\|p(\mathbf{z})) \quad (\text{consistency}) \\ & \quad + \mathbb{E}_{q_\theta(\mathbf{z})}[D_{\text{KL}}(q_\theta(\mathbf{x}|\mathbf{z})\|p_\theta(\mathbf{x}|\mathbf{z}))] \end{aligned}$$

$f(p, q)$	Likelihood Based	Unary Likelihood Free	Binary Likelihood Free
0	VAE (Kingma & Welling, 2013)	VAE-GAN (Makhzani et al., 2015)	ALI (Dumoulin et al., 2016b)
$\alpha_1 I_q$	$\beta$ -VAE (Higgins et al., 2016)	InfoVAE (Zhao et al., 2017)	ALICE (Li et al., 2017a)
$\alpha_2 I_p$	VMI (Barber & Agakov, 2003)	InfoGAN (Chen et al., 2016a)	-
$\alpha_1 I_q + \alpha_2 I_p$	-	CycleGAN (Zhu et al., 2017)	AS-VAE (Pu et al., 2017)

Table 1: For each choice of  $\alpha$  and computability class (Definition 2) we list the corresponding existing model. Several other objectives are also Lagrangian duals, but they are not listed because they are similar to models in the table. These objectives include DiscoGAN (Kim et al., 2017), BiGAN (Donahue et al., 2016), AAE (Makhzani et al., 2015), WAE (Tolstikhin et al., 2017).

where we use  $\equiv$  to denote “equal up to a value that does not depend on  $\theta$ ”. In this case,

$$\alpha_1 = \beta - 1, \quad \alpha_2 = 0$$

$$\lambda = [\beta, 1]$$

$$\mathcal{D} = [KL(q_\theta(\mathbf{z})\|p(\mathbf{z})), \mathbb{E}_{q_\theta(\mathbf{z})}[D_{\text{KL}}(q_\theta(\mathbf{x}|\mathbf{z})\|p_\theta(\mathbf{x}|\mathbf{z}))]]$$

When  $\alpha_1 > 0$  or equivalently  $\beta > 1$ , there is an incentive to minimize mutual information between  $\mathbf{x}$  and  $\mathbf{z}$ .

**InfoGAN (Chen et al., 2016a)** As another example, the InfoGAN objective <sup>1</sup> :

$$\mathcal{L}_{\text{InfoGAN}} = D_{\text{JS}}(q(\mathbf{x})\|p_\theta(\mathbf{x})) - \mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[\log q_\theta(\mathbf{z}|\mathbf{x})]$$

is equivalent to the following dual form:

$$\begin{aligned} \mathcal{L}_{\text{InfoGAN}} &\equiv \mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[-\log p_\theta(\mathbf{z}|\mathbf{x}) + \log p(\mathbf{z}) \\ &+ \log p_\theta(\mathbf{z}|\mathbf{x}) - \log q_\theta(\mathbf{z}|\mathbf{x})] + D_{\text{JS}}(q(\mathbf{x})\|p_\theta(\mathbf{x})) \\ &\equiv -I_{p_\theta}(\mathbf{x}; \mathbf{z}) \quad (\text{primal}) \\ &+ \mathbb{E}_{p_\theta(\mathbf{x})}[D_{\text{KL}}(p_\theta(\mathbf{z}|\mathbf{x})\|q_\theta(\mathbf{z}|\mathbf{x}))] \quad (\text{consistency}) \\ &+ D_{\text{JS}}(q(\mathbf{x})\|p_\theta(\mathbf{x})) \end{aligned}$$

In this case  $\alpha_1 = 0$ , and  $\alpha_2 = -1 < 0$ , the model maximizes mutual information between  $\mathbf{x}$  and  $\mathbf{z}$ .

In fact, all objectives in Table 1 belong to this class<sup>2</sup>. Derivations for additional models can be found in Appendix A.

#### 4.1 ENUMERATION OF ALL OBJECTIVES

The Lagrangian dual form of an objective reveals its mutual information preference ( $\alpha_1, \alpha_2$ ), type of consistency constraints ( $\mathcal{D}$ ), and weighting of the constraints ( $\lambda$ ). This suggests that the Lagrangian dual perspective may unify many existing training objectives. We wish to identify and categorize *all* objectives that have Lagrangian dual form as in Eq.7). However, this has two technical difficulties that we proceed to resolve.

<sup>1</sup>For conciseness we use  $\mathbf{z}$  to denote structured latent variables, which is represented as  $\mathbf{c}$  in (Chen et al., 2016a).

<sup>2</sup>Variational Mutual Information Maximization (VMI) is not truly a Lagrangian dual because it does not enforce consistency constraints ( $\lambda = 0$ ).

**1. Equivalence:** Many objectives appear different, but are actually identical for the purposes of optimization (as we have shown). To handle this we characterize “equivalent objectives” with a set of pre-specified transformations.

**Definition 1. Equivalence (Informal):** An objective  $\mathcal{L}$  is equivalent to  $\mathcal{L}'$  when there exists a constant  $C$ , so that for all parameters  $\theta$ ,  $\mathcal{L}(\theta) = \mathcal{L}'(\theta) + C$ . We denote this as  $\mathcal{L} \equiv \mathcal{L}'$ .

$\mathcal{L}$  and  $\mathcal{L}'$  are elementary equivalent if  $\mathcal{L}'$  can be obtained from  $\mathcal{L}$  by applying chain rule or Bayes rule to probabilities in  $\mathcal{L}$ , and addition/subtraction of constants  $\mathbb{E}_{q(\mathbf{x})}[\log q(\mathbf{x})]$  and  $\mathbb{E}_{p(\mathbf{z})}[\log p(\mathbf{z})]$ .

A more formal but verbose definition is in Appendix B, Definition 1.

Elementary equivalences define simple yet flexible transformations for deriving equivalent objectives. For example, all the transformations in Section 4 (VAE,  $\beta$ -VAE and InfoGAN) and Appendix A are elementary. This implies that all objectives in Table 1 are elementary equivalent to a Lagrangian dual function in Eq.(7). However, these transformations are not exhaustive. For example, transforming  $\mathbb{E}_{p_\theta}[g(\mathbf{x})]$  into  $\mathbb{E}_{q_\theta}[g(\mathbf{x})p_\theta(\mathbf{x})/q_\theta(\mathbf{x})]$  via importance sampling is not accounted for, hence the two objectives are not considered to be elementary equivalent.

**2. Optimization Difficulty:** Some objectives are easier to evaluate/optimize than others. For example, variational autoencoder training is robust and stable, adversarial training is less stable and requires careful hyper-parameter selection (Kodali et al., 2018), and direct optimization of the log-likelihood  $\log p_\theta(\mathbf{x})$  is very difficult for latent variable models and almost never used Grover et al. (2018).

To assign a “hardness score” to each objective, we first group the “terms” (an objective is a sum of terms) from easy to hard to optimize. An objective belongs to a “hardness class” if it cannot be transformed into an objective with easier terms. This is formalized below:

**Definition 2. Effective Optimization:** We define

1. Likelihood-based terms as the following set

$$T_1 = \{\mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}|\mathbf{z})], \mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}, \mathbf{z})], \\ \mathbb{E}_{p_\theta(\mathbf{z})}[\log p(\mathbf{z})], \mathbb{E}_{p_\theta(\mathbf{x}, \mathbf{z})}[\log q_\theta(\mathbf{z}|\mathbf{x})] \\ \mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}|\mathbf{z})], \mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})}[\log p_\theta(\mathbf{x}, \mathbf{z})], \\ \mathbb{E}_{q_\theta(\mathbf{z})}[\log p(\mathbf{z})], \mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})}[\log q_\theta(\mathbf{z}|\mathbf{x})]\}$$

2. Unary likelihood-free terms as the following set

$$T_2 = \{D(q(\mathbf{x})\|p_\theta(\mathbf{x})), D(q_\theta(\mathbf{z})\|p(\mathbf{z}))\}$$

3. Binary likelihood-free terms as the following set

$$T_3 = \{D(q_\theta(\mathbf{x}, \mathbf{z})\|p_\theta(\mathbf{x}, \mathbf{z}))\}$$

where each  $D$  can be  $f$ -divergence, Jensen Shannon divergence, Wasserstein distance, or Maximum Mean Discrepancy. An objective  $\mathcal{L}$  is likelihood-based computable if  $\mathcal{L}$  is elementary equivalent to some  $\mathcal{L}'$  that is a linear combination of elements in  $T_1$ ; unary likelihood-free computable if  $\mathcal{L}'$  is a linear combination of elements in  $T_1 \cup T_2$ ; binary likelihood-free computable if  $\mathcal{L}'$  is a linear combination of elements in  $T_1 \cup T_2 \cup T_3$ .

The rationale of this categorization is that elements in  $T_1$  can be estimated by Monte-Carlo estimators and optimized by stochastic gradient descent effectively in practice (with low bias and variance) (Kingma & Welling, 2013; Rezende et al., 2014). In contrast, elements in  $T_2$  are optimized by likelihood-free approaches such as adversarial training (Goodfellow et al., 2014) or kernelized methods such as MMD (Gretton et al., 2007) or Stein variational gradient (Liu & Wang, 2016). These optimization procedures are known to suffer from stability problems (Arjovsky et al., 2017) or cannot handle complex distributions in high dimensions (Ramdas et al., 2015). Finally, elements in  $T_3$  are over both  $\mathbf{x}$  and  $\mathbf{z}$ , and they are empirically shown to be even more difficult to optimize (Li et al., 2017a). We do not include terms such as  $\mathbb{E}_{q(\mathbf{x})}[\log p_\theta(\mathbf{x})]$  because they are seldom feasible to compute or optimize for latent variable generative models.

Now we are able to fully characterize all Lagrangian dual objectives in Eq. (7) that are likelihood-based / unary likelihood free / binary likelihood free computable in Table 1.

In addition, Table 1 contains essentially *all* possible models for each optimization difficulty class in Definition 2. This is shown in the following theorem (informal, formal version and proof in Appendix B, Theorem 3,4,5)

**Theorem 1. Closure theorem (Informal):** Denote a Lagrangian objectives in the form of Equation 7 where all divergences are  $D_{\text{KL}}$  a KL Lagrangian objective. Under elementary equivalence defined in Definition 1,

1) Any KL Lagrangian objective that is elementary equivalent to a likelihood based computable objective is equivalent to a linear combination of VMI and  $\beta$ -VAE.

2) Any KL Lagrangian objective that is elementary equivalent to a unary likelihood computable objective is equivalent to a linear combination of InfoVAE and InfoGAN.

3) Any KL Lagrangian objective that is elementary equivalent to a binary likelihood computable objective is equivalent to a linear combination of ALICE, InfoVAE and InfoGAN.

We also argue in the Appendix (without formal proof) that this theorem holds for other divergences including  $D_{\text{MMD}}$ ,  $D_{\text{W}}$ ,  $D_f$  or  $D_{\text{JS}}$ .

Intuitively, this suggests a rather negative result: if a new latent variable model training objective contains mutual information preference and consistency constraints (defined through  $D_{\text{KL}}$ ,  $D_{\text{MMD}}$ ,  $D_{\text{W}}$ ,  $D_f$  or  $D_{\text{JS}}$ ), and this objective can be effectively optimized as in Definition 1 and Definition 2, then this objective is a linear combination of existing objectives. Our limitation is that we are restricted to elementary transformations and the set of terms defined in Definition 2. To derive new training objectives, we should consider new transformations, non-linear combinations and/or new terms.

## 5 DUAL OPTIMIZATION FOR LATENT VARIABLE GENERATIVE MODELS

While existing objectives for latent variable generative models have dual form in Equation 7, they are not solving the dual problem exactly because the Lagrange multipliers  $\lambda$  are predetermined instead of optimized. In particular, if we can show strong duality, the optimal solution to the dual is also an optimal solution to the primal (Boyd & Vandenberghe, 2004). However if the Lagrange multipliers are fixed, this property is lost, and the parameters  $\theta$  obtained via dual optimization may be suboptimal for  $\min_{\theta} f(\theta)$ , or violate the consistency conditions  $\mathcal{D} = \mathbf{0}$ .

### 5.1 RELAXATION OF CONSISTENCY CONSTRAINTS

This observation motivates us to directly solve the dual optimization problem where we also *optimize* the Lagrange multipliers.

$$\max_{\lambda \geq 0} \min_{\theta} f(\theta) + \lambda^T \mathcal{D}$$

Unfortunately, this is usually impractical because the consistency constraints are difficult to satisfy when the model has finite capacity, so in practice the primal optimization problem is actually infeasible and  $\lambda$  will be optimized to  $+\infty$ .

One approach to this problem is to use relaxed consistency constraints, where compared to Eq.(5) we require consis-

tency up to some error  $\epsilon > 0$ :

$$\min_{\theta} f(\theta) \quad \text{subject to} \quad \mathcal{D} \leq \epsilon \quad (8)$$

For a sufficiently large  $\epsilon$ , the problem is feasible. This has the corresponding dual problem:

$$\max_{\lambda \geq 0} \min_{\theta} f(\theta) + \lambda^{\top} (\mathcal{D} - \epsilon) \quad (9)$$

When  $\lambda$  is constant (instead of maximized), Equation 9 still reduces to existing latent variable generative modeling objectives since  $\lambda^{\top} \epsilon$  is a constant, so the objective simply becomes

$$\min_{\theta} f(\theta) + \lambda^{\top} \mathcal{D} + \text{constant}$$

In contrast, we propose to find  $\lambda^*$ ,  $\theta^*$  that optimize the Lagrangian dual in Eq.(9). If we additionally have strong duality,  $\theta^*$  is also the optimal solution to the primal problem in Eq.(8).

## 5.2 STRONG DUALITY WITH MUTUAL INFORMATION OBJECTIVES

This section aims to show that strong duality for Eq.(8) holds in distribution space if we replace mutual informations in  $f$  with upper and lower bounds. We prove this via Slater's condition (Boyd & Vandenberghe, 2004), which has three requirements: 1.  $\forall D \in \mathcal{D}$ ,  $D$  is convex in  $\theta$ ; 2.  $f(\theta)$  is convex for  $\theta \in \Theta$ ; 3. the problem is strictly feasible:  $\exists \theta$  s.t.  $\mathcal{D} < \epsilon$ . We propose weak conditions to satisfy all three in distribution space, so strong duality is guaranteed.

For simplicity we focus on discrete  $\mathcal{X}$  and  $\mathcal{Z}$ . We parameterize  $q_{\theta}(z|\mathbf{x})$  with a parameter matrix  $\theta^q \in \mathbb{R}^{|\mathcal{X}||\mathcal{Z}|}$  (we add the superscript  $q$  to distinguish parameters of  $q_{\theta}$  from that of  $p_{\theta}$ ) where

$$q_{\theta}(z = j|\mathbf{x} = i) = \theta_{ij}^q, \forall i \in \mathcal{X}, j \in \mathcal{Z} \quad (10)$$

The only restriction is that  $\theta^q$  must correspond to valid conditional distributions. More formally, we require that  $\theta^q \in \Theta^q$ , where

$$\Theta^q = \left\{ \theta^q \in \mathbb{R}^{|\mathcal{X}||\mathcal{Z}|} \text{ s.t. } 0 \leq \theta_{ij}^q \leq 1, \sum_j \theta_{ij}^q = 1 \right\} \quad (11)$$

Similarly we can define  $\theta^p \in \Theta^p$  for  $p_{\theta}$ . We still use

$$\theta = [\theta^q, \theta^p], \quad \Theta = \Theta^q \times \Theta^p \quad (12)$$

to denote both sets of parameters.

**1) Constraints  $D \in \mathcal{D}$  are convex:** We show that some divergences used in existing models are convex in distribution space.

**Lemma 1** (Convex Constraints (Informal)).  $D_{\text{KL}}$ ,  $D_{\text{MMD}}$ , or  $D_f$  over any marginal distributions on  $x$  or  $z$  or joint distributions on  $(x, z)$  are convex with respect to  $\theta \in \Theta$  as defined in Eq.(12).

Therefore if one only uses these convex divergences, the first requirement for Slater's condition is satisfied.

**2) Convex Bounds for  $f(\theta)$ :**  $f(\theta) = \alpha_1 I_{q_{\theta}}(x; z) + \alpha_2 \bar{I}_{p_{\theta}}(x; z)$  is not itself guaranteed to be convex in general. However we observe that mutual information has a convex upper bound, and a concave lower bound, which we denote as  $\bar{I}_{q_{\theta}}$  and  $\underline{I}_{q_{\theta}}$  respectively:

$$\begin{aligned} I_{q_{\theta}}(\mathbf{x}; \mathbf{z}) & \quad (13) \\ &= \mathbb{E}_{q(\mathbf{x})}[D_{\text{KL}}(q_{\theta}(z|\mathbf{x})||p(z))] \quad \text{convex upper bound } \bar{I}_{q_{\theta}} \\ &\quad - D_{\text{KL}}(q_{\theta}(z)||p(z)) \quad \text{bound gap } \bar{I}_{q_{\theta}} - I_{q_{\theta}} \\ &= \mathbb{E}_{q_{\theta}(\mathbf{x}, \mathbf{z})}[\log p_{\theta}(\mathbf{x}|\mathbf{z})] + H_q(\mathbf{x}) \quad \text{concave lower bound } \underline{I}_{q_{\theta}} \\ &\quad + \mathbb{E}_{p(\mathbf{z})} D_{\text{KL}}(q(\mathbf{x}|\mathbf{z})||p_{\theta}(\mathbf{x}|\mathbf{z})) \quad \text{bound gap } I_{q_{\theta}} - \underline{I}_{q_{\theta}} \end{aligned}$$

The convexity/concavity of these bounds is shown by the following lemma, which we prove in the appendix

**Lemma 2** (Convex/Concave Bounds).  $\bar{I}_{q_{\theta}}$  is convex with respect to  $\theta \in \Theta$  as defined in Eq.(12), and  $\underline{I}_{q_{\theta}}$  is concave with respect to  $\theta \in \Theta$ .

A desirable property of these bounds is that if we look at the bound gaps (difference between bound and true value) in Eq.(13), they are 0 if the consistency constraint is satisfied (i.e.,  $p_{\theta}(\mathbf{x}, \mathbf{z}) = q_{\theta}(\mathbf{x}, \mathbf{z})$ ). They will be tight (bound gaps are small) when consistency constraints are approximately satisfied (i.e.,  $p_{\theta}(\mathbf{x}, \mathbf{z}) \approx q_{\theta}(\mathbf{x}, \mathbf{z})$ ). In addition we also denote identical bounds for  $I_{p_{\theta}}$  as  $\bar{I}_{p_{\theta}}$  and  $\underline{I}_{p_{\theta}}$ . Similar bounds for mutual information have been discussed in (Alemi et al., 2017).

**3) Strict Feasibility:** the optimization problem has non empty feasible set, which we show in the following lemma:

**Lemma 3** (Strict Feasibility). For discrete  $\mathcal{X}$  and  $\mathcal{Z}$ , and  $\epsilon > 0$ ,  $\exists \theta \in \Theta$  such that  $\mathcal{D} < \epsilon$ .

Therefore we have shown that for convex/concave upper and lower bounds on  $f$ , all three of Slater's conditions are satisfied, so strong duality holds. We summarize this in the following theorem.

**Theorem 2** (Strong Duality). If  $\mathcal{D}$  contains only divergences in Lemma 1, then for all  $\epsilon > 0$ :

If  $\alpha_1, \alpha_2 \geq 0$  strong duality holds for the following problems:

$$\min_{\theta \in \Theta} \alpha_1 \bar{I}_{q_{\theta}} + \alpha_2 \bar{I}_{p_{\theta}} \quad \text{subject to} \quad \mathcal{D} \leq \epsilon \quad (14)$$

If  $\alpha_1, \alpha_2 \leq 0$ , strong duality holds for the following problem

$$\min_{\theta \in \Theta} \alpha_1 \underline{I}_{q_{\theta}} + \alpha_2 \underline{I}_{p_{\theta}} \quad \text{subject to} \quad \mathcal{D} \leq \epsilon \quad (15)$$

---

**Algorithm 1** Dual Optimization for Latent Variable Generative Models

---

**Input:** Analytical form for  $p(\mathbf{z})$  and samples from  $q(\mathbf{x})$ ; constraints  $\mathcal{D}$ ;  $\alpha_1, \alpha_2$  that specify maximization / minimization of mutual information;  $\epsilon > 0$  which specifies the strength of constraints; step size  $\rho_\theta, \rho_\lambda$  for  $\theta$  and  $\lambda$ .

**Output:**  $\theta$  (parameters for  $p_\theta(\mathbf{x}|\mathbf{z})$  and  $q_\theta(\mathbf{z}|\mathbf{x})$ ).

---

Initialize  $\theta$  randomly

Initialize the Lagrange multipliers  $\lambda := 1$

**if**  $\alpha_1, \alpha_2 > 0$  **then**

$$f(\theta) \leftarrow \alpha_1 \bar{I}_{q_\theta} + \alpha_2 \bar{I}_{p_\theta}$$

**else**

$$f(\theta) \leftarrow \alpha_1 \underline{I}_{q_\theta} + \alpha_2 \underline{I}_{p_\theta}$$

**end if**

**for**  $t = 0, 1, 2, \dots$  **do**

$$\theta \leftarrow \theta - \rho_\theta (\nabla_\theta f(\theta) + \lambda^\top \nabla_\theta \mathcal{D})$$

$$\lambda \leftarrow \lambda + \rho_\lambda (\mathcal{D} - \epsilon)$$

**end for**

---

### 5.3 DUAL OPTIMIZATION

Because the problem is convex in distribution space and satisfies Slater’s condition, the  $\theta^*$  that achieves the saddle point

$$\lambda^*, \theta^* = \arg \max_{\lambda \geq 0} \arg \min_\theta f(\theta) + \lambda^\top (\mathcal{D} - \epsilon) \quad (16)$$

is also a solution to the original optimization problem Eq.(8) (Boyd & Vandenberghe, 2004)(Chapter 5.4). In addition the max-min problem Eq.(16) is convex with respect to  $\theta$  and concave (linear) with respect to  $\lambda$ , so one can apply iterative gradient descent/ascent over  $\theta$  (minimize) and  $\lambda$  (maximize) and achieve stable convergence to saddle point (Holding & Lestas, 2014). We describe the iterative algorithm in Algorithm 1.

