
To illustrate how a good approximation is (6) to the  $\ell_1$ -norm, see Figure 1.

We now discuss about the matrix form of (6) and its properties. With a slight overload of notation, we define the matrix version of (6) as follows:

$$\begin{aligned} h(X, \tau) &= \sum_{i=1}^m \sum_{j=1}^n h(X_{ij}, \tau) \\ &:= \tau \cdot \sum_{i=1}^m \sum_{j=1}^n \left( \sqrt{\left(\frac{X_{ij}}{\tau}\right)^2 + 1} - 1 \right). \end{aligned} \quad (7)$$

The distinction between scalar and matrix  $h$  will be apparent from the text. Gradient and Hessian information of  $h$  satisfy the following lemma; the proof is deferred to the supp. material:

**Lemma 4.1.** For any  $X \in \mathbb{R}^{m \times n}$ :

- $\nabla h(X, \tau) = \frac{1}{\tau} X \odot S \in \mathbb{R}^{m \times n}$ , where  $S \in \mathbb{R}^{m \times n}$  and  $S_{ij} := \frac{2}{\sqrt{(X_{ij}/\tau)^2 + 1}}$ ,
- $\nabla^2 h(X, \tau) = \frac{1}{\tau} I \odot Q \in \mathbb{R}^{mn \times mn}$ , where  $Q \in \mathbb{R}^{mn \times mn}$  and  $Q_{ij} := \frac{2}{((X_{ij}/\tau)^2 + 1)^{3/2}}$ .

The above lead to the following lemma; the proof is provided in the supp. material:

**Lemma 4.2.** Function  $h$  is a convex continuously differentiable function and it has Lipschitz continuous gradients with constant  $\frac{2}{\tau}$ . Moreover:

$$|X|_1 - mn\tau \leq h(X, \tau) \leq |X|_1.$$

An alternative to the Charbonnier approximation is the Huber loss function with parameter  $\tau$  [25]:

$$h(x, \tau) = \begin{cases} x^2/2\tau, & \text{if } |x| \leq \tau \\ |x| - \tau/2, & \text{otherwise.} \end{cases} \quad (8)$$

Huber loss combines a  $\ell_2$ -norm measure for small values of  $x$  and a  $\ell_1$ -norm like measure for large  $x$ . Observe in (8) that it is only first-order differentiable; thus any computations involving second order derivatives cannot be applied. On the other hand, the Charbonnier loss function, which is also known as the ‘‘pseudo-Huber loss function’’, is a smooth approximation of the Huber loss that ensures that derivatives are continuous for all degrees. W.l.o.g., we focus on the Charbonnier function.

**Approximating the entrywise  $\ell_\infty$ -norm.** Following similar procedure for the entrywise matrix  $\ell_\infty$ -norm, we will use the `logsumexp` function, defined as follows:

$$\sigma(X, \tau) = \tau \cdot \log \left( \frac{\sum_{i=1}^m \sum_{j=1}^n e^{X_{ij}/\tau} + e^{-X_{ij}/\tau}}{2mn} \right) \quad (9)$$

Define matrices  $P, N \in \mathbb{R}^{m \times n}$  such that:  $P_{ij} = e^{X_{ij}/\tau} + e^{-X_{ij}/\tau}$  and  $N_{ij} = e^{X_{ij}/\tau} - e^{-X_{ij}/\tau}$ . Then, the following lemma defines the gradient and Hessian information of the `logsumexp` function; see also the supp. material:

**Lemma 4.3.** For any  $X \in \mathbb{R}^{m \times n}$ :

- $\nabla \sigma(X, \tau) = \frac{1}{\text{Tr}(\mathbb{1} \cdot P)} \cdot N \in \mathbb{R}^{m \times n}$ ,
- $\nabla^2 \sigma(X, \tau) = \frac{\left( \text{diag}(\text{vec}(P)) - \frac{\text{vec}(N)\text{vec}(N)^\top}{\text{Tr}(\mathbb{1} \cdot P)} \right)}{\tau \cdot \text{Tr}(\mathbb{1} \cdot P)} \in \mathbb{R}^{mn \times mn}$

where  $\text{diag}(\cdot) : \mathbb{R}^{mn} \rightarrow \mathbb{R}^{mn \times mn}$  turns the vector input to a diagonal matrix output,  $\text{vec}(\cdot) : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}^{mn}$  turns a matrix to a vector by ‘‘stacking’’ its columns, and  $\mathbb{1}$  denotes the all-ones matrix.

Similar to the Charbonnier approximation, we get the following lemma; the proof is in the supp. material:

**Lemma 4.4.** *The  $\text{logsumexp}$  function  $\sigma$  is a convex continuously differentiable function and it has Lipschitz continuous gradients with constant  $\frac{1}{\tau}$ . Moreover:*

$$|X|_\infty - \tau \log(2mn) \leq \sigma(X, \tau) \leq |X|_\infty.$$

## 5 AN APPROXIMATE SOLVER FOR $\ell_p$ -NORM LOW RANK APPROXIMATION

The proposed schemes are provided in Algorithms 2-3, and are based on Algorithm 1 as a sub-solver. In order to hope for a good initialization, we consider the smooth versions of (1), as described in Section 4, with the added twist that we regularize further the objective with a strongly convex component. *I.e.*, we approximate (1) for  $p = 1$  with:

$$\min_{U \in \mathbb{R}^{m \times r}, V \in \mathbb{R}^{n \times r}} h(M - UV^\top, \tau) + \frac{\lambda}{2} |UV^\top|_2^2, \quad (10)$$

and the case  $p = \infty$  with

$$\min_{U \in \mathbb{R}^{m \times r}, V \in \mathbb{R}^{n \times r}} \sigma(M - UV^\top, \tau) + \frac{\lambda}{2} |UV^\top|_2^2. \quad (11)$$

This modification asserts that both (10)-(11) are strongly convex w.r.t.  $X$  with parameter  $\lambda$ ; see also the proof of Lemma 4.2. Observe that the smaller the  $\lambda$  parameter is, the less the “drift” from the original problem. We remind that the optimal factors of (1) are  $U^*$  and  $V^*$ , and their product is denoted as  $X^* = U^*V^{*\top}$ .

---

### Algorithm 2 $\ell_1$ -norm low rank approximation solver

- 1: **Parameters:**  $r$ , OPT, values of  $|X^*|_2^2$  and  $\sigma_r(\widehat{X}^*)$ ,  $\varepsilon > 0$ .
  - 2: Set  $\tau = \frac{\varepsilon \cdot \text{OPT}}{3mn}$ .
  - 3: Set function  $T = O\left(\frac{\sigma_r(\widehat{X}_r^*)}{\varepsilon \text{OPT}}\right)$ .
  - 4: Set  $\lambda = \frac{2\varepsilon \cdot \text{OPT}}{3|X^*|_2^2}$ .
  - 5: Compute  $\widehat{L} = \left(\frac{1}{\tau} + \lambda\right)$ .
  - 6: Set  $f(UV^\top) := h(M - UV^\top, \tau) + \frac{\lambda}{2} |UV^\top|_2^2$ .
  - 7: Run Algorithm 1  $(U_T, V_T) = \text{BFGD}(r, T, \frac{1}{4}, 1, \widehat{L})$ .
- 

Let us first focus on the case of  $\ell_1$ -norm and Algorithm 2. The following theorem states that, under proper configuration of algorithm’s hyperparameters, one can achieve  $(1 + \varepsilon)$ -OPT approximation guarantee.

**Theorem 5.1.** *Let  $\widehat{X} = U_T V_T^\top \in \mathbb{R}^{m \times n}$  be the solution of Algorithm 2. Let the optimal function value of (1) for  $p = 1$  be denoted as  $\text{OPT} := \min_{U, V} |M - UV^\top|_1$  and assumed known, or at least be approximable. Also, assume we know  $\sigma_r(\widehat{X}^*)$  and  $|X^*|_2^2$ . For user defined*

*parameter  $\varepsilon > 0$  and setting the Charbonnier parameter  $\tau = \frac{\varepsilon \cdot \text{OPT}}{3mn}$ , and the strong convexity parameter as  $\lambda = \frac{2\varepsilon \cdot \text{OPT}}{3|X^*|_2^2}$ , the pair  $(U_T, V_T)$  of Algorithm 2 satisfies:*

$$|M - U_T V_T^\top|_1 \leq (1 + \varepsilon) \cdot \text{OPT},$$

*after  $T = O\left(\sigma_r(\widehat{X}_r^*) \left(\frac{mn}{(\varepsilon \text{OPT})^2} + \frac{1}{\|X^*\|_2^2}\right)\right)$  iterations.*

The proof is provided in the appendix. In the case where OPT is only approximable, straightforward modifications lead to similar performance (where higher number of iterations required).

*Analytical complexity:* Let us denote the time to compute  $\nabla f(\cdot)$  as  $t_{\text{grad}}$ . The initialization complexity of Algorithm 1, as well as its per iteration complexity, is  $O(t_{\text{grad}} + mn r)$ , where the last term is due to either low-rank SVD calculation or matrix-matrix multiplication. Running Algorithm 1 for  $T = O\left(\frac{\sigma_r(\widehat{X}_r^*)}{\varepsilon \text{OPT}}\right)$  iterations leads to an overall  $O\left(\frac{\sigma_r(\widehat{X}_r^*)}{\varepsilon \text{OPT}} \cdot (t_{\text{grad}} + mn r)\right)$  time complexity.

Similarly for the case of  $p = \infty$ , we use the  $\text{logsumexp}$  function in Algorithm 3 to smooth the objective, and we obtain the following guarantees:

---

### Algorithm 3 $\ell_\infty$ -norm low rank approximation solver

- 1: **Parameters:**  $r$ , OPT, values of  $|X^*|_2^2$  and  $\sigma_r(\widehat{X}^*)$ ,  $\varepsilon > 0$ .
  - 2: Set  $\tau = \frac{\varepsilon \cdot \text{OPT}}{3 \log(2mn)}$ .
  - 3: Set function  $T = O\left(\frac{\sigma_r(\widehat{X}_r^*)}{\varepsilon \text{OPT}}\right)$ .
  - 4: Set  $\lambda = \frac{2\varepsilon \cdot \text{OPT}}{3|X^*|_2^2}$ .
  - 5: Compute  $\widehat{L} = \left(\frac{1}{\tau} + \lambda\right)$ .
  - 6: Set  $f(UV^\top) := \sigma(M - UV^\top, \tau) + \frac{\lambda}{2} |UV^\top|_2^2$ .
  - 7: Run Algorithm 1  $(U_T, V_T) = \text{BFGD}(r, T, \frac{1}{4}, 1, \widehat{L})$ .
- 

**Corollary 5.2.** *Let  $\widehat{X} = U_T V_T^\top \in \mathbb{R}^{m \times n}$  be the solution of Algorithm 2. Let the optimal function value of (1) for  $p = \infty$  be denoted as  $\text{OPT} := \min_{U, V} |M - UV^\top|_\infty$ , and assumed known, or be at least approximable. Also, assume we know  $\sigma_r(\widehat{X}^*)$  and  $|X^*|_2^2$ . For user defined approximation parameter  $\varepsilon > 0$  and setting the  $\text{logsumexp}$  parameter  $\tau = \frac{\varepsilon \cdot \text{OPT}}{3 \log(2mn)}$ , and the strong convexity parameter as  $\lambda = \frac{2\varepsilon \cdot \text{OPT}}{3|X^*|_2^2}$ , the pair  $(U_T, V_T)$  of Algorithm 2 satisfies:*

$$|M - U_T V_T^\top|_\infty \leq (1 + \varepsilon) \cdot \text{OPT},$$

*after  $T = O\left(\sigma_r(\widehat{X}_r^*) \left(\frac{\log(mn)}{(\varepsilon \text{OPT})^2} + \frac{1}{\|X^*\|_2^2}\right)\right)$  iterations.*

Similar analytical complexity can be derived for Algorithm 3 and is omitted due to lack of space.

Results of similar flavor (and under similar assumptions) can be found in [28] for the problem of maximum flow. There, the authors consider non-Euclidean gradient descent algorithms for the minimization of  $\ell_\infty$ -norm over vectors, where the gradient step takes into consideration the geometry of the non-smooth objective with the use of *sharp* operators. We applied a similar approach for both  $p \in \{1, \infty\}$  in our setting; however, the empirical performance was prohibitive to consider a similar approach here (despite the fact that one can still achieve  $(1 + \varepsilon)$ -optimal approximation guarantees).

Some remarks regarding the above results.

**Remark 1.** *Both algorithms require the knowledge of three quantities: OPT,  $|X^*|_2^2$  and  $\sigma_r(\hat{X}^*)$ . While finding these values could be as difficult as the original problem (1), these values do not need to be known exactly: in particular, the algorithms imply that “for sufficiently small  $\tau$  and  $\lambda$  parameters, and for a sufficiently large number of iterations  $T$ , we can find a good approximation”.*

**Remark 2.** *While finding the exact value of OPT is difficult, there are problem cases where this value could be easily upper bounded. E.g., consider the problem of low-rank matrix approximation from quantization, as noted in [17]: there, we know from structure that  $|M - X^*|_\infty = \text{OPT} \leq 0.5$ .*

**Remark 3.** *Finding a good initialization is a key assumption for Theorem 5.1 and its corollary. Such assumptions are made also in other non-convex matrix factorization results; see [47, 58, 51, 4, 42, 16, 40, 41, 35, 34, 54, 15]. From [41], it is known that we can easily compute such an initialization as the best rank- $r$  approximation of  $M$  w.r.t. the  $\ell_2$ -norm, via SVD. In particular, such an initialization satisfies  $\text{DIST}(U_0, V_0; \hat{X}^*) \leq \frac{\sqrt{2} \cdot \sigma_r(\hat{X}^*)^{1/2}}{10\sqrt{\kappa}}$ , as long as  $f$  is strongly convex with condition number  $\kappa \leq 1 + \frac{\sigma_r(\hat{X}^*)^2}{4608 \cdot |X^*|_2^2}$ . While this condition is not easily met in theory (i.e., since  $\kappa = \frac{1+\lambda}{\lambda}$ , this means that  $\tau$  should be large enough compared to  $\lambda$ ), our experiments show that such an initialization performs well.*

**Remark 4.** *As a continuation of the above remark, the reason we use the regularizer  $\frac{\lambda}{2}|UV^\top|_2^2$  is to turn the smooth approximations into strongly convex functions (and thus borrow results for initialization). In practice, the proposed schemes work as well without the addition of the regularizer; and thus, knowing a priori the quantity  $|X^*|_2^2$  is not necessary in practice.*

**Remark 5.** *The approach we follow somewhat resembles with the approach proposed in [27]. There, the authors consider (1) for  $p = 1$  and propose an alternating minimization scheme. Despite the similarities, there are differences with our approach: among which, we perform a single gradient descent step on  $U$  and  $V$  per itera-*

*tion, for a smoothed version of (1), instead of minimizing a quadratic programming formulation per each column of  $U$  and  $V$ . On the contrary, [27] handles empirically missing values and weighted low-rank matrix factorization cases; we leave this direction for future research.*

## 6 EXPERIMENTS

Our experiments include synthesized applications, in order to highlight the empirical performance of the proposed framework. We compare the algorithms in Section 5 (i) with the algorithms for  $\ell_p$ -low rank approximation in [9], and (ii) with the recent heuristic in [17] for  $\ell_\infty$ -low rank approximation.

Similarly to [9, 17] and in order to guarantee fair comparison, we follow in practice the “folklore” advice for getting an initial estimate for the  $\ell_p$ -norm problem in (1) by beginning with the optimum  $\ell_2$ -norm solution (i.e., with the low-rank SVD solution).

### 6.1 $\ell_1$ -norm approximation

We perform experiments on both real and synthetic datasets. At first, we generate data according to the recent ICML paper [9]: We use  $20 \times 30$  random matrices  $M$ , where each entry is a uniformly random value in  $[0, 1]$ . Such constructions lead to full rank matrices with high-probability. We also construct matrices  $M$  of the same size with  $\{\pm 1\}$  entries, each selected with 0.5 probability. For real datasets, similar to [9], we use the FIDAP dataset<sup>5</sup> and a word frequency dataset from UC Irvine<sup>6</sup>. The FIDAP matrix  $M$  is  $27 \times 27$  with 279 real asymmetric non-zero entries. The word frequency matrix  $M$  is  $3430 \times 6906$  with 353, 160 non-zero entries.

For the synthesized datasets, we perform 10 Monte Carlo instantiations and take the median error reported. For all datasets, we are interested in computing the best rank- $r$  approximation of each  $M$  above, w.r.t. the  $\ell_1$ -norm and for  $r \in \{1, \dots, 10\}$ . To compare with [9], we use their suggestion and run a simplified version of Algorithm 2 in [9], where we repeatedly sample  $r$  columns, uniformly at random. We then run the  $\ell_p$ -projection (see Lemma 1 in [9]) on each sampled set and finally select the solution with the smallest  $\ell_p$ -error. For a fair contrast between the algorithms, we first run our algorithm and measure the required time; for approximately the same amount of time, we run [9].<sup>7</sup> To perform the  $\ell_p$ -projection, we use

<sup>5</sup><http://math.nist.gov/MatrixMarket/data/SPARSKIT/fidap/fidap005.html>

<sup>6</sup><https://archive.ics.uci.edu/ml/datasets/Bag+of+Words>

<sup>7</sup>In all our experiments, we make sure the algorithm in [9] runs at least the same time with our scheme.

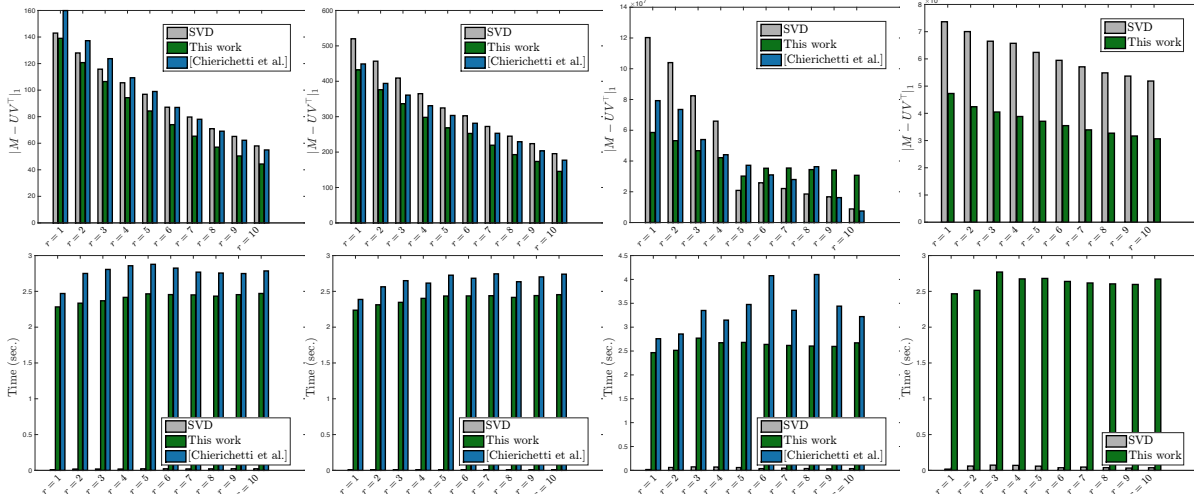

Figure 2: Top row: function value performance  $|M - UV^T|_1$ ; Bottom row: corresponding execution time. In all settings, we set problem (1) for  $r = \{1, \dots, 10\}$ . First column:  $M \in [0, 1]^{20 \times 30}$  where each entry is randomly and independently generated. Second column:  $M \in [-1, 1]^{20 \times 30}$  where each entry is randomly and independently generated. Third column:  $M \in \mathbb{R}^{27 \times 27}$  is the FIDAP matrix. Fourth column:  $M \in \mathbb{R}^{3430 \times 6906}$  is the word-frequency matrix. In the latter case, the sub-solver for  $\ell_p$ -projection was not able to complete the task, and thus the algorithm in [9] is omitted.

CVX package [14].<sup>8</sup>

In our algorithm, we set  $\tau = \lambda = 10^{-3}$ , and the maximum number of iterations as  $T = 4 \cdot 10^4$ . As mentioned above, we use the SVD initialization, and the step size is set according to Algorithm 1.

The results are provided in Figure 2. Some remarks: (i) for the synthetic cases (two leftmost columns), we observe that our approach attains a better objective function, faster, compared to [9]. Both our work and [9] is much slower than plain SVD; however, the latter gives a worse solution. (ii) for the real case (two rightmost columns), our approach is overall better in terms of objective function values; however, this is not universal; there are cases where [9] (or even SVD) gets to a better result within the same time, especially when  $r$  increases. For the large matrix case, [9] with CVX do not scale well; thus omitted.

## 6.2 $\ell_\infty$ -norm approximation

In this experiment, we follow the experimental setting in [17]. We generate matrices  $M \in \mathbb{R}^{100 \times 75}$  as follows: We generate  $\tilde{M} = UV^T$  where  $U \in \mathbb{R}^{100 \times r}$  and  $V \in \mathbb{R}^{75 \times r}$ . Each  $U$  and  $V$  is generated i.i.d. from  $N(0, 1)$ . Given  $\tilde{M}$ , we compute the rounded version of

<sup>8</sup>We are not aware of another standardized package for  $\ell_p$ -regression. To accelerate the execution of SeDuMi, we use the lowest precision set up in CVX.

$\tilde{M}$  such as  $M = \text{round}(\tilde{M})$ . This procedure guarantees that, given  $M$ , there is a low-rank matrix  $\tilde{M}$  that satisfies  $|M - \tilde{M}|_\infty \leq 0.5$  (since this is an hard problem, this construction gives an idea how far/close we are to a good solution).

We repeat the above procedure for  $r = \{1, \dots, 10\}$  and for 10 Monte Carlo instances. We report the minimum, mean and median values of the objective function attained and the time required. We compare our algorithms with plain SVD and the heuristics in [17].

The results are reported in Table 1. Our findings show that both our work and the algorithm in [17] perform much better (in terms of quality of solution) than plain SVD (the full set of results can be found in the appendix). Further, the algorithm in [17] has time comparable to the implementation of SVD in Matlab, while our proposed algorithm is much slower; accelerating our proposed algorithm is considered future research direction. However, while our algorithm does not succeed to find solutions with small objective value (see minimum value in table and compare our work with [17]), the median value of objective function values over 10 problem instances is lower than that of [17]. *I.e.*, the “typical” achieved objective value is lower than that of [17].<sup>9</sup>

<sup>9</sup>We ran the algorithm in [17] for more time (repeatedly within allowed time) and picked the best minimum result. However, this did not improve the results of [17].

## 7 CONCLUSION AND FUTURE WORK

We consider the problem of low-rank matrix approximation, w.r.t. (entrywise)  $\ell_p$ -norms, and proposed two algorithms that lead to  $(1 + \varepsilon)$ -OPT approximations. Our schemes combine ideas from smoothing techniques in convex optimization, as well as recent non-convex gradient descent algorithms. Key assumption is that problem-related quantities are known or at least are approximable. Our experiments show that our scheme performs (at least) competitively with state of the art.

We have provided several possible extensions of this work. A particularly interesting open problem is that of weighted low-rank matrix approximation:

$$\min_{U \in \mathbb{R}^{m \times r}, V \in \mathbb{R}^{n \times r}} |W \odot (M - UV^T)|_p, \quad p \in \{1, \infty\},$$

where different assumptions on  $W$  lead to different open research questions.

## Abstract

The stochastic multi-armed bandit is a well-studied abstraction of decision making in the face of uncertainty. We consider the setting in which the number of bandit arms is much larger than the possible number of pulls, and can even be infinite. With the aim of minimising regret with respect to an *optimal* arm, existing methods for this setting either assume some structure over the set of arms (Kleinberg et al., 2008, Ray Chowdhury and Gopalan, 2017), or some property of the reward distribution (Wang et al., 2008). Invariably, the validity of such assumptions—and therefore the performance of the corresponding methods—depends on instance-specific parameters, which might not be known beforehand.

We propose a conceptually simple, parameter-free, and practically effective alternative. Specifically we introduce a notion of regret with respect to the top *quantile* of a probability distribution over the expected reward of randomly drawn arms. Our main contribution is an algorithm that achieves sublinear “quantile-regret”, both (1) when it is specified a quantile, and (2) when the quantile can be any (unknown) positive value. The algorithm needs no side information about the arms or about the structure of their reward distributions: it relies on random sampling to reach arms in the top quantile. Experiments show that our algorithm outperforms several previous methods (in terms of conventional regret) when the latter are not tuned well, and often even when they are.

## 1 INTRODUCTION

The stochastic multi-armed bandit (Berry and Fristedt, 1985) is a well-studied abstraction of on-line learning. Each bandit *arm* represents a slot-machine with a fixed (but unknown) real-valued reward distribution. An experimenter is allowed

to *pull* an arm at every time instant and observe its reward. The experimenter aims to maximise the total expected reward obtained over a horizon, or equivalently, to minimise the *regret* with respect to a strategy that always plays an optimal arm. Side information regarding the bandit instance may or may not be available to the experimenter.

Regret minimisation algorithms have to achieve a balance between exploration (gathering information about the reward distributions of arms) and exploitation (pulling seemingly-good arms). For a  $K$ -armed bandit, the optimal regret that can be achieved after  $T$  pulls is  $\Omega(\sqrt{KT})$  (Auer et al., 2003). To achieve a regret of  $O(\sqrt{KT})$  (Audibert and Bubeck, 2009), algorithms invariably have to maintain separate statistics for the pulls coming from each arm (since any of them could be the sole optimal arm).

In many modern applications of bandits, the set of arms that can be pulled is very large, often even infinite. Examples include (1) sensor networks, in which a central controller must learn to deploy the most accurate sensor from among a large number of noisy sensors (Kadono and Fukuta, 2014); (2) crowd-sourcing tasks, in which a periodic task should ideally be assigned to the most skilled worker in a large pool (Tran-Thanh et al., 2014); (3) on-line advertising, in which a layout for an ad should be chosen from among a large set so as to maximise the click-through rate (Tang et al., 2013). Clearly, the  $\Theta(\sqrt{KT})$  bound on the regret is not helpful when  $K \gg T$  or  $K = \infty$ . Perhaps the most common approach to deal with infinitely-many armed bandits is to utilise some sort of side information about the arms: for example, to assume that the arms are embedded in a metric space in which the reward function is Lipschitz continuous (Kleinberg, 2005) or even linear (Auer, 2003, Chu et al., 2011). Unfortunately such side information is not always available; even if available, it is often not accurate (Ghosh et al., 2017).

In this paper, we propose an approach for exploring the arms of infinitely many-armed bandits with no recourse to side information. Naturally, we cannot always guarantee sublinear regret with respect to optimal arms (which may never get pulled in any finite horizon). Instead, assuming that the

set of arms  $\mathcal{A}$  is being accessed through a given sampling distribution  $P_{\mathcal{A}}$ , we benchmark regret against *quantiles* of the reward distribution induced by  $P_{\mathcal{A}}$ . By fixing the quantile,  $P_{\mathcal{A}}$  will eventually sample “good enough” arms. Using a doubling trick, we can also ensure that our algorithm will eventually sample every arm whose expected reward is bounded away from the optimal reward. Below we formalise the notion of *quantile regret* and outline our contributions.

**Problem Definition.** A *bandit instance*  $\mathcal{B} = (\mathcal{A}, M)$  comprises a (possibly infinite) set of *arms*  $\mathcal{A}$ , and a reward function  $M$  that gives a bounded, real-valued, reward distribution  $M(a)$  for each arm  $a \in \mathcal{A}$ . When pulled, arm  $a$  produces a reward drawn i.i.d. from  $M(a)$ . We denote the expected reward from arm  $a$  as  $\mu_a \stackrel{\text{def}}{=} \mathbb{E}[M(a)]$ . Without loss of generality, we assume that all rewards lie in  $[0, 1]$ .

An *algorithm* is a mapping from the set of histories (of arms pulled and rewards obtained) to the set of probability distributions over  $\mathcal{A}$ : thus, given a history, an algorithm specifies a probability for sampling each arm. Let  $\mu^* \stackrel{\text{def}}{=} \min\{y \in [0, 1] : \forall a \in \mathcal{A}, \mu_a \leq y\}$ . Then, for a given horizon of pulls  $T$ , the *regret* of an algorithm is

$$\mathbb{R}_T^* = T\mu^* - \sum_{t=1}^T \mathbb{E}[\mu_{a_t}], \quad (1)$$

where  $a_t$  denotes the arm pulled by the algorithm at time  $t$ . The expectation is taken over the random outcomes of pulls, as well as random choices (if any) made by the algorithm.

For us, a *problem instance*  $\mathcal{I} = (\mathcal{B}, P_{\mathcal{A}})$  contains a bandit instance  $\mathcal{B}$  with arms  $\mathcal{A}$ , and a sampling distribution  $P_{\mathcal{A}}$  to choose arms from  $\mathcal{A}$ . We apply the concept of “ $(\epsilon, \rho)$ -optimality” introduced by Roy Chaudhuri and Kalyan Krishnan (2017). For a *quantile fraction*  $\rho \in [0, 1]$  and a *tolerance*  $\epsilon \in [0, 1]$ , an arm  $a \in \mathcal{A}$  is said to be  $(\epsilon, \rho)$ -optimal if  $\Pr_{a' \sim P_{\mathcal{A}}} \{\mu_a \geq \mu_{a'} - \epsilon\} \geq 1 - \rho$ . Let  $\mathcal{TOP}_{\rho}$  be the set of all  $(0, \rho)$ -optimal arms. Also let  $\mu_{\rho} \in [0, 1]$  be a quantity such that,  $\forall a' \in \mathcal{A} \setminus \mathcal{TOP}_{\rho}$ ,  $\mu_{\rho} > \mu_{a'}$  and  $\forall a \in \mathcal{TOP}_{\rho}$ ,  $\mu_a \geq \mu_{\rho}$ . In other words, if  $\mu$  denotes the mean of an arm drawn according to  $P_{\mathcal{A}}$ , then  $\mu_{\rho}$  is the  $(1 - \rho)$ -th quantile of the distribution of  $\mu$ .

Figure 1 shows the example of an infinite set of arms  $\mathcal{A}$  whose means lie between 0.15 and 0.95. When sampled according to  $P_{\mathcal{A}}^1$ , the resulting probability density function of the mean  $\mu$  is  $D^1(\mu)$ . If an algorithm is constrained to access arms using  $P_{\mathcal{A}}^1$ , it is only natural for us to evaluate it against a baseline that is also constrained by  $P_{\mathcal{A}}^1$ . For example, we could aim for the algorithm to eventually surpass  $q^1$ , which is the 94-th percentile of the distribution induced by  $P_{\mathcal{A}}^1$ . Without additional information, such an algorithm cannot hope to surpass  $q^2$ , the 94-th percentile of a different sampling distribution  $P_{\mathcal{A}}^2$ . In general we expect that there is some “natural” way to sample the unknown set of arms—and this is given to us as  $P_{\mathcal{A}}$ . For example, if  $\mathcal{A}$  is finite, it is a reasonable choice to assign an equal probability to

Figure 1: Two problem instances that share the same set of arms  $\mathcal{A}$ , varying continuously in  $[0, 1]$ . The top panel shows the expected rewards  $\mu_a$  of each arm  $a \in \mathcal{A}$ , as well as probability density functions  $P_{\mathcal{A}}^1$  and  $P_{\mathcal{A}}^2$  for sampling  $\mathcal{A}$ . The bottom panel shows the reward distributions  $D_{\mathcal{A}}^1$  and  $D_{\mathcal{A}}^2$  induced by each of the sampling distributions, along with 94-th percentiles  $q^1$  and  $q^2$ , respectively.

sampling each arm. If  $\mathcal{A}$  corresponds to a parameterised set,  $P_{\mathcal{A}}$  could implement some distribution over the parameters.

We are now ready to define *quantile-regret* with respect to a given quantile fraction  $\rho$ . If  $a_t$  is the arm drawn by an algorithm in its  $t$ th pull, we define the (cumulative) quantile-regret (or the “ $\rho$ -regret”) after  $T$  pulls as

$$\mathbb{R}_T(\rho) = T\mu_{\rho} - \sum_{t=1}^T \mathbb{E}[\mu_{a_t}]. \quad (2)$$

Our aim is to devise algorithms to minimise  $\mathbb{R}_T(\rho)$  for a given problem instance  $\mathcal{I}$ . The quantile fraction  $\rho$  can either be given as an input to the algorithm, or left unspecified, as we describe next.

**Contributions.** We show that without any knowledge of the reward distributions of the arms, or of side information such as a distance metric over arms, it is still possible to have strategies to maximise reward over time. We articulate the problem as that of achieving sub-linear  $\rho$ -regret.

1. In Section 3.1, we present our first algorithm, QRM1, which is given a quantile fraction  $\rho$  as input. We show that for a sufficiently large horizon  $T$ , the algorithm incurs  $\mathbb{R}_T(\rho) \in O(\rho^{-1} + \sqrt{(T/\rho) \log(\rho T)})$ . We also provide a lower bound of  $\Omega(\sqrt{T/\rho})$ , establishing tightness up to a logarithmic factor with respect to  $T$ .
2. In Section 3.2, we present our second algorithm, QRM2, which does not take  $\rho$  as an input. Regardless, the algorithm achieves sub-linear  $\rho$ -regret for every  $\rho > 0$ . Specifically, for every  $\rho > 0$  and a sufficiently large horizon  $T$ , QRM2 achieves  $\mathbb{R}_T(\rho) \in o((\frac{1}{\rho} \log \frac{1}{\rho})^{2.89} + T^{0.674})$ .
3. In Section 3.3, we establish a connection between (conventional) regret  $\mathbb{R}_T^*$  and  $\mathbb{R}_T(\rho)$ . Interestingly, we find that when run on instances satisfying a common assumption made in the literature about reward distributions (Herschkorn et al., 1996, Wang et al., 2017), QRM2 also achieves sub-linear *regret*  $\mathbb{R}_T^*$ .

4. In Section 4, we present extensive experimental results comparing QRM2 with three separate categories of algorithms: (1) those assuming that the arms lie in a continuum (Kleinberg et al., 2008, Ray Chowdhury and Gopalan, 2017); (2) those assuming that the mean rewards come from a reservoir distribution (Wang et al., 2008); and (3) algorithms that only retain a constant number of arms in memory (Herschhorn et al., 1996, Berry et al., 1997). In the first two cases we find existing approaches to be sensitive to parameter-tuning, while our parameter-free approach shows robust performance across a variety of problem instances. Except when the arms’ means indeed come from a uniform distribution (as assumed by some constant-memory algorithms), QRM2 also outperforms algorithms from the third category.

We survey the literature on regret minimisation in infinite-armed bandits before presenting our algorithms.

## 2 RELATED WORK

There is a vast body of literature considering regret-minimisation for infinitely many-armed bandits. Based on the assumptions they make, we classify research efforts in the area into three broad categories. We also provide brief mentions of other related work.

**1. Lipschitz-continuity of mean rewards over  $\mathcal{A}$ .** Initiated by Agrawal (1995), the “continuum-armed bandit” models a bandit whose arms come from a segment of the real line, and the rewards are a continuous function of the arms. Generalising this setting, Kleinberg (2005) and Auer et al. (2007) proposed algorithms assuming that the mean reward function  $\mathbb{E}[\mathbb{M}(\cdot)] = \mu(\cdot)$  is Lipschitz-continuous over the set of arms  $\mathcal{A}$ . Their approaches partition  $\mathcal{A}$  into a finite number of intervals, treating each interval (say pulled at its middle arm (Kleinberg, 2005)) as an arm in a finite-armed bandit. The partition is progressively refined at a rate that ensures sub-linear regret. The ZOOMING algorithm proposed by Kleinberg et al. (2008), which assumes that the arms are embedded in a metric space with (known) covering dimension  $d$ , achieves a regret of  $O(T^{\frac{d+1}{d+2}})$ , for a horizon  $T$ . Their algorithm utilises the metric property to focus exploration on intervals potentially containing optimal arms. Understandably, the regret incurred by ZOOMING is sensitive to the definition of metric in the arms’ space, and can degrade with small misspecifications of  $d$ .

A contrasting line of work follows from the work of Srinivas et al. (2010), who introduce a Gaussian Process-based algorithm, GP-UCB, for regret minimisation on infinitely many-armed bandits. Later Valko et al. (2013) proposed KERNELUCB, showing GP-UCB to be a special case. More recently, Ray Chowdhury and Gopalan (2017) have proposed two algorithms: Improved GP-UCB (IGP-UCB) and

GP-Thompson sampling (GP-TS). They assume Gaussian likelihood models for the observed rewards, and Gaussian Process models for the uncertainty over reward functions. Although Ray Chowdhury and Gopalan (2017) show improved regret bounds over previous work, their algorithms are not easy to apply in practice. Foremost, the algorithms themselves give no guidance on the number of arms to explore. Also, the algorithms need several parameters to be tuned, including a confidence parameter  $\delta$ , a free parameter  $\lambda$ , and a schedule  $\gamma_t$  related to information gain.

**2. Particular families of reward distributions.** There is a relatively large body of work that does not assume any embedding of the arms (that is, no side information), but still assumes that the distribution of mean rewards (induced by  $P_{\mathcal{A}}$ ) comes from a particular family. Among the earliest efforts in this direction is that of Berry et al. (1997), who propose several algorithms for infinitely-many armed bandits in which the mean rewards of the arms are uniformly distributed in  $[0, \mu^*]$  for some  $0 < \mu^* \leq 1$ . An additional assumption underlying their work is that for each arm  $a \in \mathcal{A}$ , the reward distribution  $M(a)$  is Bernoulli.

Wang et al. (2008) assume that a randomly-sampled arm’s mean reward  $\mu$  comes from a *reservoir distribution*  $\mathcal{L}$ ; that is,  $\exists \mu^* \in (0, 1]$  and  $\nu > 0$ , for which  $\Pr_{\mu \sim \mathcal{L}}\{\mu > \mu^* - \epsilon\} = \Theta(\epsilon^\nu)$ , for  $\epsilon \rightarrow 0$ . Under this assumption, they present an algorithm that incurs (1)  $R_T^* = \tilde{O}(T^{1/2})$  if  $\mu^* < 1$  and  $\nu \leq 1$ , and (2)  $R_T^* = \tilde{O}(T^{\nu/(1+\nu)})$  otherwise. They have also derived lower bounds that match up to a logarithmic factor. When each arm generates Bernoulli rewards and  $\mu^* = 1$ , Bonald and Proutiere (2013) provide an algorithm that is optimal with the exact constant. In more recent work, Li and Xia (2017) consider a related setting in which the probability of a newly-pulled arm being near-optimal arm depends on the ratio of its expected reward to its expected *cost*, with arms having different random costs.

**3. Constant-memory policies.** A particular novelty of the family of algorithms studied by Berry et al. (1997) is that the algorithms maintain the reward statistics of at most one or two arms at a time. When the arms’ reward distribution is *uniformly* distributed in  $(0, 1)$ , their algorithms are shown to achieve sub-linear regret. No closed-form upper bounds are provided when this condition does not hold. Also in the constant-memory category, Herschhorn et al. (1996) present two approaches for the problem of maximising the almost sure average reward over an infinite horizon. Although they assume that each arm generates i.i.d. Bernoulli rewards, they make no assumption on the distribution of mean rewards. They present two approaches, both of which repeatedly pull an arm until it records a certain number of successive failures. They do not provide an explicit bound on the regret.

**4. Other related work.** Recently, Wang et al. (2017) have proposed CEMAB, a cross-entropy based algorithm for many-armed bandit instances. Like us, they aim to focus

exploration on a small subset of arms. However, they still require the entire set of arms to be finite, which limits their experimentation to instances with a few tens of arms. They do not present any theoretical upper bounds on the regret.

The work we have discussed thus far in this section is all targeted at minimising regret. By contrast, there has also been some effort under the “pure exploration” regime to tackle infinitely-many armed bandits. For example, Carpentier and Valko (2015) aim to minimise *simple regret*, under the same assumption of a mean reservoir distribution assumption as Wang et al. (2008). Our own conception of quantile-regret is motivated by the work of Goschin et al. (2012) and Roy Chaudhuri and Kalyanakrishnan (2017), who study a PAC formulation of identifying arms above a specified reward quantile in infinitely many-armed bandits.

The primary motivation behind our work is to eliminate assumptions regarding structure and side information. Such inductive biases become counterproductive when they are not near-perfect. In Section 4, we show that the algorithms proposed by Kleinberg (2005), Ray Chowdhury and Gopalan (2017), and Wang et al. (2008), all fare poorly when their parameters are misspecified. Constant-memory algorithms, while conceptually elegant, forego the obvious benefit of retaining the statistics of multiple arms (say a few tens or hundreds) in memory. Except in tailormade settings (i.i.d. Bernoulli rewards, uniformly distributed mean rewards), our approach performs significantly better. We proceed to describe our algorithms.

### 3 MINIMISING QUANTILE-REGRET

At the heart of our approach for minimising quantile regret on infinitely many-armed bandit instances is to first sample out suitably-sized finite bandit instances and then to apply conventional regret minimisation algorithms on the latter. For ease of analysis, we choose the MOSS algorithm (Audibert and Bubeck, 2009) for our inner loop, since it incurs optimal (distribution-free) regret (up to a constant factor) on finite bandit instances.

First, we consider the easy case: that is, when  $\rho$  is provided as an input. Then we generalise this setting to one where  $\rho$  is not specified, and the objective is to achieve sub-linear  $\rho$ -regret for all  $\rho > 0$ . Our bounds will hold for sufficiently large (but still finite) horizons  $T$ . On the other hand, for a *fixed* horizon  $T$ , it is impossible to guarantee sub-linear  $\rho$ -regret for all  $\rho > 0$  for all problem instances. For example, consider a problem instance with a fraction  $\rho < 1/T$  of arms all being optimal, and the rest sub-optimal.  $T$  pulls will not suffice even to stumble upon an optimal arm with sufficiently high probability, let alone exploit it. The  $\rho$ -regret on such an instance will have to be linear in  $T$ .

#### 3.1 With quantile fraction specified

In order to minimise  $\rho$ -regret for a given quantile fraction  $\rho \in (0, 1]$ , our primitive operation is to sample a sufficiently large number of arms using  $P_{\mathcal{A}}$ , and to minimise conventional regret on this set of arms by applying MOSS. We implement an “any time” algorithm by repeating this primitive procedure with progressively larger horizons, as shown in Algorithm 1.

---

#### Algorithm 1 QRM1 (with quantile fraction specified)

---

**Require:**  $\mathcal{I}, \rho$

**for**  $r = 1, 2, 3, \dots$  **do**

$$t_r = 2^r, \quad n_r = \left\lceil \frac{1}{\rho} \max\{1, \ln \sqrt{\rho t_r}\} \right\rceil.$$

Form a set  $\mathcal{K}_r$  by selecting additional  $n_r - |\mathcal{K}_{r-1}|$  arms from  $\mathcal{A}$  using  $P_{\mathcal{A}}$ , and adding them to  $\mathcal{K}_{r-1}$ .

Run MOSS( $\mathcal{K}_r, t_r$ ).

**end for**

---

In each phase  $r$ , MOSS is called to run on a finite bandit instance with some  $\mathcal{K}_r$  arms, over a finite horizon  $t_r$ . MOSS is known to incur a regret of at most  $C\sqrt{|\mathcal{K}_r|t_r}$  for some constant  $C$  (Audibert and Bubeck, 2009, Theorem 5). The parameters  $\mathcal{K}_r$  and  $t_r$  are specifically chosen such that with sufficiently high probability, at least one arm from  $\mathcal{TOP}_{\rho}$  is selected in  $\mathcal{K}_r$ , and consequently the overall  $\rho$ -regret remains sub-linear.

Our analysis assumes  $\rho \in (0, 1)$ . The case of  $\rho = 1$  is trivial;  $\mathbb{R}_T(1)$  cannot exceed 0. For  $\rho = 0$ , sub-linear regret can only be achieved under the additional assumption that optimal arms have a positive probability under  $P_{\mathcal{A}}$ . In the analysis that follows, we use  $\log$  to denote the logarithm to the base 2, and  $\ln$  to denote the natural logarithm. We also take the horizon  $T$  to be a power of 2—which only changes our bounds by a constant factor.

**Lemma 3.1.** *For  $\rho \in (0, 1)$  and for sufficiently large  $T$ , QRM1 achieves  $\mathbb{R}_T(\rho) = O\left(\frac{1}{\rho} + \sqrt{\frac{T}{\rho} \log(\rho T)}\right)$ .*

*Proof.* Let us consider the event during phase  $r$  that no arm from  $\mathcal{K}_r$  is in  $\mathcal{TOP}_{\rho}$ . Denote this event  $E_r \stackrel{\text{def}}{=} \{\mathcal{K}_r \cap \mathcal{TOP}_{\rho} = \emptyset\}$ . We upper-bound the  $\rho$ -regret accumulated during phase  $r$ , which we denote  $L_r$ , by conditioning separately on  $E_r$  and  $\neg E_r$ .

In phase  $r$ , the probability of occurrence of  $E_r$  is  $\Pr\{E_r\} = (1 - \rho)^{n_r}$ . Now, letting  $r^* = \log(e^2/\rho)$ , we notice that for  $r \geq r^*$ ,  $t_r \geq e^2/\rho$ , and hence we can upper bound the probability of occurrence of  $E_r$  as  $\Pr\{E_r\} \leq (1 - \rho)^{\rho^{-1} \ln(\sqrt{\rho t_r})} < \sqrt{1/(\rho t_r)}$ . We simply take  $t_r$  as an upper bound on the phase’s contribution to the regret if  $E_r$  has occurred. If  $E_r$  does not occur, then there exists at least one arm from  $\mathcal{TOP}_{\rho}$  in  $\mathcal{K}_r$ . In this case, the regret is upper-bounded by  $C\sqrt{n_r t_r} \leq C\sqrt{t_r \log(\rho t_r)}/\rho$ , for some constant  $C$  (Audibert and Bubeck, 2009). Therefore, for

$r \geq r^*$ , the  $\rho$ -regret from phase  $r$  is upper-bounded as  $L_r \leq t_r \cdot \Pr\{E_r\} + C \cdot \sqrt{n_r t_r} \leq \sqrt{\frac{t_r}{\rho}} + C \cdot \sqrt{\frac{t_r}{\rho} \log(\rho t_r)} \leq C_1 \cdot \sqrt{\frac{t_r}{\rho} \log(\rho t_r)}$  for some constant  $C_1$ .

For phases  $r < r^*$ , the  $\rho$ -regret is trivially upper-bounded by  $t_r$ . Hence summing over all phases, we get  $\mathbb{R}_T(\rho) \leq \sum_{r=1}^{r^*-1} L_r + \sum_{r=r^*}^{\log T} L_r \leq 2^{r^*} + \sum_{r=r^*}^{\log T} C_1 \cdot \sqrt{\frac{t_r}{\rho} \log(\rho t_r)}$ , which is  $\in O\left(\frac{1}{\rho} + \sqrt{\frac{T}{\rho} \log(\rho T)}\right)$ .  $\square$

We show that this upper bound on the  $\rho$ -regret is optimal up to a logarithmic factor in the horizon. Our proof is based on a well-known lower bound for finite bandit instances (Auer et al., 2003, see Theorem 5.1).

**Theorem 3.2.** [Lower bound] *For every algorithm, there exists a problem instance, along with  $\rho \in (0, 1)$  and  $T > 0$ , such that  $\mathbb{R}_T(\rho) \geq \min\left\{\frac{1}{20}\sqrt{\frac{T}{\rho}}, T\right\}$ .*

*Proof.* Let  $ALG$  be any algorithm for sampling infinitely many-armed bandits. Naturally, we can also apply  $ALG$  on finite bandit instances. Given any arbitrary  $K$ -armed bandit instance,  $K < \infty$ , we can create a corresponding problem instance  $((\mathcal{A}, M), P_{\mathcal{A}})$  wherein (1)  $\mathcal{A}$  is the finite set of  $K$  arms, (2)  $M(a)$  is the reward function for  $a \in \mathcal{A}$ , and (3)  $P_{\mathcal{A}}$  samples each arm in  $\mathcal{A}$  with an equal probability of  $1/K$ . Now, if we set  $\rho = 1/K$ , observe that  $\mathcal{TOP}_{\rho}$  can only contain *optimal* arms from  $\mathcal{A}$ , and hence, the  $\rho$ -regret incurred by  $ALG$  on  $((\mathcal{A}, M), P_{\mathcal{A}})$  is the same as the conventional regret on the original finite instance.

Suppose, contrary to the statement of the theorem,  $ALG$  is such that for all input problem instances, for all  $\rho \in (0, 1)$  and for all  $T > 0$ , its  $\rho$ -regret satisfies  $\mathbb{R}_T(\rho) < \min\left\{\frac{1}{20}\sqrt{\frac{T}{\rho}}, T\right\}$ . From the translation described above, it follows that  $ALG$  incurs  $\mathbb{R}_T^* < \min\left\{\frac{1}{20}\sqrt{KT}, T\right\}$  for all finite  $K$ -armed bandit instances,  $K > 0$  and horizons  $T > 0$ . However, Auer et al. (2003, see Theorem 5.1) have shown that no such algorithm exists for finite instances. Our proof is complete.  $\square$

### 3.2 With quantile fraction not specified

We can now drop the requirement that  $\rho$  is given to the algorithm as an input. Rather, we iteratively optimise  $\rho$ -regret for progressively decreasing values of  $\rho$ .

Algorithm 2 follows the same template as Algorithm 1, except that the number of arms to sample in each phase  $r$  is set to be a polynomial function of  $t_r$ , with the power  $\alpha = 0.347$  set to minimise the  $\rho$ -regret's dependence on  $T$ .

Although QRM2, the algorithm specified above, does not require any knowledge of  $\rho$ , we shall analyse its  $\rho$ -regret for some fixed  $\rho > 0$ .

---

#### Algorithm 2 QRM2 (with quantile fraction not specified)

---

**Require:**  $T$

Set  $\alpha = 0.347$  and  $\mathcal{K}_0 = \emptyset$ .

**for**  $r = 1, 2, 3, \dots$  **do**

$t_r = 2^r$ ,  $n_r = \lceil t_r^\alpha \rceil$ .

Form a set  $\mathcal{K}_r$  by selecting additional  $n_r - |\mathcal{K}_{r-1}|$  arms from  $\mathcal{A}$  using  $P_{\mathcal{A}}$ , and adding to  $\mathcal{K}_{r-1}$ .

Run MOSS( $\mathcal{K}_r, t_r$ ).

**end for**

---

**Theorem 3.3.** [Sub-linear quantile-regret of QRM2] *For  $\rho \in (0, 1)$  and for sufficiently large  $T$ , QRM2 incurs  $\mathbb{R}_T(\rho) \in o\left(\left(\frac{1}{\rho} \log \frac{1}{\rho}\right)^{2.89} + T^{0.674}\right)$ .*

*Proof.* Considering some fixed  $\rho \in (0, 1)$ , we upper-bound the  $\rho$ -regret in two parts: (1) when no arms from  $\mathcal{TOP}_{\rho}$  are chosen, and (2) when at least one arm is chosen. To analyse the first part, we show that for  $r^* \stackrel{\text{def}}{=} \lceil (1/\alpha) \log((1/\rho) \log(1/\rho)) \rceil$ , if  $r \geq r^*$ , then  $\mathcal{K}_r$  is sufficiently large to contain an arm from  $\mathcal{TOP}_{\rho}$  with high probability. To show that, like before, we define the event that no arm from  $\mathcal{TOP}_{\rho}$  is in  $\mathcal{K}_r$  as  $E_r(\rho) \stackrel{\text{def}}{=} \{\mathcal{K}_r \cap \mathcal{TOP}_{\rho} = \emptyset\}$ . It follows  $\Pr\{E_r(\rho)\} = (1 - \rho)^{n_r}$ . Now, for  $r \geq r^*$ , using Lemma 5.1 (provided in Appendix A<sup>1</sup>), we get  $\Pr\{E_r(\rho)\} \leq \exp(-[(\alpha(1 + \gamma))^{-1} \cdot \ln t_r^{\log e}]) \leq t_r^{-\alpha \log e / (1 + \gamma)}$ . Hence, if the algorithm runs for  $T$  pulls, then the regret due to occurrence of  $E_r(\rho)$  is upper bounded as

$$\sum_{r=1}^{\log T} t_r \Pr\{E_r(\rho)\} \in O\left(t_{r^*} + T^{1 - \frac{\alpha \log e}{1 + \gamma}}\right). \quad (3)$$

Now we analyse the second part: that is, upper-bounding the regret incurred if at least one from the  $\mathcal{TOP}_{\rho}$  is in  $\mathcal{K}_r$  (the event  $\neg E_r(\rho)$ ). Let us assume that  $C$  is a constant such that the regret incurred by MOSS in phase  $r$  (given  $\neg E_r(\rho)$ ) is at most  $C\sqrt{n_r t_r} = Ct_r^{(1+\alpha)/2}$ . Therefore, assuming total number of pulls as  $T$ , the total regret incurred on  $r^*$ -th phase onward is upper bounded as

$$\sum_{r=r^*}^{\log T} C\sqrt{n_r t_r} \leq C'T^{(1+\alpha)/2} \quad (4)$$

for some constant  $C'$ . The intermediate steps to obtain (3) and (4) are shown in Appendix-A. Combining (3) and (4), and substituting for  $t_{r^*}$ , we get  $\mathbb{R}_T(\rho) = O\left(\left(\frac{1}{\rho} \log \frac{1}{\rho}\right)^{\frac{1}{\alpha}} + T^{1 - \frac{\alpha \log e}{1 + \gamma}} + T^{(1+\alpha)/2}\right)$ . We conclude by noticing that  $\alpha = 0.5 / (0.5 + \log e / (1 + \gamma)) \approx 0.3466$  minimises  $\mathbb{R}_T(\rho)$  with respect to  $T$ .  $\square$

<sup>1</sup>Appearing at the end of the extended version of this paper at [https://www.cse.iitb.ac.in/~shivaram/papers/rk\\_uai\\_2018.pdf](https://www.cse.iitb.ac.in/~shivaram/papers/rk_uai_2018.pdf).

The upper bound in Theorem 3.3 cannot be directly compared with regret bounds in the literature (Kleinberg, 2005, Wang et al., 2008) since our bound is on the  $\rho$ -regret. As yet, we do not know if the dependence of  $\rho$ -regret on the horizon  $T$  can be improved. Even so, the sub-linear upper bound we have shown on  $\mathbb{R}_T(\rho)$  assumes a special significance in the study of infinitely-many armed bandits. Observe that the upper bound holds for every  $\rho > 0$  and for *every* bandit instance. By contrast, conventional regret-minimisation (of  $\mathbb{R}_T^*$ ) cannot assure sub-linear regret unless the bandit instance itself satisfies additional assumptions (of which several have been made in the literature). By taking  $\rho > 0$ , we have chosen to change our objective (albeit slightly), rather than place demands on the input bandit instance.

Interestingly, we find that on bandit instances that do satisfy a standard assumption made to achieve sub-linear  $\mathbb{R}_T^*$ , QRM2, too, achieves sub-linear  $\mathbb{R}_T^*$ , in spite of being designed to minimise  $\mathbb{R}_T(\rho)$  for  $\rho > 0$ . We proceed to discuss this connection between  $\mathbb{R}_T(\rho)$  and  $\mathbb{R}_T^*$ .

### 3.3 Quantile-regret and conventional regret

Given a problem instance  $((\mathcal{A}, M), P_{\mathcal{A}})$ , we first show that minimising  $\mathbb{R}_T^*$  is sufficient to minimise  $\mathbb{R}_T(\rho)$  for all  $\rho > 0$ , but the converse is not true.

**Lemma 3.4.** *For any algorithm and input problem instance, if  $\mathbb{R}_T^* \in o(T)$ , then it must hold that  $\mathbb{R}_T(\rho) \in o(T)$ , for all  $\rho > 0$ . However, the converse is not true.*

*Proof.* For the first part, (1) is written as  $\mathbb{R}_T^* = T \cdot (\mu^* - \mu_\rho) + T \cdot \mu_\rho - \sum_{t=1}^T \mathbb{E}[\mu_t] = T \cdot (\mu^* - \mu_\rho) + \mathbb{R}_T(\rho)$ . Hence,  $\mathbb{R}_T^* \in o(T) \implies \mathbb{R}_T(\rho) \in o(T)$ , for all  $\rho \in [0, 1]$ .

The second part is obtained by considering an infinitely-many armed bandit instance with finitely many optimal arms. Formally, take  $|\mathcal{A}| = \infty$  and  $P_{\mathcal{A}}$  to be the uniform distribution over  $\mathcal{A}$ . Let  $S \subset \mathcal{A}$ , such that  $\forall a \in S, \mu_a = \mu^*$ ,  $|S| < \infty$ , and  $\forall a \in \mathcal{A} \setminus S: \mu_a = \bar{\mu} < \mu^*$ . Now,  $S$  being finite, with probability 1, no arm from  $S$  will be picked by  $P_{\mathcal{A}}$ . Therefore, for  $\rho > 0$ ,  $\mu_\rho = \bar{\mu}$ , and so  $\mathbb{R}_T^* = T \cdot (\mu^* - \bar{\mu}) + \mathbb{R}_T(\rho) \geq T \cdot (\mu^* - \bar{\mu}) \in \Omega(T)$ .  $\square$

Although in general, achieving sub-linear  $\rho$ -regret does not imply achieving sub-linear regret, this turns out asymptotically true for QRM2 on the family of bandit instances considered by Wang et al. (2008), of which the family of instances considered by Berry et al. (1997) is a subset. In these instances, the distribution of the mean reward  $\mu$ , denoted  $D(\mu)$ , has the “reservoir” property, as detailed below.

**Proposition 3.5 (Case Study).** *QRM2 achieves  $\mathbb{R}_T^* \in o(T)$  as  $T \rightarrow \infty$ , under the assumption that  $\Pr_{\mu \sim D(\mu)}\{\mu > \mu^* - \epsilon\} = \Theta(\epsilon^\nu)$ , for  $\epsilon \rightarrow 0$ , where  $\nu$  is a positive constant.*

*Proof.* The assumption amounts to the existence  $\rho_0 \in (0, 1]$  such that for  $0 < \rho < \rho_0$ ,  $c_l(\mu^* - \mu_\rho)^\nu \leq \rho \leq c_u(\mu^* - \mu_\rho)^\nu$ ,

where  $c_u, c_l$  are positive constants. Defining  $h(\rho) \stackrel{\text{def}}{=} \mu^* - \mu_\rho$ , we see that for  $\rho \in (0, \rho_0]$ :  $h(\rho) \leq (\rho/c_l)^{1/\nu}$ .

We know from Theorem 3.3 that for any given  $\rho > 0$ , and for a sufficiently large horizon  $T$ , QRM2 achieves  $\mathbb{R}_T(\rho) \in o(T)$ . Equivalently, for every sufficiently large  $T$ , there exists a  $\rho(T) \in (0, 1]$  such that, for all  $\rho \geq \rho(T)$ , QRM2 achieves  $\mathbb{R}_T(\rho) \in o(T)$ . We also notice that  $\rho(T)$  is a monotonic non-increasing sequence that converges to 0. Hence, there exists a sufficiently large horizon  $T_0$  such that for all  $T \geq T_0$ ,  $\rho(T) \leq \rho_0$ . In other words, for horizon  $T > T_0$ ,  $h(\rho(T)) \leq (\rho(T)/c_l)^{1/\nu}$ . Since  $\lim_{T \rightarrow \infty} (\rho(T)/c_l)^{1/\nu} = 0$  and  $h(\rho(T)) \geq 0$ , we get  $\lim_{T \rightarrow \infty} h(\rho(T)) = 0$ . Since  $\mathbb{R}_T^* = T \cdot h(\rho(T)) + \mathbb{R}_T(\rho)$ , we get  $\lim_{T \rightarrow \infty} \frac{\mathbb{R}_T^*}{T} = \lim_{T \rightarrow \infty} \left( h(\rho(T)) + \frac{\mathbb{R}_T(\rho(T))}{T} \right) = 0$ , which means that  $\mathbb{R}_T^*$  is asymptotically  $o(T)$ .  $\square$

## 4 EXPERIMENTS AND RESULTS

In this section, we compare QRM2 with competing approaches for regret minimisation on infinitely many-armed bandits. We consider representative algorithms from the categories described in Section 2, and investigate the effect of their parameters, in tandem with a comparison with QRM2. Although QRM2 is designed to minimise  $\rho$ -regret for progressively decreasing  $\rho$  values, we use conventional regret as the evaluation metric in all our experiments. This choice essentially amounts to evaluating the total reward accrued over a given horizon, which is perhaps the most relevant measure in practice. In all our experiments, the reward distributions of arms are Bernoulli. Note that both ZOOMING (Kleinberg et al., 2008) and QRM2 proceed through phases, progressively doubling the phase length. To improve sample efficiency, we retain the statistics of pulls from previous phases and correspondingly adjust the “budget” term in the confidence bound.

### 4.1 Comparison with ZOOMING

The ZOOMING algorithm (Kleinberg et al., 2008) works on a bandit instance comprising a set of arms  $\mathcal{A} = [0, 1]$ , with the expected mean reward  $\mu_{(\cdot)}$  being Lipschitz-continuous over  $\mathcal{A}$ . The metric defined on  $\mathcal{A}$  is: for  $x, y \in \mathcal{A}$ ,  $L_d(x, y) = |x - y|^{1/d}$ , where  $d \geq 1$  is a known, user-specified parameter. For a given horizon  $T$ , ZOOMING is shown to incur a regret of  $\tilde{O}(T^{(d+1)/(d+2)})$ . The algorithm proceeds by maintaining confidence bounds on the mean rewards of contiguous regions of  $\mathcal{A}$ ; a new region is created whenever the existing ones fail to cover some portion of  $\mathcal{A}$ . In our implementation, a new region is created by picking an uncovered region uniformly at random. Its “centre” is picked uniformly at random from the points it contains.

We compare QRM2 with ZOOMING on four problem instances, shown in Figure 2 and specified in Appendix-B. On each instance we compare the cumulative regret of QRM2

with that of ZOOMING for  $d \in \{1, 2\}$ . The results at different horizons are presented in Figure 3. Foremost, observe that the performance of ZOOMING is fairly sensitive to  $d$ : on instances I-P and I-S, the variant with  $d = 1$  performs noticeably better; on instances I-N and I-W, the variant with  $d = 2$  is superior. On the instance I-N the better of these two variants performs close to QRM2. On an unknown problem instance, it is unrealistic to expect that the user will be able to guess a good value for  $d$  beforehand.

Figure 2: Four problem instances (fully specified in Appendix-B). In all four cases,  $\mathcal{A} = [0, 1]$ , as shown on the x axis. The y axis shows the mean reward  $\mu_a$  for  $a \in \mathcal{A}$ . QRM2 takes  $P_{\mathcal{A}}$  to be the uniform distribution over  $\mathcal{A}$ .

Figure 3: Cumulative regret (y axis) incurred by ZOOMING and QRM2 on the instances in Figure 2. The x axis shows the horizon /  $10^5$ . Each plot is an average of 100 runs.

A second limitation in practice arises from the quality of the features used to generalise across  $\mathcal{A}$ , which effectively determine the Lipschitz constant of the mean reward function. Instances I-W and I-S have exactly the same mean distribution  $D$ —they only differ in the indexing of the arms, which, in practice, would depend on the feature representation. The regret of ZOOMING on these instances (whether with  $d = 1$  or with  $d = 2$ ) varies at least three-fold. By ignoring the arm indices and the metric, QRM2 registers exactly the same regret on both instances.

## 4.2 Comparison with Gaussian Process algorithms

In our next set of experiments, we compare QRM2 with IGP-UCB and GP-TS (Ray Chowdhury and Gopalan, 2017). Our experiments are run on the light sensor data

set<sup>2</sup>, on which the authors have themselves benchmarked their methods. We refer the reader to the original paper for a description of the data set (Ray Chowdhury and Gopalan, 2017, see Section 6), which encodes bandit instances with arms corresponding to sensors. We run IGP-UCB and GP-TS with the same parameters used by the authors.

From Table 1, we find that GP-TS outperforms IGP-UCB, exactly as reported by Ray Chowdhury and Gopalan (2017). However, QRM2 outperforms both GP-TS and IGP-UCB by a large margin. We posit as one reason for the efficiency of QRM2 its use of MOSS as the underlying regret minimisation procedure. On the other hand, using Gaussian Processes to generalise over the space of arms would only work well if nearby arms indeed have similar mean rewards. Without good generalisation, the confidence bounds resulting from Gaussian Processes are likely to be loose, and therefore a poor guide for exploration.

Table 1: Cumulative regret after  $10^6$  pulls, averaged over 192 test instances, with one standard error.

Algorithm	Average cumulative regret
GP-TS	$2.58 \times 10^4 \pm 36.75 \times 10^2$
IGP-UCB	$3.86 \times 10^5 \pm 18.05 \times 10^4$
QRM2	$0.14 \times 10^4 \pm 0.13 \times 10^2$

## 4.3 Comparison with algorithm of Wang et al. (2008)

We compare QRM2 with the algorithm of Wang et al. (2008) for unspecified horizons. Recall that the sub-linear regret bounds shown by Wang et al. (2008) are based on the assumption that the mean distribution is a “reservoir”: that is,  $\Pr_{\mu_a \sim P_{\mathcal{A}}} \{\mu_a > \mu^* - \epsilon\} = \Theta(\epsilon^\nu)$ , for  $\epsilon \rightarrow 0$ . We notice that for  $\mu^* \in (0, 1]$  and  $\nu > 0$ ,  $f(\mu) = \frac{\nu}{\mu^{*\nu}}(\mu^* - \mu)^{\nu-1}$  is a density function of some reservoir distribution. This follows from the fact that CDF of  $f(\mu)$  is given by  $F(\mu) = 1 - \frac{1}{\mu^{*\nu}}(\mu^* - \mu)^\nu$ . Therefore  $\Pr_{\mu \sim f(\mu)} \{\mu > \mu^* - \epsilon\} = 1 - F(\mu) \in \Theta(\epsilon^\nu)$ . It is worth noting that for  $\nu = 1$ ,  $f(\mu)$  is the uniform distribution.

The any-time algorithm given by Wang et al. (2008) requires three parameters: (1) an exploration rate  $\xi_t$ , for the  $t$ -th pull, such that  $2 \ln(10 \ln t) \leq \xi_t \leq \ln t$ , (2) the shape parameter  $\nu$ , and (3) whether  $\mu^* = 1$ . We refer the reader to the original paper (Wang et al., 2008, see Section 2) for a full specification. We test this algorithm along with QRM2 on four problem instances, shown in Table 2. In all cases,  $\mathcal{A} = [0, 1]$ , and we take  $P_{\mathcal{A}}$  as the uniform distribution over  $\mathcal{A}$ . Each problem instance is such that its optimal mean  $\mu^*$  is either 1 or 0.6, and its reward distribution  $D(\mu)$  is either  $\beta(0.5, 2)$  or  $\beta(1, 1)$  (scaled to have support in  $[0, \mu^*]$ ). The algorithm of Wang et al. (2008)’s needs to be supplied  $\nu$  such that the complementary cumulative distribution func-

<sup>2</sup> [www.cs.cmu.edu/~gueztrin/Class/10708-F08/projects/lightsensor.zip](http://www.cs.cmu.edu/~gueztrin/Class/10708-F08/projects/lightsensor.zip)

tion (CCDF) of  $f(\mu)$  will overestimate that of  $D(\mu)$  beyond some  $\mu_0 < \mu^*$ . Also, as the algorithm needs to know whether or not  $\mu^* = 1$ , we supply a representative value  $\mu^\#$  for  $\mu^*$ . Table 2 explicitly shows the parameterisation used for the different instances, and Figure 4 depicts the CCDF of the corresponding  $D(\mu)$ , and that of  $f(\mu)$  for different values of  $\nu$ . In practice, an experimenter might not have a precise estimate of  $(\nu, \mu^*)$ , and hence the values supplied might not meet the above criteria. In Table 2, depending on whether or not the values of  $\nu, \mu^\#$  respect the criteria, the corresponding cells are marked by  $\checkmark$  and  $\times$ , respectively. Also, the values of  $\nu, \mu^\#$  (from our set) for which the CCDF of  $f(\mu)$  coincides with or fits  $D(\mu)$  most closely are marked Exact and Closest, respectively.

Table 2: Summary of problem instances used in Section 4.3, along with different parameterisations of the algorithm of Wang et al. (2008). For explanations see Section 4.3.

Instances	$\mu^*$	$D(\mu) = \beta(a, b)$		$\mu^\#$		$\nu$		
		$a$	$b$	1.0	0.6	0.4	1	2
I-1	1	0.5	2	$\checkmark$	$\times$	$\checkmark$	$\checkmark$	$\checkmark$ Closest
I-2	1	1	1	$\checkmark$	$\times$	$\checkmark$	$\checkmark$ Exact	$\times$
I-3	0.6	0.5	2	$\times$	$\checkmark$	$\checkmark$	$\checkmark$	$\checkmark$ Closest
I-4	0.6	1	1	$\times$	$\checkmark$	$\checkmark$	$\checkmark$ Exact	$\times$

Figure 4: Complementary CDF (CCDF) values (y axis) for various distributions. The CCDF for  $\beta(1, 1)$  coincides with that of  $f(\mu)$  for  $\nu = 1$ .

For a horizon of  $10^6$ , QRM2, which is parameter-free, explores a fixed number of arms (= 94). On the other hand, Wang et al. ’s algorithm explores  $10^4$  arms for  $\nu = 2$ . For  $\nu = 0.4$  it explores 16 and 52 arms for  $\mu^\# = 0.6$  and  $\mu^\# = 1$ , respectively. Figure 5 shows that in spite of providing values of  $(\nu, \mu^\#)$  that closely (or even exactly) track  $D(\mu)$ , QRM2 outperforms Wang et al. ’s algorithm by a significant margin. We note that optimistic values of these parameters helps their result improve, but incorrect parameterisation severely degrades performance. Another non-trivial factor in the performance of their algorithm is the exploration rate  $\xi_t$ . While varying  $\xi_t$  within their prescribed range keeps the regret upper bound unaffected, in practice it is observed to have a significant effect on regret. In Algorithm 2, we set the  $\alpha$  parameter of QRM2 to 0.347 to optimise a *theoretical* bound. In practice, tuning  $\alpha$  for different problem instances further improves QRM2’s performance. In line with our intent to not depend on tuning, we refrain from reporting these optimised results.

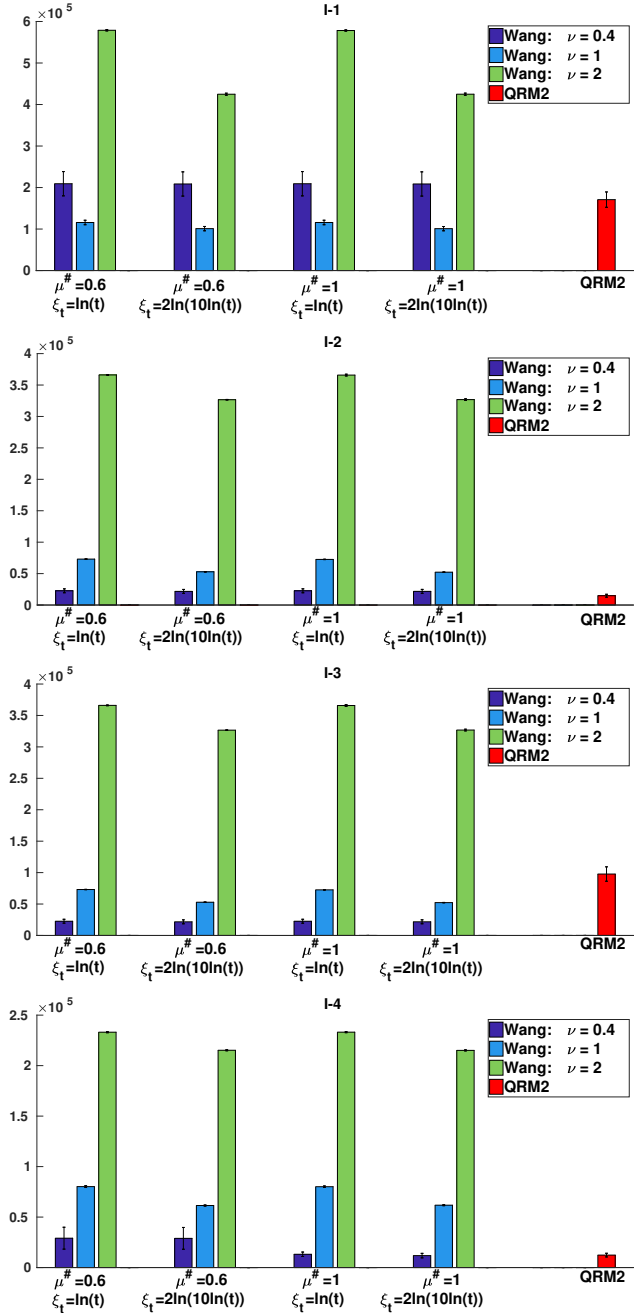

Figure 5: Cumulative regret incurred by QRM2 and the algorithm of Wang et al. (2008) after  $10^6$  pulls on the instances in Table 2. Each bar is an average of 20 runs, and shows one standard error bar. The accompanying parameters are explained in Section 4.3.

#### 4.4 Comparison with constant-memory algorithms

Recall that the algorithms of Herschkorn et al. (1996) and Berry et al. (1997) keep the statistics of only a single arm (or two) in memory. They are specifically designed for bandit instances that yield Bernoulli rewards. The “Non-stationary” algorithm of Herschkorn et al. (1996) repeatedly pulls the  $i$ -th arm, for  $i = 1, 2, \dots$ , until it produces  $i$  consecutive failures—at which point a new arm is pulled. Berry et al. (1997) propose three strategies for problem instances in which the distribution of means is uniform over  $[0, \mu^*]$  for some  $\mu^* \in [0, 1]$ . These strategies assume that the horizon  $T$  is given. For example, the “ $\sqrt{T}$ -run” switches out the current arm upon a single failure, unless the arm produces  $\sqrt{T}$  successes (in which case it is pulled for the remaining horizon). If  $\sqrt{T}$  arms have been pulled and discarded, the arm with the highest observed empirical mean thus far is pulled for the remainder of the run. The “ $\sqrt{T} \ln T$ -learning” strategy and the “Nonrecalling  $\sqrt{T}$ -run” are variants built around a similar theme; we refer the reader to the original paper (Berry et al., 1997) for precise specifications. Table 3 presents a comparison of incurred cumulative regret on the instances I-1, I-2, I-3 and I-4. On I-1, QRM2 outperforms all the other strategies by a significant margin. This result is not surprising, since (1) QRM2 uses additional memory (94 arms for a horizon of  $10^6$ ), and (2) unlike the strategies of Berry et al. (1997), it does not assume that the mean rewards are uniformly distributed. On I-2, which indeed has uniformly-distributed means, the Nonrecalling  $\sqrt{T}$ -run strategy of Berry *et al.* performs marginally better than QRM2. However, this win comes at the expense of incurring very high regret on I-1, in which near-optimal arms are less likely to be encountered. Interestingly, on I-3 and I-4, the Non-stationary policy of Herschkorn et al. (1996) policy outperforms all three from Berry et al. (1997). Yet, all these algorithms are outperformed by QRM2.

Table 3: Cumulative regret ( $/10^5$ ) of QRM2 and strategies proposed by Herschkorn et al. (1996) and Berry et al. (1997) after  $10^6$  pulls, on instances I-1, I-2, I-3 and I-4. Each result is the average of 20 runs, showing one standard error.

Algorithms	I-1	I-2	I-3	I-4
Non-stationary Policy (Herschkorn et al., 1996)	3.58 $\pm$ 0.4	1.11 $\pm$ 0.2	1.64 $\pm$ 0.2	0.79 $\pm$ 0.1
$\sqrt{T}$ -run (Berry et al., 1997)	6.18 $\pm$ 0.5	1.11 $\pm$ 0.4	4.18 $\pm$ 0.3	2.03 $\pm$ 0.3
$\sqrt{T} \ln T$ -learning (Berry et al., 1997)	6.32 $\pm$ 0.4	0.69 $\pm$ 0.3	4.38 $\pm$ 0.2	2.15 $\pm$ 0.3
Nonrecalling $\sqrt{T}$ -run (Berry et al., 1997)	5.35 $\pm$ 0.5	<b>0.03</b> $\pm$ 0.004	4.56 $\pm$ 0.001	2.55 $\pm$ 0.001
QRM2	<b>1.71</b> $\pm$ 0.2	0.15 $\pm$ 0.02	<b>0.98</b> $\pm$ 0.1	<b>0.12</b> $\pm$ 0.01

## 5 CONCLUSION

In this paper, we present an approach to manage the explore-exploit trade-off in bandit instances that contain many more arms than the possible number of experiments. While most

existing approaches in this setting assume special properties of the arms’ reward function or some structure over the set of arms, we make no such assumptions. Rather, we reformulate the problem by introducing the notion of quantile regret (or  $\rho$ -regret), which is defined with respect to the  $(1 - \rho)$ -th quantile of the mean reward distribution—unlike conventional regret, which is defined with respect to the highest mean. We present sub-linear upper bounds on the  $\rho$ -regret when (1)  $\rho$  is specified to the algorithm, and (2)  $\rho$  is not specified to the algorithm. We also prove that our QRM2 algorithm, although it is designed to minimise  $\rho$ -regret for small  $\rho$ , indeed achieves sub-linear regret under the assumption that the instance’s mean rewards come from a reservoir distribution (Wang et al., 2008).

We provide extensive empirical justification for quantile-regret minimisation. Our experiments show that the ZOOMING algorithm (Kleinberg et al., 2008) is sensitive to the given metric and the Lipschitz-continuity of the reward function. With slight perturbations to its parameters, the algorithm incurs a significantly higher regret. The GP-TS, and IGP-UCB algorithms (Ray Chowdhury and Gopalan, 2017) do not explicitly specify the number of arms to explore. Both algorithms perform much worse than QRM2 on the light sensor problem. We find that even when specified the exact distributional parameter, the algorithm proposed by Wang et al. (2008) can incur a higher regret than QRM2. It is infeasible in practice to know the optimal parameter setting for a given problem instance, and it is undesirable to have to find the right parameters using techniques such as cross-validation. The parameter-free approach taken by QRM2 makes it especially appealing to implement as a baseline across different domains and problem instances.

The constant-memory policies proposed by Herschkorn et al. (1996) and Berry et al. (1997) are akin to QRM2 in being simple and parameter-free. On the theoretical side, it seems plausible that their dependence on uniformly-distributed rewards can be removed in lieu of providing a finite time upper bound on the quantile-regret (rather than asymptotic guarantees). Practically, it also seems appealing to generalise these methods to work with larger, even if constant, memory sizes. In future work, we plan to analyse constant-memory policies within the framework of quantile-regret minimisation. We also aim to examine possible improvements to both the upper and lower bounds presented in this paper.

## Abstract

Gaussian process survival analysis model (GPSAM) was recently proposed to address key deficiencies of the Cox proportional hazard model, namely the need to account for uncertainty in the hazard function modeling while, at the same time, relaxing the time-covariates factorized assumption of the Cox model. However, the existing MCMC inference algorithms for GPSAM have proven to be slow in practice. In this paper we propose novel and scalable variational inference algorithms for GPSAM that reduce the time complexity of the sampling approaches and improve scalability to large datasets. We accomplish this by employing two effective strategies in scalable GP: i) using pseudo inputs and ii) approximation via random feature expansions. In both setups, we derive the full and partial likelihood formulations, typically considered in survival analysis settings. The proposed approaches are evaluated on two clinical and a divorce-marriage benchmark datasets, where we demonstrate improvements in prediction accuracy over the existing survival analysis methods, while reducing the complexity of inference compared to the recent state-of-the-art MCMC-based algorithms.

## 1 INTRODUCTION

Survival analysis studies statistical dependencies between the time to certain event and the covariates associated with this event. This is an important problem in statistics with applications ranging from medical prognosis in clinical studies (e.g., estimating the time of cancer

recurrence or remission from leukemia based on demographic and individual medical record factors), to other general areas where we seek to predict failure times of a system (e.g., bankruptcy of a firm). The key task in survival analysis is to estimate the conditional density function of the event time  $t$  given the covariates  $\mathbf{x}$ , from which one can immediately derive several important prognostic measures. Two most common instances of such measures are the *survival function*, defined as  $P(T \geq t|\mathbf{x})$ , or the *prognostic index*  $u(\mathbf{x})$  that quantifies the overall (anti) risk (i.e., higher index implies longer survival, and vice versa) of a patient/system with covariates  $\mathbf{x}$ .

A typical data-driven setting for survival analysis assumes availability of time-covariate pairs  $\{(t, \mathbf{x})\}$ , suggesting standard regression problem framing. However, a notable characteristic here is that some of the observed times  $t$  are *censored* in the sense that we only know the actual event time is no earlier than the observed  $t$ . In clinical studies this typically happens when the patient exits the study or the study terminates before the event occurs<sup>1</sup>. Typically, the data provides the information as to whether or not each instance is censored: the event indicator variables  $\delta = 1$  for event, and 0 for censored examples. Therefore, applying standard regression approaches by simply ignoring the censored samples can result in suboptimal use of data.

Several approaches have been proposed to deal with the censored instances. One way is to incorporate a cost-sensitive loss within the regression or ranking framework to learn the prognostic index function  $u(\mathbf{x})$  (Shivaswamy et al., 2007; Khan & Zubek, 2008; Van Belle et al., 2009; Van Belle et al., 2011). The main idea here is to impose

---

<sup>1</sup>This type of censoring is often referred to as the *right-censoring*. *Left-censoring* applies to instances when the event time is never greater than the observed time, while the *interval-censoring* refers to the cases of observed events within an interval. Most cases in practice deal with right-censoring, which we restrict to in this paper.

---

\*Also affiliated with Rutgers University.

an asymmetric loss on the incorrect prediction for censored examples. That is, we penalize the over-estimates (i.e.,  $u(\mathbf{x}) > t$ ) less than the under-estimates ( $u(\mathbf{x}) < t$ ). However, these approaches focus on the prognostic index function directly and are, therefore, inherently unable to provide a measure of uncertainty, namely the distribution of the survival time  $t$  for a given input  $\mathbf{x}$ .

The conditional density  $P(t|\mathbf{x})$  is most commonly modeled using the Cox Proportional Hazard (CoxPH) model (Cox, 1972). The model represents the distribution of the survival time as a first event arrival time in a heterogeneous Poisson process. Unlike the standard Poisson process models, the intensity function (often referred to as the *hazard* function) has a dependency on the input covariates, denoted as  $\lambda(t|\mathbf{x})$ . The CoxPH model further factorizes the hazard function over  $t$  and  $\mathbf{x}$  (see (2) in Sec. 2), allowing simplicity in hazard modeling by separating the input-dependent risk factors from the time-varying effects.

Recent efforts have focused on extending the CoxPH model to address its two drawbacks: i) the proportional and non-crossing hazard rates across instances originating from the factorized form of the hazard function can be too restrictive and oftentimes unlikely, and ii) the lack of proper treatment of uncertainty in the hazard function. (Dempsey et al., 2017) extended the model by introducing latent, continuous-time Markov dynamics to address the former limitation. The latter issue can be resolved by imposing Bayesian priors on the hazard function. Although few approaches along this direction showed initial success (Hjort et al., 2010; Iorio et al., 2009; Martino et al., 2011), they either have practical limitations (e.g., how to incorporate expert knowledge) or fail to overcome the former assumption of the proportional hazard rates. Another related method is the Random Survival Forest (Ishwaran et al., 2008), which can be seen as a generalization of the Kaplan Meier method, the traditional nonparametric hazard function estimator. Recently the Deep Survival Analysis (DSA) method was proposed (Ranganath et al., 2016), which utilizes a deep hierarchical Bayesian model for survival analysis.

To address those limitations, Gaussian process survival analysis model (GPSAM) was proposed in (Fernández et al., 2016). A GP-prioried latent function on the joint input space  $(t, \mathbf{x})$ , coupled with a non-negative link function, introduces stochasticity and removes the factorization assumption of CoxPH. The key advantage is that the Gaussian process circumvents the difficulty of modeling the hazard dependent jointly on  $(t, \mathbf{x})$  through the use of the covariance (kernel) function (Rasmussen & Williams, 2006). In essence, the GPSAM supplements the proportional hazard models with additional flexibil-

ity, while being able to account for uncertainty in the hazard function.

Nevertheless, the inference in the GPSAM model is challenging because the likelihood depends on the latent function values *for an uncountable range* of time inputs  $t \in \mathbb{R}_+$  (Sec. 2.2 for details), and not limited to only those induced by data in standard GP models. Motivated by the sophisticated MCMC inference algorithm for GP-prioried Poisson event models (Adams et al., 2009), the authors in (Fernández et al., 2016) proposed a tractable MCMC dynamics for the GPSAM by exploiting the idea of thinning-based sampling with auxiliary variables. However, the MCMC inference algorithm often exhibits slow convergence. Despite adopting the random feature kernel approximation strategy (Rahimi & Recht, 2008) to circumvent the computationally intensive matrix inversions, the MCMC inference for GPSAM proposed in (Fernández et al., 2016) incurs considerable computational issues when applied to real applications.

In this paper, we propose two novel variational inference algorithms for GPSAM, which address the computational deficiencies of the MCMC approach. To tackle the scalability of the GP nonparametric inference, we incorporate two approximations: the pseudo-input treatment (Titsias, 2009) and the random feature expansion (Rahimi & Recht, 2008). The former approach is similar to (Lloyd et al., 2015) variational inference in the GP modulated Poisson process. However, our approach is different in that we consider the GP latent function in the joint input space within the survival analysis setup. Solutions to variational inference in both approaches admit analytic forms aside from the fast univariate Monte-Carlo estimation of expected log-likelihood. We empirically demonstrate superior performance of our proposed methods over existing survival analysis approaches on several synthetic and real benchmark datasets.

## 2 BACKGROUND

In this section we briefly review the CoxPH model with two popular parameter estimation methods. Then we discuss the recent Gaussian process survival analysis model (GPSAM) (Fernández et al., 2016) that addresses the known drawbacks of the CoxPH model.

### 2.1 COX PROPORTIONAL HAZARD MODEL

The CoxPH model (Cox, 1972; Kleinbaum & Klein, 2005) represents the conditional density

$$P(t|\mathbf{x}) = \lambda(t|\mathbf{x}) \cdot \exp\left(-\int_0^t \lambda(\tau|\mathbf{x}) d\tau\right), \quad (1)$$

where  $t \in \mathbb{R}_+$  is the time of the event (e.g., death or cancer recurrence), and  $\mathbf{x} \in \mathbb{R}^d$  is the  $d$ -dim covariates of the subject (e.g. patient’s medical features). In (1),  $\lambda(t|\mathbf{x})$  is referred to as the *hazard* function, and can be interpreted as the probability of the immediate death at  $t$  given that the survival time is at least  $t$ . The hazard function is the *intensity* function of the (inhomogeneous) Poisson process (Ross, 2006) with (1) being the first event time density, however, in survival analysis this intensity is different from subject to subject, determined by the input covariates  $\mathbf{x}$ .

In the CoxPH model, the hazard function is specifically assumed to follow the factorized parametric form:

$$\lambda(t|\mathbf{x}) = \lambda_0(t) \cdot \exp(\mathbf{b}^\top \mathbf{x}), \quad (2)$$

where the model parameters are comprised of the weight vector  $\mathbf{b} \in \mathbb{R}^d$  and the non-negative function  $\lambda_0(\cdot)$ . The latter is known as the *base hazard* function which is typically modeled by the Weibull or a piecewise constant function. The consequence of the factorized form in (2) is that the hazard ratio between two subjects (with  $\mathbf{x}$  and  $\mathbf{x}'$ ) is constant over time, solely dependent on the covariates (i.e.,  $e^{\mathbf{b}^\top(\mathbf{x}-\mathbf{x}')}$ ). Also, the hazard functions of different subjects are non-crossing with each other.

Given the training data  $\mathcal{D} = \{(\delta_n, t_n, \mathbf{x}_n)\}_{n=1}^N$  where  $\delta_n \in \{0, 1\}$  indicates whether the observation  $n$  is event ( $\delta_n = 1$ ) or right-censored ( $\delta_n = 0$ ), the traditional maximum likelihood learning aims to maximize the data log-likelihood  $\sum_{n=1}^N \log FL(n)$  where

$$FL(n) = P(t_n|\mathbf{x}_n)^{\delta_n} \cdot P(T \geq t_n|\mathbf{x}_n)^{1-\delta_n}. \quad (3)$$

Often we name it the *full-likelihood* to differentiate it from the partial likelihood, discussed next.

Alternatively, also very popular in survival analysis, the parameters can be learned by the *partial likelihood* maximization. The notion of the partial likelihood comes from an alternative view of the data generation process. Namely, at a given time  $t$ , we consider a random process of selecting a subject  $\mathbf{x}$  that will face an event at  $t$ , among all survivors at that moment. The likelihood of this is proportional to the hazard value  $\lambda(t|\mathbf{x})$ . More specifically, for each event instance  $n$  ( $\delta_n = 1$ ), we can regard  $(t_n, \mathbf{x}_n)$  as the selected sample among the survivors  $\{(t_j, \mathbf{x}_j) : t_j \geq t_n\}$ , regardless of  $\delta_j$ ’s. The so-called partial likelihood is then defined as:

$$PL(n) = \frac{\lambda(t_n|\mathbf{x}_n)}{\sum_{j:t_j \geq t_n} \lambda(t_n|\mathbf{x}_j)}, \quad (4)$$

and we maximize  $\sum_{n=1}^N \delta_n \log PL(n)$ .

## 2.2 GAUSSIAN PROCESS SURVIVAL MODEL

Abbreviated as GPSAM, the model aims to address the known drawbacks of the CoxPH model discussed in Sec. 1 by endowing more flexibility and accounting for uncertainty in the hazard function. This is done by imposing Gaussian process prior on the hazard function and having the latent function dependent on both  $t$  and  $\mathbf{x}$ . More specifically,

$$\lambda(t|\mathbf{x}) = \lambda_0(t) \cdot g(f(t, \mathbf{x})), \quad f(\cdot) \sim \mathcal{GP}(0, k(\cdot, \cdot)). \quad (5)$$

Here  $g(\cdot)$  is a non-negative link function to prevent the hazard from being negative. In (Fernández et al., 2016), they used the sigmoid  $g(y) = 1/(1 + e^{-y})$ , and the Weibull for the base hazard,  $\lambda_0(t) = c \cdot t^{r-1}$  for  $c > 0, r \geq 1$ , which subsumes the constant functions ( $r = 1$ ). Note that the kernel function operates on the joint input space  $\mathbb{R}_+ \times \mathbb{R}^d$ . (Fernández et al., 2016) adopted the composite kernel

$$k((t, \mathbf{x}), (t', \mathbf{x}')) = \sum_{j=1}^d x(j) x'(j) k_j(t, t'), \quad (6)$$

where  $x(j)$  indicates the  $j$ -th element of  $\mathbf{x}$ . The kernel on time space,  $k_j(t, t')$  is typically chosen as the squared exponential for  $j = 1, \dots, d$ ,

$$k_j(t, t') = s_j^2 \exp(-0.5(t - t')^2 / l_j^2), \quad (7)$$

with the variance and length-scale parameters ( $s_j^2, l_j^2$ ).

The inference in the GPSAM model is in general difficult mainly due to the form of the likelihood (1), in which the latent function  $f(\cdot)$  is involved with *all*  $\tau \in [0, t]$ . In other words, infinitely many Gaussian latent variables need to be dealt with in principle. In (Fernández et al., 2016) they adopted the thinning-based MCMC sampling strategy motivated from (Adams et al., 2009), where the key idea is to sample<sup>2</sup> from the (inhomogeneous) Poisson process with intensity  $\lambda_0(t)$  while keeping all the thinned samples as auxiliary state variables in the inference of the latent variables<sup>3</sup>. For the censored examples  $n$ , we can do the same thing as if  $t_n$ ’s were exact, but remove all terms related to  $t_n$  from the likelihood function.

However, the MCMC algorithm is generally slow to converge. Furthermore, each MCMC step requires the kernel matrix inversion to sample from the conditional Gaussian given both the data and the thinned samples. As the number of thinned samples can be orders of magnitude larger than the data size, they also had to resort

<sup>2</sup>This sampling must be easy since  $\lambda_0(t) = c \cdot t^{r-1}$  admits a closed-form inverse cumulative function.

<sup>3</sup>Note that this thinning-based sampling is valid since they used the sigmoid link  $g(\cdot)$ , namely  $\lambda_0(t)$  is always an upper bound of  $\lambda(t|\mathbf{x})$  in (5).

to the random feature expansion trick (Rahimi & Recht, 2008) to circumvent the matrix inversion. Nevertheless, the thinned samples can grow arbitrarily large, incurring serious computational overhead. This motivates our work of variational inferences in the following section.

### 3 VARIATIONAL INFERENCE

We begin with the full joint model of the GPSAM with the observed data  $\mathcal{D} = \{(\delta_n, t_n, \mathbf{x}_n)\}_{n=1}^N$ :

$$P_\theta(\mathcal{D}, f) = P_{\theta_0}(\mathcal{D}|f) \cdot P_{\theta_k}(f). \quad (8)$$

Here  $\theta = \{\theta_0, \theta_k\}$  indicates the model parameters, where  $\theta_0 = (c, r)$  is the parameters of the Weibull base hazard  $\lambda_0(t) = c \cdot t^{r-1}$ , and  $\theta_k$  denotes all kernel parameters, specifically  $\{(s_j^2, l_j^2)\}$  in (7). The latter determines the Gaussian process prior  $P(f)$ .

The conditional data likelihood  $P(\mathcal{D}|f)$  in (8) can have either of two different forms. If we follow the full likelihood (3), then the log-likelihood can be written as:

$$\log P(\mathcal{D}|f) = \sum_{n=1}^N \left[ \delta_n \cdot \log \lambda(t_n | \mathbf{x}_n) - \int_0^{t_n} \lambda(\tau | \mathbf{x}_n) d\tau \right], \quad (9)$$

with  $\lambda(t|\mathbf{x})$  from (5). See Appendix A in the supplemental material for the detailed derivations. If we adopt the partial likelihood (4) instead, then  $\log P(\mathcal{D}|f)$  becomes:

$$\sum_{n=1}^N \delta_n \cdot \left[ \log \lambda(t_n | \mathbf{x}_n) - \log \sum_{j:t_j \geq t_n} \lambda(t_n | \mathbf{x}_j) \right]. \quad (10)$$

The posterior distribution of the latent function  $P_\theta(f|\mathcal{D})$  is analytically intractable, and we introduce a tractable density family  $Q_\alpha(f)$  with the parameters  $\alpha$ , and search for  $\alpha$  that makes  $Q_\alpha(f)$  as close as possible to the true posterior. In defining the variational density family  $Q(\cdot)$ , it should be noted that we have to deal with infinitely many latent variables from  $f(\cdot)$ . To this end, we adopt two recent scalable variational inference algorithms: the pseudo-input approximation (Titsias, 2009) and the random feature expansion (Rahimi & Recht, 2008). We frame each of the approaches within GPSAM. They are described in the following sections.

In addition, we use the square non-negative link function, i.e.,  $g(y) = y^2$  instead of the sigmoid, for its merit in analytic derivation of the objective especially in Sec. 3.1, similar in nature as (Lloyd et al., 2015). That is, the hazard function given the latent function is determined as:

$$\lambda(t|\mathbf{x}) = \lambda_0(t) \cdot f(t, \mathbf{x})^2. \quad (11)$$

#### 3.1 APPROXIMATION WITH PSEUDO INPUTS

To address the intractability of dealing with  $f(\cdot)$  at  $(\tau, \mathbf{x})$  for all time epochs  $\tau$  in the domain, stemming from the likelihood (1), we first adopt the scalable pseudo-input approximation techniques recently introduced in (Titsias, 2009; Dezfouli & Bonilla, 2015; Lloyd et al., 2015). We essentially assume that there are  $M$  pseudo inputs denoted by  $\mathcal{Z} = \{z_1, \dots, z_M\} \subset \mathbb{R}_+ \times \mathbb{R}^d$  (denoting  $z_i = (\bar{t}_i, \bar{\mathbf{x}}_i)$ ), where  $M$  is typically chosen to be small so that the inversion of  $(M \times M)$  matrices can be done efficiently. The pseudo inputs can be thought of as the representative points for the joint input space (Quiñonero-Candela & Rasmussen, 2005). We choose the pseudo inputs by clustering the points in the pool that is formed by Cartesian product of uniformly sampled times and randomly sampled covariates from data, although they can also be learned from the data itself.

We define the variational density for the posterior as:

$$Q_\alpha(f) = \int Q_\alpha(\mathbf{f}_{\mathcal{Z}}) P(f|\mathbf{f}_{\mathcal{Z}}) d\mathbf{f}_{\mathcal{Z}}. \quad (12)$$

Here we use the vector notation for the latent function: for a set  $\mathcal{A} = \{(\hat{t}_i, \hat{\mathbf{x}}_i)\}_{i=1}^p \subset \mathbb{R}_+ \times \mathbb{R}^d$ , we denote by  $\mathbf{f}_{\mathcal{A}}$  the  $p$ -dim vector of the function values on the inputs  $(\hat{t}_i, \hat{\mathbf{x}}_i) \in \mathcal{A}$ . The central idea that enables scalability and tractability in (12) is that we only model the low-dimensional density  $Q_\alpha(\mathbf{f}_{\mathcal{Z}})$  while all the other function values can be inferred using  $P(f|\mathbf{f}_{\mathcal{Z}})$ , the conditional density derived from the GP prior. We let  $Q_\alpha(\mathbf{f}_{\mathcal{Z}})$  be a Gaussian with diagonal covariance, namely

$$Q_\alpha(\mathbf{f}_{\mathcal{Z}}) = \mathcal{N}(\mathbf{f}_{\mathcal{Z}}; \boldsymbol{\mu}, \boldsymbol{\Sigma}), \quad (13)$$

where  $\alpha = \{\boldsymbol{\mu}, \boldsymbol{\Sigma}\}$  with  $(M \times 1)$  mean vector  $\boldsymbol{\mu}$  and the  $(M \times M)$  diagonal covariance matrix  $\boldsymbol{\Sigma}$ .

The variational parameters  $\alpha$  can be found by minimizing the KL divergence between the true posterior and the variational density (12):

$$\text{KL}(Q_\alpha(f) || P_\theta(f|\mathcal{D})) = \log P_\theta(\mathcal{D}) - \mathcal{L}_{PI}(\theta, \alpha), \quad (14)$$

where  $\mathcal{L}_{PI}(\theta, \alpha)$  is defined as:

$$\mathcal{L}_{PI}(\theta, \alpha) = \mathbb{E}_{Q(f)} [\log P(\mathcal{D}|f)] - \text{KL}(Q(\mathbf{f}_{\mathcal{Z}}) || P(\mathbf{f}_{\mathcal{Z}})). \quad (15)$$

Using the non-negativity of the KL divergence in (14), the  $\mathcal{L}_{PI}$  becomes a lower bound of the log-evidence,

$$\log P_\theta(\mathcal{D}) \geq \mathcal{L}_{PI}(\theta, \alpha). \quad (16)$$

Increasing  $\mathcal{L}_{PI}(\theta, \alpha)$  wrt  $\alpha$  renders the variational density closer to the true posterior, whereas improving it wrt the model parameters  $\theta$  can *potentially*<sup>4</sup> improve the data

<sup>4</sup>Similarly as in other standard variational inferences, this does not guarantee to improve the evidence  $\log P(\mathcal{D})$  since the inequality (16) is not tight.

likelihood of the model. Hence, we maximize  $\mathcal{L}_{PI}(\theta, \alpha)$  wrt all parameters to achieve both variational inference and model selection simultaneously.

Next, we provide detailed derivations necessary to evaluate the objective  $\mathcal{L}_{PI}$ . Since the second term in the right hand side of (15) is the straightforward KL divergence between two Gaussians, we focus on the expected conditional likelihood term.

For the two forms of the likelihood, full in (9) and partial in (10), we write the expectation as:

$$\mathbb{E}_{Q(f)}[\log P(\mathcal{D}|f)] = \sum_{n=1}^N (A_n - B_n), \quad (17)$$

where  $A_n$  is the expectation of the log-hazard at data point  $n$ ,

$$A_n = \delta_n \cdot \left( \log \lambda_0(t_n) + \mathbb{E}_{Q(f_n(t_n))}[\log f_n(t_n)^2] \right), \quad (18)$$

with the abbreviation  $f_n(t) = f(t, \mathbf{x}_n)$ . Whereas  $A_n$  is shared by both likelihoods,  $B_n$  is defined differently.

$$B_n^f = \int_0^{t_n} \lambda_0(\tau) \cdot \mathbb{E}_{Q(f_n(\tau))}[f_n(\tau)^2] d\tau, \quad (19)$$

is for the full likelihood, while the following is for the partial likelihood:

$$B_n^p = \delta_n \cdot \mathbb{E}_{Q(f)} \left[ \log \sum_{j:t_j \geq t_n} \lambda_0(t_n) \cdot f_j(t_n)^2 \right]. \quad (20)$$

**Full likelihood.** Note that in (18) and (19) the distributions over which the expectations are taken are univariate Gaussians, specifically from (12),  $Q(f_n(t)) = \mathcal{N}(\tilde{\mu}_n(t), \tilde{\sigma}_n^2(t))$  where

$$\tilde{\mu}_n(t) = k_{(t, \mathbf{x}_n), \mathcal{Z}} \mathbf{K}^{-1} \mu, \quad (21)$$

$$\tilde{\sigma}_n^2(t) = k_{(t, \mathbf{x}_n), (t, \mathbf{x}_n)} - k_{(t, \mathbf{x}_n), \mathcal{Z}} \mathbf{K}^{-1} k_{\mathcal{Z}, (t, \mathbf{x}_n)} + k_{(t, \mathbf{x}_n), \mathcal{Z}} \mathbf{K}^{-1} \Sigma \mathbf{K}^{-1} k_{\mathcal{Z}, (t, \mathbf{x}_n)}. \quad (22)$$

For two time-covariates input sets  $\mathcal{A}_1$  and  $\mathcal{A}_2$ , we denote by  $k_{\mathcal{A}_1, \mathcal{A}_2}$  the  $(|\mathcal{A}_1| \times |\mathcal{A}_2|)$  kernel matrix obtained by applying  $k(\cdot, \cdot)$  on  $(\mathcal{A}_1 \times \mathcal{A}_2)$ . Also,  $\mathbf{K} = k_{\mathcal{Z}, \mathcal{Z}}$  indicates the  $(M \times M)$  kernel matrix on the pseudo inputs  $\mathcal{Z}$ . The expectation of the squared-log term in (18) can be done by the Monte-Carlo estimation. For it is *univariate* sampling, this does not incur any significant computational overhead. As we also need to compute gradients of  $A_n$  wrt the parameters of the sampling distribution  $Q(f_n(t_n))$ , we adopt the re-parametrized Gaussian sampling technique (Kingma & Welling, 2014) to reduce the variance of the estimate. More specifically, we express the random samples from  $Q(f_n(t_n))$ , denoted by

$f_n^{(s)}(t_n)$  for  $s = 1, \dots, S$ , as:

$$f_n^{(s)}(t_n) = \tilde{\mu}_n(t_n) + (\tilde{\sigma}_n^2(t_n))^{1/2} \epsilon_n^{(s)}, \quad (23)$$

where  $\epsilon_n^{(s)} \sim \mathcal{N}(0, 1)$ . The expectation in  $A_n$  is then estimated as:

$$\frac{1}{S} \sum_{s=1}^S \log \left( \tilde{\mu}_n(t_n) + (\tilde{\sigma}_n^2(t_n))^{1/2} \epsilon_n^{(s)} \right)^2. \quad (24)$$

We sample  $\{\epsilon_n^{(s)}\}$  once, and fix them throughout the optimization, which empirically performed better with a lower variance than re-sampled at each iteration. As we separate randomness ( $\epsilon_n^{(s)}$ ) from the parameters to be optimized, the gradient of (24) can be computed straightforwardly while yielding an unbiased estimate of the gradient of the original (18). Optionally, we can further reduce the variance of the estimate by using the Rao-Blackwellization technique (Casella & Robert, 1996).

For  $B_n^f$  in (19), due to the square link function, the inner expectation equals  $\tilde{\mu}_n(\tau)^2 + \tilde{\sigma}_n^2(\tau)$ , which allows the integral to be derived analytically for the composite squared exponential kernel (6) and (7) (c.f. (Lloyd et al., 2015)). However, the analytic derivation has to resort to certain confluent hyper-geometric function which can be numerically unstable. In the experiments, we rather adopt the numerical integration by having uniformly sampled grid points over the time horizon.

**Partial likelihood.** Looking into  $B_n^p$  in (20), the key difference from the above full likelihood derivation stems from the multiple latent variables (i.e.,  $\{f_j(t_n)\}_{j:t_j \geq t_n}$ ) that are dependent on one another, preventing us from taking advantage of the univariate sampling. Since the number of these variables (i.e.,  $|\{j : t_j \geq t_n\}|$ ) can be as large as the entire data set, naively sampling from  $Q(f)$  jointly can yield an estimate with large variance. Instead, we consider the upper bound of  $B_n^p$  (leading to a lower bound on  $\mathcal{L}_{PI}$ ) using the Jensen's inequality. Specifically, from (20),

$$B_n^p \leq \delta_n \cdot \log \sum_{j:t_j \geq t_n} \lambda_0(t_n) \cdot \mathbb{E}_{Q(f_j(t_n))} [f_j(t_n)^2]. \quad (25)$$

The square link allows an analytical expression of the expectation in  $\tilde{B}_n^p$ ,  $\tilde{\mu}_j(t_n)^2 + \tilde{\sigma}_j^2(t_n)$ , which can be evaluated easily using (21) and (22), likewise its gradients. Note that (regardless of whether we use the upper bound or not) the base hazard term  $\log \lambda_0(t_n)$  cancels out with that in (18) in the final objective (17), preventing one from learning  $\lambda_0(t)$ . This is an inherent problem originating in the hazard form (5), where  $\lambda_0(t)$  is shared across examples. To this end, we simply borrow the estimate of  $\lambda_0(t)$  from the full-likelihood learning.

### 3.2 RANDOM FEATURES APPROXIMATION

To deal with uncountably many random variables and their matrix inversions brought about from the nonparametric Bayesian Poisson process GPSAM, we consider the random features expansion as an alternative approximation strategy. The central idea of the random features (Rahimi & Recht, 2008; Cho & Saul, 2009) is to seek a finite dimensional feature vector representation for input such that the inner product on this feature space equals (in expectation) the kernel value. For the composite kernel function (6), its GP-prior latent function  $f(t, \mathbf{x})$  can be approximated by:

$$\hat{f}(t, \mathbf{x}) = \frac{1}{m} \sum_{j=1}^d x(j) \left( \mathbf{a}_j^\top \cos(\omega_j t) + \mathbf{b}_j^\top \sin(\omega_j t) \right), \quad (26)$$

where  $\mathbf{a}_j$ ,  $\mathbf{b}_j$ , and  $\omega_j$  are all  $m$ -dim iid random variables (samples) with  $\mathbf{a}_j, \mathbf{b}_j \sim \mathcal{N}(0, s_j^2 \mathbf{I}_m)$  and  $\omega_j \sim \mathcal{N}(0, \frac{1}{t_j^2} \mathbf{I}_m)$  for  $j = 1, \dots, d$ . Here  $\mathbf{I}_m$  denotes the  $(m \times m)$  identity matrix. We let  $\mathbf{a} = \{\mathbf{a}_j\}_{j=1}^d$  and the others similarly. It can be shown that  $\text{Cov}(\hat{f}(t, \mathbf{x}), \hat{f}(t', \mathbf{x}')) = k((t, \mathbf{x}), (t', \mathbf{x}'))$ , which implies that the finite dimensional random variables  $\{\mathbf{a}, \mathbf{b}, \omega\}$  are sufficient to represent the latent function  $f \sim \mathcal{GP}(0, k(\cdot, \cdot))$ . The parameter  $m$  is the number of random samples to approximate the kernel, which trades off: large  $m$  reduces the approximation error at the cost of computational overhead.

In this treatment, we aim to infer the posterior distribution  $P(\mathbf{a}, \mathbf{b}, \omega | \mathcal{D})$ , and the variational inference reduces to maximizing:

$$\mathcal{L}_{RF}(\theta, \beta) = \mathbb{E}_{Q(\mathbf{a}, \mathbf{b}, \omega)} [\log P(\mathcal{D} | \hat{f})] - \text{KL}(\theta, \beta), \quad (27)$$

where we use the fully factorized variational density,  $Q(\mathbf{a}, \mathbf{b}, \omega) = Q(\mathbf{a})Q(\mathbf{b})Q(\omega)$ , each modeled as a Gaussian,  $Q(\mathbf{a}) = \prod_{j=1}^d \mathcal{N}(\mathbf{a}_j; \boldsymbol{\mu}_j^a, \boldsymbol{\Sigma}_j^a)$  and similarly for the others. Here  $\boldsymbol{\mu}_j^a$  and  $\boldsymbol{\Sigma}_j^a$  are  $(m \times 1)$  mean vector and  $(m \times m)$  diagonal covariance matrix, respectively, and  $\beta$  includes all these variational parameters. The term  $\text{KL}(\theta, \beta)$  denotes the sum of individual KL terms for  $\mathbf{a}$ ,  $\mathbf{b}$ , and  $\omega$ ; for instance, for  $\mathbf{a}$ , we have:  $\text{KL}(Q(\mathbf{a}) || \mathcal{N}(\mathbf{a}; 0, s_j^2 \mathbf{I}_m))$ . As before, these KL terms all involve Gaussians, having analytic forms, easy to evaluate and take derivatives.

Similarly to Sec. 3.1, the expected log-likelihood term in (27) has two variations, full or partial likelihood, and we decompose it into two parts exactly the same way as (17). For concreteness, with the abbreviation  $\hat{f}_n(t) = \hat{f}(t, \mathbf{x}_n)$ , we approximate the expected log-likelihood term in (27) using the re-parametrized Monte-Carlo estimate. That is, after sampling  $\epsilon_j^{a(s)}$ ,  $\epsilon_j^{b(s)}$  and

$\epsilon_j^{\omega(s)}$  independently from  $\mathcal{N}(0, \mathbf{I}_m)$  for  $j = 1, \dots, d$  and  $s = 1, \dots, S$ , the sampled version of the random weight vector  $\mathbf{a}_j$  is formed as  $(\mathbf{b}_j^{(s)})$  and  $\omega_j^{(s)}$  similarly):

$$\mathbf{a}_j^{(s)} = \boldsymbol{\mu}_j^a + (\boldsymbol{\Sigma}_j^a)^{1/2} \epsilon_j^{a(s)}, \quad (28)$$

Then the posterior samples  $\hat{f}_n^{(s)}(t)$  can be written as:

$$\sum_{j=1}^d \frac{x_n(j)}{m} \left( (\mathbf{a}_j^{(s)})^\top \cos(\omega_j^{(s)} t) + (\mathbf{b}_j^{(s)})^\top \sin(\omega_j^{(s)} t) \right), \quad (29)$$

With these sampled functions, one can basically obtain the estimate of the objective (27) that can be decomposed into forms similar to (18), (19), and (20), which we denote by  $\hat{A}_n$ ,  $\hat{B}_n^f$ , and  $\hat{B}_n^p$ , respectively. Although evaluating  $\hat{A}_n$  and  $\hat{B}_n^p$  (and their gradients) can be done similarly as in Sec. 3.1 with no additional difficulty, working on  $\hat{B}_n^f$  introduces a new computational challenge. Unlike the pseudo-input approximation where we were able to express  $\mathbb{E}_Q[f_n(\tau)^2]$  as an analytic form  $\tilde{\mu}_n(\tau)^2 + \tilde{\sigma}_n^2(\tau)$ , we can only estimate the expectation numerically using the samples (29) from  $Q(\cdot)$ . However, we have an outer integration of this expectation over  $\tau \in [0, t_n]$ , and the (grid-based) numerical integration would incur computational explosion as we need  $(d \cdot m \cdot S \cdot G)$  samples/numbers involved in, where  $G$  is the number of grid points over  $[0, t_n]$  (typically,  $S$  and  $G$  are several thousands, and  $d \approx 10$ ).

To address this difficulty, we propose an alternative estimation strategy for  $\hat{B}_n^f$ . We regard  $\lambda_0(\tau) = c \cdot \tau^{r-1}$  in the integration as an unnormalized density, more specifically,  $\lambda_0(\tau) = \rho_n \cdot p_n(\tau)$  where  $p_n(\tau)$  is the density having the support  $[0, t_n]$  and  $\rho_n = \int_0^{t_n} \lambda_0(\tau) d\tau = \frac{c}{r} t_n^r$  is the normalizer. Thus  $p_n(\tau) = r \frac{\tau^{r-1}}{t_n^r}$  over  $[0, t_n]$ . Then

$$\hat{B}_n^f = \rho_n \cdot \mathbb{E}_{p_n(\tau)} \left[ \mathbb{E}_Q[f_n(\tau)^2] \right]. \quad (30)$$

This allows us to sample  $\tau_n^{(s)} \sim p_n(\tau)$  for  $s = 1, \dots, S$  independently with the random features/weights in (28), and estimate  $\hat{B}_n^f$  as:

$$\rho_n \cdot \frac{1}{S} \sum_{s=1}^S \hat{f}_n^{(s)}(\tau_n^{(s)})^2. \quad (31)$$

Note that sampling from  $p_n(\tau)$  can be done using the inverse transform sampling: for its CDF is  $F_n(\tau) = (\tau/t_n)^r$ , the samples  $\tau_n^{(s)}$  can be expressed as:

$$\tau_n^{(s)} = F_n^{-1}(u^{(s)}) = t_n \cdot (u^{(s)})^{1/r}, \quad (32)$$

where  $u^{(s)}$  are uniform samples from  $[0, 1]$ . We further reduce the variance of the estimate by using the same re-parametrization trick, namely plugging (32) into (31) to separate the randomness from the parameters.

## 4 EMPIRICAL EVALUATIONS

The performance of the proposed variational inference methods is demonstrated on both synthetic and real datasets. Our approaches are denoted as follows:  $\mathbf{VI}_{PI}^f$  and  $\mathbf{VI}_{PI}^p$  are the approximations based on pseudo inputs in Sec. 3.1 with full and partial likelihood, respectively, while  $\mathbf{VI}_{RF}^f$  and  $\mathbf{VI}_{RF}^p$  indicate the variational inference with random feature expansions described in Sec. 3.2. The competing approaches are summarized, with abbreviations, as:

- **MCMC**: The MCMC-based inference method for GPSAM (Fernández et al., 2016), where we used hyperparameters similar to theirs.
- **CoxPH<sup>f</sup>** and **CoxPH<sup>p</sup>**: The full and partial likelihood maximization learning of the CoxPH model.
- **SVCR**: The support vector censored regression approach (Shivaswamy et al., 2007) with no cost imposed for the over-estimation of the censored samples.
- **SVRC**: Another regression-based approach (Khan & Zubek, 2008) that adopts asymmetric costs for over-estimation depending on the violation types.
- **MINLIP**: The ranking-based prognostic function estimation method (Van Belle et al., 2009), which enforces the correct ordering of the prognostic indices for time-comparable pairs of samples. The method further aims to preserve the relative time differences in the prognostic indices.
- **Model2**: The hybrid approach that attempts to combine the ranking constraints and the cost-sensitive loss in estimating the prognostic function (Van Belle et al., 2011).

For the performance measures, we focus on the accuracy of the estimated prognostic index function  $u(\mathbf{x})$ . Whereas the approaches based on regression and/or ranking directly estimate  $u(\mathbf{x})$ , for the CoxPH-based methods we derive it naturally by  $u(\mathbf{x}) = -\mathbf{b}^\top \mathbf{x}$  from the learned CoxPH models. For GPSAM, where the hazard function is not factorized, we estimate the expected event time  $\mathbb{E}[t|\mathbf{x}]$  as the survival index. Two performance measures popular in survival analysis are considered: i) Concordance index – the proportion of the pairs of samples whose predicted survival times are correctly ordered (i.e.,  $(u(\mathbf{x}_i) - u(\mathbf{x}_j))(t_i - t_j) \geq 0$ ), and ii) Log-rank- $\chi^2$  statistics – the statistical test score measuring the difference between two risk groups formed by thresholding the prognostic indices by their median. For both measures, higher scores are better.

For our variational inference methods, we vary the following hyperparameters: the number of pseudo inputs ( $M$ ) for the  $\mathbf{VI}_{PI}$  and the number of random features ( $m$ ) for the  $\mathbf{VI}_{RF}$ . We use the best set obtained by cross validation on the held-out portion of the training data, where the concordance index is used as the selection criterion. The optimal parameters are, consistently across all datasets,  $M = 20$  for the  $\mathbf{VI}_{PI}$  and  $m = 50$  for the  $\mathbf{VI}_{RF}$ . In the latter part of the section and in the supplemental material (Appendix B), we also compare the performances and running times of the other parameter settings. The number of samples for the Monte-Carlo estimation in our variational inference is fixed as 3000. The MCMC approach for GPSAM model (Fernández et al., 2016) used  $m = 50$  random features, and the number of MCMC iterations is chosen as 5000 with the first 1000 samples dropped out. The hyperparameters of the other competing models (e.g., the regularization parameters in the regressions) are also determined by cross validation.

### 4.1 SYNTHETIC DATASETS

To judge the effectiveness and flexibility of the proposed variational inference methods for GPSAM, we consider a synthetic scenario where the data samples are generated from a non-proportional hazard model. In particular, we consider a stratified CoxPH model, which can be seen as a conditional mixture of several CoxPH models. More specifically, the hazard function is defined as  $\lambda(t|\mathbf{x}) = \lambda_{s(\mathbf{x})}(t) \cdot \exp(\mathbf{b}_{s(\mathbf{x})}^\top \mathbf{x})$  where  $s(\mathbf{x}) \in \{1, \dots, K\}$  is a gating function among  $K$  component CoxPH models. The base hazard function  $\lambda_s(t)$  for each component model  $s = 1, \dots, K$ , is defined to be the Weibull function  $c_s \cdot t^{r_s-1}$  with different parameters ( $c_s, r_s$ ) for each  $s$ . The gating function follows a piecewise linear form,  $s(\mathbf{x}) = \arg \max_{1 \leq s \leq K} \mathbf{w}_s^\top \mathbf{x}$ , where we choose  $\mathbf{w}_s$ 's randomly. We set the number of base models as  $K = 3$ . The input covariates  $\mathbf{x}$  are sampled randomly from  $\mathcal{N}(0, \mathbf{I})$ .

To mimic the censoring process, for each generated sample, we randomly turn it into a censored one with probability  $p$ . The observed time  $t$  for the censored sample is then uniformly sampled from  $[0, t_*]$  where  $t_*$  is the original value before censoring. We choose  $p = 0.3$ . After generating 100 samples, we perform 10-fold cross validation where the averaged test scores with standard deviations are depicted in Table 1. For each measure, the best performing method in terms of the average value is boldfaced. To measure the statistical significance, we also conducted the Wilcoxon signed-rank tests, pairwise against the (boldfaced) best performing method. With the null hypothesis that two approaches result in statistically indistinguishable performance, the  $p$ -values

Table 1: (Synthetic dataset) Average test prediction performance. Our variational approximation approaches,  $VI_{PI}$  and  $VI_{RF}$ , adopt  $M = 20$  pseudo inputs and  $m = 50$  random features, respectively. Best average score method is boldfaced. Parentheses indicate the  $p$ -values from the Wilcoxon signed rank test against the best (boldfaced) approaches.

Methods	C-Index (%)	Log-Rank- $\chi^2$
$VI_{PI}^f$	<b>83.04 ± 1.91 (--)</b>	<b>13.88 ± 2.85 (--)</b>
$VI_{PI}^p$	79.68 ± 2.50 (0.002)	10.71 ± 4.73 (0.125)
$VI_{RF}^f$	81.55 ± 2.20 (0.049)	10.55 ± 5.66 (0.250)
$VI_{RF}^p$	81.28 ± 2.54 (0.049)	10.73 ± 5.38 (0.250)
MCMC	77.20 ± 3.66 (0.002)	10.81 ± 6.00 (0.193)
CoxPH <sup>f</sup>	73.43 ± 5.51 (0.002)	8.70 ± 2.88 (0.232)
CoxPH <sup>p</sup>	73.27 ± 4.99 (0.002)	9.14 ± 3.37 (0.160)
SVCR	68.32 ± 6.51 (0.002)	5.55 ± 3.48 (0.027)
SVRC	73.05 ± 4.37 (0.002)	7.81 ± 3.20 (0.084)
MINLIP	65.75 ± 4.34 (0.002)	3.40 ± 2.20 (0.004)
Model2	71.32 ± 3.04 (0.002)	5.63 ± 2.24 (0.027)

are shown in the tables.

The proposed variational inference approaches, both  $VI_{PI}$  and  $VI_{RF}$ , exhibit superior generalization performance compared to all contrasted methods. Specifically, the pseudo-input approximation optimizing the full-likelihood ( $VI_{PI}^f$ ) performs the best in both measures. With regard to the concordance index, it is significantly better than all other models ( $p$ -values  $< 0.05$ ), but leads to marginal improvements in the log-rank- $\chi^2$  measure. The CoxPH-based models (CoxPH<sup>f</sup> and CoxPH<sup>p</sup>) are mostly outperformed by the GPSAM models due to the substantial mismatch with the true data process (simplified modeling assumption of non-crossing hazard functions across instances). Compared to the MCMC approach (Fernández et al., 2016), our proposed VI methods yield higher prediction accuracies, related to improved hazard function estimation. In contrast, the MCMC potentially suffers from computational overhead, preventing convergence to the target distribution.

To investigate the computational benefits of the proposed approaches over the MCMC algorithm, we measure the actual inference times (for our variational inference, we record the entire running time until convergence). Implemented in MATLAB and run on 2.4GHz Intel Xeon CPU, the running times are: 571.7 seconds for  $VI_{PI}^f$ , 1165.1 seconds for  $VI_{RF}^f$ , and 8121.2 seconds for the MCMC, indicating significant computational advantage of our VI approaches. The log-likelihood scores  $\log P(\mathcal{D}_*)$  of GPSAM evaluated on the test data  $\mathcal{D}_*$  are also summarized in Table 3. Although the scores are mostly comparable, the MCMC attains the highest likeli-

Figure 1: The inference times of three methods: MCMC,  $VI_{PI}^f$ , and  $VI_{RF}^f$  on the MLC dataset.

hood. However, it should be noted that we only compute lower bounds of the log-likelihoods (i.e.,  $\mathcal{L}_{PI}$  in (15) and  $\mathcal{L}_{RF}$  in (27)) for our variational learning.

## 4.2 REAL DATASETS

Next we test the performance of the proposed methods on two clinical and one non-clinical datasets: i) (VLC) Veteran’s lung cancer dataset (Prentice, 1974; Kalbfleisch & Prentice, 2002) contains records of 137 patients with 6 covariates such as age, weight, treatment, cell type, and disease history, ii) (MLC) Mayo lung cancer dataset (Therneau & Grambsch, 2000) having 167 patients with similar 7 covariates, and iii) (Divorce) dataset (Lillard & Panis, 2000) which records the divorce years since marriage for 3771 couples, among which we use a fifth of the samples randomly chosen. The proportions of the censored samples are: 7% for VLC, 28% for MLC, and 70% for Divorce, where the study involved in the latter dataset often fails to track the status of many of the couples, which leads to the large proportion of the censored samples. The Divorce dataset originally provides three categorical features for each sample: the husband education years (categorized into three levels of less than 12 yrs, more than 15, and between two), whether the husband is African American or not, and whether the ethnicity of the couple is different or not. We also introduce additional nonlinear features of pairwise and triple products, yielding 7-dim covariates. Other experimental settings follow the synthetic experiment.

We performed 10-fold cross validation where the test results are shown in Table 2. The best methods, boldfaced with  $p$ -values from the statistical test against other methods, are mostly our variational inference methods (four out of six). Our approaches estimate the posterior of the latent function more accurately than the MCMC while enjoying the benefits of the GP to account for uncertainty in the hazard modeling and relaxing the time-covariates factorized assumption of the CoxPH model.

Table 2: (Real datasets) Average test prediction performance. Our variational approximation approaches,  $VI_{PI}$  and  $VI_{RF}$ , adopt the number of pseudo inputs  $M = 20$  and random features  $m = 50$ , respectively. Best method in terms of the average value is boldfaced. Figures in parentheses indicate the  $p$ -values from the Wilcoxon signed rank test against the best (boldfaced) approaches.

SVRC	55.36 $\pm$ 9.66 (0.0020)	1.10 $\pm$ 1.68 (0.0020)	54.93 $\pm$ 17.65 (0.0039)	2.61 $\pm$ 2.74 (0.2324)	54.43 $\pm$ 10.88 (0.0059)	1.14 $\pm$ 1.19 (0.3223)
MINLIP	65.64 $\pm$ 9.79 (0.0098)	2.59 $\pm$ 3.23 (0.1309)	68.60 $\pm$ 9.28 (0.2754)	3.18 $\pm$ 3.03 (0.8457)	51.75 $\pm$ 5.38 (0.0039)	0.60 $\pm$ 0.96 (0.1602)
Model2	57.40 $\pm$ 10.82 (0.0039)	1.59 $\pm$ 2.07 (0.0020)	68.81 $\pm$ 8.06 (0.1934)	3.19 $\pm$ 3.02 (0.6953)	55.83 $\pm$ 10.45 (0.0195)	0.69 $\pm$ 0.74 (0.2324)

Next we compare running times. To see the effect of the approximation model complexity on the inference time, we vary the parameters in model learning. Specifically,  $M$  is chosen from  $\{10, 20, 40, 60, 80\}$  for  $VI_{PI}$  and  $m$  is from  $\{5, 10, 20, 30, 50\}$  for  $VI_{RF}^f$  and also the MCMC method (Fernández et al., 2016) that employs the random feature approximation. All methods are implemented in MATLAB run on 2.4GHz Intel Xeon CPU. The results on the MLC dataset are visualized in Fig. 1. Results demonstrate that our variational methods are an order of magnitude faster than the MCMC while achieving comparable or often superior prediction performance. For other datasets, refer to Appendix B in the supplemental material. Finally, the test log-likelihood scores of the attained models are depicted in Table 3. Considering we report lower VI bounds of the log-likelihoods, all proposed methods exhibit comparable, or superior, generalization performance to that of the MCMC.

## 5 CONCLUSION

We have proposed a family of novel and highly scalable variational inference methods for the Gaussian process

Table 3: Average test log-likelihood scores attained by  $VI_{PI}$  ( $M = 20$ ),  $VI_{RF}$  ( $m = 50$ ), and the MCMC.

Datasets	Synthetic	VLC	MLC	Divorce
$VI_{PI}^f$	-36.40	-31.50	-40.00	-80.31
$VI_{PI}^p$	-41.13	-35.00	-41.78	-84.10

## Abstract

We propose a cost-effective framework for preference elicitation and aggregation under the Plackett-Luce model with features. Given a budget, our framework iteratively computes the most cost-effective elicitation questions in order to help the agents make a better group decision.

We illustrate the viability of the framework with experiments on Amazon Mechanical Turk, which we use to estimate the cost of answering different types of elicitation questions. We compare the prediction accuracy of our framework when adopting various information criteria that evaluate the expected information gain from a question. Our experiments show carefully designed information criteria are much more efficient, i.e., they arrive at the correct answer using fewer queries, than randomly asking questions given the budget constraint.

## 1 INTRODUCTION

Consider the hiring decision problem [Bhattacharjya and Kephart, 2014]. With the aid of an intelligent system, a group of people (the *key group*) faces a hiring decision about many candidates who are characterized by attributes, such as experiences, technical skills, communication skills, etc. The goal is to help the key group make a group decision without directly eliciting their full preferences over all candidates, which is often infeasible given the vast number of candidates. Instead, the intelligent system may ask fellow employees (the *regular group*) about their preferences in order to learn about the key group’s preferences. How can the intelligent system decide which member in the regular group to ask and

which questions to ask? Note that we discuss the presence of two groups but our framework is applicable when there is only one group of decision makers as well.

This example illustrates the *preference elicitation* problem, which has been widely studied in the field of recommender systems [Loepp et al., 2014], healthcare [Chajewska et al., 2000, Weernink et al., 2014, Erdem and Campbell, 2017], marketing [Huang and Luo, 2016], stable matching [Drummond and Boutilier, 2014, Rastegari et al., 2016], combinatorial auctions [Sandholm and Boutilier, 2006], etc. Most previous works studied a special case of the aforementioned scenario, in which the regular group is the key group. The objective of preference elicitation is to achieve some goal using as few samples (data) as possible. A common approach is to adaptively ask questions that maximize expected information gain, measured by some information criteria.

Moreover, most previous work focused on specific types of elicitation questions, e.g. pairwise comparisons. In this paper, we consider a more general framework that asks a variety of elicitation questions and can accommodate one or more groups. The diversity of elicitation questions enables us to query cost-effectively. Intuitively, an agent’s preference order over 10 alternatives tells us more about her preference in general than just her top choice among the 10; however, it may take her longer to do so. The key question we want to answer in this paper is:

*How can we compute the most cost-effective questions for preference elicitation under resource constraints?*

### 1.1 OUR CONTRIBUTIONS

We propose a flexible cost-effective preference elicitation and aggregation framework to predict a single agent’s preference or help make a group decision. The main inputs include a budget  $W$ , a set of designs (i.e. questions to ask)  $\mathcal{H}$ , a cost function  $w$ , a randomized

voting rule and an information criterion. We model non-deterministic preferences using the Plackett-Luce model with features.

**Cost-effectiveness.** We propose a flexible, cost-effective preference elicitation framework that accommodates all randomized voting rules, ranking models, and information criteria. This iterative framework leverages the *optimal design* technique. In each iteration, we choose the question that provides the most information per unit cost. The response is then recorded as a data point, leading to an update of the posterior distribution of the parameter, which is treated as the prior for the next iteration. In any iteration, the posterior estimate of the parameter can be used to compute a winner distribution using a randomized voting rule. This procedure is illustrated in Figure 1.

Figure 1: Illustration of the proposed framework.

**Randomized Voting Rules.** We use randomized voting rules to compute the winning alternatives of a group decision, which outputs the distribution of winners (see Section 4 for details). The probability for each alternative to be the winner is proportional to its score based on the voting rule. These probability estimates are more informative than only recommending a winner as it provides a distribution over the candidates as well.

We prove that when people have non-deterministic preferences, the probability of an alternative to be the winner is proportional to the total expected score of this alternative for all agents (Theorem 1). This means the randomized counterpart of any scoring rule can be used in our framework as long as the expected score of each alternative for a single agent is easy to compute. Then we prove that under the Plackett-Luce model, the winner distributions of probabilistic plurality and probabilistic Borda are easy to compute (Corollary 1 and Theorem 2).

**Information Criteria.** An information criterion plays a key role in determining the next elicitation question by measuring the information in the distribution of a parameter. We propose the minimum pairwise certainty

(MPC) criterion, extended from the information criterion by Azari Soufiani et al. [2013], which maximizes the improvement of the least certain pairwise comparison. Other commonly-used information criteria include D-optimality [Wald, 1943, Mood et al., 1946] and E-optimality [Ehrenfeld, 1955], as well as asking a question uniformly at random. All these information criteria are based on the information of the posterior distribution of the model parameter, which is approximated by its asymptotic distribution, a multivariate Gaussian computed based on the composite marginal likelihood method [Pauli et al., 2011].

**Empirical Studies & Experiments.** We carry out Amazon Mechanical Turk experiments to estimate the cost of answering various types of questions for a target domain of ranking hotels. We compare the performances of MPC, D-optimality and E-optimality with simulations and observe that these criteria have similar performance in terms of prediction accuracy, and we observe that all of them significantly outperform random elicitation questions.

## 1.2 RELATED WORK AND DISCUSSIONS

Our work is related to cost-effective experimental designs, which were investigated by Wright et al. [2010], Volkov [2014] in the context of aquatic toxicology and drug development, respectively. Volkov [2014] modeled cost-effectiveness as different types of optimization problems, e.g., minimize cost under information constraints. We take a greedy approach, similar to an algorithm proposed by Wright et al. [2010], and choose the design (elicitation question) that maximizes the expected information gain per unit cost. Our cost varies depending on the type of questions and is estimated empirically, similar to the idea in Volkov [2014]. To our best knowledge, this paper is the first work to apply cost-effective experimental design to preference elicitation.

The greedy approach is also called one-step-lookahead policy, which can be arbitrarily worse than optimal  $t$ -step-lookahead ( $t$ -step myopic active search) policies for  $t \geq 2$  [Garnett et al., 2012]. Arbitrary  $t$ -step myopic active search is hard to compute, as was shown by Jiang et al. [2017], which also proved that nonmyopic active search is computationally hard even to approximate and proposed an efficient searching algorithm. This algorithm is potentially useful in the preference elicitation context and is an interesting future direction.

Most previous works in preference elicitation assumed that people’s preferences are deterministic. For example, Bhattacharjya and Kephart [2014] proposed an even swap algorithm to reveal a single decision maker’s most

preferred alternative; Lu and Boutilier [2011a], Kalech et al. [2011] elicited preferences from a group of people in order to make a group decision under a (deterministic) voting rule. In contrast, we consider non-deterministic preferences of people, which is often the case in real-world. Moreover, we use randomized voting rules, which output the probability of each alternative to be the winner. These probabilities, which can be viewed as normalized scores over all alternatives, provide a quantitative measure of the quality of each alternative. For example, an alternative that wins with probability 0.8 can be seen as being much better than other alternatives.

Non-deterministic preferences were modeled by general random utility models by Azari Soufiani et al. [2013]. They proposed a preference elicitation framework for personalized choice and social choice (aggregated preference). We use the Plackett-Luce model with features, which is a special case of general random utility models but has easy-to-compute probabilities. More importantly, we use randomized voting rules for aggregation, which is very different from parametric modeling of social choices employed by [Azari Soufiani et al., 2013].

Pairwise elicitation questions may be the most widely explored in the literature due to their simplicity [Branke et al., 2017, Eric et al., 2008, Houlby et al., 2012, Lu and Boutilier, 2011a, Pfeiffer et al., 2012]. In contrast, Azari Soufiani et al. [2013] focused on elicitation of full rankings, though their proposed framework also allows for partial orders. Drummond and Boutilier [2014], Lu and Boutilier [2011b] studied a larger set of queries, which includes asking a person to rank her top  $k$  choices over all alternatives. In this paper, we consider an even broader set of queries, asking an agent to rank her top  $k$  choices over a subset of  $l$  alternatives ( $k < l$ ). This enables us to elicit preferences in a more cost-effective manner.

As a key role in preference elicitation, information criteria have been widely investigated for different applications. Standard information criteria include D-optimality (used in [Houlby et al., 2011, 2012, Pfeiffer et al., 2012]) and E-optimality. Drummond and Boutilier [2014] and Lu and Boutilier [2011a] use minimax-regret-based criterion for stable matching and aggregation respectively. Azari Soufiani et al. [2013] proposed yet another criterion, defined on the certainty of the least certain pairwise comparison over the intrinsic utilities (part of the parameter of their general random utility models) of all alternatives. Our MPC criterion extends the criterion by Azari Soufiani et al. [2013]. To predict a single agent's top  $k$  preference, we search over a subset of all pairwise comparisons (see Section 3.3). To help make a group decision, we search over all pairwise comparisons

of all agents in the key group to find the least certain pairwise comparison (Equation (3)).

## 2 PRELIMINARIES

Let  $\mathcal{A} = \{a_1, a_2, \dots, a_m\}$  denote a set of  $m$  alternatives and  $\{1, \dots, n_1, n_1 + 1, \dots, n_1 + n_2\}$  denote  $n_1 + n_2$  agents, where the first  $n_1$  agents belong to the key group, who will be making a group decision. The remaining  $n_2$  agents belong to the regular group. For all  $i = 1, \dots, m$ ,  $a_i$  is characterized by a real-valued column vector of  $K$  attributes  $\vec{z}_i$ . For all  $j = 1, \dots, n_1 + n_2$ , agent  $j$  is characterized by a real-valued column vector of  $L$  attributes  $\vec{x}_j$ . A full ranking  $R$  is often denoted by  $a_{i_1} \succ a_{i_2} \succ \dots \succ a_{i_m}$ , where “ $\succ$ ” means “is preferred over”. We denote the budget by  $W$ , where the money is used to pay the agents for answering elicitation questions.

For  $n_1 = 1$ , we want to predict the single key agent's full or top  $k$  ranking with as much certainty as possible given a budget  $W$ . For  $n_1 \geq 2$ , the goal is to predict the winning alternative of the key group by eliciting preferences from the regular group in the most cost-effective way. More concretely, given  $W$ , we want to output a distribution of winning alternatives, w.r.t. a randomized voting rule, which will be defined in Section 4.

### 2.1 THE PLACKETT-LUCE MODEL WITH FEATURES

Let the parameter  $B = [b_{\kappa l}]_{K \times L}$  be a matrix of real-valued coefficients, transforming features to utilities. Each value  $b_{\kappa l}$  corresponds to the  $\kappa$ -th attribute from an alternative and  $l$ -th attribute from an agent. The parameter space  $\Theta$  is a set of all real-valued  $K \times L$  matrices. Then the utility of an alternative  $a_i$  to an agent  $j$  is

$$u_{ji} = \vec{x}_j^\top B \vec{z}_i. \quad (1)$$

For any agent  $j$  and any full ranking  $R_j = a_{i_1} \succ a_{i_2} \succ \dots \succ a_{i_m}$ , the probability of  $R_j$  is

$$\Pr(R_j) = \frac{\exp(u_{ji_1})}{\sum_{q=1}^m \exp(u_{ji_q})} \times \frac{\exp(u_{ji_2})}{\sum_{q=2}^m \exp(u_{ji_q})} \times \dots \times \frac{\exp(u_{ji_{m-1}})}{\exp(u_{ji_{m-1}}) + \exp(u_{ji_m})}.$$

Given the Plackett-Luce model with features, the probability of alternative  $a_{i_1}$  to be ranked at the top among  $\{a_{i_1}, \dots, a_{i_m}\}$  by agent  $j$  is  $\frac{\exp(u_{ji_1})}{\sum_{q=1}^m \exp(u_{ji_q})}$ . Specifically, for any two alternatives  $a_1$  and  $a_2$ , the probability of  $a_1 \succ a_2$  by agent  $j$  is  $\frac{\exp(u_{j1})}{\exp(u_{j1}) + \exp(u_{j2})}$ .

## 2.2 ONE-STEP BAYESIAN EXPERIMENTAL DESIGN

Given any probabilistic model parameterized by  $B \in \Theta$  and any prior distribution  $\pi(B)$ , a one-step Bayesian experimental design consists of two parts: (i) a set of designs  $\mathcal{H}$ , where each  $h \in \mathcal{H}$  is composed of an agent and a question; (ii) an information measure  $G(\cdot)$ , which maps any distribution of  $B$  over  $\Theta$  to a real-valued scalar: a measure of information in this distribution.

For any design  $h \in \mathcal{H}$ , the distribution of responses can be computed using the ground truth parameter  $B^*$ . We use  $D$  to denote the set of all possible responses. Given a ground truth parameter  $B^*$ , the probability of any data  $d \in D$  can be computed as  $\Pr(d|h)$ . Further, we can compute the posterior distribution of parameter  $\pi(B|d, h)$  over the parameter space  $\Theta$  and the corresponding information criterion  $G(\pi(B|d, h))$ . The expected information is

$$E[G(\pi(B|h))] = \sum_{d \in D} G(\pi(B|d, h)) \Pr(d|h),$$

where the expectation is taken over all possible responses. The goal is to find the design  $h$  that maximize the expected information gain, which is  $E[G(\pi(B|h))] - G(\pi(B))$ , per unit cost. Let  $w(h)$  denote the cost function, which maps the 2-tuple (agent, question) to a positive cost. Given the cost function  $w(h)$ , we can compute the optimal design  $h^*$  that maximizes the expected information gain per unit cost by

$$h^* = \arg \max_h \frac{E[G(\pi(B|h))] - G(\pi(B))}{w(h)}. \quad (2)$$

## 3 COST-EFFECTIVE PREFERENCE ELICITATION

In our proposed framework, we iteratively adapt the one-step experimental design by querying the most cost-effective question in each iteration. At any iteration  $t$ , the prior distribution of  $B$  is the posterior distribution given data  $D^t$ , i.e.  $\pi(B^t|D^t)$ . Given this posterior, we find the most cost-effective design  $h^t$ , which consists of one agent and one question, and query  $h^t$ . The response is combined with  $D^t$  to form  $D^{t+1}$ . Then the budget  $W$  and the set of designs  $\mathcal{H}$  are updated before going to the next iteration. Finally, when  $n_1 = 1$ , we compute the predicted preference of this agent; when  $n_1 \geq 2$ , we compute the distribution of winners based on a randomized voting rule. This framework is formally illustrated in Algorithm 1.

For the rest of this section, we will explain how to approximate the posterior distribution  $\pi(B^t|D^t)$  and how  $G(\pi(B))$  is computed.

---

### Algorithm 1 Cost-Effective Preference Elicitation

---

**Input:** Budget  $W$ , randomize voting rule  $r$ , cost function  $w(h)$ , information criterion  $G(\pi(B))$ , the set of designs  $\mathcal{H}$  where for any  $h \in \mathcal{H}$ ,  $w(h) \leq W$ .

**Output:** A predicted preference when  $n_1 = 1$  or a distribution of winning alternatives for group decision when  $n_1 \geq 2$ .

**Initialization:** Randomly initialize data  $D^1$ .

**while**  $\mathcal{H}$  is not empty **do**

    Compute/approximate  $\pi(B^t|D^t)$ ;

    Compute  $h^t \in \mathcal{H}$  using (2);

    Implement  $h^t$  (query an agent a question). Let  $R^t$  denote her answer. Then  $D^{t+1} \leftarrow D^t \cup \{R^t\}$ ,  $\mathcal{H} \leftarrow \mathcal{H} - h^t$ ,  $W \leftarrow W - w^t$ ;

    Remove all  $h^t$ 's from  $\mathcal{H}$  where  $w(h^t) > W$ .

**end while**

Compute the predicted preference when  $n_1 = 1$  or a distribution of winning alternatives according to the voting rule  $r$  when  $n_1 \geq 2$ .

---

## 3.1 APPROXIMATION OF POSTERIOR DISTRIBUTION

For any prior  $\pi(B)$  and data  $D$ , the posterior distribution is given by  $\pi(B|D) = \frac{\Pr(D|B)\pi(B)}{\int_{\Theta} \Pr(D|B)\pi(B)dB}$  according to Bayes' rule. This posterior is often hard to compute. A commonly-used approach is to approximate it by its asymptotic distribution, which is a multivariate Gaussian distribution characterized by the composite marginal likelihood (CML) method [Pauli et al., 2011].

For convenience we vectorize  $B$  as a column vector, denoted by  $\vec{\beta} = \text{vec}(B)$ . The composite marginal likelihood method [Lindsay, 1988, Zhao and Xia, 2018] computes the estimate of the ground truth parameter from marginal events, e.g., pairwise comparisons. Let  $\{\mathcal{E}_1, \dots, \mathcal{E}_q\}$  denote  $q$  selected marginal events. Then the composite marginal likelihood method computes the estimate  $\vec{\beta}_{\text{CML}}$  by

$$\vec{\beta}_{\text{CML}} = \arg \max_{\vec{\beta} \in \Theta} \text{CLL}(\vec{\beta}) = \arg \max_{\vec{\beta} \in \Theta} \sum_{\lambda=1}^q \ln \Pr(\mathcal{E}_\lambda | \vec{\beta}),$$

where  $\text{CLL}(\vec{\beta})$  denotes the composite log-likelihood function. Under our Plackett-Luce model with features,  $\text{CLL}(\vec{\beta})$  is twice differentiable for all  $\vec{\beta} \in \Theta$ , i.e.  $J(\vec{\beta}) = -\nabla_{\vec{\beta}}^2 \text{CLL}(\vec{\beta})$  exists. From Pauli et al. [2011], asymptotically,  $\pi(\vec{\beta}|D)$  is a multivariate Gaussian distribution, whose mean is  $\vec{\beta}_{\text{CML}}$  and covariance matrix is  $J^{-1}(\vec{\beta})$ .

Computing  $J(\vec{\beta})$  requires computation of second order partial derivatives of  $\ln \Pr(\mathcal{E}_\lambda | \vec{\beta})$  for all  $\lambda$ . We will show the close-form second order partial derivative formula for

any response from an agent.

### 3.2 THE SET OF DESIGNS

Each design  $h \in \mathcal{H}$  is a combination of an agent and a question about her preferences. The agent can be anyone from  $\{1, \dots, n_1 + n_2\}$ . In this paper, for simplicity, we consider the case where only the agents from the regular group  $\{n_1 + 1, \dots, n_1 + n_2\}$  are queried. For any integers  $k < l \leq m$ , we may ask an agent to rank her top  $k$  alternatives over a subset of  $l$  alternatives. When  $k = 1, l = 2$ , the question is a pairwise comparison; when  $k = 1, l > 2$ , the question is to query an agent's top alternative among a subset of alternatives; when  $k = l - 1$ , we are asking a full ranking over a subset of alternatives. The advantage of this type of questions is that the probabilities of responses of these questions are easy to compute, as well as their partial derivatives. W.l.o.g. let  $R_j = a_1 \succ a_2 \succ \dots \succ a_k \succ \text{others}$  be the answer from agent  $j$ . Then we have  $\Pr(R_j|B) = \prod_{p=1}^k \frac{\exp(u_{jp})}{\sum_{i=p}^l \exp(u_{ji})}$ , and  $\ln \Pr(R_j|B) = \sum_{p=1}^k (u_{jp} - \ln \sum_{i=p}^l \exp(u_{ji}))$ .

For any  $1 \leq \kappa \leq K$  and  $1 \leq \iota \leq L$ , let  $b_{\kappa\iota}$  be the  $(\kappa, \iota)$  entry of  $B$ . We have

$$\frac{\partial \ln \Pr(R_j|B)}{\partial b_{\kappa\iota}} = \sum_{p=1}^k \left( \frac{\partial u_{jp}}{\partial b_{\kappa\iota}} - \frac{\sum_{i=p}^l \exp(u_{ji}) \frac{\partial u_{ji}}{\partial b_{\kappa\iota}}}{\sum_{i=p}^l \exp(u_{ji})} \right),$$

where  $\frac{\partial u_{jp}}{\partial b_{\kappa\iota}}$  and  $\frac{\partial u_{ji}}{\partial b_{\kappa\iota}}$  are constants (products of an agent's attribute and an alternative's attribute) by definition. Therefore, for diagonal entries, the second order partial derivatives are given by

$$\frac{\partial^2 \ln \Pr_j(R|B)}{\partial b_{\kappa\iota}^2} = \sum_{p=1}^k \left( \left( \frac{\sum_{i=p}^l \exp(u_{ji}) \frac{\partial u_{ji}}{\partial b_{\kappa\iota}}}{\sum_{i=p}^l \exp(u_{ji})} \right)^2 - \frac{\sum_{i=p}^l \exp(u_{ji}) \left( \frac{\partial u_{jp}}{\partial b_{\kappa\iota}} \right)^2}{\sum_{p=1}^l \exp(u_{jp})} \right),$$

and for non-diagonal entries, we have

$$\begin{aligned} & \frac{\partial^2 \ln \Pr_j(R|B)}{\partial b_{\kappa_1 \iota_1} \partial b_{\kappa_2 \iota_2}} \\ &= \sum_{p=1}^k \left( \frac{(\sum_{i=p}^l \exp(u_{ji}) \frac{\partial u_{ji}}{\partial b_{\kappa_1 \iota_1}}) (\sum_{i=p}^l \exp(u_{ji}) \frac{\partial u_{ji}}{\partial b_{\kappa_2 \iota_2}})}{(\sum_{i=p}^{m'} e^{u_{ji}})^2} \right. \\ & \left. - \frac{\sum_{i=p}^l \exp(u_{ji}) \left( \frac{\partial u_{ji}}{\partial b_{\kappa_1 \iota_1}} \right) \left( \frac{\partial u_{ji}}{\partial b_{\kappa_2 \iota_2}} \right)}{\sum_{i=p}^l \exp(u_{ji})} \right). \end{aligned}$$

### 3.3 INFORMATION CRITERIA

An information criterion maps the distribution of a parameter to a real-valued quality. Standard information

criteria are mostly directly computed from the covariance matrix  $J^{-1}(\vec{\beta})$  or its inverse  $J(\vec{\beta})$ . For example, D-optimality [Wald, 1943, Mood et al., 1946] computes the determinant of  $J(\vec{\beta})$ ; E-optimality [Ehrenfeld, 1955] computes the minimum eigenvalue of  $J(\vec{\beta})$ . We propose the following minimum pairwise certainty (MPC) criterion by extending the criterion from [Azari Soufiani et al., 2013] to our domain.

**MPC for Case  $n_1 = 1$ .** We consider two types of purposes: predicting the agent's (unordered) top  $k$  alternatives and predicting the agent's ranked top  $k$  alternatives. We note that the criterion by Azari Soufiani et al. [2013] only applies to full rankings, which is a special case of our ranked top  $k$ . The intuition of this criterion is to maximize the certainty of the least certain pairwise comparison among a subset of pairwise comparisons. Formally, let  $\mathcal{A}_k$  denote the set of predicted top  $k$  alternatives for this key agent.

- Unordered top- $k$  where  $1 \leq k < m$ :

$$G(\pi(\vec{\beta})) = \min_{i_1 \in \mathcal{A}_k, i_2 \notin \mathcal{A}_k} \frac{|\text{mean}(u_{1i_1} - u_{1i_2})|}{\text{std}(u_{1i_1} - u_{1i_2})}.$$

- Ranked top- $k$  where  $1 < k < m$ :

$$G(\pi(\vec{\beta})) = \min_{i_1 \in \mathcal{A}_k, i_2 \neq i_1} \frac{|\text{mean}(u_{1i_1} - u_{1i_2})|}{\text{std}(u_{1i_1} - u_{1i_2})}.$$

In the above equations,  $\text{mean}(u_{ji_1} - u_{ji_2})$  is computed using  $\vec{\beta}_{\text{CML}}$  and  $\text{std}(u_{ji_1} - u_{ji_2})$  is computed using the approximated covariance matrix  $J^{-1}(\vec{\beta})$  as follows.

Because  $u_{ji_1} - u_{ji_2}$  is linear with  $\vec{\beta}$  (see Equation (1) and recall that  $\vec{\beta}$  is the vectorization of  $B$ ), we write it as  $u_{ji_1} - u_{ji_2} = \sum_{\kappa, \iota} c_{\kappa\iota} b_{\kappa\iota}$ , where  $c_{\kappa\iota}$ 's are constants computed from attributes of  $a_{i_1}, a_{i_2}$  and agent  $j$ . Then we have  $\text{std}(u_{ji_1} - u_{ji_2}) = \sqrt{\sum_{(\kappa_1, \iota_1), (\kappa_2, \iota_2)} c_{\kappa_1 \iota_1} c_{\kappa_2 \iota_2} \text{Cov}(b_{\kappa_1, \iota_1}, b_{\kappa_2, \iota_2})}$ . When  $\kappa_1 = \kappa_2 = \kappa$  and  $\iota_1 = \iota_2 = \iota$ ,  $\text{Cov}(b_{\kappa_1, \iota_1}, b_{\kappa_2, \iota_2})$  reduces to  $\text{Var}(b_{\kappa\iota})$ . Both  $\text{Cov}(b_{\kappa_1, \iota_1}, b_{\kappa_2, \iota_2})$  and  $\text{Var}(b_{\kappa\iota})$  are entries of  $J^{-1}(\vec{\beta})$ .

**MPC for Case  $n_1 \geq 2$ .** Our MPC for this case is different from the criterion by Azari Soufiani et al. [2013] in that we find the least certain pairwise comparison across all agents in the key group. Formally, our MPC for  $n_1 \geq 2$  is

$$G(\pi(\vec{\beta})) = \min_{j \in \{1, \dots, n_1\}, i_2 \neq i_1} \frac{|\text{mean}(u_{ji_1} - u_{ji_2})|}{\text{std}(u_{ji_1} - u_{ji_2})}, \quad (3)$$

where the computation of  $\text{mean}(u_{ji_1} - u_{ji_2})$  and  $\text{std}(u_{ji_1} - u_{ji_2})$  are similar to the  $n_1 = 1$  case.

## 4 RANDOMIZED VOTING RULES

We use randomized voting rules to aggregate the key group's preferences. A randomized voting rule computes the distribution of winners given the preferences of the agents from the key group. Under non-deterministic preferences, this distribution can be computed from the parameter of the model. This section shows that under the Plackett-Luce model with features, probabilistic plurality and probabilistic Borda are easy to compute.

A randomized voting rule assigns a probability for each alternative to be the winner according to the data, usually based on a scoring function. For example, the probabilistic plurality rule, which is equivalent to random dictatorship [Gibbard, 1977], samples a winner from a distribution where the probability of each alternative being the winner is proportional to the plurality score of this alternative. Other randomized voting rules can be defined similarly, including probabilistic Borda [Heckelman, 2003]. The voting rule must have scores associated with it, but this is a very mild restriction because many commonly-studied voting rules including all positional scoring rules, Copeland, range voting, and approval voting, have randomized counterparts.

Recall that  $n_1$  agents are making a group decision among  $m$  alternatives. Let  $P$  denote the preference profile that consists of  $n_1$  full rankings over  $m$  alternatives from the key group. Let  $s_r(a_i, P)$  denote the score of alternative  $a_i$  under voting rule  $r$  and  $\Pr_r(a_i|P)$  be the probability for  $a_i$  to win under the randomized analogy of  $r$  given  $P$ . Then  $\Pr_r(a_i|P)$  is computed by  $\Pr_r(a_i|P) = \frac{s_r(a_i, P)}{\sum_{i=1}^m s_r(a_i, P)}$ .

**Example 1** Suppose the set of alternatives is  $\{a_1, a_2, a_3\}$  and the votes are  $\{a_1 \succ a_2 \succ a_3, a_1 \succ a_3 \succ a_2, a_2 \succ a_1 \succ a_3\}$ . The plurality and Borda scores are shown in Table 1. Under probabilistic plurality rule,  $a_1$  wins with probability  $2/3$  and  $a_2$  wins with probability  $1/3$ . Under probabilistic Borda,  $a_1, a_2, a_3$  win with probabilities  $5/9, 3/9, 1/9$  respectively.

	$a_1$	$a_2$	$a_3$
plurality	2	1	0
Borda	5	3	1

Table 1: Scores under plurality and Borda

We consider non-deterministic preferences from agents, where the preferences from the key agents are independent of each other. Because each agent has  $m!$  possible rankings, there are  $(m!)^{n_1}$  possible preference profiles. Then we have  $\Pr_r(a_i) = \sum_{q=1}^{(m!)^{n_1}} \Pr(P_q) \Pr_r(a_i|P_q)$ ,

where  $P_q$  denotes the  $q$ -th possible preference profile.

Given a voting rule  $r$ , let  $X_{ji}$  be the score of  $a_i$  for agent  $j$ .  $X_{ji}$  is a random variable due to the uncertainty of agent  $j$ 's preference. The following theorem shows that the probability of  $a_i$  being the winner is proportional to the sum of expected score of  $a_i$  for each agent.

**Theorem 1** For any  $1 \leq i \leq m$ ,  $\Pr_r(a_i) \propto \sum_j^{n_1} EX_{ji}$ .

**Proof:** It suffices to prove  $\Pr_r(a_1) \propto \sum_j^{n_1} EX_{j1}$ .

By definition,  $\Pr_r(a_1) = \sum_{q=1}^{(m!)^{n_1}} \Pr(P_q) \Pr_r(a_1|P_q)$ . Let  $S$  denote the score of  $a_1$  under rule  $r$ . Then  $S$  is a random variable defined over the  $(m!)^{n_1}$  cases. Let  $s_q$  denote the value that  $S$  takes for case  $q$ . In any case  $q$ , we have  $\Pr_r(a_1|P_q) \propto s_q$  by the definition of randomized voting rules. We re-write it as  $\Pr_r(a_1|P_q) = \frac{s_q}{M}$ , where  $M$  is the normalization factor. Observe that across all the  $(m!)^{n_1}$  cases,  $M$  does not change because the voting rule  $r$  and the set of agents does not change. So we have

$$\begin{aligned} \Pr_r(a_1) &= \frac{\sum_{q=1}^{(m!)^{n_1}} \Pr(P_q) s_q}{M} \\ &\propto \sum_{q=1}^{(m!)^{n_1}} \Pr(P_q) s_q = ES. \end{aligned} \quad (4)$$

Since  $S = \sum_{j=1}^{n_1} X_{j1}$ , due to linearity of expectation, we have  $ES = E[\sum_{j=1}^{n_1} X_{j1}] = \sum_j^{n_1} EX_{j1}$ . By (4), we have  $\Pr_r(a_1) \propto \sum_j^{n_1} EX_{j1}$ . ■

For probabilistic plurality, the expected score of  $a_i$  for agent  $j$  is exactly the probability of  $a_i$  being ranked at the top by agent  $j$ . So we have the following corollary:

**Corollary 1** Let  $p_j^{a_i}$  be the probability of  $a_i$  being ranked at the top by agent  $j$ . For any  $1 \leq i \leq m$ ,  $\Pr_{\text{plurality}}(a_i) = \frac{1}{n_1} \sum_j^{n_1} p_j^{a_i}$ .

**Theorem 2** Let  $p_j^{a_i \succ a_{i'}}$  denote the probability for agent  $j$  to prefer alternative  $a_i$  over  $a_{i'}$ . Then for any  $1 \leq i \leq m$ ,  $\Pr_{\text{Borda}}(a_i) \propto \sum_j^{n_1} \sum_{i' \neq i} p_j^{a_i \succ a_{i'}}$ .

**Proof:** For any  $i \in \{1, \dots, m\}$ , we have  $\Pr_{\text{Borda}}(a_i) \propto \sum_j^{n_1} EX_{ji}$  by Theorem 1, where  $X_{ji}$  here denotes the score of  $a_i$  for agent  $j$  under Borda. We only need to prove  $EX_{ji} = \sum_{i' \neq i} p_j^{a_i \succ a_{i'}}$ . This is a known result, but we were not able to find a formal proof in literature, except a proof for three alternatives by Chen and Heckelman [2005], which is easy to be extended for arbitrary number of alternatives. For completeness we provide a short proof.

By definition of Borda, we have  $EX_{ji} = \sum_{k=1}^{m-1} (m-k) \sum_{R: a_i \text{ at } k\text{th position of } R} \Pr_j(R)$ , where  $R$  is any full

ranking over the  $m$  alternatives and  $\Pr_j(R)$  is the probability of  $R$  by agent  $j$ . Imagine  $m-1$  bins, each of which is labeled with  $a_i \succ a_{i'}$  for all the remaining  $m-1$   $a_{i'}$ 's. Observe that there are  $m-k$  copies of  $\Pr_j(R)$  for all  $R$  where  $a_i$  beats exactly  $m-k$  other alternatives. We can distribute the  $m-k$  copies to the  $m-k$  bins (one in each) for all  $a_{i'}$ 's that are ranked after  $a_i$ . We do this for all possible rankings and in the end, each bin labeled by  $a_i \succ a_{i'}$  gets the probabilities of all rankings compatible with  $a_i \succ a_{i'}$ . This finishes the proof. ■

We note that for the Plackett-Luce model,  $p_j^{a_i}$ 's and  $p_j^{a_i \succ a_{i'}}$ 's are easy to compute (see Section 2.1).

## 5 EXPERIMENTS

We first introduce an example of empirically estimating the cost of asking different types of questions on MTurk. Then, we show the result of a simulation of cost-effective preference elicitation using synthetic data.

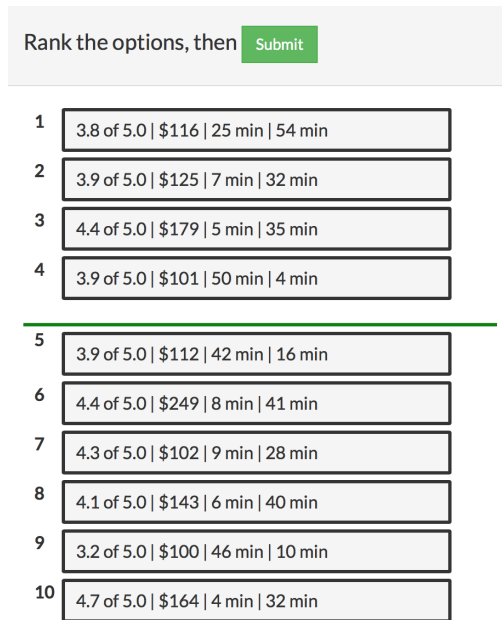

Figure 3: The user interface for a Turker to submit her ranked top 4 over 10 alternatives. The attributes are average ratings, prices per night, time to Times Square, and time to the nearest airport.

### 5.1 ESTIMATING $w(h)$

We recall that a question is defined by a pair of parameters  $(k, l)$ , where  $l$  is the number of alternatives that are presented to an agent and  $k$  is the number of alternatives that the agent is asked to rank at the top  $k$  positions.

In order to map the question types to the time to answer them, we run 2 experiments with multiple tasks on MTurk. Each task required MTurk workers to report their preferences over a set of hotels. We recorded the time they spent on each task, in order to learn such mapping in the following two cases:

- $k, l \in [2, 10], k = l - 1$ : full rankings;
- $k \in [1, 10], l = 10$ : ranked top  $k$  alternatives over 10.

**Experiment Setting.** For the first case, we looked for information on the first 54 Hotels in New York City in alphabetical order. We split the 54 randomly into 9 sets, each containing 2, 3, ..., 10 hotels. We then showed the 9 sets to MTurk workers, randomizing the order of the 9 sets as well as the initial display order of alternatives within each set, and asked them to rearrange by drag-and-dropping the alternatives according to their preferences. The alternatives were anonymous and represented by 4 attributes: average guest rating on a popular travel website, price per night, time to Times Square and time to the nearest airport.

For the second case, a separate experiment is run with another 10 sets of NYC hotels, drawn randomly again from the first 100 hotels in NYC in alphabetical order. In each task, we placed a horizontal green bar underneath the alternative above which are the  $k$  alternatives of interest. We instructed the MTurk workers before the experiment started that only the alternatives above the green bar would count, i.e. only needed to rank-order top- $k$ . All of these were done with goal of minimizing the overhead time for workers to understand the instruction so that the recorded time accurately reflect the time of decision-making. An example of the UI is show in Figure 3, where we asked Turkers to rank-order her top-4 favorite hotels over a set of 10.

The following analysis is made possible by responses from 408 MTurk workers (202 for the first case and 206 for the second).

**Experiment Results.** Although Volkov [2014] considered both linear and quadratic cost function and argued for the superiority of the latter, for simplicity, we perform a linear regression on the dataset to obtain a linear cost function. We regress the time to rearrange the alternatives and submit a full ranking on the number of alternatives in the set. We find that, on average, the time a Turker spent on rank-ordering a full ranking over  $l$  alternatives is  $t_{\text{full-}l} = 5.33l$  (Figure 2 left), and that on rank-ordering her top- $k$  alternatives over 10 alternatives is  $t_{\text{top-}k} = 1.38k + 32.25$  (Figure 2 right). In addition, the 408 workers spent an average of 341.5 seconds on the tasks and were each paid \$0.3. Therefore, the monetary cost of elicitation on average is  $w = 0.00088t$ , which correspond to an hourly wage of \$3.16.

Figure 2: The left subfigure shows the average time a user spent to submit a full ranking over 2, . . . , 10 alternatives; the right subfigure shows the average time a user spent to give her ranked top 1, . . . , 10 alternatives when 10 alternatives were proposed.

Combining these two functions with the hourly wage, we propose the following cost functions, which estimates the cost (in USD) of elicitation about hotel preferences given 4 alternative attributes:  $w_{\text{full-}l} = 0.0047l$  and  $w_{\text{top-}k} = 0.0012k + 0.028$ . We observe that the time a user spent is not very sensitive to  $k$ . This is sensible, as when a MTurk worker ranks her top  $k$  choices, she may follow the following procedure: 1. read the descriptions of all hotels, 2. form their preferences, and 3 choose top  $k$ . Step 1 and 2 do not depend on  $k$  and dominates the time for step 3, as illustrated in the right figure of Figure 2. This suggests that when a fixed number of alternatives is proposed to an agent, it’s likely that the most cost-effective question to ask is a full ranking, as we will see in the next subsection.

## 5.2 COST-EFFECTIVE PREFERENCE ELICITATION

We demonstrate the viability of our cost-effective framework and compare performances of different information criteria on synthetic data.

**Synthetic Data.** We randomly generated 10 alternatives, each of which has 3 attributes, independently normally distributed  $N(0, 1)$ . We then randomly generated 5 agents that forms the key group and 20 the regular group. Each agent also has 3 attributes, independently normally distributed  $N(0, 1)$ .  $B$  was generated from Dirichlet distribution  $\text{Dir}(\vec{1})$ . The result is averaged over 400 trials.

To echo the motivating example from the beginning of this paper, we simulated the process of eliciting key group’s preference by asking agents in the regular group questions. For simplicity, we consider 3 types of ques-

tions, represented in  $(k, l)$ :  $(1, 2)$ ,  $(1, 10)$  and  $(9, 10)$ . We run Algorithm 1 using 3 different information criteria: D-Optimality, E-Optimality, and the proposed MPC. The three elicitation processes utilized the cost function estimated in Section 5.1. They were initialized with the same set of 50 randomly generated pairwise comparisons and was given a \$0.9 budget. Agents’ answers to the elicitation questions are generated from the Plackett-Luce model.

**Metrics.** We use total variation distance to measure the difference between the winner distributions computed from the ground truth parameter and the estimates, denoted by  $\psi^*$  and  $\psi$  respectively. The total variance distance is defined as  $\delta(\psi^*, \psi) = \frac{1}{2} \sum_{i=1}^m |\psi^*(a_i) - \psi(a_i)|$ . To plot the results, at each cost  $w$ , we used the data point that is below  $w$  but closest to  $w$  in each trial. These points were averaged over all trials.

**Observations.** We observe that for both probabilistic plurality and probabilistic Borda, the performances of MPC, D-optimality, and E-optimality are similar, all of which significantly outperforms random elicitation questions (see Figures 4). For example, for probabilistic plurality and probabilistic Borda, at the budget of 0.85 dollars, MPC achieves 15% less total variation distance than that of random elicitation questions. As another example, to achieve the total variation distance of 0.064 under randomized plurality (respectively, randomized Borda), MPC uses 20% (23.5%) less money than that of random elicitation questions.

We also observe that D-optimality almost always choose a full ranking as the most cost-effective question, while MPC tends to choose more full rankings than pairwise comparisons at early stages (see Figure 5). Due to the budget limit, many trials finish after 19 iterations because

Figure 4: Total variation distance for probabilistic plurality (left) and probabilistic Borda (right).

Figure 5: Types of questions chosen by the MPC (left) and D-optimality (right). The legend “Full Ranking”, “Top Choice”, and “Pairwise” correspond to  $(k = 9, l = 10)$ ,  $(k = 1, l = 10)$  and  $(k = 1, l = 2)$  respectively.

they only query full rankings. Others finish at different iterations. The distribution of types of questions for E-optimality is similar to MPC. Under all criteria except random,  $l = 10, k = 1$  questions were rarely asked.

**Discussions.** The meaning of cost-effectiveness in this paper is twofold: (1) in the preference elicitation procedure, we ask elicitation questions that is expected to provide more information per unit cost; and (2) the presence of regular group gives us a belief on the key group’s preferences inexpensively. As we have seen in our experiments, a budget of \$0.9 gives us a reasonably good estimate of the key group’s preferences by querying the regular group.

## 6 CONCLUSIONS AND FUTURE WORK

We proposed a flexible and cost-effective framework for preference elicitation that can be adapted for any ranking

model, any information criterion, and any set of questions. We used randomized voting rules to help make group decisions and proposed MPC for both prediction of one agent’s preference and aggregation of a group of agents’ preferences. Experiments show that MPC and other commonly-used information criteria work better than asking random elicitation questions. For future work we will explore better information criteria for group decisions. We also plan to extend this framework to multiple types of resource constraints.

## Abstract

In learning-to-learn the goal is to infer a learning algorithm that works well on a class of tasks sampled from an unknown meta-distribution. In contrast to previous work on batch learning-to-learn, we consider a scenario where tasks are presented sequentially and the algorithm needs to adapt incrementally to improve its performance on future tasks. Key to this setting is for the algorithm to rapidly incorporate new observations into the model as they arrive, without keeping them in memory. We focus on the case where the underlying algorithm is Ridge Regression parametrised by a symmetric positive semidefinite matrix. We propose to learn this matrix by applying a stochastic strategy to minimize the empirical error incurred by Ridge Regression on future tasks sampled from the meta-distribution. We study the statistical properties of the proposed algorithm and prove non-asymptotic bounds on its excess transfer risk, that is, the generalization performance on new tasks from the same meta-distribution. We compare our online learning-to-learn approach with a state-of-the-art batch method, both theoretically and empirically.

## 1 INTRODUCTION

Learning-to-learn (LTL) or meta-learning aims at finding an algorithm that is best suited to address a class of learning problems (tasks). These tasks are sampled from an unknown meta-distribution and are only partially observed via a finite collection of training examples, see (Baxter, 2000; Maurer, 2005; Thrun & Pratt, 1998) and references therein. This problem plays a large role in artificial intelligence in that it can improve the efficiency

of learning from human supervision. In particular, substantial improvement over “learning in isolation” (also known as independent task learning, ITL) is to be expected when the sample size per task is small, a setting which naturally arises in many applications, see e.g. (Camoriano et al., 2017; Rebuffi et al., 2017; Rohrbach et al., 2013).

LTL is particularly appealing when considered from an online or incremental perspective. In this setting, which is sometimes referred to as lifelong learning, see e.g. (Ruvolo & Eaton, 2013), the tasks are observed sequentially – via corresponding sets of training examples – from a common environment and we aim to improve the learning ability of the underlying algorithm on future yet-to-be-seen tasks from the same environment. Practical scenarios of lifelong learning are wide ranging, including computer vision (Rebuffi et al., 2017), robotics (Camoriano et al., 2017), user modelling and many more.

Although LTL is naturally suited for the incremental setting, surprisingly, theoretical investigations are lacking. Previous studies, starting from the seminal paper (Baxter, 2000) and (Maurer, 2009; Maurer et al., 2013; 2016; Pentina & Lampert, 2014), have almost exclusively considered the setting in which the tasks are given in one batch, that is, the meta-algorithm processes multiple datasets from the environment jointly and only once as opposed to sequentially and indefinitely.

The papers (Balcan et al., 2015; Herbster et al., 2016) present results in an online framework which applies to a finite number of tasks using different performance measures. Perhaps most related to our work is (Alquier et al., 2017), where the authors consider a general PAC-Bayesian approach to lifelong learning based on the exponentially weighted aggregation procedure. Unfortunately, this approach is not efficient for large scale applications as it entails storing the entire sequence of datasets during the meta-learning process.

LTL also bears strong similarity to multi-task learning

(MTL), see e.g. (Caruana, 1997), and much work has been done on the theoretical study of both batch (Ando & Zhang, 2005; Maurer et al., 2013) and online (Cavallanti et al., 2010) multi-task learning algorithms. However multi-task learning aims to solve the different problem of learning well on a prescribed set of tasks (the learned model is tested on the same tasks used during training) whereas LTL aims to extrapolate to new tasks.

The principal contribution of this paper is to propose an incremental approach to learning-to-learn and to analyse its statistical guarantees. This incremental approach is appealing in that it efficiently processes one dataset at the time, without the need to store previously encountered datasets. We study in detail the case of linear representation learning, in which an underlying learning algorithm receives in input a sequence of datasets and incrementally updates the data representation so as to better learn future tasks. Following previous work on LTL, e.g. (Baxter, 2000; Maurer, 2009), we measure the performance of the incremental meta-algorithm by the *transfer risk*, namely the average error obtained by running the underlying algorithm with the learned representation, over tasks sampled from the meta-distribution.

Specifically, in this work we choose the underlying algorithm to be Ridge Regression parametrised by a symmetric positive semidefinite matrix. The incremental LTL approach we propose aims at optimizing the *future empirical error* (Maurer, 2009; Maurer et al., 2016) incurred by Ridge Regression over a class of linear representations. For this purpose, we propose to apply Projected Stochastic Subgradient Algorithm (PSSA). We show that the objective function of the resulting meta-algorithm is convex and we give a non-asymptotic convergence rate for the algorithm in high probability. A remarkable feature of our learning bound is that it is comparable to previous bounds for batch LTL. Our proof technique leverages previous work on learning-to-learn (Maurer, 2009) with tools from online convex optimization, see (Cesa-Bianchi et al., 2004; Hazan, 2016) and references therein.

The paper is organized as follows. In Sec. 2, we review the LTL problem and describe in detail the case of linear feature learning with Ridge Regression. In Sec. 3, we present our incremental meta-algorithm for linear feature learning. Sec. 4 contains our bound on the excess transfer risk for the proposed algorithm and in Sec. 5 we compare the bound to a previous bound for the batch setting. In Sec. 6, we report preliminary numerical experiments for the proposed algorithm and, finally, Sec. 7 summarizes the paper and highlight directions of future research. The detailed proofs of the statements in the paper are reported in the appendix.

## 2 PROBLEM FORMULATION

In the standard independent task learning setting the goal is to learn a functional relation between an input space  $\mathcal{X}$  and an output space  $\mathcal{Y}$  from a finite number of training examples. More precisely, given a loss function  $\ell : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$  measuring prediction errors and given a distribution  $\mu$  on the joint data space  $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$ , the goal is to find a function  $f : \mathcal{X} \rightarrow \mathcal{Y}$  minimizing the *expected risk*

$$\mathcal{R}_\mu(f) = \mathbb{E}_{z \sim \mu} \ell(f, z) \quad (1)$$

where, with some abuse of notation, for any  $z = (x, y) \in \mathcal{Z}$  we denoted  $\ell(f, z) = \ell(f(x), y)$ . In most practical situations the underlying distribution is *unknown* and the learner is only provided with a finite set  $Z = (z_i)_{i=1}^n \in \mathcal{Z}^n$  of observations independently sampled from  $\mu$ . The goal of a learning algorithm is therefore, given such a *training* dataset  $Z$  to return a “good” estimator  $A(Z) = f_Z$  whose expected risk is small and tends to the minimum of Eq. (1) as  $n$  increases.

A well-established approach to tackle the learning problem is offered by *regularized empirical risk minimization*. This corresponds to the family of algorithms  $A_\phi$  such that, for any  $Z \in \mathcal{Z}^n$ ,

$$A_\phi(Z) = \operatorname{argmin}_{f \in \mathcal{F}_\phi} \mathcal{R}_Z(f) + \lambda \|f\|_{\mathcal{F}_\phi}^2 \quad (2)$$

where  $\phi : \mathcal{X} \rightarrow \mathcal{F}_\phi$  is a feature map,  $\mathcal{F}_\phi$  is the Hilbert space of functions  $f : \mathcal{X} \rightarrow \mathcal{Y}$  such that  $f(x) = \langle f, \phi(x) \rangle_{\mathcal{F}_\phi}$  for any  $x \in \mathcal{X}$  and

$$\mathcal{R}_Z(f) = \frac{1}{n} \sum_{i=1}^n \ell(f, z_i)$$

denotes the *empirical risk* of function  $f$  on the set  $Z$ .

### 2.1 LINEAR FEATURE LEARNING

In this work we will focus on the case that  $\mathcal{Y} \subseteq \mathbb{R}$ ,  $\mathcal{X} \subseteq \mathbb{R}^d$ ,  $\ell$  is the square loss and  $\phi : \mathbb{R}^d \rightarrow \mathbb{R}^m$  is a *linear* feature map (also known as a representation), corresponding to the action  $\phi(x) = \Phi x$  of a matrix  $\Phi \in \mathbb{R}^{m \times d}$  on the input space. It is well known, see e.g. (Argyriou et al., 2008), that, setting  $D = \frac{1}{\lambda} \Phi^\top \Phi \in \mathbb{R}^{d \times d}$ , any problem of the form in Eq. (2) can be equivalently formulated as

$$A_D(Z) = \operatorname{argmin}_{w \in \operatorname{Ran}(D)} \mathcal{R}_Z(w) + w^\top D^\dagger w \quad (3)$$

where, with some abuse of notation, we denoted with  $\mathcal{R}_Z(w)$  the empirical risk of the linear function  $x \mapsto w^\top x$ , for any  $x \in \mathcal{X}$ . Here,  $D^\dagger$  denotes the pseudoinverse of  $D$ , which is symmetric positive semidefinite (PSD) but not necessarily invertible; when it is not

invertible the constraint requiring  $w$  to be in the range  $\text{Ran}(D) \subseteq \mathbb{R}^d$  of  $D$  is needed to grant the equivalence with Eq. (2). Since for any linear feature map  $\phi$  there exists a symmetric PSD matrix  $D$  such that Eq. (2) and Eq. (3) are equivalent, in the following we will refer to  $D$  as the *representation* used by algorithm  $A_D$ .

## 2.2 LEARNING TO LEARN $D$

A natural question is how to choose a good representation  $D$  for a given family of related learning problems. In this work we consider the approach of *learning* it from data. In particular, following the seminal work of (Baxter, 2000), we consider a setting where we are provided with an increasing number of tasks and our goal is to find a joint representation  $D$  such that the corresponding algorithm  $A_D$  is suited to address all such learning problems. The underlying assumption is that all the tasks that we observe *share a common structure* that algorithm  $A_D$  can leverage in order to achieve better prediction performance.

More formally, we assume that the tasks we observe are independently sampled from a meta-distribution  $\rho$  on the set of probability measures on  $\mathcal{Z}$ . According to the literature on the topic, see e.g. (Baxter, 2000; Maurer, 2005), we refer to the meta-distribution  $\rho$  as the *environment* and we identify each task sampled from  $\rho$  by its corresponding distribution  $\mu$ , from which we are provided with a *training* dataset  $Z \sim \mu^n$  of  $n$  points sampled independently from  $\mu$ . While it is possible to consider a more general setting, for simplicity in this work we study the case where for each task we sample the same fixed number  $n$  of training points. In line with the independent task learning setting, the goal of a “learning-to-learn” algorithm is therefore to find the best parameter  $D$  minimizing the so-called *transfer risk*

$$\mathcal{E}(D) = \mathbb{E}_{\mu \sim \rho} \mathbb{E}_{Z \sim \mu^n} \mathcal{R}_\mu(A_D(Z)) \quad (4)$$

over a set  $\mathfrak{D}$  of candidate representations. The term  $\mathcal{E}(D)$  is the expected risk that the corresponding algorithm  $A_D$ , when trained on the dataset  $Z$ , would incur *on average with respect to the distribution of tasks  $\mu$  induced by  $\rho$* . That is, to compute the transfer risk, we first draw a task  $\mu \sim \rho$  and a corresponding  $n$ -sample  $Z \in \mathcal{Z}^n$  from  $\mu^n$ , we then apply the learning algorithm to obtain an estimator  $A_D(Z)$  and finally we measure the risk of this estimator on the distribution  $\mu$ .

The problem of minimizing the transfer risk in Eq. (4) given a finite number  $T$  of training datasets  $Z_1, \dots, Z_T$  sampled from the corresponding tasks  $\mu_1, \dots, \mu_T$ , has been subject of thorough analysis in literature, see e.g. (Baxter, 2000; Maurer, 2005; Maurer et al., 2016). Most work has been focused on the so-called “batch” setting,

where all such training datasets are provided at once. However, by its nature, LTL is an ongoing (possibly never ending) process, with training datasets observed a few at the time. In such a scenario the meta-algorithm should allow for an evolving representation  $D$ , which improves over time as new datasets are observed. In the following we propose a meta-algorithm to learn  $D$  *on-line* with respect to the tasks, allowing us to transfer past experience about the environment in an efficient manner, *without requiring the memorization of training data*, which could be prohibitive in large scale applications. We will study the statistical guarantees of the proposed algorithm and compare it to its batch counterpart in terms of both theoretical and empirical performance.

## 2.3 CONNECTION WITH MULTI-TASK LEARNING

LTL is strongly related to *multi-task learning* (MTL) and in fact, as we will see later for the algorithm in Eq. (3), approaches developed for MTL can be used as inspiration to design algorithms for LTL. In multi-task learning a fixed number of tasks  $\mu_1, \dots, \mu_T$  is provided up front and, given  $T$  datasets  $Z_1, \dots, Z_T$ , each sampled from its corresponding distribution, the goal is to find a joint representation  $D$  incurring a small *average expected risk*  $\frac{1}{T} \sum_{t=1}^T \mathcal{R}_{\mu_t}(A_D(Z_t))$ . In this sense, the main difference between LTL and MTL is that the former aims to guarantee good prediction performance on *future tasks*, while the latter aims to guarantee good prediction performance on the same tasks used to train  $D$ .

A well-established approach to MTL is *multi-task feature learning* (Argyriou et al., 2008). This method consists in solving the optimization problem

$$\min_{D \in \mathfrak{D}_\lambda} \frac{1}{T} \sum_{t=1}^T \min_{w \in \text{Ran}(D)} \mathcal{R}_{Z_t}(w_t) + w_t^\top D^\dagger w_t$$

over the set

$$\mathfrak{D}_\lambda = \{D \in \mathbb{S}_+^d \mid \text{tr}(D) \leq 1/\lambda\} \quad (5)$$

where  $\mathbb{S}_+^d$  denotes the set of  $d \times d$  symmetric PSD matrices,  $\text{tr}(D)$  is the trace of  $D$  and  $\lambda$  is a positive parameter which controls the degree of regularization. In the subsequent analysis the parameter  $\lambda$  must be intended as a fixed hyper-parameter, which will be chosen by cross-validation in the experiments. This choice for  $\mathfrak{D}_\lambda$  is motivated by the following variational form, see e.g. (Argyriou et al., 2008, Prop. 4.2), of the square trace norm of  $W = [w_1, \dots, w_T] \in \mathbb{R}^{d \times T}$

$$\|W\|_1^2 = \frac{1}{\lambda} \inf_{D \in \text{Int}(\mathfrak{D}_\lambda)} \sum_{t=1}^T w_t^\top D^{-1} w_t$$

where  $\text{Int}(\mathcal{D}_\lambda)$  is the interior of  $\mathcal{D}_\lambda$ , namely the set of the symmetric PSD invertible matrices with trace strictly smaller than  $1/\lambda$ . This leads to the equivalent problem

$$\min_{W \in \mathbb{R}^{d \times T}} \frac{1}{T} \sum_{t=1}^T \mathcal{R}_{Z_t}(w_t) + \gamma \|W\|_1^2 \quad (6)$$

with  $\gamma = \lambda/T$ . The trace norm of a matrix is defined as the sum ( $\ell_1$ -norm) of its singular values, and it is known to induce low-rank solutions for Problem (6). Intuitively, this means that tasks are encouraged to *share a common set of features (or representation)*. In this paper, we adopt this perspective to design our online LTL approach for linear feature learning.

### 3 ONLINE LEARNING-TO-LEARN

Motivated by the above connection with multi-task learning, we propose an online LTL approach to approximate the solution of the learning problem

$$\min_{D \in \mathcal{D}_\lambda} \mathcal{E}(D)$$

over the set  $\mathcal{D}_\lambda$  introduced in Eq. (5). We consider the setting in which we are provided with a stream of independent datasets  $Z_1, \dots, Z_T, \dots$ , each sampled from an individual task distribution  $\mu_1, \dots, \mu_T, \dots$  coming from the environment  $\rho$  and our goal is to find an estimator in  $\mathcal{D}_\lambda$  that improves *incrementally* as the number of observed tasks  $T$  increases.

#### 3.1 MINIMIZING THE EMPIRICAL TRANSFER RISK

A key observation motivating the online procedure proposed in this work, is that in the *independent task learning* setting, standard results from learning theory, see e.g. (Shalev-Shwartz & Ben-David, 2014), allow one to control the statistical performance of regularized empirical risk minimization, providing bounds on the *generalization error* of  $A_D$  as

$$\mathbb{E}_{Z \sim \mu^n} |\mathcal{R}_\mu(A_D(Z)) - \mathcal{R}_Z(A_D(Z))| \leq G(D, n) \quad (7)$$

where  $G(\cdot, n)$  is a decreasing function converging to 0 as  $n \rightarrow +\infty$ , while  $G(D, \cdot)$  is a measure of complexity of  $D$ , which is large for more “expressive” representations and smaller otherwise.

Eq. (7) suggests us to use the empirical risk  $\mathcal{R}_Z$  as a proxy for the expected risk  $\mathcal{R}_\mu$ . Therefore, we introduce the so-called *future empirical risk* (Maurer, 2009; Maurer et al., 2016),

$$\hat{\mathcal{E}}(D) = \mathbb{E}_{\mu \sim \rho} \mathbb{E}_{Z \sim \mu^n} \mathcal{R}_Z(A_D(Z))$$

---

#### Algorithm 1 PSSA applied to $\hat{\mathcal{E}}$

---

**Input:**  $T$  number of tasks,  $\lambda > 0$  hyper-parameter,  $\{\gamma_t\}_{t \in \mathbb{N}}$  step sizes.

**Initialization:**  $D^{(1)} \in \mathcal{D}_\lambda$

**For**  $t = 1$  to  $T$ :

Sample  $\mu_t \sim \rho, Z_t \sim \mu_t^n$ .

Choose  $U_t \in \partial \mathcal{L}_{Z_t}(D^{(t)})$

Update  $D^{(t+1)} = \text{proj}_{\mathcal{D}_\lambda}(D^{(t)} - \gamma_t U_t)$

**Return**  $\bar{D}_T = \frac{1}{T} \sum_{t=1}^T D^{(t)}$

---

and consider the related problem

$$\min_{D \in \mathcal{D}_\lambda} \hat{\mathcal{E}}(D), \quad (8)$$

which in the sequel, introducing the shorthand notation  $\mathcal{L}_Z(D) = \mathcal{R}_Z(A_D(Z))$  for any  $D \in \mathbb{S}_+^d$ , will be rewritten as

$$\min_{D \in \mathcal{D}_\lambda} \mathbb{E}_{\mu \sim \rho} \mathbb{E}_{Z \sim \mu^n} \mathcal{L}_Z(D) \quad (9)$$

to highlight the dependency on  $Z$ .

Problem (9) can be approached with stochastic optimization strategies. Such methods proceed by sequentially sampling a point (dataset in this case)  $Z$  and performing an update step. In recent years, stochastic optimization, finding its origin in the Stochastic Approximation method by (Robbins & Monro, 1951), has been effectively used to deal with large scale applications. We refer to (Nemirovski et al., 2009) for a more comprehensive discussion about this topic. We therefore propose to apply Projected Stochastic Subgradient Algorithm (PSSA) (Shamir & Zhang, 2013), to solve the optimization problem in Eq. (9). The candidate representation coincides in this case with the mean after  $T$  iterations  $\bar{D}_T$  and it is known as Polyak-Ruppert averaging scheme (Nemirovskii & Yudin, 1985; Polyak & Juditsky, 1992) in the optimization literature. Alg. 1 reports the application of PSSA to  $\hat{\mathcal{E}}$  when  $\mathcal{L}_Z$  is convex on the set  $\mathbb{S}_+^d$ . It requires iteratively: *i*) sampling a dataset  $Z$ , *ii*) performing a step in the direction of a subgradient of  $\mathcal{L}_Z$  at the current point, and *iii*) projecting onto the set  $\mathcal{D}_\lambda$  (which can be done in a finite number of iterations, see Lemma 16 in App. E). Note that in this case, since the function  $\mathcal{L}_Z$  is convex, there is no ambiguity in the definition of the subdifferential  $\partial \mathcal{L}_Z$ , see e.g. (Bertsekas et al., 2003), and we can rely on the convergence of Alg. 1 to a global minimum of  $\hat{\mathcal{E}}$  over  $\mathcal{D}_\lambda$  for a suitable choice of step-sizes, as discussed in Sec. 4.

### 3.2 LTL WITH RIDGE REGRESSION

In this work, we focus on the case that the loss function  $\ell : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$  corresponds to the square loss, namely  $\ell(y, y') = (y - y')^2$  for any  $y, y' \in \mathcal{Y} \subseteq \mathbb{R}$ . In this setting, given a dataset  $Z \in \mathcal{Z}^n$ , algorithm  $A_D$  is equivalent to perform the following variant to *Ridge Regression*

$$\min_{w \in \text{Ran}(D)} \frac{1}{n} \|\mathbf{y} - Xw\|^2 + w^\top D^\dagger w \quad (10)$$

where  $X \in \mathbb{R}^{n \times d}$  is the matrix with rows corresponding to the input points  $x_i \in \mathbb{R}^d$  in the dataset  $Z$  and  $\mathbf{y} \in \mathbb{R}^n$  the vector with entries equal to the corresponding output points  $y_i \in \mathbb{R}$ . The solution to Eq. (10) can be obtained in closed form, in particular, see e.g. (Argyriou et al., 2008; Maurer, 2009),

$$A_D(Z) = DX^\top (XDX^\top + nI)^{-1} \mathbf{y}. \quad (11)$$

Plugging this solution in the definition of  $\mathcal{L}_Z(D)$ , a direct computation yields that

$$\mathcal{L}_Z(D) = n \|(XDX^\top + nI)^{-1} \mathbf{y}\|^2. \quad (12)$$

The following result characterizes some key properties of the function  $\mathcal{L}_Z$  in Eq. (12), which will be useful in our subsequent analysis. We denote by  $\mathcal{B}_r \subseteq \mathbb{R}^d$  the ball of radius  $r > 0$  centered at 0.

**Proposition 1** (Properties of  $\mathcal{L}_Z$  for the Square Loss). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and  $\ell$  be the square loss. Then, for any dataset  $Z \in \mathcal{Z}^n$  the following properties hold:*

1.  $\mathcal{L}_Z$  is convex on the set  $\mathbb{S}_+^d$ .
2.  $\mathcal{L}_Z$  is  $\mathcal{C}^\infty$  and, for every  $D \in \mathbb{S}_+^d$ ,

$$\nabla \mathcal{L}_Z(D) = -nX^\top M(D)^{-1} S(D) M(D)^{-1} X$$

where

$$\begin{aligned} M(D) &= XDX^\top + nI \\ S(D) &= \mathbf{y}\mathbf{y}^\top M(D)^{-1} + M(D)^{-1} \mathbf{y}\mathbf{y}^\top. \end{aligned}$$

3.  $\mathcal{L}_Z$  is 2-Lipschitz w.r.t. the Frobenius norm.
4.  $\nabla \mathcal{L}_Z$  is 6-Lipschitz w.r.t. the Frobenius norm.
5.  $\mathcal{L}_Z(D) \in [0, 1]$ , for any  $D \in \mathbb{S}_+^d$ .

The proposition above establishes the convexity of Problem (8) for the case of the square loss. This fact is important in that it guarantees no ambiguity in applying Alg. 1 to our setting and moreover, since  $\mathcal{L}_Z$  is differentiable, Alg. 1 becomes a *Projected Stochastic Gradient Algorithm*.

## 4 THEORETICAL ANALYSIS

In this section, we study the statistical properties of Alg. 1 for the case of the square loss. Below we report the main result of this work, which characterizes the non-asymptotic behavior of the estimator  $\bar{D}_T$  produced by Alg. 1 with respect to a minimizer  $D_* \in \text{argmin}_{D \in \mathcal{D}_\lambda} \mathcal{E}(D)$ . To present our results we introduce the  $d \times d$  matrix  $C_\rho = \mathbb{E}_{\mu \sim \rho} \mathbb{E}_{(x, y) \sim \mu} [xx^\top]$  denoting the covariance of the input data, obtained by averaging over all input marginals sampled from  $\rho$ . We also denote with  $\|C_\rho\|_\infty$  the operator norm of  $C_\rho$ , which corresponds to the largest eigen-value.

**Theorem 2** (Online LTL Bound). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and  $\ell$  be the square loss. Let  $\mu_1, \dots, \mu_T$  be independently sampled from  $\rho$  and  $Z_t$  sampled from  $\mu_t^n$  for  $t \in \{1, \dots, T\}$ . Let  $\bar{D}_T$  be the output of Alg. 1 with step sizes  $\gamma_t = (\lambda\sqrt{2t})^{-1}$ . Then, for any  $\delta \in (0, 1]$*

$$\begin{aligned} \mathcal{E}(\bar{D}_T) - \mathcal{E}(D_*) &\leq \frac{4\sqrt{2\pi}\|C_\rho\|_\infty^{1/2}}{\sqrt{n}} \frac{1 + \sqrt{\lambda}}{\lambda} \\ &\quad + \frac{4\sqrt{2}}{\lambda\sqrt{T}} + \sqrt{\frac{8 \log(2/\delta)}{T}} \end{aligned}$$

with probability at least  $1 - \delta$  with respect to the independent sampling of the tasks  $\mu_t \sim \rho$  and training sets  $Z_t \sim \mu_t^n$  for any  $t \in \{1, \dots, T\}$ .

In Sec. 5, we will compare Thm. 2 with the statistical bound available for a state-of-the-art LTL batch procedure. We will see that the statistical behaviour of these two approaches is essentially equivalent, with the online LTL approach being more appealing given the lower requirements in terms of both number of computations and memory. In the rest of this section we give a sketch of the proof for Thm. 2. Proofs of intermediate results are reported in the appendix.

### 4.1 ERROR DECOMPOSITION

The statistical analysis of Alg. 1 hinges upon the following decomposition for the excess transfer risk of the estimator  $\bar{D}_T$ :

$$\begin{aligned} \mathcal{E}(\bar{D}_T) - \mathcal{E}(D_*) &= \mathcal{E}(\bar{D}_T) \pm \hat{\mathcal{E}}(\bar{D}_T) \pm \hat{\mathcal{E}}(D_*) - \mathcal{E}(D_*) \\ &\leq 2 \sup_{D \in \mathcal{D}_\lambda} |\mathcal{E}(D) - \hat{\mathcal{E}}(D)| + \hat{\mathcal{E}}(\bar{D}_T) - \hat{\mathcal{E}}(D_*) \\ &\leq 2 \underbrace{\sup_{D \in \mathcal{D}_\lambda} |\mathcal{E}(D) - \hat{\mathcal{E}}(D)|}_{\text{Uniform generalization error}} + \underbrace{\hat{\mathcal{E}}(\bar{D}_T) - \hat{\mathcal{E}}(\hat{D}_*)}_{\text{Excess future empirical risk}} \end{aligned} \quad (13)$$

where the matrix  $\hat{D}_*$  denotes a minimizer of the future transfer risk over  $\mathcal{D}_\lambda$ , that is,  $\hat{D}_* \in \text{argmin}_{D \in \mathcal{D}_\lambda} \hat{\mathcal{E}}(D)$ .

Eq. (13) decomposes  $\mathcal{E}(\bar{D}_T) - \mathcal{E}(D_*)$  in a *uniform generalization error*, implicitly encoding the complexity of the class of algorithms parametrised by  $D$  and an *excess future empirical risk*, measuring the discrepancy between the estimator  $\bar{D}_T$  and the minimizer  $\hat{D}_*$  of  $\hat{\mathcal{E}}$ . In the following we describe how to bound these two terms.

## 4.2 BOUNDING THE UNIFORM GENERALIZATION ERROR

Results providing generalization bounds for the class of regularized empirical risk minimization algorithms  $A_D$  considered in this work are well known. The following result, which is taken from (Maurer, 2009), leverages an explicit estimate of the generalization bound  $G(D, n)$  introduced in Sec. 3.1 for independent task learning, see Eq. (7), to obtain a uniform bound over the class of algorithms parametrized by  $\mathcal{D}_\lambda$ .

**Proposition 3** (Uniform Generalization Error Bound). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and let  $\ell$  be the square loss, then*

$$\sup_{D \in \mathcal{D}_\lambda} |\mathcal{E}(D) - \hat{\mathcal{E}}(D)| \leq \frac{2\sqrt{2\pi}\|C_\rho\|_\infty^{1/2}}{\sqrt{n}} \frac{1 + \sqrt{\lambda}}{\lambda}.$$

For completeness, we report the proof of this proposition in App. B.3.

## 4.3 BOUNDING THE EXCESS FUTURE EMPIRICAL RISK

Providing bounds for the excess future empirical risk introduced in Eq. (13) consists in studying the convergence rates of Alg. 1 to the minimum of  $\hat{\mathcal{E}}$  over  $\mathcal{D}_\lambda$  in high probability with respect to the sample of  $T$  tasks  $\mu_t$  from  $\rho$  and datasets  $Z_t$  from  $\mu_t^n$  for any  $t \in \{1, \dots, T\}$ .

To this end, we leverage classical results from the online learning literature (Hazan, 2016). In online learning, the performance of an online algorithm returning a sequence  $\{D^{(t)}\}_{t=1}^T$  over  $T$  trials is measured in terms of its *regret*, which in the context of this work corresponds to

$$R_T = \frac{1}{T} \sum_{t=1}^T \mathcal{L}_{Z_t}(D^{(t)}) - \min_{D \in \mathcal{D}_\lambda} \frac{1}{T} \sum_{t=1}^T \mathcal{L}_{Z_t}(D).$$

Differently from the statistical setting considered in this work, in the online setting no assumption is made about the data generation process of  $Z_1, \dots, Z_T$ , which could be even adversely generated. Therefore, an algorithm that is able to solve the online problem (i.e. if its regret vanishes as  $T \rightarrow \infty$ ) can be also expected to solve the corresponding problem in the statistical setting. This is indeed the case for Alg. 1, for which the following lemma provides a non-asymptotic regret bound.

**Lemma 4** (Regret Bound for Alg. 1). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and  $\ell$  be the square loss. Then the regret of Alg. 1 with step-sizes  $\gamma_t = (\lambda\sqrt{2t})^{-1}$  is such that*

$$R_T \leq \frac{4\sqrt{2}}{\lambda\sqrt{T}}.$$

The above lemma is a corollary of Prop. 1 combined with classical results on regret bounds for Projected Online Subgradient Algorithm (Hazan, 2016). We refer the reader to App. D.1 for a more in-depth discussion and for a detailed proof.

In our setting, the datasets  $Z_1, \dots, Z_T$  are assumed to be independently sampled from the underlying environment. Combining this assumption with the regret bound in Lemma 4, we can control the excess future empirical risk by means of so-called *online-to-batch conversion* results (Cesa-Bianchi et al., 2004; Hazan, 2016), leading to the following proposition.

**Proposition 5** (Excess Future Empirical Risk Bound for Alg. 1). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and let  $\ell$  be the square loss. Let  $\mu_1, \dots, \mu_T$  be independently sampled from  $\rho$  and  $Z_t$  sampled from  $\mu_t^n$  for  $t \in \{1, \dots, T\}$ . Let  $\bar{D}_T$  be the output of Alg. 1 with step sizes  $\gamma_t = (\lambda\sqrt{2t})^{-1}$ . Then, for any  $\delta \in (0, 1]$*

$$\hat{\mathcal{E}}(\bar{D}_T) - \hat{\mathcal{E}}(\hat{D}_*) \leq \frac{4\sqrt{2}}{\lambda\sqrt{T}} + \sqrt{\frac{8 \log(2/\delta)}{T}}$$

with probability at least  $1 - \delta$  with respect to the independent sampling of the tasks  $\mu_t \sim \rho$  and training sets  $Z_t \sim \mu_t^n$  for any  $t \in \{1, \dots, T\}$ .

The result above follows by combining Prop. 1 with online-to-batch results, see e.g. (Hazan, 2016, Thm. 9.3) and (Cesa-Bianchi et al., 2004). In App. D.2 we provide the complete proof of this statement together with a more detailed discussion about this topic. At this point we are ready to give the proof of Thm. 2.

**Proof of Thm. 2.** The claim follows by combining Prop. 3 and Prop. 5 in the decomposition of the error  $\mathcal{E}(\bar{D}_T) - \mathcal{E}(D_*)$  given in Eq. (13). ■

## 5 ONLINE LTL VERSUS BATCH LTL

In this section, we compare the statistical guarantees obtained for our online meta-algorithm with a state-of-the-art batch LTL method for linear feature learning. We also comment on the computational cost of both procedures.

### 5.1 STATISTICAL COMPARISON

Given a finite collection  $\mathbf{Z} = \{Z_1, \dots, Z_T\}$  of datasets, a standard approach to approximate a minimizer of the

future empirical risk  $\hat{\mathcal{E}}$  is to take a representation  $\hat{D}_T$  minimizing the multi-task empirical risk

$$\hat{\mathcal{E}}_{\mathbf{Z}}(D) = \frac{1}{T} \sum_{t=1}^T \mathcal{R}_{Z_t}(A_D(Z_t)) \quad (14)$$

over the set  $\mathcal{D}_\lambda$ . Such a choice has been extensively studied in the LTL literature (Baxter, 2000; Maurer, 2009; Maurer et al., 2013; 2016). Here we report a result analogous to [Thm. 2](#), characterizing the discrepancy between the transfer risks of  $\hat{D}_T$  and  $D_*$ .

**Theorem 6** (Batch LTL Bound). *Let  $\mathcal{X} \subseteq \mathcal{B}_1$ ,  $\mathcal{Y} \subseteq [0, 1]$  and let  $\ell$  be the square loss. Let tasks  $\mu_1, \dots, \mu_T$  be independently sampled from  $\rho$  and  $Z_t$  sampled from  $\mu_t^n$  for  $t \in \{1, \dots, T\}$ . Let  $\hat{D}_T$  be a minimizer of the multi-task empirical risk in Eq. (14) over the set  $\mathcal{D}_\lambda$ . Then, for any  $\delta \in (0, 1]$*

$$\begin{aligned} \mathcal{E}(\hat{D}_T) - \mathcal{E}(D_*) &\leq \frac{4\sqrt{2\pi}\|C_\rho\|_\infty^{1/2}}{\sqrt{n}} \frac{1 + \sqrt{\lambda}}{\lambda} \\ &\quad + \frac{2\sqrt{2\pi}}{\lambda\sqrt{T}} + \sqrt{\frac{2\log(2/\delta)}{T}} \end{aligned}$$

with probability at least  $1 - \delta$  with respect to the independent sampling of the tasks  $\mu_t \sim \rho$  and training sets  $Z_t \sim \mu_t^n$  for any  $t \in \{1, \dots, T\}$ .

The result above is obtained by further decomposing the error  $\mathcal{E}(\hat{D}_T) - \mathcal{E}(D_*)$  as done in Eq. (13). In particular, since the multi-task empirical error provides an estimate for the future empirical risk, it is possible to control the overall error by further bounding the term  $|\hat{\mathcal{E}}(D) - \hat{\mathcal{E}}_{\mathbf{Z}}(D)|$  uniformly with respect to  $D \in \mathcal{D}_\lambda$ . This last result was originally presented in (Maurer, 2009); in [App. C](#) we report the complete analysis of such decomposition, leading to the bound in [Thm. 6](#).

## 5.2 STATISTICAL CONSIDERATIONS

For a fixed value of  $\lambda$ , we can now compare the bounds on the excess transfer risk for the representations resulting from the application of the online procedure (see [Thm. 2](#)) and the batch one (see [Thm. 6](#)). Since the approximation error due to the choice of  $\lambda$  will be the same for both approaches, this comparison provides a first indication of their statistical behavior. However, it should be kept in mind that we are comparing upper bounds, hence our considerations are not conclusive and further analysis by means of lower bounds for both algorithms would be valuable.

[Thm. 2](#) and [Thm. 6](#) are both composed of three terms. The first term is exactly the same for both procedures and this is obvious looking at the decompositions used

to deduce both results. This term can be interpreted as a within-task-estimation error, that depends on the number of points  $n$  used to train the underlying learning algorithm (in our case Ridge Regression with a linear feature map). This term, similarly to the MTL setting, highlights the advantage of exploiting the relatedness of the tasks in the learning process in comparison to independent task learning (ITL). Indeed, if the inputs are distributed on a high dimensional manifold, then  $\|C_\rho\|_\infty \ll 1$ , while upper bounds for ITL have a leading constant of 1. In particular,  $\|C_\rho\|_\infty = 1/d$  if the marginal distributions of the tasks are uniform on the  $d - 1$  dimensional unit sphere; see (Maurer, 2009; Maurer et al., 2016) for a more detailed discussion about this point. The last term in the bounds expresses the dependency on the confidence parameter  $\delta$  and it is again approximately the same for the batch and the online case. It follows that the main role in the comparison between the online and batch bounds is driven by the middle term, which expresses the dependency of the bound on the number of tasks  $T$ . This term originates in different ways: in the batch approach it is derived from the application of uniform bounds and it can be interpreted as an inter-task estimation error, while in the online approach, it plays the role of an optimization error. Despite the different derivations, we can ascertain from the explicit formula of the bounds that this term is approximately the same for both procedures. This is remarkable since it implies that the representation resulting from our online procedure enjoys the same statistical guarantees than the batch one, despite its more parsimonious memory and computational requirements.

## 5.3 COMPUTATIONAL CONSIDERATIONS

After discussing the theoretical comparison between the online and the batch LTL approach, in this section we point out some key aspects regarding the computational costs of both procedures.

**Memory.** The batch LTL estimator corresponds to a minimizer of the multi-task empirical risk in Eq. (14) over *all tasks observed so far*. The corresponding approach therefore requires storing in memory all training datasets as they arrive in order to perform the optimization. This is clearly not sustainable in the incremental setting, since tasks are observed sequentially and, possibly indefinitely, inevitably leading to a memory overflow. On the contrary, in line with stochastic methods, online LTL has a small memory footprint, since it requires to store only one dataset at the time, allowing to “forget” it as soon as one gradient step is performed.

**Time.** Online LTL is also advantageous in terms of the number of iterations performed whenever a new task is observed. Indeed, for every new task, online LTL per-

forms *only one step* of gradient descent for a total of  $T$  steps after  $T$  tasks. On the contrary, batch LTL requires finding a minimizer for Eq. (14), which cannot be obtained in closed form but requires adopting an iterative method such as Projected Gradient Descent, see e.g. (Combettes & Wajs, 2005). These methods typically require  $k$  iterations to achieve an error of the order of  $O(1/k)$  from the optimum (better rates are possible adopting accelerated schemes). However, since for any new task batch LTL needs to find a minimizer for the multi-task empirical error from scratch, this leads to a total of  $Tk$  iterations after  $T$  tasks. Noting that every such iteration requires to compute  $T$  gradients of  $\mathcal{L}_Z$  in contrast to the single one of PSSA, this shows that online LTL requires much less operations. In the batch case, a “warm-restart” strategy can be adopted to initialize the Projected Gradient Descent with the representation learned during the previous step, however, as we empirically observed in Sec. 6, online LTL is still significantly faster than batch.

## 6 EXPERIMENTS

In this section, we report preliminary empirical evaluations of the online LTL strategy proposed in this work; the Python implementation of our algorithm is available at <https://github.com/dstamos>. In particular we compare our method with its batch (or offline) counterpart and independent task learning (ITL), i.e. standard Ridge Regression, which does not leverage any shared structure among the tasks.

In all experiments, we obtain the online and batch estimators  $\hat{D}_{\lambda, T_{tr}}$  and  $\hat{D}_{\lambda, T_{tr}}$  by learning them on a dataset  $\mathbf{Z}_{tr}$  of  $T_{tr}$  training tasks, each comprising  $n$  input-output pairs  $(x, y) \in \mathcal{X} \times \mathcal{Y}$ . Below to simplify our notation we omit the subscript  $T_{tr}$  in these estimators. We perform this training for different values of  $\lambda \in \{\lambda_1, \dots, \lambda_p\}$  and select the best estimator based on the prediction error measured on a separate set  $\mathbf{Z}_{va}$  of  $T_{va}$  validation tasks. Once such optimal  $\lambda$  value has been selected, we report the generalization performance of the corresponding estimator on a set  $\mathbf{Z}_{te}$  of  $T_{te}$  test tasks. Note that the tasks in the test and validation sets  $\mathbf{Z}_{te}$  and  $\mathbf{Z}_{va}$  are all provided with both a training and test datasets  $Z, Z' \in \mathcal{Z}^n$ . Indeed, in order to evaluate the performance of a representation  $D$ , we need to first train the corresponding algorithm  $A_D$  on  $Z$ , and then test its performance on  $Z'$  (sampled from the same distribution), by computing the empirical risk  $\mathcal{R}_{Z'}(A_D(Z))$ . For all methods considered in this setting, we perform parameter selection over  $p = 30$  candidate values of  $\lambda$  over the range  $[10^{-6}, 10^3]$  with logarithmic spacing. In the online setting the training datasets arrive one at the time, therefore model se-

Figure 1: Relative improvement (in %) of our online LTL algorithm over the ITL baseline for a varying range of training tasks  $T_{tr}$  and number of samples  $n$  per task, during 30 trials.

lection is performed *online*: the system keeps track of all candidate representation matrices  $\bar{D}_{\lambda_1}, \dots, \bar{D}_{\lambda_m}$  and whenever a new training task is presented, these matrices are all updated by incorporating the corresponding new observations. The best representation is then returned at each iteration, based on its performance on the validation set  $\mathbf{Z}_{va}$ . Finally, in the subsequent experiments, we set the step sizes of the online LTL method in Alg. 1 equal to  $\gamma_t = c/\sqrt{t}$ , for some constant  $c > 0$  chosen by model selection. Moreover, we computed the batch LTL estimator by classical Projected Gradient Descent method up to convergence, within  $10^{-6}$  relative descent of the objective function.

**Synthetic Data.** We considered a regression problem on  $\mathcal{X} \subseteq \mathbb{R}^d$  with  $d = 50$  and a variable number of training tasks  $T_{tr}$  and training points  $n$ . We also generated  $T_{te} = 300$  test tasks and we sampled a number  $T_{va}$  of validation tasks equal to 50% of  $T_{tr}$ . For each task, the corresponding dataset  $(x_i, y_i)_{i=1}^n$  was generated according to the linear regression equation  $y = w^\top x + \epsilon$ , with  $x$  sampled uniformly on the unit sphere in  $\mathbb{R}^d$  and  $\epsilon$  sampled from a Normal distribution,  $\epsilon \sim \mathcal{N}(0, 0.2)$ . The tasks predictors  $w$  were generated as  $P\tilde{w}$  with the components of  $\tilde{w} \in \mathbb{R}^{d/2}$  sampled from  $\mathcal{N}(0, 1)$  and then  $\tilde{w}$  normalized to have unit norm, with  $P \in \mathbb{R}^{d \times d/2}$  a matrix with orthonormal rows. In this way, the tasks reflect the assumption of sharing a low dimensional representation, which needs to be inferred by the LTL algorithm.

Fig. 1 reports the comparison between the baseline ITL and the proposed online LTL approach in terms of the relative difference of the prediction error on test tasks for the two methods. More precisely, given the mean squared errors (MSE)  $R_{oLTL}$  of online LTL and  $R_{ITL}$  of ITL averaged across the test tasks, we report the ratio  $(R_{ITL} - R_{oLTL})/R_{ITL}$  as a percentage improvement. Results are reported across a range of  $T_{tr}$  and  $n$ . We note that the regime considered for these experiments is par-

Table 1: Time (in seconds) for computing online and batch LTL for  $T_{tr}$  training tasks and  $n$  of samples per task.

	$T_{tr}$ 50		$T_{tr}$ 100		$T_{tr}$ 150	
	$n$ 20	$n$ 50	$n$ 20	$n$ 50	$n$ 20	$n$ 50
<b>Batch</b>	85	227	246	617	428	2003
<b>Online</b>	36	86	108	273	227	776

ticularly favorable to LTL, almost always outperforming ITL. However, when the number of training points per task is small, the LTL algorithm, as expected, is unable to capture the underlying representation, unless several tasks are used in training.

To provide further evidence of the performance of online LTL, Fig. 2 (Top) compares the prediction error of online LTL, batch LTL, and ITL as the number of training tasks  $T_{tr}$  increases one at the time and the different methods update their corresponding representation accordingly. In this case, the number of samples per task is fixed to  $n = 40$ . We also added to the comparison the multi-task algorithm (MTL) described in Sec. 2.3, performing trace norm regularization *on the test set*. As expected, the performance of both ITL and MTL does not depend on the number of training tasks. Consistently to what observed before, ITL is outperformed by both LTL methods, which tend to converge to the MTL method as more training tasks are provided. In general, when, as in this case, the number of test tasks is large enough, the MTL method is expected to outperform LTL, since MTL optimizes the representation directly on the test tasks. Concerning the LTL methods, consistently with the theory presented in Sec. 4, the performance of the online method is equivalent to that of its batch counterpart, which is, as already stressed in Sec. 5.3, less appealing from the computational point of view. To confirm this aspect, we report in Tab. 1 the computational times required on average by online LTL and batch LTL as  $T_{tr}$  and  $n$  vary. Online LTL is faster than batch LTL.

**Schools Dataset.** We evaluated online LTL on the Schools dataset, consisting of examination records from 139 schools, see (Argyriou et al., 2008). Each school is associated to a regression task, individual students correspond to the input and their exam score to the output. In this case, the sample size  $n$  varies across the tasks and the features belong to an input space  $\mathcal{X} \subseteq \mathbb{R}^d$ , with  $d = 26$ . We randomly sampled 25% and 50% of the 139 tasks for LTL training and validation respectively and the remaining tasks were used as test set. Fig. 2 (Bottom) reports the performance of online LTL, batch LTL, ITL and MTL. Performance is reported in terms of the Explained Variance on the tasks (Argyriou et al., 2008), higher values correspond to better performance. Results are consistent with synthetic experiments; in particular, online

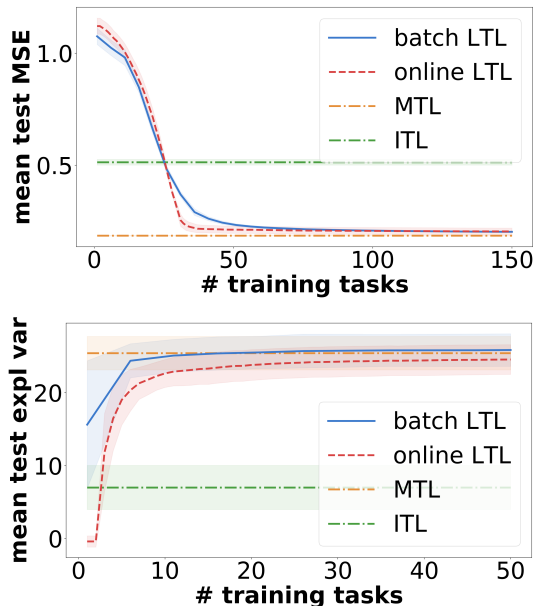

Figure 2: Performance of online LTL, batch LTL, ITL and MTL (on the test set) during 30 trials on the synthetic dataset (Top) and the Schools dataset (Bottom) as the number of training tasks increases incrementally.

and batch LTL are comparable.

## 7 CONCLUSION AND FUTURE WORK

We proposed an on-line (incremental) approach to LTL for linear data representation learning. Compared with its batch counterpart, this approach is computationally more efficient both in terms of memory and number of operations, while enjoying the same generalization properties. Preliminary experiments have highlighted the favorable learning capability of the proposed LTL strategy. Our analysis opens several future research directions. First, it would be valuable to investigate whether the same statistical guarantees hold for a projection-free meta-algorithm which does not require the computation of the entire SVD (e.g. certain variants of Frank Wolfe algorithm (Hazan & Kale, 2012), which do not require memorizing the sequence of datasets). Second, from a modeling perspective, we could take inspiration from the vast MTL literature to design new LTL methods in order to deal with tasks that are not necessarily spanning a low-rank subspace but are for instance organized into clusters (Jacob et al., 2009) or share a sparse set of relations (Ciliberto et al., 2015a;b). Finally, extending our analysis to non-convex settings would allow one to tackle more general families of learning algorithms as well as recent empirical meta-learning approaches (e.g. Franceschi et al., 2018) which implicitly attempt to directly minimize the transfer risk.

## Abstract

We consider the classical stochastic multi-armed bandit but where, from time to time and roughly with frequency  $\epsilon$ , an extra observation is gathered by the agent for free. We prove that, no matter how small  $\epsilon$  is the agent can ensure a regret uniformly bounded in time.

More precisely, we construct an algorithm with a regret smaller than  $\sum_i \frac{\log(1/\epsilon)}{\Delta_i}$ , up to multiplicative constant and  $\log \log$  terms. We also prove a matching lower-bound, stating that no reasonable algorithm can outperform this quantity.

## 1 INTRODUCTION

We consider the celebrated multi-armed bandit framework (sometimes also called online learning), a repeated decision problem where an agent (or an algorithm, a machine, a player, etc.) takes sequentially decisions from a finite set. Each decision gives a stochastic reward to the agent of fixed expectation. The main objective is to derive an algorithm maximizing the cumulative reward or minimizing its normalized version, the so-called “regret”. The latter is simply the difference between the cumulative expected reward of an agent knowing in hindsight the optimal decision, and the cumulative reward of the algorithm.

Online learning can be traced back to the 30’s, when Thompson analysed random clinical trial using an analogy with finding the best slot-machine in a casino by pulling sequentially their arms in order to minimize the total loss. During the 20th century, many improvements have been made, at least on the asymptotic version of the problem. The quantity of theoretical studies and practical applications of bandits have exploded since the early

2000. There are several reasons for that. First of all, a simple yet almost optimal algorithm called UCB has been developed. Its simple structure allows to adapt it to many different settings. As a consequence, many possible applications of online learning have been developed. Amongst them, we can mention the routing problem: given a network with congested edges, one must find the quickest way from some origin to a destination (this setting incorporates a combinatorial structure); this can be used to send packets in a network, as well as finding the quickest itinerary from a point A to a point B. Online advertising is another application: given a possible set of ads, one must find the ad with the highest probability of click. The last application we mention is concerned with wireless network and/or cognitive radio, where either a radio can change from an available channel to other channels to improve its reception or emission quality, or alternatively a wireless source, in a relay selection problem where multiple relays are available, can explore those nodes to achieve better transmissions rates. One of the typical and crucial assumption of all these models is that the agent only observes the outcome of his decisions, but not what the other decisions would have given him. For instance, using a slot machine only gives you a feedback on the performance of that very machine, displaying an ad only gives information of the probability of clicks on that specific ad, etc. This assumption is actually called “bandit feedback”. At the other end of the spectrum, the dual assumption (mostly used in non-stationary environment that we are not concerned with in that paper) is the “full information feedback”, where all the outcomes of all decisions are observed at all stages. However, none of our motivating examples satisfies this strong assumption.

However, we argue that the bandit feedback is also too strong and that in many cases more informations are available to the agent. Typically, the agent will always observe the outcome of his own decision, but with some small probability he might also get one (or several, but

that is irrelevant to our setting) extra “free” information. For instance, consider the original multi-armed bandit problem. A gambler is in a casino and wants to find out which slot machine is the best one. From time to time, he might observe other gamblers playing nearby machines. Even if this does not cost him anything, he gets feedback on the other machines. This effect also appears in other settings. In wireless network, a source with an allocated transmission capacity (because of a power-saving allocation protocol for instance) sends data through a relay and may have the opportunity to send another custom packet (so that the energy needed to send this packet is less than the available energy) through another relay in order to estimate transmissions rates. In online advertisement (and actually many other industrial markets), companies are willing to spend a small fraction of their data, say with probability  $\varepsilon$  as in the celebrated  $\varepsilon$ -greedy algorithm, just to acquire new information. An algorithm is only evaluated on the remaining (of proportion  $1 - \varepsilon$ ) fraction of the data treated. In a multi-armed bandit setting, this means that with probability  $\varepsilon$ , the next decision is “free”. Finally, we can also think that in the congested network problem, an algorithm can from time to time send “fake”, but free, packets to test the congestion; conversely, an app trying to minimize the congestion time of its users might be able to use free information if it notices that a bucket of users (for instance, those that are registered) might explore new road willingly, i.e., without uninstalling the app.

We therefore focus on the classical multi-armed bandits but where some extra and free information is available from time to time. Clearly, if the probability  $\varepsilon$  that it happens is arbitrarily close to 0, the improvement will be negligible. But we aim at constructing “optimal” algorithm, i.e., whose regret is small and in a multiplicative constant of the best regret achievable regret by “meaningful” algorithms. All these concepts are explained in details in the remaining of the paper that is organized as follows.

The model is introduced in Section 2, where we provide a very naïve algorithm achieving bounded regret (uniformly in time). We exhibit in Section 3 non-trivial lower bounds (we emphasize here that traditional bandit lower bounds are void in our setting). Algorithms are described and analysed in Section 4. Finally, Section 5 is dedicated to experiments illustrating the different guarantees and dependencies in the parameters of the models.

## 1.1 RELATED WORKS

This paper is not the first one to consider additional, free informations, available to the agents while optimizing. There are many different ways of modelling this idea,

but our paper is the first one (to our knowledge) that also focus on strategical aspects of obtaining these free informations to reduce regret, especially in the stochastic case.

There exists models where when a specific decision is taken, automatically (resp. with some probability), the performance of some other decision are observed [Alon et al., 2015, Chen et al., 2016, Caron et al., 2012]. Those models assume that there exists a directed (resp. weighted) graph whose set of nodes is the set of decisions. When the agent takes a decision, he also observes the outcome of any node linked (resp. with a probability proportional to the weight of the edge) to the current decision node. Our passive model could be recast as a specific case of that setting, but our results are much finer than the ones available for the general case.

In [Yu and Mannor, 2009] the rewards are stochastic but their means change at unknown time points. Free additional informations are queried by the algorithm in order to detect these change points. They however are not used to decrease the regret of the base bandit algorithm.

Another trend of literature of additional free information in multi-armed bandit studies the “adversarial” case, where no stationary assumption is made on the sequence of rewards (namely, there are not i.i.d.) [Audibert and Bubeck, 2010, Cesa-Bianchi et al., 2006, Mannor and Shamir, 2011]. However the rate of convergence in the two extreme cases (bandit and full information) have the same dependency in  $T$ , the total number of stages. To be precise, the regret is either of the order of  $\sqrt{KT}$  (in the bandit case) or  $\sqrt{\log(K)T}$  (in the full information case), where  $K$  is the number of decisions. Intermediate settings (where  $1 + M$  observations are available at each stage) interpolate between those two cases.

In the stochastic case though, regret is uniformly bounded with full information and grows logarithmically in the bandit case. As a consequence, even the rate of convergence will depend on the size of free informations.

## 2 MULTI-ARMED BANDITS, REGRET MINIMIZATION AND FEEDBACKS

In that section, we describe precisely the stochastic multi-armed bandit problem and its objective, the minimization of regret.

### 2.1 STOCHASTIC MULTI-ARMED BANDITS

#### 2.1.1 Bandit vs Full-Information

At each successive stage  $t \in \mathbb{N}^*$ , an agent takes a decision (or *pulls an arm* using the multi-armed bandit lingo)

$i_t$  in the finite set  $[K] := \{1, \dots, K\}$ . After pulling this arm, the agent receives the reward  $X_t^{(i_t)} \in \mathbb{R}$ , which is sampled from a real reward distribution  $\nu^{(i_t)}$  of expectation  $\mu^{(i_t)}$ . As a consequence, the stochastic bandit problem is parametrised by the vector of distribution,  $(\nu^{(1)}, \dots, \nu^{(K)})$ , or alternatively in the non-parametric case, by the vector of expected rewards  $(\mu^{(1)}, \dots, \mu^{(K)})$ . Throughout the paper, the results are stated using the arbitrary ordering  $\mu^{(1)} > \mu^{(2)} \geq \dots \geq \mu^{(K)}$ . Obviously, those vectors are unknown to the agent, who is aiming at optimizing her cumulative expected reward  $\sum_{t=1}^T \mu^{(i_t)}$ . Actually, instead of this cumulative reward, the objective is normalized into *cumulative regret* minimization.

The cumulative regret (or simply regret) of an algorithm at stage  $T$  is defined as

$$R_T = T \max_{i \in [K]} \mu^{(i)} - \sum_{t=1}^T \mu^{(i_t)},$$

i.e., it is the difference between the maximal possible cumulative reward up to stage  $T$  and the expectation of the reward gained by the successive choices of arms  $i_1, \dots, i_T$ . Following the classical notations, we define  $\mu^* = \max_{i \in [K]} \mu^{(i)}$  and the gaps  $\Delta_i = \mu^* - \mu^{(i)}$ . In the non-parametric case, these gaps are the relevant quantities characterising the complexity of a bandit problem.

There are different standard assumption on the feedbacks available to the agent before taking a new decision. In the *bandit* setting, she observes only her reward  $X_t^{(i_t)}$  (and, specifically, not the other  $X_t^{(k)}$ ) at the end of stage  $t \in \mathbb{N}^*$ . In the *full information* setting, she observes the full vector of rewards  $(X_t^{(1)}, \dots, X_t^{(K)}) \in \mathbb{R}^K$ . With full information, the *Follow The Leader* (FTL) algorithm that selects the arg max of the empirical average  $\bar{X}_t^{(i)} := \frac{1}{t} \sum_{s=1}^t X_s^{(i)}$  attains a uniformly bounded regret (with respect to  $T$ ). In the bandit setting, FTL gets a linear regret, yet the logarithmic optimal dependency in  $T$  is achieved by many algorithms. One of the most popular, called *Upper Confidence Bound* (UCB), selects the argmax of the empirical average augmented of an error term  $\hat{\mu}_t^{(i)} + \sqrt{6 \frac{\log(t)}{N_i(t)}}$  where  $N_i(t)$  is the number of pulls of arm  $i$  up to stage  $t$ , while  $\hat{\mu}_t^{(i)} := \frac{1}{N_i(t)} \sum_{s:i_s=i} X_s^{(i_s)}$ .

Many other algorithms are variants of UCB, by modifying the error term, changing some parameters, specifying it for a given class of parametric distributions, etc.

### 2.1.2 Additional Informations

As specified and motivated in the Introduction, we aim at analysing intermediate settings between bandit and full information, in which a subset of the reward vector might

be observed. More precisely, at some stages, the agent not only observes an arm by pulling it but might also observe a second arm for free, i.e., without getting a reward (and without incurring any regret). We consider several ways in which these free observations can be obtained: they can be deterministically available periodically (for instance every  $1/\varepsilon$  rounds) or arrive randomly (at each stage with probability  $\varepsilon$ ); the agent can also be a *passive observer* if she can not choose from which arm she gets an extra information (the environment chooses it for her, in a manner to be specified latter on), or she can be an *active observer* if she can choose the arm to observe freely.

