Chiou and Youngs PEER-NGA Empirical Ground Motion Model for the Average Horizontal Component of Peak Acceleration and Pseudo-Spectral Acceleration for Spectral Periods of 0.01 to 10 Seconds

June 14, 2006

INTRODUCTION

This document describes an empirically-based ground motion model for the average horizontal component of ground motion developed as part of the PEER-NGA study. The model is developed for peak ground acceleration and 5%-damped pseudo-spectral accelerations at spectral periods from 0.01 to 10 seconds (spectral frequencies of 100 Hz to 0.1 Hz, respectively). An accompanying FORTRAN routine (CY2006.for) is provided to compute the ground motion estimates given the appropriate input parameters.

EMPRIRICAL DATABASE

DATA SELECTION

The database used in this study was the PEER NGA Flatfile Version 7.2. This database contained 3,551 recordings from 173 earthquakes. The ground motion model was developed to represent the following conditions:

1. Shallow crustal earthquakes in active tectonic regions, principally California.
2. Free field ground motions.
3. Average randomly oriented component.
4. Explicit incorporation of local soil conditions.

These conditions were used to select an appropriate data set from the PEER-NGA Flatfile.

Table 1 lists the earthquakes that were removed because they do not meet the first condition. Most of these earthquakes occurred in the oceanic crust of the Gorda plate. Ground motions from earthquakes occurring in the Gorda plate have been found to be more consistent with ground motions from Benioff zone (subduction intraslab) earthquakes than shallow crustal earthquakes (Geomatrix, 1995). Four earthquakes from Taiwan were excluded because they occurred offshore in a potentially similar environment and because of the uncertainty in their location. The four northwest China earthquakes were excluded because of their large depths (≥ 20 km) and the very limited data about the events and their recordings. Data from the 1979 St Elias earthquake were excluded because this earthquake is interpreted to have occurred on a subduction zone interface. Data from the 1992 Cape Mendocino earthquakes were included. The favored interpretation is that this event occurred on reverse faults in the overriding continental crust near to but not on the subduction zone interface. Data from the 1985 Nahanni and 1992 Roermond, Netherlands earthquakes were included. These earthquakes are interpreted to have occurred at the boundary of stable continental regions (SCR) with active tectonic regions.

The remaining earthquakes are from a variety of active tectonic regions, as indicated in Table 2. Several investigators have shown that ground motion relationships based on California

data are consistent with strong motion data in other active tectonic regions (e.g. Italy – Sabetta and Pugliese, 1996; the Mediterranean basin – Ambraseys et al., 1996; Japan – Fukushima and Tanaka, 1990). It has also been common to include ground motions from earthquakes such as Gazli, 1976, and Tabas, 1978, in developing ground motion models for application in California (e.g. Abrahamson and Silva, 1997, Campbell, 1997, Sadigh et al. 1997). In this study we start with the hypothesis that the ground motions from these separate active tectonic regions are similar and can be combined. We examine this hypothesis during model development.

Table 1: Excluded Earthquakes

EQID	EQNAME	Comment
0003	Humbolt Bay	Gorda plate
0005	Northwest Calif-01	Gorda plate
0007	Northwest Calif-02	Gorda plate
0008	Northern Calif-01	Gorda plate
0011	Northwest Calif-03	Gorda plate
0013	Northern Calif-02	Gorda plate
0017	Northern Calif-03	Gorda plate
0022	Northern Calif-04	Gorda plate
0026	Northern Calif-05	Gorda plate
0035	Northern Calif-07	Gorda plate
0067	Trinidad	Gorda plate
0071	Taiwan SMART1(5)	Deep offshore event
0084	Trinidad offshore	Gorda plate
0086	Taiwan SMART1(25)	Deep offshore event
0093	Pelekanada, Greece	Deep event
0095	Taiwan SMART1(33)	Deep offshore event
0109	Taiwan SMART1(45)	Offshore event
0142	St Elias, Alaska	Subduction interface event
0153	Northwest China-01	Poorly known event
0154	Northwest China-02	Poorly known event of moderate depth
0155	Northwest China-03	Poorly known event of moderate depth
0156	Northwest China-04	Poorly known event of moderate depth

To meet the second condition, recordings made in large buildings and at depth were removed. These are indicted by the “Geomatrix” C1 site codes of ‘C’, ‘D’, ‘E’, ‘F’, ‘G’, and ‘H’ (non-abutment sites). The exclusion of basement and large building/massive foundation recordings eliminates several additional earthquakes, notably the 1935 Helena records and a number from Imperial Valley recorded at the old Imperial Valley Irrigation District site. We included records from sites that have been characterized as having topographic effects (e.g. Tarzana Cedar Hill Nursery, Pacoima Dam left abutment) and dam abutments in general. Our rationale for including these records is that the effect of topography has not been systematically studied for all of the records in the database and many of the other recording stations may have topographic enhancement or suppression of ground motions. Therefore, topographic effects are considered to be part of the variability introduced into ground motions by travel path and site effects.

The third condition is represented by specifying the ground motion component to be the orientation-independent ground motion measure GMRotI50 defined by Boore et al. (2006). Use of this ground motion measure eliminates recordings for which only a single horizontal component was obtained. The notable effect of imposing this condition is the elimination of the Cholame-Shandon Array #2 recording from the 1966 Parkfield earthquake.

The ground motion model developed in this study explicitly accounts for site conditions. Therefore, recordings from sites for which there is no available information of the local soil conditions were excluded. These data were limited to a few recordings from earthquakes in Greece and Turkey.

The regional distribution of the selected recordings is listed in Table 2

Table 2: Regional Distribution of Selected Recordings

Active Region	Number of Earthquakes	Number of Recordings
Alaska	3	57
Armenia	1	1
California	81	1311
Canada	1	3
Georgia	1	5
Greece	8	13
Idaho	2	5
Iran	2	14
Israel	1	1
Italy	8	43
Japan	1	22
the Netherlands	1	3
New Zealand	4	5
Nicaragua	2	2
Russia	1	1
San Salvador	1	2
Taiwan	6	1753
Turkey	7	56
Totals	131	3297

Figure 1 shows the magnitude-distance distribution of the selected recordings. As in most recent developments of empirical ground motion models for application in California, recordings from other regions serve the primary roll in providing data at large ($M > 7$) magnitudes.

Figure 1: Magnitude-distance-region distribution of selected recordings.

Figure 2 shows the values of peak acceleration and 1.0-sec pseudo spectral acceleration for the selected recordings plotted versus rupture distance, R_{RUP} .

During the PEER-NGA project, the issue was raised concerning the use of data from aftershocks. We have included data from aftershocks but have allowed for the possibility that there may be systematic differences in the ground motion amplitudes produced by main shocks and aftershocks. Our reason for including the data is that they provide additional information to constrain the soil amplification model parameters.

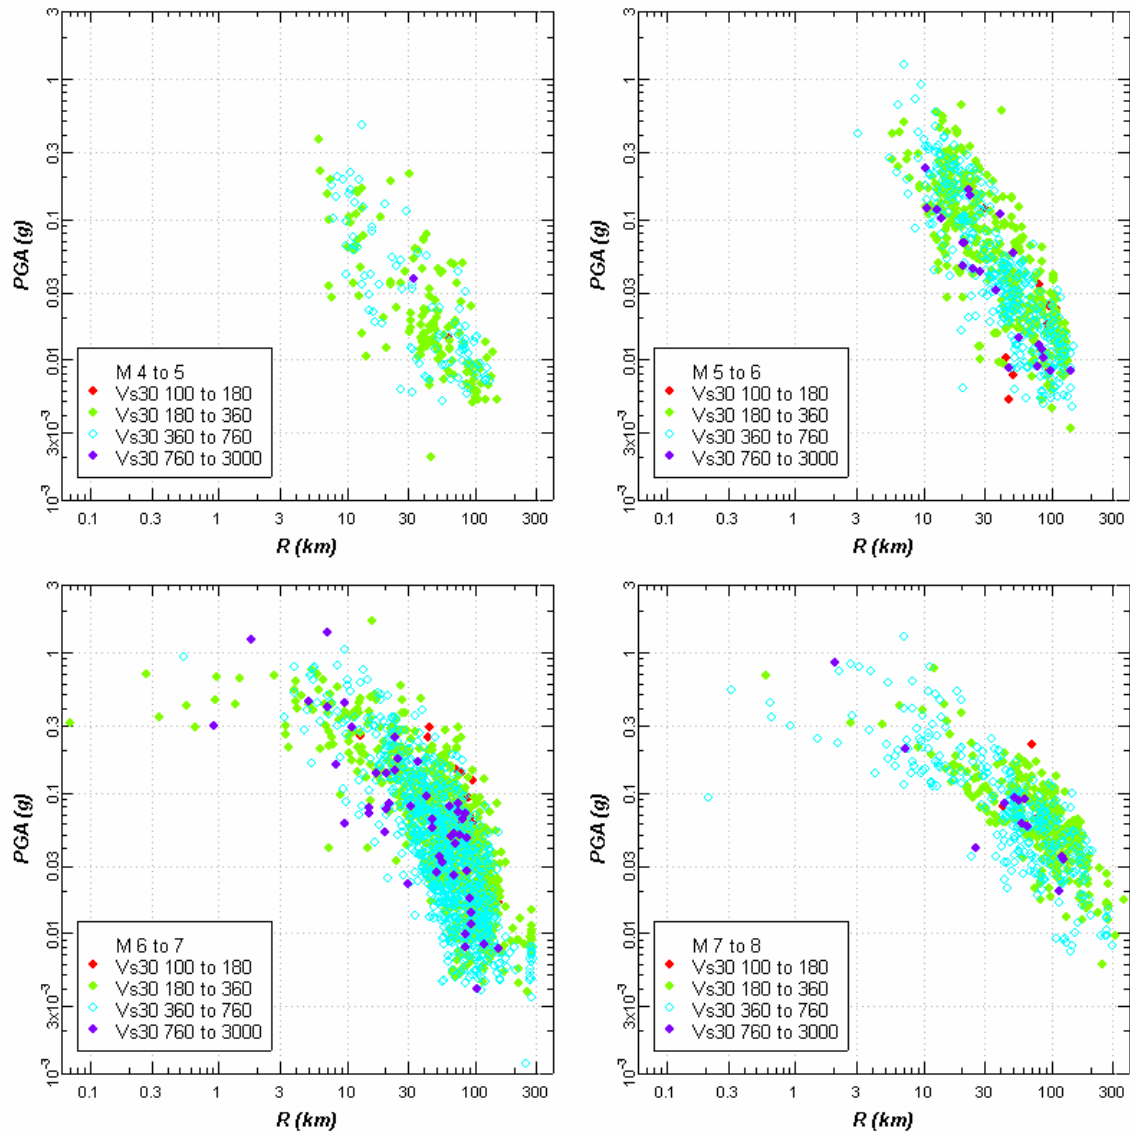

Figure 2: Empirical ground motion data used in developing the ground motion model (1 of 2).