In practice, we do not optimize over distribution space and  $\{p_\theta(\mathbf{x}|\mathbf{z})\}, \{q_\theta(\mathbf{z}|\mathbf{x})\}$  are some highly complex and non-convex families of functions. We show in the experimental section that this scheme is stable and effective despite non-convexity.

## 6 LAGRANGIAN VAE

In this section we consider a particular instantiation of the general dual problem proposed in the previous section. Consider the following primal problem, with  $\alpha_1 \in \mathbb{R}$ :

$$\begin{aligned} \min_{\theta} \quad & \alpha_1 I_{q_\theta}(\mathbf{x}; \mathbf{z}) & (17) \\ \text{subject to} \quad & D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z})) \leq \epsilon_1 \\ & D_{\text{MMD}}(q_\theta(\mathbf{z}) \| p(\mathbf{z})) \leq \epsilon_2 \end{aligned}$$

For mutual information minimization / maximization, we respectively replace the (possibly non-convex) mutual information by upper bound  $\bar{I}_{q_\theta}$  if  $\alpha_1 \geq 0$  and lower bound

$\underline{I}_{q_\theta}$  if  $\alpha_1 < 0$ . The corresponding dual optimization problem can be written as:

$$\max_{\lambda \geq 0} \min_{\theta} \begin{cases} \alpha_1 \bar{I}_{q_\theta} + \lambda^\top (\mathcal{D}_{\text{InfoVAE}} - \epsilon), & \alpha_1 \geq 0 \\ \alpha_1 \underline{I}_{q_\theta} + \lambda^\top (\mathcal{D}_{\text{InfoVAE}} - \epsilon), & \alpha_1 < 0 \end{cases} \quad (18)$$

where  $\epsilon = [\epsilon_1, \epsilon_2]$ ,  $\lambda = [\lambda_1, \lambda_2]$  and

$$\begin{aligned} \mathcal{D}_{\text{InfoVAE}} &= [D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z})), \\ &D_{\text{MMD}}(q_\theta(\mathbf{z}) \| p(\mathbf{z}))] \end{aligned}$$

We call the objective in 18 Lagrangian (Info)VAE (LagVAE). Note that setting a constant  $\lambda$  for the dual function recovers the InfoVAE objective (Zhao et al., 2017). By Theorem 2 strong duality holds for this problem and finding the max-min saddle point of LagVAE in Eq.(18) is identical to finding the optimal solution to original problem of Eq.(17).

The final issue is choosing the  $\epsilon$  hyper-parameters so that the constraints are feasible. This is non-trivial since selecting  $\epsilon$  that describe feasible constraints depends on the task and model structure. We introduce a general strategy that is effective in all of our experiments. First we learn a parameter  $\theta^*$  that satisfies the consistency constraints “as well as possible” without considering mutual information maximization/minimization. Formally this is achieved by the following optimization (for any choice of  $\lambda > 0$ ),

$$\theta^* = \arg \min_{\theta} \lambda^\top \mathcal{D}_{\text{InfoVAE}} \quad (19)$$

This is the original training objective for InfoVAE with  $\alpha_1 = 0$  and can be optimized by

$$\begin{aligned} \min_{\theta} \lambda^\top \mathcal{D}_{\text{InfoVAE}} &= \lambda_1 D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z})) + \lambda_2 D_{\text{MMD}}(q_\theta(\mathbf{z}) \| p(\mathbf{z})) \\ &\equiv \lambda_1 \mathcal{L}_{\text{ELBO}}(\theta) + \lambda_2 D_{\text{MMD}}(q_\theta(\mathbf{z}) \| p(\mathbf{z})) \end{aligned} \quad (20)$$

where  $\mathcal{L}_{\text{ELBO}}(\theta)$  is the evidence lower bound defined in Eq.(4). Because we only need a rough estimate of how well consistency constraints can be satisfied, the selection of weighing  $\lambda_1$  and  $\lambda_2$  is unimportant. The recommendation in (Zhao et al., 2017) works well in all our experiments ( $\lambda_1 = 1, \lambda_2 = 100$ ).

Now we introduce a “slack” to specify how much we are willing to tolerate consistency error to achieve higher/lower mutual information. Formally, we define  $\hat{\epsilon}$  as the divergences  $\mathcal{D}_{\text{InfoVAE}}$  evaluated at the above  $\theta^*$ . Under this  $\hat{\epsilon}$  the following constraint must be feasible (because  $\theta^*$  is a solution):

$$\mathcal{D}_{\text{InfoVAE}} \leq \hat{\epsilon}$$

Now we can safely set  $\epsilon = \gamma + \hat{\epsilon}$ , where  $\gamma > 0$ , and the constraint

$$\mathcal{D}_{\text{InfoVAE}} \leq \epsilon$$

must still be feasible (and strictly feasible).  $\gamma$  has a very nice intuitive interpretation: it is the “slack” that we are willing to accept. Compared to tuning  $\alpha_1$  and  $\lambda$  for InfoVAE, tuning  $\gamma$  is much more interpretable: we can anticipate the final consistency error before training.

Another practical consideration is that the one of the constraints  $D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z}))$  is difficult to estimate. However, we have

$$D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z})) = -\mathcal{L}_{\text{ELBO}} - H_q(\mathbf{x})$$

where  $\mathcal{L}_{\text{ELBO}}$  is again, the evidence lower bound in Eq.(4) of Section 2, and  $H_q(\mathbf{x})$  is the entropy of the true distribution  $q(\mathbf{x})$ .  $\mathcal{L}_{\text{ELBO}}$  is empirically easy to estimate, and  $H_q(\mathbf{x})$  is a constant irrelevant to the optimization problem. The optimization problem is identical if we replacing the more difficult constraint  $D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z})) \leq \epsilon_1$  with the easier-to-optimize/estimate constraint  $-\mathcal{L}_{\text{ELBO}} \leq \epsilon'_1$  (where  $\epsilon'_1 = \epsilon_1 + H_q(\mathbf{x})$ ). In addition,  $\epsilon'_1$  can be selected by the technique in the previous paragraph.

## 7 EXPERIMENTS

We compare the performance of **LagVAE**, where we learn  $\lambda$  automatically, and **InfoVAE**, where we set  $\lambda$  in advance (as hyperparameters). Our primal problem is to find solutions that maximize / minimize mutual information under the consistency constraints. Therefore, we consider two performance metrics:

- $I_q(\mathbf{x}, \mathbf{z})$  the mutual information between  $\mathbf{x}$  and  $\mathbf{z}$ . We can estimate the mutual information via the identity:

$$I_q(\mathbf{x}; \mathbf{z}) = \mathbb{E}_{q_\theta(\mathbf{x}, \mathbf{z})} [\log q_\theta(\mathbf{z} | \mathbf{x}) - \log q_\theta(\mathbf{z})] \quad (21)$$

where we approximate  $q_\theta(\mathbf{z})$  with a kernel density estimator.

- the consistency divergences  $D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z}))$  and  $D_{\text{MMD}}(q_\theta(\mathbf{z}) \| p(\mathbf{z}))$ . As stated in Section 6, we replace  $D_{\text{KL}}(q_\theta(\mathbf{x}, \mathbf{z}) \| p_\theta(\mathbf{x}, \mathbf{z}))$  with the evidence lower bound  $\mathcal{L}_{\text{ELBO}}$ .

In the remainder of this section we demonstrate the following empirical observations:

- LagVAE reliably maximizes/minimizes mutual information without violating the consistency constraints. InfoVAE, on the other hand, makes unpredictable and task-specific trade-offs between mutual information and consistency.
- LagVAE is Pareto optimal, as no InfoVAE hyperparameter choice is able to achieve both better mutual information and better consistency (measured by  $D_{\text{MMD}}$  and  $\mathcal{L}_{\text{ELBO}}$ ) than LagVAE.

### 7.1 VERIFICATION OF DUAL OPTIMIZATION

We first verify that LagVAE reliably maximizes/minimizes mutual information subject to consistency constraints. We train LagVAE on MNIST according to Algorithm 1.  $\epsilon$  is selected according to Section 6, where we first compute  $\hat{\epsilon} = (\hat{\epsilon}_1, \hat{\epsilon}_2)$  without information maximization/minimization by Eq.(20). Next we choose slack variables  $\gamma = (\gamma_1, \gamma_2)$ , and set  $\epsilon = \hat{\epsilon} + \gamma$ . For  $\gamma_1$  we explore values from 0.1 to 4.0, and for  $\gamma_2$  we use the fixed value  $0.5\hat{\epsilon}_2$ .

The results are shown in Figure 1, where mutual information is estimated according to Eq.(21). For any given slack  $\gamma$ , setting  $\alpha_1$  to positive values and negative values respectively minimizes or maximizes the mutual information within the feasible set  $\mathcal{D} \leq \epsilon$ . In particular, the absolute value of  $\alpha_1$  does not affect the outcome, and only the sign matters. This is consistent with the expected behavior (Figure 1 Left) where the model finds the maximum/minimum mutual information solution within the feasible set.

### 7.2 VERIFICATION OF PARETO IMPROVEMENTS

In this section we verify Pareto optimality of LagVAE. We evaluate LagVAE and InfoVAE on the MNIST dataset with a wide variety of hyper-parameters. For LagVAE, we set  $\epsilon_1$  for  $\mathcal{L}_{\text{ELBO}}$  to be  $\{83, 84, \dots, 95\}$  and  $\epsilon_2$  for  $D_{\text{MMD}}$  to be 0.0005. For InfoVAE, we set  $\alpha \in \{1, -1\}$ ,  $\lambda_1 \in \{1, 2, 5, 10\}$  and  $\lambda_2 \in \{1000, 2000, 5000, 10000\}$ <sup>3</sup>.

Figure 2 plots the mutual information and  $\mathcal{L}_{\text{ELBO}}$  achieved by both methods. Each point is the outcome of one hyperparameter choice of LagVAE / InfoVAE. Regardless of the hyperparameter choice of both models, no InfoVAE hyperparameter lead to better performance on both mutual information and  $\mathcal{L}_{\text{ELBO}}$  on the training set. This is expected because LagVAE always finds the maximum/minimum mutual information solution out of all solutions with given consistency value. The same trend is true even on the test set, indicating that it is not an outcome of over-fitting.

## 8 CONCLUSION

Many existing objectives for latent variable generative modeling are Lagrangian dual functions of the same type of constrained optimization problem with fixed Lagrangian multipliers. This allows us to explore their statistical and computational trade-offs, and characterize all models in this class. Moreover, we propose a practical dual optimization method that optimizes both the Lagrange multipliers and the model parameters, allowing us to specify interpretable constraints and achieve Pareto-optimality empirically.

<sup>3</sup>Code for this set of experiments is available at <https://github.com/ermongroup/lagvae>

Figure 1: **Left:** Effect of  $\alpha_1$  and  $\gamma_1$  on the primal objective (mutual information). When  $\alpha_1$  is positive we minimize mutual information within the feasible set, and when  $\alpha_1$  is negative we maximize mutual information. When  $\alpha_1$  is zero the preference is undetermined, and mutual information varies depending on initialization. Note that mutual information does not depend on the absolute value of  $\alpha_1$  but only on its sign. **Right:** An illustration of this effect. Lagrangian dual optimization finds the maximum/minimum mutual information solution in the feasible set  $\mathcal{D} \leq \epsilon$ .

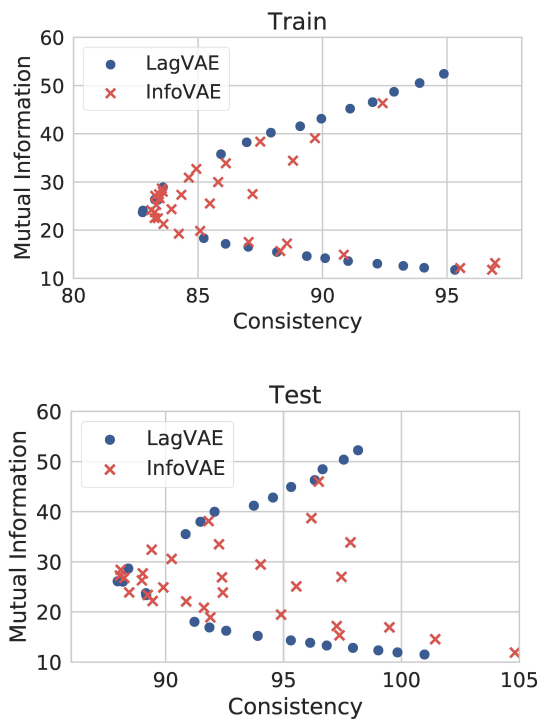

Figure 2: LagVAE Pareto dominates InfoVAE with respect to Mutual information and consistency ( $\mathcal{L}_{ELBO}$  values) on train (top) and test (bottom) set. Each point is the outcome of one hyper-parameter choice for LagVAE / InfoVAE. When we maximize mutual information ( $\alpha_1 < 0$ ), for any given  $\mathcal{L}_{ELBO}$  value, LagVAE always achieve similar or larger mutual information; when we minimize mutual information ( $\alpha_1 > 0$ ), for any given ELBO value, LagVAE always achieve similar or smaller mutual information.

In this work, we only considered Lagrangian (Info)VAE, but the method is generally applicable to other Lagrangian dual objectives. In addition we only considered mutual information preference. Exploring different preferences is a promising future directions.

## Abstract

Automatic design via Bayesian optimization holds great promise given the constant increase of available data across domains. However, it faces difficulties from high-dimensional, potentially discrete, search spaces. We propose to probabilistically embed inputs into a lower dimensional, continuous latent space, where we perform gradient-based optimization guided by a Gaussian process. Building on variational autoencoders, we use both labeled and unlabeled data to guide the encoding and increase its accuracy. In addition, we propose an adversarial extension to render the latent representation invariant with respect to specific design attributes, which allows us to transfer these attributes across structures. We apply the framework both to a functional-protein dataset and to perform optimization of drag coefficients directly over high-dimensional shapes without incorporating domain knowledge or handcrafted features.

## 1 INTRODUCTION

Developing enhanced designs is an overarching goal across engineering disciplines ranging from the optimization of planes in aeronautics (Simpson et al., 2001) and batteries for electric vehicles (Grover et al., 2018) to the development of proteins in bioengineering (Damborsky and Brezovsky, 2014). The different optimization efforts often face the same challenges in form of search-space complexity and costly design evaluations which render naive exhaustive search infeasible and make human-expert knowledge a key success factor. The ever increasing amounts of experimental data have to be considered, however, pose new challenges to manual analysis.

Increasing amounts of data open new opportunities for statistical design approaches. In this context Bayesian optimization has emerged as a data-driven tool for automated design optimization (Shahriari et al., 2016). Bayesian optimization is a model-based approach with a prescribed prior belief on the functional score of designs. Given data, we sequentially update this belief and optimize a surrogate function to our true objective. The choice of this surrogate function thereby trades exploration vs. exploitation in the design space.

By leveraging the problem structure, Bayesian optimization can be much more sample efficient than random search (Snoek et al., 2012b), but it is not immune to the curse of dimensionality. Signal is often sparse in high-dimensional input spaces of many real-world design problems. In addition, desirable target applications like drug or material design involve optimization over *discrete* structures, where even optimizing the model-based surrogate is difficult.

We target the input-space challenges of high-dimensionality and discrete designs by combining Bayesian optimization with deep generative modeling. Specifically, we built on the architecture by Gómez-Bombarelli et al. (2016a; 2016b) combining a variational autoencoder (VAE) and Gaussian process (GP) regression. VAEs (Kingma and Welling, 2013) are probabilistic models which map high-dimensional, possibly discrete inputs to a lower dimensional continuous space. The encoder consists of a neural network whose feature-construction ability is leveraged for dimensionality reduction. We learn a GP on top of the latent space as its predictions enjoy uncertainty estimates such that we can explore the design space based on a confidence measure. At the same time, the continuous space now allows us to use gradient-based methods for optimization.

In this work we make the following contributions: (i) We propose to use parametric label-guidance for the autoencoder and demonstrate how this results in increased

label-prediction accuracy for the datasets we consider. (ii) We present a corresponding graphical model and derive a variational lower bound on the marginal log-likelihood. The variational bound provides us with a principled way of incorporating unlabeled data in the joint training procedure. We show that incorporating unlabeled data results in enhanced reconstruction accuracy for our datasets. (iii) We perform Bayesian design optimization on two different domains: proteins and shapes in laminar flow. Having access to a physics simulator, we show the validity of the approach in the hydrodynamics setting. (iv) We propose an adversarial model extension to render the latent representation invariant with respect to specific, real-valued design attributes. To compensate for the loss of information, we provide these attributes as additional arguments to the decoder. This allows us to transfer attributes across designs when we generate a design from its latent representation.

## 2 PROBLEM SETUP

We consider the setting of a high-dimensional, possibly discrete input space of designs  $\mathcal{X}$ . Each design  $x$  is associated with a real-valued score  $y \in \mathbb{R}$  drawn from a conditional distribution  $p^*(y|x)$ .

Our goal is to find a design  $x \in \mathcal{X}$  that maximizes the expectation  $\mathbb{E}[y|x]$ . We are given access to an oracle providing a sample of  $y \sim p^*(\cdot|x)$ , however, we assume that obtaining a sample (evaluating  $y$  for a given design  $x$ ) is expensive. For example, it might require an expensive simulation or conducting a lab experiment.

Furthermore, we assume to have access to samples  $D_u = \{x_1, \dots, x_{N_u}\}$  from  $\mathcal{X}$ , and a (small) number of labeled examples  $D_\ell = \{(x_1, y_1), \dots, (x_{N_\ell}, y_{N_\ell})\}$ , where each pair  $(x, y)$  corresponds to a design and a measurement of its score. We assume that labeled and unlabeled examples are sampled from the same marginal distribution.

### 2.1 BAYESIAN OPTIMIZATION

Bayesian optimization is a data-driven tool to optimize expensive black-box functions. In this model-based approach we start with a prior belief on the functional relationship between inputs and outputs, and update it sequentially as new data is acquired. As actual function evaluations are expensive, we aim to optimize a surrogate or acquisition function instead. A popular choice of acquisition function is expected improvement (EI) (Jones et al., 1998) which strikes to balance exploration vs. exploitation in the search space. To calculate EI we require a prediction with uncertainty for the black-box function values. Gaussian processes (GPs) provide uncertainty quantification and as such they are a standard model in Bayesian

optimization. In the framework of GPs we assume that given a finite number of  $n$  inputs  $x_{1:n}$ , the function values  $f(x_{1:n})$  are jointly Gaussian and the observations  $y_{1:n}$  are normally distributed given  $f$  (Rasmussen and Williams, 2006). Because of the GP guidance, it can be more sample efficient than random search, however, Bayesian optimization still faces the challenges of data sparsity when operating in high dimensions. In addition, gradient-based optimization of the (EI) surrogate is not a priori applicable for discrete inputs. Finally, the benefit of uncertainty quantification comes at a price, as learning in the nonparametric GP model is cubic in the number of inputs. To circumvent this bottleneck, different sparse approximations have been developed. One approach to reduce the computational complexity is to calculate the covariance matrix with respect to  $m$  inducing points instead of  $n$  data points and typically  $m \ll n$  with complexity  $\mathcal{O}(m^2n)$  (Titsias, 2009; McIntire et al., 2016).

### 2.2 VARIATIONAL AUTOENCODERS

A variational autoencoder is a generative model defining a joint probability distribution between a latent variable  $z$  and inputs  $x$ . We commonly assume a simple Gaussian prior distribution  $p(z)$  and model the input data distribution as a more complex conditional distribution  $p_\Psi(x|z)$  where  $\Psi$  are the parameters of a neural network. Directly optimizing the marginal likelihood is intractable as it requires integration over the latent space. Kingma and Welling (2013) circumvent this obstacle by proposing an auxiliary inference distribution  $q_\Phi(z|x)$  and derive a variational lower bound on the log likelihood

$$\begin{aligned} \mathcal{L}_{\text{ELBO}} &= \mathbb{E}_{q_\Phi(z|x)} [\log p_\Psi(x|z)] - \text{D}_{\text{KL}}(q_\Phi(z|x) || p(z)) \\ &\leq \log p(x) \end{aligned} \tag{1}$$

Maximizing this objective can be naturally interpreted as minimizing the reconstruction loss of a probabilistic autoencoder and regularizing the posterior distribution towards the prior. Kingma et al. (2014) extend this work to the semi-supervised setting considering both labeled and unlabeled data.

## 3 BAYESIAN OPTIMIZATION AND A SHAPED LATENT SPACE

We address the optimization challenges of high dimensions and discrete spaces in Bayesian Optimization by combining Gaussian process regression with variational autoencoding. In addition, we further shape the latent space through adversarial training. By learning an invariant latent representation regarding input-specific attributes we are able to transfer these attributes across inputs.

We consider the directed graphical model of inputs  $x$ , corresponding labels  $y$  and latent variables  $z$  shown in Figure 1. Given  $z$ , we assume  $x$  and  $y$  to be independent:

$$p(x, y|z) = p_{\Psi}(x|z) p_{\Theta}(y|z). \quad (2)$$

The data distribution  $p_{\Psi}(x|z)$  is modeled as either multinomial (protein dataset) or multivariate normal with fixed covariance (shape dataset). The discriminative  $p_{\Theta}(y|z)$  is modeled as standard normal  $\mathcal{N}(\mu_{\theta}(z), 1)$ . Both distributions are parametrized through neural networks with parameters  $\Psi$  and  $\Theta$ .

Figure 1: Graphical model connecting input space  $x$  with latent variable  $z$  and label  $y$ . The model assumes conditional independence of  $x$  and  $y$  given  $z$ . The gray shading marks observed quantities.

### 3.1 SEMI-SUPERVISED LEARNING

Given labeled and unlabeled data  $D_{\ell}$  and  $D_u$ , respectively, we aim to optimize the likelihoods  $p(x, y)$  and  $p(x)$ . As in the case of the VAE this is intractable to compute due to integration over  $z$  and we instead resort to variational lower bounds.

Figure 2: Illustration of the parametrized distributions involved in the derivation of the variational lower bounds.

