Abstract. Biomass burning has long been recognised as an important source of trace gases and aerosols in the atmosphere. The burning of vegetation has a repeating seasonal pattern, but the intensity of burning and the exact localisation of fires vary considerably from year to year. Recent studies have demonstrated the high interannual variability of the emissions that are associated with biomass burning. In this paper I present a methodology using active fire counts from the Along-Track Scanning Radiometer (ATSR) sensor on board the ERS-2 satellite to estimate the seasonal and interannual variability of global biomass burning emissions in the time period 1996–2000. From the ATSR data, I compute relative scaling factors of burning intensity for each month, which are then applied to a standard inventory for carbon monoxide emissions from biomass burning. The new, time-resolved inventory is evaluated using the few existing multi-year burned area observations on continental scales.

1 Introduction

Emissions of greenhouse gases and pollutant species into the atmosphere have risen dramatically over the past century and have begun to exert a globally noticeable influence on the Earth's climate and the welfare of its population (Houghton et al., 2001). Because of the spatial inhomogeneity and temporal variability of the emission sources and the atmospheric transport patterns, comprehensive three-dimensional models describing the physics and chemistry of the atmosphere are necessary in order to investigate the impact of these emissions on the global and regional scale. Several such models have been developed over the past decade (c.f. Kasibhatla et al., 1991; Müller and Brasseur, 1995; Atherton et al., 1996; Brasseur et al., 1998; Hauglustaine et al., 1998; Wang et al., 1998; Bey et al., 2001, Horowitz et al., submitted to

J. Geophys. Res. 2002), and they are now beginning to be employed for decadal variability studies (e.g. Karlsdottir et al., 2000). Furthermore, such models have recently been put to use for forecasting atmospheric species concentrations in a number of large-scale airborne field experiments (c.f. Lawrence et al., 2002).

In order to achieve a realistic description of the atmospheric composition and for the comparison of model simulations with observations, one has to take into account the variability in transport, UV radiation, and emissions of key trace gases and precursor species. The first is readily accomplished through the use of assimilated meteorological fields provided by the large weather forecasting centers, e.g. ECMWF in Europe, or NCEP and NASA-DAO in the US. Interannual changes in tropospheric UV radiation can be accounted for by assimilating stratospheric ozone concentrations into the model. The model sensitivity towards stratospheric ozone change has been assessed for example by Deleeuw and Leyssius (1991) and Fuglestedt et al. (1994).

In comparison to these assessments of the meteorological and UV variability, not much has been done to address the problem of the seasonal and interannual variability of anthropogenic and natural trace gas and aerosol emissions. van Aardenne et al. (2001) has compiled a 100-year global database of emissions from fossil fuel use and other sectors, but they have not dealt with the variability of biomass burning emissions. The first global assessment of the seasonal variability of fire occurrence was made by Dwyer et al. (1999). Cooke et al. (1996), Barbosa et al. (1999b), and Amiro et al. (2001) have investigated the variability of burned areas and the resulting emissions on a continental scale for Africa and Canada, respectively, and Lavoué et al. (2000) have constructed a multi-year inventory for carbonaceous particles from temperate and boreal wildfires. All of these studies found significant interannual variations in the magnitude and the geographical location of fires. The only study, which has addressed the interannual and seasonal vari-

ability of fire emissions on the global scale so far, is that of Duncan et al. (*J. Geophys. Res.*, in press 2002), who use the Total Ozone Mapping Spectrometer (TOMS) aerosol index as a proxy for the emission flux.

It has long been recognised that biomass burning constitutes a major source term for a variety of pollution and ozone precursor species (e.g. Table 1), especially in the tropical latitudes and in the southern hemisphere, where emissions from fossil fuel combustion are relatively low. Vegetation burns for a variety of reasons, but fires are mostly of human origin with less than 20% being ignited by lightning strokes (c.f. Goldammer, 1990; Levine, 1996). Vegetation fires occur on different spatial scales and last from hours to weeks. For the purpose of this study the term biomass burning is restricted to open fires in the savanna and in tropical, temperate, and boreal forests. Emissions from agricultural waste burning and fuelwood burning also add up to a large contribution to the global source of atmospheric pollutants, but they require a different treatment and are not discussed in this paper.