We end this section with some notations. In the random time arrival of free information, we assume that at each stage  $t \in \mathbb{N}^*$  a Bernoulli random variable  $Z_t$  with expectation  $\varepsilon_t$  (whose law is denoted by  $\text{Ber}(\varepsilon_t)$ ) is sampled and a free observation is available if  $Z_t = 1$ . The particular setting in which  $\varepsilon_t$  is constant will be called static random. We will denote by  $i_t$  the arm pulled and by  $f_t$  the arm chosen to be observed using the free information (if available). The total number of pulls of arm  $i$  up to stage  $t$  is  $N_i(t)$ , the number of free observations  $F_i(t)$  and the total number of observation of arm  $i$  is  $O_i(t) = N_i(t) + F_i(t)$ .

## 2.2 A FINITE REGRET SETTING

It is not really difficult to devise a naïve algorithm with a (uniformly) bounded regret at least in the deterministic case, when a free observation is obtained every  $1/\varepsilon$  round. We consider for simplicity the case of  $K = 2$  arms in this section as it gives all the intuitions. Consider the following (heavily sub-optimal) strategy, which we denote by FTL-robin: pull the *leading arm* (the one with the highest empirical average  $\hat{\mu}_t^{(i)}$ ) and when a free sample is available, observe arms in a round-robin fashion.

After a period of  $1/\varepsilon$  stages, both arms have their observation counters increased by at least one. As a consequence, this simple algorithm FTL-robin can be seen as a full-information algorithm which would take  $1/\varepsilon$  stages to get the observations. To simplify intuitions

**Lemma 1.** *The regret of the FTL-robin algorithm on the deterministic setting with  $K = 2$  satisfies*

$$\mathbb{E} R_T \leq \frac{\bar{c}}{\varepsilon} \frac{1}{\Delta}, \text{ where } \Delta = |\mu^{(1)} - \mu^{(2)}|,$$

and there exist distributions  $(\nu^{(1)}, \nu^{(2)})$  such that

$$\frac{c}{\varepsilon} \frac{1}{\Delta} \leq \mathbb{E} R_T,$$

where  $c, \bar{c} > 0$  are universal constants that do not involve any parameter of the problem.

This lemma shows that even the simplest algorithm gets a finite regret in this setting. The proof is almost trivial and omitted. To provide some insights, just assume that  $\nu^{(1)} = \mathcal{N}(\Delta, 1)$  and  $\nu^{(2)} = \delta_0$ . Then the regret of FTL-robin is equal to the  $\Delta/\epsilon$  times the number of times that  $\overline{X}_t^{(1)}$  is smaller than 0. Basic computations show that this number is of order  $\frac{1}{\Delta^2}$ .

The relevant question is then not the asymptotic regime, but what is the precise optimal dependency on  $\epsilon$ . Indeed, when  $\epsilon < \frac{1}{\log T}$ , this bound gets larger than the  $O(\log T)$  regret of another naive approach, which is to use an algorithm for bandits and discard the additional information.

This free information problem is characterized by a transition from "small"  $\epsilon$ , where the amount of additional information is not enough to improve the performance of bandit algorithm, to "big"  $\epsilon$ , where the regret is finite and the setting is closer to full-information.

We answer the question of what "small" and "big" mean in this context and where the transition occurs and we display algorithms enjoying both logarithmic regret when  $\epsilon$  is small and finite regret when it is big.

### 3 LOWER BOUNDS

We first consider the definition of *optimality* of an algorithm, that is, what is the minimal regret achievable by any "reasonable" algorithm, in a sense we will make precise. Our lower bounds will highlight a transition from logarithmic (with respect to the horizon  $T$ ) to finite regimes when  $\epsilon$  gets big enough.

There are now quite standard techniques to devise lower bounds for stochastic bandits problems, but surprisingly these techniques are inadequate in our case, due to the finiteness of the optimal regret. As a finite regret is possible, a traditional, asymptotic lower bound for  $\frac{\mathbb{E} R_T}{\log T}$  [Lai and Robbins, 1985] could only be 0 and hence would not be informative. We can obtain a finite time version of this type of bound as in [Garivier et al., 2016] by imposing that our algorithm should perform better than a reference algorithm.

**Definition 1.** An algorithm is said to be sub-logarithmic with constants  $C, C_0$  if on all bandit problems it verifies for all stages  $T \in \mathbb{N}^*$ ,

$$\mathbb{E} R_T \leq C \sum_{i=1}^K \frac{\log T}{\Delta_i} + C_0 \sum_{i=2}^K \Delta_i.$$

There exists sub-logarithmic algorithms (UCB for example, with constants  $C = 8, C_0 = (1 + \pi^2/3)$  [Auer et al., 2002]). A sub-logarithmic algorithm is performing at least as good as the UCB baseline. This finite time

constraint on the performance of the algorithm translates into a lower bound: to perform relatively well on all bandit problems, an algorithm cannot outperform the lower bound guarantee on any of them.

#### 3.1 PASSIVE OBSERVER

When the observer is passive (i.e., she does not choose the arm  $f_t$  to observe freely), we assume that  $f_t$  is equal to  $i \in [K]$  with probability  $p_t^{(i)}$  chosen by the environment. Consider the static setting in which for all  $t$ ,  $Z_t \sim \text{Ber}(\epsilon)$  and the probabilities  $p_t^{(i)}$  do not depend on the stage  $t$  (we will thereafter omit the subscript  $t$ ).

Standard lower bound techniques proceed as follows: at stage  $T$ , the expected number of pulls of an arm is linked to the Kullback-Leibler divergence between the bandit problem studied and a related alternative, in which this arm would be the best one (roughly speaking, in order to be able to "test" that the problem is not the alternative one, a minimum number of samples of that arm must be gathered in the original problem).

A bound on this divergence gives a constraint of the form  $\mathbb{E} O_i(T) \geq h_i(t)/\Delta_i^2$  for some function  $h_i(T) = O(\log T)$ . Then a lower bound for the regret is the minimal value of  $\sum_{i=2}^K \Delta_i \mathbb{E} N_i(t)$  respecting all these constraints, that can be computed through some linear program. With this proof technique, we obtain lemma 2.

**Lemma 2.** *The regret of a sub-logarithmic algorithm with constants  $C, C_0$  must verify*

$$\mathbb{E}_1 R_T \geq \sum_{i=2}^K \max \left\{ 0, \frac{h_i(T)}{2\Delta_i} - \epsilon p^{(i)} T \Delta_i \right\}.$$

where  $h_i(T) = O(\log T)$  (see appendix for a detailed definition).

As mentioned above, this lower bound is void as it reaches 0 as soon as  $T$  is big enough, bigger than  $\frac{1}{\epsilon} \max_{j \geq 2} \frac{h_j(T)}{2p^{(j)} \Delta_j^2}$ .

We want to explain why this lower bound fails to provide relevant informations as our algorithm (see Section 4) are somehow inspired by this. Recall that the lower bound only states that any reasonable algorithm must have gathered, for each sub-optimal arm, a given number of observations, namely  $\frac{h_i(T)}{2\Delta_i^2}$ . However,  $h_i(T)$  grows sub-linearly, while the number of free observations grows linearly. So if  $T$  is large enough, there will be in total enough free observations to allocate  $\frac{h_i(T)}{2\Delta_i^2}$  of them to arm  $i$  and an optimal algorithm should somehow have used only free information to explore.

However, this is only possible if the  $\epsilon T$  free observa-

tions were gathered *at the beginning* of the problem and not scarcely with time! Indeed, in the traditional lower bounds techniques, the fact that arm  $i$  is observed at the beginning or at the end of time is irrelevant (since the cost of one pull is constant throughout time). They totally discard the fact that the quantities  $\mathbb{E} N_i(t)$  and  $\mathbb{E} R_t$  must be non-decreasing. Tighter, relevant lower bounds can be recovered using this monotonicity.

**Theorem 1.** *The regret of a sub-logarithmic algorithm with constants  $C, C_0$  must verify*

$$\mathbb{E} R_T \geq \sum_{i=2}^K \frac{1}{2\Delta_i} r_T^{(i)}$$

where

$$r_T^{(i)} = \log\left(\frac{T\Delta_i^2}{2C \log T \sum_{j \neq i} \frac{\Delta_i}{\Delta_i + \Delta_j}}\right) + \eta_i(T) - 2\epsilon p^{(i)} \Delta_i^2 T$$

if  $T \leq 1/(2\epsilon p^{(i)} \Delta_i^2)$  and otherwise

$$r_T^{(i)} = \left[ \log\left(\frac{1}{\epsilon 4C p^{(i)} \sum_{j \neq i} \frac{\Delta_i}{\Delta_i + \Delta_j}}\right) - \log \log\left(\frac{1}{2\epsilon p^{(i)} \Delta_i^2}\right) + \eta_i\left(\frac{1}{2\epsilon p^{(i)} \Delta_i^2}\right) - 1 \right].$$

The function  $\eta_i(T)$  goes to zero in  $O(1/\log T)$ . See appendix for details.

Theorem 1 correctly reports a lower bound increasing with the horizon. It shows a transition from a  $O(\log T)$  optimal regret for  $T \ll 1/(2\epsilon p^{(i)} \Delta_i^2)$  to a finite regret function of  $\epsilon$  when  $T$  gets bigger. According to Theorem 1, the correct dependency in  $\epsilon$  in the regret should be in  $O(\log(1/\epsilon))$ , not  $O(1/\epsilon)$  as seen for the naive FTL-robin algorithm.

We can also wonder what is the most favorable passive setting. Simple computations show that free observations should be drawn according to the probability vector  $(p_\star^{(1)}, \dots, p_\star^{(K)})$  where  $p_\star^{(i)}$  is proportional to  $\frac{1}{\Delta_i}$  (here, we actually ignore the log log and  $\eta$  terms of Theorem 1), leading to a lowest lower bound

$$\begin{aligned} \mathbb{E}_1 R_T &\geq \sum_{i=2}^K \frac{1}{2\Delta_i} \log\left(\frac{1}{\epsilon 4C \sum_{j \neq i} \frac{1}{\Delta_j}}\right) + \alpha \\ &\geq \sum_{i=2}^K \frac{1}{2\Delta_i} \log\left(\frac{1}{4C\epsilon}\right) + \alpha, \end{aligned}$$

where  $\alpha$  regroups the log log and  $\eta$  terms in theorem 1. This lower bound shows in particular that when all sub-optimal arms have the same gap, the optimal sample distribution is uniform and the lower bound is of order  $\frac{K}{\Delta} \log(\frac{1}{\epsilon})$ .

### 3.2 ACTIVE OBSERVER

An active observer has the possibility to chose the weights  $p_t^{(i)}$  at each stage  $t \leq T$ , potentially achieving a much better distribution of the free observations up to stage  $T$  than any static distribution. As before, standard techniques give the following lower bound.

**Lemma 3.** *The regret of a sub-logarithmic algorithm with constants  $C, C_0$  verifies*

$$\mathbb{E} R_T \geq \sum_{i=2}^k \frac{h_i(T)}{2\Delta_i} - \Delta_k(\epsilon T - \sum_{j>k} \frac{h_j(T)}{2\Delta_j^2}),$$

where  $k = \min\{i \in \{2, \dots, K\} : \sum_{j>i} \frac{h_j(T)}{2\Delta_j^2} \leq \epsilon T\}$ .

The structure of the solution to the optimization problem in this case is again educational: an optimal algorithm presented with a given amount of free observations would spend them at the beginning, before costly pulls, and will spend them on the worst arms. This intuition drove the construction of algorithms for active observer in section 4:

First gather free observations, ideally accordingly to the proportion  $(p_\star^{(1)}, \dots, p_\star^{(K)})$  then discards arms for which enough information were gathered, and use a standard optimal bandit algorithm on the remaining ones.

As in the passive observer case, although this lower bound can be meaningful for small horizon  $T$ , it becomes void for larger horizons. A better lower bound using the monotony of the number of pulls and of the regret is provided in the next theorem.

**Theorem 2.** *For  $k \in \{2, K-1\}$  let  $t_k = \max\{t \geq 1 : \sum_{j=k+1}^K \frac{h_j(t)}{2\Delta_j^2} > \epsilon t\}$ . The regret of any active sub-logarithmic algorithm with constants  $C, C_0$  verifies*

$$\begin{aligned} \mathbb{E} R_T &\geq \max_{k:t_k \leq T} \sum_{i=2}^k \frac{1}{\Delta_i} \left[ \log\left(\frac{1}{\epsilon 4C \sum_{j \neq i} \frac{\Delta_i^2}{\Delta_j}}\right) \right. \\ &\quad \left. - \log \log\left(\frac{1}{\epsilon \sum_{j=k+1}^K \frac{1}{2\Delta_j^2}}\right) + \eta\left(\frac{1}{\epsilon \sum_{j=k+1}^K \frac{1}{2\Delta_j^2}}\right) \right]. \end{aligned}$$

When all gaps are equal to the same value  $\Delta > 0$ , the leading term of this lower bound is of the form

$$\max_{k:t_k \leq T} \frac{k-1}{\Delta} \log\left(\frac{1}{\epsilon} \frac{K-k}{K}\right).$$

In particular, this result states that as  $T$  goes to infinity, the regret is asymptotically lower bounded by  $\frac{K-1}{\Delta} \left[ \log(\frac{1}{\epsilon}) - \log \log(\frac{\epsilon}{\epsilon}) \right]$ .

## 4 ALGORITHMS AND UPPER-BOUNDS

In this section, we exhibit algorithms matching the lower bounds derived in the previous section, up to  $\log \log(\cdot)$  terms, showing that they indeed represent accurately the problem complexity.

### 4.1 PASSIVE OBSERVER

A passive observer does not get to choose the arms on which free information is gained. As in the classical stochastic multi-armed bandit, the only decision is therefore which arm to pull. It is then natural to extend known algorithms by taking into account all observations from both provenances.

As UCB pulls the arm with maximal index  $\bar{X}_t^{(i)} + \sqrt{\frac{6 \log t}{N_i(t)}}$ , we extend it by using all available observations both in the empirical mean and exploration term. Algorithm 1 pulls  $i_t = \arg \max_i \bar{X}_t^{(i)} + \sqrt{\frac{6 \log t}{O_i(t)}}$ .

---

**Algorithm 1** UCB with passive observations.

---

Pull each arm once.

**loop:** at stage  $t$ ,

$$i_t = \arg \max_i \bar{X}_t^{(i)} + \sqrt{\frac{6 \log t}{O_i(t)}}$$

Pull arm  $i_t$ , observe  $X_t^{(i)}$ .

If  $Z_t = 1$ , sample  $f_t$  and observe  $X_t^{(f_t)}$ .

Update  $\bar{X}_t, N_i(t), F_i(t), O_i(t) = N_i(t) + F_i(t)$ .

**end loop**

---

**Theorem 3.** *Consider the static passive observer case, where  $f_t$  follows the categorical distribution with parameters  $(p^{(1)}, \dots, p^{(K)})$  and the probability of getting a free observation is  $\epsilon \in (0, 1]$  for all stages  $t \geq 1$ .*

Then the regret of ucb verifies both

$$\mathbb{E} R_T \leq \sum_{i=2}^K \frac{24}{\Delta_i} \log T,$$

and

$$\begin{aligned} \mathbb{E} R_T \leq & \sum_{i=2}^K \frac{24}{\Delta_i} \log \frac{50}{\epsilon p^{(i)}} \\ & + \sum_{i=2}^K \frac{24}{\Delta_i} \max \left\{ \log \frac{1}{e \Delta_i^2}, \log \log \frac{20}{\epsilon p^{(i)}} \right\}. \end{aligned}$$

Hence UCB with passive observations recovers the  $\log(\frac{1}{\epsilon})$  dependency in  $\epsilon$ , up to a doubly logarithmic term when  $\epsilon p^{(i)}$  is small compared to the squared gaps. When the dominant term in this maximum is  $\log \frac{1}{e \Delta_i^2}$ , the regret

due to arm  $i$  has the form  $\frac{1}{\Delta_i} \log \frac{1}{\epsilon p^{(i)} \Delta_i^2}$ , which is sub-optimal with respect to  $\Delta_i$  (see Theorem 1). This is due to the sub-optimality of UCB itself: while the regret of UCB on a bandit problem is  $O(\sum_{i=2}^K \frac{\log T}{\Delta_i})$ , other algorithms of the same family like UCB2 [Auer et al., 2002], Improved-UCB, [Auer and Ortner, 2010] or MOSS [Audibert and Bubeck, 2009, Degenne and Perchet, 2016] get an improved regret of order  $O(\sum_{i=2}^K \frac{\log(T \Delta_i^2)}{\Delta_i})$ .

The dependency in  $\log(\frac{1}{\epsilon})$  means that  $\epsilon$  as small as  $\frac{1}{T}$  gives useful information to a learner. Obviously there is no gain to be had if  $\epsilon < \frac{1}{T}$ , as there is in average less than one additional observation before  $T$ , but few more free observations are enough to improve the regret.

### 4.2 ACTIVE OBSERVER

While a uniform allocation of the free observations over the arms gets the right  $\log(\frac{1}{\epsilon})$  dependency in  $\epsilon$ , having the choice of the arm which will be observed allows an algorithm to get the right dependency in the parameters of the bandit problem. In the active setting, the algorithm can choose freely which of the  $[K]$  arms will get an additional observation, when such an observation is available.

To devise an algorithm taking advantage of this possibility, we try to mimic the lower bound for fixed stage, as in Lemma 3. A good algorithm should use the available free observations first to discard the worse arms, before using costly pulls only on the remaining arms.

We introduce an algorithm combining two subroutines: an Explore-Then-Commit (ETC) [Even-Dar et al., 2006, Perchet and Rigollet, 2013] algorithm on the free observations is used to narrow the set of arms which need to be pulled and an algorithm of the UCB family is used on this set. As we seek for optimality with respect to the problem parameters we use OCUCB-n [Lattimore, 2016], which is the UCB-type algorithm closest to it. ETC is described in Algorithm 3. OCUCB-n with parameters  $\eta > 1$  and  $\rho \in [1/2, 1]$  pulls at stage  $t \in \mathbb{N}^*$  the arm with maximal index

$$\bar{X}_t^{(i)} + \sqrt{\frac{2\eta \log B_{t-1}^{(i)}}{N_i(t)}}$$

where

$$B_{t-1}^{(i)} = \max \left\{ e, \log(t), \frac{t \log t}{\sum_{i=1}^K \min\{N_i, N_j^\rho N_i^{1-\rho}\}} \right\}$$

where  $N_i$  is a shorthand notation for  $N_i(t)$ .

The main algorithm use a succession of epochs. In epoch number  $m \in \mathbb{N}$ , the ETC subroutine collects (free) information on all the arms in  $[K]$ , while OCUCB-n pulls

arms in an available subset of the arms  $S_m$ . At the end of epoch  $m$ , the free observations gathered are used to discard arms from  $[K]$  which are not optimal with high enough confidence, forming  $S_{m+1}$ . There is a finite  $m_i \in \mathbb{N}$  depending on  $\epsilon$  and the gaps such that with high probability,  $i \notin S_m$  for  $m > m_i$ , hence arm  $i$  contributes to the regret only up to epoch  $m_i$  and the regret is finite.

---

**Algorithm 2** Active Algorithm.

---

**Require:** parameters  $\rho \in [1/2, 1]$ ,  $\alpha \geq 1$ ,  $\eta > 1$ .

Initialize  $S_0 = [K]$ .

**loop:** at epoch  $m$ , with duration  $d_m = 2^{2^m}$ ,

Pull arms according to OCUCB-n with parameters  $\eta$  and  $\rho$  on  $S_m$ ,

Use free observations according to ETC with parameter  $\alpha$  and horizon  $T = d_{m+1}^{3/2} \log d_{m+1}$ .

Set  $S_{m+1}$  to the set returned by ETC.

**end loop**

---

---

**Algorithm 3** Explore-Then-Commit

---

**Require:** parameter  $\alpha \geq 1$ , horizon  $T \in \mathbb{N}^*$ .

Initialize  $s = 0$ ,  $S = [K]$ .

**loop**

Observe all arms in  $S$ .

Discard from  $S$  any arm  $i$  such that

$$\hat{\mu}_s^{(i)} + \sqrt{\frac{2\alpha}{s} \log\left(\frac{T}{s}\right)} < \max_{j \in S} \hat{\mu}_s^{(j)} - \sqrt{\frac{2\alpha}{s} \log\left(\frac{T}{s}\right)}.$$

$s \leftarrow s + 1$ .

**end loop**

**return**  $S$ .

---

In order to write a regret upper bound for our active algorithm, we introduce quantities  $H_{i,\rho}$  for  $i \in \{2, \dots, K\}$  and  $\rho \in [1/2, 1]$ ,

$$H_{i,\rho} = \frac{i}{\Delta_i^2} + \sum_{j=i+1}^K \frac{1}{\Delta_i^{2(1-\rho)} \Delta_j^{2\rho}}.$$

These constants transcribe the difficulty of the problem. A number of observations of order  $\frac{1}{\epsilon} H_{i,1}$  will be necessary for ETC to eliminate arm  $i$  with high confidence.

**Theorem 4.** *The regret of the active algorithm 2 with parameters  $\rho \in [1/2, 1]$  and  $\alpha = 1$  on problems with rewards in  $[0, 1]$  is*

$$\mathbb{E} R_T \leq C_\eta \sum_{i=2}^K \frac{4}{\Delta_i} \max \left\{ \log\left(\frac{1}{\epsilon}\right), \log \sqrt{H_{i,\rho}} \right\} + 51K + O \left( \sum_{i=2}^K \frac{1}{\Delta_i} (\log \log \frac{H_{i,1}}{\epsilon})^2 \right)$$

with  $C_\eta$  a constant that depends only on  $\eta$  (see [Lattimore, 2016] for details on  $C_\eta$ ).

Our analysis of Explore-Then-Commit relies on a new maximal concentration inequality which can be of independent interest.

**Lemma 4.** *Let  $Z_t$  be a  $\sigma^2$ -sub-Gaussian martingale difference sequence then, for every  $\delta \in (0, 0.2]$  and every integers  $T \in \mathbb{N}^*$ ,*

$$\mathbb{P} \left\{ \exists t \leq T, \bar{Z}_t \geq \sqrt{\frac{2\sigma^2}{t} \log\left(\frac{T}{\delta t}\right)} \right\} \leq 6\delta \sqrt{\log\left(\frac{1}{\delta}\right)}.$$

Asymptotically, we obtain

$$\limsup_{\delta \rightarrow 0} \frac{\mathbb{P} \left\{ \exists t \leq T, \bar{Z}_t \geq \sqrt{\frac{2\sigma^2}{t} \log\left(\frac{T}{\delta t}\right)} \right\}}{\delta \sqrt{\log\left(\frac{1}{\delta}\right)}} \leq \sqrt{e/8}.$$

This value is  $\sqrt{e/8} \approx 0.6$ .

#### 4.2.1 Heuristics and Influence of $\epsilon$

Besides the algorithm already discussed, we also experimented on the following heuristic: choose a bandit algorithm of the UCB family, which pulls the arm with a maximal index; use it to pull the arm with maximal index and if an observation is available, observe the second maximal arm. We provide no regret analysis for this heuristic but study its performance in the experimental section.

Concerning the dependency in  $\epsilon$ , we can make the following interesting remark. To simplify notations, we will assume that all arms have the same gap  $\Delta$  and we remove constants for this analysis. With these simplifications, we proved that regret at stage  $T$  is of the order of  $R_T \simeq \frac{K}{\Delta} \log\left(\frac{1}{\epsilon}\right)$ . Obviously, if  $\epsilon$  is almost equal to 0, this upper-bound is void and the algorithm should not depend on the free observations. One might ask what is the threshold at which free informations become relevant at stage  $T$ .

Notice that standard information theory arguments yield that if  $\epsilon T \leq \frac{K}{2\Delta^2}$ , and even if the free observations were gathered at the beginning of the problem, only  $\frac{K}{2}$  arms could be removed (with high probability) from the set of possible optimal arms. Hence these free information are not useful for at least  $K/2$  arms and regret will have to scale as  $\frac{K}{2\Delta} \log\left(\frac{2T\Delta^2}{K}\right)$ , the optimal rate for the bandit problem with  $K/2$  arms with equal gaps  $\Delta$ .

On the other hand, if  $\epsilon T \geq \frac{K}{2\Delta^2}$ , then (up to multiplicative constant),  $\frac{K}{\Delta} \log\left(\frac{1}{\epsilon}\right)$  dominates  $\frac{K}{\Delta} \log\left(\frac{T\Delta^2}{K}\right)$ . As a consequence, the relevant threshold for the probability of free observations after  $T$  stages is

$$\epsilon^* = \frac{1}{T} \frac{K}{\Delta^2}.$$

## 5 EXPERIMENTS

All experiments are performed with Gaussian rewards with unit variance.

**Influence of  $\epsilon$ .** The goal of this first experiment is to confirm the scaling of the regret with  $\epsilon$ . That is to say, the regret scales with  $\sum_{i:\Delta_i>0} \frac{1}{\Delta_i} \log(\frac{1}{\epsilon\Delta_i^2})$ . The experiment is performed with a passive observer with either a uniform distribution or the optimal one, as defined in Section 3.1. To do so, the experiment is performed in the passive setting associated with a uniform distribution and the optimal one, as defined in Section 4.1. Also, when free observations are scarce,  $\epsilon \sim \frac{1}{T}$ , the average number of those is approximately 1 during the experience. Therefore, the regret is similar to the one suffered by an UCB algorithm in a classic multi-armed bandit setting, a behaviour captured by the function  $f$ . On Figure 1 and 2, experiments are run on four Gaussian arms with expectations 2, 1.8, 0.5, 0.2, the error bars are quantile at 10% and 90%.

Figure 1: Dependence on  $\epsilon$  of the regret of UCB as passive observer, with a uniform distribution of the free observations, averaged over 300 runs.

### Passive Observer: optimal sampling distribution.

This second experiment illustrates the induced regret in the passive setting with a probability distribution  $p^{(i)} = \frac{1}{\Delta_i}$ . This distribution is considered to be optimal because, as mentioned in Section 3.1, it achieves the lowest lower bound. It also suggests a paradigm for algorithms in the active setting i.e sampling freely as much as possible the arm with the lowest  $\Delta_i$ . A way to do so is to run an UCB type algorithm to choose which arm to pull, and use another UCB type algorithm on other arms to determine which will be observed if a free observation is available. The results of this type of policy is presented in the next paragraph.

Figure 2: Dependence on  $\epsilon$  of the regret of UCB as passive observer, with the optimal distribution of the free observations, averaged over 300 runs.

The experiment is run on the same set of arms as previously with a uniform distribution, the optimal distribution and a suboptimal one such that  $p^{(i)} = \frac{1}{\Delta_i^2}$ , referred as SubOptimal in Figure 3. Color filled regions are 25% and 75% quantiles.

Figure 3: Regret averaged over 300 runs

**Active Observer: comparison of algorithms.** This subsection is dedicated to the comparison of algorithms introduced earlier : UCB1-Double, ETC-OCUCB and ETC-OCUCB-2.

UCB1-Double uses a UCB algorithm and select the free observation as the second index maximising arm. The optimal allocation in the passive setting samples better arms more often, therefore we use the free observation to sample the arm next to optimal (according to its UCB index). The second algorithm, referred to as ETC-OCUCB, is the algorithm studied in the above section. In particular, its ETC subroutine checks for potentially

removable arms every  $C|S|$  pulls, with  $C$  a fixed parameter and  $S$  the set of currently active arm. Finally, the algorithm referred to as ETC-OCUCB-2 is a variant of ETC-OCUCB where elimination checks are made every  $2^k$  stages, thus behaving less aggressively than ETC-OCUCB. In addition, we introduced in this experiment a parameter  $p$  so that the epoch length is  $d_m = p^{2^m}$  in ETC-OCUCB. This enables us to adapt the growth of epochs to the horizon, here  $T = 10^4$ . Other parameters are :  $\alpha = 1$ ,  $\rho = \frac{1}{2}$ ,  $\eta = 2$  and  $C = 10$ .

The experiments is run on five Gaussian arms with expectations 2, 1.8, 1.5, 1 and 0.5. Color filled regions are 25% and 75% quantiles.

Figure 4: Regret for  $\epsilon = 0.1$  averaged over 100 runs

Figure 4 illustrates that:

- UCBI-Double reaches rapidly its final regret value after a logarithmic exploration phase where informations are gathered so that the policy doesn't pull an other suboptimal arm after this phase.
- ETC-OCUCB and ETC-OCUCB-2 algorithms have similar performances and the parameter  $p$  offers a control how often the set of active arms is updated which offers a slight performance increase for lower  $p$ .

ETC-OCUCB and ETC-OCUCB-2 maintain two distinct tracks of rewards, one for rewards obtained after pulling an arm and the other for rewards after sampling freely an arm. Therefore, it may be possible to increase their performance by using both sources of information in both subroutines. In the Figure below, these variants are referred as ETC-OCUCB-all-info and ETC-OCUCB-all-info-2.

This simple modification provides a clear improvement whether for the final regret or the speed at which this value is reached.

Figure 5: Regret for  $\epsilon = 0.1$  averaged over 300 runs for  $p = 2$

## 6 CONCLUSION

We analysed the multi-armed bandit problem with just a few extra free information. Interestingly, as the regret is uniformly bounded in time, standard lower bounds are void. However, a careful analysis allowed us to exhibit non-trivial guarantee that no reasonable algorithm can out-perform and we finally provided an optimal algorithm, whose regret matches the lower bound up to doubly logarithmic terms.

We would like to finally emphasize that our algorithm can be used even if the  $\epsilon T$  observations are not free. Since we used ETC on these observations, we get that our algorithm has a regret smaller (discarding multiplicative constants and log log terms) than

$$\sum_{i=2}^K \frac{\log(\epsilon T \Delta_i^2)}{\Delta_i} + \sum_{i=2}^K \frac{\log(1/\epsilon)}{\Delta_i}$$

where the first term is the guarantee of ETC on  $\epsilon T$  samples, and the second one is the guarantee of our algorithm with “free” observations. As a consequence, no matter the value of  $\epsilon$  (as long as the log log terms do not become dominant), its dependency vanishes, and we recover the expected performance of ETC.

## Abstract

Empirical evidence suggests that heavy-tailed degree distributions occurring in many real networks are well-approximated by power laws with exponents  $\eta$  that may take values either less than and greater than two. Models based on various forms of exchangeability are able to capture power laws with  $\eta < 2$ , and admit tractable inference algorithms; we draw on previous results to show that  $\eta > 2$  cannot be generated by the forms of exchangeability used in existing random graph models. Preferential attachment models generate power law exponents greater than two, but have been of limited use as statistical models due to the inherent difficulty of performing inference in non-exchangeable models. Motivated by this gap, we design and implement inference algorithms for a recently proposed class of models that generates  $\eta$  of all possible values. We show that although they are not exchangeable, these models have probabilistic structure amenable to inference. Our methods make a large class of previously intractable models useful for statistical inference.

## 1 INTRODUCTION

Sparsity and heavy-tailed degree distributions are believed to occur in many real networks (Newman, 2005; Clauset, Shalizi, and Newman, 2009). Sparsity has been well-studied and is an intuitive concept: The typical social network user interacts with only a vanishing fraction of all users as the network grows. Heavy-tailed degree distributions and the mechanisms that generate them are not as well understood. However, empirical evidence indicates that heavy-tailed distributions are expressed in a wide range of settings, including network degrees (Clauset,

Shalizi, and Newman, 2009). Power law degree distributions, in which the proportion of vertices with degree  $d$  is  $\propto d^{-\eta}$ , are often used as models for real degree distributions, and serve as a useful analytic tool for characterizing the asymptotic properties of random network models.

Many statistical network models make the assumption of exchangeability over vertices, appealing to the Aldous–Hoover theorem (Hoover, 1979; Aldous, 1981) for theoretical justification. Noting that networks sampled from these models cannot be sparse, Orbanz and Roy (2015) posed a question paraphrased as, “Can a probabilistic model for random graphs produce sparse networks and have some useful notion of probabilistic symmetry?” A generation of models answered in the affirmative by incorporating other notions of exchangeability: In an exchangeable point process representation of a network (Caron and Fox, 2017; Veitch and Roy, 2015; Borgs et al., 2016), or as an exchangeable sequence of edges (Crane and Dempsey, 2017; Cai, Campbell, and Broderick, 2016; Williamson, 2016). Under certain parameterizations, these models generate sparse networks. They are able to generate asymptotic power law degree distributions, providing a better fit to real network data than their vertex exchangeable counterparts. However, the power law exponent of the degree distribution in both model classes is constrained to the interval  $\eta \in (1, 2)$ . That interval is not an artifact of particular model specifications. Rather, it is a basic property resulting from the fact that the average vertex degree is asymptotically unbounded; vertex degrees grow, on average, linearly in the number of edges. For some data, this property may be undesirable; such properties ideally would be inferred from a model able to capture a larger range of power law behavior.

In a largely disjoint literature, so-called preferential attachment (PA) models have been studied primarily for their ability to generate power law degree distributions from a simple size-biased reinforcement mechanism, and for their analytical tractability (e.g., Barabási and Albert, 1999; Berger et al., 2014; Peköz, Röllin, and Ross, 2017).

PA models have power law exponents  $\eta > 2$ . As we explain in Section 2, the exponent range is tied to PA models' non-exchangeability—a property that has made them, until now, of limited use as statistical models. In particular, if the history of the network is unobserved, the order of the edges must be inferred or marginalized; even for networks of modest size, such inference over permutations is generally intractable.

Recently, Bloem-Reddy and Orbanz (2017) introduced a class of models that can generate random graphs with power law degree distributions of any exponent  $\eta \in (1, \infty)$ . For reasons discussed below, we propose naming them Beta Neutral-to-the-Left (BNTL) models. BNTL models generalize many known models that have a size-biased reinforcement mechanism, including a sub-class of edge exchangeable models based on the Pitman–Yor process, and variations of the PA model. The cost of the additional flexibility is exchangeability; BNTL models depend on the times at which new vertices arrive and are not exchangeable in any known sense. However, as we show in Section 3, BNTL models have probabilistic structure—namely, left-neutrality—that may be exploited for efficient computation, making a large class of previously intractable models useful for statistical inference.

Bloem-Reddy and Orbanz (2017) established the asymptotic properties of BNTL models; statistical modeling and inference were left unstudied. Our contributions are:

- We identify left-neutrality as the key property that yields tractable inference schemes.
- We categorize and give solutions to the BNTL inference problem based on what data are available: We design schemes for maximum likelihood estimation when vertex arrival times are observed, and for Bayesian inference when an unlabeled network is observed.
- We implement these schemes on real networks of various sizes, from modest ( $\sim 10^2$  vertices) to massive ( $\sim 10^6$  vertices).

## 2 POWER LAWS IN RANDOM GRAPH MODELS

This section provides some context, and collects and interprets various results from random graph models with asymptotic degree distributions exhibiting power law tails. Although none of the results here are new, to our knowledge they have not been coherently synthesized in the literature. Technical details are omitted; they may be found in the references given throughout the section. We focus our attention on edge exchangeable and PA models because they are most similar to the BNTL framework.

A graph  $G$  is a set of vertices,  $\mathcal{V}(G)$ , and of edges,<sup>1</sup>  $\mathcal{E}(G)$ , between them. A multigraph allows for multiple edges between vertices; we consider each edge to be distinct, rather than as one integer-valued edge. We consider only multigraphs and henceforth refer to them as graphs. A sequence of growing graphs  $G_1, G_2, \dots$  is a stochastic process  $\mathbf{G}$ , indexed by the number of edges,  $n$ . Hence,  $G_n$  may be interpreted as  $G_{n-1}$  with an additional edge, either between two vertices in  $\mathcal{V}(G_{n-1})$ , between two new vertices, or between one old and one new vertex. We assume that the edges are labeled according to the order in which they appear, though this assumption is not necessary for edge exchangeable models (discussed below). As such,  $G_n$  may be viewed simply as a sequence of edges  $\mathbf{E}_n := (E_1, \dots, E_n)$  or, even more simply, as a sequence of *ends of edges*, denoted  $\mathbf{Z}_{2n} = (Z_1, \dots, Z_{2n})$ . We denote by  $G(\mathbf{Z}_{2n})$  the labeled graph with  $n$  edges constructed from  $\mathbf{Z}_{2n}$ . (For convenience, we will use the subscript  $n$  for all sequences when there is no risk of confusion.)

For a graph  $G(\mathbf{Z}_n)$ ,  $K_n := |\mathcal{V}(G(\mathbf{Z}_n))|$  is the number of vertices (i.e., the number of unique values in  $\mathbf{Z}_n$ ); the degree of vertex  $j$ ,  $d_{j,n} := \sum_{i=1}^n \mathbb{1}\{Z_i = j\}$ , is equal to the number of ends of edges connected to it. Let  $m_n(d)$  denote the number of vertices with degree  $d$ . The asymptotic degree distribution of  $G_1, G_2, \dots$  is said to have power law tail with exponent  $\eta > 1$  if

$$p_n(d) = \frac{m_n(d)}{K_n} \xrightarrow[n \rightarrow \infty]{p} p_d \stackrel{a^{\uparrow} \infty}{\sim} L(d)d^{-\eta} \quad \text{for large } d,$$

such that  $\sum_{d \geq 1} p_d = 1$ , for some slowly varying function  $L(d)$ :  $\lim_{x \rightarrow \infty} L(rx)/L(x) = 1$  for all  $r > 0$  (Bingham, Goldie, and Teugels, 1989). For power law tails, we state the following fact (see Appendix A).

*Fact.* As  $n \rightarrow \infty$ , if the expected average degree is unbounded, then  $\eta \in (1, 2)$ ; if it is bounded,  $\eta \in (2, \infty)$ .

**Edge exchangeable models (Crane and Dempsey, 2017; Cai, Campbell, and Broderick, 2016).** Let  $G_n$  be specified by its sequence of edges  $\mathbf{E}_n$  (not necessarily ends of edges), which is assumed to be exchangeable: Its distribution is invariant under all permutations of the order of the edges for all  $n$ , i.e., the labels carry no information about their distribution. As a consequence of the law of large numbers for exchangeable sequences, the counts of all non-zero multi-edges grow linearly in  $n$  and thus so do the vertex degrees. That is,  $d_{j,n} = \Theta(n)$ . Furthermore,  $K_n = o(n)$ . The average degree is unbounded, implying that if the degree distribution tail follows a power law, then  $\eta \in (1, 2)$ .

<sup>1</sup>We treat all graphs as undirected; extension to directed graphs is straightforward.

As an example, consider sampling  $\mathbf{Z}$  from the the Pitman–Yor process ( $\mathcal{PYP}$ ) (Ishwaran and James, 2001) with parameters  $\tau \in (0, 1)$ ,  $\theta > -\tau$ ,

$$\mathbb{P}[Z_{n+1} \in \cdot | \mathbf{Z}_n] = \frac{\theta + K_n \tau}{n + \theta} \delta_{K_{n+1}}(\cdot) + \frac{n - K_n \tau}{\theta + n} \sum_{j=1}^{K_n} \frac{d_{j,n} - \tau}{n - K_n \tau} \delta_j(\cdot). \quad (1)$$

It can be shown that the asymptotic degree distribution has power law tail (Pitman, 2006),

$$n^{-\tau} m_d(n) \xrightarrow[n \rightarrow \infty]{\text{a.s.}} p_d \stackrel{d \uparrow \infty}{\sim} d^{-(1+\tau)},$$

which implies that  $\eta_\tau = 1 + \tau \in (1, 2)$ .

The predictive rule (1) demonstrates why the expected average degree is unbounded. The probability that  $Z_{n+1}$  corresponds to a new vertex is  $\frac{\theta + K_n \tau}{n + \theta}$ , which is arbitrarily close to zero as  $n \rightarrow \infty$ . For large  $n$ , the expected interarrival time between new vertices becomes arbitrarily large, and edges pile up on the existing vertices. Intuitively, vertex  $j$  takes part in a constant fraction of all interactions as  $n$  grows. This property is shared by all edge exchangeable models; an analogous property holds for exchangeable point process models (see Appendix B).

**Preferential attachment models.** Although the  $\mathcal{PYP}$  has the same size-biased reinforcement mechanism common to all PA models, typically it is not considered to be part of the same class as the PA models in the probability literature, of which Barabási and Albert (1999) provide the prototypical example. However, the difference between them amounts to how frequently new vertices appear (Bloem-Reddy and Orbanz, 2017). For our purposes, this is best illustrated with a simple PA model, the Yule–Simon (YS) model (Simon, 1955). For  $\beta \in (0, 1)$ ,  $\mathbf{Z}$  is generated via the predictive rule

$$\mathbb{P}[Z_{n+1} \in \cdot | \mathbf{Z}_n] = \beta \delta_{K_{n+1}}(\cdot) + (1 - \beta) \sum_{j=1}^{K_n} \frac{d_{j,n}}{n} \delta_j(\cdot). \quad (2)$$

The YS model is known to generate power law degree distributions with  $\eta_\beta = 1 + \frac{1}{1-\beta} \in (2, \infty)$  (Simon, 1955). Different versions of PA exhibit a range of possible  $\eta$ 's, but it is generally the case that  $\eta_{\text{PA}} > 2$ , and this is tied to their lack of exchangeability. The average rate at which new vertices arrive is constant in  $n$ ; hence,  $K_n = \Omega(n)$ , implying bounded expected average degree. The “edge pileup” phenomenon of exchangeable models does not occur:  $d_{j,n} = o(n)$ . In the YS model,  $d_{j,n} = \Theta(n^{1-\beta})$ .

### 3 BETA NTL MODELS

BNTL models were introduced under the name  $(\alpha, T)$ -models by Bloem-Reddy and Orbanz (2017), who studied their distributional and asymptotic properties. We briefly review the definition of BNTL models and describe the properties that make them amenable to inference.

In the predictive distributions (1)-(2), the probability that  $Z_{n+1}$  is a new vertex is independent of the degrees  $d_{j,n}$ , which allows the sampling of  $\mathbf{Z}$  to be separated into two parts: A sequence  $T_1 < T_2 < \dots$  of *arrival times* of new vertices, and size-biased reinforcement at all steps not associated with an arrival time. As such, a BNTL model is parameterized by a scalar “discount parameter”  $\alpha \in (-\infty, 1)$  and a probability distribution  $\Lambda$  on strictly increasing integer-valued sequences, which specifies the law of the arrival times  $T_1, T_2, \dots$ . A sequence  $\mathbf{Z}$  is said to have law  $\text{BNTL}(\alpha, \Lambda)$  if, for a random arrival time sequence  $\mathbf{T} = (T_1, T_2, \dots) \sim \Lambda$ ,  $\mathbf{Z}$  is sampled as

$$\mathbb{P}[Z_{n+1} \in \cdot | \mathbf{Z}_n, \mathbf{T}] = \mathbb{1}\{n+1 = T_{K_{n+1}}\} \delta_{K_{n+1}}(\cdot) + \mathbb{1}\{n+1 < T_{K_{n+1}}\} \sum_{j=1}^{K_n} \frac{d_{j,n} - \alpha}{n - K_n \alpha} \delta_j(\cdot). \quad (3)$$

In practice, it may be simpler to specify the distribution of *interarrival times*  $\Delta_j = T_j - T_{j-1}$ , and use their partial sums to construct  $\mathbf{T}$ ; we discuss this in more detail in Section 4. The similarity of (3) to (1)-(2) is not coincidental. The  $\mathcal{PYP}$  and the YS model each correspond to particular parameterizations of the BNTL model: The YS model corresponds to i.i.d.  $\Delta_j \sim \text{Geom}(\beta)$ ; the arrival time distribution induced by the  $\mathcal{PYP}$  in (1) also has known form (see (11)).

For a given  $\mathbf{T}$ , the probability of any  $G(\mathbf{Z}_n)$  is

$$\mathbb{P}[G(\mathbf{Z}_n) | \mathbf{T}] = \mathbb{P}[G(\mathbf{Z}_n) | \mathbf{T}_{K_{n+1}}, K_n] = \frac{\Gamma(d_{1,n} - \alpha)}{\Gamma(n - K_n \alpha)} \prod_{j=2}^{K_n} \frac{\Gamma(T_j - j\alpha) \Gamma(d_{j,n} - \alpha)}{\Gamma(T_j - 1 - (j-1)\alpha) \Gamma(1 - \alpha)}. \quad (4)$$

A crucial property that makes BNTL models amenable to inference is that conditioned on  $\mathbf{T}$ , the joint probability (4) factorizes over the vertices; each term is expressed in terms of its arrival time,  $T_j$ , and its degree,  $d_{j,n}$ . Note that given  $\mathbf{T}$ , the degree sequence  $\mathbf{d}_{K_n} := (d_{1,n}, \dots, d_{K_n,n})$  is a sufficient statistic for  $\alpha$ . Furthermore, the distribution of the arrival times (and therefore  $K_n$ ) is independent of the degrees. The factorization becomes explicitly useful in the Gibbs sampling updates and in the maximum likelihood estimating equations in Section 4.

**Sampling representation.** Like their exchangeable counterpart the  $\mathcal{PYP}$ , BNTL models have a sampling representation in terms of products of independent beta random

variables: (3) is an urn sequence corresponding to the following (Bloem-Reddy and Orbanz, 2017):

- $\mathbf{T} \sim \Lambda$ .
- $\Psi_j | T_j \sim \text{Beta}(1 - \alpha, T_j - 1 - (j - 1)\alpha)$  for  $j \geq 1$ .
- $P_{j, K_n} = \Psi_j \prod_{\ell=j+1}^{K_n} (1 - \Psi_\ell)$
- $Z_n \sim \begin{cases} \delta_{K_n}(\cdot) & \text{for } n = T_{K_n} \\ \text{Categorical}(P_{j, K_n}) & \text{o.w.} \end{cases}$

(By convention,  $\text{Beta}(a, 0)$  is a point mass on 1, so  $\Psi_1 = 1$ .) The last two items specify that when there are  $k$  vertices in the graph,  $Z_n$  is sampled from a categorical distribution over those vertices, each with probability  $P_{j, k}$ . After the subsequent arrival time,  $T_{k+1}$ , when there are  $k + 1$  vertices, the probability that  $Z_n = j$  is

$$P_{j, k+1} = \begin{cases} P_{j, k}(1 - \Psi_{k+1}), & j \in \{1, \dots, k\} \\ \Psi_{k+1}, & j = k + 1 \end{cases}.$$

That is, the vector of probabilities  $\mathbf{P}_k = (P_{1, k}, \dots, P_{k, k})$  grows in length as each new vertex arrives, and each of the previous entries is scaled by  $(1 - \Psi_{\text{new}})$ .

**Neutrality.** The recursive scaling of  $P_{j, k}$  is the essence of a neutral-to-the-left (NTL) sequence. A random vector  $\mathbf{X} = (X_1, \dots, X_k) \in \mathbb{R}_+^k$ , is NTL if the increments,

$$R_j := \frac{X_j}{\sum_{i=1}^j X_i}, \quad (5)$$

form a sequence of mutually independent random variables; a non-decreasing stochastic process  $Z$  defined on  $\mathbb{R}$  is NTL if the vector of increments  $\frac{Z(t_j) - Z(t_{j-1})}{Z(t_j)}$  is NTL for any finite partition  $-\infty \leq t_1 < \dots < t_k \leq \infty$  of  $\mathbb{R}$  (Doksum, 1974). A bit of algebra shows that  $\mathbf{P}_k$  is NTL: The corresponding sequence of increments is  $R_j = \Psi_j$ , for all  $k$ . Intuitively, this must be the case due to the recursive scaling construction. Together with the beta random variables in the sampling representation, left-neutrality characterizes these models; hence the name.

Neutral-to-the-right (NTR) processes are better known than NTL processes, and appear throughout the Bayesian statistics literature, both explicitly (Walker and Muliere, 1997; James, 2006) and implicitly in the form of the stick-breaking constructions of the Dirichlet Process and the  $\mathcal{PYP}$  (e.g., Ishwaran and James, 2001). The properties of right- and left-neutrality are, as their names suggest, symmetric opposites: A NTR vector in reverse order is NTL, and vice versa.

The independence properties that make NTR stick-breaking constructions useful for modeling and inference purposes transfer in large part to NTL models. The  $\Psi_j$ 's are conditionally independent given the  $T_j$ 's; along with

the parameters of the beta distribution, this independence induces the factorized form in (4). In the exchangeable random partitions literature, a model with joint probability that factorizes over the blocks and the probability of having  $K_n$  blocks is known as *Gibbs-type* (Gnedin and Pitman, 2006).

**Sparsity and power law tails in BNTL models.** The asymptotic behavior of BNTL models is controlled primarily by the arrival times,  $\mathbf{T}$ . In order to obtain sparse graphs,  $K_n$  must be  $\omega(n^{1/2})$ . If  $\mathbf{T}$  are the arrival times from an exchangeable sequence  $\mathbf{Z}$ , then  $K_n$  is at most  $\Theta(n^\delta)$ , for some  $\delta \in (0, 1)$ , in which case  $\eta = 1 + \delta$  (Pitman, 2006); thus, sparse graphs generated this way have  $\eta \in (3/2, 2)$ . For the  $\mathcal{PYP}$ ,  $\delta = \tau$ . Alternatively, for  $\mathbf{T}$  sampled such that the mean interarrival time,

$$\bar{\Delta}_{K_n} := \frac{1}{K_n - 1} \sum_{j=2}^{K_n} \Delta_j, \quad (6)$$

converges to some finite  $\mu$ , then  $K_n = \Theta(n)$  and  $\eta = 1 + \frac{\mu - \alpha}{\mu - 1} > 2$ . Furthermore, vertex degrees grow as  $d_{j, n} = \Theta(n^{\frac{\mu-1}{\mu-\alpha}})$  (Bloem-Reddy and Orbanz, 2017). Thus, depending on the specification of the arrival time distribution, BNTL models can achieve any  $\eta \in (1, \infty)$ .

**Microclustering in BNTL partitions.** The sequence  $\mathbf{Z}_n$  can be transformed into an arrival-ordered partition  $\Pi(\mathbf{Z}_n) := \{B_{1, n}, \dots, B_{K_n, n}\}$  of  $[n] := \{1, \dots, n\}$  by grouping  $\mathbf{Z}_n$  into blocks  $B_{j, n} := \{i \in [n] : Z_i = j\}$ . There is a bijective mapping between  $\Pi(\mathbf{Z}_n)$  and  $G(\mathbf{Z}_n)$  for all  $n$  (Bloem-Reddy and Orbanz, 2017), which puts blocks of the partition in correspondence with vertices of the graph. Hence, properties of  $G(\mathbf{Z}_n)$  translate into properties of  $\Pi(\mathbf{Z}_n)$ . In particular, the growth rate of vertex degrees translates to the growth rate of blocks sizes. Recent work (Betancourt et al., 2016; Di Benedetto, Caron, and Teh, 2017) has explored the so-called microclustering property, which is defined as block sizes that grow sub-linearly in  $n$ . The  $\eta > 2$  range of BNTL models corresponds precisely with this property. Although we do not make explicit statements about partition-valued data, statements about graphs are easily translated into statements about partitions via the correspondence between blocks and vertices. In particular, the inference algorithms in Section 4 are valid for partition-valued data.

## 4 INFERENCE

Although PA models exhibit a range of power laws not captured by exchangeable models, they face a significant barrier to use as statistical models due to their inherent lack of exchangeability. At a high level, applying a non-exchangeable model to data for which the order is unknown requires inference over permutations of the data.

This is, in general, a prohibitively difficult problem even for modest  $n$ . However, using the probabilistic structure of BNTL models, we design a Gibbs sampling algorithm that overcomes this difficulty for networks with thousands of vertices (Section 4.1). If the ordered edge sequence is observed, maximum likelihood estimation scales to networks with millions of vertices (Section 4.2).

Given the hierarchical nature of BNTL models, inference may be performed at a number of levels. In the simplest case, suppose the data are a sequence of edge-ends,  $\mathbf{Z}_n$ . From this sequence the arrival times and the arrival-ordered graph can be perfectly reconstructed, and inferring the parameters  $\phi$  of the arrival distribution  $\Lambda^\phi$  and the parameters  $\Psi_{K_n} := (\Psi_j)_{j=1}^{K_n}$  is straightforward: Simple maximum likelihood estimators exist for  $\Psi_{K_n}$  (see Appendix C), and for the parameters of many arrival time distributions of interest, or equally simple MCMC samplers may be constructed for Bayesian inference.

More challenging are the situations in which some aspect of the data is not perfectly observed. For graph-valued observations, the following table summarizes the range of possibilities, in order of increasing difficulty of inference:

Observation	Unobserved variables
End of edge sequence $\mathbf{Z}_n$	$\alpha, \phi, \Psi_{K_n}$
Vertex arrival-ordered graph	$\alpha, \phi, \Psi_{K_n}, \mathbf{T}_{K_n}$
Unlabeled graph	$\alpha, \phi, \Psi_{K_n}, \mathbf{T}_{K_n}, \sigma[K_n]$

The last row presents a significant challenge. In particular, the unobserved variables include a permutation  $\sigma$  mapping the arrival-ordered sequence to some arbitrary ordering of the vertices (by which the vertices are uniquely identified). For a graph with  $K_n$  vertices, there are  $K_n!$  possible permutations. Conditioned on a sequence of arrival times, some permutations have zero posterior probability, making the problem space both high-dimensional and constrained. Despite these difficulties, the inference problem is much simpler than that of a generic non-exchangeable model for a sequence of  $n$  data points: Even in sparse graphs, typically  $K_n \ll n$  and thus the dimension of the problem is exponentially smaller. Furthermore, the form of (4) yields simple conditional distributions for Gibbs sampling.

#### 4.1 GIBBS SAMPLING

In this section, we build from the simplest inference problem to the hardest, progressing through the table in the previous section. The full sampler infers the posterior distributions of the parameters  $\Psi_{K_n}$  and  $\alpha$ , of the arrival times  $\mathbf{T}_{K_n}$ , of the parameters of the arrival time distribution, and of the permutation of the vertices. In order to maintain the structure of the factorization over vertices

in (4), we assume that the arrival time distribution has a Markov factorization (with a slight abuse of notation):

$$\Lambda^\phi(\mathbf{T}_k) = \delta_{T_1}(1) \prod_{j=2}^k \Lambda_j^\phi(\Delta_j | T_{j-1}), \quad (7)$$

with  $\phi$  representing any parameters. Examples are i.i.d. interarrivals such that  $\Lambda_j^\phi(\Delta_j | T_{j-1}) = p_\phi(\Delta_j)$ ; and interarrivals that depend on the previous interarrivals through their sum and the number of previous arrivals, such as the interarrival sequence generated by exchangeable Gibbs-type sequences (De Blasi et al., 2015).

Suppose we observe a sequence of edge-ends  $\mathbf{Z}_n$ . Denote the partial sums of the ordered degree sequence as  $\bar{d}_{j,n} = \sum_{i=1}^j d_{i,n}$ . For any fixed  $\alpha$  and  $\phi$ ,

$$p_{\alpha,\phi}(\mathbf{Z}_n, \Psi_{K_n}) = \prod_{j=2}^{K_n} \frac{\Psi_j^{d_{j,n} - \alpha - 1} (1 - \Psi_j)^{\bar{d}_{j-1,n} - (j-1)\alpha - 1}}{B(1 - \alpha, T_j - 1 - (j-1)\alpha)} \Lambda_\phi(T_j | T_{j-1}) \times \Lambda_\phi(T_{K_n+1} > n | T_{K_n}), \quad (8)$$

where  $B(a, b)$  is the beta function, and  $\Lambda_\phi(T_{K_n+1} > n | T_{K_n})$  is the censored probability of vertex  $K_n + 1$ 's unobserved arrival time. Note that marginalizing  $\Psi_{K_n}$  recovers (4).

**Updates for  $\Psi_{K_n}$ .** From (8) it is clear that

$$\Psi_j | \mathbf{Z}_n, \Psi_{\setminus j} \sim \text{Beta}(d_{j,n} - \alpha, \bar{d}_{j-1,n} - (j-1)\alpha), \quad (9)$$

where  $\Psi_{\setminus j}$  is shorthand for the sequence  $\Psi_{K_n}$  with  $\Psi_j$  excluded. That is, given the arrival-ordered block sizes, the  $\Psi_{K_n}$  are independent of each other and of the arrival times, and the beta distribution is the conjugate prior for the BNTL sampling process. To understand this, consider a second scenario in which a graph is observed with vertices labeled in order of arrival (though not their time of arrival). The data consist of an ordered sequence of degrees,  $\mathbf{d}_{K_n} = (d_1, \dots, d_{K_n})$ , which corresponds to more than one possible edge-end sequence  $\mathbf{Z}_n$ . The model places equal probability on each sequence that gives rise to the same arrival-ordered degree sequence  $\mathbf{d}_{K_n}$  and the same arrival times; summing over these sequences yields

$$p_{\alpha,\phi}(\mathbf{d}_{K_n}, \Psi_{K_n} | \mathbf{T}_{K_n}, K_n) = \prod_{j=2}^{K_n} \frac{\Psi_j^{d_j - \alpha - 1} (1 - \Psi_j)^{\bar{d}_{j-1} - (j-1)\alpha - 1}}{B(1 - \alpha, T_j - 1 - (j-1)\alpha)} \binom{\bar{d}_j - T_j}{d_j - 1}. \quad (10)$$

The binomial coefficients count the number of sequences  $\mathbf{Z}_n$  that yield  $\mathbf{d}_{K_n}$ , given  $\mathbf{T}_{K_n}$  (Griffiths and Spanò, 2007). (10) is a product of binomial likelihoods with beta priors. Hence, the conjugacy derived in (9).

**Updates for  $\alpha$ .** In both observation scenarios, generic MCMC methods such as slice sampling (Neal, 2003) can be used to sample from the full conditional distribution of  $\alpha$ . We use slice sampling in the experiments in Section 5.

**Updates for  $\phi$ .** Many models of i.i.d. interarrival times will yield conjugate updates for  $\phi$ . For other models, generic MCMC methods can be used. In the experiments in Section 5, we consider three interarrival models: i.i.d.  $\text{Geom}(\beta)$  and i.i.d.  $\text{Pois}_+(\lambda)$ , which is the Poisson distribution shifted to the positive integers; and the interarrival distribution induced by the  $\mathcal{PYP}$ , which is (Griffiths and Spanò, 2007)

$$\begin{aligned} \Lambda_{j+1}^{\theta, \tau}(\Delta_{j+1} = s \mid T_j) & \quad (11) \\ & = (\theta + j\tau) \frac{\Gamma(\theta + T_j)\Gamma(T_j + s - 1 - j\tau)}{\Gamma(\theta + T_j + s)\Gamma(T_j - j\tau)}. \end{aligned}$$

In the former two cases, conjugate updates are performed (conditioned on  $\mathbf{T}_{K_n}$ ); in the latter case, we perform univariate slice sampling for each of  $\theta$  and  $\tau$ .

**Updates for  $\mathbf{T}_{K_n}$ .** The assumed Markov structure of the arrival times induces a simple conditional distribution for  $T_j$  that is supported on the set  $S_j = \{T_{j-1} + 1, \dots, T_{j-1} + M_j\}$ , where  $M_j = \min\{T_{j+1} - T_{j-1} - 1, \bar{d}_{j-1} - T_{j-1} + 1\}$ . The support set enforces the constraints that  $\bar{d}_{j-1} \geq T_j - 1$ , and that  $T_{j-1} < T_j < T_{j+1}$ . Conditioning on  $T_{j-1}$  and  $T_{j+1}$ , updating  $T_j$  is equivalent to updating  $\Delta_j$  and  $\Delta_{j+1}$ ; for  $j = 2, \dots, K_n - 1$ ,

$$\begin{aligned} p_{\alpha, \phi}(\Delta_j = s, \Delta_{j+1} = T_{j+1} - T_{j-1} - s \mid \mathbf{T}_{\setminus j}, \mathbf{d}_n) & \\ \propto \frac{\Lambda_{j+1}^{\phi}(T_{j+1} - T_{j-1} - s \mid T_{j-1} + s)\Lambda_j^{\phi}(s \mid T_{j-1})}{B(1 - \alpha, T_{j-1} + s - 1 - (j - 1)\alpha)} & \\ \times \binom{\bar{d}_j - T_{j-1} - s}{d_j - 1}. & \end{aligned}$$

For  $j = K_n$ ,

$$\begin{aligned} p_{\alpha, \phi}(\Delta_{K_n} = s \mid \mathbf{T}_{\setminus K_n}, \mathbf{d}) & \\ \propto \Lambda_{K_n}^{\phi}(s \mid T_{K_n-1}) \binom{n - T_{K_n-1} - s}{d_{K_n} - 1} & \\ \times \frac{\Lambda_{K_n+1}^{\phi}(\Delta_{K_n+1} > n - T_{K_n-1} - s \mid T_{K_n-1} - s)}{B(1 - \alpha, T_{K_n-1} + s - 1 - (K_n - 1)\alpha)}, & \end{aligned}$$

and  $M_{K_n} = \min\{n - T_{K_n-1} - 1, \bar{d}_{j-1} - T_{j-1} + 1\}$ .

For i.i.d. interarrivals with distribution  $p_{\phi}$ , the updates are particularly easy to compute because

$$\begin{aligned} \Lambda_{j+1}^{\phi}(T_{j+1} - T_{j-1} - s \mid T_{j-1} - s)\Lambda_j^{\phi}(s \mid T_{j-1}) & \\ = p_{\phi}(T_{j+1} - T_{j-1} - s)p_{\phi}(s). & \quad (12) \end{aligned}$$

$p_{\phi}(s)$  can be computed for each  $s \in \{1, \dots, M_j\}$ ; each term multiplied by the corresponding term in  $s \in$

$\{M_j, \dots, 1\}$  yields (12). In the case of  $\text{Geom}(\beta)$  interarrivals, the distribution is uniform on  $s \in \{1, \dots, M_j\}$ :

$$\begin{aligned} \Lambda_{j+1}^{\phi}(T_{j+1} - T_{j-1} - s \mid T_{j-1} - s)\Lambda_j^{\phi}(s \mid T_{j-1}) & \quad (13) \\ = \beta(1 - \beta)^{T_{j+1} - T_{j-1} - s - 1}\beta(1 - \beta)^{s-1} \propto 1. & \end{aligned}$$

**Updates for  $\sigma[K_n]$ .** Given a sample of  $\mathbf{T}_{K_n}$ , the order of the vertices can be updated via a series of adjacent swap proposals. Let  $\sigma_j$  be the identity of the  $j$ -th vertex in the current sampling iteration. A sampling update of  $\sigma$  proposes swapping  $\sigma_j \leftrightarrow \sigma_{j+1}$  with probability proportional to the value of (10), with  $\Psi_{K_n}$  marginalized and with  $d_j$  and  $d_{j+1}$  swapped. Due to the factorization over vertices, all but the  $j$ -th and  $j + 1$ -st terms are the same; as a result, swap proposals are inexpensive to compute (for compactness, ‘-’ indicates all other variables):

$$\begin{aligned} p_{\alpha, \phi}(\sigma_j \leftrightarrow \sigma_{j+1} \mid -) & \propto \frac{\Gamma(\bar{d}_{j-1} + d_{j+1} - T_j + 1)}{\Gamma(\bar{d}_{j+1} - d_j - T_{j+1} + 2)} \\ p_{\alpha, \phi}(\sigma_j \not\leftrightarrow \sigma_{j+1} \mid -) & \propto \frac{\Gamma(\bar{d}_{j-1} + d_j - T_j + 1)}{\Gamma(\bar{d}_j - T_{j+1} + 2)}. \end{aligned}$$

The simplicity of swap proposals enables many swaps to be sampled in a short amount of computational time, helping to overcome the high dimensionality of the sample space. We note that in general, local proposals of all possible permutations of  $m > 1$  consecutive vertices are possible and  $m > 2$  would likely enhance exploration of the state space; here we consider only  $m = 2$ .

**Computational complexity.** The slice sampling updates for  $\alpha$ , which require evaluation of (4), are of complexity  $\mathcal{O}(K_n)$ , as are the permutation swap proposals. Updates for the arrival parameter(s)  $\phi$  depend on the model, but as they depend only on the  $K_n$  arrival times, they are at most  $\mathcal{O}(K_n)$ . The most expensive update is that of  $\mathbf{T}_{K_n}$ , which is  $\mathcal{O}(n)$ , though the constant hidden in  $\mathcal{O}$  may vary greatly across arrival models.

## 4.2 MAXIMUM LIKELIHOOD FOR PARAMETERS IN EDGE SEQUENCES

Suppose the edge-end sequence  $\mathbf{Z}_n$  is observed. For arrival time distribution  $\Lambda^{\phi}$ ,  $\phi$  and  $\alpha$  can be estimated by maximum likelihood (ML). The likelihood admits the factorization

$$p_{\alpha, \phi}(\mathbf{Z}_n) = p_{\alpha}(\mathbf{Z}_n \mid \mathbf{T}_{K_n})\Lambda_{\phi}(\mathbf{T}_{K_n}), \quad (14)$$

with the practical implication that the estimating equations for  $\alpha$  and  $\phi$  can be solved separately. In particular,

$$\hat{\alpha} = \arg \max_{\alpha \in (-\infty, 1)} \log p_{\alpha}(\mathbf{Z}_n \mid \mathbf{T}_{K_n}), \quad (15)$$

where  $p_{\alpha}(\mathbf{Z}_n \mid \mathbf{T}_{K_n})$  is as in (4).

Table 1: Results of Gibbs sampling experiments on synthetic data ( $\alpha^* = 0.75$ ). The top four rows show results from each of four different BNTL models fit to a synthetic graph with 500 edges generated by the coupled  $\mathcal{PYP}$  BNTL model; the bottom four rows show the same BNTL models fit to a synthetic graph with  $\text{Geom}(0.25)$ -distributed interarrivals.

Closed-form MLEs are known for many i.i.d. interarrival distributions. For the  $\text{Geom}(\beta)$  and  $\text{Pois}_+(\lambda)$  distributions used in Section 5,  $\hat{\beta} = \frac{K_n - 1}{n - K_n}$  and  $\hat{\lambda} = \frac{n - K_n}{K_n - 1}$ . MLEs for  $\theta$  and  $\tau$  in  $\mathcal{PYP}$ -induced interarrivals can be found by numerically optimizing the product over arrival times of (11). See Appendix D for details. Maximum a posteriori (MAP) estimates are straightforward to compute by placing priors on the model parameters and including the relevant prior probabilities in (14)-(15).

### 4.3 RELATED WORK

There is relatively little previous work on statistical inference for non-exchangeable models of network data. Bloem-Reddy and Orbanz (2018) develop sequential Monte Carlo methods for non-exchangeable models; those methods are feasible only for networks with hundreds of vertices. See references therein for related ideas based on importance sampling. Where BNTL models overlap with edge exchangeable models, there exist inference algorithms that do not account for arrival times. Namely, if  $\mathbf{Z}_n$  is assumed to be an exchangeable sequence of edge-ends, then the sampling and estimation algorithms for Gibbs-type partitions can be used. For example, Gibbs sampling methods for the  $\mathcal{PYP}$  are derived in Ishwaran and James (2001). Crane and Dempsey (2017) give maximum likelihood estimating equations. However, neither method infers arrival times, and the inference techniques do not extend to the wider class of non-exchangeable BNTL models.

Wan et al. (2017) propose MLEs for the parameters of a class of PA models when the edge sequence is observed. A MLE of the parameter  $\alpha$  in a slightly different PA model was proposed by Gao and van der Vaart (2017) for observed edge sequences. The PA model considered there has random initial degrees, rather than random arrival times, but the initial degrees play a similar role to the arrival times. Those authors find that conditioned on

the initial degrees, the degree sequence at step  $n$ ,  $\mathbf{d}_{K_n}$ , is sufficient for  $\alpha$ , and that the MLE is asymptotically normal. Based on the similarities of the models and the corresponding log-likelihoods, it is plausible that similar properties hold for BNTL models.

## 5 EXPERIMENTS

We apply the inference methods developed in Section 4 to data. The first set of experiments is in the unlabeled network setting, in which the posterior distribution over vertex ordering must be inferred along with the model parameters. In a second set of experiments, we consider graphs with edges labeled in order of appearance, and demonstrate that maximum likelihood and MAP estimation scale to networks with millions of nodes.<sup>2</sup>

### 5.1 BAYESIAN INFERENCE

We first apply the Gibbs sampler from Section 4.1 to synthetic data, which allows us to study the effects of model misspecification on parameter estimation, and to demonstrate the feasibility of inference over the vertex order and the arrival times. We generated two synthetic graphs, each with 1,000 edges: One from a  $\mathcal{PYP}(\theta, \tau)$  sequence (1) in which  $\tau$  is forced to be equal to the BNTL parameter  $\alpha$ , which corresponds to the edge exchangeable Hollywood model of Crane and Dempsey (2017); and one from a BNTL model with i.i.d.  $\text{Geom}(\beta)$ -distributed interarrival times. We set  $\theta = 1.0$ ,  $\beta = 0.25$ , and in both cases,  $\alpha = 0.75$ .

For each of the graphs, we held out the final 500 edges for prediction, and we fit four different BNTL models to the first 500 edges whose order we treated as unknown: One with  $\mathcal{PYP}(\theta, \tau)$ -induced arrivals and  $\alpha = \tau$  (the ‘‘coupled  $\mathcal{PYP}$ ’’ model), which is the same as the generative

<sup>2</sup>Julia code is available at <https://github.com/emilemathieu/NTL.jl>.

Table 2: Scaling performance of the Gibbs sampler.

	100 edges	1,000 edges	10,000 edges
$ \hat{\alpha} - \alpha^* $	0.12 $\pm$ 0.01	0.03 $\pm$ 0.00	0.01 $\pm$ 0.00
$ \hat{\beta} - \beta^* $	0.02 $\pm$ 0.00	0.01 $\pm$ 0.00	0.00 $\pm$ 0.00
$ \hat{\mathbf{S}} - \mathbf{S}^* $	10.3 $\pm$ 0.4	33.9 $\pm$ 0.9	343 $\pm$ 1.6
ESS	0.90 $\pm$ 0.04	0.85 $\pm$ 0.05	0.75 $\pm$ 0.08
Runtime (s)	21 $\pm$ 0.0	213 $\pm$ 0.4	2267 $\pm$ 2

model of the first synthetic dataset; one with  $\mathcal{PYP}(\theta, \tau)$ -induced arrivals and  $\alpha$  allowed to vary separately from  $\tau$  (the “uncoupled  $\mathcal{PYP}$ ” model); and two i.i.d. interarrival models, with  $\text{Geom}(\beta)$ - and  $\text{Pois}_+(\lambda)$ -distributed interarrivals. We ran 125,000 Gibbs sampling iterations, including a burn-in of 25,000, and collected one in every 1,000 iterations for a total of 1,000 samples. To assess performance, we calculated the average absolute error (relative to the true value) of MCMC samples of  $\alpha$ , and of  $\mathbf{S} := \frac{1}{K_n - 1} \sum_{j>1} (\bar{d}_{j-1} - T_j)$ . The latter statistic captures how well the sampler recovers the vertex permutation and the arrival times. We also calculated the predictive log-likelihood of a further 500 edges. Average runtimes<sup>3</sup> and effective sample size (ESS) factors, based on the log of the normalized  $L_1$  distance between the sampled degree sequence and the true degree sequence, are also shown.

Table 1 summarizes the results, averaged over 10 repetitions. The top four rows show the results of fitting four BNTL inference models to the coupled  $\mathcal{PYP}$  dataset. Unsurprisingly, the inference models with arrivals induced by the  $\mathcal{PYP}$  achieve the lowest errors in  $\alpha$  and  $\mathbf{S}$ , and highest predictive log-likelihood. The bottom four rows show the same four inference models fit to the  $\text{Geom}(0.25)$  BNTL dataset; the i.i.d. interarrival models achieve lower errors, and the  $\text{Geom}(\beta)$  inference model attains the highest predictive log-likelihood. Although the  $\text{Pois}_+(\lambda)$  inference model attains low errors in  $\alpha$  and  $\mathbf{S}$ , the low variance of the Poisson distribution compared to the Geometric distribution means that it attains low predictive probability due to the relatively frequent occurrence of large interarrivals.

As discussed in Section 4.1, the most expensive Gibbs update is that of the arrival time sequence. As such, the  $\text{Geom}(\beta)$  interarrival inference model benefits greatly from (13), which implies that computation of  $\Lambda_j^\phi$  is not required. The i.i.d. interarrival models each have conjugate updates for their parameters, whereas the  $\mathcal{PYP}$  interarrival models require slice sampling for  $\phi = (\theta, \tau)$ . These differences are reflected in the runtimes shown in Table 1. Finally, all four inference models exhibit good ESS factors, indicating that the sampler is exploring per-

<sup>3</sup>All Gibbs sampling experiments were run on a quad-core (3.1 GHz) Dell desktop running Linux.

mutation space beyond simply swapping vertices of the same degree.

**Scaling in  $n$ .** In order to study how sampling and computational efficiency scale with the size of the network, we generated a single BNTL network of 10,000 edges with i.i.d.  $\text{Geom}(0.25)$ -distributed arrival times, and performed Gibbs sampling using the subgraphs formed by the first  $n$  edges, with  $n \in \{100, 1,000, 10,000\}$ . Table 2 shows the results of 10 repetitions, each of 150,000 Gibbs iterations; samples were collected once every 1,000 iterations after a burn-in period of 75,000 iterations. Parameter estimation is increasingly accurate for increasing  $n$  without major decrease in ESS, indicating that the sampler is taking advantage of the increased statistical signal in the bigger network. Runtimes increase at a rate linear in  $n$ .

## 5.2 MAXIMUM LIKELIHOOD ESTIMATION ON EDGE SEQUENCES

For observed edge sequences, maximum likelihood estimation scales to networks with millions of vertices and tens of millions of edges. To demonstrate, we compute MLEs on a collection of temporal network datasets available from the Stanford Network Analysis Project (SNAP) (Leskovec and Krevl, 2014).

For each of the datasets listed in Table 3, we fit MLEs of  $\alpha$  and of the parameters of three different interarrival models: coupled  $\mathcal{PYP}(\theta, \alpha)$ ; uncoupled  $\mathcal{PYP}(\theta, \tau)$ ; and  $\text{Geom}(\beta)$ . Table 4 displays the MLEs of the model parameters and the plug-in estimates of the asymptotic power law degree exponent,  $\eta$ . (The asymptotic degree distribution of the uncoupled  $\mathcal{PYP}$  model is unknown.) Note that due to the factorization of the likelihood in (14),  $\hat{\alpha}$  is the same for any model in which  $\alpha$  is not coupled to the arrival distribution. In order to assess model fitness, we fit MLEs for the same BNTL models to the first 80% of the edges in each network and calculated the predictive log-likelihood based on the MLEs of the remaining 20%; this is also shown in Table 4. For context, the arrival time sequence of each dataset is plotted in Figure 1. Unsurprisingly, whether or not the arrival times are approximately linear in  $n$  largely determines which BNTL model fits

best. The two densest networks, the EU email and UCI social networks, exhibit arrival times that are sub-linear in  $n$ ; as such, the  $\mathcal{PYP}$  models fit best. Note that the coupled  $\mathcal{PYP}$  model estimates  $\hat{\alpha} \approx 0$ , indicating the lack of a power law tail in the degree distribution. In the rest of the networks, the arrival times appear approximately linear in  $n$ . The  $\text{Geom}(\beta)$  and uncoupled  $\mathcal{PYP}$  model fit best. However, we note that in these cases the MLEs for the uncoupled  $\mathcal{PYP}$  model are at the boundaries of the parameter range ( $\hat{\theta} \approx -1, \hat{\tau} \approx 1$ ). This illustrates that although the uncoupled  $\mathcal{PYP}$  model is more flexible than the coupled version, the underlying arrival time model cannot capture linear arrival time sequences without driving the parameters to the boundaries.

## 6 DISCUSSION

BNTL models are a useful tool to reason about asymptotic properties of a network. For example, the exponent of the asymptotic power law tail is a function of model parameters, which can be estimated from finite-size networks without dealing with the large fluctuations of heavy-tailed degree distributions in finite samples. Furthermore, the ability to capture the full range of power law exponents and sparsity levels within the same model class allows for model fitness comparisons using the same set of techniques, as in Section 5. We have designed a set of inference algorithms for these models; in doing so, we have made a large class of previously intractable models useful for statistical inference.

**Future research directions.** The full Gibbs sampler scales reasonably well to networks with thousands of vertices; in order to scale to larger networks, further work is needed. One possible approach is via Metropolis–Hastings with cheap joint proposals of the arrival times and the permutation, which may be able to take larger steps in sample space. A different direction is variational inference, though permutations pose a significant challenge in that context; recent work (Linderman et al., 2018) is a step in that direction.

## Abstract

Estimating the dynamic connectivity structure among a system of entities has garnered much attention in recent years. While usual methods are designed to take advantage of temporal consistency to overcome noise, they conflict with the detectability of anomalies. We propose *Clustered Fused Graphical Lasso* (CFGL), a method using pre-computed clustering information to improve the signal detectability as compared to typical Fused Graphical Lasso methods. We evaluate our method in both simulated and real-world datasets and conclude that, in many cases, CFGL can significantly improve the sensitivity to signals without a significant negative effect on the temporal consistency.

## 1 INTRODUCTION

In recent years, undirected graph models have become a popular topic in machine learning. In an undirected graphical model, vertices represent entities in the system, and edges represent bi-directional effects between entities. The inverse covariance matrix is the preferred estimator for such structures since it indicates partial correlations, i.e., an off-diagonal entry is zero if and only if the entities of the corresponding column and row are conditionally independent given all the other entities. Therefore, two adjacent vertices in an estimated network correspond to a non-zero off-diagonal entry and a direct dependency. One of the most popular methods for estimating the sparse precision matrix is *Graphical Lasso* (Glasso) [Friedman et al., 2008], which assumes the connectivity structure is static. However, this assumption is not satisfied in many fields like functional MRI [Monti et al., 2014], financial markets [Namaki et al., 2011], or

social network analysis [Ahmed and Xing, 2009]. In such cases, data comes from a time series of collections, and the underlying structures are usually assumed to be non-static across time. Consequently, estimating dynamic networks at each time point becomes necessary in order to better understand the complex systems.

Compared to the static case, fewer observations at each time point are available in dynamic estimation. The lack of samples leads to higher level of noise, and thus introduces additional difficulty in estimation. Temporal consistency is a natural assumption with time-varying networks, based on the idea that in most cases, only few changes should occur between consecutive networks. Given this assumption, one may like to place an additional penalty on the difference of neighboring networks. *Fused Graphical Lasso* (Fused Glasso) achieves this using an element-wise  $l_1$  penalty, and it has become the default choice for many studies in the structure estimation field [Monti et al., 2014, Hallac et al., 2017, Danaher et al., 2014, Ahmed and Xing, 2009].

Several Fused Glasso based algorithms have been proposed in the literature on time varying network estimation, and they all have some issues with change detection. *SINGLE* [Monti et al., 2014] avoids accurate change detection by assuming temporal homogeneity (i.e., small and slow changes) on functional MRI data. It uses Fused Glasso on sample covariance estimates, which are smoothed using a Gaussian kernel, so that all abrupt changes are transferred into trends. In another study [Gibberd and Nelson, 2017], the ability to recover change points is specifically targeted. *Grouped Fused Graphical Lasso* (GFGL) uses a group  $l_{2,1}$  smoothing. The drawback is that compared to Fused Glasso results, GFGL has performance loss on static periods on a similar scale as the performance gain at change points. *Time-Varying Graphical Lasso* (TVGL) [Hallac et al., 2017] proposes a general framework, allowing various penalty functions to be applied to fit different situations. But again, it is difficult for a single penalty function to satisfy

both temporal consistency and temporal diversity. More importantly, estimating dynamic functional structures is an unsupervised task. Thus, it is usually impossible to know the correct situation beforehand or to objectively compare methods with different penalties.

In this work, we propose the *Clustered Fused Graphical Lasso* (CFGL) method, obtaining good detectability of changing events and taking care of temporal consistency. Motivated by the property that the thresholded hierarchical clustering is closely related to the connected components of Glasso estimated graphs [Mazumder and Hastie, 2012], we make the key observation that this clustering information indicates evidence of structure-change events and can be a reasonable heuristic. We propose a clustering framework to enhance the evidence of changes. CFGL incorporates the precomputed information into the smooth penalty so that local structures are free to detect change points.

Section 2 formulates the problem and briefly reviews the related background on Graphical Lasso and Fused Graphical Lasso estimation. Section 3 proposes the CFGL method and clarifies the algorithm details. Section 4 compares CFGL to existing methods in three different simulations. Section 5 evaluates CFGL in real cases. Section 6 concludes the paper and talks about future extensions.

## 2 BACKGROUND

### 2.1 PROBLEM DEFINITION

Say there is a sequence of multivariate observations at time points  $t_1 \leq \dots \leq t_T$ . At each time  $t_i$ ,  $n_i \geq 1$  observation vectors form  $X_i = \{x_i^1, \dots, x_i^{n_i}\} \in \mathcal{R}^{n_i \times p}$  with  $x_i \sim \mathcal{N}(0, \Sigma_i)$ . We would like to infer the underlying connectivity structures across time. Based on the aforementioned precision matrix properties, an equivalent problem is to estimate the corresponding precision matrices  $\{\Theta_i\} = \{\Theta_1, \dots, \Theta_T\}$ , one at each time point.

### 2.2 GRAPHICAL LASSO

We start from the static case,  $T = 1$ . An assumption on the number of dependencies (i.e., sparsity) is usually applied, so that only a subset with most dependencies is chosen. This would require placing a prior on the parameters to induce additional zeros on the off-diagonal entries of  $\{\Theta_i\}$ .

$$\arg \min_{\Theta} -l(\Theta) + \lambda_1 \|\Theta\|_1 \quad (1)$$

The equation (1) is *Graphical lasso* [Friedman et al., 2008], which is known to be one of the most effective

methods for this problem [Wang et al., 2012]. The empirical covariance  $S$  is defined to be  $\frac{1}{n} \sum_{i=1}^n x_i x_i^T$ , and then the log likelihood  $l(\Theta)$  is

$$l(\Theta_i) = \log \det(\Theta_i) - \text{trace}(S_i \Theta_i). \quad (2)$$

Minimizing  $-l(\Theta)$  would encourage  $\Theta$  to be close to the inverse covariance  $S^{-1}$  [Yuan and Lin, 2007]. The  $\lambda_1$  in Equation (1) is a non-negative tuning parameter to trade off the sparsity and likelihood.  $\|\Theta\|_1$  is defined to be the element-wise  $l_1$  norm of  $\Theta$ .

### 2.3 FUSED GRAPHICAL LASSO

In the case of  $T > 1$ , to estimate time series of graphs, we seek to take advantage of neighborhood information indicating temporal consistency, i.e., assume structures are similar to their neighbors. Previous methods [Danaher et al., 2014, Monti et al., 2014, Yang et al., 2015, Hallac et al., 2017] implement this assumption by adding an additional penalty to encourage smoothness. In particular, SINGLE [Monti et al., 2014], and  $l_1$ -penalized TVGL [Hallac et al., 2017] define this penalty to be an element-wise  $l_1$  norm of the difference between consecutive estimations:

$$\arg \min_{\{\Theta_i\}} \sum_{i=1}^T -l(\Theta_i) + \lambda_1 \sum_{i=1}^T \|\Theta_i\|_1 + \lambda_2 \sum_{i=2}^T \|\Theta_i - \Theta_{i-1}\|_1 \quad (3)$$

Equation (3) is usually called *Fused Graphical Lasso* (Fused Glasso), due to its relationship to its vector regularization analogue – *Fused Lasso* [Tibshirani et al., 2005], for estimating a sparse time-varying vector.

The variational norm in Fused Lasso is effective for introducing smoothness, but Qian and Jia [2012] prove that Fused lasso can recover exact patterns only if there are no consecutive change points on the timeline and all changes keep switching directions. Many real-world signal patterns obviously do not satisfy these conditions. In addition, even with the aforementioned conditions satisfied, simulated experiments on Fused Glasso show large  $F_1$  score performance drop in the vicinity of the only change point [Gibberd and Nelson, 2017]. In response, we propose the CFGL to improve signal recovery.

## 3 CLUSTERED FUSED GRAPHICAL LASSO

### 3.1 PROPOSED METHOD

Instead of assigning a uniform smoothing weight on all the entries of all precision matrices, we explore methods to distinguish between stable and non-stable connections

in the network and only apply smooth penalties on stable connections.

Mazumder and Hastie [2012] proves the close relation between connected components of the thresholded sample covariance graph and connected components of the Glasso-estimated graph. Tan et al. [2015] extends the conclusion and proves the following theorem, which states the relation between Glasso and clustering results.

Denote  $|S|$  as the matrix of element-wise absolute values of  $S$ , i.e.,  $|S|^{k,l} = |S^{k,l}|$ , where  $S$  is the normalized  $p \times p$  covariance matrix.

**Theorem 3.1.** Let  $C^1, \dots, C^K$  denote the clusters that result from performing *Single Linkage Hierarchical Clustering* (SLC) using similarity matrix  $|S|$  and cutting the resulting dendrogram at a height of  $0 \leq \lambda_1 \leq 1$ . Let  $D^1, \dots, D^R$  denote the connected components of the graphical lasso solution with tuning parameter  $\lambda_1$ . Then,  $K = R$ , and there exists a permutation  $\pi$  such that  $C^k = D^{\pi(k)}$  for  $k = 1, \dots, K$ .

Following Theorem 3.1, it is clear that the regularization parameter  $\lambda_1$  is the threshold to define connected components in the Glasso solution. We note that other clustering algorithms like *average linkage clustering* (ALC) are also used as alternative methods in Tan et al. [2015]. In the following sections, we will use *clusters* and *connected components* interchangeably. We also assume that  $\lambda_1$  is a good threshold resulting in clustering with reasonable accuracy.

Define  $V = \{v_1, \dots, v_p\}$  as the vertex set representing the entities, and  $C_i = \{C_i^1, \dots, C_i^K\}$  as the clustering result on  $|S_i|$  with parameter  $\lambda_1$ , where  $C_i(v_k)$  is the cluster label of  $v_k$ . We construct an undirected graph  $G_i = (V_i, E_i)$ , where  $E_i$  is represented in a similar form to adjacency matrix.  $E_i^{k,l} = 1$  if and only if there is a path between  $v_k$  and  $v_l$ , i.e.,

$$E_i^{k,l} = \mathbb{1}_{\{C_i(v_k)=C_i(v_l)\}}, \quad (4)$$

where  $\mathbb{1}$  is the indicator function.

If  $E_i^{k,l} = 0$ ,  $v_k$  and  $v_l$  have zero partial correlation at time  $t_i$  and thus  $\Theta_i^{k,l} = 0$ . If  $E_i^{k,l} \neq 0$ ,  $v_k$  and  $v_l$  have non-zero partial correlation on intuition and thus  $\Theta_i^{k,l} \neq 0$ .

Given consecutive clustering results  $C_{i-1}$  and  $C_i$ , we want to use the evidence of partial correlation change on between  $\Theta_{i-1}$  and  $\Theta_i$ , and define the weight matrix  $W_i \in \{0, 1\}^{p \times p}$  to help decide whether to apply the  $l_1$  smooth penalty on each entry.

- If  $E_{i-1}^{k,l} = E_i^{k,l}$ ,  $v_k$  and  $v_l$  both have either zero or non-zero partial correlation in time  $t_{i-1}$  and  $t_i$ , and we set  $W_i^{k,l} = 1$ .

Figure 1: Vertex 4 detaches from the green cluster and merges to the red cluster.

- If  $E_{i-1}^{k,l} \neq E_i^{k,l}$ , we want the partial correlation between  $v_k$  and  $v_l$  to change freely. Thus  $W_i^{k,l} = 0$ .

A simple example is illustrated in Figure 1. At time  $t_{i-1}$  (left),  $E_{i-1}^{4,l} = 1$  for  $l \in \{1, 2, 3\}$  and  $E_{i-1}^{4,l} = 0$  for  $l \in \{5, 6\}$ . At time  $t_i$ ,  $E_i^{4,l} = 0$  for  $l \in \{1, 2, 3\}$  and  $E_i^{4,l} = 1$  for  $l \in \{5, 6\}$ . Thus we set  $W_i^{4,l} = 0$  for  $l \in \{1, 2, 3, 5, 6\}$  to allow vertex 4 to freely change clusters.

Assuming the clustering threshold  $\lambda_1$  is known, we propose the following steps:

1. Perform the chosen clustering method on each empirical covariance matrix  $S_i$  to obtain a sequence of cluster sets  $C_1, C_2, \dots, C_T$ .
2. Let  $\oplus$  denote the **XOR** logical operations, and define the weight matrix set  $\{W_i\}$  as

$$W_i^{k,l} = 1 - \mathbb{1}_{\{E_{i-1}^{k,l} \oplus E_i^{k,l}\}}. \quad (5)$$

3. Apply these predefined weights and solve the following CFGL optimization problem:

$$\arg \min_{\{\Theta_i\}} \sum_{i=1}^T -l(\Theta_i) + \lambda_1 \sum_{i=1}^T \|\Theta_i\|_1 + \lambda_2 \sum_{i=2}^T \|(\Theta_i - \Theta_{i-1}) \circ W_i\|_1, \quad (6)$$

where the  $\circ$  denotes the element-wise Hadamard product.

### 3.2 MORE STABLE CLUSTER CHANGES ACROSS TIME

The previously defined procedure in section 3.1 is sometimes sensitive to the choice of parameter  $\lambda_1$ . If  $\lambda_1$  is small, clustering is sensitive to noise and very large clusters are always formed; if  $\lambda_1$  is large, sparse clustering is achieved, but vertex pairs with true partial correlation are

likely to be overlooked. Even if  $\lambda_1$  is within an acceptable range, the variations of values around the threshold may lead to grouped and detached clusters, introducing redundant switching. Therefore, no matter what value  $\lambda_1$  is picked, the precomputed clustering change information tends to be noisy.

Since SLC is more unstable with noise and usually has undesirable chain structures [Hastie et al., 2009], Tan et al. [2015] use ALC instead of SLC for clustering on a single network. However, when merging individual and small clusters, ALC is similar to SLC and still suffers severely from noise. The frequent switching problem occurs on boundary values as well. We propose a framework to increase the stability of clustering changing across time (Algorithm 1) and make it applicable to most clustering algorithms.

The idea can be easily explained in the simplest case of hierarchical clustering. Consider there are two vertices,  $v_k$  and  $v_l$ , we propose to have two thresholds  $\lambda_1$  and  $\lambda_1^*$ , with  $\lambda_1^*$  smaller than  $\lambda_1$ , i.e.,  $\lambda_1 = \lambda_1^* + \gamma$  and  $\gamma > 0$ .

- $\lambda_1$  is used to judge whether  $v_k$  and  $v_l$  should be grouped at time  $t_i$  if not grouped at time  $t_{i-1}$ .
- $\lambda_1^*$  is used to judge whether they should be grouped again if they are grouped at time  $t_{i-1}$ .

In other words, we define the condition of  $v_k$  and  $v_l$  being clustered together as

$$\text{Cond}_{C_i(v_k)=C_i(v_l)} = \begin{cases} |S_i^{k,l}| \geq \lambda_1, & \text{if } i = 0 \text{ or } E_{i-1}^{k,l} = 0 \\ |S_i^{k,l}| \geq \lambda_1^*, & \text{if } E_{i-1}^{k,l} = 1 \end{cases} \quad (7)$$

To generalize the idea to complex cases (e.g., merging two clusters), Algorithm 1 is proposed. The input  $\{S_i\}$  is the sequence of similarity matrices (normalized empirical covariance),  $\gamma$  can be understood as the gap or stabilizing parameter, and  $f$  is the clustering algorithm (i.e. represented as a function).

---

**Algorithm 1** Stable Clustering Framework across Time

---

**Input:**  $\{S_i\}, \gamma, f$   
**Output:**  $\{C_i\}, \{E_i\}$   
1:  $C_1 = f(|S_1|)$   
2: Construct  $E_1$  on  $C_1$  using Equation (4)  
3: **for**  $i = 2$  to  $T$  **do**  
4:  $\hat{S}_i = |S_{i-1}| + \gamma E_{i-1}$   
5:  $C_i = f(\hat{S}_i)$   
6: Construct  $E_i$  on  $C_i$  using Equation (4)  
7: **end for**

---

The choice of  $\gamma$  depends on the clustering algorithm  $f$ , and also on the level of noise  $e$  we define (to maintain

sparsity). Here we propose a heuristic choice for the hierarchical clustering case. Under the assumption that the previous clustering is accurate, there are two kinds of errors related to  $\gamma$ :

1.  $|S_i|^{k,l} \geq \lambda_1 - \gamma$  with true  $E_{i-1}^{k,l} = 1 \wedge E_i^{k,l} = 0$ .
2.  $|S_i|^{k,l} \leq \lambda_1 - \gamma$  with true  $E_{i-1}^{k,l} = 1 \wedge E_i^{k,l} = 1$ .

Let  $n$  be the sample size of each estimated  $S_i$ , the standard error of correlation coefficient  $r = S_i^{k,l}$  is  $se(r, n) = \sqrt{\frac{1-r^2}{n-2}}$ . If we assume normally distributed error, the sampled correlation is  $\bar{r} \sim \mathcal{N}(r, se(r, n)^2)$ .

Let us assume the exact true correlation coefficient of all the  $k, l$  pairs is  $\lambda_1$  if  $E^{k,l} = 1$ , and  $e$  if  $E^{k,l} = 0$ . Intuitively, we want  $\lambda_1 - \gamma$  to be as far as possible from both  $\lambda_1$  and  $e$  on their standard error normalized distances. Thus, we can heuristically estimate  $\gamma$  as:

$$\gamma = \frac{se(\lambda_1, n)(\lambda_1 - e)}{se(\lambda_1, n) + se(e, n)} \quad (8)$$

### 3.3 PARAMETER TUNING

All that remains is to tune the parameters  $\lambda_1$  and  $\lambda_2$ . Following Hallac et al. [2017] and Monti et al. [2014], we use Akaike Information Criteria (AIC) to tune these hyperparameters. For a given pair  $(\lambda_1, \lambda_2)$ , we define the AIC as:

$$AIC(\lambda_1, \lambda_2) = 2 \sum_{i=1}^T -l(\Theta_i) + 2K. \quad (9)$$

where the estimated degree of freedom  $K$  is slightly different from the definition in Tibshirani et al. [2005], and is given by:

$$K = \sum_{k,l} \sum_{i=2}^T \mathbb{1}_{\{(\Theta_i^{k,l} \neq 0 \oplus \Theta_{i-1}^{k,l} \neq 0) \wedge (\Theta_i^{k,l} \neq 0 \wedge W_i^{k,l} \neq 0)\}} \quad (10)$$

In equation (10), we do not penalize the changes unrelated to 0 since graphical lasso focuses more on the occurrence of edges. Term  $W_i^{k,l}$  is added to avoid penalizing intentionally allowed changes.

Observe that a small  $\lambda_1$  may result in huge clusters and  $W_i^{k,l} \neq 0$  everywhere, which makes CFGL equivalent to Fused Glasso. In addition to a typical grid search with AIC score, CFGL requires  $\lambda_1$  to be in a smaller pre-decided range. Therefore, we need to first tune a series of static graphical lasso (Static Glasso) with AIC to achieve an appropriate range of  $\lambda_1$ . Other methods can be used

to predefine the range, as long as they distinguish CFGL with typical Fused Glasso.

For a fixed sparse penalty  $\lambda_1$ , the clustering threshold can be either set to be  $\lambda_1$  or slightly higher in order to compensate for the use of  $\gamma$ . The CFGL algorithm is described in Algorithm 2.

---

**Algorithm 2** CFGL and Parameter Tuning

---

**Input:**  $\{S_i\}, f$

**Output:**  $\{\Theta_i\}$

- 1: Tune  $\lambda_1^*$  on static graphical lasso using AIC score
  - 2: Obtain a range of  $\lambda_1$  near the best  $\lambda_1^*$  from 1
  - 3: **for**  $\lambda_1$  among choices **do**
  - 4:   **for**  $\lambda_2$  among choices **do**
  - 5:     Compute  $\{E_i\}$  using  $\{S_i\}, f$  and  $\lambda_1$  via Algorithm 1
  - 6:     Compute  $\{W_i\}$  using  $\{E_i\}$  and equation (5)
  - 7:     Obtain  $\{\Theta_i\}_{\lambda_1, \lambda_2}$  that minimizes equation (6)
  - 8:     Compute AIC score of  $\{\Theta_i\}$
  - 9:   **end for**
  - 10: **end for**
  - 11: **return**  $\{\Theta_i\}_{\lambda_1, \lambda_2}$  which minimizes the AIC score
- 

### 3.4 OPTIMIZATION ALGORITHM

We use Alternating Directions Method of Multipliers (ADMM) [Boyd et al., 2011] algorithm to solve the optimization problem. Firstly, define the problem as:

$$\begin{aligned} \underset{\{\Theta_i\}, \{Z_i\}}{\text{minimize}} \quad & \sum_{i=1}^T -l(\Theta_i) + \lambda_1 \sum_{i=1}^T \|Z_i\|_1 \\ & + \lambda_2 \sum_{i=2}^T \|(Z_i - Z_{i-1}) \circ W_i\|_1 \end{aligned} \quad (11)$$

subject to:  $\Theta_i = Z_i$ , for  $i = 1, 2, 3, \dots, T$ .

The augmented Lagrangian corresponding to equation (11) is defined as:

$$\begin{aligned} \mathcal{L}_\rho(\{\Theta_i\}, \{Z_i\}, \{U_i\}) = & \sum_{i=1}^T -l(\Theta_i) \\ & + \lambda_1 \sum_{i=1}^T \|Z_i\|_1 + \lambda_2 \sum_{i=2}^T \|(Z_i - Z_{i-1}) \circ W_i\|_1 \\ & + \frac{\rho}{2} \sum_{i=1}^T (\|\Theta_i - Z_i + U_i\|_2^2 - \|U_i\|_2^2), \end{aligned} \quad (12)$$

where  $\{U_i\}$  are scaled dual variables, and  $\rho$  is a constant penalty parameter in ADMM which is usually set to one. Consequently, we get the update rule for  $U_i, \Theta_i$  for  $i =$

$1, \dots, T$ , and  $\{Z_i\}$  in  $j + 1$ th iteration:

$$\Theta_i^{j+1} = \arg \min_{\Theta_i^{j+1}} \frac{\rho}{2} \|\Theta_i - Z_i^j + U_i^j\|_2^2 - l(\Theta_i) \quad (13)$$

$$\{Z_i^{j+1}\} = \arg \min_{\{Z_i^{j+1}\}} \mathcal{L}_\rho(\{\Theta_i^{j+1}\}, \{Z_i\}, \{U_i^j\}) \quad (14)$$

$$U_i^{j+1} = U_i^j + \Theta_i^{j+1} - Z_i^{j+1} \quad (15)$$

Thus, the update step (13) is same in a typical fused graphical lasso, and the solution is discussed in detail by Monti et al. [2014] and Danaher et al. [2014]. For the  $Z$  update step (14), since all of these are element-wise operations, we can solve each  $\{Z_i^{j+1}\}^{k,l}$  separately.

$$\begin{aligned} & \arg \min_{\{Z_i^{j+1}\}^{k,l}} \frac{\rho}{2} \sum_{i=1}^T \|\{\Theta_i^{j+1} - Z_i + U_i^j\}^{k,l}\|_2^2 \\ & + \lambda_1 \sum_{i=1}^T \|Z_i^{k,l}\|_1 + \lambda_2 \sum_{i=2}^T \|(Z_i^{k,l} - Z_{i-1}^{k,l}) \circ W_i^{k,l}\|_1 \end{aligned}$$

Set  $y_i = (\Theta_i^{j+1} + U_i^j)^{k,l}$  and  $\beta_i = (Z_i)^{k,l}$ . We get the following equation:

$$\begin{aligned} \mathbf{f}_{1,T}^*(\beta) = & \sum_{i=1}^T \frac{\rho}{2} \|y - \beta_i\|_2^2 + \lambda_1 \sum_{i=1}^T \|\beta_i\|_1 \\ & + \sum_{i=2}^T \lambda_{i,i-1} \|\beta_i - \beta_{i-1}\|_1, \end{aligned}$$

where the  $\lambda_{i,i-1}$  is defined to be  $\lambda_2 W_i^{k,l}$ .

Note that the nonzero value of  $\lambda_{i,i-1}$  enforces  $\beta_i$  and  $\beta_{i-1}$  to be close, and a zero value in  $\lambda_{i,i-1}$  splits the above equation into several smaller pieces. If  $W_i^{k,l} \neq 0$  for all  $i$ , the equation is equivalent to a 1-dimensional FLSA as shown below, whose solver has been well discussed by Friedman et al. [2007], Hoefling [2010]:

$$\begin{aligned} \mathbf{f}_{1,T}(\beta) = & \sum_{i=1}^T \frac{\rho}{2} \|y - \beta\|_2^2 + \lambda_1 \sum_{i=1}^T \|\beta_i\|_1 \\ & + \lambda_2 \sum_{i=2}^T \|\beta_i - \beta_{i-1}\|_1. \end{aligned}$$

If  $W_i^{k,l} = 0$  for  $i \in \{m_1, \dots, m_D\}$ ,  $m_0 = 1, m_1 \geq 2, m_D \leq T$  and  $m_{D+1} = T$ , solving the above problem is equivalent to separately solving  $D + 1$  independent 1-dimensional FLSA. In other words,  $\beta$  becomes the concatenation of  $\{\beta^1, \dots, \beta^{D+1}\}$ , and

$$\beta^d = \arg \min_{\beta} f_{m_{d-1}, m_d}(\beta).$$

It is shown in the supplement that  $\{W_i\}$  does not introduce any additional complexity. Also, the update steps (13) and (14) can be easily parallelized, making the optimization algorithm very scalable.

## 4 SIMULATED EXPERIMENTS

To perform simulations, we first construct three groups of signal patterns, outlined in Figure 2, ranging from sudden stimuli to long-term switches. Group 1 has two short-term changes lasting for three time points. Group 2 has three short stimuli happening in only one time point. Signals in Group 3 have equal length and are sequentially distributed across time.

### 4.1 EXPERIMENT SETUP

We generate the simulated data from an Erdős–Rényi random graph  $G = \{V, E\}$  under the controlled sparsity  $|E| = 0.5 |V|$ . To form the precision matrix  $\hat{\Theta}_i$  and sampled observation data, we use the following method, similar to Gibberd and Nelson [2017]

1. Set an empty  $|V| \times |V|$  matrix and insert off-diagonal terms based on edges in  $G$  with values chosen from  $Unif(0.6, 0.9)$ .
2. Equally shift all the diagonal entries by a positive value so that the smallest eigenvalue is 0.1 to ensure positive semi-definiteness.
3. Normalize the matrix to have value 1 on diagonal.
4. Generate observation data  $X_i = \{x_1^1, \dots, x_1^{n_i}\}$  and  $x_i^j \sim \mathcal{N}(0, \hat{\Theta}_i^{-1})$ .

For all the three simulations datasets, we set  $|V| = 25$ . The generated precision matrices  $\{\hat{\Theta}_i\}$  have off-diagonal terms with values around 0.5. There are total 30 time points, each with 25 observations, i.e.,  $T = 30$  and  $n_i = 25$  for all  $i$ .

We compare to four state-of-the-art baseline methods, the static graphical lasso [Friedman et al., 2008], the fused graphical lasso from SINGLE [Monti et al., 2014], the  $l_1$  penalized TVGL [Hallac et al., 2017], and the group fused graphical lasso (GFGL) [Gibberd and Nelson, 2017]. For Static Glasso, the graph at each time  $t_i$  is estimated independently. So we solve a total of  $T$  Glasso (1) problems to get  $T$  separate graphs. The degree of freedom  $K$  in Glasso is defined as the number of non-zero entries [Tibshirani et al., 2005]. Although both SINGLE and  $l_1$ -TVGL have exactly the same fused graphical lasso objective in optimization, they use different optimization solvers which often result in different performance. We put both methods here as baselines and denote them as FGL-SINGLE and FGL-TVGL accordingly. Also, it is worth mentioning that CFGL shares a similar optimization solver as FGL-SINGLE.

We use four different versions of CFGL to compare to three baseline methods, listed in table 1. The  $\Gamma$  repre-

Table 1: Notation of CFGL Related Methods

Notation	Clustering Method	Threshold
CFG <sub>L</sub> -alc	ALC	$\lambda_1$
CFG <sub>L</sub> -slc	SLC	$\lambda_1$
CFG <sub>L</sub> -alc2	ALC	$\lambda_1 + \Gamma/2$
CFG <sub>L</sub> -slc2	SLC	$\lambda_1 + \Gamma/2$

sents a rough estimation by applying equation (8) on AIC tuned Static Glasso  $\lambda_1$ . CFGL related methods are tuned using Algorithm 2. The four baseline methods are tuned by a typical grid search to minimize their correspondingly defined AIC score. Gibberd and Nelson [2017] tentatively propose a BIC score to tune GFGL in unsupervised tasks, but we find AIC generates slightly better results in our simulations. To eliminate the potential performance difference caused by tuning range, baseline methods are also tuned by Algorithm 2, and the result with better  $F_1$ -score is chosen. We repeat the whole process 10 times to reduce randomness, each time generating a new set of Erdős–Rényi graphs and observations. The averaged performance results are shown in Table 2.

### 4.2 PERFORMANCE METRICS

We measure the performance of each method using three metrics:  $F_1$ -score,  $F_1$ -ratio, and edge deviation ratio.

#### 4.2.1 $F_1$ Score

This measures how close the captured structures are to the true graphs. The  $F_1$  Score shown in Table 2 is the averaged  $F_1$  score across all the time points. Thus it provides an overview of performance for both static points and signals.

#### 4.2.2 $F_1$ Ratio

We define  $F_1$  ratio to be the average ratio between  $F_1$  scores at the starting points of changing signals and the overall averaged  $F_1$  score.  $F_1$  ratio indicates the performance of accurate edge detection at change points.

#### 4.2.3 Edge Deviation (ED) Ratio

We define ED Ratio to be the average ratio between edge deviations (number of changing edges) at starting points of changing signals and the overall averaged edge deviations. Unlike  $F_1$  ratio which pays more attention to the correctness, ED ratio focuses more on changing detecting and provides an unsupervised measure.

Figure 2: Signal patterns with same numerical values have exactly same graph structure and ground truth precision matrix. Signal patterns with same absolute values but opposite signs have the same graph structure but opposite signs in the off diagonal values in precision matrix.

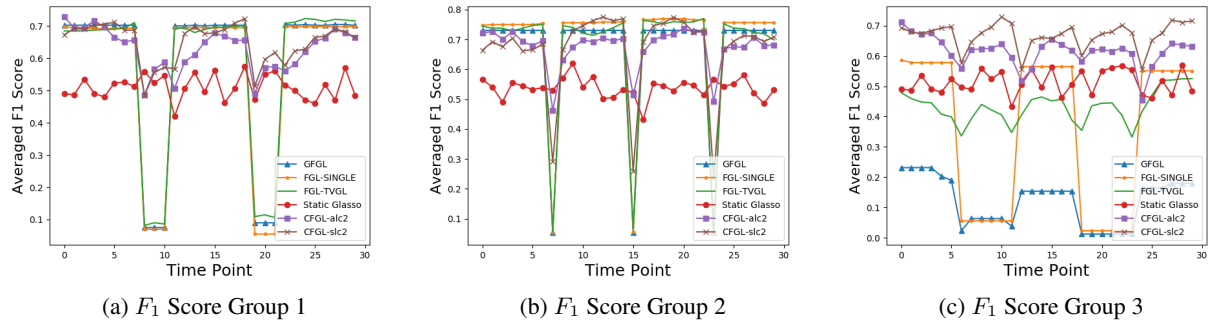

Figure 3: Each point on the curve represents the averaged  $F_1$  score at that time point among 10 repetitions.

Figure 4: Each point on the curve represents the averaged number of changing edges between consecutive time points among 10 repetitions.

### 4.3 SIMULATION RESULTS

CFGL-alc2 and CFGL-alc have stably good performance in all three metrics. The comparison between CFGL-slc2 and CFGL-slc indicates that SLC based clustering is more sensitive to the choice of thresholds.

Although Static Glasso always achieves good values on  $F_1$  ratio and ED ratio, its low  $F_1$  score implies not using neighborhood information. The performance of FGL-SINGLE shows that it tends to choose parameters which strongly highlight temporal consistency, resulting in overlooking signals. FGL-TVGL performs slightly better on signal detection, but both the metrics in Table 2 and the curves in Figures 3 and 4 show that it fails to take care of temporal consistency and diversity at the same time. For GFGL, although our simulation perfectly satisfies their assumption that change time points tend to group together and the other time points remain static, GFGL estimated structures do not reflect the changing periods properly. The static periods are also highly disturbed by long changing periods in signal group 3. This may be due to the difficulty finding good parameters for GFGL in unsupervised scenarios, which was mentioned by Gibberd and Nelson [2017] as well.

## 5 CASE STUDIES

In this section, we apply CFGL to more complicated real-world datasets to show how the CFGL method can be used to provide insights into real-world multivariate time series datasets.

### 5.1 EEG EYE STATE

Electroencephalography (EEG) is a medical imaging technique that reads scalp electrical activities generated by brain structures, and EEG measurements are commonly used in medical and research areas to infer brain

activities [Teplan et al., 2002]. The dataset we use is the EEG eye state dataset [Roesler, 2013] from the UC Irvine repository. All data is from one continuous EEG measurement with the Emotiv EEG Neuroheadset. The eye state was detected via a camera during the measurement and added later manually after analyzing the video frames.

Table 3: Cross Validated Results on Estimated Structures

Notation	Cross Validated Accuracy
Static Glasso	0.6625
FGL-TVGL	0.800
FGL-SINGLE	0.6875
CFGL-alc	0.8375
CFGL-alc2	<b>0.8875</b>

In this experiment, we pick the first 2000 observations, and we group every 25 observations to form a time point, which is roughly 0.2 seconds. All the methods use the aforementioned tuning procedure. Considering there is no ground truth graph structure in EEG data, we treat the video captured eye state as a ground truth signal. We use the estimated structures as transformed features (i.e., edges present or not) and train a linear SVM model to predict the corresponding eye state. We observe that the prediction performance is related to the feature sparsity, and thus we tune the parameters so that all methods have similar sparsity (about 25% edges present). The result of 10 fold cross-validation is shown in Table 3. In addition, we provide an aligned comparison between the eye state and edge changes. Considering the uncontrollable brain activities and the latency between brains and eye states, we smooth the edge-change signals by the Gaussian kernel. As shown in Figure 5, CFGL performs very well for capturing eye state switching events.

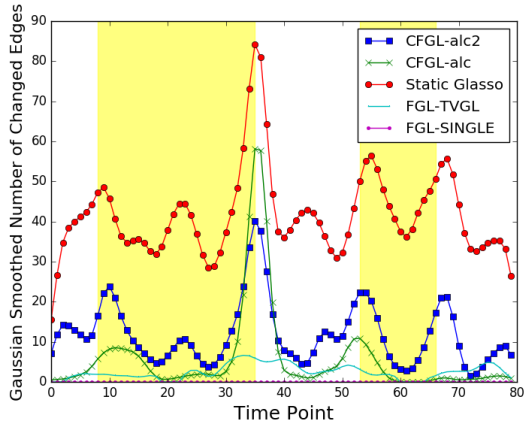

Figure 5: Edge changes are smoothed by Gaussian kernel. The yellow regions represent the period when subject closed his/her eyes.

## 5.2 STOCK MARKET

In this experiment, we apply CFGL to the financial data in the stock market to explore the economic structures of stocks. These structures can be used to provide high-level understanding of company relations. In particular, the stock prices are natural multivariate time-series datasets, and they are also good indicators of company conditions. We assume each company’s stock price is dependent on companies in the same or related fields, and is more likely to be independent to companies in unrelated fields. We pick 20 big companies, roughly 2 from each category of OS, Internet Service, PC, Auto, Restaurant, Finance, Energy, and Sales. Then we infer their structure changes during the global financial crisis of 2008<sup>1</sup>. We pick the dates starting from June 1st 2006 to August 4th 2009, total 800 days in the stock market, and use 20 days to form a time point so that each roughly represents a month.

TED spread is defined as the difference between the interest rates on interbank loans and on short-term U.S. government debt. It is usually treated as the indicator of perceived credit risk in the general economy [Boudt et al., 2017]. Thus we use the TED spread’s changes as the reference of financial events. Figure 6 shows the comparison between the structural changes in estimated stock networks, and the TED spread changes between consecutive periods. It can be observed that the two curves follow similar patterns. There is a shift between the largest change of TED spread and stock market structure. We further investigated and found that the stock market started to drop in early September (around

<sup>1</sup>Data freely available online from <https://quantquote.com/historical-stock-data>.

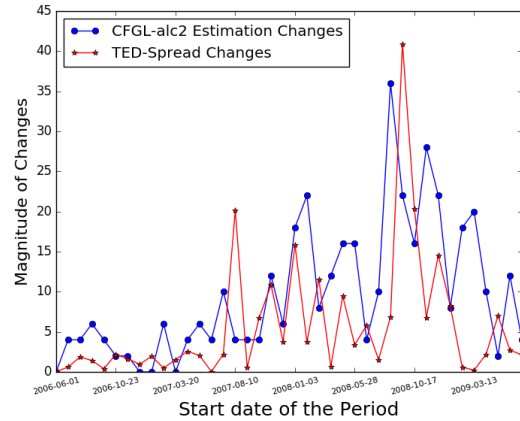

Figure 6: Edge Changes and TED Spread Changes

September 8th), which is exactly at the time of the blue peak but one time point earlier than the red peak. This result may indicate that TED spread has some latency for detecting stock market changes.

## 6 CONCLUSIONS AND FUTURE WORK

We propose *Clustered Fused Graphical Lasso* (CFGL) to improve the signal sensitivity of Fused Graphical Lasso (FGL). CFGL applies clustering based heuristic information on the smooth penalty so that temporal consistency and temporal diversity are simultaneously considered. Our experimental results show that the clustering information often makes CFGL more sensible for capturing signal changes, and CFGL outperforms FGL methods on datasets with time-varying underlying structures. The incorporated clustering information is independent of the smooth penalties. Therefore, there are many possible extensions either applying this information to other penalties, or setting up better methods for clustering.

## Abstract

We propose a framework for the completely unsupervised learning of latent object properties from their interactions: the *perception-prediction network* (PPN). Consisting of a perception module that extracts representations of latent object properties and a prediction module that uses those extracted properties to simulate system dynamics, the PPN can be trained in an end-to-end fashion purely from samples of object dynamics. The representations of latent object properties learned by PPNs not only are sufficient to accurately simulate the dynamics of systems comprised of previously unseen objects, but also can be translated directly into human-interpretable properties (*e.g.* mass, coefficient of restitution) in an entirely unsupervised manner. Crucially, PPNs also generalize to novel scenarios: their gradient-based training can be applied to many dynamical systems and their graph-based structure functions over systems comprised of different numbers of objects. Our results demonstrate the efficacy of graph-based neural architectures in object-centric inference and prediction tasks, and our model has the potential to discover relevant object properties in systems that are not yet well understood.

## 1 INTRODUCTION

The physical properties of objects, combined with the laws of physics, govern the way in which objects move and interact in our world. Assigning properties to objects we observe helps us summarize our understanding of those objects and make better predictions of their future behavior. Often, the discovery of such properties can be performed with little supervision. For instance, by watching an archer shoot several arrows, we may conclude

that properties such as the tension of the bowstring, the strength and direction of the wind, and the mass and drag coefficient of the arrow affect the arrow's ultimate trajectory. Even when given observations from entirely novel microworlds, humans are still able to learn the relevant physical properties that characterize a system [1].

Our work utilizes recent advances in neural relation networks in order to learn latent physical properties of a system in an unsupervised manner. In particular, the neural relation architectures [2, 3] have proven capable of accurately simulating complex physical interactions involving objects with known physical properties. Relation networks have several characteristics that make them particularly suitable for our task: they are fully differentiable, allowing them to be applied to a variety of different situations without the need for any architectural change; they have a modular graph-based structure that generalizes over differing numbers of objects; and their basic architecture can be easily applied to both dynamics prediction and the learning of latent properties.

We use relation networks to construct the perception-prediction network (PPN), a novel system that uses a representation learning [4] paradigm to extract an encoding of the properties of a physical system purely through observation. Unlike previous neural relation architectures, which only use relation networks to predict object states with known property values, we use relation networks to create both a *perception network*, which derives property values from observations, and a *prediction network*, which predicts object positions given property values. The PPN is able to derive unsupervised representations of the latent properties relevant to physical simulations purely by observing the dynamics of systems comprised of objects with different property values. These learned representations can be translated directly into human-interpretable properties such as mass and coefficient of restitution.

One crucial aspect of our system is generalization, which humans excel at when inferring latent properties of novel

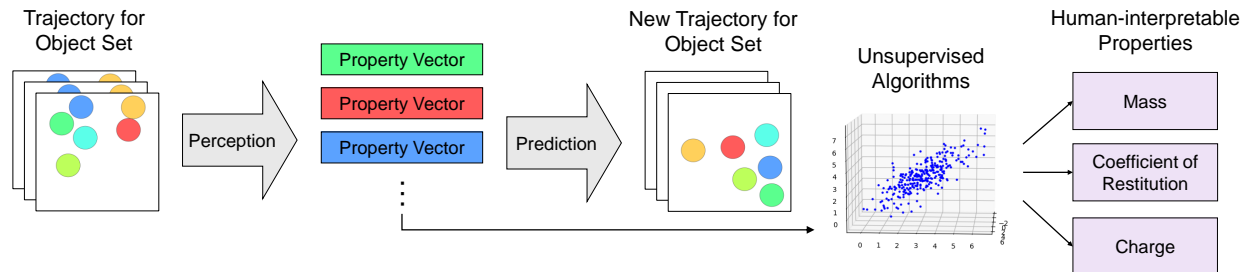

Figure 1: **Model overview.** The unsupervised object property discovery paradigm that the PPN follows extracts property vectors from samples of object dynamics to accurately predict new trajectories of those same objects. Applying unsupervised learning methods to the learned vectors allows for the extraction of human-interpretable object properties.

systems. Our proposed system is robust under several forms of generalization, and we present experiments demonstrating the ability of our unsupervised approach to discern interpretable properties even when faced with different numbers of objects during training and testing as well as property values in previously unseen ranges.

We evaluate the PPN for two major functionalities: the accuracy of dynamics prediction for unseen objects and the interpretability of properties learned by the model. We show that our model is capable of accurately simulating the dynamics of complex multi-interaction systems with unknown property values after only a short observational period to infer those property values. Furthermore, we demonstrate that the representations learned by our model can be easily translated into relevant human-interpretable properties using entirely unsupervised methods. Additionally, we use several experiments to show that both the accuracy of dynamics prediction and interpretability of properties generalize well to new scenarios with different numbers and configurations of objects. Ultimately, the PPN serves as a powerful and general framework for discovering underlying properties of a physical system and simulating its dynamics.

## 2 RELATED WORK

Previous methods of modeling intuitive physics have largely fallen under two broad categories: top-down approaches, which infer physical parameters for an existing symbolic physics engine [1, 5, 6, 7, 8, 9], and bottom-up approaches, which directly predict physical quantities or future motion given observations [10, 11, 12, 13, 14, 15, 16]. While top-down approaches are able to generalize well to any situation supported by their underlying physics engines (*e.g.* different numbers of objects, previously unseen property values, etc.), they are difficult to adapt to situations not supported by their underlying description languages, requiring manual modifications to support new types of interactions. On the other hand, bottom-up approaches are often capable of learning the dynamics of formerly unseen situations without any fur-

ther modification, though they often lack the ability to generalize in the same manner as top-down approaches.

Recently, a hybrid approach has used neural relation networks, a specific instance of the more general class of graph-based neural networks [17, 18], to attain the generalization benefits of top-down approaches without requiring an underlying physics engine. Relation networks rely on the use of a commutative and associative operation (usually vector addition) to combine pairwise interactions between object state vectors in order to predict future object states [19]. These networks have demonstrated success in simulating multiple object dynamics under interactions including Coulomb charge, object collision (with and without perfect elasticity), and spring tension [2, 3, 20, 21]. Much like a top-down approach, relation networks are able to generalize their predictions of object position and velocity to different numbers of objects (training on 6 objects and testing on 9, for instance) without any modification to the network weights; furthermore, they are fully differentiable architectures that can be trained via gradient descent on a variety of interactions. Our paper leverages the interaction network in a novel way, demonstrating for the first time its efficacy as a perception module and as a building block for unsupervised representation learning.

Additional research has looked at the supervised and unsupervised learning of latent object properties, attempting to mirror the inference of object properties that humans are able to perform in physical environments [1]. Wu *et al.* [9] leverages a deep model alongside set physical laws to estimate properties such as mass, volume, and material from raw video input. Fraccaro *et al.* [22] uses a variational autoencoder to derive the latent state of a single bouncing ball domain, which they then simulate using Kalman filtering. Chang *et al.* [3] demonstrate that their relation network based physics simulator is also capable of performing maximum-likelihood inference over a discrete set of possible property values by comparing simulation output for each possibility to reality. Our paper goes one step further by showing that physical proper-

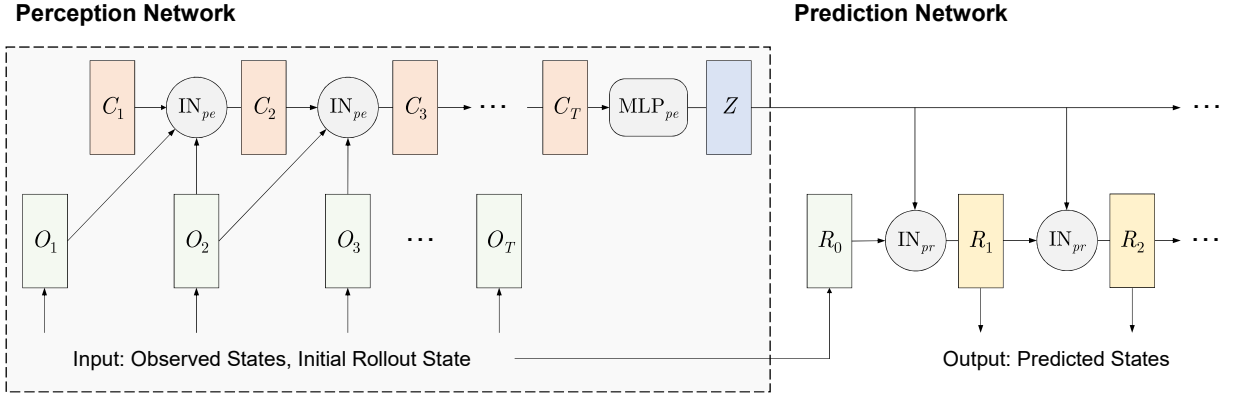

Figure 2: **Model architecture.** The PPN takes as input a sequence of observed states  $O_1, \dots, O_T$  as well an initial state  $R_0$  to begin a new rollout. Code vectors  $C_1, \dots, C_T$  are derived from the observed states using interaction networks and a final property vector  $Z$  is produced by the perception network. The property vector is then utilized by the prediction network to recursively predict future object states  $R_1, R_2, \dots$  for a new rollout given initial state  $R_0$ . We train the PPN to minimize the L2 distance between the predicted rollout states and the ground truth states for those timesteps.

ties can be learned from no more than raw motion data of multiple objects. Recently, Kipf *et al.* [23] has also utilized relation networks to infer the identity of categorical interactions between objects; in contrast, our paper is concerned with the learning of object properties.

### 3 MODEL

#### 3.1 PERCEPTION-PREDICTION NETWORK

The PPN observes the physical dynamics of objects with unknown latent properties (*e.g.* mass, coefficient of restitution) and learns to generate meaningful representations of these object properties that can be used for later simulations. An overview of the full network is shown in Figure 1. The PPN consists of the following two components:

- The **perception network** takes as input a sequence of frames on the movements of objects over a short observation window. It outputs a *property vector* for each object in the scene that encodes relevant latent physical properties for that object. Each input frame is a set of *state vectors*, consisting of each object’s position and instantaneous velocity. During training, no direct supervision target is given for the property vectors.
- The **prediction network** uses the property vectors generated by the perception network to simulate the objects from a different starting configuration. The network takes as input the property vectors generated by the perception network and new initial state vectors for all objects. Its output is a rollout of the objects’ future states from their new starting state. The training target for the prediction network is the ground truth states of the rollout sequence.

We implement both the perception and prediction networks using interaction networks [2], a specific type of neural relation network that is fully differentiable and generalizes to arbitrary numbers of objects. This enables us to train both networks end-to-end using gradient descent with just the supervision signal of the prediction network’s rollout target, as the property vectors output by the perception network feed directly into the prediction network.

#### 3.2 INTERACTION NETWORK

An interaction network (IN) is a relation network that serves as the building block for both the perception and prediction networks. At a high level, interaction networks use multilayer perceptrons (MLPs) to implement two modular functions, the relational model  $f_{\text{rel}}$  and the object model  $f_{\text{obj}}$ , which are used to transform a set of object-specific input features  $\{x^{(1)}, \dots, x^{(N)}\}$  into a set of object-specific output features  $\{y^{(1)}, \dots, y^{(N)}\}$ , where  $N$  is the number of objects in a system. Given input features for two objects  $i$  and  $j$ ,  $f_{\text{rel}}$  calculates the “effect” vector of object  $j$  on object  $i$  as  $e^{(i,j)} = f_{\text{rel}}(x^{(i)}, x^{(j)})$ . The net effect on object  $i$ ,  $e^{(i)}$ , is the vector sum of all pairwise effects  $\sum_{j \neq i} e^{(i,j)}$  on object  $i$ . Finally, the output for object  $i$  is given by  $y^{(i)} = f_{\text{obj}}(x^{(i)}, e^{(i)})$ . Importantly,  $f_{\text{obj}}$  and  $f_{\text{rel}}$  are shared functions that are applied over all objects and object-object interactions, allowing the network to generalize across variable numbers of objects.

Interaction networks are capable of learning state-to-state transition functions for systems with complex physical dynamics. More generally, however, interaction networks can be used to model functions where input and output features are specific to particular objects and the relationship between input and output is the same for each object.

While our prediction network uses an interaction network to simulate state transitions, our perception network uses an interaction network to make incremental updates on the values of object latent properties from observed evidence.

### 3.3 PERCEPTION NETWORK

The perception network produces object-specific property vectors,  $Z$ , from a sequence of observed states  $O$ . As shown in Figure 2, our perception network is a recurrent neural network that uses an interaction network as its core recurrent unit. The perception network begins with object-specific code vectors,  $C_1$ , initialized to zero vectors, with some fixed size  $L_C$  for each object. At each step  $t$ , the IN takes in the previous code vectors,  $C_{t-1}$ , as well as the last two observed states,  $O_{t-1}$  and  $O_t$ , to produce updated code vectors,  $C_t$ , also of size  $L_C$ . After processing all  $T_O$  observation frames, the perception network feeds the final code vectors  $C_{T_O}$  into a single code-to-property MLP that converts each object’s code vector into an “uncentered” property vector of size  $L_Z$  per object. We denote the final collection of uncentered property vectors as  $Z_u$ .

In many physical systems, it may be impossible or undesirable to measure the latent properties of objects on an absolute scale. For example, in a system where two balls collide elastically, a collision can only inform us on the mass of each object relative to the other object, not their absolute mass values. In order to allow for the inference of absolute property values, we let the first object of every system serve as a *reference object* and take on the same property values in each system. In doing so, we can infer the absolute property values of all other objects by observing their value relative to the reference object. To enforce inference relative to the reference object, we “center” the property vectors by subtracting the reference object’s uncentered property vector from each object’s uncentered property vector, producing the final property vectors  $Z$ . Note that this ensures that the reference object’s property vector is always a zero vector, agreeing with the fact that its properties are known to be constant. We can summarize the perception network with the following formulas:

$$C_1 = \mathbf{0} \quad (1)$$

$$C_t = \text{IN}_{pe}(C_{t-1} \| O_{t-1} \| O_t), \text{ for } t = 2, \dots, T_O \quad (2)$$

$$Z_u^{(i)} = \text{MLP}_{pe} \left( C_{T_O}^{(i)} \right), \text{ for } i = 1, \dots, N \quad (3)$$

$$Z^{(i)} = Z_u^{(i)} - Z_u^{(1)}, \text{ for } i = 1, \dots, N \quad (4)$$

where  $\|$  is the object-wise concatenation operator,  $\text{IN}_{pe}$  is the perception interaction network,  $\text{MLP}_{pe}$  is the code-to-property MLP, and  $Z_u^{(1)}$  is the reference object’s uncentered property vector.

### 3.4 PREDICTION NETWORK

The prediction network performs state-to-state rollouts of the system from a new initial state,  $R_0$ , using the property vectors produced by the perception network. Like the perception network, the prediction network is a recurrent neural network with an Interaction Network core. At step  $t$ , the IN takes in the previous state vectors,  $R_{t-1}$ , and the property vectors,  $Z$ , and outputs a prediction of the next state vectors,  $R_t$ . In other words,

$$R_t = \text{IN}_{pr}(R_{t-1} \| Z), \text{ for } t = 1, \dots, T_R \quad (5)$$

where  $\text{IN}_{pr}$  is the prediction interaction network and  $T_R$  is the number of rollout frames.

The prediction loss for the model is the total MSE between the predicted and true values of  $\{R_t\}_{t=1 \dots T_R}$ .

## 4 EXPERIMENTS

### 4.1 PHYSICAL SYSTEMS

For our experiments, we focus on 2-D domains where both the latent property inference task and the subsequent dynamics prediction task are challenging. In all systems, the first object serves as the reference object and has fixed properties. All other objects’ properties can be inferred relative to the reference object’s properties. We evaluate the PPN on the following domains (see Fig. 5):

- **Springs** Balls of equal mass have a fictitious property called “spring charge” and interact as if all pairs of objects were connected by springs governed by Hooke’s law\*. The reference object has a spring charge of 1, while all other objects have spring charges selected independently at random from the log-uniform† distribution over  $[0.25, 4]$ . The spring constant of the spring connecting any given pair of objects is the product of the spring charges of the two objects, and the equilibrium distance for all springs is a fixed constant.
- **Perfectly Elastic Bouncing Balls** Balls of fixed radius bounce off each other elastically in a closed box. The reference object has a mass of 1. Each other ball has a mass selected independently at random from the log-uniform distribution over  $[0.25, 4]$ . The four walls surrounding the balls have infinite mass and **do not move**.

\*Two objects connected by a spring governed by Hooke’s law are subject to a force  $F = -k(x - x_0)$ , where  $k$  is the spring constant of the spring,  $x$  is the distance between the two objects, and  $x_0$  is the spring’s equilibrium distance. The force is directed along the line connecting the two objects but varies in sign: it is attractive if  $x > x_0$  and repulsive if  $x < x_0$ .

†We use the phrase log-uniform distribution over  $[A, B]$  to indicate the distribution of  $\exp(x)$ , where  $x$  is drawn uniformly at random over the interval  $[\log A, \log B]$ .

- **Inelastic Bouncing Balls** Building off the previous domain, we introduce additional complexity by adding coefficient of restitution (COR) as another varying latent property of each object. The COR of a collision is the ratio of the final to initial relative velocity between the two colliding objects along the axis perpendicular to the contact plane. In a perfectly elastic domain, for example, all collisions would have a COR of 1. In our new domain, each object has a random COR selected uniformly from  $[0.5, 1]$ . The reference object has a COR of 0.75. The COR used to compute the dynamics in a collision between two balls is defined as the maximum of the two colliding objects’ CORs. When a ball collides with a wall, the ball’s COR is used for the collision.

For each domain, we train the PPN on a 6-object dataset with  $10^6$  samples and validate on a 6-object dataset with  $10^5$  samples. Each sample consists of 50 observation frames used as input into the perception network and 24 rollout frames used as targets by the prediction network. We evaluated our model on 3-object, 6-object, and 9-object test sets, each with  $10^5$  samples.

In addition, we also wish to demonstrate the PPN’s ability to generalize to new objects whose latent properties are outside of the range of values seen during training. For this experiment, we test our model on a new 2-object perfectly elastic balls dataset with  $10^5$  samples. The mass of the first ball remains fixed at 1, while the mass of the second ball is selected from 11 values ranging from  $32^{-1}$  to 32, spaced evenly on a log scale. We perform a similar experiment on the springs domain, using the same 11 values as the spring charge of the second object.

We use matter-js<sup>‡</sup>, a general-purpose rigid-body physics engine, to generate ground truth data. In all simulations, balls are contained in a  $512 \text{ px} \times 512 \text{ px}$  closed box. Each ball has a 50 px radius and randomly initialized positions such that no ball overlaps. In the springs domain, initial x- and y-velocity components are selected uniformly at random from the range  $[-15, 15]$  px/sec, the equilibrium displacement for each spring is 150, and the mass of all balls is  $10^4$ . In the perfectly elastic balls domain, initial velocity components are selected from the range  $[-9, 9]$  px/sec. In the inelastic balls domain, they are selected from the range  $[-13, 13]$  px/sec. Each dataset’s frames are sampled at 120 fps.

In the creation of our bouncing ball datasets, we use rejection sampling to filter out simulations in which some object latent properties cannot be inferred from the observation frames. In both bouncing ball domains, we must

be able to infer the mass of every object. In order to guarantee this, each object must collide directly with the reference object or be linked indirectly to it through a sequence of collisions. For the inelastic domain, we must ensure that each object’s COR can be inferred as well. In a ball-ball collision, only the higher object COR is used in determining collision dynamics, and so only the higher object COR can be inferred from the collision. For this reason, every ball must either collide with a ball of lower COR or a wall.

## 4.2 MODEL ARCHITECTURE

We use a single model architecture for all of our experiments. We set  $L_C$ , the size of each code vector, to 25 and  $L_Z$ , the size of each property vector, to 15. All MLPs in the model, including those in the interaction networks, use linear hidden layers with ReLU activation and a linear output layer.

Following the overall structure of Battaglia *et al.* [2], the perception network’s IN core consists of a 4-layer relation-centric MLP with sizes  $[75, 75, 75, 50]$  and a 3-layer object-centric MLP with sizes  $[50, 50, 25]$ . The final code vectors output by the IN feed into another object-centric MLP of size  $[15, 15, 15]$  to produce the final latent property vectors of size 15. The prediction network’s IN core consists of a 5-layer relation-centric MLP with sizes  $[100, 100, 100, 100, 50]$  and a 3-layer object-centric MLP with sizes  $[50, 50, 4]$  used to predict each object’s next position and velocity.

The perception network and prediction network are trained end-to-end using a single training loss, which we call the prediction loss. The prediction loss is the unweighted sum of the MSE of the predicted vs actual state vectors of all objects during the 24 rollout timesteps. In addition, we apply L2 regularization on the “effects” layer of both the perception and prediction networks. This regularization encourages minimal information exchange during interactions and proves to be a crucial component to generalization to different numbers of objects. We selected the penalty factor for each regularization term via grid search. We also experimented with the use of  $\beta$ -VAE regularization [24, 25] on property vectors to encourage the learning of interpretable and factorized properties.

In order to improve stability when simulating long rollouts, we added a small amount of Gaussian noise to each state vector during rollout, forcing the model to self-correct for errors. Empirically, we found that setting the noise std. dev. equal to  $0.001 \times$  the std. dev. of each state vector element’s values across the dataset stabilized rollout positions without affecting loss.

We trained the model for 150 epochs and optimized the parameters using Adam [26] with mini-batch size 256.

Component #	Springs		Perfectly Elastic Balls		Inelastic Balls		
	EVR	$R^2$ w/ log charge	EVR	$R^2$ w/ log mass	EVR	$R^2$ w/ log mass	$R^2$ w/ COR
1	0.94	0.95	0.99	0.94	0.73	0.90	0.02
2	0.06	0.02	0.006	0	0.27	0.02	0.81
3	0	0	0	0	0.006	0	0
4	0	0	0	0	0	0	0

Table 1: **Principal component analysis.** Applying PCA on the property vectors yields principal components that are highly correlated with human-interpretable latent properties such as COR and the log of mass. We compute statistics on the first four principal components of the property vectors for each training set. Explained variance ratio or EVR is the explained variance of the principal component as a fraction of overall variance, and  $R^2$  is the squared in-sample correlation between the principal component and a particular ground truth property. Values less than  $10^{-3}$  round to 0.

# Training Data	# Test Objects	Springs	Perfectly Elastic Balls	Inelastic Balls	
		$R^2$ w/ log charge	$R^2$ w/ log mass	$R^2$ w/ log mass	$R^2$ w/ COR
$10^5$	6	0.60	0.91	0.55	0.03
$2 \times 10^5$	6	0.95	0.96	0.95	0.65
$5 \times 10^5$	6	0.94	0.94	0.91	0.77
$10^6$	6	0.95	0.94	0.90	0.80
$10^6$	3	0.90	0.97	0.92	0.86
	9	0.87	0.92	0.90	0.68

Table 2: **Data-efficiency and number of objects generalization.** The PPN learns to capture physical properties with  $10^5$  training data points and converges when given  $2 \times 10^5$  instances. Its predictions generalize well to out-of-sample test sets with varying numbers of objects. We train the PPN on a 6-object dataset and test it on entirely new datasets comprised of 6, 3, and 9 objects. Above, we report the  $R^2$  when using the property vector’s first principal component to predict log mass and the second principal component to predict COR (for the inelastic balls case). Note that even in the 3 and 9 object cases the PPN is able to extract mass and coefficient of restitution with high  $R^2$ .

We used a waterfall schedule that began with a learning rate of  $5 \times 10^{-4}$  and downscaled by 0.8 each time the validation error, estimated over a window of 10 epochs, stopped decreasing.

## 5 RESULTS

### 5.1 EXTRACTING LATENT PROPERTIES

Our results show that the physical properties of objects are successfully encoded in the property vectors output by the perception network. In fact, we can extract the human-interpretable notions of spring charge, mass, and COR by applying principal component analysis (PCA) to the property vectors generated by the perception network during training. We find that the first principal component of each property vector is highly correlated with the log of spring charge in the spring domain and the log of object mass in both bouncing ball domains. In the inelastic balls domain, we also find that the second principal component of the property vector is highly correlated with COR. Table 1 shows the explained variance ratio (EVR) of each of the first 4 principal components of the learned property vectors in all three domains, along with the  $R^2$  when each component is used to predict ground truth object prop-

erties<sup>§</sup>. Since PCA is an unsupervised technique, these scalar quantities can be discovered without prior notions of mass and COR, and we can use the order-of-magnitude difference between certain principal components’ EVR to identify which components represent meaningful properties and which merely capture noise.

We also find that each learned property vector only contains information about its associated object and not any other objects. We test this hypothesis by using linear least squares to calculate the in-sample  $R^2$  between the ground truth latent properties of each object and the concatenation of the property vectors of all other objects. This  $R^2$  is less than 5% for each of the three domains and their relevant latent properties.

In order to test the generalization properties of our perception network, we calculate the out-of-sample  $R^2$  when using the perception network (trained on 6 object dynamics) and PCA to predict property values for test sets with varying number of objects, as shown in Table 2. The table

<sup>§</sup>By default, the property values produced by PCA will not be in the same scale as our ground truth values. For the purposes of correlation analysis, we linearly scale predictions to match the mean and std. dev. of the ground truth latent values.

Figure 3: **Mass prediction vs. reference distance.** Out-of-sample  $R^2$  on the two 6-object bouncing balls datasets for predicting log mass at different reference distances. The PPN must combine a sequence of intermediate mass inferences to accurately infer the mass of an object with large reference distance.

also shows how PPN performs when given a different number of training instances. In all bouncing balls test sets, for our model trained on  $10^6$  data points, the OOS  $R^2$  for log mass is above 90%, the OOS  $R^2$  for COR is above 68%, and the OOS  $R^2$  for log spring charge in the springs domain is above 87%.

We also compare the PPN against a **LSTM-PPN** baseline. The LSTM-PPN replaces each of the perception and prediction networks in the PPN with stacked LSTMs. Unlike an interaction network, an LSTM does not factorize input and output by object. Instead, state vectors for each object are concatenated and processed together, and a single property vector is learned for all objects. Table 3 shows that the LSTM-PPN does not learn meaningful latent properties. In each scenario, the linear least squares in-sample  $R^2$  between true object properties and property vectors is less than 2%. We also experiment with different values of  $\beta$  in the regularization term of the property vectors  $Z$  as in  $\beta$ -VAE [25]. The value of  $\beta$  does not impact the PPN’s performance on learning object properties.

For the two bouncing balls domains, the relative masses of objects are inferred through collisions, but not all objects collide directly with the reference object. We define the *reference distance* of an object to be the minimum number of collisions needed during observation to relate the object’s mass to that of the reference object. Inference on an object with reference distance of 3, for example, depends on the inference of the mass of two intermediate objects. Figure 3 shows the relation between the PPN’s prediction  $R^2$  and reference distance for each of the 6-object test sets. While there is a decay in  $R^2$  as reference distance increases due to compounding errors during inference, the PPN clearly demonstrates the ability to use transitivity to infer the mass of objects with large reference distance.

## 5.2 ROLLOUT PREDICTIONS

Although the PPN’s primary objective is the unsupervised learning of latent physical properties, the network can

Methods	Springs	Elastic Balls	Inelastic Balls	
	log charge	log mass	log mass	COR
LSTM	0.02	0.03	0.02	0.03
PPN ( $\beta = 0$ )	<b>0.95</b>	<b>0.94</b>	0.90	<b>0.80</b>
PPN ( $\beta = 0.01$ )	<b>0.95</b>	0.93	<b>0.93</b>	0.79
PPN ( $\beta = 1$ )	0.92	<b>0.94</b>	<b>0.93</b>	0.65

Table 3: **Comparing with baseline methods.** Varying the value of  $\beta$  in the regularization term as in  $\beta$ -VAE does not change the PPN’s performance significantly. The PPN consistently outperforms the baseline LSTM.

also be used to simulate object dynamics. To evaluate the PPN’s prediction performance, we use the mean Euclidean prediction error, or the mean Euclidean norm between the ground truth and predicted rollout positions, averaged over all samples and objects. We compare the PPN’s performance against two benchmarks. The **Mean Properties Perfect Rollout (MPPR)** baseline outputs a perfect rollout from the starting state, but incorrectly assumes that all object masses and spring charges are 1. For the inelastic balls domain, it also assumes that all object CORs are 0.75. The **Ground Truth Properties Interaction Network (GPIN)** benchmark is an IN with the same architecture as the PPN’s prediction network. Unlike the PPN, it has direct access to ground truth latent values as input, though it is still only trained on 6-object datasets. Figure 4 lists the three models’ mean Euclidean prediction errors for various scenes and shows how the prediction errors vary for different rollout steps. The PPN’s mean Euclidean prediction error is significantly better than the MPPR baseline and comes reasonably close to the GPIN model, especially for the springs and perfectly elastic balls datasets.

Finally, Figure 5 shows visualizations of the PPN’s rollout trajectories. Randomly selected simulations can be found at <http://ppn.csail.mit.edu>. Like the original IN, the PPN’s rollouts are sensitive to small prediction errors in early timesteps, but remain visually convincing.

Model	Springs			Perfectly Elastic Balls			Inelastic Balls		
	6 balls	3 balls	9 balls	6 balls	3 balls	9 balls	6 balls	3 balls	9 balls
PPN	0.020	0.078	0.057	0.025	0.017	0.032	0.048	0.041	0.054
MPPR	0.124	0.082	0.139	0.038	0.027	0.046	0.062	0.045	0.073
GPIN	0.005	0.068	0.043	0.019	0.015	0.027	0.029	0.021	0.039

Figure 4: **Mean Euclidean prediction error.** *Top:* Mean Euclidean prediction error over all timesteps and samples for each test set measured as fraction of framewidth. For each domain, the PPN and GPIN are trained on 6-object systems and tested on new systems with 6, 3, and 9 objects. *Bottom:* Mean Euclidean prediction error at different rollout timesteps for each of the 6-object scenarios. Plots for the 3-object and 9-object scenarios exhibit similar behavior.

Figure 5: **Rollout trajectories.** Sample rollout trajectories (over 24 timesteps) from each of the six test sets. Each domain’s model was trained on 6-object samples and tested on 6-, 3-, and 9-object samples.

### 5.3 GENERALIZING TO NEW OBJECTS

Our experiments also explore generalizations to objects whose property values are outside the range found in the training set. We test the PPN framework on a 2-object perfectly elastic test set where the second ball’s mass varies from  $32^{-1}$  to 32. Mass values in the range  $[0.25, 4]$  are found within the training set, while mass values outside this range require the PPN to extrapolate its understanding of mass to values it has not previously been exposed to. We perform a similar experiment on the springs domain, in which the second object’s spring charge varies from  $32^{-1}$  to 32. Figure 6 plots the relationship between true

and predicted property values for the second ball in the two domains, using the same PCA technique described in Section 5.1 to make predictions.

In the perfectly elastic balls domain, the PPN continues to offer accurate predictions of mass even when the true value lies far outside training range, despite an overall tendency to underestimate large mass values and overestimate small mass values. In the springs domain, the PPN is able to predict objects with large spring charge relatively well but performs poorly on objects with low spring charge. This is likely due to the fact that objects with low spring charge tend to feel very little spring force overall,

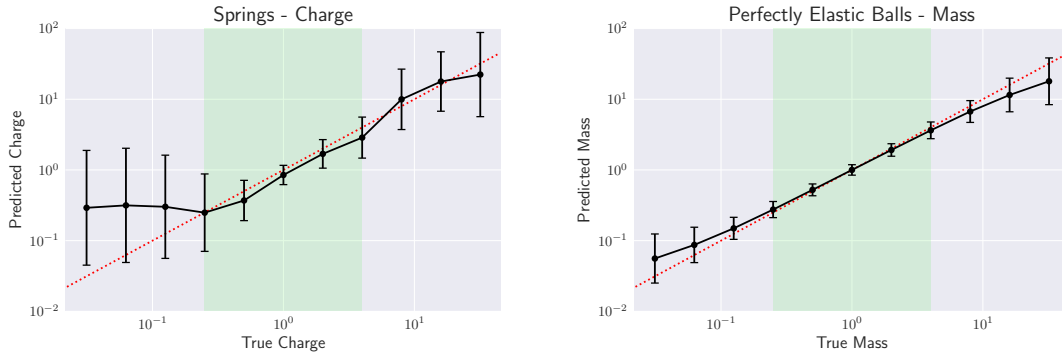

Figure 6: **Property value generalization.** Predicted property values vs. true property values of the second object in the 2-object test sets for both the springs and perfectly elastic balls domains. The true property values range from  $32^{-1}$  to 32, and the green region,  $4^{-1}$  to 4, indicates property values which appear to the PPN during training. Error bars show 95% confidence intervals. On the whole, the PPN continues to make reasonable predictions on mass and spring charge values well outside the training set, though the prediction of objects with lower spring charge than previously encountered is noticeably worse.

making the difference between charges of  $32^{-1}$  and  $16^{-1}$  much less noticeable than the difference between charges of 16 and 32.

## 6 DISCUSSION

We have presented the PPN, a model that is capable of discovering latent object properties in an entirely unsupervised manner from samples of object dynamics. Through our experiments, we showed not only that the representations of object properties learned by the PPN are sufficient to accurately simulate the dynamics of new systems under the same laws; but also that these learned representations can be readily transformed into relevant, human-interpretable properties such as mass and coefficient of restitution via principal component analysis.

The PPN demonstrates robustness by generalizing to novel scenarios with little loss in the accuracy of dynamical predictions or latent property inference. By using interaction networks as the basic building block of both our perception and prediction modules, we enabled our model to scale to arbitrary numbers of objects and interactions without architectural change. Our perception network architecture, in particular, is a simple but effective combination of relation and recurrent networks that may be useful in other time series inference tasks involving interacting objects. We also established the PPN’s ability to infer latent properties outside the range of values seen during training, further boosting its potential in discovering the relevant latent properties of new systems.

Several extensions would further improve the applicability of our model to the general discovery of latent object properties. In particular, there are a few general classes of problems that which interaction network-based architectures haven’t been able to solve: collision detec-

tion between rigid bodies of an arbitrary shape, dense fluid simulation, etc. Extending interaction networks to particle-based object representations is a promising future research direction [27].

While the interaction network framework is generally extensible to arbitrary numbers of objects, the computational time required to process all objects scales quadratically with the number of objects due to the presence of interaction terms between all pairs of objects, making it impractical for very large systems. One way to improve the computational efficiency of both the perception and prediction modules is to only consider interactions from objects in the neighborhood of target objects (with the interpretation that most interactions are only strong on shorter length scales), similar to Chang et al. [3]. A smaller, global interaction net could still be used to model longer range interactions.

The PPN provides a promising method for deriving the underlying properties governing the dynamics of systems, in addition to being a more general learnable physics engine capable of reasoning about potentially unknown object properties. The entirely unsupervised manner of its operation and its many generalization characteristics make the PPN suitable for application to a variety of systems, and it may even be able to discover relevant latent properties in domains that are yet to be well understood.

## 7 ACKNOWLEDGMENTS

We thank Michael Chang for his important insights and the anonymous reviewers for their useful suggestions. This work was supported by ONR MURI N00014-16-1-2007, the Center for Brain, Minds and Machines (NSF #1231216), Facebook, and the Toyota Research Institute.

## Abstract

Stochastic variance-reduced gradient Langevin dynamics (SVRG-LD) was recently proposed to improve the performance of stochastic gradient Langevin dynamics (SGLD) by reducing the variance of the stochastic gradient. In this paper, we propose a variant of SVRG-LD, namely SVRG-LD<sup>+</sup>, which replaces the full gradient in each epoch with a subsampled one. We provide a nonasymptotic analysis of the convergence of SVRG-LD<sup>+</sup> in 2-Wasserstein distance, and show that SVRG-LD<sup>+</sup> enjoys a lower gradient complexity<sup>1</sup> than SVRG-LD, when the sample size is large or the target accuracy requirement is moderate. Our analysis directly implies a sharper convergence rate for SVRG-LD, which improves the existing convergence rate by a factor of  $\kappa^{1/6}n^{1/6}$ , where  $\kappa$  is the condition number of the log-density function and  $n$  is the sample size. Experiments on both synthetic and real-world datasets validate our theoretical results.

## 1 INTRODUCTION

Markov chain Monte Carlo (MCMC) methods used for posterior sampling have achieved great successes in Bayesian machine learning and Bayesian statistics. Recently, a family of gradient-based MCMC algorithms derived from Langevin dynamics (Parisi, 1981) has become a research hotspot in both Bayesian sampling (Welling & Teh, 2011; Ahn et al., 2012; Wang et al., 2013; Dalalyan, 2014) and optimization (Raginsky et al., 2017; Zhang et al., 2017; Xu et al., 2017). The Langevin dynamics

is defined by the following stochastic differential equation (SDE)

$$d\mathbf{X}_t = -\nabla f(\mathbf{X}_t)dt + \sqrt{2}d\mathbf{B}_t, \quad (1.1)$$

where  $\mathbf{X}_t \in \mathbb{R}^d$  is a  $d$ -dimensional stochastic process,  $\mathbf{B}_t \in \mathbb{R}^d$  represents the standard  $d$ -dimensional Brownian motion and  $-\nabla f(\mathbf{x})$  is called the drift coefficient. It can be shown that the Langevin dynamics converges to an invariant stationary distribution  $\pi \propto \exp(-f)$  (Chiang et al., 1987). Based on this observation, various Langevin dynamics based numerical algorithms (Roberts & Tweedie, 1996; Mattingly et al., 2002) have been designed to sample from the target distribution  $\pi$ . Directly applying Euler-Maruyama discretization (Kloeden & Platen, 1992) to SDE (1.1) gives rise to

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \nabla f(\mathbf{x}_k)\eta + \sqrt{2\eta}\epsilon_k, \quad (1.2)$$

where  $\eta$  denotes the step size, and  $\epsilon_k \sim N(0, \mathbf{I}_{d \times d})$  is a  $d$ -dimensional standard Gaussian random vector. The sampling algorithm using (1.2) as its update formula is typically known as the Langevin Monte Carlo (LMC) algorithm, which has been extensively studied when the target distribution is both log-smooth and strongly log-concave, or even log-Hessian-Lipschitz (Dalalyan, 2014; Durmus & Moulines, 2016; Dalalyan, 2017; Dalalyan & Karagulyan, 2017).

On the other hand, modern machine learning problems often involve an extremely large amount of data. Suppose the dataset consists of  $n$  observations, it is often assumed that the function  $f$  in the drift term of (1.1) can be written as an average of  $n$  finite component functions, i.e.,

$$f(\mathbf{x}) = \frac{1}{n} \sum_{i=1}^n f_i(\mathbf{x}), \quad (1.3)$$

where each  $f_i$  is smooth and  $f$  is strongly convex. When  $n$  is very large, the LMC algorithm can be inefficient

---

\*Equal contribution

<sup>1</sup>Gradient complexity is defined as the required number of stochastic gradient evaluations to reach a target accuracy.

since the gradient evaluation is computationally very expensive. Following the same idea in stochastic optimization, Welling & Teh (2011) proposed the stochastic gradient Langevin dynamics (SGLD) algorithm by replacing the full gradient in (1.2) with a stochastic gradient computed only on a minibatch of data. The SGLD algorithm has been successfully applied to Bayesian learning (Welling & Teh, 2011; Ahn et al., 2012) and training deep neural networks (Chaudhari et al., 2016; Ye et al., 2017), because it can dramatically decrease the number of stochastic gradient evaluations and save a lot computation in practice. Nevertheless, the convergence rate of SGLD is much slower than LMC, which may lead to a worse runtime complexity in certain regime. Regarding the true computational cost of SGLD, Nagapetyan et al. (2017) argued that SGLD is at most better by a constant factor relative to an Euler discretization with full gradients, and raised questions about the good performance of SGLD under the big-data setting. In order to fairly evaluate the performances of stochastic algorithms, one often uses gradient complexity to indicate the efficiency of a sampling algorithm in large scale machine learning problems. When  $f$  is smooth, strongly convex and Hessian Lipschitz, Dalalyan & Karagulyan (2017) proved that the gradient complexity of LMC to converge to the stationary distribution  $\pi$  in 2-Wasserstein distance is  $\tilde{O}(n\kappa^2 d^{1/2}/\epsilon)$ , where  $\epsilon$  represents the target accuracy and  $\kappa$  is the condition number of  $f$ . In comparison, the gradient complexity of SGLD is  $\tilde{O}(\kappa^2 d\sigma^2/\epsilon^2)$  (Dalalyan, 2017; Dalalyan & Karagulyan, 2017), which is slower than LMC when  $n \lesssim d^{1/2}\sigma^2/\epsilon$ , where  $d\sigma^2$  is an upper bound on the variance of the stochastic gradient.

In order to achieve the best of both worlds, i.e., save the gradient computation of LMC as well as boost the convergence rate of SGLD, Dubey et al. (2016) proposed stochastic variance-reduced gradient Langevin dynamics (SVRG-LD) and stochastic average gradient Langevin dynamics (SAGA-LD), which adapts the idea of variance reduction in stochastic optimization such as SVRG (Johnson & Zhang, 2013; Allen-Zhu & Hazan, 2016; Reddi et al., 2016) and SAGA (Defazio et al., 2014) to gradient-based Monte Carlo methods. However, Dubey et al. (2016) only investigated the performance of both algorithms in terms of mean square error (MSE) of the averaged sample path. Baker et al. (2017) applied zero variance control variates to stochastic MCMC method, and showed that such technique is able to reduce the computational cost of stochastic gradient Langevin dynamics to  $O(1)$ . Recently, Chatterji et al. (2018) analyzed the convergence rates of SVRG-LD and SAGA-LD to the stationary distribution in 2-Wasserstein distance, and showed that SAGA-LD has a lower gradient complexity compared with SVRG-LD. However, they also observed

that when considering low target accuracy regime or the samples size is very large, both of these variance reduction based LMC algorithms perform worse than SGLD, which can converge even within a single data pass. However, their theoretical results suggest that SAGA-LD attains a faster convergence rate than SVRG-LD, which is not consistent with the convergence analyses of SAGA and SVRG for optimization, where both methods have been proved to have the same gradient complexity (Johnson & Zhang, 2013; Defazio et al., 2014). Therefore, Chatterji et al. (2018) raised a question that whether SVRG is less suited than SAGA to work with sampling methods.

In this paper, in order to overcome the shortcomings of SVRG-LD and SAGA-LD, we propose a variant of SVRG-LD, namely SVRG-LD<sup>+</sup>, by replacing the full gradient computation in the outer loop of SVRG-LD with a subsampled one. The idea of using subsampled gradient instead of full gradient in variance reduction algorithms is originated from the recent work on variance reduction for stochastic optimization (Harikandeh et al., 2015; Lei & Jordan, 2016; Lei et al., 2017), and has also been adopted to Langevin based algorithm by Chen et al. (2017). It is worthy noting that the algorithm proposed in Chen et al. (2017), namely practical vrSG-MCMC, is similar to our algorithm. Nevertheless, the practical SVRG-LD algorithm needs to output all the iterates because its theoretical guarantee is on the sample path. In contrast, our algorithm only needs to output the last iterate, because our theory holds for the last iterate.

## 1.1 OUR CONTRIBUTIONS

We highlight the major contributions of our work as follows.

- We propose the SVRG-LD<sup>+</sup> algorithm and analyze its convergence rate to the target distribution in Wasserstein distance. Specifically, we prove that the SVRG-LD<sup>+</sup> algorithm requires  $\tilde{O}((n + \kappa^{3/2}n^{1/2}d^{1/2}/\epsilon) \wedge \kappa^2 d\sigma^2/\epsilon^2)$  stochastic gradient evaluations to converge to the target distribution in 2-Wasserstein distance within  $\epsilon$ -accuracy. Our result suggests that when the sample size  $n$  is large or the target accuracy  $\epsilon$  is moderate, the gradient complexity of SVRG-LD<sup>+</sup> is better than that of SVRG-LD and SAGA-LD (Chatterji et al., 2018). In addition, the gradient complexity of SVRG-LD<sup>+</sup> is never worse than that of SGLD.
- Since SVRG-LD is a special case of SVRG-LD<sup>+</sup> when the subsampled gradient is chosen to be the full gradient, our analysis of SVRG-LD<sup>+</sup> directly implies a sharp convergence rate of SVRG-LD,

which improves the recent result in Chatterji et al. (2018) by a factor of  $\kappa^{1/6}n^{1/6}$ , and matches the convergence rate of SAGA-LD (Chatterji et al., 2018). This suggests that both SVRG and SAGA are equally suited to work with sampling methods, and therefore answers the question raised in (Chatterji et al., 2018). Our experiments on both synthetic and real data also show that SVRG-LD and SAGA-LD have comparable performance, which verifies our theory.

We summarize the gradient complexities of existing LMC methods in Table 1, from which we can see that SVRG-LD<sup>+</sup> achieves the lowest gradient complexity among all methods. Detailed discussions will be provided in the main theory section.

## 1.2 ADDITIONAL RELATED WORK

Another line of research that is related to LMC is Hamiltonian Monte Carlo (HMC) method (Neal, 2011), which is based on Hamiltonian dynamics by introducing fictitious momentum variables. Recently, the HMC method has been widely studied and developed both experimentally and theoretically. Specifically, Chen et al. (2014) proposed a stochastic gradient HMC (SG-HMC) algorithm and demonstrated its better performance than SGLD in learning Bayesian neural networks. Chen et al. (2015) conducted a comprehensive analysis for a family of SG-MCMC algorithms including SG-HMC in terms of MSE, and showed that SG-HMC attains a better performance than SGLD if adopting an appropriate discretization method. Ma et al. (2015) proposed a general framework to design samplers from the target distribution, and generated a new state-adaptive sampler on the Riemannian manifold. The nonasymptotic convergence analysis of HMC and SG-HMC was provided in Cheng et al. (2017), where the authors analyzed an underdamped Langevin MCMC algorithm and proved the convergence guarantees in 2-Wasserstein distance. Zou et al. (2018) proposed a stochastic variance-reduced HMC algorithm and proved its convergence rate in 2-Wasserstein distance. Li et al. (2018) analyzed the mean square error of the HMC based algorithm for different discretization schemes. Our work is focused on LMC and is complementary to this line of research.

<sup>2</sup>The convergence of SGLD does not require the Hessian Lipschitz condition. However, Dalalyan & Karagulyan (2017) proved that the convergence rate of SGLD remains the same even with additional Hessian Lipschitz condition.

## 1.3 NOTATION

We use  $[n]$  to denote the index set  $\{1, \dots, n\}$ . For a random vector  $\mathbf{x}_k \in \mathbb{R}^d$ , we denote its probability distribution function by  $P(\mathbf{x}_k)$ . The 2-Wasserstein distance between two probability measures  $u$  and  $v$  is defined as follows,

$$\mathcal{W}_2(u, v) = \left( \inf_{\zeta \in \Gamma(u, v)} \int_{\mathbb{R}^d \times \mathbb{R}^d} \|\mathbf{X}_u - \mathbf{X}_v\|_2^2 d\zeta(\mathbf{X}_u, \mathbf{X}_v) \right)^{1/2},$$

where the infimum is over all joint distributions  $\zeta$ . We use  $a_n = O(b_n)$  to denote that  $a_n \leq Cb_n$  for some constant  $C > 0$  independent of  $n$ , and use  $a_n = \tilde{O}(b_n)$  to hide the logarithmic terms of  $b_n$ . We also make use of the notation  $a_n \lesssim b_n$  ( $a_n \gtrsim b_n$ ) if  $a_n$  is less than (larger than)  $b_n$  up to a constant. We use  $a \wedge b$  and  $a \vee b$  to denote  $\min\{a, b\}$  and  $\max\{a, b\}$  respectively.

## 2 ALGORITHM

In this section, we present our SVRG-LD<sup>+</sup> algorithm, which is displayed in Algorithm 1.

The algorithm contains multiple epochs. At the beginning of the  $j$ -th epoch, we uniformly choose  $B$  samples from all training data and obtain a gradient estimator:

$$\tilde{\mathbf{g}}_j = \nabla f_{\mathcal{I}_j}(\tilde{\mathbf{x}}_j) = \frac{1}{|\mathcal{I}_j|} \sum_{i \in \mathcal{I}_j} \nabla f_i(\tilde{\mathbf{x}}_j), \quad (2.1)$$

where  $|\mathcal{I}_j| = B$ . At the  $l$ -th iteration in the  $j$ -th epoch, we define the semi-stochastic gradient as  $\mathbf{g}_k = \nabla f_{\tilde{\mathcal{I}}_k}(\mathbf{x}_k) - \nabla f_{\tilde{\mathcal{I}}_k}(\tilde{\mathbf{x}}_j) + \tilde{\mathbf{g}}_j$ , where  $k = jm + l$  is the total iteration of the algorithm,  $m$  is the length of each epoch, and  $\nabla f_{\tilde{\mathcal{I}}_k}(\mathbf{x}) = 1/|\tilde{\mathcal{I}}_k| \sum_{i \in \tilde{\mathcal{I}}_k} \nabla f_i(\mathbf{x})$ . Then we perform the following update

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \eta \mathbf{g}_k + \sqrt{2\eta} \boldsymbol{\epsilon}_k,$$

where  $\eta$  is the step size and  $\boldsymbol{\epsilon}_k \sim N(0, \mathbf{I}_{d \times d})$  is a Gaussian random vector.

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \eta \mathbf{g}_k + \sqrt{2\eta} \boldsymbol{\epsilon}_k,$$

where  $\eta$  is the step size and  $\boldsymbol{\epsilon}_k \sim N(0, \mathbf{I}_{d \times d})$  is a Gaussian random vector.

It is worth noting that the major difference between SVRG-LD<sup>+</sup> and SVRG-LD (Dubey et al., 2016) is that we replace the full gradient computation in the beginning of each epoch with a subsampled one. On one hand,

Table 1: Gradient complexity of gradient-based Monte Carlo algorithms in 2-Wasserstein distance for sampling from log-smooth, log-Hessian-Lipschitz and strongly log-concave distributions. For the ease of comparison, we follow Chatterji et al. (2018) that assumes  $n \lesssim d\sigma^2/(\mu^2\epsilon^2)$  and treats  $1/M$  and  $\mu$  as constants of order  $O(1)$ .

METHOD	GRADIENT COMPLEXITY	HESSIAN LIPSCHITZ
LMC (Dalalyan & Karagulyan, 2017)	$\tilde{O}\left(\frac{n\kappa^2 d^{1/2}}{\epsilon}\right)$	Yes
SGLD (Dalalyan, 2017)	$\tilde{O}\left(\frac{\kappa^2 d\sigma^2}{\epsilon^2}\right)$	No <sup>2</sup>
SAGA-LD (Chatterji et al., 2018) <sup>3</sup>	$\tilde{O}\left(n + \frac{\kappa^{3/2} n^{1/2} d^{1/2}}{\epsilon}\right)$	Yes
SVRG-LD (Chatterji et al., 2018)	$\tilde{O}\left(n + \frac{\kappa^{5/3} n^{2/3} d^{1/2}}{\epsilon}\right)$	Yes
SVRG-LD (this paper)	$\tilde{O}\left(n + \frac{\kappa^{3/2} n^{1/2} d^{1/2}}{\epsilon}\right)$	Yes
SVRG-LD <sup>+</sup> (this paper)	$\tilde{O}\left(\left(n + \frac{\kappa^{3/2} n^{1/2} d^{1/2}}{\epsilon}\right) \wedge \frac{\kappa^2 d\sigma^2}{\epsilon^2}\right)$	Yes

this leads to the consequence that the stochastic gradient  $\mathbf{g}_k$  is not an unbiased estimator of the true gradient  $\nabla f(\mathbf{x})$ , which introduces extra error that poses additional challenge in the analysis. On the other hand, compared with SVRG-LD, it saves gradient computations especially when the sample size  $n$  is large. Therefore, the crucial idea of SVRG-LD<sup>+</sup> is to make an appropriate trade-off between extra error and saving gradient computation, and the batch size  $B$  is a vital parameter which should be carefully designed.

### 3 MAIN THEORY

In this section, we are going to present our main theoretical results on the convergence rate of Algorithm 1 in

<sup>3</sup>Different from the definition in (1.3), the finite-sum function  $f$  is defined as  $f = \sum_{i=1}^n f_i(\mathbf{x})$  in Chatterji et al. (2018), which leads to a difference in the results by a factor of  $n$ . To make a fair comparison, we translate their results with the same definition in (1.3).

2-Wasserstein distance. We will first establish the convergence guarantees of Algorithm 1. Then, we will show that SVRG-LD<sup>+</sup> reduces to SVRG-LD when choosing  $B = n$ , and our analysis leads to a sharp convergence result of SVRG-LD that improves the recent result in Chaudhari et al. (2016).

For the target distribution  $\pi \propto e^{-f}$ , we first lay down the following assumptions on function  $f(\mathbf{x})$ , which are required in our analysis.

**Assumption 3.1** (Smoothness). There exists a positive constant  $M$  such that for each component function  $f_i(\mathbf{x})$ , the following holds for all  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$ ,

$$\|\nabla f_i(\mathbf{x}) - \nabla f_i(\mathbf{y})\|_2 \leq M\|\mathbf{x} - \mathbf{y}\|_2.$$

Note that Assumption 3.1 immediately implies that the function  $f$  is also  $M$ -smooth, and consequently the target distribution  $\pi$  is  $M$ -log-smooth.

**Assumption 3.2** (Strong convexity). There exists a positive constant  $\mu$  such that for function  $f$ , the following holds for all  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$ ,

$$f(\mathbf{x}) \geq f(\mathbf{y}) + \langle \nabla f(\mathbf{y}), \mathbf{x} - \mathbf{y} \rangle + \frac{\mu}{2}\|\mathbf{x} - \mathbf{y}\|_2^2.$$

The above assumption states that function  $f$  is strongly convex, which indicates that the distribution  $\pi \propto e^{-f}$  is strongly log-concave.

**Assumption 3.3** (Hessian Lipschitz). There exists a positive constant  $L$  such that for function  $f$ , the following holds for all  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$ ,

$$\|\nabla^2 f(\mathbf{x}) - \nabla^2 f(\mathbf{y})\|_2 \leq L\|\mathbf{x} - \mathbf{y}\|_2.$$

This assumption is essential and useful for proving a faster convergence rate of Langevin Monte Carlo methods (Dalalyan & Karagulyan, 2017; Chatterji et al., 2018).

**Assumption 3.4** (Bounded Variance). There exists a constant  $\sigma$ , such that the following holds for all  $\mathbf{x} \in \mathbb{R}^d$ ,

$$\mathbb{E}_i[\|\nabla f_i(\mathbf{x}) - \nabla f(\mathbf{x})\|_2^2] \leq d\sigma^2.$$

Assumption 3.4 is necessary and widely made in stochastic Langevin dynamics based methods such as SGLD (Dalalyan, 2017; Dalalyan & Karagulyan, 2017) and SGHMC (Cheng et al., 2017). However, it should be noted that this assumption is only required for the analysis of the SVRG-LD<sup>+</sup> algorithm but not required for SVRG-LD.

In what follows, we will present the convergence results of Algorithm 1. Following the literature (Dalalyan, 2017; Dalalyan & Karagulyan, 2017; Cheng & Bartlett, 2017; Zou et al., 2018; Chatterji et al., 2018), we will focus on the 2-Wasserstein distance between the target distribution  $\pi \propto e^{-f}$  and the distribution of the  $k$ -th iterate in Algorithm 1. Specifically, we have the following theorem for SVRG-LD<sup>+</sup>.

**Theorem 3.5.** Under Assumptions 3.1-3.4, let  $P(\mathbf{x}_k)$  denote the distribution of the  $k$ -th iterate  $\mathbf{x}_k$  in Algorithm 1. Set the step size  $\eta$  to satisfy

$$\eta \leq \min \left\{ \left( \frac{b\mu}{24M^4m^2} \right)^{1/3}, \frac{1}{6m(\sigma^2/B + M)} \right\}.$$

The 2-Wasserstein distance between  $P(\mathbf{x}_k)$  and  $\pi$  is bounded by

$$\begin{aligned} \mathcal{W}_2(P(\mathbf{x}_k), \pi) &\leq (1 - \eta\mu/4)^k \mathcal{W}_2(P(\mathbf{x}_0), \pi) + \frac{3\sigma d^{1/2}}{\mu B^{1/2}} \mathbf{1}(B \leq n) \\ &\quad + \frac{2\eta(Ld + M^{3/2}d^{1/2})}{\mu} \\ &\quad + \frac{4\eta M(md)^{1/2} \wedge 3\eta^{1/2}d^{1/2}\sigma}{(b\mu)^{1/2}}. \end{aligned}$$

It is worth noting that the mini-batch size  $b$  and the batch size  $B$  are two independent parameters in the algorithm that can be chosen separately. In practice, one typically chooses  $b \ll B$  (see for example, Harikandeh et al. (2015); Lei & Jordan (2016); Chen et al. (2017) in order to obtain a good convergence result. If we intentionally choose  $b > B$  in the algorithm, the evaluation of the semi-stochastic gradient will be even more expensive than that of the subsampled/full gradient in the outer loop, which makes variance reduction techniques no longer effective. The optimal choices of  $b$  and  $B$  in two different regimes of sample size  $n$  will be specified in the following corollaries.

Theorem 3.5 implies that in order to achieve  $\epsilon$  accuracy in 2-Wasserstein distance, the step size  $\eta$  should be set to

be sufficiently small, and the batch size  $B$  should be sufficiently large. To address these requirements, we present the following corollaries to show the optimal selections of  $\eta$  and  $B$ , and compute the gradient complexity of SVRG-LD<sup>+</sup> under different regimes.

We first consider the regime where  $n \gtrsim d\sigma^2/(\mu^2\epsilon^2)$ .

**Corollary 3.6.** Under the same assumptions as in Theorem 3.5, suppose the sample size satisfies  $n \gtrsim d\sigma^2/(\mu^2\epsilon^2)$ , if we set  $B = O(d\sigma^2\mu^{-2}\epsilon^{-2})$ ,  $b = O(1)$ ,  $m = O(B)$  and  $\eta = O(\mu\epsilon^2/(d\sigma^2))$ , Algorithm 1 achieves  $\epsilon$  accuracy in 2-Wasserstein distance after

$$T = \tilde{O}\left(\frac{d\sigma^2}{\mu^2\epsilon^2}\right) \quad (3.1)$$

stochastic gradient evaluations.

**Remark 3.7.** According to Corollary 3.6, if  $n \gtrsim d\sigma^2/(\mu^2\epsilon^2)$ , then the gradient complexity of SVRG-LD<sup>+</sup> in (3.1) matches that of SGLD (Dalalyan, 2017; Dalalyan & Karagulyan, 2017). Note that the gradient complexities of LMC, SAGA-LD and SVRG-LD are at least  $\tilde{O}(n)$  due to the use of full gradients, which indicates that SVRG-LD<sup>+</sup> achieves lower gradient complexity than LMC, SAGA-LD and SVRG-LD in this regime.

When the sample size satisfies  $n \lesssim d\sigma^2/(\mu^2\epsilon^2)$ , we choose the batch size  $B$  to be  $n$ , i.e., compute the full gradient in the beginning of each epoch in Algorithm 1. In this regime, Algorithm 1 reduces to SVRG-LD (Dubey et al., 2016), and its gradient complexity is characterized by the following corollary.

**Corollary 3.8.** Under the same assumptions as in Theorem 3.5, suppose the sample size satisfies  $n \lesssim d\sigma^2/(\mu^2\epsilon^2)$ , if we set  $b = 1$  and

$$\eta = \min \left\{ \frac{\mu\epsilon}{Ld + M^{2/3}d^{1/2}}, \frac{\mu^{1/2}\epsilon}{Md^{1/2}n^{1/2}} \right\},$$

SVRG-LD<sup>+</sup> achieves  $\epsilon$ -accuracy in 2-Wasserstein distance after

$$T = \tilde{O}\left(n + \frac{Ld + M^{3/2}d^{1/2}}{\mu^2\epsilon} + \frac{Md^{1/2}n^{1/2}}{\mu^{3/2}\epsilon}\right) \quad (3.2)$$

stochastic gradient evaluations.

**Remark 3.9.** According to Corollary 3.6, if  $n \lesssim d\sigma^2/(\mu^2\epsilon^2)$ , following Chatterji et al. (2018), if we further assume  $n \gtrsim L^2d/(M^2\mu) + \kappa$ , and treat  $1/M$  and  $\mu$  as constants of order  $O(1)$ , then the complexity in (3.2) can be simplified as

$$T = \tilde{O}\left(n + \frac{\kappa^{3/2}d^{1/2}n^{1/2}}{\epsilon}\right).$$

It is worth noting that in this regime, Algorithm 1 does not need Assumption 3.4. Moreover, combining the results in Corollaries 3.6 and 3.8, the gradient complexity of SVRG-LD<sup>+</sup> can be derived as follows

$$\tilde{O}\left(\left(n + \frac{\kappa^{3/2}n^{1/2}d^{1/2}}{\epsilon}\right) \wedge \frac{\kappa^2 d\sigma^2}{\epsilon^2}\right), \quad (3.3)$$

where  $O(1/\mu^2) = O(\kappa^2/M^2) = O(\kappa^2)$  as  $1/M = O(1)$ .

**Remark 3.10.** Corollary 3.8 essentially provides the gradient complexity for SVRG-LD, which is lower than that proved in Chatterji et al. (2018). Recall that their target distribution takes the form

$$\pi \propto \exp\left(-\sum_{i=1}^n f_i(\mathbf{x})\right) \triangleq \exp(-F(\mathbf{x})),$$

where the exponent term is different from our definition of  $f$  in (1.3) by a factor of  $1/n$ . In order to make their result comparable to ours, we translate their result to the same definition of  $f$  in (1.3), which gives rise to  $\tilde{O}(n + \kappa^{5/3}n^{2/3}d^{1/2}/\epsilon)$  gradient complexity of SVRG-LD (Chatterji et al., 2018). It is evident that our result improves the gradient complexity of SVRG-LD by a factor of  $(\kappa n)^{1/6}$ . Last but not the least, our proved gradient complexity of SVRG-LD matches that of SAGA-LD (Chatterji et al., 2018), which suggests that SVRG-LD and SAGA-LD enjoy the same performance.

## 4 PROOF OF THE MAIN THEORY

In this section we provide the proof for our main theory. We first define an operator  $\mathcal{L}$  derived from the Langevin dynamics. Specifically, let  $\mathbf{x}_0$  be any starting position, and we denote by  $\mathcal{L}_t\mathbf{x}_0$  the random position of the Markov process generated by Langevin dynamics (1.1) after time  $t$ . Let  $\mathbf{x}^\pi$  denote the random variable that satisfies the stationary distribution  $\pi \propto e^{-f}$ . In addition, we define  $\Delta_k = \mathcal{L}_\eta^k\mathbf{x}^\pi - \mathbf{x}_k$ , where  $\mathcal{L}_{k\eta} = \mathcal{L}_\eta \circ \mathcal{L}_\eta \circ \dots \circ \mathcal{L}_\eta = \mathcal{L}_\eta^k$  due to the Markov property of  $\mathcal{L}$ . Then the following holds trivially

$$\begin{aligned} \Delta_{k+1} &= \mathcal{L}_\eta^{k+1}\mathbf{x}^\pi - \mathbf{x}_{k+1} \\ &= \mathcal{L}_\eta^k\mathbf{x}^\pi - \mathbf{x}_k + \mathcal{L}_\eta^{k+1}\mathbf{x}^\pi - \mathcal{L}_\eta^k\mathbf{x}^\pi - (\mathbf{x}_{k+1} - \mathbf{x}_k). \end{aligned}$$

Consider two synchronously coupled Markov processes  $\mathcal{L}_\eta^k\mathbf{x}^\pi$  and  $\mathbf{x}_k$  which have shared Brownian motion term in updates  $\mathcal{L}_\eta^k\mathbf{x}^\pi \rightarrow \mathcal{L}_\eta^{k+1}\mathbf{x}^\pi$  and  $\mathbf{x}_k \rightarrow \mathbf{x}_{k+1}$ , we further have

$$\begin{aligned} \Delta_{k+1} &= \Delta_k + \eta\mathbf{g}_k - \int_0^\eta \nabla f(\mathcal{L}_{k\eta+t}\mathbf{x}^\pi)dt \\ &= \Delta_k + \eta(\mathbf{g}_k - \nabla f(\mathbf{x}_k)) - \eta(\nabla f(\mathcal{L}_\eta^k\mathbf{x}^\pi) - \nabla f(\mathbf{x}_k)) \\ &\quad - \int_0^\eta (\nabla f(\mathcal{L}_{k\eta+t}\mathbf{x}^\pi) - \nabla f(\mathcal{L}_{k\eta}\mathbf{x}^\pi))dt \\ &= \Delta_k + \eta\Phi_k - \eta\mathbf{U}_k - \mathbf{S}_k - \mathbf{V}_k, \end{aligned} \quad (4.1)$$

where we define

$$\begin{aligned} \Phi_k &= \mathbf{g}_k - \nabla f(\mathbf{x}_k), \\ \mathbf{U}_k &= \nabla f(\mathcal{L}_\eta^k\mathbf{x}^\pi) - \nabla f(\mathbf{x}_k), \\ \mathbf{S}_k &= \sqrt{2} \int_0^\eta \int_0^t \nabla^2 f(\mathcal{L}_{k\eta+s}\mathbf{x}^\pi)dB_s dt, \\ \mathbf{V}_k &= \int_0^\eta (\nabla f(\mathcal{L}_{k\eta+t}\mathbf{x}^\pi) - \nabla f(\mathcal{L}_{k\eta}\mathbf{x}^\pi))dt - \mathbf{S}_k. \end{aligned}$$

Note that in Algorithm 1, the semi-stochastic gradient  $\mathbf{g}_k$  has the following property

$$\begin{aligned} \mathbb{E}[\mathbf{g}_k|\tilde{\mathbf{x}}_j] &= \mathbb{E}[\nabla f_{\tilde{\mathcal{I}}_k}(\mathbf{x}_k) - \nabla f_{\tilde{\mathcal{I}}_k}(\tilde{\mathbf{x}}_j) + \nabla f_{\tilde{\mathcal{I}}_j}(\tilde{\mathbf{x}}_j)|\tilde{\mathbf{x}}_j] \\ &= \mathbb{E}[\nabla f(\mathbf{x}_k) - \nabla f(\tilde{\mathbf{x}}_j) + \nabla f_{\tilde{\mathcal{I}}_j}(\tilde{\mathbf{x}}_j)]. \end{aligned}$$

Then we can decompose  $\Phi_k$  as follows

$$\begin{aligned} \Phi_k &= \mathbf{g}_k - \nabla f(\mathbf{x}_k) \\ &= \underbrace{\nabla f_{\tilde{\mathcal{I}}_k}(\mathbf{x}_k) - \nabla f_{\tilde{\mathcal{I}}_k}(\tilde{\mathbf{x}}_j) - (\nabla f(\mathbf{x}_k) - \nabla f(\tilde{\mathbf{x}}_j))}_{\Psi_k} \\ &\quad + \underbrace{(\nabla f_{\tilde{\mathcal{I}}_j}(\tilde{\mathbf{x}}_j) - \nabla f(\tilde{\mathbf{x}}_j))}_{e_j}. \end{aligned} \quad (4.2)$$

Submitting the above equation into (4.1) yields

$$\Delta_{k+1} = \Delta_k - \eta\mathbf{U}_k + \eta\Psi_k + \eta e_j - \mathbf{S}_k - \mathbf{V}_k. \quad (4.3)$$

Now, we have already obtained the recursive update of  $\Delta_k$ . In what follows, we will upper bound the  $\ell_2$ -norm of each term on the R.H.S of (4.3). To begin with, we provide the following technical lemmas.

**Lemma 4.1.** (Dalalyan & Karagulyan, 2017) Under Assumptions 3.1 and 3.2, we have

$$\mathbb{E}[\|\Delta_k - \eta\mathbf{U}_k\|_2^2] \leq (1 - \eta\mu)^2\mathbb{E}[\|\Delta_k\|_2^2],$$

where  $\eta$  denotes the step size,  $\mu$  is the strongly convex parameter on function  $f(\mathbf{x})$ .

**Lemma 4.2.** Under Assumptions 3.1 and 3.2, we have the following upper bound on  $\|\Psi_k\|_2^2$ .

$$\begin{aligned} \mathbb{E}[\|\Psi_k\|_2^2] &\leq \frac{4d\sigma^2}{b} \wedge \frac{M^2}{b} (6m^2\eta^2 M^2\mathbb{E}[\|\Delta_{j_m}\|_2^2] + G_j)e^{2m^2M^2\eta^2}, \end{aligned} \quad (4.4)$$

where

$$G_j = 6m^2\eta^2(\mathbb{E}[\|e_j\|_2^2] + Md) + 2md\eta.$$

**Lemma 4.3.** Under Assumption 3.4,  $\|e_j\|_2$  is bounded as follows,

$$\mathbb{E}[\|e_j\|_2^2] = \mathbb{E}[\|\nabla f_{\tilde{\mathcal{I}}_j}(\tilde{\mathbf{x}}_j) - \nabla f(\tilde{\mathbf{x}}_j)\|_2^2] \leq \frac{d\sigma^2}{B}.$$

In addition, if  $B = n$ ,  $\mathbb{E}[\|e_j\|_2^2] = 0$ .

**Lemma 4.4.** (Dalalyan, 2017) Under Assumptions 3.1 and 3.3, regarding to terms  $\mathbf{S}_k$  and  $\mathbf{V}_k$  in (4.3), we have the following uniformly upper bound on their  $\ell_2$ -norms

$$\begin{aligned}\mathbb{E}[\|\mathbf{V}_k\|_2^2] &\leq \frac{\eta^4}{2}(L^2d^2 + M^3d), \\ \mathbb{E}[\|\mathbf{S}_k\|_2^2] &\leq \frac{\eta^3M^2d}{3},\end{aligned}$$

where  $M$  and  $L$  denotes the smoothness and Hessian Lipschitz parameters respectively.

Now, we are ready to present the proof for Theorem 3.5.

*Proof of Theorem 3.5.* Note that

$$\mathbb{E}[\boldsymbol{\Psi}_k | \mathbf{x}_k, \mathcal{L}_\eta^k \mathbf{x}^\pi, \mathcal{L}_\eta^{k+1} \mathbf{x}^\pi] = \mathbf{0},$$

which immediately implies

$$\begin{aligned}\mathbb{E}[\|\Delta_{k+1}\|_2^2] &= \mathbb{E}[\|\Delta_k - \eta\mathbf{U}_k + \eta\mathbf{e}_j - \mathbf{S}_k - \mathbf{V}_k\|_2^2] + \eta^2\mathbb{E}[\|\boldsymbol{\Psi}_k\|_2^2] \\ &\leq (1 + \alpha)\mathbb{E}[\|\Delta_k - \eta\mathbf{U}_k - \mathbf{S}_k\|_2^2] \\ &\quad + (1 + 1/\alpha)\mathbb{E}[\|\eta\mathbf{e}_j - \mathbf{V}_k\|_2^2] + \eta^2\mathbb{E}[\|\boldsymbol{\Psi}_k\|_2^2] \\ &= (1 + \alpha)\mathbb{E}[\|\Delta_k - \eta\mathbf{U}_k\|_2^2 + \|\mathbf{S}_k\|_2^2] \\ &\quad + (1 + 1/\alpha)\mathbb{E}[\|\eta\mathbf{e}_j - \mathbf{V}_k\|_2^2] + \eta^2\mathbb{E}[\|\boldsymbol{\Psi}_k\|_2^2], \\ &\leq (1 + \alpha)\mathbb{E}[\|\Delta_k - \eta\mathbf{U}_k\|_2^2 + \|\mathbf{S}_k\|_2^2] \\ &\quad + 2(1 + 1/\alpha)\mathbb{E}[\eta^2\|\mathbf{e}_j\|_2^2 + \|\mathbf{V}_k\|_2^2] + \eta^2\mathbb{E}[\|\boldsymbol{\Psi}_k\|_2^2],\end{aligned}$$

where  $\alpha > 0$  is an arbitrary chosen parameter, the first inequality is by Young's inequality, and the second equality follows from the fact  $\mathbb{E}[\mathbf{S}_k | \Delta_k, \mathbf{U}_k] = \mathbf{0}$ . Applying Lemmas 4.1 and 4.2, we have

$$\begin{aligned}\mathbb{E}[\|\Delta_{k+1}\|_2^2] &\leq (1 + \alpha)(1 - \eta\mu)^2\mathbb{E}[\|\Delta_k\|_2^2] + (1 + \alpha)\mathbb{E}[\|\mathbf{S}_k\|_2^2] \\ &\quad + 2(1 + 1/\alpha)\mathbb{E}[\eta^2\|\mathbf{e}_j\|_2^2 + \|\mathbf{V}_k\|_2^2] + \eta^2\mathbb{E}[\|\boldsymbol{\Psi}_k\|_2^2] \\ &\leq \left[ (1 + \alpha)(1 - \eta\mu)^2 + \frac{6\eta^4M^4m^2}{b}e^{2\eta^2m^2M^2} \right] \\ &\quad \times \max\{\mathbb{E}[\|\Delta_k\|_2^2], \mathbb{E}[\|\Delta_{jm}\|_2^2]\} + \Omega_1 + \Omega_2,\end{aligned}\tag{4.5}$$

where

$$\begin{aligned}\Omega_1 &= (1 + \alpha)\mathbb{E}[\|\mathbf{S}_k\|_2^2] \\ &\quad + 2(1 + 1/\alpha)\mathbb{E}[\eta^2\|\mathbf{e}_j\|_2^2 + \|\mathbf{V}_k\|_2^2], \\ \Omega_2 &= \frac{4d\sigma^2\eta^2}{b} \wedge \frac{M^2\eta^2G_j}{b}e^{2m^2M^2\eta^2}.\end{aligned}\tag{4.6}$$

Note that the step size  $\eta$  satisfies  $\eta \leq \min\{(b\mu/(24M^4m^2))^{1/3}, 1/(6m\sigma^2/B + 6mM)\}$ , we have  $\exp(2m^2M^2\eta^2) \leq 2$  and

$6\eta^4M^4m^2 \exp(2m^2M^2\eta^2)/b \leq \eta\mu/2$ . We choose  $\alpha = \eta\mu$ , which implies  $(1 + \alpha)(1 - \eta\mu)^2 \leq 1 - \eta\mu$ . Thus, (4.5) can be further rewritten as follows,

$$\mathbb{E}[\|\Delta_{k+1}\|_2^2] \leq (1 - \eta\mu/2) \max\{\mathbb{E}[\|\Delta_k\|_2^2], \mathbb{E}[\|\Delta_{jm}\|_2^2]\} + \Omega_1 + \Omega_2.\tag{4.7}$$

In order to obtain the upper bound of  $\mathbb{E}[\|\Delta_k\|_2^2]$ , we need to recursively call (4.7). Note that since  $jm \leq k$ , the number of calls to (4.7) must be smaller than  $k$ , thus we have

$$\mathbb{E}[\|\Delta_k\|_2^2] \leq (1 - \eta\mu/2)^k \mathbb{E}[\|\Delta_0\|_2^2] + \frac{\Omega_1 + \Omega_2}{\eta\mu/2}.\tag{4.8}$$

In what follows, we are going to upper bound  $\Omega_1$  and  $\Omega_2$ . Note that  $m \geq 1$  and  $M \geq \mu$ , we have  $\eta\mu \leq 1$ . Then by the application of Lemmas 4.3 and 4.4, we have

$$\begin{aligned}\Omega_1 &\leq \frac{(1 + \alpha)\eta^3M^2d}{3} + 2(1 + 1/\alpha) \\ &\quad \times \left( \frac{\eta^2d\sigma^2}{B} \mathbb{1}(B < n) + \frac{\eta^4(L^2d^2 + M^3d)}{2} \right) \\ &\leq \frac{2\eta^3M^2d}{3} + \frac{4\eta d\sigma^2}{B\mu} + \frac{2\eta^3(L^2d^2 + M^3d)}{\mu}, \\ \Omega_2 &\leq \frac{4d\sigma^2\eta^2}{b} \wedge \frac{6M^2md\eta^3}{b}.\end{aligned}$$

Then we substitute the above upper bounds of  $\Omega_1$  and  $\Omega_2$  into (4.8), and obtain

$$\begin{aligned}\mathbb{E}[\|\Delta_k\|_2^2] &\leq (1 - \eta\mu/2)^k \mathbb{E}[\|\Delta_0\|_2^2] + \frac{\Omega_1 + \Omega_2}{\eta\mu/2} \\ &\leq (1 - \eta\mu/2)^k \mathbb{E}[\|\Delta_0\|_2^2] + \frac{8d\sigma^2}{B\mu^2} \mathbb{1}(B < n) \\ &\quad + \frac{4\eta^2(L^2d^2 + M^3d)}{\mu^2} + \frac{14\eta^2mM^2d}{b\mu} \wedge \frac{8d\sigma^2\eta}{b\mu}.\end{aligned}$$

Based on the definition of 2-Wasserstein distance, we have  $\mathcal{W}_2^2(P(\mathbf{x}_k), \pi) \leq \mathbb{E}[\|\Delta_k\|_2^2]$ . Applying the inequality that  $x^2 + y^2 + z^2 \leq (|x| + |y| + |z|)^2$  for all  $x, y, z \in \mathbb{R}$ , we complete the proof of Theorem 3.5.  $\square$

## 5 EXPERIMENTS

In this section, we are going to verify our theoretical results and evaluate the performances of different Langevin based algorithms on both synthetic and real datasets.

### 5.1 SIMULATION ON SYNTHETIC DATA

We first validate our theoretical results based on synthetic data. In this simulation, we consider function  $f(\mathbf{x}) =$

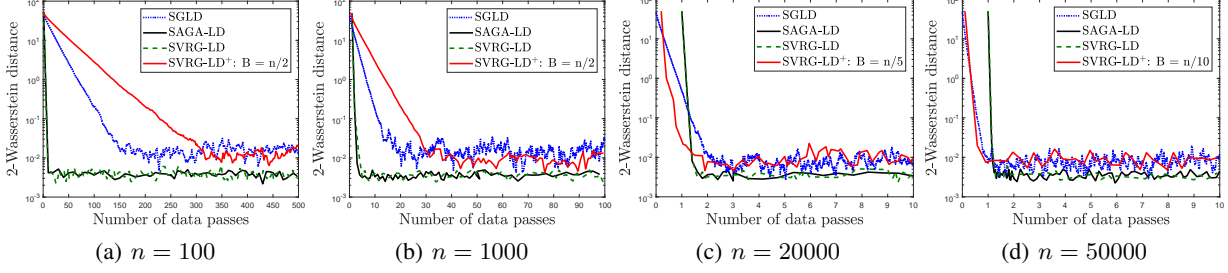

Figure 1: Comparison of different algorithms, where  $y$ -axis represents the 2-Wasserstein distance computed based on synthetic data, and  $x$ -axis is the number of data passes. (a) - (d) represent different sample sizes  $n$ .

Figure 2: Comparison of SVRG-LD<sup>+</sup> with different batch size  $B$ , where  $y$ -axis represents the 2-Wasserstein distance computed based on synthetic data, and  $x$ -axis is the number of data passes. (a) and (b) represent different sample sizes  $n$ .

$1/n \sum_{i=1}^n f_i(\mathbf{x}) = 1/n \sum_{i=1}^n (\mathbf{x} - \boldsymbol{\theta}_i)^\top \boldsymbol{\Sigma} (\mathbf{x} - \boldsymbol{\theta}_i)/2$ , where  $\boldsymbol{\Sigma}$  is a symmetric matrix having largest eigenvalue  $M = 2$  and smallest eigenvalue  $\mu = 1/2$ , and  $\boldsymbol{\theta}_i$  is drawn from standard multivariate Gaussian distribution.

We first compare the convergence rates of four different algorithms (i.e., SGLD, SVRG-LD, SAGA-LD and SVRG-LD<sup>+</sup>) to the target distribution in 2-Wasserstein distance, which are reported in Figure 1. It can be seen that there is no obvious difference between the convergence rates of SAGA-LD and SVRG-LD, which verifies our theoretical result of SVRG-LD. Moreover, Figures 1(a) and 1(b) demonstrate that the best choice of  $B$  is  $B = n$  when the sample size  $n$  is small, while Figures 1(c) and 1(d) show that using subsampled gradient  $\tilde{\mathbf{g}}$  in SVRG-LD<sup>+</sup> (i.e.,  $B < n$ ) is able to improve the performance of SVRG-LD when  $n$  is relatively large. This is well aligned with our theoretical analysis that the optimal batch size  $B$  is in the order of  $O(d\sigma^2/(\epsilon\mu)^2 \wedge n)$ .

In Figure 2, we further compare different choices of batch size  $B$  in SVRG-LD<sup>+</sup> when  $n$  is large. Note that since the optimal batch size  $B = n$  when the sample size is small, we only perform this experiment on the synthetic datasets with big sample size  $n = 20000$  and  $n = 50000$ . It can be inferred from Figure 2 that if we set  $\epsilon = 10^{-2}$ , the optimal  $B$  in SVRG-LD<sup>+</sup> for datasets

with sample sizes  $n = 20000$  and  $n = 50000$  are both  $B = 20000/2 = 50000/5 = 10000$ . This phenomenon agrees with our theory that for a large  $n \gtrsim d\sigma^2/(\epsilon\mu)^2$ , the optimal batch size  $B = O(d\sigma^2/(\epsilon\mu)^2)$  is independent of  $n$ .

## 5.2 BAYESIAN LOGISTIC REGRESSION

We also collaborate our theoretical results with Bayesian logistic regression. Suppose we are given a dataset with  $n$  examples  $\{\mathbf{X}_i, \mathbf{y}_i\}_{i=1,2,\dots,n}$ , where  $\mathbf{X}_i \in \mathbb{R}^d$  denotes the  $d$ -dimensional feature of the  $i$ -th sample, and  $\mathbf{y}_i \in \{-1, 1\}$  denotes the corresponding binary label. In Bayesian logistic regression, we assume that the input examples are independent, then the probability distribution of  $\mathbf{y}_i$  given features  $\mathbf{X}_i$  and regression coefficients  $\boldsymbol{\beta} \in \mathbb{R}^d$  has the following form

$$p(\mathbf{y}_i | \mathbf{X}_i, \boldsymbol{\beta}) = \frac{1}{1 + e^{-\mathbf{y}_i \boldsymbol{\beta}^\top \mathbf{X}_i}}.$$

Moreover, the prior of  $\boldsymbol{\beta}$  is typically modelled as a Gaussian distribution with zero mean (Dubey et al., 2016; Chatterji et al., 2018), i.e.,  $\boldsymbol{\beta} \sim N(0, \lambda \mathbf{I}_{d \times d})$ . Then we apply the Langevin based method to sample from the posterior distribution of  $\boldsymbol{\beta}$ , i.e.,  $p(\boldsymbol{\beta} | \mathbf{X}, \mathbf{y}) \propto p(\boldsymbol{\beta}) \prod_{i=1}^n p(\mathbf{y}_i | \mathbf{X}_i, \boldsymbol{\beta})$ , which implies that the component function  $f_i(\boldsymbol{\beta})$  can be written as

$$f_i(\boldsymbol{\beta}) = n \log(1 + e^{-\mathbf{y}_i \boldsymbol{\beta}^\top \mathbf{X}_i}) + \frac{\|\boldsymbol{\beta}\|_2^2}{\lambda}.$$

We apply the Langevin based algorithm to four datasets: *pima*, *mushroom*, *a9a* and *ijcnn1*, which are available at UCI repository<sup>4</sup> and Libsvm website<sup>5</sup>. It is worth noting that *pima* and *mushroom* do not have test datasets like *a9a* and *ijcnn1*, thus we manually partition them into train and test datasets. The basic information of all the datasets is summarized in Table 2. Again, we evaluate the performance of four different algorithms: SGLD,

<sup>4</sup><https://archive.ics.uci.edu/ml/>

<sup>5</sup><https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/>

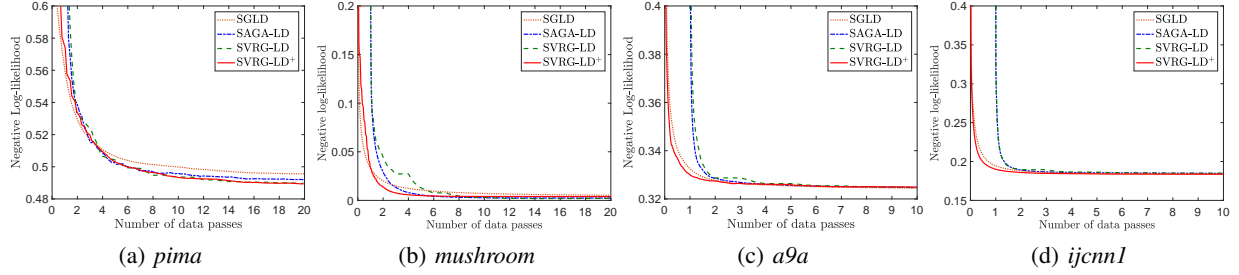

Figure 3: Comparison of different algorithms for Bayesian logistic regression, where  $y$  axis shows the negative log-likelihood on the test data, and  $x$  axis is the number of data passes. (a)-(d) correspond to 4 datasets.

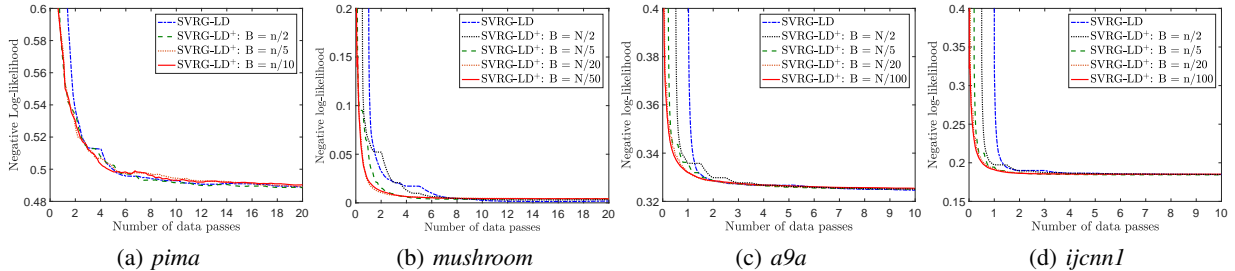

Figure 4: Bayesian Logistic regression results of SVRG-LD<sup>+</sup> using different batch size  $B$ , where  $y$  axis shows the negative log-likelihood on the test data, and  $x$  axis is the number of data passes. (a)-(d) correspond to 4 datasets.

SVRG-LD, SAGA-LD and SVRG-LD<sup>+</sup>, and perform sample path average to estimate the optimal  $\beta$ , where the minibatch size for each algorithm is set to be 1.

Figure 3 shows the negative log-likelihood of the test examples on these 4 datasets, where each algorithm has been run 10 times to calculate the averaged result. It can be seen that there exists a lag of one data pass for SAGA-LD and SVRG-LD, since they need to scan the entire dataset to compute a full gradient in the beginning. As we can see from the results in Figure 3, SVRG-LD<sup>+</sup> converges faster than the other methods, which validates the superior performance of SVRG-LD<sup>+</sup>. In detail, SVRG-LD<sup>+</sup> has a similar convergence rate as SAGA-LD and SVRG-LD when  $n$  is small, e.g. datasets *pima*, and performs close to SGLD for relatively large datasets, e.g., *a9a* and *ijcnn1*. This is also consistent with our theoretical results, since the convergence rate of SVRG-LD<sup>+</sup> matches that of SGLD when  $n \gtrsim d\sigma^2/(\epsilon\mu)^2$ .

gorithms when choosing different batch sizes  $B$ , which are reported in Figure 4. It can be observed that when the batch size is chosen appropriately, SVRG-LD<sup>+</sup> converges faster than SVRG-LD, but leading to a slightly higher error. Based on these observations, we can conclude that for Bayesian logistic regression, SVRG-LD<sup>+</sup> is more suitable than SVRG-LD when the dataset size is relatively large, and the required accuracy is moderate.

## 6 CONCLUSIONS

We propose the SVRG-LD<sup>+</sup> algorithm and analyze its convergence rate in 2-Wasserstein distance when the target distribution is log-smooth, strongly log-concave and log-Hessian-Lipschitz. Our result implies a sharper convergence analysis of SVRG-LD that improves the state-of-the-art. Experiments on synthetic and real data back up the theoretical results of this paper.

## Abstract

We study finite-state controllers (FSCs) for partially observable Markov decision processes (POMDPs) that are provably correct with respect to given specifications. The key insight is that computing (randomised) FSCs on POMDPs is equivalent to—and computationally as hard as—synthesis for parametric Markov chains (pMCs). This correspondence allows to use tools for synthesis in pMCs to compute correct-by-construction FSCs on POMDPs for a variety of specifications. Our experimental evaluation shows comparable performance to well-known POMDP solvers.

## 1 INTRODUCTION

**Partially Observable MDPs.** We intend to provide guarantees for planning scenarios given by dynamical systems with uncertainties. In particular, we want to synthesise a *strategy* for an agent that ensures certain desired behaviour (Howard, 1960). A popular formal model for planning subject to stochastic behaviour are Markov decision processes (MDPs) (Puterman, 1994). An MDP is a nondeterministic model in which the agent chooses to perform an action under full knowledge of the environment it is operating in. The outcome of the action is a probability distribution over the system states. Many applications, however, allow only *partial observability* of the current system state (Kaelbling et al., 1998; Thrun et al., 2005; Wongpiromsarn and Frazzoli, 2012; Russell and Norvig, 2010). For such applications, MDPs are extended to *partially observable Markov decision processes* (POMDPs). While the agent acts within the environment, it encounters certain *observations*, according to which it

can infer the likelihood of the system being in a certain state. This likelihood is called the *belief state*. Executing an action leads to an update of the belief state according to new observations. The belief state together with an update function form a (typically uncountably infinite) MDP, referred to as the *belief MDP* (Shani et al., 2013).

**The POMDP Synthesis Problem.** For (PO)MDPs, a *randomised strategy* is a function that resolves the non-determinism by providing a probability distribution over actions at each time step. In general, strategies depend on the full history of the current evolution of the (PO)MDP. If a strategy depends only on the current state of the system, it is called *memoryless*. For MDPs, memoryless strategies suffice to induce optimal values according to our measures of interest (Puterman, 1994). Contrarily, POMDPs require strategies taking the full observation history into account (Ross, 1983), e. g. in case of infinite-horizon objectives. Moreover, strategies inducing *optimal* values are computed by assessing the entire belief MDP (Madani et al., 1999; Braziunas, 2003; Szer and Charpillat, 2005; Norman et al., 2017), rendering the problem undecidable (Chatterjee et al., 2016c).

POMDP strategies can be represented by *infinite-state controllers*. For computational tractability, strategies are often restricted to finite memory; this amounts to using *randomised finite-state controllers* (FSCs) (Meuleau et al., 1999). We often refer to strategies as FSCs. Already the computation of a memoryless strategy adhering to a specification is NP-hard, SQRT-SUM-hard, and in PSPACE (Vlassis et al., 2012). While optimal values cannot be guaranteed, small memory in combination with *randomisation* may supersede large memory in many cases (Chatterjee et al., 2004; Amato et al., 2010).

**Correct-by-Construction Strategy Computation.** In this paper, we synthesise FSCs for POMDPs. We require these FSCs to be provably correct for specifications such as indefinite-horizon properties like expected reward or reach-avoid probabilities. State-of-the-art POMDP

Table 1: Correspondence

POMDP under FSC	pMC
states $\times$ memory same observation strategy	states same parameter parameter instantiation

solvers mainly consider expected discounted reward measures (Walraven and Spaan, 2017), which are a subclass of indefinite horizon properties (Kolobov et al., 2012).

Our key observation is that for a POMDP the *set of all FSCs* with a fixed memory bound can be succinctly represented by a *parametric Markov chain* (pMC) (Daws, 2004). Transitions of pMCs are given by functions over a finite set of parameters rather than constant probabilities. The *parameter synthesis* problem for pMCs is to determine parameter instantiations that satisfy (or refute) a given specification. We show that the pMC parameter synthesis problem and the POMDP strategy synthesis problem are equally hard. This correspondence not only yields complexity results (Hutschenreiter et al., 2017), but particularly enables using a plethora of methods for parameter synthesis implemented in sophisticated and optimised parameter synthesis tools like PARAM (Hahn et al., 2010), PRISM (Kwiatkowska et al., 2011), and PROPHESY (Dehnert et al., 2015). They turn out to be competitive alternatives to dedicated POMDP solvers. Moreover, as we are solving slightly different problems, our methods are orthogonal to, e. g., PRISM-POMDP (Norman et al., 2017) and solve-POMDP (Walraven and Spaan, 2017).

We detail our contributions and the structure of the paper, which starts with necessary formalisms in Sect. 2. A longer version of the paper (Junges et al., 2017) contains some additional material.

**Section 3:** We establish the correspondence of POMDPs and pMCs, see Tab. 1. The product of a POMDP and an FSC yields a POMDP with state-memory pairs, which we map to states in the pMC. If POMDP states share *observations*, the corresponding pMC states share *parameters* at emanating transitions. A *strategy* of the POMDP corresponds to a *parameter instantiation* in the pMC.

**Section 4:** We show the opposite direction, namely a transformation from pMCs to POMDPs. This result establishes that the synthesis problems for POMDPs and pMCs are equally hard. Technically, we identify the practically relevant class of *simple pMCs*, which coincides with POMDPs under memoryless strategies.

**Section 5:** Typical restrictions on parameter instantiations concern whether parameters may be assigned the probability zero. We discuss effects of such restrictions to the resulting POMDP strategies.

**Section 6:** We evaluate the computation of correct-by-

construction FSCs using pMC synthesis techniques. To that end, we explain how particular parameter synthesis approaches deliver optimal or near-optimal FSCs. Then, we evaluate the approach on a range of typical POMDP benchmarks. We observe that often a small amount of memory suffices. Our approach is competitive to state-of-the-art POMDP solvers and is able to synthesise small, almost-optimal FSCs.

**Related Work.** In addition to the cited works, (Meuleau et al., 1999) uses a branch-&-bound method to find optimal FSCs for POMDPs. A SAT-based approach computes FSCs for qualitative properties (Chatterjee et al., 2016a). For a survey of decidability results and algorithms for broader classes of properties refer to (Chatterjee et al., 2016c,b). Work on parameter synthesis (Hutschenreiter et al., 2017; Filieri et al., 2011) might contain additions to the methods considered here.

## 2 PRELIMINARIES

A *probability distribution* over a finite or countably infinite set  $X$  is a function  $\mu: X \rightarrow [0, 1] \subseteq \mathbb{R}$  with  $\sum_{x \in X} \mu(x) = \mu(X) = 1$ . The set of all distributions on  $X$  is  $Distr(X)$ . The support of a distribution  $\mu$  is  $\text{supp}(\mu) = \{x \in X \mid \mu(x) > 0\}$ . A distribution is *Dirac* if  $|\text{supp}(\mu)| = 1$ .

Let  $V = \{p_1, \dots, p_n\}$  be a finite set of *parameters* over the domain  $\mathbb{R}$  and let  $\mathbb{Q}[V]$  be the set of multivariate polynomials over  $V$ . An *instantiation* for  $V$  is a function  $u: V \rightarrow \mathbb{R}$ . Replacing each parameter  $p$  in a polynomial  $f \in \mathbb{Q}[V]$  by  $u(p)$  yields  $f[u] \in \mathbb{R}$ .

Decision problems can be considered as languages describing all positive instances. A language  $L_1 \subseteq \{0, 1\}^*$  is *polynomial (many-one or Karp) reducible* to  $L_2 \subseteq \{0, 1\}^*$ , written  $L_1 \leq_P L_2$ , if there exists a polynomial-time computable function  $f: \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that for all  $w \in \{0, 1\}^*$ ,  $w \in L_1 \iff f(w) \in L_2$ . Polynomial reductions are essential to define complexity classes, cf. (Papadimitriou, 1994).

### 2.1 PARAMETRIC MARKOV MODELS

**Definition 1 (pMDP)** A parametric Markov decision process (*pMDP*)  $M$  is a tuple  $M = (S, s_1, Act, V, \mathcal{P})$  with a finite (or countably infinite) set  $S$  of states, initial state  $s_1 \in S$ , a finite set  $Act$  of actions, a finite set  $V$  of parameters, and a transition function  $\mathcal{P}: S \times Act \times S \rightarrow \mathbb{Q}[V]$ .

The *available actions* in  $s \in S$  are  $A(s) = \{a \in Act \mid \exists s' \in S : \mathcal{P}(s, a, s') \neq 0\}$ . W.l. o. g. we assume  $\forall s, s' \in$

$S. \forall a \in Act. P(s, a, s') \neq 0 \wedge P(s, a, s') \neq 1 \Rightarrow \exists s'' \neq s'. P(s, a, s'') \neq 0$ . We assume that pMDP  $M$  contains no deadlock states, i. e.  $A(s) \neq \emptyset$  for all  $s \in S$ . A *path* of a pMDP  $M$  is an (in)finite sequence  $\pi = s_0 \xrightarrow{a_0} s_1 \xrightarrow{a_1} \dots$ , where  $s_0 = s_I$ ,  $s_i \in S$ ,  $a_i \in A(s_i)$ , and  $\mathcal{P}(s_i, a_i, s_{i+1}) \neq 0$  for all  $i \in \mathbb{N}$ . For finite  $\pi$ ,  $\text{last}(\pi)$  denotes the last state of  $\pi$ . The set of (in)finite paths of  $M$  is  $\text{Paths}_{fin}^M$  ( $\text{Paths}^M$ ).

**Definition 2 (MDP)** A Markov decision process (MDP) is a pMDP where  $\mathcal{P}: S \times Act \times S \rightarrow [0, 1] \subseteq \mathbb{R}$  and for all  $s \in S$  and  $a \in A(s)$ ,  $\sum_{s' \in S} \mathcal{P}(s, a, s') = 1$ .

A (*parametric*) *discrete-time Markov chain* ((p)MC) is a (p)MDP with  $|A(s)| = 1$  for all  $s \in S$ . For a (p)MC  $D$ , we may omit the actions and use the notation  $D = (S, s_I, V, P)$  with a transition function  $P$  of the form  $P: S \times S \rightarrow \mathbb{Q}[V]$ .

Applying an *instantiation*  $u: V \rightarrow \mathbb{R}$  to a pMDP or pMC  $M$ , denoted  $M[u]$ , replaces each polynomial  $f$  in  $M$  by  $f[u]$ .  $M[u]$  is also called the *instantiation* of  $M$  at  $u$ . Instantiation  $u$  is *well-defined* for  $M$  if the replacement yields probability distributions, i. e. if  $M[u]$  is an MDP or an MC, respectively.

**Strategies.** To resolve the nondeterministic action choices in MDPs, so-called *strategies* determine at each state a distribution over actions to take. This decision may be based on the *history* of the current path.

**Definition 3 (Strategy)** A strategy  $\sigma$  for (p)MDP  $M$  is a function  $\sigma: \text{Paths}_{fin}^M \rightarrow \text{Distr}(Act)$  s. t.  $\text{supp}(\sigma(\pi)) \subseteq Act(\text{last}(\pi))$  for all  $\pi \in \text{Paths}_{fin}^M$ . The set of all strategies of  $M$  is  $\Sigma^M$ .

A strategy  $\sigma$  is *memoryless* if  $\text{last}(\pi) = \text{last}(\pi')$  implies  $\sigma(\pi) = \sigma(\pi')$  for all  $\pi, \pi' \in \text{Paths}_{fin}^M$ . It is *deterministic* if  $\sigma(\pi)$  is a Dirac distribution for all  $\pi \in \text{Paths}_{fin}^M$ . A strategy that is not deterministic is *randomised*.

A strategy  $\sigma$  for an MDP  $M$  resolves all nondeterministic choices, yielding an *induced Markov chain*  $M^\sigma$ , for which a *probability measure* over infinite paths is defined by the cylinder set construction (Baier and Katoen, 2008).

**Definition 4 (Induced Markov Chain)** For an MDP  $M = (S, s_I, Act, \mathcal{P})$  and a strategy  $\sigma \in \Sigma^M$ , the MC induced by  $M$  and  $\sigma$  is given by  $M^\sigma = (\text{Paths}_{fin}^M, s_I, P^\sigma)$  where:

$$P^\sigma(\pi, \pi') = \begin{cases} \mathcal{P}(\text{last}(\pi), a, s') \cdot \sigma(\pi)(a) & \text{if } \pi' = \pi a s' \\ 0 & \text{otherwise.} \end{cases}$$

## 2.2 PARTIAL OBSERVABILITY

**Definition 5 (POMDP)** A partially observable MDP (POMDP) is a tuple  $\mathcal{M} = (M, Z, O)$ , with  $M = (S, s_I, Act, \mathcal{P})$  the underlying MDP of  $\mathcal{M}$ ,  $Z$  a finite set of observations and  $O: S \rightarrow Z$  the observation function.

We require that states with the same observations have the same set of enabled actions, i. e.  $O(s) = O(s')$  implies  $A(s) = A(s')$  for all  $s, s' \in S$ . We define  $A(z) = A(s)$  if  $O(s) = z$ . More general observation functions (Roy et al., 2005; Shani et al., 2013) take the last action into account and provide a distribution over  $Z$ . There is a transformation of the general case to the POMDP definition used here that blows up the state space polynomially (Chatterjee et al., 2016b). In Fig. 1(a), a fragment of the underlying MDP of a POMDP has two different observations, indicated by the state colouring.

We lift the observation function to paths: For  $\pi = s_0 \xrightarrow{a_0} s_1 \xrightarrow{a_1} \dots s_n \in \text{Paths}_{fin}^M$ , the associated *observation sequence* is  $O(\pi) = O(s_0) \xrightarrow{a_0} O(s_1) \xrightarrow{a_1} \dots O(s_n)$ . Several paths in the underlying MDP may yield the same observation sequence. Strategies have to take this restricted observability into account.

**Definition 6** An observation-based strategy  $\sigma$  for a POMDP  $\mathcal{M}$  is a strategy for the underlying MDP  $M$  such that  $\sigma(\pi) = \sigma(\pi')$  for all  $\pi, \pi' \in \text{Paths}_{fin}^M$  with  $O(\pi) = O(\pi')$ .  $\Sigma^{\mathcal{M}}$  is the set of observation-based strategies for  $\mathcal{M}$ .

An observation-based strategy selects actions based on observations along a path and the past actions. Applying the strategy to a POMDP yields an induced MC as in Def. 4, resolving all nondeterminism and partial observability. To represent observation-based strategies with finite memory, we define *finite-state controllers* (FSCs). A randomised observation-based strategy for a POMDP  $\mathcal{M}$  with (finite)  $k$  memory is represented by an FSC  $\mathcal{A}$  with  $k$  memory nodes. If  $k = 1$ , the FSC describes a *memoryless strategy*. We often refer to observation-based strategies as FSCs.

**Definition 7 (FSC)** A finite-state controller (FSC) for a POMDP  $\mathcal{M}$  is a tuple  $\mathcal{A} = (N, n_I, \gamma, \delta)$ , where  $N$  is a finite set of memory nodes,  $n_I \in N$  is the initial memory node,  $\gamma$  is the action mapping  $\gamma: N \times Z \rightarrow \text{Distr}(Act)$ , and  $\delta$  is the memory update  $\delta: N \times Z \times Act \rightarrow \text{Distr}(N)$ . The set  $\text{FSC}_k^{\mathcal{M}}$  denotes the set of FSCs with  $k$  memory nodes, called  $k$ -FSCs. Let  $\sigma_{\mathcal{A}} \in \Sigma^{\mathcal{M}}$  denote the observation-based strategy represented by  $\mathcal{A}$ .

From a node  $n$  and the observation  $z$  in the current state of the POMDP, the next action  $a$  is chosen from  $A(z)$

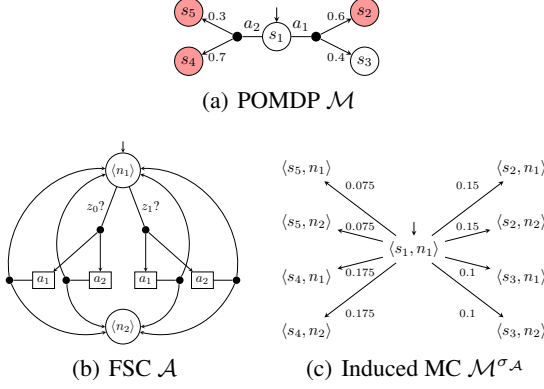

Figure 1: (a) The POMDP  $\mathcal{M}$  with observations  $O(s_1) = O(s_3) = z_0$  (white) and  $O(s_2) = O(s_4) = O(s_5) = z_1$  (red). (b) The associated (partial) FSC  $\mathcal{A}$  has two memory nodes. (c) A part of MC  $\mathcal{M}^{\sigma\mathcal{A}}$  induced by  $\mathcal{M}$  and  $\mathcal{A}$ .

randomly as given by  $\gamma(n, z)$ . Then, the successor node of the FSC is determined randomly via  $\delta(n, z, a)$ .

**Example 1** Fig. 1(b) shows an excerpt of an FSC  $\mathcal{A}$  with two memory nodes. From node  $n_1$ , the action mapping distinguishes observations  $z_0$  and  $z_1$ . The solid dots indicate a probability distribution from  $\text{Distr}(\text{Act})$ . For readability, all distributions are uniform and we omit the action mapping for node  $n_2$ .

Now recall the POMDP  $\mathcal{M}$  from Fig. 1(a). The induced MC  $\mathcal{M}^{\sigma\mathcal{A}}$  is shown in Fig. 1(c). Assume  $\mathcal{M}$  is in state  $s_1$  and  $\mathcal{A}$  in node  $n_1$ . Based on the observation  $z_0 := O(s_1)$ ,  $\sigma_{\mathcal{A}}$  chooses action  $a_1$  with probability  $\delta(n_1, z_0)(a_1) = 0.5$  leading to the probabilistic branching in the POMDP. With probability 0.6,  $\mathcal{M}$  evolves to state  $s_2$ . Next, the FSC  $\mathcal{A}$  updates its memory node; with probability  $\delta(n_1, z_0, a_1)(n_1) = 0.5$ ,  $\mathcal{A}$  stays in  $n_1$ . The corresponding transition from  $\langle s_1, n_1 \rangle$  to  $\langle s_2, n_1 \rangle$  in  $\mathcal{M}^{\sigma\mathcal{A}}$  has probability  $0.5 \cdot 0.6 \cdot 0.5 = 0.15$ .

## 2.3 SPECIFICATIONS

For a POMDP  $\mathcal{M}$ , a set  $G \subseteq S$  of goal states, a set  $B \subseteq S$  of bad states, and a threshold  $\lambda \in [0, 1)$ , we consider quantitative reach-avoid specifications  $\varphi = \mathbb{P}_{>\lambda}(\neg B \cup G)$ . The specification  $\varphi$  is satisfied for a strategy  $\sigma \in \Sigma^{\mathcal{M}}$  if the probability  $\Pr^{\mathcal{M}^{\sigma}}(\neg B \cup G)$  of reaching a goal state in  $\mathcal{M}^{\sigma}$  without entering a bad state in between exceeds  $\lambda$ , denoted by  $\mathcal{M}^{\sigma} \models \varphi$ . The task is to compute such a strategy provided that one exists. For an MDP  $M$ , there is a memoryless deterministic strategy inducing the maximal probability  $\Pr_{\max}^M(\neg B \cup G)$  (Condon, 1992). For a POMDP  $\mathcal{M}$ , however, observation-based strategies with infinite memory as in Def. 6 are

Act	$\mathcal{P}$	Node	Result
$a_1 : p$	0.6	$n_1 : q_1$	$0.6 \cdot p \cdot q_1$
		$n_2 : 1 - q_1$	$0.6 \cdot p \cdot (1 - q_1)$
	0.4	$n_1 : q_1$	$0.4 \cdot p \cdot q_1$
		$n_2 : 1 - q_1$	$0.4 \cdot p \cdot (1 - q_1)$
$a_2 : 1 - p$	0.7	$n_1 : q_2$	$0.7 \cdot (1 - p) \cdot q_2$
		$n_2 : 1 - q_2$	$0.7 \cdot (1 - p) \cdot (1 - q_2)$
	0.3	$n_1 : q_2$	$0.3 \cdot (1 - p) \cdot q_2$
		$n_2 : 1 - q_2$	$0.3 \cdot (1 - p) \cdot (1 - q_2)$

(b) Parameterised transition probabilities

Figure 2: Induced parametric Markov chain for FSCs.

necessary (Ross, 1983) to attain  $\Pr_{\max}^{\mathcal{M}}(\neg B \cup G)$ . The problem of proving the satisfaction of  $\varphi$  is therefore undecidable (Chatterjee et al., 2016c). In our experiments, we also use *undiscounted expected reachability reward properties* (Baier and Katoen, 2008).

## 3 FROM POMDPs TO PMCS

Our goal is to make pMC synthesis methods available for POMDPs. In this section we provide a transformation from a POMDP  $\mathcal{M}$  to a pMC  $D$ . We consider the following decision problems.

**Problem 1 ( $\exists k$ -FSC)** Given a POMDP  $\mathcal{M}$ , a specification  $\varphi$ , and a (unary encoded) memory bound  $k > 0$ , is there a  $k$ -FSC  $\mathcal{A}$  with  $\mathcal{M}^{\sigma\mathcal{A}} \models \varphi$ ?

**Problem 2 ( $\exists \text{INST}$ )** For a pMC  $D$  and a specification  $\varphi$ , does a well-defined instantiation  $u$  exist s.t.  $D[u] \models \varphi$ ?

**Theorem 1**  $\exists k\text{-FSC} \leq_P \exists \text{INST}$ .

The remainder of the section outlines the proof, the converse direction is addressed in Sect. 4. Consider a POMDP  $\mathcal{M}$ , a specification  $\varphi$ , and a memory bound  $k > 0$  for which  $\exists k$ -FSC is to be solved. The degrees of freedom to select a  $k$ -FSC are given by the possible choices for  $\gamma$  and  $\delta$ . For each  $\gamma$  and  $\delta$ , we get a different induced MC, but these MCs are *structurally similar* and can be represented by a single pMC.

**Example 2** Recall Fig. 1 and Ex. 1. The action mapping  $\gamma$  and the memory update  $\delta$  have arbitrary but fixed

probability distributions. For  $a_1$ , we represent the probability  $\gamma(n_1, z_0)(a_1) =: p$  by  $p \in [0, 1]$ . The memory update yields  $\delta(n_1, z_0, a_1)(n_1) =: q_1 \in [0, 1]$  and  $\delta(n_1, z_0, a_1)(n_2) =: 1 - q_1$ , respectively. Fig. 2(a) shows the induced pMC for action choice  $a_1$ . For instance, the transition from  $\langle s_1, n_1 \rangle$  to  $\langle s_2, n_1 \rangle$  is labelled with polynomial  $p \cdot 0.6 \cdot q_1$ .

We collect all polynomials for observation  $z_0$  in Fig. 2(b). The result column describes a parameterised distribution over tuples of states and memory nodes. Thus, instantiations for these polynomials need to sum up to one.

As the next step, we define the pMC that results from combining a  $k$ -FSC with a POMDP. The idea is to assign parameters as arbitrary probabilities to action choices. Each observation has one *remaining action* given by a mapping  $Remain: Z \rightarrow Act$ .  $Remain(z) \in A(z)$  is the action to which, after choosing probabilities for all other actions in  $A(z)$ , the remaining probability is assigned. A similar principle holds for the remaining memory node.

**Definition 8 (Induced pMC for a  $k$ -FSC on POMDPs)**  
Let  $\mathcal{M} = (M, Z, O)$  be a POMDP with  $M = (S, s_I, Act, \mathcal{P})$  and let  $k > 0$  be a memory bound. The induced pMC  $D_{\mathcal{M},k} = (S_{\mathcal{M},k}, s_{I,\mathcal{M},k}, V_{\mathcal{M},k}, P_{\mathcal{M},k})$  is defined by:

- $S_{\mathcal{M},k} = S \times \{0, \dots, k-1\}$ ,  $s_{I,\mathcal{M},k} = \langle s_I, 0 \rangle$ ,
- $V_{\mathcal{M},k} = \{p_a^{z,n} \mid z \in Z, n \in \{0, \dots, k-1\}, a \in A(z), a \neq Remain(z)\} \cup \{q_{a,n'}^{z,n} \mid z \in Z, n, n' \in \{0, \dots, k-1\}, n' \neq k-1, a \in A(z)\}$ ,
- $P_{\mathcal{M},k}(s, s') = \sum_{a \in A(s)} H(s, s', a)$  for all  $s, s' \in S'$ ,

where  $H: S_{\mathcal{M},k} \times S_{\mathcal{M},k} \times Act \rightarrow \mathbb{R}$  is for  $z = O(s)$  defined by  $H(\langle s, n \rangle, \langle s', n' \rangle, a) =$

$$\mathcal{P}(s, a, s') \cdot \left\{ \begin{array}{ll} p_a^{z,n}, & \text{if } a \neq Remain(z) \\ 1 - \sum_{b \neq a} p_b^{z,n}, & \text{if } a = Remain(z) \end{array} \right\} \cdot \left\{ \begin{array}{ll} q_{a,n'}^{z,n}, & \text{if } n' \neq k-1 \\ 1 - \sum_{\bar{n} \neq n'} q_{a,\bar{n}}^{z,n}, & \text{if } n' = k-1 \end{array} \right\}.$$

Intuitively,  $H(s, s', a)$  describes the probability mass from  $s$  to  $s'$  in the induced pMC that is contributed by action  $a$ . The three terms correspond to the terms as seen in the first three columns of Tab. 2(b).

