

# UNCERTAINTY IN ARTIFICIAL INTELLIGENCE

# Uncertainty in Artificial Intelligence

Proceedings of the Thirty-Fourth Conference (2018)

August 6-10, 2018, Monterey, California, USA

**Edited by**

Amir Globerson, Google Inc. and Tel Aviv University  
Ricardo Silva, University College London and The Alan Turing  
Institute

**General Chairs**

Gal Elidan, Google Inc. and The Hebrew University, Israel  
Kristian Kersting, TU Darmstadt, Germany

**Sponsored by**

Google Inc., Microsoft Research, Uber, Disney Research, Berg  
Health, Artificial Intelligence Journal, The Alan Turing Institute,  
Facebook, Noodle.ai

**AUAI Press Corvallis, Oregon**

<b>1 Proceedings</b>	<b>1</b>
Testing for Conditional Mean Independence with Covariates through Martingale Difference Divergence. <i>Ze Jin, Xiaohan Yan, David S. Matteson</i> . . . . .	1
Analysis of Thompson Sampling for Graphical Bandits Without the Graphs. <i>Fang Liu, Zizhan Zheng, Ness Shroff</i> . . . . .	13
Structured nonlinear variable selection. <i>Magda Gregorova, Alexandros Kalousis, Stephane Marchand-Maillet</i> . . . . .	23
Identification of Strong Edges in AMP Chain Graphs. <i>Jose M. Peña</i> . . . . .	33
A Univariate Bound of Area Under ROC. <i>Siwei Lyu, Yiming Ying</i> . . . . .	43
Efficient Bayesian Inference for a Gaussian Process Density Model. <i>Christian Donner, Manfred Opper</i> . . . . .	53
Comparing Direct and Indirect Temporal-Difference Methods for Estimating the Variance of the Return. <i>Craig Sherstan, Dylan R. Ashley, Brendan Bennett, Kenny Young, Adam White, Martha White, Richard S. Sutton</i> . . . . .	63
How well does your sampler really work? <i>Ryan Turner, Brady Neal</i> . . . . .	73
Learning Deep Hidden Nonlinear Dynamics from Aggregate Data. <i>Yisen Wang, Bo Dai, Lingkai Kong, Sarah Monazam Erfani, James Bailey, Hongyuan Zha</i>	83
Revisiting differentially private linear regression: optimal and adaptive prediction & estimation in unbounded domain. <i>Yu-Xiang Wang</i> . . . . .	93
Imaginary Kinematics. <i>Sabina Marchetti, Alessandro Antonucci</i> . . . . .	104
From Deterministic ODEs to Dynamic Structural Causal Models. <i>Paul K. Rubenstein, Stephan Bongers, Joris M. Mooij, Bernhard Schölkopf</i> . . . . .	114
Frank-Wolfe Optimization for Symmetric-NMF under Simplicial Constraint. <i>Han Zhao, Geoff Gordon</i> . . . . .	124

Learning Time Series Segmentation Models from Temporally Imprecise Labels. <i>Roy Adams, Benjamin M. Marlin</i> . . . . .	135
Multi-Target Optimisation via Bayesian Optimisation and Linear Programming. <i>Alistair Shilton, Santu Rana, Sunil Gupta, Svetha Venkatesh</i> . . . . .	145
Stochastic Learning for Sparse Discrete Markov Random Fields with Controlled Gradient Approximation Error. <i>Sinong Geng, Zhaobin Kuang, Jie Liu, Stephen Wright, David Page</i> . . . . .	156
Active Information Acquisition for Linear Optimization. <i>Shuran Zheng, Bo Waggoner, Yang Liu, Yiling Chen</i> . . . . .	167
Transferable Meta Learning Across Domains. <i>Bingyi Kang, Jiashi Feng</i> . . . . .	177
Learning the Causal Structure of Copula Models with Latent Variables. <i>Ruifei Cui, Perry Groot, Moritz Schauer, Tom Heskes</i> . . . . .	188
$f_{BGD}$ : Learning Embeddings From Positive Unlabeled Data with BGD. <i>Fajie YUAN, Xin Xin, Xiangnan He, Guibing Guo, Weinan Zhang, CHUA Tat-Seng, Joemon Jose</i> . . . . .	198
Soft-Robust Actor-Critic Policy-Gradient. <i>Esther Derman, Daniel J Mankowitz, Timothy A Mann, Shie Mannor</i> . . . . .	208
Constant Step Size Stochastic Gradient Descent for Probabilistic Modeling. <i>Dmitry Babichev, Francis Bach</i> . . . . .	219
Discrete Sampling using Semigradient-based Product Mixtures. <i>Alkis Gotovos, Hamed Hassani, Andreas Krause, Stefanie Jegelka</i> . . . . .	229
Combining Knowledge and Reasoning through Probabilistic Soft Logic for Image Puzzle Solving. <i>Somak Aditya, Yezhou Yang, Chitta Baral, Yiannis Aloimonos</i> . . . . .	238
Nesting Probabilistic Programs. <i>Tom Rainforth</i> . . . . .	249
Scalable Algorithms for Learning High-Dimensional Linear Mixed Models. <i>Zilong Tan, Kimberly Roche, Xiang Zhou, Sayan Mukherjee</i> . . . . .	259
Constraint-based Causal Discovery for Non-Linear Structural Causal Models with Cycles and Latent Confounders. <i>Patrick Forré, Joris M. Mooij</i> . . . . .	269
Marginal Weighted Maximum Log-likelihood for Efficient Learning of Perturb-and-Map models. <i>Tatiana Shpakova, Francis Bach, Anton Osokin</i> . . . . .	279
Variational Inference for Gaussian Processes with Panel Count Data. <i>Hongyi Ding, Young Lee, Issei Sato, Masashi Sugiyama</i> . . . . .	290
A unified probabilistic model for learning latent factors and their connectivities from high- dimensional data. <i>Ricardo Pio Monti, Aapo Hyvarinen</i> . . . . .	300
Improved Stochastic Trace Estimation using Mutually Unbiased Bases. <i>Jack Fitzsimons, Michael Osborne, Stephen Roberts, Joseph Fitzsimons</i> . . . . .	310
Unsupervised Multi-view Nonlinear Graph Embedding. <i>Jiaming Huang, Zhao Li, Vincent W. Zheng, Wen Wen, Yifan Yang, Yuanmi Chen</i> . . . . .	319
Graph-based Clustering under Differential Privacy. <i>Rafael Pinot, Anne Morvan, Florian Yger, Cedric Gouy-Pailler, Jamal Atif</i> . . . . .	329
GaAN: Gated Attention Networks for Learning on Large and Spatiotemporal Graphs. <i>Jiani Zhang, Xingjian Shi, Junyuan Xie, Hao Ma, Irwin King, Dit-yan Yeung</i> . . . . .	339
Causal Learning for Partially Observed Stochastic Dynamical Systems. <i>Søren Wengel Mogensen, Daniel Malinsky, Niels Richard Hansen</i> . . . . .	350
Variational zero-inflated Gaussian processes with sparse kernels. <i>Pashupati Hegde, Markus Heinonen, Samuel Kaski</i> . . . . .	361
KBIn: End-to-End Learning of Knowledge Base Representations with Latent, Relational, and Numerical Features. <i>Alberto Garcia-Duran, Mathias Niepert</i> . . . . .	372
Probabilistic AND-OR Attribute Grouping for Zero-Shot Learning. <i>Yuval Atzmon, Gal Chechik</i> . . . . .	382

Sylvester Normalizing Flows for Variational Inference. <i>Rianne van den Berg, Leonard Hasenclever, Jakub Tomczak, Max Welling</i> . . . . .	393
Holistic Representations for Memorization and Inference. <i>Yunpu Ma, Marcel Hildebrandt, Volker Tresp, Stephan Baier</i> . . . . .	403
Simple and practical algorithms for $\ell_p$ -norm low-rank approximation. <i>Anastasios Kyrillidis</i> . . . . .	414
Quantile-Regret Minimisation in Infinitely Many-Armed Bandits. <i>Arghya Roy Chaudhuri, Shivaram Kalyanakrishnan</i> . . . . .	425
Variational Inference for Gaussian Process Models for Survival Analysis. <i>Minyoung Kim, Vladimir Pavlovic</i> . . . . .	435
A Cost-Effective Framework for Preference Elicitation and Aggregation. <i>Zhibing Zhao, Haoming Li, Junming Wang, Jeffrey O. Kephart, Nicholas Mattei, Hui Su, Lirong Xia</i> . . . . .	446
Incremental Learning-to-Learn with Statistical Guarantees. <i>Giulia Denevi, Carlo Ciliberto, Dimitris Stamos, Massimiliano Pontil</i> . . . . .	457
Bandits with Side Observations: Bounded vs. Logarithmic Regret. <i>Rmy Degenne, Evrard Garcelon, Vianney Perchet</i> . . . . .	467
Sampling and Inference for Beta Neutral-to-the-Left Models of Sparse Networks. <i>Benjamin Bloem-Reddy, Adam Foster, Emile Mathieu, Yee Whye Teh</i> . . . . .	477
Clustered Fused Graphical Lasso. <i>Yizhi Zhu, Oluwasanmi Koyejo</i> . . . . .	487
Unsupervised Learning of Latent Physical Properties Using Perception-Prediction Networks. <i>David Zheng, Vinson Luo, Jiajun Wu, Joshua Tenenbaum</i> . . . . .	497
Subsampled Stochastic Variance-Reduced Gradient Langevin Dynamics. <i>Difan Zou, Pan Xu, Quanquan Gu</i> . . . . .	508
Finite-State Controllers of POMDPs using Parameter Synthesis. <i>Sebastian Junges, Nils Jansen, Ralf Wimmer, Tim Quatmann, Leonore Winterer, Joost-Pieter Katoen, Bernd Becker</i> . . . . .	519
Identification of Personalized Effects Associated With Causal Pathways. <i>Ilya Shpitser, Eli Sherman</i> . . . . .	530
Fast Counting in Machine Learning Applications. <i>Subhadeep Karan, Matthew Eichhorn, Blake Hurlburt, Grant Iraci, Jaroslaw Zola</i> . . . . .	540
A Dual Approach to Scalable Verification of Deep Networks. <i>Krishnamurthy Dvijotham, Robert Stanforth, Sven Gowal, Timothy Mann, Pushmeet Kohli</i>	550
Understanding Measures of Uncertainty for Adversarial Example Detection. <i>Lewis Smith, Yarin Gal</i> . . . . .	560
Causal Discovery in the Presence of Measurement Error. <i>Tineke Blom, Anna Klimovskaia, Sara Magliacane, Joris M. Mooij</i> . . . . .	570
IDK Cascades: Fast Deep Learning by Learning not to Overthink. <i>Xin Wang, Yujia Luo, Daniel Crankshaw, Alexey Tumanov, Fisher Yu, Joseph E. Gonzalez</i>	580
Learning Fast Optimizers for Contextual Stochastic Integer Programs. <i>Vinod Nair, Dj Dvijotham, Iain Dunning, Oriol Vinyals</i> . . . . .	591
Differential Analysis of Directed Networks. <i>Min Ren, Dabao Zhang</i> . . . . .	601
Sparse-Matrix Belief Propagation. <i>Reid Bixler, Bert Huang</i> . . . . .	611
Sequential Learning under Probabilistic Constraints. <i>Amirhossein Meisami, Henry Lam, Chen Dong, Abhishek Pani</i> . . . . .	621
Abstraction Sampling in Graphical Models. <i>Filjor Broka, Rina Dechter, Alexander Ihler, Kalev Kask</i> . . . . .	632
Meta Reinforcement Learning with Latent Variable Gaussian Processes. <i>Steindor Saemundsson, Katja Hofmann, Marc Peter Deisenroth</i> . . . . .	642
Non-Parametric Path Analysis in Structural Causal Models. <i>Junzhe Zhang, Elias Bareinboim</i> . . . . .	653

Stochastic Layer-Wise Precision in Deep Neural Networks. <i>Griffin Lacey, Graham W. Taylor, Shawki Areibi</i> . . . . .	663
Estimation of Personalized Effects Associated With Causal Pathways. <i>Razieh Nabi, Phyllis Kanki, Ilya Shpitser</i> . . . . .	673
High-confidence error estimates for learned value functions. <i>Touqir Sajed, Wesley Chung, Martha White</i> . . . . .	683
Combinatorial Bandits for Incentivizing Agents with Dynamic Preferences. <i>Tanner Fiez, Shreyas Sekar, Liyuan Zheng, Lillian Ratliff</i> . . . . .	693
Sparse Multi-Prototype Classification. <i>Vikas K. Garg, Lin Xiao, Ofer Dekel</i> . . . . .	704
Fast Stochastic Quadrature for Approximate Maximum-Likelihood Estimation. <i>Nico Piatkowski, Katharina Morik</i> . . . . .	715
Finite-sample Bounds for Marginal MAP. <i>Qi Lou, Rina Dechter, Alexander Ihler</i> . . . . .	725
Acyclic Linear SEMs Obey the Nested Markov Property. <i>Ilya Shpitser, Robin Evans, Thomas S. Richardson</i> . . . . .	735
A Unified Particle-Optimization Framework for Scalable Bayesian Sampling. <i>Changyou Chen, Ruiyi Zhang, Wenlin Wang, Bai Li, Liqun Chen</i> . . . . .	746
An Efficient Quantile Spatial Scan Statistic for Finding Unusual Regions in Continuous Spatial Data with Covariates. <i>Travis Moore, Weng-Keen Wong</i> . . . . .	756
Stable Gradient Descent. <i>Yingxue Zhou, Sheng Chen, Arindam Banerjee</i> . . . . .	766
Learning to select computations. <i>Frederick Callaway, Sayan Gul, Paul M. Krueger, Thomas L. Griffiths, Falk Lieder</i> . . . . .	776
Per-decision Multi-step Temporal Difference Learning with Control Variates. <i>Kristopher De Asis, Richard S. Sutton</i> . . . . .	786
The Indian Buffet Hawkes Process to Model Evolving Latent Influences. <i>Xi Tan, Vinayak Rao, Jennifer Neville</i> . . . . .	795
Battle of Bandits. <i>Aadirupa Saha, Aditya Gopalan</i> . . . . .	805
Adaptive Stochastic Dual Coordinate Ascent for Conditional Random Fields. <i>Rémi Le Priol, Alexandre Piché, Simon Lacoste-Julien</i> . . . . .	815
Adaptive Stratified Sampling for Precision-Recall Estimation. <i>Ashish Sabharwal, Yexiang Xue</i> . . . . .	825
Fast Kernel Approximations for Latent Force Models and Convolved Multiple-Output Gaussian processes. <i>Cristian Guarnizo, Mauricio Álvarez</i> . . . . .	835
Fast Policy Learning through Imitation and Reinforcement. <i>Ching-An Cheng, Xinyan Yan, Nolan Wagener, Byron Boots</i> . . . . .	845
Hyperspherical Variational Auto-Encoders. <i>Tim Davidson, Luca Falorsi, Nicola De Cao, Thomas Kipf, Jakub M. Tomczak</i> . . . . .	856
Dissociation-Based Oblivious Bounds for Weighted Model Counting. <i>Li Chou, Wolfgang Gatterbauer, Vibhav Gogate</i> . . . . .	866
Averaging Weights Leads to Wider Optima and Better Generalization. <i>Pavel Izmailov, Dmitrii Podoprikin, Timur Garipov, Dmitry Vetrov, Andrew Gordon Wilson</i> . . . . .	876
Block-Value Symmetries in Probabilistic Graphical Models. <i>Gagan Madan, Ankit Anand, Mausam, Parag Singla</i> . . . . .	886
Max-margin learning with the Bayes factor. <i>Rahul G. Krishnan, Arjun Khandelwal, Rajesh Ranganath, David Sontag</i> . . . . .	896
Densified Winner Take All (WTA) Hashing for Sparse Datasets. <i>Beidi Chen, Anshumali Shrivastava</i> . . . . .	906
Lifted Marginal MAP Inference. <i>Vishal Sharma, Noman Ahmed Sheikh, Happy Mittal, Vibhav Gogate, Parag Singla</i> . . . . .	917

PAC-Reasoning in Relational Domains. <i>Ondrej Kuzelka, Yuyi Wang, Jesse Davis, Steven Schockaert</i> . . . . .	927
Pure Exploration of Multi-Armed Bandits with Heavy-Tailed Payoffs. <i>Xiaotian Yu, Han Shao, Michael R. Lyu, Irwin King</i> . . . . .	937
Counterfactual Normalization: Proactively Addressing Dataset Shift Using Causal Mechanisms. <i>Adarsh Subbaswamy, Suchi Saria</i> . . . . .	947
Decentralized Planning for Non-dedicated Agent Teams with Submodular Rewards in Uncertain Environments. <i>Pritee Agrawal, Pradeep Varakantham, William Yeoh</i> . . . . .	958
A Forest Mixture Bound for Block-Free Parallel Inference. <i>Neal Lawton, Greg Ver Steeg, Aram Galstyan</i> . . . . .	968
Causal Identification under Markov Equivalence. <i>Amin Jaber, Jiji Zhang, Elias Bareinboim</i> . . . . .	978
The Variational Homoencoder: Learning to learn high capacity generative models from few examples. <i>Luke B. Hewitt, Maxwell I. Nye, Andreea Gane, Tommi Jaakkola, Joshua B. Tenenbaum</i> . . . . .	988
Probabilistic Collaborative Representation Learning for Personalized Item Recommendation. <i>Aghiles Salah, Hady W. Lauw</i> . . . . .	998
Reforming Generative Autoencoders via Goodness-of-Fit Hypothesis Testing. <i>Aaron Palmer, Dipak Dey, Jinbo Bi</i> . . . . .	1009
Towards Flatter Loss Surface via Nonmonotonic Learning Rate Scheduling. <i>Sihyeon Seong, Yegang Lee, Youngwook Kee, Dongyoon Han, Junmo Kim</i> . . . . .	1020
A Lagrangian Perspective on Latent Variable Generative Models. <i>Shengjia Zhao, Jiaming Song, Stefano Ermon</i> . . . . .	1031
Bayesian optimization and attribute adjustment. <i>Stephan Eismann, Daniel Levy, Rui Shu, Stefan Bartzsch, Stefano Ermon</i> . . . . .	1042
Join Graph Decomposition Bounds for Influence Diagrams. <i>Junkyu Lee, Alexander Ihler, Rina Dechter</i> . . . . .	1053
Causal Discovery with Linear Non-Gaussian Models under Measurement Error: Structural Identifiability Results. <i>Kun Zhang, Mingming Gong, Joseph Ramsey, Kayhan Batmanghelich, Peter Spirtes, Clark Glymour</i> . . . . .	1063

# Preface

The Conference on Uncertainty in Artificial Intelligence (UAI) is the premier international conference on research related to representation, inference, learning and decision making in the presence of uncertainty within the field of Artificial Intelligence. This volume contains all papers that were accepted for the 34th UAI Conference, held in Monterey, California, from August 6 to 10, 2018.

Papers appearing in this conference were subjected to a rigorous review process. A total of 337 papers were reviewed by at least 3 reviewers each. Of these, 104 papers were accepted, for an acceptance rate of close to 31%. We are very grateful to the program committee and senior program committee members for their diligent efforts. We are confident that the proceedings, like past UAI conference proceedings, will become an important archival reference for the field.

We are pleased to announce that the Best Paper Award was awarded to Krishnamurthy Dvijotham, Robert Stanforth, Sven Gowal, Timothy Mann and Pushmeet Kohli for their paper “A Dual Approach to Scalable Verification of Deep Networks.” The Best Student Paper Award was awarded to Amin Jaber, Jiji Zhang and Elias Bareinboim for their paper “Causal Identification under Markov Equivalence.” We are grateful to the members of the best paper committee: Thomas Richardson, Ilya Shpitser and David Sontag.

In addition to the presentation of technical papers, we were very pleased to have four distinguished invited speakers at UAI 2018: Michael C. Frank (Stanford University), Joelle Pineau (McGill University and Facebook), Stuart Russell (UC Berkeley) and Raquel Urtasun (University of Toronto and Uber).

The UAI 2018 tutorials program, chaired by Shakir Mohamed, consisted of four invited tutorials: “Tackling Data Scarcity in Deep Learning” by Anima Anandkumar (Caltech and Amazon AI) and Zachary Lipton (Carnegie Mellon University), “Recent Progress in the Theory of Deep Learning” by Tengyu Ma (Facebook and Stanford University), “Bayesian Approaches for Blackbox Optimization” by Matt Hoffman (DeepMind), and “Machine Reading” by Sebastian Riedel (UCL), Johannes Welbl (UCL) and Dirk Weissenborni (German Research Center for Artificial Intelligence).

UAI 2018 also hosted three workshops, chaired by Yarin Gal: Safety, Risk and Uncertainty in RL organized by Emma Brunskill (Stanford), Audrey Durand (McGill), Vincent Franois (McGill), Daniel (Zhaohan) Guo (CMU), Joelle Pineau (McGill), and Guillaume Rabusseau (McGill); The 7th Causal Inference Workshop organized by Bryant Chen (IBM), Panos Toulis (University of Chicago) and Alexander Volfovsky (Duke University); and Uncertainty in Deep Learning organized by Andrew Wilson (Cornell), Balaji Lakshminarayanan (Deepmind), Dustin Tran (Columbia, Google) and Matt Hoffman (Google).

Following the success of last years event, UAI 2018 continued to hold MLTrain, a hands-on training session on modern machine learning technologies organized by Nikolaos Vasiloglou. This year we partnered with the Linqs team from UC Santa Cruz and with the Pyro team from Uber ATG and teach UAI participants probabilistic programming. We covered the fundamentals of modeling with Probabilistic Soft Logic a new language that redefines the way we blend human expertise with machine learning.

*Amir Globerson and Ricardo Silva (Program Co-Chairs)  
Gal Elidan and Kristian Kersting (General Chair)*

# Organizing Committee

## **General Chairs**

Gal Elidan, Google Inc. and The Hebrew University, Israel  
Kristian Kersting, TU Darmstadt, Germany

## **Program Chairs**

Amir Globerson, Google Inc. and Tel Aviv University  
Ricardo Silva, University College London and The Alan Turing Institute

## **Workshops Chair**

Yarin Gal, University of Oxford

## **Tutorial Chair**

Shakir Mohamed, DeepMind, UK

## **Sponsoring and Social Media Chair**

Nikolaos Vasiloglou, Ismion, USA  
Alexander Ihler, University of California, Irvine, USA

## **Local Arrangements Chair**

Stefano Ermon, Stanford University

## **Proceedings Chair**

Matt J. Kusner, University of Oxford and The Alan Turing Institute

## **Registration Chair**

Alejandro Molina, TU Darmstadt

## **Webmaster and OpenReview Chair**

Yin Cheng Ng, University College London

## **OpenReview Team**

Michael Spector, University of Massachusetts Amherst

# Best Reviewer Awards

Jacob Andreas  
Elias Bareinboim  
Olivier Buffet  
Tom Claassen  
Aditya Deshpande  
Justin Domke  
Robin Evans  
Yuan-Ting Hu  
Daniel Lowd  
Daniel Malinsky  
Brandon Malone  
Nick Ruoizzi  
Scott Sanner  
Ilya Shpitser  
Berk Ustun  
Greg ver Steeg  
Roi Weiss  
Thomas Werner  
Raymond Yeh

# Acknowledgments

The success of UAI depends greatly on the efforts of many individuals who volunteer their time to provide expert and detailed reviews of submitted papers. In particular, the Program Committee and Senior Program Committee for UAI 2018 were responsible for generating reviews and recommendations for the submissions to the conference. Each submitted paper was reviewed by at least 3 members of the Program Committee. The Senior Program Committee then assessed the individual reviews for each paper, moderated discussion among Program Committee members if needed, and generated meta-reviews and recommendations for the program chairs. We are extremely grateful for the efforts of all of the individuals listed below.

## Senior Program Committee

Adrian Weller	University of Cambridge
Alex Schwing	University of Illinois, Urbana Champaign
Andriy Mnih	DeepMind
Andrew Wilson	Cornell University
Cassio de Campos	Queen's University Belfast
Dale Schuurmans	University of Alberta
Daniel Roy	University of Toronto
David Sontag	MIT
Doina Precup	McGill University
Fabio Cozman	Universidade de Sao Paulo
Fabio Cuzzolin	Oxford Brookes University
Guy Van den Broek	University of California, Los Angeles
Honglak Lee	Google
Jennifer Neville	Purdue University
Jonathan Berant	Tel Aviv University
Jonas Peters	University of Copenhagen
Jun Zhu	Tsinghua University
Kun Zhang	Carnegie Mellon University
Le Song	College of Computing, Georgia Institute of Technology
Marloes Maathuis	Swiss Federal Institute of Technology
Martin Zinkevich	Google
Michalis Titsias	Athens University of Economics and Business
Ofer Meshi	Google
Peter Grünwald	Leiden University, Dept. of Mathematics
Pradeep Ravikumar	Carnegie Mellon University
Roger Grosse	Department of Computer Science, University of Toronto
Sanjoy Dasgupta	UC San Diego
Sivan Sabato	Ben Gurion University of the Negev
Sinead Williamson	University of Texas, Austin
Steffen Grunewalder	Lancaster University
Sujay Sanghavi	University of Texas, Austin
Thomas Richardson	University of Washington
Tamir Hazan	Technion
Vibhav Gogate	University of Texas, Dallas
Yaron Singer	Harvard University
Yishay Mansour	Tel Aviv University

## Program Committee

Aditi Raghunathan	Stanford
Aditya Deshpande	University of Illinois, Urbana Champaign
Alan Malek	Massachusetts Institute of Technology
Alessandro Antonucci	IDSIA
Alessio Benavoli	IDSIA
Alexandre Bouchard-Cote	University of British Columbia
Ali Ghodsi	University of Waterloo
Alon Brutzkus	Tel Aviv University
Anders Madsen	Aalborg University
Andrey Kolobov	Microsoft
Angel Lee	8 Du Box Inc
Angelika Kimmig	Cardiff University
Antti Hyttinen	University of Helsinki, Helsinki Institute for Information Technology
Aonan Zhang	Columbia
April Liu	Shanghai University of Finance and Economics
Aritanan Gruber	University of ABC, São Paulo State
Arjen Hommersom	Open University of the Netherlands
Arthur Choi	University of California, Los Angeles
Arvind Agarwal	International Business Machines
Aurelie Lozano	IBM Research
Balaji Lakshminarayanan	Google DeepMind
Ben Athiwaratkun	Cornell University
Benjamin Guedj	INRIA
Berk Ustun	Harvard University
Bernie Wang	Tufts University
Biwei Huang	Carnegie Mellon University
Brandon Malone	NEC
Branislav Kveton	Adobe Research
Brian Rutenber	Charles River Analytics
Brian Westerweel	Radboud University
Changhe Yuan	Queens College
Changyou Chen	State University of New York, Buffalo
Chen Liang	Northwestern
Chengtao Li	Massachusetts Institute of Technology
Cho-Jui Hsieh	University of California, Davis
Chongxuan Li	Tsinghua University
Chris Maddison	University of Oxford, DeepMind
Christian Shelton	University of California, Riverside
Christoph Dann	Carnegie Mellon University
Christopher Srinivasa	University of Toronto
Christopher Tosh	University of California, San Diego
Ciara Pike-Burke	Lancaster University
Colin Graber	University of Illinois, Urbana Champaign
Cong Chen	City University of New York
Cory Butz	University of Regina
Creagh Briercliffe	University of British Columbia
Dan Garber	Technion
Daniel Kumor	Purdue University
Daniel Lowd	University of Oregon
Daniel Malinsky	Johns Hopkins University
Danielle Belgrave	Microsoft
David Alvarez-Melis	Massachusetts Institute of Technology
David Arbour	Facebook
David Barber	University College London
David Belanger	University of Massachusetts, Amherst
David Jensen	University of Massachusetts, Amherst
David Page	University of Wisconsin, Madison
David Pennock	Microsoft

David Pynadath	Massachusetts Institute of Technology
Debarun Bhattacharjya	Stanford University
Denis Mau	Universidade de Sao Paulo
Dmitrii Podoprikin	Lomonosov Moscow State University
Dominik Rothenhaeusler	Swiss Federal Institute of Technology
Dustin Tran	Columbia University
Elad Eban	Google
Elad Mezuman	Google

## Abstract

A crucial problem in statistics is to decide whether additional variables are needed in a regression model. We propose a new multivariate test to investigate the conditional mean independence of  $Y$  given  $X$  conditioning on some known effect  $Z$ , i.e.,  $E(Y|X, Z) = E(Y|Z)$ . Assuming that  $E(Y|Z)$  and  $Z$  are linearly related, we reformulate an equivalent notion of conditional mean independence through transformation, which is approximated in practice. We apply the martingale difference divergence (Shao and Zhang, 2014) to measure conditional mean dependence, and show that the estimation error from approximation is negligible, as it has no impact on the asymptotic distribution of the test statistic under some regularity assumptions. The implementation of our test is demonstrated by both simulations and a financial data example.

## 1 INTRODUCTION

Testing (conditional) dependence and conditional mean dependence plays an important role in statistics with various applications, including variable selection (Székely and Rizzo, 2014; Park et al., 2015; Zhang et al., 2015; Yan and Bien, 2018), feature screening (Li et al., 2012; Shao and Zhang, 2014; Yan et al., 2017), and graphical models (Gan et al., 2018; Li and McCormick, 2017; Li et al., 2018). Both areas attracted tremendous attention in the last two decades, as datasets have increased in size and dimension. Let  $X \in \mathbb{R}^p$ ,  $Y \in \mathbb{R}^q$ ,  $Z \in \mathbb{R}^r$  be the

three random vectors of interest, and denote pairwise independence by  $\perp$ .

Measures of (conditional) dependence have been extensively studied. Székely et al. (2007) proposed distance covariance (dCov) to capture the non-linear and non-monotone pairwise dependence between  $X$  and  $Y$ , and  $\text{dCov} = 0$  if and only if pairwise independence ( $X \perp Y$ ) holds. Jin and Matteson (2017) extended distance covariance to mutual dependence measures (MDMs), which have been applied to independent component analysis in Jin and Matteson (2018). To capture the conditional dependence between  $X$  and  $Y$  given  $Z$ , Székely and Rizzo (2014) generalized distance covariance to partial distance covariance (pdCov), however,  $\text{pdCov} = 0$  is not equivalent to conditional independence ( $X \perp Y | Z$ ), and neither one implies the other. Wang et al. (2015) extended distance covariance to conditional distance covariance (CDCov) using kernel estimators, and  $\text{CDCov} = 0$  if and only if conditional independence holds. Under a linear assumption between  $X, Y$  and  $Z$ , Fan et al. (2015) converted testing conditional independence to testing independence, and applied distance covariance to measure the dependence of estimated variables. Moreover, inter-temporal conditional dependence is known as Granger causality in time series analysis. Hiemstra and Jones (1994), Su and White (2007), and Chen and Hong (2012) each introduced non-parametric tests for non-linear Granger causality based on conditional probabilities and characteristic functions.

Likewise, various measures of conditional mean dependence have been broadly developed as well. Testing the conditional mean independence of  $Y$  given  $X$ , i.e.,

$$H_0 : E(Y|X) = E(Y) \text{ a.s.}, \quad H_A : \text{o.w.} \quad (1)$$

provides insight on whether  $X$  contributes to the conditional mean of  $Y$ . Shao and Zhang (2014) generalized distance covariance to martingale difference divergence (MDD), and  $\text{MDD} = 0$  if and only if (1) holds. Testing

the conditional mean independence of  $Y$  given  $X$  conditioning on some known effect  $Z$ , i.e.,

$$H_0 : E(Y|X, Z) = E(Y|Z) \text{ a.s.}, \quad H_A : o.w. \quad (2)$$

sheds light on whether  $X$  contributes to the conditional mean of  $Y$  when taking known dependence on  $Z$  into account. Park et al. (2015) generalized martingale difference divergence to partial martingale difference divergence (pMDD), however, pMDD = 0 is not equivalent to (2). Fan and Li (1996), Lavergne and Vuong (2000), and Ait-Sahalia et al. (2001) each introduced non-parametric tests for (2) using kernel estimators of conditional expectations. Assuming a linear model between  $Y$  and  $(X, Z)$ , Lan et al. (2014) generalized the classical partial F-test (Chatterjee and Hadi, 2015) to a partial covariance-based (pcov) test for (2) in the high-dimensional setting, and Tang et al. (2017) further proposed a hybrid test for (2) through finding the most predictive covariate based on both maximum-type and sum-type statistics. Conditional mean independence conditioning on lagged covariates is known as Granger causality *in mean* in time series analysis. Raïssi et al. (2011) proposed a parametric test for linear Granger causality in mean based on vector autoregressive (VAR) models, and Hong et al. (2009) introduced a non-parametric test for non-linear Granger causality in mean based on cross-correlations.

In this paper, we focus on testing conditional mean independence with covariates and develop a method to test (2) for two main reasons. As Cook and Li (2002) state, regression analysis is mostly concerned with the conditional mean of the response given the predictors, which makes testing conditional mean independence more appealing than testing conditional independence. Further, it is very common in practice that some given covariates  $Z$  have been known to affect the conditional mean of  $Y$ . In this situation, we aim to determine whether  $X$  has marginal effect on the conditional mean of  $Y$  in the presence of  $Z$ , and decide whether  $X$  should be included to model the conditional mean of  $Y$  along with  $Z$ . In general, testing (2) is more useful than testing (1), but requires more careful handling.

We first simplify testing (2) to testing conditional mean independence through a transformation. Let  $V = Y - E(Y|Z) \in \mathbb{R}^q$ , and  $U = (X, Z) \in \mathbb{R}^{p+r}$ . Then  $E(V) = 0$ , and  $E(V|U) = E(Y|X, Z) - E(Y|Z)$ . As a result, we obtain an equivalent hypothesis test to (2) as

$$H_0 : E(V|U) = E(V) = 0 \text{ a.s.}, \quad H_A : o.w. \quad (3)$$

which is conditional mean independence of  $V$  given  $U$ . Thus, we consider the MDD with  $U$  and  $V$  to investigate (3). However, there are two problems to solve when we apply MDD to  $U$  and  $V$ . First,  $V$  needs to be estimated

since it is unobserved. We will replace  $V$  by its estimate  $\widehat{V}$  in calculating MDD. Second, we need to confirm that the estimation error of  $\widehat{V}$  is negligible, i.e., MDD with  $\widehat{V}$  is close enough to that with  $V$ , such that  $\widehat{V}$  may be used for inference instead of  $V$ .

The rest of this paper is organized as follows. In Section 2, we give a brief overview of martingale difference divergence. In Section 3, we estimate  $V$  based on the assumption that  $E(Y|Z)$  is a linear function of  $Z$ , and prove that the estimation of  $V$  does not affect the asymptotic distribution of martingale difference divergence under some regularity conditions. We present simulation results in Section 4, followed by a real data analysis in Section 5<sup>1</sup>. Finally, we summarize our work in Section 6.

The following notation is used throughout this paper. Let  $\{(X_i, Y_i, Z_i) : i = 1, \dots, n\}$  be an i.i.d. sample from the joint distribution  $F_{X,Y,Z}$ . When  $A$  is a matrix, the element of  $A$  at row  $k$  and column  $\ell$  is denoted by  $A(k, \ell)$ . When  $A$  is a vector, the element of  $A$  at index  $k$  is denoted by  $A(k)$ . The Frobenius norm of matrix  $A \in \mathbb{R}^{p \times q}$  is denoted by  $\|A\|_F$ . The Euclidean norm of vector  $X \in \mathbb{R}^p$  is denoted by  $|X|$ . The weighted  $\mathcal{L}_2$  norm  $\|\cdot\|_w$  of any complex-valued function  $\eta(t)$ ,  $t \in \mathbb{R}^p$  is defined by  $\|\eta(t)\|_w^2 = \int_{\mathbb{R}^p} |\eta(t)|^2 w(t) dt$  where  $|\eta(t)|^2 = \eta(t)\overline{\eta(t)}$ ,  $\overline{\eta(t)}$  is the complex conjugate of  $\eta(t)$ , and  $w(t)$  is any positive weight function under which the integral exists. Furthermore, *a.s.* is an abbreviation of almost surely.

## 2 MARTINGALE DIFFERENCE DIVERGENCE

Shao and Zhang (2014) proposed martingale difference divergence to capture the conditional mean dependence (in any form) of  $Y \in \mathbb{R}^q$  given  $X \in \mathbb{R}^p$ .

The non-negative martingale difference divergence for  $X$  and  $Y$ ,  $MDD(Y|X)$  is defined by its square

$$\begin{aligned} MDD^2(Y|X) &= \|E(Ye^{i\langle s, X \rangle}) - E(Y)E(e^{i\langle s, X \rangle})\|_{w_p}^2 \\ &\triangleq \int_{\mathbb{R}^p} |E(Ye^{i\langle s, X \rangle}) - E(Y)E(e^{i\langle s, X \rangle})|^2 w_p(s) ds, \end{aligned}$$

where the weight  $w_p(s) = c_p |s|^{1+p}$ , with  $c_p = \frac{\pi^{(1+p)/2}}{\Gamma((1+p)/2)}$ , and  $\Gamma$  is the gamma function. If  $E(|X|^2 + |Y|^2) < \infty$ , then  $MDD(Y|X) = 0$  if and only if  $E(Y|X) = E(Y)$  holds *a.s.*

The non-negative empirical martingale difference diver-

<sup>1</sup>See CRAN for an accompanying R package `EDMeasure` (Jin et al., 2018).

gence  $\text{MDD}_n(Y|X)$  is analogously defined by

$$\text{MDD}_n^2(Y|X) = \frac{1}{n^2} \sum_{i,j=1}^n A_{ij}B_{ij},$$

where  $A_{ij} = a_{ij} - \bar{a}_{i.} - \bar{a}_{.j} + \bar{a}_{..}$ ,  $\bar{a}_{i.} = \frac{1}{n} \sum_{j=1}^n a_{ij}$ ,  $\bar{a}_{.j} = \frac{1}{n} \sum_{i=1}^n a_{ij}$ ,  $\bar{a}_{..} = \frac{1}{n^2} \sum_{i,j=1}^n a_{ij}$ ,  $a_{ij} = |X_i - X_j|$ , and similarly for  $B_{ij}$  with  $b_{ij} = \frac{1}{2}|Y_i - Y_j|^2$ .

The consistency and weak convergence of  $\text{MDD}_n(Y|X)$  are derived as follows. If  $E(|X| + |Y|^2) < \infty$ , we have (i)  $\text{MDD}_n(Y|X) \xrightarrow[n \rightarrow \infty]{a.s.} \text{MDD}(Y|X)$ ; (ii) under  $H_0$  :

$$E(Y|X) = E(Y) \text{ a.s.}, n\text{MDD}_n^2(Y|X) \xrightarrow[n \rightarrow \infty]{\mathcal{D}} \|\zeta(s)\|_{w_p}^2,$$

where  $\zeta(\cdot)$  is a complex-valued zero-mean Gaussian process whose covariance function depends on  $F_{X,Y}$ ; (iii) under  $H_A : o.w.$ ,  $n\text{MDD}_n^2(Y|X) \xrightarrow[n \rightarrow \infty]{a.s.} \infty$ . Utilizing the nice properties of MDD, we next propose our test for (3).

### 3 METHODOLOGY

Inspired by the linear assumption to simplify the conditional dependence structure in Fan et al. (2015), we assume that the conditional expectation  $E(Y|Z)$  is a linear function of  $Z$ , simplifying the conditional mean dependence structure. As a result, we can decompose  $Y$  into the conditional expectation and reminder as

$$Y = E(Y|Z) + [Y - E(Y|Z)] \triangleq BZ + V,$$

where  $B \in \mathbb{R}^{q \times r}$ ,  $V \in \mathbb{R}^q$ . Then we have  $E(V|Z) = 0$ , and  $E(V) = 0$ . Similarly, the  $i$ th sample counterpart is  $Y_i = E(Y_i|Z_i) + V_i \triangleq BZ_i + V_i$ ,  $i = 1, \dots, n$ .

Suppose  $\hat{B}$  is the ordinary least squares (OLS) estimator of  $B$  when regressing  $Y$  on  $Z$ . We will then replace  $B$  with  $\hat{B}$  to estimate  $E(Y_i|Z_i)$  as  $\hat{E}(Y_i|Z_i) = \hat{B}Z_i$ , and  $V_i$  as  $\hat{V}_i = Y_i - \hat{B}Z_i = (B - \hat{B})Z_i + V_i$ . When estimating  $B$  via the OLS,  $Z$  is implicitly assumed to have full column rank. In case  $Z$  is high-dimensional, i.e.,  $r > n$ , we can estimate  $B$  by the penalized least squares (PLS) similar to Fan et al. (2015), including ridge (Hoerl and Kennard, 1970) and lasso (Tibshirani, 1996).

We now construct a test for (3) based on  $\text{MDD}_n^2(\hat{V}|U)$  and its counterparts using permutation samples, then calculate the empirical p-value following the permutation in Park et al. (2015). Because the samples are independent, but with an unspecified distribution, permutation tests are a convenient tool for inference. We will later show in Theorem 2 that the asymptotic distribution of  $n\text{MDD}_n^2(\hat{V}|U)$  depends on an unknown underlying distribution, which justifies the use of permutation tests. To measure the conditional mean dependence of  $V$  given  $U$ , we first compute the test statistic  $\text{MDD}_n^2(\hat{V}|U)$

from the sample  $\{(\hat{V}_i, U_i) : i = 1, \dots, n\}$ , where  $U_i = (X_i, Z_i)$ . That is,  $\text{MDD}_n^2(\hat{V}|U)$  depends on the i.i.d. sample  $\{(X_i, Y_i, Z_i) : i = 1, \dots, n\}$ . Next we draw  $B$  permutation samples of size  $n$  as  $\{(X_i^*, Y_i, Z_i) : i = 1, \dots, n\}$ , where only the sample of  $X$  is permuted in order to approximate the sampling distribution. For each permutation sample, we calculate the test statistic  $\text{MDD}_{n,b}^2(\hat{V}|U)$ ,  $b = 1, \dots, B$ . Then the empirical p-value is given by

$$\hat{p} = \frac{\sum_{b=1}^B \mathbf{1} \left\{ \text{MDD}_{n,b}^2(\hat{V}|U) \geq \text{MDD}_n^2(\hat{V}|U) \right\}}{B}.$$

When  $H_0$  is false,  $\text{MDD}_n^2(\hat{V}|U)$  tends to be large while  $\text{MDD}_{n,b}^2(\hat{V}|U)$  tends to be small. As a result, the empirical p-value is expected to be very small, leading to a rejection of  $H_0$ . We name the proposed test linear martingale difference divergence (LinMDD). To justify our LinMDD test, it remains to validate that  $\text{MDD}_n^2(\hat{V}|U)$  is close enough to  $\text{MDD}_n^2(V|U)$ , i.e., the estimation error in  $\hat{V}$  is negligible for the sampling distribution of the test statistic, focusing on the asymptotic case. To begin with, we introduce some regularity conditions to derive the asymptotic distribution of  $\text{MDD}_n^2(\hat{V}|U)$ .

**Condition 1.** *There exist constants  $0 < c_1, c_2, c_3 < \infty$ , such that  $E(|U_i - U_j|^2) = c_1$ ,  $i \neq j$ ;  $E(|U_i - U_j||U_i - U_k|) = c_2$ ,  $i \neq j \neq k$ ;  $E(|U_i - U_j||U_k - U_\ell|) = c_3$ ,  $i \neq j \neq k \neq \ell$ .*

**Condition 2.** *There exists constant  $0 < c_4 < \infty$ , such that  $E[(Z_i(t) - Z_j(t))^2(Z_i(s) - Z_j(s))^2] \leq c_4$ ,  $i \neq j$ ,  $\forall t, s$ .*

**Condition 3.** *There exists constant  $0 < c_5 < \infty$ , such that  $E[(Z_i(t) - Z_j(t))^2(V_i(s) - V_j(s))^2] \leq c_5$ ,  $i \neq j$ ,  $\forall t, s$ .*

**Condition 4.**  $\|\hat{B} - B\|_F = O_p(n^{-1/2})$ .

*Remark.* Condition 4 can be derived from the bounded density of  $|V_i - V_j|$  and non-heavy tails of  $Z_i(t)$  and  $V_i(t)$  according to Fan et al. (2015) and Fan et al. (2011).

Through a similar derivation to Theorem 2 of Fan et al. (2015), we justify the choice of using  $\text{MDD}_n^2(\hat{V}|U)$  in place of  $\text{MDD}_n^2(V|U)$  by the following lemma and theorems. Lemma 1 shows that the difference between  $\text{MDD}_n^2(\hat{V}|U)$  and  $\text{MDD}_n^2(V|U)$  is negligible as the sample size increases. The proof of Lemma 1 can be found in Appendix 6.

**Lemma 1.** *If  $Y = BZ + V$  and Conditions 1-4 hold, we have*

$$\text{MDD}_n^2(\hat{V}|U) - \text{MDD}_n^2(V|U) = O_p(n^{-3/2}).$$

Consequently, the consistency and weak convergence of  $\text{MDD}_n(\hat{V}|U)$  follow from Lemma 1 and are summarized in Theorem 1 and 2 below.

**Theorem 1** (Consistency). *If  $Y = BZ + V$  and Conditions 1-4 hold, we have*

$$MDD_n(\widehat{V}|U) \xrightarrow[n \rightarrow \infty]{\mathcal{P}} MDD(V|U).$$

**Theorem 2** (Weak convergence). *If  $Y = BZ + V$  and Conditions 1-4 hold, under  $H_0$ , we have*

$$nMDD_n^2(\widehat{V}|U) \xrightarrow[n \rightarrow \infty]{\mathcal{D}} \|\zeta(s)\|_{w_p}^2,$$

where  $\zeta(\cdot)$  denotes the complex-valued Gaussian random process corresponding to the asymptotic distribution of  $nMDD_n^2(V|U)$ . Under  $H_A$ , we have

$$nMDD_n^2(\widehat{V}|U) \xrightarrow[n \rightarrow \infty]{\mathcal{P}} \infty.$$

According to Theorem 1,  $MDD_n(\widehat{V}|U)$  converges to the same population statistic  $MDD(V|U)$  as  $MDD_n(V|U)$ , and thus it can serve to measure the conditional mean dependence of  $V$  given  $U$ . In addition,  $nMDD_n^2(\widehat{V}|U)$  and  $nMDD_n^2(V|U)$  have the same asymptotic distribution stated in Theorem 2, which establishes the effectiveness of LinMDD test, as we approximate the limiting distribution of  $nMDD_n^2(V|U)$  using  $nMDD_n^2(\widehat{V}|U)$  in LinMDD test. In Section 4 and Section 5, we will present the finite-sample performance of our LinMDD test through simulations and a real data example, respectively.

## 4 SIMULATION STUDIES

To evaluate the performance of our LinMDD test, we adopt the simulation setup in Lavergne and Vuong (2000), and compare our test to the pMDD test (Park et al., 2015), pdCov test (Székely and Rizzo, 2014), and pcov test (Lan et al., 2014) as benchmarks. All tests are implemented as permutation tests with permutation size  $B = 500$ , in which we only permute the sample of  $X$  to approximate the distribution of the test statistic.

We generate data from the underlying model

$$Y = -Z + b \cdot Z^3 + f(X) + \epsilon,$$

where  $Z \sim N(0, 1)$ ,  $X \sim \mathcal{N}(0, 1)$ ,  $\epsilon \sim \mathcal{N}(0, 4)$ , and  $Z, X, \epsilon$  are independent. We test the null hypothesis  $H_0 : E(Y|X, Z) = E(Y|Z)$  a.s. with significance level  $\alpha \in \{0.05, 0.1\}$ , and examine the empirical size and power of each test. We run 1000 replications with sample size  $n \in \{20, 30, 50, 70, 100\}$  for each specific model.

**Model 1** (Linear  $Z$ , linear  $X$ ).  $b = 0$ ,  $f(X) = cX$  where  $c \in \{0, \frac{2}{3}, 1, \frac{3}{2}\}$ .

**Model 2** (Linear  $Z$ , non-linear  $X$ ).  $b = 0$ ,  $f(X) = \sin(c\pi X)$  where  $c \in \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$ . We omit  $c = 0$  as it is exactly the same as  $c = 0$  in Model 1.

From Figure 1, the empirical size of all tests is around 0.05 (0.1). The empirical power of all tests increases as  $n$  increases. For the linear  $X$  case, the empirical power of all tests is higher when  $c$  is larger, since the signal-to-noise ratio increases. Moreover, the empirical power of the LinMDD and pcov tests is consistently higher than that of the other tests, because the linear assumption is valid, and only LinMDD and pcov tests are designed for linear  $Z$ . For the non-linear  $X$  case, the LinMDD test still outperforms the other tests, while the performance of the pcov test degrades as  $c$  increases, because the LinMDD test is designed for non-linear  $X$  while pcov test is suitable only for linear  $X$ .

**Model 3** (Nonlinear  $Z$ , linear  $X$ ).  $b = 1$ ,  $f(X) = cX$  where  $c \in \{0, \frac{2}{3}, 1, \frac{3}{2}\}$ .

**Model 4** (Nonlinear  $Z$ , non-linear  $X$ ).  $b = 1$ ,  $f(X) = \sin(c\pi X)$  where  $c \in \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}\}$ . We omit  $c = 0$  as it is exactly the same as  $c = 0$  in Model 3.

From Figure 2, the empirical size of all tests is around 0.05 (0.1). For the linear  $X$  case, the empirical power of the LinMDD and pcov tests is competitive with but not always higher than that of the other tests. The reason is that the linear dependence of  $Y$  on  $Z$  is violated while the other tests do not rely it. For the non-linear  $X$  case, we similarly find that the performance of the pcov test degrades as  $c$  increases. The simulation results show that our LinMDD test achieves competitive and often better performance than the others in these situations. Next, we apply the proposed LinMDD test on a real dataset.

## 5 FINANCIAL DATA APPLICATION

In finance, the capital asset pricing model (CAPM) was proposed by Sharpe (1964), Lintner (1965), and Mossin (1966) to describe the stock returns through the market risk as

$$r_t = \alpha + \beta_1 m_t,$$

where  $r_t$  is the excess stock return (in excess the risk-free return), and  $m_t$  is the excess market return at time  $t$ . Fama and French (1993) added size and value factors to the CAPM, and proposed the Fama–French three-factor model as

$$r_t = \alpha + \beta_1 m_t + \beta_2 \text{SMB}_t + \beta_3 \text{HML}_t,$$

where SMB (small minus big) and HML (high minus low) account for stocks with small/big market capitalization and high/low book-to-market ratio, respectively. Fama and French (2015) further added profitability and investment factors to the three-factor model, and extended it to the Fama–French five-factor model as

$$r_t = \alpha + \beta_1 m_t + \beta_2 \text{SMB}_t + \beta_3 \text{HML}_t + \beta_4 \text{RMW}_t + \beta_5 \text{CMA}_t,$$

where RMW (robust minus weak) and CMA (conservative minus aggressive) further account for stocks with robust/weak operating profitability and conservative/aggressive investment, respectively.

We collect the annual risk-free returns and Fama–French five factors<sup>2</sup>, and the annual returns of Boeing (BA) stock<sup>3</sup> in the past 53 years between 1964 and 2016. The time series and histograms of excessive BA stock returns and Fama–French five factors are depicted in Figure 3.

### 5.1 CAPM VS. FAMA–FRENCH THREE-FACTOR MODEL

First, we are curious whether the size and value factors should be added to the CAPM, i.e., whether SMB and HML in the Fama–French three-factor model contribute to the expectation of excess stock returns given the market risk. Thus, we test  $H_0 : E(Y|X, Z) = E(Y|Z)$  *a.s.*, where  $X_t = (\text{SMB}_t, \text{HML}_t)$ ,  $Y_t = r_t$ , and  $Z_t = (1, m_t)$ .

We apply our LinMDD test to the data with  $n = 53$  and  $B = 500$ . Our p-value is 0.072, while the p-values are 0.012 (pMDD), 0.092 (pdCov) and 0.096 (pcov) using competing tests. As a result, we reject  $H_0$  with significance level  $\alpha = 0.1$ , and conclude that SMB and HML help determine the excess returns of BA stock in the presence of the market risk. Our results align with the research in finance that the Fama–French three-factor model remarkably outperforms the CAPM in explaining excess stock returns.

### 5.2 FAMA–FRENCH THREE-FACTOR MODEL VS. FIVE-FACTOR MODEL

Similarly, we are interested in whether the profitability and investment factors should be further added to the Fama–French three-factor model, i.e., whether RMW and CMA in the Fama–French five-factor model contribute to the description of excess stock returns given the other three factors. Hence, we test  $H_0 : E(Y|X, Z) = E(Y|Z)$  *a.s.*, in which  $X_t = (\text{RMW}_t, \text{CMA}_t)$ ,  $Y_t = r_t$ , and  $Z_t = (1, m_t, \text{SMB}_t, \text{HML}_t)$ .

We apply our LinMDD test to the data with  $n = 53$  and  $B = 500$ , and its p-value is 0.360, while the p-values are 0.358 (pMDD), 0.878 (pdCov) and 0.768 (pcov) using competing tests. As a result, we fail to reject  $H_0$  with significance level  $\alpha = 0.1$ , and conclude that RMW and CMA are unable to help determine the excess re-

turns of BA stock in the presence of the other three factors. Our results align with the research in finance that the Fama–French five-factor model has yet to be proven as a significant improvement over the three-factor model in describing excess stock returns.

### 5.3 FAMA–FRENCH FOUR-FACTOR MODEL VS. FIVE-FACTOR MODEL

Fama and French (2015) showed that the value factor HML becomes redundant when profitability and investment factors are added to the Fama–French three-factor model, because HML is fully captured by its exposures to the other four factors, especially RMW and CMA. To validate this argument, we test  $H_0 : E(Y|X, Z) = E(Y|Z)$  *a.s.*, where  $X_t = \text{HML}_t$ ,  $Y_t = r_t$ , and  $Z_t = (1, m_t, \text{SMB}_t, \text{RMW}_t, \text{CMA}_t)$ .

We apply our LinMDD test to the data with  $n = 53$  and  $B = 500$ . Our p-value is 0.218, while the p-values are 0.438 (pMDD), 0.540 (pdCov) and 0.858 (pcov) using competing tests. As a result, we fail to reject  $H_0$  with significance level  $\alpha = 0.1$ , and conclude that HML cannot help explain the excess returns of BA stock in the presence of the other four factors. Our results demonstrate that HML is redundant for describing excess stock returns in the Fama–French five-factor model.

## 6 CONCLUSION

In this paper, we propose a new test, LinMDD, for the null hypothesis  $H_0 : E(Y|X, Z) = E(Y|Z)$  *a.s.* by investigating an equivalent one  $H_0 : E(V|U) = E(V) = 0$  *a.s.*, derived from a transformation involving the conditional expectation. When applying martingale difference divergence (Shao and Zhang, 2014) to test  $H_0 : E(V|U) = E(V) = 0$  *a.s.*, we make two major contributions.

- (1) Since  $V$  is unobservable, we estimate  $V$  based on the assumption that  $E(Y|Z)$  is a linear function of  $Z$ , simplifying the conditional mean dependence structure.
- (2) We prove that the estimation error in  $\hat{V}$  is negligible for the asymptotic distribution of the test statistic. Thus, we can replace  $V$  with  $\hat{V}$  in the test statistic for inference in large samples.

We implement the LinMDD test as a permutation test following Park et al. (2015), and compare it with existing tests in various simulation studies. The LinMDD test consistently outperforms existing tests when its linear assumption is valid, and it achieves competitive results with existing tests even when its linear assumption is violated.

<sup>2</sup>Download data at [http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data\\_library.html](http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html).

<sup>3</sup>Download data using `get.hist.quote` in the R package `tseries` (Trapletti and Hornik, 2017).

To illustrate the practical value of the LinMDD test, we compare the CAPM, the Fama–French three-factor and five-factor models by applying LinMDD test to the financial data. We find that the Fama–French three-factor outperforms the CAPM, while the Fama–French five-factor is not a significant improvement over the three-factor model when explaining the excess annual returns of a major stock. Moreover, we validate the statement that the value factor is redundant in the Fama–French five-factor model (Fama and French, 2015) using the LinMDD test.

The relaxation of the linear assumption is an important topic for future research. Our method will become more general if the linear assumption of conditional mean dependence can be generalized to a non-linear one, using non-parametric regression (local regression, splines) instead of linear regression in the estimation of conditional mean. In addition, the high-dimensional setting regarding  $Z$  where  $r > n$  is an interesting direction to consider as well.

## APPENDIX

### PROOF OF LEMMA 1

*Proof.* We define  $T$

$$\begin{aligned} &= n\text{MDD}_n^2(\widehat{V}|U) - n\text{MDD}_n^2(V|U) \\ &= \frac{1}{2n} \sum_{i,j} [(F_{ij} - \frac{1}{n} \sum_k F_{kj} - \frac{1}{n} \sum_k F_{ik} + \frac{1}{n^2} \sum_{k,\ell} F_{k\ell}) \\ &\quad \times (E_{ij} - \frac{1}{n} \sum_k E_{kj} - \frac{1}{n} \sum_k E_{ik} + \frac{1}{n^2} \sum_{k,\ell} E_{k\ell})], \end{aligned}$$

where  $F_{ij} = |\widehat{V}_i - \widehat{V}_j|^2 - |V_i - V_j|^2$ ,  $E_{ij} = |U_i - U_j|$ .

We apply Taylor expansion to  $|\widehat{V}_t - \widehat{V}_s|^2$  at  $V_t - V_s$  in terms of  $f(x) = x^T x$ ,  $f'(x) = 2x^T$ , then there exists  $\lambda \in (0, 1)$ , such that  $F_{ij}$

$$\begin{aligned} &= 2[\lambda(\widehat{V}_i - \widehat{V}_j) + (1 - \lambda)(V_i - V_j)]^T (\widehat{V}_i - \widehat{V}_j - V_i + V_j) \\ &= 2[\lambda(Z_i - Z_j)^T (B - \widehat{B})^T (B - \widehat{B})(Z_i - Z_j) \\ &\quad + (V_i - V_j)^T (B - \widehat{B})(Z_i - Z_j)]. \end{aligned}$$

Thus, we have  $T = T_1 + T_2$ , where  $T_1$

$$\begin{aligned} &= \frac{\lambda}{n} \sum_{i,j} [(G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) \\ &\quad \times (E_{ij} - \frac{1}{n} \sum_k E_{kj} - \frac{1}{n} \sum_k E_{ik} + \frac{1}{n^2} \sum_{k,\ell} E_{k\ell})], \\ &G_{ij} = (Z_i - Z_j)^T (B - \widehat{B})^T (B - \widehat{B})(Z_i - Z_j), \end{aligned}$$

and  $T_2$

$$\begin{aligned} &= \frac{1}{n} \sum_{i,j} [(H_{ij} - \frac{1}{n} \sum_k H_{kj} - \frac{1}{n} \sum_k H_{ik} + \frac{1}{n^2} \sum_{k,\ell} H_{k\ell}) \\ &\quad \times (E_{ij} - \frac{1}{n} \sum_k E_{kj} - \frac{1}{n} \sum_k E_{ik} + \frac{1}{n^2} \sum_{k,\ell} E_{k\ell})], \end{aligned}$$

$$H_{ij} = (V_i - V_j)^T (B - \widehat{B})(Z_i - Z_j).$$

First, we will show (i)  $T_1 = O_p(n^{-1})$ .

After a simple calculation, we have

$$\begin{aligned} &\frac{1}{n} \sum_{i,j} (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) E_{ij} \\ &= \text{tr}[\frac{1}{n} \sum_{i,j} |U_i - U_j| (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} \\ &\quad + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell})] \\ &= \text{tr}[(B - \widehat{B})^T (B - \widehat{B})M], \end{aligned}$$

where  $M = \frac{1}{n} \sum_{i,j} |U_i - U_j| S_{ij}$ , and

$$S_{ij} = R_{ij} - \frac{1}{n} \sum_k R_{kj} - \frac{1}{n} \sum_k R_{ik} + \frac{1}{n^2} \sum_{k,\ell} R_{k\ell},$$

$R_{ij} = (Z_i - Z_j)(Z_i - Z_j)^T$ ,  $R_{ij} = R_{ji}$ ,  $S_{ij} = S_{ji}$ , then

$$\begin{aligned} &\text{E}[(M(t, s))^2] \\ &= \text{E}[\frac{1}{n^2} (\sum_{i,j} |U_i - U_j| S_{ij}(t, s))^2] \\ &= \text{E}\{\text{E}[\frac{1}{n^2} (\sum_{i,j} |U_i - U_j| S_{ij}(t, s))^2 | U_i, \forall i]\} \\ &= \text{E}[\frac{2c_1}{n^2} \sum_{i \neq j} (S_{ij}(t, s))^2 \\ &\quad + \frac{2c_2}{n^2} \sum_{i \neq j \neq k} (S_{ij}(t, s) S_{ik}(t, s) + S_{ij}(t, s) S_{kj}(t, s)) \\ &\quad + \frac{c_3}{n^2} \sum_{i \neq j \neq k \neq \ell} S_{ij}(t, s) S_{k\ell}(t, s)], \end{aligned}$$

where  $c_1 = \text{E}(|U_i - U_j|^2)$ ,  $i \neq j$ ;  $c_2 = \text{E}(|U_i - U_j| |U_i - U_k|)$ ,  $i \neq j \neq k$ ;  $c_3 = \text{E}(|U_i - U_j| |U_k - U_\ell|)$ ,  $i \neq j \neq k \neq \ell$ .

Considering that  $\text{E}[(R_{ij}(t, s))^2] = \text{E}[(Z_i - Z_j)_t^2 (Z_i - Z_j)_s^2] \leq c_4$ ,  $i \neq j$ ,  $\forall t, s$ , we have  $\text{E}[(R_{ij}(t, s))^2] = O(1)$ , which implies  $\text{E}[(S_{ij}(t, s))^2] = O(1)$ , and thus  $\text{E}[\frac{1}{n^2} \sum_{i \neq j} (S_{ij}(t, s))^2] = O(1)$ .

After a simple calculation, we have  $\sum_i S_{ij}(t, s) = 0$ ,  $\sum_j S_{ij}(t, s) = 0$ ,  $\sum_i \sum_j S_{ij}(t, s) = 0$ , and

$$\begin{aligned}
& \sum_{i \neq j \neq k} S_{ij}(t, s) S_{ik}(t, s) \\
&= \sum_i (S_{ii}(t, s))^2 - \sum_{i \neq j} (S_{ij}(t, s))^2, \\
& \sum_{i \neq j \neq k} S_{ii}(t, s) S_{jk}(t, s) \\
&= \sum_i (S_{ii}(t, s))^2 - \sum_{i \neq j} S_{ii}(t, s) S_{jj}(t, s), \\
& \sum_{i \neq j \neq k \neq \ell} S_{ij}(t, s) S_{k\ell}(t, s) \\
&= -2 \sum_{i \neq j \neq k} [S_{ii}(t, s) S_{jk}(t, s) + S_{ij}(t, s) S_{ik}(t, s) \\
&+ S_{ij}(t, s) S_{kj}(t, s)] \\
&- \sum_{i \neq j} [4S_{ii}(t, s) S_{ij}(t, s) + S_{ii}(t, s) S_{jj}(t, s) \\
&+ 2(S_{ij}(t, s))^2] - \sum_i (S_{ii}(t, s))^2,
\end{aligned}$$

we have

$$\begin{aligned}
& \mathbb{E}\left[\frac{1}{n^2} \sum_{i \neq j \neq k} S_{ij}(t, s) S_{ik}(t, s)\right] = O(1), \\
& \mathbb{E}\left[\frac{1}{n^2} \sum_{i \neq j \neq k} S_{ij}(t, s) S_{kj}(t, s)\right] = O(1), \\
& \mathbb{E}\left[\frac{1}{n^2} \sum_{i \neq j \neq k} S_{ii}(t, s) S_{jk}(t, s)\right] = O(1), \\
& \mathbb{E}\left[\frac{1}{n^2} \sum_{i \neq j \neq k \neq \ell} S_{ij}(t, s) S_{k\ell}(t, s)\right] = O(1).
\end{aligned}$$

Therefore,  $\mathbb{E}[(M(t, s))^2] = O(1)$ .

Applying Chebyshev's inequality to  $M(t, s)$ , we have

$$P(|M(t, s) - \mu| \geq k\sigma) \leq 1/k^2,$$

where  $\mu = \mathbb{E}[M(t, s)]$ ,  $\sigma^2 = \text{Var}[M(t, s)]$ . As a result,  $M(t, s) = O_p(1)$ .

Given that  $\|\widehat{B} - B\|_F = O_p(n^{-1/2})$ , we have

$$\begin{aligned}
& \frac{1}{n} \sum_{i,j} (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) E_{ij} \\
&= \text{tr}[(B - \widehat{B})^T (B - \widehat{B}) M] \\
&= pq^2 O_p(n^{-1}) O_p(1) \\
&= O_p(n^{-1}).
\end{aligned}$$

Similarly, we have

$$\begin{aligned}
& \frac{1}{n} \sum_{i,j} (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) E_{kj}, \\
& \frac{1}{n} \sum_{i,j} (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) E_{ik}, \\
& \frac{1}{n} \sum_{i,j} (G_{ij} - \frac{1}{n} \sum_k G_{kj} - \frac{1}{n} \sum_k G_{ik} + \frac{1}{n^2} \sum_{k,\ell} G_{k\ell}) E_{k\ell}
\end{aligned}$$

are all  $O_p(n^{-1})$ . Therefore,  $T_1 = O_p(n^{-1})$ .

Analogous to (i), we can show (ii)  $T_2 = O_p(n^{-1/2})$ . The only differences are

$$\begin{aligned}
& \frac{1}{n} \sum_{i,j} (H_{ij} - \frac{1}{n} \sum_k H_{kj} - \frac{1}{n} \sum_k H_{ik} + \frac{1}{n^2} \sum_{k,\ell} H_{k\ell}) E_{ij} \\
&= \text{tr}[(B - \widehat{B}) M],
\end{aligned}$$

where  $M$  is defined similarly with  $R_{ij} = (Z_i - Z_j)(V_i - V_j)^T$ , and  $\mathbb{E}[(R_{ij}(t, s))^2] = \mathbb{E}[(Z_i - Z_j)_t^2 (V_i - V_j)_s^2] \leq c_5$ ,  $i \neq j$ ,  $\forall t, s$ , and

$$\begin{aligned}
& \frac{1}{n} \sum_{i,j} (H_{ij} - \frac{1}{n} \sum_k H_{kj} - \frac{1}{n} \sum_k H_{ik} + \frac{1}{n^2} \sum_{k,\ell} H_{k\ell}) E_{ij} \\
&= \text{tr}[(B - \widehat{B}) M] \\
&= pq O_p(n^{-1/2}) O_p(1) \\
&= O_p(n^{-1/2}),
\end{aligned}$$

and therefore  $T_2 = O_p(n^{-1/2})$ .

As a conclusion,  $T = T_1 + T_2 = O_p(n^{-1/2})$ .  $\square$

## Abstract

We study multi-armed bandit problems with graph feedback, in which the decision maker is allowed to observe the neighboring actions of the chosen action, in a setting where the graph may vary over time and is never fully revealed to the decision maker. We show that when the feedback graphs are undirected, the original Thompson Sampling achieves the optimal (within logarithmic factors) regret  $\tilde{O}\left(\sqrt{\beta_0(G)T}\right)$  over time horizon  $T$ , where  $\beta_0(G)$  is the average independence number of the latent graphs. To the best of our knowledge, this is the first result showing that the original Thompson Sampling is optimal for graphical bandits in the undirected setting. A slightly weaker regret bound of Thompson Sampling in the directed setting is also presented. To fill this gap, we propose a variant of Thompson Sampling, that attains the optimal regret in the directed setting within a logarithmic factor. Both algorithms can be implemented efficiently and do not require the knowledge of the feedback graphs at any time.

## 1 INTRODUCTION

Multi-Armed Bandits (MAB) models are quintessential models for sequential decision making. In the classical MAB setting, at each time, a policy must choose an action from a set of  $K$  actions with unknown probability distributions. Choosing an action  $i$  at time  $t$  reveals a random reward  $X_i(t)$  drawn from the probability distribution of action  $i$ . The goal is to find policies that minimize the expected loss due to uncertainty about actions' distributions over a given time horizon  $T$ .

In this work, we consider an important variant of bandit problems, called graphical bandits, where choosing an action  $i$  not only generates a reward from action  $i$ , but also reveals observations for a subset of the remaining actions. Graphical bandits are also known as bandits with graph-structured feedback or bandits with side-observations, in which the feedback model is specified by a sequence  $\{G_t\}_{t \geq 1}$  of feedback graphs. Each feedback graph  $G_t$  is a directed graph whose nodes correspond to the actions. An arc<sup>1</sup>  $(i, j)$  in the graph indicates that the agent observes the reward of action  $j$  if action  $i$  is chosen in that round.

Motivating examples for situations where side observations are available include viral marketing and online pricing. Consider the viral marketing problem, where a decision maker wants to find the user with the maximum influence in an online social network (e.g., Facebook) to offer a promotion (Carpentier and Valko [2016]). Each time the decision maker offers a promotion to a user, it also has an opportunity to survey the user's neighbors in the network regarding their potential interest in the same offer. This is possible when the online network has an additional survey feature that generates "side observations". For example, when user  $i$  is offered a promotion, her neighbors may be queried as follows: "User  $i$  was recently offered a promotion. Would you also be interested in the offer?". Here, choosing an action in the graphical bandit problem corresponds to choosing a user in the network and side-observations across actions are captured by the links in the social network.

Consider another example in the online pricing problem, where a seller is selling goods on the Internet. In each round, the seller announces a price for the product. Then, a buyer arrives and decides whether or not to purchase the product based on its private value. A purchase takes place if and only if the announced price is no more than

---

<sup>1</sup>We also use the notation  $i \rightarrow j$  to represent an arc from node  $i$  to node  $j$  for simplicity.

its private value. At the end of the round, the seller observes whether or not the buyer purchased the product at the announced price. If the buyer purchases the product, then the seller knows that the buyer would have bought the product at any lower price. Otherwise, the seller knows that the buyer would not have bought the product at any higher price. Here, actions in the graphical bandit problem corresponds to the prices that the seller can choose. The feedback graph is a directed graph over the prices that a price is connected to a lower (higher) price if and only if they are both below (above) the private value of the buyer.

Graphical bandits have been studied in both non-stochastic (adversarial) domain by Mannor and Shamir [2011]; Alon *et al.* [2013, 2015]; Kocák *et al.* [2014], and stochastic domain by Caron *et al.* [2012]; Baccapatnam *et al.* [2014, 2017]; Tossou *et al.* [2017]; Liu *et al.* [2018]. Regret bounds as a function of combinatorial properties of the feedback graphs are characterized in different settings: undirected graphs vs directed graphs, time-invariant graphs vs time-variant graphs.

However, most of the existing works mentioned above require prior knowledge of the feedback graphs for their algorithms to run. These algorithms fall into either the informed setting (where the algorithms have access to the graph structure before making decisions) or the uninformed setting (where the algorithms have access to the graph for performing their updates after decisions).

The assumption that the feedback graph is disclosed to the decision maker does not hold in many real-world applications. For example, in the viral marketing problem, the third-party decision maker is not allowed to have the knowledge of the social network in order to protect the privacy of the users. In the online pricing problem, the private value of the buyer is never revealed to the seller. Thus the feedback graph is never disclosed to the seller. This motivates us to study the graphical bandits in a setting with limited information, where the feedback graphs are *never fully revealed* to the decision maker.

In this work, we study the graphical bandits without the graphs in a general setting, where the graphs are allowed to be time-variant and directed. Moreover, the only feedback available to the decision maker at the end of each round is the out-neighborhood of the chosen action in the latent graph, along with the rewards associated with the observed actions. Generally speaking, our results show that Thompson Sampling algorithms (introduced by Thompson [1933]) can achieve a regret bound of the form  $\tilde{O}\left(\sqrt{\beta_0(G)T}\right)$ , where  $\beta_0(G)$  is the average independence number<sup>2</sup> of the latent graphs, that is optimal within logarithmic factors. More specifically, we make the following contributions to graphical bandits without knowledge of the feedback graphs. (Table 1 summarizes the main results.)

<sup>2</sup>See Section 2.2 for a brief review of the combinatorial properties of graphs.

- We develop a problem-independent Bayesian regret bound for the vanilla Thompson Sampling algorithm (TS-N) for graphical bandits without the graphs. In the undirected setting, where the latent graphs are undirected, we show that TS-N obtains the optimal (within logarithmic factors) regret bound of  $O\left(\sqrt{\beta_0(G)T \log K}\right)$ , where  $\beta_0(G)$  is the average independence number of the latent graphs (Corollary 1). Our regret bound is much sharper than the form of  $O\left(\sqrt{\chi(G)T \log K}\right)$  that was shown by Liu *et al.* [2018], where  $\chi(G)$  is the average clique cover number of the latent graphs, as  $\beta_0(G) \leq \chi(G)$  in general. As far as we know, this is the first result showing that Thompson Sampling, without knowledge of the graph, can attain the optimal regret within logarithmic factors.
- In the directed setting, where the graphs are allowed to be directed, we show that TS-N achieves  $O\left(\sqrt{\text{mas}(G)T \log K}\right)$  regret in expectation, where  $\text{mas}(G)$  is the average maximal acyclic subgraph number of the latent graphs (Corollary 2). As a byproduct, our regret bounds for TS-N provide improved regret bounds for information directed sampling algorithms (IDS-N and IDSN-LP algorithms) proposed by Liu *et al.* [2018].
- We propose a variant of the Thompson Sampling algorithm, TS-U, that achieves a regret bound of  $O\left(\sqrt{\beta_0(G)T \log K \log(KT)}\right)$  for both the undirected and directed setting (Corollary 3). The regret bound of TS-U is optimal within logarithmic factors, and sharper than the state-of-the-art algorithm proposed by Cohen *et al.* [2016]. Our results offer a recipe for practitioners to choose algorithms for graphical bandits without the graphs. If the latent graphs are known to be undirected, one can choose TS-N for the best regret guarantee. Otherwise, TS-U is the choice with the best guarantee.

## 1.1 RELATED WORK

Graphical bandits were introduced in the non-stochastic domain by Mannor and Shamir [2011]. They propose the ExpBan algorithm that works in the time-invariant and informed setting, with the regret bound depending on the clique cover number. They also propose the ELP algorithm, that replaces the uniform distribution of Exp3 algorithm (proposed by Auer *et al.* [2002b]) with a distribution that maximizes the minimum probability to observe an action. An optimal (within logarithmic factors) regret bound of ELP is shown in the undirected setting.

However, the regret bound of the ELP depends on the

clique cover number in the directed setting. These results are improved by Alon *et al.* [2013]. They show that the vanilla Exp3 algorithm without mixing uniform distribution (Exp3-SET) achieves the same (but improved in the directed setting) regret bound as ELP, even in the uninformed setting. In the informed setting, they propose the Exp3-DOM algorithm, which is a variant of Exp3 algorithm with mixing uniform distribution over the dominating set of the feedback graph, achieves  $\tilde{O}\left(\sqrt{\beta_0(G)T}\right)$  regret. This regret bound is further attained by Exp3.G (Alon *et al.* [2015]) and Exp3-IX (Kocák *et al.* [2014]) in the uninformed setting. The Exp3.G algorithm is a variant of Exp3-DOM where it replaces the dominating set with the universal set. The Exp3-IX algorithm uses a novel implicit exploration idea. However, these algorithms still require the knowledge of the feedback graphs for performing updates after the decisions in the uninformed setting.

Graphical bandits have also been considered in the stochastic domain by Caron *et al.* [2012], who propose a natural variant of upper confidence bounds (introduced by Auer *et al.* [2002a]) algorithm (UCB-N) and provide a problem-dependent regret guarantee depending on the clique cover number. This result is improved by Buccapatnam *et al.* [2014] in the informed and time-invariant setting. Policies proposed by Buccapatnam *et al.* [2014], namely  $\epsilon_t$ -greedy-LP and UCB-LP, are shown to be asymptotically optimal, both in terms of the graph structure and time.

However, all of the afore-mentioned algorithms do not apply when the feedback graphs vary over the time and are never fully disclosed. Recently, researchers have developed new algorithms for graphical bandits in the setting with limited information, where the feedback graphs are time-variant, directed and never revealed to the decision maker. Cohen *et al.* [2016] propose an elimination-based algorithm that achieves the  $\tilde{O}\left(\sqrt{\beta_0(G)T}\right)$  regret bound. Tossou *et al.* [2017] analyze the Bayesian regret performance of Thompson Sampling for the graphical bandits and provide a regret bound depending on the maximal clique cover number of the latent graphs. This result is improved to a regret bound depending on the average clique cover number by Liu *et al.* [2018]. In this work, we provide sharper regret bounds for the vanilla Thompson Sampling (TS-N) and propose a variant of Thompson Sampling (TS-U) that obtains a better (within logarithmic factor) regret bound than the algorithm developed by Cohen *et al.* [2016].

Other related partial feedback models include label efficient bandit in Audibert and Bubeck [2010] and prediction with limited advice in Seldin *et al.* [2014], where side observations are limited by a budget. Graphical

bandits with Erdős-Rényi random graphs are studied by Kocák *et al.* [2016a]; Chen *et al.* [2016]; Liu *et al.* [2018]. Graphical bandits with noisy observations are studied by Kocák *et al.* [2016b]; Wu *et al.* [2015]. A survey of the graphical bandits refers to Valko [2016].

## 2 PROBLEM FORMULATION

### 2.1 STOCHASTIC BANDIT MODEL

We consider a Bayesian formulation of the stochastic  $K$ -armed bandit problem in which uncertainties are modeled as random variables. At each time  $t \in \mathbb{N}$ , a decision maker chooses an action  $A_t$  from a finite action set  $\mathcal{K} = \{1, \dots, K\}$  and receives the corresponding random reward  $Y_{t,A_t}$ . Without loss of generality, we assume the space of possible rewards  $\mathcal{Y} = [0, 1]$ . Note that the results in this work can be extended to the case where reward distributions are sub-Gaussian. There is a random variable  $Y_{t,a} \in \mathcal{Y}$  associated with each action  $a \in \mathcal{K}$  and  $t \in \mathbb{N}$ . We assume that  $\{Y_{t,a}, \forall a \in \mathcal{K}\}$  are independent for each time  $t$ . Let  $\mathbf{Y}_t \triangleq (Y_{t,a})_{a \in \mathcal{K}}$  be the vector of random variables at time  $t \in \mathbb{N}$ . The true reward distribution  $p^*$  is a distribution over  $\mathcal{Y}^{\mathcal{K}}$ , which is randomly drawn from the family of distributions  $\mathcal{P}$  and unknown to the decision maker. Conditioned on  $p^*$ ,  $(\mathbf{Y}_t)_{t \in \mathbb{N}}$  is an independent and identically distributed sequence with each element  $\mathbf{Y}_t$  sampled from the distribution  $p^*$ .

Let  $A^* \in \arg \max_{a \in \mathcal{K}} \mathbb{E}[Y_{t,a} | p^*]$  be the true optimal action conditioned on  $p^*$ . Then the  $T$  period regret of the decision maker is the expected difference between the total rewards obtained by an oracle that always chooses the optimal action and the accumulated rewards up to time horizon  $T$ . Formally, we study the expected regret

$$\mathbb{E}[R(T)] = \mathbb{E} \left[ \sum_{t=1}^T Y_{t,A^*} - Y_{t,A_t} \right], \quad (1)$$

where the expectation is taken over the randomness in the action sequence  $(A_1, \dots, A_T)$  and the outcomes  $(\mathbf{Y}_t)_{t \in \mathbb{N}}$  and over the prior distribution over  $p^*$ . This notion of regret is also known as *Bayesian regret*.

### 2.2 GRAPH FEEDBACK MODEL

In this problem, we assume the existence of side observations, which are described by a graph  $G_t = (\mathcal{K}, \mathcal{E}_t)$  over the action set for each time  $t$ . The graph  $G_t$  may be directed or undirected and can be dependent on time  $t$ . At each time  $t$ , the decision maker observes the reward  $Y_{t,A_t}$  for playing action  $A_t$  as well as the outcome  $Y_{t,a}$  for each action  $a \in \{a \in \mathcal{K} | (A_t, a) \in \mathcal{E}_t\}$ . Note that it becomes the classical bandit feedback setting when the

graph is empty (i.e., no edge exists) and it becomes the full-information (expert) setting when the graph is complete for all time  $t$ . Note that the graph  $G_t$  is *never fully revealed* to the decision maker.

Let  $\mathbf{G}_t \in \mathbb{R}^{K \times K}$  be the adjacent matrix that represents the deterministic graph feedback structure  $G_t$ . Let  $\mathbf{G}_t(i, j)$  be the element at the  $i$ -th row and  $j$ -th column of the matrix. Then  $\mathbf{G}_t(i, j) = 1$  if there exists an edge  $(i, j) \in \mathcal{E}_t$  and  $\mathbf{G}_t(i, j) = 0$  otherwise. Note that we assume  $\mathbf{G}_t(i, i) = 1$  for any  $i \in \mathcal{K}$ .

**Definition 1.** (Clique cover number) A *clique* of a graph  $G = (\mathcal{K}, \mathcal{E})$  is a subset  $S \subseteq \mathcal{K}$  such that the sub-graph formed by  $S$  and  $\mathcal{E}$  is a complete graph. A *clique cover* of a graph  $G = (\mathcal{K}, \mathcal{E})$  is a partition of  $\mathcal{K}$ , denoted by  $\mathcal{C}$ , such that  $S$  is a clique for each  $S \in \mathcal{C}$ . The cardinality of the smallest clique cover is called the *clique cover number*, which is denoted by  $\chi(G)$ .

**Definition 2.** (Independence number) An *independent set* of a graph  $G = (\mathcal{K}, \mathcal{E})$  is a subset  $S \subseteq \mathcal{K}$  such that no two  $i, j \in \mathcal{K}$  are connected by an edge in  $\mathcal{E}$ . The cardinality of a largest independent set is the *independence number* of  $G$ , denoted by  $\beta_0(G)$ .

Note that the independence number of a directed graph is equivalent to that of the undirected graph by ignoring arc orientation. We can also lift the notion of independence number of an undirected graph to directed graph through the notion of maximum acyclic subgraphs.

**Definition 3.** (Maximum acyclic subgraphs) An *acyclic subgraph* of  $G = (\mathcal{K}, \mathcal{E})$  is any graph  $G' = (\mathcal{K}', \mathcal{E}')$  such that  $\mathcal{K}' \subseteq \mathcal{K}$ , and  $\mathcal{E}' = \mathcal{E} \cap (\mathcal{K}' \times \mathcal{K}')$ , with no directed cycles. The cardinality of the largest such  $\mathcal{K}'$  is the *maximum acyclic subgraphs number*, denoted by  $mas(G)$ .

Note that  $mas(G) \geq \beta_0(G)$  in general. The equality holds when the graph  $G$  is undirected. In this work, we slightly abuse the notation of the above graph numbers and use  $\chi(G_t)$  and  $\chi(\mathbf{G}_t)$  interchangeably since  $\mathbf{G}_t$  fully characterizes the graph structure  $G_t$ .

### 2.3 RANDOMIZED POLICIES

We define all random variables with respect to a probability space  $(\Omega, \mathcal{F}, \mathbb{P})$ . Consider the filtration  $(\mathcal{F}_t)_{t \in \mathbb{N}}$  such that  $\mathcal{F}_t \subseteq \mathcal{F}$  is the  $\sigma$ -algebra generated by the observation history  $O_{t-1}$ . The observation history  $O_t$  includes all decisions, rewards and side observations from time 1 to time  $t$ . For each time  $t$ , the decision maker chooses an action based on the history  $O_{t-1}$  and possibly some randomness. Any policy of the decision maker can be viewed as a *randomized policy*  $\pi$ , which is an  $\mathcal{F}_t$ -adapted sequence  $(\pi_t)_{t \in \mathbb{N}}$ . For each time  $t$ , the decision maker chooses an action randomly according to

$\pi_t(\cdot) = \mathbb{P}(A_t = \cdot | \mathcal{F}_t)$ , which is a probability distribution over  $\mathcal{K}$ . Let  $\mathbb{E}[R(T, \pi)]$  be the Bayesian regret defined by (1) when the decisions  $(A_1, \dots, A_T)$  are chosen according to  $\pi$ .

Uncertainty about  $p^*$  induces uncertainty about the true optimal action  $A^*$ , which is described by a prior distribution  $\alpha_1$  of  $A^*$ . Let  $\alpha_t$  be the posterior distribution of  $A^*$  given the history  $O_{t-1}$ , i.e.,  $\alpha_t(\cdot) = \mathbb{P}(A^* = \cdot | \mathcal{F}_t)$ . Then,  $\alpha_{t+1}$  can be updated by Bayes rule given  $\alpha_t$ , decision  $A_t$ , reward  $Y_{t,A_t}$  and side observations. The *Shannon entropy* of  $\alpha_t$  is defined as  $H(\alpha_t) \triangleq -\sum_{i \in \mathcal{K}} \alpha_t(i) \log(\alpha_t(i))$ . We slightly abuse the notion of  $\pi_t$  and  $\alpha_t$  such that they represent distributions (or functions) over the finite set  $\mathcal{K}$  as well as vectors in a simplex  $\mathcal{S} \subset \mathbb{R}^K$ . Note that  $\mathcal{S} = \{\pi \in \mathbb{R}^K \mid \sum_{i=1}^K \pi(i) = 1, \pi(i) \geq 0, \forall i \in \mathcal{K}\}$ .

Let  $\Delta_t$  be the instantaneous regret vector such that the  $i$ -th coordinate,  $\Delta_t(i) \triangleq \mathbb{E}[Y_{t,A^*} - Y_{t,i} | \mathcal{F}_t]$ , is the expected regret of playing action  $i$  at time  $t$ . Let  $g_t$  be the information gain vector such that the  $i$ -th coordinate,  $g_t(i) = \mathbb{E}[H(\alpha_t) - H(\alpha_{t+1}) | \mathcal{F}_t, A_t = i]$ , is the expected information gain of playing action  $i$  at time  $t$ . Note that the information gain of playing action  $i$  consists of that of observing the reward  $Y_{t,i}$  and possibly some side observations. We define the information gain of observing action  $a$  (i.e.,  $Y_{t,a}$ ) as  $h_t(a) \triangleq I_t(A^*; Y_{t,a})$ , which is the *mutual information* under the posterior distribution between random variables  $A^*$  and  $Y_{t,a}$ . Let  $D(\cdot || \cdot)$  be the *Kullback-Leibler* divergence between two distributions<sup>3</sup>. By the definition of mutual information, we have that  $I_t(A^*; Y_{t,a}) \triangleq$

$$D(\mathbb{P}((A^*, Y_{t,a}) \in \cdot | \mathcal{F}_t) || \mathbb{P}(A^* \in \cdot | \mathcal{F}_t) \mathbb{P}(Y_{t,a} \in \cdot | \mathcal{F}_t)). \quad (2)$$

At each time  $t$ , a randomized policy updates  $\alpha_t$ , and makes a decision according to a sampling distribution  $\pi_t$ . For any randomized policy, we define the *information ratio* (Russo and Van Roy [2016]) of sampling distribution  $\pi_t$  at time  $t$  as

$$\Psi_t(\pi_t) \triangleq (\pi_t^T \Delta_t)^2 / (\pi_t^T g_t). \quad (3)$$

Note that  $\pi_t^T \Delta_t$  is the expected instantaneous regret of the sampling distribution  $\pi_t$ , and  $\pi_t^T g_t$  is the expected information gain of the sampling distribution  $\pi_t$ . So the information ratio  $\Psi_t(\pi_t)$  measures the “energy” cost (which is the square of the expected instantaneous regret) per bit of information acquired.

<sup>3</sup>If  $P$  is absolutely continuous with respect to  $Q$ , then  $D(P||Q) = \int \log\left(\frac{dP}{dQ}\right) dP$ , where  $\frac{dP}{dQ}$  is the Radon-Nikodym derivative of  $P$  w.r.t.  $Q$ .

## 2.4 THOMPSON SAMPLING

Thompson Sampling algorithm simply samples actions according to the posterior probability that they are optimal. In particular, actions are chosen randomly at time  $t$  according to the sampling distribution  $\pi_t = \alpha_t$ . This conceptually elegant policy can be efficiently implemented. Consider the case where  $\mathcal{P} = \{p_\theta\}_{\theta \in \Theta}$  is some parametric family of distributions. The true reward distribution  $p^*$  is indexed by  $\theta^* \in \Theta$  in the sense that  $p^* = p_{\theta^*}$ . Practical implementations of Thompson Sampling consist of two steps. First, an index  $\hat{\theta}_t \sim \mathbb{P}(\theta^* \in \cdot | \mathcal{F}_t)$  is sampled from the posterior distribution. Then, the algorithm selects the action  $A_t = \arg \max_{a \in \mathcal{K}} \mathbb{E}[Y_{t,a} | \theta^* = \hat{\theta}_t]$  that would be optimal if the sampled parameter were the true parameter. Given the observation of playing  $A_t$ , the posterior distribution is updated by Bayes’ rule.

## 3 VANILLA THOMPSON SAMPLING

In this section, we show that a vanilla Thompson Sampling algorithm, TS-N as shown in Algorithm 1, obtains optimal regret (within a logarithmic factor) in the undirected setting. A slightly weaker regret bound in the directed setting is also presented.

TS-N is the Thompson Sampling algorithm for graphical bandits such that  $\pi_t = \alpha_t$ , where  $\alpha_t$  is updated based on all the observations available, without additional modifications. It naturally keeps the information ratio  $\Psi_t(\pi_t)$  bounded as well as balances between having low expected instantaneous regret (a.k.a. exploitation) and obtaining knowledge about the optimal action (a.k.a. exploration). If the information ratio is bounded, then the expected regret is bounded in terms of the maximum amount of information one could expect to acquire, which is at most the entropy of the prior distribution of  $A^*$ , i.e.,  $H(\alpha_1)$ . First, we bound the information ratio of

TS-N in terms of the key quantity

$$Q_t(\pi_t) = \sum_{i \in \mathcal{K}} \frac{\pi_t(i)}{\sum_{j: j \xrightarrow{t} i} \pi_t(j)}. \quad (4)$$

Note that  $j \xrightarrow{t} i$  represents an arc  $(j, i)$  in graph  $G_t$ .

**Proposition 1.** *If  $\pi_t = \alpha_t$ , then the information ratio satisfies  $\Psi_t(\pi_t) \leq \frac{1}{2}Q_t(\pi_t)$  almost surely.*

Proposition 1 is a tight bound for the information ratio of the vanilla Thompson Sampling (Thompson [1933]). If the graph is empty (i.e., there is no edges in the graph), then the quantity  $Q_t(\pi_t)$  equals to  $K$ . If the graph is complete, then the quantity  $Q_t(\pi_t)$  equals to 1. These recover the information ratio bounds shown by Russo and Van Roy [2016]. Also, the quantity  $Q_t(\pi_t)$  is upper bounded by clique cover number  $\chi(G_t)$  as one can separate the sum by cliques and dropping the weights out of the clique. This recovers the information ratio bound shown by Liu *et al.* [2018]. Proposition 1 allows us to show a tighter regret bound of Thompson Sampling for graphical bandits. Next, we bound the regret of TS-N in terms of the quantity  $Q_t(\pi_t)$ .

**Theorem 1.** *The regret of TS-N satisfies*

$$\mathbb{E}[R(T, \pi)] \leq \sqrt{\frac{1}{2} \sum_{t=1}^T \mathbb{E}[Q_t(\alpha_t)] H(\alpha_1)}. \quad (5)$$

Note that the entropy is bounded, i.e.,  $H(\alpha_1) \leq \log K$ . It has been shown by Mannor and Shamir [2011]; Alon *et al.* [2014] that the quantity  $Q_t(\pi_t)$  is related to the graph numbers irrespective of the choice of the distribution  $\pi_t$ . The following graph-theoretic result shows that the quantity  $Q_t(\pi_t)$  is bounded by the independence number of the latent graph if the graph is undirected.

**Lemma 1.** (Lemma 3 in Mannor and Shamir [2011]) *Let  $G = (\mathcal{K}, \mathcal{E})$  be an undirected graph. For any distribution  $\pi$  over  $\mathcal{K}$ ,*

$$\sum_{i \in \mathcal{K}} \frac{\pi(i)}{\sum_{j: j \xrightarrow{t} i} \pi(j)} \leq \beta_0(G). \quad (6)$$

The following regret result of TS-N follows immediately from Theorem 1 and Lemma 1.

**Corollary 1.** *In the undirected setting, the regret of TS-N satisfies*

$$\mathbb{E}[R(T, \pi)] \leq \sqrt{\frac{1}{2} \sum_{t=1}^T \beta_0(G_t) H(\alpha_1)}. \quad (7)$$

As far as we know, this is the best regret bound for graphical bandits without the graphs. First, an information-theoretic lower bound of graphical bandits has been

shown by Mannor and Shamir [2011]; Alon *et al.* [2014] to be  $\Omega(\sqrt{\beta_0(G)T})$ . So Corollary 1 shows that TS-N obtains the optimal regret (within a logarithmic factor) in the undirected setting. Moreover, the bound proven in Corollary 1 is tighter than the  $O(\sqrt{\chi(G)TH(\alpha_1)})$  bound of TS-N shown by Liu *et al.* [2018] as  $\beta_0(G) \leq \chi(G)$ . At last, Corollary 1 shows that TS-N enjoys better regret bound than Cohen's Algorithm 1 developed by Cohen *et al.* [2016] in the undirected setting, both of which do not require the knowledge of the feedback graphs.

We now turn to the directed setting. The following graph-theoretic result shows that the quantity  $Q_t(\pi_t)$  is upper-bounded by the maximum acyclic subgraph number if the graph is directed.

**Lemma 2.** (Lemma 10 in Alon *et al.* [2014]) *Let  $G = (\mathcal{K}, \mathcal{E})$  be a directed graph. For any distribution  $\pi$  over  $\mathcal{K}$ ,*

$$\sum_{i \in \mathcal{K}} \frac{\pi(i)}{\sum_{j: j \xrightarrow{t} i} \pi(j)} \leq \text{mas}(G). \quad (8)$$

The following regret result of TS-N follows immediately from Theorem 1 and Lemma 2.

**Corollary 2.** *In the directed setting, the regret of TS-N satisfies*

$$\mathbb{E}[R(T, \pi)] \leq \sqrt{\frac{1}{2} \sum_{t=1}^T \text{mas}(G_t) H(\alpha_1)}. \quad (9)$$

The bound proven in Corollary 2 is tighter than the  $O(\sqrt{\chi(G)TH(\alpha_1)})$  bound of TS-N shown by Liu *et al.* [2018] since  $\text{mas}(G) \leq \chi(G)$ . However, there is a gap between the lower bound and the upper bound shown in Corollary 2. Though  $\beta_0(G) = \text{mas}(G)$  when the graph is undirected, the gap between them can be large in general directed graphs. For example, consider a directed graph  $G_0 = (\mathcal{K}, \mathcal{E})$  such that  $\text{arc}(i, j) \in \mathcal{E}$  if and only if  $i \leq j$ . It is clear that  $\beta_0(G_0) = 1$  and  $\text{mas}(G_0) = K$ . This leads us to consider a more sophisticated randomized policy. In the next section, we show that a modified Thompson Sampling algorithm results in an optimal (within a logarithmic factor) regret bound in the general setting.

**Remark 1.** *The bounds proven in Corollary 1 and 2 hold for IDS-N and IDSN-LP developed by Liu *et al.* [2018] since the information ratio of IDS-N and IDSN-LP are bounded by the information ratio of TS-N almost surely. So our results also provide tighter bounds for IDS-N and IDSN-LP algorithms. Note that IDS-N and IDSN-LP algorithms require prior knowledge of the feedback graphs.*

## 4 THOMPSON SAMPLING WITH EXPLORATION

In this section, we show that a mixture of Thompson Sampling and uniform sampling, TS-U as shown in Algorithm 2, obtains the optimal regret within a logarithmic factor in the directed setting.

TS-U algorithm is a variant of Thompson Sampling with explicit exploration that allows the algorithm to explore some suboptimal actions with large out-degrees. The collected side observations from the uniform sampling allows us to capture the latent graph information, thus yielding a regret bound in terms of the independence number.

As shown in Algorithm 2, TS-U is a randomized policy such that  $\pi_t = (1 - \epsilon)\alpha_t + \epsilon/K$  for some parameter  $\epsilon \in [0, 1]$ . The implementation and computation of TS-U is quite efficient. At each time  $t$ , TS-U algorithm plays vanilla Thompson Sampling with probability  $1 - \epsilon$  and plays uniform sampling with probability  $\epsilon$ . While the expected information gain diminishes, the expected instantaneous regret is bounded away from zero due to uniform sampling. Thus, the classical analysis of bounding the information ratio  $\Psi_t(\pi_t)$  does not work any more. Fortunately, the linear form of  $\pi_t$  allows us to bound the regret of TS-U by the regret due to uniform sampling plus the regret from Thompson Sampling, as shown in Theorem 2. Indeed, our techniques work for any variant of Thompson Sampling that is a linear combination of  $\alpha_t$  and some other distributions.

**Theorem 2.** *The regret of TS-U satisfies*

$$\mathbb{E}[R(T, \pi)] \leq \epsilon T + \sqrt{\frac{1}{2} \sum_{t=1}^T \mathbb{E}[Q_t(\pi_t)] H(\alpha_1)}. \quad (10)$$

Theorem 2 shows that the regret of TS-U consists of two parts, the regret from the uniform sampling and the regret from the Thompson Sampling. Note that the regret from the Thompson Sampling takes into account the information gain from the uniform sampling as the term

$Q_t(\pi_t)$  depends on  $\pi_t$  rather than  $\alpha_t$ . This allows us to use the following graph-theoretic result to bound the term  $Q_t(\pi_t)$ , thus the regret of TS-U, by the independence number of the latent graph.

**Lemma 3.** (Lemma 5 in Alon *et al.* [2015]) *Let  $G = (\mathcal{K}, \mathcal{E})$  be a directed graph. For any distribution  $\pi$  over  $\mathcal{K}$  such that  $\pi(i) \geq \eta$  for all  $i \in \mathcal{K}$  for some constant  $0 < \eta < 0.5$ . Then*

$$\sum_{i \in \mathcal{K}} \frac{\pi(i)}{\sum_{j: j \xrightarrow{t} i} \pi(j)} \leq 4\beta_0(G) \log \left( \frac{4K}{\beta_0(G)\eta} \right). \quad (11)$$

Lemma 3 shows that the quantity  $Q_t(\pi_t)$  can be bounded by the independence number of the directed graph if  $\pi_t$  is bounded away from zero. The uniform sampling part of TS-U allows the sampling distribution to satisfy this condition. By Theorem 2 and taking  $\eta = \epsilon/K$  in Lemma 3, we have the following result.

**Corollary 3.** *If  $\epsilon = 1/\sqrt{T}$ , then the regret of TS-U satisfies*

$$\mathbb{E}[R(T, \pi)] = O \left( \sqrt{\log(KT) \sum_{t=1}^T \beta_0(G_t) H(\alpha_1)} \right). \quad (12)$$

Comparing the regret bound in Corollary 3 to the lower bound,  $\Omega(\sqrt{\beta_0(G)T})$ , the TS-U algorithm obtains the optimal regret within a logarithmic factor in the general setting. Moreover, Corollary 3 shows that TS-U enjoys a sharper (by a logarithmic factor) regret bound than Cohen's Algorithm 1 developed by Cohen *et al.* [2016] in the directed setting, both of which do not require the knowledge of the feedback graphs. As far as we know, this is the best-known regret bound for graphical bandits without the graphs. Finally, note that a comparison between Corollary 1 and Corollary 3 reveals that a symmetric observation system (i.e., undirected feedback graphs) enjoys better regret than an asymmetric observation system as the regret bound of TS-N is sharper by a logarithmic factor than the bound in Corollary 3 in the undirected setting.

**Remark 2.** *We present TS-U algorithm with fixed exploration rate  $\epsilon$  for simplicity. It is easy to verify that the regret result of TS-U still holds if one uses some appropriate decreasing exploration rate sequence  $\{\epsilon_t\}$ . For example, when  $\epsilon_t = 1/t$ , Theorem 2 holds by replacing the term  $\epsilon T$  with  $\log T$ . Then the regret result of the corresponding TS-U algorithm follows. In practice, we recommend practitioners to use decreasing exploration rates.*

**Remark 3.** *In the informed setting (i.e., when the feedback graph are revealed to the decision maker before the*

(a) Time-invariant graphs

(a) Time-invariant graphs

(b) Time-variant graphs

(b) Time-variant graphs

Figure 1: Regret comparison under undirected graph feedback

Figure 2: Regret comparison under directed graph feedback

decisions), one may propose a variant of TS-U such that it restricts the exploration set to the dominating set of the feedback graph. In other words, one may replace uniform sampling over all the actions with uniform sampling over only the dominating set. The regret bound in Corollary 3 still holds by a variant of Lemma 3 shown in Alon et al. [2014].

## 5 NUMERICAL RESULTS

This section presents numerical results from experiments that evaluate the effectiveness of Thompson Sampling based policies in comparison to UCB-N and Cohen’s algorithm. We consider the classical Beta-Bernoulli bandit problem with independent actions. The reward of each action  $i$  is a Bernoulli( $\mu_i$ ) random variable and  $\mu_i$  is independently drawn from Beta(1,1). The implementations of TS-N and TS-U are shown in Algorithms 3 and 4. In the experiment, we set  $K = 5$ ,  $T = 1000$  and  $\epsilon_t = 1/t$  as suggested by Remark 2. All the regret results

are averaged over 1000 trials.

Figure 1 presents the cumulative regret results under undirected graph feedback. For the time-invariant case shown in Figure 1a, we use a graph with 2 cliques, presented in Figure 3. Figure 2 presents the cumulative regret results under directed graph feedback. For the time-invariant case shown in Figure 2a, we use the graph  $G = (\mathcal{K}, \mathcal{E})$  such that  $(i, j) \in \mathcal{E}$  if and only if  $i \leq j$ , presented in Figure 4. For the time-variant cases shown in Figures 1b and 2b, the sequences of graphs are generated by the Erdős-Rényi model with parameter  $p_t^4$  drawn from the uniform distribution over  $[0, 0.2]$ .

We find that TS-N and TS-U outperform the alternative algorithms, which is consistent with the empirical observation in the bandit feedback setting (Chapelle and Li [2011]). However, TS-N has better empirical performance in the tested settings even though we have

<sup>4</sup>For each time  $t$  and each pair  $(i, j)$ ,  $(i, j) \in \mathcal{E}_t$  with probability  $p_t$

   **end for**  
**end for**

---

proven a better regret bound for TS-U under directed feedback graphs. The average regrets of Cohen’s algorithm are dramatically larger than that of Thompson Sampling based policies. For this reason, parts of Cohen’s algorithm are omitted from Figures 1 and 2.

## 6 CONCLUSION

We have provided regret analysis of Thompson Sampling for graphical bandits without knowing the feedback graphs at any time. We show that the regret of TS-N is bounded by  $O\left(\sqrt{\text{mas}(G)T \log K}\right)$  in the general setting. In the undirected setting,  $\text{mas}(G) = \beta_0(G)$ , and the resulting regret bound is optimal up to a logarithmic factor. As far as we know, this is the first result that shows that Thompson Sampling, even without the knowledge of the graph, can attain the optimal regret in the graphical bandits. As a byproduct, our analysis for TS-N provide improved regret bounds for information directed sampling algorithms (IDS-N and IDS-N-LP algorithms) proposed by Liu *et al.* [2018] in the informed setting.

We have proposed a variant of Thompson Sampling, TS-U, that mixes Thompson Sampling with

Figure 3: Graph structure for the experiment under time-invariant and undirected graph

Figure 4: Graph structure for the experiment under time-invariant and directed graph

uniform sampling. This modification allows the algorithm to capture the graph structure and obtain  $O\left(\sqrt{\beta_0(G)T \log K \log(KT)}\right)$  regret bound in the directed setting, which is optimal within a logarithmic factor. Our results offer a recipe for practitioners to choose algorithms for graphical bandits without knowledge of the graphs. If the latent graphs are known to be undirected, one can choose TS-N for the best regret guarantee. Otherwise, TS-U is the choice with the best guarantee in the general (directed) setting.

## Abstract

We investigate structured sparsity methods for variable selection in regression problems where the target depends nonlinearly on the inputs. We focus on general nonlinear functions not limiting a priori the function space to additive models. We propose two new regularizers based on partial derivatives as nonlinear equivalents of group lasso and elastic net. We formulate the problem within the framework of learning in reproducing kernel Hilbert spaces and show how the variational problem can be reformulated into a more practical finite dimensional equivalent. We develop a new algorithm derived from the ADMM principles that relies solely on closed forms of the proximal operators. We explore the empirical properties of our new algorithm for Nonlinear Variable Selection based on Derivatives (NVSD) on a set of experiments and confirm favourable properties of our structured-sparsity models and the algorithm in terms of both prediction and variable selection accuracy.

## 1 INTRODUCTION

We are given a set of  $n$  input-output pairs  $\{(\mathbf{x}^i, y^i) \in (\mathcal{X} \times \mathcal{Y}) : \mathcal{X} \subseteq \mathbb{R}^d, \mathcal{Y} \subseteq \mathbb{R}, i \in \mathbb{N}_n\}$  sampled i.i.d. according to an unknown probability measure  $\rho$ . Our task is to learn a regression function  $f : \mathcal{X} \rightarrow \mathcal{Y}$  with minimal expected squared error loss  $\mathcal{L}(f) = \mathbb{E}(y - f(\mathbf{x}))^2 = \int (y - f(\mathbf{x}))^2 d\rho(\mathbf{x}, y)$ .

We follow the standard theory of regularised learning where  $\hat{f}$  is learned by minimising the regularised empirical squared error loss  $\hat{\mathcal{L}}(f) = \frac{1}{n} \sum_i^n (y^i - f(\mathbf{x}^i))^2$

$$\hat{f} = \underset{f}{\operatorname{argmin}} \hat{\mathcal{L}}(f) + \tau \mathcal{R}(f) . \quad (1)$$

In the above,  $\mathcal{R}(f)$  is a suitable penalty typically based on some prior assumption about the function space (e.g. smoothness), and  $\tau > 0$  is a suitable regularization hyper-parameter. The principal assumption we consider in this paper is that the function  $f$  is sparse with respect to the original input space  $\mathcal{X}$ , that is it depends only on  $l \ll d$  input variables.

Learning with variable selection is a well-established and rather well-explored problem in the case of linear models  $f(\mathbf{x}) = \sum_a^d x_a w_a$ , e.g. Hastie et al. (2015). The main ideas from linear models have been successfully transferred to additive models  $f(\mathbf{x}) = \sum_a^d f_a(x_a)$ , e.g. Ravikumar et al. (2007), Bach (2009), Koltchinskii and Yuan (2010), and Yin et al. (2012), or to additive models with interactions  $f(\mathbf{x}) = \sum_a^d f_a(x_a) + \sum_{a < b}^d f_{a,b}(x_a, x_b)$ , e.g. Lin and Zhang (2006) and Tyagi et al. (2016).

However, sparse modelling of general non-linear functions is more intricate. A promising stream of works focuses on the use of non-linear (conditional) cross-covariance operators arising from embedding probability measures into Hilbert function spaces, e.g. Yamada et al. (2014) and Chen et al. (2017).

In this work, we follow an alternative approach proposed in Rosasco et al. (2013) based on partial derivatives and develop new regularizers to promote structured sparsity with respect to the original input variables. We stress that our objective here is not to learn new data representations nor learn sparse models in some latent feature space, e.g. Gurram and Kwon (2014). Nor is it to learn models sparse in the data instances (in the sense of support vectors, e.g. Chan et al. (2007)). We aim at selecting the relevant input variables, the relevant dimensions of the input vectors  $\mathbf{x} \in \mathbb{R}^d$ .

After a brief review of the regularizers used in Rosasco et al. (2013) for individual variable selection in non-linear model learning (similar in spirit to lasso Tibshi-

rani (1996)) we propose two extensions motivated by the linear structured-sparsity learning literature. Using suitable norms of the partial derivatives we propose the non-linear versions of the group lasso Yuan and Lin (2006) and the elastic net Zou and Hastie (2005).

We pose our problem into the framework of learning in the reproducing kernel Hilbert space (RKHS). We extend the representer theorem to show that the minimiser of (1) with our new regularizers  $\mathcal{R}(f)$  can be conveniently written as a linear combination of kernel functions and their partial derivatives evaluated over the training set.

We further propose a new reformulation of the equivalent finite dimensional learning problem, which allows us to develop a new algorithm (NVSD) based on the Alternating Direction Method of Multipliers (ADMM) Boyd (2010). This is a generic algorithm that can be used (with small alterations) for all regularizers we discuss here. At each iteration, the algorithm needs to solve a single linear problem, perform a proximal step resulting in a soft-thresholding operation, and do a simple additive update of the dual variables. Unlike Rosasco et al. (2013), which uses approximations of the proximal operator, our algorithm is based on proximals admitting closed forms for all the discussed regularizers, including the one suggested previously in Rosasco et al. (2013). Furthermore, by avoiding the approximations in the proximal step, the algorithm directly provides also the learned sparsity patterns over the training set (up to the algorithmic convergence precision).

We explore the effect of the proposed regularizers on model learning on synthetic and real-data experiments, and confirm the superior performance of our methods in comparison to a range of baseline methods when learning structured-sparse problems. Finally, we conclude by discussing the advantages and shortcomings of the current proposal and outline some directions for future work.

## 2 REGULARIZERS FOR VARIABLE SELECTION

In Rosasco et al. (2013) the authors propose to use the partial derivatives of the function with respect to the input vector dimensions  $\{\partial_a f : a \in \mathbb{N}_d\}$  to construct a regularizer promoting sparsity. The partial derivative evaluated at an input point  $\partial_a f(\mathbf{x})$  is the rate of change of the function at that point with respect to  $x_a$  holding the other input dimensions fixed. Intuitively, when the function does not depend on an input variable (input dimension  $a$ ), its evaluations do not change with changes in the input variable:  $\partial_a f(\mathbf{x}) = 0$  at all points  $\mathbf{x} \in \mathcal{X}$ . A natural measure of the size of the partial derivatives

across the space  $\mathcal{X}$  is the  $L_2$  norm

$$\|\partial_a f\|_{L_2} = \sqrt{\int_{\mathcal{X}} |\partial_a f(\mathbf{x})|^2 d\rho_{\mathbf{x}}(\mathbf{x})} \quad (2)$$

**Remark 1.** *At this point we wish to step back and make a link to the linear models  $f(\mathbf{x}) = \sum_a^d x_a w_a$ . The partial derivatives with respect to any of the  $d$  dimensions of the input vector  $\mathbf{x}$  are the individual elements of the  $d$ -dimensional parameter vector  $\mathbf{w}$ ,  $\partial_a f(\mathbf{x}) = w_a$ , and this at every point  $\mathbf{x} \in \mathcal{X}$ . For the linear model we thus have  $\|\partial_a f\|_{L_2} = |w_a|$ . Sparsity inducing norms or constraints operating over the parameter vectors  $\mathbf{w}$  can therefore be seen as special cases of the same norms and constraints imposed on the partial-derivative norms (2).*

### 2.1 SPARSITY INDUCING NORMS

The sparsity objective over a vector  $\mathbf{v} \in \mathbb{R}^d$  can be cast as the minimization of the  $\ell_0$  norm  $\|\mathbf{v}\|_0 = \#\{a = 1, \dots, d : v_a \neq 0\}$  which counts the number of non-zero elements of the vector. Since it is well known from the linear sparse learning literature that finding the  $\ell_0$  solutions is computationally difficult in higher dimensions (NP-hard, Weston et al. (2003)), the authors in Rosasco et al. (2013) suggest to use its tightest convex relaxation, the  $\ell_1$  norm  $\|\mathbf{v}\|_1 = \sum_a^d |v_a|$ . They apply the  $\ell_1$  norm over the partial-derivative norms (2) so that the lasso-like sparsity regularizer in (1) is

$$\mathcal{R}^L(f) = \sum_{a=1}^d \|\partial_a f\|_{L_2} \quad (3)$$

In this paper we explore two extensions inspired by the linear sparse learning, opening the doors to many of the other sparsity and structured sparsity inducing norms that have been proposed in the abundant literature on this topic. Namely, we focus here on the structured sparsity induced by the mixed  $\ell_1/\ell_2$  norm known in the context of linear least squares as the group lasso Yuan and Lin (2006). For a vector  $\mathbf{v}$  composed of  $G$  groups  $\mathbf{v}_g$  (non-overlapping but not necessarily consecutive) with  $p_g$  number of elements each, the mixed  $\ell_1/\ell_2$  norm is  $\|\mathbf{v}\|_{1,2} = \sum_g^G p_g \|\mathbf{v}_g\|_2$ . The corresponding group-lasso-like regularizer to be used in (1) is

$$\mathcal{R}^{GL}(f) = \sum_{g=1}^G p_g \sqrt{\sum_{a \in g} \|\partial_a f\|_{L_2}^2} \quad (4)$$

Second, we look at the elastic net penalty proposed initially in Zou and Hastie (2005). This uses a convex combination of the  $\ell_1$  and square of the  $\ell_2$  norm and has been

shown to have better selection properties over the vanilla  $\ell_1$  norm regularization in the presence of highly correlated features. Unlike the  $\ell_1$  penalty, the combined elastic net is also strictly convex. The corresponding elastic-net-like regularizer to be used in (1) is

$$\mathcal{R}^{EN}(f) = \mu \sum_{a=1}^d \|\partial_a f\|_{L_2} + (1 - \mu) \sum_{a=1}^d \|\partial_a f\|_{L_2}^2, \quad \mu \in [0, 1]. \quad (5)$$

## 2.2 EMPIRICAL VERSIONS OF REGULARIZERS

A common problem of the regularizers introduced above is that in practice they cannot be evaluated due to the unknown probability measure  $\rho_x$  on the input space  $\mathcal{X}$ . Therefore instead of the partial-derivative norms defined in expectation in (2)

$$\|\partial_a f\|_{L_2} = \sqrt{\mathbb{E}|\partial_a f(\mathbf{x})|^2} \quad (6)$$

we use their sample estimates replacing the expectation by the training sample average

$$\|\partial_a f\|_{2_n} = \sqrt{\frac{1}{n} \sum_i |\partial_a f(\mathbf{x}^i)|^2}. \quad (7)$$

This corresponds to the move from expected loss to the empirical loss introduced in section 1 and is enabled by the i.i.d. sample assumptions.

In result, the regression function is learned from the empirical version of (1)

$$\hat{f} = \operatorname{argmin}_{f \in \mathcal{F}} \hat{\mathcal{L}}(f) + \tau \hat{\mathcal{R}}(f), \quad (8)$$

where  $\hat{\mathcal{R}}(f)$  are the empirical analogues of the regularizers (3), (4) and (5) replacing the population partial-derivative norms  $\|\partial_a f\|_{L_2}$  by their sample estimates  $\|\partial_a f\|_{2_n}$ . The function space  $\mathcal{F}$  is discussed next.

## 3 LEARNING IN RKHS

In this paper, the hypothesis space  $\mathcal{F}$  within which we learn the function  $f$  is a reproducing kernel Hilbert space (RKHS). We recall (e.g. Saitoh and Sawano (2016)) that a RKHS is a function space  $\mathcal{F}$  of real-valued functions over  $\mathcal{X}$  endowed with an inner product  $\langle \cdot, \cdot \rangle_{\mathcal{F}}$  and the induced norm  $\|\cdot\|_{\mathcal{F}}$  that is uniquely associated with a positive semidefinite kernel  $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ . The kernel  $k$  has the reproducing property  $\langle k_{\mathbf{x}}, f \rangle_{\mathcal{F}} = f(\mathbf{x})$  and, in particular,  $\langle k_{\mathbf{x}}, k_{\mathbf{x}'} \rangle_{\mathcal{F}} = k(\mathbf{x}, \mathbf{x}')$ , where  $k_{\mathbf{x}} \in \mathcal{F}$  is the kernel section centred at  $\mathbf{x}$  such that  $k_{\mathbf{x}}(\mathbf{x}') = k(\mathbf{x}, \mathbf{x}')$

for any two  $\mathbf{x}, \mathbf{x}' \in \mathcal{X}$ . Furthermore, the space  $\mathcal{F}$  is the completion of the linear span of the functions  $\{k_{\mathbf{x}} : \mathbf{x} \in \mathcal{X}\}$ .

In addition to these fairly well known properties of the RKHS and its kernel, the author in Zhou (2008) has shown that if  $k$  is continuous and sufficiently smooth the kernel partial-derivative functions belong to the RKHS and have a partial-derivative reproducing property. More specifically, we define the kernel partial-derivative function  $[\partial_a k_{\mathbf{x}}] : \mathcal{X} \rightarrow \mathbb{R}$  as

$$[\partial_a k_{\mathbf{x}}](\mathbf{x}') = \frac{\partial}{\partial x_a} k(\mathbf{x}, \mathbf{x}') \quad \forall \mathbf{x}, \mathbf{x}' \in \mathcal{X}. \quad (9)$$

The function  $[\partial_a k_{\mathbf{x}}] \in \mathcal{F}$  has the reproducing property  $\langle [\partial_a k_{\mathbf{x}}], f \rangle_{\mathcal{F}} = \partial_a f(\mathbf{x})$ . In particular  $\langle [\partial_a k_{\mathbf{x}}], k_{\mathbf{x}'} \rangle_{\mathcal{F}} = \partial_a k_{\mathbf{x}'}(\mathbf{x})$  and  $\langle [\partial_a k_{\mathbf{x}}], [\partial_b k_{\mathbf{x}'}] \rangle_{\mathcal{F}} = \frac{\partial^2}{\partial x_a \partial x'_b} k(\mathbf{x}, \mathbf{x}')$ .

**Remark 2.** *Since the notation above may seem somewhat knotty at first, we invite the reader to appreciate the difference between the function  $[\partial_a k_{\mathbf{x}}]$  and the partial derivative of the kernel section with respect to the  $a$ th dimension  $\partial_a k_{\mathbf{x}}$ . Clearly,  $[\partial_a k_{\mathbf{x}}](\mathbf{x}') \neq \partial_a k_{\mathbf{x}}(\mathbf{x}')$  for any  $\mathbf{x} \neq \mathbf{x}' \in \mathcal{X}$ . However, due to the symmetry of the kernel we do have  $[\partial_a k_{\mathbf{x}}](\mathbf{x}') = \partial_a k_{\mathbf{x}'}(\mathbf{x}) = \frac{\partial}{\partial x_a} k(\mathbf{x}, \mathbf{x}')$ .*

## 3.1 SOLUTION REPRESENTATION

The variational (infinite-dimensional) problem (8) is difficult to handle as is. However, it has been previously shown for a multitude of RKHS learning problems that their solutions  $\hat{f}$  can be expressed as finite linear combinations of the kernel evaluations over the training data Argyriou and Dinuzzo (2014). This property, known as *representer theorem*, renders the problems amenable to practical computations.

**Proposition 1.** *The minimising solution  $\hat{f}$  of the variational problem*

$$\hat{f} = \operatorname{argmin}_{f \in \mathcal{F}} \hat{\mathcal{L}}(f) + \tau \hat{\mathcal{R}}(f) + \nu \|f\|_{\mathcal{F}}^2, \quad (10)$$

where  $\tau, \nu \geq 0$  and  $\hat{\mathcal{R}}(f)$  is any of the empirical versions of the three formulations (3), (4), (5) can be represented as

$$\hat{f} = \sum_i \alpha_i k_{\mathbf{x}^i} + \sum_i \sum_a \beta_{ai} [\partial_a k_{\mathbf{x}^i}]. \quad (11)$$

The proof (available in the appendix) follows the classical approach (e.g. Schölkopf et al. (2001)) of decomposition of  $\mathcal{F}$  into the space spanned by the representation and its orthogonal complement.

The proposition extends the representer theorem of Rosasco et al. (2013) to the new regularizers (4) and (5).

Note that we included the induced Hilbert norm  $\|f\|_{\mathcal{F}}$  into (10) as a useful generalization that reduces to our original problem (8) if  $\nu = 0$ . On the other hand, when  $\tau = 0$  we recover a classical kernel regression problem which is known to have another simpler representation consisting just of the first term in (11).

## 4 ALGORITHM

In this section we describe the new algorithm we developed to solve problem (10) with the three sparse regularizers introduced in section 2. The algorithm is versatile so that it requires only small alterations in specific steps to move from one regularizer to the other. Importantly, unlike the algorithm proposed in Rosasco et al. (2013) for solving only the lasso-like problem, our algorithm does not need to rely on proximal approximations since all the proximal steps can be evaluated in closed forms. Our algorithm also directly provides values of the partial derivatives of the learned function indicating the learned sparsity.

### 4.1 FINITE DIMENSIONAL FORMULATION

To be able to develop a practical algorithm we first need to reformulate the variational optimisation problem (10) into its finite dimensional equivalent. For this we introduce the following objects: the  $n$ -long vector  $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_n]^T$ , the  $dn$ -long vector  $\boldsymbol{\beta} = [\beta_{11}, \dots, \beta_{1n}, \beta_{21}, \dots, \beta_{dn}]^T$ , the  $n \times n$  symmetric PSD kernel matrix  $\mathbf{K}$  such that  $K_{ij} = k(\mathbf{x}^i, \mathbf{x}^j)$ , the  $n \times n$  (non-symmetric) kernel derivative matrices  $\mathbf{D}^a$  and  $\tilde{\mathbf{D}}^a$ ,  $a \in \mathbb{N}_d$  such that  $D_{ij}^a = [\partial_a k_{\mathbf{x}^i}](\mathbf{x}^j) = \partial_a k_{\mathbf{x}^j}(\mathbf{x}^i) = \tilde{D}_{ji}^a$ , the  $n \times n$  (non-symmetric) kernel 2nd derivative matrices  $\mathbf{L}^{ab}$ ,  $a, b \in \mathbb{N}_d$  such that  $\mathbf{L}_{ij}^{ab} = \frac{\partial^2}{\partial x_i^a \partial x_j^b} k(\mathbf{x}^i, \mathbf{x}^j) = \frac{\partial}{\partial x_j^b} [\partial_a k_{\mathbf{x}^i}](\mathbf{x}^j) = \mathbf{L}_{ji}^{ba}$ . Further, we need the following concatenations:

$$\mathbf{D} = \begin{bmatrix} \mathbf{D}^1 \\ \dots \\ \mathbf{D}^d \end{bmatrix} \quad \mathbf{L}^a = [\mathbf{L}^{a1} \dots \mathbf{L}^{ad}] \quad \mathbf{L} = \begin{bmatrix} \mathbf{L}^1 \\ \dots \\ \mathbf{L}^d \end{bmatrix}$$

and specifically for the groups  $g$  in  $\mathcal{R}^{GL}$  the partitions

$$\ddot{\mathbf{D}}^g = \begin{bmatrix} \mathbf{D}^{g_1} \\ \dots \\ \mathbf{D}^{g_{p_g}} \end{bmatrix} \quad \dot{\mathbf{L}}^g = \begin{bmatrix} \mathbf{L}^{g_1} \\ \dots \\ \mathbf{L}^{g_{p_g}} \end{bmatrix},$$

where the subscripts  $g_i$  are the corresponding indexes of the input dimensions.

**Proposition 2.** *The variational problem (10) is equivalent to the finite dimensional problem*

$$\operatorname{argmin}_{\boldsymbol{\alpha}, \boldsymbol{\beta}} \mathcal{J}1(\boldsymbol{\alpha}, \boldsymbol{\beta}) + \tau \mathcal{J}2(\boldsymbol{\alpha}, \boldsymbol{\beta}) + \nu \mathcal{J}3(\boldsymbol{\alpha}, \boldsymbol{\beta}), \quad (12)$$

where

$$\begin{aligned} \mathcal{J}1(\boldsymbol{\alpha}, \boldsymbol{\beta}) &= \frac{1}{n} \|\mathbf{y} - \mathbf{K}\boldsymbol{\alpha} - \mathbf{D}^T \boldsymbol{\beta}\|_2^2 \\ \mathcal{R}^L : \mathcal{J}2(\boldsymbol{\alpha}, \boldsymbol{\beta}) &= \frac{1}{\sqrt{n}} \sum_a^d \|\mathbf{D}^a \boldsymbol{\alpha} + \mathbf{L}^a \boldsymbol{\beta}\|_2 \\ \mathcal{R}^{GL} : \mathcal{J}2(\boldsymbol{\alpha}, \boldsymbol{\beta}) &= \frac{1}{\sqrt{n}} \sum_g^G p_g \|\ddot{\mathbf{D}}^g \boldsymbol{\alpha} + \dot{\mathbf{L}}^g \boldsymbol{\beta}\|_2 \\ \mathcal{R}^{EN} : \mathcal{J}2(\boldsymbol{\alpha}, \boldsymbol{\beta}) &= \frac{\mu}{\sqrt{n}} \sum_a^d \|\mathbf{D}^a \boldsymbol{\alpha} + \mathbf{L}^a \boldsymbol{\beta}\|_2 \\ &\quad + \frac{1-\mu}{n} \sum_a^d \|\mathbf{D}^a \boldsymbol{\alpha} + \mathbf{L}^a \boldsymbol{\beta}\|_2^2 \\ \mathcal{J}3(\boldsymbol{\alpha}, \boldsymbol{\beta}) &= \boldsymbol{\alpha}^T \mathbf{K} \boldsymbol{\alpha} + 2\boldsymbol{\alpha}^T \mathbf{D}^T \boldsymbol{\beta} + \boldsymbol{\beta}^T \mathbf{L} \boldsymbol{\beta} \end{aligned}$$

The proof (available in the appendix) is based on the finite dimensional representation (11) of the minimising function, and the kernel and derivative reproducing properties stated in section 3.

The problem reformulation (12) is instructive in terms of observing the roles of the kernel and the derivative matrices and is reminiscent of the classical finite dimensional reformulation of Hilbert-norm regularised least squares. However, for the development of our algorithm we derive a more convenient equivalent form.

**Proposition 3.** *The variational problem (10) is equivalent to the finite dimensional problem*

$$\operatorname{argmin}_{\boldsymbol{\omega}} \frac{1}{n} \|\mathbf{y} - \mathbf{F}\boldsymbol{\omega}\|_2^2 + \tau \mathcal{J}(\boldsymbol{\omega}) + \nu \boldsymbol{\omega}^T \mathbf{Q} \boldsymbol{\omega}, \quad (13)$$

where

$$\begin{aligned} \mathcal{R}^L : \mathcal{J}(\boldsymbol{\omega}) &= \frac{1}{\sqrt{n}} \sum_a^d \|\mathbf{Z}^a \boldsymbol{\omega}\|_2 \\ \mathcal{R}^{GL} : \mathcal{J}(\boldsymbol{\omega}) &= \frac{1}{\sqrt{n}} \sum_g^G p_g \|\ddot{\mathbf{Z}}^g \boldsymbol{\omega}\|_2 \\ \mathcal{R}^{EN} : \mathcal{J}(\boldsymbol{\omega}) &= \frac{\mu}{\sqrt{n}} \sum_a^d \|\mathbf{Z}^a \boldsymbol{\omega}\|_2 + \frac{1-\mu}{n} \sum_a^d \|\mathbf{Z}^a \boldsymbol{\omega}\|_2^2, \end{aligned}$$

with

$$\boldsymbol{\omega} = \begin{bmatrix} \boldsymbol{\alpha} \\ \boldsymbol{\beta} \end{bmatrix} \quad \mathbf{F} = [\mathbf{K} \mathbf{D}^T] \quad \mathbf{Z}^a = [\mathbf{D}^a \mathbf{L}^a] \quad \mathbf{Q} = \begin{bmatrix} \mathbf{K} & \mathbf{0} \\ 2\mathbf{D} & \mathbf{L} \end{bmatrix}$$

The proof is trivial using (12) as an intermediate step.

### 4.2 DEVELOPMENT OF GENERIC ALGORITHM

Problem (13) is convex though its middle part  $\mathcal{J}(\boldsymbol{\omega})$  is non-differentiable for all three discussed regularizers. In-

deed, it is the singularities of the norms at zero points that yield the sparse solutions. A popular approach for solving convex non-differentiable problems is the proximal gradient descent Parikh and Boyd (2013). At every step it requires evaluating the proximal operator defined for any function  $f : \mathbb{R}^m \rightarrow \mathbb{R}^m$  and any vector  $\mathbf{v} \in \mathbb{R}^m$  as

$$\text{prox}_f(\mathbf{v}) = \underset{\mathbf{x}}{\operatorname{argmin}} f(\mathbf{x}) + \frac{1}{2} \|\mathbf{x} - \mathbf{v}\|_2^2. \quad (14)$$

However, proximal operators for the functions  $\mathcal{J}$  in (13) do not have closed forms or fast methods for solving which makes the proximal gradient descent algorithm difficult to use.

We therefore propose to introduce a linearizing change of variables  $\mathbf{Z}^a \boldsymbol{\omega} = \boldsymbol{\varphi}_a$  and cast the problem in a form amenable for the ADMM method Boyd (2010)

$$\min \mathcal{E}(\boldsymbol{\omega}) + \tau \mathcal{I}(\boldsymbol{\varphi}), \quad \text{s.t. } \mathbf{Z}\boldsymbol{\omega} - \boldsymbol{\varphi} = 0. \quad (15)$$

In the above

$$\boldsymbol{\varphi} = \begin{bmatrix} \boldsymbol{\varphi}_1 \\ \dots \\ \boldsymbol{\varphi}_d \end{bmatrix}, \quad \mathbf{Z} = \begin{bmatrix} \mathbf{Z}^1 \\ \dots \\ \mathbf{Z}^d \end{bmatrix},$$

(or concatenation of the double-dot version for the group structure),  $\mathcal{E} : \mathbb{R}^{n+nd} \rightarrow \mathbb{R}$  is the convex differentiable function

$$\mathcal{E}(\boldsymbol{\omega}) = \frac{1}{n} \|\mathbf{y} - \mathbf{F}\boldsymbol{\omega}\|_2^2 + \nu \boldsymbol{\omega}^T \mathbf{Q} \boldsymbol{\omega},$$

and  $\mathcal{I} : \mathbb{R}^{nd} \rightarrow \mathbb{R}$  is the convex non-differentiable function corresponding to each regularizer such that  $\mathcal{I}(\boldsymbol{\varphi}) = \mathcal{J}(\boldsymbol{\omega})$  for every  $\mathbf{Z}\boldsymbol{\omega} = \boldsymbol{\varphi}$ .

At each iteration the ADMM algorithm consists of the following three update steps (the standard approach of augmented Lagrangian with  $\boldsymbol{\lambda}$  as the scaled dual variable and  $\kappa$  as the step size):

$$S1 : \boldsymbol{\omega}^{(k+1)} = \underset{\boldsymbol{\omega}}{\operatorname{argmin}} \mathcal{E}(\boldsymbol{\omega}) + \frac{\kappa}{2} \|\mathbf{Z}\boldsymbol{\omega} - \boldsymbol{\varphi}^{(k)} + \boldsymbol{\lambda}^{(k)}\|_2^2$$

$$S2 : \boldsymbol{\varphi}^{(k+1)} = \underset{\boldsymbol{\varphi}}{\operatorname{argmin}} \tau \mathcal{I}(\boldsymbol{\varphi}) + \frac{\kappa}{2} \|\mathbf{Z}\boldsymbol{\omega}^{(k+1)} - \boldsymbol{\varphi} + \boldsymbol{\lambda}^{(k)}\|_2^2$$

$$S3 : \boldsymbol{\lambda}^{(k+1)} = \boldsymbol{\lambda}^{(k)} + \mathbf{Z}\boldsymbol{\omega}^{(k+1)} - \boldsymbol{\varphi}^{(k+1)}$$

The first step  $S1$  is a convex quadratic problem with a closed form solution

$$S1 : (\nu \mathbf{Q} + \nu \mathbf{Q}^T + 2n^{-1} \mathbf{F}^T \mathbf{F} + \kappa \mathbf{Z}^T \mathbf{Z}) \boldsymbol{\omega}^{(k+1)} = 2n^{-1} \mathbf{F}^T \mathbf{y} + \kappa \mathbf{Z}^T (\boldsymbol{\varphi}^{(k)} - \boldsymbol{\lambda}^{(k)})$$

By comparing with (14) we observe that the second step  $S2$  is a proximal update. The advantage of our problem reformulation and our algorithm is that this has a closed form for all the three discussed regularizers.

**Proposition 4.** *The proximal problem in step  $S2$  is decomposable by the  $d$  partitions of vector  $\boldsymbol{\varphi}$  (or  $G$  partition in case of the group structure) and the minimising solution is*

$$\mathcal{R}^L : \boldsymbol{\varphi}_a^{(k+1)} = (\mathbf{Z}^a \boldsymbol{\omega}^{(k+1)} + \boldsymbol{\lambda}_a^{(k)}) \left( 1 - \frac{\tau}{\kappa \sqrt{n} \|\mathbf{Z}^a \boldsymbol{\omega}^{(k+1)} + \boldsymbol{\lambda}_a^{(k)}\|_2} \right)_+$$

$$\mathcal{R}^{GL} : \boldsymbol{\varphi}_g^{(k+1)} = (\ddot{\mathbf{Z}}^g \boldsymbol{\omega}^{(k+1)} + \ddot{\boldsymbol{\lambda}}_g^{(k)}) \left( 1 - \frac{\tau p_g}{\kappa \sqrt{n} \|\mathbf{Z}^g \boldsymbol{\omega}^{(k+1)} + \boldsymbol{\lambda}_g^{(k)}\|_2} \right)_+$$

$$\mathcal{R}^{EN} : \boldsymbol{\varphi}_a^{(k+1)} = \frac{\mathbf{Z}^a \boldsymbol{\omega}^{(k+1)} + \boldsymbol{\lambda}_a^{(k)}}{2\tau(1-\mu)/(\kappa n) + 1} \left( 1 - \frac{\tau \mu}{\kappa \sqrt{n} \|\mathbf{Z}^a \boldsymbol{\omega}^{(k+1)} + \boldsymbol{\lambda}_a^{(k)}\|_2} \right)_+$$

Here  $(v)_+ = \min(0, v)$  is the thresholding operator.

The decomposability comes from the additive structure of  $\mathcal{I}$ . The derivation follows similar techniques as used for classical  $\ell_1$  and  $\ell_2$  proximals.<sup>1</sup>

### 4.3 PRACTICAL IMPLEMENTATION

In practice, the  $\mathbf{Q}$ ,  $\mathbf{F}$  and  $\mathbf{Z}$  matrices are precomputed in a preprocessing step and passed onto the algorithm as inputs. The matrices are directly computable using the kernel function  $k$  and its first and second order derivatives evaluated at the training points (following the matrix definitions introduced in section 4.1).

The algorithm converges to a global minimum by the standard properties of ADMM. In our implementation (available at [https://bitbucket.org/dmmlgeneva/nvsd\\_uai2018/](https://bitbucket.org/dmmlgeneva/nvsd_uai2018/)) we follow a simple updating rule Boyd (2010, sec. 3.4.1) for the step size  $\kappa$ . We use inexact minimization for the most expensive step  $S1$ , gradually increasing the number of steepest descent steps, each with complexity  $\mathcal{O}((nd)^2)$ .

Furthermore, we use  $S2$  to get the values of the training sample partial-derivative norms defined in equation (7) as  $\|\partial_a f^{(k)}\|_{2_n} = \|\boldsymbol{\varphi}_a^{(k)}\|_2 / \sqrt{n}$ . The sparsity pattern is obtained by examining for which of the dimensions  $a \in \mathbb{N}_d$  the norm is zero  $\|\partial_a f^{(k)}\|_{2_n} = 0$ .

<sup>1</sup>For  $\mathcal{R}^{EN}$  it is more practical to add the quadratic term into  $\mathcal{E}(\boldsymbol{\omega})$  in  $S1$  and use the corresponding scaled version of the  $\mathcal{R}^L$  proximal in  $S2$ .

## 5 EMPIRICAL EVALUATION

We conducted a set of synthetic and real-data experiments to document the efficacy of our structured-sparsity methods and the new algorithm under controlled and more realistic conditions. We compare our methods NVSD(L), NVSD(GL) and NVSD(EN) in terms of their predictive accuracy and their selection ability to the simple (non-sparse) kernel regularised least squares (Krls), to the sparse additive model (SpAM) of Ravikumar et al. (2007), to the non-linear cross-covariance-based method using the Hilbert Schmidt Independence Criterion in a lasso-like manner (HSIC) of Yamada et al. (2014), and to the derivative-based lasso-like method (Denovas) of Rosasco et al. (2013).<sup>2</sup> We compared also to simple mean and linear sparse and non-sparse models. All of these performed considerably worse than the non-linear models and therefore are not listed in the summary results. For all the sparse kernel methods we consider a two-step debiasing procedure based on variable selection via the base algorithm followed by a simple kernel regularised least squares on the selected variables.<sup>3</sup>

### 5.1 SYNTHETIC EXPERIMENTS

We motivate each synthetic experiment by a realistic story-line and explain the data generating process here below. In all the synthetic experiments we fix the input dimension to  $d = 18$  with only 6 input variables  $\{1, 2, 3, 7, 8, 9\}$  relevant for the model and the other 12 irrelevant.

**E1** In the first experiment we focus on the NVSD(GL) which assumes the input variables can be grouped a priori by some domain knowledge (e.g. each group describes a *type* of input data such as a different biological process) and the groups are expected to be completely in or out of the model. The input variables are generated independently from a standard normal distribution and they are grouped by three into 6 groups. The output is generated from the 1st and the 3rd group as

$$y = \sum_{i=1}^3 \sum_{j=i}^3 \sum_{k=j}^3 x_i x_j x_k + \sum_{q=7}^9 \sum_{r=q}^9 \sum_{s=r}^9 x_q x_r x_s + \epsilon ,$$

with  $\epsilon \sim N(0, 0.01)$ . For learning we fix the kernel to 3rd order polynomial.

<sup>2</sup>For HSIC and Denovas we used the author’s code, for SpAM the R implementation of Zhao et al. (2014). For all algorithms we kept the default settings.

<sup>3</sup>This is native to Denovas and necessary for HSIC which otherwise does not produce a predictive model.

**E2** In the second experiment we do not assume any a priori grouping of the variables. Instead some of the variables are strongly correlated (perhaps relating to a single phenomenon), a case for NVSD(EN). The input variables are generated similarly as in E1 but with the pairs  $\{1, 7\}$ ,  $\{2, 8\}$  and  $\{3, 9\}$  strongly correlated (Pearson’s population correlation coefficient 0.95). The remaining (irrelevant) input variables are also pair-wise correlated and the output is generated as

$$y = \sum_{i,j,k=1}^3 x_i x_j x_k + \sum_{q,r,s=7}^9 x_q x_r x_s + \epsilon ,$$

with  $\epsilon \sim N(0, 0.01)$ . For learning we fix the kernel to 3rd order polynomial.

**E3** In the third experiment we assume the inputs are noisy measurements of some true phenomenon (e.g. repeated measurements, measurements from multiple laboratories) for which there is no reason to prefer one over the other in the model. We first generate the true data  $z_i \sim N(0, 1)$ ,  $i = 1, \dots, 6$  and use these to generate the outputs as

$$y = 10(z_1^2 + z_3^2)e^{-2(z_1^2 + z_3^2)} + \epsilon ,$$

with  $\epsilon \sim N(0, 0.01)$ . We then generate the noisy measurements that will be used as inputs for the learning: for each  $z_i$  we create three noisy measurements  $x_{ij} = z_i + N(0, 0.1)$ ,  $j = 1, 2, 3$  (a group for the NVSD(GL) method); the input vector is the concatenation of all  $x_{ij}$  so that from the 18 long concatenated input vector  $\mathbf{x}$  again only the set  $\{1, 2, 3, 7, 8, 9\}$  of the dimensions is relevant for predicting the output  $y$ . For learning we fix the kernel to Gaussian with width  $\sigma = 4$ .

**Remark 3.** *In all the synthetic experiments we use the same experimental protocol. We split the data into train sets varying the size in  $n = \{30, 50, 70, 90, 110\}$ , a validation set of length 1000, and a test set of length 1000. We train the models over the train sets and use the validation set to select the regularization hyper-parameters (and therefore the models) based on the minimal validation MSE. We use dense grids of 50 points for the  $\tau$  search (automatically established by the algorithm) and 5 points grid for  $\mu \in \{0.1, \dots, 0.9\}$ . Complete settings (also for the baseline methods) are detailed in the replication files publicly available at [https://bitbucket.org/dmmlgeneva/nvds\\_uai2018/](https://bitbucket.org/dmmlgeneva/nvds_uai2018/).*

We report the average results across 50 independent replications of the experiments in table 1. We measure

Table 1: Results of Synthetic Experiments

the prediction accuracy by the root mean squared error (RMSE) over the test sets and the selection accuracy by the Tanimoto distance between the true sparsity and the learned sparsity patterns (section 4.3).

Our structured-sparsity methods clearly outperform all the non-structured sparse learning methods achieving better prediction accuracy based on more precise variable selection, typically with statistically significant differences. Also, the prediction and selection accuracy generally increases (errors decrease) for larger training sample sizes suggesting our methods are well-behaved in

terms of the standard statistical learning paradigms. In the E3 experiment, NVSD(GL) performs the best having the benefit of the prior knowledge of the variable groupings. Remarkably, NVSD(EN) follows closely after even without such prior information, learning about the groups of correlated variables from the data when building the model.

Figure 1: Predictions for the E3 experiment over the test data. We picked an example for the model trained with 110 instances (the 17th replication) which illustrates well the advantage our NVSD methods have over the baselines in capturing the True complex non-linear structure.

Krls can only learn full models and therefore performs rather poorly on these by-construction sparse problems. From the other three baselines, HSIC typically achieves the second best results (after our NVSD methods). SpAM is not particularly suitable for the non-additive structures of our experiments. Finally, in all the experiments our NVSD(L) outperforms Denovas though they share the same lasso-like problem formulation. We attribute this to our new algorithm developed in section 4 which, unlike Denovas, does not rely on approximations of the proximal operators.

## 5.2 REAL-DATA EXPERIMENTS

For the real-data experiments we used a collection of regression datasets from UCI Lichman (2013) and LIACC<sup>4</sup> repositories listed in table 2.

Table 2: Real Datasets Description

Code	Name	Inputs	Test Size	Source
AI	Airfoil Self Noise	5	700	UCI
BH	Boston Housing	10	200	UCI
CC	Concrete Compressive	8	450	UCI
EN	Energy Efficiency	8	300	UCI
CP	Computer Activity	21	1000	LIACC
EL	F16 Elevators	17	1000	LIACC
KN	Kynematics	8	1000	LIACC

We report the average results across 50 replications of the experiments in tables 3 and 4. We use RMSE over the test data for measuring the prediction accuracy. For the real datasets we do not know the ground-truth sparsity patterns. Instead of measuring the selection error we therefore count the number of input variables selected by each method. Krls has no selection ability, its support size is hence equal to the total number of input variables in each problem.

**Remark 4.** *We followed similar experimental protocol as for the synthetic experiments. We fixed the training sample size for all experiments to 100 instances and used 200-1000 instances for the validation and test sets (depending on the total number of available observations). We pre-processed the data by normalizing the inputs and centering the outputs. For all the experiments we used a Gaussian kernel with the width set to the median distance calculated over the nearest 20 neighbours, and the 3rd order polynomial kernel. With the exception of the EN dataset, the Gaussian kernel yielded better results and was therefore kept for the final evaluation. Full details of the settings can be found in the replication files publicly available at [https://bitbucket.org/dmmlgeneva/nvds\\_uai2018/](https://bitbucket.org/dmmlgeneva/nvds_uai2018/).*

Results in table 3 are for the original data for which we have no prior knowledge about possible variable groupings. Therefore we only use the non-structured methods and our NVSD(EN) that do not rely on any such prior information.

Our NVSD methods learned sparse non-linear models achieving better or comparable results than the baselines in 4 out of the 5 experiments (BH, CP, EN, EL). For CC reducing the number of input dimensions does not seem to bring any advantages and the methods tend to learn full

Table 3: Results of Real-data Experiments

models. For several experiments SpAM finished with errors and therefore the results in the table are missing.

To explore the performance and benefits of NVSD(GL) method we had to construct variable groups that could potentially help the model learning. We adopted two strategies:

1. For CP and EL datasets we constructed the groups based on the NVSD(EN) results. For CP we grouped together the 5 most often selected variables across the 50 replications of the experiment and created 3 other groups from the remaining variables. For EL we created five groups by 3-4 elements putting together variables with similar frequencies of occurrence in the support of the learned NVSD(EN) models over the 50 replications.
2. For AI, CC, and KN datasets we doubled the original input data dimensions by complementing the input data by a copy of each input variable with permuted instance order. We then constructed two groups, the first over the original data, the second over the permuted copy.

Table 4 confirms that our NVSD(GL) is able to use the grouping information based on prior knowledge to select better, more relevant subset of variables than the non-structured baselines. Thanks to this it achieves significantly better prediction accuracy in all the experiments.

## 6 CONCLUSIONS AND FUTURE WORK

In this work we addressed the problem of variable selection in non-linear regression problems. We followed

up from the work of Rosasco et al. (2013) arguing for the use of partial derivatives as an indication of the pertinence of an input variable for the model. Extending the existing work, we proposed two new derivative-based regularizers for learning with structured sparsity in non-linear regression similar in spirit to the linear elastic net and group lasso.

After posing the problems into the framework of RKHS learning, we designed a new NVSD algorithm for solving these. Unlike the previously proposed Denovas our new algorithm does not rely on proximal approximations. This is most likely the main reason why our NVSD(L) method achieved systematically better predictive performance than Denovas on a broad set of experiments. We also empirically demonstrated the advantages our structured sparsity methods NVSD(GL) and NVSD(EN) bring for learning tasks with a priori known group structures or correlation in the inputs.

These promising results point to questions requiring further attention:

Our NVSD algorithm achieves better results in terms of prediction accuracy than Denovas, however, at the cost of longer training times. Its  $\mathcal{O}((nd)^2)$  complexity is not favourable for scaling in neither instances nor dimensions. Exploring avenues for speeding up, possibly along the lines of random features construction, is certainly an important next step in making the algorithm operational for more practical real-life problems.

The method is based on the partial-derivative arguments and therefore assumes the functions (and therefore the kernels) are at least 2nd order differentiable (and square-integrable). We use here the polynomial and Gaussian

kernel as the most commonly used examples. What other properties of the kernels are necessary to ensure good performance and how the methods could be extended to other, more complex kernels are relevant questions.

The full problem formulation (e.g. equation (10) in proposition 1) combines the sparse regularizers with the function Hilbert-norm. This combination has been proposed in Rosasco et al. (2013) to ensure that the regularization part of the problem is strongly convex and the problem is well-posed in terms of the generalization properties.

However, interactions of the Hilbert norm with the sparsity inducing regularizers of section 2 and the effects on the learning and selection properties are not yet fully clear. Empirically (from Rosasco et al. (2013) and our own experiments) the models are often little sensitive to variations in  $\nu^5$ .

In addition, the  $\mathcal{R}^{EN}$  regularizer is already strongly convex even without the Hilbert norm. To what degree combining it with the Hilbert norm is necessary to guarantee good generalization for outside the training needs to be further investigated. So does its behaviour and the possible improvements it can bring when learning from inputs with non-linear dependencies. In view of the above considerations, our paper is posing the motivations, foundations and principles for further studies on partial derivative-based regularizations.

# Identification of Strong Edges in AMP Chain Graphs

---

Jose M. Peña

Department of Computer and Information Science  
Linköping University  
58183 Linköping, Sweden

## Abstract

The essential graph is a distinguished member of a Markov equivalence class of AMP chain graphs. However, the directed edges in the essential graph are not necessarily strong or invariant, i.e. they may not be shared by every member of the equivalence class. Likewise for the undirected edges. In this paper, we develop a procedure for identifying which edges in an essential graph are strong. We also show how this makes it possible to bound some causal effects when the true chain graph is unknown.

## 1 INTRODUCTION

In most practical applications, the data available consists of observations. Therefore, it can rarely single out the true causal model. At best, it identifies the Markov equivalence class that contains the true causal model. In this paper, we represent causal models with the help of AMP chain graphs (Andersson et al., 2001). As argued by Peña (2016), these graphs are suitable for representing causal linear models with additive Gaussian noise. Intuitively, the directed subgraph of a chain graph represents the causal relations in the domain, and the undirected subgraph represents the dependence structure of the noise terms. Additive noise is a rather common assumption in causal discovery (Peters et al., 2017), mainly because it produces tractable models which are useful for gaining insight into the system under study. Note also that linear structural equation models, which have extensively been studied for causal effect identification (Pearl, 2009), are additive noise models.

In order to represent the equivalence class of chain graphs identified from the observations at hand, we typically use a distinguished member of it. In the literature, there are two distinguished members: The essential

graph (Andersson and Perlman, 2006), and the largest deflagged graph (Roverato and Studený, 2006). In general, they do not coincide: The essential graph is a deflagged graph (Andersson and Perlman, 2006, Lemma 3.2) but not necessarily the largest in the equivalence class (Andersson et al., 2001, p. 57). Unfortunately, the directed edges in either of the two representatives are not necessarily strong,<sup>1</sup> i.e. they may not be shared by every member of the equivalence class. Likewise for the undirected edges. In this paper, we use essential graphs to represent equivalence classes of chain graphs. And we develop a procedure for identifying which edges in an essential graph are strong. Note that while we assume that the true chain graph is unknown, its corresponding essential graph can be obtained from observational data as follows. First, learn a chain graph as shown by Peña (2014, 2016) and Peña and Gómez-Olmedo (2016) and, then, transform it into an essential graph as shown by Sonntag and Peña (2015, Section 3).

Identifying the strong edges in an essential graph is important because it makes it possible to identify causal paths from data even though the data may not be able to single out the true chain graph: Simply output every directed path in the essential graph that consists of only strong edges. Of course, the true chain graph may have additional causal paths. Identifying the strong edges in an essential graph is also important because it allows to efficiently bound some causal effects of the form  $p(y|do(x))$  where  $X$  and  $Y$  are singletons. The simplest way to bound such a causal effect consists in enumerating all the chain graphs that are equivalent to the essential graph and, then, computing the causal effect for each of them from the observational data by adjusting for the appropriate variables. Although we know how to enumerate the equivalent chain graphs (Sonntag and Peña, 2015, Theorem 3), this method may be inefficient for all but small domains. Instead, we show in this paper how the knowledge of the strong edges in an essential graph

---

<sup>1</sup>The term invariant or essential is also used in the literature.

allows to enumerate the adjusting sets without enumerating the equivalent chain graphs explicitly.

The rest of the paper is organized as follows. Section 2 introduces some preliminaries. Section 3 presents our algorithm to identify strong edges in an essential graph. Section 4 presents our procedure to bound causal effects when the true chain graph is unknown but its corresponding essential graph is known. Section 5 closes the paper with some discussion and lines of future research.

## 2 PRELIMINARIES

All the graphs and probability distributions in this paper are defined over a finite set  $V$  unless otherwise stated. All the graphs contain at most one edge between a pair of nodes. The elements of  $V$  are not distinguished from singletons.

The parents of a set of nodes  $X$  of a graph  $G$  is the set  $Pa_G(X) = \{A \mid A \rightarrow B \text{ is in } G \text{ with } B \in X\}$ . The children of  $X$  is the set  $Ch_G(X) = \{A \mid B \rightarrow A \text{ is in } G \text{ with } B \in X\}$ . The neighbors of  $X$  is the set  $Ne_G(X) = \{A \mid A - B \text{ is in } G \text{ with } B \in X\}$ . The adjacents of  $X$  is the set  $Ad_G(X) = \{A \mid A \rightarrow B, B \rightarrow A \text{ or } A - B \text{ is in } G \text{ with } B \in X\}$ . The descendants of  $X$  is the set  $De_G(X) = \{A \mid B \rightarrow \dots \rightarrow A \text{ is in } G \text{ with } B \in X\}$ . A route from a node  $V_1$  to a node  $V_n$  in  $G$  is a sequence of (not necessarily distinct) nodes  $V_1, \dots, V_n$  such that  $V_i \in Ad_G(V_{i+1})$  for all  $1 \leq i < n$ . A route is called a cycle if  $V_n = V_1$ . A cycle has a chord if two non-consecutive nodes of the cycle are adjacent in  $G$ . A cycle is called semidirected if it is of the form  $V_1 \rightarrow V_2 \dashrightarrow \dots \dashrightarrow V_n$  where  $\dashrightarrow$  is a short for  $\rightarrow$  or  $-$ . A chain graph (CG) is a graph with (possibly) directed and undirected edges, and without semidirected cycles. A set of nodes of a CG  $G$  is connected if there exists a route in  $G$  between every pair of nodes in the set and such that all the edges in the route are undirected. A chain component of  $G$  is a maximal connected set. Note that the chain components of  $G$  can be sorted topologically, i.e. for every edge  $A \rightarrow B$  in  $G$ , the component containing  $A$  precedes the component containing  $B$ . A set of nodes of  $G$  is complete if there is an undirected edge between every pair of nodes in the set. Moreover, a node is called simplicial if its neighbors are a complete set.

We now recall the interpretation of CGs due to Andersson et al. (2001), also known as AMP CGs.<sup>2</sup> A node

<sup>2</sup>Andersson et al. (2001) interpret CGs via the so-called augmentation criterion. Levitz et al. (2001, Theorem 4.1) introduce the so-called p-separation criterion and prove its equivalence to the augmentation criterion. Peña (2016, Theorem 2) introduce the route-based criterion that we use in this paper and prove its equivalence to the p-separation criterion.

$B$  in a route  $\rho$  in a CG  $G$  is called a triplex node in  $\rho$  if  $A \rightarrow B \leftarrow C$ ,  $A \rightarrow B - C$ , or  $A - B \leftarrow C$  is a subroute of  $\rho$ . Moreover,  $\rho$  is said to be  $Z$ -open with  $Z \subseteq V$  when (i) every triplex node in  $\rho$  is in  $Z$ , and (ii) every non-triplex node in  $\rho$  is outside  $Z$ . Let  $X, Y$  and  $Z$  denote three disjoint subsets of  $V$ . When there is no  $Z$ -open route in  $G$  between a node in  $X$  and a node in  $Y$ , we say that  $X$  is separated from  $Y$  given  $Z$  in  $G$  and denote it as  $X \perp_G Y \mid Z$ . The statistical independences represented by  $G$  are the separations  $X \perp_G Y \mid Z$ . A probability distribution  $p$  is Markovian with respect to  $G$  if the independences represented by  $G$  are a subset of those in  $p$ . If the two sets of independences coincide, then  $p$  is faithful to  $G$ . Two CGs are Markov equivalent if the sets of distributions that are Markovian with respect to each CG are the same. If a CG has an induced subgraph of the form  $A \rightarrow B \leftarrow C$ ,  $A \rightarrow B - C$  or  $A - B \leftarrow C$ , then we say that the CG has a triplex  $(A, B, C)$ . Two CGs are Markov equivalent if and only if they have the same adjacencies and triplexes (Andersson et al., 2001, Theorem 5).

**Lemma 1.** *Two CGs  $G$  and  $H$  are Markov equivalent if and only if they represent the same independences.*

*Proof.* The if part is trivial. To see the only if part, note that Levitz et al. (2001, Theorem 6.1) prove that there are Gaussian distributions  $p$  and  $q$  that are faithful to  $G$  and  $H$ , respectively. Moreover,  $p$  is Markovian with respect to  $H$ , because  $G$  and  $H$  are Markov equivalent. Likewise for  $q$  and  $G$ . Therefore,  $G$  and  $H$  must represent the same independences.  $\square$

### 2.1 ESSENTIAL GRAPHS

The essential graph (EG)  $G^*$  is a distinguished member of a class of equivalent CGs. Specifically, an edge  $A \rightarrow B$  is in  $G^*$  if and only if  $A \rightarrow B$  is in some member of the class and  $A \leftarrow B$  is in no member of the class. An algorithm (without proof of correctness) for constructing the EG from any other member of the equivalence class has been developed by Andersson and Perlman (2004, Section 7). An alternative algorithm with proof of correctness has been developed by Sonntag and Peña (2015, Section 3). The latter algorithm can be seen in Tables 1 and 2. A perpendicular line at the end of an edge such as in  $\dashrightarrow$  or  $\dashleftarrow$  represents a block, and it means that the edge cannot be oriented in that direction. Note that the ends of some of the edges in the rules in Table 2 are labeled with a circle such as in  $\dashrightarrow$  or  $\dashleftarrow$ . The circle represents an unspecified end, i.e. a block or nothing. The modifications in the consequents of the rules consist in adding some blocks. Note that only the blocks that appear in the consequents are added, i.e. the circled ends do not get modified. In line 2 of Table 1, any such set  $S$  will do. For instance, if  $B \notin De_G(A)$ , then

Table 1: Algorithm for constructing the EG.

In: A CG $G$ .	
Out: The EG $G^*$ in the equivalence class of $G$ .	
1	For each ordered pair of non-adjacent nodes $A$ and $B$ in $G$
2	Set $S_{AB} = S_{BA} = S$ such that $A \perp_G B   S$
3	Let $G^*$ denote the undirected graph that has the same adjacencies as $G$
4	Apply the rules R1-R4 to $G^*$ while possible
5	Replace every edge $A - B$ in every cycle in $G^*$ that is of length greater than three, chordless, and without blocks with $A \dashv B$
6	Apply the rules R2-R4 to $G^*$ while possible
7	Replace every edge $A \dashv B$ and $A \vdash B$ in $G^*$ with $A \rightarrow B$ and $A - B$ , respectively

Table 2: Rules in the algorithm in Table 1. The antecedents represent induced subgraphs.

R1:		$\Rightarrow$

let  $S = Ne_G(A) \cup Pa_G(A \cup Ne_G(A))$ , otherwise let  $S = Ne_G(B) \cup Pa_G(B \cup Ne_G(B))$ . In line 5, that the cycle has no blocks means that the ends of the edges in the cycle have no blocks. Note that the rule R1 is not used in line 6, because it will never fire after its repeated application in line 4. Finally, note that  $G^*$  may have edges without blocks after line 6.

### 3 STRONG EDGES

We say that a directed edge in a CG is strong if it appears in every equivalent CG. Likewise for undirected edges. Therefore, strong edges are features of a class of equivalent CGs. Clearly, strong directed edges correspond to directed edges in the EG of the equivalence

class. However, the opposite is not true. Likewise for strong undirected edges. For an example, consider the EG  $A \rightarrow B \leftarrow C - D$ . The naive way to detect which edges in an EG are strong consists in generating all the CGs in the equivalence class and, then, recording the shared edges. Since there may be many CGs in the equivalence class, enumerating them in an efficient manner is paramount, but challenging. In truth, it suffices to enumerate what we call the minimally oriented CGs in order to identify the strong directed edges and, then, find one maximally oriented CG to identify the strong undirected edges. We prove these claims in Section 3.1. Although there are typically considerably fewer minimally oriented CGs, enumerating them in an efficient manner seems challenging too. That is why we present in Section 3.2 an algorithm that does not rely on enumerating CGs or minimally oriented CGs.

#### 3.1 MINIMALLY AND MAXIMALLY ORIENTED CGs

Given a CG  $G$ , merging two of its chain components  $U$  and  $L$  implies replacing the edge  $A \rightarrow B$  with  $A - B$  for all  $A \in U$  and  $B \in L$ . We say that a merging is feasible when

1.  $L \subseteq Ch_G(X)$  for all  $X \in Pa_G(L) \cap U$ ,
2.  $Pa_G(L) \cap U$  is a complete set,
3.  $Pa_G(Pa_G(L) \cap U) \subseteq Pa_G(Y)$  for all  $Y \in L$ , and
4.  $De_G(U) \cap Pa_G(L) = \emptyset$ .

A feasible merging of two chain components of a CG results in an equivalent CG (Sonntag and Peña, 2015, Lemma 2). If a CG does not admit any feasible merging, then we call it minimally oriented. Note that several equivalent minimally oriented CGs may exist, e.g.  $A \rightarrow B - C$  and  $A - B \leftarrow C$ . Note also that an EG is not necessarily a minimally oriented CG, e.g.  $A \rightarrow B \leftarrow C$ . If the directed edges of a CG are a subset of the directed edges of a second CG (with the same orientation), then we say that the former is larger than the latter.

**Lemma 2.** *The minimally oriented CGs in an equivalence class are the maximally large CGs in the class, and vice versa.*

*Proof.* Clearly, a maximally large CG must be minimally oriented because, otherwise, it admits a feasible merging which results in a larger CG, which is a contradiction. On the other hand, let  $G$  be a minimally oriented CG, and assume to the contrary that there is a CG  $H$  that is equivalent but larger than  $G$ . Specifically, let  $G$  have an edge  $A \rightarrow B$  whereas  $H$  has an edge  $A - B$ . Consider a

topological ordering of the chain components of  $G$ . We say that an edge  $X \rightarrow Y$  precedes an edge  $Z \rightarrow W$  in  $G$  if the chain component of  $X$  precedes the chain component of  $Z$  in the ordering, or if both chain components coincide and the chain component of  $Y$  precedes the chain component of  $W$  in the ordering. Assume without loss of generality that no other edge that is directed in  $G$  but undirected in  $H$  precedes the edge  $A \rightarrow B$  in  $G$ . Let  $U$  and  $L$  denote the chain components of  $A$  and  $B$ , respectively. Clearly, all the directed edges from  $U$  to  $L$  in  $G$  must be undirected in  $H$  because, otherwise,  $H$  has a semidirected cycle. However, this implies a contradiction. To see it, recall that  $G$  is a minimally oriented CG and, thus, merging  $U$  and  $L$  in  $G$  is not feasible. If condition 1 fails, then  $G$  has an induced subgraph  $X \rightarrow Y - Z$  where  $X \in U$  and  $Y, Z \in L$ , whereas  $H$  has an induced subgraph  $X - Y - Z$ . However, this implies that  $G$  and  $H$  are not equivalent, since  $G$  has a triplex  $(X, Y, Z)$  that  $H$  has not.

If condition 2 fails but condition 1 holds, then  $G$  has an induced subgraph  $X \rightarrow Y \leftarrow Z$  where  $X, Z \in U$  and  $Y \in L$ , whereas  $H$  has an induced subgraph  $X - Y - Z$ . However, this implies that  $G$  and  $H$  are not equivalent, since  $G$  has a triplex  $(X, Y, Z)$  that  $H$  has not.

If condition 3 fails but condition 1 holds, then  $G$  has an induced subgraph  $Z \rightarrow X \rightarrow Y$  where  $X \in U, Y \in L$  and  $Z \in V \setminus (U \cup L)$ , whereas  $H$  has an induced subgraph  $Z \rightarrow X - Y$ . However, this implies that  $G$  and  $H$  are not equivalent, since  $H$  has a triplex  $(Z, X, Y)$  that  $G$  has not. Note that  $Z \rightarrow X$  is in  $H$  because  $Z \rightarrow X$  precedes  $X \rightarrow Y$  and thus  $A \rightarrow B$  in  $G$ .

Finally, if condition 4 fails but condition 1 holds, then  $G$  has a subgraph of the form  $X \rightarrow Y \leftarrow \dots \leftarrow Z \leftarrow X' \leftarrow \dots \leftarrow X$  where  $X, X' \in U, Y \in L$  and  $Z \in V \setminus (U \cup L)$ , whereas  $H$  has a subgraph of the form  $X - Y - \dots - Z - X$ . To see it, note that any other option results in a semidirected cycle because, recall,  $H$  is larger than  $G$ . However, this is a contradiction because  $X' \rightarrow Z$  precedes  $X \rightarrow Y$  and thus  $A \rightarrow B$  in  $G$ .  $\square$

The following result follows from the previous lemma.

**Theorem 1.** *A directed edge is strong if and only if it is in every minimally oriented CG in the equivalence class.*

Finally, one may think that an undirected edge that is in every minimally oriented CG in the equivalence class is strong. But this is not true. For an example, consider the equivalence class represented by the EG  $A - B$ . Instead, an undirected edge is strong if and only if it is in any maximally oriented CG in the equivalence class (Sonntag and Peña, 2015, Theorems 4 and 5). Formally, a maximally oriented CG is a CG that does not admit any

Table 3: Algorithm to label strong edges in an EG. It replaces line 7 of the algorithm in Table 1.

7	Label every edge $X \dashv Y$ as strong in $G^*$
8	For each edge $X \dashv Y$ in $G^*$
9	Set $H = G^*$
10	Replace $X \dashv Y$ in $H$ with $X \dashv Y$
11	Apply the rules R2-3 to $H$ while possible
12	If $G^*$ has an induced subgraph $A \dashv B \dashv C$ whereas $H$ has $A \dashv B \dashv C$ then
13	Label $X \dashv Y$ as strong in $G^*$
14	Replace every edge $X \dashv Y$ and $X \dashv Y$ in $G^*$ with $X \rightarrow Y$ and $X - Y$ , respectively

feasible split, which is the inverse operation of the feasible merge operation described before. Alternatively, we can say that if the minimally oriented CGs are the maximally large CGs in an equivalence class, then the maximally oriented CGs are the minimally large (Sonntag and Peña, 2015, Lemma 13). Note that several equivalent maximally oriented CGs may exist (e.g.,  $A \rightarrow B$  and  $A \leftarrow B$ ) but all of them have the same undirected edges (Sonntag and Peña, 2015, Theorems 4 and 5). Note also that an EG is not necessarily a maximally oriented CG, e.g.  $A - B$ .

### 3.2 ENUMERATION-FREE ALGORITHM

Although the minimally and maximally oriented CGs in an equivalence class can be obtained by repeatedly performing feasible splits and merges (Sonntag and Peña, 2015, Theorem 3), the approach outlined above for identifying strong edges via enumeration may be inefficient for all but small domains. Hence, Table 3 presents an alternative algorithm that does not rely on enumerating the CGs or the minimally oriented CGs in the equivalence class. The new algorithm replaces line 7 in Table 1. In other words, the new algorithm postpones orienting edges until line 14, and in lines 7-13 it identifies which of the future directed and undirected edges are strong. Line 7 identifies the strong undirected edges, whereas lines 8-13 identify the strong directed edges. To do the latter, the algorithm tries to build a CG  $H$  that is equivalent to  $G^*$  and contains an edge  $X - Y$ . If this fails, then  $X \rightarrow Y$  is strong. Specifically, line 10 forces the edge between  $X$  and  $Y$  to be undirected in  $H$  by blocking the end at  $Y$ . Line 11 computes other blocks that follow from the new block at  $Y$ . After line 11,  $H$  can be oriented as indicated in line 14 without creating a semidirected cycle or a triplex that is not in  $G^*$ . Finally, line 12 checks if every triplex in  $G^*$  is in  $H$ . If not,  $X - Y$  is incompatible with some triplex in  $G^*$ , which implies that  $X \rightarrow Y$  is strong in  $G^*$ . We prove the correctness of the algorithm below.

**Lemma 3.** After line 11,  $H$  does not have any induced subgraph of the form  $A \overleftarrow{\circ} B \rightarrow C$ .

*Proof.* The proof is an adaptation of the proof of Lemma 5 by Peña (2014). Assume to the contrary that the lemma does not hold. We interpret the execution of lines 10-11 as a sequence of block additions and, for the rest of the proof, one particular sequence of these block additions is fixed. Fixing this sequence is a crucial point upon which some important later steps of the proof are based. Since there may be several induced subgraphs of  $H$  of the form under study after lines 10-11, let us consider any of the induced subgraphs  $A \overleftarrow{\circ} B \rightarrow C$  that appear first during the execution of lines 10-11 and fix it for the rest of the proof. Note that  $H$  has no such induced subgraph after line 9 (Sonntag and Peña, 2015, Lemma 9). Now, consider the following cases.

**Case 1** Assume that  $A \overleftarrow{\circ} B$  is in  $H$  due line 10. However, this implies that  $H$  had an induced subgraph  $A \overleftarrow{\circ} B \rightarrow C$  before line 10, which is a contradiction (Sonntag and Peña, 2015, Lemma 9).

**Case 2** Assume that  $A \overleftarrow{\circ} B$  is in  $H$  due to R2 in line 11. Then, after line 11,  $H$  has an induced subgraph of one of the following forms:

**Case 2.1** If  $A \notin S_{CD}$  then  $A \rightarrow C$  is in  $H$  by R1 in line 4 of Table 1, else  $A \leftarrow C$  is in  $H$  by R2. Either case is a contradiction.

**Case 2.2** Note that  $D \overleftarrow{\circ} A \rightarrow C$  cannot be an induced subgraph of  $H$  after line 11 because, otherwise, it would contradict the assumption that  $A \overleftarrow{\circ} B \rightarrow C$  is one of the first induced subgraph of that form that appeared during the execution of lines 10-11. So, this case is impossible.

**Case 2.3** Note that  $A \rightarrow C$  is in  $H$  by R3, which is a contradiction.

**Case 2.4** If  $C \notin S_{BD}$  then  $B \leftarrow C$  is in  $H$  by R1 in line 4 of Table 1, else  $B \rightarrow C$  is in  $H$  by R2. Either case is a contradiction.

**Case 3** Assume that  $A \overleftarrow{\circ} B$  is in  $H$  due to R3 in line 11. Then, after line 11,  $H$  had a subgraph of one of the following forms, where possible additional edges between  $C$  and internal nodes of the route  $A \overleftarrow{\circ} \dots \overleftarrow{\circ} D$  are not shown:

Note that  $C$  cannot belong to the route  $A \overleftarrow{\circ} \dots \overleftarrow{\circ} D$  because, otherwise, R3 could not have been applied since the cycle  $A \overleftarrow{\circ} \dots \overleftarrow{\circ} D \rightarrow B \rightarrow A$  would not have been chordless.

**Case 3.1** If  $B \notin S_{CD}$  then  $B \rightarrow C$  is in  $H$  by R1 in line 4 of Table 1, else  $B \leftarrow C$  is in  $H$  by R2. Either case is a contradiction.

**Case 3.2** Note that  $D \overleftarrow{\circ} B \rightarrow C$  cannot be an induced subgraph of  $H$  after line 11 because, otherwise, it would contradict the assumption that  $A \overleftarrow{\circ} B \rightarrow C$  is one of the first induced subgraph of that form that appeared during the execution of lines 10-11. So, this case is impossible.

**Case 3.3** Note that  $B \rightarrow C$  is in  $H$  by R3, which is a contradiction.

**Case 3.4** Note that  $C$  cannot be adjacent to any node of the route  $A \overleftarrow{\circ} \dots \overleftarrow{\circ} D$  besides  $A$  and  $D$  and, thus,  $A \leftarrow C$  is in  $H$  by R3. To see it, assume to the contrary that  $C$  is adjacent to some nodes  $E_1, \dots, E_n \neq A, D$  of the route  $A \overleftarrow{\circ} \dots \overleftarrow{\circ} D$ . Assume without loss of generality that  $E_i$  is closer to  $A$  in the route than  $E_{i+1}$  for all  $1 \leq i < n$ . Now, note that  $E_n \overleftarrow{\circ} C$  must be in  $H$  by R3. This implies that  $E_{n-1} \overleftarrow{\circ} C$  must be in  $H$  by R3. By repeated application of this argument, we can conclude that  $E_1 \overleftarrow{\circ} C$  must be in  $H$  and, thus,  $A \leftarrow C$  must be in  $H$  by R3, which is a contradiction.

□

**Lemma 4.** After line 11, every chordless cycle  $\rho : V_1, \dots, V_n = V_1$  in  $H$  that has an edge  $V_i \leftarrow V_{i+1}$  also has an edge  $V_j \rightarrow V_{j+1}$ .

*Proof.* The proof is an adaptation of the proof of Lemma 6 by Peña (2014). Assume for a contradiction that  $\rho$  is of the length three such that  $V_1 \vdash V_2$  occur and neither  $V_2 \dashv V_3$  nor  $V_1 \dashv V_3$  occur. Note that  $V_2 \dashv V_3$  cannot occur either because, otherwise,  $V_1 \dashv V_3$  or  $V_1 \vdash V_3$  must occur by R3. Since the former contradicts the assumption, then the latter must occur. However, this implies that  $V_1 \vdash V_2$  must occur by R3, which contradicts the assumption. Similarly,  $V_1 \dashv V_3$  cannot occur either. Then,  $\rho$  is of one of the following forms:

$$V_1 \vdash V_2 \dashv V_3 \quad V_1 \vdash V_2 \circ \dashv V_3 \quad V_1 \vdash V_2 \vdash V_3$$

The first form is impossible by Lemma 3. The second form is impossible because, otherwise,  $V_2 \circ \dashv V_3$  would occur by R3. The third form is impossible because, otherwise,  $V_1 \dashv V_3$  would be occur by R3. Thus, the lemma holds for cycles of length three.

Assume for a contradiction that  $\rho$  is of length greater than three and has an edge  $V_i \dashv V_{i+1}$  but no edge  $V_j \dashv V_{j+1}$ . Note that if  $V_l \dashv V_{l+1} \circ \dashv V_{l+2}$  is a subroute of  $\rho$ , then either  $V_{l+1} \dashv V_{l+2}$  or  $V_{l+1} \vdash V_{l+2}$  is in  $\rho$  by R1 and R2. Since  $\rho$  has no edge  $V_j \dashv V_{j+1}$ ,  $V_{l+1} \dashv V_{l+2}$  is in  $\rho$ . By repeated application of this reasoning together with the fact that  $\rho$  has an edge  $V_i \dashv V_{i+1}$ , we can conclude that every edge in  $\rho$  is  $V_k \dashv V_{k+1}$ . Then, by repeated application of R3, observe that every edge in  $\rho$  is  $V_k \vdash V_{k+1}$ , which contradicts the assumption.  $\square$

**Lemma 5.** *After line 11,  $H$  can be oriented as indicated in line 14 without creating a semidirected cycle.*

*Proof.* Assume to the contrary that the orientation produces a semidirected cycle  $\rho : V_1, \dots, V_n$ . Note that  $\rho$  must have a chord because, otherwise,  $\rho$  is impossible by Lemma 4. Specifically, let the chord be between  $V_i$  and  $V_j$  with  $i < j$ . Then, divide  $\rho$  into the cycles  $\rho_L : V_1, \dots, V_i, V_j, \dots, V_n = V_1$  and  $\rho_R : V_i, \dots, V_j, V_i$ . Note that  $\rho_L$  or  $\rho_R$  is a semidirected cycle but shorter than  $\rho$ . By repeated application of this reasoning, we can conclude that the orientation produces a chordless semidirected cycle, which contradicts Lemma 4.  $\square$

**Lemma 6.** *After line 11,  $H$  can be oriented as indicated in line 14 without creating a triplex that is not in  $G^*$ .*

*Proof.* We call pretriplex to an induced subgraph of  $G^*$  or  $H$  that results in a triplex when  $G^*$  or  $H$  are oriented as indicated in line 14. Note that  $G^*$  and  $H$  have the same pretriplexes after line 9. Assume to the contrary that after line 11  $H$  has a pretriplex that is not in  $G^*$ . Assume that the spurious pretriplex is created in line 10 when  $A \dashv B$  becomes  $A \vdash B$ . Then, after line 11  $H$

has a pretriplex (1)  $A \vdash B \dashv C$  or (2)  $C \dashv A \vdash B$ . Case (1) implies that  $H$  has actually an induced subgraph  $A \vdash B \vdash C$  by R2, which is a contradiction. To see that R2 is applicable, note that  $B \in S_{AC}$  because  $G^*$  does not have a triplex  $(A, B, C)$ . Case (2) implies that  $H$  has actually an induced subgraph  $C \vdash A \vdash B$  by R2, which again is a contradiction. As before, R2 is clearly applicable. Finally, assume that the spurious pretriplex is created in line 11. Then, after line 11  $H$  has an induced subgraph (1)  $A \vdash B \dashv C$ , (2)  $A \dashv B \dashv C$  or (3)  $A \dashv B \vdash C$ . However, this implies that  $H$  has actually an induced subgraph  $A \vdash B \vdash C$  or  $A \dashv B \vdash C$  by R2, which again is a contradiction. As before, R2 is clearly applicable.  $\square$

**Lemma 7.** *After line 14, the undirected edges in  $G^*$  that had no blocks after line 7 are not strong.*

*Proof.* The proof is an adaptation of the proof of Theorem 11 by Sonntag and Peña (2015). Let  $F$  denote the graph that contains all and only the edges of  $G^*$  resulting from the replacements in line 14, and let  $U$  denote the graph that contains the rest of the edges of  $G^*$  after line 14. Note that all the edges in  $U$  are undirected and they had no blocks when line 14 was to be executed. Therefore,  $U$  has no cycle of length greater than three that is chordless by line 5. In other words,  $U$  is chordal. Then, we can orient all the edges in  $U$  without creating triplexes nor directed cycles by using, for instance, the maximum cardinality search (MCS) algorithm (Koller and Friedman, 2009, p. 312). Consider any such orientation of the edges in  $U$  and denote it  $D$ . Now, add all the edges in  $D$  to  $F$ . As we show below, this last step does not create any triplex or semidirected cycle in  $F$ :

- It does not create a triplex  $(A, B, C)$  in  $F$  because, otherwise,  $A \dashv B \circ \dashv C$  must exist in  $G^*$  when line 14 was to be executed, which implies that  $A \dashv B$  or  $A \circ \dashv B$  was in  $G^*$  by R1 or R2 when line 14 was to be executed, which contradicts that  $A \dashv B$  is in  $U$ .
- Assume to the contrary that it does create a semidirected cycle  $\rho$  in  $F$ . We can assume without loss of generality that  $\rho$  is chordless because if it has a chord between  $V_i$  and  $V_j$  with  $i < j$ . Then, divide  $\rho$  into the cycles  $\rho_L : V_1, \dots, V_i, V_j, \dots, V_n = V_1$  and  $\rho_R : V_i, \dots, V_j, V_i$ . Note that  $\rho_L$  or  $\rho_R$  is a semidirected cycle but shorter than  $\rho$ . By repeated application of this reasoning, we can conclude that  $F$  has a chordless semidirected cycle.

Since  $D$  has no directed cycles,  $\rho$  must have a  $\dashv$  or  $\vdash$  edge when line 14 was to be executed. The former case is impossible (Sonntag and Peña, 2015,

Lemma 10). The latter case implies that  $A - B \vdash C$  must exist in  $G^*$  when line 14 was to be executed, which implies that  $A$  and  $C$  are adjacent in  $G^*$  because, otherwise,  $A \vdash B$  or  $A \dashv B$  was in  $G^*$  by R1 or R2 when line 14 was to be executed, which contradicts that  $A - B$  is in  $U$ . Then,  $A \vdash C$  or  $A \dashv C$  exists in  $G^*$  when line 14 was to be executed (Sonntag and Peña, 2015, Lemma 9), which implies that  $A \vdash B$  or  $A \dashv B$  was in  $G^*$  by R3 when line 14 was to be executed, which contradicts that  $A - B$  is in  $U$ .

Consequently,  $F$  is a CG that is Markov equivalent to  $G$ . Finally, let us recall how the MCS algorithm works. It first unmarks all the nodes in  $U$  and, then, iterates through the following step until all the nodes are marked: Select any of the unmarked nodes with the largest number of marked neighbors and mark it. Finally, the algorithm orients every edge in  $U$  away from the node that was marked earlier. Clearly, any node may get marked first by the algorithm because there is a tie among all the nodes in the first iteration, which implies that every edge may get oriented in any of the two directions in  $D$  and thus in  $F$ . Therefore, either orientation of every edge of  $U$  occurs in some CG  $F$  that is Markov equivalent to  $G$ . Then, every edge of  $U$  must be a strong undirected edge in  $G^*$ .  $\square$

**Theorem 2.** *Table 3 identifies all and only the strong edges in  $G^*$ .*

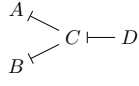

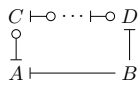

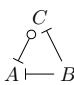

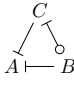

*Proof.* By definition of EG, the edges in  $G^*$  with blocks on both ends in line 7 correspond to strong undirected edges in  $G^*$  after line 14. Moreover, the edges in  $G^*$  with no blocks in line 7 correspond to non-strong undirected edges in  $G^*$  after line 14, by Lemma 7.

After line 11,  $H$  can be oriented as indicated in line 14 without creating semidirected cycles by Lemma 5, and without creating a triplex that is not in  $G^*$  by Lemma 6. Therefore, if  $H$  can be oriented as indicated in line 14 without destroying any of the triplexes in  $G^*$ , then the algorithm has found a CG that is Markov equivalent to  $G^*$  and such that  $X \rightarrow Y$  is in  $G^*$  but  $X - Y$  is in the CG found and, thus,  $X \rightarrow Y$  is non-strong in  $G^*$ . Otherwise,  $X \rightarrow Y$  is strong in  $G^*$ . This is checked in line 12.  $\square$

The algorithm in Table 3 may be sped up with the help of the rules in Table 4. S1-3 should be run while possible before line 8, and S4-6 should be run while possible after line 8 to propagate the labellings due to line 13 in the previous iteration.

**Corollary 1.** *Applying the rules in Table 4 to an EG  $G^*$  correctly identifies strong directed edges in  $G^*$ .*

Table 4: Rules for accelerating the search for strong directed edges in an EG. The antecedents represent induced subgraphs.

S1:		$\Rightarrow C \vdash D$ is strong
S2:	$A \vdash B \vdash C$	$\Rightarrow A \vdash B$ is strong
S3:		$\Rightarrow A \vdash B$ is strong
S4:	$A - B \vdash C$ and $A \vdash B$ is strong	$\Rightarrow B \vdash C$ is strong
S5:		$\Rightarrow A \vdash B$ is strong and $C \vdash B$ is strong
S6:		$\Rightarrow A \vdash B$ is strong and $A \vdash C$ is strong

*Proof.* Consider any member  $G$  of the equivalence class of  $G^*$ . Consider the rule S1. Since  $G^*$  has a triplex  $(A, C, B)$  after line 14,  $G$  must have an edge  $A \rightarrow C$  or  $B \rightarrow C$ . In either case  $G$  must also have an edge  $C \rightarrow D$ , since  $G^*$  has not a triplex  $(A, C, D)$  or  $(B, C, D)$ .

Consider the rule S2. Since  $G^*$  has a triplex  $(A, B, C)$  after line 14 and  $G$  has an edge  $B - C$  due to the blocks at  $B$  and  $C$ , then  $G$  must also have an edge  $A \rightarrow B$ .

Consider the rule S3. Assume to the contrary that  $G$  has an edge  $A - B$ . Then,  $G$  must have an edge  $D \rightarrow B$  since  $G^*$  has a triplex  $(A, B, D)$  after line 14. However, this implies that  $G$  has a semidirected cycle due to the blocks in the antecedent of the rule, which is a contradiction.

Consider the rule S4. Since  $G^*$  has not a triplex  $(A, B, C)$  after line 14 and  $G$  has an edge  $A \rightarrow B$  because it is strong, then  $G$  must also have an edge  $B \rightarrow C$ .

Consider the rule S5. Since  $G$  has an edge  $C \rightarrow B$  because it is strong, then  $G$  must also have an edge  $A \rightarrow B$  to avoid having a semidirected cycle, because either  $A \rightarrow C$  or  $A - C$  is in  $G$  due to the blocks in the antecedent of the rule. The rule S6 can be proven similarly.  $\square$

The rules in Table 4 are by no means complete, i.e. there may be strong edges that the rules alone do not detect. Thus, additional rules can be created. We doubt though that a complete set of concise rules can be produced. The difficulty lies in the disjunctive nature of some labellings. For instance, let an EG  $G^*$  have induced subgraphs  $A \rightarrow C \leftarrow B$ ,  $A \rightarrow C \rightarrow \dots \rightarrow D \rightarrow E$  and  $B \rightarrow C \rightarrow \dots \rightarrow D \rightarrow E$ . Since  $G^*$  has no triplex in  $A \rightarrow C \rightarrow \dots \rightarrow D \rightarrow E$ , if a member  $G$  of the equivalence class of  $G^*$  has an edge  $A \rightarrow C$  then it has an edge  $D \rightarrow E$ . Similarly, if  $G$  has an edge  $B \rightarrow C$  then it has an edge  $D \rightarrow E$ . Then,  $G$  has an edge  $D \rightarrow E$  because it has an edge  $A \rightarrow C$  or  $B \rightarrow C$ , since  $G^*$  and thus  $G$  has a triplex  $(A, C, B)$ . Therefore,  $D \rightarrow E$  is strong. Although it is easy to produce a rule for this example, many more such disjunctive examples exist and we do not see any way to produce concise rules for all of them.

## 4 CAUSAL EFFECT BOUNDS

When the true CG is unknown, a causal effect of the form  $p(y|do(x))$  with  $X, Y \in V$  cannot be computed, but it can be bounded as follows:

1. Obtain all the CGs that are Markov equivalent to the true one by running the learning algorithm developed by Peña (2014, 2016) or Peña and Gómez-Olmedo (2016).
2. Compute the causal effect for each CG obtained as follows. Like in a Bayesian network, any causal effect in a CG  $G$  is computable uniquely from observed quantities (i.e. it is identifiable) by adjusting for the appropriate variables. Specifically,

$$p(y|do(x)) = \int p(y|x, z)p(z)dz$$

where  $Z = Ne_G(X) \cup Pa_G(X \cup Ne_G(X))$  and  $Y \notin Z$ . The role of  $Z$  is to block every non-causal path in  $G$  between  $X$  and  $Y$ . We call  $Z$  the adjusting set in  $G$ .

Unfortunately, the learning algorithm in step 1 may be too time consuming for all but small domains. At least, this is the conclusion that follows from the experimental results reported by Sonntag et al. (2015) for a similar algorithm for learning Lauritzen-Wermuth-Frydenberg CGs. Instead, we propose the following alternative approach:

- 1'. Learn the EG  $G^*$  corresponding to the true CG from data as follows. First, learn a CG from data as shown by Peña (2014, 2016) and Peña and Gómez-Olmedo (2016) and, then, transform it into an EG as shown by Sonntag and Peña (2015, Section 3).

- 2'. Enumerate all the CGs that are Markov equivalent to  $G^*$  as shown by Sonntag and Peña (2015, Theorem 3).
- 3'. Compute the causal effect for each CG enumerated as shown above.

This approach has successfully been applied when the causal models are represented by other graphical models than CGs (Hyttinen et al., 2015; Malinsky and Spirtes, 2016; Maathuis et al., 2009). The experimental results reported by Peña and Gómez-Olmedo (2016) indicate that the learning algorithm in step 1' scales to medium sized domains. However, the enumeration in step 2' may be too time consuming for all but small domains. Alternatively, we may try to enumerate the adjusting sets in the equivalent CGs without enumerating these explicitly. Specifically, we know that all the adjusting sets are subsets of  $Ad_{G^*}(X) \cup Ad_{G^*}(Ad_{G^*}(X))$ , because all the equivalent CGs have the same adjacencies as  $G^*$ . Therefore, we can adjust for every subset of  $Ad_{G^*}(X) \cup Ad_{G^*}(Ad_{G^*}(X))$  to obtain bounds for the causal effect of interest. True that some of these subsets are not valid adjusting sets in the sense that they do not correspond to any of the equivalent CGs. However, this does not make the bounds invalid, just more loose. The rest of the section studies a case where all and only the valid adjusting sets can be enumerated efficiently.

Assume that we believe a priori that the dependencies in the domain at hand are due to causal rather than non-causal relationships. Then, we believe a posteriori that the true CG is a maximally oriented CG, because such CGs have the fewest undirected edges in the equivalence class of the EG  $G^*$  learned from the data in step 1'. Moreover, recall from Section 3.1 that all of them have the same undirected edges. Therefore, we can bound the causal effect  $p(y|do(x))$  by modifying the latter framework above so that only maximally oriented CGs are enumerated in step 2'. A maximally oriented CG that is equivalent to  $G^*$  can be obtained from  $G^*$  by repeatedly performing feasible splits (Sonntag and Peña, 2015, Theorem 3). Unfortunately, this enumeration method may be inefficient for all but small domains. Instead, we show below how to enumerate the adjusting sets in the maximally oriented CGs that are equivalent to  $G^*$  without enumerating these explicitly.

Given a node  $X \in V$ , we define  $St_{G^*}(X) = \{A|A - X \text{ is a strong edge in } G^*\}$  and  $Nst_{G^*}(X) = \{A|A - X \text{ is a non-strong edge in } G^*\}$ . Given a set  $S \subseteq Nst_{G^*}(X)$ , we let  $G_{S \rightarrow X}^*$  denote the graph that is obtained from  $G^*$  by replacing the edge  $A - X$  with  $A \rightarrow X$  for all  $A \in S$ , and replacing the edge  $A - X$  with  $A \leftarrow X$  for all  $A \in Nst_{G^*}(X) \setminus S$ . Moreover, we say that  $G_{S \rightarrow X}^*$  is locally valid if  $G_{S \rightarrow X}^*$  does not have any triplex  $(A, X, B)$  that

is not in  $G^*$ . The next theorem proves that producing the adjusting sets in the equivalent maximally oriented CGs simplifies to produce locally valid sets.

**Theorem 3.**  $G_{S \rightarrow X}^*$  is locally valid if and only if there is a maximally oriented CG  $G$  that is equivalent to  $G^*$  and such that  $Ne_G(X) = St_{G^*}(X)$  and  $Pa_G(X) = Pa_{G^*}(X) \cup S$ , which implies that the adjusting set in  $G$  is  $St_{G^*}(X) \cup Pa_{G^*}(X \cup St_{G^*}(X)) \cup S$ .

*Proof.* The proof is an adaptation of the proof of Lemma 3.1 by Maathuis et al. (2009). The if part is trivial. To prove the only if part, note first that  $S \cup X$  is a complete set because, otherwise,  $G_{S \rightarrow X}^*$  would not be locally valid.

Let  $G$  denote the graph that contains all and only the non-strong undirected edges in  $G^*$ . Recall from Lemma 7 that these edges had no blocks when line 14 in Table 3 was to be executed. Therefore,  $G$  is chordal by line 5 in Table 1. We now show that we can orient the edges of  $G$  without creating triplexes or directed cycles and such that  $Pa_G(X) = S$ . Specifically, we show that there is a perfect elimination sequence that ends with  $X$  followed by the nodes in  $S$ . Orienting the edges of  $G$  according to this sequence produces the desired graph. If  $G$  is complete, then the sequence clearly exists. If  $G$  is not complete, then note that  $G$  has at least two non-adjacent simplicial nodes (Jensen and Nielsen, 2007, Theorem 4.1). Note that one of them is outside of  $S \cup X$  because, as shown above, the latter is a complete set. Take that node as the first node in the sequence. Note moreover that the subgraph of  $G$  induced by the rest of the nodes is chordal. Therefore, we can repeat the previous step to select the next node in the sequence until we obtain the desired perfect elimination sequence.

Finally, consider the oriented  $G$  obtained in the previous paragraph, and add to it all the directed edges and strong undirected edges in  $G^*$ . We now prove that  $G$  is the desired CG in the theorem. First, note that  $G$  is maximally oriented because all the undirected edges in it are strong in  $G^*$ . Second, note that if  $G^*$  has a triplex  $(A, B, C)$  then  $A \dashv B \dashv C$  must be in  $G^*$  when line 14 was to be executed, which implies that neither of the edges in the triplex is non-strong undirected in  $G^*$ , which implies that  $G$  has a triplex  $(A, B, C)$ . Third, note that  $G$  does not have a triplex  $(A, B, C)$  that is not in  $G^*$  because, otherwise, the triplex should have been created as a product of the perfect elimination sequence above. This is possible only if  $A - B - C$  or  $A - B \dashv C$  exists in  $G^*$  when line 14 was to be executed. The former case is impossible by definition of perfect elimination sequence. The latter case implies that  $A \dashv B$  or  $A \dashv C$  was in  $G^*$  by R1 or R2 when line 14 was to be executed, which contradicts that  $A - B$  was a non-strong undirected edge in  $G^*$ .

Fourth, assume to the contrary that  $G$  has a semidirected cycle  $\rho : V_1, \dots, V_n$ . We can assume without loss of generality that  $\rho$  is chordless because if it has a chord between  $V_i$  and  $V_j$  with  $i < j$ . Then, divide  $\rho$  into the cycles  $\rho_L : V_1, \dots, V_i, V_j, \dots, V_n = V_1$  and  $\rho_R : V_i, \dots, V_j, V_i$ . Note that  $\rho_L$  or  $\rho_R$  is a semidirected cycle but shorter than  $\rho$ . By repeated application of this reasoning, we can conclude that  $G$  has a chordless semidirected cycle. Note that it follows from the paragraph above that  $\rho$  cannot consist of just non-strong undirected edges in  $G^*$ . Then, it includes some edge that was  $A \dashv B$  or  $A \dashv C$  when line 14 was to be executed. The former alternative is impossible (Sonntag and Peña, 2015, Lemma 10). The latter alternative implies that  $A \dashv B - C$  must exist in  $G^*$  when line 14 was to be executed, which implies that  $A$  and  $C$  are adjacent in  $G^*$  because, otherwise,  $B \dashv C$  or  $B \dashv C$  was in  $G^*$  by R1 or R2 when line 14 was to be executed, which contradicts that  $B - C$  is a non-strong undirected edge in  $G^*$ . Then,  $A \dashv C$  or  $A \dashv C$  exists in  $G^*$  when line 14 was to be executed (Sonntag and Peña, 2015, Lemma 9), which implies that  $B \dashv C$  or  $B \dashv C$  was in  $G^*$  by R3 when line 14 was to be executed, which contradicts that  $B - C$  is a non-strong undirected edge in  $G^*$ .  $\square$

The procedure outlined above can be simplified as follows.

**Corollary 2.**  $St_{G^*}(X) = \emptyset$  or  $Nst_{G^*}(X) = \emptyset$ .

*Proof.* Assume the contrary. Then,  $G^*$  has a subgraph  $A \dashv X - B$  when line 14 in Table 3 is to be executed. Then,  $A$  and  $B$  are adjacent in  $G^*$  because, otherwise, the edge  $X - B$  would have some block by R1 or R2. However, this implies that the edge  $A - B$  has some block by Lemma 3, which implies that  $X - B$  has some block by R3. This is a contradiction.  $\square$

## 5 DISCUSSION

In this paper, we have presented an algorithm to identify the strong edges in an EG. We have also shown how this makes it possible to compute bounds of causal effects under the assumption that the true CG is unknown but maximally oriented. In the future, we would like to derive a similar result for minimally oriented CGs. Moreover, as mentioned in the introduction, an EG is a deflagged graph but not necessarily the largest in the equivalence class. Therefore, an EG may contain a directed edge where the largest deflagged graph has an undirected edge. Then, the algorithm in Table 3 may be improved by consulting the largest deflagged graph before trying labeling a directed edge as strong. An algorithm for constructing this graph exists (Roverato and Studený, 2006).

## Abstract

Area under ROC (AUC) is an important metric for binary classification and bipartite ranking problems. However, it is difficult to directly optimize AUC as a learning objective, so most existing algorithms are based on optimizing a surrogate loss to AUC. One significant drawback of these surrogate losses is that they require pairwise comparisons among training data, which leads to slow running time and increasing local storage for online learning. In this work, we describe a new surrogate loss based on a reformulation of AUC risk, which does not require pairwise comparison but rankings of the predictions. We further show that the ranking operation can be avoided, and the learning objective obtained based on this surrogate enjoys linear complexity in time and storage. We perform experiments to demonstrate the effectiveness of the online and batch algorithms for AUC optimization based on the proposed surrogate loss.

## 1 INTRODUCTION

The *area under receiver operating characteristics curves* (AUC) is a useful quantitative metric for assessing the performance of binary classification and bipartite ranking algorithms [1, 2]. However, there are two factors make AUC difficult to be used directly as a learning objective to train classification or ranking algorithms. The foremost is due to the discontinuous indicator function in the definition of the AUC (c.f. Eq.(1)), which makes direct minimization of the AUC in general an NP-hard problem [4]. As such, most existing AUC learning algorithm replace the indicator function with surrogates that are continuous and convex upper-bounds of the AUC.

The second issue with the AUC is the requirement of pairwise comparison between all positive and negative examples in training data. This leads to algorithms with a running time complexity that is quadratic in the number of training data, and a space complexity that is linear of the training data. For batch algorithms, this means slow running time as we need to compare all pairs of positive/negative examples, and for online learning, this means ever increasing local storage as we need to store all previously seen data for the pairwise comparisons. Both are undesirable when applying these algorithms to large-scale datasets.

In this work, we describe a new surrogate loss to AUC that has a linear time complexity and constant space complexity. This new loss is based on an equivalent formulation of AUC based on ranking the prediction scores, which obviates pairwise comparisons. We further show that the ranking operation can be replaced with an equivalent optimization problem, and the learning objective affords a simple form that has a bounding relation with AUC. Furthermore, we show that the new loss has a close relation with the SVM learning objective, which sheds light on the previous observations of the effectiveness of the SVM on optimizing AUC [5, 6, 7, 8]. The new surrogate loss leads naturally to an online AUC optimization method with simple (projected) stochastic sub-gradient steps. Experimental evaluations on several standard benchmark datasets show that learning objective formed from this new loss achieves performance in par with other widely used AUC surrogates, with a significant reduction in running time and storage requirement.

## 2 DEFINITIONS

To facilitate subsequent description, we first review the definition of AUC in the context of binary classification. Assume we are given a set of data  $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$ , with  $y_i \in \{-1, +1\}$  and  $\mathbf{x}_i \in \mathcal{R}^d$ . We denote  $\mathcal{I}^+ = \{i|y_i =$

$+1\}$  and  $\mathcal{I}^- = \{i|y_i = -1\}$  as the sets of indices of positive and negative examples, respectively, with  $N^+ = |\mathcal{I}^+|$  and  $N^- = |\mathcal{I}^-|$ , and  $N^+ + N^- = N$ . Define  $\mathbf{I}$  as the *indicator function*:  $\mathbf{I}_a = 1$  if  $a$  is true and 0 otherwise. A parametric binary classifier  $c_{\mathbf{w},\theta} : \mathcal{R}^d \mapsto \{-1, +1\}$ , constructed as

$$c_{\mathbf{w},\theta}(\mathbf{x}) = 2\mathbf{I}_{f_{\mathbf{w}}(\mathbf{x}) \geq \theta} - 1 = \text{sign}(f_{\mathbf{w}}(\mathbf{x}) - \theta),$$

maps an example to the class label, where  $f_{\mathbf{w}} : \mathcal{R}^d \mapsto \mathcal{R}$  (with  $\mathbf{w} \in \mathcal{R}^m$  being the parameter) is the prediction function and  $\theta \in \mathcal{R}$  is the classification threshold. We denote  $c_i = f_{\mathbf{w}}(\mathbf{x}_i)$  as the *prediction score* of the  $i^{\text{th}}$  example ( $i = 1, \dots, N$ ). For simplicity, we assume there are no ties in the prediction scores, *i.e.*,  $c_i \neq c_j$  for  $i \neq j$ , though this condition will be relaxed later.

Given a threshold  $\theta$ , negative examples with prediction scores greater than  $\theta$  are false positives, and the false positive rate is given by  $\tau_{FP} = |\mathbf{I}_{c_i > \theta \wedge i \in \mathcal{I}^-}|/N^-$ . Correspondingly, positive examples with prediction scores greater or equal to  $\theta$  are true positives, and the true positive rate is given by  $\tau_{TP} = |\mathbf{I}_{c_i \geq \theta \wedge i \in \mathcal{I}^+}|/N^+$ . Then the receiver operation curve (ROC) is defined as the curve formed by the pair  $(\tau_{FP}, \tau_{TP})$  with  $\theta \in (-\infty, \infty)$ . With this definition, ROC is a curve confined to  $[0, 1] \times [0, 1]$  and connecting  $(0, 0)$  to  $(1, 1)$ . AUC then corresponds to the area enclosed by the ROC curve of the classifier.

It is more conveniently computed in closed form using the Wilcoxon-Mann-Whitney (WMW) statistic [3], as  $A = \frac{1}{N^+N^-} \sum_{i \in \mathcal{I}^+} \sum_{j \in \mathcal{I}^-} \mathbf{I}_{c_i > c_j}$ . In this work, we use the *AUC risk*, which is defined as

$$L_{\text{AUC}} = 1 - A = \frac{1}{N^+N^-} \sum_{i \in \mathcal{I}^+} \sum_{j \in \mathcal{I}^-} \mathbf{I}_{c_i < c_j}. \quad (1)$$

Note that  $L_{\text{AUC}}$  takes values in  $[0, 1]$  and corresponds to the fraction of pairs of positive and negative predictions that are ranked incorrectly, *i.e.*, a positive example with lower prediction score than a negative example, so  $L_{\text{AUC}} = 0$  indicates perfect classification/ranking. In addition,  $L_{\text{AUC}}$  is independent of threshold  $\theta$ , and only concerns with the overall performance of the predictor  $f_{\mathbf{w}}$ . Hence, we aim to learn a prediction function  $f_{\mathbf{w}}$  that minimizes  $L_{\text{AUC}}$ , from which we can choose  $\theta$  to construct classifier  $c_{\mathbf{w},\theta}(\mathbf{x})$ .

### 3 RELATED WORKS

Most existing works for either batch or online algorithms for AUC optimization (*e.g.*, [9, 10]) minimize surrogates to the true AUC risk, which are usually in the form of convex upper-bounds to the indicator function in Eq.(1). Specifically, denoting the prediction scores for  $\mathbf{x}_i$  and  $\mathbf{x}_j$  as  $c_i$  and  $c_j$ , respectively, the surrogate loss function

takes the form as  $\frac{1}{N^+N^-} \sum_{i \in \mathcal{I}^+} \sum_{j \in \mathcal{I}^-} \ell(c_i - c_j)$ , and common choices for  $\ell$  include

1. the hinge loss [10],  $\ell_h(c_i, c_j) = [1 - (c_i - c_j)]_+$ , where  $[a]_+ = \max\{0, a\}$  is the hinge function,
2. the squared hinge loss [11, 9],  $\ell_{sh}(c_i, c_j) = [1 - (c_i - c_j)]_+^2$ ,
3. the logistic loss,  $\ell_{lg} = \log_2(1 + e^{c_i - c_j})$ ,
4. and the rank-boost loss [12],  $\ell_e(c_i, c_j) = e^{c_i - c_j}$ .

All these surrogates are nonnegative, monotonic decreasing and satisfy  $\ell(c_i, c_j) = 1$  when  $c_i = c_j$ . One significant problem with these surrogates is that they all rely on pairwise comparisons between positive and negative training examples, which lead to algorithms with quadratic running time complexity. For large datasets, such quadratic running time will significantly slow down the training process, and the pairwise comparisons prohibit efficient online learning algorithms for AUC optimization.

One exception is the work of [11], which shows that the squared hinge surrogate of AUC risk,  $\ell_{sh}(c_i, c_j)$ , affords an equivalent saddle point reformulation. An online stochastic gradient descent method is then developed based on this reformulation that has complexities  $O(N)$  in time and  $O(1)$  in space. However, there are two issues of this method that this work aims to improve on. First, the original surrogate loss still requires pairwise comparison, and to decouple them, one needs to introduce auxiliary variables for a saddle point reformulation. In contrast, our surrogate loss obviates pairwise comparison all together. Second, our surrogate loss reduces to a minimization problem, which is easier to analyze and implement than the saddle point reformulation of [11].

In parallel with methods directly optimizing AUC, empirical observations suggest that learning objectives not designed for AUC optimization (*e.g.*, SVM or boosting) can achieve low AUC risk [5, 6, 7, 8]. For instance, in [6], a generalized SVM approach was developed that is able to optimize multivariate non-linear performance measures in polynomial time, including AUC. However, when assessed with respect to the AUC, the superiority of the direct AUC optimization approach over standard SVMs seemed less convincing. The work of [7] many performance measures for binary classification are compared experimentally, and it was found that maximum margin methods such as boosting and SVMs yield excellent performance when measured with AUC. In [5] it was shown that optimizing standard SVMs leads to maximizing the AUC in the special (trivial) case when the given data is separable. As a perfect separation implies a zero AUC risk. The work [13] uses the rank-equivalent

definition of AUC to derive a hinge rank loss and shows that it is analogous to the SVM objective. However, no explicit relation between the SVM objective and AUC or AUC surrogates are established in previous works.

Further along this line, several studies have provided results on the consistency of the univariate losses to AUC risk, *i.e.*, in the asymptotic sense, minimizing the univariate losses under certain conditions may also lead to the minimization of AUC risk [14, 15], and a similar analysis is conducted for binary surrogate losses to AUC risk in [16]. These analyses show that univariate losses such as the  $\ell_2$ , squared hinge and exponential losses are consistent with AUC risk, yet the widely used hinge loss in SVM are inconsistent. This seems to put in question whether minimizing AUC risk based on pairwise comparisons is really warranted. However, these studies are still of limited in practice due to several reasons. First, they can not explain the observation that the SVM algorithm which is based on the hinge loss, oftentimes leads to good performance when evaluated with AUC risk, though it is not theoretically consistent with AUC risk. In addition, these analysis does not reveal a direct relation between the univariate losses and AUC risk, and it is more illustrative if some bounding relation between them can be revealed. Furthermore, these analyses may not be as relevant in practice, as the learning objective in actual algorithms is usually combined with extra terms such as the regularizers.

## 4 METHOD

In this section, we start with an equivalent definition of AUC risk, which does not require pairwise comparisons of positive and negative examples. From this equivalent definition, we establish our AUC surrogate loss and its equivalent form for efficient optimization.

### 4.1 AUC Risk Without Pairwise Comparison

Besides the WMW statistics, Eq.(1), there exists another equivalent formulation of AUC risk (and AUC itself), which depends on the ranking of the prediction scores instead of all pairwise comparisons of the prediction scores of the positive and negative examples [4, 13]. To explain this equivalent form of AUC risk, we first introduce several additional notations. For simplicity, we assume there are no ties in the prediction scores, *i.e.*,  $c_i \neq c_j$  for  $i \neq j$ , though this condition will be relaxed later.

We denote  $(c_1^\uparrow, \dots, c_N^\uparrow)$  as the result of sorting  $(c_1, \dots, c_N)$  in ascending order, *i.e.*,  $c_1^\uparrow < c_2^\uparrow < \dots < c_N^\uparrow$ . Moreover, let  $r_i^+ \in \{1, \dots, N\}$  ( $i = 1, \dots, N^+$ ) be the *rank* of the  $i^{\text{th}}$  positive example encountered in the or-

Figure 1: An illustration of the ranking definition of the AUC. Note that in this case, we have  $N^+ = 7$ ,  $N^- = 6$ , and  $(r_1^+, r_2^+, r_3^+, r_4^+, r_5^+, r_6^+, r_7^+) = (4, 6, 7, 8, 9, 11, 13)$ . For the positive example highlighted with circle, it is the second positive example in the ordered list, and it is outranked by two negative examples (shown by arrows). So its contribution to AUC risk is  $N^- + i - r_i^+ = 6 + 2 - 6 = 2$ . Repeating for all 7 positive examples the total wrong pairs is  $3 + 2 + 2 + 2 + 1 + 0 = 12$  and AUC risk is  $\frac{12}{6 \times 7} = \frac{2}{7}$ , which is the same as computed with Eq.(1).

dered list  $(c_1^\uparrow, \dots, c_N^\uparrow)$  starting from the beginning. With a slight abuse of notation, let  $c_i^{\uparrow+}$  be the corresponding value of the  $i^{\text{th}}$  positive example in the ordered list  $(c_1^\uparrow, \dots, c_N^\uparrow)$ , *i.e.*,  $c_i^{\uparrow+} = c_{r_i^+}^\uparrow$ . An example illustrating these definitions is given in Fig.1. These definitions immediately lead to the following simple result that will be important subsequently.

**Lemma 1.** For  $i = 1, \dots, N^+$ , we have

$$r_i^+ \leq N^- + i, \quad c_{N^-+i}^\uparrow \geq c_i^{\uparrow+}.$$

Proof of Lemma 1 is provided in the Appendix A.

With these definitions, AUC risk can be defined using the rankings of the predictions [4], which is equivalent to the definition based on the WMW statistics as given in Eq.(1). The intuition behind this equivalent form is a different way to count the number of reverse ordered pairs of positive and negative examples, which is illustrated with the numerical example in Figure 1.

**Lemma 2** ([4]). When there is no ties in training data, *i.e.*,  $c_i \neq c_j$  for  $i \neq j$ , we have

$$\begin{aligned} L_{AUC} &= \frac{1}{N^+N^-} \sum_{i=1}^{N^+} (N^- + i - r_i^+) \\ &= 1 + \frac{N^++1}{2N^-} - \frac{1}{N^+N^-} \sum_{i=1}^{N^+} r_i^+. \end{aligned} \quad (2)$$

Proof of Lemma 2 is provided in the Appendix A. Note that  $\sum_{i=1}^{N^+} (N^- + i)$  corresponds to (trivially) the sum of the indices of the largest  $N^+$  (top- $N^+$ ) elements in the ranked list of prediction scores, and  $\sum_{i=1}^{N^+} r_i^+$  is the sum of the indices of positive examples in the ranked list of predictions. As such, AUC risk as defined in Eq.(2) is proportional to the difference between the two sums.

This gives another intuitive explanation of AUC risk: in a perfect separable case, when the prediction scores of all the positive examples rank higher than those of the negative examples, *i.e.*, all prediction scores of positive examples have ranks  $N^- + 1, \dots, N$  in the ordered list, AUC risk is zero. In the more general cases, AUC risk measures how the rankings of the prediction scores deviate from this ideal case.

## 4.2 Univariate Bound on AUC risk

The equivalent form of AUC risk of Eq.(2) inspires a new surrogate loss based on the values of the sorted prediction scores  $(c_1^\uparrow, \dots, c_N^\uparrow)$ . To be specific, let us define a new quantity

$$\tilde{L} = \frac{1}{N^+N^-} \sum_{i=N^++1}^N c_i^\uparrow - \frac{1}{N^+N^-} \sum_{i \in \mathcal{I}^+} c_i. \quad (3)$$

Like AUC risk,  $\tilde{L}$  is always nonnegative, as the second term, which is the sum of the prediction scores of all the positive examples, is less than or equal to the first term, which is the sum of the top- $N^+$  elements of  $(c_1, \dots, c_N)$ . Equality holds only when the predictions of all positive examples rank higher than any of the negative examples. Our next result shows that we can bound AUC risk using  $\tilde{L}$ .

**Theorem 1.** *When there is no ties in training data, i.e.,  $c_i \neq c_j$  for  $i \neq j$ , we have  $\tilde{L} \geq 0$ . Furthermore, there exist constants  $\bar{\alpha} \geq \underline{\alpha} > 0$ , such that  $\bar{\alpha}\tilde{L} \geq L_{AUC} \geq \underline{\alpha}\tilde{L}$ .*

*Proof.* Using Lemma 1, we have  $\sum_{i=1}^{N^+} (c_{N^++i}^\uparrow - c_i^{\uparrow+}) \geq 0$ , therefore  $\tilde{L} \geq 0$ , and it is zero when  $c_{N^++i}^\uparrow = c_i^{\uparrow+}$  for all  $i = 1, \dots, N^+$ , i.e., all positive examples outrank all negative examples.

We set  $\bar{\alpha}^{-1} = \min_i (c_{i+1}^\uparrow - c_i^\uparrow) > 0$ , and for  $i > j$ , we have  $c_i^\uparrow - c_j^\uparrow = (c_i^\uparrow - c_{i-1}^\uparrow) + (c_{i-1}^\uparrow - c_{i-2}^\uparrow) + \dots + (c_{j+1}^\uparrow - c_j^\uparrow) \geq \frac{i-j}{\bar{\alpha}}$ . Then we have

$$\begin{aligned} \bar{\alpha}\tilde{L} &= \frac{\bar{\alpha}}{N^+N^-} \sum_{i=N^++1}^N c_i^\uparrow - \frac{\bar{\alpha}}{N^+N^-} \sum_{i \in \mathcal{I}^+} c_i \\ &= \frac{\bar{\alpha}}{N^+N^-} \sum_{i=1}^{N^+} (c_{N^++i}^\uparrow - c_i^{\uparrow+}) \\ &= \frac{\bar{\alpha}}{N^+N^-} \sum_{i=1}^{N^+} (c_{N^++i}^\uparrow - c_{r_i}^{\uparrow+}) \\ &\geq \frac{1}{N^+N^-} \sum_{i=1}^{N^+} (N^- + i - r_i^{\uparrow+}) = L_{AUC}. \end{aligned}$$

Next, setting  $\underline{\alpha}^{-1} = \max_i (c_{i+1}^\uparrow - c_i^\uparrow)$ , and follow a similar derivation, we can obtain the other bound, i.e.,  $L_{AUC} \geq \underline{\alpha}\tilde{L}$ . The equalities in the bounds hold when  $c_{i+1}^\uparrow - c_i^\uparrow$  is a constant for  $i = 1, \dots, N$ , i.e., they are equally spaced.  $\square$

## 4.3 Computing $\tilde{L}$ without Explicit Ranking

However, the ranking operation in  $\tilde{L}$  is the main obstacle of using Eq.(3) as a learning objective. However, this can be solved based on the following result on the sum of the top  $k$  elements in a set [17, 18], from which we can derive an equivalent form of Eq.(3) that does not rely on ranking elements explicitly.

**Lemma 3** ([17, 18]). *For  $N$  real numbers  $z_1 < \dots < z_N$ , we have the equivalence of the sum-of-top- $k$  elements with an optimization problem as*

$$\sum_{i=N-k+1}^N z_i = \min_{\lambda} \left\{ k\lambda + \sum_{i=1}^N [z_i - \lambda]_+ \right\}, \quad (4)$$

with the optimal  $\lambda^*$  satisfying  $z_{N-k} \leq \lambda^* < z_{N-k+1}$ .

Proof of Lemma 3 is provided in the Appendix A. Using Lemma 3, we can rewrite  $\tilde{L}$  by as a minimization problem over the auxiliary variable  $\lambda$ , as

$$N^+N^-\tilde{L} = \min_{\lambda} \left\{ N^+\lambda + \sum_{i=1}^N [c_i - \lambda]_+ \right\} - \sum_{i \in \mathcal{I}^+} c_i,$$

which can be further converted to

$$\min_{\lambda} \left\{ \sum_{i \in \mathcal{I}^+} ([c_i - \lambda]_+ - (c_i - \lambda)) + \sum_{j \in \mathcal{I}^-} [c_j - \lambda]_+ \right\}.$$

Using the property of the hinge function that  $[a]_+ - a = [-a]_+$ , we can further simplify  $\tilde{L}$ , as

$$\begin{aligned} \tilde{L} &= \frac{1}{N^+N^-} \min_{\lambda} \left\{ \sum_{i \in \mathcal{I}^+} [\lambda - c_i]_+ + \sum_{j \in \mathcal{I}^-} [c_j - \lambda]_+ \right\} \\ &= \frac{1}{N^+N^-} \min_{\lambda} \sum_{i=1}^N [y_i(\lambda - c_i)]_+. \end{aligned}$$

Bringing back the parametric model to form a learning objective based on  $\tilde{L}$  as

$$\tilde{L}(\mathbf{w}) = \frac{1}{N^+N^-} \min_{\lambda} \sum_{i=1}^N [y_i(\lambda - f_{\mathbf{w}}(\mathbf{x}_i))]_+. \quad (5)$$

This reformulation of  $\tilde{L}$  is still a bound for AUC risk, but it does not require pairwise comparisons between predictions of positive and negative examples, and there is no need to explicitly ranking the predictions. Furthermore, in Eq.(5), the auxiliary variable  $\lambda$  can be understood as a threshold that separates the two classes, and  $\tilde{L}(\mathbf{w})$  becomes independent of the choice of threshold by taking the overall minimum over all possible values for the threshold, as in the case of the original definition of AUC risk.

The learning objective  $\tilde{L}(\mathbf{w})$  affords an intuitive interpretation in the context of binary classification. It only penalizes those positive examples with predictions less than the threshold, i.e.,  $[\lambda - f_{\mathbf{w}}(\mathbf{x}_i)]_+$  for  $i \in \mathcal{I}^+$ , and negative examples with predictions greater than the threshold, i.e.,  $[f_{\mathbf{w}}(\mathbf{x}_i) - \lambda]_+$  for  $i \in \mathcal{I}^-$ . All examples that are on the ‘‘correct’’ side of the threshold receive no penalty. According to Lemma 3, the optimal  $\lambda$  takes value in the range of  $[c_{N^+}^\uparrow, c_{N^++1}^\uparrow)$ .

#### 4.4 Relation with SVM Objective

There are some strong similarities between  $\tilde{L}(\mathbf{w})$  and the SVM objective, which is particularly striking in the case of linear prediction function  $f_{\mathbf{w}}(\mathbf{x}) = \mathbf{w}^\top \mathbf{x}$ . This becomes clearer if we reformulate the SVM objective: if we regard the threshold  $\lambda$  as the bias term in the linear prediction function for SVM<sup>1</sup>,  $\mathbf{w}^\top \mathbf{x} - \lambda$ , we can formulate the linear SVM objective [19] as

$$\tilde{L}_{\text{SVM}}(\mathbf{w}, \lambda) = \sum_{i=1}^N [1 + y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+.$$

Now comparing with Eq.(5), the two objectives has similar forms involving the hinge function. We can further show that  $\tilde{L}_{\text{SVM}}(\mathbf{w}, \lambda)$  is an upper-bound of  $\tilde{L}(\mathbf{w})$ . This is because we have  $[1 + y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+ \geq [y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+$ , so

$$\begin{aligned} \tilde{L}_{\text{SVM}}(\mathbf{w}, \lambda) &= \sum_{i=1}^N [1 + y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+ \\ &\geq \sum_{i=1}^N [y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+ \\ &\geq \min_{\lambda} \sum_{i=1}^N [y_i(\lambda - \mathbf{w}^\top \mathbf{x}_i)]_+ \\ &= \tilde{L}(\mathbf{w}). \end{aligned}$$

As we have shown in Theorem 1, an upper-bound of AUC risk can be established with  $\tilde{L}(\mathbf{w})$ , and this relation suggests the SVM objective  $\tilde{L}_{\text{SVM}}(\mathbf{w}, \lambda)$  is also an upper-bound (albeit looser than  $\tilde{L}$ ) of AUC risk.

This helps to explain some long standing experimental observations (e.g., [5, 6, 7, 8]) that when assessed with AUC, standard SVMs could not be consistently outperformed by other approaches tailored to directly maximize AUC, such as RankBoost [20], AUCsplit (local optimization of AUC) [21], or ROC-SVM [8].

The two learning objectives also differ in two important aspects. The first is the constant 1 in the SVM objective, which corresponds to the margin in constructing the binary classifier. The second difference is that the bias  $\lambda$  in  $\tilde{L}$  is eliminated through minimization, but it is still present in the SVM objective.

## 5 OPTIMIZATION

In this section, we discuss batch and online learning algorithms based on learning objectives formed from Eq.(5).

### 5.1 Resolving Ties in Prediction Scores

However, Eq.(5) cannot be used as a learning objective due to one important issue. Note that in Eq.(5), the scale

<sup>1</sup>Typically in SVM we define the linear prediction function as  $\mathbf{w}^\top \mathbf{x} + b$ , but here we flip the sign of the bias so to better compare with  $\tilde{L}(\mathbf{w})$ .

of the parameter  $\mathbf{w}$  is not fixed, so the learning objective can be reduced by shrinking the scale of  $\mathbf{w}$ , which leads to a trivial solution with  $\mathbf{w} = 0$ . The underlying reason is that the formulation of  $\tilde{L}$  is based on the assumption of no ties in the prediction scores, while the trivial solution corresponds to the extreme contrary, i.e., the prediction function always produce the same output (zero) regardless of the data.

To resolve this problem, we augment the objective function with two other terms

$$\min_{\mathbf{w}} \tilde{L}(\mathbf{w}) + \frac{\beta}{2} \sum_{i=1}^N (1 - y_i f_{\mathbf{w}}(\mathbf{x}_i))^2 + \gamma \Omega(\mathbf{w}), \quad (6)$$

where the second term corresponds to a least squares term to counteract the effect of concentrating  $\mathbf{w}$  to zero, the third term  $\Omega(\mathbf{w})$  is a regularizer on parameter  $\mathbf{w}$ , and  $(\beta, \gamma)$  are weights to the two extra terms.

### 5.2 Linear Predictor

In general, the learning objective of Eq.(6) is not a convex function of  $\mathbf{w}$ , but if we choose  $f_{\mathbf{w}}(\mathbf{x}) = \mathbf{w}^\top \mathbf{x}$  and  $\Omega(\mathbf{w})$  is convex with respect to  $\mathbf{w}$  (i.e.,  $\Omega(\mathbf{w}) = \frac{1}{2} \|\mathbf{w}\|^2$ ), then we can show it is a convex function of  $\mathbf{w}$ . We first show that  $[\mathbf{x}^\top \mathbf{w} - \lambda]_+$  is a convex function. For  $\alpha \in [0, 1]$ ,  $\mathbf{w}, \mathbf{w}', \lambda$ , and  $\lambda'$ , we have

$$\begin{aligned} &[\alpha \mathbf{x}^\top \mathbf{w} + (1 - \alpha) \mathbf{x}^\top \mathbf{w}' - (\alpha \lambda + (1 - \alpha) \lambda')]_+ = \\ &[\alpha (\mathbf{x}^\top \mathbf{w} - \lambda) + (1 - \alpha) (\mathbf{x}^\top \mathbf{w}' - \lambda')]_+ \leq \\ &\alpha [\mathbf{x}^\top \mathbf{w} - \lambda]_+ + (1 - \alpha) [\mathbf{x}^\top \mathbf{w}' - \lambda']_+. \end{aligned} \quad (7)$$

Therefore,  $\sum_{i=1}^N [\mathbf{x}_i^\top \mathbf{w} - \lambda]_+ + N^+ \lambda$  is a convex function jointly for  $(\mathbf{w}, \lambda)$ . As the minimization of one variable in a joint convex function,  $\min_{\lambda} \sum_{i=1}^N [c_i - \lambda]_+ + N^+ \lambda$  is also a convex function of  $\mathbf{w}$ .

In summary, for the linear case, we can obtain the following convex learning objective with regards to  $\mathbf{w}$  and  $\lambda$  jointly,

$$\begin{aligned} &(\mathbf{w}^*, \lambda^*) \leftarrow \operatorname{argmin}_{\mathbf{w}, \lambda} \frac{\gamma}{2} \|\mathbf{w}\|^2 + \\ &\sum_{i=1}^N \left\{ [y_i(\lambda - \mathbf{x}_i^\top \mathbf{w})]_+ + \frac{\beta}{2} (1 - y_i \mathbf{x}_i^\top \mathbf{w})^2 \right\} \end{aligned} \quad (8)$$

In the following, we discuss the batch and online optimization of Eq.(8), for which the convergence to global minimum is guaranteed.

#### 5.2.1 Batch Learning

In the batch setting, where we have access to all training examples, we can use block coordinate descent algorithm to optimize Eq.(8). We initialize  $\mathbf{w}$  and  $\lambda$ , then iterate between

$$\begin{aligned} \mathbf{w}^{(t+1)} &\leftarrow \operatorname{argmin}_{\mathbf{w}} \sum_{i=1}^N [y_i(\lambda^{(t)} - \mathbf{w}^\top \mathbf{x}_i)]_+ + \\ &\quad \frac{\beta}{2} \sum_{i=1}^N (1 - y_i \mathbf{x}_i^\top \mathbf{w})^2 + \frac{\gamma}{2} \|\mathbf{w}\|^2; \\ \lambda^{(t+1)} &\leftarrow \frac{1}{2} (c_{N+}^\uparrow + c_{N+1}^\uparrow), \end{aligned}$$

where  $c_i^\uparrow$  is the rerank of  $\{\mathbf{x}_i^\top \mathbf{w}^{(t+1)}\}_{i=1}^N$  in the ascending order. The  $\mathbf{w}$  sub-problem can be converted to a constrained optimization problem as

$$\begin{aligned} \min_{\mathbf{w}, \mathbf{t}} \quad & \sum_{i=1}^N t_i + \frac{\beta}{2} \sum_{i=1}^N (1 - y_i \mathbf{x}_i^\top \mathbf{w})^2 + \frac{\gamma}{2} \|\mathbf{w}\|^2; \\ \text{s.t.} \quad & \mathbf{y}_i(\lambda^{(t)} - \mathbf{w}^\top \mathbf{x}_i) \geq t_i, t_i \geq 0. \end{aligned}$$

This is a quadratic convex optimization problem and can be solved with interior point method when the dimensionality of  $\mathbf{w}$  is low to medium. For high dimensional  $\mathbf{w}$ , the online learning algorithm is more effective as it avoids building the Hessian matrix.