Introducing the auxiliary model  $q_{\Phi}(z|x)$  and using Jensen’s inequality, we derive a variational lower bound on the log-likelihood of labeled data  $(x, y)$ . The independence of the proposal distribution regarding  $y$  reflects the view that  $x$  contains all information on  $y$ . An illustration

of the parametrized distributions is shown in Figure 2.

$$\begin{aligned} \log p(x, y) &= \log \int p(x, y|z) p(z) dz \\ &= \log \int \frac{p(x, y|z)}{q_{\Phi}(z|x)} q_{\Phi}(z|x) p(z) dz \\ &= \log \mathbb{E}_{z \sim q_{\Phi}(z|x)} \left[ p(x, y|z) \frac{p(z)}{q_{\Phi}(z|x)} \right] \\ &\geq \mathbb{E}_{z \sim q_{\Phi}(z|x)} [\log p(x, y|z)] \\ &\quad - D_{\text{KL}}(q_{\Phi}(z|x) || p(z)) \\ &= \mathbb{E}_{z \sim q_{\Phi}(z|x)} [\log p_{\Psi}(x|z) + \log p_{\Theta}(y|z)] \\ &\quad - D_{\text{KL}}(q_{\Phi}(z|x) || p(z)) \\ &\equiv \mathcal{L}_{\ell} \end{aligned} \quad (3)$$

where  $D_{\text{KL}}$  indicates Kullback-Leibler divergence.

In contrast, we find in the case of unlabeled data

$$\begin{aligned} \log p(x) &= \log \int \int p(x, y|z) p(z) dz dy \\ &= \log \int \int q_{\Theta}(y|z) \frac{p(x, y|z)}{q_{\Theta}(y|z)} \\ &\quad q_{\Phi}(z|x) \frac{p(z)}{q_{\Phi}(z|x)} dz dy \\ &\geq \mathbb{E}_{z \sim q_{\Phi}(z|x)} [\log p_{\Psi}(x|z)] \\ &\quad - D_{\text{KL}}(q_{\Phi}(z|x) || p(z)) \\ &\equiv \mathcal{L}_u \end{aligned} \quad (4)$$

where we recover the ELBO objective of the VAE. Modeling the proposal distribution  $q_{\Phi}(z|x)$  as multivariate Gaussian and assuming a Gaussian prior  $p(z) = \mathcal{N}(0, I)$  results in an analytic expression for the divergence term. Together  $\mathcal{L}_u$  and  $\mathcal{L}_{\ell}$  form a joint lower bound in the semi-supervised setting. During training we optimize a weighted sum of the two bounds. Specifically, labeled and unlabeled data share the same encoder  $q_{\Phi}(z|x)$  and decoder  $p_{\Psi}(x|z)$ .

### 3.2 DESIGN OPTIMIZATION ON THE LATENT SPACE

After the designs are embedded in a lower dimensional continuous latent space we can now use a GP to perform Bayesian optimization. The algorithm for the joined procedure of latent embedding and following optimization is outlined in pseudocode in Algorithm 1.

For each  $(x_i, y_i)$  pair from the labeled set, we can compute the mean value of  $q_{\Phi}(z|x_i)$  that we denote  $z_i$ . This effectively embeds the labeled inputs from  $D_{\ell}$  in the lower-dimensional latent space. We can then fit a GP on

the set  $D'_\ell := \{(z_i, y_i)\}_{i \leq N_\ell}$ . Depending on the dataset size this is either a full GP or a sparse approximation with inducing points (Titsias, 2009). Subsequently we perform iterative optimization by sampling points from the latent prior  $p(z)$  and maximizing expected improvement via gradient ascent. Next, we generate new designs corresponding to the latent points with largest EI value using the decoder, leveraging the generative capability of a VAE. Finally we evaluate the black-box function for these designs. The new data is appended to our dataset and we continue ad libitum. For simplicity, we do not retrain the VAE with each dataset expansion.

---

**Algorithm 1** VAE-guided Bayesian Optimization

---

**Input:** Unlabeled data  $D_u$ , labeled data  $D_\ell = \{(x_i, y_i)\}_{i \leq N_\ell}$ , fitness function  $f$ , parameters  $\alpha, \beta, \kappa$ .

$y_{\max} \leftarrow \max_{i \leq N_\ell} y_i$

**TrainVAE:**

minimize $_{\Theta, \Phi, \Psi} \alpha \mathcal{L}_u(D_u) + \beta \mathcal{L}_\ell(D_\ell)$   
 $D'_\ell \leftarrow \{(z_i, y_i)\}_{i \leq N_\ell}$  with  $z_i$  mean of  $q_\Phi(\cdot|x_i)$

**loop:**

GP  $\leftarrow$  **FitGP** ( $D'_\ell; \kappa$ )

**parallel loop:**

sample  $z_i^0 \sim \mathcal{N}(0, I)$

$(z_i^*, f_i^*) \leftarrow \max_z \text{EI}(z, z_0 = z_i^0, y_{\max}, GP)$

$\hat{z} \leftarrow z_b$  with  $b \leftarrow \arg \max_i f_i^*$

$\hat{x} \leftarrow \text{decoder}_\Phi(\hat{z})$  ▷ Create design

$\hat{y} \leftarrow f(\hat{x})$  ▷ Evaluate design  $\hat{x}$

Add  $(\hat{x}, \hat{y})$  to  $D_\ell$  and  $(\hat{z}, \hat{y})$  to  $D'_\ell$

$y_{\max} \leftarrow \max\{y_{\max}, \hat{y}\}$

**return**  $D_\ell$

### 3.3 ADJUSTING ATTRIBUTES AT TIME OF DECODING

We consider a setting in which we have successfully used our Bayesian optimization framework to find an enhanced design  $x$  which we generated by decoding its corresponding latent representation  $z$ . In addition, let  $a$  be a real-valued attribute intrinsic to a given input design  $x$  which is uncorrelated to the functional score  $y$  of the design. Taking the case of car designs as an example,  $y$  could be a measure of the car’s aerodynamic properties and  $a$  reflect the car’s color.

The joint probability distribution  $p(a, x, y, z)$  factorizes as

$$p(a, x, y, z) = p_\Psi(x|z, a) p_\gamma(a|z) p_\Theta(y|z) p(z) \quad (5)$$

with the additional inference network  $p_\gamma(a|z)$  (Figure 3). We assume that the input design  $x$  and the attribute  $a$  are observed variables, and that the label  $y$  is sometimes observed (i.e. the semi-supervised setting).

The question we consider is whether we can transfer an attribute across designs, i.e., can we decode our optimized latent representation to designs which share the optimal score but differ with respect to the value of attribute  $a$ . Referring again to our example of car designs, the attribute adjustment would consist in changing a car’s color after finding an aerodynamically optimal design.

Our strategy to enable attribute adjustment is to enforce a latent representation which is invariant to  $a$ . If the latent space contains no information on the attribute, the decoder  $p_\Psi(x|z, a)$  is forced to learn how to impose  $a$  on  $z$  in order to achieve proper design reconstruction. We can then adjust attributes by decoding optimized latent points with an attribute value of our choice.

To enforce this invariance, we add adversarial training to the training objective. We formalize this in the following maxmin expression:

$$\max_{\Phi} \min_{\gamma} \mathbb{E}_{x \sim q(x)} \mathbb{E}_{z \sim q_\Phi(z|x)} \left[ (a(x) - \hat{a}_\gamma(z))^2 \right] \quad (6)$$

Here  $a$  is the attribute we want to be invariant to, and  $\hat{a}_\gamma$  is an estimator of  $a$  given the latent set  $z$ . The notation  $a(x)$  emphasizes the fact that every design  $x$  has an intrinsic attribute value  $a$ . We model  $p_\gamma(a|z)$  as Gaussian with fixed covariance and predict the mean using a neural network with parameters  $\gamma$ . If we assume that  $p_\gamma$  is expressive enough and the network trained such that it can take advantage of all information  $z$  has on  $a$ , then the objective minimizes the mutual information  $I(a; z)$  and  $p_\gamma$  is forced to settle on mean prediction. Note that this adversarial training objective does not depend on the observation of the label  $y$  and can thus leverage both labeled and unlabeled data.

Figure 3: The augmented architecture with adversarial network  $p_\gamma(a|z)$  mapping from latent space  $z$  to attribute  $a$ . Providing  $a$  as additional input to the decoder encourages an  $a$ -invariant latent representation.

## 4 DATASETS

We empirically evaluate the performance of our method on two datasets.

### 4.1 PROTEIN-FITNESS LANDSCAPE

Proteins are of paramount importance for biological systems and in industrial applications such as food processing or biomass conversion. As such the ability to design enhanced proteins is desirable. Proteins form both a high-dimensional as well as discrete design space as a protein is defined by an amino-acid sequence with alphabet size 20.

Protein optimization is especially challenging as (i) the number of target amino-acid sequences grows exponentially with the number of considered amino-acid mutations and (ii) only a very small fraction of all amino-acid sequences results in a functional protein (Keefe and Szostak, 2001).

We base our protein-optimization approach on a large fitness-landscape exploration study of the green fluorescent protein from *Aequorea victoria* (avGFP) (Sarkisyan et al., 2016). GFP is a widely used label-protein in fluorescence microscopy with a sequence of 237 amino acids. Our specific dataset consists of 51,715 different protein sequences  $D_\ell$  generated by random mutagenesis from the avGFP sequence and associated fluorescence values  $y$  as measured by fluorescence-activated cell sorting. On average each protein sequence contains 3.7 mutations compared to avGFP.

Amino acid sequences of the avGFP variants are encoded in a one-hot-style manner through a matrix of size  $20 \times 237$  – accounting for the 20 essential amino acids and the sequence length of avGFP. All entries of the columns are 0 except for one 1 encoding the amino acid at the specific sequence position.

### 4.2 DRAG IN LAMINAR FLUID FLOW

The second dataset consists of 5100 two-dimensional shapes  $x$  and scalar drag coefficients  $y$  associated with the resistance these shapes experience in a constant fluid flow. We consider the case of laminar flow around an object in two dimensions as it allows us to generate training and test data, and perform Bayesian optimization at relatively low computational cost.

We generate the dataset by numerically solving the Navier-Stokes equations (Lifshitz and Landau, 1959) which provide a theoretical description of fluid flow around objects. Figure 4 shows example simulations from the dataset generation. Generated shapes are resized to  $42 \times 56$  pixels

to reduce memory requirements. Further details on the hydrodynamics simulation can be found in the appendix.

Figure 4: Finite-element simulations of fluid flow around random shapes in two dimensions. The left wall defines the fluid inlet.

## 5 EXPERIMENTS

In a first set of experiments we investigate the effect label-guided encoding and training with additional unlabeled data have on inference and autoencoder reconstruction error. The second part is concerned with design optimization of proteins and shapes. Finally, we demonstrate how we can use invariant learning to adjust shape attributes, namely area, with little effect on the drag coefficient.

### 5.1 INFERENCE AND RECONSTRUCTION ERROR

We consider the effect of label-guided encoding and adding unlabeled data to the training on 1) inference of  $y$  and 2) autoencoder reconstruction error as defined through the first term in the ELBO objective for the test set.

Tables 1 and 2 summarize the results for the protein and shape dataset, respectively. Details on the model architectures can be found in the appendix.

In general, we notice the positive effect label-guided encoding has on test set prediction. Column ‘NN’ shows the relative prediction error when using  $p_\Theta(y|z)$  for inference. In absence of unlabeled data ( $N_U = 0$ ) we consider two settings whose corresponding values are separated by a backslash: i) training  $p_\Theta(y|z)$  and the autoencoder jointly (left value) and ii) training autoencoder and discriminative network sequentially (right value). We observe that the discriminative network guides the dimensionality reduction such that label-relevant information

Table 1: Protein dataset: Normalized test set prediction errors for different allocations of labeled ( $N_L$ ) and unlabeled ( $N_U$ ) training data. NN, GP-NN and GP-LAT describe the neural network parametrized by  $\Theta$  and GPs trained on the neural-network features and the latent space, respectively. REC describes relative reconstruction error for test set designs.

15k/15k	1.22	2.49	1.93	1.14
15k/0	1.31/1.57	2.58	2.18	1.64
5k/5k	1.18	2.62	1.89	1.90
5k/0	1.44/1.70	2.58	1.97	3.11

Table 2: Hydrodynamic dataset: Normalized test set prediction errors for different allocations of labeled ( $N_L$ ) and unlabeled ( $N_U$ ) training data. NN, GP-NN and GP-LAT describe the neural network parametrized by  $\Theta$  and GPs trained on the neural-network features and the latent space, respectively. REC describes relative reconstruction error for test set designs.

$N_L / N_U$	NN	GP-NN	GP-LAT	REC
2500/2000	<b>1.00</b>	1.41	1.02	<b>1.00</b>
2500/0	1.21/1.38	1.44	1.22	1.04
1500/2000	1.10	1.31	1.24	1.07
1500/0	1.19/1.41	1.19	1.07	1.17
500/2000	1.91	1.64	1.79	1.31
500/0	2.05/1.98	1.61	2.02	1.82

in the amino-acid sequence or shape is encoded with enhanced accuracy.

In addition, we also observe a positive effect of adding unlabeled data with respect to the reconstruction error (REC). The effect is more pronounced when less labeled data is available. Incorporating unlabeled data is also beneficial for NN prediction error in almost all cases.

In order to obtain uncertainty measures for the predictions we train and compare two GP models with squared-exponential kernel. Model 1 is trained on the latent-space embedding of the training data (GP-LAT). Model 2 is trained on the features learned by the discriminative neural network  $p_{\Theta}(y|z)$  (GP-NN). Both models consider the situation in which  $p_{\Theta}(y|z)$  and the autoencoder have previously been trained jointly.

We account for dimension-specific length scales in the covariance function such that the Gaussian process can filter irrelevant dimensions. For the protein dataset we use a sparse approximation with 500 inducing points such

that the prediction performance of both GP models is impaired compared to the neural network (NN columns in the Tables). Comparing the GPs among each other we note the in general much better performance of the GP trained on the latent-space coordinates.

## 5.2 OPTIMIZATION OF PROTEIN AND SHAPE DESIGNS

We follow the algorithm outlined in Algorithm 1 to optimize shape and protein designs.

### 5.2.1 Design of New Protein Variants

A schematic of the optimization framework is shown in Figure 5A. To find the best local EI maxima we independently sample 20,000 start points from the prior  $p(z) \sim \mathcal{N}(0, I)$  and perform gradient ascent for each point. Figure 5B visualizes amino-acid mutation sites apparent in the highest-ranked protein variants on the structure of avGFP.

While only experimental verification can provide a precise assessment of the model performance, comparison with the data from literature on development of GFP variants shows that genotypes predicted by our model are free from known deleterious mutations such as mutations in the chromophore-forming amino acids and catalytically active E222 residue (Chudakov et al., 2010). Most of the mutated amino acid side chains in predicted genotypes are oriented towards the solvent in the protein beta barrel structure, in accordance with experimental observations (Sarkisyan et al., 2016) and with the evolutionary conservation of internally oriented residues (Chudakov et al., 2010). Moreover, some predicted genotypes carry combinations of substitutions known to increase brightness of avGFP, such as the F99S/M153T pair of substitutions that in combination with mutation V163A was reported to result in avGFP being 42 times brighter when expressed *in vivo* (Battistutta et al., 2000).

### 5.2.2 Design of Drag-reduced Shapes

The time and resources required for protein synthesis and functional testing render it expensive to use this application for several rounds of Bayesian optimization given the purpose of this paper and to explore technical model aspects in more detail. For this reason we use a set of two-dimensional shapes and the drag these shapes face under laminar flow conditions. We can calculate the drag forces based on the Navier-Stokes equations in a physics simulation. As such we can perform closed-loop optimization with the goal of finding drag-reduced shapes.

Figure 6 shows a schematic of the optimization procedure which is analogous to the protein case. We generate

Figure 5: (A) Schematic illustrating the optimization of amino-acid sequences to generate variants of the green fluorescent protein (GFP) with enhanced brightness. (B) The structure of GFP annotated with the distribution of mutations among 100 sequences suggested by the design algorithm. The main chromophore complex is shown in green.

new object shapes by optimizing EI with respect to the smallest drag coefficient in our training set. Promising latent points are decoded to shape images and their drag coefficients evaluated in our hydrodynamics simulator.

Figure 6: Schematic of the Bayesian optimization procedure to design drag-reduced shapes.

To illustrate the benefits of the joint autoencoder-GP framework we compare three different strategies for Bayesian optimization. In the first setting, we sample random points from the Gaussian prior distribution  $p(z)$  and for each point optimize EI via gradient ascent. We contrast this with optimization working directly at the level of shapes. Inputs are random shapes generated in the same way as our training dataset. We consider training the GP directly on the input space ( $GP(x)$ ) as well as including the intermediary mapping of the encoder ( $GP(z(x))$ ). To be able to optimize EI via gradient ascent we relax the assumption of binary pixel values to continuous values in  $[0, 1]$ .

Figure 7 shows the best drag coefficient generated as a function of shape evaluations for the three strategies. In

all cases we sample 600 starting points for gradient ascent and evaluate the resulting 100 shapes corresponding to the largest EI values in our simulator. All models share the same GP kernel function (squared-exponential), optimization parameters and stopping criteria.

Optimizing the acquisition function over the latent space consistently yields the largest reduction in drag coefficient for all rounds of Bayesian optimization. Optimizing the acquisition function over shapes does not improve upon directly simulating the drag coefficient for the random shapes which are chosen as gradient-ascent start points. The GP kernel is unable to extract drag-relevant features from the pixel input. As a consequence of the high-dimensionality of the pixel space, mean predictions for unknown shapes are close to the Gaussian prior and the EI gradient vanishes. We can recover part of the performance by using the ‘deep kernel’ of the encoder while still optimizing directly on shape images. We reason that the remaining performance gap is due to the relaxation of continuous pixel values.

Another advantage of the latent-space optimization consists in the fact that we can generate gradient-ascent starting points by simply sampling from  $z \sim \mathcal{N}(0, I)$ . In contrast, optimization on the input space requires us to have access to new valid structures, i.e. shapes, as naive sampling in the  $[0, 1]^{42 \times 56}$  pixel space breaks the optimization routine as expected.

Figure 8 shows examples of drag-reduced shapes over the course of 500 calls to the hydrodynamics simulator during optimization.

Figure 7: Best relative drag coefficient as a function of number of shape evaluations. The plot compares optimization based on random shapes (x) versus latent points (z). Error bars indicate standard deviation from three independent experiments.

Figure 8: The Bayesian optimization routine produces shapes of reduced drag ( $< 1$ ) compared to the smallest drag coefficient in the training set ( $= 1$ ). Shape inputs to the hydrodynamic simulator (top) and corresponding flow fields (bottom).

### 5.3 ATTRIBUTE ADJUSTMENT ACROSS SHAPES

Given a set of shape designs with a real-valued attribute  $a$  our goal is for the decoder to learn how to generate a design with a given attribute value based on a latent coordinate  $z$ .

We consider two scalar attributes for our shape dataset: color and surface area. To introduce ‘color’ we create a separate channel for each shape which contains the binary mask multiplied by a random number from  $[0, 1]$ . During training we provide the true attribute value for each shape to the adversarial network and decoder. To make the learning more stable we slowly fade in the adversarial loss over half the number of maximal training epochs. Early stopping is only considered after this point.

At test time we take a given latent point and feed it along with a desired attribute value from the aforementioned range to the decoder. Figure 9 shows five example shapes decoded each with four different attribute values  $[0.2, 0.4, 0.6, 0.8]$  resulting in a specific black-white intensity.

Adjusting color is a relatively easy task as the additionally introduced color channel is entirely orthogonal to the drag coefficient - the quantity our discriminative model  $p_{\Theta}(y|z)$  promotes to be accurately encoded in the latent space. For this reason we consider the area of a shape as another more challenging attribute value to control for. Invariance to shape size requires the architecture to apply a non-trivial geometric transformation or to learn and store the shape information in the latent space in a more abstract way, e.g. through scale-invariant Fourier descriptors.

Figure 10 shows a selection of five latent points and their associated drag coefficients decoded with four different area values in analogy to the color-adjustment example.

Figure 9: Shapes generated from five exemplary latent points  $z_1 \dots z_5$  and four different color-attribute values each.

The shapes are not cherry-picked. It is difficult to name an exact drag coefficient for the very small shapes due to the necessary shape rescaling, smoothing and boundary point extraction before any finite-element simulation can be performed. The simulations indicate that the drag coefficient of the scaled shapes stay within 25% of their original values with the largest deviations occurring at the smallest scale. At the same time area values change consistently for all shapes by about 300% (compare Table 3). The consistency of the scaling is remarkable as less than 4.5% of training shapes have an area smaller or larger than 67 and 175 pixels, respectively.

Figure 10: Shapes generated from five exemplary latent points  $z_1 \dots z_5$  and four different area-attribute values each.

## 6 RELATED WORK

Our approach draws on a broad basis of prior work and is generally related to conditional VAEs (Kingma et al., 2014) and hybrid models bridging generative and discrim-

Table 3: Pixel areas corresponding to shapes generated from latent points  $z_1 \dots z_5$  and four different area-attribute values each (compare Figure 10)

$z_1$	$z_2$	$z_3$	$z_4$	$z_5$
60	67	64	64	64
91	91	90	89	89
149	143	149	152	152
174	175	176	177	177

inative architectures (Maaløe et al., 2016; Shu et al., 2016; Kuleshov and Ermon, 2017). In contrast to the conditional VAE, we choose a label-independent encoder distribution stressing the perspective on the latent space as continuous embedding of inputs  $\mathcal{X}$ .

Using neural-network learned features as input to a GP model in the context of autoencoders dates back to Bengio et al. (2007). More recently, Snoek et al. (2012a) proposed non-parametric autoencoder guidance. Wilson et al. (2016a) present deep-kernel learning in which a stacked architecture of neural network and GP is trained jointly. Wilson et al. (2016b) and Huang et al. (2015) target the scalability of these hybrid GP models. Successful optimization within our framework depends on the ability to encode high-dimensional designs in a continuous latent space of lower dimensionality. This assumption is similar to the notion of low effective dimensionality in Wang et al. (2013) and related to Garnett et al. (2014). We considered joint training of GP and autoencoder in the case of the hydrodynamic dataset (5.2.2) but did not find this to outperform the sequential setting in which we train the GP on the latent space after parametric label guidance.