**Example 3** Consider the POMDP in Fig. 3(a) and let  $k = 1$ . The induced pMC is given in Fig. 3(b). The three actions from  $s_0$  have probability  $p_1, p_2$ , and  $1 - p_1 - p_2$  for the remaining action  $a_3$ . From the indistinguishable states  $s_1, s_3$ , actions have probability  $q$  and  $1 - q$ , respectively.

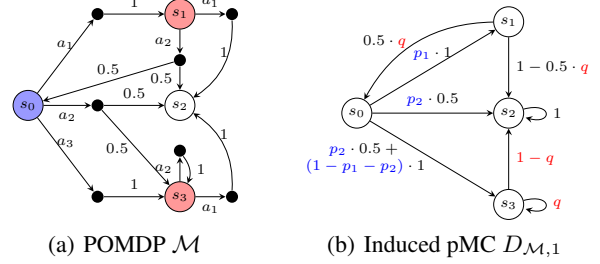

Figure 3: From POMDPs to pMCs ( $k = 1$ )

By construction, the induced pMC describes the set of all induced MCs:

**Theorem 2 (Correspondence Theorem)** For POMDP  $\mathcal{M}$ , memory bound  $k$ , and the induced pMC  $D_{\mathcal{M},k}$ :

$$\{D_{\mathcal{M},k}[u] \mid u \text{ well-defined}\} = \{\mathcal{M}^{\sigma_A} \mid \mathcal{A} \in FSC_k^{\mathcal{M}}\}.$$

In particular, every well-defined instantiation  $u$  describes an FSC  $\mathcal{A}_u \in FSC_k^{\mathcal{M}}$ .

By the correspondence, we can thus evaluate an instantiation of the induced pMC to assess whether the corresponding  $k$ -FSC satisfies a given specification.

**Corollary 1** Given an induced pMC  $D_{\mathcal{M},k}$  and a specification  $\varphi$ : For every well-defined instantiation  $u$  of  $D_{\mathcal{M},k}$  and the corresponding  $k$ -FSC  $\mathcal{A}_u$  we have:

$$\mathcal{M}^{\sigma_{\mathcal{A}_u}} \models \varphi \iff D_{\mathcal{M},k}[u] \models \varphi.$$

The number of parameters in the induced pMC  $D_{\mathcal{M},k}$  is given by  $\mathcal{O}(|Z| \cdot k^2 \cdot \max_{z \in Z} |A(z)|)$ .

## 4 FROM PMCS TO POMDPS (AND BACK AGAIN)

In the previous section we have shown that  $\exists k$ -FSC is at least as hard as  $\exists INST$ . We now discuss whether both problems are equally hard: The open question is whether we can reduce  $\exists INST$  to  $\exists k$ -FSC.

A straightforward reduction maintains the states of the pMC in the POMDP, or even yields a POMDP with the same graph structure (the topology) as the pMC. The next example shows that this naive reduction is impossible.

**Example 4** In the pMC in Fig. 4 the parameter  $p$  occurs in two different distributions (at  $s_0$  and  $s_2$ ). For defining a reduction where the resulting POMDP has the same set of states, there are two options for the observation

Figure 4: Non-simple pMC

function at the states  $s_0$  and  $s_2$ : Either  $O(s_0) = O(s_2)$  or  $O(s_0) \neq O(s_2)$ . The intuition is that every (parametric) transition in the pMC corresponds to an action choice in a POMDP. Then  $O(s_0) = O(s_2)$  is impossible as  $s_0$  and  $s_2$  have a different number of outgoing transitions (outdegree). Adding a self-loop to  $s_2$  does not alleviate the problem. Moreover,  $O(s_0) \neq O(s_2)$  is impossible, as a strategy could distinguish  $s_0$  and  $s_2$  and assign different probabilities to  $p$ .

The pMC in the example is problematic as the parameters occur at the outgoing transitions of states in different combinations. We restrict ourselves to an important subclass<sup>1</sup> of pMCs which we call *simple pMCs*. A pMC is simple if for all states  $s, s', P(s, s') \in \mathbb{Q} \cup \{p, 1-p \mid p \in V\}$ . Consequently, we can map states to parameters, and use this map to define the observations. Then, the transformation from a POMDP to a pMC is the reverse of the transformation from Def. 8. In the remainder, we detail this correspondence. The correspondence also establishes a construction to compute  $k$ -FSCs via parameter synthesis on *simple* pMCs. Current tool-support (cf. Sect. 6) for simple pMCs is more mature than for the more general pMCs obtained via Def. 8.

Let *simple- $\exists$ INST* be the restriction of  $\exists$ INST to simple pMCs. Similarly, let *simple- $\exists$ 1-FSC* be a variant of  $\exists$ 1-FSC that only considers *simple* POMDPs.

**Definition 9 (Binary/Simple POMDP)** A POMDP is binary, if  $|A(s)| \leq 2$  for all  $s \in S$ . A binary POMDP is simple, if for all  $s \in S$

$$|A(s)| = 2 \implies \forall a \in A(s) \exists s' \in S : P(s, a, s') = 1.$$

We establish the following relation between the POMDP and pMC synthesis problems, which asserts that the problems are equivalently hard.

**Theorem 3** For any  $L_1, L_2 \in \{ \exists k\text{-FSC}, \exists 1\text{-FSC}, \text{simple-}\exists 1\text{-FSC}, \text{simple-}\exists \text{INST} \}$ ,  $L_1 \leq_P L_2$ .

The proof is a direct consequence of the Lemmas 1-4 below, as well as the facts that every 1-FSC is a  $k$ -FSC, and every simple POMDP is a POMDP.

<sup>1</sup>All pMC benchmarks from the PARAM webpage (PARAM Website, 2015) are simple pMCs.

(a) Four actions in a POMDP (b) Four actions in a binary POMDP

(c) Binary POMDP (d) Simple POMDP (e) Simple pMC

Figure 5: POMDP  $\leftrightarrow$  simple pMC

The induced pMC  $D_{\mathcal{M},1}$  of a simple POMDP  $\mathcal{M}$  is also simple. Consequently, Sect. 3 yields:

**Lemma 1** *simple- $\exists$ 1-FSC*  $\leq_P$  *simple- $\exists$ INST*.

## 4.1 FROM SIMPLE PMCS TO POMDPS

**Theorem 4** Every simple pMC  $D$  with  $n$  states and  $m$  parameters is isomorphic to  $D_{\mathcal{M},1}$  for some simple POMDP  $\mathcal{M}$  with  $n$  states and  $m$  observations.

We refrain from a formal proof: The construction is the reverse of Def. 8, with observations  $\{z_p \mid p \in V_D\}$ . In a simple pMC, the outgoing transitions are either all parameter free, or of the form  $p, 1-p$ . The parameter-free case is transformed into a POMDP state with a single action (and any observation). The parametric case is transformed into a state with two actions with Dirac-distributions attached. As observation we use  $z_p$ .

**Lemma 2** *simple- $\exists$ INST*  $\leq_P$  *simple- $\exists$ 1-FSC*.

## 4.2 MAKING POMDPS SIMPLE

We present a reduction from  $\exists 1\text{-FSC}$  to *simple- $\exists$ 1-FSC* by translating a (possibly not simple) POMDP into a *binary* POMDP and subsequently into a *simple* POMDP. Examples are given in Fig. 5(a-e). We emphasise that our construction only preserves the expressiveness of 1-FSCs. Details are given in (Junges et al., 2017).

**Lemma 3**  $\exists 1\text{-FSC} \leq_P \text{simple-}\exists 1\text{-FSC}$ .

Figure 6: Unfolding a POMDP for two memory states

### 4.3 FROM $k$ -FSCS TO 1-FSCS

For a POMDP  $\mathcal{M}$  and memory bound  $k > 1$ , we construct a POMDP  $\mathcal{M}_k$  such that  $\mathcal{M}$  satisfies a specification  $\varphi$  under some  $k$ -FSC iff  $\mathcal{M}_k$  satisfies  $\varphi$  under some 1-FSC.

**Definition 10 ( $k$ -Unfolding)** Let  $\mathcal{M} = (M, Z, O)$  be a POMDP with  $M = (S, s_I, Act, \mathcal{P})$ , and  $k > 1$ . The  $k$ -unfolding of  $\mathcal{M}$  is the POMDP  $\mathcal{M}_k = (M_k, Z_k, O_k)$  with  $M_k = (S_k, s_{I,k}, Act_k, \mathcal{P}_k)$  defined by:

- $S_k = S \times \{0, \dots, k-1\}$ ,  $s_{I,k} = \langle s_I, 0 \rangle$ ,
- $Act_k = Act \times \{0, \dots, k-1\}$
- $\mathcal{P}_k(\langle s, n \rangle, \langle a, \bar{n} \rangle, \langle s', n' \rangle) = \begin{cases} \mathcal{P}(s, a, s') & n' = \bar{n}, \\ 0 & \text{else.} \end{cases}$

and  $Z_k = Z \times \{0, \dots, k-1\}$ ,  $O_k(\langle s, n \rangle) = \langle O(s), n \rangle$ .

Intuitively,  $\mathcal{M}_k$  stores the current memory node into its state space. At state  $\langle s, n \rangle$  of  $\mathcal{M}_k$ , a 1-FSC can not only choose between the available actions  $A(s)$  in  $\mathcal{M}$  but also between different successor memory nodes.

Fig. 6 shows this process for  $k = 2$ . All states of the POMDP are copied once. Different observations allow to determine in which copy of a state – and therefore, which memory cell – we currently are. Additionally, all actions are duplicated to model the option for a strategy to switch the memory cell.

The induced pMC  $D_{\mathcal{M}_k,1}$  of the  $k$ -unfolding of  $\mathcal{M}$  has the same topology as the induced pMC  $D_{\mathcal{M},k}$  of  $\mathcal{M}$  with memory bound  $k$ . In fact, both pMCs have the same instantiations.

**Proposition 1** For POMDP  $\mathcal{M}$  and memory bound  $k$ :

$$\{D_{\mathcal{M}_k,1}[u] \mid u \text{ well-def.}\} = \{D_{\mathcal{M},k}[u] \mid u \text{ well-def.}\}.$$

The intuition is that in both pMCs the parameter instantiations reflect arbitrary probability distributions over the same set of successor states. In the transition probability function of the induced pMC  $D_{\mathcal{M},k}$  of  $\mathcal{M}$  we can also substitute the multiplications of parameters  $p_a^{z,n}$  and  $q_a^{z,n}$ ,

Figure 7: MDP  $\mathcal{M}$

by single parameters. This transformation yields a *substituted induced pMC* which is isomorphic to the induced pMC  $D_{\mathcal{M}_k,1}$  of the  $k$ -unfolding of  $\mathcal{M}$ . Details are given in (Junges et al., 2017).

Proposition 1 and Thm. 2 imply that induced MCs of  $\mathcal{M}$  under  $k$ -FSCs coincide with induced MCs of  $\mathcal{M}_k$  under 1-FSCs:  $\{\mathcal{M}^{\sigma_A} \mid \mathcal{A} \in FSC_k^{\mathcal{M}}\} = \{\mathcal{M}_k^{\sigma_A} \mid \mathcal{A} \in FSC_1^{\mathcal{M}_k}\}$ .

**Lemma 4**  $\exists k\text{-FSC} \leq_P \exists 1\text{-FSC}$ .

## 5 STRATEGY RESTRICTIONS

Two simplifying restrictions on the parameters are usually made in parameter synthesis for pMCs:

- Each transition is assigned a strictly positive probability (*graph-preserving*).
- Each transition is assigned at least probability  $\varepsilon > 0$  ( $\varepsilon$ -*preserving*).

For simple pMCs, the restrictions correspond to parameters instantiations over  $(0, 1)$  or  $[\varepsilon, 1 - \varepsilon]$ , respectively.

Accordingly, we define restrictions to POMDP strategies that correspond to such restricted parameter instantiations.

**Definition 11 (Non-zero Strategies)** A strategy  $\sigma$  is non-zero if  $\sigma(\pi)(a) > 0$  for all  $\pi \in \text{Paths}_{\min}^M$ ,  $a \in A(\text{last}(\pi))$ , and min- $\varepsilon$  if additionally  $\sigma(\pi)(a) \geq \varepsilon > 0$ .

Non-zero strategies enforce  $\text{supp}(\sigma(s)) = A(s)$ . Example 5 shows the impact on reachability probabilities.

**Example 5** The MDP  $M$  in Fig. 7 has a choice between actions  $a_1$  and  $a_2$  at state  $s_0$ . If action  $a_1$  is chosen with probability zero, the probability to reach  $s_1$  from  $s_0$  becomes zero, and the corresponding parameter instantiation is not graph-preserving. Contrarily, if  $a_1$  is chosen with any positive probability, as would be enforced by a non-zero strategy, the probability to reach  $s_1$  is one.

**Proposition 2** Let  $\mathcal{M}$  be a POMDP. An instantiation  $u$  on  $D_{\mathcal{M},1}$  is graph-preserving ( $\varepsilon$ -preserving), iff  $\sigma_{\mathcal{A}_u}$  is non-zero (min- $\varepsilon$ ).

Still, for the considered specifications, we can, w. l. o. g., restrict ourselves to FSCs that induce non-zero strategies.

**Theorem 5** Let  $\mathcal{M}$  be a POMDP,  $k$  a memory bound and  $\varphi = \mathbb{P}_{>\lambda}(\neg B \cup G)$ . Either  $\forall \mathcal{A} \in k\text{-FSC} : \mathcal{M}^{\sigma_{\mathcal{A}}} \not\models \varphi$  or  $\exists \mathcal{A}' \in k\text{-FSC} : \mathcal{M}^{\sigma_{\mathcal{A}'}} \models \varphi$  with  $\sigma_{\mathcal{A}'}$  non-zero.

The statement is shown in (Junges et al., 2017) by considering the corresponding pMC.

## 6 EMPIRICAL EVALUATION

We established the correspondence between the synthesis problems for POMDPs and pMCs. Now, we discuss the available methods for pMC parameter synthesis, and how they may be exploited or adapted to synthesise FSCs. We distinguish three key problems:

1. *Find a correct-by-construction strategy for a POMDP and a specification.* To construct such a strategy, one needs to find a parameter valuation for the pMC that provably satisfies the specification. Most solution techniques focused on pMCs with a few parameters, rendering the problem at hand infeasible. Recently, efficient approaches emerged that are either based on particle swarm optimisation (PSO) (Chen et al., 2013) or on convex optimisation (Amato et al., 2010; Cubuktepe et al., 2017), in particular using quadratically-constrained quadratic programming (QCQP) (Cubuktepe et al., 2018). We employ PSO and QCQP for our evaluation.

2. *Prove that no FSC exists for a POMDP and a specification.* Proving the absence of an FSC with the given memory bound allows us to show  $\varepsilon$ -optimality of a previously synthesised strategy. Two approaches exist: An approximative technique called *parameter lifting* (Quatmann et al., 2016) and a method based on SAT-modulo-theories (SMT) solving (de Moura and Bjørner, 2008).

3. *Provide a closed-form solution for the underlying measure of a specification in form of a function over the induced parameters of an FSC.* The function may be used for further analysis, e. g. of the sensitivity of decisions or parameter values, respectively. To compute this function, all of the parameter synthesis tools PARAM (Hahn et al., 2010), PRISM (Kwiatkowska et al., 2011), Storm (Dehnert et al., 2017), and PROPhESY (Dehnert et al., 2015) employ a technique called *state elimination* (Daws, 2004).

**Implementation and Setup.** We extended the tool Storm (Dehnert et al., 2017) to parse and store POMDPs, and implemented several transformation options to pMCs. Most notably, Storm supports  $k$ -unfolding, the product with several restricted FSCs such as counters that can be incremented at will, and several types of transformation to (simple) pMCs.

We evaluate on a HP BL685C G7 with 48 2GHz cores, a 16GB memory limit, and 1800 seconds time

Table 2: Benchmarks

Id	Name	Tp.	POMDP $\mathcal{M}$			PRISM-POMDP		SolvePOMDP		MDP
			States	Bran.	Obs.	Result	Time	Result	Time	Res
1	NRP (8)	$\mathbb{P}$	125	161	41	[.125, .24]	20		TO	1.0
2	Grid (4)	$\mathbb{E}$	17	62	3	[3.97, 4.13]	1038	4.13	0.4	3.2
3	Netw (3,4,8)	$\mathbb{E}$	2729	4937	361				TO	0.83
4	Crypt (5)	$\mathbb{P}$	4885	11733	890				MO	1.0
5	Maze (2)	$\mathbb{E}$	16	58	8	[5.11, 5.23]	3.9	5.23	16	4.0
6	Load (8)	$\mathbb{E}$	16	28	5	[10.5, 10.5]	1356	10.5	7.6	10.5
7	Slippery (4)	$\mathbb{P}$	17	59	4			0.93	95	1.0

limit. The compared methods are single-threaded. We took the POMDPs from PRISM-POMDP (Norman et al., 2017), and additional maze, load/unload examples from (Meuleau et al., 1999), and a slippery gridworld with traps inspired by (Russell and Norvig, 2010). Table 2 gives details. The specifications (Tp.) are either the minimisation of expected costs from an initial state until reaching a specified target set ( $\mathbb{E}$ ), or the maximisation the probability of reaching from an initial state a target set without hitting a bad state before ( $\mathbb{P}$ ). We list the number of states, branches ( $\sum |A(s)|$ ), and observations in each POMDP. As a baseline, we provide the results and run time of the model-checking tool PRISM-POMDP, and the point-based solver SolvePOMDP (Walraven and Spaan, 2017), obtained with default settings. Both tools compute optimal memory-unbounded strategies and are prototypes. The last column contains the result on the underlying, fully observable MDP. The experiments contain minimal expected rewards, which are analysed by a straightforward extension of maximal reachability probabilities. All pMCs computed are simple pMCs, as PROPhESY typically benefits from the simpler structure. PROPhESY has been invoked with the default set-up.

### 6.1 FINDING STRATEGIES

We evaluate how quickly a strategy that satisfies the specification is synthesised. We vary the threshold used in the specification, as well as the structure of the FSC.

**Results.** We summarise the obtained results in Tab. 3. For each instance (Id), we define three thresholds (Ts), ordered from challenging (i. e. close to the optimum) to less challenging. For different types of FSCs (FSC, F=full, C=counter) and memory bounds ( $k$ ), we obtain pMCs with the given number of states, transitions and parameters. Full-FSCs are fully connected, in counter-FSCs memory state  $m$  is succeeded by either  $m$  or  $m + 1$ . For each threshold (T1, T2, T3), we report the run time of the two methods PSO and QCQP, respectively. T1 is chosen to be nearly optimal for all benchmarks. A dash indicates a combination of memory and threshold that is not realisable according to the results in Sect. 6.2. TO/MO denote violations of the time/memory limit, respectively.

Table 3: Synthesizing strategies

Id	Ts	FSC/k	States	Trans	Pars	T1		T2		T3	
						pso	qcqp	pso	qcqp	pso	qcqp
1	.124/.11/.09	F/1	75	118	8	<1	<1	<1	<1	<1	<1

		F/2	25713	51608	3907	330	MO	350	MO	326	MO
5	5.2/15/25	F/1	30	64	8	-	-	TO	TO	<1	TO
		F/2	137	294	49	TO	TO	14	TO	2	TO
		F/4	587	1214	219	93	TO	TO	TO	26	TO
		F/8	2421	4924	919	TO	TO	1034	TO	115	TO
		C/2	99	212	33	TO	TO	3.7	TO	<1	TO
C/4	231	476	81	7	TO	6	TO	3	TO		
6	10.6/10.9/82.5	F/1	16	33	1	-	-	-	-	<1	TO
		F/2	77	160	11	9	TO	6	TO	<1	TO
		F/4	354	721	63	20	TO	21	63	3	TO
7	.929/.928/.927	F/1	87	184	3	TO	TO	<1	1	<1	<1
		F/2	285	592	15	4	TO	4	20	3	22
		F/4	1017	2080	63	76	767	71	205	67	187
		F/8	3825	7744	255	TO	TO	TO	TO	TO	TO

**Evaluation.** Strategies for thresholds which are suboptimal (T3) are synthesised faster. If the memory bound is increased, the number of parameters quickly grows and the performance of the methods degrades. Additional experiments showed that the number of states has only a minor effect on the performance. The simpler FSC topology for a counter alleviates the blow-up of the pMC and is successfully utilised to find strategies for larger instances.

Trivially, a  $k$ -FSC is also a valid  $(k+i)$ -FSC for some  $i \in \mathbb{N}$ . Yet, the larger number of parameters make searching for  $(k+i)$ -FSCs significantly more difficult. We furthermore observe that the performance of PSO and QCQP is incomparable, and both methods have their merits.

Summarising, many of the POMDPs in the benchmarks allow good performance via FSCs with small memory. **We find nearly-optimal, and small, FSCs for POMDP benchmarks with thousands of states within seconds.**

## 6.2 PROVING $\varepsilon$ -OPTIMALITY

We now focus on evaluating how fast pMC techniques prove the absence of a strategy satisfying the specification. In particular, we consider proving that for a specific threshold, no strategy induces a better value. Such a proof allows us to draw conclusions about the ( $\varepsilon$ -)optimality of a strategy synthesised in Sect. 6.1.

**Results.** Table 4(a) shows the run times to prove that for the POMDP in column *Id*, there exists no strategy of type FSC with  $k$  memory that performs better than threshold  $T$ . The row indicated by \* was obtained with SMT. All

Table 4:  $\varepsilon$ -optimality and closed-form computation

(a) Proving absence				(b) Closed-form sol.		
Id	FSC/k	T	time	Id	FSC/k	time
2	F/1	5	<1	1	F/1	<1
3	F/1	5	8	1	F/2	97
3	F/4	5	183	2	F/1	155
4	F/1	0.25	2*	3	F/1	464
5	F/1	10	3	4	F/1	<1
5	F/2	5	TO	5	F/1	116
6	F/1	82	<1	6	F/1	<1
6	F/8	10.5	1	7	F/1	TO
7	F/1	0.94	5			

other results were obtained with parameter lifting.

**Evaluation.** The methods generally prove tight bounds for  $k=1$ . For  $k>1$ , the high number of parameters yields a mixed impression, the performance depends on the benchmark. **We find proofs for non-trivial bounds up to  $k=8$ , even if the pMC has hundreds of parameters.**

## 6.3 CLOSED-FORM SOLUTIONS

**Results.** Table 4(b) indicates running times to compute a closed-form solution, i. e. a rational function that maps  $k$ -FSCs to the induced probability.

**Evaluation.** Closed form computation is limited to small memory bounds. The rational functions obtained vary wildly in their structure. For (4), the result is a constant function which is trivial to analyse, while for (3), we obtained rational functions with roughly one million terms, rendering further evaluation expensive.

## 7 CONCLUSION

This paper connects two active research areas, namely verification and synthesis for POMDPs and parameter synthesis for Markov models. We see benefits for both areas. On the one hand, the rich application area for POMDPs in, e. g. robotics, yields new challenging benchmarks for parameter synthesis and can drive the development of more efficient methods. On the other hand, parameter synthesis tools and techniques extend the state-of-the-art approaches for POMDP analysis. Future work will also concern a thorough investigation of *permissive schedulers*, that correspond to regions of parameter instantiations, in concrete motion planning scenarios.

## Abstract

Unlike classical causal inference, where the goal is to estimate average causal effects within a *population*, in settings such as personalized medicine, the goal is to map a unit's characteristics to a treatment tailored to maximize the expected outcome for that unit. Obtaining high-quality mappings of this type is the goal of the dynamic treatment regime literature. In healthcare settings, optimizing policies with respect to a particular causal pathway is often of interest as well. In the context of average treatment effects, estimation of effects associated with causal pathways is considered in the mediation analysis literature.

In this paper, we combine mediation analysis and dynamic treatment regime ideas and consider how unit characteristics may be used to tailor a treatment strategy that maximizes an effect along specified sets of causal pathways. In particular, we define counterfactual responses to such policies, give a general identification algorithm for these counterfactuals, and prove completeness of the algorithm for unrestricted policies. A corollary of our results is that the identification algorithm for responses to policies given in [16] is complete for arbitrary policies.

## 1 INTRODUCTION

Establishing causal relationships between actions and outcomes is fundamental to rational decision-making. The gold standard for establishing causal relationships is the randomized controlled trial (RCT), which may be used to establish average causal effects within a population. Causal inference is a branch of statistics that seeks

to predict effects of RCTs from observational data, where treatment assignment is not randomized. Such data is often gathered from observational studies, surveys given to patients during follow up, and in-hospital electronic medical records.

While average treatment effects reported from implemented RCTs, or hypothetical RCTs emulated by causal inference methods using observational data establish whether a particular action is helpful *on average*, optimal decision making must tailor decisions to specific situations. In the context of causal inference this involves finding a map between characteristics of an experimental unit, such as baseline features, to an action that optimizes some outcome for that unit. Methods for finding such maps are studied in the dynamic treatment regime literature [3], and in off-policy reinforcement learning [2].

If an action is known to have a beneficial effect on some outcome, it is often desirable to understand the causal mechanism behind this effect. A popular type of mechanism analysis is *mediation analysis*, which seeks to decompose average treatment effects into direct and indirect components, or more generally into components associated with specific causal pathways. These components of the average causal effect are known as direct, indirect, and path-specific effects, and are also defined as population averages [1, 8, 12].

In this paper, we define counterfactual outcomes necessary to personalize effects associated with causal pathways, give an algorithm for non-parametric identification of these outcomes and prove that it is complete for arbitrary policies. We consider estimation methods for identified outcomes of this type in a companion paper [7].

### Why Personalize Effects Along Causal Pathways?

It often makes sense to structure decision-making such that the *overall* effect of an action on the outcome is maximized for a given unit. However, in some cases it is ap-

propriate to choose an action such that only a part of the effect of an action on the outcome is maximized. Consider management of HIV patients' care. Since HIV is a chronic disease, care for HIV patients involves designing a long-term treatment plan to minimize the chance of viral failure (an undesirable outcome). In designing such a plan, an important choice is when to initiate primary therapy, and when to switch to a second line therapy. Initiating or switching too early risks unneeded side effects and "wasting" treatment efficacy, while initiating or switching too late risks viral failure [4].

In the context of HIV, however, *treatment adherence* is an important component of the overall effect of the drug on the outcome. Patients who do not take prescribed doses compromise the efficacy of the drug, and different drugs may have different levels of adherence. Thus, for HIV patients, the overall effect of the drug can be viewed as a combination of the chemical effect and the adherence effect [6]. Therefore, choosing an action that maximizes the overall effect of HIV treatment on viral failure entangles these two very different causal mechanisms. One approach to tailoring treatments to patients in a way that disentangles these mechanisms is to find a policy that optimizes a part of the effect, say the chemical (direct) effect of the drug, while hypothetically keeping the adherence levels to some reference level. Finding such a policy yields information on how best to assign drugs to maximize their chemical efficacy in settings where adherence levels can be controlled to that of a reference treatment – even if the only data available is one where patients have differential adherence.

## 2 PRELIMINARIES

We proceed as follows. We first give graph theoretic preliminaries, and define graphical causal models that equate counterfactual responses to interventions (setting variables to values, contrary to fact) with truncated factorizations of the observed data distribution [11]. Next, we describe the more general *edge intervention* that sets variables to different values for different outgoing edges in a graph. Edge interventions are used to formulate direct, indirect, and path-specific effects in mediation analysis. Then, we define counterfactual responses to policies that set variables not to *constant* values but to values that potentially depend on other sets of variables. Extending these notions, we describe counterfactuals that generalize both responses to edge interventions, and responses to policies, namely responses to *edge-specific policies*. We briefly describe identification theory for these counterfactuals in causal models with no hidden variables, and note this theory is based on variations of a truncated factorization known as the g-formula [11].

We next consider identification theory for all counterfactuals we described in hidden variable causal models. This theory is more complex, and is based on the ID algorithm [14, 17]. We rephrase the algorithm and its necessary variations in a single line formula based on the fixing operator described in [10]. This reformulation allows us to express any functional corresponding to a counterfactual distribution identifiable in a hidden variable causal model as a single truncated factorization formula, just as identifiable counterfactual distributions in fully observed models are expressed via the g-formula. Finally, we describe a completeness result for the identification algorithm for responses to unrestricted edge-specific policies in hidden variable causal models.

While our primary contributions lie in the presentation of counterfactuals and identification theory for edge-specific policies, we include some discussion of prior theory to build up to our result, and show how identification theory of edge-specific policies generalizes identification theory for edge-specific effects and policy interventions.

### Graph Theory

We will define statistical and causal models as sets of distributions defined by restrictions associated with graphs. We will use vertices and variables interchangeably – capital letters for a vertex or variable ( $V$ ), bold capital letter for a set ( $\mathbf{V}$ ), lowercase letters for values ( $v$ ), and bold lowercase letters for sets of values ( $\mathbf{v}$ ). By convention, each graph is defined on a vertex set  $\mathbf{V}$ .

For a set of values  $\mathbf{a}$  of  $\mathbf{A}$ , and a subset  $\mathbf{A}^\dagger \subseteq \mathbf{A}$ , define  $\mathbf{a}_{\mathbf{A}^\dagger}$  to be a restriction of  $\mathbf{a}$  to elements in  $\mathbf{A}^\dagger$ . The state space of  $A$  will be denoted by  $\mathfrak{X}_A$ , and the (Cartesian product) state space of  $\mathbf{A}$  will be denoted by  $\mathfrak{X}_{\mathbf{A}}$ .

For a graph mixed graph  $\mathcal{G}$  with directed and bidirected edges, and any  $V \in \mathbf{V}$ , we define the following genealogic sets: parents, children, ancestors, descendants, and districts as:  $\text{pa}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid W \rightarrow V\}$ ,  $\text{ch}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid V \rightarrow W\}$ ,  $\text{an}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid W \rightarrow \dots \rightarrow V\}$ ,  $\text{de}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid V \rightarrow \dots \rightarrow W\}$ ,  $\text{dis}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid V \leftrightarrow \dots \leftrightarrow W\}$ . By convention,  $\text{an}_{\mathcal{G}}(V) \cap \text{de}_{\mathcal{G}}(V) \cap \text{dis}_{\mathcal{G}}(V) = \{V\}$ . These sets generalize to  $\mathbf{V}^\dagger \subseteq \mathbf{V}$  disjunctively. For example,  $\text{pa}_{\mathcal{G}}(\mathbf{V}^\dagger) \equiv \bigcup_{V \in \mathbf{V}^\dagger} \text{pa}_{\mathcal{G}}(V)$ . For  $\mathbf{A} \subseteq \mathbf{V}$ , define  $\text{pa}_{\mathcal{G}}^{\mathbf{A}}(\mathbf{A}) \equiv \text{pa}_{\mathcal{G}}(\mathbf{A}) \setminus \mathbf{A}$ , the parents of a set  $\mathbf{A}$ .

The non-descendants of  $V$  are denoted  $\text{nd}_{\mathcal{G}}(V) \equiv \mathbf{V} \setminus \text{de}_{\mathcal{G}}(V)$ . The set of districts forms a partition of vertices in  $\mathcal{G}$  and is denoted  $\mathcal{D}(\mathcal{G})$ . Finally, given a graph  $\mathcal{G}$  and  $\mathbf{A} \subseteq \mathbf{V}$ , the subgraph of  $\mathcal{G}$  containing only vertices in  $\mathbf{A}$  and edges between these vertices is denoted  $\mathcal{G}_{\mathbf{A}}$ .

## Statistical And Causal Models Of A Dag

A directed acyclic graph (DAG), or Bayesian network, is a graph  $\mathcal{G}$  with vertex set  $\mathbf{V}$  connected by directed edges and such that there are no directed cycles in the graph (i.e. no sequences of edges and vertices  $V \rightarrow \dots W$  and edge  $W \rightarrow V$ ). A statistical model of a DAG  $\mathcal{G}$  is the set of distributions  $p(\mathbf{V})$  such that  $p(\mathbf{V}) = \prod_{V \in \mathbf{V}} p(V | \text{pa}_{\mathcal{G}}(V))$ . Such a  $p(\mathbf{V})$  is said to be Markov relative to  $\mathcal{G}$ .

Causal models of a DAG are also sets of distributions, but on counterfactual random variables. Given  $Y \in \mathbf{V}$  and  $\mathbf{A} \subseteq \mathbf{V} \setminus \{Y\}$ , a counterfactual variable, or ‘potential outcome’, written as  $Y(\mathbf{a})$ , represents the value of  $Y$  in a hypothetical situation where  $\mathbf{A}$  were set to values  $\mathbf{a}$  by an *intervention operation* [9]. Given a set  $\mathbf{Y}$ , define  $\mathbf{Y}(\mathbf{a}) \equiv \{\mathbf{Y}\}(\mathbf{a}) \equiv \{Y(\mathbf{a}) \mid Y \in \mathbf{Y}\}$ . The distribution  $p(\mathbf{Y}(\mathbf{a}))$  is sometimes written as  $p(\mathbf{Y}|\text{do}(\mathbf{a}))$  [9].

Causal models of a DAG  $\mathcal{G}$  consist of distributions defined on counterfactual random variables of the form  $V(\mathbf{a})$  where  $\mathbf{a}$  are values of  $\text{pa}_{\mathcal{G}}(V)$ . In this paper we assume Pearl’s functional model for a DAG  $\mathcal{G}$  with vertices  $\mathbf{V}$  which is the set containing any joint distribution over all potential outcome random variables where the sets of variables

$$\{\{V(\mathbf{a}_V) \mid \mathbf{a}_V \in \mathfrak{X}_{\text{pa}_{\mathcal{G}}(V)}\} \mid V \in \mathbf{V}\}$$

are mutually independent [9]. The *atomic counterfactuals* in the above set model the relationship between  $\text{pa}_{\mathcal{G}}(V)$ , representing direct causes of  $V$ , and  $V$  itself. From these, all other counterfactuals may be defined using recursive substitution. For any  $\mathbf{A} \subseteq \mathbf{V} \setminus \{V\}$ ,

$$V(\mathbf{a}) \equiv V(\mathbf{a}_{\text{pa}_{\mathcal{G}}(V) \cap \mathbf{A}}, \{\text{pa}_{\mathcal{G}}(V) \setminus \mathbf{A}\}(\mathbf{a})). \quad (1)$$

For example, in the DAG in Fig. 1 (a),  $Y(a)$  is defined to be  $Y(a, M(a, W), W)$ .

A causal parameter is said to be *identified* in a causal model if it is a function of the observed data distribution  $p(\mathbf{V})$ . Otherwise the parameter is said to be *non-identified*. In all causal models of a DAG  $\mathcal{G}$ , all interventional distributions  $p(\{\mathbf{V} \setminus \mathbf{A}\}(\mathbf{a}))$  are identified by the *g-formula* [11]:

$$p(\{\mathbf{V} \setminus \mathbf{A}\}(\mathbf{a})) = \prod_{V \in \mathbf{V} \setminus \mathbf{A}} p(V | \text{pa}_{\mathcal{G}}(V)) \Big|_{\mathbf{A}=\mathbf{a}} \quad (2)$$

Not all interventional distributions are identified when there are hidden variables present in the causal model. We discuss identification theory in hidden variable DAGs later in this paper.

### Edge Interventions

A more general type of intervention in a graphical causal model is the *edge intervention* [15], which maps a set

of directed edges in  $\mathcal{G}$  to values of their source vertices. Edge interventions have a natural interpretation in cases where a treatment variable has multiple components that a) influence the outcome in different ways, b) occur or do not occur together in observed data, and c) may in principle be intervened on separately. For instance, smoking leads to poor health outcomes due to two components: smoke inhalation and exposure to nicotine. A smoker would be exposed to both of these components, while a non-smoker to neither. However, one might imagine exposing someone selectively only to nicotine but not smoke inhalation (via a nicotine patch), or only smoke inhalation but not nicotine (via smoking plant matter not derived from tobacco leaves). These types of hypothetical experiments correspond precisely to edge interventions, and have been used to conceptualize direct and indirect effects [8, 12], often on the mean difference scale.

Formally, we will write the mapping of a set of edges to values of their source vertices using the following shorthand:  $(a_1 W_1)_{\rightarrow}, (a_2 W_2)_{\rightarrow}, \dots, (a_k W_k)_{\rightarrow}$  to mean that edge  $(A_1 W_1)_{\rightarrow}$  is assigned to value  $a_1$ ,  $(A_2 W_2)_{\rightarrow}$  is assigned to value  $a_2$ , and so on until  $(A_k W_k)_{\rightarrow}$  is assigned to value  $a_k$ . Alternatively, we will write  $\mathbf{a}_{\alpha}$  to mean edges in  $\alpha$  are mapped to values in the *multiset*  $\mathbf{a}$  (since multiple edges may share the same source vertex, and be assigned to different values). For a subset  $\beta \subseteq \alpha$ , and an assignment  $\mathbf{a}_{\alpha}$  denote  $\mathbf{a}_{\beta}$  to be a restriction of  $\mathbf{a}_{\alpha}$  to edges in  $\beta$ .

We will write counterfactual responses to edge interventions as  $Y(\mathbf{a}_{\alpha})$  or, for simple cases, as:  $Y((aY)_{\rightarrow}, (a'M)_{\rightarrow})$  meaning the response to  $Y$  where  $A$  is set to value  $a$  for the purposes of the edge  $(AY)_{\rightarrow}$  and to  $a'$  for the purposes of the edge  $(AM)_{\rightarrow}$ . An edge intervention that sets a set of edges  $\alpha$  to values in the multiset  $\mathbf{a}$  is defined via the following generalization of recursive substitution (1):

$$Y(\mathbf{a}_{\alpha}) \equiv Y(\mathbf{a}_{\{(ZY)_{\rightarrow} \in \alpha\}}, \{\text{pa}_{\mathcal{G}}^{\bar{\alpha}}(Y)\}(\mathbf{a}_{\alpha})), \quad (3)$$

where  $\text{pa}_{\mathcal{G}}^{\bar{\alpha}}(Y) \equiv \{W \mid (WY)_{\rightarrow} \notin \alpha\}$ . For example, in the DAG in Fig. 1 (a),  $Y((a'Y)_{\rightarrow}, (aM)_{\rightarrow})$  is defined as  $Y(a', M(a, W), W)$ .

For simplicity of presentation, we will restrict attention to edge interventions with the property that if  $(AW)_{\rightarrow} \in \alpha$ , then for any  $V \in \text{ch}_{\mathcal{G}}(A)$ ,  $(AV)_{\rightarrow} \in \alpha$ . These types of edge interventions set values for all causal pathways for a set of treatment variables. This is the convention in the majority of existing mediation literature as these interventions are most relevant in practical mediation analysis problems. Specifically, in our HIV example, we are interested in the effect of a drug along all pathways that start with a particular edge, while the effect of the drug via pathways that begin with other edges is kept to a reference level. This assumption may be relaxed, at the price of complicating the theory [15].

Edge interventions are used to define direct and indirect effects. For example, in the model given by the DAG in Fig 1 (a), the direct effect of  $A$  on  $Y$  is defined as  $\mathbb{E}[Y((aY)_{\rightarrow}, (aM)_{\rightarrow})] - \mathbb{E}[Y((a'Y)_{\rightarrow}, (aM)_{\rightarrow})]$  which is equal to  $\mathbb{E}[Y(a)] - \mathbb{E}[Y(a', M(a))]$ . The indirect effect may be defined similarly as  $\mathbb{E}[Y((a'Y)_{\rightarrow}, (aM)_{\rightarrow})] - \mathbb{E}[Y((a'Y)_{\rightarrow}, (a'M)_{\rightarrow})]$ , which is equal to  $\mathbb{E}[Y(a', M(a))] - \mathbb{E}[Y(a')]$ . The direct and indirect effects add up to the ACE.

Note that while direct, indirect, and path-specific effects may be defined directly as nested counterfactuals [8, 13], this notation quickly becomes unreadable for complicated interventions applied at multiple time points. The edge intervention notation may be viewed as a generalization of the  $\text{do}(\cdot)$  operator notation of Pearl to mediation problems, which avoids having to specify the entire nested counterfactual, and instead directly ties interventions and sets of causal pathways to which these interventions apply (as represented by the first edge shared by all pathways in the set).

Identification of edge interventions in graphical causal models without hidden variables corresponds quite closely with identification of regular (node) interventions, as follows. Let  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_{\rightarrow} \in \alpha\}$ . Consider an edge intervention given by the mapping  $\alpha_\alpha$ . Then, under the functional model of a DAG  $\mathcal{G}$ , the joint distribution of counterfactual responses  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\alpha_\alpha))$  is identified via the the following generalization of (2) called the *edge g-formula*:

$$\prod_{V \in \mathbf{V} \setminus \mathbf{A}_\alpha} p(V \mid \alpha_{\{(ZV)_{\rightarrow} \in \alpha\}}, \text{pa}_{\mathcal{G}}^{\bar{\alpha}}(V)). \quad (4)$$

For example, in Fig 1 (a),  $p(Y((aY)_{\rightarrow}, (a'M)_{\rightarrow})) = \sum_{W, M} p(Y \mid a, M, W) p(M \mid a', W) p(W)$ , which is obtained by marginalizing  $W, M$  from the edge g-formula.

Edge interventions represent a special case of the more general notion of a *path intervention* [15]. Responses to both of these interventions are used to define *path-specific effects* [8], however responses to edge interventions are precisely those that are always identified under the functional model of a DAG, via (3). Responses to path interventions that cannot be rephrased as responses to edge interventions are not identified even in a DAG model, including the functional model, due to the presence of *recanting witnesses* [1]. For this reason, in this paper we restrict attention only to edge interventions and responses to edge-specific policies.

### Responses To Treatment Policies

In personalized medicine settings, counterfactual responses to conditional interventions that set treatment values in response to other variables via a known function are of interest. As an example, assume the graph

in Fig. 1 (b) represents an observational study of cancer patients where  $W_0$  represents baseline patient metrics,  $A_1$  is the primary therapy,  $W_1$  is the measured intermediate response to the primary therapy,  $A_2$  is a decision to either continue primary therapy or switch to a secondary therapy in the event of a poor response to  $A_1$ , and  $W_2$  is the outcome of interest. In this setting, we might be interested in evaluating policies in the set  $\{f_{A_1} : \mathfrak{X}_{W_0} \mapsto \mathfrak{X}_{A_1}, f_{A_2} : \mathfrak{X}_{\{W_0, W_1\}} \mapsto \mathfrak{X}_{A_2}\}$  that map patient characteristics to decisions about therapies  $A_1$  and  $A_2$ . We evaluate the efficacy of these policies via the counterfactual variable  $W_2(f_{A_1}, f_{A_2})$ , representing patient outcomes had treatment decisions been made according to those policies.

These types of variables are defined via a generalization of (1), where instead of setting values of parents in  $A_1, A_2$  to values fixed by the intervention, values of parents in  $A$  are instead set according to  $f_{A_1}$  and  $f_{A_2}$ . In particular,  $W_2(f_{A_1}, f_{A_2})$  is defined as

$$W_2[f_{A_2}(W_1[f_{A_1}(W_0), W_0], W_0), W_1[f_{A_1}(W_0), W_0], f_{A_1}(W_0), W_0]. \quad (5)$$

The distribution of this variable is identified under the functional model via the natural generalization of (2) as

$$\sum_{W_0, W_1} p(W_2 \mid W_0, f_{A_1}(W_0), W_1, f_{A_2}(W_0, W_1)) \times p(W_1 \mid W_0, f_{A_1}(W_0)) p(W_0). \quad (6)$$

More generally, given a DAG  $\mathcal{G}$ , a topological ordering  $\prec$ , and a set  $\mathbf{A} \subseteq \mathbf{V}$ , for each  $A \in \mathbf{A}$ , define  $\mathbf{W}_A$  to be some subset of predecessors of  $A$  according to  $\prec$ . Then, given a set of functions  $\mathbf{f}_A$  of the form  $f_A : \mathfrak{X}_{\mathbf{W}_A} \mapsto \mathfrak{X}_A$ , define  $Y(\mathbf{f}_A)$ , the counterfactual response  $Y \in \mathbf{V}$  to  $\mathbf{A}$  being intervened on via  $\mathbf{f}_A \equiv \{f_A \mid A \in \mathbf{A}\}$ , as

$$Y(\{f_A(\mathbf{W}_A(\mathbf{f}_A)) \mid A \in \text{pa}_{\mathcal{G}}(Y) \cap \mathbf{A}\}, \{\text{pa}_{\mathcal{G}}(Y) \setminus \mathbf{A}\}(\mathbf{f}_A)). \quad (7)$$

In a functional model of a DAG  $\mathcal{G}$ , the effect of  $\mathbf{f}_A$  on the set of variables not being intervened upon,  $\mathbf{V} \setminus \mathbf{A}$ , represented by the distribution  $p(\{\mathbf{V} \setminus \mathbf{A}\}(\mathbf{f}_A))$ , is identified by the following modification of (2) [16]:

$$\prod_{V \in \mathbf{V} \setminus \mathbf{A}} p(V \mid \{f_A(\mathbf{W}_A)\} \mid A \in \mathbf{A} \cap \text{pa}_{\mathcal{G}}(V), \text{pa}_{\mathcal{G}}(V) \setminus \mathbf{A}). \quad (8)$$

## 3 EDGE-SPECIFIC POLICIES

We now give a general definition of counterfactual responses to edge-specific policies that generalize both responses to edge interventions (where a variable is set to

Figure 1: (a) A simple causal DAG, with a treatment  $A$ , an outcome  $Y$ , a vector  $W$  of baseline variables, and a mediator  $M$ . (b) A more complex causal DAG with two treatments  $A_1, A_2$ , an intermediate outcome  $W_1$ , and the final outcome  $W_2$ .  $H$  is a hidden common cause of the  $W$  variables. (c) A graph where  $p(Y(a, M(a)))$  is identified, but  $p(Y(f_A(W), M(a)))$  is not.

different constants for different outgoing edges) and responses to policies, where a variable is set according to a single known function for all causal pathways at once.

As an example, we can view Fig. 1 (a) as representing a cross-sectional study of HIV patients of the kind described in [6], where  $W$  is a set of baseline characteristics,  $A$  is one of a set of possible antiretroviral treatments,  $M$  is adherence to treatment, and  $Y$  is a binary outcome variable signifying viral failure. In this type of study, we may wish to find  $f_A(W)$  that maximizes the expected outcome  $Y$  had  $A$  been set according to  $f_A(W)$  for the purposes of the direct effect of  $A$  on  $Y$ , and  $A$  were set to some reference level  $a$  for the purposes of the effect of  $A$  on  $M$ . In other words, we may wish to find  $f_A(W)$  to maximize the counterfactual mean  $\mathbb{E}[Y(f_A(W), M(a, W), W)]$ . This would correspond to finding a treatment policy that maximizes the direct (chemical) effect, if it were possible to keep adherence to a level  $M(a)$  as if a reference (easy to adhere to) treatment  $a$  were given.

We now give a general definition for responses to such edge-specific policies. Fix a set of directed edges  $\alpha$ , and define  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_{\rightarrow} \in \alpha\}$ . As before, we assume if  $(AW)_{\rightarrow} \in \alpha$ , then for all  $V \in \text{ch}_{\mathcal{G}}(A)$ ,  $(AV)_{\rightarrow} \in \alpha$ . Define  $\mathfrak{f}_\alpha \equiv \{f_A^{(AW)_{\rightarrow}} : \mathfrak{X}_{\mathbf{W}_A} \mapsto \mathfrak{X}_A \mid (AW)_{\rightarrow} \in \alpha\}$  as the set of policies associated with edges in  $\alpha$ . Note that  $\mathfrak{f}_\alpha$  may contain multiple policies for a given treatment variable  $A$ .

Define  $Y(\mathfrak{f}_\alpha)$ , the counterfactual response of  $Y$  to the set of edge-specific policies  $\mathfrak{f}_\alpha$ , as the following generalization of (3) and (7):

$$Y(\{f_A^{(AY)_{\rightarrow}}(\mathbf{W}_A(\mathfrak{f}_\alpha)) \mid (AY)_{\rightarrow} \in \alpha\}, \{\text{pa}_{\mathcal{G}}^\alpha(Y)\}(\mathfrak{f}_\alpha)) \quad (9)$$

In our earlier example, if  $\mathfrak{f}_{\{(AY)_{\rightarrow}, (AM)_{\rightarrow}\}} \equiv \{f_A^{(AY)_{\rightarrow}}(W), \tilde{f}_A^{(AM)_{\rightarrow}}\}$ , where  $\tilde{f}_A$  assigns  $A$  to a constant value  $a$ , then  $Y(\mathfrak{f}_{\{(AY)_{\rightarrow}, (AM)_{\rightarrow}\}}) \equiv Y(f_A(W), M(a, W), W)$ .

The joint counterfactual distribution for responses to edge-specific policies,  $p(\{V(\mathfrak{f}_\alpha) \mid V \in \mathbf{V} \setminus \mathbf{A}_\alpha\})$ , is identified under the functional model, and generalizes (4) and (6) as follows:

$$\prod_{V \in \mathbf{V} \setminus \mathbf{A}_\alpha} p(V \mid \{f_A^{(AV)_{\rightarrow}}(\mathbf{W}_A) \mid (AV)_{\rightarrow} \in \alpha\}, \text{pa}_{\mathcal{G}}^\alpha(V)). \quad (10)$$

This is a consequence of the fact that (4) holds regardless of how edge interventions are set. In Fig. 1 (a), for example,  $p(Y(f_A(W), M(a, W), W)) = \sum_{W, M} p(Y \mid f_A(W), M, W) p(M \mid a, W) p(W)$ .

## 4 IDENTIFICATION IN HIDDEN VARIABLE DAG MODELS

In a causal model of a DAG where some variables are hidden, not every causal parameter is a function of the observed data distribution. It is well known, however, that any two hidden variable DAGs which share a special mixed graph called a *latent projection* [9] share identification theory (see [10] for a proof).

Given a DAG  $\mathcal{G}(\mathbf{V} \cup \mathbf{H})$ , where  $\mathbf{V}$  are observed and  $\mathbf{H}$  are hidden variables, define a latent projection  $\mathcal{G}(\mathbf{V})$  to be an acyclic directed mixed graph (ADMG) with the vertex set  $\mathbf{V}$  and  $\rightarrow$  and  $\leftrightarrow$  edges. An edge  $A \rightarrow B$  exists in  $\mathcal{G}(\mathbf{V})$  if there is a directed path from  $A$  to  $B$  in  $\mathcal{G}(\mathbf{V} \cup \mathbf{H})$  with all intermediate vertices in  $\mathbf{H}$ . Similarly, an edge  $A \leftrightarrow B$  exists in  $\mathcal{G}(\mathbf{V})$  if there is a path without consecutive edges  $\rightarrow \circ \leftarrow$  from  $A$  to  $B$  with the first edge on the path of the form  $A \leftarrow$  and the last edge on the path of the form  $\rightarrow B$ , and all intermediate vertices on the path in  $\mathbf{H}$ . For example, the graph in Fig. 2 (b) is the latent projection of Fig. 2 (a).

We will describe identification results on latent projections directly. General algorithms for identification of interventional distributions were given in [14, 17], for responses to edge interventions in [13], and for policies in [16]. Here we reformulate these results as one line formulas using the fixing operator described in [10]. We do so to explicate the connection between these earlier results, and our new identification algorithm.

### Reformulation Of The ID Algorithm

A complete algorithm, called the ID algorithm, for identifying interventional distributions of the form  $p(\mathbf{Y} \mid \text{do}(\mathbf{a}))$ , or  $p(\mathbf{Y}(\mathbf{a}))$ , for  $\mathbf{Y} \subseteq \mathbf{V} \setminus \mathbf{A}$  was given in [17] and simplified in [14]. We now illustrate how this algorithm may be further simplified into a one line formula, which can be viewed as a generalization of the g-formula from the fully observed DAG to the hidden variable DAG case. We then show how this formula may

be generalized appropriately to yield identification algorithms for edge interventions, and edge-specific policies in hidden variable causal models, just as g-formula was generalized to these cases in fully observed DAGs.

The version of the ID algorithm in [14], shown in Fig. 1 in the Appendix, proceeds as follows. Lines 2 and 3 reformulate the original query  $p(\mathbf{Y}(\mathbf{a}))$  as  $\sum_{\mathbf{Y}^* \setminus \mathbf{Y}} p(\mathbf{Y}^*(\mathbf{a}^*))$ , where  $\mathbf{Y}^*, \mathbf{A}^*$  partition  $\text{an}_{\mathcal{G}}(\mathbf{Y})$ , and  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{V} \setminus \mathbf{A}}}(\mathbf{Y})$ . In line 4, the distribution  $p(\mathbf{Y}^*(\mathbf{a}^*))$  is factorized into terms corresponding to districts  $\mathbf{D}$  in the subgraph  $\mathcal{G}_{\mathbf{Y}^*}$ , with the ID algorithm called recursively on each term. These terms correspond to interventional distributions  $p(\mathbf{D} \mid \text{do}(\mathbf{V} \setminus \mathbf{D} = \mathbf{c}_{\mathbf{V} \setminus \mathbf{D}}))$ , where  $\mathbf{c}_{\mathbf{V} \setminus \mathbf{D}}$  is any set of values of  $\mathbf{V} \setminus \mathbf{D}$  consistent with  $\mathbf{a}$ . In subsequent recursive calls, lines 2, 6 and 7 are iterated for each term until it is identified, or the failure condition is reached. Here line 2 corresponds to marginalizing out irrelevant variables, and lines 6 and 7 correspond to identifying a part of the set of intervened on variables in  $\mathbf{V} \setminus \mathbf{D}$  via the g-formula.

Consider Fig. 2 (b), where  $A$  represents a binary treatment,  $Y$  an outcome of interest,  $W_0$  a vector of baseline confounding factors, and  $M, W_1$  variables mediating the causal effect of  $A$  on  $Y$ . We are interested in identifying the counterfactual distribution  $p(Y(a))$  as a function of the observed data distribution  $p(W_0, A, M, W_1, Y)$ . Here  $\text{an}_{\mathcal{G}}(Y) = \{Y, M, W_1, W_0, A\}$  is partitioned into  $\mathbf{Y}^* \equiv \{Y, M, W_1, W_0\}$  and  $\mathbf{A}^* \equiv \{A\}$ , with  $\mathcal{G}_{\mathbf{Y}^*}$  shown in Fig. 2 (c). There are three districts in this graph,  $\{W_0, M\}$ ,  $\{W_1\}$ , and  $\{Y\}$ . Thus, the ID algorithm attempts to identify  $p(W_0, M \mid \text{do}(w_1, y, a))$ ,  $p(W_1 \mid \text{do}(w_0, m, y, a))$  and  $p(Y \mid \text{do}(w_0, m, w_1, a))$ .

Figure 2: (a) A causal model with a treatment  $A$  and outcome  $Y$ . (b) A latent projection of the DAG in (a). (c) The graph derived from (b) corresponding to  $\mathcal{G}_{\mathbf{Y}^*} = \mathcal{G}_{\{Y, M, W_1, W_0\}}$ . (d) A CADMG corresponding to  $p(M, W_0 \mid \text{do}(a))$ .

As an example, identifying  $p(W_0, M \mid \text{do}(w_1, y, a))$  entails the following steps. First,  $Y$  and  $W_1$ , as irrelevant variables that do not cause  $W_0$  and  $M$ , are marginalized out via line 2, leading to a subproblem where  $p(W_0, M \mid \text{do}(a))$  is identified from  $p(W_0, A, M)$  with the subgraph corresponding to this subproblem shown in Fig. 2 (d). In this subproblem,  $p(W_0, M \mid \text{do}(a))$  is iden-

tified as  $p(M \mid a, W_0)p(W_0)$  via the g-formula in line 6. The recursion alternates steps that marginalize and apply the g-formula can be unified via a fixing operator applied to graphs and distributions that arise in the intermediate steps of the ID algorithm. We now define these graphs and distributions formally.

## CADMGs And Kernels

A *kernel*  $q_{\mathbf{V}}(\mathbf{V} \mid \mathbf{W})$  is a mapping from  $\mathfrak{X}_{\mathbf{W}}$  to normalized densities over  $\mathbf{V}$ . Conditioning and marginalization are defined in kernels in the usual way:

$$q_{\mathbf{V}}(\mathbf{A} \mid \mathbf{W}) \equiv \sum_{\mathbf{V} \setminus \mathbf{A}} q_{\mathbf{V}}(\mathbf{V} \mid \mathbf{W}); \quad q_{\mathbf{V}}(\mathbf{V} \setminus \mathbf{A} \mid \mathbf{A} \cup \mathbf{W}) \equiv \frac{q_{\mathbf{V}}(\mathbf{V} \mid \mathbf{W})}{q_{\mathbf{V}}(\mathbf{A} \mid \mathbf{W})},$$

for  $\mathbf{A} \subseteq \mathbf{V}$ . A conditional distribution is one type of kernel, but others are possible. The functional  $p(M \mid a, W_0)p(W_0) = p(W_0, M \mid \text{do}(a))$  in the previous example is a kernel,  $q(M, W_0 \mid a)$ , that is not in general equal to the conditional distribution  $p(M, W_0 \mid a)$ .

A conditional ADMG (CADMG)  $\mathcal{G}(\mathbf{V}, \mathbf{W})$  is a type of ADMG where nodes are partitioned into two sets. The set  $\mathbf{W}$  corresponds to *fixed* constants, and the set  $\mathbf{V}$  corresponds to *random variables*. A CADMG has the property that no edges with an arrowhead into an element of  $\mathbf{W}$  may exist. Intuitively, a CADMG represents a situation where some variables have already been intervened on. Pearl introduced a similar concept called the ‘mutilated graph’ in [9]. For example, the graph in Fig. 2 (d) is a CADMG  $\mathcal{G}(\{W_0, M\}, \{A\})$  corresponding to the situation where  $W_0, M$  are random variables and  $A$  is fixed to a constant. Just as a distribution may be associated with a DAG via factorization, so may a kernel be associated with a CADMG in a particular way [10]. For example, the CADMG in Fig. 2 (d) may be associated with  $p(W_0, M \mid \text{do}(a)) = p(M \mid a, W_0)p(W_0)$ . Genealogic definitions, such as  $\text{pa}_{\mathcal{G}}(\cdot)$ , carry over identically to CADMGs. Districts in a CADMG are defined as subsets of  $\mathbf{V}$ .

## The Fixing Operator And The ID Algorithm

Given a CADMG  $\mathcal{G}(\mathbf{V}, \mathbf{W})$ , a variable  $V \in \mathbf{V}$  is *fixable* if  $\text{deg}_{\mathcal{G}}(V) \cap \text{dis}_{\mathcal{G}}(V) = \emptyset$ . For example, in Fig. 2 (b),  $M$  is fixable, while  $W_0$  is not. Intuitively,  $V$  is fixable in a CADMG  $\mathcal{G}(\mathbf{V}, \mathbf{W})$  if, in a causal graph representing a hypothetical situation  $p(\mathbf{V} \mid \text{do}(\mathbf{w}))$ , where variables in  $\mathbf{W}$  were already intervened on,  $p(\mathbf{V} \setminus \{V\} \mid \text{do}(\mathbf{w}, v))$  is identified by the application of the g-formula to  $p(\mathbf{V} \mid \text{do}(\mathbf{w}))$ . Whenever a variable  $V$  is fixable, a fixing operator may be applied to both the CADMG and the kernel to yield a new causal graph and a new kernel representing the situation where  $V$  is also intervened on.

Given  $V \in \mathbf{V}$  fixable in a CADMG  $\mathcal{G}(\mathbf{V}, \mathbf{W})$ , the fixing operator  $\phi_V(\mathcal{G})$  yields a new CADMG  $\tilde{\mathcal{G}}(\mathbf{V} \setminus \{V\}, \mathbf{W} \cup \{V\})$ , where all vertices and edges in  $\mathcal{G}(\mathbf{V}, \mathbf{W})$  are kept, *except*  $V$  is viewed as fixed, and all edges with arrowheads into  $V$  are removed. Given  $V \in \mathbf{V}$  fixable in a CADMG  $\mathcal{G}(\mathbf{V}, \mathbf{W})$ , and a kernel  $q_V(\mathbf{V}|\mathbf{W})$  associated with  $\mathcal{G}$ , the fixing operator  $\phi_V(q_V; \mathcal{G})$  yields a new kernel  $\tilde{q}_{\mathbf{V} \setminus \{V\}}(\mathbf{V} \setminus \{V\}|\mathbf{W} \cup \{V\}) \equiv q_V(\mathbf{V}|\mathbf{W})/q_V(V|\mathbf{W} \cup \text{nd}_{\mathcal{G}}(V))$ , where the denominator is defined as above by marginalization and conditioning within the kernel  $q_V$ . If  $\text{ch}_{\mathcal{G}}(V) = \emptyset$ , division by  $q_V(V|\text{nd}_{\mathcal{G}}(V))$  is equivalent to marginalizing  $V$  from  $q_V$ . In this way, the fixing operator unifies applications of the g-formula in lines 6 and 7 of the ID algorithm, and marginalization of irrelevant variables in line 2 of the ID algorithm, and the recursive operation of the ID algorithm can be expressed concisely as repeated invocations of the operator. This allows us to concisely express functionals returned by ID algorithm and its variations, including our new algorithm for identifying responses to edge-specific policies, as one line formulas.

A set  $\mathbf{V}^\dagger \subseteq \mathbf{V}$  is said to be *fixable* in a latent projection  $\mathcal{G}(\mathbf{V})$  if there is a *valid* sequence  $\langle V_1, V_2, \dots, V_k \rangle$  of variables in  $\mathbf{V}^\dagger$  such that  $V_1$  is fixable in  $\mathcal{G}$ ,  $V_2$  is fixable in  $\phi_{V_1}(\mathcal{G})$ , and so on. If  $\mathbf{V}^\dagger$  is fixable,  $\mathbf{V} \setminus \mathbf{V}^\dagger$  is called a *reachable* set. If  $p(\mathbf{V})$  is a marginal of a distribution  $p(\mathbf{V} \cup \mathbf{H})$  Markov relative to a DAG  $\mathcal{G}(\mathbf{V} \cup \mathbf{H})$ , and  $\mathcal{G}(\mathbf{V})$  is a latent projection, then CADMG/kernel pairs obtained from  $\mathcal{G}(\mathbf{V})$  and  $p(\mathbf{V})$  by any valid sequence in  $\mathbf{V}^\dagger$  is the same [10, 17]. As a result, for any fixable set  $\mathbf{V}^\dagger$  in  $\mathcal{G}$ , writing  $\phi_{\mathbf{V}^\dagger}(\mathcal{G})$  or  $\phi_{\mathbf{V}^\dagger}(q_V; \mathcal{G})$  is well-defined, and means “apply the fixing operator to elements of  $\mathbf{V}^\dagger$  in some valid sequence,” with the understanding that any such sequence will yield the same result.

The existence of a valid fixing sequence for each district in  $\mathcal{G}_{\mathbf{Y}^*}$  implies corresponding terms may be identified via lines 2, 6, and 7 of the ID algorithm, and the overall algorithm can be rephrased as:

$$\begin{aligned} p(\mathbf{Y}|\text{do}(\mathbf{a})) &= \sum_{\mathbf{Y}^* \setminus \mathbf{Y}} \prod_{\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} p(\mathbf{D}|\text{do}(\mathbf{V} \setminus \mathbf{D}))|_{\mathbf{A}=\mathbf{a}} \quad (11) \\ &= \sum_{\mathbf{Y}^* \setminus \mathbf{Y}} \prod_{\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} \phi_{\mathbf{V} \setminus \mathbf{D}}(p(\mathbf{V}); \mathcal{G}(\mathbf{V}))|_{\mathbf{A}=\mathbf{a}}, \end{aligned}$$

which yields the following identifying formula for  $p(Y|\text{do}(a))$  in our example in Fig. 2 (a):

$$p(Y(a)) = \sum_{W_0, A, M, W_1} p(W_1|M, A=a, W_0) \times \quad (12)$$

$$p(M|A=a, W_0)p(W_0) \sum_{W_0, A} p(Y|W_1, M, A, W_0)p(W_0, A).$$

We omit the full derivation in the interest of space. See the section on identification of edge-specific policy inter-

ventions and the appendix for a complete example. Observe that this equation is a generalized version of Pearl’s front-door formula [9].

Whenever  $\mathbf{V} \setminus \mathbf{D}$  for every  $\mathbf{D}$  is fixable, the formula (11) yields the correct expression for  $p(\mathbf{Y}|\text{do}(\mathbf{a}))$  in terms of the observed data. If some  $\mathbf{V} \setminus \mathbf{D}$  is not fixable, the algorithm fails, and  $p(\mathbf{Y}|\text{do}(\mathbf{a}))$  is not identified. See [10] for a detailed proof.

## Edge Interventions

Identification of path-specific effects where each path is associated with one of two possible value sets  $\mathbf{a}, \mathbf{a}'$  was given a general characterization in [13] via the *recanting district criterion*. Here, we reformulate this result in terms of the fixing operator in a way that generalizes (11), and applies to the response of any edge intervention, including those that set edges to multiple values rather than two. This result can also be viewed as a generalization of *node consistency* of edge interventions in DAG models, found in [15].

Given  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_\rightarrow \in \alpha\}$ , and an edge intervention given by the mapping  $\alpha_\alpha$ , define  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{V} \setminus \mathbf{A}_\alpha}}(\mathbf{Y})$ . The joint distribution of the counterfactual response  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\mathbf{a}_\alpha))$  is identified if  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\mathbf{a}))$  is identified via (11), and for every  $\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})$ , for every  $A \in \mathbf{A}_\alpha$ ,  $\alpha_\alpha$  has the same value assignment for every directed edge out of  $A$  into  $\mathbf{D}$ . Under these assumptions, we have the following result.

**Theorem 1**  $p(\mathbf{Y}(\alpha_\alpha))$  is identified and equal to

$$\sum_{\mathbf{Y}^* \setminus \mathbf{Y}} \prod_{\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} \phi_{\mathbf{V} \setminus \mathbf{D}}(p(\mathbf{V}); \mathcal{G})|_{\alpha_{\{(AD)_\rightarrow \in \alpha \mid D \in \mathbf{D}, A \in \mathbf{A}_\alpha\}}} \quad (13)$$

*Proof:* This follows directly from results in [13] and [10]. Identifying edge interventions entails identifying  $\prod_{\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} p(\mathbf{D}|\text{do}(\mathbf{a}_\mathbf{D}))$ , where  $\mathbf{a}_\mathbf{D}$  is an assignment for  $\text{pa}_{\mathcal{G}}^s(\mathbf{D})$ , and  $\mathbf{a}_\mathbf{D}$  possibly assigns different values to elements of  $\mathbf{A}$  with respect to different districts. The fact that this identification algorithm can be rephrased as (13) follows directly by Theorem 60 in [10].  $\square$

Consider again the example in Fig. 2 (a). Now assume we set  $A = a$  for the edge  $(AM)_\rightarrow$  and  $A = a'$  for the edge  $(AW_1)_\rightarrow$ . The identifying functional for  $p(Y((aW_1)_\rightarrow, (a'M)_\rightarrow))$  has the same form as (12), but some terms are evaluated at  $A = a$ , and some at  $A = a'$ :

$$\sum_{W_0, A, M, W_1} p(W_1|M, A=a, W_0) \quad (14)$$

$$p(M|A=a', W_0)p(W_0) \sum_{W_0, A} p(Y|W_0, A, M, W_1)p(W_0, A)$$

### Policy Interventions (Dynamic Treatment Regimes)

A general algorithm for identification of responses to a set of policies  $\mathbf{f}_A$  was given in [16]. We again reformulate this algorithm in terms of the fixing operator. Define a graph  $\mathcal{G}_{\mathbf{f}_A}$  to be a graph obtained from  $\mathcal{G}$  by removing all edges into  $\mathbf{A}$ , and adding for any  $A \in \mathbf{A}$ , directed edges from  $\mathbf{W}_A$  to  $A$ . By definition of  $\mathbf{W}_A$ ,  $\mathcal{G}_{\mathbf{f}_A}$  is guaranteed to be acyclic. Define  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{f}_A}}(\mathbf{Y}) \setminus \mathbf{A}$ . Assume  $p(\mathbf{Y}^*(\mathbf{a}))$  is identified in  $\mathcal{G}$ . Then, under the above assumptions, we have the following result.

**Theorem 2**  $p(\mathbf{Y}(\mathbf{f}_A))$  is identified in  $\mathcal{G}$ . Moreover, the identification formula is

$$\sum_{(\mathbf{Y}^* \cup \mathbf{A}) \setminus \mathbf{Y} \mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} \prod \phi_{\mathbf{V} \setminus \mathbf{D}}(p(\mathbf{V}); \mathcal{G}) \Big|_{\tilde{\mathbf{a}}_{\text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}}} \quad (15)$$

where  $\tilde{\mathbf{a}}_{\text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}}$  is defined as

$$\begin{cases} \{A = f_A(\mathbf{W}_A) \mid A \in \text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}\} & \text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A} \neq \emptyset \\ \emptyset & \text{otherwise} \end{cases}$$

*Proof:* This follows from the fact that identification of  $p(\mathbf{Y}(\mathbf{f}_A))$  can be rephrased as identification of  $p(\mathbf{Y}^*(\mathbf{a}))$ , with values  $\mathbf{a}$  set according to  $\{\mathbf{W}_A \mid A \in \mathbf{A}\}$ , where all  $\mathbf{W}_A$  in the set are subsets of  $\mathbf{Y}^*$ . Identification of  $p(\mathbf{Y}^*(\mathbf{a}))$  may be rephrased as (15) follows by Theorem 60 in [10].  $\square$

The outer sum over  $\mathbf{A}$  in (15) is vacuous if  $\mathbf{f}_A$  is a set of deterministic policies. To illustrate (15), in our example in Fig. 2 (b),  $p(Y(A = f_A(W_0)))$  is identified as

$$\begin{aligned} & \sum_{W_0, A, M, W_1} p(W_1 | M, A = f(W_0), W_0) \\ & p(M | A = f(W_0), W_0) p(W_0) \sum_{W_0, A} p(Y | W_1, M, A, W_0) p(W_0, A) \end{aligned} \quad (16)$$

### Identification Of Edge-Specific Policies

Having reformulated existing identification results on responses to policies (15) and responses to edge interventions arising in mediation analysis (13) in terms of the fixing operator, we generalize these results for identification of responses to edge-specific policies.

Given  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_{\rightarrow} \in \alpha\}$ , and a set of edge-specific policies given by the set of mappings  $\mathbf{f}_\alpha$ , define the graph  $\mathcal{G}_{\mathbf{f}_\alpha}$  to be one where all edges with arrowheads into  $\mathbf{A}_\alpha$  are removed, and directed edges from any vertex in  $\mathbf{W}_A$  to  $A \in \mathbf{A}_\alpha$  added. Fix a set  $\mathbf{Y}$  of outcomes of interest, and define  $\mathbf{Y}^*$  equal  $\text{an}_{\mathcal{G}_{\mathbf{f}_\alpha}}(\mathbf{Y}) \setminus \mathbf{A}_\alpha$ . We have the following result.

**Theorem 3**  $p(\mathbf{Y}(\mathbf{f}_\alpha))$  is identified if  $p(\mathbf{Y}^*(\mathbf{a}))$  is identified, and for every  $\mathbf{D} \in \mathcal{D}((\mathcal{G}_{\mathbf{f}_\alpha})_{\mathbf{Y}^*})$ ,  $\mathbf{f}_\alpha$  yields the same policy assignment for every edge from  $A \in \mathbf{A}_\alpha$  to  $\mathbf{D}$ . Moreover, the identifying formula is

$$\sum_{(\mathbf{Y}^* \cup \mathbf{A}_\alpha) \setminus \mathbf{Y} \mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})} \prod \phi_{\mathbf{V} \setminus \mathbf{D}}(p(\mathbf{V}); \mathcal{G}) \Big|_{\tilde{\mathbf{a}}_{\text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}_\alpha}} \quad (17)$$

where  $\tilde{\mathbf{a}}_{\text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}_\alpha}$  is defined to be  $\{A = f_A(\mathbf{W}_A) \in \mathbf{f}_\alpha \mid A \in \text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}_\alpha\}$ , if  $\text{pa}_{\mathcal{G}}(\mathbf{D}) \cap \mathbf{A}_\alpha \neq \emptyset$ , and is defined to be the  $\emptyset$  otherwise.

*Proof:* This is a straightforward generalization of the proofs of Theorems 1 and 2.  $\square$

Responses to edge-specific policies are identified in strictly fewer cases compared to responses to edge interventions. This is because  $\mathbf{Y}^*$  is a larger set in the former case. As an example, consider the graph in Fig. 1 (c), where we are interested either in the counterfactual  $p(Y(a, M(a')))$ , used to define pure direct effects, or the counterfactual  $p(Y(f_A(W), M(a')))$ .

For the former counterfactual, we have  $\mathbf{Y}^* = \{Y, M\}$ , and  $p(Y(a, M(a')))$  equal to

$$\sum_m \left( \frac{\sum_w p(Y, m | a, w) p(w)}{\sum_w p(m | a, w) p(w)} \right) \sum_w p(m | a', w) p(w)$$

We omit the detailed derivation in the interest of space. For the latter counterfactual, however, the set  $\mathbf{Y}^* = \{Y, M, W\}$  forms a single district in  $\mathcal{G}_{\mathbf{Y}^*}$ , and the edge-specific policy set  $\mathbf{f}_{\{(AM)_{\rightarrow}, (AY)_{\rightarrow}\}}$  sets edges from  $A$  to this district to different policies. As a result, Theorem 3 is insufficient to conclude identification.

Generalizations of the example in Fig. 1 (b) are the most relevant in practice, as their causal structure corresponds to longitudinal observational studies, of the kind considered in [11], and many other papers. However, we illustrate complications that may arise in identifiability of responses to edge-specific policies with our running example in Fig. 2 (b), where we are interested in the response of  $Y$  to edge-specific policies  $\mathbf{f}_{\{(AM)_{\rightarrow}, (AW_1)_{\rightarrow}\}} = \{f_A^{(AM)_{\rightarrow}}(W_0), f_A^{(AW_1)_{\rightarrow}}(W_0)\}$ . Theorem 3 yields the following identifying formula:

$$\begin{aligned} & \sum_{W_0, A, M, W_1} \left[ p(W_1 | M, A = f_A^{(AM)_{\rightarrow}}(W_0), W_0) \right] \quad (18) \\ & \times \left[ p(M | A = f_A^{(AW_1)_{\rightarrow}}(W_0), W_0) p(W_0) \right] \\ & \times \left[ \sum_{W_0, A} p(Y | W_1, M, A, W_0) p(W_0, A) \right]. \end{aligned}$$

Note that (18) generalizes both (14), which sets  $A$  to different constants in different terms, and (16), which sets  $A$  to the output of a function that depends on  $W_0$ . We give a detailed derivation of this functional in the appendix.

## 5 ON COMPLETENESS

An identification algorithm for a class of parameters is said to be *complete* relative to a class of causal models if, whenever the algorithm fails to identify a parameter within a model class, the parameter is in fact not identified within that class.

The ID algorithm is known to be complete for the class of interventional distributions in the class of functional models [5, 14]. We restate this result here, and give a sequence of increasingly general completeness results for the identification algorithms described so far. Completeness results on policies and edge-specific policies are new. For completeness results pertaining to policies, we assume a completely unrestricted class of policies. If the set of policies of interest,  $\mathbf{f}_A$  or  $\mathbf{f}_\alpha$  is restricted, or alternatively if the causal model has parametric restrictions, completeness results we present may no longer hold.

**Theorem 4** *Given disjoint subsets  $\mathbf{Y}, \mathbf{A}$  of  $\mathbf{V}$  in an ADMG  $\mathcal{G}$ , define  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{V} \setminus \mathbf{A}}}(\mathbf{Y})$ . Then  $p(\mathbf{Y}(\mathbf{a}))$  is not identified if there exists  $\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})$  that is not a reachable set in  $\mathcal{G}$ .*

**Corollary 1** *The algorithm for identification of  $p(\mathbf{Y}(\mathbf{a}))$ , as phrased in (11), is complete.*

**Theorem 5** *Given  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_\rightarrow \in \alpha\}$ , and an edge intervention given by the mapping  $\mathbf{a}_\alpha$ , define  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{V} \setminus \mathbf{A}_\alpha}}(\mathbf{Y})$ . The joint distribution of the counterfactual response  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\mathbf{a}_\alpha))$  is not identified if  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\mathbf{a}))$  is not identified, or there exists  $\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{Y}^*})$  and  $A \in \mathbf{A}_\alpha$ , such that  $\mathbf{a}_\alpha$  has the different value assignments for a pair of directed edges out of  $A$  into  $\mathbf{D}$ .*

**Corollary 2** *The algorithm for identification of  $p(\mathbf{Y}(\mathbf{a}_\alpha))$ , as phrased in (13), is complete.*

**Theorem 6** *Define  $\mathcal{G}_{\mathbf{f}_A}$  to be a graph obtained from  $\mathcal{G}$  by removing all edges into  $\mathbf{A}$ , and adding for any  $A \in \mathbf{A}$ , directed edges from  $\mathbf{W}_A$  to  $A$ . Define  $\mathbf{Y}^* \equiv \text{an}_{\mathcal{G}_{\mathbf{f}_A}}(\mathbf{Y}) \setminus \mathbf{A}$ . Then if  $p(\mathbf{Y}^*(\mathbf{a}))$  is not identified in  $\mathcal{G}$ ,  $p(\mathbf{Y}(\mathbf{f}_A))$  is not identified in  $\mathcal{G}$  if  $\mathbf{f}_A$  is the unrestricted class of policies.*

**Corollary 3** *The algorithm for identification of  $p(\mathbf{Y}(\mathbf{f}_A))$ , as phrased in (15), is complete for unrestricted policies.*

**Theorem 7** *Define the graph  $\mathcal{G}_{\mathbf{f}_\alpha}$  to be one where all edges with arrowheads into  $\mathbf{A}_\alpha$  are removed, and directed edges from any vertex in  $\mathbf{W}_A$  to  $A \in \mathbf{A}_\alpha$  added. Fix a set  $\mathbf{Y}$  of outcomes of interest, and define  $\mathbf{Y}^*$  equal  $\text{an}_{\mathcal{G}_{\mathbf{f}_\alpha}}(\mathbf{Y}) \setminus \mathbf{A}_\alpha$ . Then if  $p(\mathbf{Y}^*(\mathbf{a}))$  is not identified, or*

*there exists  $\mathbf{D} \in \mathcal{D}((\mathcal{G}_{\mathbf{f}_\alpha})_{\mathbf{Y}^*})$ , such that  $\mathbf{f}_\alpha$  yields different policy assignments for two edges from  $A \in \mathbf{A}_\alpha$  to  $\mathbf{D}$ ,  $p(\mathbf{Y}(\mathbf{f}_\alpha))$  is not identified.*

**Corollary 4** *The algorithm for identification of  $p(\mathbf{Y}(\mathbf{f}_\alpha))$ , as phrased in (17), is complete for unrestricted policies.*

Detailed proofs of these results are in the Appendix. Corollaries are immediate consequences of the preceding Theorems.

## 6 CONCLUSION

In this paper, we defined counterfactual responses to policies that set treatment values in such a way that they affect outcomes with respect to certain causal pathways only. Such counterfactuals arise when we wish to personalize only some portion of the causal effect of a treatment, while keeping other portions set to some reference values. An example might be optimizing the chemical effect of a drug, while keeping drug adherence to a reference value.

We gave a general algorithm for identifying these responses from data, which generalizes similar algorithms due to [16, 13] for dynamic treatment regimes, and edge-specific effects, respectively. Further, we showed that given an unrestricted class of policies the algorithm is complete. As a corollary, this established that the identification algorithm for dynamic treatment regimes in [16] is complete for unrestricted policies.

Given a fixed set of policies associated with a set of causal pathways, and assuming (17) yields a functional containing only conditional densities, as is the case in the functional (18), the counterfactual mean under those policies  $\mathbb{E}[Y(\mathbf{f}_\alpha)]$  may be estimated using the maximum likelihood plug-in estimator. Such an estimator can be viewed as a generalization of the parametric g-formula [11] to edge-specific policies. More general estimation strategies, and approaches to learning the optimal set of policies are the subject of our companion paper [7].

## Abstract

We propose scalable methods to execute counting queries in machine learning applications. To achieve memory and computational efficiency, we abstract counting queries and their context such that the counts can be aggregated as a stream. We demonstrate performance and scalability of the resulting approach on random queries, and through extensive experimentation using Bayesian networks learning and association rule mining. Our methods significantly outperform commonly used ADtrees and hash tables, and are practical alternatives for processing large-scale data.

## 1 INTRODUCTION

Counting data records with instances that support some specific configuration of the selected variables is one of the basic operations utilized by machine learning (ML) algorithms. For example, when learning Bayesian network structure from data counting is necessary to evaluate a scoring function, or to assess constraints (e.g., via mutual information) [1]. In association rule mining, counting over binary data representing transactions is required to assess support and confidence for a given association rule [2]. Other examples include problems ranging from classification [3, 4] through deep learning [5, 6] to information retrieval [7].

While counting is typically viewed as a black-box procedure, and implemented using simple and not necessarily efficient strategies, e.g., contingency tables, in many practical applications it accounts for over 90% of the total execution time (we show several practical cases in Sec. 4). Consequently, improving performance of counting can directly translate into better performance of these applications. At the same time, popular specialized approaches

based on data indexes, such as ADtrees [8], have limited applicability due to the significant preprocessing and memory overheads, which easily exceed the capability of current computational servers. This holds true for a broad spectrum of problem sizes and applications, with cases involving anywhere from tens to hundreds of variables, and thousands to millions of instances. As the size of the data analyzed by ML codes increases, there is a clear need for easy-to-adopt, efficient and scalable counting strategies.

In this paper, we address the above challenge by designing simple, yet fast and memory efficient counting strategies. Our methods are derived from the standard techniques like bitmap set representation and radix sorting, which can be efficiently implemented in a software. We describe an intuitive and convenient programming interface that leverages properties of the operators used in ML to separate the counting process from how the counts are utilized. This interface enables us to aggregate counts in a stream-like fashion. We encapsulate our methods in an open source software, and demonstrate its performance on random queries, Bayesian networks learning and association rule mining. Through extensive experiments on multiple popular benchmark data, we show that our strategies are orders of magnitude faster than the commonly used methods, such as ADtrees and hash tables.

## 2 PRELIMINARIES

Consider a set of  $n$  categorical random variables  $\mathcal{X} = \{X_1, X_2, \dots, X_n\}$ , where the domain of variable  $X_i$  is represented by states  $[x_{i1}, \dots, x_{ir_i}]$ . Alternatively, we can think of  $X_i$  as a symbolic feature with arity  $r_i$ , and for convenience we can represent its states by integers  $[1, \dots, r_i]$ . Let  $D = [D_1, D_2, \dots, D_n]$  be a complete database of instances of  $\mathcal{X}$ , where  $D_i$ ,  $|D_i| = m$ , records observed states of  $X_i$ . Given  $D$ , and a set of input variables  $\{X_i, X_j, \dots\} \subseteq \mathcal{X}$ , the counting query  $Count((X_i = x_i) \wedge (X_j = x_j) \wedge \dots)$  returns the size of the support in  $D$  for the specific assignment  $[x_i, x_j, \dots]$

of variables  $[X_i, X_j, \dots]$ . For example, for the database in Fig. 1, the query  $Count((X_1 = 3) \wedge (X_2 = 2) \wedge (X_3 = 1))$  would return 2, as there are 2 instances matching the query condition. We note that the above formulation of counting is a special and simple case of the general counting problem in conjunctive queries, known from database theory [9] (we provide more details in Section 5).

Counting queries are the basic operations performed when learning statistical models from data. In some ML applications, such as association rule mining or learning probabilistic graphical models, they may account for over 90% of the total execution time. In the most basic form, the queries can be issued without shared context. For example, to estimate joint probability  $p(X_i = x_i, X_j = x_j)$  from  $D$ , we could use just one query:  $\hat{p}(x_i, x_j|D) = \frac{Count((X_i=x_i) \wedge (X_j=x_j))}{m}$ . However, in the most common use scenarios, a group of consecutive queries is executed over the same set of variables (i.e., the queries share context). For instance, consider log-likelihood score frequently used in Bayesian networks learning [10]:

$$\mathcal{L}(X_i|Pa(X_i)) = \sum_{j=1}^{q_i} \sum_{k=1}^{r_i} N_{ijk} \log \left( \frac{N_{ijk}}{N_{ij}} \right), \quad (1)$$

where  $Pa(X_i) \subseteq \mathcal{X} - \{X_i\}$  is a set of predictor variables for  $X_i$ ,  $j$  enumerates all possible  $q_i = \prod_{X_j \in Pa(X_i)} r_j$  states of variables in  $Pa(X_i)$ , and  $N_{ij}$  and  $N_{ijk}$  are respectively the counts of instances in  $D$  such that variables in  $Pa(X_i)$  are in state  $j$ , and the counts of instances such that variables in  $Pa(X_i)$  are in state  $j$  and  $X_i$  is in state  $k$ . To compute  $\mathcal{L}$  we require multiple counting queries over the same group of variables  $Pa(X_i) \cup \{X_i\}$ , testing different configurations of their states. Moreover, we care only about queries that return non-zero counts  $N_{ijk}$  (note that non-zero  $N_{ijk}$  implies non-zero  $N_{ij}$ ), since only those contribute to the final sum.

The standard approach to handle queries that share context is to either directly scan the database  $D$  to construct  $r_i \times q_i$  contingency table of counts (or its high-dimensional variant such as data cube [11]), or to first create an ADtree index to cache all sufficient statistics from  $D$ , and then to materialize contingency table on demand. Here materialization is done by retrieving the required counts via fast traversal over the index [8, 12]. However, both these approaches have significant limitations.

To use a contingency table we have to either maintain a lookup table with  $r_i \cdot q_i$  entries, or to use a dictionary (e.g., hash table) with keys over the states of  $Pa(X_i)$  and values being vectors of counts for the corresponding states of  $X_i$ . While lookup table may offer very fast memory accesses during construction and querying phases, it becomes computationally impractical, since usually it is very sparse. This is because even for large  $m$ , most of the time  $D$  will

not contain all  $q_i$  possible configurations for the majority of sets  $Pa(X_i)$ . Consequently, lookup tables become a feasible choice only when we are dealing with a small number of variables, each with very small arity. Dictionaries address the problem of sparsity, as they store only configurations that are observed in  $D$ . However, they impose non-trivial overheads owing to the cost of hashing in a hash table dictionary or traversing scattered memory in a search tree dictionary. Moreover, when large number of high-arity variables are considered, a dictionary quickly becomes memory intensive easily exceeding capacity of a typical cache memory.

The alternative approach is to use one of many published variants of the ADtree index, e.g., [8, 12, 13, 14]. Here the idea is to first invest (significant) time and memory to enumerate and cache counts of all configurations found in  $D$ , and then reference those counts to answer subsequent queries. However, even with various optimizations, the space complexity of ADtrees is exponential in the number of variables, and even for modestly sized  $D$  it may exceed the available main memory. Moreover, by caching all counts indiscriminately, ADtrees often store entries that are never referenced in a given application, creating unnecessary memoization and searching overhead. Finally, ADtrees still require that a contingency table is materialized to deliver retrieved counts, and hence they pose a significant challenge in balancing memory and computations.

### 3 PROPOSED APPROACH

Given the database  $D$ , our goal is to provide memory and computationally efficient mechanism to answer counting queries with shared context. The memory efficiency is critical, since many ML algorithms, especially in classification and probabilistic graphical modeling, already have significant memory constraints (see for example [15]). If the memory has to be devoted to handling queries instead of being used by the actual algorithm, it would clearly constrain the applicability of the algorithm. At this point it is worth noting that ML applications fall into a gray zone in terms of the size of the input data on which they typically operate. On the one hand, the size of the input is too small to benefit from many excellent optimizations known from database theory (some we review in Sec. 5), as those are targeting cases in which volume of the data necessitates concurrent use of both persistent and main memory. On the other hand, the data is too large to warrant efficient execution using direct techniques like simple contingency tables.

To address this situation, we first define an intuitive programming interface to abstract the query context, including how counts are utilized by the target application. Then,

we overlay the interface on top of two simple, yet very efficient, query execution strategies, where instead of storing counts we *consume* them in a stream-like fashion.

### 3.1 Programming Interface

In a typical application, counts provided by queries with shared context are iteratively aggregated via some associative and commutative operator. One simple example with the summation operator is given in Eq. (1). A more complex example could be Dirichlet priors with the product of gamma functions [16]. From the computational point of view, this assumption is very helpful as it provides ample opportunities for optimization. We note also that while it may look very narrow, it actually accurately captures surprisingly many ML applications, which primarily involve estimating conditional probabilities. Examples include classifiers and regression, feature extraction, different variants of probabilistic graphical models, etc..

Following notation in Sec. 2, let us consider a set of variables  $(Pa(X_i) \cup \{X_i\}) \subseteq \mathcal{X}$  and their corresponding counts  $N_{ij}$  and  $N_{ijk}$ , for some specific configuration  $j$  of  $Pa(X_i)$  and  $k$  of  $X_i$ . Here we are distinguishing between counts for  $(Pa(X_i) \cup \{X_i\})$  and  $Pa(X_i)$  to simplify computing conditional probabilities while maintaining generality – by passing  $Pa(X_i) = \emptyset$  we can execute queries over single variable  $X_i$ , and by considering only  $N_{ijk}$  we get joint queries  $Pa(X_i) \cup \{X_i\}$ . The key observation is that we can leverage associativity and commutativity, and instead of first gathering all counts and then performing aggregation, we can create a stream of counts corresponding to all unique and relevant configurations found in  $D$ , and perform the aggregation directly on the stream. This enables us to push computations to data, mitigating memory overheads due to counts caching. To achieve this, we abstract the computations via a function object (a concept supported by all modern programming languages), which is then repeatedly invoked over the stream. The example function object corresponding to Eq. (1) is given in Fig. 2. In the essence, the object receives  $N_{ijk}$  and  $N_{ij}$  via the function call operator (line 3), performs the required intermediate computations, and then aggregates the result into internal state. This internal state can be then inspected (line 7) to retrieve the final result of the aggregation. From the user perspective, the function call operator acts as an interface, and is directly invoked by a routine responsible for enumerating, and emitting, all unique configurations for the variables of interest (see parameter  $F$  in Algs. 1 and 2 in the following sections). Thus the interface provides a convenient encapsulation, and the end-user who defines the function object (e.g., implementing a scoring function in BN learning) can focus solely on expressing computations (i.e., high-level

logic and correctness), and does not have to worry about potentially complex logic of low-level details (e.g., how counts are enumerated). Additionally, because function object behaves like a function, but has the advantage of possessing an internal state, it is a convenient mechanism to express even the most demanding computations.

While the proposed interface stems from a relatively simple observation, it has several immediate advantages. First, by separating functionality (i.e., data traversing from computations) we gain flexibility to rapidly investigate different data traversal schemes to extract counts, or even alternate between different strategies depending on the query context (e.g., how many variables are involved, their domain, etc.). Second, since counts are aggregated into an isolated state represented by a function object, and multiple objects can coexist independently, multiple groups of queries, each group with individual context, can be executed concurrently and in parallel, e.g., by different threads. Collectively, this makes the proposed design extremely flexible, efficient and easy to use, as we demonstrate in the experimental results section.

### 3.2 Bitmap Strategy

For the specific  $X_i$  and  $Pa(X_i)$  our task now is to enumerate counts  $N_{ij}$  and  $N_{ijk}$  for all configurations  $j$  and  $k$  found in  $D$ , and then pass the counts to a function object for aggregation. The idea behind the Bitmap strategy is to represent each variable  $X_i$  via a set of  $r_i$  bitmaps of size  $m$ , where each bitmap indicates instances for which  $X_i$  is in the corresponding state (see Fig. 1a). Then, the entire process of enumerating counts can be reduced to performing logical AND on bitmaps, equivalent of set intersection, and to bit counting, equivalent of computing set cardinality. This is summarized in Alg. 1, with example in Fig. 1b (for convenience, in the algorithm we use set notation instead of directly representing bitmaps).

---

#### Algorithm 1 QUERY( $X_i, Pa, F, b$ )

---

```

1 if  $|Pa| = 0$  then
2    $N_{ij} \leftarrow |b|$ 
3   for  $v \in [1, \dots, r_i]$  do
4      $b_v \leftarrow \{p \mid D_i[p] = v\}$ 
5      $N_{ijk} \leftarrow |b \cap b_v|$ 
6     if  $N_{ijk} > 0$  then
7        $F(N_{ijk}, N_{ij}) \triangleleft$  emit new configuration
8 else
9    $X_h \leftarrow \text{HEAD}(Pa)$ 
10  for  $v \in [1, \dots, r_h]$  do
11     $b_v \leftarrow \{p \mid D_h[p] = v\}$ 
12    if  $|b \cap b_v| > 0$  then
13      QUERY( $X_i, \text{TAIL}(Pa), F, b \cap b_v$ )

```

---

To execute counting queries for  $X_i$  and  $Pa(X_i)$  (abbreviated to  $Pa$ ), and function object  $F$ , we perform Depth

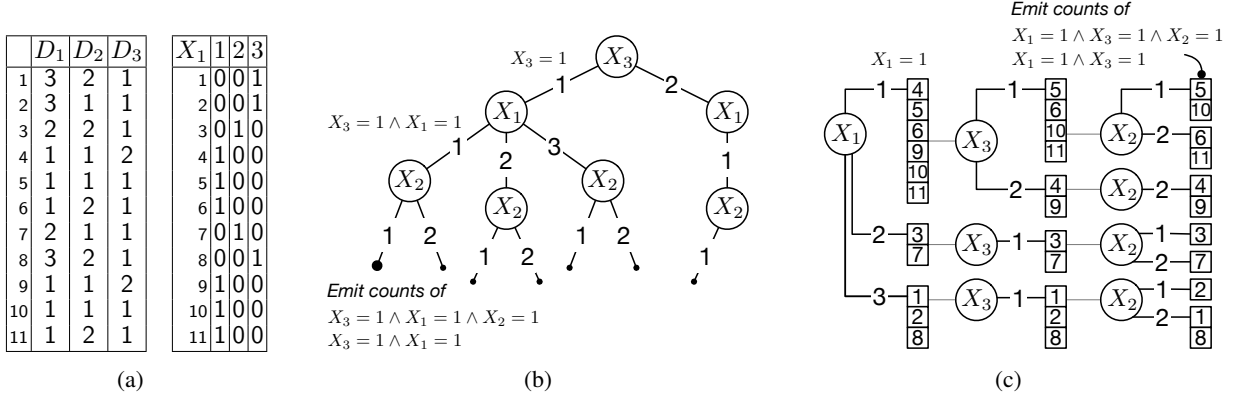

Figure 1: (a) Database  $D$  with three variables, and the corresponding bitmap representation of  $X_1$ . (b) Example of executing  $Query(X_2, \{X_1, X_3\})$  over  $D$  using Bitmap strategy, and (c) Radix strategy.

```

1 class L {
2 public:
3     void operator()(int Nijk, int Nij) {
4         double p = 1.0 * Nijk / Nij;
5         score_ += (Nijk * log2(p));
6     }
7     double score() const { return score_; }
8 private:
9     double score_ = 0.0;
10 };

```

Figure 2: Example C++ code packaging Eq. (1) into our programming interface.

First Traversal (DFS) over the tree whose leaves represent all possible  $r_i \cdot q_i$  states of interest (recall that  $q_i = \prod_{X_j \in Pa(X_i)} r_j$ ). The bottom layer of the tree is induced by the states of  $X_i$ , and the top layers correspond to variables in  $Pa$ . When moving down the tree (lines 9-13), we compute intersection between the set of instances supporting variables' configurations seen thus far (in the algorithm denoted by  $b$ , which initially consists of all  $m$  instances), and the set of instances supporting current configuration of the considered variable from  $Pa$  (in the algorithm denoted by  $b_v$ ). We continue traversal only if the size of the intersection is greater than zero, implying non-zero count for given joint configuration of variables. Once we reach a leaf of the tree (lines 1-7), we compute the final counts  $N_{ijk}$  and  $N_{ij}$  for the corresponding configurations  $j$  and  $k$ , and emit those via call to  $F$ .

The depth of the tree depends on the number of variables involved in the query, and the number of leaves is bounded by  $O(\min(q_i, m))$ , with each step in the traversal involving  $O(m)$  cost of computing intersection and cardinality. While the tree could potentially involve exponential (in the number of query variables) number of

nodes, it is never explicitly stored in the memory, and even for  $D$  with large number of instances many configurations have zero count, allowing for their corresponding sub-trees to be pruned. To further leverage this property, we order  $Pa$  such that variables with lowest entropy estimated from  $D$  are at the top of the tree. Since variables with low entropy are likely to have configurations for which there will be only few supporting instances, they are more likely to trigger zero counts and hence lead to a smaller tree to traverse. For example, consider executing  $Query(X_2, \{X_1, X_3\})$  outlined in Fig. 1b. There are total of 7 configurations which we should enumerate, and if we traverse the tree starting from variable  $X_3$ , which has lower entropy than  $X_1$ , then we will have to consider 6 intermediate states. If we were to start with variable  $X_1$ , then this number would increase to 9. This optimization performs extremely well in practice, and, as we show in the experimental results section, for certain ranges of  $n$  and  $m$ , Bitmap outperforms other strategies.

In the practical terms, the strategy can be efficiently implemented using streaming extensions (SIMD) in current processors. Bitmaps for individual variables can be pre-computed and laid out in the memory instead of  $D$ , with acceptable memory overhead (i.e.,  $m \cdot r_i$  vs.  $m \cdot \log_2(r_i)$  bits), and the relative ordering of variables in  $D$ , based on their entropy, can be established beforehand as well.

### 3.3 Radix Strategy

While the Bitmap strategy is amenable to very efficient implementation, its scalability may still suffer when datasets with very large number of instances are exercised by queries with many variables, or variables with high arity. This is because in such cases the DFS tree will have fewer nodes to prune, and the advantage of fast bit-wise operations will be offset by the poor asymptotic behavior. To address these cases, we consider an alternative

approach, which we refer to as Radix strategy. The strategy is derived from the classic radix sort algorithm, and it involves recursively partitioning instances in  $D$  such that single partition at given level captures all instances corresponding to one specific configuration of the query variables. This approach is summarized in Algs. 2 and 3, with example in Fig. 1c.

---

**Algorithm 2** QUERY( $X_i, Pa, F$ )
 

---

```

1  $B \leftarrow \llbracket 1, \dots, m \rrbracket$ 
2 if  $|Pa| \neq 0$  then
3    $B \leftarrow \text{BUCKETS}(\text{HEAD}(Pa), \text{TAIL}(Pa), \text{HEAD}(B))$ 
4 for  $b \in B$  do
5    $N_{ij} \leftarrow |b|$ 
6   if  $N_{ij} > 0$  then
7      $B' \leftarrow \text{BUCKETS}(X_i, \llbracket \rrbracket, b)$ 
8     for  $b' \in B'$  do
9        $N_{ijk} \leftarrow |b'|$ 
10      if  $N_{ijk} > 0$  then
11         $F(N_{ijk}, N_{ij}) \triangleleft$  emit new configuration

```

---

---

**Algorithm 3** BUCKETS( $X_p, Pa, b$ )
 

---

```

1  $B' \leftarrow \llbracket \rrbracket$ 
2 for  $q \in \llbracket 1, \dots, |b| \rrbracket$  do
3    $x_p \leftarrow D_p[b[q]]$ 
4    $B'[x_p].\text{APPEND}(b[q])$ 
5 if  $\text{TAIL}(Pa) = \llbracket \rrbracket$  then
6   return  $B'$ 
7  $B'' \leftarrow \llbracket \rrbracket$ 
8 for  $b' \in B'$  do
9    $B''.\text{APPEND}(\text{BUCKETS}(\text{HEAD}(Pa), \text{TAIL}(Pa), b'))$ 
10 return  $B''$ 

```

---

The algorithm follows the Most Significant Digit (MSD) radix, with the left most digits being states of individual variables in  $Pa$ , and the least significant digit representing states of  $X_i$  (Alg. 2, line 3). At each level, the number of newly created partitions is proportional to the arity of the considered variable, and the size of the partition is the support in  $D$  for the particular configuration. The order in which variables from  $Pa$  are processed is not significant, since the cost of identifying empty partitions does not induce overheads. Because the actual instances in  $D$  are not to be sorted, but only partitioned, it is sufficient that we maintain a list (in algorithms denoted by  $B$ ) of partition descriptors containing indexes of the constituent instances and partition size (Alg. 3, lines 1-4). As soon as all partitions prescribed by  $Pa$  are identified we can proceed to emitting counts (Alg. 2, lines 4-11), which must be preceded by the final round of partitioning with respect to  $X_i$  (Alg. 2, line 7).

The algorithm requires that for each variable  $X_p \in Pa$  its corresponding data vector  $D_p$  is completely scanned, leading to the overall  $O(|Pa| \cdot m)$  complexity. In practice, the entire method is efficiently implemented by first orga-

nizing the database  $D$  in the column-major format, and then maintaining a FIFO queue of partition descriptors, with  $O(m)$  auxiliary space to keep track of the assignment of indexes to partitions. Moreover, partitioning for individual variables can be precomputed in advance, further bootstrapping the first step of the algorithm.

To conclude the presentation, we note that both Bitmap and Radix strategies can be further augmented such that instead of enumerating all counts (i.e., executing queries with shared context) they deliver counts just for the specific assignment of the query variables. To achieve this, it is sufficient to process only a single path from the root to the leaf with the target assignment in the DFS tree of the Bitmap strategy, and to find the partition corresponding to the assignment, instead of all partitions, in Radix.

## 4 EXPERIMENTAL VALIDATION

We implemented both proposed strategies as a C++ software library, which we complemented with Python bindings for the ease of use. At its core, the library uses standard SSE SIMD intrinsics to implement basic bitmap operations (i.e., logical AND, and bit counting), and it exposes all functionality via the interface described in Sec. 3.1. The resulting open source package, which we call SABNatk, is available from: <https://gitlab.com/SCoRe-Group/SABNatk>.

We deployed SABNatk on a server with two Intel Xeon E5-2650 2.30 GHz 10-core CPUs, and 64 GB of RAM. To test the performance, we ran a series of experiments using popular ML benchmark datasets (see data summary in Tab. 1). For reference, we used hash table from the C++ standard library, and the sparse ADtree data index [8]. The hash table represented contingency table created by directly scanning the input database, with keys encoding specific assignment of variables in  $Pa(X_i)$ , and values representing vectors of counts for specific assignment of  $X_i$ . To maximize cache memory usage, the strategy operated on the database stored in the row-major order. Finally, to make the comparison fair and avoid biases due to the differences in programming languages, we developed an efficient ADtree implementation in C++. We note that other available implementations, for example [17], turned out to be substantially slower than our version.

In the following, we discuss in detail several key results obtained using the above setup. More extensive results (including additional test cases), together with the data that can be used to reproduce our experiments, are available from: <https://gitlab.com/SCoRe-Group/SABNatk-Benchmarks>.

Before we proceed with the results discussion, we note that in order to use ADtree, the input database has to be

Table 1: Benchmark data used in experiments.

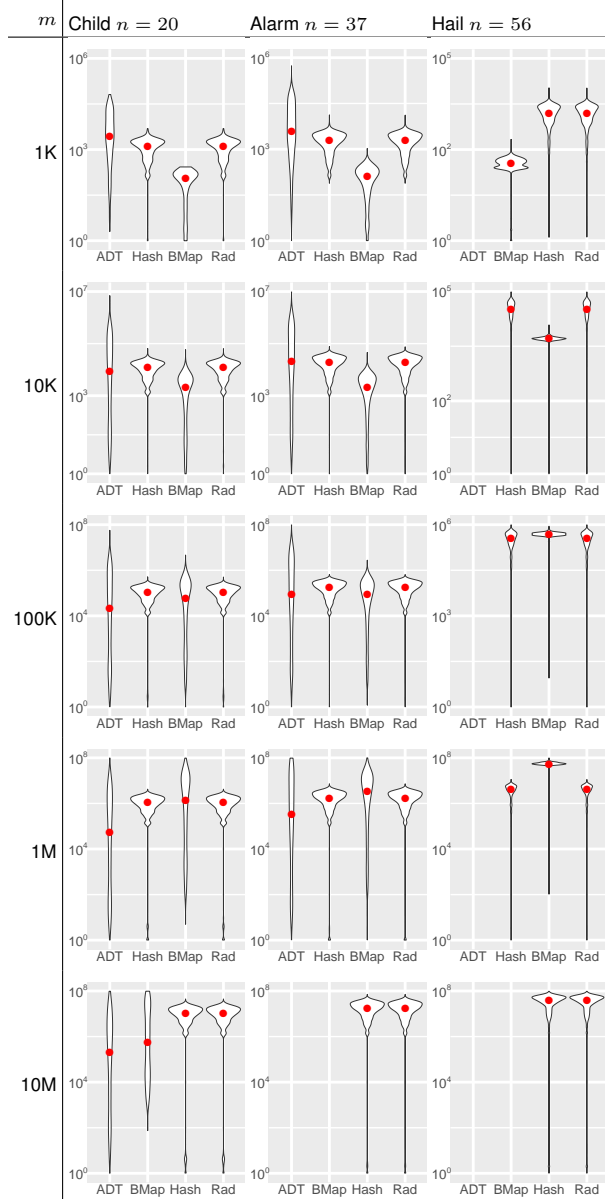

Figure 3: Comparison ADT, Hash, BMap and Rad strategies on the stream of uniformly random queries. The plots show the distribution of response time in microseconds, computed from the same sample of 1,000 queries for different number of instances  $m$ . Y-axis is in  $\log_{10}$ -scale.

first indexed. In all our experiments, we considered only the query time with index already loaded into memory. Moreover, ADtree provides a hyper-parameter  $\ell$  to configure the size of the leaf-lists [8]. We experimented with several values of the parameter, to fine-tune the trade-off between query performance and memory consumption, and we settled with  $\ell = 16$ , which we use throughout the paper. The results obtained for other ADtree configurations exhibited similar patterns to those reported in the paper, and are available online.

#### 4.1 Random Queries

In the first set of experiments we tested how ADtree (ADT), HashTable (Hash), Bitmap (BMap), and Radix (Rad) strategies respond to a stream of random queries. The idea here is to understand average performance of each strategy in case where we have no prior information about specific query execution patterns. For each benchmark database, we generated 100,000 queries of the form  $Query(X_i, Pa(X_i))$  as follows. First, the size of  $Pa(X_i)$  was sampled uniformly from the range  $[1, \dots, n - 1]$ , and then variables were assigned to  $X_i$  and  $Pa(X_i)$  by randomly sampling without replacement from  $\mathcal{X}$ . To measure time taken to execute the query, we used a simple function object that consumes and immediately discards the counts. In this way, the overhead of performing computations on the counts was negligible, and did not offset the actual time spent by each strategy to enumerate the counts. Each query was executed five times to obtain the average response time (with negligible variance), and exactly the same stream of queries was processed by each strategy. The results of this experiment are summarized in Figs. 3 and 4. Here, we note that plots are in  $\log_{10}$  scale, and should be interpreted with care.

Figure 3 shows that depending on the number of input variables  $n$ , and the number of instances  $m$ , different strategies perform better in terms of the mean response time. When the number of instances is relatively small, Bitmap strategy significantly outperforms other methods. This is explained by two factors: first, for small scale data, Bitmap benefits from continuous memory accesses, and acceleration via SIMD instructions, second, because in small datasets many possible variable configurations are unobserved, Bitmap is able to prune significant portions of the DFS tree, taking advantage of the entropy-based data reordering (see Sec. 3.2). However, as the number of instances in the input database increases these advantages diminish, to the extent where the average time taken by a query becomes unacceptable (longer than several seconds, a threshold we set to make experiments computationally feasible). The Radix and HashTable strategies perform steadily across all datasets, and are able to handle even the

Figure 4: Comparison of ADT, Hash, BMap, and Rad for different sizes of  $Pa$  (x-axis) in the sample of 1,000 uniformly random queries. The plot shows the average query response time in microseconds. Y-axis is in  $\log_{10}$ -scale.

most demanding test cases. This is expected, since both strategies involve similar data access pattern (i.e., scanning selected columns of the input database). However, Rad is on average 20 times faster than Hash (not captured in the figure due to log-scale), as it does not require costly hashing and scattered memory accesses.

The ADtree strategy exhibits the best mean response for problems with few variables and large number of instances, but it significantly underperforms in all remaining test cases. In fact, as the number of variables increases, ADtree fails to index the database and cannot be used to answer the queries. This is because the exponential growth of the number of configurations, which have to be cached, leads to the exhaustion of the main memory. Recall also that we do not include ADtree preprocessing time, which for datasets with more than 100K instances exceeds several hours, much longer than the time required to answer all 100K queries.

To further dissect performance of random queries, in Fig. 4 we show how the response time varies with the number of query variables, for an example database. When processing small queries ( $|Pa| < 4$ ), ADtree is generally outperformed by BMap, and when handling large queries ( $|Pa| > 10$ ) it is slower than Rad. Moreover, the cost of Radix strategy is linear with the query size, compared to the exponential growth of ADtree.

Based on the tests with random queries, we conclude that Bitmap and Radix strategies significantly outperform ADtree and HashTable, except of a small set of scenarios in which small queries are executed over databases with few variables and millions of instances, if we exclude the preprocessing time.

## 4.2 Queries in Bayesian Networks Learning

Counting queries with shared context are the key operations performed in score-based Bayesian networks structure learning and Markov blankets discovery [1]. Both problems depend on the parent set assignment as a subroutine [18], and for given  $X_i$  can be solved exactly by traversing a lattice with  $n$  levels formed by the partial order *set inclusion* on the power set of  $\mathcal{X} - \{X_i\}$ . For given  $\mathcal{X}$  and  $D$ , queries of the form  $Query(X_i, Pa, F)$  are performed for each  $X_i$ , where  $Pa$  iterates over all possible subsets of  $\mathcal{X} - \{X_i\}$ , starting from empty set. Hence, at level  $i = 0, \dots, n - 1$  we have that  $|Pa| = i$ , and there are total  $\binom{n-1}{i}$  queries to execute, creating interesting pattern of queries that grow in size as computations progress. The function object  $F$  implements decomposable scoring function, e.g., MDL [19], BDeu [16], etc., that evaluates the assignment of  $Pa$  as parents of  $X_i$ .

We used all tested strategies to implement count-

Figure 5: The total execution time of the parent set assignment solver with ADT, Hash, BMap and Rad strategies, normalized with respect to the fastest method. The solver was executed up to the level where  $|Pa| = 6$ .

ing queries in the open source parent set assignment solver [20]. The solver uses MDL scoring function, deploys several optimizations to eliminate some of the queries based on the results seen thus far, and because it effectively explores large combinatorial search space it has significant memory requirements. It also leverages OpenMP to execute multiple queries in parallel. As such, it serves as a practical benchmark for the query strategies. In our experiments, instead of considering all possible parent set sizes, as required by the exact solver, we limited the solver to  $|Pa| \leq 6$ , to make tests computationally feasible. This corresponds to a heuristic in which we make an assumption that no variable in the final Bayesian network can have more than six parents.

Figure 5 shows the total execution time of the solver for different input databases and query strategies. From the plots, we can see that our proposed strategies significantly outperform ADtree and HashTable, across all benchmarks. In fact, for datasets with high-arity variables, i.e., Mildew and Barley, the Radix strategy is 100 times faster than ADtree. This is explained by very large number of states that are to be expected in such datasets (and are costly to manage by ADtree), and by the pattern of how queries are generated by the solver. Because the size of the queries and their number grow together, there are only a few small queries that benefit ADtree, and increasing number of queries that are easily handled by the Radix strategy.

To illustrate how critical is the performance of counting queries for parent sets assignment, in Tab. 2 we report the total execution time of the solver, together with the fraction of the time taken by the queries, when running on databases with 100K instances. In all cases, the execution is dominated by database querying that accounts for 90%-99% of the total time. Interestingly, this fraction is smaller for ADtree than for other strategies, even though ADtree is slower (we observed this pattern in all test cases). We believe that this is because BMap and Rad are memory friendly, and have minimal effect on

Table 2: Execution time of the parent set assignment.

	Insur	Mild	Alarm	Barley
ADT	35m20s 90.2%	–	119m 98.2%	–
Hash	26m26s 98.2%	92m3s 99.1%	190m47s 99.4%	276m16s 98.2%
BMap	17m28s 98.8%	1107m57s 99.8%	100m55s 99.9%	–
Rad	4m41s 99.9%	37m28s 99.9%	43m4s 99.9%	156m32s 99.9%

memory utilization by the solver, thus minimizing cache update overheads, which in turn could slow down the solver. This is not the case for ADtree, which requires gigabytes of memory to run, and hence influences performance of the solver, affecting the ratio between the query and the solver time.

### 4.3 Queries in Association Rule Mining

Association rule mining is the classic method for establishing implication rules between a set of items in a database [2, 21]. Given a set of binary variables  $\mathcal{X}$ , and a database of transactions  $D$ , where  $D_i$  shows in which transactions item represented by  $X_i$  was involved (i.e.,  $X_i$  is in state 1), we want to identify rules of the form  $Pa(X_i) \Rightarrow X_i$  with support, i.e., how frequently  $Pa(X_i) \cup \{X_i\}$  are set together in  $D$ , and confidence, i.e., how frequently the rule is true in  $D$ , above some pre-defined thresholds. In the most direct form, the problem can be solved by traversing the power set lattice over  $\mathcal{X}$ , a query pattern similar to the one used by the parent set assignment solver. However, compared to the parent set assignment, the actual queries are simpler, since we only require the counts of query variables being in state 1. For example, to assess the rule  $\{X_1, X_2\} \Rightarrow X_3$  we would perform queries  $Count(X_1 = 1, X_2 = 1, X_3 = 1)$  and  $Count(X_1 = 1, X_2 = 1)$ . Consequently, instead of considering the query context, it is sufficient that our strategies search for one specific configuration of the query variables (as explained at the end of Sec. 3.3).

We used all four tested strategies to implement simple association rule mining engine based on the bottom-up search [21]. With the engine, we processed several large databases to enumerate rules with the support above 0.2 and confidence above 0.3, but of size less than seven. We selected these thresholds empirically to retrieve association rules with more than four variables, which allowed us to reliably measure the execution times (for smaller rules, the solver ran extremely fast). Results of this experiment are summarized in Fig. 6.

The figure shows that the Bitmap strategy significantly outperforms other approaches across all tested databases.

Figure 6: The total execution time of association rule mining with ADT, Hash, BMap and Rad strategies, normalized with respect to the fastest method. The solver was executed up to the level where  $|Pa| = 6$ .

Since in the Bitmap, processing queries with specific assignment amounts to a series of  $|Pa(X_i)| + 1$  bitmap intersections, followed by bit counting, the cost of queries becomes linear in the size of the query and the number of instances in the database. Moreover, because all bit-wise operations are implemented via SIMD extensions, BMap becomes much faster than Rad, which has the same asymptotic behavior but involves less cache friendly operations. Finally, the overheads of traversing ADtree and handling its MCV subtrees (see [12] for details) leads to its poor overall performance. At this point we should note that originally ADtree was designed for learning of association rules, however the design did not account for the memory and SIMD capabilities of modern processors.

## 5 RELATED WORK

As we mentioned through out the paper, counting queries in machine learning applications are often handled via some variant of the ADtree data index. The sparse ADtree [8, 12], which we used in our experiments, pre-computes and caches counts for all possible variable configurations. The counts are organized into a tree of *vary nodes*, encoding the choice of variables to facilitate fast searching, and *AD nodes* that store the actual query counts. To partially mitigate the excessive memory use, ADtrees do not explicitly represent most commonly occurring counts, and instead of creating AD nodes for counts lower than certain threshold, they resort to on-demand counting when such nodes are accessed. These base ideas have been extended by multiple researchers to account for dynamic data (i.e., updates to the database) [22], and to improve performance on high-arity data [13, 14]. However, as the core functionality in these data structures remains exactly the same, they suffer from the same limitations that we demonstrated in our experiments (expensive preprocessing, large memory footprint, significant traversing overheads).

Support for counting queries is a primary component in

any database management system. In such systems, the query mechanism must support conjunctive queries over multiple tables, and with a variety of possible query predicates [9]. Moreover, the queries are typically executed over tables that cannot be fully materialized in the main memory. Our Bitmap strategy can be viewed as a practical realization of the Leapfrog Trie Join [23] with an unary relation, under assumption that the entire database resides in the main memory.

The idea of using bitmaps to represent sets and their operations (e.g., intersection, cardinality, etc.) is frequent in software and databases design. This is because it allows to reduce memory, storage or network bandwidth, while maintaining the basic sets functionality [24]. In these applications, bitmaps are typically compressed following methods like for example RLE encoding or Roaring [25, 26]. The compressed bitmaps are orthogonal to our approach, and in fact we could use them to improve memory profile of our Bitmap strategy. However, as the compression induces computational overheads, and the size of the databases we consider practical is relatively small, currently we do not use compression.

## 6 CONCLUSIONS

In this paper, we describe efficient strategies for handling counting queries in machine learning applications. By combining convenient programming interface with memory efficient data traversing algorithms we are able to scale to large data instances, which we confirm via extensive experiments. The proposed solutions outperform and can substitute popular ADtree index. Moreover, to maintain best possible performance across different data instances, they can be selectively applied at the runtime depending on the properties of the queries.

While our approach is presented as a method for static databases, we note that it can be easily adopted to the cases where the input database expands with new instances during processing. This would amount to a simple update to the bitmaps in the Bitmap strategy, and is automatically handled in the Radix strategy.

## Abstract

This paper addresses the problem of formally verifying desirable properties of neural networks, *i.e.*, obtaining provable guarantees that neural networks satisfy specifications relating their inputs and outputs (robustness to bounded norm adversarial perturbations, for example). Most previous work on this topic was limited in its applicability by the size of the network, network architecture and the complexity of properties to be verified. In contrast, our framework applies to a general class of activation functions and specifications on neural network inputs and outputs. We formulate verification as an optimization problem (seeking to find the largest violation of the specification) and solve a Lagrangian relaxation of the optimization problem to obtain an upper bound on the worst case violation of the specification being verified. Our approach is *anytime* *i.e.* it can be stopped at any time and a valid bound on the maximum violation can be obtained. We develop specialized verification algorithms with provable tightness guarantees under special assumptions and demonstrate the practical significance of our general verification approach on a variety of verification tasks.

## 1 INTRODUCTION

Neural networks and deep learning have revolutionized machine learning achieving state of the art performance on a wide range of complex prediction tasks [Krizhevsky et al., 2012, Goodfellow et al., 2016]. However, in recent years, researchers have observed that even state of the art networks can be easily fooled into changing their

predictions by making small but carefully chosen modifications to the input data (known as *adversarial perturbations*) [Szegedy et al., 2013, Kurakin et al., 2016, Carlini and Wagner, 2017a, Goodfellow et al., 2014, Carlini and Wagner, 2017b]. While modifications to neural network training algorithms have been proposed to mitigate this phenomenon Madry et al. [2018], a comprehensive solution that is fully robust to adversarial attacks remains elusive [Carlini and Wagner, 2017b, Uesato et al., 2018].

Neural networks are typically tested using the standard machine learning paradigm: If the performance (accuracy) of the network is sufficiently high on a holdout (test) set that the network did not have access to while training, the network is deemed acceptable. This is justified by statistical arguments based on an *i.i.d.* assumption on the data generating mechanism, that is each input output pair is generated independently from the same (unknown) data distribution. However, this evaluation protocol is not sufficient in domains with critical safety constraints [Marston and Baca, 2015]. In these cases, we may require a stronger test: for example, we may require that the network is robust against adversarial perturbations within certain bounds.

**Adversarial evaluation.** In the context of adversarial examples, a natural idea is to test neural networks by checking if it is possible to generate an adversarial attack to change the label predicted by the neural network [Kurakin et al., 2016] and train them to be robust to these examples Madry et al. [2018]. Generating adversarial examples is a challenging computational task itself, and the attack generated by a specific attack algorithm may be far from optimal. This may lead one to falsely conclude that a given model is robust to attacks even though a stronger adversary may have broken the robustness. Recent work [Athalye et al., 2018, Uesato et al., 2018] has shown that evaluating models against weak adversaries can lead to incorrect conclusions regarding the robustness of the model. Thus, there is a need to go beyond evaluation us-

---

\*dvij@cs.washington.edu

ing specific adversarial attacks and find approaches that provide provable guarantees against attacks by *any adversary*.

**Towards verifiable models.** Verification of neural networks has seen significant research interest in recent years. In the formal verification community, Satisfiability Modulo Theory (SMT) solvers have been adapted for verification of neural networks [Ehlers, 2017, Huang et al., 2017, Katz et al., 2017]. While SMT solvers have been successfully applied to several domains, applying them to large neural networks remains a challenge due to the scale of the resulting SMT problem instances. Furthermore, these approaches have been largely limited to networks with piecewise linear activation functions since most SMT solvers are unable to deal efficiently with nonlinear arithmetic. More recently, researchers have proposed a set of approaches that make use of branch and bound algorithms either directly or via mixed-integer programming solvers [Bunel et al., 2017, Cheng et al., 2017, Tjeng and Tedrake, 2017]. While these approaches achieve strong results on smaller networks, scaling them to large networks remains an open challenge. These approaches also rely heavily on the piecewise linear structure of networks where the only nonlinearities are max-pooling and ReLUs.

**Towards scalable verification of general models.** In this paper, we develop a novel approach to neural network verification based on optimization and duality. The approach consists of formulating the verification problem as an optimization problem that tries to find the largest violation of the property being verified. If the largest violation is smaller than zero, we can conclude that the property being verified is true. By using ideas from duality in optimization, we can obtain bounds on the optimal value of this problem in a computationally tractable manner. Note that this approach is *sound but incomplete*, in that there may be cases where the property of interest is true, but the bound computed by our algorithm is not tight enough to prove the property. This strategy has been used in prior work as well [Kolter and Wong, 2018, Raghunathan et al., 2018]. However, our results improve upon prior work in the following ways:

1. Our verification approach applies to *arbitrary* feed-forward neural networks with *any architecture* and *any activation function* and our framework recovers previous results [Ehlers, 2017] when applied to the special case of piecewise linear activation functions.
2. We can handle verification of systems with discrete inputs and combinatorial constraints on the input space, including cardinality constraints.

3. The computation involved only requires solving an unconstrained convex optimization problem (of size linear in the number of neurons in the network), which can be done using a subgradient method efficiently. Further, our approach is *anytime*, in the sense that the computation can be stopped at any time and a valid bound on the verification objective can be obtained.
4. For the special case of single hidden layer networks, we develop specialized verification algorithms with provable tightness guarantees.
5. We attain state of the art verified bounds on adversarial error rates on image classifiers trained on MNIST and CIFAR-10 under adversarial perturbations in the infinity norm.

## 2 Related Work

**Certifiable training and verification of neural networks** A separate but related thread of work is on *certifiable training*, ie, training neural networks so that they are guaranteed to satisfy a desired property (for example, robustness to adversarial examples within a certain radius) [Kolter and Wong, 2018, Raghunathan et al., 2018]. These approaches use ideas from convex optimization and duality to construct bounds on an optimization formulation of verification. However, these approaches are limited to either a class of activation functions (piecewise linear models) or architectures (single hidden layer, as in Raghunathan et al. [2018]). Further, in Kolter and Wong [2018], the dual problem starts with a constrained convex formulation but is then converted into an unconstrained but nonconvex optimization problem to allow for easy optimization via a backprop-style algorithm. In contrast, our formulation allows for an unconstrained dual convex optimization problem so that for *any choice of dual variables*, we obtain a valid bound on the adversarial objective and this dual problem can be solved efficiently using subgradient methods.

We also note that the ultimate goals of [Kolter and Wong, 2018, Raghunathan et al., 2018] are different from our paper: they modify the training procedure of the neural network so that the network is trained to be easily verifiable. In contrast, our work focuses on extending verification algorithms to apply to a broader class of architectures, activation functions and - in this sense, we view our work as complementary to [Kolter and Wong, 2018, Raghunathan et al., 2018]. In fact, since the objective of our dual optimization is differentiable with respect to the network weights, we can extend our approach to training verifiable networks easily by simultaneously optimizing the network weights and dual variables to minimize the

dual objective. We leave the study of such an extension for future work.

**Theoretical analysis of robustness** Another related line of work has to do with theoretical analysis of adversarial examples. It has been shown that feedforward ReLU networks cannot learn to distinguish between points on two concentric spheres without necessarily being vulnerable to adversarial examples within a small radius [Gilmer et al., 2018]. Under a different set of assumptions, the existence of adversarial examples with high probability is also established in Fawzi et al. [2018]. In Wang et al. [2017], the authors study robustness of nearest neighbor classifiers to adversarial examples. As opposed to these theoretical analyses, our approach searches computationally for proofs of existence or non-existence of adversarial examples. The approach does not say anything a-priori about the existence of adversarial examples, but can be used to investigate their existence for a given network and compare strategies to guard against adversarial attacks.

### 3 VERIFICATION AS OPTIMIZATION

#### 3.1 NOTATION

Our techniques apply to general feedforward architectures and recurrent networks, but we focus on layered architectures for the development in this paper. The input layer is numbered 0, the hidden layers are numbered  $1, \dots, L - 1$  and the output layer is numbered  $L$ . The size of layer  $l$  is denoted  $n_l$

We denote by  $x^{in}$  the input to the neural network, by  $z^l$  the pre-activations of neurons at layer  $l$  before application of the activation function and by  $x^l$  the vector of neural activations after application of the activation function (to  $z^{l-1}$ ). For convenience, we define  $x^0 = x^{in}$ . We use  $x^l(x^{in}), z^l(x^{in})$  to denote the activations at the  $l$ -th layer as a function of the input  $x^{in}$ . Upper and lower bounds on the pre/post activations are denoted by  $\underline{x}^l, \bar{x}^l, \underline{z}^l, \bar{z}^l$  respectively. The activation function at layer  $l$  is denoted  $h^l$  and is assumed to be applied component-wise, ie,

$$[h^l(z^l)]_k = h_k^l(z_k^l)$$

Note that max-pooling is an exception to this rule - we discuss how max-pooling is handled separately in the Appendix section 6.2.1. The weights of the network at layer  $l$  are denoted  $W^l$  and the bias is denoted  $b^l$ ,  $z^l = W^l x^l + b^l$ .

#### 3.2 VERIFICATION PROBLEM

As mentioned earlier, *verification* refers to the process of checking that the output of the neural network sat-

isfies a certain desirable property for all choices of the input within a certain set. Formally, this can be stated as follows:

$$\forall x^{in} \in \mathcal{S}_{in}(x^{nom}) \quad x^L(x^{in}) \in \mathcal{S}_{out} \quad (1)$$

where  $x^{in}$  denotes the input to the network,  $x^{nom}$  denotes a nominal input,  $\mathcal{S}_{in}(x^{nom})$  defines the constrained subset of inputs induced by the nominal input, and  $\mathcal{S}_{out}$  denotes the constraints on the output that we would like to verify are true for all inputs in  $\mathcal{S}_{in}(x^{nom})$ . In the case of adversarial perturbations in image classification,  $x^{nom}$  would refer to the nominal (unperturbed image),  $\mathcal{S}_{in}(x^{nom})$  would refer to all the images that can be obtained by adding bounded perturbations to  $x^{nom}$ , and  $x^{in}$  would refer to a perturbed image.

In this paper, we will assume that:  $\mathcal{S}_{out}$  is always a described by a finite set of linear constraints on the values of final layer ie.  $\mathcal{S}_{out} = \cap_{i=1}^m \{x^L : (c^i)^T x^L + d^i \leq 0\}$ , and  $\mathcal{S}_{in}(x^{nom})$  is any bounded set such that any linear optimization problem of the form

$$\max_{x^{in} \in \mathcal{S}_{in}(x^{nom})} c^T x$$

can be solved efficiently. This includes convex sets and also sets describing combinatorial structures like spanning trees, cuts in a graph and cardinality constraints.

See the following examples for a concrete illustration of the formulation of the problem:

**Robustness to targeted adversarial attacks.** Consider an adversarial attack that seeks to perturb an input  $x^{nom}$  to an input  $x^{in}$  subject to a constraint on the perturbation  $\|x^{in} - x^{nom}\| \leq \epsilon$  to change the label from the true label  $i$  to a target label  $j$ . We can map this to (1) as follows:

$$\mathcal{S}_{in}(x^{nom}) = \{x^{in} : \|x^{in} - x^{nom}\| \leq \epsilon\}, \quad (2a)$$

$$\mathcal{S}_{out} = \{z : c^T z \leq 0\} \quad (2b)$$

where  $c$  is a vector with  $c_j = 1, c_i = -1$  and all other components 0. Thus,  $\mathcal{S}_{out}$  denotes the set of outputs for which the true label  $i$  has a higher logit value than the target label  $j$  (implying that the targeted adversarial attack did not succeed).

**Monotonic predictors.** Consider a network with a single real valued output and we are interested in ensuring that the output is monotonically increasing wrt each dimension of the input  $x^{in}$ . We can state this as a verifica-

tion problem:

$$\mathcal{S}_{in}(x^{nom}) = \{x^{in} : x^{in} \geq x^{nom}\} \quad (3a)$$

$$\mathcal{S}_{out} = \{x^L : x^L(x^{nom}) - x^L \leq 0\} \quad (3b)$$

Thus,  $\mathcal{S}_{out}$  denotes the set of outputs which are large than the network output at  $x^{nom}$ . If this is true for each value of  $x^{nom}$ , then the network is monotone.

**Cardinality constraints.** In several cases, it makes sense to constrain a perturbation not just in norm but also in terms of the number of dimensions of the input that can be perturbed. We can state this as:

$$\begin{aligned} \mathcal{S}_{in}(x^{nom}) = \\ \{x^{in} : \|x^{in} - x^{nom}\|_0 \leq k, \|x^{in} - x^{nom}\|_\infty \leq \epsilon\} \end{aligned} \quad (4a)$$

$$\mathcal{S}_{out} = \{z : c^T z \leq 0\} \quad (4b)$$

where  $\|x\|_0$  denotes the number of non-zero entries in  $x$ . Thus,  $\mathcal{S}_{out}$  denotes the set of outputs which are larger than the network output at  $x^{nom}$ . If this is true for each value of  $x^{nom}$ , then the network is monotone.

### 3.3 OPTIMIZATION PROBLEM FOR VERIFICATION

Once we have a verification problem formulated in the form (1), we can easily turn the verification procedure into an optimization problem. This is similar to the optimization based search for adversarial examples [Szegedy et al., 2013] when the property being verified is adversarial robustness. For brevity, we only consider the case where  $\mathcal{S}_{out}$  is defined by a single linear constraint  $c^T z + d \leq 0$ . If there are multiple constraints, each one can be verified separately.

$$\max_{\substack{z^0, \dots, z^{L-1} \\ x^0, \dots, x^L}} c^T x^L + d \quad (5a)$$

$$\text{s.t. } x^{l+1} = h^l(z^l), l = 0, 1, \dots, L-1 \quad (5b)$$

$$z^l = W^l x^l + b^l, l = 0, 1, \dots, L-1 \quad (5c)$$

$$x^0 = x^{in}, x^{in} \in \mathcal{S}_{in}(x^{nom}) \quad (5d)$$

If the optimal value of this problem is smaller than 0 (for each  $c, d$  in the set of linear constraints defining  $\mathcal{S}_{out}$ ), we have verified the property (1). This is a nonconvex optimization problem and finding the global optimum in general is NP-hard (see Appendix section 6.4.1 for a proof). However, if we can compute *upper bounds* on the value of the optimization problem and the upper bound is smaller than 0, we have successfully verified the property. In the following section, we describe our main approach for computing bounds on the optimal value of (5).

### 3.4 BOUNDING THE VALUE OF THE OPTIMIZATION PROBLEM

We assume that bounds on the activations  $z^l, x^l, l = 0, \dots, L-1$  are available. Section 6.1 discusses details of how such bounds may be obtained given the constraints on the input layer  $\mathcal{S}_{in}(x^{nom})$ . We can bound the optimal value of (5) using a Lagrangian relaxation of the constraints:

$$\begin{aligned} \max_{\substack{z^0, \dots, z^{L-1} \\ x^0, x^1, \dots, x^{L-1}}} c^T (h^{L-1}(z^{L-1})) + d \\ + \sum_{l=0}^{L-1} (\mu^l)^T (z^l - W^l x^l - b^l) \\ + \sum_{l=0}^{L-2} (\lambda^l)^T (x^{l+1} - h^l(z^l)) \end{aligned} \quad (6a)$$

$$\text{s.t. } \underline{z}^l \leq z^l \leq \bar{z}^l, l = 0, 1, \dots, L-1 \quad (6b)$$

$$\underline{x}^l \leq x^l \leq \bar{x}^l, l = 0, 1, \dots, L-1 \quad (6c)$$

$$x^0 \in \mathcal{S}_{in}(x^{nom}) \quad (6d)$$

Note that any feasible solution for the original problem (5) is feasible for the above problem, and for any such solution, the terms involving  $\lambda, \mu$  become 0 (since the terms multiplying  $\lambda, \mu$  are 0 for every feasible solution). Thus, for any choice of  $\lambda, \mu$ , the above optimization problem provides a valid upper bound on the optimal value of (5) (this property is known as weak duality [Vandenberghe and Boyd, 2004]).

We now look at solving the above optimization problem. Since the objective and constraints are separable in the layers, the variables in each layer can be optimized independently. For  $l = 1, \dots, L-1$ , we have

$$\begin{aligned} f_l(\lambda^{l-1}, \mu^l) = \\ \max_{x^l \in [\underline{x}^l, \bar{x}^l]} \left( \lambda^{l-1} - (W^l)^T \mu^l \right)^T x^l - (b^l)^T \mu^l \end{aligned}$$

which can be solved trivially by setting each component of  $x^l$  to its upper or lower bound depending on whether the corresponding entry in  $\lambda^{l-1} - (W^l)^T \mu^l$  is non-negative. Thus,

$$\begin{aligned} f_l(\lambda^{l-1}, \mu^l) = \\ \left[ \lambda^{l-1} - (W^l)^T \mu^l \right]_+^T \bar{x}^l \\ + \left[ \lambda^{l-1} - (W^l)^T \mu^l \right]_-^T \underline{x}^l - (b^l)^T \mu^l \end{aligned}$$

where  $[x]_+ = \max(x, 0)$ ,  $[x]_- = \min(x, 0)$  denote the positive and negative parts of  $x$ .

Similarly, collecting the terms involving  $z^l$ , we have, for  $l = 0, \dots, L-1$

$$\tilde{f}_l(\lambda^l, \mu^l) = \max_{z^l \in [\underline{z}^l, \bar{z}^l]} \mu^{lT} z^l - (\lambda^l)^T h^l(z^l)$$

where  $\lambda_{L-1} = -c$ .

Since  $h^l$  is a component-wise nonlinearity, each dimension of  $z^l$  can be optimized independently. For the  $k$ -th dimension, we obtain

$$\tilde{f}_{l,k}(\lambda_k^l, \mu_k^l) = \max_{z_k^l \in [\underline{z}_k^l, \bar{z}_k^l]} \mu_k^l z_k^l - \lambda_k^l h_k^l(z_k^l)$$

This is a one-dimensional optimization problem and can be solved easily- for common activation functions (ReLU, tanh, sigmoid, maxpool), it can be solved analytically, as discussed in appendix section 6.2. Finally, we need to solve

$$f_0(\mu^0) = \max_{x^0 \in \mathcal{S}_{in}(x^{nom})} \left( -(W^0)^T \mu_0 \right)^T x^0 - (b^0)^T \mu^0$$

which can also be solved easily given the assumption on  $\mathcal{S}_{in}$ . We work out some concrete cases in 6.3.

Once these problems are solved, we can construct the dual optimization problem:

$$\begin{aligned} \min_{\lambda, \mu} & \sum_{k=0}^{n_{L-1}} \tilde{f}_{L-1,k}(-c_k, \mu_k^L) + \sum_{l=0}^{L-2} \sum_{k=0}^{n_l} \tilde{f}_{l,k}(\lambda_k^l, \mu_k^l) \\ & + \sum_{l=1}^{L-1} f_l(\lambda^{l-1}, \mu^l) + f_0(\mu^0) + d \end{aligned} \quad (7)$$

This seeks to choose the values of  $\lambda, \mu$  so as to minimize the upper bound on the verification objective, thereby obtaining the tightest bound on the verification objective.

This optimization can be solved using a subgradient method on  $\lambda, \mu$ .

**Theorem 1.** *For any values of  $\lambda, \mu$ , the objective of (7) is an upper bound on the optimal value of (5). Hence, the optimal value of (7) is also an upper bound. Further, (7) is a convex optimization problem in  $(\lambda, \mu)$ .*

*Proof.* The upper bound property follows from weak duality [Vandenberghe and Boyd, 2004]. The fact that (7) is a convex optimization problem can be seen as each term  $f_l, \tilde{f}_{l,k}$  is expressed as a maximum over a set of linear functions of  $\lambda, \mu$  [Vandenberghe and Boyd, 2004].  $\square$

**Theorem 2.** *If each  $h$  is a ReLU function, then (7) is equivalent to the dual of the LP described in Ehlers [2017].*

*Proof.* See section 6.4.  $\square$

The LP formulation from Ehlers [2017] is also used in Kolter and Wong [2018]. The dual of the LP is derived in Kolter and Wong [2018] - however this dual is different from (7) and ends up with a constrained optimization formulation for the dual (the details of this can be found in appendix section 6.4.2). To allow for an unconstrained formulation, this dual LP is transformed to a backpropagation-like computation. While this allows for folding the verification into training, it also introduces nonconvexity in the verification optimization - our formulation of the dual differs from Kolter and Wong [2018] in that we directly solve an unconstrained dual formulation, allowing us to circumvent the need to solve a non-convex optimization for verification.

### 3.5 TOWARDS THEORETICAL GUARANTEES FOR VERIFICATION

The bounds computed by solving (7) could be loose in general, since (5) is an NP-hard optimization problem (section 6.4.1). SMT solvers and MIP solvers are guaranteed to find the exact optimum for piecewise linear neural networks, however, they may take exponential time to do so. Thus, an open question remains: Are there cases where it is possible to perform *exact verification* efficiently? If not, can we approximate the verification objective to within a certain factor (known a-priori)? We develop results answering these questions in the following sections.

*Prior work:* For any linear classifier, the scores of each label are a linear function of the inputs  $w_i^T x + b_i$ . Thus, the difference between the predictions of two classes  $j$  (target class for an adversary) and class  $i$  (true label) is  $(w_i - w_j)^T x$ . Maximizing this subject to  $\|x - x^0\|_2 \leq \epsilon$  can be solved analytically to obtain the value  $(w_i - w_j)^T x^0 + \|w_i - w_j\|_2 \epsilon$ . This observation formed the basis for algorithms in [Ragunathan et al., 2018] and [Hein and Andriushchenko, 2017]. However, once we move to nonlinear classifiers, the situation is not so simple and computing the worst case adversarial example, even in the 2-norm case, becomes a challenging task. In [Hein and Andriushchenko, 2017], the special case of kernel methods and single hidden layer classifiers are considered, but the approaches developed are only upper bounds on the verification objective (just like those computed by our dual relaxation approach). Similarly, in Ragunathan et al. [2018], a semidefinite programming approach is developed to compute bounds on the verification objective for the special case of adversarial perturbations on the infinity norm. However, none of these approaches come with a-priori guarantees on the quality of the bound, that is, before actually running the verification algorithm, one cannot predict how tight the

bound on the verification objective would be. In this section, we develop novel theoretical results that quantify when the verification problem (5) can be solved *either exactly or with a-priori approximation guarantees*. Our results require strong assumptions and do not immediately apply to most practical situations. However, we believe that they shed some understanding on the conditions under which exact verification can be performed tractably and lead to specialized verification algorithms that merit further study.

We assume the following for all results in this section:

- 1) We study networks with a single hidden layer, *i.e.*  $L = 2$ , with activation function  $h^0 = h$  and a linear mapping from the penultimate to the output layer  $x^2 = h^1(z^1) = z^1 = W^1 x^1 + b^1$ .
- 2) The network has a differentiable activation function  $h$  with Lipschitz-continuous derivatives denoted  $h'$  (tanh, sigmoid, ELU, polynomials satisfy this requirement).
- 3)  $\mathcal{S}_{in}(x^{nom}) = \{x^{in} : \|x^{in} - x^{nom}\|_2 \leq \epsilon\}$ .

Since the output layer is a linear function of the penultimate layer  $x^1$ , we have

$$\begin{aligned} c^T x^2 &= \left( (W^1)^T c \right)^T x^1 + c^T b^1 \\ &= \left( (W^1)^T c \right)^T h^0(z^0) + c^T b^1 \end{aligned}$$

For brevity, we simply denote  $(W^1)^T c$  as  $c$ , drop the constant term  $c^T b^1$  and let  $W = W^0$ ,  $b = b^0$ ,  $z^{nom} = W x^{nom} + b$  and  $W_i$  denote the  $i$ -th row of  $W$ . Then, (5) reduces to:

$$\max_{x^{in}: \|x^{in} - x^{nom}\|_2 \leq \epsilon} \sum_i c_i h_i(W_i x^{in} + b_i) \quad (8)$$

**Theorem 3.** *Suppose that  $h$  has a Lipschitz continuous first derivative:*

$$h'_i(t) - h'_i(\tilde{t}) \leq \gamma_i |t - \tilde{t}|$$

Let

$$\begin{aligned} \nu &= \|\text{diag}(c) W^T h'(z^{nom})\|_2 \\ L &= \sigma_{\max}(\text{diag}(c) W^T) \sigma_{\max}(\text{diag}(\gamma) W) \end{aligned}$$

Then  $\forall \epsilon \in (0, \frac{\nu}{2L})$ , the iteration:

$$x^{k+1} \leftarrow x^{nom} + \epsilon \left( \frac{W^T \text{diag}(c) h'(W x^k + b)}{\|W^T \text{diag}(c) h'(W x^k + b)\|_2} \right)$$

starting at  $x^0 = x^{nom}$  converges to the global optimum  $x^*$  of (8) at the rate  $\|x^k - x^*\| \leq \left( \frac{\epsilon L}{\nu - \epsilon L} \right)^k$

*Proof.* Section 6.4 □

Thus, when  $\epsilon$  is small enough, a simple algorithm exists to find the global optimum of the verification objective. However, even when  $\epsilon$  is larger, one can obtain a good approximation of the verification objective. In order to do this, consider the following quadratic approximation of the objective from (8):

$$\begin{aligned} \max \sum_i c_i (h_i(z_i^{nom}) + h'_i(z_i^{nom})(W_i z)) \\ + \sum_i \frac{c_i}{2} h''_i(z_i^{nom})(W_i z)^2 \end{aligned} \quad (9a)$$

$$\text{s.t. } \|z\|_2 \leq \epsilon \quad (9b)$$

This optimization problem corresponds to a trust region problem that can be solved to global optimality using semidefinite programming [Yakubovic, 1971]:

$$\begin{aligned} \max_{z, Z} \sum_i c_i (h_i(z_i^{nom}) + h'_i(z_i^{nom})(W_i z)) \\ + \sum_i \frac{c_i}{2} h''_i(z_i^{nom}) \text{tr}(W_i^T W_i Z) \end{aligned} \quad (10a)$$

$$\text{s.t. } \text{tr}(Z) \leq \epsilon, \begin{pmatrix} 1 & z^T \\ z & Z \end{pmatrix} \succeq 0 \quad (10b)$$

where  $X \succeq 0$  denotes that  $X$  is constrained to be a positive semidefinite matrix. While this can be solved using general semidefinite programming solvers, several special purpose algorithms exist for this trust region problem that can exploit its particular structure for efficient solution. [Hazan and Koren, 2016]

**Theorem 4.** *Suppose that  $h$  is thrice-differentiable with a globally bounded third derivative. Let*

$$\zeta_i = \|W_i\|_2, \eta_i = \sup_t |h_i'''(t)|, \kappa = \frac{1}{6} \left( \sum_i \eta_i c_i \zeta_i^3 \right)$$

For each  $\epsilon > 0$ , the difference between the optimal values of (10), (8) is at most  $\kappa \epsilon^3$ .

*Proof.* See Section 6.4 □

## 4 EXPERIMENTS

In this section, we present numerical studies validation our approach on three sets of verification tasks:

*Image classification on MNIST and CIFAR:* We use our approach to obtain guaranteed lower bounds on the accuracy of image classifiers trained on MNIST and CIFAR-10 under adversarial attack with varying sizes of the perturbation radius. We compare the bounds obtained by our method with prior work (in cases where prior work is applicable) and also with the best attacks found by various approaches.

*Classifier stability on GitHub data:* We train networks on sequences of commits on GitHub over a collection of 10K repositories - the prediction task consists of predicting whether a given repository will reach more than 40 commits within 250 days given data observed until a certain day. Input features consist a value between 0 and 1 indicating the number of days left until the 250th day, as well as another value indicating the progress of commits towards the total of 40. As the features evolve, the prediction of the classifier changes (for example, predictions should become more accurate as we move closer to the 250th day). In this situation, it is desirable that the classifier provides consistent predictions and that the number of times its prediction switches is as small as possible. It is also desirable that this switching frequency cannot be easily be changed by perturbing input features. We use our verification approach combined with dynamic programming to compute a bound on the maximum number of switches in the classifier prediction over time.

*Digit sum task:* We consider a more complex verification task here: Given a pair of MNIST digits, the goal is to bound how much the sum of predictions of a classifier can differ from the true sum of those digits under adversarial perturbation subject to a total budget on the perturbation across the two digits.

#### 4.1 IMAGE CLASSIFICATION: MNIST AND CIFAR

We study adversarial attacks subject to an  $l_\infty$  bound on the input perturbation. An adversarial example (AE) is a perturbation of an input of the neural network such that the output of the neural network differs from the correct label for that input. An AE is said to be within radius  $\epsilon$  if the  $l_\infty$  norm of the difference between the AE and the original input is smaller than  $\epsilon$ . We are interested in the *adversarial error rate*, that is,

$$\frac{\# \text{ Test examples that have an AE within radius } \epsilon}{\text{Size of test set}}$$

Computing this quantity precisely requires solving the NP-hard problem (5) for each test example, but we can obtain upper bounds on it using our (and other) verification methods and lower bounds using a fixed attack algorithm (in this paper we use a bound constrained LBFGS algorithm similar to [Carlini and Wagner, 2017b]). Since theorem 2 shows that for the special case of piecewise linear neural networks, our approach reduces to the basic LP relaxation from Ehlers [2017] (which also is the basis for the algorithms in Bunel et al. [2017] and Kolter and Wong [2018]), we focus on networks with smooth nonlinearities like tanh and sigmoid. We compare our approach with The SDP formulation from Raghunathan et al. [2018] (note that this approach only works for sin-

gle hidden layer networks, so we just show it as producing vacuous bounds for other networks).

Each approach gets a budget of 300 s per verification problem (choice of test example and target label). Since the SDP solver from [Raghunathan et al., 2018] only needs to be run once per label pair (and not per test example), its running time is amortized appropriately.

*Results on smooth activation functions:* Figures 1a,1b show that our approach is able to compute nearly tight bounds (bounds that match the upper bound) for small perturbation radii (up to 2 pixel units) and our bounds significantly outperform those from the SDP approach [Raghunathan et al., 2018] ( which is only able to compute nontrivial bounds for the smallest model with 20 hidden units).

*Results on models trained adversarially:* We use the adversarial training approach of [Uesato et al., 2018] and train models on MNIST and CIFAR that are robust to perturbations from the LBFGS-style attack on the training set. We then apply our verification algorithm to these robust models and obtain bounds on the adversarial error rate on the test set. These models are all multilayer models, so the SDP approach from [Raghunathan et al., 2018] does not apply and we do not plot it here. We simply plot the attack versus the bound from our approach. The results for MNIST are plotted in figure 2b and for CIFAR in figure 2a. On networks trained using a different procedure, the approaches from Raghunathan et al. [2018] and Kolter and Wong [2018] are able to achieve stronger results for larger values of  $\epsilon$  (they work with  $\epsilon = .1$  in real units, which corresponds to  $\epsilon = 26$  in pixel units we use here). However, we note that our verification procedure is agnostic to the training procedure, and can be used to obtain fairly tight bounds for any network and any training procedure. In comparison, the results in Kolter and Wong [2018] and Raghunathan et al. [2018] rely on the training procedure optimizing the verification bound. Since we do not rely on a particular adversarial training procedure, we were also able to obtain the first non-trivial verification bounds on CIFAR-10 (to the best of our knowledge) shown in figure 2a. While the model quality is rather poor, the results indicate that our approach could scale to more complicated models.

#### 4.2 GITHUB CLASSIFIER STABILITY

We allow the adversary to modify input features by up to 3% (at each timestep) and our goal is to bound the maximum number of prediction switches induced by each attack over time. We can model this within our verification framework as follows: Given a sequence of input features, we compute the maximum number of switches

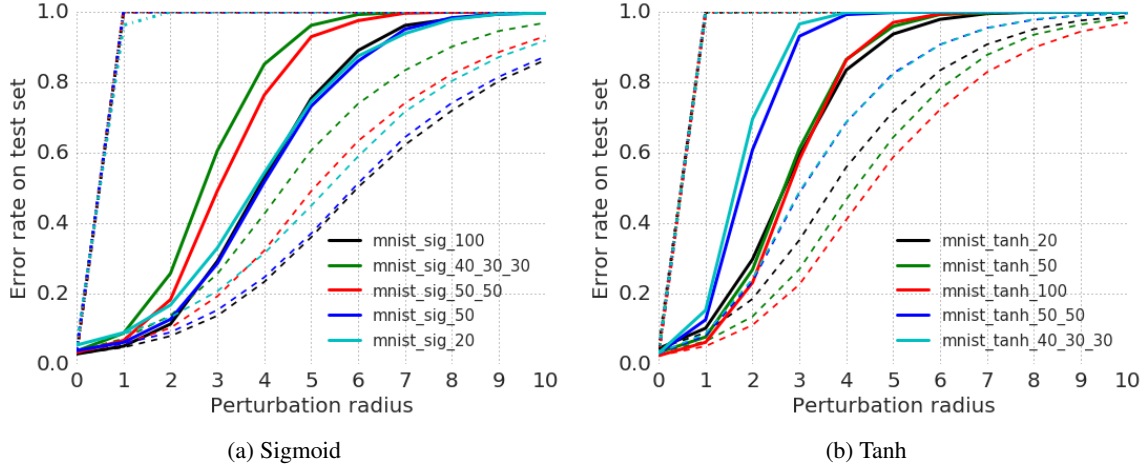

Figure 1: Figures show three curves per model - Dashed line: Lower bound from LBFSG attack. Solid line: Our verified upper bound. Dash-dot line: SDP verified upper bound from [Raghunathan et al., 2018]. Each color represents a different network. The dashed lines at the bottom are lower bounds on the error rate computed using the best attack found using the LBFSG algorithm.

achievable by first computing the target classes that are reachable through an adversarial attack at each timestep (using (7)), and then running a dynamic program to compute the choices of target classes over time (from within the reachable target classes) to maximize the number of switches over time.

Figure 3a shows how initially predictions are easily attackable (as little information is available to make predictions), and also shows how the gap between our approach and the best attack found using the LBFSG algorithm evolves over time.

### 4.3 COMPLEX VERIFICATION TASK: DIGIT SUM

In order to test our approach on a more complex specification, we study the following task: Given a pair of MNIST digits, we ask the question: Can an attacker perturb each image, subject to a constraint on the total perturbation across both digits, such that the sum of the digits predicted by the classifier differs from the true sum of those digits by as large an amount as possible? Answering this question requires solving the following optimization problem:

$$\begin{aligned} & \max_{\substack{x_a^{in}, x_b^{in} \\ \epsilon_a, \epsilon_b}} |\operatorname{argmax}(x^L(x_a^{in})) + \operatorname{argmax}(x^L(x_b^{in})) - s| \\ & \text{s.t. } \|x_a^{in} - x_a^{nom}\| \leq \epsilon_a, \|x_b^{in} - x_b^{nom}\| \leq \epsilon_b \\ & \quad \epsilon_a + \epsilon_b \leq \epsilon \end{aligned}$$

where  $s$  is the true sum of the two digits. Thus, the adversary has to decide on both the perturbation to each digit,

as well as the size of the perturbation. We can encode this within our framework (we skip the details here). The upper bound on the maximum error in the predicted sum from the verification and the lower bound on the maximum error computed from an attack for this problem (on an adversarially trained two hidden layer sigmoid network) is plotted in figure 3b. The results show that even on this rather complex verification task, our approach is able to compute tight bounds.

## 5 CONCLUSIONS

We have presented a novel framework for verification of neural networks. Our approach extends the applicability of verification algorithms to arbitrary feedforward networks with any architecture and activation function and to more general classes of input constraints than those considered previously (like cardinality constraints). The verification procedure is both efficient (given that it solves an unconstrained convex optimization problem) and practically scalable (given its anytime nature only required gradient like steps). We proved the first known (to the best of our knowledge) theorems showing that under special assumptions, nonlinear neural networks can be verified tractably. Numerical experiments demonstrate the practical performance of our approach on several classes of verification tasks.

## ACKNOWLEDGEMENTS

The authors would like to thank Brendan O’Donoghue, Csaba Szepesvari, Rudy Bunel, Jonathan Uesato and

(a) Verification of robust CIFAR-10 model as a function of perturbation radius  $\epsilon$ .

(b) Verification of robust models as a function of perturbation radius  $\epsilon$ . Solid lines:verified upper bounds and dashed lines: attack lower bounds.

(a) Maximum number of switches (over number of days evaluated so far) over different days (upper bound from our verification approach and lower bound from the best attack found). Results are averaged over 100 unseen repositories. Shaded areas are 95% confidence intervals.

(b) Maximum difference between predicted and actual sum of digits vs the perturbation budget for a pair of randomly chosen MNIST images.

Shane Legg for helpful comments and feedback on this paper. Jonathan Uesato's help on adversarial training of neural networks is also gratefully acknowledged.

## Abstract

Measuring uncertainty is a promising technique for detecting adversarial examples, crafted inputs on which the model predicts an incorrect class with high confidence. There are various measures of uncertainty, including predictive entropy and mutual information, each capturing distinct types of uncertainty. We study these measures, and shed light on why mutual information seems to be effective at the task of adversarial example detection. We highlight failure modes for MC dropout, a widely used approach for estimating uncertainty in deep models. This leads to an improved understanding of the drawbacks of current methods, and a proposal to improve the quality of uncertainty estimates using probabilistic model ensembles. We give illustrative experiments using MNIST to demonstrate the intuition underlying the different measures of uncertainty, as well as experiments on a real-world Kaggle dogs vs cats classification dataset.

## 1 INTRODUCTION

Deep neural networks are state of the art models for representing complex, high dimensional data such as natural images. However, neural networks are not robust: there exist small perturbations to the input of the network which produce erroneous and over-confident classification results. These perturbed inputs, known as adversarial examples (Szegedy et al., 2013), are a major hurdle for the use of deep networks in safety-critical applications, or those for which security is a concern.

One possible hypothesis for the existence of adversarial examples is that such images lie off the manifold of natural images, occupying regions where the model makes unconstrained extrapolations. If this hypothesis were to hold true, then one could detect adversarial perturbation

by measuring the distance of the perturbed input to the image manifold.

Hypothetically, such distances could be measured using nearest neighbour approaches, or by assessing the probability of the input under a density model on image space. However, approaches based on geometric distance are a suboptimal choice for images, as pixel-wise distance is a poor metric for perceptual similarity; similarly, density modelling is difficult to scale to the high dimensional spaces found in image recognition.

Instead, we may consider proxies to the distance from the image manifold. For example, the model uncertainty of a *discriminative* Bayesian classification model should

Figure 1: Uncertainty of a standard dropout network trained on MNIST, as measured by *mutual information*, visualized in the latent space obtained from a variational autoencoder. Colours are classes for each encoded training image. The background shows uncertainty, calculated by decoding each latent point into image space, and evaluating the mutual information between the decoded image and the model parameters. A lighter background corresponds to higher uncertainty.

be high for points far away from the training data, for a high-capacity model such as a deep network. Under the hypothesis that adversarial examples lie far from the image manifold, i.e. the training data, such uncertainty could be used to identify an input as adversarial.

The uncertainty of such models is not straightforward to obtain. Numerical methods for integrating the posterior, such as Markov Chain Monte Carlo, are difficult to scale to large datasets (Gal, 2016). As a result, approximations have been studied extensively. For example, approximate inference in Bayesian neural networks using dropout is a computationally tractable technique (Gal & Ghahramani, 2016) which has been widely used in the literature (Leibig et al., 2017; Gal, 2016). Dropout based model uncertainty can be used for the detection of adversarial examples, with moderate success (Li & Gal, 2017; Feinman et al., 2017; Rawat et al., 2017).

However, existing research has mostly overlooked the effect of the chosen *measure for uncertainty quantification*. Many such measures exist, including mutual information, predictive entropy and softmax variance. (Li & Gal, 2017) for example use expected entropy, (Rawat et al., 2017) use mutual information, whereas (Feinman et al., 2017) estimate the variance of multiple draws from the predictive distribution (obtained using dropout). Further, to date, research for the identification of adversarial examples using model uncertainty has concentrated on toy problems such as MNIST, and has not been shown to extend to more realistic data distributions and larger models such as ResNet (He et al., 2015).

In this paper we examine the differences between the various measures of uncertainty used for adversarial example detection, and in the process provide further evidence for the hypothesis that model uncertainty could be used to identify an input as adversarial. More specifically, we illustrate the differences between the measures by projecting the uncertainty onto lower dimensional spaces (see for example Fig. 1). We show that the softmax variance can be seen as an approximation to the mutual information (section 3.2), explaining the effectiveness of this rather ad-hoc technique. We show that some measures of uncertainty do not distinguish between non-adversarial off-manifold images (for example image interpolations) and adversarial inputs. We highlight ways in which dropout fails to capture the full Bayesian uncertainty by visualizing gaps in model uncertainty in the latent space (Section 4.2), and use this insight to propose a simple extension to dropout schemes to be studied in future research. We finish by demonstrating the effectiveness of dropout on the real-world ASIRRA (Elson et al., 2007) cats and dogs classification dataset (Section 4.3). Code for the experi-

ments described in this paper is available online<sup>1</sup>.

## 2 BACKGROUND

### 2.1 BAYESIAN DEEP LEARNING

A deep neural network (with a given architecture) defines a function  $f : \mathcal{X} \mapsto \mathcal{Y}$  parametrised by a set of weights and biases  $\omega = \{\mathbf{W}_l, \mathbf{b}_l\}_{l=1}^L$ . These parameters are generally chosen to minimize some loss function  $E : \mathcal{Y} \times \mathcal{Y} \mapsto \mathbb{R}$  on the model outputs and the target outputs over some dataset  $\mathcal{D} = \{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^N$  with  $\mathbf{x} \in \mathcal{X}$  and  $\mathbf{y} \in \mathcal{Y}$ . Since neural networks are highly flexible models with many degrees of freedom, a regulariser is often added to the loss, giving

$$\hat{\omega} = \arg \min_{\omega} \sum_i E(f(\mathbf{x}_i; \omega), \mathbf{y}_i) + \lambda \sum_l \|\mathbf{W}_l\|^2 \quad (1)$$

for the common choice of an  $L_2$  regulariser with weight decay  $\lambda$ .

In Bayesian approaches, rather than thinking of the weights as fixed parameters that are optimised over, we treat them as random variables, and so we place a prior distribution  $p(\omega)$  over the weights of the network. If we also have a likelihood function  $p(\mathbf{y} | \mathbf{x}, \omega)$  that gives the probability of  $\mathbf{y} \in \mathcal{Y}$  given the model parameters and an input to the network, we can conduct inference given a dataset by marginalizing the parameters. Such models are known as *Bayesian neural networks*.

If the prior on the weights is a zero mean Gaussian with diagonal covariance, and the loss of the network is the negative log likelihood (so  $p(\mathbf{y} | \omega, \mathbf{x}) = e^{-E(f(\mathbf{x}), \mathbf{y})}$ ) then the optimised solution in equation 1 corresponds to a mode of the posterior over the weights.

Ideally we would integrate out our uncertainty by taking the expectation of the predictions over the posterior, rather than using this point estimate. For neural networks this can only be done approximately. Here we discuss one practical approximation, variational inference with dropout approximating distributions.

### 2.2 VARIATIONAL INFERENCE

*Variational inference* is a general technique for approximating complex probability distributions. The idea is to approximate the intractable posterior  $p(\omega | \mathcal{D})$  with a simpler approximating distribution  $q_{\theta}(\omega)$ . By applying Jensen’s inequality to the Kullback-Leibler divergence between the approximating distribution and the true pos-

<sup>1</sup><https://github.com/lsgos/uncertainty-adversarial-paper>

terior, we obtain the log-evidence lower bound  $\mathcal{L}_{VI}$

$$\mathcal{L}_{VI} := \int q_{\theta}(\omega) \log p(\mathcal{D} | \omega) d\omega - D_{KL}(q_{\theta} || p(\omega)).$$

Since the model evidence is a constant independent of the parameters of  $q_{\theta}$ , maximizing  $\mathcal{L}_{VI}$  with respect to  $\theta$  will minimize the KL divergence between  $q$  and the model posterior. The key advantage of this from a computational perspective is that we replace an integration problem with an optimisation problem, maximising a parametrised function, which can be approached by standard gradient based techniques.

For neural networks, a common approximating distribution is *dropout* (Srivastava et al., 2014) and it’s variants. In the variational framework, this means the weights are drawn from

$$\mathbf{W}_l = \mathbf{M}_l \cdot \text{diag}([\mathbf{z}_{l,j}]_{j=1}^{K_l})$$

where  $\mathbf{z}_{l,j} \sim \text{Bernoulli}(p_l)$ ,  $l = 1..L, j = 1..K_{l-1}$

for a network with  $L$  layers, where the dimension of each layer is  $K_i \times K_{i-1}$ , and the parameters of  $q$  are  $\theta = \{\mathbf{M}_l, p_l | l = [1..L]\}$ . Informally, this corresponds to randomly setting the outputs of units in the network to zero (or zeroing the rows of the fixed matrix  $\mathbf{M}_l$ ). Often the layer dropout probabilities  $p_i$  are chosen as constant and not varied as part of the variational framework, but it is possible to learn these parameters as well (Gal et al., 2017). Using variational inference, the expectation over the posterior can be evaluated by replacing the true posterior with the approximating distribution. The dropout distribution is still challenging to marginalise, but it is readily sampled from, so expectations can be approximated using the Monte Carlo estimator

$$\begin{aligned} \mathbb{E}_{p(\omega|\mathcal{D})}[f^{\omega}(x)] &= \int p(\omega|\mathcal{D})f^{\omega}(x)d\omega \\ &\simeq \int q_{\theta}(\omega)f^{\omega}(x)d\omega \\ &\simeq \frac{1}{T} \sum_{i=1}^T f^{\omega_i}(x), \omega_{1..T} \sim q_{\theta}(\omega). \end{aligned} \quad (2)$$

### 2.3 ADVERSARIAL EXAMPLES

Works by (Szegedy et al., 2013) and others, demonstrating that state-of-the-art deep image classifiers can be fooled by small perturbations to input images, have initiated a great deal of interest in both understanding the reasons for why such adversarial examples occur, and devising methods to resist and detect adversarial attacks. So far, attacking has proven more successful than defence; a recent survey of detection methods by (Carlini & Wag-

ner, 2017a) found that, with the partial exception of the method based on dropout uncertainty analysed by (Feinman et al., 2017), all other investigated methods could be defeated straightforwardly.

There is no precise definition of when an example qualifies as ‘adversarial’. The most common definition used is of an input  $\mathbf{x}_{adv}$  which is close to a real data point  $\mathbf{x}$  as measured by some  $L_p$  norm, but is classified wrongly by the network with high score. Speaking more loosely, an adversarially perturbed input is one which a human observer would assign a certain class, but for which the network would predict a different class with a high score.

It is notable that there exists a second, related, type of images which have troubling implications for the robustness of deep models, namely meaningless images which are nevertheless classified confidently as belonging to a particular class (see, for example, Nguyen et al. (2015)). That such images can be found reveals another shortcoming of neural networks from the point of view of uncertainty, since they are far from all training data by any reasonable metric (based on either pixel-wise or perceptual distance). We refer to these as ‘rubbish class examples’ or ‘fooling images’ following (Nguyen et al., 2015) and (Goodfellow et al., 2014).

Several possible explanations for the existence of adversarial examples have been proposed in the literature (Akhtar & Mian, 2018). These include the idea, proposed in the original paper by (Szegedy et al., 2013), that the set of adversarial examples are a dense, low probability set like the rational numbers on  $\mathbb{R}$ , with the discontinuous boundary somehow due to the strong non-linearity of neural networks. Contrary to that, (Goodfellow et al., 2014) proposed that adversarial examples are partially due to the intrinsically linear response of neural network layers to their inputs. (Tanay & Griffin, 2016) have proposed that adversarial examples are possible when the decision boundaries are strongly tilted with respect to the vector separating the means of the class clusters.

Many of these ideas are consistent with the idea that the training data of the model lies on a low dimensional manifold in image space, the hypothesis we build upon in this paper.

### 2.4 MEASURES OF UNCERTAINTY

There are two major sources of uncertainty a model may have:

1. *epistemic* uncertainty is uncertainty due to our lack of knowledge; we are uncertain because we lack understanding. In terms of machine learning, this corresponds to a situation where our model parameters are poorly determined due to a lack of data, so

our posterior over parameters is broad.

2. *aleatoric* uncertainty is due to genuine stochasticity in the data. In this situation, an uncertain prediction is the best possible prediction. This corresponds to *noisy* data; no matter how much data the model has seen, if there is inherent noise then the best prediction possible may be a high entropy one (for example, if we train a model to predict coin flips, the best prediction is the max-entropy distribution  $P(\text{heads}) = P(\text{tails})$ ).

In the classification setting, where the output of a model is a conditional probability distribution  $P(y|x)$  over some discrete set of outcomes  $\mathcal{Y}$ , one straight-forward measure of uncertainty is the entropy of the predictive distribution

$$H[P(y|x)] = - \sum_{y \in \mathcal{Y}} P(y|x) \log P(y|x). \quad (3)$$

However, the predictive entropy is not an entirely satisfactory measure of uncertainty, since it does not distinguish between epistemic and aleatoric uncertainties. However, it may be of interest to do so; in particular, we want to capture when an input lies in a region of data space where the model is poorly constrained, and distinguish this from inputs near the data distribution with noisy labels.

An attractive measure of uncertainty able to distinguish epistemic from aleatoric examples is the information gain between the model parameters and the data. Recall that the mutual information (MI) between two random variables  $X$  and  $Y$  is given by

$$\begin{aligned} I(X, Y) &= H[P(X)] - \mathbb{E}_{P(y)} H[P(X | Y)] \\ &= H[P(Y)] - \mathbb{E}_{P(x)} H[P(Y | X)]. \end{aligned}$$

The amount of information we would gain about the model parameters if we were to receive a label  $y$  for a new point  $x$ , given the dataset  $\mathcal{D}$  is then given by

$$I(\omega, y | \mathcal{D}, x) = H[p(y | x, \mathcal{D})] - \mathbb{E}_{p(\omega | \mathcal{D})} H[p(y | x, \omega)] \quad (4)$$

Being uncertain about an input point  $x$  implies that if we knew the label at that point we would gain information. Conversely, if the parameters at a point are already well determined, then we would gain little information from obtaining the label. Thus, the MI is a measurement of the model’s *epistemic* uncertainty.

In the form presented above, it is also readily approximated using the Bayesian interpretation of dropout. The first term we will refer to as the ‘predictive entropy’; this is just the entropy of the predictive distribution, which we have already discussed. The second term is the mean of the entropy of the predictions given the parameters over the posterior distribution  $p(\omega | \mathcal{D})$ , and we thus refer to it as the expected entropy.

These quantities are not tractable analytically for deep

nets, but using dropout inference and equation (2), the predictive distribution, entropy and the MI are readily approximated; (Gal, 2016):

$$p(y | \mathcal{D}, \mathbf{x}) \simeq \frac{1}{T} \sum_{i=1}^T p(y | \omega_i, \mathbf{x}) \quad (5)$$

$$:= p_{MC}(y | \mathbf{x})$$

$$H[p(y | \mathcal{D}, \mathbf{x})] \simeq H[p_{MC}(y | \mathcal{D}, \mathbf{x})] \quad (6)$$

$$I(\omega, y | \mathcal{D}, x) \simeq H[p_{MC}(y | \mathcal{D}, \mathbf{x})] \quad (7)$$

$$- \frac{1}{T} \sum_{i=1}^T H[p(y | \omega_i, \mathbf{x})] \quad (8)$$

where  $\omega_i \sim q(\omega | \mathcal{D})$  are samples from the dropout distribution.

Other, measures of uncertainty include the empirical variance of the softmax probabilities  $p(y = c | \omega_i, \mathbf{x})$  (with the variance calculated over  $i$ ), and variation ratios (Gal, 2016), with the former commonly used in previous research on adversarial examples.

### 3 UNCERTAINTY FOR ADVERSARIAL EXAMPLE DETECTION

We start by explaining the type of uncertainty relevant for adversarial example detection under the hypothesis that adversarial images lie off the manifold of natural images, occupying regions where the model makes unconstrained extrapolations. We continue by relating the *softmax variance* measure of uncertainty to mutual information.

#### 3.1 WHAT KIND OF UNCERTAINTY?

Both the MI and predictive entropy should increase on inputs which lie far from the image manifold. Under our hypothesis, we expect both to be effective in highlighting such inputs. However, predictive entropy could also be high *near* the image manifold, on inputs which have inherent ambiguity. Such inputs could be ambiguous images, such as an image that contains both a cat and a dog, or more generally interpolations between classes, such as a digit that could be either a 1 or a 7. Such inputs would have high predictive probability for more than one class even in the limit of infinite data, yielding high predictive entropy (but low MI). Such inputs are clearly not adversarial, but would falsely trigger a hypothetical automatic detection system<sup>2</sup>. We demonstrate this experimentally in the next section.

Algorithms to find adversarial examples seek to create an example image with a different class to the original, typically by either minimising the predicted probability of

<sup>2</sup>We speculate that previous research using predictive entropy has not encountered this phenomenon due to insufficient coverage of the test cases.

the current class for an untargeted attack, or maximising the predicted probability of a target class. This has the side-effect of minimising the entropy of the predictions, a simple consequence of the normalisation of the probability. It is interesting to highlight that this also affects the uncertainty as measured by MI; since both the mutual information and entropy are strictly positive, the mutual information is bounded above by the predictive entropy (see equation 4). Therefore, the model giving low entropy predictions at a point is a sufficient condition for the mutual information to be low as well. Equally, the mutual information bounds the entropy from below; it is not possible for a model to give low entropy predictions when the MI is high. It is important to realise that this means that adversarial example algorithms implicitly seek low uncertainty examples: detecting adversarial examples, at least via model uncertainty, is *not* independent of being able to fool the model without explicit detection methods.

### 3.2 MI AND SOFTMAX VARIANCE

Some works in the literature estimate the epistemic uncertainty of a dropout model using the estimated variance of the MC samples, rather than the mutual information (Leibig et al., 2017; Feinman et al., 2017; Carlini & Wagner, 2017a). This is somewhat arbitrary for classification, but seems to work fairly well in practice. We suggest a possible explanation of the effectiveness of this measure, arguing that the softmax variance can be seen as a proxy to the mutual information.

One way to see the relation between the two measures of uncertainty is to observe that the variance is the leading term in the series expansion of the mutual information. For brevity, we denote the sampled distributions  $p(y | \omega_i, \mathbf{x})$  as  $p_i$  and the mean predictive distribution  $p_{MC}(y | \mathbf{x})$  as  $\hat{p}$ . These are in general distribution over  $C$  classes, and we denote the probability of the  $j^{th}$  class as  $\hat{p}_j$  and  $p_{ij}$  for the mean and  $i^{th}$  sampled distribution respectively. The variance score is the mean variance across the classes

$$\begin{aligned} \hat{\sigma}^2 &= \frac{1}{C} \sum_{j=1}^C \frac{1}{T} \sum_{i=1}^T (p_{ij} - \hat{p}_j)^2 \\ &= \frac{1}{C} \left( \sum_{j=1}^C \left( \frac{1}{T} \sum_{i=1}^T p_{ij}^2 \right) - \hat{p}_j^2 \right) \end{aligned} \quad (9)$$

And the mutual information score is

$$\begin{aligned} \hat{I} &= H(\hat{p}) - \frac{1}{T} \sum_i H(p_i) \\ &= \sum_j \left( \frac{1}{T} \sum_i p_{ij} \log p_{ij} \right) - \hat{p}_j \log \hat{p}_j \end{aligned}$$

Using a Taylor expansion of the logarithm,

$$\begin{aligned} \hat{I} &= \sum_j \left( \frac{1}{T} \sum_i p_{ij} (p_{ij} - 1) \right) - \hat{p}_j (\hat{p}_j - 1) + \dots \\ &= \sum_j \left( \frac{1}{T} \sum_i p_{ij}^2 \right) - \hat{p}_j^2 - \left( \frac{1}{T} \sum_i p_{ij} \right) + \hat{p}_j + \dots \\ &= \sum_j \left( \frac{1}{T} \sum_i p_{ij}^2 \right) - \hat{p}_j^2 + \dots \end{aligned} \quad (10)$$

we see that the first term in the series is identical up to a multiplicative constant to the mean variance of the samples.

This relation between the softmax variance and the mutual information measure could explain the effectiveness of the variance in detecting adversarial examples encountered by (Feinman et al., 2017). MI increases on images far from the image manifold and not on image interpolations (on which the predictive variance increases as well), with the variance following similar trends.

## 4 EMPIRICAL EVALUATION

In the next section we demonstrate the effectiveness of various measures of uncertainty as proxies to distance from the image manifold. We demonstrate the difference in behaviour between the predictive entropy and mutual information on image interpolations, for interpolations in the latent space as well as interpolations in image space. We continue by visualising the various measures of uncertainty, highlighting the differences discussed above. This is further developed by highlighting shortcomings with current approaches for uncertainty estimation, to which we suggest initial ideas on how to overcome and suggest new ideas for attacks (to be explored further in future research). We finish by assessing the ideas discussed in this paper on a real world dataset of cats vs dogs image classification.

### 4.1 UNCERTAINTY ON INTERPOLATIONS

We start by assessing the behaviour of the measures of uncertainty on image interpolations, comparing interpolations via convex combination  $(\lambda x_1 + (1 - \lambda)x_2, \lambda \in [0, 1], x_i \in \mathcal{D})$  in latent space to those in image space. A convex combination in image space will clearly produce off manifold images, while we assume that moving in latent space approximates the manifold of the data fairly closely. That model uncertainty can capture what we want in practice is demonstrated in Figures 2 and 3. We see that the MI distinguishes between these on-manifold and off-manifold images, whereas the entropy fails to do so. This is necessary for the hypothesis proposed in the introduction; if we are able to accurately capture the MI,

Figure 2: Entropy (middle) and the MI (bottom) vary along a convex interpolation between two images in latent space and image space (top). The entropy is high for regions along both interpolations, wherever the class of the image is ambiguous. In contrast, the MI is roughly constant along the interpolation in latent space, since these images have aleatoric uncertainty (they are ambiguous), but the model has seen data that resembles them. On the other hand, the MI has a clear peak as the pixel space interpolation produces out-of-sample images between the classes

Figure 3: The entropy (top) and mutual information (bottom) of the interpolation halfway between 3000 random points of different classes in the MNIST test set, showing that the two modes of interpolation have very different statistical properties with respect to the model uncertainty, as shown for a single example in figure 2.

it would serve well as a proxy for whether an images belongs to the learned manifold or not.

## 4.2 VISUALIZATION IN LATENT SPACE

We wish to gain intuition into how the different measures of uncertainty behave. In order to do so, we use a variational autoencoder (Kingma & Welling, 2013) to compress the MNIST latent space. We choose a latent space of two dimensions so we can use this to visualise the dataset. By decoding the image that corresponds to a point in latent space, we can classify the decoded image

Figure 4: The predictive entropy of the same network as in figure 1. Note the differences with the MI, which is low everywhere close to the data in the centre of the plot, but the entropy is high between the classes here. These points correspond to images which resemble digits, but which are inherently ambiguous. Note however that there are large regions of latent space where the predictive entropy is high and the MI low, despite being far from any training data.

and evaluate the network uncertainty, thus providing a two dimensional map of the input space. Figure 1 shows the latent space with the uncertainty measured using the MI, calculated using dropout. Similarly, Figure 4 shows the predictive entropy. Note the differences in uncertainty near the class cluster boundaries (corresponding to image interpolations) – the MI has low uncertainty in these regions, whereas the predictive entropy is high.

Another question of interest in this context is how well the dropout approximation captures uncertainty. The approximating distribution is fairly crude, and variational inference schemes are known to underestimate the uncertainty of the posterior, tending to fit an approximation to a local mode rather than capturing the full posterior<sup>3</sup>.

As seen from the figures, the network does a reasonable job of capturing uncertainty close to the data. However, the network’s uncertainty has ‘holes’ – regions where the predictions of the model are very confident, despite the images generated by the decoder here being essentially nonsense (see Figure 5). This suggests that, while the uncertainty estimates generated by MC dropout are useful,

<sup>3</sup>There are two reasons for this behaviour: firstly, that the approximating distribution  $q$  may not have sufficient capacity to represent the full posterior, and secondly, the asymmetry of the KL divergence, which penalizes  $q$  placing probability mass where the support of  $p$  is small far more heavily than the reverse.

Figure 5: A typical garbage class example from the ‘holes’ in latent space. This is classified as a 2 with high confidence.

they do not capture the full posterior, instead capturing local behaviour near one of its modes, since we would expect the uncertainty to be high for a neural network everywhere where it is not constrained by the training data due to the high capacity of the model.

This may offer an explanation as to why MC dropout nets are still vulnerable to adversarial attack; despite their treatment of uncertainty, there are still large regions where they are mistakenly overconfident due to the approximations used, which adversarial attack algorithms can exploit. It may be possible to deliberately find and exploit these ‘holes’ to create adversarial examples. This intuition suggests a simple fix; since a single dropout model averages over a single mode of the posterior, we can capture the posterior using an ensemble of dropout models using different initializations, assuming that these will converge to different local modes. We find that even a small ensemble can qualitatively improve this behaviour (Figure 6).

Figure 6: The MI calculated using an ensemble of dropout models, treating all of their predictions as Monte Carlo samples from the posterior. This mitigates some of the spuriously confident regions in latent space

It should be noted, though, that there is no guarantee that an ensemble of dropout models is a better approximation to the true posterior. It will approximate it well only if the posterior is concentrated in many local modes, all of roughly equal likelihood (since all the models in the ensemble are weighted equally), and a randomly initialized variational dropout net trained with some variant of gradient descent will converge to all of these modes with roughly equal probability<sup>4</sup>. Investigating possible theoretical justification for this ensembling procedure for variational models is a possible direction for future research.

### 4.3 EVALUATION ON CATS AND DOGS DATASET

It has been observed by (Carlini & Wagner, 2017a) that many proposed defences against adversarial examples fail to generalize from MNIST. Therefore, we also evaluate the various uncertainty measures on a more realistic dataset; the ASSIRA cats and dogs dataset (see Figure 7 for example images). The task is to distinguish pic-

<sup>4</sup>This description does coincide with common beliefs about neural network loss surfaces, for which there is some justification in the literature; see, for example, Choromanska et al. (2015)

Figure 7: Example adversarial images generated by the Momentum iterative method at  $\epsilon = 10$ , with original images on the left, adversarial images on the deterministic model in the second column, and those for the MC dropout model in the fourth column. The difference between the adversarial image and the original is shown on the right of each image.

Table 1: The AUC for the adversarial discrimination task described in the experiments section. Fields marked with (S) denote this quantity evaluated on a version of the dataset with unsuccessful adversarial examples (that do not change the label) removed. The success rate of each attack in changing the label is given as a measure of each attacks effectiveness on this dataset.

tures of cats and dogs. While this is not a state of the art problem, these are realistic, high resolution images. We finetune a ResNet model (He et al., 2015), pre-trained on Imagenet, replacing the final layer with a dropout layer followed by a new fully connected layer. We use 20 forward passes for the Monte Carlo dropout estimates. We use dropout only on the layers we retrain, treating the pre-trained convolutions as deterministic.

We compare the receiver operating characteristic (ROC) of the predictive entropy of the deterministic network, the predictive entropy of the dropout network (equation 7), and the MI of the dropout network (the MI is always zero if the model is deterministic; this corresponds to the approximating distribution  $q$  being a delta function). Note that we compare with the *same set of weights* (trained with dropout) – the only difference is whether we use dropout at test time. For each measure of uncertainty we generate the ROC plot by thresholding the uncertainty at different values, using the threshold to decide whether an input is adversarial or not.

The receiver operating characteristic is evaluated on a synthetic dataset consisting of images drawn at random from the test set and images from the test set corrupted by Gaussian noise, which comprise the negative examples, as well as adversarial examples generated with the Basic Iterative Method (Kurakin et al., 2016), Fast Gradient

method (Goodfellow et al., 2014), and Momentum Iterative Method (Dong et al., 2017). We test with the final attack because it is notably strong, winning the recent NIPS adversarial attack competition, and is simpler to adapt to stochastic models than the other strong attacks in the literature, such as that of Carlini and Wagner (Carlini & Wagner, 2017b).

We find that only the mutual information gets a useful AUC on adversarial examples. In fact, most other measures of uncertainty seem to be worse than random guessing; this suggests that this dataset has a lot of examples the model considers to be ambiguous (high aleatoric uncertainty), which mean that the entropy has a high false positive rate. The fact the AUC of the entropy is low suggests that the model is actually *more* confident about adversarial examples than natural ones under this measure.

An interesting quirk of this particular model is that the accuracy of using Monte Carlo estimation is lower than the point estimates, even though the uncertainty estimates are sensible. Possibly this is because the dropout probability is quite high; only a subset of the features in the later layers of a convnet are relevant to cat and dog discrimination, so this may be a relic of our transfer learning procedure; dropout does not normally have an adverse effect on the accuracy of fully trained models (Gal, 2016).

Figure 8: BIM with  $\epsilon = 5$

Figure 9: FGM with  $\epsilon = 5$

Figure 10: MIM with  $\epsilon = 5$

Figure 11: BIM with  $\epsilon = 10$

Figure 12: FGM with  $\epsilon = 10$

Figure 13: MIM with  $\epsilon = 10$

Figure 14: ROC plots for adversarial example detection with different measures of uncertainty and different attacks. From left to right: basic iterative method (BIM), fast gradient method (FGM), and momentum iterative method (MIM). Top row uses  $\epsilon$  of 5, bottom row uses  $\epsilon$  of 10. All use infinity norm. (succ) denotes the quantity evaluated only for successful adversarial examples. We suspect that the low FGM attack success rate is related to the difficulty we observe in identifying these using model uncertainty, however further investigation is required.

## 5 DISCUSSION & CONCLUSION

We have examined various measures of uncertainty for detecting adversarial examples, and provided both theoretical and experimental evidence that measuring the epistemic uncertainty with the mutual information is the most appropriate and effective for this task.

We do not claim, however, that using dropout provides a very convincing defence against adversarial attack. Our results (in agreement with previous literature on the subject) show that dropout networks are *more difficult* to attack than their deterministic counterparts, but attacks against them can still succeed while remaining imperceptible to the human eye, at least in the white-box setting we investigated.

It is worth noting, however, that these techniques for quantifying uncertainty can be derived without any explicit reference to the adversarial setting, and no assumptions are made about the distribution of adversarial examples.

By improving model robustness and dealing with uncertainty more rigorously, models become harder to fool as a side effect; model robustness and good uncertainty estimates are not independent, as discussed in section 3. We think the fact that dropout models can still be defeated by adversarial attack is at least partly because dropout is a fairly crude approximation that underestimates the uncertainty significantly, as we have demonstrated here. Looking for scalable ways to improve on the uncertainty quality captured by dropout is an important avenue for future research.

## Abstract

Causal discovery algorithms infer causal relations from data based on several assumptions, including notably the absence of measurement error. However, this assumption is most likely violated in practical applications, which may result in erroneous, irreproducible results. In this work we show how to obtain an upper bound for the variance of random measurement error from the covariance matrix of measured variables and how to use this upper bound as a correction for constraint-based causal discovery. We demonstrate a practical application of our approach on both simulated data and real-world protein signaling data.

## 1 INTRODUCTION

The discovery of causal relations is a fundamental objective in science, and the interest in causal discovery algorithms has increased rapidly since they were first established in the 1990s [Pearl, 2000, Spirtes et al., 2000]. In practice, it may happen that their predictions are not reproducible in independent experiments. In this article we show that the presence of measurement error may be a possible explanation for incorrect and inconsistent output and we propose a solution aimed to mitigate its ramifications.

The presence of measurement error complicates causal discovery, because measured quantities are typically not causes of one another, even when the variables that they represent are. Consider the example in Figure 1, and suppose that exercise  $E$  is a variable that can be controlled in an experiment, weight loss  $W$  can be measured very precisely, but the amount of burned calories  $C$  cannot be observed directly. Suppose we do have a measured quantity  $\tilde{C} = C + M_C$  with  $M_C$  a measurement error. Even

though exercise and weight loss are independent conditional on burned calories, they are not when we condition on the measurement  $\tilde{C}$ . If  $M_C$  is large, one might even find that the measurements of the calories are independent of exercise conditional on the weight loss. A researcher who is unaware of the measurement error could then draw incorrect conclusions (e.g. weight loss causes the burning of calories).

Figure 1: Example of causal discovery in the presence of measurement error. Gray shaded nodes are observed variables, white nodes are latent variables.

The example in Figure 1 illustrates the crucial difference between measurement error and disturbance terms that are usually considered in causal models. In particular, the fluctuations that are due to measurement error do not propagate to effect variables (e.g. measurement noise  $M_C$  in  $\tilde{C}$  cannot be seen in  $E$ ), whereas the effects of unmodeled causes do.

Following [Scheines and Ramsey, 2016, Zhang et al., 2017, Pearl, 2010] and [Kuroki and Pearl, 2014], we focus on *random* measurement error, an independent random variable that adds noise to the measurement of one variable in a model. We present a method that identifies an upper bound for the variance of random measurement error. This result builds on previous work where the identification of sets of variables that are d-separated by a common latent variable using vanishing tetrad constraints is considered, see [Silva et al., 2006, Pearl, 2010, Bollen, 1989, Sullivant et al., 2010]. Uncertainty regarding the size of the measurement error can be propagated to an uncertainty in the partial correlations of the latent variables that are yet unperturbed by measurement error,

see also [Harris and Drton, 2013]. This uncertainty can then be taken into account when performing statistical tests so that we have outputs: dependent, independent, or unknown. Although these types of outputs for independence tests have been already used in previous work, e.g. [Triantafillou et al., 2017], in that case the thresholds for the different decisions were hyperparameters of the algorithm, while we provide an adaptive and more principled way to set them. Similarly to previous work, our approach relies on strong faithfulness [Spirtes et al., 2000, Kalisch and Bühlmann, 2007, Maathuis et al., 2010] but crucially it does not require causal sufficiency, i.e. the absence of unmeasured confounders, as Zhang et al. [2017] do.

In this work, we propose a practical correction method for measurement error in the context of constraint-based causal discovery. We demonstrate the effectiveness of our approach in identifying causal structures using Local Causal Discovery (LCD) [Cooper, 1997] both on simulated data and real-world protein signaling data. Although we focus on one particular causal discovery algorithm, our ideas can be applied to other constraint-based causal discovery algorithms as well, but we consider this to be outside of the scope of this paper.

## 2 PRELIMINARIES

For the remainder of this paper, variables will be denoted by capital letters and sets of variables by bold capital letters. We will assume that the data-generating processes described here can be modeled by a causal graph  $\mathcal{G}$  with nodes  $V$  and directed and bidirected edges  $E$ , where some of the variables in  $V$  may be latent. When there is a directed edge from a variable  $X$  to a variable  $Y$ , we say that  $X$  is a direct cause of  $Y$ . When there is a sequence of directed edges from  $X$  to  $Y$  with all arrowheads pointing towards  $Y$  we call it a directed path, and we say that  $X$  is an ancestor of  $Y$ . Bidirected edges between two variables  $X$  and  $Y$  are used to represent hidden confounders. Conditional independence between  $X$  and  $Y$  while controlling for variables in  $Z$  is denoted by  $X \perp\!\!\!\perp Y \mid Z$ . If  $Z$  d-separates  $X$  from  $Y$ , we denote this as  $X \perp Y \mid Z$ .

In the absence of measurement error, the following commonly made assumptions allow us to relate conditional (in)dependences between disjoint sets of variables  $X, Y$ , and  $Z$  to d-separation in an underlying causal graph  $\mathcal{G}$  [Pearl, 2000, Spirtes et al., 2000]. Throughout the remainder of this paper we will assume that the common assumptions hold.

**Assumption 1** (Common Assumptions).

1. *There are no directed cycles in the causal graph.*

2. *Causal Markov Property: For all disjoint sets of variables  $X, Y, Z$ :  $X \perp Y \mid Z \implies X \perp\!\!\!\perp Y \mid Z$ .*
3. *Causal Faithfulness: For all disjoint sets of variables  $X, Y, Z$ :  $X \perp\!\!\!\perp Y \mid Z \implies X \perp Y \mid Z$ .*
4. *No selection bias is present.*

**Local causal discovery** The LCD (Local Causal Discovery) algorithm is a straight-forward and efficient search method to detect one specific causal structure from experimental data using dependence relations between variables in  $V$  [Cooper, 1997].<sup>1</sup> LCD uses both (conditional) independences and background knowledge to recover causal relations from data.

The LCD algorithm looks for triples of variables  $(X, Y, Z)$  for which (a)  $X$  is not caused by any observed variable and (b) the following (in)dependences hold:  $X \not\perp\!\!\!\perp Y$ ,  $Y \not\perp\!\!\!\perp Z$ , and  $X \perp\!\!\!\perp Z \mid Y$ . We henceforth call such triples *LCD triples*. Under the common assumptions, the causal model that corresponds to this independence pattern is shown in Figure 2.

Figure 2: An LCD triple has the above causal structure, with at least one of the dashed arrows present.

**Conditional (in)dependence testing** In practice, constraint-based causal discovery algorithms rely on a statistical test to assess the (in)dependence relationships between variables. For data that has a multivariate Gaussian distribution, a (conditional) independence corresponds to a vanishing (partial) correlation coefficient. For random variables  $(X_1, \dots, X_D) \sim \mathcal{N}(\mu, \Sigma)$ , the Pearson partial correlation can be calculated from the inverse covariance matrix, which we will denote by  $\Lambda = \Sigma^{-1}$ .

Conventionally, one calculates a p-value  $p_T$  for the (conditional) dependence between variables, so that dependence relations can be determined by

$$\begin{cases} X \not\perp\!\!\!\perp Y \mid Z & \text{if } p_T < \alpha \\ X \perp\!\!\!\perp Y \mid Z & \text{if } p_T > \beta, \end{cases} \quad (1)$$

where  $\alpha$  and  $\beta$  are thresholds for dependence and independence respectively. The nature of the relation is undecided when  $\alpha \leq p_T \leq \beta$ . Usually only a single threshold  $\alpha = \beta = 0.01$  or  $\alpha = \beta = 0.05$  is used.

<sup>1</sup>Triantafillou et al. [2017] give a conservative variant of LCD with an application to protein signaling data.

### 3 CAUSAL DISCOVERY UNDER MEASUREMENT ERROR

In this section we illustrate some possible negative effects of random measurement error on constraint-based causal discovery. To that end, we analyze the behavior of partial correlations for increasing measurement error in a simple model. We consider *random* measurement error, which is a vector of independent noise variables  $\mathbf{M} = (M_1, \dots, M_n)$ . The measurements of the random vector  $\mathbf{X} = (X_1, \dots, X_n)$  are then given by  $\tilde{\mathbf{X}} = (\tilde{X}_1, \dots, \tilde{X}_2) = \mathbf{X} + \mathbf{M}$ . This means that a measurement node  $\tilde{X}_i$  is always child-less and has precisely two parents:  $X_i$  and the measurement error source  $M_i$ .

In many practical applications, it is reasonable to assume that the measurement noise has a Gaussian distribution. For instance, when the measurement noise is the sum of many small independent sources of error, the measurement error approximates a normal distribution because of the central limit theorem. In this article we consider the case where the measurement error is Gaussian so that the measurement noise variables are given by  $\mathbf{M} = (M_1, \dots, M_n) \sim \mathcal{N}(0, \Sigma_M)$ , where  $\Sigma_M$  is a diagonal matrix.

#### 3.1 MOTIVATIONAL EXAMPLE

We illustrate the effects of measurement error on the following structural causal model:

$$\begin{aligned} X_1 &= E_1 \\ X_2 &= \beta_{12}X_1 + E_2 \\ X_3 &= \beta_{23}X_2 + E_3 \\ \tilde{X}_2 &= X_2 + M_2 \end{aligned}$$

where  $X_1$  and  $X_3$  are not affected by measurement error. In this model  $E_1, E_2$ , and  $E_3$  are normally distributed noise variables and  $M_2$  is a normally distributed random measurement error. The observed variables are  $X_1, \tilde{X}_2$ , and  $X_3$ , where the second represents the corrupted measurement of  $X_2$ . The corresponding causal graph is displayed in Figure 3.

Note that in the random measurement error model,  $(X_1, X_2, X_3)$  has the causal structure of an LCD triple, but  $(X_1, \tilde{X}_2, X_3)$  does not. Therefore  $X_1 \perp\!\!\!\perp X_3 \mid X_2$  and the partial correlation for the latent unmeasured variables satisfies  $\rho_{13|2} = 0$ . Let  $\tilde{\Sigma}$  be the covariance matrix of  $(X_1, \tilde{X}_2, X_3)$  and  $\tilde{\Lambda}$  its inverse. Then we have that

$$\tilde{\rho}_{13|2} = -\frac{\tilde{\Lambda}_{13}}{\sqrt{\tilde{\Lambda}_{11}\tilde{\Lambda}_{33}}} = \frac{-\beta_{12}\beta_{23}\tilde{\Sigma}_{11}\text{var}(M_2)}{|\tilde{\Sigma}|\sqrt{\tilde{\Lambda}_{11}\tilde{\Lambda}_{33}}} \neq 0,$$

for non-zero parameters, so that  $X_1 \not\perp\!\!\!\perp X_3 \mid \tilde{X}_2$ .

Figure 3: Causal graph of a model with random measurement error on  $X_2$ . Gray shaded nodes are observed variables (the others are latent), and coefficients alongside the arrows represent the coefficients in the model.

**Remark 1.** A statistical test with conventional thresholds would conclude that  $X_1$  and  $X_3$  are conditionally dependent conditional on the measurement  $\tilde{X}_2$ , if the measurement error is large enough. If we would incorrectly assume that there is no measurement error, so that  $X_2 = \tilde{X}_2$ , then the Markov assumption would appear to be violated.

#### 3.2 EMPIRICAL STUDY

For a better understanding of the impact of measurement error on causal discovery, we consider the effect of varying the measurement error variance  $\text{var}(M_2)$  relative to the total variance of the measurement  $\tilde{X}_2$  on the partial correlations in the motivational example.

Figure 4 shows the effect of increasing relative random measurement error on different partial correlations, where the dotted lines represent the  $\alpha = 0.05$  threshold at different sample sizes. It can be seen that for zero measurement error (so that  $\tilde{X}_2 = X_2$ ), only the yellow line is below the red and black dotted lines. In that case a conventional statistical test would indicate that all variables are marginally dependent and  $X_1 \perp\!\!\!\perp X_3 \mid \tilde{X}_2$ , so that  $(X_1, \tilde{X}_2, X_3)$  is an LCD triple, and the directed edge from  $\tilde{X}_2$  to  $X_3$  can be detected. For relative measurement errors larger than  $\sim 0.25$  this conditional independence is no longer detected (because the yellow line is above the black-dotted line).

In Figure 4 we can also observe that for sample size 100 and a relative measurement error larger than  $\sim 0.3$ , a conventional statistical test would indicate that  $X_1 \perp\!\!\!\perp \tilde{X}_2 \mid X_3$  since the partial correlation  $\tilde{\rho}_{12|3} \approx 0$  (i.e. below the red dotted line) and all other (partial) correlations indicate a dependence (i.e. above the red dotted line). Causal discovery algorithms cannot recover the correct causal structure from these constraints. In fact, the LCD algorithm would conclude that  $(X_1, X_3, \tilde{X}_2)$  is an LCD triple so that there must be a directed edge in the *reversed* direction.

Figure 4: Partial correlations in the random measurement error model in Figure 3. The dotted lines represent the critical values for the correlation at a significance level of  $\alpha = 5\%$  for different sample sizes. The parameter settings were  $\beta_{12} = 0.6$ ,  $\beta_{23} = 1.2$  and all noise variables had variance 1.0.

**Remark 2.** *The results of constraint-based causal discovery may depend on the sample size. This can be better understood by observing that the dependences that are identified by a statistical test, depend both on the size of the measurement error and the sample size. This may lead to inconsistent causal discoveries, which cannot be reproduced on new datasets.*

This example shows how measurement error interferes with detecting the correct causal structures, which may lead to edge deletions, insertions or reversals. Note that although we focused on the LCD algorithm here, the conclusions that we draw are more generally applicable to constraint-based causal discovery algorithms.

**Remark 3.** *For relative measurement error of  $\sim 0.25$  a conflicting set of (in)dependences arises for  $n = 100$ . Since both the yellow and purple line are below the red dotted line, a statistical test would indicate that  $X_1 \perp\!\!\!\perp X_3 \mid \tilde{X}_2$  and  $X_1 \perp\!\!\!\perp \tilde{X}_2 \mid X_3$ , while all variables are marginally dependent. But there is no model that satisfies the common assumptions and these (in)dependences.*

## 4 ERROR BOUND DETECTION

Recall that the true covariances of  $D$  random variables  $\Sigma$ , measurements  $\tilde{\Sigma}$  and random measurement errors  $\Sigma_M$  are related as follows:

$$\Sigma_M = \tilde{\Sigma} - \Sigma = \text{diag}(m_1, \dots, m_D)$$

where  $m_1, \dots, m_D > 0$  are the variances of the random measurement error associated with each variable. In this section we show how, under certain conditions, an upper bound for the variance of random measurement error can be obtained from observational data with random measurement error.

**Remark 4.** *Given an (unbiased) estimate of  $\Sigma_M$ , we can simply adjust the covariance matrix  $\tilde{\Sigma}$  as suggested by Pearl [2010]. In practice such an estimate of the covariance matrix of measurement error may not be available.*

We consider latent random variables  $X_1, \dots, X_4$  and their corresponding measurements  $\tilde{X}_1, \dots, \tilde{X}_4 \in \mathbf{V}$  with true covariance matrices  $\Sigma$  and  $\tilde{\Sigma}$  respectively. Our upper bound result relies on Lemma 1 which is due to Silva et al. [2006] and gives conditions<sup>2</sup> under which there exists a latent variable that d-separates the measured variables  $\tilde{X}_1, \dots, \tilde{X}_4$ .

**Lemma 1.** *Let  $X_1, \dots, X_4$  be variables in a linear-Gaussian model and let  $\tilde{X}_1, \dots, \tilde{X}_4$  be their measurements with random measurement error. If the correlations satisfy  $\tilde{\rho}_{ij} \neq 0$  for all  $i, j \in \{1, \dots, 4\}$  and  $\tilde{\Sigma}_{12}\tilde{\Sigma}_{34} = \tilde{\Sigma}_{13}\tilde{\Sigma}_{24} = \tilde{\Sigma}_{14}\tilde{\Sigma}_{23}$ , then there exists a node  $L$  in the true underlying DAG such that  $\tilde{X}_i \perp\!\!\!\perp \tilde{X}_j \mid L$  for all  $i \neq j \in \{1, \dots, 4\}$ .*

*Proof.* The proof can be found in Silva et al. [2006].  $\square$

When there exists a node  $L$  that d-separates  $\tilde{X}_1, \dots, \tilde{X}_4$ , then the causal graph and latent structure are represented by the causal graph in Figure 5. This follows from the fact that the variables with measurement error  $\tilde{X}_i$  can only have incoming arrows from  $X_i$  and  $M_i$  and never have any outgoing arrows. Because  $L$  d-separates all  $\tilde{X}_i$  there can be no collider at  $L$ .

Before we present our upper bound result, we introduce an adjusted covariance matrix:

$$\tilde{\Sigma}(u, j) = \tilde{\Sigma} - u \text{diag}(e_j),$$

where  $j \in \{1, 2, 3, 4\}$  and  $e_j$  is a standard basis vector. For all  $u$  such that  $\tilde{\Sigma}(u, j)$  is a valid covariance matrix, the adjusted partial correlations  $\tilde{\rho}_{ik|j}^u$  may be calculated from  $\tilde{\Lambda}(u, j) = (\tilde{\Sigma}(u, j))^{-1}$  as follows:

$$\tilde{\rho}_{ik|j}^u = -\frac{(\tilde{\Lambda}(u, j))_{ik}}{\sqrt{(\tilde{\Lambda}(u, j))_{ii}(\tilde{\Lambda}(u, j))_{kk}}}. \quad (2)$$

Theorem 1 shows how the adjusted partial correlation is related to the underlying causal graph in Figure 5. Corollary 1 shows how we can use adjusted partial correlations to find an upper bound for the measurement error on one variable.

<sup>2</sup>These conditions are known as *tetrad conditions* in the literature, see Bollen [1989], Sullivant et al. [2010], Drton et al. [2008], Sullivant et al. [2010]

Figure 5: Causal graph of upper bound pattern for model with random measurement error, where at least one of the dashed edges is present. The indexes  $1, \dots, 4$  can be permuted. Noise variables  $E_1, \dots, E_4$  may be present but are not drawn. Measurement errors  $M_1, \dots, M_4$  are present but not drawn.

**Theorem 1.** Let  $X_1, \dots, X_4, \tilde{X}_1, \dots, \tilde{X}_4$  and  $\tilde{\rho}_{ij}$  be as in Lemma 1. The true underlying DAG is as in Figure 5 if and only if there exists  $u > 0$  such that  $\tilde{\rho}_{13|2}^u = \tilde{\rho}_{14|2}^u = \rho_{34|2}^u = 0$ .

*Proof.* The proof can be obtained by explicitly calculating the adjusted partial correlations and applying Lemma 1. A complete proof can be found in the supplementary material.  $\square$

**Corollary 1.** Let  $m_2$  be the variance of the measurement error on  $X_2$ . If  $\tilde{\rho}_{13|2}^{u^*} = \tilde{\rho}_{14|2}^{u^*} = \tilde{\rho}_{34|2}^{u^*} = 0$  for some  $u^* > 0$  then  $m_2 \leq u^*$ .

*Proof.* Follows from the proof of Theorem 1.  $\square$

These results can also be applied in a practical, more general setting. If data is generated from a random measurement error model for variables  $V$ , we consider subsets of four variables. If we can find an adjustment  $u^*$  on the covariance matrix of this subset of variables so that the adjusted partial correlations in Theorem 1 vanish, then Corollary 1 implicates that this adjustment is an upper bound for the variance of random measurement error. To ensure that the causal structure of these four variables is as in Figure 5, we can test for the constraints in Lemma 1 (see [Bollen, 1989, Silva et al., 2006, Thoemmes et al., 2018]). When all variables are measured in a similar manner, it may be reasonable to assume that the variance of the measurement error is the same for all variables. Under this assumption, the upper bound for the measurement error can be extended to an upper bound for the measurement error variance on all variables.

Figure 6: Simulation results for measurement error upper bound detection.

**Data simulations** To empirically test the performance of the upper bound, we simulated 10000 datapoints for 10000 random models with causal structures as in Figure 5 with parameters chosen uniformly from the interval  $[-1, 1]$  and error variances chosen uniformly from the interval  $[0.5, 1]$ . We added random measurement error to each variable (the same variance was used for all variables) and minimized the sum of adjusted partial correlations in Corollary 1 to obtain an upper bound. The result in Figure 6 shows that this leads to a correct upper bound on the variance of the measurement error.

## 5 STRONG FAITHFULNESS

In this section we prove that conditional independences cannot be reliably detected in the presence of measurement error. We then discuss the *strong* faithfulness assumption and its repercussions. In the next section we will present our error correction method, which relies on an upper bound for measurement error and the strong faithfulness assumption.

Lemma 2 shows that for two dependent (sets of) variables, a conditional independence between these variables can never be detected if the conditioning set is subject to measurement error, *unless* the faithfulness assumption is violated.

**Lemma 2.** Let  $X, Y$  and  $\tilde{Z}$  be three sets of (disjoint) variables. If  $\tilde{Z}$  has measurement error with non-zero variance, then the (in)dependences

$$X \not\perp\!\!\!\perp Y \quad X \perp\!\!\!\perp Y | \tilde{Z},$$

must be due to a violation of the faithfulness assumption.

*Proof.* A faithfulness violation occurs when  $X \perp\!\!\!\perp Y | \tilde{Z}$  but  $\tilde{Z}$  does not d-separate  $X$  and  $Y$ . Since  $X$  and  $Y$  are dependent in the data there must be an open path between them by the Markov assumption. By definition of random measurement error the variables in  $\tilde{Z}$  are leaf nodes. Therefore  $\tilde{Z}$  cannot block the path between  $X$  and  $Y$ , so that  $X \not\perp\!\!\!\perp Y | \tilde{Z}$ .  $\square$

Under the assumption that all variables in the model have the same measurement error variance (e.g. because they are subject to the same source of measurement error), the variance of the measurement error must be zero whenever a marginal dependence and a conditional independence is detected, as shown in Proposition 1.

**Proposition 1.** *Let  $\tilde{X}, \tilde{Y}$  and  $\tilde{Z}$  be three sets of (disjoint) variables with measurement errors that have equal (possibly zero) variances. Under the faithfulness assumption, if  $\tilde{X} \not\perp\!\!\!\perp \tilde{Y}$  and  $\tilde{X} \perp\!\!\!\perp \tilde{Y} | \tilde{Z}$ , then the measurement error on all variables has zero variance.*

*Proof.* Follows directly from Lemma 2.  $\square$

Since constraint-based causal discovery algorithms rely both on the faithfulness assumption and on the results of conditional independence tests, poor performance is to be expected when variables are measured with error. In this article, we consider the *strong faithfulness* assumption [Spirtes et al., 2000] instead.

**Assumption 2.** (Strong faithfulness) *We assume that the data of the unobserved measurement-error-free variables is  $\lambda$ -strong faithful to the true underlying causal graph that generated it. That is, for all disjoint sets of variables  $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ :*

$$|\rho_{\mathbf{X}, \mathbf{Y} | \mathbf{Z}}| < \lambda \implies \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}.$$

The example in Figure 4 illustrates how the strong faithfulness assumption may alleviate some of the negative effects of measurement error, but may aggravate the risk of detecting wrong conditional independences. If the data is  $\lambda$ -strong faithful, then it is also  $\mu$ -strong faithful, where  $0 < \mu \leq \lambda$ , and  $\mu$  can then be treated as a tuning parameter. In Figure 4, for zero relative measurement error, the data is  $\mu$ -strong faithful for any  $\mu$  up to  $\lambda \sim 0.25$ . For  $\mu = 0.25$  we find from the partial correlations that  $X_1 \perp\!\!\!\perp \tilde{X}_3 | \tilde{X}_2$  upto a relative measurement error of approximately 0.3, but for large enough measurement error we may also wrongly detect that  $X_1 \perp\!\!\!\perp \tilde{X}_2 | X_3$ .<sup>3</sup>

The tuning parameter thus represents a trade-off between detecting as many as possible of the true conditional independences and wrongfully detecting conditional independences. For the identification of LCD triples this means that for small  $\mu$  and data that is corrupted by measurement error, we cannot detect the true LCD triples, while for large  $\mu$  we may detect false LCD triples, because we detect conditional independences between variables that are actually dependent.

<sup>3</sup>Small enough correlations correspond to d-separations in the underlying graph by the strong faithfulness assumption. By the causal Markov assumption, d-separations correspond to conditional independences.

## 6 ERROR PROPAGATION

In this section we consider propagation of an error bound on random measurement error to partial correlations. If the strong faithfulness assumption holds, the effectiveness of tuning the threshold parameter  $\lambda$  depends on the size of the measurement error. By taking measurement error into account, we aim to alleviate the adverse effect of wrongfully detecting conditional independences by including the possibility to adaptively assign ‘unknown’ to a statistical test result. In that case we could get the best of both worlds: detect the correct conditional independences and assign ‘unknown’ or ‘dependent’ to the conditional dependences.

We start by defining an adjusted covariance matrix for three variables. Let  $\mathbf{m} = (m_1, m_2, m_3)$  be the variances of the random measurement errors ( $M_1, M_2, M_3$ ) on the latent (unmeasured) variables ( $X_1, X_2, X_3$ ), and suppose that  $\mathbf{u}^* = (u_1^*, u_2^*, u_3^*)$  is an upper bound such that  $\mathbf{m} \preceq \mathbf{u}^*$ .<sup>4</sup> Suppose that  $\tilde{\Sigma}$  is the true covariance matrix of the measured variables  $\tilde{X}_1, \tilde{X}_2, \tilde{X}_3 \in \mathbf{V}$ . The adjusted covariance matrix is given by

$$\tilde{\Sigma}(\mathbf{u}) = \tilde{\Sigma} - \mathbf{u}^T I, \quad (3)$$

where  $I$  denotes the identity matrix, when  $\tilde{\Sigma}(\mathbf{u})$  has an inverse, otherwise  $\tilde{\Sigma}(\mathbf{u}) = \tilde{\Sigma}$ .

For  $0 \preceq \mathbf{u} \preceq \mathbf{u}^*$  we can find minimal and maximal absolute values of partial correlations based on  $\tilde{\Lambda}(\mathbf{u}) = (\tilde{\Sigma}(\mathbf{u}))^{-1}$ . We define

$$\tilde{\rho}_{12|3}^{\min} = \arg \min_{0 \preceq \mathbf{u} \preceq \mathbf{u}^*} \left| \frac{(\tilde{\Lambda}(\mathbf{u}))_{12}}{\sqrt{(\tilde{\Lambda}(\mathbf{u}))_{11}(\tilde{\Lambda}(\mathbf{u}))_{22}}} \right|, \quad (4)$$

$$\tilde{\rho}_{12|3}^{\max} = \arg \max_{0 \preceq \mathbf{u} \preceq \mathbf{u}^*} \left| \frac{(\tilde{\Lambda}(\mathbf{u}))_{12}}{\sqrt{(\tilde{\Lambda}(\mathbf{u}))_{11}(\tilde{\Lambda}(\mathbf{u}))_{22}}} \right|. \quad (5)$$

Under the  $\lambda$ -strong faithfulness assumption, the conditional (in)dependence relations can be determined as follows:

$$\begin{cases} X_1 \not\perp\!\!\!\perp X_2 | X_3 & \text{if } \tilde{\rho}_{12|3}^{\min} > \lambda \\ X_1 \perp\!\!\!\perp X_2 | X_3 & \text{if } \tilde{\rho}_{12|3}^{\max} < \lambda, \end{cases} \quad (6)$$

The nature of the relation is undecided when  $\tilde{\rho}_{12|3}^{\min} < \lambda$  and  $\tilde{\rho}_{12|3}^{\max} > \lambda$ .<sup>5</sup>

Although we consider a measurement error correction in cases where only one variable is conditioned upon, our

<sup>4</sup> $\preceq$  is the component-wise inequality between two vectors.

<sup>5</sup>In practical applications the covariance matrix  $\tilde{\Sigma}$  is estimated from data. The added uncertainty can be taken into account by using bootstrapping to obtain confidence intervals for  $\tilde{\rho}_{12|3}^{\min}$  and  $\tilde{\rho}_{12|3}^{\max}$ .

ideas can be trivially extended to accommodate larger conditioning sets when an upper bound on the measurement error is known for all variables involved<sup>6</sup>.

## 7 DATA SIMULATIONS

We now evaluate the effects of a measurement error correction on simulated data. For detailed descriptions of the simulation settings, we refer to the supplementary material.

### 7.1 CONDITIONAL INDEPENDENCE TESTING

To illustrate the effectiveness of the measurement error correction in identifying conditional (in)dependence relations, we generated data for three variables  $(X_1, X_2, X_3)$  from linear-Gaussian acyclic causal structures, possibly with latent confounders. We only considered triples that satisfied the  $\lambda$ -strong faithfulness assumption for  $\lambda = 0.1$  and  $X_1 \not\perp\!\!\!\perp X_2$  and  $X_2 \not\perp\!\!\!\perp X_3$ .

We simulated 2000 models where half of the models satisfied  $X_1 \perp\!\!\!\perp X_3 \mid X_2$ . From each model we generated 10000 samples and added normally distributed random measurement error to each variable with varying variance. The conditional (in)dependence between  $\tilde{X}_1 \perp\!\!\!\perp \tilde{X}_3 \mid \tilde{X}_2$  was tested in various ways: using a threshold on the p-value  $\alpha = 0.05$ , using a threshold  $\lambda = 0.1$  on the partial correlation, and using the same threshold with a measurement error correction with an upper bound on the measurement error of  $t$  times the true variance. We then calculated the error rate as the number of incorrect classifications relative to the total number of tests. Note that the amount of conditional (in)dependence relations that are assigned ‘unknown’ increases with the size of the measurement error and the tightness of the upper bound. For an evaluation of the amount of ‘unknown’ classifications we refer to the supplementary material.

Figure 7a shows that the measurement error correction slightly reduces the error rate for conditional dependences, and 7b shows that the error rate of detecting incorrect conditional dependences is greatly reduced.

### 7.2 APPLICATION TO LCD

Typically, when data is  $\lambda$ -strong faithful to the true underlying causal graph, the value of  $\lambda$  is not known and  $\lambda$  is therefore used as a tuning parameter instead. We generated triples  $(X_1, X_2, X_3)$  as in the previous simulation, but only selected triples where  $X_1$  was not caused

<sup>6</sup>In that case one considers a larger adjusted covariance matrix, and since the partial correlations are calculated from the covariance matrix one can use the same scheme to find minimal and maximal values for the absolute partial correlation.

by  $X_2$  and  $X_3$ . We added measurement error with a fixed variance. We then applied the LCD algorithm, testing conditional independences as in the previous section. We evaluated the results by checking whether the causal structure of the triples was correctly identified. Figure 7c shows that the precision of the algorithm with the measurement error corrected test results outperforms the standard methods.

We also consider the more realistic case where multiple variables are measured, the upper bound for the variance of the measurement error is not known in advance, and the data is not necessarily  $\lambda$ -strong faithful. To that end we simulated 10000 datapoints from a random acyclic model with 15 variables, where one variable was not caused by any of the other variables. We added measurement error to each variable with a fixed variance.

For the upper bound detection, we first tested whether the tetrad constraints vanished using Wishart’s test [Wishart, 1928] at the 5% level, and then used the result in Corollary 1 to obtain an upper bound for the measurement error. When we found multiple upper bounds (for multiple variables) we chose the median as an upper bound for the measurement error on all variables. Finally we applied the LCD algorithm, testing marginal (in)dependences with a t-test at the 5% level and conditional (in)dependences as in the previous experiments and using the detected upper bound. If we were not able to detect an upper bound, we assigned ‘unknown’ to every test result. We checked how often a correct causal structure was identified. In 200 repetitions of the experiment the upper bound was incorrect in only 3 cases and no upper bound was detected in 39 cases. Figure 7d shows that all methods score significantly better than the random baseline and that the precision for detecting LCD triples increases significantly when we use the measurement error correction.

## 8 PROTEIN SIGNALING NETWORKS

We present an application of our ideas to real-world protein signaling data that could be corrupted by measurement error. We used a dataset concerning the influence of protein abundances on the properties of a protein signaling network in human kidney cells [Lun et al., 2017], and obtained an upper bound for the variance of random measurement error from this data. In absence of a reliable ground truth for this experiment, we validated the results of a measurement error correction applied to the LCD algorithm by comparing it to a baseline derived from interventions in the data.

**Data description** For conditions  $j = 1, \dots, 20$  the abundance of a different protein labeled  $(GFP)_j$  was

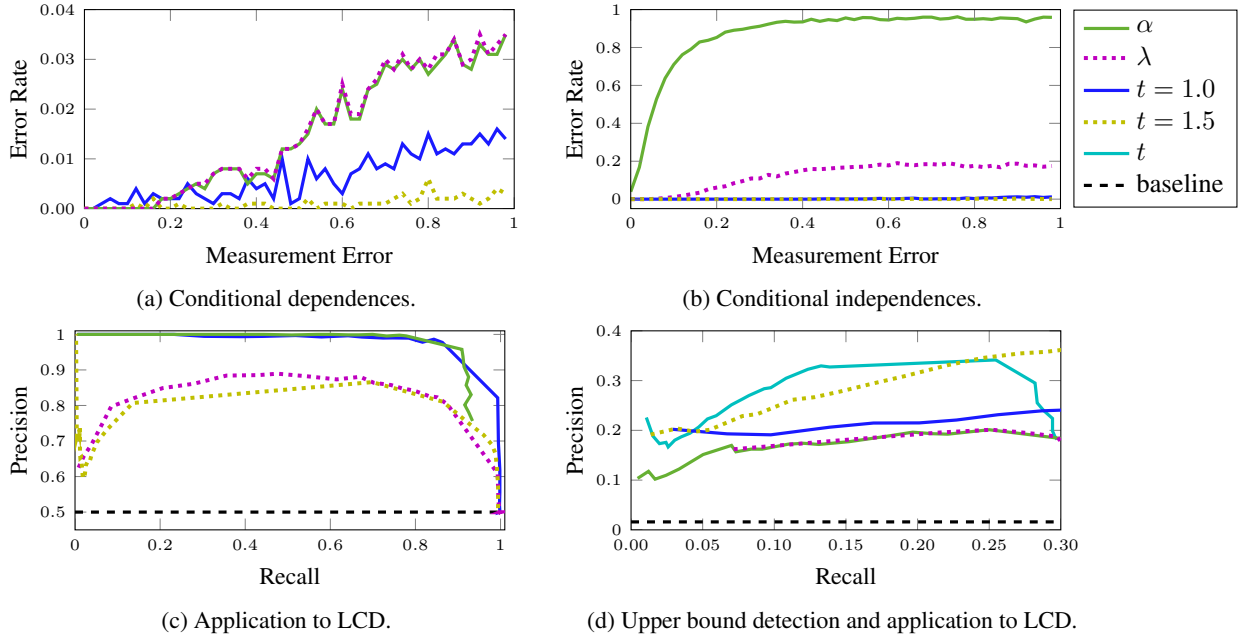

Figure 7: Simulation results. Figures a and b show the error rate for detecting conditional dependences and independences in the presence of measurement error for  $\lambda$ -strong faithful data. It is assumed that  $\lambda = 0.1$  is known, and  $\alpha = 0.05$ . Figure c shows the precision-recall curve for detecting LCD triples from  $\lambda$ -strong faithful data subject to measurement error with fixed variance and a given upper bound, where  $\lambda$  and  $\alpha$  are used as tuning parameters. Figure d shows the precision-recall curve for simulations of 15 variables, where we first apply the upper bound detection and then the measurement error correction and  $\alpha$  and  $\lambda$  are treated as tuning parameters. The baseline is at 0.016.

over-expressed and then measured [Lun et al., 2017]. The abundances of an additional 34 *phosphorylated* proteins  $P_i$  were measured after stimulation of the network. We relabeled conditions  $j$  so that over-expression of a protein  $(GFP)_j$  corresponds to the measured phosphorylated abundance  $P_j$ .

The abundance of an over-expressed protein typically differed between cells and not every cell was affected [Lun et al., 2017]. Because of the experimental design,  $(GFP)_j$  is not caused by the abundance or phosphorylation of the other proteins, which allowed us to treat the abundance of  $(GFP)_j$  as an intervention variable.

Typically  $\sim 10000$  single cells were measured for each condition. We assume that the data-generating process can be approximated by a linear-Gaussian model after pre-processing. For details about data pre-processing we refer to the supplementary material.

**Upper bound detection** We considered all proteins under over-expression of the SRC protein, for which strong signaling relations were present (see also [Lun et al., 2017]). For all 4-tuples  $((GFP)_{SRC}, P_i, P_j, P_k)$  that were all marginally dependent at the 1% level (using a t-test), we tested whether all three tetrads vanished using Wishart’s test at the 5% level. We found that these

constraints were satisfied for the 4-tuple  $((GFP)_{SRC}, pS6K, pMAPKAPK2, pMAP2K3)$ .

This allowed us to apply the results presented in Section 4 to obtain an upper bound. The upper bounds for the variance of measurement error that we found were 0.10 for pS6K, 0.15 for pMAPKAPK2, and 0.14 for pMAP2K3.<sup>7</sup> Since all proteins were measured with the same device, we assumed that the variance of the measurement error is the same for each variable, so that 0.14 is a suitable upper bound for the measurement error on any variable.

Although the detected upper bound was large for weak signals, the proteins with stronger signals typically had variances  $> 1$ , so that the relative amount of measurement error for proteins with strong signaling relations amounted to less than 10%.

**Baseline** To validate the results of LCD, we created a baseline from the interventions (corresponding to over-expression of certain proteins) in the dataset. A reasonable assumption is that  $(GFP)_j$  is a direct cause of  $P_j$ ,

<sup>7</sup>Each of the detected other bounds corresponds to adjusting the corresponding variable, as in Corollary 1. Other triples that satisfied the constraints gave similar or (much) higher upper bounds for the measurement error.

because the higher the abundance of a protein, the more it can be phosphorylated. Under the assumption that over-expression of a protein  $P_j$  does not alter the network structure [Lun et al., 2017] and that  $(\text{GFP})_j$  does not directly cause any of the other proteins  $P_i$ , with  $i \neq j$ , we have that  $P_j$  is a cause of  $P_k$ , whenever  $(\text{GFP})_j$  and  $P_k$  are dependent.

We constructed a baseline for cause-effect pairs  $(P_j, P_k)$ , where we considered 7 phosphorylated proteins  $P_j$  that were over-expressed in one of the conditions as cause variables and all 34 phosphorylated proteins as effect variables. The subset of proteins that was used to construct the baseline follows the recommendations in Lun et al. [2017]. We considered a pair  $(P_j, P_k)$  a causal pair, if a t-test indicated that  $(\text{GFP})_j$  and  $P_k$  were dependent at a level of  $10^{-4}$ . This resulted in 231 possible cause-effect pairs, 71% of which were cause-effect pairs in the baseline.

**Methods and results** We applied the LCD algorithm to the data to identify causal pairs  $(P_j, P_k)$  by treating  $(\text{GFP})_i$  as an intervention variable for conditions  $i \in \{1, \dots, 20\}$ , with  $i \neq j$  and  $i \neq k$ . Since central proteins in the network were over-expressed, true causal pairs were expected to appear under multiple conditions. To make our results more robust, we only made a positive prediction if a causal pair was predicted for at least 2 conditions. We applied three methods of conditional (in)dependence testing in combination with the LCD algorithm: a threshold  $\alpha$  on the p-value of t-tests, a threshold  $\lambda$  on the absolute value of partial correlations, and a threshold  $\lambda$  on partial correlations with a measurement error correction using the upper bound  $u = 0.14$ .

By treating  $\lambda$  and  $\alpha$  as tuning parameters and taking the baseline as ground truth, we calculated a precision-recall curve for each method of conditional (in)dependence testing. The results are displayed in Figure 8, which shows that  $\alpha$  and  $\lambda - u$  have comparable pr-curves. For this dataset there seems to exist a threshold  $\alpha$  that is already able to distinguish between conditional independences and dependences. We can see that both  $\lambda - u$  and  $\alpha$  significantly outperform random guessing, but  $\lambda$  does not. Although the differences between the methods are not significant, this seems to indicate that a measurement-error correction improves the precision at low recall for conditional independence testing with a fixed threshold on (partial) correlations.

## 9 CONCLUSION

In this paper we demonstrated that measurement error, when not taken into account, can fool causal discovery methods into wrongfully inserting, deleting or reversing

Figure 8: LCD applied to protein signaling data with  $\alpha$  or  $\lambda$  as tuning parameter and a measurement-error correction. The results are compared with the random baseline, the gray-shaded areas represent one and two standard deviations from the random baseline.

edges in the predicted causal graph. We showed that regular statistical tests with conventional thresholds would fail to detect conditional independences between the uncorrupted variables from the measurement data when measurement error is present. We also proposed a correction method aimed at mitigating the negative effects of measurement error.

The key result that we presented in this work is that, under certain conditions, we can find an upper bound for the variance of the measurement error from data that has been corrupted by measurement error. We show that this uncertainty can be propagated into an uncertainty regarding the partial correlations to correct for measurement error. We showed a successful application of our approach on simulated data.

We also applied our ideas to a real-world protein signaling dataset, and we found an upper bound for the variance of the measurement error in this dataset. We found that our approach gave significantly higher precision than a random baseline. However, also the conventional method without correction for measurement error seems to work well on this dataset. Nevertheless, it is our belief that taking measurement error into account is a promising step towards successful real-world applications of (constraint-based) causal discovery.

## Abstract

Advances in deep learning have led to substantial increases in prediction accuracy but have been accompanied by increases in the cost of rendering predictions. We conjecture that for a majority of real-world inputs, the recent advances in deep learning have created models that effectively “over-think” on simple inputs. In this paper we revisit the classic question of building model cascades that primarily leverage class asymmetry to reduce cost. We introduce the “*I Don’t Know*” (IDK) prediction cascades framework, a general framework to systematically compose a set of pre-trained models to accelerate inference without a loss in prediction accuracy. We propose two search based methods for constructing cascades as well as a new cost-aware objective within this framework. The proposed IDK cascade framework can be easily adopted in the existing model serving systems without additional model re-training. We evaluate the proposed techniques on a range of benchmarks to demonstrate the effectiveness of the proposed framework.