### 5.2.2 Online Learning

Because Eq.(8) does not involve pairwise comparison, we can also derive an online learning algorithm based on stochastic gradient descent [22, 23]. The runtime of the online algorithm does not depend on the number of training examples and thus this algorithm is especially suited for large datasets. Specifically, with initial choice for the value of  $\mathbf{w}^{(0)}$ , at the  $t^{\text{th}}$  iteration, a single training example  $(\mathbf{x}_{i_t}, y_{i_t})$  is chosen at random from the training set and used to estimate a sub-gradient of the objective, and a step with pre-determined step-size is taken in the opposite direction, as

$$\begin{aligned} \mathbf{w}^{(t+1)} &\leftarrow \mathbf{w}^{(t)} - \eta_t \left( (\gamma \mathbf{I} + \beta \mathbf{x}_{i_t} \mathbf{x}_{i_t}^\top) \mathbf{w}^{(t)} - \right. \\ &\quad \left. (\beta + \mathbf{1}_{y_i(\lambda^{(t)} - \mathbf{w}^\top \mathbf{x}_i) > 0}) y_{i_t} \mathbf{x}_{i_t} \right) \\ \lambda^{(t+1)} &\leftarrow \lambda^{(t)} - \eta_t y_{i_t} \mathbf{1}_{y_i(\lambda^{(t)} - \mathbf{w}^\top \mathbf{x}_i) > 0}, \end{aligned} \quad (9)$$

where we can choose the step-size  $\eta_t \sim \frac{1}{\sqrt{t}}$ , then the SGD algorithm will converge in  $O(1/\epsilon)$  steps to the  $\epsilon$ -accuracy of the global optimal value of Eq.(5) [22, 23]. Note that each step of our online iterative algorithm has space and time complexity of  $O(d)$  and  $O(1)$ , and obviates the need to store or buffer data in previous online AUC optimization methods [10, 9].

## 6 EXPERIMENTS

We perform several experiments of learning binary classifiers to evaluate the batch and online algorithms optimizing learning objectives given in Eq.(8) (subsequently denoted as `ba-UBAUC` and `ol-UBAUC`, respectively), and compare their performance with existing learning algorithms for AUC optimization.

As in previous works [10, 11], we perform experiments on 12 benchmark datasets that have been used in previous studies. A summary of the data in these datasets

Table 1: Summary of the 12 benchmark datasets used in our experiments. The training/testing splitting is from the original datasets.

is given in Table 1, with the training/testing split obtained from the original dataset. For datasets that are for data with more than 2 class labels (*i.e.*, `news20` and `sector`), following the convention of previous work [10, 11], we convert them to binary classification problems by randomly partitioning the data into two groups, each with equal number of classes. Then the binary class labels are determined from the group to which the original class label belongs. Following the evaluation protocol of [10, 11], the performance of reported is obtained by averaging the AUC scores on the test set for 25 models learned from subsets of the same training set, each is chosen as a random 80% of the original training data.

On these datasets, we evaluate and compare UBAUC-based algorithms with four state-of-the-art online and two batch learning algorithms for learning linear binary classifiers that minimizes various pairwise surrogates to the original AUC risk  $L_{\text{AUC}}$ . The hyper parameters  $(\beta, \gamma)$  for UBAUC are determined by a grid search on the validation set. The initial learning rate for the online learning algorithm is also set for different dataset by a grid search. We compare the following algorithms with UBAUC-based algorithms.

- SOLAM [11], an online AUC optimization algorithm based on a saddle point reformulation of the pairwise  $\ell_2$  surrogate loss of AUC risk;
- OPAUC [9], an online AUC optimization algorithm that uses the pairwise  $\ell_2$  loss surrogate of the AUC objective function;
- OAM [10], an online AUC optimization algorithm that uses the pairwise hinge loss surrogate of the AUC objective function with two variants, one with sequential update (OAMseq) and the other using gradient update (OAMgra);
- B-SVM-OR [6], a batch learning algorithm using the pairwise hinge loss surrogate of the AUC objective function;

Table 2: Comparison of the AUC scores (mean±std.) on test sets of the evaluated datasets.

- UNI-SVM, a linear SVM algorithm implemented using LIBSVM with SMO minimization [24].

Classification performances measured by the AUC score on the testing dataset of all compared methods for all 12 benchmark datasets are given in Table 2. For fair comparison, we implement all algorithms using MATLAB, and following the default parameter settings in the original papers. Note that the simple implementation of the two batch algorithms cannot handle datasets with high dimensional datasets, *i.e.*, `sector` and `news20`, due to the memory requirement. However, for those datasets that it is feasible to run, `ba-UBAUC`, the batch version optimizing the proposed learning objective, performs best. On the other hand, the results of `uUNI-SVM`, though optimizing a different objective, still achieves reasonable performance when evaluated with AUC. The online algorithm based on the proposed learning objective, `ol-UBAUC`, achieves comparable performance as other state-of-the-art online algorithms based on pairwise surrogate losses to AUC risk, although the improvements of performance on some of the datasets are not conspicuous due to the nature of the data.

On the other hand, the main advantage of `ol-UBAUC` in comparison with other online algorithms is the running efficiency – its per-iteration running time and space complexity is linear in data dimension and do not depend on the iteration number. Furthermore, each iteration of `ol-UBAUC` Eq. (9) corresponds to a simpler update step than the saddle point solve in SOLAM [11]. In Table 3, we show the per-iteration running time and the total running time for the learning objective function to converge to have smaller than  $10^{-7}$  relative changes<sup>2</sup> of the five online algorithms we compared. Note that the online version of the UBAUC-based algorithms has more efficient running time with comparable performances in

<sup>2</sup>Experiments were performed with running time reported based on a cluster with 12 nodes, each with an Intel Xeon E5-2620 2.0GHz CPU and 64GB RAM. All algorithms are implemented using MATLAB, with available code obtained from the authors of the corresponding publications.

comparison to existing AUC optimization methods.

## 7 POPULATION FORM

So far, we have described the proposed learning objective over a set of finite training data. In this section, we discuss the population form of the surrogate loss using probability distributions of data. This analysis will shed light on the formal connection of the new surrogate loss with existing methods and can lead to deeper theoretical studies.

We start with the population form of the equivalent definition of AUC risk in Eq.(2). We assume that the input data and label are from a joint model  $p(\mathbf{x}, y)$ , which induces density models for the predictions  $c = f(\mathbf{x})$ . As such, we denote  $\rho^+(c) = p(c|y = 1)$  and  $\rho^-(c) = p(c|y = -1)$  as the (conditional) probability density functions (PDFs) for positive and negative class, respectively. For simplicity, we assume both PDFs have infinite support, *i.e.*, is non-zero for the whole  $\mathcal{R}$ . Also, we denote  $p = Pr(y = 1)$  as the class prior probability.

The joint probability density function of the classification output  $c$  is then given by  $\rho(c) = p\rho^+(c) + (1 -$

$p)\rho^-(c)$ . We also denote  $F^+(c) = \int_{-\infty}^c \rho^+(c')dc'$ ,  $F^-(c) = \int_{-\infty}^c \rho^-(c')dc'$ , and  $F(c) = \int_{-\infty}^c \rho(c')dc'$  as the cumulative distribution functions (CDFs) for  $\rho^+$ ,  $\rho^-$  and  $\rho$ , respectively, with  $F(c) = pF^+(c) + (1-p)F^-(c)$ .  $F^+(c)$  is the false negative rate (FNR) and  $1 - F^-(c)$  is the false positive rate (FPR).

AUC risk is defined as the area under the whole curve of FNR vs. FPR, as  $L_{AUC} = \int_{-\infty}^{\infty} (1 - F^-(c))dF^+(c)$  [4]. Using relation  $F^-(c) = \frac{1}{1-p}(F(c) - pF^+(c))$  yields

$$L_{AUC} = \frac{1}{1-p} \int_{-\infty}^{\infty} (1 - p + pF^+(c) - F(c))dF^+(c).$$

Because  $F$  is a CDF is a continuous monotonic function and  $F(c) \leq 1 - p + pF^+(c) \leq 1$ , using the mean value theorem, there exists  $c' \geq c_0 = \max\{c|F(c) = 1 - p\}$ , such that  $1 - p = F(c_0) \leq F(c') = 1 - p + pF^+(c) \leq 1$ , and

$$L_{AUC} = \frac{1}{1-p} \int_{-\infty}^{\infty} (F(c') - F(c))dF^+(c).$$

Next, note that  $F(c)$  is Lipschitz with constant  $\alpha' \geq \max_c |\rho(c)|$ , i.e.,  $|F(c') - F(c)| \leq \alpha'|c' - c|$ , we have

$$L_{AUC} \leq \frac{\alpha'}{1-p} \int_{-\infty}^{\infty} (c' - c)dF^+(c). \quad (10)$$

Next, we use the following result

**Lemma 4.** For  $F(c') = 1 - p + pF^+(c)$ , we have

$$\int_{-\infty}^{\infty} c' dF^+(c) = \min_{\lambda} \int_{-\infty}^{\infty} \frac{(c - \lambda)_+}{p} dF(c) + \lambda.$$

Proof of Lemma 4 is provided in the Appendix A. Using Lemma 4, we can rewrite the integral of the right hand side of Eq.(10) as

$$\min_{\lambda} \int_{-\infty}^{\infty} \frac{(c - \lambda)_+}{p} dF(c) + \lambda - \int_{-\infty}^{\infty} cdF^+(c),$$

where the terms being minimized can be further simplified as

$$\int_{-\infty}^{\infty} \frac{(c - \lambda)_+}{p} dF(c) + (\lambda - c)dF^+(c).$$

This can be further expanded using the relation  $dF(c) = (1 - p)dF^-(c) + pdF^+(c)$  to have

$$\int_{-\infty}^{\infty} (c - \lambda)_+(1 - p)dF^-(c) + \int_{-\infty}^{\infty} [(\lambda - c) + (c - \lambda)_+]pdF^+(c).$$

Putting all terms together and using the relation  $(c - \lambda)_+ + (\lambda - c) = (\lambda - c)_+$  we have

$$L_{AUC} \leq \frac{\alpha'}{p(1-p)} \min_{\lambda} E_{c,y}[y(c - \lambda)_+], \quad (11)$$

where  $E_{c,y}$  represents the expectation over  $c$  and  $y$ .

## 8 CONCLUSION

In this work, we describe a new surrogate loss to the AUC metric based on a formulation of AUC, which does not require pairwise comparison but rankings of the prediction scores. We further show that the ranking operation can be avoided and the learning objective obtained based on this surrogate affords complexity in time and storage that is linear in the number of training data. We perform experiments to demonstrate the effectiveness of the online and batch algorithms for AUC optimization based on the proposed surrogate.

There are several directions we would like to further explore for this work. First, from the theoretical point of view, we would like to establish the consistency of the proposed learning objective with regards to AUC risk, i.e., the question if the surrogate loss will also lead to the convergence to the optimal AUC risk. The form of our surrogate loss (Eq.(5)) as an optimization problems makes it difficult to apply the techniques used in previous works [14, 15] to this case. We would also like to establish the generalization error between the data form of the loss Eq.(5) and its population form counterpart Eq.(11). From the algorithm perspective, we would like to extend this learning objective to substitute multi-class AUC [4], where multi-class AUC risk is computed as the average of binary class AUC between each pairs of classes. Last, we are interested in applying the online algorithm based on the proposed surrogate loss to non-convex learning objectives such as those used for training deep neural networks.

## A Appendix: Proofs

*Proof of Lemma 1.* Being the  $i^{\text{th}}$  positive example encountered in the ordered list  $(c_1^{\uparrow}, \dots, c_N^{\uparrow})$ ,  $c_i^{\uparrow+}$  can outrank no more than  $N^- + i$  elements in the list, i.e.,  $i$  positive examples and at most  $N^-$  negative examples. Therefore, we have  $r_i^+ \leq N^- + i$ . By the ranking order we also have  $c_{N^-+i}^{\uparrow} \geq c_{r_i^+}^{\uparrow} = c_i^{\uparrow+}$ .  $\square$

*Proof of Lemma 2.* Consider the  $i^{\text{th}}$  positive example encountered in  $(c_1^{\uparrow}, \dots, c_N^{\uparrow})$  starting from the beginning, which has rank  $r_i^+$ . The number of negative examples that rank lower than it is  $r_i^+ - i$ , i.e., there will be  $N^- - (r_i^+ - i) = N^- + i - r_i^+$  negative examples with

ranks higher than this positive example, *i.e.*, forming a reversed ordered pair with it. This corresponds to the sum over reversed ordered pairs in the definition of AUC risks of Eq.(1). Summing over all such reverse ordered pairs divided by the number of all such positive-negative pairs ( $N^+N^-$ ) proves the result.  $\square$

*Proof of Lemma 3.* First, we note that  $\sum_{i=N-k+1}^N z_i$  is the solution of the following linear programming problem

$$\max_{\mathbf{p} \in \mathbb{R}^{n \times 1}} \mathbf{p}^\top \mathbf{z}, \quad \text{s.t. } \mathbf{p}^\top \mathbf{1} = k, p_i \in [0, 1], \quad (12)$$

We form its Lagrangian as

$$L = -\mathbf{p}^\top \mathbf{z} - \mathbf{a}^\top \mathbf{p} + \mathbf{b}^\top (\mathbf{p} - \mathbf{1}) + \lambda (\mathbf{p}^\top \mathbf{1} - k), \quad (13)$$

where  $\mathbf{a} \geq \mathbf{0}$ ,  $\mathbf{b} \geq \mathbf{0}$  and  $\lambda$  are Lagrangian multipliers. Setting the derivative of  $L$  with respect to  $\mathbf{p}$  to be  $\mathbf{0}$ , we obtain  $\mathbf{a} = \mathbf{b} - \mathbf{z} + \lambda \mathbf{1}$ . Substituting this into Eq (13), we get the dual problem of (12) as

$$\min_{\mathbf{b}, \lambda} \mathbf{b}^\top \mathbf{1} + k\lambda, \quad \text{s.t. } \mathbf{b} \geq \mathbf{0}, \mathbf{b} + \lambda \mathbf{1} - \mathbf{z} \geq \mathbf{0}, \quad (14)$$

The constraints of Eq. (14) suggest that we should have  $\mathbf{b}^\top \mathbf{1} \geq \sum_{i=1}^n [z_i - \lambda]_+$ . As such, the objective function achieves its minimum when the equality holds. Reorganizing terms leads to Eq.(4). Further, when we choose  $\lambda^*$  satisfying  $z_{N-k} \leq \lambda^* < z_{N-k+1}$ , we have  $k\lambda^* + \sum_{i=1}^N [z_i - \lambda^*]_+ = k\lambda^* + \sum_{i=N-k+1}^N (z_i - \lambda^*) = \sum_{i=N-k+1}^N z_i$ . Thus proves the lemma.  $\square$

*Proof of Lemma 4.* First, we have  $dF(c') = p dF^+(c)$ , then  $\int_{-\infty}^{\infty} c' dF^+(c) = \frac{1}{p} \int_{c_0}^{\infty} c' dF(c')$ , where the lower limit of the integral,  $c_0 = \max\{c | F(c) = 1 - p\}$ , originates from the range of value  $c'$ . Next, we compute  $\min_{\lambda} \int_{-\infty}^{\infty} (c - \lambda)_+ dF(c) + p\lambda = \min_{\lambda} \int_{\lambda}^{\infty} c dF(c) - \lambda \int_{\lambda}^{\infty} dF(c) + p\lambda$ . Differentiating the inner terms with regards to  $\lambda$ , we obtain  $\int_{\lambda}^{\infty} dF(c) = p$ , or  $\int_{-\infty}^{\lambda} dF(c) = 1 - p$ , so we have at optimum,  $\lambda = c_0$ . Therefore we have  $\min_{\lambda} \int_{-\infty}^{\infty} (c - \lambda)_+ dF(c) + p\lambda = \int_{c_0}^{\infty} c' dF(c')$ . Further rearranging terms proves the result.  $\square$

## Abstract

We reconsider a nonparametric density model based on Gaussian processes. By augmenting the model with latent Pólya–Gamma random variables and a latent marked Poisson process we obtain a new likelihood which is conjugate to the model’s Gaussian process prior. The augmented posterior allows for efficient inference by Gibbs sampling and an approximate variational mean field approach. For the latter we utilise sparse GP approximations to tackle the infinite dimensionality of the problem. The performance of both algorithms and comparisons with other density estimators are demonstrated on artificial and real datasets with up to several thousand data points.

## 1 INTRODUCTION

Gaussian processes (GP) provide highly flexible non-parametric prior distributions over functions [1]. They have been successfully applied to various statistical problems such as e.g. regression [2], classification [3], point processes [4] or the modelling of dynamical systems [5, 6]. Hence, it would seem natural to apply Gaussian processes also to density estimation which is one of the most basic statistical problems. GP density estimation, however, is a nontrivial task: Typical realisations of a GP do not respect non-negativity and normalisation of a probability density. Hence, functions drawn from a GP prior have to be passed through a nonlinear squashing function and the results have to be normalised subsequently to model a density. These operations make the corresponding posterior distributions non-Gaussian. Moreover, likelihoods depend on all the infinitely many

---

\*Also affiliated with Bernstein Center for Computational Neuroscience.

GP function values in the domain rather than on the finite number of function values at observed data points. Since analytical inference is impossible, [7] introduced an interesting Markov chain Monte–Carlo sampler which allows for (asymptotically) exact inference for a Gaussian process density model, where the GP is passed through a sigmoid link function.<sup>1</sup> The approach is able to deal with the infinite dimensionality of the model, because the sampling of the GP variables is reduced to a finite dimensional problem by a point process representation. However, since the likelihood of the GP variables is not conjugate to the prior, the method has to resort to a time-consuming Metropolis–Hastings approach. In this paper we will use recent results on representing the sigmoidal squashing function as an infinite mixture of Gaussians involving Pólya–Gamma random variables [9] to augment the model in such a way that the model becomes tractable by a simpler Gibbs sampler. The new model structure allows also for a much faster variational Bayesian approximation.

The paper is organised as follows: Sec. 2 introduces the GP density model, followed by an augmentation scheme that makes its likelihood conjugate to the GP prior. With this model representation we derive two efficient Bayesian inference algorithms in Sec. 3, namely an exact Gibbs sampler and an approximate, fast variational Bayes algorithm. The performance of both algorithms is demonstrated in Sec. 4 on artificial and real data. Finally, Sec. 5 discusses potential extensions of the model.

## 2 GAUSSIAN PROCESS DENSITY MODEL

The generative model proposed by [7] constructs densities over some  $d$ -dimensional data space  $\mathcal{X}$  to be of the

---

<sup>1</sup>See [8] for an alternative model allowing, however, only for approximate inference schemes.

form

$$\rho(\mathbf{x}|g) = \frac{\sigma(g(\mathbf{x}))\pi(\mathbf{x})}{\int_{\mathcal{X}} \sigma(g(\mathbf{x}))\pi(\mathbf{x})d\mathbf{x}}. \quad (1)$$

$\pi(\mathbf{x})$  defines a (bounded) base probability measure over  $\mathcal{X}$ , which is usually taken from a fixed parametric family. The denominator ensures normalisation  $\int_{\mathcal{X}} \rho(\mathbf{x}|g)d\mathbf{x} = 1$ . The choice of  $\pi(\mathbf{x})$  is important as will be discussed Sec. 5. A prior distribution over densities is introduced by assuming a Gaussian process prior [1] over the function  $g(\mathbf{x}) : \mathcal{X} \rightarrow \mathbb{R}$ . The GP is defined by a mean function  $\mu(\mathbf{x})$  (in this paper, we consider only constant mean functions  $\mu(\mathbf{x}) = \mu_0$ ) and covariance kernel  $k(\mathbf{x}, \mathbf{x}')$ . Finally,  $\sigma(z) = \frac{1}{1+e^{-z}}$  is the sigmoid function, which guarantees that the density is non-negative and bounded.

In Bayesian inference, the posterior distribution of  $g$  given observed data  $\mathcal{D} = \{\mathbf{x}_n\}_{n=1}^N$  with  $\mathbf{x} \in \mathcal{X}$  is computed from the GP prior  $p(g)$  and the likelihood as

$$p(g|\mathcal{D}) \propto p(\mathcal{D}|g)p(g).$$

The likelihood is given by

$$p(\mathcal{D}|g) = \frac{\prod_{n=1}^N \sigma(g(\mathbf{x}_n))\pi(\mathbf{x}_n)}{\left(\int_{\mathcal{X}} \sigma(g(\mathbf{x}))\pi(\mathbf{x})d\mathbf{x}\right)^N}. \quad (2)$$

Practical inference for this problem, however, is non-trivial, because (i) the posterior is non-Gaussian and (ii) the likelihood involves an integral of  $g$  over the whole space. Thus, in contrast to simpler problems such as GP regression or classification, it is impossible to reduce inference to finite dimensional integrals. To circumvent the problem that the likelihood is not conjugate to the GP prior, [7] proposed a Metropolis-Hastings MCMC algorithm for this model. We will show in the next sections that one can augment the model with auxiliary latent random variables in such a way that the resulting likelihood is of a conjugate form allowing for a more efficient Gibbs sampler with explicit conditional probabilities.

## 2.1 LIKELIHOOD AUGMENTATION

To obtain a likelihood which is conjugate to the GP  $p(g)$  we require that it assumes a Gaussian form in  $g$ .

**Representing the denominator** As a starting point, we follow [10] and use the representation

$$\frac{1}{z^N} = \frac{\int_0^\infty \lambda^{N-1} e^{-\lambda z} d\lambda}{\Gamma(N)},$$

where  $\Gamma(\cdot)$  is the gamma function. Identifying  $z = \int_{\mathcal{X}} \sigma(g(\mathbf{x}))\pi(\mathbf{x})d\mathbf{x}$  in Eq. (2) we can rewrite the

likelihood as  $p(\mathcal{D}|g) = \int_0^\infty p(\mathcal{D}, \lambda|g)d\lambda$  where

$$p(\mathcal{D}, \lambda|g) \propto \exp\left(-\int_{\mathcal{X}} \lambda \sigma(g(\mathbf{x}))\pi(\mathbf{x})d\mathbf{x}\right) \times p(\lambda) \prod_{n=1}^N \lambda \sigma(g(\mathbf{x}_n))\pi(\mathbf{x}_n), \quad (3)$$

with the improper prior  $p(\lambda) = \lambda^{-1}$  over the auxiliary latent variable  $\lambda$ . To transform the likelihood further into a form which is Gaussian in  $g$ , we utilise a representation of the sigmoid function as a scale mixture of Gaussians.

### Pólya-Gamma representation of sigmoid function

As discovered by [9], the inverse hyperbolic cosine can be represented as an infinite mixture of scaled Gaussians

$$\cosh^{-b}(z/2) = \int_0^\infty e^{-\frac{z^2}{2}\omega} p_{\text{PG}}(\omega|b, 0)d\omega,$$

where  $p_{\text{PG}}(\omega|b, 0)$  is the *Pólya-Gamma density* of random variable  $\omega \in \mathbb{R}^+$ . Moments of those densities can be easily computed [9]. Later, we will also use the *tilted* Pólya-Gamma densities defined as

$$p_{\text{PG}}(\omega|b, c) \propto \exp\left(-\frac{c^2}{2}\omega\right) p_{\text{PG}}(\omega|b, 0). \quad (4)$$

These definitions allows for a Gaussian representation of the sigmoid function as

$$\sigma(z) = \frac{e^{z/2}}{2 \cosh(z/2)} = \int_0^\infty e^{f(\omega, z)} p_{\text{PG}}(\omega|1, 0)d\omega \quad (5)$$

with  $f(\omega, z) = \frac{z}{2} - \frac{z^2}{2}\omega - \ln 2$ . This result will be used to transform the products over observations  $\sigma(g(\mathbf{x}_n))$  in the likelihood (3) into a Gaussian form.

We will next deal with the first term in the likelihood (3) which contains the integral over  $\mathbf{x}$ . For this part of the model we will derive a point process representation which can be understood as a generalisation of the approach of [7].

**Marked-Poisson representation** Utilising the sigmoid property  $\sigma(z) = 1 - \sigma(-z)$  and the Pólya-Gamma representation (5) the integral in the exponent of Eq. (3) can be written as a double integral

$$\begin{aligned} -\int_{\mathcal{X}} \lambda \sigma(g(\mathbf{x}))\pi(\mathbf{x})d\mathbf{x} &= \\ \int_{\mathcal{X}} (\sigma(-g(\mathbf{x})) - 1)\lambda\pi(\mathbf{x})d\mathbf{x} &= \\ \int_{\mathcal{X}} \int_{\mathbb{R}^+} \left(e^{f(\omega, -g(\mathbf{x}))} - 1\right) \lambda\pi(\mathbf{x})p_{\text{PG}}(\omega|1, 0)d\omega d\mathbf{x} \end{aligned}$$

Next we will use a result for the characteristic function of a Poisson process. Following [11, chap. 3] one has

$$\mathbb{E}_\phi \left[ \prod_{z \in \Pi} h(z) \right] = \exp \left( \int_{\mathcal{Z}} (h(z) - 1) \phi(z) dz \right). \quad (6)$$

$h(\cdot)$  is a function on a space  $\mathcal{Z}$  and the expectation is over a Poisson process  $\Pi$  with rate function  $\phi(z)$ .  $\Pi = \{z_m\}_{m=1}^M$  denotes a random set of points on the space  $\mathcal{Z}$ . To apply this result to our problem, we identify  $\mathcal{Z} = \mathcal{X} \times \mathbb{R}^+$ ,  $z = (\mathbf{x}, \omega)$  and  $\phi_\lambda(\mathbf{x}, \omega) = \lambda \pi(\mathbf{x}) p_{\text{PG}}(\omega|1, 0)$  and finally  $h(z) = e^{f(\omega, -g(\mathbf{x}))}$  to rewrite the exponential in Eq. (3) as

$$e^{-\int_{\mathcal{X}} \lambda \sigma(g(\mathbf{x})) \pi(\mathbf{x}) d\mathbf{x}} = \mathbb{E}_{\phi_\lambda} \left[ \prod_{(\omega, \mathbf{x}) \in \Pi} e^{f(\omega, -g(\mathbf{x}))} \right]. \quad (7)$$

By substituting Eq. (5) and (7) into Eq.(3) we obtain the final augmented form of the likelihood of Eq. (2) which is one of the main results of our paper.

$$p(\mathcal{D}, \lambda, \Pi, \boldsymbol{\omega}_N | g) \propto \prod_{n=1}^N \phi_\lambda(\mathbf{x}_n, \omega_n) e^{f(\omega_n, g(\mathbf{x}_n))} \times p_{\phi_\lambda}(\Pi | \lambda) p(\lambda) \prod_{(\omega, \mathbf{x}) \in \Pi} e^{f(\omega, -g(\mathbf{x}))}, \quad (8)$$

with  $p_\phi(\Pi | \lambda)$  being the density over a Poisson process  $\Pi = \{(\mathbf{x}_m, \omega_m)\}_{m=1}^M$  in the augmented space  $\mathcal{X} \times \mathbb{R}^+$  with intensity  $\phi_\lambda(\mathbf{x}, \omega)$ .<sup>2</sup> This new process can be identified as a *marked Poisson process* [11, chap. 5], where the events  $\{\mathbf{x}_m\}_{m=1}^M$  in the original data space  $\mathcal{X}$  follow a Poisson process with rate  $\lambda \pi(\mathbf{x})$ . Then, on each event  $\mathbf{x}_m$  an independent *mark*  $\omega_m \sim p_{\text{PG}}(\omega_m | b, 0)$  is drawn at random from the Pólya–Gamma density. Finally,  $\boldsymbol{\omega}_N = \{\omega_n\}_{n=1}^N$  is the set of latent Pólya–Gamma variables which result from the sigmoid augmentation at the observations  $\mathbf{x}_n$ .

**Augmented posterior over GP density** With Eq. (8) we obtain the joint posterior over the GP  $g$ , the rate scaling  $\lambda$ , the marked Poisson process  $\Pi$ , and the Pólya–Gamma variables at the observations  $\boldsymbol{\omega}_N$  as

$$p(\boldsymbol{\omega}_N, \Pi, \lambda, g | \mathcal{D}) \propto p(\mathcal{D}, \boldsymbol{\omega}_N, \Pi, \lambda | g) p(g). \quad (9)$$

In the following, this new representation will be used to derive two inference algorithms.

<sup>2</sup>Densities such as  $p_{\phi_\lambda}(\Pi | \lambda)$  could be understood as the Radon–Nykodym derivative [12] of the corresponding probability measure with respect to some fixed dominating measure. However, we will not need an explicit form here.

### 3 INFERENCE

We will first derive an efficient Gibbs sampler which (asymptotically) solves the inference problem exactly, and then a variational mean-field algorithm, which only finds an approximate solution, but in a much faster time.

#### 3.1 GIBBS SAMPLER

Gibbs sampling [13] generates samples from the posterior by creating a Markov chain, where at each time, a block of variables is drawn from the conditional posterior given all the other variables. Hence, to perform Gibbs sampling, we have to derive these conditional distributions for each set of variables from Eq. (9). Most of the following results are easily obtained by direct inspection. The only non-trivial case is the conditional distribution over the latent point process  $\Pi$ .

**Pólya-Gamma variables at observations** The conditional posterior over the set of Pólya–Gamma variables  $\boldsymbol{\omega}_N$  depends only on the function  $g$  at the observations  $\{g(\mathbf{x}_n)\}_{n=1}^N$  and turns out to be

$$p(\boldsymbol{\omega}_N | g) = \prod_{n=1}^N p_{\text{PG}}(\omega_n | 1, g(\mathbf{x}_n)), \quad (10)$$

where we have used the definition of a tilted Pólya–Gamma density in Eq. (4). This density can be efficiently sampled by methods developed by [9]<sup>3</sup>.

**Rate scaling** The rate scaling  $\lambda$  has a conditional Gamma density given by

$$\text{Gamma}(\lambda | \alpha, 1) = \frac{(\lambda)^{\alpha-1} e^{-\lambda}}{\Gamma(\alpha)}. \quad (11)$$

with  $\alpha = |\Pi| + N = M + N$ . Hence, the posterior is dependent on the number of observations and the number on events of the marked Poisson process  $\Pi$ .

**Posterior Gaussian process** Due to the form of the augmented likelihood the conditional posterior for the GP  $g_{N+M}$  at the observations  $\{\mathbf{x}_n\}_{n=1}^N$  and the latent events  $\{\mathbf{x}_m\}_{m=1}^M$  is a multivariate Gaussian density

$$p(g_{N+M} | \Pi, \boldsymbol{\omega}_N) = \mathcal{N}(\boldsymbol{\mu}_{N+M}, \Sigma_{N+M}), \quad (12)$$

with covariance matrix  $\Sigma_{N+M} = [D + K_{N+M}^{-1}]^{-1}$ . The diagonal matrix  $D$  has its first  $N$  entries given by  $\boldsymbol{\omega}_N$  followed by  $M$  entries being  $\{\omega_m\}_{m=1}^M$ . The mean is  $\boldsymbol{\mu}_{N+M} = \Sigma_{N+M} \left[ \mathbf{u} + K_{N+M}^{-1} \boldsymbol{\mu}_0^{(N+M)} \right]$ , where the

<sup>3</sup>The sampler implemented by [14] is used for this work.

first  $N$  entries of  $N + M$  dimensional vector  $\mathbf{u}$  are  $1/2$  and the rest are  $-1/2$ .  $K_{N+M}$  is the prior covariance kernel matrix of the GP evaluated at the observed points  $\mathbf{x}_n$  and the latent events  $\mathbf{x}_m$ , and  $\boldsymbol{\mu}_0^{(N+M)}$  is an  $N + M$  dimensional vector with all entries being  $\mu_0$ .

The predictive conditional posterior for the GP for any set of points in  $\mathcal{X}$  is simply given via the conditional prior  $p(g|\mathbf{g}_{N+M})$ , which has a well known form and can be found in [1].

**Sampling the latent marked point process** We easily find that the conditional posterior of the marked point process is given by

$$p(\Pi|g, \lambda) = \frac{\prod_{\omega, \mathbf{x} \in \Pi} e^{f(\omega, -g(\mathbf{x}))} p_{\phi_\lambda}(\Pi|\lambda)}{\exp\left(\int_{\mathcal{X} \times \mathbb{R}^+} \left(e^{f(\omega, -g(\mathbf{x}))} - 1\right) \phi_\lambda(\mathbf{x}, \omega) d\omega d\mathbf{x}\right)}, \quad (13)$$

where the form of the normalising denominator is obtained using Eq. (6). By computing the characteristic function of this conditional point process (see App. A) we can show that it is again a marked Poisson process with intensity

$$\Lambda(\mathbf{x}, \omega) = \lambda \pi(\mathbf{x}) \sigma(-g(\mathbf{x})) p_{\text{PG}}(\omega|1, g(\mathbf{x})). \quad (14)$$

To sample from this process we first draw Poisson events  $\mathbf{x}_m$  in the original data space  $\mathcal{X}$  using the rate  $\int_{\mathbb{R}^+} \Lambda(\mathbf{x}, \omega) d\omega = \lambda \pi(\mathbf{x}) \sigma(-g(\mathbf{x}))$  [11, chap. 5]. Subsequently for each event  $\mathbf{x}_m$  a mark  $\omega_m$  is generated from the conditional density  $\omega_m \sim p_{\text{PG}}(\omega|1, g(\mathbf{x}_m))$ .

To sample the events  $\{\mathbf{x}_m\}_{m=1}^M$ , we use the well known approach of *thinning* [4]. We note, that the rate is upper bounded by the base measure  $\lambda \pi(\mathbf{x})$ . Hence, we first generate points  $\tilde{\mathbf{x}}_m$  from a Poisson process with intensity  $\lambda \pi(\mathbf{x})$ . This is easily achieved by noting that the required number  $M_{\text{max}}$  of such events is Poisson distributed with mean parameter  $\int_{\mathcal{X}} \lambda \pi(\mathbf{x}) d\mathbf{x} = \lambda$ . The position of the events can then be obtained by sampling  $\{\tilde{\mathbf{x}}_m\}_{m=1}^{M_{\text{max}}}$  independent points from the base density  $\tilde{\mathbf{x}}_m \sim \pi(\mathbf{x})$ . These events are *thinned* by keeping each point  $\tilde{\mathbf{x}}_m$  with probability  $\sigma(-g(\tilde{\mathbf{x}}_m))$ . The kept events constitute the final set  $\{\mathbf{x}_m\}_{m=1}^M$ .

**Sampling hyperparameters** In this work we will consider specific functional forms for the kernel  $k(\mathbf{x}, \mathbf{x}')$  and the base measure  $\pi(\mathbf{x})$  which are parametrised by hyperparameters  $\boldsymbol{\theta}_k$  and  $\boldsymbol{\theta}_\pi$ . These will be sampled by a Metropolis-Hastings method [15]. The GP prior mean  $\mu_0$  can be directly sampled from the conditional posterior given  $\mathbf{g}_{M+N}$ . In this work, the hyperparameters are sampled every  $v = 10$  step. Different choices of  $v$  might yield faster convergence of the Markov Chain. Pseudo code for the Gibbs sampler is provided in Alg. 1.

### 3.2 VARIATIONAL BAYES

While expected to be more efficient than a Metropolis-Hastings sampler based on the unaugmented likelihood [7], the Gibbs sampler is practically still limited. The main computational bottleneck comes from the sampling of the conditional Gaussian over function values of  $g$ . The computation of the covariances requires the inversion of matrices of dimensions  $N + M$ , with a complexity  $\mathcal{O}((N + M)^3)$ . Hence the algorithm does not only become infeasible, when we have many observations, i.e when  $N$  is large, but also if the sampler requires many thinned events, i.e. if  $M$  is large. This can happen in particular for bad choices of the base measure  $\pi(\mathbf{x})$ . In the following, we introduce a variational Bayes algorithm [16], which solves the inference problem approximately, but with a complexity which scales linearly in the data size and is independent of structure.

**Structured mean–field approach** The idea of variational inference [16] is to approximate an intractable posterior  $p(Z|\mathcal{D})$  by a simpler distribution  $q(Z)$  from a tractable family.  $q(Z)$  is optimised by minimising the Kullback-Leibler divergence between  $q(Z)$  and  $p(Z|\mathcal{D})$  which is equivalent to maximising the so called *variational lower bound* (sometimes also called ELBO for evidence lower bound) given by

$$\mathcal{L}(q(Z)) = \mathbb{E}_Q \left[ \ln \frac{p(Z, \mathcal{D})}{q(Z)} \right] \leq \ln p(\mathcal{D}), \quad (15)$$

where  $Q$  denotes the probability measure with density  $q(Z)$ . A common approach for variational inference is a structured mean–field method, where dependencies between sets of variables are neglected. For the problem at hand we assume that

$$q(\boldsymbol{\omega}_N, \Pi, g, \lambda) = q_1(\boldsymbol{\omega}_N, \Pi) q_2(g, \lambda). \quad (16)$$

A standard result for the variational mean–field approach shows that the optimal independent factors, which max-

imise the lower bound in Eq. (15) are given by

$$\ln q_1(\boldsymbol{\omega}_N, \Pi) = \mathbb{E}_{Q_2} [\ln p(\mathcal{D}, \boldsymbol{\omega}_N, \Pi, \lambda, g)] + \text{const.}, \quad (17)$$

$$\ln q_2(g, \lambda) = \mathbb{E}_{Q_1} [\ln p(\mathcal{D}, \boldsymbol{\omega}_N, \Pi, \lambda, g)] + \text{const.} \quad (18)$$

By inspecting Eq. (9), (17), and (18) it turns out that the densities of all four sets of variables factorise as

$$\begin{aligned} q_1(\boldsymbol{\omega}_N, \Pi) &= q_1(\boldsymbol{\omega}_N)q_1(\Pi), \\ q_2(g, \lambda) &= q_2(g)q_2(\lambda). \end{aligned}$$

We will optimise the factors by a straightforward iterative algorithm, where each factor is updated given expectations over the others based on the previous step. Hence, the lower bound in Eq. (15) is increased in each step. Again we will see that the augmented likelihood in Eq. (8) allows for analytic solutions of all required factors.

**Pólya–Gamma variables at the observations** Similar to the Gibbs sampler, the variational posterior of the Pólya–Gamma variables at the observations is a product of tilted Pólya–Gamma densities given by

$$q_1(\boldsymbol{\omega}_N) = \prod_{n=1}^N p_{\text{PG}}(\omega_n | 1, c_n), \quad (19)$$

with  $c_n = \sqrt{\mathbb{E}_{Q_2} [g(\mathbf{x}_n)^2]}$ . The only difference is, that the second argument of  $p_{\text{PG}}$  depends on the expectation of the square of  $g(\mathbf{x}_n)$ .

**Posterior marked Poisson process** Similar to the corresponding result for the Gibbs sampler we can show<sup>4</sup> that the optimal latent point process  $\Pi$  is a Poisson process with rate given by

$$\begin{aligned} \Lambda_1(\mathbf{x}, \omega) &= \lambda_1 \pi(\mathbf{x}) \sigma(-c(\mathbf{x})) p_{\text{PG}}(\omega | 1, c(\mathbf{x})) \\ &\times e^{(c(\mathbf{x}) - g_1(\mathbf{x}))/2} \end{aligned} \quad (20)$$

with  $\lambda_1 = e^{\mathbb{E}_{Q_2} [\ln \lambda]}$ ,  $c(\mathbf{x}) = \sqrt{\mathbb{E}_{Q_2} [f(\mathbf{x})^2]}$ , and  $g_1(\mathbf{x}) = \mathbb{E}_{Q_2} [g(\mathbf{x})]$ . Note also the similarity to the Gibbs sampler in Eq. (14).

**Optimal posterior for rate scaling** The posterior for the rate scaling  $\lambda$  is a Gamma distribution given by

$$q_2(\lambda) = \text{Gamma}(\lambda | \alpha_2, 1) = \frac{\lambda^{\alpha_2 - 1} e^{-\lambda}}{\Gamma(\alpha_2)}, \quad (21)$$

where  $\alpha_2 = N + \mathbb{E}_{Q_1} [\sum_{\mathbf{x}' \in \Pi} \delta(\mathbf{x} - \mathbf{x}')]$ , and  $\mathbb{E}_{Q_1} [\sum_{\mathbf{x}' \in \Pi} \delta(\mathbf{x} - \mathbf{x}')] = \int_{\mathcal{X}} \int_{\mathbb{R}^+} \Lambda_1(\mathbf{x}, \omega) d\omega d\mathbf{x}$ , and  $\delta(\cdot)$  is the Dirac delta function. The integral is solved by importance sampling as will be explained (see Eq. (25)).

<sup>4</sup>The proof is similar to the one from App. A.

**Approximation of GP via sparse GP** The optimal variational form for the posterior  $g$  is a GP given by

$$q_2(g) \propto e^{U(g)} p(g),$$

where  $U(g) = \mathbb{E}_{Q_1} [\ln p(\mathcal{D}, \boldsymbol{\omega}_N, \Pi, \lambda | g)]$  results in the Gaussian log-likelihood

$$U(g) = -\frac{1}{2} \int_{\mathcal{X}} A(\mathbf{x}) g(\mathbf{x})^2 d\mathbf{x} + \int_{\mathcal{X}} B(\mathbf{x}) g(\mathbf{x}) d\mathbf{x} + \text{const.}$$

with

$$\begin{aligned} A(\mathbf{x}) &= \sum_{n=1}^N \mathbb{E}_{Q_1} [\omega_n] \delta(\mathbf{x} - \mathbf{x}_n) + \int_{\mathbb{R}^+} \omega \Lambda_1(\mathbf{x}, \omega) d\omega, \\ B(\mathbf{x}) &= \frac{1}{2} \sum_{n=1}^N \delta(\mathbf{x} - \mathbf{x}_n) - \frac{1}{2} \int_{\mathbb{R}^+} \Lambda_1(\mathbf{x}, \omega) d\omega. \end{aligned}$$

For general GP priors, this free form optimum is intractable by the fact that the likelihood depends on  $g$  at infinitely many points. Hence, we resort to an additional approximation which makes the dimensionality of the problem again finite. The well known framework of *sparse* GPs [17, 18, 19] turns out to be useful in this case. This has been introduced for likelihoods with large, but finite dimensional likelihoods [19, 20] and later generalised to infinite dimensional problems [21, 22]. The sparse approximation assumes a variational posterior of the form

$$q_2(g) = p(g | \mathbf{g}_s) q_2(\mathbf{g}_s),$$

where  $\mathbf{g}_s$  is the GP evaluated at a finite set of *inducing points*  $\{\mathbf{x}_l\}_{l=1}^L$  and  $p(g | \mathbf{g}_s)$  is the conditional prior. A variational optimisation yields

$$q_2(\mathbf{g}_s) \propto e^{U^s(\mathbf{g}_s)} p(\mathbf{g}_s), \quad (22)$$

where the first term can be seen as a new ‘effective’ likelihood only depending on the inducing points. This new (log) likelihood is given by

$$\begin{aligned} U^s(\mathbf{g}_s) &= \mathbb{E}_P [U(g) | \mathbf{g}_s] = \\ &= -\frac{1}{2} \int_{\mathcal{X}} A(\mathbf{x}) \tilde{g}_s(\mathbf{x})^2 d\mathbf{x} + \int_{\mathcal{X}} B(\mathbf{x}) \tilde{g}_s(\mathbf{x}) d\mathbf{x} + \text{const.}, \end{aligned}$$

with  $\tilde{g}_s(\mathbf{x}) = \mu_0 + \mathbf{k}_s(\mathbf{x})^\top K_s^{-1}(\mathbf{g}_s - \boldsymbol{\mu}_0^{(L)})$ ,  $\mathbf{k}_s(\mathbf{x})$  being an  $L$  dimensional vector, where the  $l^{\text{th}}$  entry is  $k(\mathbf{x}, \mathbf{x}_l)$  and  $K_s$  being the prior covariance matrix for all inducing points. The expectation is computed with respect to the GP prior conditioned on the sparse GP  $\mathbf{g}_s$ . We identify Eq. (22) being a multivariate normal distribution with covariance matrix

$$\Sigma_2^s = \left[ K_s^{-1} \int_{\mathcal{X}} A(\mathbf{x}) \mathbf{k}_s(\mathbf{x})^\top \mathbf{k}_s(\mathbf{x}) d\mathbf{x} K_s^{-1} + K_s^{-1} \right]^{-1}, \quad (23)$$

---

and mean

$$\boldsymbol{\mu}_2^s = \Sigma_2^s \left( K_s^{-1} \int_{\mathcal{X}} \mathbf{k}_s(\mathbf{x}) \tilde{B}(\mathbf{x}) d\mathbf{x} + K_s^{-1} \boldsymbol{\mu}_0^{(L)} \right), \quad (24)$$

with  $\tilde{B}(\mathbf{x}) = B(\mathbf{x}) - A(\mathbf{x})(\mu_0 - \mathbf{k}_s(\mathbf{x})^\top K_s^{-1} \boldsymbol{\mu}_0^{(L)})$ .

**Integrals over  $\mathbf{x}$**  The sparse GP approximation and the posterior over  $\lambda$  in Eq. (21) requires the computation of integrals of the form

$$I \doteq \int_{\mathcal{X}} \int_{\mathbb{R}^+} y(\mathbf{x}, \omega) \Lambda_1(\mathbf{x}, \omega) d\omega d\mathbf{x},$$

with specific functions  $y(\mathbf{x}, \omega)$ . For these functions, the inner integral over  $\omega$  can be computed analytically, but the outer one over the space  $\mathcal{X}$  has to be treated numerically. We approximate it via importance sampling

$$I \approx \frac{1}{R} \sum_{r=1}^R \int_{\mathbb{R}^+} y(\mathbf{x}_r, \omega_r) \frac{\Lambda_1(\mathbf{x}_r, \omega_r)}{\pi(\mathbf{x}_r)} d\omega_r, \quad (25)$$

where every sample point  $\mathbf{x}_r$  is independently drawn from the base measure  $\pi(\mathbf{x})$ .

**Updating hyperparameters** Having an analytic solution for every factor of the variational posterior in Eq. (16) we further require the optimisation of hyperparameters.  $\boldsymbol{\theta}_k, \boldsymbol{\theta}_\pi$  and  $\mu_0$  are optimised by maximising the lower bound in Eq. (15) (see App. B for explicit form) with a gradient ascent algorithm having an adaptive learning rate (Adam) [23]. Additional hyperparameters are the locations of inducing points  $\{\mathbf{x}_l\}_{l=1}^L$ . Half of them are drawn randomly from the initial base measure, while half of them are positioned on regions with a high density of observations found by a k-means algorithm. Pseudo code for the complete variational algorithm is provided in Alg. 2.

Python code for Alg. 1 and 2 is provided at [24].

## 4 RESULTS

To test our two inference algorithms, the Gibbs sampler and the variational Bayes algorithm (VB), we will first evaluate them on data drawn from the generative model. Then we compare both on an artificial dataset and several real datasets. We will only consider cases with  $\mathcal{X} = \mathbb{R}^d$ . To evaluate the quality of inference we consider always the logarithm of the expected test likelihood

$$\ell_{\text{test}}(\tilde{\mathcal{D}}) \doteq \ln \left( \mathbb{E} \left[ \prod_{\mathbf{x} \in \tilde{\mathcal{D}}} \rho(\mathbf{x}) \right] \right),$$

where  $\tilde{\mathcal{D}}$  is test data unknown to the inference algorithm and the expectation is over the inferred posterior measure. In practice we sample this expectation from the inferred posterior over  $g$ . Since this quantity involves an integral, that is again approximated by Eq. (25), we check that the standard deviation  $\text{std}(I)$  is less than 1% of the value of the estimated value  $I$ .

**Data from generative model.** We generate datasets according to Eq. (1), where  $g$  is drawn from the GP prior with  $\mu_0 = 0$ . As covariance kernel we assume a squared exponential throughout this work

$$k(\mathbf{x}, \mathbf{x}') = \theta_k^{(0)} \prod_{i=1}^d \exp \left( -\frac{(x_i - x'_i)^2}{2(\theta_k^{(i)})^2} \right).$$

The base measure  $\pi(\mathbf{x})$  is a standard normal density. We use the algorithm described in [7] to generate exact samples. In this section, the hyperparameters  $\boldsymbol{\theta}_k, \boldsymbol{\theta}_\pi$  and  $\mu_0$  are fixed to the true values for inference. Unless stated otherwise for the VB the number of inducing points is fixed to 200 and the number of integration points for importance sampling to  $5 \times 10^3$ . For the Gibbs sampler, we sample a Markov chain of  $5 \times 10^3$  samples after a burn-in period of  $2 \times 10^3$  samples.

In Fig. 1 we see a 1 dimensional example dataset, where both inference algorithms recover well the structure of the underlying density. The inferred posterior means are barely distinguishable. However, evaluating the inferred densities on an unseen test set, we note that the Gibbs sampler performs slightly better. Of course, this is expected since the sampler provides exact inference for the generative model and should (on average) not be outperformed by the approximate VB as long as the sampled Markov chain is long enough. In Fig. 1 (bottom left) we see that only 13 iterations of the VB are required to meet the convergence criterion. For Markov chain samplers to be efficient, correlations between samples should decay quickly. Fig. 1 (bottom middle) shows the autocorrelation of  $\ell_{\text{test}}$ , which was evaluated at each sample of the

Markov chain. After about 10 samples the correlations reach a plateau close to 0, demonstrating excellent mixing properties of the sampler. Comparing the run time of both algorithms, VB (0.3 s) outperforms the sampler  $\sim 1$  min by more than 2 orders of magnitude.

To demonstrate the inference for more complicated problems, 2 dimensional data are generated with 200 samples (Fig. 2). The posterior mean densities inferred by both algorithms capture the structure well. As before, the log expected test likelihood is larger for the Gibbs sampler ( $\ell_{\text{test}} = -296.2$ ) compared to VB ( $\ell_{\text{test}} = -306.0$ ). However, the Gibbs sampler took  $> 20$  min while the VB required only 1.8 s to obtain the result.

In Tab. 1 we show results for datasets with different size and different dimensionality. The results confirm that the

Figure 2: **2D data from generative model.** **Right:** 200 samples from the underlying two dimensional density. **Middle:** Posterior mean of Gibbs sampler inferred density. **Right:** Posterior mean of VB inferred density.

Figure 3: **Comparison to other density estimation methods on artificial 2D data.** Training data consist of 100 data points uniformly distributed on a circle (1.5 radius) and additional Gaussian noise (0.2 std.). **From left to right:** The posterior mean inferred by Gibbs sampler and VB algorithm, followed by density estimation using KDE and GMM.

run time for the Gibbs sampler scales strongly with size and dimensionality of a problem, while the VB algorithm seems relatively unaffected in this regard. However, the VB is in general outperformed by the sampler in terms of expected test likelihood or in the same range. Note, that the runtime of the Gibbs sampler does not solely depend on the number of observed data points  $N$  (compare data set 2 and 3 in Tab. 1). As discussed earlier this can happen, when the base measure  $\pi(\mathbf{x})$  is very different from the target density  $\rho(\mathbf{x})$  resulting in many latent Poisson events (i.e.  $M$  is large).

**Circle data** In the following, we compare the GP density model and its two inference algorithms with two alternative density estimation methods. These are given by a kernel density estimator (KDE) with a Gaussian kernel and a Gaussian mixture model (GMM) [25]. The free parameters of these models (kernel bandwidth for KDE and number of components for GMM) are optimised by 10-fold cross-validation. Furthermore, GMM is initialised 10 times and the best result is reported. For the GP density model a Gaussian density is assumed as base measure  $\pi(\mathbf{x})$ , and hyperparameters  $\theta_{\pi}$ ,  $\theta_k$ , and  $\mu_0$  are now optimised. Similar to [7] we consider 100 samples uniformly drawn from a circle with additional Gaussian

	Gibbs	VB	KDE	GMM

Table 2: Log expected test likelihood for circle data.

Figure 4: **Performance on ‘Egyptian Skulls’ dataset [26].** 100 training points and 4 dimensions. Bar height shows average negative log test likelihood obtained by five random permutations of training and test set and points mark single permutation results.

noise. The inferred densities (only the mean of the posterior for Gibbs and VB) are shown in Fig. 3. Both GP density methods recover well the structure of the data, but the VB seems to overestimate the width of the Gaussian noise compared to the Gibbs sampler. While the KDE also recovers relatively well the data structure the GMM fails in this case. This is also reflected on the log expected test likelihoods (Tab. 2).

**Real data sets** The ‘Egyptian Skulls’ dataset [26] contains 150 data points in 4 dimensions. 100 training points are randomly selected and performance is evaluated on the remaining ones. Before fitting data is whitened. Base measure and fitting procedure for all algorithms are the same as for the circular data. Furthermore, fitting is done for 5 random permutations of training and test set. The results in Fig. 4 show that both algorithms for the GP density model outperform the two other ones on this dataset.

Often practical problems may consist of many more data points and dimensions. As discussed, the Gibbs sampler is not practical for such kind of problems, while the VB could handle larger amounts of data. Unfortunately, the sparsity assumption and the integration via importance sampling is expected to become poorer with increasing number of dimensions. Noting, however, that the ‘effective’ dimensionality in our model is determined by the base measure  $\pi(\mathbf{x})$ , one can circumvent this problem by an educated choice of  $\pi(\mathbf{x})$  if data  $\mathcal{D}$  lie in a submanifold of the high dimensional space  $\mathcal{X}$ .

We employ this strategy by first fitting a GMM to the problem and then utilising the fit as base measure. In Fig. 5 we consider 3 different datasets<sup>5</sup> to test this pro-

<sup>5</sup>Only real valued dimensions are considered and for the

Figure 5: **Application on higher dimensional data with many data points.** The improvement on log expected test likelihood  $\ell_{\text{test}}$  per test point compared to GMM, when using same as base measure  $\pi(\mathbf{x})$  for the VB inference. **From top to bottom:** ‘Forest Fire’ dataset [27, 28] (400 training points, 117 test points, 5 dim.), ‘Thyroid’ dataset [29] ( $3 \times 10^3$ , 772, 6), ‘Wine’ dataset [27] ( $6 \times 10^3$ , 498, 9). Bars mark improvement on average of random permutations of training and test set while points mark single runs.

cedure. As in Fig. 4, fitting is repeated 5 times for random permutations if training and test set. For the ‘Thyroid’ dataset, one of the 5 fits is excluded, because the importance sampling yielded poor approximation  $\text{std}(I) > I \times 10^{-2}$ . The training sets contain 400 to 6000 data points with 5 to 9 dimensions. The results for KDE are not reported, since it is always outperformed by the GMM. Fig. 5 demonstrates combining the GMM and VB algorithm results in an improvement of the log test likelihood  $\ell_{\text{test}}$  compared to using only GMM. Average relative improvements of  $\ell_{\text{test}}$  are 8.9 % for ‘Forest Fire’, 4.1 % for ‘Thyroid’, and 1.1 % for ‘Wine’ dataset.

## 5 DISCUSSION

We have shown how inference for a nonparametric, GP based, density model can be made efficient. In the following we would like to discuss various possible extensions but also limitations of our approach.

**Choice of base measure** As we have shown for applications to real data, the choice of the base measure is quite important, especially for the sampler and for high dimensional problems. While many datasets might favour a normal distribution as base measure, problems with outliers might favour fat tailed densities. In general, any density which can be evaluated on the data space  $\mathcal{X}$  and which allows for efficient sampling, is a valid choice as base measure  $\pi(\mathbf{x})$  in our inference approach for the GP density model. Any powerful density estima-

‘forest fire’ dataset dimensions are excluded, where data have more than half 0 entries.

tor which fulfils this condition could provide a base measure which could then potentially be improved by the GP model. It would e.g. be interesting to apply this idea to neural networks [30, 31] based estimators. Other generalisations of our model could consider alternative data spaces  $\mathcal{X}$ . One might e.g. think of specific discrete and structured sets  $\mathcal{X}$  for which appropriate Gaussian processes could be defined by suitable Mercer kernels.

**Big data & high dimensionality** Our proposed Gibbs sampler suffers from cubic scaling in the number of data points and is found to be already impractical for problems with hundreds of observations. This could potentially be tackled by using sparse (approximate) GP methods for the sampler (see [32] for a potential approach). On the other hand, the proposed VB algorithm scales only linearly with the training set size and can be applied to problems with several thousands of observations. The integration of stochastic variational inference into our method could potentially increase this limit [33].

Potential limitations of the GP density model are given by high dimensional problems. If approached naively, the combination of the sparse GP approximation and the numerical integration using importance sampling is expected to yield bad approximations in such cases.<sup>6</sup> If the data is concentrated on a low dimensional submanifold of the high-dimensional space, one could still try to combine our method with other density estimators providing a base measure  $\pi(\mathbf{x})$  that is adapted to this submanifold, to allow for tractable GP inference.

## Abstract

Temporal-difference (TD) learning methods are widely used in reinforcement learning to estimate the expected return for each state, without a model, because of their significant advantages in computational and data efficiency. For many applications involving risk mitigation, it would also be useful to estimate the *variance* of the return by TD methods. In this paper, we describe a way of doing this that is substantially simpler than those proposed by Tamar, Di Castro, and Mannor in 2012, or those proposed by White and White in 2016. We show that two TD learners operating in series can learn expectation and variance estimates. The trick is to use the square of the TD error of the expectation learner as the reward of the variance learner, and the square of the expectation learner’s discount rate as the discount rate of the variance learner. With these two modifications, the variance learning problem becomes a conventional TD learning problem to which standard theoretical results can be applied. Our formal results are limited to the table lookup case, for which our method is still novel, but the extension to function approximation is immediate, and we provide some empirical results for the linear function approximation case. Our experimental results show that our direct method behaves just as well as a comparable indirect method, but is generally more robust.

## 1 INTRODUCTION

Conventionally, in reinforcement learning (RL) the agent estimates the expected value of the return—the discounted sum of future rewards—as an intermediate step

to finding an optimal policy. The agent estimates the value function by averaging the returns observed from each state in a trajectory of experiences. To estimate this value function online—while the trajectory is still unfolding—we update the agent’s value estimates towards the expected return. Algorithms that estimate the expected value of the return in this way are called temporal-difference (TD) learning methods. However, it is reasonable to consider estimating other functions of the return beyond the first moment. For example, Belle-mare et al. (2017) estimated the distribution of returns explicitly. In this paper, we focus on estimating the variance of the return using TD methods.

The variance of the return can be used to design algorithms which account for risk in decision making. The main approach is to formulate the agent’s objective as maximizing reward, while minimizing the variance of the return (Sato et al., 2001; Prashanth and Ghavamzadeh, 2013; Tamar et al., 2012).

An estimate of the variance of the return can also be useful for adapting the parameters of a learning system automatically, thus avoiding time-consuming, human-driven meta parameter tuning. Sakaguchi and Takano (2004) used the variance estimate explicitly in the decision making policy to set the temperature variable in the Boltzmann action selection rule. Using variance in this way can automatically adjust the amount of exploration, allowing the learning system to adapt to new circumstances online. Conventionally, this temperature would either be set to a constant or decayed according to a fixed schedule. In either circumstance, the performance can be quiet poor in non-stationary domains, and a human expert is required to select the constant value or fixed schedule. Similarly, White and White (2016) estimated the variance of the return to automatically adapt the trace-decay parameter,  $\lambda$ , used in learning updates of TD algorithms (see Section 2 for an explanation of the role of  $\lambda$ ). Not only does this approach avoid the need to tune  $\lambda$  by hand, but it can result in faster learning.

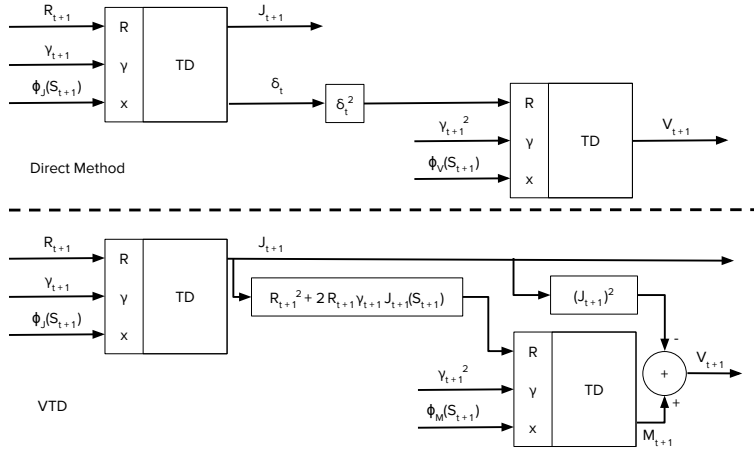

Figure 1: Each TD node takes as input a reward  $R$ , a discounting function  $\gamma$ , and features  $\phi$ . For the direct method (**top**) the squared TD error of the first-stage value estimator is used as the meta-reward for the second-stage  $V$  estimator. For VTD (**bottom**), a more complex computation is used for the meta-reward and an extra stage of computation is required.

The variance  $V$  of the return can be estimated either directly or indirectly. Indirect estimation involves computing an estimate of variance from estimates of the first and second moments. Sobel (1982) was the first to formulate Bellman operators for the second moment and showed how this could be used to compute variance indirectly. This is the approach used by Tamar et al. (2016), Tamar and Mannor (2013), and Prashanth and Ghavamzadeh (2013). White and White (2016) introduced several extensions to this indirect method including estimation of the  $\lambda$ -return (Sutton and Barto, 1998), support for off-policy learning (Sutton, Maei, et al., 2009; Maei, 2011), and state-dependent discounting (Sutton, Modayil, et al., 2011; White, 2017). Their method, which they refer to as VTD, serves as the indirect estimation algorithm used in this paper. We note that an alternative method, which we do not investigate here, could be to estimate the distribution of returns as done by Bellemare et al. (2017) and compute the variance from this estimated distribution.

Variance may also be estimated directly. Tamar et al. (2012) gave a direct algorithm but restricted it to estimating cost-to-go returns in a strictly episodic manner, i.e., estimates are only updated after an entire trajectory has been captured. We introduce a new algorithm for directly estimating the variance of the return incrementally using TD methods. Our algorithm uses two TD learners, one for estimating value and the other for estimating the variance of the return. These estimators operate in series with the squared TD error of the value learner serving as the reward of the variance learner and the squared discount rate of the value learner serving as the discount rate of the variance learner. Like VTD (White and White, 2016), our algorithm supports estimating the variance of the  $\lambda$ -return, state-dependent discounting, estimating the variance of the on-policy return from off-policy samples, and estimating the variance of the off-policy return from on-policy samples (Section 3.2 motivates these extensions). We call our new algorithm Direct Variance TD

(DVTD). We recognize that the algorithm of Sato et al. (2001) can be seen as the simplest instance of our algorithm, using the on-policy setting with fixed discounting and no traces<sup>1</sup>. Sakaguchi and Takano (2004) also used this simplified algorithm, but treated the discount of the variance estimator as a free parameter.

We introduce a Bellman operator for the variance of the return, and further prove that, even for a value function that does not satisfy the Bellman operator for the expected return, the error in this recursive formulation is proportional to the error in the value function estimate. Interestingly, the Bellman operator for the second moment requires an unbiased estimate of the return (White and White, 2016). Since our Bellman operator for the variance avoids this term, it has a simpler update. As shown in Figure 1, Both DVTD and VTD can be seen as a network of two TD estimators running sequentially. Note, that we restrict our formal derivations and subsequent analysis to the table lookup setting.

Our primary goal is to understand the empirical properties of the direct and indirect approaches. In general, we found that DVTD is just as good as VTD and in many cases better. We observe that DVTD behaves better in the early stages of learning before the value function has converged. Furthermore, we observe that the variance of the estimates of  $V$  can be higher for VTD under several circumstances: (1) when there is a mismatch in step-sizes between the value estimator and the  $V$  estimator, (2) when traces are used with the value estimator, (3) when estimating  $V$  of the off-policy return, and (4) when there is error in the value estimate. Finally, we observe significantly better performance of DVTD in a linear function approximation setting. Overall, we conclude that the direct approach to estimating  $V$ , DVTD, is both simpler and better behaved than VTD.

<sup>1</sup>Dimitrakakis (2006) used a related TD method, which estimates the squared TD error

## 2 THE MDP SETTING

We model the agent’s interaction with the environment as a finite Markov decision process (MDP) consisting of a finite set of states  $\mathcal{S}$ , a finite set of actions,  $\mathcal{A}$ , and a transition model  $p : \mathcal{S} \times \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$  defining the probability  $p(s'|s, a)$  of transitioning from state  $s$  to  $s'$  when taking action  $a$ . In the policy evaluation setting considered in this paper, the agent follows a fixed policy  $\pi(a|s) \in [0, 1]$  that provides the probability of taking action  $a$  in state  $s$ . At each timestep the agent receives a random reward  $R_{t+1}$ , dependent only on  $S_t, A_t, S_{t+1}$ . The return is the discounted sum of future rewards

$$\begin{aligned} G_t &= R_{t+1} + \gamma_{t+1}R_{t+2} + \gamma_{t+1}\gamma_{t+2}R_{t+3} + \dots \\ &= R_{t+1} + \gamma_{t+1}G_{t+1}. \end{aligned} \quad (1)$$

where  $\gamma \in [0, 1]$  specifies the degree to which future rewards are discounted. Note that we define discounting as state-dependent such that  $\gamma_{t+1} \equiv \gamma(S_{t+1})$ . This allows us to combine the specification of continuing and episodic tasks. Further implications of this are discussed in Section 3.2.

The value of a state,  $j(s)$ , is defined as the expected return from state  $s$  under a particular policy  $\pi$ :

$$j(s) = \mathbb{E}_\pi[G_t | S_t = s]. \quad (2)$$

We use  $j$  to indicate the true value function and  $J$  the estimate. The TD-error is the difference between the one-step approximation and the current estimate:

$$\delta_t = R_{t+1} + \gamma_{t+1}J_t(S_{t+1}) - J_t(S_t). \quad (3)$$

This can then be used to update the value estimator using a TD method, such as TD(0) as follows:

$$J(s)_{t+1} = J(s)_t + \alpha\delta_t \quad (4)$$

## 3 ESTIMATING THE VARIANCE OF THE RETURN

For clarity of presentation, we first discuss the simplest version of both the direct and indirect methods and present the full algorithms in Section 3.2.

The direct TD method uses both a value estimator and a variance estimator. The *value estimator* provides an estimate of the expected return. The *variance estimator*, on the other hand, uses the value estimator to provide an estimate of the variance of the return. Since we use TD methods for both the value and variance estimators we need to adopt additional notation; variables with a bar are used by either the second moment or variance estimator. Otherwise, they are used by the value estimator.

The key to using both the indirect and direct methods as TD methods is to provide a discounting function,  $\bar{\gamma}$ , and a meta-reward,  $\bar{R}$ . In the following, we present a simplified TD(0) version of both algorithms.

### Simplified Direct Variance Algorithm

$$\begin{aligned} \bar{\gamma}_{t+1} &\leftarrow \gamma_{t+1}^2 \\ \bar{R}_{t+1} &\leftarrow \delta_t^2 \\ \bar{\delta}_t &\leftarrow \bar{R}_{t+1} + \bar{\gamma}_{t+1}V_t(s') - V_t(s) \\ V_{t+1}(s) &\leftarrow V_t(s) + \bar{\alpha}\bar{\delta}_t \end{aligned} \quad (5)$$

### Simplified Second Moment Algorithm

$$\begin{aligned} \bar{\gamma}_{t+1} &\leftarrow \gamma_{t+1}^2 \\ \bar{R}_{t+1} &\leftarrow R_{t+1}^2 + 2\gamma_{t+1}R_{t+1}J_{t+1}(s') \\ \bar{\delta}_t &\leftarrow \bar{R}_{t+1} + \bar{\gamma}_{t+1}M_t(s') - M_t(s) \\ M_{t+1}(s) &\leftarrow M_t(s) + \bar{\alpha}\bar{\delta}_t \\ V_{t+1}(s) &\leftarrow M_{t+1}(s) - J_{t+1}(s)^2 \end{aligned} \quad (6)$$

### 3.1 DERIVATION OF THE DIRECT METHOD

We now derive the direct method for estimating the variance of the return. Again, for clarity, we only consider the simple case described in Section 3 (See Appendix B for a derivation of the more general extended algorithm).

The derivation of the direct method follows from characterizing the Bellman operator for the variance of the return: Theorem 1 gives a Bellman equation for the variance  $v$ . It has the form of a TD target with meta-reward  $\bar{R}_t = \delta_t^2$  and discounting function  $\bar{\gamma}_{t+1} = \gamma_{t+1}^2$ . Therefore, we can estimate  $V$  using TD methods. The Bellman operators for the variance are general, in that they allow for either the episodic or continuing setting, by using variable  $\gamma$ . By directly estimating variance, we avoid a second term in the cumulant that is present in approaches that estimate the second moment (Tamar and Mannor, 2013; Tamar et al., 2016; White and White, 2016).

To have a well-defined solution to the fixed point, we need the discount to be less than one for some transition (White, 2017; Yu, 2015). This corresponds to assuming that the policy is proper, for the cost-to-go setting (Tamar et al., 2016).

**Assumption 1.** *The policy reaches a state  $s$  where  $\gamma(s) < 1$  in a finite number of steps.*

**Theorem 1.** *For any  $s \in \mathcal{S}$ ,*

$$\begin{aligned} j(s) &= \mathbb{E}[R_{t+1} + \gamma_{t+1}j(S_{t+1}) | S_t = s] \\ v(s) &= \mathbb{E}[\delta_t^2 + \gamma_{t+1}^2v(S_{t+1}) | S_t = s] \end{aligned} \quad (7)$$

*Proof.* First we expand  $G_t - j(S_t)$ , from which we re-

cover a series with the form of a return.

$$\begin{aligned} G_t - j(S_t) &= R_{t+1} + \gamma_{t+1}G_{t+1} - j(S_t) \\ &= R_{t+1} + \gamma_{t+1}j(S_{t+1}) - j(S_t) + \gamma_{t+1}(G_{t+1} - j(S_{t+1})) \\ &= \delta_t + \gamma_{t+1}(G_{t+1} - j(S_{t+1})) \end{aligned} \quad (8)$$

The variance of  $G_t$  is therefore

$$\begin{aligned} v(s) &= \mathbb{E} \left[ (G_t - \mathbb{E}[G_t | S_t = s])^2 | S_t = s \right] \\ &= \mathbb{E} \left[ (G_t - j(s))^2 | S_t = s \right] \\ &= \mathbb{E} \left[ (\delta_t + \gamma_{t+1}(G_{t+1} - j(S_{t+1})))^2 | S_t = s \right] \\ &= \mathbb{E} [\delta_t^2 | S_t = s] \\ &\quad + \mathbb{E} [\gamma_{t+1}^2 (G_{t+1} - j(S_{t+1}))^2 | S_t = s] \\ &\quad + 2\mathbb{E} [\gamma_{t+1}\delta_t(G_{t+1} - j(S_{t+1})) | S_t = s] \end{aligned} \quad (9)$$

Equation (7) follows from Lemma 1 in Appendix B which shows  $\mathbb{E}[\gamma_{t+1}\delta_t(G_{t+1} - j(S_{t+1})) | S_t = s] = 0$ . Similar to Lemma 1, using the law of total expectation,  $\mathbb{E}[\gamma_{t+1}^2(G_{t+1} - j(S_{t+1}))^2 | S_t = s] = \mathbb{E}[\gamma_{t+1}^2 v(S_{t+1}) | S_t = s]$ .  $\square$

We provide an initial characterization of error in the variance estimate obtained under this recursion, when an approximate value function rather than the true value function is used. As we show in the below theorem, the resulting error in the variance estimator is proportional to the squared error in the value estimate, and discounted accumulated errors into the future. If the approximation error is small, we expect this accumulated error to be small, particularly as the accumulation errors are signed and so can cancel, and because they are discounted. However, more needs to be done to understand the impact of this accumulated error.

**Theorem 2.** *For approximate value function  $J$  with variance estimate  $V(s) = \mathbb{E}[\delta_t^2 + \gamma_{t+1}^2 V(S_{t+1}) | S_t = s]$ , if there exists  $\epsilon : \mathcal{S} \rightarrow [0, \infty)$  bounding squared value estimation error  $(J(s) - j(s))^2 \leq \epsilon(s)$  and accumulation error  $|\mathbb{E}[\gamma_{t+1}\delta_t(j(S_{t+1}) - J(S_{t+1})) + \gamma_{t+1}^2\gamma_{t+2}\delta_{t+1}(j(S_{t+2}) - J(S_{t+2})) + \dots | S_t = s]| \leq \epsilon(s)$ , then*

$$|v(s) - \mathbb{E}[\delta_t^2 + \gamma_{t+1}^2 V(S_{t+1}) | S_t = s]| \leq 3\epsilon(s)$$

*Proof.* We can re-express the true variance in terms of the approximation  $J$ , as

$$\begin{aligned} v(s) &= \mathbb{E} [(G_t - j(s) + J(s) - J(s))^2 | S_t = s] \\ &= \mathbb{E} [(G_t - J(s))^2 | S_t = s] + (J(s) - j(s))^2 \\ &\quad + 2\mathbb{E}[G_t - J(s) | S_t = s] (J(s) - j(s)) \end{aligned} \quad (10)$$

This last term simplifies to

$$\begin{aligned} \mathbb{E}[G_t - J(s) | S_t = s] &= \mathbb{E}[G_t - j(s) | S_t = s] + j(s) - J(s) \\ &= j(s) - J(s) \end{aligned} \quad (11)$$

giving  $(J(s) - j(s))^2 + 2(j(s) - J(s))(J(s) - j(s)) = -(J(s) - j(s))^2$ . We can use the same recursive form as (9), but with  $J$ , giving

$$\begin{aligned} \mathbb{E}[(G_t - J(s))^2 | S_t = s] &= \mathbb{E}[\delta_t^2 + \gamma_{t+1}^2 V(S_{t+1}) | S_t = s] \\ &\quad + 2\mathbb{E}[\gamma_{t+1}\delta_t(G_{t+1} - J(S_{t+1})) | S_t = s] \\ &\quad + 2\mathbb{E}[\gamma_{t+1}^2\gamma_{t+2}\delta_{t+1}(G_{t+2} - J(S_{t+2})) | S_t = s] + \dots \end{aligned} \quad (12)$$

where the terms involving  $\delta_t(G_{t+1} - J(S_{t+1}))$  accumulate. Notice that

$$\begin{aligned} &|\mathbb{E}[\gamma_{t+1}\delta_t(G_{t+1} - J(S_{t+1})) | S_t = s]| \\ &= |\mathbb{E}[\gamma_{t+1}\delta_t(G_{t+1} - j(S_{t+1})) | S_t = s] \\ &\quad + \mathbb{E}[\gamma_{t+1}\delta_t(j(S_{t+1}) - J(S_{t+1})) | S_t = s]| \\ &= |\mathbb{E}[\gamma_{t+1}\delta_t(j(S_{t+1}) - J(S_{t+1})) | S_t = s]| \end{aligned}$$

where the second equality follows from Lemma 1. By the same argument as in Lemma 1, this will also hold true for all the other terms in (12). By assumption, the sum of all these covariance terms between  $j$  and  $J$  are bounded by  $\epsilon(s)$ . Putting this together, we get

$$\begin{aligned} |v(s) - V(s)| &= |v(s) - \mathbb{E}[\delta_t^2 + \gamma_{t+1}^2 V(S_{t+1}) | S_t = s]| \\ &\leq 2\epsilon(s) + (J(s) - j(s))^2 \leq 3\epsilon(s) \end{aligned} \quad \square$$

### 3.2 THE EXTENDED DIRECT METHOD

Here, we extend the direct method to support estimating the  $\lambda$ -return, state-dependent  $\gamma$ , eligibility traces and off-policy estimation, just as White and White, 2016 did with VTD (derivation provided in Appendix B). We first explain each of these extensions before providing our full direct algorithm and VTD.

The  $\lambda$ -return is defined as

$$G_t^\lambda = R_{t+1} + \gamma_{t+1}(1 - \lambda_{t+1})J_t(S_{t+1}) + \gamma_{t+1}\lambda_{t+1}G_{t+1}^\lambda$$

and provides a bias-variance trade-off by incorporating  $J$ , which is a potentially lower-variance but biased estimate of the return. This trade-off is determined by a state-dependent trace-decay parameter,  $\lambda_t \equiv \lambda(S_t) \in [0, 1]$ . When  $J_t(S_{t+1})$  is equal to the expected return from  $S_{t+1} = s$ , then  $\mathbb{E}_\pi[(1 - \lambda_{t+1})J_t(S_{t+1}) + \gamma_{t+1}\lambda_{t+1}G_{t+1}^\lambda | S_{t+1} = s] = \mathbb{E}_\pi[G_{t+1}^\lambda | S_{t+1} = s]$ , and so the  $\lambda$ -return is unbiased. Beneficially the expected value  $J_t(S_{t+1})$  is lower-variance than the sample  $G_{t+1}^\lambda$ . If  $J_t$  is inaccurate, however, some bias is introduced. Therefore, when  $\lambda = 0$ , the  $\lambda$ -return is lower-variance but can be biased. When  $\lambda = 1$ , the  $\lambda$ -return equals the Monte Carlo return (Equation (1)); in this case, the update target exhibits more variance, but no bias. In the tabular setting evaluated in this paper,  $\lambda$  does not affect

Table 1: Algorithm Notation

$J$	estimated value function of the target policy $\pi$ .
$M$	estimate of the second moment.
$V$	estimate of the variance.
$R, \bar{R}$	meta-reward used by the $J$ and $(M, V)$ estimators.
$\lambda$	bias-variance parameter of the target $\lambda$ -return.
$\kappa, \bar{\kappa}$	trace-decay parameter of the $J$ and $(M, V)$ estimators.
$\gamma, \bar{\gamma}$	discounting function used by $J$ and $(M, V)$ estimators.
$\delta_t, \bar{\delta}_t$	TD error of the $J$ and $(M, V)$ estimators at time $t$ .
$\bar{\rho}$	importance sampling ratio for estimating the variance of the target return from off-policy samples.
$\eta$	importance sampling ratio used to estimate the variance of the off-policy return.

the fixed point solution of the value estimate, only the rate at which learning occurs. It does, however, affect the observed variance of the return, which we estimate. The  $\lambda$ -return is implemented using traces as in the following TD( $\lambda$ ) algorithm, shown with accumulating traces:

$$e_t(s) \leftarrow \begin{cases} \gamma_t \lambda_t e_{t-1}(s) + 1 & s = S_t \\ \gamma_t \lambda_t e_{t-1}(s) & \forall s \in \mathcal{S}, s \neq S_t \end{cases}$$

$$J_{t+1}(S_t) \leftarrow J_t(S_t) + \alpha \delta_t e_t(S_t) \quad (13)$$

For notational purposes, we define the trace parameter for the value and secondary estimators as  $\kappa$  and  $\bar{\kappa}$  respectively. Both of these parameters are independent of the  $\lambda$ -return for which we estimate the variance. That is, we are entirely free to estimate the variance of the  $\lambda$ -return for any value of  $\lambda$  independently of the use of any traces in either the value or secondary estimator.

**State-Dependent  $\gamma$ .** While most RL methods focus on fixed discounting values, it is straightforward to use state-based discounting (Sutton, Modayil, et al., 2011), where  $\gamma_t \equiv \gamma(S_t)$  (White (2017) go further by defining transition based discounting). This generalization enables a wider variety of returns to be considered. First, it allows a convenient means of describing both episodic and continuing tasks and provides an algorithmic mechanism for terminating an episode without defining a recurrent terminal state explicitly. Further, it allows for event-based terminations (Sutton, Modayil, et al., 2011). It also enables soft terminations which may prove useful when training an agent with sub-goals (White, 2017). The use of state-dependent discounting functions is relatively new and remains to be extensively explored.

**Off-policy learning.** Value estimates are made with respect to a target policy,  $\pi$ . If the behavior policy,  $\mu = \pi$  then we say that samples are collected on-policy, otherwise, the samples are collected off-policy. An off-policy learning approach is to weight each update by the importance sampling ratio:  $\rho_t = \frac{\pi(S_t, A_t)}{\mu(S_t, A_t)}$ . There are two different scenarios to be considered when estimating the

variance of the return in the off-policy setting. The first is estimating the variance of the on-policy return of the target policy while following a different behavior policy. The second has the goal of estimating the variance of the off-policy return itself. The off-policy  $\lambda$ -return is:

$$G_t^{\lambda:\rho} = \rho_t (R_{t+1} + \gamma_{t+1} (1 - \lambda_{t+1}) j_t(S_{t+1}) + \gamma_{t+1} \lambda_{t+1} G_{t+1}^{\lambda:\rho}). \quad (14)$$

where the multiplication by the potentially large importance sampling ratios can significantly increase variance.

It is important to note you would only ever estimate one or the other of these settings with a given estimator. Let  $\eta$  be the weighting for the value estimator, and  $\bar{\rho}$  the weighting for the variance estimator. If estimating the variance of the target return from off-policy samples, the first scenario,  $\eta_t = 1 \forall t$  and  $\bar{\rho}_t = \rho_t$ . If estimating the variance of the off-policy return  $\bar{\rho}_t = 1 \forall t$  and  $\eta_t = \rho_t$ .

### 3.2.1 The Extended Algorithms

To estimate  $V$ , our method uses both value and variance estimators. The *value estimator* provides an estimate of the expected return. The *variance estimator*, on the other hand, uses the value estimator to provide an estimate of the variance of the return. Our method, DVTD, and the indirect method, VTD, can be seen as simply defining a meta-reward and a discounting function and can thus be learned with any known TD method, such as TD with accumulating traces as shown in Equation 13. Table 1 summarizes our notation.

#### Direct Variance Algorithm - DVTD

$$\begin{aligned} \bar{R}_{t+1} &\leftarrow (\eta_t \delta_t + (\eta_t - 1) J_{t+1}(s))^2 \\ \bar{\gamma}_{t+1} &\leftarrow \gamma_{t+1}^2 \lambda_{t+1}^2 \eta_t^2 \\ \bar{\delta}_t &\leftarrow \bar{R}_{t+1} + \bar{\gamma}_{t+1} V_t(s') - V_t(s) \\ \bar{e}_t(s) &\leftarrow \begin{cases} \bar{\rho}_t (\bar{\gamma}_t \bar{\kappa}_t \bar{e}_{t-1}(s) + 1) & s = S_t \\ \bar{\rho}_t (\bar{\gamma}_t \bar{\kappa}_t \bar{e}_{t-1}(s)) & \forall s \in \mathcal{S}, s \neq S_t \end{cases} \\ V_{t+1}(s) &\leftarrow V_t(s) + \bar{\alpha} \bar{\delta}_t \bar{e}_t(s) \end{aligned} \quad (15)$$

We also present the full VTD algorithm below (again, shown with accumulating traces). Note that this algorithm does not impose that the variance be non-negative.

### Second Moment Algorithm - VTD

$$\begin{aligned}
\bar{G}_t &\leftarrow R_{t+1} + \gamma_{t+1}(1 - \lambda_{t+1})J_{t+1}(s') \\
\bar{R}_{t+1} &\leftarrow \eta_t^2 \bar{G}_t^2 + 2\eta_t^2 \gamma_{t+1} \lambda_{t+1} \bar{G}_t J_{t+1}(s') \\
\bar{\gamma}_{t+1} &\leftarrow \eta_t^2 \gamma_{t+1}^2 \lambda_{t+1}^2 \\
\bar{\delta}_t &\leftarrow \bar{R}_{t+1} + \bar{\gamma}_{t+1} M_t(s') - M_t(s) \\
\bar{e}_t(s) &\leftarrow \begin{cases} \bar{\rho}_t(\bar{\gamma}_t \bar{\kappa}_t \bar{e}_{t-1}(s) + 1) & s = S_t \\ \bar{\rho}_t(\bar{\gamma}_t \bar{\kappa}_t \bar{e}_{t-1}(s)) & \forall s \in \mathcal{S}, s \neq S_t \end{cases} \\
M_{t+1}(s) &\leftarrow M_t(s) + \bar{\alpha} \bar{\delta}_t \bar{e}_t(s) \\
V_{t+1}(s) &\leftarrow M_{t+1}(s) - J_{t+1}(s)^2
\end{aligned} \tag{16}$$

## 4 EXPERIMENTS

The primary purpose of these experiments is to demonstrate that both algorithms can approximate the true expected  $V$  under various conditions in the tabular setting. We consider two domains. The first is a deterministic chain, which is useful for basic evaluation and gives results which are easy to interpret (Figure 2). The second is a randomly generated MDP, with different discount and trace-decay parameters in each state (Figure 3). For all experiments Algorithm 13 is used as the value estimator. Unless otherwise stated, traces are not used ( $\kappa = \bar{\kappa} = 0$ ) and estimates were initialized to zero. For each experimental setting the average of 30 separate experiments is presented with standard deviation shown as shaded regions. True values were determined by Monte Carlo estimation and are shown as dashed lines in the figures.

We look at the effects of relative step-size between the value estimator and the variance estimators in Section 4.1. Then, in Section 4.2 we use the random MDP to show that both algorithms can estimate the variance with state-dependent  $\gamma$  and  $\lambda$ . In Section 4.3 we evaluate the two algorithms' responses to errors in the value estimate. Section 4.4 looks at the effect of using traces in the estimation method. We then examine the off-policy setting in Section 4.5. Finally, Section 4.6 provides experimental results in a linear function approximation setting.

### 4.1 THE EFFECT OF STEP-SIZE

We use the chain MDP to investigate the impact of step-size choice. In Figure 4(a) all step-sizes are the same ( $\alpha = \bar{\alpha} = 0.001$ ) and here both algorithms behave similarly. For Figure 4(b) the step-size of the value estimate, ( $\alpha = 0.01$ ), is greater than that of the secondary estimators, ( $\bar{\alpha} = 0.001$ ). Now DVTD smoothly approaches the

Figure 2: **Chain MDP** with 4 non-terminal states and 1 terminal state. From non-terminal states there is a single action with a deterministic transition to the right. On each transition, rewards are drawn from a normal distribution with mean and variance of 1.0. Evaluation was performed for  $\lambda = 0.9$ , which was chosen because it is not at either extreme and because 0.9 is a commonly used value for many RL experimental domains.

Figure 3: **Random MDP**, with a stochastic policy and state-based  $\gamma$  and  $\lambda$ . The state-dependent values of  $\gamma$  and  $\lambda$  are chosen to provide a range of values, with at least one state acting as a terminal state where  $\gamma = 0$ . On-policy action probabilities are indicated by  $\mu$  and off-policy ones by  $\pi$ .

correct value, while VTD first dips well below zero. This is expected as the estimates are initialized to zero and the variance is calculated as  $V(s) = M(s) - J(s)^2$ . If the second moment lags behind the value estimate, then the variance will be negative. In Figure 4(c) the step-size for the secondary estimators is larger than for the value estimator ( $0.001 = \alpha < \bar{\alpha} = 0.01$ ). While both methods overshoot the target in this example, VTD has greater overshoot. For both cases of unequal step-size, we see higher variance in the estimates for VTD.

Figure 5 explores this further. Here the value estimator is initialized to the true values and updates are turned off ( $\alpha = 0$ ). The secondary estimators are initialized to zero and learn with  $\bar{\alpha} = 0.001$ , chosen simply to match the step-sizes used in the previous experiments. Despite being given the true values the VTD algorithm produces higher variance in its estimates, suggesting that VTD is dependent on the value estimator tracking.

This sensitivity to step-size is shown in Figure 6. All estimates are initialized to their true values. For each ratio, we computed the average variance of the 30 runs of 2000

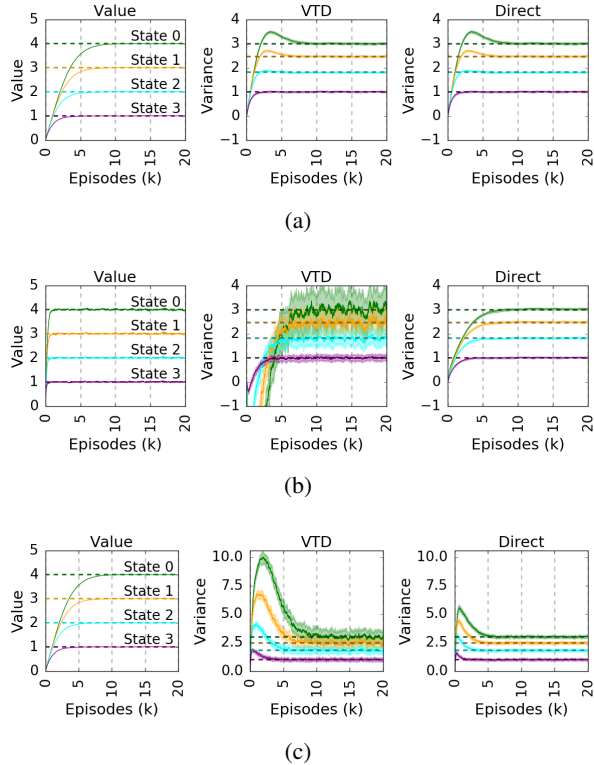

Figure 4: **Chain MDP** ( $\lambda = 0.9$ ). Varying the ratio of step-size between value and variance estimators. **a)** Step-sizes equal.  $\alpha = \bar{\alpha} = 0.001$ . **b)** Variance step-size smaller.  $\alpha = 0.01, \bar{\alpha} = 0.001$ . **c)** Variance step-size larger.  $\alpha = 0.001, \bar{\alpha} = 0.01$ . We see greater variance in the estimates and greater over/undershoot for VTD when step-sizes are not equal.

episodes. We can see that DVTD is largely insensitive to step-size ratio, but that VTD has higher mean squared error (MSE) except when the step-sizes are equal. This result holds for the other experimental settings of this paper, including the random MDP, but further results are omitted for brevity.

Would there ever be a situation where different step-sizes between value and secondary estimators is justified? The automatic tuning of parameters, such as step-size, is an important area of research, seeking to make learning algorithms more efficient, robust and easier to deploy. Methods which automatically set the step-sizes may produce different values specific to the performance of each estimator. One such algorithm is ADADELTA, which adapts the step-size based on the TD error of the estimator (Zeiler, 2012). Figure 7 shows that using a separate ADADELTA ( $\rho = 0.99, \epsilon = 1e-6$ ) step-size calculation for each estimator results in higher variance for VTD as expected, given that the value estimator and VTD produce different TD errors.

Figure 5: **Chain MDP** ( $\lambda = 0.9$ ). Value estimate held fixed at the true values ( $\alpha = 0, \bar{\alpha} = 0.001$ ). Notice the increased estimate variance for VTD, especially State 0.

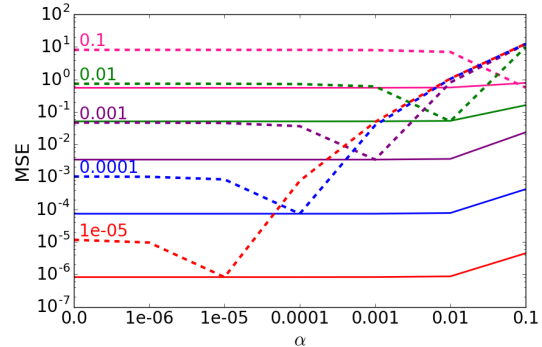

Figure 6: **Chain MDP** ( $\lambda = 0.9$ ). The MSE summed over all states as a function of ratios between the value step-size  $\alpha$  (shown along the x-axis) and the variance step-size  $\bar{\alpha}$  (shown in the 5 series). The direct algorithm is indicated by the solid lines, and VTD is indicated by the dashed. The MSE of the VTD algorithm is higher than the direct algorithm, except when the step-size is the same for all estimators,  $\alpha = \bar{\alpha}$  or for very small  $\bar{\alpha}$ .

## 4.2 STATE-DEPENDENT $\gamma$ AND $\lambda$ .

One of the contributions of VTD was the generalization to support state-based  $\gamma$  and  $\lambda$ . Here we evaluate the random MDP from Figure 3 (in the on-policy setting, using  $\mu$ ), which was designed for this scenario and which has a stochastic policy, is continuing, and has multiple possible actions from each state. Both algorithms achieved similar results (see Appendix A).

## 4.3 VARIABLE ERROR IN THE VALUE ESTIMATES

The derivation of our DVTD assumes access to the true value function. The experiments of the previous sections demonstrate that both methods are robust under this assumption, in the sense that the value function was estimated from data and used to estimate  $V$ . It remains unclear, however, how well these methods perform when the value estimates converge to biased solutions.

To examine this, we again use the random MDP shown

Figure 7: **Chain MDP** ( $\lambda = 0.9$ ). Results using ADADELTA algorithm to automatically and independently set the step-sizes  $\alpha$  and  $\bar{\alpha}$ . The step-sizes produced are given in Appendix D.

Figure 8: **Random MDP**. For each run, the value estimate of each state is offset by a random noise drawn from a uniform distribution whose size is a function of an error ratio and the maximum true value in the MDP. Standard deviation of the estimates is shown by shading.

by Figure 3. True values for the value functions and variance estimates are calculated from Monte Carlo simulation of 10,000,000 timesteps. For each run of the experiment each state of the value estimator was initialized to the true value plus an error ( $J(s)_0 = j(s) + \epsilon(s)$ ) drawn from a uniform distribution:  $\epsilon(s) \in [-\zeta, \zeta]$ , where  $\zeta = \max_s(|v(s)|) * \text{err ratio}$  (the maximum value in this domain is 1.55082409). The value estimate was held constant throughout the run ( $\alpha = 0.0$ ). The experiment consisted of 120 runs of 80,000 timesteps. To look at the steady-state response of the algorithms we use only the last 10,000 timesteps in our calculations. Figure 8 plots the average variance estimate for each state with the average standard deviation of the estimates as the shaded regions. Sweeps over step-size were conducted,  $\bar{\alpha} \in [0.05, 0.04, 0.03, 0.02, 0.01, 0.007, 0.005, 0.003, 0.001]$ , and the MSE evaluated for each state. Each data point is for the step-size with the lowest MSE for that error ratio and state. While the average estimate is closer to the true values for VTD, the variance of the estimates is much larger. Further, the average estimates for VTD are either unchanged or move negative, while those of the direct algorithm tend toward positive bias.

For Figure 9 the MSE is summed over all states. Again, for each error ratio the MSE was compared over the same

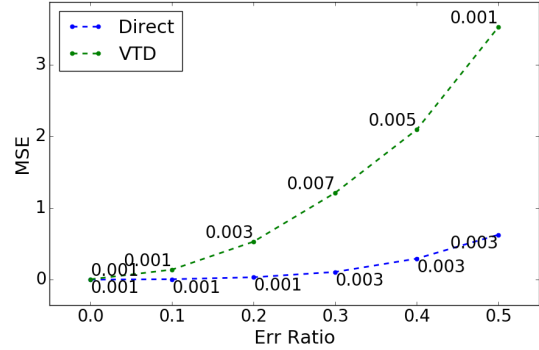

Figure 9: **Random MDP**. The MSE computed for the last 10,000 timesteps of 120 runs summed over all states using the step-size with the lowest overall MSE at each error ratio. For each point the step-size used ( $\alpha = \bar{\alpha}$ ) is displayed.

Figure 10: **Random MDP**. Using traces (TD( $\lambda$ ),  $\alpha = \bar{\alpha} = 0.01$ ). Traces only used in value estimator ( $\kappa = 1.0, \bar{\kappa} = 0.0$ ). Notice the slight increase in the variance of the VTD estimates for State 0 and 3.

step-sizes as before and, for each point, the smallest MSE is plotted. These results suggest the direct algorithm is less affected by error in  $J$ .

#### 4.4 USING TRACES

We briefly look at the behavior of the random MDP when traces are used. We found no difference when traces are only used in the secondary estimator and not in the value estimator ( $\kappa = 0.0, \bar{\kappa} = 1.0$ . See Appendix A, Figure 14). Figure 10 considers the opposite scenario, where traces are only used in the value estimator ( $\kappa = 1.0, \bar{\kappa} = 0.0$ ). Here we do see a difference. Particularly the VTD method shows more variance in its estimates for State 0 and 3.

#### 4.5 OFF-POLICY LEARNING

We evaluate two different off-policy scenarios on the random MDP. First, we estimate  $V$  under the target policy from off-policy samples. That is, we estimate the  $V$  that would be observed if we followed the target policy, i.e.,  $\eta = 1, \bar{\rho} = \rho$ . Both methods achieved similar results in

Figure 11: **Random MDP** estimating the variance of the off-policy return ( $\alpha = \bar{\alpha} = 0.01, \bar{\rho} = 1, \eta = \rho$ ).

this setting (Figure 15). In the second off-policy setting, we estimate the variance of the off-policy return (Equation 14). Here  $\bar{\rho} = 1$  and  $\eta = \rho$ . Figure 11 shows that both algorithms successfully estimate the return in this setting. However, despite having the same step-size as the value estimator, VTD produces higher variance in its estimates, as is most clearly seen in State 3.

#### 4.6 FUNCTION APPROXIMATION

While this paper has focused on the tabular case, where each state is represented uniquely, here we include a first empirical result in the function approximation setting. We evaluate both methods on the random walk shown in Figure 12(a). This domain was previously used by Tamar et al. (2016) for indirectly estimating the variance of the return with LSTD( $\lambda$ ). We use transition based  $\gamma$  (White, 2017) to remove the terminal state and translate the task into a continuing task. Further, we alter the state representation to make it more amenable to TD( $\lambda$ ). For a state  $s_i$  we used  $\phi_J(i) = [1, (i + 1)/30]^T$  as features for the value learner and  $\phi_M(i) = \phi_V(i) = [1, (i + 1)/30, (i + 1)^2/30^2]^T$  as features for the secondary learner. We set  $\kappa = \bar{\kappa} = 0.95$  and performed sweeps over step-sizes of  $\{2^i, i \in \{-15, -12, \dots, -1, 0\}\}$ . We first found the best step-size for the value learner and then found the best step-size for VTD. Using the same step-size for VTD and DVTD, we obtain the results shown in Figure 12(b). Here we see DVTD drastically outperforms VTD. Further details are available in Appendix C.

## 5 DISCUSSION

Both DVTD and VTD effectively estimate the variance across a range of settings, but DVTD is simpler and more robust. This simplicity alone makes DVTD preferable. The higher variance in estimates produced by VTD is likely due to the larger target which VTD uses in its learning updates:  $\mathbb{E}[X^2] \geq \mathbb{E}[(X - \mathbb{E}[X])^2]$ ; we show more explicitly how this affects the updates of VTD in Appendix E. We expect the differences between the two approaches to be most pronounced for domains with larger returns than those demonstrated here. Consider

Figure 12: **Random Walk.** **a)** Random walk with rewards of  $-1$  for every transition to a non-terminal state. Note that there is no discounting in this domain. **b)** Results under linear function approximation averaged over 100 runs. Shading indicates standard error (negligible).

the task of a helicopter hovering formalized as a reinforcement learning task (Kim et al., 2004). In the most well-known variants of this problem the agent receives a massive negative reward for crashing the helicopter (e.g., minus one million). In such problems the magnitude and variance of the return is large. Here, estimating the second moment may not be feasible from a statistical point of view, whereas the target of our direct variance estimate should be better behaved. By focusing on simple MDPs we were able to carefully evaluate the properties of these algorithms while keeping them isolated from additional effects like state-aliasing due to function approximation. Further studies in more complex settings, such as function approximation, are left to future work.

## Abstract

We present a data-driven benchmark system to evaluate the performance of new MCMC samplers. Taking inspiration from the COCO benchmark in optimization, we view this benchmark as having critical importance to machine learning and statistics given the rate at which new samplers are proposed. The common hand-crafted examples to test new samplers are unsatisfactory; we take a meta-learning-like approach to generate realistic benchmark examples from a large corpus of data sets and models. Surrogates of posteriors found in real problems are created using highly flexible density models including modern neural network models. We provide new insights into the real effective sample size of various samplers per unit time and the estimation efficiency of the samplers per sample. Additionally, we provide a meta-analysis to assess the predictive utility of various MCMC diagnostics and perform a nonparametric regression to combine them.

## 1 INTRODUCTION

Markov chain Monte Carlo (MCMC) methods have seen a huge increase in use over the last few decades. The goal in MCMC methods is to take samples from a complex probability distribution  $p^*$  given access only to its unnormalized density  $\tilde{p}$ . The primary use case for MCMC methods is sampling from Bayesian posteriors for the purpose of Monte Carlo integration, which includes building posterior predictive distributions and posterior summaries. These posteriors are generally intractable to normalize and sample from in modern models, including models as simple as logistic regression.

Approaches such as rejection sampling provide exact independent samples, and importance sampling provides exact independent (but weighted) samples. These approaches are generally computationally inefficient (rejection sampling) or are statistically unsound (importance sampling) except in very low dimensional problems [MacKay, 2003, Ch. 29]. MCMC methods produce a Markov chain that marginally samples from the target distribution  $p^*$  exactly and have a low per sample computation cost. The downside is that they provide a sequence of *correlated* samples, albeit marginally from the target distribution. Therefore, any estimates derived from an MCMC chain of length  $N$  will have far less accuracy than  $N$  iid samples. Despite there being numerous MCMC diagnostics, there is no practical way to guarantee the accuracy of derived estimates in practice.

Each machine learning conference contains a publication proposing a new variation on MCMC methods. The community lacks a method to determine if these new methods actually sample from posteriors found in real problems with improved accuracy over existing samplers. New methods are benchmarked via either 1) hand-crafted toy problems (where a ground-truth is known) or 2) test set performance on real problems. The issue with hand-crafted examples is obvious: Performance on these problems may have little relation to performance on real problems and it is at odds with accepted practice in modern machine learning.

Benchmarking via test set performance on real problems is laudable. However, it confounds the specification of the model and priors with the performance of the sampler. In a misspecified model it is possible that a sampler stuck in an unrepresentative part of the posterior could actually have higher test set performance [Sharp and Rattray, 2010]. Conversely, a better sampler may improve test set performance by having good local mixing; however, it is still nowhere near exact iid samples. There is no way to quantify the distance to exact iid samples from test set performance alone.

Whether current samplers are providing samples from anything close to the true posterior on difficult problems is of critical importance for determining future research directions. Are samplers with higher test set performance actually sampling from real posteriors more faithfully? Can we sample with any fidelity from complex high dimensional distributions? Is that merely a “fool’s errand”? The answers to these questions will determine if it is a worthwhile endeavor to continue to hone MCMC methods for application in successful modern models such as deep neural networks.

Practitioners in Bayesian statistics have long faced the dilemma of whether they can trust the output of their sampler, in particular, because statisticians are not traditionally concerned only with test set error rates. As a result, there is decades of work in developing MCMC diagnostics that aim to *alert* a practitioner to a *poorly mixing* chain [Cowles and Carlin, 1996]. That is, if a chain has a long autocorrelation time, the entire chain may be of equivalent accuracy to just a few iid samples. The diagnostics, by construction, have a low type I error: If a chain closely resembles iid samples, they will not alert that it is mixing poorly. However, there are no guarantees on type II error: If a chain is mixing poorly, the diagnostic might not alert. Indeed, there are many ways to construct examples where an MCMC procedure undetectably fails: distant modes, Neal’s funnel [Thompson, 2011], extreme ill-conditioning, etc. However, are these realistic stress tests for MCMC methods or merely pathological cases? We do not know.

We propose a new data-driven approach to create a benchmark that estimates how well various MCMC procedures work on real problems. Arguably, algorithms in machine learning and statistics rely on the “workhorses” of either optimization or sampling methods. The world of (non-convex) optimization has already tackled this challenge with the COCO benchmark [Hansen et al., 2016], which contains a test battery of difficult optimization problems. Various approaches are tested to validate if they can optimize the objective function to a target level within a fixed number of function evaluations. Our approach is an analogous system for sampling methods. However, we further improve upon this using flexible (including neural net based) benchmark examples that have been trained to match posteriors found in practice.

In our approach we use a large “data set of data sets” and a diverse “model zoo” to create a representative set of examples. Long MCMC chains are drawn (using NUTS [Hoffman and Gelman, 2014]) from each of these posteriors. Flexible unsupervised models that serve as a *ground-truth* in the benchmarking phase are fit to the chains to construct the benchmark examples.

More concretely, each combination of real data set (e.g., MNIST) and real model (e.g., logistic regression) results in a Markov chain from NUTS. We then fit an unsupervised model (e.g., mixture of Gaussians) to this chain to serve as a *benchmark example distribution*. Once trained, these benchmark example distributions are functionally equivalent to hand-crafted examples such as the toy posterior distributions usually used to benchmark samplers (or such as those in COCO). However, these examples are not hand-crafted but rather are much more representative of real problems. Because it is possible to draw exact (iid) samples from the benchmark example distributions, we now have a ground-truth set of samples to validate the accuracy of the sampling methods.

We derive a variety of metrics that summarize the performance of a sampler for comparing its output to ground-truth iid samples. The ground-truth samples also allow us to assess how well the MCMC diagnostics actually predict estimation performance. In particular, we look at the effective sample size (ESS) because it provides a concrete statement on sample quality [Kass et al., 1998].

The outline of this paper is as follows: In Section 2 we provide some background on MCMC and its diagnostics/performance measures. In Sections 3 and 4 we explain the methodology of the benchmark and its pipeline of five sequential phases. Finally, in Section 5, we present results illustrating the advantages of various samplers and the utility of various MCMC diagnostics.

**Contributions** We summarize the contributions of this work as follows: 1) We provide a new and novel benchmark to describe how well various samplers work on realistic problems. This involves design of fair and sensible metrics to score samplers across problems. This work creates a software system that will serve as a practical tool in algorithm development analogous to ML-comp/CodaLab or COCO. 2) We shed light on how well the common MCMC diagnostics predict the real estimation performance of MCMC methods. We further create a data-driven meta-diagnostic by combining MCMC diagnostics to predict real sampler performance. The code for the system is available at [github.com/bradyneal/sampling-benchmark](https://github.com/bradyneal/sampling-benchmark).

**Related work** The closest existing system is SamplerCompare of Thompson [2011], which tests samplers on a handful of hand-crafted stress-test cases such as Neal’s funnel. However, SamplerCompare is more an R package to aid evaluation than a complete benchmark. A recent piece of work from systems biology [Ballnus et al., 2017] compares various samplers for dynamical systems (i.e., filtering) on a set of hand-crafted ODE systems inspired by biological models.

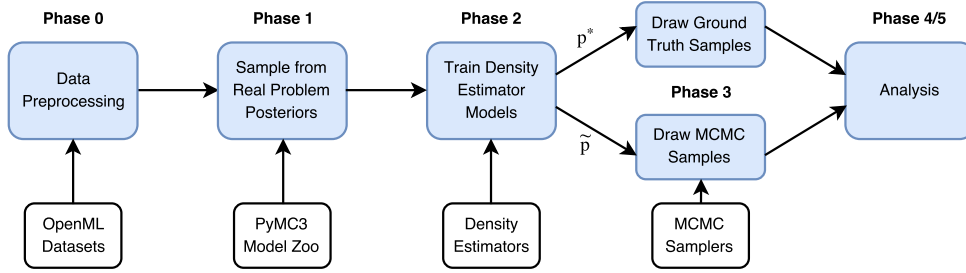

Figure 1: Flowchart illustrating the six phases in our methodology. Phases 0–2 are for creating benchmark examples and are not re-run when new samplers are tested. Phase 2 includes mixture models and modern neural net methods.

## 2 BACKGROUND

The notion of a black box is highly relevant to conceptual understanding of this work. Fundamentally, an MCMC sampler is a system that inputs a black box that computes an unnormalized density  $\tilde{p} \propto p^*$  (and possibly its gradient  $\nabla \log \tilde{p}$ ) and a previous sample  $\mathbf{x}_{t-1} \in \mathbb{R}^D$  in the Markov chain; and outputs another sample  $\mathbf{x}_t \in \mathbb{R}^D$ . Once the Markov chain has converged, these samples are theoretically guaranteed to marginally come from the density  $p^*$ , albeit with temporal correlation. If the previous sample was drawn exactly,  $\mathbf{x}_{t-1} \sim p^*$ , then  $\mathbf{x}_t \sim p^*$  exactly as well. This is a result of *detailed balance*.

By analogy, optimization algorithms take an objective function  $f \in \mathbb{R}^D \rightarrow \mathbb{R}$  (and possibly its gradient  $\nabla f$ ) as a black box and produce points  $\mathbf{x}_t \in \mathbb{R}^D$  that successively minimize  $f$  as much as possible. Just as COCO provides its benchmark objective functions  $f$  as a black box to the optimizers and keeps hidden the true optimum, our benchmark provides the unnormalized density  $\tilde{p}$  as a black box to the samplers. Our benchmark keeps hidden the parameterization of  $\tilde{p}$  needed to efficiently take iid samples from  $p^*$ .

### 2.1 TRADITIONAL MCMC DIAGNOSTICS

Given that we have a ground-truth to evaluate the performance of the various samplers, we can also benchmark the diagnostics by seeing how predictive they are of actual performance. In particular, we consider three diagnostics in this paper: ESS, Gelman-Rubin (GR), and Geweke. ESS aims to estimate how many iid samples have the same estimation performance as the correlated samples found in the MCMC chain. Gelman-Rubin [Gelman and Rubin, 1992] and Geweke [Geweke, 1992] more closely follow a test statistic paradigm than an estimation one. Gelman-Rubin compares the variance within a single chain to variance between chains (independent restarts). This quantity should be close to one

for well-mixing chains and can be very large for poorly performing chains. The Geweke diagnostic uses a single chain and compares the variance between chunks.

The ESS diagnostic is basically a rescaling of the expected square error (i.e., MSE) on estimating the mean in a *single dimension* (marginal) of  $\mathbf{x}$ . ESS is based on the notion that for the marginal  $x_d$ :

$$\begin{aligned} \mathbb{E}_{p^*}[(\hat{\mu}_d - \mu_d)^2] &= \text{Var}_{p^*}[\hat{\mu}_d - \mu_d] + \mathbb{E}_{p^*}[\hat{\mu}_d - \mu_d]^2 \\ &= \text{Var}_{p^*}[x_d]/N, \quad d \in 1:D, \end{aligned} \quad (1)$$

$$\hat{\mu} := \frac{1}{N} \sum_{i=1}^N \mathbf{x}_i, \quad \boldsymbol{\mu} := \mathbb{E}_{p^*}[\mathbf{x}], \quad (2)$$

which utilizes that  $\hat{\mu}_d$  is an unbiased estimate of  $\mu_d$ . We are careful to distinguish expectations and variances with respect to  $p^*$ , where  $\mathbf{x}$  is iid, from  $q$ , where the samples are correlated and drawn from an MCMC method. Naturally, by re-arranging (1), the effective sample size for non-iid samples is:

$$\text{ESS} := \frac{\text{Var}_q[x_d]}{\mathbb{E}_q[(\hat{\mu}_d - \mu_d)^2]} \in \mathbb{R}^+. \quad (3)$$

Unlike (1), this can be estimated without ground-truth samples from  $p^*$ . However, the difficult denominator term is typically estimated using the empirical linear auto-correlation of the Markov chain. This linearity assumption is obviously a potential source of error in the ESS. The fixation in estimating the accuracy of the mean  $\hat{\mu}$  is also a weakness. In Section 4.6, we look at the *real* effective sample size by comparing estimates with the ground-truth samples. It also allows us to look at measures other than simply the fidelity in matching the means ( $\hat{\mu} - \mu$ ), such as variance or shape of the marginals.

## 3 METHODOLOGY

Our benchmark system follows a six phase approach, which we explain at a high level in this section. In Section 4, we provide low-level specifics. A graphical summary of this section is provided in Figure 1.

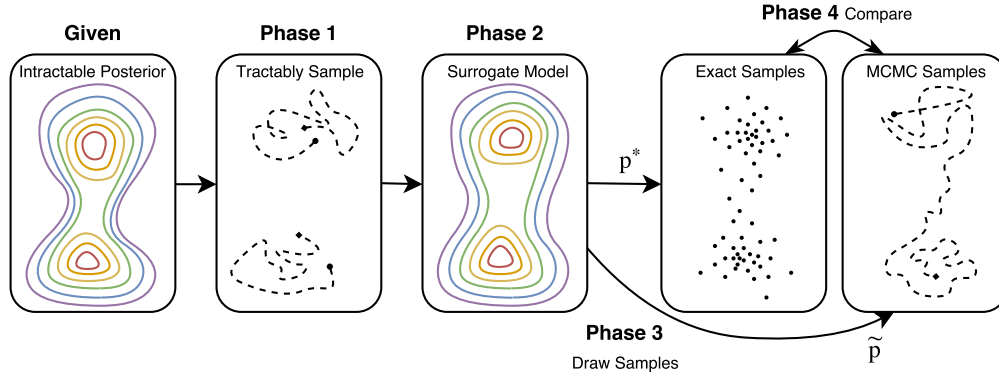

Figure 2: Graphical depiction of Figure 1 on a particular example. We begin with a real posterior from a real problem on the left, which is sampled via a Markov Chain to get samples in phase 1. These are fit to get a similar surrogate posterior in phase 2. MCMC samplers are run on this phase 2 density, but exact samples can also be taken for comparison. Note that the exact posterior, and the real data that produced it, *are not used* for comparing the exact samples and the MCMC samples in phase 4. The phase 2 models are used where toy examples are often used; although it is not the original posterior, it is a far-reaching improvement.

In phase 0, we create a “corpus” of data sets that we refer to as a “data set of data sets.” This is meant to create a realistic sample of problems that a practitioner may encounter “in the wild.” Such an approach was also taken in the AutoML competition [Guyon et al., 2015] and the automated statistician project [Lloyd et al., 2014]. Our approach can be thought of as a form of *meta-learning*.

In phase 1, we use a model zoo to simulate a variety of (Bayesian) models that a practitioner might attempt to apply to a real problem. There are models for regression and classification. Each model/data set pair results in a posterior over a parameter space, which varies in dimensionality depending on the problem. Except in very simple cases (e.g., linear regression), we are not able to obtain samples from these posteriors exactly. We use NUTS, the default sampler in probabilistic programming languages (PyMC3 [Salvatier et al., 2016] and Stan [Carpenter et al., 2016]), because it is generally considered to be a good off-the-shelf sampler—especially when paired with the intelligent initialization and automatic tuning found in these systems. Therefore, by running multiple long chains of NUTS (3–5 chains for 30 minutes each) on the posteriors, we obtain a sufficient approximation and representation for phase 2.

In phase 2, we run various density estimation models to generate benchmark example distributions on the Markov chains from phase 1. We run a separate training procedure on each model/data set pair. These benchmark example distributions serve as surrogates for the real posteriors found in phase 1. Note that the goal is not to replicate the posteriors from phase 1 exactly, but to generate example distributions that are *qualitatively similar* to the real posteriors in phase 1.

This gives us example distributions that are more realistic than the usual hand-crafted toy problems. Nonetheless, we train multiple models and take the one with the highest held-out likelihood on the last 20% of the Markov chain found in phase 1. We use held-out likelihood because it is the most widely accepted generic method of verifying model fidelity. Model checking diagnostics are also run to verify the similarity between the benchmark example distributions (surrogates) and their corresponding Markov chains from the real posteriors (originals).

When selecting models for benchmark example distributions in phase 2, we have the following requirements: 1) The models are flexible enough to closely fit the posteriors found in phase 1, 2) They can serve as a black box, providing an unnormalized density  $\tilde{p}$  (and its gradient) when queried at an arbitrary point  $\mathbf{x}$ , and 3) We can efficiently sample (ground-truth) from them given their parameters (which are hidden from the samplers).

In phase 3, we benchmark a collection of samplers. If someone invents and provides a new sampling algorithm, it is added in phase 3. Phases 0–2 remain fixed as new samplers are submitted to be benchmarked. Each sampler to be benchmarked is run on each of the benchmark example distributions for multiple chains. Each chain is allowed to run for a fixed period of time. The samples from the Markov chains are saved as the phase 3 output.

In phase 4, we take a large number (e.g.,  $\sim 10^5$ ) of exact iid samples from the benchmark example distributions as a ground-truth. The square loss between point estimates (e.g.,  $\hat{\mu}_d$  or  $\hat{\sigma}_d^2$ ) taken from the Markov chains from phase 3 and the point estimates from the exact chains are aggregated. We also compute and store the MCMC diagnostics for each chain.

In phase 5, we aggregate the performance results by looking at the real effective sample size as derived from the square errors in point estimation. We also define transformations of the real effective sample size, which we will refer to as efficiency, normalized effective sample size, and effective sample size deviation. In addition, we perform a meta-analysis using Gaussian process (GP) [Rasmussen and Williams, 2006] regression to predict the real effective sample size given the MCMC diagnostics. This will be useful to practitioners aiming to quantify their confidence in an MCMC-based estimate using the diagnostics available.

We present an example posterior following this pipeline in Figure 2. Note that after the explicit model is fit in phase 2, the data that produced the original posterior is completely *irrelevant* for the rest of the process. Only the surrogate model is used for benchmarking.

## 4 ADDITIONAL DETAILS

In this section we present additional details for the construction of each phase.

### 4.1 PHASE 0: COLLECT DATA SETS

Phase 0 involved downloading 2,200 data sets from `openml.org` to form our data set of data sets. We considered other sources, such as the classic UCI repository, `mldata.org`, and Kaggle, but settled on OpenML because it had the most standardized format and meta-data. Such systems are necessary for automated processing.

The data sets were diverse in that they varied in dimension from 1 to 61,359, sample size from 5 to 7,619,400, and the number of output classes (for classification) from binary to 100.

After downloading, we subjected each data set to some preprocessing to simulate the diverse set of practices a practitioner might follow. Each data set was randomly preprocessed in one of three ways: standardization, robust standardization (using medians and interquartile ranges), or whitening. Categorical variables were represented with one-hot encodings.

### 4.2 PHASE 1: SAMPLE THE MODEL ZOO

For the model zoo, we used all of the standard models (regression and classification) typically used with PyMC3. This includes generalized linear models (GLMs) such as logistic regression, but also atypical GLMs such as robust linear regression (linear regression with Student’s- $t$  noise). In addition to models that are linear in the feature space, we included models that

are linear in a second order transformation of the feature space. We included Gaussian processes with unknown hyper-parameters (e.g., MCMC sampling was done on the unknown hyper-parameters). Bayesian neural networks were also included.

To keep computation time reasonable, we limited the sample size for expensive models (e.g., GPs), and placed some limits on input dimensionality. Where dimensionality needed to be reduced we used PCA [Jolliffe, 1986], as that is the most frequently used method in practice to reduce dimensionality.

### 4.3 PHASE 2: FIT FLEXIBLE SURROGATES

There are three varieties of models that satisfy the three requirements (flexibility, tractable density, and fast exact sampling) for benchmark example densities: mixture models, RNADE [Uria et al., 2013], and Real NVP [Dinh et al., 2016]. In each example, we pick the model with the best held-out likelihood on the last 20% of the chain.

For mixture models, we considered mixture of Gaussians (MoG) with expectation-maximization (EM) [Dempster et al., 1977] and variational MoG. Note that, for simplicity, these models are *not* themselves fit using MCMC. The Bayesian Occam’s razor effect [Jefferys and Berger, 1992] allowed us to simply fix the number of mixture components to 25 in variational MoG. We used five-fold cross-validation to select the number of components in EM MoG. There is no consistent winner between these models; the chosen model is example dependent.

We also tuned the RNADE learning rate and hyper-parameters based on pilot runs. Surprisingly, the mixture models often, but not always, outperformed RNADE on the held-out likelihood. Real NVP based models struggled to achieve competitive test set scores.

These models behave better numerically when trained on standardized data. Care is taken to reverse this standardization in phase 3, so the samplers are forced to attempt to sample from the posterior in its original scale.

### 4.4 PHASE 3: RUN THE SAMPLERS

Phase 3 forms the real “meat” of the benchmark. This is where candidate sampling algorithms are actually run on the benchmark example densities. The list of sampling algorithms is not intended to be exhaustive but rather demonstrate the utility of the benchmark system.

Whether originally designed this way or not, nearly all respected MCMC procedures proceed by proposing a new point using a *proposal distribution*. The new point is then accepted or rejected using a Metropolis-Hastings step. Therefore, the difference between samplers is based

upon their proposal distributions. We provide a preview of the proposals used in Section 5.

Until recently, the most widely used MCMC procedure was *random walk Metropolis*, which uses a Gaussian random walk proposal  $p(\mathbf{x}_t|\mathbf{x}_{t-1}) = \mathcal{N}(\mathbf{x}_t|\mathbf{x}_{t-1}, \Sigma)$ , where  $\Sigma$  is typically diagonal. Modern packages such as PyMC3 allow for automatic tuning of the proposal width  $\Sigma$ , which is critical to achieve good performance. We also consider Cauchy and Laplace distributed proposals.

We include Hamiltonian Monte Carlo (HMC) [Duane et al., 1987] methods, which also utilize gradient information to more efficiently “explore” the space. Recently, the No-U-Turn-Sampler (NUTS) [Hoffman and Gelman, 2014] was introduced as an extension of HMC that automatically adapts some of its tuning parameters in order to attempt high off-the-shelf performance. We include an alternate auxiliary variable method known as *slice sampling* [Neal, 2003], which we apply in a coordinate Gibbs-like fashion.

We also alternate different proposals to form compound proposals. For instance, we consider mixing expensive efficient proposals like NUTS with cheap inefficient proposals like random walk Metropolis.

Finally, we consider an unconventional sampler known as *emcee* [Foreman-Mackey et al., 2013], which is popular in fields such as astrophysics. However, it has not gained much use in machine learning. It works by running multiple “walkers” to explore the space in parallel. Emcee is very fast and can be parallelized, but its efficacy in higher dimensions is somewhat controversial.

**Initialization** The accuracy of MCMC based estimates are a function of two factors: the *burn-in time* and the *mixing time*. Burn-in time, or time until convergence, is how many steps  $k$  are required before  $p(\mathbf{x}_k) \approx p^*$  if  $\mathbf{x}_0 \sim p_0$ , where  $p_0$  is some distribution to initialize the chain. The mixing time, or memory length, is how long it takes to get an independent sample once a chain has converged: how many steps  $k$  are required before  $\text{MI}(\mathbf{x}_k; \mathbf{x}_0) \approx 0$  if  $\mathbf{x}_0 \sim p^*$ . The burn-in time is crucially dependent on the initialization while the mixing time is purely a function of the proposal.

In order to evaluate these two effects separately, we offer two options for initialization: 1) initialize the chain from an exact sample (because we can do that with the benchmark density examples), or 2) initialize from an ADVI [Kucukelbir et al., 2017] fit to the example density. Additionally, most methods benefit from a prior guess at the relative scale of the variables before tuning. We can use the resulting scales from ADVI for this purpose as well. This allows us to *separate the effects* of initializa-

tion and mixing. We use the PyMC3 defaults for these tuning parameters as that is what a practitioner is most likely to use in practice. However, alternate schemes can certainly be used within the benchmark.

#### 4.5 PHASE 4: LOG PERFORMANCE

Each sampler is run for a fixed time limit of 15 minutes of CPU time. We log the performance of the chain along a uniform grid of 100 points in time (i.e., every 9s) to monitor *real* convergence over time. Fair evaluation requires evaluating each sampler with a fixed time budget rather than a fixed number of samples. We expect samplers such as NUTS to be very efficient and high performing on a per-sample basis. However, they require significantly more computation (including gradients) per sample than simpler methods. Therefore, their comparison is not as obvious a-priori. We also log the traditional MCMC diagnostics of each chain.

#### 4.6 PHASE 5: ANALYZE

To summarize the performance of a Markov chain in comparison with ground-truth samples we need to define some evaluation quantities. First, recall that we have  $K$  Markov chains  $\{\mathbf{x}_{1:N_k}\}_{k=1}^K$  for each example  $p^* \in \mathcal{M}$  and sampler  $S \in \mathcal{S}$ .

Each sampler is evaluated on each example separately and can be scored relative to a variety of *estimators*  $\hat{\theta}(\mathbf{x}_{1:N})$ . Analogous to (3), we can score the samples of a Markov chain by the closeness of its mean on a dimension  $d$  to the ground-truth samples:  $\theta = \mathbb{E}[x_d]$  and  $\hat{\theta}(\mathbf{x}_{1:N}) = \frac{1}{N} \sum_{i=1}^N [\mathbf{x}_i]_d$ . We can also consider how close the variance of the Markov chain samples match the ground-truth samples:  $\theta = \text{Var}[x_d]$ . This flexibility is a generalization of ESS. As in (3), we assume the estimators  $\hat{\theta}$  are unbiased, and just as with the sample mean  $\hat{\mu}$ :  $\text{Var}_{p^*}[\hat{\theta}] \propto N^{-1}$ . Furthermore, we assume here that each dimension of the samples  $\mathbf{x}$  has been standardized using the variance of the ground-truth samples, which makes the estimation errors on each dimension  $d$  comparable even when their units differ.

**Real ESS** In analogy to the ESS diagnostic we define the *real ESS* (RESS) based on the estimation error relative to the ground-truth:

$$\text{RESS} := \frac{R}{\text{mean sq. error}} = \frac{RK}{\sum_{k=1}^K (\hat{\theta}_k - \theta)^2} \in \mathbb{R}^+,$$

$$R := \mathbb{E}_{p^*}[(\hat{\theta} - \theta)^2] = N \text{Var}_{p^*}[\hat{\theta}] \in \mathbb{R}^+, \quad (4)$$

where  $K$  is the number of independent MCMC chains and  $R$  is a constant to make RESS comparable across different types of estimators  $\hat{\theta}$ . It also ensures that RESS

Figure 3: Performance summaries: The box plots demonstrate the distribution on NESS (left) and efficiency (center) conditional on the sampler achieving an RESS of at least 12 to only show the mode where the samplers don’t completely fail. We also show a calibration plot to assess if ESS is a good predictor of efficiency with the diagonal in dashed black. Cauchy and Laplace refer to random walk Metropolis with these corresponding proposals.

tends towards  $N$  when the samples are iid. We do not need the  $\text{Var}[x]$  term from (3) because the samples have been standardized using the ground-truth samples’ scale. If the estimator  $\theta$  in (4) is the mean  $\mu_d$ , then  $R = 1$ . In this case, the RESS measures the exact same expectation (expected square loss) as ESS attempts to estimate. Therefore, if the chain is sufficiently long for accurate estimation of ESS, the two metrics should converge. For variance  $\sigma_d^2$  estimation,  $R = 2$  in large  $N$ .

We also consider the Kolmogorov-Smirnov (KS) distance between the samples and the ground-truth samples as a metric.<sup>1</sup> This also results in a separate metric on each marginal. To match the  $N^{-1}$  convergence assumption of (4) we use  $\sum_{k=1}^K \text{KS}_d(\mathbf{x}_{1:N}^k, p^*)^2$  as the denominator in (4), where  $\text{KS}_d$  signifies the KS distance on the marginal  $x_d$ . By numerically integrating (4) with the Kolmogorov distribution, one finds that  $R = 0.822$ .

RESS is also general in that we can sensibly combine the errors across dimensions by evaluating multivariate estimators  $\hat{\theta} \in \mathbb{R}^D$ :

$$\text{RESS} = \frac{RKD}{\sum_{k=1}^K \|\hat{\theta}_k - \theta\|_2^2} \in \mathbb{R}^+. \quad (5)$$

This assumes that  $\hat{\theta}$  is an unbiased estimator of  $\theta$ . This, like (4), tends towards  $N$  for iid samples.

Because  $p^*$  may be complex, yet cheap to take many (e.g.,  $10^4$ ) iid samples from, we use the ground-truth samples from  $p^*$  to estimate  $\theta$  for use in (4). The error in estimating  $\theta$  is negligible compared to  $\hat{\theta}_k - \theta$ . Likewise, for the KS metric we use a two-sample KS distance between the MCMC samples and ground-truth from  $p^*$ .

<sup>1</sup>Recall that the KS distance between samples  $x_{1:N}$  and a CDF  $F$  is given by  $\max_a |\hat{F}(a) - F(a)|$  where  $\hat{F}$  is the empirical CDF on  $x$ .

**Efficiency** Likewise, it is useful for practitioners to get a ballpark estimate of the *efficiency* of a sampler:

$$\text{EFF} := \frac{\text{RESS}}{N} \in \mathbb{R}^+. \quad (6)$$

If the number of samples per chain  $N$  differs across chains, it is more appropriate to use the harmonic mean of  $N$  than the mean; this ensures that EFF tends towards unity when samples are drawn iid from  $p^*$ . Although EFF is useful, RESS is more appropriate for comparisons between samplers. Thinning can increase EFF without increasing estimation accuracy.

**Normalization** When looking at the distribution of sampler performance across examples it is more appropriate to look at normalized ESS (NESS):

$$\text{NESS} := \frac{\text{RESS}}{\text{median}_{S \in \mathcal{S}} N_S} \in \mathbb{R}^+, \quad (7)$$

where the median is taken across different samplers on the same example. The RESS, when evaluating with a fixed time limit, varies widely across examples. The computational cost of each sample varies greatly between benchmark examples.

**ESS Deviation** In order to evaluate the diagnostics in a meta-analysis, we define the ESS deviation (ESSD) metric, which gives a sense on whether the ESS is biased or a generally poor predictor of estimation accuracy. The ESSD is defined as:

$$\text{ESSD} := \Phi^{-1} \left( \chi_K^2 \text{CDF} \left( \frac{\text{ESS}}{\text{RESS}} K \right) \right) \in \mathbb{R}, \quad (8)$$

where  $\Phi^{-1}(\cdot)$  is the inverse CDF of the standard normal. ESSD has a standard normal distribution (under CLT assumptions) if the estimates are derived ESS iid samples;

Table 1: Quantitative summary on sampler performance. We show the NESS on various estimation tasks (e.g.,  $\mu$  vs  $\sigma^2$ ) averaged over all examples on the left. The right shows the probability of success, i.e., how often  $\text{RESS} \geq 12$ . The first three rows are different proposals for random walk Metropolis. Mix is a compound proposal of NUTS and Gauss. For both NESS and prob. success, higher is better.

sampler	NESS			prob. success		
	KS	$\mu$	$\sigma^2$	KS	$\mu$	$\sigma^2$
Cauchy	.004	.004	.003	.604	.582	.441
Laplace	.007	.004	.006	.566	.547	.439
Gauss	.007	.005	.007	.585	.565	.436
HMC	.061	.151	.106	.580	.604	.531
NUTS	<b>.068</b>	<b>.375</b>	<b>.115</b>	.875	.783	.711
emcee	.016	.038	.025	.389	.489	.379
mix	.067	.164	.113	<b>.911</b>	<b>.825</b>	<b>.715</b>
slice	.044	.078	.070	.745	.703	.643

$\text{ESSD} > 0$  indicates the estimation is higher error than expected from ESS. More precisely, if  $\hat{\theta}$  is derived from  $m$  iid samples then,

$$\hat{\theta} \stackrel{d}{\rightarrow} \mathcal{N}(\theta, \sqrt{R/m}) \implies \sqrt{m/R}(\hat{\theta} - \theta) \sim \mathcal{N}(0, 1)$$

$$\implies \sum_{k=1}^K \frac{m}{R} (\hat{\theta} - \theta)^2 = \frac{m}{\text{RESS}} K \sim \chi_K^2, \quad (9)$$

which implies that  $\text{ESSD} \sim \mathcal{N}(0, 1)$ . Note that (8) is merely a transformation to put the RESS-vs-ESS performance ratio on a standardized scale, which does not cause issues if the central limit theorem (CLT) assumption in (9) does not hold exactly.

**Meta-analysis** In our meta-analysis, we perform a Gaussian process regression to predict ESSD from  $\text{ESS} \in \mathbb{R}^+$ , Gelman-Rubin  $\text{GR} \in [1, \infty)$ , and Geweke  $G \in \mathbb{R}$ . We also include the dimension  $D$  of the sample space  $\mathbf{x}$ . Recall that if ESS is a perfect predictor of MCMC performance, then ESSD will resemble white-noise (i.e., iid standard normal). Given that the scales of diagnostics vary widely, we use  $\log \text{ESS}$ ,  $\log |\text{GR} - 1|$ , and  $\log |G|$  to put them all on a sensible scale.

To assess the regression, we test on a held-out 20% test set of unseen examples (i.e., we do random split on a per example basis) to see if we can predict the ESSD on new unseen benchmark examples from the MCMC diagnostics. We compare performance of the regression to linear regression and an iid normal to see if the features provide any predictive gain. Furthermore, we assess the predictive value of each feature by performing the regression after removing each feature and studying the performance delta.

Table 2: Results of meta-analysis. We show the MSE and log-loss of different models attempting to predict the ESSD for mean estimation on a held-out 20% of unseen examples. The log-loss has the advantage that it is parameterization invariant and provides the same results in ESSD or ESS space. The GP- rows show the results of GP regression without the feature named. GP shows the performance of the GP using all features. We assess the statistical significance of the delta to GP using a pairwise t-test in p.

method	MSE	p	NLL (nats)	p
GP	2.8588	–	0	–
GP-D	<b>2.779(70)</b>	0.0252	<b>-0.0096(97)</b>	0.0504
GP-ESS	3.16(23)	0.0097	0.045(31)	0.0034
GP-G	2.858(1)	0.0198	-0.0001(1)	0.0016
GP-GR	3.17(20)	0.0017	0.045(25)	0.0005
iid	3.30(28)	0.0016	0.067(36)	0.0003
linear	3.03(19)	0.0726	0.027(25)	0.0350

## 5 RESULTS

We first show an overall summary of final performance using NESS at the end of 15 minutes per chain, with  $K = 8$  chains in Table 1. The box plots in Figure 3 provide a sense of the variation. We found the NESS of the samplers to generally be bimodal: either the samples achieve an efficiency above 1%, or they completely fail with an  $\text{RESS} < 1$ . Therefore, in Figure 3 we show the box plots after excluding the complete failures. Inspired by the rule of  $N = 12$  from MacKay [2003], we use an RESS of 12 to threshold failure-vs-success.

Table 1 also provides an overall success probability for each method. Emcee shows the most bimodal performance: while sometimes achieving a high NESS competitive with other advanced methods, it has the lowest success probability. Emcee also has the lowest efficiency of any methods except random walk Metropolis, but emcee makes up for its lack of efficiency with higher per sample speed.

Other results from Figure 3 are unsurprising: NUTS and HMC are the highest performers, despite their higher per sample cost. Slice sampling also makes a “strong showing” with its performance more competitive in the lower dimensional examples. Random walk Metropolis methods generally have an efficiency in the 0.1% to 1% range, while slice sampling and HMC based methods have efficiencies in the ballpark of 2% to 40%, with NUTS showing the highest performance. Emcee seems to vary widely. Note that although the compound proposal (mix) does not substantially increase NESS (over NUTS), when the methods succeed Figure 3, mix increases the chance of success (Table 1).

Figure 4: Calibration plots of the ESS diagnostic against real ESS with  $\hat{\theta}$  being the mean (left), variance (center), or KS (right). We show the diagonal for a perfect match in dashed black. In dotted black we show the 95% region for what the observed real ESS would be if the estimates  $\hat{\theta}$  were derived from ESS iid samples. The RESS is below the lower error bar 55% of the time for mean estimation, 68% for variance, and 83% for KS; these would be 2.5% if a chain with  $\text{ESS} = m$  were functionally equivalent to  $m$  iid samples.

We show calibration plots of ESS in Figure 4 and efficiency in Figure 3. The ESS diagnostic is clearly best calibrated for mean estimation, which is not surprising given it was derived for that purpose. However, the ESS diagnostic clearly has an optimistic bias. These results provide caution of ESS.

Finally, we present the results of the meta-analysis to predict ESS deviation. We report the predictive value provided by various features in Table 2 by showing how much performance changes when they are removed. ESS appears very predictive in Figure 4, but the relationship has already largely been accounted for with ESSD (8). In log-loss, the remaining predictive utility of ESS equals that of Gelman-Rubin. Geweke and the dimension  $D$  show no predictive utility. Predictive performance of ESSD goes up when they are removed, which indicates they are of little utility when assessing the validity of a Markov chain. One expects sampling to be more difficult in higher dimensions  $D$ , however this slower mixing may already be evident from ESS and Gelman-Rubin.

## 6 CONCLUSIONS

We have presented a general system to benchmark the real performance of MCMC samplers on realistic problems. The data-driven nature of the benchmark makes it a highly novel development. This benchmark is intended to become a general service that will become as widespread as COCO or MLcomp. Careful attention has been paid to fairly and sensibly derive metrics that compare samplers. This benchmark will evolve with time by including ever more models in phase 1 and more advanced example densities in phase 2. New and more sophisticated samplers can easily be added in phase 3.

## Abstract

Learning nonlinear dynamics from diffusion data is a challenging problem since the individuals observed may be different at different time points, generally following an aggregate behaviour. Existing work cannot handle the tasks well since they model such dynamics either directly on observations or enforce the availability of complete longitudinal individual-level trajectories. However, in most of the practical applications, these requirements are unrealistic: the evolving dynamics may be too complex to be modeled directly on observations, and individual-level trajectories may not be available due to technical limitations, experimental costs and/or privacy issues. To address these challenges, we formulate a model of diffusion dynamics as the *hidden stochastic process* via the introduction of hidden variables for flexibility, and learn the hidden dynamics directly on *aggregate observations* without any requirement for individual-level trajectories. We propose a dynamic generative model with Wasserstein distance for LEarninG dEep hidden Nonlinear Dynamics (LEGEND) and prove its theoretical guarantees as well. Experiments on a range of synthetic and real-world datasets illustrate that LEGEND has very strong performance compared to state-of-the-art baselines.

## 1 INTRODUCTION

*Diffusion data* is a widespread form of data that involves spatial or status transitions over time, *e.g.*, Brownian movement in physics, cell differentiation or gene expression in biology, molecular motion in chemistry, bird migration in ecology, traffic flows in transportation, population trends in social sciences and so on. Learning

Figure 1: An illustration of the framework which builds dynamics on an auxiliary hidden variable  $X_t$  with a observation function. Observation  $Y_t$  is the aggregate formatted data.

the underlying dynamics which governs the evolution of such data is a fundamental problem. It reveals the nature of the dynamical phenomenon, based on which we can make better future predictions. However, in these areas, complete longitudinal individual-level trajectories (*i.e.*, the tracking of one individual over the entire diffusion process) may often not be available due to technical limitations, experimental costs and/or privacy issues. Rather, one often instead observes a random group of independently sampled individuals from the population, and the observations can contain different individuals at different time points. This is common for catch and release experiments in ecology (*e.g.*, bird migration) where it is difficult to observe a single bird twice (Bartholomew & Bohnsack, 2005), and in biological research where a cell may need to be sacrificed in order for an observation on it to be made (Banks & Potter, 2004). We refer to observations made in these scenarios as *aggregate observations* to differentiate them from the case of individual-level trajectories which provide full information.

Modeling the dynamics on aggregate observations have been investigated recently in (Hashimoto et al., 2016), where a stochastic differential equation (SDE) has been used to capture the transition directly on observations  $Y_t$ . However, its performance degrades when the dynamics

become complex due to their limited expressive ability, as illustrated later in our experiments. Instead of modeling dynamics directly on observations, a hidden variable  $X_t$  can be introduced for modeling complicated dynamics, which can be decomposed into a relatively simple hidden dynamic on  $X_t$  with a complicated observation function. As illustrated in Figure 1,  $Y_t(t \in [0, T])$  is a series of aggregated observations of a diffusion process. We formulate that  $Y_t$  is determined by the hidden dynamic on  $X_t$  and the observation function  $\mathbf{f}(X_t)$ . Existing models such as Hidden Markov Model (HMM) (Eddy, 1996), Kalman Filter (KF) (Harvey, 1990) and Particle Filter (PF) (Djuric et al., 2003) are popular methods with hidden variables. However, these models and their variants (Langford et al., 2009; Hefny et al., 2015) require individual-level trajectories, which may not be available, as was mentioned earlier. It consequently still remains an open issue as to how one can learn the underlying dynamics directly from aggregate observations with a hidden stochastic process, for complicated real-world scenarios.

To address these challenges, we propose a novel framework to incorporate the use of hidden variables into the modeling of diffusion dynamics from evolving distributions (as those approximated from aggregate observations). We bypass the need for likelihood-based estimation of model parameters and posterior estimation of hidden variables by using Wasserstein distance learning. The model we propose is named LEGEND (LEarninG dEep hidden Nonlinear Dynamics) and the main contributions are:

- We propose a framework for learning complicated nonlinear dynamics from aggregate data via a hidden continuous stochastic process.
- We extend Wasserstein learning to likelihood-free and posterior-free estimations of dynamic parameter learning and hidden state inference.
- We theoretically provide a generalization bound and convergence analysis of our framework, which is the first theoretical result as far as we know.
- We empirically demonstrate the effectiveness of our framework for learning nonlinear dynamics from aggregate observations on both synthetic and real-world datasets.

## 2 PROBLEM DEFINITION

We first introduce a continuous model of diffusion dynamics using a stochastic differential equation (SDE), then formally define the tasks of filtering and smoothing based inference, then review the Wasserstein distance objective as one of the distribution metric.

**Hidden Continuous Nonlinear Dynamics.** To characterize the dynamics of observations, we introduce a hidden continuous nonlinear dynamical system as shown in Figure 1, together with a measurement of hidden states. In particular, the hidden state  $X_t \in \mathbb{R}^n$  is the underlying auxiliary variable that cannot be accessed directly, and it follows a SDE:

$$dX_t = \mathbf{g}(X_t)dt + \Sigma^{1/2}d\omega_t, \quad (1)$$

where  $\mathbf{g} : \mathbb{R}^n \rightarrow \mathbb{R}^n$  is a nonlinear deterministic drift function, and  $\omega_t \in \mathbb{R}^n$  is a Brownian motion process with noise covariance  $\Sigma \in \mathbb{R}^n \times \mathbb{R}^n$ . At each time point, the observation  $Y_t$  is written as a measurement of the hidden state  $X_t$ :

$$Y_t = \mathbf{f}(X_t), \quad (2)$$

where  $\mathbf{f} : \mathbb{R}^n \rightarrow \mathbb{R}^m$  is a nonlinear observation function. Together, Eqs. (1) and (2) define the nonlinear dynamics with continuous hidden states.

**Aggregate Observations.** We obtain a collection of independent and identically distributed (i.i.d) samples  $\{y_t^i\}_{i=1}^N$  of  $Y_t$  at some time point  $t$ , that we term aggregate or distributional observations. The observed individuals in previous time observations  $\{y_{t-1}^i\}_{i=1}^N$  are often not identical to those for the current time observations  $\{y_t^i\}_{i=1}^N$ , implying it is not possible to construct the full trajectory of a single individual. However, we can approximate the probability distribution in terms of a finite number of samples as

$$p(Y_t) \approx \frac{1}{N} \sum_{i=1}^N \delta(Y_t - y_t^i). \quad (3)$$

Thus, we can treat these aggregate samples from the same time point together as a distribution which evolves in the dynamic system.

**Problems.** Under this aggregate setting for observations, it is difficult to obtain individual-level trajectories due to technical limitations, experimental costs and/or privacy issues. Therefore, we propose a new framework to learn the nonlinear dynamics for the distributions (as approximated from aggregate observations) without the need for individual-level trajectories. That is, we treat  $\{y_t^i\}_{i=1}^N$  as an empirical approximation to the distribution at time  $t$  and its dynamics is learned via an auxiliary hidden variable  $X_t$ . Once the dynamics are learned, we are faced with two inference tasks:

- 1) *Filtering based inference*: the task is to infer the next future observation  $Y_{T+1}$ , given observations  $\{Y_0, Y_1, \dots, Y_T\}$ .
- 2) *Smoothing based inference*: the task is to infer a missing intermediate observation  $Y_k (0 < k < T)$ , given  $\{Y_0, \dots, Y_{k-1}, Y_{k+1}, \dots, Y_T\}$ .

**Wasserstein Distance Objective.** Following our distribution-based problem definition, the metric on distributions is a key criterion for our objection function, just like the mean squared error (MSE) criterion for regression problems. Among the well-known distribution-based measures, such as Total Variation (TV) distance, Kullback-Leibler (KL) divergence, Jensen-Shannon (JS) divergence, Wasserstein distance has recently been shown to possess more appealing properties for distance measurement of distributions (Arjovsky et al., 2017). We therefore choose to adopt the Wasserstein distance for measuring the discrepancy between the learned distributions and their ground truth.

The definition of Wasserstein-1 distance (also named the Earth-Mover distance (EM)) is:

$$W(\mathbb{P}_r, \mathbb{P}_g) = \inf_{\gamma \in \Pi(\mathbb{P}_r, \mathbb{P}_g)} \mathbb{E}_{(x,y) \sim \gamma} [\|x - y\|], \quad (4)$$

where  $\Pi(\mathbb{P}_r, \mathbb{P}_g)$  denotes the set of all joint distributions  $\gamma(x, y)$  whose marginals are  $\mathbb{P}_r$  and  $\mathbb{P}_g$  respectively. The infimum in (4) is highly intractable. However, Kantorovich-Rubinstein duality (Villani, 2008) shows that

$$W(\mathbb{P}_r, \mathbb{P}_g) = \sup_{\|D\|_L \leq 1} \mathbb{E}_{x \sim \mathbb{P}_r} [D(x)] - \mathbb{E}_{x \sim \mathbb{P}_g} [D(x)], \quad (5)$$

where the supremum is over all 1-Lipschitz functions  $D$ . We can assume a parameterized family of functions  $\{D_w\}_{w \in \mathcal{W}}$  lying in the 1-Lipschitz function space. Therefore, Eq. (5) could be solved by

$$\max_{w \in \mathcal{W}} \mathbb{E}_{x \sim \mathbb{P}_r} [D_w(x)] - \mathbb{E}_{x \sim \mathbb{P}_g} [D_w(x)]. \quad (6)$$

With Wasserstein distance, our objectives for dynamic learning and inference tasks can be unified to minimize the Wasserstein distance between the generated distribution and the target distribution, which will be instantiated in the following Section 3.

### 3 PROPOSED FRAMEWORK

In this section, we first discuss our methodology for parameter learning of dynamics within the LEGEND framework, and then introduce in detail how the framework addresses the filtering and smoothing based inference problems.

#### 3.1 Parameter Learning of Dynamics

In order to efficiently solve the SDE of hidden state  $X_t$ , we adopt an approximate numerical solution called the Euler-Maruyama method (Talay, 1994). Suppose the SDE is defined on  $[0, T]$ , then the Euler-Maruyama approximation to the true solution of SDE is a Markov chain defined

as follows:

$$X_{t+\Delta t} = X_t + \mathbf{g}(X_t)\Delta t + \Sigma^{1/2}\Delta\omega_t, \quad (7)$$

where the interval  $[0, T]$  is partitioned into  $M$  equal sub-intervals of width  $\Delta t = T/M > 0$  and  $\Delta\omega_t$  are independent and identically distributed normal random variables with expected value zero and variance  $\Delta t$ . Correspondingly, observations  $Y_t$  are functions of  $X_t$ :

$$Y_t = \mathbf{f}(X_t). \quad (8)$$

Given a sequence of distributional observations, we need to minimize the Wasserstein distance between the generated distribution and the observed distribution at each time point to learn functions  $\mathbf{f}$  and  $\mathbf{g}$ . The objective function for parameter learning of dynamics is

$$\min_{\mathbf{f}, \mathbf{g}} \sum_t W(\mathbb{P}(Y_t), \mathbb{P}(\mathbf{f}(X_t))), \quad (9)$$

where  $X_t \sim \mathbb{P}(X_t|X_{t-1})$ . The evolving process<sup>1</sup> from  $X_{t-1}$  to  $X_t$  is controlled by function  $\mathbf{g}$  following the SDE in Eq. (7). One common approach for learning  $\mathbf{f}$  and  $\mathbf{g}$  is to calculate the likelihood of  $Y_t$  under distributions, however in many cases, this is intractable. Here, we propose to use generative models to directly generate samples which satisfy the target distribution  $Y_t$ . Following the minimization of the Wasserstein distance between generations and observations, the generative model can eventually learn the dynamics of  $Y_t$ . The specific form of parameterization will be described in Section 4.

#### 3.2 Filtering based Inference

The inference of  $Y_{T+1}$  given observations  $\mathcal{Y}_T = \{Y_0, Y_1, \dots, Y_T\}$  can be solved by:

$$Y_{T+1} = (\mathbf{f} \circ \mathbf{g})(X_T). \quad (10)$$

To achieve this, we need to obtain the hidden state  $X_T$  first, that is, find the posterior probability  $p(X_T|\mathcal{Y}_T)$  of the hidden state conditioned on the entire sequence of observations  $\mathcal{Y}_T$ , which is a filtering problem.

To obtain the posterior of the hidden state, the classical forward algorithm needs to solve one dynamic programming problem per sample, which requires individual-level trajectory for posterior inference. However, for our aggregate observation setting, we alternatively treat the Bayesian inference problem from an optimization perspective following (Dai et al., 2016).

We first briefly introduce the idea of the optimization method, then generalize it to solve our problem. Dai

<sup>1</sup>There may be several  $\Delta t$  intervals between time  $t - 1$  and  $t$

et al. (2016) use a probability  $q(U)$  to approximate the posterior probability  $p(U|V)$  by minimizing

$$\min_{q(U) \in \mathcal{P}} -\langle q(U), \log p(V|U) \rangle + KL(q(U) \parallel p(U)) \quad (11)$$

over the space of all valid densities  $\mathcal{P}$ .  $\langle \cdot \rangle$  is the inner product,  $KL$  is the Kullback-Leibler divergence,  $U$  is the hidden variable and  $V$  is the observation variable. Thus,  $p(V|U)$  is the likelihood of observation and  $p(U)$  is the prior of the hidden variable. Assuming we have the trajectory for a single individual ( $x_t \sim X_t, y_t \sim Y_t$ ), then the posterior probability of filtering is

$$p(x_t|y_{1:t}) = \frac{p(y_t|x_t)p(x_t|y_{1:t-1})}{\int p(y_t|x_t)p(x_t|y_{1:t-1})dx_t}, \quad (12)$$

where  $p(x_t|y_{1:t-1})$  is the propagation probability and  $p(x_t|y_{1:t})$  is the updated probability. Generally,  $p(x_t|y_{1:t-1})$  could be regarded as the prior of  $x_t$  for the updated probability  $p(x_t|y_{1:t})$ . Following the idea of Eq. (11), we can use a probability  $\pi(x_t)$  to approximate the posterior probability  $p(x_t|y_{1:t})$  by recursively optimizing

$$\min_{\pi(x_t) \in \mathcal{P}} -\langle \pi(x_t), \log p(y_t|x_t) \rangle + KL(\pi(x_t) \parallel p(x_t|y_{1:t-1})), \quad (13)$$

where

$$\begin{aligned} p(x_t|y_{1:t-1}) &= \int p(x_t, x_{t-1}|y_{1:t-1})dx_{t-1} \\ &= \int p(x_t|x_{t-1})p(x_{t-1}|y_{1:t-1})dx_{t-1} \\ &= \int p(x_t|x_{t-1})\pi(x_{t-1})dx_{t-1}. \end{aligned} \quad (14)$$

In the following, we generalize Eqs. (13) and (14) which were defined on an individual trajectory, to the case for aggregate/distributional data. In Eq. (13), to obtain the optimal solution, we need to maximize the inner product (the first term) and minimize the KL divergence (the second term). We redefine the two terms using Wasserstein distance. For the first term, since maximizing the inner product is equivalent to minimizing the distance between distributions, we replace the inner product with the Wasserstein distance between the distributions of  $\mathbf{f}(\pi_t)$  (generated) and  $Y_t$  (ground truth). For the second term, we replace KL divergence with Wasserstein distance which is a better measurement for distributions and is thus more suitable for aggregate data (Arjovsky et al., 2017). In Eq. (14), the relationship between two consecutive time of hidden variables is replaced by function  $\mathbf{g}$ . We then can generalize Eqs. (13) and (14) to our filtering objective function under aggregate observations:

$$\min \sum_t W(\mathbb{P}(\mathbf{f}(\pi_t)), \mathbb{P}(Y_t)) + W(\mathbb{P}(\pi_t), \mathbb{P}(\mathbf{g}(\pi_{t-1}))), \quad (15)$$

where  $\pi_t \sim \mathbb{P}(X_t|Y_t)$  is our target filtering distribution.

### 3.3 Smoothing based Inference

Smoothing based inference is for predicting the missing intermediate observation  $Y_k (0 < k < T)$  given observations  $\mathcal{Y}_{T \setminus k} = \{Y_0, \dots, Y_{k-1}, Y_{k+1}, \dots, Y_T\}$ . One method (Desbouvieres et al., 2011) to solve this is

$$Y_k = (\mathbf{f} \circ \mathbf{g})(X_{k-1}). \quad (16)$$

To achieve this, we need to obtain the hidden state  $X_{k-1}$  first. This is a smoothing problem which focuses on a hidden state somewhere in the middle of a sequence conditioned on the whole sequence of observations.

Different from the filtering task where the current state is estimated recursively from all past observations, smoothing computes the best state estimates given all available observations from both the past and the future. One well-known and simple approach for smoothing is the forward-backward smoother. During a forward pass the standard filtering algorithm is applied to the observations. Afterwards, on the backward pass, inverse filtering is applied to the same time series of observations. Finally the filtering estimates of both the forward and backward pass are combined into the smoothed estimates (Briers et al., 2010). Since the information from the observation should be incorporated only once into the smoothed estimate, we need to combine the posterior estimate of the forward pass with the prior estimate of the backward pass and vice versa.

Thus, following the idea in the above filtering problem (treating the posterior estimation from a optimization perspective), we first learn a forward estimate of the hidden state  $\pi_t^f$  and also a backward estimate  $\pi_t^b$  using Eq. (15). These then form a weighted Wasserstein barycenter problem (Agueh & Carlier, 2011) whose solution is the posterior of smoothing (Kitagawa, 1994). That is, we can obtain the optimal smoothing result  $\pi_t^s$  by optimizing the Wasserstein distance to the observations and the weighted Wasserstein barycenter:

$$\begin{aligned} \min \sum_t W(\mathbb{P}(\mathbf{f}(\pi_t^s)), \mathbb{P}(Y_t)) \\ + \lambda_1 W(\mathbb{P}(\pi_t^s), \mathbb{P}(\pi_t^f)) \\ + \lambda_2 W(\mathbb{P}(\pi_t^s), \mathbb{P}(\pi_t^b)), \end{aligned} \quad (17)$$

where  $\pi_t^s \sim \mathbb{P}(X_t|Y_T)$  is our target smoothing distribution. And the weights  $\lambda_1$  and  $\lambda_2$  are hyperparameters, which are given intuitively with  $\lambda_1 = t/T$  and  $\lambda_2 = 1 - \lambda_1$  such that smoothing problem becomes filtering problem when  $t = T \rightarrow \lambda_1 = 1$ . Actually, there are other alternatives one could use for the weights, but these basic settings already work well in our experiments.

## 4 MODEL PARAMETERIZATION

As stated above, we adopt Wasserstein distance to measure the difference between distributions, and have defined our objectives accordingly. In this section, we establish a dynamic generative model via neural network parameterization based on Wasserstein distance.

According to the dual formulation of Wasserstein distance Eq. (6), our distribution-based objective of parameter learning of dynamics in Eq. (9) becomes

$$\min_{\mathbf{f}, \mathbf{g}} \sum_t \left( \max_{D_t^1} (\mathbb{E}_{y_t \sim \mathbb{P}(Y_t)} [D_t^1(y_t)]) - \mathbb{E}_{x_t \sim \mathbb{P}(x_t | \mathbf{g}(x_{t-1}))} [D_t^1(\mathbf{f}(x_t))] \right). \quad (18)$$

For the filtering and smoothing tasks, we introduce a new function  $\mathbf{h}$  to characterize the target filtering or smoothing distributions. The filtering objective in Eq. (15) becomes

$$\begin{aligned} \min_{\mathbf{h}} \sum_t \left( \max_{D_t^1} (\mathbb{E}_{y_t \sim \mathbb{P}(Y_t)} [D_t^1(y_t)]) \right. \\ \left. - \mathbb{E}_{\pi_t \sim \mathbb{P}(\mathbf{h}(Y_t))} [D_t^1(\mathbf{f}(\pi_t))] \right) \\ + \max_{D_t^2} (\mathbb{E}_{\pi_t \sim \mathbb{P}(\mathbf{h}(Y_t))} [D_t^2(\pi_t)] \\ - \mathbb{E}_{\pi_{t-1} \sim \mathbb{P}(\mathbf{h}(Y_{t-1}))} [D_t^2(\mathbf{g}(\pi_{t-1}))]). \end{aligned} \quad (19)$$

And the smoothing objective in Eq. (17) becomes

$$\begin{aligned} \min_{\mathbf{h}^s} \sum_t \left( \max_{D_t^1} (\mathbb{E}_{y_t \sim \mathbb{P}(Y_t)} [D_t^1(y_t)]) \right. \\ \left. - \mathbb{E}_{\pi_t^s \sim \mathbb{P}(\mathbf{h}^s(Y_t))} [D_t^1(\mathbf{f}(\pi_t^s))] \right) \\ + \lambda_1 \max_{D_t^2} (\mathbb{E}_{\pi_t^s \sim \mathbb{P}(\mathbf{h}^s(Y_t))} [D_t^2(\pi_t^s)] \\ - \mathbb{E}_{\pi_t^f \sim \mathbb{P}(\mathbf{h}^f(Y_t))} [D_t^2(\pi_t^f)]) \\ + \lambda_2 \max_{D_t^3} (\mathbb{E}_{\pi_t^s \sim \mathbb{P}(\mathbf{h}^s(Y_t))} [D_t^3(\pi_t^s)] \\ - \mathbb{E}_{\pi_t^b \sim \mathbb{P}(\mathbf{h}^b(Y_t))} [D_t^3(\pi_t^b)]). \end{aligned} \quad (20)$$

In traditional implicit generative models, given a random variable  $z$  with a fixed distribution  $p(z)$ , we can pass it through a parametric generator  $G_\theta$  (typically a neural network) which directly generates samples following a certain distribution  $\mathbb{P}_\theta$ . Such design is of high flexibility, as by varying the parameters  $\theta$  of the neural networks, we can change this distribution to any distribution of interest. While in our framework, we need a dynamic generative model to match distributions at each time step which can be regarded as a combination of several Generative Adversarial Networks (GANs) (Goodfellow et al., 2014). Specifically, functions  $\mathbf{f}$ ,  $\mathbf{g}$ ,  $\mathbf{h}$  are all generators (sharing parameters over time) and  $D_t$  is a discriminator at time

$t$ . We formulate functions  $\mathbf{f}$ ,  $\mathbf{g}$  and  $D_t$  as normal feed-forward neural networks<sup>2</sup>:

$$f^l = \sum_k \sigma(w_k^f f^{l-1} + b_k^f), \quad (21)$$

$$g^l = \sum_k \sigma(w_k^g g^{l-1} + b_k^g), \quad (22)$$

$$D_t^l = \sum_k \sigma(w_k^{D_t} D_t^{l-1} + b_k^{D_t}), \quad (23)$$

where  $f^l$ ,  $g^l$ ,  $D_t^l$  are the  $l$ -th layers of the neural networks,  $\sigma$  is the activation function, and  $w_k$ ,  $b_k$  are the neural network parameters. Note the output layer of the discriminator  $D_t$  only has one single neuron to output a scalar value.

As for the function  $\mathbf{h}$  (in both filtering and smoothing), we use a recurrent neural network (RNN) to model it, similar to (Mogren, 2016). For the purposes of simplicity and clarity of exposition, we illustrate the computational process here using a vanilla RNN, whereas the actual recursive unit used in our experiments is LSTM unit (Hochreiter & Schmidhuber, 1997). Given inputs as sequences of observations  $\{Y_0, Y_1, \dots, Y_t, \dots, Y_T\}$  and outputs as filtering or smoothing hidden states  $\{\pi_0, \pi_1, \dots, \pi_t, \dots, \pi_T\}$ , the parameterization function  $\mathbf{h}$  works as follows:

$$s_t = \sigma(AY_t + Bs_{t-1} + b), \quad (24)$$

$$\pi_t = \sigma(Cs_t + b), \quad (25)$$

where  $s_t$  is the memorized history information and  $A, B, C$  are parameter matrices of RNN.

Note that we need to enforce the Lipschitz constraints when solving Wasserstein distance from duality in Eq. (5). To achieve this, we adopt the strategy of gradient penalty in (Gulrajani et al., 2017) to regularize the Wasserstein distance<sup>3</sup>.

For parameter learning of dynamics in Eq. (18), we can obtain the optimal discriminator and gradients by

$$D_t^* = \arg \max_{D_t} (E_{y_t^i} [D_t(y_t^i)] - E_{x_{t-1}^i} [D_t(\mathbf{f} \circ \mathbf{g})(x_{t-1}^i)]) \quad (26)$$

$$g_{\mathbf{f}, \mathbf{g}} = - \sum_t \nabla_{\mathbf{f}, \mathbf{g}} E_{x_{t-1}^i} [D_t^*((\mathbf{f} \circ \mathbf{g})(x_{t-1}^i))], \quad (27)$$

where the gradient of  $\mathbf{g}$  needs to back propagate through the entire chain. In practice, we use gradient decent to update the discriminator. The parameter learning procedure of our model is presented in Algorithm 1. Similarly, we can derive the results for filtering and smoothing from Eq. (19) and (20), respectively.

<sup>2</sup> $\mathbf{g}$  could be several nested  $\mathbf{g}$  due to the  $\Delta t$  in SDE.

<sup>3</sup>We omit this term in our equations for simplicity.

## 5 THEORETICAL ANALYSIS

In this section, we provide a generalization error analysis and a convergence guarantee for our learning framework. Our analysis mainly focuses on the parameter learning component of our method, however, similar results can also be derived for filtering and smoothing based inference. For the purpose of simplicity, we briefly present our main results here and leave detailed theorems and proofs to Appendix A.

**Generalization Error.** We denote  $\mathcal{F}$  and  $\mathcal{G}$  as the function spaces of  $\mathbf{f}$  and  $\mathbf{g}$ , respectively, and the  $\mathcal{D}$  as the function space of the  $\{D_t\}_{t=0}^T$ , and  $\mathbf{g}^{ot}(x, \xi_t) = \underbrace{((I + \mathbf{g}) \circ (I + \mathbf{g}) \circ \dots \circ (I + \mathbf{g}))}_t(x) + \xi_t$  with  $\xi_t \sim \mathcal{N}(0, \Delta t)$ . We define

$$\ell(\mathbf{f}, \mathbf{g}) = \mathbb{E}_{y_{0:T}, x_0 \sim p(x), \xi_{0:T}} \left[ \sum_{t=0}^T \max_{D_t \in \mathcal{D}} \left[ D_t(y_t) - D_t((\mathbf{f} \circ \mathbf{g}^{ot}(x_0, \xi_t))) \right] \right]. \quad (28)$$

**Theorem 1.** *Without loss of generality, we assume in each timestamp the number of the observations is  $N$ . Given the samples  $\mathcal{Y} = \{(y_t^i)_{t=0}^T\}_{i=1}^N$  ( $|\mathcal{Y}|_\infty = C_Y$ ) where  $y_{0:T} = (y_t^i)_{t=0}^T$  are sampled i.i.d. from the underline stochastic processes, and  $\mathcal{X} = \{x_0^i\}_{i=1}^N$ ,  $\Xi = \{\xi_{0:T}^i\}_{i=1}^N$  are also i.i.d. sampled. Assume  $\mathcal{D}$  is a subset of  $k$ -Lipschitz functions and denote the  $\mathfrak{R}(\mathcal{F} \circ \mathcal{G}^{ot})$  as the Rademacher complexity of the function space  $\mathcal{F} \circ \mathcal{G}^{ot}$ . We*

have

$$\frac{1}{T} \ell(\mathbf{f}, \mathbf{g}) \leq \frac{1}{T} \hat{\ell}(\mathbf{f}, \mathbf{g}) + \frac{4kC}{\sqrt{N}} + 4k \frac{\sum_{i=1}^T \mathfrak{R}(\mathcal{F} \circ \mathcal{G}^{ot})}{T}. \quad (29)$$

For the different parametrizations, *i.e.*, different function spaces  $\mathcal{F}$  and  $\mathcal{G}$ , the Rademacher complexity of  $\mathfrak{R}(\mathcal{F} \circ \mathcal{G}^{ot})$  will be different. For example, if we parametrize the  $\mathbf{f}(z) = \sigma(W_f z)$  and  $\mathbf{g}(z, \xi) = I^\top[z, \xi] + \sigma(W_g z)$  as single layer neural networks, where  $\sigma$  satisfies some mild condition (Bartlett et al., 2017), following (Bartlett et al., 2017), we have the  $\mathfrak{R}(\mathcal{F} \circ \mathcal{G}^{ot}) = \tilde{\mathcal{O}}\left(\frac{\sqrt{C_1(W_f)C_2^t(I, W_g)(\sum_{i=1}^t C_3(I, W_g))}}{N}\right)$ , where  $C_1, C_2$  and  $C_3$  are some constants related to the parameters. For the details of the conditions on  $\sigma$  and the exact formulation of the constants, please refer to (Bartlett et al., 2017).

**Convergence Analysis.** Convexity-concavity no longer holds for the objectives in the learning and inference parts, therefore, convergence analysis for convex-concave saddle point problem in (Nemirovski et al., 2009) cannot be directly applied. Inspired by (Dai et al., 2017), we can see that once we obtain  $D_t^*$ , Algorithm 1 can be understood as a special case of stochastic gradient descent for a non-convex problem. Thus, we have the following finite-step convergence guarantee for our framework.

**Theorem 2.** *Assume that the parametrized empirical loss function  $\hat{\ell}(\mathbf{f}, \mathbf{g})$  is  $K$ -Lipschitz and variance of its stochastic gradient is bounded by  $\varsigma^2$ . Let the algorithm run  $M$  iterations with stepsize  $\zeta = \min\{\frac{1}{K}, \frac{C'}{\varsigma\sqrt{M}}\}$  for some  $C' > 0$  and output  $(w_f^1, w_g^1), \dots, (w_f^M, w_g^M)$ . Setting the candidate solution to be  $w = (\hat{w}_f^M, \hat{w}_g^M)$  randomly chosen from  $(w_f^1, w_g^1), \dots, (w_f^M, w_g^M)$  such that  $P(w = w^j) = \frac{2\zeta - K\zeta^2}{\sum_{j=1}^M (2\zeta - K\zeta^2)}$ , then it holds that*

$$\mathbb{E} \left[ \left\| \nabla \hat{\ell}(\hat{\mathbf{f}}_w^M, \hat{\mathbf{g}}_w^M) \right\| \right] \leq \frac{KC^2}{M} + (C' + \frac{C}{C'}) \frac{\varsigma}{\sqrt{M}}, \quad (30)$$

where  $C := \sqrt{2(\hat{\ell}(w_f^1, w_g^1) - \min \hat{\ell}(w_f, w_g))}/K$  represents the distance of the initial solution to the optimal solution.

## 6 EXPERIMENTS

In this section, we evaluate our LEGEND framework on various types of synthetic and real-world datasets.

**Baselines:** We compare our model with two recently proposed methods that learn dynamics directly from aggregate observations — modeling directly on  $Y_t$  using a SDE. The baselines differ from one other in their characterization of the drift term  $\mathbf{g}(X_t)$  of the SDE. The two

baselines considered in our experiments are two representatives from parametric and non-parametric categories: 1) OU (Orstein-Uhlenbeck (Huang et al., 2016)): modeling the drift term using an Orstein-Uhlenbeck process (Gillespie, 1996), which is a stationary Gauss-Markov process with the drift term  $\theta(\mu - x_t)$  ( $\theta, \mu$  are parameters); and 2) NN (Hashimoto et al., 2016): modeling the drift term using a neural network (NN) which is a sum of ramps.

## 6.1 Synthetic Data

We first assess our model on three synthetic datasets generated using the following three diffusion dynamics:

### Synthetic-1:

$$\begin{aligned} x_0 &\sim \mathcal{N}(0, \Sigma_1), \\ x_{t+\Delta t} &= x_t + \frac{1}{4}x_t\Delta t + \mathcal{N}(0, \Sigma_0), \\ y_t &= 2x_t. \end{aligned} \quad (31)$$

### Synthetic-2:

$$\begin{aligned} x_0 &\sim \mathcal{N}(0, \Sigma_2), \\ x_{t+\Delta t} &= x_t + (0.1x_t^2 + 0.5x_t)\Delta t + \mathcal{N}(0, \Sigma_0), \\ y_t &= \exp(x_t). \end{aligned} \quad (32)$$

### Synthetic-3:

$$\begin{aligned} x_0 &\sim \mathcal{U}([-2, 2]), \\ x_{t+\Delta t} &= x_t + (0.5x_t + |x_t|)\Delta t + \mathcal{N}(0, \Sigma_0), \\ y_t &= \log|x_t|. \end{aligned} \quad (33)$$

*Synthetic-1* is a linear dynamic on  $x_t$  with linear measurement  $y_t$  where  $x_0$  are sampled from multivariate normal distributions with covariance matrix  $\Sigma_1$  (diagonal elements are 0.04 and others are 0.032). A nonlinear dependency between  $x_t$  and  $y_t$  is formulated in *Synthetic-2*: a quadratic dynamic on  $x_t$  and an exponential dependency of  $y_t$  on  $x_t$  where  $x_0$  are sampled from multivariate normal distributions with covariance matrix  $\Sigma_2$  (diagonal elements are 0.01 and others are 0.008). In *Synthetic-3*, we test a more complex scenario: highly nonlinear dynamics on  $x_t$  with highly nonlinear measurement  $y_t$  where  $x_0$  are sampled from a uniform distribution  $\mathcal{U}([-2, 2])$ . For each synthesized dynamic, we obtain  $x_t$  like  $\{x_0, x_1, x_2, x_3\}$  every  $5\Delta t$  time following a discretized SDE in Eq. (7), and generate 1000 samples at each time step from  $x_t$  out of which only 500 samples are chosen as observations  $y_t$  like  $\{y_0, y_1, y_2, y_3\}$ . We consider population evolution  $\mathbb{R}^d$  with three different dimensions:  $d = 2$ ,  $d = 5$  and  $d = 10$ . Note that  $\Delta t$  is set to 0.2 for all datasets. The stochastic terms are all sampled from multivariate

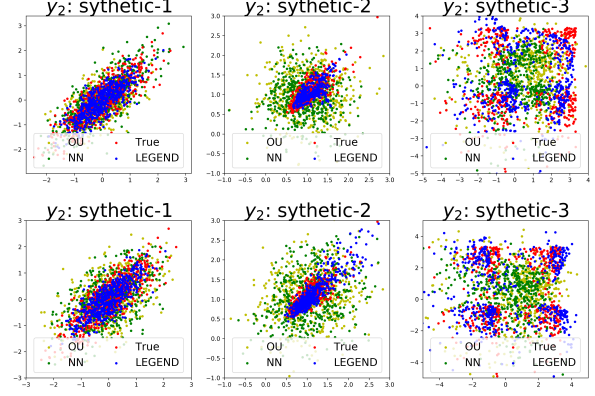

Figure 2: The true and predicted distributions for different models in filtering (top row) and smoothing (bottom row) based inference tasks on 2-dimensional synthetic-1 (left column), synthetic-2 (middle column) and synthetic-3 (right column) datasets.

normal distributions with covariance matrix  $\Sigma_0$  (diagonal elements are 0.0025 and others are 0.002).

Our proposed model along with the baselines are evaluated on two tasks: 1) filtering based inference: given observations  $y_0$  and  $y_1$ , the task is to predict  $y_2$ ; and 2) smoothing based inference: given observations  $y_0, y_1$  and  $y_3$ , the task is to predict  $y_2$ .

**Experimental Setup:** For our LEGEND model, we set  $D, \mathbf{f}, \mathbf{g}$  as a four-layer, two-layer and four-layer feed-forward neural network respectively with ReLU (Glorot et al., 2011) activation function, and set  $\mathbf{h}$  as a one-layer RNN with LSTM unit. In terms of training, we use the Adam optimizer (Kingma & Ba, 2014) with learning rate  $10^{-4}$ ,  $\beta_1 = 0.5$  and  $\beta_2 = 0.9$ . The baselines OU and NN are configured with respect to their settings in the original papers without using pre-training (Hashimoto et al., 2016).

**Results:** We first show the capability of our model for learning low-dimensional ( $d = 2$ ) diffusion dynamics. As visualized in Figure 2, given  $\{y_0\}$  and  $\{y_1\}$ , our model can precisely learn the dynamics and correctly predict  $y_2$  (top row) where a better match was observed between the predictions (blue points) and the ground truth (red points). Note that the dynamics on  $y_t$  become more and more complicated from synthetic-1 to synthetic-3. It can be seen from Figure 2 that our model works well on both simple and complex dynamics, while baselines OU and NN only work well on simple dynamics. Similar results are also observed in the smoothing based inference task, as shown in the bottom row of Figure 2.

We then evaluate our model using Wasserstein error for both low-dimensional ( $d = 2$ ) and high-dimensional ( $d =$

Table 1: The Wasserstein error of different models on synthetic-1/2/3 (Syn-1/2/3), RNA-seq (RNA) and bird migration (Bird) datasets. The best results are highlighted in **bold**.

5, 10) diffusion dynamics. Wasserstein error measures the difference between predicted distribution and the true distribution. As reported in Table 1, our model achieves much lower Wasserstein error than the two baselines on all the 3 datasets for 2/5/10-dimensional dynamics. The poor performance of OU and NN may due to the fact that  $y_t$  becomes more and more complicated as dimension increases on all three datasets. The superior performance of our model verifies the importance of hidden variables — they are necessary for the modeling of complex nonlinear dynamics and complex measurements of hidden states.

## 6.2 Real Data: Single-cell RNA-seq

In this section, we evaluate our model on a typical application of distribution based continuous diffusion dynamics in biology: learning the diffusion process where embryonic stem cells differentiate into mature cells (Klein et al., 2015). The cell population begins to differentiate from embryonic stem cells after the removal of LIF (leukemia inhibitory factor) at day 0 (D0). Single-cell RNA-seq measurements (or observations) are sampled at day 0 (D0), day 2 (D2), day 4 (D4), and day 7 (D7). At each time

Figure 3: The true and predicted marginal distributions of the differentiating genes at D7 (filtering based inference task) and D4 (smoothing based inference task) for different models.

Figure 4: The true (left column) and predicted (right 3 columns) correlations between Krt8 and Krt18 at D7 (top row) and D4 (bottom row). The closer to the true correlation the better the performance.

point, the expression of 24,175 genes for several hundreds cells are measured (933, 303, 683 and 798 cells at D0, D2, D4, and D7 respectively). We focus on the dynamics of cell differentiation for the two main epithelial makers studied in (Klein et al., 2015), *i.e.*, Keratin 8 (Krt8) and Keratin 18 (Krt18). We evaluate two tasks on this data: 1) filtering based inference: predicting the gene expression level at D7 given only the observations at D0 and D4; and 2) smoothing based inference: predicting the gene expression level at D4 given D0, D2 and D7.

**Experimental Setup:** We set  $f$  as a one-layer feed-forward neural network,  $g$  as a three-layer feed-forward neural network and  $h$  as a one-layer RNN with LSTM neurons. For preprocessing, we apply standard normalization procedures (Hicks et al., 2015) to correct for batch effects, and impute missing expression levels using non-negative matrix factorization, similarly as it did in (Hashimoto et al., 2016). The stochastic term  $\Sigma$  in SDE are sampled from multivariate normal distributions with diagonal covariance matrix (diagonal elements are 1). Other configurations and baselines are the same as those in Section 6.1.

**Results:** We first show in Table 1 that compared to other baselines our model achieves the lowest Wasserstein error in both filtering (D7) and smoothing (D4) tasks on both Krt8 and Krt18. This proves that our model is capable of learning the precise differentiation dynamics and the distributions of the two studied gene expressions. We further provide a closer look into the learned distributions of the two genes in Figure 3. As can be seen, the distributions of Krt8 and Krt18 predicted by our model (curves in blue) are much closer to their true distributions (curves in red) at both D4 and D7, as compared to the baseline models. Moreover, our model can effectively identify the correlations between Krt8 and Krt18, as shown in Figure 4. This implies that our model can accurately learn the dynamics even considering the correlational structure of the true dynamics.

### 6.3 Real Data: Bird Migration

We also evaluate our model on another typical application of distribution based diffusion dynamics: bird migration research in ecology. We use the eBird basic dataset (EBD), which gathers large volumes of information on where and when birds occur in the world (Sullivan et al., 2009). We down-sampled EBD to only include the tracking records for the species GrayJay between January, 2017 and June, 2017 (monthly data) at United States where 400 samples are randomly selected as observations for each month. There are again two tasks evaluated here: 1) filtering based inference: we apply our model on the months February and April so as to predict the population at June; 2) smoothing based inference: we apply our model on months February, March and June so as to predict the population at April. The experimental setups are the same as those in Section 6.2.

**Results:** We plot the true and predicted locations (longitude and latitude) of the species GrayJay in Figure 5, and report the Wasserstein error<sup>4</sup> in Table 1. Again, our model achieves the lowest Wasserstein error in both filtering (June) and smoothing (April) based inference tasks. The evolving dynamics of bird migration can be very complicated and extremely difficult to learn, mostly because bird migration could be affected by many irregular factors related to the specific time. Even so, with the introduction of the hidden state variable, our model can predict locations which are close to the ground truth, and with better performance than OU and NN which directly build models on observations. This result demonstrates the advantages of our framework in solving real-world problems involving complicated diffusion dynamics.

<sup>4</sup>Our model could be further improved if considering more complex hidden diffusion process, *e.g.*, jump diffusion process, but the framework is the same to this paper.

Figure 5: The true (left column) and predicted (right 3 columns) distributions of GrayJay species at month June (filtering based inference task) and April (smoothing based inference task) for different models.

## 7 CONCLUSIONS

In this paper, we formulated a novel technique to learn nonlinear continuous diffusion dynamics from *aggregate observations*. In particular, we showed how one can model dynamics as a *hidden continuous stochastic process*, and proposed a framework that employs a dynamic generative model with Wasserstein distance to learn the evolving dynamics. In addition to deriving solutions for both filtering and smoothing based inference tasks, we also established theoretical guarantees on the generalization and convergence properties of our framework. Through comprehensive experimental evaluation on synthetic and real-world datasets, we demonstrated that our approach has very strong performance compared to state-of-the-art techniques on both filtering and smoothing based inference tasks.

## Abstract

We revisit the problem of linear regression under a differential privacy constraint. By consolidating existing pieces in the literature, we clarify the correct dependence of the feature, label and coefficient domains in the optimization error and estimation error, hence revealing the delicate price of differential privacy in statistical estimation and statistical learning. Moreover, we propose simple modifications of two existing DP algorithms: (a) posterior sampling, (b) sufficient statistics perturbation, and show that they can be *upgraded* into adaptive algorithms that are able to exploit data-dependent quantities and behave nearly optimally *for every instance*. Extensive experiments are conducted on both simulated data and real data, which conclude that both ADAOPS and ADASSP outperform the existing techniques on nearly all 36 data sets that we test on.

## 1 INTRODUCTION

Linear regression is one of the oldest tools for data analysis (Galton, 1886) and it remains one of the most commonly-used as of today (Draper & Smith, 2014), especially in social sciences (Agresti & Finlay, 1997), econometrics (Greene, 2003) and medical research (Armitage et al., 2008). Moreover, many nonlinear models are either intrinsically linear in certain function spaces, e.g., kernels methods, dynamical systems, or can be reduced to solving a sequence of linear regressions, e.g., iterative reweighted least square for generalized Linear models, gradient boosting for additive models and so on (see Friedman et al., 2001, for a detailed review).

In order to apply linear regression to sensitive data such as those in social sciences and medical studies, it is of-

ten needed to do so such that the privacy of individuals in the data set is protected. Differential privacy (Dwork et al., 2006b) is a commonly-accepted criterion that provides provable protection against identification and is resilient to arbitrary auxiliary information that might be available to attackers. In this paper, we focus on linear regression with  $(\epsilon, \delta)$ -differentially privacy (Dwork et al., 2006a).

**Isn't it a solved problem?** It might be a bit surprising why this is still a problem, since several general frameworks of differential privacy have been proposed that cover linear regression. Specifically, in the agnostic setting (without a data model), linear regression is a special case of differentially private empirical risk minimization (ERM), and its theoretical properties have been quite well-understood in a sense that the minimax lower bounds are known (Bassily et al., 2014) and a number of algorithms (Chaudhuri et al., 2011; Kifer et al., 2012) have been shown to match the lower bounds under various assumptions. In the statistical estimation setting where we assume the data is generated from a linear Gaussian model, linear regression is covered by the sufficient statistics perturbation approach for exponential family models (Dwork & Smith, 2010; Foulds et al., 2016), propose-test-release framework (Dwork & Lei, 2009) as well as the the subsample-and-aggregate framework (Smith, 2008), with all three approaches achieving the asymptotic efficiency in the fixed dimension ( $d = O(1)$ ), large sample ( $n \rightarrow \infty$ ) regime.

Despite these theoretical advances, very few empirical evaluations of these algorithms were conducted and we are not aware of a commonly-accepted best practice. Practitioners are often left puzzled about which algorithm to use for the specific data set they have. The nature of differential privacy often requires them to set parameters of the algorithm (e.g., how much noise to add) according to the diameter of the parameter domain, as well as properties of a hypothetical worst-case data set, which often leads to

an inefficient use of their valuable data.

The main contribution of this paper is threefold:

1. We consolidated many bits and pieces from the literature and clarified the price of differential privacy in statistical estimation and statistical learning.
2. We carefully analyzed One Posterior Sample (OPS) and Sufficient Statistics Perturbation (SSP) for linear regression and proposed simple modifications of them into adaptive versions: ADAOPS and ADASSP. Both work near optimally for every problem instance without any hyperparameter tuning.
3. We conducted extensive real data experiments to benchmark existing techniques and concluded that the proposed techniques give rise to the more favorable privacy-utility tradeoff relative to existing methods.

**Outline of this paper.** In Section 2 we will describe the problem setup and explain differential privacy. In Section 3, we will survey the literature and discuss existing algorithms. Then we will propose and analyze our new method ADASSP and ADAOPS in Section 4 and conclude the paper with experiments in Section 5.

## 2 NOTATIONS AND SETUP

Throughout the paper we will use  $X \in \mathbb{R}^{n \times d}$  and  $\mathbf{y} \in \mathbb{R}^n$  to denote the design matrix and response vector. These are collections of data points  $(x_1, y_1), \dots, (x_n, y_n) \in \mathcal{X} \times \mathcal{Y}$ . We use  $\|\cdot\|$  to denote Euclidean norm for vector inputs,  $\ell_2$ -operator norm for matrix inputs. In addition, for set inputs,  $\|\cdot\|$  denotes the radius of the smallest Euclidean ball that contains the set. For example,  $\|\mathcal{Y}\| = \sup_{y \in \mathcal{Y}} |y|$  and  $\|\mathcal{X}\| = \sup_{x \in \mathcal{X}} \|x\|$ . Let  $\Theta$  be the domain of coefficients. Our results do not require  $\Theta$  to be compact but existing approaches often depend on  $\|\Theta\|$ .  $\lesssim$  and  $\gtrsim$  denote greater than or smaller to up to a universal multiplicative constant, which is the same as the big  $O(\cdot)$  and the big  $\Omega(\cdot)$ .  $\tilde{O}(\cdot)$  hides at most a logarithmic term.  $\prec$  and  $\succ$  denote the standard semidefinite ordering of positive semi-definite (psd) matrices.  $\cdot \vee \cdot$  and  $\cdot \wedge \cdot$  denote the bigger or smaller of the two inputs.

We now define a few data dependent quantities. We use  $\lambda_{\min}(X^T X)$  (abbrv.  $\lambda_{\min}$ ) to denote the smallest eigenvalue of  $X^T X$ , and to make the implicit dependence in  $d$  and  $n$  clear from this quantity, we define  $\alpha := \lambda_{\min} \frac{d}{n \|\mathcal{X}\|^2}$ . One can think of  $\alpha$  as a normalized smallest eigenvalue of  $X^T X$  such that  $0 \leq \alpha \leq 1$ . Also,  $1/\alpha$  is closely related to the condition number of  $X^T X$ .

Define the least square solution  $\theta^* = (X^T X)^\dagger X^T \mathbf{y}$ . It is the optimal solution to  $\min_{\theta} \frac{1}{2} \|\mathbf{y} - X\theta\|^2 =: F(\theta)$ . Similarly, we use  $\theta_\lambda^* = (X^T X + \lambda I)^{-1} X^T \mathbf{y}$  denotes the optimal solution to the ridge regression objective  $F_\lambda(\theta) = F(\theta) + \lambda \|\theta\|^2$ .

In addition, we denote the global Lipschitz constant of  $F$  as  $L^* := \|\mathcal{X}\|^2 \|\Theta\| + \|\mathcal{X}\| \|\mathcal{Y}\|$  and data-dependent local Lipschitz constant at  $\theta^*$  as  $L := \|\mathcal{X}\|^2 \|\theta^*\| + \|\mathcal{X}\| \|\mathcal{Y}\|$ . Note that when  $\Theta = \mathbb{R}^d$ ,  $L^* = \infty$ , but  $L$  will remain finite for every given data set.

**Metric of success.** We measure the performance of an estimator  $\hat{\theta}$  in two ways.

First, we consider the optimization error  $F(\hat{\theta}) - F(\theta^*)$  in expectation or with probability  $1 - \rho$ . This is related to the prediction accuracy in the distribution-free statistical learning setting.

Second, we consider how well the coefficients can be estimated under the linear Gaussian model:

$$\mathbf{y} = X\theta_0 + \mathcal{N}(0, \sigma^2 I_n)$$

in terms of  $\mathbb{E}[\|\hat{\theta} - \theta_0\|^2]$  or in some cases  $\mathbb{E}[\|\hat{\theta} - \theta_0\|^2 | E]$  where  $E$  is a high probability event.

The optimal error in either case will depend on the specific design matrix  $X$ , optimal solution  $\theta^*$ , the data domain  $\mathcal{X}, \mathcal{Y}$ , the parameter domain  $\Theta$  as well as  $\theta_0, \sigma^2$  in the statistical estimation setting.

**Differential privacy.** We will focus on estimators that are differential private, as defined below.

**Definition 1** (Differential privacy (Dwork et al., 2006b)). *We say a randomized algorithm  $\mathcal{A}$  satisfies  $(\epsilon, \delta)$ -DP if for all fixed data set  $(X, \mathbf{y})$  and data set  $(X', \mathbf{y}')$  that can be constructed by adding or removing one row  $(x, y)$  from  $(X, \mathbf{y})$ , and for any measurable set  $\mathcal{S}$  over the probability of the algorithm*

$$\mathbb{P}(\mathcal{A}((X, \mathbf{y})) \in \mathcal{S}) \leq e^\epsilon \mathbb{P}(\mathcal{A}((X', \mathbf{y}')) \in \mathcal{S}) + \delta,$$

Parameter  $\epsilon$  represents the amount of privacy loss from running the algorithm and  $\delta$  denotes a small probability of failure. These are user-specified targets to achieve and the differential privacy guarantee is considered meaningful if  $\epsilon \leq 1$  and  $\delta \ll 1/n$  (see, e.g., Section 2.3.3 of Dwork et al., 2014a, for a comprehensive review).

**The pursuit for adaptive estimators.** Another important design feature that we will mention repeatedly in this paper is *adaptivity*. We call an estimator  $\hat{\theta}$  *adaptive* if it behaves optimally simultaneously for a wide range of parameter choices. Being adaptive is of great practical

relevance because we do not need to specify the class of problems or worry about whether our specification is wrong (see examples of adaptive estimators in e.g., [Donoho, 1995](#); [Birgé & Massart, 2001](#)). *Adaptivity* is particularly important for differentially private data analysis because often we need to decide the amount of noise to add by the size of the domain. For example, an adaptive algorithm will not rely on conservative upper bounds of  $\theta_0$ , or a worst case  $\lambda_{\min}$  (which would be 0 on any  $\mathcal{X}$ ), and it can take advantage of favorable properties when they exist in the data set. We want to design an estimator that does not take these parameters as inputs and behave nearly optimally for every fixed data set  $X \in \mathcal{X}^n, \mathbf{y} \in \mathcal{Y}$  under a variety of configuration of  $\|\mathcal{X}\|, \|\mathcal{Y}\|, \|\Theta\|$ .

### 3 A SURVEY OF PRIOR WORK

In this section, we summarize existing theoretical results in linear regression with and without differential privacy constraints. We will start with lower bounds.

#### 3.1 Information-theoretic lower bounds

**Lower bounds under linear Gaussian model.** Under the statistical assumption of linear Gaussian model  $\mathbf{y} = X\theta_0 + \mathcal{N}(0, \sigma^2)$ , the minimax risk for both estimation and prediction are crisply characterized for each fixed design matrix  $X$ :

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathbb{R}^d} \mathbb{E}[F(\hat{\theta}) - F(\theta_0)|X] = \frac{d\sigma^2}{2}, \quad (1)$$

and if we further assume that  $n \geq d$  and  $X^T X$  is invertible (for identifiability), then

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathbb{R}^d} \mathbb{E}[\|\hat{\theta} - \theta_0\|_2^2|X] = \sigma^2 \text{tr}[(X^T X)^{-1}]. \quad (2)$$

In the above setup,  $\hat{\theta}$  is any measurable function of  $\hat{\mathbf{y}}$  (note that  $X$  is fixed). These are classic results that can be found in standard statistical decision theory textbooks (See, e.g., [Wasserman, 2013](#), Chapter 13).

Under the same assumptions, the Cramer-Rao lower bound mandates that the covariance matrix of any unbiased estimator  $\hat{\theta}$  of  $\theta_0$  to obey that

$$\text{Cov}(\hat{\theta}) \succ \sigma^2 (X^T X)^{-1}. \quad (3)$$

This bound applies to every problem instance separately and also implies a sharp lower bound on the prediction variance on every data point  $x$ . More precisely,  $\text{Var}(\hat{\theta}^T x) \geq \sigma^2 x^T (X^T X)^{-1} x$  for any  $x$ .

Minimax risk (1), (2) and the Cramer-Rao lower bound (3) are simultaneously attained by  $\theta^*$ .

**Statistical learning lower bounds.** Perhaps much less well-known, linear regression is also thoroughly studied in the distribution-free statistical learning setting, where the only assumption is that the data are drawn iid from some unknown distribution  $\mathcal{P}$  defined on some compact domain  $\mathcal{X} \times \mathcal{Y}$ . Specifically, let the risk ( $\mathbb{E}[\text{loss}]$ ) be

$$R(\theta) = \mathbb{E}_{(x,y) \sim \mathcal{P}} \left[ \frac{1}{2} (x^T \theta - y)^2 \right] = \frac{1}{n} \mathbb{E}_{(X,\mathbf{y}) \sim \mathcal{P}^n} [F(\theta)].$$

[Shamir \(2015\)](#) showed that when  $\Theta, \mathcal{X}$  are  $\mathcal{Y}$  are Euclidean balls,

$$\begin{aligned} & \inf_{\hat{\theta}} \sup_{\mathcal{P}} \left[ \mathbb{E}[n \cdot R(\hat{\theta})] - \inf_{\theta \in \Theta} [n \cdot R(\theta)] \right] \\ & \gtrsim \min\{n\|\mathcal{Y}\|^2, \|\Theta\|^2\|\mathcal{X}\|^2 + d\|\mathcal{Y}\|^2, \sqrt{n}\|\Theta\|\|\mathcal{X}\|\|\mathcal{Y}\|\}. \end{aligned} \quad (4)$$

where  $\hat{\theta}$  be any measurable function of the data set  $X, \mathbf{y}$  to  $\Theta$  and the expectation is taken over the data generating distribution  $X, \mathbf{y} \sim \mathcal{P}^n$ . Note that to be compatible to other bounds that appear in this paper, we multiplied the  $R(\cdot)$  by a factor of  $n$ . Informally, one can think of  $\|\mathcal{Y}\|$  as  $\sigma$  in (1) so both terms depend on  $d\sigma^2$  (or  $d\|\mathcal{Y}\|^2$ ), but the dependence on  $\|\Theta\|\|\mathcal{X}\|$  is new for the distribution-free setting.

[Koren & Levy \(2015\)](#) later showed that this lower bound is matched up to a constant by Ridge Regression with  $\lambda = 1$  and both [Koren & Levy \(2015\)](#) and [Shamir \(2015\)](#) conjecture that ERM without additional regularization should attain the lower bound (4). If the conjecture is true, then the unconstrained OLS is simultaneously optimal for all distributions supported on the smallest ball that contains all data points in  $X, \mathbf{y}$  for any  $\Theta$  being an  $\ell_2$  ball with radius larger than  $\|\theta^*\|$ .

**Lower bounds with  $(\epsilon, \delta)$ -privacy constraints.** Suppose that we further require  $\hat{\theta}$  to be  $(\epsilon, \delta)$ -differentially private, then there is an additional price to pay in terms of how accurately we can approximate the ERM solution. Specifically, the lower bounds for the *empirical* excess risk for differentially private ERM problem in ([Bassily et al., 2014](#)) implies that for  $\delta < 1/n$  and sufficiently large  $n$ :

1. There exists a triplet of  $(\mathcal{X}, \mathcal{Y}, \Theta) \subset \mathbb{R}^d \times \mathbb{R} \times \mathbb{R}^d$ , such that

$$\begin{aligned} & \inf_{\hat{\theta} \text{ is } (\epsilon, \delta)\text{-DP}} \sup_{X \in \mathcal{X}^n, \mathbf{y} \in \mathcal{Y}^n} \left[ F(\hat{\theta}) - \inf_{\theta \in \Theta} F(\theta) \right] \\ & \gtrsim \min\{n\|\mathcal{Y}\|^2, \frac{\sqrt{d}(\|\mathcal{X}\|^2\|\Theta\|^2 + \|\mathcal{X}\|\|\Theta\|\|\mathcal{Y}\|)}{\epsilon}\}. \end{aligned} \quad (5)$$

2. Consider the class of data set  $\mathcal{S}$  where all data sets  $X \in \mathcal{S} \subset \mathcal{X}^n$  obeys that the inverse condition number  $\alpha \geq \alpha^* \geq \frac{d^{1.5}(\|\mathcal{X}\|\|\Theta\| + \|\mathcal{Y}\|)}{n\|\mathcal{X}\|\|\Theta\|\epsilon}$ . There exists a

<sup>1</sup>This requires  $\lambda_{\min} \geq \sqrt{dL}/\epsilon$  for all data sets  $X$ .

triplet of  $(\mathcal{X}, \mathcal{Y}, \Theta) \subset \mathbb{R}^d \times \mathbb{R} \times \mathbb{R}^d$  such that

$$\hat{\theta} \text{ is } (\epsilon, \delta)\text{-DP } X \in \mathcal{S}, \mathbf{y} \in \mathcal{Y}^n \left[ F(\hat{\theta}) - \inf_{\theta \in \Theta} F(\theta) \right] \quad (6)$$

$$\gtrsim \min \left\{ n \|\mathcal{Y}\|^2, \frac{d^2 (\|\mathcal{X}\| \|\Theta\| + \|\mathcal{Y}\|)^2}{n \alpha^* \epsilon^2} \right\}.$$

These bounds are attained by a number of algorithms, which we will go over in Section 3.2.

Comparing to the non-private minimax rates on prediction accuracy, the bounds look different in several aspects. First, neither rate for prediction error in (1) or (4) depends on whether the design matrix  $X$  is well-conditioned or not, while  $\alpha^*$  appears explicitly in (6). Secondly, the dependence on  $\|\Theta\|, \|\mathcal{X}\|, \|\mathcal{Y}\|, d, n$  are different, which makes it hard to tell whether the optimization error lower bound due to privacy requirement is limiting. One may ask the following question:

When is privacy *for free* in statistical learning?

Specifically, what is the smallest  $\epsilon$  such that an  $(\epsilon, \delta)$ -DP algorithm matches the minimax rate in (4)? The answer really depends on the relative scale of  $\|\mathcal{X}\| \|\Theta\|$  and  $\|\mathcal{Y}\|$  and that of  $n, d$ . When  $\|\mathcal{X}\| \|\Theta\| \asymp \|\mathcal{Y}\|$ , (5) says that  $(\epsilon, \delta)$ -DP algorithms can achieve the nonconvex minimax rate provided that  $\epsilon \gtrsim \min \left\{ \frac{1}{\sqrt{d}} \sqrt{\frac{d}{n}}, \sqrt{\frac{d^2}{n^{1.5} \alpha^*}} \sqrt{\frac{d}{n \alpha^*}} \right\}$ . On the other hand, if  $\|\mathcal{X}\| \|\Theta\| \asymp \sqrt{d} \|\mathcal{Y}\|^2$  and  $n > d$ , then we need  $\epsilon \gtrsim \min \left\{ \sqrt{d} \sqrt{\frac{d^{3/2}}{n}}, \frac{d}{\sqrt{n \alpha^*}} \sqrt{\frac{d^{3/2}}{n \alpha^*}} \right\}$ .

The regions are illustrated graphically in Figure 1. In the first case, there is a large region upon  $n \gtrsim d$ , where meaningful differential privacy (with  $\epsilon \leq 1$  and  $\delta = o(1/n)$ ) can be achieved without incurring a significant toll relative to (4). In the second case, we need at least  $n \gtrsim d^2$  to achieve ‘‘privacy-for-free’’ in the most favorable case where  $\alpha^* = 1$ . In the case when  $X$  could be rank-deficient, then it is infeasible to achieve ‘‘privacy for free’’ no matter how large  $n$  is.

It might be tempting to conclude that one should always prefer Case 1 over Case 2. This is unfortunately not true because the artificial restriction of the model class via a bounded  $\|\Theta\|$  also weakens our non-private baseline. In other word, the best solution within a small  $\Theta$  might be significantly worse than the best solution in  $\mathbb{R}^d$ .

In practice, it is hard to find a  $\Theta$  with a small radius that fits all purposes<sup>3</sup> and it is unreasonable to assume  $\alpha^* > 0$ .

<sup>2</sup>This is arguably the more relevant setting. Note that if  $x \sim \mathcal{N}(0, I_d)$  and  $\theta$  is fixed, then  $x^T \theta = O_P(d^{-1/2} \|x\| \|\theta\|)$ .

<sup>3</sup>If  $\|\Theta\| \gg \|\theta^*\|$  then the constraint becomes limiting. If  $\|\theta^*\| \ll \|\Theta\|$  instead, then calibrating the noise according to  $\|\Theta\|$  will inject more noise than necessary.

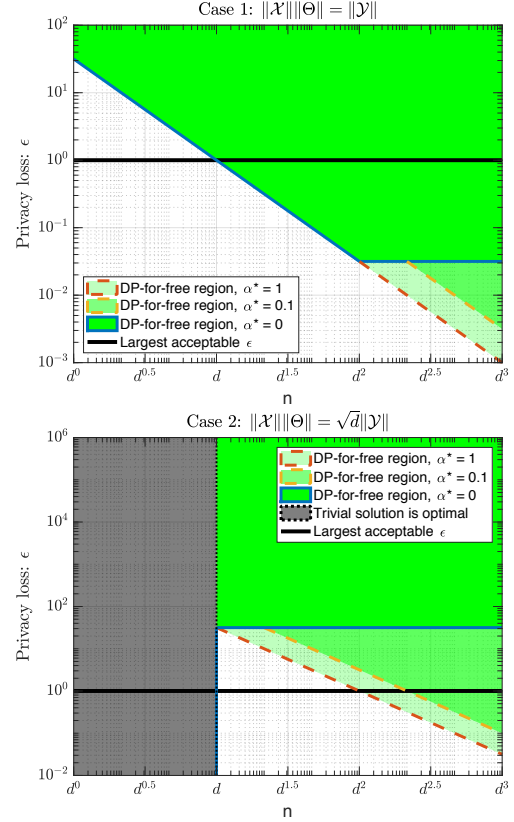

Figure 1: Illustration of the region of  $\epsilon$  where DP can be obtained without losing minimax rate (4). [Zoom to see!]

This motivates us to go beyond the worst-case and come up with *adaptive* algorithms that work without knowing  $\|\theta^*\|$  and  $\alpha$  while achieving the minimax rate for the class with  $\|\Theta\| = \|\theta^*\|$  and  $\alpha^* = \alpha$  (in hindsight).

In Appendix B, we provide an alternative illustration of the lower bounds and highlight the price of differential privacy for different configuration of  $n, d, \alpha, \epsilon$ .

### 3.2 Existing algorithms and our contribution

We now survey the following list of five popular algorithms in differentially private learning and highlight the novelty in our proposals<sup>4</sup>.

1. Sufficient statistics perturbation (SSP) (Vu & Slavkovic, 2009; Foulds et al., 2016): Release  $X^T X$  and  $X \mathbf{y}$  differentially privately and then output  $\hat{\theta} = (\widehat{X^T X})^{-1} \widehat{X \mathbf{y}}$ .
2. Objective perturbation (OBJPERT) (Kifer et al.,

<sup>4</sup>While we try to be as comprehensive as possible, the literature has grown massively and the choice of this list is limited by our knowledge and opinions.

2012):  $\hat{\theta} = \operatorname{argmin} F(\theta) + 0.5\lambda\|\theta\|^2 + Z^T\theta$  with an appropriate  $\lambda$  and  $Z$  is an appropriately chosen iid Gaussian random vector.

3. Subsample and Aggregate (Sub-Agg) (Smith, 2008; Dwork & Smith, 2010): Subsample many times, apply debiased MLE to each subset and then randomize the way we aggregate the results.
4. Posterior sampling (OPS) (Mir, 2013; Dimitrakakis et al., 2014; Wang et al., 2015; Minami et al., 2016): Output  $\hat{\theta} \sim P(\theta) \propto e^{-\gamma(F(\theta)+0.5\lambda\|\theta\|^2)}$  with parameters  $\gamma, \lambda$ .
5. NOISYSGD (Bassily et al., 2014): Run SGD for a fixed number of iterations with additional Gaussian noise added to the stochastic gradient evaluated on one randomly-chosen data point.

We omit detailed operational aspects of these algorithms and focus our discussion on their theoretical guarantees. Interested readers are encouraged to check out each paper separately. These algorithms are proven under different scalings and assumptions. To ensure fair comparison, we make sure that all results are converted to our setting under a subset of the following assumptions.

A.1  $\|\mathcal{X}\|$  is bounded,  $\|\mathcal{Y}\|$  is bounded.

A.2  $\|\Theta\|$  is bounded.

A.3 All possible data sets  $X$  obey that the smallest eigenvalue  $\lambda_{\min}(X^T X)$  is greater than  $\frac{n\|\mathcal{X}\|^2}{d}\alpha^*$ .

Note that A.3 is a restriction on the domain of the data set, rather than the domain of individual data points in the data set of size  $n$ . While it is a little unconventional, it is valid to define differential privacy within such a restricted space of data sets. It is the same assumption that we needed to assume for the lower bound in (6) to be meaningful. As in Koren & Levy (2015), we simplify the expressions of the bound by assuming  $\|\mathcal{Y}\| \leq \|\mathcal{X}\|\|\Theta\|$ , and in addition, we assume that  $\|\mathcal{Y}\| \lesssim \|\mathcal{X}\|\|\theta^*\|$ .

Table 1 summarizes the upper bounds of optimization error the aforementioned algorithms in comparison to our two proposals: ADAOPS and ADASSP. Comparing the rates to the lower bounds in the previous section, it is clear that NoisySGD, OBJPERT both achieve the minimax rate in optimization error but their hyperparameter choice depends on the unknown  $\|\Theta\|$  and  $\alpha^*$ . SSP is adaptive to  $\alpha$  and  $\|\theta^*\|$  but has a completely different type of issue — it can fail arbitrarily badly for regime covered under (5), and even for well-conditioned problems, its theoretical guarantees only kick in as  $n$  gets very large. Our proposed algorithms ADAOPS and ADASSP are able to simultaneously switch between the two regimes and get the best of both worlds.

Table 2 summarizes the upper bounds for estimation. The second row compares the approximation of  $\theta^*$  in MSE and the third column summarizes the statistical efficiency of the DP estimators relative to the MLE:  $\theta^*$  under the linear Gaussian model. All algorithms except OPS are asymptotically efficient. For the interest of  $(\epsilon, \delta)$ -DP, SSP has the fastest convergence rate and does not explicitly depend on the smallest eigenvalue, but again it behaves differently when  $n$  is small, while ADAOPS and ADASSP work optimally (up to a constant) for all  $n$ .

### 3.3 Other related work

The problem of adaptive estimation is closely related to model selection (see, e.g., Birgé & Massart, 2001) and an approach using Bayesian Information Criteria was carefully studied in the differential private setting for the problem of  $\ell_1$  constrained ridge regression by Lei et al. (2017). Their focus is different to ours in that they care about inferring the correct model, while we take the distribution-free view. Linear regression is also studied in many more specialized setups, e.g., high dimensional linear regression (Kifer et al., 2012; Talwar et al., 2014, 2015), statistical inference (Sheffet, 2017) and so on. For the interest of this paper, we focus on the standard regime of linear regression where  $d < n$  and do not use sparsity or  $\ell_1$  constraint set to achieve the  $\log(d)$  dependence. That said, we acknowledge that Sheffet (2017) analyzed SSP under the linear Gaussian model (the third row in Table 2) and their techniques of adaptively adding regularization have inspired ADASSP.

## 4 MAIN RESULTS

In this section, we present and analyze ADAOPS and ADASSP that achieve the aforementioned adaptive rate. The pseudo-code of these two algorithms are given in Algorithm 1 and Algorithm 2.

The idea of both algorithms is to release key data-dependent quantities differentially privately and then use a high probability confidence interval of these quantities to calibrate the noise to privacy budget as well as to choose the ridge regression’s hyperparameter  $\lambda$  for achieving the smallest prediction error. Specifically, ADAOPS requires us to release both the smallest eigenvalue  $\lambda_{\min}$  of  $X^T X$  and the local Lipschitz constant  $L := \|\mathcal{X}\|(\|\mathcal{X}\|\|\theta_x^*\| + \|\mathcal{Y}\|)$ , while ADASSP only needs the smallest eigenvalue  $\lambda_{\min}$ .

In both ADASSP and ADAOPS, we choose  $\lambda$  by minimizing an upper bound of  $F(\hat{\theta}) - F(\theta^*)$  in the form of “variance” and “bias”

$$\tilde{O}\left(\frac{d\|\mathcal{X}\|^4\|\theta^*\|^2}{\lambda + \lambda_{\min}}\right) + \lambda\|\theta^*\|^2.$$

Table 1: Summary of optimization error bounds. This table compares the (expected or high probability ) additive suboptimality of different differentially private linear regression procedures relative to the (non-private) empirical risk minimizer  $\theta^*$ . In particular, the results for NoisySGD holds in expectation and everything else with probability  $1 - \rho$  (hiding at most a logarithmic factor in  $\sqrt{1/\rho}$ ). Constant factors are dropped for readability.

	$F(\hat{\theta}) - F(\theta^*)$	Assumptions	Remarks
NoisySGD	$\frac{\sqrt{d \log(\frac{n}{\delta})} \ \mathcal{X}\ ^2 \ \Theta\ ^2}{\epsilon}$	A.1, A.2	Theorem 2.4 (Part 1) of (Bassily et al., 2014).

OBJPERT	$\frac{\sqrt{d \log(\frac{1}{\delta})} \ \mathcal{X}\ ^2 \ \Theta\  \ \theta^*\ }{\epsilon}$	A.1, A.2	Theorem 4 (Part 2) of (Kifer et al., 2012).
	$\frac{d^2 \log(\frac{1}{\delta}) \ \Theta\ ^2}{\alpha^* n \epsilon^2}$	A.1, A.2, A.3	Theorem 5 & Appendix E.2 of (Kifer et al., 2012).
OPS	$\frac{d \ \mathcal{X}\ ^2 \ \Theta\ ^2}{\epsilon}$	A.1, A.2	Results for $\epsilon$ -DP (Wang et al., 2015)
SSP	$\frac{d^2 \log(\frac{1}{\delta}) \ \mathcal{X}\ ^2 \ \theta^*\ ^2}{\alpha n \epsilon^2}$	A.1	Adaptive to $\ \theta^*\ , X, \alpha$ , but requires $n = \Omega(\frac{d^{1.5} \log(4/\delta)}{\alpha \epsilon})^5$ .
ADAOPS & ADASSP	$\frac{\sqrt{d \log(\frac{1}{\delta})} \ \mathcal{X}\ ^2 \ \theta^*\ ^2}{\epsilon} \wedge \frac{d^2 \log(\frac{1}{\delta}) \ \theta^*\ ^2}{\alpha n \epsilon^2}$	A.1	Adaptive in $\ \theta^*\ , X, \alpha$ .

Table 2: Summary of estimation error bounds under the linear Gaussian model. On the second column we compare the approximation of MLE  $\theta^*$  in mean square error up to a universal constant. On the third column, we compare the relative efficiency. The relative efficiency bounds are simplified with the assumption of  $\alpha = \Omega(1)$ , which implies that  $\text{tr}[(X^T X)^{-1}] = O(d^2 n^{-1} \|\mathcal{X}\|^{-2})$  and  $\text{tr}[(X^T X)^{-2}] = O(d n^{-1} \|\mathcal{X}\|^{-2} \text{tr}[(X^T X)^{-1}])$ .  $\tilde{O}(\cdot)$  hides  $\text{polylog}(1/\delta)$  terms.

	Approx. MLE: $\mathbb{E} \ \hat{\theta} - \theta^*\ ^2$	Rel. efficiency: $\frac{\mathbb{E} \ \hat{\theta} - \theta_0\ ^2}{\mathbb{E} \ \theta^* - \theta_0\ ^2}$	Remarks
Sub-Agg	$O\left(\frac{\text{poly}(d, \ \Theta\ , \ \mathcal{X}\ , \alpha^{-1})}{\epsilon^{6/5} n^{6/5}}\right)$	$1 + \tilde{O}\left(\frac{\text{poly}(d, \ \Theta\ , \ \mathcal{X}\ )}{n^{1/5} \epsilon^{6/5}}\right)$	$\epsilon$ -DP, suboptimal in $n$ , possibly also in $d$ (Dwork & Smith, 2010).
OPS	$O\left(\frac{\ \mathcal{X}\ ^2 \ \Theta\ ^2}{\epsilon} \text{tr}[(X^T X)^{-1}]\right)$	$\tilde{O}\left(\frac{\ \mathcal{X}\ ^2 \ \Theta\ ^2}{\epsilon \sigma^2}\right)$	$\epsilon$ -DP, adaptive in $X$ , but not asymptotically efficient (Wang et al., 2015).
SSP	$O\left(\frac{\log(\frac{1}{\delta}) \ \mathcal{X}\ ^4 \ \theta^*\ ^2}{\epsilon^2} \text{tr}[(X^T X)^{-2}]\right)$	$1 + \tilde{O}\left(\frac{d \ \mathcal{X}\ ^2 \ \theta_0\ ^2}{n \epsilon^2 \sigma^2} + \frac{d^3}{n^2 \epsilon^2}\right)$	Adaptive in $\ \theta^*\ , X$ , no explicit dependence on $\alpha$ , but requires large $n$ . (Sheffet, 2017, Theorem 5.1)
ADAOPS & ADASSP	$O\left(\frac{d \log(\frac{1}{\delta}) \ \mathcal{X}\ ^2 \ \theta^*\ ^2}{\alpha n \epsilon^2} \text{tr}[(X^T X)^{-1}]\right)$	$1 + \tilde{O}\left(\frac{d \ \mathcal{X}\ ^2 \ \theta_0\ ^2}{n \epsilon^2 \sigma^2} + \frac{d^3}{n^2 \epsilon^2}\right)$	Adaptive in $\ \theta^*\ , X, \alpha$ .

---

**Algorithm 1** ADAOPS: One-Posterior Sample estimator with adaptive regularization
 

---

**input** Data  $X, \mathbf{y}$ . Privacy budget:  $\epsilon, \delta$ , Bounds:  $\|\mathcal{X}\|, \|\mathcal{Y}\|$ .

1. Calculate the minimum eigenvalue  $\lambda_{\min}(X^T X)$ .
2. Sample  $Z \sim \mathcal{N}(0, 1)$  and privately release

$$\tilde{\lambda}_{\min} = \max \left\{ \lambda_{\min} + \frac{\sqrt{\log(6/\delta)}}{\epsilon/4} Z - \frac{\log(6/\delta)}{\epsilon/4}, 0 \right\}.$$

3. Set  $\bar{\epsilon}$  as the positive solution of the quadratic equation

$$\bar{\epsilon}^2 / (2 \log(6/\delta)) + \bar{\epsilon} - \epsilon/4 = 0.$$

4. Set  $\varrho = 0.05$ ,  $C_1 = (d/2 + \sqrt{d \log(1/\varrho)} + \log(1/\varrho)) \log(6/\delta) / \bar{\epsilon}^2$ ,  $C_2 = \log(6/\delta) / (\epsilon/4)$ ,  $t_{\min} = \max \left\{ \frac{\|\mathcal{X}\|^2 (1 + \log(6/\delta))}{2\epsilon} - \tilde{\lambda}_{\min}, 0 \right\}$  and solve

$$\lambda = \underset{t \geq t_{\min}}{\operatorname{argmin}} \frac{\|\mathcal{X}\|^4 C_1 [1 + \|\mathcal{X}\|^2 / (t + \tilde{\lambda}_{\min})]^{2C_2}}{t + \tilde{\lambda}_{\min}} + t. \quad (7)$$

which has a unique solution.

5. Calculate  $\hat{\theta} = (X^T X + \lambda I)^{-1} X^T \mathbf{y}$ .

6. Sample  $Z \sim \mathcal{N}(0, 1)$  and privately release

$$\Delta = \log(\|\mathcal{Y}\| + \|\mathcal{X}\| \|\hat{\theta}\|) + \frac{\log(1 + \|\mathcal{X}\|^2 / (\lambda + \tilde{\lambda}_{\min}))}{\epsilon / (4 \sqrt{\log(6/\delta)})} Z +$$

$$\frac{\log(1 + \|\mathcal{X}\|^2 / (\lambda + \tilde{\lambda}_{\min}))}{\epsilon / (4 \log(6/\delta))}. \text{ Set } \tilde{L} := \|\mathcal{X}\| e^{\Delta}.$$

7. Calibrate noise by choosing  $\tilde{\epsilon}$  as the positive solution of the quadratic equation

$$\frac{\tilde{\epsilon}^2}{2} \left[ \frac{1}{\log(6/\delta)} \frac{1 + \log(6/\delta)}{\log(6/\delta)} \right] + \tilde{\epsilon} - \epsilon/2 = 0. \quad (8)$$

and then set  $\gamma = \frac{(\tilde{\lambda}_{\min} + \lambda) \tilde{\epsilon}^2}{\log(6/\delta) \tilde{L}^2}$ .

**output**  $\tilde{\theta} \sim p(\theta | X, \mathbf{y}) \propto e^{-\frac{\gamma}{2} (\|\mathbf{y} - X\theta\|^2 + \lambda \|\theta\|^2)}$ .

---

Note that while  $\|\theta^*\|^2$  cannot be privately released in general due to unbounded sensitivity, it appears in both terms and do not enter the decision process of finding the optimal  $\lambda$  that minimizes the bound. This convenient feature follows from our assumption that  $\|\mathcal{Y}\| \lesssim \|\mathcal{X}\| \|\theta^*\|$ . Dealing with the general case involving an arbitrary  $\|\mathcal{Y}\|$  is an intriguing open problem.

A tricky situation for ADAOPS is that the choice of  $\gamma$  depends on  $\lambda$  through  $\tilde{L}$ , which is the local Lipschitz constant at the ridge regression solution  $\theta_\lambda^*$ . But the choice of  $\lambda$  also depends on  $\gamma$  since the ‘‘variance’’ term above is inversely proportional to  $\gamma$ . Our solution is to express  $\tilde{L}$  (hence  $\gamma$ ) as a function of  $\lambda$  and solve the nonlinear univariate optimization problem (7).

We are now ready to state the main results.

**Theorem 2.** *Algorithm 1 outputs  $\tilde{\theta}$  which obeys that*

- (i) *It satisfies  $(\epsilon, \delta)$ -DP.*

---

**Algorithm 2** ADASSP: Sufficient statistics perturbation with adaptive damping
 

---

**input** Data  $X, \mathbf{y}$ . Privacy budget:  $\epsilon, \delta$ , Bounds:  $\|\mathcal{X}\|, \|\mathcal{Y}\|$ .

1. Calculate the minimum eigenvalue  $\lambda_{\min}(X^T X)$ .

2. Privately release  $\tilde{\lambda}_{\min} = \max \left\{ \lambda_{\min} + \frac{\sqrt{\log(6/\delta)}}{\epsilon/3} \|\mathcal{X}\|^2 Z - \frac{\log(6/\delta)}{\epsilon/3} \|\mathcal{X}\|^2, 0 \right\}$ , where  $Z \sim \mathcal{N}(0, 1)$ .

3. Set  $\lambda = \max \left\{ 0, \frac{\sqrt{d \log(6/\delta) \log(2d^2/\rho)} \|\mathcal{X}\|^2}{\epsilon/3} - \tilde{\lambda}_{\min} \right\}$

4. Privately release  $\widehat{X^T X} = X^T X + \frac{\sqrt{\log(6/\delta)} \|\mathcal{X}\|^2}{\epsilon/3} Z$  for  $Z \in \mathbb{R}^{d \times d}$  is a symmetric matrix and every element from the upper triangular matrix is sampled from  $\mathcal{N}(0, 1)$ .

5. Privately release  $\widehat{X \mathbf{y}} = X \mathbf{y} + \frac{\sqrt{\log(6/\delta)} \|\mathcal{X}\| \|\mathcal{Y}\|}{\epsilon/3} Z$  for  $Z \sim \mathcal{N}(0, I_d)$ .

**output**  $\tilde{\theta} = (\widehat{X^T X} + \lambda I)^{-1} \widehat{X \mathbf{y}}$

---

- (ii) *Assume  $\|\mathcal{Y}\| \lesssim \|\mathcal{X}\| \|\theta^*\|$ . With probability  $1 - \varrho$ ,  $F(\tilde{\theta}) - F(\theta^*) \leq$*

$$O \left( \frac{\sqrt{d + \log(\frac{1}{\varrho})} \|\mathcal{X}\|^2 \|\theta^*\|^2}{\epsilon / \sqrt{\log(\frac{1}{\varrho})}} \wedge \frac{d [d + \log(\frac{1}{\varrho})] \|\theta^*\|^2}{\alpha n \epsilon^2 / \log(\frac{1}{\varrho})} \right).$$

- (iii) *Assume that  $\mathbf{y} | X$  obeys a linear Gaussian model and  $X$  is full-rank. Then there is an event  $E$  satisfying  $\mathbb{P}(E) \geq 1 - \delta/3$  and  $E \perp \mathbf{y} | X$ , such that  $\mathbb{E}[\tilde{\theta} | X, E] = \theta_0$  and*

$$\operatorname{Cov}[\tilde{\theta} | X, E] \prec \left( 1 + O \left( \frac{\tilde{C} d \log(6/\delta)}{\sigma^2 \alpha n \epsilon^2} \right) \right) \sigma^2 (X^T X)^{-1}$$

where constant

$$\tilde{C} := \|\mathcal{Y}\|^2 + \|\mathcal{X}\|^2 (\|\theta_0\|^2 + \sigma^2 \operatorname{tr}[(X^T X)^{-1}]).$$

The proof, deferred to Appendix D, makes use of a fine-grained DP-analysis through the recent per instance DP techniques (Wang, 2017) and then convert the results to DP by releasing data dependent bounds of  $\alpha$  and the magnitude of a ridge-regression output  $\theta_\lambda^*$  with an adaptively chosen  $\lambda$ . Note that  $\|\theta_\lambda^*\|$  does not have a bounded global sensitivity. The method to release it differentially privately (described in Lemma 12) is part of our technical contribution.

The ADASSP algorithm is simpler and enjoys slightly stronger theoretical guarantees.

**Theorem 3.** *Algorithm 2 outputs  $\tilde{\theta}$  which obeys that*

- (i) *It satisfies  $(\epsilon, \delta)$ -DP.*

- (ii) *Assume  $\|\mathcal{Y}\| \lesssim \|\mathcal{X}\| \|\theta^*\|$ . With probability  $1 - \varrho$ ,  $F(\tilde{\theta}) - F(\theta^*) \leq$*

$$O \left( \frac{\sqrt{d \log(\frac{d^2}{\varrho})} \|\mathcal{X}\|^2 \|\theta^*\|^2}{\epsilon / \sqrt{\log(\frac{6}{\varrho})}} \wedge \frac{\|\mathcal{X}\|^4 \|\theta^*\|^2 \operatorname{tr}[(X^T X)^{-1}]}{\epsilon^2 / [\log(\frac{6}{\varrho}) \log(\frac{d^2}{\varrho})]} \right)$$

(iii) Assume that  $\mathbf{y}|X$  obeys a linear Gaussian model and  $X$  has a sufficiently large  $\alpha$ . Then there is an event  $E$  satisfying  $\mathbb{P}(E) \geq 1 - \delta/3$  and  $E \perp \mathbf{y}|X$ , such that  $\mathbb{E}[\tilde{\theta}|X, E] = \theta_0$  and

$$\begin{aligned} & \mathbb{E}[\|\tilde{\theta} - \theta_0\|^2|X, E] \\ &= \sigma^2 \text{tr}[(X^T X)^{-1}] + O\left(\frac{\tilde{C}\|\mathcal{X}\|^2 \text{tr}[(X^T X)^{-2}]}{\epsilon^2 / \log(\frac{6}{\delta})}\right), \end{aligned}$$

with the same constant  $\tilde{C}$  in Theorem 2 (iii).

The proof of Statement (1) is straightforward. Note that we release the eigenvalue  $\lambda_{\min}(X^T X)$ ,  $X\mathbf{y}$  and  $X^T X$  differentially privately each with parameter  $(\epsilon/3, \delta/3)$ . For the first two, we use Gaussian mechanism and for  $X^T X$ , we use the Analyze-Gauss algorithm (Dwork et al., 2014b) with a symmetric Gaussian random matrix. The result then follows from the composition theorem of differential privacy. The proof of the second and third statements is provided in Appendix C. The main technical challenge is to prove the concentration on the spectrum and the Johnson-Lindenstrauss-like distance preserving properties for symmetric Gaussian random matrices (Lemma 6). We note that while SSP is an old algorithm the analysis of its theoretical properties is new to this paper.

**Remarks.** Both ADAOPS and ADASSP match the smaller of the two lower bounds (5) and (6) for each problem instance. They are slightly different in that ADAOPS preserves the shape of the intrinsic geometry while ADASSP’s bounds are slightly stronger as they do not explicitly depend on the smallest eigenvalue.

## 5 EXPERIMENTS

In this section, we conduct synthetic and real data experiments to benchmark the performance of ADAOPS and ADASSP relative to existing algorithms we discussed in Section 3. NOISYSGD and Sub-Agg are excluded because they are dominated by OBJPERT and an  $(\epsilon, \delta)$ -DP version of OPS (see Appendix F for details)<sup>6</sup>.