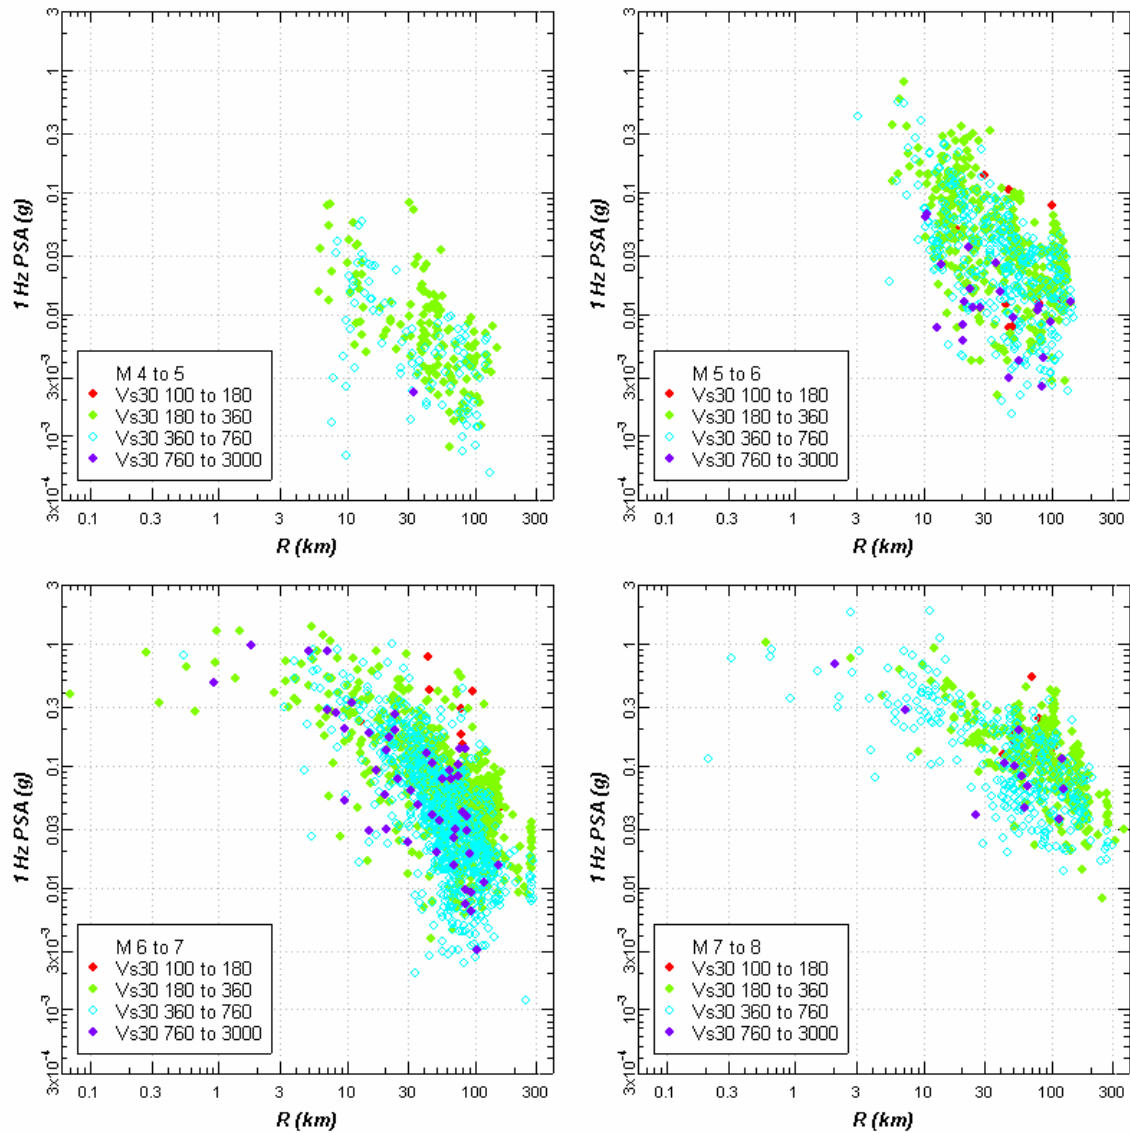

Figure 2: Empirical ground motion data used in developing the ground motion model (2 of 2).

MISSING DATA

The PEER-NGA database contains missing metadata for many of the recordings. The missing data of importance to the ground motion model developed in this study are the following: faulting mechanisms and fault dips for smaller earthquakes; rupture distances for those earthquakes without published rupture models, and for many sites, the average shear wave velocity, V_{S30} , and sediment depth defined as the depth to shear wave velocities of 1 and 2.5 km/s, $Z_{1.0}$ and $Z_{2.5}$, respectively. The missing values for these parameters were imputed (estimated) as follows.

Rupture Depth, Strike, Dip, and Rake: The PEER-NGA database contains 41 earthquakes with missing parameters defining the characteristics of the earthquake rupture. These earthquakes are listed in Table 3 along with estimated values for the missing parameters. The missing values were estimated from other associated events such as the main shock or other aftershocks, or from the tectonic environment. For those earthquakes unassociated with other events, fault dips were assigned based on known or inferred mechanisms as follows, 90° for strike-slip, 40° for reverse (based on average value reported by Sibson and Xie, 1998), and 55° for normal (generic value for normal faults and close to the average of 54° for the normal mechanisms with known dips in the PEER-NGA data base). Where fault strike could not be inferred, it was assumed to be random. The comments in Table 3 indicated the basis for each estimate.

Table 3: Inferred Mechanisms, Hypocenter Depths and Fault Dips

EQID	Earthquake	M	Inferred Mechanism ^{1,2}	Inferred Depth ¹	Inferred Strike ¹	Inferred Dip ¹	Comments
0002	Helena, Montana-02	6	SS	6	268	75	Values assumed equal to event 0001
0003	Humbolt Bay	5.8	SS	10	Random	90	Strike-slip mechanism and nominal depth of 10 km assumed for offshore Gorda plate earthquakes
0004	Imperial Valley-01	5	SS			90	Strike-slip assumed for Imperial Valley earthquakes
0005	Northwest Calif-01	5.5	SS	10	Random	90	Strike-slip mechanism and nominal depth of 10 km assumed for offshore Gorda plate earthquakes
0007	Northwest Calif-02	6.6	SS	10	Random	90	Strike-slip mechanism and nominal depth of 10 km assumed for offshore Gorda plate earthquakes

0147	Northridge-02	6.05	RV		Random	40	Assumed mechanism similar to main shock event 127 and other aftershocks
0148	Northridge-03	5.2	RV		Random	40	Assumed mechanism similar to main shock event 127 and other aftershocks

¹ Values not listed are known for specific event

² SS – strike-slip, RV – reverse, NM – normal faulting

Rupture Distances and Source-Site Geometry: One hundred and ten of the 173 earthquakes in the PEER-NGA database do not have associated finite fault models that can be used to compute the standard closest distance to rupture measures (e.g. rupture distance R_{RUP} and Joyner-Boore distance, R_{JB}) and the source-site geometry parameters such as hanging wall and foot wall positions and the source-site angle θ_{SITE} . Use of hypocentral distance, R_{HYP} , and epicentral distance, R_{EPI} , for R_{RUP} and R_{JB} , respectively, introduces a bias in the values as in most situations $R_{RUP} < R_{HYP}$ and $R_{JB} > R_{EPI}$, even for small events. The various geometry and distance measures for these earthquakes were estimated by simulating earthquake ruptures using the earthquake size and known or inferred information on the hypocentral depth, fault strike, fault dip, and rupture mechanism. Appendix B describes the simulation process. Figure 3 shows the ratios of R_{JB}/R_{EPI} and R_{RUP}/R_{HYP} for the 702 recordings from the 110 earthquakes and indicates the magnitude of the bias that could be introduced by using R_{EPI} for R_{JB} and R_{HYP} for R_{RUP} . The analysis also provided estimates of the depth to the top of rupture, Z_{TOR} , and rupture width, W , for these earthquakes.

Figure 3: Ratio of estimated values of R_{JB} and R_{RUP} to R_{EPI} and R_{HYP} for recordings from earthquakes without finite fault models in the PEER-NGA database.

Site Average Shear Wave Velocity: Approximately two-thirds of the recordings in the PEER-NGA database were obtained at sites without measured values of shear wave velocity. As part of the database compilation, empirical correlations between surface geology and the average shear wave velocity in the top 30 meters, V_{S30} were developed (ref: PEER-NGA database report). These relationships together with assessments of the surface geology from geologic maps and site descriptions were used to estimate values of V_{S30} at the sites without measured velocities. Figures 3 and 4 show the distribution of the measured (solid circles) and estimated (open circles) values of V_{S30} versus magnitude and distance for the records selected for use from the PEER-NGA database. Also indicated on the figures are the divisions of the NEHRP site categories A through E.

Figure 4: V_{S30} -magnitude-region distribution of selected recordings. Closed symbols indicated measured values, open symbols indicate inferred values. NEHRP site classes are indicated along the bottom edge.

Figure 5: V_{S30} -distance-region distribution of selected recordings. Closed symbols indicated measured values, open symbols indicate inferred values. NEHRP site classes are indicated along the bottom edge.

Additional analysis was performed as part of this study to improve the correlation between surface geology and V_{S30} for the Taiwan sites. This analysis is described in Appendix C. Additional velocity measurements and incorporation of elevation as a predictor variable were used to refine the V_{S30} estimates for the Taiwan sites.

The data distributions plotted on Figures 4 and 5 indicate that the PEER-NGA database is primarily a soil/soft rock database.