The idea of attribute adjustment draws on learning of fair representations, notably the fair VAE (Louizos et al., 2015). Purushotham et al. (2016) and recently Lample et al. (2017) explore enforcing invariance for adaptation in time-series data and natural images. We propose an adversarial objective based on mean-squared error maximization and demonstrate that attribute adjustment is feasible concurrent with Bayesian optimization.

GPs have been used for protein design and shape optimization - the two domains considered in our datasets. Romero et al. (2013) demonstrated the application of GPs to navigate the fitness landscape of proteins given limited data. The GP model is directly trained on amino acid sequences through a kernel function which relates sequence similarity to the spatial distance of amino acid positions in the folded protein structure. Previous works demonstrating the successful application of GP regression for the optimization of parametric designs in aerodynamic applications include (Simpson et al., 2001; Martin and

Simpson, 2005; Jeong et al., 2005; Jouhaud et al., 2007). The aforementioned publications leverage domain knowledge for optimization. In contrast, the approach presented here is solely data-driven and based on deep-generative models.

## 7 DISCUSSION

Bayesian optimization is a data-efficient approach to optimize complex black-box functions without the need to supply gradients. Nevertheless discrete, high-dimensional input spaces pose a challenge to successful design optimization.

In this work we explore a framework combining variational autoencoding and Gaussian process regression to approach this challenge. We present a variational bound for the underlying graphical model and show how label-guidance enhances the predictive performance and incorporating unlabeled data leads to an increase in reconstruction accuracy.

We apply the optimization framework to the design of enhanced functional proteins. One round of Bayesian optimization proposes meaningful new protein variants which are free of known deleterious mutations. We further introduce a physics-based dataset of two-dimensional shapes and associated drag coefficients in laminar flow. Having access to a simulator allows us to perform closed-loop Bayesian optimization, such that after five rounds we improve by about 30% on the best value in the training set. We demonstrate that optimization based in the latent space outperforms optimization in the design space.

Finally, we consider an adversarial extension to our model. By forcing the latent space to be invariant w.r.t. an attribute value of choice, we are able to select this attribute value when decoding a latent point and impose it on our design. The combination of label-guidance and attribute-adversarial training shapes the information encoded in the latent space. We envision that the adversarial-model extension might be a fruitful approach to transfer functional groups or domains across molecules. In addition, the performance of discriminative models trained on the latent space could benefit when uninformative factors of variation are removed from the latent code based on domain knowledge.

## Abstract

We introduce a new decomposition method for bounding the maximum expected utility of influence diagrams. While most current schemes use reductions to the Marginal Map task over a Bayesian Network, our approach is direct, aiming to avoid the large explosion in the model size that often results by such reductions. In this paper, we extend to influence diagrams the principles of decomposition methods that were applied earlier to probabilistic inference, utilizing an algebraic framework called valuation algebra which effectively captures both multiplicative and additive local structures present in influence diagrams. Empirical evaluation on four benchmarks demonstrates the effectiveness of our approach compared to reduction-based approaches and illustrates significant improvements in the upper bounds on maximum expected utility.

## 1 INTRODUCTION

An influence diagram (ID) [Howard and Matheson, 2005] is a graphical model for sequential decision-making under uncertainty that compactly captures the local structure of the conditional independence of probability functions and the additivity of utility functions. Its structure is captured by a directed acyclic graph (DAG) over nodes representing the variables (decision and chance variables). The standard query on an ID is finding the maximum expected utility (MEU) and an optimal policy, at each decision subject to the history of observations and decisions. Our focus is on computing an upper bound on the MEU in a single agent sequential decision-making scenario when we assume perfect recall. The computation of upper bounds is desirable not only because exact computation is exponential in the number of variables appearing

in the history, but also because it can be used as a building block of algorithmic frameworks such as heuristic search and sampling.

**Earlier work.** One early work that yields bounds on many inference tasks in an anytime manner is the minbucket elimination (MBE) scheme that provides upper and lower bounds of graphical model queries by enforcing problem decomposition during the variable elimination process [Dechter and Rish, 2003]. In particular, Dechter [2000] presented an MBE algorithm for influence diagrams. A different principle for generating bounds on the MEU is to relax the constraints imposed on the information available at each stage and for each decision (thus making more observations visible to each decision). This *information relaxation scheme* relaxes the constraints imposed on the information available at each stage and it also permits variable reordering during processing [Nilsson and Hohle, 2001]. In particular, Yuan et al. [2010] presented an AND/OR depth-first branch and bound search algorithm guided by upper bounds generated by such flexible variable orderings.

An alternative set of schemes exploit translations between the maximum a posteriori inference (MMAP) in a Bayesian network (BN) and the MEU inference in an ID [Mauá, 2016]. The idea is to compute the upper bound of the MMAP of the BN translated from an input ID. However, the number of auxiliary variables introduced by the translation is exponential in the size of the history under the perfect recall assumption. If all utility functions were multiplicative, an ID could be treated as an unnormalized distribution and MMAP inference would be applied directly. Liu and Ihler [2012] presented a variational formulation for computing the MEU and message passing algorithms for such IDs where the additive utilities are converted into multiplicative utilities by introducing a latent selector variable. However, such a translation can make it difficult to exploit decompositions present in the additive utility functions.

**Contributions.** We develop a decomposition scheme applied directly to IDs. It extends the decomposition scheme for MMAP [Ping et al., 2015] to IDs to accommodate multiplicative and additive terms. In particular, the upper bound is generated by relaxing the sequential structure of an ID to locally coupled decision subproblems. Subsequently, we present a message passing algorithm derived from the optimization framework that tightens the upper bound over various parameters including the reparameterization of both probability and utility functions. In summary:

- We present a new graphical model decomposition bound specialized for IDs called join graph decomposition bounds for IDs (JGDID), and a message passing algorithm that optimizes the bound.
- The proposed algorithm is compared empirically with current schemes on four benchmarks, showing a significant improvement in the quality of the upper bounds.

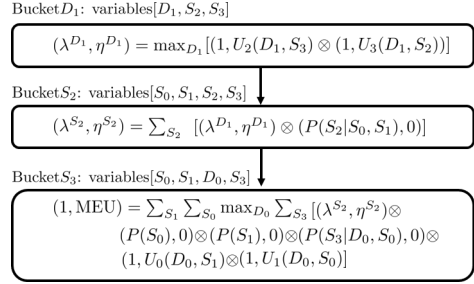

## 2 PRELIMINARIES

### 2.1 INFLUENCE DIAGRAMS

An ID is a tuple  $\mathcal{M} := \langle \mathbf{C}, \mathbf{D}, \mathbf{P}, \mathbf{U}, \mathcal{O} \rangle$  of a set of discrete random variables  $\mathbf{C} = \{C_i | i \in \mathcal{I}_{\mathbf{C}}\}$ , a set of discrete decision variables  $\mathbf{D} = \{D_i | i \in \mathcal{I}_{\mathbf{D}}\}$ , a set of conditional probability functions  $\mathbf{P} = \{P_i | P_i \in \mathcal{I}_{\mathbf{P}}\}$ , and a set of real-valued additive utility functions  $\mathbf{U} = \{U_i | U_i \in \mathcal{I}_{\mathbf{U}}\}$ . We use  $\mathcal{I}_{\mathbf{S}} = \{0, 1, \dots, |\mathbf{S}| - 1\}$  to denote the set of indices of each element in a set  $\mathbf{S}$ , where  $|\mathbf{S}|$  is the cardinality of  $\mathbf{S}$ . As illustrated in Figure 1(a), an ID can be associated with a DAG of three types of nodes: the chance nodes  $\mathbf{C}$  drawn as circles, the decision nodes  $\mathbf{D}$  drawn as squares, and the value nodes  $\mathbf{U}$  drawn as diamonds. There are also three types of directed edges: edges directed into a chance node  $C_i$  from its parents  $pa(C_i) \subset \mathbf{C} \cup \mathbf{D}$  representing the conditional probability function  $P_i(C_i | pa(C_i))$ , edges directed into a value node  $U_i$  denoting the utility function  $U_i(\mathbf{X}_i)$  from its scope  $\mathbf{X}_i \subset \mathbf{C} \cup \mathbf{D}$ , and informational arcs (dashed arrows in Figure 1(a)) directed from chance nodes to a decision node. The set of parent nodes associated with a decision node  $D_i$  is called the information set  $I_i$ , and denotes chance nodes that are assumed to be observed immediately before making decision  $D_i$ . The constrained variable ordering  $\mathcal{O}$  obeys a partial ordering which alternates between information sets and decision variables  $\{\mathbf{I}_0 < D_0 < \dots < \mathbf{I}_{|\mathbf{D}|-1} < D_{|\mathbf{D}|-1} < \mathbf{I}_{|\mathbf{D}|}\}$ . The partial elimination ordering should ensure the regularity of the ID (a decision can only be preceded by at most one decision), and dictates the available information at each decision  $D_i$  so that the *non-forgetting agent* makes decisions in multi-staged manner based on the history available at each stage

(a) Factored MDP as Influence Diagram

(b) Computing Maximum Expected Utility

Figure 1: Influence Diagram Example. A 2-step factored MDP is represented by an influence diagram, and the lower figure shows a schematic trace of the variable elimination with the valuation algebra.

$i$ ,  $H(D_i) := \cup_{k=0}^i \{D_k\} \cup \cup_{k=0}^i \mathbf{I}_k$ . The standard task of solving Influence Diagrams is computing the maximum expected utility  $E[\sum_{U_i \in \mathbf{U}} U_i | \Delta]$  and finding a set of optimal policies  $\Delta = \{\Delta_i | \Delta_i : R(D_i) \mapsto D_i, \forall D_i \in \mathbf{D}\}$ , where  $\Delta_i$  is a deterministic decision rule for  $D_i$  and  $R(D_i) \subseteq H(D_i)$  is the subset of history called  *requisite information* to  $D_i$ , namely, the only relevant history for making a decision [Nielsen and Jensen, 1999].

### 2.2 COMPUTING EXPECTED UTILITY

Unlike probabilistic graphical models, Influence Diagrams hold two type of functions combined by different operators: a product of probability functions, and a summation of utility functions. Jensen et al. [1994] presented a variable elimination algorithm that avoids the complication of dealing with two types of functions by generalizing the combination and marginalization operators such that operators act on a pair of probability and utility functions called a potential. The *valuation algebra* is an algebraic framework for computing the expected utility values, or values for short, based on the combination and marginalization on potentials [Mauá et al., 2012]. Here, we briefly summarize the essence of valuation algebra since it is what we use for developing the decomposition scheme. Let a valuation  $\Psi(\mathbf{X})$  be a pair of probability and value functions  $(P(\mathbf{X}), V(\mathbf{X}))$  over a set of variables  $\mathbf{X}$  called its scope. Occasionally, we will abuse the notation by dropping the scope from a function, e.g., writing  $P_1(\mathbf{X}_1)$  as  $P_1$ . The combination and marginalization operators

are defined as follows.

**Definition 1. (combination of two valuations)**

Given two valuations  $\Psi_1(\mathbf{X}_1) := (P_1(\mathbf{X}_1), V_1(\mathbf{X}_1))$  and  $\Psi_2(\mathbf{X}_2) := (P_2(\mathbf{X}_2), V_2(\mathbf{X}_2))$ , the combination of the two valuations over  $\mathbf{X}_1 \cup \mathbf{X}_2$  is defined by

$$\Psi_1(\mathbf{X}_1) \otimes \Psi_2(\mathbf{X}_2) := (P_1 P_2, P_1 V_2 + P_2 V_1).$$

Following Definition 1, the identity is  $(1, 0)$  and the inverse of  $(P(\mathbf{X}), V(\mathbf{X}))$  is  $(1/P(\mathbf{X}), -V(\mathbf{X})/P^2(\mathbf{X}))$ .

**Definition 2. (marginalization of a valuation)** Given a valuation  $\Psi(\mathbf{X}) := (P(\mathbf{X}), V(\mathbf{X}))$ , marginalizing over  $\mathbf{Y} \subseteq \mathbf{X}$  by summation or maximization are defined by

$$\sum_{\mathbf{Y}} \Psi(\mathbf{X}) := \left( \sum_{\mathbf{Y}} P(\mathbf{X}), \sum_{\mathbf{Y}} V(\mathbf{X}) \right),$$

$$\max_{\mathbf{Y}} \Psi(\mathbf{X}) := \left( \max_{\mathbf{Y}} P(\mathbf{X}), \max_{\mathbf{Y}} V(\mathbf{X}) \right).$$

An ID  $\mathcal{M}$  can be compactly represented by the valuation algebra as  $\mathcal{M}' := \langle \mathbf{X}, \Psi, \mathcal{O} \rangle$ , where  $\mathbf{X} = \mathbf{C} \cup \mathbf{D}$  and  $\Psi = \{(P_i, 0) | P_i \in \mathbf{P}\} \cup \{(1, U_i) | U_i \in \mathbf{U}\}$ . The MEU can be written as

$$\sum_{\mathbf{I}_0} \max_{D_0} \cdots \sum_{\mathbf{I}_{|\mathbf{D}|-1}} \max_{D_{|\mathbf{D}|-1}} \sum_{\mathbf{I}_{|\mathbf{D}|}} \bigotimes_{\alpha \in \mathcal{I}_\Psi} \Psi_\alpha(\mathbf{X}_\alpha), \quad (1)$$

where  $\mathbf{X}_\alpha$  denotes the scope of  $\Psi_\alpha$ .

The following example illustrates the variable elimination algorithm with the valuation algebra.

**Example 1.** Figure 1(b) shows a schematic trace of the variable elimination algorithm [Dechter, 1999] using the valuation algebra. We use  $\mathcal{O} : \{D_1, S_2, S_3, D_0, S_0, S_1\}$  as a legal elimination ordering. The first eliminated variable is  $D_1$ , so the variable elimination algorithm collects all valuations whose scope includes  $D_1$  in Bucket  $D_1$ . Then it generates the outgoing message  $(\lambda^{D_1}, \eta^{D_1})$  and sends it to Bucket  $S_2$ . Bucket  $S_2$  combines the preallocated valuations and the incoming message, and generates the outgoing message  $(\lambda^{S_2}, \eta^{S_2})$ . This elimination process continues until we obtain the MEU. We refer to Mauá et al. [2012] for more details.

### 2.3 JOIN GRAPH DECOMPOSITION

A probabilistic graphical model  $\mathcal{G} := \langle \mathbf{X}, \mathbf{F} \rangle$  is a tuple of a set of discrete variables  $\mathbf{X}$  and a set of non-negative real valued functions  $\mathbf{F} = \{F_\alpha(\mathbf{X}_\alpha) | \alpha \in \mathcal{I}_\mathbf{F}\}$ , where  $\mathbf{X}_\alpha \subset \mathbf{X}$  is the scope of  $F_\alpha$ . Graphical model inference tasks can be viewed as eliminating a set of variables from the joint function by either summation or maximization. The MMAP task computes the mode of the marginal of the joint function by

$$\max_{\mathbf{X}_M} \sum_{\mathbf{X}_S} \prod_{\alpha \in \mathcal{I}_\mathbf{F}} F_\alpha(\mathbf{X}_\alpha), \quad (2)$$

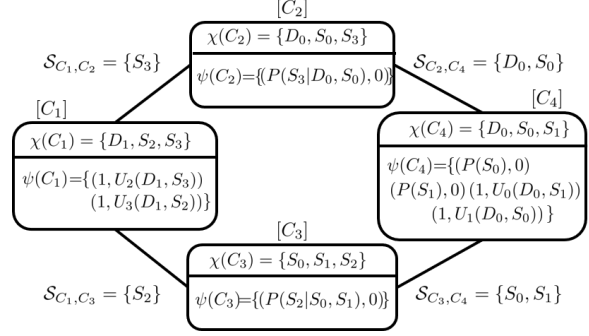

Figure 2: Join Graph Decomposition Example. Figure shows a join graph of the influence diagram in Figure 1(a). The join graph is generated by limiting the maximum cluster size from 4 to 3. The scope from a node labeling function  $\chi(C_i)$  is shown inside each node  $C_i$  and functions (valuations) are also allocated by  $\psi(C_i)$ . Separators  $S_{C_i, C_j}$  are shown next to edge  $(C_i, C_j)$ .

where  $\mathbf{X}_M$  denotes the maximization variables and  $\mathbf{X}_S$  denotes the summation variables. The relevance relation between variables is captured by an undirected graph  $\mathcal{G}_p = (V, E)$  called primal graph, where the set of nodes  $V$  represents variables, and an edge  $e \in E$  connects two nodes if both variables associated with those nodes appear in the scope of some function. A tree decomposition of  $\mathcal{G}_p$  produces a tree of clusters that captures the underlying structure of non-serial dynamic programming subject to the sequence of variable elimination operations. Namely, each cluster collects a set of functions that should be processed together. The worst-case space and time complexity of an inference query is exponential in the maximum cluster size called induced width  $w$  of  $\mathcal{G}_p$ .

Join graph decomposition [Mateescu et al., 2010] is an approximation scheme that further decomposes clusters in a join tree into a possibly loopy graph of finer grained clusters and, hence, it can control the complexity by limiting the maximum number of variables that are allowed to appear in cluster nodes.

**Definition 3. (join graph decomposition)** A join graph decomposition of a graphical model  $\mathcal{G}$  is a tuple  $\mathcal{D} := \langle \mathcal{G}_J, \chi, \psi \rangle$ , where  $\mathcal{G}_J = (\mathcal{C}, \mathcal{S})$  is a graph with nodes  $\mathcal{C}$  and edges  $\mathcal{S}$ , and  $\chi$  and  $\psi$  are labeling function that  $\chi$  maps a node  $C \in \mathcal{C}$  to a set of variables  $\chi(C_i) = \mathbf{X}_C$ , and  $\psi$  allocates each function  $F_\alpha$  exclusively to a node  $C \in \mathcal{C}$  such that  $\mathbf{X}_\alpha \subseteq \mathbf{X}_C$ . An edge  $(C_i, C_j) \in \mathcal{S}$  is associated with a subset of variables shared between the two clusters  $\chi(C_i) \cap \chi(C_j)$ , called separator  $S_{C_i, C_j}$ . The labeling function should ensure the running intersection property; for each variable  $X_i \in \mathbf{X}$ , the set  $\{C \in \mathcal{C} | X_i \in \psi(C)\}$  induces a connect subgraph.

A valid join graph can be systematically structured from a mini bucket tree produced by the MBE algorithm with the bounding parameter  $i$ -bound that controls the maximum

cluster size [Dechter and Rish, 2003]. The following example illustrates a join graph decomposition of the ID shown in Figure 1(a).

**Example 2.** Figure 2 shows a join graph decomposition  $\mathcal{D} : \langle \mathcal{G}_J, \chi, \psi \rangle$  of the ID in Figure 1(a). The primal  $\mathcal{G}_p$  of an ID can be obtained by removing all informational arcs before moralization and then removing the value nodes. From the  $\mathcal{G}_p$  and a legal variable elimination ordering compatible with the MEU query, a join graph  $\mathcal{G}_J$  can be generated by standard methods. The labeling functions  $\chi$  and  $\psi$  are displayed inside nodes and separators  $\mathcal{S}_{C_i, C_j}$  are displayed next to edges. Compared with the join tree shown in Figure 1(b), we see that the additional cluster node  $C_2$  contains a function  $P(S_3|D_0, S_0)$  that was included in Bucket  $S_3$  in the join tree.

## 2.4 DECOMPOSITION BOUNDS

Decomposition methods for bounding graphical model inference queries are based on two techniques. Namely, the graphical model decomposition with some auxiliary parameters and the optimization procedure that optimizes the parameters to improve the bound. For example, dual decomposition for MAP optimizes the dual variables, corresponding to Lagrange multipliers enforcing a set of local consistency constraints defined on the factor graph [Sontag et al., 2011]. Various decomposition bounds are available in the literature depending on decomposition schemes, methods of parameterization, and optimization frameworks. The common characteristic of such decomposition bounds is that they decompose the original graphical model to a relaxed lower complexity model, compute the global bound from decomposed local bounds and optimize the bound by additional local computations.

We review the generalized dual decomposition (GDD) bound for MMAP [Ping et al., 2015] that our bounding scheme is built upon. First, define a powered-sum elimination operator  $\sum_X^w$  by

$$\sum_X^w f(X) = [\sum_X |f(X)|^{1/w}]^w, \quad (3)$$

which generalizes maximization and summation with a weight  $0 \leq w \leq 1$  for the variable  $X$ . Note that the powered-sum elimination operator reduces to maximization and summation when  $w \rightarrow 0$  and  $w=1$ , respectively. Given a graphical model  $\mathcal{G} : \langle \mathbf{X}, \mathbf{F} \rangle$ , the MMAP task in Eq. (2) can be expressed by the powered-sum elimination operator as,

$$\sum_{\mathbf{X}}^w \prod_{\alpha \in \mathcal{I}_{\mathbf{F}}} F_{\alpha}(\mathbf{X}_{\alpha}), \quad (4)$$

where each weight  $w_i \in \mathbf{w}$  of a variable  $X_i \in \mathbf{X}$  is assigned 0 for the maximization variables and 1 for the summation variables. The bounding scheme of GDD is based on the generalization of the Hölder's inequality,

$$\sum_{\mathbf{X}}^w \prod_{\alpha \in \mathcal{I}_{\mathbf{F}}} F_{\alpha}(\mathbf{X}_{\alpha}) \leq \prod_{\alpha \in \mathcal{I}_{\mathbf{F}}} \sum_{\mathbf{X}_{\alpha}}^{w_{\alpha}} F_{\alpha}(\mathbf{X}_{\alpha}), \quad (5)$$

where  $\mathcal{I}_{\mathbf{F}}$  is the index set of functions  $\mathbf{F}$ ,  $\mathbf{w}$  is the set of weights that are either 0 or 1,  $w^{\alpha}$  is the set of non-negative weights distributed to  $\mathbf{X}_{\alpha}$  such that  $w_i = \sum_{\alpha \in \mathcal{I}_{\mathbf{F}}} w_i^{\alpha}$ . Note that the upper bound on the right-hand side of Eq. (5) combines local MMAP values only computed from a subset of variables  $\mathbf{X}_{\alpha}$ . The upper bounds of the MMAP in Eq. (5) can be formulated as an optimization problem by introducing cost-shifting parameters defined over a join graph decomposition  $\langle \mathcal{G}_J(\mathcal{C}, \mathcal{S}), \chi, \psi \rangle$  by the following equation,

$$\prod_{C_i \in \mathcal{C}} \sum_{\mathbf{X}_{C_i, \alpha \in \psi(C_i)}^{w^{C_i}}} [\prod_{F_{\alpha}(\mathbf{X}_{C_i})}] [\prod_{(\mathcal{S}_{C_i, C_j}) \in \mathcal{S}} \delta_{C_i, C_j}(\mathcal{S}_{C_i, C_j})], \quad (6)$$

where each cluster node  $C_i$  in the join graph  $\mathcal{G}_J$  collects a set of functions mapped by  $\chi(C_i)$ , and the cost-shifting parameters  $\delta_{C_j, C_i}(\mathcal{S}_{C_i, C_j})$  and  $\delta_{C_i, C_j}(\mathcal{S}_{C_i, C_j})$  are introduced on the separators  $\mathcal{S}_{C_i, C_j} \in \mathcal{S}$  such that the costs on the both sides cancel each other. The complexity of computing the upper bound is bounded by the maximum number of variables appearing in the cluster nodes. The optimization framework takes Eq. (6) as an objective function with weights  $w^{C_i}$  and cost-shifting functions  $\delta_{C_i, C_j}(\mathcal{S}_{C_i, C_j})$  as optimization parameters. Since the objective function is convex after taking log on Eq. (6), efficient optimization procedures are available for tightening the upper bound.