### Prediction accuracy in UCI data sets experiments.

The first set of experiments is on training linear regression on a number of UCI regression data sets. Standard z-scoring are performed and all data points are normalized to having an Euclidean norm of 1 as a preprocessing step. The results on four of the data sets are presented in Figure 2. As we can see, SSP is unstable for small data. OBJPERT suffers from a pre-defined bound  $\|\Theta\|$  and

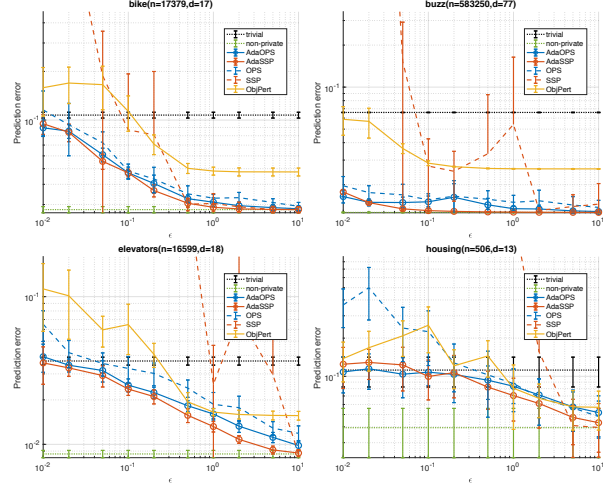

Figure 2: Example of results of differentially private linear regression algorithms on UCI data sets for a sequence of  $\epsilon$ . Reported on the y-axis is the cross-validation prediction error in MSE and their confidence intervals.

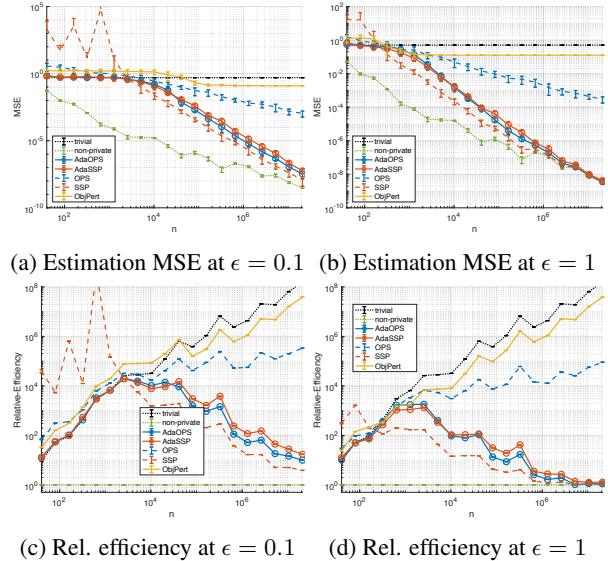

Figure 3: Example of differentially private linear regression under linear Gaussian model with an increasing data size  $n$ . We simulate the data from  $d = 10$ ,  $\theta_0$  drawn from a uniform distribution defined on  $[0, 1]^d$ . We generate  $X \in \mathbb{R}^{n \times d}$  as a Gaussian random matrix and then generate  $y \sim \mathcal{N}(X\theta_0, I_d)$ . We used  $\epsilon = 1$  and  $\epsilon = 0.1$ , both with  $\delta = 1/n^2$ . The results clearly illustrate the asymptotic efficiency of the proposed approaches.

does not converge to nonprivate solution even with a large  $\epsilon$ . OPS performs well but still does not take advantage of the strong convexity that is intrinsic to the data set. ADAOPS and ADASSP on the other hand are able to nicely interpolate between the trivial solution and the non-private baseline and performed as well as or better than baselines for all  $\epsilon$ . More detailed quantitative results on all the 36 UCI data sets are presented in Table 3.

<sup>6</sup>The code to reproduce all experimental results are available at [https://github.com/yuxiangw/optimal\\_dp\\_linear\\_regression](https://github.com/yuxiangw/optimal_dp_linear_regression).

Table 3: Summary of UCI data experiments at  $\epsilon = 0.1$ ,  $\delta = \min\{1e-6, 1/n^2\}$ . The boldface denotes the DP algorithm where the standard deviation is smaller than the error (a positive quantity), and the 95% confidence interval covers the observed best performance among benchmarked DP algorithms.

### Parameter estimation under linear Gaussian model.

To illustrate the performance of the algorithms under standard statistical assumptions, we also benchmarked the algorithms on synthetic data generated by a linear Gaussian model. The results, shown in Figure 3 illustrates that as  $n$  gets large, ADAOPS and ADASSP with  $\epsilon = 0.1$  and  $\epsilon = 1$  converge to the maximum likelihood estimator at a rate faster than the optimal statistical rate that MLE estimates  $\theta^*$ , therefore at least for large  $n$ , differential privacy comes for free. Note that there is a gap in SSP and ADASSP for large  $n$ , this can be thought of as a cost of adaptivity as ADASSP needs to spend some portion of its privacy budget to release  $\lambda_{\min}$ , which SSP does not, this can be fixed by using more careful splitting of the privacy budget.

## 6 CONCLUSION

In this paper, we presented a detailed case-study of the problem of differentially private linear regression. We clarified the relationships between various quantities of the problems as they appear in the private and non-private

information-theoretic lower bounds. We also surveyed the existing algorithms and highlighted that the main drawback using these algorithms relative to their non-private counterpart is that they cannot adapt to data-dependent quantities. This is particularly true for linear regression where the ordinary least square algorithm is able to work optimally for a large class of different settings.

We proposed ADAOPS and ADASSP to address the issue and showed that they both work in unbounded domain. Moreover, they smoothly interpolate the two regimes studied in Bassily et al. (2014) and behave nearly optimally for every instance. We tested the two algorithms on 36 real-life data sets from the UCI machine learning repository and we see significant improvement over popular algorithms for almost all configurations of  $\epsilon$ .

## Abstract

We introduce a novel class of adjustment rules for a collection of beliefs. This is an extension of Lewis' imaging to absorb probabilistic evidence in generalized settings. Unlike standard tools for belief revision, our proposal may be used when information is inconsistent with an agent's belief base. We show that the functionals we introduce are based on the *imaginary* counterpart of *probability kinematics* for standard belief revision, and prove that, under certain conditions, all standard postulates for belief revision are satisfied.

## 1 INTRODUCTION

The theory of belief revision, originated in the work of Alchourrón, Gärdenfors and Makinson [Alchourrón et al., 1985], is aimed to maintain consistency of a knowledge base when updated information is gathered to a rational agent, or *You*. In the present work we will focus on the probabilistic framework, where Your knowledge base is represented by a (closed and convex) collection of probability mass functions, and some observational process is expected to induce an adjustment in the model.<sup>1</sup> With probabilities, evidence on some variables is called *inconsistent* when it contradicts certainty (or impossibility) in Your knowledge base. We provide an example to motivate our contribution.

**Example 1.** *While swimming in a lake, Celeste sees some black birds from the distance. She knows black birds living around that lake are rather tame, while swans might be very aggressive. She is also sure that only*

---

<sup>1</sup>Here we intend an *adjustment* as a generalized *updating*. We avoid this latter term as in the literature it is often intended as equivalent to conditioning.

*white or grey swans exist, although the birds she sees actually look like swans. While reasoning about that, a sailor informs her that a small group of black swans has been spotted around the area. Should Celeste be worried about the birds she sees?*

Classic belief revision operators, introduced in Section 2, fail to absorb information from an observational process when inconsistencies arise such as in Example 1. This feature was motivated in the literature by a *partiality* principle [Cozic, 2011], discussed below. Still, a rule for the adjustment of a model to any piece of evidence ought to be required by a rational agent, to avoid building a new model from scratch when unexpected information shows up. Such an operator ought to update the knowledge base to be consistent with new evidence, while leaving previous beliefs on related events as unchanged as possible. We will characterize optimality requirements for such adjustment operators as an *imaginary kinematics* in Section 3, and extend them to deal with generalized forms of evidence. Particularly, we consider probabilistic evidence, and extend it to i) conditional assessments, and ii) *imprecise* assessments, that may be intended as originating from a qualitative judgment. Section 4 will introduce adjustment functionals based on Lewis' imaging, and study their features and properties. We will refer throughout to partial operators as *revision* rules, as opposed to general *adjustment* ones.

## 2 BACKGROUND

Let  $\Omega$  be any space of atoms - atomic (Boolean) propositional variables - and let a *world*  $\omega$  be any assignment of truth to each element from  $\Omega$ , such that there exist up to  $2^{|\Omega|}$  *conceivable* worlds.

Any propositional formula  $\phi \in \mathcal{L}$ , countable set of all formulae on  $\Omega$ , is satisfied by worlds in  $[\phi] \subseteq \Omega$ . Formally, when  $\omega$  satisfies  $\phi$  we write  $\omega \models \phi$ ; that is,  $\omega \in [\phi]$  if and only if  $\omega \models \phi$ . Logical connectives  $\{\wedge, \vee, \neg\}$  - conjunction, disjunction and negation, re-

spectively - may be used to concatenate several formulae. Also,  $\top$  and  $\perp$  denote, respectively, tautology and contradiction.

A rational agent (or You) is equipped with a collection of belief states over some  $A \subseteq \Omega$ , whose elements may be equivalently defined by closed sets of formulas in a propositional logic language. Formally, a belief state over the set of all *conceivable* worlds  $A \subseteq \Omega$ , is represented by a *probability mass function* (PMF)  $P_A$ , defined as follows:

$$P_A(A) = \left\{ (\omega, P(\omega)) : \begin{array}{l} P(\omega) \geq 0, \omega \in A, \\ \sum_{\omega \in A} P(\omega) = 1 \end{array} \right\}.$$

Granular belief  $P_\Omega$  is similarly defined with respect to every  $\omega \in \Omega$ . We just write  $P$ , when the domain is clear from the context.

Let  $\mathbf{X}$  be a collection of  $n$  discrete variables,  $n \geq 1$ ,  $\omega$  corresponds to  $\mathbf{x}$ , configuration of  $\mathbf{X}$  in its joint possibility space, and  $\Omega \equiv \Omega_{\mathbf{X}}$ , while  $\mathcal{L}$  reduces to a collection of statements  $\{\phi \bowtie c : \phi \in \mathcal{L}, \bowtie \in \{=, \geq, \leq\}, c \in [0, 1]\}$ . Also,  $A$  represents any arbitrary tautology, such that any  $P_A$  is strictly positive on  $A$  (and contains zero elements only otherwise). For a given formula  $\phi$ ,

$$P(\phi) = \sum_{\mathbf{x} \in \Omega: \mathbf{x} \sim A} P(\mathbf{X} = \mathbf{x}) \mathbb{I}_{\mathbf{x} \models \phi},$$

with  $\sim$  denoting consistency among events. E.g., let  $n = 3$ ,  $\phi = \{x \wedge \neg y\}$ ,  $(x, \neg y, z) \sim [\phi]$ , whatever  $z$  in  $\Omega_Z$ , coarse partition of  $\Omega$  induced by variable  $Z$ . For the sake of brevity, in the following, we write  $P(\mathbf{x})$ , rather than  $P(\mathbf{X} = \mathbf{x})$ .

In the general case, a collection of deductively closed set of propositions, i.e., belief states, may be used to specify a *credal set* (CS)  $K(\mathbf{X})$ . Any CS  $K$  is defined by a set of linear constraints, and may be equivalently characterized as the convexification of its extreme points, denoted as  $\text{ext}[K]$ . Let  $K_1$  and  $K_2$  be any two CSs over  $\mathbf{X}$ , they are *equivalent*,  $K_1 \equiv K_2$ , if and only if  $\text{ext}[K_1] = \text{ext}[K_2]$ . For each  $x \in \Omega_X$ ,  $\underline{P}(x) = \min_{P(x) \in \text{ext}[K(X)]} P(x)$  (and  $\overline{P}(x) = \max_{P(x) \in \text{ext}[K(X)]} P(x)$ ) corresponds to the lower (and upper) envelope of CS  $K(X)$ , for any  $X \in \mathbf{X}$ . See [Walley, 1991] for details on CSs. We refer to *sharp* or *imprecise* probabilities to distinguish between  $|\text{ext}[K]| = 1$  and  $|\text{ext}[K]| > 1$ , respectively.

$K^\Phi$  denotes the subset of belief states in  $K$  that satisfy a collection of formulae  $\Phi$ . Any belief state satisfies  $\Phi$ , i.e.,  $P \models \Phi$ , whenever it holds  $P \models \phi$ , for each  $\phi \in \Phi$ . Any set  $\Phi$  is *accepted* whenever it is consistent with each  $P \in K$ , it is *rejected* if its negation only,  $\neg\Phi$ , is, or it is *neutral* if both are consistent. Let  $c \in [0, 1]$ , for a given formula  $\phi$ ,  $P \models (\phi \bowtie x)$  whenever  $P(\phi) \left( = \sum_{\mathbf{x} \sim [\phi]} P_A(\mathbf{x}) \right) \bowtie c$ ,  $\bowtie \in \{=, \leq, \geq\}$ .

For a given belief set, three main operations relevant to adjust it to satisfy any given  $\phi$ . These are

contraction, expansion and revision from AGM theory [Alchourrón et al., 1985], whose consistency postulates are mostly known from the KM reformulation in [Katzuno and Mendelzon, 1992]. Suppose an agent's knowledge base is represented by a CS  $K$  over  $\mathbf{X}$ , and let  $\phi$  be any upcoming formula, such that adjustment of  $K$  by  $\phi$  is operated by  $\circ$ . Katzuno and Mendelzon's postulates translate as follows:

**KM1**  $(K \circ \phi) \models \phi$ ,

**KM2** Let  $K \models \phi$ ,  $(K \circ \phi) \equiv (K \cup \phi)$ ,

**KM3** If  $\phi \neq \perp$ , then  $(K \circ \phi) \neq \perp$ ,

**KM4** If  $K_1 \equiv K_2$  and  $\phi_1 \equiv \phi_2$ , then  $(K_1 \circ \phi_1) \equiv (K_2 \circ \phi_2)$ ,

**KM5** If  $(K \circ \phi) \models \psi$ , then  $(K \circ (\phi \wedge \psi))$ , for any further formula  $\psi$ ,

**KM6** If  $(K \circ \phi) \models \psi$ , then  $(K \circ (\phi \wedge \psi))$  implies  $((K \circ \phi) \models \psi)$ .

Any operator  $\circ$  that satisfies all KM postulates is equivalent to a revision process based on total pre-orders [Katzuno and Mendelzon, 1992].

AGM postulates, and their KM formulation, have been followed by a massive literature on their limitations and possible extensions. Two major shortcomings of AGM theory arise when revision involves conditional formulae [Dovven and Romeijn, 2011], and in the iterated setting [Goldszmidt, 1992]. See also [Darwiche and Pearl, 1997] on additional postulates for iterated belief revision.

In the classical probabilistic framework,  $K(\mathbf{X})$  is made by a single PMF, that is  $\text{ext}[K(\mathbf{X})] = \{P(\mathbf{X})\}$ . When one or more elements from  $\mathbf{X}$  are observed,  $P$  is adjusted, i.e., updated, accordingly by standard *conditioning*. Let  $\alpha$  be any event from  $\Sigma$ , the  $\sigma$ -algebra induced by  $\Omega$ , and suppose  $(X = x)$  with  $x \in \Omega_X$  and  $X \in \mathbf{X}$ , is observed and such that  $P(x) > 0$ , it holds:

$$P(\alpha|x) = P(\alpha, x)/P(x). \quad (1)$$

A (marginal) probabilistic observation corresponds to a PMF over the countable possibility space of variable  $X \in \mathbf{X}$ . Such evidence bears an impression of the degree of reliability that is associated to each (forecasted) event, i.e., on the *evidence of uncertainty* [Peng et al., 2010]. We define probabilistic evidence as some PMF  $P'_X$  over  $\Omega_X$ , such that  $P(x) \neq P'_X(x)$  for some  $x \in \Omega_X$ . It corresponds to the collection of formulae  $\Phi_X$ , whose generic element is  $\phi_x = (\{x\} = c_x)$ ,  $c_x \in [0, 1]$ ,  $x \in \Omega_X$ , with  $\sum_{x \in \Omega_X} c_x = 1$ .  $P'_X$  may be intended

as a set of probabilistic constraints on the system modeled by  $P$  [da Rocha et al., 2008]. A general adjustment operator is the functional  $\circ$ , mapping any  $P$  to  $P^\circ$ , such that  $P^\circ \models P'_X$ . By the partiality principle mentioned above, standard revision of  $P$  by  $P'_X$  requires preservation of zero-probability events. Rationality of partiality has been advocated by several authors (e.g., [Dietrich, 2016]). The intuition is the following: Your beliefs ought to be calibrated with available evidence, if any. This way, certainty on the occurrence of event ( $X = x'$ ) requires  $P(x) = 0$ , for each  $x \neq x'$  in  $\Omega_X$ . If You accepted to change Your mind on ( $X = x$ ), then You would rather be reasonably sure about its non-occurrence, rather than certain; but then  $P(x) \neq 0$ . As a consequence, certainty on the occurrence of an event, say  $x$ , implies certainty to  $P'_X$ , since  $P'_X(x')$  is floored to zero by every  $x' \neq x$  in  $\Omega_X$ .

Kinematical mechanics for the adjustment of a belief set are intended as consistency principles, that we are willing to choose over a purely *minimal distance* based approach [Boutilier, 1996]. We introduce *probability kinematics* following Wagner's characterization [Wagner, 2002].

**Definition 1** (Probability kinematics [Jeffrey, 1965, Wagner, 2002]). *Let  $P$  and  $P^\circ$  be any two PMFs over  $(\Omega, \Sigma)$ , and let  $\Omega_X$  be a countable collection of pairwise disjoint events in  $\Sigma$ , i.e., a coarse partition of  $\Omega$  ( $\equiv \Omega_X$ ).  $P^\circ$  comes from  $P$  on  $\Omega_X$  based on probability kinematics (PK) if there exists a sequence  $P'_X(X) = \{P'_X(x) : x \in \Omega_X, \sum_{x \in \Omega_X} P'_X(x) = 1\}$  such that it holds:*

**PK1**  $P^\circ(\alpha|x) = P(\alpha|x)$ , for each  $x \in \Omega_X$ ,

**PK2**  $P^\circ(X) = P'_X(X)$ ,

for any event  $\alpha \in \Sigma$ .

In words,  $P$  is changed to agree with  $P'_X$  (PK2), while preserving relevance of each  $x \in \Omega_X$  to any event  $\alpha \in \Sigma$  (PK1).

An equivalent characterization of PK yields the well-known Jeffrey's rule:

**Definition 2** (Jeffrey's Rule [Jeffrey, 1965]). *Let  $P$ ,  $P^\circ$  and  $P'_X$  as above. Jeffrey's rule ( $\circ_J$ ) adjusts  $P$  to satisfy  $P'_X$ :*

$$(P \circ_J P'_X)(\alpha) = \sum_{x \in \Omega_X} P(\alpha, x) \frac{P'_X(x)}{P(x)}$$

We denote the Jeffrey's revision of  $P$  on  $\Omega_X$  as  $P_X^{\circ_J}$ .

Deterministic knowledge on event ( $X = x$ ) may be specified by  $P'_X(X)$  such that  $P'_X(x) = 1$  at  $x$  and zero

otherwise.<sup>2</sup> It holds:

$$(P \circ_J P'_X)(\alpha) \equiv P(\alpha|x), \quad (2)$$

where the right hand-side is just conditioning from Eq. (1). Such *hard* evidence [Valtorta et al., 2002] trivially corresponds to  $\phi = \{x\}$ ,  $x \in \Omega_X$ .

Suppose evidence is gathered conditional on some variable  $Y$  taking value  $y \in \Omega_Y$ . We define conditional (probabilistic) evidence as the collection of probabilistic statements  $P'_{X|y}(X|y)$ , such that  $P'_{X|y}(x|y) \geq 0$ , for each  $x \in \Omega_X$ , and  $\sum_{x \in \Omega_X} P'_{X|y}(x|y) = 1$ , provided  $P(y) > 0$ . Equivalently,  $\Phi_{X|y}$ , with generic element  $\phi_{x|y} = (\{y \rightarrow x\} = c_x)$ , with  $\sum_{x \in \Omega_X} c_x = 1$ . A kinematical revision rule would require the following conditions to hold:

**Definition 3** (Conditional PK [Bradley, 2005]). *Let  $P$  and  $P^\circ$  be any two PMFs on  $(\Omega, \Sigma)$ . Let  $P(y) > 0$ ,  $P^\circ$  comes from  $P$  on  $\Omega_X \times \{Y = y\}$  based on conditional probability kinematics (CPK) if there exists a sequence  $P'_{X|y}(X|y)$  as above such that it holds:*

**CPK1**  $P^\circ(\alpha|x, y) = P(\alpha|x, y)$ , for each  $x \in \Omega_X$ ,

**CPK2**  $P^\circ(\alpha|y') = P(\alpha|y')$ , for each  $y' \in \Omega_Y \setminus \{y\}$ ,

**CPK3**  $P^\circ(Y) = P(Y)$ ,

**CPK4**  $P^\circ(X|y) = P'_{X|y}(X|y)$ .

The following operator may be used to revise  $P$ , extending Jeffrey's rule to the conditional setting:

**Definition 4** (Adams' Conditioning [Bradley, 2005, Douven and Romeijn, 2011]). *Let  $P$ ,  $P^\circ$  and  $P'_{X|y}$  as above, with  $P(y) > 0$ . Operator  $\circ_A$  yields the Adams' revision ( $P_X^{\circ_A}$ ) of  $P$  that is consistent with  $P'_{X|y}$  if it is obtained as:*

$$(P \circ_A P'_{X|y})(\alpha) = P(\alpha, \neg y) + \sum_{x \in \Omega_X} P(\alpha, x, y) \frac{P'_{X|y}(x|y)}{P(x|y)}.$$

By [Bradley, 2005, Th.5], Adams' conditioning yields the unique PMF that satisfies CPK1-CPK4. Let us consider that in the running example.

<sup>2</sup>While probabilistic findings extend standard evidence, they do not necessarily result from an observation process. E.g., they may be gathered as forecasts produced by external sourced whose system of knowledge is not disclosed (e.g., betting odds), or qualitative evaluations from experts. Thorough characterization of uncertain evidence has been provided in the survey of [Mrad et al., 2015], and related works. There, probabilistic evidence is further distinguished into fixed and not-fixed. Such distinction is critical to iterated belief revision.

**Example 2** (Ex. 1 continued). *Celeste's beliefs are formalized as follows: let  $\Omega_Y = \{y \equiv \text{Swan}, \neg y \equiv \neg \text{Swan}\}$ ,  $\Omega_X = \{x_W \equiv \text{White}, x_G \equiv \text{Grey}, x_B \equiv \text{Black}\}$  and  $\Omega_Z = \{z \equiv \text{Aggressive}, \neg z \equiv \text{Tame}\}$ .*

*It holds:*

$$P(Y) = \{(y, 0.7), (\neg y, 0.3)\},$$

$$P(X|Y) = \left\{ \begin{array}{l} (x_W|y, 0.8), (x_G|y, 0.2), \\ (x_B|y, 0), (x_W|\neg y, 0.5), \\ (x_G|\neg y, 0.3), (x_B|\neg y, 0.2) \end{array} \right\},$$

$$P(Z|Y) = \left\{ \begin{array}{l} (z|y, 0.95), (\neg z|y, 0.05), \\ (z|\neg y, 0.2), (\neg z|\neg y, 0.8) \end{array} \right\}.$$

*According to Celeste's beliefs,  $P(z|x_B) = 0.2$ . Based on the sailor's words, Celeste is willing to adjust her beliefs to be consistent with  $P'_{X|y}(X|y) = \{(x_W, 0.8), (x_G, 0.1), (x_B, 0.1)\}$ . Straightforward application of Adams' conditioning is undefined, since  $P(x_B|y) = 0$ , while  $P'_{X|y}(x_B|y) \neq 0$ . The same would occur with simple Jeffrey's rule, if any  $P'_X(x) \neq 0$  was provided, given  $P(x) = 0$ , for some  $x \in \Omega_X$ . How could Celeste incorporate such reliable knowledge in her beliefs?*

Imaging was introduced by [Lewis, 1976] as a non-trivial alternative to conditioning on inconsistent events. Roughly, it represents the “*thought experiment by a minimal action*” [Fusaoka and Hiratsuka, 2003] that makes a formula consistent.

Going back to the propositional language, if some world  $\omega$  is inconsistent with formula  $\phi$ , according to a knowledge base, imaging shifts beliefs towards those that are closest to  $\phi$ , called  $\phi$ -worlds.  $\gamma(\omega, \phi)$  is called a *closest world function*, mapping  $\omega$  to its closest  $\phi$ -world; see [Lewis, 1986] for a detailed discussion. In our formalism,  $(\phi = \{x\})$  requires  $\gamma(\mathbf{x}, \phi) = (\mathbf{x} \setminus \{X\}, x) \in \Omega$ , for any  $\mathbf{x} \in \Omega$ .

**Definition 5** (Imaging [Lewis, 1976]). *Let  $P$  be any PMF over  $(\Omega, \Sigma)$ . For a given  $\phi$  and closest world function  $\gamma(\cdot, \phi)$ .  $P_\phi^{\circ_I}$  is the image of  $P$  on  $\phi$  if it is obtained by  $\circ_I$  as:*

$$(P \circ_I \{\phi\})(\alpha) = \sum_{\omega' \in \alpha} \sum_{\omega \in \Omega} P(\omega) \mathbb{I}_{\gamma(\omega, \phi) = \omega'}.$$

In Lewis' words, by imaging on event  $\phi$ , “*probability is moved around, but not created or destroyed*”, while “*every share stays as close to it as it can to the world it was originally created*” [Lewis, 1976, p. 310-311]. To summarize: i) inconsistent evidence is accounted for in the image of  $P$ , whereas conditioning is left undefined;

ii) imaging changes the whole belief set to comply with reliable knowledge  $\phi$ , while conditioning redefines the domain of  $P$ , focusing on worlds in  $\Omega$  consistent with  $\phi$ .

**Example 3.** *Let  $\mathbf{X} = \{X, Y\}$ , with  $P(x, y) = P(x, \neg y) = 0$ ,  $P(\neg x, y) = 0.6$  and  $P(\neg x, \neg y) = 0.4$ . Given  $(\phi = \{x\})$ , imaging on it yields  $(P \circ_I \{X = x\})(y) = 0.6$ , which corresponds to  $P(y)$ . If conditioning was applied,  $P(Y|x)$  would not be defined.*

*Consider  $\alpha = \{x\}$ ,  $(P \circ_I \{X = x\})(x) = 1$ :  $\circ_I$  adjusts  $P$  to always be consistent with  $\phi = \{x\}$ .*

Generalized forms of imaging were introduced in the literature, see, e.g., [Gärdenfors, 1988, Rens et al., 2016]. See also [Zhuang et al., 2017] on a unifying approach to belief adjustment.

Günther [Günther, 2017] introduced Jeffrey's imaging, that we denote as  $\circ_{jI}$ , for the generalized case of probabilistic formula  $(\phi = c)$ , with  $c \in [0, 1]$ .<sup>3</sup> Adjustment operator  $\circ_{jI}$  trivially extends *partial* imaging [Ramachandran et al., 2010].

**Definition 6** (Jeffrey's Imaging [Günther, 2017, Ramachandran et al., 2010]). *Let  $P$  be any PMF over  $(\Omega, \Sigma)$ . For a given formula  $\{\phi = c\}$ , with  $c \in [0, 1]$ ,  $P_X^{\circ_{jI}}$  comes from  $P$  by Jeffrey's imaging  $\circ_{jI}$  on  $\{\phi = c\}$  if it holds:*

$$(P \circ_{jI} \{\phi = c\})(\alpha) = P_\phi^{\circ_I}(\alpha)c + P_{\neg\phi}^{\circ_I}(\alpha)(1 - c)$$

*We denote the Jeffrey's image of  $P$  on  $\{\phi = c\}$  as  $P_\phi^{\circ_{jI}}$ .*

Both standard and Jeffrey's imaging are *homomorphic* change functions (see [Gärdenfors, 1988] and [Ramachandran et al., 2010, Obs.1], respectively), i.e., they define a structure-preserving map. A generalized characterization of Jeffrey's imaging will be provided below, within the multi-valued imprecise-probabilistic framework (see Definition 9).

Just like Your beliefs may be encoded by a CS  $K$  on  $\Omega$ , probabilistic evidence may come as a (closed and convex) collection of PMFs  $K'_X$  on  $\Omega_X$ , i.e., a CS that we call *credal* (or imprecise) evidence. This latter generalizes sharp probabilistic evidence to the case  $|\text{ext}[K'_X(X)]| \geq 1$ :

$$K'_X(X) = \{P(x) : \underline{P}(x) \leq P(x) \leq \overline{P}(x), x \in \Omega_X\}.$$

$K'_X$  may be equivalently specified by the collection of formulae  $\phi_x = (\{x\} \bowtie c_x)$ ,  $c_x \in [0, 1]$ , for each  $x \in \Omega_X$ , provided  $\sum_{x \in \Omega_X} c_x \bowtie 1, \bowtie \in \{=, \leq, \geq\}$ .<sup>4</sup>

<sup>3</sup>Günther's definition assumes  $c \in (0, 1)$ .

<sup>4</sup>To guarantee  $P'_X(x) \in [0, 1]$ , we also require  $P'_X(x) \leq 0$  and  $P'_X(x) \geq 1$  always reduce to equalities.

Our contributions will tackle probabilistic belief adjustment by (possibly inconsistent) sharp or imprecise probabilities, following an approach based on the imaginary counterparts of PK. This is analogous to what has been done in [Ma et al., 2011, Zhou et al., 2014] within the framework of evidence theory.

Following [Zhou et al., 2014], we are willing to check a further consistency requirement, that would reproduce Eq. (2). In this way, any adjustment *kinematical* operator reduces to some form of conditioning when probabilistic evidence strengthens to full observation.

### 3 IMAGINARY KINEMATICS

We lay bare the kinematical conditions that ought to be satisfied by any belief adjustment operator, when (possibly) inconsistent probabilistic evidence is gathered.<sup>5</sup>

Let us start with simple probabilistic evidence:  $P'_X$  on  $\Omega_X$ , such that  $|\Omega_X| \geq 2$ . Imaginary kinematics can be introduced as a counterpart of PK for imaging.

**Definition 7** (Imaginary Kinematics). *Any joint CS  $K^\circ$  on  $\mathbf{X}$  comes from  $K$  by imaginary kinematics (IK) on a (possibly inconsistent) credal evidence  $K'_X$  on variable  $X$  whenever it holds:*

$$\mathbf{IK1} \quad K^\circ(\alpha|x) \supseteq K_x^{\circ I}(\alpha), \text{ for any } \alpha \in \Sigma \text{ and each } x \in \Omega_X,$$

$$\mathbf{IK2} \quad K^\circ(X) \models \Phi_X,$$

$$\mathbf{IK3} \quad K^\circ(X) \equiv K_x^{\circ I}(X) \text{ whenever } c_x = 1 \text{ for some } x \in \Omega_X.$$

Analogously, based on Definition 3, we provide an imaginary characterization of CPK defined as follows.

**Definition 8** (Imaginary Conditional Kinematics). *Let  $K$ ,  $K^\circ$  as above, such that  $\underline{P}(y) > 0$  for each  $y \in \Omega_Y$ .  $K^\circ$  comes from  $K$  on  $\Omega_X \times \{Y = y\}$  based on imaginary conditional kinematics (ICK) if there exists a (possibly inconsistent) sequence  $P'_{X|y}$  such that it holds:*

$$\mathbf{ICK1} \quad K^\circ(\alpha|x, y) \supseteq K_x^{\circ I}(\alpha|y), \text{ for each } x \in \Omega_X,$$

$$\mathbf{ICK2} \quad K^\circ(\alpha|y') \equiv K(\alpha|y'), \text{ for each } y' \in \Omega_Y \setminus \{y\},$$

$$\mathbf{ICK3} \quad K^\circ(Y) \equiv K(Y),$$

$$\mathbf{ICK4} \quad K^\circ(x|y) \models \Phi_{X|y},$$

$$\mathbf{ICK5} \quad K^\circ(X|y) \equiv K_x^{\circ I}(X), \text{ whenever } c_x = 1, \text{ for some } x \in \Omega_X.$$

<sup>5</sup>With imprecise probabilities, inconsistency occurs when  $\overline{P}(x) = 0$  and positive evidence is provided for some  $x \in \Omega_X$ .

## 4 KINEMATICAL IMAGINARY ADJUSTMENT RULES

For any  $\alpha \in \Sigma$ , if a CS  $K$  over  $\mathbf{X}$  is used to represent Your beliefs, imaging on  $(\phi = \{x\})$  extends to:

$$(K \circ_I \{x\})(\alpha) = \{P_x^{\circ I}(\alpha) = (P \circ_I \{x\})(\alpha), P \in K\},$$

so that the lower envelope of  $K$ 's image on  $\{x\}$ , denoted as  $K_x^{\circ I}$ , at  $\alpha$ , writes:

$$\underline{P}_x^{\circ I}(\alpha) = \min_{P(\mathbf{x}) \in K(\mathbf{X})} \sum_{\mathbf{x}' \sim \alpha} \sum_{\mathbf{x} \in \Omega_{\mathbf{X}}} P(\mathbf{x}) \mathbb{1}_{\gamma(\mathbf{x}, \mathbf{x}) = \mathbf{x}'}$$

By [Rens et al., 2016, Th.1],  $K_x^{\circ I}$  may be efficiently obtained by taking the convex hull (CH) of the images on  $\{x\}$  of each  $P \in \text{ext}[K]$ . Since the image of each  $P \in \text{ext}[K]$  at  $\alpha = \{x'\}$  trivially corresponds to  $P_x^{\circ I}(x') = 0$ ,<sup>6</sup> whenever  $x' \neq x$ , refinement of  $K_x^{\circ I}(X)$  degenerates to a single PMF such that  $P'_X(x) = 1$ , and zero otherwise. With a small abuse of notation, this yields the following:

$$K_x^{\circ I}(\mathbf{X}) \equiv \begin{cases} 1 \cdot K(\mathbf{X} \setminus \{X\}) & \mathbf{x} \sim x, \\ 0 & \text{otherwise.} \end{cases}$$

**Example 4.** *Let  $K$  be a CS over  $\mathbf{X} = \{X, Y\}$  specified by probability intervals as follows:*

$$K \begin{pmatrix} x_1, y_1 \\ x_1, y_2 \\ x_2, y_1 \\ x_2, y_2 \\ x_3, y_1 \\ x_3, y_2 \end{pmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0.15 - 0.35 \\ 0.25 - 0.49 \\ 0 - 0.45 \\ 0.03 - 0.5 \end{bmatrix}.$$

*It is easy to see  $\underline{P}_{x_1}^{\circ I}(y_j) = \underline{P}(y_j)$ ,  $j = 1, 2$ , while  $\overline{P}_{x_1}^{\circ I}(x_k) = 0$ ,  $k = 2, 3$ .*

### 4.1 STANDARD PROBABILISTIC EVIDENCE

We start from the case of sharp probabilistic evidence on  $\Omega_X$ , i.e.,  $K'_X(X) = \{P'_X(X)\}$ . The following adjustment operator extends Definition 6. As we did before for imaging, notation that is used with sharp beliefs applies to the generalized case of belief sets, when  $|\text{ext}[K]| \geq 1$ .

**Definition 9** ((Probabilistic) Jeffrey's Imaging). *Let  $K$  be any joint CS over  $\mathbf{X}$  as above. Suppose probabilistic evidence  $P'_X$  is provided over a (possibly) inconsistent collection of events, i.e.,  $\overline{P}(x) = 0$ , whereas  $P'_X(x) > 0$ , for some  $x \in \Omega_X$ ,  $X \in \mathbf{X}$ . For any event  $\alpha$ ,  $K_X^{\circ j I}$  is the probabilistic Jeffrey's image of  $K$  if it holds:*

$$K_X^{\circ j I}(\alpha) = \{P_X^{\circ j I}(\alpha) = \sum_{x \in \Omega_X} P_x^{\circ I}(\alpha) P'_X(x), \\ P_x^{\circ I} \in K_x^{\circ I}, x \in \Omega_X\}.$$

<sup>6</sup>By definition,  $P_x^{\circ I}(x) = \sum_{\mathbf{x} \in \Omega} P(\mathbf{x}) = 1$ .

That is,  $K_X^{\circ_{jI}}(\alpha) = (K \circ_{jI} P'_X)(\alpha)$ , for any  $\alpha \in \Sigma$ .

The following result holds (the proofs of all the theorems are in the appendix).

**Theorem 1.** *Jeffrey's imaging is based on IK, and IK1 is strongly satisfied, i.e.,  $\models$  may be replaced by  $\equiv$ .*

**Corollary 1.** *Given sharp probabilistic knowledge on  $\Omega_X$ , the Jeffrey's image of any CS may be equivalently specified by the convexification of all PMFs  $P^\circ$ , each defined as follows:*

$$P^\circ(\alpha) = \sum_{x \sim \alpha} P'_X(x) P_i(\alpha) \quad \forall P \in \text{ext}[K].$$

It is easy to see that standard imaging is also trivially based on IK.

**Example 5.** *Consider the same setup as in Example 4, and suppose  $P'_X(X) = \{(x_1, 0.3), (x_2, 0), (x_3, 0.7)\}$ . By Jeffrey's imaging on  $P'_X$ , we obtain  $K_X^{\circ_{jI}}(Y) \equiv K(Y)$ , while  $P_X^{\circ_{jI}}(y_j|x_i) \equiv K_{x_i}^{\circ_I}(y_j)$ ,  $i = 1, 2, 3$ ,  $j = 1, 2$ . Also,  $K_X^{\circ_{jI}}(X) \models P'_X(X)$ , and  $K_X^{\circ_{jI}}$  is equivalent to the convex hull of PMFs  $P^\circ$ , defined as:*

$$P^\circ(x, y) = P'_X(x)P(y),$$

for each  $x \in \Omega_X, y \in \Omega_Y$  and  $P \in \text{ext}[K]$ .

## 4.2 SHARP CONDITIONAL EVIDENCE

We now introduce Adams' imaging as an adjustment operator  $\circ_{aI}$ , that extends  $\circ_{jI}$  to the conditional case, just like revision rule  $\circ_A$  extends  $\circ_J$ .

**Definition 10** (Adams' Imaging). *Let  $K$  be any joint CS on  $(\Omega, \Sigma)$  such that  $\underline{P}(y) > 0$ ,  $Y \in \mathbf{X}$ , and let conditional probabilistic knowledge  $P'_{X|y}$  on  $\Omega_X \times \{Y = y\}$ .  $K_X^{\circ_{aI}}$ , the Adams' image of  $K$  on  $P'_{X|y}$ , comes from  $K$  by Adams' imaging  $\circ_{aI}$ , if it holds:*

$$\begin{aligned} K_X^{\circ_{aI}}(\alpha) &= \\ \{P_X^{\circ_{aI}}(\alpha) &= P(\alpha, \neg y) + \sum_{x \in \Omega_X} P_x^{\circ_I}(\alpha, y) P'_{X|y}(x|y), \\ P &\in K, P_x^{\circ_I} \in K_x^{\circ_I}, x \in \Omega_X\}. \end{aligned}$$

*I.e.,  $K_X^{\circ_{aI}}(\alpha) = (K \circ_{aI} P'_{X|y})(\alpha)$ , for any  $\alpha \in \Sigma$ .*

When  $|\text{ext}[K]| = 1$ , from previous considerations, Adams' imaging reduces to the following:

$$P_X^{\circ_{aI}}(\alpha) = P(\alpha, \neg y) + \sum_{x \in \Omega_X} P_x^{\circ_I}(\alpha, y) P'_{X|y}(x|y). \quad (3)$$

**Example 6** (Ex. 1 continued). *The Adams' image on  $P'_{X|y}$  of Celeste's beliefs on  $\Omega_X \times \Omega_Z$  is the following:*

$$P_X^{\circ_{aI}} \begin{pmatrix} x_W z \\ x_W \neg z \\ x_G z \\ x_G \neg z \\ x_B z \\ x_B \neg z \end{pmatrix} = \begin{bmatrix} 0.5620 \\ 0.1480 \\ 0.0845 \\ 0.0755 \\ 0.0785 \\ 0.0515 \end{bmatrix}.$$

*It holds  $P_X^{\circ_{aI}}(X|y) = P'_{X|y}(X|y)$  and  $P_X^{\circ_{aI}}(Y, Z) = P(Y, Z)$ . Adjustment of her beliefs by  $P'_{X|y}$  yields  $P_X^{\circ_{aI}}(z|x_B) \approx 0.6$ , whereas  $P(z|x_B) = 0.2$ . Thus, Celeste rapidly swims back to shore.*

As a remark, inconsistency of  $P'_{X|y}(x|y)$ , for some  $x \in \Omega_X$ , with respect to any PMF  $P$ , may refer to either i)  $P(x|y) = 0$ , while  $P(y) > 0$ , (this is just the case of Adams' imaging above), or ii)  $P(y) = 0$  in the first place, and possibly  $P(x|y) = 0$ . We argue case ii) deserves some caution, since full inconsistency of event  $(Y = y)$  is likely not to yield any further conjecturing on related events, from a modeler's perspective. E.g., You are certain that no alien lives on Mars. Is it worth include Your belief on the alien having long hair in Your belief base, provided that You are not admitting the alien's existence upstream? On the other hand, we reckon arguments may be easily raised against our position, starting from our proposed running example. Still, if no evidence is provided on  $\Omega_Y$ , a cautious approach would require application of an iterated procedure. We leave this point for future work.

It is now straightforward to note that Adams' imaging generalizes Jeffrey's imaging to the conditional setting.

**Theorem 2.** *Adams' imaging is based on ICK, and ICK1 is strongly satisfied. Eq. (3) strongly satisfies all conditions.*

Analogously to Corollary 1, it might be easily shown that  $K_X^{\circ_{aI}}$  at any  $x \sim y$  is equivalent to the CS obtained taking the product of sharp assessment  $P'_{X|y}$  and the marginalization over variable  $X$  of the original belief set  $K$ . We also provide the following additional result, which extends [Rens et al., 2016].

**Theorem 3.** *Both Jeffrey's and Adams' imaging satisfy consistency axioms KM1, KM3 and KM4. KM2, KM5 and KM6 are satisfied only if  $K$  is degenerate at  $(X|y)$ , i.e.,  $|K(X|y)| = 1$  (and at  $(Z|w)$ , for KM5 and KM6).*

## 4.3 CREDAL JEFFREY'S IMAGING

When beliefs are expressed as a joint CS over  $\mathbf{X}$ , adjustment by a single reliable PMF requires simultaneous

computation of all bounds spanned by the updating of each  $P \in K$ . Also in this case, adjustment may be restricted to the PMFs in  $\text{ext}[K]$  only, and their convex hull consequently considered.

**Definition 11** (Credal Jeffrey’s Imaging). *Given CS  $K$  over  $\mathbf{X}$  and credal probabilistic evidence  $K'_X(X)$ , we define credal Jeffrey’s imaging  $\circ_{cjI}$  as the functional mapping  $K$  to CS  $K_X^{\circ_{cjI}}$ , consistent with  $K'_X(X)$  as follows:*

$$K_X^{\circ_{cjI}}(\alpha) = \left\{ P^\circ(\alpha) = (P \circ_{jI} P'_X)(\alpha), \begin{array}{l} P(\mathbf{X}) \in K(\mathbf{X}), \\ P'_X \in K'_X(X) \end{array} \right\}$$

The following result generalizes Theorem 1.

**Theorem 4.** *Given (possibly) inconsistent credal probabilistic evidence, credal Jeffrey’s imaging yields the unique joint CS based on IK.*

Table 1: Summary of belief adjustment rules/properties.

RULE	$\Phi_*$	KINEMATICS
$\circ_J$	$\phi_x = c_x, \forall x$	PK
$\circ_A$	$\{y \rightarrow x\} = c_x, \forall x$	CPK
$\circ_{jI}$	$\{x\} = c_x, \forall x$	IK (Th. 1)
$\circ_{aI}$	$\{y \rightarrow x\} = c_x, \forall x$	ICK (Th. 2)
$\circ_{cjI}$	$\{x\} \bowtie c_x, \forall x$	IK (Th. 4)

## 5 CONCLUSIONS AND FUTURE WORK

We introduced adjustment operators based on Lewis’ imaging functional, to deal with probabilistic inconsistent evidence, in a generalized setting of imprecise probabilities, specified by credal sets. These are summarized in Table 1. We point out that the revision rules (conditioning, Jeffrey’s rule and Adams’ conditioning) are not fully general due to partiality, whereas the remaining succeed in adjusting a given belief set following inconsistent observations.

Further generalization to the case of credal conditional probabilistic evidence is not straightforward as the adjustment process would likely incur in dilating mechanics, resulting in detrimental loose inclusion relationships. This reasoning also applies to the iterated framework, where additional considerations must be formulated on the role evidence plays on the adjustment process. As a future work we will tackle this sort of scenarios. Besides that, we also intend to compare our approach against methods based on lexicographic probabilities (e.g., [Benavoli et al., 2017]) as well as applying

these ideas to probabilistic graphical models by extending what have been already done for Jeffrey’s rule in [Marchetti and Antonucci, 2018].

## A PROOFS

This appendix provides proofs to the results stated in the paper.

**Proof of Th. 1.** *To prove  $\circ_{jI}$  is based on IK, we must check it produces a CS that satisfies IK1-IK3. Motivated by [Rens et al., 2016, Th.1], we restrict our attention toward the extreme points of  $K$ . Without loss of generality, let  $\mathbf{X} = \{X, Y\}$ . Each extreme point of  $K(\mathbf{X})$ , say  $P_{j,k} \in \text{ext}[K]$ , may be equivalently specified as:*

$$P_{j,k}(x, y) = P(x|x'_j)P(y|x, y'_k), \quad (4)$$

with  $P(y|x, y'_k)$  is set equal to zero whenever it is undefined and  $P(x|x'_k) = 0$ .<sup>7</sup>  $X'$  and  $Y'$  are uniformly distributed auxiliary random variables, used to index  $K$ ’s extreme points at  $X$  and at  $Y|X$ , respectively. This way, for a given ordering,

$$\begin{aligned} P(x|x'_1) &= \sum_{y'_k, y} P(x|x'_1)P(y|x, y'_k)P(y'_k) \\ &= \underline{P}(x), \end{aligned}$$

and  $\underline{P}(x, y) = P(x|x'_1)P(y|x, y'_1)$ .

It holds:

$$\begin{aligned} \underline{P}_x^{\circ_I}(x) &= P_x^{\circ_I}(x|x'_1) \\ &= \sum_{y'_k, y, x} P(x|x'_1)P(y|x, y'_k)P(y'_k) \\ &\leq 1. \end{aligned}$$

Since  $P_x^{\circ_I}(x'|x'_1) = 0$ , for any  $x' \neq x$  in  $\Omega_X$ , refinement of  $K_x^{\circ_I}(x)$  degenerates at 1. If  $P'_X \models (\phi = \{x\})$ , IK3 is satisfied.

When a non-trivial PMF is provided, i.e.,  $P(x) > 0$  for at least two elements in  $\Omega_X$ , it holds:

$$\begin{aligned} P_X^{\circ_{jI}}(x|x'_1) &= \left[ \sum_{y'_k, y, x} P(x|x'_1)P(y|x, y'_k)P(y'_k) \right] P'_X(x) \\ &\leq P'_X(x), \end{aligned}$$

and similarly  $P_X^{\circ_{jI}}(x|x'_{|\text{ext}[K]}) \geq P'_X(x)$ . This proves IK2 since  $K_X^{\circ_{jI}}(X) \ni P'_X(X)$ .

<sup>7</sup>As a remark,  $P(x) = 0$  does not necessarily imply  $P(y|x) = 0$ , in De Finetti’s view.

Proof of IK1 is also straightforward:

$$\begin{aligned} P_X^{\circ_{aI}}(y|x, y'_1) &= \frac{\left[ \sum_{x, x'_j} P(x|x'_j)P(y|x, y'_1) \right] P'_X(x)}{P'_X(x)} \\ &= \sum_{x, x'_j} P(x|x'_j)P(y|x, y'_1) \\ &= P_x^{\circ_I}(y|y'_1) \end{aligned}$$

Analogous reasoning applies to the upper envelope, and thus  $K_X^{\circ_{aI}}(Y|x) \equiv K_x^{\circ_I}(Y)$ . This ends the proof.  $\square$

**Proof of Th. 2.** To prove  $\circ_{aI}$  is based on ICK we need to check ICK1-ICK5 are satisfied by  $K^\circ = (K \circ_{aI} P'_{X|y})$ . When  $|\text{ext}[K]| = 1$ , ICK1-ICK5 reduce to the following:

- ICK1'**  $P^\circ(\alpha|x, y) = P_x^{\circ_I}(\alpha|y)$ , for each  $x \in \Omega_X$ ,
- ICK2'**  $P^\circ(\alpha|y') = P(\alpha|y')$ ,
- ICK3'**  $P^\circ(Y) = P(Y)$ ,
- ICK4'**  $P^\circ(X|y) = P'_{X|y}(X|y)$ ,
- ICK5'**  $P^\circ(X|y) = P_x^{\circ_I}(X|y)$ , whenever  $P'_{X|y}(x|y) = 1$  for some  $x \in \Omega_X$ .

We first prove consistency points ICK4' and ICK5'. Let  $P'_{X|y}$  be any PMF on  $\Omega_X \times \{Y = y\}$ , it holds:

$$\begin{aligned} P_X^{\circ_{aI}}(x|y) &= \frac{P_x^{\circ_I}(y)P'_{X|y}(x|y)}{\sum_x P_x^{\circ_I}(y)P'_{X|y}(x|y)} \\ &= P'_{X|y}(x|y) \end{aligned}$$

since  $P_x^{\circ_I}(x, y) = P_x^{\circ_I}(y) = P(y)$ , whatever  $x \in \Omega_X$ . Also,  $\sum_x P'_{X|y}(x|y) = 1$  by definition. If  $P'_{X|y}(x|y) = 1$  for some  $x$ ,  $P_X^{\circ_{aI}}(x|y) = 1, 0$  otherwise. The following holds:

$$\begin{aligned} \underline{P}^\circ(x|y) &= \min_{P^\circ \in \text{ext}[K^\circ]} P^\circ(x|y) \\ &= P'_{X|y}(x|y) \frac{\overline{P}_x^{\circ_I}(y)}{\underline{P}_x^{\circ_I}(y)} \\ &\leq P'_{X|y}(x|y). \end{aligned}$$

Similarly,  $\overline{P}^\circ(X|y) \geq P'_{X|y}(X|y)$ , for each  $P^\circ \in \text{ext}[K^\circ]$ .

We now prove condition ICK1 (and thus ICK1') is satisfied by  $\circ_{aI}$ . Without loss of generality, let  $\mathbf{X} = \{X, Y, Z\}$ . It holds:

$$\begin{aligned} \underline{P}^\circ(z|x, y) &= \frac{P'_{X|y}(x|y)\overline{P}_x^{\circ_I}(z, y)}{P'_{X|y}(x|y)\overline{P}_x^{\circ_I}(y)} \\ &= \underline{P}_x^{\circ_I}(z|y). \end{aligned}$$

As for point ICK2 (and ICK2'), it trivially holds by Definition 10:

$$\underline{P}^\circ(z|y') = \underline{P}(z|y').$$

for any  $y' \neq y$ . ICK3' is proved analogously, since  $P_X^{\circ_{aI}}(y) = 1 - P(\neg y) = 1 - \sum_{y' \neq y} P_X^{\circ_{aI}}(y')$ . Similarly, fulfillment of ICK3 may be derived by the conjugacy relation [Walley, 1991].  $\square$

**Proof of Th. 3.** Consider CS  $K$  and conditional probabilistic evidence  $P'_{X|y}(X|y)$ . To avoid cumbersome notation, we write  $\circ$  to denote  $\circ_{aI}$  throughout the proof. Also, we refer to general formula  $\phi = c$  to denote both  $\phi_x$  and  $\phi_{x|y}$ .

KM1 and KM3 follow from IK2 and ICK4 (cfr Th.1 and Th.2, respectively).

We prove KM2 is not satisfied under general conditions. Consider the lower envelope of  $K$  at  $(x|y)$ . If  $K \models P'_{X|y}$ , it holds:

$$\underline{P}(x|y) \leq P'_{X|y}(x|y)$$

by definition, and  $(K \cup P'_{X|y}) = K$ . From previous discussion, we expect  $(K \circ P'_{X|y}) \supseteq K$ , equality holding if and only if  $K(\mathbf{X})$  may be equivalently specified as the product of sharp conditional assessment on  $\Omega_X \times \{Y = y\}$  and CS over  $(\mathbf{X} \setminus \{Y\}, y)$ . Same reasoning applies to KM5 and KM6. These three postulates are satisfied if and only if  $K$  is already degenerate at the domain of probabilistic evidence, and consistent with it already.

Postulate KM4 holds by [Rens et al., 2016, Th.1].  $\square$

The following preliminary result holds:

**Lemma 1.** Let  $K$  be a joint CS over  $\mathbf{X}$ , and let  $K'_X$  denote a credal probabilistic finding, gathered on  $\Omega_X$ . For any event  $\alpha$ , the Jeffrey's image  $K_X^{\circ_{c_j I}}(\alpha)$  of  $K(\alpha)$  on  $K'_X(X)$  satisfies the following:

$$K_X^{\circ_{c_j I}}(\alpha) \supseteq K_X^{\circ_{c_j I}}(\alpha|x) \supseteq K_x^{\circ_I}(\alpha)$$

for any  $\alpha \in \Sigma$ . Equality holds when  $|K'(X)| = 1$ .

**Proof of Lemma 1.** Let  $\mathbf{X} = \{X, Y\}$  and  $K$  be any CS over  $\Omega$ .  $K'_X$  is gathered on  $\Omega_X$ , to adjust  $K$  accordingly. By definition of credal Jeffrey's imaging, it holds:

$$\begin{aligned} \min_{P_X^{\circ_{c_j I}} \in K_X^{\circ_{c_j I}}} P_X^{\circ_{c_j I}}(y|x) &= \min_{P(y) \in K(Y)} P(y) \frac{P'_X(x)}{\overline{P}'_X(x)} \\ &\leq \min_{P(y) \in K(Y)} P(y), \end{aligned}$$

and analogously for the upper envelope, with  $\geq$ . This proves the rightest inclusion relationship:  $K_X^{\circ_{cjI}}(Y|x) \supseteq K_x^{\circ_I}(Y) (\equiv K(Y))$ . We now prove inclusion of  $K_X^{\circ_{cjI}}(y|x)$  by  $K_X^{\circ_{cjI}}(y)$ :

$$\begin{aligned} \frac{P_X^{\circ_{cjI}}(y)}{P_X^{\circ_{cjI}}(y|x)} &= \frac{P(y) \sum_x P'_X(x)}{P(y) \frac{P'_X(x)}{P_X(x)}} \\ &= \overline{P}'_X(x) \sum_{x' \neq x} P'_X(x') \\ &\leq 1. \end{aligned}$$

Hence  $P_X^{\circ_{cjI}}(y) \leq P_X^{\circ_{cjI}}(y|x)$ , for any  $x \in \Omega_X$ ,  $y \in \Omega_Y$ .  $\overline{P}_X^{\circ_{cjI}}(y) \geq \overline{P}_X^{\circ_{cjI}}(y|x)$  is derived analogously. Equality holds when  $K'_X(X) = \{P'_X(X)\}$  as  $P'_X(x) = \overline{P}'_X(x)$ , for each  $x \in \Omega_X$ , summing to one. □

**Proof of Th. 4.** Given a joint CS  $K$  over  $\mathbf{X}$  and  $K'_X$ , let  $\circ$  denote credal Jeffrey's imaging. IK1 is satisfied by Lemma 1. IK2 is also satisfied as it holds:

$$P_X^{\circ_{cjI}}(x) = 1 \cdot P'_X(x),$$

for each  $x \in \Omega_X$ . And analogously for  $\overline{P}_X^{\circ_{cjI}}(X)$ . When  $K'_X(X) = \{P'_X(X)\}$  such that  $P'_X(x) = 1$ , IK3 is satisfied since  $\circ_{cjI}$  reduces to  $\circ_{jI}$ . □

## Abstract

Structural Causal Models are widely used in causal modelling, but how they relate to other modelling tools is poorly understood. In this paper we provide a novel perspective on the relationship between Ordinary Differential Equations and Structural Causal Models. We show how, under certain conditions, the asymptotic behaviour of an Ordinary Differential Equation under non-constant interventions can be modelled using Dynamic Structural Causal Models. In contrast to earlier work, we study not only the effect of interventions on equilibrium states; rather, we model asymptotic behaviour that is *dynamic* under interventions that vary in time, and include as a special case the study of static equilibria.

## 1 INTRODUCTION

Ordinary Differential Equations (ODEs) provide a universal language to describe deterministic systems via equations that determine how variables change in time as a function of other variables. They provide an immensely popular and highly successful modelling framework, with applications in many diverse disciplines, such as physics, chemistry, biology, and economy. They are *causal* in the sense that at least in principle they allow us to reason about interventions: any external intervention in a system—e.g., moving an object by applying a force—can be modelled using modified differential equations by, for instance, including suitable forcing terms. In practice, of course, this may be arbitrarily difficult.

Structural Causal Models (SCMs, also known as Structural Equation Models) are another language capable of

---

\*Also affiliated with Max Planck Institute for Intelligent Systems, Tübingen.

describing causal relations and interventions and have been widely applied in the social sciences, economics, genetics and neuroscience (Pearl, 2009; Bollen, 2014). One of the successes of SCMs over other causal frameworks such as causal Bayesian networks, for instance, has been their ability to express cyclic causal models (Spirtes, 1995; Mooij et al., 2011; Hyttinen et al., 2012; Voortman et al., 2010; Lacerda et al., 2008; Bongers et al., 2018).

We view SCMs as an intermediate level of description between the highly expressive differential equation models and the probabilistic, non-causal models typically used in machine learning and statistics. This intermediate level of description ideally retains the benefits of a data-driven statistical approach while still allowing a limited set of causal statements about the effect of interventions. While it is well understood how an SCM induces a statistical model (Bongers et al., 2018), much less is known about how a differential equation model—our most fundamental level of modelling—can imply an SCM in the first place. This is an important question because if we are to have models of a system on different levels of complexity, we should understand how they relate and the conditions under which they are consistent with one another.

Indeed, recent work has begun to address the question of how SCMs arise naturally from more fundamental models by showing how, under strong assumptions, SCMs can be derived from an underlying discrete time difference equation or continuous time ODE (Iwasaki and Simon, 1994; Dash, 2005; Lacerda et al., 2008; Voortman et al., 2010; Mooij et al., 2013; Sokol and Hansen, 2014). With the exception of (Voortman et al., 2010) and (Sokol and Hansen, 2014), each of these methods assume that the dynamical system comes to a static equilibrium that is independent of initial conditions, with the derived SCM describing how this equilibrium changes under intervention. More recently, the more general case in which the equilibrium state may depend on the initial conditions has been addressed (Bongers and Mooij, 2018; Blom and Mooij, 2018).

If the assumption that the system reaches a static equilibrium is reasonable for a particular system under study, the SCM framework can be useful. Although the derived SCM then lacks information about the (possibly rich) transient dynamics of the system, if the system equilibrates quickly then the description of the system as an SCM may be a more convenient and compact representation of the causal structure of interest. By making assumptions on the dynamical system and the interventions being made, the SCM effectively allows us to reason about a ‘higher level’ qualitative description of the dynamics—in this case, the equilibrium states.

There are, however, two major limitations that stem from the equilibrium assumption. First, for many dynamical systems the assumption that the system settles to a unique equilibrium, either in its observational state or under intervention, may be a bad approximation of the actual system dynamics. Second, this framework is only capable of modelling interventions in which a subset of variables are clamped to fixed values (*constant* interventions). Even for rather simple physical systems such as a forced damped simple harmonic oscillator, these assumptions are violated.

Motivated by these observations, the work presented in this paper tries to answer the following questions: (i) Can the SCM framework be extended to model systems that do not converge to an equilibrium? (ii) If so, what assumptions need to be made on the ODE and interventions so that this is possible? Since SCMs are used in a variety of situations in which the equilibrium assumption does not necessarily hold, we view these questions as important in order to understand when they are indeed theoretically grounded as modelling tools. The main contribution of this paper is to show that the answer to the first question is ‘Yes’ and to provide sufficient conditions for the second. We do this by extending the SCM framework to encompass time-dependent dynamics and interventions and studying how such objects can arise from ODEs. We refer to this as a *Dynamic SCM (DSCM)* to distinguish it from the static equilibrium case for the purpose of exposition, but note that this is conceptually the same as an SCM on a fundamental level. Our construction draws inspiration from the approach of Mooij et al. (2013), that was recently generalized to also incorporate the stochastic setting (Bongers and Mooij, 2018). Here, we adapt the approach by replacing the static equilibrium states by continuous-time *trajectories*, considering two trajectories as equivalent if they do not differ asymptotically.

Note that whilst this paper applies a causal perspective to the study of dynamical systems, the goal of this paper is not to derive a learning algorithm which can be applied to time series data. In this sense, we view our main re-

sults as ‘orthogonal’ to methods such as Granger causality (Granger, 1969) and difference-in-differences (Card and Krueger, 1993) which aim to infer causal effects given time-series observations of a system. We envision that DSCMs may be used for causal analysis of dynamical systems that undergo periodic motion. Although these systems have been mostly ignored so far in the field of causal discovery, they have been studied extensively in the field of control theory. Some examples of systems that naturally exhibit oscillatory stationary states and where our framework may be applicable are EEG signals, circadian signals, seasonal influences, chemical oscillations, electric circuits, aerospace vehicles, and satellite control. We refer the reader to (Bittanti and Colaneri, 2009) for more details on these application areas from the perspective of periodic control theory.

Since the DSCM derived for a simple harmonic oscillator (see Example 4) is already quite complex, we leave the task of deriving methods that estimate the parameters from data for future work. Rather, our current work presents a first necessary theoretical step that needs to be done before applications of this theory can be developed, enabling the development of data-driven causal discovery and prediction methods for oscillatory systems, and possibly even more general systems, down the road.

The remainder of this paper is organised as follows. In Section 2, we introduce notation to describe ODEs. In Section 3, we describe how to apply the notion of an intervention on an ODE to the dynamic case. In Section 4, we define regularity conditions on the asymptotic behaviour of an ODE under a set of interventions. In Section 5, we present our main result: subject to conditions on the dynamical system and interventions being modelled, a *Dynamic SCM* can be derived that allows one to reason about how the asymptotic dynamics change under interventions on variables in the system. We conclude in Section 6.

## 2 ORDINARY DIFFERENTIAL EQUATIONS

Let  $\mathcal{I} = \{1, \dots, D\}$  be a set of variable labels. Consider time-indexed variables  $X_i(t) \in \mathcal{R}_i$  for  $i \in \mathcal{I}$ , where  $\mathcal{R}_i \subseteq \mathbb{R}$  and  $t \in \mathbb{R}_{\geq 0} = [0, \infty)$ . For  $I \subseteq \mathcal{I}$ , we write  $\mathbf{X}_I(t) \in \prod_{i \in I} \mathcal{R}_i$  for the tuple of variables  $(X_i(t))_{i \in I}$ . By an ODE  $\mathcal{D}$ , we mean a collection of  $D$  coupled ordinary differential equations with initial conditions  $\mathbf{X}_0^{(k)}$ :

$$\mathcal{D} : \begin{cases} f_i(X_i, \mathbf{X}_{\text{pa}(i)})(t) = 0, & X_i^{(k)}(0) = (\mathbf{X}_0^{(k)})_i, \\ & 0 \leq k \leq n_i - 1, \quad i \in \mathcal{I}, \end{cases}$$

where the  $i$ th differential equation determines the evolution of the variable  $X_i$  in terms of  $\mathbf{X}_{\text{pa}(i)}$ , where  $\text{pa}(i) \subseteq \mathcal{I}$  are the *parents of  $i$* , and  $X_i$  itself, and where

$n_i$  is the order of the highest derivative  $X_i^{(k)}$  of  $X_i$  that appears in equation  $i$ . Here,  $f_i$  is a functional that can include time-derivatives of its arguments. We think of the  $i$ th differential equation as modelling the *causal mechanism* that determines the dynamics of the effect  $X_i$  in terms of its direct causes  $\mathbf{X}_{\text{pa}(i)}$ .

One possible way to write down an ODE is to canonically decompose it into a collection of first order differential equations, such as is done in Mooij et al. (2013). We choose to present our ODEs as “one equation per variable” rather than splitting up the equations due to complications that would otherwise occur when considering time-dependent interventions (cf. Section 3.3).

**Example 1.** Consider a one-dimensional system of  $D$  particles of mass  $m_i$  ( $i = 1, \dots, D$ ) with positions  $X_i$  coupled by springs with natural lengths  $l_i$  and spring constants  $k_i$ , where the  $i$ th spring connects the  $i$ th and  $(i + 1)$ th masses and the outermost springs have fixed ends (see Figure 1a). Assume further that the  $i$ th mass undergoes linear damping with coefficient  $b_i$ .

Denoting by  $\dot{X}_i$  and  $\ddot{X}_i$  the first and second time derivatives of  $X_i$  respectively, the equation of motion for the  $i$ th variable is given by

$$m_i \ddot{X}_i(t) = k_i [X_{i+1}(t) - X_i(t) - l_i] - k_{i-1} [X_i(t) - X_{i-1}(t) - l_{i-1}] - b_i \dot{X}_i(t)$$

where we take  $X_0 = 0$  and  $X_D = L$  to be the fixed positions of the end springs. For the case that  $D = 2$ , we can write the system of equations as:

$$D : \begin{cases} 0 = m_1 \ddot{X}_1(t) + b_1 \dot{X}_1(t) + (k_1 + k_0)X_1(t) \\ \quad - k_1 X_2(t) - k_0 l_0 + k_1 l_1, \\ 0 = m_2 \ddot{X}_2(t) + b_2 \dot{X}_2(t) + (k_2 + k_1)X_2(t) \\ \quad - k_2 L - k_1 X_1(t) - k_2 l_1 + k_2 l_2, \\ X_i^{(k)}(0) = (\mathbf{X}_0^{(k)})_i \quad k \in \{0, 1\}, i \in \{1, 2\}. \end{cases}$$

We can represent the functional dependence structure between variables implied by the functions  $f_i$  with a graph, in which variables are nodes and arrows point  $X_j \rightarrow X_i$  if  $j \in \text{pa}(i)$ . Self loops  $X_i \rightarrow X_i$  exist if  $X_i^{(k)}$  appears in the expression of  $f_i$  for more than one value of  $k$ . This is illustrated for the system described in Example 1 in Figure 1b.

### 3 INTERVENTIONS ON ODES

We interpret ODEs as *causal* models. In particular, we consider the graph expressing the functional dependence structure to be the causal graph of the system, with an

edge between  $X_i$  and  $X_j$  iff  $X_i$  is a direct cause of  $X_j$  (in the context of all variables  $\mathbf{X}_{\mathcal{I}}$ ). In this section, we will formalize this causal interpretation by studying interventions on the system.

#### 3.1 TIME-DEPENDENT PERFECT INTERVENTIONS

Usually in the causality literature, by a *perfect intervention* it is meant that a variable is clamped to take a specific given value. The natural analogue of this in the time-dependent case is a perfect intervention that forces a variable to take a particular *trajectory*. That is, given a subset  $I \subseteq \mathcal{I}$  and a function  $\zeta_I : \mathbb{R}_{\geq 0} \rightarrow \prod_{i \in I} \mathcal{R}_i$ , we can intervene on the subset of variables  $\mathbf{X}_I$  by forcing  $\mathbf{X}_I(t) = \zeta_I(t) \forall t \in \mathbb{R}_{\geq 0}$ . Using Pearl’s do-calculus notation (Pearl, 2009) and for brevity omitting the  $t$ , we write  $\text{do}(\mathbf{X}_I = \zeta_I)$  for this intervention. Such interventions are more general objects than those of the equilibrium or time-independent case, but in the specific case that we restrict ourselves to constant trajectories the two notions coincide.

#### 3.2 SETS OF INTERVENTIONS

Recall that when modelling equilibrating dynamical systems under constant interventions, the set of interventions modelled coincides with the asymptotic behaviour of the system. We will generalise this relation to non-equilibrating behaviour.

The Dynamic SCMs that we will derive will describe the asymptotic dynamics of the ODE and how they change under different interventions. If we want to model ‘all possible interventions’, then the resulting asymptotic dynamics that can occur are arbitrarily complicated. The idea is to fix a simpler set of interventions and derive an SCM that models only these interventions, resulting in a model that is simpler than the original ODE but still allows us to reason about interventions we are interested in. In the examples in this paper, we restrict ourselves to periodic or quasi-periodic interventions, but the results hold for more general sets of interventions that satisfy the stability definitions presented later.

We need to define some notation to express the sets of interventions and the set of system responses to these interventions that we will model. Since interventions correspond to forcing variables to take some trajectory, we describe notation for defining sets of trajectories: For  $I \subseteq \mathcal{I}$ , let  $\text{Dyn}_I$  be a set of trajectories in  $\prod_{i \in I} \mathcal{R}_i$ . Let  $\text{Dyn} = \cup_{I \in \mathcal{P}(\mathcal{I})} \text{Dyn}_I$  (where  $\mathcal{P}(\mathcal{I})$  is the power set of  $\mathcal{I}$  i.e., the set of all subsets of  $\mathcal{I}$ ). Thus, an element  $\zeta_I \in \text{Dyn}_I$  is a function  $\mathbb{R}_{\geq 0} \rightarrow \prod_{i \in I} \mathcal{R}_i$ , and  $\text{Dyn}$  consists of such functions for different  $I \subseteq \mathcal{I}$ . The main idea is that we want both the interventions and the system

Figure 1: (a) The mass-spring system of Example 1 with  $D = 2$ ; (b–c) graphs representing the causal structure of the mass-spring system for (b) the observational system, (c) after the intervention on variable  $X_1$  described in Example 2. As a result of the intervention,  $X_1$  is not causally influenced by any variable, while the causal mechanism of  $X_2$  remains unchanged.

responses to be elements of  $\text{Dyn}$ ; in other words, the set of possible system responses should be large enough to contain all interventions that we would like to model, and in addition, all responses of the system to those interventions. The reader might wonder why we do not simply take the set of *all* possible trajectories, but that set would be so large that it would not be practical for modeling purposes.<sup>1</sup>

Since our goal will be to derive a causal model that describes the relations between components (variables) of the system, we will need the following definition in Section 5.

**Definition 1.** A set of trajectories  $\text{Dyn}$  is **modular** if, for any  $\{i_1, \dots, i_n\} = I \subseteq \mathcal{I}$ ,

$$\zeta_I \in \text{Dyn} \iff \zeta_{i_k} \in \text{Dyn} \quad \forall k \in \{1, \dots, n\}.$$

This should be interpreted as saying that admitted trajectories of single variables can be combined arbitrarily into admitted trajectories of the whole system (and *vice versa*, admitted system trajectories can be decomposed into trajectories of individual variables), and in addition, that interventions on each variable can be made independently and combined in any way.<sup>2</sup> This is not to say that all such interventions must be physically possible to implement in practice. Rather, this means that the mathematical model we derive should allow one to *reason* about all such interventions. Not all sets of trajectories  $\text{Dyn}$  are modular; in the following sections we will assume that the

<sup>1</sup>For example, one might want to parameterize the set of trajectories in order to learn the model from data. Without any restriction on the smoothness of the trajectories, the problem of estimating a trajectory from data becomes ill-posed. Secondly, since we would like to identify trajectories that are asymptotically identical in order to focus the modeling efforts on the *asymptotic* behaviour of the system, we will only put a single trajectory into  $\text{Dyn}$  to represent all trajectories that are asymptotically identical to that trajectory, but whose transient dynamics may differ.

<sup>2</sup>This is related to notions that have been discussed in the literature under various headings, for instance autonomy and invariance (Pearl, 2009).

sets of trajectories we are considering *are* for the purposes of constructing the Dynamic SCMs. Some examples of trivially modular sets of trajectories are: (i) all static (i.e., time-independent) trajectories, corresponding to (Mooij et al., 2013); (ii) all continuously-differentiable trajectories that differ asymptotically; (iii) all periodic motions. The latter is the running example in this paper.

### 3.3 DESCRIBING INTERVENTIONS ON ODES

We can realise a perfect intervention by replacing the equations of the intervened variables with new equations that fix them to take the specified trajectories:<sup>3</sup>

$$\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)} : \begin{cases} f_i(X_i, \mathbf{X}_{\text{pa}(i)})(t) = 0, & X_i^{(k)}(0) = (\mathbf{X}_0^{(k)})_i, \\ 0 \leq k \leq n_i - 1, & i \in \mathcal{I} \setminus I, \\ X_i(t) - \zeta_i(t) = 0, & i \in I. \end{cases}$$

This procedure is analogous to the notion of intervention in an SCM. In reality, this corresponds to decoupling the intervened variables from their usual causal mechanism by forcing them to take a particular value, while leaving the non-intervened variables' causal mechanisms unaffected.

Perfect interventions will not generally be realisable in the real world. In practice, an intervention on a variable would correspond to altering the differential equation governing its evolution by adding extra forcing terms; perfect interventions could be realised by adding forcing terms that push the variable towards its target value at each instant in time, and considering the limit as these forcing terms become infinitely strong so as to dominate the usual causal mechanism determining the evolution of the variable.

**Example 2 (continued).** Consider the mass-spring system described in Example 1. If we were to intervene on

<sup>3</sup>Note that in the intervened ODE, the initial conditions of the intervened variables do not need to be specified explicitly as for the other variables, since they are implied by considering  $t = 0$ .

the system to force the mass  $X_1$  to undergo simple harmonic motion, we could express this as a change to the system of differential equations as:

$$\mathcal{D}_{\text{do}(X_1(t)=l_1+A \cos(\omega t))} : \begin{cases} 0 = X_1(t) - l_1 - A \cos(\omega t), \\ 0 = m_2 \ddot{X}_2(t) + b_2 \dot{X}_2(t) + (k_2 + k_1)X_2(t) \\ \quad - k_2 L - k_1 X_1(t) - k_2 l_1 + k_2 l_2, \\ X_2^{(k)}(0) = (\mathbf{X}_0^{(k)})_2 \quad k \in \{0, 1\}. \end{cases}$$

This induces a change to the graphical description of the causal relationships between the variables. We break any incoming arrows to any intervened variable, including self loops, as the intervened variables are no longer causally influenced by any other variable in the system. See Figure 1c for the graph corresponding to the intervened ODE in Example 2.

## 4 DYNAMIC STABILITY

A crucial assumption of Mooij et al. (2013) was that the systems considered were *stable* in the sense that they would converge to unique stable equilibria (if necessary, also after performing a constant intervention). This made them amenable to study by considering the  $t \rightarrow \infty$  limit in which any complex but transient dynamical behaviour would have decayed. The SCMs derived would allow one to reason about the asymptotic equilibrium states of the systems after interventions. Since we want to consider non-constant asymptotic dynamics, this is not a notion of stability that is fit for our purposes.

Instead, we define our stability with reference to a set of trajectories. We will use  $\text{Dyn}_{\mathcal{I}}$  for this purpose. Recall that elements of  $\text{Dyn}_{\mathcal{I}}$  are trajectories for all variables in the system. To be totally explicit, we can think of an element  $\boldsymbol{\eta} \in \text{Dyn}_{\mathcal{I}}$  as a function

$$\boldsymbol{\eta} : \mathbb{R}_{\geq 0} \rightarrow \mathcal{R}_{\mathcal{I}} \\ t \mapsto (\eta_1(t), \eta_2(t), \dots, \eta_D(t))$$

where  $\eta_i(t) \in \mathcal{R}_i$  is the state of the  $i$ th variable  $X_i$  at time  $t$ . Note that  $\text{Dyn}_{\mathcal{I}}$  is not a single fixed set, independent of the situation we are considering. We can choose  $\text{Dyn}_{\mathcal{I}}$  depending on the ODE  $\mathcal{D}$  under consideration, and the interventions that we may wish to make on it.

Informally, stability in this paper means that the asymptotic dynamics of the dynamical system converge to a unique element of  $\text{Dyn}_{\mathcal{I}}$ , independent of initial condition. If  $\text{Dyn}_{\mathcal{I}}$  is in some sense simple, we can simply characterise the asymptotic dynamics of the system under study. The following definitions of stability extend those

of Mooij et al. (2013) to allow for non-constant trajectories in  $\text{Dyn}_{\mathcal{I}}$ , and coincide with them in the case that  $\text{Dyn}_{\mathcal{I}}$  consists of all constant trajectories in  $\mathcal{R}_{\mathcal{I}}$ .

**Definition 2.** The ODE  $\mathcal{D}$  is **dynamically stable with reference to**  $\text{Dyn}_{\mathcal{I}}$  if there exists a unique  $\boldsymbol{\eta}_0 \in \text{Dyn}_{\mathcal{I}}$  such that  $\mathbf{X}_{\mathcal{I}}(t) = \boldsymbol{\eta}_0(t) \forall t$  is a solution to  $\mathcal{D}$  and that for any initial condition, the solution  $\mathbf{X}_{\mathcal{I}}(t) \rightarrow \boldsymbol{\eta}_0(t)$  as  $t \rightarrow \infty$ .<sup>4</sup>

We use a subscript  $\emptyset$  to emphasise that  $\boldsymbol{\eta}_0$  describes the asymptotic dynamics of  $\mathcal{D}$  without any intervention. Observe that  $\text{Dyn}_{\mathcal{I}}$  could consist of the single element  $\boldsymbol{\eta}_0$  in this case. The requirement that this hold for all initial conditions can be relaxed to hold for all initial conditions except on a set of measure zero, but that would mean that the proofs later on require some more technical details. For the purpose of exposition, we stick to this simpler case.

**Example 3.** Consider a single mass on a spring that is undergoing simple periodic forcing and is underdamped. Such a system could be expressed as a single (parent-less) variable with ODE description:

$$\mathcal{D} : \begin{cases} m\ddot{X}_1(t) + b\dot{X}_1(t) + k(X_1(t) - l) \\ \quad = F \cos(\omega t + \phi), \\ X_1^{(k)}(0) = (X_0^{(k)}) \quad k \in \{0, 1\}. \end{cases}$$

The solution to this differential equation is

$$X_1(t) = r(t) + l + A \cos(\omega t + \phi') \quad (1)$$

where  $r(t)$  decays exponentially quickly (and is dependent on the initial conditions) and  $A$  and  $\phi'$  depend on the parameters of the equation of motion (but not on the initial conditions).

Therefore such a system would be dynamically stable with reference to (for example)

$$\text{Dyn}_{\mathcal{I}} = \{l + A \cos(\omega t + \phi') : A \in \mathbb{R}, \phi' \in [0, 2\pi)\}.$$

**Remark 1.** We use a subscript  $\zeta_I$  to emphasise that  $\boldsymbol{\eta}_{\zeta_I}$  describes the asymptotic dynamics of  $\mathcal{D}$  after performing the intervention  $\text{do}(\mathbf{X}_I = \zeta_I)$ . Observe that  $\text{Dyn}_{\mathcal{I}}$  could consist only of the single element  $\boldsymbol{\eta}_{\zeta_I}$  and the above definition would be satisfied. But then the original ODE wouldn't be dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$ , nor would other intervened versions of  $\mathcal{D}$ . This motivates the following definition, extending dynamic stability to sets of intervened systems.

<sup>4</sup>The convergence we refer to here is the usual asymptotic convergence of real-valued functions, i.e., for  $f : [0, \infty) \rightarrow \mathbb{R}^d$ ,  $g : [0, \infty) \rightarrow \mathbb{R}^d$  we have that  $f \rightarrow g$  iff for every  $\epsilon > 0$  there is a  $T \in [0, \infty)$  such that  $|f(t) - g(t)| < \epsilon$  for all  $t \in [T, \infty)$ .

**Definition 3.** Let  $\text{Traj}$  be a set of trajectories. We say that the pair  $(\mathcal{D}, \text{Traj})$  is **dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$**  if, for any  $\zeta_{\mathcal{I}} \in \text{Traj}$ ,  $\mathcal{D}_{\text{do}(\mathbf{X}_{\mathcal{I}}=\zeta_{\mathcal{I}})}$  is dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$ .

**Example 3** (continued). Suppose we are interested in modelling the effect of changing the forcing term, either in amplitude, phase or frequency. We introduce a second variable  $X_2$  to model the forcing term:

$$\mathcal{D} : \begin{cases} 0 = f_1(X_1, X_2)(t) \\ \quad = m\ddot{X}_1(t) + b\dot{X}_1(t) + k(X_1(t) - l) - X_2(t), \\ 0 = f_2(X_2)(t) \\ \quad = X_2(t) - F_0 \cos(\omega_0 t + \phi_0), \\ X_1^{(k)}(0) = (\mathbf{X}_0^{(k)})_1, \quad k \in \{0, 1\}. \end{cases}$$

If we want to change the forcing term that we apply to the mass, we can interpret this as performing an intervention on  $X_2$ . We could represent this using the notation we have developed as

$$\text{Dyn}_{\{2\}} = \{\zeta_2(t) = F_2 \cos(\omega t + \phi_2) : F_2, \omega \in \mathbb{R}, \phi_2 \in [0, 2\pi]\}.$$

For any intervention  $\zeta_2 \in \text{Dyn}_{\{2\}}$ , the dynamics of  $X_1$  in  $\mathcal{D}_{\text{do}(X_2=\zeta_2)}$  will be of the form (1). Therefore  $(\mathcal{D}, \text{Dyn}_{\{2\}})$  will be dynamically stable with reference to

$$\text{Dyn}_{\mathcal{I}} = \left\{ \zeta(t) = (l + F_1 \cos(\omega t + \phi_1), F_2 \cos(\omega t + \phi_2)) : F_1, F_2, \omega \in \mathbb{R}, \phi_1, \phi_2 \in [0, 2\pi] \right\}.$$

The independence of initial conditions for Example 3 is illustrated in Figure 2.

Note that if  $(\mathcal{D}, \text{Traj})$  is dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$ , and  $\text{Dyn}'_{\mathcal{I}} \supseteq \text{Dyn}_{\mathcal{I}}$  is a larger set of trajectories that still satisfies the uniqueness condition in the definition of dynamic stability,<sup>5</sup> then  $(\mathcal{D}, \text{Traj})$  is dynamically stable with reference to  $\text{Dyn}'_{\mathcal{I}}$ .

## 5 DYNAMIC STRUCTURAL CAUSAL MODELS

A deterministic SCM  $\mathcal{M}$  is a collection of structural equations, the  $i$ th of which defines the value of variable  $X_i$

<sup>5</sup>Namely:  $\forall \zeta_{\mathcal{I}} \in \text{Traj}, \exists! \eta_{\zeta_{\mathcal{I}}} \in \text{Dyn}'_{\mathcal{I}}$  such that under  $\mathcal{D}_{\text{do}(\mathbf{X}_{\mathcal{I}}=\zeta_{\mathcal{I}})}$  and for any initial condition,  $X_{\mathcal{I}}(t) \rightarrow \eta_{\zeta_{\mathcal{I}}}(t)$  as  $t \rightarrow \infty$ . Assuming that  $(\mathcal{D}, \text{Traj})$  is dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$ , a sufficient condition for this is that none of the elements in  $\text{Dyn}'_{\mathcal{I}} \setminus \text{Dyn}_{\mathcal{I}}$  are asymptotically equal to any of the elements of  $\text{Dyn}_{\mathcal{I}}$ . That is:  $\forall \zeta \in \text{Dyn}_{\mathcal{I}}, \forall \zeta' \in \text{Dyn}'_{\mathcal{I}} \setminus \text{Dyn}_{\mathcal{I}}, \zeta(t) \not\rightarrow \zeta'(t)$  as  $t \rightarrow \infty$ .

in terms of its parents. We extend this to the case that our variables do not take fixed values but rather represent entire trajectories.

**Definition 4.** Let  $\text{Dyn} = \bigcup_{\mathcal{I} \subseteq \mathcal{I}} \text{Dyn}_{\mathcal{I}}$  be a modular set of trajectories, where  $\text{Dyn}_{\mathcal{I}} \subseteq \mathcal{R}_{\mathcal{I}}^{\mathbb{R}_{\geq 0}}$ . A deterministic Dynamic Structural Causal Model (DSCM) on the time-indexed variables  $\mathbf{X}_{\mathcal{I}}$  taking values in  $\text{Dyn}$  is a collection of structural equations

$$\mathcal{M} : \{ X_i = F_i(\mathbf{X}_{\text{pa}(i)}) \quad i \in \mathcal{I},$$

where  $\text{pa}(i) \subseteq \mathcal{I} \setminus \{i\}$  and each  $F_i$  is a map  $\text{Dyn}_{\text{pa}(i)} \rightarrow \text{Dyn}_i$  that gives the trajectory of an effect variable in terms of the trajectories of its direct causes.

The point of this paper is to show that, subject to restrictions on  $\mathcal{D}$  and  $\text{Dyn}$ , we can derive a DSCM that allows us to reason about the effect on the asymptotic dynamics of interventions using trajectories in  $\text{Dyn}$ . ‘Traditional’ deterministic SCMs arise as a special case, where all trajectories are constant over time.

In an ODE, the equations  $f_i$  determine the causal relationship between the variable  $X_i(t)$  and its parents  $\mathbf{X}_{\text{pa}(i)}(t)$  at each instant in time. In contrast, we think of the function  $F_i$  of the DSCM as a causal mechanism that determines the entire trajectory of  $X_i$  in terms of the trajectories of the variables  $\mathbf{X}_{\text{pa}(i)}$ , integrating over the instantaneous causal effects over all time. In the case that  $\text{Dyn}$  consists of constant trajectories (and thus the instantaneous causal effects are constant over time), a DSCM reduces to a traditional deterministic SCM.

The rest of this section is laid out as follows. In Section 5.1 we define what it means to make an intervention in a DSCM. In Section 5.2 we show how, subject to certain conditions, a DSCM can be derived from a pair  $(\mathcal{D}, \text{Dyn})$ . The procedure for doing this relies on intervening on all but one variable at a time. In Section 5.3, Theorem 2 states that the DSCM thus derived is capable of modelling the effect of intervening on arbitrary subsets of variables, even though it was constructed by considering the case that we consider interventions on exactly  $D - 1$  variables. Theorem 3 and Corollary 1 in Section 5.4 prove that the notions of intervention in ODE and the derived DSCM coincide. Collectively, these theorems tell us that we can derive a DSCM that allows us to reason about the effects of interventions on the asymptotic dynamics of the ODE. Proofs of these theorems are provided in Section A of the Supplementary Material.

### 5.1 INTERVENTIONS IN A DSCM

Interventions in (D)SCMs are realized by replacing the structural equations of the intervened variables. Given

Figure 2: Simulations from the forced simple harmonic oscillator in Example 3 showing the evolution of  $X_1$  with different initial conditions for different forcing terms (interventions on  $X_2$ ). The parameters used were  $m = 1, k = 1, l = 2, F = 2, b = 0.1$ , with (a)  $\omega = 3$  and (b)  $\omega = 2$ . Dynamic stability means that asymptotic dynamics are independent of initial conditions, and the purpose of the DSCM is to quantify how the asymptotic dynamics change under intervention.

$\zeta_I \in \text{Dyn}_I$  for some  $I \subseteq \mathcal{I}$ , the intervened DSCM  $\mathcal{M}_{\text{do}(\mathbf{X}_I = \zeta_I)}$  can be written:

$$\mathcal{M}_{\text{do}(\mathbf{X}_I = \zeta_I)} : \begin{cases} X_i = F_i(\mathbf{X}_{\text{pa}(i)}) & i \in \mathcal{I} \setminus I, \\ X_i = \zeta_i & i \in I. \end{cases}$$

The causal mechanisms determining the non-intervened variables are unaffected, so their structural equations remain the same. The intervened variables are decoupled from their usual causal mechanisms and are forced to take the specified trajectory.

## 5.2 DERIVING DSCMs FROM ODEs

In order to derive a DSCM from an ODE, we require the following consistency property between the asymptotic dynamics of the ODE and the set of interventions.

**Definition 5** (Structural dynamic stability). *Let  $\text{Dyn}$  be modular. The pair  $(\mathcal{D}, \text{Dyn})$  is **structurally dynamically stable** if  $(\mathcal{D}, \text{Dyn}_{\mathcal{I} \setminus \{i\}})$  is dynamically stable with reference to  $\text{Dyn}_{\mathcal{I}}$  for all  $i$ .*

This means that for any intervention trajectory  $\zeta_{\mathcal{I} \setminus \{i\}} \in \text{Dyn}_{\mathcal{I} \setminus \{i\}}$ , the asymptotic dynamics of the intervened ODE  $\mathcal{D}_{\text{do}(\mathbf{X}_{\mathcal{I} \setminus \{i\}} = \zeta_{\mathcal{I} \setminus \{i\}})}$  are expressible uniquely as an element of  $\text{Dyn}_{\mathcal{I}}$ . Since  $\text{Dyn}$  is modular, the asymptotic dynamics of the non-intervened variable can be realised as the trajectory  $\zeta_i \in \text{Dyn}_i$ , and thus  $\text{Dyn}$  is rich enough to allow us to make an intervention which forces the non-intervened variable to take this trajectory. This is a crucial property that allows the construction of the structural equations. In the particular case that  $\text{Dyn}$  consists of all constant trajectories, structural dynamic stability means that after any intervention on all-but-one-variable, the non-intervened variable settles to a unique equilibrium. In the language of Mooij et al. (2013), this would imply that the ODE is *structurally stable*.

It should be noted that  $(\mathcal{D}, \text{Dyn})$  being structurally dynamically stable is a strong assumption in general. If  $\text{Dyn}$  is too small,<sup>6</sup> then it may be possible to find a larger set  $\text{Dyn}' \supset \text{Dyn}$  such that  $(\mathcal{D}, \text{Dyn}')$  is structurally dynamically stable. The procedure described in this section describes how to derive a DSCM capable of modelling all interventions in  $\text{Dyn}'$ , which can thus be used to model interventions in  $\text{Dyn}$ .

Henceforth, we use the notation  $I_i = \mathcal{I} \setminus \{i\}$  for brevity. Suppose that  $(\mathcal{D}, \text{Dyn})$  is structurally dynamically stable. We can **derive structural equations**  $F_i : \text{Dyn}_{\text{pa}(i)} \rightarrow \text{Dyn}_i$  to describe the asymptotic dynamics of children variables as functions of their parents as follows. Pick  $i \in \mathcal{I}$ . The variable  $X_i$  has parents  $\mathbf{X}_{\text{pa}(i)}$ . Since  $\text{Dyn}$  is modular, for any configuration of parent dynamics  $\eta_{\text{pa}(i)} \in \text{Dyn}_{\text{pa}(i)}$  there exists  $\zeta_{I_i} \in \text{Dyn}_{I_i}$  such that  $(\zeta_{I_i})_{\text{pa}(i)} = \eta_{\text{pa}(i)}$ .

By structural dynamic stability, the system  $\mathcal{D}_{\text{do}(\mathbf{X}_{I_i} = \zeta_{I_i})}$  has asymptotic dynamics specified by a unique element  $\eta \in \text{Dyn}_{\mathcal{I}}$ , which in turn defines a unique element  $\eta_i \in \text{Dyn}_i$  specifying the asymptotic dynamics of variable  $X_i$  since  $\text{Dyn}$  is modular.

**Theorem 1.** *Suppose that  $(\mathcal{D}, \text{Dyn})$  is structurally dynamically stable. Then the functions*

$$F_i : \text{Dyn}_{\text{pa}(i)} \rightarrow \text{Dyn}_i : \eta_{\text{pa}(i)} \mapsto \eta_i$$

*constructed as above are well-defined.*

Given the structurally dynamically stable pair  $(\mathcal{D}, \text{Dyn})$  we define the derived DSCM

$$\mathcal{M}_{\mathcal{D}} : \{ X_i = F_i(\mathbf{X}_{\text{pa}(i)}) \quad i \in \mathcal{I},$$

<sup>6</sup>For example, if  $\text{Dyn}$  is not modular or represents interventions on only a subset of the variables.

where the  $F_i : \text{Dyn}_{\text{pa}(i)} \rightarrow \text{Dyn}_i$  are defined as above. Note that structural dynamic stability was a crucial property that ensured  $F_i(\text{Dyn}_{\text{pa}(i)}) \subseteq \text{Dyn}_i$ . If  $(\mathcal{D}, \text{Dyn})$  is not structurally dynamically stable, we cannot build structural equations in this way.

We provide next an example of a DSCM for the mass-spring system of Example 1 with  $D = 2$ . The derivation of this for the general case of arbitrarily many masses is included in the Supplementary Material.

**Example 4.** Consider the system  $\mathcal{D}$  governed by the differential equation of Example 1 with  $D = 2$ . Let  $\text{Dyn}_{\{1,2\}}$  be the modular set of trajectories with

$$\text{Dyn}_{\{i\}} = \left\{ \sum_{j=1}^{\infty} A_i^j \cos(\omega_i^j t + \phi_i^j) : \right. \\ \left. w_i^j, \phi_i^j, A_i^j \in \mathbb{R}, \sum_{j=1}^{\infty} |A_i^j| < \infty \right\}$$

for  $i = 1, 2$ , where for each  $i$  it holds that  $\sum_{j=1}^{\infty} |A_i^j| < \infty$  (so that the series is absolutely convergent). Then  $(\mathcal{D}, \text{Dyn}_{\{1,2\}})$  is structurally dynamically stable and admits the following DSCM.

$$\mathcal{M} : \begin{cases} X_1 &= F_1(X_2) \\ X_2 &= F_2(X_1) \end{cases}$$

where, writing  $C_1^j = [k_1 + k_2 - m_1(\omega_2^j)^2]^2$  and  $C_2^j = [k_1 + k_2 - m_2(\omega_1^j)^2]^2$ , the functionals  $F_1$  and  $F_2$  are given by Equations 2 and 3 overleaf.

### 5.3 SOLUTIONS OF A DSCM

Theorem 1 states that we can construct a DSCM by the described procedure. We constructed each equation by intervening on  $D - 1$  variables at a time. The result of this section states that the DSCM can be used to correctly model interventions on arbitrary subsets of variables. We say that  $\eta_{\mathcal{I}} \in \text{Dyn}_{\mathcal{I}}$  is a solution of  $\mathcal{M}$  if  $\eta_i = F_i(\eta_{\text{pa}(i)}) \forall i \in \mathcal{I}$ .

**Theorem 2.** Suppose that  $(\mathcal{D}, \text{Dyn})$  is structurally dynamically stable. Let  $I \subseteq \mathcal{I}$ , and let  $\zeta_I \in \text{Dyn}_I$ . Then  $\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)}$  is dynamically stable if and only if the intervened SCM  $\mathcal{M}_{(\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)})}$  has a unique solution. If there is a unique solution, it coincides with the element of  $\text{Dyn}_{\mathcal{I}}$  describing the asymptotic dynamics of  $\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)}$ .

*Remark 2.* We could also take  $I = \emptyset$ , in which case the above theorem applies to just  $\mathcal{D}$ .

### 5.4 CAUSAL REASONING IS PRESERVED

We have defined ways to model interventions in both ODEs and DSCMs. The following theorem and its immediate corollary proves that these notions of intervention

coincide, and hence that DSCMs provide a representation to reason about the asymptotic behaviour of the ODE under interventions in  $\text{Dyn}$ . A consequence of these results is that the diagram in Figure 3 commutes.

**Theorem 3.** Suppose that  $(\mathcal{D}, \text{Dyn})$  is structurally dynamically stable. Let  $I \subseteq \mathcal{I}$  and let  $\zeta_I \in \text{Dyn}_I$ . Then  $\mathcal{M}_{(\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)})} = (\mathcal{M}_{\mathcal{D}})_{\text{do}(\mathbf{X}_I = \zeta_I)}$ .

**Corollary 1.** Suppose additionally that  $J \subseteq \mathcal{I} \setminus I$  and let  $\zeta_J \in \text{Dyn}_J$ . Then

$$\left( \mathcal{M}_{(\mathcal{D}_{\text{do}(\mathbf{X}_I = \zeta_I)})} \right)_{\text{do}(\mathbf{X}_J = \zeta_J)} = (\mathcal{M}_{\mathcal{D}})_{\text{do}(\mathbf{X}_I = \zeta_I, \mathbf{X}_J = \zeta_J)}.$$

To summarise, Theorems 1–3 and Corollary 1 collectively state that if  $(\mathcal{D}, \text{Dyn})$  is dynamically structurally stable then it is possible to derive a DSCM that allows us to reason about the asymptotic dynamics of the ODE under any possible intervention in  $\text{Dyn}$ .

## 5.5 RELATION TO ODEs AND DYNAMIC BAYESIAN NETWORKS

An ODE is capable of modelling arbitrary interventions on the system it describes. At the cost of only modelling a restricted set of interventions, a DSCM can be derived which describes the asymptotic behaviour of the system under these interventions. This may be desirable in cases for which transient behaviour is not important.

We now compare DSCMs to Dynamic Bayesian Networks (DBNs), an existing popular method for causal modelling of dynamical systems (Koller and Friedman, 2009). DBNs are essentially Markov chains, and thus are appropriate for discrete-time systems. When the discrete-time Markov assumption holds, DBNs are a powerful tool capable of modelling arbitrary interventions. However, approximations must be made whenever these assumptions do not hold. In particular, a continuous system must be approximately discretised in order to be modelled by a DBN (Sokol and Hansen, 2014).

By using the Euler method for numerically solving ODEs, we can make such an approximation to derive a DBN describing the system in Example 1, leading to the discrete time equation given in (8) the Supplementary Material. For DBNs, the main choice to be made is how fine the temporal discretisation should be. The smaller the value of  $\Delta$ , the better the discrete approximation will be. Even if there is a natural time-scale on which measurements can be made, choosing a finer discretisation than this will provide a better approximation to the behaviour of the true system. The choice of  $\Delta$  should reflect the natural timescales of the interventions to be considered too; for example, it is not clear how one would model the intervention  $\text{do}(X_1(t) = \cos(\frac{2\pi t}{\Delta}))$  with a discretisation length  $\Delta$ . Another notable disadvantage of DBNs is that the

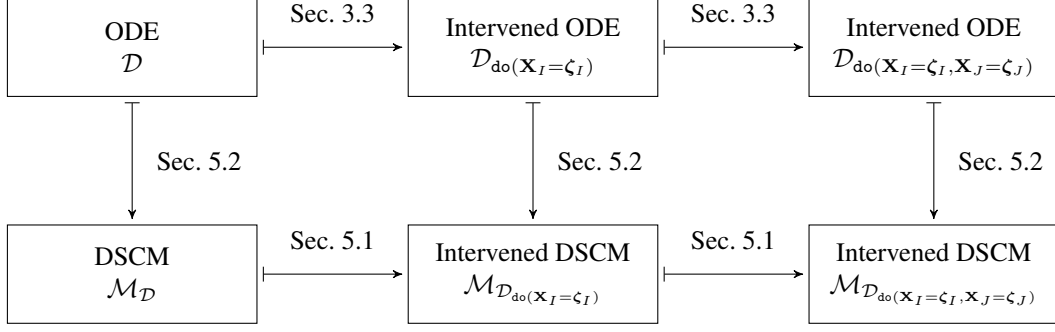

Figure 3: Top-to-bottom arrows: Theorems 1 and 2 together state that if  $(\mathcal{D}, \text{Dyn})$  is structurally dynamically stable then we can construct a DSCM to describe the asymptotic behaviour of  $\mathcal{D}$  under different interventions in the set  $\text{Dyn}$ . Left-to-right arrows: Both ODEs and DSCMs are equipped with notions of intervention. Theorem 3 and Corollary 1 say that these two notions of intervention coincide, and thus the diagram commutes.

$$F_1 \left( \sum_{j=1}^{\infty} A_2^j \cos(\omega_2^j t + \phi_2^j) \right) = \frac{-k_1 l_1}{k_1 + k_0} + \sum_{j=1}^{\infty} \frac{k_1 A_2^j}{\sqrt{C_1^j + b_1 m_1 (\omega_2^j)^2}} \cos \left( \omega_2^j t + \phi_2^j - \arctan \left[ \frac{b_1 \omega_2^j}{C_1^j} \right] \right) \quad (2)$$

$$F_2 \left( \sum_{j=1}^{\infty} A_1^j \cos(\omega_1^j t + \phi_1^j) \right) = \frac{k_1 l_1 - k_2 l_2}{k_1 + k_2} + \frac{k_2 L}{k_2 + k_3} + \sum_{j=1}^{\infty} \frac{k_1 A_1^j}{\sqrt{C_2^j + b_2 m_2 (\omega_1^j)^2}} \cos \left( \omega_1^j t + \phi_1^j - \arctan \left[ \frac{b_2 \omega_1^j}{C_2^j} \right] \right) \quad (3)$$

Figure 4: Equations giving the structural equations for the DSCM describing the mass-spring system of Example 4

computational cost of learning and inference increases for smaller  $\Delta$ , where computational cost becomes infinitely large in the limit  $\Delta \rightarrow 0$ .

In contrast, the starting point for DSCMs is to fix a convenient set of interventions we are interested in modelling. If a DSCM containing these interventions exists, it will model the asymptotic behaviour of the system under each of these interventions *exactly*, rather than approximately modelling the transient and asymptotic behaviour as in the case of a DBN. Computational cost does not relate inversely to accuracy as for DBNs, but depends on the chosen representation of the set of admitted interventions.

## 6 DISCUSSION AND FUTURE WORK

The main contribution of this paper is to show that the SCM framework can be applied to reason about time-dependent interventions on an ODE in a dynamic setting. In particular, we showed that if an ODE is sufficiently well-behaved under a set of interventions, a DSCM can be derived that captures how the asymptotic dynamics change under these interventions. This is in contrast to previous approaches to connecting the language of ODEs with the SCM framework, which used SCMs to describe the stable (constant-in-time) equilibria of the ODE and

how they change under intervention.

We identify three possible directions in which to extend this work in the future. The first is to properly understand how learning DSCMs from data could be performed. This is important if DSCMs are to be used in practical applications. Challenges to be addressed include finding practical parameterizations of DSCMs, the presence of measurement noise in the data and the fact that time-series data are usually sampled at a finite number of points in time. The second is to relax the assumption that the asymptotic dynamics are *independent of initial conditions*, as was done recently for the static equilibrium scenario by Blom and Mooij (2018). The third extension is to move away from deterministic systems and consider Random Differential Equations (Bongers and Mooij, 2018), thereby allowing to take into account model uncertainty, but also to include systems that may be inherently stochastic.

## Abstract

Symmetric nonnegative matrix factorization has found abundant applications in various domains by providing a symmetric low-rank decomposition of nonnegative matrices. In this paper we propose a Frank-Wolfe (FW) solver to optimize the symmetric nonnegative matrix factorization problem under a simplicial constraint, which has recently been proposed for probabilistic clustering. Compared with existing solutions, this algorithm is simple to implement, and has no hyperparameters to be tuned. Building on the recent advances of FW algorithms in nonconvex optimization, we prove an  $O(1/\varepsilon^2)$  convergence rate to  $\varepsilon$ -approximate KKT points, via a tight bound  $\Theta(n^2)$  on the curvature constant, which matches the best known result in unconstrained nonconvex setting using gradient methods. Numerical results demonstrate the effectiveness of our algorithm. As a side contribution, we construct a simple nonsmooth convex problem where the FW algorithm fails to converge to the optimum. This result raises an interesting question about necessary conditions of the success of the FW algorithm on convex problems.

## 1 INTRODUCTION

Nonnegative matrix factorization (NMF) has found various applications in data mining, natural language processing, and computer vision [Xu et al., 2003, Liu et al., 2003, Kuang et al., 2012], due to its ability to provide low rank approximations and interpretable decompositions. The decision version of NMF is known to be NP-hard [Vavasis, 2009], which also implies that its optimization problem is NP-hard. Recently, a variant of NMF where the input

matrix is constrained to be symmetric has become popular for clustering [He et al., 2011, Kuang et al., 2012, 2015]. The problem is known as symmetric NMF (SymNMF), and its goal is to minimize  $\|A - WW^T\|_F^2$  under the constraint that  $W \geq 0$  elementwise, where  $A$  is a symmetric matrix of cluster affinities. Compared with NMF, SymNMF is applicable even when the algorithm does not have direct access to the data instances, but only their pairwise similarity scores. Note that in general the input matrix  $A$  does not need to be nonnegative [Kuang et al., 2012]. SymNMF has been successfully applied in many different settings and was shown to be competitive with standard clustering algorithms; see [Kuang et al., 2012, 2015] and the references therein for more details.

In this paper we investigate a constrained version of SymNMF where the input matrix is required to be both nonnegative and positive semidefinite. Furthermore, we require that  $W$  is normalized such that each row of  $W$  sums to 1. This problem has an interesting application in probabilistic clustering [Zhao et al., 2015] where the  $i$ th row of  $W$  can be interpreted as the probability that the  $i$ th data point lies in each clusters. Formally, we are interested in the following optimization problem, which we name as simplicial SymNMF (SSymNMF):

$$\begin{aligned} & \underset{W}{\text{minimize}} && \frac{1}{4} \|P - WW^T\|_F^2 \\ & \text{subject to} && W \in \mathbb{R}_+^{n \times k}, \quad W\mathbf{1}_k = \mathbf{1}_n \end{aligned} \tag{1}$$

where  $P \geq 0$  and  $P \in \mathbb{S}_+^n$  is positive semidefinite. (1) was proposed as a formulation for probabilistic clustering [Zhao et al., 2015]. The input matrix  $P$  is interpreted as the co-cluster affinity matrix, i.e., entry  $P_{ij}$  corresponds to the degree to which we encourage data instances  $\mathbf{x}_i$  and  $\mathbf{x}_j$  to be in the same cluster. Each row of  $W$  then corresponds to the probability distribution of instance  $\mathbf{x}_i$  being in different clusters. A similar simplicial constraint has been considered in NMF as well [Nguyen et al., 2013], where the goal is to seek a probabilistic part-based decomposition for clustering.

Previous approaches to solve SymNMF or SSymNMF use the penalty method to convert it into an unconstrained optimization problem and then solve it iteratively, using either first-order or second-order methods [Kuang et al., 2012, Zhao et al., 2015, Kuang et al., 2015]. Such methods usually include two loops where the outer loop gradually increases the penalty coefficients and the inner loop finds a stationary point of each fixed penalized objective, hence they are often computationally expensive and slow to converge. In this paper we first give an equivalent geometric description of (1) and then propose a variant of the classic Frank-Wolfe (FW) algorithm [Frank and Wolfe, 1956], a.k.a. the conditional gradient method [Levitin and Polyak, 1966], to solve it. We also provide a non-asymptotic convergence guarantee of our algorithm under an affine invariant stationarity measure (defined in Sec. 2). More specifically, for a given approximation parameter  $\varepsilon > 0$ , we show that the algorithm converges to an  $\varepsilon$ -approximate KKT point of (1) in  $O(1/\varepsilon^2)$  iterations. This rate is analogous to the one derived by Nesterov [2013] for general unconstrained problems (potentially nonconvex) using the gradient descent method, where the measure of stationarity is given by the norm of the gradient. The  $O(1/\varepsilon^2)$  rate has recently been shown to be optimal [Cartis et al., 2010] in the unconstrained setting for gradient methods, and it also matches the best known rate to a stationary point with (accelerated) projected gradient descent [Ghadimi and Lan, 2016, Ghadimi et al., 2016] in the constrained smooth nonconvex setting.

**Contributions.** We first give a generalized definition of the curvature constant [Jaggi, 2013, Lacoste-Julien et al., 2013, Lacoste-Julien, 2016] that works for both convex and nonconvex functions, and we prove a tight bound of it in (1). We then propose a convergence measure in terms of the duality gap and show that the gap is 0 iff KKT conditions are satisfied. Using these two tools, we propose a FW algorithm to solve (1) and show that it has a non-asymptotic convergence rate  $O(1/\varepsilon^2)$  to KKT points. On the algorithmic side, we give a procedure that has the optimal linear time complexity and constant space complexity to implement the *linear minimization oracle* (LMO) in the FW algorithm. As a side contribution, we construct a piecewise linear example where the FW algorithm fails to converge to the optimum. Surprisingly, we can also show that the FW algorithm works if we slightly change the objective function, despite that the new function remains piecewise linear and has an unbounded curvature constant. These two examples then raise an interesting question w.r.t. the necessary condition of the success of the FW algorithm. At the end, we conduct several numerical experiments to demonstrate the efficiency of the proposed algorithm by comparing it with the penalty method and projected gradient descent.

## 2 PRELIMINARY

### 2.1 SymNMF UNDER SIMPLICIAL CONSTRAINT

One way to understand (1) is through its clustering based explanation: the goal is to find a probabilistic clustering of all the instances such that the given co-cluster affinity  $P_{ij}$  for a pair of instances  $(\mathbf{x}_i, \mathbf{x}_j)$  is close to the true probability that  $\mathbf{x}_i$  and  $\mathbf{x}_j$  reside in the same cluster:

$$\begin{aligned} \Pr(\mathbf{x}_i \sim \mathbf{x}_j) &= \sum_{h=1}^k \Pr(c_i = c_j = h) \\ &= \sum_{h=1}^k \Pr(c_i = h) \Pr(c_j = h) = \mathbf{w}_i^T \mathbf{w}_j \end{aligned}$$

where we use the notation  $\mathbf{x}_i \sim \mathbf{x}_j$  to mean “ $\mathbf{x}_i$  and  $\mathbf{x}_j$  reside in the same cluster”;  $c_i$  is the cluster assignment of  $\mathbf{x}_i$  and  $\mathbf{w}_i$  denotes the  $i$ th row vector of  $W$ . Note that the second equation holds because of the assumption of i.i.d. generation process of instances and their cluster assignments.

As a first note, the optimal solution  $W^*$  to (1) is not unique: for any permutation  $\pi_n$  over  $[n]$ , an equivalent solution can be constructed by  $W_{\pi_n}^* = W^* \Pi_{\pi_n}$ , where  $\Pi_{\pi_n}$  is a permutation matrix specified by  $\pi_n$ . This corresponds to an equivalence class of  $W$  by label switching. Hence for any fixed  $k$ , there are at least  $k!$  optimal solutions to (1). The uniqueness of the solution to (1) up to permutation is still an open problem. Huang et al. [2014] studied sufficient and necessary conditions for the uniqueness of SymNMF, but they are NP-hard to check in general.

Zhao et al. [2015] proposed a penalty method to transform (1) into an unconstrained problem and solve it via sequential minimization. Roughly speaking, the penalty method repeatedly solves an unconstrained problem, and enforces the constraints in (1) by gradually increasing the coefficients of the penalty terms. This process iterates until a solution is both feasible and a stopping criterion w.r.t. the objective function is met; see [Zhao et al., 2015, Algo. 1]. The penalty method contains 6 different hyperparameters to be tuned, and it is not even clear whether it will converge to a KKT point of (1). To the best of our knowledge, no other methods has been proposed to solve (1). To solve SymNMF, Kuang et al. [2012] proposed a projected Newton method and Vandaele et al. [2016] developed a block coordinate descent method. However, due to the coupling of columns of  $W$  introduced by the simplicial constraint, it is not clear how to extend these two algorithms to solve (1). On the other hand, the simplicial constraint in (1) restricts the feasible set to be compact, which makes it possible for us to apply the FW algorithm to solve it.

## 2.2 Frank-Wolfe ALGORITHM

The FW algorithm [Frank and Wolfe, 1956, Levitin and Polyak, 1966] is a popular first-order method to solve constrained convex optimization problems of the following form:

$$\text{minimize}_{\mathbf{x} \in \mathcal{D}} f(\mathbf{x}) \quad (2)$$

where  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  is a convex and continuously differentiable function over the convex and compact domain  $\mathcal{D}$ . The FW method has recently attracted a surge of interest in machine learning due to the fact that it never requires us to project onto the constraint set  $\mathcal{D}$  and its ability to cheaply exploit structure in  $\mathcal{D}$  [Clarkson, 2010, Jaggi, 2011, 2013, Lacoste-Julien et al., 2013, Lan, 2013]. Compared with projected gradient descent, it provides arguably wider applicability since projection can often be computationally expensive (e.g., for the general  $\ell_p$  ball), and in some case even computationally intractable [Collins et al., 2008]. At each iteration, the FW algorithm finds a feasible search corner  $\mathbf{s}$  by minimizing a linear approximation at the current iterate  $\mathbf{x}$  over  $\mathcal{D}$ :

$$w(\mathbf{x}) := \min_{\hat{\mathbf{s}} \in \mathcal{D}} f(\hat{\mathbf{s}}) + \nabla f(\mathbf{x})^T (\hat{\mathbf{s}} - \mathbf{x}) \quad (3)$$

The linear minimization oracle (LMO) at  $\mathbf{x}$  is defined as:

$$\mathbf{s} = \text{LMO}(\mathbf{x}) := \arg \min_{\hat{\mathbf{s}} \in \mathcal{D}} f(\hat{\mathbf{s}}) + \nabla f(\mathbf{x})^T (\hat{\mathbf{s}} - \mathbf{x}) \quad (4)$$

Given  $\mathbf{s} = \text{LMO}(\mathbf{x})$ , the next iterate is then updated as a convex combination of  $\mathbf{s}$  and the current iterate  $\mathbf{x}$ . If the FW algorithm starts with a corner as the initial point, then this property implies that at the  $t$ -th iteration, the current iterate is a convex combination of at most  $t + 1$  corners. The difference between  $f(\mathbf{x})$  and  $w(\mathbf{x})$  is known as the *Frank-Wolfe gap* (FW-gap):

$$g(\mathbf{x}) := f(\mathbf{x}) - w(\mathbf{x}) = \max_{\hat{\mathbf{s}} \in \mathcal{D}} \nabla f(\mathbf{x})^T (\mathbf{x} - \hat{\mathbf{s}}) \quad (5)$$

which turns out to be a special case of the general Fenchel duality gap when we transform (2) into an unconstrained problem by adding an indicator function over  $\mathcal{D}$  into the objective function [Lacoste-Julien et al., 2013, Appendix D]. Due to the convexity of  $f$ , we have the following inequality:  $\forall \mathbf{x}, \mathbf{y} \in \mathcal{D}$ ,  $w(\mathbf{y}) \leq f^* \leq f(\mathbf{x})$ , where  $f^*$  is the globally optimal value of  $f$ . Specifically,  $\forall \mathbf{x} \in \mathcal{D}$ ,  $w(\mathbf{x}) \leq f(\mathbf{x})$  and as a result  $g(\mathbf{x})$  can be used as an upper bound for the optimality gap:  $\forall \mathbf{x} \in \mathcal{D}$ ,  $f(\mathbf{x}) - f^* \leq g(\mathbf{x})$ , so that  $g(\mathbf{x})$  is a certificate for the approximation quality of the current solution. Furthermore, the duality gap  $g(\mathbf{x})$  can be computed *essentially for free* in each iteration:  $g(\mathbf{x}) = \nabla f(\mathbf{x})^T (\mathbf{x} - \mathbf{s})$ .

It is well known that for smooth convex optimization problems the FW algorithm converges to an  $\varepsilon$ -approximate solution in  $O(1/\varepsilon)$  iterations [Frank and Wolfe, 1956,

Dunn and Harshbarger, 1978]. This result has recently been generalized to the setting where the LMO is solved only approximately [Clarkson, 2010, Jaggi, 2013]. The analysis of convergence depends on a crucial concept known as the *curvature constant*  $C_f$  defined for a convex function  $f$ :

$$C_f := \sup_{\substack{\mathbf{x}, \mathbf{s} \in \mathcal{D}, \\ \gamma \in (0, 1], \\ \mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x})}} \frac{2}{\gamma^2} (f(\mathbf{y}) - f(\mathbf{x}) - \nabla f(\mathbf{x})^T (\mathbf{y} - \mathbf{x})) \quad (6)$$

The curvature constant measures the relative deviation of a convex function  $f$  from its linear approximation. It is clear that  $C_f \geq 0$ . Furthermore, the definition of  $C_f$  only depends on the inner product of the underlying space, which makes it affine invariant. In fact, the curvature constant, the FW algorithm, and its convergence analysis are all affine invariant [Lacoste-Julien et al., 2013]. Later we shall generalize the curvature constant to a function  $f$  that is not necessarily convex and state our result in terms of the generalized definition. The above definition of the curvature constant still works for nonconvex functions, but for a concave function  $f$ ,  $C_f = 0$ , which loses its geometric interpretation as measuring the curvature of  $f$ .

To proceed our discussion, we first establish some standard terminologies used in this paper. A continuously differentiable function  $f$  is called  $L$ -smooth w.r.t. the norm  $\|\cdot\|$  if  $\nabla f$  is  $L$ -Lipschitz continuous w.r.t. the norm  $\|\cdot\|$ :  $\forall \mathbf{x}, \mathbf{y} \in \mathcal{D}$ ,  $\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \leq L\|\mathbf{x} - \mathbf{y}\|$ . Throughout this paper, we will use  $\|\cdot\|$  to mean the Euclidean norm, i.e., the  $\ell_2$  norm for vectors and the Frobenius norm for matrices if not explicitly specified. It is standard to assume  $f$  to be  $L$ -smooth in the convergence analysis of the FW algorithm [Clarkson, 2010, Jaggi, 2013]. As we will see below, the smoothness of  $f$  also implies the boundedness of  $C_f$  on a compact set.

## 3 Frank-Wolfe FOR SYMMMF UNDER SIMPLICIAL CONSTRAINT

### 3.1 A GEOMETRIC PERSPECTIVE

In this section we complement our discussion of (1) in Sec. 2 with a geometric interpretation, which allows us to make a connection between the decision version of (1) to the well known problem of completely positive matrix factorization [Berman and Shaked-Monderer, 2003, Dickinson, 2013, Dickinson and Gijben, 2014]. The decision version of the optimization problem in (1) is formulated as follows:

**Definition 1 (SSymNMF).** Given a matrix  $P \in \mathbb{R}_+^{n \times n} \cap \mathbb{S}_+^n$ , can it be factorized as  $P = WW^T$  for some integer  $k$  such that  $W \in \mathbb{R}_+^{n \times k}$  and  $W\mathbf{1}_k = \mathbf{1}_n$ ?

Clearly, for  $P \in \mathbb{S}_+^n$ , we can decompose it as  $P = UU^T$ , where  $U \in \mathbb{R}^{n \times r}$ ,  $r = \text{rank}(P)$ . Let  $\mathbf{u}_i$  be the  $i$ th row vector of  $U$ ; then  $P$  is the *Gram matrix* of a set of  $r$  dimensional vectors  $\mathcal{U} = \{\mathbf{u}_1, \dots, \mathbf{u}_n\} \subseteq \mathbb{R}^r$ . Similarly,  $WW^T$  can be understood as the Gram matrix of a set of  $k$  dimensional vectors  $\mathcal{W} = \{\mathbf{w}_1, \dots, \mathbf{w}_n\} \subseteq \mathbb{R}^k$ , where  $\mathbf{w}_i$  is the  $i$ th row vector of  $W$ . The simplex constraint in (1) further restricts each  $\mathbf{w}_i \in \Delta^{k-1}$ , i.e.,  $\mathbf{w}_i$  resides in the  $k - 1$  dimensional probability simplex. Hence equivalently, **SSymNMF** asks the following question:

**Definition 2.** *Given a set of  $n$  instances  $\mathcal{U} = \{\mathbf{u}_i\}_{i=1}^n \subseteq \mathbb{R}^r$ , does there exist an integer  $k$  and an embedding  $\mathcal{T} : \mathbb{R}^r \rightarrow \Delta^{k-1}$ , such that inner product is preserved under  $\mathcal{T}$ , i.e.,  $\forall i, j \in [n], \langle \mathbf{u}_i, \mathbf{u}_j \rangle = \langle \mathcal{T}(\mathbf{u}_i), \mathcal{T}(\mathbf{u}_j) \rangle$ ?*

An affirmative answer to **SSymNMF** will give a certificate of the existence of such embedding  $\mathcal{T}$ :  $\mathcal{T}(\mathbf{u}_i) = \mathbf{w}_i, \forall i \in [n]$ . The goal of (1) can thus be understood as follows: find an embedding into the probability simplex such that the discrepancy of inner products between the image space and the original space is minimized. The fact that inner product is preserved immediately implies that distances between every pair of instances are also preserved. If  $k = r$ , such an embedding is also known as an *isometry*. In this case  $\mathcal{T}$  is unitary. Note in the above definition of **SSymNMF** we do not restrict that  $k = r$ , and  $\mathcal{T}$  does not have to be linear.

**SSymNMF** is closely connected to the strong membership problem for completely positive matrices [Berman and Plemmons, 1994, Berman and Shaked-Monderer, 2003]. A completely positive matrix is a matrix  $P$  that can be factorized as  $P = WW^T$  where  $W \in \mathbb{R}_+^{n \times k}$  for some  $k$ . The set of completely positive matrices forms a convex cone, and is known as the completely positive cone (CP cone). From this definition we can see that the decision version of **SymNMF** corresponds to the strong membership problem of the CP cone, which has recently been shown by Dickinson and Gijben [2014] to be NP-hard. Geometrically, the strong membership problem for CP matrices asks the following question:

**Definition 3 (SMEMCP).** *Given a set of  $n$  instances  $\mathcal{U} = \{\mathbf{u}_i\}_{i=1}^n \subseteq \mathbb{R}^r$ , does there exist an integer  $k$  and an embedding  $\mathcal{T} : \mathbb{R}^r \rightarrow \mathbb{R}_+^k$ , such that inner product is preserved under  $\mathcal{T}$ , i.e.,  $\forall i, j \in [n], \langle \mathbf{u}_i, \mathbf{u}_j \rangle = \langle \mathcal{T}(\mathbf{u}_i), \mathcal{T}(\mathbf{u}_j) \rangle$ ?*

Note that the only difference between **SSymNMF** and **SMEMCP** lies in the range of the image space: the former asks for an embedding in  $\Delta^{k-1}$  while the latter only asks for embedding to reside in  $\mathbb{R}_+^k$ . **SSymNMF** is therefore conjectured to be NP-hard as well, but this assertion has not been formally proved yet. A simple reduction from **SMEMCP** to **SSymNMF** does not work: a “yes” answer to the former does not imply a “yes” answer to the latter.

### 3.2 ALGORITHM

We list the pseudocode of the FW method in Alg. 1 and discuss how Alg. 1 can be efficiently applied and implemented to solve **SSymNMF**. We start by deriving the gradient of  $f(W) = \frac{1}{4} \|P - WW^T\|_F^2$ :

$$\nabla f(W) = (WW^T - P)W \in \mathbb{R}^{n \times k} \quad (7)$$

The normalization constraint keeps the feasible set decomposable (even though the objective function  $f$  is not decomposable): it can be equivalently represented as the product of  $n$  probability simplices  $\Delta^{k-1} \times \dots \times \Delta^{k-1} =: \Pi_n \Delta^{k-1}$ . Hence at the  $t$ -th iteration of the algorithm we solve the following linear optimization problem over  $\Pi_n \Delta^{k-1}$ :

$$\begin{aligned} & \underset{S}{\text{minimize}} && \text{tr} \left( S^T \nabla f(W^{(t)}) \right) \\ & \text{subject to} && S \in \Pi_n \Delta^{k-1} \end{aligned} \quad (8)$$

Because of the special structure of the constraint set in (8), given  $\nabla f(W)$ , we can efficiently compute the two key quantities  $\mathbf{x}^{(t+1)}$  and  $g_t$  in Alg. 1 in  $O(nk)$  time and  $O(1)$  space. The pseudocode is listed in Alg. 2. The key observation that allows us to achieve this efficient implementation is that at each iteration  $t \in [T]$ ,  $\text{LMO}(\mathbf{x}^{(t)})$  is guaranteed to be a sparse matrix that contains exactly one 1 in each row. The time complexity of Alg. 2 is  $3nk$ , which can be further reduced to  $2nk$  by additional  $O(n)$  space to store the index of the nonzero element at each row of  $\text{LMO}(\mathbf{x}^{(t)})$ . Alg. 1, together with Alg. 2 as a sub-procedure, is very efficient while at the same time being simple to implement. Furthermore, it does not have any hyperparameter to be tuned: this is in sharp contrast with the penalty method.

---

#### Algorithm 1 Frank-Wolfe algorithm (non-convex variant)

---

**Input:** Initial point  $\mathbf{x}^{(0)} \in \mathcal{D}$ , approximation parameter  $\varepsilon > 0$

- 1: **for**  $t = 0$  to  $T$  **do**
  - 2:   Compute  $\mathbf{s}^{(t)} = \text{LMO}(\mathbf{x}^{(t)}) := \arg \min_{\mathbf{s} \in \mathcal{D}} \mathbf{s}^T \nabla f(\mathbf{x}^{(t)})$
  - 3:   Compute update direction  $\mathbf{d}_t := \mathbf{s}^{(t)} - \mathbf{x}^{(t)}$
  - 4:   Compute FW-gap  $g_t := -\nabla f(\mathbf{x}^{(t)})^T \mathbf{d}_t$
  - 5:   **if**  $g_t \leq \varepsilon$  **then return**  $\mathbf{x}^{(t)}$
  - 6:   Compute  $\gamma_t := \min\{g_t/C, 1\}$  for any  $C \geq \bar{C}_f$  (defined in (10))
  - 7:   Update  $\mathbf{x}^{(t+1)} := \mathbf{x}^{(t)} + \gamma_t \mathbf{d}_t$
  - 8: **end for**
  - 9: **return**  $\mathbf{x}^{(T)}$
-

---

**Algorithm 2** Compute next iterate and the gap function
 

---

**Input:**  $\nabla f(\mathbf{x}^{(t)}), \mathbf{x}^{(t)}$   
 1:  $g_t := \langle \nabla f(\mathbf{x}^{(t)}), \mathbf{x}^{(t)} \rangle$   
 2: **for**  $i = 1$  to  $n$  **do**  
 3:    $g_t \leftarrow g_t - \min_{j \in [k]} \nabla f(\mathbf{x}^{(t)})_{ij}$   
 4: **end for**  
 5: Compute  $\gamma_t := \min\{g_t/C, 1\}$   
 6:  $\mathbf{x}^{(t+1)} := (1 - \gamma_t)\mathbf{x}^{(t)}$   
 7: **for**  $i = 1$  to  $n$  **do**  
 8:    $j_i := \arg \min_{j \in [k]} \nabla f(\mathbf{x}^{(t)})_{ij}$   
 9:    $\mathbf{x}_{ij_i}^{(t+1)} \leftarrow \mathbf{x}_{ij_i}^{(t+1)} + \gamma_t$   
 10: **end for**  
 11: **return**  $\mathbf{x}^{(t+1)}, g_t$

---

### 3.3 CONVERGENCE ANALYSIS

In this section we provide a non-asymptotic convergence rate for the FW algorithm for solving (1) and derive a tight bound for its curvature constant. Our analysis is based on the recent work [Lacoste-Julien, 2016], where we redefine the curvature constant so that the new definition works in both convex and nonconvex settings. Due to space limit, we only provide partial proofs for theorems and lemmas derived in this paper, and refer readers to supplementary material for all detailed proofs.

When applied to smooth convex constrained optimization problems, the FW algorithm is known to converge to an  $\varepsilon$ -approximate solution in  $O(1/\varepsilon)$  iterations. However the convergence of global optimality is usually unrealistic to hope for in nonconvex optimization, where even checking local optimality itself can be computationally intractable [Murty and Kabadi, 1987]. Clearly, to talk about convergence, we need to first establish a convergence criterion. For unconstrained nonconvex problems, the norm of the gradient  $\|\nabla f\|$  has been used to measure convergence [Ghadimi et al., 2016, Ghadimi and Lan, 2016], since  $\lim_{t \rightarrow \infty} \|\nabla f(\mathbf{x}^{(t)})\| = 0$  means every limit point of the sequence  $\{\mathbf{x}^{(t)}\}$  is a stationary point. But such a convergence criterion is not appropriate for constrained problems because a stationary point can lie on the boundary of the feasible region while not having a zero gradient. To address this issue, we will use the FW-gap  $g(\mathbf{x})$  as a measure of convergence. Note that the gap  $g(\mathbf{x})$  works as an optimality gap only if the original problem is convex. To see why this is also a good measure of convergence for constrained nonconvex problems, we first prove the following theorem:

**Theorem 1.** Let  $f$  be a differentiable function and  $\mathcal{D}$  be a convex compact domain. Define  $g(\mathbf{x}) := \max_{\hat{\mathbf{s}} \in \mathcal{D}} \nabla f(\mathbf{x})^T(\mathbf{x} - \hat{\mathbf{s}})$ . Then  $\forall \mathbf{x} \in \mathcal{D}, g(\mathbf{x}) \geq 0$  and  $g(\mathbf{x}) = 0$  iff  $\mathbf{x}$  is a Karush–Kuhn–Tucker (KKT) point.

*Proof.* To see  $g(\mathbf{x}) \geq 0$ , we have:

$$g(\mathbf{x}) := \max_{\hat{\mathbf{s}} \in \mathcal{D}} \nabla f(\mathbf{x})^T(\mathbf{x} - \hat{\mathbf{s}}) \geq \nabla f(\mathbf{x})^T(\mathbf{x} - \mathbf{x}) = 0$$

Reformulate the original constrained problem in the following way:

$$\begin{aligned} & \underset{\mathbf{x}}{\text{minimize}} && f(\mathbf{x}) \\ & \text{subject to} && \mathbb{I}_{\mathcal{D}}(\mathbf{x}) \leq 0 \end{aligned} \quad (9)$$

where  $\mathbb{I}_{\mathcal{D}}(\mathbf{x})$  is the indicator function of  $\mathcal{D}$  which takes value 0 iff  $\mathbf{x} \in \mathcal{D}$  otherwise  $\infty$ . Define  $\mathcal{N}_{\mathcal{D}}(\mathbf{x})$  as the normal cone at  $\mathbf{x}$  in a convex set  $\mathcal{D}$ :

$$\mathcal{N}_{\mathcal{D}}(\mathbf{x}) := \{\mathbf{z} \mid \mathbf{z}^T \mathbf{x} \geq \mathbf{z}^T \mathbf{y}, \forall \mathbf{y} \in \mathcal{D}\}$$

and realize the fact that the subdifferential of the indicator function when  $\mathbf{x} \in \mathcal{D}$  is precisely the normal cone at  $\mathbf{x}$ , i.e.,  $\partial \mathbb{I}_{\mathcal{D}}(\mathbf{x}) = \mathcal{N}_{\mathcal{D}}(\mathbf{x})$ , we have:

$$\begin{aligned} g(\mathbf{x}) = 0 & \Leftrightarrow \max_{\mathbf{y} \in \mathcal{D}} \nabla f(\mathbf{x})^T(\mathbf{x} - \mathbf{y}) = 0 \\ \Leftrightarrow \forall \mathbf{y} \in \mathcal{D}, \nabla f(\mathbf{x})^T(\mathbf{y} - \mathbf{x}) & \geq 0 \Leftrightarrow -\nabla f(\mathbf{x}) \in \mathcal{N}_{\mathcal{D}}(\mathbf{x}) \end{aligned}$$

Note that the normal cone for a convex set is a convex cone, which implies that  $\exists \lambda \geq 0$ , s.t.,

$$\nabla f(\mathbf{x}) + \lambda \partial \mathbb{I}_{\mathcal{D}}(\mathbf{x}) = 0 \Leftrightarrow \nabla_{\mathbf{x}} \mathcal{L}(\mathbf{x}, \lambda) = 0$$

where  $\mathcal{L}(\mathbf{x}, \lambda) := f(\mathbf{x}) + \lambda \mathbb{I}_{\mathcal{D}}(\mathbf{x})$  is the Lagrangian of (9). By construction,  $\lambda \geq 0$  satisfies the dual feasibility condition and  $\mathbf{x} \in \mathcal{D}$  satisfies the primal feasibility condition, which also means the complementary slackness is satisfied, i.e.,  $\lambda \mathbb{I}_{\mathcal{D}}(\mathbf{x}) = 0$ . It follows that  $g(\mathbf{x}) = 0$  iff  $\mathbf{x}$  is a KKT point of (9). ■

**Remark.** Note that in Thm. 1 we do not assume  $f$  to be convex. In fact we can also relax the differentiability of  $f$ , as long as the subgradient exists at every point of  $f$ . The proof relies on the fact that  $g(\mathbf{x}) = 0$  implies  $-\nabla f(\mathbf{x})$  is in the normal cone at  $\mathbf{x}$ . Thm. 1 justifies the use of  $g(\mathbf{x})$  as a convergence measure: if  $\lim_{t \rightarrow \infty} g(\mathbf{x}^{(t)}) = 0$ , then by the continuity of  $g$ , every limit point of  $\{\mathbf{x}^{(k)}\}$  is a KKT point of  $f$ . Since being a KKT point is also a sufficient condition for optimality when  $f$  is convex, Thm. 1 also recovers the case where  $g(\mathbf{x})$  is used as convergence measure for convex problems.

For a continuously differentiable function  $f$ , we now extend the definition of curvature constant as follows:

$$\bar{C}_f := \sup_{\substack{\mathbf{x}, \mathbf{s} \in \mathcal{D}, \\ \gamma \in (0, 1], \\ \mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x})}} \frac{2}{\gamma^2} \left| f(\mathbf{y}) - f(\mathbf{x}) - \nabla f(\mathbf{x})^T(\mathbf{y} - \mathbf{x}) \right| \quad (10)$$

Clearly  $\bar{C}_f \geq 0$  and the new definition reduces to  $C_f$  when  $f$  is a convex function. In general we have  $\bar{C}_f \geq$

$C_f$  for any function  $f$ . Again,  $\bar{C}_f$  measures the relative deviation of  $f$  from its linear approximation, and is still affine invariant. The difference of  $\bar{C}_f$  from the original  $C_f$  becomes clear when  $f$  is concave: in this case  $C_f = 0$ , but  $\bar{C}_f > 0$  and  $\bar{C}_f = C_{-f}$ . On the downside, the fact that  $\bar{C}_f \geq C_f$  means our asymptotic bound is of constant times larger than the original one proved by Lacoste-Julien [2016], but they share the same asymptotic rate in terms of the given precision parameter  $\varepsilon$ . Finally,  $\bar{C}_f = 0$  iff  $f$  is affine. As in [Jaggi, 2013, Lacoste-Julien et al., 2013], for a smooth function  $f$  with Lipschitz constant  $L$  over compact set  $\mathcal{D}$ , we can bound  $\bar{C}_f$  in terms of  $L$ :

**Lemma 1.** Let  $f$  be a  $L$ -smooth function over a convex compact domain  $\mathcal{D}$ , and define  $\text{diam}(\mathcal{D}) := \sup_{\mathbf{x}, \mathbf{y} \in \mathcal{D}} \|\mathbf{x} - \mathbf{y}\|$ . Then  $\bar{C}_f \leq \text{diam}^2(\mathcal{D})L$ .

The proof of Lemma 1 does not require  $f$  to be convex. Furthermore,  $f$  does not need to be second-order differentiable — being smooth is sufficient. We proceed to derive a convergence bound for Alg. 1 using our new  $\bar{C}_f$ , which better reflects the geometric nonlinearity of nonconvex functions. The main idea of the proof is to bound the decrease of the gap function by minimizing a quadratic function iteratively.

**Theorem 2.** Consider the problem (2) where  $f$  is a continuously differentiable function that is potentially nonconvex, but has a finite curvature constant  $\bar{C}_f$  as defined by (10) over the compact convex domain  $\mathcal{D}$ . Consider running Frank-Wolfe (Algo. 1), then the minimal FW gap  $\tilde{g}_T := \min_{0 \leq t \leq T} g_t$  encountered by the iterates during the algorithm after  $T$  iterations satisfies:

$$\tilde{g}_T \leq \frac{\max\{2h_0\bar{C}_f, \sqrt{2h_0\bar{C}_f}\}}{\sqrt{T+1}}, \quad \forall T \geq 0 \quad (11)$$

where  $h_0 := f(\mathbf{x}^{(0)}) - \min_{\mathbf{x} \in \mathcal{D}} f(\mathbf{x})$  is the initial global suboptimality. It thus takes at most  $O(1/\varepsilon^2)$  iterations to find an approximate KKT point with gap smaller than  $\varepsilon$ .

We comment that the  $O(1/\varepsilon^2)$  convergence rate is the same as the one provided by Lacoste-Julien [2016] using the original curvature constant  $C_f$  for smooth nonconvex functions, and it is also analogous to the ones derived for gradient descent for unconstrained smooth problems and (accelerated) projected gradient descent for constrained smooth problems. The convergence rate of Alg. 1 depends on the curvature constant of  $f$  over  $\mathcal{D}$ . We now bound the smoothness constant  $L$  and the diameter of the feasible set in (1).

**Bound on smoothness constant.** The objective function in (1) is second-order differentiable, hence we can bound the smoothness constant by bounding the spectral norm of the Hessian instead:

**Lemma 2** (Nesterov [2013]). Let  $f$  be twice differentiable. If  $\|\nabla^2 f(\mathbf{x})\|_2 \leq L$  for all  $\mathbf{x}$  in the domain, then  $f$  is  $L$ -smooth.

Note that (7) is a matrix function of a matrix variable, whose Hessian is a matrix of order  $nk \times nk$ . Although one can compute all the elements of the Hessian by computing all the partial derivatives  $\partial \nabla f(W)_{ij} / \partial W_{st}$  separately, this approach is tedious and may hide the structure of the Hessian matrix. Instead we apply matrix differential calculus [Magnus and Neudecker, 1985, Magnus, 2010] to derive the Hessian:

**Lemma 3.** Let  $f(W) = \frac{1}{4}\|P - WW^T\|_F^2$  and define  $\nabla^2 f(W) := \partial \text{vec} \nabla f(W) / \partial \text{vec} W$ . Then:

$$\begin{aligned} \nabla^2 f(W) &= W^T W \otimes I_n + I_k \otimes (WW^T - P) \\ &\quad + (W^T \otimes W)K_{nk} \end{aligned} \quad (12)$$

where  $K_{nk}$  is a commutation matrix such that  $K_{nk} \text{vec} W = \text{vec} W^T$ .

The derivation of the above lemma uses the matrix differential calculus with basic properties of tensors and commutation matrices. Before we proceed, we first present a lemma that will be useful to bound the spectral norm of the above Hessian matrix:

**Lemma 4.**  $\sup_{\substack{W \geq 0, \\ W\mathbf{1}_k = \mathbf{1}_n}} \|W^T W\|_2 = n$ .

We are now ready to bound the spectral norm of the Hessian  $\nabla^2 f(W)$  and use it to bound the smoothness constant of  $f$ .

**Lemma 5.** Let  $c := \|P\|_2$ .  $f = \frac{1}{4}\|P - WW^T\|_F^2$  is  $(3n + c)$ -smooth on  $\mathcal{D} = \{W \in \mathbb{R}_+^{n \times k} \mid W\mathbf{1}_k = \mathbf{1}_n\}$ .

The above lemma follows from Lemma 2 where we use Lemma 4 to help bound the spectral norm of the Hessian matrix in (12).

**Bound on diameter of  $\mathcal{D}$ .** The following lemma can be easily shown:

**Lemma 6.** Let  $\mathcal{D} = \{W \in \mathbb{R}_+^{n \times k} \mid W\mathbf{1}_k = \mathbf{1}_n\}$ . Then  $\text{diam}^2(\mathcal{D}) = 2n$  with respect to the Frobenius norm.

Combining Lemma 6 with Lemma 5 and assuming  $c$  is a constant that does not depend on  $n$ , we immediately have  $\bar{C}_f \leq 2n(3n + c) = O(n^2)$  by Lemma 1. A natural question to ask is: can we get better dependency on  $n$  in the upper bound for  $\bar{C}_f$  given the special structure that  $\mathcal{D} = \Pi_n \Delta^{k-1}$ ? The answer is negative, as we can prove the following lower bound on the Hessian:

**Lemma 7.**  $\inf_{\substack{W \geq 0, \\ W\mathbf{1}_k = \mathbf{1}_n}} \|\nabla^2 f(W)\|_2 \geq n/k^2 - c$ .

Using Lemma 7, we can prove a tight bound on our curvature constant  $\bar{C}_f$ :

**Theorem 3.** The curvature constant  $\bar{C}_f$  for  $f = \frac{1}{4}\|P - WW^T\|_F^2$  on  $\mathcal{D} = \{W \in \mathbb{R}_+^{n \times k} \mid W\mathbf{1}_k = \mathbf{1}_n\}$  satisfies:

$$2n(n/k^2 - c) \leq \bar{C}_f \leq 2n(3n + c)$$

where  $c := \|P\|_2$ . Specifically, we have  $\bar{C}_f = \Theta(n^2)$ .

*Proof.* The upper bound part is clear by combining Lemma 1 and Lemma 5. We only need to show the lower bound. Since  $f$  is twice-differentiable, we have:

$$\begin{aligned} \bar{C}_f &:= \sup_{\substack{\mathbf{x}, \mathbf{s} \in \mathcal{D}, \\ \gamma \in (0, 1], \\ \mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x})}} \frac{2}{\gamma^2} |f(\mathbf{y}) - f(\mathbf{x}) - \nabla f(\mathbf{x})^T(\mathbf{y} - \mathbf{x})| \\ &= \sup_{\substack{\mathbf{x}, \mathbf{s} \in \mathcal{D}, \\ \gamma \in (0, 1], \\ \mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x})}} \frac{2}{\gamma^2} \frac{1}{2} |(\mathbf{y} - \mathbf{x})^T \nabla^2 f(\xi)(\mathbf{y} - \mathbf{x})| \\ &\geq \sup_{\substack{\mathbf{x}, \mathbf{s} \in \mathcal{D}, \\ \gamma \in (0, 1], \\ \mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x})}} \frac{1}{\gamma^2} \|\mathbf{y} - \mathbf{x}\|_2^2 \cdot \inf_{\xi \in \mathcal{D}} \|\nabla^2 f(\xi)\|_2 \\ &\geq \frac{1}{\gamma^2} \gamma^2 \text{diam}^2(\mathcal{D}) \left( \frac{n}{k^2} - c \right) = 2n \left( \frac{n}{k^2} - c \right) \end{aligned}$$

The second equality is due to the mean-value theorem, and the third inequality holds by the definition of inf. The last inequality follows from Lemma 6 and 7. ■

Combining all the analysis above and using Alg. 2 to implement the linear minimization oracle in Alg. 1, we can bound the time complexity of the FW algorithm to solve (1):

**Corollary 1.** The FW algorithm (Alg. 1) achieves an  $\varepsilon$ -approximate KKT point of (1) in  $O(n^3k/\varepsilon^2)$  time.

*Proof.* In each iteration Alg. 1 takes  $O(nk)$  time to compute the gap function as well as the next iterate. Based on Thm. 2, the iteration complexity to achieve an  $\varepsilon$ -approximate KKT point is  $O(\bar{C}_f/\varepsilon^2)$ . The result follows from Thm. 3 showing that  $\bar{C}_f = \Theta(n^2)$ . ■

#### 4 A FAILURE CASE OF Frank-Wolfe ON A NONSMOOTH CONVEX PROBLEM

For convex problems, the theoretical convergence guarantee of Frank-Wolfe algorithm and its variants depends crucially on the smoothness of the objective function: [Freund and Grigas, 2016, Garber and Hazan, 2015, Harchaoui et al., 2015, Nesterov et al., 2015] require the gradient of the objective function to be Lipschitz continuous or Hölder continuous; the analysis in [Jaggi, 2013] requires a finite curvature constant  $C_f$ . The Lipschitz

continuous gradient condition is sufficient for the convergence analysis, but not necessary: Odor et al. [2016] shows that Frank-Wolfe works for a Poisson phase retrieval problem, where the gradient of the objective is not Lipschitz continuous. As we discuss in the last section, Lipschitz continuous gradient implies a finite curvature constant. Hence an interesting question to ask is: does there exist a constrained convex problem with unbounded curvature constant such that the Frank-Wolfe algorithm can find its optimal solution? Surprisingly, the answer to the above question is affirmative. But before we give the example, we first construct an example where the FW algorithm fails when the objective function is convex but nonsmooth.

We first construct a very simple example where the objective function is a piecewise linear and the constraint set is a polytope. We will show that when applied to this simple problem, the FW algorithm, along with its line search variant and its fully corrective variant, do not even converge to the optimal solution. In fact, as we will see shortly, the limit point of the sequence can be arbitrarily far away from the global optimum. Consider the following convex, constrained optimization problem:

$$\begin{aligned} \underset{x_1, x_2}{\text{minimize}} \quad & \max\{5x_1 + x_2, -5x_1 + x_2\} \quad (13) \\ \text{subject to} \quad & x_2 \leq 3, 3x_1 + x_2 \geq 0, -3x_1 + x_2 \geq 0 \end{aligned}$$

We plot the objective function of this example in the left figure of Fig. 1. The unique global optimum for this problem is given by  $\mathbf{x}^* = (0, 0)$  with  $f(\mathbf{x}^*) = 0$ . The feasible set  $\mathcal{D}$  contains three vertices:  $(-1, 3)$ ,  $(1, 3)$  and  $(0, 0)$ . If we apply the FW algorithm to this problem, it is straightforward to verify that the LMO( $\mathbf{x}$ ) is given by:

$$\text{LMO}(\mathbf{x}) = \begin{cases} (-1, 3) & x_1 > 0 \\ (1, 3) & x_1 < 0 \\ \{(-1, 3), (1, 3), (0, 0)\} & x_1 = 0 \end{cases}$$

Note that when  $x_1 = 0$ , the function is not differentiable, and the subdifferential is given by  $\text{conv}\{(5, 1), (-5, 1)\}$ . In this case the FW algorithm chooses arbitrary subgradient from the subdifferential and computes the corresponding LMO. From the fundamental theorem of linear programming, it is easy to see that when  $x_1 = 0$ , LMO( $\mathbf{x}$ ) can be any of the three corners depending on the choice of subgradient at  $\mathbf{x}$ . Now suppose the FW algorithm stops in  $T$  iterations. For any initial point  $\mathbf{x}^{(0)} = (x_1^{(0)}, x_2^{(0)})$  where  $x_1^{(0)} \neq 0$ , the final point output by the FW algorithm will be a convex combination of  $(-1, 3)$ ,  $(1, 3)$ ,  $(0, 0)$  and  $\mathbf{x}^{(0)}$ . Let  $\{\gamma_t\}_{t=1}^T$  be the sequence of step sizes chosen by the FW algorithm. Then we can easily check that  $x_2^{(T)} \geq 3 - \prod_{t=1}^T (1 - \gamma_t)(1 - x_2^{(0)}/3) \rightarrow 3$  as

Figure 1: Two convex examples of piecewise linear objective functions on a convex polytope. The FW algorithm fails on the left example but works on the right one. The objective functions of both examples have unbounded curvature constants.

$T \rightarrow \infty$ . Note that we can readily change this example by extending  $\mathcal{D}$  so that the distance between  $\mathbf{x}^{(T)}$  and the optimum  $\mathbf{x}^*$  becomes arbitrarily large. Furthermore, both the line search and the fully-corrective variants fail since the vertices picked by the algorithm remains the same:  $\{(-1, 3), (1, 3)\}$ . Finally, for any regular probability distribution that is absolutely continuous w.r.t. the Lebesgue measure, with probability 1 the initial points sampled from the distribution will converge to suboptimal solutions. As a comparison, it can be shown that the sub-gradient method works for this problem since the function  $f$  itself is Lipschitz continuous [Nesterov, 2013].

Pick  $\mathbf{x} = (-\varepsilon, \delta)$ ,  $\mathbf{s} - \mathbf{x} = (1, 0)$  and  $\mathbf{y} = \mathbf{x} + \gamma(\mathbf{s} - \mathbf{x}) = (\gamma - \varepsilon, \delta)$ , where  $\gamma > \varepsilon$ , and plug them in the definition of the curvature constant  $C_f$ . We have:

$$\begin{aligned} C_f &\geq \lim_{\varepsilon \rightarrow 0^+, \gamma > \varepsilon} \frac{2}{\gamma^2} (f(\mathbf{y}) - f(\mathbf{x}) - \nabla f(\mathbf{x})^T (\mathbf{y} - \mathbf{x})) \\ &= \lim_{\gamma \rightarrow 0^+} \frac{20}{\gamma} = \infty \end{aligned}$$

i.e., the curvature constant of this piecewise linear function is unbounded. The problem for this failure case of FW lies in the fact that the curvature constant is infinity.

On the other hand, we can also show that FW works even when  $C_f = \infty$  by slightly changing the objective function while keeping the constraint set:

$$\begin{aligned} \underset{x_1, x_2}{\text{minimize}} \quad & \max\left\{\frac{1}{2}x_1 + x_2, -\frac{1}{2}x_1 + x_2\right\} \quad (14) \\ \text{subject to} \quad & x_2 \leq 3, 3x_1 + x_2 \geq 0, -3x_1 + x_2 \geq 0 \end{aligned}$$

The objective function of the second example is shown in the right figure of Fig. 1. Still, the unique global optimum for the new problem is given by  $\mathbf{x}^* = (0, 0)$  with  $f(\mathbf{x}^*) = 0$ , but now the LMO( $\mathbf{x}$ ) is:

$$\text{LMO}(\mathbf{x}) = (0, 0), \quad \forall \mathbf{x} \in \mathcal{D}$$

It is not hard to see that FW converges to the global optimum, and the curvature constant  $C_f = \infty$  as well for this new problem. Combining with example (14), we can see that  $C_f < \infty$  is not a necessary condition for the success of FW algorithm on convex problems, either. Piecewise linear functions form a rich class of objectives that are frequently encountered in practice, while depending on the structure of the problem, the FW algorithm may or may not work for them. This thus raises an interesting problem: *can we develop a necessary condition for the success of the FW algorithm on convex problems?* Another interesting question is, *can we develop sufficient conditions for piecewise linear functions under which the FW algorithm converges to global optimum?*

## 5 NUMERICAL RESULTS

We evaluate the effectiveness of the FW algorithm (Alg. 1) in solving (1) by comparing it with the penalty method [Zhao et al., 2015] and the projected gradient descent method (PGD) on 4 datasets (Table 1). These datasets are standard for clustering analysis: two of them are used in [Zhao et al., 2015], and we add two more datasets with various sizes to make a more comprehensive evaluation. The instances in each dataset are associated with true class labels. For each data set, we use the number of classes as the true number of clusters.

Table 1: Statistics about datasets.

Dataset	# inst. ( $n$ )	# feats. ( $p$ )	# clusters ( $k$ )
blood	748	4	10
yeast	1,484	8	10
satimage	4,435	36	6
pendigits	10,992	16	100

Given a data matrix  $X \in \mathbb{R}^{n \times p}$ , we use a Gaussian kernel with fixed bandwidth 1.0 to construct the co-cluster matrix  $P$  as  $P_{ij} = \exp(-\|\mathbf{x}_i - \mathbf{x}_j\|_2^2)$ . For each dataset, we use its number of clusters as the rank of the decomposition, i.e.,  $W \in \mathbb{R}^{n \times k}$ . We implement the penalty method based on [Zhao et al., 2015], where we set the maximum number of inner loops to be 50, and choose the step factor for the coefficients of the two penalty terms to be 2. In each iteration of PGD, we use backtracking line search to choose the step size. For all three algorithms, the stop conditions are specified as follows: if the difference of function values in two consecutive iterations is smaller than the fixed gap  $\varepsilon = 10^{-3}$ , or the number of (outer) iterations exceed 50, then the algorithms will stop. Also, for each dataset, all three algorithms share the same initial point.

We plot the convergence speed to local optimum of these

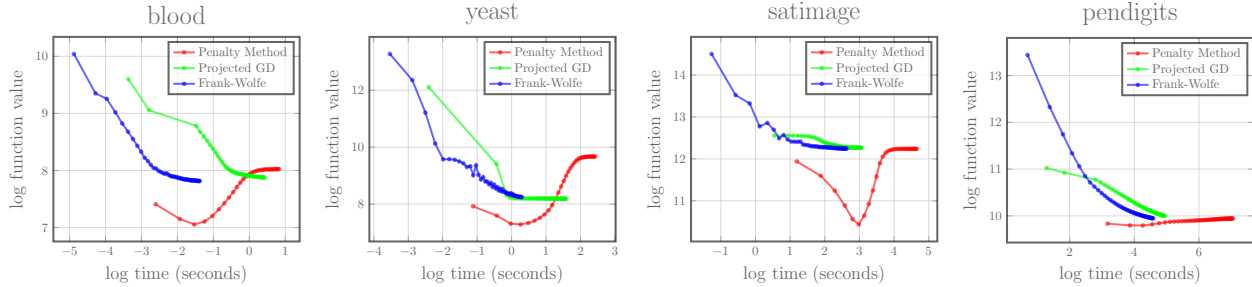

Figure 2: Convergence speed of three algorithms. The  $x$ -axis measures log-seconds and the  $y$ -axis measures log of objective function value. Note that the intermediate iterates of the penalty method are not feasible solutions, so we should only compare the convergent point of the penalty method with the other two.

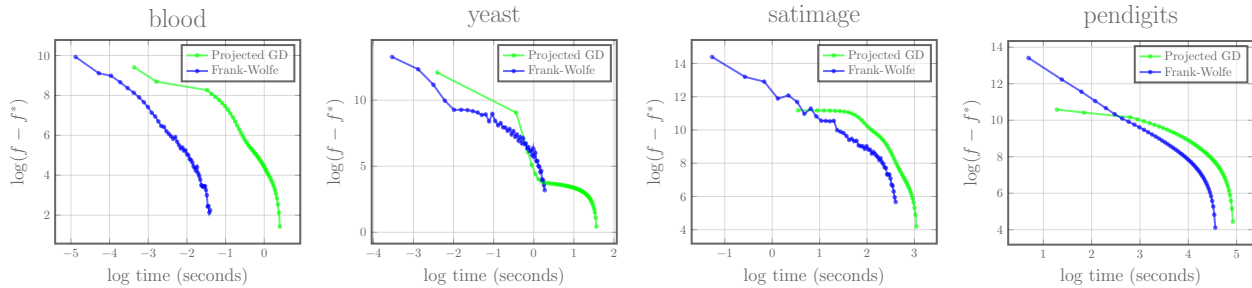

Figure 3: Convergence speed comparison between the projected gradient descent method and the FW algorithm. The  $x$ -axis measures log-seconds and the  $y$ -axis measures  $\log(f - f^*)$ , where  $f$  is the objective function value and  $f^*$  is the local optimum achieved by the algorithm. Note that the local optimum  $f^*$  achieved by PGD and FW can be different.

three algorithms in Fig. 2. Clearly, the penalty method is orders of magnitude slower than both PGD and the FW algorithm, and it usually converges to a worse solution. On the other hand, although the FW algorithm tends to have more iterations before it converges, due to its cheap computation in each iteration, it consistently takes less time than PGD. Another distinction between PGD and FW is that PGD, when implemented with backtracking line search, is a monotone descent method, while FW is not. For a better visualization to compare between the PGD and the FW algorithms, we omit the penalty method in Fig. 3, and draw the log-gap plot of the four datasets. We can confirm from Fig. 3 that both PGD and the FW algorithm have roughly the same order of convergence speed for solving (1), which is consistent with the theoretical result proved in the previous section (Thm. 2). However, the FW algorithm often converges faster than the PGD method, in terms of the gap between the objective function value and local optimum.

## 6 CONCLUSION

We propose a FW algorithm to solve the SymNMF problem under a simplicial constraint. Compared with existing solutions, the proposed algorithm enjoys a non-

asymptotic convergence guarantee to KKT points, is simple to implement, contains no hyperparameter to be tuned, and is also demonstrated to be much more efficient in practice. Theoretically, we establish a close connection of this problem to the famous completely positive matrix factorization by providing an equivalent geometric description. We also derive a tight bound on the curvature constant of this problem. As a side contribution, we give a pair of nonsmooth convex examples where the FW algorithm converges or fails to converge to its optimum. This result raises an interesting question w.r.t. the necessary condition of the success of the FW algorithm.

# Learning Time Series Segmentation Models from Temporally Imprecise Labels

---

Roy J. Adams and Benjamin M. Marlin  
University of Massachusetts, Amherst

## Abstract

This paper considers the problem of learning time series segmentation models when the labeled data are subject to temporal uncertainty or noise. Our approach augments the semi-Markov conditional random field (semi-CRF) model with a probabilistic model of the label observation process. This augmentation allows us to estimate the parameters of the semi-CRF from timestamps corresponding roughly to the occurrence of transitions between segments. We show how exact marginal inference can be performed in the augmented model in polynomial time, enabling learning based on marginal likelihood maximization. Our experiments on two activity detection problems show that the proposed approach can learn models from temporally imprecise labels, and can successfully refine imprecise segmentations through posterior inference. Finally, we show how inference complexity can be reduced by a factor of 40 using static and model-based pruning of the inference dynamic program.

## 1 INTRODUCTION

Structured prediction frameworks (e.g. conditional random fields [7]) are well-established approaches that often improve on independent prediction models when applied to problems with structured output spaces. In this paper, we consider the problem of learning and inference in structured prediction models for time series segmentation when the labels are subject to temporal imprecision. In this setting, supervision is provided in the form of timestamps that roughly correspond to segment boundaries.

This problem is an instance of weakly supervised learning [5] motivated by real-world data analytic challenges that

arise in the area of mobile health (mHealth) research. A central problem in mHealth research is learning accurate models for detecting health behaviors like eating, smoking, and sleeping from mobile sensor data [14, 18]. A key challenge in such problems is the high cost of obtaining accurately annotated data. mHealth researchers often must estimate the parameters of detection models from limited amounts of data collected in a lab setting where subjects perform scripted activities. This collection process allows researchers to observe subject behavior in detail, but severely limits the amount of data that can be gathered. Further, such data can differ systematically from data collected under real-world scenarios, leading to a lab-to-field generalization gap [10].

An alternative to gathering data in the lab is having subjects self-report their activities in the field, but this suffers from a variety of problems from a modeling perspective including limited frequency of the reports and recall bias. In both lab and field settings, annotations are generally provided in continuous time and may be subject to temporal imprecision. If ignored, such temporal imprecision in the labels may lead to the degraded performance of models trained on these labels. This is the primary problem we address in this paper.

This work makes three main contributions. First, we propose a framework for estimating the parameters of discrete time series segmentation models from temporally imprecise, continuous-time labels. Our approach augments a conditional random field (CRF) model with a probabilistic model of the label observation process. We focus on two classes of CRF models: the semi-Markov CRF (semi-CRF) [15], which models sequence segmentations, and the *hierarchical nested segmentation* (HNS) model [2], an extension of the semi-CRF that models activities composed of repeated short duration events such as eating. Our proposed observation model can account for both temporal imprecision and missingness in the labels. We evaluate this framework on sleep and smoking detection problems using data gathered in both lab

and field settings, demonstrating improved performance compared with ignoring label imprecision.

Second, we enable the synthesis of self-report and wearable sensor data. To the best of our knowledge, current methods for synthesizing these two types of observations are ad hoc and domain specific (e.g. [11]). In this work, we combine sensor data with imprecise continuous-time observations of activity segment boundaries by performing posterior inference in the proposed observation model. This leads to improved predictive performance over treating test-time observations as ground truth.

Finally, we enable the practical application of the proposed framework to long sequences. The model that we present supports exact inference via dynamic programming, but the complexity scales quadratically in the length of the input sequence. We achieve a 40 times speedup by applying a combination of static and model-based pruning techniques, while matching the performance of a model trained on hand-aligned labels.

## 2 RELATED WORK

In this section, we briefly describe related work on weakly supervised learning in the independent classification and structured prediction settings.

**Weakly supervised classification:** Reducing the cost of acquiring labeled data is a fundamental problem in supervised learning. This can often be achieved by lowering the quality of labels in some way. For example, *multiple instance learning* generalizes supervised learning by allowing for sets (or “bags”) of instances to be labeled instead of single instances. It is assumed that a positive bag contains at least one positive instance [9]. Similarly, the *label proportions* framework provides the proportion of each type of label for a group of instances [13]. These approaches avoid the need to label individual instances.

More closely related problems include learning independent classifiers in the presence of label noise [6], and learning independent sequence labeling models from temporally imprecise labels [1]. In both of these frameworks, the true instance labels are assumed to be unobserved. In the label noise framework, noisy instances of the labels are observed, while in the temporally imprecise labels framework, timestamps roughly corresponding to positive instances are observed. Approaches to both problems exist that are based on models of the noisy labeling process that marginalize over the unobserved instance labels during learning. The main difference between these models and the model presented in this work is that these models assume the true labels are independent given the features. In this paper, we consider a more complex structured

prediction setting, which in turn requires more complex observation models and inference algorithms.

**Weakly supervised structured prediction:** There has also been significant research in the area of weakly supervised structured prediction, particularly for computer vision applications. Various standard weak supervision frameworks, such as multiple instance learning, have been extended to structured prediction. [16] extend the multiple instance SVM framework to structured SVMs by considering an image to be a bag of pixels or overlapping sub-windows. [4] extend multiple instance learning to an auto-regressive HMM. While applicable to the problem considered in this paper, these methods would require discarding temporal information that was shown to be valuable in [1].

Another common approach is to assume that only a subset of the label variables in the model are exactly observed. This can be handled by marginalizing out the unobserved variables [17]; however, this framework cannot incorporate auxiliary observations such as continuous observation timestamps. [8] incorporate domain knowledge in the form of constraints on the marginal label distributions. These constraints can be enforced on unlabeled data, allowing for weak supervision. [12] use a similar constraint based approach where image tags are used to form constraints on the set of possible image segmentations. The approach in this work can be interpreted as using observation timestamps to place soft constraints on the set of segmentations; however, by using soft constraints, we can explicitly model the notion of temporal proximity.

## 3 NOTATION AND BACKGROUND

Many mHealth detection problems involve inferring activity segments from sensor data. Past work has shown improved performance when using conditional random field-based structured models to infer such segmentations [2]. We begin by the defining notation used for the input sequences and output structures in this type of problem. We then briefly review the Semi-Markov CRF model that this work extends.

### 3.1 Notation

We assume that the input data consists of  $N$  multivariate time series that we will call **sessions**. Each session contains a set of time-aligned signals gathered from one or more sensors. Separate sessions may correspond to data from different subjects data or to data from the same subject collected at different times. We assume that each session  $n$  has been discretized into a sequence of  $L_n$  potentially overlapping sub-windows and that a feature

vector  $\mathbf{x}_{ni} \in \mathbb{R}^D$  has been extracted for each sub-window  $i$ . We refer to each sub-window  $i$  as an **instance**. Further, each instance  $i$  in session  $n$  is associated with a timestamp  $t_{ni}$  which may correspond to the start, end, or other point of interest associated with instance  $i$ . We refer to the complete sequence of feature vectors  $\mathbf{x}_n = \{\mathbf{x}_{ni}\}_{i=1, \dots, L_n}$  as the **input sequence** and the complete sequence of timestamps  $\mathbf{t}_n = \{t_{ni}\}_{i=1, \dots, L_n}$  as the **timestamp sequence**. Where it does not cause ambiguity, we will drop the session index  $n$ . We use the notation  $\mathbf{x}_{j:k} = \{\mathbf{x}_i\}_{i=j, \dots, k}$  to refer to the subsequence of  $\mathbf{x}$  beginning at  $j$  and ending at  $k$  (this applies to any sequence).

In this work, our goal is to learn a model that produces a labeled segmentation of the input sequence  $\mathbf{x}$ . We represent such a segmentation as a sequence  $\mathbf{y} = \{y_s\}_{s=1, \dots, S}$  of segments where a segment  $y_s = (c_s, j_s, k_s)$  is a tuple containing a label  $c_s \in \mathcal{C}$ , a start position  $j_s \in \{1, \dots, L\}$ , and an end position  $k_s \in \{1, \dots, L\}$ . To ensure only valid segmentations, we assume  $j_1 = 1$ ,  $k_S = L$ , and  $k_s = j_{s+1}$  for all  $1 \leq s \leq S - 1$ . Our goal, then, is to learn the distribution  $p(\mathbf{y}|\mathbf{x}, \mathbf{t})$ . We will parameterize this distribution as a semi-Markov CRF.

### 3.2 Semi-Markov Conditional Random Fields

The semi-CRF [15] associates each segment  $y_s$  with a feature function  $\mathbf{f}(y_s, c_{s-1}, \mathbf{x}, \mathbf{t})$  which may depend on the segment  $y_s$ , the label of the previous segment  $c_{s-1}$ , and the complete feature and timestamp sequences  $\mathbf{x}$  and  $\mathbf{t}$ . The function  $f$  maps these inputs to a length  $F$  feature vector. Given a parameter vector  $\theta \in \mathbb{R}^F$ , the distribution over segmentations is given by

$$p_\theta(\mathbf{y}|\mathbf{x}, \mathbf{t}) = \frac{\prod_s \exp(\langle \theta, \mathbf{f}(y_s, c_{s-1}, \mathbf{x}, \mathbf{t}) \rangle)}{Z_\theta(\mathbf{x}, \mathbf{t})} \quad (1)$$

Both maximum a posteriori (MAP) and marginal inference can be performed in this model by dynamic programs with complexity  $\mathcal{O}(|\mathcal{C}|^2 L^2)$  [15]. The parameters  $\theta$  are typically estimated using maximum likelihood estimation, however, this requires observing the ground truth segmentations. In settings such as mHealth, acquiring the exact segmentation boundaries may be costly or even impossible. We next present our proposed method for estimating the parameters of the semi-CRF model from timestamps corresponding roughly to segment boundaries.

## 4 LEARNING SEMI-CRF MODELS FROM TEMPORALLY IMPRECISE LABELS

Let  $\mathbf{z} = \{z_m\}_{m=1, \dots, M}$  be a sequence of **observations** where each observation  $z_m$  is a timestamp corresponding to a particular kind of transition. For example, each  $z_m$

may be the time a subject reported going to sleep marking the start of a sleep segment. For ease of exposition, we will assume that there is only one type of observation and will later generalize to multiple observation types. To map between our labels  $\mathbf{y}$  and our observations  $\mathbf{z}$ , let  $\mathbf{o} = \{o_i\}_{i=1, \dots, L}$  be a sequence of latent binary variables where  $o_i = 1$  if and only if instance  $i$  is associated with an observation. Under the assumption that observations are recorded in the order they actually occurred and  $\sum_i o_i = M$ ,  $\mathbf{o}$  defines a matching between instances in the input sequence and observations in the observation sequence.

We model the observation sequence using a generative model with three components. The base segmentation model  $p_\theta(\mathbf{y}|\mathbf{x}, \mathbf{t})$  is the semi-CRF model whose parameters we are interested in estimating. The observation indicator distribution  $p_\pi(o|y_s, c_{s-1}, i)$  models the probability that instance  $i$  is associated with an observation given the segment it is contained in and the label of the previous segment. Finally, the observation timestamp density  $p_\phi(z|t)$  models the timestamp of an observation  $z$  given the timestamps  $t$  with which it is associated. For example, we may use a simple Bernoulli distribution for  $p_\pi(o|y_s, c_{s-1}, i)$  and a normal distribution centered at  $t$  for  $p_\phi(z|t)$ . The specific choices for these distributions are domain specific and we demonstrate a couple different choices in section 5. With these distributions, we can now write the observation generation process as shown below:

```

1:  $M \leftarrow 0$ 
2:  $\mathbf{y} \sim p_\theta(\mathbf{y}|\mathbf{x})$ 
3: for  $s = 1, \dots, S$  do
4:   for  $i = j_s, \dots, k_s$  do
5:      $o_i \sim p_\pi(o|y_s, c_{s-1}, i)$ 
6:     if  $o_i = 1$  then
7:        $M \leftarrow M + 1$ 
8:        $z_M \sim p_\phi(z|t_i)$ 

```

This generative process asserts that a complete segmentation is first sampled according to the semi-CRF model. Next, each instance either generates an observation or not according to  $p_\pi(o|y_s, c_{s-1}, i)$ . Finally, if instance  $i$  does generate an observation, an observation timestamp is sampled from  $p_\phi(z|t_i)$ . The variable  $M$  counts the number of generated observations. We note that additional structure could be encoded into the label observation process at the cost of a potentially more complex inference algorithm.

$$p_\omega(\mathbf{z}, \mathbf{y}, \mathbf{o}|\mathbf{x}, \mathbf{t}) = p_\theta(\mathbf{y}|\mathbf{x})p_\pi(\mathbf{o}|\mathbf{y})p_\phi(\mathbf{z}|\mathbf{o}, \mathbf{t}) \quad (2)$$

$$p_\pi(\mathbf{o}|\mathbf{y}) = \prod_s \prod_{i=j_s}^{k_s} p_\pi(o_i|y_s, c_{s-1}, i) \quad (3)$$

$$p_\phi(\mathbf{z}|\mathbf{o}, \mathbf{t}) = \prod_{m=1}^M p_\phi(z_m|t_{i(m)}) \quad (4)$$

The joint model implied by this generative process is

given in Equation 2 where the set of all parameters in the model is  $\omega = \{\theta, \pi, \phi\}$ . The distributions  $p_\pi(\mathbf{o}|\mathbf{y})$  and  $p_\phi(\mathbf{z}|\mathbf{o}, \mathbf{t})$  are defined in Equations 3 and 4. We define  $i(m)$  as the function mapping observation  $m$  to the instance that generated it.

#### 4.1 Inference and Learning

To learn the parameters of this model, we maximize the log marginal likelihood  $\mathcal{L}(\omega|\mathcal{D})$ :

$$\mathcal{L}(\omega|\mathcal{D}) = \sum_{n=1}^N \log p_\omega(\mathbf{z}_n|\mathbf{x}_n, \mathbf{t}_n) \quad (5)$$

$$p_\omega(\mathbf{z}|\mathbf{x}, \mathbf{t}) = \sum_{\mathbf{y} \in \mathcal{Y}} \sum_{\mathbf{o} \in \mathcal{O}} p_\omega(\mathbf{z}, \mathbf{y}, \mathbf{o}|\mathbf{x}, \mathbf{t}) \quad (6)$$

where  $\mathcal{D} = \{(\mathbf{x}_n, \mathbf{t}_n, \mathbf{z}_n)\}_{n=1, \dots, N}$  consists of the observed data for all sessions. We perform this optimization using standard gradient methods. Here, we consider the gradient equation for each of the three parameter groups:  $\theta$ ,  $\pi$ , and  $\phi$ . These equations are presented primarily to give intuition for what maximum likelihood estimation is doing in this model. The gradient equations for  $\pi$  and  $\phi$  are shown below.

$$\begin{aligned} \nabla_\phi \log p_\omega(\mathbf{z}|\mathbf{x}, \mathbf{t}) \\ = \sum_{m=1}^M \mathbb{E}_{p_\omega(i(m)|\mathbf{z}, \mathbf{x}, \mathbf{t})} [\nabla_\phi \log p_\phi(z_m|t_{i(m)})] \end{aligned} \quad (7)$$

$$\begin{aligned} \nabla_\pi \log p_\omega(\mathbf{z}|\mathbf{x}, \mathbf{t}) \\ = \sum_{i=1}^L \mathbb{E}_{p_\omega(o_i, \mathbf{y}|\mathbf{z}, \mathbf{x}, \mathbf{t})} [\nabla_\pi \log p_\pi(o_i|\mathbf{y})] \end{aligned} \quad (8)$$

Both gradient equations take the form of a posterior expectation of the log gradient of the relevant distribution. The gradient with respect to the base classifier parameters also takes the form of an expected gradient of a log density and is shown below.

$$\begin{aligned} \nabla_\theta \log p_\omega(\mathbf{z}|\mathbf{x}, \mathbf{t}) &= \mathbb{E}_{p_\omega(\mathbf{y}|\mathbf{z}, \mathbf{x}, \mathbf{t})} [\nabla_\theta \log p_\theta(\mathbf{y}|\mathbf{x})] \\ &= \mathbb{E}_{p_\omega(\mathbf{y}|\mathbf{z}, \mathbf{x}, \mathbf{t})} [\nabla_\theta \langle \theta, \mathbf{f}(\mathbf{x}, \mathbf{t}, \mathbf{y}) \rangle] - \nabla_\theta Z_\theta(\mathbf{x}) \quad (9) \\ &= \mathbb{E}_{p_\omega(\mathbf{y}|\mathbf{z}, \mathbf{x}, \mathbf{t})} [\mathbf{f}(\mathbf{x}, \mathbf{t}, \mathbf{y})] - \mathbb{E}_{p_\theta(\mathbf{y}|\mathbf{x})} [\mathbf{f}(\mathbf{x}, \mathbf{t}, \mathbf{y})] \end{aligned}$$

where  $\mathbf{f}(\mathbf{x}, \mathbf{t}, \mathbf{y})$  denotes the sufficient statistics function for the semi-CRF model. In this case, the log-linear form of the semi-CRF model gives us the further interpretation that the learning algorithm is trying to match the expected sufficient statistics under the base semi-CRF model to the posterior expected sufficient statistics given by the observation model. This is in contrast to typical maximum likelihood estimation for a log-linear model which would match the expected sufficient statistics under the model to the observed sufficient statistics.

The primary computational challenge of this learning pro-

cedure is calculating the log marginal likelihood. This can be done exactly using a dynamic program for calculating  $p_\omega(\mathbf{z}|\mathbf{x}, \mathbf{t})$ . An entry in the dynamic programming table  $\alpha$  has the following interpretation:  $\alpha(k, c, m)$  is the unnormalized probability that the input subsequence  $\mathbf{x}_{1:k}$  generated the observation subsequence  $\mathbf{z}_{1:m}$  given that the last segment in  $\mathbf{y}$  has label  $c$ . Or, written mathematically:

$$\alpha(k, c, m) \propto p_\omega(\mathbf{z}_{1:m}|\mathbf{x}_{1:k}, \mathbf{t}_{1:k}, c_{|\mathbf{y}|} = c) \quad (10)$$

Filling in this table has complexity  $\mathcal{O}(|\mathcal{C}|^2 L^2 M)$  where  $L$  is the length of the input sequence,  $\mathcal{C}$  is the set of possible segment labels, and  $M$  is the length of the observation sequence. A full description of this dynamic program can be found in section 2 of the supplementary materials. We use reverse-mode automatic differentiation [3] to derive a dynamic program with the same complexity to calculate the necessary gradients for learning.

#### 4.2 MAP Inference

Our second goal is to combine temporal observations, such as self-reported activities, and wearable sensor input to infer behaviors. That is, we would like to infer the most likely segmentation of the input sequence given  $\mathbf{x}$ ,  $\mathbf{t}$ , and  $\mathbf{z}$ . To do this, we perform full maximum a posteriori (MAP) inference over both  $\mathbf{y}$  and  $\mathbf{o}$

$$\mathbf{y}^*, \mathbf{o}^* = \arg \max_{\mathbf{y}, \mathbf{o}} p_\omega(\mathbf{y}, \mathbf{o}|\mathbf{z}, \mathbf{x}, \mathbf{t}) \quad (11)$$

The same dynamic program used to calculate the marginal likelihood can be used to perform MAP inference by swapping summation over  $\mathbf{y}$  and  $\mathbf{o}$  for maximization with no change in the computational complexity.

#### 4.3 Multiple Observation Types

In some settings, it may be desirable to allow for multiple types of observations. For example, we may want to include observations of both the beginning and end of sleep. This can be handled by including multiple observation sequences  $\mathbf{z}^{(l)}$  each with length  $M^{(l)}$  and observation indicator sequences  $\mathbf{o}^{(l)}$  where  $l$  indicates the observation type. Observation sequences of each type are assumed to be independent conditioned on the segmentation  $\mathbf{y}$  and the ordering assumption need not hold between types. The complexity of inference in this setup is  $\mathcal{O}(|\mathcal{C}|^2 L^2 \prod_l M^{(l)})$ .

## 5 EXPERIMENTS AND RESULTS

We evaluated the proposed framework’s ability to accommodate the temporal label imprecision that arises in both the lab and field settings on two mHealth detection problems: sleep detection and cigarette smoking detection. In

this section we describe the datasets and models used as well as the results of these evaluations.

## 5.1 Sleep detection

We evaluated our framework’s performance on data from the field using the Extrasensory<sup>1</sup> dataset [18]. This dataset contains signals from a variety of sensors including the accelerometer, gyroscope, GPS, and microphone on a mobile device as well as a wrist-worn accelerometer. Subjects carried these sensors during daily activities and self-reported a range of activities such as sleeping, eating, and exercising. We focus on the sleep detection problem, as this was one of the more abundantly reported activities. Signals from all sensors were recorded for 20 seconds every minute leading to a natural one minute discretization, which we downsampled to one instance every two minutes in order to run a large number of experiments (a 2x downsample results in a 4x inference speedup). We partitioned the data into 24 hour sessions beginning and ending at 2:00pm and dropped any session with less than four hours of recorded data or less than one hour of reported sleep. This resulted in 80 sessions from 28 subjects. While the researchers corrected obvious conflicts in the self-reported activities, there is no ground truth for this data, so we evaluated against the cleaned self-reported sleep. To simulate extra noise in the observation process, we added further synthetic noise (described below) to the observation timestamps.

**Instance Features:** We used the full set of instance features reported in [18] which include a number of statistical features calculated on the various accelerometer and gyroscope sensors, relative features calculated on the GPS positions, and discrete time-of-day features.

**Model:** Our goal in the sleep detection problem is to segment the input sequence into periods of sleep and non-sleep. We use a binary semi-CRF with a constraint that consecutive segments may not have the same label. We included as features the sum of all instance level features within segment  $x_{jk} = \sum_{i=j}^k x_i$  and duration based features  $\mathbb{I}[c_m = 1](t_k - t_j)$  and  $\mathbb{I}[c_m = 1](t_k - t_j)^2$ , which are similar to putting a normal distribution on the duration of sleeping activities<sup>2</sup>. We placed a zero-mean gaussian prior with tuned variance on the parameters of the semi-CRF model (i.e.  $\ell_2$  regularization).

We included two types of observations: the beginning of sleep  $\mathbf{z}^{(1)}$  and the end of sleep  $\mathbf{z}^{(2)}$ . Because sleep was observed in all sessions, we used a deterministic observation indicator distribution. If instance  $i$  is the beginning

of a sleep segment, it must generate an observation  $z_m^{(1)}$  and likewise for the end of a sleep segment. No other instances may generate observations in this model.

To model the procedure of self-reporting when you go to sleep and when you wake up, we used a one-sided distribution to model the observation timestamp noise. We used the following exponential distributions to model observation timestamp noise:

$$p_\phi(z_m^{(1)}|t_{i(m)}) = \text{Exp}(t_{i(m)} - z_m^{(1)}; \lambda)$$

$$p_\phi(z_m^{(2)}|t_{i(m)}) = \text{Exp}(z_m^{(2)} - t_{i(m)}; \lambda)$$

We placed an inverse-Gamma prior with shape  $\alpha = 1$  and scale  $\beta = 1$  on  $\lambda$ . We found parameter estimation to be fairly insensitive to changes in the settings of this prior distribution and used informative values for  $\alpha$  and  $\beta$ .

**Train and Test Procedures:** We evaluated performance using a 10-fold cross-validation procedure, where folds were calculated at the session level. The strength of the  $\ell_2$  regularizer was tuned to maximize instance-level  $F_1$  over a logarithmic grid using a further 9-fold evaluation. This procedure is equivalent to assuming that some of the data has been labeled for tuning purposes. Predictions were evaluated against the self-reported labels.

**Experiments:** We compared semi-CRF models trained in two ways. First, we trained a semi-CRF model based on a naive alignment defined by mapping each augmented observation to the nearest instance (semi-NV). Second, we trained a semi-CRF model using the proposed weak supervision framework applied to the augmented observations (semi-WS). To test these models under a variety of noise conditions, we augmented the observation timestamps by adding different amounts of exponentially distributed noise and trained both models using these augmented observations. Finally, we tested each model when provided with different amounts of information. At test time, each model was given either all segment start observations (Start), all segment end observations (End), neither observations (None), or both observations (Start+End). Observations were incorporated into semi-WS as described in section 4.2, and were incorporated into semi-NV by mapping the provided observations to the nearest instance and performing MAP inference over the label set constrained to agree with the mapped observations.

The results from these experiments are shown in figure 1. The three plots correspond to models trained and tested on observations augmented with standard deviation  $\lambda = 0, 30, 60$  minutes of temporal noise. Within each plot, the performance for each model when conditioned on different amounts of information is shown. In all cases, semi-WS outperforms semi-NV. The performance gap grows both as the standard deviation of the observation

<sup>1</sup><http://extrasensory.ucsd.edu/>

<sup>2</sup> $\mathbb{I}[\cdot]$  is the indicator function

Figure 1: Performance for the semi-WS and semi-NV models on the sleep detection problem when trained on data with  $\text{Exp}(\lambda)$  distributed noise (measured in minutes) added to the observation timestamps. Each plot shows the performance of both models when conditioned on all segment start observations (Start), all segment end observations (End), neither (None), or both (Start+End) at test time.

noise increases and as the amount of information available at test time increases. This indicates that semi-WS is better able to learn from temporally imprecise labels, and that using an explicit observation model is useful when incorporating imprecise observations.

## 5.2 Smoking detection

We evaluated the proposed framework’s ability to handle the types of imprecision that arise in a laboratory setting using the puffMarker smoking dataset [14]. This data was collected in a lab setting where subjects were fitted with chest-worn respiration monitors and wrist-worn actigraphy sensors and asked to smoke a cigarette while an observer marked the occurrence of smoking puffs using a mobile phone app. The respiration signal was discretized into a sequence of non-overlapping respiration cycles (a single inhalation and exhalation) and the goal is to label each respiration cycle as a smoking puff or not and segment the respiration cycles into periods of smoking and non-smoking activities. We created sessions by including random amounts of non-smoking on either side of each recorded smoking activity resulting in 23 sessions from five subjects. In addition to the raw observation timestamps, researchers visualized the respiration signal and hand-aligned the observation timestamps to respiration signal. We treat these hand aligned labels as ground truth for the purposes of evaluation, though we acknowledge that there may be errors in the alignment process. While most experiments on this data were conducted using the true observation timestamps, we also tested the robustness of our framework to extra noise which was generated synthetically and added to the raw observation timestamps.

**Instance Features:** Features were extracted from the respiration monitor data for each respiration cycle according to [14]. Further, we extracted features from the actigraphy data using the following procedure: Let  $t_i$  be the timestamp of the maximum peak in respiration cycle  $i$ .

For each actigraphy channel, extract a window beginning 8 seconds before  $t_i$  and ending 1 second after  $t_i$  and calculate as features the mean, max, min, standard deviation, median, and five bin histogram of the channel’s signal within this window. The actigraphy channels included were accelerometer x, y, and z, accelerometer magnitude, gyroscope x, y, and z, gyroscope magnitude, and pitch and roll angles for a total of 100 actigraphy based features. Pitch and roll calculations using accelerometer data are only valid when the hand is stationary, so these signals were filtered using the procedure described in [14].

Respiration and actigraphy-based features have different properties as a function of time. Due to the method we used to extract actigraphy-based features, these features tend to be smooth through time, particularly as compared to the respiration features extracted from non-overlapping windows. The smooth noise model we propose tends to over-emphasize temporally smooth features at the expense of less smooth features. To combat this effect, we use the actigraphy features to augment the respiration features in a manner similar to the filtering approach used in [14].

We trained a logistic regression model on a small set of instances with hand-aligned labels using only the actigraphy features, then took the predictions from this model and augmented the respiration features as  $\mathbf{x}_{aug} = [\hat{c}_{act}\mathbf{x}_{resp} \ (1 - \hat{c}_{act})\mathbf{x}_{resp}]$  where  $\hat{c}_{act} \in \{0, 1\}$  is a prediction from the filter model and  $\mathbf{x}_{resp}$  is the vector containing only respiration features. A similar effect might be achieved by including interaction effects between the actigraphy and respiration features; however, this would result in more than 10,000 features. The filtering approach can therefore also be thought of as first doing a supervised compression of the actigraphy features and then doing a polynomial basis expansion. For more details, see section 3 in the supplemental materials.

**Model:** Our goal in the smoking detection problem is to label each respiration cycle as smoking or non-smoking

and to segment the input sequence into periods of smoking and non-smoking; however, smoking detection differs from typical segmentation problems in that a complete smoking activity contains a mix of smoking puffs and non-smoking respiration cycles. In terms of the model, this means that the instances contained in a positive segment may be both positive or negative (an example of this structure with example observations is shown below). To address this we used an extension of the standard semi-CRF called the hierarchical nested segmentation (HNS) model [2]. Rather than segment a sequence into positive and negative activities, the HNS model segments the sequence into periods between positive instances, termed inter-event spans. Further, the HNS model includes a cardinality potential that models the number of positive instances that make up a positive activity (or the number of consecutive positive inter-event spans). In addition to the instance level features, we included the segment duration,  $t_k - t_j$  and segment duration squared  $(t_k - t_j)^2$  to model the time between positive instances (i.e. the time between puffs on a cigarette). For full details of the HNS model for smoking detection, see [2], and for details on how the HNS model can be written as a semi-CRF, see section 4 of the supplementary materials. We placed a zero-mean gaussian prior with tuned variance on the parameters of the HNS model (i.e.  $\ell_2$  regularization).

As seen in the figure above, we included three types of observations: positive instance observations associated with any inter-event span  $\mathbf{z}^{(1)}$ , activity start observations associated only with the first inter-event span in a complete activity  $\mathbf{z}^{(2)}$ , and activity end observations associated only with the last inter-event span in a complete activity  $\mathbf{z}^{(3)}$ . We used the following Bernoulli distributions for our observation indicator model  $p_\pi(o_i^{(l)}|\mathbf{y})$ :

$$\begin{aligned} p_\pi(o_i^{(1)} = 1 | i \text{ is the start of an inter-event span}) &= \pi_1^{(1)} \\ p_\pi(o_i^{(2)} = 1 | i \text{ is the start of a smoking activity}) &= \pi_1^{(2)} \\ p_\pi(o_i^{(3)} = 1 | i \text{ is the end of a smoking activity}) &= \pi_1^{(2)} \end{aligned}$$

where  $\pi_1^{(1)}, \pi_1^{(2)} \in [0, 1]$ . For the observation timestamp density, we used the following normal distribution:

$$p_\phi(z_m^{(l)}|t_{i(m)}) = \mathcal{N}(z_m^{(l)}; t_{i(m)} + \mu_l, \sigma_l^2)$$

for  $l \in \{1, 2, 3\}$  where  $\phi = \{\mu, \sigma\}$ . This density was chosen to match the empirical noise distribution [1]. We placed a Uniform(0, 1) prior on each  $\pi^{(l)}$ , a standard normal prior on each  $\mu_l$ , and an inverse-Gamma prior

with shape  $\alpha = 1$  and scale  $\beta = 1$  on each  $\sigma_l^2$ .

**Train and Test Procedures:** We evaluated performance using a leave-one-session-out cross-validation procedure. All tuned hyperparameters were tuned to maximize instance level  $F_1$  over a logarithmic grid using a further nested leave-one-session-out evaluation. Predictions were evaluated against the hand-aligned labels.

**Experiment 1 - Pruning Strategies:** While the inference algorithm described in section 4.1 is at most quadratic in the size of each input, the overall run time can be quite high, particularly for long sequences or models with a large label set  $\mathcal{C}$  such as the HNS model. In order to improve inference run times, we consider three strategies to prune the inference dynamic program.

**Maximum segment length:** One straightforward way to constrain the label space is to place a bound on segment lengths. For example, in the case of smoking detection, we might say that two smoking puffs separated by five minutes (or approximately 50 respiration cycles) constitute two separate smoking activities. Adding this constraint reduces the complexity of inference to  $\mathcal{O}(|\mathcal{C}|^2 L B M)$  where  $B$  is the maximum segment length.

**Maximum observation distance:** Depending on the observation process, we might also place a constraint on the maximum time between a true event and an associated timestamp. This corresponds to using a truncated distribution for  $p_\phi(z|t)$ . Given a maximum observation distance of  $r$ , we can upper bound the inference complexity by  $\mathcal{O}(|\mathcal{C}|^2 L \tilde{B} M)$  where  $\tilde{M}$  is the maximum number of observations that could be associated with a single instance or  $\tilde{M} = \max_i \sum_m \mathbb{I}[t_i - r \leq z_m \leq t_i + r]$ . In practice, the average improvement in runtime is better than this.

**Negative instance filtering:** In cascaded classification, a simple classifier is used to filter the label set for a more complex classifier [19]. This technique has been successfully applied to structured prediction problems (e.g. [20]) and we apply it here to filter the space of possible segmentations. Due to the heavy instance level class imbalance in many mHealth problems, it is often easy to learn a high recall instance-level classifier, which can then be used to clamp instance labels to the negative class. Given an instance level classifier, let  $\tilde{c}_i$  be the filter model's prediction for instance  $i$ . Then, during inference, we constrain the set of possible segmentations to agree with the negative predictions of the filter model. Using this filtering procedure, the worst case complexity remains unchanged (it is possible that the filter model filters nothing), but the average case complexity becomes  $\mathcal{O}(\gamma|\mathcal{C}|^2 L B M)$  where  $\gamma$  is the proportion of instances that pass the filter.

Figure 2: This figure shows the effect of changing the maximum segment length with no observation depth pruning or filtering (left), the effect of changing the maximum observation distance with no filtering (center), and the further marginal effect of filtering approximately 85% of instances (right). The maximum pruning configuration results in a 40x speedup.

To test the effect of the proposed pruning strategies, we ran an ablation experiment to assess the time required to run marginal inference in the HNS model augmented with an observation model using different combinations of pruning techniques. First, we varied the maximum segment length from 350 to 50. Next, with the maximum segment length fixed at 50, we varied the maximum observation distance from 350 to 50. Finally with the maximum segment length and maximum observation distance fixed at 50, we ran inference with and without negative instance filtering. For the filtering model, we used the same actigraphy-based logistic regression model used to perform feature augmentation (Section 5.2, Instance Features). Figure 2 shows the run time in seconds for each of these settings<sup>3</sup>. Using all pruning strategies, the runtime of marginal inference is decreased from approximately 600 seconds to approximately 15 seconds, a 40 times speedup. We use the most aggressive pruning settings in all subsequent experiments.

**Experiment 2 - Prior predictive performance:** We next evaluated the ability of the proposed framework to learn the parameters of the base classifier from imprecise lab data by comparing the HNS model trained in three different ways. First, we trained the HNS model directly on the hand-aligned labels (HNS-HA). This represents the gold standard performance that we would like to achieve. Second, we trained the HNS model on labels generated by associating each observation timestamp with the closest respiration cycle (HNS-NV). This represents the naive baseline and we would expect our procedure to fall somewhere between HNS-HA and HNS-NV. Third, we trained the HNS model using the weak supervision framework proposed above (HNS-WS). Figure 3 shows the performance of all three models on the instance labeling and

segmentation tasks. The HNS-WS model performs approximately as well as the HNS-HA model at both the instance labeling and segmentation tasks while the HNS-NV model performs worse than either. A paired t-test indicates that the improvement in the HNS-WS results over the HNS-NV results is statistically significant in terms of both instance labeling and segmentation ( $p \leq 0.05$ ). These results indicate that we have achieved our primary aim of enabling learning of the HNS model from data with noisy observation timestamps.

### Experiment 3 - Posterior predictive performance:

We evaluated the ability of the HNS-WS model to combine sensor data with timestamp observations at test time. As in the sleep detection experiments, we evaluated all three models when given either all activity start observations (Start), all activity end observations (End), neither (None), or both (Start+End) at test time. The results are shown in Figure 4 (left). Unlike in our sleep detection experiments, all noise present in these observations was real and all evaluations were made against carefully hand aligned labels. While conditioning on segment observations results in improvements for all three models, these gains are much larger for the HNS-WS model. In particular, conditioning on both the segment start and end timestamps results in a 6% error reduction for the HNS-HA model and a 16% error reduction for the HNS-NV model whereas conditioning on the same information results in an 89% error reduction for the HNS-WS model.

In general, we cannot expect the noise we observe in the field to look like the noise we observe in the lab, therefore it is valuable to know how sensitive the HNS-WS model is to the correctness of the observation timestamp model. To test this, we generated synthetic observation timestamps from a normal distribution centered at the true activity start or end and varied the standard deviation of the distribution. The segmentation accuracy of the HNS-WS model when conditioning on these synthetic observations at test

<sup>3</sup>Runtime experiments were performed on a 2.8 GHz Intel Core i7 processor with 8GB of RAM and the inference algorithm was coded in Cython.

Figure 3: The left plot shows instance level  $F_1$  score for all three models. The right plot shows the segmentation accuracy for all three models. The proposed HNS-WS model significantly outperforms the HNS-NV model. Error bars show one standard error.

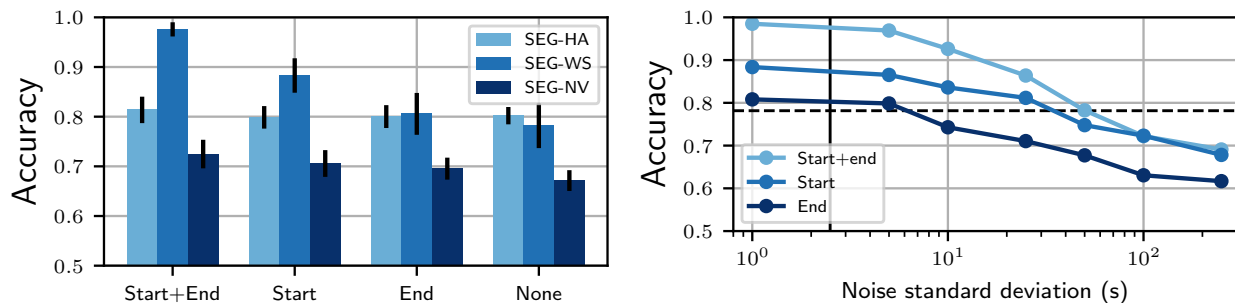

Figure 4: The left plot shows the segmentation accuracy when each HNS model is conditioned on different combinations of observations (segment start, segment end or both). The right plot shows the HNS-WS model when conditioned on segment observations with different amounts of synthetic noise added. The dashed line shows the segmentation accuracy of the HNS-WS model when conditioned on no observations (None) and the solid line shows the empirical standard deviation of the timestamp noise in the data, which reflects what HNS-WS was trained on.

time is shown in Figure 4 (right). The results show that the HNS-WS model can successfully incorporate observations with up to an order of magnitude more noise than was observed at train time. As expected, adding sufficient noise to the observations eventually causes performance to degrade; However, even with large amounts of noise, posterior segmentation accuracy plateaus between 0.6 and 0.7 compared to an accuracy of approximately 0.8 when not conditioning on any observations.

## 6 CONCLUSIONS

In this work, we have addressed the problem of learning time series segmentation models from noisy observation timestamps. We extended the weakly supervised learning framework of [1] to the semi-Markov CRF and HNS models and derived exact and approximate inference algorithms based on dynamic programming. We showed using real sleeping and smoking data that learning the segmentation models in this way can recover the performance of models trained on more expensive hand-aligned labels, while significantly out-performing the naive alignment strategy. Further, we showed that this framework can be

used to combine noisy observations with sensor input at test time in a principled way.

This work suggests a several of interesting research directions for future research. First, in many cases it is much cheaper to gather large amounts self-report data than it is to gather lab data. The proposed framework is capable of incorporating both lab data and self-report data gathered in the field to train or fine-tune a model in a noisy semi-supervised-like learning framework. Second, personalizing detection models is an important goal in mHealth research, but is typically not practical due to the cost of obtaining labels. Our approach opens the possibility of personalizing models using less costly (but more noisy) self-report data from the field.

## Acknowledgments

The authors would like to thank members of the MD2K Center (<http://www.md2k.org>) for helping to enable this research. This work was partially supported by the National Institutes of Health under award 1U54EB020404, and the National Science Foundation under award IIS-1350522.

## Abstract

In Bayesian Multi-Objective optimisation, expected hypervolume improvement is often used to measure the goodness of candidate solutions. However when there are many objectives the calculation of expected hypervolume improvement can become computationally prohibitive. An alternative approach measures the goodness of a candidate based on the distance of that candidate from the Pareto front in objective space. In this paper we present a novel distance-based Bayesian Many-Objective optimisation algorithm. We demonstrate the efficacy of our algorithm on three problems, namely the DTLZ2 benchmark problem, a hyper-parameter selection problem, and high-temperature creep-resistant alloy design.

## 1 INTRODUCTION

Bayesian optimisation (Brochu et al., 2010) is a method for maximising black-box functions that are expensive to evaluate either in terms of time or cost. Bayesian optimisation works by modelling the objective function (typically) using a Gaussian process (GP) (Rasmussen and Williams, 2006). At each iteration a point (called a recommendation) is selected to maximise an acquisition function, where the acquisition function is a measure of the *goodness* of a proposed point. Unlike the black-box function, the acquisition function is cheap to evaluate and therefore amenable to global optimisation.

In the context of multi-objective optimisation, Bayesian optimisation is typically applied using an acquisition function based on expected hypervolume improvement (EHI) (Ponweiser et al., 2008; Emmerich and Klöppel, 2008; Shir et al., 2007; Zaefferer et al., 2013; Shimoyama et al., 2013), which is the expected change in

the hypervolume dominated by the estimated Pareto front (the set of dominant evaluations of prior recommendations in objective space - see figure 1). However this can be expensive to evaluate, particularly in the many-objective case where the number of objectives is large (Wagner et al., 2010; Zaefferer et al., 2013). While optimised algorithms have been developed for calculating EHI for up to 3 dimensions (Hupkens et al., 2015) the general (many-objective (Ishibuchi et al., 2008)) case remains computationally challenging.

An alternative approach is to use a distance-based acquisition function (or score function) (Miranda and Von Zuben, 2015; Yun et al., 2004). Distance-based acquisition functions seek to maximise the signed distance of a point from the estimated Pareto front, as shown in figure 1. Unlike EHI this acquisition function is cheap to evaluate, making its global optimisation (and hence Bayesian optimisation) practical in the many-objective case. While the underlying concept is old (e.g. (Yun et al., 2004)) it has only recently been formalised in a rigorous manner (Miranda and Von Zuben, 2015) in the form of conditions that must be met by a distance (score) function measuring the signed distance *in advance of (dominating)* the Pareto front; whereas (Yun et al., 2004) for example defines the signed distance from the estimated feasible region in any direction, dominating or otherwise. However, while (Miranda and Von Zuben, 2015) defines the conditions that must be met by such a score function, the method implemented therein - namely a GP model with a probability distribution over the gradient - only approximately meets these requirements.

In the present paper we introduce an alternative model based on a modified 1-norm support vector machine (SVM) that is able to *exactly* satisfy the conditions laid down in (Miranda and Von Zuben, 2015). To be precise, we use a restricted 1-norm, 1-class SVM to define a signed distance function which is strictly positive for points that dominate the estimated Pareto front, strictly negative for points dominated by the estimated Pareto

front, and for which signed distance and the dominance relation are congruent.<sup>1</sup> This distance function forms the basis for an acquisition function that is computationally cheap to evaluate and scales well with the number of objectives, thereby making feasible Bayesian many-objective optimisation.

To test our proposed algorithm we have applied it to one benchmark problem and two practical problems. The benchmark problem used is taken from the DTLZ suite of benchmarks (Deb et al., 2005). For practical problems we have chosen a hyper-parameter selection problem and an experimental problem involving high-temperature, creep resistant alloy design.

The first practical problem considered is hyperparameter selection for a multi-class classifier where the relative weights (importance) of the various classes is unknown. While the default assumption often made for such problems is that all classes should have equal weight (or alternatively that their weight should be proportional to their class density) this will not be valid in general. Instead the accuracy of the classifier with respect to each class of training data forms an independent objective, and the problem of hyper-parameter selection in the absence of additional information regarding relative weight is one of multi-objective optimisation.

The second practical problem considered is the design of high-temperature, creep-resistant alloys. High-temperature creep resistant Ni-superalloy is used for making boilers of super-critical thermal power plants. In a joint project with metallurgists we were asked to optimize the current alloy recipe to obtain superior creep resistance than the industry standard. This involves using phase simulation (via ThermoCalc) to design an alloy with maximum good phases (those that improved creep-resistance) and minimum bad phases (those that made the alloy less creep-resistant) over a range of temperatures. The total number of objectives for this experiment is 12, each corresponding to a particular phase and temperature, which leads to recommendation times of up to 1 day/recommendation if EHI is used. We demonstrate that our approach is able to provide a range of potential alloys, each Pareto-optimal in terms of phase contents, for further assessment by the metallurgist.

We note that there exists an abundance of such many-objective optimisation problems in physical systems - for example advanced fibre production (Li et al., 2017). By making many-objective Bayesian optimisation feasible we envisage that such problems will be able to be formulated and solved.

<sup>1</sup>That is, if  $\mathbf{y}$  dominates  $\mathbf{y}'$  then the distance of  $\mathbf{y}$  from the estimated Pareto front, as measured by the score function, is greater than the distance of  $\mathbf{y}'$  from the estimated Pareto front.

## 2 NOTATION

Column vectors are written  $\mathbf{a}, \mathbf{b}, \dots$  with elements  $a_i, b_i, \dots$ . Matrices are written  $\mathbf{A}, \mathbf{B}, \dots$ , with elements  $A_{i,j}, B_{i,j}, \dots$ . If  $\mathbf{f} : \mathbb{X} \subset \mathbb{R}^m \rightarrow \mathbb{R}^n$  is a map from design to objective space then  $\forall \mathbf{x}, \mathbf{x}' \in \mathbb{X}$  we say  $\mathbf{x}$  dominates  $\mathbf{x}'$ , written  $\mathbf{x} \succeq_{\mathbf{f}} \mathbf{x}'$ , if  $f_i(\mathbf{x}) \geq f_i(\mathbf{x}') \forall i$ ; and  $\mathbf{x}$  strongly dominates  $\mathbf{x}'$ , written  $\mathbf{x} \succ_{\mathbf{f}} \mathbf{x}'$ , if  $\mathbf{x} \succeq_{\mathbf{f}} \mathbf{x}' \wedge \mathbf{f}(\mathbf{x}) \neq \mathbf{f}(\mathbf{x}')$ . Analogously,  $\forall \mathbf{y}, \mathbf{y}' \in \mathbb{R}^n$  we say  $\mathbf{y}$  dominates  $\mathbf{y}'$ , written  $\mathbf{y} \succeq \mathbf{y}'$ , if  $y_i \geq y'_i \forall i$ ; and  $\mathbf{y}$  strongly dominates  $\mathbf{y}'$ , written  $\mathbf{y} \succ \mathbf{y}'$ , if  $\mathbf{y} \succeq \mathbf{y}' \wedge \mathbf{y} \neq \mathbf{y}'$ .

## 3 BACKGROUND

Multi-objective optimisation (Deb, 2001; Coello et al., 2002; Miettinen, 1999) extends standard single-objective optimisation to the case where there are multiple, potentially conflicting objectives. The multi-objective optimisation problem is:

$$\operatorname{argmax}_{\mathbf{x} \in \mathbb{X}} \mathbf{f}(\mathbf{x}) \quad (1)$$

where  $\mathbf{f} : \mathbb{X} \rightarrow \mathbb{R}^n$  maps from design space to objective space;  $\mathbb{X} \subset [0, r]^m \subset \mathbb{R}^m$  is the feasible region; and  $\operatorname{argmax}$  is defined in the Pareto sense described below. This is known as a *many-objective optimisation problem* (Ishibuchi et al., 2008) if the number of objectives is sufficiently large to cause difficulties with standard multi-objective optimisation algorithms (as shown in our experiments, as few as 6 objectives can cause difficulties).

Our aim is to find a representation of the Pareto set:

$$\mathbb{X}^* = \{ \mathbf{x}^* \in \mathbb{X} \mid \nexists \mathbf{x} \in \mathbb{X} : \mathbf{x} \succ_{\mathbf{f}} \mathbf{x}^* \}$$

where  $\succ_{\mathbf{f}}$  is the dominance relation as defined in section 2 ( $\mathbf{x}$  strongly dominates  $\mathbf{x}'$ , written  $\mathbf{x} \succ_{\mathbf{f}} \mathbf{x}'$ , if  $f_i(\mathbf{x}) \geq f_i(\mathbf{x}') \forall i$  and  $\mathbf{f}(\mathbf{x}) \neq \mathbf{f}(\mathbf{x}')$ ). This is the set of all Pareto-optimal  $\mathbf{x} \in \mathbb{X}$ , where a vector is Pareto-optimal if it cannot be changed without causing a decrease in at least one objective  $f_i : \mathbb{X} \rightarrow \mathbb{R}$ . The Pareto front is the image of the Pareto set in objective space:

$$\mathbb{Y}^* = \{ \mathbf{y}^* \in \mathbb{Y} \mid \nexists \mathbf{y} \in \mathbb{Y} : \mathbf{y} \succ \mathbf{y}^* \}$$

where  $\mathbb{Y} = \mathbf{f}(\mathbb{X})$  and  $\succ$  is the dominance relation in objective space ( $\mathbf{y}$  strongly dominates  $\mathbf{y}'$ , written  $\mathbf{y} \succ \mathbf{y}'$ , if  $y_i \geq y'_i \forall i$  and  $\mathbf{y} \neq \mathbf{y}'$ ). The solution to (1) is a finite set of Pareto-optimal solutions  $\mathcal{X}^* \subset \mathbb{X}^*$ .

### 3.1 GAUSSIAN PROCESSES

We assume the many-objective case where, for all  $i$ ,  $f_i(\mathbf{x}) \sim \text{GP}(0, k(\mathbf{x}, \mathbf{x}'))$  is a sample from a zero-mean Gaussian process (Rasmussen and Williams, 2006;

Figure 1: Pareto front (left), expected hypervolume improvement (EHI, middle) and boundary distance (right) for a simple two-objective problem.

MacKay, 1998) (we assume the objectives are non-correlated) that is costly to evaluate. Evaluations of  $\mathbf{f}$  are presumed noisy, so  $y_i = f_i(\mathbf{x}) + \epsilon$ , where  $\epsilon \in \mathcal{N}(0, \sigma^2)$ . Given observations  $\mathcal{D}_t = \{(\mathbf{x}, \mathbf{y}) | \mathbf{y} = \mathbf{f}(\mathbf{x}) + \epsilon\}$  we have  $\mathbf{f}(\mathbf{x}) | \mathcal{D}_t \sim \mathcal{N}(\boldsymbol{\mu}_t(\mathbf{x}), \mathbf{I}\sigma_t^2(\mathbf{x}))$ , where:

$$\begin{aligned} \boldsymbol{\mu}_t(\mathbf{x}) &= \mathbf{Y}_t^T (\mathbf{K}_t + \sigma^2 \mathbf{I})^{-1} \mathbf{k}_t(\mathbf{x}) \\ \sigma_t^2(\mathbf{x}) &= k(\mathbf{x}, \mathbf{x}) - \mathbf{k}_t^T(\mathbf{x}) (\mathbf{K}_t + \sigma^2 \mathbf{I})^{-1} \mathbf{k}_t(\mathbf{x}) \end{aligned} \quad (2)$$

where  $\mathbf{Y}_t = [\mathbf{y}^T]_{(-, \mathbf{y}) \in \mathcal{D}_t}$ ,  $\mathbf{k}_t(\mathbf{x}) = [k(\mathbf{x}, \mathbf{x}')]_{(\mathbf{x}', -) \in \mathcal{D}_t}$  and  $\mathbf{K}_t = [k(\mathbf{x}, \mathbf{x}')]_{(\mathbf{x}, -), (\mathbf{x}', -) \in \mathcal{D}_t}$ .<sup>2</sup> Given  $\mathcal{D}_t$  the estimated Pareto set  $\mathcal{X}_t^*$  and Pareto front  $\mathcal{Y}_t^*$  at iteration  $t$  are the dominant subsets of  $\mathcal{D}_t$ :

$$\begin{aligned} \mathcal{X}_t^* &= \{\mathbf{x}^* \in \mathcal{X}_t | \nexists \mathbf{x} \in \mathcal{X}_t : \mathbf{x} \succ_{\mathbf{f}} \mathbf{x}^*\} \\ \mathcal{Y}_t^* &= \{\mathbf{y}^* \in \mathcal{Y}_t | \nexists \mathbf{y} \in \mathcal{Y}_t : \mathbf{y} \succ \mathbf{y}^*\} \\ \text{where: } \mathcal{X}_t &= \{\mathbf{x} \in \mathbb{X} | (\mathbf{x}, -) \in \mathcal{D}_t\} \\ \mathcal{Y}_t &= \{\mathbf{y} \in \mathbb{Y} | (-, \mathbf{y}) \in \mathcal{D}_t\} \end{aligned} \quad (3)$$

### 3.2 BAYESIAN OPTIMISATION

Bayesian optimisation (Brochu et al., 2010) is an optimisation method designed for problems where the function being optimised is expensive to evaluate in terms of time or monetary cost. A typical Bayesian optimisation algorithm is presented in algorithm 1. For each iteration  $t$  we maximise a (cheap) acquisition function  $a_t : \mathbb{X} \rightarrow \mathbb{R}$  based on  $\boldsymbol{\mu}_{t-1}$  and  $\sigma_{t-1}$ , and the resulting recommendation is evaluated to obtain  $y_t = f(\mathbf{x}_t) + \epsilon$ . GP models are updated, and the algorithm continues. Standard acquisition functions include expected improvement (EI) (Mockus et al., 1978), probability of improvement (PI) (Kushner, 1964), and GP upper confidence bound (GP-UCB) (Jones et al., 1998; Srinivas et al., 2012; Brochu et al., 2010).

<sup>2</sup>We write  $(\mathbf{x}, -) \in \mathcal{D}_t$  if  $\exists \mathbf{y} \in \mathbb{Y} : (\mathbf{x}, \mathbf{y}) \in \mathcal{D}_t$ ; and likewise  $(-, \mathbf{y}) \in \mathcal{D}_t$  if  $\exists \mathbf{x} \in \mathbb{X} : (\mathbf{x}, \mathbf{y}) \in \mathcal{D}_t$ .

---

#### Algorithm 1 Generic Bayesian Optimisation

---

**input**  $\mathcal{D}_0 := \{(\mathbf{x}_i, y_i) | y_i = f(\mathbf{x}_i) + \epsilon, i = 1, 2, \dots\}$ .  
**for**  $t = 1, 2, \dots, T$  **do**  
  Select test point  $\mathbf{x}_t = \operatorname{argmax}_{\mathbf{x}} a_t(\mathbf{x})$ .  
  Perform Experiment  $y_t = f(\mathbf{x}_t) + \epsilon$ .  
  Update  $\mathcal{D}_t := \mathcal{D}_{t-1} \cup \{(\mathbf{x}_t, y_t)\}$ .  
**end for**

---

### 3.3 MULTI-OBJECTIVE BAYESIAN OPTIMISATION

Adding an observation  $\mathbf{y}_t$  to  $\mathcal{Y}_{t-1}$  will either cause no change to the estimated Pareto front  $\mathcal{Y}_{t-1}^*$  (if  $\exists \mathbf{y} \in \mathcal{Y}_{t-1}^* : \mathbf{y} \succ \mathbf{y}_t$ ) or push it closer to the actual Pareto front  $\mathbb{Y}^*$  (if  $\nexists \mathbf{y} \in \mathcal{Y}_{t-1}^* : \mathbf{y} \succ \mathbf{y}_t$ ). The acquisition function  $a_t(\mathbf{x})$  is designed to measure this expected change. Two popular measures used, as shown in figure 1, are:

- Expected hypervolume improvement (EHI):

$$a_t(\mathbf{x}) = \mathbb{E} [S(\mathcal{Y}_{t-1}^* \cup \{\mathbf{f}(\mathbf{x})\}) - S(\mathcal{Y}_{t-1}^*)]$$

(Shir et al., 2007; Zaefferer et al., 2013; Shimoyama et al., 2013). This is the expected change in hypervolume dominated by  $\mathcal{Y}_{t-1}^*$ , where  $S(\mathcal{Y})$  is the hypervolume dominated by  $\mathcal{Y}$  (Zitzler, 1999; Huband et al., 2003; Purshouse, 2003; Laumanns et al., 2000; Fleischer, 2000).

- Boundary distance:

$$a_t(\mathbf{x}) = \mathbb{E} (d(\mathcal{Y}_{t-1}^*, \mathbf{f}(\mathbf{x})))$$

(Yun et al., 2004; Keane, 2006). This is the expected (signed) distance between the the estimated Pareto front and  $\mathbf{f}(\mathbf{x})$ .

It has been noted that calculating the EHI is non-trivial (Wagner et al., 2010; Zaefferer et al., 2013) and, while heavily optimised algorithms are available for up to 3

Figure 2: Distance maximisation of 1-class SVM (Yun et al., 2004). The set of observations (blue) are used to train a 1-class SVM, giving the boundary of the green region. Points A-E all give a positive boundary distance, but only points C and D dominate the observations as the boundary does not satisfy consistency requirements.

objectives (Hupkens et al., 2015), the computational cost in the many-objective case remains prohibitive, making EHI unsuitable in a many-objectives context. Similarly, calculating the precise distance to the Pareto front is often computationally intractable, particularly in the many-objective case. Hence when calculating the boundary distance the estimated Pareto front is usually approximated (smoothed) using a score function such as the 1-class SVM (Yun et al., 2004), and the signed distance to this front used. We note that the Pareto front approximation used by (Yun et al., 2004) is in fact a hypersurface surrounding the set of observations and may contain pairs of points where one dominates the other (i.e. it does not satisfy the consistency requirements discussed in section 4). Thus, as shown in figure 2, maximising this measure will not necessarily maximise change to the Pareto front as points may be selected that are not in advance of (dominating) the set of observations.

## 4 PROPOSED METHOD

In the present paper we will be using an acquisition function based on GP-UCB (Srinivas et al., 2012) that we call AD-GP-UCB (approximated distance GP-UCB):

$$a_t(\mathbf{x}) = g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x})) + \sqrt{\beta_t} \eta_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}), \sigma_{t-1}(\mathbf{x})) \quad (4)$$

In this expression  $g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}))$  is the approximate mean distance of  $\mathbf{f}(\mathbf{x})$  from the estimated Pareto set and  $\eta_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}), \sigma_{t-1}(\mathbf{x}))$  the approximate variance. The constants  $\beta_t$  control the trade-off between exploitation (selecting recommendations with high predicted distance from the estimated Pareto set) and exploration (exploring unexplored regions of the feasible set  $\mathbb{X}$ ) as per the GP-

UCB method (Srinivas et al., 2012):

$$\beta_t = \begin{cases} 2 \log\left(\frac{\pi^2 t^2}{6\delta} |\mathbb{X}|\right) & \text{if } |\mathbb{X}| < \infty \\ 2 \log\left(\frac{2\pi^2 t^2}{3\delta} \left(t^2 m b r (\log(\frac{2ma}{\delta}))^{\frac{1}{2}}\right)^{2m}\right) & \text{otherwise} \end{cases} \quad (5)$$

where  $0 < \delta \ll 1$  and in the infinite case we assume  $\mathbf{f}$  satisfies  $\Pr\{\sup_{\mathbf{x} \in \mathbb{X}} |\partial f_i / \partial x_j| > L\} \leq a e^{-(L/b)^2} \forall i, L$ . We have chosen GP-UCB here as it is explicitly designed to balance exploration and exploitation; and because, in the single objective case, there exist convergence bounds to show that, with probability  $1 - \delta$ , the optimisation procedure is guaranteed to converge (as measured by cumulative risk) sub-linearly as  $T \rightarrow \infty$ . While our method is not a “true” GP-UCB method ( $g_t$  and  $\eta_t$  are only approximations of the mean and variance of the predicted distance from the estimated Pareto front; and moreover the function approximated by  $g_t$  changes over time) our experimental results demonstrate its efficacy.

### 4.1 APPROXIMATING THE MEAN DISTANCE

The score function  $g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}))$  is used to approximate the signed distance between the estimated Pareto set  $\mathcal{Y}_{t-1}^*$  and the sample evaluation  $\mathbf{f}(\mathbf{x})$  for a given  $\mathbf{x} \in \mathbb{X}$ . We use the GP posterior mean  $\boldsymbol{\mu}_{t-1}(\mathbf{x})$  to estimate the mean of  $\mathbf{f}(\mathbf{x})$  and  $g_t$  to approximate the distance of this from the Pareto front  $\mathcal{Y}_{t-1}^*$ . Motivated by the “standard form” of the trained SVM in dual form, the score function  $g_t$  is defined as:

$$g_t(\mathbf{y}) = 1 - 2 \sum_{i=1}^{N_t} \alpha_i^t L(\mathbf{y}_i, \mathbf{y}) \quad (6)$$

where the indices  $i$  applied to all  $\mathbf{y}_i \in \mathcal{Y}_{t-1}$  correspond to the indices  $i$  on  $\alpha_i^t$ ,  $N_t = |\mathcal{Y}_{t-1}|$ ,  $\boldsymbol{\alpha}^t \geq \mathbf{0}$ , and  $L$  is defined to ensure that  $g_t$  satisfies consistency conditions:

1. Observational Consistency:

$$g_t(\mathbf{y}) \leq 0 \quad \forall \mathbf{y} \in \mathcal{Y}_{t-1}^*$$

2. Dominance Consistency:

$$g_t(\mathbf{y}) > g_t(\mathbf{y}') \quad \forall \mathbf{y}, \mathbf{y}' \in \mathbb{Y} : \mathbf{y} \succ \mathbf{y}'$$

Observational consistency is required to ensure that the reported distance is never positive for existing observations that are by definition dominated by the current estimated Pareto set  $\mathcal{Y}_{t-1}^*$ . Dominance consistency ensures that,  $\forall \mathbf{y}, \mathbf{y}' \in \mathbb{Y}$ , the dominant vector will receive the higher “score”. Thus  $g_t$  is a score function in the sense of (Miranda and Von Zuben, 2015) and may be said to define an estimated Pareto set:

$$\mathbb{Y}^{g_t^*} = \{\mathbf{y} \in \mathbb{R}^m \mid g(\mathbf{y}) = 0\} \quad (7)$$

that dominates all points in  $\mathcal{Y}_{t-1}$  (that is,  $\forall \mathbf{y} \in \mathcal{Y}_{t-1} \exists \mathbf{y}' \in \mathbb{Y}^{g_t^*} : \mathbf{y}' \succeq \mathbf{y}$ ). The distance reported by  $g_t$  is the signed distance from  $\mathbb{Y}^{g_t^*}$  as measured by some metric. Motivated by this we let  $L(\mathbf{y}, \mathbf{y}') = \kappa(\min_q (y_q - y'_q))$ , where:

$$\begin{aligned} \kappa(0) &= \frac{1}{2} && \text{(centred)} \\ \kappa(y + \delta) &> \kappa(y) \quad \forall y \in \mathbb{R}, \delta \in \mathbb{R}^+ && \text{(increasing)} \end{aligned} \quad (8)$$

Many standard neural activation functions are suitable choices (e.g. the logistic function  $\kappa(y) = 1/(1 + \exp(-vy))$ ). It is straightforward to see that  $g_t$  defined by (6) satisfies dominance consistency if  $\alpha^t \neq \mathbf{0}$ . To satisfy observational consistency  $\alpha^t$  is selected to solve the linear programming problem:

$$\begin{aligned} \min_{\alpha} \quad & \|\alpha^t\|_1 = \mathbf{1}^T \alpha^t \\ \text{such that:} \quad & \sum_{i=1}^{N_t} \alpha_i^t L(\mathbf{y}_i, \mathbf{y}_j) \geq \frac{1}{2} \quad \forall 1 \leq j \leq N_t \\ & \alpha^t \geq \mathbf{0} \end{aligned} \quad (9)$$

which will be referred to this as the score-function optimisation problem. It may be noted that the score-function optimisation problem, and the form of the score function  $g_t$ , are closely related to the 1-norm SVM (Bradley and Mangasarian, 1998; Zhu et al., 2004), which is a variant of the standard SVM that retains the standard (dual) form of the trained machine but minimises  $\|\alpha\|_1$  rather than  $\|\alpha\|_{\mathcal{H}_L}$ . This form has two distinct advantages: the kernel<sup>3</sup>  $L$  may be any function (not just positive definite) and the solution tends to be more sparse than the standard form. Our approach also borrows from the 1-class SVM (Schölkopf et al., 1999), but rather than using a *bias-forcing* term to achieve margin minimalisation (rather than maximising the margin of separation, the 1-class SVM seeks to minimise the margin) we instead use a fixed bias ( $b = -1$ ) and restrict  $L$  using (8) so that the margin minimalisation occurs as a direct result from minimising the regularisation term  $\|\alpha\|_1$ .

## 4.2 APPROXIMATING THE DISTANCE VARIANCE

The function  $\eta_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}), \sigma_{t-1}(\mathbf{x}))$  in the acquisition function (4) approximates the variance in the estimate  $g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}))$  of the distance between  $\mathbf{f}(\mathbf{x})$  and the estimated Pareto front  $\mathcal{Y}_{t-1}^*$ . We approximate this using a simple first-order Taylor approximation of the second moment about  $\boldsymbol{\mu}_{t-1}(\mathbf{x})$  - that is:

$$\eta_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}), \sigma_{t-1}(\mathbf{x})) = \|\nabla_{\mathbf{x}} g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x}))\| \sigma_{t-1}(\mathbf{x})$$

<sup>3</sup>In general we have tried to avoid using the word kernel to refer to  $L$  to avoid potential confusion with the covariance function (kernel)  $k$  used for Gaussian Processes.

where, defining  $q_i = \operatorname{argmin}_q (y_{i,q} - \mu_{t-1,q}(\mathbf{x})) \forall i$ :

$$\begin{aligned} \frac{\partial}{\partial x_i} g_t(\boldsymbol{\mu}_{t-1}(\mathbf{x})) &= \dots \\ &- 2 \sum_i \alpha_i^t \kappa'(y_{i,q_i} - \mu_{t-1,q_i}(\mathbf{x})) \frac{\partial}{\partial x_i} \mu_{t-1,q_i}(\mathbf{x}) \end{aligned}$$

where  $\kappa'(y) = \partial \kappa(y) / \partial y$  and:

$$\frac{\partial}{\partial x_i} \boldsymbol{\mu}_t(\mathbf{x}) = \mathbf{Y}_t^T (\mathbf{K}_t + \sigma^2 \mathbf{I})^{-1} \frac{\partial}{\partial x_i} \mathbf{k}_t(\mathbf{x})$$

We note that the accuracy of this approximation degrades as the non-linearity of  $g_t(\boldsymbol{\mu}_{t-1}(\bullet))$  increases. This is a necessary trade-off as calculating the actual variance is not feasible. Assuming an squared-exponential kernel  $k(\mathbf{x}, \mathbf{x}') = \exp(-\|\mathbf{x} - \mathbf{x}'\|_2^2/l)$  for the GP model and a sigmoid function for the score function kernel  $\kappa(y) = 1/(1 + \exp(-vy))$  we see that the variance approximation is best when the length scale  $l$  of  $k$  is large and the constant  $v$  of  $\kappa$  is small.