## 1 INTRODUCTION

Advances in deep learning have enabled substantial recent progress on challenging machine learning benchmarks. As a consequence, deep learning is being deployed in real-world applications, ranging from automated video surveillance, to voice-powered personal assistants, to self-driving cars. In these applications, accurate predictions must be delivered in *real-time* (e.g, under 200ms) under *heavy query load* (e.g., processing millions of streams) with *limited resources* (e.g., limited GPUs and power).

The need for accurate, low-latency, high-throughput, and

low-cost predictions has forced the machine learning community to explore a complex trade-off space spanning model and system design. For example, several researchers have investigated techniques for performing deep learning model compression [1, 2, 3]. However, model compression primarily reduces model memory requirements so as to fit on mobile devices or in other energy-bounded settings. There is a limit to how far compression-based techniques can be pushed to reduce latency at inference time while retaining state-of-the-art accuracy across all inputs.

We conjecture that in the pursuit of improved classification accuracy the machine learning community has developed models that effectively “*overthink*” on an increasing fraction of queries. To support this conjecture we show that while the cost of computing predictions has increased by an order of magnitude over the past 5 years, the accuracy of predictions on a large fraction of the ImageNet 2012 validation images has remained constant (see Fig. 2). This observation suggests that *if* we could distinguish between easy and challenging inputs (e.g., images) and only apply more advanced models when necessary, we could reduce computational costs without impacting accuracy. In this paper we study the design of *prediction cascades* as a mechanism to *exploit this conjecture* by combining fast models with accurate models to increase throughput and reduce mean latency without a loss in accuracy.

Though prediction cascades are well established in the machine learning literature [4, 5, 6, 7], the classic approaches focus on detection tasks and developed cascades for early rejection of negative object or region proposals – leveraging the class asymmetry of detection tasks. In this paper, we revisit the question of how to effectively build model cascades with little training overhead to trade off between prediction accuracy and cost, extending to any multi-class classification task.

We introduce *IDK prediction cascades*, a general framework to accelerate inference without reducing prediction

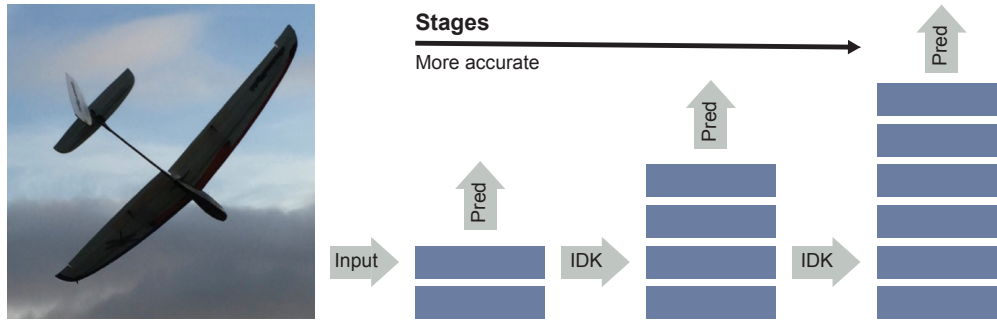

Figure 1: An IDK prediction cascade combines IDK classifiers of increasing accuracy and computational cost such that each will either render a high-accuracy prediction or return IDK passing the input to the next model in the cascade for a more accurate but higher cost prediction

accuracy by composing pre-trained models. IDK prediction cascades (see Fig. 1) are composed of IDK classifiers which are constructed by attaching an augmenting classifier to the existing classifiers, *base models*, enabling the IDK classifiers to predict an auxiliary “I don’t know” (IDK) class besides the original prediction classes. The augmenting classifiers, which are *light-weighted* (the computational cost is negligible compared to the cost of the base models) and *independent* from the base model architectures, measure the uncertainty of the base model predictions. When an IDK classifier predicts the IDK class the subsequent model in the cascade is invoked. The process is repeated until either a model in the cascade predicts a real class or the end of the cascade is reached at which point the last model must render a prediction. Furthermore, we can introduce a human expert as the last model in an IDK cascade to achieve nearly perfect accuracy while minimizing *the cost* of human intervention.

The base models in the model cascades are treated as black-boxes and thus the proposed framework can be applied to any existing model serving systems [8, 9] with little modification. In addition, the proposed IDK cascade framework model naturally fits the edge-cloud scenario where the fast models can be deployed on edge devices (e.g. Nvidia Drive PX2, Jetson TX2, etc.) while the expensive models are stored in the cloud and are only triggered when the fast model is not certain about a prediction.

To build such model cascade, we need to address the following problems: (1) without retraining the base models or obtaining the base model architecture, what is the best measure available to distinguish the easy and hard examples in the workload? (2) to construct the IDK classifiers that can effectively decide the execution path for the given input while not introducing additional computational overhead, what is the proper objective to balance the computational cost and the overall prediction accuracy of the model cascades?

In this work, we propose two search-based methods for constructing IDK classifiers: *cascading by probability* and *cascading by entropy*. Cascade by probability examines the confidence scores of a model directly to estimate uncertainty. Cascade by entropy leverages well-calibrated class conditional probabilities to estimate model uncertainty. Both techniques then search to find the optimal uncertainty threshold at which to predict the IDK class for each model in the cascade. When the uncertainty in a predicted class exceeds this threshold, the model predicts the IDK class instead. While both search-based methods produce reasonable prediction cascades, neither leverages the cascade design when *training* the augmenting classifier.

As a third approach to constructing IDK classifiers we cast the IDK cascade problem in the context of empirical risk minimization with an additional computational cost term and describe how the objective can be easily incorporated into gradient based learning procedures. The empirical risk minimization based approach allows the IDK classifier to trade-off between *cascade accuracy* and *computational cost* when building the prediction cascade.

We apply all three techniques to the image classification task on ImageNet2012 and CIFAR10 to demonstrate we can reduce computation by 37%, resulting in a 1.6x increase in throughput, while maintaining state-of-the-art accuracy. We conduct a detailed study of the impact of adding the computational-cost term to the objective and show that it is critical for training the augmenting classifiers. Compared to the cascades built with cost-oblivious objectives which cannot usually achieve the desired accuracy, the proposed cost-aware objective better serves the goal of model cascading. Furthermore, we demonstrate that in a real autonomous vehicle setting the IDK cascades framework can be applied in conjunction with human experts to achieve 95% accuracy on driving motion prediction task while requiring human intervention less than 30% of the time.

## 2 RELATED WORK

**Compression & Distillation.** Much of the existing work to accelerate predictions from deep neural networks has focused on model compression [3, 2, 1, 10] and distillation [11]. Denton et al. [2] applied low-rank approximations to exploit redundancy in convolution parameters to achieve a factor of two speedup with only 1% reduction in accuracy. Han et al. [10] introduced quantization and Huffman encoding methods to reduce network sizes by orders of magnitude and reduce prediction cost by a factor of 3 to 4. Our work on IDK prediction cascades is complementary to the work on model compression and focuses exclusively on decreasing computation costs. In fact, by coupling model compression with IDK cascades it may be possible to support more aggressive lossy compression techniques. Alternatively, Hinton et al. [11] proposed using soft-targets to transfer knowledge from a costly ensemble to a single model while largely preserving prediction accuracy. Our approach does not require retraining base models and instead focuses on accelerating inference by using more complex models only when necessary. The existing model compression and distillation techniques can be used to construct the fast base models while our framework serves as a bridge to connect models with different levels of complexity and accuracy.

**Cascaded Predictions.** Prediction cascades are a well suited approach to improve prediction performance. Much of the early work on prediction cascades was developed in the context of face detection. While Viola and Jones [5] are credited with introducing the terminology of prediction cascades, prior work by Rowley et al. [4] explored cascading neural networks by combining coarse candidate region detection with high accuracy face detection. More recently, Angelova et al. [6] proposed using deep network cascades and achieved real-time performances on pedestrian detection tasks. Cai et al. [7] also examined cascades for pedestrian detection, proposing a complexity aware term to regularize the cascade objective. While this approach has similarities to the loss function we propose, Cai et al. leverage the cost aware risk to

choose an optimal ordering of cascade elements rather than to train a specific classifier. These papers all focus on using cascades for detection tasks, and only use the earlier models in the cascade to reject negative region or object proposals more cheaply. Positive detection (e.g. object identification) can only be made by the final model in the cascade, which is the only model that can predict the full set of classes in the prediction task. Recently, Huang et al. [12] applied the cascading concept by allowing early exiting within the model. Instead of cascading features of a single model, we aim to cascade the trained models (one may not know the model structure or not be able to retrain) in a practical scenario.

**Uncertainty Classes.** The introduction of an IDK class to capture prediction uncertainty has also been studied under other settings. [13, 14]. Trappenberg [13] introduced an “*I don’t know*” (IDK) class to learn to identify input spaces with high uncertainty. Khani et al. [14] introduced a “*don’t know*” class to enable classifiers to achieve perfect precision when learning semantic mappings. In both cases, the addition of an auxiliary uncertainty class is used to improve prediction accuracy rather than performance. We build on this work by using the IDK class in the construction of cascades to improve performance.

## 3 A MOTIVATING EXAMPLE

In the pursuit of improved accuracy, deep learning models are becoming increasingly expensive to evaluate. To illustrate this trend, in Fig. 2c we plot the throughput for six benchmark models on the ImageNet 2012 datasets. We observe that prediction throughput has decreased by more than an order of magnitude. We expect the trend towards more costly models to continue with improvements in model design and increased adoption of ensemble methods [11]. In contrast, as Fig. 2b shows, the gains in prediction accuracy have increased much more slowly. A result of this trend is that even the cheaper and less advanced models can correctly classify many of the examples.

**Easy Samples.** For many prediction tasks, less accurate models are adequate *most of the time*. For example, a security camera may observe an empty street most of the time and require a more sophisticated model only in the infrequent events that people or objects enter the scene. Even in the standard benchmarks, many of the examples can be correctly classified by older, less advanced models. In Fig. 2d we plot the percentage of images that were correctly classified by an increasing fraction of models. We observe that a large fraction ( $\approx 48\%$ ) of the images are correctly classified by all six of the models, suggesting that these images are perhaps *inherently easier* and may not require the recent substantial increases in model complexity and computational cost.

## 4 IDK PREDICTION CASCADES

We start describing the IDK prediction cascade framework by examining simple two model cascades and then extend these techniques to deeper cascades at the end of this section. We start by formalizing two element cascades for the multiclass prediction problem.

We consider the  $k$  class multiclass prediction problem in which we are given two pre-trained models: (1) a fast but less accurate model  $m^{\text{fast}}$  and (2) an accurate but more costly model  $m^{\text{acc}}$ . In addition, we assume that the fast model estimates the class conditional probability:

$$m^{\text{fast}}(x) = \hat{\mathbf{P}}(\text{class label} \mid x). \quad (1)$$

Many multi-class estimators (e.g., DNNs trained using cross entropy) provide class conditional probabilities. In addition, we are given a dataset  $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$  consisting of  $n$  labeled data points.

To develop IDK prediction cascades we introduce an additional **augmenting classifier**:

$$h_\alpha(m^{\text{fast}}(x)) \rightarrow [0, 1], \quad (2)$$

which evaluates the *distributional output* of  $m^{\text{fast}}(x)$  and returns a number between 0 and 1 encoding how *uncertain* the fast model  $m^{\text{fast}}(x)$  is about a given prediction. The **IDK classifier** is composed of the base model and the augmenting classifier. For simplicity, we will refer to training the augmenting classifier as training the IDK classifier. In this paper we consider several designs for the IDK classifier:

$$h_\alpha^{\text{prb}}(m^{\text{fast}}(x)) = \mathbb{I} \left[ \max_j m^{\text{fast}}(x)_j < \alpha \right] \quad (3)$$

$$h_\alpha^{\text{ent}}(m^{\text{fast}}(x)) = \mathbb{I} \left[ \mathbf{H} \left[ m^{\text{fast}}(x) \right] > \alpha \right] \quad (4)$$

$$h_\alpha^{\text{cst}}(m^{\text{fast}}(x)) = \sigma \left( \alpha_1 f_{\alpha_2} \left( m^{\text{fast}}(x) \right) + \alpha_0 \right), \quad (5)$$

where  $\mathbb{I}$  is the indicator function,  $\mathbf{H}$  is the *entropy* function:

$$\mathbf{H}[m^{\text{fast}}(x)] = - \sum_{j=1}^k m^{\text{fast}}(x)_j \cdot \log m^{\text{fast}}(x)_j, \quad (6)$$

and  $f$  is a feature representation of  $m^{\text{fast}}(x)$ .

While  $f$  can be any featurization of the prediction  $m^{\text{fast}}(x)$ , in this work we focus on the entropy featurization  $f = \mathbf{H}$  as this is a natural measure of uncertainty. When using the entropy featurization, the IDK classifier  $h^{\text{cst}}$  becomes a differentiable approximation of  $h^{\text{ent}}$  enabling direct cost based optimization. In our experimental evaluation, we also evaluate  $f_{\alpha_2}(m^{\text{fast}}(x)) = \mathbf{NN}_{\alpha_2}(m^{\text{fast}}(x))$  which recovers a neural feature encoding of  $x$  and allows us to assess a neural network based IDK classifier in the context of the differentiable cost based optimization.

Given an IDK classifier  $h_\alpha(\cdot)$  we can define a two element IDK prediction cascade as:

$$m^{\text{casc}}(x) = \begin{cases} m^{\text{fast}}(x) & \text{if } h_\alpha(m^{\text{fast}}(x)) \leq 0.5 \\ m^{\text{acc}}(x) & \text{otherwise.} \end{cases} \quad (7)$$

Thus, for a given choice of IDK classifier  $h_\alpha$  we only need to determine the optimal value for parameter  $\alpha$  to ensure maximum accuracy while minimizing the fraction of examples for which the more expensive model is required. In the following, we formalize this objective and describe a set of techniques for choosing the optimal value of  $\alpha$ .

Given the above definition of an IDK prediction cascade we can define two quantities of interest. We define the accuracy  $\mathbf{Acc}(m)$  of a model  $m$  as the zero-one prediction accuracy evaluated on our training data  $\mathcal{D}$ :

$$\mathbf{Acc}(m) = \frac{1}{n} \sum_{i=1}^n \mathbb{I} \left[ y_i = \arg \max_j m(x_i)_j \right]. \quad (8)$$

We define the IDK rate  $\mathbf{IDKRate}(h)$  of an IDK classifier  $h$  as the fraction of training examples that are evaluated by the next model in the cascade:

$$\mathbf{IDKRate}(h) = \frac{1}{n} \sum_{i=1}^n \mathbb{I} \left[ h_\alpha(m^{\text{fast}}(x_i)) > 0.5 \right]. \quad (9)$$

Our goal in designing a prediction cascade is then to maintain the accuracy of the more accurate model while minimizing the IDK rate (i.e., the fraction of examples that require the more costly  $m^{\text{acc}}$  model). We formalize this goal as:

$$\min_{\alpha} \mathbf{IDKRate}(h_\alpha) \quad (10)$$

$$\text{s.t.: } \mathbf{Acc}(m^{\text{casc}}) \geq (1 - \epsilon) \mathbf{Acc}(m^{\text{acc}}). \quad (11)$$

In the following we describe a set of search procedures for achieving this goal for each of the IDK classifier designs.

#### 4.1 BASELINE UNCERTAINTY CASCADES

Similar to [15], as a baseline, we propose using the *confidence scores* (i.e. probability over the predicted class) of  $m^{\text{fast}}(x)$  and follow the IDK classifier design (Eq. 3). The intuition is that if the prediction of  $m^{\text{fast}}$  is insufficiently confident then the more accurate classifier is invoked.

A more rigorous measure of prediction uncertainty is the entropy of the class conditional probability. We therefore propose an entropy based IDK classifier in Eq. 4. The entropy based IDK classifier captures the overall uncertainty as well as the certainty within the dominant class.

Due to the indicator functions neither the *cascade by probability* (Eq. 3) nor the *cascade by entropy* functions (Eq. 4) are differentiable. However, because the parameter  $\alpha$  is a single scalar, we can apply a simple grid to search procedure to find the optimal value for the threshold  $\alpha$ .

#### 4.2 REGULARIZING FOR PREDICTION COST

The uncertainty based cascades described above adopt a relatively simple IDK classifier formulation and rely on grid search to select the optimal parameters. However, by reframing the cascade objective in the context of regularized empirical risk minimization and defining a differentiable regularized loss we can admit more complex IDK classifiers.

In the framework of empirical risk minimization, we define the objective as the sum of the loss  $\mathbf{L}(\cdot, \cdot)$  plus the *computational cost*  $\mathbf{C}(\cdot)$  of invoking the cascaded model:

$$J(\alpha) = \frac{1}{n} \sum_{i=1}^n [\mathbf{L}(y_i, m_\alpha^{\text{casc}}(x_i)) + \lambda \cdot \mathbf{C}(m_\alpha^{\text{casc}}(x_i))] \quad (12)$$

where  $\lambda$  is a hyper parameter which determines the trade-off between the cascade accuracy and the computational cost. Because we are not directly optimizing the fast or accurate models we can adopt the zero-one loss which is compatible with our earlier accuracy goal:

$$\mathbf{L}(y_i, m_\alpha^{\text{casc}}(x_i)) = \left(1 - h_\alpha(m^{\text{fast}}(x))\right) \cdot \mathbb{I}[y_i, m^{\text{fast}}(x_i)] + h_\alpha(m^{\text{fast}}(x)) \cdot \mathbb{I}[y_i, m^{\text{acc}}(x_i)], \quad (13)$$

where  $\mathbb{I}[y_i, m(x_i)]$  is 1 if  $\arg \max_j m(x_i)_j \neq y_i$  and 0 otherwise. The IDK classifier  $h_\alpha(m^{\text{fast}}(x))$  governs which loss is incurred. It is worth noting that alternative loss formulations could be used to further fine-tune the underlying fast and accurate model parameters in the cascaded setting.

The cascaded prediction cost  $\mathbf{C}(\cdot)$  is defined as:

$$\mathbf{C}(m_\alpha^{\text{casc}}(x_i)) = c^{\text{fast}} + h_\alpha(m^{\text{fast}}(x)) \cdot c^{\text{acc}}, \quad (14)$$

where the computational cost of  $m^{\text{fast}}$  and  $m^{\text{acc}}$ , are denoted by  $c^{\text{fast}}$  and  $c^{\text{acc}}$  respectively. In practice, the cost of model  $m^{\text{fast}}$  and  $m^{\text{acc}}$  could be measured in terms of multi-adds, latency, or number of parameters. The formulation of Eq. 14 captures the cascade formulation in which the fast model is always evaluated and the accurate model is evaluated conditioned on the IDK classifier decision.

Combining both prediction loss and computational cost of the IDK cascade, we can now use this *regularized loss* objective function to optimize the IDK prediction cascade with stochastic gradient descent based algorithms. This objective allows us to optimize both prediction precision and overall computational cost in one pass and support more complex parametric IDK classifiers.

#### 4.3 BEYOND TWO ELEMENT CASCADES

We can extend the two element cascade to construct deeper cascades by introducing additional IDK classifiers between each model and then either optimizing the IDK classifier parameters in a stage-wise fashion or by jointly optimizing the IDK classifiers using the extended loss function. More precisely, for an  $N$ -model cascade where  $m^j$  is the  $j$ -th model in the cascade, we define  $N - 1$  IDK classifiers  $h_{\alpha_j}(m^j(x))$ . For non-differentiable IDK classifiers with scalar parameters we can apply the grid search procedure in a stage wise fashion starting with the least accurate model. For more complex differentiable IDK classifiers we can define an extended loss:

$$\mathbf{L}(y_i, m_\alpha^{\text{casc}}(x_i)) = \sum_{j=1}^N \prod_{q=0}^{j-1} p_q (1 - p_j) \mathbb{I}[y_i, m^j(x_i)] \quad (15)$$

where  $p_j = h_{\alpha_j}(m^j(x))$  and  $p_0 = p_N = 1$ . The computational cost function  $\mathbf{C}(\cdot)$  is then generalized as

$$\mathbf{C}(m_\alpha^{\text{casc}}(x_i)) = \sum_{j=1}^N \prod_{q=0}^{j-1} p_q c^j \quad (16)$$

## 5 EXPERIMENTS

In this section, we evaluate the proposed cascading methods in two scenarios: cascading machine learning models with different computation budgets and collaboration between algorithms and human.

To study the prediction accuracy and cost trade-off under each cascade design, we use standard image classification benchmark tasks and models. We evaluate the cascaded models on ImageNet 2012 [16] and CIFAR-10 [17]. We assess whether the proposed IDK cascade approaches can match the state-of-the-art accuracy while significantly reducing the cost of rendering predictions. We also evaluate the robustness of the proposed framework on CIFAR-10.

Figure 3: ImageNet Two Model Cascades. **Prob+Grid**: cascade by probability with grid search. **Entropy+Grid**: cascade by entropy with grid search. **NN+Binary**: Neural Network based IDK classifier trained with cost-oblivious cross-entropy loss. **Entropy+Binary**: Entropy based IDK classifier trained with cost-oblivious cross-entropy loss. **Entropy+Cost**: Entropy based IDK classifier with cost-aware objective. **Oracle**: Using ground truth correctness labels as IDK classifier. The comparison of **Prob+Grid**, **Entropy+Grid** and **Entropy+Cost** demonstrates that the proposed cost-aware objective is more effective in constructing model cascades with lower computational costs. The comparison of **NN+Binary**, **Entropy+Binary**, **Entropy+Cost** shows that the vanilla cross-entropy loss commonly used for binary classification leads to a model cascade with lower IDK rate but not achieving the *desired accuracy*

To assess how cascades can be used to augment models with human intervention, we evaluate a motion prediction task, a representative of autonomous vehicle workloads [18]. In this human-in-the-loop prediction task, the human serves as the *accurate* model to further improve the accuracy and safety of autonomous driving. The cascade design is used to determine when the fast model can no longer be trusted and human intervention is required (e.g., by taking over steering).

We evaluate each cascade using a range of different metrics. The **accuracy** and **IDK rate** correspond to the accuracy and IDK rate defined in Eq. 8 and Eq. 9 respectively. In the multi-model cascade setting, we measure **IDK Rate** at each level in the cascade. As a measure of computational cost we compute the **average flops** which is the average floating point arithmetic operations required by the model cascade. Finally, as a relative measure of runtime we compute the **relative computational cost** which is computed as  $FLOP_{casc}/FLOP_{acc}$ .

## 5.1 IMAGE CLASSIFICATION ON IMAGENET

We first demonstrate that the proposed IDK model cascade framework can preserve the accuracy of the expen-

sive models without a loss while reducing the overall computational cost.

### 5.1.1 Experimental Details

On the ImageNet 2012 dataset we study cascades assembled from pre-trained models including AlexNet [19] and residual networks of various depths including ResNet-18, ResNet-34, ResNet-50, and ResNet-152 [20]. Detailed statistics such as top-1 accuracy, FLOPs, etc of the models are shown in Fig. 2. To train the IDK classifiers, we sample 25.6K training images randomly from the ImageNet 2012 training data and report the cascade accuracy on the entire ImageNet 2012 validation data. In grid search for cascade by probability and entropy, we evaluate 100 different settings of  $\alpha$  and select the cascade which has the lowest IDK rate while reaching the desired accuracy. Because 1% reduction in accuracy can translate to a nearly 30% reduction in computational cost on ImageNet (as measured in flops), we set the desired accuracy to be the same as the ResNet-152 (i.e., setting  $\epsilon = 0$  in Eq. 11).

For cascade by entropy via cost-aware objective, we set the hyper-parameter  $\lambda = 0.04$  across different model combinations and use the actual FLOPs number of each

Figure 4: **Three Model Cascade Results.** We consider three element cascades  $m_1 \rightarrow m_2 \rightarrow m_3$  where  $m_2$  and  $m_3$  are chosen to be the optimal two element cascade consisting of ResNet-50 and ResNet-152 respectively and we evaluate AlexNet, ResNet-18, and ResNet-34 as  $m_1$ . We also evaluate each of the three IDK cascade designs and corresponding fitting procedure. In all cases, the accuracy is set to match that of ResNet-152 and we therefore only present the computational costs relative to the ResNet-152 model. In general we find that deeper cascades have diminishing returns due to increased evaluation costs

model as the model cost in the objective. We also compare against a cascade constructed using an oracle IDK classifier as a cascade accuracy upper bound which optimally selects between the fast and accurate models. In addition to proposed cascade designs, we include two more IDK cascades constructed by supervised training an IDK classifier of the form in Eq. 5 using the oracle labels with cost-oblivious objectives. We discuss these alternative baselines in more detail in the next section.

### 5.1.2 Computation Reduction

Detailed results are shown in Fig. 3. We find the best cascade design employs the Entropy features and regularized cost formulation to combine the ResNet-50 and ResNet-152 models. This cascade is able to reduce prediction costs by 37% while achieving the accuracy of the most computationally expensive model. This is also close to the oracle performance, though it assumes a perfect IDK classifier (i.e. the IDK classifier can distinguish the prediction correctness of the fast model with 100% accuracy and only passing the incorrect predictions to the accurate model). In general we find that our regularized cost based formulation outperforms the other baseline techniques.

### 5.1.3 Effectiveness of Cost-Aware Objective

In Fig. 3 we also compare the proposed cost based IDK cascade design with two IDK classifiers following the form of Eq. 5 with cost-oblivious cross entropy loss. The training labels are the correctness of the predictions of the fast model evaluated on the ImageNet2012 dataset. We consider two forms of the feature function  $f$ : entropy based features identical to the cost based cascade and neural network features. The neural network feature function  $f_{\alpha_2}(m^{\text{fast}}(x))$  consists of a 7-layer fully connected network with 1024, 1024, 512, 512, 128, and 64 hidden units, ReLU activation functions, and trained using stochastic gradient descent with momentum and batch

normalization. In general, we find that these sophisticated baselines are unable to accurately predict the success of the fast model and as a consequence are unable to match the accuracy of the cost based cascade formulation. With the cost-aware objective, the IDK cascades can meet the desired accuracy which shows that the proposed objective is more suitable for building model cascades.

### 5.1.4 Three Model Cascades

We also investigate three model cascades and the results are shown in Fig. 4. Compared to the two models ResNet-50 + ResNet-152 cascade, adding a faster model like AlexNet, ResNet-18 or ResNet-34 actually *increases* computational cost, because a reasonable fraction of examples will need to pass through all three models in the cascade. However, the three-model cascade tends to reduce the computational cost relative to a two-model cascade including a less accurate model than ResNet-50. Moreover, adding more accurate models within a cascade consistently improves the overall cascade performance.

Table 1: CIFAR Model Details

Model	% Train Acc	% Test Acc	Flops ( $10^7$ )
VGG19	99.996	93.66	39.8
ResNet18	100.00	95.26	3.7
DLA-48-B-s	99.204	89.06	1.7

## 5.2 Robustness Analysis on CIFAR-10

To further analyze the robustness of the IDK prediction cascades, we conduct a set of experiments on the CIFAR-10 datasets. We consider three models: ResNet-18 [20], VGG19 [21] and a recently proposed compact model DLA-48-B-s [22]. Tab. 1 shows details of the models. As we can see from the table, all models overfit the training data with high accuracy close to 100%. We want to study the robustness of the IDK prediction cascades under such

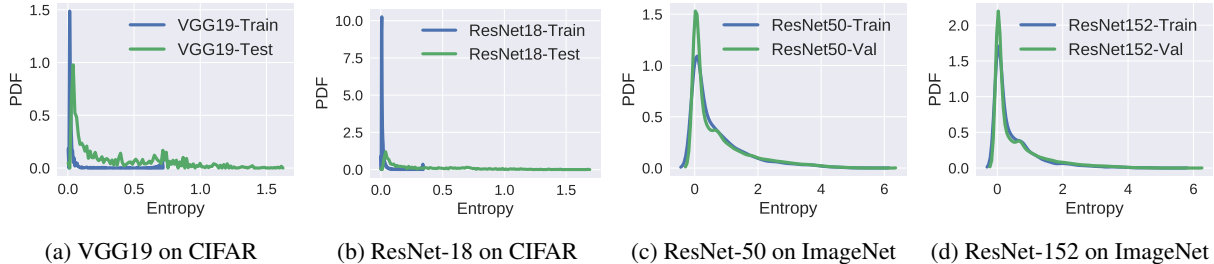

Figure 5: Entropy Distribution. We plot the entropy of the class conditional probability distributions for VGG19 and ResNet-18 on CIFAR-10 and ResNet-50 and ResNet-152 on ImageNet 2012. The VGG model severely overfits the training data and thus can not be used as the base model in the IDK classifier

Table 2: CIFAR Model DLA-48-B-s + ResNet-18 Cascade Results

Type	Desired Acc (%)	Acc (%)	IDK Rate (%)	Avg Flops ( $\times 10^7$ )	Relative Computational Cost
Prob + Grid	95.26	95.23	67.5	4.198	1.135
Entropy + Grid	95.26	95.23	51.7	3.613	0.977
Entropy + Cost	95.26	95.22	<b>48.9</b>	<b>3.509</b>	<b>0.949</b>
Entropy + Grid	95.16	95.16	40.1	3.184	0.861
Entropy + Cost	95.16	95.16	<b>40.0</b>	<b>3.179</b>	<b>0.859</b>
Prob + Grid	95.05	95.07	36.5	3.051	0.824
Entropy + Grid	95.05	95.06	33.7	2.947	0.796
Entropy + Cost	95.05	95.05	<b>32.8</b>	<b>2.915</b>	<b>0.788</b>
Prob + Grid	94.90	94.89	29.9	2.806	0.759
Entropy + Grid	94.90	94.91	30.6	2.832	0.766
Entropy + Cost	94.90	94.91	<b>30.5</b>	<b>2.827</b>	<b>0.764</b>

extreme case. In this experiment, since VGG19 is less accurate and more costly than ResNet-18, we focus on cascades constructed with DLA-48-B-s and ResNet-18.

We evaluate the model cascades with four different cascade accuracy goals shown in Tab. 2. We observe cascade by entropy via the cost-aware objective consistently outperforms grid search methods. Also, by admitting a small 0.03% reduction in accuracy, the IDK rate drops substantially from 48.9% to 30.5%. Compared to the single expensive model, the best model cascade reduces computational costs by 24%.

### 5.2.1 Robustness analysis

The proposed IDK classifiers rely on various measures of uncertainty in the class conditional probability distribution and are therefore sensitive to over confidence often as a result of over-fitting. To assess this effect, we evaluate the entropy distribution of the VGG19 and ResNet-18 models which have been trained to near perfect training accuracy (see Tab. 1). We plot the entropy distribution of these models in Figure 5a and 5b on both training and held-out test data and observe that both models substantially over-estimate their confidence on training data when compared with test data. In contrast, the ResNet-50 and

ResNet-152 models are much better estimators of prediction uncertainty as seen in Figures 5c and 5d. As a consequence, in settings where the fast model is likely to over-fit it is important to use separate held-out data when training the IDK classifier.

### 5.3 DRIVING CONTROL PREDICTION

We evaluate IDK cascades for autonomous driving and demonstrate that we can achieve nearly perfect accuracy with less than 30% human intervention. In this experiment, we apply the IDK model cascade framework on Berkeley DeepDrive Video dataset, a large scale real driving video dataset [18] containing 2.6 million frames in the training video and 384,599 frames for testing. The driving dataset contains 4 discrete motion states: left turn, right turn, forward and stop. The task is to predict the next vehicle motion given previous video frames. Fig. 6 shows some sample frames in the dataset. We use the *Long-term Recurrent Convolutional Networks* (LRCN) [23] model as  $m^{\text{fast}}$  and experiment on a large scale driving video dataset [18]. We consider a human-in-the-loop setting where human serves as the  $m^{\text{acc}}$  with 100% accuracy.

We use the same training setting for the proposed cascade approaches as the image classification task and report the results in Tab. 3. The LRCN model has an accuracy

Figure 6: Sample Frames from the Berkeley DeepDrive Video Dataset

of 84.5%<sup>1</sup> and we set the desired accuracy to 100%, 99% and 95%. We find that with only 28.88% human intervention, the cascade model can achieve 95% accuracy which is about 10% more accurate than the base LRCN model. This experiment demonstrates that the model cascade can be easily applied to real applications which are in high demand of low latency and high accuracy.

Table 3: Driving Model LRCN + Human Expert Cascades

Type	Desired Acc (%)	Acc (%)	IDK rate (%)
Prob + Grid	100.0	99.9	83.91
Ent + Grid	100.0	99.9	83.50
Ent + Cost	100.0	99.9	<b>80.70</b>

Ent + Cost	99.0	99.1	<b>59.70</b>
Prob + Grid	95.0	95.4	30.08
Ent + Grid	95.0	95.3	30.02
Ent + Cost	95.0	95.1	<b>28.88</b>

## 6 CONCLUSION AND FUTURE WORK

In this paper we revisited the classic idea of prediction cascades to reduce prediction costs. We extended the classic cascade framework focused on binary classifications to multi-class classification setting. We argue that the current deep learning models are “over-thinking” simple inputs in the majority of the real-world applications. Therefore, we aim to learn prediction cascades within the framework of empirical risk minimization and propose a new cost aware loss function, to leverage the accuracy and reduced cost of the IDK cascades.

We focused on build simple cascade with the the pre-trained base models with little training and negligible

<sup>1</sup>A slightly reduced accuracy early version was used.

computation overhead. We tried to answer two questions in this paper: (1) what is a good measure to distinguish the easy and hard examples in the workload without querying much information about the mode itself? We found that the entropy value of the model prediction distribution is a good measure than the vanilla confidence score and can be used as input data to train a light-weighted but effective IDK classifier. (2) How to design the objective function that balances the prediction accuracy and the computation cost? We proposed in this work to use the cost regularized objective which utilizes the actual FLOPs of the base models as the cost measures. Incorporating the cost factor in the objective, we found the model cascade works more effectively than the model cascades with cost-oblivious function.

We also proposed two search based methods *cascade by probability* and *cascade by entropy*, which obtain reasonable performance and require no additional training. We evaluated these techniques on both benchmarks and real-world datasets to show that our approach can successfully identify hard examples in the problem, and substantially reduce the number of invocations of the accurate model with negligible loss in accuracy. We also found that the cost based cascade formulation outperforms uncertainty based techniques.

We believe this work is a first step towards learning to compose models to reduce computational costs. Though not studied in this work, the proposed framework can be easily applied to the existing model serving systems and fit the edge-cloud scenario naturally with little modification. In the future, we would like to explore feature reusing and joint training of the cascade models so that different models can specialize in either easy or hard examples of the given workload.

## Abstract

We present a novel reinforcement learning (RL) approach to learning a fast and highly scalable solver for a two-stage stochastic integer program in the large-scale data setting. Mixed integer programming solvers do not scale to large datasets for this problem class. Additionally, they solve each instance independently, without any knowledge transfer across instances. We address these limitations with a learnable local search solver that jointly learns two policies, one to generate an initial solution and another to iteratively improve it with local moves. The policies use contextual features for a problem instance as input, which enables learning across instances and generalization to new ones. We also propose learning a policy to compute a bound on the objective using dual decomposition. Benchmark results show that on test instances our approach rapidly achieves approximately 30% to 2000% better objective value, which a state of the art integer programming solver (SCIP) requires more than an order of magnitude more running time to match. Our approach also achieves better solution quality on seven out of eight benchmark problems than standard baselines such as Tabu Search and Progressive Hedging.

## 1 INTRODUCTION

Stochastic integer programming (Birge and Louveaux [1997], Shapiro et al. [2009]) arises in various applications that require combinatorial optimization under uncertainty, such as electric grid optimization, finance, and logistics. Many domains involve large-scale data for random variables (e.g., weather, demand, etc.), and require solving a set of related problem instances instead of only one instance (e.g., solve instances periodically, each with different weather and demand forecast distributions).

While powerful solvers exist for deterministic, single-instance mixed integer programs (MIPs), this is not the case for the stochastic, multi-instance setting. Traditional solvers from the optimization literature are not able to scale to high dimensional stochastic MIPs where several thousands of samples are required to represent uncertainty, and do not reuse experience on solving past optimization problems to solve future problems.

In this paper we consider learning an approximate solver with reinforcement learning (RL). We frame optimization as a sequential decision problem where at each step the solver “agent” proposes a solution, and the “environment” evaluates the objective value and any constraint violations to provide reward and observations. Contextual features describing a problem instance are used as an input to the solver so that its actions are adapted to that instance. The parameters of such a *contextual solver* are learned offline on a training set of instances. Once trained, the solver is applied to a new instance from the same distribution. We also learn a *dual policy* that computes a bound on the optimal value to estimate how far the solution computed by the contextual solver is from the global optimum for a given instance.

The advantages of our approach are: a) it can scale to a large set of problem instances, as well as a large set of samples for the random variables in each instance, and b) it can generalize to a new instance to achieve better solution quality and/or time than a solver that treats each instance independently. As the results show, our approach is able to scale to much larger datasets and achieve significant speedups compared to SCIP (Gleixner et al. [2017]), the state-of-the-art open source MIP solver.

**Two-stage stochastic integer programs:** We focus on an important class of stochastic programs called a two-stage stochastic MIP (Birge and Louveaux [1997]). In the first stage, a *planning decision* is optimized under uncertainty, then the values of all random variables are observed, and in the second stage a *recourse decision* is

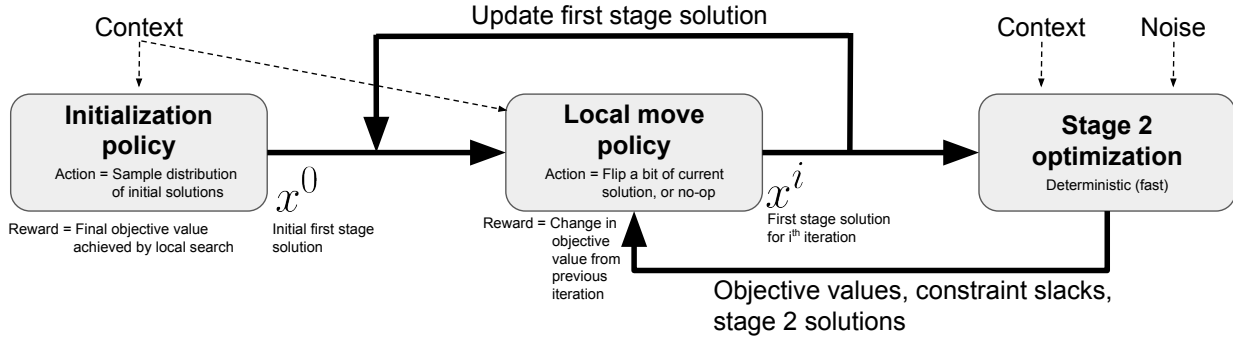

Figure 1: Local search for a two-stage stochastic MIP as an RL problem. The initialization and local move policies are part of the “agent”, while the second stage optimization is part of the “environment.” Given a problem instance specified by the context, the agent’s “action” is to propose a first stage solution at each step of local search. The environment evaluates it on a minibatch of noise samples (denoted by  $\omega$  in the text) by optimizing the second stage problem for each sample using a MIP solver to compute the reward and observations.

deterministically optimized to adapt the plan in response to observations. The uncertainty is exogenous, so it is independent of the first stage solution. This problem structure arises in many applications, such as electric grid day-ahead planning (Zheng et al. [2015]) and logistics (Laporte et al. [1992]).

**Local search solver:** The contextual solver is structured as a local search algorithm over the space of first stage solutions. It consists of two learnable components: a) an *initialization policy* that takes as input the context vector and outputs an initial solution, and b) a *local move policy* that takes the initial solution and applies a sequence of local moves such that the final solution has high objective value. Both of these policies are learned jointly.

Both during training and testing, evaluation of a first stage solution requires solving several second stage optimization problems to approximate the expected objective as a sample average. Since each such problem is a deterministic MIP, they are well-suited for solving with an off-the-shelf MIP solver, so we use SCIP to solve them. This provides another perspective of our work as a hybrid approach that combines a learned contextual solver with a MIP solver in the learning loop to efficiently optimize stochastic two-stage MIPs.

**Contributions:** We develop an approach to learn 1) a contextual local search solver with the initialization and local move policies that computes a solution to the optimization for a given problem instance, and 2) a contextual dual policy that computes an upper bound on the optimal value (achievable by *any algorithm*) for a given problem instance. We benchmark our approach on a set of two-stage stochastic MIPs and show that compared to SCIP it achieves approximately 30% to 2000% better objective value for the same running time and at least an order of magnitude faster for the same objective value. It also

outperforms baseline algorithms such as Tabu Search and Progressive Hedging on seven out of eight problems.

## 2 RELATED WORK

**Learning solvers:** Early examples of learning solvers for combinatorial optimization problems include Zhang and Dietterich [1995], Moll et al. [1999], and Boyan and Moore [2001]. The first two use TD( $\lambda$ ) to learn a value function over the solution space such that applying a local search algorithm with that value function can find a good solution and can generalize to new problem instances. These approaches assume that an initial solution is given (either randomly generated or by another algorithm), whereas our approach learns to generate the initial solution jointly with the local search policy. Boyan and Moore proposed STAGE, an iterative algorithm that alternates between learning a value function over the solution space for one instance and using that function to find a better solution for that instance. This work was primarily focused on the single instance setting.

More recently Vinyals et al. [2015] used supervised learning with pointer networks to approximately solve travelling salesman problems. Subsequent work improved on it by using the same pointer network architecture, but learned with RL (Bello et al. [2016]). Ignoring architectural differences, our initialization policy is similar to Bello et al.’s approach, but we further improve the initial solution using a learned local move policy. As our results show, this is a crucial difference for improving performance. Khalil et al. [2017a] combine graph neural networks with RL to learn a greedy solver for graph combinatorial optimization problems that incrementally extends a partial solution till its complete. Again, our idea of improving the complete solution further with a learned local search policy can be applied here as well.

Additionally, using the dual policy, we can compute a bound on the objective function value even on new problem instances. This allows us to a) assess the quality of the solution produced by the learned solver, and b) to make a fairer comparison to approaches that provide both a solution and a bound since proving the bound can be a significant part of the solver running time.

**Learning to improve solvers:** Several works have focused on applying learning to improve the decisions made by non-learning solvers, e.g., variable selection and node selection decisions in a branch and bound solver. See Lodi and Zarpellon [2017] for a survey. Khalil et al. [2016] treat variable selection as a ranking problem and learn a ranking function. Khalil et al. [2017b] use learning to predict on which nodes of the branch and bound search tree various primal heuristics will succeed. Such approaches can be used as building blocks for an end-to-end solution.

### 3 CONTEXTUAL TWO-STAGE STOCHASTIC INTEGER PROGRAM

A contextual two-stage stochastic integer program is defined as follows (for the case of maximization):

$$\max_x f(x; z) + E_{P(\omega)} \left[ \max_{y \in Y(x, \omega)} g(y; x, \omega, z) \right] \quad (1)$$

where

- $\omega \in \mathbb{R}^d$  is a random variable representing the uncertainty affecting the second stage objective function and constraints.  $\omega$  is independent of the decision variables. We are given a set of I.I.D. samples  $D_\omega = \{\omega_i \sim P(\omega)\}, i = 1, \dots, N_\omega$  with which the expectation in equation 1 is estimated as a sample average.
- $x \in \{0, 1\}^n$  is the first stage decision variable, optimized before observing  $\omega$ . We assume that every  $x$  is feasible.
- $y \in \{0, 1\}^m$  is the second stage decision variable, optimized after observing  $\omega$ , where  $Y(x, \omega) \subseteq \{0, 1\}^m$  is the feasible set defined by second stage constraints. We assume  $Y(x, \omega) \neq \emptyset$  for all  $(x, \omega)$  (i.e., *complete recourse*).
- $z \in \mathbb{R}^c$  is the context feature vector describing an instance of the optimization problem. A set of instances is generated by drawing I.I.D. samples  $D_z = \{z_j \sim P(z)\}, j = 1, \dots, N_z$ .

$f$  and  $g$  represent the first and second stage objective functions, respectively. Unlike LP relaxation based approaches to solving MIPs, our approach can be applied to

nonlinear  $f$ ,  $g$ , and constraints. However, in this work we focus on the linear case to allow a direct comparison to LP relaxation based approaches:

$$\begin{aligned} f(x; z) &= c_1^T(z)x \\ g(y; x, \omega, z) &= c_2^T(x, \omega, z)y \\ Y(x, \omega) &= \{y \in \{0, 1\}^m : B(\omega, z)x + C(\omega, z)y \leq d(\omega, z)\} \end{aligned}$$

**Sample Average Approximation:** The primary approach in the optimization literature for solving equation 1 is the *Sample Average Approximation* (SAA) method (Ahmed and Shapiro [2002]). It replaces the expectation with a sample average and replicates the second stage decision for each sample:

$$\max_x f(x; z) + \frac{1}{N_\omega} \sum_i^{N_\omega} \left[ \max_{y_i \in Y(x, \omega_i)} g(y_i; x, \omega_i, z) \right].$$

This converts the original problem into a deterministic one which can be solved using a deterministic MIP solver (assuming linear  $f$ ,  $g$ , and constraints). The key disadvantage is that the number of second stage decision variables increases by a factor of the number of samples  $N_\omega$ . As a result, the approach does not scale beyond a moderate number of variables and samples. In practice this limitation is overcome by domain experts carefully selecting a small set of samples that they judge will likely affect the solution. By being more scalable, our learning-based approach makes such expert selection unnecessary.

## 4 RL APPROACH

We describe our Reinforcement Learning (RL) approach for learning a solver for the optimization problem defined in section 3.

### 4.1 MAIN IDEA

We formulate our approach as *learning an iterative local search algorithm* over the space of first stage solutions (see figure 1). It has two learnable components which are optimized jointly:

- *Initialization policy:* Given an instance of the optimization problem, generate an initial first stage solution  $x^0$  from which local search starts.
- *Local move policy:* At each iteration of local search, select one of the neighbors of the current first stage solution as the proposal for the next iteration.

The solution  $x^K$  after a fixed number of iterations  $K$  is the solver's output. The objective function value  $r^K$  at

$x^K$  is approximated by:

$$r^K = f(x^K; z) + \frac{1}{N_\omega} \sum_{i=1}^{N_\omega} \left[ \max_{y \in Y(x^K, \omega_i)} g(y; x^K, \omega_i, z) \right] \quad (2)$$

where the expectation is approximated as a sample average. For a given  $x$  and  $\omega$ , the second stage optimization over  $y$  is deterministic. We assume that an efficient solver is available (e.g., SCIP, or a fast heuristic) so that an accurate approximation of the expectation can be computed quickly. This allows us to leverage existing efficient techniques for deterministic optimization to learn a solver for stochastic optimization.

**Limitations:** 1) Our approach relies on offline learning on a dataset of instances, and it is unlikely to be useful in a setting where there is only one instance (or few) to be solved. Our early experiments showed that in the single-instance setting (i.e., treat  $z$  as a constant), our approach’s running times tend to be much higher than baseline algorithms to achieve similar solution quality. 2) The solution found after  $K$  iterations is not guaranteed to be optimal. But if learning is successful, it can be expected to be a good solution, and the bound provided by the dual policy indicates how close to optimal it is.

## 4.2 INITIALIZATION POLICY

The initialization policy is a distribution  $P(x|z)$  over the first stage solution  $x$  given the context feature vector  $z$ . The initial solution is generated by sampling  $x^0 \sim P(x|z)$ . Reward is the expected objective function value achieved by the solution at the end of local search. We use policy gradients to learn  $P(x|z)$ .

**Architecture:** We explored two architectures: 1) a conditional autoregressive generative model, and 2) a simpler, fully connected feedforward neural network with a single hidden layer. Results are better for the former, so we describe it here. Autoregressive generative models provide a flexible neural network parameterization for high dimensional distributions while still allowing tractable exact evaluation of the log probability and its gradient with respect to model parameters. Crucially, they do not make any independence assumptions, thus capturing complicated correlations in the vector  $x$ . Here we consider a conditional version

$$P_{\theta_{init}}(x|z) = \prod_i P_{\theta_{init}}(x_i | x_{<i}, z) \quad (3)$$

where  $x_i$  is the  $i^{th}$  dimension of  $x$ ,  $x_{<i}$  is the set of first  $i - 1$  dimensions of  $x$ , and  $\theta_{init}$  denotes the model’s parameters. Specifically, we use the Neural Autoregressive Density Estimator (NADE) (Larochelle and Murray

[2011]). NADE is not specialized for a particular type of data (e.g., images, time series), which makes our approach application agnostic. It uses weight sharing across the conditional distributions in equation 3 to achieve a compact parameterization. For details see Larochelle and Murray [2011].

**Training:** The loss function for learning  $\theta_{init}$  is

$$\mathcal{L}(\theta_{init}) = -E_{P_{\theta_{init}}(x^0|z)P(r^K|x^0,z)} [r^K]. \quad (4)$$

$\theta_{init}$  is learned with stochastic gradient descent using the policy gradient method of REINFORCE (Williams [1992]). The gradient is given by:

$$\begin{aligned} \nabla_{\theta_{init}} \mathcal{L}(\theta_{init}) = \\ - E [(r^K - b_w(z)) \nabla_{\theta_{init}} (\log P_{\theta_{init}}(x|z))] \end{aligned}$$

where  $b_w(z)$  is a learned baseline function parameterized by  $w$ , and the expectation is with respect to  $P_{\theta_{init}}(x^0|z)P(r^K|x^0,z)$ . The baseline  $b_w(z)$  is a single hidden layer, fully connected feedforward neural network with ReLU hidden units. Its weights  $w$  are learned jointly with the initialization policy by stochastic gradient descent to minimize  $(r^K - b_w(z))^2$ .

## 4.3 LOCAL MOVE POLICY

We learn a policy that makes  $K$  local moves starting from the initial solution  $x^0$  to produce  $x^K$ . At an intermediate step  $k$ , the local move policy takes the first stage solution  $x^k$  and selects one of its neighbors from a Hamming ball of radius 1 as  $x^{k+1}$ . This results in  $n + 1$  possible actions per step: either toggle one of the dimensions of  $x^k$ , or a no-op. The policy outputs a categorical distribution  $\pi_{\theta_{lm}}(a^k|x^k, s^k, x^0, z)$  over the actions, given state  $s^k$  (described below), initial solution  $x^0$ , and context vector  $z$ , parameterized by  $\theta_{lm}$ . The reward at each iteration is the change in objective value from the previous iteration. So the policy is being learned to maximize the total expected increase in objective value relative to the initial solution in an episode. We use the Asynchronous Advantage Actor Critic (A3C) algorithm (Mnih et al. [2016]) for learning.

**Architecture:**  $\pi_{\theta_{lm}}(a^k|x^k, s^k, x^0, z)$  is a two hidden layer, fully connected feedforward neural network with ReLU hidden units. The observations  $o^k$  at step  $k$  consists of:

- *Constraint slacks:* The difference between a second stage constraint’s value and its upper/lower bounds obtained for each sample  $\omega_i$ .
- *Second stage solutions:* The solutions  $y^i$  obtained for each sample  $\omega_i$ .

We define state  $s^k$  to be a fixed size time window of  $J$  observations  $\{o^{k-1}, \dots, o^{k-J}\}$ . The window size is a hyperparameter tuned based on validation set performance. A3C also learns a value function  $V_{\theta_v}(s_k; x_0, z)$  jointly with the policy. Following standard practice, this function shares with the policy all the hidden layers and corresponding parameters, with unshared parameters only in the output layers to compute the value and policy outputs.

**Training:** The reward at step  $k$  of an episode is given by

$$r_{lm}^k = r^{k+1} - r^k,$$

where  $r^k$  is defined by equation 2. A3C defines its loss in terms of the *advantage function*:

$$A(a^k, s^k; x^0, z) = \sum_{l=0}^{L-1} \gamma^l r_{lm}^{k+l} + \gamma^L V_{\theta_v}(s_{k+L}; x_0, z) - V_{\theta_v}(s_k; x_0, z),$$

where the first two terms on the RHS give an estimate of the  $L$ -step return, and  $\gamma$  is the discount factor. The loss is given by

$$\mathcal{L}(\theta_{lm}, \theta_v) = -E_{\pi_{\theta_{lm}}(a^k|x^k, s^k, x^0, z)} [A(a^k, s^k; x^0, z)], \quad (5)$$

with the gradient with respect to  $\theta_{lm}$  given by:

$$\nabla_{\theta_{lm}} \mathcal{L}(\theta_{lm}, \theta_v) = -E [A(a^k, s^k; x^0, z) \nabla_{\theta_{lm}} (\log \pi_{\theta_{lm}}(a^k|x^k, s^k, x^0, z))].$$

The square of the advantage function is an additional loss used to learn the value function parameters  $\theta_v$ . We also apply entropy regularization to encourage exploration by preventing the policy from becoming deterministic. The relative magnitude of these losses' contribution to the total loss are tuned as hyperparameters based on validation set performance.

We use distributed TensorFlow with  $N_w$  parallel workers executing episodes and computing gradients, and one central learner asynchronously applying gradients to update parameters. This setup is replicated for each of the  $N_h$  randomly sampled hyperparameter settings for hyperparameter tuning. We use  $N_w = 20$  and  $N_h = 25$  for each problem in our benchmark.

## 5 BOUNDS VIA LEARNED DUAL POLICIES

An attractive feature of MIP solvers is that they provide an upper bound on the optimal value of a maximization problem, quantifying the objective value gap between a

solution and the global optimum. However, as explained in section 3, directly applying a MIP solver to a two-stage stochastic integer program with a large set of samples is computationally infeasible. We use *dual decomposition* (Carøe and Schultz [1999]) to develop an alternative approach.

The main idea is that if we are allowed to choose a different  $x = x_\omega$  for each sample  $\omega$ , the optimization problem (1) decomposes into independent subproblems for each sample that can be solved in parallel. This constitutes a relaxation of the optimization problem, and hence its optimal value is an upper bound on the original problem. Solving the relaxation only requires a deterministic MIP problem, which can be solved efficiently or bounded using a further LP relaxation.

This bound can be tightened by adding Lagrangian multipliers that encourage the scenario subproblems to agree on a single  $x = x_\omega$ . Since we are interested in large-scale stochastic MIPs and in out-of-sample tests, it is not appropriate to compute an independent dual variable for each scenario  $\omega$ . Instead, we train a neural network that, given features that depend on  $\omega$  (the sample) and  $z$  (the context), predict the dual variables for the problem. Given any such policy, we can obtain a bound on the value of the 2-stage stochastic MIP and further, we can evaluate this bound out of sample (on samples that were unavailable during training) to estimate the ‘‘generalization’’ of the bound.

### 5.1 DUAL DECOMPOSITION OF 2-STAGE STOCHASTIC MIPs

Consider equation 1 in the linear case:

$$\max_{x \in \{0,1\}^n} c_1(z)^T x + \frac{1}{N_\omega} \sum_{\omega \in D_\omega} \left[ \max_{y \in Y(x, \omega, z)} c_2(\omega, z)^T y \right]. \quad (6)$$

We now introduce independent copies  $x_\omega$  for each sample  $\omega$  with constraints to enforce equality of  $x_\omega$ :

$$\begin{aligned} \max_{x, \{x_\omega\}} \frac{1}{N_\omega} \sum_{\omega \in D_\omega} \left[ \max_{y \in Y(x_\omega, \omega, z)} c_1(z)^T x_\omega + c_2(\omega, z)^T y \right], \\ \text{s.t. } x_\omega = x \quad \forall \omega \in \Omega. \end{aligned}$$

We drop the constraints and add a Lagrangian term to obtain a relaxation:

$$\max_{x, \{x_\omega\}} \frac{1}{N_\omega} \sum_{\omega \in D_\omega} \left[ \max_{y \in Y(x_\omega, \omega, z)} c_1^T x_\omega + c_2^T y + \lambda_\omega^T (x - x_\omega) \right], \quad (7)$$

where  $\lambda_\omega$  for each  $\omega$  is a dual variables, and we dropped the dependence of  $c_1, c_2$  on  $\omega, z$  for brevity.

From equation 7 we can derive the following *dual problem* to optimize the upper bound (see supplementary material for details):

$$\min_{\{\lambda_\omega\}} \frac{1}{N_\omega} \sum_{\omega \in D_\omega} h(\omega, z, \lambda_\omega) + \mathbf{1}^T \max \left( \frac{1}{N_\omega} \sum_{\omega \in D_\omega} \lambda_\omega, 0 \right), \quad (8)$$

where

$$h(\omega, z, \lambda_\omega) = \max_{y \in Y(x_\omega, \omega, z)} c_1(z)^T x_\omega + c_2(\omega, z)^T y - \lambda_\omega^T x_\omega.$$

We use (8) to estimate a bound.

## 5.2 LEARNING DUAL POLICIES

There are three issues with applying the above dual decomposition approach to large scale contextual stochastic MIPs:

- *Context ignored:* If we directly apply dual decomposition, even after solving the problem for thousands of context vectors  $z$ , we would start from scratch for a new context. This is wasteful particularly if the solutions for the dual variables are simple functions of  $z$  that can be learned.
- *Generalization:* The problem (8) only implies a bound for the set of scenarios in the training set  $D_\omega$ . However, this does not say anything about how the bound generalizes to unseen samples.
- *Computation:* The problem (8) is expensive to solve if the number of scenarios  $D_\omega$  is large, since one has to solve an optimization problem (to compute  $h$ ) for each scenario  $\omega$  simply to evaluate the objective and compute gradients with respect to  $\lambda_\omega$ .

We address all three issues by learning a *dual policy*  $\lambda_\omega = \lambda_{\theta_d}(\omega, z)$  that maps from the context  $z$  and sample features  $\omega$  to the dual variables  $\lambda_\omega$ , parameterized by  $\theta_d$ . We train the policy to minimize the dual objective averaged over samples  $D_\omega$  and context sample set  $D_z$ :

$$\min_{\theta} \frac{1}{N_z} \sum_{z \in D_z} \frac{1}{N_\omega} \sum_{\omega \in D_\omega} h(\omega, z, \lambda_{\theta_d}(\omega, z)) \quad (9a)$$

$$+ \mathbf{1}^T \max \left( \frac{1}{N_\omega} \sum_{\omega \in D_\omega} \lambda_{\theta_d}(\omega, z), 0 \right). \quad (9b)$$

A major bottleneck in solving this problem is the need to compute  $h$  (which itself involves solving a deterministic

MIP or an LP relaxation of it). Thus, it is desirable to have an algorithm that does not compute  $h$  for each  $z, \omega$  at each iteration.

In our experiments we sample  $z^s, \omega^s$  but also get predictions of the neural network for each  $\omega \in D_\omega$  to compute  $\sigma = \sum_{\omega \in D_\omega} \lambda_\omega(\omega, z^s; \theta)$ . Then, an unbiased estimate of a (sub)-gradient of the objective is given by

$$g^s = \frac{\partial h}{\partial \lambda_\omega}(\omega^s, z^s) \frac{\partial \lambda_\omega(\omega^s, z^s; \theta)}{\partial \theta} + \text{sign}(\sigma) \frac{\partial \lambda_\omega(\omega^s, z^s; \theta)}{\partial \theta} \quad (10)$$

This only requires one backprop through the network and  $N_\omega$  forward passes and computation of  $h$  for a single  $z, \omega$ .

**Architecture:** We use a simple feedforward architecture with a single hidden layer in all our experiments. The architecture has fully connected layers with ReLU activations. We add a skip connection from the context vector  $z$  to the hidden and output layer and a skip connection from  $\omega$  to the output layer. We tune the size of the hidden layer and learning rate as hyperparameters (picked so that the dual bound on a validation set is minimized).

## 6 EVALUATION

### 6.1 BENCHMARK

There is a dearth of standardized, large-scale benchmarks for stochastic programming problems. As a first step, we construct a benchmark using stochastic versions of two standard optimization problems, knapsack and facility location, with large-scale data. We plan to add more problems in the future.

**Knapsack (KS):** The problem is to place a set of items with various sizes and values into a knapsack of specified capacity so as to maximize the total knapsack value without exceeding capacity. For a given problem instance the item sizes are stochastic. In the first stage, the items have to be selected without knowing their precise sizes. After the sizes are revealed, the second stage decision is to remove items selected in the first stage to satisfy the capacity limit, but removal incurs a penalty. Context specifies the values of the items, knapsack capacity, and removal penalty.

**Facility Location (FL):** Adapted from Ntaimo and Sen [2005], the problem is to place facilities at a set of locations with varying costs such that profit is maximized. Customer demand and revenue at the locations are stochastic. There is a linear penalty for not meeting customer demand. In the first stage, locations have to be selected without knowing precise demand and revenue. After demand and revenue are revealed, the second stage

decision is to assign customers to various facilities. Context specifies the location costs, facility capacity, and the linear penalty factor on unsatisfied demand.

**Problem size:** We define “problem size” to be the number of first stage binary decision variables. We use the following sizes:  $\{25, 50, 100, 200\}$ . The number of second stage binary decision variables for KS is the same as in the first stage, while for FL, it is the problem size multiplied by the number of customers (set to 5 in our experiments). In the SAA method the deterministic reformulation multiplies the number of second stage variables by the number of samples. So for problem size 200, even with only 1000 samples, the number of variables already exceeds  $2 \times 10^5$ .

**Data generation:** We generate samples for the context vectors and for the random variables within an instance using a Mixture of Factor Analyzers (Ghahramani and Hinton [1997]). The resulting distributions are structured with dependencies among variables, and the mixture components make them more complex than a Gaussian.

## 6.2 BASELINE SOLVERS

**SCIP** is an open source MIP solver that uses LP relaxation-based branch and bound algorithm. We apply SCIP using the SAA method.

**Tabu Search** (Glover [1986]) is a local search algorithm that makes moves in the space of the first stage decision variable and maintains a tabu list of recently visited solutions to avoid cycles. See supplementary material for more details.

**Progressive Hedging** ([Watson and Woodruff, 2011]) is based on the dual decomposition approach described in section 5.1. It iteratively fixes the relaxation introduced in the dual decomposition by adding penalty terms to promote consistency between  $x_\omega$  and  $x$ . See supplementary material for more details.

SCIP, Tabu Search, and Progressive Hedging do not support any transfer across problem instances as they are originally formulated. We implement a simple way to adapt Tabu Search and Progressive Hedging to the contextual setting. At training time, these optimizers solve as many training instances as possible within the given training budget. At test time, a test instance’s context vector is used for nearest neighbor selection of a training instance. The solution for the test instance is initialized to the final solution of the nearest training instance by L1 distance.

## 6.3 EVALUATION PROTOCOL

Solvers that support contextual optimization are given the same training budget of 500 CPU cores for 12 hours.

GPUs are not used to allow fair comparison to methods that cannot use them. The training budget is used for hyperparameter tuning and parameter learning. For Tabu Search and Progressive Hedging, instead of parameter learning, a set of training instances are solved for nearest neighbor initialization at test time.

We use 1000 contexts and  $10^5$  samples for the random variables in a problem for training, and 100 contexts and 1000 random variable samples each for validation and testing. The context distribution is independent of the distribution over random variables in a problem, so we can sample each separately. The number of variable samples is limited to 1000 only because SCIP becomes too slow and uses excessive memory for some problem instances with more samples. RL approaches can easily scale to much larger number of samples. The solver performance on the validation set is used to select the hyperparameters.

At test time we provide one CPU core per instance for all solvers. Tabu Search and Progressive Hedging both make the same number of second stage solver calls (which dominates the running time) as the local search solver so that all three have (approximately) the same computational budget. SCIP’s computation cannot be easily characterized by the number of second stage solver calls. Instead we set a maximum time limit and a 5% optimality gap, and allow SCIP to run until whichever condition is satisfied first.

# 7 EXPERIMENTS

We present the following results: a) a comparison of the local search solver to SCIP in terms of test solution objective value vs. solver running time, b) a comparison to the objective value achieved by the baselines, and c) results for estimating a bound using the dual policy.

## 7.1 OBJECTIVE VALUE VS. RUNNING TIME

We run SCIP on 100 test problem instances with different running time limits, from 1s to  $10^4$ s. We then compare its objective value to that achieved by the local search solver on the same instances. The running time of the local search solver is fixed to be the time needed to execute one episode per instance and evaluate the solution at the end of the episode.

Figure 2 summarizes the results. Each plot shows the percent difference in SCIP’s objective value with respect to that of the local search solver as a function of the running time ratio of SCIP to the local search solver. The key observation is that SCIP gives significantly worse objective value than the local search solver unless it is given much more running time. For knapsack problems

Figure 2: SCIP running time vs. objective value comparison between local search solver and SCIP on test problem instances for the benchmark problems (KS = Knapsack, FL = Facility Location) of sizes  $\{25, 50, 100, 200\}$ . x-axis is SCIP’s average running time as a factor of the local search (LS) solver’s average running time. y-axis is the percent improvement in average objective value given by local search over SCIP. Positive values mean local search is better.

of different sizes, SCIP performs 30 to 70% worse when given approximately the same running time. For problem sizes 25, 50, and 100, SCIP needs more than an order of magnitude more time to catch up with the local search solver’s solution quality. For problem size 200, running SCIP even 1000 times longer still results in more than 35% worse objective value. A similar result is seen in the facility location problem as well, where the objective value gaps are even bigger in favor of the local search solver. For problem sizes 100 and 200, it appears that SCIP needs more than  $10^4$  seconds to improve the objective value significantly, and therefore is not able to catch up with the local search solver’s objective value in that time.

These results show the speedup benefit of learning a contextual solver. Since the solver has already seen at training time problem instances from the same distribution, generalization allows it to quickly find good solutions on unseen problem instances at test time.

## 7.2 OBJECTIVE VALUE COMPARISON

We compare the objective value given by the local search solver to that of Tabu Search, Progressive Hedging, and SCIP. We set the running time of SCIP to be ten times that of the local search solver to make it a stronger baseline. We also evaluate the initialization policy and the local move policy independently to get more insight into the performance of the local search solver. For the former we train only the initialization policy to generate a solution directly, without local search. For the latter we train only a local move policy that is initialized by selecting a solution uniformly randomly.

Table 1 summarizes the results. For each (solver, problem, size) triplet the mean of the objective values over a set of 100 test instances is shown. In all but one case the learned local search solver computes the best solution among all the algorithms tried, and in the remaining case it is within

5% of the best.

Both Tabu Search and Progressive Hedging perform poorly on the larger problem sizes (100, 200), especially for Facility Location. As we have already seen in the previous section, SCIP requires significantly more time to achieve comparable objective values.

A comparison among the different variants of the learned solver shows that the best results are given by learning both the initialization and local move policies jointly. Learning a local move policy to start from a random solution performs the worst among the variants, especially for larger problem sizes (KS200, FL100 and FL200). Learning an initialization policy alone performs better, but uniformly worse than learning both jointly.

The dual policy bounds computed by the approach from section 5.2 also show that on most problems, our learning based approach not only learns to produce good solutions but is also able to prove that these solutions are within 20% of the optimum (5 of 8 problem instances).

## 7.3 INSIGHTS INTO SOLVER BEHAVIOR

Figure 3(a) shows examples of how the objective value varies as a function of solver steps (here for KS100, other problems show similar behavior). The objective value typically improves rapidly for roughly the first one-third of an episode, with smaller gains afterwards. Unlike a greedy algorithm, the solver is not constrained to always improve the objective value. Figure 3(b) shows an example. The highlighted part of an episode shows that the objective value can decrease by a large amount ( $> 10\%$ ) for a significant duration ( $> 10\%$ ) of the episode before it improves again. Approximately 7% of test instances across problem types and sizes show non-greedy behavior. The ability to learn a non-greedy policy explains how the local search solver can outperform greedy methods like Tabu Search.

Solver	KS 25	KS 50	KS 100	KS 200	FL 25	FL 50	FL 100	FL 200
SCIP @10x more runtime	0.5985	0.1681	2.731	1.1273	0.0	0.0	-7.0531	-13.8540
Tabu Search	1.3150	<b>1.4859</b>	-3.0144	-0.0851	0.9781	0.3089	0.0	0.0
Progressive Hedging	1.4666	1.2584	2.9565	1.1983	0.9301	0.0003	0.0014	0.0
RL-based solvers								
Init. policy only	1.2410	1.2977	0.1304	0.9275	0.8213	0.8148	1.1395	1.3337
Local move policy only	1.1427	1.0631	1.2481	0.1846	1.1058	0.7403	-7.3248	-36.8738
Init. policy + local move policy	<b>1.4807</b>	1.4286	<b>3.2920</b>	<b>1.3133</b>	<b>1.1352</b>	<b>1.2416</b>	<b>1.2729</b>	<b>1.8197</b>
Bounds from dual policy								
Dual policy	1.5885	2.4486	3.4289	3.8304	1.2753	1.2903	1.6489	2.4702

Table 1: Comparison of average test set objective values achieved by various solvers across benchmark problems and sizes. KS = Knapsack, FL = Facility Location. The last row shows the upper bounds computed by the dual policy.

Figure 3: Examples of local search behavior on test instances. (a) Objective value as a function of the number of local search moves for 100-d Knapsack for several test instances. (Other problems show similar behavior.) Objective values are normalized to  $[0,1]$  for display purposes. (b) Example of non-greedy behavior (highlighted) shown by the local solver. Approximately 7% of test instances show this type of behavior.

Non-greediness can also potentially make the solution worse than the initial solution. However, only 0.21% of test instances show a decrease  $> 1\%$  in objective value relative to the initial solution, while 89.8% show an increase  $> 10\%$ . It appears that on some instances the initial solution is already very good, and local search introduces small changes which reduces the objective value slightly.

## 8 CONCLUSIONS

We presented a learned contextual local search solver that jointly learns both an initialization policy and a local move policy. On benchmark problems of two-stage stochastic knapsack and facility location of different sizes, it achieves approximately 30% to 2000% better objective value for the same running time and at least an order of

magnitude faster for the same objective value. It also outperforms baseline algorithms such as Tabu Search and Progressive Hedging on seven out of eight problems. Joint learning is key as learning only one of the policies in isolation results in worse performance. The dual policy is able to compute bounds showing that the local search solver's objective value is within 20% of the optimum for 5 out of 8 problem instances.

Next directions include incorporating a more powerful search procedure such as MCTS into the agent as a policy improvement operator (Silver et al. [2017]).

## Abstract

We developed a novel statistical method to identify structural differences between networks characterized by structural equation models. We propose to reparameterize the model to separate the differential structures from common structures, and then design an algorithm with calibration and construction stages to identify these differential structures. The calibration stage serves to obtain consistent prediction by building the  $\ell_2$  regularized regression of each endogenous variables against pre-screened exogenous variables, correcting for potential endogeneity issue. The construction stage consistently selects and estimates both common and differential effects by undertaking  $\ell_1$  regularized regression of each endogenous variable against the predicts of other endogenous variables as well as its anchoring exogenous variables. Our method allows easy parallel computation at each stage. Theoretical results are obtained to establish non-asymptotic error bounds of predictions and estimates at both stages, as well as the consistency of identified common and differential effects. Our studies on synthetic data demonstrated that our proposed method performed much better than independently constructing the networks. A real data set is analyzed to illustrate the applicability of our method.

slightly from each other [West et al., 2012], and identifying the subtle difference between them helps design specific drugs. Social networks evolve over times, and monitoring their abrupt changes may serve as surveillance to economic stability or disease epidemics [Pianese et al., 2013, Berkman and Syme, 1979]. However, addressing such practical problems demands differential analysis of large networks, calling for development of efficient statistical method to infer and compare complex structures from high dimensional data. In this paper, we focus on differential analysis of directed acyclic or even cyclic networks which can be described by structural equation models (SEMs).

Many efforts have been made towards construction of a single network via SEM. For example, both Xiong et al. [2004] and Liu et al. [2008] employed a genetic algorithm to search for the best SEM using different information criteria. Most recently, Ni et al. [2017, 2018] employed a hierarchical Bayes approach to construct the SEM based networks. However, these approaches were designed for small or medium scale networks. For large-scale networks that the number of endogenous variables  $p$  exceeds the sample size  $n$ , Cai et al. [2013] proposed a regularization approach to fit a sparse model. Because this method suffers from incapability of parallel computation, it may not be feasible for large networks. Logsdon and Mezey [2010] proposed another penalization approach to fit the model in a node-wise fashion which alleviates the computational burden. Most recently, Lin et al. [2015], Zhu [2018], and Chen et al. [2017] each proposed a two-stage approach to construct SEMs, with different algorithms designed at different stages. As shown by Chen et al. [2017], such a two-stage approach can have superior performance compared to other methods.

To the best of our knowledge, no algorithm has been proposed to conduct differential analysis of directed networks characterized by SEM. While a naive approach would separately construct each individual network and identify common and differential structures, this ap-

## 1 INTRODUCTION

It is of great importance and interest to detect sparse structural differences or differential structures between two cognate networks. For instance, the gene regulatory networks of diseased and healthy individuals may differ

proach fails to take advantage of the commonality as well as sparse differential structures of the paired networks, leading to higher false positive rate or lower power. In this light, we introduce a novel statistical method, specially in the directed network regime, to conduct differential analysis of two networks via appropriate reparameterization of the corresponding models. There are two major features of our method. Firstly, we jointly model the commonality and difference between two networks explicitly. This helps us to gain dramatic performance improvements over the naive construction method. Secondly, benefiting from the flexible framework of SEMs, we are able to conduct differential analysis of directed networks. Most importantly, our method allow for both acyclic and cyclic networks. Compared to the other methods, directionality and allowing for cyclicity are crucial for many network studies, especially in constructing gene regulatory networks. As far as we know, our method is the first work on differential analysis of directed networks that enjoys the two promising features.

The rest of this paper is organized as follows. We first introduce the model and its identifiability condition in Section 2.1 and Section 2.2, respectively. Then, we present our proposed method of **Reparameterization-based Differential analysis of directed Networks**, termed as **RedNet**, in Section 2.3. The theoretical justification of the proposed method is described in Section 2.4. Section 3 includes our studies on synthetic data showing the superior performance of our method, as well as an analysis of the Genotype-Tissue Expression (GTEx) data sets. We conclude our paper with brief discussion in Section 4.

## 2 METHODS

Here we first introduce the model and its identification condition, and then describe our proposed **RedNet** method for identifying common and differential structures between two directed networks, followed with its theoretical justification.

### 2.1 THE MODEL

We consider two networks, each describing the dependencies among a common set of variables or nodes in a unique population. For each node  $i \in \{1, 2, \dots, p\}$  in network  $k \in \{1, 2\}$ , its regulation structure can be represented by the following equation,

$$\underbrace{\mathbf{Y}_i^{(k)}}_{\text{node } i} = \underbrace{\mathbf{Y}_{-i}^{(k)} \boldsymbol{\gamma}_i^{(k)}}_{\text{regulation by others}} + \underbrace{\mathbf{X}^{(k)} \boldsymbol{\phi}_i^{(k)}}_{\text{anchoring regulation}} + \underbrace{\boldsymbol{\epsilon}_i^{(k)}}_{\text{error}}, \quad (1)$$

where  $\mathbf{Y}_i^{(k)}$  is the  $i$ -th column of  $\mathbf{Y}^{(k)}$  and  $\mathbf{Y}_{-i}^{(k)}$  is the submatrix of  $\mathbf{Y}^{(k)}$  by excluding  $\mathbf{Y}_i^{(k)}$ , with  $\mathbf{Y}^{(k)}$  a

$n^{(k)} \times p$  matrix.  $\mathbf{X}^{(k)}$  is a  $n^{(k)} \times q$  matrix with each column standardized to have  $\ell_2$  norm  $\sqrt{n^{(k)}}$ . The vectors  $\boldsymbol{\gamma}_i^{(k)}$  and  $\boldsymbol{\phi}_i^{(k)}$  encode the inter-nodes and anchoring regulatory effects, respectively. The index set of non-zeros of  $\boldsymbol{\phi}_i^{(k)}$  is known and denoted by  $\mathcal{A}_i^{(k)}$ , in other words,  $\mathcal{A}_i^{(k)} = \text{supp}(\boldsymbol{\phi}_i^{(k)})$ . The support set  $\mathcal{A}_i^{(k)}$  indexes the direct causal effects for the  $i$ -th node, and can be pre-specified based on the domain knowledge. However, the size of nonzero effect  $\boldsymbol{\phi}_i^{(k)}$  is unknown and can be estimated. Further property of  $\mathcal{A}_i^{(k)}$  will be discussed in Section 2.2. All elements of the error term are independently distributed following a normal distribution with mean zero and standard deviation  $\sigma_i^{(k)}$ . We assume that the matrix  $\mathbf{X}^{(k)}$  and the error term  $\boldsymbol{\epsilon}_i^{(k)}$  are independent of each other. However  $\mathbf{Y}_{-i}^{(k)}$  and  $\boldsymbol{\epsilon}_i^{(k)}$  may correlate with each other.  $\mathbf{Y}^{(k)}$  and  $\mathbf{X}^{(k)}$  include observed endogenous variables and exogenous variables, respectively.

By combining the  $p$  linear equations in (1), we can rewrite the two sets of linear equations in a systematic fashion as two structural equation models below,

$$\begin{cases} \mathbf{Y}^{(1)} = \mathbf{Y}^{(1)} \boldsymbol{\Gamma}^{(1)} + \mathbf{X}^{(1)} \boldsymbol{\Phi}^{(1)} + \boldsymbol{\mathcal{E}}^{(1)}, \\ \mathbf{Y}^{(2)} = \mathbf{Y}^{(2)} \boldsymbol{\Gamma}^{(2)} + \mathbf{X}^{(2)} \boldsymbol{\Phi}^{(2)} + \boldsymbol{\mathcal{E}}^{(2)}, \end{cases} \quad (2)$$

where each matrix  $\boldsymbol{\Gamma}^{(k)}$  is  $p \times p$  with zero diagonal elements and represents the inter-nodes regulatory effects in the corresponding network. Specifically, excluding the  $i$ -th element (which is zero) from the  $i$ -th column of  $\boldsymbol{\Gamma}^{(k)}$  leads to  $\boldsymbol{\gamma}_i^{(k)}$ . The  $q \times p$  matrix  $\boldsymbol{\Phi}^{(k)}$  contains the anchoring regulatory effects and its  $i$ -th column is  $\boldsymbol{\phi}_i^{(k)}$ . Each error term  $\boldsymbol{\mathcal{E}}^{(k)}$  is  $n^{(k)} \times p$  and has the error term  $\boldsymbol{\epsilon}_i^{(k)}$  as its  $i$ -th column.

Figure 1 gives an illustrative example of networks with three nodes and one anchoring regulation per node for the structural equations in (2). For example, with anchoring regulation on node  $Y_1$ ,  $X_1$  has a direct effect on node  $Y_1$  but indirect effects on node  $Y_2$  and  $Y_3$  via  $Y_1$ .

Figure 1: An Illustrative Example of Differential Network Between Two Directed Networks. The error term for each node is not shown for simplicity.

For each network  $k$ , its full model in (2) can be further transformed into the reduced form as follows,

$$\mathbf{Y}^{(k)} = \mathbf{X}^{(k)}\boldsymbol{\pi}^{(k)} + \boldsymbol{\xi}^{(k)}, \quad (3)$$

where the  $q \times p$  matrix  $\boldsymbol{\pi}^{(k)} = \boldsymbol{\Phi}^{(k)}(\mathbf{I} - \boldsymbol{\Gamma}^{(k)})^{-1}$  and the transformed error term  $\boldsymbol{\xi}^{(k)} = \boldsymbol{\mathcal{E}}^{(k)}(\mathbf{I} - \boldsymbol{\Gamma}^{(k)})^{-1}$ . The reduced model (3) reveals variables observed in  $\mathbf{X}^{(k)}$  as instrumental variables which will be used later to correct for the endogeneity issue. Otherwise, directly applying any regularization based regression to equation (1) will result in non-consistent or suboptimal estimation of model parameters [Fan and Liao, 2014, Chen et al., 2017, Lin et al., 2015, Zhu, 2018].

## 2.2 THE MODEL IDENTIFIABILITY

Here we introduce an identifiability assumption which helps to infer an identifiable system (2) from available data. We assume that each endogenous variable is directly regulated by a unique set of exogenous variables as long as it regulates other endogenous variables. That is, any regulatory node needs at least one anchoring exogenous variable to distinguish the corresponding regulatory effects from association. Explicitly let  $\mathcal{M}_{i0}^{(k)}$  denote the index set of endogenous variables which either directly or indirectly regulate the  $i$ -th endogenous variable in the  $k$ -th network. Thus,  $\mathcal{A}_i^{(k)} \subseteq \mathcal{M}_{i0}^{(k)}$ . The model identification condition can be stated in the below.

**Assumption 1.** For any  $i = 1, \dots, p$ ,  $\mathcal{A}_i^{(k)} \neq \emptyset$  if there exists  $j$  such that  $i \in \mathcal{M}_{j0}^{(k)}$ . Furthermore,  $\mathcal{A}_i^{(k)} \cap \mathcal{A}_j^{(k)} = \emptyset$  as long as  $i \neq j$ .

This assumption is slightly less restrictive than the one employed by Chen et al. [2017], and is a sufficient condition for model identifiability as it satisfies the rank condition in Schmidt [1976]. It can be further relaxed to allow nonempty  $\mathcal{A}_i^{(k)} \cap \mathcal{A}_j^{(k)}$  as long as each regulatory node has its own unique anchoring exogenous variables.

The above identifiability assumption not only identifies  $\gamma_i^{(k)}$  in model (1) from  $\boldsymbol{\pi}^{(k)}$  in model (3) but also helps reveal regulatory directionality of the networks. As illustrated in Figure 2, we can not recover the directionality between nodes  $Y_1$  and  $Y_2$  without the extra information provided by the direct causal factors  $X_1$  and  $X_2$  because all four sub-networks consisting of  $Y_1$  and  $Y_2$  (without  $X_1$  and  $X_2$ ) will be Markov equivalent. The known set  $\mathcal{A}_j^{(k)}$  serves as external prior knowledge which helps recover the directionality. In our two-stage construction of the differential network, the additional anchors  $X_1$  and  $X_2$  serve as instrumental variables in the calibration stage, since both  $X_1$  and  $X_2$  are independent of the error terms. The present direct causal effects from  $\mathbf{X}^{(k)}$

together with Assumption 1 differentiates our approach from the classical graphical models [Meinshausen and Bühlmann, 2006, Yuan and Lin, 2007] or the PC algorithm approaches [Spirtes et al., 2000, Kalisch and Bühlmann, 2007], since those methods either cannot recover edge directions or do not allow for cyclic structures due to lack of additional direct causal effects from  $\mathbf{X}^{(k)}$ .

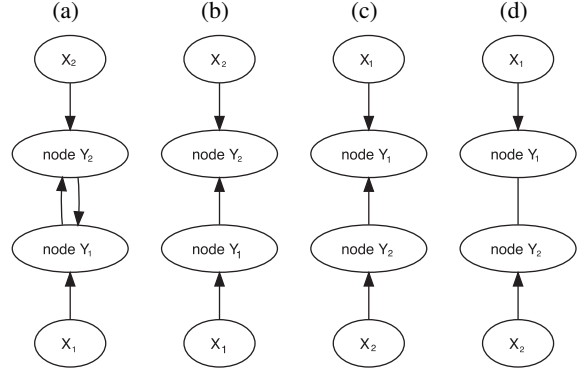

Figure 2: An Illustrative Example of Networks Which Are Not Markov Equivalent. However, without  $X_1$  and  $X_2$ , sub-networks consisting of only node  $Y_1$  and  $Y_2$  will be Markov equivalent.

## 2.3 TWO-STAGE DIFFERENTIAL ANALYSIS OF NETWORKS

Here we intend to develop a regularized version of the two-stage least squares. We first screen for exogenous variables and conduct  $\ell_2$  regularized regression of each endogenous variable against screened exogenous variables to obtain its good prediction which helps address the endogeneity issue in the following stage. At the second stage, we reparametrize the model to explicitly model the common and differential regulatory effects and identify them via the adaptive lasso method.

### 2.3.1 The Calibration Stage

To address the endogeneity issue, we aim for good prediction of each endogenous variable following the reduced model in (3). However, in the high-dimensional setting, the dimension  $q$  of  $\mathbf{X}^{(k)}$  can be much larger than the sample size  $n^{(k)}$ , and any direct prediction with all exogenous variables may not produce consistent prediction. Note that both Lin et al. [2015] and Zhu [2018] proposed to conduct variable selection with lasso or its variants and predict with selected exogenous variables. We here instead propose to first screen for exogenous variables with ISIS [Fan and Lv, 2008], and then apply ridge regression to predict the endogenous variables with screened exogenous variables. While variable screening is more robust

and provides higher coverage of true variables than variable selection, its combination with ridge regression puts less computational burden. Furthermore, as shown by Chen et al. [2017], ridge regression performs well in predicting the endogenous variables.

Let  $\mathcal{M}_i^{(k)}$  denotes the selected index set for  $i$ -th node in  $k$ -th network from the variable screening which reduces the dimension from  $q$  to  $d = |\mathcal{M}_i^{(k)}|$ . The *Sure Independence Screening Property* in Fan and Lv [2008] can be directly applied in our case to guarantee that  $\mathcal{M}_i^{(k)}$  covers the true set  $\mathcal{M}_{i0}^{(k)}$  with a large probability.

**Assumption 2.**  $n^{(1)}$  and  $n^{(2)}$  are at the same order, i.e.,  $n_{\min} = \min(n^{(1)}, n^{(2)}) \asymp n^{(1)} \asymp n^{(2)}$ , and  $p \asymp q$ .

**Theorem 1.** *Assuming Conditions 1-4 in the supplemental materials which restrict positive  $\tilde{\tau}$  and  $\tilde{\kappa}$ , under Assumption 2, there exists some  $\theta \in (0, 1 - 2\tilde{\kappa} - \tilde{\tau})$  such that, when  $d = |\mathcal{M}_i^{(k)}| = O((n_{\min})^{1-\theta})$ , we have, for some constant  $C > 0$ ,*

$$\mathbb{P}(\mathcal{M}_{i0}^{(k)} \subseteq \mathcal{M}_i^{(k)}) = 1 - \mathcal{O}\left(\exp\left\{-\frac{C(n^{(k)})^{1-2\tilde{\kappa}}}{\log(n^{(k)})}\right\}\right).$$

Hereafter we assume that  $\mathcal{M}_i^{(k)}$  successfully covers the true set  $\mathcal{M}_{i0}^{(k)}$  for convenience of stating the following assumptions and theorems. That is, the probability of successful screening is not incorporated into our assumptions or theorems in the below.

For node  $i$  in network  $k$ , let  $\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)}$  denotes the submatrix of  $\mathbf{X}^{(k)}$  with prescreened columns which are indexed by  $\mathcal{M}_i^{(k)}$ . With  $\boldsymbol{\pi}_i^{(k)}$  denoting the  $i$ -th column of  $\boldsymbol{\pi}^{(k)}$ , the subvector of  $\boldsymbol{\pi}_i^{(k)}$  indexed by  $\mathcal{M}_i^{(k)}$  will be simply denoted by  $\boldsymbol{\pi}_{\mathcal{M}_i^{(k)}}^{(k)}$  without confusion. Such simplified notations will apply to other vectors and matrices in the rest of this paper.

With  $d$  pre-screened exogenous variables, we can apply ridge regression to the model

$$\mathbf{Y}_i^{(k)} = \mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)} \boldsymbol{\pi}_{\mathcal{M}_i^{(k)}}^{(k)} + \boldsymbol{\xi}_i^{(k)}, \quad (4)$$

to obtain the estimates  $\hat{\boldsymbol{\pi}}_{\mathcal{M}_i^{(k)}}^{(k)}$  of  $\boldsymbol{\pi}_{\mathcal{M}_i^{(k)}}^{(k)}$ , and predict  $\mathbf{Y}_i^{(k)}$  with  $\hat{\mathbf{Y}}_i^{(k)} = \mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)} \hat{\boldsymbol{\pi}}_{\mathcal{M}_i^{(k)}}^{(k)}$ .

### 2.3.2 The Construction Stage

With known  $\mathcal{A}_i^{(k)}$ , we can rewrite model (1) as,

$$\mathbf{Y}_i^{(k)} = \mathbf{Y}_{-i}^{(k)} \boldsymbol{\gamma}_i^{(k)} + \mathbf{X}_{\mathcal{A}_i^{(k)}}^{(k)} \boldsymbol{\phi}_{\mathcal{A}_i^{(k)}}^{(k)} + \boldsymbol{\epsilon}_i^{(k)}. \quad (5)$$

Before we use the predicted  $\mathbf{Y}^{(k)}$  to identify both common and differential regulatory effects across the two networks, we first reparametrize the model so as to define differential regulatory effects explicitly,

$$\boldsymbol{\beta}_i^- = \frac{\boldsymbol{\gamma}_i^{(1)} - \boldsymbol{\gamma}_i^{(2)}}{2}, \quad \boldsymbol{\beta}_i^+ = \frac{\boldsymbol{\gamma}_i^{(1)} + \boldsymbol{\gamma}_i^{(2)}}{2}. \quad (6)$$

Here  $\boldsymbol{\beta}_i^-$  represents the **differential regulatory effects** between the two networks. We need compare  $\boldsymbol{\beta}_i^+$  with  $\boldsymbol{\beta}_i^-$  to identify the **common regulatory effects**, that is, effects of all regulations with nonzero values in  $\boldsymbol{\beta}_i^+$  but zero values in  $\boldsymbol{\beta}_i^-$ .

Note that other differential analysis of networks may suggest a different reparametrization to identify common and differential regulatory effects. For example, in a typical case-control study, we may expect few structures in the case network mutated from the control network. While we are interested in identifying differential structures in the case network, we may be also interested in identifying baseline network structures in the control network. Therefore we may reparametrize the model with the regulatory effects in the control network, as well as the differential regulatory effects defined as the difference of regulatory effects between case and control networks. We want to point out that the method described here still applies and we can also derive similar theoretical results as follows.

Following the reparametrization in (6), we can rewrite model (5) as follows,

$$\begin{pmatrix} \mathbf{Y}_i^{(1)} \\ \mathbf{Y}_i^{(2)} \end{pmatrix} = \begin{pmatrix} \mathbf{Y}_{-i}^{(1)} & \mathbf{Y}_{-i}^{(1)} \\ \mathbf{Y}_{-i}^{(2)} & -\mathbf{Y}_{-i}^{(2)} \end{pmatrix} \begin{pmatrix} \boldsymbol{\beta}_i^+ \\ \boldsymbol{\beta}_i^- \end{pmatrix} + \begin{pmatrix} \mathbf{X}_{\mathcal{A}_i^{(1)}}^{(1)} & 0 \\ 0 & \mathbf{X}_{\mathcal{A}_i^{(2)}}^{(2)} \end{pmatrix} \begin{pmatrix} \boldsymbol{\phi}_{\mathcal{A}_i^{(1)}}^{(1)} \\ \boldsymbol{\phi}_{\mathcal{A}_i^{(2)}}^{(2)} \end{pmatrix} + \begin{pmatrix} \boldsymbol{\epsilon}_i^{(1)} \\ \boldsymbol{\epsilon}_i^{(2)} \end{pmatrix}. \quad (7)$$

Denote

$$\mathbf{Y}_i = \begin{pmatrix} \mathbf{Y}_i^{(1)} \\ \mathbf{Y}_i^{(2)} \end{pmatrix}, \quad \mathbf{Z}_{-i} = \begin{pmatrix} \mathbf{Y}_{-i}^{(1)} & \mathbf{Y}_{-i}^{(1)} \\ \mathbf{Y}_{-i}^{(2)} & -\mathbf{Y}_{-i}^{(2)} \end{pmatrix},$$

$$\boldsymbol{\beta}_i = \begin{pmatrix} \boldsymbol{\beta}_i^+ \\ \boldsymbol{\beta}_i^- \end{pmatrix}, \quad \boldsymbol{\epsilon}_i = \begin{pmatrix} \boldsymbol{\epsilon}_i^{(1)} \\ \boldsymbol{\epsilon}_i^{(2)} \end{pmatrix}.$$

Further define the projection matrix for each network,

$$\mathbf{H}_i^{(k)} = I_{n^{(k)}} - \mathbf{X}_{\mathcal{A}_i^{(k)}}^{(k)} \left( \mathbf{X}_{\mathcal{A}_i^{(k)}}^{(k)T} \mathbf{X}_{\mathcal{A}_i^{(k)}}^{(k)} \right)^{-1} \mathbf{X}_{\mathcal{A}_i^{(k)}}^{(k)T}.$$

Applying the projection matrix  $\mathbf{H}_i = \text{diag}\{\mathbf{H}_i^{(1)}, \mathbf{H}_i^{(2)}\}$  to both sides of model (7), we can remove the exogenous variables from the model and obtain,

$$\mathbf{H}_i \mathbf{Y}_i = \mathbf{H}_i \mathbf{Z}_{-i} \boldsymbol{\beta}_i + \mathbf{H}_i \boldsymbol{\epsilon}_i. \quad (8)$$

---

**Algorithm 1** Reparameterization-Based Differential Analysis of Network (ReDNet)

---

**Input:** For  $k \in \{1, 2\}$ ,  $\mathbf{Y}^{(k)}$ ,  $\mathbf{X}^{(k)}$ , index set  $\mathcal{A}_i^{(k)}$  for each  $i \in \{1, 2, \dots, p\}$ . Set  $d = O(n_{\min}^{1-\theta})$ .

**for**  $i \rightarrow 1$  **to**  $p$  **do**

Stage 1.a. Screen for a submatrix  $\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)}$  of  $\mathbf{X}^{(k)}$  for  $\mathbf{Y}_i^{(k)}$  versus  $\mathbf{X}^{(k)}$  and set  $\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)} = \mathbf{X}^{(k)}$  if  $q \leq n^{(k)}$ .

Stage 1.b. Apply ridge regression to regress  $\mathbf{Y}_i^{(k)}$  against  $\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)}$  to obtain prediction  $\hat{\mathbf{Y}}_i^{(k)}$ .

**end for**

**for**  $i \rightarrow 1$  **to**  $p$  **do**

Stage 2. Apply adaptive lasso to regress  $\mathbf{H}_i \mathbf{Y}_i$  against  $\mathbf{H}_i \hat{\mathbf{Z}}_{-i}$  to obtain coefficients estimate  $\hat{\beta}_i$ .

**end for**

**Output:** The common and differential regulatory effects in  $\hat{\beta}_1, \dots, \hat{\beta}_p$ .

---

To address the endogeneity issue, we predict  $\mathbf{Z}_{-i}$  by replacing its component  $\mathbf{Y}_{-i}^{(k)}$  with the predicted value  $\hat{\mathbf{Y}}_{-i}^{(k)}$  from the previous stage, and then regressing  $\mathbf{H}_i \mathbf{Y}_i$  against  $\mathbf{H}_i \hat{\mathbf{Z}}_{-i}$  with the adaptive lasso to consistently estimate  $\beta_i$ . That is, an optimal  $\beta_i$  can be obtained as,

$$\hat{\beta}_i = \arg \min_{\beta_i} \left\{ \frac{1}{n} \|\mathbf{H}_i \mathbf{Y}_i - \mathbf{H}_i \hat{\mathbf{Z}}_{-i} \beta_i\|_2^2 + \lambda_i \omega_i^T |\beta_i|_1 \right\},$$

where  $|\beta_i|_1$  is a vector taking elementwise absolute values of  $\beta_i$ ,  $\omega_i$  is the adaptive weights whose components are inversely proportional to the components of an initial estimator of  $\beta_i$ , and  $\lambda_i$  is the adaptive tuning parameter.

The two-stages algorithm is summarized in Algorithm 1. With the estimator  $\hat{\beta}_i$  from the second stage, we can accordingly obtain estimators  $\hat{\gamma}_i^{(1)} = \hat{\beta}_i^+ + \hat{\beta}_i^-$  and  $\hat{\gamma}_i^{(2)} = \hat{\beta}_i^+ - \hat{\beta}_i^-$ .

## 2.4 THEORETICAL ANALYSIS

As shown in Theorem 1, a screening method like ISIS [Fan and Lv, 2008] can identify  $\mathcal{M}_i^{(k)}$  with size  $d = O(n_{\min}^{1-\theta})$  which covers the true set  $\mathcal{M}_{i0}^{(k)}$  with a sufficiently large probability. For the sake of simplicity and without loss of generality, in the following we assume  $\mathcal{M}_{i0}^{(k)} \subseteq \mathcal{M}_i^{(k)}$ .

We first investigate the consistency of predictions from the first stage. The consistency properties will be characterized by prespecified sequences  $f^{(k)} = o(n^{(k)})$  but  $f^{(k)} \rightarrow \infty$  as  $n^{(k)} \rightarrow \infty$ . We also denote  $f_{\max} = f^{(1)} \vee f^{(2)}$ , i.e.,  $\max\{f^{(1)}, f^{(2)}\}$ .

The following assumption is required for the consistency properties.

**Assumption 3.** For each network  $k$ , the singular values of  $\mathbf{I} - \mathbf{\Gamma}^{(k)}$  are positively bounded from below, and there exist some positive constants  $c_1^{(k)}$  and  $c_2^{(k)}$  such that, for each node  $i$ ,  $\max_{\|\delta\|_2=1} (n^{(k)})^{-1/2} \|\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)} \delta\|_2 \leq c_1^{(k)}$  and  $\min_{\|\delta\|_2=1} (n^{(k)})^{-1/2} \|\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)} \delta\|_2 \geq c_2^{(k)}$ . Furthermore, the ridge parameter  $\lambda_i^{(k)} = o(n_{\min})$ .

For the ease of exposition, we will omit the subscript  $\mathcal{M}_i^{(k)}$  from  $\mathbf{X}_{\mathcal{M}_i^{(k)}}^{(k)}$  henceforth, and accordingly use  $\pi_i^{(k)}$  and  $\hat{\pi}_i^{(k)}$  which include the zero components of excluded predictors.

Denote  $\mathbf{X} = \text{diag}\{\mathbf{X}^{(1)}, \mathbf{X}^{(2)}\}$ , and

$$\mathbf{Z} = \begin{pmatrix} \mathbf{Y}^{(1)} & \mathbf{Y}^{(1)} \\ \mathbf{Y}^{(2)} & -\mathbf{Y}^{(2)} \end{pmatrix}, \quad \mathbf{\Pi} = \begin{pmatrix} \pi^{(1)} & \pi^{(1)} \\ \pi^{(2)} & -\pi^{(2)} \end{pmatrix}.$$

We use  $\mathbf{\Pi}_j$  to denote the  $j$ -th column of the matrix  $\mathbf{\Pi}$  and  $\pi_j^{(k)}$  to denote the  $j$ -th column of the matrix  $\pi^{(k)}$ . We also use  $\hat{\mathbf{Z}}$  and  $\hat{\mathbf{\Pi}}$  to denote the prediction of  $\mathbf{Z}$  and estimate of  $\mathbf{\Pi}$ , respectively. Note that, with the ridge parameter  $\lambda_i^{(k)}$  for the ridge regression taken on node  $i$  in network  $k$ , we have  $r_i^{(k)} = (\lambda_i^{(k)})^2 \|\pi_i^{(k)}\|_2^2 / n^{(k)}$  and hence define  $r_{\max} = \max_{1 \leq i \leq p} [r_i^{(1)} \vee r_i^{(2)}]$ . Then the estimation and prediction losses at the first stage can be summarized in the following theorem.

**Theorem 2.** Under Assumptions 1-3, for each  $j \in \{1, 2, \dots, 2p\}$ , there will exist some constant  $C_1$  and  $C_2$  such that, with probability at least  $1 - e^{-f^{(1)}} - e^{-f^{(2)}}$ ,

1.  $\|\hat{\mathbf{\Pi}}_j - \mathbf{\Pi}_j\|_2^2 \leq C_1 (d \vee r_{\max} \vee f_{\max}) / n_{\min}$ ;
2.  $\|\mathbf{X}(\hat{\mathbf{\Pi}}_j - \mathbf{\Pi}_j)\|_2^2 \leq C_2 (d \vee r_{\max} \vee f_{\max})$ .

The proof is detailed in the supplemental materials.

Note that these two sets of losses can be controlled by the same upper bounds across the two networks with probability at least  $1 - e^{-f^{(1)} + \log(p)} - e^{-f^{(2)} + \log(p)}$ . Therefore,  $f^{(k)}$  can be selected such that  $f^{(k)} - \log(p) \rightarrow \infty$ , which will provide a probability approaching one to have the network-wide losses approaching zero.

Furthermore, the dimension  $p$  can be divergent up to an exponential order, say  $p = e^{n_{\min}^c}$  for some  $c \in (0, 1)$ . We can set  $f^{(1)} = f^{(2)} = n_{\min}^{(1+c)/2}$  and, apparently,  $f^{(k)} = o(n_{\min})$  but  $f^{(k)} - \log(p) = n_{\min}^{(1+c)/2} - n_{\min}^c \rightarrow \infty$ .

Since the ridge parameter  $\lambda_i^{(k)} = o(n_{\min})$ ,  $r_i^{(k)} = \|\pi_i^{(k)}\|_2^2 \times o(n_{\min})$ . Therefore, when all  $\|\pi_i^{(k)}\|_2$  are uniformly bounded, we have  $r_{\max} = o(n_{\min})$ . Otherwise, the ridge parameter  $\lambda_i^{(k)}$  should be adjusted accordingly

to control both estimation and prediction losses.

Before we characterize the consistency of estimated regulatory effects on the second stage, we first introduce the following concept of restricted eigenvalue which is used to present an assumption.

**Definition 2.1.** *The restricted eigenvalue of a matrix  $\mathbf{A}$  on an index set  $\mathcal{S}$  is defined as*

$$\phi_{re}(\mathbf{A}, \mathcal{S}) = \min_{\|\delta_{\mathcal{S}^c}\|_1 \leq 3\|\delta_{\mathcal{S}}\|_1} \frac{\|\mathbf{A}\delta\|_2}{\sqrt{n}\|\delta_{\mathcal{S}}\|_2}. \quad (9)$$

For the  $i$ -th node, we use  $\mathcal{S}_i$  to denote the non-zero indices of  $\beta_i$ , i.e.,  $\mathcal{S}_i = \text{supp}(\beta_i)$ . Further denote

$$\mathbf{\Pi}_{-i} = \begin{pmatrix} \pi_{-i}^{(1)} & \pi_{-i}^{(1)} \\ \pi_{-i}^{(2)} & -\pi_{-i}^{(2)} \end{pmatrix}.$$

As in Bickel et al. [2009], we impose the following restricted eigenvalue condition on the design matrix in (8).

**Assumption 4.** There exists a constant  $\phi_0 > 0$  such that  $\phi_{re}(\mathbf{H}_i \mathbf{X} \mathbf{\Pi}_{-i}, \mathcal{S}_i) \geq \phi_0$ .

Let  $n = n^{(1)} + n^{(2)}$ ,  $c_{\max} = c_1^{(1)} \vee c_1^{(2)}$ , and  $\mathbf{B} = [\beta_1, \beta_2, \dots, \beta_p]$ . The matrix norms  $\|\cdot\|_1$  and  $\|\cdot\|_{\infty}$  are the maximum of column and row sums of absolute values of the matrix, respectively. For a vector, we define  $\|\cdot\|_{\infty}$  and  $\|\cdot\|_{-\infty}$  to be the maximum and minimum absolute values of its components. Then, we can derive the following loss bounds for the estimation and prediction at the second stage on the basis of Theorem 2.

**Theorem 3.** *Suppose that, for node  $i$ , the adaptive lasso at the second stage takes the tuning parameter*

$$\lambda_i \asymp \|\omega_i\|_{-\infty}^{-1} \|\mathbf{B}\|_1 \|\mathbf{\Pi}\|_1 \sqrt{(d \vee r_{\max} \vee f_{\max}) \log(p) / n_{\min}},$$

and  $\sqrt{(d \vee r_{\max} \vee f_{\max}) / n} + c_{\max} \|\mathbf{\Pi}\|_1 \leq \sqrt{c_{\max}^2 \|\mathbf{\Pi}\|_1^2 + \phi_0^2 / (64C_2 |\mathcal{S}_i|)}$ . Let  $h_n = (\|\mathbf{B}\|_1^2 \wedge 1) \times ((n \|\mathbf{\Pi}\|_1^2 / d) \wedge (d \vee r_{\max} \vee f_{\max})) \log(p)$ . Under Assumptions 1-4, there exist positive constants  $C_3$  and  $C_4$  such that, with probability at least  $1 - 3e^{-C_3 h_n + \log(4pq)} - e^{-f^{(1)} + \log(p)} - e^{-f^{(2)} + \log(p)}$ ,

1. *Estimation Loss:*

$$\|\hat{\beta}_i - \beta_i\|_1 \leq 8C_4 |\mathcal{S}_i| \times \frac{\|\omega_{\mathcal{S}_i}\|_{\infty}^2 \|\mathbf{B}\|_1 \|\mathbf{\Pi}\|_1}{\phi_0^2 \|\omega_i\|_{-\infty}^2} \sqrt{\frac{(d \vee r_{\max} \vee f_{\max}) \log(p)}{n_{\min}}};$$

2. *Prediction Loss:*

$$\frac{1}{n} \|\mathbf{H}_i \hat{\mathbf{Z}}_{-i} (\hat{\beta}_i - \beta_i)\|_2^2 \leq C_4^2 |\mathcal{S}_i| \times \frac{\|\omega_{\mathcal{S}_i}\|_{\infty}^2 \|\mathbf{B}\|_1^2 \|\mathbf{\Pi}\|_1^2}{\phi_0^2 \|\omega_i\|_{-\infty}^2} \frac{(d \vee r_{\max} \vee f_{\max}) \log(p)}{n_{\min}}.$$

The main idea of the proof is to take advantage of the commonly used restricted eigenvalue condition and irrepresentable condition for lasso-type estimator. However, the design matrix in our case includes predicted values instead of the original one, which complicates the proof. We claim that the restricted eigenvalue and irrepresentable condition still hold for the predicted design matrix as long as the estimation and prediction losses are well controlled at the calibration stage. The proof is detailed in the supplemental materials.

The available anchoring regulators as required by Assumption 1 implies that both  $\|\mathbf{B}\|_1 > 0$  and  $\|\mathbf{\Pi}\|_1 > 0$ , so  $h_n / \log(p) \rightarrow \infty$ . That is, these loss bounds hold with a sufficient large probability with properly chosen  $f^{(k)}$ .

The two sets of losses in Theorem 3 can also be controlled across the whole system by the same upper bounds defined by replacing  $|\mathcal{S}_i|$  with  $s_{\max} = \max_i |\mathcal{S}_i|$ , with probability at least  $1 - 3e^{-C_3 h_n + \log(4q) + 2 \log(p)} - e^{-f^{(1)} + 2 \log(p)} - e^{-f^{(2)} + 2 \log(p)}$ . When both  $p$  and  $q$  are divergent up to an exponential order, say  $p \asymp q \asymp e^{n_{\min}^c}$  for some  $c \in (0, 1)$ , we can set  $f^{(1)} = f^{(2)} = n_{\min}^{(1+c)/2}$  to guarantee the bounds at a sufficient large probability. However, the bounds are determined by  $(d \vee r_{\max} \vee f_{\max}) \log(p)$  which is  $o(n_{\min})$  only when  $c < \min(1/3, \theta)$ . Therefore, if  $s_{\max}$  also diverges up to  $n_{\min}^{\tilde{c}}$  with  $\tilde{c} < \min(1/4, \theta/2, 1 - \theta)$ , the losses can be well controlled for  $c < \min((1 - 4\tilde{c})/3, \theta - 2\tilde{c})$ .

Note that, with properly chosen  $f^{(1)}$  and  $f^{(2)}$ , these losses are well controlled at  $o(n_{\min})$ , revealing the fact that we need to have sufficient observations for each network for consistent differential analysis of the two networks.

Let  $W_i = \text{diag}\{\omega_i\}$ . Denote  $\mathcal{I}_i = \frac{1}{n} \mathbf{\Pi}_{-i}^T \mathbf{X}^T \mathbf{H}_i \mathbf{X} \mathbf{\Pi}_{-i}$  and  $\hat{\mathcal{I}}_i = \frac{1}{n} \hat{\mathbf{\Pi}}_{-i}^T \mathbf{X}^T \mathbf{H}_i \mathbf{X} \hat{\mathbf{\Pi}}_{-i}$ . Let  $\mathcal{I}_{i,11}$  be a submatrix of  $\mathcal{I}_i$  with rows and columns both indexed by  $\mathcal{S}_i$ , and  $\mathcal{I}_{i,21}$  be a submatrix of  $\mathcal{I}_i$  with rows and columns indexed by  $\mathcal{S}_i^c$  and  $\mathcal{S}_i$ , respectively.  $\hat{\mathcal{I}}_{i,11}$  and  $\hat{\mathcal{I}}_{i,21}$  are similarly defined from  $\hat{\mathcal{I}}_i$ . We further define the minimal signal strength  $b_i = \max_{j \in \mathcal{S}_i} |\beta_{ij}|$  and  $\psi_i = \|\mathcal{I}_{i,11}^{-1} W_{\mathcal{S}_i}\|_{\infty}$ .

The following assumption, reminiscent of the *adaptive irrepresentable condition* in Huang et al. [2008], helps investigate the selection consistency of regulatory effects.

**Assumption 5.** (Weighted Irrepresentable Condition) There exists a constant  $\tau \in (0, 1)$  such that  $\|W_{\mathcal{S}_i^c}^{-1} \mathcal{I}_{i,21}^{-1} \mathcal{I}_{i,11} W_{\mathcal{S}_i}\|_{\infty} < 1 - \tau$ .

**Theorem 4.** (Variable Selection Consistency) Denote  $\hat{\mathcal{S}} = \{j : \hat{\beta}_{ij} \neq 0, j \neq i\}$ . Suppose that, for node  $i$ ,  $\hat{\mathcal{I}}_{i,11}$  is invertible,  $b_i > \lambda_i \psi_i / (2 - \tau)$ , and  $\sqrt{(d \vee r_{\max} \vee f_{\max}) / n + c_{\max} \|\mathbf{\Pi}\|_1} \leq$

$\sqrt{c_{\max}^2 \|\mathbf{I}\|_1^2 + \min(\phi_0^2/64, \tau(4-\tau)^{-1} \|\omega_i\|_{-\infty}/\psi_i)/(C_2|S_i|)}$ .  
*Under Assumptions 1-5, there exists some constant  $C_5 > 0$  such that  $\hat{S}_i = S_i$  with probability at least  $1 - 3e^{-C_5 h_n + \log(4pq)} - e^{-f^{(1)} + \log(p)} - e^{-f^{(2)} + \log(p)}$ .*

This theorem implies that our proposed method can identify both common and differential regulatory effects between the two networks with a sufficiently large probability. On the other hand, the assumed weighted irrepressible condition means that the true signal should not correlate too much with irrelevant predictors so as to conduct a successful differential analysis. The corresponding proof is detailed in the supplemental materials.

### 3 EXPERIMENTS

#### 3.1 SYNTHETIC DATA EVALUATION

Here we report on experiments with synthetic data to show the superior performance of our method. We compare the method **RedNet** to a naive differential analysis which employs the 2SPLS method proposed by [Chen et al., 2017] to construct each network separately. Note that the 2SPLS method is modified here by applying ISIS to screen exogenous variables before conducting ridge regression to predict endogenous variables, making the naive differential analysis comparable to **RedNet**.

Synthetic data are generated from both acyclic and cyclic networks involving 1000 endogenous variables, with the sample size from 200 to 300. Each network includes a subnetwork of 50 endogenous variables, whose shared and differential structures will be investigated against its pair. On average, each endogenous variable has one regulatory effect in a sparse subnetwork, and three regulatory effects in a dense network. While each pair of subnetworks in comparison share many identical regulatory effects, they also share five regulatory effects but with opposite signs, and each network has five unique regulatory effects (so the total number of differential regulatory effects is 15). The nonzero regulatory effects were independently sampled from a uniform distribution over the range  $[-0.8, -0.3] \cup [0.3, 8]$ . While assuming each node is directly regulated by one exogenous variable, each exogenous variable was sampled from discrete values 0, 1 and 2 with probabilities 0.25, 0.5 and 0.25, respectively. All of the noise terms were independently sampled from the normal distribution  $N(0, 0.1^2)$ . We also conducted differential analysis between two networks with both  $\mathbf{X}^{(1)} \neq \mathbf{X}^{(2)}$  and  $\mathbf{X}^{(1)} = \mathbf{X}^{(2)}$  as in practice the paired networks may or may not share identically valued exogenous variables.

We evaluate the performance in terms of the false discovery rate (FDR), power and Matthews correlation co-

efficient (MCC) [Matthews, 1975]. Let TP, TN, FP and FN denote the numbers of true positives, true negatives, false positives, and false negatives, respectively. MCC is defined as,

$$\text{MCC} = \frac{\text{TP} \times \text{TN} - \text{FP} \times \text{FN}}{\sqrt{(\text{TP} + \text{FP})(\text{TP} + \text{FN})(\text{TN} + \text{FP})(\text{TN} + \text{FN})}}.$$

Here we refer nonzero effects as positives and zero effects as negatives. The MCC varies from 0 to 1 with larger values implying better variable selection.

In each differential analysis, the ridge regression employed the generalized cross validation [Golub et al., 1979] to select the ridge parameter, and the adaptive lasso used 10-fold cross-validation to choose its tuning parameter. Following the recommendation by Fan and Lv [2008],  $(n^{(k)})^{0.9}$  variables are screened by ISIS.

For each type of networks, 100 synthetic data sets were generated, and the differential analysis results are summarized in Figure 3. Overall, both **RedNet** and the naive approach maintain high power in identifying both differential and common regulatory effects. However, the naive approach tends to report high FDR, especially over 80% false discoveries of differential regulatory effects. Such a tendency to report false positives by the naive approach results in lower MCC, with dramatic decrease in identifying differential regulatory effects.

While both methods performed stably across networks with  $\mathbf{X}^{(1)} \neq \mathbf{X}^{(2)}$  and  $\mathbf{X}^{(1)} = \mathbf{X}^{(2)}$ , **RedNet** performed better in identifying both common and differential regulatory effects from dense networks than sparse networks in terms of FDR and MCC. However, the naive approach tends to report even higher FDR and so much lower MCC when identifying differential regulatory effects from dense networks, although reporting lower FDR and higher MCC when identifying common regulatory effects from dense networks.

We also calculated the standard errors (SE) of the reported FDR, power, and MCC over 100 synthetic data sets (the results are not shown). They are all small with most at the scale of thousandth and others at the scale of hundredth. Therefore, **RedNet** performed robustly in differential analysis of networks, and the 2SPLS approach by Chen et al. [2017] performed also robustly in constructing single networks.

#### 3.2 THE GENOTYPE-TISSUE EXPRESSION DATA

We performed differential analysis of gene regulatory networks on two sets of genetic genomics data from the Genotype-Tissue Expression (GTEx) project [Carithers et al., 2015], with one collected from human whole blood

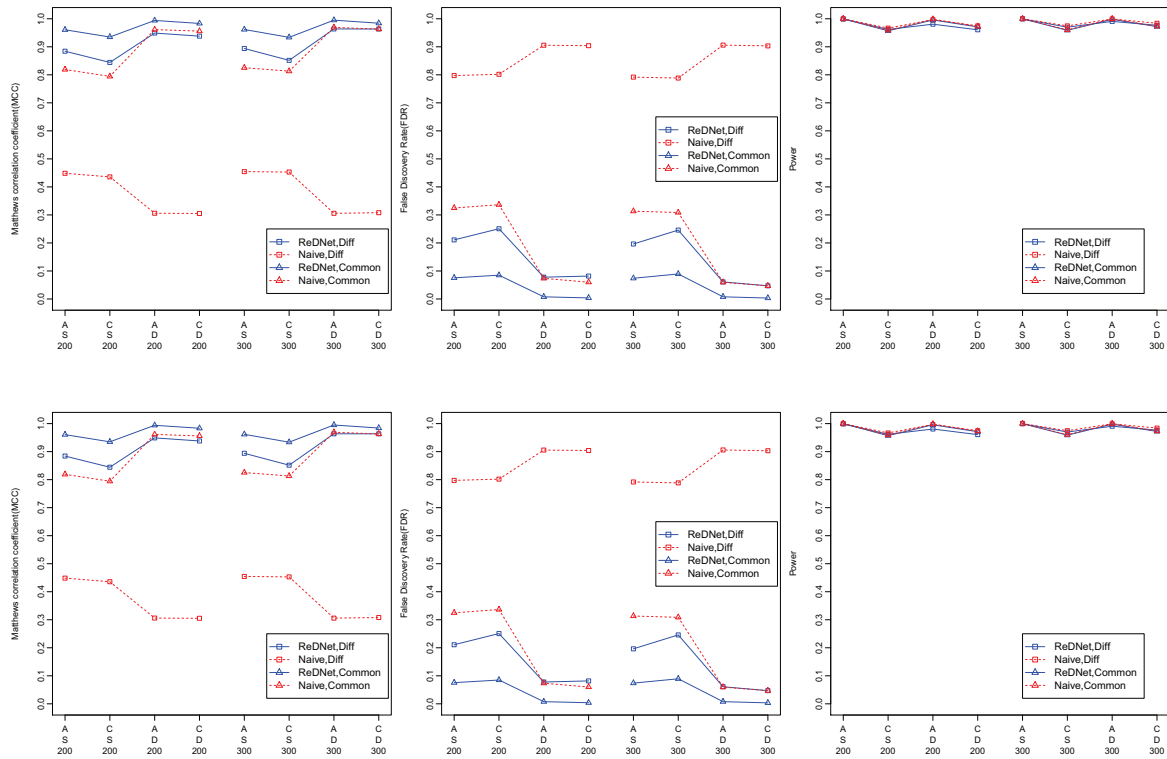

Figure 3: Performance of ReDNet Versus the Naive Approach (i.e. two networks are constructed independently). The results average over 100 synthetic data sets for different types of networks, with letters *A*, *C*, *S*, *D* in the x-axis denoting Acylic, Cyclic, Sparse and Dense networks, respectively. “Diff” and “Common” summarize the performance on differential and common regulatory effects, respectively. The sample size  $n^{(2)} = n^{(2)}$  is either 200 or 300.

(WB) and another one from human muscle skeletal (MS). The WB and MS data included genome-wide genetic and genotypic values from 350 and 367 healthy subjects, respectively. Both data sets were preprocessed following Carithers et al. [2015] and Stegle et al. [2010], resulting in a total of 15,899 genes and 1,083,917 single nucleotide polymorphisms (SNPs) being shared by WB and MS.

Expression quantitative trait loci (eQTL) mapping [Gilad et al., 2008] was conducted and identified 9875 genes with at least one marginally significant cis-eQTL (with  $p$ -value  $< 0.05$ ). For each gene, we further filtered its set of cis-eQTL by controlling the pairwise correlation under 0.9 and keeping up to three cis-eQTL which have the strongest association with the corresponding gene expression. These cis-eQTL serve as anchoring exogenous variables for the genes, and expression levels of different genes are endogenous variables. At completion of preprocessing data, we have 9,875 endogenous variables and 23,920 exogenous variables.

We applied **ReDNet** to infer the differential gene regulation on a set of eighty target genes, which had largest changes on gene-gene correlation between the two tis-

sues. We identified a total of 711 common and 572 differential regulations on the eighty target genes. To evaluate the significance of identified regulations, we bootstrapped 100 data sets, and conducted differential analysis on each bootstrap data set. As summarized in Table 1, 50, 43 and 34 differential regulatory effects were identified in over 70%, 80% and 90% of the bootstrap data sets, respectively.

Table 1: Summary of Regulations Identified in Over 70%, 80%, 90% of the Bootstrap Data Sets by **ReDNet** From GTEx Data. Shown under “Original” are for those identified from the original data.

	Original	70%	80%	90%
Common	711	116	108	93
Differential	572	50	43	34

The top four subnetworks bearing differential regulations on some of the eighty target genes were shown in Figure 4. We also constructed the differential networks using the naive approach (the results are not shown), and reported more regulations which cover the reported ones

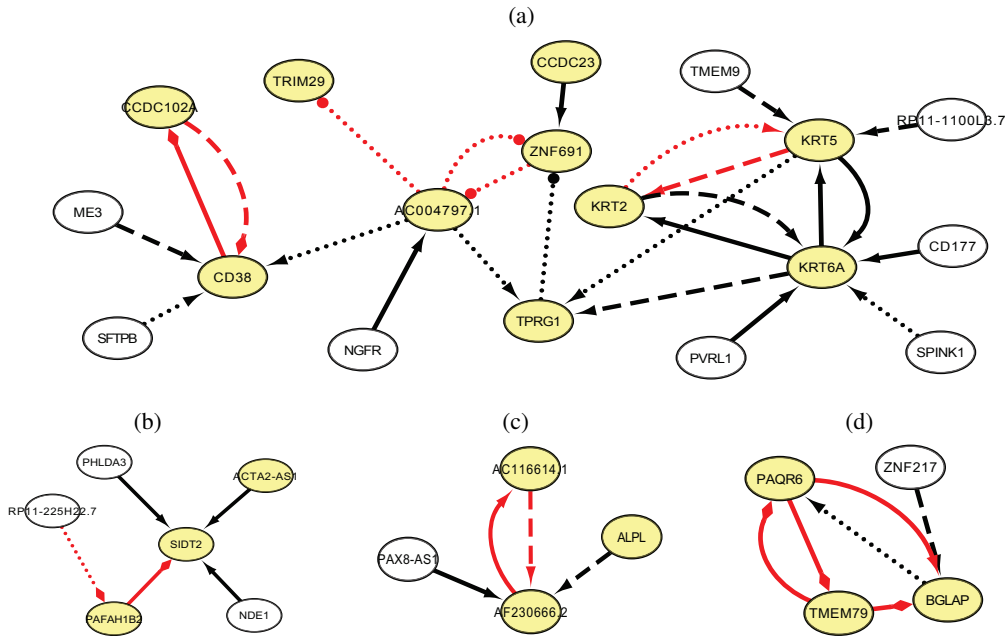

Figure 4: The Top Four Differential Subnetworks of Gene Regulation Identified by **ReDNet** From GTEx Data. The dotted, dashed, and solid lines imply regulations constructed in over 70%, 80%, and 90% of the bootstrap data sets, respectively. Highlighted in yellow are the target genes whose regulatory genes are focused in this study. The differential regulations are in red while common regulations are in black. The arrow head implies up regulation in both networks or no regulation in at most one network; the circle head implies down regulation in the whole blood but up regulation in muscle skeletal; and the diamond head implies up regulation in whole blood but down regulation muscle skeletal.

by **ReDNet**. This concurs with our observation in the synthetic data evaluation that the naive approach tends to report higher false positives, especially for differential regulatory effects.

## 4 CONCLUSION

We have developed a novel two-stage differential analysis method named **ReDNet**. The first stage, i.e., the calibration stage, aims for good prediction of the endogenous variables, and the second stage, i.e., the construction stage, identifies both common and differential network structures in a node-wise fashion. The key idea of **ReDNet** method is to appropriately reparametrize the independent models into a joint model so as to estimate differential and common effects directly. This approach can dramatically reduce the false discovery rate. In the experiments with synthetic data, we demonstrated the effectiveness of our method, which outperformed the naive approach with a large margin. Note that **ReDNet** allows independently conducting all  $\ell_2$  regularized regressions at the same time at the first stage, and all  $\ell_1$  regularized regressions at the same time at the second stage. Therefore, **ReDNet** not only permits parallel computa-

tion but also allows for fast subnetwork construction to avoid potential huge computational demands from differential analysis of large networks.

There are some interesting directions for future research. Firstly, it is worthwhile to explore other re-parametrization approaches such as baseline reparametrization in a case-control study. Secondly, while we only consider differential analysis of two networks, it is possible to generalize our method to compare multiple networks, demanding more complex reparametrization. Finally, applying the proposed method for fully differential analysis of 53 tissues in the GTEx project still provides challenging computational and methodological issues.

## Acknowledgments

The Genotype-Tissue Expression (GTEx) Project was supported by the Common Fund of the Office of the Director of the National Institutes of Health, and by NCI, NHGRI, NHLBI, NIDA, NIMH, and NINDS. The data used for the analysis described in this paper were obtained from dbGaP accession number phs000424.v7.p2 on 08/18/2017.

## Abstract

We propose sparse-matrix belief propagation, which executes loopy belief propagation in pairwise Markov random fields by replacing indexing over graph neighborhoods with sparse-matrix operations. This abstraction allows for seamless integration with optimized sparse linear algebra libraries, including those that perform matrix and tensor operations on modern hardware such as graphical processing units (GPUs). The sparse-matrix abstraction allows the implementation of belief propagation in a high-level language (e.g., Python) that is also able to leverage the power of GPU parallelization. We demonstrate sparse-matrix belief propagation by implementing it in a modern deep learning framework (PyTorch), measuring the resulting massive improvement in running time, and facilitating future integration into deep learning models.

## 1 INTRODUCTION

Belief propagation is a canonical inference algorithm for graphical models such as Markov random fields (MRFs) or Bayesian networks (Pearl, 2014; Wainwright et al., 2008). In graphs with cycles, loopy belief propagation performs approximate inference. Loopy belief propagation passes messages from the variable nodes to their neighbors along the graph structure. These messages are fused to estimate marginal probabilities, also referred to as beliefs. After enough iterations of the algorithm, these beliefs tend to represent a good approximate solution to the actual marginal probabilities. In this paper, we consider pairwise MRFs, which only have unary and pairwise factors.

One drawback of loopy belief propagation is that, though

the algorithm is relatively simple, its implementation requires management of often irregular graph structures. This fact usually results in tedious indexing in software. The algorithm’s message-passing routines can be compiled to be rather efficient, but when implemented in a high-level language, such as those used by data scientists, they can be prohibitively slow. Experts typically resort to writing external software in lower-level, compiled languages such as C++. The implementation of belief propagation (and its variants) as separate, compiled libraries creates a barrier for its integration into high-level data science workflows.

We instead derive loopy belief propagation for pairwise MRFs as a sequence of matrix operations, resulting in sparse-matrix belief propagation. In particular, we use sparse-matrix products to represent the message-passing indexing. The resulting algorithm can then be implemented in a high-level language, and it can be executed using highly optimized sparse and dense matrix operations. Since matrix operations are much more general than loopy belief propagation, they are often built in as primitives in high-level mathematical languages. Moreover, their generality provides access to interfaces that implement matrix operations on modern hardware, such as graphical processing units (GPUs).

In this paper, we describe sparse-matrix belief propagation and analyze its running time, showing that its running time is asymptotically equivalent to loopy belief propagation. We also describe how the abstraction can be used to implement other variations of belief propagation. We then demonstrate its performance on a variety of tests. We compare loopy belief propagation implemented in Python and in C++ against sparse-matrix belief propagation using `scipy.sparse` and PyTorch on CPUs and PyTorch on GPUs. The results illustrate the advantages of the sparse-matrix abstraction, and represent a first step toward full integration of belief propagation into modern machine learning and deep learning workflows.

## 1.1 RELATED WORK

Belief propagation is one of the canonical variational inference methods for probabilistic graphical models (Pearl, 2014; Wainwright et al., 2008). Loopy belief propagation is naturally amenable to fine-grained parallelism, as it involves sending messages across edges in a graph in parallel. The algorithm is classical and well studied, but because it involves tight loops and intricate indexing, it cannot be efficiently implemented in high-level or mathematical programming languages. Instead, practitioners rely on implementations in low-level languages such as C++ (Schmidt, 2007; Andres et al., 2012). Specific variations for parallel computing have been proposed (Schwing et al., 2011), and other variations have been implemented in graph-based parallel-computing frameworks (Low et al., 2014; Malewicz et al., 2010). Specialized implementations have also been created for belief propagation on GPUs (Zheng et al., 2012).

While loopy belief propagation is the canonical message-passing inference algorithm, many variations have been created to address some of its shortcomings. Some variations modify the inference objective to make belief propagation a convex optimization, such as tree-reweighted belief propagation (Wainwright et al., 2003) and convexified belief propagation (Meshi et al., 2009). Other variations compute the most likely variable state rather than marginal probabilities, such as max-product belief propagation (Wainwright et al., 2008) and max-product linear programming (Globerson and Jaakkola, 2008).

Linearized belief propagation approximates the message update formulas with linear operations (Gatterbauer et al., 2015), which, like our approach, can benefit from highly optimized linear algebra libraries and specialized hardware. However, our approach aims to retain the exact non-linear formulas of belief propagation (and variants), while linearized belief propagation is an approximation.

Our approach of using sparse matrices as an abstraction layer for implementing belief propagation relies on sparse matrix operations being implemented in efficient, optimized, compiled libraries. Special algorithms have been developed to parallelize these operations on GPUs, enabling sparse-matrix computations to use the thousands of cores typically available in such hardware (Bell and Garland, 2008). Other libraries for sparse-matrix computation, such as those built into MATLAB (Gilbert et al., 1992) and `scipy.sparse` often seamlessly provide multi-core parallelism. Frameworks for large-scale, distributed matrix computation, such as Apache Spark (Bosagh Zadeh et al., 2016), can also be used as backends for our approach. Finally, one of the more important recent advances in computing hardware, field-programmable gate arrays (FPGAs), also support sparse-

matrix operations (Zhuo and Prasanna, 2005).

By formulating belief propagation as a series of matrix and tensor operations, we make it fit into modern deep learning software frameworks, such as PyTorch (Paszke et al., 2017) and TensorFlow (Abadi et al., 2016). Since these frameworks are designed to easily switch between CPU and GPU computation, we use PyTorch for one of our belief propagation implementations in our experiments. The added advantage is that, once these frameworks fully support back-propagation through sparse matrix products, we will be able to immediately back-propagate through belief propagation. Back-propagating through inference has been shown to allow more robust training of graphical model parameters (Domke, 2013).

## 2 BACKGROUND

In this section, we review belief propagation and some common—but not often documented—simplifications. Define a pairwise Markov random field (MRF) as a factorized probability distribution such that the probability of variable  $x \in \mathbb{X}$  is

$$\Pr(X = \mathbf{x}) = \frac{1}{Z} \exp \left( \sum_{i \in \mathcal{V}} \phi_i(x_i) + \sum_{(i,j) \in \mathcal{E}} \phi(x_i, x_j) \right), \quad (1)$$

where the normalizing constant  $Z$  is

$$Z = \sum_{X \in \mathbb{X}} \exp \left( \sum_{i \in \mathcal{V}} \phi_i(x_i) + \sum_{(i,j) \in \mathcal{E}} \phi(x_i, x_j) \right), \quad (2)$$

and  $\mathbf{x}$  represents the full state vector of all variables,  $x_i \in \mathbb{X}_i$  represents the state of the  $i$ th variable, and  $G = \{\mathcal{V}, \mathcal{E}\}$  is a graph defining the structure of the MRF.

The goal of marginal inference is to compute or approximate the marginal probabilities of the variables

$$\{\Pr(x_1), \dots, \Pr(x_n)\} \quad (3)$$

and of other subsets of variables. In pairwise MRFs, the marginal inference is often limited to the unary marginals and the pairwise marginals along the edges.

### 2.1 LOOPY BELIEF PROPAGATION

Belief propagation is a dynamic programming algorithm for computing marginal inference in tree-structured MRFs that is often applied in practice on non-tree, i.e., loopy, graphs. Loopy belief propagation is therefore a heuristic approximation that works well in many practical scenarios. The algorithm operates by passing messages among variables along the edges of the MRF structure.

The message sent from variable  $x_i$  to variable  $x_j$  is

$$m_{i \rightarrow j}[x_j] = \log \left( \sum_{x_i} \exp(a_{x_i}) \right), \quad (4)$$

where (as shorthand to fit the page)

$$a_{x_i} = \phi_{ij}(x_i, x_j) + \phi_i(x_i) + \sum_{k \in N_i \setminus j} m_{k \rightarrow i}[x_i] - d_{ij}; \quad (5)$$

$N_i$  is the set of neighbors of variable  $i$ , i.e.,  $N_i = \{k | (i, k) \in \mathcal{E}\}$ ; and  $d_{ij}$  is any constant value that is eventually cancelled out by normalization (see Eq. (7)). The message itself is a function of the receiving variable's state, which in a discrete setting can be represented by a vector (hence the bracket notation  $m_{i \rightarrow j}[x_j]$  for indexing by the state of the variable).

The estimated unary marginals, i.e., the *beliefs*, are computed by fusing the incoming messages with the potential function and normalizing:

$$\Pr(x_j) \approx \exp(b_j[x_j]) = \exp \left( \phi_j(x_j) + \sum_{i \in N_j} m_{i \rightarrow j}[x_j] - z_j \right), \quad (6)$$

where  $z$  is a normalizing constant

$$z_j = \log \left( \sum_{x_j} \exp \left( \phi_j(x_j) + \sum_{i \in N_j} m_{i \rightarrow j}[x_j] \right) \right). \quad (7)$$

For convenience and numerical stability, we will consider the log-beliefs

$$b_j[x_j] = \phi_j(x_j) + \sum_{i \in N_j} m_{i \rightarrow j}[x_j] - z_j. \quad (8)$$

We again use bracket notation for indexing into the beliefs because, for discrete variables, the beliefs can most naturally be stored in a lookup table, which can be viewed as a vector.

## 2.2 SIMPLIFICATIONS

The message update in Eq. (4) contains an expression that is nearly identical to the belief definition in Eq. (8). In the message update, the exponent is

$$a_{x_i} = \phi_{ij}(x_i, x_j) + \phi_i(x_i) + \sum_{k \in N_i \setminus j} m_{k \rightarrow i}[x_i] - d_{ij}. \quad (9)$$

The only difference between this expression and the belief update is that the belief uses the constant  $z_j$  to ensure normalization and the message update omits the message

from the receiving variable ( $j$ ). For finite message values, we can use the equivalence

$$\begin{aligned} \phi_i(x_i) + \sum_{k \in N_i \setminus j} m_{k \rightarrow i}[x_i] - d_{ij} &= \\ \phi_i(x_i) + \sum_{k \in N_i} m_{j \rightarrow i}[x_i] - m_{j \rightarrow i}[x_i] - d_{ij} &= \\ b_i[x_i] - m_{j \rightarrow i}[x_i], \end{aligned} \quad (10)$$

where the last equality sets  $d_{ij} = z_i$ . The message and belief updates can then be written as

$$\begin{aligned} b_j[x_j] &= \phi_j(x_j) + \sum_{i \in N_j} m_{i \rightarrow j}[x_j] - z_j, \\ m_{i \rightarrow j}[x_j] &= \\ \log \left( \sum_{x_i} \exp(\phi_{ij}(x_i, x_j) + b_i[x_i] - m_{j \rightarrow i}[x_i]) \right). \end{aligned} \quad (11)$$

These two update equations repeat for all variables and edges, and when implemented in low-level languages optimized by pipelining compilers, yield the fastest computer programs that can run belief propagation. However, the indexing requires reasoning about the graph structure, making any code that implements such updates cumbersome to maintain, prone to errors, and difficult to adapt to new computing environments such as parallel computing settings.

## 3 SPARSE-MATRIX BELIEF PROPAGATION

In this section, we describe sparse-matrix belief propagation and analyze its complexity. Instead of directly implementing the updates, sparse-matrix belief propagation uses an abstraction layer of matrices and tensors. This abstraction allows belief propagation to be written in high-level languages such as Python and MATLAB, delegating the majority of computation into highly optimized linear algebra libraries.

### 3.1 TENSOR REPRESENTATIONS OF THE MRF, BELIEFS, AND MESSAGES

We store a  $c$  by  $n$  belief matrix  $\mathbf{B}$ , where  $n$  is the number of variables and  $c$  is the maximum number of states of any variable. For simplicity, assume all variables have the cardinality  $c$ , i.e.,  $|\mathbb{X}_i| = c$ . This belief matrix is simply the stacked belief vectors, such that  $B_{ij} = b_j[i]$ . Similarly, we rearrange this matrix into an analogously shaped and ordered unary potential function matrix  $\Phi$ , where  $\Phi_{ij} = \phi_j(x_j = i)$ .

We store the pairwise potentials in a three-dimensional tensor  $\Gamma$  of size  $c \times c \times |E|$ . Each  $k$ th slice of the tensor

is a matrix representing the  $k$ th edge potential function as a table, i.e.,  $\Gamma_{ijk} = \phi_{s_k t_k}(i, j)$ .

Consider a view  $E$  of the edge set  $\mathcal{E}$  in which each edge appears in forward and reverse order, i.e.,  $(i, j) \in E$  if and only if  $(j, i) \in E$ . Let the edges also be indexed in an arbitrary but fixed order

$$E = \{(s_1, t_1), (s_2, t_2), \dots, (s_{|E|}, t_{|E|})\}, \quad (12)$$

and define vectors  $\mathbf{s} = [s_1, \dots, s_{|E|}]^\top$  and  $\mathbf{t} = [t_1, \dots, t_{|E|}]^\top$ . These variables encode a fixed ordering for the messages. The particular order does not matter, but to convert message passing into matrix operations, we need the order to be fixed.

In addition to the fixed order, we also define a *message reversal* order vector  $\mathbf{r}$  where

$$E[r_i] = (t, s) \text{ if } E[i] = (s, t). \quad (13)$$

We can represent this reversal vector as a sparse,  $|E| \times |E|$  permutation matrix  $\mathbf{R}$  where  $R_{ij} = 1$  iff  $r_i = j$ .

Define a  $c$  by  $|E|$  message matrix  $\mathbf{M}$  whose  $i$ th column is the  $i$ th message. In other words,  $M_{ij} = m_{s_j \rightarrow t_j}[i]$ , or equivalently,  $\mathbf{M}$  is a horizontal stack of all messages:

$$\mathbf{M} = [m_{s_1 \rightarrow t_1}, m_{s_2 \rightarrow t_2}, \dots, m_{s_{|E|} \rightarrow t_{|E|}}]. \quad (14)$$

Finally, we define a binary *sparse* matrix  $\mathbf{T}$  (for *to*) with  $|E|$  rows and  $n$  columns whose nonzero entries are as follows:

$$T_{ij} = \begin{cases} 1.0 & \text{if } t_i = j \\ 0 & \text{otherwise.} \end{cases} \quad (15)$$

This matrix  $\mathbf{T}$  maps the ordered messages to the variables that receive the messages.

We define an analogous matrix  $\mathbf{F}$  (for *from*), also binary and sparse with  $|E|$  rows and  $n$  columns, whose nonzero entries are as follows:

$$F_{ij} = \begin{cases} 1.0 & \text{if } s_i = j \\ 0 & \text{otherwise.} \end{cases} \quad (16)$$

This matrix  $\mathbf{T}$  maps the ordered messages to the variables that *send* the messages.

### 3.1.1 The logsumexp operation

A common operation that occurs in various steps of computing log-space belief propagation is the logsumexp operation, which is defined as follows:

$$\text{logsumexp}(\mathbf{A}) = \log(\exp(\mathbf{A}) \cdot \mathbf{1}), \quad (17)$$

where the log and exp operations are performed element-wise, and we use the matrix-vector product with the ones

vector ( $\mathbf{1}$ ) as a compact notation for summing across the rows of the exponentiated input matrix.<sup>1</sup> The resulting output is a column vector with the same number of rows as the input matrix  $\mathbf{A}$ .

### 3.1.2 Slice Indexing

To describe the message updates in a compact notation, we use slice indexing, which is common in matrix and tensor software because it can be implemented efficiently in linear time and easy to parallelize. We borrow syntax from `numpy` that is also reminiscent of the famous MATLAB syntax, where

$$\mathbf{A}[:, \mathbf{i}] = [\mathbf{A}[:, i_1], \mathbf{A}[:, i_2], \dots]. \quad (18)$$

This slice indexing allows the reordering, selection, or repetition of the rows or columns of matrices or tensors.

## 3.2 BELIEF PROPAGATION AS TENSOR OPERATIONS

Using these constructed matrices, the belief matrix is updated with the operations

$$\begin{aligned} \tilde{\mathbf{B}} &\leftarrow \Phi + \mathbf{M}^\top \mathbf{T} \\ \mathbf{B} &\leftarrow \tilde{\mathbf{B}} - \mathbf{1} \text{logsumexp}(\tilde{\mathbf{B}}), \end{aligned} \quad (19)$$

where the last operation uses the logsumexp operation to compute the normalizing constants of each belief column vector and multiplies by the ones vector ( $\mathbf{1}$ ) to broadcast it across all rows.<sup>2</sup>

The message matrix  $\mathbf{M}$  is updated with the following formula:

$$\mathbf{M} \leftarrow \text{logsumexp}(\Gamma + \mathbf{B}[:, \mathbf{s}] - \mathbf{M}[:, \mathbf{r}]). \quad (20)$$

This expression uses two forms of shorthand that require further explanation. First, the addition of the tensor  $\Gamma$  and the matrix  $(\mathbf{B}[:, \mathbf{s}] - \mathbf{M}[:, \mathbf{r}])$  requires broadcasting. The tensor  $\Gamma$  is of size  $c \times c \times |E|$ , and the matrix  $(\mathbf{B}[:, \mathbf{s}] - \mathbf{M}[:, \mathbf{r}])$  is of size  $c \times |E|$ . The broadcasting copies the matrix  $c$  times and stacks them as rows to form the same shape as  $\Gamma$ . Second, the logsumexp operation sums across the columns of the summed tensor, outputting

<sup>1</sup>It is especially useful to form this abstraction because this operation is notoriously unstable in real floating-point arithmetic. Numerically stable implementations that adjust the exponent by subtracting a constant and adding the constant back to the output of the logarithm are possible. These stable implementations add a linear-time overhead to the otherwise linear-time operation, so they maintain the same asymptotic running time of the original logsumexp operation.

<sup>2</sup>In `numpy`, this broadcasting is automatically inferred from the size of the matrices being subtracted.

a tensor of shape  $c \times 1 \times |E|$ , which is then squeezed into a matrix of size  $c \times |E|$ .

The message matrix can equivalently be updated with this formula:

$$\mathbf{M} \leftarrow \text{logsumexp}(\mathbf{\Gamma} + \mathbf{B}\mathbf{F}^\top - \mathbf{M}\mathbf{R}). \quad (21)$$

Here  $\mathbf{B}\mathbf{F}^\top - \mathbf{M}\mathbf{R}$  is once again  $c \times |E|$ , and it is equivalent to the slice-notation form above.

Belief propagation is then implemented by iteratively running Eq. (19) and then either of the equivalent Eqs. (20) and (21).

### 3.3 VARIATIONS OF BELIEF PROPAGATION

Many variations of belief propagation can similarly be converted into a sparse-matrix format. We describe some of these variations here.

#### 3.3.1 Tree-Reweighted Belief Propagation

The tree-reweighted variation of belief propagation (TRBP) computes messages corresponding to a convex combination of spanning trees over the input graph. The result is a procedure that optimizes a convex inference objective (Wainwright et al., 2003; Wainwright et al., 2008). The belief and message updates for TRBP are adjusted according to edge-appearance probabilities in a distribution of spanning trees over the MRF graph. These updates can be implemented in matrix form by using a length  $|E|$  vector  $\boldsymbol{\rho}$  containing the appearance probabilities ordered according to edge set  $E$ . The matrix-form updates for the beliefs and messages are then

$$\begin{aligned} \tilde{\mathbf{B}} &\leftarrow \mathbf{\Phi} + (\boldsymbol{\rho} \circ \mathbf{M})^\top \mathbf{T} \\ \mathbf{B} &\leftarrow \tilde{\mathbf{B}} - \mathbf{1} \text{logsumexp} \left( \tilde{\mathbf{B}} \right), \\ \mathbf{M} &\leftarrow \text{logsumexp}(\mathbf{\Gamma}/\boldsymbol{\rho} + \mathbf{B}\mathbf{F}^\top - \mathbf{M}\mathbf{R}), \end{aligned} \quad (22)$$

where element-wise product  $\circ$  and element-wise division  $/$  are applied with appropriate broadcasting.

#### 3.3.2 Convexified Belief Propagation

Another important variation of loopy belief propagation uses counting numbers to adjust the weighting of terms in the factorized entropy approximation. The resulting message update formulas weight each marginal by these counting numbers. Under certain conditions, such as when all counting numbers are non-negative, the inference objective can be shown to be concave, so this method is often referred to as *convexified Bethe belief propagation* (Meshi et al., 2009). We can exactly mimic the message and belief update formulas for convexified belief propagation by instantiating a vector  $\mathbf{c}$  containing the counting

numbers of each edge factor, resulting in the updates

$$\begin{aligned} \tilde{\mathbf{B}} &\leftarrow \mathbf{\Phi} + \mathbf{M}^\top \mathbf{T} \\ \mathbf{B} &\leftarrow \tilde{\mathbf{B}} - \mathbf{1} \text{logsumexp} \left( \tilde{\mathbf{B}} \right), \\ \mathbf{M} &\leftarrow \text{logsumexp}(\mathbf{\Gamma} + (\mathbf{B}\mathbf{F}^\top - \mathbf{M}\mathbf{R})/\mathbf{c}) \circ \mathbf{c}. \end{aligned} \quad (23)$$

The counting numbers for unary factors can be used to compute the inference objective, but they do not appear in the message-passing updates.

#### 3.3.3 Max-Product Belief Propagation

Finally, we illustrate that sparse tensor operations can be used to conduct approximate *maximum a posteriori* (MAP) inference. The max-product belief propagation algorithm (Wainwright et al., 2008) is one method for approximating MAP inference, and it can be implemented with the following updates:

$$\begin{aligned} \mathbf{B} &\leftarrow \text{onehotmax}(\mathbf{\Phi} + \mathbf{M}^\top \mathbf{T}) \\ \mathbf{M} &\leftarrow \text{logsumexp}(\mathbf{\Gamma} + \mathbf{B}\mathbf{F}^\top - \mathbf{M}\mathbf{R}), \end{aligned} \quad (24)$$

where `onehotmax` is a function that returns an indicator vector with 1 for entries that are the maximum of each column and zeros everywhere else, e.g., the “one-hot” encoding. Similar conversions are also possible for variations of max-product, such as max-product linear programming (Globerson and Jaakkola, 2008).

### 3.4 TIME-COMPLEXITY ANALYSIS

To analyze our sparse-matrix formulation of loopy belief propagation, and to show that it requires an asymptotically equivalent running time to normal loopy belief propagation, we first revisit the sizes of all matrices involved in the update equations. The first step is the belief update operation, Eq. (19), which updates the  $c$  by  $n$  belief matrix  $\mathbf{B}$ . The potential matrix  $\mathbf{\Phi}$  is also  $c$  by  $n$ ; the message matrix  $\mathbf{M}^\top$  is  $c$  by  $|E|$ ; and the *sparse* message-recipient indexing matrix  $\mathbf{T}$  is  $|E|$  by  $n$ .

The second step in Eq. (19) normalizes the beliefs. It subtracts from  $\mathbf{B}$  the product of  $\mathbf{1}$ , which is a  $c$  by 1 vector, and  $\text{logsumexp} \left( \tilde{\mathbf{B}} \right)$ , which is 1 by  $n$ . Explicitly writing the numerically stable `logsumexp` operation, the right side of this line can be expanded to

$$\tilde{\mathbf{B}} - \mathbf{1} \log \left( \text{sum} \left( \exp \left( \mathbf{B} - \max \left( \mathbf{B} \right) \right) \right) + \max \left( \mathbf{B} \right) \right). \quad (25)$$

We next examine the message update Eq. (21), which updates  $\mathbf{M}$ . The three-dimensional tensor  $\mathbf{\Gamma}$  is of size  $c \times c \times |E|$ ; the *sparse* message-sender indexing matrix  $\mathbf{F}^\top$  is  $c$  by  $|E|$ ; and the *sparse* reversal permutation matrix  $\mathbf{R}$  is  $|E| \times |E|$ . The message matrix  $\mathbf{M}$  is  $c$  by  $|E|$ .

**CPU computation** These three update steps are the entirety of each belief propagation iteration. From the first line of Eq. (19), the main operation to analyze is the dense-sparse matrix multiplication  $\mathbf{M}^\top \mathbf{T}$ . Considering an  $n \times m$  dense matrix  $A$  and a sparse matrix  $B$  of size  $m \times p$  with  $s$  nonzero entries (i.e.,  $\|B\|_0 = s$ ), the sparse dot product has time complexity  $O(ms)$  in sequential computation, as on a CPU. The time complexity of the sparse dot product depends upon the number of rows  $m$  and the number of sparse elements in the sparse matrix  $B$ . Every other computation in Eq. (19) involves element-wise operations on  $c$  by  $n$  matrices. Thus, Eq. (19) requires  $O(nc + \|\mathbf{T}\|_0 c)$  time. Since the sparse indexing matrix  $\mathbf{T}$  is defined to have a single nonzero entry per column, corresponding to edges, the time complexity of this step is  $O(nc + |E|c)$ .

In the message-update step, Eq. (21), the outer logsumexp operation and the additions involve element-wise operations over  $c \times c \times |E|$  tensors. The matrix multiplications are all dense-sparse dot products, so the total cost of Eq. (21) is  $O(|E|c^2 + \|\mathbf{F}\|_0 c + \|\mathbf{R}\|_0 c)$  (Gilbert et al., 1992). Since both indexing matrices  $\mathbf{F}$  and  $\mathbf{R}$  have one entry per edge, the total time complexity of the message update is  $O(|E|c^2 + |E|c)$ .

The combined computational cost of both steps is  $O(nc + |E|c + |E|c^2)$ . This iteration cost is the same as traditional belief propagation.

**GPU computation** Since the matrix operations in our method are simple, they are easily parallelized on GPUs. Ignoring the overhead of transferring data to GPU memory, we focus on the time complexity of the message passing. First consider the dense-sparse matrix multiplication mentioned previously, with a dense  $n$  by  $m$  matrix  $A$  and sparse  $m$  by  $p$  matrix  $B$  with  $s$  nonzero entries. GPU algorithms for sparse dot products use all available cores to run threads of matrix operations (Bell and Garland, 2008). In this case, each thread can run the multiplication operation of a single column in the sparse matrix  $B$ .

Given  $k$  cores/threads, we assume that there will be two cases: (1) when the number of sparse columns  $m$  is *less than or equal to* the number of cores  $k$  and (2) when the number of sparse columns  $m$  is *more than* the number of cores  $k$ . For either case, let  $s_i$  be the number of nonzero entries in column  $i$ . The time complexity of case (1) is  $O(\max_i s_i)$ , which is the time needed to process whichever column requires the most multiplications. For case (2), the complexity is  $O(\lceil \frac{m}{k} \rceil \max_i s_i)$ , which is the time for each set of cores to process  $k$  columns. In case (2), we are limited by our largest columns, as the rest of our smaller columns will be processed much sooner. Overall, the GPU time complex-

ity of this operation is  $O\left(\max\left(\max_i s_i, \lceil \frac{m}{k} \rceil \max_i s_i\right)\right)$ . In our sparse indexing matrices, each column has at most one element.

For the element-wise dense matrix operations, which have time complexity  $O(nm)$  on the CPU, we can again multi-thread each entry over the number of cores  $k$  in our GPU such that the time complexity is  $O\left(\lceil \frac{nm}{k} \rceil\right)$ .

The running time of the belief propagation steps is then  $O\left(\lceil \frac{n}{k} \rceil c + \lceil \frac{|E|}{k} \rceil c + \lceil \frac{|E|c^2}{k} \rceil\right)$ .

Based on our parallelism analysis, we expect significantly faster running times when running on the GPU, especially in cases where we have a large number of cores  $k$ . While we expect some time loss due to data-transfer overhead to the GPU, this overhead may be negligible when considering the overall time cost for every iteration of the message-passing matrix operations.

Finally, this analysis also applies to other shared-memory, multi-core, multithreaded environments (e.g., on CPUs), since in both CPU and GPU settings, matrix rows can be independently processed.

## 4 EMPIRICAL EVALUATION

In this section, we describe our empirical evaluation of sparse-matrix belief propagation. We measure the running time for belief propagation on a variety of MRFs using different software implementations and hardware, including optimized and compiled code for CPU-based computation and sparse-matrix belief propagation in a high-level language for both CPU- and GPU-based computation.

### 4.1 EXPERIMENTAL SETUP

We generate grid MRFs of varying sizes. We randomly generate potential functions for each MRF such that the log potentials are independently normally distributed with variance 1.0. We use MRFs with different variable cardinalities  $c$  from the set  $\{8, 16, 32, 64\}$ . We run experiments with MRFs structured as square, two-dimensional grids, where the number of rows and columns in the grids are  $\{8, 16, 32, 64, 128, 256, 512\}$ . In other words, the number of variables in models with these grid sizes are, respectively, 64, 256, 1024, 4,096, 16,384, 64,536, and 262,144. We run all implementations of belief propagation until the total absolute change in the messages is less than  $10^{-8}$ .

We run our experiments on different hardware setups. We use two different multi-core CPUs: a 2.4 Ghz Intel i7 with 4 cores and a 4 Ghz Intel i7 with 4 cores.

We also run sparse-matrix belief propagation on various

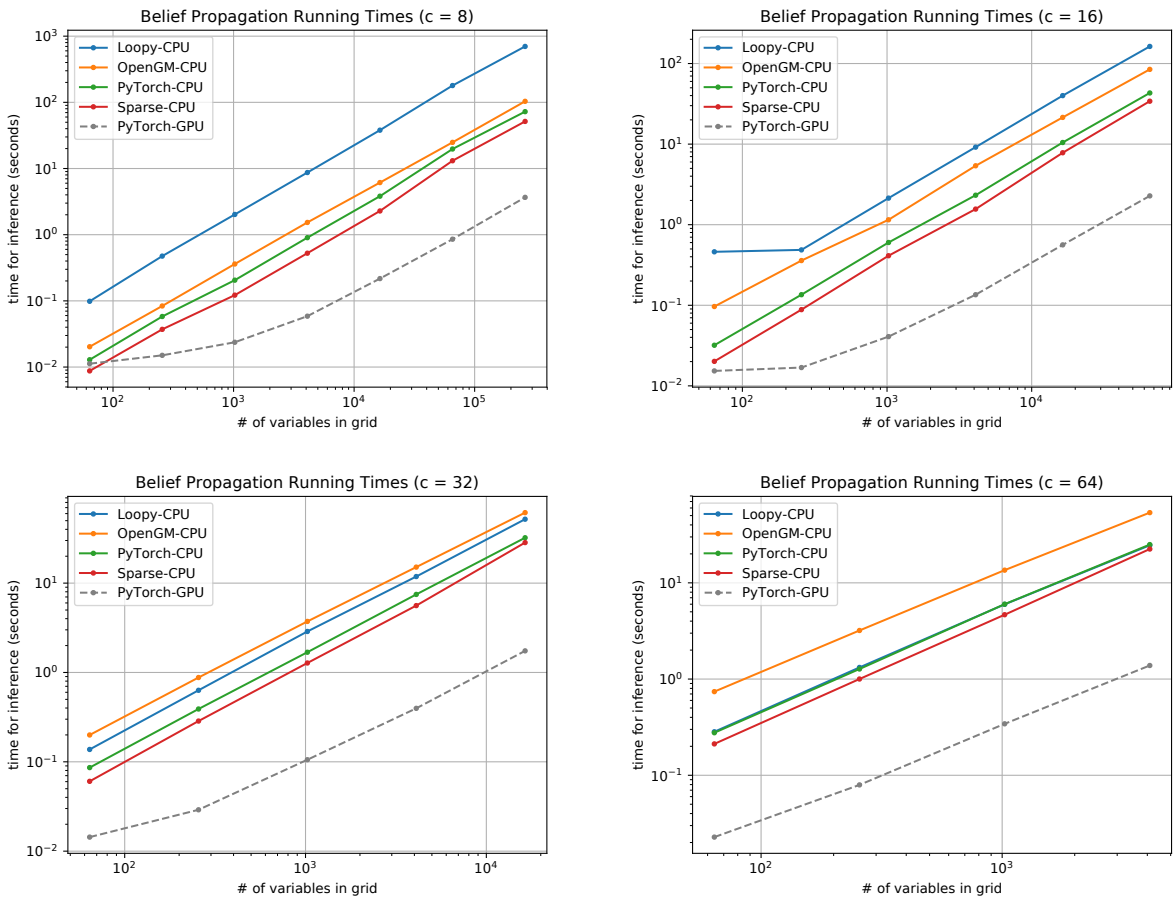

Figure 1: Log-log plots of belief propagation running times for four different implementations on the CPU. Each plot shows the results for different variable cardinalities  $c$ . OpenGM refers to the compiled C++ library, Loopy refers to the direct Python implementation. Sparse uses implements sparse-matrix belief propagation with `scipy.sparse`. And PyTorch implements it with the PyTorch library. We also plot the running time using PyTorch on the least powerful GPU we tested (Nvidia GTX780M) for comparison. The CPU runs plotted here use a 2.4 Ghz Intel i7.

GPUs. We run on an Nvidia GTX 780M (1,536 cores, 4 GB memory), an Nvidia GTX 1080 (2,560 cores, 8 GB), an Nvidia GTX 1080Ti (3,584 cores, 11 GB), and an Nvidia Tesla P40 (3840 cores, 24 GB).

Additional experiments will be available in this paper’s supplemental material.

## 4.2 IMPLEMENTATION DETAILS

We compare four different implementations of belief propagation. First, we use the compiled and optimized C++ implementation of belief propagation in the OpenGM library (Andres et al., 2012). This software represents the low-level implementation. Second, we use a direct implementation of simplified belief propagation (see Section 2.2) in Python and `numpy` using Python loops and dictionaries (hash maps) to manage indexing over graph structure.

Third, we use an implementation of sparse-matrix belief propagation in Python using `scipy.sparse`. Fourth, we use an implementation of sparse-matrix belief propagation in Python using the deep learning library PyTorch, which enables easily switching between CPU and GPU computation.

## 4.3 RESULTS AND DISCUSSION

Considering the results for CPU-based belief propagation in Fig. 1, the sparse-matrix belief propagation is faster than any other CPU-based belief propagation for all MRF sizes and all variable cardinalities. Similarly, the curves show a clear linearity, with a slope suggesting that all the CPU-based belief propagation algorithms increase in time complexity at a linear rate. It is also evident that the PyTorch implementation is consistently slower

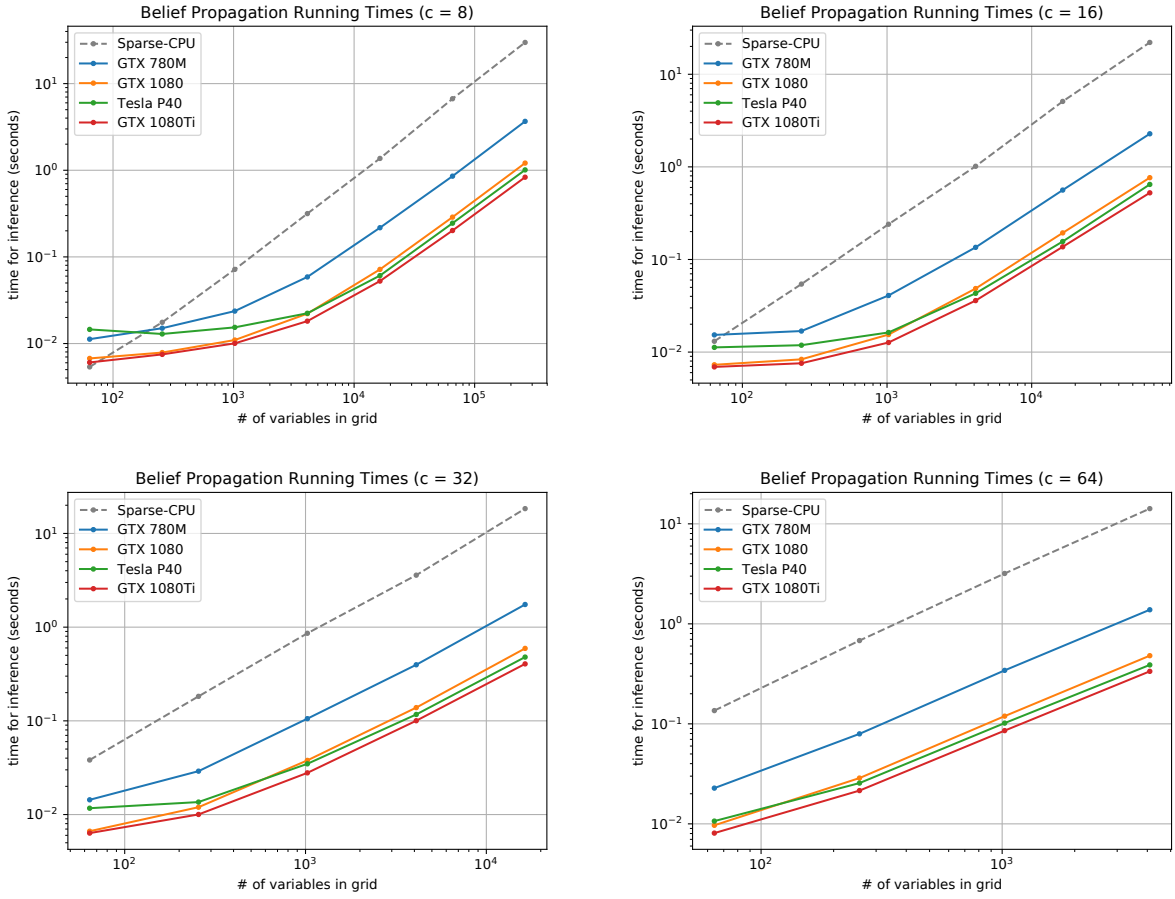

Figure 2: Log-log plots of PyTorch-GPU belief propagation running times for four different GPUs (780M, 1080, Tesla P40, 1080Ti) and the fastest CPU method (Sparse-CPU) with different variable cardinalities  $c$ . The CPU is the 4Ghz Intel i7.

than the `scipy.sparse` implementation, which is to be expected because PyTorch operations incur an additional overhead for their ability to integrate with deep learning procedures (e.g., back-propagation and related tasks).

Notably, we can see that the direct Python loop-based implementation is by far the slowest of these options. However, when the variable cardinality increases to large values, the Python implementation nearly matches the speed of sparse-matrix belief propagation with PyTorch on the CPU. While OpenGM’s belief propagation does offer some benefits compared to Python initially at a lower values of  $c$ , it actually results in the slowest running times at  $c \geq 32$ . We can conclude that despite the compiled and optimized C++ code, the number of variables and states can eventually overshadow any speedups initially seen at lower values.

In Fig. 1, we also include the running times for sparse-matrix belief propagation with PyTorch on the GPU—

shown with the dotted gray line. A direct comparison is not exactly fair, since we are comparing across different computing hardware, though these curves were measured on the same physical computer. The comparison makes clear that the GPU offers significant speed increases over any CPU-based belief propagation, even that of the faster `scipy.sparse` implementation. Interestingly, there is a trend with the GPU runtimes that are sub-linear in the log-log plots, representing the cases where the number of sparse columns is not yet more than the number of cores of the GPU.

Examining the results for GPU-based belief propagation in Fig. 2, a majority of the GPUs are fairly close in running time between the three powerful Nvidia units: the 1080, the 1080Ti, and the P40. The 780M understandably lags behind. As seen previously, until the cores are saturated with operations, there appears to be a pseudo-constant time cost. And once the cores are saturated, the running times grow linearly. This trend is best seen at

$c = 16$  for the first two or three points. We also include the fastest CPU running time, using `scipy.sparse` on an Intel 4 Ghz i7, to illustrate the drastic difference in time between sparse-matrix belief propagation on the CPU and GPU.

These results demonstrate that sparse-matrix belief propagation enables the fastest running times for inference in these grid MRFs on the CPU. And using different software backends (`scipy.sparse` or PyTorch) for the sparse-matrix operations leads to different behavior, with PyTorch incurring some overhead resulting in slower computation. Once ported to the GPU, the speedups are even more drastic, resulting in running times that are many factors faster than those seen on the CPU, easily outweighing the overhead cost of using software backends like PyTorch that support seamless switching from CPU to GPU computation.

## 5 CONCLUSION

We presented sparse-matrix belief propagation, which exactly reformulates loopy belief propagation (and its variants) as a series of matrix and tensor operations. This reformulation creates an abstract interface between belief propagation and a variety of highly optimized libraries for sparse-matrix and tensor operations. We demonstrated how sparse-matrix belief propagation scales as efficiently as low-level, compiled and optimized implementations, yet it can be implemented in high-level mathematical programming languages. We also demonstrated how the abstraction layer allows easy portability to advanced computing hardware by running sparse-matrix belief propagation on GPUs. The immediately resulting parallelization benefits required little effort once the sparse-matrix abstraction was in place. Our software library with these implementations is available at <https://bitbucket.org/berthuang/mrftools/>.

**Open Questions and Next Steps** There are still a number of research directions that we would like to pursue. We mainly focused on analyzing the benefits of sparse-matrix belief propagation on grid-based MRFs, but there are many different structures of MRFs used in important applications (chain models, random graphs, graphs based on structures of real networks). Similarly, applying our approach to real-world examples would help confirm the utility of it in current problems within machine learning. Likewise, we focused on fairly sparse graphs that did not have many non-zero entries per column. It would be interesting to explore the difference between how sparse-matrix belief propagation behaves on the dense and sparse matrices on different hardware and whether fully dense matrices would still result in notable speed improvements,

or if overhead from the sparse-matrix format would become a bottleneck.

Our sparse-matrix formulation of belief propagation is derived for pairwise MRFs, so it remains an open question what modifications are necessary for higher-order MRFs which may have arbitrarily large factors. Benefits similar to those we measured on GPUs can arise from the sparse-matrix abstraction for other computing backends, such as the use of compute-cluster parallelism through libraries such as Apache Spark, or the computation of belief propagation on FPGAs. Finally, the integration of belief propagation into deep learning models is straightforward with the matrix abstraction. Though many popular frameworks do not yet support back-propagation through sparse dot products, such support is forthcoming according to their respective developer communities.

## Abstract

We provide the first study on online learning problems under stochastic constraints that are “soft”, i.e., need to be satisfied with high probability. These constraints are imposed on all or some stages of the time horizon so that the stage decisions probabilistically satisfy some given safety conditions. The distributions that govern these conditions are learned through the collected observations. Under a Bayesian framework, we introduce a scheme that provides statistical feasibility guarantees through the time horizon, by using posterior Monte Carlo samples to form sampled constraints which leverage the scenario generation approach in chance-constrained programming. We demonstrate how our scheme can be integrated into Thompson sampling and illustrate it with an application in online advertisement.

## 1 INTRODUCTION

Most of the literature in stochastic online learning focuses on performances measured by optimality achievement. Common examples include the minimization of cumulative regret in the multi-arm bandit setting (e.g., Auer et al. (2002); Lai and Robbins (1985)), best arm selection (e.g., Audibert and Bubeck (2010)) and the closely related ranking and selection (e.g., Boesel et al. (2003)) in the simulation literature. In many situations, however, the uncertainty or the stochasticity appears not only in the objective function, but also in the constraints of the problem whose feasibility can be of utmost importance. The focus of this paper is to design sequential methodologies that maintain probabilistic feasibility requirements with rigorous statistical guarantees.

Our study is motivated from a rich set of problems where

“budgets” or “resources” are limited for various operational or commercial reasons, and these constraints are in a sense “soft”, i.e., the capacities placed on these constraints, while preferred to be satisfied, are allowed to be violated with a small probability. Such consideration is common among applications. For example, in online advertisement problems encountered by our co-authors when optimizing spending for large advertisers, the task involves sequentially picking items (e.g., keywords, targets) to maximize revenues, while adhering to a specified marketing budget for a duration. The marketer in general expects to meet the budget goals. However, if occasionally the budget is exceeded the campaign is still acceptable as long as the revenue performance is sustained. Other similar settings include clinical trials, where the costs of competing treatments are substantial and noisy, and over-budget is undesired but sometimes allowable. Whereas past work in stochastic sequential learning has focused on rewards (with hard constraints if needed), this paper provides the first study on a class of problems that not just include the rewards but also stochastic constraints that need to be satisfied with high probability.

Our framework can be viewed as a sequential problem under so-called *probabilistic* or *chance constraints* (Prékopa, 2003), which has been widely used in stochastic programming under limited and uncertain resources (e.g., Shi et al. (2015); Lejeune and Ruszczyński (2007)). A generic representation of a chance constraint is

$$P((x, \xi) \text{ satisfies a given safety condition}) \geq 1 - \alpha \quad (1)$$

where  $x$  is a decision variable and  $\xi$  denotes some randomness distributed under  $P$ . Satisfying the safety condition means that  $(x, \xi)$  lies in a desirable deterministic region, which can be represented by, e.g., a set of inequalities. The given parameter  $\alpha$  is the tolerance level that represents the allowable probabilistic violation.

In the sequential setting,  $x$  would denote a sequence of decisions. The safety condition could include individual

requirements on all or some stages. In many applications of interest,  $P$  needs to be learned as complete distributional knowledge on  $\xi$  is not available. Along the vein of conventional online problems that focus on optimality, at each stage we may observe some components of  $\xi$  so that we can update our belief on  $P$ .

As our main methodological contribution, we analyze an online strategy that provides guarantees on (1) with a high confidence, under a statistical framework that we shall describe. On a high level, it means we can guarantee, with our proposed policy, that

$$\begin{aligned} &P(P((x, \xi) \text{ satisfies a given safety condition}) \\ &\geq 1 - \alpha) \geq 1 - \beta \end{aligned} \quad (2)$$

where the outer probability now refers to the randomness of  $x$  induced by the sequential observations, and  $1 - \beta$  is a confidence level (90% for instance). Our methodology is based on a combination of two ideas. First is a Bayesian extension of the so-called scenario generation or constraint sampling (Calafiore and Campi, 2005; De Farias and Van Roy, 2004) approach in approximating chance-constrained optimization problems. This approach replaces the unknown or difficult chance constraint with a collection of sampled constraints that come from data or from numerical simulation. Viewing such an approach in a Bayesian manner allows it to be blended naturally into popularly used online learning algorithms such as Thompson sampling (Agrawal and Goyal, 2012; Russo and Van Roy, 2016) that also operates via Bayesian updating. Second, by capitalizing results on scenario generation in the static setting, we can derive the precise number of samples required at each stage of the sequential process such that (2) holds throughout the horizon. As far as we know, our formulation and analysis of chance-constraint guarantees in an online setting is new to the literature.

After presenting our theoretical investigation on feasibility guarantees, we illustrate the integration of our scheme into a variant of Thompson sampling in an online advertisement setting. We then numerically demonstrate how this chance-constrained Thompson sampling performs competitively, in achieving feasibility but also maintaining good objective values.

## 2 RELATED WORK

The earliest work in chance constraints dated back to Charnes et al. (1958) and Miller and Wagner (1965). Exact solution techniques for such problems are notoriously difficult due to non-convexity, and are only available in few instances even when  $P$  is known; e.g., Lagoa et al. (2005). Several lines of approximation methodologies

have been proposed. A conventional method is to use so-called safe convex approximation that replaces the chance constraint with more conservative convex constraints (Ben-Tal and Nemirovski, 2000). Rossi et al. (2011, 2015) used policy trees and confidence interval construction to obtain the so-called  $(\alpha, \vartheta)$ -solution. Scenario generation (Calafiore and Campi, 2006; Campi and Garatti, 2008), which we leverage on in this work, uses sampled constraints to populate the feasible region. This approach has several extensions, such as sampling-and-discarding (Campi and Garatti, 2011) and multi-phase schemes (Carè et al., 2014; Calafiore, 2017; Chamanbaz et al., 2016), and relates to sample average approximation (Luedtke et al., 2010). Other data-driven methods include distributionally robust optimization (Calafiore and El Ghaoui, 2006; Zymler et al., 2013) and data-driven robust optimization (Bertsimas et al., 2013).

Our work focuses on chance-constrained problem in an online fashion, under the broad umbrella of sequential decision-making. In the later part of this paper, we demonstrate our proposed strategy in a variant of the stochastic multi-arm bandit problem (Auer et al., 2002) used to address the well-known exploration-exploitation tradeoff. In budgeted bandits, Ding et al. (2013) consider the presence of random costs and an overall budget, where learning and revenue accumulation stops when the budget runs out. Xia et al. (2015) study Thompson sampling for a similar setting; in this work we integrate our strategy into Thompson sampling, especially the one considered in Ferreira et al. (2016) motivated from network revenue management. Other related work include those in the framework of “bandits with knapsacks” (Badanidiyuru et al., 2013; Tran-Thanh et al., 2012; Besbes and Zeevi, 2012) that have been applied in pricing and supply chain management (Wang et al. (2014)) and healthcare (Villar et al. (2015)). The works closest to our online advertisement example are Tran-Thanh et al. (2014) and Amin et al. (2012) that study the problem of item bidding under a budget, but they do not consider probabilistic violation of the constraints that we focus on.

## 3 CHANCE-CONSTRAINED ONLINE LEARNING

Consider a sequence of decision variables  $x_t \in \mathbb{R}^d$ ,  $t = 1, \dots, T$ , and a sequence of random variables  $\xi_t \in \Xi_t$ ,  $t = 1, \dots, T$  assumed independent among the steps  $t$  in a given horizon  $T$ . For convenience, denote  $\xi_{1:t} = (\xi_1, \dots, \xi_t)$  and  $x_{1:t} = (x_1, \dots, x_t)$  as the cumulative randomness and decisions up to  $t$ . Consider a sequence of safety conditions that we write as  $f_t(x_{1:t}, \xi_{1:t}) \in \mathcal{A}_t$ , where each function  $f_t$  maps to some space  $\mathcal{Y}_t$  such that

$\mathcal{A}_t \subset \mathcal{Y}_t$  (for example,  $f_t(x_{1:t}, \xi_{1:t}) \in \mathcal{A}_t$  can be a set of inequalities so that  $\mathcal{Y}_t = \mathbb{R}^m$  for some  $m$  and  $\mathcal{A}_t = \{y \in \mathbb{R}^m : y \leq 0\}$ ).

We are interested in a sequential problem with horizon  $T$ :

$$\begin{aligned} & \max_{x_1, \dots, x_T} h(x_1, \dots, x_T) \\ \text{subject to} & \quad P(f_t(x_{1:t}, \xi_{1:t}) \in \mathcal{A}_t | \mathcal{F}_{t-1}) \geq 1 - \alpha \quad \forall t \in \mathcal{S}, \end{aligned} \quad (3)$$

where the decisions  $x_1, \dots, x_T$  are sequential, i.e.,  $x_{t+1}$  depends on the past observations of  $\xi_{1:t}$  and past decisions  $x_{1:t}$ ,  $\mathcal{S} \subset \{1, \dots, T\}$  is a given set, and  $h(\cdot)$  is the objective function. Note that the function  $f_t$  and the set  $\mathcal{A}_t$  can depend on the time step  $t$ . For convenience, let  $\mathcal{F}_t = \{\xi_{1:t}, x_{1:t}\}$  be the information up to time  $t$ . In each probability  $P$  in (3), the function  $f_t(x_{1:t}, \xi_{1:t})$  can be expressed as  $f_t(x_{1:(t-1)}, x_t, \xi_{1:(t-1)}, \xi_t)$  where  $x_{1:(t-1)}$  and  $\xi_{1:(t-1)}$  belong to the past information  $\mathcal{F}_{t-1}$ .

Consistent with the introduction,  $\alpha$  is a tolerance parameter on the violation of the safety condition. This parameter is assumed constant across  $t$  for convenience, but our analysis can be easily adapted to the case where it varies. Note that  $\mathcal{S}$  determines how many chance constraints need to be maintained throughout the horizon. For example,  $\mathcal{S} = \{1, \dots, T\}$  means there is a budget requirement for each step, and  $\mathcal{S} = \{T\}$  means there is only one overall budget requirement across the whole horizon.

### 3.1 SCENARIO GENERATION FOR STATIC PROBLEMS

We first discuss a well-studied approach to approximate a static version of (3). Suppose  $T = 1$ . In this setting we can simplify notation and write the formulation as

$$\begin{aligned} & \max_x h(x) \\ \text{subject to} & \quad P(f(x, \xi) \in \mathcal{A}) \geq 1 - \alpha \end{aligned} \quad (4)$$

Suppose we can simulate or collect data for  $\xi$  to obtain, say, i.i.d.  $\xi^1, \dots, \xi^N$ . We consider replacing the constraint in (4) by sampled constraints, so that the optimization program becomes

$$\begin{aligned} & \max_x h(x) \\ \text{subject to} & \quad f(x, \xi^n) \in \mathcal{A}, \quad \forall n = 1, \dots, N \end{aligned} \quad (5)$$

We call (5) a sampled program, which serves as a reasonable approximation to (4) when  $N$  is large. However, since  $\xi^n$ 's are randomly generated, the solution obtained from (5) is subject to statistical noise and cannot be guaranteed feasible for (4). The following celebrated result from (Calafiore and Campi, 2006; Campi and Garatti,

2008) gives the sample size needed to guarantee feasibility for (4) with a certain confidence by solving (5).

**Condition 1.** *An optimization program is said to be in class  $\mathcal{R}$  if: 1) It is feasible and the feasible region has a non-empty interior; 2) Its optimal solution exists and is unique.*

**Theorem 1.** *(Adopted from Theorem 2.4, Campi and Garatti (2008)) Suppose for each  $\xi$ ,  $f(x, \xi) \in \mathcal{A}$  is a convex set in  $x \in \mathbb{R}^d$ , and  $h$  is concave. Suppose also that any instance of (5) belongs to  $\mathcal{R}$ . Fix real numbers  $\alpha, \beta \in [0, 1]$ . Then for  $N$  chosen such that*

$$\sum_{i=0}^{d-1} \binom{N}{i} \alpha^i (1 - \alpha)^{N-i} \leq \beta$$

*the optimal solution of the sampled stochastic program (5) is feasible for (4) with probability no smaller than  $1 - \beta$ .*

It is known that this result can be improved, e.g., by using sampling-and-discarding (Campi and Garatti, 2011) and multi-stage or iterative schemes (Carè et al., 2014; Calafiore, 2017; Chamanbaz et al., 2016). In this paper we stick with the requirement in Theorem 1 to illustrate our proposed strategies; improvements can be made accordingly by modifying the use of Theorem 1 to better results available in the literature.

### 3.2 SCENARIO GENERATION UNDER UNKNOWN DISTRIBUTION: A BAYESIAN PERSPECTIVE

The scenario generation approach depicted in Theorem 1 requires direct observations on  $\xi$  or the capacity to obtain Monte Carlo samples for  $\xi$ . In problems with learning, the distribution of  $\xi$  is not fully known, and Theorem 1 does not apply directly. We shall adopt a Bayesian perspective that naturally integrates to many online algorithms (e.g., Thompson sampling). Suppose  $\xi$  follows a parametric distribution  $G|\mu$  with unknown parameter  $\mu$ . After specifying a prior distribution for  $\mu$  and collecting some data historically, we have a posterior distribution for  $\mu$  denoted by  $F$ . We seek to use Monte Carlo sampling to conduct an analog of scenario generation so that a posterior credibility guarantee

$$P_\mu(P_{\xi|\mu}(f(x, \xi) \in \mathcal{A}) \geq 1 - \alpha) \geq 1 - \beta \quad (6)$$

is achieved, where  $P_\mu$  denotes the posterior probability distribution on  $\mu$ , and  $P_{\xi|\mu}$  denotes the distribution of  $\xi$  given a parameter value of  $\mu$ . In other words, we want the chance constraint to hold with a posterior credibility level  $1 - \beta$ . Note that this is a natural Bayesian analog of the frequentist result in Theorem 1. In the setting of

Theorem 1,  $P$  is not known but data are available, so that a  $1 - \beta$  confidence is attained. In our current Bayesian investigation,  $P$  is not known but subject to a posterior belief summarized by the distribution of  $\mu$ , and we want this posterior credibility to be  $1 - \beta$ .

Directly sampling  $\xi$  using any particular value of  $\mu$  does not sufficiently capture the posterior uncertainty. To blend the latter into a scenario generation, we can use a two-level sampling, where in the first level we generate a posterior sample for  $\mu$ , and in the second level we generate  $\xi$  conditional on  $\mu$ . This sampling procedure is described in Algorithm 1.

---

**Algorithm 1** Posterior Constraint Sample Generator (PCSG)

---

1. Repeat  $N$  times:
  - (a) Generate  $\mu^n \sim F$ .
  - (b) Generate  $\xi^n \sim G|\mu^n$ .
2. Impose the constraints  $f(x, \xi^n) \in \mathcal{A}$ ,  $n = 1, \dots, N$  and solve the sampled program

$$\begin{aligned} & \max_x h(x) \\ & \text{subject to } f(x, \xi^n) \in \mathcal{A}, \forall n = 1, \dots, N \end{aligned} \quad (7)$$

---

In PCSG we encounter two different sources of randomness. First is the statistical noise from the uncertainty of  $\mu$ , captured by the posterior credibility level  $1 - \beta$ . The second source is the Monte Carlo error, and we denote by  $1 - \delta$  the confidence level induced from this error. By choosing a suitable sample size  $N$  in terms of  $\alpha, \beta, \delta$ , PCSG turns out to achieve a guarantee below.

**Theorem 2.** *Suppose  $f(x, \xi) \in \mathcal{A}$  is a convex set in  $x \in \mathbb{R}^d$ , and  $h(x)$  is concave. Suppose also that any instance of (7) belongs to  $\mathcal{R}$ . Fix real numbers  $\delta, \alpha, \beta \in [0, 1]$  and choose*

$$\sum_{i=0}^{d-1} \binom{N}{i} (\alpha\beta)^i (1 - \alpha\beta)^{N-i} \leq \delta \quad (8)$$

*Consider a solution  $x$  obtained from the sampled program in PCSG. Then,*

1.  $x$  satisfies (6) with a Monte Carlo confidence  $1 - \delta$ , i.e.,

$$P_{MC}(P_\mu(P_{\xi|\mu}(f(x, \xi) \in \mathcal{A}) \geq 1 - \alpha) \geq 1 - \beta) \geq 1 - \delta \quad (9)$$

*where the outermost  $P_{MC}$  denotes the probability with respect to the  $N$  Monte Carlo samples.*

2.  $x$  satisfies

$$E_{MC}[P_\mu(P_{\xi|\mu}(f(x, \xi) \in \mathcal{A}) \geq 1 - \alpha)] \geq (1 - \beta)(1 - \delta) \quad (10)$$

*where  $E_{MC}[\cdot]$  denotes the expectation with respect to the  $N$  Monte Carlo samples.*

Theorem 2 Part 1 stipulates that choosing  $N$  in (8) achieves chance-constraint feasibility with a Bayesian credibility  $1 - \beta$ , under a Monte Carlo confidence  $1 - \delta$ . Part 2 will be useful in generalizing to the multi-stage setting presented next.

### 3.3 SEQUENTIAL POLICIES

We now move our analysis to the sequential problem depicted in (3). We generalize PCSG, with the posterior update occurring at every step of the horizon and the sample size required at each step modified in order to achieve a chance constraint guarantee over the whole horizon. Let  $N_t$  be the sample size used in step  $t$ , which depends on  $\alpha$  and also the confidence-level parameters  $\beta_t$  and  $\delta_t$ . We denote  $F_0$  as the prior distribution of  $\mu$  and  $F_t$  as the posterior distribution of  $\mu$  at step  $t$ . We denote  $G_t|\mu$  as the distribution of  $\xi_t$  given  $\mu$ . Note that  $\mu$  is a parameter shared among the  $\xi_t$  at different steps so that information can be learned over time. To distinguish the real data from the Monte Carlo samples, we use  $\tilde{\xi}_{1:(t-1)}$  to denote the actual data of  $\xi$  coming from steps 1 to  $t - 1$ .

We have the following procedure:

---

**Algorithm 2** Dynamic PCSG

---

Set  $F_0$  as the prior distribution of  $\mu$ . For  $t = 1, \dots, T$ : While  $t \in \mathcal{S}$ , and given  $F_t$  and the realized  $x_{1:(t-1)}$  and  $\tilde{\xi}_{1:(t-1)}$ :

1. Repeat  $N_t$  times:
  - (a) Generate  $\mu^n \sim F_t$ .
  - (b) Generate  $\xi^n \sim G_t|\mu^n$ .

2. Impose the constraints

$$f_t(x_{1:(t-1)}, x_t, \tilde{\xi}_{1:(t-1)}, \xi^n) \in \mathcal{A}_t, \forall n = 1, \dots, N_t \quad (11)$$

at stage  $t$ .

---

It is understood that in the second step of Dynamic PCSG, the constraints are imposed together with an appropriate objective function (typically the cost-to-go in formulation (3)) to form a stepwise optimization with decision variable  $x_t$ . The following result gives the choice of  $N_t$  and the resulting guarantee:

**Theorem 3.** *Suppose the stepwise safety conditions are all convex sets, the objective function at every step is concave, and  $x_t \in \mathbb{R}^d$ . Suppose also that any instance of the optimization resulted from imposing (11) belongs to  $\mathcal{R}$ . Suppose  $0 \leq \beta_t, \delta_t \leq 1$  are constants such that*

$$\sum_{i=0}^{d-1} \binom{N_t}{i} (\alpha\beta_t)^i (1 - \alpha\beta_t)^{N_t-i} \leq \delta_t \quad (12)$$

and

$$\sum_{t \in \mathcal{S}} (\beta_t + \delta_t - \beta_t \delta_t) \leq \beta\lambda \quad (13)$$

Then the policy obtained from Dynamic PCSG is feasible for (3) under the updated posterior distribution with probability at least  $1 - \beta$ , with overall Monte Carlo confidence  $1 - \lambda$ , i.e.,

$$P_{MC}(P_{\mu_{1:T}}(P_{\xi_t|\mu_t}(f_t(x_t, \xi_t) \in \mathcal{A}_t | \mathcal{F}_{t-1}) \geq 1 - \alpha \forall t \in \mathcal{S}) \geq 1 - \beta) \geq 1 - \lambda \quad (14)$$

where  $P_{\mu_{1:T}}$  denotes the probability with respect to  $\mu_1, \dots, \mu_t$ , where each  $\mu_t \sim F_t$ , the posterior distribution of  $\mu$  at step  $t$ , and  $P_{\xi_t|\mu_t}$  denotes the probability with respect to  $\xi_t$  given a realized parameter of  $\mu_t$ .

Theorem 3 asserts that the round-specific statistical parameters, namely the posterior credibility  $1 - \beta_t$  and the Monte Carlo confidence level  $1 - \delta_t$ , which determine the constraint sample size, can be chosen to satisfy a local condition (12) and a global condition (13) to achieve an overall statistical guarantee.

For convenience we can set  $\beta_t = \delta_t$  and both equal to some constant, say  $\gamma_t$ . This  $\gamma_t$  can be set to be stage-independent or dependent. The following subsection shows two choices of  $\gamma_t$ .

### 3.4 TWO EXPLICIT STRATEGIES

We demonstrate two choices of  $\{N_t\}$  in terms of  $\{\gamma_t\}$ . The first choice is a simple one that requires knowledge of the horizon length  $T$ , by setting  $\gamma_t$  to be a constant. The second choice uses a decaying  $\gamma_t$ , consequently an increasing sample size  $N_t$ , which does not require knowledge of  $T$  a priori. For convenience, we denote  $|\mathcal{S}|$  as the size of the set  $\mathcal{S}$ . For the first strategy, we have:

**Proposition 1.** *Given a time horizon  $T$ , if we let  $\beta_t = \delta_t = \gamma$  for all  $t \in \mathcal{S}$  such that  $\gamma \leq 1 - \sqrt{1 - \beta\lambda/|\mathcal{S}|}$ , then (14) holds.*

The following describes our second strategy that is stage-dependent such that (14) holds without knowing the horizon  $T$  or  $|\mathcal{S}|$  a priori:

**Proposition 2.** *If we let  $\beta_t = \delta_t = \gamma_t$  for all  $t \in \mathcal{S}$  such that  $\gamma_t = (1/\zeta(t)^\rho) \wedge \eta$ , where  $\rho > 1$ ,  $0 < \eta < 1$ , and  $\zeta(t) = \#\{s \in \mathcal{S} : s \leq t\}$  (i.e.,  $\zeta(t)$  is the ‘‘counter’’ of  $t$  in  $\mathcal{S}$ ) such that*

$$2\eta^{1-1/\rho} + \frac{2}{\rho-1} \frac{1}{(1/\eta^{1/\rho} - 1)^{\rho-1}} - \frac{\eta^2}{\eta^{1/\rho} + 1} - \frac{1}{2\rho-1} \frac{1}{(1/\eta^{1/\rho} + 1)^{2\rho-1}} \leq \beta\lambda \quad (15)$$

then (14) holds regardless of  $|\mathcal{S}|$ .

For example, if  $\rho$  is set to be 2, then (15) becomes  $2\sqrt{\eta} + 2\sqrt{\eta}/(1-\sqrt{\eta}) - \eta^2/(\sqrt{\eta}+1) - \eta^{3/2}/(3(1+\sqrt{\eta})^3) \leq \beta\lambda$ .

## 4 INTEGRATION INTO THOMPSON SAMPLING

We illustrate the integration of our strategies with Thompson sampling, which also operates via Bayesian updating, by an example of revenue maximization in online advertising (Pani et al., 2017). The advertiser is interested in maximizing the expected revenue across a portfolios of keywords or biddable ad units while ensuring that the budget constraint is not violated. When the advertiser selects a bid value for a keyword it results in ad clicks, the volume of which is stochastic. The distribution of clicks and the associated revenue is not initially known to the decision-maker and needs to be learned over time. Further, the cost associated with the choice of a bid is also unknown and hence, there is uncertainty regarding how the budget will be affected.

To be more concrete, consider a set of  $K$  bid values  $\{\kappa_1, \dots, \kappa_K\}$ , for  $M$  items labeled  $\{\pi_1, \dots, \pi_M\}$ , over the campaign horizon  $T$ . Bidding value  $j$  on item  $i$  will induce an average revenue  $r_{ij}$  and cost  $c_{ij}$  respectively. These quantities are assumed to follow independent Poisson distributions with initially unknown parameters (the Poisson assumptions come from the click count nature). In each period  $t = 1, \dots, T$ , the advertiser picks a bid value  $j$  from every item, observes the outcome, i.e., the realizations of  $r_{ij}, c_{ij}, i = 1, \dots, M$ . She gains  $\sum_{i=1}^M \sum_{j=1}^K r_{ij} x_{ij}$  and consumes  $\sum_{i=1}^M \sum_{j=1}^K c_{ij} x_{ij}$  from the budget, where  $x_{ij}$  is the allocation portion for bid value  $j$  of item  $i$  (i.e., the fraction of time or the probability in a randomized scheme that is allocated to this particular bid value and item).

The advertiser’s goal is to maximize the total revenue while maintain a budget constraint with high probability. In other words, letting  $r_{ij}(t)$  and  $c_{ij}(t)$  be the realized revenue and cost for a bid at time  $t$ , and  $x_{ij}(t)$  be the corresponding allocation variables, she wants to maximize  $E[\sum_{t=1}^T \sum_{i=1}^M \sum_{j=1}^K r_{ij}(t) x_{ij}(t)]$ . A typical

budget constraint is a bound given by the remaining budget averaged over the remaining horizon. Specifically, let the overall budget be  $B$ . Denoting  $B(t-1) = B - \sum_{u=1}^{t-1} \sum_{i=1}^M \sum_{j=1}^K c_{ij}(u)x_{ij}(u)$  as the remaining budget before epoch  $t \in \mathcal{S}$ , the advertiser wants to keep  $P(\sum_{u=1}^t \sum_{i=1}^M \sum_{j=1}^K c_{ij}(u)x_{ij}(u) \leq B(t-1)/(T-t+1)) \geq 1 - \alpha \forall t \in \mathcal{S}$ . This type of dynamically updated per-round budgets is common in practice and is argued to be more effective than fixed per-round budgets. In the following, we will concentrate on the particular choice described above as the feasibility requirement.

#### 4.1 A BUDGETED ALGORITHM

The setting of this problem resembles a recent study (Ferreira et al., 2016) on a network revenue management problem. They developed a Thompson sampling algorithm to sequentially assign a price vector to items under resource constraints, where each step involves a knapsack optimization problem. Here we present a variant of their algorithm to suit our setting (Algorithm 3). This initial algorithm does not take into account the possibility of constraint violation; the idea is to later illustrate how our Dynamic PCSG strategy can be integrated.

Denote by  $X_{ij}(t-1)$  the allocation units on bid value  $j$  for item  $i$  cumulated in the first  $t-1$  rounds, and denote by  $W_{ij}^r(t-1)$  and  $W_{ij}^c(t-1)$  the total revenue and cost generated by assigning bid value  $j$  to item  $i$  during these periods respectively. In Algorithm 3, the advertiser samples from the joint posterior distributions of  $\theta_{ij}$ , the unknown Poisson rate of the revenue, and  $\mu_{ij}$ , the rate of the cost, corresponding to bid value  $j$  for item  $i$ . We put independent Gamma prior distributions for these parameters and hence the posterior distributions are also independent. The posterior samples of these parameters are then used in a linear program to decide the allocation. This algorithm follows quite intuitively from standard Thompson sampling, in which one generates posterior samples for the unknown parameters, and use them as ‘‘plug-in’’ to solve stage-wise optimization problems.

#### 4.2 CHANCE-CONSTRAINED BUDGETED THOMPSON SAMPLING

We want to ensure  $P(\sum_{u=1}^t \sum_{i=1}^M \sum_{j=1}^K c_{ij}(u)x_{ij}(u) \leq B(t-1)/(T-t+1)) \geq 1 - \alpha \forall t \in \mathcal{S}$  holds with posterior credibility  $1 - \beta$ . To achieve this, we integrate our Dynamic PCSG into Step 2 of Algorithm 3 by restructuring the involved optimization program. Algorithm 4 shows Dynamic PCSG in this particular setting.

The output of this procedure is a set of constraints, which will be used in the linear program of the budgeted

---

**Algorithm 3** Budgeted Thompson Sampling for deterministically constrained problems adopted from Ferreira et al. (2016)

---

Given a total budget  $B(0) = B$ . For  $t = 1, \dots, T$ , do the following:

- 1: For each bid value  $j$  and each item  $i$ , sample  $\theta_{ij}$  from  $\text{Gamma}(W_{ij}^r(t-1) + 1, X_{ij}(t-1) + 1)$  and  $\mu_{ij}$  from  $\text{Gamma}(W_{ij}^c(t-1) + 1, X_{ij}(t-1) + 1)$ .
- 2: Solve the following linear program:

$$\begin{aligned} \max_x \quad & \sum_{j=1}^K \sum_{i=1}^M \theta_{ij} x_{ij} \\ \text{subject to} \quad & \sum_{j=1}^K \sum_{i=1}^M \mu_{ij} x_{ij} \leq \frac{B(t-1)}{T-t+1} \\ & \sum_{j=1}^K x_{ij} \leq 1, \forall i = 1, \dots, M \\ & x_{ij} \geq 0, \forall i = 1, \dots, M, j = 1, \dots, K \end{aligned}$$

to obtain  $(x_{ij}^*(t))_{i=1, \dots, M, j=1, \dots, K}$ .

- 3: The revenue,  $r_{ij}(t)$ , and the cost,  $c_{ij}(t)$ , generated by assigning bid value  $j$  on item  $i$  are revealed. We update  $X_{ij}(t) = X_{ij}(t-1) + x_{ij}^*(t)$ ,  $W_{ij}^r(t) = W_{ij}^r(t-1) + r_{ij}(t)x_{ij}^*(t)$ ,  $W_{ij}^c(t) = W_{ij}^c(t-1) + c_{ij}(t)x_{ij}^*(t)$  and  $B(t) = B(t-1) - \sum_{j=1}^K \sum_{i=1}^M c_{ij}(t)x_{ij}^*(t)$ .
  - 4: If  $B(t) \leq 0$ , the algorithm terminates.
- 

Thompson sampling. Algorithm 5 shows how Dynamic PCSG can be integrated into Algorithm 3. The following is an immediate consequence of Theorem 3:

**Corollary 4.** *Suppose that any instance of the sampled program in (16) belongs to  $\mathcal{R}$ . Suppose  $0 \leq \beta_t, \delta_t \leq 1$  are chosen to satisfy*

$$\sum_{i=0}^{KM-1} \binom{N_t}{i} (\alpha\beta_t)^i (1 - \alpha\beta_t)^{N_t-i} \leq \delta_t$$

and

$$\sum_{t \in \mathcal{S}} (\beta_t + \delta_t - \beta_t \delta_t) \leq \beta \lambda$$

Consider a modification of Algorithm 5 such that at any point of time, if the total budget  $B$  is fully depicted, we refill the shortfall and add extra budget  $B$  (so that the total remaining budget in the next step returns to the full level  $B$ ). Then the sequence of decisions obtained will satisfy

$$\begin{aligned} P_{\mu} \left( P_{\mathbf{c}_t | \mu_t} \left( \sum_{u=1}^t \sum_{i=1}^M \sum_{j=1}^K c_{ij}(u)x_{ij}(u) \leq \frac{B(t-1)}{T-t+1} \right) \right. \\ \left. \geq 1 - \alpha \forall t \in \mathcal{S} \right) \geq 1 - \beta \end{aligned}$$

---

**Algorithm 4** Dynamic PCSG for the Bidding Problem

---

1. Set  $F_{ij}(0), i = 1, \dots, M, j = 1, \dots, K$  as the prior distribution of  $\mu_{ij}$ . For  $t = 1, \dots, T$ : Given  $B(t-1)$  and  $F_{ij}(t-1)$ , the posterior distribution of  $\mu_{ij}$  given  $\mathcal{F}_{t-1}$ ,
  - (a) Repeat  $N_t$  times:
    - i. Generate  $\mu_{ij}^n \sim F_{ij}(t-1)$  independently for each item  $i = 1, \dots, M$  and bid value  $j = 1, \dots, K$ .
    - ii. Generate  $\xi_{ij}^n \sim \text{Poisson}(\mu_{ij}^n)$  for each item  $i = 1, \dots, m$  and bid value  $j = 1, \dots, K$ .
  - (b) Form the constraints

$$\sum_{j=1}^K \sum_{i=1}^M \xi_{ij}^n x_{ij} \leq \frac{B(t-1)}{T-t+1}, \forall n = 1, \dots, N_t$$

---

with Monte Carlo confidence level at least  $1 - \lambda$ .  $P_\mu$  denotes the probability of  $\{\mu_t\}_{t=1, \dots, T}$ , where  $\mu_t$  is the collection  $(\mu_{ij})_{i,j}$  and each element is distributed independently according to the posterior distribution  $F_{ij}(t-1)$ , and  $P_{c_t|\mu_t}$  denotes the probability with respect to the collection  $(c_{ij})_{i,j}$  given the realization of  $(\mu_{ij})_{i,j}$ .

We mention that the “modification of Algorithm 5” introduced in Corollary 4 is only a technicality that takes care of the unusual situation when the entire available budget is prematurely depleted. Since we divide the remaining budget by the remaining horizon (a common practice to set per-round budgets) to form our constraint at each step, the scenario of total budget depletion before the last step rarely happens.

### 4.3 NUMERICAL RESULTS

We examine the empirical performance of our proposed strategy on a synthetic dataset with two items and three bid values ( $M = 2, K = 3$ ) over the time horizon  $T = 100$ . The cost and revenue of each item-bid value pair follow Poisson distributions with parameters taken uniformly from an interval that is calibrated from a real data set owned by a prominent tech firm (blinded for peer-review purpose). We test with five different values of the overall budget  $B = (a \sum_{i=1}^M \bar{\rho}_i) \times T$  where  $a \in [0.5, 0.75, 1, 1.25, 1.5]$  and  $\bar{\rho}_i$  is the average cost of item  $i$  over the  $K$  bid values. The choice of  $B$  roughly matches the scale of the total cost over the time. The per-round budget is defined as the remainder of the overall budget divided by the remaining number of rounds.

To test our chance-constrained Thompson sampling (CCTS) in Algorithm 5, we use three different settings for  $\mathcal{S}$ , i.e.  $\mathcal{S}_1 = \{25, 50, 75\}$ ,  $\mathcal{S}_2 = \{20, 40, 60, 80, 100\}$  and  $\mathcal{S}_3 = \{10, 20, 30, 40, 50, 60, 70, 80, 90, 100\}$ . We enforce  $\alpha = 0.1, \beta = \lambda = 0.3$ , and  $\beta_t = \delta_t = \gamma$  where

---

**Algorithm 5** Chance-constrained Thompson Sampling (CCTS)

---

Initialize  $\alpha, \beta_t, \delta_t \in [0, 1]$  satisfying (13). Given a total budget  $B(0) = B$ . For  $t = 1, \dots, T$ , do the following:

- 1: For each bid value  $j$  and each item  $i$ , sample  $\theta_{ij}$  from  $\text{Gamma}(W_{ij}^r(t-1) + 1, X_{ij}(t-1) + 1)$  and  $\mu_{ij}$  from  $\text{Gamma}(W_{ij}^c(t-1) + 1, X_{ij}(t-1) + 1)$ .
- 2: Run Dynamic PCSG using  $N_t$  samples to get the constraints

$$\sum_{j=1}^K \sum_{i=1}^M \xi_{ij}^n x_{ij} \leq \frac{B(t-1)}{T-t+1}, \forall n = 1, \dots, N_t$$

- 3: Solve the following linear program:

$$\begin{aligned} \max_x \quad & \sum_{j=1}^K \sum_{i=1}^M \theta_{ij} x_{ij} \\ \text{subject to} \quad & \sum_{j=1}^K \sum_{i=1}^M \xi_{ij}^n x_{ij} \leq \frac{B(t-1)}{T-t+1}, \forall n = 1, \dots, N_t \\ & \sum_{j=1}^K x_{ij} \leq 1, \forall i = 1, \dots, M \\ & x_{ij} \geq 0, \forall i = 1, \dots, M, j = 1, \dots, K \end{aligned} \tag{16}$$

to obtain  $(x_{ij}^*(t))_{i=1, \dots, M, j=1, \dots, K}$ .

- 4: The revenue,  $r_{ij}(t)$ , and the cost,  $c_{ij}(t)$ , generated by assigning bid value  $j$  on item  $i$  are revealed. We update  $X_{ij}(t) = X_{ij}(t-1) + x_{ij}^*(t)$ ,  $W_{ij}^r(t) = W_{ij}^r(t-1) + r_{ij}(t)x_{ij}^*(t)$ ,  $W_{ij}^c(t) = W_{ij}^c(t-1) + c_{ij}(t)x_{ij}^*(t)$  and  $B(t) = B(t-1) - \sum_{j=1}^K \sum_{i=1}^M c_{ij}(t)x_{ij}^*(t)$ .
  - 5: If  $B(t) \leq 0$ , the algorithm terminates.
- 

$\gamma$  is taken as the upper bound depicted in Proposition 1. With these configurations, the number of constraints in the involved linear programs are typically in the range of thousands, which gives a run-time of a few minutes in solving the decisions for the whole horizon using our sever machine. Note that, if we consider our online problem a daily problem (common in practice) then this solution time is quite acceptable as we have hours to solve the problem at each stage. Moreover, the number of constraints and hence the run-time can be further reduced by using more recent advances in the constraint sampling literature as depicted at the end of Section 3.1.

For each considered setting, we conduct 500 simulation runs. For each run, we estimate the proportion of violation of the decision using 100 inner repetitions of  $\xi_t$ , at each step  $t \in \mathcal{S}$ . Figure 1 depicts the box-plots showing the distribution of the proportion of violation. For all the tested budget levels and choices of  $\mathcal{S}$ , CCTS was able to maintain the proportion of budget violation well below the 10% tolerance at the relevant steps. This implies, moreover, that the overall violation (i.e., at least

one violation at a step in  $\mathcal{S}$ ) is also below 10%.

Note that the theoretical guarantees studied in the previous sections focus on the feasibility in maintaining the chance constraints. In practice, the objective value performance is also important. To test this, we compare the performance of CCTS, both regarding budget violation and revenue attainment, against the following algorithms: 1) a hypothetical algorithm that assumes the distributions of the costs and revenues are all known and draws Monte Carlo samples from it, otherwise the same as CCTS; 2) the deterministically constrained Thompson sampling (DCTS) in Algorithm 3; 3) the algorithm in Badanidiyuru et al. (2013) that uses reward-to-cost ratios; and 4) Besbes and Zeevi (2012) that uses an initial learning phase (in our experiment we set the learning phase to 50 steps). Figure 2 shows the distributions of the proportion of violations at  $t \in \mathcal{S}_2$  based on 500 simulation runs, for the five described budget levels. We see that only CCTS and the hypothetical algorithm maintains the proportion of violation to well below 10%, whereas the other three algorithms fluctuate around 20-40%, as they do not account for the chance constraint on the per-round budget. On the other hand, Figure 3 shows the average cumulative revenue achieved through the horizon (the bar depicts one standard deviation around the average). DCTS appears the best in terms of cumulative rewards, and Badanidiyuru et al. (2013) and Besbes and Zeevi (2012) perform similarly. CCTS achieves less rewards (around 15%), which can be viewed as the price of maintaining the chance constraint. The hypothetical algorithm performs better than CCTS, not surprisingly given the full distributional knowledge. This behavior persists for  $\mathcal{S}_1$  and  $\mathcal{S}_3$  as well as for several priors we have tested (similar to plots Figures 2 and 3). Thus, in view of achieving overall performances in terms of both controlling violation proportions and attaining cumulative rewards, our CCTS appears to be superior to all the other considered methods.

The above experiments all used the budget violations calculated using the true underlying distribution of the cost. In Table 1, we compare with the calculation based on the evolving posterior distributions, in terms of the average of all the proportions of violations for  $t \in \mathcal{S}_1, \mathcal{S}_2$  and  $\mathcal{S}_3$  at the five described budget levels. The average proportion of violation based on the posterior distribution is consistently lower than the one based on the true distribution for all budget levels and  $\mathcal{S}$ . This is expected since our chance constraint is maintained under the posterior distribution (as Theorem 3 states). However, the proportion of violations is maintained below 10% under the true distribution, thanks to the relatively robust performance of our approach in abiding with the chance constraint.

Table 1: Comparison of the average proportions of violations based on the true distribution and the updated posterior distributions over 500 simulation runs

Budget		$\mathcal{S}_1$	$\mathcal{S}_2$	$\mathcal{S}_3$
$B_1$	True Dist.	0.018	0.019	0.018
	Posterior Dist.	0.011	0.012	0.009
$B_2$	True Dist.	0.016	0.015	0.014
	Posterior Dist.	0.01	0.01	0.008
$B_3$	True Dist.	0.014	0.013	0.013
	Posterior Dist.	0.008	0.009	0.007
$B_4$	True Dist.	0.013	0.011	0.01
	Posterior Dist.	0.009	0.007	0.005
$B_5$	True Dist.	0.008	0.008	0.007
	Posterior Dist.	0.006	0.005	0.004

Alternatively, we also investigated the amount of budget violation at  $t \in \mathcal{S}$ . Figure 4 depicts the distributions of the total amounts of budget violation in  $\mathcal{S}_1, \mathcal{S}_2$  and  $\mathcal{S}_3$  for the five budget levels over 500 simulation runs. Similar to the proportion of budget constraint violations, the average amounts of violation for CCTS and DTS tend to be much lower than the other three algorithms, with at most 25% of those of the other three algorithms in the same setting. This suggests a strong dependence between the proportion and the amount of violation which substantiates the use of CCTS in maintaining over-spending even in the monetary scale.

## 5 CONCLUSION

We studied sequential learning subject to constraints that need to be satisfied with high probability. We investigated a methodology to obtain posterior statistical guarantees for the feasibility of these constraints, by generalizing the constraint sampling approach in chance-constraint programming to a two-level Monte Carlo procedure and analyzing the sample size needed in achieving overall feasibility through the learning horizon. We further incorporated our scheme into Thompson sampling using an online advertisement example, and numerically demonstrated how it led to desirable performances in both feasibility and optimality. As far as we know, this work represents the first methodological investigation of “soft” stochastic constraints in sequential learning. In subsequent work, we will investigate the tightening of the requirements in sampled constraints, via for instance analyzing the correlation among decisions at different stages, and will also study the scalability of this approach to higher-dimensional problems.

Figure 1: Estimated proportion of violation at each step in  $\mathcal{S}$ , for  $\mathcal{S} = \mathcal{S}_1, \mathcal{S}_2, \mathcal{S}_3$  and five different budget levels, using 500 simulation runs under CCTS.

## Abstract

We present a new sampling scheme for approximating hard to compute queries over graphical models, such as computing the partition function. The scheme builds upon exact algorithms that traverse a weighted directed state-space graph representing a global function over a graphical model (e.g., probability distribution). With the aid of an abstraction function and randomization, the state space can be compacted (or trimmed) to facilitate tractable computation, yielding a Monte Carlo Estimate that is unbiased. We present the general scheme and analyze its properties analytically and empirically, investigating two specific ideas for picking abstractions - targeting reduction of variance or search space size.

## 1 INTRODUCTION

Imagine that we want to compute a function over a weighted directed graph where the graph is given implicitly, e.g., using a generative state-space search model whose explicit state graph is enormous. We therefore need to resort to approximations such as Monte-Carlo schemes. We focus on weighted search trees over probabilistic graphical models where nodes represent partial variable assignments (or configurations) and arcs are associated with weights describing probabilistic quantities from the model. The task is to compute the partition function - sum cost of all paths in the tree. Some Monte Carlo methods draw independent samples of full configurations (full paths) one variable at a time (e.g., Forward sampling). The key idea of the scheme we propose is that, guided by an abstraction function, each sample (or a “probe”) is a sampled subtree representing *multiple configurations*. We argue that, under some conditions over

the abstraction, such a sampled tree representing  $k$  configurations can be a more accurate estimator than  $k$  independent samples.

Our sampling scheme uses an *abstraction function* that partitions the nodes *at each level in the search tree* into subsets of *abstract states* under the intuition that nodes in the same abstract state root similar subtrees and therefore a single member from each can represent all others. Our *Abstraction Sampling (AS)* scheme brings together ideas from statistics and search to exploit their respective strengths. Search is a systematic process that can explore all configurations in a structured manner, *once*. “It does not leave any stone unturned and does not turn any stone more than once” [Pearl, 1984]. Sampling on the other hand explores only a subset of the paths, that can stochastically cover the whole search space. Abstraction Sampling allows a transition between search and sampling by generating and searching a subtree, and therefore a corresponding subset of configurations, in a coordinated manner that can overcome redundancy and some of the variance associated with random independent samples.

From a search perspective abstraction can be viewed as a license to merge nodes that root similar subtrees, sampling one of the subtrees, thus creating a more compact graph that can be searched more efficiently. From a sampling perspective, an abstract state can be viewed as a form of a “strata” within a stratified sampling scheme [Rubinstein and Kroese, 2007, Rizzo, 2007] where the process of stratified sampling is applied layer by layer. The variance reduction we hope to get rests on similar principles of variance reduction in stratified sampling, as we will elaborate more later.

Abstraction Sampling is inspired by the early work of Knuth and Chen [Knuth, 1975, Chen, 1992] who proposed a method for estimating quantities that can be expressed as aggregates (e.g., sum) of functions defined over the nodes in the graph. Our work extends this work to more general queries over graphical models such as

the partition function and to weighted AND/OR trees.

**Our Contributions.** In this paper we present a new algorithmic framework, Abstraction Sampling, that combines search with stratified importance sampling for answering summation queries (e.g., partition function) over graphical models. Using the notion of abstraction function we can find a cost-effective balance between search and sampling, that is tuned to the problem instance and to time and memory resources, using OR or AND/OR search algorithms. We prove unbiasedness and discuss variance reduction properties, and carry out an extensive empirical evaluation over multiple challenging benchmarks. Our results show that two classes of context-based abstractions (deterministic and randomized) can often significantly improve performance over the baseline of importance sampling, for both OR and AND/OR trees. We also show that our scheme is competitive by comparing it with two state-of-the-art importance sampling schemes.

## 2 BACKGROUND

A graphical model, such as a Bayesian or a Markov network [Pearl, 1988, Darwiche, 2009, Dechter, 2013] can be defined by a 3-tuple  $\mathcal{M} = (\mathbf{X}, \mathbf{D}, \mathbf{F})$ , where  $\mathbf{X} = \{X_i : i \in V\}$  is a set of variables indexed by a set  $V$  and  $\mathbf{D} = \{D_i : i \in D\}$  is the set of finite domains of values for each  $X_i$ . Each function  $\psi_\alpha \in \mathbf{F}$  is defined over a subset of the variables called its scope,  $X_\alpha$ , where  $\alpha \subseteq V$  are the indices of variables in its scope and  $D_\alpha$  denotes the Cartesian product of their domains, so that  $\psi_\alpha : D_\alpha \rightarrow R^{\geq 0}$ . The **primal graph** of a graphical model associates each variable with a node, while arcs connect nodes whose variables appear in the scope of the same local function. A graphical model represents a global function, often a probability distribution, defined by  $Pr(X) \propto \prod_\alpha \psi_\alpha(X_\alpha)$ . An important task is to compute the normalizing constant, also known as the partition function  $Z = \sum_X \prod_\alpha \psi_\alpha(X_\alpha)$ .

**AND/OR search spaces.** A graphical model can be expressed via a weighted state space graph. In a simple OR search space, the states (or nodes) are partial assignments relative to a variable ordering, where each layer corresponds to a new assigned variable. A graphical model can be transformed into a more compact AND/OR search space [Dechter and Mateescu, 2007] by capturing conditional independences, thus facilitating more effective algorithms [Marinescu and Dechter, 2009]. The AND/OR search space is defined relative to a *pseudo tree* of the primal graph.

**DEFINITION 1 (pseudo tree)** A pseudo tree of an undirected graph  $G = (V, E)$  is a directed rooted tree  $\mathcal{T} = (V, E')$  such that every arc of  $G$  not in  $E'$  is a back-arc

Figure 1: A Simple Graphical Model.

in  $\mathcal{T}$  connecting a node in  $\mathcal{T}$  to one of its ancestors. The arcs in  $E'$  may not all be included in  $E$ .

Given a pseudo tree  $\mathcal{T}$  of a primal graph  $G$ , the *AND/OR search tree*  $T_{\mathcal{T}}$  guided by  $\mathcal{T}$  has alternating levels of OR nodes corresponding to the variables, and AND nodes corresponding to an assignment from its domain with edge costs extracted from the original functions  $\mathbf{F}$  [Dechter and Mateescu, 2007]. Let  $s$  be a node in  $T_{\mathcal{T}}$ . We denote by  $var(s)$  the last variable of the partial value assignment associated with  $s$ . So if  $s$  stands for  $\bar{x}_{1..p} = (x_1, x_2, \dots, x_p)$ , then  $var(s) = X_p$ . Each AND node  $s$  has a cost  $c(s)$  defined to be the product of all factors  $\psi_\alpha$  that are instantiated at  $s$  but not before.

**DEFINITION 2 (solution subtree)** A solution subtree  $\hat{x}_M$  is a subtree of  $T_{\mathcal{T}}$  satisfying: (1) it contains the root of  $T_{\mathcal{T}}$ ; (2) if an OR node is in  $\hat{x}_M$ , exactly one of its AND child nodes is in  $\hat{x}_M$ ; (3) if an AND node is in  $\hat{x}_M$  then all its OR children are in  $\hat{x}_M$ . The product of arc-costs on any full solution tree equals the cost of a full configuration of the model  $\mathcal{M}$ .

**Example 1** Figure 1a is a primal graph of 4 bi-valued variables and 4 binary factors of a graphical model. Figure 1b is a pseudo tree. Figure 1c displays the AND/OR search tree guided by the pseudo tree. A solution subtree is  $(B = 1, A = 0, C = 1, D = 0)$  having a cost of 72.

Each node  $s$  in  $T_{\mathcal{T}}$  can be associated with a *value*,  $Z(s)$  expressing the conditioned partition function rooted at  $s$ . Clearly,  $Z(s)$  can be computed recursively based on the values of the children of  $s$ : OR nodes by summation and AND nodes by multiplication. The value of  $T_{\mathcal{T}}$ , is the value of its root node, which is the partition function of the underlying model,  $\mathcal{M}$ .

The size of the AND/OR search tree,  $T_{\mathcal{T}}$  is exponential in the height of the pseudo tree. It is possible to merge some subtrees using a concept known as *con-*

Figure 2: Motivating Example;  $Z=126$ .

Figure 3: Motivating Example Tree

text (defined later), yielding an AND/OR graph that is exponential in the tree-width of the primal graph [Dechter and Mateescu, 2007]. As noted,  $Z(s)$  can be computed by a depth-first search scheme from leaves to root of the AND/OR tree (See Figure 1 where the values attached to each node). When the pseudo tree is a chain we get back the regular OR tree, where each path corresponds to a full variable configuration.

**Stratified sampling** is a variance reduction technique that can be used with **importance sampling** [Rubinstein and Kroese, 2007] [Liu *et al.*, 2015] [Gogate and Dechter, 2011] to achieve further reduction in variance. Let  $f$  be a non-negative function defined on a sample space  $\mathbf{X}$ . We want to estimate the value  $Z = \sum_{\mathbf{x} \in \mathbf{X}} f(\mathbf{x})$ . In importance sampling, we can estimate  $Z$  by drawing samples from  $\mathbf{X}$  according to a proposal distribution  $q$  and estimating the equivalent expression  $Z = \sum_{\mathbf{x} \in \mathbf{X}} \frac{f(\mathbf{x})}{q(\mathbf{x})} q(\mathbf{x})$ , leading to an importance sampling estimator  $\hat{Z}^I$ . In stratified importance sampling, we first divide the sample space  $\mathbf{X}$  into  $k$  strata of equal area under the distribution  $q$ . Let  $J$  be a random variable with  $k$  values  $\{1, \dots, k\}$  assigning to each configuration in the sample space the index of its strata. For each  $j \in J$ , we compute importance sampling estimators  $\hat{Z}_j^I$  of  $Z_j = \sum_{\mathbf{x} \in \mathbf{X}} \frac{f_j(\mathbf{x})}{q_j(\mathbf{x})} q_j(\mathbf{x})$  from samples drawn from the conditional distributions  $q_j = q(J=j)$  and  $f_j(\mathbf{x})$  be defined as  $f(\mathbf{x})$  if  $J(\mathbf{x}) = j$  and 0 otherwise. The stratified importance sampling estimator is  $\hat{Z}^{SI} = \frac{1}{k} \sum_{j=1}^k \hat{Z}_j^I$ . It can be shown

**THEOREM 1 ([Rizzo, 2007])** Let  $Z_j$  be a uniform ran-

dom variable defined on  $\{1, \dots, k\}$  assigning value  $Z_j$  to  $j$ . Let  $\hat{Z}^{SI}$  be the stratified importance sampling estimator computed using  $m$  samples drawn in each of the  $k$  strata. Let  $\hat{Z}^I$  be the importance sampling estimator computed with  $M = mk$  samples. The variance reduction achieved by moving from  $\hat{Z}^I$  to  $\hat{Z}^{SI}$  is  $\frac{k}{m} \text{Var}(Z_J)$ .

### 3 ABSTRACTION SAMPLING

**A Motivating Example.** Our proposed Abstraction Sampling (AS) algorithm emulates stratified importance sampling on partial configurations (nodes in the search tree) layer by layer (each layer corresponding to a variable). To illustrate the idea consider a small two dimensional function over variables  $X_1$  and  $X_2$  with domains  $D_1 = D_2 = \{1, 2, 3, 4, 5\}$  in Figure 2. Partial configurations of length 1 (corresponding to  $X_1$ ) are partitioned into two abstract states: one where  $X_1 \in \{1, 2\}$  and the other where  $X_1 \in \{3, 4, 5\}$ . Note that this abstraction function tries to put into the same abstract states rows which have roughly the same total mass (sum of entries). At the level of  $X_2$  we have abstract states defined just by variable  $X_2$  - one where  $X_2 \in \{1, 2\}$  and the other by  $X_2 \in \{3, 4, 5\}$ . We assume a uniform proposal distribution; note that the exact answer is  $Z = 126$  (summing all entries in the table).

The sampling process is illustrated in Figure 3. Assume we pick  $X_1 = 1$  and  $X_1 = 3$  as representatives of their respective abstract states, and give them weights 2 and 3, to account for the number of states they represent. All extensions of these 2 assignments to  $X_2$  are generated, with abstract states indicated as diamonds and triangles. There are now 4 candidates for a representative of triangle abstraction with values  $\{10, 9, 8, 7\}$  and corresponding weights  $\{2, 2, 3, 3\}$ , and 6 diamond candidates with values  $\{3, 5, 4, 2, 3, 2\}$  and corresponding weights  $\{2, 2, 2, 3, 3, 3\}$ . We select a representative at random in proportion to their weights. Assume this yields configurations  $(X_1 = 3, X_2 = 2)$  and  $(X_1 = 1, X_2 = 4)$ . We next update the weights of the selected representatives to account for the mass they represent yielding:  $w(X_1 = 3, X_2 = 2) \leftarrow w(X_1 = 3, X_2 = 2)/(3/10) = 3/(3/10) = 10$  and  $w(X_1 = 1, X_2 = 4) \leftarrow w(X_1 = 1, X_2 = 4)/(2/15) = 2/(2/15) = 15$ , yielding an estimate for the partition function  $\hat{Z} = 7 \cdot 10 + 5 \cdot 15 = 145$ .

We also compared the empirical variance of our estimator with a simple importance sampler, using 100000 trials and observed variance reduction from 2337 to 398, an almost 6 fold decrease. While in this example the abstract states were not equal size, the abstractions were selected to yield a large variance between the different abstract states.

  - 18:  $\tilde{T} \leftarrow \tilde{T} \cup \{ \langle s, w(s) \rangle \}$
- 

### 3.1 THE ALGORITHM

Our proposed Abstraction Sampling algorithm is a Monte Carlo process that generates compact representatives  $\tilde{T}$  of  $T$ , guided by an *abstraction function*. Abstraction Sampling for OR trees (Algorithm 1) builds a subtree  $\tilde{T}$  of  $T$ , level-by-level, in a breadth-first manner. Starting from the root of  $T$ , at each step, it picks a leaf node having the smallest (as explained next) abstract value, and expands it to its child nodes. Each node  $s$  is associated with a weight  $w(s)$  representing the mass the abstract state stands for (root weight is 1). For each newly generated node, the algorithm checks if there already exists a node having the same abstraction. If this is the case, (line 9), it decides with some probability  $p$ , which of the representative nodes to keep and which to discard. The weight of the selected representative is adjusted to account for the discarded one (step 11). Otherwise, it adds the new node to the frontier of nodes called *OPEN* with the weight of its parent node (step 17).

**Layered Abstractions.** Given a weighted directed AND/OR tree  $T$ , an abstraction function,  $a : T \rightarrow I^+$ , where  $I^+$  are integers, partitions the nodes in  $T$ , layer by layer, with the requirements that i) if  $var(s_1) \neq var(s_2) \rightarrow a(s_1) \neq a(s_2)$ , and ii) if  $s' \in ch(s)$  then  $a(s) < a(s')$  (this enforces breadth-first exploration;  $ch(s)$  denotes the children of  $s$  in  $T$ ). Abstraction states are denoted by  $\{i\}$  for an integer  $i$ .

**The Sampling Proposal.** We use  $p$  proportional to  $w(s) \cdot g(s) \cdot h(s)$ , where  $h$  is a heuristic that provides an upper bound on the partition function (of the subproblem rooted at  $s$ ). While the algorithm is unbiased for any sampling probability, the heuristic yields a proposal function whose accuracy can significantly impact its convergence, as in any importance sampling scheme.

**Example 2** Consider the (OR) search tree  $T$  in Fig. 4a. The cost of each solution is obtained by a product on its solution arcs. In Figure 4b we show a probe generated via an abstraction function that puts all nodes that represent a single variable in a single abstract state. In 4c, we see a probe where each domain value of a variable corresponds to a different abstract state, yielding 2 states per variable, and thus 2 nodes per level of the generated tree. The estimate for (b) is  $\hat{Z} = 180$  and for (c)  $\hat{Z} = 156$ .

**Abstraction Sampling for AND/OR trees** requires several modifications. The underlying search tree is an AND/OR tree  $T_{\mathcal{T}}$  along a pseudo-tree  $\mathcal{T}$ , and the abstraction function is defined on AND nodes. The algorithm builds a subtree  $\tilde{T}_{\mathcal{T}}$  of  $T_{\mathcal{T}}$ , level-by-level, breadth first. At each step, it picks a leaf AND node having the smallest abstraction, and expands two levels down - child OR nodes, and their child AND nodes. For newly gen-

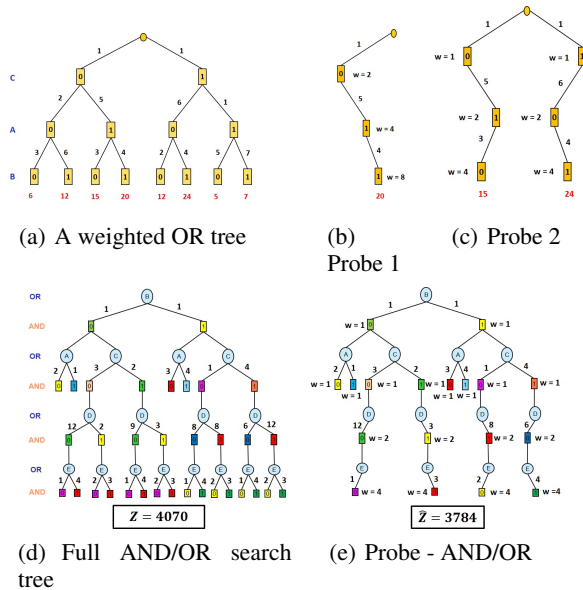

Figure 4: Example of Probes

Figure 5: Improper Abstraction for AND/OR

erated AND nodes, the algorithm proceeds as in the OR case to select stochastically the representative node. The estimate is not accumulated during the sampling process. Rather, once a probe  $\hat{T}_{\mathcal{T}}$  is generated, its partition function estimate can be computed in a depth-first manner. Figures 4d and 4e provide an example AND/OR search tree and a possible probe.<sup>1</sup>

### 3.2 PROPER ABSTRACTIONS

To guarantee the validity and unbiasedness of our sampling scheme for general AND/OR trees, we need to ensure that the sampled AND/OR probe would include only full solution subtrees of the underlying AND/OR tree. For example, the sampled subtree in Figure 5b could have been generated from the tree in Figure 5a with the colors as abstraction, yet it contains a solution tree that corresponds just to a partial configurations (e.g.  $(B=0, A=0)$ ) and therefore may lead to unbiased estimates. This situation can be avoided if we require abstractions to be *proper*, i.e. any two AND nodes of the same variable,  $X$ , can have the same abstract state, only if they are descendant of a common AND node in the sampled AND/OR tree.