## 3 DECOMPOSITION BOUNDS FOR INFLUENCE DIAGRAMS

### 3.1 DECOMPOSING INFLUENCE DIAGRAMS

In this section, we develop a decomposition bound for IDs based on the valuation algebra. First, we generalize the powered-sum elimination operator in Eq. (3) to the valuation algebra.

**Definition 4. (powered-sum elimination for a valuation)** The powered-sum elimination operator for a valuation  $\Psi(X) := (P(X), V(X))$  is defined by

$$\sum_X^{(w, A)} \Psi(X) := \left( \sum_X^w P(X), \sum_X^w h(P(X), V(X), A) \otimes (1, -A) \right) \quad (7)$$

with the activation function  $h$  that adds an arbitrary utility constant  $A$  to the normalized expected utility value  $\frac{V(X)}{P(X)}$  and clips negative expected utility value as

$$h(P(X), V(X), A) = \begin{cases} P(X) \left( \frac{V(X)}{P(X)} + A \right) & \text{if } \frac{V(X)}{P(X)} + A > 0 \\ 0, & \text{otherwise.} \end{cases} \quad (8)$$

Since the powered-sum elimination applies to the absolute values of a function, we introduce the activation function  $h$  so that the powered-sum elimination

on the value component converges to the usual sum-elimination with a constant shift by  $A$  when weights  $\mathbf{w}$  are close to 1 and the value  $V(\mathbf{X})$  is negative. Namely,  $[\sum_X^w h(P(X), V(X))] \rightarrow \sum_X V(x) + A$  when  $w \rightarrow 1$  and  $A + \min(\frac{V(X)}{P(X)}) \geq 0$ .

Next, we define the comparison operator for the valuation algebra as a partial order as follows.

**Definition 5. (comparison of two valuations)** Given two valuations  $\Psi_1 := (P_1, V_1)$  and  $\Psi_2 := (P_2, V_2)$ , we define inequality  $\Psi_1 \leq \Psi_2$  iff.  $P_1 \leq P_2$  and  $V_1 \leq V_2$ .

Equipped with the powered-sum elimination and comparison operator for the valuation algebra, we state the decomposition bounds for IDs as follows.

**Theorem 1. (decomposition bounds for IDs)** Given an ID  $\mathcal{M}' := \langle \mathbf{X}, \Psi, \mathcal{O} \rangle$ , the MEU can be bounded by

$$\sum_{\mathcal{O}}^w \otimes_{\alpha \in \mathcal{I}_{\Psi}} \Psi_{\alpha}(\mathbf{X}_{\alpha}) \leq \otimes_{\alpha \in \mathcal{I}_{\Psi}} \sum_{\mathcal{O}}^{(\mathbf{w}^{\alpha}, \mathbf{A})} \Psi_{\alpha}(\mathbf{X}_{\alpha}). \quad (9)$$

The left-hand side is the MEU in Eq. (1), by rewriting the sequence of elimination operators as the powered-sum elimination operators  $\sum_{\mathcal{I}_0}^{\mathbf{w}^{\mathcal{I}_0}} \sum_{D_0}^{\mathbf{w}^{\mathcal{I}_0}} \dots \sum_{\mathcal{I}_{|\mathcal{D}|}}^{\mathbf{w}^{\mathcal{I}_{|\mathcal{D}|}}}$  following the partial ordering  $\mathcal{O}$ , where the weights  $\mathbf{w}^{\mathcal{I}_k}$  are 1 for the summation variables, and  $\mathbf{w}^{\mathcal{I}_k}$  are 0 for the maximization variables. The right-hand side switches the order of the elimination and combination operators, hence it combines fully eliminated local valuations to the global valuation with weights  $\mathbf{w}^{\alpha}$  that are distributed from  $\mathbf{w}$  such that  $w_i = \sum_{\alpha \in \mathcal{I}_{\Psi}} w_i^{\alpha}$ , where  $w_i$  is the weight of  $X_i \in \mathbf{X}$  and  $w_i^{\alpha}$  is the weight of  $X_i$  at  $\Psi_{\alpha}$ .

*Proof.* The decomposition bound can be obtained by applying Minkowski's inequality in Eq. (10) and Hölder's inequality in Eq. (11) to the probability and value functions of the valuations.

$$\sum_X^w f(X) + g(X) \leq \sum_X^w f(x) + \sum_X^w g(X) \quad (10)$$

$$\sum_X^w f(X)g(X) \leq \sum_X^{w_1} f(x) \sum_X^{w^{-w_1}} g(X) \quad (11)$$

The probability component in the left-hand side of Eq. (9) can be bounded by applying Hölder's inequality as shown in Eq. (12).

$$\sum_{\mathcal{O}}^w \prod_{i \in \mathcal{I}_{\Psi}} P_i \leq \prod_{i \in \mathcal{I}_{\Psi}} \sum_{\mathcal{O}}^{w_i} P_i. \quad (12)$$

The value component can be bounded by the following steps. We rewrite the MEU by introducing constant utilities  $A_i$  as shown in Eq. (13), and bound the MEU by the activation function  $h_i$  defined in Eq. (8) as shown in Eq. (14). The non-constant term in Eq. (14) can be further bounded by applying Minowski's inequality and Hölder's

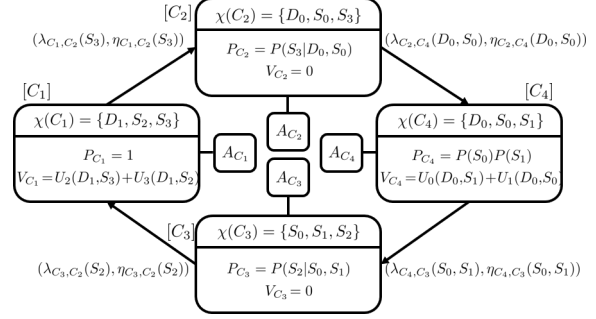

Figure 3: Optimization Parameters for Join Graph Decomposition Bounds. Figure shows the optimization parameters introduced in Proposition 1. The cost-shifting valuations are displayed next to the separators  $\mathcal{S}_{C_i, C_j}$  as  $(\lambda_{C_i, C_j}, \eta_{C_i, C_j})$ , and utility constants  $A_{C_i}$  are attached next to each cluster node  $C_i$ .

inequality as shown in Eq. (15) and (16), respectively.

$$\sum_{\mathcal{O}}^w \sum_{i \in \mathcal{I}_{\Psi}} [V_i + P_i(A_i - A_i)] [\prod_{j \neq i} P_j] \quad (13)$$

$$\leq \sum_{\mathcal{O}}^w \sum_{i \in \mathcal{I}_{\Psi}} h_i(P_i, V_i, A_i) [\prod_{j \neq i} P_j] - \sum_{i \in \mathcal{I}_{\Psi}} A_i \quad (14)$$

$$\leq \sum_{i \in \mathcal{I}_{\Psi}} [\sum_{\mathcal{O}}^w h_i(P_i, V_i, A_i)] [\prod_{j \neq i} P_j] - \sum_{i \in \mathcal{I}_{\Psi}} A_i \quad (15)$$

$$\leq \sum_{i \in \mathcal{I}_{\Psi}} [\sum_{\mathcal{O}}^{w_i} h_i(P_i, V_i, A_i)] [\prod_{j \neq i} \sum_{\mathcal{O}}^{w_j} P_j] - \sum_{i \in \mathcal{I}_{\Psi}} A_i \quad (16)$$

Note that the weights  $\mathbf{w}^i$  assigned to each valuation  $\Psi_i$  in Eq. (12) and Eq. (16) are the same. The final result can be obtained by combining the upper bound on the probability component in Eq. (12) and the upper bound on the value component in Eq. (16) as a valuation with the powered-sum elimination operator for a valuation.  $\square$

### 3.2 OPTIMIZING THE UPPER BOUNDS

The following Proposition 1 presents the parameterized decomposition bounds based on the Theorem 1 by introducing optimization parameters relative to a join graph decomposition. Then, the partial derivatives of the parameterized decomposition bounds are derived to be used in the first order optimization framework.

**Proposition 1. (parameterized decomposition bounds for IDs)** Given an ID  $\mathcal{M}' := \langle \mathbf{X}, \Psi, \mathcal{O} \rangle$  and its join graph decomposition  $\mathcal{D} := \langle \mathcal{G}_J(\mathcal{C}, \mathcal{S}), \chi, \psi \rangle$ , the decomposition bounds in Theorem 1 can be parameterized relative to a join graph decomposition  $\mathcal{G}_J$  as a pair of upper bounds on the probability component and the value component  $(L_{MMAP}, L_{MEU})$  as follows.

$$L_{MMAP} = \prod_{C_i \in \mathcal{C}} \sum_{\mathcal{O}}^{w_{C_i}} P'_{C_i}, \quad (17)$$

$$L_{MEU} = \sum_{C_i \in \mathcal{C}} [\sum_{\mathcal{O}}^{w_{C_i}} h_{C_i}(P'_{C_i}, V'_{C_i})] [\prod_{C_j \neq C_i} \sum_{\mathcal{O}}^{w_{C_j}} P'_{C_j}] - A_{C_i}. \quad (18)$$

In Proposition 1, the  $P'_{C_i}$  and  $V'_{C_i}$  are probability and value functions after incorporating cost-shifting parameters that can be written as

$$P'_{C_i} = P_{C_i} \prod_{(C_i, C_j) \in \mathcal{S}} \lambda_{C_i, C_j}, \quad (19)$$

$$V'_{C_i} = P'_{C_i} \left[ \frac{V_{C_i}}{P_{C_i}} + \sum_{(C_i, C_j) \in \mathcal{S}} \frac{\eta_{C_i, C_j}}{\lambda_{C_i, C_j}} \right]. \quad (20)$$

Each node  $C_i \in \mathcal{C}$  of the  $\mathcal{G}_J$  collects the probability and value functions by the labeling function  $\psi$ , and each edge  $(C_i, C_j) \in \mathcal{S}$  introduces a cost-shifting parameters  $\delta_{C_i, C_j} = (\lambda_{C_i, C_j}, \eta_{C_i, C_j})$  over the variables  $\mathcal{S}_{C_i, C_j}$  such that  $\delta_{C_i, C_j} \otimes \delta_{C_j, C_i} = (1, 0)$ . The utility constant parameters  $A_{C_i}$  is introduced through the activation function  $h_{C_i}$ , and the weight parameters  $\mathbf{w}^{C_i}$  are distributed from  $\mathbf{w}$  such that  $w_X = \sum_{C_i \in \mathcal{C}} w_X^{C_i}$  for all  $X \in \chi(C_i)$ . Note that the reparameterized decomposition bound for IDs subsumes the GDD bound for MMAP in Eq. (6) at the probability component,  $L_{\text{MMAP}}$ , and the new parameterized upper bound for the MEU at the value component,  $L_{\text{MEU}}$ . Note that the  $L_{\text{MEU}}$  in Eq. (20) is non-convex.

The following example illustrates the optimization parameters for the ID shown in Figure 1(a).

**Example 3.** Figure 3 illustrates the optimization parameters introduced by the join graph decomposition  $\mathcal{D} := \langle \mathcal{G}_J(\mathcal{C}, \mathcal{S}), \chi, \psi \rangle$  of Example 2. The valuations at each node  $C_i \in \mathcal{C}$  is displayed inside each node and the utility constant  $A_{C_i}$  is attached next to the node. The cost-shifting valuation  $(\lambda_{C_i, C_j}, \eta_{C_i, C_j})$  is shown next to the directed edges from  $C_i$  to  $C_j$  implying that the cost is moving from  $C_i$  to  $C_j$ , and hence  $\delta_{C_i, C_j}$  and  $\delta_{C_j, C_i}$  cancel each other.

Next, we present the first-order optimization procedures for tightening the parameterized decomposition bounds,  $L_{\text{MEU}}$  in Eq. (18). For efficiency and simplicity, we apply a block coordinate method that cycles through a subset of optimization parameters associated with the nodes and edges of the join graph  $\mathcal{G}_J$ , which we call the inner optimization problems. To optimize cost-shifting parameters  $\{\delta_{C_i, C_j} | (C_i, C_j) \in \mathcal{S}\}$  and utility constants  $\{A_{C_i} | C_i \in \mathcal{C}\}$ , we use gradient descent with line search [Wright and Nocedal, 1999] by

$$\mathbf{x}^{t+1} = \mathbf{x}^t - s \cdot [\nabla f(\mathbf{x}^t)], \quad (21)$$

where  $f$  is the objective function,  $s$  is the step size,  $\mathbf{x}^t$  is the optimization parameter at the  $t$ -th iteration. The weights  $\{\mathbf{w}^{C_i} | C_i \in \mathcal{C}\}$  are updated by exponentiated gradient descent [Kivinen and Warmuth, 1997] by

$$\mathbf{w}^{C_i, t+1} = \frac{\mathbf{w}^{C_i, t} \exp[-s \cdot [\nabla_{\mathbf{w}^{C_i}} L_{\text{MEU}}(\mathbf{w}^{C_i, t})]]}{\sum_{C_i \in \mathcal{C}} \mathbf{w}^{C_i, t} \exp[-s \cdot [\nabla_{\mathbf{w}^{C_i}} L_{\text{MEU}}(\mathbf{w}^{C_i, t})]]}. \quad (22)$$

Now, we define pseudo marginals and some useful expressions before deriving the gradients of each subset of the optimization parameters.

**Definition 6. (pseudo marginals)** Given a non-negative real-valued function  $Z_0(\mathbf{X}_{1:n})$  over a set of variables  $\mathbf{X}_{1:n} = \{X_1, \dots, X_n\}$ , and the weights  $\mathbf{w} = \{w_1, \dots, w_n\}$  associated with  $\mathbf{X}_{1:n}$ , we define a partial powered-sum elimination of variables  $\mathbf{X}_{1:i}$  from  $Z_0(\mathbf{X}_{1:n})$  by

$$Z_i(\mathbf{X}_{i+1:n}) = \sum_{\mathbf{x}_i}^{w_i} Z_{i-1}(\mathbf{X}_{i:n}).$$

The pseudo marginal of  $Z_0(\mathbf{X}_{1:n})$  is defined by

$$\Lambda(Z_0(\mathbf{X}_{1:n})) = \left[ \frac{Z_{n-1}(X_n)}{Z_n} \right]^{1/w_n} \dots \left[ \frac{Z_0(\mathbf{X}_{1:n})}{Z_1(\mathbf{X}_{2:n})} \right]^{1/w_1}.$$

Note that  $\Lambda(Z_0(\mathbf{X}_{1:n}))$  is a normalized distribution over  $\mathbf{X}_{1:n}$ , and each  $\left[ \frac{Z_{i-1}(\mathbf{X}_{i:n})}{Z_i(\mathbf{X}_{i+1:n})} \right]^{1/w_i}$  is a conditional distribution over  $X_i$  given  $\mathbf{X}_{i+1:n}$ .

Let's define a selector  $F_{C_j | C_i}$  that selects a probability or a value component depending on the indices  $i$  and  $j$  by

$$F_{C_j | C_i} = \begin{cases} h_{C_j}(P^{C_j}, V^{C_j}), & \text{if } j = i \\ P^{C_j}, & \text{otherwise.} \end{cases} \quad (23)$$

By using Eq. (23), the upper bound of the expected utility value at  $C_i$  can be expressed by

$$\Theta_{C_i} = \prod_{C_j \in \mathcal{C}} \sum_{\mathcal{O}}^{w^{C_j}} F_{C_j | C_i}. \quad (24)$$

In the following, we summarize the gradients of  $L_{\text{MEU}}$ ,  $\nabla L_{\text{MEU}}$  with respect to subsets of parameters.

$$\nabla L_{\text{MEU}}(w_k^{C_i}) = \sum_{C_j \in \mathcal{C}} \rho_{C_j} H(X_k | \mathbf{X}_{i+1:n} | \mathcal{O}; F_{C_j | C_i}) \quad (25)$$

$$\nabla L_{\text{MEU}}(A_{C_i}) = \Theta_{C_i} \sum_{\mathbf{x}_{C_i} \in \mathcal{S}_{C_i, C_j}} \frac{P^{C_i} \Lambda(h_{C_i}(P^{C_i}, V^{C_i}))}{h_{C_i}(P^{C_i}, V^{C_i})} - 1 \quad (26)$$

$$\nabla L_{\text{MEU}}(\lambda_{C_i, C_j}) = \sum_{C_k \in \mathcal{C}} \Theta_{C_k} \left[ \sum_{\mathbf{x}_{C_j} \in \mathcal{S}_{C_i, C_j}} \Lambda(F_{C_i | C_k}) - \sum_{\mathbf{x}_{C_i} \in \mathcal{S}_{C_i, C_j}} \Lambda(F_{C_j | C_k}) \right] \quad (27)$$

$$\nabla L_{\text{MEU}}(\eta_{C_i, C_j}) = \Theta_{C_j} \sum_{\mathbf{x}_{C_j} \in \mathcal{S}_{C_i, C_j}} \frac{P^{C_j} \Lambda(h_{C_j}(P^{C_j}, V^{C_j}))}{h_{C_j}(P^{C_j}, V^{C_j})} - \Theta_{C_i} \sum_{\mathbf{x}_{C_i} \in \mathcal{S}_{C_i, C_j}} \frac{P^{C_i} \Lambda(h_{C_i}(P^{C_i}, V^{C_i}))}{h_{C_i}(V^{C_i})} \quad (28)$$

The term  $H(X_k | \mathbf{X}_{i+1:n} | \mathcal{O}; F_{C_j | C_i})$  in Eq. (25) is the conditional entropy  $H(X_k | \mathbf{X}_{i+1:n} | \mathcal{O})$  of the pseudo marginal of the function selected by  $F_{C_j | C_i}$ .

### 3.3 MESSAGE PASSING ALGORITHM

Applying the parameterized decomposition bounds for IDs and the first order optimization procedures described in Section 3.2, we develop an iterative message passing algorithm that updates the optimization parameters defined relative to a join graph decomposition.

---

**Algorithm 1** Join Graph Decomposition for IDs (JGDID)

**Require:** Influence diagram  $\mathcal{M}' = \langle \mathbf{X}, \Psi, \mathcal{O} \rangle$ , initial weights  $w_i$  associated with a variable  $X_i \in \mathbf{X}$ ,  $i$ -bound, total iteration limit  $M_1$ , iteration limit  $M_2$  for updating weights and costs before updating utility constants.

**Ensure:** an upper bound of the MEU,  $L_{\text{MEU}}$ ,

```

1: generate a join graph decomposition  $\mathcal{D} = \langle \mathcal{G}_J(\mathcal{C}, \mathcal{S}), \chi, \psi \rangle$ 
   by MBE with  $i$ -bound and assign valuations to nodes by
   labeling function  $\psi$ .
2: execute single pass cost-shifting by messages generated by
   MBE algorithm based on the valuation algebra (MBE-VA)
3: initialize weights  $\mathbf{w}^{C_i}, \forall C_i \in \mathcal{C}$  by uniform weights.
4:  $iter=0, L_{\text{MEU}} = \inf$ 
5: while  $iter < M_1$  or  $L_{\text{MEU}}$  is not converged do
6:   for each variable  $X_i \in \mathbf{X}$  do
7:      $L_{\text{MEU}} \leftarrow \min(L_{\text{MEU}}, \text{UPDATE-WEIGHTS}(\mathcal{G}_J, X_i))$ 
8:   end for
9:   for each edge  $(C_i, C_j) \in \mathcal{S}$  do
10:     $L_{\text{MEU}} \leftarrow \min(L_{\text{MEU}}, \text{UPDATE-COSTS}(\mathcal{G}_J, \{C_i, C_j\}))$ 
11:   end for
12:   if  $iter > M_2$  then
13:     for each node  $C_i \in \mathcal{C}$  do
14:        $L_{\text{MEU}} \leftarrow \min(L_{\text{MEU}}, \text{UPDATE-UTIL-CONST}(\mathcal{G}_J, C_i))$ 
15:     end for
16:   end if
17:    $iter = iter + 1$ 
18: end while

```

---

Algorithm 1 outlines the procedure for updating the parameters, the Join Graph Decomposition Bound for IDs (JGDID). Given an input ID  $\mathcal{M}' := \langle \mathbf{X}, \Psi, \mathcal{O} \rangle$ , we first generate a join graph decomposition  $\mathcal{D} = \langle \mathcal{G}_J(\mathcal{C}, \mathcal{S}), \chi, \psi \rangle$  by executing the MBE algorithm with an input  $i$ -bound. For details on how to structure a join graph decomposition, see Mateescu et al. [2010]. Then, we assign valuations to the nodes in  $\mathcal{C}$  by labeling function  $\psi$  and run a single pass cost-shifting over the join graph using the messages generated by the MBE algorithm [Dechter and Rish, 2003] based on valuation algebra (MBE-VA). In our empirical evaluation, this preliminary step significantly improves the speed of convergence and the quality of the upper bound. The initial weights  $\mathbf{w}^{C_i}$  at each node  $C_i \in \mathcal{C}$  for the summation variables are uniform, and a small constant  $\epsilon \approx 10^{-6}$  initializes the weights for the maximization variables.