Sediment Thickness: The thickness of the near-surface sediments is represented by the depths to shear wave velocity horizons of 1.0, 1.5, and 2.5 km/s. These data are only available in the PEER-NGA database for sites within the Southern California Earthquake Center 3-D basin model (Magistrale et al., 2000, 200?) and for sites in the San Francisco Bay area (J. Boatwright, personal communication, 2005?). Figure 6 shows the relationship between V_{S30} and $Z_{1.0}$ and between V_{S30} and $Z_{2.5}$. The dashed line shows the relationship used to infer missing values of $Z_{1.0}$.

Figure 6: Relationship between V_{s30} and $Z_{1.0}$ and $Z_{2.5}$ for sites contained in the PEER-NGA database. Dashed line on plot for $Z_{1.0}$ was used to infer missing values.

SUPPLEMENTAL EMPRIRICAL DATA

The PEER-NGA strong motion data were supplemented with ground motion data from the California TriNet system. Time histories recorded at broad band stations for events 0163, 0167, and 0170 were provided by Dave Boore (personal communication, 2005). Peak acceleration values and estimates of site conditions for many other events were supplied by Jack Boatwright (2005, 2006 personal communication) and were obtained from the TriNet website. Appendix D describes the development of metadata and processing of these strong motion values. The data were used to provide additional guidance on function forms and provide additional constraints on parameters of the ground motion model.

MODEL FORMULATION

All ground motion models, empirical or theoretical/numerical, attempt to capture three basic aspects of ground motion estimation, the effect of the amount of energy radiated at the source, the effect of attenuation of seismic waves along the path due to geometric spreading and energy absorption, and the effect of local modification of the seismic waves by the near-surface materials. The empirical ground motion model developed in this study attempts to capture these elements using (relatively) simple algebraic expressions to represent the average behavior observed in the empirical strong motion data. The form of these expressions was guided by trends in the data, simple seismological models, past experience, and examination of the results of 1-D and 3-D ground motion simulations conducted as part of the PEER-NGA project.

Seismic Source Scaling

Effect of Earthquake Size: The simplest and most commonly used measure for correlating the amount of energy released in an earthquake with the resulting amplitudes of ground motions is the earthquake magnitude, defined in the PEER-NGA database in terms of moment magnitude \mathbf{M} . Most empirical ground motion models have used a polynomial function for scaling the log of ground motions y with magnitude of the form

$$\ln(y) \propto C_2(T) \times \mathbf{M} + C_3(T) \times (m_C - \mathbf{M})^n \quad (1)$$

where coefficients C_3 and possibly C_2 vary with spectral period T , the exponent n is typically in the range of 2 to 3, and the value of m_C is independent of T .

We have introduced an alternative form for magnitude scaling that reflects the results obtained using seismological models for the form of the earthquake source spectrum. Figure 7 shows response spectra computed using the stochastic ground motion model (e.g. Boore 2003) with two source spectra models, a Brune (1970, 1971) source with a stress parameter of 70 bars and the Atkinson and Silva (1997) empirical source spectra model for California earthquakes. Both forms of source spectra display similar trends in magnitude scaling. For high frequency motions ($> \sim 10$ Hz), the magnitude scaling of $\ln(y)$ is approximately linear at a relatively flat slope in the magnitude range of $5 \leq \mathbf{M} \leq 8.5$. The slope of the curves reflects the scaling of the source spectrum above the corner frequency. For very low frequency motions ($< \sim 0.3$ Hz) the magnitude scaling in the range of $5 \leq \mathbf{M} \leq 7$ is again approximately linear, but at a much larger slope than for high frequency motions, reflecting scaling of the source spectrum below the corner frequency.

At intermediate spectral frequencies, there is a transition in the scaling of $\ln(y)$ with magnitude from low-frequency scaling at low magnitudes to high-frequency scaling at large magnitudes. This transition occurs over the magnitude range where the corner frequency of the source spectrum is near the spectral frequency of the ground motion. As the spectral frequency of the ground motions decreases, the magnitude range for this transition shifts to larger magnitudes, reflecting the decrease in corner frequency with increasing magnitude.

The shape of the magnitude scaling curves shown in Figure 7 is modeled by the expression:

$$\ln(y) \propto C_2 \times \mathbf{M} + \frac{1}{C_n(T)} (C_2 - C_3) \times \ln[1 + \exp\{C_n(T) \times (C_M(T) - \mathbf{M})\}] \quad (2)$$

In Equation (2) parameter C_2 is the slope of the magnitude scaling relationship above the corner frequency, C_3 is the slope of the magnitude scaling relationship below the corner frequency. Parameter C_n controls the magnitude range over which the transition from C_2 scaling to C_3 scaling occurs. Parameter C_M is the magnitude at the midpoint of this transition and its value varies with the spectral period of the ground motion parameter y . The function form of Equation (2) was tested by fitting a set of ground motion response spectra simulated using the program SMSIM (Boore, 2005) and the Atkinson and Silva (2000) stochastic ground motion. Figure 8 shows the magnitude scaling obtained from the simulated ground motions. As indicated on the figure, the functional form of Equation (2) can provide a close fit to the simulations.

Figure 9 shows peak acceleration data in the distance range of 30 to 50 km and the VS30 range of 300 to 400 m/s from the PEER-NGA database and from the TriNet data (Appendix D). These values were fit using three alternative scaling relationships. The quadratic form of Equation (1) uses an exponent n of 2. The Sadigh et al. (1997) form of Equation (1) uses n equal to 2.5 and m_C equal to 8.5. In the magnitude scaling defined by Equation (2), parameter C_3 represents scaling of ground motion spectra below the corner frequency where the source spectra are directly proportional to seismic moment, M_0 . Because $\mathbf{M} \propto \frac{2}{3}M_0$, theoretically, C_3 should equal $1.5 \times \ln(10)$ or 3.45 and the fit of Equation (2) to the data shown on Figure 9 used this value of C_3 . Parameter C_2 represents the scaling of the source spectra above the corner frequency. The source spectral model defined by Atkinson and Silva (2000) produces scaling of $\ln(y) \propto 1.06\mathbf{M}$. As described in the next section, in the Sadigh et al. (1997) form of Equation (1), parameter C_2 also represents the magnitude scaling of the source spectra at distances unaffected by extended-source effects and in the Sadigh et al. (1997) values of C_2 were 1.0 to 1.1. The fit of the Sadigh et al. (1997) form of Equation (1) to the data on Figure 9 also produced C_2 equal to 1.0. In fitting Equation (2) to the data on Figure 9, C_2 was constrained to be 1.06, the value obtained from the magnitude scaling of source spectra above the corner frequency defined by Atkinson and Silva (2000). All three forms provide essentially equally good fits to the data. We prefer the scaling form of Equation (2) because we believe that it better represents our current concept of the variation in earthquake source spectra with earthquake magnitude.

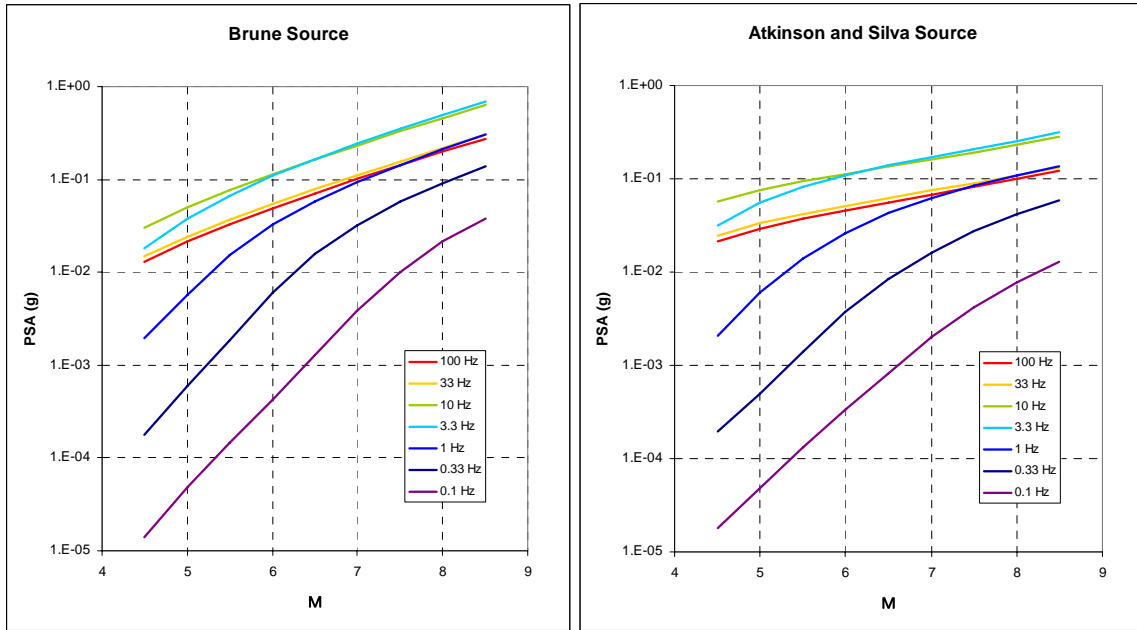

Figure 7: Response spectra at a distance of 30 km computed using the stochastic ground motion model and two source spectra, a Brune (1970, 1971) source with a 70 bar stress parameter and the Atkinson and Silva (1997) source model for California earthquakes. Western US crustal amplification (e.g. Boore and Joyner, 1997) is applied in computing the spectra.

Figure 8: Magnitude scaling predicted by the seismic source model of Atkinson and Silva (2000) (points) and the result of fitting Equation (2) to the data (lines).

Figure 9: Peak acceleration data from the PEER-NGA database and from TriNet (Appendix D) for the distance range $30 \leq R_{RUP} \leq 50$ and the velocity range $300 \leq V_{S30} \leq 400$ fit by alternative function forms of magnitude scaling.

Other Source Effects: Most recent empirical ground motion models include a scaling term that reflects alternative rupture styles. Typically it has been found that reverse faulting earthquakes produce larger high frequency motions than strike-slip earthquakes. In some of these empirical models the difference between strike-slip and reverse earthquakes diminishes as the spectral period increases, with the motion from strike-slip earthquakes becoming larger for period motions (e.g. Abrahamson and Silva, 1997; Campbell and Bozorgnia, 2003; Ambraseys et al, 2005). Chiou et al. (2000) showed that when the geometric hanging wall effect was removed from ground motion residuals by using the R_{RMS} distance measure, reverse-faulting earthquake still produced statistically significant higher motions than strike-slip earthquakes. Some empirical models have shown that normal-faulting/extension regime earthquakes produce lower ground motions than strike-slip earthquakes (e.g. Spudich et al., 1999, Ambraseys et al. 2005) while others have included normal-faulting and strike-slip together in a single class (e.g. Abrahamson and Silva, 1997; Silva et al., 1997; Campbell and Bozorgnia, 2003). The potential effect of style of faulting will be examined by including dummy variables F_{RV} and F_{NM} in the regression model. These parameters take on a value of 1.0 for earthquake ruptures with rake angles, λ , in the appropriate range and 0 otherwise.