#### DEFINITION 3 (Branching variable, Proper abstraction)

A variable  $Y$  in a pseudo-tree  $\mathcal{T}$  is a branching variable of  $X$ , if  $Y$  is  $X$ 's closest ancestor with at least 2 child nodes. An abstraction function  $a$  over AND nodes in  $T_{\mathcal{T}}$  is proper if for any two AND nodes  $n_1$  and  $n_2$  having  $\text{var}(n_1) = \text{var}(n_2) = X$ , if  $a(n_1) = a(n_2)$ , then  $n_1$  and  $n_2$  have a common ancestor AND node  $n_3$  s.t.  $\text{var}(n_3) = Y$  where  $Y$  is the branching variable of  $X$ .

Clearly, any OR tree abstraction is proper as there are no branching variables. Abstraction Sampling for AND/OR trees enforces the generation of *proper* probes during the sampling process (for details see AND/OR algorithm in

<sup>1</sup>Note that while the AND/OR-AS algorithm is defined here as a *breadth-first* (BF) traversal of the search space, other formulations are possible. Our AND/OR-AS implementation uses BF traversal on non-branching variables (chains) and *depth-first* (DF) traversal on branching variables, due to superior time/space complexity of DFS algorithms.

supplementary material). For the remainder of the paper we assume that AS is the general algorithm extended to AND/OR spaces that enforces the proper condition.

## 4 PROPERTIES

**Complexity** The *proper* restriction limits compactness of the sampled AND/OR trees. More branchings in the pseudo tree yield more abstract states and consequently larger probes. We can show that:

**THEOREM 2 (size and complexity)** Given a pseudo-tree, the number of states in a probe by AS is  $O(n \cdot m^{b+1})$ , where  $n$  is the number of variables,  $b$  bounds the number of branchings along any path of the pseudo-tree and  $m$  bounds the maximum number of abstract states in the input abstraction function,  $a$ , per variable. Clearly for OR trees,  $b = 0$  yielding size bounded by  $O(nm)$ .

Notice that when we have many branchings in the pseudo tree  $\mathcal{T}$ , the underlying AND/OR tree from which we sample is far more compact than the underlying OR tree.

**Unbiasedness** We can show that our sampling scheme generates an unbiased estimate of the partition function. Detailed proof is in the supplementary materials.

**THEOREM 3 (unbiasedness)** Given a weighted directed AND/OR search tree  $T$  derived from a graphical model, the estimate  $\hat{Z}$  generated by AS is unbiased.

## 5 ON VARIANCE AND ABSTRACTION SELECTION

The proof of unbiasedness works for any sampling distribution  $p$ . The reason for choosing our specific proposal probabilities is to reduce the variance. We can show that

**THEOREM 4 (exact proposal)** If the proposal function  $p$  in AS uses an exact heuristic  $h(n) = Z(n)$ , then  $\hat{Z}$  has zero variance (single probe is exact), for any abstraction.

Theorem 4 addresses the extreme case when the proposal is exact. Next we talk about the other extreme when the abstraction is exact.

**THEOREM 5 (exact abstraction)** When the abstraction function satisfies that  $a(n) = a(n') \Rightarrow Z(n) = Z(n')$  then,  $\hat{Z}$  is exact (i.e.  $\hat{Z} = Z$ ) with one probe, if  $h$  satisfies  $a(n) = a(n') \Rightarrow h(n) = h(n')$ .

Since AS is a type of stratified importance sampling our **sampling perspective**, (e.g., Theorem 1), suggests several variance reduction ways. The first advises to use

abstractions that at each layer partition nodes into equal area abstract states under the proposal. The second is advising towards increasing the variance of the estimators *between abstract states*. The third encourages having more refined abstractions with more abstract states per layer, as long as the condition of equal size abstract states can be maintained. At the same time, our **search perspective** suggests to always unify nodes that root the same subtrees, whenever such information is available. One possibility is to use the notion of *context*.

The **context** of a variable  $X$  in a pseudo-tree  $\mathcal{T}$  identifies a subset  $C(X)$  of its ancestor variables, whose assignment uniquely determines the AND/OR subtree below the node ([Dechter and Mateescu, 2007]). Therefore, two nodes in the search tree having the same context, (namely, the same assignment along their contexts) root identical subtrees. So, if we use abstractions that are context-isomorph and if  $h$  is the mini-bucket heuristic, the two conditions of Theorem 5 hold, yielding:

**Corollary 1** *When the abstraction function is context-isomorph, namely,  $a(n) = a(n') \leftrightarrow C(n) = C(n')$  and if  $h$  is a mini-bucket heuristic, then the partition function estimate,  $\hat{Z}$ , is exact.*

In the following we construct two abstraction function families based on the notion of context: relaxed context-based and randomized context-based abstractions.

**DEFINITION 4 (relaxed context-based abstractions)**

*An abstraction  $a$  at  $X$  is context-based relative to a subset  $S$ ,  $S \subseteq C(X)$ , iff for every  $n_1$  and  $n_2$  having  $var(n_1) = var(n_2) = X$ , we have:  $a(n_1) = a(n_2) \leftrightarrow \pi_S C(n_1) = \pi_S C(n_2)$ . If  $|S| = j$  we say that we use a  $j$ -level context-based abstraction. In particular, 0-level abstractions puts all the nodes of a variable in a single abstract state.*

This family of abstract functions will lead to abstract states in each level having the same number of nodes, which can be viewed as a first approximation to abstract states having the same area under the proposal.

Our second family of abstractions introduces randomness into the actual way the abstraction depends on the context. This can facilitate the generation of many abstractions in an automated manner and potentially lead to tighter estimates. We randomly assign nodes into abstract states based on the value of a random hash function, taking into consideration only the context of a node.

**DEFINITION 5 (randomized context-based abstraction)**

*Let  $k \in \mathbb{I}^+$  and  $d \in \mathbb{I}^+$  be parameters. Let  $N$  be the number of variables in the model and  $K = \{1, 2, \dots, k\}$ . We assume that all domains  $D_i$  of the variables are*

*subsets of the positive integers. We construct an abstraction  $a$ , by first sampling a vector  $\mathbf{c} = (c_1, c_2, \dots, c_N)$  uniformly at random from  $K^N$ . Given a node  $n_j$  at level  $j$  in the search tree, corresponding to the partial assignment  $\bar{x}_j = (x_1, x_2, x_3, \dots, x_j)$ , we compute its hash value  $hash(n_j) = \sum_{i=1}^j c_i x_i I_{C(X_j)}(X_i)$ , where  $I$  is the indicator function. We define its abstraction function value  $a(n_j) = hash(n_j) \bmod d$ . The parameter  $d$  determines the number of abstract states for each layer of the tree.*

## 6 EMPIRICAL EVALUATION

### 6.1 METHODOLOGY

**Implementation and Configuration.** We evaluate our algorithm on 4 benchmark sets using several configurations of the abstraction sampling algorithm. We implemented the algorithm in C++ and ran experiments on a 2.66 GHz processor with 2GB of memory. For our heuristic we use Weighted Mini-Bucket Elimination (WMBE) [Dechter and Rish, 2003, Liu and Ihler, 2011], whose strength is controlled by a parameter called the *i*-bound. Higher *i*-bounds lead to stronger heuristics at the expense of higher computation and memory cost. We use *i*-bound 10 in our experiments. While there is an interplay between the heuristic strength and the abstraction level, we defer such investigation to future work.

**Abstraction Functions.** We use the two types of context-based abstractions introduced in the previous section: relaxed context-based (RelCB) and randomized context-based (RandCB). RelCB is parametrized by its level  $j$ , while RandCB by its parameter  $d$ . We compare the more refined abstractions (higher  $j$  or  $d$ ) to the 0-level abstraction, that combines all nodes in a layer into a single abstract state, corresponding to baseline regular importance sampling. For OR trees, using a fixed variable order, we experiment with abstractions having  $j \in \{4, 8\}$  for RelCB, and  $d \in \{16, 256\}$  for RandCB.

For AND/OR trees we introduce hybrid abstractions that allow a better control of probe size. A hybrid abstraction with parameter  $j.k$  ( $d.k$  for RandCB) performs a  $j$ -level abstraction (parameter  $d$  for RandCB) for nodes having no more than  $k$  branching variables in the path to the root, and 0-level abstraction below it. For RelCB abstraction family, we experiment with a pure 1-level abstraction ( $j = 1$ ) and a hybrid abstraction with parameter 2.5. For RndCB family, we experiment with a pure abstraction with  $d = 2$  and a hybrid abstraction with parameter 4.5. For randomized abstractions, we tested three different random seeds and observed overall similar results; we present results from one seed selected randomly.

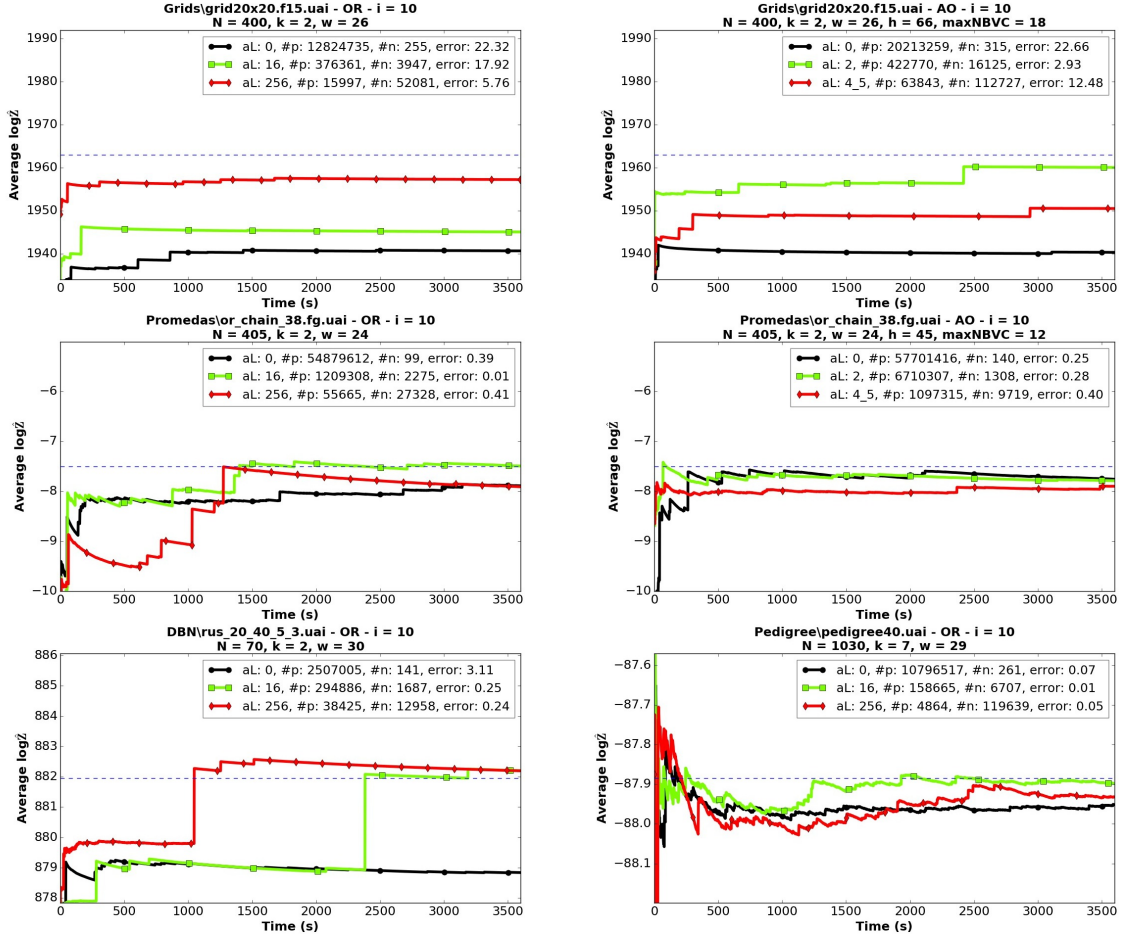

Figure 6: Convergence Plots for Different Abstraction Levels (aL) for Selected Problem Instances.  $\#p$  – number of probes,  $\#n$  – average number of expanded nodes per probe,  $h$  – height of pseudo tree, maxNBVC – max number of branching variables in any path of pseudo tree, error – distance from true value

**Benchmarks.** We tested on instances from 4 benchmarks (BN, DBN, Pedigree, Promedas). We classify instances as small (we do have the exact value of the partition function) or large (we don’t, due to high induced width). We use 130 small and 155 large instances. Summary statistics are in the first column of the results table. Since DBN instances have chain-like pseudo-trees (similar to OR), we test them only on OR trees.

**Performance Measure.** For each instance and configuration (abstraction family, tree type, abstraction level), we ran the AS algorithm for 1 hour and recorded the partition function estimate  $\hat{Z}$  at different times. For small instances (exact  $Z$  known), we compute the log partition function absolute error  $|\log_{10} \hat{Z} - \log_{10} Z|$ . For large instances (exact  $Z$  unknown), we use as a proxy the distance of the log of the estimate from the log of an upper bound of the partition  $Z_{UB}$  (computed using heuristic function)  $|\log_{10} Z_{UB} - \log_{10} \hat{Z}|$ . We present the mean

of these errors aggregated by benchmark in Table 1.

**Comparison with other schemes.** We compare our estimates with two state-of-the-art importance sampling algorithms: Weighted Mini-Bucket Importance Sampling (WMB-IS) [Liu *et al.*, 2015] and IJGP-SampleSearch (IJGP-SS) [Gogate and Dechter, 2011]. We use original implementations from the authors and set the common i-bound parameter to 10. For our algorithms and WMB-IS, we use the same fixed variable order, while IJGP-SS computes its own variable order.

The goal of WMB-IS algorithms [Lou *et al.*, 2017a], [Lou *et al.*, 2017b] is to provide (deterministic/probabilistic) upper/lower bounds of the estimate. For that, they use a “mixture wmb-is” proposal yielding bounded importance weights so that known concentration theorems can be applied. This does not necessarily yield optimal convergence. Our focus is to improve the estimate by aiming to reduce the variance. Our approach

(abstraction sampling) should work with any proposal function. We investigated two proposals, 1) multiplicative one (leading to IS weights that are unbounded), 2) "mixture wmb-is" proposal. We observed improved performance with abstraction sampling in both cases, yet the multiplicative proposal yielded faster convergence in most cases, and it is therefore the one that we report.

## 6.2 RESULTS

The questions addressed by the empirical evaluation are:

- Does Abstraction Sampling result in improved convergence and what insight do we gain on the 2 classes of abstractions?
- What is the impact of tree type (OR vs. AND/OR)?
- Performance of  $AS$  across benchmarks?
- Comparison of  $AS$  with state-of-the-art?

**Individual plots.** Figure 6 has convergence plots for selected problem instances for both OR and AND/OR, using the family of randomized context-based abstractions (RandCB). For each abstraction level we plot the anytime estimate of the log partition function. The dashed line represents the ground truth for the log partition function.

In the first row we show OR and AND/OR plots for the same Grids instance. This is an example where moving to higher level abstractions leads to faster performance (AND/OR error is reduced from 22.66 to 2.93). In the second row (a Promedas instance), the 0-level error is already small, so higher level abstractions have about the same performance. In the third row we present two instances, one from DBN and one from Pedigrees and see that higher level abstractions speed up convergence. In the Pedigree instance, all abstraction levels show similar convergence pattern (the error is small).

**Aggregate table.** Table 1 presents mean errors aggregated over each benchmark for all sampling schemes. This includes our  $AS$  algorithm with both types of trees (OR and AND/OR), and both families of abstractions (RelCB and RandCB) and the two competing schemes. For rows corresponding to our scheme, we present errors for 3 abstraction levels:  $a_0, a_1, a_2$ , where  $a_0$  is 0-level abstraction and independent of the abstraction family (RelCB or RandCB).  $a_1$  and  $a_2$  correspond to higher level abstractions and their definition varies for OR and AND/OR as described earlier. We show errors at 1 min, 20 min, 60 min. In column three we also show the average number of nodes per probe for each abstraction level. For IJGP-SS, we report results only at the 1 hour mark. An "inf" in the table means that the respective algorithm

generates a zero estimate for one or more instances in the benchmark, so the error would be infinity. In parentheses we show the fraction of instances where competing scheme outperforms 0-level abstraction in OR trees.

We see that in both small and large **Grids instances** and for all configurations (OR/AO, RelCB/RandCB), higher level abstractions lead to performance improvement over 0-level abstraction. For grids, randomized (RandCB) abstraction may lead to more significant improvements than RelCB, with AND/OR trees performing even better. For example, after 60 min with OR-RelCB for Grids-small we improve the average error from 4.94 to 3.39, while with OR-RandCB we can improve to 1.41, and AO-RandCB drives down error to 0.84. For both small and large **DBN instances**, only RandCB shows improvement (reducing error from 0.78 to 0.42 for DBN-small, and from 363.93 to 362.88 for DBN-large). For **Pedigree**, the 0-level abstraction is already good, so as expected, higher level abstractions yield little extra benefit. In large **Promedas instances**, RandCB abstraction improved performance in both OR and AND/OR cases, while RelCB was good in the AND/OR case. For small instances, all errors are quite small, still some benefits are gained with the randomized scheme over AND/OR space.

**OR vs. AND/OR.** AND/OR trees usually lead to improved performance over OR. This is expected since AND/OR search spaces are smaller. This is particularly evident for Promedas (small and large) and for large Grids. For example, in Grids-large going from OR-RandCB to AO-RandCB reduces error from 900.01 to 841.84 after 60 min, for  $a_1$  abstraction. For Grids-small the results are mixed on OR vs AND/OR for benchmarks where errors are already small in the 0-level scheme.

**Comparing with state-of-the-art Importance Sampling.** In most benchmarks our 0-level importance sampling baseline is competitive and often outperforms competing sampling algorithms. The point to remember is that the abstraction scheme can be augmented on top of any importance sampling scheme.

**Discussion.** From the analysis of results we gain several valuable insights. **Firstly**, RandCB abstraction consistently demonstrates equal and mostly improved performance compared to the baseline scheme (0-level), while RelCB abstraction is not consistently better. We hypothesize that this difference is due to the ability of RandCB abstractions to generate more uniformly sized abstract states under the proposal. **Secondly**, we observe that in general the AND/OR schemes lead to larger improvements than OR ones. This was not obvious because of the "proper" condition. **Thirdly**, we observe that as expected larger gains are achieved when the baseline importance sampling results in large errors, yet the perfor-

Table 1: Mean Error Aggregated Over Benchmark for a Given Scheme, Time and Abstraction Level ( $a_0, a_1, a_2$ ).  $a_0$  is 0-level abstraction, ( $a_1, a_2$ ) are: OR-RelCB:(4, 8), OR-RandCB:(16, 256), AO-RelCB:(1, 2\_5), AO-RandCB:(2, 4\_5). mance does not deteriorate when the baseline errors are small, especially with RandCB abstractions. This suggests using abstraction sampling as a robust enhancement to importance sampling schemes, especially in scenarios when finding a good proposal is difficult or computationally prohibitive. **Fourthly**, the results show that our scheme is competitive with state-of-the-art schemes. **Finally**, our 0-level scheme outperforms WMB-IS although they both rely on WMB-base proposal, but one is multiplicative and the other is mixture. are not identical as we explained.

## 7 CONCLUSION

The paper presents Abstraction Sampling, a scheme that augments search with sampling, exploiting the strength of both. The scheme can be viewed as extending stratified importance sampling to search spaces, allowing the generation of sub-trees representing multiple configurations, rather than a set of independent samples. We proved the scheme's correctness (unbiasedness for both

OR and AND/OR search spaces), analyzed its complexity, discussed convergence properties and provided an extensive empirical evaluation, showing its potential.

The key question is how to design effective abstraction families. In particular, can we devise abstractions yielding equal partitions under the given proposal function, as suggested by theory. Should we aim at domain dependent abstractions? What level of abstraction refinement is cost-effective? Theory suggests that more refined abstractions are superior. We observed that (higher level) abstractions get more effective as the proposals get less effective. We would like to investigate the interaction between these two functions. Finally, since AND/OR search spaces are superior overall, can we overcome the proper restriction to allow more flexible exploration of abstraction functions.

## Abstract

Learning from small data sets is critical in many practical applications where data collection is time consuming or expensive, e.g., robotics, animal experiments or drug design. Meta learning is one way to increase the data efficiency of learning algorithms by generalizing learned concepts from a set of training tasks to unseen, but related, tasks. Often, this relationship between tasks is hard coded or relies in some other way on human expertise. In this paper, we frame meta learning as a hierarchical latent variable model and infer the relationship between tasks automatically from data. We apply our framework in a model-based reinforcement learning setting and show that our meta-learning model effectively generalizes to novel tasks by identifying how new tasks relate to prior ones from minimal data. This results in up to a 60% reduction in the average interaction time needed to solve tasks compared to strong baselines.

## 1 INTRODUCTION

Reinforcement learning (RL) is a principled mathematical framework for learning optimal controllers from trial and error [28]. However, RL traditionally suffers from data inefficiency, i.e., many trials are needed to learn to solve a specific task. This can be a problem when learners operate in real-world environments where experiments can be time consuming (e.g., where experiments cannot run faster than real time) or expensive. For example, in a robot learning setting, it is impractical to conduct hundreds of thousands of experiments with a single robot because we will have to wait for a long time and the wear and tear on the hardware can cause damage.

There are various ways to address data-efficiency in RL. Model-based RL, where predictive models of the transition function are learned from data, can be used to reduce the number of experiments in the real world. The learned model serves as an emulator of the real world. A challenge with these learned models is the problem of model errors: If we learn a policy based on an incorrect model, the policy is unlikely to succeed on the real task. To mitigate the issue of these model errors it is recommended to use probabilistic models and to take model uncertainty explicitly into account during planning [27, 10]. This approach has been applied successfully to simulated and real-world RL problems [9], where a policy-search approach was used to learn optimal policy parameters. Robustness to model errors and, thereby, increased data efficiency, can be achieved by using model predictive control (MPC) instead of policy search since MPC allows for online updates of the model, whereas policy search would update the model only after a trial [17].

If we are interested in solving a set of related tasks we can use meta learning as an orthogonal approach to increase data efficiency. Generally, the aim of meta learning is to train a model on a set of training tasks and then generalize to new tasks using minimal additional data [12]. The strength of meta learning is to transfer learned knowledge to related situations. For example, we may want to control multiple robot arms with slightly different specifications (e.g., link weights or lengths) or different operating environments (e.g., underwater, in low gravity). Normally, learned controllers deal with a single task. In a robotics context, solutions for multiple related tasks are often desired, e.g., for grasping multiple objects [22] or in robot games, such as robot table tennis [24] or soccer [3]. Much of the literature on meta and transfer learning in RL has focused on multi-task learning, i.e., cases where the system/robot is the same, but the task changes [16, 29, 3, 5, 20, 21, 24, 8, 12]. Although meta learning given multiple or non-stationary dynamics has also been considered in [11, 18, 4, 1].

We adopt a meta learning [26, 32, 12] perspective on the problem of using knowledge from prior tasks for more efficient learning of new ones. We take a probabilistic view and propose to transfer knowledge within a model-based RL setting using a latent variable model. We focus on settings where system specifications differ, but where the task objective is identical. We treat system specifications as a latent variable, and infer these unobserved factors and their effects online. To address the issue of meta learning within the context of data-efficient RL, we propose to learn predictive dynamics models conditioned on the latent variable and to learn controllers using these models. We use Gaussian processes (GPs) [25] to model the dynamics, and MPC for policy learning. To obtain a posterior distribution on the latent variable, we use variational inference. The posterior can be updated online as we observe more and more data, e.g., during the execution of a control strategy. Hence, we systematically combine three orthogonal ideas (probabilistic models, MPC, meta learning) for increased data efficiency in settings where we need to solve different, but related tasks.

## 2 MODEL-BASED RL

We consider stochastic systems of the form

$$\mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{c}_t) + \epsilon \quad (1)$$

with state variables  $\mathbf{x} \in \mathbb{R}^D$ , control signals  $\mathbf{c} \in \mathbb{R}^K$  and i.i.d. system noise  $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{E})$ , where  $\mathbf{E} = \text{diag}(\sigma_1^2, \dots, \sigma_D^2)$ . For model-based RL we first aim to learn the unknown transition function  $f$ . In this context, [27, 10] highlighted that probabilistic models of  $f$  are essential for data-efficient learning as they mitigate the effect of model errors. Therefore, we learn the dynamics of the system using a GP.

**GP Dynamics** A GP is a probabilistic, non-parametric model and can be interpreted as a distribution over functions. A GP is defined as an infinite collection of random variables  $\{f_1, f_2, \dots\}$ , any finite number of which are jointly Gaussian distributed [25]. A GP is fully specified by a mean function  $m$  and a covariance function (kernel)  $k$ , which allows us to encode high-level structural assumptions on the underlying function such as smoothness or periodicity. We denote an unknown function  $f$  that is modeled by a GP by  $f \sim GP(m(\cdot), k(\cdot, \cdot))$ . We use the squared exponential (RBF) covariance function

$$k(\mathbf{x}_i, \mathbf{x}_j) = \sigma_f^2 \exp\left(-\frac{1}{2}(\mathbf{x}_i - \mathbf{x}_j)^T \mathbf{L}^{-1}(\mathbf{x}_i - \mathbf{x}_j)\right) \quad (2)$$

where  $\sigma_f^2$  is the signal variance and  $\mathbf{L}$  is a diagonal matrix of squared length-scales.

**RL with MPC** Our objective is to find a sequence of optimal controls  $\mathbf{c}_0^*, \dots, \mathbf{c}_{H-1}^*$  that minimizes the expected finite-horizon cost

$$J = \mathbb{E} \left[ \sum_{t=1}^H \ell(\mathbf{x}_t) \right], \quad (3)$$

where  $\mathbf{x}_t$  is the state of the system at time  $t$  and  $\ell$  is a known immediate/instantaneous cost function that encodes the task objective. We consider an episodic setting. Initial states  $\mathbf{x}_0$  are sampled from  $p(\mathbf{x}_0) = \mathcal{N}(\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0)$ .

To find the optimal open-loop sequence  $\mathbf{c}_0^*, \dots, \mathbf{c}_{H-1}^*$ , we compute the expected long-term cost  $J$  in (3) using Gaussian approximations  $p(\mathbf{x}_1), \dots, p(\mathbf{x}_H)$  for a given control sequence  $\mathbf{c}_0, \dots, \mathbf{c}_{H-1}$ . The computation of the expected long-term cost is detailed in the supplementary material. Then, we find an open-loop control sequence that minimizes the expected long-term cost and apply the first control signal  $\mathbf{c}_0^*$  to the system, which transitions into the next state. Next we re-plan, i.e., we determine the next open-loop control sequence  $\mathbf{c}_0^*, \dots, \mathbf{c}_{H-1}^*$  from the new state. This iterative MPC approach turns an open-loop controller into a closed-loop controller. Combining MPC with learned GP models for the underlying dynamics increases the robustness to model errors and has shown improved data efficiency in RL [17].

## 3 MODEL-BASED META RL

We assume a setting with a potentially infinite number of dynamical systems that are of the same type but with different specifications (e.g., multiple robotic arms with links of differing lengths and weight). More formally, we assume a distribution over dynamical systems with samples  $f_p \sim p(f)$  indexed by  $p = 1..P$ . Each sample  $f_p$  is a dynamical system of the form (1) with states  $\mathbf{x} \in \mathbb{R}^D$  and control signals  $\mathbf{c} \in \mathbb{R}^K$ . Instead of learning individual predictive models for each dynamical system from scratch, we look to meta learning as an approach to learning new dynamics more data efficiently by leveraging shared structure in the dynamics.

**Meta Learning** Generally, meta learning aims to learn new tasks with minimal data and/or computation using knowledge or inductive biases learned from prior tasks [12]. Here we require our model to accomplish two things simultaneously:

1. **Multi-Task Learning:** Disentangle global and task-specific properties of the different dynamics such that it can solve multiple tasks.
2. **Transfer Learning:** Use global properties to generalize predictive performance to novel dynamics.

We propose to address this meta-learning challenge in a probabilistic way: We model the distribution over systems using a latent embedding  $\mathbf{h}$  and model the dynamics using a global function conditioned on the latent embedding. Each sample  $f_p$  from the distribution is modeled as

$$\mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p) + \epsilon, \quad (4)$$

such that the successor state depends on the latent system specification  $\mathbf{h}_p$ . This means, we explicitly model the global properties through a shared function  $f$  and the task-specific variation using a distribution over the latent variables  $p(\mathbf{h}_p)$ . Framing the meta learning problem as a hierarchical Bayesian model means that meta-training becomes inference in a meta-learning model.

**Training and Evaluation** Training corresponds only to the *multi-task learning* aspect of our meta learning approach. We aim to learn the global function  $f$  and the latent embeddings  $\mathbf{h}_p$  given trajectory observations from a set of training systems. For evaluation at test time, we use inference to obtain a distribution over a set of latent variables  $\mathbf{h}_*$  for each test system. Since our objective is to improve data efficiency in an RL setting, we consider two related but distinct measures of performance. One corresponds to the transfer learning aspect of our approach, where we infer only the latent test embeddings without updating the global model  $f$ . We refer to this as the *single-shot performance*. The other measure we use is the additional data required to successfully solve a RL task: *few-shot learning*. In this case, the global model  $f$  is updated with new additional data, thus combining both the multi-task and transfer learning aspects.

The meta RL procedures for training and testing are detailed in algorithms 1 and 2, respectively.

### 3.1 META-LEARNING MODEL

Our meta-learning model is a GP prior on the unknown transition function in (4) with a concatenated state  $\tilde{\mathbf{x}}_t = (\mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p) \in \mathbb{R}^{D+K+Q}$  as the input to the model. We define  $\mathbf{y}_t = \mathbf{x}_{t+1} - \mathbf{x}_t$  as the targets of the GP and take the mean function to be  $m(\tilde{\mathbf{x}}_t) = \mathbf{0}$ , which encodes that a priori the state does not change [9]. Each dimension of the targets  $\mathbf{y}$  is modeled by an independent GP. We use a Gaussian likelihood

$$p(\mathbf{y}_t | \tilde{\mathbf{x}}_t, \mathbf{f}(\cdot), \boldsymbol{\theta}) = \mathcal{N}(\mathbf{y}_t | \mathbf{f}(\tilde{\mathbf{x}}_t), \mathbf{E}), \quad (5)$$

where  $\boldsymbol{\theta} = \{\mathbf{E}, \mathbf{L}, \sigma_f^2, Q\}$  are the model hyperparameters and  $\mathbf{f}(\cdot) = (f^1(\cdot), \dots, f^D(\cdot))$  denotes a multi-dimensional function. We place a standard-normal prior  $\mathbf{h}_p \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$  on the latent variables  $\mathbf{h}_p$ . The full

specification of the model is

$$p(\mathbf{Y}, \mathbf{H}, \mathbf{f}(\cdot) | \mathbf{X}, \mathbf{C}) \quad (6)$$

$$= \prod_{p=1}^P p(\mathbf{h}_p) \prod_{t=1}^{T_p} p(\mathbf{y}_t | \mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p, \mathbf{f}(\cdot)) p(\mathbf{f}(\cdot))$$

where we denote a collection of vectors in bold uppercase and we have dropped dependence on the hyperparameters for notation purposes. The corresponding graphical model is given in Fig. 1. The figure shows the dependence of individual system observations on the global GPs  $\mathbf{f}(\cdot)$  modeling each dimension of the outputs, the system-specific latent embeddings  $\mathbf{h}_p$  and the observed states and controls.

**Model Properties** Our meta-learning GP (ML-GP) model exhibits three important properties:

1. The latent variable encodes a distribution over plausible systems and is inferred from data
2. Conditioning the GP on the latent variable enables it to disentangle global and task specific variation in the dynamics. Generalization to new dynamics is done by inferring the latent variable of that system.
3. The latent variable is fixed within system trajectories so that inference can be performed online (e.g. while executing a controller).

Fig. 2 illustrates these properties on a toy example.

### 3.2 INFERENCE

To learn the dynamics model we seek to optimize the hyperparameters  $\theta$  w.r.t. the log-marginal likelihood, which involves marginalization of the latent variables in (6). For predictions of the evolution of a system we also need to infer the posterior GP and the posterior distribution of the latent variables  $\mathbf{H} = (h_1, \dots, h_P)$ . We approach this problem with approximate variational inference. We posit a variational distribution that assumes independence between the latent functions of the GP and the latent task variables

$$Q(\mathbf{f}(\cdot), \mathbf{H}) = q(\mathbf{f}(\cdot))q(\mathbf{H}) \quad (7)$$

and minimize the Kullback-Leibler divergence between the approximate and true posterior distributions. Equivalently we can maximize the evidence lower bound

$$\mathcal{L} = \mathbb{E}_{Q(\mathbf{f}(\cdot), \mathbf{H})} \left[ \log \frac{p(\mathbf{Y}, \mathbf{H}, \mathbf{f}(\cdot) | \mathbf{X}, \mathbf{C})}{Q(\mathbf{f}(\cdot), \mathbf{H})} \right], \quad (8)$$

which lower-bounds the log-marginal likelihood [15]. We parameterize our variational distribution such that we can compute the lower bound in (8). We then jointly optimize  $\mathcal{L}$  with respect to the model hyperparameters and the variational parameters.

**Sparse Gaussian Processes** It is important to account for the fact that training a GP on a joint data set of

Figure 1: Graphical model for our ML-GP model.

Figure 2: The figure shows six unknown tasks (toy examples) with a shared structure (the same function) and task specific variation (fixed offset). The ML-GP model is able to disentangle the two automatically given the training data (black discs) as demonstrated by the training prediction curves. It also infers a reasonable value for the offset given a single observations from unseen test tasks (orange discs) and can use the global structure to generalize predictive performance on those tasks.

$P$  different systems quickly becomes infeasible due to the  $\mathcal{O}(T^3)$  computational complexity for training and  $\mathcal{O}(T^2)$  for predictions where  $T$  is the total number of observations. To address this we turn to the variational sparse GP approximation [30] and approximate the posterior GP with a variational distribution  $q(\mathbf{f}(\cdot))$  that depends on a small set of  $M \ll T$  inducing points. We introduce a set of  $M$  inducing inputs  $\mathbf{Z} = (z_1, \dots, z_M) \in \mathbb{R}^{M \times (D+K+Q)}$ , which live in the same space as  $\tilde{\mathbf{x}}$ , with corresponding GP function values  $\mathbf{U} = (u_1, \dots, u_M) \in \mathbb{R}^{M \times D}$ . We follow [14] and specify the variational approximation as a combination of the conditional GP prior and a variational distribution over the inducing function values, independent across output dimensions

$$q(f^d(\cdot)) = \int p(f^d(\cdot) | \mathbf{u}^d) q(\mathbf{u}^d) d\mathbf{u}^d. \quad (9)$$

where  $q(\mathbf{u}^d) = \mathcal{N}(\mathbf{u}^d | \mathbf{m}^d, \mathbf{S}^d)$  is a full rank Gaussian. The integral in (9) can be computed in closed form since both terms are Gaussian, resulting in a GP with mean and

covariance functions given by

$$m_q(\cdot) = \mathbf{k}_Z^T(\cdot) \mathbf{K}_{ZZ}^{-1} \mathbf{m}^d \quad (10)$$

$$k_q(\cdot, \cdot) = k(\cdot, \cdot) - \mathbf{k}_Z^T(\cdot) \mathbf{K}_{ZZ}^{-1} (\mathbf{K}_{ZZ} - \mathbf{S}^d) \mathbf{K}_{ZZ}^{-1} \mathbf{k}_Z(\cdot) \quad (11)$$

where  $[\mathbf{k}_Z(\cdot)]_i = k(\cdot, \mathbf{z}_i)$  and  $[\mathbf{K}_{ZZ}]_{ij} = k(\mathbf{z}_i, \mathbf{z}_j)$ . Here, the variational approach has two main benefits: a) it reduces the complexity of training to  $\mathcal{O}(TM^2)$  and predictions to  $\mathcal{O}(TM)$ , b) it enables mini-batch training for further improvement in computational efficiency.

**Latent Variables** For the latent variables  $\mathbf{H}$  we assume a Gaussian variational posterior

$$q(\mathbf{H}) = \prod_{p=1}^P \mathcal{N}(\mathbf{h}_p | \mathbf{n}_p, \mathbf{T}_p) \quad (12)$$

where  $\mathbf{T}_p$  is in general a full rank covariance matrix. We use a diagonal covariance in practice for more efficient computation of the ELBO (8).

**Evidence Lower Bound (ELBO)** The ELBO can be shown to decompose into (see supplementary material)

$$\mathcal{L} = \sum_{p=1}^P \sum_{t=1}^T \mathbb{E}_{q(\mathbf{f}_t | \mathbf{x}_t, \mathbf{c}_t)} [\log p(\mathbf{y}_t | \mathbf{f}_t)] - \text{KL}[q(\mathbf{H}) || p(\mathbf{H})] - \text{KL}[q(\mathbf{U}) || p(\mathbf{U})] \quad (13)$$

where the expectation is taken with respect to

$$q(\mathbf{f}_t | \mathbf{x}_t, \mathbf{c}_t) = \int q(\mathbf{f}_t | \mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p) q(\mathbf{h}_p) d\mathbf{h}_p. \quad (14)$$

We emphasize that  $q(\mathbf{f}_t | \mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p) = q(\mathbf{f}(\tilde{\mathbf{x}}_t) | \mathbf{x}_t, \mathbf{c}_t, \mathbf{h}_p)$  is the marginal of the GP evaluated at the inputs  $\tilde{\mathbf{x}}_t$ . The integral in (14) is intractable due to the non-linear dependence on  $\mathbf{h}_p$  in (10) and (11). Given our choice of kernel (RBF) and Gaussian variational distribution  $q(\mathbf{h}_p)$  the first and second moments can be computed in closed form. We could use these terms to compute the log-likelihood term in closed form since the likelihood is Gaussian but in practice this can be prohibitively expensive since it requires the evaluation of a  $TM^2D$  tensor. Instead we avoid computing the moments by approximately integrating out the latent variable using Monte Carlo sampling.

**Training** For the update steps in algorithms 1 and 2 we jointly optimize the GP hyperparameters  $\theta$  and the variational parameters  $\phi = \{\mathbf{Z}, M \{\mathbf{m}^d, \mathbf{S}^d\}_{d=1}^D, \{\mathbf{n}_p, \mathbf{T}_p\}_{p=1}^P\}$  w.r.t. the ELBO. For the inference step in algorithm 2, we optimize only the variational parameters for the latent variables  $\mathbf{h}$ , i.e.  $\phi_{\mathbf{h}} = \{\mathbf{n}_p, \mathbf{T}_p\}_{p=1}^P$ .

In practice, we use a single sample  $\mathbf{h}_p \sim q(\mathbf{h}_p)$  drawn from the variational distribution for each system. We use stochastic mini-batch training, sampling a small number of trajectories and their associated latent variable at a time. Empirically, we found standardizing the input states and controls  $(\mathbf{x}, \mathbf{c})$  and outputs  $(\mathbf{y})$  crucial for successful training of the model. For optimization we used Adam [19] with default hyperparameters:  $\alpha = 1 \times 10^{-2}$ ,  $\beta_1 = 0.9$ ,  $\beta_2 = 0.999$ ,  $\epsilon = 10^{-8}$ .

## 4 EXPERIMENTS

Our experiments focus on evaluating our proposed model in terms of predictive performance, the nature of the latent embeddings and data efficiency. We address the following questions: “Does conditioning the GP on the latent variable allow us to disentangle system specific and global properties of the observations? Does this improve predictive performance in the transfer learning setting?” (Section 4.1). “Is the latent system embedding the model learns a sensible one?” (Section 4.2) “Does the application of our ML-GP in model-based RL lead to data-efficient learning across tasks” (Section 4.3).

As a baseline model we use a sparse GP (SGP) [30] as described in Section 3.2 but without the latent variable that explicitly represents the task. For assessing the model quality (Section 4.1) we additionally evaluate the performance of a standard GP with no sparse approximation. We use the following nonlinear dynamical systems to perform our experiments:

**Cart-pole swing-up** The cart-pole system consists of a cart that moves horizontally on a track with a freely swinging pendulum attached to it. The state of this nonlinear system is the position  $x$  and velocity  $\dot{x}$  of the cart and the angle  $\theta$  and angular velocity  $\dot{\theta}$  of the pendulum. The control signals act as a horizontal force on the cart limited to the range  $c \in [-15, 15]$  N. The mean of the initial state distribution is the state where the pendulum is hanging downward. The task is to learn to swing up and balance the pendulum in the inverted position in the middle of the track.

**Double-pendulum swing-up** The double-pendulum system is a two-link robotic arm with two motors, one in the shoulder and one in the elbow. The state of the system comprises the angles  $\theta_1, \theta_2$  and angular velocities  $\dot{\theta}_1, \dot{\theta}_2$  of the inner and outer pendulums, respectively. The control signals are the torques  $c_{1,2} \in [-4, 4]$  Nm applied to the two motors. The mean of  $p(\mathbf{x}_0)$  is the position where both pendulums are hanging downward. The goal is to find a control strategy that swings the double pendulum up and balances it in the inverted position.

## 4.1 QUALITY OF MODEL LEARNING

In the first set of experiments, we investigate if the latent variable of the ML-GP improves prediction performance on unseen systems compared to the SGP baseline. To assess the effect of the sparse approximation we also include a standard GP baseline (no sparse approximation) in this section. To test the prediction quality, we execute the same fixed control signals<sup>1</sup> on six settings of the cart-pole task to generate one 100-step (10 s) trajectory per training task. The specifications of the training tasks were all combinations  $(m, l)$  of  $m \in \{0.4, 0.6, 0.8\}$ ,  $l \in \{0.5, 0.7\}$  where  $m$  and  $l$  denote the mass and length of the pendulum, respectively. Thus, the total number of data points for our six training tasks is  $T = 600$  amounting to 60 s of interaction time.

For evaluation we use the same sequence of control signals we used for training and compute the one-step prediction quality in terms of root mean squared error (RMSE) and negative log likelihood (NLL) on a set of test tasks. We use 14 held-out test tasks specified as  $m \in \{0.4, 0.6, 0.7, 0.8, 0.9\}$ ,  $l \in \{0.4, 0.5, 0.6, 0.7\}$ , excluding the  $(m, l)$ -combinations of the training tasks.

During evaluation, we observe 10 time steps from an unseen trajectory based on which we infer the latent task  $\mathbf{h}_p$  using variational inference for the ML-GP while leaving the model hyperparameters and other variational parameters fixed. We then predict the next 90 steps using the ML-GP, SGP and GP models. ML-GP also performs online inference of the latent variable after each step. We repeat this experiment with 10 different seeds that determine the initial state, and average the results.

Fig. 3 shows the RMSE and NLL for all 3 models. The ML-GP clearly outperforms both the SGP and GP baselines in terms of both the accuracy of its mean predictions (as evident by the RMSE) as well as capturing the data better under its predictive distribution as seen by the NLL. The NLL accounts for both the mean prediction as well as the uncertainty of the model about the prediction. Both baselines have comparable RMSEs to each other with enough inducing points but generalize poorly on new tasks with overconfident predictions. Fig. 4 illustrates this behavior.

The baselines fail to generalize since they have no observations from the system with this configuration. The ML-GP generalizes from training to new test tasks naturally because it explicitly incorporates the latent variables encoding the system configuration.

<sup>1</sup>the control signals were manually chosen as ones that solved a configuration not included in either the training or test set.

Figure 3: Mean and two standard deviation confidence error-bars of the RMSE and NLL for the ML-GP, SGP and the standard GP model as a function of the number of inducing points. The ML-GP significantly outperforms both baselines.

## 4.2 LATENT EMBEDDING

In order for our model to perform well in meta learning settings, the latent variables  $\mathbf{h}_p$  need to reflect a *sensible* embedding. By sensible we mean it should take on a particular structure: a) locally similar values in the latent space should correspond to similar task specifications and b) moving in latent space should correspond to coherent transitions in task specifications.

Fig. 5 shows an example of an inferred latent embedding of both training and test tasks after the training procedure outlined above. The test-task latent variables are inferred from 10 observations from the held-out systems.

The different colors of the discs denote the four different settings of lengths whereas the colors of the dotted lines connecting the discs denote the five different settings of mass. The figure plots the mean of each  $q(\mathbf{h}_p)$  with two standard deviation error bars in each dimension. The embedding displays an intuitive structure where changes in length or mass are disentangled (denoted by the black arrows) into a length-mass coordinate system with the expected transitive properties, e.g. the lengths are ordered as blue ( $l = 0.4$ ), green ( $l = 0.5$ ), red ( $l = 0.6$ ) and orange ( $l = 0.7$ ). The uncertainty estimates also exhibit qualitatively the intuitive property of being less uncertain about tasks which are similar to (closer to) the training tasks, e.g. comparing the red and blue tasks in fig. 5.

## 4.3 DATA-EFFICIENT RL

Our second set of experiments investigates the performance of the ML-GP model in terms of data efficiency in RL settings. Specifically, we look at whether our meta learning approach is a) at least as efficient at solving a

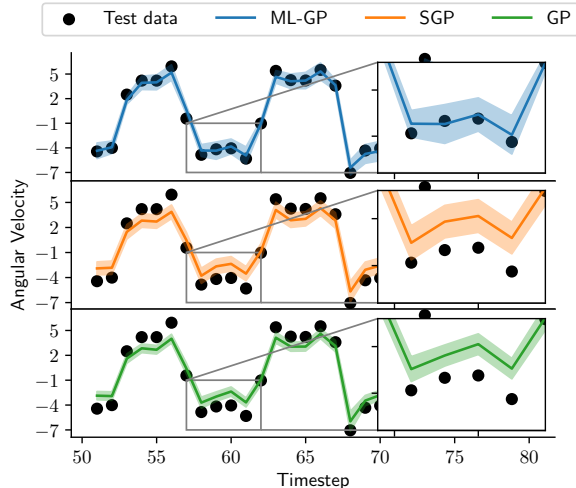

Figure 4: One-step predictions of the angular velocity in cart-pole. The figure shows the true data points (discs) and the predictive distributions with a two standard deviation confidence interval for the ML-GP, SGP and a standard GP. The ML-GP generalizes well to new tasks; both the SGP and GP baselines are overly confident.

set of training tasks, b) more efficient at solving subsequent test tasks, when compared to a non-meta learning baseline and c) whether the ML-GP model improves performance when compared to the SGP model trained with the meta learning approach.

We first learn a model of the dynamics (4), which we then use to learn a policy to control the system. For policy learning we use MPC, minimizing the cost in (3) with a moving horizon to learn an optimal sequence of control signals. We assume we have a set of training systems and evaluate the performance of the models using some held-out test systems with novel configurations (tasks).

We run experiments on both the cart-pole swing-up task and the double-pendulum swing-up task. In both scenarios, we use a sampling frequency of 10 Hz, episodes of 30 steps (3 s) and a planning horizon of 10 steps. For the cart-pole swing-up, solving the task means the pendulum is balanced closer than 8 cm from the goal position for at least the last 10 steps. For the double-pendulum swing-up, it means the outer pendulum is balanced closer than 22 cm for at least the last 10 steps.

At meta-training or test-time, a pass through the training-/test-set means executing the MPC policy learning algorithm on each of the unsolved task in that set. Each execution constitutes a trial for that task. The sets are traversed until all the tasks are solved or all unsolved tasks have executed 15 trials. The training and test procedures are detailed in algorithms 1 and 2 in section 3. All results are averaged over 20 independent random initializations.

Figure 5: Latent space embedding of cart-pole configurations/tasks. The figure shows the mean (discs) of the inferred latent variables and two standard deviation error bars. Filled discs are training tasks and empty discs are held out test tasks. The colors of the discs represent the length and the colors of the dotted lines between discs represent the mass.

Note that we execute on all (unsolved) tasks before re-training the dynamics model as detailed in section 3. This means that the model is updated with 3 s worth of experience for every task in that pass at a time. On the other hand, the model does not take advantage of additional prior experience until it has completed a pass.

For comparison with the ML-GP model, we use the SGP model trained in two different ways. To establish a lower-bound baseline, we run the model-based RL approach where we train a separate model for each task on both the training and test sets. After each training task we additionally attempt to solve each of the test tasks to evaluate single-shot performance where we report the mean across the training tasks as the single shot success rate. We refer to this baseline as SGP-I which is a sparse variant of the approach in [17] that achieves state-of-the-art in data efficiency. Secondly, we train a single SGP model on all the training tasks simultaneously using the same training approach as we do for ML-GP. We refer to this baseline as SGP-ML.

**Cart-pole swing-up** We train the models on six specifications of the cart-pole dynamics, with  $m \in \{0.4, 0.6, 0.8\}$ ,  $l \in \{0.6, 0.8\}$  and evaluate its performance on a set of four test tasks chosen as  $m \in \{0.7, 0.9\}$ ,  $l = \{0.5, 0.7\}$ . We choose these settings to examine the performance on both interpolation and extrapolation for differing lengths and masses. We choose the squared distance between the tip of the pendulum and goal position (with the pendulum balanced straight in the middle of the track) as the cost. Fig. 6 shows the mean success rate (over initializations and the four test tasks) of ML-GP, SGP-I and SGP-ML against the number of trials executed on the systems. We observe that

Figure 6: Mean success rate over initializations and the four test tasks for the cart-pole system after training on six tasks. The graph compares ML-GP with SGP-I (trained independently) and SGP-ML (trained on all tasks).

both the ML-GP model and the SGP-ML display generalization to new tasks as evident by the success rate in the first trial (see also Table 1). However, whereas the ML-GP quickly improves with more observations in subsequent trials, the SGP-ML model struggles to solve the remaining tasks. We attribute this failure to the inability of the SGP-ML model to explain variation in the dynamics caused by differences in system specifications.

When comparing with independent training of each system we see that the ML-GP compares favorably, reaching 80% success rate after only three trials and 90% after six trials compared to the SGP-I, which reaches 80% after 7 trials and 90% after 8 trials. We further analyze performance of ML-GP to identify the tasks that were additionally solved between trials 3 and 6. We find that this is due to a consistently challenging system with  $m = 0.9, l = 0.5$ , which requires the learner to extrapolate beyond the range of values seen during training. The mean number of trials required to solve this task is  $4.3 \pm 0.6$ , compared to the task mean of  $2.7 \pm 0.2$  trials. Table 1 shows the mean total time required to solve

Table 1: Mean time spent solving the cart-pole system and the single-shot success rate.

MODEL	TRAIN (s)	TEST (s)	SINGLE SHOT
SGP-I	$16.1 \pm 0.4$	$17.5 \pm 0.4$	$0.08 \pm 0.01$
SGP-ML	$23.7 \pm 1.4$	$20.8 \pm 1.2$	<b><math>0.38 \pm 0.04</math></b>
ML-GP	<b><math>15.1 \pm 0.5</math></b>	<b><math>8.1 \pm 0.6</math></b>	$0.35 \pm 0.05$

the training and test tasks. On average, ML-GP needs less than half the amount of time to solve the test tasks compared to individually training on the tasks (SGP-I). We also see an improvement in the total training time, which suggests that ML-GP derives some transfer benefit during training despite training on the systems on a concurrent trial basis, i.e. we do not update the model

until all systems have executed a given trial. Compared to the SGP-ML, the ML-GP model can maintain an accurate model while learning multiple systems and quickly adapts to new dynamics, whereas the performance of SGP-ML stagnates as reflected in the interaction time on both the training and test systems.

**Double-pendulum swing-up** We repeat the same experimental set-up on the double-pendulum task. We trained on six systems with  $m_1 \in \{0.5, 0.7\}$ ,  $l_1 \in \{0.4, 0.5, 0.7\}$  and evaluate on a set of four test tasks chosen as  $m_1 \in \{0.6, 0.8\}$ ,  $l_1 = \{0.6, 0.8\}$ , where  $m_1, l_1$  are the mass and length of the inner pendulum. The cost is the squared distance between the tip of the outer pendulum and the goal position (with both pendulums standing straight up). Fig. 7 plots the mean success rate against the number of trials executed on the system. Comparing the ML-GP model to the SGP-ML we observe comparable single-shot performance and a qualitatively similar learning curve for the test tasks. However, the ML-GP reaches 90% success rate about four trials before the SGP-ML, around trial nine, i.e. meta learning achieves a significantly higher data efficiency. Compared to independent training of the tasks using SGP-I, the ML-GP leads to significantly less (new) training data needed to solve the tasks. Table 2 reports the mean total

Figure 7: Mean success rate over initializations and the four test tasks for the double pendulum after training on six tasks. The graph compares the ML-GP against the SGP-I (trained independently on each task) and the SGP-ML (trained using the meta learning procedure).

time required to solve the tasks. Compared to the SGP-ML, the performance of the two is similar, although arguably the ML-GP compares favorably in terms of average time needed to solve the test tasks. Compared to the SGP-I, we see improvement during training as well as at test time. The average time needed for ML-GP to solve the test environments is reduced to around 40% to that of the SGP-I.

Table 2: Mean time spent solving the double-pendulum system and the single-shot success rate.

MODEL	TRAIN (s)	TEST (s)	SINGLE SHOT
SGP-I	18.9 ± 0.7	25.9 ± 1.5	0.07 ± 0.01
SGP-ML	17.9 ± 1.3	13.7 ± 2.2	0.36 ± 0.06
ML-GP	<b>16.6 ± 1.1</b>	<b>10.2 ± 1.6</b>	<b>0.43 ± 0.06</b>

## 5 RELATED WORK

Meta learning has long been proposed as a form of learning that would allow systems to systematically build up and re-use knowledge across different but related tasks [26, 32]. MAML is a recent promising model free meta learning approach that learns a set of model parameters that are used to rapidly learn novel tasks [12]. Another interpretation of MAML is formulated in [13], which shares our hierarchical Bayesian formulation of the meta learning problem. However, the model-free setting in which MAML has been applied so far typically require orders of magnitude more training data than the model-based approaches we build up on in the present work.

Our ML-GP model resembles the GP latent variable model (GPLVM), which is typically used in unsupervised settings [23]. In the GPLVM, the GP is used to map a low-dimensional latent embedding to higher-dimensional observations. A Bayesian extension (BG-PLVM) was introduced in [31] where inference over the latent variable is performed using variational inference. To enable minibatch training, and unlike BG-PLVM, we take the approach of [14] and do not marginalize out the inducing variables. The main difference of our model and the GPLVM is that we learn a mapping from both observed and latent inputs to observations.

The combination of observed and latent inputs was investigated in [33] where the authors use Metropolis sampling for inference which does not scale to larger datasets. A similar setup is found in [7] where the model is used for partially observed input data. The work also proposes uses in autoregressive settings similar to ours. Different from us, the distribution over inducing variables is analytically optimized, making minibatch training infeasible.

A related and complimentary line of research are multi-output GPs (MOGPs) [2]. Recently, [6] proposed a latent variable extension to MOGPs (LVMOGP) which is similar to our ML-GP, particularly in their missing data formulation of the model. The crucial difference from our work is that we augment the input space by concatenating the latent variable to the input space while the LVMOGP uses the Kronecker product of two separate kernels applied on the latent and input spaces respectively.

Notably, the two models are equivalent for kernels that naturally decompose as a Kronecker product (e.g. the RBF) but depart from there.

A similar framework to ours is found in [11], called hidden parameter Markov decision processes (HiP-MDP), which parametrizes a family of related dynamics through a low dimensional latent embedding. The HiP-MDP assumes a fixed latent variable within trajectories. Different from us, the authors use an infinite mixture of GP basis functions where the task specific variation is obtained through the weights of the basis functions [11]. This work was extended in [18], replacing the GP basis functions with a Bayesian neural network. This enables non-linear interactions between the latent and addresses scalability. In this work, the interactions between latent and state variables are obtained through the non-linear RBF kernel, and the scalability is addressed through the variational sparse approach.

In [8], an RL setting is considered that is closely related to our meta-learning set-up. The authors use a parametric policy that depends on a known deterministic task variable and augment the policy function to include it as well. In [8], the authors consider the same dynamical system but solve different tasks by augmenting the policy with a task variable. In our work, we look at different settings of the dynamics but the task remains the same. We show how to generalize to the setting where task variables are latent and inferred from interaction data. This dramatically extends applicability in real-world settings.

## 6 CONCLUSION

We proposed a meta learning approach within the context of model-based RL that allows us to transfer knowledge from training configurations of robotic systems to unseen test configurations. The key idea behind our approach is to address the meta learning problem probabilistically using a latent variable model. We use online variational inference to obtain a posterior distribution over the latent variable, which describes the relatedness of tasks. This posterior is then used for long-term predictions of the state evolution and controller learning within a model-based RL setting. We demonstrated that our ML-GP approach is as efficient or better than a non-meta learning baseline when solving multiple tasks at once. The ML-GP further generalizes well to learning models and controllers for unseen tasks giving rise to substantial improvements in data-efficiency on novel tasks.

# Non-Parametric Path Analysis in Structural Causal Models

---

Junzhe Zhang and Elias Bareinboim  
Purdue University, USA  
{zhang745, eb}@purdue.edu

## Abstract

One of the fundamental tasks in causal inference is to decompose the observed association between a decision  $X$  and an outcome  $Y$  into its most basic structural mechanisms. In this paper, we introduce counterfactual measures for effects along with a specific mechanism, represented as a path from  $X$  to  $Y$  in an arbitrary structural causal model. We derive a novel non-parametric decomposition formula that expresses the covariance of  $X$  and  $Y$  as a sum over unblocked paths from  $X$  to  $Y$  contained in an arbitrary causal model. This formula allows a fine-grained path analysis without requiring a commitment to any particular parametric form, and can be seen as a generalization of Wright’s decomposition method in linear systems (1923,1932) and Pearl’s non-parametric mediation formula (2001).

## 1 INTRODUCTION

Analyzing the relative strength of different pathways between a decision  $X$  and an outcome  $Y$  is a topic that has interested both scientists and practitioners across disciplines for many decades. Specifically, path analysis allows scientists to explain how Nature’s “black-box” works, and practically, it enables decision analysts to predict how an environment will change under a variety of policies and interventional conditions [Wright, 1923; Baron and Kenny, 1986; Bollen, 1989; Pearl, 2001].

More recently, understanding using causal inference tools how a black-box decision-making system operates has been a target of growing interest in the Artificial Intelligence community, most prominently in the context of Explainability, Transparency, and Fairness [Lu Zhang, 2017; Kusner *et al.*, 2017; Zafar *et al.*, 2017; Kilbertus *et al.*, 2017; Zhang and Bareinboim, 2018a]. For exam-

ple, consider the *standard fairness model* described in Fig. 1(a) that is concerned with the relation between a hiring decision ( $Y$ ) and an applicant’s religious beliefs ( $X$ ), which are *mediated* by the location ( $W$ ), and *confounded* by the education background ( $Z$ ) of the applicant.<sup>1</sup> Directed edges represent functional relations between variables. The relationship between  $X$  and  $Y$  is materialized through four different pathways in the system – the *direct* path  $l_1 : X \rightarrow Y$ , the *indirect* path  $l_2 : X \rightarrow W \rightarrow Y$ , and the *spurious* paths  $l_3 : X \leftarrow Z \rightarrow Y$  and  $l_4 : X \leftarrow Z \rightarrow W \rightarrow Y$ .

Assuming, for simplicity’s sake, that the functional relationships are linear and  $U_{V_i}$  is an independent “error” associated with each variable  $V_i$  (called the linear-standard model), Fig. 1(a) shows the structural coefficients corresponding to each edge – i.e., the value of the variable  $Y$  is decided by the structural function  $Y \leftarrow \alpha_{YX}X + \alpha_{YZ}Z + \alpha_{YW}W + U_Y$ . The celebrated result known as Wright’s method of path coefficients [Wright, 1923, 1934], also known as Wright’s rule, allows one to express the covariance of  $X$  and  $Y$ , denoted by  $\text{Cov}(X, Y)$ , as the sum of the products of the structural coefficients along the paths from  $X$  to  $Y$  in the underlying causal model.<sup>2</sup> In particular,  $\text{Cov}(X, Y)$  is equal to:

$$\underbrace{\alpha_{YX}}_{X \rightarrow Y} + \underbrace{\alpha_{WX}\alpha_{YW}}_{X \rightarrow W \rightarrow Y} + \underbrace{\alpha_{XZ}\alpha_{YZ}}_{X \leftarrow Z \rightarrow Y} + \underbrace{\alpha_{XZ}\alpha_{WZ}\alpha_{YW}}_{X \leftarrow Z \rightarrow W \rightarrow Y}. \quad (1)$$

Using the observational covariance matrix, the decomposition above allows one to answer some compelling questions about the relationship between  $X$  and  $Y$  in the underlying model. For instance, the product  $\alpha_{WX}\alpha_{YW}$  explains how much the indirect discrimination through the location (the path  $l_2$ ) accounts for the observed disparities in the religion composition among hired employees.

The path analysis method gained momentum in the so-

---

<sup>1</sup>This specific setting has been called *standard fairness model* given its generality to representing a variety of decision-making scenarios [Zhang and Bareinboim, 2018a].

<sup>2</sup>For a survey on linear methods, see [Pearl, 2000, Ch. 5].

cial sciences during 1960's, becoming extremely popular in the form of the *mediation formula* in which the total effect of  $X$  on  $Y$  is decomposed into direct and indirect components [Baron and Kenny, 1986; Bollen, 1989; Duncan, 1975; Fox, 1980].<sup>3</sup> The bulk of this literature, however, required a commitment to a particular parametric form, thus falling short of providing a general method for analyzing natural and social phenomena with nonlinearities and interactions [MacKinnon, 2008].

It took a few decades until this problem could be tackled in higher generality. In particular, the advent of non-parametric structural causal models (SCMs) allowed this leap, and a more fine-grained path-analysis with a much broader scope, including models with nonlinearities and arbitrarily complex interactions [Pearl, 2000, Ch. 7]. In particular, Pearl introduced the *causal mediation formula* for arbitrary non-parametric models, which decomposes the total effect  $TE_{x_0, x_1}(Y) = E[Y_{x_1}] - E[Y_{x_0}]$ , the difference between the causal effect of the intervention  $do(x_1)$  and  $do(x_0)$ <sup>4</sup>, into what is now known as the natural direct (*NDE*) and indirect (*NIE*) effects [Pearl, 2001] (see also [Imai *et al.*, 2010, 2011; VanderWeele, 2015]). In the case of the specific linear-standard causal model,

$$TE_{0,1}(Y) = \underbrace{\alpha_{YX}}_{NDE} + \underbrace{\alpha_{WX}\alpha_{YW}}_{NIE}$$

for  $x_0 = 0$  and  $x_1 = 1$  levels. Remarkably, when compared with Eq. 1, *NDE* and *NIE* capture the effects along with the direct and indirect paths, but omits the spurious (non-causal) paths between  $X$  and  $Y$  (in this case,  $l_3, l_4$ ). The mediation formula was recently generalized to account for these spurious paths (more akin to Wright's rules), which appears under the rubric of the *causal explanation formula* [Zhang and Bareinboim, 2018a]. This formula decomposes the total variation  $TV_{x_0, x_1}(Y) = E[Y|x_1] - E[Y|x_0]$  (difference in conditional distributions) into counterfactual measures of the direct (*Ctf-DE*), indirect (*Ctf-IE*), and spurious (*Ctf-SE*) effects. In the linear-standard model, for  $x_0 = 0, x_1 = 1$ ,

$$TV_{0,1}(Y) = \underbrace{\alpha_{YX}}_{Ctf-DE} + \underbrace{\alpha_{WX}\alpha_{YW}}_{Ctf-IE} + \underbrace{\alpha_{XZ}\alpha_{YZ} + \alpha_{XZ}\alpha_{WZ}\alpha_{YW}}_{Ctf-SE}$$

Despite the generality of such results, there are still outstanding challenges when performing path analysis in non-parametric models, i.e.: (1) Estimands are defined relative to specific values assigned to the treatment  $x_1$  and its baseline  $x_0$ , which may be difficult to select in some non-linear settings; (2) Mediators and confounders

Figure 1: Causal diagrams for (a) the standard fairness model where  $X$  stands for the protected attribute,  $Y$  for the outcome,  $W$  the mediators, and  $Z$  the confounders; (b) the two-mediators setting where causal paths from  $X$  to  $Y$  are mediated by  $W_1, W_2$ .

are collapsed and considered *en bloc*, leading to a coarse decomposition of the relationship between  $X$  and  $Y$  [Pearl, 2001; Vansteelandt and VanderWeele, 2012; Tchetgen and Shpitser, 2012; VanderWeele *et al.*, 2014; Daniel *et al.*, 2015; Zhang and Bareinboim, 2018a]; (3) Path-specific estimands are well-defined [Pearl, 2001; Avin *et al.*, 2005], but not in a way that they sum up to either the total effect (TE) or variation (TV), precluding the comparison of their relative strengths.

This paper aims to circumvent these problems. In particular, we decompose the covariance of a treatment  $X$  and an outcome  $Y$  over effects along different mechanisms between  $X$  and  $Y$ . We define a set of novel counterfactual estimands for measuring the relative strength of a specific mechanism represented as a path from  $X$  to  $Y$  in an arbitrary causal model. These estimands lead to a non-parametric decomposition formula, which expresses the covariance  $\text{Cov}(X, Y)$  as a sum of the unblocked paths from  $X$  to  $Y$  in the causal graph. This formula allows a more fine-grained analysis of the total observed variations of  $Y$  due to  $X$  (both through causal and spurious mechanisms) when compared to the state-of-art methods. More specifically, our contributions are: (1) counterfactual covariance measures for a specific pathway from  $X$  to  $Y$  (causal and spurious) in an arbitrary causal model (Defs. 8, 11-12); (2) non-parametric decomposition formulae of the covariance  $\text{Cov}(X, Y)$  over paths from  $X$  to  $Y$  in the causal model (Thm. 5); (3) the identification formulae estimating the proposed path-specific decomposition from the passively-collected data in the standard model (Thms. 6-7).

## 2 PRELIMINARIES

In this section, we introduce notations used throughout the paper. We will use capital letters to denote variables (e.g.,  $X$ ), and small letters for their values ( $x$ ). The abbreviation  $P(x)$  represents the probabilities  $P(X = x)$ . For arbitrary sets  $A$  and  $B$ , let  $A - B$  denote their differ-

<sup>3</sup>Just to give an idea of this popularity, Baron and Kenny's original paper counts more than 70,000 citations.

<sup>4</sup>By convention [Pearl, 2000], the post-interventional distribution is represented interchangeably by  $P(y_x)$  and  $P(y|do(x))$ . General notation is discussed in the next section.

ence, and let  $|A|$  be the dimension of set  $A$ .  $V_{[i,j]}$  stands for a set  $\{V_i, \dots, V_j\}$  ( $\emptyset$  if  $i > j$ ). We use graphical family abbreviations:  $An(X)_G$ ,  $De(X)_G$ ,  $Non-De(X)_G$ ,  $Pa(X)_G$ ,  $Ch(X)_G$ , which stand for the set of ancestors, descendants, non-descendants, parents and children of  $X$  in  $G$ . We omit the subscript  $G$  when obvious.

The basic semantical framework of our analysis rests on *structural causal models* (SCM) [Pearl, 2000, Ch. 7; Bareinboim and Pearl, 2016]. A SCM  $M$  consists of a set of endogenous variables  $V$  (often observed) and exogenous variables  $U$  (often unobserved). The values of each  $V_i \in V$  are determined by a structural function  $f_i$  taking as argument a combination of the other endogenous and exogenous variables (i.e.,  $V_i \leftarrow f_i(PA_i, U_i)$ ,  $PA_i \subseteq V, U_i \subseteq U$ ). Values of  $U$  are drawn from a distribution  $P(u)$ . A SCM  $M$  is called *Markovian* when the exogenous are mutually independent and each  $U_i \in U$  is associated with only one endogenous  $V_i \in V$ . If  $U_i$  is associated with two or more endogenous variables,  $M$  is called *semi-Markovian*.

Each recursive SCM  $M$  has an associated causal diagram in the form of a directed acyclic graph (DAG)  $G$ , where nodes represent endogenous variables and directed edges represent functional relations (e.g., Figs. 1-2). By convention, the exogenous  $U$  are not explicitly shown in the graph; a dashed-bidirected arrow between  $V_i$  and  $V_j$  indicates the presence of an unobserved confounder (UC)  $U_k$  affecting both  $V_i$  and  $V_j$  (e.g., the path  $V_i \leftarrow U_k \rightarrow V_j$ ).

A path from  $X$  to  $Y$  is a sequence of edges which does not include a particular node more than once. It may go either along or against the direction of the edges. Paths of the form  $X \rightarrow \dots \rightarrow Y$  are *causal* (from  $X$  to  $Y$ ). We use d-separation and blocking interchangeably, following the convention in [Pearl, 2000]. Any unblocked path that is not causal is called *spurious*. The direct link  $X \rightarrow Y$  is the *direct* path and all the other causal paths from  $X$  to  $Y$  are called *indirect*. The set of unblocked paths from  $X$  to  $Y$  given a set  $Z$  in a causal diagram  $G$  is denoted by  $\Pi(X, Y|Z)_G$ ; causal, indirect, and spurious paths are denoted by  $\Pi^c(X, Y|Z)_G$ ,  $\Pi^i(X, Y|Z)_G$ , and  $\Pi^s(X, Y|Z)_G$  ( $G$  will be omitted when obvious). For a causal path  $g$  including nodes  $V_1, V_2$ , we denote  $g(V_1, V_2)$  a subpath of  $g$  from  $V_1$  to  $V_2$ .<sup>5</sup>

An intervention on a set of endogenous variables  $X$  and exogenous variables  $U_i$ , denoted by  $do(x^*, u_i^*)$ , is an operation where values of  $X, U_i$  are set to  $x^*, u_i^*$ , respectively, without regard to how they were ordinarily determined ( $X$  through  $f_X$  and  $U_i$  through  $P(U_i)$ ). Formally, we can rewrite the definition of potential response [Pearl, 2000, Ch. 7.1] to account for operation on  $U_i$ , namely:

<sup>5</sup>Mediators (relative to  $X$  and  $Y$ ) are a set of variables  $W \subseteq De(X) \cap Non-De(Y)$  such that  $|\Pi^s(X, Y|W)| = 0$ .

**Definition 1** (Potential Response). Let  $M$  be a SCM,  $X, Y$  sets of arbitrary variables in  $V$ , and  $U_i$  a set of arbitrary variables in  $U$ . Let  $U_{-i} = U - U_i$ . The potential response of  $Y$  to the intervention  $do(x^*, u_i^*)$  in the situation  $U = u$ , denoted by  $Y_{x^*, u_i^*}(u)$ , is the solution for  $Y$  with  $U_{-i} = u_{-i}, U_i = u_i^*$  in the modified submodel  $M_{x^*}$  where functions  $f_X$  are replaced by constant functions  $X = x^*$ , i.e.,  $Y_{x^*, u_i^*}(u) \triangleq Y_{M_{x^*}}(u_i^*, u_{-i})$ .<sup>6</sup>

$Y_{x^*, u_i^*}(u)$  can be read as the counterfactual sentence “the value that  $Y$  would have obtained in situation  $U_{-i} = u_{-i}$ , had the treatment  $X$  been  $x^*$  and the situation  $U_i$  been  $u_i^*$ .” Averaging  $u$  over the distribution  $P(u)$ , we obtain a counterfactual random variable  $Y_{x^*, u_i^*}$ . If the values of  $x^*, u_i^*$  follow random variables  $X^*, U_i^*$ , we denote the resulting counterfactual  $Y_{X^*, U_i^*}$ .

### 3 A COARSE COVARIANCE DECOMPOSITION

In this section, we introduce counterfactual measures that will allow us to non-parametrically decompose the covariance  $Cov(X, Y)$  in terms of direct, indirect and spurious pathways from  $X$  to  $Y$ . Given space constraints, all proofs are included in [Zhang and Bareinboim, 2018b].

If there exists no spurious path from  $X$  to  $Y$ , then treatment  $X$  is independent of the counterfactual  $Y_{x^*}$ , i.e.,  $(X \perp\!\!\!\perp Y_{x^*})$  [Pearl, 2000, Ch. 11.3.2]. The *spurious covariance* can then be defined as the correlation between the factual variable  $X$  and counterfactual  $Y_{x^*}$ .

**Definition 2** (Spurious Covariance). The spurious covariance between treatment  $X = x^*$  and outcome  $Y$  is:

$$Cov_{x^*}^s(X, Y) = Cov(X, Y_{x^*}). \quad (2)$$

**Property 1.**  $|\Pi^s(X, Y)| = 0 \Rightarrow Cov_{x^*}^s(X, Y) = 0$ .

The *causal covariance* can naturally be defined as the difference between the total and spurious covariance.

**Definition 3** (Causal Covariance). The causal covariance of the treatment  $X = x^*$  and the outcome  $Y$  is:

$$Cov_{x^*}^c(X, Y) = Cov(X, Y - Y_{x^*}). \quad (3)$$

Prop. 2 establishes the correspondence between the causal paths and the causal covariance – if there is no causal path from  $X$  to  $Y$  in the underlying model, the causal covariance equates to zero.

**Property 2.**  $|\Pi^c(X, Y)| = 0 \Rightarrow Cov_{x^*}^c(X, Y) = 0$ .

We consider more detailed measures corresponding to the different causal pathways, and first, the direct path:

<sup>6</sup>An alternative way to see that the replacement operation relative to  $U_i$  is to envision a system where  $U_i$  is observed.

**Definition 4** (Direct Covariance). Given a semi-Markovian model  $M$ , let the set  $W$  be the mediators between  $X$  and  $Y$ . The pure ( $\text{Cov}_{x^*}^{dp}(X, Y)$ ) and total ( $\text{Cov}_{x^*}^{dt}(X, Y)$ ) direct covariance of the treatment  $X = x^*$  on the outcome  $Y$  are defined respectively as

$$\text{Cov}_{x^*}^{dp}(X, Y) = \text{Cov}(X, Y - Y_{x^*, W}), \quad (4)$$

$$\text{Cov}_{x^*}^{dt}(X, Y) = \text{Cov}(X, Y_{W_{x^*}} - Y_{x^*}). \quad (5)$$

By the composition axiom [Pearl, 2000, Ch. 7.3], Eqs. 4 and 5 can be explicitly written as follows<sup>7</sup>:

$$\begin{aligned} \text{Cov}(X, Y - Y_{x^*, W}) &= \text{Cov}(X, Y_{X, W} - Y_{x^*, W}), \\ \text{Cov}(X, Y_{W_{x^*}} - Y_{x^*}) &= \text{Cov}(X, Y_{X, W_{x^*}} - Y_{x^*, W_{x^*}}). \end{aligned}$$

The counterfactual pure direct covariance (Eq. 4) is shown graphically in Fig. 2, where (a) corresponds to the  $Y$ -side, and (b) to the  $Y_{x^*, W}$ -side. Note that from the mediator  $W$  perspective,  $X$  remains at the level that it would naturally have attained, while the “direct” input from  $X$  to  $Y$  varies from its natural level (Fig. 2a) to  $do(x^*)$  (b). The change of the outcome  $Y$  thus measures the effect of the direct path. A similar analysis also applies to the total direct covariance (Eq. 5).

**Property 3.**  $\text{Cov}_{x^*}^{dp}(X, Y) = \text{Cov}_{x^*}^{dt}(X, Y) = 0$  if  $X$  is not a parent of  $Y$  (i.e.,  $X \notin Pa(Y)$ ).

We can turn around the definitions of direct covariance and provide operational estimands for indirect paths.

**Definition 5** (Indirect Covariance). Given a semi-Markovian model  $M$ , let the set  $W$  be the mediators between  $X$  and  $Y$ . The pure ( $\text{Cov}_{x^*}^{ip}(X, Y)$ ) and total ( $\text{Cov}_{x^*}^{it}(X, Y)$ ) indirect covariance of the treatment  $X = x^*$  on the outcome  $Y$  are defined respectively as:

$$\text{Cov}_{x^*}^{ip}(X, Y) = \text{Cov}(X, Y - Y_{W_{x^*}}), \quad (6)$$

$$\text{Cov}_{x^*}^{it}(X, Y) = \text{Cov}(X, Y_{x^*, W} - Y_{x^*}). \quad (7)$$

Eqs. 6 and 7 correspond to the indirect paths, since they capture the covariance of  $X$  and  $Y$ , but only via paths mediated by  $W$ . The first argument of  $Y$  is the same in both halves of the contrast, but this value can either be  $x^*$  (Eq. 7) or at the level that  $X$  would naturally attain without intervention (Eq. 6).

**Property 4.**  $|\Pi^i(X, Y)| = 0 \Rightarrow \text{Cov}_{x^*}^{ip}(X, Y) = \text{Cov}_{x^*}^{it}(X, Y) = 0$ .

Putting these definitions together, we can prove a general non-parametric decomposition of  $\text{Cov}(X, Y)$ :

<sup>7</sup>Consider Eq. 4 as an example. For any  $U = u$ ,  $Y_{X(u), W(u)}(u) = Y_{x^*, w}(u)$  if  $X(u) = x^*$ ,  $W(u) = w$ . By the composition axiom,  $X(u) = x^*$ ,  $W(u) = w$  implies  $Y(u) = Y_{x^*, w}(u)$ , which in turn gives  $Y_{X(u), W(u)}(u) = Y(u)$ . Averaging  $u$  over  $P(u)$ , we obtain  $Y_{X, W} = Y$ .

Figure 2: The graphical representation of measuring the pure direct covariance  $\text{Cov}_{x^*}^{dp}(X, Y)$ .

**Theorem 1.**  $\text{Cov}(X, Y)$ ,  $\text{Cov}_{x^*}^s(X, Y)$  and  $\text{Cov}_{x^*}^c(X, Y)$  obey the following non-parametric relationship:

$$\text{Cov}(X, Y) = \text{Cov}_{x^*}^c(X, Y) + \text{Cov}_{x^*}^s(X, Y), \quad (8)$$

where  $\text{Cov}_{x^*}^c(X, Y) = \text{Cov}_{x^*}^{dp}(X, Y) + \text{Cov}_{x^*}^{it}(X, Y) = \text{Cov}_{x^*}^{dt}(X, Y) + \text{Cov}_{x^*}^{ip}(X, Y)$ .

In other words, the covariance between  $X$  and  $Y$  can be partitioned into its corresponding direct, indirect, and spurious components. In particular, Thm. 1 coincides with Eq. 1 in the linear-standard model.

**Corollary 1.** In the linear-standard model, for any  $x^*$ ,  $\text{Cov}_{x^*}^s(X, Y)$ ,  $\text{Cov}_{x^*}^{dp}(X, Y)$ ,  $\text{Cov}_{x^*}^{dt}(X, Y)$ ,  $\text{Cov}_{x^*}^{ip}(X, Y)$  and  $\text{Cov}_{x^*}^{it}(X, Y)$  are equal to:

$$\text{Cov}_{x^*}^s(X, Y) = \alpha_{XZ}\alpha_{YZ} + \alpha_{XZ}\alpha_{WZ}\alpha_{YW},$$

$$\text{Cov}_{x^*}^{dp}(X, Y) = \text{Cov}_{x^*}^{dt}(X, Y) = \alpha_{YX},$$

$$\text{Cov}_{x^*}^{ip}(X, Y) = \text{Cov}_{x^*}^{it}(X, Y) = \alpha_{WX}\alpha_{YW}.$$

Corol. 1 says that the proposed decomposition (Thm. 1) does not depend on the value of  $do(x^*)$  in the linear model of Fig. 1(a), which is not achievable in previous value-specific decompositions [Pearl, 2001; Zhang and Bareinboim, 2018a].<sup>8</sup>

## 4 DECOMPOSING CAUSAL RELATIONS

We now focus on the challenge of decomposing the causal covariance into more elementary components. We use the two-mediators setting (Fig. 1(b)) as example, where  $X$  and  $Y$  are connected through four causal paths: through both  $W_1, W_2$  ( $g_1 : X \rightarrow W_1 \rightarrow W_2 \rightarrow Y$ ), only through  $W_1$  ( $g_2 : X \rightarrow W_1 \rightarrow Y$ ), only through  $W_2$  ( $g_3 : X \rightarrow W_2 \rightarrow Y$ ), and directly ( $g_4 : X \rightarrow Y$ ). Our goal is to decompose the  $\text{Cov}_{x^*}^c(X, Y)$  over the paths  $g_{[1,4]}$ . Our analysis applies to semi-Markovian models, without loss of generality, and the Markovian example (Fig. 1(b)) is used for simplicity of the exposition.

<sup>8</sup>For the nonlinear models, the decomposing terms (e.g.,  $\text{Cov}_{x^*}^s(X, Y)$ ) are still sensitive to the target level  $do(x^*)$ . To circumvent the challenges of picking a specific decision value, one could assign a randomized treatment  $do(x^* \sim P(X))$ , where  $P(X)$  is the distribution over the treatment  $X$  induced by the underlying causal model.

For a node  $S_i \in Pa(Y)$  and a set of causal paths  $\pi$ , the edge  $S_i \rightarrow Y$  defines a funnel operator  $\triangleleft_{S_i \rightarrow Y}$ , which maps from  $\pi$  to the set of paths  $\triangleleft_{S_i \rightarrow Y}(\pi)$  obtained from  $\pi$  by replacing all paths of the form  $X \rightarrow \dots \rightarrow S_i \rightarrow Y$  with  $X \rightarrow \dots \rightarrow S_i$ , and removing all the other paths. As an example, for  $\pi = \{g_1, g_2, g_3\}$ ,  $\triangleleft_{W_2 \rightarrow Y}(\pi) = \{g_1(X, W_2), g_3(X, W_2)\}$ , where  $g_1(X, W_2)$  is the subpath  $X \rightarrow W_1 \rightarrow W_2$  and  $g_3(X, W_2)$  is the subpath  $X \rightarrow W_2$ . We next formalize the notion of path-specific interventions, which isolates the influence of the intervention  $do(x^*)$  passing through a subset  $\pi$  of causal paths from  $X$ , denoted by  $do(\pi[x^*])$  (a similar notion has been introduced by [Pearl, 2001], and then [Avin *et al.*, 2005; Shpitser and Tchetgen, 2016]).

**Definition 6 (Path-Specific Potential Response).** For a SCM  $M$  and an arbitrary variable  $Y \in V$ , let  $\pi$  be a set of causal paths. Let  $X$  be the source variables of paths in  $\pi$ . Further, let  $X_{\pi \rightarrow Y} = \{X_i : \forall X_i \in X, X_i \rightarrow Y \in \pi\}$  and  $S = (Pa(Y)_G \cap V) - X_{\pi \rightarrow Y}$ . The  $\pi$ -specific potential response of  $Y$  to the intervention  $do(\pi[x^*])$  in the situation  $U = u$ , denoted by  $Y_{\pi[x^*]}(u)$ , is defined as:

$$Y_{\pi[x^*]}(u) = \begin{cases} Y_{x^*, S_{\triangleleft_{S_i \rightarrow Y}(\pi)[x^*]}(u)} & \text{if } \pi \neq \emptyset \\ Y(u) & \text{otherwise} \end{cases}$$

where  $S_{\triangleleft_{S_i \rightarrow Y}(\pi)[x^*]}(u)$  is a set of  $\pi$ -specific potential response  $\{S_i \in S : S_i \rightarrow Y \in \pi[x^*]\}$ .<sup>9</sup>

Despite the non-trivial notation, the  $\pi$ -specific counterfactual  $Y_{\pi[x^*]}$  is simply assigning the treatment  $do(x^*)$  exclusively to the causal paths in  $\pi$ , while allowing all the other causal paths to behave naturally. This contrasts with the counterfactual  $Y_{x^*}$ , which can be seen as assigning the treatment  $do(x^*)$  to all causal paths from  $X$  to  $Y$ . For instance, repeatedly applying Def. 6 to  $g_1 : X \rightarrow W_1 \rightarrow W_2 \rightarrow Y$  (see [Zhang and Bareinboim, 2018b, Sec. 2.1]), we obtain the  $g_1$ -specific potential response  $Y_{g_1[x^*]}$  as

$$Y_{g_1[x^*]} = Y_{X, W_1, W_2, X, W_1, x^*} = Y_{W_2, W_1, x^*}.$$

The intervention  $do(g_1[x^*])$  can be visualized more immediately through its graphical representation (Fig. 3(b)) – the treatment  $do(x^*)$  is assigned throughout  $g_1$  while all the other paths are kept at the level that it would have attained “naturally” following  $X$ . The difference of the outcome  $Y$  (induced by  $do(g_1[x^*])$ ) and the unintervened  $Y$  (Fig. 3(a)) measures the relative strength of  $g_1$  itself, which leads to the following definition.

**Definition 7 (Pure Path-Specific Causal Covariance).** For a semi-Markovian model  $M$  and an arbitrary causal path  $g$  from  $X$ , the pure  $g$ -specific causal covariance of the treatment  $X = x^*$  on the outcome  $Y$  is defined as:

$$\text{Cov}_g^c(x^*)(X, Y) = \text{Cov}(X, Y - Y_{g[x^*]}). \quad (9)$$

<sup>9</sup>For a single causal path  $g$ , let  $Y_{g[x^*]}(u) = Y_{\{g\}[x^*]}(u)$ . Averaging  $u$  over  $P(u)$ , we obtain a random variable  $Y_{\pi[x^*]}$ .

Figure 3: Graphical representations of the causal covariance specific to  $g_1$  (a-b),  $g_{[2,3]}$  (c-d) and  $g_4$  (e-f).

In the previous example, more explicitly, the pure  $g_1$ -specific causal covariance is equal to (Fig. 3(a-b)):

$$\text{Cov}_{g_1[x^*]}^c(X, Y) = \text{Cov}(X, Y - Y_{W_2, W_1, x^*}). \quad (10)$$

For  $U = u$ , the counterfactual  $Y_{\emptyset[x^*]}(u)$  stands for the values of  $Y$  when all causal paths are under the natural regime. Eq. 9 can then be rewritten as:

$$\text{Cov}_g^c(x^*)(X, Y) = \text{Cov}(X, Y_{\emptyset[x^*]} - Y_{g[x^*]}).$$

The pure path-specific causal covariance for  $g$  can be seen as a function of the difference between two path-specific potential response  $Y_{\pi_0[x^*]}$  and  $Y_{\pi_1[x^*]}$  such that  $g \notin \pi_0$  and  $\pi_1 = \pi_0 \cup \{g\}$  (i.e., the different between  $\pi_1$  and  $\pi_0$  is  $g$ ). The difference  $Y_{\pi_1[x^*]} - Y_{\pi_0[x^*]}$ , therefore, measures precisely the effects of  $do(x^*)$  along the target causal path  $g$ . Def. 7 can be generalized to account for the path-specific covariance in terms of path-differences.

**Definition 8 (Path-Specific Causal Covariance).** For a semi-Markovian model  $M$  and an arbitrary causal path  $g$  from  $X$ , let  $\pi$  be a function mapping  $g$  to a set of causal paths  $\pi(g)$  from  $X$  such that  $g \notin \pi(g)$ . The  $g$ -specific causal covariance of the treatment  $X = x^*$  on the outcome  $Y$  is defined as:

$$\text{Cov}_g^c(x^*)(X, Y)_\pi = \text{Cov}(X, Y_{\pi(g)[x^*]} - Y_{\pi(g) \cup \{g\}[x^*]}).$$

The following property establishes the correspondence between a causal path and its path-specific estimand.

**Property 5.**  $g \notin \Pi^c(X, Y) \Rightarrow \text{Cov}_g^c(x^*)(X, Y)_\pi = 0$ .

Prop. 5 follows immediately as a corollary of Lem. 1, which implies that the counterfactuals  $Y_{\pi(g)[x^*]}$  and  $Y_{\pi(g) \cup \{g\}[x^*]}$  define the same variable over  $U$  if  $g$  is not a causal path from  $X$  to  $Y$ .

**Lemma 1.**  $g \notin \Pi^c(X, Y) \Rightarrow Y_{\pi(g)[x^*]}(u) = Y_{\pi(g) \cup \{g\}[x^*]}(u)$ .

Considering again the model in Fig. 1(b), let  $g_{[i,j]} = \{g_k\}_{i \leq k \leq j}$  ( $\emptyset$  if  $i > j$ ). Recall that  $g_4 = \{X \rightarrow Y\}$ , and note that the  $g_4$ -specific causal covariance can be computed using  $\pi(g_4) = g_{[1,3]}$ , which yields:

$$\begin{aligned} \text{Cov}_{g_4[x^*]}^c(X, Y)_\pi &= \text{Cov}(X, Y_{g_{[1,3]}[x^*]} - Y_{g_{[1,4]}[x^*]}) \\ &= \text{Cov}(X, Y_{W_{1,x^*}, W_{2,x^*}} - Y_{x^*}), \end{aligned} \quad (11)$$

which coincides with the direct effect (Eq. 5 with  $W = \{W_1, W_2\}$ ). Fig. 3(e-f) shows a graphical representation of this procedure.

The path-specific quantity given in Def. 8 has another desirable property, namely, the causal covariance  $\text{Cov}_x^c(X, Y)$  can be decomposed as a summation over causal paths from  $X$  to  $Y$ . To witness, first let an order over  $\Pi^c(X, Y)$  be  $\mathcal{L}^c : g_1 < \dots < g_n$ . For a path  $g_i \in \Pi^c(X, Y)$ , the order  $\mathcal{L}^c$  defines a function  $\mathcal{L}_\pi^c$  which maps from  $g_i$  to a set of paths  $\mathcal{L}_\pi^c(g_i)$  that precede  $g_i$  in  $\mathcal{L}^c$ , i.e.,  $\mathcal{L}_\pi^c(g_i) = g_{[1, i-1]}$ . We derive in the sequel a path-specific decomposition formula for the causal covariance relative to an order  $\mathcal{L}^c$ .

**Theorem 2.** *For a semi-Markovian model  $M$ , let  $\mathcal{L}^c$  be an order over  $\Pi^c(X, Y)$ . For any  $x^*$ , the following non-parametric relationship hold:*

$$\text{Cov}_x^c(X, Y) = \sum_{g \in \Pi^c(X, Y)} \text{Cov}_{g[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c}.$$

Thm. 2 can be demonstrated in the model of Fig. 1(a). Let an order  $\mathcal{L}^c$  over  $g_{[1,4]}$  be  $g_i < g_j$  if  $i < j$ . First note that the path-specific causal covariance of  $g_2$  ( $\text{Cov}_{g_2[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c}$ ) and  $g_3$  ( $\text{Cov}_{g_3[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c}$ ) are equal to, respectively,

$$\text{Cov}\left(X, Y_{W_{2W_{1,x^*}}} - Y_{W_{2W_{1,x^*}}, W_{1,x^*}}\right) \quad (12)$$

$$\text{Cov}\left(X, Y_{W_{2W_{1,x^*}}, W_{1,x^*}} - Y_{W_{1,x^*}, W_{2,x^*}}\right) \quad (13)$$

The causal covariance  $\text{Cov}_x^c(X, Y)$  can then be decomposed as the sum of Eqs. 10-13, respectively,  $g_1, g_4, g_2, g_3$ . Fig. 3 describes this decomposition procedure: we measure the difference of the outcome  $Y$  as the intervention  $do(x^*)$  propagates through paths  $g_1, g_2, g_3, g_4$ . The sum of these differences thus equate to the total influence of the intervention  $do(x^*)$  to the outcome  $Y$ , i.e., the causal covariance  $\text{Cov}_{x^*}^c(X, Y)$ .

## 5 DECOMPOSING SPURIOUS RELATIONS

We introduce in the sequel a new strategy to decompose the spurious covariance (Def. 2), which will play a cen-

Figure 4: Causal diagrams for (a) the one-confounder setting where  $X$  and  $Y$  are confounded by the variable  $Z_2$ , of which  $Z_1$  is a parent node; (b) the twin network for the model of (a) under  $do(x^*)$ .

tral role in the analysis of the spurious relations relative to the pair  $X, Y$ . The spurious covariance measures the correlation between the observational  $X$  and the counterfactual  $Y_{x^*}$  (Def. 2). We will employ in our analysis the twin network [Balke and Pearl, 1994; Pearl, 2000, Sec. 7.1.4], which is a graphical method to analyzing the relation between observational and counterfactual variables.

Consider the causal model  $M$  in Fig. 4(a), for example, where the exogenous variables  $\{U_1, U_2\}$  are shown explicitly. Its twin network is the union of the model  $M$  (factual) and the submodel  $M_{x^*}$  (counterfactual) under intervention  $do(x^*)$ , which is shown in Fig. 4(b). The factual ( $M$ ) and counterfactual ( $M_{x^*}$ ) worlds share only the exogenous variables (in this case,  $U_1, U_2$ ), which constitute the invariances shared across worlds. In this twin network, the observational  $X$  and the counterfactual  $Y_{x^*}$  are connected through two paths: one through  $U_1$  and the other through  $U_2$ . These paths correspond to two pathways from  $X$  to  $Y$  in the original causal diagram:  $\tau_1 : X \leftarrow Z_2 \leftarrow Z_1 \leftarrow U_1 \rightarrow Z_1 \rightarrow Z_2 \rightarrow Y$ , and  $\tau_2 : X \leftarrow Z_2 \leftarrow U_2 \rightarrow Z_2 \rightarrow Y$ .

Note that when considering the corresponding paths in the original graph (Fig. 4(a)), these paths ( $\tau_1, \tau_2$ ) are not necessarily simple, i.e., they may contain a particular node more than once. Furthermore, each path can be partitioned into a pair of causal paths (say,  $g_l, g_r$ ) from a common source  $U_i \in U$  (e.g.,  $\tau_1$  consists of a pair  $(g_{l_1}, g_{r_1})$ , where  $g_{l_1} : U_1 \rightarrow Z_1 \rightarrow Z_2 \rightarrow X$ , and  $g_{r_1} : U_1 \rightarrow Z_1 \rightarrow Z_2 \rightarrow Y$ ). Indeed, these non-simple paths are referred to as *treks* in the causal inference literature, which usually has been studied in the context of linear models [Spirtes *et al.*, 2001; Sullivant *et al.*, 2010].

**Definition 9 (Trek).** A trek  $\tau$  in  $G$  (from  $X$  to  $Y$ ) is an ordered pair of causal paths  $(g_l, g_r)$  with a common exogenous source  $U_i \in U$  such that  $g_l \in \Pi^c(U_i, X)$  and  $g_r \in \Pi^c(U_i, Y)$ . The common source  $U_i$  is called the top of the trek, denoted  $top(g_l, g_r)$ . A trek is spurious if  $g_r \in \Pi^c(U_i, Y|X)$ , i.e.,  $g_r$  is a causal path from  $U_i$  to  $Y$  that is not intercepted by  $X$ .

We denote the set of treks from  $X$  to  $Y$  in  $G$  by  $\mathcal{T}(X, Y)_G$  and spurious treks by  $\mathcal{T}^s(X, Y)_G$  ( $G$  will be omitted when obvious). We introduce next an estimand for a specific spurious trek. For a spurious trek  $\tau = (g_l, g_r)$  with  $U_i = \text{top}(\tau)$ , first let  $X_{g_l}$  denote the path-specific potential response  $X_{g_l[U_i^l]}$ , where  $U_i^l$  is an i.i.d. draw from the distribution  $P(U_i)$ . Similarly, let  $Y_{x^*, g_r} = Y_{x^*, g_r[U_i^r]}$ <sup>10</sup>, where  $U_i^r \sim P(U_i)$ . Pure trek-specific covariance can then finally be defined.

**Definition 10** (Pure Trek-Specific Spurious Covariance). For a semi-Markovian model  $M$  and a spurious trek  $\tau = (g_l, g_r)$  with  $U_i = \text{top}(g_l, g_r)$ , the pure  $\tau$ -specific covariance of the treatment  $X = x^*$  on the outcome  $Y$  is defined as:

$$\text{Cov}_{\tau[x^*]}^{ts}(X, Y) = \text{Cov}(X - X_{g_l}, Y_{x^*} - Y_{x^*, g_r}).$$

In words, the differences  $X - X_{g_l}$  and  $Y_{x^*} - Y_{x^*, g_r}$  are simply measuring the effects of the causal paths  $g_l$  and  $g_r$  (Lem. 1), while the  $\text{Cov}(\cdot)$  operator is in charge of compounding them. (In the extreme case when  $g_l$  or  $g_r$  are disconnected, the pure  $\tau$ -specific spurious covariance will equate to zero.) For example, the pure  $\tau_1$ -specific spurious covariance  $\text{Cov}_{\tau_1[x^*]}^{ts}(X, Y)$  in Fig. 4(a) is

$$\text{Cov}(X - X_{g_{l_1}}, Y_{x^*} - Y_{x^*, g_{r_1}}). \quad (14)$$

Note that the counterfactuals  $X_{g_{l_1}}$  and  $Y_{x^*, g_{r_1}}$  assign the randomized interventions  $do(U_1^l), do(U_1^r)$  to the paths  $g_{l_1}, g_{r_1}$ , respectively. By Def. 6, Eq. 14 is equal to:

$$\text{Cov}(X - X_{U_1^l}, Y_{x^*} - Y_{x^*, U_1^r}).$$

This quantity can be more easily seen through its graphical representation, see Fig. 5 (top). The main idea is to decompose  $U_1$  into two independent components  $U_1^l, U_1^r$  (Fig. 5b), which is then contrasted with the world in which  $U_1$  is kept intact (a).<sup>11 12</sup> We note that by Def. 6,  $X = X_\emptyset$  and  $Y_{x^*} = Y_{x^*, \emptyset}$ . The pure  $\tau_1$ -specific spurious covariance can be written as:

$$\text{Cov}_{\tau_1[x^*]}^{ts}(X, Y) = \text{Cov}(X_\emptyset - X_{g_{l_1}}, Y_{x^*, \emptyset} - Y_{x^*, g_{r_1}}).$$

More generally, the pure trek-specific spurious covariance for  $\tau = (g_l, g_r)$  measures the covariance of variables  $X_{\pi_l} - X_{\pi_l \cup \{g_l\}}$  and  $Y_{x^*, \pi_r} - Y_{x^*, \pi_r \cup \{g_r\}}$ , where  $\pi_l (\pi_r)$  is an arbitrary set of causal paths from  $U$  that does not contain  $g_l (g_r)$ . This observational will be useful later on, which leads to the trek-specific spurious covariance.

<sup>10</sup> $Y_{x^*, g_r[U_i^r]}$  is the  $g_r$ -specific potential response of  $Y$  to  $do(g_r[U_i^r])$  in the submodel  $M_{x^*}$ .

<sup>11</sup>This operation can be seen as the parallel to the pure path-specific covariance (Def. 7), with the distinct requirement that the replacement operator, used to generate the differences, is not relative to the observed  $X$ , but the corresponding  $U_i$ .

<sup>12</sup>To avoid clutter, Fig. 5 is a projected version of the original twin network focused on the relevant quantities (w.l.g.).

Figure 5: The decomposition procedure of the spurious covariance over the spurious treks  $\tau_1, \tau_2$  (Thm. 3).

**Definition 11** (Trek-Specific Spurious Covariance). For a semi-Markovian model  $M$ , let  $\tau$  be a spurious trek  $(g_l, g_r)$  and  $\pi$  is a function mapping  $\tau$  to a pair  $\pi(\tau) = (\pi_l, \pi_r)$  where  $\pi_l$  and  $\pi_r$  are sets of causal paths from  $U$  such that  $g_l \notin \pi_l$  and  $g_r \notin \pi_r$ . The  $\tau$ -specific spurious covariance of the treatment  $X = x^*$  on the outcome  $Y$ , denoted by  $\text{Cov}_{\tau[x^*]}^{ts}(X, Y)_\pi$ , is defined as

$$\text{Cov}(X_{\pi_l} - X_{\pi_l \cup \{g_l\}}, Y_{x^*, \pi_r} - Y_{x^*, \pi_r \cup \{g_r\}}).$$

The next proposition establishes the relationship between Def. 11 and the corresponding spurious treks. This property can be seen as a necessary condition for any measure of strength for spurious relations.

**Property 6.**  $\tau \notin \mathcal{T}^s(X, Y) \Rightarrow \text{Cov}_{\tau[x^*]}^{ts}(X, Y)_\pi = 0$ .

As an example of Def. 11, the trek  $\tau_2$  in Fig. 4(a) consists of paths  $g_{l_2} : U_2 \rightarrow Z_2 \rightarrow X$  and  $g_{r_2} : U_2 \rightarrow Z_2 \rightarrow Y$ . If we set  $\pi(\tau_2) = (\{g_{l_1}\}, \{g_{r_1}\})$ , the  $\tau_2$ -specific spurious covariance can be measured by  $\text{Cov}_{\tau_2[x^*]}^{ts}(X, Y)_\pi$ , i.e.,

$$\text{Cov}(X_{g_{l_1}} - X_{g_{l_1, [2]}}, Y_{x^*, g_{r_1}} - Y_{x^*, g_{r_1, [2]}}) \quad (15)$$

$$= \text{Cov}(X_{U_1^l} - X_{U_{[1,2]}^l}, Y_{x^*, U_1^r} - Y_{x^*, U_{[1,2]}^r}). \quad (16)$$

Eq. 16 is graphically represented in Fig. 5(c-d), where the effect of the trek  $\tau_2$  is measured. In words, the difference between Fig. 5(c) and (d) is the effect of the causal paths  $g_{l_2}$  and  $g_{r_2}$  when  $U_2$  is kept intact versus when divided into two independent components  $(U_2^l, U_2^r)$ .

Armed with the definition of trek-specific spurious covariance, we can finally study the decomposability of the spurious covariance  $\text{Cov}_{x^*}^s(X, Y)$  (Def. 2). First, let  $U^s \subseteq U$  denote the maximal set of exogenous variables that simultaneously affect variables  $X$  and  $Y_{x^*}$  (common exogenous ancestors), and let an order over  $U^s$  be  $\mathcal{L}_u^s : U_1 < \dots < U_n$ . For each  $U_i \in U^s$ , let  $\mathcal{L}_{l_i}^s$  be an order  $g_{l_1}^i < \dots < g_{l_n}^i$  over the set  $\Pi^c(U_i, X)$ . Similarly, we define  $\mathcal{L}_{r_i}^s$  for  $\Pi^c(U_i, Y|X)$ . The tuple  $\mathcal{L}^s = \langle \mathcal{L}_u^s, \{(\mathcal{L}_{l_i}^s, \mathcal{L}_{r_i}^s)\}_{1 \leq i \leq |U^s|} \rangle$  thus defines an order

for the spurious treks  $\mathcal{T}^s(X, Y)$ . We denote  $\mathcal{L}_\pi^s$  a function which maps from a trek  $\tau$  to sets of paths  $\mathcal{L}_\pi^s(\tau)$  covered by the spurious treks preceding  $\tau$  in  $\mathcal{L}^s$ . Formally, given a spurious trek  $\tau = (g_{l_j}^i, g_{r_k}^i)$ ,  $\mathcal{L}_\pi^s(\tau)$  is equal to

$$(\Pi^c(U_{[1, i-1]}, X) \cup g_{l_{[1, j-1]}}^i, \Pi^c(U_{[1, i-1]}, Y|X) \cup g_{r_{[1, k-1]}}^i).$$

We are now ready to derive the decomposition formula for the spurious covariance  $\text{Cov}_{x^*}^s(X, Y)$ .

**Theorem 3.** *For a semi-Markovian model  $M$ , let  $\mathcal{L}^s = \langle \mathcal{L}_u^s, \{(\mathcal{L}_{l_i}^s, \mathcal{L}_{r_i}^s)\}_{1 \leq i \leq |U^s|} \rangle$  be an order over spurious treks  $\mathcal{T}^s(X, Y)$ . For any  $x^*$ , the following non-parametric relationship hold:*

$$\text{Cov}_{x^*}^s(X, Y) = \sum_{\tau \in \mathcal{T}^s(X, Y)} \text{Cov}_{\tau[x^*]}^{ts}(X, Y)_{\mathcal{L}_\pi^s}$$

For example, in the model of Fig. 4(a),  $U^s = \{U_1, U_2\}$ .  $\tau_1$  ( $\tau_2$ ) is the only spurious trek associated with  $U_1$  ( $U_2$ ). If we consider the order  $\mathcal{L}^s$  such that  $\mathcal{L}_u^s : U_1 < U_2$ , Thm. 3 dictates that  $\text{Cov}_{x^*}^s(X, Y)$  should be decomposed as the sum of Eqs. 14 and 15. Fig. 5 shows the graphical representation of this decomposition procedure: we measure the change of the covariance between  $X$  and  $Y_{x^*}$  as we disconnect the relations going through  $\tau_1$  (associated with  $U_1$ ) and  $\tau_2$  ( $U_2$ ), sequentially. The sum of these changes thus equates to the correlations of  $X$  and  $Y$  along the spurious pathways, i.e., the spurious covariance  $\text{Cov}_{[x^*]}^s(X, Y)$ . (See [Zhang and Bareinboim, 2018b, Sec. 2] for more examples.)

## 6 NON-PARAMETRIC PATH ANALYSIS

In this section, we put the results of the previous sections together and derive a general path-specific decomposition for the covariance of the treatment  $X$  and the outcome  $Y$  without assuming any specific parametric form.

We start by noting that each spurious path from  $X$  to  $Y$  corresponds to a unique set of spurious treks that start on  $X$  and end in  $Y$ . Recall that a spurious path  $l$  can be seen as a pair of causal paths  $(g_l, g_r)$ , where the only node shared among  $g_l$  and  $g_r$  is the common source. For example, the spurious path  $l : X \leftarrow Z_2 \rightarrow Y$  is a pair  $(g_l, g_r)$  such that  $g_l : Z_2 \rightarrow X$  and  $g_r : Z_2 \rightarrow Y$ . We can thus define a rule  $f$  which maps a trek  $\tau \in \mathcal{T}^s(X, Y)$  to a spurious path  $l \in \Pi^s(X, Y)$ . For  $\tau = (g_l, g_r)$ , let  $V_t$  be the most distant recurring node from  $\text{top}(g_l, g_r)$  such that  $V_t$  is the only node shared among subpaths  $g_l(V_t, X)$  and  $g_r(V_t, Y)$ ; the pair  $(g_l(V_t, X), g_r(V_t, Y))$  corresponds to a path  $l$  in  $\Pi^s(X, Y)$ . As an example, the trek  $\tau_1$  in Fig. 4(a) has  $V_t = Z_2$ , which corresponds to the spurious path  $l : X \leftarrow Z_2 \rightarrow Y$ , and similarly,  $f(\tau_1) = l$  as well as  $f(\tau_2) = l$ . Lem. 2 shows that the rule  $f$  forms a valid surjective function.

**Lemma 2.** *For a semi-Markovian model  $M$ , for each spurious trek  $\tau \in \mathcal{T}^s(X, Y)$ , there always exists a unique most distant recurring node  $V_t$ .*

For a spurious path  $l$ , let  $\mathcal{T}^s(l) = f^{-1}(l)$  denote its corresponding treks. Specifically, if  $l \notin \Pi^s(X, Y)$ , then for each  $\tau \in \mathcal{T}^s(l)$ , we must have  $\tau \notin \mathcal{T}^s(X, Y)$ . For instance, if the spurious  $l$  in Fig. 4(a) is disconnected, e.g.,  $Z_2 \not\rightarrow X$ , treks  $\tau_1, \tau_2$  are both disconnected as well. From this observation, we could naturally define the spurious covariance of a path  $l$  as a sum over treks in  $\mathcal{T}^s(l)$ .

**Definition 12** (Path-Specific Spurious Covariance). For a semi-Markovian model  $M$  with an associated causal diagram  $G$ , let  $l$  be an arbitrary spurious path in  $G$ . Let  $\pi$  be a function that maps a trek  $\tau = (g_l, g_r) \in \mathcal{T}^s(l)$  to a pair  $\pi(\tau) = (\pi_l, \pi_r)$ , where  $\pi_l$  and  $\pi_r$  are arbitrary sets of causal paths from  $U$  such that  $g_l \notin \pi_l$  and  $g_r \notin \pi_r$ . The  $l$ -specific spurious covariance of the treatment  $X = x^*$  on the outcome  $Y$  is defined as

$$\text{Cov}_{l[x^*]}^s(X, Y)_\pi = \sum_{\tau \in \mathcal{T}^s(l)} \text{Cov}_{\tau[x^*]}^{ts}(X, Y)_\pi$$

**Property 7.**  $l \notin \Pi^s(X, Y) \Rightarrow \text{Cov}_{l[x^*]}^s(X, Y)_\pi = 0$ .

The surjectivity of the function  $f$  assures that the set  $\{\mathcal{T}^s(l)\}_{l \in \Pi^s(X, Y)}$  forms a partition over the spurious treks  $\mathcal{T}^s(X, Y)$ . From Thm. 3, it follows immediately that the path-specific spurious covariance (Def. 12) has the property that expresses the spurious covariance  $\text{Cov}_{x^*}^s(X, Y)$  as a sum over  $\Pi^s(X, Y)$ .

**Theorem 4.** *For a semi-Markovian model  $M$ , let  $\mathcal{L}^s = \langle \mathcal{L}_u^s, \{(\mathcal{L}_{l_i}^s, \mathcal{L}_{r_i}^s)\}_{1 \leq i \leq |U^s|} \rangle$  be an order over spurious treks  $\mathcal{T}^s(X, Y)$ . For any  $x^*$ , the following non-parametric relationship hold:*

$$\text{Cov}_{x^*}^s(X, Y) = \sum_{l \in \Pi^s(X, Y)} \text{Cov}_{l[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s}$$

As an example, the path  $l : X \leftarrow Z_2 \rightarrow Y$  in Fig. 4(a) corresponds to  $\mathcal{T}^s(l) = \{\tau_1, \tau_2\}$ . For an arbitrary order  $\mathcal{L}^s$ , Thm. 4 is applicable and immediately yields  $\text{Cov}_{x^*}^s(X, Y) = \text{Cov}_{l[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s}$ , which means that the path  $l$  accounts for all the spurious relations between  $X$  and  $Y$ . In other words, the spurious joint variability of  $X$  and  $Y$  is fully explained by the variance of  $Z_2$ , which is a function of the exogenous variables  $U_1$  (through  $\tau_1$ ) and  $U_2$  (through  $\tau_2$ ).

Thms. 1-2 and 4 together lead to a general path-specific decomposition formula, which allows one to non-parametrically decompose the covariance  $\text{Cov}(X, Y)$  over all open paths from  $X$  to  $Y$  in the underlying model.

**Theorem 5** (Path-Specific Decomposition). *For a semi-Markovian model  $M$ , let  $\mathcal{L}^c$  be an order over  $\Pi^c(X, Y)$*

and  $\mathcal{L}^s = \langle \mathcal{L}_u^s, \{(\mathcal{L}_{l_i}^s, \mathcal{L}_{r_i}^s)\}_{1 \leq i \leq |U^s|} \rangle$  be an order over  $\mathcal{T}^s(X, Y)$ . For any  $x^*$ , the following non-parametric relationship hold:

$$\begin{aligned} \text{Cov}(X, Y) &= \sum_{l \in \Pi^c(X, Y)} \text{Cov}_{l[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c} \\ &+ \sum_{l \in \Pi^s(X, Y)} \text{Cov}_{l[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s}. \end{aligned} \quad (17)$$

We illustrate the use of Thm. 5 using the model discussed in Sec. 1 (Fig. 1(a)). Recall that  $X$  and  $Y$  are connected through the causal paths  $l_1, l_2$  and spurious paths  $l_3, l_4$ . Note that  $U^s = \{U_Z\}$  spuriously affects the treatment  $X$  through the path  $g_l = U_Z \rightarrow Z \rightarrow X$ , and the outcome  $Y$  through the paths  $g_{r_1} = U_Z \rightarrow Z \rightarrow Y$  and  $g_{r_2} = U_Z \rightarrow Z \rightarrow W \rightarrow Y$ . Let order  $\mathcal{L}^c$  be  $l_1 < l_2$  and  $\mathcal{L}^s$  be  $g_{r_1} < g_{r_2}$ . For any level  $x^*$ , Thm. 5 equates the covariance  $\text{Cov}(X, Y)$  to the sum of  $\{\text{Cov}_{l_i[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c}\}_{i=1,2}$  and  $\{\text{Cov}_{l_i[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s}\}_{i=3,4}$ , which can be written as

$$\begin{aligned} &\underbrace{\text{Cov}(X, Y - Y_{x^*, W})}_{l_1: X \rightarrow Y} + \underbrace{\text{Cov}(X, Y_{x^*, W} - Y_{x^*})}_{l_2: X \rightarrow W \rightarrow Y} \\ &+ \underbrace{\text{Cov}(X - X_{U_Z^l}, Y_{x^*} - Y_{x^*, W_{x^*} Z_{U_Z^r}})}_{l_3: X \leftarrow Z \rightarrow Y} \\ &+ \underbrace{\text{Cov}(X - X_{U_Z^l}, Y_{x^*, W_{x^*} Z_{U_Z^r}} - Y_{x^*, U_Z^r})}_{l_4: X \leftarrow Z \rightarrow W \rightarrow Y}, \end{aligned} \quad (18)$$

which are all well-defined, computable from the structural causal model [Def. 1; Pearl, 2000, Sec. 7.1].

## 7 IDENTIFYING PATH-SPECIFIC DECOMPOSITION

By and large, identifiability is one of the most studied topics in causal inference. It is acknowledged in the literature that obtaining identifiability may be non-trivial even in the context of less granular measures of causal effects, including quantities without nested counterfactual and following the analysis of Pearl's do-calculus.

In this section, we start the study of identifiability conditions for when the path-specific decomposition formula (Thm. 5) can be estimated from data, when the SCM is not fully known. We'll analyze the causal model discussed in Fig. 1(a) given its generality and potential to encode more complex models. The main assumption encoded in this model is Markovianity, i.e., that all exogenous variables are independent. We show next that identifiability can be obtained under these assumptions.

**Theorem 6.** *The path-specific decomposition of Eq. 18 is identifiable if the distributions  $P(x, y_{x^*})$ ,  $P(x, y_{x^*, W})$  and  $P(x, y_{x^*, W_{x^*}, Z_{U_Z^r}})$  are identifiable. Specifically, in the model of Fig. 1(a),  $P(x, y_{x^*})$ ,  $P(x, y_{x^*, W})$ , and*

*$P(x, y_{x^*, W_{x^*}, Z_{U_Z^r}})$  can be estimated, respectively, from the observational distribution  $P(x, y, z, w)$  as follows:*

$$P(x, y_{x^*}) = \sum_{z, w} P(y|x^*, w, z)P(w|x^*, z)P(x, z)$$

$$P(x, y_{x^*, W}) = \sum_{z, w} P(y|x^*, z, w)P(x, z, w)$$

$$P(x, y_{x^*, W_{x^*}, Z_{U_Z^r}}) = \sum_{z, z', w} P(y|x^*, z, w)P(w|x^*, z')P(x, z')P(z)$$

Note that all the quantities listed in Thm. 6 are expressible in terms of conditional distributions and do not involve any counterfactual (simple nor nested), which are readily estimable from the observational distribution. As an example, the  $l_2$ -specific causal covariance  $\text{Cov}_{l_2[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c}$  in Eq. 18 can be written as  $\text{Cov}(X, Y_{x^*, W}) - \text{Cov}(X, Y_{x^*})$ , which are computed from the counterfactual distributions  $P(x, y_{x^*})$  and  $P(x, y_{x^*, W})$ , respectively. These distributions can be estimated from the observational distribution  $P(x, y, z, w)$  following Thm. 6. Indeed, the path-specific decomposition formula (Thm. 5) is identifiable in the model of Fig. 1(a) regardless of the order  $\mathcal{L}^c$  and  $\mathcal{L}^s$ . (For other decompositions, see [Zhang and Bareinboim, 2018b].)

We further considered the identifiability conditions for the path-specific decomposition formula when the more stringent assumption that the underlying structural functions are linear is imposed.

**Theorem 7.** *Under the assumption of linearity and the assumption of Fig. 1(a), for any arbitrary orders  $\mathcal{L}^c$  and  $\mathcal{L}^s$ , for any  $x$ , the path-specific covariance of  $l_1, l_2, l_3$  and  $l_4$  are equal to:*

$$\begin{aligned} \text{Cov}_{l_1[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c} &= \alpha_{YX}, \quad \text{Cov}_{l_2[x^*]}^c(X, Y)_{\mathcal{L}_\pi^c} = \alpha_{WX}\alpha_{YW} \\ \text{Cov}_{l_3[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s} &= \alpha_{XZ}\alpha_{YZ}, \quad \text{Cov}_{l_4[x^*]}^s(X, Y)_{\mathcal{L}_\pi^s} = \alpha_{XZ}\alpha_{WZ}\alpha_{YW} \end{aligned}$$

*The parameters  $\alpha$  can be estimated from the corresponding (partial) regression coefficients [Pearl, 2000, Ch. 5].*

Clearly, after applying Thm. 7 to Eq. 18, the resulting decomposition coincides with Wright's method of path coefficients in the linear-standard model (Eq. 1).

## 8 CONCLUSIONS

We introduced novel covariance-based counterfactual measures to account for effects along with a specific path from a treatment  $X$  to an outcome  $Y$  (Defs. 8, 11-12). We developed machinery to allow, for the first time, the non-parametric decomposition of the covariance of  $X$  and  $Y$  as a summation over the different pathways in the underlying causal model (Thm. 5). We further provided identification conditions under which the decomposition formula can be estimated from data (Thm. 6-7).

## Abstract

Low precision weights, activations, and gradients have been proposed as a way to improve the computational efficiency and memory footprint of deep neural networks. Recently, low precision networks have even shown to be more robust to adversarial attacks. However, typical implementations of low precision DNNs use uniform precision across all layers of the network. In this work, we explore whether a heterogeneous allocation of precision across a network leads to improved performance, and introduce a learning scheme where a DNN stochastically explores multiple precision configurations through learning. This permits a network to learn an optimal precision configuration. We show on convolutional neural networks trained on MNIST and ILSVRC12 that even though these nets learn a uniform or near-uniform allocation strategy respectively, stochastic precision leads to a favourable regularization effect improving generalization.

## 1 INTRODUCTION

Recent advances in deep learning, and convolutional neural networks (CNN) in particular, have led to well-publicized breakthroughs in computer vision (Krizhevsky et al., 2012), speech recognition (Hinton et al., 2012), and natural language processing (NLP) (Bahdanau et al., 2014). Modern CNNs, however, have increasingly large storage and computational requirements (Canziani et al., 2016). This has limited the application scope to data centres that can accommodate clusters of massively parallel hardware accelerators, such as graphics processing units (GPUs). Still, GPU training

of CNNs on large datasets like ImageNet (Deng et al., 2009) can take hours, even on networks with hundreds of GPUs, and achieving linear scaling beyond these sizes is difficult (Goyal et al., 2017). As such, there is a growing interest in investigating more fine-grained optimizations, especially since deployment on embedded devices with limited power, compute, and memory budgets remains an imposing challenge.

Research efforts to reduce model size and speed up inference have shown that training networks with binary or ternary weights and activations (Courbariaux and Bengio, 2016; Rastegari et al., 2016; Li et al., 2016a) can achieve comparable accuracy to full precision networks, while benefiting from reduced memory requirements and improved computational efficiency using bit operations. They may even confer additional robustness to adversarial attacks (Galloway et al., 2018). More recently, the DoReFa-Net model has generalized this finding to include different precision settings for weights vs. activations, and demonstrated how low precision *gradients* can be also employed at training time (Zhou et al., 2016).

These findings suggest that precision in deep learning is not an arbitrary design choice, but rather a dial that controls the trade-off between model complexity and accuracy. However, precision is typically considered at the design level of an entire model, making it difficult to consider as a tunable hyperparameter. We posit that considering precision at a finer granularity, such as a layer or even per-example could grant models more flexibility in which to find optimal configurations, which maximizes accuracy and minimizes computational cost. To remain deterministic about hardware efficiency, we aim to do this for fixed budgets of precision, which have predictable acceleration properties.

In this work we consider learning an optimal precision configuration across the layers of a deep neural network, where the precision assigned to each layer may be different. We propose a stochastic regularization technique

---

\*Work completed while at the University of Guelph

akin to Dropout (Srivastava et al., 2014) where a network explores a different precision configuration per example. This introduces non-differentiable elements in the computational graph which we circumvent using recently proposed gradient estimation techniques.

## 2 RELATED WORK

Recent work related to efficient learning has explored a number of different approaches to reducing the effective parameter count or memory footprint of CNN architectures. Network compression techniques (Han et al., 2015a; Wang and Liang, 2016; Choi et al., 2016; Agustsson et al., 2017) typically compress a pre-trained network while minimizing the degradation of network accuracy. However, these methods are decoupled from learning, and are only suitable for efficient deployment. Network pruning techniques (Wan et al., 2013; Han et al., 2015b; Jin et al., 2016; Li et al., 2016b; Anwar et al., 2017; Molchanov et al., 2016; Tung et al., 2017) take a more iterative approach, often using regularized training and retraining to rank and modify network parameters based on their magnitude. Though coupled with the learning process, iterative pruning techniques tend to contribute to slower learning, and result in sparse connections, which are not hardware efficient.

Our work relates primarily to low precision techniques, which have tended to focus on reducing the precision of weights and activations used for deployment while maintaining dense connectivity. Courbariaux et al. were among the first to explore binary weights and activations (Courbariaux et al., 2015; Courbariaux and Bengio, 2016), demonstrating state-of-the-art results for smaller datasets (MNIST, CIFAR-10, and CVHN). This idea was then extended further with CNNs on larger datasets like ImageNet with binary weights and activations, while approximating convolutions using binary operations (Rastegari et al., 2016). Related work (Kim and Smaragdis, 2016) has validated these results and shown neural networks to be remarkably robust to an even wider class of non-linear projections (Merolla et al., 2016). Ternary quantization strategies (Li et al., 2016a) have been shown to outperform their binary counterparts, moreso when parameters of the quantization module are learned through backpropagation (Zhu et al., 2016). Cai et al. have investigated how to improve the gradient quality of quantization operations (Cai et al., 2017), which is complimentary to our work which relies on these gradients to learn precision. Zhou et al. further explored this idea of variable precision (i.e. heterogeneity across weights and activations) and discussed the general trade-off of precision and accuracy, exploring strategies for training with low precision gradients (Zhou et al., 2016).

Our approach for learning precision closely resembles BitNet (Raghavan et al., 2017), where the optimal precision for each network layer is learned through gradient descent, and network parameter encodings act as regularizers. While BitNet uses the Lagrangian approach of adding constraints on quantization error and precision to the objective function, we allocate bits to layers through sampling from a Gumbel-Softmax distribution constructed over the network layers. This has the advantage of accommodating a defined precision budget, which allows more deterministic hardware constraints, as well as a wider range of quantization encodings through the use of non-integer quantization values early in training. In the allocation of bits on a budget, our work resembles (Wang and Liang, 2016), though we allow more fine-grained control over precision, and prefer a gradient-based approach over clustering techniques for learning optimal precision configurations.

To the best of our knowledge, our work is the first to explore learning precision in deep networks through a continuous-to-discrete annealed quantization strategy. Our contributions are as follows:

- We experimentally confirm a linear relationship between total number of bits and speedup for low precision arithmetic, motivating the use of precision budgets.
- We introduce a gradient-based approach to learning precision through sampling from a Gumbel-Softmax distribution constructed over the network layers, constrained by a precision budget.
- We empirically demonstrate the advantage of our end-to-end training strategy as it improves model performance over simple uniform bit allocations.

## 3 EFFICIENT LOW PRECISION NETWORKS

Low precision learning describes a set of techniques that take network parameters, typically stored at native 32-bit floating point (FP32) precision, and quantize them to a much smaller range of representation, typically 1-bit (binary) or 2-bit (ternary) integer values. While low precision learning could refer to any combination of quantizing weights (W), activations (A), and gradients (G), most relevant work investigates the effects of quantizing weights and activations on model performance. The benefits of quantization are seen in both computational and memory efficiency, though generally speaking, quantization leads to a decrease in model accuracy (Zhou et al., 2016). However, in some cases, the effects of quantization can be lossless or even slightly improve accu-

racy by behaving as a type of noisy regularization (Zhu et al., 2016; Yin et al., 2016). In this work, we adopt the DoReFa-Net model (Zhou et al., 2016) of quantizing all network parameters (W,A,G) albeit at different precision. Table 1 demonstrates this trade-off of precision and accuracy for some common low precision configurations.

The justification for this loss in accuracy is the efficiency gain of storing and computing low precision values. The computational benefits of using binary values are seen from approximating expensive full precision matrix operations with binary operations (Rastegari et al., 2016), as well as reducing memory requirements by packing many low precision values into full precision data types. For other low precision configurations that fall between binary and full precision, a similar formulation is used. The bit dot product equation (Equation 1) shows how both the logical `and` and `bitcount` operations are used to compute the dot product of two low-bitwidth fixed-point integers (bit vectors) (Zhou et al., 2016). Assume  $c_m(x)$  is a placewise bit vector formed from a sequence of  $M$ -bit fixed-point integers  $x = \sum_{m=0}^{M-1} c_m(x)2^m$  and  $c_k(y)$  is a placewise bit vector formed from a sequence of  $K$ -bit fixed-point integers  $y = \sum_{k=0}^{K-1} c_k(y)2^k$ , then

$$x \cdot y = \sum_{m=0}^{M-1} \sum_{k=0}^{K-1} 2^{m+k} \text{bitcount}[\text{and}(c_m(x), c_k(y))],$$

$$c_m(x)_i, c_k(y)_i \in \{0, 1\} \forall i, m, k. \quad (1)$$

Since the computational complexity of the operation is  $\mathcal{O}(MK)$ , the speedup is a function of the total number of bits used to quantize the inputs. Since matrix multiplications are simply sequences of dot products computed over the rows and columns of matrices, this is also true of matrix multiplication operations. As a demonstration, we implement this variable precision bit general matrix multiplication (bit-GEMM) using CUDA, and show the GPU speedup for several configurations in Figure 1.

As seen in Figure 1, there is a correlation between the total number of bits used in each bit-GEMM (shade) and the resulting speedup (point size). As such, from a hardware perspective, it is important to know how many total bits are used for bit-GEMM operations to allow for budgeting computation and memory. It should also be noted that, in our experiments, operations with over 16 total bits of precision were shown to be slower than the full precision equivalent. This is due to the computational complexity of the worst case of  $\mathcal{O}(8 \times 8)$  being slower than the equivalent full precision operation. We therefore focus on operations with 16 or less total bits of precision.

A natural question to follow is then, for a given budget of precision (total number of bits), how do we most

Figure 1: GPU-based bit-GEMM speedup for low precision matrices A and B. Results are compared with a similarly optimized 32-bit GEMM kernel, and run on a NVIDIA Tesla V100 GPU.

efficiently allocate precision to maximize model performance? We seek to answer this question by parametrizing the precision at each layer and learning these additional parameters by gradient descent.

### 3.1 LEARNING PRECISION

The selection of precision for variables in a model can have a significant impact on performance. Consider the DoReFa-Net model — if we decide on a budget of the total number of bits to assign to the weights layer-wise, and train the model under a number of different manual allocations, we obtain the training curves in Figure 2. For each training curve, the number of bits assigned to each layer’s weights are indicated by the integer at the appropriate position (e.g. **444444** indicates 6 quantized layers, all assigned 4 bits).

Varying the number of bits assigned to each layer can cause the error to change by up to several percent, but the best configuration of these bits is unclear without exhaustively testing all possible configurations. This motivates *learning* the most efficient allocation of precision to each layer. However, this is a difficult task for two important reasons:

- unconstrained parameters that control precision will only grow, as higher precision leads to a reduction of loss; and
- quantization involves discrete operations, which are non-differentiable and therefore unsuitable for naïve backpropagation.

The first issue is easily addressed by fixing the total net-

Table 1: DoReFa-Net single-crop top-1 validation error for common weight (W), activation (A), and gradient (G) quantization configurations on the ImageNet Large-Scale Visual Recognition Challenge 2012 (ILSVRC12) dataset. The results are slightly improved over the results originally reported and were reproduced by us based on the public DoReFa-Net (Zhou et al., 2016) codebase.

Model	W	A	G	Top-1 Validation Error
AlexNet (Krizhevsky et al., 2012)	32	32	32	41.4%
BWN (Courbariaux and Bengio, 2016)	1	32	32	44.3%
DoReFa-Net (Zhou et al., 2016)	1	2	6	47.6%
DoReFa-Net (Zhou et al., 2016)	1	2	4	58.4%

Figure 2: The training error for a variety of DoReFa-Net manual precision allocations is plotted for each weight update. The uniform distribution of bits (i.e. **444444**) leads to the lowest error, while the least uniform configurations (e.g. **222288**, **882222**) lead to the highest error.

work precision (i.e. the sum of the bits of precision at each layer) to a budget  $B$ , similar to the  $B = 24$  configurations seen in Figure 2. The task is then to learn the allocation of precision across layers. The second issue: the non-differentiable nature of quantization operations is an unavoidable problem, as transforming continuous values into discrete values must apply some kind of discrete operator. We avoid this issue by employing a kind of stochastic allocation of precision and rely on recently developed techniques from the deep learning community to backpropagate gradients through discrete stochastic operations.

Intuitively, we can view the precision allocation procedure as sequentially allocating one bit of precision to one of  $L$  layers. Each time we allocate, we draw from a categorical variable with  $L$  outcomes, and allocate that bit to the corresponding layer. This is repeated  $B$  times to match the precision budget. An allocation of  $B$  bits corresponds to a particular precision configuration, and

we sample a new configuration for each input example. The idea of stochastically sampling architectural configurations is akin to Dropout (Srivastava et al., 2014), where each example is processed by a different architecture with tied parameters.

Different from Dropout, which uses a fixed dropout probability, we would like to parametrize the categorical distribution across layers such that we can learn to prefer to allocate precision to certain layers. Learning these parameters by gradient descent requires backprop through an operator that samples from a discrete distribution. To deal with its non-differentiability, we use the Gumbel-Softmax, also known as the Concrete distribution (Jang et al., 2016; Maddison et al., 2016), which, using a temperature parameter, can be smoothly annealed from a uniform continuous distribution on the simplex to a discrete categorical distribution from which we sample precision allocations. This allows us to use a high temperature at the beginning of training to stochastically explore different precision configurations and use a low temperature at the end of training to discretely allocate precision to network layers according to the learned distribution.

Though non-integer bits of precision can be implemented (detailed below), integer bits are more amenable to hardware implementations, which is why we aim to converge toward discrete samples. Table 2 shows examples of sampling from this distribution at different temperatures for a three class distribution. It should be noted that in order to perform unconstrained optimization we parametrize the unnormalized logits (also known as log-odds) instead of the probabilities themselves.

Since the class logits  $\pi_i$  control the probability of allocating a bit of precision to a network layer  $l_i$ , at low temperatures the one-hot samples will allocate bits of precision to the network according to the learned parameters  $\pi_i$ . However, at high temperatures we allocate partial bits to layers. This is possible due to our quantization straight-through estimator (STE), `quantize`, adopted

Table 2: Examples of single samples drawn from a Gumbel-Softmax distribution, parametrized by logits for three classes  $\pi_1, \pi_2, \pi_3$  and a variety of temperatures  $\tau$ . The probability of allocating a bit to layer  $l_i$  is impacted by the logit  $\pi_i$ , where higher values correspond to higher probabilities. The Gumbel-Softmax interpolates between continuous densities on the simplex (at high temperature) and discrete one-hot-encoded categorical distributions (at low temperature).

$\tau$	Class 1 ( $\pi_1 = 1.00$ )	Class 2 ( $\pi_2 = 2.00$ )	Class 3 ( $\pi_3 = -0.50$ )
100.0	0.33	0.33	0.33
10.0	0.33	0.41	0.26
1.00	0.31	0.60	0.09
0.10	0.00	1.00	0.00

from (Zhou et al., 2016):

**Forward:**

$$r_o = \text{quantize}(r_i) = \frac{1}{2^k - 1} \text{round}((2^k - 1)r_i), \quad (2)$$

**Backward:**  $\frac{\partial c}{\partial r_i} = \frac{\partial c}{\partial r_o} \quad (3)$

where  $r_i$  is the real number input,  $r_o$  is the  $k$ -bit output, and  $c$  is the objective function. Since `quantize` produces a  $k$ -bit value on  $[0, 1]$ , quantizing to non-integer values of  $k$  simply produces a more fine-grained range of representation compared to integer values of  $k$ . This is demonstrated in Table 3.

Table 3: The possible output values of the `quantize` operation are shown for a variety of values of  $k$ , clipped between 0 and 1. Non-integer values of  $k$  provide a more fine-grained range of representation between successive integer values (underlined).

$k$	<u>1</u>	1.50	<u>2</u>	2.25	2.50	2.75	<u>3</u>
	0.00	0.00	0.00	0.00	0.00	0.00	0.00
	1.00	0.55	0.33	0.26	0.21	0.17	0.14
		1.00	0.66	0.53	0.42	0.34	0.28
			1.00	0.80	0.64	0.52	0.42
				1.00	0.85	0.69	0.57
					1.00	0.87	0.71
						1.00	0.85
							1.00

Using real values for quantization also provides useful gradients for backpropagation, whereas the small finite set of possible integer values would yield zero gradient almost everywhere.

### 3.2 PRECISION ALLOCATION LAYER

We introduce a new layer type, the precision allocation layer, to implement our precision learning technique. This layer is inserted as a leaf in the computational graph, and is executed on each forward-pass of training. The precision allocation layer is parametrized by the learnable class probabilities  $\pi_i$ , which define the Gumbel-Softmax distribution. Each class probability is associated with a layer  $l_i$ , so the samples assigned to each class are allocated as bits to the appropriate layer. This is illustrated in Figure 3 and stepped through in Example 1.

It should be noted that during the early stages of training before the network performance has converged, allowing the temperature to drop too low results in high-variance gradients while also encouraging largely uneven allocations of bits. This severely hurts the generalization of the network. To deal with this, we empirically observe a temperature where the class probabilities have sufficiently stabilized, and perform hard assignments of bits of precision based on these stabilized class probabilities. To do this, we sample from the Gumbel-Softmax a large number of times and average the results, in order to converge on the expected class values, we fix the layers at these precision values for the remainder of training. We observe that the regularization effects of stochastic bit allocations are most useful during early training, and performing hard assignments greatly improves generalization performance. For all experiments considered, we implement a hard assignment of bits after the temperature drops below 3.0.

## 4 EXPERIMENTS

We evaluate the effects of our precision layer on two common image classification benchmarks, MNIST and ILSVRC12. We consider two separate CNN architectures, a 5-layer network similar to LeNet-5 (Lecun et al., 1998) trained on MNIST, and the AlexNet network (Krizhevsky et al., 2012) trained on ILSVRC12. We use the top-1 single-crop error as a measure of performance, and quantize both the weights and activations in all experiments considered. As in previous works (Zhou et al., 2016), the first layer of AlexNet was not quantized. Initial experiments showed that the effects of learning precision were less beneficial to gradients, so we leave them at full precision in all reported experiments.

Since our motivation is to show the precision layer as an improvement over uniformly quantized low precision models, we compare our results to networks with evenly distributed precision over all layers. We consider three common low precision budgets as powers of

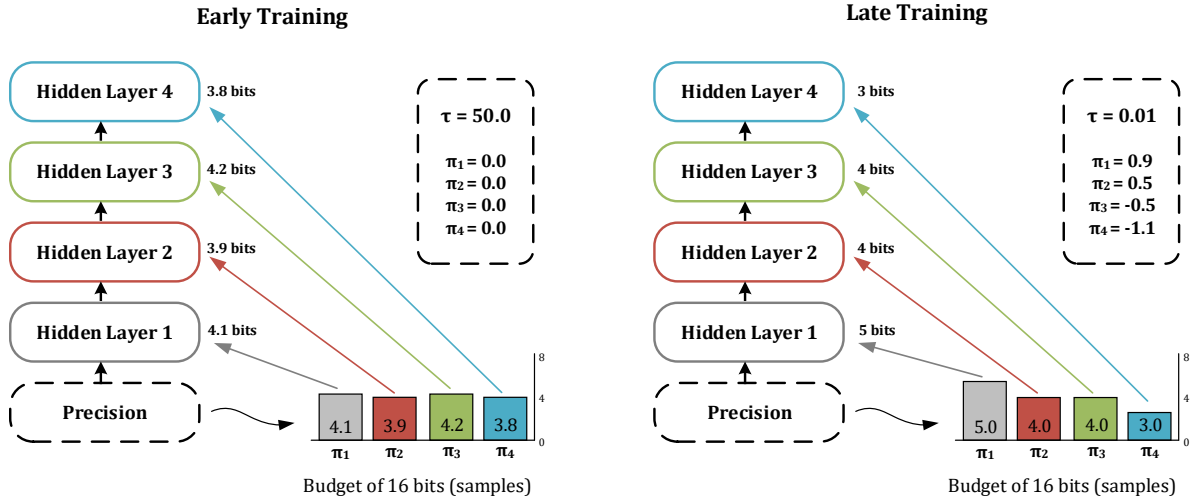

Figure 3: Early in training, the Gumbel-Softmax class probabilities  $\pi_i$  are initialized to 0 while the temperature  $\tau$  is high, generally resulting in uniform allocations of real-valued bits of precision. Later in training, with a low temperature, the learned class probabilities usually result in some layers being allocated more or less discrete bits of precision. In practice, the computational overhead of the precision layer is not noticeable.

**Example 1.** Consider a network with 4 layers, each denoted by  $l_i$ . To learn the precision of these layers, we add a precision layer which constructs a Gumbel-Softmax distribution with 4 classes  $\pi_i$ , where each class is assigned to a layer. Each class probability is initialized to 0.0, and the temperature is initialized to 50.0. For a budget of 16 total bits, two example iterations representative of early training (first iteration of epoch 0) and late training (first iteration of epoch 50) are shown below:

**Epoch = 0**,  $\pi_1 = 0.0$ ,  $\pi_2 = 0.0$ ,  $\pi_3 = 0.0$ ,  $\pi_4 = 0.0$ ,  $\tau = 50.0$

- The precision layer is executed first, which means we sample from the Gumbel-Softmax 16 times because our budget is 16 bits, and accumulate the results of the 16 samples. Each individual sample gives us 4 class outputs which sum to 1 (e.g. [0.25, 0.25, 0.25, 0.25]), so sampling 16 times and accumulating the results for each class means our final results will add to 16. Since the class probabilities are initialized to 0.0, and the temperature is high, the expected samples will be continuous and relatively uniform across all classes.
  - The samples associated with each layer  $l_i$  are:  $l_1 = 4.1$ ,  $l_2 = 3.9$ ,  $l_3 = 4.2$ ,  $l_4 = 3.8$ .
  - We now assign 4.1 bits to layer 1, 3.9 bits to layer 2, 4.2 bits to layer 3, and 3.8 bits to layer 4. These bits are assigned to the appropriate layer by applying the `quantize` operation of Equation 2 to the desired parameters (e.g. weights) with  $k$  as the appropriate bit assignment (e.g.  $k = 4.1$  for  $l_1$ ).
  - The `quantize` operation will transform the layer parameters to one of several discrete positive quantities between 0 and 1 (see Table 3). Though these are fractional bit assignments, the `quantize` operations works the same as if these were integer bit assignments.
  - The iteration then proceeds as normal, with the quantized parameters and class probabilities  $\pi_i$  updated during back-propagation.

**Epoch = 50**,  $\pi_1 = 0.9$ ,  $\pi_2 = 0.5$ ,  $\pi_3 = -0.5$ ,  $\pi_4 = -1.1$ ,  $\tau = 0.01$

- Similar to before, we begin by sampling from the Gumbel-Softmax 16 times because our budget is 16 bits, and accumulate the results. However, the class probabilities have now changed such that  $\pi_1$  corresponds to the most likely class, and  $\pi_4$  the least likely class, so the distribution is no longer uniform. As well, since the temperature is low ( $\tau = 0.01$ ), the samples will now approach discrete.
  - Samples:  $l_1 = 5.0$ ,  $l_2 = 4.0$ ,  $l_3 = 4.0$ ,  $l_4 = 3.0$ .
  - We now assign 5.0 bits to layer 1, 4.0 bits to layer 2, 4.0 bits to layer 3, and 3.0 bits to layer 4, similar to before. Since these bit assignments are integer values, the activity of the `quantize` operation is more intuitive.
  - Similar to before, the `quantize` operation will transform the layer parameters to one of several discrete positive quantities between 0 and 1 (see Table 3).
  - The forward-pass then proceeds as normal, with the quantized parameters and class probabilities  $\pi_i$  updated during back-propagation. Since this is late training, parameter updates will be smaller in magnitude than in early training.

Figure 4: The top-1 errors for the MNIST networks are shown. Both baseline networks with uniform precision allocation (i.e. **budget=10\_22222**) and learned precision networks (i.e. **budget=10\_learn**) are assigned the same total precision budget, indicated by the prefix.

2, which would provide efficient hardware acceleration, where each layer is allocated 2, 4, or 8 bits. Baseline networks with uniform precision allocation are denoted with the allocation for each layer and the budget (e.g. **budget=10\_22222** denotes a baseline network with 2 bits manually allocated to each of 5 layers for a budget of 10 bits), while the networks with learned precision are denoted with the precision budget and *learn* (e.g. **budget=10\_learn** denotes a learned precision network with a budget of 10 total bits, averaging 2 bits per layer).

#### 4.1 MNIST

The training curves for the MNIST-trained models are shown in Figure 4. The learned Gumbel-Softmax class logits are shown in Figure 5.

We observe that the models with learned precision converge faster and reach a lower test error compared to the baseline models across all precision budgets considered, and the relative improvement is more substantial for lower precision budgets. From Figure 5, we observe that the models learn to assign fewer bits to early layers of the network (conv0, conv1) while assigning more bits to later layers of the network (conv2, conv3), as well as preferring smoother (i.e. more uniform) allocations. This result agrees with the empirical observations of (Raghavan et al., 2017). The results on MNIST are summarized in Table 4. Uncertainty is calculated by averaging over 10 runs for each network with different random initializations of the parameters.

#### 4.2 ILSVRC12

The results for ILSVRC12 are summarized in Table 5. Again, models that employ stochastic precision allocation converge faster and ultimately reach a lower test error than their fixed-precision counterparts on the same budget. We observe that networks trained with stochastic precision learn to take bits from early layers and assign these to later layers, similar to the MNIST results. While the class logits for the MNIST network were similar to the ILSVRC12 results, they were not substantial enough to cause changes in bit allocation during our hard assignments. However, the ILSVRC12-trained networks actually make non-uniform hard assignments. This suggests that the precision layer has a larger affect on more complex networks.

### 5 CONCLUSION AND FUTURE WORK

We introduced a precision allocation layer for DNNs, and proposed a stochastic allocation scheme for learning precision on a fixed budget. We have shown that learned precision models outperform uniformly-allocated low precision models. This effect is due to both learning the optimal configuration of precision layer-wise, as well as the regularization effects of stochastically exploring different precision configurations during training. Moreover, the use of precision budgets allow a high level of hardware acceleration determinism which has practical implications.

While the present experiments were focused on accuracy rather than computational efficiency, future work will examine using GPU bit kernels in place of the full precision kernels we used in our experiments. We also intend to investigate stochastic precision in the adversarial setting. This is inspired by Galloway et al. (2018), who report that stochastic quantization at test time yields robustness towards iterative attacks.

Finally, we are interested in a variant of the model where rather than directly parametrizing precision, precision is conditioned on the input. While this reduces hardware acceleration determinism in real-time or memory-constrained settings, it would enable a DNN to dynamically adapt its precision configuration to individual examples.

## Abstract

The goal of personalized decision making is to map a unit's characteristics to an action tailored to maximize the expected outcome for that unit. Obtaining high-quality mappings of this type is the goal of the dynamic regime literature. In healthcare settings, optimizing policies with respect to a particular causal pathway may be of interest as well. For example, we may wish to maximize the chemical effect of a drug given data from an observational study where the chemical effect of the drug on the outcome is entangled with the indirect effect mediated by differential adherence. In such cases, we may wish to optimize the direct effect of a drug, while keeping the indirect effect to that of some reference treatment. [15] shows how to combine mediation analysis and dynamic treatment regime ideas to define policies associated with causal pathways and counterfactual responses to these policies. In this paper, we derive a variety of methods for learning high quality policies of this type from data, in a causal model corresponding to a longitudinal setting of practical importance. We illustrate our methods via a dataset of HIV patients undergoing therapy, gathered in the Nigerian PEPFAR program.

## 1 INTRODUCTION

There has been growing interest in making personalized decisions in different domains to account for inherent heterogeneity among individuals and optimize individual-level experiences. For instance, personalized medicine aims at systematic use of individual patient history including biological information and biomarkers to

improve patient's health care. Personalized actions can be viewed as realizations of decision rules where available information is mapped to the space of possible decisions.

Making good personalized decisions often involves acting in multiple stages. For instance, multiple successive medical interventions may be required for long-term care of patients with chronic diseases. The goal of personalized medicine is to tailor a sequence of decision rules on treatment, known as dynamic treatment regimes, based on patient characteristics seen so far, to maximize the likelihood of a desirable outcome. A number of algorithms have been developed for finding optimal treatment regimes from either observational data, or data from experiments tailored for providing information on regime quality, such as sequential multiple assignment randomized trials (SMARTs) [3, 6]. These algorithms use methods from causal inference, and aim to predict counterfactual outcomes under policies different from those actually followed in the data [11, 5, 2].

A natural extension of these methods is finding treatment regimes that optimizes a *part* of the effect of the treatment on the outcome. We illustrate the utility of this problem with the following example. Patients infected with human immunodeficiency virus (HIV) are typically put on courses of antiretroviral therapy, as a first line of therapy. Although these sort of medications are effective in combating the disease, the full benefit is not realized since patients often do not fully adhere to the medication regimen. One of the causes of poor adherence to the therapy is toxicity of the medication. Hence, viral failure in a patient receiving treatment may be attributed to either poor drug effectiveness or lack of adherence to an otherwise effective treatment plan. In observational studies of HIV patients, treatments are not randomly assigned, and patients have differential adherence. Because of this, finding a policy that optimizes the *overall effect* of the treatment plan on the outcome entangles two very different causal pathways – the chemical pathway asso-

ciated with the active ingredients in the treatment, and the pathway associated with adherence.

We may, instead, consider the problem of finding a set of policies that optimize only the direct chemical effect of the drug, in the counterfactual situations where the indirect effect mediated by adherence can be kept to that of some reference treatment. Policies of this type may be more directly relevant in precision medicine contexts where adherence varies among patients.

[15] defines counterfactual responses to policies that set treatments only with respect to a particular causal pathway, and gives a general identification algorithm for these responses, as a generalization of similar algorithms for standard dynamic treatment regimes [19], and effects associated with causal pathways in mediation analysis [14]. In this paper, we consider algorithms that can be used to find policies that maximize effects along particular causal pathways from data, in a causal model of most immediate relevance in longitudinal settings.

The paper is organized as follows. We fix our notation, and define counterfactual responses to treatment policies and policies associated with pathways in Section 2. In Section 3, we review existing techniques used in learning policies optimizing the *overall effect* of actions. In Section 4, we fix the causal model corresponding to a typical longitudinal study, prove identification of counterfactual policy responses under this model, and show how techniques for maximizing treatment policies, described in Section 4, may be extended to maximize policies associated with causal pathways. In Section 5, we illustrate the methods we propose via an application involving data on treatment of HIV patients in Nigeria. Our conclusions are in Section 6. The Appendix contains the proofs of all claims, a basic description of statistical inference in semi-parametric models, as context for some of our estimation strategies, visualizations of learned policies, and descriptions of the experiments.

## 2 NOTATIONS AND PRELIMINARIES

Consider a multi-stage decision problem with  $K$  pre-specified decision points, indexed by  $i = 1, \dots, K$ . Let  $Y$  denote the final outcome of interest and  $A_i$  denote the action made at decision point  $i$  with the finite state space of  $\mathfrak{X}_{A_i}$ . The set of all actions is denoted by  $\mathbf{A}$ . Let  $W_0$  denote the available information prior to the first decision, and  $W_i$  denote the information collected between decisions  $i$  and  $i+1$ , ( $Y \equiv W_K$ ). Given  $A_i$ , denote  $\bar{A}_i$  to be all treatments administered from time 1 to  $i$ , similarly for  $W_i$  and  $\bar{W}_i$ . We combine the treatment and covariate history up to treatment decision  $A_i$  into a history vector  $H_i$ . The state space of  $H_i$  is denoted by  $\mathfrak{X}_{H_i}$ .

We are interested in learning policies that map  $H_i$  to values of  $A_i$ , for all  $i$ , that maximize the expected value of the outcome  $Y$ . Doing this from observed data entails considering *counterfactual outcomes*  $Y$  had  $A_i$  been assigned in a different way from what was actually observed. We briefly review graphical causal models, and the potential outcome notation from causal inference, which will be used to define such counterfactuals.

Causal models are sets of distributions defined by restrictions associated with directed acyclic graphs (DAGs). We will use vertices and variables interchangeably – capital letters for a vertex or variable ( $V$ ), bold capital letter for a set ( $\mathbf{V}$ ), lowercase letters for values ( $v$ ), and bold lowercase letters for sets of values ( $\mathbf{v}$ ). By convention, each graph is defined on a vertex set  $\mathbf{V}$ . For a set of values  $\mathbf{a}$  of  $\mathbf{A}$ , and a subset  $\mathbf{A}^\dagger \subseteq \mathbf{A}$ , define  $\mathbf{a}_{\mathbf{A}^\dagger}$  to be a restriction of  $\mathbf{a}$  to elements in  $\mathbf{A}^\dagger$ . For a DAG  $\mathcal{G}$ , and any  $V \in \mathbf{V}$ , we define the parents of  $V \in \mathbf{V}$  to be the set  $\text{pa}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid W \rightarrow V\}$ , and the children of  $V \in \mathbf{V}$  to be the set  $\text{ch}_{\mathcal{G}}(V) \equiv \{W \in \mathbf{V} \mid V \rightarrow W\}$ .

Causal models of a DAG  $\mathcal{G}$  consist of distributions defined on counterfactual random variables of the form  $V(\mathbf{a})$  where  $\mathbf{a}$  are values of  $\text{pa}_{\mathcal{G}}(V)$ . These variables represent outcomes of  $V$  had all variables in  $\text{pa}_{\mathcal{G}}(V)$  been set, possibly contrary to fact, to  $\mathbf{a}$ . In this paper we assume Pearl’s functional model for a DAG  $\mathcal{G}$  with vertices  $\mathbf{V}$  which is the set containing any joint distribution over all potential outcome random variables where the sets of variables  $\{\{V(\mathbf{a}_V) \mid \mathbf{a}_V \in \mathfrak{X}_{\text{pa}_{\mathcal{G}}(V)}\} \mid V \in \mathbf{V}\}$  are mutually independent [8]. The *atomic counterfactuals* in the above set model the relationship between  $\text{pa}_{\mathcal{G}}(V)$ , representing direct causes of  $V$ , and  $V$  itself. From these, all other counterfactuals may be defined using *recursive substitution*. For any  $\mathbf{A} \subseteq \mathbf{V} \setminus \{V\}$ ,

$$V(\mathbf{a}) \equiv V(\mathbf{a}_{\text{pa}_{\mathcal{G}}(V) \cap \mathbf{A}}, \{\text{pa}_{\mathcal{G}}(V) \setminus \mathbf{A}\}(\mathbf{a})), \quad (1)$$

where  $\{\text{pa}_{\mathcal{G}}(V) \setminus \mathbf{A}\}(\mathbf{a})$  is taken to mean the (recursively defined) set of counterfactuals associated with variables in  $\text{pa}_{\mathcal{G}}(V)$ , had  $\mathbf{A}$  been set to  $\mathbf{a}$ .

A causal parameter is said to be *identified* in a causal model if it is a function of the observed data distribution  $p(\mathbf{V})$ . In all causal models of a DAG  $\mathcal{G}$  in the literature, all interventional distributions  $p(\{\mathbf{V} \setminus \mathbf{A}\}(\mathbf{a}))$  are identified by the *g-formula*:

$$p(\{\mathbf{V} \setminus \mathbf{A}\}(\mathbf{a})) = \prod_{V \in \mathbf{V} \setminus \mathbf{A}} p(V \mid \text{pa}_{\mathcal{G}}(V)) \Big|_{\mathbf{A}=\mathbf{a}} \quad (2)$$

As an example,  $Y(\mathbf{a})$  in the DAG in Fig. 1 (a), is defined to be  $Y(a, M(a, W), W)$ , and its distribution is identified as  $\sum_{w,m} p(Y|a, m, w)p(m|a, w)p(w)$ . In our sequential decision setting, the relevant counterfactual is  $Y(\bar{a}_K)$ , i.e. the response of  $Y$  had the treatment history  $\bar{A}_K = \bar{a}_K$  been administered, possibly contrary to fact. Comparison of  $Y(\bar{a}_K)$  and  $Y(\bar{a}'_K)$  in expectation,

Figure 1: (a) A simple causal DAG, with a single treatment  $A$ , a single outcome  $Y$ , a vector  $W$  of baseline variables, and a single mediator  $M$ . (b) A more complex causal DAG with two treatments  $A_1, A_2$ , an intermediate outcome  $W_1$ , and the final outcome  $W_2$ .

$\mathbb{E}[Y(\bar{a}_K)] - \mathbb{E}[Y(\bar{a}'_K)]$ , where  $\bar{a}_K$  is the treatment history of interest, and  $\bar{a}'_K$  is the reference treatment history, gives the average causal effect of  $\bar{a}_K$  on the outcome  $Y$ .

### Counterfactual Response to Policies

A dynamic treatment regime  $\mathbf{f}_A = \{f_{A_1}, \dots, f_{A_K}\}$  is a sequence of decision rules that forms a treatment plan for patients over time. At the  $i$ th decision point, the  $i$ th rule  $f_{A_i}$  maps the available information  $H_i$  prior to the  $i$ th decision point to a treatment  $a_i$ , i.e.  $f_{A_i} : \mathfrak{X}_{H_i} \mapsto \mathfrak{X}_{A_i}$ . Given a treatment regime  $\mathbf{f}_A$ , we define the counterfactual response  $Y$  had  $\mathbf{A}$  been assigned according to  $\mathbf{f}_A$ , or  $Y(\mathbf{f}_A)$ , as the following generalization of (1)

$$Y(\{f_{A_i}(H_i(\mathbf{f}_A)) | A_i \in \text{pa}_{\mathcal{G}}(Y) \cap \mathbf{A}\}, \{\text{pa}_{\mathcal{G}}(Y) \setminus \mathbf{A}\}(\mathbf{f}_A)). \quad (3)$$

Under a causal model associated with the DAG  $\mathcal{G}$ , the distribution  $p(Y(\mathbf{f}_A))$ , is identified as the following generalization of the g-formula

$$\sum_{V \setminus Y, A_V \in V \setminus \mathbf{A}} \prod p(V | \{f_{A_i}(H_i) | A_i \in \text{pa}_{\mathcal{G}}(V) \cap \mathbf{A}\}, \text{pa}_{\mathcal{G}}(V) \setminus \mathbf{A}) \quad (4)$$

As an example,  $Y(a = f_A(W))$  in Fig. 1 (a) is defined as  $Y(a = f_A(W), M(a = f_A(W), W), W)$ , and its distribution is identified as  $\sum_{w,m} p(Y | a = f_A(w), m, w) p(m | a = f_A(w), w) p(w)$ . We will call policies corresponding to counterfactuals defined in (3) *overall policies*, to distinguish them from policies associated with causal pathways to be defined later.

### Mediation Analysis

An important goal of causal inference is understanding the mechanisms by which the treatment  $A$  influences the outcome  $Y$ . A common framework for mechanism analysis is *mediation analysis* which seeks to decompose the effect of  $A$  on  $Y$  into the *direct effect* and the *indirect effect* mediated by a third variable, or more generally into components associated with particular causal pathways. Consider the graph in Fig. 1 (a): the direct effect corresponds to the effect along the edge  $A \rightarrow Y$ , and indirect effect corresponds to the effect along the path  $A \rightarrow M \rightarrow Y$ , mediated by  $M$ .

Counterfactuals associated with mediation analysis have been defined using a more general type of intervention in a graphical causal model, namely the *edge intervention* [16], which maps a set of directed edges in  $\mathcal{G}$  to values of their source vertices. Edge interventions have a natural interpretation in cases where a treatment variable has multiple components that a) influence the outcome in different ways, b) occur or do not occur together in observed data, and c) may in principle be intervened on separately. For instance, smoking leads to poor health outcomes due to two components: smoke inhalation and exposure to nicotine. A smoker would be exposed to both of these components, while a non-smoker to neither. However, one might imagine exposing someone selectively only to nicotine but not smoke inhalation (via a nicotine patch), or only smoke inhalation but not nicotine (via smoking plant matter not derived from tobacco leaves). These types of hypothetical experiments correspond precisely to edge interventions, and have been used to conceptualize direct and indirect effects [12, 7].

We will write the mapping of a set of edges to values of their source vertices as  $\mathbf{a}_\alpha$  to mean edges in  $\alpha$  are mapped to values in the *multiset*  $\mathbf{a}$  (since multiple edges may share the same source vertex, and be assigned to different values). For a subset  $\beta \subseteq \alpha$  and an assignment  $\mathbf{a}_\alpha$ , denote  $\mathbf{a}_\beta$  to be a restriction of  $\mathbf{a}_\alpha$  to edges in  $\beta$ . For simplicity, in the remainder of the paper we assume that if  $(AW)_{\rightarrow} \in \alpha$ , then for all  $V \in \text{ch}_{\mathcal{G}}(A)$ ,  $(AV)_{\rightarrow} \in \alpha$ , where  $(XY)_{\rightarrow}$  is a directed edge from  $X$  to  $Y$ .

We will write counterfactual responses to edge interventions as  $Y(\mathbf{a}_\alpha)$ . An edge intervention that sets a set of edges  $\alpha$  to values in the multiset  $\mathbf{a}$  is defined via the following generalization of recursive substitution (1):

$$Y(\mathbf{a}_\alpha) \equiv Y(\mathbf{a}_{\{(ZY)_{\rightarrow} \in \alpha\}}, \{\text{pa}_{\mathcal{G}}^{\bar{\alpha}}(Y)\}(\mathbf{a}_\alpha)), \quad (5)$$

where  $\text{pa}_{\mathcal{G}}^{\bar{\alpha}}(Y) \equiv \{W \mid (WY)_{\rightarrow} \notin \alpha\}$ . For example, in the DAG in Fig. 1 (a),  $Y(\mathbf{a}_{\{(AY)_{\rightarrow}, (AM)_{\rightarrow}\}})$  assigning  $(AY)_{\rightarrow}$  to  $a$  and  $(AM)_{\rightarrow}$  to  $a'$  is defined as  $Y(a, M(a', W), W)$ .

Identification of edge interventions in graphical causal models of a DAG corresponds quite closely with identification of regular (node) interventions, as follows. Let  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_{\rightarrow} \in \alpha\}$ . Consider an edge intervention given by the mapping  $\mathbf{a}_\alpha$ . Then, under the functional model of a DAG  $\mathcal{G}$ , the joint distribution of counterfactual responses  $p(\{\mathbf{V} \setminus \mathbf{A}_\alpha\}(\mathbf{a}_\alpha))$  is identified via the following generalization of (2) called the *edge g-formula*:

$$\prod_{V \in \mathbf{V} \setminus \mathbf{A}_\alpha} p(V | \mathbf{a}_{\{(ZV)_{\rightarrow} \in \alpha\}}, \text{pa}_{\mathcal{G}}^{\bar{\alpha}}(V)). \quad (6)$$

For example, in Fig 1 (a),  $p(Y(\mathbf{a}_{\{(AY)_{\rightarrow}, (AM)_{\rightarrow}\}})) = \sum_{W,M} p(Y | a, M, W) p(M | a', W) p(W)$ , which is obtained by marginalizing  $W$  and  $M$  from the edge g-formula.

## Counterfactual Responses To Policies Associated With Pathways

We now define counterfactual responses to policies that operate only with respect to particular outgoing edges from  $\mathbf{A}$ . These counterfactuals generalize those in the previous two sections.

As an example, we can view Fig. 1 (a) as representing a cross-sectional study of HIV patients of the kind described in [4], where  $W$  is a set of baseline characteristics,  $A$  is one of a set of possible antiretroviral treatments,  $M$  is adherence to treatment, and  $Y$  is a binary outcome variable signifying viral failure. In this type of study, we may wish to find  $f_A(W)$  that maximizes the expected outcome  $Y$  had  $A$  been set according to  $f_A(W)$  for the purposes of the direct effect of  $A$  on  $Y$ , and  $A$  were set to some reference level  $a'$  for the purposes of the effect of  $A$  on  $M$ . In other words, we may wish to find  $f_A(W)$  to maximize the counterfactual mean  $\mathbb{E}[Y(f_A(W), M(a', W), W)]$ . This would correspond to finding a treatment policy that maximizes the direct (chemical) effect, if it were possible to keep adherence to a level  $M(a')$  as if a reference (easy to adhere to) treatment  $a$  were given.

We now give a general definition for responses to such path-specific policies. Fix a set of directed edges  $\alpha$ , and define  $\mathbf{A}_\alpha \equiv \{A \mid (AB)_\rightarrow \in \alpha\}$ . As before, we assume if  $(AW)_\rightarrow \in \alpha$ , then for all  $V \in \text{ch}_G(A)$ ,  $(AV)_\rightarrow \in \alpha$ . Define  $f_\alpha \equiv \{f_{A_i}^{(A_i W)_\rightarrow} : \mathfrak{X}_{H_i} \mapsto \mathfrak{X}_{A_i} \mid (A_i W)_\rightarrow \in \alpha\}$  as the set of policies associated with edges in  $\alpha$ . Note that  $f_\alpha$  may contain multiple policies for a given treatment variable  $A$ .

Define  $Y(f_\alpha)$ , the counterfactual response of  $Y$  to the set of path-specific policies  $f_\alpha$ , as the following generalization of (5) and (3):

$$Y(\{f_{A_i}^{(A_i Y)_\rightarrow}(H_i(f_\alpha)) \mid (A_i Y)_\rightarrow \in \alpha\}, \{\text{pa}_G^\alpha(Y)\}(f_\alpha)) \quad (7)$$

To reformulate our earlier example, if  $\tilde{f}_A^{(AM)_\rightarrow}$  assigns  $A$  to a constant value  $a'$ , and  $\tilde{f}_{\{(AY)_\rightarrow, (AM)_\rightarrow\}} \equiv \{f_A^{(AY)_\rightarrow}(W), \tilde{f}_A^{(AM)_\rightarrow}\}$ , then  $Y(\tilde{f}_{\{(AY)_\rightarrow, (AM)_\rightarrow\}}) \equiv Y(f_A^{(AY)_\rightarrow}(W), M(a', W), W)$ .

The joint counterfactual distribution for responses to path-specific policies,  $p(\{V(f_\alpha) \mid V \in \mathbf{V} \setminus \mathbf{A}_\alpha\})$ , is identified under the functional model, and generalizes (6) and (4) as follows:

$$\prod_{V \in \mathbf{V} \setminus \mathbf{A}_\alpha} p(V \mid \{f_{A_i}^{(A_i V)_\rightarrow}(H_i) \mid (A_i V)_\rightarrow \in \alpha\}, \text{pa}_G^\alpha(V)) \quad (8)$$

For example,  $p(Y(f_A(W), M(a', W), W))$  is identified as  $\sum_{W, M} p(Y \mid f_A(W), M, W) p(M \mid a', W) p(W)$  in Fig. 1 (a). We prove a general version of this result in the Appendix. A general identification theory for responses to path-specific policies can be found in [15].

## 3 LEARNING OPTIMAL OVERALL POLICIES

The goal of this paper is developing methods for learning optimal path-specific policies, in cases where responses to such policies are identified. Before discussing optimal path-specific policies, we first review existing approaches to finding optimal overall policies. Optimality may be quantified in a number of ways. The set of optimal policies is commonly defined as  $\mathbf{f}_\mathbf{A}^* \equiv \arg \max_{\mathbf{f}_\mathbf{A}} \mathbb{E}[Y(\mathbf{f}_\mathbf{A})]$ .

We will discuss existing methods for finding optimal policies  $\mathbf{f}_\mathbf{A}^*$  in the context of a causal model implying *positivity and sequential ignorability* [10]. This model is graphically represented, for two time points, in Fig. 1 (b), where  $W_0$  are baseline factors,  $W_1$  and  $W_2$  are intermediate and final outcomes,  $A_1, A_2$  are treatments. Variables  $W_0, W_1, W_2$  may be confounded by a hidden common cause  $U$ . It is well known that in this model,  $\mathbb{E}[Y(\mathbf{f}_\mathbf{A})]$  is identified via (4). We now discuss a number of approaches for computing the optimal set  $\mathbf{f}_\mathbf{A}^*$  given this identifying formula.

### Approaches Based on Backwards Induction

In sequential decision problems, choosing optimal functions  $\mathbf{f}_\mathbf{A}$  may appear to be a difficult search problem over a large set of function combinations. However, it is possible to use ideas from dynamic programming to transform the problem of choosing optimal  $\mathbf{f}_\mathbf{A}$  into a sequential problem where only a single optimal function is chosen at a time.

Multiple modeling approaches are possible here. A simple approach is to model conditional densities of all outcomes  $W_i$  given their past. Assuming all such models were correctly specified, given any particular history  $H_K$  up to the last decision point  $A_K$ , the optimal  $f_{A_K}^*$  is equal to  $\mathbb{I}(\mathbb{E}[W_K(A_K = 1) \mid H_K] > \mathbb{E}[W_K(A_K = 0) \mid H_K])$ , which under our model is equal to  $\mathbb{I}(\mathbb{E}[W_K \mid A_K = 1, H_K] > \mathbb{E}[W_K \mid A_K = 0, H_K])$ . Assuming optimal  $f_{A_{i+1}}^*, \dots, f_{A_K}^*$ , denoted by  $f_{\Delta_{i+1}}^*$ , were already chosen, the optimal  $f_{A_i}^*$  is defined inductively as

$$\mathbb{I} \left[ \mathbb{E}[W_K(A_i = 1, f_{\Delta_{i+1}}^*) \mid H_i] > \mathbb{E}[W_K(A_i = 0, f_{\Delta_{i+1}}^*) \mid H_i] \right].$$

Note that under our model, the counterfactual expectations above are identified via a modification of (4) where the outer summation is only with respect to variables  $W_{i+1}, \dots, W_{K-1}$ . For many kinds of statistical models for densities appearing as terms in (4), evaluating this sum may be challenging. An alternative strategy that avoids repeated summations is modeling the above expectations directly via *Q-functions*  $Q_i$ , which are conditional expectations over *value functions*  $V_{i+1}$ , given the

history. These are defined recursively as follows:

$$\begin{aligned} Q_K(H_K, A_K; \gamma_K) &= \mathbb{E}[W_K | A_K, H_K], \\ V_K(H_K) &= \max_{a_K} Q_K(H_K, a_K; \gamma_K), \end{aligned}$$

and for  $i = K - 1, \dots, 1$ , as

$$\begin{aligned} Q_i(H_i, A_i; \gamma_i) &= \mathbb{E}[V_{i+1}(H_{i+1}) | A_i, H_i], \\ V_i(H_i) &= \max_{a_i} Q_i(H_i, a_i; \gamma_i). \end{aligned}$$

The optimal policy at each stage may be easily derived from Q-functions as  $f_{A_i}^*(H_i) = \arg \max_{a_i} Q_i(H_i, a_i; \gamma_i)$ . Q-functions are recursively defined regression models where outcomes are value functions, and features are histories up to the current decision point. Thus, parameters  $\gamma_i, i = 1, \dots, K$ , of all Q-functions may be learned recursively by maximum likelihood methods applied to regression at stage  $i$ , given that the value function at stage  $i + 1$  was already computed for every row [2, 13].

### Value Search

Consider a restricted class of policies  $\mathcal{F}$  with elements  $\mathbf{f}_A \equiv \{f_{A_i}(H_i); A_i \in \mathbf{A}\}$ . It is often of interest to estimate the optimal policy within the class  $\mathcal{F}$ , even if the class does not contain the true optimal policy. For example,  $\mathcal{F}$  may be the set of clinically interpretable policies. For a sufficiently simple class  $\mathcal{F}$ , we can directly search for the optimal  $\mathbf{f}_A^{*\mathcal{F}} \equiv \arg \max_{\mathbf{f}_A \in \mathcal{F}} \mathbb{E}[Y(\mathbf{f}_A)]$ . This is called policy search or value search.

The expected response to an arbitrary treatment policy  $\beta = \mathbb{E}[Y(\mathbf{f}_A)]$ , for  $\mathbf{f}_A \in \mathcal{F}$  can be estimated in a number of ways. For  $\mathbf{A} = \{A\}$ , a simple estimator for  $\beta$  that uses only the treatment assignment model  $\pi(H; \psi)$  for  $p(A = 1|H)$  is the inverse probability weighting (IPW) estimator:

$$\mathbb{E} \left[ Y C_{f_A} / \pi_{f_A}(H; \hat{\psi}) \right], \quad (9)$$

where  $C_{f_A} \equiv \mathbb{I}(A = f_A(H))$ ,  $\pi_{f_A}(H; \psi) \equiv \pi(H; \psi) f_A(H) + (1 - \pi(H; \psi))(1 - f_A(H))$ , the expectation is evaluated empirically, and  $\hat{\psi}$  is fit by maximum likelihood. This estimator will not in general yield the optimal policy within  $\mathcal{F}$  if  $\pi$  is misspecified. An alternative estimator for  $\beta$  that provides some protection against this is the following:

$$\mathbb{E} \left[ \frac{C_{f_A} Y}{\pi_{f_A}(H; \hat{\psi})} - \frac{C_{f_A} - \pi_{f_A}(H; \hat{\psi})}{\pi_{f_A}(H; \hat{\psi})} \mathbb{E}[Y|H, A = f_A(H); \hat{\gamma}] \right]. \quad (10)$$

The above estimator is *doubly-robust* meaning that it is a consistent estimator if either the propensity score model  $\pi(H; \psi)$  or the regression model  $\mathbb{E}[Y|H, A; \gamma]$  is correctly specified.

Value search methods can in some cases be rephrased as a weighted classification problem in machine learning [20]. In the interest of space, we do not discuss methods based on this observation further here.

### G-Estimation

An alternative method for learning policies is to directly model the counterfactual contrast functions known as *optimal blip-to-zero functions*, or the counterfactual deviations in outcome from a reference treatment value (which we take to be  $A = 0$ ), conditional on history, assuming all future decisions are already optimal. Specifically, for each decision point  $i$ , we posit a *structural nested mean model (SNMM)*  $\gamma_i(H_i, A_i; \psi)$  for the contrast

$$\mathbb{E} \left[ Y(\bar{a}_i, f_{A_{i+1}}^*) | H_i \right] - \mathbb{E} \left[ Y(\bar{a}_{i-1}, a_i = 0, f_{A_{i+1}}^*) | H_i \right].$$

Note that if the true  $\gamma_i(H_i, A_i; \psi)$  were known, the optimal treatment policies are those that maximize the blip function at each stage:  $f_{A_i}^* = \arg \max_{a_i} \gamma_i(H_i, A_i; \psi_i)$ . In order to estimate  $\psi$  using data, let

$$\begin{aligned} U(\psi, \zeta(\psi), \alpha) &= \sum_{i=1}^K \{G_i(\psi) - \mathbb{E}[G_i(\psi) | H_i; \zeta]\} \\ &\quad \times \{d_i(H_i, A_i) - \mathbb{E}[d_i(H_i, A_i) | H_i; \alpha]\}, \quad (11) \end{aligned}$$

where  $d_i(H_i, A_i)$  is any function of  $H_i$  and  $A_i$ , and

$$G_i(\psi) = Y - \gamma_j(H_i, A_i; \psi) + \sum_{k=i+1}^K [\gamma_k(H_k, a_k^*; \psi) - \gamma_k(H_k, a_k; \psi)].$$

Consistent and asymptotically normal (CAN) estimators of  $\psi$  can be obtained using the estimating equations  $\mathbb{E}[U(\psi, \zeta(\psi), \alpha)] = 0$ , as shown in [11]. The estimate obtained in (11) is doubly-robust, meaning that the estimator  $\hat{\psi}$  is consistent if either  $\mathbb{E}[G_i(\psi) | H_i; \zeta]$  or  $p_i(A_i = 1 | H_i; \alpha)$  is correctly specified.

Methods closely related to G-estimation based on *counterfactual regret* were developed in [5]. We do not discuss them here in the interest of space.

## 4 LEARNING OPTIMAL PATH-SPECIFIC POLICIES

We now consider how the methods for optimizing overall policies translate to optimizing path-specific policies. Some of the generalizations we consider are currently only known for single-stage decision problems.

Consider the generalization of Fig. 1 (b) to the longitudinal setting with mediators, shown (for two time points) in Fig. 2 (a). This causal model corresponds to the setting described in detail in [4], representing an observational longitudinal study of HIV patients. Here,  $W_0$  represents the baseline variables of a patient,  $A_1, A_2$  represent treatment assignments, which were chosen based on observed treatment history according to physician's best judgement,  $W_1, W_2$  are intermediate and final outcomes (such as CD4 count or viral failure), and  $M_1, M_2$  are measures of patient adherence to their treatment regimen. We are interested in finding policies  $f_{A_1}(H_1), f_{A_2}(H_2)$  that optimize the effect of  $A_1, A_2$  on  $W_2$  that is either direct or via intermediate outcomes, but not via adherence, and where adherence is kept to that of a reference

treatment  $a'_1, a'_2$ . Specifically, we are interested in choosing  $f_{A_1}, f_{A_2}$  to optimize the counterfactual expectation  $\mathbb{E}[W_2(f_{A_1}, f_{A_2})]$ , which expands via (7) to

$$\mathbb{E} \left[ W_2 \left( \begin{array}{c} W_0, f_{A_1}(H_1), M_1(a'_1), \\ W_1(f_{A_1}(H_1), M_1(a'_1)), f_{A_2}(H_2), \\ M_2(a'_1, a'_2, W_1(f_{A_1}(H_1), M_1(a'_1)), M_1(a'_1)) \end{array} \right) \right). \quad (12)$$

The  $K$  stage version of the causal model in Fig. 2 (a) is given by a complete DAG on variables  $W_0, A_1, M_1, W_1, \dots, A_K, M_K, W_K$ , listed in topological order, with a hidden common cause  $U$  of  $W_0, \dots, W_K$ . Let  $\alpha$  be all directed edges out of  $A_1, \dots, A_K$ . The general version of (12) is the expectation of  $W_K$  taken with respect to the distribution  $p(W_K(f_\alpha))$ , where  $f_\alpha$  sets all edges  $(A_i M_j) \rightarrow$  to  $a'_i$ , and all other edges in  $\alpha$  to a policy  $f_{A_i}(H_i)$ .

Identifiability of  $p(W_K(f_\alpha))$  is given by the following corollary of results in [14], which can be viewed as a generalization of the *collapse of the g-formula* [10] to longitudinal mediation settings.

**Theorem 1** *In the above model, with a positive observed data distribution  $p(W_K(f_\alpha))$  is identified as*

$$\sum_{H_K, M_K} \prod_{i=1}^K \left\{ p(W_i | \bar{M}_{i-1}, \bar{W}_{i-1}, f_{A_i}(H_i)) p(M_i | \bar{a}'_i, \bar{W}_{i-1}, \bar{M}_{i-1}) \right\} p(W_0) \quad (13)$$

As a consequence (12) is identified as

$$\sum_{\bar{W}_1, \bar{M}_2} \mathbb{E} \left[ W_2 | f_{A_1}(H_1), f_{A_2}(H_2), \bar{W}_1, \bar{M}_2 \right] p(M_1 | a'_1, W_0) \times p(W_1 | W_0, f_{A_1}(H_1), M_1) p(M_2 | \bar{W}_1, M_1, a'_1, a'_2) p(W_0).$$

We now discuss a number of strategies for finding optimal path-specific policies identified by (13).

### Parametric Backwards Induction

A simple approach for finding optimal path-specific policies is to combine backwards induction with a maximum likelihood estimator for the conditional densities in the identifying functional (13).

Consider Fig. 2 (a), and let  $a_i$  and  $a'_i$  denote the active and reference levels of  $a_i$ , respectively. Beginning at the last stage  $K = 2$ , and assuming treatment is binary, the optimal decision,  $f_{A_2}^*$ , for a given patient with history  $(w_0, a_1, m_1, w_1)$  sets  $A_2$  to either  $a_2$  or  $a'_2$  to maximize the response  $W_2$ , while keeping  $M_2$  at whatever value it would have attained under a sequence of reference interventions  $(a'_1, a'_2)$ :

$$f_{A_2}^* = \mathbb{I} \left( \mathbb{E}[W_2(a_2, M_2(\bar{a}'_2)) | H_2] > \mathbb{E}[W_2(a'_2, M_2(\bar{a}'_2)) | H_2] \right).$$

The optimal decision at the first stage,  $f_{A_1}^*$ , is given by

$$\mathbb{I} \left\{ \mathbb{E} \left[ W_2 \left( \begin{array}{c} a_1, f_{A_2}^*(H_2), M_1(a'_1), W_1(a_1, M_1(a'_1)), \\ M_2(\bar{a}'_2, M_1(a'_1), W_1(a_1, M_1(a'_1))) \end{array} \right) \middle| H_1 \right] > \mathbb{E} \left[ W_2 \left( \begin{array}{c} a'_1, f_{A_2}^*(H_2), M_1(a'_1), W_1(a'_1, M_1(a'_1)), \\ M_2(\bar{a}'_2, M_1(a'_1), W_1(a'_1, M_1(a'_1))) \end{array} \right) \middle| H_1 \right] \right\}.$$

Under the causal model we described, the above counterfactuals can be estimated using a modification of (13) with no summations over, but instead conditioning on histories  $H_1$  or  $H_2$ . This approach easily generalizes to any number of decision stages. The difficulty here, as before, is the increasing amount of marginalizations that must be performed as the number of stages grows.

### Path-Specific Policies Via Q-Learning

We now describe how to generalize Q-learning to path-specific policies, using the HIV example in Fig. 2 (a) to ground the discussion. Recall that in this example, we wish to set  $A_1$  and  $A_2$  with respect to edges into  $W_1, W_2$  to maximize the outcome, while setting  $A_1$  and  $A_2$  to reference values  $a'_1, a'_2$  for the purposes of edges into  $M_1, M_2$ .

Simply defining Q-functions as expectations over value functions conditional on history does not work in our setting, since mediators behave in a counterfactually different way from either observed variables, or variables we wish to set according to a policy. Moreover, the sequential nature of the problem means the nested counterfactuals needed become quite involved to write down.

An alternative is to define Q-functions not in the observed data distribution, corresponding to Fig. 2 (a), but in a counterfactual distribution where  $A_1, A_2$  behave as observed, *except* for the purposes of edges into  $M_1, M_2$ , in which case they are counterfactually set to  $a'_1, a'_2$ . The graph corresponding to this counterfactual world is shown in Fig. 2 (b), and can be viewed as a generalization of a single world intervention graph [9], where treatment variables are only intervened on for the purposes of certain outgoing edges. Note that descendant variables of  $M_1, M_2$  are marked with a tilde to make clear that these variables are counterfactual and no longer equal to their observed counterparts.

The distribution corresponding to this situation is simply  $p(\mathbf{V}(\alpha_{(A_1 M_1) \rightarrow, (A_1 M_2) \rightarrow, (A_2 M_2) \rightarrow}))$ , where  $\alpha$  sets these edges to  $a'_1, a'_2$ . For  $K$  stages, the distribution is  $p(\mathbf{V}(\alpha_\alpha))$ , where  $\alpha$  are all edges of the form  $(A_i M_j) \rightarrow$ , and  $\alpha$  sets each such edge to the reference value  $a'_i$ . We have the following claim.

**Theorem 2** *In  $K$  stage version of the model in Fig. 2(a),  $p(\mathbf{V}(\alpha_\alpha))$  is identified as*

$$\bar{p}(\tilde{W}_0, \tilde{A}_1, \tilde{M}_1, \tilde{W}_1, \dots, \tilde{W}_K, \tilde{A}_K, \tilde{M}_K) = p(W_0) \prod_{i=1}^K p(W_i | M_i, A_i, H_i) p(A_i | H_i) p(M_i | \bar{a}'_i, H_i \setminus A) \quad (14)$$

We can now define Q-functions as value function expectations on this new distribution, and proceed with backwards induction as before. The only difference between

the previous formulation is how Q-functions parameters are fit. In particular, we must compensate for the fact that  $\tilde{p}$  above is not the observed data distribution. Define

$$\begin{aligned}\tilde{Q}_K(\tilde{H}_K, \tilde{A}_K; \gamma_K) &= \mathbb{E}[\tilde{W}_K | \tilde{A}_K, \tilde{H}_K], \\ \tilde{V}_K(\tilde{H}_K) &= \max_{a_K} \tilde{Q}_K(\tilde{H}_K, a_K; \gamma_K),\end{aligned}\quad (15)$$

and for  $i = K - 1, \dots, 1$ , define

$$\begin{aligned}\tilde{Q}_i(H_i, A_i; \gamma_i) &= \mathbb{E}[\tilde{V}_{i+1}(\tilde{H}_{i+1}) | \tilde{A}_i, \tilde{H}_i], \\ \tilde{V}_i(\tilde{H}_i) &= \max_{a_i} \tilde{Q}_i(\tilde{H}_i, a_i; \gamma_i).\end{aligned}\quad (16)$$

In our example in Fig. 2 (a),  $K = 2$ ,  $H_1 \equiv \{W_0\}$ ,  $\tilde{H}_2 \equiv \{W_0, M_1, W_1\}$ , and  $\mathbb{E}$  denotes expectations with respect to appropriate conditional distributions derived from  $\tilde{p}$ . Q-functions defined in this way can be used to obtain the optimal path-specific policy at each stage.

**Theorem 3** *Given that each  $\tilde{Q}_i, i = 1, \dots, K$  is specified correctly, the optimal treatment at stage  $i$  given  $H_i$  is equal to:  $f_{A_i}^*(H_i) = \arg \max_{a_i} \tilde{Q}_i(H_i, a_i; \gamma_i)$ . Since parameters  $\gamma$  are not generally known, they must be estimated from data. This can be done as follows.*

**Theorem 4** *Assume models in the set  $\{\tilde{Q}_i(\tilde{H}_i, \tilde{A}_i; \gamma_i), p(M_i | A_i, H_i; \phi) | \forall i\}$  are correctly specified. Then the estimation equations*

$$\begin{aligned}\mathbb{E} \left[ \frac{\partial \tilde{Q}_K}{\partial \gamma_K} \{W_K - \tilde{Q}_K(A_K, H_K; \gamma_K)\} w_K(H_K; \hat{\phi}_K) \right] &= 0, \text{ and} \\ \mathbb{E} \left[ \frac{\partial \tilde{Q}_i}{\partial \gamma_i} \{V_{i+1}(H_{i+1}) - \tilde{Q}_i(H_i, A_i; \gamma_i)\} w_i(H_i; \hat{\phi}_i) \right] &= 0,\end{aligned}$$

are consistent for  $\gamma_K$  and  $\gamma_i$ , where

$$w_i(H_i; \hat{\phi}_i) \equiv \frac{p(M_i | \tilde{A}_i = a', H_i; \hat{\phi}_i)}{p(M_i | \tilde{A}_i, H_i; \hat{\phi}_i)} \forall i = 1, \dots, K.$$

## Path-Specific Value Search

For simplicity, we restrict attention to a single-stage decision problem, as shown in Fig. 1 (a), where we are interested in picking a policy that maximizes the counterfactual mean  $\beta = \mathbb{E}[Y(A = f(W), M(a'))]$ .

Consider a restricted class of path-specific policies  $\mathcal{F}$  with elements  $f \equiv \{f(W), \tilde{f}\}$  the latter setting  $A$  to a constant value  $a'$ , regardless of  $W$ . Give any estimation strategy for the counterfactual mean under a path-specific policy, we can implement a direct search for the optimal policies within  $\mathcal{F}$  as before. By analogy with earlier discussion of value search, we give an IPW estimator for  $\beta$  which generalizes (9):

$$\mathbb{E} \left[ \frac{Y \tilde{C}}{\tilde{\pi}(W; \hat{\psi})} \cdot \frac{p(M|A = a', W; \hat{\phi})}{p(M|A = f(W), W; \hat{\phi})} \right], \quad (17)$$

Figure 2: (a) A causal model that generalized Fig. 1 (b) by also considering mediators. (b) A “multiple world intervention graph,” representing the counterfactual situation where adherence levels are kept to a reference treatment level, but the chemical effect of drugs is operating normally.

and an estimator which generalizes (10):

$$\begin{aligned}\mathbb{E} \left[ \frac{\tilde{C}}{\tilde{\pi}(W; \hat{\psi})} \frac{f(M|W, A = a'; \hat{\phi})}{f(M|W, f(W); \hat{\phi})} \{Y - \mathbb{E}[Y|f(W), M, W; \hat{\zeta}]\} \right] &+ \\ \frac{\mathbb{I}(A = a')}{\pi_{a'}(W; \hat{\psi})} \left\{ \mathbb{E}[Y|f(W), M, W; \hat{\zeta}] - \sum_M \mathbb{E}[Y|f(W), M, W; \hat{\zeta}] \right. & \\ \left. p(M|W, A = a'; \hat{\zeta}) \right\} + \sum_M \mathbb{E}[Y|f(W), M, W; \hat{\zeta}] p(M|W, A = a'; \hat{\phi}) &, \quad (18)\end{aligned}$$

where the expectation is evaluated empirically,  $\tilde{C} \equiv \mathbb{I}(A = f(W))$ ,  $\pi_{a'}(W; \psi) = p(A = a' | W; \psi)$ ,  $\tilde{\pi}(W; \hat{\psi}) \equiv \sum_a \pi_a(W; \psi) \mathbb{I}(a = f(W))$ , and  $\hat{\psi}, \hat{\phi}, \hat{\zeta}$  are fit by maximum likelihood. We have the following.

**Theorem 5** *Under regularity assumptions referenced in the Appendix, the estimator in (17) is consistent and asymptotically normal (CAN) if the models in the set  $\{\pi(W; \psi), p(M|W, A; \phi)\}$  are correctly specified, and the estimator in (18) is CAN in the union model, where any two models in the set  $\{\pi(W; \psi), \mathbb{E}[Y|A, M, W; \zeta], p(M|W, A; \phi)\}$  are correctly specified.*

This claim, and the estimators above, are extensions of the results in [17].

## Single-Stage G-Estimation For Path-Specific Policies

Results in [18] generalized optimal blip-to-zero functions to mediation settings, by positing the following SNMM  $\gamma(A, W; \psi)$ :

$$\mathbb{E}[Y(A, M(A = 0)) | W] - \mathbb{E}[Y(A = 0, M(A = 0)) | W]. \quad (19)$$

Note that the policy  $f_A^*$  maximizing  $\mathbb{E}[Y(A = f_A^*(W), M(0))]$  can be directly obtained from  $\gamma$  via  $f_A^*(W) = \arg \max_a \gamma(A, W; \psi)$ . Since  $\psi$  is not generally known, it must be estimated from data. The following is a consistent set of estimating equations for  $\psi$ ,

under assumptions described in [18]:

$$\mathbb{E} \left[ \left( \frac{\mathbb{I}(A=1)p(M|A=0, W)}{p(A=1|W)p(M|A=1, W)} \{Y - \mathbb{E}[Y|A=1, M, W]\} - \right. \right. \\ \left. \left. \frac{\mathbb{I}(A=0)}{p(A=0|W)} \{Y - \mathbb{E}[Y|A=1, M, W] + \gamma(1, W; \psi)\} \right) h(W) \right] = 0 \quad (20)$$

for  $h(W)$  any  $|\psi|$ -dimensional function of  $W$ .

Note that unlike SNMMs associated with overall policies, which can be defined for any number of treatments, SNMMs associated with path-specific policies have only been defined for a single treatment. A longitudinal generalization of these models is left to future work.

## 5 EXPERIMENTS

We now illustrate our methods via a dataset on HIV patients from Nigeria. The data consists of more than 50k treatment-naive HIV-1 infected patients who were enrolled in the Harvard PEPFAR/AIDS Prevention Initiative program prior to Oct 2010. The patients were put on courses of antiretroviral therapy (ART), with five standard first-line regimen, and were followed every six months for at least one year after the ART initiation. Patients stayed on their initial treatment plan unless they were experiencing toxicity within a first-line drug regimen and consequently moved to a second-line regimen. The data has records on demographics and clinical test results such as CD4 counts, viral loads, and toxicity measures at 6-month intervals.

In order to combat chronic diseases such as HIV, patients are required to follow long term use of medications. Full benefits of the medications are realized when patients take their medications as prescribed. Unfortunately, factors such as side effects, caused by drug toxicities, can be developed alongside the course of treatment and lead to poor adherence to the therapy. A primary measure of adherence is provided in the data as average percent adherence that is the total number of days that the patient has drug supply over the total number of days in the time period (6-month intervals).

We restricted our attention to the first year of follow up, including two decision points and picked (log) CD4 count at the end of the first year as the outcome of interest. CD4 count is one of the biomarkers that quantifies how well the immune system is functioning and higher values are more favorable. Drug toxicity and adherence can mediate the effect of treatment on outcome. Since reactions to drug toxicity and adherence behavior vary among patients, we consider the problem of finding policies that optimize the direct chemical effect of the drug where the indirect effect mediated through drug toxicity and adherence are set to some reference levels. We run

an additional experiment where only the effect through adherence is set to a reference level [4]. The latter results are provided in the Appendix for the interest of space.

The causal model can be represented by the DAG in Fig. 2 (a). Treatment decisions at the baseline and the first follow up are respectively denoted by  $A_1$  and  $A_2$ .  $W_1$  is a dichotomized intermediate outcome that indicates whether the CD4 count is above 450 cells/mm<sup>3</sup> at the the end of the same six month period.  $W_2$  is the final outcome and denotes the log CD4 count at the end of the first year after ART initiation.  $W_0$  includes all the baseline factors such as sex, age, and test results prior to any treatment initiation. Toxicity and adherence measures during the first six months and the first year after treatment initiation are collected in  $M_1$  and  $M_2$ , respectively. Drug toxicity indicates any lab toxicities (alanine transaminase  $\geq 120$  UI/L, creatinine  $\geq 260$  mmol/L, hemoglobin  $\leq 8$  g/dL), and adherence indicates whether average percent adherence was no less than 95%.

We first illustrate the results on finding optimal policies in a two-stage decision problem using G-formula and Q-learning methods, and then provide the results for finding optimal policies for the single (first) stage decision problem using value search and G-estimation. In the single stage analysis, we consider the log CD4 count at the end of the sixth month as the outcome of interest. All modeling assumptions are described in the Appendix.

### Methods For The Two-Stage Decision Problem

Optimal overall polices and path policies are estimated as described in Sections 3 and 4. Expected outcomes under optimal policies we learned, along with 95% confidence intervals obtained by bootstrap, are shown in Table. 1. In the interest of space, we do not consider corrections necessary to preserve the validity of these intervals in cases of model discontinuities, but these are straightforward [1]. Both optimal polices have higher expected outcomes than the observed data, using either method. Path-specific policies led to higher expected outcomes compared to overall policies. This could be explained by the phenomenon of countervailing adherence-mediated effect, described in [4]. In other words, in some cases the more chemically effective drugs are also harder to take. In order to visualize optimal policies we learned as clinically interpretable flowcharts, we viewed policy-recommended decisions as class labels, and history as features, and used a multilabel decision tree classifier, as implemented in the `rpart` R package. The results are shown in Fig. 1 and 2 in the Appendix. Since the classifiers are not perfect predictors of the policies, they are to be viewed as interpretable approximations of the true learned policy. Variables involved in the decisions, such

Table 1: Comparison of population log CD4 counts under different policies (under treatment assignments in the observed data, the value is  $5.64 \pm 0.01$  in the 2-stage and  $5.54 \pm 0.01$  in the 1-stage problem). G-formula and Q-learning are used with 2-stage decision points. Value search and G-estimation are used with 1-stage decision point.

	Path Policies	Overall Policies
<b>G-formula</b>	6.89 (5.76, 7.10)	6.79 (5.68, 6.90)
<b>Q-learning</b>	7.34 (6.10, 7.55)	6.89 (5.82, 7.12)
<b>Value search</b>	5.58 (5.54, 5.62)	5.56 (5.55, 5.58)
<b>G-estimation</b>	5.62 (5.50, 5.67)	5.79 (5.59, 6.04)

as age, gender, CD4, virological status, and so on, are clinically reasonable.

### Methods For The Single-Stage Decision Problem

We focus on patients that appear at baseline, and treat the five first-line treatments as a binary decision by grouping the first three (which we denote as group 1) and the last two treatments (which we denote as group 2). We are interested in finding a treatment group assignment at the first decision point that leads to a higher CD4 count at the first follow up, assuming adherence and toxicity are set to a reference point for every patient. The model for this setting is Fig. 1(a), where  $W$  is observed history up to the first decision.

We considered policies of the form  $\mathbb{I}\{CD4_{m00} < \alpha\}$ , where  $CD4_{m00}$  denotes the CD4 count right before the first decision point, to decide what treatment group the patient should be assigned to. The normal range for this variable is 500 to 1500 cells/mm<sup>3</sup>. We searched for an optimal policy in this restricted class by varying  $\alpha$  from 100 cells/mm<sup>3</sup> to 1000 cells/mm<sup>3</sup> by 50 cells/mm<sup>3</sup> increments, and estimated the value for each  $\alpha$  using (18). Under the modeling assumptions described in the Appendix, the optimal threshold between group 1 and group 2 treatments was chosen to be  $\mathbb{I}\{CD4_{m00} < 550 \text{ cells/mm}^3\}$ . In other words, if the CD4 count is less than 550, it is better for the patients to receive any of the treatments in the first treatment group. However, if we pick the optimal policy based on the overall effect of treatment on outcome, then value search leads to policies of the form  $\mathbb{I}\{CD4_{m00} < 250 \text{ cells/mm}^3\}$ . The optimal overall policy decides to switch to group 2 treatments when HIV gets more severe, while the optimal path policy decides on switching when CD4 count is still within a healthy range but at lower values. This implies that if treatment adherence could be kept to that of a reference treatment, initiation of treatments within group 2 could be delayed to lower CD4 values. As before, both policies lead to a higher than observed log CD4 count, with the path policy yielding slightly higher outcomes than the overall policy.

Finally, we learned optimal path policies via G-estimation. We estimated the parameters  $\psi$  for the SNMM using (20). The population log CD4 count under path policies and overall policies learned by G-estimation are given in Table. (1), and a decision tree view of the policies is shown in Fig. 3 in the Appendix. Under our assumptions, the optimal path policy found by G-estimation did not do much better than the outcomes under observed treatments and the overall policies.

## 6 CONCLUSIONS

In this paper, we generalized ideas in mediation analysis and dynamic treatment regimes to consider the problem of estimation of responses to policies associated with particular causal pathways, and methods for learning policies that optimize these responses. Since validating findings in causal inference is difficult, and conclusions are sensitive to specific modeling assumptions made, we developed multiple approaches for learning optimal policies that rely on orthogonal sets of modeling strategies. In particular, we considered strategies based on backwards induction with either plug-in estimation or Q-learning, value search for restricted classes of policies, and G-estimation of structural nested mean models (SNMMs) generalized to mediation.

We illustrated these methods by finding policies for HIV-positive patients that optimize the direct chemical effect of antiretroviral therapy, where the indirect effect mediated through drug toxicity and adherence are set to a reference level. The results in the experiment section suggest that policies that aim to optimize the direct effect of the treatment have better outcome responses than policies that optimize the overall effect of the treatment, and optimal policies decide on clinically relevant variables, such as age, gender, viral load, and CD4 count.

The estimation methods we described are applicable to sequential decision problems, except for G-estimation which is currently only limited to single-stage decision problems. Generalizing the version of G-estimation to longitudinal mediation problems, and deriving semi-parametric estimators for the version of Q-learning we described are areas for future work.

### Acknowledgments

This research was supported in part by the NIH grants R01 AI104459-01A1 and R01 AI127271-01A1. We thank the anonymous reviewers for their insightful comments that greatly improved this manuscript. An earlier version of this manuscript contained simulations by Sourjya Sarkar.

## Abstract

Estimating the value function for a fixed policy is a fundamental problem in reinforcement learning. Policy evaluation algorithms—to estimate value functions—continue to be developed, to improve convergence rates, improve stability and handle variability, particularly for off-policy learning. To understand the properties of these algorithms, the experimenter needs high-confidence estimates of the accuracy of the learned value functions. For environments with small, finite state-spaces, like chains, the true value function can be easily computed, to compute accuracy. For large, or continuous state-spaces, however, this is no longer feasible. In this paper, we address the largely open problem of how to obtain these high-confidence estimates, for general state-spaces. We provide a high-confidence bound on an empirical estimate of the value error to the true value error. We use this bound to design an offline sampling algorithm, which stores the required quantities to repeatedly compute value error estimates for any learned value function. We provide experiments investigating the number of samples required by this offline algorithm in simple benchmark reinforcement learning domains, and highlight that there are still many open questions to be solved for this important problem.

## 1 INTRODUCTION

Policy evaluation is a key step in many reinforcement learning systems. Policy evaluation approximates the value of each state—future sum of rewards—given a policy and either a model of the world or a stream of data

produced by an agents choices. In classical policy iteration schemes, the agent continually alternates between improving the policy using the current approximation of the value function, and updating the approximate value function for the new policy. Policy search methods like actor-critic estimate the value function of the current policy to perform gradient updates for the policy.

However, there has been relatively little research into methods for accurately evaluating policy evaluation algorithms when the true values are not available. In most domains where we are interested in performing policy evaluation, it is difficult or impossible to compute the true value function. We may not have access to the transition probabilities or the reward function in every state, making it impossible to obtain the closed form solution of the true value function  $v^*$ . Even if we have access to a full model of the environment, we may not be able to represent the value function if the number of states is too large or the state is continuous. Aside from small finite MDPs like gridworlds and random MDPs, where closed-form solutions can be computed [Geist and Scherrer, 2014, White and White, 2016], we often do not have access to  $v^*$ . In nearly all our well-known benchmark domains, such as Mountain Car, Puddle World, Cart pole, and Acrobot, we must turn to some other method to evaluate learning progress.

One option that has been considered is to estimate the objective minimized by the algorithms. Several papers [Sutton et al., 2008, Du et al., 2017] have compared the performance of the algorithms in terms of their target objective on a batch of samples, using the approximate linear system for the mean-squared projected Bellman error (MSPBE). One estimator, called RUPEE [White, 2015], is designed to incrementally approximate the MSPBE by keeping a running average across data produced during learning. Some terms, such as the feature covariance matrix, can be estimated easily; however, one component of the MSPBE includes the current weights, and is biased by this moving average approach. More problematically,

some algorithms do not converge to the minimum of the MSPBE, such as residual gradient for the mean-squared Bellman error [Baird, 1995] or Emphatic Temporal Difference (ETD) learning [Sutton et al., 2016], which minimize a variant of the MSPBE with a different weighting. This approach, therefore, is limited to comparing algorithms that minimize the same objective.

The more standard approach has been to use rollouts from states to obtain samples of returns. To obtain these rollout estimates, three parameters need to be chosen: the number of states  $m$  from which to rollout, the number of rollouts or trajectories  $t$ , and the length of each rollout. Given these rollouts, the true values can be estimated from each of the  $m$  chosen states, stored offline, and then used for comparison repeatedly during experiments. These evaluation schemes, however, have intuitively chosen parameters, without any guarantees that the distance to the true values, the error, is well-estimated. Early work comparing gradient TD algorithms [Maei et al., 2009] used sampled trajectories—2500 of them—but compared to returns, rather than value estimates. For several empirical studies using benchmark domains, like Mountain Car and Acrobot, there are a variety of choices, including  $t = m = 500$  [Gehring et al., 2016];  $m = 2000$ ,  $t = 300$  and 1000 length rollouts [Pan et al., 2017]; and  $m = 5000$ ,  $t = 5000$  [Le et al., 2017]. For a continuous physical system, [Dann et al., 2014] used as little as 10 rollouts from a state. Otherwise, other papers have mentioned that extensive rollouts are used<sup>1</sup>, but did not describe how [Konidaris et al., 2011, Dabney and Thomas, 2014]. In general, as new policy evaluation algorithms are derived, it is essential to find a solution to this open problem: How can we confidently compare value estimates returned by our algorithms?

In this work, we provide an algorithm that ensures, with high-probability, that the estimated distance has small error in approximating the true distance between the true value function  $v^*$  for an arbitrary estimate  $\hat{v}$ . We focus in the main body of the paper on the clipped mean-absolute percentage value error (CMAPVE) as a representative example of the general strategy. We provide additional results for a variety of other losses in the appendix, to facilitate use for a broader range of error choices. We conclude by demonstrating the rollout parameters chosen for several case studies, highlighting that previous intuitive choices did not effectively direct sampling. We hope for this algorithm to become a standard approach for generating estimates of the true values to facilitate comparison of policy evaluation algorithms by reinforcement learning researchers.

<sup>1</sup>Note that [Boyan and Moore, 1995] used rollouts for a complementary purpose, to train a nonlinear value function, rather than for evaluating policy evaluation algorithms.

## 2 MEASURES OF LEARNING PERFORMANCE

This paper investigates the problem of comparing algorithms that estimate the discounted sum of future rewards *incrementally* for a fixed policy. In this section, we first introduce the policy evaluation problem and motivate a particular measure of learning performance for policy evaluation algorithms. In the following section, we discuss how to estimate this measure.

We model the agent’s interaction with the world as a Markov decision process (MDP), defined by a (potentially uncountable) set of states  $\mathcal{S}$ , a finite set of actions  $\mathcal{A}$ , transitions  $P : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, \infty)$ , rewards  $R : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$  and a scalar discount function  $\gamma : \mathcal{S} \rightarrow \mathbb{R}$ . On each time step  $t$ , the agent selects an action according to its *behaviour policy*  $A_t \sim \mu(\cdot|S_t)$ , the environment transitions into a new state  $S_{t+1} \sim P(\cdot|S_t, A_t)$  and the agent receives a scalar reward  $R_{t+1} \stackrel{\text{def}}{=} R(S_t, A_t, S_{t+1})$ . In policy evaluation, the agent’s objective is to estimate the expected return

$$v^*(s) = \mathbb{E}[G_t | S_t = s, A_t \sim \pi] \quad (1)$$

$$\text{for return } G_t = \sum_{i=0}^{\infty} \gamma^i R_{t+i+1}$$

where  $v^*(s)$  is called the *state-value function* for the *target policy*  $\pi : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$ . From a stream of data, the agent incrementally approximates this value function,  $\hat{v}$ . For experiments, to report learning curves, we need to measure the accuracy of this estimate every step or at least periodically, such as every 10 steps.

For policy evaluation, when the policy remains fixed, the value error remains the gold standard of evaluation. Ignoring how useful the value function is for policy improvement, our only goal is accuracy with respect to  $v^*$ . Assume some weighting  $d : \mathcal{S} \rightarrow [0, \infty)$ , a probability distribution over states. Given access to  $v^*$ , it is common to estimate the mean squared value error

$$\text{MSVE}(\hat{v}) \stackrel{\text{def}}{=} \mathbb{E}[(\hat{v}(S) - v^*(S))^2] \quad (2)$$

$$= \int_{\mathcal{S}} d(s) (\hat{v}(s) - v^*(s))^2 ds$$

or the mean absolute value error

$$\text{MAVE}(\hat{v}) \stackrel{\text{def}}{=} \mathbb{E}[|\hat{v}(s) - v^*(s)|]. \quad (3)$$

The integral is replaced with a sum if the set of states is finite. Because we consider how to estimate this error for continuous state domains—for which it is more difficult to directly estimate  $v^*$ —we preferentially assume the states are continuous.

These losses, however, have several issues, beyond estimating them. The key issue is that the scale of the returns can be quite different across states. This skews the loss and, as we will see, makes it more difficult to get high-accuracy estimates. Consider a cost-to-goal problem, where the agent receives a reward of  $-1$  per step. From one state the value could be  $-1000$  and for another it could be  $-1$ . For a prediction of  $-990$  and  $-11$  respectively, the absolute value error for both states would be  $-10$ . However, the prediction of  $-990$  for the first state is quite accurate, whereas a prediction of  $-11$  for the second state is highly inaccurate.

One alternative is to estimate a percentage error, or relative error. The mean absolute percentage value error is

$$\text{MAPVE}(\hat{v}) \stackrel{\text{def}}{=} \mathbb{E} \left[ \frac{|\hat{v}(S) - v^*(S)|}{|v^*(S)| + \tau} \right] \quad (4)$$

for some  $\tau \geq 0$ . The term  $\tau$  in the denominator ensures the MAPVE does not become excessively high, if true values of states are zero or near zero. For example, for  $\tau = 1$ , the MAPVE is essentially the MAVE for small  $v^*(s)$ , which reflects that small absolute differences are meaningful for these smaller numbers. For large  $v^*(s)$ , the  $\tau$  has little effect, and the MAPVE becomes a true percentage error, reflecting the fact that we are particularly interested in relative errors for larger  $v^*(s)$ .

Additionally, the MAPVE can be quite large if  $\hat{v}$  is highly inaccurate. When estimating these performance measures, however, it is uninteresting to focus on obtaining high-accuracy estimate of very large MAPVE. Rather, it is sufficient to report that  $\hat{v}$  is highly inaccurate, and focus the estimation of the loss on more accurate  $\hat{v}$ . Towards this goal, we introduce the clipped MAPVE

$$\text{CMAPVE}(\hat{v}) \stackrel{\text{def}}{=} \mathbb{E} \left[ \min \left( c, \frac{|\hat{v}(S) - v^*(S)|}{|v^*(S)| + \tau} \right) \right]$$

for some  $c > 0$ . This  $c$  provides a maximum percentage error. For example, setting  $c = 2$  caps error estimates for approximate values that are worse than 200% inaccurate. Such a level of inaccuracy is already high, and when comparing policy evaluation algorithms, we are much more interested in their percentage error—particularly compared to each other—once we are within a reasonable range around the true values. Note that  $c$  can be chosen to be the maximum value of the loss, and so the following results remain quite general.

Though many losses could be considered, we put forward the CMAPVE as a proposed standard for policy evaluation. The parameters  $\tau$  and  $c$  can both be appropriately chosen by the experimentalist, for a given MDP. These parameters give sufficient flexibility in highlighting differences between algorithms, while still enabling

high-confidence estimates of these errors, which we discuss next. For this reason, we use CMAPVE as the loss in the main body of the text. However, for completeness, we also show how to modify the analysis and algorithms for other losses in the appendix.

### 3 HIGH-CONFIDENCE ESTIMATES OF VALUE ERROR

Our goal now is to approximate the value error, CMAPVE, with high-confidence, for any value function  $\hat{v}$ . Instead of approximating the error directly for each  $\hat{v}$ , the typical approach is to estimate  $v^*$  as accurately as possible, for a large set of states  $s_1, \dots, s_m \sim d$ . Given these high-accuracy estimates  $\bar{v}$ , the true expected error can be approximated from this subset of states for any  $\hat{v}$ .

$$\text{CMAPVE}(\hat{v}) \approx \frac{1}{m} \sum_{i=1}^m \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|\bar{v}(s_i)| + \tau} \right)$$

Since the CMAPVE needs to be computed frequently, for many steps during learning potentially across many algorithms, it is important for this estimate of CMAPVE to be efficiently computable. An important requirement, then, is for the number of states  $m$  to be as small as possible, so that all the  $\bar{v}(s_i)$  can be stored and the summed difference is quick to compute.

One possible approach is to estimate the true value function  $v^*$  using a powerful function approximator, offline. A large batch of data could be gathered, and a learning method used to train  $\bar{v}$ . This large function approximator would not even need to be stored: only  $\bar{v}(s_i)$  would need to be saved once this offline procedure was complete. This approach, however, will be biased by the form of the function approximator, which can favor certain policy evaluation algorithms during evaluation. Further, it is difficult to quantify this bias, particularly in a general way agnostic to the type of function approximator an experimentalist might use for their learning setting.

An alternative strategy is to use many sampled rollouts from this subset of states. This strategy is general—requiring only access to samples from the MDP. A much larger number of interactions can be used with the MDP, to compute  $\bar{v}$ , because this is computed once, offline, to facilitate many further empirical comparisons between algorithms after. For example, one may want to examine the early learning performance of two different policy evaluation algorithms—which may themselves receive only a small number of samples. The cached  $\bar{v}$  then enables computing this early learning performance. However, even offline, there are limits to how many samples can be computed feasibly, particularly for computationally costly simulators [Dann et al., 2014].

Therefore, our goal is the following: how can we *efficiently* compute *high-confidence* estimates of CMAPVE, using a *minimal number of offline rollouts*. The choice of a clipped loss actually enables the number of states  $m$  to remain small (shown in Lemma 2), enabling efficient computation of CMAPVE. In the next section, we address the second point: how to obtain high-confidence estimates, given access to  $\bar{v}$  that approximates  $v^*$ . In the following section, we discuss how to obtain these  $\bar{v}$ .

### 3.1 OVERVIEW

We first provide an overview of the approach, to make it easier to follow the argument. We additionally include a notation table (Table 1), particularly to help discern the various value functions.

Table 1: Table of Notation

$v^*$	true values for policy $\pi$
$\bar{v}^*$	true values for policy $\pi$ , when using truncated rollouts to length $l$
$\bar{v}$	estimated values for policy $\pi$ using $t$ rollouts, when using truncated rollouts to length $l$
$\hat{v}$	estimated values for policy $\pi$ , being evaluated
$d$	distribution over the states $\mathcal{S}$ , $d : \mathcal{S} \rightarrow [0, \infty)$
$m$	number of states $\{s_1, \dots, s_m\}$ , $s_i \sim d$
$\ell_c$	clipped error, $\ell_c(v_1, v_2) = \min\left(c, \frac{ v_1 - v_2 }{ v_2  + \tau}\right)$
$\ell$	true error, $\ell(\hat{v}, v^*) = \mathbb{E}[\ell_c(\hat{v}(S), v^*(S))]$ under $d$
$\hat{\ell}$	approximate error, $\hat{\ell}(\hat{v}, v^*) = \frac{1}{m} \sum_{i=1}^m \ell_c(\hat{v}(s_i), v^*(s_i))$
$R_{\max}$	an upper bound on the maximum absolute value reward, $R_{\max} \geq \sup  R(s, a, s') $
$V_{\max}$	maximum absolute value for the policy $\pi$ for any state, e.g., $V_{\max} = \frac{\max \text{reward} - \min \text{reward}}{1 - \gamma}$
$K$	the number of times the error estimate is queried

First, we consider several value function approximations, for use within the bound, summarized in Table 1. The goal is to determine the accuracy of the estimates of the learned  $\hat{v}$  with respect to the true values  $v^*$ . We estimate true values  $v^*(s_i)$  for  $s_i$  using repeated rollouts from  $s_i$ ; this results in two forms of error. The first is due to truncated rollouts, which for the continuing case would otherwise be infinitely long. The second source of error is due to using an empirical estimate of the true values, by averaging sampled returns. We denote  $\bar{v}^*$  as the true values, for truncated returns, and  $\bar{v}$  as the sample estimate of  $\bar{v}^*$  from  $m$  truncated rollouts.

Second, we consider the approximation in computing the loss: the difference between  $\hat{v}$  and  $v^*$ . We consider the true loss  $\ell(\hat{v}, v^*)$  and the approximate loss  $\hat{\ell}(\hat{v}, v^*)$ , in Table 1. The argument in Theorem 1 revolves around

upper bounding the difference between these two losses, in terms of three terms. These terms are bounded in Lemmas 2, 3 and 4. Lemma 2 bounds the error due to sampling only a subset of  $m$ . Lemma 3 bounds the error from approximating  $v^*$  with truncated rollouts. Lemma 4 bounds the error from dividing by  $|\bar{v}(s_i)| + \tau$  instead of  $|v^*(s_i)| + \tau$ .

Finally, to obtain this general bound, we first assume that we can obtain highly-accurate estimates  $\bar{v}$  of  $\bar{v}^*$ . We state these two assumptions in Assumptions 1 and 2. These estimates could be obtained with a variety of sampling strategies, and so separate it from the main proof. We later develop one algorithm to obtain such estimates, in Section 4.

### 3.2 MAIN RESULT

We will compute rollout values from a set of sampled states  $\{s_i\}_{i=1}^m$ . Each rollout consists of a trajectory simulated, or rolled out, some number of steps. The length of this trajectory can itself be random, depending on if an episode terminates or if the trajectory is estimated to be a sufficiently accurate sample of the full, non-truncated return. We first assume that we have access to such trajectories and rollout estimates and in later sections show how to obtain such trajectories and estimates.

**Assumption 1.** For any  $\epsilon > 0$  and sampled state  $s_i$ , the trajectory lengths  $l_i$  are specified such that,

$$|\bar{v}^*(s_i) - v^*(s_i)| \leq \epsilon (|v^*(s_i)| + \tau) \quad (5)$$

**Assumption 2.** Starting from  $s_i$ , assume you have trajectories of rewards  $\{r_{ijk}\}$  for trajectory index  $j \in \{1, \dots, t\}$  and rollout index  $k \in \{0, \dots, l_{ij} - 1\}$  for a trajectory length  $l_{ij}$  that depends on the trajectory. The approximated rollout values

$$\bar{v}(s_i) \stackrel{\text{def}}{=} \frac{1}{t} \sum_{j=1}^t \sum_{k=0}^{l_{ij}-1} \gamma^k r_{ijk} \quad (6)$$

are an  $(\epsilon, \delta, \tau)$ -approximation to the true expected values, where  $l_{ij}$  is an instance of the random variable  $l_i$

$$\bar{v}^*(s) \stackrel{\text{def}}{=} \mathbb{E} \left[ \sum_{k=0}^{l_i-1} \gamma^k R_k \right] \quad (7)$$

i.e, for  $0 < \epsilon$ , with probability at least  $1 - \delta/2$ , the following holds for all states

$$|\bar{v}^*(s_i) - \bar{v}(s_i)| \leq \epsilon (|\bar{v}^*(s_i)| + \tau) \quad (8)$$

**Theorem 1.** Let  $\{s_1, \dots, s_m\}$  be states sampled according to  $d$ . Assume  $\bar{v}(s_i)$  satisfies Assumption 1 and 2 for

all  $i \in \{1, \dots, m\}$ . Suppose the empirical loss mean estimates are computed  $K$  number of times with different learned value functions  $\hat{v}$  each time. Then the approximation error

$$\hat{\ell}(\hat{v}, \bar{v}) \stackrel{\text{def}}{=} \frac{1}{m} \sum_{i=1}^m \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \quad (9)$$

for all the  $\hat{v}$  satisfies, with probability at least  $1 - \delta$ ,

$$\left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, \bar{v}) \right| \leq (11) + (12) + (13) \quad (10)$$

**Proof:** We need to bound the errors introduced from having a reduced number of states, a finite set of trajectories to approximate the expected returns for each of those states and truncated rollouts to get estimates of returns. To do so, we first consider the difference under the approximate clipped loss, to the true value function.

$$\left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, \bar{v}) \right| \leq \left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| + \left| \hat{\ell}(\hat{v}, v^*) - \hat{\ell}(\hat{v}, \bar{v}) \right|$$

The first component is bounded in Lemma 2. For the second component, notice that

$$\left| \hat{\ell}(\hat{v}, v^*) - \hat{\ell}(\hat{v}, \bar{v}) \right| \leq \frac{1}{m} \sum_{i=1}^m \left| \ell_c(\hat{v}(s_i), v^*(s_i)) - \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \right|$$

However, these two differences are difficult to compare, because they have different denominators: the first has  $|v^*(s_i)| + \tau$ , whereas the second has  $|\bar{v}(s_i)| + \tau$ . We therefore further separate each component in the sum

$$\begin{aligned} & \left| \ell_c(\hat{v}(s_i), v^*(s_i)) - \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \right| \\ & \leq \left| \ell_c(\hat{v}(s_i), v^*(s_i)) - \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) \right| \\ & \quad + \left| \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) - \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \right| \end{aligned}$$

The first difference has the same denominator, so

$$\begin{aligned} & \left| \ell_c(\hat{v}(s_i), v^*(s_i)) - \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) \right| \\ & = \left| \min \left( c, \frac{|\hat{v}(s_i) - v^*(s_i)|}{|v^*(s_i)| + \tau} \right) - \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) \right| \\ & = \frac{1}{|v^*(s_i)| + \tau} \left| \min(c(|v^*(s_i)| + \tau), |\hat{v}(s_i) - v^*(s_i)|) \right. \\ & \quad \left. - \min(c(|v^*(s_i)| + \tau), |\hat{v}(s_i) - \bar{v}(s_i)|) \right| \\ & \leq \frac{1}{|v^*(s_i)| + \tau} \min(c(|v^*(s_i)| + \tau), |v^*(s_i) - \bar{v}(s_i)|) \\ & = \ell_c(\bar{v}(s_i), v^*(s_i)) \end{aligned}$$

The last step follows from the triangle inequality  $\left| |x| - |y| \right| \leq |x - y|$  on the clipped loss (see Lemma 7, in Appendix A, for an explicit proof that the triangle inequality holds for the clipped loss).

Therefore, putting it all together, we have

$$\begin{aligned} & \left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, \bar{v}) \right| \\ & \leq \left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| \\ & \quad + \frac{1}{m} \sum_{i=1}^m \ell_c(\bar{v}(s_i), v^*(s_i)) \\ & \quad + \frac{1}{m} \sum_{i=1}^m \left| \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) - \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \right| \end{aligned}$$

where the first, second and third components are bounded in Lemmas 2, 3 and 4 respectively. Finally, due to the application of Hoeffding's bound (Lemma 2) with error probability of atmost  $\delta/2$  and assumption 2 which may not hold with probability atmost  $\delta/2$  and the union bound, we conclude that the final bound holds with probability at least  $1 - \delta$ . ■

**Lemma 2** (Dependence on  $m$ ). *Suppose the empirical loss mean estimates are computed  $K$  number of times. Then with probability at least  $1 - \delta/2$ :*

$$\left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| \leq \sqrt{\frac{\log(4K/\delta)c^2}{2m}} \quad (11)$$

**Proof:** Since  $\hat{\ell}(\hat{v}, v^*) = \frac{1}{m} \sum_{i=1}^m \ell_c(\hat{v}(s_i), v^*(s_i))$  is an unbiased estimate of  $\ell(\hat{v}, v^*)$ , we can use Hoeffding's bound for variables bounded between  $[0, c]$ . For any of the  $K$  times, the concentration probability is as follows:

$$\begin{aligned} \Pr \left( \left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| \geq t \right) & \leq 2 \exp \left( \frac{-2t^2 m^2}{\sum_{i=1}^m c^2} \right) \\ & = 2 \exp \left( \frac{-2mt^2}{c^2} \right) = \frac{\delta}{2K} \end{aligned}$$

Thus, due to union bound over all the  $K$  times, for all those empirical loss mean estimates, the following holds

$$\Pr \left( \left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| \leq t \right) \geq 1 - \delta/2.$$

Rearranging the above, to express  $t$  in terms of  $\delta$ ,

$$2 \exp \left( \frac{-2mt^2}{c^2} \right) = \frac{\delta}{2K} \implies t = \sqrt{\frac{\log(4K/\delta)c^2}{2m}}.$$

Therefore, with probability at least  $1 - \delta$ ,

$$\left| \ell(\hat{v}, v^*) - \hat{\ell}(\hat{v}, v^*) \right| \leq \sqrt{\frac{\log(4K/\delta)c^2}{2m}}. \quad \blacksquare$$

**Lemma 3** (Dependence on Truncated Rollout Errors). *Under Assumption 2 and 1,*

$$\frac{1}{m} \sum_{i=1}^m \ell_c(\bar{v}(s_i), v^*(s_i)) \leq 2\epsilon \quad (12)$$

**Proof:** We can split up this error into sampling error for a finite length rollout and for a finite number of trajectories. We can consider the unclipped error, which is an upper bound on the clipped error.

$$\frac{|v^*(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \leq \frac{|v^*(s_i) - \bar{v}^*(s_i)|}{|v^*(s_i)| + \tau} + \frac{|\bar{v}^*(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau}$$

These two terms are both bounded by  $\epsilon$ , by assumption. ■

**Lemma 4.** *Under Assumption 2,*

$$\left| \min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) - \min \left( c, \frac{|\bar{v}(s_i) - \bar{v}(s_i)|}{|\bar{v}(s_i)| + \tau} \right) \right| \leq c(1 - (1 + \epsilon)^{-2}) \quad (13)$$

**Proof:** We need to bound the difference due to the difference in normalizer. To do so, we simply need to find a constant  $\beta > 0$  such that  $\min \left( c, \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|v^*(s_i)| + \tau} \right) \geq \beta$

The key is to lower bound  $|v^*(s_i)| + \tau$ , which results in an upper bound on the first term and consequently an upper bound on the difference between the two terms.

$$\begin{aligned} \frac{|\bar{v}(s_i)| + \tau}{|v^*(s_i)| + \tau} &\leq \frac{|\bar{v}(s_i) - \bar{v}^*(s_i)| + |\bar{v}^*(s_i)| + \tau}{|v^*(s_i)| + \tau} \\ &= \frac{|\bar{v}(s_i) - \bar{v}^*(s_i)|}{|v^*(s_i)| + \tau} + \frac{|\bar{v}^*(s_i)| + \tau}{|v^*(s_i)| + \tau} \\ &\leq \frac{\epsilon(|\bar{v}^*(s_i)| + \tau)}{|v^*(s_i)| + \tau} + \frac{|\bar{v}^*(s_i)| + \tau}{|v^*(s_i)| + \tau} \\ &= \frac{(1 + \epsilon)(|\bar{v}^*(s_i)| + \tau)}{|v^*(s_i)| + \tau} \end{aligned}$$

where the second inequality is due to Assumption 2. Now further

$$\begin{aligned} \frac{(|\bar{v}^*(s_i)| + \tau)}{|v^*(s_i)| + \tau} &\leq \frac{|\bar{v}^*(s_i) - v^*(s_i)|}{|v^*(s_i)| + \tau} + \frac{|v^*(s_i)| + \tau}{|v^*(s_i)| + \tau} \\ &\leq \frac{\epsilon(|v^*(s_i)| + \tau)}{|v^*(s_i)| + \tau} + 1 \\ &= \epsilon + 1 \end{aligned}$$

giving

$$\frac{|\bar{v}(s_i)| + \tau}{|v^*(s_i)| + \tau} \leq (1 + \epsilon)^2 \implies |v^*(s_i)| + \tau \geq \frac{|\bar{v}(s_i)| + \tau}{(1 + \epsilon)^2}.$$

So, for  $a = (1 + \epsilon)^2$  and  $b = \frac{|\hat{v}(s_i) - \bar{v}(s_i)|}{|\bar{v}(s_i)| + \tau}$ , the term  $|\min(c, ab) - \min(c, b)|$  upper bounds the difference. Because  $a > 1$  and  $b > 0$ , this term  $|\min(c, ab) - \min(c, b)|$  is maximized when  $ab = c$ , and  $b = c/a$ . In the worst case, therefore,  $|\min(c, ab) - \min(c, b)| \leq c(1 - a^{-1})$  which finishes the proof. ■

### 3.3 SATISFYING THE ASSUMPTIONS

The bounds above relied heavily on accurate sample estimates of  $v^*(s_i)$ . To obtain Assumption 1, we need to rollout trajectories sufficiently far to ensure that truncated sampled returns do not incur too much bias. For problems with discounting, for  $\gamma < 1$ , the returns can be truncated once  $\gamma^l$  becomes sufficiently small, as the remaining terms in the sum for the return have negligible weight. For episodic problems with no discounting, it is likely that trajectories need to be simulated until termination, since rewards beyond the truncation horizon would not be discounted and so could have considerable weight.

We show how to satisfy Assumption 1, for the discounted setting. Note that for the trivial setting of  $R_{\max} = 0$ , it is sufficient to use  $l = 1$ , so we assume  $R_{\max} > 0$ .

**Lemma 5.** *For  $\gamma < 1$  and  $R_{\max} > 0$ , if*

$$l = \left\lceil \frac{\log(\epsilon\tau(1 - \gamma)) - \log(R_{\max})}{\log \gamma} \right\rceil \quad (14)$$

*then  $\bar{v}^*(s)$  satisfies Assumption 1:*

$$|\bar{v}^*(s) - v^*(s)| \leq \epsilon(|v^*(s)| + \tau) \quad (15)$$

**Proof:** The first component can be bounded as

$$\begin{aligned} |\bar{v}^*(s) - v^*(s)| &\leq \left| E \left[ \sum_{k=0}^{\infty} \gamma^k R_k \right] - E \left[ \sum_{k=0}^{l-1} \gamma^k R_k \right] \right| \\ &\leq R_{\max} \left( \frac{1}{1 - \gamma} - \frac{1 - \gamma^l}{1 - \gamma} \right) \\ &= R_{\max} \frac{\gamma^l}{1 - \gamma} \end{aligned}$$

giving

$$\frac{|\bar{v}^*(s) - v^*(s)|}{|v^*(s)| + \tau} \leq R_{\max} \frac{\gamma^l}{\tau(1 - \gamma)}.$$

Setting  $l$  as in (14) ensures  $R_{\max} \frac{\gamma^l}{\tau(1 - \gamma)} \leq \epsilon$ , completing the proof. ■

For Assumption 2, we need a stopping rule for sampling truncated returns that ensures  $\bar{v}$  is within  $\epsilon$  of the true expected value of the truncated returns,  $\bar{v}^*$ . The idea is to continue sampling truncated returns, until the confidence interval around the mean estimate shrinks sufficiently to ensure, with high probability, that the values estimates are within  $\epsilon$  of the true values. Such stopping rules have been designed for non-negative random variables [Domingos and Hulten, 2001, Dagum et al., 2006], and extended to more general random variables [Mnih et al., 2008]. We defer the development of such an algorithm for this setting until the next section.

## 4 THE ROLLOUT ALGORITHM

We can now design a high-confidence algorithm for estimating the accuracy of a value function. Practically, the most important number to reduce is  $m$ , because these values will be stored and used for comparisons on each step. The choice of a clipped loss, however, makes it more manageable to control  $m$ . In this section, we focus more on how much the variability in trajectories, and trajectory length, impact the number of required samples.

The general algorithm framework is given in Algorithm 1. The algorithm is straightforward once given an algorithm to sample rollouts from a given state. The rollout algorithm is where development can be directed, to reduce the required number of samples. This rollout algorithm needs to be designed to satisfy Assumptions 1 and 2. We have already shown how to select trajectory lengths to satisfy Assumption 1. Below, we describe how to select  $m$  and how to satisfy Assumption 2.