In order to estimate emissions from vegetation fires, one needs to know the amount of fuel that is available for burning and the percentage of fuel that is actually burned over a specific time period. The amount of fuel that is burned in a given region and the fraction of fuel burned depend on a number of factors, such as the vegetation density, fuel composition and dryness, and meteorological parameters like wind speed, humidity, and temperature (c.f. Goldammer, 1990; Levine, 1996). For practical purposes, the emissions of other trace

gases and aerosol are typically scaled to the amount of CO₂ released, although these emission ratios can vary depending on the type of combustion (e.g. flaming vs. smoldering fires, Andreae and Merlet, 2001). All of these parameters exhibit a great temporal and spatial variability, which has not been included in the global model inventories up to the present. Existing emission inventories (e.g. Hao and Liu, 1994) have been compiled using a variety of data from national reports (e.g. Goldammer, 1999) and a statistical approach in order to arrive at a globally consistent picture. The uncertainties of these inventories are considerable, and they are difficult to evaluate because of the seasonal and interannual variability of these emissions.

This paper presents a simple method to introduce the seasonal and interannual variability of biomass burning emissions into global emission inventories for atmospheric trace gases and aerosol. Monthly composites of active fires detected from space are used as a proxy for the relative strength of the biomass burning source in a model grid box. Currently, this method is limited to the time period August 1996–December 2000, because of the availability of a consistent data set of global fire count data. However, with the successful launch of Envisat and the current push towards operational environmental prediction systems, it is likely that such data sets will become routinely available in the future. The 4-year inventory resulting from this study is evaluated by comparing its variability with literature estimates for specific regions.

2 Method

The compilation of a global inventory of biomass burning emissions is a labor-intensive and tedious task, requiring a lot of detailed knowledge about agricultural and landuse practices, vegetation properties, and climatological conditions in individual countries and regions. Due to the sparsity of such information, the existing global inventories have to rely on statistical assumptions, which obviously prevent their usefulness for assessing the interannual variability of fire emissions. Only few attempts have been made to assess the variability of biomass burning on the continental scale (Barbosa et al., 1999b; Amiro et al., 2001; Wotawa et al., 2001).

In this paper, a simple scaling approach is used in order to estimate the variability of biomass burning emissions on the global scale. The method is based on the assumption that the annual totals of the existing inventories represent approximately average conditions, and that the seasonal and interannual variability can be introduced by scaling these emissions with some measure of fire activity. This study does therefore not try to improve existing estimates of the absolute magnitude of vegetation fire emissions, but rather attempts to lay out a conceptually simple approach that can be used for sensitivity and variability experiments in global modeling. The base inventory for this study is that of the MOZART2 model

Fig. 1. Areas with hot pixels in the ATSR world fire atlas, which are unlikely caused by vegetation burning. All $1^{\circ} \times 1^{\circ}$ grid boxes where more than 3 active fires occur over 7 months each year are marked with a red x.

(Horowitz et al., submitted to *J. Geophys. Res.*, 2002), which includes the inventories from Hao and Liu (1994) and Ward (1990) for tropical savanna and forest fires, respectively, and from Müller and Brasseur (1995) for temperate and boreal forest fires. The original $5^{\circ} \times 5^{\circ}$ inventory has been interpolated onto a $1^{\circ} \times 1^{\circ}$ grid, and a land-sea mask has been applied in order to constrain emission fluxes to the land surface and to better localise the emission sources in individual years. Emission estimates for species other than CO_2 are derived by calculating emission ratios from the emission factors given in Andreae and Merlet (2001).

Because there is no longer-term global data set of burned areas available at present, monthly composites of active fire observations from the ATSR sensor on board the ERS-2 satellite (Arino and Melinotte, 1998) are used as a surrogate (“world fire atlas” <http://shark1.esrin.esa.it/ionia/FIRE/>). This data set is the only one with global coverage that is available for a reasonably long time period.