Other source parameters that will be examined include depth to top of rupture Z_{TOR} , aspect ratio, AR , and static stress drop, $\Delta\sigma_s$.

PATH SCALING

Near-Source Distance Scaling: The scaling or attenuation of ground motion amplitude with distance from the earthquake rupture involves a number of issues. Foremost of interest for engineering application in active tectonic regions is the effect of extended sources that leads to magnitude-dependent attenuation rates at least within the distance range of 0 to 100 km. The consequence of this effect is what has been termed near-source saturation – less magnitude scaling at small source-site distances than at large source-site distances. There are four functional forms that have been used to model this effect in empirical ground motion models. These forms are shown on Figure 10 in terms of recent applications. The form that has been used for many years by Ross Sadigh and also by Ken Campbell is defined by Equation (3):

$$\ln(y) \propto C_2 \mathbf{M} + C_4 \times \ln[R + c(\mathbf{M})] \quad (3)$$

$$c(\mathbf{M}) = C_5 \exp\{C_6 \mathbf{M}\}$$

In this form, magnitude-dependence is introduced by making parameter c a function of magnitude. Campbell (1993) introduced a modified version of Equation (3):

$$\ln(y) \propto C_2 \mathbf{M} + C_4 \times \ln\left[\sqrt{R^2 + c(\mathbf{M})^2}\right] \quad (4)$$

$$c(\mathbf{M}) = C_5 \exp\{C_6 \mathbf{M}\}$$

Campbell and Bozorgnia (2003) further modified Equation (4) to introduce a quadratic magnitude term in defining $c(\mathbf{M})$.

The forms defined by Equations (3) and (4) introduce magnitude dependence through the parameter $c(\mathbf{M})$. An alternative approach is to incorporate magnitude-dependence in the “slope” term. Idriss (1991) introduced the form

$$\ln(y) \propto C_2 \mathbf{M} + (C_4 + C_5 \mathbf{M}) \times \ln[R + c] \quad (5)$$

Abrahamson and Silva (1997) introduced a modified version of (5):

$$\ln(y) \propto C_2 \mathbf{M} + (C_4 + C_5 \mathbf{M}) \times \ln\left[\sqrt{R^2 + c^2}\right] \quad (6)$$

The attenuation behavior of the four models shown on Figure 10 can be illustrated by plotting the attenuation rate, defined as $\partial \ln(y) / \partial \ln(R)$, versus distance. Figure 11 shows the results. For those models that use the term $\ln\left[\sqrt{R^2 + c^2}\right]$, the rate of attenuation approaches the value of the parameter C_4 or $C_4 + C_5 \mathbf{M}$ at relatively short distances, allowing an interpretation of its value as an estimate of the rate of geometric spreading. For those models that use the term $\ln[R + c]$, the attenuation rate approaches the value of C_4 or

C_4+C_5M slowly and the value of the parameter cannot be interpreted as an estimate of the rate of geometric spreading at distances less than 50 km.

Figure 10: Illustration functional forms used to capture magnitude-dependence of distance attenuation for distances less than 100 km. All plots are for rupture distance to a vertical strike-slip fault rupturing the surface and the values for Campbell and Bozorgnia (2003) were computed using a minimum R_{SEIS} of 3 km.

Figure 11: Plots of the instantaneous slope of the attenuation curve for the four ground motion models shown in Figure 10. The attenuation rate is defined as $\partial \ln(pga) / \partial \ln(R)$.

The different forms of distance scaling defined by Equations (3) through (6) also result in differences in the variation in the scaling of ground motions with magnitude at different distances. Figure 12 shows the magnitude scaling, defined as $\partial \ln(y) / \partial M$, for the four ground motion models shown in Figure 10. The steps in the values of $\partial \ln(y) / \partial M$ occur where there are changes in the model parameters for different magnitude ranges. The distance attenuation functional forms that use a magnitude-dependent slope, Equations (5) and (6) produce continued increases in magnitude scaling with increasing distance. Those that use a magnitude-dependent near-source adjustment term, $c(M)$, result in a gradual approach to distance-independent magnitude scaling.

Figure 12: Plots of magnitude scaling at a range of distances produced by the form of the attenuation curve for the four ground motion models shown in Figure 10. Magnitude scaling is defined as $\partial \ln(pga) / \partial M$.

We examined the alternative forms and their fit to the PEER-NGA data and came to the conclusion that they all would work equally well given the data distribution. Discrimination among them would require a great deal more data at distances less than 10 km. The relationships we are to develop are required to cover the distance range of 0 to 200 km. We based our selection of the functional form on the behavior over the full magnitude range. The data show magnitude-dependence in the rate of attenuation at all distances. However, we believe that the mechanisms that cause this behavior may be different at different distances. At distances less than ~ 50 km, magnitude-dependence is due to the effect of extended sources. This effect can be modeled by all of the form. However, at large distances, > 100 km, we think that another effect may be causing magnitude-dependence in the attenuation of response spectral ordinates – the interaction of Q with the differences in source Fourier spectra as a function of magnitude. This concept is explored below. The magnitude-dependence at large distances may also be modeled by the various functional forms. We prefer to use a model form that allows for separation of the effect of magnitude at small and at large distances, and therefore select the form defined by Equation (3). This form

allows the interpretation of the coefficient C_2 as the asymptotic value of magnitude scaling at large distances from the source. This same argument should make us favor the functional form of Equation (4) over that of Equation (3) in that with the function form of Equation (4) the coefficient C_4 can be interpreted as the geometric spreading at distances greater than about $2 \times c(\mathbf{M})$. We experimented extensively with this form, but ultimately decided not to use it because we judged that it resulted in too little distance scaling over the distance range of 0 to 10 km for large-magnitude earthquakes.

Previous implementations of the functional form of Equation (3) (e.g. Sadigh et al., 1997) have typically specified different parameters for large and small magnitude earthquakes. This results in a step function for the magnitude scaling, as illustrated in the upper left-hand plot of Figure 12. We prefer to have a smooth transition in the magnitude scaling over the full magnitude range. This was accomplished by using the relationship:

$$c(\mathbf{M}) = C_5 \cosh\{C_6 \max(\mathbf{M} - 3, 0)\} \quad (7)$$

The use of Equation (7) has the property that $c(\mathbf{M})$ varies smoothly from a constant at small magnitudes to $c(\mathbf{M}) \propto \exp(C_6 \mathbf{M})$ at large magnitudes.

Path Scaling at Large Distances: Many studies of the attenuation of ground motion Fourier amplitudes with distance have indicated that there is a change in the rate of geometric spreading from approximately proportional to $1/R$ at short distances to $1/\sqrt{R}$ at large distances, with this transition occurring in the range of 40 to 70 km. This change has been interpreted to be the combination of the effects of post-critical reflections from the lower crust and transition from direct body wave to Lg wave spreading (e.g. Atkinson and Mereu, 1992). Models of the decay of Fourier spectra with distance in California have found or assumed that the geometric spreading is proportional to $1/\sqrt{R}$ for distances greater than 40 km (Raouf et al., 1999; Erickson et al., 2004) and this form of geometric spreading was used by Atkinson and Silva (2000) to model strong ground motions. Earlier, Atkinson and Silva (1997) used a tri-linear form of attenuation similar to that defined by Atkinson and Mereu (1992), but indicated that a bi-linear form would also work.

We explored this effect by modeling the broadband data assembled for three small (\mathbf{M} 4.3 to 4.9) Southern California earthquakes (Anza, Yorba Linda, and Big Bear City, events 0163, 0167, and 0170, respectively). These data were fit with three functional forms, a 1-slope model:

$$\begin{aligned} \ln(y) &= C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \ln(R_0) + \gamma R + \phi_1 \ln(V_{S30} / 400) \\ R_0 &= \sqrt{R^2 + 6^2} \end{aligned} \quad (8)$$

a 2-slope model with the second slope $1/2$ of the first:

$$\begin{aligned} \ln(y) &= C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \{\ln(R_1) + \ln(R_2) / 2\} + \gamma R + \phi_1 \ln(V_{S30} / 400) \\ R_0 &= \sqrt{R^2 + 6^2}, R_1 = \min(R_0, C_8), R_2 = \max(1, R_0 / C_8) \end{aligned} \quad (9)$$

and a 2-slope model with the second slope fixed at -0.5:

$$\ln(y) = C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \ln(R_1) - 0.5 \ln(R_2) + \gamma R + \phi_1 \ln(V_{S30} / 400) \quad (10)$$

$$R_0 = \sqrt{R^2 + 6^2}, R_1 = \min(R_0, C_8), R_2 = \max(1, R_0 / C_8)$$

This study was performed before our final decision on the function form for distance attenuation near the source but alternative forms were found to produce similar results. The data cannot determine h (insufficient data at small distances) so it was fixed at 6. Dummy variables F_{BBC} and F_{YL} were used for the intercepts rather than magnitude scaling with random effects. There is sufficient data for each event (~200 records) that the random effect should equal the mean residual and the magnitude range is small (4.33 to 4.92). The analysis was conducted for spectral periods in the range of 0.01 to 5 seconds. Examination of the recordings (Appendix D) indicated that they could be used without processing to periods at least as long as 5 seconds.

Figure 13 shows the results of fitting Equations 8 and 9 to the data. At all spectral periods, the 2-slope models produced slightly smaller standard errors than the single slope model. The location for the break in slope varied between 40 and 60 km. In addition, use of the single-slope model produces unrealistic positive values of the anelastic attenuation term γ for longer period motions, a fact also noted by Atkinson and Silva (1997).

The TRI-Net *pga* data from many of the better-recorded small magnitude earthquakes display the change in attenuation rate slope. Tests of the PEER-NGA data also show that a two-slope model is statistically significant with a slope break also in the range of 45 to 60 km. Examination of the 1-D rock numerical simulation data also indicate that two-slope model provides a good fit with a break in slope at about 60 km.