## 5 THEORETICAL ANALYSIS

It is useful at this point to analyse the theoretical properties of our proposed algorithm. We have already noted that the score function  $g_t$  satisfies both observational and dominance consistency and so provides a sensible approximation of distance from the estimated Pareto front. Applying SVM techniques we find the following properties (all proofs presented in the supplementary material):

**Theorem 1 (Non-triviality)** *Let  $\alpha^t$  be the solution to the score-function optimisation problem (9). Then  $\alpha^t \neq \mathbf{0}$ .*

**Theorem 2 (Margin Minimisation)** *Let  $\alpha^t$  be the solution to the score-function optimisation problem (9). Let  $\mathbb{Y}^{g_t^*}$  be the estimated Pareto front defined by  $g_t$ . The minimum distance between  $\mathcal{Y}_{t-1}$  and the estimated Pareto front  $\mathbb{Y}^{g_t^*}$  is zero:*

$$\min_{\mathbf{y} \in \mathcal{Y}_{t-1}, \mathbf{y}' \in \mathbb{Y}^{g_t^*}} \|\mathbf{y} - \mathbf{y}'\| = 0$$

**Theorem 3 (Sparsity)** *Let  $\alpha^t$  be the solution to the score-function optimisation problem (9). Then  $\alpha_i^t = 0 \forall i : \mathbf{y}_i \notin \mathcal{Y}_{t-1}^*$  (ie. points not in the estimated Pareto front cannot be support vectors).*

**Theorem 4 (Heaviside Limit)** *Let  $\kappa = \kappa_{\perp}$ , where*

$$\kappa_{\perp}(y) = \lim_{v \rightarrow \infty} \frac{1}{1 + \exp(-vy)} = \frac{1}{2} (1 + \operatorname{sgn}(y)),$$

*and  $\nexists i \neq j : \mathbf{y}_i = \mathbf{y}_j$ . Then  $\alpha_i^t = 1 \forall i : \mathbf{y}_i \in \mathcal{Y}_{t-1}^*$ ,  $\alpha_i^t = 0$  otherwise (ie. in the limiting case the support vectors are precisely the estimated Pareto set).*

Figure 3: Estimated front  $\mathbb{Y}^{g_t^*}$  (objective space) given  $\mathbf{y}_1 = [-1; 1]$ ,  $\mathbf{y}_2 = [1; -1]$ , where  $\kappa(y) = \frac{1}{1+\exp(-vy)}$  and  $v = 0.5, 1, 2, 4$ , respectively.

It follows that solving (9) will define a score function, and hence an estimated Pareto front  $\mathbb{Y}^{g_t^*}$ , that is as tight as possible (insofar as it lies as close to  $\mathcal{Y}_t$  as possible while maintaining observational consistency) and sparsely represented. As shown in figure 3 the parameter  $v$  in the  $\kappa$  function acts as a smoothing parameter on the estimated Pareto front, where smaller  $v$  will tend to favour smoother fronts while larger  $v$  will attempt to achieve a tighter “fit” to the observations  $\mathcal{Y}_t$ . In the limiting case  $v \rightarrow \infty$  the Pareto front becomes stepwise, as shown by theorem 4.

## 6 EXPERIMENTS

We consider three experiments in this section: standard test function optimisation, hyper-parameter selection in multi-class SVM classification in the absence of relative class weighting, and high-temperature alloy design. All SVM and related code was written in C++ with linking to ThermoCalc via a Matlab interface. Where relevant EHI estimation was performed using the IRS algorithm (Hupkens et al., 2015). Global optimisation on our acquisition function was carried out using the DIRECT algorithm (Jones et al., 1993). The objective function  $\mathbf{f}$  was modelled using a GP with a squared-exponential kernel. For the score function we use  $\kappa(y) = \frac{1}{1+\exp(-vy)}$ .

### 6.1 STANDARD TEST FUNCTION

In our first experiment we have evaluated the performance of AD-GP-UCB on the standard DTLZ2 multi-objective test function (Deb et al., 2005). We have run simulations for Bayesian optimisation using both EHI and AD-GP-UCB acquisition functions over a budget of  $T = 200$  iterations for  $n = 2, 3, \dots, 10$  objectives.

We have evaluated performance on four criteria:

1. How close the elements of the estimated Pareto front  $\mathcal{Y}_t^*$  are to the actual Pareto front  $\mathbb{Y}^*$  (how optimal the elements of the  $\mathcal{Y}_t^*$  are):

$$d_{\mathbb{Y}^*} = \sup_{\mathbf{y} \in \mathcal{Y}_t^*} d(\mathbf{y}, \mathbb{Y}^*) = \sup_{\mathbf{y} \in \mathcal{Y}_t^*} \left( \inf_{\mathbf{y}' \in \mathbb{Y}^*} \|\mathbf{y} - \mathbf{y}'\| \right)$$

2. The maximum distance between any point on the actual Pareto front  $\mathbb{Y}^*$  and the closest point to it in the estimated Pareto front (how well  $\mathcal{Y}_t^*$  approximates  $\mathbb{Y}^*$ ):

$$d_{\mathcal{Y}_T^*} = \sup_{\mathbf{y}' \in \mathbb{Y}^*} d(\mathcal{Y}_t^*, \mathbf{y}') = \sup_{\mathbf{y}' \in \mathbb{Y}^*} \left( \inf_{\mathbf{y} \in \mathcal{Y}_t^*} \|\mathbf{y} - \mathbf{y}'\| \right)$$

3. The Hausdorff distance between the estimated Pareto front  $\mathcal{Y}_t^*$  and the actual Pareto front  $\mathbb{Y}^*$ :

$$d_{\mathcal{H}} = d(\mathcal{Y}_T^*, \mathbb{Y}^*) = \max(d_{\mathbb{Y}^*}, d_{\mathcal{Y}_T^*})$$

4. Simulation time per recommendation produced.

Results are summarised in table 1. It may be seen from this that in terms of the Hausdorff distance between estimated and actual Pareto fronts AD-GP-UCB consistently outperformed EHI in this experiment. Moreover although the EHI estimated Pareto front was closer to the actual Pareto front (measure 1) the AD-GP-UCB estimated Pareto front better approximated the actual Pareto front in terms of coverage (measure 2). We note that the hypervolume dominated by the AD-GP-UCB estimated Pareto front was consistently higher than the hypervolume dominated by the EHI estimated Pareto front. Figure 5 shows the average time required per recommendation for each of the algorithms. We have chosen this measure to factor out extraneous fluctuations observed in the estimated Pareto set size generated by the EHI method as  $n$  varied.

To aid visualisation the estimated Pareto fronts for AD-GP-UCB and EHI in the case  $n = 3$  are shown in figure 4, where the Pareto front for DTLZ2 consists of a first-quadrant unit sphere in objective space (Deb et al., 2005). From this figure it may be seen that EHI constructs a cluster of recommendations that are close to a fragment of the actual Pareto front; whereas AD-GP-UCB creates a more diverse coverage of the Pareto front. We postulate that this results from the fact that AD-GP-UCB explicitly incorporates an exploration term  $\sqrt{\beta_t} \eta_t$  in the acquisition function, encouraging greater exploration and hence more diversity in  $\mathcal{Y}_T^*$ .

As noted previously, and as may be seen from table 1, the size of the estimated Pareto front found by EHI was surprisingly small for larger  $n$ . It is unclear why this occurs; however it appears to contribute to the significant fluctuation in the total time  $\tau$  for required EHI to complete  $T = 200$  iterations.

Table 1: Results summary for DTLZ2 optimisation over range of  $n$ . In this table  $d_{\mathbb{Y}^*}$  measures how close the estimated Pareto front is to the actual Pareto front (optimality);  $d_{\mathcal{Y}_T^*}$  measures the maximum distance from any point on the actual Pareto front to any point in the estimated Pareto front (coverage) (for calculation  $\mathbb{Y}^*$  is approximated as a projected grid);  $d_{\mathcal{H}}$  is the Hausdorff distance between the estimated and actual Pareto fronts; and HV is the dominated hypervolume.  $T = 200$  iterations were used, producing an estimated Pareto front  $\mathcal{Y}_T^*$  containing  $N^* = |\mathcal{Y}_T^*|$  recommendations in  $\tau$  seconds - ie.  $\tau/N^*$  recommendations per second.  $\uparrow$  indicates that larger values are preferable and  $\downarrow$  that smaller values are preferable.

Figure 4: Estimated Pareto fronts for EHI (left) and AD-GP-UCB (right) for  $n = 3$  objectives. Note that DTLZ2 is a minimisation problem, so the BO maximises its negative.

## 6.2 HYPERPARAMETER SELECTION

In this experiment we have compared our algorithm to Bayesian multi-objective optimisation with an expected hypervolume improvement (EHI) based acquisition function. We consider hyper-parameter selection for multi-class classifiers in the absence of information about the relative importance of classes. As there is no objective way to compare (weight) the cost of misclassification for the different classes this is an example of a multi-objective optimisation, where the classification accuracy with respect to each class is a single objective.

For multi-class classification we used the CS-SVM algorithm (Shilton et al., 2012) in SVMHeavy (Shilton, 2001)

with an RBF kernel with length-scale  $g$ . Performance on each class was measured using 10-fold cross-validation. The hyper-parameters being tuned were the CS-SVM trade-off parameter  $C \in [0.1, 10]$  and the kernel parameter  $g \in [0.1, 10]$ . Three datasets from the UCI collection (Dheeru and Karra Taniskidou, 2017) were used: SAT (6 classes,  $N = 4435$  vectors), SEG (7 classes,  $N = 2310$ ), and WAV (3 classes,  $N = 5000$ ).

Results of simulations are shown in figure 6. These figures show both hypervolume as a function of iteration number (the hypervolume is used as a measure of the optimality of the Pareto set) and also the time required to recommend the next sample at each iteration. As may be seen from the graphs our proposed method is significantly faster than EHI. In fact, in the higher-dimensional

Figure 5: Average time taken to produce Pareto front in seconds/recommendation ( $\tau/N^*$ ).

cases - namely SAT (6 classes/objectives) and SEG (7 classes/objectives) - the EHI simulations had to be terminated early due to excessive computation time when computing the next recommendation (up to 1 day to produce a single recommendation). With regard to optimality (as measured by dominated hypervolume) it is somewhat difficult to say with certainty, but based on the WAV dataset at least our algorithm is certainly competitive (particularly given that the EHI alternative was unable to finish for either the SAT or SEG datasets due to excessive computational load resulting from EHI calculations made inside the global optimisation DIRECT call).

### 6.3 ALLOY DESIGN

High-temperature creep resistant Ni-superalloy is used for making boilers of super-critical thermal power plants. In a joint project with metallurgist we were asked to optimize the current alloy recipe to obtain superior creep resistance to the industry standard. The alloy consist of Ni, Cr, Co, Al, Ti, Mo, Ta, W and V. We use ThermoCalc software for phase simulation i.e. to predict what compounds (phases) get formed at a given temperature. Based on the existing knowledge, phases were clubbed into either good or bad for creep resistance. The phase simulation is performed at 6 different temperatures and a total of 12 objectives are created. Recommendation times for EHI were found to be excessive ( $\sim 1$  day), whereas our method was able to complete the task without difficulty.

Results for our simulation are shown in figure 7. In these figures dominated hypervolume has been used as a measure of convergence (Zitzler, 1999; Huband et al., 2003; Purshouse, 2003; Laumanns et al., 2000; Fleischer, 2000). The GP length scale in these results is 20 and was selected experimentally to optimise the rate of conver-

gence; and the time budget  $T = 100$  was chosen for practical reasons. A total of 21 Pareto-optimal alloys were found by our simulation. As may be seen our algorithm was able to calculate a set of Pareto-optimal recommendations within a reasonable time-frame despite the high number of objectives to provide the experimentalist with a good selection of options for further investigation.

Figure 7: Simulation results for alloy design. Top: dominated hypervolume. Bottom: recommendation time (solid red), ThermoCalc simulation time (dashed blue).

## 7 CONCLUSIONS

In this paper we have proposed a method for Bayesian multi-objective optimisation based on score functions. Our proposed method is particularly well suited to the many-objective case where the number of objectives is significant and renders alternative methods such as EHI unsuitable due to reasons of computational infeasibility (for example, on 2 of our datasets we found that the EHI method failed early as the time required for a single recommendation grew to over 1 day). We have analysed the theoretical properties of our method and shown that it possesses properties such as sparseness, inherited from the 1-norm SVM, that make it well suited to the task. For

Figure 6: Hyper-parameter tuning results. Top row: recommendation times per iteration. Bottom row: enclosed hypervolume. EHI shown as black (dashed) line, our method as red (solid) line. EHI Simulations for SAT/SEG datasets had to be terminated early due to excessive recommendation times (we estimate for example that running the SAT dataset simulation to completion using the EHI method would have taken at least 3 months, which is clearly impractical).

experimental validation we have applied our proposed method to high-temperature alloy design and hyperparameter selection in the multi-class case where no information is provided with regard to the relative weight (or importance) of the classes. Our results clearly showed that our method is able to continue in cases where EHI breaks down due to computational complexity, and moreover that the results achieved by our method are competitive with those achieved by EHI.

## Abstract

We study the  $L_1$ -regularized maximum likelihood estimator/estimation (MLE) problem for discrete Markov random fields (MRFs), where efficient and scalable learning requires both sparse regularization and approximate inference. To address these challenges, we consider a stochastic learning framework called stochastic proximal gradient (SPG; Honorio 2012a, Atchade et al. 2014, Miasojedow and Rejchel 2016). SPG is an *inexact* proximal gradient algorithm [Schmidt et al., 2011], whose inexactness stems from the stochastic oracle (Gibbs sampling) for gradient approximation – exact gradient evaluation is infeasible in general due to the NP-hard inference problem for discrete MRFs [Koller and Friedman, 2009]. Theoretically, we provide novel *verifiable* bounds to inspect and control the quality of gradient approximation. Empirically, we propose the *tighten asymptotically* (TAY) learning strategy based on the verifiable bounds to boost the performance of SPG.

## 1 INTRODUCTION

Markov random fields (MRFs, a.k.a. Markov networks, undirected graphical models) are a compact representation of the joint distribution among multiple variables, with each variable being a node and an edge between two nodes indicating conditional dependence between the two corresponding variables. Sparse discrete MRF learning is proposed in the seminal work of

Lee et al. [2006]. By considering an  $L_1$ -regularized MLE problem, many components of the parameterization are driven to zero, yielding a sparse solution to structure learning. However, in general, solving an  $L_1$ -regularized MLE problem exactly for a discrete MRF is infamously difficult due to the NP-hard inference problem posed by exact gradient evaluation [Koller and Friedman, 2009]. We hence inevitably have to compromise accuracy for the gain of efficiency and scalability via *inexact* learning techniques [Liu and Page, 2013, Liu et al., 2014b, 2016, Geng et al., 2018].

In this paper, we consider stochastic proximal gradient (SPG; Honorio 2012a, Atchade et al. 2014, Miasojedow and Rejchel 2016), a stochastic learning framework for  $L_1$ -regularized discrete MRFs. SPG hinges on a stochastic oracle for gradient approximation of the log-likelihood function (inexact inference). However, both the theoretical guarantees and the practical performances of existing algorithms are unsatisfactory.

The stochastic oracle behind SPG is Gibbs sampling [Levin et al., 2009], which is an effective approach to draw samples from an intractable probability distribution. With enough samples, the intractable distribution can be approximated effectively by the empirical distribution, and hence many quantities (e.g., the gradient of the log-likelihood function) related to the intractable distribution can be estimated efficiently. Since SPG uses Gibbs sampling for gradient approximation, it can be viewed as an inexact proximal gradient method [Schmidt et al., 2011], whose success depends on whether the gradient approximation error can be effectively controlled. While previous works [Honorio, 2012a, Atchade et al., 2014, Miasojedow and Rejchel, 2016] have shown that the quality of the gradient approximation can be improved *in the long run* with increasingly demanding computational resources, such long term guarantees might not translate to satisfactory performance in practice (see Section 7). Therefore, it is desirable to estimate and control the

gradient approximation error of SPG meticulously in each iteration so that a more refined approximation to the exact gradient will be rewarded with a higher gain of efficiency and accuracy in practice.

Careful analysis and control of the quality of the gradient approximation of SPG call for the cross-fertilization of theoretical and empirical insights from stochastic approximate inference [Bengio and Delalleau, 2009, Fischer and Igel, 2011], inexact proximal methods [Schmidt et al., 2011], and statistical sampling [Mitliagkas and Mackey, 2017]. Our contributions are hence both theoretical and empirical. Theoretically, we provide novel *verifiable* bounds (Section 4) to inspect and control the gradient approximation error induced by Gibbs sampling. Also, we provide a proof sketch for the main results in Section 5. Empirically, we propose the *tighten asymptotically* (TAY) learning strategy (Section 6) based on the verifiable bounds to boost the performance of SPG.

## 2 BACKGROUND

We first introduce  $L_1$ -regularized discrete MRFs in Section 2.1. We then briefly review SPG as a combination of proximal gradient for sparse statistical learning and Gibbs sampling for addressing the intractable exact gradient evaluation problem.

### 2.1 $L_1$ -Regularized Discrete MRF

For the derivation, we focus on the binary pairwise case and we illustrate that our framework can be generalized to other models in Section 6. Let  $\mathbf{X} = [X_1, X_2, \dots, X_p]^\top \in \{0, 1\}^p$  be a  $p \times 1$  binary random vector. We use an uppercase letter such as  $X$  to denote a random variable and the corresponding lowercase letter to denote a particular *assignment* of the random variable, i.e.,  $X = x$ . We also use boldface letters to represent vectors and matrices and regular letters to represent scalars. We define the function  $\psi : \{0, 1\}^p \rightarrow \{0, 1\}^m$ ,  $\mathbf{x} \rightarrow \psi(\mathbf{x})$  to represent the *sufficient statistics* (a.k.a. *features*) whose values depend on the assignment  $\mathbf{x}$  and compose an  $m \times 1$  vector  $\psi(\mathbf{x})$ , with its  $j^{\text{th}}$  component denoted as  $\psi_j(\mathbf{x})$ . We use  $\mathbb{X}$  to represent a dataset with  $n$  independent and identically distributed (i.i.d.) samples.

With the notation introduced above, the  $L_1$ -regularized discrete MRF problem can be formulated as the following convex optimization problem:

$$\hat{\theta} = \arg \min_{\theta \in \Theta} -\frac{1}{n} \sum_{\mathbf{x} \in \mathbb{X}} \theta^\top \psi(\mathbf{x}) + A(\theta) + \lambda \|\theta\|_1, \quad (1)$$

---

### Algorithm 1 Gibbs Sampling (Gibbs-1)

---

**Require:** initial samples  $\mathbb{S}_0$  and  $\theta$ .

**Ensure:**  $\mathbb{S}$ .

```

1: function GIBBS-1( $\mathbb{S}_0, \theta$ )
2:    $\mathbb{S} \leftarrow \mathbb{S}_0$ , and decide  $p$  from  $\mathbb{S}_0$ .
3:   for  $i \in \{1, \dots, p\}$  do
4:     for  $\mathbf{x} \in \mathbb{S}$  do
5:       Compute  $P_\theta(X_i | \mathbf{x}_{-i})$  according to (5).
6:       Update  $x_i$  by  $P_\theta(X_i | \mathbf{x}_{-i})$ .
7:     end for
8:   end for
9:   return  $\mathbb{S}$ .
10: end function

```

---

---

### Algorithm 2 Gradient Approximation (GRAD)

---

**Require:**  $\theta$ ,  $\mathbb{E}_{\mathbb{X}} \psi(\mathbf{x})$ , and  $q$ .

**Ensure:**  $\Delta f(\theta)$ .

```

1: function GRAD( $\theta, \mathbb{E}_{\mathbb{X}} \psi(\mathbf{x}), q$ )
2:   Initialize  $\mathbb{S}$  with  $q$  samples.
3:   while true do
4:      $\mathbb{S} \leftarrow \text{GIBBS-1}(\mathbb{S}, \theta)$ .
5:     if stopping criteria met then
6:       Compute  $\mathbb{E}_{\mathbb{S}} \psi(\mathbf{x})$  according to (6).
7:        $\Delta f(\theta) \leftarrow \mathbb{E}_{\mathbb{S}} \psi(\mathbf{x}) - \mathbb{E}_{\mathbb{X}} \psi(\mathbf{x})$ .
8:       break.
9:     end if
10:  end while
11:  return  $\Delta f(\theta)$ .
12: end function

```

---

---

### Algorithm 3 Stochastic Proximal Gradient (SPG)

---

**Require:**  $\mathbb{X}$ ,  $\lambda$ , and  $q$ .

**Ensure:**  $\tilde{\theta}$ .

```

1: function SPG( $\mathbb{X}, \lambda, q$ )
2:   Compute  $\mathbb{E}_{\mathbb{X}} \psi(\mathbf{x})$  according to (4).
3:   Initialize  $\theta^{(0)}$  randomly and  $k \leftarrow 0$ .
4:   Choose step length  $\alpha$ .
5:   while true do
6:      $\Delta f(\theta^{(k)}) \leftarrow \text{GRAD}(\theta^{(k)}, \mathbb{E}_{\mathbb{X}} \psi(\mathbf{x}), q)$ .
7:      $\theta^{(k+1)} \leftarrow \mathcal{S}_{\alpha\lambda}(\theta^{(k)} - \alpha \Delta f(\theta^{(k)}))$ .
8:     if Stopping criteria met then
9:        $\tilde{\theta} = \theta^{(k+1)}$ , return  $\tilde{\theta}$ .
10:    end if
11:     $k \leftarrow k + 1$ 
12:  end while
13: end function

```

---

with

$$A(\theta) = \log \sum_{\mathbf{x} \in \{0, 1\}^p} \exp(\theta^\top \psi(\mathbf{x})),$$

where  $\Theta \subseteq \mathbb{R}^m$  is the parameter space of  $\theta$ 's,  $\lambda \geq 0$ ,

and  $A(\boldsymbol{\theta})$  is the *log partition function*. We denote the differentiable part of (1) as

$$f(\boldsymbol{\theta}) = -\frac{1}{n} \sum_{\mathbf{x} \in \mathbb{X}} \boldsymbol{\theta}^\top \boldsymbol{\psi}(\mathbf{x}) + A(\boldsymbol{\theta}). \quad (2)$$

Solving (1) requires evaluating the gradient of  $f(\boldsymbol{\theta})$ , which is given by:

$$\nabla f(\boldsymbol{\theta}) = \mathbb{E}_{\boldsymbol{\theta}} \boldsymbol{\psi}(\mathbf{x}) - \mathbb{E}_{\mathbb{X}} \boldsymbol{\psi}(\mathbf{x}), \quad (3)$$

with

$$\mathbb{E}_{\boldsymbol{\theta}} \boldsymbol{\psi}(\mathbf{x}) = \sum_{\mathbf{x} \in \{0,1\}^p} P_{\boldsymbol{\theta}}(\mathbf{x}) \boldsymbol{\psi}(\mathbf{x}), \quad \mathbb{E}_{\mathbb{X}} \boldsymbol{\psi}(\mathbf{x}) = \frac{1}{n} \sum_{\mathbf{x} \in \mathbb{X}} \boldsymbol{\psi}(\mathbf{x}). \quad (4)$$

$\mathbb{E}_{\boldsymbol{\theta}} \boldsymbol{\psi}(\mathbf{x})$  represents the expectation of the sufficient statistics under  $P_{\boldsymbol{\theta}}(\mathbf{x}) = \frac{\exp(\boldsymbol{\theta}^\top \boldsymbol{\psi}(\mathbf{x}))}{\exp(A(\boldsymbol{\theta}))}$ , which is a discrete MRF probability distribution parameterized by  $\boldsymbol{\theta}$ .  $\mathbb{E}_{\mathbb{X}} \boldsymbol{\psi}(\mathbf{x})$  represents the expectation of the sufficient statistics under the empirical distribution. Computing  $\mathbb{E}_{\mathbb{X}} \boldsymbol{\psi}(\mathbf{x})$  is straightforward, but computing  $\mathbb{E}_{\boldsymbol{\theta}} \boldsymbol{\psi}(\mathbf{x})$  exactly is intractable due to the entanglement of  $A(\boldsymbol{\theta})$ . As a result, various approximations have been made [Wainwright et al., 2007, Höfling and Tibshirani, 2009, Viallon et al., 2014].

## 2.2 Stochastic Proximal Gradient

To efficiently solve (1), many efforts have been made in combining Gibbs sampling [Levin et al., 2009] and proximal gradient descent [Parikh et al., 2014] into SPG, a method that adopts the proximal gradient framework to update iterates, but uses Gibbs sampling as a stochastic oracle to approximate the gradient when the gradient information is needed [Honorio, 2012a, Atchade et al., 2014, Miasojedow and Rejchel, 2016].

Specifically, Gibbs sampling with  $q$  chains running  $\tau$  steps (Gibbs- $\tau$ ) can generate  $q$  samples for  $P_{\boldsymbol{\theta}}(\mathbf{x})$ . Gibbs- $\tau$  is achieved by iteratively applying Gibbs-1 for  $\tau$  times. Gibbs-1 is summarized in Algorithm 1, where

$$P_{\boldsymbol{\theta}}(X_i | \mathbf{x}_{-i}) = P_{\boldsymbol{\theta}}(x_i | x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_p) \quad (5)$$

represents the conditional distribution of  $X_i$  given the assignment of the remaining variables  $\mathbf{x}_{-i}$  under the parameterization  $\boldsymbol{\theta}$ . Denoting the set of these  $q$  (potentially repetitive) samples as  $\mathbb{S}$ , we can approximate  $\mathbb{E}_{\boldsymbol{\theta}} \boldsymbol{\psi}(\mathbf{x})$  by the easily computable

$$\mathbb{E}_{\mathbb{S}} \boldsymbol{\psi}(\mathbf{x}) = \frac{1}{q} \sum_{\mathbf{x} \in \mathbb{S}} \boldsymbol{\psi}(\mathbf{x}) \quad (6)$$

and thus reach the approximated gradient  $\Delta f(\boldsymbol{\theta}) = \mathbb{E}_{\mathbb{S}} \boldsymbol{\psi}(\mathbf{x}) - \mathbb{E}_{\mathbb{X}} \boldsymbol{\psi}(\mathbf{x})$  with the gradient

approximation error:

$$\delta(\boldsymbol{\theta}) = \Delta f(\boldsymbol{\theta}) - \nabla f(\boldsymbol{\theta}).$$

By replacing  $\nabla f(\boldsymbol{\theta})$  with  $\Delta f(\boldsymbol{\theta})$  in proximal gradient, the update rule for SPG can be derived as  $\boldsymbol{\theta}^{(k+1)} = \mathcal{S}_{\alpha\lambda}(\boldsymbol{\theta}^{(k)} - \alpha \Delta f(\boldsymbol{\theta}^{(k)}))$ , where  $\alpha > 0$  is the step length and  $\mathcal{S}_{\lambda}(\mathbf{a})$  is the soft-thresholding operator whose value is also an  $m \times 1$  vector, with its  $i^{\text{th}}$  component defined as  $\mathcal{S}_{\lambda}(\mathbf{a})_i = \text{sgn}(a_i) \max(0, |a_i| - \lambda)$  and  $\text{sgn}(a_i)$  is the sign function.

By defining

$$\begin{aligned} \mathbf{G}_{\alpha}(\boldsymbol{\theta}^{(k)}) &:= \frac{1}{\alpha} \left( \boldsymbol{\theta}^{(k)} - \boldsymbol{\theta}^{(k+1)} \right) \\ &= \frac{1}{\alpha} \left( \boldsymbol{\theta}^{(k)} - \mathcal{S}_{\alpha\lambda} \left( \boldsymbol{\theta}^{(k)} - \alpha \Delta f(\boldsymbol{\theta}^{(k)}) \right) \right), \end{aligned} \quad (7)$$

we can rewrite the previous update rule in a form analogous to the update rule of a standard gradient descent, resulting in the update rule of a *generalized gradient descent* algorithm:

$$\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}^{(k)} - \alpha \mathbf{G}_{\alpha}(\boldsymbol{\theta}^{(k)}). \quad (8)$$

SPG is summarized in Algorithm 3. Its gradient evaluation procedure based on Algorithm 1 is given in Algorithm 2.

## 3 MOTIVATION

Both practical performance and theoretical guarantees of SPG are still far from satisfactory. Empirically, there are no convincing schemes for selecting  $\tau$  and  $q$ , which hinders the efficiency and accuracy of SPG. Theoretically, to the best of our knowledge, existing non-asymptotic convergence rate guarantees can only be achieved for SPG with an averaging scheme [Schmidt et al., 2011, Honorio, 2012a, Atchade et al., 2014] (see also Section 3.3), instead of ordinary SPG. In contrast, in the exact proximal gradient descent method, the objective function value is non-decreasing and convergent to the optimal value under some mild assumptions [Parikh et al., 2014]. In Section 3.2, we identify that the absence of non-asymptotic convergence rate guarantee for SPG primarily comes from the existence of gradient approximation error  $\delta(\boldsymbol{\theta})$ . In Section 3.3, we further validate that the objective function value achieved by SPG is also highly dependent on  $\delta(\boldsymbol{\theta})$ . These issues bring about the demand of inspecting and controlling  $\delta(\boldsymbol{\theta})$  in each iteration.

### 3.1 Setup and Assumptions

For the ease of presentation, we rewrite the objective function in (1) as  $g(\boldsymbol{\theta}) = f(\boldsymbol{\theta}) + h(\boldsymbol{\theta})$ , where  $h(\boldsymbol{\theta}) = \lambda \|\boldsymbol{\theta}\|_1$ , and  $f(\boldsymbol{\theta})$  is given in (2). Since  $\nabla f(\boldsymbol{\theta})$  is Lipschitz continuous [Honorio, 2012b], we denote its Lipschitz constant as  $L$ . We also make the same assumption that  $\alpha \leq 1/L$  as Schmidt et al. [2011].

### 3.2 Decreasing Objective

It is well-known that exact proximal gradient enjoys a  $O\left(\frac{1}{k}\right)$  convergence rate [Parikh et al., 2014]. One premise for this convergence result is that the objective function value decreases in each iteration. However, satisfying the decreasing condition is much more intricate in the context of SPG. Theorem 1 clearly points out that  $\boldsymbol{\delta}(\boldsymbol{\theta})$  is one main factor determining whether the objective function decreases in SPG.

**Theorem 1.** Let  $\boldsymbol{\theta}^{(k)}$  be the iterate of SPG after the  $k^{\text{th}}$  iteration. Let  $\boldsymbol{\theta}^{(k+1)}$  be defined as in (8). With  $\alpha \leq 1/L$ , we have

$$g(\boldsymbol{\theta}^{(k+1)}) - g(\boldsymbol{\theta}^{(k)}) \leq \alpha \boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})^\top \mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)}) - \frac{\alpha}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2^2.$$

Furthermore, a sufficient condition for  $g(\boldsymbol{\theta}^{(k+1)}) < g(\boldsymbol{\theta}^{(k)})$  is

$$\|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 < \frac{1}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2.$$

According to Theorem 1, if the magnitude of the noise, quantified by  $\|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2$ , is reasonably small, the objective function value decreases in each iteration. Under this condition, we can further construct a theoretical support for the convergence rate of the objective function value in the Section 3.3.

### 3.3 Convergence Rate

Assuming that  $\boldsymbol{\delta}(\boldsymbol{\theta})$  is small enough in each iteration to generate a decreasing objective value sequence, we can derive Theorem 2 following Proposition 1 in Schmidt et al. [2011]:

**Theorem 2.** Let  $\mathcal{K} = (\boldsymbol{\theta}^{(0)}, \boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \dots, \boldsymbol{\theta}^{(\kappa)})$  be the iterates generated by Algorithm 3. Then if  $g(\boldsymbol{\theta}^{(k+1)}) \leq g(\boldsymbol{\theta}^{(k)})$  with  $k \in \{1, 2, \dots, \kappa - 1\}$ , we have

$$g(\boldsymbol{\theta}^{(\kappa)}) - g(\hat{\boldsymbol{\theta}}) \leq \frac{L}{2\kappa} \left( \|\boldsymbol{\theta}^{(0)} - \hat{\boldsymbol{\theta}}\|_2 + \frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 \right)^2. \quad (9)$$

Recall that  $\hat{\boldsymbol{\theta}}$  is an optimal solution to the sparse MLE problem defined in (1). From (9), it is obvious that if the gradient approximation error is reasonably small, then during the early iterations of SPG,  $\|\boldsymbol{\theta}^{(0)} - \hat{\boldsymbol{\theta}}\|_2$  dominates  $\frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2$ . Therefore, in the beginning, the convergence rate is  $O(1/\kappa)$ . However, as the iteration proceeds,  $\frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2$  accumulates and hence in practice SPG can only maintain a convergence rate of  $O(1/\kappa)$  up to some noise level that is closely related to  $\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})$ . Therefore,  $\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})$  plays an importance role in the performance of SPG.

Notice that Theorem 2 offers convergence analysis of the objective function value in the last iteration  $g(\boldsymbol{\theta}^{(\kappa)})$ . This result is different from the existing non-asymptotic analysis on  $g(\sum_{k=1}^{\kappa} \boldsymbol{\theta}^{(k)}/\kappa)$ , the objective function evaluated on the average of all the visited solutions [Schmidt et al., 2011, Honorio, 2012a, Atchade et al., 2014]. Theorem 2 is more practical than previous analysis, since  $\sum_{k=1}^{\kappa} \boldsymbol{\theta}^{(k)}/\kappa$  is a dense parameterization not applicable to structure learning.

According to the analysis above, we need to control  $\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})$  in each iteration to achieve a decreasing and  $O\left(\frac{1}{k}\right)$ -converging objective function value sequence. Therefore, we focus on checkable bounds for gradient approximation error in Section 4.

## 4 MAIN RESULTS

In this section, we derive an asymptotic and a non-asymptotic bound to control the gradient approximation error  $\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})$  in each iteration. For this purpose, we consider an arbitrary  $\boldsymbol{\theta}$ , and perform gradient approximation via Gibbs- $\tau$  using Algorithm 2, given an initial value for the Gibbs sampling algorithm,  $\tilde{\mathbf{x}}_0$ . By bounding  $\boldsymbol{\delta}(\boldsymbol{\theta})$ , we can apply the same technique to address  $\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})$ .

We first provide a bound for the magnitude of the conditional expectation of  $\boldsymbol{\delta}(\boldsymbol{\theta})$ ,  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2$ , in Section 4.1. Based on this result, we further draw a non-asymptotic bound for the magnitude of the gradient approximation error,  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$ , in Section 4.2. Both results are *verifiable* in each iteration.

For the derivation of the conclusions, we will focus on binary pairwise Markov networks (BPMNs). Let  $\mathbf{x} \in \{0, 1\}^p$  and  $\boldsymbol{\theta}$  be given, a binary pairwise Markov network [Höfling and Tibshirani, 2009, Geng et al., 2017] is defined as:

$$P_{\boldsymbol{\theta}}(\mathbf{x}) = \frac{1}{Z(\boldsymbol{\theta})} \exp \left( \sum_{i=1}^p \sum_{j \geq i}^p \theta_{ij} x_i x_j \right), \quad (10)$$

where  $Z(\boldsymbol{\theta}) = \exp(A(\boldsymbol{\theta}))$  is the partition function.

$\theta_{ij}$  is a component of  $\boldsymbol{\theta}$  that represents the strength of conditional dependence between  $X_i$  and  $X_j$ .

#### 4.1 An Asymptotic Bound

We first consider the magnitude of the conditional expectation of  $\boldsymbol{\delta}(\boldsymbol{\theta})$  with respect to  $\tilde{\mathbf{x}}_\tau$ ,  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2$ . To this end, we define  $\mathbf{U}$  a  $p \times p$  computable matrix that is related to  $\boldsymbol{\theta}$  and the type of MRF in question.  $U_{ij}$ , the component in the  $i^{\text{th}}$  row and the  $j^{\text{th}}$  column of  $\mathbf{U}$ , is defined as follows:

$$U_{ij} = \frac{|\exp(-\xi_{ij}) - 1|b^*}{(1 + b^* \exp(-\xi_{ij}))(1 + b^*)}, \quad (11)$$

where

$$b^* = \max \left\{ r, \min \left\{ s, \exp \left( \frac{\xi_{ij}}{2} \right) \right\} \right\},$$

$$s = \exp \left( -\xi_{ii} - \sum_{k \neq i, k \neq j} \xi_{ik} \max \{ -\text{sgn}(\xi_{ik}), 0 \} \right)$$

$$r = \exp \left( -\theta_{ii} - \sum_{k \neq i, k \neq j} \xi_{i,k} \max \{ \text{sgn}(\xi_{i,k}), 0 \} \right),$$

and  $\text{sgn}(\xi_{ik})$  is the sign function evaluated on  $\xi_{ij} = \theta_{\min\{i,j\}, \max\{i,j\}}$ .

We then define  $\mathbf{B}_i$  as a  $p \times p$  identity matrix except that its  $i^{\text{th}}$  row is replaced by the  $i^{\text{th}}$  row of  $\mathbf{U}$ , with  $i \in \{1, 2, \dots, p\}$ . We further define

$$\mathbf{B} = \mathbf{B}_p \mathbf{B}_{p-1} \mathbf{B}_{p-2} \cdots \mathbf{B}_i \cdots \mathbf{B}_1$$

and the grand sum  $\mathcal{G}(\mathbf{B}) = \sum_{i=1}^p \sum_{j=1}^p B_{ij}$ , where  $B_{ij}$  is the entry in the  $i^{\text{th}}$  row and the  $j^{\text{th}}$  column of  $\mathbf{B}$ . With the definitions above,  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2$  can be upper bounded by Theorem 3.

**Theorem 3.** Let  $\tilde{\mathbf{x}}_\tau$  be the sample generated after running Gibbs sampling for  $\tau$  steps (Gibbs- $\tau$ ) under the parameterization  $\boldsymbol{\theta}$  initialized by  $\tilde{\mathbf{x}}_0 \in \{0, 1\}^p$ ; then with  $m$  denoting the size of sufficient statistics, the following inequality holds:

$$\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2 \leq 2\sqrt{m}\mathcal{G}(\mathbf{B}^\tau), \quad (12)$$

where  $\mathbf{B}^\tau$  represents the  $\tau^{\text{th}}$  power of  $\mathbf{B}$ .

In Theorem 3, the bound provided is not only observable in each iteration, but also efficient to compute, offering a convenient method to inspect the quality of the gradient approximation. When the spectral norm of  $\mathbf{U}$  is less than 1, the left hand side of (12) will converge to 0. Thus, by increasing  $\tau$ , we can decrease  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2$  to an arbitrarily small value.

Theorem 3 is derived by bounding the influence of a variable on another variable in  $\mathbf{X}$  (i.e., the Dobrushin influence defined in 2) with  $\mathbf{U}$ . Furthermore,  $\mathbf{U}$  defined in (11) is a sharp bound of the Dobrushin influence whenever  $b^* \neq \exp\left(\frac{\xi_{ij}}{2}\right)$ , explaining why (12) using the definition of  $\mathbf{U}$  is tight enough for practical applications.

#### 4.2 A Non-Asymptotic Bound

In order to provide a non-asymptotic guarantee for the quality of the gradient approximation, we need to concentrate  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$  around  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\boldsymbol{\delta}(\boldsymbol{\theta}) \mid \tilde{\mathbf{x}}_0]\|_2$ . Let  $q$  defined in Section 2.2 be given. Then,  $q$  trials of Gibbs sampling are run, resulting in  $q$  samples,  $\{\tilde{\mathbf{x}}_\tau^{(1)}, \tilde{\mathbf{x}}_\tau^{(2)}, \dots, \tilde{\mathbf{x}}_\tau^{(q)}\}$ . That is to say, for each sufficient statistic,  $\psi_j(\boldsymbol{\theta})$ , with  $j \in \{1, 2, \dots, m\}$ , we have  $q$  samples,  $\{\psi_j^{(1)}(\boldsymbol{\theta}), \psi_j^{(2)}(\boldsymbol{\theta}), \dots, \psi_j^{(q)}(\boldsymbol{\theta})\}$ . Defining the sample variance of the corresponding sufficient statistics as  $V_{\psi_j}$ , we have Theorem 4 to provide a non-asymptotic bound for  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$ :

**Theorem 4.** Let  $\boldsymbol{\theta}$ ,  $q$ , and an arbitrary  $\tilde{\mathbf{x}}_0 \in \{0, 1\}^p$  be given. Let  $m$  represent the dimension of  $\boldsymbol{\theta}$  and  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$  represent the magnitude of the gradient approximation error by running  $q$  trials of Gibbs- $\tau$  initialized by  $\tilde{\mathbf{x}}_0$ . Compute  $\mathbf{B}$  according to Section 4.1 and choose  $\epsilon_j > 0$ . Then, with probability at least  $1 - 2\sum_{j=1}^m \beta_j$ , where  $\beta_j > 0$ ,  $j \in \{1, 2, \dots, m\}$ ,

$$\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2 \leq 2\sqrt{m} \left( \mathcal{G}(\mathbf{B}^\tau) + \sqrt{\frac{\sum_{j=1}^m \epsilon_j^2}{4m}} \right), \quad (13)$$

with  $\beta_j$  satisfying

$$\epsilon_j = 2 \left( \sqrt{\frac{V_{\psi_j} \ln 2 / \beta_j}{2q}} + \frac{7 \ln 2 / \beta_j}{3(q-1)} \right). \quad (14)$$

Notice that the bound in Theorem 4 is easily *checkable*, i.e., given  $\tau$ ,  $q$ ,  $V_{\psi_j}$ 's, and  $\boldsymbol{\theta}$ , we can determine a bound for  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$  that holds with high probability. Furthermore, Theorem 4 provides the sample complexity needed for gradient estimation. Specifically, given small enough  $\beta_j$ 's, if we let

$$\mathcal{G}(\mathbf{B}^\tau) = \sqrt{\sum_{j=1}^m \epsilon_j^2 / 4m},$$

we can show that

$$2\sqrt{m} \left( \mathcal{G}(\mathbf{B}^\tau) + \sqrt{\sum_{j=1}^m \epsilon_j^2 / 4m} \right) = O\left(\frac{1}{q}\right).$$

That is to say, by assuming that  $\mathcal{G}(\mathbf{B}^\tau)$  and  $\sqrt{\sum_{j=1}^m \epsilon_j^2 / 4m}$  share the same scale, the upper bound of the gradient approximation error converges to 0 as  $q$  increases. Moreover, we include sample variance,  $V_{\psi_j}$ 's, in (13). This is because the information provided by sample variance leads to an improved data dependent bound.

## 5 PROOF SKETCH OF MAIN RESULTS

As mentioned in Section sec:non-asy-bound, the non-asymptotic result in Theorem 4 is derived from the asymptotic bound in Theorem 3 by concentration inequalities, we therefore only highlight the proof of Theorem 3 in this section, and defer other technical results to Supplements. Specifically, the proof of Theorem 3 is divided into two parts: bounding  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2$  by the total variation distance (Section 5.1) and bounding the total variation distance (Section 5.2).

### 5.1 Bounding $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2$ by the Total Variation Distance

To quantify  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2$ , we first introduce the concept of total variation distance [Levin et al., 2009] that measures the distance between two distributions over  $\{0, 1\}^p$ .

**Definition 1.** Let  $u(\mathbf{x})$ , and  $v(\mathbf{x})$  be two probability distributions of  $\mathbf{x} \in \{0, 1\}^p$ . Then the total variation distance between  $u(\mathbf{x})$  and  $v(\mathbf{x})$  is given as:

$$\|u(\mathbf{x}) - v(\mathbf{x})\|_{\text{TV}} = \frac{1}{2} \sum_{\mathbf{x} \in \{0, 1\}^p} |u(\mathbf{x}) - v(\mathbf{x})|.$$

With the definition above,  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2$  can be upper bounded by the total variation distance between two distributions ( $P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0)$  and  $P_\theta(\mathbf{x})$ ) using the following lemma:

**Lemma 1.** Let  $\tilde{\mathbf{x}}_\tau$  be the sample generated after running Gibbs sampling for  $\tau$  steps (Gibbs- $\tau$ ) under the parameterization  $\boldsymbol{\theta}$  initialized by  $\tilde{\mathbf{x}}_0 \in \{0, 1\}^p$ , then the following is true:

$$\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2 \leq 2\sqrt{m} \|P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0) - P_\theta(\mathbf{x})\|_{\text{TV}}.$$

With Lemma 1, bounding  $\|\mathbb{E}_{\tilde{\mathbf{x}}_\tau}[\delta(\boldsymbol{\theta}) | \tilde{\mathbf{x}}_0]\|_2$  can be achieved by bounding the total variation distance  $\|P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0) - P_\theta(\mathbf{x})\|_{\text{TV}}$ . Recent advances in the quality control of Gibbs samplers offer us emphverifiable upper bounds for  $\|P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0) - P_\theta(\mathbf{x})\|_{\text{TV}}$  on the learning of a variety of MRFs [Mitliagkas and Mackey,

2017]. However, they can not be applied to BPMNs because of the positive constraint on parameters. We describe these next.

### 5.2 Bounding $\|P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0) - P_\theta(\mathbf{x})\|_{\text{TV}}$

Now we generalize the analysis in Mitliagkas and Mackey [2017] to BPMNs without constraints on the sign of parameters by introducing the definition of the Dobrushin influence matrix and a technical lemma.

**Definition 2** (Dobrushin influence matrix). The Dobrushin influence matrix of  $P_\theta(\mathbf{x})$  is a  $p \times p$  matrix  $\mathbf{C}$  with its component in the  $i^{\text{th}}$  row and the  $j^{\text{th}}$  column,  $C_{ij}$ , representing the influence of  $X_j$  on  $X_i$  given as:

$$C_{ij} = \max_{(\mathbf{X}, \mathbf{Y}) \in N_j} \|P_\theta(X_i | \mathbf{X}_{-i}) - P_\theta(Y_i | \mathbf{Y}_{-i})\|_{\text{TV}},$$

where  $(\mathbf{X}, \mathbf{Y}) \in N_j$  represents  $X_l = Y_l$  for all  $l \neq j$ .

**Lemma 2.** Let  $P_\theta(\mathbf{x})$  represent a binary pairwise Markov network defined in (10) that is parameterized by  $\boldsymbol{\theta}$ . An upper bound of the total influence matrix is given by  $\mathbf{U}$  defined in Section 4.1.

It should be noticed that, similar to the Theorem 12 in Mitliagkas and Mackey [2017], Lemma 2 provides an exact calculation except when  $b^* = \exp\left(\frac{\xi_{i,j}}{2}\right)$ .

Therefore, we can consider the  $\mathbf{U}$  defined in Section 4.1 as an upper bound for Dobrushin influence matrix in BPMN and thus apply  $\mathbf{U}$  to Theorem 9 in Mitliagkas and Mackey [2017]. Then, we have

$$\|P_\tau(\mathbf{x} | \tilde{\mathbf{x}}_0) - P_\theta(\mathbf{x})\|_{\text{TV}} \leq \mathcal{G}(\mathbf{B}^\tau),$$

where  $\mathbf{B}^\tau$  represents the  $\tau^{\text{th}}$  power of  $\mathbf{B}$ . Theorem 3 follows this combined with Lemma 1

## 6 STRUCTURE LEARNING

With the two bounds introduced in Section 4, we can easily examine and control the quality of gradient approximation in each iteration by choosing  $\tau$ . In detail, we introduce a criterion for the selection of  $\tau$  in each iteration. Satisfying the proposed criterion, the objective function is guaranteed to decrease asymptotically. That is to say, the difference between  $g(\boldsymbol{\theta}^{(k+1)})$  and  $g(\hat{\boldsymbol{\theta}})$  is asymptotically *tightened*, compared with the difference between  $g(\boldsymbol{\theta}^{(k)})$  and  $g(\hat{\boldsymbol{\theta}})$ . Therefore, we refer to the proposed criterion as TAY-CRITERION. Furthermore, using TAY-CRITERION we provide an improved SPG method denoted by TAY for short.

Specifically, starting from  $\tau = 1$ , TAY stops increasing  $\tau$  when the following is satisfied:

$$2\sqrt{m}\mathcal{G}(\mathbf{B}^\tau) < \frac{1}{2}\|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2. \quad (\text{TAY-CRITERION})$$

We can also derive a non-asymptotic counterpart of TAY-CRITERION by combining the results of Theorem 1 and Theorem 4:

$$0 < 2\sqrt{m} \left( \mathcal{G}(\mathbf{B}^\tau) + \sqrt{\frac{\sum_{j=1}^m \epsilon_j^2}{4m}} \right) \leq \frac{1}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2,$$

$$\epsilon_j = 2 \left( \sqrt{\frac{2V_{\psi_j} \ln 2/\beta_j}{4q}} + \frac{7 \ln 2/\beta_j}{3(q-1)} \right), \quad (15)$$

where the  $V_{\psi_j}$ 's and  $\beta_j$ 's are defined in Theorem 4. (15) provides the required sample complexity,  $q$ , for TAY in each iteration. However, the selection of  $q$  according to (15) is conservative, because it includes the worst-case scenario where the gradient approximation errors in any two iterations cannot offset each other.

In Section 6.1 and 6.2, we theoretically analyze the performance guarantees of TAY-CRITERION and the convergence of TAY, respectively.

### 6.1 Guarantees of TAY-CRITERION

The theorem below provides the performance guarantee for TAY-CRITERION in each iteration.

**Theorem 5.** Let  $\boldsymbol{\theta}^{(k)}$  and  $\tilde{\mathbf{x}}_0$  be given. Let  $q$  and  $\mathbf{B}$  defined in Theorem 4 be given. For  $\boldsymbol{\theta}^{(k+1)}$  generated in Algorithm 3 using TAY-CRITERION, the following is true:

$$\lim_{q \rightarrow \infty} \mathbb{P} \left( g(\boldsymbol{\theta}^{(k+1)}) < g(\boldsymbol{\theta}^{(k)}) \mid 2\sqrt{m} \mathcal{G}(\mathbf{B}^\tau) < \frac{1}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2 \right) = 1.$$

Theorem 5 makes a statement that the objective function value decreases with large  $q$ . Specifically, TAY-CRITERION assumes that the upper bound of the conditional expectation of  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$  is small enough to satisfy the sufficient condition proven in Theorem 1. When the number of samples  $q$  is large enough,  $\|\boldsymbol{\delta}(\boldsymbol{\theta})\|_2$  itself is very likely to meet the condition and hence the objective function is also likely to decrease with TAY-CRITERION satisfied.

### 6.2 Convergence of TAY

Finally, based on Theorem 2 and Theorem 5, we derive the following theorem on the convergence of TAY.

**Theorem 6.** Let  $\mathcal{K} = (\boldsymbol{\theta}^{(0)}, \boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \dots, \boldsymbol{\theta}^{(\kappa)})$  be the iterates generated by TAY. Then, with  $k \in \{1, 2, \dots, \kappa - 1\}$ , the following is true:

$$\lim_{q \rightarrow \infty} \mathbb{P} \left[ g(\boldsymbol{\theta}^{(\kappa)}) - g(\hat{\boldsymbol{\theta}}) \leq \frac{L}{2\kappa} \left( \|\boldsymbol{\theta}^{(0)} - \hat{\boldsymbol{\theta}}\|_2 + \frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 \right)^2 \right] = 1,$$

where  $\hat{\boldsymbol{\theta}}$  is defined in (1).

### 6.3 Generalizations

As we demonstrate in Section 4 and Section 5, the derivation of our main results relies on bounding the Dobrushin influence with  $\mathbf{U}$  and we show a procedure to construct  $\mathbf{U}$  in the context of BPMNs. Moreover, Mitliagkas and Mackey [2017] and Liu and Domke [2014] provide upper bounds  $\mathbf{U}$ 's for other types of discrete pairwise MRFs. Therefore, combined with their results, our framework can also be applied to other discrete pairwise Markov networks. Dealing with pairwise MRFs is without any loss of generality, since any discrete MRF can be transformed into a pairwise one [Wainwright et al., 2008, Ravikumar et al., 2010].

## 7 EXPERIMENTS

We demonstrate that the structure learning of discrete MRFs benefits substantially from the application of TAY with synthetic data and that the bound provided on the gradient estimation error by Theorem 3 is tighter than existing bounds. To illustrate that TAY is readily available for practical problems, we also run TAY using a real world dataset. Because of the limit of space, we only report the experiments under one set of representative experiment configurations. Exhaustive results using different experiment configurations are presented in the Supplements.

### 7.1 Structure Learning

In order to demonstrate the utility of TAY for effectively learning the structures of BPMNs, we simulate two BPMNs (one with 10 nodes and the other one with 20 nodes):

- We set the number of features to  $p = 10$  ( $p = 20$ ). Components of  $\boldsymbol{\theta}$  in the ground truth model are randomly chosen to be nonzero with an edge generation probability of 0.3. The non-zero components of the real parameter have a uniform distribution on  $[-2, -1] \cup [1, 2]$
- 1000 (2000 for 20 nodes) samples are generated by Gibbs sampling with 1000 burn-in steps.

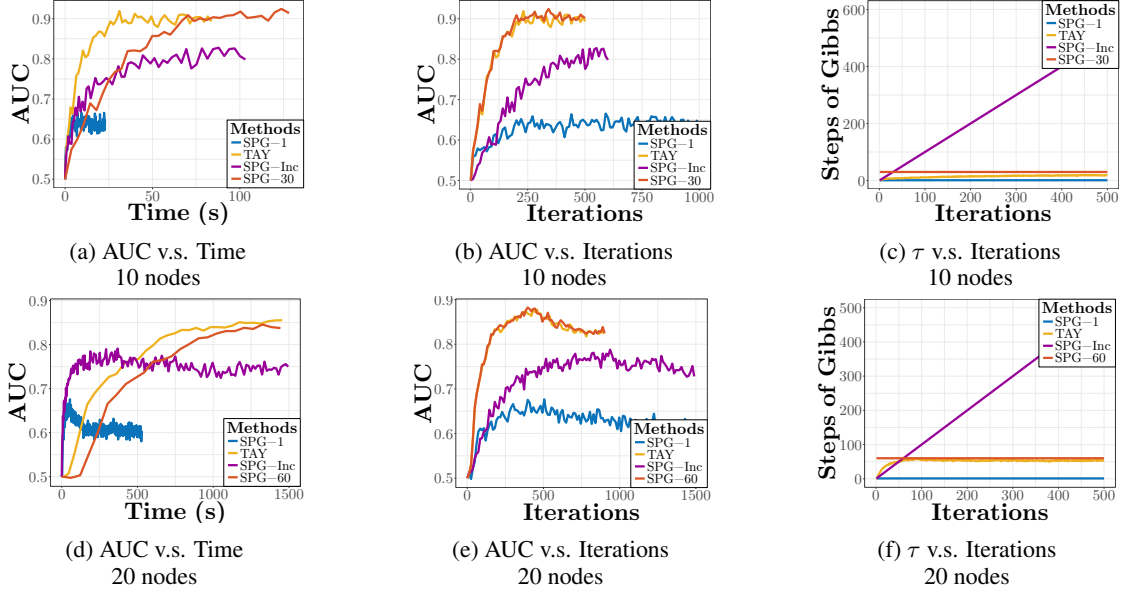

Figure 1: Area under curve (AUC) and the steps of Gibbs sampling ( $\tau$ ) in each iteration for structure learning of a 20-node network.

Figure 2: The gradient approximation error, the existing bound and the bound (12) in the structure learning of a 10-node network.

- The results are averaged over 10 trials.

The sizes of the BPMNs generated in this paper are comparable to those in [Honorio, 2012a, Atchade et al., 2014, Miasojedow and Rejchel, 2016].

Then, using the generated samples, we consider SPG and TAY. According to the analysis in Section 4, the quality of the gradient approximation is closely related to the number of Gibbs sampling steps  $\tau$ . However, for SPG, there are no convincing schemes for selecting  $\tau$ . Therefore, we consider a large enough  $\tau = 30$  ( $\tau = 60$  for 20 nodes) to make sure that the gradient approximation error is small enough. Furthermore, we also evaluate the performance of the algorithm using an increasing  $\tau$  ( $\tau = k$  in the  $k^{th}$  iteration), suggested by Atchade et al. [2014] (SPG-Inc).

To strike a fair comparison, we use the same step length  $\alpha = 0.4$  and regularization parameter  $\lambda = 0.025$  ( $\lambda = 0.017$  for 20 nodes) for different methods. We do not tune the step length individually for each method, since Atchade et al. [2014] has shown that various learning rate selection schemes have minimal impact on the performance in the context of SPG. The number of chains used in Gibbs sampling,  $q$ , is not typically a tunable parameter either, since it indicates the allocation of the computational resources. For each method, it can be easily noticed that the larger the number of samples is the slower but more accurate the method will be. Furthermore, if the  $q$ 's are different for different methods, it would be difficult to distinguish the effect of  $\tau$  from that of  $q$ . Therefore, we set it to 2000 for 10-node networks and 5000 for 20-node networks. Performances of different methods are compared using the area under curve (AUC) of receiver operating characteristic (ROC) for structure learning in Figure 1. The Gibbs sampling steps in each method are also compared in Figure 1.

Notice that we plot AUCs against both time (Figure 1a and Figure 1d) and iterations (Figure 1b and Figure 1e). The two kinds of plots provide different information about the performances of different methods: the former ones focus on overall complexity and the latter illustrate iteration complexity. We run each method until it converges. Using much less time, TAY achieves a similar AUC to SPG with  $\tau = 30$  and  $\tau = 60$ . Moreover, SPG with  $\tau = 1$  reaches the lowest AUC, since the quality of the gradient approximation cannot be guaranteed with such a small  $\tau$ . Therefore, the experimental results

Figure 3: The result of TAY on the senator voting data: Red vertices denote Republicans, blue Democrats, and green Independent. The figure is rendered by Gephi [Bastian et al., 2009].

indicate that TAY adaptively chooses a  $\tau$  achieving reasonable accuracy as well as efficiency for structure learning in each iteration. For a more thorough comparison, we also contrast the performance of TAY and a non-SPG-based method, i.e., the pseudo-likelihood method [Höfling and Tibshirani, 2009, Geng et al., 2017], in the Supplements. As a result, the two methods achieve comparable AUCs.

## 7.2 Tightness of the Proposed Bound

According to the empirical results above, TAY needs a  $\tau$  only on the order of ten, suggesting that the bound in Theorem 3 is tight enough for practical applications. To illustrate this more clearly, we compare (12) with another bound on the expectation of the gradient approximation error derived by Fischer [2015]. Specifically, we calculate the gradient approximation error, the bound (12), and Fischer [2015]’s bound, in each iteration of learning a 10-node network. The results are reported in Figure 2. Notice that the bound in Fischer [2015] gets extraordinarily loose with more iterations. Considering this, we may need run Gibbs chains for thousands of steps if we use this bound. In contrast, bound (12) is close to and even slightly less than the real error. This is reflective of the fact that the proposed bound is on the expectation instead of the error itself. As a result, (12) is much tighter and thus more applicable.

## 7.3 Real World Data

In our final experiment, we run TAY using the Senate voting data from the second session of the 109<sup>th</sup> Congress [USS]. The dataset has 279 samples and 100 variables. Each sample represents the vote cast by each of the 100 senators for a particular bill, where 0 represents nay, and 1 represents yea. Missing data are imputed as 0’s. The task of interest is to learn a

BPMN model that identifies some clusters that represent the dependency between the voting inclination of each senator and the party with which the senator is affiliated.

We use TAY with  $\alpha = 0.4$ . 5000 Markov chains are used for Gibbs sampling. Since our task is exploratory analysis,  $\lambda = 0.1$  is selected in order to deliver an interpretable result. The proposed algorithm is run for 100 iterations. The resultant BPMN with only edges corresponding to the positive parameters is shown in Figure 3, where each node represents the voting record of a senator and the edges represent some positive dependency between the pair of senators connected. The nodes in red represent Republicans and the nodes in blue represents Democrats. The clustering effects of voting consistency within a party are captured, coinciding with conventional wisdom. More interestingly, Jay Rockefeller, as a Democrat, has many connections with Republicans. This is consistent with the fact that his family has been a “traditionally Republican dynasty” [Wikipedia, 2017].

## 8 CONCLUSION

We consider SPG for  $L_1$ -regularized discrete MRF estimation. Furthermore, we conduct a careful analysis of the gradient approximation error of SPG and provide upper bounds to quantify its magnitude. With the aforementioned analysis, we introduce a learning strategy called TAY and show that it can improve the accuracy and efficiency of SPG.

## Supplements

### A Proofs

#### A.1 Proof of Theorem 1

We first introduce the following technical lemma.

**Lemma 3.** Let  $g(\boldsymbol{\theta})$ ,  $f(\boldsymbol{\theta})$ , and  $h(\boldsymbol{\theta})$  be defined as in Section 2.1; hence  $f(\boldsymbol{\theta})$  is convex and differentiable, and  $\nabla f(\boldsymbol{\theta})$  is Lipschitz continuous with Lipschitz constant  $L$ . Let  $\alpha \leq 1/L$ . Let  $\mathbf{G}_\alpha(\boldsymbol{\theta})$  and  $\Delta f(\boldsymbol{\theta})$  be defined as in Section (2.2). Then for all  $\boldsymbol{\theta}_1$  and  $\boldsymbol{\theta}_2$ , the following inequality holds:

$$g(\boldsymbol{\theta}_1^\dagger) \leq g(\boldsymbol{\theta}_2) + \mathbf{G}_\alpha^\top(\boldsymbol{\theta}_1)(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2) + (\nabla f(\boldsymbol{\theta}_1) - \Delta f(\boldsymbol{\theta}_1))^\top (\boldsymbol{\theta}_1^\dagger - \boldsymbol{\theta}_2) - \frac{\alpha}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}_1)\|_2^2, \quad (16)$$

where  $\boldsymbol{\theta}_1^\dagger = \boldsymbol{\theta}_1 - \alpha \mathbf{G}_\alpha(\boldsymbol{\theta}_1)$ .

*Proof.* The proof is based on the convergence analysis of the standard proximal gradient method [Vandenberghe, 2016].  $f(\boldsymbol{\theta})$  is a convex differentiable function whose gradient is Lipschitz continuous with Lipschitz constant  $L$ . By the quadratic bound of the Lipschitz property:

$$f(\boldsymbol{\theta}_1^\dagger) \leq f(\boldsymbol{\theta}_1) - \alpha \nabla^\top f(\boldsymbol{\theta}_1) \mathbf{G}_\alpha(\boldsymbol{\theta}_1) + \frac{\alpha^2 L}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}_1)\|_2^2.$$

With  $\alpha \leq 1/L$ , and adding  $h(\boldsymbol{\theta}_1^\dagger)$  on both sides of the quadratic bound, we have an upper bound for  $g(\boldsymbol{\theta}_1^\dagger)$ :

$$g(\boldsymbol{\theta}_1^\dagger) \leq f(\boldsymbol{\theta}_1) - \alpha \nabla^\top f(\boldsymbol{\theta}_1) \mathbf{G}_\alpha(\boldsymbol{\theta}_1) + \frac{\alpha}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}_1)\|_2^2 + h(\boldsymbol{\theta}_1^\dagger).$$

By convexity of  $f(\boldsymbol{\theta})$  and  $h(\boldsymbol{\theta})$ , we have:

$$\begin{aligned} f(\boldsymbol{\theta}_1) &\leq f(\boldsymbol{\theta}_2) + \nabla^\top f(\boldsymbol{\theta}_1)(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2), \\ h(\boldsymbol{\theta}_1^\dagger) &\leq h(\boldsymbol{\theta}_2) + (\mathbf{G}_\alpha(\boldsymbol{\theta}_1) - \Delta f(\boldsymbol{\theta}_1))^\top (\boldsymbol{\theta}_1^\dagger - \boldsymbol{\theta}_2), \end{aligned}$$

which can be used to further upper bound  $g(\boldsymbol{\theta}_1^\dagger)$ , and results in (16). Note that we have used the fact that  $\mathbf{G}_\alpha(\boldsymbol{\theta}_1) - \Delta f(\boldsymbol{\theta}_1)$  is a subgradient of  $h(\boldsymbol{\theta}_1^\dagger)$  in the last inequality.  $\square$

With Lemma 3, we are now able to prove Theorem 1. In Lemma 3, let  $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_2 = \boldsymbol{\theta}^{(k)}$ . Then by (8),  $\boldsymbol{\theta}_1^\dagger = \boldsymbol{\theta}^{(k+1)}$ . The inequality in (16) can then be simplified as:

$$g(\boldsymbol{\theta}^{(k+1)}) - g(\boldsymbol{\theta}^{(k)}) \leq \alpha \boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})^\top \mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)}) - \frac{\alpha}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2^2.$$

By the Cauchy-Schwarz inequality and the sufficient condition that  $\|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 < \frac{1}{2} \|\mathbf{G}_\alpha(\boldsymbol{\theta}^{(k)})\|_2$ , we can further simplify the inequality and conclude  $g(\boldsymbol{\theta}^{(k+1)}) < g(\boldsymbol{\theta}^{(k)})$ .

#### A.2 Proof of Theorem 2

To prove Theorem 2, we first review Proposition 1 in Schmidt et al. [2011]:

**Theorem 7** (Convergence on Average, Schmidt et al. [2011]). Let  $\mathcal{K} = (\boldsymbol{\theta}^{(0)}, \boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \dots, \boldsymbol{\theta}^{(\kappa)})$  be the iterates generated by Algorithm 3, then

$$g\left(\frac{1}{\kappa} \sum_{k=1}^{\kappa} \boldsymbol{\theta}^{(k)}\right) - g(\hat{\boldsymbol{\theta}}) \leq \frac{L}{2\kappa} \left( \|\boldsymbol{\theta}^{(0)} - \hat{\boldsymbol{\theta}}\|_2 + \frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 \right)^2.$$

Furthermore, according to the assumption that  $g(\boldsymbol{\theta}^{(k+1)}) \leq g(\boldsymbol{\theta}^{(k)})$  with  $k \in \{1, 2, \dots, \kappa\}$ , we have:  $g\left(\frac{1}{\kappa} \sum_{k=1}^{\kappa} \boldsymbol{\theta}^{(k)}\right) \geq g(\boldsymbol{\theta}^{(\kappa)})$ . Therefore,

$$g(\boldsymbol{\theta}^{(\kappa)}) - g(\hat{\boldsymbol{\theta}}) \leq \frac{L}{2\kappa} \left( \|\boldsymbol{\theta}^{(0)} - \hat{\boldsymbol{\theta}}\|_2 + \frac{2}{L} \sum_{k=1}^{\kappa} \|\boldsymbol{\delta}(\boldsymbol{\theta}^{(k)})\|_2 \right)^2.$$

## Abstract

We consider partially-specified optimization problems where the goal is to actively, but efficiently, acquire missing information about the problem in order to solve it. An algorithm designer wishes to solve a linear program (LP),  $\max c^T \mathbf{x}$  s.t.  $\mathbf{Ax} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$ , but does not initially know some of the parameters. The algorithm can iteratively choose an unknown parameter and gather information in the form of a noisy sample centered at the parameter's (unknown) value. The goal is to find an approximately feasible and optimal solution to the underlying LP with high probability while drawing a small number of samples. We focus on two cases. (1) When the parameters  $\mathbf{b}$  of the constraints are initially unknown, we propose an efficient algorithm combining techniques from the ellipsoid method for LP and confidence-bound approaches from bandit algorithms. The algorithm adaptively gathers information about constraints only as needed in order to make progress. We give sample complexity bounds for the algorithm and demonstrate its improvement over a naive approach via simulation. (2) When the parameters  $\mathbf{c}$  of the objective are initially unknown, we take an information-theoretic approach and give roughly matching upper and lower sample complexity bounds, with an (inefficient) successive-elimination algorithm.

## 1 INTRODUCTION

Many real-world settings are modeled as optimization problems. For example, a delivery company plans driver routes to minimize the driver's total travel time; an airline

assigns vehicles to different origin-destination pairs to maximize profit. However, in practice, some parameters of the optimization problems may be initially unknown. The delivery company may not know the average congestion or travel time of various links of the network, but has ways to poll Waze<sup>1</sup> drivers to get samples of travel times on links of the network. The delivery company may not know the demand and the revenues for each origin-destination pair, but can get estimates of them by selling tickets on chosen origin-destination pairs.

To capture such settings, this paper proposes a model of optimization wherein the algorithm can iteratively choose a parameter and draw a "sample" that gives information about that parameter; specifically, the sample is an independent draw from a subgaussian random variable centered at the true value of the parameter. This models, for instance, observing the congestion on a particular segment of road on a particular day. Drawing each sample is presumed to be costly, so the goal of the algorithm is to draw the fewest samples necessary in order to find a solution that is approximately feasible and approximately optimal.

Thus, the challenge falls under an umbrella we term *active information acquisition for optimization (AIAO)*. The key feature of the AIAO setting is the structure of the optimization problem itself, i.e. the objective and constraints. The challenge is to understand how the difficulty of information acquisition relates to this underlying structure. For example, are there information-theoretic quantities relating the structure to the sample complexity? Meanwhile, the opportunity of AIAO is to exploit algorithms for the underlying optimization problem. For example, can one interface with the algorithm to reduce sample complexity by only acquiring the information needed, as it is needed?

These are the questions investigated in this paper, which focuses on active information acquisition for linear opti-

---

<sup>1</sup><https://www.waze.com>

mization problems. Specifically, we consider linear programs in the form

$$\max_{\mathbf{x}} \mathbf{c}^T \mathbf{x}, \text{ s.t. } \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0} \quad (1)$$

with  $\mathbf{A} \in \mathbb{R}^{m \times n}$ ,  $\mathbf{c} \in \mathbb{R}^n$ , and  $\mathbf{b} \in \mathbb{R}^m$ . We will consider either the case that the  $\mathbf{b}$  in the constraints is unknown or else the case that the  $\mathbf{c}$  in the objective is unknown, with all other parameters initially known to the algorithm. The algorithm can iteratively choose an unknown parameter, e.g.  $b_i$ , and draw a “sample” from it, e.g. observing  $b_i + \eta$  for an independent, zero-mean, sub-gaussian  $\eta$ . The algorithm must eventually output a solution  $\mathbf{x}$  such that, with probability  $1 - \delta$ ,  $\mathbf{A}\mathbf{x} \leq \mathbf{b} + \varepsilon_1 \mathbf{1}$  and  $\mathbf{c}^T \mathbf{x} \geq \mathbf{c}^T \mathbf{x}^* - \varepsilon_2$ , where  $\mathbf{x}^*$  is the optimal solution. The goal is for the algorithm to achieve this while using as few total samples as possible.

There is a natural “naive” or “static” approach: draw samples for all unknown parameters until they are known to high accuracy with high probability, then solve the “empirical” linear program. However, we can hope to improve by leveraging known algorithms and properties of linear programs. For example, in the case that  $\mathbf{b}$  is unknown, if a linear program has an optimal solution, it has an optimal solution that is an extreme point (a corner point of the feasible region); and at this extremal optimal solution, several constraints are binding. These suggest that it is more important to focus on binding constraints and to gather information on the differing objective values of extreme points. Algorithms developed in this paper leverage these properties of linear programs to decide how much information to acquire for each unknown parameter.

## 1.1 APPROACHES AND RESULTS

**Two settings and our approaches.** The paper investigates two settings: unknown  $\mathbf{b}$  but known  $\mathbf{c}$ , and unknown  $\mathbf{c}$  but known  $\mathbf{b}$ . We always suppose  $\mathbf{A}$  is known and assume that the linear program has an optimal solution.

It might initially appear that these cases are “equivalent” via duality theory, but we argue that the two cases are quite different when we do not know the parameters of LP exactly. Given a *primal* linear program of the form (1), the *dual* program is given by  $\min_{\mathbf{y}} \mathbf{b}^T \mathbf{y}$  s.t.  $\mathbf{A}^T \mathbf{y} \geq \mathbf{c}, \mathbf{y} \geq \mathbf{0}$ , which is easily transformed into the maximization format of (1). In particular, the parameters  $\mathbf{c}$  in the objective function of a primal LP becomes the parameters in the constraints of the dual LP. By duality theory, the (exact) optimal solutions to the primal and dual are connected by *complementary slackness* conditions. However, this approach breaks down in

the approximate setting for two reasons. First, approximately optimal solutions do not satisfy complementary slackness; and second, even knowing which constraints bind does not suffice to determine the optimal solution  $\mathbf{x}^*$  when some of the constraint or objective parameters are unknown.<sup>2</sup> We hence take two different approaches toward our two settings.

**Unknown- $\mathbf{b}$  case.** In the unknown  $\mathbf{b}$  setting, the uncertainty is over the constraints. Our algorithm combines two main ideas: the ellipsoid method for solving linear programs, and multi-armed bandit techniques for gathering data. The ellipsoid algorithm only requires the information of one violated constraint at each iteration, if there exists a violated one. We then leverage the multi-armed bandits method to find the most violated constraint (if there exists one) using as few samples as possible.

We theoretically bound the number of samples drawn by our algorithm as a function of the parameters of the problem. In simulations on generated linear programs, UCB-Ellipsoid far outperforms the naive approach of sampling all parameters to high accuracy, and approaches the performance of an oracle that knows the binding constraints in advance and needs only to sample these. In other words, the algorithm spends very few resources on unimportant parameters.

**Unknown- $\mathbf{c}$  case.** In the unknown-objective setting, we know the feasible region exactly. Our algorithm focuses only on the set of extreme points of the feasible region. For each of the extreme point, there are a set of possible values for  $\mathbf{c}$  such that if  $\mathbf{c}$  takes any value in the set, this extreme point is the optimal solution to the LP. The algorithm hence draws just enough samples to determine with high probability which is actually the case for the true  $\mathbf{c}$ .

We define an information-theoretic measure,  $Low(\mathcal{I})$  for an instance  $\mathcal{I}$ . We show that this quantity essentially characterizes the sample complexity of a problem instance and we give an algorithm, not necessarily efficient, for achieving it up to low-order factors.

## 2 RELATED WORK

The setting considered in this paper, active information acquisition for optimization, is related to a conceptual

<sup>2</sup>Nor does knowing which constraints bind even necessarily help, as approximately satisfying them may still lead to large violations of other constraints. Thus, while we do not rule out some future approach that connects approximate solutions of the primal and dual, the evidence suggests to us that the two settings are quite different and we approach each differently in this paper.

level to a large number of lines of work that deal with optimization and uncertainty. But it differs from them mostly in either the active aspect or the optimization aspect. We'll discuss some of these related lines of work and the differences below.

**Optimization under uncertainty** Our problem considers optimization with uncertain model parameters, which is also a theme in stochastic programming [Heyman and Sobel, 2003, Neely, 2010], chance-constrained programming [Ben-Tal et al., 2009], and robust optimization [Ben-Tal et al., 2009, Bertsimas et al., 2004]. In both stochastic optimization and chance-constrained programming, there are no underlying true, fixed values of the parameters; instead, a probabilistic, distributional model of the parameters is used to capture the uncertainty and such model of uncertainty becomes part of the optimization formulation. Hence, optimality in expectation or approximate optimality is sought after under the probabilistic model. But in our problem underlying fixed parameters exist, and the problem is only how much information to gather about them. Meanwhile, robust optimization models deterministic uncertainty (e.g. parameters come from a known set) and often seeks for a worst-case solution, *i.e.* a solution that is feasible in the worst case over a set of possible constraints. A key distinction of our model is that there are underlying true values of the parameters and we do not incorporate any probabilistic or deterministic model of the uncertainty into the optimization problem itself. Instead, we take an "active querying" approach to approximately solve the true optimization problem with high probability.

**Artificial intelligence.** Several existing lines of work in the artificial intelligence literature, deal with actively acquiring information about parameters of an optimization problem in order to solve it. Preference elicitation [Braziunas, 2006, Blum et al., 2004] typically focuses on acquiring information about parameters of the *objective* by querying a user about his preferences, this is similar to our goal for the unknown-*c* setting. Relevant to our unknown-*b* case, for more combinatorial problems, the constraint acquisition literature [OConnell et al., 2002, Bessiere et al., 2015] is closer to our problem in some respects, as it posits an optimization problem with unknown constraints that must be learned via interactive querying. We emphasize that a central feature of the model in this paper is *noisy observations*: the observations of the algorithm are only noisy samples of a true underlying parameter. The key challenge is to choose how many repeated samples of each parameter to draw. This aspect of the problem is not to our knowledge present in preference elicitation or model/constraint acquisition.

### **Machine learning and theoretical computer science.**

Much work in *active learning* considers acquiring data points iteratively with a goal of low sample complexity [Balcan et al., 2006, 2007, Castro and Nowak, 2008]. The key difference to AIAO is between *data* and *parameters*. In learning, the goal is to minimize the average or expectation of some loss function over a distribution of data points. Other than its likelihood, each data point plays the same role in the problem. Here, the focus is on how much information about each of various parameters is necessary to solve a structured optimization problem to a desired level of accuracy. In other words, the key question here, which is how much an optimization algorithm needs to know about the parameters of the problem it is solving, does not apply in active learning.

A line of work on sample complexity of reinforcement learning (or approximate reinforcement learning) [Kakade et al., 2003, Lattimore and Hutter, 2012, Azar et al., 2012, Wang, 2017, Chen and Wang, 2016] also bears some resemblance to our problem. A typical setting considered is solving a model-free Markov Decision Processes (MDP), where the transition probabilities and the reward functions are initially unknown but the algorithm can query an oracle to get samples. This problem is a special case of our AIALO problem with unknown *A* and *b* because an MDP can be formulated as an linear program. The solutions provided focuses on the particular structure of MDP, while we consider general linear programs.

Broadly related is recent work on *optimization from samples* Balkanski et al. [2016], which considers the sample complexity of a two-stage process: (1) draw some number of i.i.d. data points; (2) optimize some loss function or submodular function on the data. In that setting, the algorithm sees a number of input-output pairs of the function, randomly distributed, and must eventually choose a particular input to optimize the function. Therefore, it is quite different from our setting in both important ways: (1) the information collected are data points (and evaluations), as in ML above, rather than parameters as in our problem; (2) (so far) it is not active, but acquires information in a batch.

A line of work that is closely related to our unknown-*c* problem is the study of *combinatorial pure exploration* (CPE) problem, where a learner collects samples of unknown parameters of an objective function to identify the optimal member in a solution set. The problem was first proposed in Chen et al. [2014], and subsequently studied by Gabillon et al. [2016], Chen et al. [2016a,b, 2017]. CPE only considers combinatorial optimization problems whose solution set contains only binary vectors of length *n*. A recent work by Chen et al. [2017]

extended CPE to a *General-Sampling* problem by allowing general solution sets. Our unknown- $c$  problem can be fitted into the setting of General-Sampling. Our algorithm for unknown- $c$  was inspired by the work of [Chen et al. \[2017\]](#), but leverages the structure of LP and hence has better sample complexity performance than directly treating it as a General-Sampling problem. The General-Sampling problem does not encompass all AIAO settings, e.g., our unknown- $b$  case.

### 3 MODEL AND PRELIMINARIES

#### 3.1 THE AIALO PROBLEM

We now formally define an instance  $\mathcal{I}$  of the *active information acquisition for linear optimization (AIALO)* problem. We then describe the format of algorithms for solving this problem. Note that one can easily extend this into a more general formal definition of AIAO, for more general optimization problems, but we leave this for future work.

An instance  $\mathcal{I}$  consists of three components. The first component consists of the *parameters* of the underlying linear program on  $n$  variables and  $m$  constraints: a vector  $\mathbf{c} \in \mathbb{R}^n$ , a vector  $\mathbf{b} \in \mathbb{R}^m$ , and a matrix  $\mathbf{A} \in \mathbb{R}^{n \times m}$ . Naturally, these specify the program<sup>3</sup>

$$\max_{\mathbf{x}} \mathbf{c}^T \mathbf{x} \text{ s.t. } \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}. \quad (2)$$

We assume for simplicity in this paper that all linear programs are feasible and are known *a priori* to have a solution of norm at most  $R$ . The second component specifies which parameters are *initially known* and which are *initially unknown*. The third and final component specifies, for each unknown parameter (say  $c_i$ ), of a  $\sigma^2$ -subgaussian distribution with mean equal to the value of the parameter.<sup>4</sup>

Given  $\mathcal{I}$ , we define the following sets of approximately-feasible, approximately-optimal solutions.

**Definition 3.1.** *Given an instance  $\mathcal{I}$ , let  $\mathbf{x}^*$  be an optimal solution to the LP. Define  $OPT(\mathcal{I}; \varepsilon_1, \varepsilon_2)$  to be the set of solutions  $\mathbf{x}$  satisfying  $\mathbf{c}^T \mathbf{x} \geq \mathbf{c}^T \mathbf{x}^* - \varepsilon_1$  and  $\mathbf{A}\mathbf{x} \leq \mathbf{b} + \varepsilon_2 \mathbf{1}$ . We use  $OPT(\mathcal{I})$  as shorthand for  $OPT(\mathcal{I}; 0, 0)$ .*

<sup>3</sup>Note that any linear program can be transformed into the given format with at most a factor 2 increase in  $n$  and  $m$ .

<sup>4</sup>Distribution  $\mathcal{D}$  with mean  $\mu$  is  $\sigma^2$ -subgaussian if, for  $X \sim \mathcal{D}$ , we have  $\mathbb{E}[e^{t(X-\mu)}] \leq e^{\sigma^2 t^2/2}$  for all  $t$ . The family of sub-Gaussian distributions with parameter  $\sigma$  encompasses all distributions that are supported on  $[0, \sigma]$  as well as many unbounded distributions such as Gaussian distributions with variance  $\sigma^2$ .

#### 3.2 ALGORITHM SPECIFICATION

An algorithm for the AIALO problem, run on an instance  $\mathcal{I}$ , functions as follows. The algorithm is given as input  $n$  (number of variables),  $m$  (number of constraints), and  $\sigma^2$  (subgaussian parameter). It is also given the second component of the instance  $\mathcal{I}$ , i.e. a specification of which parameters are known and which are unknown. For each parameter that is specified as “known”, the algorithm is given the value of that parameter, e.g. it is given “ $A_{11} = 42$ .” Finally, the algorithm is given an optimality parameter  $\varepsilon_1$ , a feasibility parameter  $\varepsilon_2$ , and a failure probability parameter  $\delta$ .

The algorithm may iteratively choose an unknown parameter and *sample* that parameter: observe an independent and identically-distributed draw from the distribution corresponding to that parameter (as specified in the third component of the instance  $\mathcal{I}$ ). At some point, the algorithm stops and outputs a *solution*  $\mathbf{x} \in \mathbb{R}^n$ .

**Definition 3.2** ( $(\delta, \varepsilon_1, \varepsilon_2)$ -correct algorithm). *An algorithm  $\mathcal{A}$  is  $(\delta, \varepsilon_1, \varepsilon_2)$ -correct if for any instance  $\mathcal{I}$  and inputs  $(\delta, \varepsilon_1, \varepsilon_2)$ , with probability at least  $1 - \delta$ ,  $\mathcal{A}$  outputs a solution  $\mathbf{x} \in OPT(\mathcal{I}; \varepsilon_1, \varepsilon_2)$ . In the case  $\varepsilon_1 = \varepsilon_2 = 0$ , we say  $\mathcal{A}$  is  $\delta$ -correct.*

Our goal is to find algorithms with low *sample complexity*, i.e., the number of samples drawn by the algorithm.

### 4 UNKNOWN CONSTRAINTS

We will first consider the *unknown-b case* where every parameter of the constraint vector  $\mathbf{b}$  is initially unknown, and all other parameters are initially known. Geometrically, the algorithm is given an objective “direction” ( $\mathbf{c}$ ) and a set of constraint “orientations” ( $\mathbf{A}$ ), but does not initially know the “offset” or displacement  $b_i$  of each constraint  $i$ .

In this setting, we do not expect to attain either exact feasibility or exact optimality, as the exact constraints can never be known, and in general an arbitrarily small change in constraints of an LP leads to a nonzero change in the value of the optimal solution.

The section begins with a lower bound of the sample complexity (across all LP instances) of any correct algorithm.

**Theorem 4.1** (Lower bound for unknown  $\mathbf{b}$ ). *Suppose we have a  $(\delta, \varepsilon_1, \varepsilon_2)$ -correct algorithm  $\mathcal{A}$  where  $\delta \in (0, 0.1)$ ,  $\varepsilon_1 > 0$ ,  $\varepsilon_2 > 0$ . Then for any  $n > 0$ , there exists infinitely many instances of the AIALO problem with unknown- $\mathbf{b}$  with  $n$  variables with objective function  $\|\mathbf{c}\|_\infty = 1$  such that  $\mathcal{A}$  must draw at least*

$$\Omega(n \ln(1/\delta) \cdot \max\{\varepsilon_1, \varepsilon_2\}^{-2})$$

samples in expectation on each of them.

The idea of the lower bound (proof in Appendix C.1) is that in the worst case, an algorithm must accurately estimate at least all  $n$  binding constraints (in general with  $n$  variables, up to  $n$  constraints bind at the optimal solution). It remains open whether we can get a tighter lower bound which also captures the difficulty of ruling out non-binding constraints.

#### 4.1 ELLIPSOID-UCB ALGORITHM

**Background.** The standard ellipsoid algorithm for linear programming begins with an ellipsoid  $\mathcal{E}^{(0)}$  known to contain the optimal solution. Then, it checks two cases: (1) The center of this ellipsoid  $\mathbf{x}^{(0)}$  is feasible, or (2) it is not feasible. If (2), say it violates constraint  $i$ , then the algorithm considers the halfspace defined by the constraint  $\mathbf{A}_i \mathbf{x}^{(0)} \leq b_i$ . If (1), the algorithm considers the halfspace defined by the “constraint”  $\mathbf{c}^T \mathbf{x} \geq \mathbf{c}^T \mathbf{x}^{(0)}$ , as the optimal solution must satisfy this constraint. In either case, it updates to a new ellipsoid  $\mathcal{E}^{(1)}$  defined as the minimal ellipsoid containing the intersection of  $\mathcal{E}^{(0)}$  with the halfspace under consideration.

The obstacle is that, now,  $\mathbf{b}$  is initially unknown. A first observation is that we only need to find a single violated constraint, so there may be no need to sample most parameters at a given round. A second observation is that it suffices to find the **most violated** constraint. This can be beneficial as it may require only a few samples to find the most violated constraint; and in the event that no constraint is violated, we still need to find an upper bound on “closest to violated” constraint in order to certify that no constraint is violated.

To do so, we draw inspiration from algorithms for *bandits* problems (whose details are not important to this paper). Suppose we have  $m$  distributions with means  $\mu_1, \dots, \mu_m$  and variances  $\sigma_1^2, \dots, \sigma_m^2$ , and we wish to find the largest  $\mu_i$ . After drawing a few samples from each distribution, we obtain estimates  $\hat{\mu}_i$  along with confidence intervals given by tail bounds. Roughly, an “upper confidence bound” (UCB) algorithm (see *e.g.* Jamieson and Nowak [2014]) for finding  $\max_i \mu_i$  proceeds by always sampling the  $i$  whose upper confidence bound is the highest.

We therefore will propose a UCB-style approach to doing so, but with the advantage that we can re-use any samples from earlier stages of the ellipsoid algorithm.

**Algorithm and results.** Ellipsoid-UCB is given in Algorithm 1. At each round  $k = 1, 2, \dots$ , we choose the center point  $\mathbf{x}^{(k)}$  of the current ellipsoid  $\mathcal{E}^{(k)}$  and call the subroutine Algorithm 2 to draw samples and check for

violated constraints. We use the result of the oracle to cut the current space exactly as in the standard ellipsoid method, and continue.

Some notation:  $t$  is used to track the total number of samples drawn (from all parameters) and  $T_i(t)$  denotes the number of samples of  $b_i$  drawn up to “time”  $t$ . The average of these samples is:

**Definition 4.1.** Let  $X_{i,s}$  denote the  $s$ -th sample of  $b_i$  and let  $T_i(t)$  denote the number of times  $b_i$  is sampled in the first  $t$  samples. Define  $\hat{b}_{i,T_i(t)} = \sum_{s=1}^{T_i(t)} X_{i,s} / T_i(t)$  to be the empirical mean of  $b_i$  up to “time”  $t$ .

---

#### Algorithm 1 Modified ellipsoid algorithm

---

Let  $\mathcal{E}^{(0)}$  be the initial ellipsoid containing the feasible region.  
 Draw one sample for each  $b_i$ ,  $i \in [m]$ .  
 Let  $k = 0$  and  $t = m$ .  
 Let  $T_i(t) = 1$  for all  $i$ .  
**while** stopping criterion is not met<sup>5</sup> **do**  
 Let  $\mathbf{x}^{(k)}$  be the center of  $\mathcal{E}^{(k)}$   
 Call UCB method to get constraint  $i$  or “feasible”  
**if**  $\mathbf{x}^{(k)}$  is feasible **then**  
 $\mathbf{x} \leftarrow \mathbf{x}^{(k)}$  if  $\mathbf{x}$  not initialized or  $\mathbf{c}^T \mathbf{x}^{(k)} > \mathbf{c}^T \mathbf{x}$ .  
 $\mathbf{y} \leftarrow -\mathbf{c}$   
**else**  
 $\mathbf{y} \leftarrow \mathbf{A}_i^T$   
**end if**  
 Let  $\mathcal{E}^{(k+1)}$  be the minimal ellipsoid that contains  $\mathcal{E}^{(k)} \cap \{\mathbf{p} : \mathbf{y}^T \mathbf{p} \leq \mathbf{y}^T \mathbf{x}^{(k)}\}$   
 Let  $k \leftarrow k + 1$   
**end while**  
 Output  $\mathbf{x}$  or “failure” if it was never set.

---

The performance of the algorithm is measured by how many samples (observations) it needs to draw. To state our theoretical results, define  $V_i(k) = \mathbf{A}_i \mathbf{x}^{(k)} - b_i$  to be the amount by which the  $i$ -th constraint is violated by  $\mathbf{x}^{(k)}$ , and  $V^*(k) = \max_i V_i(k)$ . Define  $gap_{i,\varepsilon}(k) = \max\{|V_i(k)|, V^*(k) - V_i(k), \varepsilon\}$  and  $\Delta_{i,\varepsilon} = \min_k gap_{i,\varepsilon}(k)$ .

**Theorem 4.2** (Ellipsoid-UCB algorithm). *The Ellipsoid-UCB algorithm is  $(\delta, \varepsilon_1, \varepsilon_2)$ -correct and with probability  $1 - \delta$ , draws at most the following number of samples:*

$$O\left(\sum_{i=1}^m \frac{\sigma_i^2}{\Delta_{i,\varepsilon_2/2}^2} \log \frac{m}{\delta} + \sum_{i=1}^m \frac{\sigma_i^2}{\Delta_{i,\varepsilon_2/2}^2} \log \log \left(\frac{\sigma_i^2}{\Delta_{i,\varepsilon_2/2}^2}\right)\right).$$

*Specifically, the number of samples used for  $b_i$  is at most  $\frac{\sigma_i^2}{\Delta_{i,\varepsilon_2/2}^2} \left(\log(m/\delta) + \log \log(\sigma_i^2/\Delta_{i,\varepsilon_2/2}^2)\right)$ .*

---

<sup>5</sup>Our stopping criterion is exactly the same as in the standard ellipsoid algorithm, for which there are a variety of possible criteria that work. In particular, one is  $\sqrt{\mathbf{c}^T \mathbf{P}^{-1} \mathbf{c}} \leq \min\{\varepsilon_1, \varepsilon_2\}$ , where  $\mathbf{P}$  is the matrix corresponding to ellipsoid  $\mathcal{E}^{(k)}$  as discussed above.

---

**Algorithm 2** UCB-method

---

Input  $\mathbf{x}^{(k)}$ Output either index  $j$  of a violated constraint, or “feasible”.Set  $\delta' = \left(\frac{\delta}{20m}\right)^{2/3}$ **loop**

1. Let
- $j$
- be the constraint with the largest index,

$$j = \arg \max_i \mathbf{A}_i \mathbf{x}^{(k)} - \widehat{b}_{i, T_i(t)} + U_i(T_i(t)),$$

where  $U_i(s) = 3\sqrt{2\sigma_i^2 \log(\log(3s/2)/\delta')/s}$  and  $\widehat{b}_{i, T_i(t)}$  as in Definition 4.1.

2. If  $\mathbf{A}_j \mathbf{x}^{(k)} - \widehat{b}_{j, T_j(t)} - U_j(T_j(t)) > 0$  return  $j$ .
3. If  $\mathbf{A}_j \mathbf{x}^{(k)} - \widehat{b}_{j, T_j(t)} + U_j(T_j(t)) < 0$  return “feasible”.
4. If  $U_j(T_j(t)) < \varepsilon_2/2$  return “feasible”.
5. Let  $t \leftarrow t + 1$
6. Draw a sample of  $b_j$ .
7. Let  $T_j(t) = T_j(t-1) + 1$ .
8. Let  $T_i(t) = T_i(t-1)$  for all  $i \neq j$ .

**end loop**

---

*Proof Sketch:* Define event  $\mathcal{A}$  to be the event that  $|\widehat{b}_{i,s} - b_i| \leq U_i(s)$  for all  $s$  and  $i \in [m]$ . According to Lemma 3 in Jamieson et al. [2014],  $\mathcal{A}$  holds with probability at least  $1 - \delta$ .

**Correctness:** Conditioning on event  $\mathcal{A}$  holds, our UCB method will only return a constraint that is violated (line 2) and when it returns “feasible”, no constraint is violated more than  $\varepsilon_2$  (line 3 and 4).

**Number of samples:** We bound the number of samples used on each constraint separately. Consider a fixed ellipsoid iteration  $k$  in which UCB method is given input  $\mathbf{x}^{(k)}$ , the key idea is to prove that if  $b_i$  is sampled in this iteration at “time”  $t$ ,  $U_i(T_i(t))$  should be larger than  $\text{gap}_{i, \varepsilon_2/2}(k)$ . This gives an upper bound of  $T_i(t)$ . Taking the maximum of them, we get the final result.  $\square$

**Discussion.** To understand the bound, suppose for simplicity that each  $\sigma_i = 1$ . We observe that the first term will dominate in all reasonable parameter settings, so we can ignore the second summation in this discussion.

Next, note that each term in the sum reflects a bound on how many times constraint  $i$  must be sampled over the course of the algorithm. This depends inversely on  $\Delta_{i, \varepsilon_2/2}$ , which is a minimum over all stages  $k$  of the “precision” we need of constraint  $i$  at stage  $k$ . We only need a very precise estimate if both of the following conditions are satisfied: (1)  $|V_i(k)|$  is small, meaning that the ellipsoid center  $\mathbf{x}^{(k)}$  is very close to binding constraint  $i$ ; (2) There is no other constraint that is significantly violated, meaning that  $i$  is very close to the most-violated

constraint for  $\mathbf{x}^{(k)}$  if any. Because this is unlikely to happen for most constraints, we expect  $\Delta_{i, \varepsilon_2/2}$  to generally be large (leading to a good bound), although we do not have more precise theoretical bounds. The only constraints where we might expect  $\Delta_{i, \varepsilon_2/2}$  to be small are the binding constraints, which we expect to come close to satisfying the above two conditions at some point. Indeed, this seems inevitable for any algorithm, as we explore in our experiments.

**Comparison to static approach.** Again suppose each  $\sigma_i = 1$  for simplicity. Note that each  $\Delta_{i, \varepsilon_2/2} \geq \varepsilon_2/2$ . This implies that our bound is always better than  $O\left(\frac{m \log(m/\delta)}{\varepsilon_2^2}\right)$ , ignoring the dominated second term.

The static approach is to measure each  $b_i$  with enough samples to obtain a good precision so that relaxed feasibility can be satisfied with high probability, then solve the linear program using the estimated constraints. This uses  $\frac{4m \log(m/\delta)}{\varepsilon_2^2}$  samples. (This number comes from using tail bounds to ensure good precision is achieved on every  $b_i$ .)

Therefore, the UCB-Ellipsoid algorithm dominates the static approach up to some constant factors and can show dramatic instance-wise improvements. Indeed, in some simple cases, such as the number of variables equal to the number of constraints, we do not expect any algorithm to be able to improve over the static approach. However, a nice direction for future work is to show that, if  $m$  is very large compared to  $n$ , then the UCB-Ellipsoid algorithm (or some other algorithm) is guaranteed to asymptotically improve on the static approach.

## 5 UNKNOWN OBJECTIVE FUNCTION

In this section, we consider the *unknown-c case*. Here, every parameter of the objective  $\mathbf{c}$  is initially unknown, and all other parameters are initially known. Geometrically, the algorithm is initially given an exact description of the feasible polytope, in the form of  $\mathbf{A}\mathbf{x} \leq \mathbf{b}$  and  $\mathbf{x} \geq 0$ , but no information about the “direction” of the objective.

Because the constraints are known exactly, we focus on exact feasibility in this setting, i.e.  $\varepsilon_2 = 0$ . We also focus on an information-theoretic understanding of the problem, and produce an essentially optimal but computationally inefficient algorithm. We assume that there is a unique optimal solution  $\mathbf{x}^*$ ,<sup>6</sup> and consider the problem of

---

<sup>6</sup>If we only aim for a  $\varepsilon_1$ -suboptimal solution, we can terminate our algorithm when  $\varepsilon^{(r)}$  (defined in Line 5 of Algorithm 3) becomes smaller than  $\varepsilon_1/2$ , such that the algorithm no longer requires the best point to be unique.

finding an exact optimal solution with confidence  $\delta$  (i.e., a  $\delta$ -correct algorithm). We also make the simplifying assumption that each parameter’s distribution is a Gaussian of variance 1 (in particular is 1-subgaussian). Our results can be easily extend to the general case.

Our approaches are based on the techniques used in [Chen et al. \[2017\]](#), but address a different class of optimization problems. We thus use the same notations as in [Chen et al. \[2017\]](#). We first introduce a function  $Low(\mathcal{I})$  that characterizes the sample complexity required for an LP instance  $\mathcal{I}$ . The function  $Low(\mathcal{I})$  is defined by the solution of a convex program. We then give an instance-wise lower bound in terms of the  $Low(\mathcal{I})$  function and the failure probability parameter  $\delta$ . We also formulate a worst-case lower bound of the problem, which is polynomially related to the instance-wise lower bound. Finally, we give an algorithm based on successive elimination that matches the worst-case lower bound within a factor of  $\ln(1/\Delta)$ , where  $\Delta$  is the gap between the objective function value of the optimal extreme point ( $\mathbf{x}^*$ ) and the second-best.

## 5.1 LOWER BOUNDS

The function  $Low(\mathcal{I})$  is defined as follows.

**Definition 5.1** ( $Low(\mathcal{I})$ ). *For any instance  $\mathcal{I}$  of AIALO (or more generally, for any linear program), we define  $Low(\mathcal{I}) \in \mathbb{R}$  to be the optimal solution to the following convex program.*

$$\begin{aligned} \min_{\tau} \quad & \sum_{i=1}^n \tau_i & (3) \\ \text{s.t.} \quad & \sum_{i=1}^n \frac{(s_i^{(k)} - x_i^*)^2}{\tau_i} \leq \left( \mathbf{c}^T(\mathbf{x}^* - \mathbf{s}^{(k)}) \right)^2, \forall k \\ & \tau_i \geq 0, \forall i \end{aligned}$$

Here  $\mathbf{x}^*$  is the optimal solution to the LP in  $\mathcal{I}$  and  $\mathbf{s}^{(1)}, \dots, \mathbf{s}^{(k)}$  are the extreme points of the feasible region  $\{\mathbf{x} : \mathbf{Ax} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$ .

For intuition about  $Low(\mathcal{I})$ , consider a thought experiment where we are given an extreme point  $\mathbf{x}^*$ , and we want to check whether or not  $\mathbf{x}^*$  is the optimal solution using as few samples as possible. Given our empirical estimate  $\hat{\mathbf{c}}$  we would like to have enough samples so that with high probability, for each  $\mathbf{s}^{(k)} \neq \mathbf{x}^*$ , we have

$$\hat{\mathbf{c}}^T(\mathbf{x}^* - \mathbf{s}^{(k)}) > 0 \iff \mathbf{c}^T(\mathbf{x}^* - \mathbf{s}^{(k)}) > 0.$$

This will hold by a standard concentration bound (Lemma D.2) if enough samples of each parameter are drawn; in particular, “enough” is given by the  $k$ -th constraint in (3).

**Theorem 5.1** (Instance lower bound). *Let  $\mathcal{I}$  be an instance of AIALO in the unknown- $\mathbf{c}$  case. For  $0 < \delta < 0.1$ , any  $\delta$ -correct algorithm  $\mathcal{A}$  must draw*

$$\Omega(Low(\mathcal{I}) \ln \delta^{-1})$$

*samples in expectation on  $\mathcal{I}$ .*

We believe that it is unlikely for an algorithm to match the instance-wise lower bound without knowing the value of  $\mathbf{c}$  and  $\mathbf{x}^*$  in the definition of  $Low(\mathcal{I})$ . To formally prove this claim, for any  $\delta$ -correct algorithm  $\mathcal{A}$ , we construct a group of LP instances that share the same feasible region  $\mathbf{Ax} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}$  but have different objective functions and different optimal solutions. We prove that  $\mathcal{A}$  will have unmatched performance on at least one of these LP instances.

Our worst-case lower bound can be stated as follows.

**Theorem 5.2** (Worst-case lower bound for unknown  $\mathbf{c}$ ). *Let  $n$  be a positive integer and  $\delta \in (0, 0.1)$ . For any  $\delta$ -correct algorithm  $\mathcal{A}$ , there exists an infinite sequence of LP instances with  $n$  variables,  $\mathcal{I}_1, \mathcal{I}_2, \dots$ , such that  $\mathcal{A}$  takes*

$$\Omega \left( Low(\mathcal{I}_k) (\ln |S_k^{(1)}| + \ln \delta^{-1}) \right)$$

*samples in expectation on  $\mathcal{I}_k$ , where  $S_k^{(1)}$  is the set of all extreme points of the feasible region of  $\mathcal{I}_k$ , and  $Low(\mathcal{I}_k)$  goes to infinity.*

## 5.2 SUCCESSIVE ELIMINATION ALGORITHM

Before the description of the algorithm, we first define a function  $LowAll(S, \varepsilon, \delta)$  that indicates the number of samples we should take for each  $c_i$ , such that the difference in objective value between any two points in  $S$  can be estimated to an accuracy  $\varepsilon$  with probability  $1 - \delta$ . Define  $LowAll(S, \varepsilon, \delta)$  to be the optimal solution of the following convex program,

$$\begin{aligned} \min_{\tau} \quad & \sum_{i=1}^n \tau_i & (4) \\ \text{s.t.} \quad & \sum_{i=1}^n \frac{(x_i - y_i)^2}{\tau_i} \leq \frac{\varepsilon^2}{2 \ln(2/\delta)}, \forall \mathbf{x}, \mathbf{y} \in S \\ & \tau_i \geq 0, \forall i. \end{aligned}$$

Our algorithm starts with a set  $S^{(1)}$  that contains all extreme points of the feasible region  $\{\mathbf{x} : \mathbf{Ax} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$ , which is the set of all possible optimal solutions. We first draw samples so that the difference between each pairs in  $S^{(1)}$  is estimated to accuracy  $\varepsilon^{(1)}$ . Then we delete all points that are not optimal with high probability. In the next iteration, we halve the accuracy

$\varepsilon^{(2)} = \varepsilon^{(1)}/2$  and repeat the process. The algorithm terminates when the set contains only one point.

---

**Algorithm 3** A successive elimination algorithm

---

- 1:  $S^{(1)} \leftarrow$  set of all extreme points of feasible region  $\{\mathbf{x} : \mathbf{Ax} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$
  - 2:  $r \leftarrow 1$
  - 3:  $\lambda \leftarrow 10$
  - 4: **while**  $|S^{(r)}| > 1$  **do**
  - 5:    $\varepsilon^{(r)} \leftarrow 2^{-r}, \delta^{(r)} \leftarrow \delta/(10r^2|S^{(1)}|^2)$
  - 6:    $(t_1^{(r)}, \dots, t_n^{(r)}) \leftarrow \text{LowAll}(S^{(r)}, \varepsilon^{(r)}/\lambda, \delta^{(r)})$
  - 7:   Sample  $c_i$  for  $t_i^{(r)}$  times. Let  $\hat{c}_i^{(r)}$  be its empirical mean
  - 8:   Let  $\mathbf{x}^{(r)}$  be the optimal solution in  $S^{(r)}$  with respect to  $\hat{\mathbf{c}}^{(r)}$
  - 9:   Eliminate the points in  $S^{(r)}$  that are  $\varepsilon^{(r)}/2 + 2\varepsilon^{(r)}/\lambda$  worse than  $\mathbf{x}^{(r)}$  when the objective function is  $\hat{\mathbf{c}}^{(r)}$ ,
 
$$S^{(r+1)} \leftarrow \{\mathbf{x} \in S^{(r)} : \langle \mathbf{x}, \hat{\mathbf{c}}^{(r)} \rangle \geq \langle \mathbf{x}^{(r)}, \hat{\mathbf{c}}^{(r)} \rangle - \varepsilon^{(r)}/2 - 2\varepsilon^{(r)}/\lambda\} \quad (5)$$
  - 10:    $r \leftarrow r + 1$
  - 11: **end while**
  - 12: Output  $\mathbf{x} \in S^{(r)}$
- 

The algorithm has the following sample complexity bound.

**Theorem 5.3** (Sample complexity of Algorithm 3). *For the AIALO with unknown-c problem, Algorithm 3 is  $\delta$ -correct and, on instance  $\mathcal{I}$ , with probability  $1 - \delta$  draws at most the following number of samples:*

$$O\left(\text{Low}(\mathcal{I}) \ln \Delta^{-1} (\ln |S^{(1)}| + \ln \delta^{-1} + \ln \ln \Delta^{-1})\right),$$

where  $S^{(1)}$  is the set of all extreme points of the feasible region and  $\Delta$  is the gap in objective value between the optimal extreme point and the second-best,

$$\Delta = \max_{\mathbf{x} \in S^{(1)}} \mathbf{c}^T \mathbf{x} - \max_{\mathbf{x} \in S^{(1)} \setminus \mathbf{x}^*} \mathbf{c}^T \mathbf{x}.$$

*Proof Sketch:* We prove that conditioning on a good event  $\mathcal{E}$  that holds with probability at least  $1 - \delta$ , the algorithm will not delete the optimal solution and will terminate before  $\lceil \log(\Delta^{-1}) \rceil + 1$  iterations. Then we bound the number of samples used in iteration  $r$  by showing that the optimal solution of  $\text{Low}(\mathcal{I})$  times  $\alpha^{(r)} = 32\lambda^2 \ln(2/\delta^{(r)})$  is a feasible solution of the convex program that defines  $\text{LowAll}(S^{(r)}, \varepsilon^{(r)}/\lambda, \delta^{(r)})$ . Therefore the number of samples used in iteration  $r$  is no more than  $\alpha^{(r)} \text{Low}(\mathcal{I})$ .  $\square$

This matches the worst-case lower bound within a problem-dependent factor  $\ln(1/\Delta)$ . Notice, however, that the size of  $|S^{(1)}|$  can be exponentially large, and so

is the size of the convex program (4). So Algorithm 3 is computationally inefficient if implemented straightforwardly, and it remains open whether the algorithm can be implemented in polynomial time or an alternative algorithm with similar sample complexity and better performance can be found.

## 6 EXPERIMENTS

In this section, we investigate the empirical number of samples used by Ellipsoid-UCB algorithm for the unknown-b case of AIALO. We fix  $\delta = 0.1$  and focus on the impact of the other parameters<sup>7</sup>, which are more interesting.

We compare three algorithms on randomly generated LP problems. The first is Ellipsoid-UCB. The second is the naive “static approach”, namely, draw  $4\sigma^2 \log(m/\delta)/\varepsilon_2^2$  samples of each constraint, then solve the LP using estimated means of the parameters. (This is the same approach mentioned in the previous section, except that previously we discussed the case  $\sigma = 1$  for simplicity.) The third is designed to intuitively match the lower bound of Theorem 4.1: Draw  $4\sigma^2 \log(d/\delta)/\varepsilon_2^2$  samples of each of only the binding constraints, where there are  $d$  of them, then solve the LP using estimated means of the  $b_i$ . (For a more fair comparison, we use the same tail bound to derive the number of samples needed for high confidence, so that the constants match more appropriately.)

We generate instances as follows.  $\mathbf{c}$  is sampled from  $[-10, 10]^n$  uniformly at random.  $\mathbf{b}$  is uniformly drawn from  $[0, 10]^n$ . Each  $\mathbf{A}_i$  is sampled from unit ball uniformly at random. Notice that the choice of  $b_i \geq 0$  guarantees feasibility because the origin is always a feasible solution. We also add additional constraints  $x_i \leq 500$  to make sure that the LP generated is bounded. When the algorithm makes an observation, a sample is drawn from Gaussian distribution with variance  $\sigma^2$ .

In Figure 1, each algorithm’s number of samples (average of 50 instances) is plotted as function of different parameters. The number of samples used by Ellipsoid-UCB is proportional to  $n, \sigma^2$  and  $\varepsilon^{-2}$ . However, it does not change much as  $m$  increases.<sup>8</sup> This will not be surprising if ellipsoid uses most of its samples on binding constraints, just as the lower bound does. This is shown in Table 1, where it can be seen that Ellipsoid-UCB re-

<sup>7</sup>99.5 percent of the outputs turn out to satisfy relaxed feasibility and relaxed optimality.

<sup>8</sup>Indeed, the standard ellipsoid algorithm for linear programming requires a number of iterations that is bounded in terms of the number of variables regardless of the number of constraints.

quires much fewer samples of non-binding constraints than binding constraints.

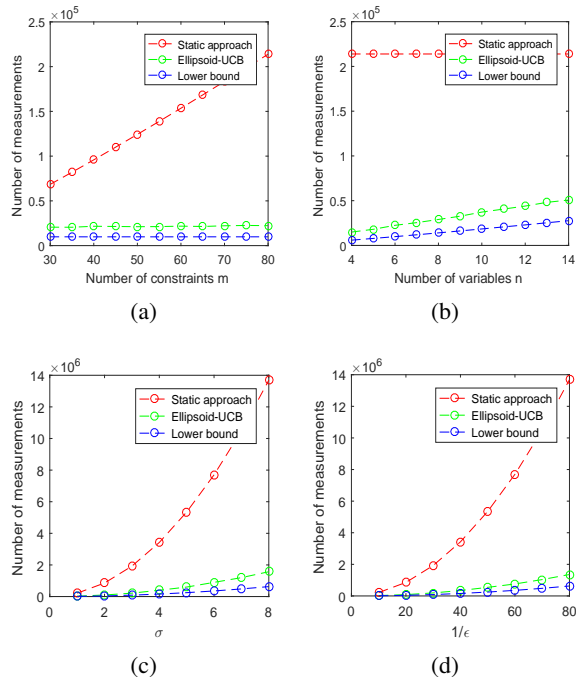

Figure 1: Number of samples as we vary  $m$ ,  $n$ ,  $\sigma$  and  $1/\epsilon$ . Every data point is the mean of 50 randomly drawn problem instances. The baseline parameters are  $m = 80$ ,  $n = 6$ ,  $\sigma = 1$ ,  $\epsilon_1 = \epsilon_2 = 0.1$ . In figure (d),  $\epsilon_1 = \epsilon_2 = \epsilon$ .

	Binding	Non-binding
Static approach	2674	2674
Ellipsoid-UCB	3325	11.7
Lower bound	1476	0

Table 1: Average number of samples used per binding constraint and per non-binding constraint. Numbers are average from 100 trials. Here,  $m = 80$ ,  $n = 4$ ,  $\sigma = 1$ ,  $\epsilon_1 = \epsilon_2 = 0.1$ .

Figure 2 addresses the variance in the number of samples drawn by Ellipsoid-UCB by plotting its empirical CDF over 500 random trials. The horizontal axis is the ratio of samples required by Ellipsoid-UCB to those of the lower bound. For comparison, we also mention  $R$ , the ratio between the performances of the static approach and the lower bound. These results suggest that the variance is quite moderate, particularly when the total number of samples needed grows.

## 7 DISCUSSION AND FUTURE WORK

One question is whether we can extend our results to situations when the constraint matrix  $\mathbf{A}$  is unknown as well as  $\mathbf{b}$ . The goal is again to solve the problem with few

Figure 2: Empirical cumulative distribution function of Ellipsoid-UCB’s number of samples, in units of the “lower bound”, over 500 trials. Note that the lower bound varies when parameters change.  $R = \frac{m \log(m)}{d \log(d)}$  is the ratio between the number of samples used by static approach and lower bound.

total observations. This extended model will allow us to study a wider range of problems. For example, the sample complexity problem in Reinforcement Learning studied by Kakade et al. [2003], Wang [2017], Chen and Wang [2016] is a special case of our AIALO problem with unknown  $\mathbf{A}$  and  $\mathbf{b}$ .

A second extension to the model would allow algorithms access to varying qualities of samples for varying costs. For instance, perhaps some crowd workers can give very low-variance estimates for high costs, while some workers can give cheaper estimates, but have larger variance. In this case, some preliminary theoretical investigations suggest picking the worker that minimizes the product (price)(variance). A direction for future work is for the algorithm to select samples dynamically depending on the payment-variance tradeoffs currently available. A final interested direction is a more mechanism-design approach where the designer collects bids from the agents and selects a winner whose data is used to update the algorithm.

## Abstract

Meta learning algorithms are effective at obtaining meta models with the capability of solving new tasks quickly. However, they critically require sufficient tasks for meta model training and the resulted model can only solve new tasks similar to the training ones. These limitations make them suffer performance decline in presence of insufficiency of training tasks in target domains and task heterogeneity—the source (model training) tasks presents different characteristics from target (model application) tasks. To overcome these two significant limitations of existing meta learning algorithms, we introduce the cross-domain meta learning framework and propose a new transferable meta learning (TML) algorithm. TML performs meta task adaptation jointly with meta model learning, which effectively narrows divergence between source and target tasks and enables transferring source meta-knowledge to solve target tasks. Thus, the resulted transferable meta model can solve new learning tasks in new domains quickly. We apply the proposed TML to cross-domain few-shot classification problems and evaluate its performance on multiple benchmarks. It performs significantly better and faster than well-established meta learning algorithms and fine-tuned domain-adapted models.

## 1 Introduction

Meta learning aims at obtaining a model that can capture common characteristics across different learning tasks, such that the learned model can adapt to new tasks quickly. Recently, various meta learning methods (Hariharan & Girshick, 2016; Koch et al., 2015; Lake

et al., 2013; Ravi & Larochelle, 2016; Santoro et al., 2016b; Vinyals et al., 2016) have been developed to solve multiple challenging problems, *e.g.*, few-shot classification (Fei-Fei et al., 2006), and achieved promising performance. Those methods devise different approaches to train a meta model that can be applied to new tasks via simple fine-tuning. In contrast to conventional supervised learning methods that suffer poor generalization performance, meta learning methods explicitly optimize the model generalization ability to new tasks and therefore achieve better performance.

Under the standard meta learning paradigm, the meta model is trained on a meta-training dataset consisting of sufficient training tasks and evaluated on another dataset with novel tasks. However, existing meta learning methods usually assume the training and test tasks have similar characteristics. For instance, for few-shot classification tasks, the samples of different tasks are usually from splits of the *same* dataset (Finn et al., 2017; Hariharan & Girshick, 2016; Vinyals et al., 2016). This actually deviates from the real world scenarios where a pre-trained meta model usually needs to be applicable to heterogeneous tasks in different domains. Moreover, constructing the meta-training set demands sufficiently many labeled examples, which are usually not available in practice considering the “few-shot” nature of meta learning problems. Existing meta learning methods generally ignore such discrepancy between the traditional meta learning paradigm and realistic application scenarios, leading to poor generalization ability of the obtained model to new tasks in new domains.

To extend applicability of meta learning methods, we propose a new framework to utilize data from another (source) domain to construct the meta-training set and aim to develop a new meta learning algorithm to learn a meta model from the source domain that can be directly applied to target domains, without requiring further meta-training. We term this new framework as the cross-domain meta learning. See Fig. 1 for an exam-

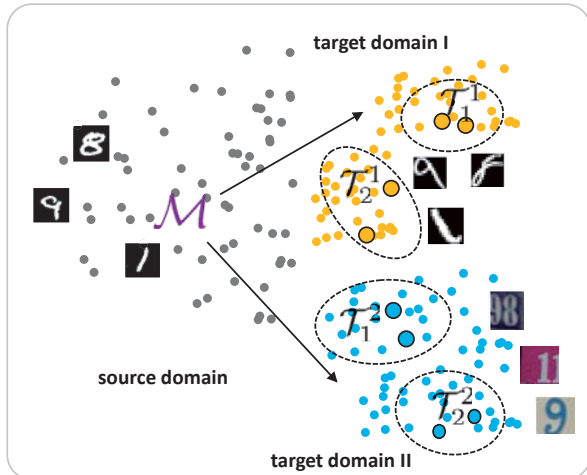

Figure 1: Illustration of the cross-domain meta learning. The pre-trained meta learning model  $\mathcal{M}$  in the source domain is applied to solve new learning tasks  $\mathcal{T}_1^1, \dots, \mathcal{T}_2^2$  in different target domains. The target domains have too few labeled samples to construct sufficient meta-training tasks. Our proposed TML algorithm solves this problem by learning a transferable meta model which can be directly applied to target tasks.

ple. Developing cross-domain meta learning algorithms is difficult due to the scarcity of meta-training examples in target domains and task heterogeneity caused by domain shift. As far as we know, none of existing meta learning methods can deal with these challenging issues.

To address the above challenges, we propose a novel transferable meta learning (TML) algorithm, which provides a meta model capable of fast adapting to new learning tasks in different domains via a few simple gradient descent fine-tuning. Inspired by state-of-the-art meta learning methods (Finn et al., 2017; Vinyals et al., 2016), TML introduces a new learning scheme. It first organizes available training data, very few of which are from target domains, to form a collection of cross-domain meta learning tasks. Taking these tasks as training examples, TML explicitly optimizes the capability of “learning to fast adapt” of the meta model. By taking sensitivity of model parameters to different tasks and domain shift as the joint learning objective, TML effectively trains the meta model to learn task representations robust to domain-shift, enables cross-domain meta-knowledge transfer and makes the model fast adaptable to novel target tasks of different characteristics from the source ones.

TML trains a meta model in two alternating phases. In *meta learning*, TML optimizes the meta model to minimize the loss over all its task-specific fine-tuned models, *i.e.*, minimizing the meta loss. In *meta adaptation*, TML

reinforces the meta model by adapting task representations to minimize domain divergence and thus facilitates meta-knowledge transfer across heterogeneous tasks. We use a domain discriminative loss for measuring domain divergence. Through these two phases, TML effectively minimizes the source domain meta loss and domain divergence jointly, which together serve as an accurate surrogate for learning to minimize the meta loss in the target domain. Therefore, a meta model trained by TML is readily applicable to solving new tasks in target domains.

We apply and evaluate TML for cross-domain few-shot learning problems, on multiple datasets with various domain shift issues. The results demonstrate that TML surpasses fine-tuning based methods and other meta learning models significantly in terms of few-shot classification accuracy and adaptation speed. To our best knowledge, TML is the first one that considers the illness of current meta learning frameworks and explicitly pursues generalization across heterogeneous tasks in different domains. It substantially extends existing meta learning algorithms and mitigates the gap between meta learning frameworks and realistic application scenarios.

## 2 Related Work

**Meta Learning** Recently, some meta learning (Koch et al., 2015; Ravi & Larochelle, 2016; Santoro et al., 2016b; Snell et al., 2017; Vinyals et al., 2016; Wang & Hebert, 2016) works are developed to solve the few-shot learning problems. A meta model is usually trained over a set of similar tasks to capture generalizable properties across tasks, such that it can fast adapt to new similar tasks. Several different strategies for designing meta-learning algorithms are adopted (Andrychowicz et al., 2016; Ravi & Larochelle, 2016). For instance, “learning to compare” aims to learn a comparison metric that can be used to find the most similar labeled sample for each unlabeled input (Koch et al., 2015; Mishra et al., 2017; Vinyals et al., 2016). Some meta learning methods adopt external memory to augment the model (Munkhdalai & Yu, 2017; Santoro et al., 2016a). For example, (Santoro et al., 2016a) builds a meta model upon a Neural Turing Machine (Graves et al., 2014), which encodes and writes labeled examples into the memory and retrieve relevant information from the memory for classifying an unlabeled sample. Differently, Model-Agnostic Meta-Learning (MAML) (Finn et al., 2017) tries to find a proper intermediate model, which can be fine-tuned for several steps to produce a task-specific model given very few samples. However, all these existing models assume that training and testing tasks have similar characteristics, and suffer performance decline in presence of task heterogeneity. Moreover, they all require suffi-

ciently many training tasks. Our proposed TML algorithm is the first one that tries to achieve fast adaptation to new meta learning tasks in presence of varying in the task characteristics in applied domains.

**Few-shot Learning** Few-shot learning (Fei-Fei et al., 2006; Hariharan & Girshick, 2016; Lake et al., 2013) is proposed to learn to recognize new categories with few examples. (Fei-Fei et al., 2006) provides a solution based on Bayesian inference over a pre-trained model to capture general knowledge from previously learned categories, whose generalization ability however is limited by heavy dependency on the relation between previously seen and new objects. Recently, (Hariharan & Girshick, 2016; Luo et al., 2017) propose to transfer intra-class features from base classes to new classes. This method achieves good performance on new examples while maintaining the accuracy on original training classes. But all these conventional few-shot learning methods require retraining the model from scratch when applied to new few-shot learning tasks with randomly assigned labels, thus are incapable of fast adapting to multiple new tasks.

**Domain Adaptation** Many works have been developed for domain adaptation learning (Ganin et al., 2016; Hoffman et al., 2013; Liu & Tuzel, 2016; Motiian et al., 2017a,b; Tzeng et al., 2015, 2017). Maximum Mean Discrepancy (MMD) Tzeng et al. (2014) measures the distribution difference between the source and target domains by computing norm of the mean feature difference between two domains. (Long et al., 2015; Sun & Saenko, 2016) have shown that combining MMD with popular deep learning models is effective. More recently, Generative Adversarial Network (GAN) (Goodfellow et al., 2014) based models have achieved remarkable success, *e.g.* Adversarial Discriminative Domain Adaptation (ADDA) (Tzeng et al., 2017) and CoGAN (Liu & Tuzel, 2016). ADDA adapts a well-learned source CNN by learning a target CNN that maps target-domain images into a feature space, where they are indistinguishable from the source feature space by the GAN discriminator. However, existing domain adaptation methods cannot be applied to solve meta learning tasks.

### 3 The Proposed Algorithm

Meta learning aims to learn a meta model that captures generalizable properties across tasks, such that the model can adapt to solving new similar tasks quickly. In this work, we consider the few-shot classification tasks in particular, which are widely adopted for evaluating meta learning methods. We first define the problem of meta learning for few-shot classification. Then we elaborate

on our target problem, cross-domain meta learning, and our proposed TML algorithm.

#### 3.1 Problem Definition

Let  $\mathcal{X}$  denote the input space and  $\mathcal{Y}$  be the label space. We are interested in meta learning for the  $N$ -category  $k$ -shot learning tasks, where only a small number of  $k$  annotated samples per category (*e.g.*,  $k \leq 5$ ) are available for training a classification model within each task.

Let  $f_\theta(\cdot): \mathcal{X} \rightarrow \mathcal{Y}$  denote the meta learning model with learnable parameter  $\theta$  which is optimized to solve the following few-shot learning tasks:

$$\mathcal{T} \triangleq \{ \underbrace{(x_1, y_1), \dots, (x_{Nk}, y_{Nk})}_{\text{training samples}}, \underbrace{(x_t, y_t)}_{\text{test samples}}, f_\theta, \ell \}. \quad (1)$$

More specifically, each task is to learn a specific classification model  $f_{\theta'}(\cdot)$  from only  $Nk$  training samples such that the following task-specific classification loss on test samples  $(x_t, y_t)$  can be minimized:

$$\mathcal{L}_{\mathcal{T}}(f_{\theta'}) \triangleq \ell(f_{\theta'}(x_t), y_t), \quad (2)$$

where  $\ell$  is the classification loss function.

Existing meta learning approaches generally learn a meta model  $f_\theta(\cdot)$  through meta-training over a collection of tasks  $\mathcal{T} \sim p(\mathcal{T})$  with similar distribution. In meta training, the meta model parameter  $\theta$  is learned to minimize the *meta loss* computed from all the training tasks:

$$\theta = \arg \min_{\theta} \sum_{i=1}^m \mathcal{L}_{\mathcal{T}_i}(f_{\theta'_i}), \mathcal{T}_i \sim p(\mathcal{T}), \quad (3)$$

where  $\theta'_i$  is derived from the meta model  $\theta$  through task-specific adaptation, *e.g.*, by fine-tuning  $\theta$  on training samples of task  $\mathcal{T}_i$ . When there are sufficiently many meta-training tasks  $\mathcal{T}_i$  from the same distribution  $p(\mathcal{T})$ , *i.e.*,  $m$  is sufficiently large, one can reliably obtain a well-performing meta model that can solve new task  $\mathcal{T}_t \sim p(\mathcal{T})$  with satisfactory task-specific loss.

However, in many realistic few-shot learning problems, only a few labeled data are available which are not sufficient to form many tasks for performing meta-training in Eqn. (3). Thus the resulted meta model would suffer from insufficient meta-training and would not generalize well to new tasks. In this work, we propose to address this problem by constructing a meta-training set from another (source) domain of different characteristics where rich labeled data are available. Despite being promising and fitting realistic scenarios better, such a method brings a cross-domain meta learning problem as defined below. This problem is challenging to existing meta learning

methods as they usually assume the meta-training and meta-test tasks are from the same distribution. We aim to solve the following problem in this work, whose solution would also bring significant practical benefits in extending application of meta learning models to other heterogeneous tasks in different domains.

**Definition 1** (Cross-domain Meta Learning). *Suppose there are two different datasets of  $\mathcal{X} \times \mathcal{Y}$  with domain shift in  $\mathcal{X}$ , called source data  $D_S$  and target data  $D_T$ , and  $D_T$  only provides very few labeled samples. We aim to learn a meta model  $f_\theta(\cdot)$  by leveraging the sufficiently many source data  $D_S$  and their formed meta-training tasks  $\mathcal{T}_i \in p_S(\mathcal{T})$ , such that the model can generalize well to new tasks  $\mathcal{T}_i \in p_T(\mathcal{T})$  in target dataset  $D_T$  with small task loss. Here  $p_T(\mathcal{T})$  is different from  $p_S(\mathcal{T})$  in terms of label space  $\mathcal{Y}$  and data distribution  $\mathcal{X}$ .*

Directly training a meta model via minimizing the meta loss (Eqn. (3)) in target dataset  $D_T$  is infeasible due to limited labeled data and consequently insufficient meta-training tasks. On the other hand, although the source domain data is enough for training a meta model, directly applying it to the target domain will suffer poor generalization performance due to domain shift (verified by experiments in Sec. 4). To address this problem, we aim to fully utilize cross-domain knowledge to learn a powerful meta model  $f_\theta$ , which is well prepared for fast adaptation to new few-shot learning tasks in target dataset  $D_T$ . To this end, we develop the transferable meta learning algorithm in this work.

### 3.2 Model-Agnostic Meta-Learning (MAML)

We develop our transferable meta learning (TML) algorithm from the state-of-the-art MAML algorithm (Finn et al., 2017). While we extend MAML here, our proposed idea is applicable to other meta-learning methods.

MAML solves above few-shot learning problems by learning the parameter  $\theta$  such that  $f_\theta$  can solve a new task rapidly via several gradient descent steps on few-shot task-related training examples. To this end, MAML forms a set of training tasks  $\mathcal{T} = \{\mathcal{T}_1, \dots, \mathcal{T}_m\}$ , where each task instantiates an  $N$ -category  $k$ -shot classification problem  $\mathcal{T}_i = \{(x_1^{(i)}, y_1^{(i)}), \dots, (x_{Nk}^{(i)}, y_{Nk}^{(i)}), (x_t^{(i)}, y_t^{(i)}), f_\theta, \ell\}$  as in Eqn. (1).

MAML fine-tunes the meta model  $f_\theta$  to a particular task  $\mathcal{T}_i$  by gradient descent:

$$\theta'_i \leftarrow \theta - \alpha \nabla \mathcal{L}_{\mathcal{T}_i}(f_\theta) \quad (4)$$

where  $\mathcal{L}_{\mathcal{T}_i}(f_\theta) = \frac{1}{Nk} \sum_{j=1}^{Nk} \ell(f_\theta(x_j^{(i)}), y_j^{(i)})$  is the task-related training loss and  $\alpha$  is a universal learning rate.

By treating each task as a training example, MAML optimizes meta model parameter  $\theta$  such that the total loss for the task-wise fine-tuned parameter  $\theta'_i$  over testing samples  $(x_t^{(i)}, y_t^{(i)})$  can be minimized:

$$\min_{\theta} \sum_{i=1}^m \mathcal{L}_{\mathcal{T}_i}(f_{\theta'}) = \sum_{i=1}^m \mathcal{L}_{\mathcal{T}_i}(f_{\theta - \alpha \nabla_{\theta} \mathcal{L}_{\mathcal{T}_i}(f_{\theta})}),$$

where  $\mathcal{L}_{\mathcal{T}_i}(f_{\theta'}) = \ell(f_{\theta'}(x_t^{(i)}), y_t^{(i)})$ , i.e., classification loss on the reserved testing samples. The meta parameter  $\theta$  is then updated by gradient descent  $\theta \leftarrow \theta - \beta \nabla_{\theta} \sum_{i=1}^m \mathcal{L}_{\mathcal{T}_i}(f_{\theta'})$ . The trained meta model  $f_\theta$  can be applied directly to a new similar  $N$ -category  $k$ -shot learning task through gradient descent fine-tuning in Eqn. (4) and performs remarkably well.

MAML inspires us in two aspects for solving few-shot learning problems. First, instead of training a single model on all available training data at once (which is a common practice in most few-shot learning methods (Fei-Fei et al., 2006; Hariharan & Girshick, 2016; Lake et al., 2013)), we should construct learning tasks exactly matching the testing case for model training, which is a more suitable learning scheme for obtaining strong generalization ability from few examples. Second, compared with optimizing the classification accuracy, optimizing the model adaptive capability to new tasks better fits the nature of few-shot learning.

Although MAML provides promising solutions to few-shot learning, its performance highly depends on the similarity of training and testing tasks. It cannot handle discrepancies among tasks—in particular the domain shift between source and target data we aim to address—and suffers performance decline.

### 3.3 Transferable Meta Learning Algorithm

Our proposed Transferable Meta Learning (TML) algorithm solves cross-domain meta learning problems by learning a meta model from the source data  $D_S$  along with a few *unlabeled* target data, which can fast adapt to various few-shot classification tasks in target data  $D_T$ . Beyond existing meta-learning algorithms (like MAML), TML entails the meta model with two-fold fast adaptation capability. First, the model can learn from few training examples fast through simple fine-tuning, solving the few-shot learning tasks. Second, the model can adapt to tasks in different domains, addressing the task heterogeneity issues caused by domain shift.

TML is developed following a simple intuition: the loss function computed in the source domain is expected to be a good indicator of the target loss when both tasks are similar. The main idea of TML is to learn

a meta model that is capable of adapting to new tasks fast and meanwhile learning domain-invariant representations such that source tasks can provide useful meta-knowledge for training models in target domains. To this end, we develop a new learning scheme and propose a novel meta model architecture. The meta model  $f_{\varphi,\theta}$  learned by TML includes two components, a domain-invariant representation learner  $f_{\varphi}$  parameterized by  $\varphi$  and a meta-classifier  $f_{\theta}$  with parameters  $\theta$ , as illustrated in Fig. 2. TML optimizes these two components jointly such that the domain divergence can be reduced in a way favorable for few-shot learning and facilitate cross-domain meta-knowledge transfer.

**TML Learning Scheme** We apply TML to train a meta model on a collection of source training tasks, with a new learning scheme suiting cross-domain meta learning. For notational simplicity, we use  $(\mathbf{x}_S, \mathbf{y}_S)$  and  $\mathbf{x}_T$  to collectively denote source data and unlabeled target data respectively, and let  $(\mathbf{x}_{t,S}, \mathbf{y}_{t,S})$  denote another source sample reserved for evaluating the loss in Eqn. (2). Then, we define a cross-domain few-shot learning task for TML as

$$\mathcal{T}_i \triangleq \{(\mathbf{x}_S^{(i)}, \mathbf{y}_S^{(i)}), (\mathbf{x}_{t,S}^{(i)}, \mathbf{y}_{t,S}^{(i)}), \mathbf{x}_T^{(i)}, f_{\varphi,\theta}, \ell\}, \quad (5)$$

which includes two model training steps. First, fine-tune the meta-classifier  $\theta$  and representation learner  $\varphi$  with few-shot source training samples  $(\mathbf{x}_S^{(i)}, \mathbf{y}_S^{(i)})$  by gradient descent:

$$\varphi'_i, \theta'_i \leftarrow (\varphi, \theta) - \alpha \nabla_{\varphi,\theta} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi,\theta}), \quad (6)$$

and evaluate classification loss on  $(\mathbf{x}_{t,S}^{(i)}, \mathbf{y}_{t,S}^{(i)})$  based on  $\ell$  as in Eqn. (2). Second, optimize representation learner  $\varphi$  to minimize distribution divergence (see below) between source data  $\mathbf{x}_S^{(i)}$  and target data  $\mathbf{x}_T^{(i)}$ . This new task formulation distinguishes TML from existing meta learning algorithms. TML explicitly meta-learns both few-shot classification and task adaptation.

When applying the meta model  $f_{\varphi,\theta}$  to few-shot learning tasks in target domain  $\mathcal{D}_T$ , we apply gradient descent to fine-tune the model parameters  $\varphi$  and  $\theta$  over the few labeled target data, following Eqn. (6).

**TML Algorithm** We explain how TML trains a meta model on the training tasks  $\{\mathcal{T}_i\}$  constructed as above, which alternates between two optimization sub-procedures, as illustrated in Fig. 2.

The first is *meta learning* step, where TML tries to learn a domain-specific meta-classifier  $\theta$  and representation learner  $\varphi$  such that fine-tuning over them can minimize

Figure 2: TML for meta model training. TML performs meta learning and task adaptation jointly to optimize the meta model (consisting of representation learner  $\varphi$  and classifier  $\theta$ ) and the discriminative model  $\omega$ .

the loss over source test data:

$$\begin{aligned} \min_{\varphi,\theta} \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i}) \\ = \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i}(f_{(\varphi - \alpha \nabla_{\varphi} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi,\theta}), (\theta - \alpha \nabla_{\theta} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi,\theta}))}) \end{aligned}$$

where the inner loss  $\mathcal{L}_{\mathcal{T}_i}(f_{\varphi,\theta})$  is the total cross-entropy loss over the training samples  $(\mathbf{x}_S^{(i)}, \mathbf{y}_S^{(i)})$  in task  $i$ :

$$\begin{aligned} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi,\theta}) = \sum_{(x_j, y_j) \in (\mathbf{x}_S^{(i)}, \mathbf{y}_S^{(i)})} y_j \log f_{\varphi,\theta}(x_j) \\ + (1 - y_j) \log(1 - f_{\varphi,\theta}(x_j)). \end{aligned} \quad (7)$$

The outer meta loss  $\mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i})$  is the cross-entropy loss defined on the task-specific testing samples  $(\mathbf{x}_{t,S}^{(i)}, \mathbf{y}_{t,S}^{(i)}) \in \mathcal{T}_i$  for the fine-tuned model after one gradient descent step  $f_{\varphi'_i, \theta'_i}$ :

$$\begin{aligned} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i}) = \sum_{(x_{t,S}, y_{t,S}) \in \mathcal{T}_i} y_{t,S} \log f_{\varphi'_i, \theta'_i}(x_{t,S}) \\ + (1 - y_{t,S}) \log(1 - f_{\varphi'_i, \theta'_i}(x_{t,S})). \end{aligned}$$

The involved meta model parameters are updated by gradient descent:

$$\begin{aligned} \varphi \leftarrow \varphi - \beta \nabla_{\varphi} \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i}), \\ \theta \leftarrow \theta - \beta \nabla_{\theta} \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i}). \end{aligned}$$

This meta learning step is similar to MAML but it decouples the representation learner  $\varphi$  and classifier  $\theta$  for developing the following meta adaptation learning.

The second step in TML is *meta adaptation* with a target to make the meta model fast adaptable to the target

domain  $\mathcal{D}_T$  which is different from the source  $\mathcal{D}_S$  used for extensive meta model training. In particular, TML trains the representation learner  $f_\varphi$  in this step such that it can be adapted through fine-tuning to minimize the distribution divergence between  $\mathcal{D}_T$  and  $\mathcal{D}_S$ , to alleviate domain-shift issues when applying the meta-classifier  $f_\theta$ . Specifically, we use a domain adversarial discriminative loss to measure divergence between domains  $\mathcal{D}_S$  and  $\mathcal{D}_T$ , in the feature space produced by the representation learner  $f_\varphi$ , inspired by (Ganin et al., 2016).

Formally, we use  $\mathcal{U}_S$  to denote the source feature space derived by passing source data  $\mathbf{x}_S$  through the representation learner  $f_\varphi$ . The target feature space  $\mathcal{U}_T \leftarrow \mathbf{x}_T : f_\varphi$  is derived similarly. A domain discriminator  $D_\omega$  parameterized by  $\omega$  is trained on tasks  $\mathcal{T}_i$  to distinguish whether a sample  $x$  is from  $\mathcal{U}_S$  or  $\mathcal{U}_T$ :

$$\omega = \arg \max \log D_\omega(f_\varphi(\mathbf{x}_S)) + \log(1 - D_\omega(f_\varphi(\mathbf{x}_T))),$$

where we give label 1 to the data from source domain and 0 otherwise. We use the negative cross-entropy loss of  $D_\omega$  as a measure over the domain divergence—a larger discriminative loss means the samples are indistinguishable w.r.t. domain shift, indicating a small domain divergence. The domain divergence is calculated as below, dependent on the meta model parameter  $\varphi$  and discriminator  $\omega$ :

$$d_{\varphi,\omega}(\mathcal{D}_S, \mathcal{D}_T) := -\mathbb{E}_{x_S \in \mathcal{D}_S} [\log D_\omega(f_\varphi(x_S))] - \mathbb{E}_{x_T \in \mathcal{D}_T} [\log(1 - D_\omega(f_\varphi(x_T)))].$$

In meta adaptation, TML learns  $\varphi$  and  $\omega$  jointly to minimize the domain divergence derived from samples provided in training tasks  $\mathcal{T}_i$ , *i.e.*,

$$d_{\varphi,\omega}(\mathcal{D}_S, \mathcal{D}_T; \mathcal{T}_i) := -\sum_{x_S \in \mathbf{x}_S^{(i)}} [\log D_\omega(f_\varphi(x_S))] - \sum_{x_T \in \mathbf{x}_T^{(i)}} [\log(1 - D_\omega(f_\varphi(x_T)))].$$

In all, the learning objective for TML is

$$\begin{aligned} \min_{\theta, \varphi} \max_{\omega} \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi'_i, \theta'_i}) - d_{\varphi,\omega}(\mathcal{D}_S, \mathcal{D}_T; \mathcal{T}_i), \\ \text{s.t. } \varphi'_i, \theta'_i \leftarrow (\varphi, \theta) - \alpha \nabla_{(\varphi, \theta)} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi, \theta}). \end{aligned}$$

TML updates meta model parameters  $\varphi, \theta$  and discriminator  $\omega$  by gradient descent. Details for our proposed TML algorithm are summarized in Alg. 1. The output meta model has following attractive advantages. First, it is well prepared for fast adapting to new tasks and domains through gradient based fine-tuning. Second, its representation learner maps the heterogeneous-domain

---

### Algorithm 1: Transferable Meta Learning

---

**Input:** Source domain data  $\mathcal{D}_S$ , target domain data  $\mathcal{D}_T$ , task set  $\mathcal{T}$ , learning rates  $\alpha, \beta, \gamma$ , max iteration  $I$

**Output:** Representation learner  $\varphi$ , classifier  $\theta$ , domain discriminator  $\omega$

```

1 Randomly initialize  $\theta, \varphi, \omega$ 
2 for  $i = 1, \dots, I$  do
3   Sample task  $\mathcal{T}_i \in \mathcal{T}$ .
4   Estimate  $\nabla \mathcal{L}_{\mathcal{T}_i}(f_{\varphi, \theta})$  using task provided training
   samples  $(\mathbf{x}, \mathbf{y})$  based on Eqn. (7)
5   Fine-tune the parameters  $\varphi, \theta$  as Eqn. (6):
    $(\varphi'_i, \theta'_i) = (\varphi, \theta) - \alpha \nabla_{(\varphi, \theta)} \mathcal{L}_{\mathcal{T}_i}(f_{\varphi, \theta})$ 
6   Estimate meta learning gradient w.r.t.  $(\varphi, \theta)$  on the
   testing examples in task  $\mathcal{T}_i$  by:
    $(\Delta_\varphi^{cls}, \Delta_\theta^{cls}) = \nabla_{(\varphi, \theta)} \sum_{\mathcal{T}_i \in \mathcal{T}} \mathcal{L}_{\mathcal{T}_i^S}(f_{\varphi'_i, \theta'_i})$ 
7   Sample source data  $\mathbf{x}_S \in \mathcal{D}_S$ , target data  $\mathbf{x}_T \in \mathcal{D}_T$ 
8   Estimate meta adaptation gradient w.r.t.  $\varphi$  based on
    $(\mathbf{x}_S, \mathbf{x}_T)$  by:  $\Delta_\varphi^{adpt} = \nabla_\varphi d_{\varphi, \omega}(\mathcal{D}_S, \mathcal{D}_T)$ 
9   Update model parameters:
10   $\varphi \leftarrow \varphi - \beta \Delta_\varphi^{cls} - \gamma \Delta_\varphi^{adpt}$ 
11   $\theta \leftarrow \theta - \beta \Delta_\theta^{cls}$ 
12   $\omega \leftarrow \omega - \gamma \nabla_\omega d_{\varphi, \omega}(\mathcal{D}_S, \mathcal{D}_T)$ 
13 end

```

---

data into a common space with minimized domain divergence such that model can effectively transfer meta-knowledge for few-shot learning across domains. In the experiments, we also verify that TML is superior to the approach that performs domain adaptation and meta learning separately.

## 4 Experiments

**Datasets** We first conduct experiments on learning a meta few-shot classification model with TML across three digits datasets, *i.e.*, MNIST (LeCun et al., 1998), USPS (Le Cun et al., 1989) and SVHN (Netzer et al., 2011). Each dataset contains 10 categories of digit images with varying characteristics. Then we evaluate TML on the office dataset (Saenko et al., 2010), which is a more challenging benchmark with more complex image contents and more significant domain shift. The dataset contains 31 classes of office supplies from three distinct domains, *i.e.*, Amazon, DSLR and Webcam.

**Experiment Settings** All experiments follow the standard  $N$ -way  $K$ -shot protocol (Vinyals et al., 2016) for few-shot learning, which is widely used for evaluating meta learning algorithms. Under this protocol, samples from one dataset are split and re-organized into multiple tasks. Each task provides  $N$  selected classes with  $K$  labeled training instances per class. Each task requires training a few-shot learning model on the provided la-

beled samples. See Sec. 3.1 for the formal definition of the task. We form the learning tasks for TML in the way described in Sec. 3.3. Note the labels for the  $N$  selected classes are randomly assigned under the few-shot learning protocol. The purpose is to evaluate whether the model indeed gains the capability of learning to recognize from few examples, instead of memorizing training examples from all the tasks. In our implementation, both the  $N$  classes and  $K$  samples are randomly selected from the whole dataset. Performance of a few-shot learning model is measured by the classification accuracy on another  $K \times N$  unseen samples.

As we are interested in the cross-domain setting, in the experiments we train a model with access to the source data but evaluate its performance on tasks from the specified target domain. For instance, under the cross-domain setting of “MNIST  $\Rightarrow$  USPS”, we train a model on MNIST data and evaluate its performance in USPS few-shot learning tasks.

**Baselines** Since the problem of cross-domain few-shot classification is new, few valid methods are available for solving it. Here we compare TML with following strong baselines, which leverage the state-of-the-art meta learning algorithms and domain adaptation methods, for obtaining the meta model. 1) Train a standard supervised-learning classifier on the source dataset, and fine-tune it for each specific target task. Comparing with this baseline aims to verify effectiveness of TML in training a meta few-shot learning model with strong generalization ability from few samples, compared with standard supervised learning methods. 2) The state-of-the-art meta learning algorithm, MAML (Finn et al., 2017). In particular, we use MAML to train the meta model in the source domain following the few-shot learning protocols and directly apply MAML to solve target tasks. We aim to demonstrate the advantage of TML over MAML in handling cross-domain few-shot learning problems. 3) The “oracle” MAML. It is trained using the full target datasets and provides performance upper bound for all the cross-domain trained models. 4) MAML+ADDA. Concretely, apply state-of-the-art domain adaptation method ADDA (Tzeng et al., 2017) to align target domain samples with the source domain at first, and then apply MAML on the adapted sample representations. For this baseline, the domain adaptation is blind and unaware of few-shot learning tasks. Comparing TML with it verifies the benefits of end-to-end meta-adaptation and meta-learning in TML.

**Implementation Details** The meta model in TML consists of two components, a meta representation learner and a meta classifier. The former contains four cascade convolutional units, while the latter is built with a linear transformation layer followed by a softmax layer, follow-

ing similar architectures in (Finn et al., 2017; Vinyals et al., 2016). The architecture of the convolutional units varies along with the number of input image channels. For gray-scale images (*e.g.*, digit images), each convolutional unit is composed of 1)  $3 \times 3$  2D convolution with 64 filters and stride  $2 \times 2$ , 2) batch normalization (Ioffe & Szegedy, 2015), and 3) ReLU nonlinear activation function. After the convolutions, a mean pooling layer is used to transform multiple 2D feature maps into a linear feature vector. For color images (*e.g.*, office images), the convolutional unit changes to 1)  $3 \times 3$  2-D convolution with 32 filters and stride 1, 2) batch normalization, 3)  $2 \times 2$  max pooling layer, and 4) ReLU nonlinearity. Then the feature maps are simply flatten to produce a feature vector for classification. The domain discriminator consists of 3 fully connected layers. Each of the two hidden layers has 500 neurons and is followed by a ReLU activation function. One single unit in the output layer is used to indicate the input is from the source or target domain.

To train all network models, we adopt Adam (Kingma & Ba, 2014) as the optimizer. The meta learning rate  $\beta$  is set as 0.001, while the adaptation learning rate  $\gamma$  is set as  $2 \times 10^{-4}$ . The update (or fine-tuning) learning rate  $\alpha$  is fixed as 0.4 for training on gray images and 0.01 for color images. The task batch size is 32 for gray images and 4 for color image due to GPU memory limitation. All models are trained on a single GeForce GTX TITAN Black GPU with 12G memory.

#### 4.1 Results on Digit Datasets

We present results on the digit datasets with multiple cross-domain directions. We first convert all images to gray scale and resize them to  $28 \times 28$ . When building learning tasks, we rotate images class-wise by  $90^\circ$  randomly for data augmentation (Santoro et al., 2016a).

We test our TML in following few-shot settings: 5-way 1-shot and 5-way 5-shot, and four cross-domain directions: MNIST  $\Rightarrow$  USPS, MNIST  $\Rightarrow$  SVHN, USPS  $\Rightarrow$  MNIST and SVHN  $\Rightarrow$  USPS. For the fine-tuning baseline, we first train three classifiers of the same architecture as our model on the three full digit datasets (using the training set) individually. Then the learned classifier on source domain is fine-tuned on the other two target domains under the few-shot setting, *i.e.*, fine-tuning the model on a few training samples and evaluating it on the testing samples for each task individually. For effectively preventing over-fitting, we carefully select the fine-tune learning rate which is set as  $2 \times 10^{-4}$ .

Table 1 reports the few-shot classification accuracy averaged over 500 randomly sampled tasks. One can observe that MAML, MMAL+ADDA and TML all surpass the fine-tune baseline by a large margin in all settings,

Table 1: Few-shot classification results for digit images. The left-most column shows the cross-domain direction, where **M**, **U**, **S** denotes MNIST, USPS, SVHN respectively. The results are reported in terms of classification accuracy (%) averaged over 500 tasks. The gray number in parentheses for MAML is the averaged accuracy obtained by training MAML on the full target datasets. “M + A” denotes the MAML+ADDA baseline.

Direction	5-way 1-shot				5-way 5-shot

<b>S</b>	83.87	89.82

proving the benefits of considering the nature of few-shot learning in model training. More importantly, TML outperforms MAML for almost all settings, by a margin up to 8%. This shows effectiveness of TML in solving domain-shift issues for few-shot learning tasks. The second-best baseline ADDA+MAML also tries to solve domain-shift explicitly by applying ADDA to align domains at first. However its performance is inferior to TML as it conducts domain adaptation blindly which may harm the few-shot learning performance. In contrast, our proposed TML performs meta-adaptation and meta-learning jointly, providing fast adaptation abilities to both new tasks and new domains. Thus it improves ADDA+MAML by up to 9.5%. The superiority of TML over ADDA+MAML becomes more significant when training samples are very limited.

For the  $U \Rightarrow M$  (5-way, 5-shot) setting, TML performs comparably well as ADDA+MAML, where the target domain data are sufficient for ADDA to achieve good domain adaptation. For the  $S \Rightarrow U$  (5-way, 1-shot) setting, MAML performs slightly better than TML. This is because the domain divergence between **S** and **U** is large and target data from a single task are limited for TML to perform meta-adaptation sufficiently well.

For better understanding the domain shift challenge to few-shot learning, we also evaluate the oracle MAML

Figure 3: Adaptation speed comparison. Left: MNIST  $\Rightarrow$  USPS, 5-way 1-shot. Right: SVHN  $\Rightarrow$  USPS, 10-way 1-shot. The fine-tuning baseline updates for 300 steps in total, *i.e.*, one step amounts to 30 actual steps.

baseline which has full access to samples in the target domain. The results in Table 1 show that domain shift brings a significant performance drop to MAML, demonstrating the necessity of addressing domain-shift in few-shot learning. TML can reduce the performance gap moderately. TML is effective at minimizing the domain divergence without harming performance in source domain. To show this, we also evaluate its few-shot classification performance on the source domain. The results in Table 2 demonstrate that TML performs as well as MAML in the source domain, proving TML can learn domain-invariant representations benefiting applications in both source and target domains.

Moreover, fast adaptation is important in practical applications. Therefore, we evaluate adaptation speed (in terms of adaptation steps) of different methods. Given a new task from the target domain, each model is updated for several steps (*e.g.*, 10) with gradient descent using the task-provided few-shot training data. We plot the few-shot classification performance against model updating steps for the naive fine-tuning model, MAML,

Table 3: Few-shot classification results for office images. The left-most column shows the cross-domain direction, where **A**, **D**, **W** denote Amazon, DSLR, Webcam respectively. The results are reported in terms of classification accuracy (in %), averaged over 500 tasks. “M + A” denotes the MAML+ADDA baseline.

Direction	5-way 1-shot				5-way 5-shot			
	Fine-tune	MAML	M + A	TML	Fine-tune	MAML	M + A	TML
<b>A ⇒ D</b>	42.44	45.90	49.43	<b>54.50</b>	74.12	71.74	71.63	<b>80.72</b>

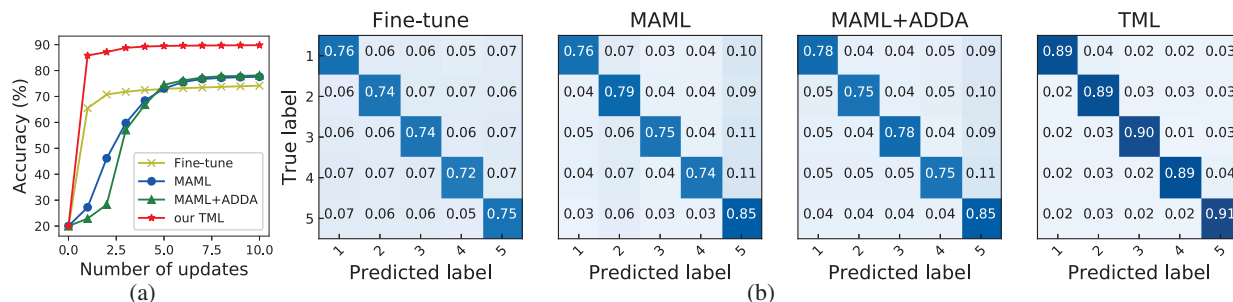

Figure 4: (a) Adaptation speed comparison on office datasets ( $D \Rightarrow W$ , 5-way 5-shot). (b) Corresponding few-shot classification confusion matrices on task-specific testing set.

MAML+ADDA and TML in Fig. 3. TML presents much faster adaptation than others and achieves the best performance. Notably, TML only needs one step adaptation to achieve better performance than all the baselines.

## 4.2 Results on Office Datasets

We then evaluate TML on the more challenging office dataset for four few-shot settings and three cross-domain directions: Amazon  $\Rightarrow$  DSLR, Amazon  $\Rightarrow$  Webcam and Webcam  $\Rightarrow$  DSLR. Since Amazon provides sufficient training examples, we always take it as source domain. The experimental results are shown in Table 1. Similar to the digit images, TML brings improvement up to 10.72% over MAML and MAML+ADDA, and performs significantly better than the fine-tuning baseline.

We also analyze the adaptation speed of different approaches to multiple 5-way 5-shot learning tasks from Dslr to Webcam domains, which is visualized in Fig. 4a. TML adapts significantly faster than all the baselines, demonstrating the meta-adaptation is effective for augmenting model adaptation ability. For understanding few-shot classification performance more transparently, we also plot classification confusion matrix for all the approaches in Fig. 4b. TML provides more accurate clas-

sification for all the 5 categories than baselines, showing its effectiveness in overcoming challenges from both domain-shift and limited training examples. In contrast, MAML+ADDA degrades the performance of MAML for the second category, demonstrating blind domain adaptation may confuse some categories and harm the few-shot learning performance.

## 5 Conclusion

This work introduced the new cross-domain meta learning problems challenged by insufficiency of training examples and varying characteristics of tasks. We developed the first transferable meta learning (TML) algorithm which substantially extends existing meta learning algorithms to solve new tasks in different domains and relieve the issues brought by insufficient training tasks.

## Abstract

A common goal in psychometrics, sociology, and econometrics is to uncover causal relations among latent variables representing hypothetical constructs that cannot be measured directly, such as attitude, intelligence, and motivation. Through measurement models, these constructs are typically linked to measurable indicators, e.g., responses to questionnaire items. This paper addresses the problem of causal structure learning among such latent variables and other observed variables. We propose the ‘Copula Factor PC’ algorithm as a novel two-step approach. It first draws samples of the underlying correlation matrix in a Gaussian copula factor model via a Gibbs sampler on rank-based data. These are then translated into an average correlation matrix and an effective sample size, which are taken as input to the standard PC algorithm for causal discovery in the second step. We prove the consistency of our ‘Copula Factor PC’ algorithm, and demonstrate that it outperforms the PC-MIMBuild algorithm and a greedy step-wise approach. We illustrate our method on a real-world data set about children with Attention Deficit Hyperactivity Disorder.

## 1 INTRODUCTION

Social scientists, psychologists, and many other scientists are usually interested in learning causal relations between latent variables that cannot be measured directly, e.g., attitude, intelligence, and motivation (see [15, 24], and Chapter 10 of [27] for more details). In order to get a grip on these latent concepts, one commonly-used strategy is to construct a measurement model for such a

latent variable, in the sense that domain experts design a set of measurable “items” or survey “questions” that are considered to be indicators of the latent variable. For instance, in the study of Attention Deficit Hyperactivity Disorder (ADHD), 18 questions are designed to measure three latent variables: inattention, hyperactivity, and impulsivity [29]. In some other cases where it is difficult to design a measurement model due to the absence of domain knowledge or for other reasons, there are some off-the-shelf algorithms, e.g., BPC [24] and FOFC [15], for learning the measurement models from indicator data. In this paper, we focus on inferring the causal structure among latent variables, assuming that the measurement models are given. We also allow interactions between these latent variables and other (explicit) variables, e.g., subject characteristics like gender and age. Another issue we consider is that there are diverse types of variables in most real-world data: the questionnaire data in a survey is typically ordinal, whereas other variables might be binary, or continuous.

In this paper, we use a Gaussian copula factor model (the formal definition is given in Section 3) to describe such situations, in which a factor can be connected to either one or more observed variables (indicators). Factors with multiple indicators are used to model latent variables corresponding to psychological traits, such as attitude and intelligence. The copula model provides a good way of analyzing diverse types of variables, where the associations between variables are parameterized separately from their marginal distributions [13].

We propose the ‘Copula Factor PC’ algorithm for estimating the causal structure among factors of a Gaussian copula factor model, which is based on a two-step approach. The first step draws samples of the underlying correlation matrix, where the Gibbs sampler by [13] for Gaussian copula models is extended to Gaussian copula factor models by replacing the Wishart prior with the  $G$ -Wishart prior and adding a new strategy to sample latent factors. These samples are then translated into an aver-

age correlation matrix, and an effective sample size that is used to account for information loss incurred by discrete variables [9]. The second step takes the estimated correlation matrix and effective sample size as input to the standard PC algorithm [27] for causal discovery.

The rest of this paper is organized as follows. Section 2 reviews necessary knowledge and related work. Section 3 gives the definition of a Gaussian copula factor model. Section 4 describes our ‘Copula Factor PC’ algorithm, and introduces two alternative approaches: the PC-MIMBuild algorithm [24] and a greedy step-wise approach. Section 5 compares the ‘Copula Factor PC’ algorithm with the two alternative approaches on simulated data, and Section 6 gives an illustration on real-world data of ADHD patients. Section 7 concludes this paper and gives some discussion.

## 2 BACKGROUND

**Causal discovery** A graphical model is a graph  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ , where the vertices  $\mathbf{V} = \{X_1, \dots, X_d\}$  correspond to random variables and the edges  $\mathbf{E}$  represent dependence structure among the variables. A graph is *directed* if it just contains directed edges and *undirected* if all edges are undirected. A graph that contains both directed and undirected edges is called a *partially directed graph*. Graphs without directed cycles (e.g.,  $X_i \rightarrow X_j \rightarrow X_i$ ) are *acyclic*. We refer to a graph as a *Directed Acyclic Graph* (DAG) if it is both directed and acyclic. If there is a directed edge  $X_i \rightarrow X_j$ ,  $X_i$  is called a parent of  $X_j$ . A distribution over a random vector  $\mathbf{X}$  with  $X_i \in \mathbf{V}$  is said to be Markov w.r.t. a DAG  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ , if  $\mathbf{X}$  satisfies the *Causal Markov Condition*: each variable in the DAG  $\mathcal{G}$  is independent of its non-descendants given its parents, which is also implied by the so-called *d-separation* [20]. A distribution is *faithful* w.r.t. a DAG  $\mathcal{G}$  if there are no conditional independencies in the distribution that are not encoded by the Causal Markov Condition. If a distribution is both Markov and faithful w.r.t. a DAG  $\mathcal{G}$ , the DAG is called a *perfect map* of the distribution.

Several DAGs may, via *d-separation*, correspond to the same set of conditional independencies. The set of such DAGs is called a Markov equivalence class, which can be represented by a *completed partially directed acyclic graph* (CPDAG). Arcs in a CPDAG suggest a cause-effect relationship between pairs of variables since the same arc appears in all members of the CPDAG. An undirected edge  $X_i - X_j$  in a CPDAG implies that some of its members contain an arc  $X_i \rightarrow X_j$  while others contain an arc  $X_j \rightarrow X_i$ . Causal discovery aims to learn the Markov equivalence class of the underlying DAG from observations.

**The PC algorithm** The PC algorithm [27], a reference algorithm for causal discovery, consists of two stages: adjacency search and orientation. The adjacency search starts with a fully connected undirected graph, and then recursively removes the edges according to conditional independence decisions, yielding the skeleton and separation sets. In the orientation stage, we first orient the unshielded triples according to the separation sets, and then orient as many of the remaining undirected edges as possible by applying the orientation rules repeatedly.

A key part of the procedure is to test for conditional independencies. When a random vector  $\mathbf{X} \sim \mathcal{N}(0, C)$ , the PC algorithm considers the so-called partial correlation, denoted by  $\rho_{uv|S}$ , which can be obtained by the correlation matrix  $C$  [1]. Given observations of  $\mathbf{X}$  and significance level  $\alpha$ , classical decision theory yields

$$X_u \perp\!\!\!\perp X_v | \mathbf{X}_S \Leftrightarrow \sqrt{n - |S| - 3} \left| \frac{1}{2} \log \left( \frac{1 + \hat{\rho}_{uv|S}}{1 - \hat{\rho}_{uv|S}} \right) \right| \leq \Phi^{-1}(1 - \alpha/2), \quad (1)$$

where  $u \neq v$ ,  $S \subseteq \{1, \dots, d\} \setminus \{u, v\}$  and  $\Phi$  is the cumulative distribution function of the standard Gaussian. Hence, the PC algorithm requires the correlation matrix  $C$  (to compute partial correlations  $\rho_{uv|S}$ ) and the sample size  $n$  as input. Uniform consistency of the PC algorithm for Gaussian data is shown under some relatively mild assumptions on the sparsity of the true underlying structure [14].

Harris & Drton [11] use rank correlations, typically Spearman’s  $\rho$  and Kendall’s  $\tau$ , to replace the Pearson correlation, which extends the PC algorithm to the so-called nonparanormal models. The resulting ‘Rank PC’ algorithm performs as well as the PC algorithm using Pearson correlations on Gaussian data, yet much better on nonparanormal data. The PC algorithms using both Pearson and rank correlations require all univariate marginal distributions to be continuous. Cui et al. [9] extend the PC algorithm to mixed discrete and continuous data assumed to be drawn from a Gaussian copula model, where each observed variable is assumed to be induced by a latent Gaussian variable and the dependence between observed variables is determined by the correlation matrix of the latent variables. The resulting ‘Copula PC’ algorithm works well for mixed data, but requires each latent variable to have only a single indicator. Silva et al. [24] propose the PC-MIMBuild algorithm, which allows a latent variable to have multiple indicators, but it is limited to continuous observations and assumes that each latent variable has at least two indicators.

In this paper, we aim to generalize the PC algorithm to handle latent variables having one or more indicators and observations being either discrete or continuous.

### 3 GAUSSIAN COPULA FACTOR MODEL

#### Definition 1 (Gaussian Copula Factor Model).

Consider a latent random (factor) vector  $\boldsymbol{\eta} = (\eta_1, \dots, \eta_k)^T$ , a response random vector  $\mathbf{Z} = (Z_1, \dots, Z_p)^T$  and an observed random vector  $\mathbf{Y} = (Y_1, \dots, Y_p)^T$ , satisfying

$$\boldsymbol{\eta} \sim \mathcal{N}(0, C), \quad (2)$$

$$\mathbf{Z} = \Lambda \boldsymbol{\eta} + \boldsymbol{\epsilon}, \quad (3)$$

$$Y_j = F_j^{-1}(\Phi[Z_j/\sigma(Z_j)]), \forall j = 1, \dots, p, \quad (4)$$

with  $\Lambda = (\lambda_{ij})$  a  $p \times k$  matrix of factor loadings ( $k \leq p$ ),  $\boldsymbol{\epsilon} \sim \mathcal{N}(0, D)$  Gaussian noise with  $D = \text{diag}(\sigma_1^2, \dots, \sigma_p^2)$ ,  $\sigma(Z_j)$  the standard deviation of  $Z_j$ , and  $F_j^{-1}(t) = \inf\{x : F_j(x) \geq t\}$  the pseudo-inverse of a cumulative distribution function  $F_j$ . This model is called a *Gaussian Copula Factor Model* with correlation matrix  $C$ , factor loadings  $\Lambda$ , and univariate margins  $F_j$ .

Figure 1: Gaussian copula factor model.

The model is also defined in [18], but the authors restrict the factors to be independent of each other while we allow for their interactions. An example of the model is shown in Figure 1. Our model is a combination of a Gaussian factor model (from  $\boldsymbol{\eta}$  to  $\mathbf{Z}$ ) and a Gaussian copula model (from  $\mathbf{Z}$  to  $\mathbf{Y}$ ). In the special case of a factor having a single response (thus a single observed variable), e.g.,  $\eta_1 \rightarrow Z_1 \rightarrow Y_1$ , it reduces to a Gaussian copula model where we set  $\lambda_{11} = 1$  and  $\epsilon_1 = 0$ , thus  $Y_1 = F_1^{-1}(\Phi[\eta_1])$ .

In the typical design for questionnaires, one tries to get a grip on a latent concept through a particular set of well-designed questions [16, 4], which implies that a factor (latent concept) in our model is connected to multiple indicators (questions) while an indicator is only used to measure a single factor, as shown in Figure 1. This kind of measurement model is called a pure measurement model (Definition 2 of [23]). Throughout this paper, we assume that all measurement models are given and pure, which makes that there is only a single non-zero entry in

each row of the factor loadings matrix  $\Lambda$ . This inductive bias about the sparsity pattern of  $\Lambda$  is fully motivated by the typical design of a measurement model.

In what follows, we transform the Gaussian copula factor model into an equivalent model, which we will use for inference in the next section. We consider an integrated random vector  $\mathbf{X} = (\mathbf{Z}^T, \boldsymbol{\eta}^T)^T$ , which is still multivariate Gaussian, and obtain its covariance matrix

$$\Sigma = \begin{bmatrix} \Lambda C \Lambda^T + D & \Lambda C \\ C \Lambda^T & C \end{bmatrix}, \quad (5)$$

and precision matrix

$$\Omega = \Sigma^{-1} = \begin{bmatrix} D^{-1} & -D^{-1}\Lambda \\ -\Lambda^T D^{-1} & C^{-1} + \Lambda^T D^{-1}\Lambda \end{bmatrix}. \quad (6)$$

Since  $D$  is diagonal and  $\Lambda$  only has one non-zero entry per row,  $\Omega$  contains many intrinsic zeros. The sparsity pattern of such  $\Omega = (\omega_{ij})$  can be represented by an undirected graph  $G = (\mathbf{V}, \mathbf{E})$ , where  $(i, j) \notin \mathbf{E}$  whenever  $\omega_{ij} = 0$  by construction. Then, a Gaussian copula factor model can be transformed into an equivalent model controlled by a single precision matrix  $\Omega$ , which in turn is constrained by  $G$ , i.e.,  $P(\mathbf{X}|C, \Lambda, D) = P(\mathbf{X}|\Omega_G)$ .

**Definition 2 ( $G$ -Wishart Distribution [22]).** Given an undirected graph  $G = (\mathbf{V}, \mathbf{E})$ , a zero-constrained random matrix  $\Omega$  has a  $G$ -Wishart distribution, if its density is

$$p(\Omega|G) = \frac{|\Omega|^{(\nu-2)/2}}{I_G(\nu, \Psi)} \exp \left[ -\frac{1}{2} \text{tr}(\Psi \Omega) \right] \mathbb{1}_{\Omega \in M^+(G)},$$

with  $M^+(G)$  the space of symmetric positive definite matrices with off-diagonal elements  $\omega_{ij} = 0$  whenever  $(i, j) \notin \mathbf{E}$ ,  $\nu$  the number of degrees of freedom,  $\Psi$  a scale matrix,  $I_G(\nu, \Psi)$  the normalizing constant, and  $\mathbb{1}$  the indicator function.

The  $G$ -Wishart distribution is the conjugate prior of precision matrices  $\Omega$  that are constrained by a graph  $G$  [22]. That is, given the  $G$ -Wishart prior, i.e.,  $P(\Omega|G) = \mathcal{W}_G(\nu_0, \Psi_0)$  and data  $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)^T$  drawn from  $\mathcal{N}(0, \Omega^{-1})$ , the posterior for  $\Omega$  is another  $G$ -Wishart distribution:

$$P(\Omega|G, \mathbf{X}) = \mathcal{W}_G(\nu_0 + n, \Psi_0 + \mathbf{X}^T \mathbf{X}).$$

When the graph  $G$  is fully connected, the  $G$ -Wishart distribution reduces to a Wishart distribution [17]. Placing a  $G$ -Wishart prior on  $\Omega$  is equivalent to placing an inverse-Wishart on  $C$ , a product of multivariate normals on  $\Lambda$ , and an inverse-gamma on the diagonal elements of  $D$ . With a diagonal scale matrix  $\Psi_0$  and the number of degrees of freedom  $\nu_0$  equal to the number of factors plus one, the implied marginal densities between any pair of factors are uniformly distributed in the interval  $[-1, 1]$  [3].

## 4 METHODS

In this section, we propose a Bayesian inference method for Gaussian copula factor models, based on which we derive our ‘Copula Factor PC’ algorithm. Then, we introduce two alternative approaches.

### 4.1 INFERENCE FOR GAUSSIAN COPULA FACTOR MODEL

For a Gaussian copula model, Hoff [13] proposed a likelihood that only concerns the ranks among observations, which is derived as follows. Since the transformation  $Y_j = F_j^{-1}(\Phi[Z_j])$  is non-decreasing, observing  $\mathbf{y}_j = (y_{1,j}, \dots, y_{n,j})^T$  implies a partial ordering on  $\mathbf{z}_j = (z_{1,j}, \dots, z_{n,j})^T$ , namely,  $\mathbf{z}_j$  must lie in the space restricted by  $\mathbf{y}_j$ :

$$\mathcal{D}(\mathbf{y}_j) = \{\mathbf{z}_j \in \mathbb{R}^n : y_{i,j} < y_{k,j} \Rightarrow z_{i,j} < z_{k,j}\}.$$

Therefore, observing  $\mathbf{Y}$  suggests that  $\mathbf{Z}$  must be in

$$\mathcal{D}(\mathbf{Y}) = \{\mathbf{Z} \in \mathbb{R}^{n \times p} : \mathbf{z}_j \in \mathcal{D}(\mathbf{y}_j), \forall j = 1, \dots, p\}.$$

Taking the occurrence of this event as the data, one can compute the following likelihood

$$\begin{aligned} P(\mathbf{Z} \in \mathcal{D}(\mathbf{Y}) | S, F_1, \dots, F_p) &= \int_{\mathcal{D}(\mathbf{Y})} p(\mathbf{Z} | S) d\mathbf{Z} \\ &= P(\mathbf{Z} \in \mathcal{D}(\mathbf{Y}) | S), \end{aligned}$$

where  $S$  is the correlation matrix over  $\mathbf{Z}$ .

Following the same argumentation, the likelihood in our Gaussian copula factor model reads

$$P(\mathbf{Z} \in \mathcal{D}(\mathbf{Y}) | \boldsymbol{\eta}, \Omega, F_1, \dots, F_p) = P(\mathbf{Z} \in \mathcal{D}(\mathbf{Y}) | \boldsymbol{\eta}, \Omega),$$

which is independent of the margins  $F_j$ .

For the Gaussian copula factor model, inference for the precision matrix  $\Omega$  of the vector  $\mathbf{X} = (\mathbf{Z}^T, \boldsymbol{\eta}^T)^T$  can now proceed via construction of a Markov chain having its stationary distribution equal to  $P(\mathbf{Z}, \boldsymbol{\eta}, \Omega | \mathbf{Z} \in \mathcal{D}(\mathbf{Y}), G)$ , where we ignore the values for  $\boldsymbol{\eta}$  and  $\mathbf{Z}$  in our samples. The prior graph  $G$  is uniquely determined by the sparsity pattern of the loading matrix  $\Lambda = (\lambda_{ij})$  and the residual matrix  $D$  (see Equation 6), which in turn is uniquely decided by the pure measurement models. The Markov chain can be constructed by iterating the following three steps:

1. **Sample  $\mathbf{Z}$ :**  $\mathbf{Z} \sim P(\mathbf{Z} | \boldsymbol{\eta}, \mathbf{Z} \in \mathcal{D}(\mathbf{Y}), \Omega)$ ;  
Since each coordinate  $Z_j$  directly depends on only one factor, i.e.,  $\eta_q$  such that  $\lambda_{jq} \neq 0$ , we can sample each of them independently through  $Z_j \sim P(Z_j | \eta_q, \mathbf{z}_j \in \mathcal{D}(\mathbf{y}_j), \Omega)$ .

---

### Algorithm 1 Gibbs sampler for Gaussian copula factor model

---

**Require:** Measurement models (decide sparsity of  $\Lambda$  and thus  $G$ ), and indicator data  $\mathbf{Y}$ .

- 1: **Step 1:** sample  $\mathbf{Z} \sim P(\mathbf{Z} | \boldsymbol{\eta}, \mathbf{Z} \in \mathcal{D}(\mathbf{Y}), \Omega)$ .
  - 2: **for**  $j \in \{1, \dots, p\}$  **do**
  - 3:    $q =$  factor index of  $Z_j$
  - 4:    $a = \Sigma_{[j, q+p]} / \Sigma_{[q+p, q+p]}$
  - 5:    $\sigma_j^2 = \Sigma_{[j, j]} - a \Sigma_{[q+p, j]}$
  - 6:   **for**  $\mathbf{y} \in \text{unique}\{y_{1,j}, \dots, y_{n,j}\}$  **do**
  - 7:      $z_l = \max\{z_{i,j} : y_{i,j} < \mathbf{y}\}$
  - 8:      $z_u = \min\{z_{i,j} : \mathbf{y} < y_{i,j}\}$
  - 9:     **for**  $i$  such that  $y_{i,j} = \mathbf{y}$  **do**
  - 10:        $\mu_{i,j} = \boldsymbol{\eta}_{[i,q]} \times a$
  - 11:        $u_{i,j} \sim \mathcal{U}(\Phi[\frac{z_l - \mu_{i,j}}{\sigma_j}], \Phi[\frac{z_u - \mu_{i,j}}{\sigma_j}])$
  - 12:        $z_{i,j} = \mu_{i,j} + \sigma_j \times \Phi^{-1}(u_{i,j})$
  - 13:     **end for**
  - 14:   **end for**
  - 15: **end for**
  - 16: **Step 2:** sample  $\boldsymbol{\eta} \sim P(\boldsymbol{\eta} | \mathbf{Z}, \Omega)$ .
  - 17:  $A = \Sigma_{[\boldsymbol{\eta}, \mathbf{Z}]} \Sigma_{[\mathbf{Z}, \mathbf{Z}]}^{-1}$
  - 18:  $B = \Sigma_{[\boldsymbol{\eta}, \boldsymbol{\eta}]} - A \Sigma_{[\mathbf{Z}, \boldsymbol{\eta}]}$
  - 19: **for**  $i \in \{1, \dots, n\}$  **do**
  - 20:    $\boldsymbol{\mu}_i = (\mathbf{Z}_{[i,:]} A^T)^T$
  - 21:    $\boldsymbol{\eta}_{[i,:]} \sim \mathcal{N}(\boldsymbol{\mu}_i, B)$
  - 22: **end for**
  - 23:  $\boldsymbol{\eta}_{[:,j]} = \boldsymbol{\eta}_{[:,j]} \times \text{sign}(\text{Cov}[\boldsymbol{\eta}_{[:,j]}, \mathbf{Z}_{[:,f(j)}])$ ,  $\forall j$ , where  $f(j)$  is the index of the first indicator of  $\eta_j$ .
  - 24: **Step 3:** sample  $\Omega \sim P(\Omega | \mathbf{Z}, \boldsymbol{\eta}, G)$ .
  - 25:  $\mathbf{X} = (\mathbf{Z}, \boldsymbol{\eta})$
  - 26:  $\Omega \sim \mathcal{W}_G(\nu_0 + n, \Psi_0 + \mathbf{X}^T \mathbf{X})$
  - 27:  $\Sigma = \Omega^{-1}$
  - 28:  $\Sigma_{ij} = \Sigma_{ij} / \sqrt{\Sigma_{ii} \Sigma_{jj}}$ ,  $\forall i, j$
- 

2. **Sample  $\boldsymbol{\eta}$ :**  $\boldsymbol{\eta} \sim P(\boldsymbol{\eta} | \mathbf{Z}, \Omega)$ ;
3. **Sample  $\Omega$ :**  $\Omega \sim P(\Omega | \mathbf{Z}, \boldsymbol{\eta}, G)$ .

A Gibbs sampler that implements the Markov chain is summarized in Algorithm 1.

**Identifiability of  $C$ :** Without additional constraints, the correlation matrix  $C$  over factors is non-identifiable [2]. More precisely, given a decomposable covariance matrix  $S = \Lambda C \Lambda^T + D$ , we can always replace  $\Lambda$  with  $\Lambda U$  and  $C$  with  $U^{-1} C U^{-T}$  to obtain an equivalent decomposition  $S = (\Lambda U)(U^{-1} C U^{-T})(U^T \Lambda^T) + D$ , where  $U$  is a  $k \times k$  invertible matrix. Since  $\Lambda$  only has one non-zero entry per row in our model,  $U$  can only be diagonal to ensure that  $\Lambda U$  has the same sparsity pattern as  $\Lambda$  (see Lemma 3 in Supplement). Thus, from the same  $S$ , we get a class of solutions for  $C$ , i.e.,  $U^{-1} C U^{-1}$ , where

$U$  can be any invertible diagonal matrix. However, we find that all members in this class encode the same set of conditional independencies (see Lemma 4 in Supplement), and therefore imply the same causal structure [27]. Hence, any solution in this class is appropriate for finding the underlying causal structure among latent variables.

In order to get a unique solution for  $C$ , we impose two sufficient identifying conditions: 1) restrict  $C$  to be a correlation matrix; 2) force the first non-zero entry in each column of  $\Lambda$  to be positive (see Lemma 5 in Supplement). Condition 1 is implemented via line 28 in Algorithm 1. As for the second condition, we force the covariance between a factor and its first indicator to be positive (line 23), which is equivalent to Condition 2. One could also choose one’s favorite constraints for identifying  $C$ , as long as the unique solution belongs to the class  $U^{-1}CU^{-1}$ .

## 4.2 COPULA FACTOR PC ALGORITHM

By iterating the steps in Algorithm 1 and extracting the submatrix over  $\eta$ , we can draw samples of  $C$ , denoted by  $\{C^{(1)}, \dots, C^{(m)}\}$ . The mean over all the samples is a natural estimate of the underlying correlation matrix  $\hat{C}$ , i.e.,  $\hat{C} = \frac{1}{m} \sum_{i=1}^m C^{(i)}$ . As for the effective sample size  $\hat{n}$ , we build upon the idea in [9], that is, taking the posterior distribution’s degrees of freedom  $\nu$  as an approximation to  $\hat{n}$ . Theorem 1 (the proof is provided in the Supplement) suggests a procedure to estimate the degrees of freedom of a  $G$ -Wishart distribution.

**Theorem 1.** *Consider a random matrix  $\Omega$  following a  $G$ -Wishart distribution with graph  $G = (\mathbf{V}, \mathbf{E})$  as well as parameters  $\nu$  and  $\Psi$ , i.e.,  $\Omega \sim \mathcal{W}_G(\nu, \Psi)$ . Let  $\Sigma = \Omega^{-1}$  and  $\tilde{\Sigma}$  be the normalized matrix of  $\Sigma$ , i.e.,  $\tilde{\Sigma}_{ij} = \Sigma_{ij} / \sqrt{\Sigma_{ii}\Sigma_{jj}}$ . Then, for large  $\nu$ , we have*

$$\text{Var} [\tilde{\Sigma}_{ij}] \approx \frac{(1 - (\mathbb{E} [\tilde{\Sigma}_{ij}])^2)^2}{\nu}, \quad (7)$$

for off-diagonal elements  $\tilde{\Sigma}_{ij}$  whenever  $(i, j) \in \mathbf{E}$ .

From the theorem, we have that all off-diagonal elements of the latent correlation matrix satisfy Equation (7), because the prior subgraph over latent factors is fully connected. Therefore, we estimate  $\hat{n}$  as follows

$$\hat{n} = \frac{1}{k(k-1)} \sum_{i \neq j} \nu_{ij}, \quad \text{where } \nu_{ij} = \frac{(1 - (\mathbb{E} [C_{ij}])^2)^2}{\text{Var} [C_{ij}]}.$$

The ‘Copula Factor PC’ (CFPC) algorithm arises when taking the estimated correlation matrix  $\hat{C}$  and the effective sample size  $\hat{n}$  (to replace the  $n$  in Equation 1) as the

input to the standard PC algorithm.<sup>1</sup> The CFPC algorithm is consistent, as shown in Theorem 2 (see proof in the Supplement).

### Theorem 2 (Consistency of the CFPC algorithm).

Let  $\mathbf{Y}_n = (\mathbf{y}_1, \dots, \mathbf{y}_n)^T$  be independent observations drawn from a Gaussian copula factor model. If 1) the measurement model per factor is known and pure; and 2) the distribution over factors is faithful to a DAG  $\mathcal{G}$ , then

$$\lim_{n \rightarrow \infty} P(\hat{\mathcal{M}}_n(\mathcal{G}) = \mathcal{M}(\mathcal{G})) = 1,$$

where  $\hat{\mathcal{M}}_n(\mathcal{G})$  is the output of the CFPC algorithm and  $\mathcal{M}(\mathcal{G})$  is the Markov equivalent class of the true underlying DAG  $\mathcal{G}$ .

## 4.3 ALTERNATIVE APPROACHES

**The PC-MIMBuild algorithm** The original PC-MIMBuild algorithm only works for continuous data. Here, we extend it to mixed cases by learning the correlation matrix of response variables via the Gibbs sampler by [13] and taking it as input to the original PC-MIMBuild. We further generalize the PC-MIMBuild algorithm to handle latent factors with just a single indicator, by replacing the conditional independence testing method designed only for factors with at least two indicators (Theorem 19 in [24]) with a test based on partial correlation. See Supplement B for more details.

**A greedy step-wise approach** This approach first extracts the measurement model of a factor with multiple indicators, e.g., the subpart of Figure 1 consisting of the variables  $\{\eta_3, Z_3, Z_4, Z_5, Y_3, Y_4, Y_5\}$ . Then, it uses off-the-shelf techniques [10] to fit such a model and obtain pseudo-data of the factor (factor scores). Using pseudo-data for factors with multiple indicators together with real data for factors with a single indicator, the ‘Copula PC’ algorithm is next applied for causal discovery. We refer to this approach as the greedy step-wise PC algorithm, whose pseudo-code is written out step by step in the Supplement C. One disadvantage of this approach is that it can overestimate the effective sample size when treating the pseudo-data at the same footing as real data. This might incur many false positives, as we will indeed observe in the experiment section.

## 5 SIMULATION STUDY

In this section, we compare our ‘Copula Factor PC’ algorithm (CFPC) with the PC-MIMBuild algorithm (MBPC) and the greedy step-wise PC algorithm (GSPC)

<sup>1</sup>The R code is publicly available in <https://github.com/cuiruifei/CopulaFactorModel>.

on simulated data. Kalisch & Buhlmann [14] provide a procedure to generate random DAGs and simulate normally distributed samples that are faithful to them. It first generates a  $k \times k$  adjacency matrix  $A$  representing a random DAG: 1) generate a  $k \times k$  zero matrix, 2) randomly set entries in the lower-triangle area to be *one* with probability  $s$  (measuring the sparseness), 3) change the *ones* to be random weights in the interval  $[0.1, 1]$ . Given the adjacency matrix  $A$ , values of a random vector  $\boldsymbol{\eta}$  are drawn recursively via

$$\eta_i = \sum_{k < i} A_{ik} \eta_k + \epsilon_i,$$

with each  $\epsilon_i \sim \mathcal{N}(0, 1)$ . Following this procedure, we simulate the factors of a Gaussian copula factor model, i.e., the  $\boldsymbol{\eta}$  in Equation (2). Then, the edge weights from factors to response variables (non-zero elements of  $\Lambda$  in Equation 3) are uniformly drawn from the interval  $[0.1, 1]$ . We next generate response variables using Equation (3) together with standard Gaussian noise. After discretizing some response variables, we obtain data following a Gaussian copula factor distribution.

Three metrics are used to evaluate the algorithms: the true and false positive rate (TPR and FPR) for assessing the skeleton, and the structural Hamming distance (SHD), counting the number of edge insertions, deletions, and flips to transfer the estimated CPDAG into the correct CPDAG [28], for assessing the CPDAG. A higher TPR, a lower FPR, and a smaller SHD imply better performance. We set the significance level in the PC algorithm to  $\alpha = 0.01$  (experiments with other values done suggest the same conclusion) and the sparseness parameter in generating DAGs to  $s = 2/(k - 1)$ , such that the average neighbors of each node is 2 [14]. For the Gibbs sampler, the first 500 samples (burn-in) are discarded and the next 500 samples are stored. We test the algorithms for different numbers of factors  $k \in \{4, 10\}$ , and sample sizes  $n \in \{500, 1000, 2000\}$ .

**Evaluation on Gaussian data** We first consider the case where the observed data are Gaussian and all factors have multiple indicators, since this matches the assumptions of the original PC-MIMBuild algorithm. The number of indicators per factor is randomly chosen from 3 to 10, to mimic typical real-world datasets [25, 29].

Figure 2 shows the results, providing the mean of TPR, FPR, and SHD over 100 repeated experiments with errorbars representing 95% confidence intervals. First, we see that CFPC performs clearly better than MBPC w.r.t. TPR despite an indistinguishable performance w.r.t. FPR (CFPC is slightly better than MBPC for  $k = 4$  while the other way around for  $k = 10$ ). Therefore, w.r.t. the overall metric SHD, CFPC significantly outperforms MBPC.

Our analysis is that MBPC tests for conditional independencies between all pairs of indicators and claims a dependence between factors even if just one of the pairs fails the test. This multiple testing approach, although elegant in theory, is difficult to make robust for largely varying numbers of indicators and sizes of the conditioning set. Second, while CFPC and GSPC report similar TPR scores, CFPC shows a clear advantage over GSPC w.r.t. FPR (thus a better SHD than GSPC), which becomes more prominent for a larger sample size. This is because the correlations between factors are estimated indirectly through their indicators, which makes the correlations less reliable than those estimated directly through the observed data. The effective sample size used in CFPC naturally incorporates the reduced reliability, whereas GSPC that still uses the original sample size rejects the null hypothesis of conditional independence more easily, resulting in more false positives.

**Evaluation on mixed data** We now focus on mixed data, in which two cases are considered: 1) all factors have multiple indicators; 2) half of the factors have multiple indicators and half only have a single indicator. When a factor has multiple indicators, the number of indicators per factor is randomly chosen from 3 to 10, and all such indicators are discretized into ordinal variables where the number of levels per variable is randomly chosen from 2 to 5. For factors with a single indicator, we discretize half into ordinal variables (from 2 to 5 levels) and keep the other half continuous.

Figures 3 and 4 summarize the experimental results, providing the mean of TPR, FPR, and SHD over 100 repeated experiments with 95% confidence intervals. From Figure 3a, we first see that GSPC is slightly better than CFPC w.r.t. TPR while GSPC and CFPC show a clear advantage over MBPC. Second, MBPC is rather sensitive to sample sizes in cases with only multiple indicators, where a small sample size incurs a poor performance. Figure 3b shows that CFPC is significantly better than GSPC w.r.t. FPR, which becomes more prominent in cases with only multiple indicators and larger sample sizes. This is because the effective sample size in CFPC better than GSPC represents the uncertainty in the partial correlation estimates and then incurs less false positives. CFPC also shows clear advantages over MBPC w.r.t. FPR when the number of factors is 4 ( $k = 4$ ), whereas MBPC works slightly better than CFPC when  $k = 10$ . As for the overall metric SHD shown in Figure 4, CFPC and GSPC perform clearly better than MBPC in almost all situations because of the bad performance of MBPC w.r.t. TPR. Meanwhile, we can see that CFPC generates a more accurate CPDAG than GSPC, in particular for larger sample sizes. This is because our proposed infer-

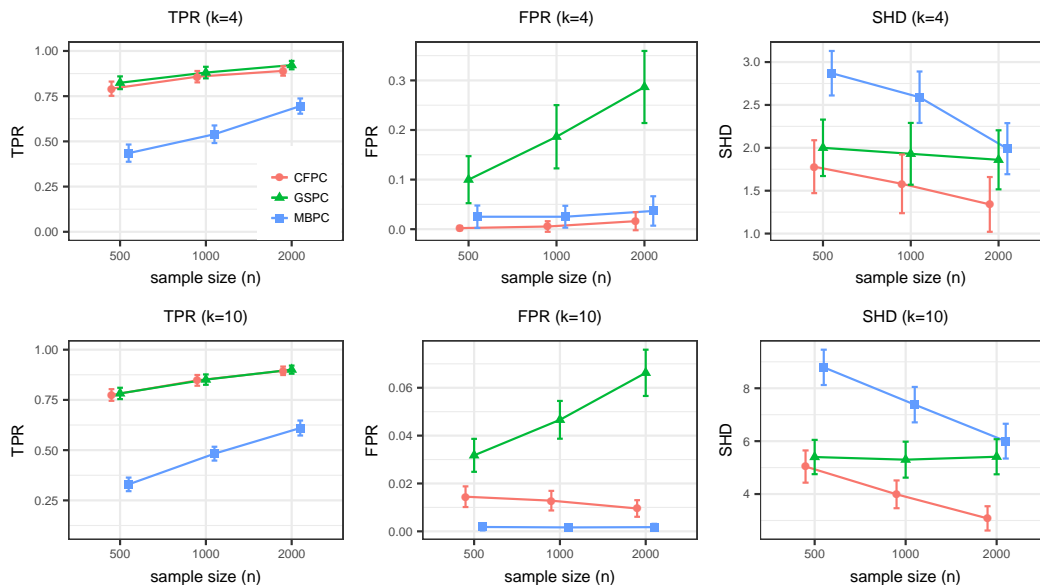

Figure 2: TPR, FPR, and SHD of CFPC, GSPC, and MBPC over different sample sizes when the data are fully Gaussian and all factors have multiple indicators, showing the mean over 100 experiments together with 95% confidence intervals. The two rows represent the results when the number of latent factors is 4 and 10 respectively.

ence procedure more accurately estimates the correlation matrix (not shown here) and, through the effective sample size, better represents the uncertainty in the correlation estimates than the greedy step-wise method. In a nutshell, our ‘Copula Factor PC’ algorithm, outperforms its two competitors in almost all situations.

## 6 REAL-WORLD APPLICATION

In this section, we give an illustration on a real-world dataset collected by [30] that includes 236 children with Attention Deficit Hyperactivity Disorder (ADHD) and 406 controls. We focus on 4 (explicit) variables that are related to ADHD symptoms: gender (Gen), Age, verbal IQ (VIQ), performance IQ (PIQ), as well as 18 questions that are designed to measure three latent concepts: inattention (Inatt), hyperactivity (Hyper), and impulsivity (Impul). The first 9 questions (Q1-Q9) are designed to measure ‘Inatt’, while the next 5 questions (Q10-Q14) and the last 4 questions (Q15-Q18) are used to measure ‘Hyper’ and ‘Impul’ respectively [29]. All the questions are ordinal with four levels: never (0), sometimes (1), frequently (2), and always (3).

Our task is to infer the causal structure among the 4 variables and 3 latent concepts from observations of the 4 variables and 18 questions. We run our ‘Copula Factor PC’ algorithm (using the order-independent version of the PC algorithm [7]) on this dataset and enforce the prior knowledge that no variables cause gender. The resulting

graph is shown in Figure 5, in which double arrows ‘ $\Rightarrow$ ’ represent the mapping from the three latent concepts to their corresponding questions (known) and other edges are those learned by our algorithm.

First, in the inferred model, we find that ‘Gen’ has a direct causal influence on ‘Inatt’. The finding is in the expected direction, namely males are at an increased risk of inattention, hyperactivity, and impulsivity problems. Meta-analyses in population-based samples suggested that males are 24 times more likely to meet full criteria for ADHD than females [31] and in clinically referred ADHD samples, the gender ratio was about 5:1 [19].

Second, the causal model implies that there is a significant causal path from inattention to hyperactivity (and subsequently to impulsivity), but not the other way around. It suggests that factors that cause inattention affect hyperactivity/impulsivity downstream of that, whereas those factors that lead to high hyperactivity/impulsivity do not necessarily lead to higher inattention. This causal path was previously observed in this sample and was also confirmed in two independent ADHD samples [26].

Third, the causal direction of the associations between verbal IQ and inattention as well as impulsivity is not clear from our model. Both interpretations seem reasonable. Previous studies suggest that ADHD is associated with lower (verbal) IQ, and particularly attention problems have been found to be strong predictors for lower

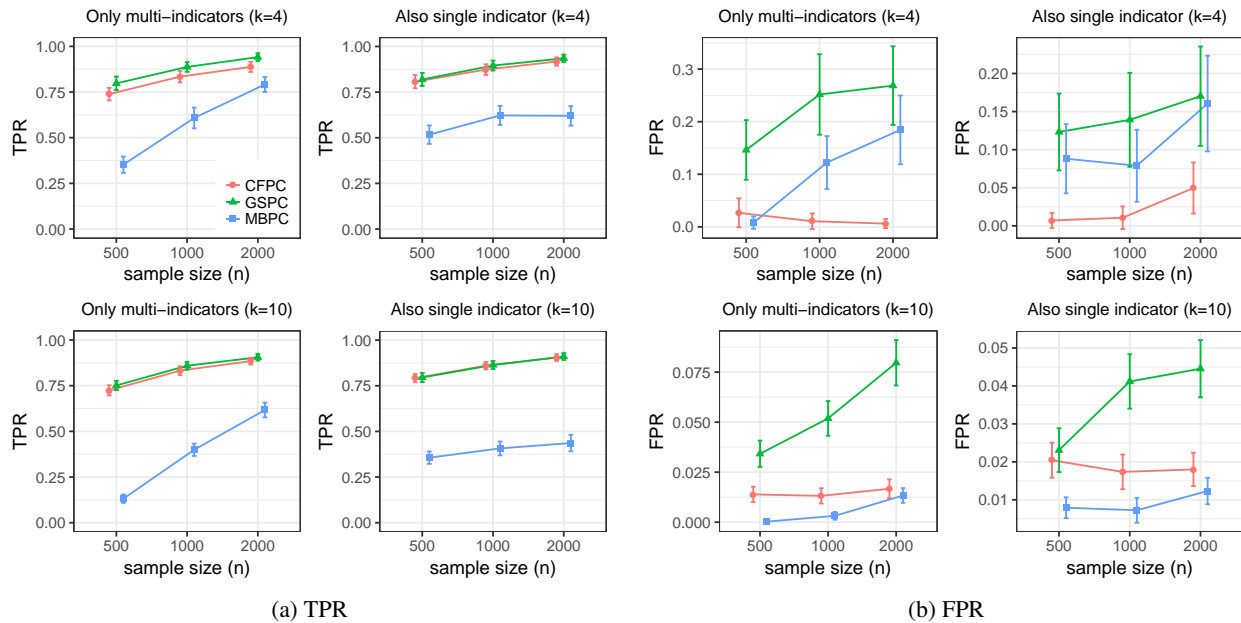

Figure 3: (a) TPR of CFPC, GSPC, and MBPC for the case where all factors have multiple indicators (left column) and the case where half of the factors have multiple indicators while the other half have a single indicator (right column), showing the mean over 100 experiments together with 95% confidence intervals. The two rows represent the results when the number of latent factors is 4 and 10 respectively. (b) FPR for the same experiments as in (a).

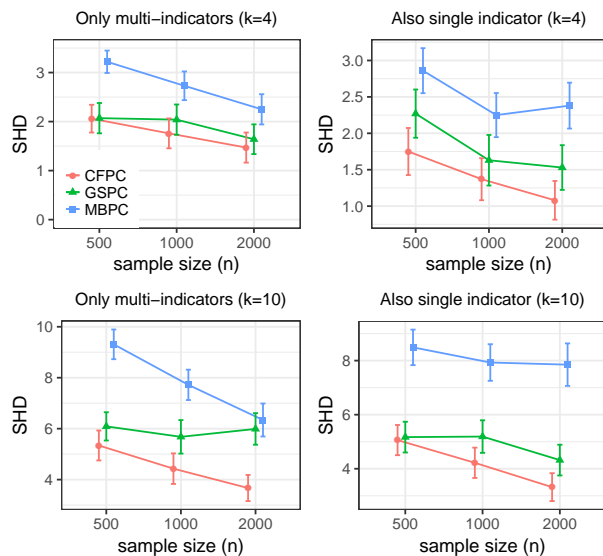

Figure 4: SHD of CFPC, GSPC, and MBPC, showing the mean over 100 experiments together with 95% confidence intervals, for the same experiments as in Figure 3.

IQ and poorer academic performance [12].

To conclude, using the Copula Factor PC algorithm in an ADHD sample allows us to infer causal relations between the different ADHD traits and generic factors

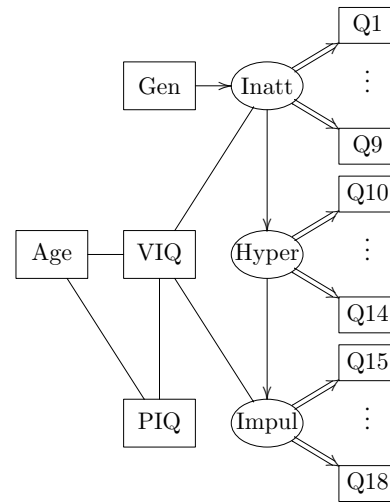

Figure 5: The resulting causal graph obtained by the ‘Copula Factor PC’ algorithm on the ADHD dataset, in which double arrows ‘ $\Rightarrow$ ’ represent the mapping from latent concepts to their corresponding questions (known) and other edges are those learned by our algorithm.

(age, gender, and IQ). This enhances knowledge of the causal structure of ADHD (e.g., by answering the question whether inattention is causing hyperactivity, or vice versa), which may have significant clinical implications, as it may inform therapeutic interventions.

## 7 CONCLUSION AND DISCUSSION

In this paper, we focused on learning causal relations between latent variables with pre-designed or pre-fitted measurement models. Our typical use case is that of psychological constructs that are linked to responses on questionnaire items. To the best of our knowledge, we are the first to propose a provably convergent algorithm that is able to recover the underlying causal structure between such factors and other observed variables, which can be both discrete and continuous.

In the experiments, our ‘Copula Factor PC’ algorithm clearly outperformed both the PC-MIMBuild algorithm and the greedy step-wise approach. PC-MIMBuild tests for conditional independencies between all pairs of indicators and concludes that the latent factors are dependent even if just one of the pairs fails the independence test. In our experience, this multiple testing approach, although elegant in theory, is difficult to make robust for largely varying numbers of indicators and sizes of the conditioning set. The ‘Copula Factor PC’ algorithm more naturally appears to find the right balance between true positives and false positives under varying conditions. It improves upon the greedy step-wise approach by estimating the full correlation matrix instead of individual sub-parts, which increases the power of the conditional independence tests.

Our approach extends earlier work, particularly [9] and [11], with various novel and essential ingredients needed to handle latent variables. Compared to [9], we replaced the Wishart prior with a  $G$ -Wishart distribution over factors and indicator variables, whose structure directly follows from the measurement model. The corresponding marginal prior on the factors is then still a Wishart distribution, which can be chosen such that the pairwise correlations are uniformly distributed. As in [11], but unlike [9], we can prove that our procedure is consistent. In the Supplement we show that, although the correlation matrix over factors itself is non-identifiable, all characteristics that relate to the identification of the correct causal structure can be consistently recovered.

While we considered the PC algorithm for inferring the underlying causal structure, one could plug in other standard algorithms like FCI [27], GES [5], or the recent improvements [6, 8, 32]. We further focused on so-called pure measurement models [24, 15], which is the major simplifying assumption of our procedure. We would argue that this is often satisfied, since it is the way in which questionnaires are typically designed by domain experts and that allows for a specific interpretation of the factors (e.g., a predefined set of items relates to the concept “hyperactivity”, another non-overlapping set of items to the

concept “inattention”). If the measurement models are not given, they can be learned using off-the-shelf algorithms, such as BPC [24] and FOFC [15], which output pure measurement models.

## Acknowledgements

We thank Anoeck Sluiter-Oerlemans for the profound analysis about experimental results on the ADHD dataset, and Ioan Gabriel Bucur for valuable discussions on the proof of Theorem 2. This research has been partially financed by the Netherlands Organisation for Scientific Research (NWO) under project 617.001.451.

## Abstract

Learning sparse features from only positive and unlabeled (PU) data is a fundamental task for problems of several domains, such as natural language processing (NLP), computer vision (CV), information retrieval (IR). Considering the numerous amount of unlabeled data, most prevalent methods rely on negative sampling (NS) to increase computational efficiency. However, sampling a fraction of unlabeled data as negative for training may ignore other important examples, and thus lead to non-optimal prediction performance. To address this, we present a fast and generic batch gradient descent optimizer ( $f_{BGD}$ ) to learn from *all* training examples without sampling. By leveraging sparsity in PU data, we accelerate  $f_{BGD}$  by several magnitudes, making its time complexity the same level as the NS-based stochastic gradient descent method. Meanwhile, we observe that the standard batch gradient method suffers from gradient instability issues due to the sparsity property. Driven by a theoretical analysis for this potential cause, an intuitive solution arises naturally. To verify its efficacy, we perform experiments on multiple tasks with PU data across domains, and show that  $f_{BGD}$  consistently outperforms NS-based models on all tasks with comparable efficiency.

## 1 INTRODUCTION

Learning from only positive and unlabeled (or non-observed) data, aka PU learning, occurs in numerous domains such as NLP, CV, IR. In these scenarios, the observed training data usually consists of positive data only. Moreover, the overall training data is typically very sparse, since

only a small fraction of positive examples are observed, and the non-observed negative examples are of a much larger scale.

To generalize well on such sparse data (He and Chua, 2017), embedding learning, such as word embedding in NLP (Mikolov et al., 2013b), image (category) embedding in CV (Weston et al., 2011), user (item) embedding in IR (Koren et al., 2009; Yuan et al., 2016a), and DNA k-mer embedding in genetic engineering (Ng, 2017), has become a common practice. However, learning embeddings from PU (or positive-only) data is computationally expensive, since each observed positive example needs to be paired with *all* non-observed negatives.

To learn from large-scale non-observed data, most recent embedding methods employ negative sampling (NS) and stochastic gradient descent (SGD) for efficient optimization (Mikolov et al., 2013b; Weston et al., 2012; Guo et al., 2018a,b; Yuan et al., 2016a, 2017). However, the training time and prediction accuracy are largely determined by the sampling distribution and size of negative samples. Sampling a fraction of non-observed data as negative for training may ignore other useful examples, or lead to insufficient training of them. This is our main motivation in this work. Another well-known difficulty is that the SGD optimizer performs frequent gradient updates with a high variance, which can cause the objective function to fluctuate heavily near the optimum (Ruder, 2016). By contrast, batch gradient descent (BGD) computes the gradient on all training data for updating a model parameter. As such, the learning process has the potential to converge to a better optimum. Unfortunately, the low efficiency caused by the full-batch gradient computation makes it less applicable to large-scale datasets.

To deal with these issues, we present a fast and generic batch gradient descent algorithm (called  $f_{BGD}$ ) for learning embeddings from positive-only data.  $f_{BGD}$  optimizes a commonly used square loss function that accounts for all

non-observed examples without any sampling. To ensure the learning efficiency, we accelerate  $f_{BGD}$  with rigorous mathematical reasoning. Notably, despite that  $f_{BGD}$  computes loss and gradients over all examples, its actual complexity is comparable with NS-based SGD methods that utilize only partial examples. Furthermore, we show that standard batch learning are prone to the gradient exploding and vanishing problem and stabilize it by an intuitive way.

To summarize, the main contributions of this paper are as follows:

- We propose a unified BGD approach to solve the sparse feature learning problem from PU data. For efficiency optimization, we accelerate it by a natural reformulation of the loss and rearrangement for the dot product operation. For generality, we identify the dot product structure for a variety of embedding models.
- We provide theoretical explanations that the standard batch gradient learning suffers from gradient instability issues when learning embedding models due to large batched summation of sparse features.
- We implement a general weighting scheme that suits well for unlabeled examples in various domains, which not only largely improves the prediction accuracy of  $f_{BGD}$ , but also makes efficiency optimization possible.
- $f_{BGD}$  achieves state-of-the-art performance in multiple research fields with comparable costs to NS-based SGD methods. Insightful comparisons for sampling based methods have been thoroughly studied. Another insightful observation is that many specific models used in one of these fields are promising to benefit others by minor (or no) changes. This opens a new direction of research to bridge these fields.
- We release the source code of  $f_{BGD}$  at: <https://github.com/fajieyuan/fBGD>.

## 2 PROBLEM FORMULATION

### 2.1 LEARNING FROM POSITIVE-ONLY DATA

Assuming we have two sets of examples that are available for training: the positive set  $P$  and an unlabeled set  $U$ , which is typically non-observed and contains both positive and negative samples. Each sample in  $P$  is an observed  $(x, y)$  pair, where  $x \in X$  and  $y \in Y$ .  $X$  and  $Y$  are the set of distinct  $x$  and  $y$  respectively. For a given  $x$ , we have a set of relevant  $y$  labelled, denoted by  $Y_x^+$ , the size of which is much smaller than that of the non-observed set  $Y_x^-$ . As shown in Figure 1 (a), we can use a matrix  $\mathbf{H} \in \mathbb{R}^{|X| \times |Y|}$  to denote the historical interactions between  $x$  and  $y$ . The goal of PU learning is to find a function  $\hat{r}_{xy}$  (parameterized by  $\Theta$ ) that explains a set of observed pairs  $(x, y)$ , such as “relevant-or-not” and “like-or-not”.

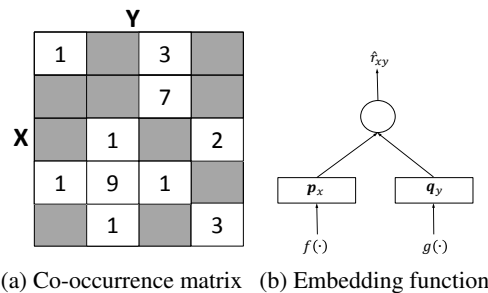

Figure 1: (a): PU data with  $(x, y)$  co-occurrence matrix  $\mathbf{H}$ . The grey cells denote no explicitly observed  $(x, y)$  examples. (b): Embedding function.  $f(\cdot)$  and  $g(\cdot)$  are functions to construct the embedding vectors  $\mathbf{p}_x$  and  $\mathbf{q}_y$  respectively.

### 2.2 EMBEDDING MODELS

Embedding models have been widely adopted in many specific PU learning tasks. In this work, we focus on optimizing the embedding functions that can be *explicitly* or *implicitly* expressed by a dot product structure, given below.

$$\hat{r}_{xy} = \langle \mathbf{p}_x, \mathbf{q}_y \rangle = \sum_{d=1}^g p_{x,d} q_{y,d} \quad (1)$$

where  $\mathbf{p}_x$  and  $\mathbf{q}_y$  are *compressed* embedding vectors with embedding dimension  $g$ . They can be obtained by directly projecting the ID of row/column into the embedding space (i.e., explicit structure as in Xin et al. (2018) and He et al. (2016b)), or projecting with other features of row/column (i.e., implicit structure as in Rendle and Freudenthaler (2014); Bayer et al. (2017)). The time complexity of evaluating this equation is  $O(g)$ . Note that the implicit dot product structure can describe a variety of multi-linear models, such as SVDFeature (Chen et al., 2012) and tensor models (Bailey and Aeron, 2017; Rendle and Schmidt-Thieme, 2010). Later, we will show how to construct this dot product structure for some state-of-the-art embedding models.

### 2.3 LOSS FUNCTION AND BGD OPTIMIZATION

We propose optimizing the standard regression loss, which can also be used for classification and ranking tasks. Unlike previous works (Pennington et al., 2014; Cer et al., 2017), the optimized loss function should explicitly account for all unlabeled samples.

$$J(\Theta) = \sum_{(x,y) \in P} \alpha_{xy}^+ (r^+ - \hat{r}_{xy})^2 + \underbrace{\sum_{(x,y) \in U} \alpha_{xy}^- (r^- - \hat{r}_{xy})^2}_{JM(\Theta)} \quad (2)$$

where  $JM(\Theta)$  denotes the errors of all unlabeled examples,  $\alpha_{xy}^+$  and  $\alpha_{xy}^-$  are the weight functions. Eq. (2) can be minimized by BGD, which computes the gradient of loss function w.r.t.  $\theta \in \Theta$  on the entire (positive and unlabeled) samples:

$$\theta \leftarrow \theta - \gamma \nabla_{\theta} J(\theta) \quad (3)$$

where  $\gamma$  is the learning rate, and  $\nabla_{\theta} J(\theta)$  is the gradient of  $J(\Theta)$  w.r.t.  $\theta$ , given below:

$$\begin{aligned} \nabla_{\theta} J(\theta) = & 2 \left( \underbrace{\sum_{(x,y) \in P} \alpha_{xy}^+ (r^+ - \hat{r}_{xy}) \nabla_{\theta} \hat{r}_{xy}}_{O(|Y_x^+|g)} \right. \\ & \left. + \underbrace{\sum_{(x,y) \in U} \alpha_{xy}^- (r^- - \hat{r}_{xy}) \nabla_{\theta} \hat{r}_{xy}}_{O(|Y_x^-|g)} \right) \end{aligned} \quad (4)$$

where  $O(|Y_x^+|g)$  and  $O(|Y_x^-|g)$  are the complexity of gradient computation on positive and unlabeled data.

## 2.4 EFFICIENCY ISSUES

As can be seen, the second term  $J_M(\Theta)$  in Eq.(2) dominates the computational complexity. This is because computing  $J_M(\Theta)$  in Eq.(2) has almost  $O(|X||Y|g)$  time because  $|P| \ll |U|$ . Similarly, updating a parameter (under the explicit dot product setting), e.g.,  $p_{x,d}$ , by Eq.(4) is  $O((|Y_x^-|)g)$ , or  $O(|Y|g)$ , because  $|Y_x^+| \ll |Y_x^-|$ . The total cost by iterating over all  $p_{x,d}$  in  $\Theta$  in each iteration becomes  $O(|X||Y|g)$ . Clearly, the straight-forward way to calculate gradients by BGD is generally infeasible, because  $|X||Y|$  can easily reach billion level or even higher.

## 3 FAST & GENERIC BGD For PU DATA

In this section, we first describe the derivation of  $f_{BGD}$  for the optimization of Eq.(1), and show how to generalize it to complex embedding models. Then, we design a general weighting scheme for the missing examples in  $f_{BGD}$ .

### 3.1 EFFICIENT $f_{BGD}$ LOSS

In the above learning setting, the dominant computation is the minimization of  $J_M(\Theta)$  in Eq.(2) since each  $x$  has its standalone unlabeled set of  $y$ , i.e.,  $Y_x^-$ . As such, the BGD algorithm basically needs to iterate through all elements in  $Y_x^-$ , and repeat the operation for all  $x \in X$ , which produces the main cost. To solve the problem, we reformulate the standard BGD loss according to the set theory<sup>1</sup>. Naturally, for any PU learning problem the loss of  $U$  (unlabeled) data can be expressed by the *residual* between the loss of *all* data and that of  $P$  (positive) data.

$$J_M(\Theta) = \sum_{x \in X} \left( \sum_{y \in Y} \alpha_{xy}^- (r^- - \hat{r}_{xy})^2 - \sum_{y \in Y_x^+} \alpha_{xy}^- (r^- - \hat{r}_{xy})^2 \right) \quad (5)$$

A new objective function can be achieved by substituting Eq.(5) in Eq.(2). We combine the two terms that associates with  $P$  data together into a single term (Note that  $r^+$ ,  $r^-$ ,

<sup>1</sup>The set relation was also applied in He et al. (2016b); Xin et al. (2018), which can be regarded as a special case of  $f_{BGD}$  as  $\hat{r}_{xy}$  is only limited to an explicit dot product function that deals with two features in a specific domain.

$\alpha_{xy}^+$ ,  $\alpha_{xy}^-$  are independent of  $\theta \in \Theta$ ).  $J(\Theta)$  is rewritten as

$$J(\Theta) = const + J_A(\Theta) + J_P(\Theta) \quad (6)$$

where

$$\begin{aligned} J_A(\Theta) &= \sum_{x \in X} \sum_{y \in Y} \alpha_{xy}^- (\hat{r}_{xy} - r^-)^2 \\ J_P(\Theta) &= \sum_{x \in X} \sum_{y \in Y_x^+} (\alpha_{xy}^+ - \alpha_{xy}^-) \left( \hat{r}_{xy} - \frac{\alpha_{xy}^+ r^+ - \alpha_{xy}^- r^-}{\alpha_{xy}^+ - \alpha_{xy}^-} \right)^2 \end{aligned} \quad (7)$$

where  $J_A(\Theta)$  and  $J_P(\Theta)$  denote the loss for *all* and  $P$  data respectively; *const* denotes a  $\Theta$ -invariant constant value. Clearly, the loss of  $U$  data has been eliminated. The new computation complexity is now in  $\tilde{J}_A(\Theta)$ , which is part of  $J_A(\Theta)$ , defined as:

$$\tilde{J}_A(\Theta) = \sum_{x \in X} \sum_{y \in Y} \alpha_{xy}^- \hat{r}_{xy}^2 - 2r^- \sum_{x \in X} \sum_{y \in Y} \alpha_{xy}^- \hat{r}_{xy} \quad (8)$$

So far, we have focused on the loss without considering the specific formulation of model prediction  $\hat{r}_{xy}$ . As described in Section 2.2, we focus on  $\hat{r}_{xy}$  that can be either *explicitly* or *implicitly* formalized as a dot product (i.e., Eq.(1)) structure based on embedding vectors of  $x$  and  $y$ . In the following, we first show the generalized transformation for a *compressed* dot product structure. Then, we show how to apply  $f_{BGD}$  to various complex embedding functions with more input features by constructing the similar structure.

$$\begin{aligned} \alpha_{xy}^- \hat{r}_{xy}^2 &= \alpha_{xy}^- \sum_{d=1}^g p_{x,d} q_{y,d} \sum_{d'=1}^g p_{x,d'} q_{y,d'} \\ &= \sum_{d=1}^g \sum_{d'=1}^g \alpha_{xy}^- (p_{x,d} p_{x,d'}) (q_{y,d} q_{y,d'}) \end{aligned} \quad (9)$$

where we observe that there exists a very nice structure in above equation — if  $\alpha_{xy}^-$  is a constant value or a value only associates with  $x$  or  $y$  but not  $(x, y)$  pair. Considering that there is no observed  $(x, y)$  interaction in unlabeled examples, it is reasonable to set  $\alpha_{xy}^-$  as  $\alpha_y^-$  or  $\alpha_x^-$ . The simplified weight design is a necessary condition for efficient optimization in the following. Here we continue to discuss the algorithm, assuming  $\alpha_{xy}^- = \alpha_y^-$ , and later show how to design a good weighting scheme. With this setting, the interaction between  $p_{x,d}$  and  $q_{y,d}$  can be safely separated. Thereby,  $\sum_{y \in Y} \alpha_y^- q_{y,d} q_{y,d'}$  can be independent of the optimization of  $x$ -related parameters. That is, we could achieve a significant speed-up by precomputing this term. Let caches  $S_{dd'}^q = \sum_{y \in Y} \alpha_y^- q_{y,d} q_{y,d'}$ , and  $S_d^q = \sum_{y \in Y} \alpha_y^- q_{y,d}$ ,  $\tilde{J}_A(\Theta)$  is derived as follows

$$\tilde{J}_A(\Theta) = \sum_{d=1}^g \sum_{d'=1}^g S_{dd'}^q \sum_{x \in X} p_{x,d} p_{x,d'} - 2r^- \sum_{d=1}^g S_d^q \sum_{x \in X} p_{x,d} \quad (10)$$

The rearrangement of nested sums in Eq.(10) is the key transformation that allows the fast optimization of  $f_{BGD}$ . The computation complexity has reduced from  $O(|X||Y|g)$  in Eq.(8) to  $O((|X| + |Y|)g^2)$  in Eq.(10). Optimization details regarding the gradient computation are given in Section 3.3.

### 3.2 IDENTIFYING THE DOT PRODUCT STRUCTURE

Figure 2: (a) denotes the explicit dot product structure, such as in AllVec (Xin et al., 2018), while (b) is the dot product that implicitly exists in SVDFeature. Each cell denotes a real value.

We notice that the dot product structure implicitly exists in a variety of embedding modes. Here we show the structure for a general embedding model, aka SVDFeature (Chen et al., 2012), which can be used in context-aware recommender systems (CARS), content-based image retrieval system (CBIR) and prior knowledge based word representation. We also identify the dot product structure for two tensor-based embedding models (Bailey and Aeron, 2017; Rendle and Schmidt-Thieme, 2010) in Appendix A. The model equation of SVDFeature is defined as

$$\hat{r}_{xy} = w_0 + \mathbf{wz}^T + \sum_{j=1}^{pX} \sum_{j'=1}^{pY} \langle \mathbf{v}_j^X, \mathbf{v}_{j'}^Y \rangle z_{x,j}^X z_{y,j'}^Y \quad (11)$$

where  $\mathbf{z}$  is the feature vector. E.g., in a context-aware music recommender system, it is defined as

$$\mathbf{z} = \underbrace{(0, \dots, 1, \dots, 0, 0, 0.1, \dots, 0.1, 0, 0, 1, \dots, 1, \dots, 0, 0, 1, \dots, 0, 0, 1, \dots, 0)}_{\mathbf{z}_x^X} \underbrace{, \dots, 1, \dots, 0, 0, 1, \dots, 0)}_{\mathbf{z}_y^Y}$$

$x$  and  $y$  are described by  $\mathbf{z}_x^X$  and  $\mathbf{z}_y^Y$  respectively.  $z_{x,j}^X$  is  $j$ -th element in  $\mathbf{z}_x^X$ , which is  $x$ -th row in  $\mathbf{Z}^X \in \mathbb{R}^{|X| \times pX}$ .  $pX$  is the number of features in  $\mathbf{z}_x^X$ .  $\mathbf{v}_j^X$  is the  $j$ -th row in  $\mathbf{V}^X \in \mathbb{R}^{pX \times f}$ , where  $f$  is the original embedding size. Inspired by Rendle and Freudenthaler (2014), we rewrite Eq.(11) as an implicit dot product structure (see Figure 2).

$$\hat{r}_{xy} = \sum_{d=1}^g p_{x,d} q_{y,d} \quad (12)$$

where  $g = f + 2$  and

$$\begin{aligned} p_{x,d} &= \sum_{j=1}^{pX} z_{x,j}^X v_{j,d}^X, & q_{y,d} &= \sum_{j=1}^{pY} z_{y,j}^Y v_{j,d}^Y, \\ p_{x,f+1} &= w_0 + \sum_{j=1}^{pX} w_j z_{x,j}^X, & q_{y,f+1} &= 1 \\ p_{x,f+2} &= 1, & q_{y,f+2} &= \sum_{j=1}^{pY} w_{(j+pX)} z_{y,j}^Y \end{aligned} \quad (13)$$

where  $v_{j,d}^X$  is the  $d$ -th element in  $\mathbf{v}_j^X$ . Next, we show the gradient computation for both explicit (i.e., Eq. (1)) and implicit dot product (e.g., Eq. (11)) structure.

### 3.3 EFFICIENT GRADIENTS

Following Section 3.1, the gradients of  $\tilde{J}_A(\theta)$  w.r.t.  $\theta^X \in \Theta^X$  is given by

$$\begin{aligned} \nabla_{\theta^X} \tilde{J}_A(\theta) &= 2 \sum_{d=1}^g \sum_{d'=1}^g S_{dd'}^q \sum_{x \in X} p_{x,d'} \nabla_{\theta} p_{x,d} \\ &\quad - 2r^- \sum_{d=1}^g S_d^q \sum_{x \in X} \nabla_{\theta} p_{x,d} \end{aligned} \quad (14)$$

The optimization process of  $\theta^Y \in \Theta^Y$  is almost symmetric to  $\theta^X$ , except that the weighting scheme  $\alpha_y^-$  is inside the sum of  $y \in Y$ . In what follows, we present the gradient computation for Eq.(14) with both explicit and implicit dot products.

#### 3.3.1 GRADIENT COMPUTATION WITH EQ.(1)

Assume Eq.(1) is a basic dot product, the gradient of  $p_{x,d}$  with respect to  $p_{x^*,d^*}$  is given by

$$\nabla_{p_{x^*,d^*}} p_{x,d} = \begin{cases} 1 & x = x^* \wedge d = d^* \\ 0 & \text{otherwise} \end{cases} \quad (15)$$

Thus, Eq.(14) simplifies to

$$\nabla_{p_{x^*,d^*}} \tilde{J}_A(\theta) = 2 \sum_{d=1}^g S_{d^*d}^q p_{x^*,d} - 2r^- S_{d^*}^q \quad (16)$$

The complexity of Eq.(16) is in  $O(g)$ , and correspondingly, updating all  $\theta^X \in \Theta^X$  is  $O(|X|g^2)$ . Overall, gradient computation for all  $\theta \in \Theta$  is  $O((|X| + |Y|)g^2 + |P|g)$ , where  $O(|P|g)$  is the complexity for the gradients of the positive loss. In contrast, the cost of NS-SGD is  $O((n+1)|P|g)$ , where  $n+1$  denotes  $n$  negative  $y$  and 1 positive  $y$ .

#### 3.3.2 GRADIENT COMPUTATION WITH EQ.(11)

The gradients of  $p_{x,d}$  with respect to  $w_{j^*}$  and  $v_{j^*,d^*}^X$  are given by

$$\nabla_{w_{j^*}} p_{x,d} = \begin{cases} z_{x,j^*}^X & d = f + 1 \\ 0 & \text{otherwise} \end{cases}, \quad \nabla_{v_{j^*,d^*}^X} p_{x,d} = \begin{cases} z_{x,j^*}^X & d \leq f \\ 0 & \text{otherwise} \end{cases} \quad (17)$$

Thus, Eq.(14) w.r.t. to  $w_{j^*}$  and  $v_{j^*,d^*}^X$  simplifies to

$$\nabla_{w_{j^*}} \tilde{J}_A(\theta) = 2 \sum_{d=1}^g S_{(f+1)d}^q \sum_{x \in X} p_{x,d} z_{x,j^*}^X - 2r^- S_{(f+1)}^q \sum_{x \in X} z_{x,j^*}^X \quad (18)$$

$$\nabla_{v_{j^*,d^*}^X} \tilde{J}_A(\theta) = 2 \sum_{d=1}^g S_{d^*d}^q \sum_{x \in X} p_{x,d} z_{x,j^*}^X - 2r^- S_{d^*}^q \sum_{x \in X} z_{x,j^*}^X \quad (19)$$

Note that the computation of sums over  $x \in X$  can be accelerated by only iterating over  $x$  where  $z_{x,j^*}^X \neq 0$ . Moreover,  $p_{x,d}$  is able to be precomputed to reduce the cost.

Although  $p_{x,d}$  changes when updating  $\theta^X$ , it can be updated in synchronization with the changes in  $\theta^X$ , denoted by  $\Delta\theta^X$ .

$$p_{x,d} \leftarrow p_{x,d} + z_{x,j}^X \Delta\theta^X = p_{x,d} - z_{x,j}^X \gamma \nabla_{\theta} J(\theta) \quad (20)$$

Analogously with Section 3.3.1, the total time complexity of  $\nabla_{\theta} J_A(\theta)$  (or  $\nabla_{\theta} \tilde{J}_A(\theta)$ ) in one iteration for all parameters is  $O(g^2(N(X) + N(Y)))$ , where  $N(X)$  and  $N(Y)$  are the number of non-zero elements in  $\mathbf{Z}^X$  and  $\mathbf{Z}^Y$ . Finally, the efficient computation for  $\theta$  is reasonably given as follows<sup>2</sup>

$$\theta \leftarrow \theta - \gamma(\nabla_{\theta} J_A(\theta) + \nabla_{\theta} J_p(\theta)) \quad (21)$$

The detailed implementation of  $f_{BGD}$  is in Appendix B.

### 3.4 WEIGHTING ON UNLABELED DATA

Now that the basic description of the speed-up process for  $f_{BGD}$  is completed, we proceed to discuss the weighting scheme in this section. First, in terms of  $\alpha_{xy}^+$ , any reasonable weighting scheme could be adopted and will not affect the analysed computation. For example, on the word embedding task (see Section 5) we set  $\alpha_{xy}^+$  the same as in GloVe (Pennington et al., 2014), while we set it as 1 for the other tasks considering that there is no available frequency information for positive  $(x, y)$  pairs.