For the ATSR fire product, only nighttime observations are used, and a threshold of 312 K (algorithm 1) or 308 K (algorithm 2) is applied to the radiance of the $3.7 \mu\text{m}$ channel in order to detect fires. The resolution of the ATSR sensor is $1 \times 1 \text{ km}^2$, which allows for detection of a 600 K hot spot of 0.1 ha or an 800 K hot spot of 0.01 ha (Arino and Melinotte, 1998). The sensor achieves complete global coverage every three days. Compared to daytime observations from the Ad-

vanced Very High Resolution Radiometer (AVHRR) (Barbosa et al., 1999a), the number of fires detected from the ATSR nighttime scans is considerably smaller. However, many of the fires detected during daytime are relatively small controlled burns, which generally attribute little to the large-scale regional burned area. The validity of this assumption is discussed in Sect. 3.

The ATSR data set contains a number of events from heat sources other than vegetation fires. These have been removed from the analysis based on the criterion that no grid box should contain more than 3 active fires for more than 7 months per year. This criterion is based on the presumption that true fire activity shows a distinct seasonality and usually ceases during winter or during the wet season. Visual inspection of the grid boxes that are removed from the analysis shows that they are predominantly located in areas where oil and gas flaring is known to occur, i.e. Northern Siberia, the Persian Gulf region, Mediterranean North Africa, etc. (Fig. 1). A few falsely detected fires are also seen in the Sahara region.

In order to derive a measure for the relative fire activity in a given month, the time series of individual fires (ATSR pixels above the 308 K threshold) for the observation period from August 1996 to December 2000 are sampled into $1^{\circ} \times 1^{\circ}$ grid boxes and normalized, so that the cumulative fire frequency in each grid box is 1/year on average. Grid boxes with no

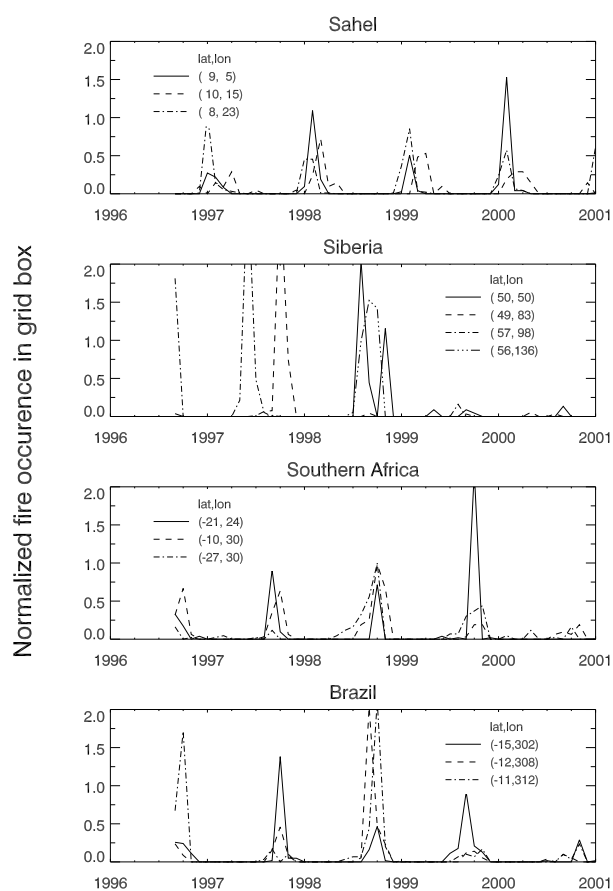

Fig. 2. Time series of the normalised monthly fire occurrence in selected grid boxes. The fire frequency has been derived by sampling ATSR nighttime active fire observations into $1^\circ \times 1^\circ$ grid boxes.

fires throughout the 5-year period and ocean grid boxes are marked with a 0 value.