The block coordinate method updates the subset of the parameters by solving inner optimization problems following the structure of  $\mathcal{G}_J$ . The UPDATE-WEIGHTS routine in line 7 updates the weights  $w_i^{C_j}$  for a variable  $X_i$  over  $\forall C_j \in \mathcal{C}$  by Eq. (22) with the gradient in Eq. (25), the UPDATE-COSTS routine in line 10 updates cost-shifting valuations  $\delta_{C_i, C_j}$  over each edge  $(C_i, C_j) \in \mathcal{S}$  by the gradient descent with the gradients in Eq. (27) and in Eq. (28), and the UPDATE-UTIL-CONST routine in line 14 updates the utility constants  $A_{C_i}$  for each node  $C_i \in \mathcal{C}$  by the gradient descent with the gradient in Eq. (26). Since

Table 1: Benchmark statistics. Table shows the minimum, median, and maximum instance statistics from 10 instances. n is the number of chance and decision variables, f is the number of probability and utility functions, k is the maximum domain size, s is the maximum scope size, and w is the induced width.

Domain	n	f	k	s	w
FH-MDP	25, 110, 170	30, 143, 170	2, 3, 5	4, 7, 9	5, 25, 43
FH-POMDP	15, 51, 96	18, 61, 140	2, 2, 3	3, 5, 9	10, 27, 47
RAND	22, 57, 91	22, 57, 91	2, 2, 2	3, 3, 3	6, 18, 41
BN	54, 100, 115	54, 100, 115	2, 2, 2	6, 8, 10	18, 28, 45

the optimization objective function  $L_{\text{MEU}}$  is non-convex, the block coordinate method with our first-order optimization procedures is not guaranteed to provide a globally minimum bound, yet often performs well in practice.

In our empirical evaluation, we set the hyperparameters for the number of gradient updates for the inner optimization to 10, and the number of updates  $M_2$  for the weights and costs before updating utility constants to 20 and 50, which yielded a good convergence behavior.

## 4 EXPERIMENTS

We empirically compare the performance of our proposed algorithm JGDID with earlier approaches for bounding the MEU on four problem domains.

**Benchmarks.** The benchmarks are generated as follows. (1) Factored FH-MDP instances are generated from two stage factored MDP templates by controlling the number of state and action variables, the scope of functions, and the time horizon. (2) Factored FH-POMDP instances are generated similarly to FH-MDP instances, but we incorporate partial observability. (3) Random influence diagram (RAND) instances are generated by randomly generating influence diagram topology given the number of chance, decision, and value nodes. (4) BN instances are converted to ID from existing Bayesian networks used in the UAI-2006 probabilistic inference competitions by adding utility functions and randomly selecting decision variables. We generated 10 instances for each benchmark with increasing difficulty; Table 1 summarizes the instance statistics of the 4 benchmarks.

**Algorithms.** The first approach we compare against is the upper bounding algorithms for MMAP using the reduction from ID to MMAP. The reduction of Mauá [2016] generates standard MMAP instances, while Liu and Ihler [2012] generates MMAP instances with interleaved max and sum operators, which we call mixed MMAP. For the standard MMAP instances, we applied weighted mini-bucket with moment matching (WMBMM) [Liu and Ihler, 2011; Marinescu et al., 2014], and for the mixed MMAP instances, we applied GDD [Ping et al., 2015].

The second set of algorithms are applied directly to the In-

Table 2: Instance statistics of MMAP translation. Table shows the minimum, median, and maximum instance statistics of the standard MMAP reduction (MM) and the mixed MMAP reduction (MI).

Domain	Trans	n	k	w
FH-MDP	ID	25, 110, 170	2, 3, 5	5, 25, 43
	MI	26, 111, 171	10, 27, 80	15, 86, 160
FH-POMDP	ID	15, 51, 96	2, 3, 2	10, 27, 47
	MM	28, 188, 5277	6, 16, 48	14, 141, 5192
	MI	16, 52, 97	6, 16, 48	10, 28, 48
RAND	ID	22, 57, 91	2, 2, 2	6, 18, 41
	MM	29, 79, 142	2, 8, 21	8, 25, 58
	MI	23, 58, 92	2, 8, 21	6, 20, 42
BN	ID	54, 100, 115	2, 2, 2	18, 28, 45
	MM	69, 126, 202	3, 6, 12	20, 40, 92
	MI	55, 101, 116	3, 6, 12	19, 29, 46

fluence Diagram. One scheme is based on the mini-bucket idea which bounds the induced width by the  $i$ -bound, and then applies variable elimination using valuation algebra, yielding algorithm MBE-VA. The second is an information relaxation scheme, which relaxes the constrained variable ordering, denoted IR-SIS. [Nilsson and Hohle, 2001; Yuan et al., 2010]. The information relaxation is orthogonal to approximate elimination, and so both can be applied together; when we apply MBE-VA and JGDD together with the relaxed ordering of IR-SIS we call the hybrid algorithms MBE-VA+IR-SIS and JGDID-IR-SIS.

In summary, we evaluated 6 algorithms. We have JGDID and MBE-VA applied directly to the input IDs assuming only constrained ordering. We have JGDID+IR-SIS and MBE-VA+IR-SIS applied to the IDs but allowing relaxed ordering by IR-SIS, and finally we have WMBMM and GDD that are applied to MMAP reductions from IDs.

**Performance measure.** We report the quality of upper bounds for individual instances, and the average quality of the upper bounds by the mean of the ratio between the best upper bound found by all configurations (6 algorithms with  $i$ -bounds 1 and 15) and the upper bound of each under comparison; the closer the value to 1.0, the better the quality.

#### 4.1 COMPARING AGAINST MMAP TRANSLATIONS

Next, we compare our JGDID approach with WMBMM and GDD bounds based on MMAP translations.

**Impact of MMAP translation.** Table 2 summarizes the changes in the number of variables, the maximum domain size, and the induced width  $w$  due to the translation. When computing the induced width, we used the randomized min-fill algorithm. The reduction from ID to MMAP for the FH-MDP benchmark is not shown in the table because the translation was not feasible for most of the instances. Note that the standard MMAP reduction (MM)

Table 3: Average Quality of Upper Bounds.

Algorithm	FH-MDP	FH-POMDP	RAND	BN
JGDID+IR-SIS( $i=1$ )	NA	0.88	0.87	0.99
JGDID+IR-SIS( $i=15$ )	NA	0.76	0.85	0.64
JGDID( $i=1$ )	0.88	0.38	0.86	0.89
JGDID( $i=15$ )	0.49	0.38	0.85	0.64
MBE-VA+IR-SIS( $i=1$ )	NA	0.03	0.01	0.00
MBE-VA+IR-SIS( $i=15$ )	NA	0.54	0.46	0.15
MBE-VA( $i=1$ )	0.00	0.00	0.00	0.00
MBE-VA( $i=15$ )	0.40	0.29	0.46	0.17
GDD( $i=1$ )	0.87	0.03	0.11	0.24
GDD( $i=15$ )	0.22	0.11	0.15	0.05
WMBMM( $i=1$ )	0.00	0.00	0.01	0.01
WMBMM( $i=15$ )	0.01	0.23	0.35	0.24

inflates all input statistics. The number of variables is exponential in the size of the largest information set, the maximum domain size is increased to the total number of utility functions, and the induced width also increased significantly higher than input IDs. The mixed MMAP translation (MI) increases the number of variables by 1 which has domain size equal to the total number of utility functions. The induced width is increased by 1 except for the FH-MDP domain.

**Upper bounds from individual instances.** Figure 4 illustrates the quality of the obtained upper bounds for instances having the largest induced width in each benchmark. We ran JGDID and GDD algorithms up to 2000 iterations or until convergence. We can see from Figure 4 that JGDID dominates GDD and WMBMM on all instances except pomdp8. Comparing the upper bounds across  $i$ -bounds, JGDID and GDD do not show notable improvement on the speed of convergence with higher  $i$ -bounds due to the large overhead of a single iteration. We see that JGDID shows the step-wise improvement of upper bounds when it optimizes the utility constants.

**Average quality of upper bounds.** Table 3 shows the average quality of upper bounds. We see that the average quality of JGDID dominates both GDD and WMBMM in all benchmarks. Comparing JGDID and GDD, both generated upper bounds with similar quality on average in the FH-MDP benchmark. However, bounds from GDD are significantly worse than JGDID in other benchmarks. The upper bounds from WMBMM( $i=1$ ) is so large that the average ratios for all instances are close to 0.0.

#### 4.2 COMPARING AGAINST DIRECT ALGORITHMS

In this section we compare JGDID, MBE-VA, JGDID+IR-SIS, and MBE-VA+IR-SIS that are applied directly to IDs. They are all obtained by relaxing the input IDs either by decomposing graphical model or information relaxation.

**Impact of IR-SIS.** The IR-SIS relaxation often produces

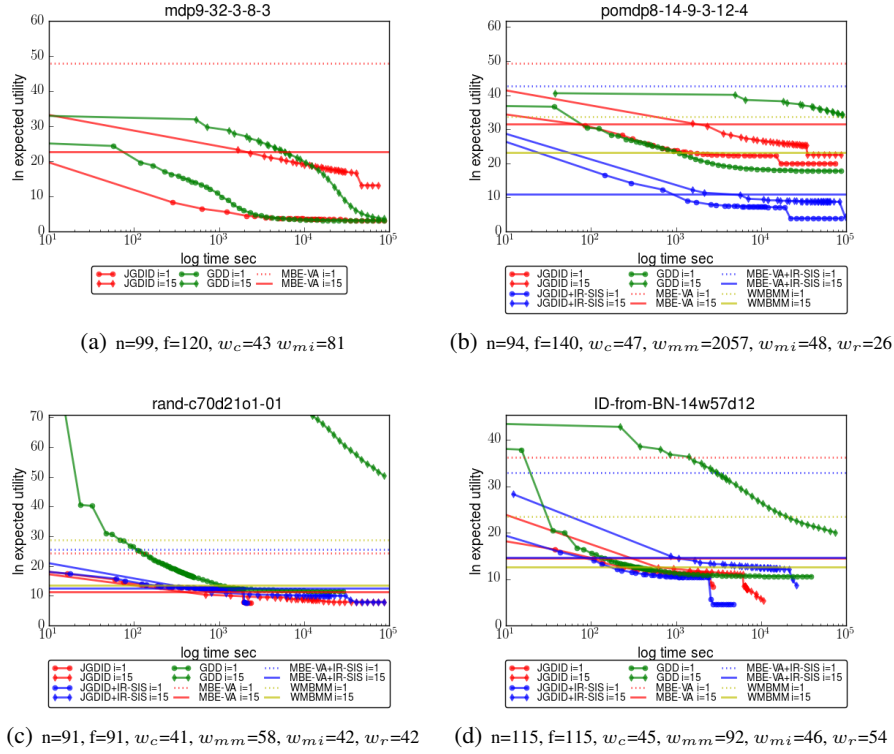

Figure 4: Upper Bounds of the MEU. Each plot shows the convergence of upper bounds over time. We draw horizontal lines for the bounds computed by non-iterative algorithms. The  $w_c$ ,  $w_{mm}$ ,  $w_{mi}$ , and  $w_r$  are the induced width of the input ID, standard MMAP reduction, mixed MMAP reduction, and relaxed ID with IR-SIS, respectively.

IDs with a lower induced width by reordering the variables in the information sets. It is shown to be very effective for FH-POMDP instances because IR-SIS transforms POMDP instances to MDP. The minimum, the median and the maximum induced width of FH-POMDP instances decreased from 10 to 3, 27 to 14, and 47 to 35, respectively via this relaxation. In other benchmarks, the improvement was negligible and often IR-SIS increased induced width.

**Upper bounds from individual instances.** Figure 4 illustrates also upper bounds obtained by direct algorithms. Comparing JGDID with MBE-VA, we see in the figure that JGDID improved the quality of the upper bound significantly in all instances. IR-SIS often significantly improves the quality of the bounds when the upper bounds from decomposition methods is still weak. In case of `pomdp8`, we see that the JGDID+IR-SIS improved the upper bound significantly compared to JGDID.

**Average quality of upper bounds.** Table 3 also shows the average quality of the upper bounds for the 4 direct algorithms. We see that the average quality of JGDID dominates MBE-VA. The average quality of the upper bounds obtained from MBE-VA( $i=1$ ) are so weak that their value is closed to 0.0 in all benchmarks. Both JGDID and MBE-VA improve the average quality of the upper bounds when they are combined with IR-SIS, and

JGDID+IR-SIS presents the best average quality overall.

## 5 CONCLUSIONS

We present a new algorithm, Join Graph Decomposition for solving Influence Diagrams, called JGDID, using the valuation algebra. Our scheme subsumes the decomposition bounds for marginal MAP, and also provide a bound for the MEU. Our experiments show the effectiveness of the translation free approach and the significant improvement in the quality of upper bounds compared with earlier state-of-the-art approaches. We also demonstrate that a join graph decomposition scheme can be combined with information relaxation scheme to yield superior bounds. The principle of decomposing a sequence of decision problems to a collection of weakly coupled subproblems can be further developed by incorporating advanced optimization frameworks, and the resulting, effective upper bounding schemes can be applied to probabilistic planning and stochastic programming.

## Abstract

Causal discovery methods aim to recover the causal process that generated purely observational data. Despite its successes on a number of real problems, the presence of measurement error in the observed data can produce serious mistakes in the output of various causal discovery methods. Given the ubiquity of measurement error caused by instruments or proxies used in the measuring process, this problem is one of the main obstacles to reliable causal discovery. It is still unknown to what extent the causal structure of relevant variables can be identified in principle. This study aims to take a step towards filling that void. We assume that the underlining process or the measurement-error free variables follows a linear, non-Gaussian causal model, and show that the so-called ordered group decomposition of the causal model, which contains major causal information, is identifiable. The causal structure identifiability is further improved with different types of sparsity constraints on the causal structure. Finally, we give rather mild conditions under which the whole causal structure is fully identifiable.

## 1 INTRODUCTION

Understanding and using causal relations among variables of interest has been a fundamental problem in various fields, including biology, neuroscience, and social sciences. Since interventions or controlled randomized experiments are usually expensive or even impossible to conduct, discovering causal information from observational data, known as causal discovery (Spirtes et al., 2001; Pearl, 2000), has been an important task and received much attention in computer science, statistics, and philosophy. Roughly speaking, methods for causal

discovery are categorized into constraint-based ones, such as the PC algorithm (Spirtes et al., 2001), and score-based ones, such as Greedy Equivalence Search (GES) (Chickering, 2002).

Almost all current causal discovery methods assume that the recorded values are realizations of the variables of interest. Typically, however, the measured values are not identical to the values of the variables that they are intended to measure. The measuring process may involve nonlinear distortion, as already address by the post-nonlinear causal model (Zhang & Hyvärinen, 2009; Zhang & Chan, 2006), and may introduce a lot of error. For instance, in neuroscience the measured brain signals obtained by functional magnetic resonance (fMRI) usually contain error introduced by instruments. In this paper, we consider the so-called random measurement error model, as defined by Scheines & Ramsey (2017), in which observed variables  $X_i$ ,  $i = 1, \dots, n$ , are generated from the underlying measurement-error-free variables  $\tilde{X}_i$  with additive measurement errors  $E_i$ :

$$X_i = \tilde{X}_i + E_i. \quad (1)$$

We further assume that the errors  $E_i$  are mutually independent and independent from  $\tilde{X}_i$ . Putting the causal model for  $\tilde{X}_i$  and the random measurement error model together, we have the whole process that generates the measured data. We call this process the CAusal Model with Measurement Error (CAMME).

Generally speaking, because of the presence of measurement errors, the d-separation patterns among  $X_i$  are different from those among the underlying variables  $\tilde{X}_i$ . This generating process has been called the random measurement error model in (Scheines & Ramsey, 2017). According to the causal Markov condition (Spirtes et al., 2001; Pearl, 2000), observed variables  $X_i$  and the underlying variables  $\tilde{X}_i$  may have different conditional independence/dependence relations and, as a consequence, the output of approaches to causal discovery that exploit conditional independence and dependence relations are unreliable in the

presence of such errors, as demonstrated in (Scheines & Ramsey, 2017). In Section 2 we will give an example to show how conditional independence/dependence between the variables is changed by measurement error, and discuss its implication in applications of causal discovery to real problems. Furthermore, because of the measurement error, the structural equation models according to which the measurement-error-free variables  $\tilde{X}_i$  are generated usually do not hold for the observed variables  $X_i$ . (In fact,  $X_i$  follow error-in-variables models, for which the identifiability of the underlying causal relation is not clear.) Hence, approaches based on structural equation models, such as the linear, non-Gaussian, acyclic model (LiNGAM (Shimizu et al., 2006)), will generally fail to find the correct causal direction.

In this paper, we aim to estimate the causal model underlying the measurement-error-free variables  $\tilde{X}_i$  from their observed values  $X_i$  contaminated by random measurement error. We assume linearity of the causal model and causal sufficiency relative to  $\{\tilde{X}_i\}_{i=1}^n$ . We particularly focus on the case where the causal structure for  $\tilde{X}_i$  is represented by a Directed Acyclic Graph (DAG), although this condition can be weakened. In order to develop principled causal discovery methods to recover the causal model for  $\{\tilde{X}_i\}_{i=1}^n$  from observed values of  $\{X_i\}_{i=1}^n$ , we have to address theoretical issues include 1) whether the causal model of interest is completely or partially identifiable from the contaminated observations and 2) what are the precise identifiability conditions.

There exist causal discovery methods, such as the Fast Causal Inference (FCI) algorithm (Spirtes et al., 2001), to deal with confounders, i.e., hidden direct common causes. However, they cannot estimate the causal relations among the "latent" variables, which is what we aim to recover in this paper. Silva et al. (2006) and Kummerfeld et al. (2014) have provided algorithms for recovering latent variables and their causal relations when each latent variable has multiple measured effects; Shimizu et al. (2011a) further applied LiNGAM to the recovered latent variables to improve the estimated causal relations between them. Their problem is different from the measurement error setting we consider, where clustering for latent common causes is not required and each measured variable is the direct effect of a single "true" variable. As discussed in Section 3, their models can be seen as special cases of our setting.

## 2 EFFECT OF MEASUREMENT ERROR

Suppose we observe variables  $X_1$ ,  $X_2$ , and  $X_3$ , which are generated from measurement-error-free variables  $\tilde{X}_i$  according to the structure given in Figure 1. By

the Markov condition and Faithfulness assumption, all three of the  $\tilde{X}_i$  variables are dependent on one another, while  $\tilde{X}_1$  and  $\tilde{X}_3$  are conditionally independent given  $\tilde{X}_2$ . That conditional independence does not hold for  $X_i$ , the variables actually observable. The measurement error  $E_2$  produces the trouble. We will treat the distributions as Gaussian purely for illustration; again, the point is general.

Figure 1: A linear CAMME to demonstrate the effect of measurement error on conditional independence and dependence relationships. For simplicity, we consider the special case where there is measurement error only in  $X_2$ , i.e.,  $X_2 = \tilde{X}_2 + E_2$ , but  $X_1 = \tilde{X}_1$  and  $X_3 = \tilde{X}_3$ .

Let  $\tilde{\rho}_{12}$  be the correlation coefficient between  $\tilde{X}_1$  and  $\tilde{X}_2$  and  $\tilde{\rho}_{13,2}$  be the partial correlation coefficient between  $\tilde{X}_1$  and  $\tilde{X}_3$  given  $\tilde{X}_2$ , which is zero. Let  $\rho_{12}$  and  $\rho_{13,2}$  be the corresponding correlation coefficient and partial correlation coefficient in the presence of measurement error. We let  $\tilde{\rho}_{12} = \tilde{\rho}_{23} = \tilde{\rho}$  to make the argument simpler, but the point is quite general. So we have  $\rho_{13} = \tilde{\rho}_{13} = \tilde{\rho}_{12}\tilde{\rho}_{23} = \tilde{\rho}^2$ . Let  $\gamma = \frac{\text{Std}(E_2)}{\text{Std}(\tilde{X}_2)}$ . For the data with measurement error, we have

$$\begin{aligned} \rho_{12} &= \frac{\text{Cov}(X_1, X_2)}{\text{Var}^{1/2}(X_1)\text{Var}^{1/2}(X_2)} \\ &= \frac{\text{Cov}(\tilde{X}_1, \tilde{X}_2)}{\text{Var}^{1/2}(\tilde{X}_1)(\text{Var}(\tilde{X}_2) + \text{Var}(E_2))^{1/2}} \\ &= \frac{\tilde{\rho}}{(1 + \gamma^2)^{1/2}}; \\ \rho_{13,2} &= \frac{\rho_{13} - \rho_{12}\rho_{23}}{(1 - \rho_{12}^2)^{1/2}(1 - \rho_{23}^2)^{1/2}} \\ &= \frac{\tilde{\rho}_{13} - \frac{\tilde{\rho}_{12}\tilde{\rho}_{23}}{1 + \gamma^2}}{(1 - \frac{\tilde{\rho}^2}{(1 + \gamma^2)})^{1/2}(1 - \frac{\tilde{\rho}^2}{(1 + \gamma^2)})^{1/2}} \\ &= \frac{\tilde{\rho}^2}{1 + \gamma^2 - \tilde{\rho}^2}. \end{aligned}$$

As the variance of the measurement error in  $X_2$  increases,  $\gamma$  become larger, and  $\rho_{12}$  decreases and finally goes to zero; in contrast,  $\rho_{13,2}$ , which is zero for the measurement-error-free variables, is increasing and finally converges to  $\tilde{\rho}^2$ . See Figure 2 for an illustration. In other words, in this example as the variance of the measurement error in  $X_2$  increases,  $X_1$  and  $X_2$  become more and more independent, while  $X_1$  and  $X_3$  are conditionally more and more dependent given  $X_2$ . However, for the measurement-error-free variables,  $\tilde{X}_1$  and  $\tilde{X}_2$  are dependent and  $\tilde{X}_1$  and  $\tilde{X}_3$  are conditionally independent given  $\tilde{X}_2$ . The PC algorithm and other methods that explicitly or implicitly exploit con-

ditional independence and dependence relations will find an edge between  $X_1$  and  $X_3$  that does not exist between  $X_1$  and  $X_3$ . Multiple regression of  $X_3$  on  $X_1$  and  $X_2$ , or  $X_1$  on  $X_3$  and  $X_2$ , will make the same error.