---

**Algorithm 1** Offline computation of  $\bar{v}$ , to get high-confidence estimates of value error

---

- 1: ▷ Input  $\epsilon, \delta, \tau$
  - 2: ▷ Compute the values  $\bar{v}$  once offline and store for repeated use
  - 3: Set  $\epsilon_m = \epsilon/2$  and  $\bar{\epsilon} = \epsilon/(2(1+c))$
  - 4:  $m \leftarrow \frac{\log(4K/\delta)c^2}{2\epsilon_m^2}$
  - 5: **for**  $1, \dots, m$  **do**
  - 6:     Sample  $s_i \sim d$
  - 7:      $\bar{v}(s_i) \leftarrow$  Algorithm 2 with  $\bar{\epsilon}, \frac{\delta}{2m}, \tau$
- 

**Specifying the number of sampled states  $m$ .** For the number of required samples for the outer loop in Algorithm 1, we need enough samples to match the bound in Lemma 2.

$$\epsilon_m = \sqrt{\frac{\log(4K/\delta)c^2}{2m}} \implies m = \frac{\log(4K/\delta)c^2}{2\epsilon_m^2} \quad (16)$$

$m$  is chosen as  $\left\lceil \frac{\log(4K/\delta)c^2}{2\epsilon_m^2} \right\rceil \geq \epsilon_m$  and thus we are being slightly conservative regarding the error to ensure correctness with high probability. We opt for a separate choice of  $\epsilon_m$  for this part of the bound, because it is completely separate from the other errors. This number  $\epsilon_m$  could be chosen slightly larger, to reduce the number of required sampled states to compare to, whereas  $\epsilon$  might need to be smaller depending on the choice of  $c$  and  $\tau$ . Separating them explicitly can significantly reduce the  $m$  in the outer loop, both improving time and storage, as well as later comparison time, without impacting the accuracy of the algorithm.

  - 23:         **if**  $\frac{\widehat{\text{UB}} - \widehat{\text{LB}}}{2} \leq \epsilon\tau$  **then return**  $\frac{\widehat{\text{UB}} + \widehat{\text{LB}}}{2}$
  - 24:          $j = j + 1$
  - return**  $\frac{\text{sign}(\bar{g})}{2}((1+\epsilon)\text{LB} + (1-\epsilon)\text{UB})$
- 

**Satisfying Assumption 2.** Our goal is to get an  $(\epsilon, \delta, \tau)$ -approximation of  $\bar{v}(s_i)$ , with a feasible number of samples. In many cases, it is difficult to make parametric assumptions about returns in reinforcement learning. A simple strategy is to use a stopping rule for generating returns, based on general concentration inequalities—like Hoeffding’s bound—that make few assumptions about the random variables. If we had a bit more information, however, such as the variance of the returns, we could obtain a tighter bound, using Bernstein’s inequality and so reduce the number of required samples. We cannot know this variance a priori, but fortunately an empirical Bernstein bound has been developed [Mnih et al., 2008]. Using this bound, Mnih et al. [2008] designed EBGStop, which incrementally estimates variance and significantly reduces the number of samples required to get high-confidence estimates.

EBGStop can be used, without modification, given a mechanism to sample truncated returns that satisfy Assumption 1. However, we generalize the algorithm to

allow for our less restrictive condition  $|\bar{v}^*(s_i) - \bar{v}(s_i)| \leq \epsilon(|\bar{v}^*(s_i)| + \tau)$ , as opposed to the original algorithm which ensured  $|\bar{v}^*(s_i) - \bar{v}(s_i)| \leq \epsilon|\bar{v}^*(s_i)|$ . When  $\tau = 0$  in our algorithm, it reduces to the original; since this is a generalization on that algorithm, we continue to call it EBGStop. This modification is important when  $v^*(s_i) = 0$ , since this would require  $\bar{v}^*(s_i) = v^*(s_i)$  when  $\tau = 0$ . For  $\tau > 0$ , once the accuracy is within  $\tau$ , the algorithm can stop. The Algorithm is summarized in Algorithm 2. The proof follows closely to the proof for EBGStop; we include it in Appendix A. Algorithm 2 uses geometric sampling, like EBGStop, to improve sample efficiency. The idea is to avoid checking the stopping condition after every sample. Instead, for some  $\beta > 1$ , the condition is checked after  $\beta^k$  samples; the next check occurs at  $\beta^{k+1}$ . This modification improves sample efficiency from a multiplicative factor of  $\log(\frac{R}{\epsilon|\mu|})$  to  $\log \log(\frac{R}{\epsilon|\mu|})$ , where  $R$  is the range of the random variables and  $\mu$  is the mean.

**Lemma 6.** *Algorithm 2 returns an  $\epsilon, \delta, \tau$ -approximation  $\bar{v}(s_i)$ :*

$$|\bar{v}^*(s_i) - \bar{v}(s_i)| \leq \epsilon(|\bar{v}^*(s_i)| + \tau)$$

**Corollary 1.** *For any  $0 < \epsilon_m$  and  $0 < \bar{\epsilon} < 1$ , Algorithm 1 returns an  $\epsilon, \delta$ -accurate approximation: with probability at least  $1 - \delta$ ,*

$$\left| \ell(\hat{v}, v^*) - \frac{1}{m} \sum_{i=1}^m \ell_c(\hat{v}(s_i), \bar{v}(s_i)) \right| \leq \epsilon$$

where

$$\epsilon = \epsilon_m + 2(1 + c)\bar{\epsilon} \quad (17)$$

Algorithm 1 uses this theorem, for a given desired level of accuracy  $\epsilon$ . To obtain this level of accuracy,  $\epsilon_m = \epsilon/2$  and  $\bar{\epsilon}$  given to Algorithm 2 is set to ensure  $2(1 + c)\bar{\epsilon} = \epsilon$ .

## 5 EXPERIMENTS ON BENCHMARK PROBLEMS

We investigate the required number of samples to get with a level of accuracy, for different probability levels. We report this for two continuous-state benchmark problems—Mountain Car and Puddle World—which have previously been used to compare policy evaluation algorithms. Our goal is to (a) demonstrate how this framework can be used to obtain high-confidence estimates of accuracy and (b) provide some insight into how many samples are needed, even for simple reinforcement learning benchmark domains.

We report the number of returns sampled by Algorithm 2, averaged across several states. The domains, Mountain Car and Puddle World, are as specified in the policy

evaluation experiments by Pan et al. [2017]. For Mountain Car, we use the energy pumping policy, with 60% random action selection for the three actions. For Puddle World, we used a uniform random policy for the four actions. They are both episodic tasks, with a maximum absolute value of  $V_{\max} = 100$  and  $V_{\max} = 8000$  respectively. The variance in Puddle World is particularly high, as it has regions with high-variance, high-magnitude rewards. We sampled  $m = 100$  states uniformly across the state-space, to provide some insight into the variability of the number of returns sampled across the state-space. We tested  $\epsilon \in \{0.01, 0.05, 0.1\}$  and  $\delta \in \{0.01, 0.1\}$ , and set  $\tau = 1.0$ . We focus here on how many returns need to be sampled, rather than the trajectory length, and so do not use  $c$  nor explicitly compute clipped errors  $\ell_c$ .

The results indicate that EBGStop requires a large number of samples, particularly in Puddle World. Figure 1b for Mountain Car and Figure 1a both indicate that decreasing  $\epsilon$  from 0.05 to 0.01, to enable higher-accuracy estimates of value function error, causes an exponential increase in the required number of samples, an increase of  $10^3$  to  $10^4$  for Mountain Car and  $10^5$  to  $10^6$  for Puddle World. An accuracy level of 0.01, which corresponds to difference of 1% for clipped errors, is a typical choice for policy evaluation experiments, yet requires an inordinate number of samples, particularly in Puddle World.

We further investigated lower bounds on the required number of samples. Though EBGStop is a state-of-the-art stopping algorithm, to ensure high-confidence bounds for any distribution with bounded mean and variance, it collects more samples than is actually required. To assess its efficiency gap, we also include an idealistic approach to computing the confidence intervals, using repeated subsamples computed from the simulator. By obtaining many, many estimates of the sample average, using  $t$  samples of the truncated return, we can estimate the actual variability of the sample average. We provide additional details in Appendix D. Such a method to compute the confidence interval is not a viable algorithm to reduce the number of samples generated. Rather, the goal here is to report a lower bound on the number of samples required, for comparison and to motivate the amount the sampling algorithm could be improved. The number of samples generated by EBGStop is typically between 10 to 100 times more than the optimal number of samples, which indicates that there is much room to improve sample efficiency.

## 6 CONCLUSION

In this work, we present the first principled approach to obtain high-confidence error estimates of learned value functions. Our strategy is focused on the setting tackled

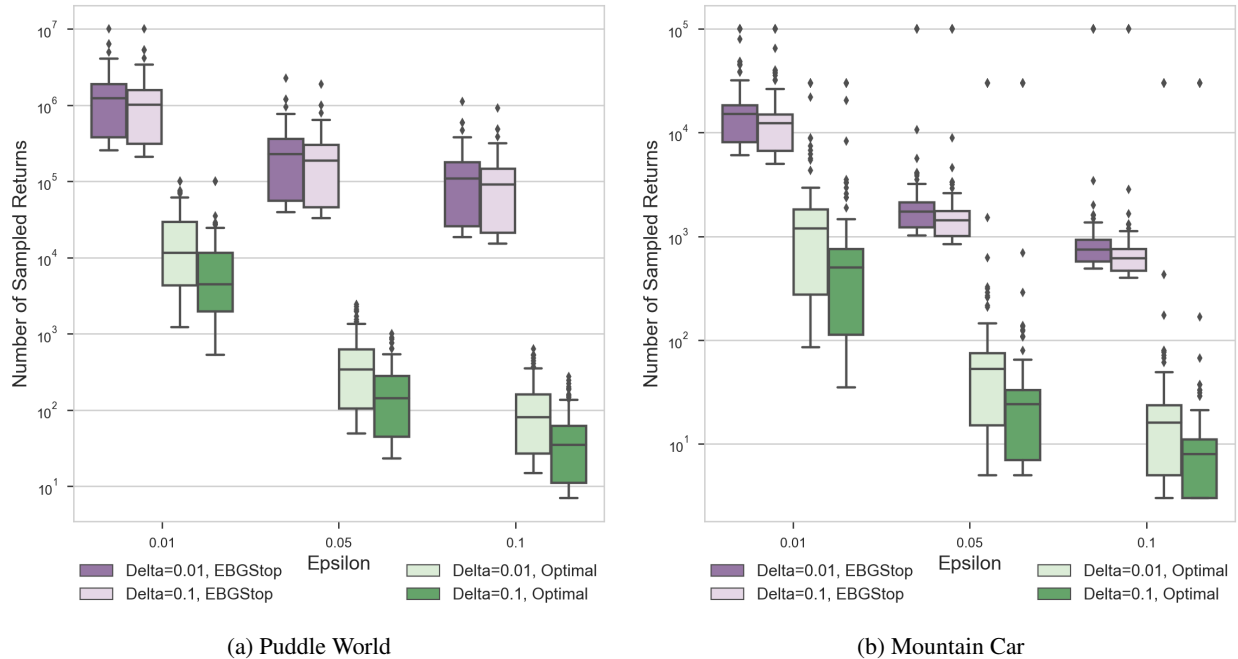

Figure 1: The number of sampled returns to obtain high-confidence estimates  $\bar{v}$  of the true values  $v^*$ . The y-axis is logarithmic, with many more samples used for smaller  $\epsilon$ . The box-plot similarly are logarithmic, and so are actually much larger for smaller  $\epsilon$  than larger  $\epsilon$ . The accuracy  $\epsilon$  has a much larger effect on the number of sampled returns that are required, than the probability  $\delta$ . An additional point of interest is that there are a few states that required significantly more samples for the returns, indicated by the outliers depicted as individual points.

by reinforcement learning empiricists, comparing value function-learning algorithms. In this context, accuracy of value estimates, for multiple algorithms, need to be computed repeatedly, every few steps with increasing data given to the learning algorithms. We provide a general framework for such a setting, where we store estimates of true value functions using samples of truncated returns. The framework for estimating true values for comparison is intentionally generic, to enable any (sample-efficient) stopping algorithm to be used. We propose one solution, which uses empirical Bernstein bounds, to significantly reduce the required number of samples over other concentration inequalities, such as Hoeffding’s bound.

This paper highlights several open challenges. As demonstrated in the experiments, there is a large gap between the actual required number of samples and that provided by the algorithm using an empirical Bernstein stopping-rule. For some simulators, this overestimate could result in a prohibitively large number of samples. Although this is a problem more generally faced by the sampling literature, it is particularly exacerbated in reinforcement learning where the variability across states and returns can be high, with large maximum values. An important avenue, then, is to develop more sample-efficient sampling algorithms to make high-confidence error es-

timates feasible for a broader range of settings in reinforcement learning.

Another open challenge is to address how to sample states  $\{s_1, \dots, s_m\}$ . This paper is agnostic to how these states are obtained. However, it is not always straightforward to sample these from a desired distribution. Some choices are simple, such as randomly selecting these across the state space. For other cases, it is more complicated, such as sampling these from the stationary distribution of the behaviour policy,  $d^\mu$ . The typical strategy is to run  $\mu$  for a burn-in period, so that afterwards it is more likely for states to be sampled from the stationary distribution. The theoretical effectiveness of this strategy, however, is not yet well-understood. There has been work estimating empirical mixing times [Hsu et al., 2015] and some work bounding the number of samples required for burn-in [Paulin, 2015]. Nonetheless, it remains an important open question on how to adapt these results for the general reinforcement learning setting.

One goal of this paper has been to highlight an open problem that has largely been ignored by reinforcement learning empiricists. We hope for this framework to stimulate further work in high-confidence estimates of value function accuracy.

# Combinatorial Bandits for Incentivizing Agents with Dynamic Preferences

---

Tanner Fiez\*, Shreyas Sekar\*, Liyuan Zheng, and Lillian J. Ratliff  
Electrical Engineering Department, University of Washington

## Abstract

The design of personalized incentives or recommendations to improve user engagement is gaining prominence as digital platform providers continually emerge. We propose a multi-armed bandit framework for matching incentives to users, whose preferences are unknown *a priori* and evolving dynamically in time, in a resource constrained environment. We design an algorithm that combines ideas from three distinct domains: (i) a greedy matching paradigm, (ii) the upper confidence bound algorithm (UCB) for bandits, and (iii) mixing times from the theory of Markov chains. For this algorithm, we provide theoretical bounds on the regret and demonstrate its performance via both synthetic and realistic (matching supply and demand in a bike-sharing platform) examples.

## 1 INTRODUCTION

The theory of *multi-armed bandits* plays a key role in enabling personalization in the digital economy (Scott, 2015). Algorithms from this domain have successfully been deployed in a diverse array of applications including online advertising (Lu et al., 2010; Mehta and Mirrokni, 2011), crowdsourcing (Tran-Thanh et al., 2014), content recommendation (Li et al., 2010), and selecting user-specific incentives (Ghosh and Hummel, 2013; Jain et al., 2014) (e.g., a retailer offering discounts). On the theoretical side, this has been complemented by a litany of *near-optimal regret bounds* for multi-armed bandit settings with rich combinatorial structures and complex agent behavior models (Chen et al., 2016; Gai et al., 2011; Kveton et al., 2015; Sani et al., 2012). At a high

level, the broad appeal of bandit approaches for allocating resources to human agents stems from its focus on balancing *exploration* with *exploitation*, thereby allowing a decision-maker to efficiently identify users' preferences without sacrificing short-term rewards.

Implicit in most of these works is the notion that in large-scale environments, a designer can simultaneously allocate resources to multiple users by running independent bandit instances. In reality, such independent decompositions do not make sense in applications where resources are subject to physical or monetary constraints. In simple terms, matching an agent to a resource immediately constrains the set of resources to which another agent can be matched. Such supply constraints may arise even when dealing with intangible products. For instance, social media platforms (e.g., Quora) seek to maximize user participation by offering incentives in the form of increased recognition—e.g., featured posts or badges (Immorlica et al., 2015). Of course, there are supply constraints on the number of posts or users that can be featured at a given time. As a consequence of these coupling constraints, much of the existing work on multi-armed bandits does not extend naturally to multi-agent economies.

Yet, another important aspect not addressed by the literature concerns human behavior. Specifically, users' preferences over the various resources may be dynamic—i.e. evolve in time as they are repeatedly exposed to the available options. The problem faced by a designer in such a dynamic environment is compounded by the lack of information regarding each user's current state or beliefs, as well as how these beliefs influence their preferences and their evolution in time.

Bearing in mind these limitations, we study a multi-armed bandit problem for matching multiple agents to a finite set of incentives<sup>1</sup>: each incentive belongs to a cate-

---

<sup>1</sup>We use the term incentive broadly to refer to any resource or action available to the agent. That is, incentives are not limited to monetary or financial mechanisms.

\* Authors contributed equally.

gory and global capacity constraints control the number of incentives that can be chosen from each category. In our model, each agent has a *preference profile* or a *type* that determines its rewards for being matched to different incentives. The agent’s type evolves according to a Markov decision process (MDP), and therefore, the rewards vary over time *in a correlated fashion*.

Our work is primarily motivated by the problem faced by a technological platform that seeks to not just maximize user engagement but also to encourage users to make changes in their *status quo* decision-making process by offering incentives. For concreteness, consider a bike-sharing service—an application we explore in our simulations—that seeks to identify optimal incentives for each user from a finite bundle of options—e.g., varying discount levels, free future rides, bulk ride offers, etc. Users’ preferences over the incentives may evolve with time depending on their current type, which in turn depends on their previous experience with the incentives. In addition to their marketing benefits, such incentives can serve as a powerful instrument for *nudging* users to park their bikes at alternative locations—this can lead to spatially balanced supply and consequently, lower rejection rates (Singla et al., 2015).

## 1.1 CONTRIBUTIONS AND ORGANIZATION

Our objective is to design a multi-armed bandit algorithm that repeatedly matches agents to incentives in order to minimize the cumulative *regret* over a finite time horizon. Here, regret is defined as the difference in the reward obtained by a problem specific benchmark strategy and the proposed algorithm (see Definition 1). A preliminary impediment in achieving this goal is the fact that the capacitated matching problem studied in this work is NP-Hard even in the offline case. The major challenge therefore is whether *we can achieve sub-linear (in the length of the horizon) regret in the more general matching environment without any information on the users’ underlying beliefs or how they evolve?*

Following preliminaries (Section 2), we introduce a simple greedy algorithm that provides a  $1/3$ -approximation to the optimal offline matching solution (Section 3). Leveraging this first contribution, the central result in this paper (Section 4) is a new multi-armed bandit algorithm—*MatchGreedy-EpochUCB* (MG-EUCB)—for capacitated matching problems with time-evolving rewards. Our algorithm obtains logarithmic (and hence sub-linear) regret even for this more general bandit problem. The proposed approach combines ideas from three distinct domains: (i) the  $1/3$ -rd approximate greedy matching algorithm, (ii) the traditional UCB algorithm (Auer et al., 2002), and

(iii) mixing times from the theory of Markov chains.

We validate our theoretical results (Section 5) by performing simulations on both synthetic and realistic instances derived using data obtained from a Boston-based bike-sharing service *Hubway* (hub). We compare our algorithm to existing UCB-based approaches and show that the proposed method enjoys favorable convergence rates, computational efficiency on large data sets, and does not get stuck at sub-optimal matching solutions.

## 1.2 BACKGROUND AND RELATED WORK

Two distinct features separate our model from the majority of work on the multi-armed bandit problem: (i) our focus on a capacitated matching problem with finite supply (every user cannot be matched to their optimal incentive), and (ii) the rewards associated with each agent evolve in a correlated fashion but the designer is unaware of each agent’s current state. Our work is closest to (Gai et al., 2011) which considers a matching problem with Markovian rewards. However, in their model the rewards associated with each edge evolve independently of the other edges; as we show via a simple example in Section 2.2, the correlated nature of rewards in our instance can lead to additional challenges and convergence to sub-optimal matchings if we employ a traditional approach as in (Gai et al., 2011).

Our work also bears conceptual similarities to the rich literature on combinatorial bandits (Badanidiyuru et al., 2013; Chen et al., 2016; Kveton et al., 2014, 2015; Wen et al., 2015). However, unlike our work, these papers consider a model where the distribution of the rewards is static in time. For this reason, efficient learning algorithms leveraging oracles to solve generic constrained combinatorial optimization problems developed for the combinatorial semi-bandit setting (Chen et al., 2016; Kveton et al., 2015) face similar limitations in our model as the approach of (Gai et al., 2011). Moreover, the rewards in our problem may not have a linear structure so the approach of (Wen et al., 2015) is not applicable.

The novelty in this work is not the combinatorial aspect but the interplay between combinatorial bandits and the edge rewards evolving according to an MDP. When an arm is selected by an oracle, the reward of every edge in the graph evolves—how it evolves depends on which arm is chosen. If the change occurs in a sub-optimal direction, this can affect future rewards. Indeed, the difficulties in our proofs do not stem from applying an oracle for combinatorial optimization, but from bounding the secondary regret that arises when rewards evolve in a sub-optimal way.

Finally, there is a somewhat parallel body of work

on single-agent reinforcement learning techniques (Azar et al., 2013; Jaksch et al., 2010; Mazumdar et al., 2017; Ratliff et al., 2018) and expert selection where the rewards on the arms evolve in a correlated fashion as in our work. In addition to our focus on multi-agent matchings, we remark that many of these works assume that the designer is aware (at least partially) of the agent’s exact state and thus, can eventually infer the nature of the evolution. Consequently, a major contribution of this work is the extension of UCB-based approaches to solve MDPs with a *fully unobserved state* and rewards associated with each edge that evolve in a correlated fashion.

## 2 PRELIMINARIES

A designer faces the problem of matching  $m$  agents to incentives (more generally jobs, goods, content, etc.) without violating certain capacity constraints. We model this setting by means of a bipartite graph  $(\mathcal{A}, \mathcal{I}, \mathcal{P})$  where  $\mathcal{A}$  is the set of agents,  $\mathcal{I}$  is the set of incentives to which the agents can be matched, and  $\mathcal{P} = \mathcal{A} \times \mathcal{I}$  is the set of all pairings between agents and incentives. We sometimes refer to  $\mathcal{P}$  as the set of arms. In this regard, a matching is a set  $M \subseteq \mathcal{P}$  such that every agent  $a \in \mathcal{A}$  and incentive  $i \in \mathcal{I}$  is present in at most one edge belonging to  $M$ .

Each agent  $a \in \mathcal{A}$  is associated with a type or state  $\theta_a \in \Theta_a$ , which influences the reward received by this agent when matched with some incentive  $i \in \mathcal{I}$ . When agent  $a$  is matched to incentive  $i$ , its type evolves according to a Markov process with transition probability kernel  $P_{a,i} : \Theta_a \times \Theta_a \rightarrow [0, 1]$ . Each pairing or edge of the bipartite graph is associated with some reward that depends on the agent–incentive pair,  $(a, i)$ , as well as the type  $\theta_a$ .

The designer’s policy (algorithm) is to compute a matching repeatedly over a finite time horizon in order to maximize the expected aggregate reward. In this work, we restrict our attention to a specific type of multi-armed bandit algorithm that we refer to as an *epoch mixing policy*. Formally, the execution of such a policy  $\alpha$  is divided into a finite number of time indices  $[n] = \{1, 2, \dots, n\}$ , where  $n$  is the length of the time horizon. In each time index  $k \in [n]$ , the policy selects a matching  $\alpha(k)$  and repeatedly ‘plays’ this matching for  $\tau_k > 0$  iterations within this time index. We refer to the set of iterations within a time index collectively as an *epoch*. That is, within the  $k$ –th epoch, for each edge  $(a, i) \in \alpha(k)$ , agent  $a$  is matched to incentive  $i$  and the agent’s type is allowed to evolve for  $\tau_k$  iterations. In short, an epoch mixing policy proceeds in two time scales—each selection of a matching corresponds to an epoch comprising of  $\tau_k$  iterations for  $k \in [n]$ , and there are a total of  $n$  epochs. It is worth noting that an epoch-based policy was used in the UCB2 algorithm (Auer et al., 2002), albeit with

stationary rewards.

Agents’ types evolve based on the incentives to which they are matched. Suppose that  $\beta_a^{(k)}$  denotes the type distribution on  $\Theta_a$  at epoch  $k$  and  $i \in \mathcal{I}$  is the incentive to which agent  $a$  is matched by  $\alpha$  (i.e.,  $(a, i) \in \alpha(k)$ ). Then,  $\beta_a^{(k+1)}(\theta_a) = \sum_{\theta' \in \Theta_a} P_{a,i}^{\tau_k}(\theta', \theta_a) \beta_a^{(k)}(\theta')$ .

For epoch  $k$ , the rewards are averaged over the  $\tau_k$  iterations in that epoch. Let  $r_{a,i}^\theta$  denote the reward received by agent  $a$  when it is matched to incentive  $i$  given type  $\theta \in \Theta_a$ . We assume that  $r_{a,i}^\theta \in [0, 1]$  and is drawn from a distribution  $\mathcal{T}_r(a, i, \theta)$ . The reward distributions for different edges and states in  $\Theta_a$  are assumed to be independent of each other. Suppose that an algorithm  $\alpha$  selects the edge  $(a, i)$  for  $\tau$  iterations within an epoch. The observed reward at the end of this epoch is taken to be the time-averaged reward over the epoch. Specifically, suppose that the  $k$ –th epoch proceeds for  $\tau_k$  iterations beginning with time  $t_k$ —i.e. one plus the total iterations completed before this—and ending at time  $t_{k+1} - 1 = t_k + \tau_k - 1$ , and that  $\theta_a(t)$  denotes agent  $a$ ’s state at time  $t \in [t_k, t_{k+1} - 1]$ . Then, the time-averaged reward in the epoch is given by  $\mathbf{r}_{a,i}^{\theta_a(t_k)} = \frac{1}{\tau_k} \sum_{t=t_k}^{t_{k+1}-1} r_{a,i}^{\theta_a(t)}$ . We use the state as a superscript to denote dependence of the reward on the agent’s type at the beginning of the epoch. Finally, the total (time-averaged) reward due to a matching  $\alpha(k)$  at the end of an epoch can be written as  $\sum_{(a,i) \in \alpha(k)} \mathbf{r}_{a,i}^{\theta_a(t_k)}$ .

We assume that the Markov chain corresponding to each edge  $(a, i) \in \mathcal{P}$  is *aperiodic* and *irreducible* (Levin et al., 2009). We denote the stationary or steady-state distribution for this edge as  $\pi_{a,i} : \Theta_a \rightarrow [0, 1]$ . Hence, we define the expected reward for edge  $(a, i)$ , given its stationary distribution, to be  $\mu_{a,i} = \mathbb{E} [\sum_{\theta \in \Theta_a} r_{a,i}^\theta \pi_{a,i}(\theta)]$  where the expectation is with respect to the distribution on the reward given  $\theta$ .

### 2.1 CAPACITATED MATCHING

Given  $\mathcal{P} = \mathcal{A} \times \mathcal{I}$ , the designer’s goal at the beginning of each epoch is to select a matching  $M \subseteq \mathcal{P}$ —i.e. a collection of edges—that satisfies some cardinality constraints. We partition the edges in  $\mathcal{P}$  into a mutually exclusive set of classes allowing for edges possessing identical characteristics to be grouped together. In the bike-sharing example, the various classes could denote types of incentives—e.g., edges that match agents to discounts, free-rides, etc. Suppose that  $\mathcal{C} = \{\xi_1, \xi_2, \dots, \xi_q\}$  denotes a partitioning of the edge set such that (i)  $\xi_j \subseteq \mathcal{P}$  for all  $1 \leq j \leq q$ , (ii)  $\bigcup_{j=1}^q \xi_j = \mathcal{P}$ , and (iii)  $\xi_j \cap \xi_{j'} = \emptyset$  for all  $j \neq j'$ . We refer to each  $\xi_j$  as a class and for any given edge  $(a, i) \in \mathcal{P}$ , use  $c(a, i)$  to denote the class that this edge belongs to, i.e.,  $(a, i) \in c(a, i)$  and  $c(a, i) \in \mathcal{C}$ .

Given a capacity vector  $\mathbf{b} = (b_{\xi_1}, \dots, b_{\xi_q})$  indexed on the set of classes, we say that a matching  $M \subseteq \mathcal{P}$  is a feasible solution to the capacitated matching problem if:

- a) for every  $a \in \mathcal{A}$  (resp.,  $i \in \mathcal{I}$ ), the matching must contain at most one edge containing this agent (resp., incentive)
- b) and, the total number of edges from each class  $\xi_j$  contained in the matching cannot be larger than  $b_{\xi_j}$ .

In summary, the *capacitated matching problem* can be formulated as the following integer program:

$$\begin{aligned}
 \max \quad & \sum_{(a,i) \in \mathcal{P}} w(a,i)x(a,i) \\
 \text{s.t.} \quad & \sum_{i \in \mathcal{I}} x(a,i) \leq 1 \quad \forall a \in \mathcal{A} \\
 & \sum_{a \in \mathcal{A}} x(a,i) \leq 1 \quad \forall i \in \mathcal{I} \\
 & \sum_{(a,i) \in \xi_j} x(a,i) \leq b_{\xi_j}, \quad \forall \xi_j \in \mathcal{C} \\
 & x(a,i) \in \{0, 1\}, \quad \forall (a,i) \in \mathcal{P}
 \end{aligned} \tag{P1}$$

We use the notation  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a,i))_{(a,i) \in \mathcal{P}}\}$  for a *capacitated matching problem instance*. In (P1),  $w(a,i)$  refers to the weight or the reward to be obtained from the given edge. The term  $x(a,i)$  is an indicator on whether the edge  $(a,i)$  is included in the solution to (P1). Clearly, the goal is to select a maximum weight matching subject to the constraints. In our online bandit problem, the designer’s actual goal in a fixed epoch  $k$  is to maximize the quantity  $\sum_{(a,i) \in \mathcal{P}} \mathbf{r}_{a,i}^{\theta_a(t_k)} x(a,i)$ , i.e.,  $w(a,i) = \mathbf{r}_{a,i}^{\theta_a(t_k)}$ . However, since the reward distributions and the current user type are not known beforehand, our MG-EUCB algorithm (detailed in Section 4.2) approximates this objective by setting the weights to be the average observed reward from the edges in combination with the corresponding confidence bounds.

## 2.2 TECHNICAL CHALLENGES

There are two key obstacles involved in extending traditional bandit approaches to our combinatorial setting with evolving rewards, namely, *cascading sub-optimality* and *correlated convergence*. The first phenomenon occurs when an agent  $a$  is matched to a sub-optimal arm  $i$  (incentive) because its optimal arm  $i^*$  has already been assigned to another agent. Such sub-optimal pairings have the potential to cascade, e.g., when another agent  $a_1$  who is matched to  $i$  in the optimal solution can no longer receive this incentive and so on. Therefore, unlike the classical bandit analysis, the selection of sub-optimal arms cannot be directly mapped to the empirical rewards.

*Correlated Convergence.* As mentioned previously, in our model, the rewards depend on the type or state of an agent, and hence, the reward distribution on any given edge  $(a,i)$  can vary even when the algorithm does not select this edge. As a result, a naïve application of a bandit algorithm can severely under-estimate the expected

reward on each edge and eventually converge to a sub-optimal matching. A concrete example of the poor convergence effect is provided in Example 1. In Section 4.2, we describe how our central bandit algorithm limits the damage due to cascading while simultaneously avoiding the correlated convergence problem.

**Example 1** (Failure of Classical UCB). *Consider a problem instance with two agents  $\mathcal{A} = \{a_1, a_2\}$ , two incentives  $\mathcal{I} = \{i_1, i_2\}$  and identical state space i.e.,  $\Theta_{a_1} = \Theta_{a_2} = \{\theta_1, \theta_2\}$ . The transition matrices and deterministic rewards for the agents for being matched to each incentive are depicted pictorially below: we assume that  $\epsilon > 0$  is a sufficiently small constant.*

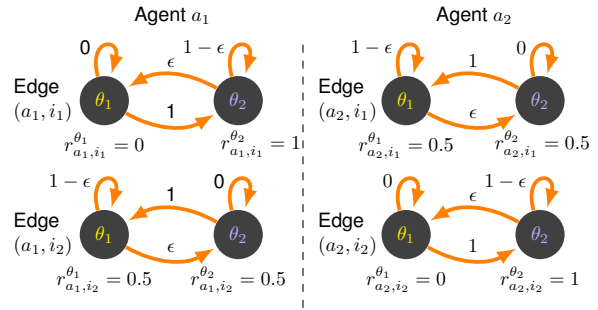

Figure 1: (a) State transition diagram and reward for each edge: note that the state is associated with the agent and not the edge.

Clearly, the optimal strategy is to repeatedly choose the matching  $\{(a_1, i_1), (a_2, i_2)\}$  achieving a reward of (almost) two in each epoch. An implementation of traditional UCB for the matching problem—e.g., the approach in (Chen et al., 2016; Gai et al., 2011; Kveton et al., 2015)—selects a matching based on the empirical rewards and confidence bounds for a total of  $\sum_{k=1}^n \tau_k$  iterations, which are then divided into epochs for convenience. This approach converges to the sub-optimal matching of  $M = \{(a_1, i_2), (a_2, i_1)\}$ . Indeed, every time the algorithm selects this matching, both the agents’ states are reset to  $\theta_1$  and when the algorithm explores the optimum matching, the reward consistently happens to be zero since the agents are in state  $\theta_1$ . Hence, the rewards for the (edges in the) optimum matching are grossly underestimated.

## 3 GREEDY OFFLINE MATCHING

In this section, we consider the capacitated matching problem in the offline case, where the edge weights are provided as input. The techniques developed in this section serve as a base in order to solve the more general online problem in the next section. More specifically, we assume that we are given an arbitrary instance of the capacitated matching problem  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a,i))_{(a,i) \in \mathcal{P}}\}$ .

---

**Algorithm 1** Capacitated-Greedy Matching Algorithm

---

```
1: function MG( $(w(a, i))_{(a, i) \in \mathcal{P}}, \mathbf{b}$ )
2:    $G^* \leftarrow \emptyset, E' \leftarrow \mathcal{P}$ 
3:   while  $E' \neq \emptyset$ :
4:     Select  $(a, i) = \arg \max_{(a', i') \in E'} w(a', i')$ 
5:     if  $|G^* \cap c(a, i)| < b_{c(a, i)}$  then
6:        $G^* \leftarrow G^* \cup \{(a, i)\}$ 
7:        $E' \leftarrow E' \setminus \{(a', i') \mid \forall (a', i') : a' = a \text{ or } i' = i\}$ 
8:     else
9:        $E' \leftarrow E' \setminus \{(a, i)\}$ 
10:    return  $G^*$ 
11: end function
```

---

Given this instance, the designer’s objective is to solve (P1). Surprisingly, this problem turns out to be NP-Hard and thus cannot be optimally solved in polynomial time (Garey and Johnson, 1979)—this marks a stark contrast with the classic maximum weighted matching problem, which can be solved efficiently using the Hungarian method (Kuhn, 1955).

In view of these computational difficulties, we develop a simple greedy approach for the capacitated matching problem and formally prove that it results in a one-third approximation to the optimum solution. The greedy method studied in this work comes with a multitude of desirable properties that render it suitable for matching problems arising in large-scale economies. Firstly, the greedy algorithm has a running time of  $O(m^2 \log m)$ , where  $m$  is the number of agents—this near-linear execution time in the number of edges makes it ideal for platforms comprising of a large number of agents. Secondly, since the output of the greedy algorithm depends only on the ordering of the edge weights and is not sensitive to their exact numerical value, learning approaches tend to converge faster to the ‘optimum solution’. This property is validated by our simulations (see Figure 2c). Finally, the performance of the greedy algorithm in practice (e.g., see Figure 2b) appears to be much closer to the optimum solution than the 1/3 approximation guaranteed by Theorem 1 below.

### 3.1 ANALYSIS OF GREEDY ALGORITHM

The greedy matching is outlined in Algorithm 1. Given an instance  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a, i))_{(a, i) \in \mathcal{P}}\}$ , Algorithm 1 ‘greedily’ selects the highest weight feasible edge in each iteration—this step is repeated until all available edges that are feasible are added to  $G^*$ . Our main result in this section is that for any given instance of the capacitated matching problem, the matching  $G^*$  returned by Algorithm 1 has a total weight that is at least 1/3-rd that of the maximum weight matching.

**Theorem 1.** *For any given capacitated matching problem instance  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a, i))_{(a, i) \in \mathcal{P}}\}$ , let  $G^*$  denote the output of Algorithm 1 and  $M^*$  be any other feasible solution to the optimization problem in (P1) including the optimum matching. Then,  $\sum_{(a, i) \in M^*} w(a, i) \leq 3 \sum_{(a, i) \in G^*} w(a, i)$ .*

The proof is based on a *charging argument* that takes into account the capacity constraints and can be found in Section B.1 of the supplementary material. At a high level, we take each edge belonging to the benchmark  $M^*$  and identify a corresponding edge in  $G^*$  whose weight is larger than that of the benchmark edge. This allows us to charge the weight of the original edge to an edge in  $G^*$ . During the charging process, we ensure that no more than three edges in  $M^*$  are charged to each edge in  $G^*$ . This gives us an approximation factor of three.

### 3.2 PROPERTIES OF GREEDY MATCHINGS

We conclude this section by providing a hierarchical decomposition of the edges in  $\mathcal{P}$  for a fixed instance  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a, i))_{(a, i) \in \mathcal{P}}\}$ . In Section 4.1, we will use this property to reconcile the offline version of the problem with the online bandit case. Let  $G^* = \{g_1^*, g_2^*, \dots, g_m^*\}$  denote the matching computed by Algorithm 1 for the given instance such that  $w(g_1^*) \geq w(g_2^*) \geq \dots \geq w(g_m^*)$  without loss of generality<sup>2</sup>. Next, let  $G_j^* = \{g_1^*, g_2^*, \dots, g_j^*\}$  for all  $1 \leq j \leq m$ —i.e. the  $j$  highest-weight edges in the greedy matching.

For each  $1 \leq j \leq m$ , we define the infeasibility set  $H_j^{G^*}$  as the set of edges in  $\mathcal{P}$  that when added to  $G_j^*$  violates the feasibility constraints of (P1). Finally, we use  $L_j^{G^*}$  to denote the marginal infeasibility sets—i.e.  $L_1^{G^*} = H_1^{G^*}$  and

$$L_j^{G^*} = H_j^{G^*} \setminus H_{j-1}^{G^*}, \forall 2 \leq j \leq m. \quad (1)$$

We note that the marginal infeasibility sets denote a mutually exclusive partition of the edge set minus the greedy matching—i.e.,  $\bigcup_{1 \leq j \leq m} L_j^{G^*} = \mathcal{P} \setminus G^*$ . Moreover, since the greedy matching selects its edges in the decreasing order of weight, for any  $g_j^* \in G^*$ , and every  $(a, i) \in L_j^{G^*}$ , we have that  $w(g_j^*) \geq w(a, i)$ .

Armed with our decomposition of the edges in  $\mathcal{P} \setminus G^*$ , we now present a crucial structural lemma. The following lemma identifies sufficient conditions on the *local ordering* of the edge weights for two different instances under which the outputs of the greedy matching for the instances are non-identical.

**Lemma 1.** *Given instances  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a, i))_{(a, i) \in \mathcal{P}}\}$  and  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (\tilde{w}(a, i))_{(a, i) \in \mathcal{P}}\}$  of the capacitated matching problem, let  $G^* = \{g_1^*, g_2^*, \dots, g_m^*\}$  and  $\tilde{G}$  denote*

<sup>2</sup>If  $g = (a, i)$ , we abuse notation and let  $w(g) = w(a, i)$ .

the output of Algorithm 1 for these instances, respectively. Let  $E_1, E_2$  be conditions described as follows:

$$\begin{aligned} E_1 &= \{\exists j < j' \mid (\tilde{w}(g_j^*) < \tilde{w}(g_{j'}^*)) \wedge (g_j^* \in \tilde{G})\} \\ E_2 &= \{\exists g_j^* \in G^*, (a, i) \in L_j^{G^*} \mid \\ &\quad (\tilde{w}(g_j^*) < \tilde{w}(a, i)) \wedge ((a, i) \in \tilde{G})\}. \end{aligned}$$

If  $G^* \neq \tilde{G}$ , then at least one of  $E_1$  or  $E_2$  must be true.

Lemma 1 is fundamental in the analysis of our MG-EUCB algorithm because it provides a method to map the selection of each sub-optimal edge to a familiar condition comparing empirical rewards to stationary rewards.

## 4 ONLINE MATCHING—BANDIT ALGORITHM

In this section, we propose a multi-armed bandit algorithm for the capacitated matching problem and analyze its regret. For concreteness, we first highlight the information and action sets available to the designer in the online problem. The designer is presented with a *partial instance* of the matching problem without the weights, i.e.,  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}\}$  along with a fixed time horizon of  $n$  epochs but has the ability to set the parameters  $(\tau_1, \tau_2, \dots, \tau_n)$ , where  $\tau_k$  is the number of iterations under epoch  $k$ . The designer’s goal is to design a policy  $\alpha$  that selects a matching  $\alpha(k)$  in the  $k$ -th epoch that is a feasible solution for (P1). At the end of the  $k$ -th epoch, the designer observes the average reward  $\mathbf{r}_{a,i}^{\theta_a(k)}$  for each  $(a, i) \in \alpha(k)$  but *not the agent’s type*. We abuse notation and take  $\theta_a(k)$  to be the agent’s state at the beginning of epoch  $k$ . The designer’s objective is to minimize the regret over the finite horizon.

The expected regret of a policy  $\alpha$  is the difference in the expected aggregate reward of a benchmark matching and that of the matching returned by the policy, summed over  $n$  epochs. Owing to its favorable properties (see Section 3), we use the greedy matching on the stationary state rewards as our benchmark. Measuring the regret with respect to the unknown stationary-distribution is standard with MDPs (e.g., see (Gai et al., 2011; Tekin and Liu, 2010, 2012)). Formally, let  $G^*$  denote the output of Algorithm 1 on the instance  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (\mu_{a,i})_{(a,i) \in \mathcal{P}}\}$ —i.e., with the weights  $w(a, i)$  equal the stationary state rewards  $\mu_{a,i}$ .

**Definition 1.** *The expected regret of a policy  $\alpha$  with respect to the greedy matching  $G^*$  is given by*

$$R^\alpha(n) = n \sum_{(a,i) \in G^*} \mu_{a,i} - \sum_{k=1}^n \sum_{(a,i) \in \alpha(k)} \mathbb{E}[\mathbf{r}_{a,i}^{\theta_a(k)}],$$

where the expectation is with respect to the reward and the state of the agents during each epoch.

## 4.1 REGRET DECOMPOSITION

As is usual in this type of analysis, we start by decomposing the regret in terms of the number of selections of each sub-optimal arm (edge). We state some assumptions and define notation before proving our generic regret decomposition theorem. A complete list of the notation used can be found in Section A of the supplementary material.

1. For analytic convenience, we assume that the number of agents and incentives is balanced and therefore,  $|\mathcal{A}| = |\mathcal{I}| = m$ . WLOG, every agent is matched to some incentive in  $G^*$ ; if this is not the case, we can add *dummy incentives* with zero reward.
2. Suppose that  $G^* = \{g_1^*, g_2^*, \dots, g_m^*\}$  such that  $\mu_{g_1^*} \geq \dots \geq \mu_{g_m^*}$  and let  $i^*(a)$  denote the incentive that  $a$  is matched to in  $G^*$ . Let  $L_1^*, \dots, L_m^*$  be the marginal infeasibility sets as defined in (1).
3. Suppose that  $\tau_0 \geq 1$  and  $\tau_k = \tau_0 + \zeta k$  for some non-negative integer  $\zeta$ .

Let  $\mathbb{1}\{\cdot\}$  be the indicator function—e.g.,  $\mathbb{1}\{(a, i) \in \alpha(k)\}$  is one when the edge  $(a, i)$  belongs to the matching  $\alpha(k)$ , and zero otherwise. Define  $T_{a,i}^\alpha(n) = \sum_{k=1}^n \mathbb{1}\{(a, i) \in \alpha(k)\}$  to be the random variable that denotes the number of epochs in which an edge is selected under an algorithm  $\alpha$ . By relating  $\mathbb{E}[T_{a,i}^\alpha(n)]$  to the regret  $R^\alpha(n)$ , we are able to provide bounds on the performance of  $\alpha$ .

By adding and subtracting  $\sum_{(a,i) \in \mathcal{P}} \mathbb{E}[T_{a,i}^\alpha(n)] \mu_{a,i}$  from the equation in Definition 1, we get that

$$\begin{aligned} R^\alpha(n) &= \sum_{(a,i) \in \mathcal{P}} \mathbb{E}[T_{a,i}^\alpha(n)] (\mu_{a,i^*(a)} - \mu_{a,i}) \\ &\quad + \sum_{k=1}^n \sum_{(a,i) \in \mathcal{P}} \mathbb{E}[\mathbb{1}\{(a, i) \in \alpha(k)\} (\mu_{a,i} - \mathbf{r}_{a,i}^{\theta_a(k)})]. \end{aligned}$$

To further simplify the regret, we separate the edges in  $\mathcal{P}$  by introducing the notion of a sub-optimal edge. Formally, for any given  $a \in \mathcal{A}$ , define  $S_a := \{(a, i) \mid \mu_{a,i^*(a)} \geq \mu_{a,i} \forall i \in \mathcal{I}\}$  and  $\mathcal{S} := \bigcup_{a \in \mathcal{A}} S_a$ . Then, the regret bound in the above equation can be simplified by ignoring the contribution of the terms in  $\mathcal{P} \setminus \mathcal{S}$ . That is, since  $\mu_{a,i^*(a)} < \mu_{a,i}$  for all  $(a, i) \in \mathcal{P} \setminus \mathcal{S}$ ,

$$\begin{aligned} R^\alpha(n) &\leq \sum_{(a,i) \in \mathcal{S}} \mathbb{E}[T_{a,i}^\alpha(n)] (\mu_{a,i^*(a)} - \mu_{a,i}) \\ &\quad + \sum_{k=1}^n \sum_{(a,i) \in \mathcal{P}} \mathbb{E}[\mathbb{1}\{(a, i) \in \alpha(k)\} (\mu_{a,i} - \mathbf{r}_{a,i}^{\theta_a(k)})]. \end{aligned} \quad (2)$$

Recall from the definition of the marginal infeasibility sets in (1) that for any given  $(a, i) \in \mathcal{P} \setminus G^*$ , there exists a unique edge  $g_j^* \in G^*$  such that  $(a, i) \in L_j^*$ . Define  $L^{-1}(a, i) := g_j^* \in G^*$  such that  $(a, i) \in L_j^*$ . Now, we can define the reward gap for any given edge as follows:

$$\Delta_{a,i} = \begin{cases} \mu_{a,i^*(a)} - \mu_{a,i}, & \text{if } (a, i) \in \mathcal{S} \\ \mu_{L^{-1}(a,i)} - \mu_{a,i}, & \text{if } (a, i) \in (\mathcal{P} \setminus G^*) \setminus \mathcal{S} \\ \mu_{g_{j-1}^*} - \mu_{g_j^*}, & \text{if } (a, i) = g_j^* \text{ for } j \geq 2 \end{cases}$$

This leads us to our main regret decomposition result which leverages mixing times for Markov chains (Fill, 1991) along with Equation (2) in deriving regret bounds. For an aperiodic, irreducible Markov chain  $P_{a,i}$ , using the notion that it converges to its stationary state under repeated plays of a fixed action, we can prove that for every arm  $(a, i)$ , there exists a constant  $C_{a,i} > 0$  such that  $|\mathbb{E}[\mu_{a,i} - r_{a,i}^{\theta_a^{(k)}}]| \leq C_{a,i}/\tau_k$ —in fact, this result holds for all type distributions  $\beta_a^{(k)}$  of the agent.

**Proposition 1.** *Suppose for each  $(a, i) \in \mathcal{P}$ ,  $P_{a,i}$  is an aperiodic, irreducible Markov chain with corresponding constant  $C_{a,i}$ . Then, for a given algorithm  $\alpha$  where  $\tau_k = \tau_0 + \zeta k$  for some fixed  $\zeta > 0$ , we have that*

$$R^\alpha(n) \leq \sum_{(a,i) \in \mathcal{S}} \mathbb{E}_\alpha [T_{a,i}^\alpha(n)] (\Delta_{a,i} + \frac{C_{a,i}}{\tau_0}) + m \frac{C_{a,i}}{\zeta} (1 + \log(\zeta(n-1)/\tau_0 + 1)).$$

The proof of this proposition is in Section B.2 of the supplementary material.

## 4.2 MG-EUCB ALGORITHM AND ANALYSIS

In the initialization phase, the algorithm computes and plays a sequence of matchings  $M_1, M_2, \dots, M_p$  for a total of  $p$  epochs. The initial matchings ensure that every edge in  $\mathcal{P}$  is selected at least once—the computation of these initial matchings relies on a *greedy covering* algorithm that is described in Section C.1 of the supplementary material. Following this, our algorithm maintains the cumulative empirical reward  $\bar{r}_{a,i}$  for every  $(a, i) \in \mathcal{P}$ . At the beginning of (say) epoch  $k$ , the algorithm computes a greedy matching for the instance  $\{\mathcal{P}, \mathcal{C}, \mathbf{b}, (w(a, i))_{(a,i) \in \mathcal{P}}\}$  where  $w(a, i) = \bar{r}_{a,i}/T_{a,i} + c_{a,i}$ , i.e., the average empirical reward for the edge added to a suitably chosen confidence window. The `INCENT`( $\cdot$ ) function (Algorithm 2, described in the supplementary material since it is a trivial function) plays each edge in the greedy matching for  $\tau_k$  iterations, where  $\tau_k$  increases linearly with  $k$ . This process is repeated for  $n-p$  epochs. Prior to theoretically analyzing MG-EUCB, we return to Example 1 in order to provide intuition for how the algorithm overcomes correlated convergence of rewards.

**Revisiting Example 1:** Why does MG-EUCB work? In Example 1, the algorithm initially estimates the empirical reward of  $(a_1, i_1)$  and  $(a_2, i_2)$  to be zero respectively. However, during the UCB exploration phase, the matching  $M_1 = (a_1, i_1), (a_2, i_2)$  is played again for epoch length  $> 1$  and the state of agent  $a_1$  moves from  $\theta_1$  to  $\theta_2$  during the epoch. Therefore, the algorithm estimates the average reward of each edge within the epoch to be  $\geq 0.5$ , and the empirical reward increases. This continues as the epoch length increases, so that eventually the

empirical reward for  $(a_1, i_1)$  exceeds that of  $(a_1, i_2)$  and the algorithm correctly identifies the optimal matching as we move from exploration to exploitation.

In order to characterize the regret of the MG-EUCB algorithm, Proposition 1 implies that it is sufficient to bound the expected number of epochs in which our algorithm selects each sub-optimal edge. The following theorem presents an upper bound on this quantity.

**Theorem 2.** *Consider a finite set of  $m$  agents  $\mathcal{A}$  and incentives  $\mathcal{I}$  with corresponding aperiodic, irreducible Markov chains  $P_{a,i}$  for each  $(a, i) \in \mathcal{P}$ . Let  $\alpha$  be the MG-EUCB algorithm with mixing time sequence  $\{\tau_k\}$  where  $\tau_k = \tau_0 + \zeta k$ ,  $\tau_0 > 0$ , and  $\zeta > 0$ . Then for every  $(a, i) \in \mathcal{S}$ ,*

$$\mathbb{E}_\alpha [T_{a,i}(n)] \leq \frac{4m^2}{\Delta_{a^*,i^*}^2} \left( \frac{\rho_{a^*,i^*}}{\sqrt{\tau_0}} + \sqrt{6 \log n + 4 \log m} \right)^2 + 2(1 + \log(n))$$

where  $(a^*, i^*) = \operatorname{argmax}_{(a_1, i_1) \in \mathcal{P} \setminus g_1^*} \left[ \frac{4}{\Delta_{a_1, i_1}^2} \left( \frac{\rho_{a_1, i_1}}{\sqrt{\tau_0}} + \sqrt{6 \log n + 4 \log m} \right)^2 \right]$ , and  $\rho_{a,i}$  is a constant specific to edge  $(a, i)$ .

The full proof of the theorem is provided can be found in the supplementary material.

**Proof** (sketch.) There are three key ingredients to the proof: (i) linearly increasing epoch lengths, (ii) overcoming cascading errors, and (iii) application of the Azuma-Hoeffding concentration inequality.

By increasing the epoch length linearly, MG-EUCB ensures that as the algorithm converges to the optimal

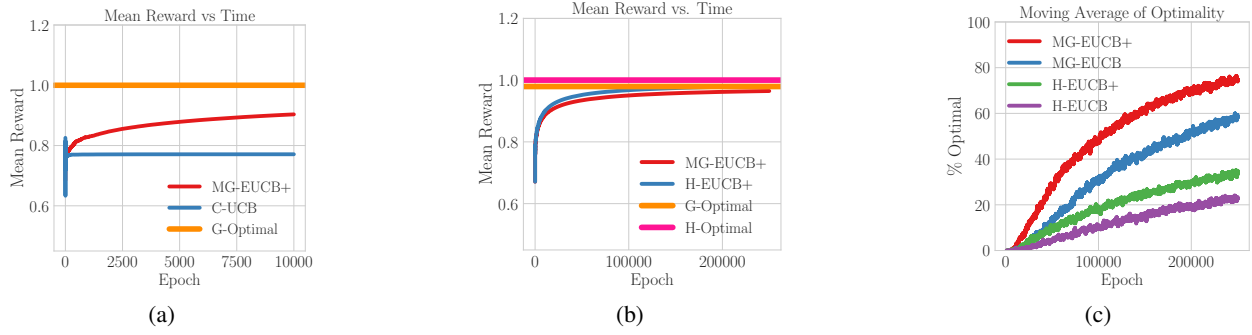

Figure 2: Synthetic Experiments: Comparison of MG-EUCB(+) and H-EUCB(+) to their respective offline solutions (G- and H-optimal, respectively) and to C-UCB (classical UCB). We use the following set up: (i)  $|\mathcal{A}| = |\mathcal{I}| = |\Theta_a| = 10$  (see Supplement D for more extensive experiments) (ii) each state transition matrix  $P_{a,i}$  associated with an arm  $(a, i) \in \mathcal{P}$  was selected uniformly at random within the class of aperiodic and irreducible stochastic matrices; (iii) the reward for each arm, state pair  $r_{a,i}^\theta$  is drawn i.i.d. from a distribution  $\mathcal{T}_r(a, i, \theta)$  belonging to either a Bernoulli, Uniform, or Beta distribution; (iv)  $\tau_0 = 50$  and  $\zeta = 1$ .

matching, it also plays each arm for a longer duration within an epoch. This helps the algorithm to progressively discard sub-optimal arms without selecting them too many times when the epoch length is still small. At the same time, the epoch length is long enough to allow for sufficient mixing and separation between multiple near-optimal matchings. If we fix the epoch length as a constant, the resulting regret bounds are considerably worse because the agent states may never converge to the steady-state distributions.

To address cascading errors, we provide a useful characterization. For a given  $(a, i)$ , suppose that  $u_{a,i}^k(t)$  refers to the average empirical reward obtained from edge  $(a, i)$  up to epoch  $t-1$  plus the upper confidence bound parameter, given that edge  $(a, i)$  has been selected for exactly  $k$  times in epochs 1 to  $t-1$ . For any given epoch  $k$  where the algorithm selects a sub-optimal matching, i.e.,  $\alpha(k) \neq G^*$ , we can apply Lemma 1 and get that at least one of the following conditions must be true:

1.  $\mathbb{1}\{\exists j < j' \mid (u_{g_j^*}^k(t) > u_{g_{j'}^*}^k(t)) \wedge (g_{j'}^* \in \alpha(t))\}$
2.  $\mathbb{1}\{\exists j, (a, i) \in L_j^* \mid (u_{g_j^*}^k(t) < u_{a,i}^k(t)) \vee ((a, i) \in \alpha(k))\} = 1$

This is a particularly useful characterization because it maps the selection of each sub-optimal edge to a familiar condition that compares the empirical rewards to the stationary rewards. Therefore, once each arm is selected for  $O(\log(n))$  epochs, the empirical rewards approach the ‘true’ rewards and our algorithm discards sub-optimal edges. Mathematically, this can be written as

$$\begin{aligned} \mathbb{E}_\alpha[T_{a',i'}(n)] &= 1 + \sum_{t=p+1}^n \mathbb{1}\{(a', i') \in \alpha(t)\} \\ &\leq \ell m^2 + \sum_{j=1}^m \sum_{(a,i) \in L_j^+} \sum_{t=p+1}^n \sum_{s=1}^{t-1} \sum_{k=\ell}^{t-1} ( \\ &\mathbb{1}\{u_{g_j^*}^s(t) \leq u_{a,i}^k(t)\}), \end{aligned}$$

where  $\ell$  is some carefully chosen constant,  $L_j^+ = L_j^* \cup \{g_{j+1}^*\}$  and  $L_m^+ = L_m^*$ .

With this characterization, for each  $s$ , we find an upper bound on the probability of the event  $\{u_{g_j^*}^s(t) \leq u_{a,i}^k(t)\}$ . However, this is a non-trivial task since the reward obtained in any given epoch is *not independent* of the previous actions. Specifically, the underlying Markov process that generates the rewards is common across the edges connected to any given agent in the sense, that the initial distribution for each Markov chain that results from pulling an edge is the distribution at the end of the preceding pull. Therefore, we employ Azuma-Hoeffding (Azuma, 1967; Hoeffding, 1963), a concentration inequality that does not require independence in the arm-based observed rewards. Moreover, unlike the classical UCB analysis, the empirical reward can differ from the expected stationary reward due to the distributions  $\mathcal{T}_r(a, i, \theta)$  and  $\beta_{a,i}^k \neq \pi_{a,i}$ . To account for this additional error term, we use bounds on the convergence rates of Markov chains to guide the choice of the confidence parameter  $c_{a,i}^k(t)$  in Algorithm 2. Applying the Azuma-Hoeffding inequality, we can show that with high probability, the difference between the empirical reward and the stationary reward of edge  $(a, i)$  is no larger than  $c_{a,i}^k(t)$ . ■

As a direct consequence of Proposition 1 and Theorem 2, we get that for a fixed instance, the regret only increases logarithmically with  $n$ .

## 5 EXPERIMENTS

In this section, we present a set of illustrative experiments with our algorithm (MG-EUCB) on synthetic and

Figure 3: Bike-share Experiments: Figures 3a and 3b compare the efficiency (percentage of demand satisfied) of the bike-share system with two demand models under incentive matchings selected by MG-EUCB+ with upper and lower bounds given by the system performance when the incentives are computed via the benchmark greedy matching that uses the state information and when no incentives are offered respectively. In Figure 3c we plot the mean reward of the MG-EUCB+ algorithm with static and random demand which gives the expected number of agents who accept an incentive within each epoch.

real data. We observe much faster convergence with the greedy matching as compared to the Hungarian algorithm. Moreover, as is typical in the bandit literature (e.g., (Auer et al., 2002)), we show that a *tuned* version of our algorithm (MG-EUCB+), in which we reduce the coefficient on the  $\log(n)$  term in the UCB ‘confidence parameter’ from six to three, further improves the convergence of our algorithm. Finally we show that our algorithm can be effectively used as an incentive design scheme to improve the performance of a bike-share system.

## 5.1 SYNTHETIC EXPERIMENTS

We first highlight the failure of classical UCB approaches (C-UCB)—e.g., as in (Gai et al., 2011)—for problems with correlated reward evolution. In Figure 2a, we demonstrate that C-UCB converges almost immediately to a suboptimal solution, while this is not the case for our algorithm (MG-EUCB+). In Figure 2b, we compare MG-EUCB and MG-EUCB+ with a variant of Algorithm 2 that uses the Hungarian method (H-EUCB) for matchings. While H-EUCB does have a ‘marginally’ higher mean reward, Figure 2c reveals that the MG-EUCB and MG-EUCB+ algorithms converge much faster to the optimum solution of the greedy matching than the Hungarian alternatives.

## 5.2 BIKE-SHARE EXPERIMENTS

In this problem, we seek to incentivize participants in a bike-sharing system; our goal is to alter their intended destination in order to balance the spatial supply of available bikes appropriately and meet future user demand. We use data from the Boston-based bike-sharing service Hubway (hub) to construct the example. Formally, we

consider matching each agent  $a$  to an incentive  $i = s'_a$ , meaning the algorithm proposes that agent  $a$  travel to station  $s'_a$  as opposed to its intended destination  $s_a$  (potentially, for some monetary benefit). The agent’s state  $\theta_a$  controls the probability of accepting the incentive by means of a distance threshold parameter and a parameter of a Bernoulli distribution, both of which are drawn uniformly at random. More details on the data and problem setup can be found in Section D of the supplementary material.

Our bike-share simulations presented in Figure 3 show approximately a 40% improvement in system performance when compared to an environment without incentives and convergence towards an upper bound on system performance. Moreover, our algorithm achieves this significant performance increase while on average matching less than 1% of users in the system to an incentive.

## 6 Conclusion

We combine ideas from greedy matching, the UCB multi-armed bandit strategy, and the theory of Markov chain mixing times to propose a bandit algorithm for matching incentives to users, whose preferences are unknown a priori and evolving dynamically in time, in a resource constrained environment. For this algorithm, we derive logarithmic gap-dependent regret bounds despite the additional technical challenges of cascading sub-optimality and correlated convergence. Finally, we demonstrate the empirical performance via examples.

## Abstract

We introduce a new class of sparse multi-prototype classifiers, designed to combine the computational advantages of sparse predictors with the non-linear power of prototype-based classification techniques. This combination makes sparse multi-prototype models especially well-suited for resource constrained computational platforms, such as the IoT devices. We cast our supervised learning problem as a convex-concave saddle point problem and design a provably-fast algorithm to solve it. We complement our theoretical analysis with an empirical study that demonstrates the merits of our methodology.

## 1 INTRODUCTION

As modern machine-learned models become more accurate, they also tend to grow bigger and become more expensive to compute. Deep neural networks, massive decision tree ensembles, and other contemporary machine learning predictors can have hundreds of millions of parameters, resulting in a large memory footprint and a high computational cost. These models become especially prohibitive when the goal is to deploy them on resource impoverished platforms, such as wearable computers or IoT devices (Kumar *et al.*, 2017). Similarly, their high cost makes it difficult to build systems that need to keep track of many different models, such as those that maintain a separate model per user. Unsurprisingly, these issues have fostered a renewed interest in learning models that strike a better balance between accuracy and cost.

Efforts to develop machine learning techniques that

produce more compact models can be broadly bifurcated into two schools of thought. The first approach is to train a large and accurate model topology, and subsequently compress it using an approximation method. Some of these approximation techniques include pruning (Han *et al.*, 2016; Nan *et al.*, 2016; Luo *et al.*, 2017), low-rank matrix approximation (Sainath *et al.*, 2013; Nakkiran *et al.*, 2015), hashing (Chen *et al.*, 2015), and parameter quantization or binarization (Hubara *et al.*, 2016; Han *et al.*, 2016). Another popular technique is to use a large model to generate training data for a smaller model (Bucila *et al.*, 2006).

The second approach incorporates compression more intimately into the training objective. For example, the well-known Lasso (Tibshirani, 1996) and Elastic-Net (Zou & Hastie, 2005) algorithms use a sparsity-inducing regularization term to control the sparsity of a linear model. The resulting sparse predictor relies only on a small subset of the available features, and is therefore economical to store and make predictions. The weakness of these approaches is that linear predictors are typically not expressive enough to achieve state-of-the-art accuracy. Another common idea is to define models that are specified by a small number of prototypes, for example, by learning a Support Vector Machine (SVM) with a small support set (Dekel & Singer, 2007; Dekel *et al.*, 2008), or by finding a compressed set of reference points for a Nearest Neighbor model (Kusner *et al.*, 2014; Zhong *et al.*, 2017; Gupta *et al.*, 2017). A main drawback of these techniques is that they typically require solving highly non-convex optimization problems, which makes it difficult to guarantee their convergence and optimality. Another shortcoming of many of these approaches is that the prototypes that they learn are typically dense.

In this paper, we subscribe to the second approach mentioned above, and address the cost-accuracy

tradeoff by designing the training objective appropriately. Specifically, we introduce a class of models that we call *Sparse Multi-Prototype* (SMP) classifiers. SMP classifiers attempt to combine the sparsity benefits of linear models with the non-linear power of multi-prototype methods. Namely, each class is associated with a small set of prototypes, and each of those prototypes is sparse. But for their sparsity, SMP classifiers are reminiscent of multi-class SVMs (Weston & Watkins, 1999; Crammer & Singer, 2001), and their multi-prototype extensions (Aiolli & Sperduti, 2005).

We formulate the training procedure for SMP classifiers as a convex optimization problem. Specifically, we cast the SMP training problem as a convex-concave saddle point optimization problem and show that this formulation admits fast convergence via a primal-dual proximal point algorithm due to Chambolle and Pock (Chambolle & Pock, 2011, 2016; He *et al.*, 2017; Zhang & Xiao, 2015; Yu *et al.*, 2017). On one hand, our formulation induces sparsity by incorporating a regularization term, similar to the  $\ell_1$  term used in Lasso and Elastic-Net. On the other hand, it controls the number of prototypes using another regularization term, similar to the one used to derive convex formulations of clustering (Hocking *et al.*, 2011) and regression (Feng *et al.*, 2012). Our optimization formulation and algorithm are different from the ones used in these papers.

The rest of the paper is organized as follows. We set up the problem in Section 2. We then show, in Section 3, how our problem can be posed as a saddle point problem that admits fast and provable convergence via the Chambolle-Pock procedure. We present the results of our experiments in Section 4.

## 2 PROBLEM FORMULATION

Let  $\mathcal{Y}$  be a finite set of labels. Suppose that we are given a set of training examples  $\{(x_i, y_i)\}_{i=1}^m$ , where each  $x_i \in \mathbb{R}^n$  and  $y_i \in \mathcal{Y}$ . Without loss of generality, we assume an ordering of the training examples: examples from first class precede those in second, examples from second precede those in third, and so on.

Our goal is to learn a classifier  $c: \mathbb{R}^n \mapsto \mathcal{Y}$ . Assume (without loss of generality) that  $c$  is defined by a set of scoring functions  $\{\phi_y\}_{y \in \mathcal{Y}}$ , where the value  $\phi_y(x)$  is interpreted as the score of predicting the label  $y$  for the instance  $x$ . Using these scoring functions,

our classifier takes the form

$$c(x) = \arg \max_{y \in \mathcal{Y}} \phi_y(x).$$

The classifier  $c(x)$  correctly classifies the example  $(x, y)$  if and only if

$$\phi_y(x) - \max_{y' \neq y} \phi_{y'}(x) > 0. \quad (1)$$

We use this property to define the empirical loss

$$\sum_{i=1}^m \ell \left( \phi_{y_i}(x_i) - \max_{y' \neq y_i} \phi_{y'}(x_i) \right),$$

where  $\ell$  is a convex monotonically non-increasing loss function that upper bounds the error indicator function (for instance,  $\ell$  could be hinge-loss or log-loss). Clearly, this loss is an upper-bound on the number of multiclass classification mistakes.

If we use a linear score function for each class, i.e.,

$$\phi_y(x) = w_y \cdot x, \quad y \in \mathcal{Y},$$

where each  $w_y \in \mathbb{R}^n$  is called a *class prototype*, and  $\cdot$  denotes the inner product of two vectors, then we obtain the multi-class support vector machine (Weston & Watkins, 1999; Crammer & Singer, 2001).

In this paper, we allow multiple prototypes for each class (Aiolli & Sperduti, 2005). Suppose we have in total  $N$  prototypes  $w_1, \dots, w_N \in \mathbb{R}^n$ , and let  $J_y$  be the set of the prototype indices associated with class  $y$  for each  $y \in \mathcal{Y}$ . We let the score function for class label  $y$  be

$$\phi_y(x) = \max_{j \in J_y} w_j \cdot x.$$

Since  $\ell$  is monotonically non-increasing, we have

$$\begin{aligned} & \ell \left( \phi_{y_i}(x_i) - \max_{y' \neq y_i} \phi_{y'}(x_i) \right) \\ &= \ell \left( \max_{j \in J_{y_i}} w_j \cdot x_i - \max_{j \notin J_{y_i}} w_j \cdot x_i \right) \\ &\leq \ell \left( w_{j(i)} \cdot x_i - \max_{j \notin J_{y_i}} w_j \cdot x_i \right) \\ &= \max_{j \notin J_{y_i}} \ell \left( (w_{j(i)} - w_j) \cdot x_i \right), \end{aligned}$$

where  $j(i) \in J_{y_i}$  is any fixed assignment of prototype to the example  $(x_i, y_i)$ . The last expression above is a convex function in all the prototypes  $w_1, \dots, w_N$ , and so is the average loss function

$$\frac{1}{m} \sum_{i=1}^m \max_{j \notin J_{y_i}} \ell \left( (w_{j(i)} - w_j) \cdot x_i \right). \quad (2)$$

Note that  $j(i)$  needs to be fixed before we optimize over the prototypes, but is not required to maximize  $w_j \cdot x_i$  over  $j \in J_{y_i}$ . This relaxation helps us to obtain a convex upper bound on the loss in the general case.

Setting  $N = |\mathcal{Y}|$  and  $|J_y| = 1$  recovers the loss for the multi-class SVM, and we have  $j(i) = \arg \max_{j \in J_{y_i}} w_j \cdot x_i$ . In the other extreme case, we can let  $N = m$  and associate each training example  $(x_i, y_i)$  with a prototype  $w_i$ . In this case, we can have  $\phi_{y_i}(x_i) = w_i \cdot x_i = \arg \max_{j \in J_{y_i}} w_j \cdot x_i$ . However, this approach requires excessive amount of storage and computation, and also may cause significant overfitting.

In practice, we can cluster the training examples in each class into  $p$  groups, where  $p$  is much smaller than the number of examples in the class. Then we can have  $p$  prototypes for each class  $y \in \mathcal{Y}$ , and associate the examples in each cluster within the class with a common prototype:  $j(i) = j(i')$  if  $y_i = y_{i'}$ , and  $x_i$  and  $x_{i'}$  belong to the same cluster.

## 2.1 SMOOTHING THE LOSS

In order to leverage the fast algorithms designed for smooth convex optimization, we focus on smooth loss functions. In particular, we use the log-loss

$$\ell(\alpha) = \log(1 + \exp(-\alpha)).$$

Although this is a smooth function, the average loss function defined in (2) is non-smooth, due to the max operators in the sum. We can make the loss function smooth using the usual trick of softmax. Specifically, we can replace the function  $u(z) = \max_j \ell(z_j)$  with

$$\tilde{u}(z) = \log \left( 1 + \sum_j \exp(-z_j) \right). \quad (3)$$

As a result, the smoothed loss function is

$$f(W) = \frac{1}{m} \sum_{i=1}^m \log \left( 1 + \sum_{j \notin J_{y_i}} \exp((w_j - w_{j(i)}) \cdot x_i) \right), \quad (4)$$

where  $W \in \mathbb{R}^{N \times n}$  is a matrix formed by stacking the vectors  $w_1^T, \dots, w_N^T$  as its rows.

## 2.2 ENFORCING GROUP SPARSITY

Instead of relying on a separate clustering stage to reduce the number of prototypes, we can use a more principled approach based on convex optimization. Suppose we start with a large number of prototypes, for example, by having a separate prototype for each

training example. While minimizing the average loss function, we may add the regularization term

$$\sum_{y \in \mathcal{Y}} \sum_{\substack{j > i \\ i, j \in J_y}} \|w_i - w_j\|_\infty, \quad (5)$$

which encourages some of the prototypes in each class to merge, forming a smaller set of distinct prototypes.

We introduce some notations to simplify our presentation. Let  $W_y \in \mathbb{R}^{|J_y| \times n}$  be the matrix formed by stacking the set of prototypes  $\{w_j^T : j \in J_y\}$  as its rows. For each class  $y \in \mathcal{Y}$ , we form a  $b_y \times |J_y|$  matrix  $B_y$ , where  $b_y = \binom{|J_y|}{2}$ . Specifically, each row of  $B_y$  corresponds to a pair  $(i, j)$  such that  $i < j$  and  $i, j \in J_y$ , with value 1 at index  $i$ , -1 at index  $j$ , and 0 elsewhere. Then the penalty function in (5) can be written as

$$\sum_{y \in \mathcal{Y}} \|B_y W_y\|_{\infty, 1},$$

where the matrix norm  $\|\cdot\|_{\infty, 1}$  is defined as

$$\|U\|_{\infty, 1} = \sum_i \|U_{i, \cdot}\|_\infty = \sum_i \max_{r \in [n]} |U_{i, r}|.$$

Therefore, the regularized loss can be written as

$$f(W) + \lambda \sum_{y \in \mathcal{Y}} \|B_y W_y\|_{\infty, 1},$$

where  $\lambda > 0$  is a regularization parameter and  $f$  is the smoothed average loss defined in (4).

## 2.3 IMPOSING PROTOTYPE SPARSITY

In addition to the group sparsity aimed at having fewer prototypes, we can also induce sparsity in each prototype by adding the following regularization:

$$h_\eta(W_y) \triangleq \|W_y\|_{1, 1} + \frac{\eta}{2} \|W_y\|_F^2,$$

where  $\|\cdot\|_F$  denotes the matrix Frobenius norm and

$$\|U\|_{1, 1} = \sum_i \|U_{i, \cdot}\|_1 = \sum_i \sum_{r \in [n]} |U_{i, r}|.$$

In other words,  $h_\eta$  is an elastic-net type of regularization, where  $\eta$  is a parameter to trade off between the  $\ell_1$  and  $\ell_2$  regularizations.

In summary, we would like to solve the following sparse multi-prototype (SMP) classification problem:

$$\min_W \left\{ f(W) + \lambda \sum_{y \in \mathcal{Y}} \|B_y W_y\|_{\infty, 1} + \mu \sum_{y \in \mathcal{Y}} h_\eta(W_y) \right\}, \quad (6)$$

---

**Algorithm 1** The Chambolle-Pock (CP) Algorithm

---

**input:** parameters  $\tau, \sigma$ , and initial point  $(w^0, v^0)$   
Set  $\bar{w}^0 = w^0$   
**for**  $t = 0, 1, 2, \dots$  **do**  
     $v^{t+1} = \text{prox}_{\sigma g}(v^t + \sigma K \bar{w}^t)$   
     $w^{t+1} = \text{prox}_{\tau h}(w^t - \tau(\nabla f(w^t) + K^T v^{t+1}))$   
     $\bar{w}^{t+1} = 2w^{t+1} - w^t$

---

where  $\lambda, \mu > 0$  are regularization hyperparameters. This is a convex optimization problem. However, due to the complex structure of the regularization terms, it is not clear how to solve this minimization problem directly in an efficient manner (e.g., how to compute the proximal mapping of the group sparsity regularization). In the next section, we tackle this problem using a primal-dual first-order algorithm.

### 3 PRIMAL-DUAL ALGORITHM

Chambolle & Pock (2011, 2016) developed a class of primal-dual first-order algorithms for solving the following form of convex-concave saddle-point problems with bilinear coupling:

$$\min_{w \in \mathbb{R}^d} \max_{v \in \mathbb{R}^{d'}} f(w) + h(w) + \langle Kw, v \rangle - g^*(v), \quad (7)$$

where  $f$  is convex and differentiable, and both  $h$  and  $g^*$  are convex but may be non-differentiable. In particular,  $g^*$  can be considered as the conjugate function of some convex function  $g$ . Here  $K$  is a bilinear coupling matrix of dimension  $d' \times d$ . In addition, it is assumed that the proximal mappings of  $h$  and  $g^*$ ,

$$\begin{aligned} \text{prox}_h(w) &= \arg \min_{u \in \mathbb{R}^d} \left\{ f(u) + \frac{1}{2} \|u - w\|_2^2 \right\}, \\ \text{prox}_{g^*}(v) &= \arg \min_{z \in \mathbb{R}^{d'}} \left\{ g^*(z) + \frac{1}{2} \|z - v\|_2^2 \right\}, \end{aligned}$$

can be computed efficiently. Intuitively, the proximal map  $\text{prox}_h(w)$  looks for a point  $u$  that has a low cost  $f(u)$  and is not too far from  $w$ .

Algorithm 1 shows the CP algorithm (Chambolle & Pock, 2016) for solving the convex-concave saddle-point problem (7). Suppose  $\nabla f$  is Lipschitz continuous with Lipschitz constant  $L_f$ , i.e.,

$$\|\nabla f(u) - \nabla f(w)\|_2 \leq L_f \|u - w\|_2, \quad \forall u, w \in \mathbb{R}^d,$$

and the spectral norm of  $K$  is bounded by  $L$ , i.e.,  $\|K\| \leq L$ . Chambolle & Pock (2016) showed that this algorithm enjoys an  $O(1/t)$  convergence rate (the reduction of optimization error after  $t$  iterations) provided that the step size parameters  $\sigma$  and

$\tau$  satisfy the condition

$$\left( \frac{1}{\tau} - L_f \right) \frac{1}{\sigma} \geq L^2. \quad (8)$$

In the rest of this section, we show how to transform the SMP problem (6) into the form of (7), and how to compute the relevant proximal mappings as well as choose the step sizes.

#### 3.1 SADDLE-POINT FORMULATION

Let  $g(U) = \|U\|_{\infty,1}$ , and let  $\langle U, V \rangle$  denote the inner product between the two matrices, i.e.,  $\langle U, V \rangle = \text{Tr}(U^T V)$ . The conjugate function of  $g$  is defined as

$$g^*(V) = \max_U \{ \langle U, V \rangle - g(U) \} = \begin{cases} 0 & \text{if } \|V\|_{1,\infty} \leq 1 \\ +\infty & \text{otherwise,} \end{cases}$$

where  $\|V\|_{1,\infty} = \max_i \|V_i, \cdot\|_1 = \max_i \sum_j |V_{i,j}|$  is the dual norm of  $\|\cdot\|_{\infty,1}$ . We replace the group sparsity regularizations  $g_y(B_y W_y) = \|B_y W_y\|_{\infty,1}$  in (6) by

$$\max_{V_y} \{ \langle B_y W_y, V_y \rangle - g_y^*(V_y) \},$$

which yields the convex-concave saddle-point problem

$$\begin{aligned} \min_W \max_V \left\{ f(W) + \mu \sum_{y \in \mathcal{Y}} h_\eta(W_y) \right. \\ \left. + \lambda \sum_{y \in \mathcal{Y}} \left( \langle B_y W_y, V_y \rangle - g_y^*(V_y) \right) \right\}. \quad (9) \end{aligned}$$

Here the subscript  $y$  in  $g_y$  and  $g_y^*$  indicates that their arguments may have different dimensions; more specifically,  $V_y \in \mathbb{R}^{b_y \times n}$  with  $b_y = \binom{|J_y|}{2}$ . With some delicate vectorization of the matrix variables, we can put the formulation from (9) in the exact form of (7).

Without loss of generality, let the multi-class labels be  $\{1, 2, \dots, |\mathcal{Y}|\}$ . Denote by  $\text{vec}(A)$  the column vector formed by stacking the columns of matrix  $A$  on top of one another. By a slight abuse of notation, we define

$$\text{vec}(W) \triangleq [\text{vec}(W_1^\top)^\top \text{vec}(W_2^\top)^\top \dots \text{vec}(W_{|\mathcal{Y}|}^\top)^\top]^\top.$$

Note that  $\text{vec}(W) \in \mathbb{R}^{Nn}$ , where  $N$  is the total number of prototypes. Likewise, we form  $\text{vec}(V) \in \mathbb{R}^{bn}$ , where  $b \triangleq \sum_{y \in \mathcal{Y}} b_y$ , by concatenating the vectorizations of  $\{V_y\}$ . Let  $I_d$  and  $0_d$  be, respectively, the identity matrix and the zero matrix of order  $d$ . Let  $\mathbf{1}_d$  be a  $d$ -dimensional vector with all coordinates set to 1. We use  $A_1 \otimes A_2$  to denote the Kronecker

product of any two vectors or matrices  $A_1$  and  $A_2$ . Finally, we represent the  $k^{\text{th}}$  standard basis in  $\mathbb{R}^{|\mathcal{Y}|}$  by  $e_k$ , i.e.,  $e_k$  has coordinate  $k$  set to 1 and all the others set to 0.

With the above notations, and letting  $\tilde{w} = \text{vec}(W)$  and  $\tilde{v} = \text{vec}(V)$ , we can show that the saddle-point problem in (9) can be expressed as

$$\min_{\tilde{w} \in \mathbb{R}^{Nn}} \min_{\tilde{v} \in \mathbb{R}^{bn}} \tilde{f}(\tilde{w}) + \langle \tilde{B}\tilde{w}, \tilde{v} \rangle - \tilde{g}^*(\tilde{v}),$$

with appropriate definitions of  $\tilde{f}$ ,  $\tilde{B}$  and  $\tilde{g}^*$ . First, we have (with some tedious algebra)

$$\lambda \sum_{y \in \mathcal{Y}} \langle B_y W_y, V_y \rangle = \langle \tilde{B}\tilde{w}, \tilde{v} \rangle,$$

where

$$\tilde{B} \triangleq \left( \sum_{k=1}^{|\mathcal{Y}|} e_k e_k^\top \otimes B_k \right) \otimes \lambda I_n. \quad (10)$$

We define  $\text{abs}(z) \triangleq [|z_1|, |z_2|, \dots, |z_k|]$  for any vector  $z \in \mathbb{R}^k$ . We note that  $\sum_{y \in \mathcal{Y}} \lambda g_y^*(V_y)$  is finite (when it is 0) only if  $g_y^*(V_y) = 0$ , i.e. only if  $\|V_y\|_{1,\infty} \leq 1$ , for all  $y \in \mathcal{Y}$ . Moreover, for  $\lambda$  finite and positive, we have  $\lambda g_y^*(V_y) = g_y^*(V_y)$ . This lets us define

$$\tilde{g}^*(\tilde{v}) \triangleq g^*(C_g \text{abs}(\tilde{v})), \quad \text{where}$$

$$C_g = \sum_{k=1}^{|\mathcal{Y}|} e_k e_k^\top \otimes \mathbb{1}_n^\top$$

is a block diagonal matrix with  $|\mathcal{Y}|$  blocks each equal to  $\mathbb{1}_n^\top$ , and  $g^*(z) = 0$  if  $z_k \in [-1, 1]$  for all  $k \in \{1, \dots, |\mathcal{Y}|\}$  and  $\infty$  otherwise.

Finally, we can write the smoothed loss function  $f(W)$  defined in (4) as

$$f(W) = \tilde{f}(\tilde{w}) = \frac{1}{m} \sum_{i=1}^m \tilde{u}(A_i \tilde{w}), \quad (11)$$

where  $\tilde{u}$  is the soft-max function defined in (3), and

$$A_i = C_i (I_N \otimes x_i^\top).$$

Here  $C_i$  is a matrix with  $(N - |J_{y_i}|)$  rows and  $N$  columns. Each row of  $C_i$  corresponds to some  $j \notin J_{y_i}$ , with its  $j(i)$ th coordinate being 1,  $j$ th coordinate being  $-1$ , and all the other coordinates being 0.

### 3.2 BOUNDS ON THE LIPSCHITZ CONSTANTS

In order to choose the step sizes  $\sigma$  and  $\tau$  in the CP algorithm appropriately, we need to estimate the two parameters  $L_f$  and  $L$  that appeared in (8). First, we give an upper bound on  $L_f$ .

**Proposition 1.** *The Lipschitz constant  $L_f$  of  $\nabla \tilde{f}(\tilde{w})$  defined in (11) is bounded as*

$$L_f \leq NR^2,$$

where  $N$  is the total number of prototypes and  $R$  is an upper bound on  $\|x_i\|$  for all  $i = 1, \dots, m$ .

*Proof.* We derive the desired result by bounding the spectral norm of the Hessian matrix of  $\tilde{f}$  defined in (11). It is sufficient to consider the Hessian of each  $\tilde{u}(A_i \tilde{w})$ , which can be written as

$$H_i = A_i^\top \nabla^2 \tilde{u}(A_i \tilde{w}) A_i.$$

It is not hard to check that  $\nabla^2 \tilde{u}(A_i \tilde{w}) \preceq I$ , i.e., the matrix  $I - \nabla^2 \tilde{u}(A_i \tilde{w})$  is positive semidefinite for any  $\tilde{w}$ . Therefore we have

$$H_i \preceq A_i^\top A_i = (I_N \otimes x_i^\top)^\top C_i^\top C_i (I_N \otimes x_i^\top).$$

In terms of their spectral norm, we have

$$\|H_i\| \leq \|C_i^\top C_i\| \|I_N \otimes x_i^\top\|^2. \quad (12)$$

If  $\|x_i\|_2 \leq R$ , then we have  $\|I_N \otimes x_i^\top\| \leq R$ .

It remains to bound  $\|C_i^\top C_i\|$ , which is the same as  $\|C_i C_i^\top\|$ . By construction of  $C_i$  at the end of Section 3.1, we have

$$C_i C_i^\top = I_{d_i} + \mathbb{1}_{d_i} \mathbb{1}_{d_i}^\top$$

where  $d_i = N - |J_{y_i}|$ . Therefore we have

$$\|C_i^\top C_i\| = \|C_i C_i^\top\| = N - |J_{y_i}| + 1 \leq N.$$

Combining with (12), we conclude that  $\|H_i\| \leq NR^2$ . Finally, since  $\|\nabla^2 \tilde{f}(\tilde{w})\| \leq (1/m) \sum_{i=1}^m \|H_i\|$ , we obtain the desired result.  $\square$

Next we derive the precise value of  $L = \|\tilde{B}\|$ .

**Proposition 2.** *The singular values of the matrix  $\tilde{B}$  defined in (10) belong to the set*

$$\left\{ \lambda \sqrt{|J_1|}, \dots, \lambda \sqrt{|J_{|\mathcal{Y}|}|}, 0 \right\}.$$

Therefore, the spectral norm of  $\tilde{B}$  is

$$L = \max_{k=1, \dots, |\mathcal{Y}|} \lambda \sqrt{|J_k|}.$$

*Proof.* We first claim that  $B_k$  has two distinct singular values, viz.,  $\sqrt{|J_k|}$  (with multiplicity  $|J_k| - 1$ ) and 0 (with multiplicity 1). We invoke a characterization of the singular values in terms of the eigen decomposition of positive semidefinite matrix  $B_k^\top B_k \in \mathbb{R}^{|J_k| \times |J_k|}$  to argue for the full spectrum of  $B_k$ . Specifically, if  $\eta^2$  is an eigenvalue of the matrix  $B_k^\top B_k$ , then  $\eta$  is a singular value of  $B_k$ .

Now note that  $B_k^\top B_k$  has all the off-diagonal coordinates equal to -1 and all the diagonal coordinates equal to  $|J_k| - 1$ . This is precisely the Laplacian of the complete graph with  $|J_k|$  nodes, which is known to have the eigenvalue  $|J_k|$  with multiplicity  $|J_k| - 1$  and 0 with multiplicity one. This completes the analysis for the spectrum of  $B_k$ .

Next, we note the term within the parentheses in the definition of  $\tilde{B}$  is a block diagonal matrix with blocks  $B_1, \dots, B_{|\mathcal{Y}|}$ , and therefore, the set of the singular values of this set is simply the union of the singular values of each block, i.e., the set  $\{\sqrt{|J_1|}, \dots, \sqrt{|J_{|\mathcal{Y}|}|}, 0\}$ . Finally, the distinct singular values of  $\tilde{B}$  are  $\{\lambda\sqrt{|J_1|}, \dots, \lambda\sqrt{|J_{|\mathcal{Y}|}|}, 0\}$ , since  $\lambda$  is the unique singular value (multiplicity  $n$ ) of the matrix  $\lambda I_n$ . This follows since every singular value  $\mu_{12}$  of  $A_1 \otimes A_2$  can be expressed as the product of singular values  $\mu_1$  of  $A_1$  and  $\mu_2$  of  $A_2$ .  $\square$

We can rewrite the condition in (8) as

$$\tau \leq \frac{1}{L_f}, \quad \frac{\sigma\tau}{1 - \tau L_f} L^2 \leq 1.$$

Given the bounds for  $L_f$  and  $L$  derived in Proposition 1 and Proposition 2, we can choose the step sizes  $\tau$  and  $\sigma$  to satisfy the conditions above, which lead to  $O(1/t)$  convergence of the CP algorithm. For example, if we start with  $p$  prototypes for each class, then  $|J_k| = p$  for  $k \in \{1, \dots, |\mathcal{Y}|\}$  and  $N = p|\mathcal{Y}|$ . Therefore we have  $L_f \leq p|\mathcal{Y}|R^2$  and  $L^2 = \lambda^2 p$ , and can choose

$$\tau = \frac{1}{2pR^2|\mathcal{Y}|}, \quad \sigma \leq \frac{1}{2\lambda^2 p \tau}.$$

We note that the bound on  $L_f$  can be very loose. Some trial-and-error for tuning the step sizes is expected in practice.

### 3.3 COMPUTING PROXIMAL MAPS

We denote the sign of a real number  $p$  by  $\text{sign}(p) \in \{0, \pm 1\}$ , and the positive part  $\max(0, p)$  by  $(p)_+$ . For clarity of presentation, in this section, we use  $A(i, j)$  to denote the entry of the matrix  $A$  at the  $i$ th row

and  $j$ th column. Our next result shows that the Chambolle-Pock (CP) update for each  $W_y$ ,  $y \in \mathcal{Y}$ , can be computed via a closed form expression.

**Proposition 3.** *The CP update rule for  $W_y$  is*

$$W_y^{t+1}(i, j) = \frac{\text{sign}(U_y^t(i, j))}{\mu\tau\eta + 1} (|U_y^t(i, j)| - \mu\tau)_+,$$

where  $U_y^t \triangleq W_y^t - \tau(\nabla_y f(W^t) + \lambda B_y^\top V_y^{t+1})$ .

*Proof.* In the CP algorithm, the matrix  $W_y$  is updated as

$$W_y^{t+1} = \text{prox}_{\mu\tau h_\eta}(W_y^t - \tau(\nabla_y f(W^t) + \lambda B_y^\top V_y^{t+1})),$$

where  $\nabla_y f(W^t)$  denotes the partial gradient of  $f$  with respect to  $W_y$  at the previous iterate  $W^t$ . We can equivalently write the above proximal mapping as

$$W_y^{t+1} = \underset{Z}{\text{argmin}} \left\{ h_\eta(Z) + \frac{1}{2\mu\tau} \|Z - U_y^t\|_F^2 \right\}. \quad (13)$$

Since  $W_y^{t+1}$  is optimal for the above minimization problem, the (sub-)gradient of the corresponding objective function must vanish. Recall that

$$h_\eta(W_y) = \|W_y\|_{1,1} + (\eta/2) \|W_y\|_F^2.$$

The optimality condition for (13) means that there exists  $Z(i, j) \in \partial|W_y^{t+1}(i, j)|$  such that

$$Z(i, j) + \eta W_y^{t+1}(i, j) + \frac{1}{\mu\tau} (W_y^{t+1}(i, j) - U_y^t(i, j)) = 0.$$

When  $W_y^{t+1}(i, j) = 0$ , we have  $\partial|W_y^{t+1}(i, j)| \in [-1, 1]$ , which implies  $|U_y^t(i, j)| \leq \mu\tau$ . Otherwise, we have  $\partial Z^*(i, j) = \text{sign}(Z^*(i, j))$ , whence

$$|U_y^t(i, j)| > \mu\tau \text{ and } \text{sign}(Z^*(i, j)) = \text{sign}(U_y^t(i, j)).$$

So, we can perform soft thresholding to obtain  $Z^*$ , i.e.  $W_y^{t+1}$ , for all cases, and it turns out as claimed.  $\square$

We next derive an expression for updating  $V_y$ .

**Proposition 4.** *The CP update rule for  $V_y$  is*

$$V_y^{t+1} = \underset{\|Z\|_{1,\infty} \leq 1}{\text{arg min}} \frac{1}{2} \|Z - (V_y^t + \lambda \sigma_t B_y \bar{W}_y^t)\|_F^2.$$

*Proof.* Since the empirical loss term and the sparsity term depend only on  $W$ , the update rule for  $V_y$  is

$$V_y^{t+1} = \underset{Z}{\text{arg max}} \left\{ \lambda (\langle B_y \bar{W}_y^t, Z \rangle - g_y^*(Z)) - \frac{1}{2\sigma} \|Z - V_y^t\|_F^2 \right\}.$$

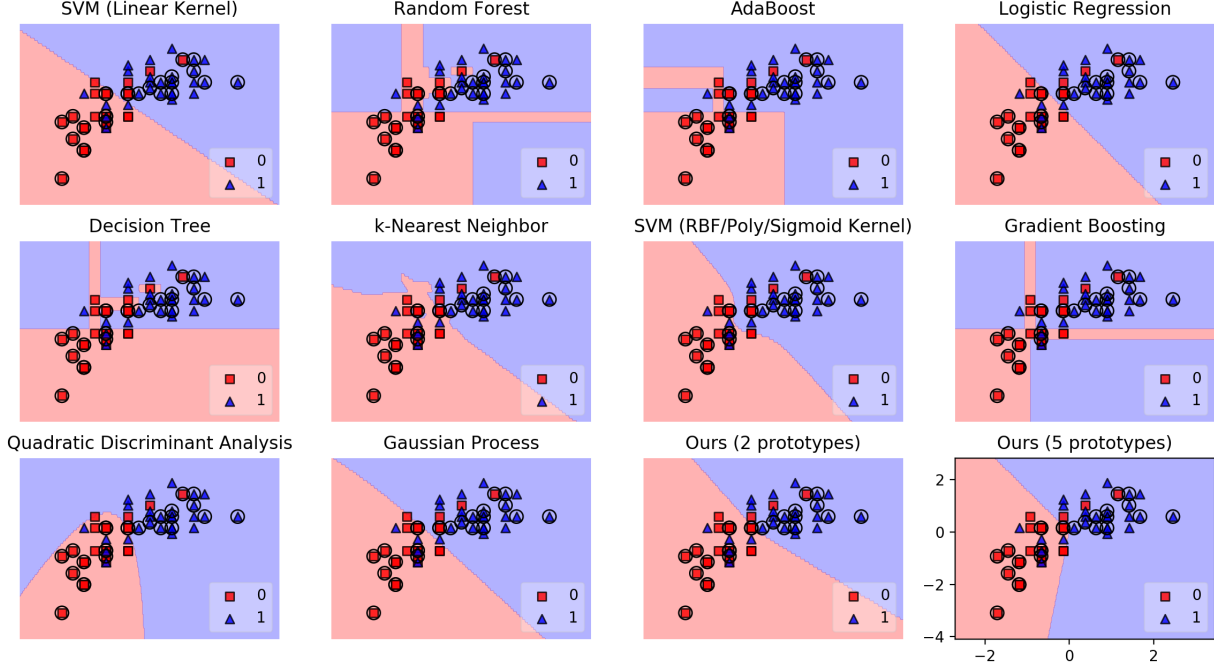

Figure 1: **Visual comparison of the decision boundary of classifiers on a run of the vineyard dataset.** The instances for two classes are shown in red and blue, with the test data, additionally, encircled.

We note that

$$\begin{aligned}
& \lambda(\langle B_y \bar{W}_y^t, Z \rangle - g_y^*(Z)) - \frac{1}{2\sigma} \|Z - V_y^t\|_F^2 \\
&= -\lambda g_y^*(Z) - \frac{1}{2\sigma} \left( \|Z - V_y^t\|_F^2 - 2\sigma \lambda \langle B_y \bar{W}_y^t, Z \rangle \right) \\
&= -\lambda g_y^*(Z) - \frac{1}{2\sigma} \|Z - (V_y^t + \sigma \lambda B_y \bar{W}_y^t)\|_F^2.
\end{aligned}$$

Since  $g_y^*(Z)$  is the indicator function of the unit norm ball  $\|Z\|_{1,\infty}$ , i.e.,  $g_y^*(Z) = 0$  if  $\|Z\|_{1,\infty} \leq 1$  and  $\infty$  otherwise, we have  $V_y^{t+1}$

$$\begin{aligned}
&= \operatorname{argmin}_Z \left\{ \lambda g_y^*(Z) + \frac{1}{2\sigma} \|Z - (V_y^t + \sigma \lambda B_y \bar{W}_y^t)\|_F^2 \right\} \\
&= \operatorname{argmin}_{\|Z\|_{1,\infty} \leq 1} \frac{1}{2} \|Z - (V_y^t + \lambda \sigma_t B_y \bar{W}_y^t)\|_F^2,
\end{aligned}$$

which is what we set out to prove.  $\square$

Using the results of Propositions 3 and 4, we arrive at the customized CP algorithm in Algorithm 2 for solving the SMP problem. For the updates on  $V_y$ , we can compute  $V_y^{t+1}$  by projecting independently the rows of  $(V_y^t + \sigma \lambda B_y \bar{W}_y^t)$  on the  $\ell_1$  unit ball. This can be done efficiently (Brucker, 1984; Pardalos & Kovoor, 1990; Duchi *et al.*, 2008).

## 4 EXPERIMENTS

We conducted several experiments<sup>1</sup> to substantiate the benefits of our framework. Our experiments are designed to convey two salient aspects of our approach. First, we attempt to position our method as an alternative to the standard classification algorithms. Second, we underscore the aptness of our approach as a viable means to obtaining highly sparse yet accurate representations. Before we dive into the details, we provide some visual intuition to differentiate our method from the other models.

We consider the following classifiers for the pictorial depiction: linear SVM (LSVM), SVM with a non-linear kernel (RSVM) selected from radial basis function, polynomial, and sigmoid via cross validation, Logistic Regression (LR), Decision Trees (DT), Random Forest (RF),  $k$ -Nearest Neighbor (kNN), Gaussian Process (GP), Gradient Boosting (GB), AdaBoost (AB), and Quadratic Discriminant Analysis (QDA). Our baselines are popular in the machine learning literature, have varying degrees of

<sup>1</sup>All our experiments used the average loss function from (2) in Algorithm 2 directly (i.e. without any smoothing), and we set  $T = 200$ .

Table 1: Comparison of test accuracy of the different classification algorithms on low dimensional OpenML datasets. The number of prototypes per class for the proposed algorithm, i.e. SMP, was set to 2.

(non-)linearity, and include models from both the generative and the discriminative families.

Fig. 1 shows the decision boundaries obtained by the different classifiers on the vineyard data. The two classes are depicted in red and blue. The test data have been encircled to distinguish them from the

training instances. We observe that, on this problem, the different instantiations of our model provide a better separation of the two classes compared to the other models. For instance, both the linear classifiers, i.e. Logistic Regression and SVM with linear kernel, seem to underfit the data. On the other hand, the SMP models are able to carve out good decision boundaries. We further observe that our model trained with five prototypes performs better than that trained with two on this data. However, this phenomenon does not hold in general, since having multiple prototypes might lead to overfitting, especially in small datasets, for low values of  $\lambda$ .

#### 4.1 LOW-DIMENSIONAL REGIME (NO SPARSITY)

We found that the SMP performed very well on several low-dimensional (i.e.  $n \leq 20$ ) OpenML datasets.<sup>2</sup> We now describe the results of our experiments with these datasets. We preprocessed all the data to normalize each feature to have zero mean and unit variance. We split each dataset evenly into train and test sets using random partitioning. For SMP, we clustered the training examples in each class into  $p = 2$  clusters using  $k$ -means, and initial-

<sup>2</sup>Available at <https://www.openml.org/>

Figure 2: **Comparison on high dimensional OpenML datasets.** Each stacked bar shows two numbers: average test accuracy on the left, and total number of selected features (including multiplicities) on the right.

ized the class prototypes with the cluster centers. We followed 5-fold cross-validation (CV) for each method to obtain a good setting of hyperparameters. The details are given in the Supplementary. We report the average test accuracy and standard deviation over five random partitions per dataset.

The results on test accuracy are documented in Table 1. Evidently, SMP is seen to perform very well on many of these datasets. Note that these results should not be misconstrued as implying that SMP would generally work well with arbitrary data. Indeed, we discovered that the performance of SMP was suboptimal on many other datasets, where algorithms like RSVM and GB performed much better due to highly non-linear structure in the data.

## 4.2 HIGH-DIMENSIONAL REGIME

In this section, we explicate the results of our experiments on high dimensional data, where feature selection becomes especially critical. Our objective is to demonstrate the efficacy of SMP in recovering discriminative sparse features.

We first describe the experimental setup. We compare SMP with six baselines that induce sparsity by minimizing an  $\ell_1$ -regularized loss function (Bach *et al.*, 2012). These baselines minimize a regularized empirical loss function, namely hinge loss, log loss, or the binary-classification Huber loss, where

the regularization consisted of either  $\ell_1$  or elastic net penalty (i.e. both  $\ell_1$  and  $\ell_2$  terms). We call these six baselines as L1Hi ( $\ell_1$ , hinge), L1L ( $\ell_1$ , log), L1Hu ( $\ell_1$ , Huber), ENHi (elastic net, hinge), ENL (elastic net, log) and ENHu (elastic net, huber) respectively.

The amount of sparsity achieved by different baselines at any fixed penalty is method specific. Therefore, we first observed the sparsity obtained with SMP on each method, and then modulated the  $\ell_1$  penalty for other methods to have roughly the same number of selected features. Then, we retrained these classifier using only the selected features, using the same loss (hinge, loss, or log) and an additional  $\ell_2$  penalty. Our procedure ensured that each baseline benefited, in effect, from an *elastic net*-like regularization while having the most important features at its disposal. We followed 5-fold CV to find a good setting of hyperparameters for each method.

Our results on several high dimensional OpenML datasets are summarized in Fig. 2. The first number in the name of a dataset represents the number of instances in the dataset, while the second term represents dimensionality. In SMP, since some features might be selected in more than one prototype, for fairness of evaluation, we included the multiplicity while computing the selected feature count. These results underscore the merits in combining the power of multiple prototypes with sparse representations.

## Abstract

Recent stochastic quadrature techniques for undirected graphical models rely on near-minimax degree- $k$  polynomial approximations to the model’s potential function for inferring the partition function. While providing desirable statistical guarantees, typical constructions of such approximations are themselves not amenable to efficient inference. Here, we develop a class of Monte Carlo sampling algorithms for efficiently approximating the value of the partition function, as well as the associated pseudo-marginals. More precisely, for pairwise models with  $n$  vertices and  $m$  edges, the complexity can be reduced from  $\mathcal{O}(d^k)$  to  $\mathcal{O}(k^4 + kn + m)$ , where  $d \geq 4m$  is the parameter dimension. We also consider the uses of stochastic quadrature for the problem of maximum-likelihood (ML) parameter estimation. For completely observed data, our analysis gives rise to a probabilistic bound on the log-likelihood of the model. Maximizing this bound yields an approximate ML estimate which, in analogy to the moment-matching of exact ML estimation, can be interpreted in terms of pseudo-moment-matching. We present experimental results illustrating the behavior of this approximate ML estimator.

## 1 INTRODUCTION

The major source of complexity in the course of parameter estimation for undirected graphical models is the #P-hardness of the partition function (Valiant, 1979; Bulatov and Grohe, 2004). This quantity plays a fundamental role in various contexts, including approximate inference, maximum-likelihood (ML) parameter estimation, and large deviations analysis—to mention just a

few. For a general undirected model, exact computation of this partition function is intractable; therefore, developing approximations and bounds is an important problem. The dominant approaches in this area are Markov Chain Monte Carlo (MCMC) sampling approaches (Andrieu et al., 2003) and variational inference (Wainwright and Jordan, 2008). While both directions work very well in practice, theoretical quality guarantees cannot be asserted. Some of the existing techniques indeed deliver error bounds, but the error cannot be quantified without making assumptions that go beyond the ordinary variational principle or sampling procedures.

Our recent stochastic quadrature technique (Piatkowski and Morik, 2016) for undirected graphical models relies on a near-minimax degree- $k$  polynomial approximation to the model’s potential function for inferring the partition function. While providing desirable statistical guarantees, typical constructions of such approximations are themselves not amenable to efficient inference. Here, we develop a class of Monte Carlo sampling algorithms for efficiently approximating the value of the partition function, as well as the associated pseudo-marginals.

Our contributions can be summarized as follows:

- We provide a Monte Carlo sampling procedure that reduces the complexity of the stochastic quadrature inference method from  $\mathcal{O}(d^k)$  to  $\mathcal{O}(k^4 + kn + m)$  when certain combinatorial quantities are precomputed. An empirical evaluation shows that our new method is several orders of magnitude faster than the existing approach.
- We provide the first stochastic quadrature based algorithm for marginal inference, and thus, for approximate maximum-likelihood parameter estimation. Experimental results show that approximate log-likelihood and predicted marginal probabilities are close to their exact counterparts.
- We explain how the stochastic quadrature can be ap-

plied to models with continuous random variables.

- Our results are derived from first-principles and work with any discrete and some continuous exponential family members.

## 2 NOTATION AND BACKGROUND

Let us summarize the notation and background necessary for subsequent development. The set that contains the first  $n$  strictly positive integers is denoted by  $[n] = \{1, 2, \dots, n\}$ .

**Graphical Models:** An undirected graph  $G = (V, E)$  consists of  $n = |V|$  vertices, connected via edges  $(v, w) \in E$ . For each vertex  $v \in V$ , we denote the set of adjacent vertices by  $\mathcal{N}(v)$ . A clique  $C$  is a fully-connected subset of vertices, i.e.,  $\forall v, w \in C : (v, w) \in E$ . The set of all cliques of  $G$  is denoted by  $\mathcal{C}$ . Here, any undirected graph represents the conditional independence structure of an undirected graphical model or Markov random field (MRF). To this end, we identify each vertex  $v \in V$  with a random variable  $\mathbf{X}_v$  taking values in the state space  $\mathcal{X}_v$ . The random vector  $\mathbf{X} = (\mathbf{X}_v : v \in V)$  contains the joint state of all vertices in some arbitrary but fixed order, taking values  $\mathbf{x}$  in the Cartesian product space  $\mathcal{X} = \bigotimes_{v \in V} \mathcal{X}_v$ . Moreover, we allow to access these quantities for any proper subset of variables  $S \subset V$ , i.e.,  $\mathbf{X}_S = (\mathbf{X}_v : v \in S)$ ,  $\mathbf{x}_S$ , and  $\mathcal{X}_S$ , respectively.

**Exponential Families:** Markov random fields with strictly positive density can be represented via exponential family members, which have been studied extensively during the last century, e.g. (Pitman, 1936; Hammersley and Clifford, 1971; Besag, 1975; Wainwright and Jordan, 2008). The probability density of  $\mathbf{X}$  w.r.t. some probability measure  $\mathbb{P}_\theta$  can hence be written as

$$p_\theta(\mathbf{x}) = \exp(\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle - A(\boldsymbol{\theta})) \quad (1)$$

where  $\boldsymbol{\theta} \in \mathbb{R}^d$  is the  $d$ -dimensional parameter vector, and  $\phi(\mathbf{x})$  is a statistic, sufficient for  $\boldsymbol{\theta}$ —it captures all properties of  $\mathbf{X}$  which are relevant for inferring  $\boldsymbol{\theta}$ , i.e.,  $\mathbb{P}(\boldsymbol{\theta} \in \Omega \mid \phi(\mathbf{x})) = \mathbb{P}(\boldsymbol{\theta} \in \Omega \mid \mathbf{x})$  for all  $\Omega \subseteq \mathbb{R}^d$ . Normalization of  $p_\theta$  is guaranteed via  $A(\boldsymbol{\theta}) = \ln Z(\boldsymbol{\theta}) = \ln \int_{\mathcal{X}} \exp(\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle) d\nu(\mathbf{x})$  w.r.t. some base measure  $\nu$ . Different base measures allow for either discrete or continuous random variables  $\mathbf{X}$  (Wainwright and Jordan, 2008). When  $\mathcal{X}$  is discrete, the statistic  $\phi(\mathbf{x})$ , given via  $\phi(\mathbf{x})_{C=\mathbf{y}} = \prod_{v \in V} \delta_{\{\mathbf{x}_C=\mathbf{y}\}}$  with  $\mathbf{y} \in \mathcal{X}_C$ , is always sufficient for  $\boldsymbol{\theta}$ . Here,  $\delta_{\{\text{expression}\}}$  is the indicator function that evaluates to 1 if and only if the expression is true, and 0 otherwise. Note that each dimension of  $\phi$ ,

say  $\phi(\mathbf{x})_i$ , corresponds to  $\phi(\mathbf{x})_{C=\mathbf{y}}$ . That is, we have an equivalence between indices  $i \in [d]$  and pairs of clique  $C \in \mathcal{C}$  and clique-state  $\mathbf{y} \in \mathcal{X}_C$ , in short:  $i \equiv (C, \mathbf{y})$ . Thus, we have  $d = \sum_{C \in \mathcal{C}} |\mathcal{X}_C|$  dimensions in total. This kind of sufficient statistic is also called *overcomplete*. In various applications (Ising, 1925; Sutton and McCallum, 2011), the dimensionality of the model is reduced by assuming a pairwise factorization. Only cliques of size  $\leq 2$  are considered in this case, which implies  $d \leq \sum_{v \in V} |\mathcal{X}_v| + \sum_{\{v, w\} \in E} |\mathcal{X}_v| |\mathcal{X}_w|$ .

**Quadrature:** Whenever integrating a function  $f$  is not tractable, one may resort to numerical methods in order to approximate the definite integral  $\mathcal{I}[f] = \int_l^u f(z) dz$ . A different way of performing numeric integration are general quadrature rules. There, the basic idea is to replace the integrand  $f$  by an approximation  $h \approx f$ , that admits tractable integration. It turns out, that choosing  $h = h_k$  to be a degree- $k$  Chebyshev polynomial approximation of  $f$ , delivers highly accurate results, due to the equioscillation property implied by near-minimax optimality. The general quadrature procedure can be summarized as

$$\int_l^u f(x) dx \approx \int_l^u h_k(x) dx = \sum_{i=0}^k w_i f(x_i) = \mathcal{I}_k[f]$$

where  $w_i$  are certain coefficients and  $x_i$  are certain abscissae in  $[l, u]$  (all to be determined) (Mason and Handscomb, 2002).

In general, any polynomial approximation works. It can be shown that an optimal (w.r.t. the  $l_p$ -norm) degree- $k$  polynomial approximation  $h_k$  of any function  $f$  on a fixed interval  $[l, u]$  always exists and is uniquely characterized by the equioscillation property (Mason and Handscomb, 2002). That is, the error function  $E(z) = f(z) - h_k(z)$  oscillates on  $[l, u]$  and has exactly  $k + 2$  extrema (Jr., 1966).

Due to their oscillation property, Chebyshev polynomials are an important building block in the construction and analysis of minimax optimal approximations. Chebyshev polynomials are specified by the fundamental recurrence relation

$$T_0(z) = 1, T_1(z) = z, T_k(z) = 2zT_{k-1}(z) - T_{k-2}(z).$$

They have an extraordinary large variety of convenient properties, like rapidly decreasing and individually converging coefficients (Gautschi, 1985), which make them ubiquitous in virtually any field of numerical analysis. An excellent discussion of Chebyshev polynomials in general, can be found in (Mason and Handscomb, 2002). Depending on the choice of interpolation points and different kinds of orthogonality properties, Chebyshev

polynomial based quadrature rules are termed Gauss-Chebyshev quadrature, Fejér quadrature or Clenshaw-Curtis quadrature (Clenshaw and Curtis, 1960).

Putting all together, the (deterministic) quadrature approximation to the partition function  $Z(\boldsymbol{\theta})$  is

$$\begin{aligned} Z(\boldsymbol{\theta}) &= \int_{\mathcal{X}} \exp(\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle) d\nu(\mathbf{x}) \\ &\approx \int_{\mathcal{X}} \text{exp}_{\zeta}^k(\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle) d\nu(\mathbf{x}) = \hat{Z}_{\zeta}^k(\boldsymbol{\theta}), \end{aligned} \quad (2)$$

where  $\text{exp}_{\zeta}^k$  is a degree- $k$  Chebyshev approximation to the exponential function on the interval  $[l; u]$ , and  $\zeta$  are the corresponding coefficients. Chebyshev approximations yield the best uniform approximation on  $[l; u]$ .  $\zeta$  can be approximated numerically via discrete cosine transformation or the Remez exchange algorithm (Fraser, 1965). It can be shown that the approximation error  $\varepsilon$  is bounded and exponentially small in  $k \ln k$  (Xiang et al., 2010) when  $l \leq \min_{\mathbf{x}} \langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle$  and  $u \geq \max_{\mathbf{x}} \langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle$ .

### 3 FAST STOCHASTIC QUADRATURE

In this section, we present the stochastic Clenshaw-Curtis quadrature that yields an  $(1 \pm \varepsilon)$ -approximation to the partition function (Piatkowski and Morik, 2016). We then develop a class of Monte Carlo algorithms designed to perform the actual estimation of  $A(\boldsymbol{\theta})$  efficiently.

**$k$ -Integrable Statistics:** Let  $\phi$  denote the  $d$ -dimensional statistic of the exponential family representation (1) of some undirected graphical model for  $\mathbf{X}$ . Of particular interest are statistics which are  $k$ -integrable—that is, the function

$$\chi_{\phi}^k(\mathbf{j}) = \int_{\mathcal{X}} \prod_{i=1}^k \phi(\mathbf{x})_{j_i} d\nu(\mathbf{x}) \quad (3)$$

admits a polynomial time computable closed-form expression for all index tuples  $\mathbf{j} \in [d]^k$ . It can be shown (Piatkowski and Morik, 2016) that overcomplete sufficient statistics of discrete Markov random fields are all ways  $k$ -integrable. In this case,

$$\chi_{\phi}^k(\mathbf{j}) = \begin{cases} \frac{|\mathcal{X}|}{|\mathcal{X}_{\cup_{i=1}^k C(j_i)}|}, & \mathbf{j} \text{ is realizable} \\ 0, & \text{otherwise.} \end{cases} \quad (4)$$

Here,  $C(j_i)$  denotes the clique that corresponds to the  $i$ -th entry of  $\mathbf{j}$ , i.e.,  $\mathbf{j}_i \equiv (C(j_i), \mathbf{y}(j_i))$ . An index tuple  $\mathbf{j}$  is not realizable, if two (or more) indices imply that the same vertex is in two (or more) different states at the same time.

Let us extend this result by showing that various sufficient statistics for continuous random variables are as well  $k$ -integrable.

**Lemma 1 (Continuous  $k$ -integrability)** *Let  $\mathbf{X}$  be an  $n$ -dimensional continuous random vector. Any statistic  $\phi(\mathbf{x}) : \mathbb{R}^n \rightarrow \mathbb{R}^d$  whose coordinate-wise statistics  $\phi(\mathbf{x})_i$  are (linear transformations of)*

$$\phi(\mathbf{x})_i = \mathbf{x}_j^c, \text{ or } \phi(\mathbf{x})_i = \frac{1}{\mathbf{x}_j^c}, \text{ or } \phi(\mathbf{x})_i = \ln(\mathbf{x}_j)^c,$$

with  $c \in \mathbb{N}$ ,  $j \in [n]$ , is  $k$ -integrable for all  $k \in \mathbb{N}$ .

Details on the integration of elementary functions can be found in (Bronstein, 1990). In fact, the sufficient statistics of the Gaussian, Poisson, exponential, beta, Dirichlet, Pareto, Weibull with known shape, chi-squared, log-normal, beta, and gamma distributions, restricted to the interval  $(0; u]$ , consist only of terms of the form  $1/x^c$ ,  $x^c$ , and  $\ln(x)^c$  which implies their  $k$ -integrability. E.g., assume that  $\phi(x)_1 = x$  and  $\phi(x)_2 = \ln_2(x)^2$  with  $x \in (0; u]$ , then, for  $\mathbf{j} = (1, 2, 1)$ , we have  $\chi_{\phi}^k(\mathbf{j}) = u^3(9 \ln(u)^2 - 6 \ln(u) + 2)/(27 \ln(2)^2)$ , which is indeed a polynomial time computable closed-form.

One may extend Lemma 1 to include statistics of the form  $|x - m|^c$ , which appear in the density of the Laplace distribution. Closed-form expressions exist, but we excluded them here due to the notational clutter that arises when products of such functions are integrated.

**Stochastic Clenshaw-Curtis Quadrature (SCCQ):**

The major ingredient of the stochastic quadrature is a specific probability mass function (pmf) over index tuples  $\mathbf{j} \in [d]^i$  of length  $0 \leq i \leq k$ . For ease of notation, we assume that indices of  $(k + 1)$ -dimensional objects start at 0. Suppose  $\phi : \mathcal{X} \rightarrow \mathbb{R}_+^d$  is a non-negative,  $k$ -integrable statistic. Let  $\|\chi_{\phi}^i\|_1$  denote the 1-norm of the function  $\chi_{\phi}^i$ . Moreover, for any  $(k + 1)$ -dimensional real-valued vector  $\zeta$ , let  $|\zeta|$  denote the element-wise absolute value of  $\zeta$ , i.e.,  $\|\chi_{\phi}^i\|_1 = \sum_{j \in [d]^i} |\chi_{\phi}^i(\mathbf{j})|$ .

Let further  $(\mathbf{J}, I)$  be the discrete random variable with state space  $[d]^k \otimes ([k] \cup \{0\})$  and pmf  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i) = \mathbb{P}_{\phi}(\mathbf{J} = \mathbf{j} \mid I = i) \mathbb{P}_{\zeta, \phi}(I = i)$  with

$$\mathbb{P}_{\zeta, \phi}(I = i) = \frac{|\zeta_i| \|\chi_{\phi}^i\|_1}{\sum_{j=0}^k |\zeta_j| \|\chi_{\phi}^j\|_1} \quad (5)$$

and

$$\mathbb{P}_{\phi}(\mathbf{J} = \mathbf{j} \mid I = i) = \frac{\chi_{\phi}^i(\mathbf{j})}{\|\chi_{\phi}^i\|_1}. \quad (6)$$

We call  $\mathbb{P}_{\zeta, \phi}$  the *tuple mass* with parameter  $(\zeta, \phi)$ .

Now, we define the random variable which constitutes the core of SCCQ.

---

**Algorithm 1:** Stochastic Clenshaw-Curtis Quadrature

---

**input**  $\boldsymbol{\theta}, \zeta, k, N$

**output** Approximate partition function  $\hat{Z}_{\zeta}^{N,k}(\boldsymbol{\theta})$

- 1:  $S \leftarrow 0$
  - 2: **for**  $l = 1$  to  $N$  **do**
  - 3:    $(\mathbf{j}, i) \sim \mathbb{P}_{\zeta, \phi}$
  - 4:    $S \leftarrow S + \hat{Z}_{\mathbf{j}, i}^k(\boldsymbol{\theta})$
  - 5: **end for**
  - 6:  $\hat{Z}_{\zeta}^{N,k}(\boldsymbol{\theta}) \leftarrow \frac{1}{N} S$
- 

**Definition 1 (1-SCCQ)** Let  $k \in \mathbb{N}$ ,  $\boldsymbol{\theta} \in \mathbb{R}^d$ , and let  $\mathbf{J}$  be a random index tuple of random length  $I$ , both having joint tuple mass  $\mathbb{P}_{\zeta, \phi}$ . The random variable

$$\hat{Z}_{\mathbf{J}, I}^k(\boldsymbol{\theta}) = \tau \operatorname{sgn}(\zeta_I) \prod_{r=0}^I \boldsymbol{\theta}_{\mathbf{j}_r}$$

with  $\tau = \sum_{j=0}^k |\zeta_j| \|\chi_{\phi}^j\|_1$  is called 1-SCCQ.

Surprisingly, this random variable is closely related to the quadrature approximation to  $Z(\boldsymbol{\theta})$  from equation (2).

**Theorem 1 (Unbiasedness of SCCQ)** Let  $\zeta$  be the coefficient vector  $\zeta$  of a degree- $k$  polynomial approximation to  $\exp$  over some arbitrary but fixed interval  $[l; u]$ , and let  $\phi$  be a non-negative and  $k$ -integrable statistic. The random variable  $\hat{Z}_{\mathbf{J}, I}^k(\boldsymbol{\theta})$  is an unbiased estimator for  $\hat{Z}_{\zeta}^k(\boldsymbol{\theta}) = \int_{\mathcal{X}} \exp_{\zeta}^k(\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle) d\nu(\mathbf{x})$ .

**Proof.** Using equations (3), (5), and (6), as well as Definition 1, it follows that

$$\begin{aligned} & \mathbb{E} \left[ \hat{Z}_{\mathbf{J}, I}^k(\boldsymbol{\theta}) \right] \\ &= \sum_{i=0}^k \sum_{\mathbf{j} \in [d]^k} \mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i) \tau \operatorname{sgn}(\zeta_i) \prod_{r=0}^i \boldsymbol{\theta}_{\mathbf{j}_r} \\ &= \sum_{i=0}^k \zeta_i \sum_{\mathbf{j} \in [d]^i} \prod_{r=0}^i \boldsymbol{\theta}_{\mathbf{j}_r} \int_{\mathcal{X}} \prod_{r=0}^i \phi(\mathbf{x})_{\mathbf{j}_r} d\nu(\mathbf{x}) \\ &= \int_{\mathcal{X}} \sum_{i=0}^k \zeta_i \langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle^i d\nu(\mathbf{x}) = \hat{Z}_{\zeta}^k(\boldsymbol{\theta}), \end{aligned}$$

where the last line stems from the fact that

$$\langle \boldsymbol{\theta}, \phi(\mathbf{x}) \rangle^i = \sum_{j_1=1}^d \sum_{j_2=1}^d \cdots \sum_{j_i=1}^d \prod_{l=0}^i \boldsymbol{\theta}_{\mathbf{j}_l} \prod_{r=0}^i \phi(\mathbf{x})_{\mathbf{j}_r} .$$

■

Based on the theorem, we devise a Monte Carlo procedure, called  $N$ -SCCQ or simply SCCQ, shown in Algorithm 1. By combining the error  $\varepsilon$  that is introduced by

the polynomial approximation with the error that is introduced by the sampling procedure, an overall error bound can be derived<sup>1</sup>.

**Theorem 2 (SCCQ Error Bound)** Let  $\zeta$  be the coefficient vector of a degree- $k$  Chebyshev approximation to  $\exp$  on  $[l; u] = [-\|\boldsymbol{\theta}\|_1; +\|\boldsymbol{\theta}\|_1]$  with worst-case error  $\varepsilon$ . Let  $\hat{Z}_{\zeta}^{N,k}(\boldsymbol{\theta})$  be the output of Algorithm 1. Furthermore, let  $\delta \in (0, 1]$ ,  $\epsilon > 0$ ,  $N = (\ln 2/\delta)\tau^2 2\|\boldsymbol{\theta}\|_{\infty}^{2k'} \varepsilon^{-2} |\mathcal{X}|^{-2}$ , with  $(k-1)k! \geq 8 \exp(2\|\boldsymbol{\theta}\|_1)/(\pi\epsilon)$ , and  $k' = 1$  if  $\|\boldsymbol{\theta}\|_{\infty} < 1$  or otherwise  $k' = k$ . Then,

$$\mathbb{P}[|\hat{Z}_{\zeta}^{N,k}(\boldsymbol{\theta}) - Z(\boldsymbol{\theta})| < \epsilon Z(\boldsymbol{\theta})] \geq 1 - \delta .$$

### 3.1 COMPUTATIONAL COMPLEXITY

While SCCQ enjoys a bounded error and an apparently simple algorithm, the actual sampling of index tuples from  $\mathbb{P}_{\zeta, \phi}$  (line 3 in Algorithm 1) and the computation of  $\hat{Z}_{\mathbf{j}, I}^k(\boldsymbol{\theta})$  (line 4 in Algorithm 1) turn out to be computationally hard. Computing  $\hat{Z}_{\mathbf{j}, I}^k(\boldsymbol{\theta})$  requires the  $\|\chi_{\phi}^i\|_1$  values. In (Piatkowski and Morik, 2016), the authors assume that the values of  $\|\chi_{\phi}^i\|_1$  for all  $0 \leq i \leq k$  are pre-computed, which requires  $\mathcal{O}(d^k)$  additions. While rather small polynomial degrees ( $k \approx 8$ ) suffice to achieve reasonable results, the overcomplete dimension  $d$  of a  $10 \times 10$  binary Ising grid model is 720. Hence, at least  $d^k = 720^8 > 2^{75}$  additions are required to compute  $\|\chi_{\phi}^i\|_1$ . In our initial work on SCCQ (Piatkowski and Morik, 2016), rejection sampling was used to generate the samples from  $\mathbb{P}_{\zeta, \phi}$  with a uniform proposal  $\mathbb{Q}$  on  $[d]^k \otimes ([k] \cup \{0\})$ . Since the ratio  $\mathbb{P}_{\zeta, \phi}(\mathbf{j}, i)/\mathbb{Q}(\mathbf{j}, i) = (k+1)d^k \mathbb{P}_{\zeta, \phi}(\mathbf{j}, i)$  is large, one shall expect that many samples will be rejected.

### 3.2 NORMALIZING THE TUPLE MASS

To alleviate the complexity issues of SCCQ, we now present a closed-form expression for  $\|\chi_{\phi}^i\|_1$ . Our result relies on the closed-form of  $k$ -integrable statistics, which is given by equation (4) for discrete state space models. We restrict ourselves to discrete models, since a general closed-form that covers all continuous state space models does not exist. However, the general methodology can be transferred to the continuous case.

The forthcoming results make heavy use of equivalence classes of index tuples  $\mathbf{j} \in [d]^i$  and their cardinalities. In

<sup>1</sup>An earlier result can be found in (Piatkowski and Morik, 2016). There, the bound on the error of the polynomial approximation uses an inequality which is originally designed for complex-valued functions. Here, we apply a recent inequality due to Trefethen (Trefethen, 2008). Both results are qualitatively equivalent w.r.t.  $N$  and  $k$ . Nevertheless, the new proof is simplified.

this context, it is important to recall that any index  $j \in [d]$  corresponds to a pair of clique and state:  $i \equiv (C, \mathbf{y})$ . Consequently, a tuple of indices corresponds to a tuple of cliques and states.

**Definition 2 (Sub-Alphabets)** Let  $\mathcal{A}$  be some set of objects or symbols— $\mathcal{A}$  is an alphabet—and let  $\mathcal{P}(\mathcal{A})$  be its power set. The set  $\mathcal{P}(\mathcal{A}, n) \subseteq \mathcal{P}(\mathcal{A})$  contains all subsets of  $\mathcal{A}$  with at most  $n$  elements, i.e.,

$$\mathcal{P}(\mathcal{A}, n) = \{S \in \mathcal{P}(\mathcal{A}) \mid |S| \leq n\}.$$

The size of  $\mathcal{P}(\mathcal{A}, n)$  is thus

$$|\mathcal{P}(\mathcal{A}, n)| = \sum_{i=1}^n \binom{|\mathcal{A}|}{i}.$$

**Definition 3 (Tuple Classes)** Let  $i \in \mathbb{N}$ , and denote the clique tuple that corresponds to an index tuple  $\mathbf{j} \in [d]^i$  by  $\mathcal{C}(\mathbf{j}) \in \mathcal{C}^i$ . Two or more index tuples  $\mathbf{j}, \mathbf{j}'$  may correspond to the same clique tuple, i.e.,  $\mathcal{C}(\mathbf{j}) = \mathcal{C}(\mathbf{j}')$ . The equivalence class of all index tuples that correspond to the same clique tuple is denoted by

$$[\mathbf{j}] = \{\mathbf{j}' \in [d]^i \mid \mathcal{C}(\mathbf{j}) = \mathcal{C}(\mathbf{j}')\}.$$

Similarly, two or more clique tuples  $\mathcal{C}, \mathcal{C}'$  may correspond to the same set of cliques. The equivalence class of clique tuples that correspond to the same set of cliques is denoted by

$$[\mathcal{C}] = \left\{ \mathcal{C}' \in \mathcal{C}^i \mid \bigcup_{c \in \mathcal{C}} \{c\} = \bigcup_{c' \in \mathcal{C}'} \{c'\} \right\}.$$

Combining both, the equivalence class of all index tuples, whose corresponding clique tuples are in the same equivalence class, is denoted by

$$[\mathbf{j}]^* = \{\mathbf{j}' \in [d]^i \mid \mathcal{C}(\mathbf{j}') \in [\mathcal{C}(\mathbf{j})]\}.$$

Note that all members of a specific clique tuple equivalence class  $[\mathcal{C}]$  are determined by a unique set of cliques which come from the alphabet  $\mathcal{C}$ . Hence, we identify each class  $[\mathcal{C}]$  with this unique set of cliques and treat each  $[\mathcal{C}]$  as an element of  $\mathcal{P}(\mathcal{C}, i)$ . Moreover, there are  $|\mathcal{P}(\mathcal{C}, i)|$  distinct size- $i$  clique tuple equivalence classes.

In the remainder, it will be important to know how large these equivalence classes are.

**Lemma 2 (Counting Tuples)** Let  $i, j \in \mathbb{N}$ ,  $\mathbf{j} \in [d]^j$ ,  $\mathcal{C} \in \mathcal{C}^i$ , and consider the equivalence classes defined above. Then,

$$\begin{aligned} |[\mathbf{j}]| &= \prod_{l=1}^i |\mathcal{X}_{\mathcal{C}(\mathbf{j})_l}|, & |[\mathcal{C}]| &= h(\mathcal{C})! \binom{i}{h(\mathcal{C})}, \\ |[\mathbf{j}]^*| &= |[\mathcal{C}(\mathbf{j})]| |[\mathbf{j}]| \end{aligned}$$

where  $h(\mathcal{C})$  is the number of distinct cliques which appear in the tuple  $\mathcal{C}$ ,  $n!$  is the factorial, and  $\{n \ k\}^\top$  is the Stirling number of second kind.

It will be helpful to define equivalence classes of index tuples w.r.t. some  $k$ -integrable statistics. Here, equivalence w.r.t.  $\chi_\phi^i$  is established by the value that each member of an equivalence class contributes to  $\|\chi_\phi^i\|_1$ .

**Definition 4 (Tuple Classes and  $k$ -integrability)** Let  $\phi$  be a  $k$ -integrable statistic,  $i \in \mathbb{N}$ , and  $\mathbf{j} \in [d]^i$ . The equivalence class of all index tuples which correspond to the same clique tuple and have non-zero  $\chi_\phi^i$ -value is denoted by

$$[\mathbf{j}]_\phi = \{\mathbf{j}' \in [d]^i \mid \mathbf{j}' \in [\mathbf{j}] \wedge \chi_\phi^i(\mathbf{j}') \neq 0\}.$$

The corresponding extension to equivalence classes of clique tuples, is denoted by

$$[\mathbf{j}]_\phi^* = \{\mathbf{j}' \in [d]^i \mid \mathbf{j}' \in [\mathbf{j}]^* \wedge \chi_\phi^i(\mathbf{j}') \neq 0\}.$$

Up to now, we made no use of the fact that our state space is discrete. The above definitions and lemmas are valid for any exponential family model with positive  $k$ -integrable statistic. However, the proof of the next lemma makes use of equation (4). In order to extend our results to continuous random variables, one has to invoke Lemma 1 to derive a closed-form for  $\chi_\phi^i$ .

**Lemma 3 (Counting Realizable Tuples)** Suppose  $\phi$  is the binary, overcomplete sufficient statistic of discrete MRFs. Then,

$$|[\mathbf{j}]_\phi| = |\mathcal{X}_{\mathcal{C}(\mathbf{j})}|, \quad \text{and} \quad |[\mathbf{j}]_\phi^*| = |[\mathcal{C}(\mathbf{j})]| |[\mathbf{j}]_\phi|,$$

with  $\mathcal{X}_{\mathcal{C}(\mathbf{j})} = \mathcal{X}_{\cup_{l=1}^i \mathcal{C}(\mathbf{j})_l}$  and  $\mathcal{C}(\mathbf{j}) \in \mathcal{C}^i$ .

Now, we have gathered all terms and definitions to devise an improved procedure for the normalization of the index tuple mass.

**Theorem 3 (Tuple Mass Normalization)** Suppose  $\phi$  is the binary, overcomplete sufficient statistic of discrete MRFs. The conditional index tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j} \mid I = i)$  (equation (6)) can be normalized in  $\mathcal{O}(1)$  steps. More precisely,

$$\|\chi_\phi^i\|_1 = |\mathcal{X}| \sum_{l=0}^i \binom{i}{l} \binom{|\mathcal{C}|}{l} l! = |\mathcal{X}| |\mathcal{C}|^i. \quad (7)$$

The complexity  $\mathcal{O}(1)$  provided in the theorem is an overwhelming improvement, compared to the naive summation, i.e.,  $\mathcal{O}(d^k)$ . Since we need the normalization  $\|\chi_\phi^i\|_1$  for all  $1 \leq i \leq k$  tuple lengths,  $\hat{Z}_{\mathbf{J}, I}^k(\boldsymbol{\theta})$  can be computed in  $\mathcal{O}(k)$  steps when a pair  $(\mathbf{j}, i)$  is given.

---

**Algorithm 2:** Fast Index Tuple Sampler
 

---

**input** Tuple length  $i$ 
**output** Sample  $\mathbf{j} \mid I = i$  from  $\mathbb{P}_{\zeta, \phi}$ 

- 1:  $l \sim \mathbb{P}(l \mid i)$  // See Theorem 4
  - 2:  $a \sim \mathbb{U}(1; \mathbf{binom}(|\mathcal{C}|, l))$
  - 3:  $b \sim \mathbb{U}(1; \mathbf{Stirling2}(i, l) \times \mathbf{factorial}(l))$
  - 4:  $[\mathcal{C}] \leftarrow$  compute  $a$ -th  $l$ -combination of  $\{1, 2, \dots, |\mathcal{C}|\}$  // via (Buckles and Lybanon, 1977)
  - 5:  $\mathcal{C} \leftarrow$  compute  $b$ -th composition of  $\{1, 2, \dots, i\}$  with  $l$  subsets // via (Ehrlich, 1973)
  - 6:  $S \leftarrow \bigcup_{h=1}^i \mathcal{C}_h$
  - 7:  $c \sim \mathbb{U}(1; \prod_{v \in S} |\mathcal{X}_v|)$
  - 8:  $\mathbf{y} \leftarrow$  compute  $c$ -th joint state of all vertices in  $S$
  - 9: **return**  $\mathbf{j}$  that corresponds to  $\mathcal{C} = \mathbf{y}$
- 

### 3.3 FAST INDEX TUPLE SAMPLER

Based on the insights that we gained so far, we derive a direct sampling scheme for index tuples that circumvents any rejection step (Algorithm 2).

Given our results from the last subsection, drawing a random tuple length from  $\mathbb{P}_{\zeta}(I)$  can be done efficiently—it is a draw from a categorical distribution with state space size  $k$  (which is rather small). Sampling from the tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j} \mid I = i)$  can be more involved, which motivates the derivation of a specialized sampling scheme. Our algorithm is motivated by inversion sampling: For any fixed  $i$ , inversion sampling of  $\mathbf{j}$  then consists of drawing a uniform random number  $u$  in  $(0; 1)$ , and finding the smallest  $L \in \mathbb{N}$ , such that the sum of the first  $L$  tuple masses exceeds  $u$ . The  $L$ -th tuple is then the sample. The worst-case runtime complexity is then  $\mathcal{O}(d^k)$  per sample, which can be prohibitively expensive whenever the dimension  $d$  of the model is large. Based on the equivalence classes that we exploited already for the normalization of the tuple mass, we derive a factorization of  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j} \mid I = i)$  which in turn implies an efficient stagewise sampling procedure.

To this end, let  $\prec$  be an any arbitrary but fixed strict total ordering on the equivalence classes of clique tuples. I.e.,  $\forall \mathbf{A}, \mathbf{B} \in \mathcal{P}(\mathcal{C}, i)$  with  $\mathbf{A} \neq \mathbf{B}$ , either  $[\mathbf{A}] \prec [\mathbf{B}]$  or  $[\mathbf{B}] \prec [\mathbf{A}]$ —by definition, each element of  $\mathcal{P}(\mathcal{C}, i)$  corresponds to a unique equivalence class. This order induces an order on clique tuples and index tuples, i.e.,  $\mathbf{j}, \mathbf{j}' \in [d]^i$ ,  $\mathbf{j} \leq \mathbf{j}' \Leftrightarrow [\mathcal{C}(\mathbf{j})] \preceq [\mathcal{C}(\mathbf{j}')]$ . Within each equivalence class, we assume that tuples are ordered lexicographically.

**Theorem 4 (Tuple Mass Factorization)** *Suppose that  $\phi$  is the binary, overcomplete sufficient statistic of a dis-*

Figure 1: Directed graphical model for the factorization of the tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i)$ . Any index tuple  $\mathbf{j}$  can be identified with some pair  $(\mathcal{C}, \mathbf{y})$  of clique tuple and state tuple.

crete state MRF. The tuple mass of any  $\mathbf{j}$  factorizes:

$$\begin{aligned} \mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j} \mid I = i) \\ = \mathbb{P}(\mathcal{C} \mid [\mathcal{C}], l, i) \mathbb{P}(\mathbf{y} \mid [\mathcal{C}], i) \mathbb{P}([\mathcal{C}] \mid l) \mathbb{P}(l \mid i) \end{aligned}$$

with

$$\begin{aligned} \mathbb{P}(l \mid i) &= |\mathcal{C}|^{-i} \binom{i}{l} \binom{|\mathcal{C}|}{l} l! \\ \mathbb{P}([\mathcal{C}] \mid l) &= \frac{1}{\binom{|\mathcal{C}|}{l}} \mathbb{P}(\mathcal{C} \mid [\mathcal{C}], l, i) = \frac{1}{\binom{i}{l} l!} \\ \mathbb{P}(\mathbf{y} \mid [\mathcal{C}], i) &= \begin{cases} \frac{1}{|\mathcal{X}_{[\mathcal{C}]}|} & , \mathbf{y} \in \mathcal{X}_{[\mathcal{C}]} \\ 0 & , \text{otherwise,} \end{cases} \end{aligned}$$

where  $l$  denotes the number of distinct cliques in the clique tuple  $\mathcal{C}$ ,  $[\mathcal{C}]$  denotes the equivalence class that contains  $\mathcal{C}$ , and  $\mathbf{y}$  is the joint state of all cliques in the tuple  $\mathcal{C}$ .

While the proof is rather simple, it is not obvious how to come up with this factorization. The idea is to first draw the equivalence class  $[\mathcal{C}]$ , then a uniform member  $\mathcal{C}$  of this class, then a uniform joint state  $\mathbf{y}$  of all cliques in  $\mathcal{C}$ . Notice that the sampling steps for  $[\mathcal{C}]$ ,  $\mathcal{C}$  and  $\mathbf{y}$  are uniform, while the probability mass of the number  $l$  of distinct cliques that will appear in the tuple is a function of  $l$ . Let us now investigate the complexity of our new method.

**Theorem 5 (Complexity of Tuple Sampling)**

*Algorithm 2 samples an index tuple  $\mathbf{j}$  of given length  $i$  from  $\mathbb{P}_{\zeta, \phi}$  in*

$$\mathcal{O}(k^4 + kn + |\mathcal{C}| + \{i l\}^\top + l!)$$

*steps. When permutations and partitions are precomputed, the runtime reduces to*

$$\mathcal{O}(k^4 + kn + |\mathcal{C}|)$$

per sample. Here,  $k$  is the polynomial degree,  $l \leq i$  is the number of distinct cliques in the generated tuple, and  $n = |V|$ .

Thus, we found a Monte Carlo algorithm to sample from  $\mathbb{P}_{\zeta, \phi}$  without any rejection step. Since the algorithm does not use a Markov chain, the generated samples are truly independent. Any number of samples can thus be generated in parallel. Because no data has to be exchanged, the overall runtime scales linearly with the number of processors. This is a superior property compared to MCMC methods, where sampling cannot be parallelized and consecutive samples are not independent. Moreover, the theorem tells us how the complexity of stochastic quadrature is related to the graphical structure and the polynomial degree. The runtime is independent of the parameter dimension  $d$  and the state space sizes. In contrast, the runtime of loopy belief propagation (Pearl, 1988; Kschischang et al., 2001) and similar variational techniques (like TRW-BP (Wainwright et al., 2003)) is at least quadratic in the vertex state space sizes.

## 4 APPROXIMATE ML ESTIMATION

An important feature of maximum-likelihood parameter estimation is that the solution is specified by moment-matching. To illustrate this notion, suppose that we are given an i.i.d. data set  $\mathcal{D} = \{\mathbf{x}^1, \mathbf{x}^2, \dots, \mathbf{x}^N\}$  from some unknown measure  $\mathbb{P}_{\theta^*}$ . By using an exponential family model (which is exact whenever the state space  $\mathcal{X}$  is discrete), the log-likelihood of  $\theta$  on  $\mathcal{D}$  is given by:

$$\ell(\theta) = \frac{1}{N} \sum_{i=1}^N \ln \mathbb{P}_{\theta}(\mathbf{x}^i) = \langle \theta, \tilde{\mu} \rangle - A(\theta)$$

with  $\tilde{\mu} = (1/N) \sum_{i=1}^N \phi(\mathbf{x}^i)$ . Taking the derivatives of  $\ell$  w.r.t. some  $\theta_i$ , we find that  $(1/N) \sum_{i=1}^N \phi(\mathbf{x}^i) = \mathbb{E}_{\theta}[\phi(\mathbf{X})_i]$  at any critical point  $\theta$  where  $\mathbb{E}_{\theta}$  denotes the expectation under  $\mathbb{P}_{\theta}$ . That is, the maximum-likelihood solution has its moments matched to the empirical average  $\tilde{\mu}$ . In this section, we show how SCCQ can be used to develop a method for approximate ML estimation that, in analogy to this exact moment-matching, performs a type of pseudo-moment matching. To this end, a means of computing  $\nabla A(\theta) = \nabla \ln Z(\theta) = \mathbb{E}_{\theta}[\phi(\mathbf{X})]$  via SCCQ is required. Recalling that  $i \equiv (C, \mathbf{y})$  and that  $\phi(\mathbf{y})$  is binary in discrete models reveals that  $\mathbb{E}_{\theta}[\phi(\mathbf{X})_i] = \mathbb{P}_{\theta}(\phi(\mathbf{X})_i = 1) = \mathbb{P}_{\theta}(\mathbf{X}_C = \mathbf{y})$ . Since  $\mathbb{P}_{\theta}(\mathbf{X}_C = \mathbf{y})$  is the marginal probability mass of the event  $\{C = \mathbf{y}\}$ , the problem of computing  $\mathbb{E}_{\theta}[\phi(\mathbf{X})_i]$  is also called *marginal inference*.

## 4.1 MARGINAL INFERENCE

For any subset  $U \subseteq V$  of variables, and any joint state  $\mathbf{x}_U$ , the marginal density is defined by

$$\begin{aligned} \mathbb{P}_{\theta}(\mathbf{X}_U = \mathbf{x}_U) &= \int_{\mathcal{X}_{V \setminus U}} \mathbb{P}_{\theta}(\mathbf{x}_U, \mathbf{x}_{V \setminus U}) \, d\nu(\mathbf{x}) \\ &= \frac{1}{Z(\theta)} \int_{\mathcal{X}_{V \setminus U}} \exp(\langle \theta, \phi(\mathbf{x}) \rangle) \, d\nu(\mathbf{x}), \end{aligned}$$

with  $\mathbf{x} = (\mathbf{x}_U, \mathbf{x}_{V \setminus U})$ . Especially the last integral is reminiscent of the partition function. In fact, it can be interpreted as the partition function of another model with state space  $\mathcal{X}_{V \setminus U}$ . It is this sum that will be approximated via SCCQ to estimate the marginal. To formalize this idea, we provide adjusted definitions of the SCCQ core concepts. First, we adapt the notion of  $k$ -integrability to marginal densities. In accordance to equation (3), we call  $\phi$  marginally  $k$ -integrable, if

$$\chi_{\phi, U}^k(\mathbf{j}, \mathbf{x}_U) = \int_{\mathcal{X}_{V \setminus U}} \prod_{i=1}^k \phi(\mathbf{x}_U, \mathbf{x}_{V \setminus U})_{\mathbf{j}_i} \, d\nu(\mathbf{x}_{V \setminus U})$$

admits a polynomial time computable closed-form expression for all  $\mathbf{j} \in [d]^k$ , for all  $U \subseteq V$ , and for all  $\mathbf{x}_U \in \mathcal{X}_{V \setminus U}$ . The difference to ordinary  $k$ -integrability is merely symbolical. In fact, all  $k$ -integrable statistics that are mentioned in this paper are also marginally  $k$ -integrable. Moreover, marginally  $k$ -integrable statistics give rise to the marginal tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, \mathbf{X}_U = \mathbf{x}_U, I = i)$  in the same way how the ordinary tuple mass from equation (6) arises from ordinary  $k$ -integrability. Moreover, the marginal tuple mass factorizes.

### Corollary 1 (Marginal Tuple Mass Factorization)

Suppose that  $\phi$  is the binary, overcomplete sufficient statistic. The marginal tuple mass factorizes:

$$\begin{aligned} &\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i, \mathbf{X}_U = \mathbf{x}_U) \\ &= \mathbb{P}(\mathbf{C} \mid \llbracket \mathbf{C} \rrbracket, l, i) \mathbb{P}(\mathbf{y}, \mathbf{x}_U \mid \llbracket \mathbf{C} \rrbracket, i) \mathbb{P}(\llbracket \mathbf{C} \rrbracket \mid l) \mathbb{P}(l \mid i) p(i) \end{aligned}$$

where  $\mathbb{P}(l \mid i)$ ,  $\mathbb{P}(\llbracket \mathbf{C} \rrbracket \mid l)$ , and  $\mathbb{P}(\mathbf{C} \mid \llbracket \mathbf{C} \rrbracket, l, i)$  are given by Theorem 4, and

$$\mathbb{P}(\mathbf{y}, \mathbf{x}_U \mid \llbracket \mathbf{C} \rrbracket, i) = \begin{cases} \frac{1}{|\mathcal{X}_{\llbracket \mathbf{C} \rrbracket \cup U}|} & , \mathbf{y} \in \mathcal{X}_{\llbracket \mathbf{C} \rrbracket} \\ & \wedge \nexists v \in U : \mathbf{x}_v \neq \mathbf{y}_v \\ 0 & , \text{otherwise} . \end{cases}$$

The ordinary tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i)$  and the marginal tuple mass  $\mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, \mathbf{X}_U = \mathbf{x}_U, I = i)$  differ only in the factor  $\mathbb{P}(\mathbf{y}, \mathbf{x}_U \mid \llbracket \mathbf{C} \rrbracket, i)$ . We may hence use their quotient as importance weight to convert SCCQ samples for the partition function into SCCQ samples for

marginal probabilities. We have

$$\begin{aligned} & \mathbb{E}_{\mathbf{J}, I} \left[ \frac{p(\mathbf{y}(\mathbf{J}), \mathbf{x}_U | \llbracket C(\mathbf{J}) \rrbracket, I)}{p(\mathbf{y}(\mathbf{J}) | \llbracket C(\mathbf{J}) \rrbracket, I)} \hat{Z}_{\mathbf{J}, I}^k(\theta) \right] \\ &= \sum_{i=0}^k \sum_{j \in [d]^i} \mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i) w_{j, i, U} \hat{Z}_{j, i}^k(\theta) \\ &= \sum_{i=0}^k \sum_{j \in [d]^i} \mathbb{P}_{\zeta, \phi}(\mathbf{J} = \mathbf{j}, I = i, \mathbf{X}_U = \mathbf{x}_U) \hat{Z}_{j, i}^k(\theta) \\ &= \mathbb{E}_{\mathbf{J}, I, \mathbf{X}_U = \mathbf{x}_U} \left[ \hat{Z}_{\mathbf{J}, I}^k(\theta) \right], \end{aligned}$$

with importance weight  $w_{j, i, U} = \frac{p(\mathbf{y}(j), \mathbf{x}_U | \llbracket C(j) \rrbracket, i)}{p(\mathbf{y}(j) | \llbracket C(j) \rrbracket, i)}$ .

Now, we gathered all parts which are required for marginal inference. The corresponding inference procedure is provided in Algorithm 3. While the main idea is to perform  $d$  separate runs of Algorithm 1, such a naive approach would result in an unnecessary high runtime. Instead, we make use of Corollary 1 to propose an importance sampling approach, in which each SCCQ sample is shared among all marginals. For each marginal  $p(\mathbf{X}_C = \mathbf{x}_C)$ , we validate if the pair  $(j, i)$  that is sampled in line 3 agrees with the assignment  $\mathbf{x}_C$  (line 6)—otherwise, its marginal tuple mass is zero. If they agree, we reweigh the sample, perform the summation and count the number of successes in lines 7 and 8. In lines 13–17, the estimated sums are normalized and written to  $\hat{\mu}$ .

## 4.2 PARAMETER ESTIMATION

With Algorithm 3, we can compute the log-likelihood's gradient  $\nabla \ell(\theta)$ , and employ any first-order method to estimate the parameters. To measure the progress of parameter estimation, it is convenient to estimate the log-likelihood of the model, which inherits its computational complexity from the log-partition function. Before we proceed to some experimental results, we close this section by translating the SCCQ error bound from Theorem 2 to an error bound on the log-likelihood.

**Theorem 6 (SCCQ Log-Likelihood Error)** *Assume that the preconditions of Theorem 2 hold. Let  $\hat{\ell}(\theta) = \langle \theta, \hat{\mu} \rangle - \ln \hat{Z}_{\zeta}^{N, k}(\theta)$  be the SCCQ approximation to the log-likelihood. Whenever the outcome  $\hat{Z}_{\zeta}^{N, k}(\theta)$  of Algorithm 1 is positive, we have*

$$\mathbb{P} \left[ |\hat{\ell}(\theta) - \ell(\theta)| < \frac{\epsilon Z(\theta)}{\min\{\hat{Z}_{\zeta}^{N, k}(\theta), Z(\theta)\}} \right] \geq 1 - \delta.$$

That is, with probability of at least  $1 - \delta$ , the absolute error in the approximated log-likelihood is roughly  $\epsilon$  when  $\hat{Z}_{\zeta}^{N, k}(\theta)$  and  $Z(\theta)$  have the same order of magnitude.

## 5 EXPERIMENTAL DEMONSTRATION

Theoretical insights from the previous sections do provably reduce the computational complexity. Moreover, pseudo marginals, based on unbiased estimates of the quadrature approximation to the partition function, facilitate approximate maximum-likelihood estimation. We conduct a small set of experiments to assess our methods empirically and answer the following questions:

- Q1** What is the runtime improvement when  $\|\chi_{\phi}^k\|$  is computed via Theorem 3 instead of naive summation?
- Q2** What is the runtime improvement when index tuples are sampled with Algorithm 2 instead of rejection sampling?
- Q3** Does SCCQ-based approximate maximum-likelihood estimation work in practice?

To answer **Q1**, we measure the runtime in nanoseconds for computing  $\|\chi_{\phi}^k\|$  via Theorem 3 and via naive summation on a  $4 \times 4$  binary Ising grid for polynomial degree  $k \in \{1, 2, 3, 4\}$ . The results are depicted in the leftmost plot of Figure 2. All results are averaged over 10 independent runs and error-bars show the standard deviation (if any). The runtime is shown in log-scale. Normalizing the tuple mass via Theorem 3 is several orders

Figure 2: From left to right: (1) Runtime in log-scale for computing  $\|\chi_\phi^k\|$  with Theorem 3 (light blue) and naive summation (dark blue). Runtime in log-scale for drawing a single index tuple via Algorithm 2 (light blue) and rejection sampling (dark blue). (3) and (4): Progress of (approximate) negative log-likelihood  $-\ell(\theta)$  and mean squared error (MSE) between predicted and empirical marginals during parameter estimation on the mushroom data set. The solid line indicates the exact outcome, while the dashed lines represent SCCQ results with  $N = 10^4$  samples and  $k \in \{1, 3\}$ .

of magnitude faster than the standard approach, as expected. Regarding **Q2**, the situation looks similar. The corresponding results are depicted in the second plot of Figure 2. We see that increasing the polynomial degree and thus the maximal tuple length increases the runtime of rejection sampling. Clearly, the proportion of rejected samples increases when the state space size of the random tuples increases. On the other hand, the runtime of Algorithm 2 is almost constant in practice. To answer **Q3**, a regularized maximum-likelihood estimation on the mushroom data set<sup>2</sup> is conducted. The set contains 5644 fully observed training instances. Each data point  $x$  consists of 23 categorical features with up to 9 different states, representing properties of mushrooms. In total,  $|\mathcal{X}| \approx 2^{43}$ . To facilitate exact computation of likelihood and marginals, we use the Chow-Liu tree (Chow and Liu, 1968) as the conditional independence structure of the model. Note, however, that SCCQ is completely oblivious of the graphical structure. Hence, the reported results are valid for intractable non-tree-structured models as well. To prevent the model parameters from becoming too large,  $l_1$ -regularization with  $\lambda = 1/2$  is applied. The actual parameter estimation is carried out via the fast iterative shrinkage-thresholding algorithm (FISTA) (Beck and Teboulle, 2009) with stepsize  $1/L$  where  $L$  is an upper bound on the log-likelihood’s gradient’s Lipschitz constant. We run SCCQ with  $N = 10^4$  Monte Carlo samples. In each training iteration, we assess the (approximate) negative log-likelihood and the mean squared error (MSE) between predicted and empirical marginal probabilities. The last two plots of Figure 2 show the corresponding results. Each line corresponds to one parameter estimation. Since the runs converge in different iterations, the three lines have slightly different lengths. The results show that even the very coarse linear ( $k = 1$ ) approximation yields a reasonable approximate log-likelihood and approximate marginals. The learning

process evolves similar to the exact computation. When the polynomial degree is increased to  $k = 3$ , the approximation is even closer to the exact outcome as predicted by the theory. Especially the SCCQ marginal probabilities are often indistinguishable from the exact marginals.

## 6 CONCLUSION

We presented the first complete framework for SCCQ-based parameter learning for undirected graphical models. Quadrature-based inference provides bounds on the partition function. However, the complexity of existing algorithms is exponential in the degree of the underlying polynomial approximation and polynomial in the dimension of the model’s parameter vector—the accompanying computational complexity is not practical. We provide accelerated SCCQ algorithms whose complexity is independent of the dimension. Our empirical evaluation shows that the new algorithms are several orders of magnitude faster. In addition, we provide the first algorithm for SCCQ-based marginal inference whose practical speed and accuracy are sufficient to be used for approximate maximum-likelihood estimation. Hence, SCCQ is a highly parallel drop-in replacement for MCMC and message-passing whenever the parameter norm is bounded (e.g., via regularization). Finally, we explained how the stochastic quadrature can be applied to models with continuous random variables, which opens new research opportunities, e.g., inference in exponential family models with mixed domains, where some dimensions are discrete and others are continuous.

## Abstract

Marginal MAP is a key task in Bayesian inference and decision-making, and known to be very challenging in general. In this paper, we present an algorithm that blends heuristic search and importance sampling to provide anytime finite-sample bounds for marginal MAP along with predicted MAP solutions. We convert bounding marginal MAP to a surrogate task of bounding a series of summation problems of an augmented graphical model, and then adapt dynamic importance sampling [Lou *et al.*, 2017b], a recent advance in bounding the partition function, to provide finite-sample bounds for the surrogate task. Those bounds are guaranteed to be tight given enough time, and the values of the predicted MAP solutions will converge to the optimum. Our algorithm runs in an anytime/anyspace manner, which gives flexible trade-offs between memory, time, and solution quality. We demonstrate the effectiveness of our approach empirically on multiple challenging benchmarks in comparison with some state-of-the-art search algorithms.

## 1 INTRODUCTION

Probabilistic graphical models, including Bayesian networks and Markov random fields, provide a framework for representing and reasoning with probabilistic and deterministic information [Dechter, 2013; Dechter *et al.*, 2010; Darwiche, 2009]. Typical inference queries in graphical models include *maximum a posteriori* (MAP) that aims to find an assignment of MAP (or MAX) variables with the highest value, the *partition function* that is the normalizing constant ensuring a proper probability measure over all variables, and marginal MAP (MMAP) that

generalizes the aforementioned two tasks by maximizing over a subset of variables with the remaining variables marginalized, which arises in many scenarios such as latent variable models [Ping *et al.*, 2014] and decision-making tasks [Kiselev and Poupart, 2014].

MMAP has complexity  $\text{NP}^{\text{PP}}$  [Park, 2002], commonly believed to be more challenging than either max inference (NP-complete [Darwiche, 2009]) or sum inference ( $\#\text{P}$ -hard [Valiant, 1979]), and can be intractable even for tree-structured models [Park, 2002]. Because of the inherent difficulty of MMAP, recent works on MMAP often focus on approximate schemes. Among these, approximations with deterministic or probabilistic guarantees are of particular interest because they quantify bounds on the approximation errors. We also prefer approaches with an anytime behavior because they allow users to trade off computational resources with solution quality.

Approaches that offer deterministic bounds are typically based on search or variational methods. Some early works [Park and Darwiche, 2003; Yuan and Hansen, 2009] in search solve MMAP exactly based on depth-first branch and bound. Marinescu *et al.* [2014] outperformed its predecessors by introducing AND/OR search spaces and high-quality variational heuristics; this was further improved using best-first search variants, including weighted heuristic search [Lee *et al.*, 2016b], and alternating depth-first and best-first AND/OR search (AAOBF [Marinescu *et al.*, 2017]). However, these methods typically require regular evaluation of internal summation problems when traversing the MAP space; when these internal sums are difficult, the search process may stall completely. One way to avoid this issue is to unify the summation with the MAP search in a single, best-first search framework (UBFS [Lou *et al.*, 2018]), which allows the bounds to improve as the summation is performed, and switch to other MAP configurations when appropriate. However, another promising approach is to make use of probabilistic bounds (e.g., Lou *et al.* [2017b]), which hold with a user-selected probability, and can be significantly faster

and tighter than deterministic bounds. However, since each MAP configuration is associated with an independent summation problem, comparing MAP configurations using probabilistic bounds must compensate for the presence of many uncertain tests (in effect, a multiple hypothesis testing problem), and is thus non-trivial to adapt to the MAP search, which may contain exponentially many such configurations.

Variational methods [Wainwright and Jordan, 2008] offer another class of deterministic bounds for MMAP. However, these bounds are often not anytime (e.g., [Liu and Ihler, 2013]), and those, such as [Ping *et al.*, 2015], are often not “any-space”, meaning that their quality depends heavily on the available memory and may not continue to improve without more. Other types of algorithms can provide anytime deterministic bounds for MMAP as well, for example, one based on factor set elimination [Mauá and de Campos, 2012]; however, the factor sets that it maintains tend to grow very large, which limits its practical use to problems with relatively small induced widths (see Marinescu *et al.* [2017] or Lou *et al.* [2018]).

Some Monte Carlo approaches are able to provide probabilistic bounds; for example, Xue *et al.* [2016] proposes a random hashing based algorithm that provides a constant factor approximation. However, this approach can have difficulty on large scale problem instances (see [Lou *et al.*, 2018]). Other Monte Carlo methods may have no bound guarantees at all, e.g., those based on Markov chain Monte Carlo [Yuan *et al.*, 2004; Doucet *et al.*, 2002].

To some extent, the intrinsic hardness of MMAP arises from the non-commutativity of the sum and max operations. One natural idea to alleviate this issue is to convert the mixed inference task to a pure sum or a pure max one first. For example, Cheng *et al.* [2012] constructs an explicit factorized approximation of the marginalized distribution using a form of approximate variable elimination, which results in a structured MAP problem.

**Our Contributions.** In this paper, we present an approach that provides anytime finite-sample bounds (i.e., they hold with probability  $1 - \delta$  for some confidence parameter  $\delta$ ) for MMAP, that enjoys the benefits of both heuristic search and importance sampling. Briefly speaking, we follow Doucet *et al.* [2002] to construct an augmented graphical model from the original model by replicating the marginalized variables and potential functions. From this augmented model, we derive a sequence of decreasing summation objectives that bound the MMAP optimum raised to some fixed power. Then, we adapt dynamic importance sampling [Lou *et al.*, 2017b] to bound these summation objectives and provide finite-sample bounds of the MMAP optimum.

Our framework has several key advantages: 1) it provides anytime probabilistic upper and lower bounds that are guaranteed to be tight given enough time. 2) it is able to predict high-quality MAP solutions whose values converge to the optimum; the exploration-exploitation trade-off of searching MAP solutions is controlled by the number of replicates of the marginalized variables. 3) it runs in an anytime/anyspace manner, which gives flexible trade-offs between memory, time, and solution quality.

## 2 BACKGROUND

Let  $X = (X_1, \dots, X_N)$  be a vector of random variables, where each  $X_i$  takes values in a discrete domain  $\mathcal{X}_i$ ; we use lower case letters, e.g.  $x_i \in \mathcal{X}_i$ , to indicate a value of  $X_i$ , and  $x$  to indicate an assignment of  $X$ . A graphical model over  $X$  consists of a set of factors  $\mathcal{F} = \{f_\alpha(X_\alpha) \mid \alpha \in \mathcal{I}\}$ , where each factor (a.k.a. potential function)  $f_\alpha$  is defined on a subset  $X_\alpha = \{X_i \mid i \in \alpha\}$  of  $X$ , called its scope.

We associate an undirected graph  $\mathcal{G} = (V, E)$ , or *primal graph*, with  $\mathcal{F}$ , where each node  $i \in V$  corresponds to a variable  $X_i$  and we connect two nodes,  $(i, j) \in E$ , iff  $\{i, j\} \subseteq \alpha$  for some  $\alpha$ . Then,

$$f(x) = \prod_{\alpha \in \mathcal{I}} f_\alpha(x_\alpha)$$

defines an unnormalized probability measure over  $X$ .

Let  $X_M$  be a subset of  $X$  called MAX variables, and  $X_S = X \setminus X_M$  SUM variables. The MMAP task seeks an assignment  $x_M^*$  of  $X_M$  with the largest marginal probability:

$$x_M^* = \operatorname{argmax}_{x_M} \pi(x_M) \quad (1)$$

where

$$\pi(x_M) = \sum_{x_S} f(x).$$

If  $X_M$  is an empty set, the MMAP task reduces to computing the normalizing constant (a.k.a. partition function); if  $X_S$  is empty, it becomes the standard MAP inference task. We use  $\mathcal{X}_M$  to denote the MAP space, i.e., the Cartesian product of all  $\mathcal{X}_i$ 's where  $X_i$  is a MAX variable. We will assume in the sequel that  $x_M^*$  is unique for convenience, though our algorithm and analysis still hold without this assumption.

### 2.1 AND/OR Search Spaces

An AND/OR search space is a generalization of the standard (“OR”) search space, that enables us to exploit conditional independence structure during search [Dechter and

Figure 1: (a) A primal graph of a graphical model over 7 variables (A, B, C are MAX variables and D, E, F, G are SUM variables) with unary and pairwise potential functions. (b) A valid pseudo tree for the primal graph. (c) An AND/OR search tree guided by the pseudo tree. (d) An augmented model created by replicating SUM variables and factors of the model in (a). Plate notations used here. (e) A valid pseudo tree for the augmented model.

Mateescu, 2007]. The AND/OR search space for a graphical model is defined relative to a *pseudo tree* that captures problem decomposition along a fixed search order.

**Definition 1 (pseudo tree).** A *pseudo tree* of a primal graph  $\mathcal{G} = (V, E)$  is a directed tree  $\mathcal{T} = (V, E')$  sharing the same set of nodes as  $\mathcal{G}$ . The tree edges  $E'$  form a subset of  $E$ , and each edge  $(i, j) \in E \setminus E'$  are required to be a “back edge”, i.e., the path from the root of  $\mathcal{T}$  to  $j$  passes through  $i$  (denoted  $i \leq j$ ).

If a tree node of a pseudo tree corresponds to a MAX variable in the associated graphical model of the pseudo tree, we call it MAX node, otherwise we call it SUM node. A pseudo tree is called *valid* for an MMAP task if there is *no* MAX variable descended from any SUM variable. Thus, all MAX variables of a valid pseudo tree form a subtree (assuming a dummy MAX root) that contains the

root. We assume valid pseudo trees in the sequel.

Guided by a pseudo tree, we can construct an AND/OR search tree consisting of alternating levels of OR and AND nodes for a graphical model. Each OR node  $s$  is associated with a variable, which we lightly abuse notation to denote  $X_s$ ; the children of  $s$ ,  $ch(s)$ , are AND nodes corresponding to the possible values of  $X_s$ . If an OR node is associated with some MAX variable, it is called OR-MAX node. Notions of OR-SUM, AND-MAX, AND-SUM nodes are defined analogously. The root  $\emptyset$  of the AND/OR search tree corresponds to the root of the pseudo tree. Let  $pa(c) = s$  indicate the parent of  $c$  in the AND/OR tree, and  $an(c) = \{n \mid n \leq c\}$  indicate the ancestors of  $c$  (including itself) in the tree.

In an AND/OR tree, any AND node  $c$  corresponds to a partial configuration  $x_{\leq c}$  of  $X$ , defined by its assignment and that of its ancestors:  $x_{\leq c} = x_{\leq p} \cup \{X_s = x_c\}$ , where  $s = pa(c)$ ,  $p = pa(s)$ . For completeness, we also define  $x_{\leq s}$  for any OR node  $s$ , which is the same as that of its AND parent, i.e.,  $x_{\leq s} = x_{\leq pa(s)}$ . For any node  $n$ , the corresponding variables of  $x_{\leq n}$  are denoted as  $X_{\leq n}$ . Let  $de(X_n)$  be the set of variables below  $X_n$  in the pseudo tree; we define  $X_{>n} = de(X_n)$  if  $n$  is an AND node;  $X_{>n} = de(X_n) \cup \{X_n\}$  if  $n$  is an OR node.

We also associate a weight  $w_c$  with each AND node, defined to be the product of all factors  $f_\alpha$  that are instantiated at  $c$  but not before:

$$w_c = \prod_{\alpha \in \mathcal{I}_c} f_\alpha(x_\alpha), \quad \mathcal{I}_c = \{\alpha \mid X_{pa(c)} \in X_\alpha \subseteq X_{an(c)}\}.$$

**Example.** Fig. 1(a) shows the primal graph of a pairwise model. Variables A, B, C are MAX variables, and the rest SUM. Fig. 1(b) shows one valid pseudo tree of the model. Fig. 1(c) shows the AND/OR search tree that respects the pseudo tree.

## 2.2 SEARCH IN AND/OR SEARCH TREES

Finally, the purpose of the search tree is to compute some inference quantity for the model, such as the MAP optimum  $\max_x f(x)$ , the partition function  $Z = \sum_x f(x)$  and the MMAP optimum  $\max_{x_M} \sum_{x_S} f(x)$ . To this end, we associate a “value”  $v_n$  with each node  $n$  in the AND/OR search tree, which represents the inference task’s value on the unexpanded portion of the search space below node  $n$ . The value  $v_n$  can be defined recursively in terms of its children and grandchildren as follows. We first define  $v_l = 1$  for any leaf (since no part of the model remains uninstantiated). Let  $n$  be a non-leaf node; for maximization tasks, we have

$$\text{Max: } v_n = \begin{cases} \prod_{c \in ch(n)} v_c, & \text{if AND node } n. \\ \max_{c \in ch(n)} w_c v_c, & \text{if OR node } n. \end{cases}$$

while for summation, the recursion defining  $v_n$  for  $n$  is

$$\text{Sum: } v_n = \begin{cases} \prod_{c \in \text{ch}(n)} v_c, & \text{if AND node } n. \\ \sum_{c \in \text{ch}(n)} w_c v_c, & \text{if OR node } n. \end{cases}$$

For MMAP tasks, the recursion for AND nodes is the same as the aforementioned tasks, while the recursion for OR nodes is more involved:

$$\text{MMAP: } v_n = \begin{cases} \max_{c \in \text{ch}(n)} w_c v_c, & \text{if OR-MAX node } n. \\ \sum_{c \in \text{ch}(n)} w_c v_c, & \text{if OR-SUM node } n. \end{cases}$$

Any search algorithm for reasoning about the model can be thought of as maintaining upper (and/or lower) bounds on these quantities at each node. In particular, for heuristic search, we assume that we have a heuristic function  $h_n$  that gives upper (or lower) bound on  $v_n$ . These heuristics typically are more accurate deeper in the search tree, and therefore their updates can be propagated upwards to the root to yield tighter bounds to the overall inference value. Any search algorithm is then defined by the order of expansion of the search tree.

A typical example of this kind of search algorithms is AOBFS [Lou *et al.*, 2017a], a best-first search algorithm that can provide anytime upper (and/or lower) bounds for the summation task. Since AOBFS will be a component of our proposed algorithm, we briefly present some of its essence here. AOBFS maintains an explicit AND/OR search tree of visited nodes, denoted  $\mathcal{S}$ . For each node  $n$  in the AND/OR search tree, AOBFS maintains  $u_n$ , an upper bound on  $v_n$ , initialized via a pre-compiled heuristic  $v_n \leq h_n^+$ , and subsequently updated during search using information propagated from the frontier:

$$u_n = \begin{cases} \prod_{c \in \text{ch}(n)} u_c, & \text{if AND node } n. \\ \sum_{c \in \text{ch}(n)} w_c u_c, & \text{if OR node } n. \end{cases}$$

Thus, the upper bound at the root,  $u_\emptyset$ , is an anytime deterministic upper bound of the partition function. Note that this upper bound depends on the current search tree  $\mathcal{S}$ , so we write  $U^\mathcal{S} = u_\emptyset$ .

If all nodes below  $n$  have been visited, then  $u_n = v_n$ ; we call  $n$  *solved* and can remove the subtree below  $n$  from memory. Hence we can partition the frontier nodes into two sets: solved frontier nodes,  $\text{SOLVED}(\mathcal{S})$ , and unsolved ones,  $\text{OPEN}(\mathcal{S})$ .

### 2.3 DYNAMIC IMPORTANCE SAMPLING

Our work can be viewed as a generalization of dynamic importance sampling (DIS) [Lou *et al.*, 2017b], a recent

advance in bounding the partition function with finite-sample bounds (see also [Liu *et al.*, 2015]), which we briefly introduce here to make our paper self-contained.

DIS interleaves search with sampling: search, as it improves the deterministic upper bound of the partition function by expanding nodes in the AND/OR search tree, also induces a sequence of importance sampling proposal distributions with bounded importance weights that are unbiased estimators of the partition function. Meanwhile, samples are drawn independently from those improving proposal distributions. By averaging those importance weights based on their corresponding upper bounds, DIS constructs an unbiased estimator of the partition function  $Z$  with strong probabilistic guarantees.

To be more specific, DIS applies AOBFS with its ‘‘upper priority’’ to quickly drive down the deterministic upper bound. The current search tree  $\mathcal{S}$  induces a proposal distribution  $q^\mathcal{S}$ ; importance weights  $f(x)/q^\mathcal{S}(x)$  are bounded by  $U^\mathcal{S}$  and give an unbiased estimator of  $Z$ :

$$f(x)/q^\mathcal{S}(x) \leq U^\mathcal{S}, \quad \mathbb{E} \left[ f(x)/q^\mathcal{S}(x) \right] = Z.$$

Drawing a sample from  $q^\mathcal{S}$  can be described as a ‘‘two-step’’ top-down sampling process from the root:

**Step 1** For an internal node  $n \in \mathcal{S}$ : if it is an AND node, all its children are selected; if  $n$  is an OR node, one child  $c \in \text{ch}(n)$  is randomly selected with probability  $w_c u_c / u_n$ .

**Step 2** When an unsolved frontier node  $n \in \text{OPEN}(\mathcal{S})$  is reached, draw a sample of its descendant variables  $X_{>n}$  in the pseudo tree according to the mixture proposal  $q(x_{>n} | x_{\leq n})$  derived from *weighted mini-bucket* (WMB, [Liu and Ihler, 2011]).

DIS introduces an unbiased estimator  $\widehat{Z}$  of  $Z$ :

$$\widehat{Z} = \frac{\text{HM}(\mathbf{U})}{N} \sum_{i=1}^N \frac{\widehat{Z}_i}{U_i}, \quad \text{HM}(\mathbf{U}) = \left[ \frac{1}{N} \sum_{i=1}^N \frac{1}{U_i} \right]^{-1}.$$

where  $\{\widehat{Z}_i = f(x^i)/q^{\mathcal{S}_i}(x^i)\}_{i=1}^N$  are importance weights from samples  $\{x^i | x^i \sim q^{\mathcal{S}_i}(x)\}$  with  $\{\mathcal{S}_i\}$  the corresponding search trees, and  $\{U_i = U^{\mathcal{S}_i}\}_{i=1}^N$  the corresponding upper bounds on the importance weights respectively. By defining

$$\Delta = \text{HM}(\mathbf{U}) \left[ \sqrt{\frac{2\widehat{\text{Var}}(\{\widehat{Z}_i/U_i\}_{i=1}^N) \ln(2/\delta)}{N}} + \frac{7 \ln(2/\delta)}{3(N-1)} \right]$$

where  $\widehat{\text{Var}}(\{\widehat{Z}_i/U_i\}_{i=1}^N)$  is the unbiased empirical variance of  $\{\widehat{Z}_i/U_i\}_{i=1}^N$ ,  $\widehat{Z}$  enjoys the finite-sample guarantees: with probability at least  $1 - \delta$ ,  $\widehat{Z} + \Delta$  and  $\widehat{Z} - \Delta$  are upper and lower bounds of  $Z$ , respectively, i.e.,  $\Pr[Z \leq \widehat{Z} + \Delta] \geq 1 - \delta$  and  $\Pr[Z \geq \widehat{Z} - \Delta] \geq 1 - \delta$ .

### 3 OUR ALGORITHM

In this section, we introduce our algorithm, the general idea of which is to first bound the mixed inference objective with a series of sum inference objectives whose finite-sample bounds can be established by generalizing DIS, and then translate the bounds back to those of the original objective in which we are interested.

#### 3.1 AN AUGMENTED GRAPHICAL MODEL

We first introduce an augmented graphical model which connects the MMAP optimum to a series of summation tasks. The augmented graphical model is built from the original model by replicating the SUM variables and the factors. Note that the idea of introducing an augmented space on which we perform inference is adopted from Doucet *et al.* [2002].

Let  $X_{\text{aug}} = (X_M, X_S^1, \dots, X_S^K)$  be all the variables of the augmented model where  $X_S^1, \dots, X_S^K$  are  $K$  replicates of the SUM variables  $X_S$ . The overall function  $f_{\text{aug}}$  of the augmented model is defined as

$$f_{\text{aug}}(x_{\text{aug}}) = \prod_{k=1}^K f(x_M, x_S^k).$$

Thus, the partition function of the augmented model is

$$Z_{\text{aug}} = \sum_{x_M, x_S^1, \dots, x_S^K} \prod_{k=1}^K f(x_M, x_S^k) = \sum_{x_M} \pi^K(x_M).$$

Considering that  $\pi^K(x_M^*)$  (see (1)) is the largest term in the sum on the r.h.s., we have

$$Z_{\text{aug}}/|\mathcal{X}_M| \leq \pi^K(x_M^*) \leq Z_{\text{aug}}, \quad (2)$$

that is to say,

$$(Z_{\text{aug}}/|\mathcal{X}_M|)^{1/K} \leq \pi(x_M^*) \leq Z_{\text{aug}}^{1/K},$$

where  $|\mathcal{X}_M|$  is the size of the MAP space. The above inequalities are actually well-known boundedness relations between the  $\infty$ -norm and  $p$ -norms of the Euclidean space  $\mathbb{R}^{|\mathcal{X}_M|}$ . These bounds are monotonic in  $K$ , i.e., they improve as  $K$  increases, and become tight as  $K$  goes to infinity. In other words,  $K$  acts as a “reverse temperature” parameter. The lower bound is negatively impacted by the domain sizes of the MAX variables, which can be quite loose if  $|\mathcal{X}_M|$  is large compared to the scale of  $K$ .

The significance of (2) is that it connects the MMAP optimum to a summation quantity  $Z_{\text{aug}}$  that can be easily approximated using Monte Carlo methods such as importance sampling.

**Example.** Fig. 1(d) shows an augmented graphical model created from the model of Fig. 1(a). Fig. 1(e) shows one valid pseudo tree for the augmented model.

#### 3.2 MIXED DYNAMIC IMPORTANCE SAMPLING

A straightforward idea is to apply DIS to bound  $Z_{\text{aug}}$  whose finite-sample bounds can then be translated to those of  $\pi(x_M^*)$ . However, several key issues remain to be addressed for this idea to work well.

The first issue is about how to adapt DIS to the augmented model in an efficient manner. Since the augmented model might have many more variables compared to the original model, a naïve construction of AND/OR trees leads to an excessively large search space. Note that any  $X_S^k$  in the augmented model is an identical copy of  $X_S$ ; we thus do not necessarily distinguish those  $X_S$  copies during search. That is to say, when search instantiates those factors involving SUM variables, it behaves as usual but takes into account the effect of replication when using information propagated from SUM nodes. We can also apply an analogous idea to construct weighted mini-bucket (WMB) [Liu and Ihler, 2011] heuristics to ensure that they are still compatible with the new search process. In a nutshell, search for the augmented model can enjoy the same complexity as that for the original model.

Meanwhile, the proposal distribution  $q_{\text{aug}}^S(x_{\text{aug}})$  associated with a search tree  $\mathcal{S}$  has a decomposition property:

$$q_{\text{aug}}^S(x_{\text{aug}}) = q_{\text{aug}}^S(x_M) \prod_{k=1}^K q_{\text{aug}}^S(x_S^k|x_M), \quad (3)$$

with  $q_{\text{aug}}^S(x_S^k|x_M)$  are identical conditional distributions. Its importance weights also share the boundedness property:

$$f_{\text{aug}}(x_{\text{aug}})/q_{\text{aug}}^S(x_{\text{aug}}) \leq U_{\text{aug}}^S,$$

where  $U_{\text{aug}}^S$  is the upper bound associated with  $\mathcal{S}$ . Note that sampling from  $q_{\text{aug}}^S$  can also be done via a two-step sampling procedure analogous to that in DIS.

One point worth mentioning is that

$$\pi(x_M) = \mathbb{E}[f(x_M, x_S^k)/q_{\text{aug}}^S(x_S^k|x_M)]$$

implies that we can estimate the value of each sampled MAP configuration  $x_M$  along the way.

Another issue is that if  $Z_{\text{aug}}$  is much larger than  $\pi^K(x_M^*)$ , even high-quality bounds of  $Z_{\text{aug}}$  might not result in reasonably good bounds of  $\pi(x_M^*)$ , let alone those bounds will never be tight in general for  $\pi(x_M^*)$  with a finite  $K$ . One way to alleviate this issue is based on the following key observation: for any subset  $\mathcal{A}$  of  $\mathcal{X}_M$  that contains  $x_M^*$ , we have

$$Z_{\text{aug}}^{\mathcal{A}}/|\mathcal{A}| \leq \pi^K(x_M^*) \leq Z_{\text{aug}}^{\mathcal{A}}, \quad (4)$$

---

**Algorithm 1** Mixed Dynamic Importance Sampling

---

**Require:** Control parameters  $K, N_d, N_l$ ; confidence parameter  $\delta$ ; memory budget, time budget.

**Ensure:**  $\widehat{Z}_{\text{aug}}, \Delta, \text{HM}(\mathbf{U}), \text{HM}(\mathbf{U}/|\mathcal{A}|)$ .

- 1: Construct WMB heuristics for the augmented model.
  - 2: Initialize  $\mathcal{S} \leftarrow \{\emptyset\}$  with the root  $\emptyset$ .
  - 3: **while** within the time budget
  - 4:     *// update  $\mathcal{S}, U^{\mathcal{S}}, \mathcal{A}^{\mathcal{S}}$  during search.*
  - 5:     **if** within the memory budget
  - 6:         Expand  $N_d$  nodes via AOBFS (Alg. 1 of Lou *et al.* [2017a]) with its “upper priority”.
  - 7:     **else**
  - 8:         Expand  $N_d$  nodes via depth-first search.
  - 9:     **end if**
  - 10:     Draw  $N_l$  samples from  $q_{\text{aug}}^{\mathcal{S}}$  (see (3)).
  - 11:     After drawing each sample:
  - 12:         Update  $N, \widehat{Z}_{\text{aug}}, \text{HM}(\mathbf{U}), \text{HM}(\mathbf{U}/|\mathcal{A}|), \widehat{\text{Var}}, \Delta$  via (5), (6), (11), (12).
  - 13: **end while**
- 

where

$$Z_{\text{aug}}^{\mathcal{A}} = \sum_{x_M \in \mathcal{A}} \pi^K(x_M).$$

The above inequalities tell us that if we know an instantiation of  $X_M$  is not optimal, we can mute its contribution to  $Z_{\text{aug}}$  and use the resulting smaller summation quantity to bound  $\pi^K(x_M^*)$ .

This observation enables pruning during search: any node ruled out from being associated with the optimal configuration can be removed from memory. Such pruning is particularly useful to prune MAX nodes: for any AND-MAX node with its sub-problem beneath solved, if it holds the highest value among its siblings, all its siblings (solved or not) and their descendants can be pruned immediately. Thus, as pruning proceeds along with search,  $\mathcal{A}$  shrinks towards  $\{x_M^*\}$ . We use  $\mathcal{A}^{\mathcal{S}}$  to denote the remaining MAP space associated with the search tree  $\mathcal{S}$ .

Note that when we approach the memory limit, we switch the default best-first search to a depth-first search (DFS) that is also compatible with the sampling procedure, and leads to a complete search algorithm with the capability to identify  $x_M^*$  and its value given enough time. By interleaving search and sampling, we derive our algorithm named *mixed dynamic importance sampling* (MDIS) and present it in Alg. 1.

**Remarks on Alg. 1.**

1)  $K$  as the number of replicates of the SUM variables controls the exploration-exploitation trade-off. When  $K$  is small, we draw a small number of samples for the

SUM variables in each iteration, which allows us to evaluate each sampled MAP configuration fast, however introduces more randomness when assessing the MAP configuration; when  $K$  is large, we have more accurate estimate of a MAP configuration being sampled, but also slow down exploration of the MAP space.

2) To predict MAP solutions in an anytime manner, one can simply choose the one with the highest estimated value among those configurations that have been sampled.

**3.2.1 Finite-sample Bounds for Marginal MAP**

In MDIS, each sample not only comes from a different proposal distribution but also gives importance weights corresponding to a different expectation, which is more complicated than in DIS.

Let  $\{x_{\text{aug}}^i\}_{i=1}^N$  be a series of samples drawn via Alg. 1, with  $\{\mathcal{S}_i\}$  the corresponding search trees,  $\{\widehat{Z}_{\text{aug}}^i = f_{\text{aug}}(x_{\text{aug}}^i)/q_{\text{aug}}^{\mathcal{S}_i}(x_{\text{aug}}^i)\}_{i=1}^N$  the corresponding importance weights, and  $\{U_i = U_{\text{aug}}^{\mathcal{S}_i}\}_{i=1}^N$  the corresponding upper bounds associated with those search trees respectively. We denote  $\mathcal{A}_i$  as the MAP space preserved in  $\mathcal{S}_i$ . Thus,

$$\mathbb{E}[\widehat{Z}_{\text{aug}}^i] = Z_{\text{aug}}^{\mathcal{A}_i}.$$

That is to say, the importance weights have different (in fact, decreasing) expectations; this differs from the case of DIS where any importance weight has the same expectation (the partition function). We propose an estimate  $\widehat{Z}_{\text{aug}}$  whose expectation is again an upper bound of  $\pi^K(x_M^*)$  in the following way:

$$\widehat{Z}_{\text{aug}} = \frac{\text{HM}(\mathbf{U})}{N} \sum_{i=1}^N \frac{\widehat{Z}_{\text{aug}}^i}{U_i}, \quad (5)$$

where

$$\text{HM}(\mathbf{U}) = \left[ \frac{1}{N} \sum_{i=1}^N \frac{1}{U_i} \right]^{-1} \quad (6)$$

is the harmonic mean of the upper bounds  $\{U_i\}_{i=1}^N$ . Thus,  $\widehat{Z}_{\text{aug}}$  upweights the terms  $\widehat{Z}_{\text{aug}}^i$  whose expectations are closer to  $\pi^K(x_M^*)$ . The expectation of  $\widehat{Z}_{\text{aug}}$  is

$$\mathbb{E}[\widehat{Z}_{\text{aug}}] = \frac{\text{HM}(\mathbf{U})}{N} \sum_{i=1}^N \frac{Z_{\text{aug}}^{\mathcal{A}_i}}{U_i}.$$

$\mathbb{E}[\widehat{Z}_{\text{aug}}]$  is a convex combination of  $\{Z_{\text{aug}}^{\mathcal{A}_i}\}_{i=1}^N$  with coefficients  $\{\frac{\text{HM}(\mathbf{U})}{NU_i}\}_{i=1}^N$ , shrinking towards  $\pi^K(x_M^*)$  as search proceeds.

According to (4), since  $\pi^K(x_M^*) \leq Z_{\text{aug}}^{\mathcal{A}_i}$ , we know

$$\pi^K(x_M^*) \leq \mathbb{E}[\widehat{Z}_{\text{aug}}], \quad (7)$$

and from  $Z_{\text{aug}}^{\mathcal{A}_i} \leq |\mathcal{A}_i| \pi^K(x_M^*)$ , we know

$$\mathbb{E} [\widehat{Z}_{\text{aug}}] \leq \pi^K(x_M^*) \frac{\text{HM}(\mathbf{U})}{N} \sum_{i=1}^N \frac{|\mathcal{A}_i|}{U_i}. \quad (8)$$

By combining (6), (7), and (8), we derive two-sided bounds for  $\pi^K(x_M^*)$  involving  $\mathbb{E} [\widehat{Z}_{\text{aug}}]$ :

$$\frac{\sum_{i=1}^N 1/U_i}{\sum_{i=1}^N |\mathcal{A}_i|/U_i} \mathbb{E} [\widehat{Z}_{\text{aug}}] \leq \pi^K(x_M^*) \leq \mathbb{E} [\widehat{Z}_{\text{aug}}]. \quad (9)$$

From the above, we can see that the bounds get tight only when  $\mathcal{A}_i$  approaches  $\{x_M^*\}$ . To be concise, we re-arrange the L.H.S. of (9) to derive:

$$\frac{\text{HM}(\mathbf{U}/|\mathcal{A}|)}{\text{HM}(\mathbf{U})} \mathbb{E} [\widehat{Z}_{\text{aug}}] \leq \pi^K(x_M^*) \leq \mathbb{E} [\widehat{Z}_{\text{aug}}], \quad (10)$$

where

$$\text{HM}(\mathbf{U}/|\mathcal{A}|) = \left[ \frac{1}{N} \sum_{i=1}^N \frac{|\mathcal{A}_i|}{U_i} \right]^{-1} \quad (11)$$

is the harmonic mean of  $\{U_i/|\mathcal{A}_i|\}_{i=1}^N$ .

Considering  $\widehat{Z}_{\text{aug}}^i$  are independent, and  $\mathbb{E} \widehat{Z}_{\text{aug}}/\text{HM}(\mathbf{U})$ ,  $\widehat{Z}_{\text{aug}}/\text{HM}(\mathbf{U})$ ,  $\widehat{Z}_{\text{aug}}^i/U_i$  are all within the interval  $[0, 1]$ , we can apply an empirical Bernstein bound [Maurer and Pontil, 2009] to derive finite-sample bounds on  $\mathbb{E} \widehat{Z}_{\text{aug}}$  and translate those bounds to  $\pi(x_M^*)$  based on (10).

**Theorem 1.** For any  $\delta \in (0, 1)$ , we define

$$\Delta = \text{HM}(\mathbf{U}) \left( \sqrt{\frac{2\widehat{\text{Var}} \ln(2/\delta)}{N}} + \frac{7 \ln(2/\delta)}{3(N-1)} \right), \quad (12)$$

where  $\widehat{\text{Var}}$  is the unbiased empirical variance of  $\{\widehat{Z}_{\text{aug}}^i/U_i\}_{i=1}^N$ . Then, the following probabilistic bounds hold for  $\pi(x_M^*)$ :

$$\begin{aligned} \Pr [\pi(x_M^*) \leq (\widehat{Z}_{\text{aug}} + \Delta)^{\frac{1}{K}}] &\geq 1 - \delta, \\ \Pr [\pi(x_M^*) \geq \left( \frac{(\widehat{Z}_{\text{aug}} - \Delta) \text{HM}(\mathbf{U}/|\mathcal{A}|)}{\text{HM}(\mathbf{U})} \right)^{\frac{1}{K}}] &\geq 1 - \delta, \end{aligned}$$

i.e.,  $(\widehat{Z}_{\text{aug}} + \Delta)^{\frac{1}{K}}$  and  $\left( \frac{(\widehat{Z}_{\text{aug}} - \Delta) \text{HM}(\mathbf{U}/|\mathcal{A}|)}{\text{HM}(\mathbf{U})} \right)^{\frac{1}{K}}$  are upper and lower bounds of  $\pi(x_M^*)$  with probability at least  $1 - \delta$ , respectively.

Note that it is possible that  $\widehat{Z}_{\text{aug}} - \Delta < 0$  early on; if so, we may replace  $\widehat{Z}_{\text{aug}} - \Delta$  with any non-trivial lower bound of  $Z_{\text{aug}}$ . In the experiments, we use  $\delta \widehat{Z}_{\text{aug}}$ , a  $(1 - \delta)$  probabilistic bound by the Markov inequality [Gogate and Dechter, 2011]. We can replace  $\widehat{Z}_{\text{aug}} + \Delta$  with the current deterministic upper bound if the latter is tighter.

## 4 EXPERIMENTS

We evaluate our proposed approach (MDIS) against two baseline methods on five benchmarks. The baselines include UBFS [Lou *et al.*, 2018], a unified best-first search algorithm that emphasizes rapidly tightening the upper bound, and AAOBF [Marinescu *et al.*, 2017], a best-first/depth-first hybrid search algorithm that balances upper bound quality with generating and evaluating potential solutions. These two are state-of-the-art algorithms for anytime upper and lower bounds respectively. We do not compare to XOR\_MMAP [Xue *et al.*, 2016] and AFSE [Mauá and de Campos, 2012] due to their limitations to relatively easy problem instances as shown in Lou *et al.* [2018].

Three benchmarks are formed by problem instances from recent UAI competitions: `grid`- 50 grid networks with size no smaller than 25 by 25, `promedas`- 50 medical diagnosis expert systems, `protein`- 44 instances made from the ‘‘small’’ protein side-chains of [Yanover and Weiss, 2002]. Since the original UAI instances are pure MAP tasks, we generate MMAP instances by randomly selecting 10% of the variables as MAP variables. The fourth benchmark is `planning`, formed by 15 instances from probabilistic conformant planning with a finite-time horizon [Lee *et al.*, 2016a]. On these four benchmarks, we compare anytime bounds. Some statistics of the four benchmarks are shown in Table 1. These benchmarks are selected to illustrate different problem characteristics; for example, `protein` instances are relatively small but high cardinality, while `planning` instances have more variables and higher induced width, but lower cardinality. The fifth benchmark, which we will describe in detail later, is created from an image denoising model in order to evaluate quality of the predicted MAP solutions.

The time budget is set to 1 hour for the experiments on the first four benchmarks. We allot 4GB memory to all algorithms, with 1GB extra memory to AAOBF for caching. For our experiments, we use the weighted mini-bucket [Liu and Ihler, 2011] heuristics, whose memory usage is roughly controlled by an *ibound* parameter. For a given memory budget, we first compute the largest *ibound* that fits in memory, then use the remaining memory for search. Since all the competing algorithms use weighted mini-bucket heuristics, the same *ibound* is shared during heuristic construction. We set  $N_d = 100$  and  $N_l = 1$  (see Alg. 1) as suggested by the experimental results in Lou *et al.* [2017b]. We set  $\delta = 0.025$ . All implementations are in C/C++ courtesy of the original authors.

**Anytime bounds for individual instances.** Fig. 2 shows the anytime behavior of all the methods on instances from four benchmarks. In terms of lower bounds,

Table 1: Statistics of the four evaluated benchmarks. The first three benchmarks are formed by problem instances from recent UAI competitions, where 10% of variables are randomly selected as MAX variables. “avg. ind. width of sum” in the last row stands for the average induced width of the internal summation problems.

	grid	promedas	protein	planning
# instances	50	50	44	15
avg. # variables	1248.20	982.10	109.55	1122.33
avg. % of MAX vars	10%	10%	10%	12%
avg. # of factors	1248.20	994.76	394.64	1127.67
avg. max domain size	2.00	2.00	81.00	3.00
avg. max scope	3.00	3.00	2.00	5.00
avg. induced width	124.82	108.14	15.84	165.00
avg. pseudo tree depth	228.92	158.78	33.52	799.33
avg. ind. width of sum	43.44	40.32	10.20	49.67

our approach can always provide decent lower bounds even when the internal summation problems are quite challenging, while AAOBF may not work well since it relies on exact evaluation of those internal summation problems, e.g., on those shown in Fig. 2(b)-2(d). When the internal summation problems are relatively easy, their exact evaluation is cheap; thus AAOBF might perform better than ours. Fig. 2(a) gives a typical example. In terms of upper bounds, our bound quality is often eventually comparable to UBFS, e.g., Fig. 2(b)-2(d). UBFS typically performs better than MDIS early on, while MDIS quickly catches up and becomes comparable. Improvement in AAOBF on upper bounds also requires fast exact evaluation of the internal summation problems, which might not be possible in many cases. So, AAOBF is usually not as competitive as the other two methods on upper bounds.

**Anytime bounds across benchmarks.** We present the anytime performance across the four benchmarks in Table 2 and 3 where we compare anytime bounds at three different timestamps: 1 minute, 10 minutes and 1 hour. From Table 2, we can observe that MDIS with  $K=5$  is dominant at any of these timestamp/benchmark combinations for lower bounds. MDIS with  $K=10$  performs less well, perhaps because it requires more time to draw one full sample compared to when  $K=5$ , leading the empirical Bernstein lower bounds to kick in relatively late; this phenomenon can be also observed in all the plots in Fig. 2. UBFS provides the best upper bounds as shown in Table 3. However, our algorithm generally performs better than AAOBF in terms of upper bounds.

**Empirical evaluation of solution quality.** To evaluate the MAP solution quality predicted by our algorithm, we create an image denoising task from the MNIST database<sup>1</sup>

<sup>1</sup><http://yann.lecun.com/exdb/mnist/>

Table 2: Number of instances that an algorithm achieves the best *lower bounds* at each timestamp (1 min, 10 min, and 1 hour) for each benchmark. The best for each setting is bolded. Entries for UBFS are blank because UBFS does not provide lower bounds.

	grid	promedas	protein	planning
# instances	50	50	44	15

MDIS ( $K=5$ )	<b>47/44/45</b>	<b>32/34/31</b>	<b>31/27/28</b>	<b>14/13/13</b>
MDIS ( $K=10$ )	3/2/1	4/5/6	11/13/14	1/2/2
UBFS	-/-/-	-/-/-	-/-/-	-/-/-
AAOBF	0/4/4	16/21/24	2/4/4	0/0/0

Table 3: Number of instances that an algorithm achieves the best *upper bounds* at each timestamp (1 min, 10 min, and 1 hour) for each benchmark. The best for each setting is bolded.

	grid	promedas	protein	planning
# instances	50	50	44	15
Timestamp: 1min/10min/1hr				
MDIS ( $K=5$ )	0/0/0	9/12/13	5/9/15	1/1/1
MDIS ( $K=10$ )	0/0/0	10/13/14	9/10/13	1/2/3
UBFS	<b>50/50/50</b>	<b>50/50/50</b>	<b>36/32/26</b>	<b>14/14/13</b>
AAOBF	0/0/1	2/4/6	2/2/2	1/1/1

of handwritten digits [LeCun *et al.*, 1998]. We binarize each image, resize it to 14 by 14, and then randomly flip 5% of the pixels to generate a corrupt one. We train a conditional restricted Boltzmann machine (CRBM) [Mnih *et al.*, 2011] model with 64 hidden units and 196 visible units using mixed-product BP [Ping and Ihler, 2017; Liu and Ihler, 2013] for the denoising task. The resulting graphical model thus has 64 SUM variables and 196 MAX variables. Fig. 3(c) gives an illustration of this model. The advantage of this model is that we can easily evaluate any MAP configuration since the internal summation problem only contains singleton potentials; thus this model favors AAOBF since AAOBF is able to evaluate MAP configurations at a very low cost. We set  $K$  to 5 and runtime to 10 minutes for convenience. We test on 100 images with 10 images per digit. Fig. 3(a) compares the denoising results among all the algorithms for one instance per digit. Fig. 3(b) gives an example of the quality of the predicted MAP solutions of our algorithm. In general, the quality of predicted MAP solutions for our algorithm are better than the other two baselines in 51 of 100 instances, which is generally as good as AAOBF (47/100) despite the model being well-suited to AAOBF. A possible reason is that our algorithm is able to traverse the MAP space very quickly and get cheap stochastic estimates of the most promising MAP solutions.

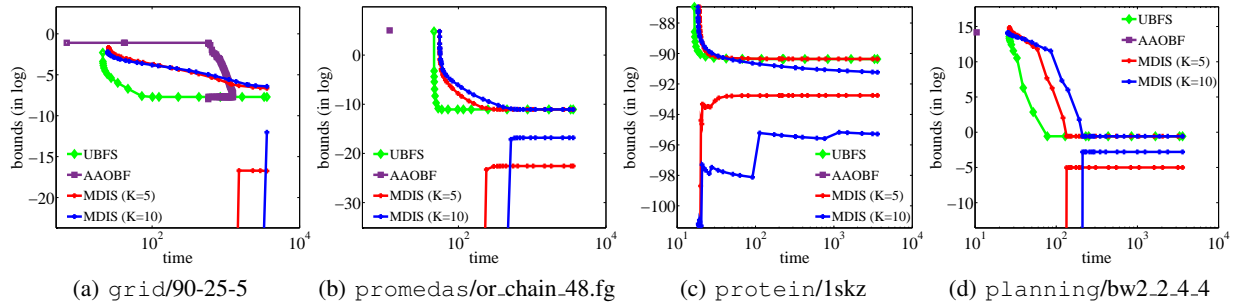

Figure 2: Anytime bounds for MMAP on instances from four benchmarks. The max domain sizes of those instances from (a)-(d) are 2, 2, 81, 3 respectively, and the induced widths of the internal summation problems are 25, 28, 8, 24 respectively. Curves for some bounds may be (partially) missing because they are not in a reasonable scope. UBFS only provides upper bounds. The time limit is 1 hour.

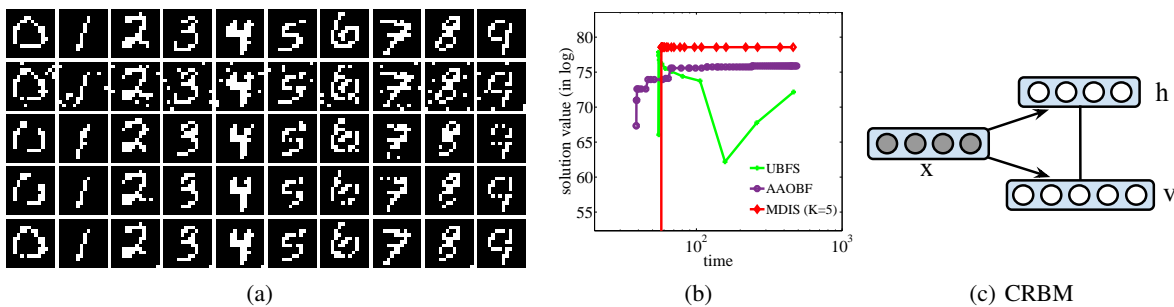

Figure 3: (a) Image denoising results for one instance per digit. The first row is for the ground truth images. The second row is for the noisy inputs created from the ground truth by randomly flipping 5% pixels. Below the first two rows are denoised images from UBFS, AAOBF, MDIS ( $K=5$ ) respectively. (b) An example on MAP solution quality comparison. (c) Illustration of the conditional restricted Boltzmann machine (CRBM) model used for the image denoising task. When conditioned on an input “X”, this model has a bipartite graph structure between hidden units “h” (SUM variables) and visible units “v” (MAX variables).

## 5 CONCLUSION

In this paper, we propose an approach that provides anytime finite-sample upper and lower bounds for MMAP, which enjoys the merits of both heuristic search and importance sampling. Our approach is particularly useful for problem instances whose internal summation problems are challenging. It predicts high-quality MAP solutions along with their estimated values. It runs in an anytime/anyspace manner, which gives flexible trade-offs between memory, time, and solution quality.

## Abstract

The conditional independence structure induced on the observed marginal distribution by a hidden variable directed acyclic graph (DAG) may be represented by a graphical model represented by mixed graphs called maximal ancestral graphs (MAGs). This model has a number of desirable properties, in particular the set of Gaussian distributions can be parameterized by viewing the graph as a path diagram. Models represented by MAGs have been used for causal discovery [22], and identification theory for causal effects [28].

In addition to ordinary conditional independence constraints, hidden variable DAGs also induce generalized independence constraints. These constraints form the nested Markov property [20]. We first show that acyclic linear SEMs obey this property. Further we show that a natural parameterization for all Gaussian distributions obeying the nested Markov property arises from a generalization of maximal ancestral graphs that we call maximal arid graphs (MArG). We show that every nested Markov model can be associated with a MArG; viewed as a path diagram this MArG parametrizes the Gaussian nested Markov model. This leads directly to methods for ML fitting and computing BIC scores for Gaussian nested models.

## 1 INTRODUCTION

Causal models associated with graphs have a long history in statistics, beginning with the seminal work of Wright in pedigree analysis [27], Haavelmo's work on simultaneous equations in econometrics [13] and the more recent synthesis of earlier work into a general causal modeling framework due to Pearl [17]. Causal graphical

models are widely used in a variety of disciplines, with many theoretical developments and applications.

An important parametric subclass of causal graphical models are the linear structural equation models with correlated errors (SEMs). In fact, Wright and to some extent Haavelmo's work was originally within the SEM class. SEMs are defined over a class of mixed graphs containing directed ( $\rightarrow$ ) edges representing direct causation, and bidirected ( $\leftrightarrow$ ) edges representing correlated errors. Mixed graphs of this type without directed cycles—an assumption that rules out cyclic causation—are called *acyclic directed mixed graphs* (ADMGs).

Given an ADMG  $\mathcal{G}$ , the *linear structural equation model with correlated errors (SEM)* associated with  $\mathcal{G}$  is formally defined as the set of multivariate normal distributions with covariance matrices of the form

$$\Sigma = (I - B)^{-T} \Omega (I - B)^{-1},$$

where  $\omega_{ij} = \omega_{ji} = 0$  unless  $i \leftrightarrow j$  exists in  $\mathcal{G}$ , and  $b_{ij} = 0$  unless  $i \rightarrow j$  exists in  $\mathcal{G}$ . The matrix  $\Omega$ —and therefore  $\Sigma$ —is assumed to be positive definite. We denote this set by  $\mathcal{P}_{\text{sem}}(\mathcal{G})$ , and the set of Gaussians with arbitrary covariances  $\mathcal{N}$ .

It is easy to show that this model is equivalent to assuming that each variable  $X_i$  is a linear function of its parents with coefficients  $b_{ji}$  together with an additive error term. The error terms are assumed to have a multivariate normal distribution with covariance matrix given by  $\Omega$ . If  $\Omega = I$ , error terms are uncorrelated and the SEM corresponds to a directed acyclic graph (DAG).

Elements of  $\mathcal{P}_{\text{sem}}(\mathcal{G})$  are known to obey the global Markov property for  $\mathcal{G}$  given by a criterion called *m-separation* [15, 19, 23]; this is the natural extension of d-separation to mixed graphs—see the Appendix for a definition. This criterion implies that absences of certain edges in  $\mathcal{G}$  correspond to conditional independences in elements of  $\mathcal{P}_{\text{sem}}(\mathcal{G})$ . Densities that obey this global Markov property are said to be in the *ordinary Markov model* of  $\mathcal{G}$ , a set of densities we denote  $\mathcal{P}_o(\mathcal{G})$  [9].

Hence  $\mathcal{P}_{\text{sem}}(\mathcal{G}) \subseteq \mathcal{P}_o(\mathcal{G}) \cap \mathcal{N}$ ; that is elements of the SEM for  $\mathcal{G}$  are multivariate normal and are in the ordinary Markov model of  $\mathcal{G}$ .

Given a DAG  $\mathcal{D}$  with observed variables  $O$  and hidden variables  $H$ , a simple operation, called the latent projection [26], maps it to an ADMG  $\mathcal{G}$  with only observed variables  $O$ , such that d-separation applied to any variables in  $O$  in  $\mathcal{D}$ , and m-separation applied to  $\mathcal{G}$  yields the same set of conditional independence relations on  $O$ . Thus, distributions Markov relative to a hidden variable DAG yield marginal distributions in  $\mathcal{P}_o(\mathcal{G})$  for a latent projection  $\mathcal{G}$ .

However, more recent work has shown that these marginal distributions also obey certain *generalized conditional independence constraints*, sometimes called *Verma constraints* [6]. These define a model known as the *nested Markov model*, also associated with  $\mathcal{G}$ , and denoted  $\mathcal{P}_n(\mathcal{G})$  [20]; generally  $\mathcal{P}_n(\mathcal{G}) \subseteq \mathcal{P}_o(\mathcal{G})$ , since the nested model implies all the constraints of m-separation. In this paper we show that distributions in the SEM for  $\mathcal{G}$  also obey the additional constraints of the nested Markov model, so  $\mathcal{P}_{\text{sem}}(\mathcal{G}) \subseteq \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ .

Although well-studied, general SEMs possess many complexities that make them potentially difficult to work with. The models may not be everywhere identifiable, and may contain singularities that prevent convergence of fitting algorithms [5]. No general distributional equivalence result is available for SEMs; see [25] for recent developments. In addition, while characterization of identifiability of causal effects is known for non-parametric structural equations [14, 21], a similar result is not known for SEMs despite decades of work [1, 2, 3, 4, 8, 11, 12, 24].

It is known that SEMs are everywhere identified if and only if they are associated with ADMGs in a special class [7]; in this paper we call this class *arid graphs*. We show that in a further subclass called *maximal arid graphs* (MARGs), it is the case that  $\mathcal{P}_{\text{sem}}(\mathcal{G}) = \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ . Moreover, we show that restricting to maximal arid graphs is without loss of generality in the sense that for any ADMG  $\mathcal{G}$ , there exists a maximal arid graph  $\mathcal{G}^\dagger$  such that  $\mathcal{P}_n(\mathcal{G}) = \mathcal{P}_n(\mathcal{G}^\dagger)$ . We also provide an algorithm for obtaining this *maximal arid projection* from  $\mathcal{G}$ , and show that  $\mathcal{G}^\dagger$  has the same ancestral relations as  $\mathcal{G}$ .

Our results immediately imply that the nested Markov model over multivariate normal densities is a curved exponential family of known dimension, and is everywhere identifiable. They also imply that Gaussian nested models can be fitted efficiently with existing algorithms, such as RICF [5], applied to the SEM associated with  $\mathcal{G}^\dagger$ . Conversely, our results imply that every SEM obeys all the generalized independence constraints implied by  $\mathcal{P}_n(\mathcal{G})$ .

MARGs form a natural subclass of ADMGs for the purposes of nested Markov model search methods, which could be used for causal discovery. This would be a more powerful alternative to model search with maximal ancestral graphs (MAGs), since nested models are more fine-grained and therefore make more unambiguous causal information available. Though the results in this paper make significant progress towards causal structure learning with nested Markov models, more work is required. In particular, a natural next step would be to fully describe equivalence classes of nested Markov models, and develop a constraint based model search algorithm that is akin to the FCI algorithm [22], but that also takes generalized conditional independence constraints into account.

The remainder of the paper is organized as follows. Section 2 gives some preliminary definitions, including that of acyclic directed mixed graphs (ADMGs). In Section 3 we define the nested Markov model associated with ADMGs formally, including the central notion of ‘fixing’. Section 4 shows that the class of nested models can be represented, without loss of generality, by the class of maximal arid graphs. Section 5 characterizes fixing in terms of zeroes of SEM parameters; this leads to the result in Section 6, which shows that for maximal arid graphs, the nested model and SEM coincide. We conclude with an example in Section 7, and discussion in Section 8. The proofs of certain results that are not essential to the presentation are deferred to the Appendix.

## 2 PRELIMINARIES

In this paper, we consider mixed graphs with directed ( $\rightarrow$ ) and bidirected ( $\leftrightarrow$ ) arrows connecting pairs of distinct vertices. There is at most one edge of each type between any pair of vertices, and we forbid directed cycles (i.e. sequences of the form  $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_k \rightarrow v_1$  for  $k \geq 2$ ). Graphs in this class are called *acyclic directed mixed graphs* (ADMGs). ADMGs may contain *bows*, where both  $a \rightarrow b$  and  $a \leftrightarrow b$ , but this is the only circumstance in which more than one edge may be present between two vertices. See Fig. 2, 3 and 4 for examples of ADMGs.

We will use standard genealogical terminology for relations between vertices. Given a vertex  $v$  in an ADMG  $\mathcal{G}$  with a vertex set  $V$ , define the sets of *parents*, *children*, *ancestors*, *descendants*, and *siblings* of  $v$  as

$$\begin{aligned} \text{pa}_{\mathcal{G}}(v) &\equiv \{w : w \rightarrow v \text{ in } \mathcal{G}\} \\ \text{ch}_{\mathcal{G}}(v) &\equiv \{w : v \rightarrow w \text{ in } \mathcal{G}\} \\ \text{an}_{\mathcal{G}}(v) &\equiv \{w : w = v \text{ or } w \rightarrow \dots \rightarrow v \text{ in } \mathcal{G}\} \\ \text{de}_{\mathcal{G}}(v) &\equiv \{w : w = v \text{ or } v \rightarrow \dots \rightarrow w \text{ in } \mathcal{G}\} \\ \text{sib}_{\mathcal{G}}(v) &\equiv \{w : w \leftrightarrow v \text{ in } \mathcal{G}\}. \end{aligned}$$

respectively. Define also the *non-descendants* of  $v$  to be  $\text{nd}_{\mathcal{G}}(v) \equiv V \setminus \text{de}_{\mathcal{G}}(v)$ . The definitions apply disjointly to sets, e.g. for a set of vertices  $W \subseteq V$ ,  $\text{pa}_{\mathcal{G}}(W) \equiv \bigcup_{w \in W} \text{pa}_{\mathcal{G}}(w)$ . In addition, we define the *district* of  $v$  to be the set

$$\text{dis}_{\mathcal{G}}(v) \equiv \{w : w \leftrightarrow \dots \leftrightarrow v \text{ in } \mathcal{G}\}.$$

The set of districts of an ADMG  $\mathcal{G}$ , which we denote by  $\mathcal{D}(\mathcal{G})$ , always partitions the set of vertices in  $\mathcal{G}$ .

An internal vertex  $v$  on a path is a *collider* (on the path) if both adjacent edges have an arrowhead at  $v$ . A path from  $w$  to  $v$  in  $\mathcal{G}$  is called a *collider path* if every internal vertex is a collider on the path. For example  $w \rightarrow z \leftrightarrow m \leftarrow v$  is a collider path, while  $w \rightarrow z \rightarrow m \rightarrow v$  is not.

Given an ADMG  $\mathcal{G}$ , and a subset  $S$  of vertices  $V$  in  $\mathcal{G}$ , the *induced subgraph*  $\mathcal{G}_S$  is the graph with vertex set  $S$ , and those edges in  $\mathcal{G}$  between elements in  $S$ . A set  $S$  is called *bidirected-connected* in  $\mathcal{G}$  if  $\mathcal{D}(\mathcal{G}_S)$  contains a single set.

### 3 NESTED MARKOV MODELS

Nested Markov models are a class of graphical models associated with ADMGs, and defined by generalized independence constraints. We consider random variables  $X_V \equiv (X_v : v \in V)$  taking values in the product space  $\mathfrak{X}_V = \times_{v \in V} \mathfrak{X}_v$ , for finite dimensional sets  $\mathfrak{X}_v$ . For any  $A \subseteq V$  we denote the subset  $(X_v : v \in A)$  by  $X_A$ .

A *kernel*  $q_V(x_V | x_W)$  is a collection of densities over  $X_V$ , indexed by  $x_W \in \mathfrak{X}_W$ . Conditional densities are kernels, but not all kernels are obtained by conditioning; we give some examples later. Conditioning and marginalization are defined in the usual way in kernels.

A joint density  $p(x_V)$  over  $X_V$  is said to be *nested Markov* with respect to an ADMG  $\mathcal{G}$  if it obeys certain independence constraints in kernels derived from  $p(x_V)$  using a ‘fixing’ operation. These constraints are implied by the m-separation criterion applied to *conditional ADMGs* (*CADMGs*) obtained from  $\mathcal{G}$  by an analogous fixing operation. We now define these terms, and the nested Markov model, precisely.

A CADMG  $\mathcal{G}(V, W)$  is an ADMG with a set of *random* vertices  $V$  and *fixed* vertices  $W$ , with the property that  $\text{sib}_{\mathcal{G}}(w) \cup \text{pa}_{\mathcal{G}}(w) = \emptyset$  for every  $w \in W$ . An example can be found in Fig. 1(b); note that we depict fixed vertices with rectangular nodes, and random vertices with round nodes. Vertices  $V$  in a CADMG correspond to random variables, as in standard graphical models, while vertices in  $W$  correspond to variables that were fixed to a specific value by some operation, such as conditioning or causal interventions. The genealogical relations in

Section 2 generalize in a straightforward way to CADMGs by ignoring the distinction between  $V$  and  $W$ ; the only exception is that districts are only defined for random vertices, so  $\mathcal{D}(\mathcal{G}(V, W))$  partitions  $V$ .

#### 3.1 Fixing

A vertex  $r \in V$  is said to be *fixable* in a CADMG  $\mathcal{G}(V, W)$  if  $\text{dis}_{\mathcal{G}}(r) \cap \text{de}_{\mathcal{G}}(r) = \emptyset$ . Given a CADMG  $\mathcal{G}(V, W)$ , and a fixable  $r \in V$ , the fixing operation  $\phi_r(\mathcal{G})$  yields a new CADMG  $\tilde{\mathcal{G}}(V \setminus \{r\}, W \cup \{r\})$  obtained from  $\mathcal{G}(V, W)$  by removing all edges of the form  $\rightarrow r$  and  $\leftrightarrow r$ , and keeping all other edges. Given a kernel  $q_V(x_V | x_W)$  associated with a CADMG  $\mathcal{G}(V, W)$ , and a fixable  $r \in V$ , the fixing operation  $\phi_r(q_V; \mathcal{G})$  yields a new kernel

$$\tilde{q}_{V \setminus \{r\}}(x_{V \setminus \{r\}} | x_W, x_r) \equiv \frac{q_V(x_V | x_W)}{q_V(x_r | x_{\text{nd}_{\mathcal{G}}(r)})}.$$

A sequence  $r_1, \dots, r_k$  of vertices in  $V$  is said to be *fixable* if  $r_1$  is fixable in  $\mathcal{G}$ ,  $r_2$  is fixable in  $\phi_{r_1}(\mathcal{G})$ , etc. A result in [20] states that for any  $p(x_V) \in \mathcal{P}_n(\mathcal{G})$ , two valid fixing sequences on the same set of variables  $R$  yield the same CADMG and kernel. We therefore unambiguously define

$$\phi_R(\mathcal{G}) \equiv \phi_{r_k}(\dots \phi_{r_2}(\phi_{r_1}(\mathcal{G})) \dots),$$

and similarly the kernel  $\phi_R(p; \mathcal{G})$ .

If a fixing sequence exists for a set  $R \subseteq V$  in  $\mathcal{G}(V, W)$ , we say  $V \setminus R$  is a *reachable set*. Such a set is called *intrinsic* if the vertices in  $V \setminus R$  are bidirected-connected (so that  $\mathcal{D}(\phi_R(\mathcal{G}))$  has a single element). We denote the collections of reachable and intrinsic sets in  $\mathcal{G}$  respectively by  $\mathcal{R}(\mathcal{G})$  and  $\mathcal{I}(\mathcal{G})$ .

For any  $v \in V$ , such that  $\text{ch}_{\mathcal{G}}(v) = \emptyset$ , the *Markov blanket* of  $v$  in a CADMG  $\mathcal{G}(V, W)$  is defined as

$$\text{mb}_{\mathcal{G}}(v) \equiv (\text{dis}_{\mathcal{G}}(v) \cup \text{pa}_{\mathcal{G}}(\text{dis}_{\mathcal{G}}(v))) \setminus \{v\},$$

this is the set of vertices that are connected to  $v$  by collider paths. For brevity, we will denote  $\text{mb}_{\phi_{V \setminus S}(\mathcal{G})}(v)$  by  $\text{mb}_{\mathcal{G}}(v, S)$ .

We are now ready to define the nested Markov model  $\mathcal{P}_n(\mathcal{G})$ . Given an ADMG  $\mathcal{G}$ , let  $\prec$  be any topological ordering on  $V$ . A distribution  $p(x_V)$  is in the nested Markov model associated with  $\mathcal{G}$  if, for each intrinsic  $S \subseteq V$  and  $\prec$ -maximal  $v \in S$ ,

$$X_v \perp\!\!\!\perp X_{V \setminus (\{v\} \cup \text{mb}_{\mathcal{G}}(v, S))} \mid X_{\text{mb}_{\mathcal{G}}(v, S)}$$

holds in  $\phi_{V \setminus S}(p(x_V); \mathcal{G})$ . This is known as the *ordered local Markov property* for nested models. As a consequence, under the nested model, fixing  $r$

Figure 1: (a) An ADMG  $\mathcal{G}$  that is not ancestral; (b) a CADMG obtained from  $\mathcal{G}$  in (a) by fixing  $a$  and  $c$ ; (c) the graph obtained from (b) that is used to check conditional independence statements associated with  $\phi_{\{a,c\}}(p(a,b,c,d); \mathcal{G})$ .

within any  $R \in \mathcal{R}(\mathcal{G})$  may be redefined as dividing by  $q_R(x_r | x_{\text{mb}_{\mathcal{G}}(r,R)})$ , instead of dividing by  $q_R(x_r | x_{\text{nd}_{\mathcal{G}}(r)})$  (see section 2.11 in [20]). Nested models can be equivalently defined by a *global nested Markov property* obtained by applying the m-separation criterion to each reachable graph  $\phi_{V \setminus S}(\mathcal{G})$  after adding bidirected edges between all pairs of fixed vertices; adding these bidirected edges ensures no independences are implied between vertices in  $W$ . These m-separations imply independences in the kernel  $\phi_{V \setminus S}(p; \mathcal{G})$ ; see [20].

**Example 1.** Consider the ADMG in Fig. 1(a). The vertices  $a$ ,  $c$  and  $d$  all satisfy the condition of being fixable, but  $b$  does not since  $d$  is both a descendant of, and in the same district as,  $b$ . The CADMG  $\mathcal{G}(\{b, d\}, \{a, c\})$  obtained after fixing  $a$  and  $c$  is shown in Fig. 1(b). Notice that fixing  $c$  removes the edge  $b \rightarrow c$ , but that the edge  $c \rightarrow d$  is preserved. Applying m-separation to the graph shown in Fig. 1 (c), obtained from Fig. 1 (b) by connecting  $a, c$  by a bidirected edge, yields

$$X_d \perp\!\!\!\perp X_a \mid X_c \text{ in } \phi_{\{a,c\}}(p(x_{\{a,b,c,d\}}); \mathcal{G}).$$

In addition, one can see easily that if an edge  $a \rightarrow d$  had been present in the original graph, then we would not have obtained this m-separation.

## 4 ARID GRAPHS

The main result of this section is that the nested Markov model associated with *any* ADMG  $\mathcal{G}$  can be associated, without loss of generality, with a closely related *maximal arid graph* (MARG)  $\mathcal{G}^\dagger$ .

Arid graphs lack certain structures called C-trees [21] (aka convergent arborescences [7]) that present difficulties for identifiability. As a result, any linear SEM associated with an arid graph is everywhere identifiable [7].

In addition, maximal arid graphs are analogous to (but a strict superset of) maximal ancestral graphs (MAGs), a class of ADMGs also used for causal discovery.

The section proceeds as follows. In Section 4.1 we define the reachable closure of a set which is the smallest reachable superset of that set. These structures will be used in the proofs of our results, and to define C-trees and (maximal) arid graphs in Section 4.2. In Section 4.3 we define a projection operation which constructs, for any ADMG, its maximal arid graph counterpart. In Section 4.4, we show a number of useful graphical properties remain invariant between the original ADMG, and its maximal arid graph, leading to the proof of our main result in Section 4.5.

### 4.1 Reachable Closures

For a CADMG  $\mathcal{G}(V, W)$ , a (reachable) subset  $C \subseteq V$  is called a *reachable closure* for  $S \subseteq C$  if the set of fixable vertices in  $\phi_{V \setminus C}(\mathcal{G})$  is a subset of  $S$ . Every set  $S$  in  $\mathcal{G}$  has a reachable closure.

**Proposition 2.** *If  $A, B \in \mathcal{R}(\mathcal{G})$ , then  $A \cap B \in \mathcal{R}(\mathcal{G})$ .*

*Proof.* This follows from the fact that if a vertex is fixable, it remains fixable after fixing other vertices (see Lemma 27 of [20]).  $\square$

**Proposition 3.** *For any set of random vertices  $S$  in a CADMG  $\mathcal{G}$ , there is a unique reachable closure.*

*Proof.* Assume there are two such distinct closures  $W_1, W_2$ . Since both  $W_1$  and  $W_2$  are reachable, so is  $W_1 \cap W_2$ , by Proposition 2. Since  $S \subseteq W_1$  and  $S \subseteq W_2$ ,  $S \subseteq W_1 \cap W_2$ . Consider a fixing sequence  $\sigma_1$  for  $V \setminus W_1$ . Then there exists a fixing sequence  $\sigma_2$  for  $V \setminus (W_1 \cap W_2)$  which contains  $\sigma_1$  as a prefix. Note that  $W_1$  being reachable implies that  $W_1 \not\subseteq W_2$ , by the same argument as in the proof of Proposition 2; hence  $\sigma_2$  is non-empty. But this implies  $W_1$  is not a reachable closure for  $S$ , since the next element in  $\sigma_2$  after the  $\sigma_1$  prefix cannot lie in  $S$ . This is a contradiction.  $\square$

In light of Proposition 3, we denote the unique reachable closure of a set  $S$  in  $\mathcal{G}$  by  $\langle S \rangle_{\mathcal{G}}$ . By definition  $\langle S \rangle_{\mathcal{G}} \in \mathcal{R}(\mathcal{G})$  for any  $S$ , and if  $S \in \mathcal{R}(\mathcal{G})$  then  $\langle S \rangle_{\mathcal{G}} = S$ . To avoid clutter, if  $S = \{s\}$ , we write  $\langle \{s\} \rangle_{\mathcal{G}}$  as  $\langle s \rangle_{\mathcal{G}}$ .

**Proposition 4.** *Let  $A \subseteq B$  with  $B$  a reachable set; then  $\langle A \rangle_{\phi_{V \setminus B}(\mathcal{G})} = \langle A \rangle_{\mathcal{G}}$ .*

**Lemma 5.**  $\langle S \rangle_{\mathcal{G}} \subseteq S \cup \text{pa}_{\mathcal{G}}(\langle S \rangle_{\mathcal{G}})$ .

*Proof.* If  $s \in \langle S \rangle_{\mathcal{G}} \setminus S$  then  $s$  has a child in  $\langle S \rangle_{\mathcal{G}}$  since otherwise  $s$  is fixable, which is a contradiction.  $\square$

## 4.2 C-Trees and Arid Graphs

For any  $v \in V$  in an ADMG  $\mathcal{G}$ , the induced subgraph  $\mathcal{G}_{\langle v \rangle}$  is called a  $v$ -rooted C-tree [21] or an *arborescence converging on  $v$*  [7]. These subgraphs are particularly important because of the following result.

**Theorem 6** ([7], Theorem 2). *The SEM for an ADMG  $\mathcal{G}$  is everywhere identifiable if and only if  $\langle v \rangle_{\mathcal{G}} = \{v\}$  for all  $v \in V$ .*

In other words, the SEM parameterization is identifiable everywhere if and only if  $\mathcal{G}$  does not contain any non-trivial converging arborescences. We call such graphs ‘arid’, since they do not contain such ‘trees’.

**Definition 7.** An ADMG  $\mathcal{G}$  is called *arid* if for every vertex  $v$  in  $\mathcal{G}$ ,  $\langle v \rangle_{\mathcal{G}} = \{v\}$ .

Arid ADMGs are “DAG-like,” in the sense that in any DAG  $\mathcal{G}$ , it is also the case that  $\langle v \rangle_{\mathcal{G}} = \{v\}$ . The central result of this section is that the nested Markov model  $\mathcal{P}_n(\mathcal{G})$ , a statistical model with desirable properties, may be associated without loss of generality with arid graphs.

The ordinary Markov model  $\mathcal{P}_o(\mathcal{G})$  has previously been associated with another special class of ADMGs called *ancestral graphs* in [18].

**Definition 8.** An ADMG  $\mathcal{G}$  is called *ancestral* if for every vertex  $v$  in  $\mathcal{G}$ ,  $\text{sib}_{\mathcal{G}}(v) \cap \text{an}_{\mathcal{G}}(v) = \emptyset$ .

Arid graphs may be viewed as a strict generalization of ancestral graphs of [18], due to the following property of C-trees.

**Proposition 9.** *If  $\langle a \rangle_{\mathcal{G}}$  contains more than one element, then there exists  $b \in \langle a \rangle_{\mathcal{G}}$  with  $a \leftrightarrow b$  in  $\mathcal{G}$ .*

*Proof.* If no such element exists then every element in  $\text{pa}_{\mathcal{G}}(a) \cap \langle a \rangle_{\mathcal{G}}$  is fixable in  $\phi_{V \setminus \langle a \rangle_{\mathcal{G}}}(\mathcal{G})$ , which is a contradiction.  $\square$

**Proposition 10.** *Ancestral graphs are arid.*

*Proof.* Follows immediately by the contrapositive application of Proposition 9 and  $\langle a \rangle_{\mathcal{G}} \subseteq \text{an}_{\mathcal{G}}(a)$ .  $\square$

**Proposition 11.** *An arid graph with at least two vertices contains at least two fixable vertices.*

*Proof.* Since the graph is acyclic, there is some childless  $v$  that is therefore fixable. Since the graph is arid,  $\langle v \rangle_{\mathcal{G}} = \{v\} \subset V$ , and so there is also some other vertex that can be fixed to make  $\{v\}$  reachable.  $\square$

## 4.3 Maximal Arid Projection

To prove that  $\mathcal{P}_n(\mathcal{G})$  can always be associated with an arid graph, we define the *maximal arid projection* operation which, for every ADMG  $\mathcal{G}$ , yields a closely related

Figure 2: Graphs illustrating maximal arid projection. The graphs (a) and (c) are not arid, but have maximal arid projections given by (b) and (d) respectively.

graph  $\mathcal{G}^\dagger$  that is arid, and ultimately show that  $\mathcal{G}$  and  $\mathcal{G}^\dagger$  yield the same nested model.