As for  $\alpha_y^-$ , we design a non-uniform weighting scheme based on the property of  $y$ . Our weighting scheme is originally motivated by the frequency-based oversampling idea such as Skip-gram model (Mikolov et al., 2013b) and (Yuan et al., 2016a). However, both methods are tailored for the SGD or the mini-batch gradient descent (MGD) (He and Chua, 2017) optimization. Clearly, sampling techniques do not suit our model, because the focus of  $f_{BGD}$  is an all-sample based optimization method. Hence, a frequency-based weighting scheme is more suitable for our optimization setting. To effectively differentiate true negative and unknown examples, we assign a larger weight for the unlabeled data with high  $y$  frequency, and a smaller weight for the low-frequency  $y$ .

$$\alpha_y^- = \alpha_0 \frac{(e^{z_y} - 1)^\rho}{\sum_{y=1}^{|Y|} (e^{z_y} - 1)^\rho} \text{ where } z_y = \frac{p_y}{|P|} \quad (22)$$

where  $p_y$  denotes the frequency of  $y$ , given by the number of observations in  $P$ , and  $\alpha_0$  determinates the overall weight of unlabeled examples to solve the imbalanced-class problem. The exponent  $\rho$  controls weight distribution, which should be tuned based on the dataset.

## 4 IMPROVED $f_{BGD}$

So far, we have discussed the efficiency optimization of  $f_{BGD}$ . However, we observe unreliable results during evaluation especially for complex embedding models with

<sup>2</sup> Again,  $\nabla_{\theta} J_p(\theta)$  can be calculated by the standard way, which has the same time complexity with NS-SGD with the same ratio of negative and positive samples.

Figure 3: Performance of the improved  $f_{BGD}$  (Section 4.2) and standard  $f_{BGD}$  on Last.fm with four features. Note for the standard  $f_{BGD}$ , some gradients will be evaluated as infinite (NaN) when  $\gamma > 5 \times 10^{-5}$ . Clearly,  $f_{BGD}$  with vanishing gradient performs poorly on Last.fm even by fine tuning the learning rate.

more input features, as shown in Figure 3. A novel contribution here is to reveal why unstable gradient issues will occur for the standard BGD.

### 4.1 GRADIENT INSTABILITY OF $f_{BGD}$

While the unstable gradient problem, such as the gradient exploding and vanishing, has been observed when training deep neural networks (He et al., 2016a), the optimized models of  $f_{BGD}$  in this paper are mostly shallow embeddings. Therefore, the cause of the unstable gradient issue in our case is fundamentally different from that in the existing deep layer models, in the sense that in deep models unstable gradients occur mainly due to cumulative multiplying of small/big numbers from previous layers, whereas in  $f_{BGD}$  it is caused by the large batched summation of sparse features. We expect the following theoretical analysis and solution could provide practical guidelines for the future development of batch gradient optimization.

To understand the weird behavior of gradient instability, we need to revisit the form of gradients. We take the derivation of  $v_{j^*,d}^X$  ( $d \leq f$ ) in Eq. (11) w.r.t. the loss of positive data as an example.

$$\nabla_{v_{j^*,d}^X} J_P(\theta) = 2 \sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X (\alpha_{xy}^+ - \alpha_y^-) \left( \hat{r}_{xy} - \frac{\alpha_{xy}^+ \hat{r}_{xy}^+ - \alpha_y^- \hat{r}_{xy}^-}{\alpha_{xy}^+ - \alpha_y^-} \right) q_{y,d^*} \quad (23)$$

Due to the data sparsity, to compute  $\sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X$  we only need to consider  $x \in X$  that has a non-zero  $z_{x,j^*}^X$  (note that for a feature  $j$ , most  $x$  have  $z_{x,j^*}^X$  equal to zero which can be safely ignored). Let  $l_{j^*}$  be the number of non-zero elements in the  $j^*$ -th column of  $\mathbf{Z}^X$ .

In real-world data sets, the number of rows in  $\mathbf{Z}^X$ , i.e.,  $|X|$ , can easily scale to many millions or even billion level and, therefore, it is very likely that  $l_{j^*}$  has distinct magnitudes for a different column  $j^*$ . Moreover, in

Eq.(23) there is another summation  $\sum_{y \in Y_x^+}$ , which represents the size of observed  $y$  for  $x$ . The component value of  $\sum_{x \in X} \sum_{y \in Y_x^+} x_{x,j^*}^X$  in Eq.(23) varies from 1 to  $|X| \cdot |Y|$ , assuming  $\mathbf{Z}^X$  is a binary matrix. This indicates the value of Eq.(23) may be very unstable:  $\nabla_{v_{j^*,d}^X} J_P(\theta)$  can be too large for a denser feature  $j^*$  that is accompanied by a large  $\sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X$  (e.g.,  $= 10^6$ ), while it may be too small for a sparser feature with a small  $\sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X$  (e.g.,  $= 1$ ). Accordingly, the overall gradient  $\nabla_{\theta} J(\theta)$  in Eq.(21) has the same unstable problem. In this case, a uniform learning rate  $\gamma$  is no longer suitable because  $\nabla_{\theta} J(\theta)$  with a larger  $\sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X$  is likely to explode (i.e.  $\nabla_{\theta} J(\theta) = \text{NaN}$ ) if using a large  $\gamma$ , while  $\nabla_{\theta} J(\theta)$  with a smaller  $\sum_{x \in X} \sum_{y \in Y_x^+} z_{x,j^*}^X$  may vanish (i.e.  $\nabla_{\theta} J(\theta) \approx 0$ ) if using a small  $\gamma$ . Generally, it is hard or even impossible to find a medium learning rate that balances reasonably well in both conditions. To gain more insight into the performance of  $f_{BGD}$  with unstable gradients, we show results with different learning rates in Figure 3.

Interestingly, we empirically find that on many datasets with only two input features (or an explicit dot product structure), the gradient instability problem may be alleviated by carefully tuning  $\gamma$ . In other words, by many trials with different learning rates,  $f_{BGD}$  sometimes is able to offer reasonable results. However, on data sets with more feature variables (e.g., Last.fm), the outputs of  $f_{BGD}$  are prone to the NaN error. This is because in the pure dot product setting, the nested summation  $\sum_{x \in X}$  can be dropped. As such, although the gradient instability issue may still happen because of  $\sum_{y \in Y_x^+}$ , it is less severe as the value of  $|Y_x^+|$  is much smaller than that of  $l_j \cdot |Y_x^+|$ .

## 4.2 SOLVING THE UNSTABLE GRADIENT ISSUE

The above theoretical analysis for the gradient estimation over all data suggests that the same learning rate does not hold for all model parameters due to the large batched summation of sparse features. Analytically, by assigning a specific learning rate for each parameter update, we can control the unstable gradient to a certain extent. In other words,  $f_{BGD}$  should perform larger updates for small  $\nabla_{\theta} J(\theta)$ , and vice versa.

Based on the above analysis, an intuitive solution is to adapt the learning rate for each parameter, such as having done in Adagrad Duchi et al. (2011). While Adagrad is originally proposed for stochastic gradient method to accelerate convergence, here we show how to apply it on the full gradient method to address the gradient instability issue. Denoting  $\gamma_t$  as the learning rate for the  $t$ -th update, we then assign a personalized learning rate for each parameter  $\theta$ :

$$\gamma_t(\theta) = \frac{\gamma}{G_t(\theta)}, \quad G_t(\theta) = \begin{cases} \nabla_{\theta} J(\theta)_t + \epsilon & G_t(\theta) = 0 \\ \sqrt{\sum_{i=1}^t (\nabla_{\theta} J(\theta)_i)^2} & G_t(\theta) \neq 0 \end{cases} \quad (24)$$

Table 1: Dataset statistics ( $|U| = |X \times Y| - |P|$ ). ‘‘Open’’ is the OpenImages dataset. ‘‘K’’, ‘‘M’’ and ‘‘B’’ are short for thousand, million and billion.  $(x, y)$  denotes (word, context), (user, item) and (image, label) on the WE, CF and IC tasks respectively. Note that user and item in Lastfm contain user- and item-related variables. The density can be calculated by  $\frac{|P|}{|X \times Y|}$

Data	$ X $	$ Y $	$pX$	$pY$	$ P $	$ X \times Y $
NewsIR	83K	83K	83K	83K	150M	6.9B
Text8	71K	71K	71K	71K	47M	5.0B
Yahoo	200K	136K	200K	136K	76M	27.2B
Lastfm	63K	58K	65K	75K	1.3M	3.7B
Open	1.4M	7.5K	1.4M	7.5K	11.4M	10.5B

where  $\nabla_{\theta} J(\theta)_t$  is the gradient w.r.t.  $\theta$  for the  $t$ -th update,  $G_T(\theta)$  is the accumulation of the squared gradients, and  $\epsilon$  is a smoothing term to avoid division by zero, set as  $10^{-4}$ . The overall algorithm of improved  $f_{BGD}$  can be implemented by replacing  $\gamma$  in Eq.(21) and Eq.(20) with the new  $\gamma_t(\theta)$ .

## 5 EXPERIMENTS

$f_{BGD}$  is a generic PU learning model and can be applied in a wide range of tasks with PU data and sparse features. For evaluation purpose, we verify its performance in three fields — word embedding (WC) of NLP, collaborative filtering (CF) of IR, and image classification (IC) of CV.

### 5.1 EXPERIMENTAL SETUP

#### 5.1.1 Datasets

We use five large benchmark datasets for evaluation: NewsIR<sup>3</sup> and Text8<sup>4</sup> for WE, Yahoo music<sup>5</sup> and Lastfm<sup>6</sup> for CF, and OpenImages Krasin et al. (2017) for IC. For NewsIR, we preprocess them by a standard pipeline, i.e., removing non-textual elements, lowercasing and tokenization. For Yahoo, we use the ‘‘train\_0’’ file. For Lastfm, we follow Weston et al. (2012) by extracting the latest one-week actions per user via the timestamp, and consider two tracks played by the same user as ‘‘consecutive’’ if they are played within 90 minutes. It is used as a context-aware (or next-item) recommendation dataset, where each  $x$  contains a user and his previously played music tracks and each  $y$  contains a music track and its artist. For OpenImages, we randomly sample a number of (image, label) pairs from the original dataset. The statistics of datasets are summarized

<sup>3</sup><http://research.signalmedia.co/newsir16/signal-dataset.html>

<sup>4</sup><http://matthahoney.net/dc/text8.zip>

<sup>5</sup><http://webscope.sandbox.yahoo.com/catalog.php?datatype=r&did=2>

<sup>6</sup><http://www.dtic.upf.edu/~ocelma/MusicRecommendationDataset/>

Table 2: Comparison of well-known PU learning models. “SG” and “SVDF” is short for Skip-gram and SVDFeature respectively.

Model	Sampler	Ratio	Optimizer	Loss
SG×10	Static	1:10	SGD	LOG
GloVe	-	-	SGD	LS
SVDF×8	Uniform	1:8	SGD	LS
BPRFM	Uniform	1:1	SGD	L2R
λFM	Static	1:1	SGD	L2R
WARP	Dynamic	1:1	SGD	L2R
VSE-ens	Dynamic	1:1	SGD	L2R
$f_{BGD}$	-	-	BGD	LS

“Uniform”, “Static” and “Dynamic” are short for a uniform, static and dynamic sampler respectively. Static sampler means the sampling distribution of negative examples is defined before training and keeps unchanged during the whole optimization process. Dynamic sampler changes the sampling distribution of negative examples according to the current state of the learning algorithm. “Ratio” represents the positive-to-negative example ratio. “LS”, “LOG”, and “L2R” are short for the least square, logistic, and learning-to-rank loss function respectively. Note that we only evaluate λFM with the static sampler in this paper, considering the efficiency issues of the dynamic samplers.

in Table 1.

### 5.1.2 Baselines and Evaluation

For WE, we compare  $f_{BGD}$  with Skip-gram (Mikolov et al., 2013b) and GloVe (Pennington et al., 2014). For CF, we compare it with SVDFeature (Chen et al., 2012), BPRFM (Rendle, 2012; Rendle et al., 2009), and λFM (Yuan et al., 2016a). For IC, we compare it with SVDFeature, WARP (Weston et al., 2011) and VSE-ens (Guo et al., 2018b). For SVDFeature, we optimize it with the least square loss, and use the negative sampling strategy. The negative examples used for training are uniformly sampled from  $U$ . To show the impact of negative sampling, we vary the size of negative examples for each positive one. E.g., SVDFeature×8 means the positive-to-negative ratio is 1:8. Table 2 summarizes the characteristics of these baselines.

To assess the performance of  $f_{BGD}$  on the WE task, we use the analogical reasoning task introduced by Mikolov et al. (2013a). While to evaluate the CF and IC tasks, we regard them as a ranking or classification task. We report NDCG@10 (Normalized Discounted Cumulative Gain) and MRR@10 (Mean Reciprocal Rank) for CF and AUC (Area Under ROC Curve) for IC.

On the WE task, we evaluate the quality of the word vectors learned from the training datasets. For CF and IC, we adopt the leave-one-out evaluation protocol (Rendle et al., 2009).

### 5.1.3 Experimental Reproducibility

All reported results on each task use a fixed-size embedding dimension without special mention. Specifically, we set embedding dimension as 200, 20 and 100 for the WE, CF and IC tasks respectively. For  $f_{BGD}$ , we set the learning rate  $\gamma$  as 0.05 on all three tasks. Regarding  $r^+$ , we apply the PPMI (positive pointwise mutual information) on the WE task inspired by Levy and Goldberg (2014). For the

Table 3: Results on the word analogy task. “Sem”, “Syn” and “Tot” denote the semantic, syntactic and total accuracy [%]. The positive-to-negative example ratio in SG is 1 : 10 and 1 : 25 in NewsIR and Text8 respectively suggested by Mikolov et al. (2013b).

Model	NewsIR			Text8		
	Sem	Syn	Tot	Sem	Syn	Tot
SG	70.8	47.5	58.1	47.5	32.3	38.6
GloVe	78.8	41.6	58.5	45.1	26.9	34.5
$f_{BGD}$	77.0	46.1	<b>59.7</b>	56.5	30.4	<b>41.3</b>

Table 4: Results on the CF task. NDCG and MRR denote NDCG@10 and MRR@10 respectively. For each measure, the best results for SVDFeature (SVDF) and all models are indicated in bold. The results of SVDF, BPRFM, λFM and  $f_{BGD}$  are reported with all features in the Lastfm dataset.

Model	Yahoo		Lastfm	
	NDCG	MRR	NDCG	MRR
SVDF×1	0.0067	0.0044	0.0436	0.0285
SVDF×4	0.0133	0.009	<b>0.0565</b>	<b>0.0391</b>
SVDF×16	0.0186	0.0132	0.0535	0.0390
SVDF×64	<b>0.0197</b>	<b>0.0139</b>	0.0360	0.0263
SVDF×256	0.0193	0.0139	-	-
BPRFM	0.0178	0.0124	0.1056	0.0740
λFM	0.0200	0.0140	0.1312	0.0950
$f_{BGD}$	<b>0.0224</b>	<b>0.0161</b>	<b>0.1800</b>	<b>0.1371</b>

other two tasks, we simply set it as 1.  $r^-$  can be set as 0 or -0.5. Empirically, we report results of baseline models with optimal hyperparameters whereas for  $f_{BGD}$ , we only report results with above default settings.

## 5.2 ACCURACY AND DISCUSSION

### 5.2.1 Overall Results and Sampling Bias

We report results of all models in Tables 3, 4 and 5 for the three tasks. Our first observation is that  $f_{BGD}$  achieves the best performance across all the evaluation metrics and all the datasets. For example,  $f_{BGD}$  outperforms Skip-gram and GloVe in the two text corpora w.r.t. the total accuracy.

Remarkably,  $f_{BGD}$  can easily outperform the strong baselines (e.g., λFM, WARP and VSE-ens) in the ranking and classification tasks, although it optimizes a regression loss which is typically suboptimal for ranking and classification. We attribute the advantage of  $f_{BGD}$  to two aspects: (1) the optimization of each model parameter in  $f_{BGD}$

Table 5: Results on the IC task.

Metric	SVDF×1	SVDF×4	SVDF×16	
AUC	0.681	0.724	<b>0.747</b>	
Metric	SVDF×64	WARP	VSE-ens	$f_{BGD}$
AUC	0.663	0.696	0.723	<b>0.772</b>

(a) NewsIR: tune  $\alpha_0$  ( $\rho = 0.8$ ) (b) NewsIR: tune  $\rho$  ( $\alpha_0=128$ )

(c) Lastfm: tune  $\alpha_0$  ( $\rho = 0$ ) (d) Lastfm: tune  $\rho$  ( $\alpha_0=32$ )

Figure 4: Impact of  $\alpha_0$  and  $\rho$  on  $f_{BGD}$ .

Table 6: Accuracy evaluation of  $f_{BGD}$  by adding features.  $u$ ,  $p$ ,  $i$  and  $a$  denote user, last item (song), next item and artist respectively. All hyperparameters of  $f_{BGD}$  are fixed.

Metrics	$(u, i)$	$(u, p, i)$	$(u, p, i, a)$
NDCG@10	0.0416	0.1722	0.1800
MRR@10	0.0281	0.1301	0.1371

makes use of all unlabeled data, whereas the SGD models (including MGD) only use a fraction of sampled data. In other words, important negative examples may be ignored or under-trained; (2) the tailored weighting scheme can help BGD address the imbalanced-class problem in PU data (see Table 1), and assign fine-grained penalties for further improvement.

Our second key observation in the following also verifies the above analysis. As shown in Table 4 (Yahoo),  $SVDF \times 64 > SVDF \times 16 > SVDF \times 4 > SVDF \times 1$ , while  $SVDF \times 256 < SVDF \times 64$ . The results suggest that the performance of SGD models is sensitive to the sampling size of negative examples. To be more specific, one negative sample for a positive example is insufficient to achieve optimal performance; sampling more negative examples is beneficial but too many negative examples may also hurt the performance. In addition, although  $SVDF \times 64 > SVDF \times 1$ , the theoretical computation complexity of  $SVDF \times 64$  is about 32 times higher than  $SVDF \times 1$ . Still in Table 4,  $\lambda FM$  largely improves BPRFM, which demonstrates the impact of sampling distribution of negative examples (see Table 2). However, the true distribution of negative  $(x, y)$  pairs in unlabeled samples is unknown in practice. That is, regardless of what samplers are used, sampling based methods cannot converge to the same loss with all examples or true data.

Table 7: Time Complexity of various optimizers per iteration.  $|X||Y|g$  is much larger than  $(|X| + |Y|)g^2$  and  $|P|g$ . The size relation between  $|P|g$  and  $(|X| + |Y|)g^2$  depends on the sparsity of the data and the embedding dimension  $g$ .

Model	Time Complexity
$SGD \times n$	$O((n+1) P g)$
BGD	$O( X  Y g)$
$f_{BGD}$	$O(( X  +  Y )g^2 +  P g)$

Table 8: Comparison of runtime (second/minute/hour [s/m/h]). ‘‘S’’, ‘‘I’’ and ‘‘T’’ represents the training time for a single iteration, overall iterations and total time respectively. SGD denotes Skip-gram for NewsIR and SVDFeature for other datasets.  $n$  is set as the optimal value, i.e., 10, 4 and 16 for NewsIR, Lastfm and OpenImages respectively.

Model	NewsIR			Lastfm			OpenImages		
	S	I	T	S	I	T	S	I	T
$SGD \times n$	715s	15	179m	156s	50	130m	26m	100	43h
$f_{BGD}$	388s	75	485m	26s	200	87m	576s	200	32h

## 5.2.2 Impact of Weighting in $f_{BGD}$

In this section, we show the impact of the weighting function for  $f_{BGD}$ . We take the NewsIR and Lastfm datasets as an example, and omit similar results in other datasets. Figure 4 shows the prediction quality by tuning  $\alpha_0$  and  $\rho$  in the weight function. We first fix the value of  $\rho$  (e.g., 0 in CF and 0.8 in WE) to study the impact of  $\alpha_0$ . Then, we use the best value of  $\alpha_0$  to study  $\rho$ . As shown, the overall coefficient  $\alpha_0$  largely impacts the performance as the amount of positive and ‘‘negative’’ examples fed in  $f_{BGD}$  is highly imbalanced, the results of which are reflected in (a) and (c). We observe that a proper  $\rho$  can improve the performance, as shown in (b) and (d). The intuition behind the improvement is that high-frequent  $y$  (words or items) that are not observed in  $Y_x^+$  have a higher likelihood to be true negatives, and thus deserve more penalties.

## 5.2.3 Effectiveness in Modelling features

To show the generality of  $f_{BGD}$ , we have described how to apply it to complex embedding models, e.g., SVDFeature used in CARS. For example, we gradually add features for  $f_{BGD}$  on Lastfm and report results in Table 6. As expected,  $f_{BGD}$  performs largely better with  $(u, p, i)$  than  $(u, i)$  and that performance is further enhanced with  $(u, p, i, a)$ . That is,  $f_{BGD}$  yields the best prediction accuracy with all features, demonstrating its power on feature engineering.

## 5.2.4 Runtime

Table 7 summarizes the time complexity of the SGD, BGD and  $f_{BGD}$  algorithms in one iteration when optimizing the pure dot product function. As shown, the complexity of

$f_{BGD}$  is determined by the gradient computation of both positive and unlabeled data, rather than the unlabeled data only. In practice, the runtime is mainly affected by the data sparsity and embedding size. For example, on the WE task,  $O(|P|g)$  is larger than  $O((|X| + |Y|)g^2)$ , while on the IC task  $O((|X| + |Y|)g^2)$  is almost 10 times larger than  $O(|P|g)$  because the NewsIR and Text8 datasets are much denser than the OpenImages dataset (see Table 1). We have compared the overall training time<sup>7</sup> of  $f_{BGD}$  with the NS-based SGD methods in Table 8. It shows that  $f_{BGD}$  obtains comparable efficiency to the classic SGD-based algorithm. More detailed runtime results are shown in Appendix C.

## 6 RELATED WORK

Gradient methods are one of the most popular algorithms to perform optimization in the practice of machine learning. They have also been widely used for training embedding models, and have almost dominated the optimization field. So far the most commonly used gradient optimization method is SGD (Mikolov et al., 2013a,b; Pennington et al., 2014; Rendle et al., 2009; Weston et al., 2011) or a compromise MGD (mini-batch gradient descent) (Li et al., 2014; He et al., 2017), which attempts to approximate the true gradient by a single or a mini-batch of instances with sampling techniques. However, the balance between computing the expensive true gradient based on the whole batch and the immediate gradient based on a single or a fraction of instances could easily result in suboptimal performance. More importantly, on large-scale data the sampling size and distribution for SGD/MGD also significantly affect the convergence rate and prediction accuracy (Bengio and Senécal, 2008). In particular for PU data, it is non-trivial to sample from large and highly imbalanced unlabeled data. Most works deal with this issue by proposing a certain trade-off between efficiency and accuracy. For example, various negative sampling methods have been proposed in recent literature (Mikolov et al., 2013b; Pan et al., 2008; Weston et al., 2012; Yuan et al., 2016a, 2017; Wang et al., 2017; Guo et al., 2018a,b). The basic idea behind this is to select the most informative unlabeled instances as negative examples for an SGD/MGD trainer which, however, easily leads to bias itself. Moreover, all aforementioned works either expose efficiency issues with a dynamic sampler (Weston et al., 2012; Wang et al., 2017; Yuan et al., 2016a) or result in suboptimal training instances with a uniform (Rendle et al., 2009) or static (defined before optimization) sampler (Mikolov et al., 2013a,b; Yuan et al., 2016b, 2017) in practice. Our  $f_{BGD}$  in this work departs from all above studies by adopting BGD to optimize general embedding models with the entire batch of data.

It is worth mentioning that the  $f_{BGD}$  method is inspired

<sup>7</sup>For fairness, efficiency tests for all training models were running on Intel(R) Xeon(R) E5620 @ 2.40GHz CPU and 49G RAM. Note that on the WE task, we implemented all models using C++ with 8 threads in parallel, while on the other two tasks, we implemented the models using Java in a single-thread.

from our extensive empirical studies on previous works (He et al., 2016b; Bayer et al., 2017; Xin et al., 2018). The main difference is that these works are focused on a specific task, e.g., He et al. (2016b); Bayer et al. (2017) are only on recommendation and Xin et al. (2018) is on word representation. Specifically, He et al. (2016b); Xin et al. (2018) worked on the simple matrix factorization model, which cannot be used to incorporate other features, such as contextual variables associated with each observed example. While the alternating least squares (ALS) method proposed in Bayer et al. (2017) can be applied to any  $k$ -separable model<sup>8</sup>, it requires to estimate the second-order derivatives to apply the Newton update and only supports a constant weight on unlabeled examples; moreover, our empirical evidence shows that training with Newton update is (1) very sensitive to initialization point and the regularization term, and (2) highly unstable due to some gradient issues, especially for embedding models (e.g., FM and SVD-Feature) with many input features or large word corpus. By contrast, this work targets at solving the generic PU learning problem with generic embedding models. It leads to a unified solution that is applicable to a wide range of tasks, including but not limited to the ones demonstrated in this paper, with just simple changes on input features.

## 7 CONCLUSION

This work has several key contributions. First, we showed how to efficiently train a class of embedding models by batch gradient descent for positive unlabeled (PU) data. Second, we identified an unstable gradient issue in  $f_{BGD}$  due to the large batched summation of sparse features, and solve it by an intuitive way. To make the prediction accuracy of  $f_{BGD}$  comparable to the state-of-the-arts, we employed a general weighting scheme for unlabeled examples. Despite simple, the weighting scheme could address two challenges, namely imbalanced-class issue in PU data and the differentiation of true negative and unknown examples. We studied the performance of  $f_{BGD}$  in three sub-fields, and showed that  $f_{BGD}$  outperformed state-of-the-art baselines. Compared with the ranking or classification models,  $f_{BGD}$  is clearly a regression model, which means the real-valued scores estimated by it are more informative than those by ranking or classification algorithms. This will make our method highly attractive for practical usage. Moreover, the proposed  $f_{BGD}$  is not limited to the domains discussed in this paper. It potentially benefits many real-world applications with PU data, such as genes association studies (Asgari and Mofrad, 2015; Yang et al., 2014) and data stream mining (Li et al., 2009), etc.

<sup>8</sup>In essence, the concept of  $k$ -separable is to describe a model with a dot product structure of Equation (1).

## Abstract

Robust Reinforcement Learning aims to derive an optimal behavior that accounts for model uncertainty in dynamical systems. However, previous studies have shown that by considering the worst case scenario, robust policies can be overly conservative. Our *soft-robust* framework is an attempt to overcome this issue. In this paper, we present a novel Soft-Robust Actor-Critic algorithm (SR-AC). It learns an optimal policy with respect to a distribution over an uncertainty set and stays robust to model uncertainty but avoids the conservativeness of robust strategies. We show the convergence of SR-AC and test the efficiency of our approach on different domains by comparing it against regular learning methods and their robust formulations.

## 1 INTRODUCTION

Markov Decision Processes (MDPs) are commonly used to model sequential decision making in stochastic environments. A strategy that maximizes the accumulated expected reward is then considered as optimal and can be learned from sampling. However, besides the uncertainty that results from stochasticity of the environment, model parameters are often estimated from noisy data or can change during testing [Mannor et al., 2007; Roy et al., 2017]. This second type of uncertainty can significantly degrade the performance of the optimal strategy from the model’s prediction.

Robust MDPs were proposed to address this problem [Iyengar, 2005; Nilim and El Ghaoui, 2005; Tamar et al., 2014]. In this framework, a transition model is assumed to belong to a known uncertainty set and an optimal strategy is learned under the worst parameter realizations. Although the robust approach is computationally efficient

when the uncertainty set is state-wise independent, compact and convex, it can lead to overly conservative results [Mannor et al., 2012, 2016; Xu and Mannor, 2012; Yu and Xu, 2016].

For example, consider a business scenario where an agent’s goal is to make as much money as possible. It can either create a startup which may make a fortune but may also result in bankruptcy. Alternatively, it can choose to live off school teaching and have almost no risk but low reward. By choosing the teaching strategy, the agent may be overly conservative and not account for opportunities to invest in his own promising projects. Our claim is that one could relax this conservativeness and construct a softer behavior that interpolates between being aggressive and robust. Ideally, the *soft-robust* agent should stay agnostic to outside financing uncertainty but still be able to take advantage of the startup experience.

This type of dilemma can be found in various domains. In the financial market, investors seek a good trade-off between low risk and high returns regarding portfolio management [Mitchell and Smetters, 2013]. In strategic management, product firms must choose the amount of resources they put into innovation. A conservative strategy would then consist of innovating only under necessary conditions [Miller and Friesen, 1982].

In this paper, we focus on learning a *soft-robust policy* (defined below) by incorporating soft-robustness into an online actor-critic algorithm and show its convergence properties. Existing works mitigate conservativeness of robust MDP either by introducing coupled uncertainties [Mannor et al., 2012, 2016] or by assuming prior information on the uncertainty set [Xu and Mannor, 2012; Yu and Xu, 2016]. They use dynamic programming techniques to estimate a robust policy. However, these methods present some limiting restrictions such as non-scalability and offline estimation. Besides being computationally more efficient than batch learning [Wiering and van Otterlo, 2012], the use of an online algorithm is of significant interest in

robust MDPs because it can detect non-adversarial state-action pairs along a trajectory and result in less conservative results, something which cannot be performed when solving the planning problem [Lim et al., 2016]. Other works have attempted to incorporate robustness into an online algorithm for policy optimization [Mankowitz et al., 2018; Tamar et al., 2015]. Although these approaches can deal with large domains, a sampling procedure is required for each critic estimate in Tamar et al. [2015], which differs from the strictly-speaking actor-critic. In Mankowitz et al. [2018], the authors introduce a robust version of actor-critic policy-gradient but its convergence results are only shown for the actor updates. Moreover, these works target the robust solution which may be too conservative. We review all existing methods in Section 7 and compare them to our approach.

To the best of our knowledge, our proposed work is the first attempt to incorporate a soft form of robustness into an online algorithm that has convergence guarantees besides being computationally scalable. We deal with the curse of dimensionality by using function approximation that parameterizes the expected value within a space of much smaller dimension than the state space. By fixing a distribution over the uncertainty set, the induced soft-robust actor-critic learns a locally optimal policy in an online manner. Under mild assumptions on the set of distributions and uncertainty set, we show that our novel Soft-Robust Actor-Critic (SR-AC) algorithm converges. We test the performance of soft-robustness on different domains, including a large state space with continuous actions. As far as we know, no other work has previously incorporated robustness into continuous action spaces.

Our specific contributions are: (1) A soft-robust derivation of the objective function for policy-gradient; (2) An SR-AC algorithm that uses stochastic approximation to learn a variant of distributionally robust policy in an online manner; (3) Convergence proofs of SR-AC; (4) An experiment of our framework to different domains that shows the efficiency of soft-robust behaviors in a continuous action space as well. All proofs can be found in the Appendix.

## 2 BACKGROUND

In this section, we introduce the background material related to our soft-robust approach.

**Robust MDP** A robust MDP is a tuple  $\langle \mathcal{X}, \mathcal{A}, r, \mathcal{P} \rangle$  where  $\mathcal{X}$  is a finite state-space,  $\mathcal{A}$  is a finite set of actions,  $r : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$  is the immediate reward function which is deterministic and bounded and  $\mathcal{P}$  is a set of transition matrices. We assume that  $\mathcal{P}$  is structured as a cartesian product  $\bigotimes_{x \in \mathcal{X}} \mathcal{P}_x$ , which is known as the

rectangularity assumption [Nilim and El Ghaoui, 2005]. Given a state  $x \in \mathcal{X}$ , the uncertainty set  $\mathcal{P}_x$  is a family of transition models  $p_x \in \mathcal{P}_x$  we represent as vectors in which the transition probabilities of each action are arranged in the same block. For  $x, y \in \mathcal{X}$  and  $a \in \mathcal{A}$ , denote by  $p(x, a, y)$  the probability of getting from state  $x$  to state  $y$  given action  $a$ .

At timestep  $t$ , the agent is in state  $x_t$  and chooses an action  $a_t$  according to a stochastic policy  $\pi : \mathcal{X} \rightarrow \mathcal{M}(\mathcal{A})$  that maps each state to a probability distribution over the action space,  $\mathcal{M}(\mathcal{A})$  denoting the set of distributions over  $\mathcal{A}$ . It then gets a reward  $r_{t+1}$  and is brought to state  $x_{t+1}$  with probability  $p(x_t, a_t, x_{t+1})$ .

**Policy-Gradient** Policy-gradient methods are commonly used to learn an agent policy. A policy  $\pi$  is parametrized by  $\theta$  and estimated by optimizing an objective function using stochastic gradient descent. A typical objective to be considered is the average reward function

$$\begin{aligned} J_p(\pi) &= \lim_{T \rightarrow +\infty} \mathbb{E}^p \left[ \frac{1}{T} \sum_{t=0}^{T-1} r_{t+1} \mid \pi \right] \\ &= \sum_{x \in \mathcal{X}} d_p^\pi(x) \sum_{a \in \mathcal{A}} \pi(x, a) r(x, a) \end{aligned}$$

where  $r_t$  is the reward at time  $t$ ,  $p$  an aperiodic and irreducible transition model under which the agent operates and  $d_p^\pi$  is the stationary distribution of the Markov process induced by  $p$  under policy  $\pi$ . The gradient objective has previously been shown to be

$$\nabla_\theta J_p(\pi) = \sum_{x \in \mathcal{X}} d_p^\pi(x) \sum_{a \in \mathcal{A}} \nabla_\theta \pi(x, a) Q_p^\pi(x, a)$$

where  $Q_p^\pi(x, a)$  is the expected differential reward associated with state-action pair  $(x, a)$ . This gradient is then used to update the policy parameters according to:  $\theta_{t+1} = \theta_t + \beta_t \nabla_\theta J_p(\pi)$ , with  $\beta_t$  a positive step-size [Sutton et al., 2000].

**Actor-Critic Algorithm** Theoretical analysis and empirical experiments have shown that regular policy-gradient methods present a major issue namely high variance in the gradient estimates that results in slow convergence and inefficient sampling [Grondman et al., 2012]. First proposed by Barto et al. [1983], actor-critic methods attempt to reduce the variance by using a critic that estimates the value function. They borrow elements from both value function and policy-based methods. The value function estimate plays the role of a critic that helps evaluating the performance of the policy. As in policy-based methods, the actor then uses this signal to update policy parameters in the direction of a gradient estimate of a performance measure. Under appropriate conditions, the resulting algorithm is tractable and converges to a locally optimal policy [Bhatnagar et al., 2009; Konda and Tsitsiklis, 2000].

**Deep Q-networks** Deep Q-Networks (DQNs) have proven their capability of solving complex learning tasks such as Atari video games [Mnih et al., 2013]. The Q-learning of Watkins and Dayan [1992] typically learns a greedy or  $\epsilon$ -greedy policy by updating the Q-function based on a TD-error. In Deep Q-learning [Mnih et al., 2013, 2015], a non-linear function such as a neural network is used as an approximator of the Q-function. It is referred to as a Q-network. The agent is then trained by optimizing the induced TD loss function thanks to stochastic gradient descent. Like actor-critic, DQN is an online algorithm that aims at finding an optimal policy. The main difference with actor-critic is that it is *off-policy*: it learns a greedy strategy while following an arbitrary behavior [Mnih et al., 2013].

**Deep Deterministic Policy-Gradient** Since DQN acts greedily at each iteration, it can only handle small action spaces. The Deep Deterministic Policy-Gradient (DDPG) is an *off-policy* algorithm that can learn behaviors in continuous action spaces [Lillicrap et al., 2016]. It is based on an actor-critic architecture that follows the same baseline as in DQN. The critic estimates the current Q-value of the actor using a TD-error while the actor is updated according to the critic. This update is based on the chain rule principle which establishes equivalence between the stochastic and the deterministic policy gradient [Silver et al., 2014].

### 3 SOFT-ROBUSTNESS

#### 3.1 SOFT-ROBUST FRAMEWORK

Unlike robust MDPs that maximize the worst-case performance, we fix a prior on how transition models are distributed over the uncertainty set. A distribution over  $\mathcal{P}$  is denoted by  $\omega$  and is structured as a cartesian product  $\otimes_{x \in \mathcal{X}} \omega_x$ . We find the same structure in Xu and Mannor [2012]; Yu and Xu [2016]. Intuitively,  $\omega$  can be thought as the way the adversary distributes over different transition models. The product structure then means that this adversarial distribution only depends on the current state of the agent without taking into account its whole trajectory. This defines a probability distribution  $\omega_x$  over  $\mathcal{P}_x$  independently for each state.

We further assume that  $\omega$  is non-diffuse. This implies that the uncertainty set is non-trivial with respect to  $\omega$  in a sense that the distribution does not affect zero mass to all of the models.

#### 3.2 SOFT-ROBUST OBJECTIVE

Throughout this paper, we make the following assumption:

**Assumption 3.1.** *Under any policy  $\pi$ , the Markov chains resulting from any of the MDPs with transition laws  $p \in \mathcal{P}$  are irreducible and aperiodic.*

Define  $d_p^\pi$  as the stationary distribution of the Markov chain that results from following policy  $\pi$  under transition model  $p \in \mathcal{P}$ .

**Definition 3.1.** *We call soft-robust objective or soft-robust average reward the function  $\bar{J}(\pi) := \mathbb{E}_{p \sim \omega} [J_p(\pi)]$ .*

The distribution  $\omega$  introduces a softer form of robustness in the objective function because it averages over the uncertainty set instead of considering the worst-case scenario. It also gives flexibility over the level of robustness one would like to keep. A robust strategy would then consist of putting more mass on pessimistic transition models. Likewise, a distribution that puts all of its mass on one target model would lead to an aggressive behavior and result in model misspecification.

The *soft-robust differential reward* is given by  $\bar{Q}^\pi(x, a) := \mathbb{E}_{p \sim \omega} [Q_p^\pi(x, a)]$  where

$$Q_p^\pi(x, a) := \mathbb{E}^p \left[ \sum_{t=0}^{+\infty} r_{t+1} - J_p(\pi) \mid x_0 = x, a_0 = a, \pi \right].$$

Similarly, we introduce the quantity

$$\bar{V}^\pi(x) := \sum_{a \in \mathcal{A}} \pi(x, a) \bar{Q}^\pi(x, a) = \mathbb{E}_{p \sim \omega} [V_p^\pi(x)]$$

with  $V_p^\pi(x) := \sum_{a \in \mathcal{A}} \pi(x, a) Q_p^\pi(x, a)$ . We will interchangeably term it as *soft-robust expected differential reward* or *soft-robust value function*.

#### 3.3 SOFT-ROBUST STATIONARY DISTRIBUTION

The above performance objective  $\bar{J}(\pi)$  cannot as yet be written as an expectation of the reward over a stationary distribution because of the added measure  $\omega$  on transition models. Define the average transition model as  $\bar{p} := \mathbb{E}_{p \sim \omega} [p]$ . It corresponds to the transition probability that results from distributing all transition models according to  $\omega$ . In analogy to the transition probability that minimizes the reward for each given state and action in the robust transition function [Mankowitz et al., 2018], our average model rather selects the expected distribution over all the uncertainty set for each state and action. Under Assumption 3.1, we can show that the transition  $\bar{p}$  as defined is irreducible and aperiodic, which ensures the existence of a unique stationary law we will denote by  $\bar{d}^\pi$ .

**Proposition 3.1** (Stationary distribution in the average transition model). *Under Assumption 3.1, the average transition matrix  $\bar{p} := \mathbb{E}_{p \sim \omega}[p]$  is irreducible and aperiodic. In particular, it admits a unique stationary distribution.*

As in regular MDPs, the soft-robust average reward satisfies a Poisson equation, as it was first stated in the discounted reward case in Lemma 3.1 of Xu and Mannor [2012]. The following proposition reformulates this result for the average reward.

**Proposition 3.2** (Soft-Robust Poisson equation).

$$\begin{aligned} \bar{J}(\pi) + \bar{V}^\pi(x) \\ = \sum_{a \in \mathcal{A}} \pi(x, a) \left( r(x, a) + \sum_{x' \in \mathcal{X}} \bar{p}(x, a, x') \bar{V}^\pi(x') \right) \end{aligned}$$

This Poisson equation enables us to establish an equivalence between the expectation of the stationary distributions over the uncertainty set and the stationary distribution of the average transition model, naming  $\bar{d}^\pi(x) = \mathbb{E}_{p \sim \omega}[d_p^\pi(x)]$  with  $x \in \mathcal{X}$ . Indeed, we have the following:

**Corollary 3.1.** *Recall  $\bar{d}^\pi$  the stationary distribution for the average transition model  $\bar{p}$ . Then*

$$\bar{J}(\pi) = \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \pi(x, a) r(x, a).$$

The goal is to learn a policy that maximizes the soft-robust average reward  $\bar{J}$ . We use a policy-gradient method for that purpose.

## 4 SOFT-ROBUST POLICY-GRADIENT

In policy-gradient methods, we consider a class of parametrized stochastic policies  $\pi_\theta : \mathcal{X} \rightarrow \mathcal{M}(\mathcal{A})$  with  $\theta \in \mathbb{R}^{d_\theta}$  and estimate the gradient of the objective function  $\bar{J}$  with respect to policy parameters in order to update the policy in the direction of the estimated gradient of  $\bar{J}$ . The optimal set of parameters thus obtained is denoted by

$$\theta^* := \arg \max_{\theta} \bar{J}(\pi_\theta).$$

When clear in the context, we will omit the subscript  $\theta$  in  $\pi_\theta$  for notation ease. We further make the following assumption, which is standard in policy-gradient literature:

**Assumption 4.1.** *For any  $(x, a) \in \mathcal{X} \times \mathcal{A}$ , the mapping  $\theta \mapsto \pi_\theta(x, a)$  is continuously differentiable with respect to  $\theta$ .*

Using the same method as in Sutton et al. [2000], we can derive the gradient of the soft-robust average reward thanks to the previous results.

**Theorem 4.1** (Soft-Robust Policy-Gradient). *For any MDP satisfying previous assumptions, we have*

$$\nabla_{\theta} \bar{J}(\pi) = \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \nabla_{\theta} \pi(x, a) \bar{Q}^\pi(x, a).$$

In order to manage with large state spaces, we also introduce a linear approximation of  $\bar{Q}^\pi$  we define as  $f_w(x, a) := w^T \psi_{xa}$ . Sutton et al. [2000] showed that if the features  $\psi_{xa}$  satisfy a compatibility condition and the approximation is locally optimal, then we can use it in place of  $\bar{Q}^\pi$  and still point roughly in the direction of the true gradient.

In the case of soft-robust average reward, this defines a soft-robust gradient update that possesses the ability to incorporate function approximation, as stated in the following result. The main difference with that of Sutton et al. [2000] is that we combine the dynamics of the system with distributed transitions over the uncertainty set.

**Theorem 4.2** (Soft-Robust Policy-Gradient with Function Approximation). *Let  $f_w : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$  be a linear approximator of the soft-robust differential reward  $\bar{Q}^\pi$ . If  $f_w$  minimizes the mean squared error*

$$\mathcal{E}^\pi(w) := \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \pi(x, a) \left[ \bar{Q}^\pi(x, a) - f_w(x, a) \right]^2$$

*and is compatible in a sense that  $\nabla_w f_w(x, a) = \nabla_{\theta} \log \pi(x, a)$ , then*

$$\nabla_{\theta} \bar{J}(\pi) = \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \nabla_{\theta} \pi(x, a) f_w(x, a)$$

We can further improve our gradient estimate by reducing its variance. One direct method to do so is to subtract a baseline  $b(x)$  from the previous gradient update. It is easy to show that this will not affect the gradient derivation. In particular, Bhatnagar et al. [2009] proved that the value function minimizes the variance. It is therefore a proper baseline to choose. We can thus write the following:

$$\begin{aligned} \nabla_{\theta} \bar{J}(\pi) &= \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \nabla_{\theta} \pi(x, a) \left( \bar{Q}^\pi(x, a) - \bar{V}^\pi(x) \right) \\ &= \sum_{x \in \mathcal{X}} \bar{d}^\pi(x) \sum_{a \in \mathcal{A}} \pi(x, a) \psi_{xa} \bar{A}^\pi(x, a), \end{aligned} \tag{1}$$

where  $\bar{A}^\pi(x, a)$  is the *soft-robust advantage function* defined by  $\bar{A}^\pi(x, a) := \bar{Q}^\pi(x, a) - \bar{V}^\pi(x)$ .

## 5 SOFT-ROBUST ACTOR-CRITIC ALGORITHM

In this section, we present our SR-AC algorithm which is defined as Algorithm 1. This novel approach incorporates a variation of distributional robustness into an online algorithm that effectively learns an optimal policy in a scalable manner. Under mild assumptions, the resulting two-timescale stochastic approximation algorithm converges to a locally optimal policy.

### 5.1 SR-AC ALGORITHM

An uncertainty set and a nominal model without uncertainty are provided as inputs. In practice, the nominal model and the uncertainty set can respectively be an estimate of the transition model resulting from data sampling and its corresponding confidence interval. A distribution  $\omega$  over the uncertainty set is also provided. It corresponds to our prior information on the uncertainty set. The step-size sequences  $(\alpha_t, \beta_t, \xi_t; t \geq 0)$  consist of small non-negative numbers properly chosen by the user (see Appendix for more details).

At each iteration, samples are generated using the nominal model and the current policy. These are utilized to update the soft-robust average reward (Line 5) and the critic (Line 7) based on an estimate of a soft-robust TD-error we detail further. In our setting, the soft-robust value function plays the role of the critic according to which the actor parameters are updated. We then exploit the critic to improve our policy by updating the policy parameters in the direction of a gradient estimate for the soft-robust objective (Line 8). This process is repeated until convergence.

### 5.2 CONVERGENCE ANALYSIS

We establish convergence of SR-AC to a local maximum of the soft-robust objective function by following an ODE approach [Kushner and Yin, 1997].

Consider  $\hat{V}$  and  $\hat{J}$  as unbiased estimates of  $\bar{V}$  and  $\bar{J}$  respectively. Calculating  $\delta_t$  (Line 6 in Algorithm 1) requires an estimate of the soft-robust average-reward that can be obtained by averaging over samples given immediate reward  $r$  and distribution  $\omega$  (Line 5). In order to get an estimate of the soft-robust differential value  $\hat{V}$ , we use linear function approximation. Considering  $\varphi$  as a  $d_2$ -dimensional feature extractor over the state space  $\mathcal{X}$ , we may then approximate  $\bar{V}^\pi(x)$  as  $v^T \varphi_x$ , where  $v$  is a  $d_2$ -dimensional parameter vector that we tune using linear TD. This results in the following soft-robust TD-error:

$$\delta_t := r_{t+1} - \hat{J}_{t+1} + \sum_{x' \in \mathcal{X}} \bar{p}(x_t, a_t, x') v_t^T \varphi_{x'} - v_t^T \varphi_{x_t},$$

---

### Algorithm 1 SR-AC

---

- 1: **Input:**  $\mathcal{P}$  - An uncertainty set;  $\hat{p} \in \mathcal{P}$  - A nominal model;  $\omega$  - A distribution over  $\mathcal{P}$ ;  $f_x$  - A feature extractor for the SR value function;
  - 2: **Initialize:**  $\theta = \theta_0$  - An arbitrary policy parameter;  $v = v_0$  - An arbitrary set of value function parameters;  $\alpha_0, \beta_0, \xi_0$  - Initial learning-rates;  $x_0$  - Initial state
  - 3: **repeat**
  - 4:   Act under  $a_t \sim \pi_{\theta_t}(x_t, a_t)$   
    Observe next state  $x_{t+1}$  and reward  $r_{t+1}$
  - 5:   **SR Average Reward Update:**  
     $\hat{J}_{t+1} = (1 - \xi_t)\hat{J}_t + \xi_t r_{t+1}$
  - 6:   **SR TD-Error:**  
     $\delta_t = r_{t+1} - \hat{J}_{t+1} + \sum_{x' \in \mathcal{X}} \bar{p}(x_t, a_t, x') \hat{V}_{x'} - \hat{V}_{x_t}$
  - 7:   **Critic Update:**  $v_{t+1} = v_t + \alpha_t \delta_t \varphi_{x_t}$
  - 8:   **Actor Update:**  $\theta_{t+1} = \theta_t + \beta_t \delta_t \psi_{x_t a_t}$
  - 9: **until** convergence
  - 10: **Return:** SR policy parameters  $\theta$  and SR value-function parameters  $v$
- 

where  $v_t$  corresponds to the current estimate of the soft-robust value function parameter.

As in regular MDPs, when doing linear TD learning, the function approximation of the value function introduces a bias in the gradient estimate [Bhatnagar et al., 2009]. Denoting it as  $e^\pi$ , we have  $E[\widehat{\nabla_\theta J}(\pi) | \theta] = \nabla_\theta \bar{J}(\pi) + e^\pi$  (see Appendix). This bias term then needs to be small enough in order to ensure convergence.

Convergence of Algorithm 1 can be established by applying Theorem 2 from Bhatnagar et al. [2009] which exploits Borkar’s work on two-timescale algorithms [1997]. The convergence result is presented as Theorem 5.1.

**Theorem 5.1.** *Under all the previous assumptions, given  $\epsilon > 0$ , there exists  $\delta > 0$  such that for a parameter vector  $\theta_t, t \geq 0$  obtained using the algorithm, if  $\sup_{\pi_t} \|e^{\pi_t}\| < \delta$ , then the SR-AC algorithm converges almost surely to an  $\epsilon$ -neighborhood of a local maximum of  $\bar{J}$ .*

## 6 NUMERICAL EXPERIMENTS

We demonstrate the performance of soft-robustness on various domains of finite as well as continuous state and action spaces. We used the existing structure of OpenAI Gym environments to run our experiments [Brockman et al., 2016].

### 6.1 DOMAINS

**Single-step MDP** We consider a simplified formulation of the startup vs teaching dilemma described in Section 1.

Figure 1: Illustration of the MDP with initial state  $s_0$ . States  $F_1, F_2, F_3$  correspond to failing scenarios for each action. The succeeding states are represented by states  $S_1, S_2, S_3$ .

The problem is modeled as a 7-state MDP in which one action corresponds to one strategy. An illustration of this construction is given in Figure 1. At the starting state  $s_0$ , the agent chooses one of three actions. Action  $a_1$  [corresponds to the startup adventure] may lead it to a very high reward in case of success but can be catastrophic in case of failure. Action  $a_2$  [corresponds to the teaching carrier] leads it to low positive reward in case of success with no possibility of negative reward. Action  $a_3$  [corresponds to an intermediate strategy] can lead to an intermediate positive reward with a slight risk of negative reward. Depending on the action it chose and if it succeeded or not, the agent is brought to one of the six right-hand states and receives the corresponding reward. It is brought back to  $s_0$  at the end of each episode. We assume the probability of success to be the same for all three actions.

**Cart-Pole** In the Cart-Pole system, the agent’s goal consists of balancing a pole atop a cart in a vertical position. It is modeled as a continuous MDP in which each state consists of a 4-tuple  $\langle x, \dot{x}, \theta, \dot{\theta} \rangle$  which represents the cart position, the cart speed, the pole angle with respect to the vertical and its angular speed respectively. The agent can make two possible actions: apply a constant force either to the right or to the left of the pole. It gets a positive reward of 1 if the pole has not fallen down and if it stayed in the boundary sides of the screen. If it terminates, the agent receives a reward of 0. Since each episode lasts for

200 timesteps, the maximal reward an agent can get is 200 over one episode.

**Pendulum** In the inverted pendulum problem, a pendulum starts in a random position and the goal is to swing it up so that it stabilizes upright. The state domain consists in a 2-tuple  $\langle \theta, \dot{\theta} \rangle$  which represents the pendulum angle with respect to the vertical and its angular velocity. At each timestep, the agent’s possible actions belong to a continuous interval  $[-a, a]$  which represents the force level being applied. Since there is no specified termination, we establish a maximal number of 200 steps for each episode.

## 6.2 UNCERTAINTY SETS

For each experiment, we generate an uncertainty set  $\mathcal{P}$  before training. In the single-step MDP, we sample from 5 different probabilities of success using a uniform distribution over  $[0, 1]$ . In Cart-Pole, we sample 5 different lengths from a normal distribution centered at the nominal length of the pole which we fix at 0.3. We proceed similarly for Pendulum by generating 10 different masses of pendulum around a nominal mass of 2. Each corresponding model thus generates a different transition function. We then sample the average model by fixing  $\omega$  as a realization of a Dirichlet distribution. A soft-robust update for the actor is applied by taking the optimal action according to this average transition function.

## 6.3 LEARNING ALGORITHMS

We trained the agent on the nominal model in each experiment. The soft-robust agent was learned using SR-AC in the single-step MDP. In Cart-Pole, we run a soft-robust version of a DQN algorithm. The soft-robust agent in Pendulum was trained using a soft-robust DDPG.

**Soft-Robust AC** We analyze the performance of SR-AC by training a soft-robust agent on the single-step MDP. We run a regular AC algorithm to derive an aggressive policy and learn a robust behavior by using a robust formulation of AC which consists in replacing the TD-error with a robust TD-error, as implemented in Mankowitz et al. [2018]. The derived soft-robust agent is then compared with the resulting aggressive and robust strategies respectively.

**Soft-Robust DQN** Robustness has already been incorporated in DQN [Di-Castro Shashua and Mannor, 2017]. The Q-network addressed there performs an online estimation of the Q-function by minimizing at each timestep

$t$  the following robust TD-error:

$$\begin{aligned} \delta_{dqn,t}^{rob} &:= r(x_t, a_t) - Q(x_t, a_t) \\ &+ \gamma \inf_{p \in \mathcal{P}} \sum_{x' \in \mathcal{X}} p(x_t, a_t, x') \max_{a' \in \mathcal{A}} Q(x', a'), \end{aligned}$$

where  $\gamma$  is a discount factor.

In our experiments, we incorporate a soft-robust TD-error inside a DQN that trains a soft-robust agent according to the induced loss function. The soft-robust TD-error for DQN is given by:

$$\begin{aligned} \delta_{dqn,t}^{srob} &:= r(x_t, a_t) - Q(x_t, a_t) \\ &+ \gamma \sum_{x' \in \mathcal{X}} \bar{p}(x_t, a_t, x') \max_{a' \in \mathcal{A}} Q(x', a') \end{aligned}$$

We use the Cart-Pole domain to compare the resulting policy with the aggressive and robust strategies that were obtained from a regular and a robust DQN respectively.

**Soft-Robust DDPG** Define  $\mu_t$  as the estimated deterministic policy at step  $t$ . We incorporate robustness in DDPG by updating the critic network according to the following robust TD-error:

$$\begin{aligned} \delta_{ddpg,t}^{rob} &:= r(x_t, a_t) - Q(x_t, a_t) \\ &+ \gamma \inf_{p \in \mathcal{P}} \sum_{x' \in \mathcal{X}} p(x_t, a_t, x') Q(x', \mu(x_t)), \end{aligned}$$

Similarly, we incorporate soft-robustness in DDPG by using the soft-robust TD-error:

$$\begin{aligned} \delta_{ddpg,t}^{srob} &:= r(x_t, a_t) - Q(x_t, a_t) \\ &+ \gamma \sum_{x' \in \mathcal{X}} \bar{p}(x_t, a_t, x') Q(x', \mu(x_t)) \end{aligned}$$

We compare the resulting soft-robust DDPG with its regular and robust formulations in the Pendulum domain.

## 6.4 IMPLEMENTATION

For each experiment, we train the agent on the nominal model but incorporate soft-robustness during learning. A soft-robust policy is learned thanks to SR-AC in the single-step MDP. We use a linear function approximation with 5 features to estimate the value function. For Cart-Pole, we run a DQN using a neural network of 3 fully-connected hidden layers with 128 weights per layer and ReLU activations. In Pendulum, a DDPG algorithm learns a policy based on two target networks: the actor and the critic network. Both have 2 fully-connected hidden layers with 400 and 300 units respectively. We use a tanh activation for the actor and a ReLU activation for the critic output. We chose the ADAM optimizer to minimize all the induced loss functions. We used constant

learning rates which worked well in practice. Each agent was trained over 3000 episodes for the single-step MDP and Cartpole and tested over 600 episodes per parameter setting. For Pendulum, the agents were trained over 5000 episodes evaluated over 800 episodes per parameter setting. Other hyper-parameter values can be found in the Appendix.

## 6.5 RESULTS

**Single-step MDP** Figure 2 shows the evolution of the performance for all three agents during training. It becomes more stable along training time, which confirms convergence of SR-AC. We see that the aggressive agent performs best due to the highest reward it can reach on the nominal model. The soft-robust agent gets rewards in between the aggressive and the robust agent which performs the worst due to its pessimistic learning method.

Figure 2: Comparison of robust, soft-robust and aggressive agents during training. One training epoch corresponds to 300 episodes.

The evaluation of each strategy is represented in Figure 3. As the probability of success gets low, the performance of the aggressive agent drops down below the robust and the soft-robust agents, although it performs best when the probability of success gets close to 1. The robust agent stays stable independently of the parameters but underperforms soft-robust agent which presents the best balance between high reward and low risk. We noticed that depending on the weighting distribution initially set, soft-robustness tends to being more or less aggressive (see Appendix). Incorporating a distribution over the uncertainty set thus gives significant flexibility on the level of aggressiveness to be assigned to the soft-robust agent.

**Cart-Pole** In Figure 4, we show the performance of all three strategies over different values of pole length during

Figure 3: Average reward for AC, robust AC and SR-AC methods

testing. Similarly to our previous example, the non-robust agent performs well around the nominal model but its reward degrades on more extreme values of pole length. The robust agent keeps a stable reward under model uncertainty which is consistent with the results obtained in Di-Castro Shashua and Mannor [2017]; Mankowitz et al. [2018]. However, it is outperformed by the soft-robust agent around the nominal model. Furthermore, the soft-robust strategy shows an equilibrium between aggressiveness and robustness thus leading to better performance than the non-robust agent on larger pole lengths. We trained a soft-robust agent on other weighting distributions and noted that depending on its structure, soft-robustness interpolates between aggressive and robust behaviors (see Appendix).

Figure 4: Average reward performance for DQN, robust DQN and soft-robust DQN

**Pendulum** Figure 5 shows the performance of all three

Figure 5: Max-200 episodes average performance for DDPG, robust DDPG and soft-robust DDPG

agents when evaluating them on different masses. Since the performance among different episodes is highly variable, we considered the best 200-episodes average reward as a performance measure. As seen in the figure, the robust strategy solves the task in a sub-optimal fashion, but is less affected by model misspecification due to its conservative strategy. The aggressive non-robust agent is more sensitive to model misspecification compared to the other methods as can be seen by its sudden dip in performance, below even that of the robust agent. The soft-robust solution strikes a nice balance between being less sensitive to model misspecification than the aggressive agent, and producing better performance compared to the robust solution.

## 7 RELATED WORK

This paper is related to several domains in RL such as robust and distributionally robust MDPs, actor-critic methods and online learning via stochastic approximation algorithms. Our work solves the problem of conservativeness encountered in robust MDPs by incorporating a variational form of distributional robustness. The SR-AC algorithm combines scalability to large scale state-spaces and online estimation of the optimal policy in an actor-critic algorithm. Table 1 compares our proposed algorithm with previous approaches.

Many solutions have been addressed to mitigate conservativeness of robust MDP. Mannor et al. [2012, 2016] relax the state-wise independence property of the uncertainty set and assume it to be coupled in a way such that the planning problem stays tractable. Another approach tends to assume *a priori* information on the parameter set. These

methods include distributionally robust MDPs [Xu and Mannor, 2012; Yu and Xu, 2016] in which the optimal strategy maximizes the expected reward under the most adversarial distribution over the uncertainty set. For finite and known MDPs, under some structural assumptions on the considered set of distributions, this max-min problem reduces to classical robust MDPs and can be solved efficiently by dynamic programming [Puterman, 2009].

However, besides becoming untractable under large-sized MDPs, these methods use an offline learning approach which cannot adapt its level of protection against model uncertainty and may lead to overly conservative results. The work of Lim et al. [2016] solutions this issue and addresses an online algorithm that learns the transitions that are purely stochastic and those that are adversarial. Although it ensures less conservative results as well as low regret, this method sticks to the robust objective while strongly relying on the finite structure of the state-space. To alleviate the curse of dimensionality, we incorporate function approximation of the objective value and define it as a linear functional of features.

First introduced in Barto et al. [1983] and later addressed by Bhatnagar et al. [2009], actor-critic algorithms are online learning methods that aim at finding an optimal policy. We used the formulation of Bhatnagar et al. [2009] as a baseline for the algorithm we proposed. The key difference between their work and ours is that we incorporate soft-robustness. This relates in a sense to the Bayesian Actor-Critic setup in which the critic returns a complete posterior distribution of value functions using Bayes’ rule [Ghavamzadeh and Engel, 2007; Ghavamzadeh et al., 2015, 2016]. Our study keeps a frequentist approach, meaning that our algorithm updates return point estimates of the average value-function which prevents from tractability issues besides enabling the distribution to be more

flexible. Another major distinction is that the Bayesian approach incorporates a prior distribution on one model parameters whereas our method considers a prior on different transition models over an uncertainty set.

In Mankowitz et al. [2018]; Tamar et al. [2015], the authors incorporate robustness into policy-gradient methods. A sampling procedure is required for each critic estimate in Tamar et al. [2015], which differs from the strictly-speaking actor-critic. A robust version of actor-critic policy-gradient is introduced in Mankowitz et al. [2018] but its convergence guarantees are only shown for robust policy-gradient ascent. Both of these methods target the robust strategy whereas we seek a soft-robust policy that is less conservative while protecting itself against model uncertainty.

## 8 DISCUSSION

We have presented the SR-AC framework that is able to learn policies which keep a balance between aggressive and robust behaviors. SR-AC requires a stationary distribution under the average transition model and compatibility conditions for deriving a soft-robust policy-gradient. We have shown that this ensures convergence of SR-AC. This is the first work that has attempted to incorporate a soft form of robustness into an online actor-critic method. Our approach has been shown to be computationally scalable to large domains because of its low computational price. In our experiments, we have also shown that the soft-robust agent interpolates between aggressive and robust strategies without being overly conservative which leads it to outperform robust policies under model uncertainty even when the action space is continuous. Subsequent experiments should test the efficiency of soft-robustness on more complex domains.

The chosen weighting over the uncertainty set can be thought as the way the adversary distributes over different transition laws. In our current setting, this adversarial distribution stays constant without accounting for the rewards obtained by the agent. Future work should address the problem of learning the sequential game induced by an evolving adversarial distribution to derive an optimal soft-robust policy. Other extensions of our work may also consider non-linear objective functions such as higher order moments with respect to the adversarial distribution.

## Abstract

Stochastic gradient methods enable learning probabilistic models from large amounts of data. While large step-sizes (learning rates) have shown to be best for least-squares (e.g., Gaussian noise) once combined with parameter averaging, these are not leading to convergent algorithms in general. In this paper, we consider generalized linear models, that is, conditional models based on exponential families. We propose averaging moment parameters instead of natural parameters for constant-step-size stochastic gradient descent. For finite-dimensional models, we show that this can sometimes (and surprisingly) lead to better predictions than the best linear model. For infinite-dimensional models, we show that it always converges to optimal predictions, while averaging natural parameters never does. We illustrate our findings with simulations on synthetic data and classical benchmarks with many observations.

## 1 INTRODUCTION

Faced with large amounts of data, efficient parameter estimation remains one of the key bottlenecks in the application of probabilistic models. Once cast as an optimization problem, for example through the maximum likelihood principle, difficulties may arise from the size of the model, the number of observations, or the potential non-convexity of the objective functions, and often all three (Koller and Friedman, 2009; Murphy, 2012).

In this paper we focus primarily on situations where the number of observations is large; in this context, stochastic gradient descent (SGD) methods which look at one sample at a time are usually favored for their cheap iter-

ation cost. However, finding the correct step-size (sometimes referred to as the learning rate) remains a practical and theoretical challenge, for probabilistic modeling but also in most other situations beyond maximum likelihood (Bottou et al., 2016).

In order to preserve convergence, the step size  $\gamma_n$  at the  $n$ -th iteration typically has to decay with the number of gradient steps (here equal to the number of data points which are processed), typically as  $C/n^\alpha$  for  $\alpha \in [1/2, 1]$  (see, e.g., Bach and Moulines, 2011; Bottou et al., 2016). However, these often leads to slow convergence and the choice of  $\alpha$  and  $C$  is difficult in practice. More recently, constant step-sizes have been advocated for their fast convergence towards a neighborhood of the optimal solution (Bach and Moulines, 2013), while it is a standard practice in many areas (Goodfellow et al., 2016). However, it is not convergent in general and thus small step-sizes are still needed to converge to a decent estimator.

Constant step-sizes can however be made to converge in one situation. When the functions to optimize are quadratic, like for least-squares regression, using a constant step-size combined with an averaging of all estimators along the algorithm can be shown to converge to the global solution with the optimal convergence rates (Bach and Moulines, 2013; Dieuleveut and Bach, 2016).

The goal of this paper is to explore the possibility of such global convergence with a constant step-size in the context of probabilistic modeling with exponential families, e.g., for logistic regression or Poisson regression (McCullagh, 1984). This would lead to the possibility of using probabilistic models (thus with a principled quantification of uncertainty) with rapidly converging algorithms. Our main novel idea is to replace the averaging of the *natural* parameters of the exponential family by the averaging of the *moment* parameters, which can also be formulated as averaging *predictions* instead of *estimators*. For example, in the context of predicting bi-

Figure 1: Convergence of iterates  $\theta_n$  and averaged iterates  $\bar{\theta}_n$  to the mean  $\bar{\theta}_\gamma$  under the stationary distribution  $\pi_\gamma$ .

nary outcomes in  $\{0, 1\}$  through a Bernoulli distribution, the moment parameter is the probability  $p \in [0, 1]$  that the variable is equal to one, while the natural parameter is the “log odds ratio”  $\log \frac{p}{1-p}$ , which is unconstrained. This lack of constraint is often seen as a benefit for optimization; it turns out that for stochastic gradient methods, the moment parameter is better suited to averaging. Note that for least-squares, which corresponds to modeling with the Gaussian distribution with fixed variance, moment and natural parameters are equal, so it does not make a difference.

More precisely, our main contributions are:

- For generalized linear models, we propose in Section 4 averaging moment parameters instead of natural parameters for constant-step-size stochastic gradient descent.
- For finite-dimensional models, we show in Section 5 that this can sometimes (and surprisingly) lead to better predictions than the best linear model.
- For infinite-dimensional models, we show in Section 6 that it always converges to optimal predictions, while averaging natural parameters never does.
- We illustrate our findings in Section 7 with simulations on synthetic data and classical benchmarks with many observations.

## 2 CONSTANT STEP SIZE STOCHASTIC GRADIENT DESCENT

In this section, we present the main intuitions behind stochastic gradient descent (SGD) with constant step-size. For more details, see Dieuleveut et al. (2017). We

consider a real-valued function  $F$  defined on the Euclidean space  $\mathbb{R}^d$  (this can be generalized to any Hilbert space, as done in Section 6 when considering Gaussian processes and positive-definite kernels), and a sequence of random functions  $(f_n)_{n \geq 1}$  which are independent and identically distributed and such that  $\mathbb{E}f_n(\theta) = F(\theta)$  for all  $\theta \in \mathbb{R}^d$ . Typically,  $F$  will be the expected negative log-likelihood on unseen data, while  $f_n$  will be the negative log-likelihood for a single observation. Since we require *independent* random functions, we assume that we make single pass over the data, and thus the number of iterations is equal to the number of observations.

Starting from an initial  $\theta_0 \in \mathbb{R}^d$ , then SGD will perform the following recursion, from  $n = 1$  to the total number of observations:

$$\theta_n = \theta_{n-1} - \gamma_n \nabla f_n(\theta_{n-1}). \quad (1)$$

Since the functions  $f_n$  are independent, the iterates  $(\theta_n)_n$  form a Markov chain. When the step-size  $\gamma_n$  is constant (equal to  $\gamma$ ) and the functions  $f_n$  are identically distributed, the Markov chain is *homogeneous*. Thus, under additional assumptions (see, e.g., Dieuleveut et al., 2017; Meyn and Tweedie, 1993), it converges in distribution to a stationary distribution, which we refer to as  $\pi_\gamma$ . These additional assumptions include that  $\gamma$  is not too large (otherwise the algorithm diverges) and in the traditional analysis of step-sizes for gradient descent techniques, we analyze the situation of small  $\gamma$ 's (and thus perform asymptotic expansions around  $\gamma = 0$ ).

The distribution  $\pi_\gamma$  is in general not equal to a Dirac mass, and thus, constant-step-size SGD is *not* convergent. However, averaging along the path of the Markov chain has some interesting properties. Indeed, several versions of the “ergodic theorem” (see, e.g., Meyn and Tweedie, 1993) show that for functions  $g$  from  $\mathbb{R}^d$  to any vector space, then the empirical average  $\frac{1}{n} \sum_{i=1}^n g(\theta_i)$  converges in probability to the expectation  $\int g(\theta) d\pi_\gamma(\theta)$  of  $g$  under the stationary distribution  $\pi_\gamma$ . This convergence can also be quantified by a central limit theorem with an error which tends to a normal distribution with variance proportional equal to a constant times  $1/n$ .

Thus, if denote  $\bar{\theta}_n = \frac{1}{n+1} \sum_{i=0}^n \theta_i$ , applying the previous result to the identity function  $g$ , we immediately obtain that  $\bar{\theta}_n$  converges to  $\bar{\theta}_\gamma = \int \theta d\pi_\gamma(\theta)$ , with a squared error converging in  $O(1/n)$ . The key question is the relationship between  $\bar{\theta}_\gamma$  and the global optimizer  $\theta_*$  of  $F$ , as this characterizes the performance of the algorithm with an infinite number of observations.

By taking expectations in Eq. (1), and taking a limit with  $n$  tending to infinity we obtain that

$$\int \nabla F(\theta) d\pi_\gamma(\theta) = 0, \quad (2)$$

that is, under the stationary distribution  $\pi_\gamma$ , the average gradient is zero. When the gradient is a linear function (like for a quadratic objective  $F$ ), this leads to  $\nabla F(\int \theta d\pi_\gamma(\theta)) = \nabla F(\bar{\theta}_\gamma) = 0$ , and thus  $\bar{\theta}_\gamma$  is a stationary point of  $F$  (and hence the global minimizer if  $F$  is convex). However this is not true in general.

As shown by Dieuleveut et al. (2017), the deviation  $\bar{\theta}_\gamma - \theta_*$  is of order  $\gamma$ , which is an improvement on the non-averaged recursion, which is at average distance  $O(\gamma^{1/2})$  (see an illustration in Figure 1); thus, small or decaying step-sizes are needed. In this paper, we explore alternatives which are not averaging the estimators  $\theta_1, \dots, \theta_n$ , and rely instead on the specific structure of our cost functions, namely negative log-likelihoods.

### 3 WARM-UP: EXPONENTIAL FAMILIES

In order to highlight the benefits of averaging moment parameters, we first consider unconditional exponential families. We thus consider the standard exponential family  $q(x|\theta) = h(x) \exp(\theta^\top T(x) - A(\theta))$ , where  $h(x)$  is the base measure,  $T(x) \in \mathbb{R}^d$  is the sufficient statistics and  $A$  the log-partition function. The function  $A$  is always convex (see, e.g., Koller and Friedman, 2009; Murphy, 2012). Note that we do not assume that the data distribution  $p(x)$  comes from this exponential family. The expected (with respect to the input distribution  $p(x)$ ) negative log-likelihood is equal to

$$\begin{aligned} F(\theta) &= -\mathbb{E}_{p(x)} \log q(x|\theta) \\ &= A(\theta) - \theta^\top \mathbb{E}_{p(x)} T(x) - \mathbb{E}_{p(x)} \log h(x). \end{aligned}$$

It is known to be minimized by  $\theta_*$  such that  $\nabla A(\theta_*) = \mathbb{E}_{p(x)} T(x)$ . Given i.i.d. data  $(x_n)_{n \geq 1}$  sampled from  $p(x)$ , then the SGD recursion from Eq. (1) becomes:

$$\theta_n = \theta_{n-1} - \gamma [\nabla A(\theta_{n-1}) - T(x_n)],$$

while the stationarity equation in Eq. (2) becomes

$$\int [\nabla A(\theta) - \mathbb{E}_{p(x)} T(x)] d\pi_\gamma(\theta) = 0,$$

which leads to

$$\int \nabla A(\theta) d\pi_\gamma(\theta) = \mathbb{E}_{p(x)} T(x) = \nabla A(\theta_*).$$

Thus, averaging  $\nabla A(\theta_n)$  will converge to  $\nabla A(\theta_*)$ , while averaging  $\theta_n$  will *not* converge to  $\theta_*$ . This simple observation is the basis of our work.

Note that in this context of unconditional models, a simpler estimator exists, that is, we can simply compute the

empirical average  $\frac{1}{n} \sum_{i=1}^n T(x_i)$  that will converge to  $\nabla A(\theta_*)$ . Nevertheless, this shows that averaging moment parameters  $\nabla A(\theta)$  rather than natural parameters  $\theta$  can bring convergence benefits. We now turn to conditional models, for which no closed-form solutions exist.

## 4 CONDITIONAL EXPONENTIAL FAMILIES

Now we consider the conditional exponential family  $q(y|x, \theta) = h(y) \exp(y \cdot \eta_\theta(x) - a(\eta_\theta(x)))$ . For simplicity we consider only one-dimensional families where  $y \in \mathbb{R}$ —but our framework would also extend to more complex models such as conditional random fields (Lafferty et al., 2001). We will also assume that  $h(y) = 1$  for all  $y$  to avoid carrying constant terms in log-likelihoods. We consider functions of the form  $\eta_\theta(x) = \theta^\top \Phi(x)$ , which are linear in a feature vector  $\Phi(x)$ , where  $\Phi : \mathcal{X} \rightarrow \mathbb{R}^d$  can be defined on an arbitrary input set  $\mathcal{X}$ . Calculating the negative log-likelihood, one obtains:

$$f_n(\theta) = -\log q(y_n|x_n, \theta) = -y_n \Phi(x_n)^\top \theta + a(\Phi(x_n) \theta),$$

and, for any distribution  $p(x, y)$ , for which  $p(y|x)$  may not be a member of the conditional exponential family,

$$\begin{aligned} F(\theta) &= \mathbb{E}_{p(x_n, y_n)} f_n(\theta) \\ &= \mathbb{E}_{p(x_n, y_n)} \left[ -y_n \Phi(x_n)^\top \theta + a(\Phi(x_n) \theta) \right]. \end{aligned}$$

The goal of estimation in such generalized linear models is to find an unknown parameter  $\theta$  given  $n$  observations  $(x_i, y_i)_{i=1, \dots, n}$ :

$$\theta_* = \arg \min_{\theta \in \mathbb{R}^d} F(\theta). \quad (3)$$

### 4.1 FROM ESTIMATORS TO PREDICTION FUNCTIONS

Another point of view is to consider that an estimator  $\theta \in \mathbb{R}^d$  in fact defines a function  $\eta : \mathcal{X} \rightarrow \mathbb{R}$ , with value a natural parameter for the exponential family  $q(y) = \exp(\eta y - a(\eta))$ . This particular choice of function  $\eta_\theta$  is linear in  $\Phi(x)$ , and we have, by decomposing the joint probability  $p(x_n, y_n)$  in two (and dropping the dependence on  $n$  since we have assumed i.i.d. data):

$$\begin{aligned} F(\theta) &= \mathbb{E}_{p(x)} \left( \mathbb{E}_{p(y|x)} \left[ -y \Phi(x)^\top \theta + a(\Phi(x)^\top \theta) \right] \right) \\ &= \mathbb{E}_{p(x)} \left( -\mathbb{E}_{p(y|x)} y \Phi(x)^\top \theta + a(\Phi(x)^\top \theta) \right) \\ &= \mathcal{F}(\eta_\theta), \end{aligned}$$

with  $\mathcal{F}(\eta) = \mathbb{E}_{p(x)} (-\mathbb{E}_{p(y|x)} y \cdot \eta(x) + a(\eta(x)))$  is the performance measure defined for a function  $\eta : \mathcal{X} \rightarrow \mathbb{R}$ . By definition  $F(\theta) = \mathcal{F}(\eta_\theta) = \mathcal{F}(\theta^\top \Phi(\cdot))$ .

Figure 2: Graphical representation of reparametrization: firstly we expand the class of functions, replacing parameter  $\theta$  with function  $\eta(\cdot) = \Phi^\top(\cdot)\theta$  and then we do one more reparametrization:  $\mu(\cdot) = a'(\eta(\cdot))$ . Best linear prediction  $\mu_*$  is constructed using  $\theta_*$  and the global minimizer of  $\mathcal{G}$  is  $\mu_{**}$ . Model is well-specified if and only if  $\mu_* = \mu_{**}$ .

However, the global minimizer of  $\mathcal{F}(\eta)$  over all functions  $\eta : \mathcal{X} \rightarrow \mathbb{R}$  may not be attained at a linear function in  $\Phi(x)$  (this can only be the case if the linear model is well-specified or if the feature vector  $\Phi(x)$  is flexible enough). Indeed, the global minimizer of  $\mathcal{F}$  is the function  $\eta_{**} : x \mapsto (a')^{-1}(\mathbb{E}_{p(y|x)}y)$  (starting from  $\mathcal{F}(\eta) = \int [a(\eta(x)) - \mathbb{E}_{p(x|y)}y \cdot \eta(x)]p(x)dx$  and writing down the Euler - Lagrange equation:  $\frac{\partial \mathcal{F}}{\partial \eta} - \frac{d}{dx} \frac{\partial \mathcal{F}}{\partial \eta'} = 0 \Leftrightarrow [a'(\eta) - \mathbb{E}_{p(x|y)}y]p(x) = 0$  and finally  $\eta \mapsto (a')^{-1}(\mathbb{E}_{p(x|y)}y)$ ) and is typically not a linear function in  $\Phi(x)$  (note here that  $p(y|x)$  is the conditional data-generating distribution).

The function  $\eta$  corresponds to the *natural* parameter of the exponential family, and it is often more intuitive to consider the *moment* parameter, that is defining functions  $\mu : \mathcal{X} \rightarrow \mathbb{R}$  that now correspond to moments of outputs  $y$ ; we will refer to them as *prediction functions*. Going from natural to moment parameter is known to be done through the gradient of the log-partition function, and we thus consider for  $\eta$  a function from  $\mathcal{X}$  to  $\mathbb{R}$ ,  $\mu(\cdot) = a'(\eta(\cdot))$ , and this leads to the performance measure

$$\mathcal{G}(\mu) = \mathcal{F}((a')^{-1}(\mu(\cdot))).$$

Note now, that the global minimum of  $\mathcal{G}$  is reached at

$$\mu_{**}(x) = \mathbb{E}_{p(y|x)}y.$$

We introduce also the prediction function  $\mu_*(x)$  corresponding to the best  $\eta$  which is linear in  $\Phi(x)$ , that is:

$$\mu_*(x) = a'(\theta_*^\top \Phi(x)).$$

We say that the model is well-specified when  $\mu_* = \mu_{**}$ , and for these models,  $\inf_\theta F(\theta) = \inf_\mu \mathcal{G}(\mu)$ . However, in general, we only have  $\inf_\theta F(\theta) > \inf_\mu \mathcal{G}(\mu)$

and (very often) the inequality is strict (see examples in our simulations).

To make the further developments more concrete, we now present two classical examples: logistic regression and Poisson regression.

**Logistic regression.** The special case of conditional family is logistic regression, where  $y \in \{0, 1\}$ ,  $a(t) = \log(1 + e^{-t})$  and  $a'(t) = \sigma(t) = \frac{1}{1+e^{-t}}$  is the sigmoid function and the probability mass function is given by  $p(y|\eta) = \exp(\eta y - \log(1 + e^\eta))$ .

**Poisson regression.** One more special case is Poisson regression with  $y \in \mathbb{N}$ ,  $a(t) = \exp(t)$  and the response variable  $y$  has a Poisson distribution. The probability mass function is given by  $p(y|\eta) = \exp(\eta y - e^\eta - \log(y!))$ . Poisson regression may be appropriate when the dependent variable is a count, for example in genomics, network packet analysis, crime rate analysis, fluorescence microscopy, etc. (Hilbe, 2011).

## 4.2 AVERAGING PREDICTIONS

Recall from Section 2 that  $\pi_\gamma$  is the stationary distribution of  $\theta$ . Taking expectation of both parts of Eq. (1), we get, by using the fact that  $\pi_\gamma$  is the limiting distribution of  $\theta_n$  and  $\theta_{n-1}$ :

$$\begin{aligned} & \mathbb{E}_{\pi_\gamma(\theta_n)}\theta_n \\ &= \mathbb{E}_{\pi_\gamma(\theta_{n-1})}\theta_{n-1} - \gamma \mathbb{E}_{\pi_\gamma(\theta_{n-1})}\mathbb{E}_{p(x_n, y_n)}f'_n(\theta_{n-1}), \end{aligned}$$

which leads to  $\mathbb{E}_{\pi_\gamma(\theta)}\mathbb{E}_{p(x_n, y_n)}\nabla f_n(\theta) = 0$ , that is, now removing the dependence on  $n$  (data  $(x, y)$  are i.i.d.):

$$\mathbb{E}_{\pi_\gamma(\theta)}\mathbb{E}_{p(x, y)}\left[-y\Phi(x) + a'(\Phi(x)^\top \theta)\Phi(x)\right] = 0,$$

which finally leads to

$$\mathbb{E}_{p(x)}\left[\mathbb{E}_{\pi_\gamma(\theta)}a'(\Phi(x)^\top \theta) - \mu_{**}(x)\right]\Phi(x) = 0. \quad (4)$$

This is the core equation our method relies on. It does not imply that  $b(x) = \mathbb{E}_{\pi_\gamma(\theta)}a'(\Phi(x)^\top \theta) - \mu_{**}(x)$  is uniformly equal to zero (which we want), but only that  $\mathbb{E}_{p(x)}\Phi(x)b(x) = 0$ , i.e.,  $b(x)$  is uncorrelated with  $\Phi(x)$ .

If the feature vector  $\Phi(x)$  is “large enough” then this is equivalent to  $b = 0$ .<sup>1</sup> For example, when  $\Phi(x)$  is composed of an orthonormal basis of the space of integrable

<sup>1</sup>Let  $\Phi(x) = (\phi_1(x), \dots, \phi_n(x))^\top$  be an orthogonal basis and  $b(x) = \sum_{i=1}^n c_i \phi_i(x) + \varepsilon(x)$ , where  $\varepsilon(x)$  is small if the basis is big enough. Then  $\mathbb{E}_{p(x)}\Phi(x)b(x) = 0 \Leftrightarrow \mathbb{E}\phi_i(x)[\sum_{i=1}^n c_i \phi_i(x) + \varepsilon(x)] = 0$  for every  $i$ , and due to the orthogonality of the basis and the smallness of  $\varepsilon(x)$ :  $c_i \cdot \mathbb{E}_{p(x)}\phi_i^2(x) \approx 0$  and hence  $c_i \approx 0$  and thus  $b(x) \approx 0$ .

functions (like for kernels in Section 6), then this is exactly true. Thus, in this situation,

$$\mu_{**}(x) = \mathbb{E}_{\pi_\gamma(\theta)} a'(\Phi(x)^\top \theta), \quad (5)$$

and averaging predictions  $a'(\Phi(x)^\top \theta_n)$ , along the path  $(\theta_n)$  of the Markov chain should exactly converge to the optimal prediction.

This exact convergence is weaker (requires high-dimensional features) than for the unconditional family in Section 3 but it can still bring surprising benefits even when  $\Phi$  is not large enough, as we present in Section 5 and Section 6.

### 4.3 TWO TYPES OF AVERAGING

Now we can introduce two possible ways to estimate the prediction function  $\mu(x)$ .

**Averaging estimators.** The first one is the usual way: we first estimate parameter  $\theta$ , using Ruppert-Polyak averaging (Polyak and Juditsky, 1992):  $\bar{\theta}_n = \frac{1}{n+1} \sum_{i=0}^n \theta_i$  and then we denote

$$\bar{\mu}_n(x) = a'(\Phi(x)^\top \bar{\theta}_n) = a'(\Phi(x)^\top \frac{1}{n+1} \sum_{i=0}^n \theta_i)$$

the corresponding prediction. As discussed in Section 2 it converges to  $\bar{\mu}_\gamma : x \mapsto a'(\Phi(x)^\top \bar{\theta}_\gamma)$ , which is *not* equal to in general to  $a'(\Phi(x)^\top \theta_*)$ , where  $\theta_*$  is the optimal parameter in  $\mathbb{R}^d$ . Since, as presented at the end of Section 2,  $\bar{\theta}_\gamma - \theta_*$  is of order  $O(\gamma)$ ,  $F(\bar{\theta}_\gamma) - F(\theta_*)$  is of order  $O(\gamma^2)$  (because  $\nabla F(\theta_*) = 0$ ), and thus an error of  $O(\gamma^2)$  is added to the usual convergence rates in  $O(1/n)$ .

Note that we are limited here to prediction functions which corresponds to *linear functions* in  $\Phi(x)$  in the natural parameterization, and thus  $F(\theta_*) \geq \mathcal{G}(\mu_{**})$ , and the inequality is often strict.

**Averaging predictions.** We propose a new estimator

$$\bar{\bar{\mu}}_n(x) = \frac{1}{n+1} \sum_{i=0}^n a'(\theta_i^\top \Phi(x)).$$

In general  $\mathcal{G}(\bar{\bar{\mu}}_n) - \mathcal{G}(\mu_{**})$  does not converge to zero either (unless the feature vector  $\Phi$  is large enough and Eq. (5) is satisfied). Thus, on top of the usual convergence in  $O(1/n)$  with respect to the number of iterations, we have an extra term that depends only on  $\gamma$ , which we will study in Section 5 and Section 6.

We denote by  $\bar{\bar{\mu}}_\gamma(x)$  the limit when  $n \rightarrow \infty$ , that is, using properties of converging Markov chains,  $\bar{\bar{\mu}}_\gamma(x) = \mathbb{E}_{\pi_\gamma(\theta)} a'(\Phi(x)^\top \theta)$ .

Rewriting Eq. (4) using our new notations, we get:

$$\mathbb{E}[(\mu_{**}(x) - \bar{\bar{\mu}}_\gamma(x))\Phi(x_n)] = 0.$$

When  $\Phi : \mathbb{R} \rightarrow \mathbb{R}^d$  is high-dimensional, this leads to  $\mu_{**} = \bar{\bar{\mu}}_\gamma$  and in contrast to  $\bar{\mu}_\gamma$ , averaging predictions potentially converge to the optimal prediction.

**Computational complexity.** Usual averaging of estimators (Polyak and Juditsky, 1992) to compute  $\bar{\mu}_n(x) = a'(\Phi(x)^\top \bar{\theta}_n)$  is simple to implement as we can simply update the average  $\bar{\theta}_n$  with essentially no extra cost on top the complexity  $O(nd)$  of the SGD recursion. Given the number  $n$  of training data points and the number  $m$  of testing data points, the overall complexity is  $O(d(n+m))$ .

Averaging prediction functions is more challenging as we have to store all iterates  $\theta_i$ ,  $i = 1, \dots, n$ , and for each testing point  $x$ , compute  $\bar{\bar{\mu}}_n(x) = \frac{1}{n+1} \sum_{i=0}^n a'(\theta_i^\top \Phi(x))$ . Thus the overall complexity is  $O(dn + mnd)$ , which could be too costly with many test points (i.e.,  $m$  large).

There are several ways to alleviate this extra cost: (a) using sketching techniques (Woodruff et al., 2014), (b) using summary statistics like done in applications of MCMC (Gilks et al., 1995), or (c) leveraging the fact that all iterates  $\theta_i$  will end up being close to  $\bar{\theta}_\gamma$  and use a Taylor expansion of  $a'(\theta^\top \Phi(x))$  around  $\bar{\theta}_\gamma$ . This expansion is equal to:

$$\begin{aligned} & a'(\Phi(x)^\top \bar{\theta}_\gamma) + (\theta - \bar{\theta}_\gamma)^\top \Phi(x) \cdot a''(\Phi(x)^\top \bar{\theta}_\gamma) + \\ & + \frac{1}{2} ((\theta - \bar{\theta}_\gamma)^\top \Phi(x))^2 \cdot a'''(\Phi(x)^\top \bar{\theta}_\gamma) + O(\|\theta - \bar{\theta}_\gamma\|^3). \end{aligned}$$

Taking expectation in both sides above leads to:

$$\bar{\bar{\mu}}_\gamma(x) \approx \bar{\mu}_\gamma(x) + \frac{1}{2} \Phi(x)^\top \text{cov}(\theta) \cdot \Phi(x) \cdot a'''(\bar{\theta}_\gamma^\top \Phi(x)),$$

where  $\text{cov}(\theta)$  is the covariance matrix of  $\theta$  under  $\pi_\gamma$ . This provides a simple correction to  $\bar{\mu}_\gamma$ , and leads to an approximation of  $\bar{\bar{\mu}}_n(x)$  as

$$\bar{\bar{\mu}}_n(x) + \frac{1}{2} \Phi(x)^\top \text{cov}_n(\theta) \cdot \Phi(x) \cdot a'''(\bar{\theta}_n^\top \Phi(x)),$$

where  $\text{cov}_n(\theta)$  is the empirical covariance matrix of the iterates  $(\theta_i)$ .

The computational complexity now becomes  $O(nd^2 + md^2)$ , which is an improvement when the number of testing points  $m$  is large. In all of our experiments, we used this approximation.

## 5 FINITE-DIMENSIONAL MODELS

In this section we study the behavior of  $\bar{A}(\gamma) = \mathcal{G}(\bar{\mu}_\gamma) - \mathcal{G}(\mu_*)$  for finite-dimensional models, for which it is usually not equal to zero. We know that our estimators  $\bar{\mu}_n$  will converge to  $\bar{\mu}_\gamma$ , and our goal is to compare it to  $\bar{A}(\gamma) = \mathcal{G}(\bar{\mu}_\gamma) - \mathcal{G}(\mu_*) = F(\bar{\theta}_\gamma) - F(\theta_*)$  which is what averaging estimators tends to. We also consider for completeness the non-averaged performance  $A(\gamma) = \mathbb{E}_{\pi_\gamma(\theta)} [F(\theta) - F(\theta_*)]$ .

Note that we must have  $A(\gamma)$  and  $\bar{A}(\gamma)$  non-negative, because we compare the negative log-likelihood performances to the one of the best linear prediction (in the natural parameter), while  $\bar{A}(\gamma)$  could potentially be negative (it will in certain situations), because the corresponding natural parameters may not be linear in  $\Phi(x)$ .

We consider the same standard assumptions as Dieuleveut et al. (2017), namely smoothness of the negative log-likelihoods  $f_n(\theta)$  and strong convexity of the expected negative log-likelihood  $F(\theta)$ . We first recall the results from Dieuleveut et al. (2017). See detailed explicit formulas in the supplementary material.

### 5.1 EARLIER WORK

**Without averaging.** We have that  $A(\gamma) = \gamma B + O(\gamma^{3/2})$ , that is  $\gamma$  is *linear* in  $\gamma$ , with  $B$  non-negative.

**Averaging estimators.** We have that  $\bar{A}(\gamma) = \gamma^2 \bar{B} + O(\gamma^{5/2})$ , that is  $\bar{A}$  is *quadratic* in  $\gamma$ , with  $\bar{B}$  non-negative. Averaging does provably bring some benefits because the order in  $\gamma$  is higher (we assume  $\gamma$  small).

### 5.2 AVERAGING PREDICTIONS

We are now ready to analyze the behavior of our new framework of averaging predictions. The following result is shown in the supplementary material.

**Proposition 1** *Under the assumptions on the negative loglikelihoods  $f_n$  of each observation from Dieuleveut et al. (2017):*

- *In the case of well-specified data, that is, there exists  $\theta_*$  such that for all  $(x, y)$ ,  $p(y|x) = q(y|x, \theta_*)$ , then  $\bar{A} \sim \gamma^2 \bar{B}^{\text{well}}$ , where  $\bar{B}^{\text{well}}$  is a positive constant.*
- *In the general case of potentially mis-specified data,  $\bar{A} = \gamma \bar{B}^{\text{mis}} + O(\gamma^2)$ , where  $\bar{B}^{\text{mis}}$  is constant which may be positive or negative.*

Note, that in contrast to averaging parameters, the constant  $\bar{B}^{\text{mis}}$  can be negative. It means, that we obtain the

estimator better than the optimal linear estimator, which is the limit of capacity for averaging parameters. In our simulations, we show examples for which  $\bar{B}^{\text{mis}}$  is positive, and examples for which it is negative. Thus, in general, for low-dimensional models, averaging predictions can be worse or better than averaging parameters. However, as we show in the next section, for infinite-dimensional models, we always get convergence.

## 6 INFINITE-DIMENSIONAL MODELS

Recall, that we have the following objective function to minimize:

$$F(\theta) = \mathbb{E}_{x,y} \left[ -y \cdot \eta_\theta(x) + a(\eta_\theta(x)) \right], \quad (6)$$

where till this moment we consider unknown functions  $\eta_\theta(x)$  which were linear in  $\Phi(x)$  with  $\Phi(x) \in \mathbb{R}^d$ , leading to a complexity in  $O(dn)$ .

We now consider infinite-dimensional features, by considering that  $\Phi(x) \in \mathcal{H}$ , where  $\mathcal{H}$  is a Hilbert space. Note that this corresponds to modeling the function  $\eta_\theta$  as a Gaussian process (Rasmussen and Williams, 2006).

This is computationally feasible through the usual “kernel trick” (Scholkopf and Smola, 2001; Shawe-Taylor and Cristianini, 2004), where we assume that the kernel function  $k(x, y) = \langle \Phi(x), \Phi(y) \rangle$  is easy to compute. Indeed, following Bordes et al. (2005) and Dieuleveut and Bach (2016), starting from  $\theta_0$ , each iterate of constant-step-size SGD is of the form  $\theta_n = \sum_{t=1}^n \alpha_t \Phi(x_t)$ , and the gradient descent recursion  $\theta_n = \theta_{n-1} - \gamma [a'(\eta_{\theta_{n-1}}(x_n)) - y_n] \Phi(x_n)$  leads to the following recursion on  $\alpha_t$ 's:

$$\begin{aligned} \alpha_n &= -\gamma \left[ a' \left( \sum_{t=1}^{n-1} \alpha_t \langle \Phi(x_t), \Phi(x_n) \rangle \right) - y_n \right] \\ &= -\gamma \left[ a' \left( \sum_{t=1}^{n-1} \alpha_t k(x_t, x_n) \right) - y_n \right]. \end{aligned}$$

This leads to  $\eta_{\theta_n}(x) = \langle \Phi(x), \theta_n \rangle$  and  $\mu_{\theta_n}(x) = a'(\eta_{\theta_n}(x))$  with

$$\eta_{\theta_n}(x) = \sum_{t=1}^n \alpha_t \langle \Phi(x), \Phi(x_t) \rangle = \sum_{t=1}^n \alpha_t k(x, x_t),$$

and finally we can express  $\bar{\mu}_n(x)$  in kernel form as:

$$\bar{\mu}_n(x) = \frac{1}{n+1} \sum_{t=0}^n a' \left[ \sum_{l=1}^t \alpha_l \cdot k(x, x_l) \right].$$

There is also a straightforward estimator for averaging parameters, i.e.,  $\bar{\mu}_n(x) = a' \left( \frac{1}{n+1} \sum_{t=0}^n \sum_{l=1}^t \alpha_l k(x, x_l) \right)$ . If we assume that the kernel function is *universal*, that is,  $\mathcal{H}$

is dense in the space of squared integrable functions, then it is known that if  $\mathbb{E}_x b(x)\Phi(x) = 0$ , then  $b = 0$  (Sriperumbudur et al., 2008). This implies that we must have  $\bar{\mu}_\gamma = 0$  and thus averaging predictions does always converge to the global optimum (note that in this setting, we must have a well-specified model because we are in a non-parametric setting).

**Column sampling.** Because of the usual high running-time complexity of kernel method in  $O(n^2)$ , we consider a ‘‘column-sampling approximation’’ (Williams and Seeger, 2001). We thus choose a small subset  $I = (x_1, \dots, x_m)$  of samples and construct a new finite  $m$ -dimensional feature map  $\bar{\Phi}(x) = K(I, I)^{-1/2}K(I, x) \in \mathbb{R}^m$ , where  $K(I, I)$  is the  $m \times m$  kernel matrix of the  $m$  points and  $K(I, x)$  the vector composed of kernel evaluations  $k(x_i, x)$ . This allows a running-time complexity in  $O(m^2n)$ . In theory and practice,  $m$  can be chosen small (Bach, 2013; Rudi et al., 2017).

**Regularized learning with kernels.** Although we can use an unregularized recursion with good convergence properties (Dieuleveut and Bach, 2016), adding a regularisation by the squared Hilbertian norm is easier to analyze and more stable with limited amounts of data. We thus consider the recursion (in Hilbert space), with  $\lambda$  small:

$$\begin{aligned} \theta_n &= \theta_{n-1} - \gamma [f'_n(\theta_{n-1}) + \lambda \theta_{n-1}] \\ &= \theta_{n-1} + \gamma (y_n - a'(\langle \Phi(x_n), \theta \rangle)) \Phi(x_n) - \gamma \lambda \theta_{n-1}. \end{aligned}$$

This recursion can also be computed efficiently as above using the kernel trick and column sampling approximations.

In terms of convergence, the best we can hope for is to converge to the minimizer  $\theta_{*,\lambda}$  of the regularized expected negative log-likelihood  $F(\theta) + \frac{\lambda}{2} \|\theta\|^2$  (which we assume to exist). When  $\lambda$  tends to zero, then  $\theta_{*,\lambda}$  converges to  $\theta_*$ .

Averaging *parameters* will tend to a limit  $\bar{\theta}_{\gamma,\lambda}$  which is  $O(\gamma)$ -close to  $\theta_{*,\lambda}$ , thus leading to predictions which deviate from the optimal predictions for two reasons: because of regularization and because of the constant step-size. Since  $\lambda$  should decrease as we get more data, the first effect will vanish, while the second will not.

When averaging *predictions*, the two effects will vanish as  $\lambda$  tends to zero. Indeed, by taking limits of the gradient equation, and denoting by  $\bar{\mu}_{\gamma,\lambda}$  the limit of  $\bar{\mu}_n$ , we have

$$\mathbb{E}[(\mu_{**}(x) - \bar{\mu}_{\gamma,\lambda}(x))\Phi(x)] = \lambda \bar{\theta}_{\gamma,\lambda}. \quad (7)$$

Given that  $\bar{\theta}_{\gamma,\lambda}$  is  $O(\gamma)$ -away from  $\theta_*$ , if we assume that

$\theta_*$  corresponds to a sufficiently regular<sup>2</sup> element of the Hilbert space  $\mathcal{H}$ , then the  $L_2$ -norm of the deviation satisfies  $\|\mu_{**}(x) - \bar{\mu}_{\gamma,\lambda}\| = O(\lambda)$  and thus as the regularization parameter  $\lambda$  tends to zero, our predictions tend to the optimal one.

## 7 EXPERIMENTS

In this section, we compare the two types of averaging (estimators and predictions) on a variety of problems, both on synthetic data and on standard benchmarks. When averaging predictions, we always consider the Taylor expansion approximation presented at the end of Section 4.3.

### 7.1 SYNTHETIC DATA

**Finite-dimensional models.** we consider the following logistic regression model:

$$q(y|x, \theta) = \exp(y \cdot \eta_\theta(x) - a(\eta_\theta(x))),$$

where we consider a linear model  $\eta_\theta(x) = \theta^\top x$  in  $x$  (i.e.,  $\Phi(x) = x$ ), the link function  $a(t) = \log(1 + e^t)$  and  $a'(t) = \sigma(t)$  is the sigmoid function. Let  $x$  be distributed as a standard normal random variable in dimension  $d = 2$ ,  $y \in \{0, 1\}$  and  $\mathbb{P}(y = 1|x) = \mu_{**}(x) = \sigma(\eta_{**}(x))$ , where we consider two different settings:

- Model 1:  $\eta_{**}(x) = \sin x_1 + \sin x_2$ ,
- Model 2:  $\eta_{**}(x) = x_1^3 + x_2^3$ .

The global minimum  $\mathcal{F}_{**}$  of the corresponding optimization problem can be found as

$$\mathcal{F}_{**} = \mathbb{E}_{p(x)}[-\mu_{**}(x) \cdot \eta_{**}(x) + a(\eta_{**}(x))].$$

We also introduce the performance measure  $\mathcal{F}(\eta)$

$$\mathcal{F}(\eta) = \mathbb{E}_{p(x)}[-\mu_{**}(x) \cdot \eta(x) + a(\eta(x))], \quad (8)$$

which can be evaluated directly in the case of synthetic data. Note that in our situation, the model is misspecified because  $\eta_{**}(x)$  is not linear in  $\Phi(x) = x$ , and thus,  $\inf_\theta F(\theta) > \mathcal{F}_{**}$ , and thus our performance measures  $\mathcal{F}(\mu_n) - \mathcal{F}_{**}$  for various estimators  $\mu_n$  will not converge to zero.

The results of averaging 10 replications are shown in Fig. 3 and Fig. 4. We first observed that constant step-size SGD without averaging leads to a bad performance.

<sup>2</sup>While our reasoning is informal here, it can be made more precise by considering so-called ‘‘source conditions’’ commonly used in the analysis of kernel methods (Caponnetto and De Vito, 2007), but this is out of the scope of this paper.

Figure 3: Synthetic data for linear model  $\eta_\theta(x) = \theta^\top x$  and  $\eta_{**}(x) = \sin x_1 + \sin x_2$ . Excess prediction performance vs. number of iterations (both in log-scale).

Figure 4: Synthetic data for linear model  $\eta_\theta(x) = \theta^\top x$  and  $\eta_{**}(x) = x_1^3 + x_2^3$ . Excess prediction performance vs. number of iterations (both in log-scale).

Moreover, we can see, that in the first case (Fig. 3) averaging predictions beats averaging parameters, and moreover beats the best linear model: if we use the best linear error  $\mathcal{F}_*$  instead of  $\mathcal{F}_{**}$ , at some moment  $\mathcal{F}(\eta_n) - \mathcal{F}_*$  becomes negative. However in the second case (Fig. 4), averaging predictions is not superior to averaging parameters. Moreover, by looking at the final differences between performances with different values of  $\gamma$ , we can see the dependency of the final performance in  $\gamma$  for averaging predictions, instead of  $\gamma^2$  for averaging parameters (as suggested by our theoretical results in Section 5). In particular in Fig. 3, we can observe the surprising behavior of a larger step-size leading to a better performance (note that we cannot increase too much otherwise the algorithm would diverge).

Figure 5: Synthetic data for Laplacian kernel for  $\eta_{**}(x) = \frac{5}{5+x^\top x}$ . Excess prediction performance vs. number of iterations (both in log-scale).

**Infinite-dimensional models** Here we consider the kernel setup described in Section 6. We consider Laplacian kernels  $k(s, t) = \exp\left(-\frac{\|s-t\|_1}{\sigma}\right)$  with  $\sigma = 50$ , dimension  $d = 5$  and generating log odds ratio  $\eta_{**}(x) = \frac{5}{5+x^\top x}$ . We also use a squared norm regularization with several values of  $\lambda$  and column sampling with  $m = 100$  points. We use the exact value of  $\mathcal{F}_{**}$  which we can compute directly for synthetic data. The results are shown in Fig. 5, where averaging predictions leads to a better performance than averaging estimators.

## 7.2 REAL DATA

Note, that in the case of real data, one does not have access to unknown  $\mu_{**}(x)$  and computing the performance measure in Eq. (8) is inapplicable. Instead of it we use its sampled version on held out data:

$$\hat{\mathcal{F}}(\eta) = - \sum_{i:y_i=1} \log(\mu(x_i)) - \sum_{j:y_j=0} \log(1 - \mu(x_j)).$$

We use two datasets, with  $d$  not too large, and  $n$  large, from (Lichman, 2013): the “MiniBooNE particle identification” dataset ( $d = 50$ ,  $n = 130\,064$ ), the “Covertypes” dataset ( $d = 54$ ,  $n = 581\,012$ ).

We use two different approaches for each of them: a linear model  $\eta_\theta(x) = \theta^\top x$  and a kernel approach with Laplacian kernel  $k(s, t) = \exp\left(-\frac{\|s-t\|_1}{\sigma}\right)$ , where  $\sigma = d$ . The results are shown in Figures 6 to 9. Note, that for linear models we use  $\hat{\mathcal{F}}_*$ —the estimator of the best performance among linear models (learned on the test set, and hence not reachable from learning on the training data), and for kernels we use  $\hat{\mathcal{F}}_{**}$  (same definition as  $\hat{\mathcal{F}}_*$  but with the kernelized model), that is why graphs are not comparable (but, as shown below, the value of  $\hat{\mathcal{F}}_{**}$  is

Figure 6: MiniBooNE dataset, dimension  $d = 50$ , linear model. Excess prediction performance vs. number of iterations (both in log-scale).

Figure 7: MiniBooNE dataset, dimension  $d = 50$ , kernel approach, column sampling  $m = 200$ . Excess prediction performance vs. number of iterations (both in log-scale).

lower than the value of  $\hat{\mathcal{F}}_*$  because using kernels correspond to a larger feature space).

For the “MiniBooNE particle identification” dataset  $\hat{\mathcal{F}}_* = 0.35$  and  $\hat{\mathcal{F}}_{**} = 0.21$ ; for the “Covertypes” dataset  $\hat{\mathcal{F}}_* = 0.46$  and  $\hat{\mathcal{F}}_{**} = 0.39$ . We can see from the four plots that, especially in the kernel setting, averaging predictions also shows better performance than averaging parameters.

## 8 CONCLUSION

In this paper, we have explored how averaging procedures in stochastic gradient descent, which are crucial for fast convergence, could be improved by looking at the specifics of probabilistic modeling. Namely, averaging

Figure 8: CoverType dataset, dimension  $d = 54$ , linear model. Excess prediction performance vs. number of iterations (both in log-scale).

in the moment parameterization can have better properties than averaging in the natural parameterization.

While we have provided some theoretical arguments (asymptotic expansion in the finite-dimensional case, convergence to optimal predictions in the infinite-dimensional case), a detailed theoretical analysis with explicit convergence rates would provide a better understanding of the benefits of averaging predictions.

## Abstract

We consider the problem of inference in discrete probabilistic models, that is, distributions over subsets of a finite ground set. These encompass a range of well-known models in machine learning, such as determinantal point processes and Ising models. Locally-moving Markov chain Monte Carlo algorithms, such as the Gibbs sampler, are commonly used for inference in such models, but their convergence is, at times, prohibitively slow. This is often caused by state-space bottlenecks that greatly hinder the movement of such samplers. We propose a novel sampling strategy that uses a specific mixture of product distributions to propose global moves and, thus, accelerate convergence. Furthermore, we show how to construct such a mixture using semigradient information. We illustrate the effectiveness of combining our sampler with existing ones, both theoretically on an example model, as well as practically on three models learned from real-world data sets.

## 1 INTRODUCTION

Discrete probabilistic models have played a fundamental role in machine learning. Examples range from classic graphical models, such as Ising and Potts models (Koller and Friedman, 2009), which have long been used in computer vision applications (Boykov et al., 2001), to determinantal point processes (Kulesza and Taskar, 2012) used in video summarization (Gong et al., 2014), and facility location diversity models used for product recommendation (Tschitschek et al., 2016). Recently, there has been increased interest in general distributions over subsets of a finite ground set  $V$ ; that is, given a

set function  $F : 2^V \rightarrow \mathbb{R}$ , distributions of the form  $\pi(S) \propto \exp(F(S))$ , for all  $S \subseteq V$ . These can be equivalently seen as distributions over binary random vectors, if  $S$  is replaced by the indicator function of the corresponding vector. All the aforementioned examples can be expressed in this form for a suitable choice of  $F$ .

While exact inference in such models is known to be intractable in general (Jerrum and Sinclair, 1993), there has been recent work on analyzing approximate inference techniques, such as variational methods (Djolonga and Krause, 2014; Djolonga et al., 2016b), and Markov chain Monte Carlo (MCMC) sampling (Gotovos et al., 2015; Rebeschini and Karbasi, 2015). The sampling analyses, in particular, focus on the Gibbs sampler, and derive sufficient conditions under which it mixes—converges toward the target distribution—sufficiently fast.

Unfortunately, oftentimes in practice these conditions do not hold and the Gibbs sampler mixes prohibitively slowly. A fundamental reason for this slow mixing behavior is the existence of bottlenecks in the state space of the Markov chain. Conceptually, one can think about the state-space graph containing several isolated components that are poorly connected to each other, thus making it hard for the Gibbs sampler to move between them.

In this work, we propose a novel sampling strategy that allows for global moves in the state space, thereby avoiding bottlenecks, and, thus, accelerating mixing. Our sampler is based on using a proposal distribution that approximates the target  $\pi$  by a mixture of product distributions. We further propose an algorithm for constructing such a mixture using discrete semigradient information of the associated function  $F$ . This idea makes a step towards bridging optimization and sampling, a theme that has been successful in continuous spaces. Our sampler is readily combined with other existing samplers, and we show provable theoretical, as well as empirical examples of speedups.

**Contributions.** The main contributions of this paper are as follows.

- We propose the  $M^3$  sampler, which makes global moves according to a specific mixture of product distributions.
- We theoretically analyze mixing times on an illustrative family of Ising models, and prove that adding the  $M^3$  sampler results in an exponential improvement over the Gibbs sampler.
- We demonstrate the effectiveness of combining the  $M^3$  and Gibbs samplers in practice on three models learned from real-world data.

**Related work.** Recent work on analyzing the mixing time of MCMC samplers for discrete probabilistic models includes deriving general conditions on  $F$  to achieve fast mixing (Gotovos et al., 2015; Rebeschini and Karbasi, 2015; Li et al., 2016), as well as looking at specific subclasses, such as strongly Rayleigh distributions (Li et al., 2016; Anari et al., 2016).

There has also been work on mapping discrete inference to continuous domains (Zhang et al., 2012; Pakman and Paninski, 2013; Dinh et al., 2017; Nishimura et al., 2018) to enable the use of well-established continuous samplers, such as Hamiltonian Monte Carlo (Neal, 2012; Betancourt, 2017). It is worth pointing out that, while these methods usually outperform simple Gibbs or Metropolis samplers, they still tend to suffer from considerable slowdowns in multimodal distributions (Neal, 2012). Our work is orthogonal to these methods, in the sense that our proposed sampler can be combined with any of the existing ones to provide a principled way for performing global moves that can lead to improved mixing.

Both darting Monte Carlo (Sminchisescu and Welling, 2007; Ahn et al., 2013) and variational MCMC (de Freitas et al., 2001) share the high-level concept of combining two chains, one making global moves between high-probability regions, and another making local moves around those regions. However, their proposed global samplers for continuous spaces are generally not applicable to the class of discrete distributions we consider.

There are several well-known results on mixing of the Gibbs sampler for the Ising model on different graph structures (Jerrum and Sinclair, 1993; Berger et al., 2005; Levin et al., 2008a;b). Other (non-MCMC) approaches to discrete sampling include Perturb-and-MAP (Papan-dreou and Yuille, 2011; Hazan et al., 2013), and random projections (Zhu and Ermon, 2015). Semigradients of submodular set functions have recently been exploited

for optimization (Iyer et al., 2013; Jegelka and Bilmes, 2011) and variational inference (Djolonga et al., 2016a), but, to our knowledge, no prior work has used them for sampling.

## 2 BACKGROUND

We consider set functions  $F : 2^V \rightarrow \mathbb{R}$ , where  $V$  is a finite ground set of size  $n$  that can be assumed to be  $V = \{1, \dots, n\}$  without loss of generality. In this paper, we focus on distributions over  $\Omega := 2^V$  of the form

$$\pi(S) = \frac{1}{Z} \exp(F(S)), \quad (1)$$

for all  $S \in \Omega$ . The partition function  $Z := \sum_{S \in \Omega} \exp(F(S))$  serves as the normalizer of the distribution. Alternatively, we can describe distributions of the above form via binary vectors  $X \in \{0, 1\}^n$ . If we define  $V(X) := \{v \in V \mid X_v = 1\}$ , then the distribution  $p_X(X) \propto \exp(F(V(X)))$  over binary vectors is isomorphic to the distribution (1) over sets.

Perhaps the simplest family of such models are log-modular distributions, which describe a collection of independent binary random variables. Equivalently, they are distributions of the form (1) where  $F$  is a modular function, that is, a function of the form  $F(S) = c + \sum_{v \in S} m_v$ , where  $c, m_v \in \mathbb{R}$ , for all  $v \in V$ . The partition function of a log-modular distribution can be derived in closed form as  $Z_m = \exp(c) \prod_{v \in V} (1 + \exp(m_v))$ . Consequently, the corresponding log-modular distribution is

$$\pi_m(S) = \frac{\exp(\sum_{v \in S} m_v)}{\prod_{v \in V} (1 + \exp(m_v))}.$$

**Inference and sampling.** Performing exact inference in models of the form (1), that is, computing conditional probabilities such as  $\pi(A \subseteq S \subseteq B \mid C \subseteq S \subseteq D)$ , is known to be in general #P-hard (Jerrum and Sinclair, 1993). As a result, we have to resort to approximate inference algorithms, such as Markov chain Monte Carlo sampling (Levin et al., 2008b), which is the primary focus of this paper. An MCMC algorithm for distribution  $\pi$  simulates a Markov chain in state space  $\Omega$  in such a way that the sequence of visited states  $(X_0, X_1, \dots) \in \Omega^{\mathbb{N}}$  ultimately converges to  $\pi$ .

**Gibbs sampler.** One of the most commonly used chains is the (single-site) Gibbs sampler, which adds or removes a single element at a time. It first selects uniformly at random an element  $v \in V$ ; subsequently, it adds or removes  $v$  to the current state  $X_t$  according to the probability of the resulting state. We denote by  $P : \Omega \times$

$\Omega \rightarrow \mathbb{R}$  the transition matrix of a Markov chain, that is, for all  $S, R \in \Omega$ ,  $P(S, R) := \mathbb{P}[X_{t+1} = R \mid X_t = S]$ . Then, if we define

$$p_{S \rightarrow R} = \frac{\exp(F(R))}{\exp(F(R)) + \exp(F(S))},$$

and denote by  $S \sim R$  states that differ by exactly one element (i.e.,  $\|R\| - \|S\| = 1$ ), the transition matrix  $P^G$  of the Gibbs sampler is

$$P^G(S, R) = \begin{cases} \frac{1}{n} p_{S \rightarrow R}, & \text{if } R \sim S \\ 1 - \sum_{T \sim S} \frac{1}{n} p_{S \rightarrow T}, & \text{if } R = S \\ 0, & \text{otherwise} \end{cases}.$$

**Mixing.** The efficiency of a Markov chain in approximating its target distribution depends largely on the speed of convergence of the chain, which is quantified by the chain's mixing time. Most commonly, distance from stationarity is measured by the maximum total variation distance, over all starting states, between  $X_t$  and the target distribution  $\pi$ , that is,  $d(t) := \max_{X_0 \in \Omega} d_{\text{TV}}(P^t(X_0, \cdot), \pi)$ . Then, the mixing time denotes the minimum number of iterations required to get  $\epsilon$ -close to stationarity,  $t_{\text{mix}}(\epsilon) := \min\{t \mid d(t) \leq \epsilon\}$ .

A common way to obtain an upper bound on the mixing time of a chain is by lower bounding its spectral gap, defined as  $\gamma := 1 - \lambda_2$ , where  $\lambda_2$  is the second largest eigenvalue of the transition matrix  $P$ . The following well-known theorem connects the spectral gap to mixing time.

**Theorem 1** (cf. Theorems 12.3, 12.4 in (Levin et al., 2008b)). *Let  $P$  be the transition matrix of a lazy, irreducible, and reversible Markov chain, and let  $\gamma$  be its spectral gap, and  $\pi_{\min} := \min_{S \in \Omega} \pi(S)$ . Then,*

$$\left(\frac{1}{\gamma} - 1\right) \log\left(\frac{1}{2\epsilon}\right) \leq t_{\text{mix}}(\epsilon) \leq \frac{1}{\gamma} \log\left(\frac{1}{\epsilon \pi_{\min}}\right).$$

### 3 THE MIXTURE CHAIN

Despite the simplicity and computational efficiency of the Gibbs sampler, the fact that it is constrained to performing local moves makes it susceptible to state-space bottlenecks, which hinder the movement of the chain around the state space. Intuitively, the state space may contain several high-probability regions arranged in such a way that moving from one to another using only single-element additions and deletions requires passing through states of very low probability. As a result, the Gibbs sampler may mix extremely slowly on the whole state space, despite the fact that it can move sufficiently fast within each of the high-probability regions.

To alleviate this shortcoming, it is natural to ask whether it is possible to bypass such bottlenecks by using a chain that performs larger moves. In this paper, we introduce a novel approach that uses a Metropolis chain based on a specific mixture of log-modular distributions, which we call the  $M^3$  chain, to perform global moves in state space. Concretely, we define a proposal distribution

$$\begin{aligned} q(S, R) &= q(R) = \frac{1}{Z_q} \sum_{i=1}^r \exp(F_i(R)) \\ &= \frac{1}{Z_q} \sum_{i=1}^r w_i \exp(m_i(R)), \end{aligned} \quad (2)$$

where each  $F_i(R) = c_i + \sum_{v \in R} m_{iv}$  is a modular function, while each  $m_i(R) = \sum_{v \in R} m_{iv}$  is a normalized modular function ( $m_i(\emptyset) = 0$ ), and  $w_i = \exp(c_i) > 0$ . If we denote by  $Z_i$  the normalizer of  $m_i$ , then the normalizer of the mixture can be written in closed form as

$$\begin{aligned} Z_q &= \sum_{R \in \Omega} q(R) = \sum_{R \in \Omega} \sum_{i=1}^r w_i \exp(m_i(R)) \\ &= \sum_{i=1}^r w_i \sum_{R \in \Omega} \exp(m_i(R)) \\ &= \sum_{i=1}^r w_i Z_i. \end{aligned}$$

We define the  $M^3$  chain as a Metropolis chain (Levin et al., 2008b) using  $q$  as a proposal distribution; its transition matrix  $P^M : \Omega \times \Omega \rightarrow \mathbb{R}$  is given by

$$P^M(S, R) = \begin{cases} q(R) p_a(S, R), & \text{if } R \neq S \\ 1 - \sum_{T \neq S} q(T) p_a(S, T), & \text{otherwise} \end{cases},$$

where

$$p_a(S, R) := \min \left\{ 1, \frac{\pi(R) q(S)}{\pi(S) q(R)} \right\}.$$

Note that, contrary to usual practice, the proposal  $q$  only depends on the proposed state, but not on the current state of the chain. As a result, the chain is not constrained to local moves, but rather can potentially jump to any part of the state space. In practice,  $M^3$  sampling proceeds in two steps: first, a candidate set  $R$  is sampled according to  $q$ ; then, the move to  $R$  is accepted with probability  $p_a$ . Sampling from  $q$  can be done in  $\mathcal{O}(n)$  time—first, sample a log-modular component, then sample a set from that component. Computing  $p_a$  requires  $\mathcal{O}(r)$  time for the sum in (2), and it can be straightforwardly improved by parallelizing this computation. All in all, the total time for one step of  $M^3$  is  $\mathcal{O}(n + r)$ .

As is always the case with Metropolis chains, the mixing time of the  $M^3$  sampler will depend on how well the proposal  $q$  approximates the target distribution  $\pi$ . The following observation shows that, in theory, we can approximate any distribution of the form (1) by a mixture of the form (2).

**Proposition 1.** *For any  $\pi$  on  $\Omega$  as in (1), and any  $\epsilon > 0$ , there are positive constants  $w_i = w_i(\epsilon) > 0$ , and normalized modular functions  $m_i = m_i(\epsilon)$ , such that, if we define  $q(S) := \sum_{i=1}^r w_i \exp(m_i(S))$ , for all  $S \in \Omega$ , then  $d_{TV}(\pi, q) \leq \epsilon$ .*

Conceptually, the proof relies on having one log-modular term per set in  $\Omega$ .<sup>1</sup> Therefore, while the above result shows that mixtures of log-modulars are expressive enough, the constructed mixture of exponential size in  $n$  is not useful for practical purposes. On the other hand, it is not necessary for us to have  $q$  be an accurate approximation of  $\pi$  everywhere, as long as the corresponding  $M^3$  chain is able to bypass state-space bottlenecks. With this in mind, we suggest combining the  $M^3$  and Gibbs chains, so that each of them serve complementary purposes in the final chain; the role of  $M^3$  is to make global moves and avoid bottlenecks, while the role of Gibbs is to move fast within well-connected regions of the state space. To make this happen, we define the transition matrix  $P^C : \Omega \times \Omega \rightarrow \mathbb{R}$  of the combined chain as

$$P^C(S, R) = \alpha P^G(S, R) + (1 - \alpha) P^M(S, R), \quad (3)$$

where  $0 < \alpha < 1$ . It is easy to see that  $P^C$  is reversible, and has stationary distribution  $\pi$ .

We next illustrate how combining the two chains works on a simple example, where a mixture of only a few log-modular distributions can dramatically improve mixing compared to running the vanilla Gibbs chain. Then we propose an algorithm for automatically creating such a mixture.

### 3.1 EXAMPLE: ISING MODEL ON THE COMPLETE GRAPH

We consider the Ising model on a finite complete graph (Levin et al., 2008a), also known as the Curie-Weiss model in statistical physics, which can be written in the form of (1) as follows:

$$\pi_\beta(S) = \frac{1}{Z(\beta)} \exp\left(-\frac{2\beta}{n} |S|(n - |S|)\right). \quad (\text{ISING}_\beta)$$

<sup>1</sup>Detailed proofs of all our results can be found in the appendix.

In particular, we focus on the case where  $\beta = \ln(n)$ , that is,

$$\pi(S) = \frac{1}{Z} \exp\left(-\frac{2 \ln(n)}{n} |S|(n - |S|)\right). \quad (\text{ISING})$$

In this case, if we define  $d_n := 2 \ln(n)/n$ , then  $F(S) = -d_n |S|(n - |S|)$ .

The Gibbs sampler is known to experience poor mixing in this model; the following is an immediate corollary of Theorem 15.3 in (Levin et al., 2008b).

**Corollary 1** (cf. Theorem 15.3 in (Levin et al., 2008b)). *For  $n \geq 3$ , the Gibbs sampler on ISING has spectral gap  $\gamma^G = \mathcal{O}(e^{-cn})$ , where  $c > 0$  is a constant.*

From Theorem 1 it follows that the mixing time of Gibbs is  $t_{\text{mix}}(\epsilon) = \Omega((e^{cn} - 1) \log(1/(2\epsilon)))$ . Yet, it has been shown that the only reason for this is a single bottleneck in the state space (Levin et al., 2008a). To make this statement more formal, let us define a decomposition of  $\Omega$  into two disjoint sets,  $\Omega_0 := \{S \in \Omega \mid |S| < n/2\}$ , and  $\Omega_1 := \{S \in \Omega \mid |S| > n/2\}$  (Jerrum et al., 2004). To keep things simple, we will assume for the remainder of this section that  $n$  is odd; the analysis when  $n$  is even follows from the same arguments with only a minor technical adjustment. Our goal is to separately examine two characteristics of the sampler: (i) its movement between the two sets  $\Omega_0$ ,  $\Omega_1$ , and (ii) its movement when restricted to stay within each of these sets.

For analyzing the “between-sets” behavior, we define the projection  $\bar{\pi} : \{0, 1\} \rightarrow \mathbb{R}$  of  $\pi$  as

$$\bar{\pi}(i) := \sum_{S \in \Omega_i} \pi(S),$$

and, for any reversible chain  $P$ , we define its projection chain  $\bar{P} : \{0, 1\} \times \{0, 1\} \rightarrow \mathbb{R}$  as

$$\bar{P}(i, j) := \frac{1}{\bar{\pi}(i)} \sum_{S \in \Omega_i, R \in \Omega_j} \pi(S) P(S, R).$$

It is easy to see that  $\bar{P}$  is also reversible and has stationary distribution  $\bar{\pi}$ . For analyzing the “within-set” behavior, we define the restrictions  $\pi_i : \Omega_i \rightarrow \mathbb{R}$  of  $\pi$  as

$$\pi_i(S) := \frac{\pi(S)}{\bar{\pi}(i)},$$

and the two restriction chains  $P_i : \Omega_i \times \Omega_i \rightarrow \mathbb{R}$  of  $P$  as

$$P_i(S, R) := \begin{cases} P(S, R), & \text{if } S \neq R \\ 1 - \sum_{T \in \Omega_i: T \neq S} P(S, T), & \text{otherwise} \end{cases}.$$

Again, it is easy to see that each of the  $P_i$  is also reversible and has stationary distribution  $\pi_i$ .

Coming back to the Gibbs sampler, if we could show that it mixes fast within each of  $\Omega_0$  and  $\Omega_1$ , then we could deduce that the only reason for the slow mixing on  $\Omega$  is the bottleneck between these two sets. Indeed, the following corollary of a theorem by [Ding et al. \(2009\)](#) shows exactly that.

**Corollary 2** (cf. Theorem 2 in ([Ding et al., 2009](#))). *For all  $n \geq 3$ , the restriction chains of the Gibbs sampler  $P_i^G$ ,  $i = 0, 1$ , on ISING have spectral gap  $\gamma_i^G = \Theta\left(\frac{2\ln(n)-1}{n}\right)$ .*

To improve mixing we want to create an  $M^3$  chain that is able to bypass the aforementioned bottleneck. For this purpose, we use a mixture of two log-modular distributions, the first of which puts most of its mass on  $\Omega_0$ , and the second on  $\Omega_1$ . We define the mixture of the form (4) by

$$m_1(S) = \sum_{v \in S} -d_n(n-1) = -d_n(n-1)|S|,$$

$$m_2(S) = \sum_{v \in S} d_n(n-1) = d_n(n-1)|S|.$$

We also use  $w_1 = 1/Z_1$  and  $w_2 = 1/Z_2$ , where  $Z_1$  and  $Z_2$  are the normalizers of  $m_1$  and  $m_2$  respectively. It follows that  $Z_q = 1/2$ , and, furthermore, the mixture  $q$  is symmetric, that is,  $q(S) = q(V \setminus S)$ . Since the proposal  $q$  is symmetric and state independent, we would expect the  $M^3$  chain to jump between  $\Omega_0$  and  $\Omega_1$  without being hindered by the bottleneck described previously. We verify this intuition by proving the following lemma.

**Lemma 1.** *For all  $n \geq 10$ , the projection chain  $\bar{P}^M$  of the  $M^3$  sampler on ISING has spectral gap  $\bar{\gamma}^M = \Omega(1)$ .*

Putting everything together we show the following result about the combined chain  $P^C$ .

**Theorem 2.** *For all  $n \geq 10$ , the combined chain  $P^C$  on ISING has spectral gap*

$$\gamma^C = \Omega\left(\frac{2\ln(n)-1}{2n}\right).$$

The proof consists of two steps. In the first step we make a comparison argument ([Diaconis and Saloff-Coste, 1993](#); [Levin et al., 2008b](#)) to show that the spectral gaps of the projection and restriction chains of the combined sampler are smaller by at most a constant factor in  $\alpha$  compared to those of Gibbs and  $M^3$ . In particular, we use the  $M^3$  bound ([Lemma 1](#)) for the projection chain, and the Gibbs bound ([Theorem 2](#)) for the restriction chains. The second step, then, combines the projection and restriction bounds to establish a bound on the spectral gap of the combined chain. To accomplish this we use a result by [Jerrum et al. \(2004\)](#), which, roughly

---

### Algorithm 1 Iterative semigradient-based mixture construction

---

**Input:** Set function  $F$ , mixture size  $r$

- 1: **for**  $i = 1$  **to**  $r$  **do**
- 2:    $\sigma \leftarrow \text{GREEDY}(F, \{m_1, \dots, m_{i-1}\})$
- 3:    $m_i \leftarrow \text{SEMIGRAIDENT}(F, \sigma)$
- 4: **return**  $\{m_1, \dots, m_r\}$

---

speaking, states that the spectral gap of the whole chain cannot be much smaller than the smallest of the projection and restriction spectral gaps.

Finally, using [Theorem 1](#), and noting that, in this case,  $\pi_{\min} = \mathcal{O}(e^{-n})$  (cf. proof of [Lemma 1](#)), we get a mixing time of  $t_{\text{mix}}(\epsilon) = \mathcal{O}(n^2 \log(1/\epsilon))$  for the combined chain. This shows that the addition of the  $M^3$  sampler results in an exponential improvement in mixing time over the Gibbs sampler by itself.

## 4 CONSTRUCTING THE MIXTURE

Having seen the positive effect of the  $M^3$  sampler, we now turn to the issue of how to choose the proposal  $q$ . While a manual construction like the one we just presented for the Ising model may be feasible in some cases, it is often more practical to have an automated way of obtaining the mixture.

Let us assume, as is usually the case, that we have access to a function oracle for  $F$ , and we want to create a mixture of size  $r$ . Ideally, we would like to construct a proposal  $q$  that is as close to  $\pi$  as possible, that is, minimize an objective such as the following,

$$E_1(q) := \min_q \|\pi - q\|$$

$$= \min_q \left\| \frac{\exp(F(\cdot))}{Z} - \frac{1}{Z_q} \sum_{i=1}^r w_i \exp(m_i(\cdot)) \right\|,$$

where  $\|\cdot\|$  could be, for example, total variation distance or the maximum norm. Unfortunately, this problem is hard: both computing the partition function  $Z$ , and jointly optimizing over all  $w_i, m_i$  are infeasible in practice. To make the problem easier, we could try to get rid of the normalizers and weights  $w_i$ , and iteratively minimize over each  $m_i$  individually:

$$E_2^{(i)}(m_i) := \min_{m_i} \left\| \exp(F(\cdot)) - \sum_{j=1}^{i-1} \exp(m_j(\cdot)) \right\|,$$

for  $i \in \{1, \dots, r\}$ . This problem is still hard, since optimizing  $\|\exp(F(\cdot))\|$  is by itself infeasible in general.

To arrive at a practical algorithm, we approximate the above objective using the two-step procedure described in [Algorithm 1](#). In the first step, we generate a permutation  $\sigma$  of the ground set  $V$  by running

---

**Algorithm 2** Greedy difference maximization

---

**Input:** Set function  $F$ , modular functions  $\{m_1, \dots, m_{i-1}\}$

- 1:  $D_i(S) \leftarrow F(S) - \log \sum_{j=1}^{i-1} \exp(m_j(S))$ , for all  $S \in \Omega$
- 2:  $\sigma \leftarrow (1, \dots, n)$
- 3:  $A \leftarrow \emptyset$
- 4: **for**  $i = 1$  **to**  $n$  **do**
- 5:    $v^* \leftarrow \operatorname{argmax}_{v \in V} (D_i(A \cup \{v\}) - D_i(A))$
- 6:    $\sigma_i \leftarrow v^*$
- 7:    $A \leftarrow A \cup \{v^*\}$
- 8: **return**  $\sigma$

---

the greedy algorithm on function  $D_i(S) := F(S) - \log \sum_{j=1}^{i-1} \exp(m_j(S))$ , as shown in [Algorithm 2](#). Intuitively, the sets that are formed by elements near the beginning of  $\sigma$  are those on which  $F$  and the current mixture disagree by the most. Therefore, in the second step, we would like to add to the mixture a modular function  $m_i$  that is a good approximation for  $F$  on  $\{\sigma_1, \dots, \sigma_k\}$ , for a choice of  $1 \leq k \leq n$ . To accomplish this, we propose using discrete semigradients.

Semigradients are modular functions that provide lower (subgradient) or upper (supergradient) approximations of a set function  $F$  ([Fujishige, 2005](#); [Iyer et al., 2013](#)). More concretely, given a set  $S \in \Omega$ , a modular function  $m$  is a subgradient of  $F$  at  $S$ , if, for all  $R \in \Omega$ ,  $F(R) \geq F(S) + m(R) - m(S)$ . Similarly,  $m$  is a supergradient if the inequality is reversed. Although, in general, a function is not guaranteed to have sub- or supergradients at each  $S \in \Omega$ , it has been shown that this is true when  $F$  is submodular or supermodular ([Fujishige, 2005](#); [Jegelka and Bilmes, 2011](#); [Iyer and Bilmes, 2012](#)).

Submodularity expresses a notion of diminishing returns; that is, adding an element to a larger set provides less benefit than adding that same element to a smaller set. More formally,  $F$  is submodular if, for any  $S \subseteq R \subseteq V$ , and any  $v \in V \setminus R$ , it holds that  $F(R \cup \{v\}) - F(R) \leq F(S \cup \{v\}) - F(S)$ . Supermodularity is defined in a similar way by reversing the sign of this inequality. The resulting models of the form (1) are referred to as log-submodular and log-supermodular respectively. Many commonly used models fall under these categories; Ising and Potts models, including our example in the previous section, are log-supermodular, while determinantal point processes and facility location diversity models are log-submodular.

Coming back to the second step of [Algorithm 1](#), to create a subgradient of  $F$  given permutation  $\sigma$  we just need to define a modular function via marginal gains according to the permutation order ([Iyer et al., 2013](#)), as shown in [Algorithm 3](#). Moreover, this is a subgradient of  $F$  at  $\{\sigma_1, \dots, \sigma_k\}$ , for all  $1 \leq k \leq n$ . On the other hand,

---

**Algorithm 3** Subgradient computation

---

**Input:** Set function  $F$ , permutation  $\sigma$

- 1:  $A \leftarrow \emptyset$
- 2:  $f \leftarrow F(\emptyset)$
- 3: **for**  $v = 1$  **to**  $n$  **do**
- 4:    $m_v \leftarrow F(A \cup \{\sigma_v\}) - F(A)$
- 5:    $A \leftarrow A \cup \sigma_v$
- 6: **return**  $m(S) := \sum_{v \in S} m_v$ , for all  $S \in \Omega$

---

---

**Algorithm 4** Supergradient computation

---

**Input:** Set function  $F$ , permutation  $\sigma$

- 1:  $k \leftarrow \text{DRAWUNIFORM}(1, n)$
- 2: **for**  $v = 1$  **to**  $k$  **do**
- 3:    $m_v \leftarrow F(V) - F(V \setminus \{v\})$
- 4: **for**  $v = k + 1$  **to**  $n$  **do**
- 5:    $m_v \leftarrow F(\{v\})$
- 6: **return**  $m(S) := \sum_{v \in S} m_v$ , for all  $S \in \Omega$

---

[Algorithm 4](#) creates a supergradient of  $F$  at  $\{\sigma_1, \dots, \sigma_k\}$  for a randomly chosen  $k$ . (This type of supergradient is denoted by  $\bar{g}_Y$  by [Iyer et al. \(2013\)](#).) In fact, the modular functions  $m_1, m_2$  that we used in analyzing the Ising model in the previous section were supergradients of  $F$  at sets  $S_1 = \emptyset$ , and  $S_2 = V$  respectively.

In practice, we can use [Algorithm 1](#) regardless of whether  $F$  is sub- or supermodular. We have, however, noticed that subgradients give better results when  $F$  is submodular, and the same goes for supergradients and supermodular functions.

## 5 EXPERIMENTS

We now evaluate the performance of our proposed sampler on the Ising model we analyzed earlier, as well as the following three models learned from real-world data sets.

**WATER.** A (log-submodular) facility location model, which was used in a problem of sensor placement in a water distribution network ([Krause et al., 2008](#)). The function  $F$  is of the form

$$F(S) = \sum_{j=1}^L \max_{i \in S} c_{ij}.$$

We randomly subsample the original facility location matrix  $C = (c_{ij})$ , so that  $n = 50$ , and  $L = 500$ .

**SENSOR.** A (log-submodular) determinantal point process ([Kulesza and Taskar, 2012](#)), which was used in a problem of sensor placement for indoor temperature

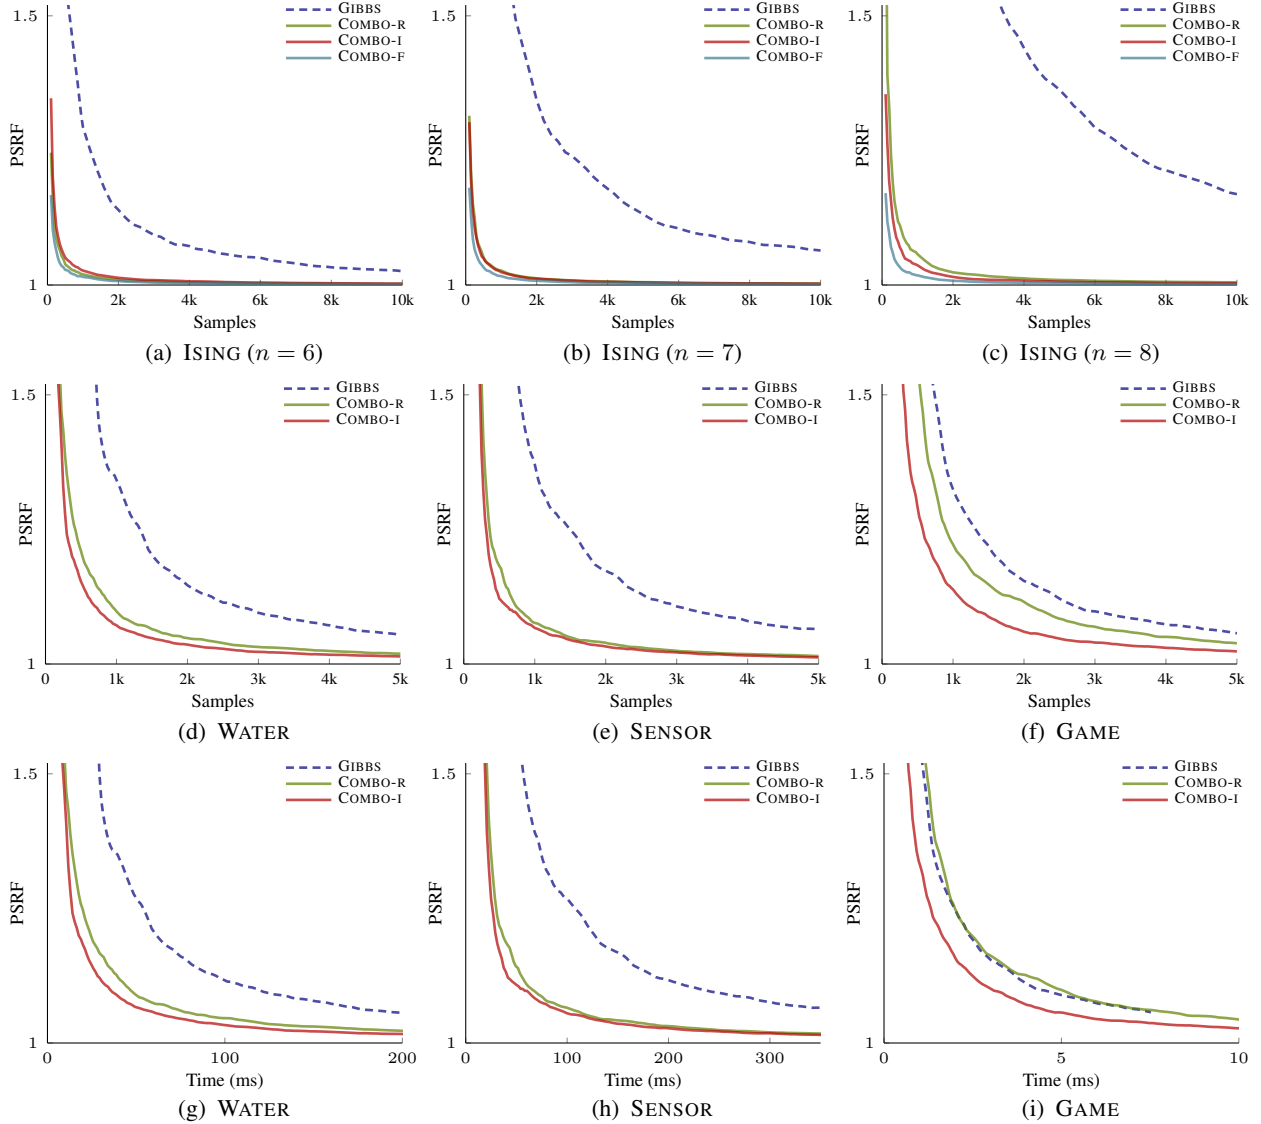

Figure 1: (a)-(c) Ising model results for increasing  $n$ . Note how the Gibbs sampler gets worse significantly faster than the combined ones. (d)-(f) Potential scale reduction factor (PSRF) as a function of sampling iterations. (g)-(i) PSRF as a function of wall-clock time in milliseconds. The combined sampler outperforms Gibbs both in terms of samples required, as well as actual runtime.

monitoring (Guestrin et al., 2005). The function  $F$  is of the form

$$F(S) = \log |K + \sigma^2 I|,$$

where  $K$  is a kernel matrix, and  $\sigma$  is a noise parameter. The size of the ground set is  $n = 46$ .

**GAME.** A (log-submodular) facility location diversity model (Tschitschek et al., 2016), which represents the characters that are chosen by players in the popular online game “Heroes of the Storm”. We learned the model from an online data set of approximately 8,000 teams of

5 characters<sup>2</sup> using noise-contrastive estimation, as described by Tschitschek et al. (2016). The function  $F$  is of the form

$$F(S) = \sum_{v \in S} w_v + \sum_{j=1}^L \max_{i \in S} c_{ij},$$

with  $n = 48$ , and  $L = 10$ . In practice, we would only be interested in sampling sets of fixed size  $\ell = 5$ . The Gibbs sampler can be easily modified to sample under a cardinality constraint by using moves that swap an element in

<sup>2</sup><https://www.hotlogs.com>

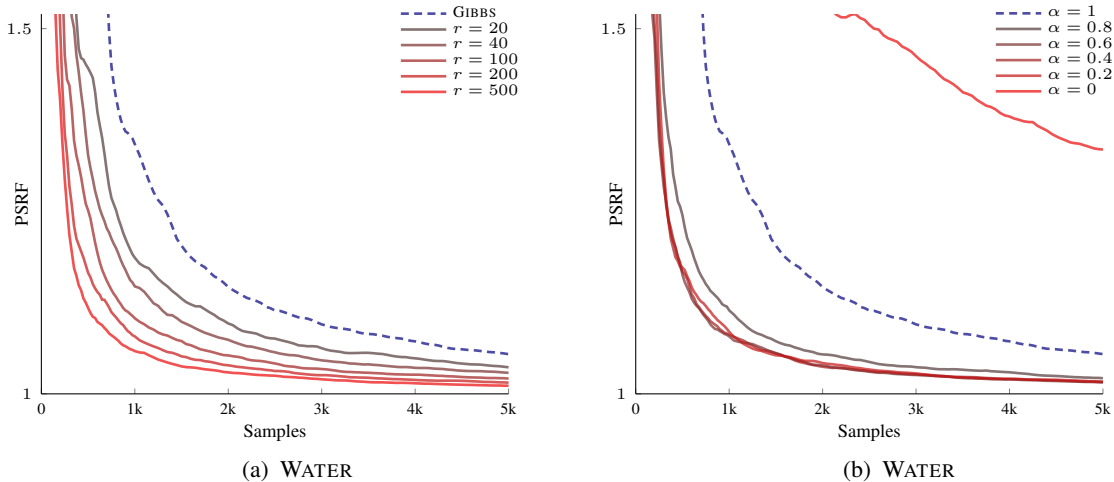

Figure 2: (a) Increasing the number of mixture components improves performance. (b) The combination of Gibbs and  $M^3$  performs better than either of them does individually.

the current set  $X_t$  with an element in  $V \setminus X_t$ . Extending the  $M^3$  chain to sample from cardinality-constrained models is also straightforward. In fact, the only additional ingredient required is a procedure to sample a set of size  $\ell$  from a log-modular distribution, which can be easily done, as before, in  $\mathcal{O}(n)$  time.

In what follows, we compare the performance of the Gibbs sampler (GIBBS) against our proposed combined sampler using a proposal mixture  $q$  constructed by **Algorithm 1** (COMBO-I). We also compare against a variation where we substitute the greedy procedure in **line 2** of **Algorithm 1** with picking a permutation  $\sigma$  of the ground set uniformly at random (COMBO-R).

To assess convergence we use the potential scale reduction factor (PSRF) (Brooks et al., 2011) using 20 parallel chains. We compute the PSRF using single-element marginal probabilities averaged over 50 repetitions of each simulation.

In **Figures 1a–1c** we show the results for the Ising model ( $n = 6, 7, 8$ ) with the additional COMBO-F line denoting the combined sampler with two mixture components described in **Section 3.1**. The other two combined samplers use mixtures of size  $r = 20$ . Note that Gibbs mixes dramatically slower than the combined sampler, even for such small  $n$ .

In **Figures 1d–1f** we show the results on the three log-submodular models described before using mixtures of size  $r = 200$ . It is interesting to see that even random permutations are enough to significantly improve over the performance of Gibbs. Similar observations can be made with respect to computation time, as shown in **Figures 1g–1i**, which measure wall-clock time on the  $x$ -axis.

In **Figure 2a** we show how mixture size affects performance; as expected, adding more components to the mixture results in a proposal that approximates the target distribution better, and, therefore, mixes faster. Finally, in **Figure 2b** we see that both Gibbs ( $\alpha = 1$ ) and  $M^3$  ( $\alpha = 0, r = 200$ ) perform poorly by themselves, but combining them results in much improved performance. This highlights again the complementary nature of the two chains (local vs. global moves) we discussed earlier.

## 6 CONCLUSION

We considered the problem of sampling from general discrete probabilistic models, and presented the  $M^3$  sampler that proposes global moves using a mixture of log-modular distributions. We theoretically analyzed the effect of combining our sampler with the Gibbs sampler on a class of Ising models, and proved an exponential improvement in mixing time. We also demonstrated notable improvements when combining the two samplers on three models of practical interest. We believe that our work represents a step towards moving beyond local samplers, and incorporating ideas from optimization, such as semigradients, into probabilistic inference.

## Abstract

The uncertainty associated with human perception is often reduced by one’s extensive prior experience and knowledge. Current datasets and systems do not emphasize the necessity and benefit of using such knowledge. In this work, we propose the task of solving a genre of image-puzzles (“image riddles”) that require both capabilities involving visual detection (including object, activity recognition) and, knowledge-based or commonsense reasoning. Each puzzle involves a set of images and the question “what word connects these images?”. We compile a dataset of over 3k riddles where each riddle consists of 4 images and a groundtruth answer. The annotations are validated using crowd-sourced evaluation. We also define an automatic evaluation metric to track future progress. Our task bears similarity with the commonly known IQ tasks such as analogy solving, sequence filling that are often used to test intelligence. We develop a Probabilistic Reasoning-based approach that utilizes commonsense knowledge about words and phrases to answer these riddles with a reasonable accuracy. Our approach achieves some promising results for these riddles and provides a strong baseline for future attempts. We make the entire dataset and related materials publicly available to the community ([bit.ly/22f9Ala](http://bit.ly/22f9Ala)).

## 1 INTRODUCTION

Human visual perception is greatly aided by the human’s knowledge and reasoning (with that knowledge) about the domain (what it is looking at) and purpose (what it is looking for and why) (Lake et al., 2016). This knowledge

Figure 1: An Image Riddle Example. Question: “What word connects these images?” .

greatly helps in overcoming the uncertainty often associated with perception. Most work in computer vision do not take into account the vast body of knowledge that humans use in their visual perception. Several researchers<sup>1</sup> have recently pointed out the necessity and the potential benefit of using such knowledge, as well as the lack of it in current systems. This absence is also reflected in the various popular data sets and benchmarks. Our goal in this paper is to present a new task, a corresponding new data set, and our approach to them that highlights the importance of using knowledge and reasoning in visual perception. This necessitates considering issues such as what kind of knowledge is needed, where and how to get them, and what kind of reasoning mechanism to adopt for such knowledge.

The new task we propose in this paper is referred to as Image Riddles which requires deep conceptual understanding of images. In this task a set of images are provided and one needs to find a common concept that is invoked by all the images. Often the common concept is not something that even a human can observe in the first glance; but after some thought about the images, he/she can come up with it. Hence the word “riddle” in the phrase “image riddles”. Figure 1 shows an example

---

<sup>1</sup>Lake et al. (2016) quotes a reviewer: “Human learners - unlike DQN and many other deep Learning systems - approach new problems armed with extensive prior experience.”. The authors also ask “How do we bring to bear rich prior knowledge to learn new tasks and solve new problems?”. In “A Path to AI”, Prof. Yann Lecun recognizes the absence of common-sense to be an obstacle to AI.

of an image riddle. The images individually connect to multiple concepts such as: *outdoors, nature, trees, road, forest, rainfall, waterfall, statue, rope, mosque* etc. On further thought, the common concept that emerges for this example is “fall”. Here, the first image represents the fall season (*concept*). There is a “waterfall” (*region*) in the second image. In the third image, it shows “rain-fall” (*concept*) and the fourth image depicts that a statue is “fall”ing (*action/event*). The word “fall” is invoked by all the images as it shows logical connections to objects, regions, actions or concepts specific to each image. Additionally, the answer also connects the most salient aspects of the images. Other possible answers like “nature” or “outdoors” do not demonstrate such properties. They are too abstract. In essence, answering Image Riddles is a challenging task that not only tests an intelligent agent’s ability to detect visual concepts, but also tests its (ontological) knowledge and its ability to think and reason.

Image Riddles can also be thought of as a visual counterpart to IQ tests such as sequence filling ( $x_1, x_2, x_3, ?$ ) and analogy solving ( $x_1 : y_1 :: x_2 : ?$ )<sup>2</sup>, where one needs to find commonalities between items. It is worth to note that this task is different from traditional Visual Question-Answering (VQA), as in VQA the queries provide some clues regarding what to look for in the image. Most Image Riddles require both superior detection and reasoning capabilities, whereas a large percentage of questions from the VQA dataset tests mainly the system’s detection capabilities. Moreover, answering Image Riddles differs from both VQA and Captioning in that it requires analysis of multiple seemingly different images.

Hence, this task of answering Image Riddles is simple to explain; shares similarities with well-known and pre-defined types of IQ questions and it requires a combination of vision and reasoning capabilities. In this paper, we introduce a novel benchmark for Image Riddles and put forward a promising approach to tackle it. In our approach, we first use the state-of-the-art Image Classification techniques (Sood (2015) and He et al. (2016)) to get the top identified class-labels from each image. Given these detections, we use ontological and commonsense relations of these words to infer a set of most probable concepts. We adopt ConceptNet 5 (Liu and Singh, 2004) as the source of commonsense and background knowledge that encodes the relations between words and short phrases through a structured graph. Note, the possible range of candidates are **the entire vocabulary** of ConceptNet 5 (roughly 0.2 million), which is fundamentally different from supervised end-to-end models. For representation and reasoning with this huge probabilis-

<sup>2</sup>Examples are: word analogy tasks (male : female :: king : ?); numeric sequence filling tasks: (1, 2, 3, 5, ?).

tic knowledge one needs a powerful reasoning engine. Here, we adopt the Probabilistic Soft Logic (PSL) (Kim-mig et al., 2012; Bach et al., 2013) framework. Given the inferred concepts of each image, we adopt a second stage inference to output the final answer.

Our **contributions** are threefold: i) we introduce the 3K Image Riddles Dataset; ii) we present a probabilistic reasoning approach to solve the riddles with reasonable accuracy; iii) our reasoning module inputs detected words (a closed set of class-labels) and *logically* infers all relevant concepts (belonging to a much larger vocabulary), using background knowledge about words.

## 2 RELATED WORK

The problem of Image Riddles has some similarities to the genre of topic modeling (Blei, 2012) and Zero-shot Learning (Larochelle et al., 2008). However, this dataset imposes a few unique challenges: i) the possible set of target labels is the entire natural language vocabulary; ii) each image, when grouped with different sets of images can map to a different label; iii) almost all the target labels in the dataset are unique (3k examples with 3k class-labels). These challenges make it hard to simply adopt topic model-based or Zero-shot learning-based approaches.

Our work is also related to the field of **Visual Question Answering** (VQA). Very recently, researchers spent a significant amount of efforts on both creating datasets and proposing new models (Antol et al., 2015; Malinowski et al., 2015; Gao et al., 2015; Ma et al., 2016) for VQA. Interestingly both (Antol et al., 2015; Goyal et al., 2017) and Gao et al. (2015) adapted MS-COCO (Lin et al., 2014) images and created an open domain dataset with human generated questions and answers. Both Malinowski et al. (2015) and Gao et al. (2015) use recurrent networks to encode the sentence and output the answer.

Even though some questions from Antol et al. (2015) and Gao et al. (2015) are very challenging, and actually require logical reasoning in order to answer correctly, popular approaches still aim to learn the direct signal-to-signal mapping from image and question to its answer, given a large enough annotated data. The necessity of common-sense reasoning is often neglected. Here we introduce the new Image Riddle problem to serve as the testbed for vision and reasoning research.

## 3 KNOWLEDGE AND REASONING MECHANISM

In this Section, we briefly introduce the kind of knowledge that is useful for solving Image Riddles and the

kind of reasoning needed. The primary types of knowledge needed are the distributional and relational similarities between words and concepts. We obtain them from analyzing the ConceptNet knowledge base and using Word2Vec. Both the knowledge sources are considered because ConceptNet embodies commonsense knowledge and Word2vec encodes word-meanings.

**ConceptNet** (Speer and Havasi, 2012), is a multilingual Knowledge Graph, that encodes commonsense knowledge about the world and is built primarily to assist systems that attempts to understand natural language text. The knowledge in ConceptNet is semi-curated. The nodes (called concepts) in the graph are words or short phrases written in natural language. The nodes are connected by edges which are labeled with meaningful relations. For example: (*reptile, IsA, animal*), (*reptile, HasProperty, cold blood*) are some edges. Each edge has an associated confidence score. Compared to other knowledge-bases such as WordNet, YAGO, NELL (Suchanek et al., 2007; Mitchell et al., 2015), ConceptNet has a more extensive coverage of English language words and phrases. These properties make this Knowledge Graph a perfect source for the required probabilistic commonsense knowledge. We use different methods on ConceptNet, elaborated in the next section, to define similarity between different types of words and concepts.

**Word2vec** uses the theory of distributional semantics to capture word meanings and produce word embeddings (vectors). The pre-trained word-embeddings have been successfully used in numerous Natural Language Processing applications and the induced vector-space is known to capture the graded similarities between words with reasonable accuracy (Mikolov et al., 2013). Throughout the paper, for word2vec-based similarities, we use the 3 Million word-vectors trained on Google-News corpus (Mikolov et al., 2013).

The similarity between words  $w_i$  and  $w_j$  with a similarity score  $w_{ij}$  is expressed as propositional formulas of the form:  $w_i \Rightarrow w_j : w_{ij}$ . (The exact formulas, and when they are bidirectional and when they are not are elaborated in the next section.) To reason with such knowledge we explored various reasoning formalisms and found Probabilistic Soft Logic (PSL) (Kimmig et al., 2012; Bach et al., 2013) to be the most suitable, as it can not only handle relational structure, inconsistencies and uncertainty, thus allowing one to express rich probabilistic graphical models (such as Hinge-loss Markov random fields), but it also seems to scale up better than its alternatives such as Markov Logic Networks (Richardson and Domingos, 2006). In this work, we also use different weights for different groundings of the same rule. Even though some work has been done along this line

for MLNs (Mittal et al., 2015), implementing those ideas in MLNs to define weights using word2vec and ConceptNet is not straightforward. Learning grounding-specific weights is also difficult as that will require augmentation of MLN syntax and learning.

### 3.1 PROBABILISTIC SOFT LOGIC (PSL)

Probabilistic soft logic (PSL) differs from most other probabilistic formalisms in that its ground atoms have continuous truth values in the interval  $[0,1]$ , instead of having binary truth values. The syntactic structure of rules and the characterization of the logical operations have been chosen judiciously so that the space of interpretations with nonzero density forms a convex polytope. This makes inference in PSL a convex optimization problem in continuous space, which in turn allows efficient inference. We now give a brief overview of PSL.

A PSL model is defined using a set of weighted if-then rules in first-order logic. Let  $\mathcal{C} = (C_1, \dots, C_m)$  be such a collection where each  $C_j$  is a disjunction of literals, where each literal is a variable  $y_i$  or its negation  $\neg y_i$ , where  $y_i \in \mathbf{y}$ . Let  $I_j^+$  (resp.  $I_j^-$ ) be the set of indices of the variables that are not negated (resp. negated) in  $C_j$ . Each  $C_j$  is:

$$w_j : \bigwedge_{i \in I_j^-} \neg y_i \rightarrow \bigvee_{i \in I_j^+} y_i, \quad (1)$$

or equivalently,  $w_j : \bigvee_{i \in I_j^-} (\neg y_i) \vee \bigvee_{i \in I_j^+} y_i$ . Each rule  $C_j$  is associated with a non-negative weight  $w_j$ . PSL relaxes the boolean truth values of each ground atom  $a$  (constant term or predicate with all variables replaced by constants) to the interval  $[0, 1]$ , denoted as  $I(a)$ . To compute soft truth values, Lukasiewicz’s relaxation (Klir and Yuan, 1995) of conjunctions ( $\wedge$ ), disjunctions ( $\vee$ ) and negations ( $\neg$ ) is used:

$$\begin{aligned} I(l_1 \wedge l_2) &= \max\{0, I(l_1) + I(l_2) - 1\} \\ I(l_1 \vee l_2) &= \min\{1, I(l_1) + I(l_2)\} \\ I(\neg l_1) &= 1 - I(l_1). \end{aligned} \quad (2)$$

In PSL, the ground atoms are considered as random variables and the distribution is modeled using **Hinge-Loss Markov Random Field**, which is defined as follows: Let  $\mathbf{y}$  and  $\mathbf{x}$  be two vectors of  $n$  and  $n'$  random variables respectively, over the domain  $D = [0, 1]^{n+n'}$ . The feasible set  $\tilde{D}$  is a subset of  $D$ , which satisfies a set of inequality constraints over the random variables. A *Hinge-Loss Markov Random Field*  $\mathbb{P}$  is a probability density, defined as: if  $(\mathbf{y}, \mathbf{x}) \notin \tilde{D}$ , then  $\mathbb{P}(\mathbf{y}|\mathbf{x}) = 0$ ; if  $(\mathbf{y}, \mathbf{x}) \in \tilde{D}$ , then:

$$\mathbb{P}(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{w}, \mathbf{x})} \exp(-f_{\mathbf{w}}(\mathbf{y}, \mathbf{x})), \quad (3)$$

where  $Z(\mathbf{w}, \mathbf{x}) = \int_{\mathbf{y} | (\mathbf{y}, \mathbf{x}) \in \tilde{D}} \exp(-f_{\mathbf{w}}(\mathbf{y}, \mathbf{x})) d\mathbf{y}$ .

Here, the hinge-loss energy function  $f_{\mathbf{w}}$  is defined as:  $f_{\mathbf{w}}(\mathbf{y}, \mathbf{x}) = \sum_{j=1}^m w_j (\max\{l_j(\mathbf{y}, \mathbf{x}), 0\})^{p_j}$ , where  $w_j$ ’s

are non-negative free parameters and  $l_j(\mathbf{y}, \mathbf{x})$  are linear constraints over  $\mathbf{y}, \mathbf{x}$  and  $p_j \in \{1, 2\}$ . As we are interested in finding the maximum probable solution given the evidence, the inference objective of HL-MRF becomes:

$$\mathbb{P}(\mathbf{y}|\mathbf{x}) \equiv \arg \min_{\mathbf{y} \in [0,1]^n} \sum_{j=1}^m w_j (\max\{l_j(\mathbf{y}, \mathbf{x}), 0\})^{p_j}. \quad (4)$$

In PSL, each logical rule  $C_j$  in the database  $\mathcal{C}$  is used to define  $l_j(\mathbf{y}, \mathbf{x})$ , i.e. the linear constraints over  $(\mathbf{y}, \mathbf{x})$ . Given a set of weighted logical formulas, PSL builds a graphical model defining a probability distribution over the continuous value space of the random variables in the model.

More precisely,  $l_j(\cdot)$  is defined in terms of “distance to satisfaction”. For each rule  $C_j \in \mathcal{C}$  this “distance to satisfaction” is measured using the term  $w_j \times \max\{1 - \sum_{i \in I_j^+} y_i - \sum_{i \in I_j^-} (1 - y_i), 0\}$ . This encodes the penalty if a rule is not satisfied. Then, the right hand side of the Eq. 4 becomes:

$$\arg \min_{\mathbf{y} \in [0,1]^n} \sum_{C_j \in \mathcal{C}} w_j \max\{1 - \sum_{i \in I_j^+} y_i - \sum_{i \in I_j^-} (1 - y_i), 0\}, \quad (5)$$

which is used to estimate  $\mathbb{P}(\mathbf{y}|\mathbf{x})$  efficiently.

## 4 APPROACH

Given a set of images  $(\{\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3, \mathcal{I}_4\})$ , our objective is to determine a set of ranked words ( $T$ ) based on how well they semantically connect the images. In this work, we present an approach that uses the previously introduced Probabilistic Reasoning framework on top of a probabilistic Knowledge Base (ConceptNet). It also uses additional semantic knowledge from Word2vec. Using these knowledge sources, we predict the answers to the riddles. Although our approach consists of multiple resources and stages, it can be easily modularized, pipelined and reproduced. It is also worth to mention that the PSL engine is a general tool. It could be used for further research along the conjunction of vision, language and reasoning.

### 4.1 OUTLINE OF OUR FRAMEWORK

As outlined in algorithm 1, for each image  $\mathcal{I}_k$  (here,  $k \in \{1, \dots, 4\}$ ), we follow three steps to infer related words and phrases: i) Image Classification: we get top class labels and the confidence from Image Classifier ( $\mathcal{S}_k, \tilde{P}(\mathcal{S}_k|\mathcal{I}_k)$ ), ii) Rank and Retrieve: using these labels and confidence scores, we rank and retrieve top related words ( $T_k$ ) from ConceptNet ( $\mathcal{K}_{cnet}$ ), iii) Probabilistic Reasoning and Inference (Stage I): using the labels ( $\mathcal{S}_k$ ) and the top related words ( $T_k$ ), we design an inference model to logically infer final set of words ( $\hat{T}_k$ )

### Algorithm 1: Solving Image Riddles

```

1: procedure UNRIDDLER( $\mathcal{I} = \{\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3, \mathcal{I}_4\}, \mathcal{K}_{cnet}$ )
2:   for  $\mathcal{I}_k \in \mathcal{I}$  do
3:      $\tilde{P}(\mathcal{S}_k|\mathcal{I}_k) = \text{getClassLabelsNeuralNetwork}(\mathcal{I}_k)$ .
4:     for  $s \in \mathcal{S}_k$  do
5:        $T_s, W_m(s, T_s) = \text{retrieveTargets}(s, \mathcal{K}_{cnet})$ ;
6:        $W_m(s, t_j) = \text{sim}(s, t_j) \forall t_j \in T_s$ .
7:     end for
8:      $T_k = \text{rankTopTargets}(\tilde{P}(\mathcal{S}_k|\mathcal{I}_k), T_{\mathcal{S}_k}, W_m)$ ;
9:      $I(\hat{T}_k) = \text{inferConfidenceStageI}(T_k, \tilde{P}(\mathcal{S}_k|\mathcal{I}_k))$ .
10:    end for
11:     $I(T) = \text{inferConfidenceStageII}([\hat{T}_k]_{k=1}^4, [\tilde{P}(\mathcal{S}_k|\mathcal{I}_k)]_{k=1}^4)$ .
12: end procedure

```

for each image. Lastly, we use another probabilistic reasoning model (Stage II) on the combined set of inferred words (*targets*) from all images in a riddle. This model assigns the final confidence scores on the combined set of targets ( $T$ ). We depict the pipeline with an example in Figure 2.

Figure 2: An overview of the framework followed for each Image; demonstrated using an example image of an *aardvark* (resembles animals such as tapir, ant-eater). As shown, the uncertainty in detecting concepts is reduced after considering additional knowledge. We run a similar pipeline for each image and then infer final results using a final Probabilistic Inference Stage (Stage II).

### 4.2 IMAGE CLASSIFICATION

Neural Networks trained on ample source of images and numerous image classes has been very effective. Studies have found that convolutional neural networks (CNN) can produce near human level image classification accuracy (Krizhevsky et al., 2012), and related work has been used in various visual recognition tasks such as scene labeling (Farabet et al., 2013) and object recognition (Girshick et al., 2014). To exploit these advances, we use the state-of-the-art class detections provided by the Clarifai API (Sood, 2015) and the Deep Residual Network Architecture by (He et al., 2016) (using the trained ResNet-200 model). For each image ( $\mathcal{I}_k$ ) we use top 20 detections ( $\mathcal{S}_k$ ) (*seeds*). Figure 2 provides an example. Each detection is accompanied with the classifier’s confidence score ( $\tilde{P}(\mathcal{S}_k|\mathcal{I}_k)$ ).

### 4.3 RETRIEVE AND RANK RELATED WORDS

Our goal is to logically infer words or phrases that represent (higher or lower-level) concepts that can best explain the co-existence of the detected *seeds* in a scene. For examples, for “hand” and “care”, implied words could be “massage”, “ill”, “ache” etc. For “transportation” and “sit”, implied words/phrases could be “sit in bus” and “sit in plane”. The reader might be inclined to infer other concepts. However, to “infer” is to derive “logical” conclusions. Hence, we prefer the concepts which shares strong explainable connections (i.e. relational similarity) with the *seeds*.

A logical choice would be traversing a knowledge-graph like ConceptNet and find the common reachable nodes from these *seeds*. As this is computationally infeasible, we use the association-space matrix representation of ConceptNet, where the words are represented as vectors. The similarity between two words approximately embodies the strength of the connection over all paths connecting the two words in the graph. We get the top similar words for each *seed*, approximating the reachable nodes.

#### 4.3.1 Retrieve Related Words For a Seed

We observe that, for objects, the ConceptNet-similarity gives a poor result (See Table 1). So, we define a metric called **visual similarity**. Let us call the similar words as *targets*. In this metric, we represent the seed and the target as vectors. To define the dimensions, for each *seed*, we use the relations (HasA, HasProperty, PartOf and MemberOf). We query ConceptNet to get the related words ( $W1, W2, W3, \dots$ ) under such relations for the seed-word and its superclasses. Each of these relation-word pairs (i.e.  $HasA-W1, HasA-W2, PartOf-W3, \dots$ ) becomes a separate dimension. The values for the seed-vector are the weights assigned to the assertions. For each *target*, we query ConceptNet and populate the target-vector using the edge-weights for the dimensions defined by the seed-vector.

To get the top words using visual similarity, we use the cosine similarity of the seed-vector and the target-vector to re-rank the top 10000 retrieved similar target-words. For abstract *seeds*, we do not get any such relations and thus use the ConceptNet similarity directly.

Table 1 shows the top similar words using ConceptNet, word2vec and visual-similarity for the word “men”.

**Formulation:** For each seed ( $s$ ), we get the top words ( $T_s$ ) from ConceptNet using the visual similarity metric and the similarity vector  $W_m(s, T_s)$ . Together for an image, these constitute  $T_{S_k}$  and the matrix  $W_m$ , where

ConceptNet	Visual Similarity	Word2vec
man, merby, misandrous, philandry, male_human, dirty_pig, mantyhose, date_woman, guyliner, manslut	priest, uncle, guy, geezer, bloke, pope, bouncer, ecologist, cupid, fella	women, men, males, mens, boys, man, female, teenagers, girls, ladies

Table 1: Top 10 similar Words for “Men”. The ranked list based on visual-similarity ranks *boy, chap, husband, godfather, male person, male* in the ranks 16 to 22. See appendix for more.

$$W_m(s_i, t_j) = sim_{vis}(s_i, t_j) \forall s_i \in S_k, t_j \in T_{S_k}.$$

A large percentage of the error from Image Classifiers are due to visually similar objects or objects from the same category (Hoiem et al., 2012). In such cases, we use this visual similarity metric to predict the possible visually similar objects and then use an inference model to infer the actual object.

#### 4.3.2 Rank Targets

We use the classifier confidence scores  $\tilde{P}(S_k | I_k)$  as an approximate vector representation for an image, in which the *seeds* are the dimensions. The columns of  $W_m$  provides vector representations for the target words ( $t \in T_{S_k}$ ) in the space. We calculate cosine similarities for each target with such a image-vector and then re-rank the targets. We denote the top  $\theta_{\#t}$  targets as  $T_k$  (see Table. 2).

### 4.4 PROBABILISTIC REASONING AND INFERENCE

#### 4.4.1 PSL Inference Stage I

Given a set of candidate *targets*  $T_k$  and a set of weighted *seeds* ( $S_k, \tilde{P}(S_k | I_k)$ ), we build an inference model to infer a set of most probable *targets* ( $\hat{T}_k$ ). We model the joint distribution using PSL as this formalism adopts Markov Random Field which obeys the properties of Gibbs Distribution. In addition, a PSL model is declared using rules. Given the final answer, the set of satisfied rules show the logical connections between the detected words and the final answer. The PSL model can be best explained as an Undirected Graphical Model involving *seeds* (observed) and *targets* (unobserved). We define the seed-target and target-target potentials using PSL rules. We connect each seed to each target and the potential depends on their similarity and the target’s popularity bias. We connect each target to  $\theta_{t-t}$  (1 or 2) maximally similar targets. The potential depends on their similarity.

**Formulation:** Using PSL, we add two sets of rules: i) to define seed-target potentials, we add rules of the form  $wt_{ij} : s_{ik} \rightarrow t_{jk}$  for each word  $s_{ik} \in S_k$  and target  $t_{jk} \in T_k$ ; ii) to define target-target potentials, for each target  $t_{jk}$ , we take the most similar  $\theta_{t-t}$  targets ( $T_j^{max}$ ).

For each target  $t_{jk}$  and each  $t_{mk} \in T_j^{max}$ , we add two rules  $wt_{jm} : t_{jk} \rightarrow t_{mk}$  and  $wt_{jm} : t_{mk} \rightarrow t_{jk}$ . Next, we describe the choices in detail.

i) From the perspective of optimization, the rule  $wt_{ij} : s_{ik} \rightarrow t_{jk}$  adds the term  $wt_{ij} * \max\{I(s_{ik}) - I(t_{jk}), 0\}$  to the objective. This means that if confidence score of the target  $t_{jk}$  is not greater than  $I(s_{ik})$  (i.e.  $\tilde{P}(\mathbf{S}_k | \mathcal{I}_k)$ ), then the rule is not satisfied and we penalize the model by  $wt_{ij}$  times the difference between the confidence scores. We add the above rule for seeds and targets for which the combined similarity ( $wt_{ij}$ ) exceeds certain threshold  $\theta_{sim,psl1}$ . We encode the commonsense knowledge of words and phrases obtained from different knowledge sources into the weights of these rules  $wt_{ij}$ . It is also important that the inference model is not biased towards more popular targets (i.e. abstract words or words too commonly used/detected in corpus). We compute eigenvector centrality score ( $\mathbb{C}(\cdot)$ ) for each word in the context of ConceptNet. Higher  $\mathbb{C}(\cdot)$  indicates higher connectivity of a word in the graph. This yields a higher similarity score to many words and might give an unfair bias to this *target* in the inference model. Hence, the higher the  $\mathbb{C}(\cdot)$ , the word provides less specific information for an image. Hence, the weight becomes

$$wt_{ij} = \theta_{\alpha_1} * sim_{cn}(s_{ik}, t_{jk}) + \theta_{\alpha_2} * sim_{w2v}(s_{ik}, t_{jk}) + 1/\mathbb{C}(t_{jk}), \quad (6)$$

where  $sim_{cn}(\cdot, \cdot)$  is the normalized ConceptNet-based similarity.  $sim_{w2v}(\cdot, \cdot)$  is the normalized word2vec similarity of two words and  $\mathbb{C}(\cdot)$  is the eigenvector-centrality score of the argument in the ConceptNet matrix.

ii) To model dependencies among the targets, we observe that if two concepts  $t_1$  and  $t_2$  are very similar in meaning, then a system that infer  $t_1$  should infer  $t_2$  too, given the same set of observed words. Therefore, the two rules  $wt_{jm} : t_{jk} \rightarrow t_{mk}$  and  $wt_{jm} : t_{mk} \rightarrow t_{jk}$  are designed to force the confidence values of  $t_{jk}$  and  $t_{mk}$  to be as close to each other as possible.  $wt_{jm}$  is the same as Equation 6 without the penalty for popularity.

Using Equation 5, the PSL inference objective becomes:

$$\begin{aligned} \arg \min_{I(\mathbf{T}_k) \in [0,1]^{|\mathcal{T}_k|}} & \sum_{s_{ik} \in \mathbf{S}_k} \sum_{t_{jk} \in \mathcal{T}_k} wt_{ij} \max\{I(s_{ik}) - I(t_{jk}), 0\} + \\ & \sum_{t_{jk} \in \mathcal{T}_k} \sum_{t_{mk} \in T_j^{max}} wt_{jm} \left\{ \max\{I(t_{mk}) - I(t_{jk}), 0\} + \right. \\ & \left. \max\{I(t_{jk}) - I(t_{mk}), 0\} \right\}. \end{aligned}$$

To let the targets compete against each other, we add one more constraint on the sum of the confidence scores of the targets i.e.  $\sum_{j:t_{jk} \in \mathcal{T}_k} I(t_{jk}) \leq \theta_{sum1}$ . Here  $\theta_{sum1} \in \{1, 2\}$  and  $I(t_{jk}) \in [0, 1]$ . The above optimizer provides us  $\mathbb{P}(\mathbf{T}_k | \mathbf{S}_k)$  and thus the top set of targets  $[\hat{\mathbf{T}}_k]_{k=1}^4$ .

## 4.4.2 PSL Inference Stage II

To learn the most probable common targets jointly, we consider the *targets* and the *seeds* from all images together. Assume that the *seeds* and the *targets* are nodes in a knowledge-graph. Then, the most appropriate target-nodes should observe similar properties as an appropriate answer to the riddle: i) a target-node should be connected to the high-weight seeds in an image i.e. should relate to the important aspects of the image; and ii) a target-node should be connected to seeds from all images.

**Formulation:** Here, we use the rules  $wt_{ij} : s_{ik} \rightarrow t_{jk}$  for each word  $s_{ik} \in \mathbf{S}_k$  and target  $t_{jk} \in \hat{\mathbf{T}}_k$  for all  $k \in \{1, 2, \dots, 4\}$ . To let the set of targets compete against each other, we add the constraint  $\sum_{k=1}^4 \sum_{j:t_{jk} \in \hat{\mathbf{T}}_k} I(t_{jk}) \leq \theta_{s2}$ . Here  $\theta_{s2} = 1$  and  $I(t_{jk}) \in [0, 1]$ . The second inference stage provides us  $\mathbb{P}([\hat{\mathbf{T}}_k]_{k=1}^4 | \mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3, \mathbf{S}_4)$  and thus the top targets that constitutes the final answers. To minimize the penalty for each rule, the optimal solution maximizes the confidence score of  $t_{jk}$ . To minimize the overall penalty, it should maximize the confidence scores of these targets which satisfy most of the rules. As the summation of confidence scores is bounded, only a few top inferred targets should have non-zero confidence.

## 5 EXPERIMENTS AND RESULTS

### 5.1 DATASET VALIDATION AND ANALYSIS

We have collected a set of 3333 riddles from the Internet (puzzle websites). Each riddle has 4 images and a groundtruth answer associated with it. To make it more challenging to computer systems, we include both photographic and non-photographic images in the dataset.

To verify the groundtruth answers, we define the metrics: i) ‘‘correctness’’ - how correct and appropriate the answers are, and ii) ‘‘difficulty’’ - how difficult are the riddles. We conduct an Amazon Mechanical Turk (AMT)-based evaluation for dataset validation. We ask them to rate the correctness from 1-6<sup>3</sup>. The ‘‘difficulty’’ is rated from 1-7<sup>4</sup>. We provide the Turkers with examples to calibrate our evaluation. According to the Turkers, the mean correctness rating is 4.4 (with Standard Deviation

<sup>3</sup>1: Completely gibberish, incorrect, 2: relates to one image, 3 and 4: connects two and three images respectively, 5: connects all 4 images, but could be a better answer, 6: connects all images and an appropriate answer.

<sup>4</sup>These gradings are adopted from VQA AMT instructions (Antol et al., 2015). 1: A toddler can solve it (ages:3-4), 2: A younger child can solve it (ages:5-8), 3: A older child can solve it (ages:9-12), 4: A teenager can solve it (ages:13-17), 5: An adult can solve it (ages:18+), 6: Only a Linguist (one who has above-average knowledge about English words and the language in general) can solve it, 7: No-one can solve it.

1.5). The “difficulty” ratings show the following distribution: toddler (0.27%), younger child (8.96%), older child (30.3%), teenager (36.7%), adult (19%), linguist (3.6%), no-one (0.64%). In short, the average age to answer the riddles is closer to **13-17yrs**. Also, few of these (4.2%) riddles seem to be incredibly hard. Interestingly, the average age perceived reported for the recently proposed VQA dataset (Antol et al., 2015) is **8.92 yrs**. Although, this experiment measures “the turkers’ perception of the required age”, one can conclude with statistical significance that the riddles are comparably harder.

## 5.2 SYSTEMS EVALUATION

The presented approach suggests the following hypotheses that requires empirical tests: I) the proposed approach (and their variants) attain reasonable accuracy in solving the riddles; II) the individual stages of the framework improves the final inference accuracy of the answers. In addition, we also experiment to observe the effect of using commercial classification methods like Clarifai against a published state-of-the-art Image Classification method.

### 5.2.1 Systems

We propose several variations of the proposed approach and compare them with simple vision-only baselines. We introduce an additional Bias-Correction stage after the Image Classification, which aims to re-weight the detected seeds using additional information from other images. The variations then are created to test the effects of varying the Bias-Correction stage and the effects of the individual stages of the framework on the final accuracy (hypothesis II). We also vary the initial Image Classification Methods (Clarifai, Deep Residual Network).

**Bias-Correction:** We experimented with two variations: i) greedy bias-correction and ii) no bias-correction. We follow the intuition that the re-weighting of the seeds of one image can be influenced by the others<sup>5</sup>. To this end, we develop the “GreedyUnRiddler” (**GUR**) approach. In this approach, we consider all of the images together to dictate the new weight of each seed. Take image  $\mathcal{I}_k$  for example. To re-weight seeds in  $\mathcal{S}_k$ , we calculate the weights using the following equation:  $\tilde{W}(s_k) = \frac{\sum_{j \in 1, \dots, 4} \text{sim}_{\cosine}(V_{s_k, j}, V_j)}{4.0}$ .  $V_j$  is vector of the weights assigned  $\tilde{P}(\mathcal{S}_j | \mathcal{I}_j)$  i.e. confidence scores of each seed in the image. Each element of  $V_{s_k, j}[i]$  is the ConceptNet-similarity score between the seed  $s_k$  and  $s_{i, j}$  i.e. the  $i^{th}$  seed of the  $j^{th}$  image. The re-weighted seeds ( $\mathcal{S}_k, \tilde{W}(\mathcal{S}_k)$ ) of an image are then passed through

<sup>5</sup>A person often skims through all the images at one go and will try to come up with the aspects that needs more attention.

the rest of the pipeline to infer the final answers.

In the original pipeline (“UnRiddler”, in short **UR**), we just normalize the weights of the seeds and pass on to the next stage. We experiment with another variation (called BiasedUnRiddler or **BUR**), the results of which are included in appendix, as **GUR** achieves the best results.

**Effect of Stages:** We observe the accuracy after each stage in the pipeline (**VB**: Up to Bias Correction, **RR**: Up to Rank and Retrieve stage, **All**: The entire Pipeline). For **VB**, we use the normalized weighted seeds, get the weighted centroid vector over the word2vec embeddings of the seeds for each image. Then we obtain the mean vector over these centroids. The top similar words from the word2vec vocabulary to this mean vector, constitutes the final answers. For **RR**, we get the mean vector over the top predicted targets for all images. Again, the most similar words from the word2vec vocabulary constitutes the answers.

**Baseline (VQA+VB+UR):** For the sake of completion, we experiment with a pre-trained Visual Question Answering system (from Lu et al. (2016)). For each image, we take top 20 answers for the question “What is the image about”, and, then we follow the above procedure (**VB+UR**) to calculate the mean. We get the closest word using the mean vector, from the Word2vec vocabulary. We observe that, the detected words are primarily top frequent answers and do not contain any specific information. Therefore, subsequent stages hardly improve the results. We provide one detailed example in appendix.

**Baseline (Clarifai+VB+UR and ResNet+VB+UR):** We create a strong baseline by directly going from seeds to target using word2vec-based similarities. We use the class-labels and the confidence scores predicted using the state-of-the-art classifiers. For each image, we calculate the weighted centroid of the word2vec embeddings of these labels and the mean of these centroids for the 4 images. For the automatic evaluation we use top  $K$  (10) similar words and for human evaluation, we use the most similar word to this vector, from the word2vec vocabulary. The Baseline performances are listed in Table 3.

**Human Baseline:** In an independent AMT study, we ask the turkers to answer each riddle without any hint towards the answer. We ask them to input maximum 5 words (comma-separated) that can connect all four of the images. In cases, where the riddles are difficult we instruct them to find words that connect at least three images. These answers constitute our human baseline.

### 5.2.2 Experiment I: Automatic Evaluation

We evaluate the performance of the proposed approach on the Image Riddles dataset using both automatic and

Amazon Mechanical Turker (AMT)-based evaluations. An answer to a riddle may have several semantically similar answers. Hence, as evaluation metrics, we use both word2vec and WordNet-based similarity measures. For each riddle, we calculate the maximum similarity between the groundtruth with the top 10 detections, and report the average of such maximum similarities in percentage form:  $S = \frac{1}{n} \sum_{i=1}^n \max_{1 \leq l \leq 10} sim(GT_i, T_l)$ . To calculate phrase similarities, i) we use `n_similarity` method of the `gensim.models.word2vec` package; or, ii) average of WordNet-based word pair similarities that is calculated as a product of `length` (of the shortest path between sysnsets of the words), and `depth` (the depth of the subsumer in the hierarchical semantic net) (Li et al., 2006)<sup>6</sup>.

Number of Targets: $\theta_{\#t}$ (2500), ConceptNet-similarity Weight: $\theta_{\alpha_1}$ (1), word2vec-similarity weight: $\theta_{\alpha_2}$ (4), Number of maximum similar Targets: $\theta_{t-l}$ (1) Seed-target similarity Threshold: $\theta_{sim\_psl1}$ (0.8), Sum of confidence scores in Stage I: $\theta_{sum1}$ (2)

Table 3: Accuracy (in percentage) on the Image Riddle Dataset. Pipeline variants (VB, RR and All) are combined with Bias-Correction stage variants (GUR, UR). We show both word2vec and WordNet-based (WN) accuracies. (\*- Best, † - Baselines).

To select the parameters in the parameter vector  $\theta$ , We employed a random search on the parameter-space over first 500 riddles over 500 combinations. The final set of parameters used and their values are tabulated in Table 2.

The accuracies after different stages of the pipeline (VB, RR and All) combined with variations of the initial Bias-Correction stage (GUR and UR), are listed in Table 3<sup>7</sup>. We provide our experimental results on this 3333 riddles

<sup>6</sup>The groundtruth is a single word. Code: [bit.ly/2gqmnwEe](http://bit.ly/2gqmnwEe).

<sup>7</sup>For ablation study on varying top  $K$ , check appendix.

and 2833 riddles (barring 500 riddles as validation set for the parameter search).

### 5.2.3 Experiment II: Human Evaluation

We conduct an AMT-based comparative evaluation of the results of the proposed approach (GUR+All using Clarifai) and two vision-only baselines. We define two metrics: i) “correctness” and ii) “intelligence”. Turkers are presented with the instructions: *We have three separate robots that attempted to answer this riddle. You have to rate the answer based on the correctness and the degree of intelligence (explainability)*. The correctness is defined as before. In addition, turkers are asked to rate intelligence in a scale of 1-4<sup>8</sup>. Figure 3 plots the percentage of total riddles per each value of correctness and intelligence. In these histograms plots, we expect an increase in the rightmost buckets for the more “correct” and “intelligent” systems.

Figure 3: AMT Results of The Clarifai+GUR+All (our), Clarifai+UR+VB (baseline 1) and ResNet+UR+VB (baseline 2) approaches. Correctness Means are:  $2.6 \pm 1.4$ ,  $2.4 \pm 1.45$ ,  $2.3 \pm 1.4$ . For Intelligence:  $2.2 \pm 0.87$ ,  $2 \pm 0.87$ ,  $1.8 \pm 0.8$

### 5.2.4 Analysis

Experiment I shows that the GUR variant (Clarifai+GUR+All in Table 3) achieves the best results in terms of word2vec-based accuracy. The WordNet-based metric gives clear evidence of improvement by the stages of our pipeline (a sharp 14% increase over Clarifai and 6% increase over ResNet baselines). Improvement from the final reasoning stage is also evident from the result. The increase in accuracy after reasoning shows how knowledge helped in decreasing overall uncertainty in perception. Similar trend is reflected in the AMT-based evaluations (Figure 3).

<sup>8</sup>{1: Not, 2: Moderately, 3: Normal, 4: Very} intelligent

Figure 4: Positive and Negative (in red) results of the “GUR” approach (**Clarifai+GUR+All**) on some of the riddles. The groundtruth labels, closest label among top 10 from GUR and the Clarifai+VB+UR baseline are provided for all images. For more results, check Appendix.

Our system has increased the percentage of puzzles for the rightmost bins i.e. produces more “correct” and “intelligent” answers for more number of puzzles. The word2vec-based accuracy puts the performance of ResNet baseline close to that of the GUR variant. However, as evident from the WordNet-based metric and the AMT evaluation of the correctness (Figure 3), the GUR variant clearly predicts more meaningful answers than the ResNet baseline. Experiment II also includes what the turkers think about the intelligence of the systems that tried to solve the puzzles. This also puts the GUR variant at the top. The above two experiments empirically show that our approach achieves a reasonable accuracy in solving the riddles (Hypothesis I). In table 3, we observe how the accuracy varies after each stage of the pipeline (hypothesis II). The table shows a jump in the (WN) accuracy after the RR stage, which leads us to believe the primary improvement of our approach is attributed to the Probabilistic Reasoning model. We also provide our detailed results for the “GUR” approach using a few riddles in Figure 4.

**Difficulty of Riddles:** From our AMT study (**Human** baseline), we observe that the riddles are quite difficult for (untrained) human mechanical turkers. There are around 500 riddles which were labeled as “blank”, another 500 riddles were labeled as “not found”. Lastly, 457 riddles (391 with wordnet similarity higher than 0.9 and 66 higher than 0.8) were predicted perfectly, which leads us to believe that these easy riddles mostly show visual similarities (object-level) whereas others mostly

show conceptual similarity.

**Running Time:** Our implementation of PSL solves each riddle in nearly 20s in an Intel core i7 2.0 GHz processor, with 4 parallel threads. Solving each riddle boils down to solving 5 optimization problems (1 for each image and 1 joint). This eventually means our engine takes nearly 4 sec. to solve an inference problem with approximately  $20 \times 2500$  i.e. 50k rules.

**Reason to use a Probabilistic Logic:** We stated our reasons for choosing PSL over other available Probabilistic Logics. However, the simplicity of the used rules can leave the reader wondering about the reason for choosing a complex probabilistic logic in the first place. Each riddle requires an answer which is “logically” connected to each image. To show such logical connection, we need ontological knowledge graphs such as ConceptNet which shows connections between the answer and words detected from the images. To integrate ConceptNet’s knowledge seamlessly into the reasoning mechanism, we use a probabilistic logic such as PSL.

## 6 CONCLUSION

In this work, we presented a Probabilistic Reasoning based approach that uses background knowledge to solve a new class of image puzzles, called “Image Riddles”. We have collected over 3k such riddles. Crowd-sourced evaluation of the dataset demonstrates the validity of the annotations and the nature of the difficulty of the riddles. We empirically show that our approach improves on vision-only baselines and provides a stronger baseline for future attempts. The task of “Image Riddles” is equivalent to conventional IQ test questions such as analogy solving, sequence filling; which are often used to test human intelligence. This task of “Image Riddles” is also in line with the current trend of VQA datasets which require visual recognition and reasoning capabilities. However, it focuses more on the combination of both vision and reasoning capabilities. In addition to the task, the proposed approach introduces a novel inference model to infer related words (from a large vocabulary) given class labels (from a smaller set), using semantic knowledge of words. This method is general in terms of its applications. Systems such as (Wu et al., 2016), which use a collection of high-level concepts to boost VQA performance; can benefit from this approach.

## Abstract

We formalize the notion of nesting probabilistic programming queries and investigate the resulting statistical implications. We demonstrate that while query nesting allows the definition of models which could not otherwise be expressed, such as those involving agents reasoning about other agents, existing systems take approaches which lead to inconsistent estimates. We show how to correct this by delineating possible ways one might want to nest queries and asserting the respective conditions required for convergence. We further introduce a new *on-line* nested Monte Carlo estimator that makes it substantially easier to ensure these conditions are met, thereby providing a simple framework for designing statistically correct inference engines. We prove the correctness of this online estimator and show that, when using the recommended setup, its asymptotic variance is always better than that of the equivalent fixed estimator, while its bias is always within a factor of two.

## 1 INTRODUCTION

Probabilistic programming systems (PPSs) allow probabilistic models to be represented in the form of a generative model and statements for conditioning on data (Goodman et al., 2008; Gordon et al., 2014). Informally, one can think of the generative model as the definition of a prior, the conditioning statements as the definition of a likelihood, and the output of the program as samples from a posterior distribution. Their core philosophy is to decouple model specification and inference, the former corresponding to the user-specified program code and the latter to an inference engine capable of operating on arbitrary programs. Removing the need for users to write inference algorithms significantly reduces the burden of developing new models and makes effective statistical methods accessible to non-experts.

Some, so-called universal, systems (Goodman et al., 2008; Goodman and Stuhlmüller, 2014; Mansinghka et al., 2014; Wood et al., 2014) further allow the definition of models that would be hard, or even impossible, to convey using conventional frameworks such as graphical models. One enticing manner they do this is by allowing arbitrary nesting of models, known in the probabilistic programming literature as queries (Goodman et al., 2008), such that it is easy to define and run problems that fall outside the standard inference framework (Goodman et al., 2008; Mantadelis and Janssens, 2011; Stuhlmüller and Goodman, 2014; Le et al., 2016). This allows the definition of models that could not be encoded without nesting, such as experimental design problems (Ouyang et al., 2016) and various models for theory-of-mind (Stuhlmüller and Goodman, 2014). In particular, models that involve agents reasoning about other agents require, in general, some form of nesting. For example, one might use such nesting to model a poker player reasoning about another player as shown in Section 3.1. As machine learning increasingly starts to try and tackle problem domains that require interaction with humans or other external systems, such as the need for self-driving cars to account for the behavior of pedestrians, we believe that such nested problems are likely to become increasingly common and that PPSs will form a powerful tool for encoding them.

However, previous work has, in general, implicitly, and incorrectly, assumed that the convergence results from standard inference schemes carry over directly to the nested setting. In truth, inference for nested queries falls outside the scope of conventional proofs and so additional work is required to prove the consistency of PPS inference engines for nested queries. Such problems constitute special cases of *nested estimation*. In particular, the use of Monte Carlo (MC) methods by most PPSs mean they form particular instances of *nested Monte Carlo* (NMC) estimation (Hong and Juneja, 2009). Recent work (Rainforth et al., 2016a, 2018; Fort et al., 2017) has demonstrated that NMC is consistent for a general class of models, but

also that it entails a convergence rate in the total computational cost which decreases exponentially with the depth of the nesting. Furthermore, additional assumptions are required to achieve this convergence, most noticeably that, except in a few special cases, one needs to drive not only the total number of samples used to infinity, but also the number of samples used at each layer of the estimator, a requirement generally flaunted by existing PPSs.

The aim of this work is to formalize the notion of query nesting and use these recent NMC results to investigate the statistical correctness of the resulting procedures carried out by PPS inference engines. To do this, we postulate that there are three distinct ways one might nest one query within another: sampling from the conditional distribution of another query (which we refer to as *nested inference*), factoring the trace probability of one query with the partition function estimate of another (which we refer to as *nested conditioning*), and using expectation estimates calculated using one query as *first class variables* in another. We use the aforementioned NMC results to assess the relative correctness of each of these categories of nesting. In the interest of exposition, we will mostly focus on the PPS *Anglican* (Tolpin et al., 2016; Wood et al., 2014) (and also occasionally Church (Goodman et al., 2008)) as a basis for our discussion, but note that our results apply more generally. For example, our nested inference case covers the problem of sampling from cut distributions in OpenBugs (Plummer, 2015).

We find that nested inference is statistically challenging and incorrectly handled by existing systems, while nested conditioning is statistically straightforward and done correctly. Using estimates as variables turns out to be exactly equivalent to generic NMC estimation and must thus be dealt with on a case-by-case basis. Consequently, we will focus more on nested inference than the other cases.

To assist in the development of consistent approaches, we further introduce a new *online* NMC (ONMC) scheme that obviates the need to revisit previous samples when refining estimates, thereby simplifying the process of writing consistent online nested estimation schemes, as required by most PPSs. We show that ONMC’s convergence rate only varies by a small constant factor relative to conventional NMC: given some weak assumptions and the use of recommended parameter settings, its asymptotic variance is always better than the equivalent NMC estimator with matched total sample budget, while its asymptotic bias is always within a factor of two.

## 2 BACKGROUND

### 2.1 NESTED MONTE CARLO

We start by providing a brief introduction to NMC, using similar notation to that of Rainforth et al. (2018). Conventional MC estimation approximates an intractable

expectation  $\gamma_0$  of a function  $\lambda$  using

$$\gamma_0 = \mathbb{E} \left[ \lambda(y^{(0)}) \right] \approx I_0 = \frac{1}{N_0} \sum_{n=1}^{N_0} \lambda(y_n^{(0)}) \quad (1)$$

where  $y_n^{(0)} \stackrel{i.i.d.}{\sim} p(y^{(0)})$ , resulting in a mean squared error (MSE) that decreases at a rate  $O(1/N_0)$ . For nested estimation problems,  $\lambda(y^{(0)})$  is itself intractable, corresponding to a nonlinear mapping of a (nested) estimation. Thus in the single nesting case,  $\lambda(y^{(0)}) = f_0(y^{(0)}, \mathbb{E}[f_1(y^{(0)}, y^{(1)})|y^{(0)}])$  giving

$$\begin{aligned} \gamma_0 &= \mathbb{E} \left[ f_0 \left( y^{(0)}, \mathbb{E} \left[ f_1 \left( y^{(0)}, y^{(1)} \right) \middle| y^{(0)} \right] \right) \right] \\ &\approx I_0 = \frac{1}{N_0} \sum_{n=1}^{N_0} f_0 \left( y_n^{(0)}, \frac{1}{N_1} \sum_{m=1}^{N_1} f_1 \left( y_n^{(0)}, y_{n,m}^{(1)} \right) \right) \end{aligned}$$

where each  $y_{n,m}^{(1)} \sim p(y^{(1)}|y_n^{(0)})$  is drawn independently and  $I_0$  is now a NMC estimate using  $T = N_0 N_1$  samples.

More generally, one may have multiple layers of nesting. To notate this, we first presume some fixed integral depth  $D \geq 0$  (with  $D = 0$  corresponding to conventional estimation), and real-valued functions  $f_0, \dots, f_D$ . We then recursively define

$$\begin{aligned} \gamma_D \left( y^{(0:D-1)} \right) &= \mathbb{E} \left[ f_D \left( y^{(0:D)} \right) \middle| y^{(0:D-1)} \right], \quad \text{and} \\ \gamma_k \left( y^{(0:k-1)} \right) &= \mathbb{E} \left[ f_k \left( y^{(0:k)}, \gamma_{k+1} \left( y^{(0:k)} \right) \right) \middle| y^{(0:k-1)} \right] \end{aligned}$$

for  $0 \leq k < D$ . Our goal is to estimate  $\gamma_0 = \mathbb{E}[f_0(y^{(0)}, \gamma_1(y^{(0)}))]$ , for which the NMC estimate is  $I_0$  defined recursively using

$$\begin{aligned} I_D \left( y^{(0:D-1)} \right) &= \frac{1}{N_D} \sum_{n_D=1}^{N_D} f_D \left( y^{(0:D-1)}, y_{n_D}^{(D)} \right) \quad \text{and} \\ I_k \left( y^{(0:k-1)} \right) &= \frac{1}{N_k} \sum_{n_k=1}^{N_k} f_k \left( y^{(0:k-1)}, y_{n_k}^{(k)}, I_{k+1} \left( y^{(0:k-1)}, y_{n_k}^{(k)} \right) \right) \end{aligned} \quad (2)$$

for  $0 \leq k < D$ , where each  $y_{n_k}^{(k)} \sim p(y^{(k)}|y^{(0:k-1)})$  is drawn independently. Note that there are multiple values of  $y^{(k)}$  for each associated  $y^{(0:k-1)}$  and that  $I_k(y^{(0:k-1)})$  is still a random variable given  $y^{(0:k-1)}$ .

As shown by (Rainforth et al., 2018, Theorem 3), if each  $f_k$  is continuously differentiable and

$$\begin{aligned} \varsigma_k^2 &= \mathbb{E} \left[ \left( f_k \left( y^{(0:k)}, \gamma_{k+1} \left( y^{(0:k)} \right) \right) - \gamma_k \left( y^{(0:k-1)} \right) \right)^2 \right] \\ &< \infty \quad \forall k \in 0, \dots, D, \end{aligned}$$

then the MSE converges at rate

$$\begin{aligned} \mathbb{E} \left[ (I_0 - \gamma_0)^2 \right] &\leq \frac{\varsigma_0^2}{N_0} + \\ &\left( \frac{C_0 \varsigma_1^2}{2N_1} + \sum_{k=0}^{D-2} \left( \prod_{d=0}^k K_d \right) \frac{C_{k+1} \varsigma_{k+2}^2}{2N_{k+2}} \right)^2 + O(\epsilon) \end{aligned} \quad (3)$$

where  $K_k$  and  $C_k$  are respectively bounds on the magni-

tude of the first and second derivatives of  $f_k$ , and  $O(\epsilon)$  represents asymptotically dominated terms – a convention we will use throughout. Note that the dominant terms in the bound correspond respectively to the variance and the bias squared. Theorem 2 of Rainforth et al. (2018) further shows that the continuously differentiable assumption must hold almost surely, rather than absolutely, for convergence more generally, such that functions with measure-zero discontinuities still converge in general.

We see from (3) that if any of the  $N_k$  remain fixed, there is a minimum error that can be achieved: convergence requires each  $N_k \rightarrow \infty$ . As we will later show, many of the shortfalls in dealing with nested queries by existing PPSs revolve around implicitly fixing  $N_k \forall k \geq 1$ .

For a given total sample budget  $T = N_0 N_1 \dots N_D$ , the bound is tightest when  $\sqrt{N_0} \propto N_1 \propto \dots \propto N_D$  giving a convergence rate of  $O(1/T^{\frac{2}{D+2}})$ . The intuition behind this potentially surprising optimum setting is that the variance is mostly dictated by  $N_0$  and bias by the other  $N_k$ . We see that the convergence rate diminishes exponentially with  $D$ . However, this optimal setting of the  $N_k$  still gives a substantially faster rate than the  $O(1/T^{\frac{1}{D+1}})$  from naively setting  $N_0 \propto N_1 \propto \dots \propto N_D$ .

## 2.2 THE ANGLICAN PPS

Anglican is a universal probabilistic programming language integrated into *Clojure* (Hickey, 2008), a dialect of Lisp. There are two important ideas to understand for reading Clojure: almost everything is a function and parentheses cause evaluation. For example,  $a + b$  is coded as `(+ a b)` where `+` is a function taking two arguments and the parentheses cause the function to evaluate.

Anglican inherits most of the syntax of Clojure, but extends it with the key special forms `sample` and `observe` (Wood et al., 2014; Tolpin et al., 2015, 2016), between which the distribution of the query is defined. Informally, `sample` specifies terms in the prior and `observe` terms in the likelihood. More precisely, `sample` is used to make random draws from a provided distribution and `observe` is used to apply conditioning, factoring the probability density of a program trace by a provided density evaluated at an “observed” point.

The syntax of `sample` is to take a *distribution object* as its only input and return a sample. `observe` instead takes a distribution object and an observation and returns `nil`, while changing the program trace probability in Anglican’s back-end. Anglican provides a number of *elementary random procedures*, i.e. distribution object constructors for common sampling distributions, but also allows users to define their own distribution object constructors using the `defdist` macro. Distribution objects are generated by calling a class constructor with the required parameters, e.g. `(normal 0 1)`.

Anglican queries are written using the macro `defquery`. This allows users to define a model using a mixture of `sample` and `observe` statements and deterministic code, and bind that model to a variable. As a simple example,

```
(defquery my-query [data]
  (let [μ (sample (normal 0 1))
        σ (sample (gamma 2 2))
        lik (normal μ σ)]
    (map (fn [obs] (observe lik obs)) data)
        [μ σ]))
```

corresponds to a model where we are trying to infer the mean and standard deviation of a Gaussian given some data. The syntax of `defquery` is `(defquery name [args] body)` such that we are binding the query to `my-query` here. The query starts by sampling  $\mu \sim \mathcal{N}(0, 1)$  and  $\sigma \sim \Gamma(2, 2)$ , before constructing a distribution object `lik` to use for the observations. It then maps over each datapoint and observes it under the distribution `lik`. After the observations are made,  $\mu$  and  $\sigma$  are returned from the variable-binding `let` block and then by proxy the query itself. Denoting the data as  $y_{1:S}$  this particular query defines the joint distribution

$$p(\mu, \sigma, y_{1:S}) = \mathcal{N}(\mu; 0, 1) \Gamma(\sigma; 2, 2) \prod_{s=1}^S \mathcal{N}(y_s; \mu, \sigma).$$

Inference on a query is performed using the macro `doquery`, which produces a lazy infinite sequence of approximate samples from the conditional distribution and, for appropriate inference algorithms, an estimate of the partition function. Its calling syntax is `(doquery inf-alg model inputs & options)`.

Key to our purposes is Anglican’s ability to *nest* queries within one another. In particular, the special form `conditional` takes a query and returns a distribution object constructor, the outputs of which ostensibly corresponds to the conditional distribution defined by the query, with the inputs to the query becoming its parameters. However, as we will show in the next section, the true behavior of `conditional` deviates from this, thereby leading to inconsistent nested inference schemes.

## 3 NESTED INFERENCE

One of the clearest ways one might want to nest queries is by sampling from the conditional distribution of one query inside another. A number of examples of this are provided for Church in (Stuhlmüller and Goodman, 2014).<sup>1</sup> Such *nested inference* problems fall under a more general framework of inference for so-called doubly (or multiply) intractable distributions (Murray et al., 2006). The key feature of these problems is that they include terms with unknown, *parameter dependent*, normalization constants. For nested probabilistic programming queries, this manifests through *conditional normalization*.

<sup>1</sup>Though their nesting happens within the conditioning predicate, Church’s semantics means they constitute nested inference.

Consider the following unnested model using the Anglican function declaration `defm`

```
(defm inner [y D]
  (let [z (sample (gamma y 1))]
    (observe (normal y z) D)
    z))

(defquery outer [D]
  (let [y (sample (beta 2 3))
        z (inner y D)]
    (* y z)))
```

Here `inner` is simply an Anglican function: it takes in inputs `y` and `D`, effects the trace probability through its `observe` statement, and returns the random variable `z` as output. The unnormalized distribution for this model is thus straightforwardly given by

$$\begin{aligned}\pi_u(y, z, D) &= p(y)p(z|y)p(D|y, z) \\ &= \text{BETA}(y; 2, 3) \Gamma(z; y, 1) \mathcal{N}(D; y, z^2),\end{aligned}$$

for which we can use conventional inference schemes.

We can convert this model to a nested inference problem by using `defquery` and `conditional` as follows

```
(defquery inner [y D]
  (let [z (sample (gamma y 1))]
    (observe (normal y z) D)
    z))

(defquery outer [D]
  (let [y (sample (beta 2 3))
        dist (conditional inner)
        z (sample (dist y D))]
    (* y z)))
```

This is now a nested query: a separate inference procedure is invoked for each call of `(sample (dist y D))`, returning an approximate sample from the conditional distribution defined by `inner` when input with the current values of `y` and `D`. Mathematically, `conditional` applies a conditional normalization. Specifically, the component of  $\pi_u$  from the previous example corresponding to `inner` was  $p(z|y)p(D|y, z)$  and `conditional` locally normalizes this to the probability distribution  $p(z|D, y)$ . The distribution now defined by `outer` is thus given by

$$\begin{aligned}\pi_n(y, z, D) &= p(y)p(z|y, D) = \frac{p(y)p(z|y)p(D|y, z)}{\int p(z|y)p(D|y, z)dz} \\ &= p(y) \frac{p(z|y)p(D|y, z)}{p(D|y)} \neq \pi_u(z, y, D).\end{aligned}$$

Critically, the partial normalization constant  $p(D|y)$  depends on `y` and so the conditional distribution is doubly intractable: we cannot evaluate  $\pi_n(y, z, D)$  exactly.

Another way of looking at this is that wrapping `inner` in `conditional` has “protected” `y` from the conditioning in `inner` (noting  $\pi_u(y, z, D) \propto p(y|D)p(z|y, D)$ ), such that its `observe` statement only affects the probability of `z` given `y` and not the marginal probability of `y`. This is why, when there is only a single layer of nesting, nested inference is equivalent to the notion of sampling from “cut

distributions” (Plummer, 2015), whereby the sampling of certain subsets of the variables in a model are made with factors of the overall likelihood omitted.

It is important to note that if we had observed the *output* of the inner query, rather than sampling from it, this would still constitute a nested inference problem. The key to the nesting is the conditional normalization applied by `conditional`, not the exact usage of the generated distribution object `dist`. However, as discussed in Appendix B, actually observing a nested query requires numerous additional computational issues to be overcome, which are beyond the scope of this paper. We thus focus on the nested sampling scenario.

### 3.1 MOTIVATING EXAMPLE

Before jumping into a full formalization of nested inference, we first consider the motivating example of modeling a poker player who reasons about another player. Here each player has access to information the other does not, namely the cards in their hand, and they must perform their own inference to deal with the resulting uncertainty.

Imagine that the first player is deciding whether or not to bet. She could naïvely just make this decision based on the strength of her hand, but more advanced play requires her to reason about actions the other player might take given her own action, e.g. by considering whether a bluff is likely to be successful. She can carry out such reasoning by constructing a model for the other player to try and predict their action given her action and their hand. Again this nested model could just simply be based on a naïve simulation, but we can refine it by adding another layer of meta-reasoning: the other player will themselves try to infer the first player’s hand to inform their own decision.

These layers of meta-reasoning create a nesting: for the first player to choose an action, they must run multiple simulations for what the other player will do given that action and their hand, each of which requires inference to be carried out. Here adding more levels of meta-reasoning can produce smarter models, but also requires additional layers of nesting. We expand on this example to give a concrete nested inference problem in Appendix E.

### 3.2 FORMALIZATION

To formalize the nested inference problem more generally, let `y` and `x` denote all the random variables of an outer query that are respectively passed or not to the inner query. Further, let `z` denote all random variables generated in the inner query – for simplicity, we will assume, without loss of generality, that these are all returned to the outer query, but that some may not be used. The unnormalized density for the outer query can now be written in the form

$$\pi_o(x, y, z) = \psi(x, y, z)p_i(z|y) \quad (4)$$

where  $p_i(z|y)$  is the normalized density of the outputs of the inner query and  $\psi(x, y, z)$  encapsulates all other terms influencing the trace probability of the outer query. Now the inner query defines an unnormalized density  $\pi_i(y, z)$  that can be evaluated pointwise and we have

$$p_i(z|y) = \frac{\pi_i(y, z)}{\int \pi_i(y, z') dz'} \quad \text{giving} \quad (5)$$

$$p_o(x, y, z) \propto \pi_o(x, y, z) = \frac{\psi(x, y, z)\pi_i(y, z)}{\int \pi_i(y, z') dz'} \quad (6)$$

where  $p_o(x, y, z)$  is our target distribution, for which we can directly evaluate the numerator, but the denominator is intractable and must be evaluated separately for each possible value of  $y$ . Our previous example is achieved by fixing  $\psi(x, y, z) = p(y)$  and  $\pi_i(y, z) = p(z|y)p(D|y, z)$ . We can further straightforwardly extend to the multiple layers of nesting setting by recursively defining  $\pi_i(y, z)$  in the same way as  $\pi_o(x, y, z)$ .

### 3.3 RELATIONSHIP TO NESTED ESTIMATION

To relate the nested inference problem back to the nested estimation formulation from Section 2.1, we consider using a proposal  $q(x, y, z) = q(x, y)q(z|y)$  to calculate the expectation of some arbitrary function  $g(x, y, z)$  under  $p_o(x, y, z)$  as per self-normalized importance sampling

$$\begin{aligned} \mathbb{E}_{p_o(x, y, z)} [g(x, y, z)] &= \frac{\mathbb{E}_{q(x, y, z)} \left[ \frac{g(x, y, z)\pi_o(x, y, z)}{q(x, y, z)} \right]}{\mathbb{E}_{q(x, y, z)} \left[ \frac{\pi_o(x, y, z)}{q(x, y, z)} \right]} \\ &= \frac{\mathbb{E}_{q(x, y, z)} \left[ \frac{g(x, y, z)\psi(x, y, z)\pi_i(y, z)}{q(x, y, z)\mathbb{E}_{z' \sim q(z|y)} [\pi_i(y, z')/q(z'|y)]} \right]}{\mathbb{E}_{q(x, y, z)} \left[ \frac{\psi(x, y, z)\pi_i(y, z)}{q(x, y, z)\mathbb{E}_{z' \sim q(z|y)} [\pi_i(y, z')/q(z'|y)]} \right]}. \end{aligned} \quad (7)$$

Here both the denominator and numerator are nested expectations with a nonlinearity coming from the fact that we are using the reciprocal of an expectation. A similar reformulation could also be applied in cases with multiple layers of nesting, i.e. where `inner` itself makes use of another query. The formalization can also be directly extended to the sequential MC (SMC) setting by invoking extended space arguments (Andrieu et al., 2010).

Typically  $g(x, y, z)$  is not known upfront and we instead return an empirical measure from the program in the form of weighted samples which can later be used to estimate an expectation. That is, if we sample  $(x_n, y_n) \sim q(x, y)$  and  $z_{n,m} \sim q(z|y_n)$  and return all samples  $(x_n, y_n, z_{n,m})$  (such that each  $(x_n, y_n)$  is duplicated  $N_1$  times in the sample set) then our unnormalized weights are given by

$$w_{n,m} = \frac{\psi(x_n, y_n, z_{n,m})\pi_i(y_n, z_{n,m})}{q(x_n, y_n, z_{n,m}) \frac{1}{N_1} \sum_{\ell=1}^{N_1} \frac{\pi_i(y_n, z_{n,\ell})}{q(z_{n,\ell}|y_n)}}. \quad (8)$$

This, in turn, gives us the empirical measure

$$\hat{p}(\cdot) = \frac{\sum_{n=1}^{N_0} \sum_{m=1}^{N_1} w_{n,m} \delta_{(x_n, y_n, z_{n,m})}(\cdot)}{\sum_{n=1}^{N_0} \sum_{m=1}^{N_1} w_{n,m}} \quad (9)$$

where  $\delta_{(x_n, y_n, z_{n,m})}(\cdot)$  is a delta function centered on  $(x_n, y_n, z_{n,m})$ . By definition, the convergence of this empirical measure to the target requires that expectation estimates calculated using it converge in probability for any integrable  $g(x, y, z)$  (presuming our proposal is valid). We thus see that the convergence of the ratio of nested expectations in (7) for any arbitrary  $g(x, y, z)$ , is equivalent to the produced samples converging to the distribution defined by the program. Informally, the NMC results then tell us this will happen in the limit  $N_0, N_1 \rightarrow \infty$  provided that  $\int \pi_i(y, z) dz$  is strictly positive for all possible  $y$  (as otherwise the problem becomes ill-defined). More formally we have the following result. Its proof, along with all others, is given in Appendix A.

**Theorem 1.** *Let  $g(x, y, z)$  be an integrable function, let  $\gamma_0 = \mathbb{E}_{p_o(x, y, z)}[g(x, y, z)]$ , and let  $I_0$  be a self-normalized MC estimate for  $\gamma_0$  calculated using  $\hat{p}(\cdot)$  as per (9). Assuming that  $q(x, y, z)$  forms a valid importance sampling proposal distribution for  $p_o(x, y, z)$ , then*

$$\mathbb{E} \left[ (I_0 - \gamma_0)^2 \right] = \frac{\sigma^2}{N_0} + \frac{\delta^2}{N_1^2} + O(\epsilon) \quad (10)$$

where  $\sigma$  and  $\delta$  are constants derived in the proof and, as before,  $O(\epsilon)$  represents asymptotically dominated terms.

Note that rather than simply being a bound, this result is an equality and thus provides the exact asymptotic rate. Using the arguments of (Rainforth et al., 2018, Theorem 3), it can be straightforwardly extended to cases of multiple nesting (giving a rate analogous to (3)), though characterizing  $\sigma$  and  $\delta$  becomes more challenging.

### 3.4 CONVERGENCE REQUIREMENTS

We have demonstrated that the problem of nested inference is a particular case of nested estimation. This problem equivalence will hold whether we elect to use the aforementioned nested importance sampling based approach or not, while we see that our finite sample estimates must be biased for non-trivial  $g$  by the convexity of  $f_0$  and Theorem 4 of Rainforth et al. (2018). Presuming we cannot produce exact samples from the inner query and that the set of possible inputs to the inner query is not finite (these are respectively considered in Appendix D and Appendix C), we thus see that there is no ‘‘silver bullet’’ that can reduce the problem to a standard estimation.

We now ask, what behavior do we need for Anglican’s **conditional**, and nested inference more generally, to ensure convergence? At a high level, the NMC results show us that we need the computational budget of each call of a nested query to become arbitrarily large, such that we use an infinite number of samples at each layer of

the estimator: we require each  $N_k \rightarrow \infty$ .

We have formally demonstrated convergence when this requirement is satisfied and the previously introduced nested importance sampling approach is used. Another possible approach would be to, instead of drawing samples to estimate (7) directly, importance sample  $N_1$  times for each call of the inner query and then return a single sample from these, drawn in proportion to the inner query importance weights. We can think of this as drawing the same raw samples, but then constructing the estimator as

$$\hat{p}^*(\cdot) = \frac{\sum_{n=1}^{N_0} w_n^* \delta_{(x_n, y_n, z_n, m^*(n))}(\cdot)}{\sum_{n=1}^{N_0} w_n^*} \quad (11)$$

where  $w_n^* = \frac{\psi(x_n, y_n, z_n, m^*(n))}{q(x_n, y_n)}$  and  $(12)$

$$m^*(n) \sim \text{DISCRETE} \left( \frac{\pi_i(y_n, z_n, m) / q(z_n, m | y_n)}{\sum_{\ell=1}^{N_1} \pi_i(y_n, z_n, \ell) / q(z_n, \ell | y_n)} \right)$$

As demonstrated formally in Appendix A, this approach also converges. However, if we Rao Blackwellize (Casella and Robert, 1996) the sampling of  $m^*(n)$ , we find that this recovers (9). Consequently, this is a strictly inferior estimator (it has an increased variance relative to (9)). Nonetheless, it may often be a convenient setup from the perspective of the PPS semantics and it will typically have substantially reduced memory requirements: we need only store the single returned sample from the inner query to construct our empirical measure, rather than all of the samples generated within the inner query.

Though one can use the results of Fort et al. (2017) to show the correctness of instead using an MCMC estimator for the outer query, the correctness of using MCMC methods for the inner queries is not explicitly covered by existing results. Here we find that we need to start a new Markov chain for each call of the inner query because each value of  $y$  defines a different local inference problem. One would intuitively expect the NMC results to carry over – as  $N_1 \rightarrow \infty$  all the inner queries will run their Markov chains for an infinitely long time, thereby in principle returning exact samples – but we leave formal proof of this case to future work. We note that such an approach effectively equates to what is referred to as *multiple imputation* by Plummer (2015).

### 3.5 SHORTFALLS OF EXISTING SYSTEMS

Using the empirical measure (9) provides one possible manner of producing a consistent estimate of our target by taking  $N_0, N_1 \rightarrow \infty$  and so we can use this as a gold-standard reference approach (with a large value of  $N_1$ ) to assess whether Anglican returns samples for the correct target distribution. To this end, we ran Anglican’s importance sampling inference engine on the simple model introduced earlier and compared its output to the reference approach using  $N_0 = 5 \times 10^6$  and  $N_1 = 10^3$ . As

Figure 1: Empirical densities produced by running the nested Anglican queries given in the text, a reference NMC estimate, the unnested model, a naïve estimation scheme where  $N_1 = 1$ , and the ONMC approach introduced in Section 6, with the same computational budget of  $T = 5 \times 10^9$  and  $\tau_1(n_0) = \min(500, \sqrt{n_0})$ . Note that the results for ONMC and the reference approach overlap.

shown in Figure 1, the samples produced by Anglican are substantially different to the reference code, demonstrating that the outputs do not match their semantically intended distribution. For reference, we also considered the distribution induced by the aforementioned unnested model and a naïve estimation scheme where a sample budget of  $N_1 = 1$  is used for each call to `inner`, effectively corresponding to ignoring the `observe` statement by directly returning the first draw of  $z$ .

We see that the unnested model defines a noticeably different distribution, while the behavior of Anglican is similar, but distinct, to ignoring the `observe` statement in the inner query. Further investigation shows that the default behavior of `conditional` in a query nesting context is equivalent to using (11) but with  $N_1$  held fixed to at  $N_1 = 2$ , inducing a substantial bias. More generally, the Anglican source code shows that `conditional` defines a Markov chain generated by equalizing the output of the weighted samples generated by running inference on the query. When used to nest queries, this Markov chain is only ever run for a finite length of time, specifically one accept-reject step is carried out, and so does not produce samples from the true conditional distribution.

Plummer (2015) noticed that WinBugs and OpenBugs (Spiegelhalter et al., 1996) similarly do not provide valid inference when using their cut function primitives, which effectively allow the definition of nested inference problems. However, they do not notice the equivalence to the NMC formulation and instead propose a heuristic for reducing the bias that itself has no theoretical guarantees.

## 4 NESTED CONDITIONING

An alternative way one might wish to nest queries is to use the partition function estimate of one query to factor the trace probability of another. We refer to this as *nested conditioning*. In its simplest form, we can think about

conditioning on the values input to the inner query. In Anglican we can carry this out by using the following custom distribution object constructor

```
(defdist nest [inner inputs inf-alg M] []
  (sample [this] nil)
  (observe [this] _)
  (log-marginal (take M
    (doquery inf-alg inner inputs))))
```

When the resulting distribution object is observed, this will now generate, and factor the trace probability by, a partition function estimate for `inner` with inputs `inputs`, constructed using `M` samples of the inference algorithm `inf-alg`. For example, if we were to use the query

```
(defquery outer [D]
  (let [y (sample (beta 2 3))]
    (observe (nest inner [y D] :smc 100) nil
      y)))
```

with `inner` from the nested inference example, then this would form a pseudo marginal sampler (Andrieu and Roberts, 2009) for the unnormalized target distribution

$$\pi_c(y, D) = \text{BETA}(y; 2, 3) \int \Gamma(z; y, 1) \mathcal{N}(D; y, z^2) dz.$$

Unlike the nested inference case, nested conditioning turns out to be valid even if our budget is held fixed, provided that the partition function estimate is unbiased, as is satisfied by, for example, importance sampling and SMC. In fact, it is important to hold the budget fixed to achieve a MC convergence rate. In general, we can define our target density as

$$p_o(x, y) \propto \pi_o(x, y) = \psi(x, y) p_i(y), \quad (13)$$

where  $\psi(x, y)$  is as before (except that we no longer have returned variables from the inner query) and  $p_i(y)$  is the true partition function of the inner query when given input  $y$ . In practice, we cannot evaluate  $p_i(y)$  exactly, but instead produce unbiased estimates  $\hat{p}_i(y)$ . Using an analogous self-normalized importance sampling to the nested inference case leads to the weights

$$w_n = \psi(x_n, y_n) \hat{p}_i(y_n) / q(x_n, y_n) \quad (14)$$

and corresponding empirical measure

$$\hat{p}(\cdot) = \frac{1}{\sum_{n=1}^{N_0} w_n} \sum_{n=1}^{N_0} w_n \delta_{(x_n, y_n)}(\cdot) \quad (15)$$

such that we are conducting conventional MC estimation, but our weights are now themselves random variables for a given  $(x_n, y_n)$  due to the  $\hat{p}_i(y_n)$  term. However, the weights are unbiased estimates of the “true weights”  $\psi(x_n, y_n) p_i(y_n) / q(x_n, y_n)$  such that we have proper weighting (Naesseth et al., 2015) and thus convergence at the standard MC rate, provided the budget of the inner query remains fixed. This result also follows directly from Theorem 6 of Rainforth et al. (2018), which further ensures no complications arise when conditioning on multiple queries if the corresponding partition function estimates are generated independently. These results

further trivially extend to the repeated nesting case by recursion, while using the idea of pseudo-marginal methods (Andrieu and Roberts, 2009), the results also extend to using MCMC based inference for the outermost query.

Rather than just fixing the inputs to the nested query, one can also consider conditioning on the internally sampled variables in the program taking on certain values. Such a nested conditioning approach has been implicitly carried out by Rainforth et al. (2016b); Zinkov and Shan (2017); Scibior and Ghahramani (2016); Ge et al. (2018), each of which manipulate the original program in some fashion to construct a partition function estimator that is used within a greater inference scheme, e.g. a PMMH estimator (Andrieu et al., 2010).

## 5 ESTIMATES AS VARIABLES

Our final case is that one might wish to use estimates as first class variables in another query. In other words, a variable in an outer query is assigned to a MC expectation estimate calculated from the outputs of running inference on another, nested, query. By comparison, the nested inference case (without Rao-Blackwellization) can be thought of as assigning a variable in the outer query to a single approximate sample from the conditional distribution of the inner query, rather than an MC expectation estimate constructed by averaging over multiple samples.

Whereas nested inference can only encode a certain class of nested estimation problems – because the only nonlinearity originates from taking the reciprocal of the partition function – using estimates as variables allows, in principle, the encoding of any nested estimation. This is because using the estimate as a first class variable allows arbitrary nonlinear mappings to be applied by the outer query.

An example of this approach is shown in Appendix G, where we construct a generic estimator for Bayesian experimental design problems. Here a partition function estimate is constructed for an inner query and is then used in an outer query. The output of the outer query depends on the logarithm of this estimate, thereby creating the nonlinearity required to form a nested expectation.

Because using estimates as variables allows the encoding of any nested estimation problem, the validity of doing so is equivalent to that of NMC more generally and must thus satisfy the requirements set out in (Rainforth et al., 2018). In particular, one needs to ensure that the budgets used for the inner estimates increase as more samples of the outermost query are taken.

## 6 ONLINE NESTED MONTE CARLO

NMC will be highly inconvenient to actually implement in a PPS whenever one desires to provide online estimates; for example, a lazy sequence of samples that converges to the target distribution. Suppose that we have already

calculated an NMC estimate, but now desire to refine it further. In general, this will require an increase to all  $N_k$  for each sample of the outermost estimator. Consequently, the previous samples of the outermost query must be revisited to refine their estimates. This significantly complicates practical implementation, necessitating additional communication between queries, introducing computational overhead, and potentially substantially increasing the memory requirements.