Figure 2: The correlation coefficient  $\rho_{12}$  between  $X_1$  and  $X_2$  and partial correlation coefficient  $\rho_{13,2}$  between  $X_1$  and  $X_3$  given  $X_2$  as functions of  $\gamma$ , the ratio of the standard deviation of measurement error to the that of  $\tilde{X}_2$ . We have assumed that the correlation coefficient between  $\tilde{X}_1$  and  $\tilde{X}_2$  and that between  $\tilde{X}_2$  and  $\tilde{X}_3$  are the same (denoted by  $\tilde{\rho}$ ), and that there is measurement error only in  $X_2$ .

Roughly speaking, originally conditionally independent (or dependent) variables will become less independent (or dependent), due to the effect of measurement error. In order to correctly detect conditional independence relations between measurement-error-free variables from the observed noisy values, one may use a very small significance level (or type I error level,  $\alpha$ ) when performing conditional independence tests—the smaller the significance level, the less often the independence null hypothesis is rejected, and more pairs of variables are likely to be considered as conditionally independent. This, inevitably, risks high type II errors (i.e., conditionally dependent variable pairs are likely to be considered as independent), especially when the sample size is relatively small. Therefore it is desirable to develop principled causal discovery methods to deal with measurement error.

One might apply other types of methods instead of the constraint-based ones for causal discovery from data with measurement error. In fact, as the measurement-error-free variables are not observable,  $\tilde{X}_2$  in Figure 1 is actually a confounder for observed variables. As a consequence, generally speaking, due to the effect of the confounders, the independence noise assumption underlying functional causal model-based approaches, such as the method based on the linear, non-Gaussian, acyclic model (Shimizu et al., 2006), will not hold for the observed variables any more. Figure 3 gives an

Figure 3: Illustration on how measurement error leads to dependence between regression residual and contaminated cause. (a) Scatter plot of  $X_2$  and  $X_1$  with measurement error in  $X_2$  together with the regression line. (b) Scatter plot of the regression residual and  $X_2$ . Note that if we regress  $\tilde{X}_1$  on  $\tilde{X}_2$ , the residual is independent from  $\tilde{X}_2$ .

illustration on this. Figure 3(a) shows the scatter plot of  $X_1$  vs.  $X_2$  and the regression line from  $X_2$  to  $X_1$ , where  $\tilde{X}_2$ , the noise in  $\tilde{X}_1$ , and the measurement error  $E_2$ , are all uniformly distributed ( $\rho = 0.4$ , and  $\gamma = 1.4$ ). As seen from Figure 3(b), the residual of regressing  $X_1$  on  $X_2$  is not independent from  $X_2$ , although the residual of regressing  $\tilde{X}_1$  on  $\tilde{X}_2$  is independent from  $\tilde{X}_2$ . As a result, the functional causal model-based approaches to causal discovery may also fail to find the causal structure of the measurement-error-free variables from their contaminated observations. The effect of measurement error on causal direction identification in the two-variable case was also studied by Wiedermann et al. (2018) under some further assumptions.

### 3 MODEL CANONICAL REPRESENTATION

Let  $\tilde{G}$  be the acyclic causal model over  $\tilde{X}_i$ . Here we call it *measurement-error-free causal model*. Let  $\mathbf{B}$  be the corresponding causal adjacency matrix for  $\tilde{X}_i$ , in which  $B_{ij}$  is the coefficient of the direct causal influence

from  $\tilde{X}_j$  to  $\tilde{X}_i$  and  $B_{ii} = 0$ . We have,

$$\tilde{\mathbf{X}} = \mathbf{B}\tilde{\mathbf{X}} + \tilde{\mathbf{E}}, \quad (2)$$

where the components of  $\tilde{\mathbf{E}}$ ,  $\tilde{E}_i$ , have non-zero, finite variances. Then  $\tilde{\mathbf{X}}$  is actually a linear transformation of the error terms in  $\tilde{\mathbf{E}}$  because (2) implies

$$\tilde{\mathbf{X}} = \underbrace{(\mathbf{I} - \mathbf{B})^{-1}}_{\triangleq \mathbf{A}} \tilde{\mathbf{E}}. \quad (3)$$

Now let us consider two types of nodes of  $\tilde{G}$ , namely, leaf nodes (i.e., those that do not influence any other node) and non-leaf nodes. Accordingly, the noise term in their structural equation models also has distinct behaviors: If  $\tilde{X}_i$  is a leaf node, then  $\tilde{E}_i$  influences only  $\tilde{X}_i$ , not any other; otherwise  $\tilde{E}_i$  influences  $\tilde{X}_i$  and at least one other variable,  $\tilde{X}_j$ ,  $j \neq i$ . Consequently, we can decompose the noise vector into two groups:  $\tilde{\mathbf{E}}^L$  consists of the  $l$  noise terms that influence only leaf nodes, and  $\tilde{\mathbf{E}}^{\text{NL}}$  contains the remaining noise terms. Equation (3) can be rewritten as

$$\tilde{\mathbf{X}} = \mathbf{A}^{\text{NL}}\tilde{\mathbf{E}}^{\text{NL}} + \mathbf{A}^L\tilde{\mathbf{E}}^L = \tilde{\mathbf{X}}^* + \mathbf{A}^L\tilde{\mathbf{E}}^L, \quad (4)$$

where  $\tilde{\mathbf{X}}^* \triangleq \mathbf{A}^{\text{NL}}\tilde{\mathbf{E}}^{\text{NL}}$ ,  $\mathbf{A}^{\text{NL}}$  and  $\mathbf{A}^L$  are  $n \times (n-l)$  and  $n \times l$  matrices, respectively. Here both  $\mathbf{A}^L$  and  $\mathbf{A}^{\text{NL}}$  have specific structures. All entries of  $\mathbf{A}^L$  are 0 or 1; for each column of  $\mathbf{A}^L$ , there is only one non-zero entry. In contrast, each column of  $\mathbf{A}^{\text{NL}}$  has at least two non-zero entries, representing the influences from the corresponding non-leaf noise term.

We give a more formal way to derive the above result and make it clear how  $\mathbf{A}^{\text{NL}}$  and  $\mathbf{A}^L$  depend on  $\mathbf{B}$ . For any graph  $\tilde{G}$  there always exists a suitable permutation matrix, denoted by  $\Omega$ , such that the last  $l$  elements of the permuted variables  $\Omega\tilde{\mathbf{X}}$  are all leaf nodes. Hence,  $\Omega\tilde{\mathbf{E}} = \begin{bmatrix} \tilde{\mathbf{E}}^{\text{NL}} \\ \tilde{\mathbf{E}}^L \end{bmatrix}$ . Accordingly, (2) implies that

$$\Omega\tilde{\mathbf{X}} = \mathbf{B}_\Omega \cdot \Omega\tilde{\mathbf{X}} + \Omega\tilde{\mathbf{E}}, \quad (5)$$

where  $\mathbf{B}_\Omega = \Omega\mathbf{B}\Omega^\top$ . Since the last  $l$  variables in  $\Omega\tilde{\mathbf{X}}$  are leaf nodes, the last  $l$  columns of  $\mathbf{B}_\Omega$  are zero. Let  $\mathbf{B}_\Omega^{\text{NL}}$  be the causal influence matrix for the non-leaf nodes and  $\mathbf{B}_\Omega^L$  denote the causal influence from non-leaf nodes to leaf nodes. We have  $\mathbf{B}_\Omega = \begin{bmatrix} \mathbf{B}_\Omega^{\text{NL}} & \mathbf{0} \\ \mathbf{B}_\Omega^L & \mathbf{0} \end{bmatrix}$ . Consequently,

$$(\mathbf{I} - \mathbf{B}_\Omega)^{-1} = \begin{bmatrix} (\mathbf{I} - \mathbf{B}_\Omega^{\text{NL}})^{-1} & \mathbf{0} \\ \mathbf{B}_\Omega^L(\mathbf{I} - \mathbf{B}_\Omega^{\text{NL}})^{-1} & \mathbf{I} \end{bmatrix}. \quad (6)$$

Combining (5) and (6) gives

$$\begin{aligned} \tilde{\mathbf{X}} &= \Omega^\top(\mathbf{I} - \mathbf{B}_\Omega)^{-1}\Omega\tilde{\mathbf{E}} \\ &= \underbrace{\Omega^\top \cdot \begin{bmatrix} \mathbf{I} \\ \mathbf{B}_\Omega^L \end{bmatrix}}_{\mathbf{A}^{\text{NL}}} \cdot (\mathbf{I} - \mathbf{B}_\Omega^{\text{NL}})^{-1} \tilde{\mathbf{E}}^{\text{NL}} + \underbrace{\Omega^\top \begin{bmatrix} \mathbf{0} \\ \tilde{\mathbf{E}}^L \end{bmatrix}}_{\mathbf{A}^L\tilde{\mathbf{E}}^L}. \end{aligned}$$

Further consider the generating process of observed variables  $X_i$ . Combining (1) and (4) gives

$$\begin{aligned} \mathbf{X} &= \tilde{\mathbf{X}}^* + \mathbf{A}^L\tilde{\mathbf{E}}^L + \mathbf{E} = \mathbf{A}^{\text{NL}}\tilde{\mathbf{E}}^{\text{NL}} + (\mathbf{A}^L\tilde{\mathbf{E}}^L + \mathbf{E}) \\ &= \mathbf{A}^{\text{NL}}\tilde{\mathbf{E}}^{\text{NL}} + \mathbf{E}^* \\ &= \begin{bmatrix} \mathbf{A}^{\text{NL}} & \mathbf{I} \end{bmatrix} \cdot \begin{bmatrix} \tilde{\mathbf{E}}^{\text{NL}} \\ \mathbf{E}^* \end{bmatrix}, \end{aligned} \quad (7)$$

where  $\mathbf{E}^* = \mathbf{A}^L\tilde{\mathbf{E}}^L + \mathbf{E}$  and  $\mathbf{I}$  denotes the identity matrix. To make it more explicit, we give how  $\tilde{X}_i^*$  and  $E_i^*$  are related to the original CAMME process:

$$\tilde{X}_i^* = \begin{cases} \tilde{X}_i, & \text{if } \tilde{X}_i \text{ is not a leaf node in } \tilde{G}; \\ \tilde{X}_i - \tilde{E}_i, & \text{otherwise;} \end{cases}, \text{ and} \quad (9)$$

$$E_i^* = \begin{cases} E_i, & \text{if } \tilde{X}_i \text{ is not a leaf node in } \tilde{G}; \\ E_i + \tilde{E}_i, & \text{otherwise.} \end{cases}$$

Clearly  $E_i^*$ s are independent across  $i$ , and as we shall see in Section 4, the information shared by difference  $X_i$  is still captured by  $\tilde{\mathbf{X}}^*$ . For each CAMME specified by (2) and (1), there always exists an observationally equivalent representation in the form of (7). We call the representation (7) the canonical representation of the CAMME (CR-CAMME).

**Example Set 1** Consider the following example with three observed variables  $X_i$ ,  $i = 1, 2, 3$ , for which  $\tilde{X}_1 \rightarrow \tilde{X}_2 \leftarrow \tilde{X}_3$ , with causal relations  $\tilde{X}_2 = a\tilde{X}_1 + b\tilde{X}_3 + \tilde{E}_2$ . That is,

$$\mathbf{B} = \begin{bmatrix} 0 & 0 & 0 \\ a & 0 & b \\ 0 & 0 & 0 \end{bmatrix}, \text{ and } \mathbf{A} = \begin{bmatrix} 1 & 0 & 0 \\ a & 1 & b \\ 0 & 0 & 1 \end{bmatrix}.$$

Therefore,

$$\begin{aligned} \mathbf{X} &= \tilde{\mathbf{X}} + \mathbf{E} = \tilde{\mathbf{X}}^* + \mathbf{E}^* \\ &= \begin{bmatrix} 1 & 0 \\ a & b \\ 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} \tilde{E}_1 \\ \tilde{E}_3 \end{bmatrix} + \begin{bmatrix} E_1 \\ \tilde{E}_2 + E_2 \\ E_3 \end{bmatrix} \\ &= \begin{bmatrix} 1 & 0 & | & 1 & 0 & 0 \\ a & b & | & 0 & 1 & 0 \\ 0 & 1 & | & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} \tilde{E}_1 \\ \tilde{E}_3 \\ E_1 \\ \tilde{E}_2 + E_2 \\ E_3 \end{bmatrix}. \end{aligned}$$

In causal discovery from observations in the presence of measurement error, we aim to recover information of the measurement-error-free causal model  $\tilde{G}$ . Let us define a new graphical model,  $\tilde{G}^*$ . It is obtained by replacing variables  $\tilde{X}_i$  in  $\tilde{G}$  with variables  $\tilde{X}_i^*$ . In other words, it has the same causal structure and causal parameters (given by the  $\mathbf{B}$  matrix) as  $\tilde{G}$ , but with

variables  $\tilde{X}_i^*$  as its nodes. If we manage to estimate the structure of and the involved causal parameters in  $\tilde{G}^*$ , then the causal model of interest,  $\tilde{G}$ , is recovered. We defined the graphical model  $\tilde{G}^*$  because we cannot fully estimate the distribution of measurement-error-free variables  $\tilde{\mathbf{X}}$ , but might be able to estimate that of  $\tilde{\mathbf{X}}^*$  under proper assumptions, as shown in Section 4.

Compared to  $\tilde{G}$ ,  $\tilde{G}^*$  involves some deterministic causal relations because each leaf node is a deterministic function of its parents (the noise in leaf nodes has been removed; see (9)). For instance, suppose in  $\tilde{G}^*$ ,  $\text{PA}(\tilde{X}_3^*) = \{\tilde{X}_1^*, \tilde{X}_2^*\}$ , where  $\text{PA}(\tilde{X}_3^*)$  denotes the set of parents of  $\tilde{X}_3^*$  in  $\tilde{G}^*$ , and that  $\tilde{X}_3$  is a leaf node. Then each of  $\tilde{X}_1$ ,  $\tilde{X}_2$ , and  $\tilde{X}_3$  is a deterministic function of the remaining two. More generally, let  $\tilde{X}_l^*$  be a leaf node in the causal graph  $\tilde{G}^*$ ; then each of the variables in  $\{\tilde{X}_l^*\} \cup \text{PA}(\tilde{X}_l^*)$ , denoted by  $\tilde{X}_k^*$ , is a deterministic function of the remaining variables.

To make it possible to identify the structure of  $\tilde{G}$  from the distribution of  $\mathbf{X}$ , in what follows we assume the distribution of  $\tilde{\mathbf{X}}^*$  satisfies the following assumption.

A0. The causal Markov condition holds for  $\tilde{G}$  and the distribution of  $\tilde{X}_i$  is faithful w.r.t.  $\tilde{G}$ . Furthermore, the distribution of  $\tilde{X}_i^*$  is *non-deterministically faithful* w.r.t.  $\tilde{G}^*$ , in the sense that if there exists  $\mathbf{S}$ , a subset of  $\{\tilde{X}_k^* : k \neq i, k \neq j\}$ , such that neither of  $\tilde{X}_i^*$  and  $\tilde{X}_j^*$  is a deterministic function of  $\mathbf{S}$  and  $\tilde{X}_i^* \perp\!\!\!\perp \tilde{X}_j^* \mid \mathbf{S}$  holds, then  $\tilde{X}_i^*$  and  $\tilde{X}_j^*$  (or  $\tilde{X}_i$  and  $\tilde{X}_j$ ) are d-separated by  $\mathbf{S}$  in  $\tilde{G}^*$ .

This non-deterministically faithfulness assumption excludes a particular type of parameter coupling in the causal model for  $\tilde{X}_i$ . In Figure 4 we give a causal model in which the causal coefficients are carefully chosen so that this assumption is violated: because  $\tilde{X}_3^* = a\tilde{X}_1^* + b\tilde{X}_2^*$  and  $\tilde{X}_4^* = 2a\tilde{X}_1^* + 2b\tilde{X}_2^* + E_4^*$ , we have  $\tilde{X}_4^* = 2\tilde{X}_3^* + E_4^*$ , implying  $\tilde{X}_4^* \perp\!\!\!\perp \tilde{X}_1^* \mid \tilde{X}_3^*$  and  $\tilde{X}_4^* \perp\!\!\!\perp \tilde{X}_2^* \mid \tilde{X}_3^*$ , which are not given by the causal Markov condition on  $\tilde{G}$ . We note that this non-deterministic faithfulness is defined for the distribution of the constructed variables  $\tilde{X}_i^*$ , not the measurement-error-free variables  $\tilde{X}_i$ . (Bear in mind their relationship given in (9).) This assumption is generally stronger than the faithfulness assumption for the distribution of  $\tilde{X}_i$ . In particular, in the causal model given in Figure 4, the distribution of  $\tilde{X}_i$  is still faithful w.r.t.  $\tilde{G}$ . Below we call the conditional independence relationship between  $\tilde{X}_i^*$  and  $\tilde{X}_j^*$  given  $\mathbf{S}$  where neither of  $\tilde{X}_i^*$  and  $\tilde{X}_j^*$  is a deterministic function of  $\mathbf{S}$  *non-deterministic conditional independence*.

Now we have two concerns. One is whether essential information of the CR-CAMME is identifiable from

Figure 4: A specification of the causal model  $\tilde{G}$  in which  $\tilde{X}_i^*$  are not *non-deterministically faithful* w.r.t.  $\tilde{G}$  because of parameter coupling.

observed values of  $\mathbf{X}$ . The other is what information of the original CAMME, in particular, the causal model over  $\tilde{X}_i$ , can be estimated from the above identifiable information of the CR-CAMME. Although the transformation from the original CAMME to a CR-CAMME is straightforward, without further knowledge there does not necessarily exist a unique CAMME corresponding to a given CR-CAMME: first, the CR-CAMME does not tell us which nodes  $\tilde{X}_i$  are leaf nodes in  $\tilde{G}$ ; second, even if  $\tilde{X}_i$  is known to be a leaf node, it is impossible to separate the measurement error  $E_i$  from the noise  $\tilde{E}_i$  in  $E_i^*$ . Fortunately, we are not interested in everything of the original CAMME, but only the causal graph  $\tilde{G}$  and the corresponding causal influences  $\mathbf{B}$ . Accordingly, in the next section we will explore what information of the CR-CAMME is identifiable from the observations of  $\mathbf{X}$  and how to further reconstruct necessary information of the original CAMME.

In the measurement error model (1) we assumed that each observed variable  $X_i$  is generated from its own latent variable  $\tilde{X}_i$ . We note that in case multiple observed variables are generated from a single latent variable or a single observed variable is generated by multiple latent variables (see, e.g., Silva et al. (2006)), we can still use the CR-CAMME to represent the process. In the former case, certain rows of  $\mathbf{A}^{\text{NL}}$  are identical. For instance, if  $X_1$  and  $X_2$  are generated as noisy observations of the same latent variable, then in (7) the first two rows of  $\mathbf{A}_{\text{NL}}$  are identical. (More generally, if one allows different coefficients to generate them from the latent variable, the two rows are proportional to each other.) Let us then consider an example in the latter case. Suppose  $X_3$  is generated by latent variables  $\tilde{X}_1$  and  $\tilde{X}_2$ , for each of which there is also an observable counterpart. Write the causal model as  $X_3 = f(\tilde{X}_1, \tilde{X}_2) + E_3$  and introduce the latent variable  $\tilde{X}_3 = f(\tilde{X}_1, \tilde{X}_2)$ , and then we have  $X_3 = \tilde{X}_3 + E_3$ . The CR-CAMME formulation then follows.

#### 4 IDENTIFIABILITY IN THE LINEAR, NON-GAUSSIAN CASE

The CR-CAMME (7) has a form of the factor analysis model (FA) (Everitt, 1984), which has been a funda-

mental tool in data analysis. Accordingly, one can study the identifiability for CAMME by making use of the identifiability of FA, as reported by Zhang et al. (2017). The identifiability of FA, however, relies heavily on the assumption that there are a relatively large number of leaf variables in the causal graph  $\tilde{G}$  (Bekker & ten Berge, 1997), which seems rather strong. Moreover, it has been shown that second-order statistics usually is not informative enough to recover a unique causal model (Spirtes et al., 2001). Interestingly, we show that the identifiability results can greatly benefit from the non-Gaussianity assumption on the data. In this paper we make the following assumption on the distribution of  $\tilde{E}_i$ :

A1. All  $\tilde{E}_i$  are non-Gaussian.

We note that under the above assumption,  $\mathbf{A}^{\text{NL}}$  in (8) can be estimated up to the permutation and scaling indeterminacies (including the sign indeterminacy) of the columns, as given in the following lemma. This can be achieved by using overcomplete Independent Component Analysis (ICA) (Hyvärinen et al., 2001).

**Lemma 1.** *Suppose assumption A1 holds. Given  $\mathbf{X}$  which is generated according to (8),  $\mathbf{A}^{\text{NL}}$  is identifiable up to permutation and scaling of columns as the sample size  $N \rightarrow \infty$ .*

*Proof.* This lemma is implied by Theorem 10.3.1 in (Kagan et al., 1973) or Theorem 1 in (Eriksson & Koivunen, 2004).  $\square$

What information of the causal structure  $\tilde{G}$  can we recover? Can we apply existing methods for causal discovery based on LiNGAM, such as ICA-LiNGAM (Shimizu et al., 2006) and Direct-LiNGAM (Shimizu et al., 2011b), to recover it? LiNGAM assumes that the system is non-deterministic: each variable is generated as a linear combination of its direct causes plus a non-degenerate noise term. As a consequence, the linear transformation from the vector of observed variables to the vector of independent noise terms is a square matrix; ICA-LiNGAM applies certain operations to this matrix to find the causal model, and Direct-LiNGAM estimates the causal ordering by enforcing the property that the residual of regressing the effect on the root cause is always independent from the root cause.