Based on the above considerations, we adopted the concept of a change in the rate of attenuation occurring at a distance of approximately 50 km from the source. The appropriate value of the attenuation rate at distances beyond this point cannot be readily determined from the data because it is highly correlated with the assessment of the anelastic attenuation term γ , as had been noted by many previous investigators (e.g. Atkinson, 1989; Frankel et al., 1990). Therefore, we assume that the rate of attenuation can be modeled by a slope of -0.5 and will let the anelastic attenuation term γ account for departures from this value.

The anelastic attenuation parameter γ is likely to have some degree of magnitude dependence. Boatwright et al. (2003) found magnitude-dependence in the anelastic attenuation term from their study of *pga* and *pgv* from northern California ShakeMap data, with increasing magnitude producing smaller absolute values of γ (less energy absorption). In addition, stochastic simulations of ground motions using a magnitude-independent Q model will produce magnitude-dependence in the resulting anelastic attenuation term γ fit to response spectra ordinates (e.g. Campbell, 2003). This effect was also noted by us in fitting ground motions using the Atkinson and Silva (2000) ground motion model. The effect is likely due to the shift to lower frequencies driving the damped oscillator response (and driving *pga*, Boatwright et al., 2003) as the size of the earthquake increases and lower frequency motions typically display lower values of Q .

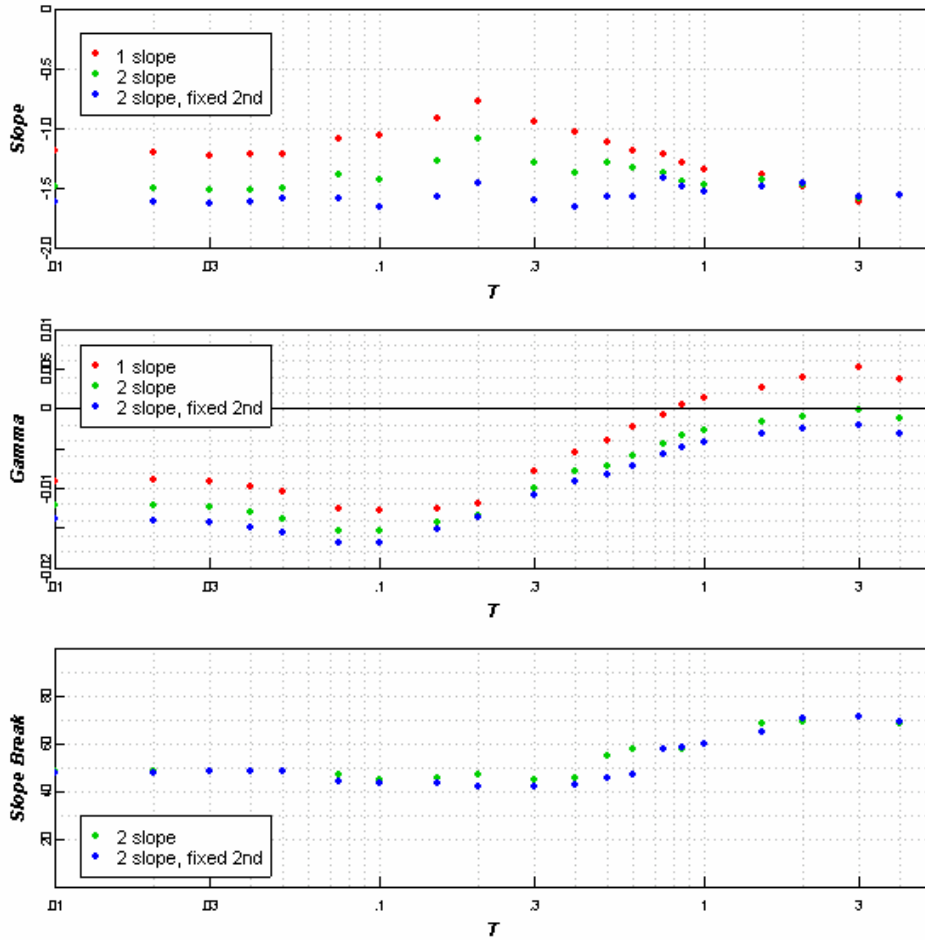

Figure 13: Coefficients resulting from fits of Equations (8), (9), and (10) to the broad band data for earthquakes 0163, 0167, and 0170. T is spectral period in seconds.

The form of Equation (10) has a sharp break in the slope of the attenuation curve. This form appears to work well for individual earthquakes. However, the ground motion model developed in this study is intended to apply over all of California and includes data from a number of active tectonic regions. Therefore, Equation (10) was modified to introduce a smooth transition from near-source to far-source attenuation rates. The selected form for the distance attenuation function for the ground motion model developed in this study is:

$$\ln(y) \propto C_4 \ln[R_{RUP} + C_5 \cosh\{C_6 \max(\mathbf{M} - 3, 0)\}] + (-0.5 - C_4) \ln \sqrt{R_{RUP}^2 + R_B^2} + \gamma(\mathbf{M}) \quad (11)$$

This form incorporates magnitude-dependent extended source effects, potentially magnitude-dependent wave propagation effects on responds spectra at large distances and a smooth transition from dominance of ground motions by direct waves at small distances to dominance by Lg waves at large distances.

Source-Site Geometry Effects: Analyses of ground motions from thrust earthquakes by Somerville and Abrahamson (1995) and Abrahamson and Somerville (1996) proposed the so called “hanging wall” effect in which ground motions are enhanced in the hanging wall of

thrust earthquakes. The effect was attributed to the inability of the R_{RUP} distance measure to capture the general proximity of a hanging wall site to rupture on the fault plane dipping beneath it. Chiou et al. (2000) performed extensive analyses of empirical and numerical modeling data for dipping fault ruptures and reached the same conclusion. They were able to remove the effect by using a root-mean-squared distance measure, R_{RMS} .

The hanging wall effect is seen in the PEER-NGA data. Figure 14 shows intra-event residuals for data from dip-slip earthquakes (both reverse/thrust and normal) plotted versus horizontal distance from a point above the top of the fault rupture. The dashed line is a locally-weighted least-squares fit to the residual. It shows an upward warp in the region where the hanging wall effect is expected to be present. The effect is also seen in the 1-D rock ground motion simulations conducted for the PEER-NGA project (Somerville et al., 2006).

Figure 14: Intra-event residual for sites in the hanging wall (positive fault tip distance) and footwall (negative fault tip distance) from dip-slip earthquakes. Black dashed line is a locally-weighted least-squares (lowess) fit to the residuals.

Abrahamson and Silva (1997) included the hanging wall effect in their empirical ground motion model as a distance-dependent term with an abrupt switch from no effect to full effect as one crosses into the hanging wall region, defined as sites with a source-site angle, θ_{SITE} , between 60° and 120° . Boore et al. (1997) conclude that their use of R_{JB} implicitly accounts for the hanging wall effect in that all site directly above the rupture have $R_{JB} = 0$. Campbell and Bozorgnia (2003) introduces a smooth variation in the hanging wall effect by tapering the effect from a maximum at $R_{JB} = 0$ to zero for $R_{JB} > 5$ km while using R_{SEIS} as the primary distance measure for assessing ground motion amplitudes.

We have extended the concept proposed by Campbell and Bozorgnia (2003) by defining the hanging wall effect to be proportional to the factor $[1 - R_{JB} / R_{RUP}]$. Figures 15 through 17 illustrate the behavior of this function. Figure 15 shows a map view of a fault rupture with

the top of rupture located at $x = 0$ and the fault dipping downward towards positive x . Figure 16 show the variation of the factor $[1 - R_{JB} / R_{RUP}]$ with location along three lines for the case when the top of rupture at $x=0$ is at the ground surface. Line 1 runs from negative values in the foot wall to positive values in the hanging wall. In the foot wall, $R_{JB} = R_{RUP}$ and the hanging wall effect is zero. Thus the function acts as a switch equivalent to other formulations that only apply the effect on the hanging wall side of the fault. Lines 2 and 3 show the variation of $[1 - R_{JB} / R_{RUP}]$ as one moves away from the rupture along strike. Line 2 is located near the top of the rupture and line 3 near the bottom. The function $[1 - R_{JB} / R_{RUP}]$ decays much more rapidly for Line 2 than for Line 3. Most of Line 2 lies outside of the area typically defined as subject to the hanging wall effect while much of Line 3 for small values of y lines within the hanging wall area. The term $[1 - R_{JB} / R_{RUP}]$ provides for a smooth transition in the level of the hanging wall effect throughout the along strike region.

Figure 15: Map view of example fault rupture.

Figure 16: Variation of the term $[1 - R_{JB} / R_{RUP}]$ with location for the three lines shown on Figure 15. Top of rupture is at the ground surface at $x=0$.

Figure 17 shows the variation of the term $[1 - R_{JB} / R_{RUP}]$ for the case when the top of rupture is located at a depth of 5 km. Now, the hanging wall effect extends into the footwall side of

the rupture, although this region is mostly to the hanging wall side of a projection of the rupture to the surface (i.e. on the hanging wall of the fault, but the foot wall side of the rupture). It seems reasonable that there should be some increased motion in this area for a buried fault.

Figure 17: Variation of the term $[1 - R_{JB} / R_{RUP}]$ with location for the three lines shown on Figure 15. Top of rupture is at a depth of 5 km at $x=0$.

The effectiveness of the term $[1 - R_{JB} / R_{RUP}]$ to capture the hanging wall effect was tested by fitting the selected PEER-NGA data for peak acceleration with a regression model without a hanging wall term. The residuals were found to be correlated with $[1 - R_{JB} / R_{RUP}]$ with a p-value of 0.0024. Exploratory analysis indicated that the model $[1 - R_{JB} / R_{RUP}]^n$ with n equal to 2 and $\frac{1}{2}$ produced poorer fits to the data (larger standard error) than a linear model ($n=1$). No significant difference between normal and reverse faulting data was found (p value of 0.63 for adding a normal fault difference in the correlation). The behavior of the residuals with respect to $[1 - R_{JB} / R_{RUP}]$ was checked by separately fitting the data on the hanging wall, $60^\circ \leq \theta_{SITE} \leq 120^\circ$, and footwall, $-60^\circ \leq \theta_{SITE} \leq -120^\circ$ sides of the rupture, excluding sites directly above the rupture ($R_{JB}=0$). Figure 18 shows the residuals and linear fits with respect to $[1 - R_{JB} / R_{RUP}]$ constrained to go through 0 at $[1 - R_{JB} / R_{RUP}]=0$. The solid lines show the mean trend and the dashed lines the 90% confidence interval for the mean. The residuals on the hanging wall and footwall side of the ruptures have essentially identical trends.