To highlight these shortfalls concretely, consider the nested inference class of problems and, in particular, constructing the un–Rao–Blackwellized estimator (11) in an online fashion. Increasing  $N_1$  requires  $m^*(n)$  to be redrawn for each  $n$ , which in turn necessitates storage of previous samples and weights.<sup>2</sup> This leads to an overhead cost from the extra computation carried out for revisitation and a memory overhead from having to store information about each call of the inner query.

Perhaps even more problematically, the need to revisit old samples when drawing new samples can cause substantial complications for implementation. Consider implementing such an approach in Anglican. Anglican is designed to return a lazy infinite sequence of samples converging to the target distribution. Once samples are taken from this sequence, they become external to Anglican and cannot be posthumously updated when further samples are requested. Even when all the output samples remain internal, revisiting samples remains difficult: one either needs to implement some form of memory for nested queries so they can be run further, or, if all information is instead stored at the outermost level, additional non-trivial code is necessary to apply post-processing and to revisit queries with previously tested inputs. The latter of these is likely to necessitate inference–algorithm–specific changes, particularly when there are multiple levels of nesting, thereby hampering the entire language construction.

To alleviate these issues, we propose to only increase the computational budget of *new* calls to nested queries, such that earlier calls use fewer samples than later calls. This simple adjustment removes the need for communication between different calls and requires only the storage of the number of times the outermost query has previously been sampled to make updates to the overall estimate. We refer to this approach as *online* NMC (ONMC), which, to the best of our knowledge, has not been previously considered in the literature. As we now show, ONMC only leads to small changes in the convergence rate of the resultant estimator compared to NMC: using recommended parameter settings, the asymptotic root mean squared error

<sup>2</sup>Note that not all previous samples and weights need storing – when making the update we can sample whether to change  $m^*(n)$  or not based on combined weights from all the old samples compared to all the new samples.

for ONMC is never more than twice that of NMC for a matched sample budget and can even be smaller.

Let  $\tau_k(n_0) \in \mathbb{N}^+$ ,  $k = 1, \dots, D$  be monotonically increasing functions dictating the number of samples used by ONMC at depth  $k$  for the  $n_0$ -th iteration of the outermost estimator. The ONMC estimator is defined as

$$J_0 = \frac{1}{N_0} \sum_{n_0=1}^{N_0} f_0 \left( y_{n_0}^{(0)}, I_1 \left( y_{n_0}^{(0)}, \tau_{1:D}(n_0) \right) \right) \quad (16)$$

where  $I_1(y_{n_0}^{(0)}, \tau_{1:D}(n_0))$  is calculated using  $I_1$  in (2), setting  $y^{(0)} = y_{n_0}^{(0)}$  and  $N_k = \tau_k(n_0)$ ,  $\forall k \in 1, \dots, D$ . For reference, the NMC estimator,  $I_0$ , is as per (16), except for replacing  $\tau_{1:D}(n_0)$  with  $\tau_{1:D}(N_0)$ . Algorithmically, we have that the ONMC approach is defined as follows.

---

**Algorithm 1** Online Nested Monte Carlo

---

- 1:  $n_0 \leftarrow 0, \quad J_0 \leftarrow 0$
  - 2: **while** true **do**
  - 3:    $n_0 \leftarrow n_0 + 1, \quad y_{n_0}^{(0)} \sim p(y^{(0)})$
  - 4:   Construct  $I_1 \left( y_{n_0}^{(0)}, \tau_{1:D}(n_0) \right)$  using  $N_k = \tau_k(n_0) \forall k$
  - 5:    $J_0 \leftarrow \frac{n_0-1}{n_0} J_0 + f_0 \left( y_{n_0}^{(0)}, I_1 \left( y_{n_0}^{(0)}, \tau_{1:D}(n_0) \right) \right)$
- 

We see that OMMC uses fewer samples at inner layers for earlier samples of the outermost level, and that each of resulting inner estimates is calculated as per an NMC estimator with a reduced sample budget. We now show the consistency of the ONMC estimator.

**Theorem 2.** *If each  $\tau_k(n_0) \geq A(\log(n_0))^\alpha$ ,  $\forall n_0 > B$  for some constants  $A, B, \alpha > 0$  and each  $f_k$  is continuously differentiable, then the mean squared error of  $J_0$  as an estimator for  $\gamma_0$  converges to zero as  $N_0 \rightarrow \infty$ .*

In other words, ONMC converges for any realistic choice of  $\tau_k(n_0)$  provided  $\lim_{n_0 \rightarrow \infty} \tau_k(n_0) = \infty$ : the requirements on  $\tau_k(n_0)$  are, for example, much weaker than requiring a logarithmic or faster rate of growth, which would already be an impractically slow rate of increase.

In the case where  $\tau_k(n_0)$  increases at a polynomial rate, we can further quantify the rate of convergence, along with the relative variance and bias compared to NMC:

**Theorem 3.** *If each  $\tau_k(n_0) \geq An_0^\alpha$ ,  $\forall n_0 > B$  for some constants  $A, B, \alpha > 0$  and each  $f_k$  is continuously differentiable, then*

$$\mathbb{E} \left[ (J_0 - \gamma_0)^2 \right] \leq \frac{s_0^2}{N_0} + \left( \frac{\beta g(\alpha, N_0)}{AN_0^\alpha} \right)^2 + O(\epsilon), \quad (17)$$

$$\text{where } g(\alpha, N_0) = \begin{cases} 1/(1-\alpha), & \alpha < 1 \\ \log(N_0) + \eta, & \alpha = 1; \\ \zeta(\alpha)N_0^{\alpha-1}, & \alpha > 1 \end{cases} \quad (18)$$

$$\beta = \frac{C_0 s_1^2}{2} + \sum_{k=0}^{D-2} \left( \prod_{d=0}^k K_d \right) \frac{C_{k+1} s_{k+2}^2}{2}; \quad (19)$$

$\eta \approx 0.577$  is the Euler–Mascheroni constant;  $\zeta$  is the

Riemann–zeta function; and  $C_k$ ,  $K_k$ , and  $\varsigma_k$  are constants defined as per the corresponding NMC bound given in (3).

**Corollary 1.** Let  $J_0$  be an ONMC estimator setup as per Theorem 3 with  $N_0$  outermost samples and let  $I_0$  be an NMC estimator with a matched overall sample budget. Defining  $c = (1 + \alpha D)^{-1/(1+\alpha D)}$ , then

$$\text{Var}[J_0] \rightarrow c \text{Var}[I_0] \quad \text{as } N_0 \rightarrow \infty.$$

Further, if the NMC bias decreases at a rate proportional to that implied by the bound given in (3), namely

$$|\mathbb{E}[I_0 - \gamma_0]| = \frac{b}{M_0^\alpha} + O(\epsilon) \quad (20)$$

for some constant  $b > 0$ , where  $M_0$  is the number of outermost samples used by the NMC sampler, then

$$|\mathbb{E}[J_0 - \gamma_0]| \leq c^\alpha g(\alpha, N_0) |\mathbb{E}[I_0 - \gamma_0]| + O(\epsilon).$$

We expect the assumption that the bias scales as  $1/M_0^\alpha$  to be satisfied in the vast majority of scenarios, but there may be edge cases, e.g. when an  $f_k$  gives a constant output, for which faster rates are observed. Critically, the assumption holds for all nested inference problems because the rate given in (10) is an equality.

We see that if  $\alpha < 1$ , which will generally be the case in practice for sensible setups, then the convergence rates for ONMC and NMC vary only by a constant factor. Specifically, for a fixed value of  $N_0$ , they have the same asymptotic variance and ONMC has a factor of  $1/(1-\alpha)$  higher bias. However, the cost of ONMC is (asymptotically) only  $c < 1$  times that of NMC, so for a fixed overall sample budget it has lower variance.

As the bound varies only in constant factors for  $\alpha < 1$ , the asymptotically optimal value for  $\alpha$  for ONMC is the same as that for NMC, namely  $\alpha = 0.5$  (Rainforth et al., 2018). For this setup, we have  $c \in \{0.763, 0.707, 0.693, 0.693, 0.699, 1\}$  respectively for  $D \in \{1, 2, 3, 4, 5, \infty\}$ . Consequently, when  $\alpha = 0.5$ , the fixed budget variance of ONMC is always better than NMC, while the bias is no more than 1.75 times larger if  $D \leq 13$  and no more than 2 times large more generally.

## 6.1 EMPIRICAL CONFIRMATION

To test ONMC empirically, we consider the simple analytic model given in Appendix F, setting  $\tau_1(n_0) = \max(25, \sqrt{n_0})$ . The rationale for setting a minimum value of  $N_1$  is to minimize the burn-in effect of ONMC – earlier samples will have larger bias than later samples and we can mitigate this by ensuring a minimum value for  $N_1$ . More generally, we recommend setting (in the absence of other information)  $\tau_1(n_0) = \tau_2(n_0) = \dots = \tau_D(n_0) = \max(T_{\min}^{1/3}, \sqrt{n_0})$ , where  $T_{\min}$  is the minimum overall budget we expect to spend. In Figure 2, we have chosen to set  $T_{\min}$  deliberately low so as to emphasize the differences between NMC and ONMC. Given our value for  $T_{\min}$ , the ONMC approach is identical to fix-

Figure 2: Convergence of ONMC, NMC, and fixed  $N_1$ . Results are averaged over 1000 runs, with solid lines showing the mean and shading the 25-75% quantiles. The theoretical rates for NMC are shown by the dashed lines.

ing  $N_1 = 25$  for  $T < 25^3 = 15625$ , but unlike fixing  $N_1$ , it continues to improve beyond this because it is not limited by asymptotic bias. Instead, we see an inflection point-like behavior around  $T_{\min}$ , with the rate recovering to effectively match that of the NMC estimator.

## 6.2 USING ONMC IN PPSs

Using ONMC based estimation schemes to ensure consistent estimation for nested inference in PPSs is straightforward – the number of iterations the outermost query has been run for is stored and used to set the number of iterations used for the inner queries. In fact, even this minimal level of communication is not necessary –  $n_0$  can be inferred from the number of times we have previously run inference on the current query, the current depth  $k$ , and  $\tau_1(\cdot), \dots, \tau_{k-1}(\cdot)$ .

As with NMC, for nested inference problems ONMC can either return a single sample from each call of a nested query, or Rao–Blackwellize the drawing of this sample when possible. Each respectively produces an estimator analogous to (11) and (9) respectively, except that  $N_1$  in the definition of the inner weights is now a function of  $n$ . Returning to Figure 1, we see that using ONMC with nested importance sampling and only returning a single sample corrects the previous issues with how Anglican deals with nested inference, producing samples indistinguishable from the reference code.

## 7 CONCLUSIONS

We have formalized the notion of nesting probabilistic program queries and investigated the statistical validity of different categories of nesting. We have found that current systems tend to use methods that lead to asymptotic bias for nested inference problems, but that they are consistent for nested conditioning. We have shown how to carry out the former in a consistent manner and developed a new *online* estimator that simplifies the construction algorithms that satisfy the conditions required for convergence.

## Abstract

Linear mixed models (LMMs) are used extensively to model observations that are not independent. Parameter estimation for LMMs can be computationally prohibitive on big data. State-of-the-art learning algorithms require computational complexity which depends at least linearly on the dimension  $p$  of the covariates, and often use heuristics that do not offer theoretical guarantees. We present scalable algorithms for learning high-dimensional LMMs with sublinear computational complexity dependence on  $p$ . Key to our approach are novel dual estimators which use only kernel functions of the data, and fast computational techniques based on the subsampled randomized Hadamard transform. We provide theoretical guarantees for our learning algorithms, demonstrating the robustness of parameter estimation. Finally, we complement the theory with experiments on large synthetic and real data.

## 1 INTRODUCTION

Linear mixed models (LMMs) are widely used in many real world applications ranging from longitudinal data analysis (Laird and Ware, 1982; Demidenko, 2013) and genome wide association studies (Kang et al., 2008; Lippert et al., 2011; Zhou, 2017) to recommender systems (Zhang et al., 2016). LMMs provide a flexible framework for modeling a wide range of data types, including clustered, longitudinal, and spatial data. Parameter estimation for LMMs is computationally prohibitive for big data, both for large sample size  $n$  (Zhou and Stephens, 2014; Darnell et al., 2017; Perry, 2017) and for high-dimensional covariates  $p$  (Schelldorfer et al., 2011). The

main computational bottlenecks for parameter estimation arise from the non-convexity of the optimization problem (Kang et al., 2008; Perry, 2017) as well as the computational cost of matrix inversions (Zhou, 2017; Laird et al., 1987; Lindstrom and Bates, 1988; Bates et al., 2015). State-of-the-art methods for parameter estimation in LMMs require computational complexity that depends at least linearly on  $p$ : (i)  $O(nkp)$  for the setting  $n > p$  with a rank  $k$  covariance matrix (Zhou, 2017; Darnell et al., 2017); and (ii)  $O(n^2p)$  per iteration for  $p \gg n$  (Schelldorfer et al., 2011, 2014; Jakubik, 2015). In this paper, we present scalable algorithms with sublinear computational complexity in  $p$ , making the proposed approach useful for high-dimensional LMMs. In addition, we provide a theoretical analysis for our approach that states provable error guarantees between the estimated and ground-truth parameters.

Two sets of parameters are estimated in LMMs, the fixed-effects coefficients and the variances for the unobservable random effects and noise. The random-effects variance is generally assumed to have a certain structure, such as a block-diagonal matrix (Laird and Ware, 1982; Demidenko, 2013). To estimate both sets of parameters, an expectation maximization (EM) algorithm is typically used (Laird et al., 1987; Bates et al., 2015) to handle the latent random-effect variable. The M-step in the EM algorithm incurs high computational costs due to matrix inversions. Newton-Raphson has been used to reduce the number of iterations required for parameter estimates to converge (Lindstrom and Bates, 1988); however, each iteration is still costly due to matrix inversions. A recent research focus is to avoid matrix inversions at each iteration. For instance, when  $n > p$  a spectral algorithm is available (Kang et al., 2008; Lippert et al., 2011; Patterson and Thompson, 1971). The state-of-the-art algorithm (Darnell et al., 2017) further improved the computational complexity of the spectral algorithm using randomized singular value decomposition (Darnell et al., 2017).

While approximate learning algorithms (Zhou, 2017;

Darnell et al., 2017) are efficient, few provide provable guarantees in terms of estimation accuracy. Recently, a guaranteed non-iterative algorithm was proposed in (Perry, 2017), which runs in  $O(n(p+d)^4)$  time for  $d$  random effects. Inference with guarantees for high-dimensional LMMs, i.e.,  $p \gg n$ , typically incurs greater computational complexity due to the regularization required to address high-dimensional data (Schell-dorfer et al., 2011, 2014). In the high-dimensional setting, most algorithms perform block coordinate descent with an  $O(n^2p)$  per-iteration cost (Schell-dorfer et al., 2011, 2014). In this paper, we show that efficiency and provable guarantees can be achieved simultaneously for learning high-dimensional LMMs.

There are two key ideas we use in our efficient algorithms. The first idea is to propose an approximate estimator that relies on an  $n \times n$  kernel matrix (§ 3) which can be computed efficiently using the subsampled randomized Hadamard transform (SRHT) (Tropp, 2011). This reduces the linear complexity dependence on  $p$ . Unlike some other approximation algorithms (Lu et al., 2013), the proposed estimator also has the advantage of recovering the fixed-effects coefficients for all  $p$  dimensions as opposed to the reduced dimensions. This allows us to provide effect sizes in terms of the original covariates, a requirement in many applications. The second idea is the introduction of *approximate variance components* (AVCs) to replace variance components when estimating the fixed-effects coefficients. These AVCs have a closed-form expression and are fast to compute.

We apply our novel approach to LMMs with a both general covariances as well as a block-diagonal covariances for the random effects. The former can be viewed as a special case of the latter with a single block, and has been adopted in genome-wide association studies (Kang et al., 2008; Lippert et al., 2011; Zhou, 2017). LMMs with a block-diagonal covariance structure have been widely used for modeling repeated measures data (Laird and Ware, 1982). We propose a non-iterative algorithm for the general covariance setting and a fast EM variant for the block-diagonal setting.

**Contribution** Our main contribution is providing a class of approximation algorithms for parameter inference in high-dimensional LMMs with provable guarantees. In Table 1, we state the computational complexity for several standard and state-of-the-art parameter inference algorithms. In the table and in this paper,  $n$  is the sample size,  $p$  is the number of covariates,  $k$  is the rank of the covariance matrix,  $s$  are the number of subsamples, and  $\epsilon$  is the approximation error. Our method is the only one that is sublinear in  $p$ , and can be a  $n/\log p$  magnitude

Table 1: Computational complexity for parameter inference. † denotes that the estimator has provable guarantees.

REML (LIPPERT ET AL., 2011)	$O(n^2p)$
†MOMENTS (PERRY, 2017)	$O(n(p+q)^4)$
SUBSAMPLING (ZHOU, 2017)	$O(ps^2)$
RSVD (DARNELL ET AL., 2017)	$O(pnk)$
†THIS WORK	$O\left(\frac{n^2(k+\log p)\log k}{\epsilon^2}\right)$

faster than the others (discussed in § 4.1). In addition to theoretical advantages, we demonstrate the empirical accuracy and speed of our method on both synthetic and real data in § 6.

**Notation** We denote the maximum and minimum eigenvalues of a matrix  $\mathbf{A}$  by  $\lambda_{\max}(\mathbf{A})$  and  $\lambda_{\min}(\mathbf{A})$ , respectively. Similarly, we denote the maximum and minimum singular values respectively by  $\sigma_{\max}(\mathbf{A})$  and  $\sigma_{\min}(\mathbf{A})$ .  $\mathbf{A}^\dagger$  represents the Moore–Penrose pseudoinverse of  $\mathbf{A}$ , and  $\kappa(\mathbf{A})$  denotes the condition number of  $\mathbf{A}$ . The superscripted notation  $\mathbf{y}^{(i)}$  refers to the copy of  $\mathbf{y}$  for group  $i$ . We write the spectral norm of a matrix as  $\|\cdot\|_2$ , the Frobenius norm as  $\|\cdot\|_F$ , and the Ky Fan  $k$ -norm (the sum of the  $k$  largest singular values) as  $\|\cdot\|_k$ .

**Organization** Section 2 provides the background on standard LMMs. In section 3, we formulate the  $L_2$ -regularized LMMs and present approximate estimators based on a kernel matrix. Section 4 describes fast computational techniques for the approximate estimators. In section 5, we provide theoretical guarantees for our estimators. Section 6 reports empirical evidence of the speed and accuracy of our methods, and section 7 concludes this paper.

## 2 LINEAR MIXED MODELS

Consider a regression problem with  $n$  observations, where  $\mathbf{y} \in \mathbb{R}^n$  denotes the response vector and  $\mathbf{X} \in \mathbb{R}^{n \times p}$  represents the covariate matrix with  $p$  covariates. The standard LMM is given by

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + c\mathbf{1} + \mathbf{e} \quad \text{with} \quad (1)$$

$$\begin{bmatrix} \boldsymbol{\gamma} \\ \mathbf{e} \end{bmatrix} \sim \text{MVN}\left(\mathbf{0}, \begin{bmatrix} \boldsymbol{\Lambda} & \mathbf{0} \\ \mathbf{0} & \sigma^2\mathbf{I} \end{bmatrix}\right),$$

where  $\boldsymbol{\beta} \in \mathbb{R}^p$  is the fixed-effect coefficient vector,  $\mathbf{Z} \in \mathbb{R}^{n \times q}$  is a full-rank random-effects design matrix,  $\boldsymbol{\gamma} \in \mathbb{R}^q$  is the random-effect coefficient vector,  $c$  is the intercept, and  $\mathbf{e} \in \mathbb{R}^n$  is the noise vector. The parameters to be estimated are the fixed-effects coefficients  $\boldsymbol{\beta}$ , and variance components  $\boldsymbol{\Lambda}$  and  $\sigma^2$ .

In general, the variables  $\mathbf{X}$ ,  $\mathbf{y}$ ,  $\boldsymbol{\gamma}$ , and  $\mathbf{e}$  in (1) correspond to observations from  $m$  classes, and are grouped by the following structure (Laird and Ware, 1982):

$$\begin{bmatrix} \mathbf{X}^{(1)} \\ \mathbf{X}^{(2)} \\ \vdots \\ \mathbf{X}^{(m)} \end{bmatrix}, \begin{bmatrix} \mathbf{y}^{(1)} \\ \mathbf{y}^{(2)} \\ \vdots \\ \mathbf{y}^{(m)} \end{bmatrix}, \begin{bmatrix} \boldsymbol{\gamma}^{(1)} \\ \boldsymbol{\gamma}^{(2)} \\ \vdots \\ \boldsymbol{\gamma}^{(m)} \end{bmatrix}, \begin{bmatrix} \mathbf{e}^{(1)} \\ \mathbf{e}^{(2)} \\ \vdots \\ \mathbf{e}^{(m)} \end{bmatrix},$$

where  $\cdot^{(i)}$  denote the variables specific to group  $i$ , whose dimensions are  $\mathbf{X}^{(i)} \in \mathbb{R}^{n_i \times p}$ ,  $\boldsymbol{\gamma}^{(i)} \in \mathbb{R}^d$ , and  $\mathbf{y}^{(i)}, \mathbf{e}^{(i)} \in \mathbb{R}^{n_i}$ ,  $\sum_{i=1}^m n_i = n$ . The LMM assumes that  $\boldsymbol{\gamma}^{(i)}$  corresponding to distinct classes are independent. In particular, the random-effects design matrix  $\mathbf{Z}$  and the random-effects covariance are block-diagonal

$$\mathbf{Z} = \begin{bmatrix} \mathbf{Z}^{(1)} & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \mathbf{Z}^{(m)} \end{bmatrix}, \quad \boldsymbol{\Lambda} = \begin{bmatrix} \mathbf{H} & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \mathbf{H} \end{bmatrix}$$

with  $\mathbf{Z}^{(i)} \in \mathbb{R}^{n_i \times d}$ ,  $\mathbf{H} \in \mathbb{R}^{d \times d}$ , and  $q = md$ .

**Computational challenges** Parameter inference in LMMs aims to accurately recover  $\mathcal{P} := \{\boldsymbol{\beta}, \boldsymbol{\Lambda}, \sigma^2\}$  from  $\{\mathbf{X}, \mathbf{y}, \mathbf{Z}\}$ . This is straightforward if  $\boldsymbol{\Lambda}$  is given. When  $\boldsymbol{\Lambda}$  is unknown, inference can be computationally challenging even in the standard setting where  $n > p$  (Laird and Ware, 1982; Lippert et al., 2011; Zhou, 2017; Laird et al., 1987; Lindstrom and Bates, 1988; Patterson and Thompson, 1971; Zhang et al., 2011).

First, parameter estimation problem is non-convex for both maximum likelihood and restricted maximum likelihood (REML) (Laird et al., 1987; Patterson and Thompson, 1971; Harville, 1974). For instance, the methods using REML (Kang et al., 2008; Lippert et al., 2011) project the data onto two uncorrelated parts, and then estimate the fixed-effects and variance components separately on each part. This has the advantage of giving unbiased estimates of the variance components. However, the REML likelihood function is a non-convex function which involves the eigenvalues of the variance of the projected data (Patterson and Thompson, 1971).

Second, regularization is typically required to support the high-dimensional setting, which adds further computational overheads (Lippert et al., 2011; Zhou, 2017; Schelldorfer et al., 2011, 2014; Jakubík, 2015). To address these challenges, we develop novel approximate estimators that are efficient to compute (§ 4), and have provable accuracy guarantees (§ 5).

### 3 APPROXIMATE ESTIMATORS FOR HIGH-DIMENSIONAL LMMS

In this section, we consider an  $L_2$ -regularized LMM to support the high-dimensional setting  $p > n$ , and develop efficient approximate estimators for the parameters.

Standard parameter estimation algorithms for LMMs such as (Kang et al., 2008; Laird et al., 1987; Bates et al., 2015) do not support the high-dimensional setting  $p > n$ . We consider introducing the  $L_2$  regularization on the fixed-effects coefficients, which can be viewed as adding the prior  $\boldsymbol{\beta} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Phi})$ . The  $L_2$ -regularized LMM has the following log-likelihood

$$\begin{aligned} & \log p(\mathbf{y}, \boldsymbol{\beta} \mid \mathbf{X}; \mathbf{V}) \\ & \propto -\frac{1}{2} \boldsymbol{\beta}^\top \boldsymbol{\Phi}^{-1} \boldsymbol{\beta} - \frac{1}{2} \log \det \mathbf{V} \\ & \quad - \frac{1}{2} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{c}\mathbf{1}) \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{c}\mathbf{1}) \end{aligned} \quad (2)$$

with the marginal variance  $\mathbf{V} := \mathbf{Z}\boldsymbol{\Lambda}\mathbf{Z}^\top + \sigma^2\mathbf{I}$ .

Parameter estimation of an LMM is typically iterative and computationally prohibitive, especially in the high-dimensional setting (Darnell et al., 2017; Perry, 2017; Schelldorfer et al., 2011). To improve the computational efficiency, we propose dual as well as approximate estimators. These estimators are non-iterative and have reduced computational complexity, as we will show in § 4.

#### 3.1 FIXED-EFFECT COEFFICIENTS

We first derive the estimators for the fixed-effects coefficients  $\hat{\boldsymbol{\beta}}$  and  $\hat{\mathbf{c}}$ , which are the maximizers of the log-likelihood (2). A dual estimator of  $\boldsymbol{\beta}$  is then given for use in the high-dimensional setting. Using the partial derivatives, it is straightforward to show

$$(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X} + \boldsymbol{\Phi}^{-1}) \hat{\boldsymbol{\beta}} = \mathbf{X}^\top \mathbf{V}^{-1} (\mathbf{y} - \hat{\mathbf{c}}\mathbf{1}) \quad (3)$$

$$\hat{\mathbf{c}} = \frac{\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{y} - \mathbf{1}^\top \mathbf{V}^{-1} \mathbf{X} \hat{\boldsymbol{\beta}}}{\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{1}}. \quad (4)$$

Let  $\mathbf{L} = \mathbf{I} - \mathbf{1}\mathbf{1}^\top \mathbf{V}^{-1} (\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{1})^{-1}$ , we obtain

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{L} \mathbf{X} + \boldsymbol{\Phi}^{-1})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{L} \mathbf{y}. \quad (5)$$

The dual estimator using  $\mathbf{X}\boldsymbol{\Phi}\mathbf{X}^\top$  was proposed in (Saunders et al., 1998) where the authors used Lagrange multipliers to obtain the following estimator for ridge regression:

$$\hat{\boldsymbol{\beta}}_{\text{Dual}} = \boldsymbol{\Phi} \mathbf{X}^\top (\mathbf{V} + \mathbf{X}\boldsymbol{\Phi}\mathbf{X}^\top)^{-1} \mathbf{y}.$$

Here,  $\boldsymbol{\Phi}$  is set to be diagonal, and the above estimator (6) can be evaluated in  $O(n^2p)$  time, a significant improvement when  $p \gg n$ . However, the computational bottleneck becomes evaluating the *kernel matrix*  $\mathbf{X}\boldsymbol{\Phi}\mathbf{X}^\top$ .

For the zero intercept case  $\hat{c} = 0$ , the dual estimator (6) is equivalent to (5) from the following variant of the Woodbury identity  $(\mathbf{U}^{-1} + \mathbf{A}^\top \mathbf{V}^{-1} \mathbf{A})^{-1} \mathbf{A}^\top \mathbf{V}^{-1} = \mathbf{U} \mathbf{A}^\top (\mathbf{A} \mathbf{U} \mathbf{A}^\top + \mathbf{V})^{-1}$  for invertible matrices  $\mathbf{U}$  and  $\mathbf{V}$ . The dual estimator can be generalized to any intercept,

$$\hat{\beta} = \Phi \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{L} (\mathbf{X} \Phi \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{L} + \mathbf{I})^{-1} \mathbf{y}. \quad (6)$$

Computing the dual estimator (6) takes  $O(n^2 p)$  time as opposed to  $O(p^3)$  time required by (5). This complexity will be further improved in § 4 for the setting  $p \gg n$ .

### 3.2 APPROXIMATE VARIANCE COMPONENTS

The variance components  $\Lambda$  and  $\sigma^2$  are typically estimated using an iterative EM algorithm with a per-iteration cost  $O(p^3)$  (Laird et al., 1987; Lindstrom and Bates, 1988) or an exhaustive grid search for the solution of a system of eigenvalue equations (Kang et al., 2008; Lippert et al., 2011). We consider an approximate non-iterative estimator based on the key observation that the optimization of the (2) has a simple closed-form solution if carried out with respect to  $\mathbf{M} = \mathbf{V} + \mathbf{X} \Phi \mathbf{X}^\top$ . We will estimate  $\mathbf{M}$  and use it as a proxy for estimating  $\Lambda$  as well as  $\sigma^2$ . The variance components inferred using  $\mathbf{M}$  are referred to as the *approximate variance components* (AVCs). While AVCs may be used as variance components estimates under certain circumstances, the main purpose is to serve as fast replacements in estimating fixed-effects coefficients.

**Proxy component estimation** To perform the REML estimation of the variance components in terms of  $\mathbf{M}$ , we first rewrite the log-likelihood (2) as

$$\begin{aligned} l(\beta, \mathbf{V}) &= -\frac{1}{2} \log \det \mathbf{V} \\ &\quad - \frac{1}{2} (\mathbf{y} - \hat{c} \mathbf{1})^\top \mathbf{M}^{-1} (\mathbf{y} - \hat{c} \mathbf{1}) \\ &\quad - \frac{1}{2} (\beta - \hat{\beta}(\mathbf{V}))^\top \mathbf{Q} (\beta - \hat{\beta}(\mathbf{V})) \end{aligned} \quad (7)$$

where  $\mathbf{Q} = \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X} + \Phi^{-1}$  and  $\hat{\beta}(\mathbf{V}) = (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X} + \Phi^{-1})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} (\mathbf{y} - \hat{c} \mathbf{1})$ . Here, the estimate  $\hat{\beta}$  depends on  $\mathbf{V}$ , and is consistent with the estimate given by (5). The  $\hat{c}$  in (7) can be set to the mean response, or estimated based on a prior distribution as in (Zhou et al., 2013).

Then, the REML estimator for the variance components is based on marginalizing the fixed effects  $\beta$  (Harville,

1974). It follows that

$$\begin{aligned} l_p(\mathbf{V}) &\propto \log \int_{\mathbb{R}^p} \exp(l(\beta, \mathbf{V})) d\beta \\ &\propto -\frac{1}{2} \log \det \mathbf{V} - \frac{1}{2} \log \det \mathbf{Q} \\ &\quad - \frac{1}{2} (\mathbf{y} - \hat{c} \mathbf{1})^\top \mathbf{M}^{-1} (\mathbf{y} - \hat{c} \mathbf{1}). \end{aligned}$$

From Sylvester's determinant theorem, one observes that  $\det(\mathbf{M}) = \det(\Phi) \det(\mathbf{V}) \det(\mathbf{Q})$ . Thus, we arrive at

$$\begin{aligned} l_p(\mathbf{V}) &\propto -\frac{1}{2} \log \det \mathbf{M} \\ &\quad - \frac{1}{2} (\mathbf{y} - \hat{c} \mathbf{1})^\top \mathbf{M}^{-1} (\mathbf{y} - \hat{c} \mathbf{1}). \end{aligned} \quad (8)$$

Now, what we have achieved through (8) is a simple closed-form REML estimate of  $\hat{\mathbf{V}}$ , rather than the non-convex or iterative updates for  $\hat{\Lambda}$  and  $\hat{\sigma}^2$  in state-of-the-art LMM parameter estimation algorithms. Unconstrained maximization of (8) with respect to  $\mathbf{M}$  results in the closed-form equality

$$\mathbf{Z} \hat{\Lambda} \mathbf{Z}^\top + \hat{\sigma}^2 \mathbf{I} = (\mathbf{y} - \hat{c} \mathbf{1}) (\mathbf{y} - \hat{c} \mathbf{1})^\top - \mathbf{X} \Phi \mathbf{X}^\top, \quad (9)$$

for an optimal  $\mathbf{M}$ . Note that  $\mathbf{Z} \hat{\Lambda} \mathbf{Z}^\top$  is positive semidefinite, whereas the right hand side has at most one positive eigenvalue. Thus, this optimal  $\mathbf{M}$  may not be achievable and the unbiased estimate of  $\Lambda$  may possibly have negative eigenvalues. The issue of negative variance estimates in linear mixed models is an open problem (Demidenko, 2013) and beyond the scope of this paper. One resolution is to introduce a Gamma prior on  $\Lambda$  (Chung et al., 2013). For unbiased estimation, we allow  $\Lambda$  to have negative eigenvalues, and intuitively we refer to the variance estimators obtained this way as *approximate variance components*.

**Approximate variance estimators** Assume that  $\mathbf{Z}$  has full column rank and let  $\mathbf{S} = (\mathbf{y} - \hat{c} \mathbf{1}) (\mathbf{y} - \hat{c} \mathbf{1})^\top - \mathbf{X} \Phi \mathbf{X}^\top$ . The approximate variance components  $\hat{\Lambda}_{\text{AVC}}$  and  $\hat{\sigma}_{\text{AVC}}^2$  can be obtained via

$$\arg \min_{\Lambda, \sigma^2} \|\mathbf{Z} \Lambda \mathbf{Z}^\top - \mathbf{S} + \sigma^2 \mathbf{I}\|_F^2. \quad (10)$$

Optimizing with respect to  $\Lambda$  yields

$$\Lambda_\star = \mathbf{Z}^\dagger (\mathbf{S} - \sigma^2 \mathbf{I}) \mathbf{Z}^{\dagger \top}, \quad (11)$$

where  $\mathbf{Z}^\dagger := (\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{Z}^\top$ . The estimators are computed by substituting  $\Lambda_\star$  into (10) and optimizing with respect to  $\sigma^2$ :

$$\begin{aligned} \hat{\sigma}_{\text{AVC}}^2 &= \frac{\text{tr}[\mathbf{S} (\mathbf{I} - \mathbf{Z} \mathbf{Z}^\dagger)]}{n - q} \\ \hat{\Lambda}_{\text{AVC}} &= \mathbf{Z}^\dagger \mathbf{S} \mathbf{Z}^{\dagger \top} - \hat{\sigma}_{\text{AVC}}^2 (\mathbf{Z}^\top \mathbf{Z})^{-1}. \end{aligned} \quad (12)$$

Consider the parameterization  $\Lambda = \theta D$  in (Kang et al., 2008; Lippert et al., 2011) with a fixed symmetric positive semi-definite  $D$ , the solution to (10) is written as

$$\Lambda_* = \frac{\text{tr}(\mathbf{G}(\mathbf{S} - \sigma^2 \mathbf{I}))}{\text{tr}(\mathbf{G}^2)} \mathbf{D} \quad (13)$$

with  $\mathbf{G} = \mathbf{Z}\mathbf{D}\mathbf{Z}^\top$ . Substituting into (10), we obtain

$$\hat{\sigma}_{\text{AVC}}^2 = \frac{1}{n - \alpha} \left[ \text{tr}(\mathbf{S}) - \frac{\text{tr}(\mathbf{G}\mathbf{S})}{\text{tr}(\mathbf{G}^2)} \right], \quad (14)$$

where  $\alpha = \text{tr}(\mathbf{G})^2 / \text{tr}(\mathbf{G}^2)$ . Combined with (13), we arrive at

$$\hat{\Lambda}_{\text{AVC}} = \frac{\text{tr}(\mathbf{G}(\mathbf{S} - \hat{\sigma}_{\text{AVC}}^2 \mathbf{I}))}{\text{tr}(\mathbf{G}^2)} \mathbf{D}. \quad (15)$$

While AVCs may be used as variance components estimates under certain circumstances, the main purpose is to speed up estimating the fixed-effect coefficients. The complexity for computing the AVCs is  $O(n^3)$ , if  $\mathbf{S}$  is given. Like the dual fixed-effects estimator (6), the computational bottleneck of AVCs also lies in evaluating  $\mathbf{X}\Phi\mathbf{X}^\top$ .

## 4 FAST COMPUTATIONAL ALGORITHMS

In this section, we further improve the computational complexity  $O(n^2p)$  of the proposed approximate estimators in the high-dimensional setting  $p \gg n$ , where the computation bottleneck lies in evaluating the kernel  $\mathbf{X}\Phi\mathbf{X}^\top$ . We adopt the subsampled randomized Hadamard transform (SRHT) (Tropp, 2011) to compute the kernel matrix efficiently. In particular, the high-dimensional data is first projected into lower dimensions using SRHT, and the parameters of the LMM are then estimated using the projected data. However, there are two main challenges involved: 1) the estimated parameter  $\hat{\beta}$  now corresponds to the projected data of reduced dimensions, whereas the coefficients of the full original covariates are desired; and 2) the impact of applying the SRHT on the accuracy of parameter estimation needs to be justified. The techniques developed in this section recovers the coefficients to the full covariates from the SRHT projected data with high accuracy, as will be shown in § 5.

### 4.1 NON-ITERATIVE ALGORITHM FOR GENERAL LMMS

In this subsection, we provide a fast algorithm for parameter estimation in case of a general covariance matrix. Algorithm 1 takes as input the matrices  $\mathbf{X}$  and  $\Phi$

---

#### Algorithm 1 Approximate kernel matrix computation.

---

**Require:**  $\mathbf{X}$ ,  $\Phi$ , and error tolerance  $\epsilon$ .

- 1: Let  $p' = 2^{\lceil \log_2 p \rceil}$ , append  $p' - p$  all zero columns to  $\mathbf{X}$ , and  $p' - p$  all zero rows and columns to  $\Phi$ . Compute a diagonal matrix  $\mathbf{D}$  of dimension  $p'$  with Rademacher random diagonal elements.
- 2: Denote the fast Walsh-Hadamard transform by

$$\mathbf{W}_{p'} = \begin{bmatrix} \mathbf{W}_{p'/2} & \mathbf{W}_{p'/2} \\ \mathbf{W}_{p'/2} & -\mathbf{W}_{p'/2} \end{bmatrix} \quad \text{with } \mathbf{W}_1 = 1.$$

Let  $r$  be the rank of  $\mathbf{X}$  or  $r = n$  for unknown rank, then define

$$s_\epsilon := \frac{6 \left[ \sqrt{r} + \sqrt{8 \log(rp')} \right]^2 \log r}{\epsilon^2}.$$

Sample without replacement  $m$  rows of  $\mathbf{W}_{p'}\mathbf{D}/\sqrt{s_\epsilon}$  to obtain the SRHT  $\Pi$ . Compute  $\mathbf{A} = \mathbf{X}\sqrt{\Phi}\Pi^\top$ .

- 3: **return** the approximate kernel  $\mathbf{A}\mathbf{A}^\top$ ,  $\mathbf{A}$ , and  $\Pi$ .
- 

(which will be typically diagonal) and an approximation error  $\epsilon$  described in § 5. Both an approximation to the kernel matrix  $\mathbf{X}\Phi\mathbf{X}^\top$  and the SRHT matrix  $\Pi$  are computed. The computational efficiency of the algorithm is a result of replacing  $\mathbf{X}$  with the smaller transform  $\mathbf{A}$  in subsequent operations. Additionally, the structure of the SRHT allows for a divide-and-conquer scheme to compute  $\mathbf{A} = \mathbf{X}\sqrt{\Phi}\Pi^\top$  in  $O(np \log p)$  time. Note that the matrix  $\mathbf{W}_{p'}$  is not formed explicitly. The computation  $\mathbf{A}\mathbf{A}^\top$  requires  $O(n^2 s_\epsilon)$  time, which becomes dominant setting  $\epsilon \leq Cn\sqrt{\frac{\log n}{p \log p}}$  for some universal constant  $C$ . Thus, the overall runtime for the algorithm is  $O\left(\frac{n^3 \log n}{\epsilon^2}\right)$  for dense full-rank  $\mathbf{X}$ , and will be faster if  $\mathbf{X}$  is of low rank. The quality of the approximation depends on  $\epsilon$ , which will be discussed in § 5.

Given the approximate kernel, it is straight forward to compute the AVCs  $\Lambda_{\text{AVC}}$  and  $\sigma_{\text{AVC}}^2$  via (12). The coefficients for the fixed-effects can also be computed efficiently using the following estimator

$$\hat{\beta} = \sqrt{\Phi}\Pi^\top \mathbf{A}^\top \hat{\mathbf{V}}^{-1} \mathbf{L} \left( \mathbf{I} + \mathbf{A}\mathbf{A}^\top \hat{\mathbf{V}}^{-1} \mathbf{L} \right)^{-1} \mathbf{y}. \quad (16)$$

Given the approximate kernel matrix and  $\mathbf{A}$ , computing  $\mathbf{A}^\top \hat{\mathbf{V}}^{-1} \mathbf{L} \left( \mathbf{I} + \mathbf{A}\mathbf{A}^\top \hat{\mathbf{V}}^{-1} \mathbf{L} \right)^{-1} \mathbf{y}$  takes time  $O(\max\{n^2 s_\epsilon, n^3\})$  and multiplication of this vector by  $\sqrt{\Phi}\Pi^\top$  is  $O(p \log p)$  due to the structure of the SRHT matrix as well as the fact that  $\sqrt{\Phi}$  is diagonal. The resulting complexity in computing (16) is  $O(\max\{n^2 s_\epsilon, n^3, p \log p\})$ .

Approximating the kernel matrix using the SRHT was proposed for ridge regression in (Lu et al., 2013), a special case of our setting. A method for estimating the full set of fixed-effects coefficients was not provided in (Lu et al., 2013). Instead, a reduced set of  $m$  fixed-effects coefficients corresponding to the transformed covariate matrix  $\mathbf{X}\mathbf{\Pi}^\top$  was reported. For many applications, a major point of using an LMM is to estimate the effect-size of the fixed-effect coefficients, so computing  $\widehat{\boldsymbol{\beta}}$  is essential to the problem.

## 4.2 FAST EM FOR MULTI-GROUP LMMS

For efficient parameter estimation in  $L_2$ -regularized LMMS with repeated measurements, we extend the EM algorithm for the low-dimensional setting  $n \geq p$  (Laird et al., 1987) by combing the kernel estimators and Algorithm 1. While this high-dimensional EM variant is iterative, we show that the per-iteration computational cost is scalable in  $p$ .

The log-likelihood of the  $L_2$ -regularized LMM (17) can be rewritten in terms of class-specific variables as

$$\begin{aligned} & \log p(\mathbf{y}, \boldsymbol{\gamma}, \boldsymbol{\beta} \mid \mathbf{X}; \sigma^2, \boldsymbol{\Lambda}) \\ & \propto -\frac{1}{2} \boldsymbol{\beta}^\top \boldsymbol{\Phi}^{-1} \boldsymbol{\beta} - \frac{n}{2} \log \sigma^2 - \frac{m}{2} \log \det \mathbf{H} \\ & \quad - \frac{1}{2} \sum_{i=1}^m \boldsymbol{\gamma}^{(i)\top} \mathbf{H}^{-1} \boldsymbol{\gamma}^{(i)} - \frac{\mathbf{e}^\top \mathbf{e}}{2\sigma^2}, \end{aligned} \quad (17)$$

where  $\mathbf{e} = \mathbf{y} - c\mathbf{1} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\boldsymbol{\gamma}$ .

From the above log-likelihood, the posterior distribution of  $\boldsymbol{\beta}$  conditioned on the data and parameter estimates  $\widehat{\mathcal{P}} := \{\widehat{c}, \widehat{\sigma}^2, \widehat{\mathbf{H}}\}$  is multivariate normal with mean  $\boldsymbol{\Phi}\mathbf{X}^\top \widehat{\mathbf{M}}^{-1}(\mathbf{y} - \widehat{c}\mathbf{1})$  and covariance  $\boldsymbol{\Phi} - \boldsymbol{\Phi}\mathbf{X}^\top \widehat{\mathbf{M}}^{-1} \mathbf{X}\boldsymbol{\Phi}$ . Similarly, the posterior distribution of the vector of latent variables  $\boldsymbol{\gamma}$  is multivariate normal with mean  $\widehat{\boldsymbol{\Lambda}}\mathbf{Z}^\top \widehat{\mathbf{M}}^{-1}(\mathbf{y} - \widehat{c}\mathbf{1})$  and covariance  $\widehat{\boldsymbol{\Lambda}} - \widehat{\boldsymbol{\Lambda}}\mathbf{Z}^\top \widehat{\mathbf{M}}^{-1} \mathbf{Z}\widehat{\boldsymbol{\Lambda}}$ . Denote by  $\widehat{\boldsymbol{\gamma}}$  the mean of the posterior distribution of  $\boldsymbol{\gamma}$ , we also obtain the following posterior distributions of class-specific latent variable  $\boldsymbol{\gamma}^{(i)}$ :

$$\mathcal{N}\left(\widehat{\boldsymbol{\gamma}}^{(i)}, \widehat{\mathbf{H}} - \widehat{\mathbf{H}}\mathbf{Z}^{(i)\top} \left(\widehat{\mathbf{M}}^{-1}\right)^{(i)} \mathbf{Z}^{(i)} \widehat{\mathbf{H}}\right). \quad (18)$$

Note that  $\cdot^{(i)}$  represents the block matrix corresponding to group  $i$ . These posteriors are used in the E-step, discussed next.

**E-step** In the E-step, we derive the expectation of the log-likelihood (17) with respect to the aforementioned posterior distribution of  $\boldsymbol{\beta}$  and  $\boldsymbol{\gamma}^{(i)}$ :

$$\mathbb{E}_{\boldsymbol{\beta}, \boldsymbol{\gamma} \mid \mathbf{y}, \widehat{\mathcal{P}}} \left[ \log p(\mathbf{y}, \boldsymbol{\gamma}, \boldsymbol{\beta} \mid \mathbf{X}; \sigma^2, \mathbf{H}) \right].$$

We only need to consider terms in the expectation that involve  $c$ ,  $\sigma^2$ , and  $\mathbf{H}$ . Denote by  $\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{\gamma}^{(i)}}$  the variance of (18), the following holds  $\mathbb{E}_{\boldsymbol{\beta}, \boldsymbol{\gamma} \mid \mathbf{y}, \widehat{\mathcal{P}}} (\boldsymbol{\gamma}^{(i)\top} \mathbf{H}^{-1} \boldsymbol{\gamma}^{(i)}) = \widehat{\boldsymbol{\gamma}}^{(i)\top} \mathbf{H}^{-1} \widehat{\boldsymbol{\gamma}}^{(i)} + \text{tr}(\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{\gamma}^{(i)}} \mathbf{H}^{-1})$ . Using the previously derived posterior distributions, we get

$$\begin{aligned} \mathbb{E}(\mathbf{e} \mid \mathbf{y}, \widehat{\mathcal{P}}) &= \mathbf{y} - \mathbf{X}\widehat{\boldsymbol{\beta}} - \mathbf{Z}\widehat{\boldsymbol{\gamma}} - \widehat{c}\mathbf{1} \\ \text{cov}(\mathbf{e} \mid \mathbf{y}, \widehat{\mathcal{P}}) &= \widehat{\sigma}^2 \mathbf{I} - \widehat{\sigma}^4 \widehat{\mathbf{M}}^{-1}. \end{aligned}$$

Thus, we arrive at  $\mathbb{E}_{\boldsymbol{\beta}, \boldsymbol{\gamma} \mid \mathbf{y}, \widehat{\mathcal{P}}} (\mathbf{e}^\top \mathbf{e}) = \widehat{\mathbf{e}}^\top \widehat{\mathbf{e}} + \widehat{\sigma}^2 \mathbf{I} - \widehat{\sigma}^4 \widehat{\mathbf{M}}^{-1}$ , where  $\widehat{\mathbf{e}} := \mathbb{E}(\mathbf{e} \mid \mathbf{y}, \widehat{\mathcal{P}})$ .

**M-step** We now update the parameter estimates with the maximizers of the expectation from the E-step. First, observe that the  $\boldsymbol{\beta}$  estimate from the posterior distribution is the same as the the dual estimator developed in § 3. To maximize the expectation with respect to  $\mathbf{H}$  and  $\sigma^2$ , we take the partial derivatives with respect to  $\mathbf{H}^{-1}$  and  $\sigma^{-2}$ , and set them to zero. This gives the following M-step updates:

$$\begin{aligned} \widehat{\mathbf{H}} &\leftarrow \frac{1}{m} \sum_{i=1}^m \left( \widehat{\boldsymbol{\gamma}}^{(i)} \widehat{\boldsymbol{\gamma}}^{(i)\top} + \widehat{\boldsymbol{\Sigma}}_{\boldsymbol{\gamma}^{(i)}} \right) \\ \widehat{\sigma}^2 &\leftarrow \widehat{\sigma}^2 + \frac{1}{n} \left[ \widehat{\mathbf{e}}^\top \widehat{\mathbf{e}} - \widehat{\sigma}^4 \text{tr}(\widehat{\mathbf{M}}^{-1}) \right]. \end{aligned} \quad (19)$$

The fast version of the above EM variant uses Algorithm 1 for computing the kernel. Note that the original  $\mathbf{X}$  is no longer needed after the SRHT projection. This provides additional space advantages as data  $\mathbf{X}$  can be preprocessed, and the Hadamard transform in Step 1 requires a small constant amount of memory. Overall, the per-iteration computational complexity of the EM algorithm is  $O(\max\{n^2 s_\epsilon, n^3\})$ .

## 5 THEORETICAL GUARANTEES

In this section, we provide an analysis of the difference in the parameters estimated via the approximate algorithms versus minimizing the  $L_2$ -regularized LMM. We are not proving consistency of our estimator—convergence of the parameter estimates to the population quantity. Consistency results for LMMS and-regularized LMMS were provided in (Schelldorfer et al., 2011; Cui et al., 2004; Hall and Yao, 2003). See the supplementary materials for proofs of the theorems in this section.

**Theorem 1** (Fixed-effect norm error). *Let  $\widehat{\boldsymbol{\beta}}$  be the fixed-effect coefficients estimated by (5) and  $\widehat{\boldsymbol{\beta}}'$  be the fixed-effect coefficients estimated by the approximate proce-*

ture in (16). Then, with probability at least  $1 - 3/n$

$$\frac{\|\widehat{\boldsymbol{\beta}} - \widehat{\boldsymbol{\beta}}'\|}{\|\widehat{\boldsymbol{\beta}}\|} \leq \frac{\epsilon}{1 - \epsilon} \frac{\|\boldsymbol{\Phi}^{-1}\|_2 \kappa(\boldsymbol{\Gamma})}{\frac{\|\boldsymbol{\Phi}\|_2^{-1}}{1 + \sqrt{2/3}\epsilon} + \lambda_{\min}(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})}$$

with  $\boldsymbol{\Gamma} := \boldsymbol{\Phi}^{-1} + \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}$ , or loosely

$$\frac{\|\widehat{\boldsymbol{\beta}} - \widehat{\boldsymbol{\beta}}'\|}{\|\widehat{\boldsymbol{\beta}}\|} \leq \frac{\epsilon(1 + \sqrt{2/3}\epsilon)}{1 - \epsilon} \kappa(\boldsymbol{\Phi}) \kappa(\boldsymbol{\Gamma})$$

for all  $0 \leq \epsilon < 1$ .

An intuitive interpretation of the theorem is that the fixed-effects coefficients estimator (16) has better accuracy when the predefined  $\boldsymbol{\Phi}$  is better conditioned and has smaller spectral norm. One can certainly improve the accuracy by setting a smaller  $\epsilon$ , which in turn uses more samples in Algorithm 1.

**Theorem 2** (AVC approximation errors). *Let  $\sigma_{AVC}^2$  and  $\widehat{\boldsymbol{\Lambda}}_{AVC}$  be computed using (12). Let  $\widehat{\sigma}_{AVC}'^2$  and  $\widehat{\boldsymbol{\Lambda}}'_{AVC}$  be computed using the same equations but with approximate kernel from Algorithm 1. Then, the following two statements hold jointly with probability at least  $1 - 3/n$ :*

$$\begin{aligned} |\widehat{\sigma}_{AVC}^2 - \widehat{\sigma}_{AVC}'^2| &\leq \epsilon \cdot \frac{\|\|\mathbf{X} \boldsymbol{\Phi} \mathbf{X}^\top\|\|_{n-q}}{n-q} \quad \text{and} \\ \|\widehat{\boldsymbol{\Lambda}}_{AVC} - \widehat{\boldsymbol{\Lambda}}'_{AVC}\|_2 &\leq \frac{\epsilon}{\widehat{\sigma}_{\min}(\mathbf{Z})^2} \left( \|\|\mathbf{X} \boldsymbol{\Phi} \mathbf{X}^\top\|\|_2 + \frac{\|\|\mathbf{X} \boldsymbol{\Phi} \mathbf{X}^\top\|\|_{n-q}}{n-q} \right). \end{aligned}$$

Note that the fraction of the Ky Fan norm does not exceed the spectral norm. A looser but more convenient bounds are  $|\widehat{\sigma}_{AVC}^2 - \widehat{\sigma}_{AVC}'^2| \leq \epsilon \|\|\mathbf{X} \boldsymbol{\Phi} \mathbf{X}^\top\|\|_2$  and  $\|\widehat{\boldsymbol{\Lambda}}_{AVC} - \widehat{\boldsymbol{\Lambda}}'_{AVC}\|_2 \leq 2\epsilon \sigma_{\min}(\mathbf{Z})^{-2} \|\|\mathbf{X} \boldsymbol{\Phi} \mathbf{X}^\top\|\|_2$ .

## 6 EXPERIMENTS

In this section, we conduct a simulation study as well as numerical experiments on real data. The simulation study demonstrates the accuracy of parameter estimation using the proposed Approximate Ridge LMM (arLMM) methods. We also examined the results on a real data example from the Wellcome Trust Case Control Consortium (WTCCC) study (The Wellcome Trust Case Control Consortium, 2007), which include about 14,000 cases from seven common diseases and a total of about 450,000 SNPs.

The main finding of the experiments is that the proposed approximate inference algorithms enjoy similar

predictive accuracy as state-of-the-art methods at a significantly reduced computation cost in practice. In particular, our Matlab prototype implementation is 6x faster than the optimized C implementation of the state-of-the-art BSLMM method for genome-wide association studies.

### 6.1 SIMULATION STUDIES

To evaluate parameter estimation, we consider two performance metrics. The first one is the correlation between the estimated and ground-truth fixed-effect coefficients. The second metric is the Negative Log Likelihood (NLL) of the standard LMM, which meaningfully reflects the quality of variance estimation.

For the simulation, we compare the performance of our non-iterative algorithm arLMM-AVC based on (16) and (12), the proposed multi-group variant arLMM-EM based on (19), the standard REML (Bates et al., 2015),  $L_1$ -regularized LMM lmmlasso (Schelldorfer et al., 2011), and CovexLasso using both  $L_1$ - and  $L_2$ -regularization (Jakubik, 2015).

**Synthetic data generation** The simulation is based on synthetic training and validation sets sampled from a fixed LMM distribution. The design matrices as well as the parameters for the fixed LMM are randomly generated. Specifically,

$$\begin{aligned} X_{ij} &\stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, 1) & Z_{ij}^{(k)} &\stackrel{\text{i.i.d.}}{\sim} \mathcal{U}(0, 1) \\ \boldsymbol{\gamma}^{(k)} &\stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(\mathbf{0}, \mathbf{K}^\top \mathbf{K}) & K_{ij} &\stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, 1) \\ \boldsymbol{\beta} &\sim \mathcal{N}(\mathbf{0}, \mathbf{I}) & \sigma^2 &\sim \mathcal{U}(0, d). \end{aligned}$$

Note that there are  $d$  random-effect variables with covariance  $\mathbf{K}^\top \mathbf{K}$ . Thus, the random-effect design matrix  $\mathbf{Z} \in \mathbb{R}^{n \times q}$ ,  $q = md$ , will be block-diagonal with diagonal blocks  $\mathbf{Z}^{(k)}$ . Given the number of observations  $n$ , we randomly sample  $n_k$  observations for each group  $k$ , where the fractions  $n_k/n$  are specified by the Dirichlet distribution with the concentration parameters  $(1, 1, \dots)^\top$ .

**Overdetermined settings** Let us first consider the standard setting  $n > p$ , which are supported by many parameter estimation algorithms of LMMs. We evaluate the performance of arLMM-AVC and arLMM-EM in a variety of  $p$ ,  $d$ , and  $m$  settings. The parameter estimates obtained using the proposed methods are compared with the estimates given by the standard REML (see e.g., (Kang et al., 2008; Lippert et al., 2011; Laird et al., 1987; Bates et al., 2015)) which is known to produce unbiased estimates.

(a) Correlation between estimated and true  $\beta$ 's.

(b) NLL at convergence.

Figure 1: Comparing the performance of parameter estimation on synthetic data with  $n = 1,000$  observations. Note that arLMM-AVC is only applicable to the single group setting. This figure shows that the arLMM-EM and arLMM-AVC achieve comparable estimation performance as REML.

Figure 1 shows the error for the fitted parameters using 1,000 observations sampled from the underlying LMM. The average results are reported over 10 runs on independently generated datasets. These generated datasets have the same number of observations  $n = 1,000$  but different settings of  $p$ ,  $d$ , and  $m$ .

As shown in Figure 1, arLMM-EM and arLMM-AVC exhibit comparable estimation accuracy as the standard REML. Note that arLMM-AVC is applicable only when  $m = 1$  (the first row of Figure 1). Since arLMM-AVC is based on non-iterative approximation to the variance components, the error is slighted higher than the others as expected.

**High-dimensional (underdetermined) setting** We also examined the performance of our model in the high-

dimensional setting where we are interested in variable selection based on the fixed-effects coefficients. In Table 2, we specify the three regimes for which we generate simulated data: an overdetermined LMM, a moderate-dimensional LMM, and a high-dimensional LMM. Each regime is characterized by  $n$ ,  $p$ ,  $d$ , and  $m$ , and an extra parameter  $s$ , the number of non-zeros in the ground-truth  $\beta_{\text{True}}$ . Since  $m > 1$  we did not apply arLMM-AVC.

Table 2: Regimes of data.

	$(n, p, d, m, s)$
LOW	$(100, 1000, 5, 3, 10)$
MOD	$(200, 10^4, 5, 3, 10)$
HIGH	$(10^4, 10^6, 10, 100, 100)$

Figure 2 reports variable selection results for arLMM-EM, lmmlasso (Schelldorfer et al., 2011), and ConvexLasso. All the settings in Table 2 have sparse ground-truth  $\beta_{\text{True}}$ . Figure 2 shows the fraction of the signal (non-zeros in  $\beta_{\text{True}}$ ) recovered in the estimate  $\hat{\beta}$ . We varied the regularization parameters to obtain  $\hat{\beta}$  with different sparsity  $\|\hat{\beta}\|_0$ . The entries with the largest magnitude of  $\hat{\beta}$  is considered the signal in these evaluations. As can be seen, arLMM-EM delivers a competitive signal recovery ratio for  $p = 10^3, 10^4$ , and scales to considerably large dimensions  $n = 10^4$  and  $p = 10^6$ , which the other two methods cannot handle.

## 6.2 GENOME WIDE ASSOCIATION STUDIES

LMMs have been used extensively for mapping traits in statistical genetics. The problem formulation is that of regressing a quantitative or categorical trait onto a high-dimensional vector of 450,000 single nucleotide polymorphisms (SNPs), or locations of discrete genetic variation, for each subject included in the study. The random effects are driven by population structure or the pairwise similarity or relatedness between individuals.

We compare our approximate estimator to the performance of a state-of-the-art estimator called BSLMM (Bayesian sparse linear mixed model) (Zhou et al., 2013). Specifically, we run BSLMM in its ridge-regression with mixed models setting, the fastest setting of the package for a fair comparison. In this setting BSLMM is computing the maximum a posteriori estimate of the regularized LMM. We compare performance on the Wellcome Trust Case Control Consortium (WTCCC) dataset of 14,000 cases of 7 diseases - bipolar disorder (BD), coronary artery disease (CAD), Crohn's disease (CD), hypertension (HT), rheumatoid arthritis (RA), type 1 diabetes (T1D), and type 2 diabetes (T2D) - and 3,000 shared controls. This dataset characterizes over 450,000 single nu-

Figure 2: Fraction of signals captured by  $\hat{\beta}$ . From left to right, the configurations are respectively LOW, MOD, and HIGH in Table 2. It shows that arLMM-EM performs competitively in variable selection.

Table 3: Comparing the prediction performance as well as the runtime of BSLMM and arLMM-AVC on the WTCCC dataset.  $\text{Corr}(\hat{\beta}_{\text{BSLMM}}, \hat{\beta}_{\text{arLMM-AVC}})$  denotes the correlation between the fixed-effect coefficient estimates given by BSLMM and arLMM-AVC.

DISEASE	TIME (MIN)		AUC		CORR ( $\hat{\beta}_{\text{BSLMM}}, \hat{\beta}_{\text{arLMM-AVC}}$ )

cleotide polymorphisms (SNPs), or locations of discrete genetic variation, for each subject included in the study. Disease status is indicated as a binary response (1 for disease case,  $-1$  for control). Each of the datasets had roughly equal numbers of cases and controls.

For this experiment, we adopted the same random-effect covariance parameterization used to control for population structure  $\theta \mathbf{X} \mathbf{X}^T / p$  as BSLMM, and used arLMM-AVC with AVCs (15) and (14). arLMM-AVC and BSLMM were run under identical conditions on each of the seven approximately 5,000-subject  $\times$  450,000-SNP datasets. This was the same experimental setup used to validate BSLMM in (Zhou et al., 2013).

Observed runtimes for each of the seven datasets are reported in Table 3. Correlation between the  $\hat{\beta}$  reported by arLMM-AVC and BSLMM in all cases was very high, 0.977 or greater.

We also compared disease status prediction by splitting each dataset into a training set comprised of 80% of subjects and a test set of the remaining 20%, selected at random. arLMM-AVC and BSLMM each estimated  $\hat{\beta}$  from the training set and attempted to predict disease status on the held-out set. We repeated this 20 times for each of the

seven datasets and evaluated performance of prediction on the held-out set by area under the ROC curve (AUC). These results are also given in Table 3. Predictive performance by arLMM-AVC and BSLMM was almost identical. Predicting disease status from genetic markers is hard and it is well known that the effect sizes of genetic variants are individually small and that a great deal of variance in the response will also be driven by environmental factors.

## 7 CONCLUSIONS

State-of-the-art parameter inference in LMMs requires computational complexity which depends at least linearly on the number of covariates  $p$  and generally relies on heuristics. In this paper, we presented scalable learning algorithms which have sublinear computational complexity in  $p$  and provide theoretical guarantees for the accuracy of parameter estimation. Our approach combines novel approximate estimators that use a kernel matrix of the observations and the subsampled randomized Hadamard transform. Experiments on synthetic and real data corroborate the theory.

## Abstract

We address the problem of causal discovery from data, making use of the recently proposed causal modeling framework of *modular structural causal models (mSCM)* to handle cycles, latent confounders and non-linearities. We introduce  $\sigma$ -connection graphs ( $\sigma$ -CG), a new class of mixed graphs (containing undirected, bidirected and directed edges) with additional structure, and extend the concept of  $\sigma$ -separation, the appropriate generalization of the well-known notion of d-separation in this setting, to apply to  $\sigma$ -CGs. We prove the closedness of  $\sigma$ -separation under marginalisation and conditioning and exploit this to implement a test of  $\sigma$ -separation on a  $\sigma$ -CG. This then leads us to the first causal discovery algorithm that can handle non-linear functional relations, latent confounders, cyclic causal relationships, and data from different (stochastic) perfect interventions. As a proof of concept, we show on synthetic data how well the algorithm recovers features of the causal graph of modular structural causal models.

## 1 INTRODUCTION

Correlation does not imply causation. To go beyond spurious probabilistic associations and infer the asymmetric causal relations we need sufficiently powerful models. Structural causal models (SCMs), also known as structural equation models (SEMs), provide a popular modeling framework (see [12, 25, 26, 32]) that is up to this task. Still, the problem of causal discovery from data is notoriously hard. Theory and algorithms need to address several challenges like probabilistic settings, stability under interventions, combining observational and

interventional data, latent confounders and marginalisation, selection bias and conditioning, faithfulness violations, cyclic causation like feedback loops and pairwise interactions, and non-linear functional relations in order to go beyond artificial simulation settings and become successful on real-world data.

Several algorithms for causal discovery have been introduced over the years. For the acyclic case without latent confounders, numerous constraint-based [25,32] and score-based approaches [6, 14, 17] exist. More sophisticated constraint-based [5, 25, 32, 34] and score-based approaches [4, 7, 8, 10, 11] can deal with latent confounders in the acyclic case. For the linear cyclic case, most algorithms assume no latent confounders [18, 27, 29], though some of the more recent ones allow for those [19, 30]. To the best of our knowledge, no algorithms have yet been proposed for the general non-linear cyclic case.

In this work we present a novel conditional independence constraint-based causal discovery algorithm that—up to the knowledge of the authors—is the first causal discovery algorithm that addresses most of the previously mentioned problems at once, notably non-linearities, cycles, latent confounders, and multiple interventional data sets, only excluding selection bias and faithfulness violations.

For this to work we build upon the theory of *modular structural causal models (mSCM)* introduced in [12]. mSCMs form a general and convenient class of structural causal models that can deal with cycles and latent confounders. The measure-theoretically rigorous presentation opens the door for general non-linear measurable functions and any kind of probability distributions (e.g. mixtures of discrete or continuous ones). mSCM are provably closed under any combination of perfect interventions and marginalisations (see [12]).

Unfortunately, it is known that the direct generalization of the *d-separation criterion* (also called m- or m\*-separation, see [9, 24, 25, 28, 33]), which relates the conditional independencies of the model to its underlying

graphical structure, does not apply in general if the structural equations are *non-linear* and the graph contains *cycles* (see [12, 31] or example 2.17).

Luckily, one key property of mSCMs is that the variables of the mSCM always entail the conditional independences implied by  $\sigma$ -separation, a non-naive generalization of the d/m/m\*-separation (see [12]), which also works in the presence of cycles, non-linearities and latent confounders, and reduces to d-separation in the acyclic case.

To prove the  $\sigma$ -separation criterion, the authors of [12] have constructed an extensive theory for directed graphs with hyperedges. As a first contribution in this paper we give a simplified but equivalent definition of mSCMs plainly in terms of directed graphs and prove the  $\sigma$ -separation criterion directly under weaker assumptions.

As a second contribution we extend the definition of  $\sigma$ -separation to mixed graphs (including also bi- and undirected edges) by introducing additional structure. We will refer to this class of mixed graphs as  $\sigma$ -connection graphs ( $\sigma$ -CG), since they are inspired by the d-connection graphs introduced by [19]. We prove that  $\sigma$ -CGs and  $\sigma$ -separation are closed under marginalisation and conditioning, in analogy with the d-connection graphs (d-CG) from [19].

The work of [19] provides an elegant approach to causal discovery using a weighted SAT solver to find the causal graph that is most compatible with (weighted) conditional independences in the data, encoding the notion of d-separation into *answer set programming (ASP)*, a declarative programming language with an expressive syntax for implementing discrete or integer optimization problems. Our third contribution is to adapt the approach of [19] by replacing d-separation by  $\sigma$ -separation and d-CGs by  $\sigma$ -CGs. The results mentioned above will then ensure all the needed properties to make the adapted algorithm of [19] applicable to general mSCMs, i.e., to non-linear causal models with cycles and latent confounders, under the additional assumptions of *no selection bias* and of  $\sigma$ -faithfulness.

Finally, as a proof of concept, we will show the effectiveness of our proposed algorithm in recovering features of the causal graphs of mSCMs from simulated data.

## 2 THEORY

### 2.1 MODULAR STRUCTURAL CAUSAL MODELS

Structural causal or equation models (SCM/SEM) usually start with a set of variables  $(X_v)_{v \in V}$  attached to a

graph  $G$  that satisfy (or are even defined by) equations of the form:

$$X_v = g_{\{v\}}(X_{\text{Pa}^G(v)}, E_v),$$

with a function  $g_{\{v\}}$  and noise variable  $E_v$  attached to each node  $v \in V$ . Here  $\text{Pa}^G(v)$  denotes the set of (direct causal) parents of  $v$ . In *linear* models the functions  $g_{\{v\}}$  are linear functions, in *acyclic* models the nodes of  $V$  form an acyclic graph  $G$ , and under *causal sufficiency* the variables  $E_v$  are independent (i.e. “no latent confounders”). The functions  $g_{\{v\}}$  are usually interpreted as *local causal mechanisms* that produce the values of  $X_v$  from the values of  $X_{\text{Pa}^G(v)}$  and  $E_v$ . These local mechanisms  $g_{\{v\}}$  are—in the causal setting—assumed to be stable even when one intervenes upon some of the variables, i.e. one makes a causal *local compatibility* assumption. One important observation now is that one can also consider the *global mechanism*  $g$  that maps the values of the latent variables  $(E_v)_{v \in V}$  to the values of the observed variables  $(X_v)_{v \in V}$ . The assumption of acyclicity or invertible linearity will then guarantee the *global compatibility* of all these mechanisms  $g_{\{v\}}$  and  $g$ . However, if we now abstain from assuming acyclicity or linearity, the global compatibility does not follow from the local compatibility anymore (see figure 1). So in a general consistent causal setting this needs to be *guaranteed or assumed*.

Figure 1: Gear analogy. Left: A cyclic mechanism that is locally compatible but not globally. Center: For acyclic mechanisms local compatibility implies global compatibility. Right: A cyclic mechanism that is locally and globally compatible. This shows that the assumption of global compatibility is needed when cycles are present.

The definition of modular structural causal models (mSCM) and the mentioned list of desirable properties basically follow directly from *causal* postulates:

**Postulate 2.1** (Causal postulates). *The observed world appears as the projection of an extended world such that:*

1. All latent and observed variables in this extended world are causally linked by a directed graph.
2. Every subsystem of this extended world can be expressed as the joint effect of its joint direct causes.
3. All these mechanisms are globally compatible.

Special subsystems of interest are the loops of a graph.

**Definition 2.2** (Loops). *Let  $G = (V, E)$  be a directed graph (with or without cycles).*

1. A loop of  $G$  is a set of nodes  $S \subseteq V$  such that for every two nodes  $v_1, v_2 \in S$  there are two directed paths  $v_1 \rightarrow \dots \rightarrow v_2$  and  $v_2 \rightarrow \dots \rightarrow v_1$  in  $G$  with all the intermediate nodes also in  $S$  (if any). The single element sets  $S = \{v\}$  are also considered as loops.
2. The strongly connected component of  $v$  in  $G$  is defined to be:

$$\text{Sc}^G(v) := \text{Anc}^G(v) \cap \text{Desc}^G(v),$$

*the set of nodes that are both ancestors and descendants of  $v$  (including  $v$  itself).*

3. Let  $\mathcal{L}(G) := \{S \subseteq G \mid S \text{ a loop of } G\}$  be the loop set of  $G$ .

**Remark 2.3.** *Note that the loop set  $\mathcal{L}(G)$  contains all single element loops  $\{v\} \in \mathcal{L}(G)$ ,  $v \in V$ , as the smallest loops and all strongly connected components  $\text{Sc}^G(v) \in \mathcal{L}(G)$ ,  $v \in V$ , as the largest loops, but also all non-trivial intermediate loops  $S$  with  $\{v\} \subsetneq S \subsetneq \text{Sc}^G(v)$  inside the strongly connected components (if existent). If  $G$  is acyclic then  $\mathcal{L}(G)$  only consists of the single element loops:  $\mathcal{L}(G) = \{\{v\} \mid v \in V\}$ .*

The definition of mSCM is made in such a way that it will automatically incorporate the causal postulates 2.1. In the following, all spaces are meant to be equipped with  $\sigma$ -algebras, forming standard measurable spaces, and all maps to be measurable.

**Definition 2.4** (Modular Structural Causal Model, [12]). *A modular structural causal model (mSCM) by definition consists of:*

1. a set of nodes  $V^+ = U \dot{\cup} V$ , where elements of  $V$  correspond to observed variables and elements of  $U$  to latent variables,
2. an observation/latent space  $\mathcal{X}_v$  for every  $v \in V^+$ ,  $\mathcal{X} := \prod_{v \in V^+} \mathcal{X}_v$ ,
3. a product probability measure  $\mathbb{P} := \mathbb{P}_U = \otimes_{u \in U} \mathbb{P}_u$  on the latent space  $\prod_{u \in U} \mathcal{X}_u$ ,<sup>1</sup>

<sup>1</sup>The assumption of independence of the noise variables here is not to be confused with causal sufficiency. The noise variables here might have two or more child nodes and thus can play the role of latent confounders. The independence assumption here also does not restrict the model class. If they were dependent we would just consider them as one variable and use a different graph that encoded this.

4. a directed graph structure  $G^+ = (V^+, E^+)$  with the properties:<sup>2</sup>

$$(a) V = \text{Ch}^{G^+}(U),$$

$$(b) \text{Pa}^{G^+}(U) = \emptyset,<sup>3</sup>$$

$$(c) \text{Ch}^{G^+}(u_1) \not\subseteq \text{Ch}^{G^+}(u_2) \text{ for every two distinct } u_1, u_2 \in U,<sup>3</sup>$$

where  $\text{Ch}^{G^+}$  and  $\text{Pa}^{G^+}$  stand for children and parents in  $G^+$ , resp.,

5. a system of structural equations  $g = (g_S)_{S \in \mathcal{L}(G^+): S \subseteq V}$ :

$$g_S : \prod_{v \in \text{Pa}^{G^+}(S) \setminus S} \mathcal{X}_v \rightarrow \prod_{v \in S} \mathcal{X}_v,<sup>24</sup>$$

that satisfy the following global compatibility conditions: For every nested pair of loops  $S' \subseteq S \subseteq V$  of  $G^+$  and every element  $x_{\text{Pa}^{G^+}(S) \cup S} \in \prod_{v \in \text{Pa}^{G^+}(S) \cup S} \mathcal{X}_v$  we have the implication:

$$\begin{aligned} g_S(x_{\text{Pa}^{G^+}(S) \setminus S}) &= x_S \\ \implies g_{S'}(x_{\text{Pa}^{G^+}(S') \setminus S'}) &= x_{S'}, \end{aligned}$$

where  $x_{\text{Pa}^{G^+}(S') \setminus S'}$  and  $x_{S'}$  denote the corresponding components of  $x_{\text{Pa}^{G^+}(S) \cup S}$ .

The mSCM can be summarized by the tuple  $M = (G^+, \mathcal{X}, \mathbb{P}, g)$ .

**Remark 2.5.** *Given the mechanisms attached to the nodes  $g_{\{v\}}$  the existence (and compatibility) of the other mechanisms  $g_S$  for non-trivial loops  $S$  can be guaranteed under certain conditions, e.g. trivially in the acyclic case, or if every cycle is contractive (see subsection 4.1), or more generally if the cycles are “uniquely solvable” (see [3, 12]).*

We are now going to define the actual random variables  $(X_u)_{u \in V^+}$  attached to any mSCM.

**Remark 2.6.** *Let  $M = (G^+, \mathcal{X}, \mathbb{P}, g)$  be a mSCM with  $G^+ = (U \dot{\cup} V, E^+)$ .*

<sup>2</sup>Even though we allow for selfloops in the directed graph  $G^+$  we note that the causal mechanisms  $g_S$  will depend only on  $\text{Pa}^{G^+}(S) \setminus S$ , removing the self-dependence on the functional level. Otherwise, the functions  $g_S$  would not hold up to a direct interventional interpretation and one would want to replace them with functions that do.

<sup>3</sup>This assumption is only necessary to give the mSCM a “reduced/summarized” form. In practice one could allow for more latent variables and more complex latent structure.

<sup>4</sup>Note that the index set runs over all “observable loops”  $S \subseteq V$ ,  $S \in \mathcal{L}(G^+)$ , which contains the usual single element sets  $S = \{v\}$ , which relate to the usual mechanisms  $g_{\{v\}}$ .

Figure 2: The graph  $G^+$  of a modular structural causal model (mSCM). The observed variables  $v_i \in V$  are in blue and the latent variables  $u_j \in U$  are in red. We have the four observed strongly connected components:  $\{v_1\}$ ,  $\{v_2, v_3, v_4, v_5\}$ ,  $\{v_6, v_7\}$ ,  $\{v_8\}$ .

1. The latent variables  $(X_u)_{u \in U}$  are given by the canonical projections  $E_u : \prod_{u' \in U} \mathcal{X}_{u'} \rightarrow \mathcal{X}_u$  and are jointly  $\mathbb{P}$ -independent (by 3). Sometimes we will write  $(E_u)_{u \in U}$  instead of  $(X_u)_{u \in U}$  to stress their interpretation as error/noise variables.
2. The observed variables  $(X_v)_{v \in V}$  are inductively defined by:

$$X_v := g_{S,v}((X_w)_{w \in \text{Pa}^{G^+}(S) \setminus S}),$$

where  $S := \text{Sc}^{G^+}(v) := \text{Anc}^{G^+}(v) \cap \text{Desc}^{G^+}(v)$  and where the second index  $v$  refers to the  $v$ -component of  $g_S$ . Note that the inductive definition is possible because when “aggregating” each of the biggest cycles  $\text{Sc}^{G^+}(v)$  into one node then only an acyclic graph is left, which can be totally ordered.

3. By the compatibility condition for  $g$  we then have that for every  $S \in \mathcal{L}(G^+)$  with  $S \subseteq V$  the following equality holds:

$$X_S = g_S(X_{\text{Pa}^{G^+}(S) \setminus S}),$$

where we put  $X_A := (X_v)_{v \in A}$  for subsets  $A$ .

As a consequence of the convenient definition 2.4 all the following desirable constructions (like marginalisations and interventions) are easily seen to be well-defined (for proofs see [12]). Note that already defining these constructions was a key challenge in the theory of causal models in the presence of cycles (see [3, 12], a.o.).

**Definition 2.7.** Let  $M = (G^+, \mathcal{X}, \mathbb{P}, g)$  be a mSCM with  $G^+ = (U \dot{\cup} V, E^+)$ .

1. By plugging the functions  $g_S$  into each other we can define the marginalised mSCM  $M'$  w.r.t. a subset  $W \subseteq V$ . For example, when marginalizing out  $W = \{w\}$  we can define (for the non-trivial case  $w \in \text{Pa}^{G^+}(S) \setminus S$ ):

$$g_{S',v}(x_{\text{Pa}^{G'}(S') \setminus S'}) := g_{S,v}(x_{\text{Pa}^{G^+}(S) \setminus (S \cup \{w\})}, g_{\{w\}}(x_{\text{Pa}^{G^+}(w) \setminus \{w\}})),$$

where  $G'$  is the marginalised graph of  $G^+$ ,  $S' \subseteq V'$  is any loop of  $G'$  and  $S$  the corresponding induced loop in  $G^+$ .

2. For a subset  $I \subseteq V$  and a value  $x_I \in \prod_{v \in I} \mathcal{X}_v$  we define the intervened graph  $G'$  by removing all the edges from parents of  $I$  to  $I$ . We put  $X_u^{\text{do}(x_I)} := X_u$  for  $u \in U$  and  $X_I^{\text{do}(x_I)} := x_I$  and inductively ( $S := \text{Sc}^{G'}(v)$ ):

$$X_v^{\text{do}(x_I)} := g_{S,v}(X_{\text{Pa}^{G'}(S) \setminus S}^{\text{do}(x_I)}).$$

By selecting all functions  $g_S$  where  $S$  is still a loop in the intervened graph  $G'$  we get the post-interventional mSCM  $M'$ . These constructions give us all interventional distributions, e.g. (cf. [25]):

$$\mathbb{P}(X_A | \text{do}(x_I), X_B) := \mathbb{P}(X_A^{\text{do}(x_I)} | X_B^{\text{do}(x_I)}).$$

Instead of fixing  $X_I^{\text{do}(x_I)}$  to a value  $x_I$  we could also specify a distribution  $\mathbb{P}'_I$  for it (“randomization”). In this way we define stochastic interventions  $\text{do}(\xi_I)$  with an independent random variable  $\xi_I$  taking values in  $\mathcal{X}_I$  and get a  $\mathbb{P}^{\text{do}(I)}$  similarly.

## 2.2 $\Sigma$ -SEPARATION IN MSCMS AND $\Sigma$ -CONNECTION GRAPHS

We now introduce  $\sigma$ -separation as a generalization of d-separation directly on the level of mixed graphs. To make the definition stable under marginalisation and conditioning we need to carry extra structure. The resulting graphs will be called  $\sigma$ -connection graphs ( $\sigma$ -CG), where the name is inspired by [19]. An example that shall clarify the difference between d- and  $\sigma$ -separation is given later in figure 2 and table 1.

**Definition 2.8** ( $\sigma$ -Connection Graphs ( $\sigma$ -CG)). A  $\sigma$ -connection graph ( $\sigma$ -CG) is a mixed graph  $G$  with a set of nodes  $V$  and directed ( $\rightarrow$ ), undirected ( $—$ ) and bi-directed ( $\leftrightarrow$ ) edges, together with an equivalence relation  $\sim_\sigma$  on  $V$  that has the property that every equivalence class  $\sigma(v)$ ,  $v \in V$ , is a loop in the underlying directed graph structure:  $\sigma(v) \in \mathcal{L}(G)$ . Undirected self-loops ( $v — v$ ) are allowed, (bi)-directed self-loops ( $v \rightarrow v$ ,  $v \leftrightarrow v$ ) are not.

In particular, every node is assigned to a unique fixed loop  $\sigma(v)$  in  $G$  with  $v \in \sigma(v)$  and two of such loops  $\sigma(v_1)$ ,  $\sigma(v_2)$  are either identical or disjoint. The reason for why we need such structure is illustrated in figure 5.

**Definition 2.9** ( $\sigma$ -Open Path in a  $\sigma$ -CG). Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$  and  $Z \subseteq V$  a subset. Consider

a path  $\pi$  in  $G$  with  $n \geq 1$  nodes:

$$v_1 \rightleftarrows \dots \rightleftarrows v_n.^5$$

The path will be called  $Z$ - $\sigma$ -open if:

1. the endnodes  $v_1, v_n \notin Z$ , and
2. every triple of adjacent nodes in  $\pi$  that is of the form:

(a) collider:

$$v_{i-1} \rightleftarrows v_i \rightleftarrows v_{i+1},$$

satisfies  $v_i \in Z$ ,

(b) (non-collider) left chain:

$$v_{i-1} \leftarrow v_i \rightleftarrows v_{i+1},$$

satisfies  $v_i \notin Z$  or  $v_i \in Z \cap \sigma(v_{i-1})$ ,

(c) (non-collider) right chain:

$$v_{i-1} \rightleftarrows v_i \rightarrow v_{i+1},$$

satisfies  $v_i \notin Z$  or  $v_i \in Z \cap \sigma(v_{i+1})$ ,

(d) (non-collider) fork:

$$v_{i-1} \leftarrow v_i \rightarrow v_{i+1},$$

satisfies  $v_i \notin Z$  or  $v_i \in Z \cap \sigma(v_{i-1}) \cap \sigma(v_{i+1})$ ,

(e) (non-collider) with undirected edge:

$$v_{i-1} \text{ --- } v_i \rightleftarrows v_{i+1},$$

$$v_{i-1} \rightleftarrows v_i \text{ --- } v_{i+1},$$

satisfies  $v_i \notin Z$ .

The difference between  $\sigma$ - and  $d$ -separation lies in the additional conditions involving  $Z \cap \sigma(v_{i\pm 1})$ . The intuition behind them is that the dependence structure inside a loop  $\sigma(v_i)$  is so strong that non-colliders can only be blocked by conditioning if an edge is pointing out of the loop (see example 2.17 and table 1).

Similar to  $d$ -separation we can now define  $\sigma$ -separation in a  $\sigma$ -CG.

**Definition 2.10** ( $\sigma$ -Separation in a  $\sigma$ -CG). *Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$ . Let  $X, Y, Z \subseteq V$  be subsets.*

1. We say that  $X$  and  $Y$  are  $\sigma$ -connected by  $Z$  or not  $\sigma$ -separated by  $Z$  if there exists a path  $\pi$  (with some  $n \geq 1$  nodes) in  $G$  with one endnode in  $X$  and one endnode in  $Y$  that is  $Z$ - $\sigma$ -open. In symbols this statement will be written as follows:

$$X \underset{G}{\overset{\sigma}{\not\perp}} Y | Z.$$

<sup>5</sup>The stacked edges are meant to be read as an ‘‘OR’’ at each place independently. We also allow for repeated nodes in the paths.

2. Otherwise, we will say that  $X$  and  $Y$  are  $\sigma$ -separated by  $Z$  and write:

$$X \underset{G}{\overset{\sigma}{\perp}} Y | Z.$$

**Remark 2.11.** 1. The finest/trivial  $\sigma$ -CG structure of a mixed graph  $G$  is given by  $\sigma(v) := \{v\}$  for all  $v \in V$ . In this way  $\sigma$ -separation in  $G$  coincides with the usual notion of  $d$ -separation in a  $d$ -connection graph ( $d$ -CG)  $G$  (see [19]). We will take this as the definition of  $d$ -separation and  $d$ -CG in the following.

2. The coarsest  $\sigma$ -CG structure of a mixed graph  $G$  is given by  $\sigma(v) := \text{Sc}^G(v) := \text{Anc}^G(v) \cap \text{Desc}^G(v)$  w.r.t. the underlying directed graph. Note that the definition of strongly connected component totally ignores the bi- and undirected edges of the  $\sigma$ -CG.
3. In any  $\sigma$ -CG we will always have that  $\sigma$ -separation implies  $d$ -separation, since every  $Z$ - $d$ -open path is also  $Z$ - $\sigma$ -open because  $\{v\} \subseteq \sigma(v)$ .
4. If a  $\sigma$ -CG  $G$  is acyclic (implying  $\text{Sc}^G(v) = \{v\}$ ) then  $\sigma$ -separation coincides with  $d$ -separation.

We now want to ‘‘hide’’ or marginalise out the latent nodes  $u \in U$  from the graph of any mSCM and represent their induced dependence structure with bidirected edges.

**Definition 2.12** (Induced  $\sigma$ -CG of a mSCM). *Let  $M = (G^+, \mathcal{X}, \mathbb{P}, g)$  be a mSCM with  $G^+ = (U \dot{\cup} V, E^+)$ . The induced  $\sigma$ -CG  $G$  of  $M$ , also referred to as the causal graph  $G$  of  $M$  is defined as follows:*

1. The nodes of  $G$  are all  $v \in V$ , i.e. all observed nodes of  $G^+$ .
2.  $G$  contains all the directed edges of  $G^+$  whose endnodes are both in  $V$ , i.e. observed.
3.  $G$  contains the bidirected edge  $v \leftrightarrow w$  with  $v, w \in V$  if and only if  $v \neq w$  and there exists a  $u \in U$  with  $v, w \in \text{Ch}^{G^+}(u)$ , i.e.  $v$  and  $w$  have a common latent confounder.
4.  $G$  contains no undirected edges.
5. We put  $\sigma(v) := \text{Sc}^G(v) = \text{Anc}^G(v) \cap \text{Desc}^G(v)$ .

**Remark 2.13.** Caution must be applied when going from  $G^+$  to  $G$ : It is possible that three observed nodes  $v_1, v_2, v_3$  have one joint latent common cause  $u_1$ , which can be read off  $G^+$ . This information will get lost when going from  $G^+$  to  $G$ , as we will represent this with three bidirected edges.  $G$  will nonetheless capture the conditional independence relations (see Theorem 2.14).

We now present the most important ingredient for our constraint-based causal discovery algorithm, namely a generalized directed global Markov property that relates the underlying causal graph ( $\sigma$ -CG)  $G$  of any mSCM  $M$  to the conditional independencies of the observed random variables  $(X_v)_{v \in V}$  via a  $\sigma$ -separation criterion.

**Theorem 2.14** ( $\sigma$ -Separation Criterion, see Corollary B.3). *The observed variables  $(X_v)_{v \in V}$  of any mSCM  $M$  satisfy the  $\sigma$ -separation criterion w.r.t. the induced  $\sigma$ -CG  $G$ . In other words, for all subsets  $W, Y, Z \subseteq V$  we have the implication:*

$$W \perp\!\!\!\perp_G^\sigma Y \mid Z \implies X_W \perp\!\!\!\perp_{\mathbb{P}} X_Y \mid X_Z.$$

Figure 3: The induced  $\sigma$ -connection graph (causal graph) of the modular structural causal model (mSCM) of figure 2, with  $\sigma$ -equivalence classes  $\{\{v_1\}, \{v_2, v_3, v_4, v_5\}, \{v_6, v_7\}, \{v_8\}\}$ .

Table 1: d- and  $\sigma$ -separation in the  $\sigma$ -connection graph  $G$  from figure 3.  $\sigma$ -separation implies d-separation, but i.g. d-separation encodes more conditional independencies than  $\sigma$ -separation:

d-separation	$\sigma$ -separation
$\{v_2\} \perp\!\!\!\perp_G^d \{v_4\} \mid \{v_3, v_5\}$	$\{v_2\} \not\perp\!\!\!\perp_G^\sigma \{v_4\} \mid \{v_3, v_5\}$
$\{v_1\} \perp\!\!\!\perp_G^d \{v_6\}$	$\{v_1\} \perp\!\!\!\perp_G^\sigma \{v_6\}$
$\{v_1\} \perp\!\!\!\perp_G^d \{v_6\} \mid \{v_3, v_5\}$	$\{v_1\} \not\perp\!\!\!\perp_G^\sigma \{v_6\} \mid \{v_3, v_5\}$
$\{v_1\} \not\perp\!\!\!\perp_G^d \{v_8\}$	$\{v_1\} \not\perp\!\!\!\perp_G^\sigma \{v_8\}$
$\{v_1\} \perp\!\!\!\perp_G^d \{v_8\} \mid \{v_3, v_5\}$	$\{v_1\} \not\perp\!\!\!\perp_G^\sigma \{v_8\} \mid \{v_3, v_5\}$
$\{v_1\} \perp\!\!\!\perp_G^d \{v_8\} \mid \{v_4\}$	$\{v_1\} \perp\!\!\!\perp_G^\sigma \{v_8\} \mid \{v_4\}$

If we want to infer the causal graph ( $\sigma$ -CG)  $G$  of a mSCM from data with help of conditional independence tests in practice we usually need to assume also the reverse implication of the  $\sigma$ -separation criterion from 2.14 for the observational distribution  $\mathbb{P}(X_V)$  and the relevant interventional distributions  $\mathbb{P}(X_V \mid \text{do}(\xi_I))$  (see 2.7). This will be called  $\sigma$ -faithfulness.

**Definition 2.15** ( $\sigma$ -faithfulness). *We will say that the tuple  $(G, \mathbb{P})$  is  $\sigma$ -faithful if for every three subsets  $W, Y, Z \subseteq V$  we have the equivalence:*

$$W \perp\!\!\!\perp_G^\sigma Y \mid Z \iff X_W \perp\!\!\!\perp_{\mathbb{P}} X_Y \mid X_Z.$$

**Remark 2.16** (Strong  $\sigma$ -completeness, cf. [22]). *We do believe that the generic non-linear mSCM is  $\sigma$ -faithful to  $G$ , as the needed conditional dependence structure in all our simulated (sufficiently non-linear) cases was observed (cf. example 2.17). But proving such a strong  $\sigma$ -completeness result is difficult (and to our knowledge only done for multinomial and linear Gaussian DAG models, see [22]) and left for future research. Further note that the class of linear models, which even follow d-separation, would i.g. not be considered  $\sigma$ -faithful. Since linear models are of measure zero in the bigger class of general mSCMs this would not contradict our conjecture.*

**Example 2.17.** *Consider a directed four-cycle, e.g. the subgraph  $\{v_2, v_3, v_4, v_5\}$  from figure 2, where all other observed nodes are assumed to be absent. Consider only the non-linear causal mechanisms given by ( $i = 3, 4, 5$ ):*

$$\begin{aligned} g_{\{v_2\}}(X_5, E_1) &:= \tanh(0.9 \cdot X_5 + 0.5) + E_1, \\ g_{\{v_i\}}(X_{i-1}, E_i) &:= \tanh(0.9 \cdot X_{i-1} + 0.5) + E_i, \end{aligned}$$

where  $E_1, E_3, E_4, E_5$  are assumed to be independent. The equations  $X_i = g_{\{v_i\}}(X_{i-1}, E_i)$  and the one for  $X_2$  will imply the conditional dependence

$$X_2 \not\perp\!\!\!\perp_{\mathbb{P}} X_4 \mid (X_3, X_5),$$

which can be checked by computations and/or simulations. As one can read off table 1, d-separation fails to express the dependence, in contrast to  $\sigma$ -separation, which captures it correctly.

### 2.3 MARGINALISATION AND CONDITIONING IN $\Sigma$ -CONNECTION GRAPHS

Inspired by [19] we will define marginalisation and conditioning operations on  $\sigma$ -connection graphs ( $\sigma$ -CG) and prove the closedness of  $\sigma$ -separation (and thus its criterion) under these operations. These are key results to extend the algorithm of [19] to the setting of mSCMs.

**Definition 2.18** (Marginalisation of a  $\sigma$ -CG). *Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$  and  $w \in V$ ,  $W := \{w\}$ . We define the marginalised  $\sigma$ -CG  $G^W$  with set of nodes  $V \setminus W$  via the rules for  $v_1, v_2 \in V \setminus W$ :*

$v_1 \overset{a}{\circ} \overset{b}{\circ} v_2 \in G^W$  with arrow heads/tails  $a$  and  $b$  if and only if there exists:

1.  $v_1 \overset{a}{\circ} \overset{b}{\circ} v_2$  in  $G$ , or
2.  $v_1 \overset{a}{\circ} w \overset{q}{\circ} \overset{b}{\circ} v_2$  in  $G$ , or
3.  $v_1 \overset{a}{\circ} \overset{q}{\circ} w \overset{b}{\circ} v_2$  in  $G$ , or
4.  $v_1 \overset{a}{\circ} \rightarrow w \leftarrow \overset{b}{\circ} v_2$  in  $G$ .

Note that directed paths in  $G$  have no colliders, so loops in  $G$  map to loops in  $G^W$  (if not empty). Thus we have the induced  $\sigma$ -CG structure  $\sim_\sigma$  on  $G^W$ .

**Definition 2.19** (Conditioning of a  $\sigma$ -CG). *Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$  and  $c \in V$ ,  $C := \{c\}$ . We define the conditioned  $\sigma$ -CG  $G_C$  with set of nodes  $V \setminus C$  via the rules for  $v_1, v_2 \in V \setminus C$ :*

$v_1 a \overset{\sigma}{\leftarrow} v_2 \in G_C$  if and only if there exists:

1.  $v_1 a \overset{\sigma}{\leftarrow} v_2$  in  $G$ , or
2.  $v_1 a \overset{\sigma}{\rightarrow} c \overset{\sigma}{\leftarrow} v_2$  in  $G$ , or
3.  $v_1 a \overset{\sigma}{\leftarrow} c \overset{\sigma}{\leftarrow} v_2$  in  $G$ ,  $\sigma(v_1) = \sigma(c)$ , or
4.  $v_1 a \overset{\sigma}{\rightarrow} c \overset{\sigma}{\rightarrow} v_2$  in  $G$ ,  $\sigma(c) = \sigma(v_2)$ , or
5.  $v_1 a \overset{\sigma}{\leftarrow} c \overset{\sigma}{\rightarrow} v_2$  in  $G$ ,  $\sigma(v_1) = \sigma(c) = \sigma(v_2)$ .

Note that directed paths in  $\sigma(v)$  in  $G$  condition to directed paths, so loops in  $\sigma(v)$  in  $G$  map to loops in  $G_C$  (if not empty). Thus we have a well-defined induced  $\sigma$ -CG structure  $\sim_\sigma$  on  $G_C$ .

The proofs of the following theorem, stating the closedness of  $\sigma$ -separation under marginalisation and conditioning, can be found in the supplementary material (Theorem A.1 and Theorem A.2). See also figure 5.

**Theorem 2.20.** *Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$  and  $X, Y, Z \subseteq V$  any subsets. For any nodes  $w, c \in V \setminus (X \cup Y \cup Z)$ ,  $W := \{w\}$ ,  $C := \{c\}$ , we then have the equivalences:*

$$\begin{aligned} X \underset{G^W}{\perp\!\!\!\perp} Y | Z &\iff X \underset{G}{\perp\!\!\!\perp} Y | Z, \\ X \underset{G_C}{\perp\!\!\!\perp} Y | Z &\iff X \underset{G}{\perp\!\!\!\perp} Y | Z \cup C. \end{aligned}$$

**Corollary 2.21.** *Let  $G$  be a  $\sigma$ -CG with set of nodes  $V$  and  $X, Y, Z \subseteq V$  pairwise disjoint subsets and  $W := V \setminus (X \cup Y \cup Z)$ . Then we have the equivalence:*

$$X \underset{G}{\perp\!\!\!\perp} Y | Z \iff X \underset{G_Z^W}{\perp\!\!\!\perp} Y,$$

where  $G_Z^W$  is any  $\sigma$ -CG with set of nodes  $X \cup Y$  obtained by marginalising out all the nodes from  $W$  and conditioning on all the nodes from  $Z$  in any order. This means that if  $X = \{x\}$  and  $Y = \{y\}$  then  $x$  and  $y$  are  $\sigma$ -separated by  $Z$  in  $G$  if and only if  $x$  and  $y$  are not connected by any edge in the  $\sigma$ -CG  $G_Z^W$ .

It is also tempting to introduce an intervention operator directly on the level of  $\sigma$ -CGs. However, since the interplay between conditioning and intervention is complicated (e.g. they do not commute i.g.) we do not investigate this further in this paper. The intervention operator on the level of mSCMs will be enough for our purposes as we assume no pre-interventional selection bias and then only encounter observational or post-interventional conditioning, which is covered by our framework.

### 3 ALGORITHM

In this section, we propose an algorithm for causal discovery that is based on the theory in the previous section. Given that theory, our proposed algorithm is a straightforward modification of the algorithm by [19]. The main idea is to formulate the causal discovery problem as an optimization problem that aims at finding the causal graph that best matches the data at hand. This is done by encoding the rules for conditioning, marginalisation, and intervention (see below) on a  $\sigma$ -CG into Answer Set Programming (ASP), an expressive declarative programming language based on stable model semantics that supports optimization [15, 20]. The optimization problem can then be solved by employing an off-the-shelf ASP solver.

#### 3.1 CAUSAL DISCOVERY WITH $\Sigma$ -CONNECTION GRAPHS

Let  $M = (G^+, \mathcal{X}, \mathbb{P}, g)$  be a mSCM with  $G^+ = (U \dot{\cup} V, E^+)$  and  $I \subseteq V$  a subset. Consider a (stochastic) perfect intervention  $\text{do}(\xi_I)$  that enforces  $X_I = \xi_I$  for an independent random variable  $\xi_I$  taking values in  $\mathcal{X}_I$ . Denote the (unique) induced distribution of the intervened mSCM  $M_{\text{do}(\xi_I)}$  by  $\mathbb{P}^{\text{do}(I)}$ , and the causal graph (i.e., induced  $\sigma$ -CG of the intervened mSCM on the observed variables) by  $G_{\text{do}(I)} = (G_{\text{do}(I)}^+)^U$ .

Under  $\mathbb{P}^{\text{do}(I)}$ , the observed variables  $(X_v)_{v \in V}$  satisfy the  $\sigma$ -separation criterion w.r.t.  $G_{\text{do}(I)}$  by Theorem 2.14. For the purpose of causal discovery, we will in addition assume  $\sigma$ -faithfulness (Definition 2.15), i.e., that each conditional independence between observed variables is due to a  $\sigma$ -separation in the causal graph. Taken together, and by applying Corollary 2.21, we get for all subsets  $W, Y, Z \subseteq V$  the equivalences:

$$\begin{aligned} X_W \underset{\mathbb{P}^{\text{do}(I)}}{\perp\!\!\!\perp} X_Y | X_Z &\iff W \underset{G_{\text{do}(I)}}{\perp\!\!\!\perp} Y | Z \\ &\iff W \underset{(G_{\text{do}(I)})_Z}{\perp\!\!\!\perp} Y. \end{aligned} \quad (1)$$

If  $W = \{w\}$  and  $Y = \{y\}$  consist of a single node each, the latter can be easily checked by testing whether  $w$  is non-adjacent to  $y$  in  $(G_{\text{do}(I)})_Z^{V \setminus W \cup Y \cup Z}$ .

#### 3.2 CAUSAL DISCOVERY AS AN OPTIMIZATION PROBLEM

Following [19], we formulate causal discovery as an optimization problem where a certain loss function is optimized over possible causal graphs. This loss function sums the weights of all the inputs that are violated assuming a certain underlying causal graph.

The input for the algorithm is a list  $S = ((w_j, y_j, Z_j, I_j, \lambda_j))_{j=1}^n$  of weighted conditional independence statements. Here, the weighted statement  $(w_j, y_j, Z_j, I_j, \lambda_j)$  with  $w_j, y_j \in V$ ,  $Z_j, I_j \subseteq V$ , and  $\lambda_j \in \mathbb{R} := \mathbb{R} \cup \{-\infty, +\infty\}$  encodes that  $X_{w_j} \perp\!\!\!\perp_{\mathbb{P}^{\text{do}(X_{I_j})}} X_{y_j} \mid X_{Z_j}$  holds with confidence  $\lambda_j$ , where a finite value of  $\lambda_j$  gives a “soft constraint” and a value of  $\lambda_j = \pm\infty$  imposes a “hard constraint”. Positive weights encode that we have empirical support *in favor* of the independence, whereas negative weights encode empirical support *against* the independence (in other words, in favor of *dependence*).

As in [19], we define a loss function that measures the amount of evidence *against* the hypothesis that the data was generated by an mSCM with causal graph  $G$ , by simply summing the absolute weights of the input statements that conflict with  $G$  under the  $\sigma$ -Markov and  $\sigma$ -faithfulness assumptions:

$$\begin{aligned} \mathcal{L}(G, S) \\ := \sum_{(w_j, y_j, Z_j, I_j, \lambda_j) \in S} \lambda_j (\mathbb{1}_{\lambda_j > 0} - \mathbb{1}_{w_j \perp\!\!\!\perp_{\sigma_{\text{do}(I_j)}} y_j \mid Z_j}) \end{aligned} \quad (2)$$

where  $\mathbb{1}$  is the indicator function. This loss function differs from the one used in [19] in that we use  $\sigma$ -separation instead of d-separation. Causal discovery can now be formulated as the optimization problem:

$$G^* = \arg \min_{G \in \mathbb{G}(V)} \mathcal{L}_R(G, S) \quad (3)$$

where  $\mathbb{G}(V)$  denotes the set of all possible causal graphs with variables  $V$ .

The optimization problem (3) may have multiple optimal solutions, because the underlying causal graph may not be identifiable from the inputs. Nonetheless, some of the features of the causal graph (e.g., the presence or absence of a certain directed edge) may still be identifiable. We employ the method proposed by [21] for scoring the confidence that a certain feature  $f$  is present by calculating the difference between the optimal losses under the additional hard constraints that the feature  $f$  is present vs. that the feature  $f$  is absent in  $G$ .

In our experiments, we will use the weights proposed in [21]:  $\lambda_j = \log p_j - \log \alpha$ , where  $p_j$  is the p-value of a statistical test with independence as null hypothesis, and  $\alpha$  is a significance level (e.g., 1%). This test is performed on the data measured in the context of the (stochastic) perfect intervention  $I_j$ . These weights have the desirable property that independences typically get a lower absolute weight than strong dependences. For the conditional independence test, we use a standard partial

correlation test after marginal rank-transformation of the data so as to obtain marginals with standard-normal distributions.

### 3.3 FORMULATING THE OPTIMIZATION PROBLEM IN ASP

In order to calculate the loss function (2), we make use of Corollary 2.21 to reduce the  $\sigma$ -separation test to a simple non-adjacency test in a conditioned and marginalised  $\sigma$ -CG, as in (1). We do this by encoding  $\sigma$ -CGs, Theorem 2.20 and the marginalisation and conditioning operations on  $\sigma$ -CGs (Definitions 2.18 and 2.19) in ASP. The details of the encoding are provided in the Supplementary Material.<sup>6</sup> The optimization problem in (3) can then be solved straightforwardly by running an off-the-shelf ASP solver with as input the encoding and the weighted independence statements.

A more precise statement of the following result is provided in the Supplementary Material. The proof is basically the same as the one given in [21].

**Theorem 3.1.** *The algorithm for scoring features  $f$  is sound for oracle inputs and asymptotically consistent under mild assumptions.*

## 4 EXPERIMENTS

### 4.1 CONSTRUCTING MSCMS AND SAMPLING FROM MSCMS

To construct a modular structural causal model (mSCM) in practice we need to specify the compatible system of functions  $(g_S)_{S \in \mathcal{L}(G)}$ . The following Theorem is helpful (and a direct consequence of Banach’s fixed point theorem).

**Theorem 4.1.** *Consider the functions  $g_{\{v\}}$  for the trivial loops  $\{v\} \in \mathcal{L}(G)$ ,  $v \in V$  and assume the following contractivity condition:*

*For every non-trivial loop  $S \in \mathcal{L}(G)$  and for every value  $x_{\text{Pa}^{G^+}(S) \setminus S}$  the multi-dimensional function:*

$$x'_S \mapsto \left( g_{\{v\}}(x'_{S \cap \text{Pa}^{G^+}(v) \setminus \{v\}}, x_{\text{Pa}^{G^+}(v) \setminus S}) \right)_{v \in S}$$

*is a contraction, i.e. Lipschitz continuous with Lipschitz constant  $L(x_{\text{Pa}^{G^+}(S) \setminus S}) < 1$  w.r.t. a suitable norm  $\|\cdot\|$ .*

*Then all the functions  $g_S$  for the non-trivial loops  $S \in \mathcal{L}(G)$  exist, are unique and  $g = (g_S)_{S \in \mathcal{L}(G)}$  forms a*

<sup>6</sup>The full source code for the algorithm and to reproduce our experiments is available under an open source license from <https://github.com/caus-am/sigmasep>.

globally compatible system.

More constructively, for every value  $x_{\text{Pa}G^+(S)\setminus S}$  and initialization  $x_S^{(0)}$  the iteration scheme (using vector notations):

$$x_S^{(t+1)} := (g_{\{v\}})_{v \in S}(x_S^{(t)}, x_{\text{Pa}G^+(S)\setminus S})$$

converges to a unique limit vector  $x_S$  (for  $t \rightarrow \infty$  and independent of  $x_S^{(0)}$ ).  $g_S$  is then given by putting:

$$g_S(x_{\text{Pa}G^+(S)\setminus S}) := x_S.$$

This provides us with a method for constructing very general non-linear mSCMs (e.g. neural networks, see Section C in Supplementary Material) and to sample from them: by sampling  $x_U$  from the external distribution and then apply the above iteration scheme until convergence for all loops, yielding the limit  $x_V$  as one data point.

## 4.2 RESULTS ON SYNTHETIC DATA

In our experiments we will—due to computational restrictions—only allow for  $d = 5$  observed nodes and  $k = 2$  additional latent confounders. We sample edges independently with a probability of  $p = 0.3$ . We model the non-linear function  $g_{\{v\}}$  as a neural network with tanh activation, bias terms that have a normal distribution with mean  $-0.5$  and standard deviation  $0.2$ , and weights sampled uniformly from the L1-unit ball to satisfy the contraction condition of Theorem 4.1 (see also Supplementary Material, Section C). We simulate 0–5 single-variable interventions with random (unique) targets. For each intervened model we sample from standard-normal noise terms and compute the observations. To also detect weak dependencies in cyclic models we allow for  $n = 10^4$  samples in each such model for each allowed intervention. We then run all possible conditional independence tests between every pair of single nodes and calculate their  $p$ -values. We used  $\alpha = 10^{-3}$  as the threshold between dependence and independence. For computational reasons we restrict to partial correlation tests of marginal Gaussian rank-transforms of the data. These tests are then fed into the ASP solver together with our encoding of the optimization problem (3). We query the ASP solver for the confidence for the absence or presence of each possible directed and bidirected edge. We simulate 300 models and aggregate results, using the confidence scores to compute ROC- and PR-curves for features. Figure 4 shows that, as expected, our algorithm recovers more directed edges of the underlying causal graph in the simulation setting as the number of single-variable interventions increases. More results (ROC- and PR-curves for directed edges and con-

founders for different numbers of single-variable interventions and for different encodings) are provided in the Supplementary Material.

Figure 4: The ROC curves for identifying directed edges. See also figures 6 and 7 in the Supplementary Material.

## 5 CONCLUSION

We introduced  $\sigma$ -connection graphs ( $\sigma$ -CG) as a generalization of the d-connection graphs (d-CG) of [19] and extended the notion of  $\sigma$ -separation that was introduced in [12] to  $\sigma$ -CGs. We showed how  $\sigma$ -CGs behave under marginalisation and conditioning. This provides a graphical representation of how conditional independencies of modular structural causal models (mSCMs) behave under these operations. We provided a sufficient condition that allows constructing mSCMs and sampling from them. We extended the algorithm of [19] to deal with the more generally applicable notion of  $\sigma$ -separation instead of d-separation, thereby obtaining the first algorithm for causal discovery that can deal with cycles, nonlinearities, latent confounders and a combination of data sets corresponding to observational and different interventional settings. We illustrated the effectiveness of the algorithm on simulated data. In this work, we restricted attention to (stochastic) perfect (“surgical”) interventions, but a straightforward extension to deal with other types of interventions and to generalize the idea of randomized controlled trials can be obtained by applying the JCI framework [23]. In future work we wish to improve our algorithm to also handle selection bias, become more scalable and apply it to real world data sets.

## Abstract

We consider the structured-output prediction problem through probabilistic approaches and generalize the “perturb-and-MAP” framework to more challenging weighted Hamming losses, which are crucial in applications. While in principle our approach is a straightforward marginalization, it requires solving many related MAP inference problems. We show that for log-supermodular pairwise models these operations can be performed efficiently using the machinery of dynamic graph cuts. We also propose to use *double* stochastic gradient descent, both on the data and on the perturbations, for efficient learning. Our framework can naturally take weak supervision (e.g., partial labels) into account. We conduct a set of experiments on medium-scale character recognition and image segmentation, showing the benefits of our algorithms.

## 1 INTRODUCTION

Structured-output prediction is an important and challenging problem in the field of machine learning. When outputs have a structure, often in terms of parts or elements (e.g., pixels, sentences or characters), methods that do take it into account typically outperform more naive methods that consider outputs as a set of independent elements. Structured-output methods based on optimization can be broadly separated in two main families: *max-margin methods*, such as structured support vector machines (SSVM) (Taskar et al., 2003; Tsochantaridis et al., 2005) and *probabilistic methods based on maximum likelihoods* such as conditional random fields (CRF) (Laferty et al., 2001).

Structured-output prediction faces many challenges:

(1) on top of large input dimensions, problems also have large outputs, leading to scalability issues, in particular when prediction or learning depends on combinatorial optimization problems (which are often polynomial-time, but still slow given they are run many times); (2) it is often necessary to use losses which go beyond the traditional 0-1 loss to shape the behavior of the learned models towards the final evaluation metric; (3) having fully labelled data is either rare or expensive and thus, methods should be able to deal with weak supervision.

Max-margin methods can be used with predefined losses, and have been made scalable by several recent contributions (see, e.g., Lacoste-Julien et al., 2013, and references therein), but do not deal naturally with weak supervision. However, a few works (Yu and Joachims, 2009; Kumar et al., 2010; Girshick et al., 2011) incorporate weak supervision into the max-margin approach via the CCCP (Yuille and Rangarajan, 2003) algorithm.

The flexibility of probabilistic modeling naturally allows (a) taking into consideration weak supervision and (b) characterizing the uncertainty of predictions, but it comes with strong computational challenges as well as a non-natural way of dealing with predefined losses beyond the 0-1 loss. The main goal of this paper is to provide new tools for structured-output inference with probabilistic models, thus making them more widely applicable, while still being efficient. There are two main techniques to allow for scalable learning in CRFs: stochastic optimization (Vishwanathan et al., 2006) and piecewise training (Sutton and McCallum, 2005, 2007; Kolesnikov et al., 2014); note that the techniques above can also be used for weak supervision (and we reuse some of them in this work).

Learning and inference in probabilistic structured-output models recently received a lot of attention from the research community (Bakir et al., 2007; Nowozin and Lempert, 2011; Smith, 2011). In this paper we consider only models for which maximum-a posteriori (MAP)

inference is feasible (a step often referred to as decoding in max-margin formulations, and which typically makes them tractable). A lot of efforts were spent to explore MAP-solvers algorithms for various problems, leveraging various structures, e.g., graphs of low tree-width (Bishop, 2006; Wainwright and Jordan, 2008; Sontag et al., 2008; Komodakis et al., 2011) and function submodularity (Boros and Hammer, 2002; Kolmogorov and Zabih, 2004; Bach, 2013; Osokin and Vetrov, 2015).

Naturally, the existence of even an exact and efficient MAP-solver does not mean that the partition function (a key tool for probabilistic inference as shown below) is tractable to compute. Indeed, the partition function computation is known to be  $\#P$ -hard (Jerrum and Sinclair, 1993) in general. For example, MAP-inference is efficient for log-supermodular probabilistic models, while computation of their partition function is not (Djolonga and Krause, 2014).

For such problems where MAP-inference is efficient, but partition function computation is not, “perturb-and-MAP” ideas such as proposed by Papandreou and Yuille (2011); Hazan and Jaakkola (2012) are a very suitable treatment. By adding random perturbations, and then performing MAP-inference, they can lead to estimates of the partition function. In Section 2, we review the existing approaches to the partition function approximation, parameter learning and inference.

An attempt to learn parameters via “perturb-and-MAP” ideas was made by Hazan et al. (2013), where the authors have developed a PAC-Bayesian-flavoured approach for the non-decomposable loss functions. While the presented algorithm has something in common with ours (gradient descent optimization of the objective upper bound), it differs in the sense of the objective function and the problem setup, which is more general but that requires a different (potentially with higher variance) estimates of the gradients. Such estimates are usual in reinforcement learning, e.g., the log-derivative trick from the REINFORCE algorithm (Williams, 1992).

The goal of this paper is to make the “perturb-and-MAP” technique applicable to practical problems, in terms of (a) scale, by increasing the problem size significantly, and (b) losses, by treating structured losses such as the Hamming loss or its weighted version, which are crucial to obtaining good performance in practice.

Overall, we make the following contributions:

- In Section 3, we generalize the “perturb-and-MAP” framework to more challenging weighted Hamming losses which are commonly used in applications. In principle, this is a straightforward marginalization but this requires solving many related MAP inference prob-

lems. We show that for graph cuts (our main inference algorithm for image segmentation), this can be done particularly efficiently. Besides that, we propose to use a *double* stochastic gradient descent, both on the data and on the perturbations.

- In Section 4, we show how weak supervision (e.g., partial labels) can be naturally dealt with. Our method in this case relies on approximating marginal probabilities that can be done almost at the cost of the partition function approximation.
- In Section 5, we conduct a set of experiments on medium-scale character recognition and image segmentation, showing the benefits of our new algorithms.

## 2 PERTURB-AND-MAP

In this section, we introduce the notation and review the relevant background. We study the following probabilistic model (a.k.a. a Gibbs distribution) over a discrete product space  $Y = Y_1 \times \dots \times Y_D$ ,

$$P(y) = \frac{1}{Z(f)} e^{f(y)}, \quad (1)$$

which is defined by a potential function  $f : Y \rightarrow \mathbb{R}$ . The constant  $Z(f) = \sum_{y \in Y} e^{f(y)}$  is called the partition function and normalizes  $P(y)$  to be a valid probability function, i.e., to sum to one.  $Z(f)$  is in general intractable to compute as the direct computation requires summing over exponentially (in  $D$ ) many elements.

Various partition function approximations methods have been used in parameter learning algorithms (Parise and Welling, 2005), e.g., mean-field (MF, Jordan et al., 1999), tree-reweighted belief propagation (TRW, Wainwright and Jordan, 2008) or loopy belief propagation (LBP, Weiss, 2001). We will work with the upper bound on the partition function proposed by Hazan and Jaakkola (2012) as it allows us to approximate the partition function via MAP-inference, calculate gradients efficiently, approximate marginal probabilities and guarantee tightness for some probabilistic models. We introduce this class of techniques below.

### 2.1 Gumbel perturbations

Recently, Hazan and Jaakkola (2012) provided a general-purpose upper bound on the *log-partition function*  $A(f) = \log Z(f)$ , based on the “perturb-and-MAP” idea (Papandreou and Yuille, 2011): maximize the potential function perturbed by Gumbel-distributed noise.<sup>1</sup>

<sup>1</sup>The Gumbel distribution on the real line has cumulative distribution function  $F(z) = \exp(-\exp(-(z+c)))$ , where  $c$  is the Euler constant.

**Proposition 1** (Hazan and Jaakkola (2012), Corollary 1). For any function  $f : Y \rightarrow \mathbb{R}$ , we have  $A(f) \leq A_G(f)$ , where

$$A_G(f) = \mathbb{E}_{z_1, \dots, z_D \sim \text{Gumbel}} \left[ \max_{y \in Y} \left( f(y) + \sum_{d=1}^D z_d(y_d) \right) \right]. \quad (2)$$

Gumbel denotes the Gumbel distribution and  $\{z_d(y_d)\}_{y_d \in Y_d}^{d=1, \dots, D}$  is a collection of independent Gumbel samples.

The bound is tight when  $f(y)$  is a separable function (i.e., a sum of functions of single variables), and the tightness of this bound was further studied by Shpakova and Bach (2016) for log-supermodular models (where  $f$  is supermodular). They have shown that the bound  $A_G$  is always lower (and thus provide a better bound) than the ‘‘L-field’’ bound proposed by Djolonga and Krause (2014, 2015), which is itself based on separable optimization on the base polytope of the associated supermodular function.

The partition function bound  $A_G$  can be approximated by replacing the expectation by an empirical average. That is, to approximate it we need to solve a large number (as many as the number of Gumbel samples used to approximate the expectation) of MAP-like problems (i.e., maximizing  $f$  plus a separable function) which are feasible by our assumption. Strictly speaking, the MAP-inference is NP-hard in general, but firstly, it is much easier than the partition function calculation, secondly, there are solvers for special cases, e.g., for log-supermodular models (which include functions  $f$  which are negatives of cuts (Kolmogorov and Zabih, 2004; Boykov and Kolmogorov, 2004)) and those solvers are often efficient enough in practice. In this paper, we will focus primarily on a subcase of supermodular potentials, namely negatives of graph cuts.

## 2.2 Parameter learning and Inference

In the standard supervised setting of structured prediction, we are given  $N$  pairs of observations  $\mathcal{D} = \{(x^n, y^n)\}_{n=1}^N$ , where  $x^n$  is a feature representation of the  $n$ -th object and  $y^n \in Y = Y_1 \times \dots \times Y_{D^n}$  is a structured vector of interest (e.g., a sequence of tags, a segmentation MAP or a document summarization representation). In the standard linear model, the potential function  $f(y|x)$  is represented as a linear combination:  $f(y|x) = w^T \Psi(x, y)$ , where  $w$  is a vector of weights and the structured feature map  $\Psi(x, y)$  contains the relevant information for the feature-label pair  $(x, y)$ . To learn the parameters using the predefined probabilistic model, one can use the (regularized) maximum likelihood approach:

$$\max_w \frac{1}{N} \sum_{n=1}^N \log P(y^n|x^n, w) - \frac{\lambda}{2} \|w\|^2, \quad (3)$$

where  $\lambda > 0$  is a regularization parameter and the likelihood  $P(y|x, w)$  is defined as  $\frac{\exp(f(y|x))}{Z(f, x)} = \exp(f(y|x) - A(f, x))$ , where  $A(f, x)$  is the log-partition function (that now depends on  $x$ , since we consider conditional models).

Hazan and Jaakkola (2012) proposed to learn parameters based on the Gumbel bound  $A_G(f, x)$  instead of the intractable log-partition function:

$$\begin{aligned} \log P(y|x) &= f(y|x) - A(f, x) \leq f(y|x) - A_G(f, x) \\ &= f(y|x) - \mathbb{E}_z \left[ \max_{y \in Y} \left\{ \sum_{d=1}^D z_d(y_d) + f(y) \right\} \right] \\ &\approx f(y|x) - \frac{1}{M} \sum_{m=1}^M \max_{y^{(m)} \in Y} \left\{ \sum_{d=1}^D z_d^{(m)}(y_d^{(m)}) + f(y^{(m)}) \right\}. \end{aligned}$$

Hazan and Jaakkola (2012) considered the fully-supervised setup where labels  $y^n$  were given for all data points  $x^n$ . Shpakova and Bach (2016) developed the approach, but also considered a setup with missing data (part of the labels  $y^n$  are unknown) for the small Weizmann Horse dataset (Borenstein et al., 2004). Leveraging the additional stochasticity present in the Gumbel samples, Shpakova and Bach (2016) extend the use of stochastic gradient descent, not on the data as usually done, but on the Gumbel randomization. It is equivalent to the choice of parameter  $M = 1$  for every gradient computation (but with a new Gumbel sample at every iteration). In our work, we use the stochastic gradient descent in a regime stochastic w.r.t. both the data and the Gumbel perturbations. This allows us to apply the method to large-scale datasets.

For linear models, we have  $f(y|x) = w^T \Psi(x, y)$  and  $\Psi(x, y)$  is usually given or takes zero effort to compute. We assume that the gradient calculation  $\nabla_w f(y|x) = \Psi(x, y)$  does not add complexity to the optimization algorithm. The gradient of  $\log P(y|x)$  is equal to  $\nabla_w f(y|x) - \nabla_w \max_{y \in Y} \left\{ \sum_{d=1}^D z_d(y_d) + f(y|x) \right\} = \nabla_w f(y|x) - \nabla_w f(y^*|x)$ , where  $y^*$  lies in  $\arg \max$  of the perturbed optimization problem. The gradient of  $\langle \log P(y|x) \rangle$  (the average over a subsample of data, typically a mini-batch) has the form  $\langle \nabla_w f(y|x) \rangle - \langle \nabla_w f(y^*|x) \rangle = \langle \Psi(x, y) \rangle_{emp.} - \langle \Psi(x, y^*) \rangle$ , where  $\langle \Psi(x, y) \rangle_{emp.}$  denotes the empirical average over the data. Algorithm 1 contains this double stochastic gradient descent (SGD) with stochasticity w.r.t. both sampled data and Gumbel samples. The choice of the stepsize  $\gamma_h = \frac{1}{\lambda h}$  is standard for strongly-convex problems (Shalev-Shwartz et al., 2011).

Note, that the classic log-likelihood formulation (3) is implicitly considering a ‘‘0-1 loss’’  $l_{0-1}(y, \hat{y}) = [y \neq \hat{y}]$  as it takes probability of the entire output object  $y^n$  conditioned on the observed feature representation  $x^n$ .

However, in many structured-output problems 0-1 loss

---

**Algorithm 1** Double SGD: stochasticity w.r.t. data and Gumbel samples

---

**Input:** dataset  $\mathcal{D} = \{(x^n, y^n)\}_{n=1}^N$ , number of iterations  $H$ , size of the mini-batch  $T$ , stepsize sequence  $\{\gamma_h\}_{h=1}^H$ , regularization parameter  $\lambda$

**Output:** model parameters  $w$

- 1: **Initialization:**  $w = 0$
  - 2: **for**  $h = 1$  **to**  $H$  **do**
  - 3:   Sample data mini-batch of small size  $T$  (that is,  $T$  pairs of observations)
  - 4:   Calculate sufficient statistics  $\langle \Psi(x, y) \rangle_{emp.}$  from the mini-batch
  - 5:   **for**  $t=1$  **to**  $T$  **do**
  - 6:     Sample  $z_d(y_d)$  as independent Gumbels for all  $y_d \in Y_d$  and for all  $d$
  - 7:     Find  $y^* \in \arg \max_{y \in Y} \left\{ \sum_{d=1}^D z_d(y_d) + f(y) \right\}$
  - 8:   **end for**
  - 9:   Make a gradient step:  
 $w_{h+1} \rightarrow w_h + \gamma_h \left( \langle \Psi(x, y) \rangle_{emp.} - \langle \Psi(x, y^*) \rangle - \lambda w_h \right)$
  - 10: **end for**
- 

evaluation is not an adequate performance measure. The Hamming or weighted Hamming losses that sum mistakes across the  $D$  elements of the outputs, are more in demand as they count misclassification per element.

### 2.3 Marginal probability estimation

Either at testing time (to provide an estimate of the uncertainty of the model) or at training time (in the case of weak supervision, see Section 4), we need to compute marginal probabilities for a single variable  $y_d$  out of the  $d$  ones, that is,

$$P(y_d|x) = \sum_{y_{-d}} P(y_{-d}, y_d|x),$$

where  $y_{-d}$  is a sub-vector of  $y$  obtained by elimination of the variable  $y_d$ . Following Hazan and Jaakkola (2012) and Shpakova and Bach (2016), this can be obtained by taking  $m$  Gumbel samples and the associated maximizers  $y^m \in Y = Y_1 \times \dots \times Y_D$ , and, for any particular  $d$ , counting the number of occurrences in each possible value in all the  $d$ -th components  $y_d^m$  of the maximizers  $y^m$ .

While this provides an estimate of the marginal probability, this is not an easy expression to optimize at it depends on several maximizers of potentially complex optimization problems. In the next section, we show how we can compute a different (and new) approximation which is easily differentiable and on which we can apply stochastic gradient descent.

## 3 MARGINAL LIKELIHOOD

In this section, we demonstrate the learning procedure for the element-decoupled losses. We consider the regularized empirical risk minimization problem in a general form:

$$\max_w \frac{1}{N} \sum_{n=1}^N \ell(w, x^n, y^n) - \frac{\lambda}{2} \|w\|^2, \quad (4)$$

where  $\ell(w, x, y)$  can take various forms from Table 1 and  $\lambda$  is the regularization parameter. The choice of the likelihood form is based on the problem setting such as presence of missing data and the considered test-time evaluation function.

### 3.1 Hamming loss

The Hamming loss is a loss function that counts misclassification per dimension:  $l_h(y, \hat{y}) = \frac{1}{D} \sum_{d=1}^D [y_d \neq \hat{y}_d]$ . For this type of loss instead of the classic log-likelihood objective it is more reasonable to consider the following decoupling representation from Table 1:

$$\ell(w, x, y) = \sum_{d=1}^D \log P(y_d|x, w), \quad (5)$$

where

$$\begin{aligned} P(y_d|x, w) &= \sum_{y_{-d}} \exp(f(w, y_{-d}|y_d, x) - A(f, x)) \\ &= \exp(B(f, y_d, x) - A(f, x)) \end{aligned}$$

is the marginal probability of the single element  $y_d$  given the entire input  $x$ , and  $B(f, y_d) = \log \sum_{y_{-d}} \exp(f(w, y_{-d}|y_d))$ , where  $y_{-d} \in Y_1 \times \dots \times Y_{d-1} \times Y_{d+1} \times \dots \times Y_D$ . Thus, the log-marginal probability may be obtained from the difference of two log-partition functions (which we will approximate below with Gumbel samples).

This idea of considering the marginal likelihood was proposed by Kakade et al. (2002). Our contribution is to consider the approximation by ‘‘perturb-and-MAP’’ techniques. We thus have a new objective function  $\ell(w, x, y)$ :  $\ell(w, x, y) = \sum_{d=1}^D [(B(f, x, y_d) - A(f, x))]$ , and now the following approximation could be applied:

$$\begin{aligned} A(f) &\approx A_G(f) = \mathbb{E}_z \left\{ \max_{y \in Y} \sum_{d=1}^D z_d(y_d) + f(y) \right\}, \\ B(f|y_d) &\approx B_G(f|y_d) \\ &= \mathbb{E}_z \left\{ \max_{y_{-d} \in Y_{-d}} \sum_{s=1: s \neq d}^D z_s(y_s) + f(y_{-d}|y_d) \right\}. \end{aligned}$$

It is worth noting, that the approximation is not anymore an upper bound of the marginal likelihood; moreover it is a difference of convex functions. Remarkably, the objective function exactly matches the log-likelihood in the

Table 1: Variants of the Objective Loss  $\ell(w, x, y)$  Function.  $\{\theta_d(y_d)\}_{d=1}^D$  are the weights of the weighted Hamming loss,  $\{q_d(y_d)\}_{d=1}^D$  are the marginal probabilities  $P(y_d|x)$ .

Loss	Labelled Data	Unlabelled Data
0-1	$\log P(w, y x)$	$\log \sum_{y \in Y} P(w, y, x)$
Hamming	$\sum_{d=1}^D \log P(w, y_d x_d)$	$\sum_{d=1}^D \sum_{y_d \in Y_d} q_d(y_d) \log P(w, y_d x_d)$
Weighted Hamming	$\sum_{d=1}^D \theta_d(y_d) \log P(w, y_d x_d)$	$\sum_{d=1}^D \sum_{y_d \in Y_d} q_d(y_d) \theta_d(y_d) \log P(w, y_d x_d)$

case of unary potentials (separable potential function) as the log-likelihood function becomes the sum of marginal likelihoods.

As noted, the objective  $\ell(w, x, y)$  is not convex anymore, but it is presented as the difference of two convex functions. We can still try to approximate with stochastic gradient descent (which then only converges to a stationary point, typically a local minimum). Algorithm 2 describes the implementation details.

- 

**Acceleration trick.** Interestingly we can use the same Gumbel perturbation realizations for approximating  $A_G(f)$  and  $B_G(f|y_d)$  through an empirical average. On the one hand, this restriction should not influence on the result as with a sufficient large averaging number  $M$ ,  $A_G(f)$  and  $B_G(f|y_d)$  converges to their expectations. This is the same for stochastic gradients: on every itera-

tion, we use a different Gumbel perturbation, but we share this one for the estimation of the gradients of  $A_G(f)$  and  $B_G(f|y_d)$ . This allows us to save some computations as shown below, while preserving convergence (the extra correlation added by using the same samples for the two gradients does not change the unbiasedness of our estimates).

Moreover, if  $y_A^*$  has the same label value  $y_d$  as the ground truth, then the MAP inference problem for  $y_A^*$  exactly matches the one for  $y_B^*$  (with the element  $y_d$  fixed from the ground truth). Then  $y_A^* = y_B^*$  and the corresponding difference of gradients gives zero impact into the gradient step. This fact allows us to reduce the number of MAP-inference problems. We should thus calculate  $y_B^*$  only for those indices  $d$  that leads to a mismatch between  $d$ -th label of  $y_A^*$  and the ground truth one. Remarkably, during the convergence to the optimal value, the reduction will occur more often and decrease the execution time with the number of iteration increase. Besides that, in the experiments with graph cuts in Section 5 we use dynamic graph cut algorithm for solving several optimization problems of similar structure (here  $D$  marginal probabilities calculation). We describe it in more details in Section 3.3.

### 3.2 Weighted Hamming loss

The weighted Hamming loss is used for performance evaluation in the models, where each dimension has its own level of importance, e.g., in an image segmentation with superpixels, proportional to the size of superpixels. It differs from the usual Hamming loss in this way:  $l_h(y, \hat{y}) = \frac{1}{D} \sum_{d=1}^D \theta_d(y_d) [y_d \neq \hat{y}_d]$ .

Thus we consider a dimension-weighted model as it can be adjusted for the problem of interest that gives the model more flexibility. The optimization problem of interest is transformed from the previous case by weighted multiplication:

$$\ell(w, x, y) = \sum_{d=1}^D \theta_d(y_d) [(B(f, x, y_d) - A(f, x))]. \quad (6)$$

To justify this objective function, we notice that in the case of unit weights, the weighted loss and objective

function (6) match the loss and the objective from the previous section. Furthermore,  $y_d$  with a large weight  $\theta_d(y_d)$  puts more importance towards making the right prediction for this  $y_d$ , and that is why we put more weight on the  $d$ -th marginal likelihood. This corresponds to the usual rebalancing used in binary classification (see, e.g., Bach et al., 2006, and references therein). Then, the algorithm for this case duplicated the one for the usual Hamming loss and the acceleration trick can be used as well.

### 3.3 Scalable algorithms for graph cuts

As a classical efficient MAP-solver for pairwise potentials problem we will use graph cut algorithms from Boykov and Kolmogorov (2004). The function  $f(y|x)$  should then be supermodular, i.e., with pairwise potentials, all pairwise weights of  $w$  should remain negative.

In both Sections 3.1 and 3.2 we can apply the dynamic graphcut algorithm proposed by Kohli and Torr (2007), which is a modification of the Boykov-Kolmogorov graphcut algorithms. It is dedicated to situations when a sequence of graphcut problems with slightly different unary potentials need to be solved. Then, instead of solving them separately, we can use the dynamic procedure and find the solutions for slightly different problems with less costs. This makes graphcut scalable for a special class of problems.

It can easily be seen that our sequence of problems  $y_B^* \in \arg \max_{y_{-d} \in Y_{-d}} \{ \sum_{s=1: s \neq d} z_s(y_s) + f(y_{-d}|y_d) \}$  for  $d = 1, \dots, D$  is a perfect application for the dynamic graph cut algorithm. At each iteration we solve  $T$  sets of graph cut problems, each of set contains  $1 + a_t$  problems solvable by the same dynamic cut, where  $a_t$  is the number of not matched pixels between  $y_A^*$  and ground truth  $y^n$ . Finally, using acceleration trick and dynamic cuts we reduce the gradient descent iteration complexity from  $\sum_{t=1}^T (1 + D_t)$  graphcut problems to  $T$  dynamic graph cut problems. We make the approach scalable and can apply it for large datasets.

## 4 PARAMETER LEARNING IN THE SEMISUPERVISED SETUP

In this section we assume the presence of objects with unknown labels in the train dataset. We can separate the given data in two parts: fully annotated data  $\mathcal{D}_1 = \{(x^n, y^n)\}_{n=1}^N$  as in the supervised case and unlabeled data  $\mathcal{D}_2 = \{x^l\}_{l=1}^L$ . Then, the optimal model parameter  $w$  is a solution of the following optimization problem:

$$\max_w L_1(w) + \kappa L_2(w) - \frac{\lambda}{2} \|w\|^2, \quad (7)$$

where  $L_1(w) = \sum_{n=1}^N \ell_1(w, x^n, y^n)$ ,  $L_2(w) =$

$\sum_{l=1}^L \ell_2(w, x^l)$  and the parameter  $\kappa$  governs the importance of the unlabeled data.  $\ell_1(w, x^n, y^n)$  can have a form from the left column of the Table 1, and  $\ell_2(w, x^l)$  from the right one.

**Marginal calculations.** It is worth reminding from Section 2.3, that we can approximate marginal probabilities  $q(y)$  of holding  $y_d = k$  along with the partition function approximation almost for free. This can be obtained by taking  $m$  Gumbel samples and the associated maximizers  $y^m \in Y = Y_1 \times \dots \times Y_D$ , and, for any particular  $d$ , counting the number of occurrences in each possible value in all the  $d$ -th components  $y_d^m$  of the maximizers  $y^m$ . The approximation accuracy depends on number of samples  $M$ . To calculate this we already need to have a trained weight vector  $w$  which we can obtain from the fully annotated dataset  $\mathcal{D} = \{(x^n, y^n)\}_{n=1}^N$ . We will calculate  $q(y)$  for the unlabelled data  $\mathcal{D}_2 = \{x^l\}_{l=1}^L$ . Those marginal probabilities contain much more information than MAP inference for the new data as can be seen on the example in Figure 1. We believe that proper use of the marginal probabilities will help to gain better result than using labels from the MAP inference (which we observe in experiments).

It is worth noting that for the inference and learning phases we use a different number of Gumbel samples. During the learning phase, we incorporate the double stochastic procedure and use 1 sample per 1 iteration and 1 label. For the marginal calculation (inference) we should use large number of samples (e.g. 100 samples) to get accurate approximation.

2: **Find  $w_1$  via Algorithm 2**

**Input:** fully annotated dataset  $\mathcal{D}_1 = \{(x^n, y^n)\}_{n=1}^N$ , unlabeled dataset  $\mathcal{D}_2 = \{x^l\}_{l=1}^L$ , number of iterations  $H$ , size of the mini-batch  $T$ , stepsize sequence  $\{\gamma_h\}_{h=1}^H$ , regularization parameter  $\lambda$

**Output:** model parameters  $w_{1,2}$

3: **Initialization:**  $w_{1,2} = w_1$

4: **Calculate:**  $q(y)$  for unlabeled data via  $w_1$

5: **Find  $w_{1,2}$  via mixture of Algorithms 2 and 4**

---

We provide the sketch of the proposed optimization algorithm in Algorithm 3. The optimization of  $L_1$  is fully supervised and this can be done with tools of the previous section. The optimization of  $L_2$  requires the specification of  $\ell_2(w, x)$ , which we take as

$\ell_2(w, x) = \sum_{d=1}^D \sum_{y_d \in \{0, \dots, K\}} q_d(y_d) \log P(w, y_d | x_d) =$   
 $\sum_{d=1}^D \sum_{y_d \in \{0, \dots, K\}} q_d(y_d) B(f|y_d) - DA(f)$ , that is, the average of the fully supervised cost function with labels generated from the model  $q$ . The term  $L_2$  corresponds to the common way of treating unlabeled data through the marginal likelihood. The sub-algorithm for the optimization of  $\ell_2$  is presented as Algorithm 4.

---

**Algorithm 4** Double SGD for Unsupervised Learning

---

**Input:** unlabeled dataset  $\mathcal{D}_2 = \{x^l\}_{l=1}^L$ , parameter estimate  $w_1$ , number of iterations  $H$ , size of the mini-batch  $T$ , stepsize sequence  $\{\gamma_h\}_{h=1}^H$ , regularization parameter  $\lambda$

**Output:** model parameters  $w_{1,2}$

- 1: **Initialization:**  $w_{1,2} = w_1$
  - 2: **for**  $h = 1$  **to**  $H$  **do**
  - 3:   Sample data mini-batch of small size  $T$  (that is,  $T$  pairs of observations)
  - 4:   **for**  $t=1$  **to**  $T$  **do**
  - 5:     Sample  $z_d(y_d)$  as independent Gumbels for all  $y_d \in Y_d$  and for all  $d$
  - 6:     Find  $y_A^* \in \arg \max_{y \in Y} \left\{ \sum_{d=1}^D z_d(y_d) + f(y) \right\}$
  - 7:     **for**  $d=1$  **to**  $D$  **and**  $k=0$  **to**  $K$  **do**
  - 8:       Find  $y_{B,d,k}^* \in \arg \max_{y_{-d} \in Y_{-d}} \left\{ \sum_{s=1: s \neq d}^D z_s(y_s) + f(y_{-d} | y_d = k) \right\}$
  - 9:     **end for**
  - 10:   **end for**
  - 11:   Make a gradient step:  

$$w_{h+1} \rightarrow w_h + \gamma_h \left( \left\langle \sum_{k=0}^K q_d(k) \Psi(x, y_{B,d,k}^*) \right\rangle - \Psi(x, y_A^*) \right) - \lambda w_h$$
  - 12: **end for**
- 

**Acceleration trick.** Suppose, that  $y_d$  can take values in the range  $\{0, \dots, K\}$ . Again we use the same Gumbel perturbation for estimating  $A_G(f)$  and  $B_{dkG}(f|y_d = k)$  for all  $k \in \{0, \dots, K\}$ . The consequence of using the same perturbations is that if the  $d$ -th label  $y_d$  of  $y_A^*$  takes value  $k$ , then the corresponding  $d$ -th gradient will cancel out with one of the  $y_{B,k}^*$ . Thus, we will calculate only  $K$  (instead of  $K + 1$  labels) structured labels  $y_{B,l}^* (l \neq k)$  and reduce the number of optimization problems to be solved. Dynamic graph cuts are applied here as well.

Finally in Table 1 we see the relationships between the proposed objective functions. Firstly, the known labels  $y^n$  in the supervised case are equivalent to the binary marginal probabilities  $q(y^n) \in \{0, 1\}^{D^n}$ . Secondly, the unit weights  $\theta_d(y_d) = 1$  in the weighted Hamming loss are equivalent to the basic Hamming loss.

**Partial labels.** Another case that we would like to mention is annotation with partial labels, e.g., in an image segmentation application, the bounding boxes of the images are given. Then denote  $y^{given}$  as the set of given labels. In this setup the marginal probabilities become conditional ones  $q(y_d | y^{given})$  and to approximate this we need to solve several conditional MAP-inference problems. The objective function  $\ell_2(w) = \sum_d \sum_{y_d \in \{0, \dots, K\}} q_d(y_d | y^{given}) \log P(w, y_d | x_d, y^{given})$  remains feasible to optimize.

## 5 EXPERIMENTS

The experimental evaluation consists of two parts: Section 5.1 is dedicated to the chain model problem, where we compare the different algorithms for supervised learning; Section 5.2 is focused on evaluating our approach for the pairwise model on a weakly-supervised problem.

### 5.1 OCR dataset

The given OCR dataset from Taskar et al. (2003) consists of handwritten words which are separated in letters in a chain manner. The OCR dataset contains 10 folds of  $\sim 6000$  words overall. The average length of the word is  $\sim 9$  characters. Two traditional setups of these datasets are considered: 1) “small” dataset when one fold is considered as a training data and the rest is for test, 2) “large” dataset when 9 folds of 10 compose the train data and the rest is the test data. We perform cross-validation over both setups and present results in Table 2.

As the MAP oracle we use the dynamic programming algorithm of Viterbi (1967). The chain structure also allows us to calculate the partition function and marginal probabilities exactly. Thus, the CRF approach can be applied. We compare its performance with the structured SVM from Osokin et al. (2016), perturb-and-MAP (Hazan and Jaakkola, 2012) and the one we propose for marginal perturb-and-MAP (as Hamming loss is used for evaluation).

The goal of this experiment is to demonstrate that the CRF approach with exact marginals shows a slightly worse performance as the proposed one with approximated marginals but correct Hamming loss.

Table 2: OCR Dataset. Performance Comparison.

method	small dataset	large dataset
CRF	19.5 $\pm$ 0.4	13.1 $\pm$ 0.8
S-SVM+BCFW	19.5 $\pm$ 0.4	12.0 $\pm$ 1.1
perturb&MAP	19.1 $\pm$ 0.3	12.5 $\pm$ 1.1
marg. perturb&MAP	19.1 $\pm$ 0.3	12.8 $\pm$ 1.2

For the OCR dataset, we performed 10-fold cross-validation and the numbers of Table 2 correspond to the averaged loss function (Hamming loss) values over the 10 folds. As we can see from the result in Table 2, the approximate probabilistic approaches slightly outperforms the CRF on both datasets. The Gumbel approximation (with or without marginal likelihoods) does lead to a better estimation for the Hamming loss. Note that S-SVM performs better in the case of a larger dataset, which might be explained by stronger effects of model misspecification that hurts probabilistic models more than S-SVM (Pletscher et al., 2011).

## 5.2 HorseSeg dataset

The problem of interest is foreground/background superpixel segmentation. We consider a training set of images  $\{x^n\}_{n=1\dots N}$  that contain different numbers of superpixels. A hard segmentation of the image is expressed by an array  $y^n \in \{0, 1\}^{D^n}$ , where  $D^n$  is the number of superpixels for the  $n$ -th image.

The HorseSeg dataset was created by Kolesnikov et al. (2014) and contains horse images. The “small” dataset has images with manually annotated labels and contains 147 images. The second “medium” dataset is partially annotated (only bounding boxes are given) and contains 5974 images. The remaining “large” one has 19317 images with no annotations at all. A fully annotated hold out dataset was used for the test stage. It consists of 241 images.

The graphical model is a pairwise model with loops. We consider log-supermodular distribution and thus, the max oracle is available as the graph cut algorithm by Boykov and Kolmogorov (2004). Note that CRFs with exact inference cannot be used here.

Following Kolesnikov et al. (2014), for the performance evaluation the weighted Hamming loss is used, where the weight is governed by the superpixel size and foreground/background ratio in the particular image.

That is,  $l_h(y, \hat{y}) = \frac{1}{D} \sum_{d=1}^D \theta_d(y_d)[y_d \neq \hat{y}_d]$ , where

$$\theta_d(y_d) = \begin{cases} \frac{V_d}{2V_{foreground}}, & \text{if } y_d = 1. \\ \frac{V_d}{2V_{background}}, & \text{if } y_d = 0. \end{cases}$$

$V_d$  is the size of superpixel  $d$ ,  $V_{background}$  and  $V_{foreground}$  are the sizes of the background and the foreground respectively. In this way smaller object sizes have more penalized mistakes.

Since we incorporate  $\theta(y)$  into the learning process and for its evaluation we need to know the background and foreground sizes of the image, this formulation is only applicable for the supervised case, where  $y_d$  is given for

Figure 1: Example of the marginal and MAP inference for an image from the HorseSeg database Kolesnikov et al. (2014).

Table 3: HorseSeg Dataset. Performance Comparison.

method	“small”	“medium”	“large”
S-SVM+BCFW	12.3	10.9	10.9
perturb&MAP	20.9	21.0	20.9
w.m. perturb&MAP	11.6	10.9	10.9

all superpixels. However, in this dataset we have plenty of images with partial or zero annotation. For these set of images  $\mathcal{D}_2 = \{x^l\}_{l=1}^L$ , we handle approximate marginal probabilities  $q_d^l$  associated to the unknown labels. Using them we can approximate the foreground and background volumes:  $V_{foreground}^l \approx \sum_{d=1}^{D^l} q_d^l$  and  $V_{background}^l \approx \sum_{d=1}^{D^l} (1 - q_d^l)$ .

We provide an example of the marginal and MAP inference in Figure 1. The difference of the information compression between these two approaches is visually comparable. We believe that the smoother and accurate marginal approach should have a positive impact on the result, as the uncertainty about the prediction is well propagated.

As an example of the max-margin approaches we take S-SVM+BCFW from the paper of Osokin et al. (2016) which is well adapted to large-scale problems. For S-SVM+BCFW and perturb-and-MAP methods we use MAP-inference for labelling unlabelled data using  $w_1$  (see Section 4).

For the HorseSeg dataset (Table 3), the numbers correspond to the averaged loss function (weighted Hamming loss) values over the hold out test dataset. The results of the experiment in Table 3 demonstrate that the approaches taking into account the weights of the loss  $\theta_d(\cdot)$  (S-SVM+BCFW and w.m. perturb&MAP) give a much better accuracy than the regular perturb&MAP. S-SVM+BCFW uses loss-augmented inference and thereby augments the weighted loss structure into the learning phase. Weighted marginal perturb-and-MAP plugs the weights of the weighted Hamming loss inside the objective log-likelihood function. Basic perturb-and-MAP does

Table 4: Reduced HorseSeg Dataset. Performance Comparison.

method	10% of “small”	“medium” with bbox	“medium” w/o bbox
S-SVM+BCFW	17.3	14.0	16.1
perturb&MAP	23.2	23.4	23.0
w.m. p.&MAP	18.1	13.7	14.4

not use the weights  $\theta_a(\cdot)$  and loses a lot of accuracy. This shows us that the predefined loss for performance evaluation has a significant influence on the result and should be taken into account.

**Small dataset size influence.** We now investigate the effect of the reduced “small” dataset. We preserve the setup from the previous section and the only thing that we change is  $N$ , the size of the “small” fully-annotated dataset  $\mathcal{D}_1 = \{(x^n, y^n)\}_{n=1}^N$ . The new “small” dataset is 10% the size of the initial one, i.e., only 14 images. By taking a small labelled dataset, we test the limit of supervised learning when few labels are present.

For the HorseSeg dataset (Table 4), the numbers correspond to the averaged loss function (weighted Hamming loss) values over the hold out test dataset. The results of this experiments are presented in Table 4. In this setup, the probabilistic approach “weighted marginal perturb-and-MAP” gains more than max-margin “S-SVM+BCFW”. This could happen because of very limited fully supervised data. The learned parameter  $w_1$  gives a noisy model and this noisy model produces a lot of noisy labels for the unlabeled data, while weighted perturb-and-MAP is more cautious as it uses probabilities that contain more information (see Figure 1).

### 5.2.1 Acceleration trick impact

We now compare the execution time of the algorithm with and without our acceleration techniques (namely Dynamic Cuts [DC] and Gumbel Reduction[ GR]) to get an idea on how helpful they are. Table 5 shows the execution time for calculating all  $y_B^*$  (Algorithm 2) for different numbers of iterations on the HorseSeg small dataset. We conclude that the impact of DC does not depend on the total number of iterations always leading to acceleration around 1.3. For GR, acceleration goes from 3.5 for 100 iterations to 7.6 for one million iterations. Overall, we get acceleration of factor around 10 for one million iterations.

## 5.3 Experiments analysis

The experiments results mainly show that not taking into account the right loss in the learning procedure is detrimental to probabilistic technique such as CRFs, while

method \ it	100	$10^3$	$10^4$	$10^5$	$10^6$
basic	0.9	9.2	89.5	900	8993
DC	0.7	6.9	69.0	696	7171
GR	0.3	2.1	15.5	133.4	1186
DC+GR	0.2	1.5	10.9	83.5	727

Table 5: Execution time comparison in seconds. HorseSeg small dataset.

taking it into account (our novelty) improves results. Also, Tables 2 and 3 show that the proposed methods achieves (and sometimes surpasses) the level performance of the max-margin approach (with loss-augmented inference).

Further, we observed that the size of the training set influences the SSVM and perturb-and-MAP approaches differently. For smaller datasets, the max-margin approaches tend to lose information due to usage of the hard estimates for the unlabelled data (e.g. in Table 4: 16.1 against 14.4 for “medium” dataset without bounding boxes labeling).

Table 4 reports an experiment about using weakly-labeled data at the training stage (the results on the partially annotated “medium” dataset). This experiment studied the impact on the final prediction quality of the training set of “medium” size on top of the reduced “small” fully-labelled set. The results of Table 4 mean that the usage of our approach adopted to the correct test measure outperforms the default perturb-and-MAP by a large margin. Our approach also significantly outperformed the comparable baseline of SSVM due to reduced size of the “small” fully-labelled set.

## 6 CONCLUSION

In this paper, we have proposed an approximate learning technique for problems with non-trivial losses. We were able to make marginal weighted log-likelihood for perturb-and-MAP tractable. Moreover, we used it for semi-supervised and weakly-supervised learning. Finally, we have successfully demonstrated good performance of the marginal-based and weighted-marginal-based approaches on the middle-scale experiments. As a future direction, we can go beyond the graph cuts and image segmentation application and consider other combinatorial problems with feasible MAP-inference, e.g., matching.

## Abstract

We present the first framework for Gaussian-process-modulated Poisson processes when the temporal data appear in the form of panel counts. Panel count data frequently arise when experimental subjects are observed only at discrete time points and only the numbers of occurrences of the events between subsequent observation times are available. The exact occurrence timestamps of the events are unknown. The method of conducting the efficient variational inference is presented, based on the assumption of a Gaussian-process-modulated intensity function. We derive a tractable lower bound to alleviate the problems of the intractable evidence lower bound inherent in the variational inference framework. Our algorithm outperforms classical methods on both synthetic and three real panel count sets.

## 1 INTRODUCTION

**Background and issues.** Temporal data frequently arise as outcomes of an underlying *temporal point process* (Kingman, 1993) in continuous time. Temporal data can generally be classified into two types. One is from experiments that monitor subjects in a continuous fashion; and thereby the exact timestamps of all occurrences of the events are fully observable. These data are usually referred to as *recurrent event data* (Cook and Lawless, 2007). On the other hand, we have the so-called *panel count data* (Sun and Zhao, 2016), which is the focus of our paper. Under this framework, subjects are examined or observed only at discrete time-points and thus give only the numbers of occurrences of the events between subsequent observation times.

**Characteristics of panel count data.** A common characteristic of the panel count data is that we only have the numbers of occurrences between subsequent observation times. In particular, the exact occurrence times of the events are unknown. Hence, panel counts are non-negative integers and they represent the number of occurrences of events within a fixed period. Classical examples often arise in the clinical trials (Thall and Lachin, 1988) where patients are required to go back to the hospital after a certain treatment and only the numbers of symptoms between subsequent visits are recorded, such as the number of vomits or new tumors. Figure 1 gives an example of panel count data.

**Objective of this study.** The purpose of this paper is to present the variational Bayesian inference on Gaussian-process-modulated Poisson processes (GP3) that permits panel data observations.

There have been extensive studies on GP3 models and various inference algorithms are introduced for *recurrent event data* when timestamps of the events are fully observable, e.g., Monte Carlo sampling (Diggle et al., 2013; Adams et al., 2009), Laplace approximation (Flaxman et al., 2015) and variational inference (Lloyd et al., 2015). Among these approaches, the variational inference method (Lloyd et al., 2015) provides a computationally efficient estimate of the intensity function and does not require a careful discretization of the underlying space.

To the best of our knowledge, however, there has not been any study carried out on the variational inference of the GP3 model when the data come in the form of panel counts. Our ultimate goal is to infer the underlying intensity function in the panel count data.

**Related statistical works.** Based on the maximum likelihood criterion, several non-parametric estimators have been proposed to infer the underlying intensity function (Sun and Zhao, 2016), e.g., a

Figure 1: **Bladder Cancer Data Set.** This figure illustrates the panel count data from the patients. For the  $k$ th subject (or the  $k$ th patient), his/her observation window  $\mathcal{X}^{(k)}$  is divided into disjoint intervals. The  $i$ th interval is denoted as  $\mathcal{X}_i^{(k)}$ . For example, patient No. 4 ( $k = 4$ ) has an observation window which is divided into 8 disjoint intervals, i.e.,  $\bigcup_{i=1}^8 \mathcal{X}_i^{(4)} = \mathcal{X}^{(4)}$  and  $X_i \cap X_j = \emptyset$  for  $i \neq j$ . Patients may drop out from the study at any time and therefore their observation windows are different. An interval is shown by a rectangle. We use different colors to indicate the different numbers of new bladder tumors observed in this interval. Note that we only have access to *the number of events* in each interval.

non-parametric maximum pseudo-likelihood estimator (NPMPLE) (Wellner and Zhang, 2000), a non-parametric maximum pseudo-likelihood estimator with gamma frailty (NPMPPLGF) (Zhang and Jamshidian, 2003) and the local Expectation-Maximization (LocalEM) estimator (Fan et al., 2011). Unlike NPMPLE and NPMPPLGF, which only estimate the cumulative intensity function at a set of points, LocalEM provides a smooth estimate of the underlying intensity function due to the use of an exponential quadratic kernel (Fan et al., 2011).

Besides the computational cost in selecting the bandwidth of the exponential quadratic kernel, the estimators obtained by the LocalEM algorithm and other similar algorithms are point-estimates in the sense that the estimated intensity function is a point in the functional space. These point-estimates fail to capture the uncertainty in the data set. We show an example of the estimated intensity function by LocalEM in Figure 2. The uncertainty of the intensity function helps us understand the difficulty of the prediction at a given time.

**Contributions.** The contributions of our work are twofold. 1) In the first place it undertakes to construct a variational inference procedure for the **Gaussian-Process**

Figure 2: **Bladder Cancer Data Set.** Inferred intensity function by the LocalEM and GP4C methods. For GP4C, a 75% credible interval is given by dotted lines. Our estimator GP4C provides the additional uncertainty in the estimated intensity function compared with LocalEM. See Section 5 for details.

modulated **Poisson Process** model for **Panel Count** data (GP4C). 2) To carry out a variational inference in this setting, we derive a simple and tractable lower bound of the intractable evidence lower bound and demonstrate through empirical evidence that with this lower bound, GP4C outperforms a non-Bayesian method.

## 2 BACKGROUND

Throughout this paper, we denote the set of panel count data from  $K \in \mathbb{N}^+$  independent subjects as  $\mathcal{D}$ . Each subject will generate a sequence of events in the continuous space  $\mathcal{X}$ . We only consider the temporal point processes where the continuous space  $\mathcal{X}$  is a subset of  $\mathbb{R}$ . In the *recurrent event data*, the timestamps of the events are fully observable. We denote the timestamps from the  $k$ th subject as  $\{x_j^{(k)} \in \mathcal{X}\}$ .

In the *panel count data*, the  $k$ th subject is assessed in  $N_k$  disjoint intervals  $\{\mathcal{X}_i^{(k)}\}_{i=1}^{N_k}$ , where  $\bigcup_i \mathcal{X}_i^{(k)} = \mathcal{X}^{(k)} \subset \mathcal{X}$ . We have access to each interval  $\mathcal{X}_i^{(k)}$  and the number of events observed in this interval  $m_i^{(k)} = |\{x_j^{(k)} \in \mathcal{X}_i^{(k)}\}|$ . Let  $\mathbf{d}_k = \{(\mathcal{X}_i^{(k)}, m_i^{(k)})\}_{i=1}^{N_k}$  and  $\mathcal{D} = \{\mathbf{d}_k\}$ . Figure 1 illustrates an example of the panel count data.

### 2.1 LIKELIHOOD OF PANEL COUNT DATA

In the *recurrent event data*, one approach to modeling the events  $\{x_j^{(k)} \in \mathcal{X}\}$  from each subject is to use the inhomogeneous Poisson processes (IPP) (Kingman, 1993) and assume that there is a fixed underlying intensity function  $\lambda(x) : \mathcal{X} \rightarrow \mathbb{R}^+$ . Given the intensity function  $\lambda(x)$ ,

the likelihood for the observed events is

$$p(\{x_j^{(k)}\}|\lambda(x)) = \exp\left(-\int_{\mathcal{X}} \lambda(x)dx\right) \prod_j \lambda(x_j^{(k)}).$$

To derive the likelihood of the *panel count data*  $\mathcal{D}$ , we use two important features of an IPP (Kingman, 1993). The first is that given the intensity function  $\lambda(x)$ , the probability that we observe  $m_i^{(k)}$  events in the interval  $\mathcal{X}_i^{(k)}$  is given as follows:

$$p(m_i^{(k)}|\lambda(x); \mathcal{X}_i^{(k)}) = \frac{r_{ik}^{m_i^{(k)}}}{m_i^{(k)}!} \exp(-r_{ik}), \quad (1)$$

where  $r_{ik} \triangleq \int_{\mathcal{X}_i^{(k)}} \lambda(x)dx$  is the rate parameter of the Poisson distribution. Hereafter, we omit the dependency on  $\mathcal{X}_i^{(k)}$  for simplicity. However, the likelihood depends on the intervals and even for the same sequence, after censored with different intervals, the likelihood of the sequence will vary. See Appendix E.1 for a brief discussion.

The second feature is that on two disjoint intervals  $\mathcal{X}_i^{(k)}$  and  $\mathcal{X}_j^{(k)}$  ( $\mathcal{X}_i^{(k)} \cap \mathcal{X}_j^{(k)} = \emptyset$ ), the numbers of events on these intervals are independent random variables.

$$p(m_j^{(k)}, m_i^{(k)}|\lambda(x)) = p(m_j^{(k)}|\lambda(x))p(m_i^{(k)}|\lambda(x)). \quad (2)$$

Based on these two features, the likelihood of the panel count data  $\mathcal{D}$  can be derived. We assume that all subjects share the same intensity function  $\lambda(x)$ . Since  $K$  subjects are independent of each other and for the  $k$ th subject, the  $N_k$  intervals  $\{\mathcal{X}_i^{(k)}\}_{i=1}^{N_k}$  are disjoint, we obtain the following likelihood:

$$p(\mathcal{D}|\lambda(x)) = \prod_{k=1}^K p(\mathbf{d}_k|\lambda(x)) = \prod_{k=1}^K \prod_{i=1}^{N_k} p(m_i^{(k)}|\lambda(x)). \quad (3)$$

Several maximum likelihood estimators have been proposed on the basis of this likelihood or its variants, e.g., NPMPLE (Wellner and Zhang, 2000; Wellner et al., 2007), NPMPLEGF (Zhang and Jamshidian, 2003) and the LocalEM estimator (Fan et al., 2011). An estimate from LocalEM on the data set in Figure 1 is given in Figure 2. As we discussed, these estimators fail to model the uncertainty in the intensity function.

## 2.2 GP3 MODEL

In order to model the uncertainty of the intensity function  $\lambda(x)$  via a kernel, the traditional approach is to use the Cox process (Kingman, 1993). A Cox process is defined via a stochastic intensity function  $\lambda(x)$ . The stochastic

process to generate the intensity function is usually chosen to be a Gaussian process (GP) (Adams et al., 2009) and the model using a GP is called a GP3 model.

For the *recurrent event data*, GP3 models have been studied extensively (Adams et al., 2009; Gunter et al., 2014; Lloyd et al., 2015). The following model is an example of GP3 models (Lloyd et al., 2015),

$$\lambda(x) = f^2(x), \quad f \sim \mathcal{GP}(g(x), \kappa(x, x')), \quad (4)$$

where  $\mathcal{GP}(g(x), \kappa(x, x'))$  denotes the Gaussian process with mean function  $g(x)$  and covariance function  $\kappa(x, x')$ . The function  $f(x)$  drawn from a GP prior is squared to ensure the non-negativity of the intensity function. The GP3 model in Equation (4) admits a complete variational inference framework. Moreover, this intensity model can be enhanced with an independent variable for each subject or a mixture structure (Lloyd et al., 2016) to flexibly model the heterogeneity of the intensity functions across several subjects.

## 3 OUR MODEL GP4C : GP3 MODEL FOR PANEL COUNT DATA

In order to retain the scalability and efficiency of the variational inference approach (Lloyd et al., 2015) and add the uncertainty on the intensity function when we only observe the panel count data, we use the GP3 model defined in Equation (4) as the underlying intensity model.

The joint distribution  $p(\mathcal{D}, f)$  can be obtained by combining the likelihood model in Equation (3) and the intensity model in Equation (4).

$$p(\mathcal{D}, f) = \left[ \prod_{k=1}^K p(\mathbf{d}_k|\lambda(x)) \right] p(f; g, \kappa). \quad (5)$$

We call this model the **GP**-modulated **Poisson Process** model for **Panel Count** data (GP4C).

## 4 INFERENCE

In this section, we will discuss the problems when applying variational inference techniques on the GP4C model.

### 4.1 VARIATIONAL INFERENCE

We use sparse GPs to reduce the computational complexity with the set of pseudo inputs  $\{x_r\}_{r=1}^R$  on  $\mathcal{X}$  (Titsias, 2009). Let  $\mathbf{f}_R \triangleq [f(x_1), \dots, f(x_R)]^\top$ . The joint model with additional pseudo inputs is  $p(\mathcal{D}, f, \mathbf{f}_R) = p(\mathcal{D}|f)p(f|\mathbf{f}_R)p(\mathbf{f}_R)$  and the variational distribution is defined as follows:

$$q(f, \mathbf{f}_R) = p(f|\mathbf{f}_R)q(\mathbf{f}_R), \quad (6)$$

where  $q(\mathbf{f}_R) = \mathcal{N}(\boldsymbol{\mu}, \Sigma)$  and  $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$  denotes the normal distribution with mean  $\boldsymbol{\mu}$  and covariance matrix  $\Sigma$ . The evidence lower bound (ELBO)  $\mathcal{L}$  can be obtained by using Jensen's inequality.

$$\begin{aligned} \ln p(\mathcal{D}) &\geq \iint q(f, \mathbf{f}_R) \ln \frac{p(\mathcal{D}, f, \mathbf{f}_R)}{q(f, \mathbf{f}_R)} df d\mathbf{f}_R \\ &= \sum_{k=1}^K \sum_{i=1}^{N_k} \left( m_i^{(k)} \mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} f^2(x) dx \right] - \ln(m_i^{(k)}!) \right) \\ &\quad - \sum_{k=1}^K \mathbb{E}_q \left[ \int_{\mathcal{X}^{(k)}} f^2(x) dx \right] + \mathbb{E}_q \left[ \ln \frac{p(\mathbf{f}_R)}{q(\mathbf{f}_R)} \right] \triangleq \mathcal{L}. \end{aligned} \quad (7)$$

In ELBO, when assuming that the covariance function  $\kappa(x, x')$  is the automatic relevance determination (ARD) function  $\kappa(x, x') = \gamma \exp\left(-\frac{(x-x')^2}{2a^2}\right)$ ,  $x, x' \in \mathcal{X}$ , the second term in the ELBO can be analytically calculated (Lloyd et al., 2015) as follows:

$$\begin{aligned} \mathbb{E}_q \left[ \int_{\mathcal{X}^{(k)}} f^2(x) dx \right] &= \gamma |\mathcal{X}^{(k)}| - \text{tr}(K_{RR}^{-1} \Phi) \\ &\quad + \text{tr}(K_{RR}^{-1} \Phi K_{RR}^{-1} (\boldsymbol{\mu} \boldsymbol{\mu}^\top + \Sigma)), \end{aligned} \quad (8)$$

where  $\Phi$  is an  $R \times R$  matrix related to the pseudo inputs with its  $(i, j)$ -th entry equal to  $\int_{\mathcal{X}^{(k)}} \kappa(x_i, x) \kappa(x, x_j) dx$  and  $K_{RR}$  is the covariance matrix computed at the pseudo inputs. However, the ELBO  $\mathcal{L}$  is still intractable, since we can not analytically compute the expected integral  $\mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} f^2(x) dx \right]$  in the first term.

## 4.2 A TRACTABLE LOWER BOUND

We tackle the intractable expectation by deriving a tractable lower bound. First we introduce a relevant lemma on the expectation of the logarithm of the square of a normal-distributed random variable.

**Lemma 1.** *Let  $y \sim \mathcal{N}(\mu, \sigma^2)$  and  $\varphi = (\mu/\sigma)^2$ . Then*

$$\mathbb{E}_y[\ln y^2] = \ln(2\sigma^2) + \sum_{j=0}^{\infty} \frac{(\varphi/2)^j \exp(-\varphi/2)}{j!} \psi(j+1/2), \quad (9)$$

where  $\psi(\cdot)$  is the digamma function.

The proof of Lemma 1 can be found in Appendix A. Let

$$g_m(y) = \sum_{j=0}^{\infty} \frac{y^j \exp(-y)}{j!} \psi(j+m). \quad (10)$$

Then  $\mathbb{E}_y[\ln y^2] = \ln(2\sigma^2) + g_{0.5}(\varphi/2)$ . The function  $g_m(y)$ , where  $y$  is a positive real number and  $m$  is a positive integer, has been studied in the analysis of mobile

and wireless communication systems (Moser, 2007). For  $m = 1/2$ ,  $g_{0.5}(\varphi/2)$  can be computed using a confluent hyper-geometric function  $G(\cdot)$  (Lloyd et al., 2015), which is stored in a pre-computed look-up table.

$$g_{0.5}(\varphi/2) = -G(-\varphi/2) - 2 \ln 2 - C, \quad (11)$$

where  $C$  is Euler's constant and  $C \approx 0.5772$ . However, to the best of our knowledge, it is still not clear how to calculate the integral of the function  $G(-\varphi/2)$  when using a GP. To derive a tractable lower bound of the intractable expectation, we introduce the following lemma to give a lower bound of the function  $g_m(y)$  and the proof can be found in Appendix B.

**Lemma 2.** *Let  $y \sim \mathcal{N}(\mu, \sigma^2)$  and  $C$  be Euler's constant.*

$$\mathbb{E}_y[\ln y^2] \geq \ln(\mu^2 + b\sigma^2) - C - \ln 2, \quad \forall b \in [0, 1]. \quad (12)$$

Based on Lemma 2, we propose the following lower bound for the intractable expectation in the ELBO.

**Theorem 1.** *Let  $f$  be a GP as defined in Equation (4). For  $b \in [0, 1]$ , the following bound holds:*

$$\begin{aligned} \mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} f^2(x) dx \right] &\geq -C - \ln 2 \\ &\quad + \ln \left( \int_{\mathcal{X}_i^{(k)}} \left( \mathbb{E}_q^2 f(x) + b \text{Var}_q f(x) \right) dx \right), \end{aligned} \quad (13)$$

where the distribution  $q$  is given in Equation (6).

*Proof.* We first use Jensen's inequality on the logarithm function and then interchange the order of integration and expectation.

$$\begin{aligned} \mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} f^2(x) dx \right] &= \mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} \tilde{p}(x) \frac{f^2(x)}{\tilde{p}(x)} dx \right] \\ &\geq \int_{\mathcal{X}_i^{(k)}} \tilde{p}(x) \mathbb{E}_q \left[ \ln \frac{f^2(x)}{\tilde{p}(x)} \right] dx, \end{aligned} \quad (14)$$

where  $\tilde{p}(x)$  is a probability distribution on  $\mathcal{X}_i^{(k)}$ . Furthermore, maximizing this lower bound with respect to  $\tilde{p}(x)$  yields the optimal distribution:

$$\tilde{p}_{\text{opt}}(x) \propto \exp \left( \mathbb{E}_q \ln f^2(x) \right). \quad (15)$$

We remark that this result is analogous to that of the discrete version presented in Paisley (2010). Substituting Equation (15) into the right-hand side of Equation (14)

yields

$$\begin{aligned}
\mathbb{E}_q \left[ \ln \int_{\mathcal{X}_i^{(k)}} f^2(x) dx \right] &\geq \ln \left( \int_{\mathcal{X}_i^{(k)}} e^{\mathbb{E}_q \ln f^2(x)} dx \right) \\
&\stackrel{(13)}{\geq} \ln \left( \int_{\mathcal{X}_i^{(k)}} e^{\ln(\mathbb{E}_q^2 f(x) + b \text{Var}_q f(x)) - C - \ln 2} dx \right) \\
&= \ln \left( \int_{\mathcal{X}_i^{(k)}} \left( \mathbb{E}_q^2 f(x) + b \text{Var}_q f(x) \right) dx \right) - C - \ln 2,
\end{aligned}$$

where we have invoked Lemma 2 in the penultimate line whilst defining  $y := f(x)$ .  $\square$

It should be emphasized that we are making no further assumptions on the dimensionality of  $x$  in the proof of Theorem 1. Hence we may augment the dimensionality of  $x$  in Theorem 1 such that it can also be applied to problems in spatial point processes. In summary, the ELBO in Equation (7) inherits an analytical bound. We present the following:

**Theorem 2.** *A tractable lower bound of the ELBO  $\mathcal{L}$  in the GP4C model is given as follows:*

$$\begin{aligned}
\mathcal{L} &\geq \tilde{\mathcal{L}} \triangleq - \sum_{k=1}^K \mathbb{E}_q \left[ \int_{\mathcal{X}^{(k)}} f^2(x) dx \right] + \mathbb{E}_q \left[ \ln \frac{p(\mathbf{f}_R)}{q(\mathbf{f}_R)} \right] \\
&+ \sum_{k=1}^K \sum_{i=1}^{N_k} m_i^{(k)} \ln \left( \int_{\mathcal{X}_i^{(k)}} \left( \mathbb{E}_q^2 f(x) + b \text{Var}_q f(x) \right) dx \right) \\
&- \sum_{k=1}^K \sum_{i=1}^{N_k} \left( m_i^{(k)} (C + \ln 2) + \ln(m_i^{(k)}!) \right). \quad (16)
\end{aligned}$$

The details of the proof are deferred to Appendix C. The derivations of  $\mathbb{E}_q^2 f(x)$  and  $\text{Var}_q f(x)$  follow similar lines to the derivation of Equation (8). The third part of  $\tilde{\mathcal{L}}$  is a constant and thus can be omitted when maximizing the lower bound. Let  $\Psi = \{\boldsymbol{\mu}, \Sigma\}$  and  $\Phi = \{\gamma, a\}$  be the variational parameters and hyper-parameters in the covariance function of a GP, respectively. We use the variational Expectation-Maximization (vEM) algorithm (Dempster et al., 1977) to update the parameters  $\Psi$  and  $\Phi$  iteratively on the modified ELBO  $\tilde{\mathcal{L}}$ .

### 4.3 THE VALUE OF PARAMETER $b$

A natural question is, how do we select the parameter  $b$  in Theorem 1? Recall that two inequalities were used in the proof. It is cumbersome to evaluate Inequality (14) since it is an integral over  $\mathcal{X}_i^{(k)}$ . We first examine different choices of  $b$  in Lemma 2.

In Paisley et al. (2012), a more correlated lower bound of the ELBO serves as a better control variate in reducing the variance of a stochastic gradient. Inspired by this

**Figure 3: Influences of  $b$  in Lemma 2.** (Left) The true value of  $-G(-\varphi/2)$  by a look-up table and two simple lower bounds. The bound  $\ln(\phi + b)$  with  $b = 0.3$  correlates with the curve of the true value better. (Right). The variance  $\text{Var}[h(\varphi; b)]$  when varying the choices of  $b$  and the best  $b$  is shown with a red circle.

study, we introduce a heuristic method and conduct the following experiment to evaluate the correlation for different choices of  $b$ . In Lemma 2, the difference between the lower bound and the true value is

$$\begin{aligned}
&\ln(\mu^2 + b\sigma^2) - C - \ln 2 - \mathbb{E}_y[\ln y^2] \\
&= \ln(\varphi + b) + G(-\varphi/2) \triangleq h(\varphi; b). \quad (17)
\end{aligned}$$

For each choice of  $b$ , we vary  $\varphi = (\mu/\sigma)^2$  on a vector of 5000 logarithmically spaced points between  $10^{-6}$  and  $10^6$  and evaluate the correlation between the lower bound and the true value by the variance  $\text{Var}[h(\varphi; b)]$ . We calculate  $\text{Var}[h(\varphi; b)]$  on a vector of 50 evenly spaced choices of  $b$  between 0 and 1 and the result is shown in Figure 3. We see that the optimal choice of  $b$  is 0.3061 if  $\varphi$  ranges from  $10^{-6}$  to  $10^6$ . In the actual situation, this optimal value of  $b$  depends on the range of  $\varphi$  in the data and the influence of Inequality (14), we evaluate several choices of  $b$  on synthetic data sets in Section 5.

### 4.4 COMPUTATIONAL COMPLEXITY

Let each interval in temporal point processes be  $\mathcal{X}_i^{(k)} = [x_{ai}^{(k)}, x_{bi}^{(k)}]$  with two end points  $x_{ai}^{(k)}$  and  $x_{bi}^{(k)}$ . Two intervals are different if at least one end point is different. We denote the number of different intervals in the data set as  $N$  and the number of pseudo inputs as  $M$ . For each interval, the computation complexity of GP4C is  $\mathcal{O}(M^3)$  which is determined by the matrix-matrix calculation when evaluating  $\text{Var}_q f(x)$  in Equation (16). The computational complexity during one iteration of the vEM algorithm is  $\mathcal{O}(NM^3)$  since in our implementation, we calculate the integral of all  $N$  different intervals.

We analyze the computational complexity of the Lo-

calEM (Fan et al., 2011) algorithm for comparison. In LocalEM,  $\{x_{ai}^{(k)}\}$  and  $\{x_{bi}^{(k)}\}$  are first merged into a single ordered set  $X$  where duplicated values are removed. We denote the size of the merged set  $X$  as  $\bar{N}$  and generally  $\bar{N} \leq N$ . Then the Gaussian quadratic rule with  $\bar{M}$  points is used to calculate the integral of the intensity function between subsequent values in the set  $X$  and the computational complexity during one iteration is  $\mathcal{O}(\bar{N}^2 \bar{M}^2)$ . If the size of the merged set  $\bar{N}$  is significantly smaller than  $N$ , LocalEM may be computationally more efficient than GP4C. However, if  $\bar{N} \approx N$ , LocalEM may suffer from the term  $\bar{N}^2$  in the computational complexity. We provide additional experiments on the influence of the number  $\bar{N}$  in Appendix E.3.

## 5 EXPERIMENTS

We evaluate our proposed GP4C model and compare it with the benchmark methods on both synthetic and real-world data sets. The algorithms are programmed in Matlab R2015b and run on an Intel Xeon E5-2667 CPU with a memory of 64GB. Our code is available at [github.com/Dinghy/GP4C](https://github.com/Dinghy/GP4C).

### 5.1 EXPERIMENT SETTINGS

For each data set  $\mathcal{D}$ , we randomly partition the subjects into training and testing sets, which we denote as  $\mathcal{D}_{\text{train}}$  and  $\mathcal{D}_{\text{test}}$ , respectively. We repeat each setting for  $S = 40$  times. In the  $s$ th trial, the training and testing sets are denoted as  $\mathcal{D}_{\text{train}}^{(s)}$  and  $\mathcal{D}_{\text{test}}^{(s)}$ .

**Benchmark.** Two benchmark algorithms are used.

- a) **GP3** (Lloyd et al., 2015). This benchmark reflects the best performance that can be obtained if we obtain the recurrent event data set where we have the exact timestamps.
- b) **LocalEM** (Fan et al., 2011). Both LocalEM and GP4C are nonparametric estimators based on the maximum likelihood criterion. To fairly compare the computation time, we implemented the LocalEM algorithm in MATLAB based on the R code provided in Fan et al. (2011). This method produces a smooth estimate of the intensity function due to the use of an exponential quadratic kernel. We use a 5-fold cross-validation on the training set to select the bandwidth of the exponential quadratic kernel.

**Evaluation Metric.** We evaluate the performance of the algorithms in terms of three metrics.

- a) Mean of the integrated squared error (MISE). In synthetic data sets, we have the ground truth of the

intensity function  $\lambda_{\text{true}}$  and the integrated squared error can be calculated using our estimated intensity function  $\lambda_{\text{est}}^{(s)}$  during the  $s$ th trial. To measure the bias of each estimator, we calculate the mean of the integrated squared error as follows:

$$\text{MISE}(s) \triangleq \int_{\mathcal{X}} (\lambda_{\text{est}}^{(s)}(x) - \lambda_{\text{true}}(x))^2 dx. \quad (18)$$

For GP4C, to measure its bias, we omit the variance of the estimator and use the expectation of the intensity function  $\mathbb{E}_{q^{(s)}}[f^2(x)]$  as  $\lambda_{\text{est}}^{(s)}(x)$ .

- b) Test log likelihood  $\mathcal{L}_{\text{test}}$ . During the  $s$ th trial, the logarithm of the test likelihood can be written as follows:

$$\mathcal{L}_{\text{test}}(s) \triangleq \ln \int p(\mathcal{D}_{\text{test}}^{(s)} | f) p(f | \mathcal{D}_{\text{train}}^{(s)}) df. \quad (19)$$

For LocalEM, since this estimator provides a point-estimate and we directly use the estimated function  $f^{(s)}$  to calculate  $\mathcal{L}_{\text{test}}(s)$ . For GP4C and GP3, we need to sample the function  $f^{(s)}$  from the variational distribution and the detailed calculation can be found in Appendix D.

- c) Computation time  $T$ . We record the training time measured in seconds for each setting. For GP3 and GP4C, we record the computation time of the training process. For LocalEM, it includes the time of 5-fold cross-validation on the training set to select the bandwidth of the exponential quadratic kernel and the time of a training process over the whole training set.

**Optimization Settings.** For GP3 and GP4C, following Lian et al. (2015), we use the re-parametrization trick  $\Sigma = LL^T$  by Cholesky decomposition and add positivity constraints to the diagonal elements in  $L$ . Due to this constraint on  $L$ , we use the limited-memory projected quasi-Newton algorithm (Schmidt et al., 2009) to optimize the variational parameters  $\Psi = \{\mu, \Sigma\}$ . We add a jitter term  $\epsilon I$  where  $\epsilon = 10^{-6}$  to the covariance matrix  $K_{RR}$  to avoid numerical instability (Titsias, 2009).

### 5.2 SYNTHETIC DATA SETS

We test three synthetic data sets which we denote as the Synthetic A, B and C data sets, respectively.

On the Synthetic A data set, the intensity function is a square wave function  $h_1(x)$  as follows. See Figure 4 for an illustration of  $h_1(x)$ .

$$h_1(x) = \begin{cases} 7 & \text{if } \text{mod}\left(\left\lfloor \frac{x}{10} \right\rfloor, 2\right) = 0, \\ 2 & \text{otherwise.} \end{cases}$$

Table 1: **Synthetic data sets.** Mean and standard deviation of statistics about different choices of  $b$  over 40 runs. GP3 uses the *recurrent event data* while LocalEM and GP4C use the *panel count data*. For GP4C,  $b = 0.3$  and  $b = 0$  perform better than  $b = 1$  in terms of MISE and  $\mathcal{L}_{\text{test}}$ .

Method	MISE	$\mathcal{L}_{\text{test}}$	$T$ [s]
(Synthetic A)			
GP3	29.5±1.0	-1366.5±17.4	16±4
GP4C(1)	41.8±6.2	-3236.9±542.3	25±5
GP4C(0)	40.8±3.3	-1378.1±16.9	19±4
GP4C(0.3)	40.2±3.2	-1377.8±17.5	20±3
LocalEM	44.6±3.1	-1383.5±17.0	33±2
(Synthetic B)			
GP3	0.5±0.2	-783.1±20.7	8±1
GP4C(1)	1.9±2.1	-1005.8±81.5	55±44
GP4C(0)	2.7±0.8	-794.5±20.1	17±3
GP4C(0.3)	2.4±0.7	-794.2±20.2	17±4
LocalEM	3.5±0.7	-800.3±19.6	33±2
(Synthetic C)			
GP3	1.2±0.4	-864.1±14.9	8±3
GP4C(1)	2.3±1.5	-1194.6±100.5	52±53
GP4C(0)	2.1±0.6	-871.2±15.9	17±2
GP4C(0.3)	2.0±0.7	-872.0±15.7	18±3
LocalEM	5.2±1.1	-882.7±16.5	34±2

On the Synthetic B and C data set, the underlying intensity functions are drawn according to Equation (4). We first draw a function from a GP on a vector of 3001 evenly-spaced points in  $\mathcal{X} = [0, T]$ , where  $T = 60$ . We approximate the value of the function at an arbitrary position with linear interpolation. The function is then squared to guarantee the positiveness of the intensity function. See Figure 5 for an illustration.

During the  $s$ th trial, we first generate a *recurrent event data set* with 100 subjects on the same observation window  $\mathcal{X}^{(k)} = \mathcal{X}$ . Then we generate the corresponding *panel count data set*  $\mathcal{D}^{(s)}$  by censoring each subject with 10 intervals. We generate the censored intervals by a draw from a Dirichlet distribution  $\mathbf{w}^{(k)} \sim \text{Dir}(\boldsymbol{\theta})$  and  $\boldsymbol{\theta}$  is a 10-dimensional vector with all elements equal to 1. The  $i$ th interval of the  $k$ th subject can be computed as  $\mathcal{X}_i^{(k)} = [\sum_{j=1}^{i-1} w_j^{(k)} T, \sum_{j=1}^i w_j^{(k)} T]$ . We randomly partition  $\mathcal{D}^{(s)}$  into two parts, where 50 subjects are used for training and 50 for testing.

**Different choices of the hyper-parameter  $b$ .** On all three synthetic data sets, we test three different choices of  $b$  in  $\{0, 0.3, 1\}$ . We choose the number of pseudo inputs to be 30. We calculate the MISE and  $\mathcal{L}_{\text{test}}$  and the results

Figure 4: **Synthetic A Data Set.** The estimated intensity functions from GP4C ( $b = 1$ ) and GP4C ( $b = 0.3$ ) are shown with 75% credible intervals. True intensity function  $h_1(x)$  is given for comparison. We see that GP4C ( $b = 1$ ) over-estimates the variance of the intensity function.

Figure 5: **Synthetic B & C Data Sets.** An illustration of the underlying intensity functions and inferred intensity functions by the LocalEM and GP4C methods. The underlying intensity function is drawn from a Gaussian process. For GP4C, a 75% credible interval is given by dotted lines.

are provided in Table 1. We see that  $b = 0, 0.3$  generally outperform  $b = 1$  on these simple synthetic data sets. However, the difference between  $b = 0$  and  $b = 0.3$  is not significant. The reason is that Inequality (14) and the range of  $\varphi$  on  $\mathcal{X}$  are also relevant to the actual performance of different  $b$ , as we discussed in Section 4.3.

To investigate the reason behind the bad performance of  $\mathcal{L}_{\text{test}}$  when  $b = 1$ , we plot the best result in terms of MISE during 40 trials in Figure 4. We see that GP4C ( $b = 1$ ) over-estimates the variance of the intensity function and the over-estimated variance leads to the poor performance in  $\mathcal{L}_{\text{test}}$ . We fix  $b = 0.3$  during the remaining experiments for simplicity.

**Number of the pseudo inputs.** We vary the number of pseudo inputs in GP3 and GP4C since this number de-

Figure 6: **Synthetic Data Set.** Comparison of performance of GP3, GP4C and LocalEM in terms of  $\mathcal{L}_{\text{test}}$ , MISE and  $T$  when varying the number of pseudo inputs for sparse GPs. For the test likelihood, MISE and the computation time, the median, the 0.25 and 0.75 quantiles of the statistics in 40 experiments are shown with error bars or shaded area. For GP3 and GP4C, MISE and  $\mathcal{L}_{\text{test}}$  stay relatively stable with the increase of the number of pseudo inputs.

terminates the accuracy of approximation in a sparse GP. We expect that for GP-based methods the test likelihood will be relatively stable when increasing the number of pseudo inputs according to previous studies on sparse GPs (Titsias, 2009).

The result for the Synthetic A data set is given in Figures 6. In Figure 6, we see that for GP3 and GP4C, MISE and  $\mathcal{L}_{\text{test}}$  stay relatively stable with the increase of the number of pseudo inputs. The computation time of GP3 and GP4C will grow with the increase of the number of pseudo inputs.

In both Table 1 and Figure 6, we see that GP4C outperforms LocalEM on these three datasets. However, we also notice that there is still a gap between GP3 and GP4C in terms of  $\mathcal{L}_{\text{test}}$  and MISE in Table 1. Two reasons may account for this fact. The first one is that the data are provided in the form of panel counts rather than exact timestamps. The second reason is that we use a lower bound of the true ELBO to perform the variational inference, which may lead to a bias. This bias can be alleviated with the stochastic variational inference (Paisley et al., 2012), where our lower bound can serve as a control variate. We leave this as a future study.

An additional experiment in which we increase the number of training subjects to evaluate the gain in performance on the Synthetic A data set is given in Appendix E.2.

### 5.3 REAL WORLD DATA SETS

Sun and Zhao (2016) provided three panel count data sets. Some statistics can be found in Table 2. A brief description about the these data sets can be found in Ap-

Table 2: Statistics about the three data sets, where  $K$ ,  $\mathcal{X}$ ,  $\bar{N}$  and  $N$  denote the number of subjects in each data set, the underlying continuous space, the number of different end points and the number of different intervals  $\mathcal{X}_i^{(k)}$ , respectively.

Data Set	$\mathcal{X}$	$K$	$\bar{N}$	$N$
Na-A	[0, 55]	65	45	109
Na-B	[0, 55]	48	38	84
Bl-A	[0, 53]	38	52	176
Bl-B	[0, 53]	47	52	201
Sk-A & Sk-B	[0, 61.57]	143	751	816
Sk-C & Sk-D	[0, 62.63]	147	808	887

pendix F.

We use 18 pseudo inputs for all real world experiments. In each trial, we randomly split each data set into two parts, which are  $\mathcal{D}_{\text{train}}^{(s)}$  (50%) and  $\mathcal{D}_{\text{test}}^{(s)}$  (50%). On these three data sets, since the original data are in the form of panel counts, GP3 is not tested. We compare GP4C with LocalEM in terms of  $\mathcal{L}_{\text{test}}$  and the computation time  $T$ .

The results are given in Table 3. The standard deviation of the likelihood is large since the likelihood depends on the censored intervals of the subjects, which vary greatly in different train/test split. We conduct an experiment to reduce the standard deviation in Appendix H. In Table 3, LocalEM performs better on the Nausea and Bladder data sets in terms of the computation time  $T$ . GP4C outperforms LocalEM in terms of test likelihood  $\mathcal{L}_{\text{test}}$  in all data sets.

Figure 7: **Bladder A Data Set.** An illustration of the panel count data in the test set (Left) and the test likelihood from GP4C and LocalEM of each subject (Right). GP4C mainly outperforms LocalEM on two subjects whose numbers of newly-occurred cancers are large (No. 12 and 15).

To see the difference between GP4C and LocalEM, we show the result of inferred intensities by two algorithms during one trial on the Bladder A data set in Figure 2. We see that GP4C provides the additional uncertainty which helps improve  $\mathcal{L}_{\text{test}}$  compared with LocalEM. Since the Bladder A set is small, we plot the panel count data in the training set in Figure 1. The test set and the test likelihood of all its subjects are given in Figure 7. From the test likelihood of each subject, we see that GP4C outperforms LocalEM on two subjects whose counts of newly-occurred tumors are large (No. 12 and No. 15). The count 8 never occurs in the training set and a point-estimate will fail to model this uncertainty while a GP-modulated method will take the uncertainty into consideration.

Another observation about this data set is that there is a heterogeneity across all subjects. The traditional approach to modeling heterogeneity is to add an additional variable on the intensity function for each subject (Cook and Lawless, 2007). We briefly discuss how to add this change to GP4C in Appendix G.

## 6 CONCLUSION

We presented the first framework for GP-modulated Poisson processes when data appear in the form of panel counts. We derived a tractable lower bound for the intractable evidence lower bound when modeling the panel count data using the GP-modulated intensity function. Our model, GP4C, outperforms a non-Bayesian method using the maximum likelihood criterion in terms of test likelihood and achieves comparable results in terms of

Table 3: Mean and standard deviation of the test likelihood ( $\mathcal{L}_{\text{test}}$ ) and the computation time  $T$  measured in seconds on the three panel count data sets over 40 runs. LocalEM performs better on the Nausea and Bladder data sets in terms of computation time. In all data sets, GP4C performs better on the test likelihood and outperforms LocalEM on computation time in the Skin data sets.

Data Set	METHOD	$\mathcal{L}_{\text{test}}$	$T[s]$
Na-A	LocalEM	$-492.1 \pm 306.1$	$1 \pm 0$
	GP4C	$-484.9 \pm 201.8$	$10 \pm 10$
Na-B	LocalEM	$-473.2 \pm 212.2$	$1 \pm 0$
	GP4C	$-411.0 \pm 184.3$	$10 \pm 7$

	GP4C	$-191.2 \pm 42.5$	$24 \pm 4$
Sk-C	LocalEM	$-358.0 \pm 35.8$	$47 \pm 4$
	GP4C	$-355.7 \pm 36.0$	$21 \pm 12$
Sk-D	LocalEM	$-200.9 \pm 31.9$	$46 \pm 3$
	GP4C	$-198.9 \pm 30.6$	$27 \pm 4$

computational time.

In the future, we plan to implement the stochastic variational inference algorithm to evaluate the bias in the tractable lower bound. We are also considering to find an applicable two-dimensional data set where we can extend our algorithm to spatial point processes.

## Abstract

Connectivity estimation is challenging in the context of high-dimensional data. A useful preprocessing step is to group variables into clusters, however, it is not always clear how to do so from the perspective of connectivity estimation. Another practical challenge is that we may have data from multiple related classes (e.g., multiple subjects or conditions) and wish to incorporate constraints on the similarities across classes. We propose a probabilistic model which simultaneously performs both a grouping of variables (i.e., detecting community structure) and estimation of connectivities between the groups which correspond to latent variables. The model is essentially a factor analysis model where the factors are allowed to have arbitrary correlations, while the factor loading matrix is constrained to express a community structure. The model can be applied on multiple classes so that the connectivities can be different between the classes, while the community structure is the same for all classes. We propose an efficient estimation algorithm based on score matching, and prove the identifiability of the model. Finally, we present an extension to directed (causal) connectivities over latent variables. Simulations and experiments on fMRI data validate the practical utility of the method.

## 1 INTRODUCTION

Estimating the connectivity structure between observed variables is a fundamental problem in statistics and machine learning. Probabilistic methods are often based on estimation of the covariance matrix or its inverse. A number of estimators have been proposed for both (Dempster, 1972; Ledoit & Wolf, 2003). On a more general

level, such undirected connectivity estimation is a special case of modelling the covariance matrix, which is one of the goals of classical dimensionality reduction methods such as factor analysis and principal components analysis (PCA). In contrast, directed connectivity estimation studies the causal dependence structure across variables (Pearl, 2009). In this work we present methods to perform both directed and undirected connectivity estimation of latent variables in the context of high-dimensional data.

An important problem in practice is that many connectivity estimation methods assume we observe, and know how to choose, the variables between which the connectivity is to be estimated. However, in practice we often have very high-dimensional data, and it may not be useful or feasible to estimate the connectivities between all of them. It is important to somehow reduce the number of variables so that the connectivity estimation is feasible, and furthermore, such reduction can greatly facilitate interpretation of the results. It is often useful to perform the dimension reduction so that it can be interpreted as clustering, as in non-negative PCA (Sigg & Buhmann, 2008). A relevant challenge is how such reduction in the number of variables should be combined with connectivity estimation. In the past, approaches based on stochastic block models (Airoldi et al., 2008; Marlin & Murphy, 2009) or clustered factor analysis (Buesing et al., 2014) have been employed. However, such methods do not explicitly model the connectivity over latent variables and cannot easily be extended to accommodate multiple classes of related datasets, both of which are of interest in this work. Alternative methods recover correlation structure over latent variables but do not focus on dimensionality reduction (Sasaki et al., 2017). Conversely, in the context of directed connectivity, the causal clustering of observed variables has been studied by Silva et al. (2006), Shimizu et al. (2009) and Kummerfeld & Ramsey (2016).

A further challenge is estimating multiple related connectivity matrices, assuming the data is divided into a number of classes, such as subjects in a biomedical setting.

While the estimation of multiple related Gaussian graphical models, parameterized by the inverse covariance, has been extensively studied (Varoquaux et al., 2010; Danaher et al., 2014; Monti et al., 2017), we want to combine such multiple connectivity estimation with the variable reduction scheme described above as well as extend such methods to the domain of directed connectivities.

A practical application that motivates our theoretical developments is functional MRI (fMRI) data, where estimation of “functional connectivity” is widely practiced. Such analysis is a cornerstone of modern neuroscientific research, having provided fundamental insights into the structure and architecture of the human connectome. However, the existing methods are often not very rigorous and would benefit from a proper probabilistic formulation. Traditionally, functional connectivity networks have been modeled as covariance graphs, where the nodes in the network correspond to spatially remote brain regions and edges encode the marginal dependence structure (often simply the covariance). In fMRI, we very clearly see the importance of the theoretical points raised above, in the form of the following challenges:

- **Inter-subject consistency:** Data is often collected across a cohort of subjects. A hallmark of brain networks is their inter-subject consistency; observed patterns in connectivity have been shown to demonstrate reproducible properties across subjects (Damoiseaux et al., 2006). This suggests significant benefits can be obtained by sharing information across subjects in a judicious manner. In fact, some of the most recent developments are based on collecting hundreds or even thousands of subjects’ data in a single data base (Di Martino et al., 2014).
- **Modularity:** Current methods do not actively incorporate domain knowledge relating to brain networks, a prime example of which is their modular structure which suggests that variables can be aggregated into non-overlapping modules or sub-networks (Sporns & Betzel, 2016). We note this property is not unique to brain networks, but also present in many real-world networks (Newman, 2006).

While motivated by fMRI, we note that these two properties are relevant to wide range of applications such as cyber-security, gene expression data and econometrics.

In this work, we propose a probabilistic latent variable model which is able to directly address the aforementioned issues. The proposed model consists of a low dimensional set of latent variables in a factor analytic model. The associated factor loading matrix is shared across classes and constrained to be non-negative and

orthonormal, thereby encoding module/community membership along its columns. Thus, the factors are interpreted as the activities in modules or communities.

Importantly, and in contrast to almost all related models, these latent variables or factors have full (i.e., non-diagonal) covariance structure which we term *latent connectivities*, giving the connectivity structure of the non-overlapping modules. The connectivity structure can be different between classes; however, the model can equally well be applied on data from a single class. Thus, we model both the grouping of variables, and the connectivity between the groups in a single probabilistic model, which can be seen as a variant of factor analysis. We argue that such a formulation leads to important benefits from the viewpoint of interpretation and identifiability whilst remaining plausible from an application perspective.

In contrast to classical Gaussian factor analysis, we are able to prove the uniqueness of the solution: the factors and loadings are identifiable like in (non-Gaussian) independent component analysis (Comon, 1994), largely based on non-negativity inherent in the module structure (Paatero & Tapper, 1994; Seung & Lee, 1999; Donoho & Stodden, 2004). We further propose an efficient parameter estimation algorithm based on score matching. Finally, we demonstrate that the proposed model can be extended to modelling directed connectivities between the latent variables. In this context, the factor loading matrix can be seen as a “pure” measurement model of a Bayesian network (Silva et al., 2006) of causal relationships between high-dimensional observations and their latent variables.

The remainder of this manuscript is organized as follows; in Section 2 we present the proposed model in the context of undirected latent variables. Section 3 provides an identifiability analysis for the proposed method. An efficient estimation algorithm based on score matching is presented in Section 4. The proposed method is extended to recover causal structure over latent variables in Section 5. Experimental results are presented in Section 6.

## 2 LATENT CONNECTIVITIES MODEL

We propose a latent variable model to accurately find modules (communities, clusters) and model their connectivities, possibly across multiple related classes (conditions, subjects). We assume we have access to multivariate data over  $N$  distinct classes, but all our results allow for the simple case  $N = 1$  as well. For a given class  $i$ , we write  $X^{(i)} \in \mathbb{R}^p$  to denote the  $p$ -dimensional observed random vector. The  $i$ th class is associated with a  $k$ -dimensional latent vector,  $Z^{(i)}$ , which is related to observations,  $X^{(i)}$ , via a loading matrix  $W \in \mathbb{R}^{p \times k}$ . We note that the loading matrix is shared across all classes and will serve to encode

module memberships across classes.

We start by a model of undirected connectivities in this section. Here, we assume that the data for each class follows a stationary multivariate Gaussian distribution with zero mean and covariance  $\Sigma^{(i)} \in \mathbb{R}^{p \times p}$ . Both observations and latent variables are taken to follow multivariate Gaussian distributions, such that:

$$Z^{(i)} \sim \mathcal{N}\left(0, G^{(i)}\right) \quad (1)$$

$$X^{(i)}|Z^{(i)} = z^{(i)} \sim \mathcal{N}\left(Wz^{(i)}, v^{(i)}I\right). \quad (2)$$

If  $G^{(i)}$  were diagonal, equations (1) and (2) would correspond to the traditional factor analysis or probabilistic PCA models (Tipping & Bishop, 1999). Our model is able to capture low-rank covariance structure via the loading matrix,  $W$ , as follows:

$$\Sigma^{(i)} = WG^{(i)}W^T + v^{(i)}I. \quad (3)$$

From equation (3) it follows that the loading matrix  $W$  serves to encode reproducible covariance structure which is present across all classes. In this work, we extend the traditional factor analysis model as follows:

- The loading matrix,  $W$ , is constrained to be non-negative and orthonormal. This leads to a loading matrix with at most one non-zero entry per row. We may interpret the columns of  $W$  as encoding membership to  $k$  non-overlapping modules or sub-networks.
- We introduce latent variables with a non-diagonal covariance structure, which we term *latent connectivities*. While the columns of the loading matrix encode module membership, the non-trivial covariance structure over latent variables may be interpreted as modeling marginal dependencies (i.e., connectivity) across distinct modules or sub-networks. Such an interpretation is very natural in many applied settings.

We note that the introduction of marginally dependent latent variables is not possible in the context of traditional factor analysis, since the effects of factor connectivity and factor loadings cannot be distinguished. In fact, an ordinary factor analysis model is non-identifiable even with uncorrelated factors. However, in combination with the aforementioned constraints on the loading matrix, it is possible to identify the latent connectivities in our model (see next section). We thus argue that our model is able to capture the modular nature of many real-world datasets and, due to its identifiability, yields easily interpretable results. Figure 1 provides an overview of the proposed model in the context of estimating brain connectivity networks.

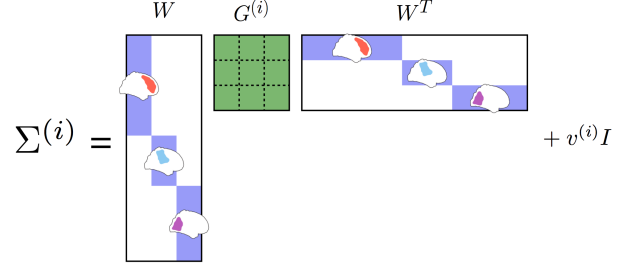

Figure 1: Visualization describing the various components of the proposed covariance model. The factor loading matrix,  $W$ , is shared across all subjects and serves to denote membership into non-overlapping brain modules. The *latent connectivity* across modules, parameterized by  $G^{(i)}$ , is allowed to vary across subjects.

### 3 IDENTIFIABILITY ANALYSIS

We note that without the introduction of constraints on  $W$ , the covariance model proposed in equation (3) is not unique. For example, it would be possible to reparameterize  $W$  such that  $G^{(i)}$  is diagonal matrix by using an eigen-value decomposition of  $G^{(i)}$ . However, the following properties demonstrate that non-negativity and orthonormality constraints are sufficient to ensure the solution is identifiable.

**Property 1.** *Assume non-negative, orthonormal  $W$ . Then at most one entry per row of  $W$  can be non-zero.*

*Proof.* Directly from the constraints on  $W$ , we can express the  $(i, j)$  entry of  $W^T W$  as:

$$(W^T W)_{ij} = \sum_{r=1}^k (W^T)_{ir} W_{rj} = \sum_{r=1}^k W_{ri} W_{rj} = \delta_{ij}$$

which, combined with non-negativity, implies that the  $i$  and  $j$  columns of  $W$  can have no overlapping support for  $i \neq j$ .  $\square$

**Property 2.** *Assume non-negative, orthonormal  $W$ . Then any matrix  $V \in \mathbb{R}^{k \times k}$  for which  $\tilde{W} = WV$  is non-negative and orthonormal must be the identity matrix or some permutation of the identity.*

*Proof.* By Property 1 we have that both  $W$  and  $\tilde{W}$  have at most one non-zero entry per row. Since  $\tilde{W}^T \tilde{W} = I$  we have that  $V^T V = I$ . Define  $c_i$  and  $\tilde{c}_i$  to be the index of the non-zero entry along the  $i$ th row for  $W$  and  $\tilde{W}$  respectively. By construction:

$$\tilde{W}_{i\tilde{c}_i} = (WV)_{i\tilde{c}_i} = \sum_{r=1}^k W_{ir} V_{r\tilde{c}_i} = W_{ic_i} V_{c_i\tilde{c}_i} > 0$$

where the final equality follows from the fact that  $W_{ic_i}$  is the only non-zero entry along the  $i$ th row of  $W$ . Since  $W_{ic_i} > 0$ , this implies that  $V_{c_i \tilde{c}_i} > 0$ . Furthermore, for  $j \neq \tilde{c}_i$  we have

$$\tilde{W}_{ij} = (WV)_{ij} = \sum_{r=1}^k W_{ir} V_{rj} = W_{ic_i} V_{c_i j} = 0$$

Since  $W_{ic_i} > 0$ , we must have that  $V_{c_i j} = 0$  whenever  $j \neq \tilde{c}_i$ . When combined with the fact that  $V^T V = I$ , it follows that  $V$  must either be the identity matrix of a permutation it.  $\square$

Property 2 indicates that the matrix  $W$  is uniquely defined in our model, and there is nothing like an undetermined factor rotation in conventional Gaussian factor analysis. By similar logic, Property 2 also implies the uniqueness of  $G^{(i)}$ .

## 4 ESTIMATION BY SCORE MATCHING

The parameters associated with the proposed model consist of the loading matrix,  $W$ , the latent variable covariances,  $\{G^{(i)}\}$ , and the observation noise,  $\{v^{(i)}\}$ . One potential strategy is to estimate latent variables in an expectation-maximization framework. However, due to relative simplicity of the proposed covariance model we propose to directly marginalize out latent variables.

Parameters may also be estimated via maximum likelihood estimation, however, this results in an iterative algorithm where the computational cost of each parameter update is  $\mathcal{O}(p^3)$  (a derivation of which is provided in the Supplementary materials). Instead, we propose to estimate parameters by score matching (Hyvärinen, 2005), leading to an algorithm with a computational cost of  $\mathcal{O}(p^2 k)$  per iteration. This is a significant reduction as we will typically expect  $k \ll p$ . While score matching is typically used in the context of unnormalized statistical models, it may often result in optimization-related benefits for normalized models as well (Hyvärinen, 2007; Lin et al., 2016).

In the context of multivariate Gaussian data, the score matching objective function is defined as (Hyvärinen, 2005):

$$J = \sum_{i=1}^N -\text{tr}(\Omega^{(i)}) + \frac{1}{2} \text{tr}(\Omega^{(i)} \Omega^{(i)} K^{(i)}), \quad (4)$$

where  $K^{(i)}$  is the sample covariance matrix for class  $i$  and  $\Omega^{(i)}$  is the inverse covariance, which may be computed by the Sherman-Woodbury identity as:

$$\Omega^{(i)} = v^{(i)-1} \left( I - W G^{(i)} (G^{(i)} + v^{(i)} I)^{-1} W^T \right).$$

Directly optimizing the score matching objective (equation (4)) under non-negativity and orthonormality constraints on the loading matrix is challenging. One potential strategy is to employ projected gradient descent as suggested by Hirayama et al. (2016). However, projecting onto the non-negative Stiefel manifold is undesirable as it requires  $W$  to have at most one non-zero entry per row at each step of the optimization algorithm (see Property 1 above). Such an approach is therefore highly dependent to the random initialization of the loading matrix.

In this work we seek to minimize equation (4) in a constrained optimization framework. This allows for the orthonormality constraints to be enforced via an augmented Lagrangian penalty (Bertsekas, 2014), while the non-negativity is enforced at each iteration by projecting onto the non-negative orthant.

The objective function associated with the augmented Lagrangian is defined as:

$$\tilde{J} = J + \frac{\rho}{2} \|W^T W - I_k\|_2^2 + \text{tr}(\Lambda^T (W^T W - I_k)),$$

where  $\Lambda \in \mathbb{R}^{k \times k}$  are Lagrange multipliers enforcing the orthonormality constraints,  $\rho$  is a positive scalar parameter parameterizing the augmented penalty term and  $J$  is the original score matching objective. We may then proceed to iteratively optimize each of the parameters using gradient descent. In particular, the gradient of the score matching objective with respect to the loading matrix can be computed as:

$$\frac{\partial J}{\partial W} = - \sum_{i=1}^N K^{(i)} W A^{(i)} \left( I - \frac{1}{2} A^{(i)} \right),$$

where we define  $A^{(i)} = G^{(i)} (G^{(i)} + v^{(i)} I)^{-1}$ . Similarly, in the case of the latent connectivities,  $G^{(i)}$ , and observation noise,  $v^{(i)}$ , we have

$$\frac{\partial J}{\partial G^{(i)}} = v^{(i)-2} \left[ v^{(i)} I - W^T K^{(i)} W \left( I - A^{(i)} \right) \right] \times \left[ (G^{(i)} + v^{(i)} I)^{-1} \left( I - A^{(i)} \right) \right].$$

$$\begin{aligned} \frac{\partial J}{\partial v^{(i)}} &= \sum_{i=1}^N -v^{(i)-3} \text{tr} \left( K^{(i)} - v^{(i)} I \right) \\ &\quad + v^{(i)-3} \text{tr} \left( W^T K^{(i)} W H_1^{(i)} \right) + H_2^{(i)} \end{aligned}$$

where  $H_1^{(i)} \in \mathbb{R}^{k \times k}$  and  $H_2^{(i)} \in \mathbb{R}$  are defined, together with the relevant derivations, in the Supplementary material.

Estimation proceeds by iteratively updating each of the parameters in a gradient descent framework. In the context of the loading matrix the step-size,  $\eta$ , is selected via the

Armijo rule and we project onto the non-negative orthant at each iteration, resulting in an update of the form:

$$W \leftarrow \mathcal{P}_+ \left( W - \eta \left( \frac{\partial J}{\partial W} + \rho(WW^T W - W) + W\Lambda \right) \right)$$

where  $\mathcal{P}_+(x) = \max(0, x)$  is the projection onto the non-negative orthant. Moreover, in the case of latent variable connectivities we have:

$$\frac{\partial J}{\partial G^{(i)}} = 0 \iff G^{(i)}(G^{(i)} + v^{(i)}I)^{-1} = I - v^{(i)}(W^T K^{(i)} W)$$

which after some manipulation yields a closed form update for the latent connectivity structure as:

$$G^{(i)} \leftarrow W^T K^{(i)} W - v^{(i)} I \quad (5)$$

By writing  $W^T K^{(i)} W = (X^{(i)} W)^T (X^{(i)} W)$  we note that this update has an intuitive interpretation as the covariance across estimated modules. The Lagrange multipliers are updated as (Bertsekas, 2014):

$$\Lambda \leftarrow \Lambda + \rho(W^T W - I)$$

It is important to note that the proposed method only enforces orthonormality on the loading matrix in the limit of convergence. However, the updates provided above are premised on the assumption that  $W$  is orthonormal. As such, the aforementioned updates only correspond to approximations in the case where  $W$  is non-orthonormal.

**Hyper-parameter Tuning** In practice, the proposed model requires the selection of a single hyper-parameter,  $k$ , which determines the dimensionality of latent variables. We propose to tune  $k$  by minimizing the negative log-likelihood over held-out data.

## 5 EXTENSION TO DIRECTED CONNECTIVITY

In this section we describe a natural extension of the aforementioned model to estimate causal structure (directed connectivity) across latent variables. As in the previous section, we restrict ourselves to linear latent variables models where each observed variable is conditionally dependent on a single latent variable. In the context of Bayesian networks such models are known as *Pure 1-Factor* models (Silva et al., 2006; Kummerfeld & Ramsey, 2016). We note that such an assumption directly corresponds to each row of the loading matrix,  $W$ , containing at most one non-zero entry. This is precisely what is enforced by the non-negativity and orthonormality assumptions introduced in this work. As such, restricting the loading matrix in this manner corresponds to a natural and frequently employed assumption when attempting to recover causal structure (Silva et al., 2006).

We follow Shimizu et al. (2006) and study a non-Gaussian variant of Bayesian networks over latent variables. Formally, we assume variables  $Z_j^{(i)}, j \in \{1 \dots k\}$  can be arranged in a causal ordering such no later variables causes a variable ahead of it in the order. We denote such an ordering by  $k(j)$  and assume that each variable,  $Z_j^{(i)}$ , is a linear function of earlier variables together with a non-Gaussian disturbance,  $e_j^{(i)}$ , such that:

$$Z_j^{(i)} = \sum_{k(r) < k(j)} b_{jr}^{(i)} Z_r^{(i)} + e_j^{(i)}. \quad (6)$$

Due to the linear nature of dependencies, we can write equation (6) as follows:

$$Z^{(i)} = B^{(i)} Z^{(i)} + e^{(i)} \quad (7)$$

$$= \left( I - B^{(i)} \right)^{-1} e^{(i)}. \quad (8)$$

The matrix  $B^{(i)}$  encodes a Directed Acyclic Graph (DAG), which corresponds to the *structural model* over latent variables. We note that equation (7) corresponds to a Linear, non-Gaussian, acyclic model (LiNGAM; Shimizu et al., 2006). As in the previous section, observed data are subsequently related as follows:

$$X^{(i)} | Z^{(i)} = z^{(i)} \sim \mathcal{N}(W z^{(i)}, v^{(i)} I) \quad (9)$$

where the loading matrix encodes the *measurement model*.

To date, a wide range of algorithms have been proposed to estimate measurement models. Prominent examples include the `BuildPureClusters` and `FindOneFactorCluster` algorithms. However, such methods cannot easily be extended to the context of multiple related datasets where the underlying structural models are heterogeneous. Moreover, such methods do not scale well to high-dimensional data. In contrast, our method proposed below can easily accommodate such data and is therefore a good candidate to accurately recover the measurement model. Once the measurement model has been estimated, we may proceed to infer the causal structure over latent variables using established methods such as LiNGAM.

We now outline our two-stage procedure to estimate *Pure 1-Factor* latent variable models. First, the score matching algorithm detailed in Section 4 is employed to estimate the measurement model (i.e., the loading matrix  $W$ ). Given a measurement model, there are a variety of algorithms to estimate the structural model. In this work we follow Shimizu et al. (2009) and propose to recover causal dependencies over latent variables by applying LiNGAM to projected observations,  $\hat{W}^T X^{(i)}$ . This step is performed independently for each of the  $N$  classes.

We note that the likelihood proposed in Section 2 is misspecified in the context of non-Gaussian Bayesian networks considered here (as latent variables follow non-Gaussian distribution). However, in the first stage we are only interested in the estimation of the loading matrix,  $W$ , using covariance information which is unaffected by non-Gaussianity over latent variables. In fact, as we allow for arbitrary (i.e., non-diagonal) latent connectivities, the proposed model is able to accommodate covariances induced by the causal structure whilst estimating the loading matrix. Alternative approaches, such as the `BuildPureClusters` algorithm, are also based exclusively on studying covariance structure, albeit while introducing additional higher-order algebraic constraints.

## 6 EXPERIMENTAL RESULTS

We systematically assess the performance of the proposed model using simulated data under the Gaussian factor analysis model of Section 2 as well as the directed latent Pure Bayesian network model described in Section 5. Finally, we present an application to resting-state fMRI data from the ABIDE consortium (Di Martino et al., 2014).

### 6.1 PERFORMANCE METRICS

We assess the performance of the proposed method in the context of both a single class and multiple related classes. Throughout these simulations, we quantify the performance of various methods based on three distinct tasks:

1. Recovery of the loading matrix,  $W$ . This corresponds to accurately recovering the mixing matrix, and by implication, the module memberships for each variable.
2. Recovery of the latent connectivity structure. In the context of undirected latent connectivities, this corresponds to accurately recovering the covariance structure,  $G^{(i)}$ , across estimated modules. Conversely, in the context of directed latent Bayesian network models it corresponds to accurately recovering the causal dependence structure over latent variables, encoded in  $B^{(i)}$ .
3. In the context of undirected connectivities we also measure the negative log-likelihood over unseen data. This provides an objective quantification of how well the proposed method is able to model the data in comparison to alternative methods.

### 6.2 GAUSSIAN FACTOR ANALYSIS MODEL

Data was generated according to the model described in Section 2. The covariance structure for latent variables,  $G^{(i)}$ , was randomly generated for each class by sampling the lower triangular entries from a standard Gaussian distribution and multiplying by its transpose. We note that generating  $G^{(i)}$  in this fashion will randomly introduce both positive and negative correlations across modules. A random loading matrix,  $W$ , was generated by sampling uniform random variables and projecting onto the non-negative Stiefel manifold (this involved retaining the largest entry per row and setting all other entries to zero). Observations for each class were subsequently generated according to equations (1) and (2). The dimensionality of observations and latent variables was set to  $p = 50$  and  $k = 5$  respectively. Data was generated in this manner for  $N$  subjects. We consider two cases:  $N = 1$  and  $N = 10$ , which correspond to the single class and multiple class scenarios. Each experiment was repeated 500 times.

The proposed method was benchmarked against several widely used alternatives. In the context of recovering the loading matrix,  $W$ , and covariance structure of latent variables,  $G^{(i)}$ , we compare to non-negative PCA (using the method proposed by Sigg & Buhmann (2008)) and traditional factor analysis (where Varimax rotation was employed, since it should be able to recover module structure in the factor loadings). We note that while these methods do not explicitly model the covariance structure across latent variables, this can be estimated by first projecting observations using the estimated loading matrix and subsequently studying the covariance structure. Indeed, this is related to the update performed by the proposed method in equation (5). When measuring the negative log-likelihood over unseen data we add additional comparisons against the sample covariance matrix and the estimate proposed by Ledoit & Wolf (2003) and the graphical Lasso.

Simulation results for a single ( $N = 1$ ) class are shown along the top panel of Figure 2. The top left panel plots the squared error when estimating the loading matrix. In the presence of small sample sizes, the proposed method is comparable to non-negative PCA. However, as the sample size increases the proposed method consistently outperforms alternative methods as it is able to model the connectivity of latent variables. Additional results relating the clustering implied by estimated loading matrices are provided in the supplementary materials. Results for the estimation of latent connectivities,  $G^{(i)}$ , are shown in the top middle panel. We note that the proposed method comfortably outperforms competing methods. Finally, the right panel shows mean negative log-likelihood over unseen data; the proposed method consistently outperforms

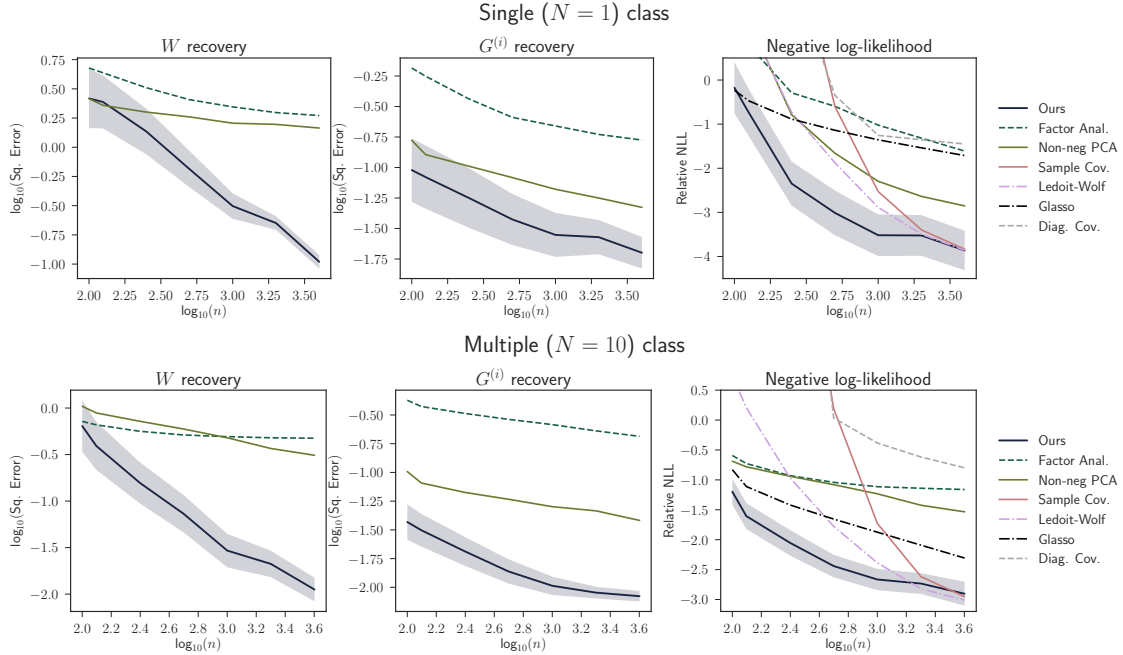

Figure 2: Simulated data results for Gaussian latent variable models with single ( $N = 1$ ) and multiple ( $N = 10$ ) classes are shown along the top and bottom panels respectively. Left and middle panels plot the mean squared error for the estimated loading and latent variable covariance matrices as a function of sample size,  $n$ . Right panels shows the mean negative log-likelihood for unseen data as a function of sample size,  $n$ . Shaded regions correspond to 95% error bars.

alternative methods for small and moderate sample sizes and remains competitive as sample size increases.

The bottom panel of Figure 2 plots results for the general case of multiple subjects. While the loading matrix is shared across all classes, the latent covariance structure is heterogeneous. While the proposed method is well-suited to accommodate such data, methods such as PCA and factor analysis are not directly applicable. As such, non-negative PCA and factor analysis models were applied using a naive aggregation of the data which concatenated observations across all classes. As before, by accurately modeling the marginal dependencies across latent variables, the proposed method is able to obtain far more accurate estimates of both the loading matrix as well as the latent connectivity structure. The bottom right panel of Figure 2 plots the mean negative log-likelihoods over unseen data and provides empirical evidence that the proposed model provides an accurate estimate of covariance structure.

In addition to quantifying the recovery of the loading matrix and latent connectivities, we also quantify the computation cost associated with each algorithm. The top panel of Figure 4 shows the mean running time as a function of the number of observed variables,  $p$ . The results validate our prior claims that the score matching

algorithm yields significant computational improvements compared to the maximum likelihood algorithm described in the Supplementary material. For high-dimensional data, the proposed score matching algorithm also improves on the running time compared to both factor analysis and non-negative PCA.

### 6.3 LATENT PURE BAYESIAN NETWORKS

In this section we perform experiments where the data is generated as described in Section 5. This involved generating latent variables following a non-Gaussian variant of Bayesian networks where the disturbances,  $e^{(i)}$ , were simulated according to a Logistic distribution. The weights for the structural model, encoded in  $B^{(i)}$ , were randomly generated together with a distinct random causal ordering for each class. The loading matrix,  $W$ , was generated as in Section 6.2.

In the context of recovering the measurement model (i.e., the loading matrix  $W$ ) we benchmark the proposed method with factor analysis and non-negative PCA as well as the `FindOneFactorClusters` (FOFC) algorithm<sup>1</sup> proposed by Kummerfeld & Ramsey (2016). Formally, the FOFC algorithm only returns non-overlapping

<sup>1</sup>The Tetrad project implementation was employed.

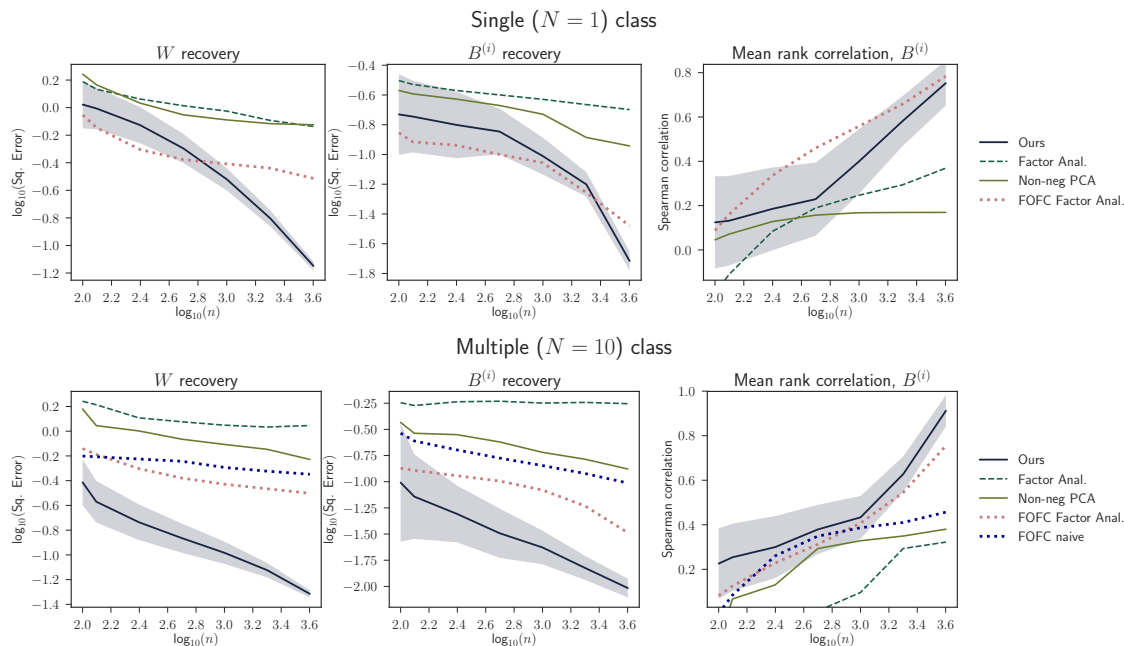

Figure 3: Simulated data results for latent Bayesian networks with single ( $N = 1$ ) and multiple ( $N = 10$ ) classes are shown along the top and bottom panels respectively. Left and middle panels plot the mean squared error for the estimated loading matrix and structural dependency matrices as a function of sample size,  $n$ . The right panels show the mean correlation between the estimated causal ordering of latent variables and the true causal order. For all algorithms the causal structure over latent variables was estimated by LiNGAM. Shaded regions correspond to 95% error bars.

clusters of observed variables which share the same latent parent. In order to estimate the associated loading matrix we subsequently employ factor analysis whilst preserving the 1-Factor structure as suggested by Shimizu et al. (2009). Given an accurate estimate of  $W$ , we may directly project observations,  $\hat{Z}^{(i)} = \hat{W}^T X^{(i)}$  and apply traditional causal discovery algorithms by treating  $\hat{Z}^{(i)}$  as observed variables (Silva et al., 2006; Shimizu et al., 2009). Throughout these experiments, the causal structure of latent variables was inferred using LiNGAM.