In our case,  $\mathbf{A}^{\text{NL}}$ , the essential part of the mixing matrix in (8), is  $n \times r$ , where  $r < n$ . In other words, for some of the variables  $\tilde{X}_i^*$ , the causal relations are deterministic. (In fact, if  $\tilde{X}_k$  is a leaf node in  $\tilde{G}$ ,  $\tilde{X}_k^*$  is a deterministic function of  $\tilde{X}_k$ 's direct causes.) As a consequence, unfortunately, the above causal analysis methods based on LiNGAM, including ICA-LiNGAM

and Direct-LiNGAM, do not apply. We will see how to recover information of  $\tilde{G}$  by analyzing the estimated  $\mathbf{A}^{\text{NL}}$ .

We will show that some group structure and the group-wise causal ordering in  $\tilde{G}$  can always be recovered. Before presenting the results, let us define the following ordered group decomposition according to causal structure  $\tilde{G}$ .

**Definition 2 (ordered group decomposition).** *Consider the causal model  $\tilde{G}^*$ . Decompose all involved nodes into disjoint groups in the following way. First put all leaf nodes which share the same direct-and-only-direct cause in the same group; further incorporate the corresponding direct-and-only-direct cause in the same group. Here we say a node  $\tilde{X}_i^*$  is the "direct-and-only-direct" cause of  $\tilde{X}_j^*$  if and only if  $\tilde{X}_i^*$  is a direct cause of  $\tilde{X}_j^*$  and there is no other directed path from  $\tilde{X}_i^*$  to  $\tilde{X}_j^*$ . After forming all groups each of which involves at least one leaf node, each of the remaining nodes forms a separate group. **Each node is guaranteed to be in one and only one group.** We call the set of all such groups ordered according to the causal ordering of the non-leaf nodes in DAG  $\tilde{G}^*$  an ordered group decomposition of  $\tilde{G}^*$ , denoted by  $\mathcal{G}_{\tilde{G}^*}$ .*

Figure 5: A set of causal DAGs  $\tilde{G}$  as illustrative examples. (a) DAG  $\tilde{G}_A$ . (b)  $\tilde{G}_B$ . (c) Two DAGs  $\tilde{G}_C$  and  $\tilde{G}_D$ . (d)  $\tilde{G}_E$ .

**Example Set 2** As seen from the process of ordered group decomposition, each non-leaf node is in one and only one ordered group, and it is possible for multiple leaf nodes to be in the same group. Therefore, in total there are  $(n - l)$  ordered groups. For example, for  $\tilde{G}_A$  given in Figure 5(a), a corresponding group structure for the corresponding  $\tilde{G}^*$  is  $\mathcal{G}_{\tilde{G}_A^*} = (\{\tilde{X}_1^*\} \rightarrow \{\tilde{X}_2^*, \tilde{X}_5^*\} \rightarrow \{\tilde{X}_3^*, \tilde{X}_6^*\} \rightarrow \{\tilde{X}_4^*, \tilde{X}_7^*, \tilde{X}_8^*\})$ , and for  $\tilde{G}_B$  in Figure 5(b), there is only one group:

$\mathcal{G}_{\tilde{G}_B^*} = (\{\tilde{X}_1^*, \tilde{X}_2^*, \tilde{X}_3^*, \tilde{X}_4^*\})$ . For both  $\tilde{G}_C$  and  $\tilde{G}_D$ , given in Figure 5(c), an ordered group decomposition is  $(\{\tilde{X}_1^*\} \rightarrow \{\tilde{X}_2^*, \tilde{X}_3^*\} \rightarrow \{\tilde{X}_4^*\} \rightarrow \{\tilde{X}_5^*, \tilde{X}_6^*\})$ .

Note that the causal ordering and the ordered group decomposition of given variables according to the graphical model  $\tilde{G}^*$  may not be unique (this will actually give rise to the possibility of distinguishing between the non-leaf and leaf node in the group, as shown next). For instance, if  $\tilde{G}^*$  has only two variables  $\tilde{X}_1^*$  and  $\tilde{X}_2^*$  which are not adjacent, both decompositions  $(\{\tilde{X}_1^*\} \rightarrow \{\tilde{X}_2^*\})$  and  $(\{\tilde{X}_2^*\} \rightarrow \{\tilde{X}_1^*\})$  are correct. Consider  $\tilde{G}^*$  over three variables,  $\tilde{X}_1^*, \tilde{X}_2^*, \tilde{X}_3^*$ , where  $\tilde{X}_1^*$  and  $\tilde{X}_2^*$  are not adjacent and are both causes of  $\tilde{X}_3^*$ ; then both  $(\{\tilde{X}_1^*\} \rightarrow \{\tilde{X}_2^*, \tilde{X}_3^*\})$  and  $(\{\tilde{X}_2^*\} \rightarrow \{\tilde{X}_1^*, \tilde{X}_3^*\})$  are valid ordered group decompositions.

We first present a procedure to construct the ordered group decomposition and the causal ordering among the groups from the estimated  $\mathbf{A}^{\text{NL}}$ . We will further show that the recovered ordered group decomposition is always asymptotically correct under assumption A1.

#### 4.1 Construction and Identifiability of ordered Group Decomposition

First of all, Lemma 1 tells us that  $\hat{\mathbf{A}}^{\text{NL}}$  in (8) is identifiable up to permutation and scaling columns. Let us start with the asymptotic case, where the columns of the estimated  $\mathbf{A}^{\text{NL}}$  from values of  $X_i$  are a permuted and rescaled version of the columns of  $\mathbf{A}^{\text{NL}}$ . In what follows the permutation and rescaling of the columns of  $\mathbf{A}^{\text{NL}}$  does not change the result, so below we just work with the true  $\mathbf{A}^{\text{NL}}$ , instead of its estimate.

$\tilde{X}_i^*$  and  $\tilde{X}_i$  follow the same causal DAG,  $\tilde{G}$ , and  $\tilde{X}_i^*$  are causally sufficient, although some variables among them (corresponding to leaf nodes in  $\tilde{G}^*$ ) are determined by their direct causes. Let us find the causal ordering of  $\tilde{X}_i^*$ . If there are no deterministic relations and the values of  $\tilde{X}_i^*$  are given, the causal ordering can be estimated by recursively performing regression and checking independence between the regression residual and the predictor (Shimizu et al., 2011b). Specifically, if one regresses all the remaining variables on the root cause, the residuals are always independent from the predictor (the root cause). After detecting a root cause, the residuals of regressing all the other variables on the discovered root cause are still causally sufficient and follow a DAG. One can repeat the above procedure to find a new root cause over such regression residuals, until no variable is left.

However, in our case we have access to  $\mathbf{A}^{\text{NL}}$  but not the values of  $\tilde{X}_i^*$ . Fortunately, the independence between regression residuals and the predictor can still be checked by analyzing  $\mathbf{A}^{\text{NL}}$ . Recall that  $\tilde{\mathbf{X}}^* = \mathbf{A}^{\text{NL}} \tilde{\mathbf{E}}^{\text{NL}}$ ,

where the components of  $\tilde{\mathbf{E}}^{\text{NL}}$  are independent. Without loss of generality, here we assume that all components of  $\tilde{\mathbf{E}}^{\text{NL}}$  are standardized, i.e., they have a zero mean and unit variance. Denote by  $\mathbf{A}_{i \cdot}^{\text{NL}}$  the  $i$ th row of  $\mathbf{A}^{\text{NL}}$ . We have  $\mathbb{E}[\tilde{X}_j^* \tilde{X}_i^*] = \mathbf{A}_{j \cdot}^{\text{NL}} \mathbf{A}_{i \cdot}^{\text{NL}\top}$  and  $\mathbb{E}[\tilde{X}_i^{*2}] = \mathbf{A}_{i \cdot}^{\text{NL}} \mathbf{A}_{i \cdot}^{\text{NL}\top} = \|\mathbf{A}_{i \cdot}^{\text{NL}}\|^2$ . The regression model for  $\tilde{X}_j^*$  on  $\tilde{X}_i^*$  is

$$\tilde{X}_j^* = \frac{\mathbb{E}[\tilde{X}_j^* \tilde{X}_i^*]}{\mathbb{E}[\tilde{X}_i^{*2}]} \tilde{X}_i^* + R_{j \leftarrow i} = \frac{\mathbf{A}_{j \cdot}^{\text{NL}} \mathbf{A}_{i \cdot}^{\text{NL}\top}}{\|\mathbf{A}_{i \cdot}^{\text{NL}}\|^2} \tilde{X}_i^* + R_{j \leftarrow i}.$$

Here the residual can be written as

$$\begin{aligned} R_{j \leftarrow i} &= \tilde{X}_j^* - \frac{\mathbf{A}_{j \cdot}^{\text{NL}} \mathbf{A}_{i \cdot}^{\text{NL}\top}}{\|\mathbf{A}_{i \cdot}^{\text{NL}}\|^2} \tilde{X}_i^* \\ &= \underbrace{\left( \mathbf{A}_{j \cdot}^{\text{NL}} - \frac{\mathbf{A}_{j \cdot}^{\text{NL}} \mathbf{A}_{i \cdot}^{\text{NL}\top} \mathbf{A}_{i \cdot}^{\text{NL}}}{\|\mathbf{A}_{i \cdot}^{\text{NL}}\|^2} \right)}_{\triangleq \alpha_{j \leftarrow i}} \tilde{\mathbf{E}}^{\text{NL}}. \end{aligned} \quad (10)$$

If for all  $j$ ,  $R_{j \leftarrow i}$  is either zero or independent from  $\tilde{X}_i^*$ , we consider  $\tilde{X}_i^*$  as the current root cause and put it and all the other variables which are deterministically related to it in the first group, which is a *root cause group*. Now the problem is whether we can check for independence between nonzero residuals  $R_{j \leftarrow i}$  and the predictor  $\tilde{X}_i^*$ . Interestingly, the answer is yes, as stated in the following proposition.

**Proposition 3.** *Suppose assumption A1 holds. For variables  $\tilde{\mathbf{X}}^*$  generated by (7), regression residual  $R_{j \leftarrow i}$  given in (10) is independent from variable  $\tilde{X}_i^*$  if and only if*

$$\left\| \alpha_{j \leftarrow i} \circ \mathbf{A}_{i \cdot}^{\text{NL}} \right\|_2 = 0, \quad (11)$$

where  $\circ$  denotes entrywise product.

So we can check for independence between the predictor and regression residual as if the values of  $\tilde{\mathbf{X}}^*$  were given. Consequently, we can find the root cause group.

We then consider the residuals of regressing all the remaining variables  $\tilde{X}_k^*$  on the discovered root cause as a new set of variables. Note that like the variables  $\tilde{X}_j^*$ , these variables are again linear mixtures of  $\tilde{E}_i$ . Repeating the above procedure on this new set of variables will give the second root cause and its ordered group. Applying this procedure repeatedly until no variable is left finally discovers all ordered groups following the causal ordering. The constructed ordered group decomposition is asymptotically correct, as stated in the following proposition. We denote by **OICA+Reg** the above two-stage procedure: we first apply overcomplete ICA to find an estimate of  $\mathbf{A}^{\text{NL}}$ , and then do regression and check for independence between the residuals and the current candidate root cause by analyzing  $\mathbf{A}^{\text{NL}}$ .

**Proposition 4. (Identifiable ordered group decomposition)** Let  $X_i$  be generated by the CAMME with the corresponding measurement-error-free variables generated by the causal DAG  $\tilde{G}$  and suppose assumptions A0 and A1 hold. The ordered group decomposition constructed by the above procedure is asymptotically correct, in the sense that as the sample size  $N \rightarrow \infty$ , if non-leaf node  $\tilde{X}_i$  is a cause of non-leaf node  $\tilde{X}_j$ , then the ordered group which  $\tilde{X}_i$  is in precedes the group which  $\tilde{X}_j$  belongs to. However, the causal ordering among the nodes within the same ordered group may not be identifiable.

The result of Proposition 4 applies to any DAG structure  $\tilde{G}$ . Clearly, the identifiability can be naturally improved if additional assumptions on the causal structure  $\tilde{G}$  hold. In particular, to recover information of  $\tilde{G}$ , it is essential to answer the following questions.

- Can we determine which nodes in an ordered group are leaf nodes?
- Can we find the causal edges into a particular node?

Below we will show that under rather mild assumptions, the answers to both questions are yes.

## 4.2 Identifying Leaf Nodes and Individual Causal Edges

If for each ordered group we can determine which variable is the non-leaf node, the causal ordering among the variables  $\tilde{X}_i^*$  is then fully known. The causal structure in  $\tilde{G}^*$  as well as the causal model can then be readily estimated by regression: for a leaf node, its direct causes are those non-leaf nodes that determine it; for a non-leaf node, we can regress it on all non-leaf nodes that precede it according to the causal ordering, and those predictors with non-zero linear coefficients are its parents. This way the structure can be estimated uniquely under Assumption A0, although whether the causal parameters in the causal model are uniquely identifiable is another issue for investigation.

Now the goal is to see whether it is possible to find out which variables in a given ordered group are leaf nodes; if all leaf nodes are found, then the remaining one is the (only) non-leaf node in the considered ordered group. Below we will show that it is possible to find leaf nodes by “looking backward” or “looking forward”; the former makes use of the parents of the variables in the considered group, and the latter exploits the fact leaf nodes do not have any child.

**Proposition 5. (Leaf node determination by “looking backward”)** Suppose the observed data were

generated by the CAMME where Assumptions A0 and A1 hold.<sup>1</sup> Let the sample size  $N \rightarrow \infty$ . Then if assumption A2 holds, leaf node  $O$  is correctly identified from observations of  $\mathbf{X}$  (more specifically, from the estimated  $\mathbf{A}^{\text{NL}}$  or the distribution of  $\tilde{\mathbf{X}}^*$ ).

A2. According to  $\tilde{G}^*$ , for leaf node  $O$  in the considered ordered group  $g^{(k)}$ , at least one of its parents is not a parent of the non-leaf node in  $g^{(k)}$  or some other leaf node in  $g^{(k)}$ .

**Example Set 3** Suppose Assumptions A0 and A1 hold.

- For  $\tilde{G}_A$  in Figure 5(a), assumption A2 holds for  $\tilde{X}_7^*$  and  $\tilde{X}_8^*$  in the ordered group  $\{\tilde{X}_4^*, \tilde{X}_7^*, \tilde{X}_8^*\}$ : each of them has a parent which is not a parent of the other; so both of them are identified to be leaf nodes from the estimated  $\mathbf{A}^{\text{NL}}$  or the distribution of  $\tilde{\mathbf{X}}^*$ , and  $\tilde{X}_4^*$  can then be determined as a non-leaf node.
- For  $\tilde{G}_B$ , we cannot detect which node is a leaf node or a non-leaf node.
- For both  $\tilde{G}_C$  and  $\tilde{G}_D$  in Figure 5(c),  $\tilde{X}_6^*$ , in the ordered group  $\{\tilde{X}_5^*, \tilde{X}_6^*\}$ , follows assumption A2 and can be found to be a leaf node from the matrix  $\mathbf{A}^{\text{NL}}$ ; accordingly,  $\tilde{X}_5^*$  has to be a non-leaf node.
- For  $\tilde{G}_E$  in Figure 5(d), assumption A2 holds for all leaf nodes,  $\tilde{X}_4^*$ ,  $\tilde{X}_5^*$ , and  $\tilde{X}_8^*$ , which can then be found to be leaf nodes.

We can also determine leaf nodes by looking at the relationships between the considered variables and the variables causally following them, as stated in the following proposition.

**Proposition 6. (Leaf node determination by “looking forward”)** Suppose the observed data were generated by the CAMME where Assumptions A0 and A1 hold. Then as the sample size  $N \rightarrow \infty$ , we can correctly identify the leaf node  $U$  in the considered ordered group  $g^{(k)}$  from values of  $\mathbf{X}$  if assumption A3 holds for it:

A3. For leaf node  $U$  in  $g^{(k)}$ , there exists at least one node causally following  $g^{(k)}$  that 1) is  $d$ -separated from  $U$  by a subset of variables in  $g^{(1)} \cup g^{(2)} \dots \cup g^{(k)} \setminus \{U\}$  which does not include all parents of  $U$  and 2) is a child of the non-leaf node in  $g^{(k)}$ .

<sup>1</sup>In this non-Gaussian case (implied by assumption A1), the result reported in this proposition may still hold if one avoids the non-deterministic faithfulness assumption and assumes a weaker condition; however, for simplicity of the proof we currently still assume non-deterministic faithfulness.

**Example Set 4** Let Assumptions A0 and A1 hold.

- For data generated by  $\tilde{G}_A$  in Figure 5(a), we already found  $\tilde{X}_4^*$  in ordered group  $\{\tilde{X}_4^*, \tilde{X}_7^*, \tilde{X}_8^*\}$  to be a non-leaf node because of Proposition 5. Proposition 6 further indicates that  $\tilde{X}_2^*$  (in group  $\{\tilde{X}_2^*, \tilde{X}_5^*\}$ ) and  $\tilde{X}_3^*$  (in group  $\{\tilde{X}_3^*, \tilde{X}_6^*\}$ ) are non-leaf nodes, and all leaf nodes are identified.
- For  $\tilde{G}_B$  in Figure 5(b), there is only one ordered group, and it does not provide further information by looking "backward" or "forward", and it is impossible to find the non-leaf node with Proposition 5 or 6.
- For both  $\tilde{G}_C$  and  $\tilde{G}_D$  in Figure 5(c),  $\tilde{X}_6^*$  was found to be a leaf node due to Proposition 5; thanks to Proposition 6, the other leaf node,  $\tilde{X}_3^*$ , was also detected. In particular, in  $\tilde{G}_C$ , for leaf node  $\tilde{X}_3^*$  both  $\tilde{X}_4^*$  and  $\tilde{X}_6^*$  satisfy the two conditions in Assumption A3; however, in  $\tilde{G}_D$ , for leaf node  $\tilde{X}_3^*$  only  $\tilde{X}_4^*$  satisfies them. All leaf nodes were successfully found.
- For  $\tilde{G}_E$  in Figure 5(d), Proposition 5 already allows us to identify all leaf nodes,  $\tilde{X}_4^*$ ,  $\tilde{X}_5^*$ , and  $\tilde{X}_8^*$ . The assumptions in Propositions 5 and 6 are not exclusive: Assumption A3 also holds for  $\tilde{X}_4^*$  (for it  $\tilde{X}_7^*$  satisfies the two conditions), we can alternatively identify this leaf node by making use of Proposition 6.

For contaminated data generated by any of  $\tilde{G}_A$ ,  $\tilde{G}_C$ ,  $\tilde{G}_D$ , and  $\tilde{G}_E$ , now we can find all leaf nodes in the measurement-error-free causal model. One can then immediately estimate the whole structure of the measurement-error-free model.

The above two propositions are about the identifiability of leaf nodes in the measurement-error-free causal model. By applying them to all leaf nodes, we have (sufficient) conditions under which the causal graph of  $\tilde{G}$  is fully identifiable.

**Proposition 7. (Full identifiability)** *Suppose the observed data were generated by the CAMME where Assumptions A0 and A1 hold. Assume that for each leaf node in  $\tilde{G}^*$ , at least one of the two assumptions, A2 and A3, holds. Then as the sample size  $N \rightarrow \infty$ , the causal structure  $\tilde{G}$  is fully identifiable from the observations with random measurement error.*

In the general case, the causal structure  $\tilde{G}$  might not be fully identifiable, and the above propositions may allow partial identifiability of the underlying causal structure. Roughly speaking, the ordered group decomposition is identifiable in the non-Gaussian case; with Propositions 5 and 6 one can further identify some leaf nodes as well as their parents.

## 5 CONCLUSION AND DISCUSSIONS

The measured values of variables of interest in various fields, including the social sciences, neuroscience, and biology, are often contaminated by measurement error. Unfortunately, the output of existing causal discovery methods is sensitive to the existence of measurement error, and it is desirable to develop causal discovery methods that can estimate the causal model for the measurement-error-free variables without using much prior knowledge about the measurement error. To this end, this paper investigates identifiability conditions for the underlying measurement-error-free causal structure given contaminated observations. We have shown that under appropriate conditions, the causal structure of interest is partially or even fully identifiable.

We formulated four assumptions. Assumption A0 is about the Markov condition and non-deterministic faithfulness assumption for causal model  $\tilde{G}^*$ . Assumption A1 is about the distribution of the underlying noise terms in the causal process. The remaining two are about particular types of "sparsity" of the underlying causal graph. We note that in principle, all assumptions except A0 are testable from the observed data. This suggests that it is possible to develop practical causal discovery methods to deal with measurement error that are able to produce reliable information at least in the asymptotic case. In addition, it is worth noting that some involved assumptions may be weakened. For instance, faithfulness is not required to find the correct ordered group decomposition, but just needed for detecting leaf nodes in the ordered groups. Suppose Assumptions A0 and A1 hold; we conjecture that the necessary and sufficient condition for the non-leaf node to be identifiable is that at least one of the two assumptions, A2 and A3, holds. To falsify or prove this conjecture is part of our future work.

It is worth noting that various kinds of background knowledge of the causal model may further help improve the identifiability of the measurement-error-free causal model. For instance, if one knows that all causal coefficients are smaller than one in absolute value, then the measurement-error-free causal model in Figure 5(b) is immediately identifiable from contaminated data. Our future research further includes 1) establishing identifiability conditions that allow cycles in the measurement-error-free causal model in light of ubiquity of cycles in causal models, 2) developing computationally efficient algorithms for causal discovery under measurement error based on the established theory, and 3) proposing efficient methods for particular cases where each measurement-error-free variable has multiple measured effects or multiplied measurement-error-free variables generate a single measured effect.