Previous empirical models (Abrahamson and Silva, 1997; Campbell and Bozorgnia, 2003) have limited the hanging wall effect to faults with dip angles, δ , less than 70° . Assuming the hanging wall effect is a geometric effect, one might expect that it might correlate with δ . Figure 19 shows residuals for sites on the hanging wall of reverse faults ($R_{JB} = 0$) plotted versus δ . The data indicate increasing motion with decreasing δ . The trend was modeled with linear functions with $90^\circ - \delta$, $\cos(\delta)$ and $\cos^2(\delta)$. All three functions show a significant trend with the residuals, with $\cos^2(\delta)$ providing a slightly better fit than the other two models. Similar results were found including data from sites with $[1 - R_{JB} / R_{RUP}] > 0.8$ and for data from sites with $R_{JB} < 5$ km.

Figure 18: Intra-event residuals for dip-slip earthquake for a model without a hanging wall term. The residuals were fit with a linear regression line constrained to pass through 0 at $[1 - R_{JB} / R_{RUP}] = 0$. Solid line shows the mean trend and the dashed lines indicate the 90% confidence interval for the mean.

Figure 19: Intra-event residuals from fitting a model without a hanging wall term for sites with $R_{JB} = 0$ and $F_{HW} = 1$ plotted against fault dip, δ .

Although, the term $[1 - R_{JB} / R_{RUP}]$ appears to model well the hanging wall effect, there are two additional aspects it does not capture. Assuming that the hanging wall effect is a

geometric effect, we expect that smaller overall ruptures would produce less effect than larger rupture, given the same values of R_{JB} and R_{RUP} . Previous implementations of the hanging wall effect in empirical models have reduced the effect to 0 for magnitudes less than **M** 6. Similarly, as the same size rupture is moved to deeper depths, we would also expect the hanging wall effect to be reduced. Both smaller rupture sizes and greater depths would tend to move make R_{RMS} closer to R_{RUP} , and thus, according to the analysis of Chiou et al. (2000), reduce the hanging wall effect.

We propose a geometric factor, $HW^* = 2\psi/\pi$, to represent the combined effect of rupture size and rupture depth. The factor is illustrated on Figure 20. The angle ψ represents the half-angle of the exposure of the surface to the fault plane and is a function of the rupture width, W , and the rupture depth, Z_{TOR} . Using the geometry of the fault rupture, HW^* is computed by the relationship:

$$HW^* = \frac{2}{\pi} \tan^{-1} \left(\frac{W \cos(\delta)}{2(Z_{TOR} + \zeta)} \right) \quad (12)$$

The factor ζ is included to remove singularities in the calculation and to limit the hanging wall effect for small magnitudes at shallow depths. Figure 21 show the variation of HW^* with **M** and Z_{TOR} with ζ set equal to 1 km. The function introduces a decrease in the hanging wall effect with increasing rupture depth that is magnitude-dependent.

Figure 20: Illustration of the hanging wall geometric factor HW^* .

Figure 22 shows that HW^* correlates with both magnitude and Z_{TOR} for the data selected for use in this study.

One additional aspect of the hanging wall effect needs to be addressed. The function $[1 - R_{JB} / R_{RUP}]$ produces the same level of hanging wall effect at locations on top of the rupture. However, the numerical modeling results presented in Chiou et al. (2000) and those conducted for the PEER-NGA project (Somerville et al., 2006) show the hanging wall effect tapering to zero at the fault tip for faults with surface rupture. We model this effect by multiplying the hanging wall term by $\tanh(0.5R_{RUP})$.

Figure 21: Variation of HW^* with magnitude, depth to top of rupture for $\zeta = 1$ km and a range of fault dips.

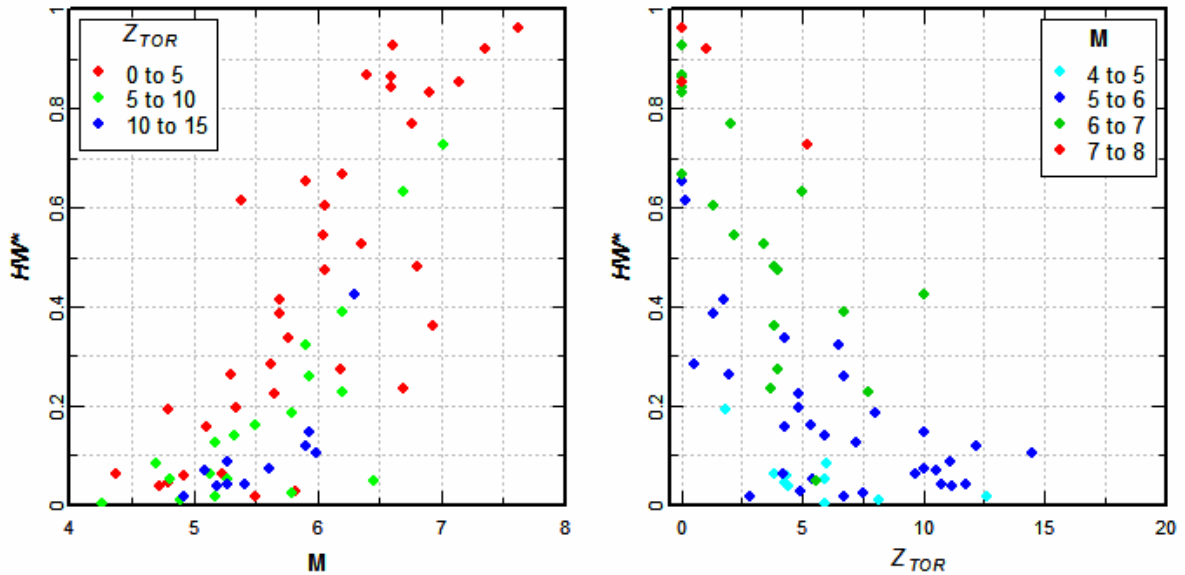

Figure 22: Correlation of HW^* with magnitude and depth to top of rupture for the earthquakes in the PEER-NGA database selected for use in this study.

The complete hanging wall function is given by:

$$f_{HW} = \tanh(0.5R_{RUP}) \times \cos^2(\delta) \times \frac{2}{\pi} \tan^{-1}\left(\frac{W \cos(\delta)}{2(Z_{TOR} + 1)}\right) \times \left[1 - \frac{R_{JB}}{R_{RUP} + 0.001}\right] \quad (13)$$

The factor of 0.001 is added in the denominator of R_{JB}/R_{RUP} to prevent a singularity at $R_{RUP}=0$. We admit that the formulation is defined somewhat arbitrarily. However, we think that it serves the function of reducing the hanging wall effect with decreasing magnitude and

with increasing rupture depth. The data in the PEER-NGA data set are insufficient to test if Equation (13) performs better than piece-wise linear functions of R_{RUP} , \mathbf{M} and Z_{TOR} .

SITE EFFECTS

Near-Surface Geology: The incorporation of the effects of near-surface geology or site classification has gone through an evolution in the past 10 years. At the beginning of this period, ground motion models typically contained a scaling parameter based on site classification (e.g. Boore et al., 1993), or presented different models for “rock” and “soil” sites (e.g. Campbell, 1993; Sadigh et al. 1997). Classification of recording sites into rock or soil sites varied among investigators. Boore et al. (1997) introduced the explicit use of the average shear wave velocity in the upper 30 meters, V_{S30} , in the ground motion model. Abrahamson and Silva (1997) building on an earlier model by Youngs (1993) introduced the explicit modeling of non-linear site effects in the ground motion model. The model we have developed for incorporating near-surface geology combines these concepts.

$$\ln(y_{site}) = \ln(y_{ref}) + f_{Site}(V_{S30}, y_{ref}) \quad (14)$$

The parameter y_{ref} is the ground motion on the reference site condition derived from the source and path scaling models described in the previous section. The reference site shear wave velocity was chosen to be 1130 m/sec because of the initial use of site response data to develop the functional form (Silva, 2004) and because it is expected that there will not be significant nonlinear site response at this velocity. As indicated on Figures 4 and 5, there are very few data with values of V_{S30} greater than 1100 m/sec. The reference motion is defined to be the spectral acceleration at the spectral period of interest for two reasons. Bazzurro and Cornell (2004) indicate that the spectral acceleration at spectral period T is “the single most helpful parameter” for the prediction of site amplification at that period. In addition, the estimation of the coefficients of the ground motion model is performed using random (mixed) effects regression in which the reference motion includes the random event term representing the deviation of the average ground motions from a given earthquake from the global population mean. Use of the reference spectral acceleration at period T to estimate surface ground motions at the same period eliminates the need to include the correlation in the random effects between those at period T and those at another period, such as pga at “zero” period.

The function form for the site response model f_{Site} with $y_{ref} = SA_{1130}$ is given by:

$$f_{Site}(V_{S30}, T, SA_{1130}) = a(V_{S30}, T) + b(V_{S30}, T) \ln \left[\frac{SA_{1130}(T) + c(T)}{c(T)} \right]$$

where

$$a(V_{S30}, T) = \phi_1 \ln \left[\frac{V_{S30}}{1130} \right] \quad (15)$$

$$b(V_{S30}, T) = \phi_2(T) \exp\{\phi_3(T) \times (V_{S30} - 360)\}$$

$$c(T) = \phi_4(T)$$

The interpretation of the parameters a , b , and c is illustrated in Figure 23. Parameter a represents the linear site response that occurs at small level of reference site motion. It is modeled as a linear function of $\ln[V_{S30}]$ consistent with previous representations (e.g. Boore et al., 1997). Parameter c represents the ground motion level in the middle of the transition from linear to nonlinear behavior. Parameter b represents the nonlinear behavior in terms of a linear decrease in the natural log of site amplification, f_s , with increasing amplitude of the reference motion. In general, a stronger nonlinearity in soil response corresponds to a more negative value for b (stronger dependence on SA_{1130}). It is expected that the degree of nonlinearity is a function of the stiffness of the site soils and is represented by making b a function of V_{S30} .