In this section we define this projection operation and derive several of its properties, culminating in a proof that the projection and fixing operations commute. We first need a preliminary definition.

**Definition 12.** A pair of vertices  $a \neq b$  in an ADMG  $\mathcal{G}$  is *densely connected* if either  $a \in \text{pa}_{\mathcal{G}}(\langle b \rangle_{\mathcal{G}})$ , or  $b \in \text{pa}_{\mathcal{G}}(\langle a \rangle_{\mathcal{G}})$ , or  $\langle \{a, b\} \rangle_{\mathcal{G}}$  is a bidirected-connected set.

A CADMG  $\mathcal{G}$  is called *maximal* if every pair of densely connected vertices in  $\mathcal{G}$  are adjacent.

Densely connected vertex pairs form the nested Markov analogue of *inducing paths* [26]. Just as the existence of an inducing path between a pair of vertices prevents m-separation by any set, so does the existence of dense connectedness between a pair of vertices prevents m-separation by any set within any CADMG corresponding to a reachable set. In effect, a densely connected pair cannot be made independent, by any combination of conditioning and fixing operations.

**Definition 13.** For a CADMG  $\mathcal{G}$ , we define the *maximal arid projection* of  $\mathcal{G}$ , denoted  $\mathcal{G}^\dagger$ , to be the graph that shares the vertex sets  $V, W$  with  $\mathcal{G}$ , and that contains the following edges:

- for  $b \in V$ , the edge  $a \rightarrow b$  exists in  $\mathcal{G}^\dagger$  if  $a \in \text{pa}_{\mathcal{G}}(\langle b \rangle_{\mathcal{G}})$ ,
- for  $a, b \in V$ , the edge  $a \leftrightarrow b$  exists in  $\mathcal{G}^\dagger$  if neither  $a \in \text{pa}_{\mathcal{G}}(\langle b \rangle_{\mathcal{G}})$ , nor  $b \in \text{pa}_{\mathcal{G}}(\langle a \rangle_{\mathcal{G}})$ , but  $\langle \{a, b\} \rangle_{\mathcal{G}}$  is a bidirected-connected set.

Fig. 2 provides some elementary examples of the maximal arid projection. In each of (a) and (c) we have a dense inducing path between the vertices  $a$  and  $c$ . For (a) we insert the edge  $a \rightarrow c$  to represent this (yielding (b)), while in (c) we add  $a \leftrightarrow c$  (yielding (d)). In each case the bow arcs are replaced by directed edges.

We provide several results characterizing the output of the maximal arid projection operation, first noting that pairs of vertices adjacent in  $\mathcal{G}$  are also adjacent in  $\mathcal{G}^\dagger$ .

**Proposition 14.**

- (i) If  $a \in \text{pa}_{\mathcal{G}}(b)$ , then  $a \in \text{pa}_{\mathcal{G}^\dagger}(b)$ .
- (ii) If  $a \in \text{sib}_{\mathcal{G}}(b)$ , then either  $a \in \text{pa}_{\mathcal{G}^\dagger}(b)$  or  $a \in \text{sib}_{\mathcal{G}^\dagger}(b)$  or  $b \in \text{pa}_{\mathcal{G}^\dagger}(a)$ .

Ancestral relationships are also preserved in  $\mathcal{G}^\dagger$ .

**Proposition 15.**  $a \in \text{an}_{\mathcal{G}}(b)$  if and only if  $a \in \text{an}_{\mathcal{G}^\dagger}(b)$ .

*Proof.* If  $a \in \text{an}_{\mathcal{G}}(b)$ , then  $a \in \text{an}_{\mathcal{G}^\dagger}(b)$  follows by an inductive application of Proposition 14(i). If  $a \in \text{an}_{\mathcal{G}^\dagger}(b)$ , then fix a directed path  $a \rightarrow w_1 \rightarrow \dots \rightarrow w_k \rightarrow b$  in  $\mathcal{G}^\dagger$ . Each directed edge on this path from  $c$  to  $d$  is due to  $c \in \text{pa}_{\mathcal{G}}(\langle d \rangle_{\mathcal{G}})$  being true. But since every element  $\langle d \rangle_{\mathcal{G}}$  is an ancestor of  $d$  in  $\mathcal{G}$ , this implies the existence of a directed path from  $c$  to  $d$  in  $\mathcal{G}$ . Thus, there is a directed path from  $a$  to  $b$  in  $\mathcal{G}$ .  $\square$

**Proposition 16.** If  $\mathcal{G}$  is a (C)ADMG, then so is  $\mathcal{G}^\dagger$ .

*Proof.* Acyclicity of  $\mathcal{G}^\dagger$  follows from Proposition 15; in addition, in a CADMG it is clear from the definition that no arrowheads are introduced into  $W$ .  $\square$

If  $\mathcal{G}$  is acyclic then  $\mathcal{G}^\dagger$  is simple, i.e. contains at most one edge between each pair of vertices, so if  $\mathcal{G}$  is an ADMG then  $\mathcal{G}^\dagger$  is an example of a bow-free acyclic path diagram (BAP) [5, 16].

**Proposition 17.**  $\mathcal{D}(\mathcal{G}^\dagger)$  is a sub-partition of  $\mathcal{D}(\mathcal{G})$ . Further, for any  $S$  reachable in  $\mathcal{G}$  and  $\mathcal{G}^\dagger$ ,  $\mathcal{D}(\phi_{V \setminus S}(\mathcal{G}^\dagger))$  forms a sub-partition of  $\mathcal{D}(\phi_{V \setminus S}(\mathcal{G}))$ .

Note that it will follow from Theorem 19 that if  $S$  is reachable in  $\mathcal{G}$  then it is also reachable in  $\mathcal{G}^\dagger$ .

**Lemma 18.** Let  $v$  be fixable in  $\mathcal{G}$ . For any  $a, b \in V$  there is a directed path from  $a$  to  $b$  in  $\mathcal{G}$  with no intermediate vertex being  $v$ , if and only if there is such a path in  $\mathcal{G}^\dagger$ .

**Theorem 19.** If  $S$  is reachable in an ADMG  $\mathcal{G}$ , then it is also reachable in  $\mathcal{G}^\dagger$  via the same fixing sequence. In this case,  $(\phi_{V \setminus S}(\mathcal{G}))^\dagger = \phi_{V \setminus S}(\mathcal{G}^\dagger)$ .

**Corollary 20.**  $\langle S \rangle_{\mathcal{G}^\dagger} \subseteq \langle S \rangle_{\mathcal{G}}$  for any set  $S$ .

**Proposition 21.**  $\mathcal{G}^\dagger$  is a maximal arid graph.

#### 4.4 Invariance Results In Maximal Arid Projections

A key result will be that the nested Markov model associated with a maximal arid projection is the same as that for the original graph, and this will be proven by showing that the Markov blankets in the two graphs are the same.

**Lemma 22.** Suppose that  $w \in \text{pa}_{\mathcal{G}}(\langle v \rangle_{\mathcal{G}})$ , and that  $\langle \{v, w\} \rangle_{\mathcal{G}}$  is bidirected-connected. Then  $\langle \{v, w\} \rangle_{\mathcal{G}} = \langle v \rangle_{\mathcal{G}}$  and in particular  $w \in \langle v \rangle_{\mathcal{G}}$ .

**Lemma 23.** If  $v, w \in V$  are connected by a collider path  $\pi$  in  $\mathcal{G}$  then they are connected by a collider path  $\pi^\dagger$  in  $\mathcal{G}^\dagger$  that uses a subset of the internal vertices of  $\pi$ . In addition, if  $\pi$  starts with an edge  $v \rightarrow$ , then so does  $\pi^\dagger$ .

This follows by definition of  $\mathcal{G}^\dagger$ , and properties of closures of sets of vertices of size 1 and 2. A detailed proof is in the Appendix.

As an example of this result, notice that the path  $t \rightarrow x \leftrightarrow bp \leftrightarrow y$  in Fig. 4 (a) is replaced by  $t \rightarrow bp \leftrightarrow y$  in the maximal arid projection in Fig. 4 (b).

We provide a partial converse.

**Lemma 24.** If  $v, w \in V$  are connected by a collider path  $\pi^\dagger$  in  $\mathcal{G}^\dagger$ , then they are also connected by a collider path in  $\mathcal{G}$ .

*Proof.*  $\pi^\dagger$  is of the form  $\rightarrow \leftrightarrow \dots \leftrightarrow \leftarrow$  (possibly without the directed edges). Each  $\leftrightarrow$  represents a bidirected path in  $\mathcal{G}$ . A directed edge in  $\mathcal{G}^\dagger$ , say  $v \rightarrow t$ , represents an edge  $v \rightarrow s$  for  $s \in \langle t \rangle_{\mathcal{G}}$ . Since  $\langle t \rangle_{\mathcal{G}}$  is bidirected-connected, there is a path of the form  $v \rightarrow \leftrightarrow \dots \leftrightarrow t$  in  $\mathcal{G}$ . Concatenating these paths (and possibly shortening) gives another collider path.  $\square$

**Theorem 25.** Let  $S$  be a reachable set in  $\mathcal{G}$ . Then  $\text{mb}_{\mathcal{G}}(v, S) = \text{mb}_{\mathcal{G}^\dagger}(v, S)$ .

*Proof.* First note that  $v$  is childless in  $\phi_{V \setminus S}(\mathcal{G})$  if and only if it is so in  $\phi_{V \setminus S}(\mathcal{G}^\dagger)$ , so the statement is well-defined. Theorem 19 shows that it is enough to show this for  $S = V$ . The result is then a direct consequence of Lemmas 23 and 24, since the Markov blanket is just the set of vertices connected to  $v$  by collider paths.  $\square$

**Proposition 26.** There is a one-to-one correspondence between intrinsic sets in  $\mathcal{G}$  and in  $\mathcal{G}^\dagger$ .

**Remark 27.** The set  $H$  is referred to by [10] as the recursive head associated with  $S$ . A consequence of the argument in the proof above is that the discrete parameterization given by [10] is identical for  $\mathcal{G}$  and  $\mathcal{G}^\dagger$ .

An important result is that fixing corresponds to the same probabilistic operation in  $\mathcal{G}$  and  $\mathcal{G}^\dagger$ .

**Proposition 28.** If  $S \in \mathcal{R}(\mathcal{G})$ , then any fixing sequence  $\sigma$  for  $V \setminus S$  valid in  $\mathcal{G}$  consists of the same set of fixing operations when applied to  $p(x_V)$  using  $\mathcal{G}$  and when applied to  $p(x_V)$  using  $\mathcal{G}^\dagger$ .

*Proof.* Recall that fixing is division of  $\phi_W(p(x_V); \mathcal{G}) \equiv q_V(x_V | x_W)$  by  $q_V(x_v | x_{\text{mb}_{\mathcal{G}}(v, S) \cup W})$ . By Theorem 25,  $\text{mb}_{\mathcal{G}}(v, S) = \text{mb}_{\mathcal{G}^\dagger}(v, S)$ , and a simple induction gives the result.  $\square$

Thus, for any  $S \in \mathcal{R}(\mathcal{G}^\dagger)$ ,  $q_S$  is well defined without specifying the particular sequence of fixing operations in  $\mathcal{G}^\dagger$ . Some fixing sequences may be valid in  $\mathcal{G}^\dagger$  but not in  $\mathcal{G}$ ; however the kernels reached in  $\mathcal{G}^\dagger$  are related to those reachable in  $\mathcal{G}$  by the following result.

**Lemma 29.** *Suppose  $S \in \mathcal{I}(\mathcal{G}^\dagger)$ , and let  $S^\dagger = \langle S \rangle_{\mathcal{G}}$ . Let  $v$  be the maximal element of  $S$ . Any independences involving the full conditional of  $v$  hold in  $q_S$  if and only if they hold in  $q_{S^\dagger}$ .*

*Proof.* For simplicity assume  $S^\dagger = V$ , so we write  $\mathcal{G}$  and  $\mathcal{G}^\dagger$  in place of  $\phi_{V \setminus S^\dagger}(\mathcal{G})$  and  $\phi_{V \setminus S^\dagger}(\mathcal{G}^\dagger)$  respectively. This is justified by Theorem 19.

Suppose that  $s \in S^\dagger \setminus S$  is fixable in  $\mathcal{G}^\dagger$  but not in  $\mathcal{G}$ . Then  $s \in \text{dis}_{\mathcal{G}}(v)$  and is an ancestor of some  $r \in S$  such that  $\text{ch}_{\mathcal{G}}(r) = \emptyset$  (in both  $\mathcal{G}$  and  $\mathcal{G}^\dagger$ ).

The vertices  $r$  and  $v$  are connected by a collider path in  $\mathcal{G}$ , and so also are in  $\mathcal{G}^\dagger$ . Further, since they have no children in  $\mathcal{G}$ , they also have no children in  $\mathcal{G}^\dagger$ , and these paths are therefore made up entirely of bidirected edges in both graphs; in other words,  $r$  and  $v$  are in the same district in both graphs. Since  $s$  is fixable in  $\mathcal{G}^\dagger$  but not in  $\mathcal{G}$ , and since ancestor relations are preserved, it follows that  $s$  is in the same district as  $r$  and  $v$  in  $\mathcal{G}$ , but not in  $\mathcal{G}^\dagger$ .

Fixing  $s$  involves division by  $q_{S^\dagger}(x_s | x_{\text{mb}_{\mathcal{G}^\dagger}(s)})$ . Since  $v$  is in a different district to  $s$  and has no children, then  $v \notin \text{mb}_{\mathcal{G}^\dagger}(s)$ , and so by Lemma 10 of [20] we have  $q_{S^\dagger}(x_v | x_{S^\dagger \setminus \{v\}}, x_W) = q_{S^\dagger \setminus \{s\}}(x_v | x_{S^\dagger \setminus \{v\}}, x_W)$ . Any further vertices in  $S^\dagger \setminus S$  are also not in the same district as  $v$  for the same reason, so  $v$  never appears in their Markov blankets and hence this is also the same as the full conditional  $q_S(x_v | x_{S \setminus \{v\}}, x_{W \cup (S^\dagger \setminus S)})$ . The result follows.  $\square$

#### 4.5 Any ADMG And Its Maximal Arid Projection Define The Same Nested Model

We are now ready to state and prove the main result of this section.

**Theorem 30.**  $\mathcal{P}_n(\mathcal{G}) = \mathcal{P}_n(\mathcal{G}^\dagger)$ .

*Proof.* Let  $\prec$  be a topological order and consider any pair  $S, S^\dagger$  as defined in Proposition 26. We will show that the corresponding independences for the ordered local nested Markov property are equivalent. Let  $v$  be the  $\prec$ -maximal element of  $S$  (and therefore of  $S^\dagger$ ). Then the two independences are

$$(X_v \perp\!\!\!\perp X_{V \setminus (\text{mb}_{\mathcal{G}}(v, S) \cup \{v\})} \mid X_{\text{mb}_{\mathcal{G}}(v, S)})$$

in  $\phi_{V \setminus S}(p(x_V); \mathcal{G})$ , and

$$(X_v \perp\!\!\!\perp X_{V \setminus (\text{mb}_{\mathcal{G}^\dagger}(v, S^\dagger) \cup \{v\})} \mid X_{\text{mb}_{\mathcal{G}^\dagger}(v, S^\dagger)})$$

Figure 3: (a) A graph with a non-nested SEM constraint, and (b) A nested Markov equivalent graph. (c) A graph in which the parameter  $\omega_{bc}$  is not identifiable after any fixing.

in  $\phi_{V \setminus S^\dagger}(p(x_V); \mathcal{G}^\dagger)$ . Since—as follows from the proof of Proposition 26—we have  $\text{mb}_{\mathcal{G}}(v, S) = \text{mb}_{\mathcal{G}^\dagger}(v, S^\dagger)$ , it only remains to bridge the difference between the kernels. But this is an independence on the full conditional of  $\phi_{V \setminus S^\dagger}(p(x_V); \mathcal{G})$ , so by Lemma 29, it holds in that kernel if and only if it holds in  $\phi_{V \setminus S}(p(x_V); \mathcal{G}^\dagger)$ .  $\square$

## 5 THE FIXING OPERATION IN STRUCTURAL EQUATION MODELS

If  $v$  is fixable in an ADMG  $\mathcal{G}$ , the kernel  $q_{V \setminus \{v\}}$  resulting from fixing  $v$  is obtained by dividing  $p(x_V)$  by the conditional distribution  $p(x_v | x_{\text{nd}(v)})$ . Hence

$$\begin{aligned} q_{V \setminus \{v\}}(x_{V \setminus \{v\}} | x_v) \\ \equiv p(x_{\text{nd}(v)}) \cdot p(x_{\text{de}(v) \setminus \{v\}} | x_{\text{nd}(v) \cup \{v\}}), \end{aligned}$$

and therefore  $q_{V \setminus \{v\}}$  preserves both the marginal distribution of  $X_{\text{nd}(v)}$  and the conditional distribution of  $X_{\text{de}(v) \setminus \{v\}}$  given  $X_{\text{nd}(v) \cup \{v\}}$ .

**Remark 31.** A Gaussian kernel  $q(x_S | x_{V \setminus S})$  is parameterized via a set of means  $E[x_S | x_{V \setminus S}]$  indexed by  $x_{V \setminus S}$  and variances  $\text{Cov}[x_S | x_{V \setminus S}]$ . There is a distribution naturally associated with  $q(x_S | x_{V \setminus S})$  given by:

$$p_S^*(x_V) \equiv q_S(x_S | x_{V \setminus S}) \prod_{v \in V \setminus S} q_v^*(x_v),$$

where  $q_v^*(x_v)$  is an arbitrary marginal distribution.

In what follows we will consider kernels  $q_S(x_S | x_{V \setminus S})$  derived from a mean zero Gaussian distribution  $p(x_V)$ , hence parameterized via  $\text{Cov}[x_V]$ . We will then take  $q_v^*(x_v)$  to be the univariate normal distribution  $p(x_v)$ . It then follows that the Gaussian distribution  $p_S^*(x_V)$  corresponding to  $q_S(x_S | x_{V \setminus S})$  will also be parameterized via a covariance matrix  $\text{Cov}_S^*[x_V]$ .

**Proposition 32.** *Every conditional independence that holds in  $q_S$  also holds in  $p_S^*$ .*

We now show that fixing in the linear SEM corresponds to setting all coefficients corresponding to incoming edges to zero, but keeping all other parameters constant.

**Lemma 33.** *Let  $v$  be fixable in an ADMG  $\mathcal{G}$ . Then in an SEM corresponding to  $\mathcal{G}$ , setting  $b_{wv} = \omega_{vw} = \omega_{wv} = 0$  for all  $w \neq v$  is equivalent to dividing by  $p(x_v | x_{\text{nd}(v)})/q_v^*(x_v)$ .*

*Proof.* We show that setting parameters to zero as indicated leaves the marginal distribution  $p(x_{\text{nd}(v)})$  and the conditional distribution  $p(x_{\text{de}(v) \setminus \{v\}} | x_{\text{nd}(v)}, x_v)$  unchanged. The former follows easily from the trek rule (see, for example, [7]), since no edge in any trek between non-descendants of  $v$  is altered. Similarly, since we choose  $\text{Var } X_v = \omega_{vv}$  (see Remark 31), and the only trek from  $v$  to itself in the fixed graph is the trivial trek; hence  $\omega_{vv}$  is also preserved.

It remains to show that the same holds for the conditional distribution of the strict descendants given  $\{v\} \cup \text{nd}(v)$ . To see this, note that it is equivalent to check that the concentration  $k_{ij} = (\Sigma^{-1})_{ij}$  remains the same whenever either  $i$  or  $j$  is a descendant of  $v$ . Without loss of generality we may assume that  $j$  has no descendants (by marginalizing anything which is not an ancestor of  $i, j, v$ ). Then we have

$$K = \Sigma^{-1} = (I - B)^T \Omega^{-1} (I - B);$$

denote  $\omega^{ij} = (\Omega^{-1})_{ij}$ . By definition of the model,  $\Omega$  is a block-diagonal matrix with blocks corresponding to districts in the graph  $\mathcal{G}$ , and therefore so is  $\Omega^{-1}$ . Hence  $k_{ij}$  (including the case  $i = j$ ) can be written as

$$k_{ij} = \sum_{d=1}^p b_{id} \omega^{dj} + \omega^{ij} = \sum_{d \in \text{dis}(j)} b_{id} \omega^{dj} + \omega^{ij}, \quad (1)$$

(corresponding to paths of the form  $i \rightarrow d \leftrightarrow \dots \leftrightarrow j$  and  $i \leftrightarrow \dots \leftrightarrow j$  respectively). We claim none of the quantities in (1) are modified by setting the parameters  $b_{wv}$  and  $\omega_{vw} = \omega_{wv}$  to zero.

Suppose for a contradiction that  $b_{id}$  for  $d \in \text{dis}_{\mathcal{G}}(j)$  is one of the parameters set to zero; this could happen only if  $d = v$ . Now, if  $i$  is the descendant of  $v$  then this would imply a cycle, and if  $j$  is the descendant of  $v$  then  $d \in \text{dis}_{\mathcal{G}}(j)$  implies  $v$  is not fixable which is also a contradiction. Hence  $b_{id}$  is not set to zero.

Next consider  $\omega^{dj}$ . If  $d, j$  are in different districts then  $\omega^{dj} = 0$ . Since  $\Omega^{-1}$  is block diagonal, this parameter will only change if  $v$  is in the same district as  $j$  and  $d$ . If  $j$  is a descendant of  $v$  then  $v \notin \text{dis}_{\mathcal{G}}(j)$  since  $v$  is fixable. If  $i$  is a descendant of  $v$  then so is  $d$ , and therefore  $v \notin \text{dis}(j) = \text{dis}(d)$  for the same reason. Therefore the quantities  $\omega^{ij}, \omega^{dj}$  all remain unchanged, as they are a function only of the block of  $\Omega$  corresponding to  $\text{dis}(j)$ .

Hence if either  $i$  or  $j$  is a descendant of  $v$ , then none of the terms in (1) is changed by setting  $b_{wv} = \omega_{vw} = \omega_{wv} = 0$  for all  $w \neq v$ .  $\square$

Thus in the context of a linear SEM fixing  $v$  corresponds to setting the parameters  $b_{wv}$  and  $\omega_{vw} = \omega_{wv}$  to zero. We have the following result as a direct consequence:

**Theorem 34.** *Let  $\mathcal{G}$  be an ADMG then  $\mathcal{P}_{\text{sem}}(\mathcal{G}) \subseteq \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ .*

Recall that  $\mathcal{N}$  is the set of multivariate Gaussian distributions with positive definite covariance matrix.

## 6 ARID SEMS REPRESENT ALL GAUSSIAN NESTED MODELS

The Gaussian nested Markov model associated with an ADMG  $\mathcal{G}$  is exactly the linear SEM corresponding to the maximal arid projection  $\mathcal{G}^\dagger$  of  $\mathcal{G}$ :

**Theorem 35.** *Let  $\mathcal{G}$  be an ADMG. Then  $\mathcal{P}_{\text{sem}}(\mathcal{G}^\dagger) = \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ .*

*Proof.* By Theorem 34  $\mathcal{P}_{\text{sem}}(\mathcal{G}^\dagger) \subseteq \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ . Further, by Theorem 30,  $\mathcal{P}_n(\mathcal{G}) = \mathcal{P}_n(\mathcal{G}^\dagger)$ . Thus it suffices to prove that  $\mathcal{P}_n(\mathcal{G}) \cap \mathcal{N} \subseteq \mathcal{P}_{\text{sem}}(\mathcal{G})$  where  $\mathcal{G}$  is maximal and arid.

In order to facilitate our inductive argument, we extend the definitions of  $\mathcal{P}_n(\mathcal{G})$  and  $\mathcal{P}_{\text{sem}}(\mathcal{G})$  and the result to CADMGs and kernels. Specifically, if  $\mathcal{G}(V, W)$  is a CADMG and  $\prec$  is a topological ordering on  $V$ , then kernel  $q_V \in \mathcal{P}_n(\mathcal{G})$  if, for each intrinsic  $S \subseteq V$  and  $\prec$ -maximal  $v \in S$ ,

$$X_v \perp\!\!\!\perp X_{V \setminus (\{v\} \cup \text{mb}_{\mathcal{G}}(v, S))} \mid X_{\text{mb}_{\mathcal{G}}(v, S)}$$

holds in  $\phi_{V \setminus S}(q_V(x_V | x_W); \mathcal{G})$ . Similarly,  $\mathcal{P}_{\text{sem}}(\mathcal{G})$  represents a SEM where, if there is an edge  $w \rightarrow v$  with  $w \in W, v \in V$  then the equation for  $X_v$  contains  $b_{wv}x_w$  as a summand. We now claim that if  $\mathcal{G}$  is a CADMG then  $\mathcal{P}_{\text{sem}}(\mathcal{G}^\dagger) = \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ , where  $\mathcal{N}$  is the set of Gaussian kernels. This is clearly sufficient.

Suppose  $p \in \mathcal{P}_n(\mathcal{G}) \cap \mathcal{N}$ , where  $\mathcal{G}(V, W)$  is a CADMG with topological ordering  $\prec$ .

If  $|V| = 1$  then the result follows by regression on  $X_{\text{pa}_{\mathcal{G}}(v)}$ . Otherwise we proceed by induction on  $|V|$ . Let  $v$  be the maximal vertex under  $\prec$ .

For any fixable  $w$  in  $\mathcal{G}$  we obtain by the induction hypothesis that  $q_{V \setminus \{w\}} \in \mathcal{P}_n(\phi_w(\mathcal{G})) = \mathcal{P}_{\text{sem}}(\phi_w(\mathcal{G}))$ . Hence we can identify parameters for edges not involving  $v$  by fixing  $v$ . Any directed edge parameter  $b_{ij}$  can be identified provided  $j$  is not fixed; if  $|V| \geq 2$  then, since  $\mathcal{G}$  is arid, it contains at least two fixable vertices by Proposition 11. Hence we can identify every  $b_{ij}$  in this manner. [Since valid fixings commute, all such results will agree.]

Similarly we can identify any bidirected edge this way except possibly  $\omega_{vw}$  if  $w$  and  $v$  are the only two fixable vertices in  $\mathcal{G}$ . In this case,  $\mathcal{G}$  contains only one district and every vertex is an ancestor of  $v$  or  $w$ .

Since we have identified every other parameter, let  $\tilde{p}_\gamma$  be the distribution obtained from all the other parameters with  $\omega_{vw} = \gamma$ . Then by construction,  $\tilde{p}_\gamma$  and  $p$  have the same margins over  $V \setminus \{v\}$  and  $V \setminus \{w\}$ . If we can choose  $\gamma$  so that the covariance  $\sigma_{vw}$  matches that in  $p$ , then  $p = \tilde{p}_\gamma$ . It is not hard to see that  $\sigma_{vw}$  is a monotonic function of  $\omega_{vw}$ , so the only restriction is on the positive definiteness of the relevant covariance matrices. Since the set of positive definite matrices is convex, the set of valid  $\omega_{vw}$  is an interval; in addition,  $\Omega$  is positive definite if and only if  $\Sigma$  is positive definite. Hence, by the intermediate value theorem there exists a  $\gamma$  that maps to the appropriate  $\sigma_{vw}$ .  $\square$

**Example 36.** To see the difficulty with the induction in the previous proof, consider the graph in Fig. 3 (c). There are two fixable vertices,  $b$  and  $c$ , and in either case the fixing corresponds to marginalizing over the corresponding random variable. This means that, in either case, the edge parameter  $\omega_{bc}$  is not identifiable. Every other parameter can be identified inductively, and we may finally use  $\sigma_{bc}$  to identify  $\omega_{bc}$ .

## 7 EXAMPLE

Consider the following simplified medical trial to examine the effect of diet and exercise on diabetes, adapted from [5]. At baseline, patients are randomly assigned to perform  $t$  hours of exercise in a week, but actually perform  $x$  hours. At the end of the week their blood pressure (bp) is measured, this is assumed to depend upon  $x$ , but also to be confounded with it by lifestyle factors. In the second phase of the trial, patients are assigned to lose  $\Delta\text{bmi}$  kilograms in weight; the value of  $\Delta\text{bmi}$  is random, but for ethical reasons depends linearly on  $x$  and bp. Finally, at the end of the trial, triglyceride levels ( $y$ ) are measured, which is used to diagnose diabetes; these are assumed to be correlated with blood pressure, and dependent on exercise and weight loss. This causal structure naturally yields the ADMG shown in Fig. 4(a).

Though a perfectly reasonable causal description of the model, Fig. 4(a) contains a bow and therefore the associated model is non-smooth and not everywhere identifiable. Performing maximal arid projection gives the graph  $\mathcal{G}^\dagger$  in Fig. 4(b), which gives an SEM that induces a curved exponential family and is nested Markov equivalent to the SEM corresponding to the original graph. Note that the resulting graph is not an ancestral graph; indeed  $\mathcal{G}^\dagger$  preserves more of the structure than the corresponding MAG.

Figure 4: (a) A graph representing a clinical trial for interventions in diabetes; the associated SEM is non-smooth. (b) A nested Markov equivalent graph whose SEM represents a curved exponential family.

## 8 DISCUSSION

We have presented a subclass of ADMGs—the maximal arid graphs (MARGs)—that fully represents the class of nested Markov models. We have shown that any linear SEM associated with a MARG is precisely equal to the class of Gaussian densities in the nested Markov model for that MARG.

We remark that the results on arid graphs we derived in Section 4 are completely non-parametric, and apply not only to the Gaussian models that we study here, but to any model; we showed that any nested Markov equivalence class contains a MARG which, since MARGs are maximal and simple graphs, is a canonical representative of the class to use in search procedures within the set of nested models. In this sense MARGs serve a similar role to MAGs for scoring-based searches for ordinary Markov models corresponding to ADMGs.

Duke University

## Abstract

There has been recent interest in developing scalable Bayesian sampling methods such as stochastic gradient MCMC (SG-MCMC) and Stein variational gradient descent (SVGD) for big-data analysis. A standard SG-MCMC algorithm simulates samples from a discrete-time Markov chain to approximate a target distribution, thus samples could be highly correlated, an undesired property for SG-MCMC. In contrary, SVGD directly optimizes a set of particles to approximate a target distribution, and thus is able to obtain good approximations with relatively much fewer samples. In this paper, we propose a principle particle-optimization framework based on Wasserstein gradient flows to unify SG-MCMC and SVGD, and to allow new algorithms to be developed. Our framework interprets SG-MCMC as particle optimization on the space of probability measures, revealing a strong connection between SG-MCMC and SVGD. The key component of our framework is several particle-approximate techniques to efficiently solve the original partial differential equations on the space of probability measures. Extensive experiments on both synthetic data and deep neural networks demonstrate the effectiveness and efficiency of our framework for scalable Bayesian sampling.

## 1 INTRODUCTION

Bayesian methods have been playing an important role in modern machine learning, especially in unsupervised learning (Kingma and Welling, 2014; Li et al., 2017), and recently in deep reinforcement learning (Houthoofd et al., 2016; Liu et al., 2017). When dealing with big data, two lines of research directions have been developed to scale

up Bayesian methods, *e.g.*, variational-Bayes-based and sampling-based methods. Stochastic gradient Markov chain Monte Carlo (SG-MCMC) is a family of scalable Bayesian learning algorithms designed to efficiently sample from a target distribution such as a posterior distribution (Welling and Teh, 2011; Chen et al., 2014; Ding et al., 2014; Chen et al., 2015). In principle, SG-MCMC generates samples from a Markov chain, which are used to approximate a target distribution. Under a standard setting, samples from SG-MCMC are able to match a target distribution exactly with an infinite number of samples (Teh et al., 2016; Chen et al., 2015). However, this is practically infeasible, as only a finite number of samples are obtained. Although nonasymptotic approximation bounds w.r.t. the number of samples have been investigated (Teh et al., 2016; Vollmer et al., 2016; Chen et al., 2015), there are no theory/algorithms to guide learning an optimal set of fixed-size samples/particles. This is an undesirable property of SG-MCMC, because in practice one often seeks to learn the optimal samples of a finite size that best approximate a target distribution.

A remedy for this issue is to adopt the idea of particle-based sampling methods, where a set of particles (or samples) are initialized from some simple distribution, followed by iterative updates to better approximate a target distribution. The updating procedure is usually done by optimizing some metrics such as a distance measure between the target distribution and the current approximation. There is not much work in this direction for large-scale Bayesian sampling, with an outstanding representative being the Stein variational gradient descent (SVGD) (Liu and Wang, 2016a). In SVGD, the update of particles are done by optimizing the KL-divergence between the empirical particle distribution and a target distribution, thus the samples are designed to be updated optimally to reduce the KL-divergence in each iteration. Because of this property, SVGD is found to perform better than SG-MCMC when the number of samples used to approximate a target distribution is limited, and has been

applied to other problems such as deep generative models (Feng et al., 2017) and deep reinforcement learning (Liu et al., 2017; Haarnoja et al., 2017; Zhang et al., 2018b).

Though often achieving comparable performance in practice, little work has been done on investigating connections between SG-MCMC and SVGD, and on developing particle-optimization schemes for SG-MCMC. In this paper, adopting ideas from Wasserstein-gradient-flow literature, we propose a unified particle-optimization framework for scalable Bayesian sampling. The idea of our framework is to work directly on the evolution of a density functions on the space of probability measures, *e.g.*, the Fokker-Planck equation in SG-MCMC. To make the evolution solution computationally feasible, particle approximations are adopted for densities, where particles can be optimized during the evolution process. Both SG-MCMC and SVGD are special cases of our framework, and are shown to be highly related. Notably, sampling with SG-MCMC becomes a deterministic particle-optimization problem as SVGD on the space of probability measures, overcoming the aforementioned correlated-sample issue. Furthermore, we are able to develop new *unified* particle-optimization algorithms by combing SG-MCMC and SVGD, which is less prone to high-dimension space and thus obtains better performance for large-scale Bayesian sampling. We conduct extensive experiments on both synthetic data and Bayesian learning of deep neural networks, verifying the effectiveness and efficiency of our proposed framework.

## 2 PRELIMINARIES

In this section, we review related concepts and algorithms for SG-MCMC, SVGD, and Wasserstein gradient flows (WGF) on the space of probability measures.

### 2.1 Stochastic gradient MCMC

**Diffusion-based sampling methods** Generating random samples from a distribution (*e.g.*, a posterior distribution) is one of the fundamental problems in Bayesian statistics, which has many important applications in machine learning. Traditional Markov Chain Monte Carlo methods (MCMC), such as the Metropolis–Hastings algorithm (Metropolis et al., 1953) produces unbiased samples from a desired distribution when the density function is known up to a normalizing constant. However, most of these methods are based on random walk proposals which suffer from high dimensionality and often lead to highly correlated samples. On the other hand, dynamics-based sampling methods such as the Metropolis adjusted Langevin algorithm (MALA) (Xifara et al., 2014) avoid this high degree of correlation by combining dynamical

systems with the Metropolis step. In fact, these dynamical systems are derived from a more general mathematical technique called diffusion process, or more specifically, Itô diffusion (Øksendal, 1985).

Specifically, our objective is to generate random samples from a posterior distribution  $p(\boldsymbol{\theta} | \mathbf{X}) \propto p(\mathbf{X} | \boldsymbol{\theta})p(\boldsymbol{\theta})$ , where  $\boldsymbol{\theta} \in \mathbb{R}^r$  represents the model parameter, and  $\mathbf{X} \triangleq \{\mathbf{x}_i\}_{i=1}^N$  represents the data. The canonical form is  $p(\boldsymbol{\theta} | \mathbf{X}) = (1/Z) \exp(U(\boldsymbol{\theta}))$ , where  $U(\boldsymbol{\theta}) =$

$$\log p(\mathbf{X} | \boldsymbol{\theta}) + \log p(\boldsymbol{\theta}) \triangleq \sum_{i=1}^N \log p(\mathbf{x}_i | \boldsymbol{\theta}) + \log p(\boldsymbol{\theta})$$

is referred to as the potential energy based on an i.i.d. assumption of the model, and  $Z$  is the normalizing constant. In Bayesian sampling, the posterior distribution corresponds to the (marginal) stationary distribution of a (continuous-time) Itô diffusion, defined as a stochastic differential equation of the form:

$$d\boldsymbol{\Theta}_t = F(\boldsymbol{\Theta}_t)dt + g(\boldsymbol{\Theta}_t)d\mathcal{W}_t, \quad (1)$$

where  $t$  is the time index;  $\boldsymbol{\Theta}_t \in \mathbb{R}^p$  represents the full variables in a dynamical system, and  $\boldsymbol{\Theta}_t \supseteq \boldsymbol{\theta}_t$  (thus  $p \geq r$ ) is potentially an augmentation of model parameter  $\boldsymbol{\theta}$ ;  $\mathcal{W}_t \in \mathbb{R}^p$  is  $p$ -dimensional Brownian motion. Functions  $F : \mathbb{R}^p \rightarrow \mathbb{R}^p$  and  $g : \mathbb{R}^p \rightarrow \mathbb{R}^p \times \mathbb{R}^p$  are assumed to satisfy the Lipschitz continuity condition (Ghosh, 2011). By Fokker-Planck equation (or the forward Kolmogorov equation) (Kolmogoroff, 1931; Risken, 1989), when appropriately designing the diffusion-coefficient functions  $F(\cdot)$  and  $g(\cdot)$ , the stationary distribution of the corresponding Itô diffusion equals the posterior distribution of interest,  $p(\boldsymbol{\theta} | \mathbf{X})$ . For example, the 1st-order Langevin dynamic defines  $\boldsymbol{\Theta} = \boldsymbol{\theta}$ , and  $F(\boldsymbol{\Theta}_t) = \frac{1}{2}\nabla_{\boldsymbol{\theta}}U(\boldsymbol{\theta})$ ,  $g(\boldsymbol{\Theta}_t) = \mathbf{I}_r$ ; the 2nd-order Langevin diffusion defines  $\boldsymbol{\Theta} = (\boldsymbol{\theta}, \mathbf{q})$ , and  $F(\boldsymbol{\Theta}_t) = \begin{pmatrix} \mathbf{q} \\ -B\mathbf{q} - \nabla_{\boldsymbol{\theta}}U(\boldsymbol{\theta}) \end{pmatrix}$ ,  $g(\boldsymbol{\Theta}_t) = \sqrt{2B} \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_r \end{pmatrix}$  for a scalar  $B > 0$ ;  $\mathbf{q}$  is an auxiliary variable known as the momentum (Chen et al., 2014; Ding et al., 2014).

Let the density of  $\boldsymbol{\Theta}_t$  be  $\mu_t$ , it is known  $\mu_t$  is characterized by the Fokker-Planck (FP) equation (Risen, 1989):

$$\frac{\partial \mu_t}{\partial t} = -\nabla_{\boldsymbol{\Theta}} \cdot (\mu_t F(\boldsymbol{\Theta}_t)) + \nabla_{\boldsymbol{\Theta}} \nabla_{\boldsymbol{\Theta}} : (\mu_t \Sigma(\boldsymbol{\Theta}_t)) \quad (2)$$

where  $\Sigma(\boldsymbol{\Theta}_t) \triangleq g(\boldsymbol{\Theta}_t)g^\top(\boldsymbol{\Theta}_t)$ ,  $\mathbf{a} \cdot \mathbf{b} \triangleq \mathbf{a}^\top \mathbf{b}$  for vectors  $\mathbf{a}$  and  $\mathbf{b}$ ,  $\mathbf{A} : \mathbf{B} \triangleq \text{trace}(\mathbf{A}^\top \mathbf{B})$  for matrices  $\mathbf{A}$  and  $\mathbf{B}$ . The FP equation is the key to develop our particle-optimization framework for SG-MCMC. In the following, we focus on the simplest case of 1st-order Langevin dynamics if not stated explicitly, though the derivations apply to other variants.

**Stochastic gradient MCMC** SG-MCMC algorithms are discretized numerical approximations of the Itô dif-

fusion (1). They mitigate the slow mixing and non-scalability issues encountered in traditional MCMC algorithms by *i*) adopting gradient information of the posterior distribution, *ii*) using minibatches of the data in each iteration of the algorithm to generate samples, and *iii*) ignoring the rejection step as in standard MCMC. To make the algorithms scalable in a big-data setting, three developments will be implemented based on the Itô diffusion: *i*) define appropriate functions  $F$  and  $g$  in the Itô-diffusion formula so that the (marginal) stationary distributions coincide with the target posterior distribution  $p(\boldsymbol{\theta} | \mathbf{X})$ ; *ii*) replace  $F$  or  $g$  with unbiased stochastic approximations to reduce the computational complexity, *e.g.*, approximating  $F$  with a random subset of the data instead of using the full data. For example, in the 1st-order Langevin dynamics,  $\nabla_{\boldsymbol{\theta}} U(\boldsymbol{\theta})$  could be *approximated* by an unbiased estimator with a subset of data:

$$\nabla_{\boldsymbol{\theta}} \tilde{U}(\boldsymbol{\theta}) \triangleq \nabla \log p(\boldsymbol{\theta}) + \frac{N}{n} \sum_{i=1}^n \nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}_{\pi_i} | \boldsymbol{\theta}) \quad (3)$$

where  $\pi$  is a size- $n$  random subset of  $\{1, 2, \dots, N\}$ , leading to the first SG-MCMC algorithm in machine learning – stochastic gradient Langevin dynamics (SGLD) (Welling and Teh, 2011); and *iii*) solve the generally intractable continuous-time Itô diffusions with a numerical method, *e.g.*, the Euler method (Chen et al., 2015). For example, this leads to the following update in SGLD:

$$\boldsymbol{\theta}_{\ell} = \boldsymbol{\theta}_{\ell-1} + \nabla_{\boldsymbol{\theta}} \tilde{U}(\boldsymbol{\theta}_{\ell-1})h + \sqrt{2h} \boldsymbol{\delta}_{\ell},$$

where  $h$  means the stepsize,  $\ell$  indexes the samples,  $\boldsymbol{\delta}_{\ell} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$  is a random sample from an isotropic normal distribution. After running the algorithm for  $L$  steps, the collection of samples  $\{\boldsymbol{\theta}_{\ell}\}_{\ell=1}^L$  are used to approximate the unknown posterior distribution  $\frac{1}{L} e^{U(\boldsymbol{\theta})}$ .

## 2.2 Stein variational gradient descent

Different from SG-MCMC, SVGD initializes a set of particles which are iteratively updated so that the empirical particle distribution approximates the posterior distribution. Specifically, we consider a set of particles  $\{\boldsymbol{\theta}^{(i)}\}_{i=1}^M$  drawn from some distribution  $q$ . SVGD tries to update these particles by doing gradient descent on the interactive particle system via

$$\boldsymbol{\theta}^{(i)} \leftarrow \boldsymbol{\theta}^{(i)} + h\phi(\boldsymbol{\theta}^{(i)}), \quad \phi = \arg \max_{\phi \in \mathcal{F}} \left\{ \frac{\partial}{\partial h} \text{KL}(q_{[h\phi]} || p) \right\}$$

where  $\phi$  is a function perturbation direction chosen to minimize the KL divergence between the updated density  $q_{[h\phi]}$  estimated by the particles and the posterior  $p(\boldsymbol{\theta} | \mathbf{X})$  ( $p$  for short). Since  $\text{KL}(q || p)$  is convex in  $q$ , global optimum of  $q = p$  can be guaranteed. SVGD considers  $\mathcal{F}$  as the unit ball of a vector-valued reproducing kernel Hilbert

space (RKHS)  $\mathcal{H}$  associated with a kernel  $\kappa(\boldsymbol{\theta}, \boldsymbol{\theta}')$ . In such as setting, Liu and Wang (2016b) shown:

$$-\frac{\partial}{\partial h} \text{KL}(q_{[h\phi]} || p)|_{h=0} = \mathbb{E}_{\boldsymbol{\theta} \sim q} [\text{trace}(\Gamma_p \phi(\boldsymbol{\theta}))], \quad (4)$$

with  $\Gamma_p \phi(\boldsymbol{\theta}) \triangleq \nabla_{\boldsymbol{\theta}} U(\boldsymbol{\theta})^{\top} \phi(\boldsymbol{\theta}) + \nabla_{\boldsymbol{\theta}} \cdot \phi(\boldsymbol{\theta})$ ,

where  $\Gamma_p$  is called the Stein operator. Assuming that the update function  $\phi(\boldsymbol{\theta})$  is in a RKHS with kernel  $\kappa(\cdot, \cdot)$ , it was shown in (Liu and Wang, 2016b) that (4) is maximized with:

$$\phi(\boldsymbol{\theta}) = \mathbb{E}_{\boldsymbol{\theta} \sim q} [\kappa(\boldsymbol{\theta}, \boldsymbol{\theta}') \nabla_{\boldsymbol{\theta}} U(\boldsymbol{\theta}) + \nabla_{\boldsymbol{\theta}} \kappa(\boldsymbol{\theta}, \boldsymbol{\theta}')]. \quad (5)$$

When approximating the expectation  $\mathbb{E}_{\boldsymbol{\theta} \sim q}[\cdot]$  with empirical particle distribution and adopting stochastic gradients, we arrive at the following updates for the particles ( $\ell$  denotes the iteration number):  $\boldsymbol{\theta}_{\ell+1}^{(i)} = \boldsymbol{\theta}_{\ell}^{(i)} +$

$$\frac{h}{M} \sum_{j=1}^M \left[ \kappa(\boldsymbol{\theta}_{\ell}^{(j)}, \boldsymbol{\theta}_{\ell}^{(i)}) \nabla_{\boldsymbol{\theta}_{\ell}^{(j)}} \tilde{U}(\boldsymbol{\theta}_{\ell}^{(j)}) + \nabla_{\boldsymbol{\theta}_{\ell}^{(j)}} \kappa(\boldsymbol{\theta}_{\ell}^{(j)}, \boldsymbol{\theta}_{\ell}^{(i)}) \right] \quad (6)$$

SVGD applies updates (6) repeatedly, moving the samples to a target distribution  $p$ .

## 2.3 Wasserstein Gradient Flows

For a better motivation of WGF, we start from gradient flows defined on the Euclidean space.

**Gradient flows on the Euclidean space** For a smooth function  $E : \mathbb{R}^r \rightarrow \mathbb{R}$ , and a starting point  $\boldsymbol{\theta}_0 \in \mathbb{R}^r$ , the gradient flow of  $E(\boldsymbol{\theta})$  is defined as the solution of the differential equation:  $\frac{d\boldsymbol{\theta}}{dt} = -\nabla E(\boldsymbol{\theta}(t))$ , s.t.  $\boldsymbol{\theta}(0) = \boldsymbol{\theta}_0$ . This is a standard Cauchy problem (Rulla, 1996), endowed with a unique solution if  $\nabla E$  is Lipschitz continuous. When  $E$  is non-differentiable, the gradient is replaced with its subgradient, defined as  $\partial E(\boldsymbol{\theta}) \triangleq \{\mathbf{p} \in \mathbb{R}^r : F(\boldsymbol{\theta}') \geq F(\boldsymbol{\theta}) + \mathbf{p} \cdot (\boldsymbol{\theta}' - \boldsymbol{\theta}), \forall \boldsymbol{\theta}' \in \mathbb{R}^r\}$ . Note  $\partial E(\boldsymbol{\theta}) = \{\nabla E(\boldsymbol{\theta})\}$  if  $E$  is differentiable at  $\boldsymbol{\theta}$ . In this case, the gradient flow formula above is replaced with:  $\frac{d\boldsymbol{\theta}}{dt} \in -\partial E(\boldsymbol{\theta}(t))$ .

**Wasserstein gradient flows** Let  $\mathcal{P}(\Omega)$  denote the space of probability measures on  $\Omega \subset \mathbb{R}^r$ . WGF is an extension of gradient flows in Euclidean space by lifting the definition onto the space of probability measures. Formally, let  $\mathcal{P}(\Omega)$  be endowed with a Riemannian geometry induced by the 2nd-order Wasserstein distance, *i.e.*, the curve length between two elements (two distributions) is defined as:

$$W_2^2(\mu, \nu) \triangleq \inf_{\gamma} \left\{ \int_{\Omega \times \Omega} \|\boldsymbol{\theta} - \boldsymbol{\theta}'\|_2^2 d\gamma(\boldsymbol{\theta}, \boldsymbol{\theta}') : \gamma \in \Gamma(\mu, \nu) \right\}$$

where  $\Gamma(\mu, \nu)$  is the set of joint distributions over  $(\boldsymbol{\theta}, \boldsymbol{\theta}')$  such that the two marginals equal  $\mu$  and  $\nu$ , respectively. The Wasserstein distance can be explained as an optimal-transport problem, where one wants to transform elements

in the domain of  $\mu$  to  $\nu$  with a minimum cost (Villani, 2008). The term  $\|\theta - \theta'\|_2^2$  represents the cost to transport  $\theta$  in  $\mu$  to  $\theta'$  in  $\nu$ , and can be replaced by a general metric  $c(\theta, \theta')$  in a metric space. If  $\mu$  is absolutely continuous w.r.t. the Lebesgue measure, there is a unique optimal transport plan from  $\mu$  to  $\nu$ , i.e., a mapping  $\mathcal{T} : \mathbb{R}^r \rightarrow \mathbb{R}^r$  pushing elements in the domain of  $\mu$  onto  $\nu$  satisfying  $\mathcal{T}_\# \mu = \nu$ . Here  $\mathcal{T}_\# \mu$  denotes the pushforward measure of  $\mu$ . The Wasserstein distance is equivalently reformulated as:  $W_2^2(\mu, \nu) \triangleq \inf_{\mathcal{T}} \left\{ \int_{\Omega} c(\theta, \mathcal{T}(\theta)) d\mu(\theta) \right\}$ .

Let  $\{\mu_t\}_{t \in [0,1]}$  be an absolutely continuous curve in  $\mathcal{P}(\Omega)$  with finite second-order moments. We consider to define the change of  $\mu_t$ 's by investigating  $W_2^2(\mu_t, \mu_{t+h})$ . Motivated by the Euclidean-space case, this is reflected by a vector field,  $\mathbf{v}_t(\theta) \triangleq \lim_{h \rightarrow 0} \frac{\mathcal{T}(\theta_t) - \theta_t}{h}$  called the *velocity of the particle*. A gradient flow can be defined on  $\mathcal{P}(\Omega)$  correspondingly (Ambrosio et al., 2005).

**Lemma 1** *Let  $\{\mu_t\}_{t \in [0,1]}$  be an absolutely-continuous curve in  $\mathcal{P}(\Omega)$  with finite second-order moments. Then for a.e.  $t \in [0,1]$ , the above vector field  $\mathbf{v}_t$  defines a gradient flow on  $\mathcal{P}(\Omega)$  as:  $\partial_t \mu_t + \nabla \cdot (\mathbf{v}_t \mu_t) = 0$ .*

The gradient flow describes the evolution of a functional  $E$ , which is a lifted version of the function in the case of Euclidean space in Section 2.3 to the space of probability measures.  $E$  maps a probability measure  $\mu$  to a real value, i.e.,  $E : \mathcal{P}(\Omega) \rightarrow \mathbb{R}$ . We will focus on the case where  $E$  is convex in this paper, which is enough considering gradient flows for SG-MCMC and SVGD, though the theory applies to a more general  $\lambda$ -convex energy functional setting (Ambrosio et al., 2005). It can be shown that  $\mathbf{v}_t$  in Lemma 1 has the form  $\mathbf{v}_t = -\nabla \frac{\delta E}{\delta \mu_t}(\mu_t)$  (Ambrosio et al., 2005), where  $\frac{\delta E}{\delta \mu_t}$  is called the *first variation* of  $E$  at  $\mu_t$ . Based on this, gradient flows on  $\mathcal{P}(\Omega)$  can be written

$$\partial_t \mu_t = -\nabla \cdot (\mathbf{v}_t \mu_t) = \nabla \cdot \left( \mu_t \nabla \left( \frac{\delta E}{\delta \mu_t}(\mu_t) \right) \right). \quad (7)$$

**Remark 1** *Intuitively, an energy functional  $E$  characterizes the landscape structure (appearance) of the corresponding manifold in  $\mathcal{P}(\Omega)$ , and the gradient flow (7) defines a geodesic path on this manifold. Usually, by choosing appropriate  $E$ , the landscape is convex, e.g., for the cases of both SG-MCMC and SVGD described below. This provides a theoretical guarantee on the optimal convergence of a gradient flow.*

### 3 PARTICLE-OPTIMIZATION-BASED SAMPLING

In this section, we interpret the continuous versions of both SG-MCMC and SVGD as WGFs, followed by several techniques for particle optimization in the next section. In the following,  $\mu_t$  denotes the distribution of  $\theta_t$ .

#### 3.1 SVGD as WGF

The continuous-time and infinite-particle limit of SVGD with full gradients, denoted as  $\text{SVGd}^\infty$ , is known to be a special instance of the Vlasov equation in nonlinear partial-differential-equation literature (Liu, 2017):

$$\partial_t \mu_t = \nabla \cdot ((\mathbf{W} * \mu_t) \mu_t), \quad (8)$$

where  $(\mathbf{W} * \mu_t)(\theta) \triangleq \int \mathbf{W}(\theta - \theta') \mu_t(\theta') d\theta'$  is the convolutional operator applied for some function  $\mathbf{W} : \mathbb{R}^r \rightarrow \mathbb{R}$ . To specify  $\text{SVGd}^\infty$ , we generalize the convolutional operator, and consider  $\mathbf{W}$  as a function with two input arguments, i.e.,

$$(\mathbf{W} * \mu_t)(\theta) \triangleq \int \mathbf{W}(\theta, \theta') \mu_t(\theta') d\theta'.$$

Under this setting, we can specify the function  $\mathbf{W}(\cdot, \cdot)$  for  $\text{SVGd}^\infty$  as

$$\begin{aligned} \mathbf{W}(\theta, \theta') &\triangleq \nabla_{\theta'} \log p(\theta' | \mathbf{X}) \kappa(\theta', \theta) + \nabla_{\theta'} \kappa(\theta', \theta) \\ &= \nabla_{\theta'} [p(\theta' | \mathbf{X}) \kappa(\theta, \theta')] / p(\theta'). \end{aligned} \quad (9)$$

As will be shown in Section 4,  $\mathbf{W}$  in (9) naturally leads to the SVGD algorithm, without the need to derive from an RKHS perspective.

**Proposition 2** *The stationary distribution of (8) is  $\lim_{t \rightarrow \infty} \mu_t \triangleq \mu = p(\theta | \mathbf{X})$ .*

To interpret  $\text{SVGd}^\infty$  as a WGF, we need to specify two quantities, the energy functional and an underlying metric to measure distances between density functions.

#### Energy functional and distance metric of $\text{SVGd}^\infty$

There are two ways to derive energy functionals for  $\text{SVGd}^\infty$ , depending on the underlying metrics for probability distributions. When adopting the WGF framework where  $W_2$  is used as the underlying metric, according to (7), the energy functional  $E_s$  must satisfy

$$\begin{aligned} \nabla_{\theta} \left( \frac{\delta E_s}{\delta \mu_t}(\mu_t) \right) &= \mathbf{W}(\theta, \theta') * \mu_t \\ &= \mathbb{E}_{\theta' \sim \mu_t} [\nabla_{\theta'} [p(\theta' | \mathbf{X}) K(\theta, \theta')] / p(\theta' | \mathbf{X})]. \end{aligned} \quad (10)$$

In general, there is no close-form solution for the above equation. Alternatively, Liu (2017) proved another form of the energy functional by defining a different distance metric on the space of probability measures, called  $\mathcal{H}$ -Wasserstein distance:

$$W_{\mathcal{H}}(q_1, q_2) \triangleq \inf_{\phi_t, \mu_t} \left\{ \int_0^1 \|\phi_t\|_{\mathcal{H}} dt, \text{ s.t. } \mu_t = -\nabla_{\theta} \cdot (\phi_t \mu_t), \mu_0 = q_1, \mu_1 = q_2 \right\}, \quad (11)$$

where  $\phi_t \triangleq \mathbf{W} * \mu_t$ , and  $\|\cdot\|_{\mathcal{H}}$  is the norm in the Hilbert space induced by  $\kappa(\cdot, \cdot)$ . Under this metric, the underlying energy functional is proved to be the standard KL-divergence between  $\mu_t$  and  $p$ , e.g.,

$$E_s = \text{KL}(\mu_t, p(\cdot | \mathbf{X})).$$

As can be seen in Section 4, this interpretation allows one to derive SVGD, a particle-optimization-based algorithm to approximate the continuous-time equation (8).

### 3.2 SG-MCMC as WGF

The continuous-time limit of SG-MCMC, when considering gradients to be exact, corresponds to standard Itô diffusions. We consider the Itô diffusion of SGLD for simplicity, *e.g.*,

$$d\boldsymbol{\theta}_t = \frac{1}{2} \nabla U(\boldsymbol{\theta}_t) dt + d\mathcal{W}. \quad (12)$$

**Energy functional** The energy functional for SG-MCMC is easily seen by noting that the corresponding FP equation (2) is in the gradient-flow form of (7). Specifically, the energy functional  $E$  is defined as:

$$E(\mu) \triangleq \underbrace{- \int U(\boldsymbol{\theta}) \mu(\boldsymbol{\theta}) d\boldsymbol{\theta}}_{E_1} + \underbrace{\int \mu(\boldsymbol{\theta}) \log \mu(\boldsymbol{\theta}) d\boldsymbol{\theta}}_{E_2} \quad (13)$$

Note  $E_2$  is the energy functional of a pure Brownian motion (*e.g.*,  $U(\boldsymbol{\theta}) = 0$  in (12)). We can verify (13) by showing that it satisfies that FP equation. According to (7), the first variation of  $E_1$  and  $E_2$  is calculated as

$$\frac{\delta E_1}{\delta \mu} = -U, \quad \frac{\delta E_2}{\delta \mu} = \log \mu + 1. \quad (14)$$

Substituting (14) into (7) recovers the FP equation (2) for the Itô diffusion (12).

## 4 PARTICLE OPTIMIZATION

An efficient way to solve the generally infeasible WGF formula (7) is to adopt numerical methods with particle approximation. With a little abuse of notation but for conciseness, we do not distinguish subscripts  $t$  and  $\ell$  for the particle  $\boldsymbol{\theta}$ , *i.e.*,  $\boldsymbol{\theta}_t$  denotes the continuous-time version of the particle, while  $\boldsymbol{\theta}_\ell$  denotes the discrete-time version. We develop several techniques to approximate different types of WGF for SG-MCMC and SVGD. In particle approximation, the continuous density  $\mu_t$  is approximated by a set of  $M$  particles  $(\boldsymbol{\theta}_t^{(i)})_{i=1}^M$  that evolve over time  $t$  with weights  $(m_i)_{i=1}^M$  such that  $\sum_{i=1}^M m_i = 1$ , *i.e.*,  $\mu_t \approx \sum_{i=1}^M m_i \delta(\boldsymbol{\theta}_t^{(i)})$ , where  $\delta(\boldsymbol{\theta}_t^{(i)}) = 1$  when  $\boldsymbol{\theta} = \boldsymbol{\theta}_t^{(i)}$  and 0 otherwise. Typically  $m_i$ 's are chosen at the beginning and fixed over time, thus we assume  $m_i = \frac{1}{M}$  and rewrite  $\mu_t \approx \frac{1}{M} \sum_{i=1}^M \delta(\boldsymbol{\theta}_t^{(i)})$  in the following for simplicity. We investigate two types of particle-approximation methods in the following, discrete gradient flows and by blob methods.

#### Particle approximation by discrete gradient flows

Denote  $\mathcal{P}_s(\mathbb{R}^r)$  be the space of probability measures with finite 2nd-order moments. Define the following optimization problem with stepsize  $h$ :

$$J_h(\mu) \triangleq \arg \min_{\nu \in \mathcal{P}_s(\mathbb{R}^d)} \left\{ \frac{1}{2h} W_2^2(\mu, \nu) + E(\nu) \right\}. \quad (15)$$

A discrete gradient flow of the continuous one in (7) up to time  $T$  is the composition of a sequence of the solutions  $(\tilde{\mu}_\ell)_{\ell=1}^{T/h}$  of (15), *i.e.*,

$$\tilde{\mu}_\ell \triangleq J_h(\tilde{\mu}_{\ell-1}) = J_h(J_h(\cdots \mu_0)) \triangleq J_h^\ell \mu_0. \quad (16)$$

One can show that when  $h \rightarrow 0$ , the discrete gradient flow (16) converges to the true flow (7) for all  $\ell$ . Specifically, let  $\partial E(\mu)$  be the set of Wasserstein subdifferential of  $E$  at  $\mu$ , *i.e.*,  $\xi \in \partial E(\mu)$  if  $\partial_t \mu = \xi$  is satisfied. Define  $|\partial E|(\mu) = \min\{\|\xi\|_{L^2(\mu)} : \xi \in \partial E(\mu)\}$  to be the minimum norm of the elements in  $\partial E(\mu)$ . We have

**Lemma 3 (Craig (2014))** *Assume  $E$  is proper, coercive and lower semicontinuous (specify in Section B of the Supplementary Material (SM)). For an  $\mu_0$  and  $t \geq 0$ , as  $\frac{T}{h} \rightarrow \infty$ , the discrete gradient sequence  $\tilde{\mu}_{T/h} \triangleq J_h^{T/h} \mu_0$  converge uniformly in  $t$  to a compact subset of  $[0, +\infty)$ , and  $W_2^2(\tilde{\mu}_{T/h}, \mu_T) \leq \sqrt{3} |\partial E|(\mu) \sqrt{T} h$ .*

Lemma 3 suggests the discrete gradient flow can approximate the original WGF arbitrarily well if a small enough stepsize  $h$  is adopted. Consequently, one solves (16) through a sequence of optimization procedures to update the particles. We will derive a particle-approximation method for the  $W_2$  term in (15), which allows us to solve SG-MCMC efficiently. However, this technique is not applicable to SVGD, as we neither have an explicit form of the energy functional in (10) when adopting the  $W_2$  metric, nor have an explicit form for the metric  $W_{\mathcal{H}}$  in (11) when adopting the KL-divergence as the energy functional. Fortunately, this can be solved by the second approximation method called blob methods.

**Particle approximation by blob methods** The name of blob methods comes from the classical fluids literature, where instead of evolving the density in (7), one evolves all particles on a grid with time-spacing  $h$  (Carrillo et al., 2017). Specifically, note the function  $\mathbf{v}_t$  in (7) represents velocity of particles via transportation map  $\mathcal{T}$ , thus solving a WGF is equivalent to evolving the particles along their velocity in each iteration. Formally, one can prove

**Proposition 4 (Craig and Bertozzi (2016))** *Let  $\mu_0 \approx \frac{1}{M} \sum_{i=1}^M \delta(\boldsymbol{\theta}_0^{(i)})$ . Assume  $\mathbf{v}_t$  in (7) is well-defined and continuous w.r.t. each  $\boldsymbol{\theta}_t^{(i)}$  at time  $t$ . Then solving the PDE (7) reduces to solving a system of ordinary differential equations for the locations of the Dirac masses:*

$$d\boldsymbol{\theta}_t^{(i)} / dt = -\mathbf{v}_t(\boldsymbol{\theta}_t^{(i)}). \quad (17)$$

Proposition 4 suggests evolving each particle along the directions defined by  $\mathbf{v}_t$ , eliminating the requirement to know an explicit form of the energy functional. In the following, we apply the above particle-optimization techniques to derive algorithms for SVGD and SG-MCMC.

## 4.1 A particle-optimization algorithm for SVGD

As mentioned above, discrete-gradient-flow approximation does not apply to SVGD. We thus rely on the blob method. From Section 3.1,  $\mathbf{v}_t$  in SVGD is defined as  $\mathbf{v}_t(\boldsymbol{\theta}) = (\mathbf{W} * \mu_t)(\boldsymbol{\theta})$ . When  $\mu_t(\boldsymbol{\theta})$  is approximated by particles,  $\mathbf{v}_t(\boldsymbol{\theta}_t^{(i)})$  is simplified as:

$$\mathbf{v}_t(\boldsymbol{\theta}_t^{(i)}) = \frac{1}{M} \sum_{j=1}^M \mathbf{W}(\boldsymbol{\theta}_t^{(i)}, \boldsymbol{\theta}_t^{(j)}).$$

As a result, with the definition of  $\mathbf{W}$  in (9), updating  $\{\boldsymbol{\theta}_t^{(i)}\}$  by time discretizing (17) recovers the update equations for standard SVGD in (6).

## 4.2 Particle-optimization algorithms for SG-MCMC

Both the discrete-gradient-flow and the blob methods can be applied for SG-MCMC, which are detailed below.

**Particle optimization with discrete gradient flows**  
We first specify Lemma 3 in the case of SG-MCMC in Lemma 5, which is known as the Jordan-Kinderlehrer-Otto scheme (Jordan et al., 1998).

**Lemma 5 (Jordan et al. (1998))** *Assume that  $p(\boldsymbol{\theta}_t | \mathbf{X}) \leq C_1$  is infinitely differentiable, and  $\|\nabla_{\boldsymbol{\theta}} \log p(\boldsymbol{\theta} | \mathbf{X})\| \leq C_2 (1 + C_1 - \log p(\boldsymbol{\theta} | \mathbf{X}))$  ( $\forall \boldsymbol{\theta}$ ) for some constants  $\{C_1, C_2\}$ . Let  $T = hK$  with  $K$  the number of iterations,  $\tilde{\mu}_0$  be an arbitrary distribution with same support as  $p(\boldsymbol{\theta} | \mathbf{X})$ , and  $\{\tilde{\mu}_k\}_{k=1}^K$  be the solution of the functional optimization problem:*

$$\tilde{\mu}_k = \arg \min_{\mu \in \mathcal{P}_s(\mathbb{R}^r)} KL(\mu || p) + \frac{1}{2h} W_2^2(\tilde{\mu}_{k-1}, \mu). \quad (18)$$

*Then  $\tilde{\mu}_K$  converges to  $\mu_T$  in the limit of  $h \rightarrow 0$ , i.e.,  $\lim_{h \rightarrow 0} \tilde{\mu}_K = \mu_T$ , where  $\mu_T$  is the solution of the FP equation (2) at time  $T$ .*

According to Lemma 5, it is apparent that SG-MCMC can be implemented by iteratively solving the optimization problem in (18). However, particle approximations for both terms in (18) are challenging. In the following, we develop efficient techniques to solve the problem.

First, rewrite the optimization problem in (18) as

$$\min_{\mu \in \mathcal{P}_s(\mathbb{R}^r)} \underbrace{-\mathbb{E}_{\mu}[\log p(\boldsymbol{\theta} | \mathbf{X})]}_{F_1} + \underbrace{\mathbb{E}_{\mu}[\log \mu] + \frac{1}{2h} W_2^2(\tilde{\mu}_{k-1}, \mu)}_{F_2}$$

We aim at deriving gradient formulas for both the  $F_1$  and  $F_2$  terms under a particle approximation in order to perform gradient descent for the particles. Let  $\mu \approx \frac{1}{M} \sum_{i=1}^M \delta(\boldsymbol{\theta}^{(i)})$ . The gradient of  $F_1$  is easily approximated as

$$\frac{\partial F_1}{\partial \boldsymbol{\theta}^{(i)}} \approx -\nabla_{\boldsymbol{\theta}^{(i)}} \log p(\boldsymbol{\theta}^{(i)} | \mathbf{X}). \quad (19)$$

To approximate the gradient for  $F_2$ , let  $p_{ij}$  denote the joint distribution of the particle-pair  $(\boldsymbol{\theta}^{(i)}, \boldsymbol{\theta}_{k-1}^{(j)})$ . Note  $\mathbb{E}_{\mu}[\log \mu]$  is minimized when the particles  $\{\boldsymbol{\theta}^{(i)}\}$  are uniformly distributed. In other words, the marginal distribution vector  $(\sum_j p_{ij})_i$  is a uniform distribution. Combining  $\mathbb{E}_{\mu}[\log \mu]$  with the definition of  $W_2$ , calculating  $F_2$  is equivalent to solving the following optimization problem:

$$P \triangleq \{p_{ij}\} = \arg \min_{p_{i,j}} \sum_{i,j} p_{ij} d_{ij} \quad (20)$$

$$s.t. \quad \sum_j p_{ij} = \frac{1}{M}, \quad \sum_i p_{ij} = \frac{1}{M},$$

where  $d_{ij} \triangleq \|\boldsymbol{\theta}^{(i)} - \boldsymbol{\theta}_{k-1}^{(j)}\|^2$ . We can further enforce the joint distribution  $\{p_{ij}\}$  to have maximum entropy by introducing a regularization term  $\mathbb{E}_{p_{ij}}[\log p_{ij}]$ , which is stronger than the regularizer enforced for the marginal distribution above. After introducing Lagrangian multipliers  $\{\alpha_i, \beta_j\}$  to deal with the constraints in (20), we arrive at the dual problem:

$$\begin{aligned} \max \mathcal{L}^D(\{p_{ij}\}, \{\alpha_i\}, \{\beta_j\}) &= \lambda \sum_{i,j} p_{ij} \log p_{ij} + p_{ij} d_{ij} \\ &+ \sum_i \alpha_i \left( \sum_j p_{ij} - \frac{1}{M} \right) + \sum_j \beta_j \left( \sum_i p_{ij} - \frac{1}{M} \right), \end{aligned}$$

where  $\lambda$  is the weight for the regularizer. The optimal  $p_{ij}$ 's can be obtained by applying KKT conditions to set the derivative w.r.t.  $p_{ij}$  to be zero, ending up with the following form:

$$p_{ij}^* = u_i e^{-d_{ij}/\lambda} v_j,$$

where  $u_i \triangleq e^{-\frac{1}{2} - \frac{\alpha_i}{\lambda}}$ ,  $v_j \triangleq e^{-\frac{1}{2} - \frac{\beta_j}{\lambda}}$ . As a result, the particle gradients on  $F_2$  can be approximated as

$$\begin{aligned} \frac{\partial F_2}{\partial \boldsymbol{\theta}^{(i)}} &\approx - \frac{\sum_j u_i v_j d_{ij} e^{-d_{ij}/\lambda}}{\partial \boldsymbol{\theta}^{(i)}} \\ &= \sum_j 2u_i v_j \left( \frac{d_{ij}}{\lambda} - 1 \right) e^{-d_{ij}/\lambda} (\boldsymbol{\theta}^{(i)} - \boldsymbol{\theta}_{k-1}^{(j)}). \end{aligned} \quad (21)$$

Theoretically, we need to adaptively update  $\{u_i, v_j\}$  as well to ensure the constraints in (20). In practice, however, we use a fixed scaling factor  $\gamma$  to approximate  $u_i v_j$  for the sake of simplicity.

Particle gradients are obtained by combining (19) and (21), which are then used to update the particles  $\{\boldsymbol{\theta}^{(i)}\}$  by standard gradient descent. Intuitively, (19) encourages particles move to local modes while (21) regularizes particle interactions. Different from SVGD, our scheme imposes both attractive and repulsive forces for the particles. Specifically, by inspecting (21), we can conclude that: *i)* When  $\boldsymbol{\theta}^{(i)}$  is far from a previous particle  $\boldsymbol{\theta}_k^{(j)}$ , i.e.,  $\frac{d_{ij}}{\lambda} > 1$ ,  $\boldsymbol{\theta}^{(i)}$  is pulled close to  $\{\boldsymbol{\theta}_k^{(j)}\}$  with force proportional to  $(\frac{d_{ij}}{\lambda} - 1)e^{-d_{ij}/\lambda}$ ; *ii)* when  $\boldsymbol{\theta}^{(i)}$  is close enough to a previous particle  $\boldsymbol{\theta}_k^{(j)}$ , i.e.,  $\frac{d_{ij}}{\lambda} < 1$ ,  $\boldsymbol{\theta}^{(i)}$  is pushed away, preventing it from collapsing to  $\boldsymbol{\theta}_k^{(j)}$ .

**Particle optimization with blob methods** The idea of blob methods can also be applied to particle approximation for SG-MCMC, which require the velocity vector field  $\mathbf{v}_t$ . According to (13), this is calculated as:  $\mathbf{v}_t(\boldsymbol{\theta}) = -\nabla_{\boldsymbol{\theta}} \frac{\delta(E_1+E_2)}{\delta\mu} = -\nabla_{\boldsymbol{\theta}} U - \nabla_{\boldsymbol{\theta}} \mu / \mu$ . Unfortunately, direct application of particle approximation is infeasible because the term  $\nabla_{\boldsymbol{\theta}} \mu$  is undefined with discrete  $\mu$ . To tackle this problem, we adopt the idea in Carrillo et al. (2017) to approximate the energy functional  $E_2$  in (13) as:  $E_2 \approx \int \mu(\boldsymbol{\theta}) \log(\mu * K)(\boldsymbol{\theta}) d\boldsymbol{\theta}$ , where  $K(\cdot, \cdot)$  is another kernel function to smooth out  $\mu$ . Consequently, based on Carrillo et al. (2017), the velocity  $\mathbf{v}_t$  can be calculated as (details in Section C of the SM):

$$\mathbf{v}_t(\boldsymbol{\theta}) = -\nabla_{\boldsymbol{\theta}} U - \sum_{j=1}^n \nabla_{\boldsymbol{\theta}_t^{(j)}} K(\boldsymbol{\theta}, \boldsymbol{\theta}_t^{(j)}) / \sum_k K(\boldsymbol{\theta}_t^{(j)}, \boldsymbol{\theta}_t^{(k)}) - \sum_{j=1}^n \nabla_{\boldsymbol{\theta}_t^{(j)}} K(\boldsymbol{\theta}, \boldsymbol{\theta}_t^{(j)}) / \sum_{k=1}^n K(\boldsymbol{\theta}, \boldsymbol{\theta}_t^{(k)}) \quad (22)$$

Given  $\mathbf{v}_t$ , particle updates can be obtained by solving (17) numerically as in SVGD. By inspecting the formula of  $\mathbf{v}_t$  in (22), the last two terms both act as repulsive forces. Interestingly, the mechanism is similar to SVGD, but with adaptive force between different particle pairs.

## 5 THE GENERAL RECIPE

Based on the above development, a more general particle-optimization framework is proposed by combining the PDEs of both SG-MCMC and SVGD. As a result, we propose the following PDE to drive evolution of densities

$$\frac{\partial \mu_t}{\partial t} = -\nabla_{\boldsymbol{\theta}} \cdot (\mu_t F(\boldsymbol{\theta}_t)) + \lambda_1 \nabla_{\boldsymbol{\theta}} \cdot ((\mathbf{W} * \mu_t) \mu_t) + \lambda_2 \nabla_{\boldsymbol{\theta}} \nabla_{\boldsymbol{\theta}} : (\mu_t g(\boldsymbol{\theta}_t) g^{\top}(\boldsymbol{\theta}_t)) , \quad (23)$$

where  $\lambda_1$  and  $\lambda_2$  are two constants. It is easily seen that to ensure the stationary distribution of (23) to be equal to  $p(\boldsymbol{\theta} | \mathbf{X})$ , the following condition must be satisfied:

$$\nabla_{\boldsymbol{\theta}} \cdot (p(\boldsymbol{\theta} | \mathbf{X}) F(\boldsymbol{\theta})) = \lambda_1 \nabla_{\boldsymbol{\theta}} \cdot ((\mathbf{W} * p(\boldsymbol{\theta} | \mathbf{X})) p(\boldsymbol{\theta} | \mathbf{X})) + \lambda_2 \nabla_{\boldsymbol{\theta}} \nabla_{\boldsymbol{\theta}} : (p(\boldsymbol{\theta} | \mathbf{X}) g(\boldsymbol{\theta}) g^{\top}(\boldsymbol{\theta})) \quad (24)$$

There are many feasible choices for the functions and parameters  $\{F(\boldsymbol{\theta}), \mathbf{W}, g(\boldsymbol{\theta}), \lambda_1, \lambda_2\}$  to satisfy (24). However, the verification procedure might be complicated given the present of a convolutional term in (24). We recommend the following choices for simplicity:

- $F(\boldsymbol{\theta}) = \frac{1}{2}U(\boldsymbol{\theta})$ ,  $\mathbf{W} = 0$ ,  $g(\boldsymbol{\theta}) = \mathbf{I}$  and  $\lambda_2 = 1$ : this reduces to the Wasserstein-based SGLD with particle optimization. Specifically, when the discrete-gradient-flow approximation is adopted, the algorithm is denoted as  $w$ -SGLD; whereas when the blob method is adopted, it is denoted as  $w$ -SGLD-B.

- $F(\boldsymbol{\theta}) = 0$ ,  $g(\boldsymbol{\theta}) = 0$ ,  $\mathbf{W}$  is defined as (9): this reduces to standard SVGD.

- $F(\boldsymbol{\theta}) = \frac{1}{2}U(\boldsymbol{\theta})$ ,  $g(\boldsymbol{\theta}) = \mathbf{I}$ ,  $\mathbf{W}$  is defined as (9), and  $\lambda_2 = 1$ : this is the combination of SGLD and SVGD, and is called particle interactive SGLD, denoted as PI-SGLD or  $\pi$ -SGLD.

It is easy to verify that condition (24) is satisfied for all the above three particle-optimization algorithms. Furthermore, particle updates are readily developed by applying either the discrete-gradient-flow or blob-based methods.

## 6 RELATED PARTICLE-BASED MCMC METHODS

There have been related particle-based MCMC algorithms. Representative methods are sequential Monte Carlo (SMC) (Moral et al., 2006), particle MCMC (PMCMC) (Andrieu et al., 2010) and many variants. In SMC, particles are sample from a proposal distribution, and the corresponding weights are updated by a resampling step. PMCMC extends SMC by sampling from an extended distribution interacted with a MH-rejection step. Compared to our framework, their proposal distributions are typically hard to choose; furthermore, optimality of the particles from both methods can not be guaranteed. Furthermore, the methods are typically much more computationally expensive. Recently, Dai et al. (2016) proposed a particle-based MCMC algorithm by approximating a target distribution with weighted kernel density estimator, which updates particle weights based on likelihoods of the corresponding particles. This approach is theoretically sound but lacks an underlying geometry interpretation. Finally, we note that  $w$ -SGLD has been successfully applied to reinforcement learning recently for improved policy optimization (Zhang et al., 2018a).

## 7 EXPERIMENTS

We verify our framework on a set of experiments, including a number of toy experiments and applications to Bayesian sampling of deep neural networks (DNNs).

### 7.1 Demonstrations

**Toy Distributions** We compare various sampling methods on multi-mode toy examples, *i.e.*, SGLD, SVGD,  $w$ -SGLD,  $w$ -SGLD-B and  $\pi$ -SGLD. We aim to sample from four unnormalized 2D densities  $p(z) \propto \exp\{U(z)\}$ , with detailed functional form provided in the SM. We optimize/sample 2000 particles to approximate target distributions. The results are shown in Figure 1. It can be seen from Figure 1 that though SGLD maintains good asymptotic properties, it is inaccurate to approximate distributions with only a few samples; in some case, the

samples cannot even cover all the modes. Interestingly, all other particle-optimization-based algorithms successfully find all the modes and fit the distributions well.  $w$ -SGLD is good at finding modes, but worse at modeling the correct variance due to difficulty of controlling the balance between attractive and repulsive forces between particles.  $w$ -SGLD-B is better than  $w$ -SGLD at modeling the distribution variance, performing similarly to SVGD and  $\pi$ -SGLD. Even though, we note that  $w$ -SGLD is very useful when the number of particles is small, which fits a distribution better, as shown in Section E of the SM.

Figure 1: Illustration of different algorithms on toy distributions. Each column is a distribution case. 1st row: Ground truth; 2nd row: standard SGLD; 3rd row:  $w$ -SGLD; 4th row:  $w$ -SGLD-B; 5th row: SVGD; 6th row:  $\pi$ -SGLD.

**Bayesian Logistic regression** We next compare the three variants of our framework (*i.e.* SVGD,  $w$ -SGLD and  $w$ -SGLD-B) on a simple logistic-regression task with quantitative evaluations. We use the same model, data and experimental settings as Liu and Wang (2016a). The Covertypes dataset contains 581,012 data points and 54 features. We perform 5 runs for each setting and report the mean of testing accuracies/log-likelihoods. Figure 2 plots both test accuracies and test log-likelihoods w.r.t. the

Figure 2: Test accuracies (left) and log-likelihoods (right) v.s. iterations for SVGD,  $w$ -SGLD and  $w$ -SGLD-B.

number of training iterations. It is clearly that while all methods converge to the same accuracy/likelihood level, both  $w$ -SGLD and  $w$ -SGLD-B converge slightly faster than SVGD. In addition,  $w$ -SGLD and  $w$ -SGLD-B have similar convergence behaviors, thus we only use  $w$ -SGLD in the DNN experiments below.

### Parameter Sensitivity

Now we study the role of hyper-parameters in  $\pi$ -SGLD: the number of particles  $M$  and the scaling factor  $\gamma$  to

Figure 3: Impact of  $W_2^2$  factor  $\gamma$  and particle number  $M$ .

replace the  $u_i v_j$ -term in (21). We use the same dataset and model as the above experiment. Figure 3 plots test accuracies along with different parameter settings. As expected, the best performance is achieved with appropriate scale of  $W_2^2$ . The performance keep improving with increasing particles. Interestingly, the Wasserstein regularization is more important when the number of particles is small, demonstrating the superiority when approximate distributions with very few particles.

## 7.2 Applications on deep neural networks

We conduct experiments for Bayesian learning of DNNs. Different from traditional optimization for DNNs, we are interested in modeling weight uncertainty of neural networks, an important topic that has been well explored (Hernández-Lobato and Adams, 2015; Blundell et al., 2015a; Li et al., 2016; Louizos and Welling, 2016). We assign priors to the weights, which are simple isotropic Gaussian priors in our case, and perform posterior sampling with the proposed particle-optimization-based algorithms, as well as other standard algorithms such as SGLD and SGD. We use the RMSprop optimizer for feed-forward networks (FNN), and Adam for for convolutional neural networks (CNNs) and recurrent neural

networks (RNNs). For all methods, we use a RBF kernel  $K(\theta, \theta') = \exp(-\|\theta - \theta'\|_2^2/h)$ , with the bandwidth set to  $h = \text{med}^2/\log M$ . Here med is the median of the pairwise distance between particles. All experiments are conducted on a single TITAN X GPU.

**Feed-forward Neural Networks** We perform the classification tasks on the standard MNIST dataset. A two-layer model 784-X-X-10 with ReLU activation function is used, with X being the number of hidden units for each layer. The training epoch is set to 100. The test errors are reported in Table 1. Not surprisingly, Bayesian methods generally perform better than their optimization counterparts. The new  $\pi$ -SGLD which combines  $w$ -SGLD and SVGD improves both methods with little computational overhead. In addition,  $w$ -SGLD seems to perform better than SVGD in this case, partially due to a better asymptotic property mentioned in (Liu, 2017). Furthermore, standard SGLD which is based on MCMC obtains higher test errors compared to particle-optimization-based algorithms, partially due to the correlated-sample issue discussed in the introduction. See (Blundell et al., 2015b) for details on the other methods in Table 1.

Table 1: Classification error of FNN on MNIST.

Method	Test Error	
	400-400	800-800
$\pi$ -SGLD	<b>1.36%</b>	<b>1.30%</b>
$w$ -SGLD	1.44%	1.37%
SVGD	1.53%	1.40%
SGLD	1.64%	1.41%
RMSprop	1.59%	1.43%
RMSspectral	1.65%	1.56%
SGD	1.72%	1.47%
BPB, Gaussian	1.82%	1.99%
SGD, dropout	1.51%	1.33%

**Convolution Neural Networks** We use the CIFAR-10 dataset to test our framework on CNNs. We adopt a CNN of three convolution layers, using  $3 \times 3$  filter size with C64-C128-C256 channels, and  $2 \times 2$  max-pooling after each convolution layer. Our implementation adopts batch normalization, drop out and data augmentation to improve the performance. Training losses and test accuracies are presented in Table 2. Consistently,  $\pi$ -SGLD outperforms all other algorithms in terms of test accuracy. ADAM obtains a better training loss but worse test accuracy, indicating worse generalization ability of the optimization-based methods compared to Bayesian methods.

**Recurrent Neural Networks** For RNNs, we run standard language models. Experiments are presented on three publicly available corpora: APNEWS, IMDB and BNC. APNEWS is a collection of Associated Press news articles from 2009 to 2016. IMDB is a set of movie re-

Table 2: Classification error of CNN on CIFAR-10.

Method	Training Loss	Test Accuracy
ADAM	23.80	86.76%
SVGD	30.57	88.72%
SGLD	28.52	88.64%
$w$ -SGLD	31.26	88.80%
$\pi$ -SGLD	25.06	<b>89.52%</b>

views collected by Maas et al. (2011), and BNC BNC Consortium (2007) is the written portion of the British National Corpus, which contains excerpts from journals, books, letters, essays, memoranda, news and other types of text. These datasets can be downloaded from Github\*.

Table 3: Perplexity of language model on three corpora.

Method	APNEWS	IMDB	BNC
SGD	64.13	72.14	102.89
SGLD	63.01	68.12	95.13
SVGD	61.64	69.25	94.99
$w$ -SGLD	61.22	67.41	93.68
$\pi$ -SGLD	<b>59.83</b>	<b>67.04</b>	<b>92.33</b>

We follow the standard set up as Wang et al. (2017). Specifically, we lower case all the word tokens and filter out word tokens that occur less than 10 times. All the datasets are divided into training, development and testing sets. For the language model set up, we consider a 1-layer LSTM model with 600 hidden units. The sequence length is fixed to be 30. In order to alleviate overfitting, dropout with a rate of 0.4 is used in each LSTM layer. Results in terms of test perplexities are presented in Table 3. Again, we see that  $\pi$ -SGLD performs best among all algorithms, and  $w$ -SGLD is slightly better than SVGD, both of which are better than other algorithms.

## 8 CONCLUSION

We propose a unified particle-optimization framework for large-scale Bayesian sampling. Our framework defines gradient flows on the space of probability measures, and uses particles to approximate the corresponding densities. Consequently, solving gradient flows reduces to optimizing particles on the parameter space. Our framework includes the standard SVGD as a special case, and also allows us to develop efficient particle-optimization algorithms for SG-MCMC, which is highly related to SVGD. Extensive experiments are conducted, demonstrating the effectiveness and efficiency of our proposed framework. Interesting future work includes designing more practically efficient variants of the proposed particle-optimization framework, and developing theory to study general convergence behaviors of the algorithms, in addition to the asymptotic results presented in (Liu, 2017).

## Abstract

Domains such as citizen science biodiversity monitoring and real estate sales are producing spatial data with a continuous response and a vector of covariates associated with each spatial data point. A common data analysis task involves finding unusual regions that differ from the surrounding area. Existing techniques compare regions according to the means of their distributions to measure unusualness. Comparing means is not only vulnerable to outliers, but it is also restrictive as an analyst may want to compare other parts of the probability distributions. For instance, an analyst interested in unusual areas for high-end homes would be more interested in the 90th percentile of home sale prices than in the mean. We introduce the Quantile Spatial Scan Statistic (QSSS), which finds unusual regions in spatial data by comparing quantiles of data distributions while accounting for covariates at each data point. We also develop an exact incremental update of the hypothesis test used by the QSSS, which results in a massive speedup over a naive implementation.

## 1 INTRODUCTION

Analysis of spatial data often involves finding spatial regions that are different from the surrounding area. For example, epidemiologists are interested in finding regions with an unusually high incidence of disease while criminologists are interested in identifying crime hotspots. The spatial scan statistic (SSS) (Kulldorff, 1997) is a widely used technique to discover unusual regions from a Bernoulli or Poisson point process. The SSS searches over a given set of regions, scoring each

region according to how a quantity of interest (eg. the disease rate) inside the region differs from outside the region. Finally, the SSS computes the p-value of the highest scoring region using a randomization test.

Many spatial data sets, however, are more complex than point processes, which focus on the spatial locations of the data. Real-world spatial data sets from domains such as citizen science biodiversity monitoring and real estate associate a response value with each point as well as a set of covariates (i.e. features). For example, in a real estate data set, each data point has a location, a sale price, and associated features such as square footage, number of bedrooms, age, etc. Formally, we represent the  $i$ th data point of dataset  $D$  as a tuple  $(Y_i, X_{i,1}, \dots, X_{i,p}, L_{i,1}, \dots, L_{i,d})$ , where  $Y_i$  is a continuous response,  $(X_{i,1}, \dots, X_{i,p})$  are the  $p$  covariates and  $(L_{i,1}, \dots, L_{i,d})$  are coordinates in  $d$ -dimensions; for simplicity, we assume  $d = 2$ . In later sections, we will refer to the data as  $D = \{Y, X, L\}$  to represent the distinct aspects of response, covariates and locations.

We can follow the SSS framework to find unusual regions in this more complex setting. For each region, we fit a model that captures the relationship between the features and the response variable. Then, we use a scoring function to compare the models from the “inside” versus the “outside” regions, by using a hypothesis test that compares the means of the models. While such an approach seems reasonable, there are two shortcomings. First, the approach is not robust as the mean is well known to be vulnerable to outliers and the models for each region can be badly skewed by outliers with extreme values for the response variable (Rousseeuw and Leroy, 1987). Second, many real-world tasks involve comparing spatial regions using other parts of their distributions besides the mean. For instance, a real-estate agent interested in high-end homes may want to compare regions based on the 90th percentile of the sale price distribution. To overcome both of these problems, we develop a novel method for comparing quantiles of spatial regions.

To accomplish our goal of comparing quantiles of spatial regions, we modify the proposed SSS variant by fitting quantile regression models to the “inside” and “outside” regions. Unfortunately, this naive approach is computationally expensive; fitting a quantile regression requires a linear program and this step would be required in the inner loop of the algorithm. To make the algorithm efficient, we replace the likelihood ratio test with the rank test, which is a non-parametric hypothesis test that avoids the need to fit quantile regressions to the “inside” regions. However, performing a rank test from scratch every time we score a new region is also computationally expensive. Instead, we develop an incremental version of the rank test that allows the rank test from a smaller region to be updated when the region is grown to include more spatial data points.

The contributions of our work are as follows. First, we introduce the Quantile Spatial Scan Statistic (QSSS), which discovers unusual regions for continuous spatial data with covariates. The comparison between regions to determine unusualness is based on a comparison of the  $\tau$ -th quantile of the response variable distributions. To our knowledge, no such version of the SSS currently exists in the literature. This algorithm is also robust to outliers, unlike an analogous algorithm that makes comparisons based on the mean of a region. Second, we show how to make the QSSS over an order of magnitude faster than a naive implementation by introducing an incremental update to the rank test. This update is exact and not an approximation. Finally, we evaluate the QSSS on simulated data and also show interesting results from case studies on three real-world datasets.

## 2 RELATED WORK AND BACKGROUND

We first discuss related work and then provide some background needed to understand our approach. A large body of work that is seemingly related to our task has focused on producing disease maps that illustrate how disease cases vary across space (eg. (Best et al., 2005)). Researchers have also investigated spatial quantile regression (eg. (Reich et al., 2011; Macmillan, 2013)). These modeling approaches generally produce a probabilistic surface, which results in a useful visualization but does not directly solve our goal of identifying specific unusual regions. Achieving this goal requires a human to inspect the probabilistic surface, manually segment it into unusual regions and rank these regions according to some unusualness criterion. This human intervention is not desirable when the spatial region is large and also if the goal is to create an automated monitoring system. Our QSSS algorithm essentially automates these steps in a compu-

tationally efficient manner.

### 2.1 THE SPATIAL SCAN STATISTIC

The Spatial Scan Statistic, introduced by Kulldorff (1997) is a widely used approach for finding anomalous regions. For the SSS, each spatial data point is represented by a tuple  $(c_i, b_i)$  along with its location. The value  $c_i$  corresponds to a count at location  $i$  (e.g. the number of disease cases) and  $b_i$  is the baseline value (e.g. the population) at location  $i$ . The value  $c_i$  is Poisson distributed with mean  $qb_i$ , where  $q$  is the probability of an event of interest occurring.

The original SSS used a scanning window in the shape of a circle to discover unusual regions. While in theory the search should be over all circular regions, the search is, in practice, often limited to circles with centers determined by a fixed grid superimposed on the spatial area. Let  $\mathcal{C}$  be the set of all circular regions searched by the SSS and let  $C \in \mathcal{C}$  be the region under consideration. For a region  $C$  under consideration, let  $c_{in} = \sum_{i \in C} c_i$ ,  $c_{out} = \sum_{i \notin C} c_i$ ,  $b_{in} = \sum_{i \in C} b_i$ ,  $b_{out} = \sum_{i \notin C} b_i$ . Let  $q_{in}$  be the event probability inside the region  $C$  and let  $q_{out}$  be the probability outside the region  $C$ .

Under the null hypothesis  $H_0$ , the event probability is uniform across the entire area i.e.  $q_{in} = q_{out}$ . Under the alternate hypothesis  $H_1(C)$ ,  $q_{in} > q_{out}$ . We estimate  $q_{in}$  and  $q_{out}$  using maximum likelihood estimation. The SSS uses the likelihood ratio test to score a region  $C$ :

$$\begin{aligned} \text{Score}(C) &= \frac{P(\mathbf{D}|H_1(C))}{P(\mathbf{D}|H_0)} \\ &= \left(\frac{c_{in}}{b_{in}}\right)^{c_{in}} \left(\frac{c_{out}}{b_{out}}\right)^{c_{out}} \left(\frac{c_{in} + c_{out}}{b_{in} + b_{out}}\right)^{-(c_{in} + c_{out})} \end{aligned}$$

if  $\left(\frac{c_{in}}{b_{in}}\right) > \left(\frac{c_{out}}{b_{out}}\right)$  and 1 otherwise.

The SSS then selects the region with the highest score i.e.  $C^* = \underset{C \in \mathcal{C}}{\operatorname{argmax}} \text{Score}(C)$ . Due to the multiple hypothesis testing problem, we cannot interpret the score from the likelihood ratio test as a true p-value. Instead, we estimate the p-value through a randomization test. In each replication of the randomization test, we maintain the same underlying population as the original problem, but generate events assuming a uniform probability. Then, the search for the best scoring region is performed. The process is repeated for  $R$  replications to produce an empirical distribution which determines how likely it is to obtain a best score of  $C^*$ .

Many researchers have extended the original SSS approach, including using scanning windows that are arbitrarily shaped (Duczmal and Assuncao, 2004) and incorporating mobility patterns (Lan et al., 2014). One variant

goes beyond shifts in means by discovering which sub-population is most affected by a treatment (McFowland et al., 2018). We point out that performing a quantile-based comparison results in a fundamentally different type of optimization problem and past work on speeding up the SSS (eg. (Neill and Moore, 2004; Neill, 2012)) is not readily applicable. Finally, Moore and Wong (2015) use the SSS to find species rich hotspots but they do not compare quantiles of distributions.

## 2.2 QUANTILE REGRESSION

Suppose we have a continuous random variable  $Y$  with distribution function  $F(Y) = P(Y \leq y)$ . The  $\tau$ -th quantile  $q(\tau)$ , with  $0 < \tau < 1$ , is defined as  $q(\tau) = F^{-1}(\tau) = \inf_y \{F(y) \geq \tau\}$ . For example, when  $\tau = 0.5$ , we get the median. Given a dataset  $Y_1, \dots, Y_n$ , the  $\tau$ -th sample quantile  $\hat{q}(\tau)$ , can be computed by solving the optimization problem:

$$\hat{q}(\tau) = \underset{q}{\operatorname{argmin}} \sum_{i=1}^n \rho_\tau(Y_i - q)$$

where  $\rho_\tau(r) = r(\tau - I(r < 0))$ .

Quantile regression, introduced by Koenker and Bassett (1978), fits a regression to the conditional  $\tau$ -th quantile of the response variable. Given a dataset  $\mathbf{D} = \{(Y_1, \mathbf{X}_1), \dots, (Y_n, \mathbf{X}_n)\}$  where  $Y_i$  is the response variable and  $\mathbf{X}_i$  are the covariates, fitting a quantile regression involves solving:

$$\hat{\beta}(\tau) = \underset{\beta}{\operatorname{argmin}} \sum_{i=1}^n \rho_\tau(Y_i - \mathbf{X}_i \beta)$$

The solution  $\hat{\beta}(\tau)$  produces a conditional quantile function  $Q_Y(\tau | \mathbf{X} = \mathbf{x}) = \mathbf{x}' \hat{\beta}(\tau)$ , similar to how a standard regression produces the conditional mean when the coefficients are multiplied with the covariate values.

Quantile regression is a useful tool for analyzing specific parts of a distribution. It can model the data extremes by setting  $\tau$  close to either 1 or 0, or it can reduce the influence of these points by modeling  $\tau$  close to 0.5.

There are several methods for comparing two quantile regression models. These test include applications of Wald's test, the Likelihood Ratio test, and Rank test (Koenker and Machado, 1999). Mood's median test (Mood, 1950) can also be adapted to perform a comparison at a given quantile. While fast to compute, this version of Mood's test lacks the power of the Wald, Likelihood Ratio, and Rank alternatives. Any of these methods are still usable when the covariate set  $\mathbf{X}$  is empty by using the quantiles of  $\mathbf{Y}$ . We use the Rank test, as

it can be implemented without repeatedly re-estimating the quantile regression coefficients for each data subset, thereby reducing its computation time without sacrificing power. In the following section we explain the Rank test for quantile regression.

## 2.3 RANK TEST FOR QUANTILE REGRESSION

Let the regression model for the  $\tau$ th quantile have the form  $Y = \mathbf{X} \beta_1 + \tilde{\mathbf{X}} \beta_2$  where each row  $\mathbf{X}_i$  corresponds to a data point. For a given data subset  $\mathbf{C} \subseteq \mathbf{D}$ ,  $\tilde{\mathbf{X}}_i = \mathbf{X}_i$  if  $\mathbf{X}_i \in \mathbf{C}$  and  $\tilde{\mathbf{X}}_i = \mathbf{0}$  if  $\mathbf{X}_i \notin \mathbf{C}$ . This model will simultaneously fit a regression to  $\mathbf{C}$  and  $\mathbf{D} \setminus \mathbf{C}$ . In the spatial scan context  $\mathbf{C}$  is the region inside our circle and  $\mathbf{D} \setminus \mathbf{C}$  is the region outside. The goal is then to test the null hypothesis  $H_0 : \beta_2 = \mathbf{0}$  against the alternative  $H_1 : \beta_2 \neq \mathbf{0}$  to see if the subset  $\mathbf{C}$  is sufficiently different from the full distribution of  $\mathbf{D}$ .

The Rank test is an application of the score test, using a score function and ranking process to estimate the data distribution when the true likelihood is unknown. In general terms, the score test statistic is composed of the product of the square of a score vector, an approximation of the derivative using a score function in place of the true likelihood, and the inverse of the Fischer information. The Rank test statistic takes the following form when applied to quantile regression for the null hypothesis above (Gutenbrunner et al., 1993).

$$T = \mathbf{S}' \mathbf{M}^{-1} \mathbf{S} / \Psi^2 \quad (1)$$

We include the following definitions along with the dimensions of each term in braces for clarity.

$$\begin{aligned} \mathbf{S}_{[p \times 1]} &= n^{-1/2} (\tilde{\mathbf{X}} - \mathbf{H} \tilde{\mathbf{X}})' \hat{\mathbf{b}} \\ \mathbf{H}_{[n \times n]} &= \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \\ \hat{\mathbf{b}}_{[n \times 1]} &= - \int \psi(t) d\hat{\mathbf{a}}(t) \\ \mathbf{M}_{[p \times p]} &= n^{-1} (\tilde{\mathbf{X}} - \mathbf{H} \tilde{\mathbf{X}})' (\tilde{\mathbf{X}} - \mathbf{H} \tilde{\mathbf{X}}) \end{aligned}$$

We now provide an intuitive explanation for each term.  $\mathbf{S}$  is the score vector for the test. It represents an approximate derivative of  $\beta$  under the null hypothesis. By formulating  $\mathbf{S}$  with the matrix  $\tilde{\mathbf{X}} - \mathbf{H} \tilde{\mathbf{X}}$ , the influence of  $\mathbf{X}$  (and  $\beta_1$ ) is removed, focusing the approximate derivative on  $\beta_2$ , the parameters of interest. When  $\mathbf{S}$  is large, it indicates that the null hypothesis is ill-suited to the data.

With the true likelihood unknown,  $\mathbf{S}$  is calculated using  $\hat{\mathbf{b}}$ , an  $n$  vector of scores calculated for each data point. These scores are computed by integrating the score function  $\psi(t)$  with respect to the regression rankscores  $\hat{\mathbf{a}}$  de-

finied by Gutenbrunner and Jureckov (1992). The regression rankscores allow the rank test to be applied to quantile regression by converting the multi-dimensional data into a single-dimensional ranking for the chosen quantile.  $\hat{\alpha}$  is equal to the dual solution of the quantile regression under the null hypothesis, and can be calculated using the primal solution  $\beta_1$ . The value  $\hat{\alpha}_i = 1$  if  $\beta_1 \mathbf{X}_i > 0$ , 0 if  $\beta_1 \mathbf{X}_i < 0$ , and between 0 and 1 if  $\beta_1 \mathbf{X}_i = 0$ , satisfying  $\mathbf{X}'\hat{\alpha} = (1 - \tau)\mathbf{X}'\mathbf{1}$ .

$\Psi^2 = \int (\psi(t) - \bar{\psi})^2 dt$  is an additional normalization term for the covariance of the score function. Koenker and Machado (1999) highlight the quantile score function  $\psi(t) = \tau - I(t < \tau)$ , which focuses the test on a specific quantile. This gives us  $\hat{\mathbf{b}}_i = \hat{\alpha}_i(\tau) - (1 - \tau)$  and  $\Psi^2 = \tau(1 - \tau)$ . With this choice of score function,  $\hat{\mathbf{b}}_i$  is either  $\tau$  if  $\beta_1 \mathbf{X}_i > 0$ ,  $\tau - 1$  if  $\beta_1 \mathbf{X}_i < 0$ , or a value inbetween otherwise.

The test statistic  $T$  follows a Chi-squared distribution with  $p$  degrees of freedom under the null hypothesis. It has the desirable properties of not depending on the error distribution, and not needing to learn the model under the alternative hypothesis. The values  $\hat{\mathbf{b}}$  are calculated under the null hypothesis that  $\beta_2 = \mathbf{0}$ .

### 3 METHODOLOGY

We start with a high level overview of our QSSS<sup>1</sup>. Given a dataset  $\mathbf{D} = \{\mathbf{Y}, \mathbf{X}, \mathbf{L}\}$ , and a list of starting locations  $\mathbf{P}$ , the QSSS searches over circular areas in  $\mathbf{L}$ , beginning at each starting location in  $\mathbf{P}$  and growing the regions one data point at a time, starting from some minimum number of points. The regions are grown as circles of increasing radius. Each time the region grows, we calculate its test statistic using our Incremental Rank test (Section 3.1). Once the region cannot be grown any larger, or reaches a maximum size, we move on to the next starting point in  $\mathbf{P}$ . After all starting points have been exhausted, an adjusted p-value is calculated for the region with the highest test statistic using a Gumbel correction (Section 3.2). We chose the Gumbel correction because it is much faster than the traditional randomization test. If the adjusted p-value is significant then the algorithm returns the region, otherwise it says that no significant region was found.

#### 3.1 FASTER RANK TEST FOR QSSS

In the QSSS framework, the Rank test needs to be performed for every circular subset  $\mathbf{C} \subseteq \mathbf{D}$ . We can choose a set of starting points (either each data point or a grid

<sup>1</sup>Matlab code for our experiments and algorithms can be found at <https://github.com/moortrav/QSSS>

formed over  $\mathbf{L}$ ) for the regions and grow each one, recalculating our hypothesis test each time the region overlaps a new data point. The inclusion of a new data point  $i$  into the region will change the  $i$ th row of  $\tilde{\mathbf{X}}$  from a row of zeros to the  $i$ th row of  $\mathbf{X}$ . Under the framework of the Rank test,  $\mathbf{X}$ ,  $\mathbf{H}$ , and  $\hat{\mathbf{b}}$  will be the same for every choice of region  $\mathbf{C}$ . Thus our only task is to update  $T$  as  $\tilde{\mathbf{X}}$  changes.

The primary bottlenecks in updating  $T$  are in updating  $\mathbf{S}$  and recomputing  $\mathbf{M}^{-1}$ .  $\mathbf{M}^{-1}$  can be updated incrementally using applications of the Sherman-Morrison formula (Sherman and Morrison, 1950), but a more efficient update can be performed by leveraging the special structure of  $T$ . Note that we can re-write  $T$  as

$$T = \hat{\mathbf{b}}\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\hat{\mathbf{b}}/\Psi^2 \quad (2)$$

where  $\mathbf{Z} = \tilde{\mathbf{X}} - \mathbf{H}\tilde{\mathbf{X}}$ .  $\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$  is by definition a projection matrix onto the space of  $\mathbf{Z}$ . If we let  $\mathbf{U}$  be an  $n \times p$  orthonormal column basis of  $\mathbf{Z}$ , then

$$T = \hat{\mathbf{b}}\mathbf{U}\mathbf{U}'\hat{\mathbf{b}}/\Psi^2 \quad (3)$$

The inverse in Equation 2 is a normalization term. Since  $\mathbf{U}$  is already normalized, the formulation of Equation 3 allows us to forgo the matrix inverse calculation. Thus we can quickly recalculate  $T$  by performing incremental updates to our orthonormal basis  $\mathbf{U}$  as  $\tilde{\mathbf{X}}$  changes.

##### 3.1.1 Incremental Orthogonalization of Rank Test

Our goal is to take an existing orthonormal basis at iteration  $t$  (i.e.  $\mathbf{U}^t$ ), and calculate  $\mathbf{U}^{t+1}$  based on the (small) change in  $\tilde{\mathbf{X}}$  when a new data point is added to the inside region. To do this efficiently, we leverage the QR decomposibility of  $\mathbf{Z}^t$ , which enables a rank one update. However, we also need to efficiently preserve the QR decomposibility of  $\mathbf{Z}^{t+1}$ , which we do through a series of Givens rotations.

Let  $\mathbf{K}_{[n \times n]}$  be a row selector matrix, where  $K_{[j,j]} = 1$  if point  $j$  is in  $\mathbf{C}$ , and all other values are zero. For a current region  $\mathbf{C}^t$  at iteration  $t$ ,  $\tilde{\mathbf{X}} = \mathbf{K}^t \mathbf{X}$ . If we add point  $i$  to  $\tilde{\mathbf{X}}$  during iteration  $t + 1$ , then this is equivalent to changing the  $i$ th diagonal of  $\mathbf{K}^t$  from 0 to 1. We can express this change as a matrix sum  $\mathbf{K}^{t+1} = \mathbf{K}^t + \mathbf{K}_i$  where  $\mathbf{K}_i$  is zero except for the  $i$ th diagonal. This allows us to decompose the change in  $\mathbf{Z}^{t+1}$  as follows:

$$\mathbf{Z}^{t+1} = (\mathbf{K}^t + \mathbf{K}_i)\mathbf{X} - \mathbf{H}(\mathbf{K}^t + \mathbf{K}_i)\mathbf{X} \quad (4)$$

$$= \mathbf{Z}^t + \mathbf{K}_i\mathbf{X} - \mathbf{H}\mathbf{K}_i\mathbf{X} \quad (5)$$

$$= \mathbf{Z}^t + (\mathbf{e}_i - \mathbf{H}_i)'\mathbf{X}_i \quad (6)$$

where  $\mathbf{e}_i$  is the  $i$ th unit basis vector of size  $1 \times n$ . Note that  $\mathbf{e}_i'\mathbf{X}_i$  is an outer product producing a matrix of size  $n \times p$ .  $\mathbf{H}$  is a symmetric matrix, so we use the row vector  $\mathbf{H}_i$  to keep our notation consistent. In Equation 6 we have reduced the update to  $\mathbf{Z}^t$  to the product of a column and row vector i.e.  $(\mathbf{e}_i - \mathbf{H}_i)'\mathbf{X}_i$ . This means that the matrix added to  $\mathbf{Z}^t$  has a rank of one, and the change to each column of  $\mathbf{Z}^t$  is a multiple of the same column vector  $(\mathbf{e}_i - \mathbf{H}_i)'$ . We can use this special update structure in an algorithm to find  $\mathbf{U}^{t+1}$  efficiently.

If the QR factorization of  $\mathbf{Z}^t$  is known, where  $\mathbf{R}$  is an upper triangular matrix and  $\mathbf{Q} = \mathbf{U}^t$  is an orthonormal column basis, then the factorization for  $\mathbf{Z}^{t+1}$  can be found with the rank one update algorithm detailed in section 12.5.1 of Golub and Loan (2012). This algorithm lets us find the factorization  $\mathbf{Z}^{t+1} = \mathbf{Q}^{t+1}\mathbf{R}^{t+1}$  using the previous factorization  $\mathbf{Z}^t = \mathbf{Q}^t\mathbf{R}^t$ , giving us  $\mathbf{U}^{t+1} = \mathbf{Q}^{t+1}$  for our update to the test statistic  $T$ .

Let  $\mathbf{v} = \mathbf{e}_i - \mathbf{H}_i$ . We start by refactoring the update as

$$\mathbf{Z}^{t+1} = \mathbf{Q}^t\mathbf{R}^t + \mathbf{v}'\mathbf{X}_i = \mathbf{Q}^t(\mathbf{R}^t + \mathbf{w}'\mathbf{X}_i) \quad (7)$$

Where  $\mathbf{w}' = (\mathbf{Q}^t)^{-1}\mathbf{v}' = (\mathbf{Q}^t)'\mathbf{v}'$ . Our goal is to turn  $\mathbf{Z}^{t+1}$  into the product of an orthonormal matrix (which will be  $\mathbf{Q}^{t+1}$ ) and an upper triangular matrix to be produced from  $(\mathbf{R}^t + \mathbf{w}'\mathbf{X}_i)$  through Givens rotations. The details of the Golub and Loan (2012) algorithm that does this can be found in the supplemental materials.

This algorithm is not ideal in its current form, because creating the upper triangular matrix takes  $O(n)$  Givens rotations, a result of  $\mathbf{Q}$  being  $n \times n$ . However, the first  $p$  columns of  $\mathbf{Q}$  and  $p$  rows of  $\mathbf{R}$ , denoted as  $\mathbf{Q}_{[:,1:p]}$  and  $\mathbf{R}_{[1:p,:]}$ , are sufficient to reconstruct  $\mathbf{Z}$ , as  $\mathbf{Z} = \mathbf{Q}_{[:,1:p]}\mathbf{R}_{[1:p,:]} = \mathbf{Q}\mathbf{R}$ . Working with this reduced factorization would reduce the storage and number of Givens rotations required for the algorithm.

Unfortunately this representation is insufficient to perform the update. If we were to compute the vector  $\mathbf{w}$  from Equation 7 with  $\mathbf{Q}_{[:,1:p]}$ , then  $\mathbf{w}' = \mathbf{Q}'_{[:,1:p]}\mathbf{v}' = \mathbf{Q}'_{[:,1:p]}\mathbf{e}_i' - \mathbf{Q}'_{[:,1:p]}\mathbf{H}_i' = \mathbf{0}$ . To see this, note that  $\mathbf{Q}'_{[:,1:p]}\mathbf{e}_i'$  is zero because the  $i$ th row of  $\mathbf{Z}^t$  and  $\mathbf{Q}$  is zero, since the  $i$ th data point has not been added to the inside region yet.  $\mathbf{Q}'_{[:,1:p]}\mathbf{H}_i'$  is also zero because  $\mathbf{H}_i$  is perpendicular to  $\mathbf{Z}^t$  and thus perpendicular to  $\mathbf{Q}_{[:,1:p]}$ . With  $\mathbf{w}' = \mathbf{0}$ , Equation 7 becomes  $\mathbf{Z}^{t+1} = \mathbf{Q}^t_{[:,1:p]}\mathbf{R}^t_{[1:p,:]}$ ,

which completely ignores the update term. Intuitively speaking, we cannot update the column basis of  $\mathbf{Z}^t$  by only considering that basis.

Fortunately, there is a way to summarize the influence of the last  $n-p$  columns of  $\mathbf{Q}$ , denoted  $\mathbf{Q}_{[:,(p+1):n]}$ , into a single vector. When the Givens rotations zero out element  $j$  in  $\mathbf{w}$ , it changes element  $j - 1$  to  $\sqrt{w_{j-1}^2 + w_j^2}$ . Consequently, the result of rotations  $\mathbf{J}'_{p+1} \dots \mathbf{J}'_{n-1}$  will set  $w_{p+1} = \sqrt{w_{p+1}^2 + \dots + w_n^2} = \sqrt{\sum_{j=p+1}^n (\mathbf{Q}'_j\mathbf{H}_i)^2} = |\mathbf{Q}_{[:,(p+1):n]}\mathbf{H}_i|$ . Because  $\mathbf{Q}_{[:,1:p]}$  is perpendicular to  $\mathbf{H}_i$ , the columns  $\mathbf{Q}_{[:,p+1]} \dots \mathbf{Q}_{[:,n]}$  are an orthonormal basis of  $\mathbf{H}_i$ . Projecting  $\mathbf{H}_i$  onto its own basis will preserve its length, giving us  $|\mathbf{Q}_{[:,(p+1):n]}\mathbf{H}_i| = |\mathbf{H}_i|$ . Thus, we can summarize all  $n-p$  Givens rotations with a single vector  $\mathbf{q}$  such that  $\mathbf{q}\mathbf{H}_i = |\mathbf{H}_i|$ , which gives us  $\mathbf{q} = \mathbf{H}_i/|\mathbf{H}_i|$ . If we append  $\mathbf{q}$  as a new column of  $\mathbf{Q}_{[:,1:p]}$  to produce  $\tilde{\mathbf{Q}}_{[:,1:p]}$  and a zero row to the bottom of  $\mathbf{R}_{[1:p,:]}$  to produce  $\tilde{\mathbf{R}}_{[1:p,:]}$  then we can run the algorithm with only  $O(p)$  Givens rotations and still produce the same result. Since  $\mathbf{q}$  is normalized and perpendicular to  $\mathbf{Q}_{[:,1:p]}$ ,  $\tilde{\mathbf{Q}}_{[:,1:p]}$  is still orthonormal.

We can perform the rank one update on  $\tilde{\mathbf{Q}}_{[:,1:p]}^t$  and  $\tilde{\mathbf{R}}_{[1:p,:]}^t$  using the algorithm in Golub and Loan (2012). The first  $p$  columns of  $\tilde{\mathbf{Q}}_{[:,1:p]}^{t+1}$  make our new orthonormal column basis  $\mathbf{U}^{t+1}$  used to calculate our test statistic  $T$ .

---

#### Algorithm 1 Incremental Rank Test

---

Inputs:  $\mathbf{X}, \mathbf{H}, \hat{\mathbf{b}}, \mathbf{Q}, \mathbf{R}, \tau, i$   
 $\mathbf{v} = \mathbf{e}_i - \mathbf{H}_i$   
 $\mathbf{Q}, \mathbf{R} = \text{qr\_update}(\mathbf{Q}, \mathbf{R}, \mathbf{v}, \mathbf{X}_i)$   
 $T = \hat{\mathbf{b}}'\mathbf{Q}\mathbf{Q}'\hat{\mathbf{b}}/(\tau(1 - \tau))$   
Return( $T$ )

---

Algorithm 1 shows the incremental rank test which calls `qr_update`. It takes the index  $i$  of the datapoint being added to the region, along with the QR factorization for the previous iteration as inputs. The details of `qr_update` can be found in the supplementary materials. We can run the algorithm with either the full QR factorization, or the abridged form represented by  $\tilde{\mathbf{Q}}_{[:,1:p]}$  and  $\tilde{\mathbf{R}}_{[1:p,:]}$

Note that our incremental rank test is not an approximation as it computes the test statistic (Equation 1) exactly.

### 3.1.2 Update Runtime

With our compact representation for  $\tilde{\mathbf{Q}}_{[:,1:p]}$  and  $\tilde{\mathbf{R}}_{[1:p,:]}$ , the rank one update to our QR factorization takes  $O(np)$  time. Each Givens rotation is an  $O(n)$  operation, and we perform  $O(p)$  of them in total. Once  $\mathbf{U}^{t+1}$  is found,

$T^{t+1}$  can be calculated in  $O(np)$  time by computing  $\hat{\mathbf{b}}\mathbf{U}^{t+1} = \mathbf{u}$ , and then finding  $T^{t+1} = \mathbf{u}\mathbf{u}'$ . Thus the entire update to  $T$  can be performed in  $O(np)$  time when a single point is added to  $\tilde{\mathbf{X}}$ .

### 3.2 MULTIPLE HYPOTHESIS TEST CORRECTION

To account for the multiple hypothesis test problem, we perform a correction using the method in Abrams et al. (2010). We generate 1000 simulations of the data under the null hypothesis. The maximum test statistic from each of these simulations are used to fit the parameters  $\mu, \gamma$  of a Gumbel distribution. We calculate the adjusted p-value of a region with test statistic  $T$  as  $1 - g(T|\mu, \gamma)$ , where  $g$  is the CDF of the Gumbel distribution. This tells us the rarity of drawing a value at least as large as  $T$  from the distribution of maximum test statistics. In all of our applications we report the most significant region found by QSSS, provided that the adjusted p-value of the region is less than 0.05. Otherwise no significantly different region is found.

## 4 RESULTS

### 4.1 SYNTHETIC DATA EXPERIMENTS

We begin by demonstrating the speedup from our incremental formulation of the Rank test, followed by a comparison of the Rank test to other possible choices of hypothesis tests. We use synthetic data to evaluate these two criteria, as it is easy to generate in large quantities, and it can contain a verifiable ground truth.

#### 4.1.1 Simulator

The purpose of our simulator is to inject data points in spatial regions where the data distribution is altered at a specific percentile. We start with a default distribution, then modify a specific range of the distribution for a random spatial region. This acts as the target region for the algorithm to identify. A detailed description of our simulator can be found in the supplemental materials.

#### 4.1.2 Incremental Rank Test Timing

Using our simulated data, we compare the runtime of our incremental version of the Rank test to its naive (non-incremental) formulation. For each algorithm we calculated the Rank test statistic  $T$ , starting from a base radius, then expanding to include 100 new points. In Figure 1 we show the average time, in milliseconds, that each algorithm took to calculate  $T$  when a new point was added. These tests were done for increasing values of  $n$  while

keeping  $p$  constant at 5. The two algorithms start out at similar times when  $n = 1000$ , but quickly diverge. At  $n = 16,000$  our incremental Rank test takes only 2.83 ms to compute each update, while the non-incremental version takes 166.9 ms. The incremental speedup for the Rank test makes it usable within the framework of the QSSS, while the naive calculation would take far too much time to be feasible for large  $n$ .

Figure 1: Average time to update the Rank test statistic, for the full and incremental formulations. Times were averaged over 100 updates for randomly generated data with different values of  $n$  and constant  $p = 5$ .

### 4.1.3 Comparison against Other Baselines

We are unaware of other methods that can solve exactly the same problem as the QSSS. As a result, we develop three baseline algorithms that can be used for comparison. We create the first baseline by adapting the SSS to account for covariates by modeling the response for the inside (and outside) region using least squares regression. This baseline compares means (not quantiles) of distributions by using a likelihood ratio test. We add the Mean test to show the ineffectiveness of a mean-based test statistic in finding regions that differ only in specific quantiles. For the second baseline, we modify the SSS to focus on a specific quantile of the distribution. We do this by fitting a  $\tau$ th quantile regression with coefficients  $\beta$  to the entire data set; then, for each test region, this baseline calculates Mood's test at  $\tau$ , which is a statistic from a  $2 \times 2$  Chi-Squared table that compares the number of points above and below the  $\beta$  plane from both inside and outside of the region. Finally, our third baseline is similar to the second baseline but it replaces Mood's test with the more powerful but computationally expensive likelihood ratio test from Koenker and Machado (1999) (LR) for quantile regression. This LR test forms a Chi-squared statistic from the residuals of the quantile regressions fit to the null and alternative models.

Using our simulator, we produced 30 randomly generated data sets with  $n = 1000$ .  $B_2$  (parameters for the

injected data) is the same as  $B_1$  (parameters for the normal data) in these datasets, except between the 70th and 100th percentiles of the distribution. 100 of the points are generated from  $f(B_2)$  and 900 of the points are generated from  $f(B_1)$ . Our Moods, LR, and Rank test search for regions that differ at the 90th percentile. For each algorithm, we look at the most significant region found for each dataset, provided it has a p-value of at most 0.05 after the Gumbel correction. Otherwise we count the algorithm as finding no significant region for that dataset. Note that this experiment setup is extremely challenging. The ground truth region to detect makes up 10% of the total dataset, but only 30% of the points in the region on average indicate that it has a different distribution. Adding in the random noise term further complicates the detection task.

Table 1: The precision, recall, F1 and running time of QSSS on synthetic data using various algorithms. The \* indicates statistical significance (paired t-test,  $\alpha = 0.05$ ).

Table 1 shows the results of the simulation experiments. The precision, recall and F1 score of each algorithm is reported in the task of finding the region generated from  $B_2$  in each dataset. These values are calculated on a per data point basis for each dataset, then averaged over the 30 datasets. Three experiment runs were performed, with dimensionality  $p = 3, 5$  and 10. LR and Rank are the two most accurate tests for  $p = 3$  and 5, with Rank being the most accurate for  $p = 10$ . The poor performance of Mood’s and Mean is expected, since Mood’s is a low power test and Mean is ill-suited to find such subtle distributional variations.

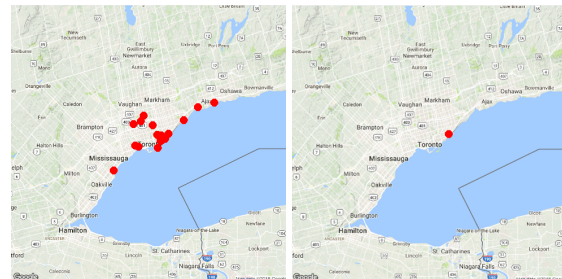

Table 1 also shows the average total runtime of each spatial scan algorithm on the simulation data. This table illustrates the speed of Mood’s test compared to the other hypothesis tests. We can also see that the LR test is sig-

nificantly slower than the others, a result of needing to fit a quantile regression to the alternative model for every test region. In our implementation of LR, we use warm-starting to increase the speed of the quantile regression algorithm as the regions grow point by point. Even with warmstarting, the LR algorithm still takes at least four times longer to run on the simulation data than our other hypothesis choices.

Comparing the accuracy and timing results, we see that while the Rank and LR test are the most accurate, the Rank test offers the best tradeoff in terms of usability between speed and power. We found it infeasible to use the computationally expensive LR test, even on moderately sized datasets. While the Mood’s and Mean tests were faster, neither one was very capable at detecting differences in our simulated data. Due to these result, we primarily use the Rank test in our case studies below; we also include results from the Mean test to illustrate the differences between the two.

## 4.2 ROBUSTNESS TO OUTLIERS

One of the benefits of quantile based analysis is that it is more robust to data outliers than mean-based methods. We illustrate how this can affect spatial scan analysis using eButterfly data as an example use case.

(a) 50th Percentile

(b) Mean

Figure 2: Most significant regions found from eButterfly data, with data points in the region shown as red dots. The figures are zoomed in on the Toronto region for visibility. Figure 2a is from the QSSS algorithm at the 50th percentile, Figure 2b is from the mean regression spatial scan. The region in 2b represents a single location, rather than an area, as all the data from that subset have the same location parameters.

Citizen science biodiversity monitoring programs, such as eButterfly (Prudic et al., 2017), play an important role in ecology as it informs species distribution models and also conservation programs. Citizen scientists participating in these programs submit checklists which record observations of certain types of organisms, such as butterflies in the case of eButterfly, identified by species.

We construct a dataset out of the abundance counts of monarch butterflies (i.e. the number of butterfly individuals observed) in Ontario in 2016. Quantile regression on count data can be addressed using the smoothing method in Machado and Silva (2002), which turns the counts into continuous values by adding uniform noise. This transformation allows us to perform inference with the Rank test as we would with continuous data.

In our analysis, we include the time spent observing for each checklist as the covariate, since there should be a strong correlation between this value and the number of monarchs observed. We ran our QSSS algorithm on several different quantiles and compared the top region for each to the top region found by a mean-based least squares spatial scan.

Figure 2 shows the most significant regions found by the mean regression spatial scan and QSSS at the 50th percentile<sup>2</sup>. Inspection of the data, and verification with domain experts at eButterfly reveal two interesting results identified by the algorithms. Within the data time window there is a single observer who heavily skews the distribution. This observer was involved in a monarch tagging project, and submitted a significant number of very high monarch checklists. The region found by the mean spatial scan only includes the checklists from this observer, all at the same spatial location. When QSSS is run at the 50th percentile, a different trend emerges. The checklists from the observer has much less influence on the model at this level, and the algorithm instead picks up an area of high monarch counts due to migration routes around the great lakes.

If we were limited to only mean-based spatial scans, we would have to filter out the outlier data from the monarch tagging observer to find the desired trends in the dataset. Being able to adjust the percentile of QSSS allows us to reduce the influence of outliers as desired, without explicit removal of outliers from the data.

### 4.3 QUANTILE BASED REGION DETECTION

We now demonstrate the usefulness of detecting unusual spatial regions based on different quantiles.

#### 4.3.1 Education and Unemployment Data

We combine the county-level education and unemployment datasets from the USDA Economic Research Service web page (Parker, 2017). We use the county-level unemployment rates from 2016 as the response variable, and combine the education percentages from 2012-2016

<sup>2</sup>All maps generated using ggmap in R (Kahle and Wickham, 2013)

with median household income (as percentage of state total) values from 2016 as the covariates. The education percentages are the proportion of adults in each county with less than a high school diploma, just a high school diploma, one to three years of college, and four years of college or more. We only use the counties from the continental US.

We ran our QSSS algorithm on the 10th and 90th percentile of the data, along with a mean-based approach using least squares regression. Figure 3 shows the most significant region found by each algorithm. Both the mean and 90th percentile search found the Appalachian region that intersects Kentucky, West Virginia and Virginia, which is well-known to have high unemployment rates with the collapse of the coal industry (Caruthers, 2016). In the 10th percentile region, South Dakota, North Dakota, Nebraska, and Colorado are rated 2,3,4, and 6 in unemployment in the continental US as a whole. This middle region of the country enjoys lower unemployment rates due to the local oil industry and relatively low fallout from the Great Recession (DePillis, 2018). The most significant region discovered at the 10th percentile has a 2 point lower unemployment rate on average, which is abnormally low even when compared to other low unemployment areas.

The unemployment data results highlight the fact that the QSSS, unlike the mean scan, can identify multiple trends in a dataset by changing the modeled quantile.

#### 4.3.2 eBird

The final case study presents the results of applying QSSS to eBird (Sullivan et al., 2014) data. The eBird project collects bird observation checklists from citizen scientists around the world. We compiled two datasets from eBird data collected in 2017 between March and April. These datasets correspond to two different Bird Conservation Regions (BCRs) within the U.S. We divide the data by BCR because they represent cohesive habitats for different bird species. Our choice of March and April is to mitigate the effects of seasonality on the algorithms.

Different from our eButterfly study, we used the total number of species observed from each checklist as our response variable, and the time spent observing as the covariate. Past work has shown that the number of species observed per unit time is highly predictive of the skill level of an observer (Kelling et al., 2015). We use the same count smoothing approach on the eBird data as we did on eButterfly to fit the quantile regression model.

Figure 4 shows the most significant regions found for the mean spatial scan and our QSSS run at the 90th percentile. We corresponded with domain experts from

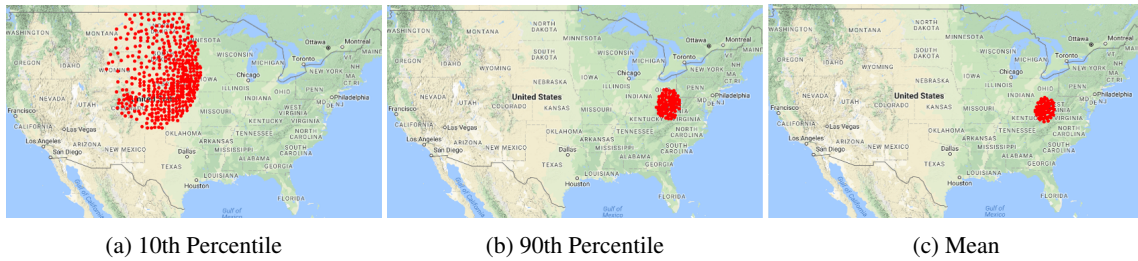

Figure 3: Most significant region found by the QSSS algorithm for the 10th and 90th percentiles of the Education and Unemployment dataset. Most significant region by the mean spatial scan is included for comparison. Regions are illustrated by the centroids of the counties they contain.

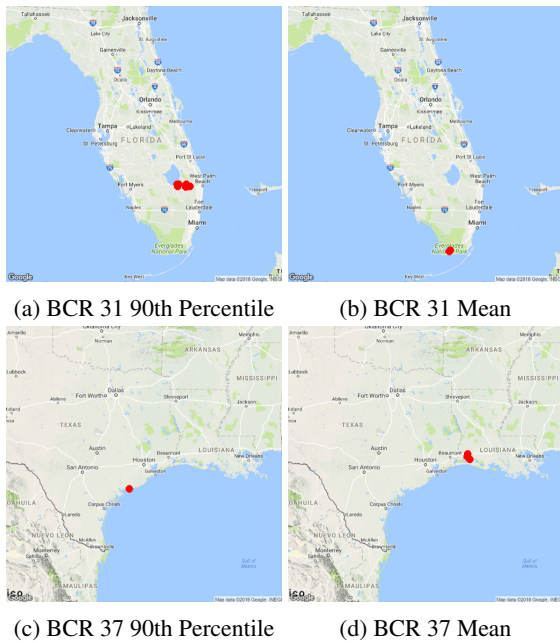

Figure 4: The most significant regions found by QSSS at the 90th percentile and by the mean spatial scan on eBird data from BCRs 31 (Florida) and 37 (Gulf coast). Data points within a region are shown as red dots.

eBird, who offered an analysis on the regions detected.

For BCR 31, the QSSS found an unusual birding location – one that is less frequented by beginners. The birders who visit this region are highly skilled and are able to continue observing a high number of bird species as they stay there. In contrast, the mean scan found a popular species-rich hotspot in the Everglades frequented by both experts and novices. This region has many large wading birds which are easy to see and identify initially.

In BCR 37, the QSSS found a hotspot in Matagorda Bay because it has an unusually high number of bird species along the shoreline that can be readily observed as compared to the surrounding area. Our domain expert com-

mented that the area found by the mean scan was an area that was not particularly high in species. Upon inspecting the models for the inside versus outside region, we found that the models indicate that observers appear to find less species initially inside that area than outside that area.

The mean scan and QSSS algorithms both found very different but meaningful regions for the BCRs. We hypothesize that the QSSS is finding unusual areas in terms of the observation process for more skilled observers (as in BCR 31) and we will continue our analysis on other BCRs in future work.

## 5 FUTURE WORK AND CONCLUSION

The QSSS discovers unusual spatial regions that differ from the surrounding area. The inner loop of the algorithm relies on comparing quantile regressions fit to data from inside and outside a region under consideration. To perform these comparisons efficiently, we developed an incremental rank test, which is over an order of magnitude faster than a naive implementation. Our results on simulated data and on three real-world datasets show that QSSS enables a new type of analysis for spatial data that is different from mean-based methods and that the QSSS is also robust to outliers. For future work, we would like to investigate reporting the top  $K$  most unusual regions rather than the top 1 and we would also like to extend our work to find unusual regions in both space and time.

## ACKNOWLEDGEMENTS

We thank our collaborators from eButterfly (Katy Prudic, Max Larrivee, Jeffrey Oliver and Jeremy Kerr) and eBird (Daniel Fink, Chris Wood). Moore was supported by NSF grant CCF-1521687. ## Abstract

The goal of many machine learning tasks is to learn a model that has small population risk. While mini-batch stochastic gradient descent (SGD) and variants are popular approaches for achieving this goal, it is hard to prescribe a clear stopping criterion and to establish high probability convergence bounds to the population risk. In this paper, we introduce *Stable Gradient Descent* which validates stochastic gradient computations by splitting data into training and validation sets and reuses samples using a differential private mechanism. StGD comes with a natural upper bound on the number of iterations and has high-probability convergence to the population risk. Experimental results illustrate that StGD is empirically competitive and often better than SGD and GD.

## 1 INTRODUCTION

The primary goal in several machine learning tasks is to learn a model with finite training samples that generalizes well to unseen instances. One typically attempt to solve the following optimization problem which finds a minimizer  $w^*$  of the *population risk*  $F$  over some model class  $\mathcal{W}$ :

$$w^* \in \operatorname{argmin}_{w \in \mathcal{W}} F(w) \triangleq \mathbb{E}_{z \sim \mathcal{P}}[l(w, z)], \quad (1)$$

where  $z \in \mathcal{Z}$  is a data point in domain  $\mathcal{Z}$  following the unknown distribution  $\mathcal{P}$ , and  $l : \mathcal{W} \times \mathcal{Z} \mapsto \mathbb{R}$  is a certain loss function associated with the learning problem. For example, in classification problems  $z = (\mathbf{x}, y)$  is an instance-label pair,  $w$  denotes a classifier, and  $l(w, z)$  can be the hinge loss or logistic loss.

Due to the unavailability of distribution  $\mathcal{P}$ , the challenge of a learning algorithm is to search for an approximate minimizer  $\hat{w}_n$  of the risk  $F$  based *only* on a set of finite samples  $Z_n = \{z_1, z_2, \dots, z_n\}$ . A good criterion for quantifying the quality of  $\hat{w}_n$  is through the *excess risk*:

$$F(\hat{w}_n) - F(w^*). \quad (2)$$

A learning algorithm for obtaining  $\hat{w}_n$  should have small excess risk. Being a function of the random set of samples  $Z_n$ ,  $F(\hat{w}_n)$  is a random variable and a good learning algorithm is expected to have small excess risk with high probability.

In the literature, there are several approaches to tackle the problem. The classical approach is *empirical risk minimization* (ERM) (Shalev-Shwartz and Ben-David [2014]) which aims to find an empirical minimizer defined as  $\hat{w}_n^{ERM} \in \operatorname{argmin}_{w \in \mathcal{W}} \hat{F}(w) \triangleq \frac{1}{n} \sum_{j=1}^n l(w, z_j)$ . Usually first-order iterative optimization methods such as *gradient descent* (GD) are used to obtain the minimizer. However, GD uses all samples to compute gradients in each iteration and is quite slow for large datasets. A popular approach in modern machine learning is *stochastic gradient descent* (SGD) (Zhang [2004]; Rakhlin et al. [2012]; Hazan and Kale [2014]). SGD

minimizes the population risk directly by descending along stochastic gradients, computed based on a single sample or a mini-batch of samples. The stochastic gradient equals the population gradient in expectation (Shalev-Shwartz and Ben-David [2014]). Convergence of SGD is typically analyzed in expectation rather than with high probability with a few notable exceptions (Rakhlin et al. [2012]). In practice, since the improvements in the objective function value is non-monotonic, it is hard to prescribe a theoretically well grounded stopping criterion.

Conceptually, a mini-batch SGD algorithm would be much more well behaved if we had access to  $n$  fresh samples in each iteration. In such a setting, one would be able establish high probability bounds on the sample gradients staying close to the population gradient across all iterations, leading to high probability bounds on the excess risk. In this paper, we introduce *Stable Gradient Descent* (StGD), which behaves similar to the ideal case of  $n$  fresh samples per iteration using ideas from *adaptive data analysis* (Dwork et al. [2015c]) and *differential privacy* (Dwork and Roth [2014]). Each iteration leads to a small privacy loss which, unlike SGD, automatically puts a bound on the number of iterations StGD can be run. We present basic and mini-batch StGD and provide high probability bounds on the excess risk for different types of convex loss functions.

The main idea in StGD is simple: separate the available samples into a training and a validation set, compute stochastic gradient on both, and check if they are close. If they are indeed close, there is confidence in that descent direction and StGD proceeds with the descent. On the other hand, if they are not close, there is lack of confidence in the descent direction, and StGD uses a noisy version of the estimated gradient to do descent. The challenge in naively carrying out the simple idea is that the algorithm may overfit on both the training and the validation set. As a result, StGD carries out the comparison of training and validation gradients using a differentially private mechanism, which allows StGD to reuse the same samples over iterations

but still get high probability bounds across all iterations as if the samples were fresh.

The remainder of the paper is organized as follows. Section 2 describes related work. We present basic StGD in Section 3, and present mini-batch StGD in Section 4, along with high probability excess risk bounds. We present experimental results in Section 5, and conclude in Section 6. All technical proofs are deferred to the supplementary material.

## 2 RELATED WORK

**ERM and SGD:** For ERM, a common algorithm is gradient descent (Shalev-Shwartz and Ben-David [2014]) which computes the full gradient of the empirical risk and takes a step along it at each iteration. The performance of ERM is usually measured in terms of the uniform convergence of  $\hat{F}(w)$  to  $F(w)$  over  $\mathcal{W}$ . (Hardt et al. [2015]) analyzed the stochastic gradient method (SGM) for ERM in terms of stability and optimization error:  $\mathbb{E}[F(\hat{w}_n)] - F(w^*) \leq \epsilon_{opt}(w) + \epsilon_{stab}$ . They demonstrated that for  $L$ -Lipschitz continuous function, SGM has the convergence rate of  $O(L/\sqrt{n})$ . SGD minimizes the population risk by allowing the optimization procedure to take a step along a random direction, as long as the expected value of the direction is the population gradient (Shalev-Shwartz and Ben-David [2014]). In this case, with  $n$  to be the number of stochastic gradient computations. For strongly convex functions, SGD can achieve an expectation risk bound of rate  $O(1/n)$  (Hazan and Kale [2014], Rakhlin et al. [2012]). (Rakhlin et al. [2012]) also presented a similar high probability bound for SGD.

**Differential Privacy:** Informally, differential private analysis ensures that the outcome of analysis on two nearly identical input datasets (different on a single component) should also be nearly identical. As a result, an analyst will not be able to distinguish any single data by comparing the change of output. In the context of machine learning, this randomized algorithm  $\mathcal{M}$  can be a learning algorithm that outputs a classifier  $\mathcal{M}(D) = f$  where  $D$  is the training set. Some work (Chaudhuri et al. [2011], Bass-

ily et al. [2014]) introduced differential privacy to ERM to protect sensitive information about training data. (Dwork et al. [2015b], Dwork et al. [2015a]) introduced differential privacy to adaptive data analysis (ADA). In ADA, analyst test adaptively generated hypotheses on one holdout set where those hypotheses have dependence on the holdout set. To ensure the repeatedly used holdout set to provide valid validations, they designed a *Thresholdout* mechanism which allows the analyst to query the holdout set via a differentially private way. They showed differentially private reused holdout set maintains the statistical nature of fresh sample.

The main contribution of this paper is, we introduce differential privacy to gradient descent by applying *Thresholdout* to the training set. We show that the training set can be reused and maintains the statistical nature of fresh sample in all iterations. Mathematically speaking, gradients computed on the differentially-private reused training set concentrate around the population value with high probability. We exploit the concentration property to derive high-probability risk bounds of StGD.

### 3 STABLE GRADIENT DESCENT

#### 3.1 PRELIMINARIES

We consider the problem of minimizing the population risk defined in Equation 1. We denote  $\nabla l(w, z)$  as the gradient of  $l(w, z)$ . We use  $\nabla_i l(\cdot)$  to denote the  $i$ -th coordinate of  $\nabla l(\cdot)$ . Besides, we use  $g_i(w)$ ,  $\tilde{g}_i(w)$  and  $\hat{g}_i(w)$  to be the  $i$ -th coordinate of  $g(w)$  (population gradient),  $\tilde{g}(w)$  (gradient computed by StGD) and  $\hat{g}(w)$  (empirical gradient), respectively, for  $i \in \{1, \dots, d\}$ , where  $d$  is the dimension of  $w$ . For example, given the sample set  $S$ ,  $\hat{g}(w) = \sum_{z_j \in S} \nabla l(w, z_j) / |S|$ . We consider some special cases of  $F(w)$  with the following assumptions (Boyd and Vandenberghe [2004]):

**1. Convex and  $L$ -Lipschitz:** Function  $F$  is convex with  $L$ -Lipschitz if for all  $w, w' \in \mathcal{W}$  and  $L \geq 0$ :

$$|F(w') - F(w)| \leq L \|w' - w\|.$$

**2. Strongly Convex:** Formally, a function  $F$

---

#### Algorithm 1 Stable Gradient Descent (StGD) Algorithm

---

- 1: **Input:** Dataset  $S$ , certain loss  $l(\cdot)$ , initial point  $w_0$ .
  - 2: **Set:** Noise variance  $\sigma$ , iteration time  $T$ , step size  $\eta$ .
  - 3: Separate  $S$  randomly and evenly into  $S_t$  and  $S_h$ .
  - 4: **for**  $s = 0, \dots, T$  **do**
  - 5:   Run **DPGC**( $S_t, S_h, w_s, \sigma, l(\cdot)$ ) to compute gradient  $\tilde{g}(w_s)$ .
  - 6:    $w_{s+1} = w_s - \eta \tilde{g}(w_s)$ .
  - 7: **end for**
- 

is  $\alpha$ -strongly convex, if for all  $w, w' \in \mathcal{W}$  and any subgradient  $g(w)$  of  $F$  at  $w$ , we have

$$F(w') \geq F(w) + (w' - w)^T g(w) + \frac{\alpha}{2} \|w' - w\|^2.$$

**3. Smooth:** We say a function  $F$  is  $\beta$ -smooth, if  $w, w' \in \mathcal{W}$  and any subgradient  $g(w)$  of  $F$  at  $w$ , we have

$$F(w') \leq F(w) + (w' - w)^T g(w) + \frac{\beta}{2} \|w' - w\|^2.$$

#### 3.2 STGD ALGORITHM

We present StGD in two parts: Algorithm 1 and Algorithm 2 (**DPGC**). To simplify, we suppose there are  $2n$  available samples  $S \sim \mathcal{P}^{2n}$ . The StGD randomly and evenly separates them into two datasets: training set  $S_t$  and validation set  $S_h$ , both of which are of size  $n$ . We set a noise parameter  $\sigma$  and the total iterations  $T$ . We analyze the optimal values of parameters  $\sigma$  and  $T$  in the next section. Starting from initial point  $w_0$ , at each  $s$ -th iteration, StGD runs **DPGC** (Algorithm 2) to query the training set  $S_t$  in order to obtain an estimated gradient  $\tilde{g}(w_s)$ , then updates the  $w_{s+1}$  based on  $\tilde{g}(w_s)$  (line 5, 6 in Algorithm 1).

We present the pseudo-code of **DPGC** in Algorithm 2. **DPGC** unrestrictedly accesses the validation set  $S_h$ , but accesses  $S_t$  via a differentially private way: Given  $w_s$ , **DPGC** first computes gradients on  $S_t$  and  $S_h$ :  $g^t(w_s) = \sum_{z_i \in S_t} \nabla l(w_s, z_i) / |S_t|$ ,  $g^h(w_s) =$

---

**Algorithm 2** Differentially Private Gradient Computation (DPGC)

---

- 1: **Input:** Dataset  $S_t$  and  $S_h$ , parameter  $w_s$ , noise variance  $\sigma$ , loss  $l(\cdot)$ .
  - 2: Compute gradients  $g^t(w_s)$  and  $g^h(w_s)$ :  
 $g^t(w_s) = \sum_{z_i \in S_t} \nabla l(w_s, z_i) / |S_t|$ ,  
 $g^h(w_s) = \sum_{z_i \in S_h} \nabla l(w_s, z_i) / |S_h|$ .
  - 3: **for**  $i = 1, \dots, d$  **do**
  - 4:   Sample  $\xi \sim \text{Lap}(\sigma)$ ,  $\gamma \sim \text{Lap}(2 \cdot \sigma)$ ,  
 $\tau \sim \text{Lap}(4 \cdot \sigma)$ .
  - 5:   **if**  $|g_i^t(w_s) - g_i^h(w_s)| > \gamma + \tau$  **then**
  - 6:      $\tilde{g}_i(w_s) = g_i^t(w_s) + \xi$ .
  - 7:   **else**
  - 8:      $\tilde{g}_i(w_s) = g_i^h(w_s)$ .
  - 9:   **end if**
  - 10: **end for**
  - 11: **Return:**  $\tilde{g}(w_s)$ .
- 

$\sum_{z_i \in S_h} \nabla l(w_s, z_i) / |S_h|$ . Second, for each coordinate  $i \in \{1, \dots, d\}$ , **DPGC** validates  $g_i^t(w_s)$  with  $g_i^h(w_s)$  (line 5-line 8 in Algorithm 2): If their absolute difference is beyond the threshold  $\gamma + \tau$ , **DPGC** outputs  $g_i^t(w_s)$  with noise. Otherwise, **DPGC** returns  $g_i^h(w_s)$ .

### 3.3 CONVERGENCE ANALYSIS

We assume that for every  $i$ -th coordinate, the gradient function  $|\nabla_i l(w, z)| \leq G$  for a fixed constant  $G$ . Given an  $n$ -sample set  $S \in \mathcal{Z}^n$  and a fixed  $w_0$  that is chosen independent of the dataset  $S$ ,  $\hat{g}_i(w_0) = \sum_{z_j \in S} \nabla_i l(w_0, z_j) / n$  and  $g_i(w_0) = \mathbb{E}_{z \sim \mathcal{P}}[\nabla_i l(w_0, z)]$ , by Hoeffding's bound, we have the concentration as

$$P\{|\hat{g}_i(w_0) - g_i(w_0)| \geq \sigma\} \leq 2 \exp\left(\frac{-2n\sigma^2}{4G^2}\right). \quad (3)$$

In general, updating  $w_1$  through typical gradient descent:  $w_1 = w_0 - \eta \hat{g}(w_0)$ , the above concentration bound does not hold for  $\hat{g}_i(w_1) = \sum_{z_j \in S} \nabla_i l(w_1, z_j) / n$ , because  $w_1$  is no longer independent of dataset  $S$ . In the next lemma, we demonstrate that  $w_1, w_2, \dots, w_T$  updated by a differential private mechanism have similar concentration bounds as described in Equation 3.

**Lemma 1.** *Let  $\mathcal{M}$  be an  $\epsilon$ -differentially private gradient descent algorithm and  $S_t \sim \mathcal{P}^n$  be the*

*training set. Let  $w_s = \mathcal{M}(S_t)$  be the corresponding output for  $s \in 1, \dots, T$  and  $\hat{g}(w_s)$  be the empirical gradient on  $S_t$ . For any  $\sigma > 0$ ,  $i \in 1, \dots, d$  and  $s \in 1, \dots, T$ , setting  $\epsilon \leq \frac{\sigma}{2G}$  ensures*

$$P\{|\hat{g}_i(w_s) - g_i(w_s)| \geq \sigma\} \leq 6\sqrt{2} \exp\left(\frac{-n\sigma^2}{4G^2}\right). \quad (4)$$

Lemma 1 illustrates that differential privacy enables the reused training set to maintain the statistical guarantee as a fresh set under the condition that the privacy parameter  $\epsilon$  is bounded by the estimation error  $\sigma$ . Next, we analyze the privacy parameter  $\epsilon$  of StGD.

**Lemma 2.** *StGD satisfies  $\frac{2TG}{n\sigma}$ -differentially private.*

In order to achieve the gradient concentration bound described in Lemma 1 by considering the guarantee of Lemma 2 (i.e. to guarantee that for every  $w_s$ , we have  $P\{|\hat{g}_i(w_s) - g_i(w_s)| \geq \sigma\} \leq 6\sqrt{2} \exp(\frac{-n\sigma^2}{4G^2})$ ), we need to set  $\frac{2TG}{n\sigma} \leq \frac{\sigma}{2G}$  so that we achieve  $\epsilon$ -differential privacy for  $\epsilon \leq \frac{\sigma}{2G}$ . As a result, we get the upper bound of iteration time  $T$  in StGD as  $T = \frac{\sigma^2 n}{4G^2}$ . Next theorem shows that across all iterations, gradients produced by StGD maintain high probability concentration bounds.

**Theorem 1.** *Given parameter  $\sigma > 0$ , let  $w_1, w_2, \dots, w_T$  be the adaptively updated points by StGD and  $\tilde{g}(w_1), \dots, \tilde{g}(w_T)$  be the corresponding output gradient. If we set  $T = \frac{\sigma^2 n}{4G^2}$ , then for all  $s \in 1, \dots, T$  and for all  $t > 0$ , we have*

$$P\left\{ \|\tilde{g}(w_s) - g(w_s)\|^2 \geq d(6t + 1)^2 \sigma^2 \right. \\ \left. \leq 2d \exp(-t) + 6\sqrt{2}d \exp\left(\frac{-n\sigma^2}{4G^2}\right) \right\}. \quad (5)$$

Theorem 1 concludes that the gradient  $\tilde{g}(w_s)$  produced by StGD concentrates to the population gradient  $g(w_s)$  and the concentration error is tightly around  $(6t + 1)^2 \sigma^2$ . Increasing noise parameter  $\sigma$  increases the privacy guarantee as well as the total number of iterations, but also increases the concentration error. Decreasing  $\sigma$  has the opposite effect. We consider StGD in two cases: 1)  $F$  is  $L$ -Lipschitz and  $\alpha$ -strongly convex; 2)  $F$  is  $\beta$ -smooth and  $\alpha$ -strongly convex. For these two cases, we present the best value of  $\sigma$  for the trade-off between statistical rate

and optimization rate which depends on number of iterations in order to achieve the optimal risk bound. To simplify the result, we use the notation  $\rho_{n,d} = \ln n + \ln d$ .

**Theorem 2.** For  $L$ -Lipschitz and  $\alpha$ -strongly convex function  $F$ , given  $2n$  available samples, set noise parameter  $\sigma^2 = 4G^2\rho_{n,d}/\sqrt{n}$ , step size  $\eta_s = \frac{2}{\alpha(s+1)}$  and iteration time  $T = \rho_{n,d}\sqrt{n}$  for StGD. Let  $\hat{w}_n = \sum_{s=0}^T w_s/(T+1)$ , StGD achieves:

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\ln(\sqrt{n}\rho_{n,d})}{\sqrt{n}\rho_{n,d}}\right) + O\left(\frac{d\rho_{n,d}^3}{\sqrt{n}}\right), \quad (6)$$

with probability at least  $1 - O\left(\frac{\rho_{n,d}}{\sqrt{n}}\right)$

The first term of the risk bound in Theorem 2 corresponds to typical strongly convex optimization rate  $O(\ln T/T)$  (Bubeck [2015]) ( $T = \rho_{n,d}\sqrt{n}$  in our case) and is similar to the high probability bound of SGD analyzed in Rakhlin et al. [2012]. The second term comes from the statistical error that depends on available sample size  $n$  and dimension  $d$ .

**Theorem 3.** For  $\beta$ -smooth and  $\alpha$ -strongly convex function  $F$ , given  $2n$  available samples, set noise parameter  $\sigma^2 = \frac{\rho_{n,d}(4G^2\alpha+\beta)^2}{n\alpha\beta}$ , step size  $\eta = \frac{1}{\alpha+\beta}$  and iteration time  $T = (\kappa + \frac{1}{\kappa} + 2)\rho_{n,d}$  where  $\kappa = \beta/\alpha$ . Let  $\hat{w}_n = w_T$  be the output of StGD, we have the following excess risk bound:

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\|w_1 - w^*\|^2}{n}\right) + O\left(\frac{d\rho_{n,d}^3}{n}\right) \quad (7)$$

with probability at least  $1 - O\left(\frac{\rho_{n,d}}{n^{\frac{1}{4}}d^{\frac{1}{3}}}\right)$ .

The risk bound in Theorem 3 is also composed of optimization term and statistical term (same for the subsequent theorems). Factor  $\|w_1 - w^*\|^2$  implies a good initial point can be beneficial. In terms of computational complexity, StGD repeats  $O(\ln n)$  iterations on  $n$  samples. It requires a complexity of  $O(n \ln n)$  gradient computations.

## 4 MINI-BATCH EXTENSIONS

In this section, we extend StGD to its mini-batch version for large-scale machine learning tasks. We first introduce a simple *mini-batch*

---

### Algorithm 3 mini-batch SGD

---

- 1: **Input:** Dataset  $S$ , loss  $l(\cdot)$ , initial point  $w_0$
  - 2: **Set:** Step size  $\eta$ , batch size  $m$ .
  - 3: Separate  $S$  into  $T$  parts:  $S_0, \dots, S_{T-1}$  with  $m$  samples each part.
  - 4: **for**  $s = 0, \dots, T-1$  **do**
  - 5:   Compute gradient  $\hat{g}(w_s)$  on  $S_s$
  - 6:    $w_{s+1} = w_s - \eta_s \cdot \hat{g}(w_s)$
  - 7: **end for**
- 

SGD algorithm, then we present the differentially private algorithm *mini-batch StGD*.

The mini-batch SGD algorithm is described in Algorithm 3. The available set is first partitioned into  $T$  batches with  $m$  samples each batch. Then Algorithm 3 updates  $w_s$  based on the gradient computed on each batch. Mini-batch SGD terminates after a single pass over all batches. The following theorem analyzes the risk bound of mini-batch SGD.

**Theorem 4.** Given  $2n$  available samples, *mini-batch SGD* can achieve the following:

1.  $F$  is  $L$ -Lipschitz and  $\alpha$ -strongly convex: If we set the step size  $\eta_s = \frac{2}{\alpha(s+1)}$ , batch size  $m = \sqrt{n}$  and iteration time  $T = 2n/m$ , output  $\hat{w}_n = \sum_{s=1}^T w_s/T$  of mini-batch SGD satisfies:

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\ln(\sqrt{n}+1)}{\sqrt{n}}\right) + O\left(\frac{d \ln \sqrt{n}}{\sqrt{n}}\right) \quad (8)$$

with probability at least  $1 - d/\sqrt{n}$ .

2.  $F$  is  $\beta$  smooth and  $\alpha$ -strongly convex: If we set the step size  $\eta = \frac{1}{\alpha+\beta}$ ,  $m = \frac{\alpha\beta n}{(\alpha+\beta)^2 \ln n}$ ,  $T = 2n/m$ , output  $\hat{w}_n = w_T$  of StGD satisfies:

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\|w_1 - w^*\|^2}{n}\right) + O\left(\frac{d \ln^2 n}{n}\right) \quad (9)$$

with probability  $1 - O\left(\frac{\ln n}{n}\right)$ .

(Frostig et al. [2015]) proposed a variant of mini-batch SGD that also does a single pass of the available data. For smooth and strongly convex function, they established a convergence rate of  $O(1/n)$  in expectation that is similar to the rate in Theorem 4.

---

**Algorithm 4** mini-batch StGD

---

- 1: **Input:** Dataset  $S$ , loss  $l(\cdot)$ , initial point  $w_0$
  - 2: **Set:** Step size  $\eta$ , batch size  $m$ , inner iterations  $T_1$ , noise  $\sigma$
  - 3: Separate  $S$  into  $T$  parts:  $S_0, \dots, S_{T-1}$  with  $m$  samples each part.
  - 4: **for**  $s = 0, \dots, T - 1$  **do**
  - 5:    $w_{s+1} = \text{StGD}(w_s, S_s, \eta, T_1, \sigma)$
  - 6: **end for**
- 

The mini-batch version of StGD is given in Algorithm 4 (mini-batch StGD) that is also a private version of mini-batch SGD: For each batch  $S_s$ , where  $s \in \{0, \dots, T - 1\}$ , call StGD to query  $S_s$  and update  $w_{s+1}$  as the initial point for next batch  $S_{s+1}$ . In each call, there are  $T_1$  inner iterations that StGD queries  $S_s$  for  $T_1$  times through DPGD. Let  $\tilde{w}_0 = w_s$  as the initial point in each call, then sub-algorithm StGD updates  $\tilde{w}_{k+1} = \tilde{w}_k + \eta \tilde{g}(\tilde{w}_k)$  for  $k = \{0, \dots, T_1 - 1\}$  and  $w_{s+1} = \tilde{w}_{T_1}$ .

**Theorem 5.** *Given  $2n$  available samples, mini-batch StGD can achieve the following:*

1.  **$F$  is  $L$ -Lipschitz and  $\alpha$ -strongly convex:** *If we set the step size  $\eta_s = \frac{2}{\alpha(s+1)}$ , batch size  $m = \sqrt{n}$ ,  $T = 2n/m$ , noise parameter  $\sigma^2 = 8G^2 \ln n / \sqrt{n}$  and  $T_1 = \ln n$ , output  $\hat{w}_n = \sum_{s=1}^T w_s / T$  of mini-batch StGD satisfies:*

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\ln(\sqrt{n}+1)}{\sqrt{n} \ln n}\right) + O\left(\frac{\ln^3 n}{\sqrt{n}}\right) \quad (10)$$

with probability at least  $1 - d/\sqrt{n}$ .

2.  **$F$  is  $\beta$  smooth and  $\alpha$ -strongly convex:** *If we set the step size  $\eta = \frac{1}{\alpha+\beta}$ ,  $m = \frac{\alpha\beta n}{(\alpha+\beta)^2 \ln n}$ ,  $T = 2n/m$ ,  $T_1 = \ln n$ , noise parameter  $\sigma^2 = \frac{4G^2(\alpha+\beta)^2(\ln n)^2}{\alpha\beta n}$ , output  $\hat{w}_n = w_T$  of mini-batch StGD satisfies:*

$$F(\hat{w}_n) - F(w^*) \leq O\left(\frac{\|w_1 - w^*\|^2}{n \ln n}\right) + O\left(\frac{d \ln^4 n}{n}\right) \quad (11)$$

with probability at least  $1 - O\left(\frac{\ln^2 n}{n}\right)$ .

Theorem 5 shows that, compared to the basic mini-batch SGD (Theorem 4), the private ver-

sion improves the rate of the first term for both types of functions.

## 5 EXPERIMENTS

In this section, we conduct experiments to evaluate performances of the proposed algorithms on artificial data and real world data. We divide our experiments into three sets to address questions: (i) How do the StGD and the mini-batch StGD perform regarding the convergence to the population optimum? (ii) For small datasets, how does StGD perform compared to SGD and GD. (iii) For large datasets, does mini-batch StGD outperform SGD and mini-batch SGD? After discussing the experimental setup, we evaluate these questions empirically in Sections 5.2, 5.3, and 5.4 respectively.

### 5.1 EXPERIMENTAL SETTING

**Datasets:** We use both artificial datasets and real-world datasets for our experiments. We discuss the datasets in two categories: the small datasets (i.e., *small artificial dataset, breast cancer, diabetes and german.numer*) for StGD, SGD and GD, and large datasets (i.e., *large artificial dataset, cove type, rcv1 and real-sim*) for mini-batch StGD, SGD and mini-batch SGD. All the real-world datasets are from LIBSVM (Chang and Lin [2011]). The real-world datasets are described in the Table 1. The small artificial dataset, consists of 50 features and one label:  $z_i = (\mathbf{x}_i, y_i) \in \mathbb{R}^{50} \times \{1, -1\}$ . The large artificial dataset consists of 500 features and one label:  $z_i = (\mathbf{x}_i, y_i) \in \mathbb{R}^{500} \times \{1, -1\}$ . The value of each feature is random noise, drawn i.i.d. from normal distribution  $N(0, 1)$ . To generate the label, we first set an optimal minimizer  $w^* \in \mathbb{R}^{50}$  for small datasets and  $w^* \in \mathbb{R}^{500}$  for large datasets. Then, we draw the label  $y_i$  corresponding to  $\mathbf{x}_i$  from the Bernoulli distribution  $y_i \sim B\left(\frac{1}{1+\exp(-w^{*T} \mathbf{x}_i)}, \frac{\exp(-w^{*T} \mathbf{x}_i)}{1+\exp(-w^{*T} \mathbf{x}_i)}\right)$ .

**Evaluation Metrics:** We measure the performance of these algorithms for binary classification problem with linear models. We focus on the smooth and strongly convex loss function case and define the loss function  $F$  to be the

Table 1: Datasets

Datasets	Data size	Features
breast cancer	683	10
diabetes	768	8
german.numer	1000	24
cove type	581012	54
rcv1	697641	47236
real-sim	72309	20958

logistic loss. Thus, the population risk is

$$F(w) = \mathbb{E}[\ln(1 + \exp(-y_i w^T \mathbf{x}_i))]. \quad (12)$$

Given a training set of instance-label pairs  $\{\mathbf{x}_i, y_i\}_{i=1}^n$  the empirical risk is

$$\hat{F}(w) = \frac{1}{n} \sum_{i=1}^n \ln(1 + \exp(-y_i w^T \mathbf{x}_i)). \quad (13)$$

The population optimum is

$$F(w^*) = \mathbb{E}[\ln(1 + \exp(-y_i w^{*T} \mathbf{x}_i))]. \quad (14)$$

We use  $\hat{w}_n$  to be the output trained on  $n$  samples. We evaluate these algorithms in terms of the excess risk  $F(\hat{w}_n) - F(w^*)$  and test error rate for artificial datasets. Since we cannot know the population optimum  $F(w^*)$  out of the expectation, we let the loss computed on a large fresh set (2000 fresh samples for small data case, 20000 fresh samples for large data case) to represent the population risk. As for the real-world datasets, since the population minimizer is unknown, we evaluate these algorithms based on the test loss and test error rate.

**Setup and parameters:** We set  $w_0 = \{1\}^d$  as the initial point for artificial datasets and  $w_0 = \{0\}^d$  for real-world datasets. As for the step size, we use the typical  $\eta = a_1/\sqrt{n}$  for SGD,  $\eta = a_2$  for StGD, mini-batch SGD and mini-batch StGD (which is the default setting in our theoretical analysis) and  $\eta = a_3$  for GD. The above  $a_1$ ,  $a_2$  and  $a_3$  are all constants and we use grid search to find the best values of them for different datasets. As for the iteration times, given the training set with size  $n$  and  $d$  features, we set 500 iterations for GD and  $10 * (\ln n + \ln d)$  for StGD. SGD stops iteration after a single pass over all training samples. Mini-batch StGD has batch size  $n/\ln n$  and  $\ln^2 n$  iterations. Mini-batch SGD has the same batch size, but  $\ln n$

iterations. Finally, we set the noise parameter  $\sigma = (\ln n + \ln d)/n$  for StGD and  $\sigma = \ln^2 n/n$  for mini-batch StGD.

## 5.2 EVALUATIONS OF STGD

In the first set of experiments, we validate the theoretical promise of StGD and mini-batch SGD on artificial datasets. To show the convergence in terms of the sample size  $n$ , we sample a series of artificial datasets with size  $n \in \{50, 100, 150, \dots, 2000\}$  and run these algorithms on those datasets. To show how feature size  $d$  influences the convergence of StGD, we generate samples with feature size  $d = 100$  and  $d = 150$  and report corresponding risks. We repeat the experiment 50 times and report the mean and standard deviation of the results.

We report the population risks (test loss on the large fresh set)  $F(\hat{w}_n)$ , empirical risks (train loss)  $\hat{F}(w_n)$ , population optimum (estimated by the large fresh set) and excess risks  $F(\hat{w}_n) - F(w^*)$ . Fig. 1 (a) and Fig.1 (c) illustrate the convergence rate of StGD and mini-batch SGD respectively. As  $n$  increases, the population risks of StGD and mini-batch StGD converge to population optimum. Fig. 1 (b) and (d) show how the feature size  $d$  influences the convergence rate. Larger  $d$  implies a slower convergence rate.

## 5.3 COMPARISON of STGD, SGD AND GD

In the second set of experiments, we compare StGD, SGD and GD on small datasets in terms of excess risk/test loss and test error rate. For the real-world datasets, we first sample 20% data points from the whole datasets to be the test set, and let the remaining samples to be the train set. Afterwards, we sample a series of datasets with size  $n \in \{10, 20, \dots, 250\}$  (for diabetes and breast cancer) and  $n \in \{20, 40, \dots, 400\}$  (for german.numer) from the remaining train set and run these algorithms on those datasets. The artificial data split is the same as the first set experiment. Given each  $n$ , we train the model and report the loss and error rate on the test set. We repeat the above procedure 10 times and report the mean and standard deviation of

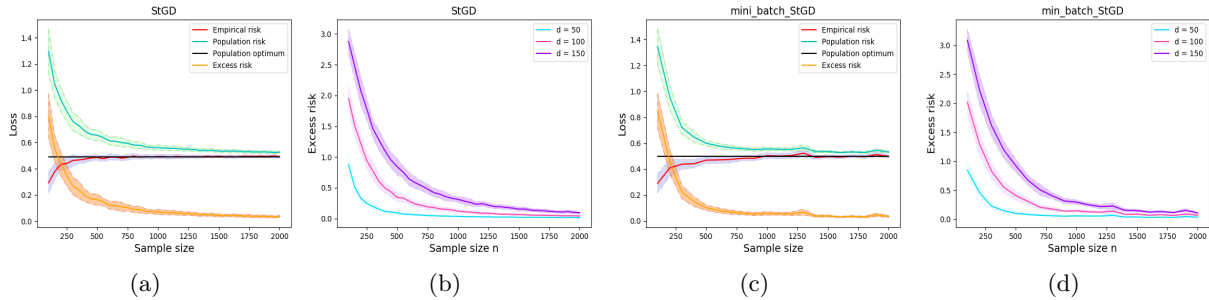

Figure 1: The StGD and mini-batch StGD on artificial data. (a) The risks of StGD. (b) The excess risks of StGD with different data dimension  $d$ . (c) The risks of mini-batch StGD. (d) The excess risks of mini-batch StGD with different data dimension  $d$ . The X-axis is the number of samples, and the Y-axis is the Risk/Loss.

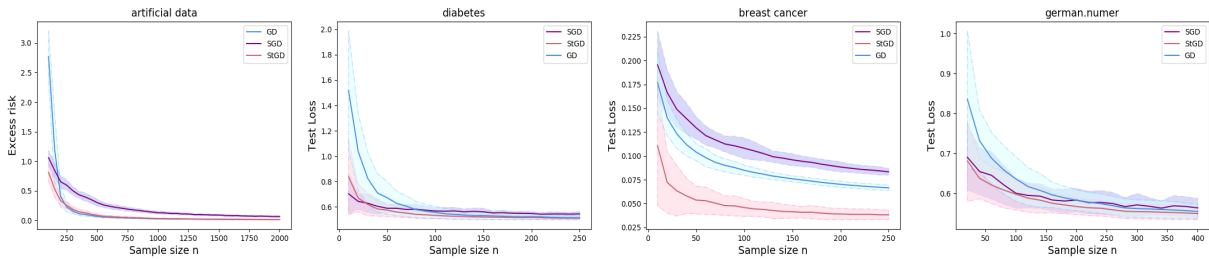

Figure 2: Compare the StGD, SGD and GD on both artificial datasets and small real-world datasets. The X-axis and the Y-axis refer to Fig. 1. The excess risk of StGD converges as fast as GD on artificial dataset. The StGD outperforms GD and SGD in terms of the test loss on real-world datasets.

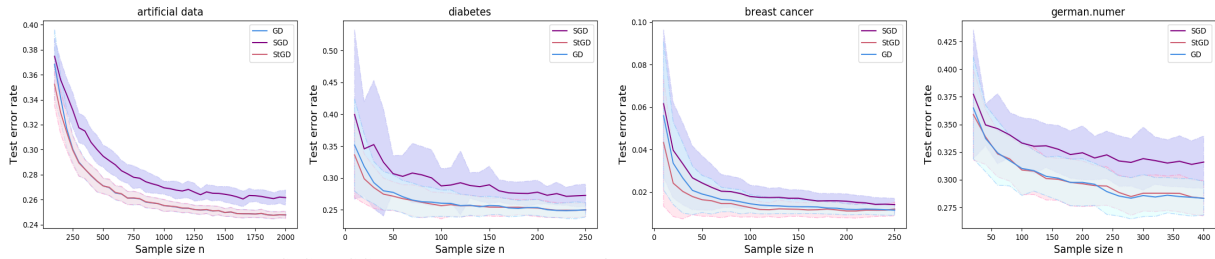

Figure 3: Compare the StGD, SGD and GD on both artificial dataset and small real-world datasets. The X-axis and the Y-axis refer to Fig. 1. The StGD outperforms GD and SGD in terms of the test error rate on artificial dataset and real-world datasets.

Figure 4: Compare the mini-batch StGD, SGD and mini-batch SGD on both artificial dataset and large real-world datasets. The X-axis and the Y-axis refer to Fig. 1. The excess risk of mini-batch StGD converges as fast as GD on artificial dataset. The mini-batch StGD outperforms SGD and mini-batch SGD in terms of the test loss on real-world datasets.

the results.

Fig. 2 presents the excess risks and test losses on four small datasets of the three algorithms and Fig. 3 compares the test error rates. For artificial datasets, StGD performs nearly the

same as GD in terms of the excess risks and test error rates. For diabetes, breast cancer and german.numer, StGD converges better than GD. In terms of the variance, these three algorithms perform more variance on real-world data

Figure 5: Compare the mini-batch StGD, SGD and mini-batch SGD on both artificial dataset and large real-world datasets. The X-axis and the Y-axis refer to Fig. 1. The test error rate of mini-batch StGD converges as fast as GD on artificial dataset. The mini-batch StGD outperforms SGD and mini-batch SGD in terms of the test error rate on real-world datasets.

than artificial data. The variance of the losses and error rates from repeated runs come from the training data and the algorithm themselves. The noise amount in StGD and the size of the training sample play an important role in variances. Repeating training the models with small dataset brings out large variance. Fig. 2 and Fig. 3 show that the variances decrease as the sample size increases.

#### 5.4 COMPARISON of MINI-BATCH SGD, MINI-BATCH STGD AND SGD

In the third set of experiments, we compare mini-batch StGD, mini-batch SGD and SGD on large datasets. For the real-world datasets, the train and test data split is the same as the second set experiment. From the train set, we sample a series of datasets with size  $n \in \{100, 300, \dots, 50000\}$  for artificial data,  $n \in \{100, 200, \dots, 20000\}$  for cover type,  $n \in \{100, 500, \dots, 100000\}$  for rcv1 and  $n \in \{100, 500, \dots, 70000\}$  for real-sim. Given each  $n$ , we train the model and report the loss and error rate on the test set. We repeat the above procedure 10 times and report the mean and standard deviation of the results.

The excess risks on artificial dataset and the test losses on real-world datasets are shown in Fig. 4 and the test error rates is given in Fig. 5. The results show mini-batch StGD achieves the lowest test loss and test error rate for four datasets and lowest variance for cover type (three algorithms perform low variance in the other three datasets). Compared to training with small datasets (Fig.2 and Fig. 3), we observe less variance with large

datasets.

## 6 CONCLUSION

In this paper, we study the optimization problems in machine learning. Considering the difficulty of obtaining new samples for gradient descent to approximate population gradient, we propose a stable gradient descent algorithm based on adaptive data analysis and differential privacy. We demonstrate StGD works as a basic gradient descent which has access to fresh sample at each iteration. Furthermore, we theoretically analyze that the proposed algorithm converges fast to the population optimum with high probability. Finally, we compare the proposed algorithm with existing methods in experiments. The empirical evaluation illustrate the promise of the proposed algorithm and demonstrated it outperforms existing methods.

## Abstract

The efficient use of limited computational resources is an essential ingredient of intelligence. Selecting computations optimally according to rational metareasoning would achieve this, but this is computationally intractable. Inspired by psychology and neuroscience, we propose the first concrete and domain-general learning algorithm for approximating the optimal selection of computations: Bayesian metalevel policy search (BMPS). We derive this general, sample-efficient search algorithm for a computation-selecting metalevel policy based on the insight that the value of information lies between the myopic value of information and the value of perfect information. We evaluate BMPS on three increasingly difficult metareasoning problems: when to terminate computation, how to allocate computation between competing options, and planning. Across all three domains, BMPS achieved near-optimal performance and compared favorably to previously proposed metareasoning heuristics. Finally, we demonstrate the practical utility of BMPS in an emergency management scenario, even accounting for the overhead of metareasoning.

## 1 INTRODUCTION

The human brain is the best example of an intelligent system we have so far. One feature that sets it apart from current AI is the remarkable computational efficiency that enables people to effortlessly solve hard problems for which artificial intelligence either under-performs humans or requires superhuman computing power and training time. For instance, to defeat Garry Kasparov

3.5–2.5, Deep Blue had to evaluate 200 000 000 positions per second, whereas Kasparov was able to perform at almost the same level by evaluating only 3 positions per second (Campbell, Hoane, & Hsu, 2002; IBM Research, 1997). This ability to make efficient use of limited computational resources is the essence of intelligence (Russell & Wefald, 1991a). People accomplish this feat by being very selective about when to think and what to think about, choosing computations adaptively and terminating deliberation when its expected benefit falls below its cost (Gershman, Horvitz, & Tenenbaum, 2015; Lieder & Griffiths, 2017; Payne, Bettman, & Johnson, 1988).

Rational metareasoning was introduced to recreate such intelligent control over computation in machines (Horvitz, Cooper, & Heckerman, 1989; Russell & Wefald, 1991b; Hay, Russell, Tolpin, & Shimony, 2012). In principle, rational metareasoning can be used to always select those computations that make optimal use of the agent’s finite computational resources. However, its computational complexity is prohibitive (Hay et al., 2012). The human mind circumvents this computational challenge by learning to select computations through metacognitive reinforcement learning (Krueger, Lieder, & Griffiths, 2017; Lieder & Griffiths, 2017; Wang et al., 2017). Concretely, people appear to learn to predict the value of alternative cognitive operations from features of the task, their current belief state, and the cognitive operations themselves. If humans learn to metareason through metacognitive reinforcement learning, then it should be possible to build intelligent systems that learn to metareason as efficiently as people.

In this paper, we introduce Bayesian metalevel policy search (BMPS), the first domain-general algorithm for learning how to metareason, and evaluate it against existing methods for approximate metareasoning on three increasingly more complex toy problems. Finally, we show that our method makes metareasoning efficient enough to offset its cost in a more realistic emergency management

scenario. In this problem, which we use as a running example, an emergency manager must decide which cities to evacuate in the face of an approaching tornado. She bases her decision on a series of computationally intensive simulations that noisily estimate the impact of the tornado on each city. Because time is short, she is forced to decide which simulations are the most important to run. In the following section, we discuss how to formalize this problem as a sequential decision process.

## 2 BACKGROUND

### 2.1 METAREASONING

If reasoning seeks an answer to the question “what should I do?”, metareasoning seeks to answer the question “how should I decide what to do?”. The theory of rational metareasoning (Russell & Wefald, 1991b; Russell & Subramanian, 1995) frames this problem as selecting computations so as to maximize the sum of the rewards of resulting decisions minus the costs of the computations involved. Concretely, one can formalize reasoning as a metalevel Markov decision process (metalevel MDP) and metareasoning as solving that MDP (Hay et al., 2012). While traditional (object-level) MDPs describe the objects of reasoning—the state of the external environment and how it is affected by physical actions—a metalevel MDP describes reasoning itself. Formally, a metalevel MDP  $M_{\text{meta}} = (\mathcal{B}, \mathcal{A}, T_{\text{meta}}, r_{\text{meta}})$  is an MDP where the states  $\mathcal{B}$  encode the agent’s beliefs, the actions  $\mathcal{A}$  are computations, the transition function  $T_{\text{meta}}$  describes how computations update beliefs, and the reward function  $r_{\text{meta}}$  describes the costs and benefits of computation. A definition table for our notation is included in the Supplementary Material.

A belief state  $b \in \mathcal{B}$  encodes a probability distribution over parameters  $\theta$  of a model of the domain. For example, in the tornado problem described in the introduction,  $\theta$  could be a vector of  $k$  probabilities that each of the  $k$  cities will incur evacuation-warranting damage;  $b$  would thus encode  $k$  distributions over  $[0, 1]$ , e.g.  $k$  Beta distributions. The parameters  $\theta$  determine the utility of acting according to a policy  $\pi$ , that is  $U_{\pi}(\theta)$ . For one-shot decisions,  $U_{\pi}(\theta)$  is the expected reward of taking the single action identified with  $\pi$ . In the tornado problem, for example,  $\pi$  can be represented as a binary vector of length  $k$  indicating whether each city should be evacuated, and  $U_{\pi}(\theta)$  is the cost of making the evacuations plus the expected cost of failing to evacuate cities that incur major damage. In sequential decision-problems,  $U_{\pi}(\theta) = V_{\pi}^{(\theta)}(s)$  is the expected sum of rewards the agent will obtain by acting according to policy  $\pi$  if the environment has the characteristics encoded by  $\theta$ .

$\mathcal{A}$  includes computations  $\mathcal{C}$  that update the belief, as well as a special metalevel action  $\perp$  that terminates deliberation and initiates acting on the current belief. The effects of computations are encoded by  $T_{\text{meta}} : \mathcal{B} \times \mathcal{A} \times \mathcal{B} \rightarrow [0, 1]$  analogously to a standard transition function. The termination action always leads to a unique end state.

The metalevel reward function  $r_{\text{meta}}$  captures the cost of thinking (Shugan, 1980) and the external reward the agent expects to receive from the environment. The computations  $\mathcal{C}$  have no external effects and thus always incur a negative reward  $r_{\text{meta}}(b, c) = -\text{cost}(c)$ . In the problems studied below, all computations that deliberate have the same cost, that is  $\text{cost}(c) = \lambda$  for all  $c \in \mathcal{C}$  whereas  $\text{cost}(\perp) = 0$ . An external reward is received only when the agent terminates deliberation and makes a decision, which is assumed to be optimal given the current belief. The metalevel reward for terminating is thus  $r_{\text{meta}}(b, \perp) = \max_{\pi} \mathbb{E}_{\theta \sim b}[U_{\pi}(\theta)]$ .<sup>1</sup>

Early work on rational metareasoning (Russell & Wefald, 1991b) defined the optimal way to select computations as maximizing the value of computation (VOC):

$$\pi_{\text{meta}}^* = \arg \max_c \text{VOC}(c, b), \quad (1)$$

where  $\text{VOC}(c, b)$  is the expected improvement in decision quality that can be achieved by performing computation  $c$  in belief state  $b$  and continuing optimally, minus the cost of the optimal sequence of computations (Russell & Wefald, 1991b). When no computation has positive value, the policy terminates computation and executes the best object-level action, thus  $\text{VOC}(\perp, b) = 0$ .

### 2.2 APPROXIMATE METAREASONING

Previous work (Russell & Wefald, 1991b; Lin, Kolobov, Kamar, & Horvitz, 2015) has approximated rational metareasoning by the meta-greedy policy  $\arg \max_c \text{VOC}_1(c, b)$  where  $\text{VOC}_1(c, b) = \mathbb{E}_{B' \sim T_{\text{meta}}(b, c, \cdot)} [r_{\text{meta}}(B', \perp)] - r_{\text{meta}}(b, \perp) + r_{\text{meta}}(b, c)$ , is the myopic value of computation (Russell & Wefald, 1991b). The meta-greedy policy selects each computation assuming that it will be the last computation. This policy is optimal when computation provides diminishing returns (i.e. the improvement from each additional computation is less than that from the previous one), but it deliberates too little when this assumption is violated. For example, in the tornado problem (where false negatives have high cost), a single simulation may be unable to ensure that evacuation is unnecessary with sufficient confidence, while two or more could.

<sup>1</sup>If the agent’s model is unbiased, this reward has the same expectation but lower variance than the true external reward.

Hay et al. (2012) approximated rational metareasoning by combining the solutions to smaller metalevel MDPs that formalize the problem of deciding how to decide between one object-level action and the expected return of its best alternative. Each of these smaller metalevel MDPs includes only the computations for reasoning about the expected return of the corresponding object-level action. While this *blinkered* approximation is more accurate than the meta-greedy policy, it is also significantly less scalable and not directly applicable to metareasoning about planning.

These are the main approximations to rational metareasoning. So, to date, there appears to be no accurate and scalable method for solving general metalevel MDPs.

### 2.3 METACOGNITIVE RL

It has been proposed that metareasoning can be made tractable by learning an approximation to the value of computation (Russell & Wefald, 1991b). However, despite some preliminary steps in this direction (Harada & Russell, 1998; Lieder et al., 2014; Lieder, Krueger, & Griffiths, 2017) and related work on meta-learning (Smith-Miles, 2009; Thornton, Hutter, Hoos, & Leyton-Brown, 2013; Wang et al., 2017), learning to approximate bounded optimal information processing remains an unsolved problem in artificial intelligence.

Previous research in cognitive science suggests that people circumvent the intractability of metareasoning by learning a metalevel policy from experience (Lieder & Griffiths, 2017; Cushman & Morris, 2015; Krueger et al., 2017). At least in some cases, the underlying mechanism appears to be model-free reinforcement learning (RL) (Cushman & Morris, 2015; Krueger et al., 2017). This suggests that model-free reinforcement learning might be a promising approach to solving metalevel MDPs. To our knowledge, this approach is yet to be explored in artificial intelligence. Here, we present a proof-of-concept that near-optimal metalevel policies can be learned through metacognitive reinforcement learning.

## 3 BAYESIAN METALEVEL POLICY SEARCH

According to rational metareasoning, an optimal metalevel policy is one that maximizes the VOC (Equation 1). Although the VOC is intractable to compute, it can be bounded. Bayesian metalevel policy search (BMPS) capitalizes on these bounds to dramatically reduce the difficulty of learning near-optimal metalevel policies. Figure 1 illustrates that if the expected decision quality improves monotonically with the number of computa-

tions, then the improvement achieved by the optimal sequence of computations should lie between the benefit of deciding immediately after the first computation and the benefit of obtaining perfect information (Howard, 1966). The former is given by the myopic value of information,<sup>2</sup>

$$\text{VOI}_1(c, b) = \mathbb{E}_{B' \sim T_{\text{meta}}(b, c, \cdot)} [U(B')] - U(b). \quad (2)$$

and the latter is given by the value of perfect information,

$$\text{VPI}(b) = \mathbb{E}_{\theta^* \sim b} [U(B^*(\cdot; \theta^*))] - U(b), \quad (3)$$

where  $U(b) = r_{\text{meta}}(b, \perp)$  is shorthand for the expected value of terminating computation and  $B^*(\theta; \theta^*) = \delta(\theta_i - \theta_i^*)$  is the belief state with perfect knowledge of the true environment parameters  $\theta^*$ .

In problems with many parameters, this upper bound can be very loose because the optimal metalevel policy might reason only about a small subset of relevant parameters. To capture this, we introduce an additional feature  $\text{VPI}_{\text{sub}}(c, b)$  that measures how beneficial it would be to have full information about a subset of the parameters that are most relevant to the given computation. We model relevance with a function  $f(c, i)$  that returns 1 if  $\theta_i$  is relevant to what  $c$  is reasoning about and 0 otherwise. Using this relevance function, we define the value of gaining perfect information about the relevant subset of parameters as

$$\text{VPI}_{\text{sub}}(c, b) = \mathbb{E}_{\theta^* \sim b} [U(B'_{\text{sub}}(\cdot; c, b, \theta^*))] - U(b), \quad (4)$$

<sup>2</sup>The  $\text{VOI}_1$  defined here is equal to the myopic VOC defined by Russell and Wefald (1991) plus the cost of the computation.

Figure 1: Expected performance in metareasoning about how to choose between three actions increases monotonically with the number of computations, asymptoting at the value of perfect information (VPI). Consequently, the value of executing a single computation must lie between the myopic value of information ( $\text{VOI}_1$ ) and the VPI.

with

$$B'_{\text{sub}}(\theta; c, b, \theta^*) = \prod_i^k B^*(\theta_i; \theta^*)^{f(c,i)} \cdot b(\theta_i)^{1-f(c,i)},$$

where  $k$  is the number of parameters in the agent’s model of the environment. In the tornado problem, for example, each simulation is informative about a single parameter (the probability that the target city will sustain evacuation-warranting damage); thus, we define  $f(c_j, i) = \mathbb{1}(j = i)$ . In the general case, the relevance function is a design choice that affords an easy opportunity to imbue BMPS with domain knowledge. In the simulations reported below, the relevance function associates each  $c$  with the set of parameters that inform the value of the actions (or, in the case of planning, options) that  $c$  reasons about.

Critically, all three VOI features can be computed efficiently or can be efficiently approximated by Monte-Carlo integration (Hammersley, 2013). BMPS thus approximates the VOC by a mixture of VOI features and an estimate of the cost of future computations

$$\begin{aligned} \text{V}\hat{\text{O}}\text{C}(c, b; \mathbf{w}) = & w_1 \cdot \text{VOI}_1(c, b) + w_2 \cdot \text{VPI}(b) \\ & + w_3 \cdot \text{VPI}_{\text{sub}}(c, b) - w_4 \cdot \text{cost}(c), \end{aligned} \quad (5)$$

with the constraints that  $w_1, w_2, w_3 \in [0, 1]$ ,  $w_1 + w_2 + w_3 = 1$ , and  $w_4 \in [1, h]$  where  $h$  is an upper bound on how many computations can be performed. Since the VOC defines the optimal metalevel policy (Equation 1), we can define an approximately optimal policy,  $\pi_{\text{meta}}(b; \mathbf{w}) = \arg \max_c \text{V}\hat{\text{O}}\text{C}(c, b; \mathbf{w})$ .

The parameters  $\mathbf{w}$  of this policy are optimized by maximizing the expected return  $\mathbb{E}[\sum_t r_{\text{meta}}(b_t, \pi_{\text{meta}}(b_t; \mathbf{w}))]$ , i.e. direct policy search. Because there are only three free parameters with the summation constraint, we propose using Bayesian optimization (BO) (Mockus, 2012) to optimize the weights in a sample efficient manner.

The novelty of BMPS lies in leveraging machine learning to approximate the solution to metalevel MDPs and in the discovery of features that make this tractable. As far as we know, BMPS is the first general approach to metacognitive RL. In the following sections, we validate the assumptions of BMPS, evaluate its performance on increasingly complex metareasoning problems, compare it to existing methods, and discuss potential applications.

## 4 EVALUATIONS OF BMPS

We evaluate how accurately BMPS can approximate rational metareasoning against two state-of-the-

art approximations—the meta-greedy policy and the blinkered approximation—on three increasingly difficult metareasoning problems.

### 4.1 WHEN TO STOP DELIBERATING?

How long should an agent deliberate before answering a question? Our evaluation mimics this problem for a binary prediction task (e.g., “Will the price of the stock go up or down?”). Every deliberation incurs a cost and provides probabilistic evidence  $X_t \sim \text{Bernoulli}(\theta)$  in favor of one outcome or the other. At any point the agent can stop deliberating and predict the outcome supported by previous deliberations. The agent receives a reward of +1 if its prediction is correct, or incurs a loss of −1 if it is incorrect. The goal is to maximize the expected reward of this one prediction minus the cost of computation.

#### 4.1.1 Metalevel MDP

We formalize the problem of deciding when to stop thinking as a metalevel MDP  $M_{\text{meta}} = (\mathcal{B}, \mathcal{A}, T_{\text{meta}}, r_{\text{meta}})$  where each belief state  $(\alpha, \beta) \in \mathcal{B}$  defines a beta distribution over the probability  $\theta$  of the first outcome. The metalevel actions  $\mathcal{A}$  are  $\{c_1, \perp\}$  where  $c_1$  refines the belief by sampling, and  $\perp$  terminates deliberation and predicts the outcome that is most likely according to the current belief. The transition probabilities for sampling are defined by the agent’s belief state, that is  $T_{\text{meta}}((\alpha, \beta), c_1, (\alpha + 1, \beta)) = \frac{\alpha}{\alpha + \beta}$  and  $T_{\text{meta}}((\alpha, \beta), c_1, (\alpha, \beta + 1)) = \frac{\beta}{\alpha + \beta}$ . The reward function  $r_{\text{meta}}$  reflects the cost of computation,  $r_{\text{meta}}(b, c_1) = -\lambda$ , and the probability of making the correct prediction,  $r_{\text{meta}}(b, \perp) = +1 \cdot p_{\text{correct}}(\alpha, \beta) - 1 \cdot (1 - p_{\text{correct}}(\alpha, \beta))$ , where  $p_{\text{correct}}(\alpha, \beta) = \max\{\frac{\alpha}{\alpha + \beta}, \frac{\beta}{\alpha + \beta}\}$ . We set the horizon to  $h = 30$ , meaning that the agent can perform at most 29 computations before making a prediction (the 30th metalevel action must be  $\perp$ ).

Since there is only one parameter ( $\theta$  has length one), the  $\text{VPI}_{\text{sub}}$  feature is identical with the VPI feature; thus, we exclude it. For the same reason, the blinkered approximation is equivalent to solving the problem exactly, and we exclude it from the comparison.

#### 4.1.2 Evaluation procedure

We evaluated the potential of BMPS in two steps: First, we performed a regression analysis to evaluate whether the proposed features are sufficient to capture the value of computation, computed exactly by backward induction (Puterman, 2014). Second, we tested whether a near-optimal metalevel policy can be learned by Bayesian optimization of the weights of the metalevel policy. We ran 500 iterations of optimization, estimating

Figure 2: Results of performance evaluation on the problem of metareasoning about when to stop deliberating.

the expected return of the policy entailed by the probed weight vector by its average return across 2500 episodes. The performance of the learned policy was evaluated on an independent test set of 3000 episodes.

#### 4.1.3 Results

First, linear regression analyses confirmed that the three features ( $\text{VOI}_1(c, b)$ ,  $\text{VPI}(c, b)$ , and  $\text{cost}(c)$ ) are sufficient to capture between 90.8% and 100.0% of the variance in the value of computation for performing a simulation ( $\text{VOC}(b, c_1)$ ) across different states  $b$ , depending on the cost of computation. Concretely, as the cost of computation increased from 0.001 to 0.1 the regression weights shifted from  $0.76 \cdot \text{VPI} + 0.46 \cdot \text{VOI}_1 - 4.5 \cdot \text{cost}$  to  $0.00 \cdot \text{VPI} + 1.00 \cdot \text{VOI}_1 - 1.00 \cdot \text{cost}$  and the explained variance increased from 90.8% to 100.0%. The explained variance and the weights remained the same for costs greater than 0.1. Supplementary Figure 1 illustrates this fit for  $\lambda = 0.02$ .

Second, we found that the  $\text{VOI}_1$  and the  $\text{VPI}$  features are sufficient to learn a near-optimal metalevel policy. As shown in Figure 2, the performance of BMPS was at most 5.19% lower than the performance of the optimal metalevel policy across all costs. The difference in performance was largest for the lowest cost  $\lambda = 0.001$  ( $t(2999) = 3.75, p = 0.0002$ ) and decreased with increasing cost so that there was no statistically significant performance difference between BMPS and the optimal metalevel policy for costs greater than  $\lambda = 0.0025$  (all  $p > 0.15$ ). BMPS performed between 6.78% and 35.8% better than the meta-greedy policy across all costs where the optimal policy made more than one observation (all  $p < 0.0001$ ) and 20.3% better on average ( $t(44999) = 42.4, p < 10^{-15}$ ).

## 4.2 META-DECISION-MAKING

How should an agent allocate its limited decision-time across estimating the expected utilities of multiple alternatives? To evaluate how well BMPS can solve this kind of problem, we evaluate it on the *Bernoulli metalevel probability model* introduced by Hay et al. (2012). This problem is similar to the standard multi-armed bandit problem with one critical difference: Only the reward from the final pull counts—the previous “simulated” pulls provide information, but no reward. Like the first problem, the agent takes a single object-level action, choosing arm  $i$  and receiving reward  $r(s, a_i) \sim \text{Bernoulli}(\theta_i)$ . Unlike the first problem, however, the agent must track multiple environment parameters and select among competing computations.

### 4.2.1 Metalevel MDP

The Bernoulli metalevel probability model is a metalevel MDP  $M_{\text{meta}} = (\mathcal{B}, \mathcal{A}, T_{\text{meta}}, r_{\text{meta}}, h)$  where each belief state  $b$  defines  $k$  Beta distributions over the reward probabilities  $\theta_1, \dots, \theta_k$  of the  $k$  possible actions. Thus  $b$  can be represented by  $((\alpha_1, \beta_1), \dots, (\alpha_k, \beta_k))$  where  $b(\theta_i) = \text{Beta}(\theta_i; \alpha_i, \beta_i)$ . For the initial belief state  $b_0$ , these parameters are  $\alpha_i = \beta_i = 1$ . The metalevel actions  $\mathcal{A}$  are  $\{c_1, \dots, c_k, \perp\}$  where  $c_i$  simulates action  $a_i$  and  $\perp$  terminates deliberation and executes the action with the highest expected return. The metalevel transition function  $T_{\text{meta}}$  encodes that performing computation  $c_i$  increments  $\alpha_i$  with probability  $\frac{\alpha_i}{\alpha_i + \beta_i}$  and increments  $\beta_i$  with probability  $\frac{\beta_i}{\alpha_i + \beta_i}$ . The metalevel reward function  $r_{\text{meta}}(b, c)$  is  $-\lambda$  for  $c \in \{c_1, \dots, c_k\}$  and  $r_{\text{meta}}(b, \perp) = \max_i \frac{\alpha_i}{\alpha_i + \beta_i}$ . Finally, the horizon  $h$  is the maximum number of metalevel actions that can be performed and the last metalevel action must be  $\perp$ .

### 4.2.2 Evaluation procedure

We evaluated BMPS on Bernoulli metalevel probability problems with  $k \in \{2, \dots, 5\}$  object-level actions, a horizon of  $h = 25$ , and computational costs ranging from  $10^{-4}$  to  $10^{-1}$ . We compared the policy learned by BMPS with the optimal metalevel policy and three alternative approximations: the meta-greedy heuristic (Russell & Wefald, 1991b), the blinkered approximation (Hay et al., 2012), and the metalevel policy that always deliberates as much as possible. In addition to these, we also trained a Deep-Q-Network (DQN) (Mnih et al., 2015) on the metalevel MDP to compare the performance of our method to baselines achieved by off-the-shelf deep RL methods (Dhariwal et al., 2017).

We trained BMPS as described above, but with 10 iterations of 1000 episodes each. To combat the possibil-

ity of overfitting, we evaluated the average returns of the five best weight vectors over 5000 more episodes and selected the one that performed best. The relevance function for  $VPI_{\text{sub}}$  matches each computation with the single parameter it is informative about, i.e.,  $f(c_j, i) = \mathbb{1}(j = i)$ . The optimal metalevel policy and the blinkered policy were computed using backward induction (Puterman, 2014). The DQN was trained for 5,000,000 steps. Since the episodes have a horizon of  $h = 25$ , this resulted in more than 200,000 training episodes for the DQN. We evaluated the performance of each policy by its average return across 2000 test episodes for each combination of computational cost and number of object-level actions.

### 4.2.3 Results

We found that the BMPS policy attained 99.1% of optimal performance (0.6535 vs. 0.6596,  $t(1998) = -7.43, p < 0.0001$ ) and significantly outperformed the meta-greedy heuristic (0.60,  $t(1998) = 83.9, p < 10^{-15}$ ), the full-deliberation policy (0.20,  $t(1998) = 469.1, p < 10^{-15}$ ), and the DQN (0.58,  $t(1998) = 79.2, p < 10^{-15}$ ). The performance of BMPS (0.6535) and the blinkered approximation (0.6559) differed by only 0.37%.

Figure 3a shows the methods’ average performance as a function of the cost of computation. BMPS outperformed the meta-greedy heuristic for costs smaller than 0.03 (all  $p < 10^{-15}$ ), the full-deliberation policy for costs greater than 0.0003 (all  $p < 0.005$ ), and the DQN for all costs (all  $p < 10^{-15}$ ). For costs below 0.0003, the blinkered policy performed slightly better than BMPS (all  $p < 0.01$ ). For all other costs both methods performed at the same level (all  $p > 0.1$ ). For costs above 0.01, performance of BMPS becomes indistinguishable from the optimal policy’s performance (all  $p > 0.1$ ).

Figure 3b shows the metareasoning performance of each method as a function of the number of options. We found that the performance of BMPS scaled well with the size of the decision problem. For each number of options, the relative performance of the different methods was consistent with the results reported above.

Finally, as illustrated in Supplementary Figure 2, we found that BMPS learned surprisingly quickly, usually discovering near-optimal policies in less than 10 iterations. In particular, BMPS was able to perform significantly better than the DQN, despite being trained on fewer than 20% as many episodes. This demonstrates the value of the proposed VOI features, which dramatically constrain the space of possible metalevel policies to be considered.

## 4.3 METAREASONING ABOUT PLANNING

Having evaluated BMPS on problems of metareasoning about how to make a one-shot decision, we now evaluate its performance at deciding how to plan. To do so, we define the *Bernoulli metalevel tree*, which generalizes the Bernoulli metalevel probability model by replacing the one-shot decision between  $k$  options by a tree-structured sequential decision problem that we will refer to as the *object-level MDP*. The transitions of the object-level MDP are deterministic and known to the agent. The reward associated with each of  $k = 2^{h+1} - 1$  states in the tree is deterministic, but initially unknown;  $r(s, a, s_i) = \theta_i \in \{-1, 1\}$ . The agent can uncover these rewards through reasoning at a cost of  $-\lambda$  per reward. When the agent terminates deliberation, it executes a policy with maximal expected utility. Unlike in the previous domains, this policy entails a sequence of actions rather than a single action.

### 4.3.1 Metalevel MDP

The Bernoulli metalevel tree is a metalevel MDP  $M_{\text{meta}} = (\mathcal{B}, \mathcal{A}, T_{\text{meta}}, r_{\text{meta}})$  where each belief state  $b$  encodes one Bernoulli distribution for each transition’s reward. Thus,  $b$  can be represented as  $(p_1, \dots, p_i)$  such that  $b(\theta_i = 1) = p_i$  and  $b(\theta_i = -1) = 1 - p_i$ . The initial belief  $b_0$  has  $p_i = 0.5$  for all  $i$ . The metalevel actions are defined  $\mathcal{A} = \{c_1, \dots, c_k, \perp\}$  where  $c_i$  reveals the reward at state  $s_i$  and  $\perp$  selects the path with highest expected sum of rewards according to the current belief state. The transition function  $T_{\text{meta}}$  encodes that performing computation  $c_i$  sets  $p_i$  to 1 or 0 with equal probability (unless  $p_i$  has already been updated, in which case  $c_i$  has no effect). The metalevel reward function is defined  $r_{\text{meta}}(b, c) = -\lambda$  for  $c \in \{c_1, \dots, c_k\}$ , and  $r_{\text{meta}}(b, \perp) = \max_{\mathbf{t} \in \mathcal{T}} \sum_{i \in \mathbf{t}} \mathbb{E}[\theta_i | p_i]$  where  $\mathcal{T}$  is the set of possible trajectories  $\mathbf{t}$  through the environment, and  $\mathbb{E}[\theta_i | p_i] = 2p_i - 1$  is the expected reward attained at state  $s_i$ .

### 4.3.3 Evaluation procedure

We evaluated each method’s performance by its average return over 5000 episodes for each combination of tree-height  $h \in \{2, \dots, 6\}$  and computational cost  $\lambda \in \{2^{-7}, \dots, 2^0\}$ . To facilitate comparisons across planning problems with different numbers of steps, we measured the performance of metalevel policies by their expected return divided by the tree-height.

We trained the BMPS policy with 100 iterations of 1000 episodes each. To combat the possibility of overfitting, we evaluated the average returns of the three best weight vectors over 2000 more episodes and selected

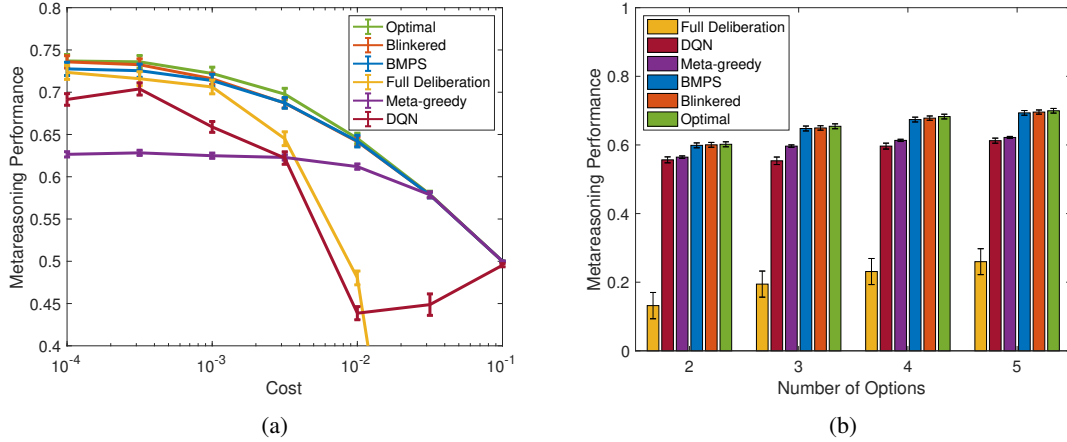

Figure 3: Metareasoning performance of alternative methods on the Bernoulli metalevel probability model (a) as a function of the cost of computation and (b) as a function of the number of actions. Metareasoning performance is defined as the expected reward for the chosen option minus the computational cost of the decision process. Error bars enclose 95% confidence intervals.

the one that performed best. The relevance function for  $VPI_{\text{sub}}$  maps a computation to all the parameters that affect the value of any policy that the initial computation is informative about, i.e.  $f(c_j, i) = \mathbb{1}(i \in \{j\} \cup \text{descendents}(j) \cup \text{ancestors}(j))$

For metareasoning about how to plan in trees of height 2 and 3, we were able to compute the optimal metalevel policy using dynamic programming. But for larger trees, computing the optimal metalevel policy would have taken significantly longer than 6 hours and was therefore not undertaken.

The blinkered policy of Hay et al. (2012) is not directly applicable to planning because of its assumption of “independent actions” which is violated in the Bernoulli metalevel tree. Briefly, the assumption is violated because the reward at a given state affects the value of multiple policies. Thus, we derived a recursive generalization of the blinkered policy to compare with our method. See the Supporting Materials for details.

#### 4.3.4 Results

We first compared BMPS with the optimal policy for  $h \in \{2, 3\}$ , finding that it attained 98.4% of optimal performance (0.367 vs. 0.373,  $t(159998) = -2.87$ ,  $p < 10^{-15}$ ). Metareasoning performance differed significantly across the four methods we evaluated ( $F(3, 799840) = 4625010$ ,  $p < 10^{-15}$ ), and the magnitude of this effect depends on the height of the tree ( $F(12, 799840) = 1110179$ ,  $p < 10^{-15}$ ) and the cost of computation ( $F(21, 799840) = 1266582$ ,  $p < 10^{-15}$ ).

Across all heights and costs, BMPS achieved a metareasoning

performance of 0.392 units of reward per object-level action, thereby outperforming the meta-greedy heuristic (0.307,  $t(399998) = 72.84$ ,  $p < 10^{-15}$ ), the recursively blinkered policy (0.368,  $t(399998) = 20.77$ ,  $p < 10^{-15}$ ), and the full-deliberation policy ( $-1.740$ ,  $t(399998) = 231.18$ ,  $p < 10^{-15}$ ).

As shown in Figure 4a, BMPS performed near-optimally across all computational costs, and its advantage over the meta-greedy heuristic and the tree-blinkered approximation was largest when the cost of computation was low, whereas its benefit over the full-deliberation policy increased with the cost of computation.

Figure 4b shows that the performance of BMPS scaled very well with the size of the planning problem, and that its advantage over the meta-greedy heuristic increased with the height of the tree.

## 5 IS METAREASONING USEFUL?

The costs of metareasoning often outweigh the resulting improvements in object-level reasoning. But here we show that the benefits of BMPS outweigh its costs in a potential application to emergency management.

During severe weather, important decisions—such as which cities to evacuate in the face of an approaching tornado—must be based on a limited number of computationally intense weather simulations that estimate the probability that a city will be severely hit (Baumgart, Bass, Philips, & Kloesel, 2008). Based on these simulations, an emergency manager makes evacuation decisions so as to minimize the risk of false positive errors

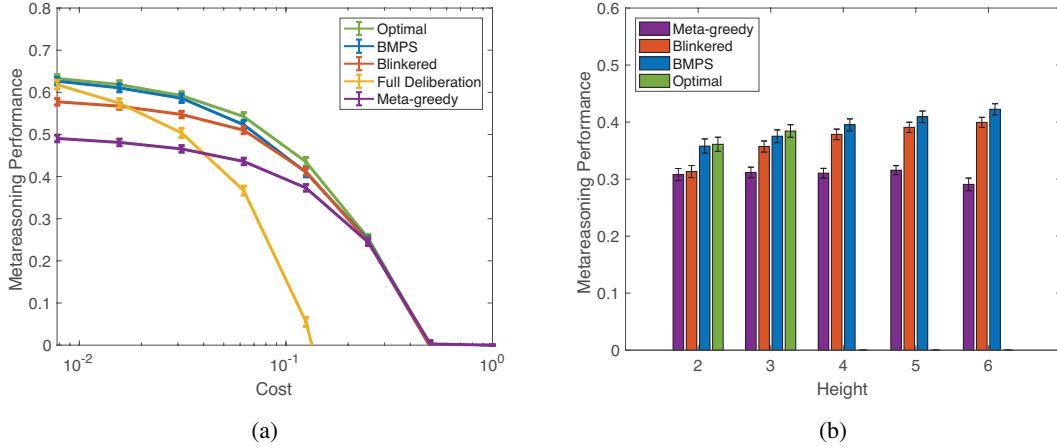

Figure 4: Metareasoning performance of alternative methods on the Bernoulli tree (a) as a function of computational cost (with tree-height 3) and (b) as a function of the number of actions (marginalizing over computational costs between  $10^{-4}$  and  $10^{-1}$ ). Metareasoning performance is normalized by tree height to facilitate comparison. In (b), the optimal policy is only shown for heights at which it can be computed in under six hours and the full observation policy is not shown because its performance is negative for all heights. Error bars enclose 95% confidence intervals.

(evacuating cities that are safe) and false negative errors (failing to evacuate a city the tornado hits). We assume that the manager has access to a single supercomputer, but pays no cost for running each simulation. Thus, the manager has a fixed budget of simulations and her goal is to maximize the expected utility of the final decision.

## 5.1 METHODS

We model the above scenario as follows: There is a finite amount of time  $T$  until evacuation decisions about  $k$  cities have to be made. For each city  $i$ , the emergency manager can run a fine grained, stochastic simulation ( $c_i$ ) of how it will be impacted by the approaching tornado. Each simulation yields a binary outcome, indicating whether the simulated impact would warrant an evacuation or not. The belief state  $b$  and transition function  $T_{\text{meta}}$  of the corresponding metalevel MDP are the same as in the Bernoulli metalevel probability model: Each belief state defines  $k$  Beta distributions that track the probability that the tornado will cause evacuation-warranting damage in each city. The parameters  $\alpha_i$  and  $\beta_i$  correspond to the number of simulations predicting that the tornado {would — would not} be strong enough to warrant an evacuation of city  $i$ . Prior to the first simulation, the parameters for each city  $i$  are initialized as  $\alpha_i = 0.1$  and  $\beta_i = 0.9$  to capture the prior knowledge that evacuations are rarely necessary. The primary formal difference from the Bernoulli metalevel probability model lies in how the final belief state is translated into a decision and reward. Rather than choosing a single option, the agent must make  $k$  independent binary deci-

sions about whether to evacuate each city. Evacuation has a cost,  $\lambda_{\text{evac}} = -1$ , but failing to evacuate a heavily-hit city has a much larger cost,  $\lambda_{\text{fn}} = -20$ . Thus, the metalevel reward function is

$$r_{\text{meta}}(b, \perp) = \sum_{1 \leq i \leq k} \max \left\{ \frac{\alpha_i}{\alpha_i + \beta_i} \cdot \lambda_{\text{fn}}, \lambda_{\text{evac}} \right\}. \quad (6)$$

In contrast to the previous simulations, we now explicitly consider the cost of metareasoning. The decision time  $T$  has to be allocated between reasoning about the cities and metareasoning about which city to reason about so that  $T = n_{\text{sim}} \cdot (t_{\text{MR}} + t_{\text{sim}})$ , where  $n_{\text{sim}}$  is the number of simulations run,  $t_{\text{MR}}$  is the amount of time it takes to choose one simulation to run (i.e. by metareasoning), and  $t_{\text{sim}}$  is the amount of time it takes to run one simulation. Thus, for given values of  $t_{\text{MR}}$  and  $t_{\text{sim}}$  the number of simulations that can be performed is  $n_{\text{sim}} = \left\lfloor \frac{T}{t_{\text{MR}} + t_{\text{sim}}} \right\rfloor$ , where  $\lfloor x \rfloor$  rounds  $x$  down to the closest integer. Note that metalevel policy is computed offline, and thus training time does not factor into the above equation. The simulations reported below use a single BMPS policy optimized for  $k = 20$  and  $n_{\text{sim}} = 50$  to mimic the reuse of pre-computed weights in practical applications; the weights are relatively insensitive to these parameters.

To assess if BMPS could be useful in practice, we compare the utility of evacuation decisions made by its metalevel policy to those made by a baseline metalevel policy that uniformly distributes simulations across the  $k$  cities. Since the BMPS policy has  $t_{\text{MR}} > 0$  while the baseline policy has  $t_{\text{MR}} \approx 0$ , BMPS will typically run

fewer simulations and must make up for this by choosing more valuable ones.

## 5.2 RESULTS

We evaluated the BMPS policy and the uniform computation policy on the tornado problem with  $T = 24$  hours,  $k \in \{10, 30\}$  cities, and a range of plausible values for the duration of each weather simulation ( $t_{\text{sim}} \in [2^{-2}, 2^4]$  hours). For each policy and parameter setting we estimate utility as the mean return over 5000 rollouts.

Empirically, we found that  $t_{\text{MR}} \approx 1$  ms for  $k = 10$  and  $t_{\text{MR}} \approx 3$  ms for  $k = 30$ . Thus, even with a conservative estimate of  $t_{\text{MR}} = 0.001$  hours, metareasoning would cost at most one simulation. Consequently, in our simulations, diverting some of the computational resources to metareasoning was advantageous regardless of how long exactly a tornado simulation might take and the number of cities being considered. As Figure 5 shows, the benefit of metareasoning was larger for the more complex problem with more cities and peaked for an intermediate cost of object-level reasoning.

While this is a hypothetical scenario, it suggests that BMPS could be useful for practical applications. Specifically, we suggest that the method will be most valuable when a metareasoning problem must be faced multiple times (so that the cost of training BMPS offline can be amortized) and object-level computations are expensive (so that the resulting savings in object-level reasoning outweigh the online cost of computing the features used for metareasoning). In follow-up simulations, we explored conditions in which the cost of metareasoning causes a substantial reduction in the number of simulations that can be run. We found that metareasoning continues to be useful as long as object-level computation is substantially more expensive than metareasoning (see Supplementary Material).

Figure 5: Benefit of metareasoning in the tornado evacuation scenario depending on the duration of each simulation ( $t_{\text{sim}}$ ) and the number of cities considered.

## 6 DISCUSSION

We have introduced a new approach to solving the foundational problem of rational metareasoning: metacognitive reinforcement learning. This approach applies algorithms from RL to metalevel MDPs to learn a policy for selecting computations. Our results show that BMPS can outperform the state of the art for approximate metareasoning. While we illustrated this approach using a policy search algorithm based on Bayesian optimization, there are many other RL algorithms that could be used instead, including policy gradient algorithms, actor-critic methods, and temporal difference learning with function approximation.

Since BMPS approximates the value of computation as a mixture of the myopic VOI and two other VOI features, it can be seen as a generalization of the meta-greedy approximation (Lin et al., 2015; Russell & Wefald, 1991a). It is the combination of these features with RL that makes BMPS tractable and powerful. BMPS works well across a wider range of problems than previous approximations because it reduces arbitrarily complex metalevel MDPs to low-dimensional optimization problems. We predict that metacognitive RL will enable significant advances in artificial intelligence and its applications. In the long view, metacognitive RL may become a foundation for self-improving AI systems that learn how to solve increasingly complex problems with increasing efficiency.

One weakness of our approach is that the time required to compute the value of perfect information by exact integration increases exponentially with the number of parameters in the agent’s model of the environment. Thus, an important direction for future work is developing efficient approximations or alternatives to this feature, and/or discovering new features via deep RL (Mnih et al., 2015). A second limitation is our assumption that the meta-reasoner has an exact model of its own computational architecture in the form of a metalevel MDP. This motivates the incorporation of model-learning mechanisms into a metacognitive RL algorithm.

We have shown that the benefits of metareasoning with our method already more than outweigh its computational costs in scenarios where the object-level computations are very expensive. It might therefore benefit practical applications that involve complex large-scale simulations, active learning problems, hyperparameter search, and the optimization of functions that are very expensive to evaluate. Finally, BMPS could also be applied to derive rational process models of human cognition.

## Abstract

Multi-step temporal difference (TD) learning is an important approach in reinforcement learning, as it unifies one-step TD learning with Monte Carlo methods in a way where intermediate algorithms can outperform either extreme. They address a bias-variance trade off between reliance on current estimates, which could be poor, and incorporating longer sampled reward sequences into the updates. Especially in the off-policy setting, where the agent aims to learn about a policy different from the one generating its behaviour, the variance in the updates can cause learning to diverge as the number of sampled rewards used in the estimates increases. In this paper, we introduce per-decision control variates for multi-step TD algorithms, and compare them to existing methods. Our results show that including the control variates can greatly improve performance on both on and off-policy multi-step temporal difference learning tasks.

## 1 TEMPORAL DIFFERENCE LEARNING

*Temporal-difference* (TD) methods (Sutton, 1988) combine ideas from Monte Carlo and dynamic programming methods, and are an important approach in *reinforcement learning*. They allow learning to occur from raw experience in the absence of a model of the environment's dynamics, like with Monte Carlo methods, while computing estimates which bootstrap off of other estimates, like with dynamic programming. TD methods provide a way to learn online and incrementally in both prediction and control settings.

Several TD methods have been proposed. Sarsa (Rum-

mery & Niranjan, 1994; Sutton, 1996) is a classical *on-policy* algorithm, where the policy being learned about, the *target policy*, is identical to the one generating the behaviour, the *behaviour policy*. However, Sarsa can be extended to learn *off-policy*, where the target policy can differ from the behaviour policy, through the use of per-decision *importance sampling* (Precup et al., 2000). Expected Sarsa (van Seijen et al., 2009) is another extension of Sarsa where instead of using the value of the current state-action pair to update the value of the previous state, it uses the expectation of the values of all actions in the current state under the target policy. Since Expected Sarsa takes the expectation under the target policy, it can be used off-policy without importance sampling to correct for the discrepancy between its target and behaviour policies. *Q-learning* (Watkins, 1989) is arguably the most popular off-policy TD control algorithm, as it can also perform off-policy learning without importance sampling, but it is equivalent to Expected Sarsa where the target policy is greedy. The above methods are often described in the one-step case, but they can be extended across multiple time steps.

Multi-step TD methods, such as the  $n$ -step TD and TD( $\lambda$ ) methods, create a spectrum of algorithms where at one end exists one-step TD learning, and at the other, exists Monte Carlo Methods. Intermediate algorithms are created which, due to a bias-variance tradeoff, can outperform either extreme (Jaakkola et al., 1994). Multi-step off-policy algorithms, especially ones with explicit use of importance sampling, have significantly larger variance than their on-policy counterparts (Sutton & Barto, 1998), and several proposals have been made to address this issue in the TD( $\lambda$ ) space of algorithms (Munos et al., 2016; Mahmood et al., 2017).

In this paper, we focus on  $n$ -step TD algorithms as they provide exact computation of the multi-step return, have conceptual clarity, and provide the foundation for TD( $\lambda$ ) methods. We formulate per-decision control variates for existing  $n$ -step TD algorithms, and give insight on their

implications in the TD( $\lambda$ ) space of algorithms. On problems with tabular representations as well as one with function approximation, we show that the introduction of per-decision control variates can improve the performance of existing  $n$ -step TD methods on both on and off-policy prediction and control tasks.

## 2 ONE-STEP TD METHODS

The sequential decision-making problem in reinforcement learning is often modeled as a *Markov decision process* (MDP). Under the MDP framework, an *agent* interacts with an environment over a sequence of discrete time steps. At each time step  $t$ , the agent receives information about the environment's current *state*,  $S_t \in \mathcal{S}$ , where  $\mathcal{S}$  is the set of all possible states in the MDP. The agent is to use this state information to select an *action*,  $A_t \in \mathcal{A}(S_t)$ , where  $\mathcal{A}(s)$  is the set of possible actions in state  $s$ . Based on the environment's current state and the agent's selected action, the agent receives a *reward*,  $R_{t+1} \in \mathbb{R}$ , and gets information about the environment's next state,  $S_{t+1} \in \mathcal{S}$ , according to the *environment model*:  $p(r, s' | s, a) = P(R_{t+1} = r, S_{t+1} = s' | S_t = s, A_t = a)$ .

The agent selects actions according to a *policy*,  $\pi(s, a) = P(A_t = a | S_t = s)$ , which gives a probability distribution across actions  $a \in \mathcal{A}(s)$  for a given state  $s$ . Through policy iteration (Sutton & Barto, 1998), the agent can learn an optimal policy,  $\pi^*$ , where behaving under it will maximize the expected discounted return:

$$G_t = R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \dots = \sum_{k=0}^{T-t-1} \gamma^k R_{t+k+1} \quad (1)$$

given a discount factor  $\gamma \in [0, 1]$  and  $T$  equal to the final time step in an episodic task, or  $\gamma \in [0, 1)$  and  $T$  equal to infinity for a continuing task.

*Value-based methods* approach the sequential decision-making problem by computing *value functions*, which provide estimates of what the return will be from a particular state onwards. In prediction problems, also referred to as *policy evaluation*, the goal is to estimate the return under a particular policy as accurately as possible, and a *state-value function* is often estimated. It is defined to be the expected return when starting in state  $s$  and following policy  $\pi$ :  $v_\pi(s) = \mathbb{E}_\pi[G_t | S_t = s]$ . For control problems, the policy which maximizes the expected return is to be learned, and an *action-value function* from which a policy can be derived is instead estimated. It is defined to be the expected return when taking action  $a$  in state  $s$ , and following policy  $\pi$ :

$$q_\pi(s, a) = \mathbb{E}_\pi[G_t | S_t = s, A_t = a] \quad (2)$$

Of note, the action-value function can still be used for prediction problems, and the state-value can be computed as an expectation across action-values under the policy  $\pi$  for a given state:

$$v_\pi(s) = \mathbb{E}_\pi[q_\pi(s, \cdot)] = \sum_a \pi(s, a) q_\pi(s, a) \quad (3)$$

One-step TD methods learn an approximate value function, such as  $Q \approx q_\pi$  for action-values, by computing an estimate of the return,  $\hat{G}_t$ . First, Equation 2 can be written in terms of its successor state-action pairs, also known as the *Bellman equation* for  $q_\pi$ :

$$q_\pi(s, a) = \sum_{r, s'} p(r, s' | s, a) \left( r + \gamma \sum_{a'} \pi(s', a') q_\pi(s', a') \right) \quad (4)$$

Based on Equation 4, one-step TD methods estimate the return by taking an action in the environment according to a policy, sampling the immediate reward, and bootstrapping off of the current estimates in the value function for the remainder of the return. The difference between this *TD target* and the value of the previous state-action pair is then computed, and is often referred to as the *TD error*. The previous state-action pair's value is then updated by taking a step proportional to the TD error with step size  $\alpha \in (0, 1]$ :

$$\hat{G}_t = R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) \quad (5)$$

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha [\hat{G}_t - Q(S_t, A_t)] \quad (6)$$

Equations 5 and 6 correspond to the Sarsa algorithm. It can be seen that in state  $S_{t+1}$ , it samples an action  $A_{t+1}$  according to its behaviour policy, and then bootstraps off of the value of this state-action pair. With a sufficiently small step size, this estimates the expectation under its behaviour policy over the values of successor state-action pairs in Equation 4, allowing for on-policy learning.

In the off-policy case, the discrepancy from  $A_{t+1}$  being drawn from the behaviour policy needs to be corrected. One approach is to correct the affected terms with per-decision *importance sampling*. With actions sampled from a behaviour policy  $\mu$ , and a target policy  $\pi$ , the estimate of the return of off-policy Sarsa with per-decision importance sampling becomes:

$$\rho_t = \frac{\pi(S_t, A_t)}{\mu(S_t, A_t)} \quad (7)$$

$$\hat{G}_t = R_{t+1} + \gamma \rho_{t+1} Q(S_{t+1}, A_{t+1}) \quad (8)$$

Note that in the on-policy case,  $\rho_t$  is always 1, strictly generalizing the original on-policy TD target in Equation 5.

Another approach for the off-policy case is to compute the expectation of all successor state action pairs under

the target policy directly, instead of sampling and correcting the discrepancy. This approach has lower variance and is often preferred in the one-step setting for action-values, and gives the *Expected Sarsa* algorithm (van Seijen et al., 2009) characterized by the following TD target:

$$\hat{G}_t = R_{t+1} + \gamma \mathbb{E}_\pi[Q(S_{t+1}, \cdot)] \quad (9)$$

### 3 MULTI-STEP TD LEARNING

TD algorithms are referred to as one-step TD algorithms when they only incorporate information from a single time step in the estimate of the return that the value function is being updated towards. In multi-step TD methods, a longer sequence of experienced rewards is used to estimate the return. For example, on-policy  $n$ -step Sarsa would update an action-value  $Q(S_t, A_t)$  towards the following estimate:

$$\begin{aligned} \hat{G}_{t:t+n} &= R_{t+1} + \gamma R_{t+2} + \dots + \gamma^n Q(S_{t+n}, A_{t+n}) \\ &= \sum_{k=0}^{n-1} \gamma^k R_{t+k+1} + \gamma^n Q(S_{t+n}, A_{t+n}) \end{aligned} \quad (10)$$

Of note,  $n$ -step Expected Sarsa (Sutton & Barto, 2018) is identical up until the  $n$ -th step, where it instead bootstraps off of the expectation under the target policy:

$$\hat{G}_{t:t+n} = \sum_{k=0}^{n-1} \gamma^k R_{t+k+1} + \gamma^n \mathbb{E}_\pi[Q(S_{t+n}, \cdot)] \quad (11)$$

The  $n$ -step returns can also be written recursively, and is convenient in the more general per-decision off-policy case. If we define the following bootstrapping condition:

$$\hat{G}_{t:t} = Q(S_t, A_t) \quad (12)$$

The  $n$ -step extension of off-policy Sarsa with per-decision importance sampling, as characterized by Equations 7 and 8, can now be written as:

$$\hat{G}_{t:t+n} = R_{t+1} + \gamma \rho_{t+1} \hat{G}_{t+1:t+n} \quad (13)$$

TD algorithms which update towards these  $n$ -step estimates of the return constitute the  $n$ -step TD algorithm family (Sutton & Barto, 2018). Their computational complexity increases with  $n$ , but have the benefit of conceptual clarity, and exact computation of the multi-step return. The  $n$ -step returns also provide the foundation for other multi-step TD algorithms.

Another family of multi-step per-decision TD algorithms,  $TD(\lambda)$ , is also used in practice. They are characterized by computing a geometrically weighted sum of

$n$ -step returns, denoted as the  $\lambda$ -return:

$$\hat{G}_t^\lambda = (1 - \lambda) \sum_{n=1}^{\infty} \lambda^{n-1} \hat{G}_{t:t+n} \quad (14)$$

It introduces a hyperparameter  $\lambda \in [0, 1]$  where  $\lambda = 0$  gives one-step TD, and increasing  $\lambda$  effectively increases the number of sampled rewards included in the estimated return. Substituting the  $n$ -step Sarsa return (13) into Equation 14 gives the  $\lambda$ -return for the Sarsa( $\lambda$ ) algorithm, and assuming  $Q$  does not change, it can be expressed as a sum of one-step Sarsa's TD errors:

$$\begin{aligned} \hat{G}_t &= R_{t+1} + \gamma \rho_{t+1} Q(S_{t+1}, A_{t+1}) \\ \hat{G}_t^\lambda &= Q(S_t, A_t) + \sum_{k=t}^{\infty} (\hat{G}_k - Q(S_k, A_k)) \prod_{i=t+1}^k \gamma \lambda \rho_i \end{aligned} \quad (15)$$

This shows that the  $\lambda$ -return for Sarsa( $\lambda$ ) can be estimated by computing one-step TD errors, and decaying the weight of later TD errors at a rate of  $\gamma \lambda \rho_t$ . Implementing this online and incrementally, an *eligibility trace* vector is maintained to track which state-action pairs led to the current step's TD error. The traces of earlier state-action pairs are decayed at each step by the aforementioned decay rate, and each action-value is adjusted by the current TD error weighted by the trace of the corresponding state-action pair.

Contrasting with  $n$ -step TD methods, the computational complexity of TD( $\lambda$ ) control algorithms scales with the size of the environment,  $|S| \times |A|$ . That is, there is an environment-specific increase in complexity, but it no longer scales with the number of sampled rewards in the estimate of the return.