Figure 2 shows the resulting scale factors for a few selected grid boxes as a function of time. The seasonality generally follows the expected behaviour with most intense burning in the dry seasons, i.e. December/January for the Sahel, July/August for the northern hemisphere boreal forests, and September/October for southern hemispheric Africa and South America. There is considerable variability from year to year for some grid boxes, whereas others (notably in the Sahel) exhibit a relatively periodic pattern. Because of the long fire return interval in boreal regions (c.f. Thonicke et al., 2001), some of the grid boxes in Fig. 2 show fire activity only during one of the 5 years (e.g. 83° E, 49° N in 1997, and 50° E, 50° N in 1998). It should be emphasized, that Fig. 2 does not contain information about the differences between grid boxes, but only shows the time series of fire occurrences within individual boxes.

The final step in deriving biomass burning emissions for individual years and months is multiplication of the scale factors with the “climatological” annual biomass burning

emissions from the MOZART2 inventory. The result is a monthly resolved, global gridded inventory of savanna and forest burning emissions for the time period August 1996 – December 2000.

Some of the grid boxes do not exhibit any fire activity during the time period considered here, but they are associated with non-zero emissions in the climatological inventory. Therefore, the average annual global total of the CO emissions from the new inventory is about 15% lower than the annual total of the original inventory of the MOZART2 model. While this is well within the uncertainty range for biomass burning emissions, I decided to apply a uniform scaling factor of 1.2 to the new inventory in order to facilitate comparison with previous model results and to be able to investigate the effects from the better localisation and timing of fires without changing the global “background” concentrations.

3 Results and evaluation

As an example for the final product, Fig. 3 shows the global biomass burning emission inventory for CO for the months of January, April, July, and October in the individual years from 1997 to 2000. One can clearly identify a number of outstanding events, such as the Indonesian forest fires in October 1997, or the Canadian boreal fires in the summer of 1998. Significant interannual variability is seen in Southern Africa and South America during the fire season from July to October, as well as in northern India, South East Asia, and Central America in April.

Table 2 lists the cumulated annual CO emissions from biomass burning for various regions and compares them with the base emission inventory. The largest year-to-year variability can be seen in Indonesia, where the extreme fires in 1997 led to a factor of 3 increase in the emissions of CO. Africa and South America are estimated to have the largest emissions from fires and show the lowest interannual variability (20% and 30%, respectively). According to the scaling method, 1998 was the year with the largest biomass burning emissions in the four-year period. Globally, the release of CO is estimated to be 20% higher in 1998 than on average, and it is highest in all the regions listed in Table 2, except for continental South East Asia, the Indian subcontinent, and Indonesia. This result is in qualitative agreement with the study of Duncan et al. (J. Geophys. Res., in press 2002), who use a more elaborate method involving different satellite products. The reasons of this significantly increased fire activity are not clear yet, but several news reports indicate that 1998 has been an exceptionally dry year. From the ATSR data set, it becomes clear that enhanced fire frequency was not limited to one region and season, but affected several areas of the world at different times.

While it is clear that the active fire detection from ATSR cannot be directly translated into the amount of burnt material or released trace substances, the data set nevertheless

Fig. 3. Monthly global $1^{\circ} \times 1^{\circ}$ emissions of carbon monoxide from forest and savanna burning for January and April 1997–2000 after applying the scale factors derived from the ATSR active fire observations (unit: GgCO/month)

contains information about the variability and the timing specifically of the larger fires, which very likely constitute the majority of the burnt area, at least in boreal and temperate forests (Stocks, 1991). Assuming that the amount of biomass that is available for burning does not vary too much from year to year and within a given geographic region, the variability in the number of nighttime fires should therefore be a good proxy for the variability in burnt area, and the variability in burnt area should provide a reasonable estimate of the variability in the emissions.

The year-to-year changes of the burned area in North

American and Russian forest fires have been analysed by Wotawa et al. (2001). Their estimates are compared with the new CO emission estimates in Fig. 5. The variability for North American fires compares well even in relative magnitude, whereas the CO emissions show less variability than the burned area estimates in Russia. It is possible that this difference can be attributed to the poorer data quality for the Russian burned area estimates as pointed out by Wotawa et al. (2001). Another factor could be the higher fraction of ground fires in Russia, which are not detected by the satellite sensor (M. Simon, personal communication 2002).