Figure 3 shows results for a single ( $N = 1$ ) and multiple ( $N = 10$ ) class cases along the top and bottom row respectively. The left panels show the squared error when estimating the loading matrix. In the context of causal models this corresponds to accurately recovering the measurement model. When data is only available for a single class (top left panel) the performance of the proposed method is similar to that of the FOFC algorithm. However, when data across multiple classes is available, the proposed method is able to exploit this information and improve upon the FOFC algorithm as shown in the bottom left panel. We also plot the performance of running the FOFC when naively aggregating data across multiple subjects. Such a naive aggregation leads to worse performance as each class has its own latent causal structure.

We observe a similar pattern when studying the recovery of the structural equations, as shown in the middle and right panels. The proposed method out-performs both factor analysis and PCA and is comparable to FOFC in the context of a single ( $N = 1$ ) class. However, in the context of multiple classes the proposed method is able to out-perform alternative methods.

Finally, the bottom panel of Figure 4 plots the mean running time as the number of observed variables,  $p$ , increases. In terms of running time, the proposed method is significantly faster than the FOFC algorithm.

#### 6.4 APPLICATION TO FMRI DATA

In this section we apply the proposed method to resting-state fMRI data taken from the ABIDE consortium (Di Martino et al., 2014). Data was collected from the University of Maryland site corresponding to 53 healthy controls as well as 53 age matched Autism Spectrum Disorder (ASD) subjects. Data from each subject was treated as a distinct class, resulting in  $N = 106$  classes. Data were preprocessed via the CPAC pipeline from the ABIDE repository<sup>2</sup>. Time courses were then extracted from 116

<sup>2</sup><http://preprocessed-connectomes-project.org/abide/>

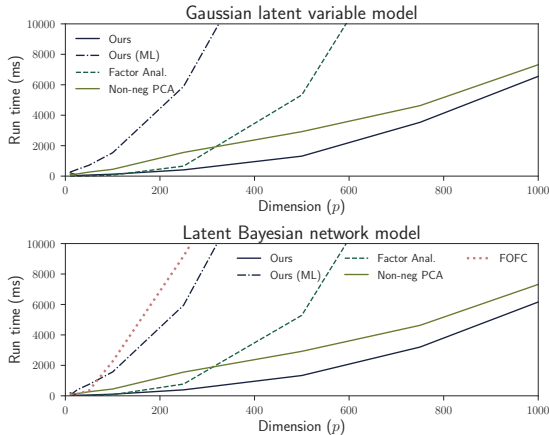

Figure 4: Mean running times (in milliseconds) taken to estimate the factor loading matrix,  $W$ , when data is generated according to the Gaussian latent variable model (top) and latent Bayesian network model (bottom). Mean run times based on 10 experiments run on a Macbook Pro (3.5 GHz Intel Core i7, 16 GB RAM).

regions defined by the Automated Anatomical Labeling (AAL) atlas, yielding 296 observations over 116 nodes for each subject. The data was analyzed under the assumption of undirected latent connectivity structure as there is a large literature discussing differences in covariance structure between healthy controls and ASD subjects (Fox & Greicius, 2010).

The proposed method requires the specification of a single parameter,  $k$ , which dictates the dimensionality of latent variables. As discussed in Section 4, this parameter was selected by minimizing the negative log-likelihood over held-out data, resulting in an choice of  $k = 5$  modules. Figure 5 shows the  $k = 5$  estimated modules obtained by applying the proposed method. The spatial consistency and inter-hemispheric symmetry of module assignments reflects the anatomical and functional architecture of the brain. Moreover, edges in Figure 5 highlight significant differences in covariance structure of latent variables between healthy controls and ASD subjects. Permutation tests were performed on each edge of the latent connectiv-

Table 1: Mean log-likelihood scores on unseen data for  $N = 106$  subjects (standard deviations are provided in brackets).

Method	Log-likelihood

Sample Cov.	-329.75 (14.98)

Figure 5: Visualization of estimation brain modules. Each black node represents a distinct brain region. Note that estimated modules are both spatially consistent and symmetric across hemispheres. Edges indicate significant increase in inter-module marginal dependence for ASD subjects compared to healthy controls (edge-wise Bonferroni corrected permutation tests,  $p < 0.01$ ).

ity structure and Bonferroni corrected for multiple testing. Results indicate that ASD subjects demonstrate increased connectivity for which there is growing evidence (Keown et al., 2013). In particular, we note increased connectivity between the frontoparietal regions (module 2) and both the occipital regions (module 1) and the hippocampus, amygdala and temporal lobes (module 3). Finally, Table 1 reports the mean log-likelihood scores on unseen data for all  $N = 106$  subjects, demonstrating the proposed model accurately captures covariance structure of fMRI data.

## 7 CONCLUSION

We have proposed a probabilistic model which simultaneously performs grouping of variables as well as estimation of the *latent connectivities* between groups. The proposed method can be seen as an extension of traditional factor analysis with the important difference that latent variables are allowed to have a full (i.e., non-diagonal) covariance structure while the loading matrix is restricted to encode module membership. The proposed model can directly accommodate datasets across multiple related classes under the assumption that variables across classes share the same modularity or community structure. While the proposed method is introduced in the context of Gaussian latent variable models, we also demonstrate that it may be extended to latent Bayesian network models. We present experiments on synthetic and fMRI data which demonstrate the capabilities of our approach, in particular showing it successfully scales to high-dimensional data.

## Abstract

The paper begins by introducing the definition and construction of mutually unbiased bases, which are a widely used concept in quantum information processing but have received little to no attention in the machine learning and statistics literature. We demonstrate their usefulness by using them to create a new sampling technique which offers an improvement on the previously well established bounds of stochastic trace estimation. This approach offers a new state of the art single shot sampling variance while requiring  $\mathcal{O}(\log(n))$  random bits for  $\mathbf{x} \in \mathbb{R}^n$  which significantly improves on traditional methods such as fixed basis methods, Hutchinson’s and Gaussian estimators in terms of the number of random bits required and worst case sample variance.

## 1 INTRODUCTION

Function space representations and transformations are at the heart of many machine learning techniques. For example, the relationship between computational space and Fourier space arises throughout machine learning literature, from classic shift invariant filters studied in image processing through to modern techniques for kernel approximation such as random Fourier features [1]. The power of random Fourier features, for example, is introduced by the unbiased relationship of the computational and Fourier bases, that is to say that a Dirac-delta distribution in one basis is represented with uniformly distributed mass in the other.

In this work we take advantage of not only pairs of mutually unbiased bases, but entire sets of them. We believe that the application of mutually unbiased bases has potential to improve kernel matrix approximation

and feature learning. To exemplify their applicability, we demonstrate their ability to create a novel sampling method which improves upon the well established error bounds of stochastic trace estimation.

The problem of stochastic trace estimation is relevant to a range of problems from physics and applied mathematics such as electronic structure calculations [2], seismic waveform inversion [3], discretized parameter estimation problems with PDEs as constraints [4] and approximating the log determinant of symmetric positive semi-definite matrices [5]. Machine learning, in particular, is a research domain which has many uses for stochastic trace estimation. They have been used efficiently by Generalised Cross Validation (GCV) in discretized iterative methods for fitting Laplacian smoothing splines to very large datasets [6], computing the number of triangles in a graph [7, 8], string pattern matching [9, 10] and training Gaussian Processes using score functions [11]. Motivated by accelerating Gaussian graphical models, Markov random fields, variational methods and Bregman divergences, work based on stochastic trace estimation has also been developed to improve the computational efficiency of log determinant calculations [12].

Stochastic trace estimation endeavours to choose  $n$ -dimensional vectors  $\mathbf{x}$  such that the expectation of  $\mathbf{x}^T A \mathbf{x}$  is equal to the trace of the implicit symmetrical positive semi definite matrix  $A \in \mathbb{R}^{n \times n}$ . It can be seen that many sampling policies satisfy this condition. Due to this, several metrics are used in order to choose a sampling policy such as the single shot sampling variance, the number of samples to achieve a  $(\epsilon, \delta)$ -approximation and the number of random bits required to create  $\mathbf{x}$  [13]. This last metric is motivated in part by the relatively long timescales for hardware random number generation, and concerns about parallelising pseudo-random number generators.

In this work we propose a new stochastic trace estimator based on mutually unbiased bases (MUBs) [14], and

quantify the single shot sampling variance of the proposed MUBs sampling method and its corresponding required number of random bits. We will refer to methods which sample from a fixed set of basis functions as being fixed basis sampling methods. For example, we can randomly sample the diagonal values of the matrix  $A$  by sampling  $\mathbf{x}$  from the set of columns which form the identity matrix. This is referred to as the unit vector estimator in the literature [13]. Other similar methods sample from the columns Discrete Fourier Transform (DFT), the Discrete Hartley Transform (DHT), the Discrete Cosine Transform (DCT) or a Hadamard matrix. We prove that sampling from the set of mutually unbiased bases significantly reduces this single shot sample variance, in particular in the worst case bound.

The paper is laid out as follows: Section 2 gives a brief introduction to mutually unbiased basis and their construction, Section 3 describes our novel approach of using mutually unbiased bases for trace estimation and Section 3.2 gives a rigorous analysis of the new estimator. Section 4 compares the proposed MUBs estimator to established approaches both in terms of the analytic expectation of sample variance and as applied to synthetic and real data. The tasks of counting the number of triangles in a graph and of estimating the log determinant of kernel matrices are considered as an example application.

## 2 MUTUALLY UNBIASED BASES

Linear algebra has found application in a diverse range of fields, with each field drawing from a common set of tools. However, occasionally, techniques developed in one field do not become well known outside of that community, despite the potential for wider use. In this work, we will make extensive use of mutually unbiased bases, sets of bases that arise from physical considerations in the context of quantum mechanics [14] and which have been extensively exploited within the quantum information community [15]. In quantum mechanics, physical states are represented as vectors in a complex vector space, and the simplest form of measurement projects the state onto one of the vectors from some fixed orthonormal basis for the space, with the probability for a particular outcome given by the square of the length of the projection onto the corresponding basis vector<sup>1</sup>. In such a setting, it is natural to ask about the existence of pairs or sets of measurements where the outcome of one measurement reveals nothing about the outcome of another measurement, and effectively erases any information about the outcome had the alternate measure-

<sup>1</sup>For a more comprehensive introduction to the mathematics of quantum mechanics in finite-dimensional systems, we refer the reader to [16]

ment instead been performed. As each measurement corresponds to a particular basis, such a requirement implies that the absolute value of the overlap between pairs of vectors drawn from bases corresponding to different measurements be constant. This leads directly to the concept of mutually unbiased bases (MUBs).

A set of orthonormal bases  $\{B_1, \dots, B_n\}$  are said to be mutually unbiased if for all choices of  $i$  and  $j$ , such that  $i \neq j$ , and for every  $\mathbf{u} \in B_i$  and every  $\mathbf{v} \in B_j$ ,  $|\mathbf{u}^\dagger \mathbf{v}| = \frac{1}{\sqrt{n}}$ , where  $n$  is the dimension of the space. While for real vector spaces the number of mutually unbiased bases has a complicated relationship with the dimensionality [17], for complex vector spaces the number of mutually unbiased bases is known to be exactly  $n + 1$  when  $n$  is either a prime or an integer power of a prime [18]. Furthermore, a number of constructions are known for finding such bases [18]. When  $n$  is neither prime nor a power of a prime, the number of mutually unbiased bases remains open, even for the case of  $n = 6$  [19], but is known to be at least  $p_1^{d_1} + 1$ , where  $n = \prod_i p_i^{d_i}$  and  $p_i$  are prime numbers such that  $p_i < p_{i+1}$  for all  $i$ .

One practical method for constructing MUBs is to use the unitary operators method with finite fields [20], which is effective when the dimensionality of the space is either prime or a prime power. For conciseness, we will outline the procedure for only the prime dimensionality case but note that any integer dimensional space is at most bounded by two times its closest prime power dimension which adds a constant cost to the memory and runtime performance. First, let us construct the matrix  $X$  as the identity matrix with the columns shifted one to the left creating the form,

$$X = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \\ 1 & 0 & 0 & \dots & 0 \end{bmatrix}$$

and letting  $Z$  be a diagonal matrix with elements set to the roots of unity,  $Z_{k,k} = \exp\left(\frac{2k\pi i}{n}\right)$ . Given these two matrices a set of mutually unbiased bases are found as the eigenvectors of the matrices,

$$X, Z, XZ, XZ^2, \dots, XZ^{n-1}.$$

At first glance it may appear that the computational cost of constructing vectors from these bases is  $\mathcal{O}(d^3)$  due to the cost decomposing these matrices in  $\mathbb{C}^{n \times n}$ , however, under more scrutiny we can see that  $X$  is a circulant permutation matrix and as such its eigenvectors are equal to  $U_{k,j} = \frac{1}{\sqrt{n}} \exp\left(\frac{jk2\pi i}{n}\right)$  irrespective of the dimensionality,

where  $j$  indexes the elements of the eigenvector and  $v$  indexes which eigenvector is under consideration.

As the elements the diagonal matrix  $Z$  are the roots of unity in ascending order, it can be seen that  $\exp\left(\frac{2\pi i}{n}\right)^k Z^k X = Q^k X = X Z^k$ , where  $Q$  is some matrix of the same form as  $Z$  but with a shift of phase of the non-zero elements. As such, by writing the eigenbasis of  $X = U^{-1}\Sigma U$  we can derive the eigenbasis of  $XZ^k$  for arbitrary value  $k$  with eigen decomposition  $XZ^k = \hat{U}^{-1}\hat{\Sigma}\hat{U}$ ,

$$\begin{aligned} XZ^k &= U^\dagger \Sigma U Z^k \\ &= Q^k U^{-1} \Sigma U \end{aligned}$$

Next, we pull  $Q^{\frac{k}{2}}$  and  $Z^{\frac{k}{2}}$  through the eigenvectors by observing that we can transform the eigenvectors as  $\Sigma = Z^{\frac{1}{2}} \hat{\Sigma} Q^{\frac{k}{2}}$ ,

$$\begin{aligned} XZ^k &= Q^{\frac{k}{2}} U^{-1} \Sigma U Z^{\frac{k}{2}} \\ &= Q^{\frac{k}{2}} U^{-1} Z^{\frac{1}{2}} \hat{\Sigma} Q^{\frac{k}{2}} U Z^{\frac{k}{2}} \\ &= \hat{U}^{-1} \hat{\Sigma} \hat{U} \end{aligned}$$

where  $\hat{U} = Q^{-\frac{k}{2}} Z^{\frac{k}{2}} U$  and hence the  $\hat{U}_{i,j} = \frac{1}{\sqrt{n}} \exp\left(\frac{2\pi i}{n} \left(jv + \frac{(j+1)(j+2)}{2} k\right)\right)$  using the same indexing as before.

As a result, we can simply use the following procedure to sample the vector  $\mathbf{x}$  in linear computational time and memory:

- 1 Choose  $k$  and  $v$ , representing the basis and the vector to select respectively, uniformly at random.
- 2 If  $k = 0$ , then we select the vector  $v$  from the computational basis, that is to say the columns of the identity matrix.
- 3 Else, let  $x_j = \frac{1}{\sqrt{n}} \exp\left(\frac{2\pi i}{n} \left(jv + \frac{(j+1)(j+2)}{2} k\right)\right)$

### 3 TRACE ESTIMATORS

In order to estimate the trace of a  $n \times n$  positive semi-definite matrix  $A$  from a single call to an oracle for  $\mathbf{x}^\dagger A \mathbf{x}$ , we consider four strategies:

- **Fixed basis estimator:** For a fixed orthonormal basis  $B$ , choose  $\mathbf{x}$  uniformly at random from the elements of  $B$ . The trace is then estimated to be  $n \mathbf{x}^\dagger A \mathbf{x}$ .

- **Mutually unbiased bases (MUBs) estimator:** For a fixed choice of a set of  $b$  mutually unbiased bases  $\mathbb{B} = \{B_1, \dots, B_b\}$ , choose  $B$  uniformly at random from  $\mathbb{B}$  and then choose  $\mathbf{x}$  uniformly at random from the elements of  $B$ . Here  $b$  is taken to be the maximum number of mutually unbiased bases for a complex vector space of dimension  $n$ . As in the fixed basis strategy, the trace is then estimated to be  $n \mathbf{x}^\dagger A \mathbf{x}$ .
- **Hutchinson's estimator:** Randomly choose the elements of  $\mathbf{x}$  independently and identically distributed from a Rademacher distribution ( $Pr(x_i = \pm 1) = \frac{1}{2}$ ). The trace is then estimated to be  $n \mathbf{x}^\dagger A \mathbf{x}$ .
- **Gaussian estimator:** Randomly choose the elements of  $\mathbf{x}$  independently and identically distributed from a zero mean unit variance Gaussian distribution. The trace is then estimated to be  $n \mathbf{x}^\dagger A \mathbf{x}$ .

The first strategy is a generic formulation of approaches which sample vectors from a fixed orthogonal basis, the most efficient sampling method in terms of the number of random bits required in the literature [13], while the second strategy is novel and represents our main contribution. Both strategies have similar randomness requirements: In the first strategy at least  $\lceil \log_2(n) \rceil$  random bits are necessary to ensure the possibility of choosing every element of  $B$ . In the second strategy, an identical number of random bits is necessary to choose  $\mathbf{x}$  for a fixed  $B$ , and  $\lceil \log_2(b) \rceil$  random bits are necessary to choose  $B$ . Note that an upper bound on the number of mutually unbiased bases is one greater than dimensionality of the space, and this bound is saturated for spaces where the dimensionality is prime or an integer power of a prime, i.e.  $b \leq n + 1$ . Thus the number of random bits necessary to implement these strategies differs by a factor of approximately two. The third and fourth strategies significantly outperform the fixed basis estimator in terms of single-shot variance, at the cost of a dramatic increase in the amount of randomness required, and have been extensively studied in the literature [13, 21, 22]. For conciseness we will not repeat the analysis of these methods in this paper but will compare the fixed basis estimator and MUBs estimator to them in Table 4.1.

#### 3.1 ANALYSIS OF FIXED BASIS ESTIMATOR

We first analyse the worst case variance of the fixed base estimator. In this analysis and the analysis for the MUBs estimator which follows, we make no assumption on  $A$  and consider the worst case variance.

We begin from the definition of the variance of the estimator for a single query. Let  $X$  be a random variable

such that  $X = \mathbf{x}^\dagger A \mathbf{x}$ , where  $\mathbf{x}$  is chosen according to the fixed basis strategy. Then

$$\text{Var}(X) = E(X^2) - E(X)^2, \quad (1)$$

where  $E(\cdot)$  denotes the expectation value of the argument. We compute this term by term. First

$$E(X) = \frac{1}{n} \sum_{\mathbf{x} \in B} \mathbf{x}^\dagger A \mathbf{x} = \frac{\text{Tr}(A)}{n},$$

where  $n = \dim A$ , and hence the second term in Eq. 1 is equal to  $\frac{\text{Tr}(A)^2}{n^2}$ . Turning to the first term,

$$\begin{aligned} E(X^2) &= \frac{1}{n} \sum_{\mathbf{x} \in B} (\mathbf{x}^\dagger A \mathbf{x})^2 \\ &= \frac{1}{n} \sum_{i=1}^n M_{ii}^2, \end{aligned}$$

where  $M = UAU^\dagger$  for some fixed unitary matrix  $U$  such that  $U^\dagger \mathbf{x}$  is a vector in the standard basis for all  $x \in B$ , and  $M_{ii}$  is the  $i$ th entry on the main diagonal of  $M$ . The variance for the fixed basis estimator is then given by  $V_{\text{fixed}} = n \sum_{i=1}^n M_{ii}^2 - \text{Tr}(A)^2$ . The worst case occurs when the value of  $\sum_{i=1}^n M_{ii}^2$  is maximized for fixed trace of  $A$  (and hence  $M$ ), and so the worst case single shot variance for the fixed basis estimator is  $V_{\text{fixed}}^{\text{worst}} = (n-1)\text{Tr}(A)^2$ .

### 3.2 ANALYSIS OF MUBS ESTIMATOR

We now turn to analysis of the MUBs estimator. We assume that  $n$  is either prime or a prime raised to some integer power. In this case, it has been established that  $b = n + 1$  [18]. The variance is defined as in Eq. 1, except that  $X$  is defined in terms of  $\mathbf{x}$  chosen according to the MUBs strategy. Again, we analyse the individual terms making up the variance. We begin with

$$E(X) = \frac{1}{nb} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} \mathbf{x}^\dagger A \mathbf{x} = \frac{\text{Tr}(A)}{n},$$

and hence the second term in the variance is the same as for the fixed basis estimator. Analysing the first term is, however, more difficult. We begin with the observation that  $E(X^2)$  can be expressed in terms of the trace of the Kronecker product of two matrices, as follows

$$\begin{aligned} E(X^2) &= \frac{1}{nb} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} (\mathbf{x}^\dagger A \mathbf{x})^2 \\ &= \frac{1}{nb} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} \text{Tr}((\mathbf{x} \mathbf{x}^\dagger A)^{\otimes 2}). \end{aligned}$$

Moving the summations inside the equation we obtain

$$\begin{aligned} E(X^2) &= \frac{1}{nb} \text{Tr} \left( \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} (\mathbf{x} \mathbf{x}^\dagger)^{\otimes 2} A^{\otimes 2} \right) \\ &= \frac{2}{nb} \text{Tr}(PA^{\otimes 2}), \end{aligned} \quad (2)$$

where  $P = \frac{1}{2} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} (\mathbf{x} \mathbf{x}^\dagger)^{\otimes 2}$ .

While this form of  $P$  may appear intimidating, we now prove that  $P$  is in fact a projector with each eigenvalue being either 0 or 1. We prove this indirectly, first by showing that  $P$  has rank at most  $n(n+1)/2$ , and then using the relationship between the traces of  $P$  and  $P^2$  to conclude that the non-zero  $n(n+1)/2$  eigenvalues are equal to unity. Any vector of the form  $\mathbf{w} = \mathbf{u} \otimes \mathbf{v} - \mathbf{u} \otimes \mathbf{v}$  for  $\mathbf{u}, \mathbf{v} \in B_1$  trivially satisfies  $P\mathbf{w} = \mathbf{0}$ . Since such vectors form a basis for a subspace of dimension  $n(n-1)/2$ , we conclude that  $\text{rank}(P) \leq n^2 - n(n-1)/2 = n(n+1)/2$ . Turning now to the issue of trace, we have

$$\begin{aligned} \text{Tr}(P) &= \text{Tr} \left( \frac{1}{2} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} (\mathbf{x} \mathbf{x}^\dagger)^{\otimes 2} \right) \\ &= \frac{1}{2} \sum_{B \in \mathbb{B}} \sum_{\mathbf{x} \in B} (\mathbf{x}^\dagger \mathbf{x})^2 \\ &= \frac{nb}{2}. \end{aligned}$$

We can similarly compute the trace of  $P^2$  to obtain

$$\begin{aligned} \text{Tr}(P^2) &= \text{Tr} \left( \frac{1}{4} \sum_{B, B' \in \mathbb{B}} \sum_{\mathbf{x} \in B} \sum_{\mathbf{y} \in B'} (\mathbf{x} \mathbf{x}^\dagger)^{\otimes 2} (\mathbf{y} \mathbf{y}^\dagger)^{\otimes 2} \right) \\ &= \frac{1}{4} \sum_{B, B' \in \mathbb{B}} \sum_{\mathbf{x} \in B} \sum_{\mathbf{y} \in B'} |\mathbf{x}^\dagger \mathbf{y}|^4 \\ &= \frac{nb}{4} + \frac{n^2 b(b-1)}{4n^2} \\ &= \frac{b(n+b-1)}{4}. \end{aligned}$$

Notice that this implies that  $\text{Tr}(P) = \text{Tr}(P^2)$  for dimensions which are prime or integer powers of a prime, since in such cases  $b = n + 1$ . This implies that the eigenvalues on the non-zero subspace minimize the sum of their squares for a fixed sum, and since  $P$  is positive semi-definite, we can conclude that each non-zero eigenvalue must be equal to unity.

Returning to the calculation of variance, we then have

$$\begin{aligned} E(X^2) &\leq \frac{2}{nb} \text{Tr}(A^{\otimes 2}) \\ &= \frac{2}{nb} \text{Tr}(A)^2, \end{aligned}$$

and hence

$$\text{Var}(X) \leq \left( \frac{2}{nb} - \frac{1}{n^2} \right) \text{Tr}(M)^2 \leq \frac{\text{Tr}(A)^2}{n^2}. \quad (3)$$

This implies that the variance on the estimate of  $\text{Tr}(A)$  is bounded from above by  $\text{Tr}(A)^2$ . It is, in fact, possible to compute the variance exactly from Eq. 2 by observing

that  $M$  is the projector onto the symmetric subspace when  $n$  is an integer power of a prime. That is to say, for any vector  $\mathbf{u}$  and any vector  $\mathbf{v}$  orthogonal to  $\mathbf{u}$ , the vectors  $\mathbf{u} \otimes \mathbf{v} + \mathbf{v} \otimes \mathbf{u}$ ,  $\mathbf{u} \otimes \mathbf{u}$  and  $\mathbf{v} \otimes \mathbf{v}$  are in the  $+1$  eigenspace of  $M$ , whereas the vector  $\mathbf{u} \otimes \mathbf{v} - \mathbf{v} \otimes \mathbf{u}$  is in the null space of  $M$ . Thus we can compute the exact variance of the MUBs estimator, using the spectral decomposition  $A = \sum_i \lambda_i \mathbf{u}_i \mathbf{u}_i^\dagger$  as

$$\begin{aligned} V_{\text{MUBs}} &= \frac{2n}{n+1} \text{Tr}(PA^{\otimes 2}) - \text{Tr}(A)^2 \\ &= \frac{2n}{n+1} \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \\ &\quad \text{Tr}(P(\mathbf{u}_i \otimes \mathbf{u}_j)(\mathbf{u}_i \otimes \mathbf{u}_j)^\dagger) - \text{Tr}(A)^2 \\ &= \frac{2n}{n+1} \sum_{i=1}^n \left( \lambda_i^2 + \frac{1}{2} \sum_{j \neq i} \lambda_i \lambda_j \right) - \text{Tr}(A)^2 \\ &= \frac{n}{n+1} \text{Tr}(A^2) - \frac{1}{n+1} \text{Tr}(A)^2. \end{aligned}$$

Since for all positive semi-definite matrices  $A$  the value of  $\text{Tr}(A)^2$  is bounded from below by  $\text{Tr}(A^2)$ , the single shot variance on the MUBs estimator is bounded by  $V_{\text{MUBs}}^{\text{worst}} = \frac{n-1}{n+1} \text{Tr}(A^2)$  in the worst case, a significant improvement on the bound stemming from Eq. 3. The worst case single shot variance of the MUBs estimator is then at least a factor of  $n+1$  better than that of any fixed basis estimator. Furthermore, the variance for the widely used Hutchinson estimator [21, 13], is given by  $V_H = 2(\text{Tr}(A^2) - \sum_{i=1}^n A_{ii}^2)$ . In the worst case,  $\sum_{i=1}^n A_{ii}^2 = \frac{1}{n} \text{Tr}(A^2)$ , and hence the worst case single shot variance for Hutchinson estimator is  $V_H^{\text{worst}} = \frac{2(n-1)}{n} \text{Tr}(A^2)$ . Thus, the MUBs estimator has better worst case performance than the Hutchinson estimator by a factor  $\frac{2(n+1)}{n}$  which approaches 2 from above for large  $n$ .

## 4 RESULTS

### 4.1 THEORETICAL RESULTS

Table 1 compares the single shot variance, worst case single shot variance and randomness requirements of the trace estimators. As can be seen from the comparison the MUBs estimator has strictly smaller variance than either the Hutchinson or Gaussian methods, while requiring significantly less randomness to implement. Given the drastic reduction in randomness requirements, and the improved worst case performance, the MUBs estimator provides an attractive alternative to previous methods for estimating the trace of implicit matrices.

## 4.2 NUMERICAL RESULTS

### 4.2.1 Example Matrices

Before we demonstrate the use of the MUBs estimator on example applications we draw the readers attention to a situation where the traditional methods perform poorly. This occurs when the values of the matrix  $A$  are close to the ones matrix with a small proportion of the diagonal values much greater. The most extreme example being when this small proportion is only one element of the matrix. Due to the relationship between each of the unbiased bases this ‘spikiness’ only appears in one of the  $n+1$  bases and hence the MUBs estimator appears very robust to the condition.

It is worth noting the reason we observe an order of magnitude improvement in this setting over the competing methods. The spikes matrix described can be written as the sum of two rank one matrices. Each of these matrices will perform very poorly for the unitary estimator in that basis but gets exactly the correct result in the  $n$  other mutually unbiased bases. Naturally as  $n$  becomes large and the number of samples utilised is relatively small, then we sample the exact result with high probability.

Figure 1: Convergence of the methods when estimating the trace of a  $1000 \times 1000$  ones matrix with 1 diagonal element replaced with 1001. This ‘spike’ has little effect of the convergence of the MUBs estimator and hence the method vastly out performs the others. The experiment was run 500 times and the mean and standard deviation have been plotted for each method.

We can generalise this result to low rank matrices more broadly. Any given rank- $m$  matrix can be written as the sum of  $m$  rank-1 matrices. Figure 2, demonstrates the convergence of of the stochastic trace estimators to rank-10  $1000 \times 1000$  matrices. These were created by sam-

Estimator	$V$	$V^{\text{worst}}$	$R$
Fixed basis	$n \sum_{i=1}^n M_{ii}^2 - \text{Tr}(A)^2$	$(n-1)\text{Tr}(A)^2$	$\log_2(n)$
MUBs	$\frac{n}{n+1} \text{Tr}(A^2) - \frac{1}{n+1} \text{Tr}(A)^2$	$\frac{n-1}{n+1} \text{Tr}(A^2)$	$\log_2(n) + \log_2(n+1)$
Hutchinson [21]	$2(\text{Tr}(A^2) - \sum_{i=1}^n A_{ii}^2)$	$\frac{2(n-1)}{n} \text{Tr}(A^2)$	$n$
Gaussian [22]	$2\text{Tr}(A^2)$	$2\text{Tr}(A^2)$	$\infty$ for exact; $\mathcal{O}(n)$ for fixed precision

pling 10 eigenvalues from a standard  $\chi^2$  distribution and sampling the first 10 eigenvectors of a Gaussian random matrix.

Figure 2: Convergence of the methods when estimating the trace of a  $1000 \times 1000$  rank-10 matrix. The eigenvalues were sampled from a standard  $\chi^2$ -distribution. As the rank of the matrix is only 1% of the dimensionality of the space we once again see substantially improved convergence rates. The experiment was run 30 times and the mean and standard deviation have been plotted for each method.

#### 4.2.2 Counting Triangles in Graphs

As an example application we will consider counting the number of triangles in a graph. This is an important problem in a number of application domains such as identifying the number of ‘friend of a friend’ connections in a social network which is important for friendship suggestions [23, 24], identifying spam like behaviour [25] and even identifying thematic structures in the internet [26]. An efficient method to do this is the Trace Triangle

algorithm [9]. The algorithm is based on a relationship between the adjacency matrix,  $A$ , and the number of triangles for an undirected graph,  $\Delta_g$ ,

$$\Delta_g = \frac{\text{Tr}(A^3)}{6}.$$

The trace of the adjacency matrix cubed can be sampled in  $\mathcal{O}(n^2)$  per sample as opposed to being explicitly computed in  $\mathcal{O}(n^3)$ . We compared Gaussian, Hutchinson’s, Unit and MUBs estimators performance at predicting the number of triangles for the graphs presented in Table 2 and the results of the experiment are presented in Figure 3. An efficient Python implementation for generating the MUBs sample vectors in  $\mathcal{O}(n)$ , is available at [www.github.com/OxfordMLRG/traceEst](http://www.github.com/OxfordMLRG/traceEst). The MUBs estimator outperforms each of the classical methods in all of the experiments, as would be implied by the theory.

#### 4.2.3 Log Determinant of Covariance Matrix

Next, let us consider a common linear algebraic calculation required in the training of Gaussian processes, determinantal point processes and Gauss Markov random field modelling to name just a few applications, namely the log determinant of a kernel matrix.

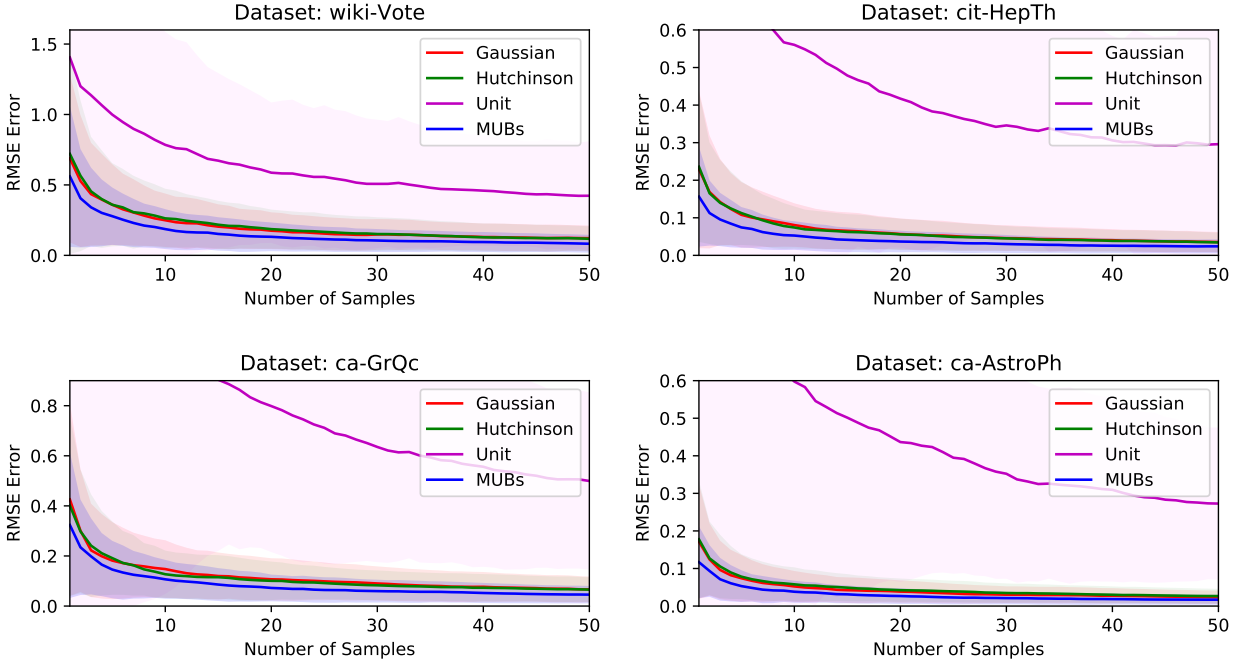

Figure 3: A comparison of the performance of the stochastic trace estimation methods on the four datasets. The experiments were performed 500 times each. The solid line indicated the empirical mean absolute relative error and the surrounding transparent region indicates one empirical standard deviation of the 500 trials.

The use of stochastic trace estimation to approximate log determinant calculations of kernel matrices has been well studied [12, 27, 28] and a range of methods are feasible. Most notably, polynomial approaches such as truncated Taylor approximations and Chebyshev approximations [12, 29] have been applied, with the latter achieving consistently better results. The general concept relies on the fact that the trace of a matrix is simply the sum of its eigenvalues and the log determinant is the sum of the log of its eigenvalues. Stochastic trace estimation aids us in approximating the sum of the eigenvalues squared, cubed and so on which we can use in a polynomial approximation of the log function,

$$\log(x) \approx \sum_{j=0}^m c_j x^j \quad \rightarrow \quad \log(|K|) \approx \sum_{j=0}^m c_j \text{Tr}(K^j)$$

where the constants  $c_j$  refer to the coefficients of the polynomial approximation. In practice, the trace of  $K^0$  is simply the dimensionality of the matrix,  $K^1$  is the trace of the explicit matrix and  $K^2$  can be found as  $\sum_{i,j} K_{i,j}^2$  due to the relationship between the matrix elements and the Frobenius norm. As such, the approximation error incurred is only due to the trace of the matrix raised to

three and above.

In order to demonstrate the effect of improved stochastic trace estimation on log determinant estimations, we sampled 1000 points from a 5-dimensional hypercube uniformly at random. These points in turn formed a covariance matrix using an isotropic Gaussian kernel function. This aimed to emulate a realistic dataset which may be used by practitioners.

We used a order-6 Chebyshev polynomial approximation and recorded estimation errors of the relative root mean squared error (RMSE) for each power of the covariance matrix. These can be seen in Figure 4. Also plotted is the estimation error of the log determinant itself, as it compounds both the polynomial approximation error and the error due to the stochastic trace estimation. A fixed budget of 25 probing vectors was allowed for each of the approaches. As can be seen in the figure, the error incurred due to the stochastic trace estimation is non-negligible and for the higher order estimates the MUBs approach was achieving improved results in terms of both its expectation and standard error.

Figure 4: The performance of estimating the trace of  $K^3$ ,  $K^4$ ,  $K^5$ ,  $K^6$  and their combined result in the Chebyshev polynomial approximation of  $\log(|K|)$ . The experiment we ran 20 times and their expectation and standard error have been shown above.

## 5 CONCLUSION

We have introduced a new MUBs sampler for stochastic trace estimation which combines the efficiency of fixed basis methods with performance which outperforms the state of the art methods. We offer both empirical and theoretical comparisons to the previously established state of the art techniques and clearly demonstrate the benefit of using mutually unbiased bases for stochastic linear algebraic procedures to accelerate machine learning algorithms.

## Abstract

In this paper, we study the unsupervised multi-view graph embedding (UMGE) problem, which aims to learn graph embedding from multiple perspectives in an unsupervised manner. However, the vast majority of multi-view learning work focuses on non-graph data, and surprisingly there are limited work on UMGE. By systematically analyzing different existing methods for UMGE, we discover that cross-view and nonlinearity play a vital role in efficiently improving graph embedding quality. Motivated by this concept, we develop an unsupervised Multi-viEW nonlinear Graph Embedding (MERGE) approach to model relational multi-view consistency. Experimental results on five benchmark datasets demonstrate that MERGE significantly outperforms the state-of-the-art baselines in terms of accuracy in node classification tasks without sacrificing the computational efficiency.

## 1 INTRODUCTION

Most of the recent work on graph embedding [25, 9, 5] focuses on the network information alone. In practice, a graph may consist of additional node features; *e.g.*, in a paper citation network, each paper node includes text content. Thus some pioneer work has started to consider the node features in graph embedding; *e.g.*, Planetoid [33] uses a semi-supervised framework to learn a network embedding for each node from its network features and a content embedding from its content features. Generally, network structure and node features are considered as two different “views” for a node in the graph. Motivated by *multi-view learning* [31, 11], we allow the

In (c) ~ (d), we let view 1’s features be network, and view 2’s be content. ① denotes the cross-instance in single view. ② denotes the intra-instance–cross-view. ③ denotes the cross-instance–cross-view.

two views to reinforce each other, so as to obtain a better graph embedding.

In this paper, we try to solve the *Unsupervised Multi-view Graph Embedding* (UMGE) problem. Given a graph with node features, we aim to learn a network embedding and a content embedding simultaneously for each node in an unsupervised manner. Most of the multi-view learning work focuses on non-graph data, such as image and caption features in [18], acoustic and articulatory features in speech [2], and so on. Combining network and node features has been popular for graph classification [17] and graph clustering [36]. However, it has been under-explored in the literature for UMGE [2, 32, 37]. Moreover, despite the success of these prior methods, their development appears ad hoc and underlying connections are not investigated yet.

To approach the problem of UMGE, we start with systematically analyzing the underlying connections among different prior methods in Fig. 1 (two-view example). For simple discussion, let us denote  $\mathbf{x}_{i,k}$  as the features corresponding to the  $i^{\text{th}}$  instance in  $k^{\text{th}}$  view, and  $\mathbf{e}_{i,k}$  as its embedding. A naive way to extend the single view graph embedding methods into multi-view scenarios is concatenating the graph embedding (learned in network structure only) and the node features directly. For example, as shown in Fig. 1(a), SDNE [27] learns the graph embedding taking no account of the node features. By using a deep AutoEncoder [4] to model the node features and concatenating these two kinds of embeddings as node representation, SDNE can be extended to multi-view scenarios. However, simply concatenating the two views has no guarantee to reinforce each other. Typically, multi-view learning focuses on enforcing intra-instance–cross-view consistency on irrelevant data. In Fig. 1(b), DCCA [2] first embeds each instance’s multi-view features  $\mathbf{x}_{i,k}$ ’s into low-dimensional representations  $\mathbf{e}_{i,k}$ ’s, then enforces the maximal correlation between  $\mathbf{e}_{i,1}$  and  $\mathbf{e}_{i,2}$  for each  $i$ , which does not take the relational information into consideration. Some recent work exploits a different approach to model the relational information by enforcing cross-instance–cross-view consistency. In Fig. 1(c), TADW [32] recovers an adjacency matrix with the multiplication between a network embedding matrix and a text embedding matrix. Thus, two nodes with similar neighbors tend to have similar multi-view embedding.

Despite the recent advance of UMGE in network representation, there are still rooms for improvement, as current work has some limitations. First, the feature embedding in TADW is linear. However, in practice, data non-linearity is common for both network features [27] and content features [30]. Second, the network structure is under-explored. For example, DCCA does not preserve any relational proximity. However, preserving network structure is useful for graph embedding [25]. TADW preserves the second-order proximity by using matrix decomposition, which is computationally expensive. It takes a complexity of  $O(\text{nnz}(M) + |V|)$  to decompose the adjacency matrix  $M$  for a graph  $G = (V, E)$ , where  $V$  and  $E$  are the sets of nodes and edges respectively, and  $\text{nnz}(M)$  is the number of non-zero entries in  $M$ . In other words, its complexity is at least  $O(|E| + |V|)$ , since  $\text{nnz}(M) \geq |E|$ . Therefore, our goal is to efficiently solve UMGE with nonlinearity. We consider nonlinear embedding for both views in order to deal with the non-linear data nature. Besides, we also preserve the second-order proximity by enforcing cross-instance–cross-view consistency, yet with less computational cost compared against TADW.

In this paper, we propose a simple, yet effective un-

supervised Multi-view nonlinear Graph Embedding (MERGE) model. Our insights are two-fold. First, inspired by SDNE [27], MERGE encodes the nonlinearity of the network/content by taking the network/content features as input, and then applying a deep AutoEncoder [4] to learn a nonlinear network/content embedding for each node. Second, MERGE preserves the second-order proximity by extending DeepWalk [20] to the multi-view setting. On the one hand, DeepWalk preserves the second-order proximity by using one node’s network embedding to interpret its “neighbor” node’s context embedding. MERGE is easy to extend DeepWalk for using one node’s network embedding to interpret its “neighbor” node’s content embedding, so as to enforce cross-instance–cross-view consistency. Besides, MERGE also fully leverages this formulation to enforce intra-instance–cross-view consistency by using one node’s network embedding to interpret its own content embedding. On the other hand, DeepWalk employs a graph sampling approach to achieve comparable performance, which takes an  $O(|V| \log |V|)$  complexity with a hierarchical softmax objective function. MERGE further reduces the complexity to  $O(|V|)$  by using *negative sampling* [19]. We back up this argument later with a detailed complexity analysis of the MERGE algorithm in Sec. 4.

Our contributions are summarize as follows. It is the first time that different existing methods for UMGE are systematically analyzed, where cross-view and non-linearity are discovered to be critical in improving graph embedding quality, and we develop a simple, yet effective MERGE model to efficiently incorporate nonlinearity in graph embedding. MERGE is evaluated on five benchmark datasets, and it exceedingly outperforms the state-of-the-art baselines by at least relatively 1.5% ~ 17.9% (macro-F1) and 0.4% ~ 14.9% (micro-F1) over all the datasets. Moreover, the computational complexity of MERGE scales linearly with  $|V|$ , which is more favorably applied to real-world scenarios.

## 2 RELATED WORD

Graph embedding is an important task for graph analytics. Generally, it aims to learn a vector representation for each node, such that two nodes being “close” on the graph have similar vectors. Earlier work on graph embedding, such as MDS [7], LLE [23], IsoMap [26] and Laplacian eigenmap [3], typically treats to solve the leading eigenvectors of graph affinity matrices as node embedding. Recent methods explore deep learning for graph embedding. For example, LINE [25] models the node closeness by using both first-order and second-order proximity, therefore two nodes either connect di-

rectly or share the common neighbors result in similar embedding. Node2Vec [9] considers how to sample paths for DeepWalk, with awareness of node homophily and structural role. Besides, there are a number of works study the heterogeneous graph embedding [24, 6, 16]. Most existing graph embedding work focuses on single-view setting; *i.e.*, only network structure is considered. Only little work considers a multi-view setting, such as COLDA [12], TADW [32] and GCN [13]. Yet, COLDA is supervised; GCN is semi-supervised; only TADW is unsupervised.

Multi-view learning is a machine learning paradigm, which handles the data with multiple views of features in its instances [28]. Some detailed surveys about multi-view learning are available in [31, 15]. A large portion of multi-view learning literatures focus on supervised or semi-supervised settings, such as recommendation [8] and classification [10, 35]. Some other work considers an unsupervised setting, but not particularly for representation learning. For example, in [14], multi-view learning is used to improve spectral clustering; whereas in [34], the focus is to tackle the corrupted view with intra-view and inter-view noises. An overall review of recent multi-view embedding models is in [29]. Among them, a notable method is DCCA [2]. It extends CCA [1] by learning embedding for each view with a deep neural network and then enforcing the maximal correlation across two views' embedding. However, some recent multi-view embedding work, including COLDA [12], and TADW [32], has paid less attention to graph data.

### 3 UNSUPERVISED MULTI-VIEW GRAPH EMBEDDING

The UMGE is formalized as follows. Given a graph  $G = (V, E)$  as the input, each node  $v_i \in V$  has a network feature vector  $\mathbf{x}_{i,1} \in \mathbb{R}^{m_1}$  and a content feature vector  $\mathbf{x}_{i,2} \in \mathbb{R}^{m_2}$ . UMGE then generates two embedding vectors in a  $d$ -dimensional common space for each node as the output. For instance, the network features  $\mathbf{x}_{i,1}$  is extracted from  $G$ 's adjacency matrix, and the content features  $\mathbf{x}_{i,2}$  is extracted from each node's text information or attributes. They are treated as two different views to represent node  $v_i$ 's by generating the network embedding  $\mathbf{e}_{i,1} \in \mathbb{R}^d$  and the content embedding  $\mathbf{e}_{i,2} \in \mathbb{R}^d$  accordingly.

To tackle the problem, we propose MERGE, as shown in Fig. 1(d), to efficiently model the relational multi-view consistency with nonlinearity. MERGE enforces the cross-instance–cross-view and intra-instance–cross-view consistencies by DeepWalk style formulations with an inexpensive realization, which models the relational

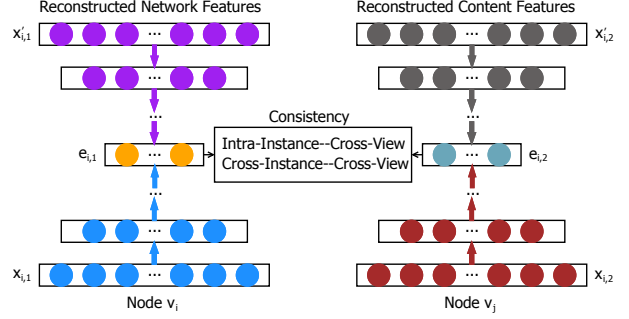

Figure 2: Illustration of the MERGE model.

information with second-order proximity and the multiple views correspondingly. Additionally, MERGE applies a deep neural network on the multi-view features and couples the nonlinear embedding outputs with the rich relational multi-view consistencies to model the feature nonlinearity. Fig. 2 summarizes the three major components of the proposed MERGE model:

- A direct formulation of intra-instance–cross-view and cross-instance–cross-view consistencies between node  $v_i$ 's network embedding  $\mathbf{e}_{i,1}$  and its “neighbor” node  $v_j$ 's content embedding  $\mathbf{e}_{j,2}$  (by setting  $i$  as a special “neighbor” node of itself, this component handles the intra-instance–cross-view as well);
- A nonlinear formulation of learning a network embedding  $\mathbf{e}_{i,1}$  from node  $v_i$ 's network features  $\mathbf{x}_{i,1}$ ;
- A nonlinear formulation of learning a content embedding  $\mathbf{e}_{j,2}$  from node  $v_j$ 's content features  $\mathbf{x}_{j,2}$ .

By integrating all these components together, MERGE learns the embedding  $\mathbf{e}_{i,1}$  and  $\mathbf{e}_{j,2}$  from  $G$ . In the following sections, we introduce the methodology to model these consistencies.

**Cross-instance–cross-view consistency for second-order proximity.** Formally, we define this consistency between one node  $v_i$ 's view-1 embedding  $\mathbf{e}_{i,1}$  and another node  $v_j$ 's view-2 embedding  $\mathbf{e}_{j,2}$  as a probability  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$ . To enforce this cross-instance–cross-view consistency between  $\mathbf{e}_{i,1}$  and  $\mathbf{e}_{j,2}$ , MERGE maximizes  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$ . Inspired by DeepWalk [20], which preserves second-order proximity and uses graph sampling for efficient realization, MERGE defines  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$  with a softmax function over  $\mathbf{e}_{i,1}$  and  $\mathbf{e}_{j,2}$ :

$$p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1}) = \frac{\exp(\mathbf{e}_{j,2}^\top \mathbf{e}_{i,1})}{\sum_{v_k \in V} \exp(\mathbf{e}_{k,2}^\top \mathbf{e}_{i,1})}. \quad (1)$$

Following the similar intuition as DeepWalk, MERGE uses node  $v_i$ 's network embedding  $\mathbf{e}_{i,1}$  to interpret its "neighbor"  $v_j$ 's content embedding  $\mathbf{e}_{j,2}$ . Different from DeepWalk, Eq. 1 does not contain any "context embedding" as additional parameters. Instead, MERGE uses one view's embedding to interpret the other view's embedding across the nodes. If two nodes have similar neighbors, the interpretations to the other view of these neighbors tend to be similar. Therefore MERGE still favors the second-order proximity with Eq. 1. Generally, it is possible to symmetrically define  $p(\mathbf{e}_{i,1}|\mathbf{e}_{j,2}) \propto \exp(\mathbf{e}_{i,1}^\top \mathbf{e}_{j,2})$ . Since  $\exp(\mathbf{e}_{i,1}^\top \mathbf{e}_{j,2}) = \exp(\mathbf{e}_{j,2}^\top \mathbf{e}_{i,1})$ , introducing  $p(\mathbf{e}_{i,1}|\mathbf{e}_{j,2})$  tends to achieve a similar effect as Eq. 1. For simplicity, only  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$  is used to represent cross-instance–cross-view consistency in this paper.

Additionally, MERGE uses graph sampling to enforce  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$  on a size-controllable set of  $(v_i, v_j)$ 's to reduce computation cost. On the one hand,  $v_i$  and  $v_j$  are supposed to be "close" in  $G$ ; otherwise it is not desirable to require their network embedding and content embedding to be consistent. We exploit a broad definition of "closeness" for  $v_i$  and  $v_j$  as [20, 9]; *i.e.*, a node  $v_j$  is the neighbor of  $v_i$  if  $v_j$  appears in a context window of  $v_i$  on a randomly sampled path from  $G$ . On the other hand, MERGE controls the number of "neighbors" of  $v_i$  by an adjustable amount of sampled paths from  $G$ . Usually, the number of sampled paths is set as a constant to avoid computing all the edges in  $G$ , which leads the complexity of TADW to be  $O(|E|)$ .

**Intra-instance–cross-view consistency for multiple views.** Formally, MERGE defines this consistency between node  $v_i$ 's view-1 embedding  $\mathbf{e}_{i,1}$  and its view-2 embedding  $\mathbf{e}_{i,2}$  as a probability  $p(\mathbf{e}_{i,2}|\mathbf{e}_{i,1})$ . To enforce this intra-instance–cross-view consistency between  $\mathbf{e}_{i,1}$  and  $\mathbf{e}_{i,2}$ , MERGE maximizes the likelihood  $\prod_i p(\mathbf{e}_{i,2}|\mathbf{e}_{i,1})$ . Considering the similar intuition as Eq. 1 that utilizes a given node's network embedding to interpret its content embedding, MERGE defines

$$p(\mathbf{e}_{i,2}|\mathbf{e}_{i,1}) = \frac{\exp(\mathbf{e}_{i,2}^\top \mathbf{e}_{i,1})}{\sum_{v_k \in V} \exp(\mathbf{e}_{k,2}^\top \mathbf{e}_{i,1})}. \quad (2)$$

In this regard, we simplify the objective function with a unified formulation about the cross-view consistency.

**Nonlinearity for feature embedding.** To handle the nonlinearity of each view's features, we propose to learn each  $v_i$ 's embedding  $\mathbf{e}_{i,k}$  as a nonlinear function of its corresponding feature vector  $\mathbf{x}_{i,k}$ . Specifically, we introduce AutoEncoder [4], a deep neural network, to enable this nonlinear embedding. For simplicity, we use a three-layer architecture as an example to explain how AutoEncoder works. For any input vector  $\mathbf{z} \in \mathbb{R}^d$ , we denote

$\tanh(\mathbf{z})$  to return a vector value of the hyperbolic tanh function over each dimension of  $\mathbf{z}$ . For any view  $k$ , we model each  $\mathbf{e}_{i,k}$  as

$$\mathbf{e}_{i,k} = \tanh(W_1^{(k)} \mathbf{x}_{i,k} + \mathbf{b}_1^{(k)}), \quad (3)$$

where  $W_1^{(k)} \in \mathbb{R}^{d \times |V|}$ ,  $\mathbf{x}_{i,k} \in \mathbb{R}^{m_k}$  and  $\mathbf{b}_1^{(k)} \in \mathbb{R}^d$  are parameters. Here  $\mathbf{x}_{i,k}$  is assumed to be reconstructible from  $\mathbf{e}_{i,k}$  by a nonlinear function:

$$\mathbf{x}'_{i,k} = \tanh((W_2^{(k)})^\top \mathbf{e}_{i,k} + \mathbf{b}_2^{(k)}), \quad (4)$$

where  $W_2^{(k)} \in \mathbb{R}^{d \times m_k}$  and  $\mathbf{b}_2^{(k)} \in \mathbb{R}^{m_k}$  are parameters. Finally, MERGE minimizes the  $\ell_2$ -distance between  $\mathbf{x}_{i,k}$  and  $\mathbf{x}'_{i,k}$  over all possible  $(i, k)$  pairs.

## 4 LEARNING WITH MERGE

In this section, we derive the overall objective function to compute the graph embedding. First of all, we consider the two cross-view consistencies in Eq. 1 and Eq. 2. Ideally, to enforce the two cross-view consistencies, we can directly maximize both  $p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1})$  and  $p(\mathbf{e}_{i,2}|\mathbf{e}_{i,1})$  for all the  $i$ 's and their neighboring  $j$ 's. However, since we need to sum up all the nodes in  $V$ , it is time consuming to compute the normalization terms in Eq. 1 and Eq. 2. DeepWalk exploits a hierarchical approximation to the softmax function in Eq. 1 and Eq. 2, which reduces the overall complexity to  $O(|V| \log |V|)$ . MERGE applies negative sampling [19] to replace the softmax function to further reduce the complexity. Specifically, instead of maximizing  $\log p(\mathbf{e}_{j,2}|\mathbf{e}_{i,1}) + \log p(\mathbf{e}_{i,2}|\mathbf{e}_{i,1})$ , MERGE introduces a surrogate function:

$$\begin{aligned} \Delta_{i,j} &= \log \sigma(\mathbf{e}_{j,2}^\top \mathbf{e}_{i,1}) \\ &\quad + \sum_{t=1}^{\ell_1} \mathbb{E}_{v_h \sim P_n(v_i)} [\log \sigma(-\mathbf{e}_{h,2}^\top \mathbf{e}_{i,1})]. \end{aligned} \quad (5)$$

Here  $\sigma(x) = 1/(1 + \exp(-x))$  is the sigmoid function;  $v_h \sim P_n(v_i)$  indicates sampling a node  $v_h$  as a *negative context* of node  $v_i$  from a distribution  $P_n(v_i)$ . We follow [19] to define  $P_n(v_i) \propto \text{deg}(v_i)^{3/4}$ , where  $\text{deg}(v_i)$  is  $v_i$ 's degree. Besides,  $\mathbb{E}_{v_h \sim P_n(v_i)}[\cdot]$  is the expectation over  $P_n(v_i)$ . Denote the positive context set of node  $v_i$  as  $C_i$ , where  $C_i \subset V$ . Then, we define the objective function by enforcing the two cross-view consistencies as

$$O_1 = -\frac{1}{n} \sum_{v_i \in V} \sum_{v_j \in C_i \cup v_i} \Delta_{i,j}, \quad (6)$$

where  $n = \sum_{i: v_i \in V} |C_i \cup v_i|$  is the number of  $\Delta_{i,j}$ 's. By minimizing  $O_1$ , we enforce the two cross-view consistencies with second-order proximity. This  $O_1$  formulation Eq. 6 also leads to reduce the complexity to  $O(|V|)$ , as we will see later.

Next, we consider the nonlinear embedding for two

---

**Algorithm 1** Learning Algorithm for MERGE

---

**Require:** graph  $G = (V, E)$  with node features  $\mathbf{x}_{i,k}$ 's, context window size  $\ell_0$ , # of negative samples  $\ell_1$ , sample path length  $\tau$ , # of paths per node  $\ell_3$ .

**Ensure:** embedding  $\mathbf{e}_{i,k}$ 's, parameters  $\Theta$ .

- 1: Initialize the parameters in  $\mathcal{M}$ ;
  - 2: **while** not converged **do**
  - 3: Paths  $P \leftarrow \text{SamplePath}(G, \ell_0, \ell_1, \tau, \ell_3)$ ;
  - 4: Batches  $\{(v_i, v_j, \lambda)\}, B \leftarrow \text{ConstructBatch}(P)$ ;
  - 5: **for** each batch  $\{(v_i, v_j, \lambda)\}$  **do**
  - 6:  $\nabla_{\mathcal{M}} \leftarrow \frac{\partial \mathcal{L}}{\partial \mathcal{M}}$  by AdaDelta;
  - 7:  $\mathcal{M} \leftarrow \text{GradDescent}(\nabla_{\mathcal{M}}, \mathcal{M})$ ;
  - 8: **end for**
  - 9: **end while**
- 

views. Specifically, we learn the nonlinear network embedding and nonlinear content embedding by minimizing:

$$\begin{cases} O_2 = \sum_{v_i \in V} \|\mathbf{x}'_{i,1} - \mathbf{x}_{i,1}\|^2 \\ O_3 = \sum_{v_i \in V} \|\mathbf{x}'_{i,2} - \mathbf{x}_{i,2}\|^2. \end{cases} \quad (7)$$

**Objective function.** MERGE combines  $O_1$ ,  $O_2$  and  $O_3$  together to learn  $\mathbf{e}_{i,k}$ 's. Denote our model  $\mathcal{M}$  as  $\{\mathbf{e}_{i,k}, \Theta | i = 1, \dots, |V|, k = 1, 2\}$ , which parameters are listed in  $\Theta = \{W_1^{(k)}, W_2^{(k)}, \mathbf{b}_1^{(k)}, \mathbf{b}_2^{(k)}\}$ . The overall objective function to minimize is

$$\mathcal{L}(\mathcal{M}) = O_1 + \alpha O_2 + \beta O_3 + \gamma \Omega(\mathcal{M}), \quad (8)$$

where  $\alpha, \beta, \gamma$  are a set of positive trade-off parameters.  $\Omega(\mathcal{M})$  is a regularization term over  $\mathcal{M}$ ; *e.g.*, it sums up the  $\ell_2$ -norm of each parameter in  $\mathcal{M}$ .

**Learning algorithm.** To optimize  $\mathcal{L}$  in Eq. 8, we use batch stochastic gradient descent algorithm. The detailed derivations of the parameter gradients are complex, especially when the layers of deep AutoEncoder increases. Due to space limit, we skip the gradient details in this paper. Empirically, these gradients can be automatically computed in the state-of-the-art deep learning toolkits. Since all the  $O_1$ ,  $O_2$  and  $O_3$  are larger than zero,  $\mathcal{L}$  is bounded, the minimization will converge in the end. Empirically, the MERGE algorithm converges quickly, as shown later in Sec. 5.

We summarize learning algorithm for MERGE in Alg. 1. In line 1, we initialize all the parameters  $\mathbf{e}_{i,k}$ 's and  $\Theta$ . In line 3, we sample a set of paths from  $G$ , in order to identify the context neighbors for each node  $v_i$ . In particular, starting from each node  $v \in V$ , we sample  $\ell_3$  paths by random walk. Each path's length is  $\tau$ . As we use nega-

tive sampling for  $O_1$ , each node  $v_i$  has both positive context and negative context. Thus, in line 4, we construct  $B$  batches, each of which has a set of tuples  $\{(v_i, v_j, \lambda)\}$  from the sampled paths  $P$ . Here,  $v_j$  is  $v_i$ 's positive context when  $\lambda = 1$ , negative when  $\lambda = -1$ . Empirically, we find the batch size range from 100 to 1000 working well. In lines 5 ~ 8, we compute the batch gradient for each parameter in  $\mathcal{M}$  and do gradient descent.

**Algorithm complexity.** We analyze the complexity of Alg. 1. Parameter initialization in line 1 takes  $O(|V|)$ . Path sampling in line 3 takes  $O(|V|\tau\ell_3)$ . In line 4, the following steps are implemented:

1. extracting all the  $v_i$  and its context neighbor pairs, which takes  $O(|V|\tau\ell_3)$ ;
2. sampling  $\ell_4$  negative context nodes for  $v_i$ , which takes  $O(\ell_4)$ ;
3. sampling  $B$  batches, each of size  $\ell_4$ , which takes  $O(B\ell_4)$ .

In line 6, we compute the gradient of  $\mathcal{L}$  w.r.t. each batch. For  $O_1$ , it takes  $O(1)$  for a single node. For  $O_2$ , as each network feature vector has the length of  $O(|V|)$ , it takes  $O(|V|)$  to compute the gradient. For  $O_3$ , it takes  $O(1)$  for a single node. For  $\Omega$ , it takes  $O(|V|)$  since the network embedding has  $O(|V|)$  dimensions. In total, line 6 takes  $O(|V|\ell_4)$ . Line 7 takes  $O(|V|)$  to update the parameters. The complexity of Alg. 1 is  $O(|V|) = O(|V| + |V|\tau\ell_3 + \ell_4 + B\ell_4 + B(|V|\ell_4 + |V|))$ , which is much smaller than the TADW's  $O(|E| + |V|)$ .

## 5 EXPERIMENTS

In this section, we demonstrate the effectiveness of MERGE by comparing it against the current state-of-the-art baselines. MERGE shows a superior advantage over all other models in extensive experiments. In addition, we present a comprehensive analysis on MERGE in terms of its parameter sensitivity, algorithm convergence and computational complexity.

### 5.1 Experimental Setup

To quantitatively evaluate the quality of our node embedding, we follow [20, 5] to use node classification as the evaluation task. We feed the embedding output from each method into a logistic regression model for node classification. We use *micro-F1* (*i.e.*, the overall F1 w.r.t. all the classes) and *macro-F1* (*i.e.*, the average F1 w.r.t. each class) as the evaluation metrics. For each dataset, we randomly sample 50% of nodes as the test set  $D_{test}$ ,

Table 1: Benchmark datasets.

Dataset	#(node)	#(edge)	#(class)
<b>Cora</b>	2708	5429	7
<b>PubMed</b>	19717	44338	3
<b>CiteSeer</b>	3264	4591	6
<b>Wikipedia</b>	2405	17981	19
<b>MicroblogPCU</b>	781	3315	2

30% as the training set  $D_{trn}$  and the remaining as the development set  $D_{dev}$ . We first train the model on  $D_{trn}$  and tune the hyperparameters with  $D_{dev}$ . Then we fix the hyperparameters, re-train our model on  $D_{trn} \cup D_{dev}$  and test it on  $D_{tst}$ . We repeat this procedure for 10 times and report the average results. All experiments are implemented on a Linux server with 64GB memory, 24 Intel Xeon CPUs (2.40GHz) and 1 Intel Tesla K80 GPU.

**Datasets.** Five different benchmark datasets are used for evaluation:

1. Three paper citation networks<sup>1</sup> as used in [33], including *Cora*, *PubMed* and *CiteSeer*. In these networks, nodes are papers, edges are citations and classes are paper categories.
2. One web document network<sup>2</sup>, *i.e.*, *Wikipedia*, as used in [32]. In this network, nodes are Wikipedia articles, edges are hyperlinks and classes are web page categories.
3. One microblog user network, *i.e.*, *MicroblogPCU*<sup>3</sup>. In this network, nodes are users, edges are follow-ship and classes indicate spam users.

The network statistics of these datasets are summarized in Table 1. Next we introduce the node features of each dataset. For *Cora* and *Citeseer*, each node contains a pre-processed bag-of-words text feature vector. For *PubMed* and *Wikipedia*, each node corresponds a preprocessed *tf-idf* text feature vector. For *MicroblogPCU*, each node contains a raw document. As the vocabulary size is large and the text is noisy, we follow TADW [32] to apply PCA for dimensionality reduction on the node-by-text feature matrix of each dataset. Then we keep  $m_2$  dimensions corresponding to the largest singular values, which retain 90% of the *energy* [21]. Thus each node has an  $m_2$ -dimensional content feature vector. Similarly, we also apply PCA to reduce each dataset’s node adjacency matrix to  $m_1$ -dimensional network feature vector.

**Baselines.** To give a clear illustration on the contribution of cross-view consistency and model nonlinearity

<sup>1</sup><http://linqs.umiacs.umd.edu/projects/projects/lbc>

<sup>2</sup><http://linqs.cs.umd.edu/projects/projects/lbc/index.html>

<sup>3</sup><https://archive.ics.uci.edu/ml/datasets/microblogPCU>

respectively, we classify our baselines into several categories:

1. Models which only use content information, such as *AEC*: AutoEncoder of Content applies AutoEncoder [4] to the content features.
2. Models which only explore relational information, such as *DeepWalk* [20], *Node2Vec* [9], *SDNE* [27] and *struc2vec* [22].
3. Models which naively concatenate a content feature vector and a network embedding vector. These approaches do not model the cross-view consistency, which include: *DeepWalk+AEC*, *Node2Vec+AEC*, *SDNE+AEC*, *struc2vec+AEC* and *AEG+AEC*, where AutoEncoder of Graph (AEG) is a method that applies AutoEncoder to the network features to learn a network embedding for each node.
4. *TADW* [32]: it learns both network embedding and content embedding by matrix decomposition, which only models the linearity.
5. *DCCA* [2]: it learns a network embedding and a content embedding for each node by applying a deep neural network to the corresponding features and enforcing the embedding to be maximally correlated. It does not consider relational information.

**Parameters.** MERGE has a similar set of hyperparameters as DeepWalk, which includes the context window size  $\ell_0$ , the number of negative samples  $\ell_1$ , the sample path length  $\tau$ , the number of paths per node  $\ell_3$  and the embedding dimension  $d$ . Typically, we set  $\ell_0 = 4$ ,  $\ell_1 = 9$ ,  $\tau = 10$ ,  $\ell_3 = 10$  and  $d = 128$  for all of the datasets. An exception is in *PubMed*, which is larger than the other datasets: we follow the suggestion in [19] to set a larger dimension  $d = 256$  and a smaller number of negative samples  $\ell_1 = 2$ . In addition, we have trade-off hyperparameters  $\{\alpha, \beta, \gamma\}$ . We use grid search over  $\{1e-6, 1e-5, 1e-4, 1e-3, 1e-2\}$  to tune each of them (results to be shown later). Typically, we set  $\alpha = 1e-4$ ,  $\beta = 1e-3$ ,  $\gamma = 1e-5$  for all the datasets.

For each baseline’s hyperparameters, we take their suggested values as in references and fine tune them with the development set on each dataset. For DeepWalk and Node2Vec, we set  $\ell_0 = 10$ ,  $\tau = 10$ ,  $\ell_3 = 80$ ,  $d = 128$ . For Node2Vec, we optimize  $p$  and  $q$  with a grid search over  $p, q \in 0.25, 0.50, 1, 2, 4$  as suggested by [9] on each dataset’s development set. For TADW, we use the optimal parameter values reported by [32] for *Cora*, *CiteSeer* and *Wikipedia*; besides, we set its hyperparameter  $k =$

200 for *PubMed* and  $k = 100$  for *MicroblogPCU*. For DCCA, we set its hyperparameters  $\alpha = 1e-4$  and  $\beta = 1e-4$ . For SDNE, we optimize the hyperparameters of  $\alpha \in \{1, 10, 100, 300, 500, 700\}$ ,  $\beta \in \{1, 10, 30, 50, 100\}$ , and  $\gamma \in \{1e-4, 1e-3, 1e-2, 1e-1, 1, 10\}$  on the validation set. For struc2vec, we fine tune the hyperparameters of  $\ell_0 \in (0, 10)$ ,  $\tau \in \{10, 30, 50, 70, 90\}$  and  $\ell_3 \in \{1, 5, 10, 15\}$  on the validation set. Besides, we set the maximum layer used in struc2vec as six and enable all of the optimization options in the paper. Note that it is time consuming to get the comparable results when the optimization options are disabled.

## 5.2 Model Performances

We report the results in Table 2. Note that all the improvements discussed below are calculated in relative values. For each dataset, we average the improvements over all the training ratios due to space limit. We draw conclusions as follows.

- Jointly considering both content and network information for graph embedding is critical, as indicated by the uncompetitive performance of AEC, DeepWalk, Node2Vec, SDNE, and struc2vec. In contrast, the naive method of concatenating content-based feature with network embedding vector already improves the overall performance. DeepWalk + AEC improves by 1% ~ 28% over DeepWalk alone, Node2Vec + AEC improves by 1% ~ 24%, SDNE + AEC improves by 1% ~ 60% and struc2vec improves by 5% ~ 320% in terms of macro-F1. Similarly, AEG+AEC improves AEC by 1% ~ 24%. However, directly concatenating two embeddings does not exploit the cross-view relations among data, and thus cannot guarantee the performance improvements. For example, AEC outperforms both DeepWalk+AEC and Node2Vec+AEC in PubMed and CiteSeer.
- Utilization of either cross-instance consistency (DeepWalk+AEC, node2vec+AEC, AEG+AEC, SDNE+AEC, struc2vec+AEC) or cross-view consistency (DCCA) alone is not sufficient to model the relations in data. Particularly, by enforcing cross-instance-cross-view consistency, MERGE outperforms cross-instance-only baselines by at least 2% ~ 17% (macro-F1) and 2% ~ 9% (micro-F1) on average, and it improves DCCA by averagely 4% ~ 20% (macro-F1) and 4% ~ 17% (micro-F1). This again proves that maximizing the utility of both views for graph embedding, we need to carefully leverage the interdependency between the two views rather than simply concatenating them.

- Modeling data nonlinearity in graph embedding gives rise to an enhancement of performances. It is shown that MERGE is better than TADW by 6.87% ~ 20% (macro-F1) and 4% ~ 16% (micro-F1) on average.
- By comprehensively modeling cross-instance-cross-view consistency with nonlinearity, MERGE consistently and significantly outperforms all the baselines on all the five datasets with different training ratios. Specifically, in most datasets training with only 30% of labeled nodes, MERGE outperforms the baselines which are trained with 100% of the training data(micro-F1) except Wikipedia and MicroblogPCU. On average, MERGE improves the best baselines by 2.1% ~ 10.3% (macro-F1) and 2.3% ~ 9.3% (micro-F1) across all the datasets. The advantage of MERGE is more favorable especially with less training data. For example, in Cora, MERGE outperforms the baselines at least by 17.8% when using 10% training data and 6.2% when using 100% training data in terms of macro-F1.

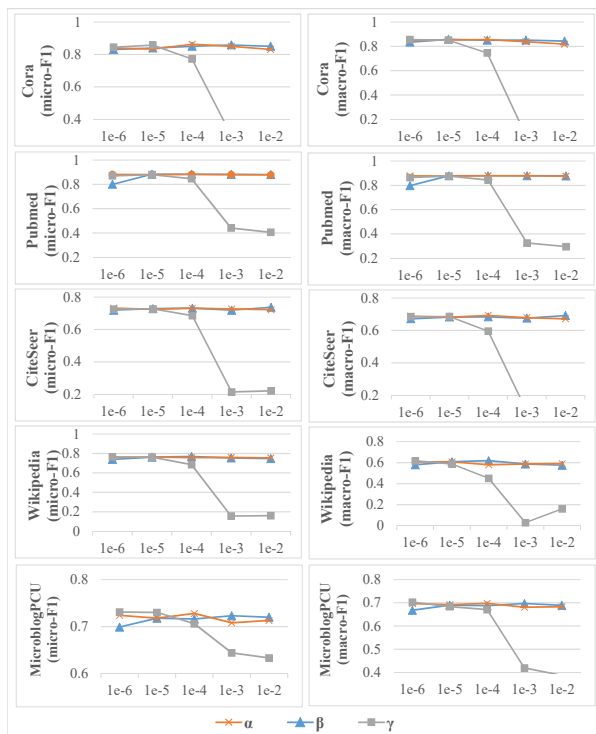

Figure 3: Results on parameter sensitivity.

## 5.3 Model Analysis

We validate the parameter sensitivity for MERGE by tuning our model parameters  $\alpha$ ,  $\beta$  and  $\gamma$ . As shown in

Table 2: Comparison with the baselines under different amounts of training labels. The bigger F1 value is better.

		macro-F1 (%)										micro-F1 (%)									
		% Labels	10%	20%	30%	40%	50%	60%	70%	80%	90%	100%	10%	20%	30%	40%	50%	60%	70%	80%	90%

Figure 4: Results on convergence.

Figure 5: Results on running time.

Fig. 3, MERGE performs optimally when  $\alpha$  and  $\beta \in \{1e-5, 1e-4, 1e-3, 1e-2\}$  and  $\gamma \in \{1e-6, 1e-5\}$ . Detailed parameter settings are described in Sec. 5.1. Specifically, our model is relatively robust to the values of  $\alpha$  and  $\beta$ . While taking large value for  $\gamma$  causes over-regularization of the model, which leads to poor performance. The suggested  $\gamma$  value is less than  $1e-4$ . We further validate the convergence and time complexity of MERGE. As shown in Fig. 4, the loss of the model normalized by the number of nodes converges quickly within a few iterations. In terms of asymptotic computation complexity, we test the algorithm complexity with different amounts of nodes (*i.e.*, different  $|V|$  values). As shown in Fig. 5, it is observed that the running time of MERGE scales linearly with  $|V|$ .

## 6 CONCLUSION

In this paper, we systematically investigate the problem of UMGE, where multiple perspectives such as content and network features are exploited to learn graph embedding in an unsupervised fashion. We discover that cross-view and nonlinearity play a critical role in improving graph embedding quality. Therefore, we develop a simple, yet effective approach, Multi-viEW non-linear Graph Embedding (MERGE), to model relational multi-view consistency with nonlinearity. MERGE incorporates both network embedding and content embedding with a nonlinear AutoEncoder. Then, it enforces both intra-instance-cross-view consistency and cross-instance-cross-view consistency among nodes' network embedding with its neighbors' content embedding. The

experimental results demonstrate that MERGE consistently outperforms the state-of-the-art baselines by at least relatively 2.12%  $\sim$  10.91% (macro-F1) and 2.29%  $\sim$  10.12% (micro-F1) on average over five public datasets, yet with  $O(|V|)$  complexity. It is worthy to note that, in most cases, MERGE outperforms the baselines in favor of using relatively one third of training data yet with superior performance.

## Abstract

In this paper, we present the first differentially private clustering method for arbitrary-shaped node clusters in a graph. This algorithm takes as input only an approximate Minimum Spanning Tree (MST)  $\mathcal{T}$  released under weight differential privacy constraints from the graph. Then, the underlying nonconvex clustering partition is successfully recovered from cutting optimal cuts on  $\mathcal{T}$ . As opposed to existing methods, our algorithm is theoretically well-motivated. Experiments support our theoretical findings.

## 1 INTRODUCTION

Weighted graph data is known to be a useful representation data type in many fields, such as bioinformatics or analysis of social, computer and information networks. More generally, a graph can always be built based on the data dissimilarity where points of the dataset are the vertices and weighted edges express “distances” between those objects. For both cases, graph clustering is one of the key tools for understanding the underlying structure in the graph (Schaeffer, 2007). These clusters can be seen as groups of nodes close in terms of some specific similarity.

Nevertheless, it is critical that the data representation used in machine learning applications protects the private characteristics contained into it. Let us consider an application where one wants to identify groups of similar web pages in the sense of traffic volume *i.e.* web pages with similar audience. In that case, the nodes stand for the websites. The link between two vertices represents

the fact that some people consult them both. In such a framework, the web browsing history of an individual is used to set the edge weights. We consider that this history can be a very sensitive information for the user, since he/she could have visited sensible content web pages. Treating such datasets as non-private could lead to leaking information such as his/her political, sexual, or religious preferences. As a standard for data privacy preservation, differential privacy (Dwork et al., 2006b) has been designed: an algorithm is differentially private if, given two close databases, it produces statistically indistinguishable outputs. Since then, its definition has been extended to weighted graphs. Though, machine learning applications ensuring data privacy remain rare, in particular for clustering which encounters severe theoretical and practical limitations. Indeed, some clustering methods lack of theoretical support and most of them restrict the data distribution to convex-shaped clusters (Nissim et al., 2007; Blum et al., 2008; McSherry, 2009; Dwork, 2011) or unstructured data (Ho and Ruan, 2013; Chen et al., 2015). Hence, the aim of this paper is to offer a theoretically motivated private graph clustering. Moreover, to the best of our knowledge, this is the first weight differentially-private clustering algorithm able to detect clusters with an arbitrary shape for weighted graph data.

Our method belongs to the family of Minimum Spanning Tree (MST)-based approaches. An MST represents a useful summary of the graph, and appears to be a natural object to describe it at a lower cost. For clustering purposes, it has the appealing property to help retrieving non-convex shapes (Zahn, 1971; Asano et al., 1988; Grygorash et al., 2006; Morvan et al., 2017). Moreover, they appear to be well-suited for incorporating privacy constraints as will be formally proved in this work.

**Contributions:** Our contributions are threefold: 1) we provide the first theoretical justifications of MST-based clustering algorithms. 2) We endow DBMSTCLU algorithm (Morvan et al., 2017), an MST-based clustering algorithm from the literature, with theoretical guarantees.

---

\*Rafael Pinot and Anne Morvan contributed equally.

†Partly supported by the *Direction Générale de l'Armement* (French Ministry of Defense).

3) We introduce a differentially-private version of DBM-STCLU and give several results on its privacy/utility tradeoff.

## 2 PRELIMINARIES

### 2.1 NOTATIONS

Let  $\mathcal{G} = (V, E, w)$  be a simple undirected weighted graph with a vertex set  $V$ , an edge set  $E$ , and a weight function  $w := E \rightarrow \mathbb{R}$ . One will respectively call the edge set and the node set of a graph  $\mathcal{G}$  using the applications  $E(\mathcal{G})$  and  $V(\mathcal{G})$ . Given a node set  $S \subset V$ , one denotes by  $\mathcal{G}_{|S}$  the subgraph induced by  $S$ . We call  $G = (V, E)$  the topology of the graph, and  $\mathcal{W}_E$  denotes the set of all possible weight functions mapping  $E$  to weights in  $\mathbb{R}$ . For the remaining of this work, cursive letter are used to represent weighted graphs and straight letters refer to topological arguments. Since graphs are simple, the path  $\mathcal{P}_{u-v}$  between two vertices  $u$  and  $v$  is characterized either as the ordered sequence of vertices  $\{u, \dots, v\}$  or corresponding binding edges depending on the context. We also denote  $V_{\mathcal{P}_{u-v}}$  the unordered set of such vertices. Besides, edges  $e_{ij}$  denote an edge between nodes  $i$  and  $j$ . Finally, for all positive integer  $K$ ,  $[K] := \{1, \dots, K\}$ .

### 2.2 DIFFERENTIAL PRIVACY IN GRAPHS

As opposed to node-differential privacy (Kasiviswanathan et al., 2013) and edge-differential privacy (Hay et al., 2009), both based on the graph topology, the privacy framework considered here is weight-differential privacy where the graph topology  $G = (V, E)$  is assumed to be public and the private information to protect is the weight function  $w := E \rightarrow \mathbb{R}$ . Under this model introduced by Sealfon (2016), two graphs are said to be neighbors if they have the same topology, and *close* weight functions. This framework allows one to release an almost minimum spanning tree with weight-approximation error of  $O(|V| \log |E|)$  for fixed privacy parameters. Differential privacy is ensured in that case by using the Laplace mechanism on every edges weight to release a spanning tree based on a perturbed version of the weight function. The privacy of the spanning tree construction is thus provided by post-processing (cf. Th. 2.5). However, under a similar privacy setting, Pinot (2018) recently manages to produce the topology of a tree under differential privacy without relying on the post-processing of a more general mechanism such as the ‘‘Laplace mechanism’’. Their algorithm, called PAMST, privately releases the topology of an almost minimum spanning tree thanks to an iterative use of the ‘‘Exponential mechanism’’ instead.

For fixed privacy parameters, the weight approximation error is  $O\left(\frac{|V|^2}{|E|} \log |V|\right)$ , which outperforms the former method from Sealfon (2016) on arbitrary weighted graphs under weak assumptions on the graph sparseness. Thus, we keep here privacy setting from Pinot (2018).

**Definition 2.1** (Pinot (2018)). *For any edge set  $E$ , two weight functions  $w, w' \in \mathcal{W}_E$  are neighboring, denoted  $w \sim w'$ , if  $\|w - w'\|_\infty := \max_{e \in E} |w(e) - w'(e)| \leq \mu$ .*

$\mu$  represents the sensitivity of the weight function and should be chosen according to the application and the range of this function. The neighborhood between such graphs is clarified in the following definition.

**Definition 2.2.** *Let  $\mathcal{G} = (V, E, w)$  and  $\mathcal{G}' = (V', E', w')$ , two weighted graphs,  $\mathcal{G}$  and  $\mathcal{G}'$  are said to be neighbors if  $V = V'$ ,  $E = E'$  and  $w \sim w'$ .*

The so-called weight-differential privacy for graph algorithms is now formally defined.

**Definition 2.3** (Sealfon (2016)). *For any graph topology  $G = (V, E)$ , let  $\mathcal{A}$  be a randomized algorithm that takes as input a weight function  $w \in \mathcal{W}_E$ .  $\mathcal{A}$  is called  $(\epsilon, \delta)$ -differentially private on  $G = (V, E)$  if for all pairs of neighboring weight functions  $w, w' \in \mathcal{W}_E$ , and for all set of possible outputs  $S$ , one has*

$$\mathbb{P}[\mathcal{A}(w) \in S] \leq e^\epsilon \mathbb{P}[\mathcal{A}(w') \in S] + \delta.$$

*If  $\mathcal{A}$  is  $(\epsilon, \delta)$ -differentially private on every graph topology in a class  $\mathcal{C}$ , it is said to be  $(\epsilon, \delta)$ -differentially private on  $\mathcal{C}$ .*

One of the first, and most used differentially private mechanisms is the Laplace mechanism. It is based on the process of releasing a numerical query perturbed by a noise drawn from a centered Laplace distribution scaled to the sensitivity of the query. We present here its graph-based reformulation.

**Definition 2.4** (reformulation Dwork et al. (2006b)). *Given some graph topology  $G = (V, E)$ , for any  $f_G : \mathcal{W}_E \rightarrow \mathbb{R}^k$ , the sensitivity of the function is defined as  $\Delta f_G = \max_{w \sim w' \in \mathcal{W}_E} \|f_G(w) - f_G(w')\|_1$ .*

**Definition 2.5** (reformulation Dwork et al. (2006b)). *Given some graph topology  $G = (V, E)$ , any function  $f_G : \mathcal{W}_E \rightarrow \mathbb{R}^k$ , any  $\epsilon > 0$ , and  $w \in \mathcal{W}_E$ , the graph-based Laplace mechanism is  $\mathcal{M}_L(w, f_G, \epsilon) = f_G(w) + (Y_1, \dots, Y_k)$  where  $Y_i$  are i.i.d. random variables drawn from  $\text{Lap}(\Delta f_G / \epsilon)$ , and  $\text{Lap}(b)$  denotes the Laplace distribution with scale  $b$  (i.e probability density  $\frac{1}{2b} \exp\left(-\frac{|x|}{b}\right)$ ).*

**Theorem 2.1** (Dwork et al. (2006b)). *The Laplace mechanism is  $\epsilon$ -differentially private.*

We define hereafter the graph-based Exponential mechanism. In the sequel we refer to it simply as Exponential mechanism. The Exponential mechanism represents a way of privately answering arbitrary range queries. Given some range of possible responses to the query  $\mathcal{R}$ , it is defined according to a utility function  $u_G := \mathcal{W}_E \times \mathcal{R} \rightarrow \mathbb{R}$ , which aims at providing some total preorder on the range  $\mathcal{R}$  according to the total order in  $\mathbb{R}$ . The sensitivity of this function is denoted  $\Delta u_G := \max_{r \in \mathcal{R}} \max_{w \sim w' \in \mathcal{W}_E} |u_G(w, r) - u_G(w', r)|$ .

**Definition 2.6.** *Given some graph topology  $G = (V, E)$ , some output range  $\mathcal{R} \subset E$ , some privacy parameter  $\epsilon > 0$ , some utility function  $u_G := \mathcal{W}_E \times \mathcal{R} \rightarrow \mathbb{R}$ , and some  $w \in \mathcal{W}_E$  the graph-based Exponential mechanism  $\mathcal{M}_{Exp}(G, w, u_G, \mathcal{R}, \epsilon)$  selects and outputs an element  $r \in \mathcal{R}$  with probability proportional to  $\exp\left(\frac{\epsilon u_G(w, r)}{2\Delta u_G}\right)$ .*

The Exponential mechanism defines a distribution on a potentially complex and large range  $\mathcal{R}$ . As the following theorem states, sampling from such a distribution preserves  $\epsilon$ -differential privacy.

**Theorem 2.2** (reformulation McSherry and Talwar (2007)). *For any non-empty range  $\mathcal{R}$ , given some graph topology  $G = (V, E)$ , the graph-based Exponential mechanism preserves  $\epsilon$ -differential privacy, i.e if  $w \sim w' \in \mathcal{W}_E$ ,*

$$\begin{aligned} \mathbb{P}[\mathcal{M}_{Exp}(G, w, u_G, \mathcal{R}, \epsilon) = r] \\ \leq e^\epsilon \mathbb{P}[\mathcal{M}_{Exp}(G, w', u_G, \mathcal{R}, \epsilon) = r]. \end{aligned}$$

Further, Th 2.3 highlights the trade-off between privacy and accuracy for the Exponential mechanism when  $0 < |\mathcal{R}| < +\infty$ . Th 2.4 presents the ability of differential privacy to comply with composition while Th 2.5 introduces its post-processing property.

**Theorem 2.3** (reformulation Dwork and Roth (2013)). *Given some graph topology  $G = (V, E)$ , some  $w \in \mathcal{W}_E$ , some output range  $\mathcal{R}$ , some privacy parameter  $\epsilon > 0$ , some utility function  $u_G := \mathcal{W}_E \times \mathcal{R} \rightarrow \mathbb{R}$ , and denoting  $OPT_{u_G}(w) = \max_{r \in \mathcal{R}} u_G(w, r)$ , one has  $\forall t \in \mathbb{R}$ ,*

$$\begin{aligned} u_G(G, w, \mathcal{M}_{Exp}(w, u_G, \mathcal{R}, \epsilon)) \\ \leq OPT_{u_G}(w) - \frac{2\Delta u_G}{\epsilon} (t + \ln |\mathcal{R}|) \end{aligned}$$

with probability at most  $\exp(-t)$ .

**Theorem 2.4** (Dwork et al. (2006a)). *For any  $\epsilon > 0$ ,  $\delta \geq 0$  the adaptive composition of  $k$   $(\epsilon, \delta)$ -differentially private mechanisms is  $(k\epsilon, k\delta)$ -differentially private.*

**Theorem 2.5** (Post-Processing Dwork and Roth (2013)). *Let  $\mathcal{A} : \mathcal{W}_E \rightarrow B$  be a randomized algorithm that is  $(\epsilon, \delta)$ -differentially private, and  $h : B \rightarrow B'$  a deterministic mapping. Then  $h \circ \mathcal{A}$  is  $(\epsilon, \delta)$ -differentially private.*

## 2.3 DIFFERENTIALLY-PRIVATE CLUSTERING

Differentially private clustering for unstructured datasets has been first discussed in Nissim et al. (2007). This work introduced the first method for differentially private clustering based on the k-means algorithm. Since then most of the work in the field focused on adaptation of this method (Blum et al., 2008; McSherry, 2009; Dwork, 2011). The main drawback of this work is that it is not able to deal with arbitrary shaped clusters. This issue has been recently investigated in Ho and Ruan (2013) and Chen et al. (2015). They proposed two new methods to find arbitrary shaped clusters in unstructured datasets respectively based on density clustering and wavelet decomposition. Even though both of them allow one to produce non-convex clusters, they only deal with unstructured datasets and thus are not applicable to node clustering in a graph. Our work focuses on node clustering in a graph under weight-differential privacy. Graph clustering has already been investigated in a topology-based privacy framework (Mülle et al., 2015; Nguyen et al., 2016), however, these works do not consider weight-differential privacy. Our work is, to the best of our knowledge, the first attempt to define node clustering in a graph under weight differential privacy.

## 3 DIFFERENTIALLY-PRIVATE TREE-BASED CLUSTERING

We aim at producing a private clustering method while providing bounds on the accuracy loss. Our method is an adaptation of an existing clustering algorithm DBMST-CLU. However, to provide theoretical guarantees under differential privacy, one needs to rely on the same kind of guarantees in the non-private setting. Morvan et al. (2017) did not bring them in their initial work. Hence, our second contribution is to demonstrate the accuracy of this method, first in the non-private context.

In the following we present 1) the theoretical framework motivating MST-based clustering methods, 2) accuracy guarantees of DBMSTCLU in the non-private setting, 3) PTCLUST our private clustering algorithm, 4) its accuracy under differential privacy constraints.

### 3.1 THEORETICAL FRAMEWORK FOR MST-BASED CLUSTERING METHODS

MST-based clustering methods, however efficient, lack proper motivation. This Section closes this gap by providing a theoretical framework for MST-based clustering. In the sequel, notations from Section 2.1 are kept. The minimum path distance between two nodes in the graph is defined which enables to explicit our notion of

Cluster.

**Definition 3.1** (Minimum path distance). *Let be  $\mathcal{G} = (V, E, w)$  and  $u, v \in V$ . The minimum path distance between  $u$  and  $v$  is*

$$d(u, v) = \min_{\mathcal{P}_{u-v}} \sum_{e \in \mathcal{P}_{u-v}} w(e)$$

with  $\mathcal{P}_{u-v}$  a path (edge version) from  $u$  to  $v$  in  $\mathcal{G}$ .

**Definition 3.2** (Cluster). *Let be  $\mathcal{G} = (V, E, w)$ ,  $0 < w(e) \leq 1 \forall e \in E$  a graph,  $(V, d)$  a metric space based on the minimum path distance  $d$  defined on  $\mathcal{G}$  and  $D \subset V$  a node set.  $C \subset D$  is a cluster iff.  $|C| > 2$  and  $\forall C_1, C_2$  s.t.  $C = C_1 \cup C_2$  and  $C_1 \cap C_2 = \emptyset$ , one has:*

$$\operatorname{argmin}_{z \in D \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\} \subset C_2$$

Assuming that a cluster is built of at least 3 points makes sense since singletons or groups of 2 nodes can be legitimately considered as noise. For simplicity of the proofs, the following theorems hold in the case where noise is neglected. However, they are still valid in the setting where noise is considered as singletons (with each singleton representing a generalized notion of cluster).

**Theorem 3.1.** *Let be  $\mathcal{G} = (V, E, w)$  a graph and  $\mathcal{T}$  a minimum spanning tree of  $\mathcal{G}$ . Let also be  $C$  a cluster in the sense of Def. 3.2 and two vertices  $v_1, v_2 \in C$ . Then,  $V_{\mathcal{P}_{v_1-v_2}} \subset C$  with  $\mathcal{P}_{v_1-v_2}$  a path from  $v_1$  to  $v_2$  in  $\mathcal{G}$ , and  $V_{\mathcal{P}_{v_1-v_2}}$  the set of vertices contained in  $\mathcal{P}_{v_1-v_2}$ .*

*Proof.* Let be  $v_1, v_2 \in C$ . If  $v_1$  and  $v_2$  are neighbors, the result is trivial. Otherwise, as  $\mathcal{T}$  is a tree, there exist a unique path within  $\mathcal{T}$  between  $v_1$  and  $v_2$  denoted by  $\mathcal{P}_{v_1-v_2} = \{v_1, \dots, v_2\}$ . Let now prove by *reductio ad absurdum* that  $V_{\mathcal{P}_{v_1-v_2}} \subset C$ . Suppose there is  $h \in V_{\mathcal{P}_{v_1-v_2}}$  s.t.  $h \notin C$ . We will see that it leads to a contradiction. We set  $C_1$  to be the largest connected component (regarding the number of vertices) of  $\mathcal{T}$  s.t.  $v_1 \in C_1$ , and every nodes from  $C_1$  are in  $C$ . Because of  $h$ 's definition,  $v_2 \notin C_1$ . Let be  $C_2 = C \setminus C_1$ .  $C_2 \neq \emptyset$  since  $v_2 \in C_2$ . Let be  $z^* \in \operatorname{argmin}_{z \in V \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\}$  and  $e^* = (z^*, v^*)$  an edge that reaches this minimum. Let us show that  $z^* \notin C$ . If  $z^* \in C$ , then two possibilities hold:

1. There is an edge  $e_{z^*} \in \mathcal{T}$ , s.t.  $e_{z^*} = (z^*, z')$  with  $z' \in C_1$ . This is impossible, otherwise by definition of a connected component,  $z^* \in C_1$ . Contradiction.
2. For all  $e_{z^*} = (z^*, z')$  s.t.  $z' \in C_1$ , one has  $e_{z^*} \notin \mathcal{T}$ . In particular  $e^* \notin \mathcal{T}$ . Since  $h$  is the neighbor of  $C_1$  in  $\mathcal{G}$  there is also  $e_h \in \mathcal{T}$ , s.t.  $e_h = (h, h')$  with  $h' \in C_1$ . Once again two possibilities hold:

$$(a) w(e_{z^*}) = \min_{z \in V \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\} < w(e_h).$$

Then, if we replace  $e_h$  by  $e_{z^*}$  in  $\mathcal{T}$ , its total weight decreases. So  $\mathcal{T}$  is not a minimum spanning tree. Contradiction.

$$(b) w(e_{z^*}) = w(e_h), \text{ therefore } h \in \operatorname{argmin}_{z \in V \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\}. \text{ Since } h \notin C, \text{ one gets that } \operatorname{argmin}_{z \in V \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\} \not\subset C_2.$$

Thus,  $C$  is not a cluster. Contradiction.

We proved that  $z^* \notin C$ . In particular,  $z^* \notin C_2$ . Then,  $\operatorname{argmin}_{z \in V \setminus C_1} \left\{ \min_{v \in C_1} d(z, v) \right\} \not\subset C_2$ . Thus,  $C$  is not a cluster. Contradiction. Finally  $h \in C$  and  $V_{\mathcal{P}_{v_1-v_2}} \subset C$ .  $\square$

This theorem states that, given a graph  $\mathcal{G}$ , an MST  $\mathcal{T}$ , and any two nodes of  $C$ , every node in the path between them is in  $C$ . This means that a cluster can be characterized by a subtree of  $\mathcal{T}$ . It justifies the use of all MST-based methods for data clustering or node clustering in a graph. All the clustering algorithms based on successively cutting edges in an MST to obtain a subtree forest are meaningful in the sense of Th.3.1. In particular, this theorem holds for the use of DBMSTCLU (Morvan et al., 2017) presented in Section 3.2.1.

## 3.2 DETERMINISTIC MST-BASED CLUSTERING

This Section introduces DBMSTCLU (Morvan et al., 2017) that will be adapted to be differentially-private, and provide accuracy results on the recovery of the ground-truth clustering partition.

### 3.2.1 DBMSTCLU algorithm

Let us consider  $\mathcal{T}$  an MST of  $\mathcal{G}$ , as the unique input of the clustering algorithm DBMSTCLU. The clustering partition results then from successive cuts on  $\mathcal{T}$  so that a new cut in  $\mathcal{T}$  splits a connected component into two new ones. Each final connected component, a subtree of  $\mathcal{T}$ , represents a cluster. Initially,  $\mathcal{T}$  is one cluster containing all nodes. Then, at each iteration, an edge is cut if some criterion, called *Validity Index of a Clustering Partition* (DBCVI) is improved. This edge is greedily chosen to locally maximize the DBCVI at each step. When no improvement on DBCVI can be further made, the algorithm stops. The DBCVI is defined as the weighted average of all *cluster validity indices* which are based on two positive quantities, the *Dispersion* and the *Separation* of a cluster:

**Definition 3.3** (Cluster Dispersion). *The Dispersion of a cluster  $C_i$  (DISP) is defined as the maximum edge*

weight of  $C_i$ . If the cluster is a singleton (i.e. contains only one node), the associated Dispersion is set to 0. More formally:

$$\forall i \in [K], \text{DISP}(C_i) = \begin{cases} \max_{j, e_j \in C_i} w_j & \text{if } |E(C_i)| \neq 0 \\ 0 & \text{otherwise.} \end{cases}$$

**Definition 3.4** (Cluster Separation). *The Separation of a cluster  $C_i$  (SEP) is defined as the minimum distance between the nodes of  $C_i$  and the ones of all other clusters  $C_j, j \neq i, 1 \leq i, j \leq K, K \neq 1$  where  $K$  is the total number of clusters. In practice, it corresponds to the minimum weight among all already cut edges from  $\mathcal{T}$  comprising a node from  $C_i$ . If  $K = 1$ , the Separation is set to 1. More formally, with  $\text{incCuts}(C_i)$  denoting cut edges incident to  $C_i$ ,*

$$\forall i \in [K], \text{SEP}(C_i) = \begin{cases} \min_{j, e_j \in \text{incCuts}(C_i)} w_j & \text{if } K \neq 1 \\ 1 & \text{otherwise.} \end{cases}$$

**Definition 3.5** (Validity Index of a Cluster). *The Validity Index of a cluster  $C_i$  is defined as:*

$$V_C(C_i) = \frac{\text{SEP}(C_i) - \text{DISP}(C_i)}{\max(\text{SEP}(C_i), \text{DISP}(C_i))} \in [-1; 1]$$

**Definition 3.6** (Validity Index of a Clustering Partition). *The Density-Based Validity Index of a Clustering partition  $\Pi = \{C_i\}, 1 \leq i \leq K$ ,  $\text{DBCVI}(\Pi)$  is defined as the weighted average of the Validity Indices of all clusters in the partition where  $N$  is the number of vertices.*

$$\text{DBCVI}(\Pi) = \sum_{i=1}^K \frac{|C_i|}{N} V_C(C_i) \in [-1, 1]$$

DBMSTCLU is summarized in Algorithm 1: `evaluateCut(.)` computes the DBCVI when the cut in parameter is applied to  $\mathcal{T}$ . Initial DBCVI is set  $-1$ . Interested reader could refer to (Morvan et al., 2017) Section 4. for a complete insight on this notions.

### 3.2.2 DBMSTClu exact clustering recovery proof

In this section, we provide theoretical guarantees for the cluster recovery accuracy of DBMSTClu. Let us first begin by introducing some definitions.

**Definition 3.7** (Cut). *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  clusters,  $\mathcal{T}$  an MST of  $\mathcal{G}$ . Let denote  $(C_i^*)_{i \in [K]}$  the set of the clusters. Then,  $\text{Cut}_{\mathcal{G}}(\mathcal{T}) := \{e_{kl} \in \mathcal{T} \mid k \in C_i^*, l \in C_j^*, i, j \in [K]^2, i \neq j\}$ . In the sequel, for simplicity, we denote  $e^{(ij)} \in \text{Cut}_{\mathcal{G}}(\mathcal{T})$  the edge between cluster  $C_i^*$  and  $C_j^*$ .*

$\text{Cut}_{\mathcal{G}}(\mathcal{T})$  is basically the set of effective cuts to perform on  $\mathcal{T}$  in order to ensure the exact recovery of the clustering partition. More generally, trees on which  $\text{Cut}_{\mathcal{G}}(\cdot)$

---

```

---

enables to find the right partition are said to be a partitioning topology.

**Definition 3.8** (Partitioning topology). *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  clusters  $C_1^*, \dots, C_K^*$ . A spanning tree  $\mathcal{T}$  of  $\mathcal{G}$  is said to have a partitioning topology if  $\forall i, j \in [K], i \neq j, |\{e = (u, v) \in \text{Cut}_{\mathcal{G}}(\mathcal{T}) \mid u \in C_i^*, v \in C_j^*\}| = 1$ .*

Def. 3.7 and 3.8 introduce a topological condition on the tree as input of the algorithm. Nevertheless, conditions on weights are necessary too. Hence, we define homogeneous separability which expresses the fact that within a cluster the edge weights are spread in a controlled manner.

**Definition 3.9** (Homogeneous separability condition). *Let us consider a graph  $\mathcal{G} = (V, E, w)$ ,  $s \in E$  and  $\mathcal{T}$  a tree of  $\mathcal{G}$ .  $\mathcal{T}$  is said to be homogeneously separable by  $s$ , if*

$$\alpha_{\mathcal{T}} \max_{e \in E(\mathcal{T})} w(e) < w(s) \text{ with } \alpha_{\mathcal{T}} = \frac{\max_{e \in E(\mathcal{T})} w(e)}{\min_{e \in E(\mathcal{T})} w(e)} \geq 1.$$

One will write for simplicity that  $H_{\mathcal{T}}(s)$  is verified.

**Definition 3.10** (Weak homogeneity condition of a Cluster). *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  clusters  $C_1^*, \dots, C_K^*$ . A given cluster  $C_i^*, i \in [K]$ ,  $C_i^*$  is weakly homogeneous if: for all  $\mathcal{T}$  an MST of  $\mathcal{G}$ , and  $\forall j \in [K], j \neq i$ , s.t.  $e^{(ij)} \in \text{Cut}_{\mathcal{G}}(\mathcal{T})$ ,  $H_{\mathcal{T}_{C_i^*}}(e^{(ij)})$  is verified. For simplicity, one denote  $\alpha_i = \max_{\mathcal{T} \text{ MST of } \mathcal{G}} \alpha_{\mathcal{T}_{C_i^*}}$*

**Definition 3.11** (Strong homogeneity condition of a Cluster). *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with*

$K$  clusters  $C_1^*, \dots, C_K^*$ . A given cluster  $C_i^*$ ,  $i \in [K]$ ,  $C_i^*$  is strongly homogeneous if: for all  $\mathcal{T}$  a spanning tree (ST) of  $\mathcal{G}$ , and  $\forall j \in [K]$ ,  $j \neq i$ , s.t.  $e^{(ij)} \in \text{Cut}_{\mathcal{G}}(\mathcal{T})$ ,  $H_{\mathcal{T}|_{C_i^*}}(e^{(ij)})$  is verified. For simplicity, one denote  $\bar{\alpha}_i = \max_{\mathcal{T} \text{ ST of } \mathcal{G}} \alpha_{\mathcal{T}|_{C_i^*}}$

Weak homogeneity is indeed really natural considering the non-private cases using an MST. Strong homogeneity is more demanding, but still a reachable condition. Section 4 presents an experiment where the graph respects strong homogeneity as well as being organised in arbitrary shaped clusters. We show that the weak homogeneity condition is implied by the strong homogeneity condition.

**Proposition 3.1.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  clusters  $C_1^*, \dots, C_K^*$ . If a given cluster  $C_i^*$ ,  $i \in [K]$  is strongly homogeneous, then, it is weakly homogeneous.*

*Proof.* If  $\mathcal{T}$  a spanning tree of  $\mathcal{G}$ , and  $\forall j \in [K]$ ,  $j \neq i$ , s.t.  $e^{(ij)} \in \text{Cut}_{\mathcal{G}}(\mathcal{T})$ ,  $H_{\mathcal{T}|_{C_i^*}}(e^{(ij)})$  is verified, then in particular, it is true for any MST.  $\square$

Strong homogeneity condition appears to be naturally more constraining on the edge weights than the weak one. The accuracy of DBMSTCLU is proved under the weak homogeneity condition, while the accuracy of its differentially-private version is only given under the strong homogeneity condition.

**Theorem 3.2.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $\mathcal{T}$  an MST of  $\mathcal{G}$ . Let now assume that at step  $k < K - 1$ , DBMSTClu built  $k + 1$  subtrees  $\mathcal{C}_1, \dots, \mathcal{C}_{k+1}$  by cutting  $e_1, e_2, \dots, e_k \in E$ .*

*Then,  $\text{Cut}_k := \text{Cut}_{\mathcal{G}}(\mathcal{T}) \setminus \{e_1, e_2, \dots, e_k\} \neq \emptyset \implies \text{DBCVI}_{k+1} \geq \text{DBCVI}_k$ , i.e. if there are still edges in  $\text{Cut}_k$ , the algorithm will continue to perform some cut.*

*Proof.* See supplementary material.  $\square$

**Theorem 3.3.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $\mathcal{T}$  an MST of  $\mathcal{G}$ .*

*Assume now that at step  $k < K - 1$ , DBMSTClu built  $k + 1$  subtrees  $\mathcal{C}_1, \dots, \mathcal{C}_{k+1}$  by cutting  $e_1, e_2, \dots, e_k \in E$ . We still denote  $\text{Cut}_k := \text{Cut}_{\mathcal{G}}(\mathcal{T}) \setminus \{e_1, e_2, \dots, e_k\}$ .*

*If  $\text{Cut}_k \neq \emptyset$  then  $\arg\max_{e \in \mathcal{T} \setminus \{e_1, e_2, \dots, e_k\}} \text{DBCVI}_{k+1}(e) \subset \text{Cut}_k$  i.e. the cut edge at step  $k + 1$  is in  $\text{Cut}_k$ .*

*Proof.* See supplementary material.  $\square$

**Theorem 3.4.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  weakly homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $\mathcal{T}$  an MST of  $\mathcal{G}$ . Let now assume that at step  $K - 1$ , DBMSTClu built  $K$  subtrees  $\mathcal{C}_1, \dots, \mathcal{C}_K$  by cutting  $e_1, e_2, \dots, e_{K-1} \in E$ . We still denote  $\text{Cut}_{K-1} := \text{Cut}_{\mathcal{G}}(\mathcal{T}) \setminus \{e_1, e_2, \dots, e_{K-1}\}$ .*

*Then, for all  $e \in \mathcal{T} \setminus \{e_1, e_2, \dots, e_{K-1}\}$ ,  $\text{DBCVI}_K(e) < \text{DBCVI}_{K-1}$  i.e. the algorithm stops: no edge gets cut during step  $K$ .*

*Proof.* See supplementary material.  $\square$

**Corollary 3.1.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  weakly homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $\mathcal{T}$  an MST of  $\mathcal{G}$ . DBMSTClu( $\mathcal{T}$ ) stops after  $K - 1$  iterations and the  $K$  subtrees produced match exactly the clusters i.e. under homogeneity condition, the algorithm finds automatically the underlying clustering partition.*

*Proof.* Th. 3.2 and 3.4 ensure that under homogeneity condition on all clusters, the algorithm performs the  $K - 1$  distinct cuts within  $\text{Cut}_{\mathcal{G}}(\mathcal{T})$  and stops afterwards. By definition of  $\text{Cut}_{\mathcal{G}}(\mathcal{T})$ , it means the DBMSTClu correctly builds the  $K$  clusters.  $\square$

### 3.3 PRIVATE MST-BASED CLUSTERING

This section presents our new node clustering algorithm PTCLUST for weight differential privacy. It relies on a mixed adaptation of PAMST algorithm (Pinot, 2018) for recovering a differentially-private MST of a graph and DBMSTCLU.

#### 3.3.1 PAMST algorithm

Given a simple-undirected-weighted graph  $\mathcal{G} = (V, E, w)$ , PAMST outputs an almost minimal weight spanning tree topology under differential privacy constraints. It relies on a Prim-like MST algorithm, and an iterative use of the graph-based Exponential mechanism. PAMST takes as an input a weighted graph, and a utility function. It outputs the topology of a spanning tree which weight is almost minimal. Algorithm 2 presents this new method, using the following utility function:

$$u_{\mathcal{G}} : \mathcal{W}_E \times \mathcal{R} \rightarrow \mathbb{R} \\ (w, r) \mapsto -|w(r) - \min_{r' \in \mathcal{R}} w(r')|.$$

PAMST starts by choosing an arbitrary node to construct iteratively the tree topology. At every iteration, it uses the Exponential mechanism to find the next edge to be added to the current tree topology while keeping the weights private. This algorithm is the state of the art to find a spanning tree topology under differential privacy. For

readability, let us introduce some additional notations. Let  $S$  be a set of nodes from  $G$ , and  $\mathcal{R}_S$  the set of edges that are incident to one and only one node in  $S$  (also denoted xor-incident). For any edge  $r$  in such a set, the incident node to  $r$  that is not in  $S$  is denoted  $r_{\rightarrow}$ . Finally, the restriction of the weight function to an edge set  $\mathcal{R}$  is denoted  $w|_{\mathcal{R}}$ .

---

**Algorithm 2** PAMST( $G, u_G, w, \epsilon$ )

---

- 1: **Input:**  $\mathcal{G} = (V, E, w)$  a weighted graph (separately the topology  $G$  and the weight function  $w$ ),  $\epsilon$  a degree of privacy and  $u_G$  utility function.
  - 2: **Pick**  $v \in V$  at random
  - 3:  $S_V \leftarrow \{v\}$
  - 4:  $S_E \leftarrow \emptyset$
  - 5: **while**  $S_V \neq V$  **do**
  - 6:    $r = \mathcal{M}_{Exp}(\mathcal{G}, w, u_G, \mathcal{R}_{S_V}, \frac{\epsilon}{|V|-1})$
  - 7:    $S_V \leftarrow S_V \cup \{r_{\rightarrow}\}$
  - 8:    $S_E \leftarrow S_E \cup \{r\}$
  - 9: **return**  $S_E$
- 

Theorem 3.5 states that using PAMST to get an almost minimal spanning tree topology preserves weight-differential privacy.

**Theorem 3.5.** *Let  $G = (V, E)$  be the topology of a simple-undirected graph, then  $\forall \epsilon > 0$ , PAMST( $G, u_G, \bullet, \epsilon$ ) is  $\epsilon$ -differentially private on  $G$ .*

### 3.3.2 Differentially-private clustering

The overall goal of this Section is to show that one can obtain a differentially-private clustering algorithm by combining PAMST and DBMSTCLU algorithms. However, PAMST does not output a weighted tree which is inappropriate for clustering purposes. To overcome this, one could rely on a sanitizing mechanism such as the Laplace mechanism. Moreover, since DBMSTCLU only takes weights from  $(0,1]$ , two normalizing parameters  $\tau$  and  $p$  are introduced, respectively to ensure lower and upper bounds to the weights that fit within DBMSTCLU needs. This sanitizing mechanism is called the Weight-Release mechanism. Coupled with PAMST, it will allow us to produce a weighted spanning tree with differential privacy, that will be exploited in our private graph clustering.

**Definition 3.12** (Weight-Release mechanism). *Let  $\mathcal{G} = (G, w)$  be a weighted graph,  $\epsilon > 0$  a privacy parameter,  $s$  a scaling parameter,  $\tau \geq 0$ , and  $p \geq 1$  two normalization parameters. The Weight-Release mechanism is defined as*

$$\mathcal{M}_{w,r}(G, w, s, \tau, p) = \left( G, w' = \frac{w + (Y_1, \dots, Y_{|E|}) + \tau}{p} \right)$$

where  $Y_i$  are i.i.d. random variables drawn from  $Lap(0, s)$ . With  $w + (Y_1, \dots, Y_{|E|})$  meaning that if one gives an arbitrary order to the edges  $E = (e_i)_{i \in [|E|]}$ , one has  $\forall i \in [|E|], w'(e_i) = w(e_i) + Y_i$ .

The following theorem presents the privacy guarantees of the Weight-Release mechanism.

**Theorem 3.6.** *Let  $G = (V, E)$  be the topology of a simple-undirected graph,  $\tau \geq 0$ ,  $p \geq 1$ , then  $\forall \epsilon > 0$ ,  $\mathcal{M}_{w,r}(G, \bullet, \frac{\mu}{\epsilon}, \tau, p)$  is  $\epsilon$ -differentially private on  $G$ .*

*Proof.* Given  $\tau \geq 0$ ,  $p \geq 1$ , and  $\epsilon > 0$ , the Weight release mechanism scaled to  $\frac{\mu}{\epsilon}$  can be break down into a Laplace mechanism and a post-processing consisting in adding  $\tau$  to every edge and dividing them by  $p$ . Using Theorems 2.1 and 2.5, one gets the expected result.  $\square$

So far we have presented DBMSTCLU and PAMST algorithms, and the Weight-Release mechanism. Let us now introduce how to compose those blocks to obtain a Private node clustering in a graph, called PTCLUST. The

---

**Algorithm 3** PTCLUST( $G, w, u_G, \epsilon, \tau, p$ )

---

- 1: **Input:**  $\mathcal{G} = (V, E, w)$  a weighted graph (separately the topology  $G$  and the weight function  $w$ ),  $\epsilon$  a degree of privacy and  $u_G$  utility function.
  - 2:  $T = \text{PAMST}(G, w, u_G, \epsilon/2)$
  - 3:  $\mathcal{T}' = \mathcal{M}_{w,r}(T, w|_{E(T)}, \frac{2\mu}{\epsilon}, \tau, p)$
  - 4: **return** DBMSTCLU( $\mathcal{T}'$ )
- 

algorithm 3 takes as an input a weighted graph (dissociated topology and weight function), a utility function, a privacy degree and two normalization parameters. It outputs a clustering partition. To do so, a spanning tree topology is produced using PAMST with time and space complexities respectively equal to  $O(|V|^2)$  and  $O(|E|)$ . Afterward a randomized and normalized version of the associated weight function is released using the Weight-release mechanism. Finally the obtained weighted tree is given as an input to DBMSTCLU that performs a clustering partition with  $O(|V|)$  time and space complexities. The following theorem ensures that our method preserves  $\epsilon$ -differential privacy.

**Theorem 3.7.** *Let  $G = (V, E)$  be the topology of a simple-undirected graph,  $\tau \geq 0$ , and  $p \geq 1$ , then  $\forall \epsilon > 0$ , PTCLUST( $G, \bullet, u_G, \epsilon, \tau, p$ ) is  $\epsilon$ -differentially private on  $G$ .*

*Proof.* Using Theorem 3.5 one has that  $T$  is produced with  $\epsilon/2$ -differential privacy, and using Theorem 3.6 one has that  $w'$  is obtained with  $\epsilon/2$ -differential privacy as

well. Therefore using Theorem 2.4,  $\mathcal{T}'$  is released with  $\epsilon$ -differential privacy. Using the post-processing property (Theorem 2.5) one gets the expected result.  $\square$

### 3.4 DIFFERENTIAL PRIVACY TRADE-OFF OF CLUSTERING

The results stated in this section present the security/accuracy trade-off of our new method in the differentially-private framework. PTCLUST relies on two differentially -private mechanisms, namely PAMST and the Weight-Release mechanism. Evaluating the accuracy of this method amounts to check whether using these methods for ensuring privacy does not deteriorate the final clustering partition. The accuracy is preserved if PAMST outputs the same topology as the MST-based clustering and if the Weight-Release mechanism preserves enough the weight function. According to Def. 3.8, if a tree has a partitioning topology, then it fits the tree-based clustering. The following theorem states that with high probability PAMST outputs a tree with a partitioning topology.

**Theorem 3.8.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  strongly homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $T = \text{PAMST}(\mathcal{G}, u_{\mathcal{G}}, w, \epsilon)$ ,  $\epsilon > 0$ .  $T$  has a partitioning topology with probability at least*

$$1 - \sum_{i=1}^K (|C_i^*| - 1) \exp\left(-\frac{A}{2\Delta u_{\mathcal{G}}(|V| - 1)}\right)$$

$$\text{with } A = \epsilon \left( \begin{array}{cc} \bar{\alpha}_i \max_{e \in E(\mathcal{G}_{|C_i^*})}(w(e)) & - \min_{e \in E(\mathcal{G}_{|C_i^*})}(w(e)) \end{array} \right) + \ln |E|.$$

*Proof.* See supplementary material.  $\square$

The following theorem states that given a tree  $\mathcal{T}$  under the strong homogeneity condition, if the subtree associated to a cluster respects Def. 3.9, then it still holds after applying the Weight-Release mechanism to this tree.

**Theorem 3.9.** *Let us consider a graph  $\mathcal{G} = (V, E, w)$  with  $K$  strongly homogeneous clusters  $C_1^*, \dots, C_K^*$  and  $T = \text{PAMST}(\mathcal{G}, u_{\mathcal{G}}, w, \epsilon)$ ,  $\mathcal{T} = (T, w|_{\mathcal{T}})$  and  $\mathcal{T}' = \mathcal{M}_{w,r}(T, w|_{\mathcal{T}}, s, \tau, p)$  with  $s \ll p, \tau$ . Given some cluster  $C_i^*$ , and  $j \neq i$  s.t.  $e^{(ij)} \in \text{Cut}_{\mathcal{G}}(\mathcal{T})$ , if  $H_{\mathcal{T}|_{C_i^*}}(e^{(ij)})$  is verified, then  $H_{\mathcal{T}'|_{C_i^*}}(e^{(ij)})$  is verified with probability at least*

$$1 - \frac{\mathbb{V}(\varphi)}{\mathbb{V}(\varphi) + \mathbb{E}(\varphi)^2}$$

with the following notations :

$$\bullet \varphi = \left( \max_{j \in [|C_i^*| - 1]} Y_j \right)^2 - \min_{j \in [|C_i^*| - 1]} Z_j \times X^{\text{out}}$$

- $Y_j \underset{iid}{\sim} \text{Lap}\left(\frac{\max_{e \in E(\mathcal{T})} w(e) + \tau}{p}, \frac{s}{p}\right)$
- $Z_j \underset{iid}{\sim} \text{Lap}\left(\frac{\min_{e \in E(\mathcal{T})} w(e) + \tau}{p}, \frac{s}{p}\right)$
- $X^{\text{out}} \sim \text{Lap}\left(\frac{w(e^{(ij)}) + \tau}{p}, \frac{s}{p}\right),$

*Proof.* See supplementary material.  $\square$

Note that Theorem 3.9 is stated in a simplified version. A more complete version (specifying an analytic version of  $\mathbb{V}(\varphi)$  and  $\mathbb{E}(\varphi)$ ) is given in the supplementary material.

## 4 EXPERIMENTS

So far we have exhibited the trade-off between clustering accuracy and privacy and we experimentally illustrate it with some qualitative results. We have performed experiments on two classical synthetic graph datasets for clustering with nonconvex shapes: two concentric circles and two moons, both in their noisy versions. For the sake of readability and for visualization purposes, both graph datasets are embedded into a two dimensional Euclidean space. Each dataset contains 100 data nodes that are represented by a point of two coordinates. Both graphs have been built with respect to the strong homogeneity condition: edge weights within clusters are between  $w_{\min} = 0.1$  and  $w_{\max} = 0.3$  while edges between clusters have a weight strictly above  $w_{\max}^2/w_{\min} = 0.9$ . In practice, the complete graph has trimmed from its irrelevant edges (*i.e.* not respecting the strong homogeneity condition). Hence, those graphs are not necessarily Euclidean since close nodes in the visual representation may not be connected in the graph. Finally, weights are normalized between 0 and 1.

Figures 1 and 2 (best viewed in color) show for each dataset (a) the original homogeneous graph  $\mathcal{G}$  built by respecting the homogeneity condition, (b) the clustering partition<sup>1</sup> of DBMSTCLU with the used underlying MST, the clustering partitions for PTCLUST with  $\mu = 0.1$  obtained respectively with different privacy degrees<sup>2</sup> : (c)  $\epsilon = 0.5$ , (d)  $\epsilon = 0.7$  and (e)  $\epsilon = 1.0$ . The utility function  $u_{\mathcal{G}}$  corresponds to the graph weight. Each experiment is carried out independently and the tree topology obtained by PAMST will eventually be different. This explains why the edge between clusters may not be the same when the experiment is repeated with a

<sup>1</sup>For the sake of clarity, the edges in those Figures are represented based on the original weights and not on the privately released weights.

<sup>2</sup>Note that, although the range of  $\epsilon$  is in  $\mathbb{R}_+^*$ , it is usually chosen in practice in  $(0, 1]$  (Dwork and Roth, 2013, Chap 1&2).

Figure 1: Circles experiments for  $n = 100$ . PTCLUST parameters:  $w_{min} = 0.1$ ,  $w_{max} = 0.3$ ,  $\mu = 0.1$ .

Figure 2: Moons experiments for  $n = 100$ . PTCLUST parameters:  $w_{min} = 0.1$ ,  $w_{max} = 0.3$ ,  $\mu = 0.1$ .

different level of privacy. However, this will marginally affect the overall quality of the clustering.

As expected, DBMSTCLU recovers automatically the right partition and the results are shown here for comparison with PTCLUST. For PTCLUST, the true MST is replaced with a private approximate MST obtained for suitable  $\tau$  and  $p$  ensuring final weights between 0 and 1.

When the privacy degree is moderate ( $\epsilon \in \{1.0, 0.7\}$ ), it appears that the clustering result is slightly affected. More precisely, in Figures 1c and 1d the two main clusters are recovered while one point is isolated as a singleton. This is due to the randomization involved in determining the edge weights for the topology returned by PAMST. In Figure 2c, the clustering is identical to the one from DBMSTCLU in Figure 2b. In Figure 1d, the clustering is very similar to the DBMSTCLU one, with the exception of an isolated singleton. However, as expected from our theoretical results, when  $\epsilon$  is decreasing (even below 0.5), the clustering quality deteriorates, as DBMSTCLU is sensitive to severe changes in the MST (cf. Figure 1e, 2e).

## 5 CONCLUSION

In this paper, we introduced PTCLUST, a novel graph clustering algorithm able to recover arbitrarily-shaped clusters while preserving differential privacy on the weights of the graph. It is based on the release of a private approximate minimum spanning tree of the graph of

the dataset, by performing suitable cuts to reveal the clusters. To the best of our knowledge, this is the first differentially private graph-based clustering algorithm adapted to nonconvex clusters. The theoretical analysis exhibited a trade-off between the degree of privacy and the accuracy of the clustering result. Differential privacy is investigated in the framework of strong homogeneity but this is quite restrictive. A smoother result would be very interesting but it is more challenging. This will be a focus of our future work. Our work suits to applications where privacy is a critical issue and it could pave the way to metagenomics and genes classification using individual gene maps while protecting patient privacy. Future work will also be devoted to deeply investigate these applications.

## Abstract

We propose a new network architecture, *Gated Attention Networks* (GaAN), for learning on graphs. Unlike the traditional multi-head attention mechanism, which equally consumes all attention heads, GaAN uses a convolutional sub-network to control each attention head’s importance. We demonstrate the effectiveness of GaAN on the inductive node classification problem on large graphs. Moreover, with GaAN as a building block, we construct the *Graph Gated Recurrent Unit* (GGRU) to address the traffic speed forecasting problem. Extensive experiments on three real-world datasets show that our GaAN framework achieves state-of-the-art results on both tasks.

## 1 INTRODUCTION

Many crucial machine learning tasks involve graph-structured datasets, such as classifying posts in a social network (Hamilton et al., 2017a), predicting interfaces between proteins (Fout et al., 2017) and forecasting the future traffic speed in a road network (Li et al., 2018). The main difficulty in solving these tasks is how to find the right way to express and exploit the graph’s underlying structural information. Traditionally, this is achieved by calculating various graph statistics like degree and centrality, using graph kernels, or extracting human engineered features (Hamilton et al., 2017b).

Recent research, however, has pivoted to solving these problems by *graph convolution* (Duvenaud et al., 2015; Atwood and Towsley, 2016; Kipf and Welling, 2017; Fout et al., 2017; Hamilton et al., 2017a; Veličković et al., 2018; Li et al., 2018), which generalizes the stan-

dard definition of convolution over a regular grid topology (Gehring et al., 2017; Krizhevsky et al., 2012) to ‘convolution’ over graph structures. The basic idea behind ‘graph convolution’ is to develop a localized parameter-sharing operator on a set of neighboring nodes to aggregate a local set of lower-level features. We refer to such an operator as a *graph aggregator* (Hamilton et al., 2017a) and the set of local nodes as the *receptive field* of the aggregator. Then, by stacking multiple graph aggregators, we build a deep neural network model which can be trained end-to-end to extract the local and global features across the graph. Note that we use the spatial definition instead of the spectral definition (Hammond et al., 2011; Bruna et al., 2014) of graph convolution because the full spectral treatment requires eigen-decomposition of the Laplacian matrix, which is computationally intractable on large graphs, while the localized versions (Defferrard et al., 2016; Kipf and Welling, 2017) can be interpreted as graph aggregators (Hamilton et al., 2017a).

Graph aggregators are the basic building blocks of graph convolutional neural networks. A model’s ability to capture the structural information of graphs is largely determined by the design of its aggregators. Most existing graph aggregators are based on either pooling over neighborhoods (Kipf and Welling, 2017; Hamilton et al., 2017a) or computing a weighted sum of the neighboring features (Monti et al., 2017). In essence, functions that are permutation invariant and can be dynamically resizing are eligible graph aggregators. One class of such functions is the neural attention network (Bahdanau et al., 2015), which uses a subnetwork to compute the correlation weight of the elements in a set. Among the family of attention models, the multi-head attention model has been shown to be effective for machine translation task (Lin et al., 2017; Vaswani et al., 2017). It has later been adopted as a graph aggregator to solve the node classification problem (Veličković et al., 2018). A single attention head sums up the elements that are similar

---

\* These two authors contributed equally.

to the query vector in one representation subspace. Using multiple attention heads allows exploring features in different representation subspaces, which provides more modeling power in nature. However, treating each attention head equally loses the opportunity to benefit from some attention heads which are inherently more important than others. For instance, assume there are ten different relationships in the graph and only two of them are valid for each node. If we use ten attention heads to model these relationships and treat them equally, each node will still aggregate features from eight non-existent subspaces. This will mislead the final prediction.

To this end, we propose the *Gated Attention Networks* (GaAN) for learning on graphs. GaAN uses a small convolutional subnetwork to compute a soft gate at each attention head to control its importance. Unlike the traditional multi-head attention that admits all attended contents, the gated attention can modulate the amount of attended content via the introduced gates. From this perspective, the gate-generation network acts as a high-level controller that determines how to aggregate the features extracted by the attention heads. Moreover, since only a simple and light-weighted subnetwork is introduced in constructing the gates, the computational overhead is negligible and the model is easy to train. We demonstrate the effectiveness of our new aggregator by applying it to the inductive node classification problem. To train our model and other graph aggregators on relatively large graphs, we also improve the sampling strategy introduced in (Hamilton et al., 2017a) to reduce the memory cost and increase the run-time efficiency. Furthermore, since our proposed aggregator is very general, we extend it to construct a *Graph Gated Recurrent Unit* (GGRU), which is directly applicable for spatiotemporal forecasting problem. Extensive experiments on two node classification datasets, PPI and the large Reddit dataset (Hamilton et al., 2017a), and one traffic speed forecasting dataset, METR-LA (Li et al., 2018), show that GaAN consistently outperforms the baseline models and achieves the state-of-the-art performance.

In summary, our main contributions include: (a) a new multi-head attention-based aggregator with additional gates on the attention heads; (b) a unified framework for transforming graph aggregators to graph recurrent neural networks; and (c) the state-of-the-art prediction performance on three real-world datasets. To the best of our knowledge, this is the first work to study the attention-based aggregators on large and spatiotemporal graphs.

## 2 NOTATIONS

We denote vectors with bold lowercase letters, matrices with bold uppercase letters, and sets with calligraphy let-

ters. We denote a single fully-connected layer with a non-linear activation  $\alpha(\cdot)$  as  $\text{FC}_\theta^\alpha(\mathbf{x}) = \alpha(\mathbf{W}\mathbf{x} + \mathbf{b})$ , where  $\theta = \{\mathbf{W}, \mathbf{b}\}$  are the parameters. Also,  $\theta$  with different subscripts mean different transformation parameters. For activation functions, we denote  $h(\cdot)$  to be the LeakyReLU activation (Xu et al., 2015a) with negative slope equals to 0.1 and  $\sigma(\cdot)$  to be the sigmoid activation.  $\text{FC}_\theta(\mathbf{x})$  means applying no activation function after the linear transform. We denote  $\oplus$  as the concatenation operation and  $\|_{k=1}^K \mathbf{x}_k$  as sequentially concatenating  $\mathbf{x}_1$  through  $\mathbf{x}_K$ . We denote the Hadamard product as ‘ $\circ$ ’ and the dot product between two vectors as  $\langle \cdot, \cdot \rangle$ .

## 3 RELATED WORK

In this section, we will review relevant research on learning on graphs. Our model is also related to many graph aggregators proposed by previous work. We will discuss these aggregators in Section 4.3.

**Neural attention mechanism** Neural attention mechanism is widely adopted in deep learning literature and many variants have been proposed (Xu et al., 2015b; Seo et al., 2017; Zhang et al., 2017; Vaswani et al., 2017; Cheng et al., 2017; Zhang et al., 2018). Among them, our model takes inspiration from the multi-head attention architecture proposed in (Vaswani et al., 2017). Given a query vector  $\mathbf{q}$  and a set of key-value pairs  $\{(\mathbf{k}_1, \mathbf{v}_1), \dots, (\mathbf{k}_n, \mathbf{v}_n)\}$ , a single attention head computes a weighted combination of the value vectors  $\sum_{i=1}^n w_i \mathbf{v}_i$ . The weights are generated by applying softmax to the inner product between the query and keys, i.e.,  $\mathbf{w} = \text{softmax}(\{\mathbf{q}^T \mathbf{k}_1, \dots, \mathbf{q}^T \mathbf{k}_n\})$ . In the multi-head case, the outputs of  $K$  different heads are concatenated to form an output vector with fixed dimensionality. The difference between the proposed GaAN and the multi-head attention mechanism is that we compute additional gates to control the importance of each head’s output.

**Graph convolutional networks on large graph** Applying graph convolution on large graphs is challenging because the memory complexity is proportional to the total number of nodes, which could be hundreds of thousands of nodes in large graphs (Hamilton et al., 2017a). To reduce memory usage and computational cost, (Hamilton et al., 2017a) proposed the GraphSAGE framework that uses a sampling algorithm to select a small subset of the nodes and edges. On each iteration, GraphSAGE first uniformly samples a mini-batch of nodes. Then, for each node, only a fixed number of neighborhoods are selected for aggregation. More recently, Chen et al. (Chen et al., 2018) proposed a new sampling method that randomly samples two sets of nodes according to a proposed distribution. However, this method is only applicable to one aggregator,

i.e., the *Graph Convolutional Network* (GCN) (Kipf and Welling, 2017). For the usage of the gate mechanism, the gate in Li et al. (2016) refers to the gate in Gated Recurrent Units, which are imposed on the activations of the neural network, while our gates are added to the attention heads to control each head’s relative importance.

**Graph convolution networks for spatiotemporal forecasting** Recently, researchers have applied graph convolution, which is commonly used for learning on static graphs, to spatiotemporal forecasting (Yuan et al., 2017). (Seo et al., 2016) proposed *Graph Convolutional Recurrent Neural Network* (GCRNN), which replaced the fully-connected layers in LSTM (Hochreiter and Schmidhuber, 1997) with the ChebNet operator (Defferrard et al., 2016), and applied it to a synthetic video prediction task. Li et al. (Li et al., 2018) proposed *Diffusion Convolutional Recurrent Neural Network* (DCRNN) to address the traffic forecasting problem, where the goal is to predict future traffic speeds in a sensor network given historical traffic speeds and the underlying road graph. DCRNN replaces the fully-connected layers in GRU (Chung et al., 2014) with the diffusion convolution operator (Atwood and Towsley, 2016). Furthermore, DCRNN takes the direction of graph edges into account. The difference between our GGRU with GCRNN and DCRNN is that we proposed a unified method for constructing a recurrent neural network based on an arbitrary graph aggregator rather than proposing a single model.

## 4 GATED ATTENTION NETWORKS

In this section, we first give a generic formulation of graph aggregators followed by the multi-head attention mechanism. Then, we introduce the proposed gated attention aggregator. Finally, we review the other kinds of graph aggregators proposed by previous work and explain their relationships with ours.

**Generic formulation of graph aggregators** Given a node  $i$  and its neighboring nodes  $\mathcal{N}_i$ , a graph aggregator is a function  $\gamma$  in the form of  $\mathbf{y}_i = \gamma_{\Theta}(\mathbf{x}_i, \{\mathbf{z}_{\mathcal{N}_i}\})$ , where  $\mathbf{x}_i$  and  $\mathbf{y}_i$  are the input and output vectors of the center node  $i$ .  $\mathbf{z}_{\mathcal{N}_i} = \{\mathbf{z}_j | j \in \mathcal{N}_i\}$  is a set of the reference vectors in the neighboring nodes and  $\Theta$  is the learnable parameters of the aggregator. In this paper, we do not consider aggregators that use edge features. However, it is straightforward to incorporate edges in our definition by defining  $\mathbf{z}_j$  to contain the edge feature vectors  $\mathbf{e}_{i,j}$ .

### 4.1 MULTI-HEAD ATTENTION AGGREGATOR

We linearly project the center node feature  $\mathbf{x}_i$  to get the query vector and project the neighboring node features to get the key and value vectors. We then apply the

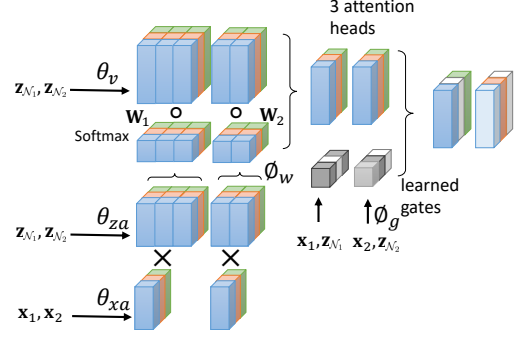

Figure 1: Illustration of a three-head gated attention aggregator with two center nodes in a mini-batch.  $|\mathcal{N}_1| = 3$  and  $|\mathcal{N}_2| = 2$  respectively. Different colors indicate different attention heads. Gates in darker color stands for larger values. (Best viewed in color)

multi-head attention mechanism (Vaswani et al., 2017) to obtain the final aggregation function. For the multi-head attention mechanism, different heads capture features from different representation subspaces. The detailed formulation of the multi-head attention aggregator is as follows:

$$\mathbf{y}_i = \text{FC}_{\theta_o}(\mathbf{x}_i \oplus \prod_{k=1}^K \sum_{j \in \mathcal{N}_i} w_{i,j}^{(k)} \text{FC}_{\theta_v}^h(\mathbf{z}_j)),$$

$$w_{i,j}^{(k)} = \frac{\exp(\phi_w^{(k)}(\mathbf{x}_i, \mathbf{z}_j))}{\sum_{l=1}^{|\mathcal{N}_i|} \exp(\phi_w^{(k)}(\mathbf{x}_i, \mathbf{z}_l))},$$

$$\phi_w^{(k)}(\mathbf{x}, \mathbf{z}) = \langle \text{FC}_{\theta_{xa}}^{(k)}(\mathbf{x}), \text{FC}_{\theta_{za}}^{(k)}(\mathbf{z}) \rangle.$$

Here,  $K$  is the number of attention heads.  $w_{i,j}^{(k)}$  is the  $k$ th attentional weights between the center node  $i$  and the neighboring node  $j$ , which is generated by applying a softmax to the dot product values.  $\theta_{xa}^{(k)}$ ,  $\theta_{za}^{(k)}$  and  $\theta_v^{(k)}$  are the parameters of the  $k$ th head for computing the query, key, and value vectors, which have dimensions of  $d_a$ ,  $d_a$  and  $d_v$  respectively. The  $K$  attention outputs are concatenated with the input vector and passed to a fully-connected layer parameterized by  $\theta_o$  to get the final output  $\mathbf{y}_i$ , which has dimension  $d_o$ . The difference between our aggregator and that in GAT (Veličković et al., 2018) is that we have adopted the key-value attention mechanism and the dot product attention while GAT does not compute additional value vectors and uses a fully-connected layer to compute  $\phi_w^{(k)}$ .

### 4.2 GATED ATTENTION AGGREGATOR

While the multi-head attention aggregator can explore multiple representation subspaces between the center node and its neighborhoods, not all of these subspaces are equally important; some subspaces may not even exist for specific nodes. Feeding the output of an attention

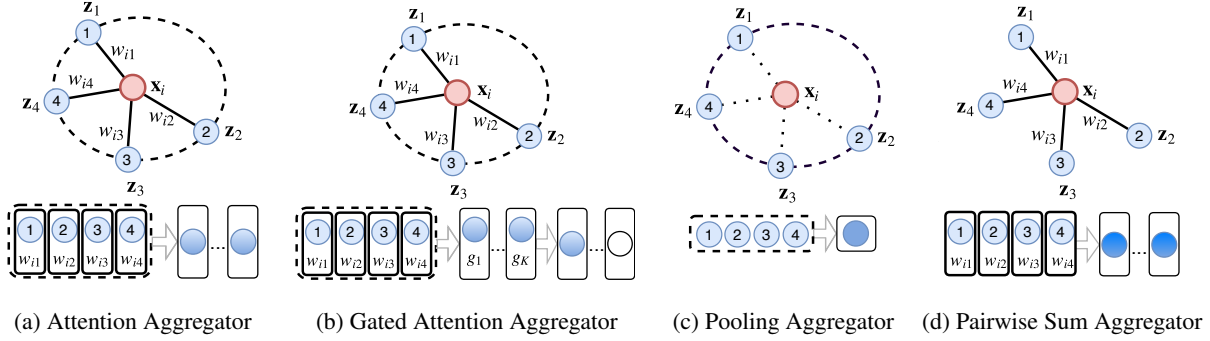

Figure 2: Comparison of different graph aggregators. The aggregators are drawn for only one aggregation step. The nodes in red are center nodes and the nodes in blue are neighboring nodes. The bold black lines between the center node and neighbor nodes indicate that a learned pairwise relationship is used for calculating the relative importance. The oval in dash line around the neighbors means the interaction among neighbors is utilized when determining the weights. (Best viewed in color)

head that captures a useless representation can mislead the mode’s final prediction.

Therefore, we compute an additional soft gate between 0 (low importance) and 1 (high importance) to assign different importance to each head. In combination with the multi-head attention aggregator, we get the formulation of the gated attention aggregator:

$$\begin{aligned}
 \mathbf{y}_i &= \text{FC}_{\theta_o}(\mathbf{x}_i \oplus \parallel_{k=1}^K (g_i^{(k)} \sum_{j \in \mathcal{N}_i} w_{i,j}^{(k)} \text{FC}_{\theta_v}^h(\mathbf{z}_j))), \quad (2) \\
 \mathbf{g}_i &= [g_i^{(1)}, \dots, g_i^{(K)}] = \psi_g(\mathbf{x}_i, \mathcal{Z}_{\mathcal{N}_i}),
 \end{aligned}$$

where  $g_i^{(k)}$  is a scalar, the gate value of the  $k$ th head at node  $i$ . To make sure adding gates will not introduce too many additional parameters, we use a convolutional network  $\psi_g$  that takes the center node and neighboring node features as the input to generate the gate values. All the other parameters have the same meanings as in Eqn. (1).

There are multiple possible designs of the  $\psi_g$  network. In this paper, we combine average pooling and max pooling to construct the network. The detailed formula is:

$$\mathbf{g}_i = \text{FC}_{\theta_g}^\sigma(\mathbf{x}_i \oplus \max_{j \in \mathcal{N}_i} \{\text{FC}_{\theta_m}(\mathbf{z}_j)\}) \oplus \frac{\sum_{j \in \mathcal{N}_i} \mathbf{z}_j}{|\mathcal{N}_i|}. \quad (3)$$

Here,  $\theta_m$  maps the neighbor features to a  $d_m$  dimensional vector before taking the element-wise max and  $\theta_g$  maps the concatenated features to the final  $K$  gates. By setting a small  $d_m$ , the subnetwork for computing the gates will have negligible computational overhead. A visual illustration of GaAN aggregator’s structure can be found in Figure 1. Also, we compare the general structures of the multi-head attention aggregator and the gated attention aggregator in Figure 2a and Figure 2b.

### 4.3 OTHER GRAPH AGGREGATORS

Most previous graph aggregators except attention-based aggregators can be summarized into two general categories: graph pooling aggregators and graph pairwise sum aggregators. In this section, we first describe these two types of aggregators and then explain their relationship with the attention-based aggregator. Finally, we give a list of the baseline aggregators used in the experiments.

**Graph pooling aggregators** The main characteristic of graph pooling aggregators is that they do not consider the correlation between neighboring nodes and the center node. Instead, neighboring nodes’ features are directly aggregated and the center node’s feature is simply concatenated or added to the aggregated vector and then passed through an output function  $\phi_o$ :

$$\mathbf{y}_i = \phi_o(\mathbf{x}_i \oplus \text{pool}_{j \in \mathcal{N}_i}(\phi_v(\mathbf{z}_j))). \quad (4)$$

Here, the projection function  $\phi_v$  and the output function  $\phi_o$  can be a single fully-connected layer and the  $\text{pool}(\cdot)$  operator can be average pooling, max pooling, or sum pooling. The majority of existing graph aggregators are special cases of the graph pooling aggregators. Some models only integrate the node features of neighborhoods (Duvenaud et al., 2015; Kipf and Welling, 2017; Hamilton et al., 2017a), while others integrated edge features as well (Atwood and Towsley, 2016; Fout et al., 2017; Schütt et al., 2017). In Figure 2c, we illustrate the architecture of the graph pooling aggregators.

**Graph pairwise sum aggregators** Like attention-based aggregators, graph pairwise sum aggregators also aggregate the neighborhood features by taking  $K$  weighted sums. The difference is that the weight between node  $i$  and its neighbor  $j$  is not related to the other neighbors in  $\mathcal{N}_i$ . The formula of graph pairwise sum aggregator is given as follows:

$$\mathbf{y}_i = \phi_o(\mathbf{x}_i \oplus \prod_{k=1}^K \sum_{j \in \mathcal{N}_i} w_{i,j}^{(k)} \phi_v^{(k)}(\mathbf{z}_j)), \quad (5)$$

$$w_{i,j}^{(k)} = \phi_w^{(k)}(\mathbf{x}_i, \mathbf{z}_j).$$

Here,  $w_{i,j}^{(k)}$  is only related to the pair  $\mathbf{x}_i$  and  $\mathbf{z}_j$ , while in attention-based models  $w_{i,j}^{(k)}$  is related to features of all neighbors  $\mathbf{z}_{\mathcal{N}_i}$ . Models like the adaptive forget gate strategy in *Graph LSTM* (Liang et al., 2016) and MoNet (Monti et al., 2017) employed pairwise sum aggregators with a single head or multiple heads. In Figure 2d, we illustrate the architecture of the graph pairwise sum aggregators.

**Baseline aggregators** To fairly evaluate the effectiveness of GaAN against previous work, we choose two representative aggregators in each category as baselines:

- **Avg. pooling:**  $\mathbf{y}_i = \text{FC}_{\theta_o}(\mathbf{x}_i \oplus \text{pool}_{j \in \mathcal{N}_i}^{\text{avg}}(\text{FC}_{\theta_v}^h(\mathbf{z}_j)))$ .
- **Max pooling:**  $\mathbf{y}_i = \text{FC}_{\theta_o}(\mathbf{x}_i \oplus \text{pool}_{j \in \mathcal{N}_i}^{\text{max}}(\text{FC}_{\theta_v}^h(\mathbf{z}_j)))$ .

- **Pairwise + sigmoid:**

$$\mathbf{y}_i = \text{FC}_{\theta_o}(\mathbf{x}_i \oplus \prod_{k=1}^K \sum_{j \in \mathcal{N}_i} w_{i,j}^{(k)} \text{FC}_{\theta_v}^h(\mathbf{z}_j)),$$

$$w_{i,j}^{(k)} = \frac{1}{|\mathcal{N}_i|} \sigma(\langle \text{FC}_{\theta_{x_a}}^{(k)}(\mathbf{x}_i), \text{FC}_{\theta_{z_a}}^{(k)}(\mathbf{z}_j) \rangle).$$

- **Pairwise + tanh:** Replace the sigmoid activation in **Pairwise + sigmoid** to tanh.

## 5 INDUCTIVE NODE CLASSIFICATION

### 5.1 MODEL

In the inductive node classification task, every node is assigned one or multiple labels. During training, the validation and testing nodes are not observable. And the goal is to predict the labels of the unseen testing nodes. Our approach follows that of (Hamilton et al., 2017a), where a mini-batch of nodes are sampled on each iteration during training and multiple layers of graph aggregators are stacked to compute the predictions.

With a stack of  $M$  layers of graph aggregators, we will first sample a mini-batch of nodes  $\mathcal{B}_0$  and then recursively expand  $\mathcal{B}_\ell$  to be  $\mathcal{B}_{\ell+1}$  by sampling the neighboring nodes of  $\mathcal{B}_\ell$ . After  $M$  sampling steps, we can get a hierarchy of node batches:  $\mathcal{B}_1, \dots, \mathcal{B}_M$ . The node representations, which are initialized to be the node features, will be aggregated in reverse order from  $\mathcal{B}_M$  to  $\mathcal{B}_0$ . The representations of the last layer, i.e., the final representations of the nodes in  $\mathcal{B}_0$ , are projected to get the output. We use the sigmoid activation for multi-label classification

Table 1: Effect of the merge operation. Both methods sample a maximum of 15 neighborhoods without replacement for three recursive steps on the Reddit dataset. We start from 512 seed nodes. The total number of nodes after the  $\ell$ th sampling step is denoted as  $|\mathcal{B}_\ell|$ . The sampling process is repeated for ten times and the mean is reported.

Strategy/Sample Step	$ \mathcal{B}_0 $	$ \mathcal{B}_1 $	$ \mathcal{B}_2 $	$ \mathcal{B}_3 $
Sample without merge	512	7.8K	124.4K	1.9M
Sample and merge	512	7.5K	70.7K	0.2M

and the softmax activation for multi-class classification. Also, we use the cross-entropy loss to train the model.

A naive sampling algorithm is always to sample all neighbors. However, it is not practical on large graphs because the memory complexity is  $O(|\mathcal{V}|)$  and the time complexity is  $O(|\mathcal{E}|)$ , where  $|\mathcal{V}|$  and  $|\mathcal{E}|$  are the total number of nodes and edges. Instead, similar to GraphSAGE (Hamilton et al., 2017a), we only sample a subset of the neighborhoods for each node. In our implementation, at the  $\ell$ th sampling step, we sample  $\min(|\mathcal{N}_i|, S_\ell)$  neighbors without replacement for the node  $i$ , where  $S_\ell$  is a hyperparameter that controls the maximum number of sampled neighbors at the  $\ell$ th step. Moreover, to improve over GraphSAGE and further reduce memory cost, we merge repeated nodes that are sampled from different seeds’ neighborhoods within each mini-batch. This greatly reduces the size of  $\mathcal{B}_\ell$ s as shown in Table 1.

Note that  $\min(|\mathcal{N}_i|, S_\ell)$  is not the same for all the nodes  $i$ . Thus, instead of padding the sampled neighborhood set to the same size for utilizing fast tensor operation, we implemented new GPU kernels that directly operate on inputs with variable lengths to accelerate computations.

### 5.2 EXPERIMENTAL SETUP

We performed a thorough comparison of GaAN with the state-of-the-art models, five aggregator-based models in our framework and a two-layer fully connected neural network on the PPI and Reddit datasets (Hamilton et al., 2017a). The five baseline aggregators include the multi-head attention aggregator, two pooling based aggregators, and two pairwise sum based aggregators mentioned in Section 4.3. We also conducted comprehensive ablation analysis.

The PPI dataset was collected from the molecular signatures database (Subramanian et al., 2005). Each node represents a protein and edges represent the interaction between proteins. Labels represent the cellular functions of each protein from gene ontology. Reddit is an online discussion forum where users can post and discuss contents on different topics. Each node represents a post and

Table 2: Datasets for inductive node classification. ‘multi’ stands for multilabel classification and ‘single’ otherwise.

Data	#Nodes	#Edges	#Fea	#Classes
PPI	56.9K	806.2K	50	121(multi)
Reddit	233.0K	114.6M	602	41(single)

two nodes are connected if they are commented by the same user. The labels indicate the community a post belongs to. Detailed statistics are listed in Table 2.

### 5.3 MODEL ARCHITECTURES AND IMPLEMENTATION DETAIL

The GaAN and other five aggregator-based networks are stacked with two graph aggregators. Each aggregator is followed by the LeakyReLU activation with negative slope equals to 0.1 and a dropout layer with dropout rate set to be 0.1. The output dimension  $d_o$  of all layers are fixed to be 128 except when we compare the relative performance with different output dimensions. To keep the number of parameters comparable for the multi-head models with a different number of heads, we fix the product of the dimension of the value vector and the number of heads, i.e.,  $d_v \times K$  to be the same when evaluating the effect of varying the number of heads. Also, the hyperparameters of the first and the second layer are assumed to be the same if no special explanation is given.

In the PPI experiments, both pooling aggregators have  $d_v = 512$ , where  $d_v$  means the dimensionality of the value vector projected by  $\theta_v$ . For the pairwise sum aggregators, the dimension of the keys  $d_a$  is set to be 24,  $d_v = 64$ , and  $K = 8$ . For both GaAN and the multi-head attention based aggregator,  $d_a$  is set to be 24 and the product  $d_v \times K$  is fixed to be 256. For GaAN, we set  $d_m$  to be 64 in the gate-generation network. Also, we use the entire neighborhoods in the mini-batch training algorithm. In the Reddit experiments, both pooling aggregators have  $d_v = 1024$ . For the pairwise sum aggregators,  $d_a = 32$ ,  $d_v = 256$  and  $K = 4$ . For the attention based aggregators,  $d_a$  is set to be 32 and  $d_v \times K$  is fixed to be 512. We set the gate-generation network in GaAN to have  $d_m = 64$ . Also, the number of heads is fixed to 1 in the first layer for both attention-based models. The maximum number of sampled neighbors in the first and second sampling steps are denoted as  $S_1$  and  $S_2$  and are respectively set to be 25 and 10 in Table 3. In the ablation analysis, we also show the performance when setting them to be (50, 20), (100, 40), and (200, 80).

To illustrate the effectiveness of incorporating graph structures, we also evaluate a two-layer fully-connected neural network with the hidden dimension of 1024 and

Table 3: Summary of different models’ test micro F1 scores in the inductive node classification task. In the first block, we include the best-reported results in the previous papers. In the second block, we report the results obtained by our models. For the PPI dataset, we do not use any sampling strategies. For the Reddit dataset, we use the maximum number sampling strategy with  $S_1=25$  and  $S_2=10$ .

Models / Datasets	PPI	Reddit

ReLU activation. It only takes node features as input and ignores graph structures.

We train all the aggregator-based models with Adam (Kingma and Ba, 2015) and early stopping on the validation set. Besides, we use the validation set to perform learning rate decay scheduler. For Reddit, before training we normalize all the features and project all the features to a hidden dimension of 256. The initial learning rate is 0.001 and gradually decreases to 0.0001 with the decay rate of 0.5 each time the validation F1 score does not decrease in a window of 4 epochs and early stopping occurs for 10 epochs. The gradient normalization value clips no larger than 1.0. For the PPI dataset, all the input features are projected to a 64-dimension hidden state before passing to the aggregators. The learning rate begins at 0.01 and decays to 0.001 with the decay rate of 0.5 if the validation F1 score does not increase for 15 epochs and stops training for 30 epochs.

The training batch size is fixed to be 512. Also, in all experiments, we use the validation set to select the optimal hyperparameters for training. The training, validation, and testing splits are the same as that in (Hamilton et al., 2017a). The micro-averaged F1 score is used to evaluate the prediction accuracy for both datasets. We repeat the training five times for Reddit and three times for PPI with different random seeds and report the average test F1 score along with the standard deviation.

<sup>1</sup>The performance reported in the paper is relatively low because the author has not trained their model into convergence. Also, it is not fair to compare it with the other scores because it uses the sampling strategy while the others have not.

Table 4: Comparison of the test F1 score on the Reddit and PPI datasets with different sampling neighborhood sizes and attention head number  $K$ .  $S_1$  and  $S_2$  are the maximum number of sampled neighborhoods in the 1st and 2nd sampling steps. ‘all’ means to sample all the neighborhoods.

## 5.4 MAIN RESULTS

We compare our model with the previous state-of-the-art methods on inductive node classification. This includes GraphSAGE (Hamilton et al., 2017a), GAT (Veličković et al., 2018), and FastGCN (Chen et al., 2018). The GraphSAGE model used a 2-layer sample and aggregate model with a neighborhood size of  $S^{(1)} = 25$  and  $S^{(2)} = 10$  without dropout. The 3-layer GAT model consisted of 4, 4, and 6 heads in the first, second, and third layer respectively. Each attention head had 256 dimensions. GAT did not use neighborhood sampling, L2 regularization, or dropout. The FastGCN model is a fast version of the 3-layer, 128-dimension GCN with sampled neighborhood size being 400, 100, and 400 for each layer and no sampling is done during testing.

Table 3 summarizes all results of the state-of-the-art models and the models proposed in this paper. We denote the multi-head attention aggregator as ‘Attention-only’ in the tables and figures. We find that the proposed model, GaAN, achieves the best F1 score on both datasets and the other baseline aggregators can also show competitive results to the state-of-the-art. We note that aggregator-based models produce much higher F1 score than the fully-connected model, which shows the effectiveness of the graph aggregators. Our max pooling and avg. pooling baselines have higher scores on Reddit than that in the original GraphSAGE record. This mainly contributes to our usage of dropout and the LeakyReLU activation.

Regarding the training time, the average training time of the attention-only model for the first 100 epochs on PPI is 36.5s and that of GaAN is 37.0s when we run on the

machine with a single TitanX GPU and Intel Xeon CPU 3.70 GHz. This shows that the computational overhead of adding the gates is negligible.

## 5.5 ABLATION ANALYSIS

We ran some ablation experiments to analyze the performance of different graph aggregators when different hyperparameters were used. We also visualized the gates of the GaAN model.

**Effect of the number of attention heads and the sample size** We compare the performance of the aggregators when a different number of attention heads and sampling strategies are used. Results are shown in Table 4. We find that attention-based models consistently outperform pooling and pairwise sum based models with the fewer number of parameters, which demonstrates the effectiveness of the attention mechanism in this task. Moreover, GaAN consistently beats the multi-head attention model with the same number of attention heads  $K$ . This proves that adding additional gates to control the importance of the attention heads is beneficial to the final classification performance. From the last two row blocks of Table 4, we note that increasing the number of attention heads will not always produce better results on Reddit. In contrast, on PPI, the larger the  $K$ , the better the prediction results. Also, we can see steady improvement with larger sampling sizes, which is consistent with the observation in (Hamilton et al., 2017a).

**Effect of output dimensions in the PPI dataset** We changed the output dimension to be 64, 96, and 128 in the models for training in the PPI dataset. The test F1 score

(a) Performance of different models with a varying number of output dimensions on PPI.

(b) Visualization of 8 gate values of 5 example nodes on Reddit. Each row represents a learned gate vector for one node.

Figure 3: Ablation analysis on PPI and Reddit

is shown in Figure 3a. All multi-head models have  $K=8$ . We find that the performance becomes better for larger output dimensions and the proposed GaAN consistently outperforms the other models.

**Visualization of gate values** In Figure 3b, we visualized the gate values of five different nodes output by the GaAN-K8 model trained on the Reddit dataset. It illustrates the diversity of the learned gate combinations for different nodes. In most cases, the gates vary across attention heads, which shows that the gate-generation network can be learned to assign different importance to different heads.

## 6 TRAFFIC SPEED FORECASTING

### 6.1 GRAPH GRU

Following (Lin et al., 2017), we formulate traffic speed forecasting as a spatiotemporal sequence forecasting problem where the input and the target are sequences defined on a fixed spatiotemporal graph, e.g., the road network. To simplify notations, we denote  $\mathbf{Y} = \Gamma_{\Theta}(\mathbf{X}, \mathbf{Z}; \mathcal{G})$  as applying the  $\gamma$  aggregator for all nodes in  $\mathcal{G}$ , i.e.,  $\mathbf{y}_i = \gamma_{\Theta}(\mathbf{x}, \mathbf{z}_{\mathcal{N}_i})$ . Based on a given graph aggregator  $\Gamma$ , we can construct a GRU-like RNN structure

Figure 4: Illustration of the encoder-decoder structure used in the paper. We use two layers of Graph GRUs to predict a length-3 output sequence based on a length-2 input sequence. ‘SS’ denotes the scheduled sampling step.

Table 5: The Dataset used for traffic speed forecasting.

Data	#Nodes	#Edges	#Timestamps
METR-LA	207	1,515	34,272

using the following equations:

$$\begin{aligned}
 \mathbf{U}_t &= \sigma(\Gamma_{\Theta_{xu}}(\mathbf{X}_t, \mathbf{X}_t; \mathcal{G}) + \Gamma_{\Theta_{hu}}(\mathbf{X}_t \oplus \mathbf{H}_{t-1}, \mathbf{H}_{t-1}; \mathcal{G})), \\
 \mathbf{R}_t &= \sigma(\Gamma_{\Theta_{xr}}(\mathbf{X}_t, \mathbf{X}_t; \mathcal{G}) + \Gamma_{\Theta_{hr}}(\mathbf{X}_t \oplus \mathbf{H}_{t-1}, \mathbf{H}_{t-1}; \mathcal{G})), \\
 \mathbf{H}'_t &= h(\Gamma_{\Theta_{xh}}(\mathbf{X}_t, \mathbf{X}_t; \mathcal{G}) + \mathbf{R}_t \circ \Gamma_{\Theta_{hh}}(\mathbf{X}_t \oplus \mathbf{H}_{t-1}, \mathbf{H}_{t-1}; \mathcal{G})), \\
 \mathbf{H}_t &= (1 - \mathbf{U}_t) \circ \mathbf{H}'_t + \mathbf{U}_t \circ \mathbf{H}_{t-1}.
 \end{aligned} \tag{6}$$

Here,  $\mathbf{X}_t \in \mathbb{R}^{|\mathcal{V}| \times d_i}$  are the input features and  $\mathbf{H}_t \in \mathbb{R}^{|\mathcal{V}| \times d_o}$  are the hidden states of the nodes at the  $t$ th timestamp.  $|\mathcal{V}|$  is the total number of nodes,  $d_i$  is the dimension of the input, and  $d_o$  is the dimension of the state.  $\mathbf{U}_t$  and  $\mathbf{R}_t$  are the update gate and reset gate that controls how  $\mathbf{H}_t$  is calculated.  $\mathcal{G}$  is the graph that defines the connection structure between all the nodes.

We refer to this RNN structure as *Graph GRU* (GGRU). GGRU can be used as the basic building block for RNN encoder-decoder structure (Lin et al., 2017) to predict the future  $K$  steps of traffic speeds, i.e.,  $\hat{\mathbf{X}}_{J+1}, \hat{\mathbf{X}}_{J+2}, \dots, \hat{\mathbf{X}}_{J+K}$ , based on the previous  $J$  steps of observed traffic speeds, i.e.,  $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_J$ . In the decoder, we use the scheduled sampling (Bengio et al., 2015) technique described in (Lin et al., 2017). Figure 4 illustrates our encoder-decoder structure. When attention-based aggregators are used, i.e., the multi-head attention aggregator or our GaAN aggregator, the connection structure in the recurrent step will also be learned based on the attention process. This can be viewed as an extension of *Trajectory GRU* (TrajGRU) (Shi et al., 2017) on irregular or graph-structured data.

### 6.2 EXPERIMENTAL SETUP

To evaluate the proposed GGRU model on traffic speed forecasting, we use the METR-LA dataset from (Li et al.,

Table 6: Performance comparison of different models for traffic speed forecasting on the METR-LA dataset. Models marked with ‘†’ treat sensor map as a directed graph while other models convert it into an undirected graph. Scores under “ $\tau$ min” are the scores at the  $\frac{\tau}{5}$ th predicted frame. The last three columns contain the average scores of the 15 min, 30 min, and 60 min forecasting horizons.

Models / T	15 min			30 min			60 min			Average		
	MAE	RMSE	MAPE	MAE	RMSE	MAPE	MAE	RMSE	MAPE	MAE	RMSE	MAPE
FC-LSTM (Li et al., 2018)	3.44	6.30	9.6%	3.77	7.23	10.9%	4.37	8.69	13.2%	3.86	7.41	11.2%
GCRNN (Li et al., 2018)	2.80	5.51	7.5%	3.24	6.74	9.0%	3.81	8.16	10.9%	3.28	6.80	9.13%

Avg Pool	2.79	5.42	7.26%	3.20	6.52	8.84%	3.69	7.69	10.73%	3.22	6.54	8.94%
Max Pool	2.77	5.36	7.21%	3.18	6.45	8.78%	3.69	7.73	10.80%	3.21	6.51	8.93%
Pairwise + Sigmoid	2.76	5.36	7.14%	3.18	6.46	8.72%	3.70	7.73	10.77%	3.22	6.52	8.88%
Pairwise + Tanh	2.76	5.34	7.14%	3.18	6.46	8.73%	3.70	7.73	10.73%	3.21	6.51	8.87%
Attention-only	2.74	5.33	7.09%	3.16	6.45	8.69%	3.67	7.61	10.77%	3.19	6.49	8.85%
GaAN	<b>2.71</b>	<b>5.24</b>	<b>6.99%</b>	<b>3.12</b>	<b>6.36</b>	<b>8.56%</b>	3.64	7.65	10.62%	<b>3.16</b>	<b>6.41</b>	<b>8.72%</b>

2018). The nodes in the dataset represent sensors measuring traffic speed and edges denote proximity between sensor pairs measured by road network distance. The sensor speeds are recorded every five minutes. Complete dataset statistics are given in Table 5. We follow (Li et al., 2018)’s way to split the dataset. The first 70% of the sequences are used for training, the middle 10% are used for validation, and the final 20% are used for testing. We also use the same evaluation metrics as in (Li et al., 2018) for evaluation, including *Mean Absolute Error* (MAE), *Root Mean Squared Error* (RMSE), and *Mean Absolute Percentage Error* (MAPE). A sequence of length 12 is used as the input to predict the future traffic speed in one hour (12 steps).

### 6.3 MAIN RESULTS

We compare six variations of the proposed GGRU architecture with three baseline models, including fully-connected LSTM, GCRNN, and DCRNN (Li et al., 2018). We use the same set of six aggregators as in the inductive node classification experiment to construct the GGRU and we use two layers of GGRUs with the state dimension of 64 both in the encoder and the decoder. For attention based models, we set  $K = 4$ ,  $d_a = 16$ , and  $d_v = 16$ . For GaAN, we set  $d_m = 64$  and only use max pooling in the gate-generation network. For pooling based aggregators, we set  $d_v = 128$ . For pairwise sum aggregators, we set  $K = 4$ ,  $d_a = 32$ , and  $d_v = 16$ .

Since the road map is directed and our model does not deal with edge information, we first convert the road map into an undirected graph and use it as the  $\mathcal{G}$  in Eqn. (6). All models are trained by minimizing MAE loss with Adam optimizer. The initial learning rate is set to 0.001 and the batch-size is 64. We use the same scheduled sam-

pling strategy as in (Li et al., 2018). Table 1 shows the comparison of different approaches for 15 minutes, 30 minutes and 1 hour ahead forecasting on both datasets.

The scores for 15 minutes, 30 minutes, and 1 hour ahead forecasting as well as the average scores over three forecasting horizons are shown in Table 6. For the average score, we can see that the proposed GGRU models consistently give better results than GCRNN, which models the traffic network as an undirected graph. Moreover, the GaAN based GGRU model, which does not use edge information, achieves higher accuracy than DCRNN, which uses edge information in the road network.

## 7 CONCLUSION AND FUTURE WORK

We introduced the GaAN model and applied it to two challenging tasks: inductive node classification and traffic speed forecasting. GaAN beats previous state-of-the-art algorithms in both cases. In the future, we plan to extend GaAN by integrating edge features and processing massive graphs with millions or even billions of nodes. Moreover, our model is not restricted to graph learning. A particularly exciting direction for future work is to apply GaAN to natural language processing tasks like machine translation.

## Abstract

Many models of dynamical systems have causal interpretations that support reasoning about the consequences of interventions, suitably defined. Furthermore, local independence has been suggested as a useful independence concept for stochastic dynamical systems. There is, however, no well-developed theoretical framework for causal learning based on this notion of independence. We study independence models induced by directed graphs (DGs) and provide abstract graphoid properties that guarantee that an independence model has the global Markov property w.r.t. a DG. We apply these results to Itô diffusions and event processes. For a partially observed system, directed mixed graphs (DMGs) represent the marginalized local independence model, and we develop, under a faithfulness assumption, a sound and complete learning algorithm of the directed mixed equivalence graph (DMEG) as a summary of all Markov equivalent DMGs.

## 1 INTRODUCTION

Causal learning has been developed extensively using structural causal models and graphical representations of the conditional independence relations that they induce. The Fast Causal Inference (FCI) algorithm and its variations (RFCI, FCI+, ...) can learn a representation of the independence relations induced by a causal model even when the causal system is only partially observed, i.e., the data is “causally insufficient” in the terminology of Spirtes et al. (2000). FCI is, however, not directly applicable for learning causal relations among entire processes in a continuous-time dynamical system. The dy-

namic evolution of such a system cannot be modeled using a finite number of variables related via a structural causal model, and standard probabilistic independence cannot adequately capture infinitesimal conditional independence relationships between processes since such relationships can be asymmetric. The asymmetry can intuitively be explained by the fact that the present of one process may be independent of the past of another process, or the reverse, or both.

Local independence was introduced by Schweder (1970) and is a formalization of how the present of one stochastic process depends on the past of others in a dynamical system. This concept directly lends itself to a causal interpretation as dynamical systems develop as functions of their pasts, see e.g. Aalen (1987). Didelez (2000, 2006a, 2008) considered graphical representations of local independence models using directed graphs (DGs) and  $\delta$ -separation and proved the equivalence of the pairwise and global Markov properties in the case of multivariate counting processes. Nodelman et al. (2002, 2003) and Gunawardana et al. (2011) also considered learning problems in continuous-time models. In this paper, we extend the theory to a broader class of semimartingales, showing the equivalence of pairwise and global Markov properties in DGs. To represent marginalized local independence models, Mogensen and Hansen (2018) introduced directed mixed graphs (DMGs) with  $\mu$ -separation. Bidirected edges in DMGs (roughly) correspond to dependencies induced by latent processes, and in this sense DMGs can represent partially observed dynamical systems. In contrast to the “causally sufficient” setting as represented by a DG, multiple DMGs may represent the same set of (marginal) local independence relations; thus we use the characterization of Markov equivalent DMGs by Mogensen and Hansen (2018) to propose a sound and complete algorithm for selecting a set of DMGs consistent with a given collection of independence relations.

Proofs omitted from the main text can be found in the supplementary material.

Figure 1: Simulated sample paths (left) for the linear SDE determined by  $B$  in (1). The sample paths are from the observational distribution started in the stationary mean as well as under an intervention regime on  $\alpha$ . For the local independence graph (middle) the color of the edge  $j \rightarrow i$  indicates if the nonzero entry  $B_{ij}$  is positive (red) or negative (blue). The step size  $h$  difference quotient at 0 for the semigroup  $t \mapsto \exp(tB)$  (right) determines the discrete time conditional means for time step  $h$  transitions. It does not directly reflect the local independences except in the limit  $h \rightarrow 0$ , where it converges to the infinitesimal generator  $B$ . Danks and Plis (2013) make a similar point in the case of subsampled time series.

## 2 CAUSAL DYNAMICAL MODELS

The notion of interventions in a continuous-time model of a dynamical system is not new, and has been investigated thoroughly in the context of control theory. Causal models and interventions for event processes and their relation to graphical independence models have been treated in detail (Didelez, 2008, 2015). Relations to structural causal models have been established for ordinary differential equations (ODEs) (Mooij et al., 2013; Rubenstein et al., 2016). Notions of causality and interventions have also been treated for general stochastic processes such as stochastic differential equations (SDEs) (Aalen et al., 2012; Commenges and Gégout-Petit, 2009; Sokol and Hansen, 2014).

To motivate and explain the general results of this paper, we introduce the toy linear SDE model in  $\mathbb{R}^5$  given by  $dX_t = B(X_t - A)dt + dW_t$  with  $A = (1, 2, 3, 4, 5)^T$ ,

$$B = \begin{pmatrix} -1.1 & 1 & 1 & \cdot & \cdot \\ \cdot & -1.1 & \cdot & 2.0 & \cdot \\ \cdot & \cdot & -1.1 & \cdot & 1 \\ \cdot & \cdot & -1 & -1.1 & \cdot \\ 1 & \cdot & \cdot & \cdot & -1.1 \end{pmatrix}, \quad (1)$$

and  $(W_t)$  a five-dimensional standard Brownian motion. The coordinates of this process will be denoted  $\alpha, \beta, \gamma, \delta$ , and  $\epsilon$ . If we assume that this SDE has a causal interpretation, we can obtain predictions under interventions via manipulations of the SDE itself, see e.g. Sokol and Hansen (2014). In Figure 1, for instance, we replace the  $\alpha$  coordinate of the SDE by

$$dX_t^\alpha = 1(X_t^\beta > 1)dt, \quad X_t^\alpha - X_{t-}^\alpha = -X_{t-}^\alpha 1(X_t^\beta \leq 1).$$

The nonzero pattern of the  $B$  matrix defines a directed

graph which we identify as the *local independence graph* below, which in turn is related to the local independence model of the SDE. It is a main result of this paper that the local independence model satisfies the global Markov property w.r.t. this graph. Under a faithfulness assumption we can identify (aspects of) the causal system from observational data even when some processes are unobserved.

It is well known that

$$X_{t+h} - X_t \mid X_t \sim \mathcal{N}((e^{hB} - I)(X_t - A), \Sigma(h))$$

with  $\Sigma(h)$  given in terms of  $B$ . Thus a sample of the process at equidistant time points is a vector autoregressive process with correlated errors. We note that  $e^{hB} - I$  is a dense matrix that will not reveal the local independence graph unless  $h$  is sufficiently small, see Figure 1. The matrix  $B$  is, furthermore, a stable matrix, hence there is a stationary solution to the SDE and for  $h \rightarrow \infty$  we have  $\Sigma(h) \rightarrow \Sigma$ , the invariant covariance matrix. We note that  $\Sigma^{-1}$  is also a dense matrix, thus the invariant distribution does not satisfy the global Markov property w.r.t. to any undirected graph but the complete graph.

In conclusion, the local independence model of the SDE is not encoded directly neither by Markov properties of discrete time samples, nor by Markov properties of the invariant distribution. This is the motivation for our abstract development of local independence models, their relation to continuous-time stochastic processes, and a dedicated learning algorithm.

### 3 INDEPENDENCE MODELS

Consider some finite set  $V$ . An *independence model* over  $V$  is a set of triples  $\langle A, B \mid C \rangle$  such that  $A, B, C \subseteq V$ . We let  $\mathcal{I}$  denote a generic independence model. Following Didelez (2000, 2008) we will consider independence models that are not assumed to be symmetric in  $A$  and  $B$ . The independence models we consider do however satisfy other properties which allow us to deduce some independences from others. We define the following properties, some of which have previously been described as *asymmetric (semi)graphoid properties* (Didelez, 2006b, 2008). Many of them are analogous to properties in the literature on conditional independence models (Lauritzen, 1996), though due to the lack of symmetry, one may define both left and right versions.

- Left redundancy:  $\langle A, B \mid A \rangle \in \mathcal{I}$
- Left decomposition:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, D \subseteq A \Rightarrow \langle D, B \mid C \rangle \in \mathcal{I}$
- Right decomposition:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, D \subseteq B \Rightarrow \langle A, D \mid C \rangle \in \mathcal{I}$
- Left weak union:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, D \subseteq A \Rightarrow \langle A, B \mid C \cup D \rangle \in \mathcal{I}$
- Right weak union:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, D \subseteq B \Rightarrow \langle A, B \mid C \cup D \rangle \in \mathcal{I}$
- Left intersection:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, \langle C, B \mid A \rangle \in \mathcal{I} \Rightarrow$   
 $\langle A \cup C, B \mid A \cap C \rangle \in \mathcal{I}$
- Left composition:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, \langle D, B \mid C \rangle \in \mathcal{I} \Rightarrow$   
 $\langle A \cup D, B \mid C \rangle \in \mathcal{I}$
- Right composition:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, \langle A, D \mid C \rangle \in \mathcal{I} \Rightarrow$   
 $\langle A, B \cup D \mid C \rangle \in \mathcal{I}$
- Left weak composition:  
 $\langle A, B \mid C \rangle \in \mathcal{I}, D \subseteq C \Rightarrow \langle A \cup D, B \mid C \rangle \in \mathcal{I}$

For disjoint sets  $A, C, D \subseteq V$ , we say that  $A$  and  $D$  *factorize* w.r.t.  $C$  if there exists a partition  $C = C_1 \dot{\cup} C_2$  such that (i) and (ii) hold:

- (i)  $\langle A, C_1 \cup D \mid C \cup D \rangle \in \mathcal{I}$
- (ii)  $\langle D, C_2 \cup A \mid C \cup A \rangle \in \mathcal{I}$ .

**Definition 1.** The independence model  $\mathcal{I}$  satisfies *cancellation* if  $\langle A, B \mid C \cup \{\delta\} \rangle \in \mathcal{I}$  implies  $\langle A, B \mid C \rangle \in \mathcal{I}$  whenever  $A$  and  $\{\delta\}$  factorize w.r.t.  $C$ . Such an independence model is called *cancellative*.

Cancellation is related to ordered downward-stability as defined by Sadeghi (2017) for symmetric independence models over a set with a preorder and studied in relation to separation in acyclic graphs.

### 3.1 DIRECTED MIXED GRAPHS

We wish to relate a local independence model, as defined in Section 4, to a graph and therefore we need a notion of graphical separation which allows for asymmetry. *Directed mixed graphs* along with  $\mu$ -separation will provide the means for such graphical modeling of local independence. The subsequent definitions follow Mogensen and Hansen (2018), which we refer to for further details.

**Definition 2** (Directed mixed graph). A *directed mixed graph* (DMG) is an ordered pair  $(V, E)$  where  $V$  is a finite set of vertices (also called nodes) and  $E$  is a finite set of edges of the types  $\rightarrow$  and  $\leftrightarrow$ . A pair of vertices  $\alpha, \beta \in V$  may be joined by any subset of  $\{\alpha \rightarrow \beta, \alpha \leftarrow \beta, \alpha \leftrightarrow \beta\}$ . Note that we allow for loops, i.e., edges  $\alpha \rightarrow \alpha$  and/or  $\alpha \leftrightarrow \alpha$ .

Let  $\mathcal{G}_1 = (V, E_1)$  and  $\mathcal{G}_2 = (V, E_2)$  be DMGs. If  $E_1 \subseteq E_2$ , then we write  $\mathcal{G}_1 \subseteq \mathcal{G}_2$  and say that  $\mathcal{G}_2$  is a *supergraph* of  $\mathcal{G}_1$ . The *complete* DMG on  $V$  is the DMG which is a supergraph of all other DMGs with vertices  $V$ . Throughout this paper,  $\mathcal{G}$  will denote a DMG with node set  $V$  and edge set  $E$ . We will also consider *directed graphs* (DGs) which are DMGs with no bidirected edges. Let  $\alpha, \beta \in V$ . We will say that the edge  $\alpha \rightarrow \beta$  has a *head* at  $\beta$  and a *tail* at  $\alpha$ , and that the edge  $\alpha \leftrightarrow \beta$  has heads at both  $\alpha$  and  $\beta$ . When we write e.g.  $\alpha \rightarrow \beta$  this does not preclude other edges between these nodes. We use  $\alpha * \rightarrow \beta$  to denote any edge between  $\alpha$  and  $\beta$  that has a head at  $\beta$ . A letter over an edge, e.g.  $\alpha \xrightarrow{e} \beta$ , denotes simply that  $e$  refers to that specific edge. If the edge  $\alpha \rightarrow \beta$  is in the graph then we say that  $\alpha$  is a *parent* of  $\beta$  and if  $\alpha \leftrightarrow \beta$  then we say that  $\alpha$  and  $\beta$  are *siblings*. Let  $\text{pa}(\alpha)$  (or  $\text{pa}_{\mathcal{G}}(\alpha)$  to make the graph explicit) denote the set of parents of  $\alpha$  in  $\mathcal{G}$ . Note that due to loops,  $\alpha$  can be both a parent and a sibling of itself.

A *walk* is an alternating, ordered sequence of nodes and edges along with an orientation of the edge such that each edge is between its two adjacent nodes,  $\langle \nu_1, e_1, \nu_2, \dots, e_n, \nu_{n+1} \rangle$ , where  $\nu_i \in V$  and  $e_j \in E$ . We say that the walk is between  $\nu_1$  and  $\nu_{n+1}$  or from  $\nu_1$  to  $\nu_{n+1}$ . The  $\nu_1$  and  $\nu_{n+1}$  are called the *endpoint nodes* of the walk. A non-endpoint node  $\nu_i, i \neq 1, n+1$ , is called a *collider* if the two adjacent edges on the walk both have heads at the node, and otherwise a *non-collider*. Note that the endpoint nodes are neither colliders nor non-colliders. A walk is called *trivial* if it consists of a single node and no edges. A *path* is a walk where no node is repeated. A path from  $\alpha$  to  $\beta$  is *directed* if every edge on the path is directed and points towards  $\beta$ . We say that  $\alpha$  is an ancestor of a set  $C \subseteq V$  if there exists a (possibly trivial) directed path from  $\alpha$  to  $\gamma \in C$ . We let  $\text{an}(C)$  denote the set of nodes that are ancestors to  $C$ . Note that  $C \subseteq \text{an}(C)$ .

Figure 2: A DMG  $\mathcal{G}$  (left) with sets  $\{\alpha\}$  and  $\{\delta\}$  that factorize w.r.t.  $C = \{\gamma_1, \gamma_2, \gamma_3\}$  such that  $\alpha \perp_{\mu} \beta \mid C \cup \{\delta\}$ . Any node is  $\mu$ -separated from either  $\alpha$  by  $C \cup \{\delta\}$  or  $\delta$  by  $C \cup \{\alpha\}$  (middle), and as  $\mathcal{I}(\mathcal{G})$  is cancellative,  $\alpha \perp_{\mu} \beta \mid C$ . A corresponding factor graph (right) with the three factor nodes  $\Psi^1$ ,  $\Psi^2$  and  $\bar{\lambda}^{\beta}$ , cf. Theorem 14.

### 3.1.1 $\mu$ -separation

**Definition 3** ( $\mu$ -connecting walk). A  $\mu$ -connecting walk from  $\alpha$  to  $\beta$  given  $C$  is a non-trivial walk from  $\alpha$  to  $\beta$  such that  $\alpha \notin C$ , every non-collider is not in  $C$  and every collider is in  $\text{an}(C)$ , and such that the final edge has a head at  $\beta$ .

**Definition 4.** Let  $\alpha, \beta \in V, C \subseteq V$ . We say that  $\beta$  is  $\mu$ -separated from  $\alpha$  given  $C$  in the graph  $\mathcal{G}$  if there is no  $\mu$ -connecting walk from  $\alpha$  to  $\beta$  in  $\mathcal{G}$  given  $C$ . For general sets,  $A, B, C \subseteq V$ , we say that  $B$  is  $\mu$ -separated from  $A$  given  $C$  and write  $A \perp_{\mu} B \mid C$  if  $\beta$  is  $\mu$ -separated from  $\alpha$  given  $C$  for every  $\alpha \in A$  and  $\beta \in B$ . We write  $A \perp_{\mu} B \mid C [\mathcal{G}]$  if we wish to make explicit to which graph the statement applies.

Note that this definition means that  $B$  is separated from  $A$  given  $C$  whenever  $A \subseteq C$ . We associate an independence model  $\mathcal{I}(\mathcal{G})$  with a DMG  $\mathcal{G}$  by

$$\langle A, B \mid C \rangle \in \mathcal{I}(\mathcal{G}) \Leftrightarrow A \perp_{\mu} B \mid C [\mathcal{G}].$$

**Lemma 5.** The independence model  $\mathcal{I}(\mathcal{G})$  satisfies left and right {decomposition, weak union, composition} and left {redundancy, intersection, weak composition}. Furthermore,  $\langle A, B \mid C \rangle \in \mathcal{I}(\mathcal{G})$  whenever  $B = \emptyset$ .

**Lemma 6.**  $\mathcal{I}(\mathcal{G})$  satisfies cancellation.

### 3.1.2 Markov equivalence

We say that DMGs  $\mathcal{G}_1 = (V, E_1)$ ,  $\mathcal{G}_2 = (V, E_2)$  are *Markov equivalent* if  $\mathcal{I}(\mathcal{G}_1) = \mathcal{I}(\mathcal{G}_2)$  and this defines an equivalence relation. We let  $[\mathcal{G}]$  denote the (Markov) equivalence class of  $\mathcal{G}$ . For DMGs, it does not hold that Markov equivalent graphs have the same adjacencies. Note that the same is true for the directed (cyclic) graphs with no loops considered by Richardson (1996,

1997) in another context. We say that a DMG is *maximal* if it is complete or if no edge can be added without changing the associated Markov equivalence class. Mogensen and Hansen (2018) define for every vertex in a DMG a set of *potential parents* and *potential siblings* (both subsets of  $V$ ) using the independence model induced by the graph (these definitions are also included in the supplementary material). We let  $\text{pp}(\alpha, \mathcal{I})$  denote the set of potential parents of  $\alpha$  and  $\text{ps}(\alpha, \mathcal{I})$  denote the set of potential siblings of  $\alpha$  in the independence model  $\mathcal{I}$ . If  $\mathcal{G}_1$  and  $\mathcal{G}_2$  are Markov equivalent we thus have  $\text{pp}(\alpha, \mathcal{I}(\mathcal{G}_1)) = \text{pp}(\alpha, \mathcal{I}(\mathcal{G}_2))$  and  $\text{ps}(\alpha, \mathcal{I}(\mathcal{G}_1)) = \text{ps}(\alpha, \mathcal{I}(\mathcal{G}_2))$  for each  $\alpha \in V$ . Given a DMG  $\mathcal{G}$  and independence model  $\mathcal{I} = \mathcal{I}(\mathcal{G})$ , one can construct another DMG  $\mathcal{N}$  in which  $\alpha$  is a parent of  $\beta$  if and only if  $\alpha \in \text{pp}(\beta, \mathcal{I})$  and  $\alpha$  and  $\beta$  are siblings if and only if  $\alpha \in \text{ps}(\beta, \mathcal{I})$ . Mogensen and Hansen (2018) showed that  $\mathcal{N} \in [\mathcal{G}]$ , that it is a supergraph of all elements of  $[\mathcal{G}]$ , and that  $\mathcal{N}$  is maximal. This allows one to define a *directed mixed equivalence graph* (DMEG) from the (unique) maximal graph  $\mathcal{N}$  in the equivalence class to summarize the entire equivalence class. The DMEG is constructed from  $\mathcal{N}$  by partitioning the edge set into two subsets: one consisting of the edges which are common to all graphs in the Markov equivalence class, and one consisting of edges that are present in some members of the equivalence class but absent in others. One may visualize the DMEG by drawing  $\mathcal{N}$  and making the edges in the latter set dashed. Note that by collapsing the distinction between dashed and solid edges one may straightforwardly apply  $\mu$ -separation to a given DMEG.

## 3.2 MARKOV PROPERTIES

The main result of this section gives conditions on an abstract independence model ensuring equivalence be-

tween the *pairwise* and the *global Markov properties* w.r.t. a directed graph with  $\mu$ -separation. In the next section we give examples of classes of processes that fulfill these conditions, extending results in Didelez (2008) to a broader class of models. We take an axiomatic approach to proving the equivalence in the sense that we describe some abstract properties and use only these to show the equivalence. This is analogous to what Lauritzen and Sadeghi (2017) did in the case of symmetric independence models.

**Definition 7.** A DG and an independence model satisfy the pairwise Markov property if for  $\alpha, \beta \in V$ ,

$$\alpha \notin \text{pa}(\beta) \Rightarrow \langle \alpha, \beta \mid V \setminus \{\alpha\} \rangle \in \mathcal{I}$$

A DMG and an independence model satisfy the global Markov property if for  $A, B, C \subseteq V$ ,

$$A \perp_{\mu} B \mid C \Rightarrow \langle A, B \mid C \rangle \in \mathcal{I}.$$

**Theorem 8.** Assume that  $\mathcal{I}$  is an independence model that satisfies left {redundancy, intersection, decomposition, weak union, weak composition}, right {decomposition, composition}, is cancellative, and furthermore  $\langle A, B \mid C \rangle \in \mathcal{I}$  whenever  $B = \emptyset$ . Let  $\mathcal{D}$  be a DG. Then  $\mathcal{I}$  satisfies the pairwise Markov property with respect to  $\mathcal{D}$  if and only if it satisfies the global Markov property with respect to  $\mathcal{D}$ .

To keep consistency with earlier literature, we define the pairwise Markov condition above as the absence of an edge, which does not directly generalize to DMGs. Therefore, we prove the equivalence of pairwise and global Markov only in the class of DGs. The main purpose of DMGs is to represent Markov properties from marginalized DGs as defined below, in which case the global Markov property w.r.t. a DMG is inherited from the DG.

**Definition 9** (Marginal independence model). Assume that  $\mathcal{I}$  is an independence model over  $V$ . Then the marginal independence model of  $\mathcal{I}$  over  $O \subseteq V$ ,  $\mathcal{I}^O$ , is the independence model,

$$\mathcal{I}^O = \{ \langle A, B \mid C \rangle \mid \langle A, B \mid C \rangle \in \mathcal{I}; A, B, C \subseteq O \}.$$

Mogensen and Hansen (2018) give a marginalization algorithm (a.k.a. a “latent projection”), which outputs a marginal DMG,  $\mathcal{G} = (O, F)$ , from a DG,  $\mathcal{D} = (V, E)$ , such that  $\mathcal{I}(\mathcal{D})^O = \mathcal{I}(\mathcal{G})$ . If  $\mathcal{I}$  satisfies the global Markov property w.r.t.  $\mathcal{D}$  then

$$\mathcal{I}(\mathcal{G}) = \mathcal{I}(\mathcal{D})^O \subseteq \mathcal{I}^O.$$

This shows that the marginalized independence model  $\mathcal{I}^O$  then satisfies the global Markov property w.r.t. the DMG  $\mathcal{G}$ .

## 4 LOCAL INDEPENDENCE

This section introduces local independence models and local independence graphs. The main results of the section provide verifiable conditions that ensure that a local independence model satisfies the global Markov property w.r.t. the local independence graph.

Let  $X = (X_t^1, \dots, X_t^n)$  for  $t \in [0, T]$  be a càdlàg stochastic process defined on the probability space  $(\Omega, \mathcal{F}, P)$ . Introduce for  $A \subseteq V = \{1, \dots, n\}$  the filtration  $\mathcal{F}_t^A$  as the completed and right continuous version of  $\sigma(\{X_s^\alpha, s \leq t, \alpha \in A\})$ . Let also  $\lambda = (\lambda_t^1, \dots, \lambda_t^n)$  be an integrable càdlàg stochastic process. This  $\lambda$ -process need not have any specific relation to  $X$  *a priori*, but for the main Theorem 14 the relation is through the compatibility processes defined below. Note that some computations below technically require that  $E(\cdot \mid \mathcal{F}_t)$  is computed as the optional projection, cf. Theorem VI.7.1 and Lemma VI.7.8 in Rogers and Williams (2000). This is unproblematic, and will not be discussed any further.

**Definition 10.** We say that  $B$  is  $\lambda$ -locally independent of  $A$  given  $C$  if the process

$$t \mapsto E(\lambda_t^\beta \mid \mathcal{F}_t^{A \cup C})$$

has an  $\mathcal{F}_t^C$ -adapted version for all  $\beta \in B$ . In this case we write  $A \not\rightarrow_{\lambda} B \mid C$ .

This is slightly different from the definition in Didelez (2008) in that  $\beta$  is not necessarily in the conditioning set. This change in the definition makes it possible for a process to be locally independent from itself given some separating set. We define the local independence model,  $\mathcal{I}(X, \lambda)$ , determined by  $X$  and  $\lambda$  via

$$\langle A, B \mid C \rangle \in \mathcal{I}(X, \lambda) \Leftrightarrow A \not\rightarrow_{\lambda} B \mid C.$$

When there is no risk of ambiguity we say that  $B$  is locally independent of  $A$  given  $C$ , and we write  $A \not\rightarrow B \mid C$  and  $\mathcal{I} = \mathcal{I}(X, \lambda)$ .

The local independence model satisfies a number of the properties listed in Section 3.

**Lemma 11.** Let  $\mathcal{I}$  be a local independence model. Then it satisfies left {redundancy, decomposition, weak union, weak composition} and right {decomposition, composition} and furthermore  $\langle A, B \mid C \rangle \in \mathcal{I}$  whenever  $B = \emptyset$ . If  $\mathcal{F}_t^A \cap \mathcal{F}_t^C = \mathcal{F}_t^{A \cap C}$  holds for all  $A, C \subseteq V$  and  $t \in [0, T]$ , then left intersection holds.

**Definition 12.** The local independence graph is the directed graph with node set  $V = \{1, \dots, n\}$  such that

$$\alpha \notin \text{pa}(\beta) \Leftrightarrow \alpha \not\rightarrow_{\lambda} \beta \mid V \setminus \{\alpha\}.$$

By Theorem 8 and Lemma 11 a local independence model that satisfies left intersection and is cancellative satisfies the global Markov property w.r.t. the local independence graph. Left intersection holds by Lemma 11 whenever  $\mathcal{F}_t^A \cap \mathcal{F}_t^C = \mathcal{F}_t^{A \cap C}$ . Theorem 14 below gives a general factorization condition on the distribution of the stochastic processes that ensures a local independence model to be cancellative. This condition is satisfied for example by event and Itô processes.

Introduce for  $C \subseteq V$  and  $\beta \in V$  the shorthand notation

$$\lambda_t^{C,\beta} = E(\lambda_t^\beta | \mathcal{F}_t^C).$$

Furthermore, for  $\alpha \in A \subseteq V$  let

$$\Psi_t^{A,\alpha} = \psi_t^\alpha((\lambda_s^{A,\alpha})_{s \leq t}, (X_s^\alpha)_{s \leq t})$$

denote a càdlàg process that is given in terms of a positive functional  $\psi_t^\alpha$  of the history of the  $\lambda^{A,\alpha}$ - and the  $X^\alpha$ -processes up to time  $t$ .

**Definition 13.** We say that  $P$   $\lambda$ -factorizes with compatibility processes  $\Psi^{A,\alpha} > 0$  if for all  $A \subseteq V$

$$P = \frac{1}{Z_t^A} \prod_{\alpha \in A} \Psi_t^{A,\alpha} \cdot Q_t^A$$

with  $Q_t^A$  a probability measure on  $(\Omega, \mathcal{F})$  such that  $(X_s^\alpha)_{0 \leq s \leq t}$  for  $\alpha \in A$  are independent under  $Q_t^A$ . Here,  $Z_t^A$  is a deterministic normalization constant.

**Theorem 14.** The local independence model  $\mathcal{I}(X, \lambda)$  is cancellative if  $P$   $\lambda$ -factorizes.

*Proof.* Assume that  $A, \{\delta\} \subseteq V$  factorize w.r.t.  $C = C_1 \dot{\cup} C_2$ . In this proof, (i) and (ii) refer to the factorization properties, see Definition 1. Let  $F = C \cup A \cup \{\delta\}$ . Then by (i)

$$\Psi_t^{F,\gamma} = \psi_t^\gamma((\lambda_s^{C \cup \{\delta\}, \gamma})_{s \leq t}, (X_s^\gamma)_{s \leq t}) = \Psi_t^{C \cup \{\delta\}, \gamma}$$

for  $\gamma \in C_1 \cup \{\delta\}$ , and by (ii)

$$\Psi_t^{F,\gamma} = \psi_t^\gamma((\lambda_s^{C \cup A, \gamma})_{s \leq t}, (X_s^\gamma)_{s \leq t}) = \Psi_t^{C \cup A, \gamma}$$

for  $\gamma \in C_2 \cup A$ .

It follows that

$$\begin{aligned} \prod_{\gamma \in F} \Psi_t^{F,\gamma} &= \overbrace{\prod_{\gamma \in C_1 \cup \{\delta\}} \Psi_t^{C \cup \{\delta\}, \gamma}}^{\Psi_t^1} \overbrace{\prod_{\gamma \in C_2 \cup A} \Psi_t^{C \cup A, \gamma}}^{\Psi_t^2} \\ &= \Psi_t^1 \Psi_t^2, \end{aligned}$$

cf. Figure 2. Note that  $\Psi_t^2$  is  $\mathcal{F}_t^{C \cup A}$ -adapted. Let  $\beta \in B$ . We have  $\langle A, B \mid C \cup \{\delta\} \rangle \in \mathcal{I}$ , hence with  $\bar{\lambda}_t^\beta =$

$$\lambda_t^{C \cup \{\delta\}, \beta}$$

$$\begin{aligned} E(\lambda_t^\beta | \mathcal{F}_t^{C \cup A}) &= E(E(\lambda_t^\beta | \mathcal{F}_t^{C \cup A \cup \{\delta\}}) | \mathcal{F}_t^{C \cup A}) \\ &= E(\bar{\lambda}_t^\beta | \mathcal{F}_t^{C \cup A}) \\ &= \frac{E_{Q_t^F}(\bar{\lambda}_t^\beta \Psi_t^1 \Psi_t^2 | \mathcal{F}_t^{C \cup A})}{E_{Q_t^F}(\Psi_t^1 \Psi_t^2 | \mathcal{F}_t^{C \cup A})} \\ &= \frac{E_{Q_t^F}(\bar{\lambda}_t^\beta \Psi_t^1 | \mathcal{F}_t^{C \cup A})}{E_{Q_t^F}(\Psi_t^1 | \mathcal{F}_t^{C \cup A})} \\ &= \frac{E_{Q_t^F}(\bar{\lambda}_t^\beta \Psi_t^1 | \mathcal{F}_t^C)}{E_{Q_t^F}(\Psi_t^1 | \mathcal{F}_t^C)} \\ &= \lambda_t^{C,\beta} \end{aligned}$$

where the second last identity follows from  $X^\alpha$  for  $\alpha \in A$  being independent of  $X^\gamma$  for  $\gamma \in C \cup \{\delta\}$  under  $Q_t^F$ . We conclude that  $\langle A, B \mid C \rangle \in \mathcal{I}$ , and this shows that  $\mathcal{I}$  is cancellative.  $\square$

## 4.1 ITÔ PROCESSES

For  $X$  a multivariate Itô process with  $X^\alpha$  fulfilling the equation

$$X_t^\alpha = \int_0^t \lambda_s^\alpha ds + \sigma_t(\alpha) W_t^\alpha$$

with  $W_t$  a standard Brownian motion ( $\sigma_t(\alpha) > 0$  deterministic) we introduce the compatibility processes

$$\Psi_t^{A,\alpha} = \exp\left(\int_0^t \frac{\lambda_s^{A,\alpha}}{\sigma_s^2(\alpha)} dX_s^\alpha - \frac{1}{2} \int_0^t \left(\frac{\lambda_s^{A,\alpha}}{\sigma_s(\alpha)}\right)^2 ds\right).$$

The following result is a consequence of Theorem 7.3 in Liptser and Shirayev (1977) combined with Theorem VI.8.4 in Rogers and Williams (2000).

**Proposition 15.** If for all  $A \subseteq V$

$$E\left(\prod_{\alpha \in A} (\Psi_t^{A,\alpha})^{-1}\right) = 1 \quad (2)$$

then  $P$   $\lambda$ -factorizes.

It can be shown that the linear SDE introduced earlier satisfies the integrability condition (2).

## 4.2 EVENT PROCESSES

For  $X$  a multivariate counting process with  $X^\alpha$  having intensity process  $\lambda^\alpha$  we introduce the compatibility processes

$$\Psi_t^{A,\alpha} = \exp\left(\int_0^t \log(\lambda_{s-}^{A,\alpha}) dX_s^\alpha - \int_0^t \lambda_s^{A,\alpha} ds\right).$$

Here  $\lambda_{s-}^{A,\alpha} = \lim_{r \rightarrow s-} \lambda_r^{A,\alpha}$  denotes the left continuous (and thus predictable) version of the intensity process  $\lambda_t^{A,\alpha} = E(\lambda_t^\alpha \mid \mathcal{F}_t^A)$ . With these compatibility processes, Proposition 15 above holds exactly as formulated for Itô processes, see e.g. Sokol and Hansen (2015) for details and weak conditions ensuring that (2) holds.

## 5 LEARNING ALGORITHMS

In this section, we assume that we have access to a local independence oracle that can answer whether or not some independence statement is in  $\mathcal{I}$ . In applications, the oracle would of course be substituted with statistical tests of local independence. The local independence model,  $\mathcal{I}$ , is assumed to be faithful to some DMG  $\mathcal{G}_0$ , i.e.  $\mathcal{I} = \mathcal{I}(\mathcal{G}_0)$ .

Meek (2014) described a related algorithm for learning local independence graphs which is, however, not complete when the system of stochastic processes is only partially observed. In the FCI algorithm, which learns an equivalence class of MAGs (Maximal Ancestral Graphs), one can exploit the fact that Markov equivalent graphs have the same adjacencies, so the learning algorithm can first find this so-called *skeleton* of the graph and then orient the edges by applying a finite set of rules (Zhang, 2008; Ali et al., 2009). Since Markov equivalent DMGs may have different adjacencies, we cannot straightforwardly copy the FCI strategy here, and our procedure is more complicated.

### 5.1 A THREE-STEP PROCEDURE

As described in Section 3.1.2, we know that there exists a unique graph which is Markov equivalent to  $\mathcal{G}_0$  and a supergraph of all DMGs in  $[\mathcal{G}_0]$  and we denote this graph by  $\mathcal{N}$ . In this section we give a learning algorithm exploiting this fact. Having learned the maximal DMG  $\mathcal{N}$  we can subsequently construct a DMEG to summarize the Markov equivalence class.

The characterization of Markov equivalence of DMGs in Mogensen and Hansen (2018) implies a learning algorithm to construct  $\mathcal{N}$  which is Markov equivalent to  $\mathcal{G}_0$ . For each pair of nodes  $\alpha, \beta$  there exists a well-defined list of independence tests such that  $\alpha \rightarrow \beta$  is in  $\mathcal{N}$  if and only if all requirements in the list is met by  $\mathcal{I}(\mathcal{G}_0)$ , analogously for the edge  $\alpha \leftrightarrow \beta$  (see conditions (p1)-(p4) and (s1)-(s3) in the supplementary material). This means that we can use these lists of tests to construct a maximal graph  $\mathcal{N}$  such that  $\mathcal{I}(\mathcal{N}) = \mathcal{I}(\mathcal{G}_0)$ . However such an algorithm would perform many more independence tests than needed and one can reduce the number of independence tests conducted by a kind of preprocessing. Our proposed algorithm starts from the complete DMG

**input** : a local independence oracle for  $\mathcal{I}$

**output**: a DMG,  $\mathcal{G} = (V, E)$

initialize  $\mathcal{G}$  as the complete DMG, set  $n = 0$ , initialize  $\mathcal{L}_s = \emptyset, \mathcal{L}_n = \emptyset$ ;

```

while  $n \leq \max_{\beta \in V} |\text{pa}_{\mathcal{G}}(\beta)|$  do
  foreach  $\alpha \rightarrow \beta \in E$  do
    foreach  $C \subseteq \text{pa}_{\mathcal{G}}(\beta) \setminus \{\alpha\}, |C| = n$  do
      if  $\alpha \not\rightarrow_{\lambda} \beta \mid C$  then
        delete  $\alpha \rightarrow \beta$  and  $\alpha \leftrightarrow \beta$  from  $\mathcal{G}$ ;
        update  $\mathcal{L}_s = \mathcal{L}_s \cup \{\langle \alpha, \beta \mid C \rangle\}$ ;
      else
        update  $\mathcal{L}_n = \mathcal{L}_n \cup \{\langle \alpha, \beta \mid C \rangle\}$ ;
      end
    end
  end
  end
  update  $n = n + 1$ ;
end
set  $n = 1$ ;

#### Subalgorithm 1: Separation step

and removes edges that are not in  $\mathcal{G}_0$  by an FCI-like approach, exploiting properties of DMGs and  $\mu$ -separation, and then in the end applies the potential parents and potential siblings definitions (see the supplementary material), but only if and when needed.

In this section we describe three steps (and three subalgorithms): a *separation*, a *pruning*, and a *potential* step, and then we argue that we can construct a sound and complete algorithm by using these steps. For all three steps, we sequentially remove edges starting from the complete DMG on nodes  $V$ . We will also along the way update a set of triples  $\mathcal{L}_s$  corresponding to independence statements that we know to be in  $\mathcal{I}$  and a set of triples  $\mathcal{L}_n$  corresponding to independence statements that we know to not be in  $\mathcal{I}$ . We keep track of this information as we will reuse some of it to reduce the number of independence tests that we conduct. Figure 3 illustrates what

**input** : a separability graph,  $\mathcal{S}$ , a set of known independencies  $\mathcal{L}_s$   
**output**: a DMG  
initialize  $\mathcal{G} = \mathcal{S}$ ;  
**foreach** *unshielded*  $W$ -structure in  $\mathcal{S}$ ,  $w(\alpha, \beta, \gamma)$  **do**  
    **if**  $\beta \in S_{\alpha, \gamma}$  such that  $\langle \alpha, \gamma \mid S_{\alpha, \gamma} \rangle \in \mathcal{L}_s$  **then**  
        **if**  $\beta \leftrightarrow \gamma$  is in  $\mathcal{G}$  **then**  
            delete  $\beta \leftrightarrow \gamma$  from  $\mathcal{G}$ ;  
        **end**  
    **else**  
        **if**  $\beta \rightarrow \gamma$  is in  $\mathcal{G}$  **then**  
            delete  $\beta \rightarrow \gamma$  from  $\mathcal{G}$ ;  
        **end**  
    **end**  
**end**  
**return**  $\mathcal{G}$

**Subalgorithm 2:** Pruning step

each subalgorithm outputs for an example  $\mathcal{G}_0$ .

### 5.1.1 The separation step

When we have an independence model  $\mathcal{I}$  over  $V$ , we will for  $\alpha, \beta \in V$  say that  $\beta$  is *inseparable* from  $\alpha$  if there exists no  $C \subseteq V \setminus \{\alpha\}$  such that  $\langle \alpha, \beta \mid C \rangle \in \mathcal{I}$ . Let

$$u(\beta, \mathcal{I}) = \{\gamma \in V \mid \beta \text{ is inseparable from } \gamma \text{ in } \mathcal{I}\}.$$

The purpose of the first step is to output a *separability graph*. The separability graph of an independence model  $\mathcal{I}$  is the DMG such that the edge  $\alpha \rightarrow \beta$  is in the DMG if and only if  $\alpha \in u(\beta, \mathcal{I})$  and the edge  $\alpha \leftrightarrow \beta$  is in the DMG if and only if  $\alpha \in u(\beta, \mathcal{I})$  and  $\beta \in u(\alpha, \mathcal{I})$ .

We say that  $\gamma$  is *directedly collider connected* to  $\beta$  if there exists a non-trivial walk from  $\gamma$  to  $\beta$  such that every non-endpoint node on the walk is a collider and such that the final edge has a head at  $\beta$ . As shorthand, we write  $\gamma \twoheadrightarrow \beta$ . We define the separator set of  $\beta$  from  $\alpha$ ,

$$D_{\mathcal{G}}(\alpha, \beta) = \{\gamma \in \text{an}(\alpha, \beta) \mid \gamma \twoheadrightarrow \beta\} \setminus \{\alpha\}.$$

If there exists a subset of  $V \setminus \{\alpha\}$  that separates  $\beta$  from  $\alpha$ , then this set does (Mogensen and Hansen, 2018). This set will play a role analogous to that of the set **Possible-D-Sep** in the FCI algorithm (Spirtes et al., 2000).

In the first part of Subalgorithm 1, we consider pairs of nodes,  $\alpha, \beta$ , and test if they can be separated by larger and larger conditioning sets, though only subsets of  $\text{pa}_{\mathcal{G}}(\beta) \setminus \{\alpha\}$  in the current  $\mathcal{G}$ . In the second part, we use all subsets of the current separator set  $D_{\mathcal{G}}(\alpha, \beta)$  to determine separability of each pair of nodes. Note that separability is not symmetric, hence, one needs to determine separability of  $\beta$  from  $\alpha$  and of  $\alpha$  from  $\beta$ . The

**input** : a local independence oracle for  $\mathcal{I}$ , a DMG  $\mathcal{G} = (V, E)$ , a set of known dependencies  $\mathcal{L}_n$   
**output**: a DMG  
**foreach**  $\alpha \xrightarrow{e} \beta \in E$  **do**  
    **if**  $\mathcal{I}(\mathcal{G} - e) \cap \mathcal{L}_n = \emptyset$  **then**  
        **if**  $\alpha \notin \text{pp}(\beta, \mathcal{I})$  **then**  
            delete  $\alpha \rightarrow \beta$  in  $\mathcal{G}$ ;  
        **end**  
    **end**  
**end**  
**foreach**  $\alpha \xleftrightarrow{e} \beta \in E$  **do**  
    **if**  $\mathcal{I}(\mathcal{G} - e) \cap \mathcal{L}_n = \emptyset$  **then**  
        **if**  $\alpha \notin \text{ps}(\beta, \mathcal{I})$  **then**  
            delete  $\alpha \leftrightarrow \beta$  in  $\mathcal{G}$ ;  
        **end**  
    **end**  
**end**  
**return**  $\mathcal{G}$

**Subalgorithm 3:** Potential step

candidate separator sets may be chosen in more-or-less efficient ways, but we will not discuss this aspect of the algorithm (Colombo et al., 2012; Claassen et al., 2013).

**Lemma 16.** Subalgorithm 1 outputs the separability graph of  $\mathcal{I}$ ,  $\mathcal{S}$ , and furthermore  $\mathcal{N} \subseteq \mathcal{S}$ .

### 5.1.2 The pruning step

Let  $\mathcal{S}$  denote the graph in the output of Subalgorithm 1. One can use some of the information encoded by the graph along with the set  $\mathcal{L}_s$  to further prune the graph. For this purpose, we consider *W-structures* which are triples of nodes  $\alpha, \beta, \gamma$  such that  $\alpha \neq \beta \neq \gamma$ , and  $\alpha \rightarrow \beta \twoheadrightarrow \gamma$ . We denote such a triple by  $w(\alpha, \beta, \gamma)$ . We will say that a *W-structure* is *unshielded* if the edge  $\alpha \rightarrow \gamma$  is not in the graph. For every unshielded *W-structure*  $w(\alpha, \beta, \gamma)$ , there exists exactly one triple  $\langle \alpha, \gamma \mid C \rangle$  in  $\mathcal{L}_s$  (output from Subalgorithm 1) and we let  $S_{\alpha, \gamma}$  denote the separating set  $C$ .

**Lemma 17.** Subalgorithm 2 outputs a supergraph of  $\mathcal{N}$ .

### 5.1.3 Potential step

In the final step, we sequentially consider each edge which is still in the graph. If  $\mathcal{G} = (V, E)$  and  $e \in E$  we let  $\mathcal{G} - e$  denote the DMG  $(V, E \setminus \{e\})$ . We then check if  $\mathcal{I}(\mathcal{G} - e) \cap \mathcal{L}_n = \emptyset$ . If not, we leave this edge in the graph. On the other hand, if the intersection is the empty set, we check if the edge is between a pair of potential parents/siblings using the definition of these sets. That is, in the case of a directed edge we check each of

Figure 3: Illustration of the learning algorithm. The DMG  $\mathcal{G}_0$  is the underlying graph and we have access to  $\mathcal{I} = \mathcal{I}(\mathcal{G}_0)$ . Subalgorithm 1 outputs  $\mathcal{S}$ , the separability graph of  $\mathcal{I}(\mathcal{G}_0)$ . Subalgorithm 2 prunes  $\mathcal{S}$  and outputs  $\tilde{\mathcal{S}}$ . Note e.g. the unshielded  $W$ -structure  $\alpha \rightarrow \beta \rightarrow \varepsilon$  in  $\mathcal{S}$ . The DMG  $\mathcal{N}$  is the maximal element in  $[\mathcal{G}_0]$ . Note that  $\delta \rightarrow \varepsilon$  has been removed by Subalgorithm 3 using the potential parent criteria. The final graph  $\tilde{\mathcal{N}}$  is the DMEG constructed from  $\mathcal{N}$ .

Figure 4: Left: linear SDE example (see Figure 1). Right: the DMEG after marginalization over  $\gamma$ . It is not possible to decide if a loop is directed or bidirected from the independence model only and we choose only to draw the directed loop and to not present it as dashed.

the conditions (p1)-(p4) and in the case of a bidirected edge each of the conditions (s1)-(s3); both sets of conditions are in the supplementary material. Note that if  $\alpha \in \text{ps}(\beta, \mathcal{I})$ , then also  $\beta \in \text{ps}(\alpha, \mathcal{I})$ .

**Theorem 18.** The algorithm defined by first doing the separation step, then the pruning, and finally the potential step outputs  $\mathcal{N}$ , the maximal element of  $[\mathcal{G}_0]$ .

Using properties of maximal DMGs, Mogensen and Hansen (2018) showed how one can construct the DMEG efficiently. The learning algorithm that is defined by first constructing  $\mathcal{N}$  and then constructing the DMEG is sound and complete in the sense that if an edge is absent in the DMEG, then it is also absent in any element of  $[\mathcal{G}_0]$  and therefore also in  $\mathcal{G}_0$ . If it is present and not dashed in the DMEG, then it is present in all elements of  $[\mathcal{G}_0]$  and therefore also in  $\mathcal{G}_0$ . Finally, if it is present and dashed in the DMEG, then there exist  $\mathcal{G}_1, \mathcal{G}_2 \in [\mathcal{G}_0]$  such that the edge is present in  $\mathcal{G}_1$  and absent in  $\mathcal{G}_2$  and therefore it is impossible to determine if the edge is in  $\mathcal{G}_0$  using

knowledge of  $\mathcal{I}(\mathcal{G}_0)$  only.

One could also skip the potential step to reduce the computational requirements. The resulting DMG is then a supergraph of the true graph. A small simulation study (supplementary material) indicates that one could save quite a number of tests and still get close to the true  $\mathcal{N}$ .

## 6 CONCLUSION AND DISCUSSION

We have shown that for a given directed graph with  $\mu$ -separation it is possible to specify abstract properties that ensure equivalence of the pairwise and global Markov properties in asymmetric independence models. We have shown that under certain conditions these properties hold in local independence models of Itô diffusions and event processes, extending known results.

Assuming faithfulness, we have given a sound and complete learning algorithm for the Markov equivalence class of directed mixed graphs representing a marginalized local independence model. Faithfulness is not an innocuous assumption and it remains an open research question how common this property is in different classes of stochastic processes.

## Abstract

Zero-inflated datasets, which have an excess of zero outputs, are commonly encountered in problems such as climate or rare event modelling. Conventional machine learning approaches tend to overestimate the non-zeros leading to poor performance. We propose a novel model family of *zero-inflated Gaussian processes* (ZiGP) for such zero-inflated datasets, produced by *sparse kernels* through learning a latent probit Gaussian process that can zero out kernel rows and columns whenever the signal is absent. The ZiGPs are particularly useful for making the powerful Gaussian process networks more interpretable. We introduce *sparse GP networks* where variable-order latent modelling is achieved through sparse mixing signals. We derive the non-trivial stochastic variational inference tractably for scalable learning of the sparse kernels in both models. The novel output-sparse approach improves both prediction of zero-inflated data and interpretability of latent mixing models.

## 1 INTRODUCTION

Zero-inflated quantitative datasets with overabundance of zero output observations are common in many domains, such as climate and earth sciences (Enke & Spekat, 1997; Wilby, 1998; Charles et al., 2004), ecology (del Saz-Salazar & Rausell-Köster, 2008; Ancelet et al., 2009), social sciences (Bohning et al., 1997), and in count processes (Barry & Welsh, 2002). Traditional regression modelling of such data tends to underestimate zeros and overestimate nonzeros (Andersen et al., 2014).

A conventional way of forming zero-inflated models is to estimate a mixture of a Bernoulli “on-off” process and a Poisson count distribution (Johnson & Kotz, 1969; Lambert, 1992). In hurdle models a binary “on-off” process determines whether a hurdle is crossed, and the positive responses are governed by a subsequent process (Cragg, 1971; Mullahy, 1986). The hurdle model is analogous to first performing classification and training a continuous predictor on the positive values only, while the zero-inflated model would regress with all observations. Both stages can be combined for simultaneous classification and regression Abraham & Tan (2010).

Gaussian process models have not been proposed for zero-inflated datasets since their posteriors are Gaussian, which are ill-fitted for zero predictions. A suite of Gaussian process models have been proposed for partially related problems, such as mixture models (Tresp, 2001; Rasmussen & Ghahramani, 2002; Lázaro-Gredilla et al., 2012) and change point detection (Herlands et al., 2016). Structured spike-and-slab models place smoothly sparse priors over the structured inputs (Andersen et al., 2014).

In contrast to other approaches, we propose a Bayesian model that learns the underlying latent prediction function, whose covariance is sparsified through another Gaussian process switching between the ‘on’ and ‘off’ states, resulting in an zero-inflated Gaussian process model. This approach introduces a tendency of predicting exact zeros to Gaussian processes, which is directly useful in datasets with excess zeros.

A Gaussian process network (GPRN) is a latent signal framework where multi-output data are explained through a set of latent signals and mixing weight Gaussian processes (Wilson et al., 2012). The standard GPRN tends to have dense mixing that combines all latent signals for all latent outputs. By

applying the zero-predicting Gaussian processes to latent mixture models, we introduce sparse GPRNs where latent signals are mixed with sparse instead of dense mixing weight functions. The sparse model induces variable-order mixtures of latent signals resulting in simpler and more interpretable models. We demonstrate both of these properties in our experiments with spatio-temporal and multi-output datasets.

**Main contributions.** Our contributions include<sup>1</sup>

1. A novel zero-inflated Gaussian process formalism consisting of a latent Gaussian process and a separate ‘on-off’ probit-linked Gaussian process that can zero out rows and columns of the model covariance. The novel sparse kernel adds to GPs the ability to predict zeros.
2. Novel stochastic variational inference (SVI) for such sparse probit covariances, which in general are intractable due to having to compute expectations of GP covariances with respect to probit-linked processes. We derive the SVI for learning both of the underlying processes.
3. A novel sparse GPRN with an on-off process in the mixing matrices leading to sparse and variable-order mixtures of latent signals.
4. A solution to the stochastic variational inference of sparse GPRN where the SVI is derived for the network of full probit-linked covariances.

## 2 GAUSSIAN PROCESSES

We begin by introducing the basics of conventional Gaussian processes. Gaussian processes (GP) are a family of non-parametric, non-linear Bayesian models (Rasmussen & Williams, 2006). Assume a dataset of  $n$  inputs  $X = (\mathbf{x}_1, \dots, \mathbf{x}_n)$  with  $\mathbf{x}_i \in \mathbb{R}^D$  and noisy outputs  $\mathbf{y} = (y_1, \dots, y_n) \in \mathbb{R}^n$ . The observations  $y = f(\mathbf{x}) + \varepsilon$  are assumed to have additive, zero mean noise  $\varepsilon \sim \mathcal{N}(0, \sigma_y^2)$  with a zero-mean GP prior on the latent function  $f(\mathbf{x})$ ,

$$f(\mathbf{x}) \sim \mathcal{GP}(0, K(\mathbf{x}, \mathbf{x}')), \quad (1)$$

which defines a distribution over functions  $f(\mathbf{x})$  whose mean and covariance are

$$\mathbb{E}[f(\mathbf{x})] = 0 \quad (2)$$

$$\text{cov}[f(\mathbf{x}), f(\mathbf{x}')] = K(\mathbf{x}, \mathbf{x}'). \quad (3)$$

<sup>1</sup>The TensorFlow compatible code will be made publicly available at <https://github.com/hegdepashupati/zero-inflated-gp>

Figure 1: Illustration of a zero-inflated GP (a) and standard GP regression (b). The standard approach is unable to model sudden loss of signal (at 4...5) and signal close to zero (at 0...1 and 7...9).

Then for any collection of inputs  $X$ , the function values follow a multivariate normal distribution  $\mathbf{f} \sim \mathcal{N}(\mathbf{0}, K_{XX})$ , where  $\mathbf{f} = (f(\mathbf{x}_1), \dots, f(\mathbf{x}_N))^T \in \mathbb{R}^n$ , and where  $K_{XX} \in \mathbb{R}^{n \times n}$  with  $[K_{XX}]_{ij} = K(\mathbf{x}_i, \mathbf{x}_j)$ . The key property of Gaussian processes is that they encode functions that predict similar output values  $f(\mathbf{x}), f(\mathbf{x}')$  for similar inputs  $\mathbf{x}, \mathbf{x}'$ , with similarity determined by the kernel  $K(\mathbf{x}, \mathbf{x}')$ . In this paper we assume the Gaussian ARD kernel

$$K(\mathbf{x}, \mathbf{x}') = \sigma_f^2 \exp\left(-\frac{1}{2} \sum_{j=1}^D \frac{(x_j - x'_j)^2}{\ell_j^2}\right), \quad (4)$$

with a signal variance  $\sigma_f^2$  and dimension-specific lengthscales  $\ell_1, \dots, \ell_D$  parameters.

The inference of the hyperparameters  $\theta = (\sigma_y, \sigma_f, \ell_1, \dots, \ell_D)$  is performed commonly by maximizing the marginal likelihood

$$p(\mathbf{y}|\theta) = \int p(\mathbf{y}|\mathbf{f})p(\mathbf{f}|\theta)d\mathbf{f}, \quad (5)$$

which results in a convenient marginal likelihood called evidence,  $p(\mathbf{y}|\theta) = N(\mathbf{y}|\mathbf{0}, K_{XX} + \sigma_y^2 I)$  for a Gaussian likelihood.

The Gaussian process defines a univariate normal predictive posterior distribution  $f(\mathbf{x})|\mathbf{y}, X \sim \mathcal{N}(\mu(\mathbf{x}), \sigma^2(\mathbf{x}))$  for an arbitrary input  $\mathbf{x}$  with the prediction mean and variance<sup>2</sup>

$$\mu(\mathbf{x}) = K_{\mathbf{x}X}(K_{XX} + \sigma_y^2 I)^{-1}\mathbf{y}, \quad (6)$$

$$\sigma^2(\mathbf{x}) = K_{\mathbf{x}\mathbf{x}} - K_{\mathbf{x}X}(K_{XX} + \sigma_y^2 I)^{-1}K_{X\mathbf{x}}, \quad (7)$$

<sup>2</sup>In the following we omit the implicit conditioning on data inputs  $X$  for clarity.

where  $K_{X\mathbf{x}} = K_{\mathbf{x}X}^T \in \mathbb{R}^n$  is the kernel column vector over pairs  $X \times \mathbf{x}$ , and  $K_{\mathbf{x}\mathbf{x}} = K(\mathbf{x}, \mathbf{x}) \in \mathbb{R}$  is a scalar. The predictions  $\mu(\mathbf{x}) \pm \sigma(\mathbf{x})$  come with uncertainty estimates in GP regression.

### 3 ZERO-INFLATED GAUSSIAN PROCESSES

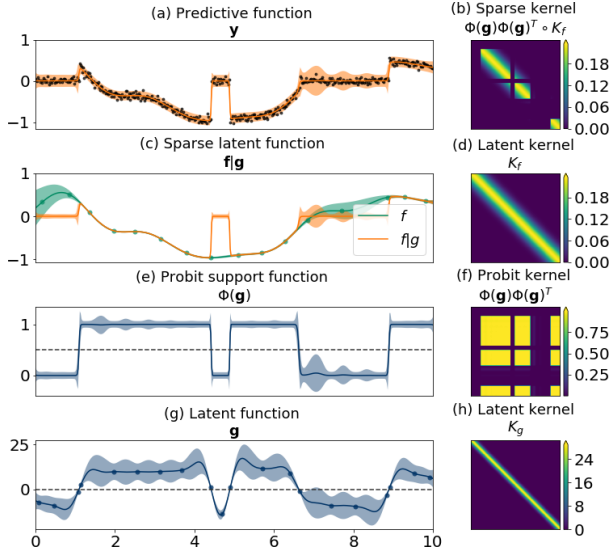

Figure 2: Illustration of the zero-inflated GP (a) and the sparse kernel (b) composed of a smooth latent function (c,d) filtered by a probit support function (e,f), which is induced by the underlying latent sparsity (g,h).

We introduce zero-inflated Gaussian processes that have – in contrast to standard GP’s – a tendency to produce exactly zero predictions (See Figure 1). Let  $g(\mathbf{x})$  denote the latent “on-off” state of a function  $f(\mathbf{x})$ . We assume GP priors for both functions with a joint model

$$p(\mathbf{y}, \mathbf{f}, \mathbf{g}) = p(\mathbf{y}|\mathbf{f})p(\mathbf{f}|\mathbf{g})p(\mathbf{g}), \quad (8)$$

where

$$p(\mathbf{y}|\mathbf{f}) = \mathcal{N}(\mathbf{y}|\mathbf{f}, \sigma_y^2 I) \quad (9)$$

$$p(\mathbf{f}|\mathbf{g}) = \mathcal{N}(\mathbf{f}|\mathbf{0}, \Phi(\mathbf{g})\Phi(\mathbf{g})^T \circ K_f) \quad (10)$$

$$p(\mathbf{g}) = \mathcal{N}(\mathbf{g}|\beta\mathbf{1}, K_g) \quad (11)$$

The sparsity values  $g(\mathbf{x})$  are squashed between 0 and 1 through a standard Normal cumulative distribution, or a probit link function,  $\Phi: \mathbb{R} \rightarrow [0, 1]$

$$\Phi(g) = \int_{-\infty}^g \phi(\tau) d\tau = \frac{1}{2} \left( 1 + \operatorname{erf} \left( \frac{g}{\sqrt{2}} \right) \right), \quad (12)$$

where  $\phi(\tau) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}\tau^2}$  is the standard normal density function. The structured probit sparsity  $\Phi(\mathbf{g})$  models the “on-off” smoothly due to the latent sparsity function  $\mathbf{g}$  having a GP prior with prior mean  $\beta$ . The latent function  $\mathbf{f}$  is modeled throughout but it is only visible during the “on” states. This masking effect has similarities to both zero-inflated and hurdle models. The underlying latent function  $\mathbf{f}$  is learned from only non-zero data similarly to in hurdle models, but the function  $\mathbf{f}$  is allowed to predict zeros similarly to zero-inflated models.