### 4 PER-DECISION CONTROL VARIATES

When trying to estimate the expectation of some variable  $X$ , control variates are often of the following form (Ross, 2013):

$$X^* = X + c(Y - \mathbb{E}[Y]) \quad (16)$$

where  $Y$  is the outcome of another variable with a known expected value, and  $c$  is a coefficient to be set.  $X^*$  then has the following variance:

$$\text{Var}(X^*) = \text{Var}(X) + c^2 \text{Var}(Y) + 2c \text{Cov}(X, Y) \quad (17)$$

From this, the variance can be minimized with the optimal coefficient  $c^*$ :

$$c^* = -\frac{\text{Cov}(X, Y)}{\text{Var}(Y)} \quad (18)$$

Suppose the  $n$ -step Sarsa algorithm samples the importance sampling-corrected  $n$ -step return, jointly samples the importance sampling-corrected action-value (through the sampled action), and computes the expected action-value under the target policy. We get the following estimate of this term of the multi-step return:

$$\begin{aligned} (\rho_{t+1}\hat{G}_{t+1:t+n})^* &= \rho_{t+1}\hat{G}_{t+1:t+n} \\ &+ c(\rho_{t+1}Q(S_{t+1}, A_{t+1}) - \mathbb{E}_\pi[Q(S_{t+1}, \cdot)]) \end{aligned} \quad (19)$$

Under the assumption that the current estimates are accurate, the action-values represent the expected return. Due to this, the sampled reward sequence and the action-value are, in expectation, perfectly correlated. The covariance term in Equation 18 would then be the variance of the action-value due to the policy, and from this, a reasonable choice for the coefficient would be  $-1$ . This gives:

$$\begin{aligned} (\rho_{t+1}\hat{G}_{t+1:t+n})^* &= \rho_{t+1}\hat{G}_{t+1:t+n} \\ &+ \mathbb{E}_\pi[Q(S_{t+1}, \cdot)] - \rho_{t+1}Q(S_{t+1}, A_{t+1}) \end{aligned} \quad (20)$$

Substituting this estimate into the recursive definition of  $n$ -step Sarsa (13) and maintaining the same bootstrapping condition in Equation 12 gives the following  $n$ -step return:

$$\begin{aligned} \hat{G}_{t:t+n} &= R_{t+1} + \gamma(\rho_{t+1}\hat{G}_{t+1:t+n} \\ &+ \mathbb{E}_\pi[Q(S_{t+1}, \cdot)] - \rho_{t+1}Q(S_{t+1}, A_{t+1})) \end{aligned} \quad (21)$$

Because  $\mathbb{E}_\mu[\mathbb{E}_\pi[Q(S_{t+1}, \cdot)] - \rho_{t+1}Q(S_{t+1}, A_{t+1})] = 0$ , the additional term does not introduce bias into the estimate. To provide an intuition of how it might reduce the variance in the estimate, we can consider some extreme cases of the importance sampling ratio. If  $\rho_{t+1} = 0$ , when the behaviour policy takes an action that the target policy would have never taken, it will bootstrap off of the expectation of its current estimates instead of cutting the return. If  $\rho_{t+1}$  is much greater than 1, an equivalent amount of its current action-value estimate is subtracted to compensate.

In the one-step case, the introduction of this control variate results in one-step Expected Sarsa's target:

$$\begin{aligned} \hat{G}_{t:t+n} &= R_{t+1} + \gamma(\rho_{t+1}Q(S_{t+1}, A_{t+1}) \\ &+ \mathbb{E}_\pi[Q(S_{t+1}, \cdot)] - \rho_{t+1}Q(S_{t+1}, A_{t+1})) \\ \hat{G}_{t:t+n} &= R_{t+1} + \gamma\mathbb{E}_\pi[Q(S_{t+1}, \cdot)] \end{aligned}$$

When applied at the bootstrapping step, it implicitly results in bootstrapping off of the expectation under the target policy as opposed to the importance sampling-corrected action-value. It can be viewed as an alternate generalization of Expected Sarsa to the multi-step setting, where the control variate is applied to the sampled reward sequence in addition to the bootstrapping step.

The control variate can be interpreted as performing an *expectation correction* at each step based on current estimates. Each reward in the trajectory depends on the sampled action at each step, but the algorithm aims to learn the expectation across all possible trajectories under a policy. The importance sampling-corrected action-value is a closer estimate to the sampled return, as the agent knows which action resulted in the immediate reward at each step. Because of this, the action-value is like a guess of what the remainder of the sampled reward sequence will be, and the difference between that and the expectation across all actions provides a per-step estimate of the discrepancy between the sampled reward sequence and the expectation across all reward sequences from the current step onwards.

It can also be seen as implicitly performing adaptive  $n$ -step learning, adjusting the amount of information included based on how accurate its current estimates are. If we rearrange the  $n$ -step return:

$$\begin{aligned} \hat{G}_{t:t+n} &= R_{t+1} + \gamma\mathbb{E}_\pi[Q(S_{t+1}, \cdot)] \\ &+ \gamma(\rho_{t+1}\hat{G}_{t+1:t+n} - \rho_{t+1}Q(S_{t+1}, A_{t+1})) \end{aligned} \quad (22)$$

We get the one-step Expected Sarsa target, along with some difference between the actual sampled rewards and its current estimates. If the value estimates are poor, more rewards will be effectively included in the estimate, and vice-versa. If there is no stochasticity in the environment, it ends up approaching one-step Expected Sarsa as the estimates get close to the true value function.

If we follow similar steps in the state-value case, we arrive at the following  $n$ -step return with a per-decision control variate:

$$\begin{aligned} \hat{G}_{t:t} &= V(S_t) \\ \hat{G}_{t:t+n} &= \rho_t(R_{t+1} + \gamma\hat{G}_{t+1:t+n}) + V(S_t) - \rho_tV(S_t) \\ \hat{G}_{t:t+n} &= \rho_t(R_{t+1} + \gamma\hat{G}_{t+1:t+n}) + (1 - \rho_t)V(S_t) \end{aligned} \quad (23)$$

Of note, the state-value control variate disappears in the on-policy case, but the action-value one does not.

## 5 RELATIONSHIP WITH EXISTING ALGORITHMS

If we substitute the  $n$ -step Sarsa return with the per-decision control variate (21) into the definition of the  $\lambda$ -return in Equation 14, we can rearrange it into a sum of

one-step Expected Sarsa’s TD errors:

$$\begin{aligned}\hat{G}_t &= R_{t+1} + \gamma \mathbb{E}_\pi [Q(S_{t+1}, \cdot)] \\ \hat{G}_t^\lambda &= Q(S_t, A_t) + \sum_{k=t}^{\infty} (\hat{G}_k - Q(S_k, A_k)) \prod_{i=t+1}^k \gamma \lambda \rho_i\end{aligned}\quad (24)$$

This is equivalent to using the eligibility trace decay rate of Sarsa( $\lambda$ ), but backing up the TD error of one-step Expected Sarsa. That is, in the space of action-value TD( $\lambda$ ) algorithms, having the one-step estimates of the return bootstrap off of the expectation under the target policy implicitly induces this per-decision control variate in the corresponding  $n$ -step returns.

An existing algorithm that also uses one-step Expected Sarsa’s TD error in its  $\lambda$ -return is the Tree-backup( $\lambda$ ) algorithm (Precup et al., 2000). Denoting  $\pi_t = \pi(S_t, A_t)$ , Tree-backup( $\lambda$ ) is characterized by the following equations:

$$\begin{aligned}\hat{G}_t &= R_{t+1} + \gamma \mathbb{E}_\pi [Q(S_{t+1}, \cdot)] \\ \hat{G}_t^\lambda &= Q(S_t, A_t) + \sum_{k=t}^{\infty} (\hat{G}_k - Q(S_k, A_k)) \prod_{i=t+1}^k \gamma \lambda \pi_t\end{aligned}\quad (25)$$

If we look at  $n$ -step Tree-backup’s estimate of the return, we can show that it also includes the expectation correction terms:

$$\begin{aligned}\hat{G}_{t:t+n} &= R_{t+1} + \gamma (\pi_{t+1} \hat{G}_{t+1:t+n} \\ &\quad + \sum_{a \neq A_{t+1}} \pi(S_{t+1}, a) Q(S_{t+1}, a)) \\ \hat{G}_{t:t+n} &= R_{t+1} + \gamma (\pi_{t+1} \hat{G}_{t+1:t+n} \\ &\quad + \mathbb{E}_\pi [Q(S_{t+1}, \cdot)] - \pi_{t+1} Q(S_{t+1}, A_{t+1}))\end{aligned}\quad (26)$$

The estimate takes some portion of the sampled reward sequence, and the difference between the expectation under the target policy and an equivalent portion of the sampled action-value estimate.

The introduction of the control variates with the aforementioned choice of the control variate parameter results in an instance of a doubly robust estimator. The use of doubly-robust estimators in off-policy policy evaluation has been investigated by Jiang et al. (2016) and Thomas et al. (2016). However, results when applying the approaches in an online, model-free setting, as well as its view as a multi-step generalization of Expected Sarsa, appear to be novel.

Harutyunyan et al. (2016) has acknowledged the implicit introduction of these terms when using the expectation form of the TD error in action-value TD( $\lambda$ ) algorithms.

However, their work investigated the off-policy correcting effects of including the difference between the expectation under the target policy with an action-value sampled from the behaviour policy (without importance sampling corrections). This work focuses on the effect of explicitly including the additional terms, with importance sampling, in the  $n$ -step setting for both on and off-policy TD learning.

In the state-value setting, combining Equations 23 and 14 gives the following  $\lambda$ -return:

$$\begin{aligned}\hat{G}_t &= R_{t+1} + \gamma V(S_{t+1}) \\ \hat{G}_t^\lambda &= V(S_t) + \rho_t \sum_{k=t}^{\infty} (\hat{G}_k - V(S_k)) \prod_{i=t+1}^k \gamma \lambda \rho_i\end{aligned}\quad (27)$$

which is an intuitive generalization of off-policy per-decision importance sampling for state-values, having an additional importance sampling correction term for the first reward in the sequence. It can be seen that the inclusion of an action-dependent trace decay rate scaling a TD error, as opposed to the return estimate alone, implicitly induces the state-value control variate in the  $n$ -step estimate of the return.

## 6 EXPERIMENTS

In this section, we focus on the action-value setting and investigate the performance of  $n$ -step Sarsa with the per-decision control variate (denoted as *n-step CV Sarsa*) on three problems. The first two are multi-step prediction tasks in a tabular environment, one being off-policy and one being on-policy. The remaining one is a control problem involving function approximation, evaluating the performance of  $n$ -step CV Sarsa beyond the tabular setting, as well as how it handles a changing (greedifying) policy.

Figure 1: 5×5 Grid World environment. It was set up as an on and off-policy multi-step prediction task where the goal was to estimate the expected return under the target policy as accurately as possible.

Figure 2: 5x5 Grid World off-policy prediction results. The plot shows the performance of various parameter settings of each algorithm in terms of RMS error after 200 episodes in the learned value function. The shaded region corresponds to one standard deviation, and the results are averaged over 1000 runs.

Since  $n$ -step CV Sarsa ends up bootstrapping off of the expectation over action-values at the end of the reward sequence, we compare the algorithm to  $n$ -step Expected Sarsa as characterized by Equation 11. This allows for examining the effects of the control variate being applied to each reward in the reward sequence in an online and incremental setting.

## 6.1 5x5 GRID WORLD

The 5x5 *Grid World* is a 2-dimensional grid world having terminal states in two opposite corners. The actions consist of 4-directional movement, and moving into a wall transitions the agent to the same state. The agent starts in the center, and a reward of  $-1$  is received at each transition. Experiments were run in both the off-policy and on-policy settings with no discounting ( $\gamma = 1$ ), and the root-mean-square (RMS) error between the learned value function and the true value function were compared.

### 6.1.1 Off-policy Prediction

For the off-policy experiments, the target policy would move north with probability  $1 - \epsilon$ , and select a random action equiprobably otherwise.  $\epsilon$  was set to 0.5, and the behaviour policy was equiprobable random for all states. A parameter study was done for 1, 2, and 4 steps, and the RMS error was measured after 200 episodes. The results are averaged over 1000 runs, and can be seen in Figure 2.

It can be seen that 2-step Expected Sarsa only outperforms 1-step Expected Sarsa for a very limited range of parameters, but is worse otherwise. 4-step Expected

Sarsa was unable to learn for most parameter settings. When the control variate is applied to each reward, we can see that 2-step CV Sarsa outperforms 1-step Expected Sarsa for all parameter settings, and the variance is reduced relative to 2-step Expected Sarsa. Furthermore, 4-step CV Sarsa ends up being able to learn, and can outperform 2-step CV Sarsa for a reasonably wide range of parameters.

### 6.1.2 On-policy Prediction

In the on-policy case, the target policy and behaviour policy were both equiprobable random for all states. The parameters tested are identical to the off-policy experiment with the addition of 8-step instances of each algorithm. The RMS error was measured after 200 episodes, and are also averaged over 1000 runs. The results are summarized in Figure 3.

2-step Expected Sarsa ends up performing better than 1-step Expected Sarsa for a wider range of parameters than in the off-policy case, but the best parameter settings for each perform similarly. Further increasing the number of steps results in relatively poor performance, and doesn't do better than the best parameter setting of 1-step Expected Sarsa. Looking at  $n$ -step CV Sarsa, we can see that performance is drastically improved for all tested settings of  $n$ . Of note, while introducing the per-decision control variate resulted in lower variance for a reasonable range of parameters, assumptions were made regarding the accuracy of the value function when setting the control variate parameter  $c$  in Equation 19. If the number of steps  $n$  and the step size  $\alpha$  get too large, it can result in larger variance and divergence on parameter settings where  $n$ -step Expected Sarsa did not diverge.

Figure 3: 5x5 Grid World on-policy prediction results. The plot shows the performance of various parameter settings of each algorithm in terms of RMS error after 200 episodes in the learned value function. The shaded region corresponds to one standard deviation, and the results are averaged over 1000 runs.

We did not investigate alternate methods of setting the control variate parameter in this work.

## 6.2 MOUNTAIN CAR

To show that this use of control variates is compatible with function approximation, we ran experiments on *mountain car* as described by Sutton and Barto (1998). A reward of  $-1$  is received at each step, and there is no discounting.

Figure 4: The mountain car environment (Sutton & Barto, 1998). The agent starts at a random location in the valley, receives a reward of  $-1$  at each step, and its goal is to drive past the flag in as few steps as possible.

Because the environment's state space is continuous, we used *tile coding* (Sutton & Barto, 1998) to produce a feature representation for use with linear function approximation. The tile coder used 16 tilings, an asymmetric

offset by consecutive odd numbers, and each tile covered  $1/8$ -th of the feature space in each direction.

We compared  $n$ -step Expected Sarsa and  $n$ -step CV Sarsa with 1, 2, 4, and 8 steps across different step sizes  $\alpha$ . Each algorithm learned on-policy with an  $\epsilon$ -greedy policy which selects an action greedily with respect to its value function with probability  $1 - \epsilon$ , and selected a random action equiprobably otherwise. In this experiment,  $\epsilon$  was set to 0.1. We measured the return per episode up to 100 episodes, and averaged the results over 100 runs. The results for the best parameter setting for each algorithm can be found in Figure 5.

Figure 5: Mountain Car on-policy control results. The plot shows the return per episode of the best parameter setting of each algorithm in terms of the mean return over all episodes. The shaded region corresponds to one standard error, and the results are averaged over 100 runs.

The two algorithms showed a similar trend in the parameters as in the  $5 \times 5$  Grid World environment, but were less pronounced. This is likely due to not requiring accurate value function estimates to perform the task well, and the control variate having less of an effect with greedier target policies, because  $\mathbb{E}_\pi[Q(S_t, \cdot)]$  gets relatively close to  $Q(S_t, A_t)$ . Despite this, as seen in the results for the best parameter settings,  $n$ -step CV Sarsa still outperforms  $n$ -step Expected Sarsa on this task.

## 7 DISCUSSION

From our experiments,  $n$ -step CV Sarsa appears to be an improved multi-step generalization of Expected Sarsa. In both on and off-policy prediction tasks on the  $5 \times 5$  Grid World environment, it generally resulted in lower variance as well as considerably lower error in the estimates compared to  $n$ -step Expected Sarsa, an algorithm which can be interpreted as only applying the control variate at the bootstrapping step. Moreover, when used on a continuous state space control problem with function approximation, applying the control variate on a per-reward level still resulted in greater performance in terms of average return per episode.

Despite the improvement on most of the tested parameter settings, the results also showed that the addition of the per-decision control variates can cause learning to diverge for large  $n$  and large step size  $\alpha$ , even on settings where  $n$ -step Expected Sarsa did not diverge. It is suspected that this is due to assuming the estimates are accurate when setting the control variate parameter in Equation 19. This was not further investigated, but it could be an avenue for future work.

While our results focused on the action-value per-decision control variate, other experiments not included in this paper showed that the state-value per-decision control variate in Equation 23 can also be applied in the off-policy action-value setting. It resulted in performance in between that of  $n$ -step Expected Sarsa and  $n$ -step CV Sarsa, supporting that it is beneficial to add it, but better to use the action-value control variate if the agent is learning action-values.

## 8 CONCLUSIONS

In this paper, we presented a way to derive per-decision control variates in both state-value and action-value  $n$ -step TD methods. The state-value control variate is only present in the off-policy setting, but the action-value control variate affects both on and off-policy learning. In the action-value case, applying the per-decision control variate results in an alternative multi-step extension of Ex-

pected Sarsa. With this control variate perspective, the existing  $n$ -step Expected Sarsa algorithm can be interpreted as only applying a control variate at the bootstrapping step, when it can be applied to the sampled reward sequence as well. Our results on prediction and control problems show that applying it on a per-decision level can greatly improve the accuracy of the learned value function, and consequently perform better when doing TD control.

We also showed how the per-decision control variates relate to TD( $\lambda$ ) algorithms. This provided insight on how minor adjustments in the TD( $\lambda$ ) space can implicitly induce these per-decision control variates in the underlying  $n$ -step returns, resulting in a more unified view of per-decision multi-step TD methods.

Our experiments were limited to the  $n$ -step TD setting without eligibility traces, and focused on learning action-values. We only considered a naive setting of the control variate scaling parameter  $c$ , when our results suggest that the way we set it can negatively affect learning for a few (relatively extreme) parameter combinations. Perhaps insight from the analytical optimal coefficient in Equation 18 can be used to adapt the control variate online to further improve performance.

## Acknowledgements

The authors thank Yi Wan for insights and discussions contributing to the results presented in this paper, and the entire Reinforcement Learning and Artificial Intelligence research group for providing the environment to nurture and support this research. ## Abstract

Temporal events in the real world often exhibit reinforcing dynamics, where earlier events trigger follow-up activity in the near future. A canonical example of modeling such dynamics is the Hawkes process (HP). However, previous HP models do not capture the rich dynamics of real-world activity—which can be driven by multiple latent triggering factors shared by past and future events, with the latent features themselves exhibiting temporal dependency structures. For instance, rather than view a new document just as a response to other documents in the recent past, it is important to account for the factor-structure underlying all previous documents. This structure itself is not fixed, with the influence of earlier documents decaying with time. To this end, we propose a novel Bayesian nonparametric stochastic point process model, the Indian Buffet Hawkes Processes (IBHP), to learn multiple latent triggering factors underlying streaming document/message data. The IBP facilitates the inclusion of multiple triggering factors in the HP, and the HP allows for modeling latent factor evolution in the IBP. We develop a learning algorithm for the IBHP based on Sequential Monte Carlo and demonstrate the effectiveness of the model. In both synthetic and real data experiments, our model achieves equivalent or higher likelihood and provides interpretable topics and shows their dynamics.

## 1 INTRODUCTION

Temporal activity in real applications exhibit rich dynamics, with past events influencing the future through multiple structured latent factors. For example, the ideas in a research paper may be derived from multiple existing works in the literature, each of which contributes one

or more factors, with only their combination serving to trigger the event. Similarly, a conversation among individuals may heat up or cool down due to the topics being discussed (e.g., politics vs. weather). Communications via email or on social media platforms like Facebook or Twitter may exhibit analogous dynamics. In addition, individual checkin data on platforms like Foursquare or Yelp may depend on combinations of characteristics and activities from previous visited locations. Finally in biological data, pathways are often only activated when a set of genes is expressed together.

Latent feature models (both parametric and nonparametric) have found wide application in settings where exchangeability holds. A canonical model from Bayesian nonparametrics is the Indian Buffet process (IBP). While there has been some work towards relaxing exchangeability assumptions to allow for temporal dynamics, modeling the full richness of interactions remains an open challenge. Our main contribution in this work is a framework that facilitates the modeling of temporal dynamics through a combination of ideas from the IBP with those of Hawkes processes (HP).

In recent years, Hawkes processes [11, 10, 12, 15, 22] have become a popular modeling choice to capture such temporal dynamics [4, 18, 14, 19, 13, 7, 17, 8, 16, 21]. As we outline later, the standard Hawkes process has a number of limitations centering around the fact that each event is triggered by a single observation instead of possibly multiple events and/or factors. To this end, we propose a novel Bayesian nonparametric stochastic point process model, the Indian Buffet Hawkes Processes (IBHP), that synergizes ideas between the IBP and the HP. The contributions of our work include:

1. The use of the IBP to add multiple triggering factors to the HP, which helps to better model dynamics and improves interpretation.
2. Embedding the temporal information from the HP into the IBP to drive the latent factor estimation,

which expands its capability to model factor evolution over time.

3. Developing an efficient and scalable learning algorithm for the IBHP model, based on Sequential Monte Carlo (SMC).
4. Demonstrating the effectiveness of the IBHP on both synthetic and four real-world datasets, where we also show how our framework enables the construction of more flexible (e.g., multi-event) triggering rules.

## 2 PRELIMINARIES

Formally, we are given a sequence of  $N$  observations  $y_n = \{t_n, \mathcal{T}_n\}$ ,  $n = 1, \dots, N$ . For the  $n$ th event,  $t_n$  is the time of occurrence, and  $\mathcal{T}_n$  represents observed attributes attached to it. Since our focus is mostly on settings where events are messages, we will refer to attributes as text. We will model the event times  $t_n$  and event text  $\mathcal{T}_n$  as realizations of a process whose states depend on a hidden state variable  $\mathbf{z}_n$ , summarizing the past observations  $y_{1:(n-1)}$ . Before outlining our model, we first review existing work related to our problem.

### 2.1 HAWKES PROCESSES (HP)

Hawkes processes (HP) [11, 10, 12, 15, 22] are self-exciting point processes [5] where earlier events have a time-decaying influence on future events. Parametrized by a base rate  $\gamma$  and a non-negative triggering kernel  $\kappa(\cdot)$  (the latter models the contribution of each past observation), the rate function at time  $t$  can be written as:

$$\lambda(t) = \gamma + \int_0^t \kappa(t-s) dN(s) \quad (1)$$

where  $N(s)$  is the number of observations within  $[0, s)$ . Given the rate function  $\lambda(t)$  and observation history  $\mathcal{H}_{(0,T]} = (t_1, \dots, t_n)$ , the likelihood function of a Hawkes process is:

$$\mathcal{L}(\mathcal{H}) = \exp\{-\Lambda(0, T)\} \prod_{i=1}^n \lambda(t_i) \quad (2)$$

where  $\Lambda(0, T) = \int_0^T \lambda(t) dt$  is the cumulative rate. The events in a standard HP are triggered by a single event at a time (see Figure 1).

### 2.2 INDIAN BUFFET PROCESSES (IBP)

The Indian Buffet Process (IBP) [9] is a Bayesian non-parametric prior over an infinite dimensional binary matrix whose columns represent exchangeable factors underlying observations. Suppose there are  $N$  customers (observations) arriving sequentially in a restaurant with infinite number of dishes (factors). Each customer is assigned dishes as follows:

- The first customer comes in and helps herself to  $\text{Poisson}(\alpha)$  dishes.

(a) A Hawkes process with single triggers.

(b) A Hawkes process with multiple triggers.

Figure 1: HP with single and multiple triggers. In (a), #3 is triggered by a single event #1, while in (b) it is triggered by #1 and #2. The triggering kernels can be quite different depending on how the triggering has happened. HP with single triggers would fail to model influences from both #1 and #2 at the same time, as shown in (b).

- When the  $n^{\text{th}}$  customer arrives, they independently choose each existing dish with probability  $m_k/n$ , where  $m_k$  is the number of customers that have already sampled dish  $k$  (the popularity of the dish).
- In addition, they sample  $\text{Poisson}(\alpha/n)$  new dishes.

The IBP has several distinctive features: 1) Each observation can have multiple factors; 2) The number of factors grows non-parametrically depending on the size of the dataset; 3) The probability of adding new factors decreases – since the number of new factors follows  $\text{Poisson}(\alpha/n)$  which decreases as  $n$  increases; 4) The rows are exchangeable, with the row sums distributed  $\text{Poisson}(\alpha)$ .

We write the binary feature matrix as  $\mathbf{C}$ . The conditional probability that element  $c_{ik} = 1$  is given by

$$P(c_{ik} = 1 | \mathbf{c}_{-i,k}) = \frac{m_{-ik}}{N} \quad (3)$$

where  $\mathbf{c}_{-ik}$  is the  $k^{\text{th}}$  column without considering the  $i^{\text{th}}$  observation, and  $m_{-ik}$  is the sum of  $\mathbf{c}_{-ik}$ . We need only condition on  $\mathbf{c}_{-ik}$  rather than including other columns because the columns of the matrix are generated independently under this prior. In a Bayesian framework with observations  $\mathbf{X}$ , the posterior can be written as:

$$P(c_{ik} = 1 | \mathbf{C}_{-ik}, \mathbf{X}) \propto P(\mathbf{X} | \mathbf{C}) P(c_{ik} = 1 | \mathbf{c}_{-ik}) \quad (4)$$

where  $P(\mathbf{X} | \mathbf{C})$  is the data likelihood.

### 3 MODEL

Our proposed model, the IBHP, can be viewed as a non-parametric latent state space model, where past events  $y_n = \{t_n, \mathcal{T}_n\}$  influence future observations through latent state variables  $\mathbf{z}_n = \{\mathbf{K}_n, \mathbf{V}_n\}$  (described below). The  $\mathbf{z}_n$ 's summarize information about the past, and themselves evolve following dynamics based on the IBP. Algorithmically, the generative process (see Algorithm 1 for the pseudocode and Figure 2 for an illustrative example) can be described in the following three steps.

#### 3.1 INITIALIZATION ( $\mathcal{M}, \Pi, \Theta$ )

To setup the model, we first specify a triplet  $\mathcal{M} = \{\mathcal{S}, D, L\}$ , with  $\mathcal{S}$  representing the vocabulary of all possible words in the observations,  $D$  representing the length of each document (for simplicity we assume all are equal), and  $L$  representing the number of basis kernels. We also require a pair of hyper parameters  $\Pi = \{\mathbf{w}_0, \mathbf{v}_0\}$  for the priors of the kernel and word distribution weights.

Each latent factor influences the content of future events through a set of *dictionary weights*, which are used to generate text. We write  $\mathbf{v}_k$  for the vector of weights over the words in the vocabulary for the  $k^{\text{th}}$  factor – a length  $|\mathcal{S}|$  vector which sums to one. The weights  $\mathbf{v}_k$  are sampled from a Dirichlet prior (with hyper parameter  $\mathbf{v}_0$ ) whenever a new factor is created (see later). Each latent factor also influences the timing of future events through a *triggering kernel*, and we assume each kernel is a linear combination of a set of  $L$  bases. Throughout, we assume  $L$  exponential basis kernels:

$$\gamma_l(\delta) = \beta_l e^{-\frac{\delta}{\tau_l}}, \quad l = 1, \dots, L. \quad (5)$$

This requires a set of parameters  $\{(\beta_l, \tau_l)\}$ , each of which captures a distinct type of excitation pattern. A binary matrix  $\mathbf{C}$  indicates which factors are associated with each observation. The  $k^{\text{th}}$  factor kernel for the  $i^{\text{th}}$  observation  $\kappa_{ik}$  is a weighted sum of the  $L$  basis kernels:

$$\kappa_{ik}(\delta | \mathbf{w}_k, c_{ik}) = \begin{cases} \sum_{l=1}^L w_{kl} \cdot \gamma_l(\delta), & \text{if } c_{ik} = 1 \\ 0, & \text{if } c_{ik} = 0 \end{cases} \quad (6)$$

The weights  $w_{kl}$ , loadings of the basis kernels for the factors, are sampled from a Dirichlet prior (with hyper parameter  $\mathbf{w}_0$ ) whenever a new factor is created (see later). Thus, immediately after an event (when  $\delta = 0$ ), there is a jump in the event rate with amplitude equal to  $\kappa_{ik} = \mathbf{w}_k^T \beta$ . Observations with the same factor share the factor kernel. We write the model parameters as  $\Theta = \{\lambda_0, \{\beta_l\}, \{\tau_l\}\}$ , where  $\lambda_0$  is a base-rate at which events happen spontaneously.

#### 3.2 THE FIRST EVENT ( $\mathcal{M}, \Theta \rightarrow \mathbf{z}_1 \rightarrow \mathbf{y}_1$ )

To generate the observation  $\mathbf{y}_1 = \{t_1, \mathcal{T}_1\}$ , we first sample the auxiliary variables  $\mathbf{c}_1$  and  $\mathbf{w}_{1:K}$ . The *factor label variable*  $\mathbf{c}_1$  is a binary vector of length  $K$ , where  $K \sim \text{Poisson}(\lambda_0)$  is the number of existing factors.  $c_{nk} = 1$  implies that the  $n^{\text{th}}$  observation has a label of factor  $k$ . Set  $c_{1k} = 1$  for  $k = 1, \dots, K$ . The *kernel weights*  $\mathbf{w}_k$  is a vector of weights for the  $k^{\text{th}}$  factor to load the basis kernels. Each  $\mathbf{w}_k$  is of length  $L$  (the number of basis kernels), and sums to one. Sample  $\mathbf{w}_k \sim \text{Dir}(\mathbf{w} | \mathbf{w}_0)$  for  $k = 1, \dots, K$ .

Given the values of  $\mathbf{c}_1$  and  $\mathbf{w}_{1:K}$ , we can sample the associated latent variables  $\mathbf{z}_1 = \{\mathbf{K}_1, \mathbf{V}_1\}$ . Define the  $1 \times K$  IBHP matrix  $\mathbf{K}_1$ , whose rows are  $\kappa_{1k}$ , with values  $\mathbf{w}_k^T \beta$  (see Equation 6) – since  $\delta = 0$ . For  $n = 1$ , sample  $\mathbf{v}_k \sim \text{Dir}(\mathbf{v} | \mathbf{v}_0)$  for  $k = 1, \dots, K$ , and define the  $|\mathcal{S}| \times K$  matrix  $\mathbf{V}_1$ , whose columns are  $\mathbf{v}_k$ . Conditioned on these state variables  $\mathbf{z}_1$ , we sample the first observation  $\mathbf{y}_1 = \{t_1, \mathcal{T}_1\}$ : The *time stamp*  $t_1$  is sampled from a Poisson process with rate  $\lambda_0$ ; and the *text*  $\mathcal{T}_1$  is sampled from  $\text{Multi}(D, \sum_{k=1}^K \mathbf{v}_k / K)$ , where the weight parameter is the averaged factor weight of the first observation.

#### 3.3 FOLLOW-UP EVENTS ( $\mathbf{z}_{n-1} \rightarrow \mathbf{z}_n \rightarrow \mathbf{y}_n$ )

For a new event, we first decide its associated factors, and sample its time stamp afterwards. Conditioning on  $\mathbf{z}_{n-1}$ , suppose there are  $K$  existing factors, each of which can be represented by an independent Hawkes process. At time  $t_{n-1}$ , the *factor rate* for the  $k^{\text{th}}$  factor is:

$$\lambda_k(t_{n-1}) = \sum_{i=1}^{n-1} \frac{\kappa_{ik}(t_{n-1} - t_i)}{\|\kappa_i\|_0} \quad (7)$$

As with the generation of the initial event, follow-up events ( $n > 1$ ) are also generated by two steps. First, we sample the auxiliary variables  $\mathbf{c}_n$  and set  $\mathbf{w}$  and  $\mathbf{v}$  for any newly generated factors. The first  $K$  components of the *factor label variable*  $\mathbf{c}_n$  is sampled independently from a Bernoulli distribution with probability parameter

$$p_k = \frac{\lambda_k(t_{n-1})}{\lambda_0/K + \lambda_k(t_{n-1})} \quad (8)$$

Meanwhile,  $K^+$  new factors are created by setting  $c_{nk'} = 1$ , for  $k' = K + \{1, \dots, K^+\}$ , where

$$K^+ \sim \text{Poisson} \left( \frac{\lambda_0}{\lambda_0 + \sum_{k=1}^K \lambda_k(t_{n-1})} \right) \quad (9)$$

If  $\kappa$  are binary, which is the case in IBP, and  $\lambda_0 = 1$ , then the mean of  $K^+$  becomes  $1/n$  and  $p_k = (n-1)/n$ , which reduces to the case of IBP with parameter 1:

$$\sum_{k=1}^K \sum_{i=1}^{n-1} \frac{\kappa_{ik}(t_{n-1} - t_i)}{\|\kappa_i\|_0} = \sum_{i=1}^{n-1} \frac{\|\kappa_i\|_0}{\|\kappa_i\|_0} = n-1 \quad (10)$$

For each new factor  $k'$ , we draw from the corresponding priors for  $\mathbf{w}_{k'} \sim \text{Dir}(\mathbf{w}|\mathbf{w}_0)$  and  $\mathbf{v}_{k'} \sim \text{Dir}(\mathbf{v}|\mathbf{v}_0)$ .

Next, we decide the hidden state variables  $\mathbf{z}_n = \{\mathbf{K}_n, \mathbf{V}_n\}$ .  $\mathbf{V}_n$  is constructed by simply adding columns for the  $\mathbf{v}_{k'}$  for newly sampled factors to  $\mathbf{V}_{n-1}$ .  $\mathbf{K}_n$  is constructed by first updating  $\mathbf{K}_{n-1}$  with respect to the new lag time  $\delta = t_n - t_i$ . This step is done *symbolically*, since we do not know  $t_n$  yet. Then we add the rows  $\kappa_{ik'}$  for the newly sampled event based on Equation 6 with  $\delta = 0$ . We emphasize that  $K_n(t_n) : \mathbf{R}^+ \rightarrow \mathbf{R}^{n \times (K+K')}$  at this moment is a symbolic function of  $t_n$ .

Conditioned on these state variables  $\mathbf{z}_n$ , we sample the  $n^{\text{th}}$  observation  $\mathbf{y}_n = \{t_n, \mathcal{T}_n\}$ : The *time stamp*  $t_n$ , depending on its related factors, is sampled from a Poisson process with rate

$$\lambda(t_n) = \sum_{\kappa_{nk} \neq 0} \lambda_k(t_n) = \sum_{\kappa_{nk} \neq 0} \sum_{i=1}^n \frac{\kappa_{ik}(t_n - t_i)}{\|\boldsymbol{\kappa}_i\|_0} \quad (11)$$

The overall rate of IBHP, however, includes the base rate and other factors too:

$$\bar{\lambda}(t_n) = \lambda_0 + \lambda(t_n) + \sum_{\kappa_{nk}=0} \lambda_k(t_n) \quad (12)$$

Now, at this point, since  $t_n$  is known, we can proceed to compute the actual values of  $\mathbf{K}_n$ . Finally, we sample the *dictionary text*  $\mathcal{T}_n$  from  $\text{Multi}(D, \sum_{\kappa_{nk} \neq 0} \mathbf{v}_k / \|\boldsymbol{\kappa}_n\|_0)$ , where the weight parameter is the averaged of all  $\|\boldsymbol{\kappa}_n\|_0$  factor weights associated with the  $n^{\text{th}}$  observation.

## 4 POSTERIOR INFERENCE

### 4.1 SMC FOR IBHP

Sequential Monte Carlo [6] (SMC) methods are powerful and flexible tools for posterior inference in time-series models such as ours. Here, we adapt particle filtering methods to our set up, allowing us to scale our model to large-data regimes. The idea here is to represent the state of the system at any time (from 1 to  $N$ ) with a set of  $F$  particles. We build on ideas from [20], extending them to our more structured setting.

The idea at a high level is to propagate each particle forward by one time step according to the prior, and then reweight each particle by how “compatible” it is with the observation at that time. If the effective number of particles is small (according to their weights), then the algorithm resamples the particles with replacement. Our algorithm to learn the IBHP factors and model parameters can be described as follows (see Algorithm 2 for the pseudocode):

*A. Initialize Particle Weights.* The particle weights are initialized uniformly:  $u_1^f = \frac{1}{F}$ , for  $f = 1, \dots, F$ . Then for each time step  $i = [1 \dots N]$ , we do the following:

---

### 1. Initialization:

- Model specifications:  $\mathcal{M} = \{L, D, \mathcal{S}\}$ ;
- Model hyper parameters:  $\boldsymbol{\Pi} = \{\mathbf{w}_0, \mathbf{v}_0\}$ ;
- Model parameters:  $\boldsymbol{\Theta} = \{\lambda_0, \{\beta_l, \tau_l\}\}$ ;

### 2. Generate the First Event:

- Set  $c_{1,1:K} = 1$ , where  $K \sim \text{Poisson}(\alpha_0)$ ;
- Sample  $\mathbf{w}_k \sim \text{Dir}(\mathbf{w}|\mathbf{w}_0)$  and set  $\boldsymbol{\kappa}_1$ ;
- Sample  $\mathbf{v}_k \sim \text{Dir}(\mathbf{v}|\mathbf{v}_0)$ ;
- Sample  $t_1 \sim \mathcal{PP}(\lambda_0)$ ;
- Sample  $\mathcal{T}_1 \sim \text{Multi}\left(D, \sum_{\kappa_{1k} \neq 0} \mathbf{v}_k / \|\boldsymbol{\kappa}_1\|_0\right)$

### 3. Generate Follow-up Events:

**for**  $n = 2, \dots, N$  **do**

- Sample  $\mathbf{c}_n$  according to Equations 8 and 9.
- Sample  $\mathbf{w}_{k'} \sim \text{Dir}(\mathbf{w}|\mathbf{w}_0)$  and set  $\boldsymbol{\kappa}_n$ ;
- Sample  $\mathbf{v}_{k'} \sim \text{Dir}(\mathbf{v}|\mathbf{v}_0)$ ;
- Sample  $t_n \sim \mathcal{PP}(\lambda(t_n))$  by Equation 11.
- Sample

$$\mathcal{T}_n \sim \text{Multi}\left(D, \sum_{\kappa_{nk} \neq 0} \mathbf{v}_k / \|\boldsymbol{\kappa}_n\|_0\right).$$

**end**

---

**Algorithm 1:** Generative process of IBHP.

*B. Sample Particles.* According to [20], our particles  $\tilde{\mathbf{z}}_i^f = \{\tilde{\mathbf{K}}_i^f, \tilde{\mathbf{V}}_i^f\}$  are sampled based on the conditional distributions  $p(\mathbf{z}_i|\mathbf{z}_{i-1})$  described in Section 3.3.

*C. Sample Model Parameters.* Since the posterior of the model parameter  $\boldsymbol{\Theta} = \{\lambda_0, \{\beta_l\}, \{\tau_l\}\}$  is proportional to the product of its prior and the data likelihood described in Equation 2 and Section 3, we can first sample from its prior, and then use the product of the prior and the HP data likelihood as weights of the samples to approximate the posterior [8]. We update the triggering kernels using the new parameters.

*D. Update Particle Weights.* The importance weight is the ratio between the true posterior and the proposal distribution. Since we use the prior as the proposal, we update the particle weights by  $u_i^f = u_{i-1}^f p(\mathbf{y}_i|\tilde{\mathbf{z}}_i^f, \boldsymbol{\Theta})$  and then normalize them to  $u_j^f = u_j^f / (\sum_{f=1}^F u_j^f)$ .

*E. Resample Particles.* If the effective number of particles is too small, we resample with replacement  $F$  particles from the existing ones with the normalized weights.

### 4.2 COMPLEXITY AND SCALABILITY

The SMC algorithm for the IBHP is easy to implement and scalable. Due to the sequential updating strategy, the time complexity of this algorithm is  $\mathcal{O}(NF)$ , where  $N$  is the number of observations and  $F$  is the number of particles. We will demonstrate and discuss the effectiveness of the algorithm in the experiment section in more detail.

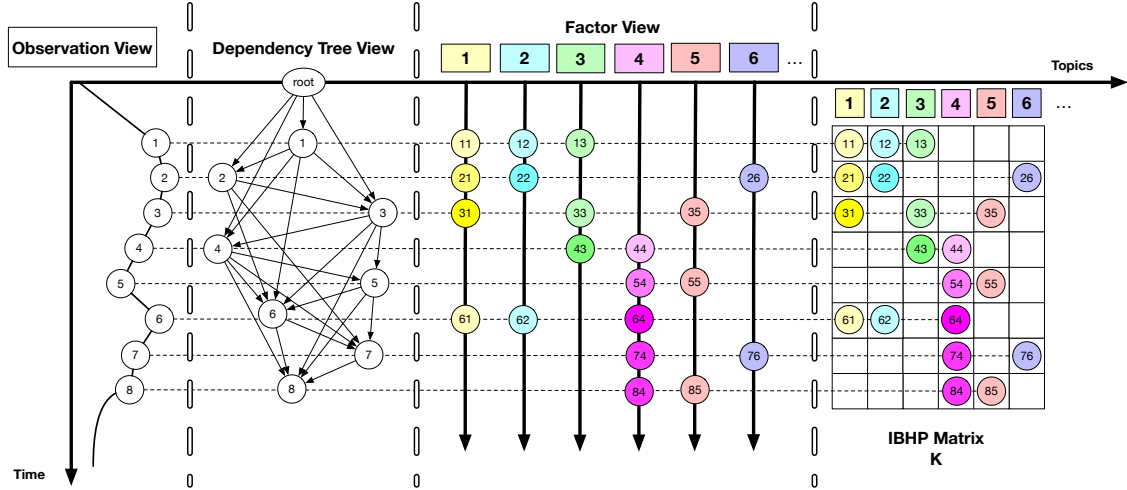

Figure 2: An example of IBHP. In this IBHP realization, the first 8 observations created 6 factors. Each factor has a distinctive color, and color intensities represent instantaneous factor popularities. An observation may be labeled with multiple factors, and are colored in its decomposed factor view accordingly. The dependency tree describes the related events for each observation, where the directed arrows indicate dependency relations. The rate for any *observation* is the aggregation of all its *related factor* rates (see Equation 11), whereas the overall rate at any *time* is the sum of *all factor* rates – so the overall rate can be excited by one observation multiple times through different factors. The overall rate is represented by its height relative to the reference time line. See Section 6.1 for more details.

Initialize the  $F$  uniform particle weights.

**for** each observation  $\mathbf{y}_i = \{t_i, \mathcal{T}_i\}$ ,  $i = 1, \dots, n$   
**do**

**for** each particle  $\mathbf{z}_i^f = \{\mathbf{K}_i, \mathbf{V}_i\}$  of  
    observation  $\mathbf{y}_i$ ,  $f \in \{1, \dots, F\}$  **do**

- Sample the auxiliary variables  $\mathbf{w}_i, \mathbf{c}_i$  and latent factor particles  $\mathbf{z}_i^f = \{\mathbf{K}_i, \mathbf{V}_i\}$ .
- Sample the model parameters  $\Theta = \{\lambda_0, \{\beta_l\}, \{\tau_l\}\}$ .
- Update the triggering kernels.
- Update the particle weights  $\mathbf{u}_i^f$ .

**end**

Normalize the particle weights.

**if**  $\|\mathbf{u}_i\|_2^{-2} < \text{threshold}$ , *i.e.*, the effective number of particles is too low **then**  
    Resample particles with replacement based on the particle weights.

**end**

**end**

**Algorithm 2:** SMC inference algorithm for IBHP.

## 5 RELATED WORK

The idea of considering nonparametric Bayesian models with temporal point processes in a unified framework has been popular in recent years. For example, [4] proposed

a Bayesian nonparametric model that utilizes the Chinese Restaurant Processes (CRP) as a prior for the clusters among individuals, whose rates of communications are modeled by HP. [18] used a similar idea but further extended the model by modeling the jump sizes of HP using Gaussian Processes (GP). HP models with various generalizations of a CRP, such as the distance dependent CRP (ddCRP) [14], the nested CRP (nCRP) [19], and the Chinese Restaurant Franchise Processes (CRFP) [13], have also been explored.

Other attempts have been made by borrowing the ideas from Deep Learning. For example, [7] proposed a model to view the intensity function of a temporal point process as a nonlinear function of the history, and use recurrent neural networks to automatically learn a representation of the influences from the event history. [17] modeled streams of events by constructing a neurally self-modulating multivariate point process where the intensities of multiple event types evolve based on a continuous-time LSTM. Lastly, [21] considered the use of latent factors in HP models to represent dependencies among instances that influence reciprocity over time. But the work focused on modeling static factors of homophily and reciprocity in social networks and not the evolution of factors over time.

Perhaps the closest works to our model are [8] and [16]. In [8], the authors proposed a Dirichlet Hawkes Processes (DHP) model that combines the CRP with HP in a

unified framework, where the cluster assignment in CRP is driven by the intensities of HP. [16] further developed this in their Hierarchical Dirichlet Hawkes Processes (HDHP) model by replacing the CRP with a CRFP that is capable of modeling steaming data for multiple users. However, there are several major distinctions compared to our IBHP: 1) In both the DHP and HDHP models, events are triggered by single factors, while in our IBHP, multiple latent triggering factors are introduced; 2) the form of the triggering kernels do not depend on history events, and in contrast, our IBHP model is more flexible to be able to adopt non-additive triggering rules to learn different perspectives of the observed data. We will compare our model to [8] and [16] next.

## 6 EXPERIMENTS

We compare IBHP with three methods from the previous section: the vanilla Hawkes process (HP), the Dirichlet Hawkes (DHP; [8]), and the Hierarchical Dirichlet Hawkes (HDHP; [16]). We evaluate the models on both synthetic and real-world data.

### 6.1 SYNTHETIC DATASETS

The purpose of our synthetic-data experiments is twofold: 1) to understand the identifiability of our model and the accuracy of our SMC algorithm when the true data generation process satisfies the model assumptions, and 2) to understand the effects of misspecification.

Our setup is as follows. The Hawkes process base rate is  $\lambda_0 = 2$ . For the basis kernels, we use:  $\gamma_1(\delta) = e^{-\delta/0.3}$ ,  $\gamma_2(\delta) = 2e^{-\delta/0.2}$ ,  $\gamma_3(\delta) = 3e^{-\delta/0.1}$ .  $\gamma_1$  has the smallest jump but also the largest time-scale; at the other extreme,  $\gamma_3$  has the largest jump with a fast decay-parameter.  $\gamma_2$  might be used to model ‘regular’ events, while  $\gamma_1$  and  $\gamma_3$  are for non-urgent and urgent ones respectively. We construct the dictionary  $\mathcal{S}$  from the top 1000 words from the NIPS dataset [2], and the document lengths are set to  $D = 20$ . The hyperparameters, which are not to be estimated, are set as  $\mathbf{w}_0 = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ ,  $\mathbf{v}_0 = (\frac{1}{1000}, \dots, \frac{1}{1000})$ . We generate  $N = 1000$  observations with this setup, and use the first 80% of the dataset for training, and the last 20% for testing. For each SMC iteration, we use 10 particles, and report averages and error bars based on 10 runs with different random seeds.

**A. Parameter learning and prediction.** Experiments A1 and A2 shown in Table 1 are the parameter estimates and the log-likelihoods over training and test datasets. Our model outperforms other models in terms of predictive log-likelihood. This demonstrates two points. Firstly, our SMC algorithm is able to accurately recover the underlying model parameters. Furthermore, estimating parameters for the misspecified models on this dataset is fair, since they have the same interpretation. Thus for

instance, our results tell us that fitting a Hawkes model that does not include multiple triggering factors results in a significant overestimation of the base rate  $\lambda_0$ : a result that one might have expected.

A1. Parameter Estimation			
Parameter Values	$\lambda_0$	$\{\beta_i\}$	$\{\pi_i\}$
	2	1,2,3	0.3,0.2,0.1
<b>IBHP</b>	<b>1.8</b>	<b>0.92, 1.63, 2.71</b>	<b>0.33, 0.18, 0.09</b>
HDHP	3.3	0.77, 4.56, 6.11	3.75, 3.20, 2.94
DHP	2.9	0.83, 5.72, 5.83	1.21, 1.58, 1.28
HP	5.4	2.25, 4.38, 3.01	0.73, 2.54, 3.56
A2. Log-likelihoods			
	Training		Test
<b>IBHP</b>	<b>318.52</b>		<b>47.68</b>
HDHP	192.74		12.23
DHP	201.96		11.78
HP	81.68		6.18
B. Learn Latent State Variables ( $K = 5, 10, 20$ )			
	Jaccard(K)		1 - Hellinger(V)
<b>IBHP</b>	<b>0.83, 0.81, 0.77</b>		<b>0.79, 0.73, 0.68</b>
HDHP	0.56, 0.40, 0.35		0.51, 0.44, 0.29
DHP	0.61, 0.42, 0.38		0.64, 0.41, 0.36

Table 1: Model comparison over the synthetic datasets.

**B. Learn latent state variables.** Table 1 part B focuses on learning the latent state variables. Now, rather than generating data from our nonparametric model, we fix  $K = 5, 10, 20$  in the data-generating process, and then compare these with our nonparametric estimates using two metrics: the Jaccard Index to compare the *binary* matrices  $\mathbf{C}$  and the Hellinger distance for  $\mathbf{V}$ . A first complication is that these matrices need not have the same number of columns, and so for each comparison, we pad the smaller matrix with zero-columns to facilitate comparison. A bigger challenge is a ‘label-switching’ issue that arises since column permutations do not effect the quality of the estimates. To overcome this, after matching dimensions, we greedily match columns, and then compute scores. We point out that padding with zeros favors the alternative methods, since their solutions have many zeros; nevertheless, our model still gives the best Jaccard scores as well as Hellinger distances (we actually report *complementary* Hellinger distances (viz. one minus the actual distance), so that large numbers imply better performance for both statistics. As before, our results demonstrate the insufficiency of the alternate models and justifies the need for multiple factors.

**C. The effects of base rate and basis kernels.** The base rate  $\lambda_0$ , together with the evolving kernels, control the dynamics of latent factors. In Table 2 part C, we see that increasing  $\lambda_0$  increases the average number of factors per observation increases—more strongly violating the *single* factor assumption of competing methods. This observation is also accompanied by a widening performance gap between our model and the alternatives.

	$\lambda_0$	Topics	Jaccard	Hellinger	Test
IBHP	4	9.01	0.79	0.75	50.21
	8	12.28	0.72	0.69	68.37
	16	28.33	0.64	0.61	72.07
HDHP	4		0.32	0.40	43.78
	8	1	0.28	0.38	51.06
	16		0.31	0.26	50.79
DHP	4		0.29	0.37	41.67
	8	1	0.33	0.31	49.18
	16		0.27	0.28	52.33

Table 2: Effects of model specifications.

**D. The effects of triggering rule.** In Equation 11, the event rate depends on the rates of the underlying factors in an additive manner. We can allow more flexible triggering rules by allowing richer interactions among factor dynamics. For example, we define a “double-sharing” triggering rule as follows: *trigger a jump in the rate function only when two or more factors are shared with a previous observation.* Thus Equation 11 becomes:

$$\lambda(t_n) = \sum_{\kappa_{nk} \neq 0} \left[ \sum_{i=1}^{n-1} \frac{\kappa_{ik}(t_n, t_i)}{\|\kappa_i\|_0} + \phi \left( \frac{\kappa_{ik}(t_n, t_n)}{\|\kappa_n\|_0} \right) \right] \quad (13)$$

where  $\phi = 0$  if the rule is not triggered—there is no “jump”, otherwise  $\phi = \mathbf{w}_k^T \beta / \|\kappa_n\|_0$ —there is a “jump”. We sketch this out in Figure 3.

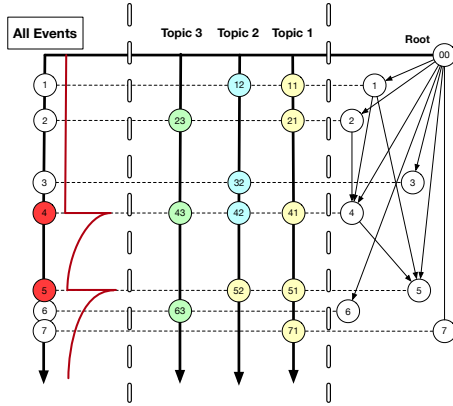

Figure 3: IBHP with “double-sharing” rule. Obs. 2 does not trigger a “jump” because no previous observations share more than two factors with it. However, obs. 4 triggers *two* jumps because it shares two factors with obs. 1 (factor 1 and 2), and two with obs. 2 (factor 1 and 3).

Incorporating such nonlinearities result in dynamics that are significantly different from the additive setup: this is evidenced in Table 3, where the simpler additive version the IBHP now has a degraded score. There are numerous variations to our simple “double-sharing” rule that are relevant across a variety of situations.

	Additive Model	Double-sharing Model
IBHP	15.38 $\pm 3.82$	20.82 $\pm 3.23$
HDHP	8.97 $\pm 4.07$	12.36 $\pm 3.18$
DHP	8.26 $\pm 3.19$	10.17 $\pm 3.20$
HP	4.98 $\pm 3.61$	5.04 $\pm 3.22$

Table 3: Model comparison with “double-sharing” data.

## 6.2 REAL DATASETS

The purpose of our real data experiments is threefold: 1) to verify that the multiple triggering factors in IBHP are indeed relevant to real applications, 2) to demonstrate that our SMC inference algorithm is scalable for real-world datasets, and 3) to use our IBHP model to present meaningful findings, both quantitative and qualitative. We consider four different datasets: **Facebook Dataset**. This data contains Facebook message communications among 20,603 individuals. We pick the top 10 most connected individuals (based on the number of friends), and add in their one-hop and two-hop friends. This results in a total of 376 individuals. **NIPS Dataset [2]**. The Kaggle NIPS dataset contains the title, authors, abstracts, and extracted text for all 7241 NIPS papers from the first 1987 conference to the current 2017 conference. This dataset is different in that it contains rich message information; however the number of time-points is just 30. **Santa Barbara Corpus Dataset [3]**. This is a standard dataset used for applications involving Hawkes processes. We use conversation #33, a lively family discussion which centers around a disagreement that an individual, Jennifer, is having with her mother, Lisbeth. **Enron Email Dataset[1]**. The Enron dataset contains about half a million email messages communicated among about 150 senior managers of the Enron corporation. We pick the longest thread of emails.

For each experiment, we use the first 80% of the dataset as training set, the next 10% as validation set, and the last 10% as test set. We train our model on training sets with different hyperparameters, then pick the best one based on their performances on the validation set, and use this model to report performances on the test set. The reported values are based on ten runs with different random number seeds. The dictionary  $\mathcal{S}$  is all the unique words in the dataset; the document length  $D_n$  is counted from each observed text  $\mathcal{T}_n$ ; and we use the three ( $L = 3$ ) exponential basis kernels defined in Equation 5.

**A. Predictive log-likelihood.** The log-likelihoods in Table 4 show that for three of four datasets, our model outperforms the alternatives. The performance gaps exhibit a range of values. On the NIPS dataset, our model shows a massive improvement over the competition, while there is no significant improvement for the Enron dataset. The numbers in parentheses, giving the average number of

Figure 4: **FB dataset**. Topic dynamics.

topics associated with each message, provides a partial explanation. For the Enron dataset, this number is just two, suggesting that there is limited benefit from modeling multiple factors, and that the simpler HDHP model may be more appropriate. For the NIPS dataset, this number is about 10, explaining the gap in performance.

**B. Latent structure vs. dynamics.** The rich structure of the NIPS dataset is balanced by its simple temporal structure just with 30 time points. This raises the question: how much of our models performance is due to the latent structure incorporated into our modeling framework, and how much is due to temporal dynamics of this structure. To study this more carefully, we shuffle the publication years (documents published in the same year remain together, however), thus destroying temporal information. Table 5 shows that this incurs a relatively small loss now, suggesting that most of the performance gains observed in Table 4 are due to the latent factors. However, removing temporal information still incurs enough of a hit in performance to justify our methodology.

<i>Test Log-likelihoods on the NIPS Dataset</i>			
	Original	Shuffled	Relative Loss
<b>IBHP</b>	<b>1012.08</b>	<b>914.76</b>	<b>-9.62%</b>

HP	40.17	18.22	-54.64%

Table 5: Model comparison on the shuffled NIPS dataset.

**C. Discovering popular topics and words.** One of the immediate benefits of our IBHP is that it returns the factor rate matrix  $\mathbf{K}$  and the word-distribution matrix  $\mathbf{V}$ , providing a rich summary of popular topics and words. Figure 5 shows, in the NIPS dataset, the most popular three topics at the end of the training dataset time span. The lists of words suggest that the first topic is related to kernel methods, the second to deep learning, and the third to Bayesian methods. The intensity of the colors indicates popularities. Our model suggests that topic 2, which hypothetically is related to deep learning, has been increasingly more popular in the NIPS community.

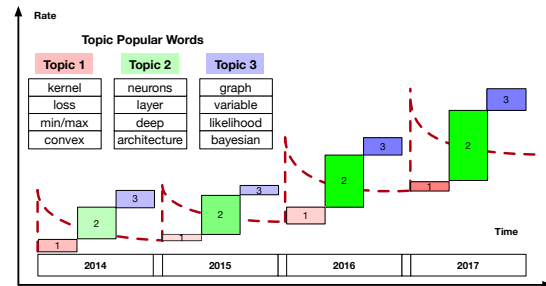

Figure 5: **NIPS dataset**. Popular topics and words.

**D. Learning factor dynamics.** Unlike the IBP, the IBHP matrix not only carries binary “present/missing” information, but also real-valued kernel weights  $\kappa_{ik}$ , which reveal the temporal dynamics of the factors. Figure 4 shows two most popular factors from the FB dataset. The first relates to school life, and the second to off-class activities. To confirm this, we plot the average of the estimated rate functions across four similar one week periods in Figure 4. The patterns of the two factor rates are quite different: The first factor is active after Monday, and peaks in the middle of the week, before cooling down near the weekend. The second factor, however, climbs steadily and becomes more excited during the weekend.

**E. Inferring dependencies and causalities.** According to Equation 11, the rate after an event depends on earlier events that share factors with it. Figure 6 provides a detailed view of IBHP on the SB dataset under the usual additive rule. We also apply the “double-sharing” rule to the dataset. In Figure 7, we see several consequences: 1) the rate functions are not triggered until the 6<sup>th</sup> observation under the double-sharing rule, 2) the IBHP matrices are different, and 3) the inferred factors are different. Further investigation shows the first red circle corresponds to the observation with text “I am mean to you all the time!” and the last red circle to “What time is it?”—one to heat up the process and one to cool it down. This suggests that adopting different triggering rules may allow us to capture different aspects of the data, which in our SB double-sharing case, bookends an active family discussion.

Figure 6: **SB Dataset.** Additive rule. Every observation creates a jump of the rate function. Topics can be interpreted as background, cooling, and heating activities.

Figure 7: **SB Dataset with double-sharing.** White circles represent observations that do not trigger the rule. Topics can be interpreted as background activities, and those of Jennifer and Lisbeth.

**F. Predict future event times.** In Table 4, we report the log-likelihoods on the test datasets for each a model. To evaluate the predictive ability of our model in more depth, we use it for a different predictive task: predict the time of the next event in windows of increasing sizes, and for each case, report the absolute different from the observed data. Table 6 shows that, as the size of predictions increases, the mean absolute error increases, as well as

the standard error: as the predictions becomes harder, the predictions becomes inaccurate and unreliable. Nonetheless, our model outperforms competing models according to this metric as well.

	Prediction Window Size		
	$pws = 1$	$pws = 5$	$pws = 10$
IBHP	$0.61 \pm 0.11$	$0.97 \pm 0.18$	$1.37 \pm 0.28$
HDHP	$0.82 \pm 0.13$	$1.24 \pm 0.20$	$2.18 \pm 0.33$
DHP	$0.87 \pm 0.10$	$1.19 \pm 0.16$	$2.21 \pm 0.29$
HP	$0.92 \pm 0.17$	$2.06 \pm 0.23$	$3.56 \pm 0.31$

Table 6: **FB Dataset.** Predicting future event times.

**G. Predicting future topics and words.** Our last experiment is concerned with the prediction of the latent state variables. The dotted line in Figure 8 represents the end of the training phase, where we have obtained the latent factor rate matrix  $\mathbf{K}$  and the latent factor word distribution matrix  $\mathbf{V}$ . To the right of the dotted line, we show the projected rate function, along with the first three predictions and their predicted top words. Our model suggests that, for the NIPS dataset, topic 2 is taking over topic 3 and may become dominant in the next few events.

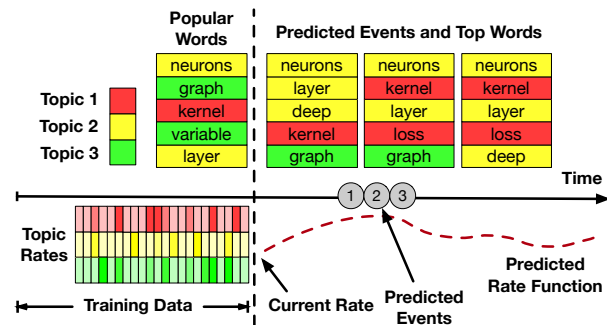

Figure 8: **NIPS dataset.** Predicted events.

## 7 CONCLUSION

In this paper, we proposed the Indian Buffet Hawkes Process (IBHP)—a novel Bayesian nonparametric stochastic point process model for learning multiple latent triggering factors of streaming document/message data. Our approach establishes the synergy between Indian Buffet Processes (IBP) and Hawkes processes (HP): on the one hand, we use the IBP to add multiple triggering factors to the HP, which helps to better model dynamics and improves interpretation, and on the other hand, the temporal information from the HP is embedded into the IBP to drive the latent factor estimation, which expands its capability to model evolution of factors.

## Abstract

We introduce *Battling-Bandits* – an online learning framework where given a set of  $n$  arms, the learner needs to select a subset of  $k \geq 2$  arms in each round and subsequently observes a stochastic feedback indicating the winner of the round. This framework generalizes the standard *Dueling-Bandit* framework which applies to several practical scenarios such as medical treatment preferences, recommender systems, search engine optimization etc., where it is easier and more effective to collect feedback for multiple options simultaneously. We develop a novel class of *pairwise-subset choice model*, for modelling the subset-wise winner feedback and propose three algorithms - *Battling-Doubler*, *Battling-MultiSBM* and *Battling-Duel*: While the first two are designed for a special class of *linear-link* based choice models, the third one applies to a much general class of *pairwise-subset choice models* with *Condorcet winner*. We also analyzed their regret guarantees and show the optimality of *Battling-Duel* proving a matching regret lower bound of  $\Omega(n \log T)$ , which (perhaps surprisingly) shows that the flexibility of playing size- $k$  subsets does not really help to gather information faster than the corresponding dueling case ( $k = 2$ ), at least for the current subsetwise feedback choice model. The efficacy of our algorithms are demonstrated through extensive experimental evaluations on a variety of synthetic and real world datasets.

## 1 INTRODUCTION

The problem of *Dueling-Bandits* has recently gained much attention in the machine learning community [22, 4, 24, 25, 23, 16]. Dueling bandits is an online learn-

ing framework, generalizing multi-armed bandits [5], in which learning proceeds in rounds: At each round the learner selects a pair of arm and observes a stochastic feedback of the winner of the comparison (duel) between the selected arms. Several algorithms have been proposed for this problem which are designed to learn to play the best arm as often as possible over time [22, 4, 24, 25, 23, 16]. These algorithms are tailor-made to work well under specific assumptions on the underlying pairwise comparison model that generates the stochastic feedback and under specific definition of the winner of a set of arms [16].

In this work, we introduce a natural generalization of the dueling bandits problem where given a set of  $n$  items (bandit arms), the learner’s objective at each round is to choose a subset of  $k \geq 2$  arms (unlike selecting just *two* arms as in case of dueling bandits), upon which the winner of the ‘battle’ among these  $k$  selected items is revealed by the environment as stochastic feedback. The goal of the learner is to identify an appropriately defined ‘best’ item in the process and play it often as possible.

We term this as the problem of *Battling-Bandits* as at each round, essentially a subset of  $k$  items are competing against each other unlike a pairwise duel as in the case of *Dueling-Bandits*. Such settings occur naturally in many application domains where it is practically easier for customers or patients to give a *single* feedback for a set of options (products or medical treatments), click on one link from set of search engine outcomes etc., as opposed to comparing only two options at a time. To the best of our knowledge this is the first work to generalize the pairwise feedback model of dueling bandits to a subsetwise model in an online regret minimization setup.

## Related Work

The most related work to the current problem setup is [17], where also a fixed set of arms is chosen in each round. However, the key difference lies in the feedback structure. While in [17] the feedback is a pairwise prefer-

ence matrix consisting outcomes of one or more chosen pairs (maximum of  $\binom{n}{2}$  pairs), in our setting we only observe a single index of the winning arm. In [8], the authors also consider an extension of the dueling bandits framework where multiple arms are chosen in each round. We differ from their setup since we allow to choose only a fixed  $k$ -set of arms at each round, whereas [8] allows a variable number of arm selection. Moreover their work does not have any theoretical guarantees while we provide regret guarantees for our algorithms. Another work in the similar essence is DCM-bandits [12], where a list of  $k$  distinct items are offered at each round and the users choose one or more from it scanning the list from top to bottom. Their learning objective differs substantially from ours since the DCM feedback is based on a fairly different cascading feedback model. Moreover, their regret objective demands to find the set of best  $k$  items as opposed to finding a unique best item as in our case.

Another related body of literature is dynamic assortment optimization where the objective is offer a subset of a fixed set of items to the customers in order to maximize the expected revenue. The demand of any item depends on the substitution behavior of the customers that is captured mathematically by a choice model specifying the probability of a consumer selecting a particular item from any offered set. The problem has been studied under different choice models – e.g. multinomial logit [19], mallows and mixture of mallows [9], markov chain based choice models [10], single transition model [15], general discrete choice models [7] etc. A related bandit setting has also been studied as the MNL-Bandits problem in [2] where the learner selects a fixed set of  $k$  arms in each iteration. However, the feedback is observed from a multinomial logit model (MNL) which is different from the subset choice model we considered here. Moreover their setting takes item prices into account due to which the notion of the ‘best item’ is different from ours, i.e. the *Condorcet winner*. Thus our current problem setting can not be reduced to theirs and vice-versa.

## Proposed Work

The main challenge of *Battling-Bandits* lies in keeping track of the subset choice probabilities, i.e. the probability of an item winning in a given subset of  $k$  items, which could be potentially of size  $O(kn^k)$  as our objective is to find the “best” (Condorcet winner) item in the hindsight, we must allow repetitions of items within a offered set, which actually results in  $n^k$  possible number of subsets and each subset may give rise to atmost  $k$  choice probabilities depending on number of distinct items in the subset. Thus without any further structural or parametric assumptions on the feedback choice model, the problem becomes computationally intractable.

We thus introduce the *pairwise-subset choice model* for the purpose which is based on a pairwise preference model with Condorcet winner (Section 2) and propose three different algorithms (Section 3): The first two – *Battling-Doubler* and *Battling-MultiSBM*, are inspired by the Doubler and MultiSBM algorithms of [4] which works under a special class of *pairwise-subset choice model*, viz. *linear-subset choice model*, which naturally generalizes the linear-link based dueling feedback model of [4]. Both the algorithms are based on a novel reduction of the *battling bandit* problem to classical *multiarmed bandit* (MAB) [5]. Note that, although they apply to a special subclass of choice models, their regret guarantees hold for a richer class of arm sets, e.g. the regret of *Battling-Doubler* holds for any general class of (even infinitely many!) structured arms, whereas *Battling-MultiSBM* applies to any finite set of unstructured arms.

Our third algorithm, *Battling-duel*, works for the most general class of *pairwise subset choice models*, which is built on the novel idea of reducing *battling bandits* to the *dueling* case by using a dueling bandit algorithm as a black box, e.g. Relative-UCB [24] or Double-Thompson Sampling [21] which are guaranteed to work optimally (with  $O(n \log T)$  regret guarantee) under any pairwise preference based feedback model with Condorcet winner.

**Contributions.** The specific contributions of this paper can be summarized as follows:

1. We develop a novel class of subsetwise feedback model, called *pairwise-subset choice model*, which is based on a pairwise preference model with Condorcet winner that models the winning probability of an item in a battle in terms of its pairwise winning probabilities over others. We further analyse a special class of the above model, namely *linear-subset choice model* which generalizes the linear-link based dueling feedback model of [4] (Section 2).
2. We propose three algorithms for the problem of *Battling-Bandits* and analyze the regret guarantees of each under a natural notion of regret with respect to the Condorcet item (see Section 2.2). In particular, we show that the regret for the first two algorithms, *Battling-Doubler* and *Battling-MultiSBM*, scales as  $O(nk \ln^2(T))$  and  $O(nK(\ln(T) + n \ln(n) + n \ln \ln(T)))$  respectively, under *linear-subset choice model*. The regret of our third algorithm *Battling-Duel* holds under the general class of *pairwise-subset choice model* that scales as  $O(n \ln T)$  (Section 3).
3. We also prove a lower bound of  $\Omega(n \ln(T))$  for *Battling-Bandits* under *pairwise-subset choice model* which shows that the regret of *Battling-Duel* algorithm matches the lower bound (upto constant factor),

thereby making it the optimal possible algorithm for the current problem setup (Section 4). An interesting and perhaps surprising point to note here is that our regret bounds are independent of the subset size  $k$ , which implies the flexibility of playing larger subsets does not really help to gather information faster than the corresponding dueling case ( $k = 2$ ), atleast with the current setting of the battling problem.

4. Our extensive simulation based experiments justifies the derived theoretical guarantees of our proposed algorithms. We also compare our algorithms to *Self-Sparring* algorithm of [17], which is the only existing work applicable to our setting and show the superior performance of our algorithms on both synthetic and real word data sets (Section 5).

**Organization:** In Section 2, we describe the problem setup and introduce our notions of regret. Section 3 describes our three proposed algorithms along with theoretical regret guarantees. In Section 4, we derive the lower bound for *Battling-Bandits* problem. Section 5 presents our experimental evaluations and finally we conclude with remarks and directions for future work in Section 6.

## 2 PROBLEM SETUP

We proposed the problem of *Battling-Bandit* (or in short BB) as a natural generalization of the well-studied *Dueling-Bandit* (DB) problem in the bandit literature: Given a set of  $n \geq 2$  items (equivalently, bandit arms) denoted by  $[n] = \{1, 2, \dots, n\}$ , at each round  $t \in \mathbb{N}$ , the learner’s task is to build a multiset of  $k \geq 2$  items from  $[n]$ . The environment then picks a ‘winner’ – one of the  $k$  items from the chosen set – according to a subset choice model, unknown to the learner, and reveals the winner’s identity to the learner. We denote by  $S_t \subseteq [n]$  the multiset of  $k$  items chosen by the learner, i.e.,  $S_t \equiv (S_t(1), \dots, S_t(k)) \in [n]^k$ , and  $i_t^* \in [k]$  to be the index of the winning item in  $S_t$ , at iteration  $t$ . Each selection of  $k$  items also carries with it a cost or regret. The aim of the learner is to choose sets of items to minimize the total cumulative regret over a time horizon  $T$ .

From a different point of view, the setting of receiving the winner information of the subset  $S_t$  at each round  $t$  can be seen as a game between  $k$  players. Each player is associated with an index  $i \in [k]$  and chooses an arm from  $[n]$ , thus specifying the multiset  $S_t$ . The winning player is the index of the winning item revealed to the learner at time  $t$  – the winner of the battle among  $k$  players. Hence we named it as the problem of *Battling-Bandit* (BB). We next describe the rule of winner selection in a given battle.

### 2.1 Subset Choice Models

Given a fixed set of items (context), choice modeling defines the decision probability of preferring an individual or set of items through stochastic models. In the present case, we use subset choice models to specify the winning probability of an item in a given set. We first introduce a broad class of subset choice models, called *pairwise-subset choice models*, extending the notions from pairwise preference models for the dueling bandit ( $k = 2$ ) problem.

**Pairwise-subset choice model.** We define a class of subset choice models based on any pairwise preference matrix  $\mathbf{Q} \in [0, 1]^{n \times n}$ , where  $Q_{a,b}$  denotes the probability of arm  $a$  beating  $b$ , for any  $a, b \in [n]$ . Clearly,  $Q_{a,b} + Q_{b,a} = 1$ . Now given a set  $S \subseteq [n]$  of  $k$  items with  $S \equiv (a_1, \dots, a_k) \in [n]^k$  and any  $i \in [k]$ , we define the probability of  $i^{\text{th}}$  index gets selected as the winner as:

$$P(i|S) = \sum_{j=1, j \neq i}^k \frac{2Q_{a_i, a_j}}{k(k-1)} \quad \forall i \in [k]. \quad (1)$$

It can be easily checked that the formula above defines a valid probability distribution over the indices  $i \in [k]$ . We remark that since  $S$  is a multiset, the arm corresponding to the winning index is not necessarily unique; as an extreme example, in the multiset of  $k$  items  $(a_1, a_2, \dots, a_k)$ , we might have  $a_i = a \in [n]$ ,  $\forall i \in [k]$ , in which case each index  $i \in [k]$  wins with probability  $1/k$ .

Note that when  $k = 2$  (the dueling bandit case), for any  $S = (a, b)$ , we have  $P(i|S) = Q_{a_i, a_j}$ , where  $i, j \in [2], i \neq j$  and  $a_1 = a$  and  $a_2 = b$ ; which defines the pairwise probability of item  $a$  winning over item  $b$  in a pairwise duel. The following result provides an alternative interpretation of the *pairwise-subset choice model* in terms of the average probability that the item in question wins in a randomly chosen duel:

**Lemma 1.** *Let  $S \equiv (a_1, \dots, a_k) \in [n]^k$  be a multiset of  $k$  arms from  $[n]$ . Suppose  $U$  and  $V$  are two items (indices) chosen uniformly at random without replacement from  $[k]$ , and  $W \in [2]$  is drawn as the winning index according to the pairwise preference model  $\mathbf{Q}$  over the set  $(a_U, a_V)$ . Let  $X = U$  if  $W = 1$  and  $X = V$  if  $W = 2$ . Then, for each  $i \in [k]$ ,  $\mathbf{P}(i|S)$  in (1) is the probability that  $X = i$ .*

**Remark 1.** Note that if a *Condorcet winner* [16]  $a^* \in [n]$  exists with respect to the preference matrix  $\mathbf{Q}$ , i.e.  $\exists a^* \in [n]$ , such that  $Q_{a^*, j} > \frac{1}{2}$ ,  $\forall j \in [n] \setminus \{a^*\}$ , then it is easy to verify that for any (multi)set  $S \subseteq [n]$ ,  $P(i|S) > P(j|S)$  whenever  $a_i = a^*$  and  $a_j \in [n] \setminus \{a^*\}$ ,  $\forall i, j \in [k], i \neq j$ . Our objective is to identify this ‘best’ arm  $a^*$  and play it as often as possible; as spelt out in the definition of our regret (Section 2.2).

We now define an utility score based subset choice model as a special class of *pairwise-subset choice models*.

**Linear-subset choice model.** Let us assume that each arm  $a \in [n]$  is associated with an unknown utility score  $\theta_a \in [0, 1]$ . Then given a multiset of  $k$  items  $S \equiv (a_1, \dots, a_k) \in [n]^k$ , the probability that its  $i^{\text{th}}$  index gets selected as the winner with probability

$$\begin{aligned} \mathbf{P}(i|S) &= \frac{\sum_{j=1, j \neq i}^k (\theta_{a_i} - \theta_{a_j} + 1)}{k(k-1)} \\ &= \frac{1}{k} + \frac{\sum_{j=1, j \neq i}^k (\theta_{a_i} - \theta_{a_j})}{k(k-1)}, \forall i \in [k]. \end{aligned} \quad (2)$$

We call this the *linear-subset choice model* since the model is can be seen as a special case of *pairwise-subset choice model* when the underlying pairwise preference model  $\mathbf{Q}^\theta$  is linear, i.e.  $\Pr(a \text{ beats } b) = Q_{a,b}^\theta = \frac{(\theta_a - \theta_b + 1)}{2}$ ,  $a, b \in [n]$ . Note that this model generalizes the linear-link based pairwise feedback model of [4] at  $k = 2$ , as for any  $S = (a, b)$ , the probability  $\Pr(a \text{ beats } b) = (\theta_a - \theta_b + 1)/2$  becomes exactly equal to that of [4] used for modeling the dueling bandit feedback.

**Remark 2.** The *linear-subset choice model* satisfy a natural monotonicity property: For any set  $S \equiv (a_1, \dots, a_k)$  and  $i, j \in [k]$ ,  $\theta_{a_i} > \theta_{a_j} \Rightarrow P(i|S) > P(j|S)$ , thus the element with highest  $\theta$  score is most likely to get selected as the winner of set  $S$ . In other words, an ordering over  $\theta$  values, induces an ordering over the arms as well.

There also exist other notions subset choice models in the literature, e.g., one popular class among them is the *random utility based models* (RUM) [6] as described below:

**RUM based Choice Models.** One of the most popularly studied class of choice models are *Random Utility Models (RUM)*. RUM assumes an underlying ground truth of utility score  $\theta_i \in \mathbb{R}$  for each item  $i \in [n]$ , and assigns a conditional distribution  $\mathcal{D}_i(\cdot|\theta_i)$  for scoring item  $i$ . So given  $S \subseteq [n]$ , one first draws a random utility score  $X_i \sim \mathcal{D}_i(x_i|\theta_i)$   $x_i \in \mathbb{R}$ , for each item  $i \in S$ , and selects  $i$  with probability of  $X_i$  being the maximum among all the scores of items in  $S$ , i.e.  $i \sim \mathbf{P}(i|S) = \Pr(X_i > X_j \forall j \in S \setminus \{i\})$ ,  $\forall i \in S$

One widely used example of RUM is the *Multinomial-Logit (MNL)* or famously called *Plackett-Luce model (PL)* where  $\mathcal{D}_i$ 's are independent Gumbel distributions [6], i.e.  $\mathcal{D}_i(x_i|\theta_i) = e^{-(x_i - \theta_i)} e^{-e^{-(x_i - \theta_i)}}$ . In this case it can be shown that  $\mathbf{P}(i|S) = \frac{e^{\theta_{a_i}}}{\sum_{j \in S} e^{\theta_{a_j}}}$ ,  $\forall i \in S$ .

Similarly, alternative family of discrete choice models can be obtained assuming different distributions over the utility scores  $X_i$ , e.g. when  $(X_1, \dots, X_n) \sim \mathcal{N}(\boldsymbol{\theta}, \boldsymbol{\Sigma})$  are jointly normal with mean  $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$  and covariance  $\boldsymbol{\Sigma}$ , above reduces to *Multinomial Probit Model (MNP)*, although unlike MNL, choice probabilities  $\mathbf{P}(i|S)$  for MNP do not have a closed formed solution [20].

## 2.2 Measuring performance – Regret

We compare the performance of the learner's strategy with respect to a 'best' arm of the choice model. As defined before, for *pairwise-subset choice models*, the most natural candidate for the 'best' arm is the Condorcet winner  $a^* \in [n]$ , i.e.  $Q_{a^*,a} > \frac{1}{2}$ ,  $\forall a \in [n] \setminus \{a^*\}$ , assuming  $\mathbf{Q}$  contains a Condorcet arm. Then an intuitive way to define the regret of *Battling-Bandit* is by extending the notion of dueling bandit regret [24, 22, 4] as follows:

$$R_T^{BB} = \sum_{t=1}^T \left( \frac{\sum_{a \in S_t} (Q_{a^*,a} - \frac{1}{2})}{k} \right), \quad (3)$$

Consequently, the aim of the learner is to play sets  $S_t$  at times  $t = 1, 2, \dots$  to keep the regret as *low* as possible which in fact corresponds to playing  $a^*$  as many times as possible in  $S_t$ , at any round  $t$ . Clearly only if the learner plays the set  $S_t = (a_1, a_2, \dots, a_k)$  such that  $a_i = a^* \forall i \in [k]$ , the corresponding regret incurred at round  $t$  is 0.

Note that, for *linear-subset choice models*, the 'best' arm is  $a^* = \operatorname{argmax}_{a \in [n]} \theta_a$ , i.e., an arm having the highest utility score, as that happens to be the Condorcet winner of the underlying pairwise preference model  $\mathbf{Q}^\theta$ . Thus using (3), we can similarly define the regret  $R_T^{BB}$  in this case as well with  $Q_{a^*,a}^\theta = \frac{(\theta_{a^*} - \theta_a + 1)}{2}$ ,  $\forall a \in [n]$ .

## 3 PROPOSED ALGORITHMS

In this section we describe three algorithms for the *Battling-Bandit* problem. The first two algorithms, *Battling-Doubler* and *Battling-MultiSBM*, respectively generalize the two algorithms for utility based dueling bandits (UBDB) Doubler and MultiSBM, proposed by Ailon et al. [4], which essentially address the problem by using classical multi-armed bandit (MAB) algorithm as an underlying black box. Our third algorithm, *Battling-Duel* is based on dueling matches that uses black-box instances of a dueling bandit algorithms for the purpose.

The main advantage of *Battling-Doubler* is that it works even with an infinite set of arms, although its regret guarantee is off by an extra multiplicative factor of  $\ln T$ . On the other hand, *Battling-MultiSBM* guarantees  $O(nk \ln T)$  regret for any finite set of  $n$  arms. However both these algorithms are tailored for *linear-subset choice model*, unlike our third algorithm, *Battling-duel*, which in contrast applies to the general class of *pairwise-subset choice models* (Section 2) and is shown to perform optimally with a regret guarantee of  $O(n \log T)$  as long as the it uses an optimal dueling bandit algorithm as the black box.

Before describing our proposed algorithms, it is worth describing the black-box algorithms used to design them.

**SBM:** We call a black box algorithm for the classical

MAB problem<sup>1</sup> as a single bandit machine (SBM). Any SBM instance  $\mathcal{S}$  supports three operations: Reset, Advance and Feedback.  $\text{Reset}(\mathcal{S})$  initializes the instance  $\mathcal{S}$ .  $\text{Advance}(\mathcal{S})$  suggests which arm to play next and  $\text{Feedback}(\mathcal{S}, r)$  feedbacks a reward  $r \in [0, 1]$  to  $\mathcal{S}$ .

**Definition 2. ( $\alpha$ -robust SBM) [4]** Consider a SBM instance  $\mathcal{S}$  with  $n$  arms. For any sub-optimal arm  $x \in [n]$ , let  $T_x$  be the number of times  $x$  is played by  $\mathcal{S}$  in  $T$  rounds. The SBM  $\mathcal{S}$  is said to be  $\alpha$ -robust if  $\forall s \geq 4\alpha\Delta_x^{-2} \ln T$ , it holds that  $\mathbf{P}[T_x > s] < \frac{2}{\alpha}(s/2)^{-\alpha}$ , where  $\Delta_x$  denotes the gap between the expected reward of the best arm and that of arm  $x$  in the underlying MAB instance.

**DBM:** Similar to SBM, we call a black box algorithm for the dueling bandit problem as dueling bandit machine (DBM). A DBM also supports the same three operations as that of a SBM instance, with the only difference being that a DBM instance  $\mathcal{D}$ , outputs *two* arms  $x, y \in [n]$  on the  $\text{Advance}(\mathcal{D})$  operation instead of one. We refer  $x$  as the right arm and  $y$  the left arm. Also, in this case, the feedback  $r$  upon  $\text{Feedback}(\mathcal{S}, r)$  is a preference relation between  $x$  and  $y$  defined as  $r = \mathbf{1}(y \text{ beats } x)$ . We now describe our main algorithms and their regret guarantees. Proofs of all the theorems are deferred to the Appendix.

### 3.1 Battling-Doubler

The first algorithm, *Battling-Doubler*, maintains a single SBM instance  $\mathcal{S}$ . The total time horizon  $T$  is divided into exponentially growing epochs, and a MAB game is played within each epoch using  $\mathcal{S}$ . Specifically, at any epoch, the algorithm plays the first  $(k-1)$  arms uniformly from the multiset of arms  $\mathcal{L}$  selected by  $\mathcal{S}$  in the previous epoch, the  $k^{\text{th}}$  arm is played adaptively according to suggestion of the SBM  $\mathcal{S}$  upon which  $\mathcal{S}$  receives a binary reward based on the defeat or victory of the  $k^{\text{th}}$  arm it suggested. Algorithm 1 describes *Battling-Doubler* formally.

**Remark 3.** Note that when  $[n]$  is finite, in order to save the memory overhead of maintaining the multiset  $\mathcal{L}$  (line 14), a more elegant approach can be to instead maintain a probability distribution  $\mathbf{p}^t \in \Delta_n$  over the  $n$  arms, where  $p_a^t \in [0, 1]$  denotes the fraction of times arm  $a \in [n]$  was played as the  $k^{\text{th}}$  arm of  $\mathcal{S}_{t-1}$  at round  $(t-1)$ , and sample  $a_1^t, a_2^t, \dots, a_{k-1}^t$  according to  $\mathbf{p}^t$  (in line 7).

**Theorem 3. Battling-Doubler Regret for general arm sets.** Assume that the SBM  $\mathcal{S}$  used by *Battling-Doubler* has expected regret no more than  $c \ln^\beta(t)$  at the end of  $t \in \mathbb{N}$  rounds, where  $c > 0, \beta > 0$  are constants independent

<sup>1</sup>Given a fixed set of  $n$  arms, each associated to a reward distribution with their expectation bounded in the range  $[0, 1]$ , the classical MAB defines the problem of identifying the best arm with highest expected reward by actively selecting one arm at each round sequentially and receiving a feedback from its underlying reward distribution in an online fashion [5].

---

#### Algorithm 1 Battling-Doubler

---

```

1: Initialize:  $\mathcal{S} \leftarrow$  an SBM over set of  $[n]$  arms
2:    $\mathcal{L} \leftarrow [n]$ 
3:    $\ell \leftarrow 1, t \leftarrow 1$ 
4: while true do
5:   reset( $\mathcal{S}$ )
6:   for  $j = 1, 2, 3 \dots 2^\ell$  do
7:     Select  $a_1^t, a_2^t, \dots, a_{k-1}^t$  uniformly from  $\mathcal{L}$ 
8:      $a_k^t \leftarrow \text{Advance}(\mathcal{S})$ 
9:     Play  $S_t = (a_1^t, a_2^t, \dots, a_k^t)$ 
10:    Receive winner  $i_t^* \in [k]$ 
11:    Feedback( $\mathcal{S}, \mathbf{1}(i_t^* = k)$ )
12:     $t \leftarrow t + 1$ 
13:   end for
14:    $\mathcal{L} \leftarrow$  the multiset of arms played as  $a_k^t$  in epoch  $\ell$ 
15:    $\ell \leftarrow \ell + 1$ 
16: end while

```

---

of  $t$ . Then, under the linear-subset choice model, the expected regret of *Battling-Doubler* at the end of  $T$  rounds is at most  $2c \frac{k\beta}{\beta+1} \ln^{\beta+1}(T)$ .

**Corollary 4. Battling-Doubler Regret for finite set of arms.** Assume the SBM  $\mathcal{S}$  used in *Battling-Doubler* is the Upper Confidence Bound (UCB) algorithm [5] and suppose the underlying feedback model used for the *Battling-Bandit* problem is linear-subset choice model with parameter  $\theta \in [0, 1]^n$ , such that  $\theta_1 > \max_{i=2}^n \theta_i$ . Then the expected regret of *Battling-Doubler* is  $O(kH \log^2 T)$ , where  $H := \sum_{i=2}^n \frac{1}{\Delta_i}$ , and  $\Delta_i = \theta_1 - \theta_i \forall i \in [n]$ .

Note that, the above regret guarantee becomes trivial if the gap parameter  $H$  is large. Instead, we can also derive the a gap-independent regret bound as follows:

**Corollary 5. Battling-Doubler Regret (Gap-independent regret bound)** Assume that the SBM  $\mathcal{S}$  in *Battling-Doubler* is the Upper Confidence Bound (UCB) algorithm [5]. Then under any linear-subset choice model, the expected regret of *Battling-Doubler* is at most  $O(k\sqrt{nT \log^3 T})$ .

### 3.2 The Battling-MultiSBM algorithm

Unlike *Battling-Doubler*, *Battling-MultiSBM* simultaneously maintains  $n$  independent SBMs  $\mathcal{S}_a, \forall a \in [n]$ . At each round  $t$ , the first  $(k-1)$  arms are played according to the last  $(k-1)$  arms of round  $(t-1)$  and the  $k^{\text{th}}$  arm is played according to the suggestion of SBM  $\mathcal{S}_{a_k^{t-1}}$  which corresponds to the  $k^{\text{th}}$  arm played at round  $t-1$ . As before, a binary reward is fed back to  $\mathcal{S}_{a_k^{t-1}}$  based on whether the arm it suggested at round  $t$  wins or not. *Battling-MultiSBM* is formally described in Algorithm 2.

**Theorem 6. Battling-MultiSBM Regret with finite arms.** Suppose all the SBMs used

---

**Algorithm 2 Battling-MultiSBM**

---

- 1: **Initialize:** For each arm  $a \in [n]$ ,  $\mathcal{S}_a \leftarrow$  new SBM over set of arms  $[n]$ .  $\text{Reset}(\mathcal{S}_a)$ .
  - 2:       Select  $a_2^0, a_3^0, \dots, a_k^0$  uniformly from  $[n]$
  - 3: **for**  $t = 1, 2, \dots, T$  **do**
  - 4:    $a_j^t = a_{j+1}^{t-1}, \forall j \in [k-1]$
  - 5:    $a_k^t \leftarrow \text{advance}(\mathcal{S}_{a_{k-1}^t})$
  - 6:   Play  $S_t = (a_1^t, a_2^t, \dots, a_k^t)$
  - 7:   Receive winner  $i_t^* \in [k]$
  - 8:   Feedback  $(\mathcal{S}_{a_{k-1}^t}, \mathbf{1}(i_t^* = k))$
  - 9: **end for**
- 

in *Battling-MultiSBM* are  $\alpha$ -robust, where  $\alpha = \max\{3, 2 + \frac{\ln K}{\ln \ln T}\}$ . Also assume  $\theta_1 > \max_{i=2}^n \theta_i$ ,  $\Delta_i = (\theta_1 - \theta_i)$ ,  $\forall i \in [n]$  and  $H := \sum_{i=2}^n \frac{1}{\Delta_i}$ . Then, under the linear-subset choice model with parameter  $\theta \in [0, 1]^n$ , the regret of *Battling-MultiSBM* is  $O\left(kH\alpha \left(\ln T + n \ln n + n \ln \ln T + 2 \sum_{i=2}^n \ln \frac{1}{\theta_1 - \theta_i}\right)\right)$ .

Note that the above bound is essentially of  $O(nk \log T)$ , since  $H = O(n)$  given a fixed instance of *linear-subset choice model*  $\theta$ . Similar *Battling-Doubler*, here also we can derive a gap-independent regret bound as follows:

**Corollary 7. Battling-MultiSBM Regret (Gap independent regret bound).** *If the SBMs used in Battling-MultiSBM are  $\alpha$ -robust,  $\alpha = \max\{3, 2 + \frac{\ln K}{\ln \ln T}\}$ , then under any linear subset choice model, the regret of Battling-MultiSBM is  $O\left(k\sqrt{nT}\alpha \left(\sqrt{\ln T} + n \frac{(\ln n + \ln \ln T)}{\sqrt{\ln T}}\right)\right)$ .*

### 3.3 Battling-Duel

Our third algorithm *Battling-Duel*, is a simple general algorithm for *Battling-Bandits* that uses a good (low-regret) dueling bandit algorithm as its black-box and works under any *pairwise-subset choice model*. *Battling-Duel* maintains an instance of a dueling bandit algorithm (DBM)  $\mathcal{D}$ , at each round  $t$ , the algorithm receives two arms  $x_t, y_t \in [n]$  from  $\mathcal{D}$ , and plays the multiset  $S_t = (x_t, x_t, \dots, x_t, y_t, y_t, \dots, y_t)$  of  $k$  arms by replicating  $x_t$  and  $y_t$  equal number of times on an average. More precisely,  $x_t$  is replicated for either  $\lfloor k/2 \rfloor$  or  $\lceil k/2 \rceil$  number of times with equal probability of  $\frac{1}{2}$  and the rest half of  $S_t$  is filled with  $y_t$ . Upon playing  $S_t$ , once the identity of the battling winner is revealed,  $\mathcal{D}$  receives a corresponding dueling feedback depending on if its  $x_t$  or  $y_t$ . The formal description is given in Algorithm 3.

The following result shows an exact equivalence between the regret of *Battling-Duel*  $R_T^{BB}(BD)$  and that of its underlying dueling bandit algorithm  $R_T^{DB}(\mathcal{D})$ .

**Theorem 8. Battling-Duel Regret.** *Under any pairwise-subset choice model with preference matrix  $\mathbf{Q}$ , the regret*

---

**Algorithm 3 Battling-Duel**

---

- 1: **Initialize:**  $\mathcal{D} \leftarrow$  new dueling bandit algorithm over set of  $[n]$  arms
  - 2: **for**  $t = 1, 2, \dots$  **do**
  - 3:    $\{x_t, y_t\} \leftarrow \text{Advance}(\mathcal{D})$
  - 4:    $S_t = (x_t, \dots, x_t, y_t, \dots, y_t)$ , where  $x_t$  and  $y_t$  are respectively replicated for  $\lfloor k/2 \rfloor$  and  $\lceil k/2 \rceil$  or  $\lceil k/2 \rceil$  and  $\lfloor k/2 \rfloor$  times, each with probability  $\frac{1}{2}$ .
  - 5:   Receive winner  $i_t^* \in [k]$
  - 6:   Feedback:  $(\mathcal{D}, \mathbf{1}(S_t(i_t^*) = y_t))$
  - 7: **end for**
- 

incurred by *Battling-Duel (BD)* in  $T$  rounds is

$$R_T^{BB}(BD) = \kappa R_T^{DB}(\mathcal{D}),$$

where  $\kappa = \frac{2(k-1)}{k}$  if  $k$  is even, or  $\kappa = \frac{2k}{k+1}$  otherwise.  $R_T^{DB}(\mathcal{D})$  is the regret incurred by  $\mathcal{D}$  in  $T$  rounds, i.e.  $R_T^{DB}(\mathcal{D}) = \sum_{t=1}^T \frac{(Q'_{a^*, x_t} - \frac{1}{2}) + (Q'_{a^*, y_t} - \frac{1}{2})}{2}$  as per the standard definition of regret for any dueling bandit algorithm  $\mathcal{D}$  [24, 22] under  $\mathbf{Q}'$  (as also obtained from (3) with  $k = 2$ ),  $\mathbf{Q}'$  being the pairwise preference model perceived by  $\mathcal{D}$  in Algorithm 3, such that  $Q'_{x_t, y_t} := \mathbf{P}(i_t^* = x_t)$ , for any choices of  $(x_t, y_t)$ , at any round  $t$ .

Using  $\mathcal{D}$  as the state-of-the-art RUCB algorithm [24], gives the following regret guarantee for *Battling-Doubler*:

**Corollary 9. Battling-Duel Regret with RUCB.** *Assume that the DBM  $\mathcal{D}$  in Battling-Duel is RUCB [24], then under any pairwise-subset choice models with preference matrix  $\mathbf{Q}$ , the regret of Battling-Duel is*

$$\kappa \left( \tilde{C} + \sum_{i \in [a] \setminus \{a^*\}} \frac{2\alpha(\Delta_i + 4\Delta_{\max})}{\Delta_i^2} \ln T \right), \quad (4)$$

where  $\tilde{C}$  is a problem instance (i.e.  $\mathbf{Q}$ ) dependent constant, independent of the time horizon  $T$ ,  $\Delta_i = \left(Q_{a^*, i} - \frac{1}{2}\right)$ ,  $\Delta_{\max} = \max_{i \in [n]} \Delta_i$ ,  $\forall i \in [n]$ ,  $\kappa = \frac{2(k-1)}{k}$  if  $k$  is even, or  $\kappa = \frac{2k}{k+1}$  otherwise.

Note that Corollary 9 essentially gives an  $O(n \log T)$  regret guarantee for *Battling-Duel* since the first term of (4) is constant given a fixed  $\mathbf{Q}$ , whereas the second term scales as  $\log T$  for each  $(n-1)$  suboptimal arms. Clearly *Battling-Duel* performs the best in terms of dependency of its regret guarantee on  $n$ ,  $k$  and  $T$ , among all three of our proposed algorithms. We next establish a matching regret lower bound of  $\Omega(n \log T)$  for the problem, which essentially proves the optimality of *Battling-Duel*.

## 4 REGRET LOWER BOUND

In this section, we derive an  $\Omega(n \ln T)$  regret lower bound (Theorem 8) for the problem of *Battling-Bandit* under any

*pairwise-subset choice model*. Our proof involves reduction of an instance of the *Dueling-Bandit (DB)* problem to an instance of the *Battling-Bandit (BB)* problem and solve the former using an algorithm designed for the later. More specifically, we first prove the following key result:

**Theorem 10** (Reducing *Dueling-Bandit* to *Battling-Bandit*). *There exists a reduction from the Dueling-Bandits problem to Battling-Bandits, which preserves expected regret under any pairwise-subset choice model.*

*Proof.* Consider that we have an algorithm  $\mathcal{A}_{BB}$  for the BB problem and our goal is to construct a DB algorithm  $\mathcal{A}_{DB}$  using this. One intuitive way to do this is: At any round  $t$ , first play  $\mathcal{A}_{BB}$  to generate the set  $S_t$  of  $k$  arms, randomly sample two indices  $i_t, j_t \in [k]$  from the set  $[k]$ , play  $a_{i_t}, a_{j_t}$  respectively as the left and right arm of DB, receive the winner  $w_t$  of the duel ( $a_{i_t}, a_{j_t}$ ) from the DB environment and feedback a winning index  $i_t^*$  to  $\mathcal{A}_{BB}$  accordingly as the winner of the  $S_t$  battle. The resulting algorithm  $\mathcal{A}_{DB}$  is as summarized in Algorithm 4.

---

**Algorithm 4**  $\mathcal{A}_{DB}$ : Reducing DB to BB

---

- 1: **for**  $t = 1, 2, \dots$  **do**
  - 2:    $S_t \leftarrow$  Multiset of arms played by  $\mathcal{A}_{BB}$  at round  $t$
  - 3:   Draw  $i_t, j_t \sim \text{Unif}[k]$  (without replacement)
  - 4:   Play  $(a_{i_t}, a_{j_t})$
  - 5:   Receive feedback  $w_t = \mathbf{1}\{a_{i_t} \text{ beats } a_{j_t}\}$
  - 6:   Return  $i_t^* = i_t w_t + j_t (1 - w_t) \in \{i_t, j_t\}$  to  $\mathcal{A}_{BB}$  as winning index to  $\mathcal{A}_{BB}$
  - 7: **end for**
- 

The crucial observation is that if the DB environment actually simulates the winner from an underlying (unknown) preference matrix  $\mathbf{Q}$ , then internally  $\mathcal{A}_{BB}$  sees a world where subset choice probabilities are given by  $\mathbf{P}(i|S) = \frac{\sum_{j=1, j \neq i}^k 2Q_{a_i, a_j}}{k(k-1)}$ , due to Lemma 1. Thus at each round  $t$ , the average instantaneous regret of  $\mathcal{A}_{DB}$  is:

$$\begin{aligned} & \mathbf{E}_{i_t, j_t \sim [k], i_t \neq j_t} [r_t(\mathcal{A}_{DB})] \\ &= \mathbf{E}_{i_t, j_t \sim [k], i_t \neq j_t} \left[ \frac{(Q_{a^*, a_{i_t}} - \frac{1}{2}) + (Q_{a^*, a_{j_t}} - \frac{1}{2})}{2} \right] \\ &= \frac{1}{k(k-1)} \sum_{i=1}^k 2(k-1) \left[ \frac{(Q_{a^*, i} - \frac{1}{2})}{2} \right] \\ &= \sum_{i=1}^k \left[ \frac{(Q_{a^*, i} - \frac{1}{2})}{k} \right] = r_t(\mathcal{A}_{BB}). \end{aligned}$$

where the second equality follows since the expectation is taken over the random draw of two indices  $i_t, j_t$  from  $[k]$  without replacement,  $a^* \in [n]$  being the Condorcet arm of  $\mathbf{Q}$  and  $r_t(\mathcal{A}_{BB})$  denotes the instantaneous

regret of  $\mathcal{A}_{BB}$  at round  $t$ , as defined in Section 2.2. Thus we get  $\mathbf{E}[R_T(\mathcal{A}_{DB})] = \mathbf{E} \left[ \sum_{t=1}^T r_t(\mathcal{A}_{DB}) \right] = \sum_{t=1}^T r_t(\mathcal{A}_{BB}) = R_T(\mathcal{A}_{BB})$ , proving the claim.  $\square$

**Corollary 11.** *Given any algorithm  $\mathcal{A}_{BB}$  for Battling-Bandits (BB) under pairwise-subset choice model associated to a preference matrix  $\mathbf{Q}$  with Condorcet winner, there exists a problem instance of BB such that*

$$\liminf_{T \rightarrow \infty} \frac{\mathbf{E}[R_T(\mathcal{A}_{BB})]}{\ln T} \geq \sum_{i \in [n] \setminus \{a^*\}} \min_{j \in B_i} \frac{\Delta_{ij}}{\text{kl}(Q_{i,j}, \frac{1}{2})},$$

where  $\Delta_{ij} = \frac{(Q_{a^*, i} - \frac{1}{2}) + (Q_{a^*, j} - \frac{1}{2})}{2}$ ,  $B_i = \{j \mid Q_{i,j} < \frac{1}{2}\}$ , and  $\text{kl}(p, q) = p \log \frac{p}{q} + (1-p) \log \frac{1-p}{1-q}$  denotes the *kl-divergence* between two Bernoulli distributions with parameters  $p$  and  $q$ .

**Remark 4.** Note that Corollary 11 implies that the asymptotic regret lower bound is  $\Omega(n \log T)$  since  $\sum_{i \in [n] \setminus \{a^*\}} \min_{j \in B_i} \frac{\Delta_{ij}}{\text{kl}(Q_{i,j}, \frac{1}{2})}$  essentially involves a sum over  $(n-1)$  terms, each being a constant for a fixed  $\mathbf{Q}$ , thus making it  $\Omega(n)$ . This therefore concludes that the regret guarantee of *Battling-Duel* (Theorem 8) is indeed optimal when used with a ‘good’ dueling bandit algorithm of  $O(n \log T)$  regret guarantee (Corollary 9).

**Remark 5.** The optimal regret guarantee of  $O(n \log T)$  of *Battling-Bandits* with *pairwise-subset choice model* is independent of the subset size  $k$ , which essentially clarifies the *tradeoff of learning rate with subset size  $k$*  — even with the flexibility of playing larger  $k$ -sized sets ( $k \geq 2$ ) does not help in faster information aggregation than the corresponding dueling setup ( $k = 2$ ) — which might appear counter intuitive but is justified as information theoretically the winner information of a  $k$ -set does not reveal any additional information over that in a 2-set.

## 5 EXPERIMENTS

We now present empirical evaluations for our proposed algorithms on different synthetic and real world datasets and also compare them with the *Self-Sparring* algorithm of [17], which is the only existing work applicable to our framework. In all our experimental results, our proposed algorithm *Battling-Duel* outperforms the rest, rightfully justifying the optimality of its regret guarantees as discussed in Remark 4. A detailed discussion is given below:

**Algorithms.** We compared the performances of the following 5 algorithms: **1. BD-RUCB:** *Battling-Duel* (Section 3.3) with *RUCB* [24] as the DBM  $\mathcal{D}$ . **2. BD-TS:** *Battling-Duel* (Section 3.3) with *Double-Thompson Sampling* [21] as the DBM  $\mathcal{D}$ . **3. B-Dblr:** *Battling-Doubler* (Section 3.1) with *UCB* [5] as the SBM  $\mathcal{S}$ . **4. B-Msbm:** *Battling-MultiSBM* (Section 3.2) with *UCB* [5] as the

SBM  $S$ . **5. SS-TS:** *Self-Sparring* algorithm [17] with Thompson Sampling [3]. This algorithm closely resembles to the Sparring algorithm of [4] that maintains a single copy of SBM (a MAB algorithm), and at each round  $t$ , it queries the SBM  $k$  times to produce a  $k$ -sized battling set  $S_t$ . To the best of our knowledge no other existing work applies to the setup of *Battling-Bandits*.

**Experimental Setup and Performance Measures** We plot regret of each of the 5 algorithms for different real world and synthetic datasets, as describe in Section 5.1 and 5.2. In all the experiments the time horizon is fixed to  $T = 5000$  (with few exceptions if the regret plot do not converge within 5000 time iterations) and the experiments are run for different item sizes  $n$  and subset sizes  $k$  as specified in the corresponding experiments. The measure of performances in all the plots is the total regret  $R_T^{BB}$  in  $T$  round as defined in (3). All results are reported as average across 50 runs along with the standard deviations.

### 5.1 Experiments on Synthetic Datasets

For synthetic experiments with *linear-subset choice model* (Section 2), we use the following four different utility score vectors  $\theta$ : 1. *arith* 2. *geom* 3. *g1* and 4. *g3*.

Both *arith* and *geom* has  $n = 8$  items, with item 1 being the ‘best’ (Condorcet) item of highest score, i.e.  $\theta_1 > \max_{i=2}^8 \theta_i$ ; the rest of the  $\theta_i$ s are in an arithmetic or geometric progression respectively, as their names suggest. The two score vectors are described in Table 2.

arith	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
geom	0.8	0.7	0.512	0.374	0.274	0.2	0.147	0.108

Table 1: Parameters for *linear-subset choice model*

The next two utility score vectors has  $n = 15$  items in each. Similarly as before, item 1 is the Condorcet winner here as well, with  $\theta_1 > \max_{i=2}^{15} \theta_i$ . More specifically for *g1*, the individual score vectors are of the form:  $\theta_i = 0.8$ , if  $i = 1$  and  $\theta_i = 0.2$ ,  $\forall i \in [15] \setminus \{1\}$ . For *g3*, the individual score vectors are of the form:  $\theta_i = 0.8$ , if  $i = 1$ ,  $\theta_i = 0.7$ ,  $\forall i \in [8] \setminus \{1\}$  and  $\theta_i = 0.6$ , otherwise

Clearly, *g3* is a harder model (for learning the Condorcet item), than *g1* as in the former case, the gap between the items scores are very close to each other and the best and the second best item is only 0.1 distance apart, whereas gap is 0.6 for every suboptimal items in the later case. The fact is reflected in our experimental results as well.

**Results on linear-subset choice model.** Figure 1 shows the comparative regret performances of the 5 algorithms, for *Battling-Bandits* with *linear-subset choice model* on 4 different utility score vectors as described above. We set  $k = 4$  for *arith* and *geom* and  $k = 8$  for the rest two.

The results clearly shows the superiority of *Battling-Duel* compared to the rest. In fact, BD-TS performs slightly better than BD-RUCB as Thompson sampling based algorithms are known to perform empirically well compared to UCB based algorithms (in spite of both having a similar  $O(n \log T)$  regret guarantee), although it comes at the cost of a higher performance variability as evident from our plots. SS-TS being a Thompson Sampling based algorithm, it exhibits a very high variability too.

Figure 1: Averaged regret over time on synthetic datasets (on *linear-subset choice model*)

**Results on MNL choice model.** We also run the above experiment for the same 4 utility scores 1. *arith* 2. *geom* 3. *g1* and 4. *g3* on *Multinomial Logit (MNL)* choice model (as describes in Section 2). Similarly as before, even in this case the two *Battling-Duel* algorithms, BD-RUCB and BD-TS, perform the best among all 5. As argued before, *g3* being the ‘hardest instance to learn’, for both *linear* and MNL choice models, we had to run the algorithms for comparatively larger number of iterations until convergence. The results are shown in Figure 2.

Figure 2: Averaged regret over time on synthetic datasets (on *multinomial logit (MNL) model*)

**Results on Pairwise-subset choice model.** We finally run experiments for the general *pairwise-subset choice model* on two synthetic pairwise preference matrices: *arxiv-pref* and *arith-pref* with  $n = 6$  and  $n = 8$  respectively. See Appendix E.2 for the details of the datasets.

We run the experiments for  $k = 4$  for both the datasets. As before, the two *Battling-Duel* algorithms excel the rest in this case as well, as follows from Figure 3.

Figure 3: Averaged regret over time on synthetic datasets (on *pairwise-subset choice model*)

## 5.2 Experiments on Real Datasets

We also evaluated our method on four real-world preference learning datasets: 1. *Car* [1] 2. *Hurdy* [16] 3. *Tennis* [16] and 4. *Sushi* [11]. Each of the dataset contains pairwise preferences of a given set of  $n$  items, where  $n = 10$  for both *Car* and *Hurdy*, and it is respectively 8 and 16 for *Tennis* and *Sushi*. All the preference matrices contain a Condorcet winner (as required as per our problem setup in Section 2). We set  $k = 6$  for both *Hurdy* and *Tennis* and respectively 4 and 10 for *Car* and *Sushi*. The description of the datasets along with data extraction procedure and the actual preference matrices are given in Appendix E.

Figure 4: Averaged regret over time on real datasets (on *pairwise-subset choice model*)

**Results.** Figure 4 shows the comparative regret performances of the 5 algorithms used. As expected, BD-TS turns out to be the best algorithm for most of the cases, with BD-RUCB following it closely, whereas B-BMsbm and B-Dblr performs poorly in comparison, rightfully justifying their suboptimal regret guarantees (Theorem 3 and 6). SS-TS shows a very high variability as usual and performs worse than both BD-RUCB and BD-TS.

## 5.3 Effect of varying subset size $k$

We also analyze the scaling of the regret performances our optimal algorithm *Battling-Duel* with increasing  $k$ .

We use BD-RUCB for the purpose on two score vectors 1.  $g1$  and 2.  $g1-big$  with varying  $k$ , keeping  $n$  fixed to 15 and 50 respectively. Here  $g1-big$  is just a larger version of  $g1$  utility score with  $n = 50$  items, such that  $\theta_1 = 0.8$  and  $\theta_i = 0.2, \forall i \in [50] \setminus \{1\}$  (see Appendix E for details). The results are shown in Figure 5, which clearly reflects that the learning rate of *Battling-Duel* does not scale with  $k$ , justifying that its regret guarantee is indeed independent of the subset size  $k$  (Theorem 8).

Figure 5: Averaged regret over time with varying  $k$  and fixed  $n$  (on *linear-subset choice model*)

## 6 CONCLUSION AND FUTURE WORK

We introduce the problem of *Battling-Bandit* – generalization of the well-studied *Dueling-Bandit* problem, where the objective is to find the ‘best’ arm by successively playing a subset of  $k$  arms from a pool of  $n$  arms and subsequently receiving the winner feedback in an online fashion. For this we develop a novel  $k$ -wise feedback model, viz. *pairwise-subset choice model* and propose three algorithms along with their regret bound guarantees. We also show a matching regret lower bound of  $\Omega(n \log T)$  proving the optimality of our algorithms.

Our proposed framework of *Battling-Bandits* opens up a set of new directions to explore – with different choices of feedback models, regret objectives, or even applying this to new settings like revenue maximization, contextual or adversarial bandits etc. One very interesting point noted here is that the optimal regret guarantee is independent of the subset size  $k \geq 2$ , which implies the flexibility of playing larger subsets does not really help to gather information faster than the corresponding dueling case ( $k = 2$ ), atleast with the current *pairwise-subset choice feedback model*. It will be interesting to study the tradeoff of the subset size on the regret (learning rate to identify the ‘best’ arm) for different subset choice models, e.g. MNL, MNP etc. Lastly, it would also be useful to analyze other dueling bandit algorithms, e.g. Sparring [4], especially for large set of structured arms and their implications in solving *Battling-Bandit* with different settings.

## ACKNOWLEDGEMENTS

Thanks to Arun Rajkumar (Conduent Labs, India) for all the useful discussions and the anonymous reviewers for their insightful comments. This work is supported by Qualcomm, ACM-India and IARCS travel grant.

## Abstract

This work investigates the training of conditional random fields (CRFs) via the stochastic dual coordinate ascent (SDCA) algorithm of [Shalev-Shwartz and Zhang \(2016\)](#). SDCA enjoys a linear convergence rate and a strong empirical performance for binary classification problems. However, it has never been used to train CRFs. Yet it benefits from an “exact” line search with a single marginalization oracle call, unlike previous approaches. In this paper, we adapt SDCA to train CRFs, and we enhance it with an adaptive non-uniform sampling strategy based on block duality gaps. We perform experiments on four standard sequence prediction tasks. SDCA demonstrates performances on par with the state of the art, and improves over it on three of the four datasets, which have in common the use of sparse features.

## 1 INTRODUCTION

The conditional random field (CRF) model ([Lafferty et al., 2001](#)) is a common tool in natural language processing and computer vision for structured prediction. The optimization of this model is notoriously challenging. [Schmidt et al. \(2015\)](#) describes a practical implementation of the stochastic average gradient (SAG) algorithm ([Roux et al., 2012](#)) for CRFs and proposes a non-uniform sampling scheme that boosts performance. This algorithm (SAG-NUS) is currently the state of the art for CRFs optimization and we refer to [Schmidt et al. \(2015\)](#) for a detailed review of competing methods.

Deterministic (batch) methods such as L-BFGS ([Sha and Pereira, 2003](#); [Wallach, 2002](#)) have linear convergence rate but the cost per iteration is large. On the other hand, the online exponentiated gradient method (OEG) ([Collins et al., 2008](#)) and SAG are both members of a family of

algorithms with cheap stochastic updates and linear convergence rates, and they have both been applied to the training of CRFs. They are called variance reduced algorithms, because their common point is to use memory to reduce the variance of the stochastic update direction as they get closer from the optimum. [Johnson and Zhang \(2013\)](#) coined the name stochastic variance reduced gradient (SVRG) and [Defazio et al. \(2014\)](#) unified the family.

The stochastic dual coordinate ascent (SDCA) algorithm proposed by [Shalev-Shwartz and Zhang \(2013b, 2016\)](#) is a member of this family that has not yet been applied to CRFs. It is closely related to OEG in that it also does block-coordinate ascent on the dual objective. Yet an interesting advantage of SDCA over OEG (and SAG) is that the form of its update makes it possible to perform an “exact” line search with only *one* call to the *marginalization oracle*, i.e. the computation of the marginal probabilities for the CRF. This is in contrast to both SAG and OEG where each step size change requires a new call to the marginalization oracle. We thus propose in this paper to investigate the performance of SDCA for training CRFs.

**Contributions.** We adapt the multiclass variant of SDCA to the CRF setting by considering the marginal probabilities over the cliques of the graphical model. We provide a novel interpretation of SDCA as a relaxed fixed point update and highlights the block separability of the duality gap. We propose to enhance SDCA with an adaptive non-uniform sampling strategy based on the block gaps, and analyze its theoretical convergence improvement over uniform sampling. We compare the state-of-the-art methods on four prediction tasks with a sequence structure. SDCA with uniform sampling performs comparably with OEG and SAG. When SDCA is enhanced with the adaptive sampling strategy, it outperforms its competitors in terms of number of parameters updates on three of the tasks. These three tasks are all about natural language with handcrafted sparse features. We hypothesize that the efficiency of the dual methods can be related to the sparsity of these features.

**Related work.** Our proposed gap sampling strategy is similar to the one from [Osokin et al. \(2016\)](#) in the context of SDCA applied to the structured SVM objective, which reduces to the block-coordinate Frank-Wolfe (BCFW) algorithm ([Lacoste-Julien et al., 2013](#)). [Dünner et al. \(2017\)](#) recently analyzed a general adaptive sampling scheme for approximate block coordinate ascent that generalizes SDCA. Their proposed sampling scheme (which basically chooses the biggest gap) was motivated in the different context of mixed GPU and CPU computations, which does not apply to our setting. Our proposed practical strategy takes in consideration the staleness of the gaps and is more robust in our experimental setting. [Csiba et al. \(2015\)](#) proposes an adaptive sampling scheme for SDCA for binary classification which unfortunately cannot be generalized to the CRF setting due to an intractable computation. Closely related to our work is [Perekrestenko et al. \(2017\)](#) who analyzed several adaptive sampling strategies for a generalization of the primal-dual SDCA setup, including our proposed gap sampling scheme. However their analysis was focused on the single coordinate descent method (e.g. binary SDCA) and on sublinear convergence results obtained when strong convexity is not assumed. We cover instead the block-coordinate approach relevant to CRFs, and one of our notable results is to show that the linear convergence rate for gap sampling **dominates** the one for uniform sampling, in contrast to what happens in the sublinear regime studied by [Perekrestenko et al. \(2017\)](#).

**Outline.** We review the optimization problem for CRFs as well as provide novel insights on the primal-dual optimization structure in Section 2. We present SDCA for CRFs in Section 3 and discuss important implementation aspects in Section 4. We present and analyze various adaptive sampling schemes for SDCA in Section 5. We provide experiments in Section 6 and discuss the implications in Section 7.

## 2 CONDITIONAL RANDOM FIELDS

In this section, we review the CRF model and its associated primal and dual optimization problems. We then derive some interesting properties which motivate several optimization algorithms.

### 2.1 DEFINITION

A CRF models the conditional probability of a structured output  $y \in \mathcal{Y}$  (e.g. a sequence) given an input  $x \in \mathcal{X}$  with a Markov random field that uses an exponential family parameterization with sufficient statistics  $F(x, y) \in \mathbb{R}^d$  and parameters  $w \in \mathbb{R}^d$ :  $p(y|x; w) \propto \exp(w^\top F(x, y))$ . The feature vector  $F$  decomposes as a

Figure 1: Example of graphical model for the optical character recognition (OCR) task. We want to exploit the structure of the word to predict that  $y_{i,5}$  is an "e" and not a "c". This can be done by working on the pairs  $y_{i,\{t,t+1\}} = (y_{i,t}, y_{i,t+1})$ , the cliques of that model.

sum over the cliques  $C \in \mathcal{C}$  of the graphical model for  $y$ :  $F(x, y) = \sum_C F_C(x, y_C)$ , where  $y_C$  denotes the subset of coordinates of  $y$  selected by the indices from the set  $C$ . See Figure 1 for an illustration.

### 2.2 PRIMAL PROBLEM

We have a data set  $(x_i, y_i)_{i \in [1, n]}$  of  $n$  i.i.d. input and structured output pairs. The parameter is learned by minimizing the  $\ell_2$ -regularized negative log-likelihood:

$$\min_{w \in \mathbb{R}^d} \frac{\lambda}{2} \|w\|_2^2 + \frac{1}{n} \sum_{i=1}^n -\log(p(y_i|x_i; w)). \quad (1)$$

We now rewrite it using the notation for the SDCA setup for multi-class classification from [Shalev-Shwartz and Zhang \(2016\)](#). Denote  $M_i = |\mathcal{Y}_i|$  the number of labelings for sequence  $i$ . Denote  $A_i$  the  $d \times M_i$  matrix whose columns are the *corrected features*  $\{\psi_i(y) := F(x_i, y) - F(x_i, y^*)\}_{y \in \mathcal{Y}_i}$ . Denote also  $\phi_i(s) := \log(\sum_{y \in \mathcal{Y}_i} \exp(s_y))$  the log-partition function for the scores  $s \in \mathbb{R}^{M_i}$ . The negative log-likelihood can be written  $-\log(p(y_i|x_i; w)) = \phi_i(-A_i^\top w)$ . The primal objective function to minimize over  $w \in \mathbb{R}^d$  thus becomes:

$$\mathcal{P}(w) := \frac{\lambda}{2} \|w\|_2^2 + \frac{1}{n} \sum_{i=1}^n \phi_i(-A_i^\top w). \quad (2)$$

### 2.3 DUAL FORMULATION

The above minimization problem (2) has an equivalent *Fenchel convex dual* problem ([Lebanon and Lafferty, 2002](#)). Denote  $\Delta_M$  the probability simplex over  $M$  elements. Denote  $\alpha_i \in \Delta_{M_i}$  the set of dual variables for a given  $x_i$ . The dual problem handles directly the probability of the labels for the training set. The dual objective to maximize over the choice of  $\alpha = (\alpha_1, \dots, \alpha_n) \in$

$\Delta_{|\mathcal{Y}_1|} \times \dots \times \Delta_{|\mathcal{Y}_n|}$  is:

$$\mathcal{D}(\boldsymbol{\alpha}) := -\frac{\lambda}{2} \left\| \frac{1}{n\lambda} \sum_i A_i \alpha_i \right\|^2 + \frac{1}{n} \sum_{i=1}^n H(\alpha_i), \quad (3)$$

where  $H(\alpha_i) := -\sum_{y \in \mathcal{Y}_i} \alpha_i(y) \log(\alpha_i(y))$  is the entropy of the probability distribution  $\alpha_i$ . The negative entropy appears as the convex conjugate of the softmax:  $-H = \phi^*$ .

## 2.4 OPTIMALITY CONDITION

We define the *conjugate weight* function  $\hat{w}$  as follows:

$$\begin{aligned} \hat{w}(\boldsymbol{\alpha}) &:= \frac{1}{n\lambda} \sum_i A_i \alpha_i = \frac{1}{\lambda n} \sum_{i=1}^n \mathbb{E}_{y \sim \alpha_i} [\psi_i(y)] \\ &= \frac{1}{\lambda} \left( \frac{1}{n} \sum_{i=1}^n F(x_i, y_i) - \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{y \sim \alpha_i} [F(x_i, y)] \right). \end{aligned}$$

It is the difference between the average of the ground truth features, and the average of the expected features for the dual variable, up to a factor  $\frac{1}{\lambda}$ . We can show that  $\hat{w}(\boldsymbol{\alpha}^*) = \mathbf{w}^*$  where  $\mathbf{w}^*$  and  $\boldsymbol{\alpha}^*$  are respectively the optimal primal parameters and the optimal dual parameters.

We can also define the *conjugate* probabilities  $\hat{\alpha}_i$  as follows:

$$\forall i, \quad \hat{\alpha}_i(\mathbf{w}) := \nabla_s \phi_i(-A_i^\top \mathbf{w}) = p(\cdot | x_i; \mathbf{w}). \quad (4)$$

We get another optimality condition  $\hat{\alpha}(\mathbf{w}^*) = \boldsymbol{\alpha}^*$ . These two optimality conditions can be deduced directly from the structure of the duality gaps.

## 2.5 DUALITY GAPS

Note that  $\mathcal{P}(\mathbf{w}) \geq \mathcal{D}(\boldsymbol{\alpha})$  is always true, with equality at the optimum. The *duality gap* is defined by:

$$g(\mathbf{w}, \boldsymbol{\alpha}) = \mathcal{P}(\mathbf{w}) - \mathcal{D}(\boldsymbol{\alpha}). \quad (5)$$

Note that we can rewrite the primal gradient as following:

$$\nabla \mathcal{P}(\mathbf{w}) = \lambda(\mathbf{w} - \hat{w} \circ \hat{\alpha}(\mathbf{w})). \quad (6)$$

One can verify that:

$$g(\mathbf{w}, \hat{\alpha}(\mathbf{w})) = \frac{\lambda}{2} \|\mathbf{w} - \hat{w}(\hat{\alpha}(\mathbf{w}))\|^2 \quad (7)$$

$$= \frac{1}{2\lambda} \|\nabla \mathcal{P}(\mathbf{w})\|^2. \quad (8)$$

This structure of the gap for the primal weights and its conjugate dual probabilities have an equivalent in the dual. Denote the Fenchel duality gap of  $\phi_i$  for the scores  $s_i = -A_i^\top \mathbf{w}$  and probabilities  $\alpha_i$ :

$$F_i(s_i, \alpha_i) := \phi_i(s_i) + \phi_i^*(\alpha_i) + s_i^\top \alpha_i \geq 0. \quad (9)$$

The positivity comes from the definition of convex conjugates. The gap is zero when  $s_i$  and  $\alpha_i$  are conjugate variables for  $\phi_i$ , e.g.  $\alpha_i = \nabla \phi_i(s_i)$ . For any smooth loss  $\phi_i$ , the duality gap between  $\hat{w}(\boldsymbol{\alpha})$  and  $\boldsymbol{\alpha}$  decomposes as a sum of Fenchel gaps (Shalev-Shwartz and Zhang, 2013a):

$$g(\hat{w}(\boldsymbol{\alpha}), \boldsymbol{\alpha}) = \frac{1}{n} \sum_i F(-A_i^\top \hat{w}(\boldsymbol{\alpha}), \alpha_i). \quad (10)$$

The log-sum-exp and the entropy are a special pair of conjugates. Their Fenchel duality gap is also equal to the Bregman divergence generated by  $\phi_i^* = -H$ , the Kullback-Leibler divergence:  $F_i(s_i, \alpha_i) = D_{KL}(\alpha_i \| \nabla \phi_i(s_i))$ . Writing this for the same pair of conjugate variables yields:

$$g(\hat{w}(\boldsymbol{\alpha}), \boldsymbol{\alpha}) = \frac{1}{n} \sum_i D_{KL}(\alpha_i \| \hat{\alpha}_i(\hat{w}(\boldsymbol{\alpha}))). \quad (11)$$

The duality gaps (7) and (11) are typically used to monitor the optimization. In Appendix D, we explain how one can transfer a convergence guarantee on the primal or dual suboptimality to a convergence guarantee on the duality gap.<sup>1</sup> Moreover, the block-separability of gaps from (11) can motivate an adaptive sampling scheme, as we describe in Section 5.

## 2.6 INTERPRETATION

The primal formulation chooses a  $\mathbf{w}$  of small norm so as to maximise the conditional probability of observing the labels. Conversely, the dual formulation chooses conditional probabilities of the labels so as to minimize the  $\ell_2$  distance between the expected features and empirical expectation of the ground truth features. The optimal distribution would be the empirical distribution, if not for the entropic regularization that favors more uniform probabilities. This is the regularized version of the classical duality between maximum-likelihood and maximum-entropy for exponential families.

The optimality conditions show that the solution of the primal Problem (2) is also a *fixed point* for the function  $\hat{w} \circ \hat{\alpha}$ . Because of the gradient form (6), the gradient descent update can also be written as a *relaxed* fixed point update:

$$\mathbf{w}^+ = \mathbf{w} - \gamma \nabla \mathcal{P}(\mathbf{w}) \quad (12)$$

$$= (1 - \gamma\lambda)\mathbf{w} + \gamma\lambda \hat{w} \circ \hat{\alpha}(\mathbf{w}). \quad (13)$$

The algorithm SDCA described in the next section also admits a relaxed fixed point update on the block  $\alpha_i$

<sup>1</sup> This implies that convergence results on the dual problem directly translates to convergence results on the primal and vice-versa; a fact apparently missed in the linear rate comparison of Schmidt et al. (2015).

(see (14)). More generally, optimization algorithms for Problem (2) can often be interpreted as a back and forth between the conjugate variables  $w$  and  $\hat{w}(\hat{\alpha}(w))$  (primal methods) or  $\alpha$  and  $\hat{\alpha}(\hat{w}(\alpha))$  (dual methods). For instance, one could interpret OEG as a relaxed fixed point iteration over the score variables  $s_i = -A_i^T w$ .

Most of the results presented in this section and in Section 5 can be transposed to other kinds of loss and regularization, under some regularity assumptions. Our focus in this paper is the application of SDCA to CRF models and thus we focused the discussion on the log-likelihood setting and the  $\ell_2$  norm, which are widely used.

### 3 PROXIMAL STOCHASTIC DUAL COORDINATE ASCENT

We first describe the SDCA in its general setting, and then describe the necessary modifications for training a CRF.

#### 3.1 GENERAL SETTING

The stochastic dual coordinate ascent algorithm (SDCA) updates one dual coordinate at a time so as to maximize the dual objective. SDCA was originally proposed for binary classification (Shalev-Shwartz and Zhang, 2013b) where each dual variable  $\alpha_i$  lives in  $\Delta_2 = [0, 1]$ . In this case, it is possible to do exact coordinate maximization of the dual objective over a single  $\alpha_i$  with standard one dimensional optimization.

In the multi-class setting however, there is no simple way to maximize the dual objective over the block  $\alpha_i \in \Delta_K$ . The algorithm with the surprising name of Proximal-SDCA<sup>2</sup>, option II (Shalev-Shwartz and Zhang, 2016) proposes a solution to this problem. It updates  $\alpha_i$  in a clever direction derived from the primal-dual relationship, which amounts to a relaxed fixed point update. See Algorithm 1.

We now describe the idea. At all time, we maintain the pair of dual and primal variables  $(\alpha, w = \hat{w}(\alpha))$ . At each step, we sample a training point  $i$ . We compute  $\beta_i = \nabla_s \phi_i(-A_i^T w) = \hat{\alpha}_i \circ \hat{w}(\alpha)$ , the next fixed point iterate. We then define the dual ascent direction by  $\delta_i := \beta_i - \alpha_i$ . Finally we update the block  $\alpha_i$  with the right step size so as to increase the dual objective  $\mathcal{D}(\alpha)$  using a relaxed fixed point update:

$$\alpha_i^+ \leftarrow \alpha_i + \gamma \delta_i = (1 - \gamma)\alpha_i + \gamma \hat{\alpha}_i \circ \hat{w}(\alpha). \quad (14)$$

<sup>2</sup>We simply call it SDCA in the rest of this paper

---

#### Algorithm 1 Prox-SDCA (option II) called SDCA here

---

```

Initialize  $\alpha_i^{(0)} \in \Delta_{M_i}, \forall i$ 
Let  $w^{(0)} = \hat{w}(\alpha^{(0)}) = \frac{1}{\lambda n} \sum_i A_i \alpha_i$ 
for  $t = 0, 1 \dots$  do
  Sample  $i$  uniformly at random in  $\{1, \dots, n\}$ 
  Let  $\beta_i := \hat{\alpha}_i(w) = \nabla_s \phi(-A_i^T w)$ 
  Let  $\delta_i = \beta_i - \alpha_i^{(t)}$  {dual ascent direction}
  Let  $v_i = \frac{1}{\lambda n} A_i \delta_i$  {primal direction}
  Solve Equation (15) to get  $\gamma^*$  {Line Search}
  Update  $\alpha_i^{(t+1)} := \alpha_i^{(t)} + \gamma^* \delta_i$ 
  Update  $w^{(t+1)} := \hat{w}(\alpha^{(t+1)}) = w^{(t)} + \gamma^* v_i$ 

```

---

The dual ascent direction is guaranteed to increase  $\mathcal{D}(\alpha)$ , unless  $\delta_i = 0$  (this actually means that the block is already optimal, see (11)). The primal weights  $w = \hat{w}(\alpha)$  are related to  $\alpha$  by a linear transformation. Define the primal direction  $v_i = \frac{1}{\lambda n} A_i \delta_i \in \mathbb{R}^d$ . One can update the weights directly:  $w^+ \leftarrow w + \gamma v_i$ .

The step size  $\gamma \in [0, 1]$  is either fixed, or found via line search. In practice the fixed step size for which convergence is guaranteed is really small. The line search is relatively cheap as we are looking at only one block:

$$\gamma^* := \arg \max_{\gamma \in [0, 1]} -\phi_i^*(\alpha_i + \gamma \delta_i) - \frac{\lambda n}{2} \|w + \gamma v_i\|^2. \quad (15)$$

Note that one can decompose the quadratic term and precompute  $\langle w, v_i \rangle$  and  $\|v_i\|^2$  to accelerate the optimisation. The bottleneck remains the computation of  $\phi_i^*$  (and its derivatives).

#### 3.2 ADAPTATION TO CRF

In the CRF setting, the dual variable  $\alpha_i$  is exponentially large in the input size  $x_i$ . For a sequence  $x_i$  of length  $T$  where each node can take up to  $K$  values, the number of possible labels is  $|\mathcal{Y}_i| = K^T$ . It might not even fit in memory. Instead, the standard approach used in OEG and SAG is to consider the marginal probabilities  $(\mu_C)_{C \in \mathcal{C}}$  on the cliques of the graphical model. Similarly, we replace  $\alpha$  by  $\mu = (\mu_1, \dots, \mu_n)$ , where  $\mu_i \in \prod_C \Delta_C$  is the concatenation of all the clique marginal vectors for the sample  $i$ . For the same sequence  $x_i$ , this reduces the memory cost to  $K^2(T - 1)$  for the pair marginals. We denote  $m_i = \sum_C |\mathcal{Y}_{i,C}|$  this new memory fingerprint. For a sequence long enough, we have  $m_i \ll M_i$ . The associated weight vector can still be expressed as function of  $\mu$  thanks to the separability of the features:

$$\hat{w}(\mu) = \frac{1}{\lambda n} \sum_i \sum_C \mathbb{E}_{\mu_{i,C}} [\psi_{i,C}] = \frac{1}{\lambda n} \sum_i B_i \mu_i, \quad (16)$$

where  $B_i = (\psi_{i,C}(y_C))_{C, y_C} \in \mathbb{R}^{d \times m_i}$  is the horizontal concatenation of the cliques feature vectors.

---

**Algorithm 2** SDCA for CRF
 

---

Initialize  $\mu_i^{(0)} \in \prod_C \Delta_C$  consistently  $\forall i$  {use (21)}  
 Set  $\mathbf{w}^{(0)} := \hat{\mathbf{w}}(\boldsymbol{\mu}^{(0)}) = \frac{1}{\lambda n} \sum_i B_i \mu_i^{(0)}$  {See (16)}  
 (Optional) Let  $g_i = 100, \forall i$   
**for**  $t = 0, 1 \dots$  **do**  
   Sample  $i$  uniformly at random in  $\{1, \dots, n\}$   
   (Alternatively) Sample  $i$  proportionally to  $g_i$   
   Let  $\nu_{i,C}(y_C) := p(y_C | x_i; \mathbf{w}^{(t)}, \forall C \in \mathcal{C}$  {**oracle**}  
   (Optional) Let  $g_i = \tilde{D}(\mu_i || \nu_i)$  {duality gap (19)}  
   Let  $\delta_i = \nu_i - \mu_i^{(t)}$  {ascent direction}  
   Let  $\mathbf{v}_i = \frac{1}{\lambda n} \hat{\mathbf{w}}(\delta_i)$  {primal direction}  
   Solve Equation (20) to get  $\gamma^*$  {Line Search}  
   Update  $\mu_i^{(t+1)} := \mu_i^{(t)} + \gamma^* \delta_i$   
   Update  $\mathbf{w}^{(t+1)} := \hat{\mathbf{w}}(\boldsymbol{\mu}^{(t+1)}) = \mathbf{w}^{(t)} + \gamma^* \mathbf{v}_i$

---

Now, assume that the graph has a *junction tree* structure  $T = (\mathcal{C}, \mathcal{S})$  (Koller and Friedman, 2009, Def. 10.3), where  $\mathcal{C}$  is the set of maximal cliques and  $\mathcal{S}$  the set of separators. We can then run message passing on the junction tree to infer the new marginals given weights  $\mathbf{w}$ :  $\hat{\mu}_i(\mathbf{w}) = p(y_C = \cdot | x_i; \mathbf{w})$ . We can also now recover the joint probability  $\alpha_i(y)$  as a function of its marginals  $\mu_{i,C}$  (Koller and Friedman, 2009, Def. 10.6):

$$\alpha_i(y) = \frac{\prod_{C \in \mathcal{C}} \mu_{i,C}(y_C)}{\prod_{S \in \mathcal{S}} \mu_{i,S}(y_S)}. \quad (17)$$

Equation (17) in turn allows us to compute the entropy and the divergences of the joints, using only the marginals. Let  $\mu_i$  and  $\nu_i$  be the marginals of respectively  $\alpha_i$  and  $\beta_i$ , then the entropy and the Kullback-Leibler divergence are given by:

$$\tilde{H}(\mu_i) := H(\alpha_i) = \sum_C H(\mu_{i,C}) - \sum_S H(\mu_{i,S}) \quad (18)$$

and

$$\begin{aligned} \tilde{D}(\mu_i || \nu_i) &:= D_{KL}(\alpha_i || \beta_i) \\ &= \sum_C D_{KL}(\mu_{i,C} || \nu_{i,C}) - \sum_S D_{KL}(\mu_{i,S} || \nu_{i,S}). \end{aligned} \quad (19)$$

With this expression of the entropy (18), we can compute the dual objective, and thus perform the line search:

$$\gamma^* = \arg \max_{\gamma \in [0,1]} \tilde{H}(\mu_i^{(t)} + \gamma \delta_i) - \frac{\lambda n}{2} \|\mathbf{w}^{(t)} + \gamma \mathbf{v}_i\|^2. \quad (20)$$

With the Kullback-Leibler divergence (19), we can compute efficiently the individual duality gaps from (11). Algorithm 2 describes this variation of SDCA, with as an option a non-uniform sampling strategy defined in Section 5.3.

## 4 IMPLEMENTATION

We provide in Appendix A a discussion of various important implementation aspects summarized here.

1. The initialization of dual methods for CRFs can significantly influence their performance. As explained in Appendix A, we use:

$$\boldsymbol{\alpha}^{(0)} := \varepsilon \mathbf{u} + (1 - \varepsilon) \boldsymbol{\delta}, \quad (21)$$

where  $\mathbf{u}$  is the uniform distribution on each block,  $\boldsymbol{\delta}$  is a unit mass on each ground truth label and  $\varepsilon$  is a small number.

2. Storing the dual variable may be expensive and one should allocate a decent amount of memory.
3. The line search requires computing the entropy of the marginals. This is costly and we used Newton-Raphson algorithm to minimize the number of iterations. This in turn requires storing the logarithm of the dual variable.

## 5 ADAPTIVE SAMPLING FOR SDCA

Recently, there has been a lot of attention on non-uniform sampling for stochastic methods. The general goal is to sample more often points which are harder to classify and can bring more progress on the objective. These methods are said to be *adaptive* when the sampling probability changes during the optimization. SDCA itself has had several adaptive schemes proposed. In the following, we attempt to explain and relate these methods, and suggest new schemes that work well on our problem.

### 5.1 ASCENT LEMMA

We start by restating the ascent lemma from Equation (25) in Shalev-Shwartz and Zhang (2013a). This lemma inspires and supports all the strategies.

**Ascent after sampling  $i$ :** At iteration  $t$ , if we sample  $i$  and take a step of size  $\gamma_i \in [0, 1]$ , we can lower bound the resulting dual improvement:

$$\begin{aligned} &n(\mathcal{D}(\boldsymbol{\alpha}^+) - \mathcal{D}(\boldsymbol{\alpha})) \\ &\geq \gamma_i \underbrace{\left[ \phi(-A_i^T \mathbf{w}) + \phi^*(\alpha_i) + \mathbf{w}^T A_i \alpha_i \right]}_{\text{Fenchel gap} =: g_i} \\ &\quad + \gamma_i \left( \frac{(1 - \gamma_i)}{2} - \frac{\gamma_i R_i}{2\lambda n} \right) \|\beta_i - \alpha_i\|_1^2 \end{aligned} \quad (22)$$

where  $R_i := \|A_i\|_{1 \rightarrow 2}^2 = \max_{y \in \mathcal{Y}_i} \|\psi_i(y)\|_2^2$  is the squared radius of the corrected features for sample  $i$ .

Note that compared to the original text, we used the fact that the regularizer is the  $\ell_2$  norm and the loss is 1-smooth

with respect to the  $\ell_\infty$  norm. We define  $R := \max_i R_i$ ,  $\bar{R} := \frac{1}{n} \sum_i R_i$  and  $\bar{g} := \frac{1}{n} \sum_i g_i$  the true duality gap (see (9)-(10)). We also introduce  $L_i := \lambda + \frac{R_i}{n}$  an upper bound on the smoothness of loss  $i$  plus regularizer for the  $\ell_2$  norm. We recall from Section 2.5 that  $g_i = D_{KL}(\alpha_i || \beta_i)$  (11). We give the name *residual* to  $d_i := \|\beta_i - \alpha_i\|_1^2$ .

This lemma is derived with standard assumptions and inequalities on the smoothness of the loss and the strong convexity of the regularizer. The first term of the lower bound is the ascent guarantee while the other term gives condition on the step-size to ensure progress. We refer the reader to the original paper for more details.

To get the expected progress (conditioned on the past) after sampling with probability  $p$ , we simply need to take the sum of the inequality above after multiplying both sides by  $p_i$ . Our goal is to maximize this lower bound by choosing the right probability  $p$  and step sizes  $\gamma$ . To be able to conclude the proof with the original method, we also want some constants time the duality gap  $\bar{g}$  to appear in the lower bound – the gap is lower bounded by the dual suboptimality and thus this constant will give the linear rate of convergence. The lemma can then transpose this result from the dual sub-optimality to the duality gap as described in Appendix D. From there on there are two general approaches: importance sampling and duality gap sampling.

## 5.2 IMPORTANCE AND RESIDUAL SAMPLING

With the importance sampling approach, the goal is to set the step-size and the probability so that they cancel each other out:  $\gamma_i = \frac{\gamma}{p_i}$ . One then get an unbiased estimate of the true duality gap from (11) as the first term of the upper bound. What is left is maximizing the second term with respect to  $p$ . This is the approach proposed by [Zhao and Zhang \(2015\)](#) (Importance Sampling, left term below) and generalized by [Csiba et al. \(2015\)](#) (Residual sampling, a.k.a. AdaSDCA for binary classification, right term):

$$p_i \propto L_i \quad \text{or} \quad p_i \propto d_i \sqrt{L_i}. \quad (23)$$

These sampling schemes somehow allow to maximize the second term of (22). Intuitively, they replace a dependency on  $R$  in the convergence rate by a dependency on  $\bar{R}$ . They can give good results on binary and multi-class logistic regression. There are a few issues though.

- One needs an accurate estimate of the  $L_i$ .
- Importance sampling is not adaptive.
- In the CRF setting, the residual is  $d_i = \|\beta_i - \alpha_i\|_1^2$ . It is the squared  $\ell^1$  norm of a vector of exponential size. We are not aware of any trick to compute it efficiently.

## 5.3 GAP SAMPLING

To make sure that the second term is positive, the original proof of uniform SDCA sets  $\gamma_i = \gamma = (1 + \frac{R}{\lambda n})^{-1}$  to obtain:

$$n\mathbb{E}_p[D(\alpha^+) - D(\alpha)] \geq \gamma \sum_i p_i g_i. \quad (24)$$

Assuming a full knowledge of the duality gaps  $g_i$ , the optimal decision is to sample the point with maximum duality gap. This was done by [Dünner et al. \(2017\)](#) in the context of multi-class classification on a pair CPU-GPU. While the GPU computes the update, the CPU updates as many duality gaps as possible. This lead to impressive acceleration over massive datasets.

However, this is not our current setting. We know and update only one gap at a time (for efficiency). Because of staleness of the gaps, our experiments with this method did not even converge for the most part (see Section 6.3). We need a more robust method.

We take inspiration from what was done by [Osokin et al. \(2016\)](#) to improve the Block-Coordinate Frank-Wolfe (BCFW) algorithm ([Lacoste-Julien et al., 2013](#)). We propose to bias sampling towards examples whose duality gaps are large:  $p_i \propto g_i$ . If we know all the duality gaps, the expected improvement reads:

$$n\mathbb{E}_p[D(\alpha^+) - D(\alpha)] \geq \chi(\mathbf{g})^2 \gamma \bar{g}, \quad (25)$$

where  $\chi(\mathbf{g}) = \sqrt{\frac{\frac{1}{n} \sum_i g_i^2}{\bar{g}^2}} \in [1, \sqrt{n}]$  is the non-uniformity of the duality gaps, as defined in [Osokin et al. \(2016, Section 3.1\)](#). The value  $\chi(\mathbf{g})^2 \gamma$  is the value that will appear in the linear convergence rate of this method. It means that the convergence rate for gap sampling **dominates** the one for uniform sampling. This is different from what was observed for BCFW where they could not prove dominance in general.

In practice we use stale estimates of the gaps and there are no convergence guarantees. We discuss more this issue in section 6.3.

We also explored a combination of gap sampling and importance sampling. We could get similar convergence rate where a trade-off appeared between the mean smoothness and the non-uniformity. We detail these considerations as a technical report in Appendix F for the interested reader.

## 6 EXPERIMENTS

We conducted these experiments to answer three questions: (1) How does the line search influence SDCA? (2) How do the non-uniform sampling schemes compare with each other? and (3) How does SDCA compare with SAG and OEG on sequence prediction?

Table 1: Dataset summary.  $d$  is the dimension of  $w$ .  $n$  is the number of data points (sequences).  $N$  is the number of nodes (e.g. sum of sequences length).  $K$  is the number of possible labels for each node.  $A$  is the number of attributes (see Appendix B).  $a$  is the maximum number of attributes extracted from one node. Mem. is the memory required by the pairwise marginals stored as float 64. The pairwise marginals dominate the memory cost.

Dataset	OCR	CONLL	NER	POS
$d$	4,082	$1.6 \times 10^6$	$2.8 \times 10^6$	$8.6 \times 10^6$
$n$	6,202	8,936	15,806	38,219
$N$	52,827	$2.1 \times 10^5$	$2 \times 10^5$	$9.1 \times 10^5$

## 6.1 EXPERIMENTAL SETTING

We applied the experimental setup outlined by Schmidt et al. (2015). We implemented SDCA to train a classifier on four CRF training tasks: (1) the optical character recognition (OCR) dataset (Taskar et al., 2004), (2) the CoNLL-2000 shallow parse chunking dataset (CONLL), (3) the CoNLL-2002 Dutch named-entity recognition dataset (NER), and (4) a part-of-speech (POS) tagging task using the Penn Treebank Wall Street Journal data. Additional details regarding these datasets are provided in Table 1. Note that the tasks (2), (3), (4) are about language understanding. They use sparse features (the ratio  $a/A$  from the table is small). The sparsest data set is NER. Note that POS is considerably larger than other datasets. All experiments are performed with a regularization factor  $\lambda = 1/n$ . We used our own implementation<sup>3</sup> of SDCA coded in plain Python and Numpy (Walt et al., 2011). In most plots we report the logarithm base 10 of the primal sub-optimality. We got the optimum by running L-BFGS a large number of iterations.

## 6.2 EFFECT OF THE LINE SEARCH

We implemented the safe bounded Newton-Raphson method from Press et al. (1992, Section 9.4) on the derivative of the line search function. A natural question to ask is : how precise should the line search be? The stopping criterion for this algorithm is the size of the last step taken so there is no proper precision parameter. We refer to this stopping criterion for the line search as the sub-precision of SDCA.

<sup>3</sup>The code to reproduce our experiments is available at: <https://remileprieol.github.io/research/sdca4crf.html>.

We discovered experimentally that the convergence of SDCA is mostly independent of the sub-precision. On all datasets, if we ask 0.01 sub-precision or less, SDCA converges with the same rate. An explanation is that the accuracy of the optimization arises from iterates  $\alpha$  and  $\hat{\alpha}(\hat{w}(\alpha))$  getting closer to each other in the simplex with each iteration.

Reaching 0.01 or 0.001 takes on average 2 iterations. Each iteration of Newton’s method require the computation of the first and second derivative of the line search objective (20). In the following we report results with sub-precision 0.001 to be on the safe side. These 2 iterations were taking about 30% of the algorithms running time for each dataset.<sup>4</sup>

We also performed experiments with only one step of the Newton update. The convergence was not affected on OCR, CONLL and POS, but convergence failed on NER (see Figure 8 of Appendix E). This phenomenon could be related to sparsity.

## 6.3 COMPARISON OF SAMPLING SCHEMES

We compare the performance of four sampling strategies with 20% of uniform sampling against the full Uniform approach, on the OCR dataset (see results in Figure 2):

- *Importance*: sample proportionally to the smoothness constants  $L_i = \lambda + \frac{R_i}{n}$ . We report how we evaluated the radii  $R_i$  in Appendix C.
- *Gap*: sample proportionally to our current estimate of the duality gaps.<sup>5</sup>
- *Gap  $\times$  importance*: sample proportionally to the product of the gap and smoothness constants.
- *Max*: sample deterministically the variable with the largest recorded gap (Dünner et al., 2017).

As discussed in Section 5.3, Max sampling is not robust enough to the staleness of the gap estimates and fails to converge here. We also observe that Importance performs worse than Uniform, and that Gap  $\times$  Importance performs worse than Gap. This indicates that the smoothness upper bounds we estimated are not informative of the difficulty of optimizing a point for SDCA. Overall, Gap sampling gives the best performance and this is what we use in the following experiments.

The ratio of uniform sampling is here to mitigate the fact that we sample proportionally to stale gaps. This is

<sup>4</sup> We also tried initializing the line search with 0.5 or with the previous step size. There was no significant difference.

<sup>5</sup> For the gap approaches, we initialize the gap estimates with large values (100) so as to perform a pass over the whole dataset before starting to sample proportionally to the stale estimates.

Figure 2: Performance of competing sampling schemes on the OCR dataset with 80% of non-uniformity. Sampling proportionally to the gap gives the best performance.

Figure 3: SDCA with Gap sampling applied on NER with various fractions of non-uniform sampling, as indicated by the number in the legend. Increasing the fraction only improves the performance, up to a certain point.

the strategy adopted by SAG-NUS (Schmidt et al., 2015) which samples uniformly half of the time. Another strategy used by Osokin et al. (2016) is to update all the duality gaps at once every 10 epochs or so. Our experiments indicate that these strategies are not needed for SDCA-GAP. Increasing the ratio of non-uniformity up to 1 only improves the performance on all datasets, though after 0.8 the improvements are marginal, as illustrated by Figure 3 for the NER dataset.

In fact, the estimate of the total gap maintained by SDCA is somewhat accurate, as illustrated for different datasets in Figure 9 of Appendix E. Empirically, it always remains within a factor 2 of the true duality gap. This accuracy is a good news because one can use this estimate of the duality gap as a stopping criterion for the whole algorithm. Once it reaches a certain precision threshold, one just has to perform one last batch update to check the real value. This is similar in spirit to SAG, which uses the norm of its estimate of the true gradient as a stopping criterion. Both are duality gaps estimators (see Equation (7)).

## 6.4 COMPARISON AGAINST SAG AND OEG

We downloaded the code for OEG and SAG-NUS as implemented by Schmidt et al. (2015) from the SAG4CRF project page.<sup>6</sup> We used our own implementation of SDCA with a line search sub-precision of 0.001. We provide the comparison in Figure 4 according to two different measures of complexity which are implementation independent.

**Oracle calls.** Schmidt et al. (2015) compared the algorithms on the basis of the number of oracle calls. We report these on OCR and NER in Figures 4a and 4d. Results on the other datasets are in Figure 6 in Appendix E. This metric was suitable for the methods they compared. Both OEG and SAG-NUS use a line search where they call an oracle on each step. SDCA does not need the oracle to perform its line search. However the oracle is message passing on a junction tree. It has a cost proportional to the size of the marginals. Each iteration of the line search require computing the entropy of these marginals, or their derivatives. These costs are roughly the same. Comparing the number of oracle calls for each method is thus unfairly advantaging SDCA by hiding the cost of its line search. It becomes a relevant comparison when a marginalization oracle becomes much more expensive than approximating the entropy (see the discussion in Section 7). When this cost is hidden, SDCA-GAP is on par with SAG-NUS\* on OCR and it is much faster on the sparse datasets.

**Parameter updates.** To give a different perspective, we report the log of the sub-optimality against the number of parameter updates in Figures 4b, 4c, 4e and 4f. This removes the additional cost of the line search for all methods.<sup>7</sup>

We observe that uniform SDCA and OEG need roughly the same number of parameters update on all four datasets. When we add the adaptive gap sampling, SDCA outperforms OEG by a margin. On OCR, SDCA and SDCA-GAP do not perform as well as SAG-NUS. On the three other datasets, SDCA-GAP needs less iterations. In fact, the more sparse the dataset, the less iterations are needed.

This is likely explained by SDCA’s ability to almost perfectly optimize each block separately due to its line search method. More specifically, as the datasets become sparser, the prediction between data points becomes less and less correlated (i.e. the label distribution for two points that share no attributes will not influence each other directly through their primal weights). In settings where no points

<sup>6</sup><https://www.cs.ubc.ca/~schmidtm/Software/SAG4CRF.html>

<sup>7</sup> This is a penalty for SAG-NUS\* which enforces a line-search skipping strategy.

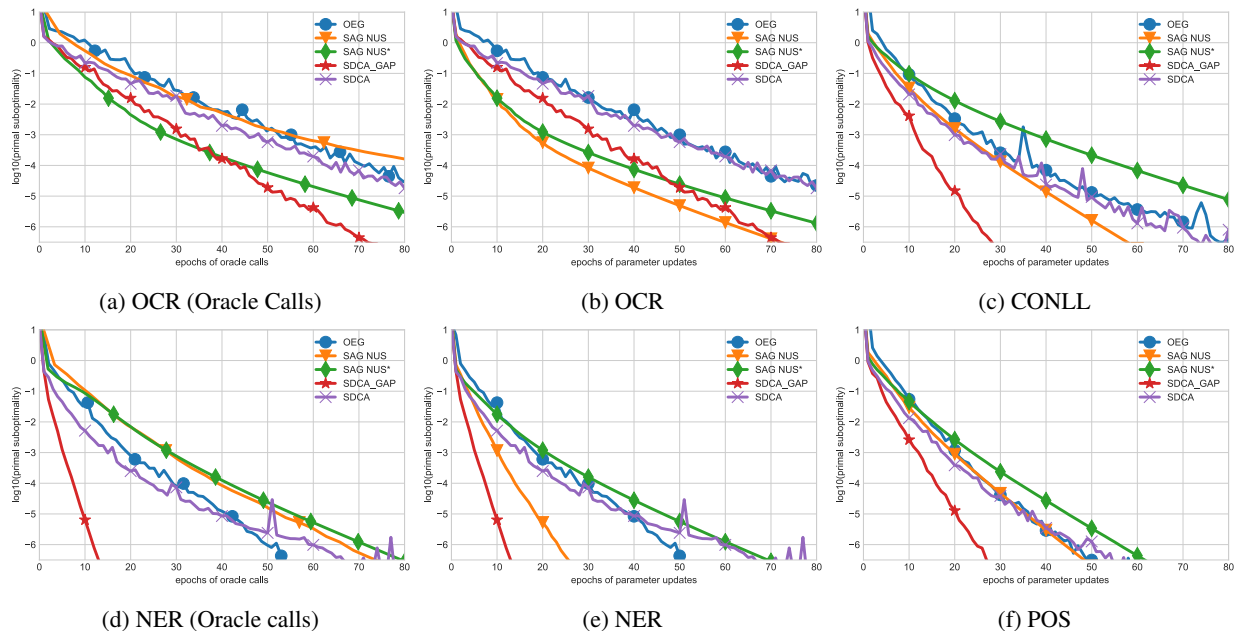

Figure 4: Primal sub-optimality as a function of the number of oracle calls (left) or parameters updates (center and right). SDCA refers to uniform sampling. SDCA-GAP refers to sampling Gap sampling 80% of the time. SAG-NUS performs a line search at every iteration. SAG-NUS\* implements a line-search skipping strategy. It appears worse than SAG-NUS when we look at the number of updates, which hides the cost of the line search.

share any attributes (completely sparse), all methods optimize each point independently. SDCA may perform very well thanks to its precise line search.

In terms of test error, SDCA is on par with SAG, and a bit better than OEG. All methods reach maximum accuracy after a few epochs. We report the evolution of the test error in Figure 7 of Appendix E.

Comparing the number of parameters updates also has a disadvantage. It penalizes methods with line search skipping strategies like OEG and SAG. The running time is highly implementation dependent and providing a fair comparison is non-trivial. We focused on implementation independent comparisons. SDCA, SAG and OEG have many common operations: the oracle, the computation of the scores and the primal direction. The fact that the line search took only 30% of SDCA’s runtime indicates that the conclusion drawn from the number of updates may hold for other metrics.

## 7 DISCUSSION

In this work, we investigated using SDCA for training CRFs for the first time. The observed empirical convergence per parameter update was similar for standard SDCA and OEG. However, SDCA can be enhanced with an adaptive sampling scheme, consistently accelerating

its convergence and also yielding faster convergence than SAG with non-uniform sampling on datasets with sparse features. It would be natural to also implement a gap sampling scheme for OEG, though several quantities needed for the computation are not readily available in standard OEG and would yield higher overhead in actual implementation. We leave finding a more efficient implementation of a gap sampling scheme for OEG as an interesting research direction.

A key feature of SDCA is to only require one marginalization oracle per line-search. This could become advantageous over SAG or OEG when the marginalization oracle becomes much more expensive than evaluating the entropy function from the marginals. Examples for this scenario include: when a parallel implementation is used for the entropy computation; or when the marginalization oracle uses an iterative approximate inference algorithms such as TRW BP whereas an approximation of the entropy is direct from the marginals (Krishnan et al., 2015). Investigating these scenarios with full timing comparison (which is implementation dependent) is a further interesting direction of future work.

We also note that acceleration schemes have been proposed for both SAG and SDCA (Lin et al., 2015; Shalev-Shwartz and Zhang, 2016), though they have not been tested yet for training CRFs.

## Acknowledgments

We are thankful to Thomas Schweizer for his numerous software engineering advices. We thank Gauthier Gidel and Akram Erraqabi who started this project. We are indebted to Ahmed Touati for his involvement during the first phase of the project. Alexandre Piché was supported by the Open Philanthropy Project. ## Abstract

We propose a new algorithm for computing a constant-factor approximation of precision-recall (PR) curves for massive noisy datasets produced by generative models. Assessing validity of items in such datasets requires human annotation, which is costly and must be minimized. Our algorithm, ADASTRAT, is the first data-aware method for this task. It chooses the next point to query on the PR curve adaptively, based on previous observations. It then selects specific items to annotate using stratified sampling. Under a mild monotonicity assumption, ADASTRAT outputs a guaranteed approximation of the underlying precision function, while using a number of annotations that scales very slowly with  $N$ , the dataset size. For example, when the minimum precision is bounded by a constant, it issues only  $\log \log N$  precision queries. In general, it has a regret of no more than  $\log \log N$  w.r.t. an oracle that issues queries at data-dependent (unknown) optimal points. On a scaled-up NLP dataset of 3.5M items, ADASTRAT achieves a remarkably close approximation of the true precision function using only 18 precision queries, 13x fewer than best previous approaches.

## 1 INTRODUCTION

Generative machine learning models can produce massive amounts of noisy data. To be fruitfully used as a standalone resource for human consumption or in downstream applications, a practitioner must understand the quality of such data. This is often done with a precision-recall or PR curve, which characterizes how data quality degrades as the model’s confidence in the validity of each

item reduces. While a PR curve can be easily created for discriminative models by using pre-annotated held-out data, doing so for generative models is not straightforward. The latter is particularly challenging when human judgment or an expensive simulation is required to assess the validity or quality of generated data items.

Consider, for example, a creative deep learning system that can generate a million poems about a given topic (Ghazvininejad et al., 2016) or a natural language system that has produced over a hundred million English paraphrase pairs (Ganitkevitch et al., 2013; Pavlick et al., 2015). How does one go about assessing the quality of such generated data or of the models behind them?

A key bottleneck is annotation: Despite substantial advances in crowdsourcing technology, our ability to annotate novel data at a reasonable cost is far outpaced by increasingly sophisticated models that generate data at an even quicker pace. Computing the exact precision of a dataset of  $N$  items requires annotating the validity of every item, making exact computation infeasible for all but the smallest datasets. Conventional random sampling methods can achieve a constant-factor approximation of the PR curve with  $\Theta(\sqrt{N \log N})$  valid/invalid annotations, but this, as Sabharwal and Sedghi (2017) argued, is also impractical in the modern era of big data. They proposed a logarithmic stratified sampling algorithm, henceforth referred to as LOGSTRAT, that can do so using only  $O(\log N \log \log N)$  annotations,<sup>1</sup> as long as the underlying precision function satisfies a *weak monotonicity* property. They also proposed PAULA, which achieves this with  $O(\Delta \log N)$  annotations, but requires a stronger notion of local monotonicity akin to concavity. This stronger monotonicity is characterized by a parameter  $\Delta$ , which is difficult to estimate from data.

Both of these algorithms *query* the precision function at a set  $S$  of geometrically spaced points (thus  $|S| = \log N$ ),

---

<sup>1</sup>These logarithms are w.r.t. base  $1 + \epsilon$ , the guaranteed approximation factor. The bounds thus scale roughly as  $1/\epsilon$ .

and interpolate between them. They, however, suffer from a limitation that  $S$  is chosen in a *data oblivious* way—it depends only on  $N$  and the desired approximation ratio, independent of the actual data. While  $\log N$  queries are sufficient, they might be overkill, e.g., in the extreme case when the precision function is a constant.

We present a new algorithm, called ADASTRAT for adaptive stratified sampling, that *adaptively chooses what to query next based on current observations of the data*. It provides a guaranteed approximation under the same weak monotonicity condition as LOGSTRAT, without the stronger condition needed by PAULA.

The main novelty is the following: Given any  $k$  points observed on a PR curve, we show how to precisely characterize the “envelope” (Figure 1) of all possible PR curves that pass through these  $k$  points (Theorem 2). This envelope can be maintained efficiently as more points are observed. This leads to a natural bisection-style algorithm, which iterates until the “height” of the envelope (i.e., the maximum gap between its upper and lower boundaries) falls within the desired approximation ratio. The approximate curve ADASTRAT outputs is the geometric mean of the resulting upper and lower envelopes, which are *non-linear*, in line with the fact that a linear interpolation isn’t appropriate in the precision-recall space (Davis and Goadrich, 2006).

ADASTRAT is surprisingly powerful both in theory and in practice. Formally, besides the initial few data points that each of these algorithm annotates, ADASTRAT uses  $O(K \log K)$  annotations chosen via adaptive stratified sampling (Theorem 8) if it ends up querying  $K$  points before meeting the stopping condition. The data determines how large  $K$  is. When the precision function decays very rapidly or very slowly,  $K$  can be as small as 2. Indeed, in two extreme cases, ADASTRAT queries only the first and last points of the PR curve and accurately interpolates everything in-between. When the minimum precision is bounded by a constant (e.g., 0.5 or 0.3) as in most practical cases,  $K$  scales as  $\log \log N$  (Corollary 1). In the worst case,  $K$  is  $\log N$  (Theorem 4), matching the asymptotic bound for LOGSTRAT.

We perform a *regret analysis* of ADASTRAT, showing (Theorem 6) that it never needs more than roughly  $\log \log N$  times more queries than an “optimal” oracle algorithm that may use *a priori* knowledge of the shape of the precision function to decide which points to query.

Using the envelope view, we also provide a *matching lower bound*: every algorithm that operates by querying the precision function at some subset of points and guarantees a constant-factor approximation, must query  $\Omega(\log N)$  points in the worst case (Theorem 7).

From a practical perspective, we evaluate various algorithms on scaled-up versions of the fully-annotated PPDB dataset used by Sabharwal and Sedghi (2017). On the PPDB-36K dataset with 35,615 items, we find that ADASTRAT *queries only 18 points* of the precision function, a 4.3x reduction from the 78 points queried by both LOGSTRAT and PAULA. Its strength is further highlighted by larger datasets, such as PPDB-100x, a 100x larger fully-annotated randomized variant that we created with a similar PR curve as the original. Here, despite the 100-fold increase in dataset size, ADASTRAT continues to query only 18 points, 13x fewer than the 234 needed by LOGSTRAT and PAULA. ADASTRAT uses mere 24K annotations,<sup>2</sup> a tiny fraction of the 3.5M items in this expanded dataset, while still yielding an impressive practical approximation (Figure 4).

## 1.1 RELATED WORK

Despite the importance of evaluating the precision-recall tradeoff of generative machine learning models, much research has been devoted to computing summary statistics (average precision AP, discounted cumulative gain DCG, etc.). Various results provide confidence intervals around estimated statistics (Carterette et al., 2006; Yilmaz et al., 2008; Aslam et al., 2006; Yilmaz and Aslam, 2006; Schnabel et al., 2016), often using different sampling approaches equipped with variance reduction techniques. Kanoulas (2015) provides a survey of relevant quality evaluation approaches in information retrieval.

In contrast to these efforts, we focus on characterizing the full precision recall curve at scale (over millions of items) and with provable guarantees. This task is considerably more challenging than computing summary statistics, an evidence of which is that these statistics can often be easily “read off” if one has computed the entire curve.

Relatively little research effort has been devoted to capturing an entire precision curve. In the area of vision, Welinder et al. (2013) propose semi-supervised performance evaluation, which is a generative model to capture a classifier’s confidence scores. Unlike their use of a parametric model that makes certain assumptions about the curve, ours is a model-free approach relying only on a (weak form of) monotonicity.

Our setup is closest to that of Sabharwal and Sedghi (2017). Different from their approach, we propose to access the precision-recall curve in a data-aware, *adaptive* fashion. This, as we show, greatly reduces the sample complexity. Further, we do not make the strong monotonicity assumption needed for their strongest algorithm.

<sup>2</sup>The conventional method needs 284K annotations and LOGSTRAT needs 54K.

## 2 PRELIMINARIES

Consider the ranked output  $T = (t_1, t_2, \dots, t_N)$  of an algorithm  $\mathcal{A}$ , where each  $t_i$  comes from some universe  $U$  (e.g., all documents on the Web, all paraphrase pairs, all subject-verb-object triples, etc.). Each item  $u \in U$  is associated with an unknown true label  $v(u) \in \{0, 1\}$  that captures the semantics of some underlying task (e.g., whether a document is relevant to a query, whether a pair of phrases is a linguistic paraphrase, whether a triple denotes a true fact, etc.). We assume access to a noisy estimator, e.g., a crowd-sourced annotation,  $\tilde{v}(u)$  of  $v(u)$  that equals  $1 - v(u)$  with probability  $\eta < 1/2$ , and equals  $v(u)$  otherwise. The **precision function of  $\mathcal{A}$** ,  $p : [N] \rightarrow [0, 1]$ , maps each rank  $r \in [N]$  to the fraction of the top  $r$  items in  $T$  that are positive, i.e., labeled as 1:

$$p(r) = \frac{1}{r} \sum_{i=1}^r v(t_i) \quad (1)$$

where we omit  $\mathcal{A}$  from the notation for brevity.

Precision functions are widely used in machine learning. In fact, they are the building blocks of many statistical metrics. For example, a commonly used metric, precision-at- $k$ , which measures the quality of the top- $k$  ranked items, is exactly  $p(k)$ . As a second example, precision-recall curves can be built from precision functions. To see this, suppose a classifier outputs and ranks items based on its belief that each item is positive.  $v(t_i)$  is an indicator variable, that is 1 if and only if the item ranked at the  $i$ -th place is positive. The classifier draws a line and classifies the top  $k$  items as positive examples. The precision of such a decision is  $1/k \sum_{i=1}^k v(t_i)$ , which is exactly  $p(k)$ , while the recall is  $\sum_{i=1}^k v(t_i) / \sum_{i=1}^N v(t_i)$ , which is  $p(k)/p(N)$ . Other metrics, such as Gain@ $k$ , accuracy, F1, true positive rate (TPR), false positive rate (FPR), Receiver Operating Characteristic (ROC) curve, average precision (AP), specificity, sensitivity, etc, can all be computed from  $p$ . Surveys by Fawcett (2006), Davis and Goadrich (2006), and Majnik and Bosnic (2013) provide more examples.

Given  $T$ , indirect access to  $\tilde{v}$ , and  $\epsilon \in (0, 1]$ , our goal is to compute a pointwise  $(1 + \epsilon)$ -approximation  $\tilde{p}$  of  $p$ . We assume accessing each  $\tilde{v}(t_i)$  is costly, e.g., needs human annotation. Therefore, we would like to compute  $\tilde{p}$  efficiently in terms of the number of evaluations of  $\tilde{v}$ .

### 2.1 POINT ESTIMATES: RANDOM SAMPLING

A simple way to obtain an estimate  $\tilde{p}(r)$  of  $p(r)$  for a fixed rank  $r$ , which we refer to as a *point estimate* at  $r$ , is via random sampling: Sample (with repetition) a set of indices  $J$  independently and uniformly

from  $\{1, 2, \dots, r\}$ , obtain a noisy estimate  $\tilde{v}(t_j)$  for each  $v(t_j)$ , and compute the empirical average  $\tilde{p}(r) = \frac{1}{z} \sum_{j \in J} \tilde{v}(t_j)$  where  $z = |J|$ . Then, assuming  $p \geq 1/3$ , the expected value of  $\tilde{p}(r)$  is within a factor of  $1 + \eta$  of  $p(r)$  (see Appendix). One can apply tail inequalities such as the two-sided Hoeffding bound (Hoeffding, 1963) to compute how tight the estimate is. For any  $\epsilon > \eta$ , to obtain a  $(1 + \epsilon)$ -approximation of  $p(r)$  with a confidence of  $1 - \delta$  (e.g., a 95% confidence would mean  $\delta = 0.05$ ), it suffices to have  $z$  samples where:

$$z \geq \frac{(1 + \eta)^2}{2(\epsilon - \eta)^2 p(r)^2} \ln \frac{2}{\delta}. \quad (2)$$

Details are deferred to the Appendix. When  $\eta = 0$ , this simplifies to the bound of Sabharwal and Sedghi (2017).

### 2.2 WEAK MONOTONICITY

Being the average of  $r$  0-1 numbers,  $p(r)$  necessarily fluctuates up and down as  $r$  increases. Nevertheless, we assume that  $T = (t_1, t_2, \dots, t_N)$  is a ranked output of an algorithm  $\mathcal{A}$ , where the true  $v(t_i)$  in the beginning are more likely to be 1. In other words, one expects  $p(r)$  to broadly decrease with increasing  $r$ . This property is captured by the following weak monotonicity notion introduced by Sabharwal and Sedghi (2017), for which we use a slightly different notation:

**Definition 1** (Weak Monotonicity). *Let  $m, \tilde{r} \in \mathbb{N}^+$ . Then  $p$  is  $(\tilde{r}, m)$ -weak monotone if for all  $r_1 \geq \tilde{r}$  and  $r_2 \geq r_1 + m$ , we have  $p(r_1) \geq p(r_2)$ .*

Weak monotonicity guarantees that, after the first  $\tilde{r}$  points, precision is non-increasing for points ranked at least  $m$  apart. Under this property, Sabharwal and Sedghi (2017) showed that it is sufficient to compute precision at only logarithmically many points in order to guarantee a tight approximation of the entire PR curve, which is reflect by their algorithm LOGSTRAT. They also relied on a stronger monotonicity assumption for their strongest algorithm, which we do *not* assume here.

**Theorem 1** (LOGSTRAT (Sabharwal and Sedghi, 2017)). *Let  $T, v, p, \tilde{r}, m$  be as above. Let  $\epsilon \in (0, 1], \delta > 0, p_{\min}$  be the minimum value of  $p$ , and  $\beta > 1$ . Let  $\ell = \lceil \log_{1+\epsilon} \tilde{r} \rceil$  and  $L = \lfloor \log_{1+\epsilon} N \rfloor$ . If  $m \leq \lfloor \epsilon(1 + \epsilon)^\ell - 1 \rfloor$  and  $p$  is  $(\tilde{r}, m)$ -monotone, then with probability at least  $1 - \delta$ , the output of LOGSTRAT on input  $(T, v, \epsilon, \tilde{r}, \delta, p_{\min}, \beta)$  is a  $\beta(1 + \epsilon)$ -approximation of  $p(r)$ . Further, LOGSTRAT queries  $p$  at  $L - \ell$  points, and uses annotation of the first (roughly)  $\tilde{r}$  points and of  $\frac{\epsilon(L-\ell)}{2(\beta-1)^2(1+\epsilon)p_{\min}^2} \ln \frac{L-\ell}{\delta/2}$  points chosen randomly via stratified sampling.*

Note that this result assumes the noiseless setting,  $\eta = 0$ . Note also that since  $L = \Theta(\log N)$ , LOGSTRAT re-

quires querying  $p$  at  $\Theta(\log N)$  points and annotating  $\Theta(\log N \log \log N)$  data points. Our goal is to improve upon this by adaptively deciding where to query (and which points to annotate), and when to stop.

### 3 CHARACTERIZING PRECISION FUNCTIONS THROUGH $k$ POINTS

What could a precision function possibly look like if we know values of it at  $k$  points? We answer this question by providing a precise characterization of all precision functions passing through  $k$  given points, under the assumption of weak monotonicity. First, we characterize a tight upper bound  $ub(v; y, p(y))$  and a lower bound  $lb(v; y, p(y))$  for every point  $p(v)$  at the precision function if we know the value of a single point  $p(y)$ . We call the space between  $ub$  and  $lb$  an *envelope* induced by the value of  $p(y)$ , because any  $p(v)$  must be sandwiched between  $lb(v; y, p(y))$  and  $ub(v; y, p(y))$ . These bounds are formally defined next, and illustrated in Figure 1.

Figure 1: A graphical illustration of the upper bound  $ub$  (red line) and the lower bound  $lb$  (dashed blue line) induced by one point  $p(y)$ . The envelope is shaded.

**Definition 2.** Let  $p$  be a precision function whose value  $p(y)$  is known at a point  $y$ . Define  $ub$  and  $lb$ , each parameterized by  $y, p(y)$ , and (implicitly) by  $m$ , as:

$$ub(v; y, p(y)) = \begin{cases} p(y)y/v & \text{if } v \leq y \\ (p(y)y + v - y)/v & \text{if } y < v \leq y + \lfloor mp(y) \rfloor \\ (p(y)y + \lfloor mp(y) \rfloor)/v & \text{if } y + \lfloor mp(y) \rfloor < v \leq y + m \\ p(y) & \text{if } v > y + m \end{cases}$$

$$lb(v; y, p(y)) = \begin{cases} p(y), & \text{if } v < y - m, \\ (p(y)y - \lfloor mp(y) \rfloor)/v, & \text{if } y - m \leq v < y - \lfloor mp(y) \rfloor \\ (p(y)y + v - y)/v, & \text{if } y - \lfloor mp(y) \rfloor \leq v < y, \\ p(y)y/v, & \text{if } v \geq y. \end{cases}$$

Our characterization is summarized by the following theorem, whose proof is left to the appendix:

**Theorem 2.** Let  $p$  be any  $(\tilde{r}, m)$ -monotonic precision function. Then, for any  $v, y > \tilde{r}$ , we have:

$$lb(v; y, p(y)) \leq p(v) \leq ub(v; y, p(y))$$

Further,  $ub$  and  $lb$  are tight—each corresponds to a valid precision function whose value at  $y$  is  $p(y)$ .

This single point envelope characterization easily extends to the case where the values of  $p$  at are known at  $k$  points,  $p(y_1), p(y_2), \dots, p(y_k)$ . The envelope here is the intersection of the  $k$  single point envelopes:

$$ub(v) = \min_{j=1}^k ub(v; y_j, p(y_j)) \quad (3)$$

$$lb(v) = \max_{j=1}^k lb(v; y_j, p(y_j)) \quad (4)$$

Finally, we define the *height* of the envelope induced by  $ub$  and  $lb$  as the maximum over  $i$  of  $ub(i)/lb(i)$ .

### 4 The ADASTRAT ALGORITHM

Armed with the notion of an envelope characterizing all precision functions that could possibly pass through  $k$  observed points, we describe ADASTRAT (Algorithm 1). The idea is to *query*  $p$  near the beginning and the end, compute the envelope induced by these two observations, and continue making further queries in the middle and tightening the envelope until its height is within (the square of) the desired approximation ratio. The algorithm then outputs the geometric mean of the (non-linear) upper and lower bounds of the final envelope.

As before,  $T = (t_1, t_2, \dots, t_N)$  are the ranked data items with (unknown) true binary labels  $v(t_i)$  and precision function  $p$ . We assume access to an  $\eta$ -noisy estimator  $\tilde{v}$  of  $v$  and an oracle  $\text{QUERY}(i, T, \tilde{v})$  that returns a guaranteed  $\beta$ -approximation of the true precision  $p(i)$  at a given point  $i$ , for some  $\beta \geq 1 + \eta$ . Given  $\epsilon, \delta > 0$ , our goal is to obtain a  $\beta(1 + \epsilon)$ -approximation of the entire  $p$  with confidence at least  $1 - \delta$ . For  $m, \tilde{r} \in \mathbb{N}^+$ , we assume  $p$  is  $(\tilde{r}, m)$ -weak monotonic. For brevity, we define:

$$\tilde{l} = \max \left\{ \left\lceil \frac{(1 + \epsilon)^2 m}{2\epsilon + \epsilon^2} \right\rceil, \tilde{r} \right\}.$$

We first discuss a simple case, where  $\text{QUERY}(i, T, \tilde{v})$  returns the exact value of  $p(i)$ , i.e.,  $\beta = 1$  (and thus  $\eta = 0$ ). We will extend our result to the case where  $\beta > 1$  later. In Algorithm (1), we maintain the envelope of possible precision functions represented by the upper bound  $\tilde{ub}(i)$  and the lower bound  $\tilde{lb}(i)$ . We update these bounds in function  $\text{UPDATEUL}$  as we get access to the values of the precision function at different locations.  $\text{UPDATEUL}$

intersects the old envelope with a new pointwise upper and lower bound, just as in Equation (3,4). We compute the exact values of  $p(1), \dots, p(\tilde{l})$  by accessing the values of  $v(t_1), \dots, v(t_{\tilde{l}})$  directly. Here, ACCESS( $i, T$ ) returns the exact value of  $v(t_i)$ .<sup>3</sup>

Function PR returns  $\tilde{p}(l+1), \dots, \tilde{p}(r-1)$ , which form an  $(1 + \epsilon)$ -approximation to the true values  $p(l+1), \dots, p(r-1)$ . In function PR, first the algorithm checks the height of the envelope between  $\tilde{p}(l)$  and  $\tilde{p}(r)$ . If the height is less than  $(1 + \epsilon)^2$ , then the algorithm stops,

<sup>3</sup>For simplicity, we assume ACCESS uses  $v$  instead of  $\tilde{v}$ . Under the noisy setting where ACCESS uses  $\tilde{v}$ , the results can be extended by averaging multiple calls to ACCESS.

returning the geometric mean of  $\tilde{ub}$  and  $\tilde{lb}$ . When  $\beta = 1$ , the second stopping condition  $r/l \leq (1 + \epsilon)^2$  is redundant, because for any  $l, r$ , such that  $\tilde{l} \leq l < r < (1 + \epsilon)^2 l$ , we must have  $p(r) \geq p(l)l/r \geq p(l)/(1 + \epsilon)^2$  and  $p(l) \geq p(r)(r - m)/l \geq p(r)/(1 + \epsilon)^2$ , due to Theorem 2. In other words, if condition  $r/l < (1 + \epsilon)^2$  is met, then the height of the envelope has already dropped below  $(1 + \epsilon)^2$ . If the function does not stop, there is at least one point  $i$  between  $l$  and  $r$ , where  $\tilde{ub}(i)/\tilde{lb}(i)$  exceeds  $(1 + \epsilon)^2$ . In this case, we query the function value at a middle point  $c = \text{round}(\sqrt{lr})$ , and recursively call PR on intervals  $(\tilde{p}(l), \dots, \tilde{p}(c))$  and  $(\tilde{p}(c), \dots, \tilde{p}(r))$ .

When  $\beta > 1$ , we stop first when the estimated boundaries  $\tilde{ub}$  and  $\tilde{lb}$  are within  $(1 + \epsilon)^2$ . In this case, we know that true values of  $p$  lie in the range between  $\beta \tilde{ub}$  and  $\tilde{lb}/\beta$ , which are at most  $\beta^2(1 + \epsilon)^2$  apart. It is easy to see that  $\tilde{p} = \sqrt{\tilde{ub} \tilde{lb}}$  provides a  $\beta(1 + \epsilon)$  approximation to any curve in this range, which includes  $p$ . We also stop when  $r/l \leq (1 + \epsilon)^2$ . In this case, we know that the actual height of the envelope (distance between the true boundaries  $ub$  and  $lb$ ) is bounded by  $(1 + \epsilon)^2$  (due to the same reason as why  $r/l \leq (1 + \epsilon)^2$  is redundant when  $\beta = 1$ ). Since all point estimations are at most off by  $\beta$ ,  $\tilde{ub}$  is at most  $\beta ub$  and  $\tilde{lb}$  is at least  $lb/\beta$ . Therefore,  $\tilde{p} = \sqrt{\tilde{ub} \tilde{lb}}$  is a  $\beta(1 + \epsilon)$  approximation. Putting this all together, we have the following theorem:

**Theorem 3.** *Let  $T, \tilde{v}, p, m, \tilde{r}, \tilde{l}, \beta$ , and  $\epsilon$  be as defined before. If the precision function  $p$  is  $(\tilde{r}, m)$ -weak monotonic and QUERY( $i, T, \tilde{v}$ ) is a  $\beta$ -approximation of  $p(i)$  for all  $i$ , then the output of ADASTRAT (Algorithm 1) on input  $(T, \tilde{l}, \tilde{v}, \epsilon)$  is a pointwise  $\beta(1 + \epsilon)$ -approximation of the true precision values  $p(1), \dots, p(N)$ .*

### Sufficient Conditions for Stopping

To understand the complexity of ADASTRAT in terms of the number of calls to QUERY, we analyze the stopping condition of PR, namely, whether the height of the envelope is within than  $(1 + \epsilon)^2$ . We provide two sufficient conditions for stopping. The two lemmas below follow by writing down the pointwise envelopes induced by  $\tilde{p}(l)$  and  $\tilde{p}(r)$  and making use of the fact that  $r > l \geq \tilde{l}$ .

**Lemma 1.** *Under weak monotonicity, if  $\tilde{p}(l)/\tilde{p}(r) \leq (1 + \epsilon)^2$ , the height of the envelope<sup>4</sup> is bounded by  $(1 + \epsilon)^2$ .*

**Lemma 2.** *Under weak monotonicity, if  $(\tilde{p}(r)^r)/(\tilde{p}(l)^l) \leq (1 + \epsilon)^2$ , the height of the envelope is bounded by  $(1 + \epsilon)^2$ .*

The sufficient stopping conditions captured by Lemmas 1 and 2 are two interesting cases of early stopping, in

<sup>4</sup>defined by substituting  $\tilde{p}$  into (3) and (4).

contrast to LOGSTRAT, where  $O(\log_{1+\epsilon} N)$  queries are needed regardless of the shape of the precision function.

Lemma 1 captures the case where  $p$  does not drop too much from  $l$  to  $r$ . This corresponds to the density of  $v(t_i)$  that are 1 staying almost the same for all entries in the range from  $l$  to  $r$ . Notice that the density almost always cannot increase, because of weak monotonicity.

Lemma 2 captures the other extreme, where  $v(t_i)$  is almost always zero for the entries in the range from  $l$  to  $r$ . In this case, the precision function drops at its fastest rate. Our algorithm is able to capture these two cases, stopping early, thereby preventing unnecessary queries.

### Upper Bound on the Number of Query Calls

The above stopping conditions imply that ADASTRAT never makes more calls to QUERY than LOGSTRAT does. Specifically, deferring a proof to the Appendix:

**Theorem 4.** *Under the conditions of Theorem 3, the number of calls to QUERY is at most  $\log_{1+\epsilon}(N/\tilde{l})$ .*

## 4.1 REGRET BOUNDS

Consider an “optimal” algorithm that is guaranteed to produce a  $(1 + \epsilon)$ -approximation of all weak monotonic precision function with as few accesses to QUERY as possible. If this algorithm knew the shape of  $p$  a priori, it could clearly be very smart about where it queries  $p$  in order to generate a guaranteed approximation. The *regret* of any algorithm, then, is defined as how many (multiplicatively) more accesses to QUERY it needs, compared to this optimal algorithm who knows all. We prove that ADASTRAT has a regret of no more than  $\log_2 \log_{1+\epsilon} N$ .

We start by exploring how such an “optimal” algorithm might behave. Suppose it has access to the maximum and minimum precision values,  $p_{\max}$  and  $p_{\min}$ , as well as to  $q_1, \dots, q_K$ , where  $K = \left\lceil \log_{1+\epsilon} \frac{p_{\max}}{p_{\min}} \right\rceil$  and  $q_i$  is the *first* location where  $p$  falls below  $p_{\max}/(1 + \epsilon)^{i-1}$ . Then, as we show next, it suffice for the “optimal” algorithm to make only  $K$  queries, namely to  $p(q_1), \dots, p(q_K)$ , to guarantee a  $(1 + \epsilon)$ -approximation:

**Lemma 3.** *Let  $q_1, \dots, q_K$  be as defined above. Let  $\tilde{p}(j) = p(q_i)$  whenever  $j \in \{q_i, \dots, q_{i+1}\}$ . Then  $\tilde{p}$  is a  $(1 + \epsilon)$ -approximation of  $p$  in the range  $[\tilde{l}', N]$ .*

Lemma 3 guarantees that the “optimal” algorithm does not make too many queries when the precision function decays slowly, i.e.,  $p_{\max}/p_{\min}$  is small. In the other extreme, where the precision function decays in its fastest possible way,  $p(r)r$  stays almost as a constant. In this case, we can prove that the “optimal” algorithm does not make much more queries beyond the ratio of the maximal and minimal values of  $p(r)r$ . Specifically, suppose

the “optimal” algorithm has access to  $s_1, \dots, s_P$ , where  $s_j$  is the first location that function  $p(r)r$  goes above  $p(\tilde{l})\tilde{l}(1+\epsilon)^{j-1}$ . Then  $P = \left\lceil \log_{1+\epsilon} \frac{p(N)N}{p(\tilde{l})\tilde{l}} \right\rceil$ . We can also prove that it suffices for the “optimal” algorithm to query the above  $P$  points to obtain a  $(1 + \epsilon)$ -approximation:

**Lemma 4.** *Let  $s_1, \dots, s_P$  be as defined above. Let  $\tilde{p}(j) = p(s_i)s_i/j$  whenever  $j \in \{s_i, \dots, s_{i+1}\}$ . Then  $\tilde{p}$  is a  $(1 + \epsilon)$ -approximation of  $p$  in the range  $[\tilde{l}, N]$ .*

Proofs of these two lemmas may be found in Appendix B. Putting these together gives a bound on OPT, the number of times the optimal algorithm calls QUERY:

**Theorem 5.** *Under the conditions of Theorem 3,*

$$\text{OPT} \leq \left\lceil \log_{1+\epsilon} \min \left( \frac{p_{\max}}{p_{\min}}, \frac{p(N)N}{p(\tilde{l})\tilde{l}} \right) \right\rceil.$$

Now we state our main regret bound:

**Theorem 6.** *Under the conditions of Theorem 3, ADASTRAT calls QUERY no more than  $(\text{OPT} + 1)(1 + \log_2 \log_{1+\epsilon} N) + 1$  times.*

This says that the number of QUERY calls made by ADASTRAT is roughly  $O(\text{OPT} \cdot \log_2 \log_{1+\epsilon} N)$ . The high level idea to prove Theorem 6 is as follows. Suppose  $r_1, \dots, r_{\text{OPT}}$  are the actual query points of the optimal algorithm. Because ADASTRAT uses a binary search, i.e., it always splits an interval at its geometric middle point. Then it takes ADASTRAT roughly  $O(\log_2 \log_{1+\epsilon} N)$  splits to “locate” one query point  $r_i$  of the optimal algorithm (more precisely, find a point that is sufficiently close to  $r_i$  that guarantees the approximation bound). Hence, the total number of queries of ADASTRAT is bounded by OPT times  $\log_2 \log_{1+\epsilon} N$ . Our actual proof to Theorem 6 is based on walking through the actual calling map of the function PR, where each node in this map represents an actual interval  $(p(l), p(r))$  that PR called. We leave this proof to Appendix B.

Combining Theorems 5 and 6, we immediately obtain the following worst case upper bound for ADASTRAT.

**Corollary 1.** *Under the conditions of Theorem 3, ADASTRAT calls QUERY no more than*

$$O \left( \log_{1+\epsilon} \min \left\{ \frac{p_{\max}}{p_{\min}}, \frac{p(N)N}{p(\tilde{l})\tilde{l}} \right\} \cdot \log_2 \log_{1+\epsilon} N \right)$$

*times.*

Thus, ADASTRAT makes very few queries when  $p$  is flat or decays very fast. In general, when  $p_{\min}$  may be treated as a constant bounded away from zero (e.g., 0.5 or 0.3, as is the case in many practical applications), this shows that ADASTRAT scales essentially as  $\log \log N$ .

## 4.2 ASYMPTOTIC LOWER BOUND

What is the minimum number of calls to the QUERY function needed in order to guarantee an  $(1 + \epsilon)$ -approximation to  $p$ ? We provide a worst-case lower bound, confirming that ADASTRAT is asymptotically optimal in terms of the number of queries.

**Theorem 7.** *Let  $\mathcal{A}$  be any algorithm that accesses the precision function only via the QUERY oracle and, for any  $(\tilde{r}, m)$ -weak monotonic precision function, outputs a curve that  $(1 + \epsilon)$ -approximates it. For any  $\epsilon' > \epsilon$ ,  $\mathcal{A}$  must make at least  $\Omega(\log_{1+\epsilon'} N)$  accesses to QUERY.*

The high level idea of the proof to Theorem 7 is as follows: let  $J \approx \log_{1+\epsilon'} N$ . We carefully construct a family of  $2^J$  valid precision functions  $F = \{f_0, f_1, \dots, f_{2^J-1}\}$  such that, for any two functions  $f_i$  and  $f_j$ , there exists at least one point  $y_{i,j}$ , such that  $f_i(y_{i,j})$  and  $f_j(y_{i,j})$  are separated by more than  $(1 + \epsilon)^2$  (i.e., either  $f_i(y_{i,j}) > (1 + \epsilon)^2 f_j(y_{i,j})$  or  $f_j(y_{i,j}) > (1 + \epsilon)^2 f_i(y_{i,j})$ ). We call this point  $y_{i,j}$  a *separating point* between  $f_i$  and  $f_j$ .

Now suppose algorithm  $\mathcal{A}$  can output a  $(1 + \epsilon)$ -approximation to any given precision function. Starting with an unknown function  $f \in F$ , we can use  $\mathcal{A}$  to identify  $f$ . To do so, we run  $\mathcal{A}$  to obtain a  $(1 + \epsilon)$ -approximate curve  $\tilde{f}$  and examine its values at all separating points. Because  $\tilde{f}$  is a  $(1 + \epsilon)$ -approximation and the distance between two functions at a separating point is more than  $(1 + \epsilon)^2$ , we can unambiguously determine the correct  $f$ . Appendix B includes a detailed construction of the function family  $F$  following this high-level idea.

## 4.3 STRATIFIED SAMPLING FOR QUERY

Suppose ADASTRAT ends up calling QUERY on the  $K$  points  $r_1 < r_2 \dots < r_K$  (generally not in this order) before terminating. By design,  $r_1 > \tilde{l}$  and  $r_K = N$ . Let  $\delta > 0$  and  $\beta > 1 + \eta \geq 1$ . We would like QUERY to provide a  $\beta$ -approximation of  $p(r_i)$  for all  $i \in \{1, \dots, K\}$  with an overall (cumulative) confidence of at least  $1 - \delta$ . To achieve this, QUERY proceeds similarly to LOGSTRAT but with  $\tilde{v}$  rather than  $v$ : it uses as an estimate of  $p(r_i)$  the empirical average of  $\eta$ -noisy estimates  $\tilde{v}(t_j)$  of true labels  $v(t_j)$  for  $s$  uniform random samples  $j$  drawn independently from  $[1, r_i]$ , where:

$$s = \left\lceil \frac{(1 + \eta)^2}{2(\beta - 1 - \eta)^2 p_{\min}^2} \ln \frac{2K}{\delta} \right\rceil \quad (5)$$

Here  $p_{\min}$  is an estimate of (a lower bound on) the minimum value of  $p$  for the given data.<sup>5</sup>

<sup>5</sup>Domain knowledge about the data might allow using a small constant, such as 0.3, for  $p_{\min}$ . Alternatively, one can use an estimate of  $p(N)$  obtained via an *adaptive concen-*

Of course, we don't know  $K$  *a priori*; we will address this shortly. It follows from the Hoeffding bound, Eq. (2), that such an empirical average provides a  $\beta$ -approximation of  $p(r_i)$  with confidence at least  $1 - \delta/K$ . Applying the union bound over all  $i$ , ADASTRAT has overall confidence at least  $1 - \delta$  in its estimates being correct simultaneously at all  $K$  points  $r_1, \dots, r_K$ .

As in LOGSTRAT, since we rely only on the union bound, the samples obtained for  $r_1$  can be (partially) reused as samples for all  $r_i > r_1$ . The amount of reuse is determined by what we will refer to as the *sample density* of an interval in  $\{1, \dots, N\}$ , defined as the ratio of the number of samples in this interval to the size of the interval. Clearly, in order to have  $s$  uniform samples available for  $r_i$ , we must have a sample density of at least  $s/r_i$  in the interval  $[1, r_i]$ . We would like to achieve this while minimizing the total number of samples.

It can be verified that the following *stratified sampling strategy*, henceforth referred to as  $\mathcal{S}$ , results in the minimum overall number of samples while ensuring that the sample density in  $[1, r_i]$  is at least  $s/r_i$ :

$$\begin{aligned} &\text{draw } \left\lceil \frac{(r_1 - \tilde{l})s}{r_1} \right\rceil \text{ samples in } [\tilde{l} + 1, r_1] \\ &\text{draw } \left\lceil \frac{(r_i - r_{i-1})s}{r_i} \right\rceil \text{ samples in } [r_{i-1} + 1, r_i] \text{ for } i > 1 \end{aligned}$$

In LOGSTRAT, the  $K$  points are visited in increasing order, simplifying the implementation of  $\mathcal{S}$  in practice. Further,  $K$  is known *a priori* to be  $\log_{1+\epsilon} N/\tilde{l}$  and  $r_i$  by design equals  $r_{i-1}(1 + \epsilon)$ . This makes it easy to compute the total number of evaluations of  $v$  needed, which sums up to  $\tilde{l} + \frac{\epsilon}{1+\epsilon} s \log_{1+\epsilon} N/\tilde{l}$ , in line with Theorem 1.

The adaptive nature of ADASTRAT makes both the implementation of  $\mathcal{S}$  and a similar calculation challenging. Nevertheless, the following result holds:

**Theorem 8.** *Under the conditions of Theorem 3, for any  $\delta > 0$  and  $\beta > 1 + \eta \geq 1$ , QUERY can be implemented using a stratified sampling strategy such that ADASTRAT provides a  $\beta(1 + \epsilon)$ -approximation of the precision function  $p$  with a confidence of at least  $1 - \delta$  using  $\tilde{l}$  evaluations of the true label  $v$  and:*

$$\left( \left\lceil \frac{r_1 - \tilde{l}}{r_1} \right\rceil + \sum_{i=2}^K \left\lceil \frac{r_i - r_{i-1}}{r_i} \right\rceil \right) \cdot s$$

evaluations of the noisy estimate  $\tilde{v}$ , where  $s = \left\lceil \frac{(1 + \eta)^2}{2(\beta - 1 - \eta)^2 p_{\min}^2} \ln \frac{2K}{\delta} \right\rceil$  and  $r_1, r_2, \dots, r_K$  are the points where ADASTRAT calls QUERY.

*tration inequality*, such as Corollary 1 of Zhao et al. (2016), which provides a dynamic stopping condition to decide how many samples are sufficient, and guarantees that this number,  $z_{\min}$ , is upper bounded by a generalization of Hoeffding's bound with an additional log log term:  $1.8z_{\min}(\gamma^2 p(N)^2 - 0.6 \log(\log_{1.1} z_{\min} + 1)) \leq \ln(12/\delta)$ , where  $1 + \gamma = \frac{\beta}{1 + \eta}$ .

We note that this quantity is bounded above by  $Ks$ , which scales as  $O(K \log K)$ , considering other parameters as constants. This simplified expression is equivalent to *not* reusing samples at all, and thus quite loose in practice. Even so, for datasets requiring  $K \ll \log N$ , this is substantially smaller than the equivalent  $O(\log N \log \log N)$  expression for LOGSTRAT.

Unlike LOGSTRAT, there are two hurdles to implementing a stratified sampling strategy that supports the number of annotations claimed in Theorem 8:  $K$  is unknown in the beginning and ADASTRAT does not visit  $r_1, \dots, r_K$  in increasing order. Let  $r'_1, \dots, r'_K$  be the order in which ADASTRAT actually queries the  $K$  points. To address the first hurdle (unknown  $K$ ), we follow an **iterative deepening approach** and simply begin by assuming  $K = 1$  when querying  $r'_1$ . When ADASTRAT decides to make the next query at  $r'_2$ , we set  $K = 2$ , go back to  $r'_1$  to obtain correspondingly more annotations for it, and then obtain samples for  $r'_2$  based on  $K = 2$ . This process continues, slowly incrementing  $K$  and obtaining more samples at previously queried points to make up for the difference. Since the samples are drawn independently, this yields the same outcome as if we had known the true value of  $K$  in advance and obtained the corresponding number of samples for each  $r'_i$  in a single shot.

To address the second hurdle (queries not in increasing order), we **adapt stratified sampling** as follows. For simplicity of exposition, we assume here that  $K$  is known at the start. When querying  $r'_1$ , we use stratification similar to LOGSTRAT and obtain  $s(r'_1 - \bar{l})/r'_1$  fresh samples in the range  $[\bar{l} + 1, r'_1]$ , inducing a sample density  $s/r'_1$  in this range. When querying  $r'_2$ , there are two possibilities. If  $r'_2 > r'_1$ , then again we obtain fresh samples with density  $s/r'_2$  in the range  $[r'_1 + 1, r'_2]$ , similar to LOGSTRAT. If, on the other hand,  $r'_2 < r'_1$ , we obtain fresh samples instead in the range  $[\bar{l} + 1, r'_2]$  to increase the sample density here from  $s/r'_1$  to  $s/r'_2$ . This process continues with each new query, whose effect is to raise the sample density between the immediately lower queried point and the current point. It can be verified that this process ends with the sample density underlying the expression in Theorem 8, namely  $s/r_i$  in the range  $[r_{i-1} + 1, r_i]$ .

## 5 EXPERIMENTS

For an empirical evaluation, we consider the fully-annotated subset of PPDB 2.0 (Ganitkevitch et al., 2013) used by Sabharwal and Sedghi (2017), henceforth referred to as PPDB-36K. It contains  $N = 35,615$  English language paraphrase pairs for each of which Pavlick et al. (2015) provide a correctness confidence score (thus inducing an overall ranking) obtained using a machine learning algorithm, as well as crowdsourced annotations

Figure 2: Number of queries of the precision function as dataset size increases. ADASTRAT uses only 21 queries even for PPDB-36K-1000x with 35M items.

of the validity of each pair as a valid paraphrase, on a 5-point scale (1-5). A pair  $t_i$  receiving an average human judgment of at least 3 is considered correct, i.e.,  $v(t_i) = 1$  for such  $i$ , and 0 otherwise. For a direct comparison with prior work, we experiment with noiseless access to  $v$ , i.e.,  $\eta = 0$  and  $\tilde{v} = v$ .

Given the fully-annotated nature of PPDB-36K, the true precision function for it can be easily calculated and used to assess the performance of algorithms such as ADASTRAT. One drawback of this dataset, however, is its relatively small size. To alleviate this while still retaining the property of having a fully-annotated yet realistic dataset, we consider *scaled up variants* of PPDB-36k, created as follows. Using a sliding window of size  $\Delta = 100$ , we compute the running average  $q(i)$  of  $v(t_i)$  for  $1 \leq i \leq N$ , using smaller sliding windows as appropriate when  $i < \Delta$  or  $i > N - \Delta$ . For a scaling factor  $s \in \{10, 100, 1000\}$ , for each  $1 \leq i \leq N$ , we draw  $s$  independent random samples from the Bernoulli distribution with parameter  $q(i)$ . This results in 3 datasets, PPDB-36K-10x, PPDB-36K-100x, and PPDB-36K-1000x, that are 10, 100, and 1000 times larger than PPDB-36K, resp.

### 5.1 SCALING: QUERIES AND ANNOTATIONS

Our first experiment evaluates the number of queries (of the precision function) used by various algorithms, as well as the total number of annotations, as the dataset size is varied from 36K to 35M. We use the following parameters throughout:  $\epsilon = 0.03, \delta = 0.05, \beta = 1.05$ .<sup>6</sup>

Figure 2 shows in a semi-log plot the number of queries needed, as the dataset size grows.<sup>7</sup> As expected, both LOGSTRAT and PAULA use the same number of queries, which starts with 78 for PPDB-36K and grows propor-

<sup>6</sup>Code and data available at <http://allenai.org>.

<sup>7</sup>The exact number of queries is reported in Appendix A.

Figure 3: Number of annotations needed by various algorithms as dataset size increases. ADASTRAT needs substantially fewer annotations than competing algorithms that also do not assume strong monotonicity.

tional to  $\log N$ , reaching 312 queries for PPDB-36K-1000x. In contrast, ADASTRAT uses only 18 queries, even for the largest dataset with over 35M items. This aligns with the intuition that the adaptive nature of ADASTRAT allows it to be driven more by the “shape” of the precision function, rather than by the raw data size.

Figure 3 illustrates in a log-log plot the total number of samples used by each method, as the dataset size grows; again, exact numbers may be found in Appendix A. The conventional random sampling baseline asymptotically scales as  $\Theta(\sqrt{N \log N})$ . In line with this, the corresponding blue curve has a slope of roughly 0.5, reaching close to 1M required annotations for PPDB-36K-1000x. LOGSTRAT (red curve) is substantially more practical, growing from 18K annotations to 73K. PAULA (dashed purple line) needs the fewest annotations for the two smaller datasets, but relies the assumption of strong local monotonicity, which is difficult to verify in practice. Finally, ADASTRAT (green line) uses the fewest number of annotations (24K and 28K, resp.) for the two larger datasets. Further, among algorithms that do not rely on strong monotonicity, ADASTRAT has 20%-61% higher annotation efficiency than LOGSTRAT and 41%-97% higher than conventional random sampling.

## 5.2 APPROXIMATION QUALITY

The top plot in Figure 4 shows the approximate precision function  $\tilde{p}$  (green curve) produced by ADASTRAT for PPDB-36K-1000x. Despite querying only 18 points (marked with small red squares) along the true curve, ADASTRAT is able to obtain a remarkably good approximation of the entire true precision function (shown in black, and often occluded by the green curve).

Both LOGSTRAT and PAULA (bottom plot, red) also obtain a similarly tight approximation, except towards the

Figure 4: Precision function approximations generated by ADASTRAT (top) and LOGSTRAT and PAULA (bottom), for PPDB-36K-1000x. 18 green markers (top) and 234 corners of red boxes (bottom) are the points queried by the corresponding algorithm.

right end of the curve. Importantly, however, they do so by querying the true precision at 234 points, visually identifiable as the “corners” of the little red boxes. In particular, because of the geometrically spaced nature of the points they query, there is an enormous number of queries in the left part of the curve, which, as illustrated by ADASTRAT’s more spaced-out query points, is unnecessary. This demonstrates the strength of ADASTRAT in exploiting data observations to be smart about where and how often to query the true precision function.

## 6 CONCLUSION

We proposed ADASTRAT, a data-aware algorithm for computing the precision function of massive noisy datasets, with a constant-factor approximation guarantee. ADASTRAT intelligently chooses precision points to query. Under a mild monotonicity assumption, it outputs a guaranteed curve with minimal queries made to the PR curve, scaling very slowly with  $N$ , the number of items. ADASTRAT’s regret w.r.t. an oracle is bounded by  $\log \log N$ . We also provide a matching asymptotic lower bound in terms of the number of queries. On an NLP dataset of 3.5M items, ADASTRAT achieves a close approximation with merely 18 precision queries.

## Abstract

A latent force model is a Gaussian process with a covariance function inspired by a differential operator. Such covariance function is obtained by performing convolution integrals between Green's functions associated to the differential operators, and covariance functions associated to latent functions. In the classical formulation of latent force models, the covariance functions are obtained analytically by solving a double integral, leading to expressions that involve numerical solutions of different types of error functions. In consequence, the covariance matrix calculation is considerably expensive, because it requires the evaluation of one or more of these error functions. In this paper, we use random Fourier features to approximate the solution of these double integrals obtaining simpler analytical expressions for such covariance functions. We show experimental results using ordinary differential operators and provide an extension to build general kernel functions for convolved multiple output Gaussian processes.

## 1 INTRODUCTION

Latent force models (LFMs) [Álvarez et al., 2009] are a type of multiple-output Gaussian processes (GPs) where the covariance function has been derived from physical models. In particular, LFMs assume that each output  $\{f_d(t)\}_{d=1}^D$  can be expressed as the convolution integral of a latent function  $u(t)$ , and a Green's function  $G_d(t)$  associated to a linear dynamical system, one per output,  $f_d(t) = \int_0^t G_d(t - \tau)u(\tau)d\tau$ . Such representation for  $f_d(t)$  introduces a dependency between outputs  $f_d(t)$  and  $f_{d'}(t)$ . For example, if we assume that  $u(t)$  follows a Gaussian process prior with zero mean function and covariance  $k(t, t')$ , due to the linearity of the

integral transform,  $f_d(t)$  and  $f_{d'}(t)$  are jointly Gaussian with a cross-covariance function given as  $k_{f_d, f_{d'}}(t, t') = \int_0^t G_d(t - \tau) \int_0^{t'} G_{d'}(t' - \tau')k(\tau, \tau')d\tau'd\tau$ .

LFMs have been used for uncovering the dynamics of transcription factors in a gene network [Gao et al., 2008], for extrapolating human motion from motion capture data [Álvarez et al., 2013], for segmenting motor primitives in humanoid robotics [Álvarez et al., 2011], for modeling the thermal properties of buildings [Ghosh and et al., 2015], among several other applications for which prior knowledge of a mechanistic model can be coded in the covariance function of a GP. By including physics in the covariance function of a GP, we grant extrapolation abilities to an otherwise interpolation only-model.

In a classical latent force model, the covariance of the latent function  $k(t, t')$  follows an Exponentiated Quadratic (EQ) form, leading to analytical solutions for the cross-covariances  $k_{f_d, f_{d'}}(t, t')$ . However, these solutions are computationally expensive since they involve calculating functions that can only be obtained by numerical methods. For example, using the second order LFM introduced in Álvarez et al. [2009], involves computing the error function  $\text{erf}(\cdot)$  with a complex argument or the Faddeeva function, that require the evaluation of numerical integrals that are expensive to compute.

In this work, we use random Fourier features (RFF) [Rahimi and Recht, 2008] to reduce the mathematical complexity of the expressions involved in the covariance functions of the LFM. In particular, we approximate the calculation of the EQ kernel, with a representation that involves its probability density via the Bochner's theorem. Such representation for the covariance of  $k(\tau, \tau')$  transforms the double integral for  $k_{f_d, f_{d'}}(t, t')$  into two separate integrals that can easily be solved using the Laplace or Fourier transforms. Once the inner integrals are solved (the integrals that depend on  $\tau$  and  $\tau'$ ), the remaining integral is solved using a Monte Carlo approximation with  $S$  samples. The quality of the approximation of the

cross-covariances  $k_{f_d, f_{d'}}(t, t')$  will depend, then, on the number of samples  $S$  used. Additionally, by representing the latent force model kernel using a sum of basis functions, we are able to reduce the computational complexity of inverting the  $ND \times ND$  kernel matrix obtained from the multiple outputs, assuming that each output has  $N$  data observations.

Following a similar procedure, we also introduce a random Fourier feature approximation for the more general convolved multiple output Gaussian process kernel, a model that can be used for multiple-output with no particular known dynamics.

## 2 LATENT FORCE MODELS

Latent force models are Gaussian processes for multiple outputs with the characteristic that their covariance function involves ordinary or partial differential equations. In particular, LFMs assume that each output  $\{f_d(t)\}_{d=1}^D$  can be described using

$$\mathcal{D}_d\{f_d(t)\} = u(t),$$

where  $\mathcal{D}_d$  is the differential operator associated to a linear ordinary differential equation (ODE) or a linear partial differential equation (PDE), and  $u(t)$  is the excitation function. LFMs assume that  $u(t)$  is unknown and place a Gaussian process prior over it. The solution for  $f_d(t)$  follows as

$$f_d(t) = \int_0^t G_d(t - \tau)u(\tau)d\tau, \quad (1)$$

where  $G_d(\cdot)$  corresponds to the Green's function associated to the differential operator  $\mathcal{D}_d$ . The latent force or function  $u(t)$  is unobserved, and follows a Gaussian process prior with zero mean function, and covariance function given by  $k(t, t')$ . Since  $u(t)$  is being transformed by a linear operator,  $f_d(t)$  also follows a Gaussian process with covariance function  $k_{f_d, f_d}(t, t')$ . Furthermore, since all  $f_d(t)$  have a common input  $u(t)$ , it is also possible to compute a cross-covariance function between  $f_d(t)$ , and  $f_{d'}(t')$ ,  $k_{f_d, f_{d'}}(t, t')$ .

Equation (1) can be extended to include additional latent functions with different characteristics, leading to express each output as

$$f_d(t) = \sum_{q=1}^Q S_{d,q} \int_0^t G_d(t - \tau)u_q(\tau)d\tau,$$

where there are  $Q$  latent functions or forces  $\{u_q(t)\}_{q=1}^Q$ , and  $S_{d,q}$  is a sensitivity parameter that accounts for the influence of force  $u_q(t)$  over output  $d$ . Assuming the

independence of these latent forces and that they all follow Gaussian process priors with covariance functions  $k_q(t, t')$ , it is possible to compute the cross-covariance functions  $k_{f_d, f_{d'}}(t, t')$ ,  $\forall d, d' = 1 \dots, D$ . The following general expression can be used to build the covariance  $k_{f_d, f_{d'}}(t, t')$  of a LFM

$$\sum_{q=1}^Q S_{d,q} S_{d',q} \int_0^t G_d(t - \tau) \int_0^{t'} G_{d'}(t' - \tau') \times k_q(\tau, \tau') d\tau' d\tau. \quad (2)$$

Depending on the form for the covariance function for  $k_q(t, t')$ , it is possible to find a closed-form expression for  $k_{f_d, f_{d'}}(t, t')$ . A common option for  $k_q(\tau, \tau')$  is the Exponentiated Quadratic form

$$k_q(\tau, \tau') = \exp\left[-\frac{(\tau - \tau')^2}{\ell_q^2}\right],$$

where  $\ell_q$  is known as the length-scale parameter.

LFMs have mostly being used for multiple output regression. In this case, the observed output  $d$ ,  $y_d(t)$ , is assumed to follow a Gaussian likelihood,  $y_d(t) = f_d(t) + \epsilon_d$ , where  $\epsilon_d \sim \mathcal{N}(0, \sigma_d^2)$ .

## 3 FEATURE EXPANSIONS FOR KERNELS DERIVED FROM LATENT FORCE MODELS

In order to scale kernel machines, Rahimi and Recht [2008] introduced the idea of random Fourier features to approximate a kernel function using inner products between basis functions. Parameters of these basis functions are sampled from a distribution associated to the kernel function. We are particularly interested in the approximation for the EQ kernel, which has been commonly used in LFMs. The idea is to replace the EQ kernel that is usually assumed for  $k_q(\tau, \tau')$  by providing a random Fourier feature representation for it via the Bochner's theorem,

$$k_q(\tau, \tau') = e^{-\frac{(\tau - \tau')^2}{\ell_q^2}} = \int p(\lambda) e^{j(\tau - \tau')\lambda} d\lambda, \quad (3)$$

where  $p(\lambda) = \mathcal{N}(\lambda|0, \frac{2}{\ell_q^2})$ . A key insight from Rahimi and Recht [2008] was to use a finite approximation for  $k_q(\tau, \tau')$  by using Monte Carlo sampling to solve the above integral over  $\lambda$ ,

$$\begin{aligned} k_q(\tau, \tau') &\approx \frac{1}{S} \sum_{s=1}^S e^{j\lambda_s \tau} e^{-j\lambda_s \tau'}, \\ &= \frac{1}{S} \sum_{s=1}^S v(\tau, \lambda_s) v^*(\tau, \lambda_s), \end{aligned}$$

where  $S$  is the number of Monte Carlo samples,  $v(\tau, \lambda_s)$  is a basis function with parameter  $\lambda_s$ ,  $v^*(\tau, \lambda_s)$  is the complex conjugate of  $v(\tau, \lambda_s)$ , and  $\lambda_s \sim p(\lambda)$ . Since the kernel function is a real function, the real part of the product  $v(\tau, \lambda_s)v^*(\tau, \lambda_s)$  is used instead.

Using the expression for  $k_q(\tau, \tau')$  in Eq. (3) inside the expression for the cross-covariance function for the LFM,  $k_{f_d f_{d'}}(t, t')$ , we get

$$\sum_{q=1}^Q S_{d,q} S_{d',q} \int_0^t G_d(t-\tau) \int_0^{t'} G_{d'}(t'-\tau') \times \int p(\lambda) e^{j(\tau-\tau')\lambda} d\lambda d\tau d\tau'.$$

Organizing the above expression we obtain

$$\sum_{q=1}^Q S_{d,q} S_{d',q} \int p(\lambda) v_d(t, \theta_d \lambda) v_{d'}^*(t', \theta_{d'} \lambda) d\lambda, \quad (4)$$

with

$$v_d(t, \theta_d, \lambda) = \int_0^t G_d(t-\tau) e^{j\lambda\tau} d\tau,$$

where  $\theta_d$  makes reference to the parameters of the Green's function  $G_d(\cdot)$ . Also,  $v_{d'}^*(t', \theta_{d'} \lambda)$  is the complex conjugate for  $v_{d'}(t', \theta_{d'} \lambda)$ . The integrals over  $t$  and  $t'$  above can be solved using the Laplace transform  $\mathcal{L}\{\cdot\}$

$$\begin{aligned} v_d(t, \theta_d, \lambda) &= \mathcal{L}^{-1} \mathcal{L} \left\{ \int_0^t G_d(t-\tau) e^{j\lambda\tau} d\tau \right\} \\ &= \mathcal{L}^{-1} \left\{ \mathcal{G}_d(s) \mathcal{L} \{ e^{j\lambda\tau} \} \right\}, \end{aligned}$$

where  $\mathcal{G}_d(s)$  is the Laplace transform for  $G_d(t)$ . The operator  $\mathcal{L}^{-1}\{\cdot\}$  refers to the inverse Laplace transform. Furthermore, notice that when  $G_{d'}(\cdot)$  is a real function, we can compute  $v_{d'}^*(t', \theta_{d'} \lambda) = v_{d'}(t', \theta_{d'} \lambda)$ .

Similarly to Rahimi and Recht [2008], we use Monte Carlo sampling to approximate the integral over  $\lambda$  in Eq. (4), leading to

$$\sum_{q=1}^Q \frac{S_{d,q} S_{d',q}}{S} \left[ \sum_{s=1}^S v_d(t, \theta_d, \lambda_s) v_{d'}^*(t', \theta_{d'} \lambda_s) \right],$$

where  $\lambda_s \sim p(\lambda)$ .

The steps to compute a RFF approximation of the LFM kernel are

1. Compute  $v_d(t, \theta_d, \lambda) = \int_0^t G_d(t-\tau) e^{j\lambda\tau} d\tau$  using the Laplace transform.

2. Compute the RFF approximation for the LFM covariance function  $k_{f_d f_{d'}}(t, t')$  using

$$\sum_{q=1}^Q \frac{S_{d,q} S_{d',q}}{S} \left[ \sum_{s=1}^S v_d(t, \theta_d, \lambda_s) v_{d'}^*(t', \theta_{d'} \lambda_s) \right],$$

where  $\lambda_s \sim p(\lambda)$ . The distribution we use to sample from,  $p(\lambda)$ , depends on the kernel assumed for the latent forces  $u_q(t)$ .

Interestingly,  $v_d(t, \theta_d, \lambda)$  represents the response of the dynamical system to the excitation  $e^{j\lambda t}$  up to time  $t$ . We will occasionally refer to this random feature as a *random Fourier response feature* (RFRF).

In different applications of LFMs, we need to perform inference over the latent forces  $u_q(t)$ . Inference over  $u_q(t)$  requires the evaluation of the cross-covariance functions  $k_{f_d, u_q}(t, t')$ . Such cross-covariances are also important in schemes that reduce computational complexity in convolved multiple output Gaussian processes, where the underlying process  $u_q(t)$  evaluated at a discrete set of input locations serve the purpose of *inducing variables* [Álvarez et al., 2010, Álvarez and Lawrence, 2011]. The approximation of  $k_{f_d, u_q}(t, t')$  using RFFs is given by

$$k_{f_d, u_q}(t, t') = \frac{1}{S} \sum_{s=1}^S v_d(t, \theta_d, \lambda_s) e^{-j\lambda_s t'}.$$

## 4 HYPERPARAMETER SELECTION AND COMPUTATIONAL COMPLEXITY

Let us assume, we are given observations  $\{\mathbf{y}, \mathbf{X}\} = \{\mathbf{y}_d, \mathbf{X}_d\}_{d=1}^D$  (each  $\mathbf{y}_d \in \mathbb{R}^N$  and  $\mathbf{X}_d \in \mathbb{R}^{N \times p}$ ), and we want to learn the hyperparameters of the kernel function,  $\{\{\theta_d, \sigma_d^2\}_{d=1}^D, \{\ell_q\}_{q=1}^Q\}$ , that allow us to explain  $\mathbf{y}$ . With that in mind, the hyperparameters can be learned from the log-marginal likelihood [Rasmussen and Williams, 2006]

$$\begin{aligned} \log p(\mathbf{y}|\mathbf{X}) &= -\frac{ND}{2} \log(2\pi) - \frac{1}{2} \mathbf{y}^\top (\mathbf{K}_{f,f} + \mathbf{\Sigma})^{-1} \mathbf{y} \\ &\quad - \frac{1}{2} \log |\mathbf{K}_{f,f} + \mathbf{\Sigma}|, \end{aligned} \quad (5)$$

where  $\mathbf{\Sigma}$  is a diagonal matrix containing the variances of the noise level per output, and  $\mathbf{K}_{f,f} \in \mathbb{R}^{ND \times ND}$  is a block-wise matrix with blocks calculated using (2). As it is usual, we can use a gradient-based optimization procedure to estimate the hyperparameters that maximize the log-marginal likelihood leading to the infamous computational complexity of  $\mathcal{O}(D^3 N^3)$ .

However, notice that by the elegance of the RFF representation, the covariance matrix can instead be approximated

as  $\mathbf{K}_{\mathbf{f},\mathbf{f}} = \mathbb{R} \{ \Phi \Phi^H \}$ , where  $\Phi \in \mathbb{C}^{ND \times QS}$  has entries  $v_d(t, \theta_d, \lambda_s)$ , and  $\Phi^H$  is the conjugate transpose of  $\Phi$ . Furthermore, the covariance matrix can be re-written as  $\mathbf{K}_{\mathbf{f},\mathbf{f}} = \Phi_c \Phi_c^T$ , with  $\Phi_c = [\mathbb{R}\{\Phi\} \ \text{I}\{\Phi\}] \in \mathbb{C}^{ND \times 2QS}$ . Using the matrix inversion and determinant lemmas, we express the log-marginal likelihood as

$$\begin{aligned} \log p(\mathbf{y}|\mathbf{X}) &= -\frac{1}{2} \log |\Sigma| - \frac{1}{2} (\mathbf{y}^T \Sigma^{-1} \mathbf{y} - \boldsymbol{\alpha}^T \mathbf{A}^{-1} \boldsymbol{\alpha}) \\ &\quad - \frac{1}{2} \log |\mathbf{A}| - \frac{ND}{2} \log(2\pi), \end{aligned} \quad (6)$$

with  $\mathbf{A} = \mathbf{I} + \Phi_c^T \Sigma^{-1} \Phi_c$  and  $\boldsymbol{\alpha} = \Phi_c^T \Sigma^{-1} \mathbf{y}$ , effectively reducing computational complexity from  $\mathcal{O}(D^3 N^3)$  to  $\mathcal{O}(DNQ^2 S^2)$ , which is now linear with respect to the data size.

Alternatively, one could couple the computation of the kernel functions  $k_{f_d, f_{d'}}(t, t')$  and  $k_{f_d, u_q}(t, t')$  through random Fourier response features, with (i) any of the different computationally efficient approximations for optimizing the log-marginal likelihood in convolved multiple-output Gaussian process [Álvarez and Lawrence, 2011], or (ii) a lower bound on the log-marginal likelihood through a variational approximation [Álvarez et al., 2010]. Both styles of approximations require the specification of  $K$  inducing variables.

## 5 FAST KERNEL BUILDING FROM ORDINARY DIFFERENTIAL EQUATIONS

Let us assume we are interested in analyzing an ODE of order  $P$  given as

$$\mathcal{D}_d^{(P)} \{f_d(t)\} = \sum_{q=1}^Q S_{d,q} u_q(t),$$

where the differential operator  $\mathcal{D}_d^{(P)}$  is defined as

$$\mathcal{D}_d^{(P)} = a_0 \frac{d^P}{dt^P} + a_1 \frac{d^{P-1}}{dt^{P-1}} + \dots + a_{P-1} \frac{d}{dt} + a_P.$$

The Laplace transform of the Green's function  $G_d(t)$  for the above ODE can be found as

$$\begin{aligned} \mathcal{G}_d(s) &= \frac{1}{a_0} \frac{1}{s^P + \frac{a_1}{a_0} s^{P-1} + \dots + \frac{a_P}{a_0}} \quad (7) \\ &= \frac{1}{a_0} \frac{1}{(s - s_1)(s - s_2) \dots (s - s_P)}, \end{aligned}$$

where the  $s_i$ 's represent the roots of the polynomial given in the denominator of (7). Additionally, the Laplace transform for  $\mathcal{L}\{e^{j\lambda\tau}\} = \frac{1}{s - j\lambda}$ . We can use a partial-fraction expansion for  $\mathcal{G}_d(s)$ , and then apply the inverse

Laplace transform over the product  $\mathcal{G}_d(s) \mathcal{L}\{e^{j\lambda\tau}\}$  to find  $v_d(t, \theta_d, \lambda)$ .

Interestingly, if all the roots  $s_1, \dots, s_P$  are distinct real or distinct complex, and  $s_{P+1} = j\lambda$  (the additional root obtained from  $\mathcal{L}\{e^{j\lambda\tau}\}$ ), the random Fourier response feature  $v_d(t, \theta_d, \lambda)$  can be expressed as

$$\frac{1}{a_0} \mathcal{L}^{-1} \left\{ \sum_{p=1}^{P+1} \frac{A_p}{(s - s_p)} \right\} = \frac{1}{a_0} \sum_{p=1}^{P+1} A_p e^{s_p t},$$

where each coefficient  $A_p$  is calculated as

$$A_p = \frac{1}{\prod_{\forall i \neq p} (s_p - s_i)}, \quad (8)$$

and, as before,  $s_{P+1} = j\lambda$ .

Next, we show some examples of the expressions obtained for the random Fourier response features associated to the ODE of first and second orders. Besides, for all ODE experiments the hyperparameters are learned using the variational approach described in Álvarez et al. [2010] and they were carried out using a single core of an AMD FX-8350 @ 4.0 GHz. We also include measures of the time required to evaluate the objective function and its gradients to compare the time cost induced by the evaluation of the different covariance functions. Code to replicate the following experiments is available at [github.com/cdguarnizo/kff\\_lfm](https://github.com/cdguarnizo/kff_lfm).

### 5.1 FIRST-ORDER MODEL (ODE1)

For the first-order ODE we have the following equation

$$\mathcal{D}_d^{(1)} \{f_d(t)\} = \frac{df_d(t)}{dt} + \gamma_d f_d(t) = \sum_{q=1}^Q u_q(t),$$

from which the Laplace transform is given by  $\mathcal{G}_d(s) = \frac{1}{s + \gamma_d}$ . We then have  $s_1 = -\gamma_d$ , and  $s_2 = j\lambda$ . The random Fourier response feature for the  $d$ -th output function of a first-order ODE is obtained as

$$\begin{aligned} v_d^{(1)}(t, \theta_d, \lambda) &= A_1 e^{s_1 t} + A_2 e^{s_2 t} \\ &= -\frac{e^{-\gamma_d t}}{\gamma_d + j\lambda} + \frac{e^{j\lambda t}}{\gamma_d + j\lambda} \\ &= \frac{e^{j\lambda t} - e^{-\gamma_d t}}{\gamma_d + j\lambda}. \end{aligned}$$

Next, we compare the performance of the first order ODE described in Gao et al. [2008] with the kernel obtained by using the above random Fourier response feature for interpolation of Air temperature.

Figure 1: Comparison of the predictive GPs, for the air temperature experiment, using the standard LFM (first column) and the RFRF approximation for  $S = 100$  (second column) and  $S = 10$  samples (third column). Training data is represented using red dots and Test data using blue dots. The black line in the mean over the predictive GP function, and the shaded region denotes two times the standard deviation.

**Air temperature** Here, we consider the problem of modeling and predicting air temperature time series from a network sensor located at the south coast of England. The dataset consists of temperature measurements at four locations known as Bramblemet, Sotonmet, Cambermet and Chimet.<sup>1</sup> The air temperatures are measured during the period from July 10 to July 15, 2013. Specifically, we adopt the same experiment (train and test data) used in Nguyen and Bonilla [2014] and described in Tab. 1. The variational approach is configured with 200 inducing variables, six latent forces and the maximum number of iterations for the optimization procedure is set to 500.

Table 1: Number of training and test data-points considered on the air temperature experiment.

#	Name	Training	Test
1	Bramblemet	1425	0
2	Cambermet	1268	173
3	Chimet	1235	201
4	Sotonmet	1097	0

Table 2 reports the predictive performance using the covariance functions build from the LFM and the proposed RFRF. Note that for a low number of samples  $S$ , the proposed approach presents the worst performance. This is because the more samples we use the better the mean of predictive GP is able to fit the coarse behavior from the observed data, as shown in figure 1. Interestingly, the

<sup>1</sup>Weather data can be found in <http://www.bramblemet.co.uk>.

RFRF starts to outperform the standard one, using only 50 or 100 samples with about half of the time required by the original covariance function.

Table 2: Results on air temperature data.

Kernel	Cambermet		Chimet		Time [s]
	NMSE	NLPD	NMSE	NLPD	
ODE1+S10	0.74	3.26	0.58	1.53	1.89
ODE1+S20	0.45	1.95	0.93	1.75	2.09
ODE1+S50	<b>0.08</b>	<b>1.10</b>	0.21	1.08	2.68
ODE1+S100	0.12	1.18	<b>0.12</b>	<b>0.82</b>	3.93
ODE1	0.11	1.37	0.19	0.99	6.28

## 5.2 SECOND-ORDER MODEL (ODE2)

As a second example of a random Fourier feature representation of a LFM, we use a second-order ordinary differential operator  $\mathcal{D}_d^{(2)}\{\cdot\}$  that represents, e.g., a mass-spring-damper system. The second-order operator is given as

$$\mathcal{D}_d^{(2)} = m_d \frac{d^2}{dt^2} + c_d \frac{d}{dt} + b_d,$$

where  $m_d$ ,  $c_d$  and  $b_d$  are the mass, damper and spring constants, respectively. From the above equation, we obtain the Laplace transform of the Green's function as

$$\mathcal{G}_d(s) = \frac{1}{m_d s^2 + \frac{c_d}{m_d} s + \frac{b_d}{m_d}}.$$

Following the procedure described above, it can be shown that the random Fourier response feature for the  $d$ -th out-

put is given by

$$v_d^{(2)}(t, \theta_d, \lambda) = \frac{1}{m_d} \left[ A_1 e^{s_1 t} + A_2 e^{s_2 t} + A_3 e^{s_3 t} \right],$$

where