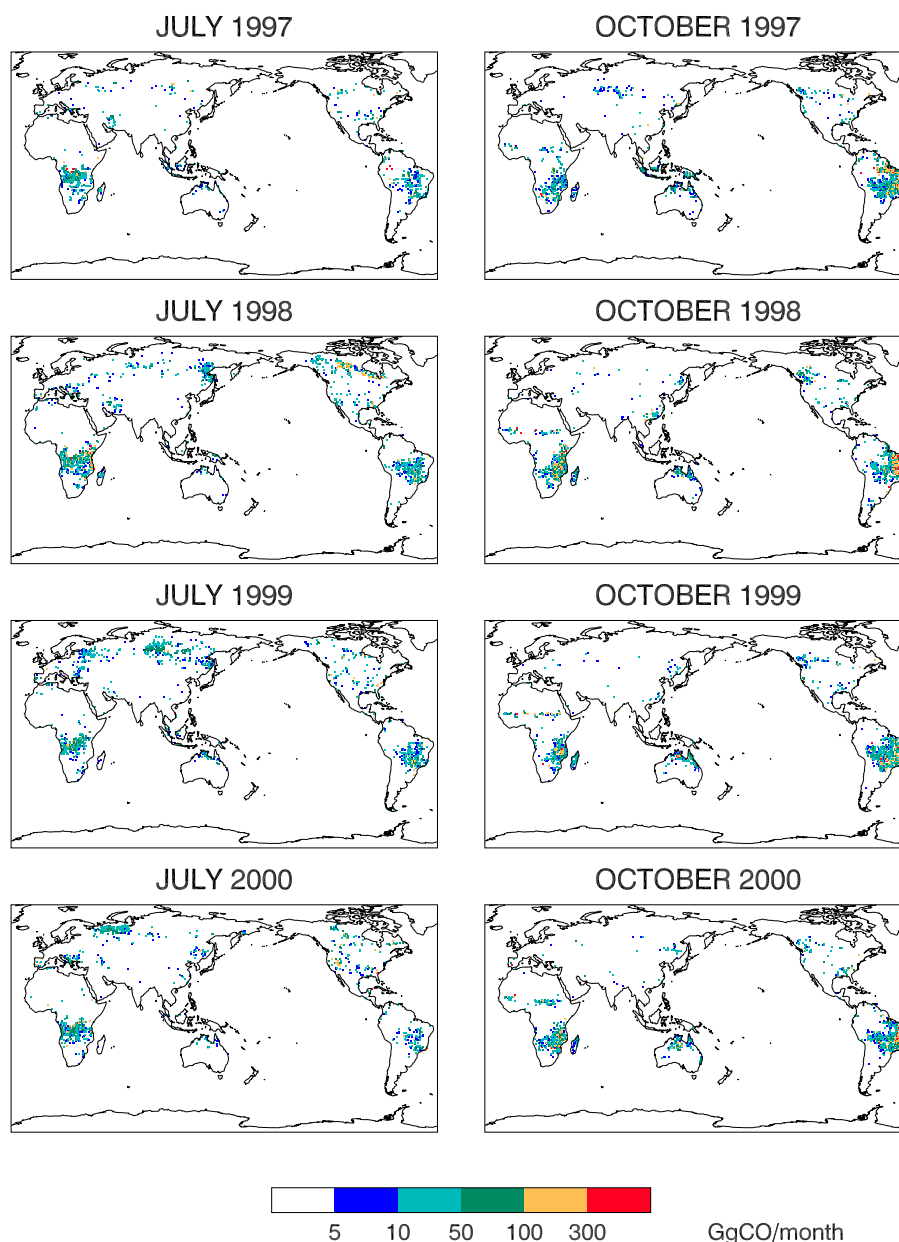

Fig. 4. Dto. for July and October

For savanna fires, the relationship between fire counts and emissions is not as straight forward, because of the large fraction of small controlled daytime burns in these regions. Hely et al. (J. Geophys. Res., in press, 2002) estimate that approximately 50% of the burnt area in southern Africa during the dry season is produced from fires smaller than 2 km^2 . Nevertheless, even in these regions a correlation may exist between the relative frequency of active fire observations and vegetation fire emissions, because – regardless of the scale – the intensity and spread of fires will depend on the same parameters (humidity, temperature, wind speed, etc.). Therefore, in an integral sense, the relative change in the number of large

intensive fires in a grid box should provide a first order approximation for the variability of the trace gas emissions in that region.

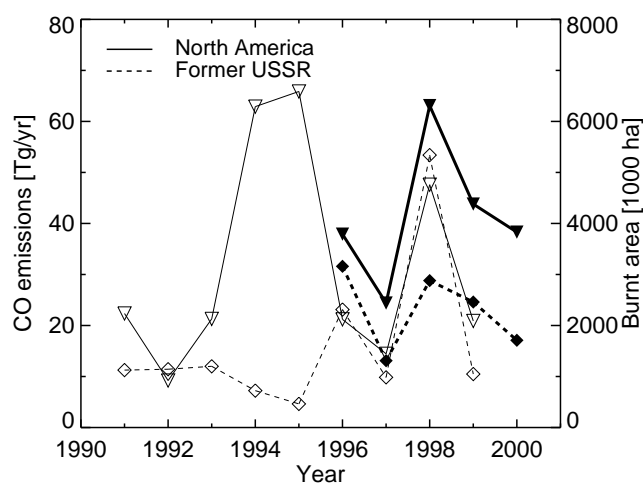

Barbosa et al. (1999b) (subsequently labeled as B99) have compiled data for Africa for the time period 1981–1991. They present statistics for burned area and estimates for the amount of burned material and trace gas emissions during six “fire years” (November–October). Unfortunately, there is no overlap between the time period of the B99 study and the emission estimates from this paper. Nevertheless, it is worthwhile to compare the variability derived with the two approaches. B99 give a low and a high estimate of burned

Table 2. Regional totals of biomass burning emissions estimated from the ATSR scale factor approach (in TgCO/yr)

Region	Standard Inventory	1997	1998	1999	2000
global	678	624	806	681	594