Figure 23: Soil amplification function

The ability of Equation (15) to represent nonlinear site response is illustrated in Figures 24 and 25. Figure 24 shows site amplification factors for pga derived from Silva's (2004) simulations. Two soil property models were used by Silva (2004), the EPRI (1993) set of soil modulus and damping relationships and the less nonlinear set Peninsular Range set developed by Silva et al. (1996). The solid lines shown on the figure are the result of fitting Equation (15) to the combined amplification factors for the two soil model sets and indicate that the function form can well represent the behavior implied by nonlinear (equivalent-linear) site response. Figure 25 shows the values of parameters a and b derived from the results of Silva (2004). The dashed lines show that the function forms for a and b in Equation (15) provide a good match to the site response results.

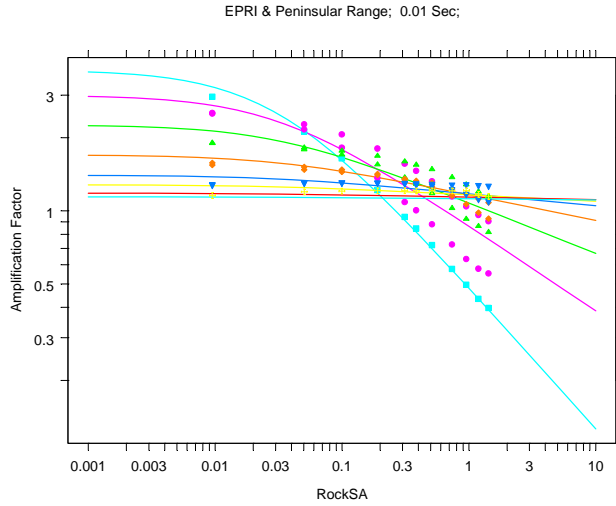

Figure 24: Soil amplification as a function of ground motion level from 1-D equivalent linear site response analyses (Silva, 2004). Colors denote VS30 as follows: light blue - 150m/s, magenta - 270m/s, green - 400m/s, red - 560m/s, and blue - 750m/s.

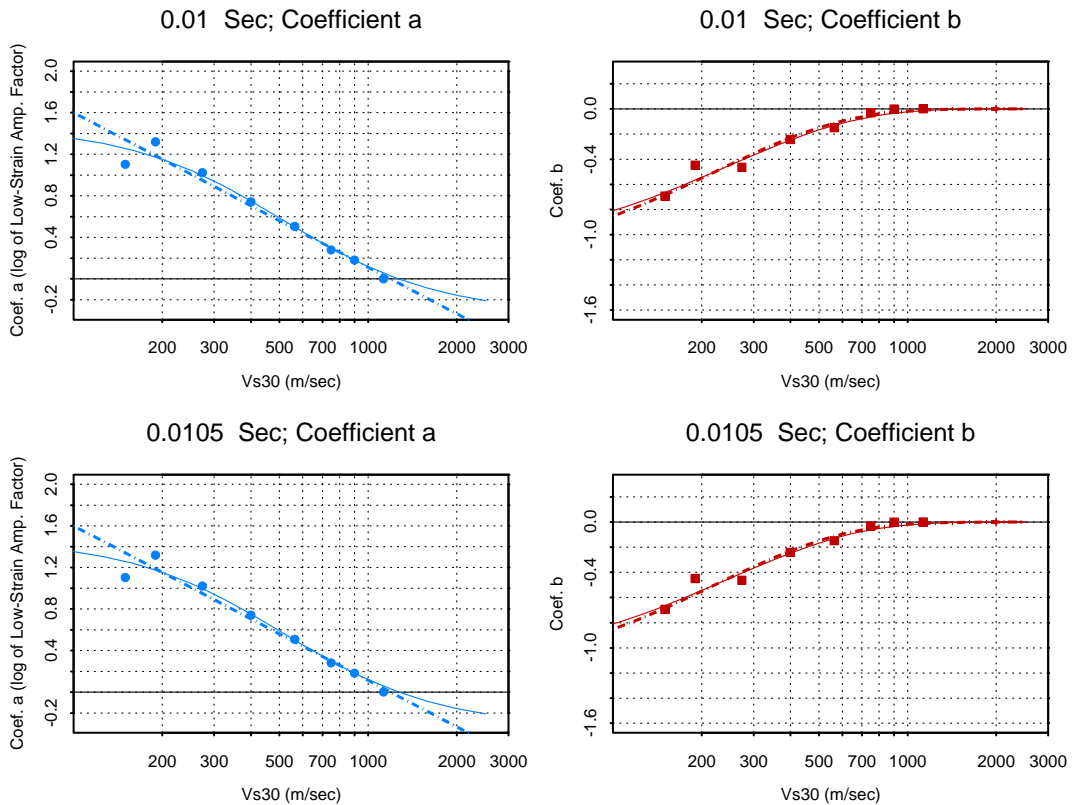

Figure 25: Fit of models for coefficients a and b to the 1-D site response results from Silva (2004). The dashed lines represent fits using the functional forms in Equation 15.

Choi and Stewart (2005) developed a model for the dependence of nonlinear site amplification on V_{S30} and the level of input rock motion. Figure 26 compares the variation of the parameter b computed from their models with results obtained from fitting Equation (15)

to the PEER-NGA pga data selected for use in this study. The functional form of Equation (15) provides a good match to the general behavior of the models developed by Choi and Stewart (2003).

Figure 26: Comparison of parameter b dependence on V_{S30} obtained by Choi and Stewart (2003) (blue curve – Abrahamson and Silva, 1997, reference motions, red – Sadigh et al., 1997, reference motions) with the trend obtained in this study from the PEER-NGA data (black line).

Basin Depth: As discussed in Campbell (1997), a number of investigators have indicated the importance influence of sediment/basin depth on site ground motions and the parameter has been included in several of the models developed by Ken Campbell (e.g. Campbell, 1997). Day et al. (2006) developed a model for site amplification as a function of the depth to shear wave velocities of 1.0, 1.5, and 2.5 km/s ($Z_{1.0}$, $Z_{1.5}$, and $Z_{2.5}$, respectively) based on 3-D ground motion simulations using the SCEC 3-D velocity model (Magistrale et al., 2000). We have found that Day et al.’s model compares well with site amplifications observed in the broad band data for earthquakes 0163, 0167, and 0170. The model developed by Day et al. (2006) represents site amplification solely in terms of the sediment depth. As shown on Figure 6, there is a high degree of correlation between V_{S30} and $Z_{1.0}$ or $Z_{2.5}$. Our preliminary analysis indicates that it is very difficult to separate the effect of these two parameters at low frequencies. Use of the Day et al. (2006) model results would require accounting for removal of portion of the site amplification represented by the function f_s defined above. In addition, values of $Z_{1.0}$ or $Z_{2.5}$ are not readily available on a global basis. Therefore, we have developed the base model without including sediment thickness. We have computed residuals with respect to this model as a function of $Z_{1.0}$ and $Z_{2.5}$ and intend to develop ground motion adjustments that can be performed if these parameters are known for a site.

MODEL PARAMETER DEVELOPMENT

The general form of the ground motion model used to assess the model parameters is shown in Equation (16):

$$\begin{aligned}
 \ln[y_{Surface}] &= \ln[y_{1130}] + f_{Site} + \sigma \cdot z_{ij} \\
 \ln[y_{1130}] &= c_1 + f_{Source} + f_{Path} + f_{HW} + \tau \cdot z_i \\
 f_{Source} &= c_2(\mathbf{M} - 6) + \left(\frac{c_2 - c_3}{c_n} \right) \times \ln[1 + \exp\{c_n(c_M - \mathbf{M})\}] + c_{1a}F_{RV} + c_{1b}F_{NM} + c_7(Z_{TOR} - 4) \\
 f_{Path} &= c_4 \ln[R_{RUP} + c_5 \cosh\{c_6 \max(\mathbf{M} - c_{HM}, 0)\}] + (c_{4a} - c_4) \times \ln\left[\sqrt{R_{RUP}^2 + c_{RB}^2}\right] + \\
 &\quad [c_{\gamma 1} + c_{\gamma 2} / \cosh\{\max(\mathbf{M} - c_{\gamma 3}, 0)\}] \times R_{RUP} \\
 f_{HW} &= c_9 \cos^2(\delta) \times \tanh(R_{RUP} / 2) \times \frac{\tan^{-1}\left\{\frac{W \cos(\delta)}{2(Z_{TOR} + 1)}\right\}}{\pi / 2} \times \left\{1 - \frac{R_{JB}}{R_{RUP} + 0.001}\right\} \\
 f_{Site} &= \phi_1 \min\left\{\ln\left[\frac{V_{S30}}{1130}\right], 0\right\} + b_{Site} \ln\left[\frac{\exp\{\ln[y_{1130}]\} + \phi_4}{\phi_4}\right] \\
 b_{Site} &= \phi_2 \times [\exp\{\phi_3(\min(V_{S30}, 1130) - 360)\} - \exp\{\phi_3(1130 - 360)\}]
 \end{aligned} \tag{16}$$

The parameter y_{1130} is the ground motion on the reference site condition ($V_{S30} = 1130$ m/sec). Its level is based on the source scaling function f_{Source} , the path scaling function, f_{Path} , the hanging wall function f_{HW} , and a random effect τz_i that is modeled as a Gaussian random variate with inter-event standard deviation τ . The log of the ground motion at a site is the sum of the log of the reference motion and a nonlinear amplification, f_{Site} , that is a function of V_{S30} and the level of the reference motion. The ground motions at the site also include a random Gaussian variate with intra-event standard deviation σ . The inter-event component of randomness is included when computing the site amplification. Also note that the site amplification function uses the reference motion for the same spectral period. The additional parameters in Equation (16) are: R_{RUP} , closest distance to the rupture plane (km); R_{JB} , Joyner-Boore distance to the rupture plane (km); δ , rupture dip; W , rupture width (km); Z_{TOR} , depth to top of rupture (km); F_{RV} , reverse faulting factor equal to 1 for $30^\circ \leq \lambda \leq 150^\circ$, and 0 otherwise; F_{NM} , normal faulting factor equal to 1 for $-120^\circ \leq \lambda \leq -60^\circ$, 0 otherwise; λ , slip rake angle; V_{S30} , average shear wave velocity for top 30 m (m/s). Note, f_{HW} applies to all faulting styles.

The model parameters were obtained by fitting the model to the selected PEER-NGA data using the nonlinear mixed effects method *nlme* implemented in the statistical packages S-Plus and R. The process used to obtain these parameters is described below.