The key part of our model is the sparse *probit-sparsified covariance*  $\Phi(\mathbf{g})\Phi(\mathbf{g})^T \circ K$  where the “on-off” state  $\Phi(\mathbf{g})$  has the ability to zero out rows and columns of the kernel matrix at the “off” states (See Figure 2f for the probit pattern  $\Phi(\mathbf{g})\Phi(\mathbf{g})^T$  and Figure 2b for the resulting sparse kernel). Since the sparse kernel is represented as Hadamard product between a covariance kernel  $K$  and an outer product kernel  $\Phi(\mathbf{g})\Phi(\mathbf{g})^T$ , Schur product theorem implies that it is a valid kernel. As the sparsity  $g(\mathbf{x})$  converges towards minus infinity, the probit link  $\Phi(g(\mathbf{x}))$  approaches zero, which leads the function distribution approaching  $\mathcal{N}(f_i|0, 0)$ , or  $f_i = 0$ . Numerical problems are avoided since in practice  $\Phi(g) > 0$ , and due to the conditioning noise variance term  $\sigma_y^2 > 0$ .

The marginal likelihood of the zero-inflated Gaussian process is intractable due to the probit-sparsification of the kernel. We derive a stochastic variational Bayes approximation, which we show to be tractable due to the choice of using the probit link function.

#### 3.1 STOCHASTIC VARIATIONAL INFERENCE

Inference for standard Gaussian process models is difficult to scale as complexity grows with  $\mathcal{O}(n^3)$  as a function of the data size  $n$ . Titsias (2009) proposed a variational inference approach for GPs using  $m < n$  inducing variables, with a reduced computational complexity of  $\mathcal{O}(m^3)$  for  $m$  inducing points. The novelty of this approach lies in the idea that the locations and values of inducing points can be treated as variational parameters, and optimized. Hensman et al. (2013, 2015) introduced more efficient stochastic variational inference (SVI) with factorised likelihoods that has been demonstrated with up to billion data points (Salimbeni & Deisenroth, 2017). This approach cannot be directly applied to sparse kernels due to having to compute expectation of the probit product in the covariance. We derive

the SVI bound tractably for the zero-inflated model and its sparse kernel, which is necessary in order to apply the efficient parameter estimation techniques with automatic differentiation with frameworks such as TensorFlow (Abadi et al., 2016).

We begin by applying the inducing point augmentations  $f(\mathbf{z}_f) = \mathbf{u}_f$  and  $g(\mathbf{z}_g) = \mathbf{u}_g$  for both the latent function  $f(\cdot)$  and the sparsity function  $g(\cdot)$ . We place  $m$  inducing points  $\mathbf{u}_{f1}, \dots, \mathbf{u}_{fm}$  and  $\mathbf{u}_{g1}, \dots, \mathbf{u}_{gm}$  for the two functions. The augmented joint distribution is  $p(\mathbf{y}, \mathbf{f}, \mathbf{g}, \mathbf{u}_f, \mathbf{u}_g) = p(\mathbf{y}|\mathbf{f})p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f)p(\mathbf{g}|\mathbf{u}_g)p(\mathbf{u}_f)p(\mathbf{u}_g)$ , where<sup>3</sup>

$$p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f) = \mathcal{N}(\mathbf{f}|\text{diag}(\Phi(\mathbf{g}))Q_f\mathbf{u}_f, \Phi(\mathbf{g})\Phi(\mathbf{g})^T \circ \tilde{K}_f) \quad (13)$$

$$p(\mathbf{g}|\mathbf{u}_g) = \mathcal{N}(\mathbf{g}|Q_g\mathbf{u}_g, \tilde{K}_g) \quad (14)$$

$$p(\mathbf{u}_f) = \mathcal{N}(\mathbf{u}_f|\mathbf{0}, K_{fmm}) \quad (15)$$

$$p(\mathbf{u}_g) = \mathcal{N}(\mathbf{u}_g|\mathbf{0}, K_{gmm}) \quad (16)$$

and where

$$Q_f = K_{fnm}K_{fmm}^{-1} \quad (17)$$

$$Q_g = K_{gnm}K_{gmm}^{-1} \quad (18)$$

$$\tilde{K}_f = K_{fnn} - K_{fnm}K_{fmm}^{-1}K_{fmn} \quad (19)$$

$$\tilde{K}_g = K_{gnn} - K_{gnm}K_{gmm}^{-1}K_{gmn}. \quad (20)$$

We denote the kernels for functions  $f$  and  $g$  by the corresponding subscripts. The kernel  $K_{fnn}$  is between all  $n$  data points, the kernel  $K_{fnm}$  is between all  $n$  datapoints and  $m$  inducing points, and the kernel  $K_{fmm}$  is between all  $m$  inducing points (similarly for  $g$  as well).

The distributions  $p(\mathbf{f}|\mathbf{u}_f)$  and  $p(\mathbf{g}|\mathbf{u}_g)$  can be obtained by conditioning the joint GP prior between respective latent and inducing functions. Further, the conditional distribution  $p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f)$  can be obtained by the sparsity augmentation of latent conditional  $\mathbf{f}|\mathbf{u}_f$  similar to equation (10) (See Supplements).

Next we use the standard variational approach by introducing approximative variational distributions for the inducing points,

$$q(\mathbf{u}_f) = \mathcal{N}(\mathbf{u}_f|\mathbf{m}_f, \mathbf{S}_f) \quad (21)$$

$$q(\mathbf{u}_g) = \mathcal{N}(\mathbf{u}_g|\mathbf{m}_g, \mathbf{S}_g) \quad (22)$$

where  $\mathbf{S}_f, \mathbf{S}_g \in \mathbb{R}^{m \times m}$  are square positive semi-definite matrices. The variational joint posterior is

$$q(\mathbf{f}, \mathbf{g}, \mathbf{u}_f, \mathbf{u}_g) = p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f)p(\mathbf{g}|\mathbf{u}_g)q(\mathbf{u}_f)q(\mathbf{u}_g). \quad (23)$$

<sup>3</sup>We drop the implicit conditioning on  $\mathbf{z}$ 's for clarity.

We minimize the Kullback-Leibler divergence between the true augmented posterior  $p(\mathbf{f}, \mathbf{g}, \mathbf{u}_f, \mathbf{u}_g|\mathbf{y})$  and the variational distribution  $q(\mathbf{f}, \mathbf{g}, \mathbf{u}_f, \mathbf{u}_g)$ , which is equivalent to solving the following evidence lower bound (as shown by e.g. Hensman et al. (2015)):

$$\log p(\mathbf{y}) \geq \mathbb{E}_{q(\mathbf{f})} \log p(\mathbf{y}|\mathbf{f}) - \text{KL}[q(\mathbf{u}_f, \mathbf{u}_g)||p(\mathbf{u}_f, \mathbf{u}_g)], \quad (24)$$

where we define

$$\begin{aligned} q(\mathbf{f}) &= \iiint p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f)q(\mathbf{u}_f)p(\mathbf{g}|\mathbf{u}_g)q(\mathbf{u}_g)d\mathbf{u}_fd\mathbf{u}_gd\mathbf{g} \\ &= \int q(\mathbf{f}|\mathbf{g})q(\mathbf{g})d\mathbf{g}, \end{aligned} \quad (25)$$

where the variational approximations are tractably

$$\begin{aligned} q(\mathbf{g}) &= \int p(\mathbf{g}|\mathbf{u}_g)q(\mathbf{u}_g)d\mathbf{u}_g \\ &= \mathcal{N}(\mathbf{g}|\boldsymbol{\mu}_g, \Sigma_g) \end{aligned} \quad (26)$$

$$\begin{aligned} q(\mathbf{f}|\mathbf{g}) &= \int p(\mathbf{f}|\mathbf{g}, \mathbf{u}_f)q(\mathbf{u}_f)d\mathbf{u}_f \\ &= \mathcal{N}(\mathbf{f}|\text{diag}(\Phi(\mathbf{g}))\boldsymbol{\mu}_f, \Phi(\mathbf{g})\Phi(\mathbf{g})^T \circ \Sigma_f) \end{aligned} \quad (27)$$

with

$$\boldsymbol{\mu}_f = Q_f\mathbf{m}_f \quad (28)$$

$$\boldsymbol{\mu}_g = Q_g\mathbf{m}_g \quad (29)$$

$$\Sigma_f = K_{fnn} + Q_f(\mathbf{S}_f - K_{fmm})Q_f^T \quad (30)$$

$$\Sigma_g = K_{gnn} + Q_g(\mathbf{S}_g - K_{gmm})Q_g^T. \quad (31)$$

We additionally assume the likelihood  $p(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^N p(y_i|f_i)$  factorises.

We solve the final ELBO of equations (24) and (25) as (See Supplements for detailed derivation)

$$\begin{aligned} \mathcal{L}_{\text{ZI}} &= \sum_{i=1}^N \left\{ \log \mathcal{N}(y_i|\langle \Phi(g_i) \rangle_{q(g_i)}\mu_{fi}, \sigma_{fi}^2) \right. \\ &\quad \left. - \frac{1}{2\sigma_{fi}^2} (\text{Var}[\Phi(g_i)]\mu_{fi}^2 + \langle \Phi(g_i)^2 \rangle_{q(g_i)}\sigma_{fi}^2) \right\} \\ &\quad - \text{KL}[q(\mathbf{u}_f)||p(\mathbf{u}_f)] - \text{KL}[q(\mathbf{u}_g)||p(\mathbf{u}_g)], \end{aligned} \quad (32)$$

where  $\mu_{fi}$  is the  $i$ 'th element of  $\boldsymbol{\mu}_f$  and  $\sigma_{fi}^2$  is the  $i$ 'th diagonal element of  $\Sigma_f$  (similarly with  $g$ ).

The expectations are tractable,

$$\langle \Phi(g_i) \rangle_{q(g_i)} = \Phi(\lambda_{gi}), \quad \lambda_{gi} = \frac{\mu_{gi}}{\sqrt{1 + \sigma_{gi}^2}} \quad (33)$$

$$\langle \Phi(g_i)^2 \rangle_{q(g_i)} = \Phi(\lambda_{gi}) - 2T\left(\lambda_{gi}, \frac{\lambda_{gi}}{\mu_{gi}}\right) \quad (34)$$

$$\text{Var}[\Phi(g_i)] = \Phi(\lambda_{gi}) - 2T\left(\lambda_{gi}, \frac{\lambda_{gi}}{\mu_{gi}}\right) - \Phi(\lambda_{gi})^2. \quad (35)$$

The Owen's T function  $T(a, b) = \phi(a) \int_0^b \frac{\phi(a\tau)}{1+\tau^2} d\tau$  (Owen, 1956) has efficient numerical solutions in practise (Patefield & Tandy, 2000).

The ELBO is considerably more complex than the standard stochastic variational bound of a Gaussian process (Hensman et al., 2013), due to the probit-sparsified covariance.

The bound is likely only tractable for the choice of probit link function  $\Phi(\mathbf{g})$ , while other link functions such as the logit would lead to intractable bounds necessitating slower numerical integration (Hensman et al., 2015).

We optimize the  $\mathcal{L}_{\text{ZI}}$  with stochastic gradient ascent techniques with respect to the inducing locations  $\mathbf{z}_g, \mathbf{z}_f$ , inducing value means  $\mathbf{m}_f, \mathbf{m}_g$  and covariances  $\mathbf{S}_f, \mathbf{S}_g$ , the sparsity prior mean  $\beta$ , the noise variance  $\sigma_y^2$ , the signal variances  $\sigma_f, \sigma_g$ , and finally the dimensions-specific lengthscales  $\ell_{f1}, \dots, \ell_{fD}; \ell_{g1}, \dots, \ell_{gD}$  of the Gaussian ARD kernel.

## 4 GAUSSIAN PROCESS NETWORK

The Gaussian Process Regression Networks (GPRN) framework by Wilson et al. (2012) is an efficient model for multi-target regression problems, where each individual output is a linear but non-stationary combination of shared latent functions. Formally, a vector-valued output function  $\mathbf{y}(\mathbf{x}) \in \mathbb{R}^P$  with  $P$  outputs is modeled using vector-valued latent functions  $\mathbf{f}(\mathbf{x}) \in \mathbb{R}^Q$  with  $Q$  latent values and mixing weights  $W(\mathbf{x}) \in \mathbb{R}^{P \times Q}$  as

$$\mathbf{y}(x) = W(x)[\mathbf{f}(x) + \boldsymbol{\epsilon}] + \boldsymbol{\varepsilon}, \quad (36)$$

where for all  $q = 1, \dots, Q$  and  $p = 1, \dots, P$  we assume GP priors and additive zero-mean noises,

$$f_q(\mathbf{x}) \sim \mathcal{GP}(0, K_f(\mathbf{x}, \mathbf{x}')) \quad (37)$$

$$W_{qp}(\mathbf{x}) \sim \mathcal{GP}(0, K_w(\mathbf{x}, \mathbf{x}')) \quad (38)$$

$$\epsilon_q \sim \mathcal{N}(0, \sigma_f^2) \quad (39)$$

$$\varepsilon_p \sim \mathcal{N}(0, \sigma_y^2). \quad (40)$$

The subscripts are used to denote individual components of  $\mathbf{f}$  and  $W$  with  $p$  and  $q$  indicating  $p^{\text{th}}$  output dimension and  $q^{\text{th}}$  latent dimension, respectively. We assume shared latent and output noise variances  $\sigma_f^2, \sigma_y^2$  without loss of generality. The distributions of both functions  $\mathbf{f}$  and  $W$  have been inferred either with variational EM (Wilson et al., 2012) or by variational mean-field approximation with diagonalized latent and mixing functions (Nguyen & Bonilla, 2013).

### 4.1 STOCHASTIC VARIATIONAL INFERENCE

Variational inference for GPRN has been proposed earlier with diagonalized mean-field approximation by (Nguyen & Bonilla, 2013). Further, stochastic variational inference by introducing inducing variables has been proposed for GPRN (Nguyen et al., 2014). In this section we rederive the SVI bound for standard GPRN for completeness and then propose the novel sparse GPRN model, and solve its SVI bounds as well, in the following section.

We begin by introducing the inducing variable augmentation technique for latent functions  $\mathbf{f}(\mathbf{x})$  and mixing weights  $W(\mathbf{x})$  with  $\mathbf{u}_f, \mathbf{z}_f = \{\mathbf{u}_{f_q}, \mathbf{z}_{f_q}\}_{q=1}^Q$  and  $\mathbf{u}_w, \mathbf{z}_w = \{\mathbf{u}_{w_{qp}}, \mathbf{z}_{w_{qp}}\}_{q,p=1}^{Q,P}$ :

$$p(\mathbf{y}, \mathbf{f}, W, \mathbf{u}_f, \mathbf{u}_w) \quad (41)$$

$$= p(\mathbf{y}|\mathbf{f}, W)p(\mathbf{f}|\mathbf{u}_f)p(W|\mathbf{u}_w)p(\mathbf{u}_f)p(\mathbf{u}_w)$$

$$p(\mathbf{f}|\mathbf{u}_f) = \prod_{q=1}^Q \mathcal{N}(\mathbf{f}_q | Q_{f_q} \mathbf{u}_{f_q}, \tilde{K}_{f_q}) \quad (42)$$

$$p(W|\mathbf{u}_w) = \prod_{q,p=1}^{Q,P} \mathcal{N}(\mathbf{w}_{qp} | Q_{w_{qp}} \mathbf{u}_{w_{qp}}, \tilde{K}_{w_{qp}}) \quad (43)$$

$$p(\mathbf{u}_f) = \prod_{q=1}^Q \mathcal{N}(\mathbf{u}_{f_q} | \mathbf{0}, K_{f_q, mm}) \quad (44)$$

$$p(\mathbf{u}_w) = \prod_{q,p=1}^{Q,P} \mathcal{N}(\mathbf{u}_{w_{qp}} | \mathbf{0}, K_{w_{qp}, mm}), \quad (45)$$

where we have separate kernels  $K$  and extrapolation matrices  $Q$  for each component of  $W(\mathbf{x})$  and  $\mathbf{f}(\mathbf{x})$

that are of the same form as in equations (17–20). The  $\mathbf{w}$  is a vectorised form of  $W$ . The variational approximation is then

$$q(\mathbf{f}, W, \mathbf{u}_f, \mathbf{u}_w) = p(\mathbf{f}|\mathbf{u}_f)p(W|\mathbf{u}_w)q(\mathbf{u}_f)q(\mathbf{u}_w) \quad (46)$$

$$q(\mathbf{u}_{f_q}) = \prod_{q=1}^Q \mathcal{N}(\mathbf{u}_{f_q}|\mathbf{m}_{f_q}, \mathbf{S}_{f_q}) \quad (47)$$

$$q(\mathbf{u}_{w_{qp}}) = \prod_{q,p=1}^{Q,P} \mathcal{N}(\mathbf{u}_{w_{qp}}|\mathbf{m}_{w_{qp}}, \mathbf{S}_{w_{qp}}), \quad (48)$$

where  $\mathbf{u}_{w_{qp}}$  and  $\mathbf{u}_{f_q}$  indicate the inducing points for the functions  $W_{qp}(\mathbf{x})$  and  $f_q(\mathbf{x})$ , respectively. The ELBO can be now stated as

$$\log p(\mathbf{y}) \geq \mathbb{E}_{q(\mathbf{f}, W)} \log p(\mathbf{y}|\mathbf{f}, W) - \text{KL}[q(\mathbf{u}_f, \mathbf{u}_w)||p(\mathbf{u}_f, \mathbf{u}_w)], \quad (49)$$

where the variational distributions decompose as  $q(\mathbf{f}, W) = q(\mathbf{f})q(W)$  with marginals of the same form as in equations (28–31),

$$q(\mathbf{f}) = \int q(\mathbf{f}|\mathbf{u}_f)q(\mathbf{u}_f)d\mathbf{u}_f = \mathcal{N}(\mathbf{f}|\boldsymbol{\mu}_f, \Sigma_f) \quad (50)$$

$$q(W) = \int q(W|\mathbf{u}_w)q(\mathbf{u}_w)d\mathbf{u}_w = \mathcal{N}(\mathbf{w}|\boldsymbol{\mu}_w, \Sigma_w). \quad (51)$$

Since the noise term  $\boldsymbol{\varepsilon}$  is assumed to be isotropic Gaussian, the density  $p(\mathbf{y}|W, \mathbf{f})$  factorises across all target observations and dimensions. The expectation term in equation (49) then reduces to solving the following integral for the  $i^{\text{th}}$  observation and  $p^{\text{th}}$  target dimension,

$$\sum_{i,p=1}^{N,P} \iint \log \mathcal{N}(y_{p,i}|\mathbf{w}_{p,i}^T \mathbf{f}_i, \sigma_y^2) q(\mathbf{f}_i, \mathbf{w}_{p,i}) d\mathbf{w}_{p,i} d\mathbf{f}_i. \quad (52)$$

The above integral has a closed form solution resulting in the final ELBO as (See Supplements)

$$\begin{aligned} \mathcal{L}_{\text{GPRN}} &= \sum_{i=1}^N \left\{ \sum_{p=1}^P \log \mathcal{N}(y_{p,i} | \sum_{q=1}^Q \mu_{w_{qp},i} \mu_{f_q,i}, \sigma_y^2) \right. \\ &\quad \left. - \frac{1}{2\sigma_y^2} \sum_{q,p=1}^{Q,P} \left( \mu_{w_{qp},i}^2 \sigma_{f_q,i}^2 + \mu_{f_q,i}^2 \sigma_{w_{qp},i}^2 + \sigma_{w_{qp},i}^2 \sigma_{f_q,i}^2 \right) \right\} \\ &\quad - \sum_{q,p=1}^{Q,P} \text{KL}[q(\mathbf{u}_{w_{qp}}, \mathbf{u}_{f_q})||p(\mathbf{u}_{w_{qp}}, \mathbf{u}_{f_q})], \quad (53) \end{aligned}$$

where  $\mu_{f_q,i}$  is the  $i^{\text{th}}$  element of  $\boldsymbol{\mu}_{f_q}$  and  $\sigma_{f_q,i}^2$  is the  $i^{\text{th}}$  diagonal element of  $\Sigma_{f_q}$  (similarly for the  $W_{qp}$ 's).

## 5 SPARSE GAUSSIAN PROCESS NETWORK

In this section we demonstrate how zero-inflated GPs can be used as plug-in components in other standard models. In particular, we propose a significant modification to GPRN by adding sparsity to the mixing matrix components. This corresponds to each of the  $p$  outputs being a sparse mixture of the latent  $Q$  functions, i.e. they can effectively use any subset of the  $Q$  latent dimensions by having zeros for the rest in the mixing functions. This makes the mixture more easily interpretable, and induces a variable number of latent functions to explain the output of each input  $\mathbf{x}$ . The latent function  $\mathbf{f}$  can also be sparsified, with a derivation analogous to the derivation below.

We extend the GPRN with probit sparsity for the mixing matrix  $W$ , resulting in a joint model

$$p(\mathbf{y}, \mathbf{f}, W, \mathbf{g}) = p(\mathbf{y}|\mathbf{f}, W)p(\mathbf{f})p(W|\mathbf{g})p(\mathbf{g}), \quad (54)$$

where all individual components of the latent function  $\mathbf{f}$  and mixing matrix  $W$  are given GP priors. We encode the sparsity terms  $\mathbf{g}$  for all the  $Q \times P$  mixing functions  $W_{qp}(\mathbf{x})$  as

$$p(W_{qp}|\mathbf{g}_{qp}) = \mathcal{N}(\mathbf{w}_{qp}|\mathbf{0}, \Phi(\mathbf{g}_{qp})\Phi(\mathbf{g}_{qp})^T \circ K_w). \quad (55)$$

To introduce variational inference, the joint model is augmented with three sets of inducing variables for  $\mathbf{f}$ ,  $W$  and  $\mathbf{g}$ . After marginalizing out the inducing variables as in equations (25–27), the marginal likelihood can be written as

$$\log p(\mathbf{y}) \geq \mathbb{E}_{q(\mathbf{f}, W, \mathbf{g})} \log p(\mathbf{y}|\mathbf{f}, W) - \text{KL}[q(\mathbf{u}_f, \mathbf{u}_w, \mathbf{u}_g)||p(\mathbf{u}_f, \mathbf{u}_w, \mathbf{u}_g)]. \quad (56)$$

The joint distribution in the variational expectation factorizes as  $q(\mathbf{f}, W, \mathbf{g}) = q(\mathbf{f})q(W|\mathbf{g})q(\mathbf{g})$ . Also, with a Gaussian noise assumption, the expectation term factorizes across all the observations and target dimensions. The key step reduces to solving the following integrals:

$$\sum_{i,p=1}^{N,P} \iiint \log \mathcal{N}(y_{p,i} | (\mathbf{w}_{p,i} \circ \mathbf{g}_{p,i})^T \mathbf{f}_i, \sigma_y^2) \cdot q(\mathbf{f}_i, \mathbf{w}_{p,i}, \mathbf{g}_{p,i}) d\mathbf{w}_{p,i} d\mathbf{f}_i d\mathbf{g}_{p,i}. \quad (57)$$

The above integral has a tractable solution leading to the final sparse GPRN evidence lower bound (See Supplements)

$$\begin{aligned}
\mathcal{L}_{\text{sGPRN}} = & \sum_{i=1}^N \left\{ \sum_{p=1}^P \log \mathcal{N}(y_{p,i} | \sum_{q=1}^Q \mu_{w_{qp},i} \mu_{g_{qp},i} \mu_{f_q,i}, \sigma_y^2) \right. \\
& - \frac{1}{2\sigma_y^2} \sum_{q,p=1}^{Q,P} \left( (\mu_{g_{qp},i}^2 + \sigma_{g_{qp},i}^2) \right. \\
& \quad \cdot (\mu_{w_{qp},i}^2 \sigma_{f_q,i}^2 + \mu_{f_q,i}^2 \sigma_{w_{qp},i}^2 + \sigma_{w_{qp},i}^2 \sigma_{f_q,i}^2) \\
& \quad \left. \left. - \frac{1}{2\sigma_y^2} \sum_{q,p=1}^{Q,P} \left( \sigma_{g_{qp},i}^2 \mu_{f_q,i}^2 \mu_{w_{qp},i}^2 \right) \right\} \right. \\
& \left. - \sum_{q,p}^{Q,P} \text{KL}[q(\mathbf{u}_{f_q}, \mathbf{u}_{w_{qp}}, \mathbf{u}_{g_{qp}}) || p(\mathbf{u}_{f_q}, \mathbf{u}_{w_{qp}}, \mathbf{u}_{g_{qp}})], \right.
\end{aligned} \tag{58}$$

where  $\mu_{f_q,i}, \mu_{w_{qp},i}$  are the variational expectation means for  $\mathbf{f}(\cdot), W(\cdot)$  as in equations (28, 29),  $\mu_{g_{qp},i}$  is the variational expectation mean of  $g(\cdot)$  as in equation (33), and analogously for the variances.

## 6 EXPERIMENTS

First we demonstrate how the proposed method can be used for regression problems with zero-inflated targets. We do that both on a simulated dataset and for real-world climate modeling scenarios on a Finnish rain precipitation dataset with approximately 90% zeros. Finally, we demonstrate the GPRN model and how it improves both the interpretability and predictive performance in the JURA geological dataset.

We use the squared exponential kernel with ARD in all experiments. All the parameters including inducing locations, values and variances and kernel parameters were learned through stochastic Adam optimization (Kingma & Ba, 2014) on the TensorFlow (Abadi et al., 2016) platform.

We compare our approach ZIGP to baseline ZERO voting, to conventional Gaussian process regression (GPR) and classification (GPC) with SVI approximations from the GPflow package (Matthews et al., 2017). Finally, we also compare to first classifying the non-zeros, and successively applying regression either to all data points (GPCR), or to only predicted non-zeros (GPCR<sub>≠0</sub>, hurdle model).

We record the predictive performance by considering mean squared error and mean absolute error. We also compare the models' ability to predict true zeros with F1, accuracy, precision, and recall of the optimal models.

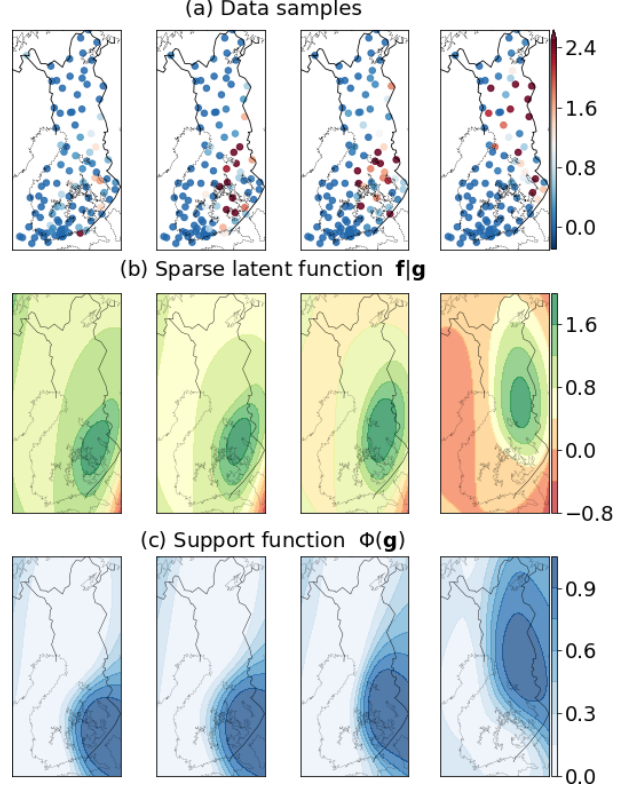

Figure 3: ZIGP model fit on the precipitation dataset. Sample of the actual data (a) against the sparse rain function estimate (b), with the probit support function (c) showing the rain progress.

### 6.1 SPATIO-TEMPORAL DATASET

Zero-inflated cases are commonly found in climatology and ecology domains. In this experiment we demonstrate the proposed method by modeling precipitation in Finland<sup>4</sup>. The dataset consists of hourly quantitative non-negative observations of precipitation amount across 105 observatory locations in Finland for the month of July 2018. The dataset contains 113015 datapoints with approximately 90% zero precipitation observations. The data inputs are three-dimensional: latitude, longitude and time. Due to the size of the data, this experiment illustrates the scalability of the variational inference.

We randomly split 80% of the data for training and the rest 20% for testing purposes. We split across time only, such that at a single measurement time, all locations are simultaneously either in the training set, or in the test set.

<sup>4</sup>Data can be found at <http://en.ilmatieteenlaitos.fi/>

Table 1: Results for the precipitation dataset over baseline (Zero; majority voting), four competing methods and the proposed method ZiGP on test data. The columns list both quantitative and qualitative performance criteria, best performance is boldfaced.

MODEL	RMSE	MAE	F1	ACC.	PREC.	RECALL
ZERO	0.615	0.104	0.000	0.898	0.000	0.000
GPC	-	-	0.367	<b>0.911</b>	0.675	0.252
GPR	0.569	0.159	0.401	0.750	0.266	<b>0.817</b>
GPCR	0.589	<b>0.102</b>	0.366	<b>0.911</b>	0.679	0.251
GPCR <sub>≠0</sub>	0.575	<b>0.101</b>	0.358	<b>0.912</b>	<b>0.712</b>	0.240
ZiGP	<b>0.561</b>	0.121	<b>0.448</b>	0.861	0.381	0.558

We further utilize the underlying spatio-temporal grid structure of the data to perform inference in an efficient manner by Kronecker techniques (Saatchi, 2011). All the kernels for latent processes are assumed to factorise as  $\mathbf{K} = \mathbf{K}_{space} \otimes \mathbf{K}_{time}$  which allows placing inducing points independently on spatial and temporal grids.

Figure 4: The distribution of errors with the rain dataset with the ZiGP and the GPR. The zero-inflated GP achieves much higher number of perfect (zero) predictions.

Figure 3 depicts the components of the zero-inflated GP model on the precipitation dataset. As shown in panel (c), the latent support function models the presence or absence of rainfall. It smoothly follows the change in rain patterns across hourly observations. The amount of precipitation is modeled by the other latent process and the combination of these two results in sparse predictions. Figure 4 shows that the absolute error distribution is remarkably better with the ZiGP model due to it identifying the absence of rain exactly. While both models fit the high rainfall regions well, for zero and near-zero regions GPR does not refine its small errors. Table 1 indicates that the ZiGP model achieves the lowest mean square error, while also achieving the highest F1 score that takes into account the class imbalance,

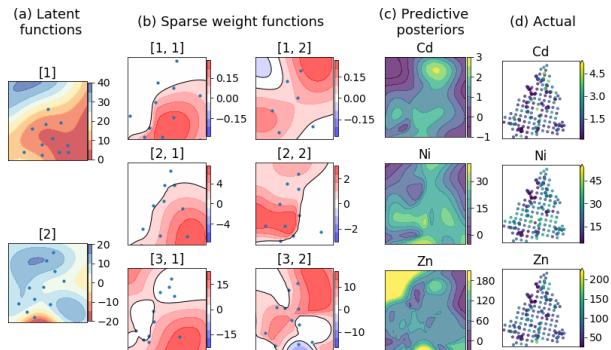

Figure 5: The sparse GPRN model fit on the Jura dataset with 11 inducing points. The  $Q = 2$  (dense) latent functions (a) are combined with the  $3 \times 2$  sparse mixing functions (b) into the  $P = 3$  output predictions (c). The real data are shown in (d). The white mixing regions are estimated ‘off’.

which biases the elementary accuracy, precision and recall quantities towards the majority class.

## 6.2 MULTI-OUTPUT PREDICTION - JURA

In this experiment we model the multi-response Jura dataset with the sparse Gaussian process regression network sGPRN model and compare it with standard GPRN as baseline. Jura contains concentration measurements of cadmium, nickel and zinc metals in the region of Swiss Jura. We follow the experimental procedure of Wilson et al. (2012) and Nguyen & Bonilla (2013). The training set consists of  $n = 259$  observations across  $D = 2$  dimensional geo-spatial locations, and the test set consists of 100 separate locations. For both models we use  $Q = 2$  latent functions with the stochastic variational inference techniques proposed in this paper. Sparse GPRN uses a sparsity inducing kernel in the mixing weights. The locations of inducing points for the weights  $W(\mathbf{x})$  and the support  $g(\mathbf{x})$  are shared. The kernel length-scales are given a gamma prior with the shape parameter  $\alpha = 0.3$  and rate parameter  $\beta = 1.0$  to induce smoothness. We train both the models 30 times with random initialization.

Table 2 shows that our model performs better than the state-of-the-art SVI-GPRN, both with  $m = 5$  and  $m = 10$  inducing points. Figure 5 visualises the optimized sparse GPRN model, while Figure 6 indicates the sparsity pattern in the mixing weights. The weights have considerable smooth ‘on’ regions (black) and ‘off’ regions (white). The ‘off’ regions indicate that for certain locations, only one of the two latent functions is adaptively utilised.

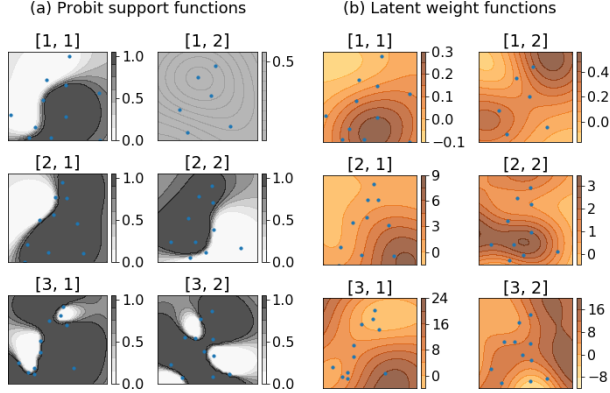

Figure 6: The sparse probit support (a) and latent functions (b) of the weight function  $W(\mathbf{x})$  of the optimized sparse GPRN model. The black regions of (a) show regional activations, while the white regions show where the latent functions are ‘off’. The elementwise product of the support and weight functions is indicated in the Figure 5b).

Table 2: Results for the Jura dataset for sparse GPRN and vanilla GPRN models with test data. Best performance is with boldface. We do not report RMSE and MAE values GPC, since its a classification method.

MODEL	$m$	CADMIUM		NICKEL		ZINC	
		RMSE	MAE	RMSE	MAE	RMSE	MAE
GPRN	5	0.724	0.566	<b>6.469</b>	<b>4.958</b>	33.729	21.959
	10	0.736	0.574	6.626	5.109	34.923	22.544
	15	0.749	0.590	6.526	5.033	35.033	22.670

### 6.3 MULTI-OUTPUT PREDICTION - SARCOS

In this experiment we tackle the problem of learning inverse dynamics for seven degrees of freedom of SARCOS anthropomorphic robot arm (Vijayakumar et al., 2005). The dataset consists of 48,933 observations with an input space of 21 dimensions (7 joints positions, 7 joint velocities, 7 joint accelerations). The multi-output prediction task is to learn a mapping from these input variables to the corresponding 7 joint torques of the robot. Multi-output GP has been previously used for inverse dynamics modeling (Williams et al., 2009), but in a different model setting and on a smaller dataset. GPRN with stochastic inference framework has also been explored to model SARCOS dataset (Nguyen et al., 2014), however, they use a different experimental setting and consider 2 of the 7 joint torques as multi-output targets.

Table 3: Normalized MSE results on the SARCOS test data for sparse GPRN and standard GPRN models. Best performance is mentioned with boldface.

MODEL		$m = 50$	$m = 100$	$m = 150$
GPRN	$Q = 2$	0.0167	0.0145	0.0127
	$Q = 3$	0.0146	0.0121	0.0108
sGPRN	$Q = 2$	<b>0.0159</b>	<b>0.0131</b>	<b>0.0125</b>
	$Q = 3$	<b>0.0140</b>	<b>0.0117</b>	<b>0.0096</b>

We consider 80%+20% random split of the full dataset for training and testing respectively. Both GPRN and sGPRN model are trained with  $m = 50, 100$  and  $150$  inducing points and  $Q = 2$  and  $3$  latent functions. We repeat the experiment 20 times and report normalized-MSE in Table 3. Sparse GPRN gives better results than standard GPRN in all our experimental settings. Moreover, sparse model (nMSE= 0.0096) gives gives 12% improvement over the standard model (nMSE= 0.0108) for the best test performance with  $Q = 3$  latent functions and  $m = 150$ .

## 7 DISCUSSION

We proposed a novel paradigm of zero-inflated Gaussian processes with a novel sparse kernel. The sparsity in the kernel is modeled with smooth probit filtering of the covariance rows and columns. This model induces zeros in the prediction function outputs, which is highly useful for zero-inflated datasets with excess of zero observations. Furthermore, we showed how the zero-inflated GP can be used to model sparse mixtures of latent signals with the proposed sparse Gaussian process network. The latent mixture model with sparse mixing coefficients leads to locally using only a subset of the latent functions, which improves interpretability and reduces model complexity. We demonstrated tractable solutions to stochastic variational inference of the sparse probit kernel for the zero-inflated GP, conventional GPRN, and sparse GPRN models, which leads to efficient exploration of the parameter space of the model.

## Abstract

We present KBLRN, a framework for end-to-end learning of knowledge base representations from latent, relational, and numerical features. KBLRN integrates feature types with a novel combination of neural representation learning and probabilistic product of experts models. To the best of our knowledge, KBLRN is the first approach that learns representations of knowledge bases by integrating latent, relational, and numerical features. We show that instances of KBLRN outperform existing methods on a range of knowledge base completion tasks. We contribute a novel data set enriching commonly used knowledge base completion benchmarks with numerical features. The data sets are available under a permissive BSD-3 license<sup>1</sup>. We also investigate the impact numerical features have on the KB completion performance of KBLRN.

## 1 INTRODUCTION

The importance of knowledge bases (KBs) for AI systems has been demonstrated in numerous application domains. KBs provide ways to organize, manage, and retrieve structured data and allow AI system to perform reasoning. In recent years, KBs have been playing an increasingly crucial role in AI applications. Purely logical representations of knowledge bases have a long history in AI [27]. However, they suffer from being inefficient and brittle. Inefficient because the computational complexity of reasoning is exponential in the worst case and, therefore, the time required by a reasoner highly unpredictable. Brittle because a purely logical KB requires a large set of logical rules that are handcrafted and/or

<sup>1</sup><https://github.com/nle-ml/mmkb>

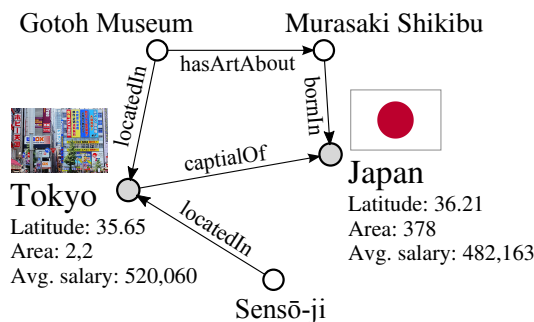

Figure 1: A small part of a knowledge base.

mined. These problems are even more pressing in applications whose environments are changing over time.

Motivated by these shortcomings, there has been a flurry of work on combining logical and statistical approaches to build systems capable of reasoning over and learning from incomplete structured data. Most notably, the statistical relational learning community has proposed numerous formalisms that combine logic and probability [24]. These formalisms are able to address the learning problem and make the resulting AI systems more robust to missing data and missing rules. Intuitively, logical formulas act as relational features and the probability of a possible world is determined by a sufficient statistic for the values of these features. These approaches, however, are in most cases even less efficient because logical inference is substituted with probabilistic inference.

More recently, the research community has focused on efficient machine learning models that perform well on restricted tasks such as link prediction in KBs. Examples are knowledge base factorization and embedding approaches [3, 21, 11, 20] and random-walk based ML models [15, 7]. The former learn latent features for the entities and relations in the knowledge base and use those to perform link prediction. The latter explore specific re-

lational features such as path types between two entities and train a machine learning model for link prediction.

With this work, we propose KBLRN, a novel approach to combining relational, latent (learned), and numerical features, that is, features that can take on a large or infinite number of real values. The combination of various features types is achieved by integrating embedding-based learning with probabilistic models in two ways. First, we show that modeling numerical features with radial basis functions is beneficial and can be integrated in an end-to-end differentiable learning system. Second, we propose a probabilistic product of experts (PoE) [13] approach to combine the feature types. Instead of training the PoE with contrastive divergence, we approximate the partition function with a negative sampling strategy. The PoE approach has the advantage of being able to train the model jointly and end-to-end.

The paper is organized as follows. First, we discuss relational, latent, and numerical features. Second, we describe KBLRN. Third, we present empirical evidence that instances of KBLRN outperform state of the art methods for KB completion. We also investigate in detail under what conditions numerical features are beneficial.

## 2 RELATIONAL, LATENT, AND NUMERICAL FEATURES

We assume that the facts of a knowledge base (KB) are given as a set of triples of the form  $(h, r, t)$  where  $h$  and  $t$  are the head and tail entities and  $r$  is a relation type. Figure 1 depicts a small fragment of a KB with relations and numerical features. KB completion is the problem of answering queries of the form  $(?, r, t)$  or  $(h, r, ?)$ . While the proposed approach can be generalized to more complex queries, we focus on completion queries for the sake of simplicity. We now discuss the three feature types used in KBLRN and motivate their utility for knowledge base completion. How exactly we extract features from a given KB is described in the experimental section.

### 2.1 Relational Features

Each relational feature is given as a logical formula which is evaluated in the KB to determine the feature’s value. For instance, the formula  $\exists x (A, \text{bornIn}, x) \wedge (x, \text{capitalOf}, B)$  corresponds to a binary feature which is 1 if there exists a path of that type from entity A to entity B, and 0 otherwise. These features are often used in relational models [30, 22] and random-walk based models such as PRA and SFE [15, 7]. In this work, we use relational paths of length one and two and use the rule mining approach AMIE+ [5]. We detail the generation of

the relational features in the experimental section. For a pair of entities  $(h, t)$ , we denote the feature vector computed based on a set of relational features by  $r_{(h,t)}$ .

### 2.2 Latent Features

Numerous embedding methods for KBs have been proposed in recent years [21, 3, 11, 20]. Embedding methods provide fixed-size vector representations (embeddings) for all entities in the KB. In the simplest of cases, relations are modeled as translations in the entity embedding space [3]. We incorporate typical embedding learning objectives into KBLRN and write  $e_h$  and  $e_t$  to refer to an embedding of a head entity and a tail entity, respectively. The advantages of latent feature models are their computational efficiency and their ability to learn latent entity types suitable for downstream ML tasks without hand-crafted or mined logical rules.

### 2.3 Numerical Features

Numerical features are entity features whose values can take on a very large or infinite number of real values. To the best of our knowledge, there does not exist a principled approach that integrates numerical features into a relational ML model for KB completion. This is surprising, considering that numerical data is available in almost all existing large-scale KBs. The assumption that numerical data is helpful for KB completion tasks is reasonable. For several relations types the *differences* between the *head* and *tail* are characteristic of the relation itself. For example, while the mean difference of birth years is 0.4 for the Freebase relation `/people/marriage/spouse`, it is 32.4 for the relation `/person/children`. These observations motivate specifically the use of *differences* of numerical feature values. Taking the difference has the advantage that even if a numerical feature is not distributed according to a normal distribution (e.g., birth years in a KB), the difference is often normally distributed. This is important as we need to fit simple parametric distributions to the sparse numerical data. We detail the fully automated extraction and generation of the numerical features in the experimental section.

## 3 KBLRN: LEARNING END-TO-END JOINT REPRESENTATIONS FOR KNOWLEDGE BASES

With KBLRN we aim to provide a framework for end-to-end learning of KB representations. Since we want to combine different feature types (relational, latent or learned, and numerical) we need to find a suitable

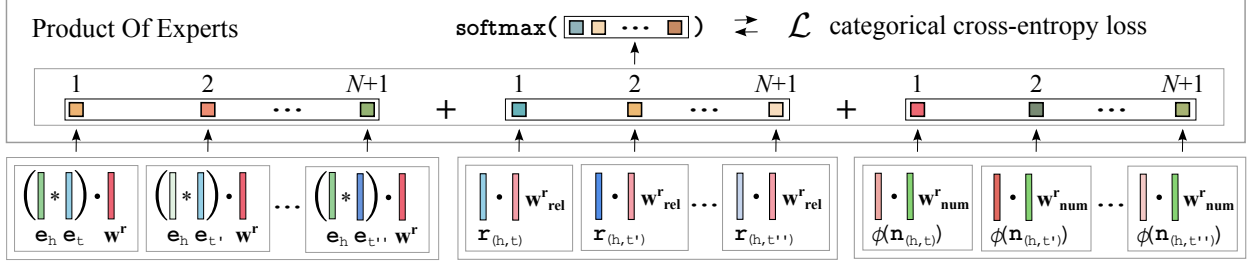

Figure 2: An illustration of an instance of KBLRN implemented with standard deep learning framework components. For every relation type, there is a separate expert for each of the different feature types. The entities  $\tau'$  and  $\tau''$  are two of  $N$  randomly sampled entities. The scores of the various submodels are added and normalized with a softmax function. A categorical cross-entropy loss is applied to the normalized scores.

method for integrating the respective submodels, one per feature type. We propose a product of experts (PoE) approach where one expert is trained for each (relation type, feature type) pair. We extend the product of experts approach in two novel ways. First, we create dependencies between the experts by sharing the parameters of the entity embedding model across relation types. By doing this, we combine a probabilistic model with a model that learns vector representations from discrete and numerical data. Second, while product of experts are commonly trained with contrastive divergence [13], we train it with negative sampling and a cross-entropy loss.

In general, a PoE's probability distribution is

$$p(\mathbf{d} \mid \theta_1, \dots, \theta_n) = \frac{\prod_m f_m(\mathbf{d} \mid \theta_m)}{\sum_c \prod_m f_m(\mathbf{c} \mid \theta_m)},$$

where  $\mathbf{d}$  is a data vector in a discrete space,  $\theta_m$  are the parameters of individual model  $m$ ,  $f_m(\mathbf{d} \mid \theta_m)$  is the value of  $d$  under model  $m$ , and the  $\mathbf{c}$ 's index all possible vectors in the data space. The PoE model is now trained to assign high probability to observed data vectors.

In the KB context, the data vector  $\mathbf{d}$  is always a triple  $\mathbf{d} = (\mathbf{h}, \mathbf{r}, \mathbf{t})$  and the objective is to learn a PoE that assigns high probability to true triples and low probabilities to triples assumed to be false. If  $(\mathbf{h}, \mathbf{r}, \mathbf{t})$  holds in the KB, the pair's vector representations are used as positive training examples. Let  $\mathbf{d} = (\mathbf{h}, \mathbf{r}, \mathbf{t})$ . We can now define one individual expert  $f_{(\mathbf{r}, \mathbf{F})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{F})})$  for each (relation type  $\mathbf{r}$ , feature type  $\mathbf{F}$ ) pair.

The specific experts we utilize here are based on simple linear models and the DistMult embedding method.

$$\begin{aligned} f_{(\mathbf{r}, \mathbf{L})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{L})}) &= \exp((\mathbf{e}_h * \mathbf{e}_t) \cdot \mathbf{w}^{\mathbf{r}}) \\ f_{(\mathbf{r}, \mathbf{R})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{R})}) &= \exp(\mathbf{r}_{(\mathbf{h}, \mathbf{t})} \cdot \mathbf{w}_{\text{rel}}^{\mathbf{r}}) \\ f_{(\mathbf{r}, \mathbf{N})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{N})}) &= \exp(\phi(\mathbf{n}_{(\mathbf{h}, \mathbf{t})}) \cdot \mathbf{w}_{\text{num}}^{\mathbf{r}}) \text{ and} \\ f_{(\mathbf{r}', \mathbf{F})}(\mathbf{d} \mid \theta_{(\mathbf{r}', \mathbf{F})}) &= 1 \text{ for all } \mathbf{r}' \neq \mathbf{r} \text{ and } \mathbf{F} \in \{\mathbf{L}, \mathbf{R}, \mathbf{N}\}, \end{aligned}$$

where  $*$  is the element-wise product,  $\cdot$  is the dot product,  $\mathbf{w}^{\mathbf{r}}$ ,  $\mathbf{w}_{\text{rel}}^{\mathbf{r}}$ ,  $\mathbf{w}_{\text{num}}^{\mathbf{r}}$  are the parameter vectors for the latent, relational, and numerical features corresponding to the relation  $\mathbf{r}$ , and  $\phi$  is the radial basis function (RBF) applied element-wise to  $\mathbf{n}_{(\mathbf{h}, \mathbf{t})}$ .  $f_{(\mathbf{r}, \mathbf{L})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{L})})$  is equivalent to the exponential of the DISTMULT [35] scoring function but with KBLRN we can use any of the existing KB embedding scoring functions.

The probability for triple  $\mathbf{d} = (\mathbf{h}, \mathbf{r}, \mathbf{t})$  of the PoE model is now

$$p(\mathbf{d} \mid \theta_1, \dots, \theta_n) = \frac{\prod_{\mathbf{F} \in \{\mathbf{R}, \mathbf{L}, \mathbf{N}\}} f_{(\mathbf{r}, \mathbf{F})}(\mathbf{d} \mid \theta_{(\mathbf{r}, \mathbf{F})})}{\sum_c \prod_{\mathbf{F} \in \{\mathbf{R}, \mathbf{L}, \mathbf{N}\}} f_{(\mathbf{r}, \mathbf{F})}(\mathbf{c} \mid \theta_{(\mathbf{r}, \mathbf{F})})},$$

where  $\mathbf{c}$  indexes all possible triples.

For numerical features, an activation function should fire when the difference of values is in a specific *range*. For example, we want the activation to be high when the difference of the birth years between a parent and its child is close to 32.4 years. Commonly used activation functions such as sigmoid or tanh are not suitable here, since they saturate whenever they exceed a certain threshold. For each relation  $\mathbf{r}$  and the  $d_n$  corresponding relevant numerical features, therefore, we apply a radial basis function over the differences of values  $\phi(\mathbf{n}_{(\mathbf{h}, \mathbf{t})}) = [\phi(\mathbf{n}_{(\mathbf{h}, \mathbf{t})}^{(1)}), \dots, \phi(\mathbf{n}_{(\mathbf{h}, \mathbf{t})}^{(d_n)})]$ , where

$$\phi(\mathbf{n}_{(\mathbf{h}, \mathbf{t})}^{(i)}) = \exp\left(\frac{-\|\mathbf{n}_{(\mathbf{h}, \mathbf{t})}^{(i)} - c_i\|_2^2}{\sigma_i^2}\right).$$

This results in the RBF kernel being activated whenever the difference of values is close to the expected value  $c_i$ . We discuss and evaluate several alternative strategies for incorporating numerical features in the experimental section.

### 3.1 Learning

Product of experts are usually trained with contrastive divergence (CD) [13] which relies on an approximation of the gradient of the log-likelihood using a short Markov chain started at the current seen example. The advantage of CD is that the partition function, that is, the denominator of the probability  $p$ , which is intractable to compute, does not need to be approximated. Due to the parameterization of the PoE we have defined here, however, it is not possible to perform CD since there is no way to sample a hidden state given a triple  $\mathbf{d}$ . Hence, instead of using CD, we approximate the partition function by performing negative sampling.

The logarithmic loss for the given training triples  $\mathbf{T}$  is defined as

$$\mathcal{L} = - \sum_{\mathbf{t} \in \mathbf{T}} \log p(\mathbf{t} \mid \theta_1, \dots, \theta_n).$$

To fit the PoE to the training triples, we follow the derivative of the log likelihood of each observed triple  $\mathbf{d} \in \mathbf{T}$  under the PoE

$$\frac{\partial \log p(\mathbf{d} \mid \theta_1, \dots, \theta_n)}{\partial \theta_m} = \frac{\partial \log f_m(\mathbf{d} \mid \theta_m)}{\partial \theta_m} - \frac{\partial \log \sum_c \prod_m f_m(\mathbf{c} \mid \theta_m)}{\partial \theta_m}$$

Now, to approximate the intractable second term of the right hand side of the above equation, we generate for each triple  $\mathbf{d} = (\mathbf{h}, \mathbf{r}, \mathbf{t})$  a set  $\mathbf{E}$  consisting of  $N$  triples  $(\mathbf{h}, \mathbf{r}, \mathbf{t}')$  by sampling exactly  $N$  entities  $\mathbf{t}'$  uniformly at random from the set of all entities. The term

$$\frac{\partial \log \sum_c \prod_m f_m(\mathbf{c} \mid \theta_m)}{\partial \theta_m}$$

is then approximated by the term

$$\frac{\partial \log \sum_{\mathbf{c} \in \mathbf{E}} \prod_m f_m(\mathbf{c} \mid \theta_m)}{\partial \theta_m}.$$

Analogously for the head of the triple. This is often referred to as negative sampling. Figure 2 illustrates the KBLRN framework.

## 4 RELATED WORK

A combination of latent and relational features has been explored by Toutanova et al. [30, 31]. There, a weighted combination of two independently learned models, a latent feature model [35] and a model fed with a binary vector reflecting the presence of paths of length one between the *head* and *tail*, is proposed. These simple relational features aim at capturing association

strengths between pairs of relationships (e.g. contains and contained\_by). Riedel et al. [25] proposed a method that learns implicit associations between pairs of relations in addition to a latent feature model in the context of relation extraction. Gardner et al. [8] modifies the path ranking algorithm (PRA) [15] to incorporate latent representations into models based on random walks in KBs. Gardner et al. [7] extracted relational features other than paths to better capture entity type information. There are a number of recent approaches that combine relational and latent representations by incorporating known logical rules into the embedding learning formulation [26, 10, 18]. Despite its simplicity, KBLRN’s combination of relational and latent representations significantly outperforms all these approaches.

There exists additional work on combining various types of KB features. Nickel et al. [19] proposed a modification of the well-known tensor factorization method RESCAL [21], called ARE, which adds a learnable matrix that weighs a set of metrics (e.g. Common Neighbors) between pairs of entities; Garcia-Duran et al. [6] proposed a combination of latent features, aiming to take advantage of the different interaction patterns between the elements of a triple. The integration of different feature types into relational machine learning models has been previously addressed [1] [17], but not in the context of link prediction in multi-relational graphs.

KBLRN is different to these approaches in that (i) we incorporate numerical features for KB completion, (ii) we propose a unifying end-to-end learning framework that integrates arbitrary relational, latent, and numerical features.

More recent work [23] combines numerical, visual, and textual features by learning feature type specific encoders and using the vector representations in an off-the-shelf scoring function such as DISTMULT. In contrast to this approach, KBLRN combines experts that are specialized to a specific feature type with a product of expert approach. Moreover, by taking the *difference* between numerical features and explicitly modeling relational features that hold *between* head and tail entities, KBLRN incorporates dependencies between modalities of the head and tail entities. These dependencies cannot be captured with a model that only includes modalities of either the head or the tail entity but not both at the same time.

## 5 EXPERIMENTS

We conducted experiments on six different knowledge base completion data sets. Primarily, we wanted to understand for what type of relations numerical features are helpful and what input representation of numerical fea-

tures achieves the best results. An additional objective was the comparison to state of the art methods.

## 5.1 Datasets

We conducted experiments on six different data sets: FB15k, FB15k-237, FB15k-num, FB15k-237-num, WN18, and FB122. FB15k [3] and Wordnet (WN) [2] are knowledge base completion data sets commonly used in the literature. The FB15k data set is a representative subset of the Freebase knowledge base. WN18 represents lexical relations between word senses. The two data sets are being increasingly criticized for the frequent occurrence of reverse relations causing simple relational baselines to outperform most embedding-based methods [30]. For these reasons, we also conducted experiments with FB15k-237 a variant of FB15k where reverse relations have been removed [30]. FB122 is a subset of FB15k focusing on relations pertaining to the topics of “people”, “location”, and “sports.” In previous work, a set of 47 logical rules was created for FB122 and subsequently used in experiments for methods that take logical rules into account [10, 18].

The main objective of this paper is to investigate the impact of incorporating numerical features. Hence, we created two additional data set by removing those triples from FB15k’s and FB15k-237’s validation and test sets where numerical features are never used for the triples’ relation type. Hence, the remaining test and validation triples lead to completion queries where the numerical features under consideration are potentially used. We refer to these new data sets as FB15k-num and FB15k-237-num. A similar methodology can be followed to evaluate the performance on a different set of numerical features.

We extracted numerical data from the 1.9 billion triple Freebase RDF dump by mining triples that associate entities to literals of some numerical type. For example, the relation `/location/geocode/latitude` maps entities to their latitude. We performed these extractions for all entities in FB15k but only kept a numerical feature if at least 5 entities had values for it. This resulted in 116 different numerical features and 12,826 entities for which at least one of the numerical features had a value. On average each entity had 2.3 numerical features with a

value. Since numerical data is not available for Wordnet, we do not perform experiments with numerical features for variants of this KB.

Each data set contains a set of triples that are known to be true (usually referred to as positive triples). Statistics of the data sets are provided in Table 1. Since the identifiers for entities and relations have been changed in FB13 [29], we could not extract numerical features for the data set and excluded it from the experiments.

## 5.2 General Set-up

We evaluated the different methods by their ability to answer completion queries of the form  $(h, r, ?)$  and  $(?, r, t)$ . For queries of the form  $(h, r, ?)$ , we replaced the tail by each of the KB’s entities in turn, sorted the triples based on the scores or probabilities returned by the different methods, and computed the rank of the correct entity. We repeated the same process for the queries of type  $(?, r, t)$ . We follow the filtered setting described in [3] which removes correct triples that are different to the target triple from the ranked list. The mean of all computed ranks is the Mean Rank (lower is better) and the fraction of correct entities ranked in the top  $n$  is called hits@ $n$  (higher is better). We also compute the Mean Reciprocal Rank (higher is better) which is an evaluation measure for rankings that is less susceptible to outliers.

We conduct experiments with the scoring function of DISTMULT [35] which is an application of parallel factor analysis to multi-relational graphs. For a review on parallel factor analysis we refer the reader to [12]. We validated the embedding size of KBLRN from the values  $\{100, 200\}$  for all experiments. These values are used in most of the literature on KB embedding methods. For all other embedding methods, we report the original results from the literature or run the authors’ original implementation. For FB15k and FB15k-237, the results for Dist-

Table 5: Results (filtered setting) for KB completion benchmarks where logical rules are provided.

Mult, Complex, and R-GCN+ are taken from [28]; results for the relational baseline Node+LinkFeat are taken from [30]; results for ConvE are taken from [4] and results for TransE were obtained by running the authors’ implementation. For WN18-rules and FB122-all, the results for TransE, TransH, TransR, and KALE are taken from [10], and results for Complex and ASR-Complex are taken from [18]. All methods were tuned for each of the respective data sets.

For KBLRN we used ADAM [14] for parameter learning in a mini-batch setting with a learning rate of 0.001, the categorical cross-entropy as loss function and the number of epochs was set to 100. We validated every 5 epochs and stopped learning whenever the MRR (Mean Reciprocal Rank) values on the validation set decreased. The batch size was set to 512 and the number  $N$  of negative samples to 500 for all experiments. We use the abbreviations  $KB_{suffix}$  to refer to the different instances of

KBLRN. *suffix* is a combination of the letters L (Latent), R (Relational) and N (Numerical) to indicate the inclusion of each of the three feature types.

### 5.3 Automated Generation of Relational and Numerical Features

For the data sets FB15k, FB15k-237, and their numerical versions, we used all relational paths of length one and two found in the training data as relational features. These correspond to the formula types  $(h, r, t)$  (1-hop) and  $\exists x (h, r_1, x) \wedge (x, r_2, t)$  (2-hops). We computed these relational paths with AMIE+ [5], a highly efficient system for mining logical rules from knowledge bases. We used the standard settings of AMIE+ with the exception that the minimal head support was set to 1. With these settings, AMIE+ returns horn rules of the form  $body \Rightarrow (x, r, y)$  that are present for at least 1% of the triples of the form  $(x, r, y)$ . For each relation  $r$ , we used the body of those rules where  $r$  occurs in the head as  $r$ 's relational path features. For instance, given a rule such as  $(x, r_1, z), (z, r_2, y) \Rightarrow (x, r, y)$ , we introduce the relational feature  $\exists x (h, r_1, x) \wedge (x, r_2, t)$  for the relation  $r$ . Table 7 lists a sample of relational features that contributed positively to the performance of KBLRN for specific relation types. For the data sets WN18 and FB122, we used the set of logical formulas previously used in the literature [10]. Using the same set of relational features allows us to compare KBLRN with existing approaches that incorporate logical rules into the embedding learning objective [10, 18].

For each relation  $r$  we only included a numerical feature if, in at least  $\tau = 90\%$  of training triples, both the head and the tail had a value for it. This increases the likelihood that the feature is usable during test time. For  $\tau = 90\%$  there were 105 relations in FB15k for which at least one numerical feature was included during learning, and 33 relations in FB15k-237. With the exception of the RBF parameters, all network weights are initialized following [9]. The parameters of KBLRN's RBF kernels are initialized and fixed to  $c_i = \frac{1}{|\mathbf{T}|} \sum_{(h,r,t) \in \mathbf{T}} \mathbf{n}_{(h,t)}^{(i)}$ , where  $\mathbf{T}$  is the set of training triples  $(h, r, t)$  for the relation  $r$  for which both  $\mathbf{n}_h^{(i)}$  and  $\mathbf{n}_t^{(i)}$  have a value; and  $\sigma_i = \sqrt{\frac{1}{|\mathbf{T}|} \sum_{(h,r,t) \in \mathbf{T}} (\mathbf{n}_{(h,t)}^{(i)} - c_i)^2}$ .

### 5.4 Representations of Numerical Features

We experimented with different strategies for incorporating raw numerical features. For the difference of feature values the simplest method is the application of the sign function. For a numerical attribute  $i$ , the activation is either 1 or  $-1$  depending on whether the difference  $\mathbf{n}_h^{(i)} - \mathbf{n}_t^{(i)}$  is positive or negative. For a more

Relation	KBLR		KBLRN	
	MRR	H@10	MRR	H@10
capital_of	5.7	13.6	<b>14.6</b>	<b>18.2</b>
spouse_of	4.4	<b>0.0</b>	<b>7.9</b>	<b>0.0</b>
influenced_by	7.3	20.9	<b>9.9</b>	<b>26.8</b>

Table 6: MRR and hits@10 results (filtered) for KBLRN with and without numerical features in FB15k-237. Results improve for relations where the difference of the relevant features is approximately normal (see Figure 3).

Figure 3: Histograms and fitted RBFs for three representative relations and numerical features.

nuanced representation of differences of numerical features, a layer of RBF kernels is a suitable choice since the activation is here highest in a particular range of input values. The RBF kernel might not be appropriate, however, in cases where the underlying distribution is not normal.

To evaluate different input representations, we conducted experiments with KBLRN on the FB15k-237-num data set. Table 2 depicts the KB completion performance of two representation strategies for the difference of head and tail values. Each row corresponds to one evaluated strategy. “sign” stands for applying the sign function to the difference of numerical feature values. RBF stands for using an RBF kernel layer for the differences of numerical feature values. All results are for the FB15k-237-num test triples.

The RBF kernels outperform the sign functions significantly. This indicates that the difference of feature values is often distributed normally and that having a region of activation is beneficial. Given these results, we use the RBF input layer for  $\mathbf{n}_{(h,t)}$  for the remainder of the experiments.

### 5.5 Comparison to State of the Art

For the standard benchmark data sets FB15k and FB15k-237, we compare KBLRN with TRANSE, DISTMULT, COMPLEX [32], R-GCN+ [28], and ConvE [4].

Table 3 lists the KB completion results. KBLRN is competitive with state of the art knowledge base comple-

Relational Feature	Triple (h, r, t)
$\exists x (h, \text{containedby}, x) \wedge (t, \text{locations\_in\_this\_time\_zone}, x)$	(h, time\_zone, t)
$\exists x (t, \text{prequel}, x) \wedge (x, \text{character}, h)$	(h, character\_in\_film, t)
$\exists x (x, \text{cause\_of\_death}, h) \wedge (x, \text{cause\_of\_death}, t)$	(h, includes\_causes\_of\_death, t)

Table 7: Relational features found by AMIE+ that positively contributed to the performance of KBLRN for the particular relation type holding between a head entity h and tail entity t.

	MR		MRR	
	ONE	MANY	ONE	MANY
KBLR	<b>42</b>	201	<b>74.9</b>	21.0
KBLRN	60	<b>135</b>	74.2	<b>22.8</b>

Table 8: MR and MRR results (filtered) on FB15k-237-num based on the cardinality of the test queries.

tion methods on FB15k and significantly outperforms all other methods on the more challenging FB15k-237 data set. Since the fraction of triples that can potentially benefit from numerical features is very small for FB15k, the inclusion of numerical features is only slightly beneficial. For FB15k-237, however, the numerical features significantly improve the results.

For the numerical versions of FB15k and FB15k-237, we compared KBLRN to TransE and DistMult. Table 4 lists the results for the KB completion task on these data sets. KBLRN significantly outperforms the KB embedding approaches. The positive impact of including the numerical features is significant.

For the data sets WN18-rules and FB122-all we compared KBLRN to KB embedding methods TransE, TransR [16], TransH [34], and ComplEx [32] as well as state of the art approaches for incorporating logical rules into the learning process. The experimental set-up is consistent with that of previous work. Table 5 lists the results for the KB completion task on these data sets. KBLRN combining relational and latent representations significantly outperforms existing approaches on FB122 with exactly the same set of rules. This provides evidence that KBLRN’s strategy to combine latent and relational features is effective despite its simplicity relative to existing approaches. For WN18+rules, KBLRN is competitive with ComplEx, the best performing method on this data set. In addition, KBLRN’s performance improves significantly when relational and latent representations are combined. In contrast, ASR-COMPLEX is not able to improve the results of ComplEx, its underlying latent representation.

## 5.6 The Impact of Numerical Features

The integration of numerical features improves KBLRN’s performance significantly. We performed

	AUC-PR	MR	MRR
TRANSE	0.837	231	26.5
KBLR	0.913	94	66.8
KBLRN	<b>0.958</b>	<b>43</b>	<b>70.8</b>

Table 9: AUC-PR, MR, and MRR results for the completion query (USA, /location/contains, ?).

several additional experiments so as to gain a deeper understanding of the impact numerical features have.

Table 6 compares KBLRN’s performance with and without integrating numerical features on three relations. The performance of the model with numerical features is clearly superior for all three relationships (capital\_of, spouse and influenced\_by). Figure 3 shows the normalized histograms for the values  $n_{(h,t)}$  for these relations. We observe the differences of feature values are approximately normal.

Following previous work [3], we have classified each test query of FB15k-237-num as either ONE or MANY, depending on the whether one or many entities can complete that query. For the queries labeled ONE the model without numerical features shows a slightly worse performance with respect to the model that makes use of them, whereas for the queries labeled MANY, KBLRN significantly outperforms KBLR in both MR and MRR.

A well-known finding is the lack of completeness of FB15k and FB15k-237. This results in numerous cases where the correct entity for a completion query is not contained in the ground truth (neither in the training, nor test, nor validation data set). This is especially problematic for queries where a large number of entities are correct completions. To investigate the actual benefits of the numerical features we carried out the following experiment: We manually determined all correct completions for the query (USA, /location/contains, ?). We ended up with 1619 entities that correctly complete the query. FB15k-237 contains only 954 of these correct completions. With a complete ground truth, we can now use the precision-recall area under the curve (PR-AUC) metric to evaluate KB completion methods [21, 19, 6]. A high PR-AUC represents both high recall and high precision. Table 9 lists the results for the different methods. KBLRN with numerical features consistently and significantly outperformed all other approaches.

## 6 CONCLUSIONS

We introduced KBLRN, a class of machine learning models that, to the best of our knowledge, is the first proposal aiming at integrating relational, latent, and continuous features of head and tail entities in KBs into a single end-to-end differentiable framework. KBLRN outperforms state of the art KB completion methods on a range of data sets. We show that the inclusion of numerical features is beneficial for KB completion tasks.

Future work will primarily study instances of experts that can combine different numerical features such as life expectancy and latitude. Furthermore, combinations of multiple different embedding methods, which was shown to be beneficial in recent work [33], is also possible with our PoE approach.

## Abstract

In zero-shot learning (ZSL), a classifier is trained to recognize visual classes without any image samples. Instead, it is given semantic information about the class, like a textual description or a set of attributes. Learning from attributes could benefit from explicitly modeling structure of the attribute space. Unfortunately, learning of general structure from empirical samples is hard with typical dataset sizes.

Here we describe LAGO<sup>1</sup>, a probabilistic model designed to capture natural soft *and-or* relations across *groups of attributes*. We show how this model can be learned end-to-end with a deep attribute-detection model. The soft group structure can be learned from data jointly as part of the model, and can also readily incorporate prior knowledge about groups if available. The soft and-or structure succeeds to capture meaningful and predictive structures, improving the accuracy of zero-shot learning on two of three benchmarks.

Finally, LAGO reveals a unified formulation over two ZSL approaches: DAP (Lampert et al., 2009) and ESZSL (Romera-Paredes & Torr, 2015). Interestingly, taking only one singleton group for each attribute, introduces a *new* soft-relaxation of DAP, that outperforms DAP by ~40%.

The *Mourning Warbler* has an olive-green wing, a grey-blue head and pink feet.

**A "hard" logical expression**  
AND [OR(wing\_color:olive, wing\_color:green),  
OR (forehead\_color:grey, forehead\_color:blue),  
OR (leg\_color:pink)]

**A "soft" model:**  
[ weight<sub>wing:olive</sub> P(wing:olive|image) +  
weight<sub>wing:green</sub> P(wing:green|image) +  
weight<sub>wing:red</sub> P(wing:red|image) + ... ] x  
...  
x [weight<sub>leg:pink</sub> P(leg:pink|image) + ...]

Figure 1: Classifying a bird species based on attributes from (Wah et al., 2011). The *Mourning Warbler* can be distinguished from other species by a combination of a grey head and olive-green underparts. Both human raters and machine learning models may confuse semantically-similar attributes like olive or green wings. These attributes naturally cluster into "OR" groups, where we aim to recognize this species if the wing is labeled as either green or olive. The LAGO model (Eq. 4) weighs attributes detection, inferring classes based on within-group soft-OR and across-groups soft-AND. In general, OR-groups include alternative choices of a property ( $wing\_color:\{red, olive, green\}$ ) and soft-OR allows to weigh down class-irrelevant attributes (here,  $wing:red$ ).

## 1 INTRODUCTION

People can easily learn to recognize visual entities based on a handful of semantic attributes. For example, we can recognize a bird based by its visual features (long beak, red crown), or find a location based on a language description (a 2-stories brick town house). Unfortunately, when training models that use such semantic features, it is typically very hard to leverage semantic information effectively. With semantic features, the input space has rich and complex structure, due to nontrivial interactions and logical relations among attributes. For example, the color of petals may be red or blue but rarely both, while the size of a bird is often not indicative of its color.

Taking into account the semantics of features or at-

<sup>1</sup> A video of the highlights, and code is available at: <http://chechiklab.biu.ac.il/~yuvval/LAGO/>

tributes becomes crucial when no training samples are available. This learning setup, called zero-shot learning (ZSL) is the task of learning to recognize objects from classes without any image samples to train on. (Lampert et al., 2009; Farhadi et al., 2009; Palatucci et al., 2009; Xian et al., 2017b). Instead, learning is based on semantic knowledge about the classes (Socher et al., 2013; Elhoseiny et al., 2013; Berg et al., 2010), like in the case of attribute sharing (Lampert et al., 2009, 2014). Here, the training and test classes are accompanied by a set of predefined attributes, like "A Zebra is striped" or "A Hummingbird has a long bill", provided by human experts. Then, a classifier is trained to detect these attributes in images (Ferrari & Zisserman, 2008), and test images are classified by detecting attributes and mapping to test classes based on the expert knowledge.

Broadly speaking, approaches to ZSL with attributes can be viewed as learning a compatibility function  $f(Attr(image), Attr(class))$  between an attribute-based representation of an image and an attribute-based representation of classes (Romera-Paredes & Torr, 2015; Akata et al., 2016; Frome et al., 2013; Akata et al., 2015). Here, the attributes of a class are provided by (possibly several) experts, the image attributes are automatically detected, and one aims to learn a scoring function that can find the class whose attributes are most compatible with an image. Most ZSL approaches represent attributes as embedded in a "flat" space, Euclidean or Simplex, but flat embedding may miss important semantic structures. Other studies aimed to learn a structured scoring function, for example using a structured graphical model over the attributes (Wang & Ji, 2013). Unfortunately, learning complex structures of probabilistic models from data requires large datasets, which are rarely available.

Here we put forward an intermediate approach: We use training classes to learn a simple structure that can capture simple (soft) and-or logical relations among attributes. More concretely, after mapping an image to attributes, we aggregate attributes into groups using a soft OR (weighted-sum), and then score a class by taking a soft AND (product of probabilities) over group activations (Figure 2). While the attributes are predefined and provided by experts, the soft groups are learned from the training data.

The motivation for learning the and-or structure becomes clear when observing how attributes tend to cluster naturally into semantically-related groups. For example, descriptions of bird species in the CUB dataset include attributes like  $\{wing-color:green, wing-color:olive, wing-color:red\}$  (Wah et al., 2011). As another example, animal attributes in (Lampert et al., 2009) include  $\{texture:hairless, texture:tough-skin\}$ . In these two ex-

amples, the attributes are semantically related, and raters (or a classifier) may mistakenly interchange them, as evident by how Wikipedia describes the Mourning Warbler (Figure 1) as having "olive-green underparts". In such cases, it is natural to model attribute structure as a soft OR relation over attributes ("olive" or "green") in a group ("underparts"). It is also natural to apply a soft AND relation across groups, since a class is often recognized by a set of necessary properties.

We describe LAGO, "*Learning Attribute Grouping for 0-shot learning*", a new zero-shot probabilistic model that leverages and-or semantic structure in attribute space. LAGO achieves new state-of-the-art result on CUB and AWA2 (Lampert et al., 2009), and competitive performance on SUN (Patterson & Hays, 2012). Interestingly, when considering two extremes of attribute grouping, LAGO becomes closely related to two important ZSL approaches. First, in the case of a single group (all OR), LAGO is closely related to ESZSL (Romera-Paredes & Torr, 2015). At the opposite extreme where each attribute forms a singleton group, (all AND), LAGO is closely related to DAP (Lampert et al., 2009). LAGO therefore reveals an interesting unified formulation over seemingly unrelated ZSL approaches.

Our paper makes the following novel contributions. We develop a new probabilistic model that captures soft logical relations over semantic attributes, and can be trained end-to-end jointly with deep attribute detectors. The model learns attribute grouping from data, and can effectively use domain knowledge about semantic grouping of attributes. We further show that it outperforms competing methods on two ZSL benchmarks, CUB and AWA2, and obtain comparable performance on another benchmark (SUN). Finally, LAGO provides a unified probabilistic framework, where two previous important ZSL methods approximate extreme cases of LAGO.

## 2 RELATED WORK

Zero-shot-learning with attributes attracted significant interest recently (Xian et al., 2017b; Fu et al., 2017). One influential early works is *Direct Attribute Prediction* (DAP), which takes a Bayesian approach to predict unseen classes from binary attributes (Lampert et al., 2009). In DAP, a class is predicted by the product of attribute-classifier scores, using a hard-threshold over the semantic information of attribute-to-class mapping. DAP is related in an interesting way to LAGO. We show below that DAP can be viewed as a hard-threshold special case of LAGO where each group consists of a single attribute.

Going beyond a flat representation of attributes, several studies modeled structure among attributes. Wang & Ji (2013) learned a Bayesian network over attribute space

that captures object-dependent and object-independent relationships. Jiang et al. (2017) learned latent attributes that preserve semantics and also provide discriminative combinations of given semantic attributes. Structure in attribute space was also used to improve attribute prediction: Jayaraman et al. (2014) leveraged side information about semantic relatedness of attributes in given groups and proposed a multi-task learning framework, where same-group attributes are encouraged to share low-level features. In Park & Zhu (2015); Park et al. (2017), the authors propose an AND-OR grammar model (Zhu & Mumford, 2006), to jointly represent both the object parts and their semantic attributes within a unified compositional hierarchy. For that, they decompose an object to its constituent parts with a parse tree. In their model, the tree nodes (the parts) constitute an AND relation, and each OR-node points to alternative sub-configurations

Our approach resonates with *Markov Logic Networks* (MLN), (Richardson & Domingos, 2006) and *Probabilistic Soft Logic* (PSL), (Kimmig et al., 2012; Bach et al., 2017). It shares the idea of modeling domain knowledge using soft logical relations. Yet, LAGO formulation provides a complementary point of view: (1) LAGO derivation reveals the probabilistic meaning of every soft weight of the logical relation Eq. (3), and offers a principled way to set priors when deriving the soft logical expression. (2) The step-by-step derivation reveals which approximations are taken when mapping features to classes with soft logical relations. (3) Logical relations are incorporated in LAGO as part of an end-to-end deep network. PSL and MLN use Markov random field with logical relations as constraints or potentials.

The study of ZSL goes beyond learning with attributes (Changpinyo et al., 2016; Tsai et al., 2017b; Morgado & Vasconcelos, 2017; Rohrbach et al., 2011; Al-Halah & Stiefelhagen, 2015; Zhang et al., 2017; Ye & Guo, 2017; Tsai et al., 2017a; Xu et al., 2017; Li et al., 2017; Zhang & Koniusz, 2018). Recently, Zhang & Koniusz (2018) described a kernel alignment approach, mapping images to attribute space such that projected samples match the distribution of attributes in terms of a nonlinear kernel. Another popular approach to ZSL learns a bi-linear compatibility function  $F(\mathbf{x}, y; W) = \theta(\mathbf{x})^\top W \phi(y)$  to match visual information  $\theta(\mathbf{x})$  with semantic information  $\phi(y)$  (Romera-Paredes & Torr, 2015; Akata et al., 2016; Frome et al., 2013; Akata et al., 2015). In this context, most related to our work is ESZSL (Romera-Paredes & Torr, 2015), which uses a one-hot encoding of class labels to define a mean-squared-error loss function. This allows ESZSL to have a closed-form solution where reaching the optimum is guaranteed. We show below that ESZSL is closely related to a special case of LAGO where all attributes are assigned to a single group.

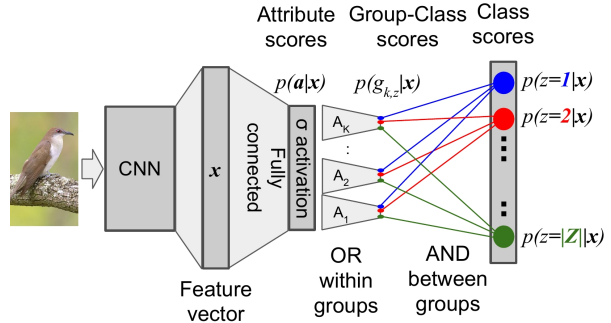

Figure 2: LAGO network architecture (Sec 3). Image features are extracted by a deep ConvNet and fed to a FC sigmoid layer ( $\sigma$ ) that outputs a prediction score  $p(a_m|x)$  for each binary attribute  $a_m$ . Attribute scores are grouped into  $K$  soft groups, and mapped to a set  $\{g_{k,z}\}$  of  $K \times |Z|$  binary classifiers, according to a soft-OR Eq. (3). Finally, a class is computed by the soft product of all group-scores for that class, approximating a conjunction (AND). In the diagram, each colored circle represents a classifier score for a separate class.

The current work focuses on a new architecture for ZSL with attributes. Other aspects of ZSL, including feature selection (Guo et al., 2018) and data augmentation (Mishra et al., 2018; Arora et al., 2018; Xian et al., 2018), can improve accuracy significantly, but are orthogonal to the current work.

### 3 A PROBABILISTIC AND-OR MODEL

**The Problem Setup:** Following the notations of (Lampert et al., 2009), we are given a set of labeled training images  $(\mathbf{x}_i \in \mathcal{X}, z_i \in \mathcal{Z})$  drawn from a distribution  $D$ . Each image  $\mathbf{x}$  is accompanied by a vector of binary attributes  $\mathbf{a} \in \{True, False\}^{|A|}$ ,  $\mathbf{a} = (a_1, \dots, a_m, \dots, a_{|A|})$ , where  $a_m = True$  if the image has attribute  $a_m$ . We are also given a set of class "descriptions" in the form class-conditioned attribute distribution  $p(\mathbf{a}|z)$ . In practice, the descriptions are often collected separately per attribute ( $m$ ), and only the marginals  $p(a_m|z)$ ,  $\forall m$  are available.

At training time, we aim to learn a classifier that predicts a class  $z$  of an image  $\mathbf{x}$  by first learning to predict the attributes  $\mathbf{a}$ , and then use  $p(a_m|z)$ ,  $\forall m$  to predict a class  $z$  based on the attributes.

At inference time (the zero-shot phase), we are given images  $\mathbf{x}$  from new unseen classes with labels  $y \in \mathcal{Y}$ , and together with their class descriptions  $p(a_m|y)$ ,  $\forall m$ . We similarly predict the class  $y$  by first predicting attributes  $\mathbf{a}$  and then use  $p(a_m|z)$ ,  $\forall m$  to predict a class  $y$  based on the attributes.

**Model Overview:** The LAGO model (Figures 1, 2) learns a soft logical AND-OR structure over semantic attributes. It can be viewed as a concatenation of three

mapping steps  $\mathcal{X} \rightarrow \mathcal{A} \rightarrow \mathcal{G} \rightarrow \mathcal{Z}$ . First, **attribute predictions**: an image  $\mathbf{x}$  is mapped to a vector of attribute detection probabilities  $f_W^1 : \mathcal{X} \rightarrow \mathcal{A}$ ,  $\mathcal{A} = [0, 1]^{|A|}$ . The mapping parameters  $W$  determine the weights of the attribute detectors and are learned from labeled training data. Second, **weighted-OR group scores**: Attribute probabilities are mapped to  $K$  groups. Each group calculates a class-dependent weighted-OR over the  $|Z|$  classes  $f_{U,V}^2 : \mathcal{A} \rightarrow \mathcal{G}$ ,  $\mathcal{G} = [0, 1]^{K \times |Z|}$ . The mapping parameters  $U$  are the distributions  $p(\mathbf{a}|z)$  provided with each class; The mapping parameters  $V$  determine how attributes are grouped and are learned from data. Last, **soft-AND group conjunction**: Per-group scores are mapped to class detection probabilities by a soft-AND, approximating group conjunction.  $f^3 : \mathcal{G} \rightarrow \mathcal{Z}$ ,  $\mathcal{Z} = [0, 1]^{|Z|}$ . The parameters  $W, V$  are learned jointly to minimize a regularized loss with a regularizer  $R$ :

$$\min_{W,V} \text{loss}(f^3(f_{U,V}^2(f_W^1(\mathbf{x}_i))), z_i) + R(W, V) \quad . \quad (1)$$

The key idea in the proposed approach is to define a layer of binary classifiers  $g_{k,z}$ , each evaluating a class  $z$  based only on a subset  $G_k \subset \mathcal{A}$  of attributes. For example, for bird-species recognition, one classifier may detect a *Mourning Warbler* based on wing colors and another based on bill shapes. In this example, each of the classifiers output the probability  $p(g_{k,z} = \text{True}|\mathbf{a})$  that the image has a *Mourning Warbler*, but based on different subsets of attributes. The partition of attributes to subsets is shared across classes, hence with  $K$  subsets we have  $K \times |Z|$  binary classifiers. We also define  $\mathbf{a}_k$  to be the vector of attributes detections for  $G_k$ ,  $\mathbf{a}_k \in \{T, F\}^{|G_k|}$ . For clarity, we first derive the algorithm for groups that are fixed (not learned) and hard (non-overlapping). Section 3.1 then generalizes the derivation to soft learned groups.

Consider now how we compute  $p(g_{k,z} = T|\mathbf{x})$ . According to the Markov property, it equals  $\sum_{\mathbf{a}_k} p(g_{k,z}|\mathbf{a}_k)p(\mathbf{a}_k|\mathbf{x})$ , but computing this sum raises several challenges. First, since the number of possible patterns in a group grows exponentially with its size, the summation becomes prohibitively large when attribute groups are large. Second, estimating  $p(g_{k,z}|\mathbf{a}_k)$  from data may also be hard because the number of samples is often limited. Finally, description information is often available for the marginals only,  $(z, a_m)$ , rather than the full distribution  $(z, \mathbf{a}_k)$ . We now discuss a model that addresses these constraints.

**The Within-Group Model  $\mathcal{A} \rightarrow \mathcal{G}$ :** We now show how one can compute  $p(g_{k,z}|\mathbf{x})$  efficiently by treating attributes within group as obeying a soft OR relation. As discussed above, OR relations are in good agreement with how real-world classes are described using hard

semantic attributes, because a single property (a group like *beak-shape*) may be mapped to several semantically-similar attributes (*pointy, long*).

Formally, we first define a complementary attribute per group,  $\tilde{a}_k = (\bigcup_{m \in G_k} a_m)^c$ , handling the case where no attributes are detected or described, and accordingly define  $G'_k = G_k \cup \tilde{a}_k$ . We then use the identity  $p(A) = p(A, B) + p(A, B^c)$  to partition  $p(g_{k,z} = T|\mathbf{x})$  to a union (OR) of its contributions from each of its attributes. Specifically,  $p(g_{k,z} = T|\mathbf{x}) = p(g_{k,z} = T, \bigcup_{m \in G_k} a_m = T|\mathbf{x}) + p(g_{k,z} = T, \tilde{a}_k = T|\mathbf{x}) = p(\bigcup_{m \in G'_k} (g_{k,z} = T, a_m = T)|\mathbf{x})$ . Using this equality and approximating attributes within a group as being mutually exclusive, we have

$$p(g_{k,z} = T|\mathbf{x}) \approx \sum_{m \in G'_k} p(g_{k,z} = T, a_m = T|\mathbf{x}). \quad (2)$$

To rewrite this expression in terms of class descriptions  $p(a_m|z)$  we take the following steps. First, the Markov chain  $\mathcal{X} \rightarrow \mathcal{A} \rightarrow \mathcal{G}$  gives  $p(g_{k,z} = T, a_m|\mathbf{x}) = p(g_{k,z} = T|a_m)p(a_m|\mathbf{x})$ . Second, we note that by the definition of  $g_{k,z}$ ,  $p(g_{k,z}|\mathbf{a}_k) = p(z|\mathbf{a}_k)$ , because  $g_{k,z}$  is the classifier of  $z$  based on  $\mathbf{a}_k$ . This yields  $p(g_{k,z} = T, a_m) = p(z, a_m)$  by marginalization. Applying Bayes to the last identity gives  $p(g_{k,z} = T|a_m) = p(a_m|z)p(g_{k,z} = T)/p(a_m)$  (more details in Supplementary Material D.1). Finally, combining it with the expression for  $p(g_{k,z} = T, a_m|\mathbf{x})$  and with Eq. (2) we can express  $p(g_{k,z} = T|\mathbf{x})$  as

$$p(g_{k,z} = T|\mathbf{x}) \approx p(g_{k,z} = T) \sum_{m \in G'_k} \frac{p(a_m = T|z)}{p(a_m = T)} p(a_m = T|\mathbf{x}). \quad (3)$$

**Conjunction of Groups  $\mathcal{G} \rightarrow \mathcal{Z}$ :** Next, we derive an expression of the conditional probability of classes  $p(z|\mathbf{x})$  using soft-conjunction of group-class classifiers  $g_{k,z}$ . Using the Markov property  $\mathcal{X} \rightarrow \mathcal{A} \rightarrow \mathcal{G} \rightarrow \mathcal{Z}$ , and denoting  $g_{1,z} \dots g_{K,z}$  by  $\mathbf{g}_z$ , we can write  $p(z|\mathbf{x}) = \sum_{\mathbf{g}_z} p(z|\mathbf{g}_z)p(\mathbf{g}_z|\mathbf{x})$ . We show on Supplementary D.2, that making a similar approximation as in DAP (Lampert et al., 2009), for groups instead of attributes, yields Eq. (A.10):  $p(z|\mathbf{x}) \approx p(z) \prod_{k=1}^K \frac{p(g_{k,z} = T|\mathbf{x})}{p(g_{k,z} = T)}$ . Combining it with Eq. (3), we conclude

$$p(z|\mathbf{x}) \approx p(z) \prod_{k=1}^K \left[ \sum_{m \in G'_k} \frac{p(a_m = T|z)}{p(a_m = T)} p(a_m = T|\mathbf{x}) \right]. \quad (4)$$

### 3.1 SOFT GROUPS:

The above derivation treated attribute groups as hard: deterministic and non-overlapping. We now discuss the

more general case where attributes are *probabilistically* assigned to groups.

We introduce a soft group-membership variable  $\Gamma_{m,k} = p(m \in G'_k)$ , yielding a soft version of Eq. (3)

$$p(g_{k,z} = T|\mathbf{x}) \approx p(g_{k,z} = T) \sum_{m=1}^{|\mathcal{A}|} \Gamma_{m,k} \frac{p(a_m = T|z)}{p(a_m = T)} p(a_m = T|\mathbf{x}), \quad (5)$$

where each row of  $\Gamma$  represents a distribution over  $K$  groups per attribute in the simplex  $\Delta^K$ . Hard grouping is a special case of this model where all probability mass is assigned to a single group for each row of  $\Gamma$ . The full derivation is detailed in Supplementary Material (D.3).

### 3.2 LEARNING

LAGO has three sets of parameters learned from data.

First, a matrix  $W$  parametrizes the mapping  $f_W^1 : \mathbf{x} \rightarrow [0, 1]^{|\mathcal{A}|}$  from image features to attribute detection probabilities  $p(a_m|\mathbf{x})$ . This mapping is implemented as a fully-connected layer with sigmoid activation over image features extracted from ResNet-101.

Second, a matrix  $U$ , where its entry  $U_{m,z}$  parametrizes the class-level description  $p(a_m|z)$ . When attribute ratings are given per image, we estimate  $U$  using maximum likelihood from co-occurrence data over attributes and classes.

Third, a matrix  $V_{|\mathcal{A}| \times K}$  parametrizes the soft group assignments  $\Gamma_{|\mathcal{A}| \times K}$ , such that each row  $m$  maintains  $\Gamma_{(m,:)} = \text{softmax}(\zeta V_{(m,:)})$ , where  $\zeta \in \mathbb{R}^+$  is a smoothing coefficient. This parametrization allows taking arbitrary gradient steps over  $V$ , while guaranteeing that each row of  $\Gamma$  corresponds to a probability distribution in the simplex  $\Delta^K$ .

Since  $W$  and  $V$  are shared across all classes, they are learned over the training classes and transferred to the test classes at (zero-shot) inference time. They are learned end-to-end by applying cross-entropy loss over the outputs of Eq. (4) normalized by their sum across classes (forcing a unit sum of class predictions). As in (Romera-Paredes & Torr, 2015), the objective includes two regularization terms over  $W$ : A standard  $L_2$  regularizer  $\|W\|_{Fro}^2$  and a term  $\|WU\|_{Fro}^2$ , which is equivalent for an ellipsoid Gaussian prior for  $W$ . For the "LAGO-Semantic-Soft" learning-setup (Section 4) we introduce an additional regularization term  $\|\Gamma_{(V)} - \Gamma_{(V_{SEM})}\|_{Fro}^2$ , pushing the solutions closer to known semantic hard-grouping  $\Gamma_{(V_{SEM})}$ . Finally, we optimize the loss:

$$L(W, U, V, Z, A, X) = \text{CXE}_{p(z|\mathbf{x}; W, U, V)}(X, Z) + \alpha \text{BXE}_{p(a|\mathbf{x}; W)}(X, A) + \beta \|W\|_{Fro}^2 + \lambda \|WS\|_{Fro}^2 + \psi \|\Gamma_{(V)} - \Gamma_{(V_{SEM})}\|_{Fro}^2, \quad (6)$$

where CXE is the categorical cross-entropy loss for  $p(z|\mathbf{x})$ , BXE is the binary cross-entropy loss for  $p(a|\mathbf{x})$ ,  $X, Z$  and  $A$  denote the training samples, labels and attribute-labels. Per-sample attribute labels are provided as their empirical mean per class. In practice, we set  $\alpha = 0$  (See Section 4.2) and cross-validate to select the values of  $\beta$ ,  $\lambda$  and  $\psi$  when relevant.

### 3.3 INFERENCE

At inference time, we are given images from new classes  $y \in \mathcal{Y}$ . As with the training data, we are given semantic information about the classes in the form of the distribution  $p(a_m|y)$ . In practice, we are often not given that distribution directly, but instead estimate it using maximum likelihood from a set of labeled attribute vectors.

To infer the class of a given test image  $\mathbf{x}$ , we plug  $p(a_m|y)$  estimates instead of  $p(a_m|z)$  in Eq. (4), and select the class  $y$  that maximizes Eq. (4).

### 3.4 DAP, ESZSL AS SPECIAL CASES OF LAGO

LAGO encapsulates similar versions of two other zero-shot learning approaches as extreme cases: DAP (Lampert et al., 2009), when having each attribute in its own singleton group ( $K = |\mathcal{A}|$ ), and ESZSL (Romera-Paredes & Torr, 2015), when having one big group over all attributes ( $K = 1$ ).

Assigning each single attribute  $a_m$  to its own singleton group reduces Eq. (4) to Eq. (A.20) (details in Supplementary D.4). This formulation is closely related to DAP. When expert annotations  $p(a_m = T|z)$  are thresholded to  $\{0, 1\}$  and denoted by  $a_m^z$ , Eq. (A.20) become the DAP posterior Eq. (A.22). This makes the singletons variant a **new** soft relaxation of DAP.

At the second extreme (details in Supplementary D.4), all attributes are assigned to a single group,  $K = 1$ . Taking a uniform prior for  $p(z)$  and  $p(a_m)$ , and replacing  $p(a_m = T|\mathbf{x})$  with the network model  $\sigma(\mathbf{x}^\top W)$ , transforms Eq. (4) to  $p(z|\mathbf{x}) \propto \sum_{m=1}^{|\mathcal{A}|} \sigma(\mathbf{x}^\top W) p(a_m = T|z)$ . Denoting  $U_{m,z} = p(a_m = T|z)$ , this formulation reveals that at the extreme case of  $K = 1$ , LAGO can be viewed as a non-linear variant that is closely related to ESZSL:  $\text{Score}(z|\mathbf{x}) = \mathbf{x}^\top WU$ , with same entries  $U_{m,z}$ .

## 4 EXPERIMENTS

Fair comparisons across ZSL studies tends to be tricky, since not all papers use a unified evaluation protocol. To guarantee an "apple-to-apple" comparison, we follow the protocol of a recent meta-analysis by Xian et al. (2017b) and compare to the leading methods evaluated with that protocol: **DAP** (Lampert et al., 2009), **ESZSL** (Romera-Paredes & Torr, 2015), **ALE** (Akata et al., 2016), **SYNC**

(Changpinyo et al., 2016), **SJE** (Akata et al., 2015), **DE-VICE** (Frome et al., 2013), **Zhang2018** (Zhang & Koniusz, 2018). Recent work showed that data augmentation and feature selection can be very useful for ZSL (Mishra et al., 2018; Arora et al., 2018; Xian et al., 2018; Guo et al., 2018). Since such augmentation are orthogonal to the modelling part, which is the focus of this paper, we do not use them here.

#### 4.1 DATASETS

We tested LAGO on three datasets: CUB, AWA2 and SUN. First, we tested LAGO in a fine-grained classification task of bird-species recognition using CUB-2011 (Wah et al., 2011). CUB has 11,788 images of 200 bird species and a vocabulary of 312 binary attributes (wing-color:olive), derived from 28 attribute groups (wing-color). Each image is annotated with attributes generated by one rater. We used the class description  $p(a_m|z)$  provided in the data. The names of the CUB attributes provide a strong prior for grouping (wing-color:olive, wing-color:red, ...  $\rightarrow$  wing-color:{olive, red, ...}).

The second dataset, Animals with Attributes2 (AWA2), (Xian et al., 2017a) consists of 37,322 images of 50 animal classes with pre-extracted feature representations for each image. Classes and attributes are aligned with the class-attribute matrix of (Osherson et al., 1991; Kemp et al., 2006). We use the class-attribute matrix as a proxy for the class description  $p(a_m|z)$ , since human subjects in (Osherson et al., 1991) did not see any image samples during the data-collection process. As a prior over attribute groups, we used the 9 groups proposed by (Lampert, 2011; Jayaraman et al., 2014) for 82 of 85 attributes, like *texture*:{furry, hairless, ...} and *shape*:{big, bulbous, ...}. We added two groups for remaining attributes: *world*:{new-world, old-world}, *smelly*:{smelly}.

As the third dataset, we used SUN (Patterson & Hays, 2012), a dataset of complex visual scenes, having 14,340 images from 717 scene types and 102 binary attributes from four groups.

#### 4.2 EXPERIMENTAL SETUP

We tested four variants of LAGO:

- (1) **LAGO-Singletons**: The model of Eq. (4) for the extreme case using  $K = |A|$  groups, where each attribute forms its own hard group.
- (2) **LAGO-Semantic-Hard**: The model of Eq. (4) with hard groups determined by attribute names. As explained in Section 4.1.
- (3) **LAGO-K-Soft**: The soft model of Eqs. 4-5, learning  $K$  soft group assignments with  $\Gamma$  initialized uniformly up to a small random perturbation.  $K$  is a hyper parameter with a value between 1 and the number of attributes. It is chosen by cross-validation.

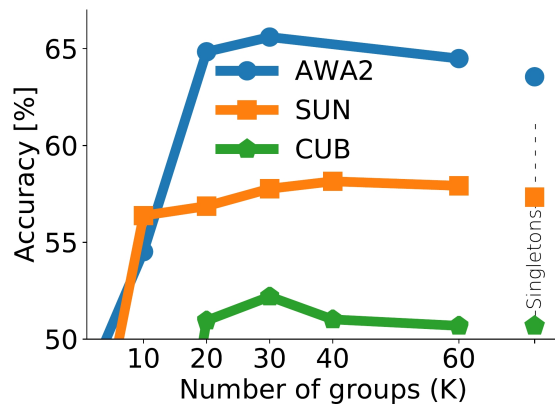

Figure 3: Learning  $K$  soft-group assignments: Validation-set accuracy for different number of groups ( $K$ ) for the LAGO-K-Soft variant and of the LAGO-Singletons baseline. Here, no prior information is given about the groups, and the model successfully learns groups assignments from data, and better than the group-naive LAGO-Singletons baseline.

(4) **LAGO-Semantic-Soft**: The model as in LAGO-K-Soft, but the soft groups  $\Gamma$  are initialized using the dataset-specific semantic groups assignments. These are also used as the prior  $\Gamma_{SEM}$  in Eq. (6).

Importantly, to avoid implicit overfitting to the test set, we used the validation set to select a single best variant, so we can report only a single prediction accuracy for the test set. For reference, we provide detailed test results of all variants in the Supplementary Material, Table A.1.

To learn the parameters  $W, V$ , we trained the weights with cross entropy-loss over outputs (and regularization terms) described in section 3.2. **In the hard-group case**, we only train  $W$ , while keeping  $V$  fixed. We sparsely initialize  $V$  with ones on every intersection of an attribute and its hard-assigned group and choose a high constant value for  $\zeta$  ( $\zeta = 10$ ). Since the rows of  $\Gamma$  correspond to attributes, it renders each row of  $\Gamma$  as a unit mass probability on a certain group. **In the soft-group case**, we train  $W, V$  alternately per epoch, allowing us to choose different learning rate for  $W$  and  $V$ . For LAGO-K-Soft,  $V$  was initialized with uniform random weights in  $[0, 1e-3]$ , inducing a uniform distribution over  $\Gamma$  up to a small random perturbation. **For LAGO-Semantic-Soft**, we initialized  $V$  as in the hard-group case, and we also used this initialization for the prior  $V_{SEM}$  Eq. (6).

**Design decisions:** (1) We use a uniform prior for  $p(z)$  as in (Xian et al., 2017b; Lampert et al., 2009; Romera-Paredes & Torr, 2015).  $p(a_m)$  can be estimated by marginalizing over  $p(a_m, z)$ , but as in ESZSL and DAP, we found that uniform priors performed better empirically. (2) To approximate the complementary attribute terms we used a De-Morgan based approximation for

Figure 4: Validation accuracy (in %) of LAGO variants for three ZSL benchmark datasets. (1) On all the datasets, using semantic grouping information improves the performance relative to LAGO-K-Soft with  $K =$  number of semantic hard-groups. (2) We used these results to select which variant to use for the test set. Explicitly, when training the model on train+validation data, we used the *LAGO-Semantic-Soft* variant for CUB & AWA2, and *LAGO-K-Soft* variant for SUN.

$p(\tilde{a}_k = T|z) \approx \prod_{m \in G_k \setminus \{\tilde{a}_k\}} p(a_m^c|z)$ . For  $p(\tilde{a}_k = T|\mathbf{x})$ , we found that setting a constant value was empirically better than using a De-Morgan based approximation. (3) Our model does not use an explicit supervision signal for learning the weights of the attributes-prediction layer. Experiments showed that usage of explicit attributes supervision, by setting a non-zero value for  $\alpha$  in Eq. (6), results in deteriorated performance.

In Section 4.4, we demonstrate the above design decision with ablation experiments on the validation sets of CUB and AWA2.

**Implementation and training details:** The Supplementary Material (A) describes the training protocol, including the cross-validation procedure, optimization and tuning of hyper parameters.

### 4.3 RESULTS

Our experiments first compare variants of LAGO, and then compare the best variant to baseline methods. We then study in more depth the properties of the learned models.

Figure 3 shows validation-set accuracy of LAGO-K-Soft variants as a function of the number of groups ( $K$ ) and for the LAGO-Singletons baseline. We used these results to select the optimal number of groups  $K$ . In these experiments, even-though no prior information is provided about grouping, LAGO successfully learns group assignments from data, performing better than the group-naïve LAGO-Singletons baseline. The performance degrades largely when the number of groups is small.

Figure 4 shows validation-set accuracy for main variants of LAGO for three benchmark datasets. We used these results to select the variant of LAGO applied to

	CUB	AWA2	SUN
<b>DAP</b>	40.0	46.2	39.9
<b>ALE</b>	54.9	62.5	<b>58.1</b>
<b>ESZSL</b>	53.9	58.6	54.5
<b>SYNC</b>	55.6	46.6	56.3
<b>SJE</b>	53.9	61.9	53.7
<b>DEVISE</b>	52.0	59.7	56.5
<b>ZHANG2018*</b>	48.7-57.1	58.3- <b>70.5</b>	57.8- <b>61.7</b>
<b>LAGO (OURS)</b>	<b>57.8</b>	<b>64.8</b>	57.5

Table 1: Test accuracy (in %) of LAGO and compared methods on three ZSL benchmark datasets. We follow the protocol of a meta-analysis by (Xian et al., 2017b) and compare to leading methods evaluated with it. Only one LAGO variant is shown, selected using a validation set. See Table A.1 in the supplementary for more results. LAGO outperforms previous baselines on CUB and AWA2 by a significant margin. On SUN, LAGO loses by a small margin. (\*) Comparison with *Zhang2018* is inconclusive. Zhang & Koniusz (2018) report the results for 7 kernel types on the test set, but results on a validation set were not published, hence taking the best kernel over the test set may be optimistic.

the test split of each dataset. Specifically, when training the model on train+validation data, we used *LAGO-Semantic-Soft* for CUB & AWA2, and *LAGO-K-Soft* ( $K = 40$ ) for SUN. This demonstrates that LAGO is useful even when the semantic-grouping prior is of low quality as in SUN. Figure 4 also shows that semantic grouping, significantly improves performance, relative to LAGO-K-Soft with a similar number of groups.

We draw three conclusions from Figures 3-4. (1) The prior grouping based on attribute semantics contains very valuable information that LAGO can effectively use. (2) LAGO succeeds even when no prior group information is given, effectively learning group assignments from data. (3) Using the semantic hard-groups as a prior, allows us to soften the semantic hard-groups and optimize the grouping structure from data.

Table 1 details the main empirical results, comparing test accuracy of LAGO with the competing methods. Importantly, to guarantee "apple-to-apple" comparison, evaluations are made based on the standard evaluation protocol from Xian et al. (2017b), using the same underlying image features, data splits and metrics. Results are averaged over 5 random initializations (seeds) of the model weights ( $W, V$ ). Standard-error-of-the-mean (S.E.M) is  $\sim 0.4\%$ . On CUB and AWA2, LAGO outperform all competing approaches by a significant margin. On CUB, reaching 57.8% versus 55.6% for SYNC (Changpinyo et al., 2016). On AWA2, reaching 64.8% versus 62.5% for ALE (Akata et al., 2016). On SUN, LAGO loses by a small margin (57.5% versus 58.1%). Note that comparison with "Zhang2018" (Zhang & Koniusz, 2018) is

inconclusive. "Zhang2018" reports the results for 7 kernel types on the test set, but results on a validation set were not published, hence taking the best kernel over the test set may be optimistic.

**LAGO-Singletons versus DAP:** LAGO-Singletons is a reminiscent of DAP, but unlike DAP, it applies a soft relaxation that balances between appearance of an attribute and its negation. Interestingly, this minor change allows LAGO-Singletons to outperform DAP by  $\sim 40\%$  on average over all three datasets, while keeping an appealing simplicity as of DAP (Supplementary Table A.1).

**LAGO with few groups:** When the number of groups is small, the accuracy of LAGO is poor (Fig 3, 4) This happens because when groups have too many attributes, the AND-OR structure of LAGO becomes too permissive. For example, when all attributes are grouped into a single group, an OR is applied over all attributes and no AND, leading to many spurious matches when partial attributes are observed. A similar effect is observed when applying LAGO to SUN data which has only 4 semantic hard groups for 102 attributes. Indeed applying LAGO-Semantic-Hard to SUN performs poorly since it is too permissive. Another interesting effect arises when comparing the the poor performance of the single-group case with ESZSL. ESZSL is convex and with a closed-form solution, hence reaching the optimum is guaranteed. Single-group LAGO is non-convex (due to sigmoidal activation) making it harder to find the optimum. Indeed, we observed a worse training accuracy for single-group LAGO compared with ESZSL (61% vs 84% on CUB), suggesting that single-group LAGO tends to underfit the data.

**Learned Soft Group Assignments  $\Gamma$ :** We analyzed the structure of learned soft group assignments ( $\Gamma$ ) for LAGO-K-Soft (details in Supplementary B). We found two interesting observations: First, we find that the learned  $\Gamma$  tends to be sparse: with 2.5% non-zero values on SUN, 8.7% on AWA2 and 3.3% on CUB. Second, we observed that the model tends to group anti-correlated attributes. This is consistent with human-based grouping, whose attribute are also often anti correlated (red foot, blue foot). In SUN, 45% of attribute-pairs that are grouped together were anti-correlated, versus 23% of all attribute-pairs. In AWA2, 38% vs 5% baseline, CUB 16% vs 10% baseline (p-value  $\leq 0.003$ , KS-test).

**Qualitative Results:** To gain insight into why and when attribute grouping can reduce false positives and false negatives, we discuss in more depth two examples shown on Figure 5, predicted by LAGO-Semantic-Hard on CUB. The analysis demonstrates an interpretable quality of LAGO, allowing to "look under the hood" and explain class-predictions based on seen attributes.

**The effect of within-group disjunction (OR):** Image 5a is correctly classified by LAGO as a *Black-billed Cuckoo*, even-though a detector misses its brown primary-color. In more detail, for this class, raters disagreed whether the primary-color is mostly brown ( $p(\text{brown}|z) = 0.6$ ) or white (0.5), because this property largely depends on the point-of view. Somewhat surprisingly, the primary color in this photo was detected to be mostly white ( $p(\text{white}|\mathbf{x}) = 0.7$ ), and hardly brown (0.1), perhaps because of a brown branch that interferes with segmenting out the bird. Missing the brown color hurts any classifier that requires both brown and white, like DAP. LAGO treats the detected primary color as a good match because it takes a soft OR relation over the two primary colors, hence avoids missing the right class.

**The effect of group conjunction (AND):** Image 5b.1 was correctly classified by LAGO as a *White-Breasted Nuthatch*, even-though a detector incorrectly detects a yellow primary color ( $p(\text{yellow}|\mathbf{x}) = 0.6$ ) together with white and grey primary colors (0.7). As a comparison, the perceived yellow primary color confused ESZSL to mistake this image for a *Cape-May Warbler*, shown in image (b.2). Since ESZSL treats attributes as "flat", it does not use the fact that the breast pattern does not match a Warbler, and adheres to other attributes that produce a false positive detection of the Warbler. Yet, LAGO successfully avoids being confused by the yellow primary color, since the Nuthatch is expected to have a solid breast pattern, which is correctly detected  $p(\text{breast} : \text{solid}|\mathbf{x}) = 0.6$ . The Warbler is ranked lower because it is expected to have a striped breast pattern, which does not satisfy the AND condition because stripes are not detected  $p(\text{breast} : \text{striped}|x) = 0$ .

#### 4.4 ABLATION EXPERIMENTS

We carried empirical ablation experiments with the semantic hard-grouping of LAGO. Specifically, we tested three design decisions we made, as described above. **(1) Uniform** relates to taking a uniform prior for  $p(a_m)$ , which is the average of the estimated  $p(a_m)$ . "Per-attribute" relates to using the estimated  $p(a_m)$  directly. **(2) Const** relates to setting a constant value for the approximation of the complementary attribute  $p(\tilde{a}_k|\mathbf{x})$ . "DeMorgan" relates to approximating it from predictions of other attributes with De-Morgan's rule. **(3) Implicit** relates to setting a zero weight ( $\alpha = 0$ ) for the loss term of the attribute supervision. I.e. attributes are learned implicitly, because only class-level supervision is given. "Explicit" related to setting a non-zero  $\alpha$  respectively.

Table A.2 (in Supplementary) shows contributions of each combination of the design decisions to prediction accuracy, on the validation set of CUB and AWA2. The results are consistent for both CUB and AWA2. The

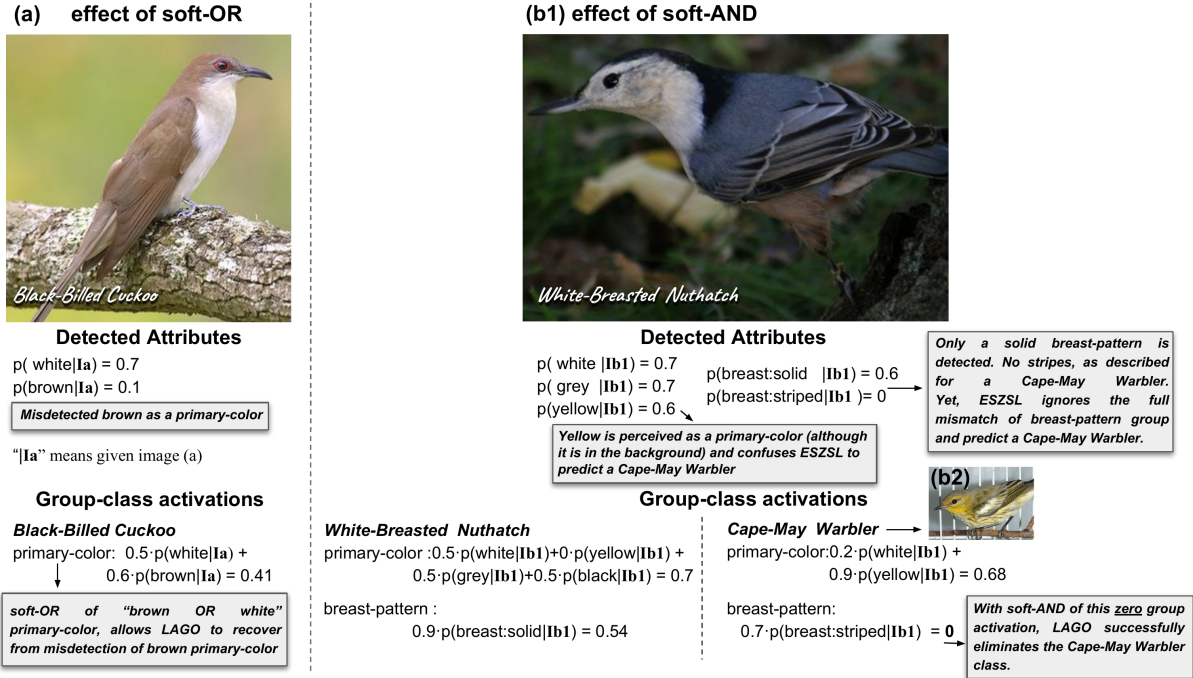

Figure 5: Qualitative examples. **(a)** LAGO correctly classifies a Black-billed Cuckoo, due to soft-OR of “brown or white” primary-color, although a detector misses its brown primary-color. **(b1)** LAGO correctly classifies a White-Breasted Nuthatch: The soft-intersection across groups prevents incorrect classification. ESZSL incorrectly classified Image (b1) as class of (b2), despite irrelevant attribute groups like its breast pattern **(b2)** A typical Cape-May Warbler. ESZSL mistakes (b1) image for this class

most major effect is contributed for the uniform prior of  $p(a_m)$ . All experiments that use the uniform prior yield better accuracy. We observe that taking a uniform prior also reduces variability due to the other approximations we take. Specifically, on CUB there is  $\approx 4.5\%$  best-to-worst gap with a uniform prior, vs  $\approx 12.5\%$  without ( $\approx 11\%$  vs  $\approx 16\%$  for AWA2 respectively). Next we observe that in the uniform case, approximating  $p(\tilde{a}_k|\mathbf{x})$  by a constant, is superior to approximating it with DeMorgan’s rule, and similarly, reduces the impact of the variability of the implicit/explicit condition. Last, the contribution of attributes supervision condition mostly depends on selection of the previous two conditions.

## 5 DISCUSSION

Three interesting future research directions can be followed. First, since LAGO is probabilistic, one can plug measures for model uncertainty (Gal & Ghahramani, 2016), to improve model prediction and increase robustness to adversarial attacks. Second, descriptions of fine-grained categories often provide richer logical expressions to describe and differentiate classes. It will be interesting to study how LAGO may be extended to incorporate richer relations that could be explicitly discriminative (Vedantam et al., 2017). For example, Wikipedia describes *White-Breasted-Nuthatch* to make it distinct from other, commonly confused, Nuthatches

by: “Three other, significantly smaller, nuthatches have ranges which overlap that of white-breasted, but none has white plumage completely surrounding the eye.”.

Third, when people describe classes, they often use a handful of attributes instead of listing all values for the full set of attributes. The complementary attribute used in LAGO allows to model a “don’t-care” about a group, when no description is provided for a group. Such an approach could enable to recognize visual entities based on a handful and partial indication of semantic properties.

## 6 SUMMARY

We presented LAGO, a new probabilistic zero-shot-learning approach that can be trained end-to-end. LAGO approximates  $p(\text{class} = z | \text{image} = \mathbf{x})$  by capturing natural soft *and-or* logical relations among *groups of attributes*, unlike most ZSL approaches that represent attributes as embedded in a “flat” space. LAGO learns the grouping structure from data, and can effectively incorporate prior domain knowledge about the grouping of attributes when available. We find that LAGO achieves new state-of-the-art result on CUB (Wah et al., 2011), AWA2 (Lampert et al., 2009), and is competitive on SUN (Patterson & Hays, 2012). Finally, LAGO reveals an interesting unified formulation over seemingly-unrelated ZSL approaches, DAP (Lampert et al., 2009) and ESZSL (Romera-Paredes & Torr, 2015).

## Abstract

Variational inference relies on flexible approximate posterior distributions. Normalizing flows provide a general recipe to construct flexible variational posteriors. We introduce Sylvester normalizing flows, which can be seen as a generalization of planar flows. Sylvester normalizing flows remove the well-known single-unit bottleneck from planar flows, making a single transformation much more flexible. We compare the performance of Sylvester normalizing flows against planar flows and inverse autoregressive flows and demonstrate that they compare favorably on several datasets.

## 1 INTRODUCTION

Stochastic variational inference [Hoffman et al., 2013] allows for posterior inference in increasingly large and complex problems using stochastic gradient ascent. In continuous latent variable models, variational inference can be made particularly efficient through the amortized inference, in which inference networks amortize the cost of calculating the variational posterior for a data point [Gershman and Goodman, 2014]. A particularly successful class of models is the variational autoencoder (VAE) in which both the generative model and the inference network are given by neural networks, and sampling from the variational posterior is efficient through the non-centered parameterization [Kingma and Welling, 2014], also known as the reparameterization trick [Kingma and Welling, 2013, Rezende et al., 2014].

Despite its success, variational inference has drawbacks compared to other inference methods such as MCMC. Variational inference searches for the best posterior approximation within a parametric family of distributions. Hence, the true posterior distribution can only be recovered exactly if it happens to be in the chosen family. In particular, with widely used simple variational families such as diagonal covariance Gaussian distributions, the variational approximation is likely to be insufficient. More complex variational families enable better posterior approximations, resulting in improved model performance. Therefore, designing tractable and more expressive variational families is an important problem in variational inference [Nalisnick et al., 2016, Salimans et al., 2015, Tran et al., 2015].

Rezende and Mohamed [2015] introduced a general framework for constructing more flexible variational distributions, called normalizing flows. Normalizing flows transform a base density through a number of invertible parametric transformations with tractable Jacobians into more complicated distributions. They proposed two classes of normalizing flows: planar flows and radial flows. While effective for small problems, these can be hard to train and often many transformations are required to get good performance. For planar flows, Kingma et al. [2016] argue that this is due to the fact that the transformation used acts as a bottleneck, warping one direction at a time. Having a large number of flows makes the inference network very deep and harder to train, empirically resulting in suboptimal performance. Kingma et al. [2016] proposed inverse auto-regressive flows (IAF), achieving state of the art results on dynamically binarized MNIST at the time of publication. While very successful, IAFs require a very large number of parameters. Due to the large number of parameters IAFs cannot amortize all flow parameters. Instead amortization is achieved through an additional context vector that is fed into each flow step.

**Paper contribution** In this paper, we use Sylvester’s determinant identity to introduce Sylvester normalizing flows (SNFs). This family of flows is a generalization of planar flows, removing the bottleneck. We compare a number of different variants of SNFs and show that they compare favorably against planar flows and IAFs. We show that one specific variant of SNFs is related to IAFs, while requiring many fewer parameters due to direct amortization of all flow parameters.

## 2 VARIATIONAL INFERENCE

Consider a probabilistic model with observations  $\mathbf{x}$  and continuous latent variables  $\mathbf{z}$  and model parameters  $\theta$ . In generative modeling we are often interested in performing maximum (marginal) likelihood learning of the parameters  $\theta$  of the latent-variable model  $p_\theta(\mathbf{x}, \mathbf{z})$ . This requires marginalization over the unobserved latent variables  $\mathbf{z}$ . Unfortunately, this integration is generally intractable. Variational inference [Jordan et al., 1999] instead introduces a variational approximation  $q_\phi(\mathbf{z}|\mathbf{x})$  to the posterior with learnable parameters  $\phi$ , to construct a lower bound on the log marginal likelihood:

$$\log p_\theta(\mathbf{x}) \geq \log p_\theta(\mathbf{x}) - \text{KL}(q_\phi(\mathbf{z}|\mathbf{x}) || p(\mathbf{z}|\mathbf{x})) \quad (1)$$

$$= \mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{x}|\mathbf{z})] - \text{KL}(q_\phi(\mathbf{z}|\mathbf{x}) || p(\mathbf{z})) \quad (2)$$

$$=: -\mathcal{F}(\theta, \phi) \quad (3)$$

This bound is known as the evidence lower bound (ELBO) and  $\mathcal{F}$  is referred to as the variational free energy. In equation (2), the first term represents the reconstruction error, and the second term is the Kullback-Leibler (KL) divergence from the approximate posterior to the prior distribution, which acts as a regularizer. In this paper we consider variational autoencoders (VAEs), where both  $p_\theta(\mathbf{x}|\mathbf{z})$  and  $q_\phi(\mathbf{z}|\mathbf{x})$  are distributions whose parameters are given by neural networks. The parameters  $\theta$  and  $\phi$  of the generative model and inference model, respectively, are trained jointly through stochastic minimisation of  $\mathcal{F}$  which can be made efficient through the reparameterization trick [Kingma and Welling, 2013, Rezende et al., 2014].

From equation (1) we see that the better the variational approximation to the posterior the tighter the ELBO. The simplest, but probably most widely used choice of variation distribution  $q_\phi(\mathbf{z}|\mathbf{x})$  is diagonal-covariance Gaussians of the form  $\mathcal{N}(\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\sigma}^2(\mathbf{x}))$ . However, with such simple variational distributions the ELBO will be fairly loose, resulting in biased maximum likelihood estimates of the model parameters  $\theta$  (see Fig. 2) and harming generative performance. Thus, for variational inference to work well, more flexible approximate posterior distributions are needed.

Figure 1: Since the ELBO is only a lower bound on the log marginal likelihood, they do not share the same local maxima. The looser the ELBO is the more this can bias maximum likelihood estimates of the model parameters.

### 2.1 NORMALIZING FLOWS

Rezende and Mohamed [2015] propose a way to construct more flexible posteriors by transforming a simple base distribution with a series of invertible transformations (known as normalizing flows) with easily computable Jacobians. The resulting transformed density after one such transformation  $f$  is as follows [Tabak and Turner, 2013, Tabak and Vanden-Eijnden, 2010]:

$$p_1(\mathbf{z}') = p_0(\mathbf{z}) \left| \det \left( \frac{\partial f(\mathbf{z})}{\partial \mathbf{z}} \right) \right|^{-1}, \quad (4)$$

where  $\mathbf{z}' = f(\mathbf{z})$ ,  $\mathbf{z}, \mathbf{z}' \in \mathbb{R}^D$  and  $f : \mathbb{R}^D \mapsto \mathbb{R}^D$  is an invertible function. In general the cost of computing the Jacobian will be  $\mathcal{O}(D^3)$ . However, it is possible to design transformations with more efficiently computable Jacobians.

This strategy is used in variational inference as follows: first, a stochastic variable is drawn from a simple base posterior distribution such as a diagonal Gaussian  $\mathcal{N}(\mathbf{z}_0|\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\sigma}^2(\mathbf{x}))$ . The sample is then transformed with a number of flows. After applying  $K$  flows, the final latent stochastic variables are given by  $\mathbf{z}_K = f_K \circ \dots \circ f_2 \circ f_1(\mathbf{z}_0)$ . The corresponding log-density is then given by:

$$\log q_K(\mathbf{z}_K|\mathbf{x}) = \log q_0(\mathbf{z}_0|\mathbf{x}) - \sum_{k=1}^K \log \left| \det \left( \frac{\partial f_k(\mathbf{z}_{k-1}; \lambda_k(\mathbf{x}))}{\partial \mathbf{z}_{k-1}} \right) \right|, \quad (5)$$

where  $\lambda_k$  are the parameters of the  $k$ -th transformation. Given variational posterior  $q_\phi(\mathbf{z}|\mathbf{x}) = q_K(\mathbf{z}|\mathbf{x})$  parametrized by a normalizing flow of length  $K$ , the vari-

ational objective can be rewritten as:

$$\begin{aligned} \mathcal{F}(\theta, \phi) &= \mathbb{E}_{q_\phi} [\log q_\phi(\mathbf{z}|\mathbf{x}) - \log p_\theta(\mathbf{x}, \mathbf{z})] \\ &= \mathbb{E}_{q_0} [\log q_0(\mathbf{z}_0|\mathbf{x}) - \log p_\theta(\mathbf{x}, \mathbf{z})] \\ &\quad - \mathbb{E}_{q_0} \left[ \sum_{k=1}^K \log \left| \det \left( \frac{\partial f_k(\mathbf{z}_{k-1}; \lambda_k(\mathbf{x}))}{\partial \mathbf{z}_{k-1}} \right) \right| \right]. \end{aligned} \quad (6)$$

Normalizing flows are normally used with amortized variational inference. Instead of learning variational parameters for each data point, both  $\boldsymbol{\mu}$  and  $\boldsymbol{\sigma}$ , as well as all the flow parameters are outputs of a deep neural network conditioned on  $\mathbf{x}$ . This is referred to as the inference network.

Rezende and Mohamed [2015] introduced a normalizing flow, called planar flow, for which the Jacobian determinant could be computed efficiently. A single transformation of the planar flow is given by:

$$\mathbf{z}' = \mathbf{z} + \mathbf{u}h(\mathbf{w}^T \mathbf{z} + b). \quad (8)$$

Here,  $\mathbf{u}, \mathbf{w} \in \mathbb{R}^D$ ,  $b \in \mathbb{R}$  and  $h$  is a suitable smooth activation function. Rezende and Mohamed [2015] show that for  $h = \tanh$ , transformations of this kind are invertible as long as  $\mathbf{u}^T \mathbf{w} \geq -1$ .

By the *Matrix determinant lemma* the Jacobian of this transformation is given by:

$$\begin{aligned} \det \frac{\partial \mathbf{z}'}{\partial \mathbf{z}} &= \det (\mathbf{I} + \mathbf{u}h'(\mathbf{w}^T \mathbf{z} + b)\mathbf{w}^T) \\ &= 1 + \mathbf{u}^T h'(\mathbf{w}^T \mathbf{z} + b)\mathbf{w}, \end{aligned} \quad (9)$$

where  $h'$  denotes the derivative of  $h$  and which can be computed in  $O(D)$  time.

In practice, many planar flow transformations are required to transform a simple base distribution into a flexible distribution, especially for high dimensional latent spaces. Kingma et al. [2016] argue that this is related to the term  $\mathbf{u}h(\mathbf{w}^T \mathbf{z} + b)$  in Eq. (8), which effectively acts as a single-neuron MLP. In the next section we will derive a generalization of planar flows, which does not have a single-neuron bottleneck, while still maintaining the property of an efficiently computable Jacobian determinant.

### 3 SYLVESTER NORMALIZING FLOWS

Consider the following more general transformation similar to a single layer MLP with  $M$  hidden units and a residual connection:

$$\mathbf{z}' = \mathbf{z} + \mathbf{A}h(\mathbf{B}\mathbf{z} + \mathbf{b}), \quad (10)$$

with  $\mathbf{A} \in \mathbb{R}^{D \times M}$ ,  $\mathbf{B} \in \mathbb{R}^{M \times D}$ ,  $\mathbf{b} \in \mathbb{R}^M$ , and  $M \leq D$ . The Jacobian determinant of this transformation can be obtained using Sylvester's determinant identity, which is a generalization of the matrix determinant lemma.

**Theorem 1** (Sylvester's determinant identity). *For all  $\mathbf{A} \in \mathbb{R}^{D \times M}$ ,  $\mathbf{B} \in \mathbb{R}^{M \times D}$ ,*

$$\det(\mathbf{I}_D + \mathbf{A}\mathbf{B}) = \det(\mathbf{I}_M + \mathbf{B}\mathbf{A}), \quad (11)$$

where  $\mathbf{I}_M$  and  $\mathbf{I}_D$  are  $M$  and  $D$ -dimensional identity matrices, respectively.

When  $M < D$ , the computation of the determinant of a  $D \times D$  matrix is thus reduced to the computation of the determinant of an  $M \times M$  matrix.

Using Sylvester's determinant identity, the Jacobian determinant of the transformation in Eq. (10) is given by:

$$\det \left( \frac{\partial \mathbf{z}'}{\partial \mathbf{z}} \right) = \det (\mathbf{I}_M + \text{diag} (h'(\mathbf{B}\mathbf{z} + \mathbf{b})) \mathbf{B}\mathbf{A}). \quad (12)$$

Since Sylvester's determinant identity plays a crucial role in the proposed family of normalizing flows, we will refer to them as *Sylvester normalizing flows*.

#### 3.1 PARAMETERIZATION OF A AND B

In general, the transformation in (10) will not be invertible. Therefore, we propose the following special case of the above transformation:

$$\mathbf{z}' = \mathbf{z} + \mathbf{Q}\mathbf{R}h(\tilde{\mathbf{R}}\mathbf{Q}^T \mathbf{z} + \mathbf{b}) = \phi(\mathbf{z}), \quad (13)$$

where  $\mathbf{R}$  and  $\tilde{\mathbf{R}}$  are upper triangular  $M \times M$  matrices, and

$$\mathbf{Q} = (\mathbf{q}_1 \dots \mathbf{q}_M)$$

with the columns  $\mathbf{q}_m \in \mathbb{R}^D$  forming an orthonormal set of vectors. By theorem 1, the determinant of the Jacobian  $\mathbf{J}$  of this transformation reduces to:

$$\begin{aligned} \det \mathbf{J} &= \det \left( \mathbf{I}_M + \text{diag} \left( h'(\tilde{\mathbf{R}}\mathbf{Q}^T \mathbf{z} + \mathbf{b}) \right) \tilde{\mathbf{R}}\mathbf{Q}^T \mathbf{Q}\mathbf{R} \right) \\ &= \det \left( \mathbf{I}_M + \text{diag} \left( h'(\tilde{\mathbf{R}}\mathbf{Q}^T \mathbf{z} + \mathbf{b}) \right) \tilde{\mathbf{R}}\mathbf{R} \right), \end{aligned} \quad (14)$$

which can be computed in  $O(M)$ , since  $\tilde{\mathbf{R}}\mathbf{R}$  is also upper triangular. The following theorem gives a sufficient condition for this transformation to be invertible.

**Theorem 2.** *Let  $\mathbf{R}$  and  $\tilde{\mathbf{R}}$  be upper triangular matrices. Let  $h : \mathbb{R} \rightarrow \mathbb{R}$  be a smooth function with bounded, positive derivative. Then, if the diagonal entries of  $\mathbf{R}$  and  $\tilde{\mathbf{R}}$  satisfy  $r_{ii}\tilde{r}_{ii} > -1/\|h'\|_\infty$  and  $\tilde{\mathbf{R}}$  is invertible, the transformation given by (13) is invertible.*

*Proof. Case 1: R and R-tilde diagonal*

Recall that one-dimensional real functions with strictly positive derivatives are invertible. The columns of  $\mathbf{Q}$  are orthonormal and span a subspace  $\mathcal{W} = \text{span}\{\mathbf{q}_1, \dots, \mathbf{q}_M\}$  of  $\mathbb{R}^D$ . Let  $\mathcal{W}^\perp$  denote its orthogonal complement. We can decompose  $\mathbf{z} = \mathbf{z}_\parallel + \mathbf{z}_\perp$ , where  $\mathbf{z}_\parallel \in \mathcal{W}$  and  $\mathbf{z}_\perp \in \mathcal{W}^\perp$ . Similarly we can decompose  $\mathbf{z}' = \mathbf{z}'_\parallel + \mathbf{z}'_\perp$ . Clearly,  $\mathbf{Q}\mathbf{R}h(\tilde{\mathbf{R}}\mathbf{Q}^T\mathbf{z} + \mathbf{b}) \in \mathcal{W}$ . Hence  $\phi$  only acts on  $\mathbf{z}_\parallel$  and  $\mathbf{z}_\perp = \phi(\mathbf{z})_\perp = \mathbf{z}'_\perp$ . Thus, it suffices to consider the effect of  $\phi$  on  $\mathbf{z}_\parallel$ . Multiplying (13) by  $\mathbf{Q}^T$  from the left gives:

$$\underbrace{\mathbf{Q}^T\mathbf{z}'}_{\mathbf{v}'} = \underbrace{\mathbf{Q}^T\mathbf{z}}_{\mathbf{v}} + \mathbf{R}h(\underbrace{\tilde{\mathbf{R}}\mathbf{Q}^T\mathbf{z} + \mathbf{b}}_{\mathbf{v}}) \quad (15)$$

$$= (f_1(v_1), \dots, f_M(v_M))^T,$$

where the vectors  $\mathbf{v}$  and  $\mathbf{v}'$  are the respective coordinates of  $\mathbf{z}_\parallel$  and  $\mathbf{z}'_\parallel$  w.r.t.  $\mathbf{q}_1, \dots, \mathbf{q}_M$ . The dimensions in (15) are completely independent and each dimension is transformed by a real function  $f_i(v) = v + r_{ii}h(\tilde{r}_{ii}v + b_i)$ . Consider a single dimension  $i$  of (15). Since  $\|h'\|_\infty r_{ii}\tilde{r}_{ii} > -1$ , we have  $f'_i(v) > 0$  and thus  $f_i$  is invertible. Since all dimensions are independent and the transformation is invertible in each dimension we can find  $f^{-1} : \mathcal{W} \rightarrow \mathcal{W}$  such that  $\mathbf{z}_\parallel = f^{-1}(\mathbf{z}'_\parallel)$ . Hence we can write the inverse of  $\phi$  as:

$$\phi^{-1}(\mathbf{z}') = \underbrace{\mathbf{z}'_\perp}_{\mathbf{z}_\perp} + \underbrace{f^{-1}(\mathbf{z}'_\parallel)}_{\mathbf{z}_\parallel} = \mathbf{z}, \quad (16)$$

**Case 2: R triangular, R-tilde diagonal**

Let us now consider the case when  $\mathbf{R}$  is an upper triangular matrix. By the argument for the diagonal case above, it suffices to consider the effect of the transformation in  $\mathcal{W}$ . Multiplying (13) by  $\mathbf{Q}^T$  from the left gives:

$$\underbrace{\mathbf{Q}^T\mathbf{z}'}_{\mathbf{v}'} = \underbrace{\mathbf{Q}^T\mathbf{z}}_{\mathbf{v}} + \mathbf{R}h(\underbrace{\tilde{\mathbf{R}}\mathbf{Q}^T\mathbf{z} + \mathbf{b}}_{\mathbf{v}}) \quad (17)$$

where the vectors  $\mathbf{v}$  and  $\mathbf{v}'$  contain the respective coordinates of  $\mathbf{z}_\parallel$  and  $\mathbf{z}'_\parallel$  w.r.t.  $\mathbf{q}_1, \dots, \mathbf{q}_M$ . As in the diagonal case consider the functions  $f_i(v) = v + r_{ii}h(\tilde{r}_{ii}v + b_i)$ . Since  $\|h'\|_\infty r_{ii}\tilde{r}_{ii} > -1$ , we have  $f'_i(v) > 0$  and thus  $f_i$  is invertible. Let us rewrite (17) in terms of  $f_i$ :

$$v'_1 = f_1(v_1) + \sum_{j=2}^M r_{1j}h(\tilde{r}_{jj}v_j + b_j) \quad (18)$$

...

$$v'_k = f_k(v_k) + \sum_{j=k+1}^M r_{kj}h(\tilde{r}_{jj}v_j + b_j) \quad (19)$$

...

$$v'_M = f_M(v_M) \quad (20)$$

Since  $f_M$  is invertible we can write  $v_M = f_M^{-1}(v'_M)$ . Now suppose we have expressed  $\{v_j, \forall j > k\}$  in terms of  $\{v'_j, \forall j > k\}$ . Then

$$f_k(v_k) = v'_k - \underbrace{\sum_{j=k+1}^M r_{kj}h(\tilde{r}_{jj}v_j + b_j)}_{\text{some function of } \{v'_j, \forall j > k\}}$$

$$=: g_k(v'_k, v'_{k+1}, \dots, v'_M) \quad (21)$$

$$v_k = f_k^{-1}(g_k(v'_k, v'_{k+1}, \dots, v'_M)).$$

Thus we have expressed  $\{v_j, \forall j \geq k\}$  in terms of  $\{v'_j, \forall j \geq k\}$ . By induction, we can express  $\{v_j, \forall j\}$  in terms of  $\{v'_j, \forall j\}$  and hence the transformation is invertible.

**Case 3: R and R-tilde triangular**

Now consider the general case when  $\tilde{\mathbf{R}}$  is triangular. As before we only need to consider the effect of the transformation in  $\mathcal{W}$ .

$$\underbrace{\mathbf{Q}^T\mathbf{z}'}_{\mathbf{v}'} = \underbrace{\mathbf{Q}^T\mathbf{z}}_{\mathbf{v}} + \mathbf{R}h(\underbrace{\tilde{\mathbf{R}}\mathbf{Q}^T\mathbf{z} + \mathbf{b}}_{\mathbf{v}}) \quad (22)$$

Let  $g$  be the function  $g(\mathbf{v}) = \tilde{\mathbf{R}}\mathbf{v}$ . By assumption,  $g$  is invertible with inverse  $g^{-1}$ . Multiplying (22) by  $\tilde{\mathbf{R}}$  gives:

$$g(\mathbf{v}') = \underbrace{g(\mathbf{v}) + \tilde{\mathbf{R}}\mathbf{R}h(g(\mathbf{v}) + \mathbf{b})}_{=: f(g(\mathbf{v}))} \quad (23)$$

Since  $\tilde{\mathbf{R}}\mathbf{R}$  is upper triangular with diagonal entries  $\tilde{r}_{jj}r_{jj}$ ,  $f$  is covered by case 2 considered before and is invertible. Thus,  $\mathbf{v}$  can be written as:

$$\mathbf{v} = g^{-1}(f^{-1}(g(\mathbf{v}'))). \quad (24)$$

Hence the transformation in (22) is invertible.  $\square$

**3.2 PRESERVING ORTHOGONALITY OF Q**

Orthogonality is a convenient property, mathematically, but hard to achieve in practice. In this paper we consider three different flows based on the theorem above and various ways to preserve the orthogonality of  $\mathbf{Q}$ . The first two use explicit differentiable constructions of orthogonal matrices, while the third variant assumes a specific fixed permutation matrix as the orthogonal matrix.

**Orthogonal Sylvester flows.** First, we consider a Sylvester flow using matrices with  $M$  orthogonal columns (O-SNF). In this flow we can choose  $M < D$ , and thus introduce a flexible bottleneck. Similar to [Hasenclever et al., 2017], we ensure orthogonality of

$\mathbf{Q}$  by applying the following differentiable iterative procedure proposed by [Björck and Bowie, 1971, Kovarik, 1970]:

$$\mathbf{Q}^{(k+1)} = \mathbf{Q}^{(k)} \left( \mathbf{I} + \frac{1}{2} \left( \mathbf{I} - \mathbf{Q}^{(k)\top} \mathbf{Q}^{(k)} \right) \right). \quad (25)$$

with a sufficient condition for convergence given by  $\|\mathbf{Q}^{(0)\top} \mathbf{Q}^{(0)} - \mathbf{I}\|_2 < 1$ . Here, the 2-norm of a matrix  $\mathbf{X}$  refers to  $\|\mathbf{X}\|_2 = \lambda_{\max}(\mathbf{X})$ , with  $\lambda_{\max}(\mathbf{X})$  representing the largest singular value of  $\mathbf{X}$ . In our experimental evaluations we ran the iterative procedure until  $\|\mathbf{Q}^{(k)\top} \mathbf{Q}^{(k)} - \mathbf{I}\|_F \leq \epsilon$ , with  $\|\mathbf{X}\|_F$  the Frobenius norm, and  $\epsilon$  a small convergence threshold. We observed that running this procedure up to 30 steps was sufficient to ensure convergence with respect to this threshold. To minimize the computational overhead introduced by orthogonalization we perform this orthogonalization in parallel for all flows.

Since this orthogonalization procedure is differentiable, it allows for the calculation of gradients with respect to  $\mathbf{Q}^{(0)}$  by backpropagation, allowing for any standard optimization scheme such as stochastic gradient descent to be used for updating the flow parameters.

**Householder Sylvester flows.** Second, we study Householder Sylvester flows (H-SNF) where the orthogonal matrices are constructed by products of Householder reflections. Householder transformations are reflections about hyperplanes. Let  $\mathbf{v} \in \mathbb{R}^D$ , then the reflection about the hyperplane orthogonal to  $\mathbf{v}$  is given by:

$$H(\mathbf{z}) = \mathbf{z} - \frac{\mathbf{v}\mathbf{v}^T}{\|\mathbf{v}\|^2} \mathbf{z} \quad (26)$$

It is worth noting that performing a single Householder transformation is very cheap to compute, as it only requires  $D$  parameters. Chaining together several Householder transformations results in more general orthogonal matrices, and it can be shown [Bischof and Sun, 1997, Sun and Bischof, 1995] that any  $M \times M$  orthogonal matrix can be written as the product of  $M - 1$  Householder transformations. In our Householder Sylvester flow, the number of Householder transformations  $H$  is a hyperparameter that trades off the number of parameters and the generality of the orthogonal transformation. Note that the use of Householder transformations forces us to use  $M = D$ , since Householder transformation result in square matrices.

**Triangular Sylvester flows.** Third, we consider a triangular Sylvester flow (T-SNF), in which all orthogonal matrices  $\mathbf{Q}$  alternate per transformation between the

identity matrix and the permutation matrix corresponding to reversing the order of  $\mathbf{z}$ . This is equivalent to alternating between lower and upper triangular  $\tilde{\mathbf{R}}$  and  $\mathbf{R}$  for each flow.

### 3.3 AMORTIZING FLOW PARAMETERS

When using normalizing flows in an amortized inference setting, the parameters of the base distribution as well as the flow parameters can be functions of the data point  $\mathbf{x}$  [Rezende and Mohamed, 2015]. Figure 2 (left) shows a diagram of one SNF step and the amortization procedure. The inference network takes datapoints  $\mathbf{x}$  as input, and provides as an output the mean and variance of  $\mathbf{z}^0$  such that  $\mathbf{z}^0 \sim \mathcal{N}(\mathbf{z}|\mu^0, \sigma^0)$ . Several SNF transformations are then applied to  $\mathbf{z}^0 \rightarrow \mathbf{z}^1 \rightarrow \dots \rightarrow \mathbf{z}^K$ , producing a flexible posterior distribution for  $\mathbf{z}^K$ . All of the flow parameters ( $\mathbf{R}$ ,  $\tilde{\mathbf{R}}$  and  $\mathbf{Q}$  for each transformation) are produced as an output by the inference network, and are thus fully amortized.

## 4 RELATED WORK

### 4.1 NORMALIZING FLOWS FOR VARIATIONAL INFERENCE

A number of invertible transformations with tractable Jacobians have been proposed in recent years. Rezende and Mohamed [2015] first discussed such transformations in the context of stochastic variation inference, coining the term normalizing flows.

Rezende and Mohamed [2015] proposed two different parametric families of transformations with tractable Jacobians: planar and radial flows. While effective for small problems, these transformations are hard to scale to large latent spaces and often require a large number of transformations. The transformation corresponding to planar flows is given in Eq. (8).

More recently, a successful class of flows called Inverse Autoregressive Flows was introduced in [Kingma et al., 2016]. As the name suggests, one IAF transformation can be seen as the inverse of an autoregressive transformation. Consider the following autoregressive transformation:

$$\begin{aligned} z_0 &= \bar{\mu}_0 + \bar{\sigma}_0 \cdot \epsilon_0 \\ z_i &= \bar{\mu}_i(\mathbf{z}_{1:i-1}) + \bar{\sigma}_i(\mathbf{z}_{1:i-1}) \cdot \epsilon_i, \quad i = 1, \dots, D \end{aligned} \quad (27)$$

with  $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ . This transformation models the distribution over the variable  $\mathbf{z}$  with an autoregressive factorization  $p(\mathbf{z}) = p(z_0) \prod_{i=1}^D p(z_i|z_{i-1}, \dots, z_0)$ . Since the parameters of transformation for  $z_i$  are dependent on  $\mathbf{z}_{1:i-1}$ , this procedure requires  $D$  sequential steps to sam-

Figure 2: Different amortization strategies for Sylvester normalizing flows and Inverse Autoregressive Flows. Left: our inference network produces amortized flow parameters. This strategy is also employed by planar flows. Right: IAF has a large number of parameters, and introduces a measure of  $\mathbf{x}$  dependence through a context  $\mathbf{h}(\mathbf{x})$ . This context acts as an additional input for each transformation. The flow parameters themselves are independent of  $\mathbf{x}$ .

ple a single vector  $\mathbf{z}$ . This is undesirable for variational inference, where sampling occurs for every forward pass.

However, the inverse transformation (which exists if  $\bar{\sigma}_i > 0 \forall i$ ) is easy to sample from:

$$\epsilon_i = \frac{z_i - \bar{\mu}_i(\mathbf{z}_{1:i-1})}{\bar{\sigma}_i(\mathbf{z}_{1:i-1})}. \quad (28)$$

For this inverse transformation,  $\epsilon_i$  is no longer dependent on the transformation of  $\epsilon_j$  for  $j \neq i$ . Hence, this transformation can be computed in parallel:  $\epsilon = (\mathbf{z} - \bar{\boldsymbol{\mu}}(\mathbf{z})) / \bar{\boldsymbol{\sigma}}(\mathbf{z})$ . Rewriting  $\sigma_i(z_{1:i-1}) = 1/\bar{\sigma}_i(z_{1:i-1})$  and  $\mu_i(z_{1:i-1}) = -\bar{\mu}(z_{1:i-1})/\bar{\sigma}_i(z_{1:i-1})$ , yields the IAF transformation:

$$z_i^t = \mu_i^t(\mathbf{z}_{1:i-1}^{t-1}) + \sigma_i^t(\mathbf{z}_{1:i-1}^{t-1}) \cdot z_i^{t-1}, \quad i = 1, \dots, D. \quad (29)$$

Starting from  $\mathbf{z}^0 \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ , multiple IAF transformations can be stacked on top of each other to produce flexible probability distributions.

If  $\boldsymbol{\mu}^t$  and  $\boldsymbol{\sigma}^t$  depend on  $\mathbf{z}^{t-1}$  linearly, IAF can model full covariance Gaussian distributions. In order to move away from Gaussian distributions to more flexible distributions, it is important that  $\boldsymbol{\mu}^t$  and  $\boldsymbol{\sigma}^t$  are nonlinear functions of  $\mathbf{z}^{t-1}$ .

In practice, wide MADEs [Germain et al., 2015] or deep PixelCNN layers [van den Oord et al., 2016] are needed to increase the flexibility of IAF transformations. This results in transformations with a large number of parameters. As shown in Figure 2 (right), amortization is achieved through a context  $\mathbf{h}(\mathbf{x})$  that is fed into the autoregressive networks as an additional input at every IAF step.

Our Triangular Sylvester flows are strongly related to mean-only IAF transformations ( $\boldsymbol{\sigma}^t = 1$ ). As mentioned

in Kingma et al. [2016], between every IAF transformation the order of  $\mathbf{z}$  is reversed, in order to ensure that on average all dimensions get warped equally. In T-SNF, the same effect is achieved by using the permutation matrix that reverses the order of  $\mathbf{z}$  in every other transformation as the orthogonal matrix. However, mean-only IAF is a volume-preserving transformation, i.e. the determinant of the Jacobian has absolute value one. T-SNF is not volume preserving due to the nonzero elements on the diagonals of  $\mathbf{R}$  and  $\tilde{\mathbf{R}}$ . Note, that in Kingma et al. [2016] it was shown that the empirical difference in performance between mean-only IAF and the general IAF transformation is negligible.

The most important difference between IAF and T-SNF is the way parameters are amortized. In T-SNF,  $\mathbf{R}$  and  $\tilde{\mathbf{R}}$  are directly amortized functions of the input  $\mathbf{x}$  (see Fig. 2). This is equivalent to amortizing the MADE parameters in mean-only IAF. Having input dependent MADE parameters allows for flexible transformations with fewer parameters.

Householder Sylvester flows can also be seen as a non-linear extension of Householder flows [Tomczak and Welling, 2016]. Householder flows are volume-preserving flows, which transform the variational posterior with a diagonal covariance matrix to a full-covariance posterior. Householder flows are a special case of H-SNF if  $h(\mathbf{z}) = \mathbf{z}$ ,  $\mathbf{R}$  is the identity matrix, and the residual connection in Eq. (13) is left out.

## 4.2 NORMALIZING FLOWS FOR DENSITY ESTIMATION

A number of invertible transformations have been proposed in the context of density estimation. Note that density estimation requires the inverse of the flow to be tractable. Having a provably invertible transformation is

not the same as being able to compute the inverse.

For density estimation with normalizing flows, we are interested maximizing the log-likelihood of the data:

$$\log p(\mathbf{x}) = \log p_0(f^{-1}(\mathbf{x})) + \log \left| \det \left( \frac{\partial f^{-1}(\mathbf{x})}{\partial \mathbf{x}} \right) \right|. \quad (30)$$

Thus, the goal is to transform a complicated data distribution back to a simple distribution. In general, both directions of an invertible transformations need not be tractable. Hence, methods developed for density estimation are generally not directly applicable to variational inference.

Non-linear independent component estimation (NICE, Dinh et al. [2014]) and the related Real NVP [Dinh et al., 2016], and Masked Autoregressive Flow (MAF, Papamakarios et al. [2017]) are recent examples of normalizing flows for density estimation.

In NICE, each transformation splits the variables into two disjoint subsets  $\mathbf{z}_A, \mathbf{z}_B$ . One of the subsets is transformed as  $\mathbf{z}'_A = \mathbf{z}_A + f(\mathbf{z}_B)$ , while  $\mathbf{z}_B$  is left unchanged. In the next transformation a different subset of variables is transformed. This results in a transformation which is trivially invertible and has a tractable Jacobian. Real NVP uses the same fundamental idea. Appealingly, because of the tractable inverse, NICE and real NVP can generate data and estimate density with one forward pass. However due to fact that only a subset of variables is updated in each transformation many transformations are needed in practice. Rezende and Mohamed [2015] compared NICE to planar flows in the context of variational inference and found that planar flows empirically perform better.

Finally, Papamakarios et al. [2017] showed that fitting an MAF can be seen as fitting an implicit IAF from the data distribution to the base distribution. However, generating data from an MAF density model requires  $D$  passes, making it unappealing for variational inference.

## 5 NUMBER OF PARAMETERS

Here, we briefly compare the number of parameters needed by planar flows, IAF and the three Sylvester normalizing flows. We denote the size of the stochastic variables  $z$  with  $D$ , and the number of output units of the inference network with  $E$ .

Planar flows use amortized parameters  $\mathbf{u}, \mathbf{w} \in \mathbb{R}^D$  and  $b \in \mathbb{R}$  for each flow transformation. Therefore, the number of parameters related to  $K$  flow transformations is equal to  $2EDK + EK$ .

For the implementation of IAF as described in Section 6, the inference network needs to produce a context of size  $C$ , where  $C$  denotes the width of the MADE layers. The total number of flow related learnable parameters then comes down to  $EC + K \times (C^2 + 3CD)$ .

In the case of Orthogonal Sylvester flows with a bottleneck of size  $M$ , we require  $KE \times (MD + 2M^2 + M)$  parameters. For Householder Sylvester flows with  $H$  Householder reflections per flow transformation,  $KE \times (HD + 2D^2 + D)$  parameters are needed. Finally, for triangular Sylvester flows  $KE \times (2D^2 + D)$  parameters require optimization.

Planar flows require the smallest number of parameters but generally result in worse results. IAFs on the other hand require a number of parameters that is quadratic in the width of the MADE layers. For good results this has to be quite large. In contrast, for SNFs the number of parameters is quadratic in the dimension of the latent space and while large, this can still be amortized.

## 6 EXPERIMENTS

We perform empirical studies of the performance of Sylvester flows on four datasets: statically binarized MNIST, Freyfaces, Omniglot and Caltech 101 Silhouettes. The baseline model is a plain VAE with a fully factorized Gaussian distribution. We furthermore compare against planar flows and Inverse Autoregressive Flows of different sizes.

We use annealing to optimize the lower bound, where the prefactor of the KL divergence is linearly increased from 0 to 1 during 100 epochs as suggested by Bowman et al. [2015] and Sønderby et al. [2016]. A learning rate of 0.0005 was used in all experiments. In order to obtain estimates for the negative log likelihood we used importance sampling (as proposed in [Rezende et al., 2014]). Unless otherwise stated, 5000 importance samples were used.

In order to assess the performance of the different flows properly, we use the same base encoder and decoder architecture for all models. We use gated convolutions and transposed convolutions as base layers for the encoder and decoder architecture respectively. The inference network consists of several gated convolution layers that produce a hidden unit vector. After being flattened, these hidden units act as an input to two fully connected layers that predict the mean and variance of  $\mathbf{z}^0$ .

For planar and Sylvester flows, the flattened hidden units are passed to a separate linear layer that output the amortized flow parameters. For IAF, the flattened hidden units are also passed to a linear layer to produce the context

vector  $\mathbf{h}_{\text{context}}(\mathbf{x})$ . For details of the architecture see Section A of the appendix. In all models the latent space is of dimension 64.

Figure 3: The negative evidence lower bound for static MNIST. The results for H-SNF with 4 reflections per orthogonal matrix are left out for clarity, as they are very similar to the results with 8 reflections. Each model is evaluated 3 times. The shaded areas indicate  $\pm$  one standard deviation.

We use the following implementation for each IAF transformation<sup>1</sup>: one IAF transformation first applies one MADE Layer (denoted as MaskedLinear) followed by a nonlinearity to the input  $z$ , upscaling it to a hidden variable of size  $M$ . At this point the context vector  $\mathbf{h}_{\text{context}}(\mathbf{x})$  is added to the hidden units, after which two more masked layers are applied to produce the mean and scale of the IAF transformation:

$$\begin{aligned}
 \mathbf{h}_z &\leftarrow \text{ELU}(\text{MaskedLinear}(\mathbf{z})) \\
 \mathbf{h} &\leftarrow \mathbf{h}_z + \mathbf{h}_{\text{context}}(\mathbf{x}) \\
 \mathbf{h} &\leftarrow \text{ELU}(\text{MaskedLinear}(\mathbf{h})) \\
 \boldsymbol{\mu} &\leftarrow \text{MaskedLinear}(\mathbf{h}), \quad \mathbf{s} \leftarrow \text{MaskedLinear}(\mathbf{h}) \\
 \mathbf{z}' &\leftarrow \sigma(\mathbf{s}) \odot \mathbf{z} + (1 - \sigma(\mathbf{s})) \odot \boldsymbol{\mu}. \tag{31}
 \end{aligned}$$

Here,  $\sigma(\cdot)$  denotes the sigmoid activation function. In Kingma et al. [2016] it was mentioned that the gated form of IAF in Eq. (31) is more stable than the form of Eq. (29). Note that the size of  $\mathbf{h}_{\text{context}}(\mathbf{x})$  scales with the width of the MADE layers  $C$ .

<sup>1</sup>This implementation is based on the open source code for IAF available at <https://github.com/openai/iaf>

Table 1: Negative log-likelihood and free energy (negative evidence lower bound) for static MNIST. Numbers are produced with 3 runs per model with different random initializations. Standard deviations over the 3 different runs are also shown.

Model	-ELBO	NLL
VAE	$86.55 \pm 0.06$	$82.14 \pm 0.07$
Planar	$86.06 \pm 0.31$	$81.91 \pm 0.22$
IAF	$84.20 \pm 0.17$	$80.79 \pm 0.12$
O-SNF	<b><math>83.32 \pm 0.06</math></b>	<b><math>80.22 \pm 0.03</math></b>
H-SNF	$83.40 \pm 0.01$	$80.29 \pm 0.02$
T-SNF	$83.40 \pm 0.10$	$80.28 \pm 0.06$

## 6.1 MNIST

Figure 3 shows the dependence of the negative evidence lower bound (or free energy) on the number of flows and the type of flow for static MNIST. The exact numbers corresponding to the figure are shown in Section C in the appendix.

For all models the performance improves as a functions of the number of flows. For 4 flows the difference between the baseline VAE and planar flows is very small. However, planar flows clearly benefit from more flow transformations.

For IAF three different widths of the MADE layers were used:  $C = 320, 640$  and  $1280$ . Surprisingly, for 4 flows the widest IAF with 1280 hidden units is outperformed by an IAF with 640 hidden units in the MADE layers. We expect this to be due to the fact that this model has more parameters and can therefore be harder to train, as indicated by the larger standard deviation for this model.

All three Sylvester flows outperform IAF and planar flows. For Orthogonal Sylvester flows, we show results for  $M = 16$  and  $M = 32$  orthogonal vectors per orthogonal matrix, thus corresponding to bottlenecks of size 16 and 32 respectively for a latent space of size  $D = 64$ . Clearly, a larger bottleneck improves performance. For Householder Sylvester flows we experimented with  $H = 4$  and  $H = 8$  Householder reflections per orthogonal matrix. Since the results were nearly indistinguishable between these two variants, we have left out the curve for  $H = 4$  to avoid clutter. O-SNF with  $M = 32$ , H-SNF and T-SNF seem to perform on par.

In Table 1, the negative evidence lower bound and the estimated negative log-likelihood are shown for the baseline VAE, together with all flow models for 16 flows. The reported result for IAF is for a MADE width of 1280. The O-SNF model has a bottleneck of  $M = 32$ , and

Table 2: Results for Freyfaces, Omniglot and Caltech 101 Silhouettes datasets. For the Freyfaces dataset the results are reported in bits per dim. For the other datasets the results are reported in nats. For each flow model 16 flows are used. For IAF a MADE width of 1280 was used, and for O-SNF flow a bottleneck of  $M = 32$  was used. For H-SNF 8 householder reflections were used to construct orthogonal matrices. For all datasets 3 runs per model were performed.

Model	Freyfaces		Omniglot		Caltech 101	
	-ELBO	NLL	-ELBO	NLL	-ELBO	NLL
VAE	$4.53 \pm 0.02$	$4.40 \pm 0.03$	$104.28 \pm 0.39$	$97.25 \pm 0.23$	$110.80 \pm 0.46$	$99.62 \pm 0.74$
Planar	<b><math>4.40 \pm 0.06</math></b>	<b><math>4.31 \pm 0.06</math></b>	$102.65 \pm 0.42$	$96.04 \pm 0.28$	$109.66 \pm 0.42$	$98.53 \pm 0.68$
IAF	$4.47 \pm 0.05$	$4.38 \pm 0.04$	$102.41 \pm 0.04$	$96.08 \pm 0.16$	$111.58 \pm 0.38$	$99.92 \pm 0.30$
O-SNF	$4.51 \pm 0.04$	$4.39 \pm 0.05$	$99.00 \pm 0.29$	$93.82 \pm 0.21$	$106.08 \pm 0.39$	$94.61 \pm 0.83$
H-SNF	$4.46 \pm 0.05$	$4.35 \pm 0.05$	<b><math>99.00 \pm 0.04</math></b>	<b><math>93.77 \pm 0.03</math></b>	<b><math>104.62 \pm 0.29</math></b>	<b><math>93.82 \pm 0.62</math></b>
T-SNF	$4.45 \pm 0.04$	$4.35 \pm 0.04$	$99.33 \pm 0.23$	$93.97 \pm 0.13$	$105.29 \pm 0.64$	$94.92 \pm 0.73$

H-SNF contains 8 Householder reflections per orthogonal matrix. Again, all Sylvester flows outperform planar flows and IAF, both in terms of the free energy and the negative log-likelihood.

As discussed in Section 4, T-SNF is closely related to mean-only IAF, but with the MADE parameters directly amortized. The fact that T-SNF outperforms IAF indicates that amortizing the parameters directly leads to a more flexible transformation compared to taking a very wide MADE with a data dependent context as an additional input.

## 6.2 FREYFACES, OMNIGLOT AND CALTECH 101 SILHOUETTES

We further assess the performance of the different models on Freyfaces, Omniglot and Caltech 101 Silhouettes. The results are shown in Table 2. The model settings are the same<sup>2</sup> as those used for Table 1.

Freyfaces is a very small dataset of around 2000 faces. All normalizing flows increase the performance, with planar flows yielding the best result, closely followed by Triangular and Householder Sylvester flows. We expect planar flows to perform the best in this case since it is the least sensitive to overfitting.

For Omniglot and Caltech 101 Silhouettes the results are clearer, with the Sylvester normalizing flows family resulting in the best performance. Both H-SNF and T-SNF perform better than O-SNF. This could be attributed to the fact that O-SNF has a bottleneck of  $M = 32$  for a latent space size of  $D = 64$ . The IAF scores for Caltech 101 are surprisingly bad. We expect this could be the case due to the large number of parameters that need to be trained for IAF(1280). Therefore we also evaluated

<sup>2</sup>For Caltech 101 Silhouettes we used 2000 importance samples for the estimation of the negative log-likelihood.

the result for MADEs of width 320 for 16 flows. The resulting free energy and estimated negative log-likelihood are  $111.23 \pm 0.45$  and  $99.74 \pm 0.28$  respectively, only slightly improving on the results of 1280 wide IAFs.

## 7 CONCLUSION

We present a new family of normalizing flows: Sylvester normalizing flows. These flows generalize planar flows, while maintaining an efficiently computable Jacobian determinant through the use of Sylvester’s determinant identity. We ensure invertibility of the flows through the use of orthogonal and triangular parameter matrices. Three variants of Sylvester flows are investigated. First, orthogonal Sylvester flows use an iterative procedure to maintain orthogonality of parameter matrices. Second, Householder Sylvester flows use Householder reflections to construct orthogonal matrices. Third, triangular Sylvester flows alternate between fixed permutation and identity matrices for the orthogonal matrices. We show that the triangular Sylvester flows are closely related to mean-only IAF, with directly amortized MADE parameters. While performing comparably with planar flows and IAF for the Freyfaces dataset, our proposed family of flows improve significantly upon planar flows and IAF on the three other datasets.

## Abstract

In this paper we introduce a novel holographic memory model for the distributed storage of complex association patterns and apply it to knowledge graphs. In a knowledge graph, a labelled link connects a subject node with an object node, jointly forming a subject-predicate-objects triple. In the presented work, nodes and links have initial random representations, plus *holistic representations* derived from the initial representations of nodes and links in their local neighbourhoods. A memory trace is represented in the same vector space as the holistic representations themselves. To reduce the interference between stored information, it is required that the initial random vectors should be pairwise quasi-orthogonal. We show that pairwise quasi-orthogonality can be improved by drawing vectors from heavy-tailed distributions, e.g., a Cauchy distribution, and, thus, memory capacity of holistic representations can significantly be improved. Furthermore, we show that, in combination with a simple neural network, the presented holistic representation approach is superior to other methods for link predictions on knowledge graphs.

## 1 INTRODUCTION

An associative memory is a key concept in artificial intelligence and cognitive neuroscience for learning and memorizing relationships between entities and concepts. Various computational models of associative memory have been proposed, see, e.g., [Hopfield 1982; Gentner 1983]. One important family of associative memory

models is the holographic associative memory (HAM), which was first proposed in [Gabor 1969]. HAMS can store a large number of stimulus-response pairs as additive superpositions of memory traces. It has been suggested that this holographic storage is related to the working principle of the human brain [Westlake 1970].

An important extension to the HAM is based on holographic reduced representations (HRR) [Plate 1995]. In HRR, each entity or symbol is represented as a vector defined in a continuous space. Associations between two entities are compressed in the same vector space via a vector binding operation; the resulting vector is a memory trace. Two associated entities are referred to as a *cue-filler* pair, since a noisy version of the *filler* can be recovered from the memory trace and the *cue* vector via a decoding operation. Multiple *cue-filler* pairs can be compressed in a single memory trace through superposition. Associations can be read out from this single trace, however with large distortions. Thus, a clean-up mechanism was introduced into HRR, such that associations can be *retrieved* with high probability.

The number of associations which can be compressed in a single trace is referred to as *memory capacity*. It has been shown in [Plate 1995] that the memory capacity of the HRR depends on the degree of the pairwise orthogonality of initial random vectors associated with the entities.

Quasi-orthogonality was put forward in [Diaconis et al. 1984; Hall et al. 2005]. They informally stated that “most independent high-dimensional random vectors are nearly orthogonal to each other”. A rigorous mathematical justification to this statement has only recently been given in [Cai et al. 2012; Cai et al. 2013], where the density function of pairwise angles among a large number of Gaussian random vectors was derived. To the best of our knowledge, density functions for other distributions have not been derived, so far. As a first contribution, we will derive a significantly improved quasi-orthogonality, and

---

\*yunpu.ma@siemens.com

we show that memory capacity of holographic representations can significantly be improved. Our result could potentially have numerous applications, e.g., in sparse random projections or random geometric graphs [Penrose 2003].

After the HRR had been proposed, it had mainly been tested on small toy datasets. Quasi-orthogonality becomes exceedingly important when a large amount of entities needs to be initialized with random vectors, as in applications involving large-scale knowledge graphs.

Modern knowledge graphs (KGs), such as FREEBASE [Bollacker et al. 2008], YAGO [Suchanek et al. 2007], and GDELTA [Leetaru et al. 2013], are relational knowledge bases, where nodes represent entities and directed labelled links represent predicates. An existing labelled link between a head node (or subject) and a tail node (or object) is a triple and represents a fact, e.g. (*California, locatedIn, USA*).

As a second contribution, we demonstrate how the holographic representations can be applied to KGs. First, one needs to define association pairs (or *cue-filler* pairs). We propose that the representation of a *subject* should encode all *predicate-object* pairs, such that given the *predicate* representation as a *cue*, the *object* should be recovered or at least recognized. Similarly, the representation of an *object* should encode all *predicate-subject* pairs, such that the *subject* can be retrieved after decoding with the *predicate* representation. We call those representations *holistic*, since they are inspired by the semantic holism in the philosophy of language, in the sense that an abstract entity can only be comprehended through its relationships to other abstract entities.

So far we have discussed memory formation and memory retrieval. Another important function is the generalization of stored memory to novel facts. This has technical applications and there are interesting links to human memory. From a cognitive neuroscientist point of view, the brain requires a dual learning system: one is the hippocampus for rapid memorization, and the other is the neocortex for gradual consolidation and comprehension. This hypothesis is the basis for the *Complementary Learning System* (CLS) which was first proposed in [McClelland et al. 1995]. Connections between KGs and long-term declarative memories has recently been stated in [Tresp et al. 2017a; Ma et al. 2018; Tresp et al. 2017b].

As a third contribution of this paper, we propose a model which not only memorizes patterns in the training datasets through holistic representations, but also is able to infer missing links in the KG, by a simple neural network that uses the holistic representations as input representations. Thus, our model realizes a form of

a *complementary learning system*. We compare our results on multiple datasets with other state-of-the-art link prediction models, such as RESCAL [Nickel et al. 2011; Nickel et al. 2012], DISTMULT [Yang et al. 2014], COMPLEX [Trouillon et al. 2016], and R-GCN [Schlichtkrull et al. 2018].

The above mentioned learning-based methods model the KGs by optimizing the latent representations of entities and predicates through minimizing the loss function. It had been observed that latent embeddings are suitable for capturing global connectivity patterns and generalization [Nickel et al. 2016a; Toutanova et al. 2015], but are not as good in memorizing unusual patterns, such as patterns associated with locally and sparsely connected entities. This motivates us to *separate* the memorization and inference tasks. As we will show in our experiments, our approach can, on the one hand, memorize local graph structures, but, on the other hand, also generalizes well to global connectivity patterns, as required by complementary learning systems.

Note, that in our approach holistic representations are derived from random vectors and are **not** learned from data via backpropagation, as in most learning-based approaches to representation learning on knowledge graphs. One might consider representations derived from random vectors to be biologically more plausible, if compared to representations which are learned via complex gradient based update rules [Nickel et al. 2016a]. Thus, in addition to its very competitive technical performance, one of the interesting aspects of our approach is its biological plausibility.

In Section 2 we introduce notations for KGs and embedding learning. In Section 3 we discuss improved quasi-orthogonality by using heavy-tailed distributions. In Section 4 we propose our own algorithm for holistic representations, and test it on various datasets. We also discuss how the memory capacity can be improved. In Section 5 we propose a model which can infer implicit links on KGs through holistic representations. Section 6 contains our conclusions.

## 2 REPRESENTATION LEARNING

In this section we provide a brief introduction to representation learning in KGs, where we adapt the notation of [Nickel et al. 2016b]. Let  $\mathcal{E}$  denotes the set of entities, and  $\mathcal{P}$  the set of predicates. Let  $N_e$  be the number of entities in  $\mathcal{E}$ , and  $N_p$  the number of predicates in  $\mathcal{P}$ .

Given a predicate  $p \in \mathcal{P}$ , the characteristic function  $\phi_p : \mathcal{E} \times \mathcal{E} \rightarrow \{1, 0\}$  indicates whether a triple  $(\cdot, p, \cdot)$  is true or false. Moreover,  $\mathcal{R}_p$  denotes the set of all subject-object pairs, such that  $\phi_p = 1$ . The entire KG can be

written as  $\chi = \{(i, j, k)\}$ , with  $i = 1, \dots, N_e$ ,  $j = 1, \dots, N_p$ , and  $k = 1, \dots, N_e$ .

We assume that each entity and predicate has a unique latent representation. Let  $\mathbf{a}_{e_i}$ ,  $i = 1, \dots, N_e$ , be the representations of entities, and  $\mathbf{a}_{p_i}$ ,  $i = 1, \dots, N_p$ , be the representations of predicates. Note that  $\mathbf{a}_{e_i}$  and  $\mathbf{a}_{p_i}$  could be real- or complex-valued vectors/matrices.

A probabilistic model for the KG  $\chi$  is defined as  $\Pr(\phi_p(s, o) = 1 | \mathcal{A}) = \sigma(\eta_{spo})$  for all  $(s, p, o)$ -triples in  $\chi$ , where  $\mathcal{A} = \{\mathbf{a}_{e_i}\}_i^{N_e} \cup \{\mathbf{a}_{p_i}\}_i^{N_p}$  denotes the collection of all embeddings;  $\sigma(\cdot)$  denotes the sigmoid function; and  $\eta_{spo}$  is the a function of latent representations,  $\mathbf{a}_s$ ,  $\mathbf{a}_p$  and  $\mathbf{a}_o$ . Given a labeled dataset containing both true and false triples  $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^m$ , with  $x_i \in \chi$ , and  $y_i \in \{1, 0\}$ , latent representations can be learned. Commonly, one minimizes a binary cross-entropy loss

$$-\frac{1}{m} \sum_{i=1}^m (y_i \log(p_i) + (1 - y_i) \log(1 - p_i)) + \lambda \|\mathcal{A}\|_2^2, \quad (1)$$

where  $m$  is the number of training samples, and  $\lambda$  is the regularization parameter;  $p_i := \sigma(\eta_{x_i})$  with  $\sigma(\cdot)$  being the sigmoid function.  $\eta_{spo}$  is defined differently in various models.

For instance, for RESCAL entities are represented as  $r$ -dimensional vectors,  $\mathbf{a}_{e_i} \in \mathbb{R}^r$ ,  $i = 1, \dots, N_e$ , and predicates are represented as matrices,  $\mathbf{a}_{p_i} \in \mathbb{R}^{r \times r}$ ,  $i = 1, \dots, N_p$ . Moreover, one uses  $\eta_{spo} = \mathbf{a}_s^\top \mathbf{a}_p \mathbf{a}_o$ .

For DISTMULT,  $\mathbf{a}_{e_i}, \mathbf{a}_{p_j} \in \mathbb{R}^r$ , with  $i = 1, \dots, N_e, j = 1, \dots, N_p$ ;  $\eta_{spo} = \langle \mathbf{a}_s, \mathbf{a}_p, \mathbf{a}_o \rangle$ , where  $\langle \cdot, \cdot, \cdot \rangle$  denotes the tri-linear dot product.

For COMPLEX,  $\mathbf{a}_{e_i}, \mathbf{a}_{p_j} \in \mathbb{C}^r$ , with  $i = 1, \dots, N_e, j = 1, \dots, N_p$ ;  $\eta_{spo} = \Re(\langle \mathbf{a}_s, \mathbf{a}_p, \bar{\mathbf{a}}_o \rangle)$ , where the bar denotes complex conjugate, and  $\Re$  denotes the real part.

### 3 DERIVATION OF $\epsilon$ -ORTHOGONALITY

As we have discussed in the introduction, quasi-orthogonality of the random vectors representing the entities and the predicates is required for low interference memory retrieval. In this section we investigate the asymptotic distribution of pairwise angles in a set of independently and identically drawn random vectors. In particular, we study random vectors drawn from either a Gaussian or a heavy-tailed Cauchy distribution distribution. A brief summary of notations is referred to the A.7. First we define the term “ $\epsilon$ -orthogonality”.

**Definition 1.** A set of  $n$  vectors  $\mathbf{x}_1, \dots, \mathbf{x}_n$  is said to be pairwise  $\epsilon$ -orthogonal, if  $|\langle \mathbf{x}_i, \mathbf{x}_j \rangle| < \epsilon$  for  $i, j = 1, \dots, n, i \neq j$ .

Here,  $\epsilon > 0$  is a small positive number, and  $\langle \cdot, \cdot \rangle$  denotes the inner product in the vector space.

#### 3.1 $\epsilon$ -ORTHOGONALITY FOR A GAUSSIAN DISTRIBUTION

In this section we revisit the empirical distribution of pairwise angles among a set of random vectors. More specifically, let  $\mathbf{X}_1, \dots, \mathbf{X}_n$  be independent  $q$ -dimensional Gaussian variables with distribution  $\mathcal{N}(\mathbf{0}, \mathbf{I}_q)$ . Denote with  $\Theta_{ij}$  the angle between  $\mathbf{X}_i$  and  $\mathbf{X}_j$ , and  $\rho_{ij} := \cos \Theta_{ij} \in [-1, 1]$ . [Cai et al. 2012; Muirhead 2009] derived the density function of  $\rho_{ij}$  in the following Lemma.

**Lemma 1.** Consider  $\rho_{ij}$  as defined above. Then  $\{\rho_{ij} | 1 < i < j \leq n\}$  are pairwise i.i.d. random variables with the following asymptotic probability density function

$$g(\rho_G) = \frac{1}{\sqrt{\pi}} \frac{\Gamma(\frac{q}{2})}{\Gamma(\frac{q-1}{2})} (1 - \rho_G^2)^{\frac{q-3}{2}}, \quad |\rho_G| < 1, \quad (2)$$

with fixed dimensionality  $q$ .

[Cai et al. 2013] also derived the following Theorem 1.

**Theorem 1.** Let the empirical distribution  $\mu_n$  of pairwise angles  $\Theta_{ij}, 1 \leq i < j \leq n$  be defined as  $\mu_n := \frac{1}{\binom{n}{2}} \sum_{1 \leq i < j \leq n} \delta_{\Theta_{ij}}$ . With fixed dimension  $q$ , as  $n \rightarrow \infty$ ,  $\mu_n$  converges weakly to the distribution with density

$$h(\theta) = \frac{1}{\sqrt{\pi}} \frac{\Gamma(\frac{q}{2})}{\Gamma(\frac{q-1}{2})} (\sin \theta)^{q-2}, \quad \theta \in [0, \pi]. \quad (3)$$

From the above distribution function we can derive the upper bound of quasi-orthogonal random vectors with pairwise  $\epsilon$ -orthogonality in the Euclidean space  $\mathbb{R}^q$ .

**Corollary 1.** Consider a set of independent  $q$ -dimensional Gaussian random vectors which are pairwise  $\epsilon$ -orthogonal with probability  $1 - \nu$ , then the number of such Gaussian random vectors is bounded by

$$N \leq \sqrt[4]{\frac{\pi}{2q}} e^{\frac{\epsilon^2 q}{4}} \left[ \log \left( \frac{1}{1 - \nu} \right) \right]^{\frac{1}{2}}. \quad (4)$$

The derivation is given in A.1. Due to the symmetry of density function  $g(\rho_G)$ , we immediately have  $\mathbb{E}[\rho_G] = 0$ , moreover,  $\mathbb{E}[\theta] = \frac{\pi}{2}$ . However, for the later use, it is important to consider the expected absolute value of  $\rho_G$ :

**Corollary 2.** Consider a set of  $n$   $q$ -dimensional random Gaussian vectors, we have

$$\lambda_G := \mathbb{E}[|\rho_G|] = \sqrt{\frac{2}{\pi q}}. \quad (5)$$

Figure 1: Empirical pairwise angle distribution in a set of Gaussian random vectors (green) is compared with theoretical prediction Eq. 2 (magenta); Empirical pairwise angle distribution in a set of Cauchy random vectors (blue) is compared with prediction Eq. 6 (red)

Figure 2: Compare  $\lambda_G$  and  $\lambda_C$  from simulation and theory, see Eq. 5 and Eq. 9.

Note, that the quantity  $\frac{\pi}{2} - \arccos \mathbb{E}[|\rho_G|]$  has a clear geometrical meaning: It indicates the expected deviation from  $\frac{\pi}{2}$  of pairwise angles. In fact, in the extreme case when  $q \rightarrow \infty$ , the deviation converges to 0 with the rate  $\sqrt{q}$ .

### 3.2 $\epsilon$ -ORTHOGONALITY FOR A CAUCHY DISTRIBUTION

In this subsection, we show that the set of random vectors whose elements are initialized with a heavy-tailed distribution, e.g., a Cauchy distribution  $\mathcal{C}(0, 1)$ , has improved  $\epsilon$ -orthogonality. The intuition is as follows: Consider a set of  $q$ -dimensional random vectors initialized with a heavy-tailed distribution. After normalization, each random vector can be approximated by only the elements which significantly deviate from zero and were drawn from the heavy tails. If the number of those elements is  $k$  with  $k \ll q$ , then there are at most  $\binom{q}{k}$  orthogonal random vectors.

Moreover,  $\binom{q}{k} \approx \frac{q^k}{k\Gamma(k)}$  could be much larger than  $\sqrt[4]{\frac{\pi}{2q}} e^{\frac{\epsilon^2 q}{4}}$  from Eq. 4, when  $q$  is sufficiently large,  $k \ll q$ , and  $\epsilon \rightarrow 0$ . In other words, under stricter quasi-orthogonality condition with smaller  $\epsilon$ , random vectors drawn from a heavy-tailed distribution could have more pairs satisfying the quasi-orthogonality condition.

Consider a set of  $q$ -dimensional Cauchy random vectors. As  $q \rightarrow \infty$  the approximate density function of  $\rho_{ij}$ , with  $1 \leq i < j \leq n$  is described in the following conjecture.

**Conjecture 1.** Let  $\mathbf{X}_1, \dots, \mathbf{X}_n$  be independent  $q$ -dimensional random vectors whose elements are independently and identically drawn from Cauchy a distribution  $\mathcal{C}(0, 1)$ . Moreover, consider the angle  $\Theta_{ij}$  between  $\mathbf{X}_i$ , and  $\mathbf{X}_j$ . Then, as  $q \rightarrow \infty$ ,  $\rho_{ij} := \cos \Theta_{ij} \in [-1, 1]$ ,  $1 \leq i < j \leq n$  are pairwise i.i.d. with a density function approximated by

$$g(\rho_C) = -\frac{2}{\pi^2 q^2 \rho_C^3} \cdot \frac{1}{z^{\frac{3}{2}}} \left[ e^{\frac{1}{\pi z}} \text{Ei} \left( -\frac{1}{\pi z} \right) \right], \quad (6)$$

where  $z := \frac{1}{q^2} \left( \frac{1}{\rho_C^2} - 1 \right)$ , and the exponential integral

$$\text{Ei}(x) \text{ is defined as } \text{Ei}(x) = -\int_{-x}^{\infty} \frac{e^{-t}}{t} dt.$$

The intuition behind the conjecture is as follows. Suppose  $\mathbf{X} = (X_1, \dots, X_q)$  and  $\mathbf{Y} = (Y_1, \dots, Y_q)$  are random vector variables, and assume that elements of  $\mathbf{X}$  and  $\mathbf{Y}$  are independently Gaussian distributed. In order to derive  $g(\rho_{\mathbf{X}, \mathbf{Y}})$  in Lemma 1, [Cai et al. 2012; Muirhead 2009] compute the distribution function for  $\frac{\alpha^T \mathbf{X}}{\|\mathbf{X}\|}$  instead, where  $\alpha^T \alpha = 1$ . In particular, they assume that  $\alpha = (1, 0, \dots, 0)$ . The underlying reason for this assumption is that the random vector  $\frac{\mathbf{X}}{\|\mathbf{X}\|}$  is uniformly distributed on the  $(q-1)$ -dimensional sphere.

Here, elements of  $\mathbf{X}$  and  $\mathbf{Y}$  are independently Cauchy distributed. We derive the approximation in Eq. 6 under the same assumption by taking  $g(\rho_{\mathbf{X}, \mathbf{Y}}) \approx \frac{X_1}{\sqrt{X_1^2 + \dots + X_q^2}}$ . Furthermore, we introduce a new variable  $z_{\mathbf{X}, \mathbf{Y}} := \frac{1}{q^2} \left( \frac{1}{\rho_{\mathbf{X}, \mathbf{Y}}^2} - 1 \right) = \frac{1}{q^2} \frac{X_2^2 + \dots + X_q^2}{X_1^2}$ , and derive the density function  $\hat{g}(z_{\mathbf{X}, \mathbf{Y}})$  by using the generalized central limit theorem [Gnedenko et al. 1954] and properties of quotient distributions of two independent random variables.  $g(\rho_{\mathbf{X}, \mathbf{Y}})$  can be directly obtained from  $\hat{g}(z_{\mathbf{X}, \mathbf{Y}})$  by a variable transform. More details and derivation are referred to the A.2.

We turn to study the limiting behaviour of the density function when  $\rho$  approaches zero. In this case, the variable  $z$  defined in in Conjecture 1 can be approximated by  $z \approx \frac{1}{q^2 \rho_C^2}$ . Using properties of the exponential integral, as  $q \rightarrow \infty$ , the density function in Eq. 6 can be approximated by its Laurent series,

$$g(\rho_C) \approx \frac{2}{\pi q \rho_C^2} - \frac{2}{q^3 \rho_C^4} + \frac{4\pi}{q^5 \rho_C^6} + \mathcal{O} \left( \frac{1}{q^7 \rho_C^8} \right) \quad (7)$$

In the following corollary we give the upper bound of the number of pairwise  $\epsilon$ -orthogonal Cauchy random vectors using Eq. 6.

**Corollary 3.** Consider a set of independent  $q$ -dimensional Cauchy random vectors which are pairwise  $\epsilon$ -orthogonal with probability  $1 - \nu$ , then the number of such Cauchy random vectors is bounded by

$$N \leq \sqrt{\frac{\pi \epsilon q}{4}} \left[ \log \left( \frac{1}{1 - \nu} \right) \right]^{\frac{1}{2}}. \quad (8)$$

Let us compare the prefactor of this upper bound for two distributions: That is  $\sqrt[4]{\frac{\pi}{2q}} e^{\frac{\epsilon^2 q}{4}}$  for the Gaussian distribution, and  $\sqrt{\frac{\pi \epsilon q}{4}}$  for the Cauchy distribution. Under strict quasi-orthogonal conditions with arbitrarily small but fixed  $\epsilon > 0$ , for the dimension  $q \gg 2 \sqrt[3]{\frac{1}{\pi \epsilon^2}}$  we have that  $\sqrt{\frac{\pi \epsilon q}{4}} \gg \sqrt[4]{\frac{\pi}{2q}} e^{\frac{\epsilon^2 q}{4}} \approx \sqrt[4]{\frac{\pi}{2q}}$ . It implies that in sufficiently high-dimensional spaces, random vectors which are independently drawn from a Cauchy distribution are more likely to satisfy the pairwise  $\epsilon$ -orthogonality condition - particularly when  $\epsilon \ll 1$ .

**Remark 1.** For the later use, we define  $\lambda_C$  as  $\lambda_C := \mathbb{E}[|\rho_C|]$  for the case of Cauchy distribution. However, no simple analytic form is known for this integral. Thus we use the following numerically stable and non-divergent equation to approximate  $\lambda_C$ ,

$$\lambda_C \approx -\frac{4q}{\pi^2} \int_0^1 \rho \left[ e^{\frac{q^2 \rho^2}{\pi}} \text{Ei} \left( -\frac{q^2 \rho^2}{\pi} \right) \right] d\rho. \quad (9)$$

This simpler form is derived from Eq. 6 using the approximation  $z \approx \frac{1}{q^2 \rho^2}$ .

Fig. 1 shows the empirical distribution of  $\rho_C$  in a set of Gaussian random vectors (green) compared with theoretical prediction in Eq.2 (magenta); and the empirical distribution of  $\rho_C$  in a set of Cauchy random vectors (blue) compared with theoretical prediction (red). In the case of Cauchy random vectors, the leading orders of the Laurent expansion of Eq. 6 are used, see Eq. 7. For the empirical simulation, 10000 random vectors with dimensionality  $q = 2000$  were drawn independently from either a Gaussian or a Cauchy distribution.

In addition, in Fig. 2 we plot  $\lambda_G$  and  $\lambda_C$  as a function of  $q$  in comparison with the theoretical predictions from Eq. 5 and Eq. 9, respectively, under the same simulation condition. It is necessary to emphasize that  $\lambda_C(q) < \lambda_G(q)$  for all the dimensions  $q$ ; this fact will be used to explain the relatively high memory capacity encoded from Cauchy random vectors.

In the Appendix, see Remark A 2, the distribution of elements from the normalized random variable  $\frac{\mathbf{x}}{\|\mathbf{x}\|}$  is also considered. In particular, for normalized Cauchy random vector most of its elements are nearly zero, and it realizes a **sparse** representation.

## 4 HOLISTIC REPRESENTATIONS FOR KGS

### 4.1 HRR MODEL

First, we briefly review HRR. Three operations are defined in HRR to model associative memories: *encoding*, *decoding*, and *composition*.

Let  $\mathbf{a}$ ,  $\mathbf{b}$ ,  $\mathbf{c}$ , and  $\mathbf{d}$  be random vectors representing different entities. The encoding phase stores the association between  $\mathbf{a}$  and  $\mathbf{b}$  in a memory trace  $\mathbf{a} * \mathbf{b}$ , where  $*$  :  $\mathbb{R}^q \times \mathbb{R}^q \rightarrow \mathbb{R}^q$  denotes circular convolution, which is defined as  $[\mathbf{a} * \mathbf{b}]_k = \sum_{i=0}^{q-1} a_i b_{(k-i) \bmod q}$ .

A noisy version of  $\mathbf{b}$  can be retrieved from the memory trace, using the item  $\mathbf{a}$  as a cue, with:  $\mathbf{b} \approx \mathbf{a} \star (\mathbf{a} * \mathbf{b})$ , where  $\star$  :  $\mathbb{R}^q \times \mathbb{R}^q \rightarrow \mathbb{R}^q$  denotes the circular correlation<sup>1</sup>. It is defined as  $[\mathbf{a} \star \mathbf{b}]_k = \sum_{i=0}^{q-1} a_i b_{(k+i) \bmod q}$ . In addition, several associations can be superimposed in a single trace via the addition operation:  $(\mathbf{a} * \mathbf{b}) + (\mathbf{c} * \mathbf{d}) + \dots$ .

### 4.2 HOLISTIC MODEL

Initially, each entity and predicate in a KG is associated with a  $q$ -dimensional normalized random vector, which is then normalized. We denote them as  $\mathbf{r}_{e_i}^{G/C}$ ,  $i = 1, \dots, N_e$ , and  $\mathbf{r}_{p_i}^{G/C}$ ,  $i = 1, \dots, N_p$ , respectively. The superscript indicates from which distribution vector elements are independently drawn, either the Gaussian or Cauchy distribution. If there is no confusion, we may omit the superscript.

Consider an entity  $e_i$ . Let  $\mathcal{S}^s(e_i) = \{(p, o) | \phi_p(e_i, o) = 1\}$  be the set of all predicate-object pairs for which triples  $(e_i, p, o)$  is true and where  $e_i$  is the subject. We store these multiple associations in a single memory trace via circular correlation and superposition:

$$\mathbf{h}_{e_i}^s = \sum_{(p, o) \in \mathcal{S}^s(e_i)} [\text{Norm}(\mathbf{r}_p \star \mathbf{r}_o) + \xi \mathbf{r}_{e_i}], \quad (10)$$

where  $\text{Norm} : \mathbb{R}^q \rightarrow \mathbb{R}^q$  represents the normalization operation<sup>2</sup>, which is defined as  $\text{Norm}(\mathbf{r}) := \frac{\mathbf{r}}{\|\mathbf{r}\|}$ . Moreover, the hyper-parameter  $\xi > 0$  determines the contribution of the individual initial representation  $\mathbf{r}$ .

<sup>1</sup>It uses the fact that  $\mathbf{a} \star \mathbf{a} \approx \delta$ , where  $\delta$  is the identity operation of convolution.

<sup>2</sup>In other sections, we may obviate Norm operator in the equation for the sake of simplicity, since it can be shown that the circular correlation of two normalized high-dimensional random vectors are almost normalized.

Note, that the same entity  $e_i$  could also play the role of an object. For instance, the entity *California* could be the subject in the triple (*California, locatedIn, USA*), or the object in another triple (*Paul, livesIn, California*). Thus, it is necessary to have another representation to specify its role in the triples. Consider the set of subject-predicate pairs  $\mathcal{S}^o(e_i) = \{(s, p) | \phi_p(s, e_i) = 1\}$  for which triples  $(s, p, e_i)$  are true. These pairs are stored in a single trace via  $\mathbf{h}_{e_i}^o = \sum_{(s,p) \in \mathcal{S}^o(e_i)} [\text{Norm}(\mathbf{r}_p \star \mathbf{r}_s) + \xi \mathbf{r}_{e_i}]$ , where  $\mathbf{h}_{e_i}^o$  is the representation of the entity  $e_i$  when it acts as an object.

For the later generalization task, the overall holistic representation for the entity  $e_i$  is defined as the summation of both representations, namely

$$\mathbf{h}_{e_i} = \mathbf{h}_{e_i}^s + \mathbf{h}_{e_i}^o. \quad (11)$$

In this way, the complete neighbourhood information of an entity can be used for generalization.

Furthermore, given a predicate  $p_i$ , the holistic representation  $\mathbf{h}_{p_i}$  encodes all the subject-object pairs in the set  $\mathcal{S}(p_i) = \{(s, o) | \phi_{p_i}(s, o) = 1\}$  via

$$\mathbf{h}_{p_i} = \sum_{(s,o) \in \mathcal{S}(p_i)} [\text{Norm}(\mathbf{r}_s \star \mathbf{r}_o) + \xi \mathbf{r}_{p_i}]. \quad (12)$$

After storing all the association pairs into holistic features of entities and predicates, the initial randomly assigned representations are not required anymore and can be deleted. These representations are then fixed and not trainable unlike other embedding models.

After encoding, entity retrieval is performed via a circular convolution. Consider a concrete triple  $(e_1, p_1, e_2)$  with unknown  $e_2$ . The identity of  $e_2$  could be revealed with the holistic representation of  $p_1$  and the holistic representation of  $e_1$  as a subject, namely  $\mathbf{h}_{p_1}$  and  $\mathbf{h}_{e_1}^s$ . Then retrieval is performed as  $\mathbf{h}_{p_1} \star \mathbf{h}_{e_1}^s$ . The associations can be retrieved from the holography memory with low fidelity due to interference. Therefore, after decoding, a clean-up operation is employed, as in the HRR model. Specifically, a nearest neighbour is determined using cosine similarity. The pseudo-code for encoding holistic representations is provided in A.6.

### 4.3 EXPERIMENTS ON MEMORIZATION

We test the memorization of complex structure on different datasets and compare the performance of different models. Recall that  $\mathcal{R}_p$  is the set of all true triples with respect to a given predicate  $p$ . Consider a possible triple  $(s, p, o) \in \mathcal{R}_p$ . The task is now to retrieve the object entity from holistic vectors  $\mathbf{h}_s$  and  $\mathbf{h}_p$ , and to retrieve the subject entity from holistic vectors  $\mathbf{h}_p$  and  $\mathbf{h}_o$ .

As discussed, in retrieval, the noisy vector  $\mathbf{r}'_o = \mathbf{h}_p \star \mathbf{h}_s$  is compared to the holistic representations of all entities using cosine similarity, according to which the entities are then ranked. In general, multiple objects could be connected to a single subject-predicate pair. Thus, we employ the *filtered mean rank* introduced in [Bordes et al. 2013] to evaluate the memorization task.

We have discussed that the number of pairwise quasi-orthogonal vectors crucially depends on the random initialization. Now we analyse, if the memory capacity depends on the quasi-orthogonality of the initial representation vectors, as well. We perform memorization task on three different KGs, which are FB15k-237 [Toutanova et al. 2015], YAGO3 [Mahdisoltani et al. 2013], and a subset of GDEL T [Leetaru et al. 2013]. The exact statistics of the datasets are given in Table. 1.

Table 1: Statistics of KGs

	$\#\mathcal{D}$	$N_a$	$N_e$	$N_p$
<b>GDEL T</b>	497, 605	$\approx 73$	6786	231
<b>FB15k-237</b>	301, 080	$\approx 20$	14505	237
<b>YAGO3</b>	1, 089, 000	$\approx 9$	123143	37

Recall that  $N_e$  and  $N_p$  denote the number of entities and predicates, respectively. Moreover,  $\#\mathcal{D}$  denotes the total number of triples in a KG, and  $N_a$  is the average number of association pairs compressed into holistic feature vectors of entities, which can be estimated as  $\frac{\#\mathcal{D}}{N_e}$ . After encoding triples in a dataset into holistic features, filtered mean rank is evaluated by ranking retrieved subjects and objects of all triples. Filtered mean ranks on three datasets with holistic representations encoded from Gaussian and Cauchy distributions are displayed in Fig. 3 (a)-(c).

Cauchy holistic representations outperform Gaussian holistic representations significantly when the total number of entities is large (see, Fig. 3(c) for YAGO3), or the average number of encoded associations is large (see, Fig. 3(a) for GDEL T). This implies that quasi-orthogonality plays an important role in holographic memory. Improved quasi-orthogonality allows for more entities to be initialized with quasi-orthogonal representations, which is very important for memorizing huge KGs. In addition, it reduces the interference between associations. Moreover, Cauchy holistic features are intrinsically very sparse, making them an attractive candidate for modeling biologically plausible memory systems.

### 4.4 CORRELATION VERSUS CONVOLUTION

One of the main differences between *holistic representation* and the *holographic reduced representation* is the binding operation. In HRR, two vectors are composed

Figure 3: Filtered MR vs. the dimensionality of holistic representations evaluated on dataset: (a) GDEL, (b) FB15k-237, and (c) YAGO3. Blues lines denote holistic representations encoded from Gaussian random vectors, and green lines denote holistic representations encoded from Cauchy random vectors. Lower values are preferred.

Figure 4: Filtered MR vs. the dimensionality of holistic representations evaluated on the GDEL dataset with Gaussian initialization.

via circular convolution, while in holistic representation, they are composed via circular correlation.

Binding with convolution and correlation is compared in Fig. 4. We report the filtered MR scores on the GDEL dataset versus the dimensionality of holistic representations. It can be seen that binding with circular correlation is significantly superior to convolution. Therefore, a non-commutative compositional operator is essential for storing the directed structures of KG into holographic memory. A theoretical explanation is given in the A.4, along with experimental results on other datasets.

#### 4.5 HYPER-PARAMETER $\xi$

In the experiments so far, the optimal hyper-parameter  $\xi$  is found via grid search. However, it is possible to roughly estimate the range of the optimal hyper-parameter  $\xi$ . Indeed,  $\xi$  strongly depends on  $\lambda_G$  or  $\lambda_C$  and the average number of encoded association pairs  $N_a$ .

So far, the deep relation between holographic memory capacity and quasi-orthogonality has not been discussed in the literature. In the original work on HRR, memory capacity and information retrieval quality are estimated from the distribution of elements in random vectors. In this section we give a plausible explanation from the point of view of the pairwise angle distribution.

Consider a subject  $s$ . The predicate-object pair  $(p, o)$

is stored in the holistic representation  $\mathbf{h}_s$  along with the other  $N_a - 1$  pairs, such that

$$\mathbf{h}_s = \xi N_a \mathbf{r}_s + \mathbf{r}_p \star \mathbf{r}_o + \sum_{i=2}^{N_a} \mathbf{r}_{p_i} \star \mathbf{r}_{o_i}.$$

Suppose we try to identify the object in the triple  $(s, p, \cdot)$  via  $\mathbf{h}_s$  and  $\mathbf{h}_p$ . After decoding, the noisy vector  $\mathbf{r}'_o = \mathbf{h}_p \star \mathbf{h}_s$  should be recalled with  $\mathbf{h}_o$ , which is the holistic representation of  $o$ . Let  $\theta_{\mathbf{r}'_o, \mathbf{h}_o}$  denote the angle between  $\mathbf{r}'_o$  and  $\mathbf{h}_o$ . The cosine function of this angle is again defined as  $\rho_{\mathbf{r}'_o, \mathbf{h}_o} := \cos \theta_{\mathbf{r}'_o, \mathbf{h}_o}$ .

In order to recall the object successfully, the angle between  $\mathbf{r}'_o$  and  $\mathbf{h}_o$  should be smaller than the expected absolute angle between two arbitrary vectors, namely

$$\theta_{\mathbf{r}'_o, \mathbf{h}_o} < \mathbb{E}[\|\theta_{G/C}\|], \quad (13)$$

This inequality first implies that the optimal  $\xi$  should be a positive number. Given the definition of  $\lambda_{G/C}$  in Eq. 5 and 9, equivalently, Eq. 13 requires

$$\rho_{\mathbf{r}'_o, \mathbf{h}_o} > \lambda_{G/C}. \quad (14)$$

After some manipulations, a sufficient condition to recognize the object correctly is given by (see A.5)

$$\begin{aligned} \rho_{\mathbf{r}'_o, \mathbf{h}_o} > & \frac{\xi^2 N_a^2 - (\xi^3 N_a^3 + 2\xi^2 N_a^3 - \xi^2 N_a^2 + \xi N_a^2 + \xi N_a^3) \lambda_{G/C}}{\xi^2 N_a^2 + N_a + 2\xi N_a^2 \lambda_{G/C} + N_a(N_a - 1) \lambda_{G/C}} \\ & > \lambda_{G/C}. \end{aligned} \quad (15)$$

In the following, we verify this condition on the FB15k-237 dataset. We consider one of the experimental settings employed in the memorization task. The dimension of holistic features is  $q = 5200$ , with  $\lambda_G = 0.0111$  computed from Eq. 5, and  $\lambda_C = 0.00204$  from Eq. 9. For Gaussian initialization, the optimum is found at  $\xi = 0.14$  via grid search, while for Cauchy initialization, the optimum is found at  $\xi = 0.05$ .

Figure 5: Analysis of the hyper-parameter  $\xi$  on the FB15k-237 dataset. (a): Approximation of  $\rho_{r'_o, h_o}$  for Gaussian initialization. Curves with  $N_a = 10$  (blue),  $N_a = 20$  (magenta) and their intersections with the retrieval threshold  $\lambda_G$  are displayed. The red vertical line denotes the experimentally determined optimal  $\xi$ . Insert shows the curves with  $\xi \in [-3, 3]$ . (b): Approximation of  $\rho_{r'_o, h_o}$  for Cauchy initialization with  $N_a = 10$  (blue), and  $N_a = 20$  (magenta). Rest remains the same.

To verify these optima, Fig. 5 (a) and (b) display the approximation of  $\rho_{r'_o, h_o}(\xi, N_a)$  as a function of  $\xi$ .<sup>3</sup> Its intersection with  $\lambda_{G/C}$  is marked with a black dot. In FB15k-237,  $N_a$  is estimated to be 20, while, in general, a KG could be quite imbalanced. Thus,  $\rho_{r'_o, h_o}(\xi, N_a)$  with  $N_a = 10$ , and 20 are shown together for comparison.

In Fig. 5 (a) for Gaussian initialization, experimentally determined optimal  $\xi$  (red vertical line) is found close to the intersection of  $\rho_{r'_o, h_o}(\xi, N_a = 10)$  and threshold  $\lambda_G$ , meaning that Gaussian holistic features tend to memorize fewer association pairs. They can only map sparsely connected graph structures into meaningful representations.

In Fig. 5 (b) for Cauchy initialization, however, the optimal  $\xi$  is close to the intersection of  $\rho_{r'_o, h_o}(\xi, N_a = 20)$  and  $\lambda_C$ . Thus, Cauchy holistic features are more suitable to memorize a larger chunk of associations, meaning that they are capable of mapping densely connected graph structures into meaningful representations. All optima are found near the intersection points instead of the local maximum with  $\xi > 0$ . It indicates that, to maximize the memory capacity, the holistic features can only store information with very low fidelity.

## 5 INFERENCE ON KG

### 5.1 INFERENCE VIA HOLISTIC REPRESENTATION

In this section, we describe the model for inferring the missing links in the KG. Recall the scoring function  $\eta_{spo}$  defined in Sec. 2. Our model uses holistic representations as input and generalizes them to implicit facts, by a two-layer neural network<sup>6</sup>. Formally, the scoring function is given as follow:

$$\eta_{spo} = \langle \text{ReLU}(\mathbf{h}_s \mathbf{W}_1^e) \mathbf{W}_2^e, \text{ReLU}(\mathbf{h}_p \mathbf{W}_1^p) \mathbf{W}_2^p, \text{ReLU}(\mathbf{h}_o \mathbf{W}_1^e) \mathbf{W}_2^e \rangle, \quad (16)$$

where  $\langle \cdot, \cdot, \cdot \rangle$  denotes tri-linear dot product;  $\mathbf{h}_s, \mathbf{h}_o$  are the holistic representations for entities defined in Eq. 11,  $\mathbf{h}_p$  is defined in Eq. 12.

Suppose that the holistic representations are defined in  $\mathbb{R}^q$ . Then  $\mathbf{W}_1^e \in \mathbb{R}^{q \times h_1}$  and  $\mathbf{W}_2^e \in \mathbb{R}^{h_1 \times h_2}$  are shared weights for entities;  $\mathbf{W}_1^p \in \mathbb{R}^{q \times h_1}$  and  $\mathbf{W}_2^p \in \mathbb{R}^{h_1 \times h_2}$  are shared weights for predicates. We refer Eq. 16 as HOLNN, a combination of holistic representations and a simple neural network.

As an example, for training on FB15k-237, we take  $q = 3600$ ,  $h_1 = 64$ , and  $h_2 = 256$ . Note that only weight matrices in the neural network are trainable parameters, holistic representations are fixed after encoding. Thus, the total number of trainable parameters in HOLNN is  $0.48M$ , which is much smaller than COM-

<sup>4</sup>see [Schlichtkrull et al. 2018]

<sup>5</sup>G stands for Gaussian holistic features, and C for Cauchy holistic features.

<sup>6</sup>Further experimental details are referred to A.8

PLEX with 5.9M parameters, by assuming that the dimension of embeddings in the COMPLEX is 200.

To evaluate the performance of HOLNN for missing links prediction, we compare it to the state-of-the-art models on two datasets: FB15k-237, and GDELTA. They were split randomly in training, validation, and test sets. We implement all models with the identical loss function Eq. 1, and minimize the loss on the training set using Adam as the optimization method. Hyper-parameters, e.g., the learning rate, and  $l2$  regularization, are optimized based on the validation set.

We use filtered MR, filtered mean reciprocal rank (MRR), and filtered Hits at  $n$  (Hits@ $n$ ) as evaluation metrics [Bordes et al. 2013]. Table 2 and Table 3 report different metrics on the FB15k-237, and GDELTA dataset, respectively. It can be seen that HOLNN is superior to all the baseline methods on both datasets with considerably less trainable parameters. Moreover, HOLNN<sub>C</sub> consistently outperforms HOLNN<sub>G</sub>, indicating that the memory capacity of holistic representations is important for generalization.

## 5.2 INFERENCE ON NEW ENTITIES

In additional experiments, we show that HOLNN is capable of inferring implicit facts on new entities without re-training the neural network. Experiments are performed on FB15k-237 as follows. We split the entire FB15k-237 dataset  $\mathcal{D}$  into  $\mathcal{D}_{old}$  and  $\mathcal{D}_{new}$ . In  $\mathcal{D}_{new}$ , the subjects of triples are new entities which do not show up in  $\mathcal{D}_{old}$ , while objects and predicates are already seen in the  $\mathcal{D}_{old}$ . Suppose our task is to predict implicit links between new entities (subjects in  $\mathcal{D}_{new}$ ) and old entities (entities in  $\mathcal{D}_{old}$ ). Thus, we further split  $\mathcal{D}_{new}$  into  $\mathcal{D}_{new}^{train}$ ,  $\mathcal{D}_{new}^{valid}$ , and  $\mathcal{D}_{new}^{test}$  sets.

For embedding models, e.g., COMPLEX, after training on  $\mathcal{D}_{old}$ , the most efficient way to solve this task is to adapt the embeddings of new entities on  $\mathcal{D}_{new}^{train}$ , with fixed embeddings of old entities. On the other hand, for the HOLNN model, new entities obtain their holistic representations via triples in the  $\mathcal{D}_{new}^{train}$  set. These holistic features are then fed into the trained two-layer neural network. Table 4 shows filtered recall scores for predict-

ing links between new entities and old entities on  $\mathcal{D}_{new}^{test}$ , with the number of new entities in  $\mathcal{D}_{new}$  being 300, 600, or 900. COMPLEX and HOLNN with Cauchy holistic features are compared.

There are two settings for the HOLNN<sub>C</sub> model. New entities could be encoded either from holistic features of old entities, or from random initializations of old entities<sup>7</sup>. We denote these two cases as HOLNN<sub>C</sub>(**h**) and HOLNN<sub>C</sub>(**r**), respectively. It can be seen that HOLNN<sub>C</sub>(**r**) outperforms HOLNN<sub>C</sub>(**h**) only to some degree. It indicates that HOLNN<sub>C</sub> is robust to the noise, making it generalizes well.

## 6 CONCLUSION

We have introduced the holistic representation for the distributed storage of complex association patterns and have applied it to knowledge graphs. We have shown that interference between stored information is reduced with initial random vectors which are pairwise quasi-orthogonal and that pairwise quasi-orthogonality can be improved by drawing vectors from heavy-tailed distributions, e.g., a Cauchy distribution. The experiments demonstrated excellent performance on memory retrieval and competitive results on link prediction.

In our approach, latent representations are derived from random vectors and are not learned from data, as in most modern approaches to representation learning on knowledge graphs. One might consider representations derived from random vectors to be biologically more plausible, if compared to representations which are learned via complex gradient based update rules. Thus in addition to its very competitive technical performance, one of the interesting aspects of our approach is its biological plausibility.

*Outlook:* Potential applications could be applying the holistic encoding algorithm to Lexical Functional for modeling distributional semantics [Coecke et al. 2010], or graph convolutional network [Kipf et al. 2017] for semi-supervised learning using holistic representations as feature vectors of nodes on a graph.

<sup>7</sup>Recall that random initializations are actually deleted after encoding. Here we use them just for comparison.

Rice University

anastasios@rice.edu

## Abstract

We propose practical algorithms for entrywise  $\ell_p$ -norm low-rank approximation, for  $p = 1$  or  $p = \infty$ . The proposed framework, which is non-convex and gradient-based, is easy to implement and typically attains better approximations, faster, than state of the art.

From a theoretical standpoint, we show that the proposed scheme can attain  $(1 + \varepsilon)$ -OPT approximations. Our algorithms are not hyperparameter-free: they achieve the desiderata only assuming algorithm’s hyperparameters are known *a priori*—or are at least approximable. *I.e.*, our theory indicates what problem quantities need to be known, in order to get a good solution within polynomial time, and does not contradict to recent inapproximability results, as in [46].

## 1 INTRODUCTION

We focus on the following optimization problem:

$$\min_{U \in \mathbb{R}^{m \times r}, V \in \mathbb{R}^{n \times r}} \|M - UV^\top\|_p, \quad p \in \{1, \infty\}. \quad (1)$$

Here,  $M \in \mathbb{R}^{m \times n}$  is a given input matrix of arbitrary rank,  $r \leq \{m, n\}$  is the target rank,  $(U, V)$  represent the variables such that  $\text{rank}(UV^\top) \leq r$ , and  $\|\cdot\|_p$  denotes the  $p$ -th, *entrywise*, matrix norm. In words, (1) is described as “finding the factors of the best rank- $r$  approximation of  $M$ , with respect to the  $\ell_p$ -norm”. We denote such optimal factors  $U^*$  and  $V^*$ , and their product  $X^* = U^*V^{*\top}$ . We focus on  $p \in \{1, \infty\}$ , since these instances are the most common found in practice, beyond the classic  $p = 2$  (Frobenius) norm; we will use the terms “Frobenius” and “ $\ell_2$ ” norm, interchangeably.

There are numerous applications where  $\ell_1$ - /  $\ell_\infty$ -norm low rank approximations are useful in practice. First, the  $\ell_1$ -norm is more robust than the  $\ell_2$ -norm, and is suited in problem settings where Gaussian assumptions for noise models may not apply.  $\ell_1$ -norm low rank applications include robust PCA applications [56, 6, 31, 32, 24, 57], computer vision tasks such as background subtraction and motion detection [52, 1, 38], detection of brain activation patterns [44], and detection of anomalous behavior in dynamic networks [44].<sup>1</sup>

For the  $\ell_\infty$ -norm version of (1), the problem cases are only a few. [43] considers the special case of  $m = n$  and  $r = \min\{m, n\} - 1$  as the problem of distance to robust non-singularity. [22, 23] use the notion of  $\ell_\infty$ -norm low rank approximation for the maximal-volume concept in approximation, as well as for the skeleton approximation of a matrix. Finally, [17] identifies that (1) with  $p = \infty$  can be used for the recovery of a low-rank matrix from a quantized  $M$ .

Despite the utility of (1), its solution is not straightforward. While (1) with  $\ell_2$ -norm has a closed-form solution via the Singular Value Decomposition (SVD), the same does not hold for  $p \in \{1, \infty\}$ . Additionally, it has been proved that actually finding the exact solution to (1) can be exponentially complex:

---

<sup>1</sup>Closely related to the  $\ell_1$ -norm low-rank approximation is the problem of  $\ell_1$ -norm subspace recovery [30]. Briefly, it is well-known that, for  $p = 2$  in (1), the SVD solution is also the solution to the dual problem:  $U^* = \text{argmax}_{U \in \mathbb{R}^{m \times r}} |U^\top M|_2$ , subject to  $U^\top U = I$ .  $V^*$  is then set as  $V^* = U^{*\top} M$ ; this can be easily proved due to the orthogonality of  $U^*$  [20]. Motivated by this dual formulation,  $\ell_1$ -norm subspace recovery is defined as

$$U^* = \text{argmax}_{U \in \mathbb{R}^{m \times r}} |U^\top M|_1, \quad \text{subject to } U^\top U = I.$$

Algorithmic solutions to this criterion are usually greedy [30], even combinatorial [36, 37]. However, in this case,  $U^*$  does not necessarily resemble with that of (1) with  $p = 1$  (up to orthogonal rotations).

[19] show that  $\ell_1$ -norm low rank matrix approximation is NP-hard, even for  $r = 1$ ; further, under the exponential time hypothesis for 3SAT problems, [46] provide a  $\left(1 + \frac{1}{\log^{1+\gamma}(\max\{m,n\})}\right)$ -inapproximability result for some hard instances  $M$ , where  $\gamma > 0$  is an arbitrary small constant. [17] proves the NP-completeness of (1) for  $p = \infty$ , using a reduction from not-all-equal-3SAT.

The above restrict research to only approximations of (1). To the best of our knowledge only the works in [9, 46] present polynomial and provably good approximation schemes: [46] focuses mostly on the case of  $\ell_1$ -norm, and proves the existence of a  $O(\log(\min\{m,n\}) \cdot \text{poly}(r))$ -approximation scheme with  $O(\text{nnz}(M) + (m+n)\text{poly}(r))$  computational complexity. [9] extends the ideas in [46] for  $\ell_p$ -norms, where  $p \in [1, \infty]$ : there, the authors describe a  $\text{poly}(r)$ -approximation with  $O(\text{poly}(m,n)(r \log \max\{m,n\})^r)$  computational complexity. Both approaches are based on numerical linear algebra and sketching techniques.

Apart from the above provable schemes, there are numerous heuristics proposed for (1), with no rigorous approximation guarantees. Starting with  $\ell_1$ -norm, [38] propose a coordinate descent algorithm for (1), where a sequence of alternating scalar minimization sub-problems are solved using a (weighted) median filter; see also [29]. Previously to that work, [26, 27] follow a similar approach, where each sub-problem is solved using linear or quadratic programming<sup>2</sup>. Inspired by [55], [13] propose a  $\ell_1$ -norm version of the Wiberg method; the resulting algorithm involves several matrix-matrix multiplications (even of size greater than the input matrix), and the solution of linear programming criteria, per iteration. Cabral et al. use Augmented Lagrange Multipliers (ALM) method and handle the weighted  $\ell_1$ -norm low rank approximation problem in [5]; however, no non-asymptotic convergence guarantees are provided. We note that most of the above heuristics are designed to handle *missing data* in  $M$  or the case of *weighted* factorization; we plan to consider such cases for our future research directions. For the  $\ell_\infty$ -norm case, we mention the recent work of Gillis et al. [17] that proposes a block coordinate descent method that operates in an alternating minimization fashion over subsets of variables in (1).

**Our approach and main contributions:** Inspired by the recent advances on smooth non-convex optimization for matrix factorization [47, 58, 51, 4, 42, 16, 40, 41, 35, 34,

<sup>2</sup>In [26, 27], there are some convergence guarantees for the alternating optimization scheme; however, there are no results w.r.t. whether we converge to a saddle point or local minimum, nor results on the convergence rate.

50, 54, 15, 33], we study the application of alternating gradient descent in (1). Despite its NP-hardness, this paper follows a more optimistic course and works towards deciphering the components/quantities that, if known a priori, could lead to a  $(1 + \varepsilon)$ -approximation for (1).

Our approach is based on two techniques from optimization theory: (i) the smoothing technique for non-smooth convex optimization by Nesterov [39, 12] (Section 4), and (ii) the recent theoretical results on finding the global minimum of matrix factorization problems using non-convex smooth methods (Section 3); see also references above. Our theory relies on provably bounding the objective function in  $\ell_1$ - or  $\ell_\infty$ -norm by its smoothing counterpart (Sections 4), using the provable performance of the non-convex algorithm (Section 3), and properly setting up the input parameters (Section 5). Our guarantees assume that we can at least approximate the optimal function value of (1), and that the optimal low-rank solution of the smoothed problem is well-conditioned; the latter assumption is required for a good initialization to be easily found. The above are summarized as:

- Under assumptions, we provide a polynomial approximation algorithm for  $p = \{1, \infty\}$  in (1) that achieves a  $(1 + \varepsilon)$ -approximation guarantee.
- We experimentally show that our scheme outperforms in practice state-of-the-art approaches.

There are several questions that remain open and need further investigation. In Section 7, we discuss what are the advantages and disadvantages of our approach and point to possible future research directions.

## 2 NOTATION AND ASSUMPTIONS

*Notation.* For matrices  $X, Y \in \mathbb{R}^{m \times n}$ ,  $\langle X, Y \rangle = \text{Tr}(X^\top Y)$  represents their inner product and  $X \odot Y$  their Hadamard product. We represent matrix norms as follows:  $|X|_2 = \sqrt{\sum_{i=1}^m \sum_{j=1}^n |X_{ij}|^2}$  denotes the Frobenius (or  $\ell_2$ -) norm,  $|X|_1 = \sum_{i=1}^m \sum_{j=1}^n |X_{ij}|$  denotes the entrywise  $\ell_1$ -norm, and  $|X|_\infty = \max_{i,j} |X_{ij}|$  denotes the entrywise  $\ell_\infty$ -norm. For the spectral norm, we use  $\sigma_1(X)$ ; this also denotes the largest singular value of  $X$ . For vectors, we use  $\|x\|_2$  to denote its Euclidean  $\ell_2$ -norm. For a differentiable function  $f(X)$  with  $X = UV^\top$ , the gradient of  $f$  w.r.t.  $U$  and  $V$  is  $\nabla f(X)V$  and  $\nabla f(X)^\top U$ , respectively.

*Assumptions.* For our discussion, we will need two well-known notions of convex analysis: (restricted) *strong* convexity and (restricted) Lipschitz gradient continuity.

**Definition 2.1.** *Let  $f : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}$  be a convex differentiable function. Then,  $f$  is (resp. restricted) gradient Lip-*

schitz continuous with parameter  $L$  if  $\forall X, Y \in \mathbb{R}^{m \times n}$  (resp.  $\forall X, Y \in \mathbb{R}^{m \times n}$  that are at most rank- $r$ ):

$$f(Y) \leq f(X) + \langle \nabla f(X), Y - X \rangle + \frac{L}{2} \|Y - X\|_2^2. \quad (2)$$

**Definition 2.2.** Let  $f : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}$  be convex and differentiable. Then,  $f$  is (resp. restricted)  $\mu$ -strongly convex if  $\forall X, Y \in \mathbb{R}^{m \times n}$  (resp.  $\forall X, Y \in \mathbb{R}^{m \times n}$  that are at most rank- $r$ ):

$$f(Y) \geq f(X) + \langle \nabla f(X), Y - X \rangle + \frac{\mu}{2} \|Y - X\|_2^2. \quad (3)$$

### 3 BFGD FOR SMOOTH OBJECTIVES

Let us first succinctly describe the Bi-Factored Gradient Descent (BFGD) algorithm [41], upon which our proposal is based. BFGD is a non-convex gradient descent scheme for *smooth* problems such as:

$$\min_{U \in \mathbb{R}^{m \times r}, V \in \mathbb{R}^{n \times r}} f(UV^\top), \quad (4)$$

where  $f$  is assumed to be convex, *differentiable*, and at least have Lipschitz continuous gradients. Observe that while  $f$  is convex w.r.t. to any input  $\in \mathbb{R}^{m \times n}$ , motions over  $U$  and  $V$  jointly lead to non-convex optimization. Such approaches have a long history and different variants have been proposed for (4).

For the rest of this section, we denote  $X = UV^\top$  as the result of the factorization. Also, let  $\hat{X}^*$  be the optimal point of (4): if  $\text{rank}(X^*) = r$ , then  $\hat{X}^* = X_r^*$ ; otherwise, denote its best rank- $r$  approximation (w.r.t. the  $\ell_2$ -norm) as  $\hat{X}_r^*$ .

---

#### Algorithm 1 Bi-factored gradient descent (BFGD)

---

- 1: **Input:**  $r, T, \gamma$  (e.g.,  $\frac{1}{4}$ ),  $C > 0$  (e.g.,  $C = 1$ ),  $\hat{L}$ .
- 2: Compute  $X_0 := \frac{1}{\hat{L}} \cdot (-\nabla f(0_{m \times n}))$ .
- 3: Set  $U_0 \in \mathbb{R}^{m \times r}, V_0 \in \mathbb{R}^{n \times r}$  s.t.  $X_0 = U_0 V_0^\top$ , via SVD.
- 4: **for**  $i = 0$  to  $T - 1$  **do**
- 5:   Set  $\eta$  such that:  $\eta \leq \frac{C}{15\hat{L} \left( \| [U_i \ V_i]^\top \|^2 + 3 \|\nabla f(U_i V_i^\top)\|_2 \right)}$ .
- 6:   • If  $f$  satisfies Definition 2.1: **Rule 1**

$$\begin{bmatrix} U_{i+1} \\ V_{i+1} \end{bmatrix} = \begin{bmatrix} U_i \\ V_i \end{bmatrix} - \eta \begin{bmatrix} \nabla f(U_i V_i^\top) \cdot V_i \\ \nabla f(U_i V_i^\top)^\top \cdot U_i \end{bmatrix}$$

- If  $f$  satisfies Definitions 2.1-2.2: **Rule 2**

$$\begin{bmatrix} U_{i+1} \\ V_{i+1} \end{bmatrix} = \begin{bmatrix} U_i \\ V_i \end{bmatrix} - \eta \begin{bmatrix} \nabla f(U_i V_i^\top) V_i + \gamma U_i (U_i^\top U_i - V_i^\top V_i) \\ \nabla f(U_i V_i^\top)^\top U_i - \gamma V_i (U_i^\top U_i - V_i^\top V_i) \end{bmatrix}$$

7: **end for**

8: **Output:**  $\hat{X} = U_T V_T^\top$ .

---

The pseudocode for BFGD is provided in Algorithm 1 and obeys the following motions: (i) given a proper ini-

tialization  $X_0 = U_0 V_0^\top$ , and (ii) a proper step size  $\eta$ ,<sup>3</sup> BFGD applies iteratively **Rule 1** if  $f$  satisfies only Definition 2.1, or **Rule 2** if  $f$  also satisfies Definition 2.2. The algorithm assumes an approximation of  $L$ —say  $\hat{L}$  and see [4]—and a good initialization point  $(U_0, V_0)$ . For a more complete discussion of initialization  $(U_0, V_0)$ , we refer the reader to [4, 41]; we briefly discuss this issue in Section 5.

An important issue in optimizing  $f$  over  $(U, V)$  is the existence of non-unique possible factorizations for a given  $X$ . We need a notion of distance to the low-rank solution  $X_r^*$  over the factors. Similar to [51, 41], we focus on the set of “equally-footed” factorizations:

$$\hat{\mathcal{X}}_r^* = \left\{ (\hat{U}^*, \hat{V}^*) : \hat{U}^* \in \mathbb{R}^{m \times r}, \hat{V}^* \in \mathbb{R}^{n \times r}, \hat{U}^* \hat{V}^{*\top} = \hat{X}_r^*, \sigma_i(\hat{U}^*) = \sigma_i(\hat{V}^*) = \sigma_i(\hat{X}_r^*)^{1/2}, \forall i \in [r] \right\}. \quad (5)$$

Given a pair  $(U, V)$ , we define the distance to  $\hat{\mathcal{X}}_r^*$  as:

$$\text{DIST}(U, V; \hat{\mathcal{X}}_r^*) = \min_{(\hat{U}^*, \hat{V}^*) \in \hat{\mathcal{X}}_r^*} \left\| \begin{bmatrix} U \\ V \end{bmatrix} - \begin{bmatrix} \hat{U}^* \\ \hat{V}^* \end{bmatrix} \right\|_2.$$

Algorithm 1 has local convergence guarantees, when  $f$  is  $\mu$ -strongly convex and has  $L$ -Lipschitz continuous gradients, according to the following theorem:<sup>4</sup>

**Theorem 3.1** (Theorem 4.4 in [41]). Let  $\kappa = L/\mu$ . If the initial point  $X_0 = U_0 V_0^\top$ , satisfies  $\text{DIST}(U_0, V_0; X_r^*) \leq \frac{\sqrt{2} \cdot \sigma_r(X_r^*)^{1/2}}{10}$ , then BFGD converges with rate  $O(1/T)$ :

$$f(U_T V_T^\top) - f(\hat{U}^* \hat{V}^{*\top}) \leq \frac{10 \cdot \text{DIST}(U_0, V_0; \hat{\mathcal{X}}_r^*)^2}{\eta T}$$

### 4 CHARBONNIER APPROXIMATION AND THE $\text{logsumexp}$ FUNCTION

A key assumption in BFGD is that  $f$  is at least once *differentiable* and has Lipschitz continuous gradients. Therefore, to connect BFGD with our original objective in (1), we will first approximate both the  $\ell_1$  and  $\ell_\infty$  entrywise matrix norms by smooth functions that have derivatives at least in two degrees. For similar approaches in optimization where non-smooth functions are substituted by smooth ones, we refer to the seminal paper of Nesterov [39] and follow-up works [12, 28].

<sup>3</sup>In this work, we do not focus on the most efficient step size selections: e.g., the step size considered in this work varies per iteration, and it is less efficient than a constant step size selection as in [4, 41]. However, in all cases, we could bound the varying step size with one that is constant.

<sup>4</sup>In this work, we will borrow only the sublinear rate results in [41], since that result alone is sufficient to lead to polynomial algorithms for (1). Using the linear convergence rate result in [41] is left for the extension of this work.

Figure 1:  $\ell_1$ -norm and its Charbonnier smooth approximations. *Left and middle*: Function values vs. input variable. *Right*: Gradient approximation.

**Approximating the entrywise  $\ell_1$ -norm.** For the approximation of the  $\ell_1$ -norm, we will use the Charbonnier loss function [7, 3], parameterized as follows:

$$h(x, \tau) = \tau \cdot \left( \sqrt{\left(\frac{x}{\tau}\right)^2 + 1} - 1 \right). \quad (6)$$