North America (20°–82° N, 50°–168° W)	74	40	88	68	63
Russian Federation (40°–76° N, 42°–185° E)	47	39	59	37	40
Mediterranean Europe (36°–49° N, 10° W–42° E)	35	18	46	34	44
Continental South East Asia (7°–30° N, 92°–119° E)	46	29	64	70	27
Indian subcontinent (3°–28° N, 67°–91° E)	45	30	36	63	47
Indonesia (11° S–6° N, 96°–150° E)	14	47	13	6	5
Africa (42° S–22° N, 22° W–53° E)	198	195	239	173	198
South America (54° S–11° N, 33°–82° W)	146	166	196	159	100
Australia (45°–10° S, 114°–156° E)	16	18	13	22	20

area, which naturally results in a range for the emission estimates as well. For the period November 1985–October 1991 they derive CO emissions of 40 ± 11 Tg/yr (low estimate) to 152 ± 41 Tg/yr (high estimate). In absolute values, these estimates are lower by a factor of 1.3–5 compared to those from the standard inventory used in this study. This is due to the lower burned area estimates by B99 compared to Hao and Liu (1994). B99 also use somewhat different emission factors (230 g/kg and 68 g/kg for tropical forests and savanna, respectively compared to 104 g/kg and 65 g/kg from Andreae and Merlet (2001)). The percent variability ($1 \sigma / \text{mean} \times 100$) of the B99 emission estimates is 27% for both the low and high estimates. This is almost twice as high as the variability of 14% that can be derived from Table 2. If the scaled emissions are analysed for “fire years” instead of calendar years, the interannual variability is slightly increased to 17%. Broken down by latitude, the variability in southern hemispheric Africa, where 43% of the emissions are located, amounts to 25% in the scaled inventory, whereas northern hemispheric Africa only varies by 13% between the years.

The different variability estimates might in part be explained by variations in fuel load and burning efficiency, which have been taken into account by B99 using a correlation with the normalised differential vegetation index (NDVI) as a proxy for the biomass density and an inverse correlation with the relative greenness index (RGI) for estimating the burning efficiency. Another important aspect is the subgrid-scale variability of vegetation types and their different burning behaviour. Since the scaling approach starts from a gridded emission inventory, it necessarily assumes average vegetation properties. B99 provide annual burned area estimates for 16 individual vegetation classes. Interannual variability of burned area ranges from less than 10% for some classes to more than 50% for other classes. Averaged

**Fig. 5.** Comparison of the variability of CO emissions from biomass burning (this study, filled symbols) with estimates of burned area for North America and the Russian Federation (Wotawa et al., 2001, open symbols).

over all vegetation classes, the variations in the burned area of B99 account for 95% of the variability in the CO emissions.

The little information available for evaluation of the scale factor method thus indicates an uncertainty of about a factor of 2 for the variability of vegetation fire emissions on the continental scale. For example, the changes from year to year or the differences between seasons prognosed by this method may be over- or underestimated by 100% or 50%, respectively. This uncertainty must be added to the uncertainty of the underlying “climatological” inventory, which is estimated to be a factor of 2–3. It can be expected that forthcoming satellite derived estimates of the burned area should allow for better quantitative estimates of vegetation fire emis-

sions and provide a better measure of the variability if they are augmented by information on the vegetation type and fuel load on a high resolution.

4 Conclusions

The use of ATSR fire count data to derive scaling factors for a global biomass burning emission inventory is a simple approach that allows for a more realistic description of particular large-scale fire situations compared to the present use of average emissions in global chemistry transport modeling. It has been demonstrated that the normalized scaling method qualitatively reproduces outstanding fire events. The algorithm produces an interannual variability that is similar to the variability observed in burned area statistics for some regions (e.g. North America and Southern Africa), but only about half as large in other regions (e.g. Russian Federation and Sahel). However, these comparisons remain somewhat qualitative, because there is no direct quantitative relation between the burned area and the trace gas and aerosol emissions from fires.

Preliminary model results indicate that the impact of using these more localised and intense emissions on the CO concentration can easily reach 30% in the free troposphere downwind of emission regions. A more detailed analysis of the model results will be subject of a different paper.

With over four years of sampling, the ATSR data set is beginning to become statistically robust, and there is reason to believe that a similar and consistent product will also be available from the Advanced Along-Track Scanning Radiometer (AATSR) on the recently launched Envisat. New satellite products giving estimates of the burned area, such as GLOBSCAR, GBA 2000 (Grégoire et al., 2002) or the Vegetation Cover Change product from the Moderate Resolution Imaging Spectroradiometer (MODIS) will be augmented with high-resolution vegetation data. This will allow for a more quantitative estimate of emissions in individual years by allowing to reprocess the inventory from scratch for each year instead of scaling an existing inventory. For multi-year simulations of the past, the fire count approach should be considered as an interim solution until such more sophisticated products become available.

A new and emerging application of global chemistry transport models is the prediction of pollutant concentrations (“chemical weather”) to provide boundary conditions for regional forecast models or to support large-scale field experiments. Because of the simplicity of the technique, the active fire scaling approach appears well suited for quasi-realtime emission estimates as they will be necessary for such endeavours. However, this would require a near real-time operational active fire satellite data product, which is currently not available.

Acknowledgements. The author would like to thank O. Arino and M. Simon (European Space Agency) for providing the ATSR fire

count data and detailed information on the algorithms and processing chain of these data. W. M. Hao, J. A. Logan, and J. Goldammer deserve a lot of credit for helpful discussions on the subject, and C. Granier, B. Langmann, and J. Hölzemann for reviewing draft versions of this manuscript.