EFFECT OF DATA TRUNCATION

The initial analyses of the PEER-NGA data suggested that the anelastic attenuation term γ in Equation (11) was 50-percent larger in absolute value for earthquakes from Taiwan than for earthquakes in California or the other active tectonic regions represented in the selected database (Table 2). For *pga* the estimated values of γ were approximately -0.006 for California earthquakes and approximately -0.009 for Taiwan earthquakes. This would imply that Q for Taiwan was significantly lower than Q for California or the other regions. However, review of the literature failed to produce studies that confirmed this result. The comparison of Q estimates was made more difficult by the varying assumptions about geometric spreading made by the various investigators. In addition, the estimates of γ obtained from the broadband data for the three southern California earthquakes 0163, 0167 and 0170 were in the range of -0.012 to -0.014 (Figure 13).

These results led us to consideration of the effects of missing response data on the estimation of ground motion model parameters. There are two forms of missing response data treated in the literature: censoring and truncation. Censoring occurs when a known set of instruments is triggered, but the response is only known to be below $y_{\text{truncation}}$. In this case, the number of censored observations and predictor variables for these observations (e.g. \mathbf{M} , R_{RUP} , and $VS30$) are known for the censored sample. Truncation occurs when the observed sample is truncated at some response level $y_{\text{truncation}}$ such that no responses are reported below this level. The number of missing values and values of the predictor variables for these observations are unknown. The two forms of missing response variables lead to different forms of the sample likelihood function in fitting models by maximum likelihood.

Censoring/truncation of the strong motion database occur due to the occurrence of ground motions below the trigger threshold for the recording instruments and from the selective processing of recordings favoring those with larger amplitudes. Censoring/truncation occurs also from record processing as frequency bands with low signal/noise ratios are filtered out of the process records. Although the number of possible recordings in a given earthquake is knowable, some instruments may have malfunctioned and there is not a complete accounting of the possible instruments available. Therefore, the truncation model is considered the most appropriate condition.

Some evidence of truncation of the data is seen in Figure 2, but it is more apparent when examining individual earthquakes. An obvious case is shown in Figure 27 for the three small southern California earthquakes analyzed previously. The left hand plot shows the 660 *pga* values for the three earthquakes obtained from the broad band recordings and the right hand plot shows the 119 *pga* values for the processed records that are in the PEER-NGA database for these earthquakes. Approximate truncation levels are indicated by the dashed horizontal lines. The curves indicate fits to the data using truncated regression techniques with random effects as follows.

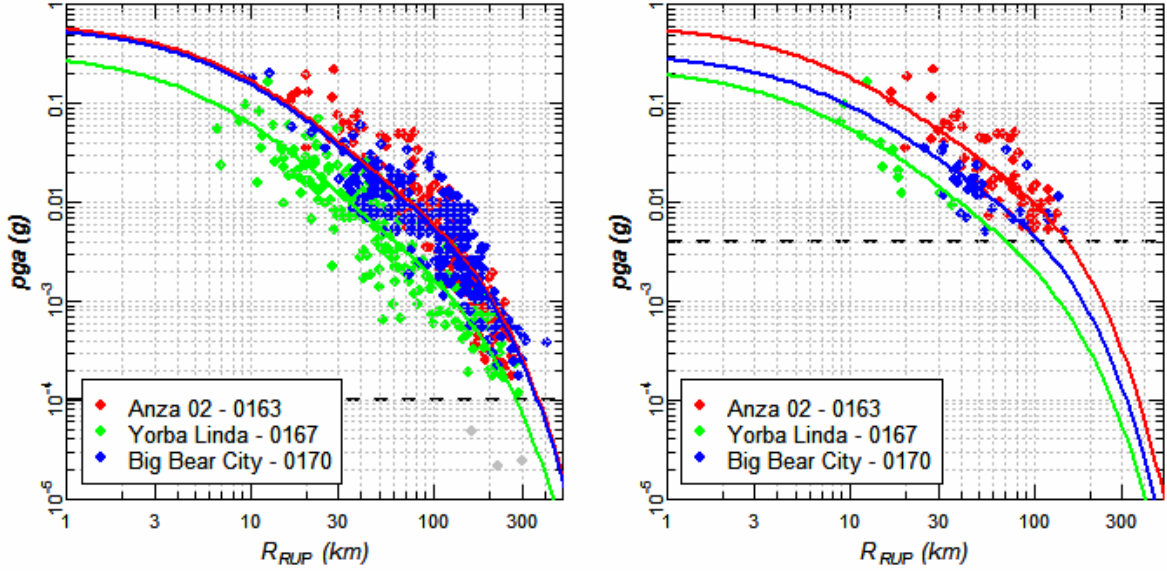

Figure 27: Example of data truncation. Left hand plot shows broad-band peak acceleration data for three small southern California earthquakes and right hand plot shows PEER-NGA data for the same events. Curves show truncated regression fits to the combined data with the truncation level indicated by the horizontal dashed line.

The sample likelihood and log likelihood functions for a regression model without random effects in which the responses have been truncated below a level $y_{\text{truncation}}$ are given by:

$$L = \prod_i \frac{\varphi_N(y_i | \mathbf{x}_i, \boldsymbol{\beta})}{1 - \Phi_N(z_{\text{trunc}} | \mathbf{x}_i, \boldsymbol{\beta})} \quad (17)$$

$$\ln(L) = \sum_i \left[-\ln(\sigma^2) / 2 - \{\ln(y_i) - \mu(\mathbf{x}_i, \boldsymbol{\beta})\}^2 / 2\sigma^2 \right] - \sum_i \ln[1 - \Phi_N(y_{\text{truncation}} | \mathbf{x}_i, \boldsymbol{\beta})]$$

In Equation (17) φ_N and Φ_N are the normal density and cumulative normal functions, \mathbf{x}_i is the vector of predictor variables for the i^{th} observation and $\boldsymbol{\beta}$ is the vector of model coefficients. Application of this to the analysis of ground motion data has been performed by Toro (1981) and more recently by Bragato (2004). We have extended the concept of truncation to the mixed effects model. Using the formulation of Brillinger and Preisler (1984), the sample likelihood function is:

$$L = \prod_i \int \left[\frac{1}{\sqrt{2\pi}} \exp\{-z_i^2 / 2\} \cdot \prod_j \left(\frac{1}{\sigma\sqrt{2\pi}} \frac{\exp\{-(y_{ij} - \mu_{ij}(\theta) - \tau \cdot z_i)^2 / 2\sigma^2\}}{[1 - \Phi(y_{\text{truncation}} | \mu_{ij}(\theta) + \tau \cdot z_i, \sigma)]} \right) \right] dz \quad (18)$$

In Equation (18), the index i refers to the individual earthquakes and the index j refers to the separate observations for the i^{th} earthquake. The term $[1 - \Phi(y_{\text{truncation}} | \mu_{ij}(\theta) + \tau \cdot z_i, \sigma)]$ normalizes the probability for the y_{ij}^{th} observation by dividing by 1 minus the probability distribution tail below the truncation limit $y_{\text{truncation}}$. The random effect for the i^{th} earthquake, $\tau \cdot z_i$, appears in both the error term for the ij^{th} observation and in the density normalization

term $\left[1 - \Phi(y_{truncation} | \mu_{ij}(\theta) + \tau \cdot z_i, \sigma)\right]$. Maximum likelihood solutions to Equation (18) were performed using numerical integration and the general optimization routine *optim* in R.

The data shown in Figure 27 were fit by maximum likelihood using Equation (18) and a ground motion model in which all the parameters were fixed except γ and the random effect for each event. The truncation levels for each case are indicated on the figure. For this example, $\gamma = -0.013$ was obtained from the fit to the full data set and $\gamma = -0.015$ was obtained from the fit to the PEER-NGA data for these three events.

To further evaluate the potential impact of data truncation on the model development, we developed extended *pga* data sets for 10 additional California earthquakes. These extended data sets are described in Appendix D and the earthquakes are listed in Table 4. Additional *pga* data for Northridge (EQID 0127) were supplied by Vladimir Graizer (personal communication, 2006). The remaining data were obtained from the TriNet/ShakeMap webpages. Only the High Broadband data were used. The PEER-NGA set of earthquakes was supplemented by data from the Feb 2, 2000 Loma Linda; Dec 23, 2003 San Simeon; and the Sept 28, 2004 Parkfield earthquake. In addition, an extended data set was developed for the 1995 Kobe earthquake using the data presented in Fukushima et al. (2000).

For each of these earthquakes, estimates of γ were made using truncated regression and a ground motion model with fixed values of the other parameters. To remove the influence of hanging wall effects, hanging wall and footwall sites were removed. Estimates of γ were obtained using just the PEER-NGA data and using the extended data and these are listed in Table 4 along with the number of recordings used in each analysis. Figure 28 shows examples of the results for four of the earthquakes. For the Northridge earthquake, similar estimates of γ were obtained from the PEER-NGA and extended data set. However, for the other three earthquakes shown on Figure 28, the estimate of γ obtained from the PEER-NGA data set were approximately 2/3 of the values obtained from the extended data sets. As indicated by the results in Table 4, the values of γ computed using only PEER-NGA data are typically smaller than obtained from the extended data. The few cases where the PEER-NGA data produced larger (and often unrealistic) values of γ are for earthquakes with very limited samples in the PEER-NGA database (e.g. San Juan Bautista, Mohawk Valley). Truncated regression analyses performed using the combined PEER-NGA data for these earthquakes also produce smaller value for γ than analysis using the combined extended data sets.

As a short-term solution to this problem, we decided to develop the ground motion model using the PEER-NGA data truncated at a maximum distance of 70 km. This distance was selected by visual inspection as the point where, on average, data truncation may begin to affect the distribution of recordings in the PEER-NGA data base. The regression analyses were performed using a model for γ determined from the combined extended data sets for California earthquakes. Figure 29 shows the values of γ for the earthquakes listed in Table 4. The results indicate that γ decreases in absolute value with increasing magnitude, similar to results reported by others from analysis of empirical data (e.g. Campbell, 1993) and stochastic ground motion simulations (e.g. Campbell, 2003).

Figure 28: Comparison of fits to expanded data sets (red plus black points) and PEER-NGA data only (black points) for individual earthquakes using truncated regression. Truncation levels are indicated by the horizontal dashed lines for the enhanced (red) and PEER-NGA only (black) data sets. Only neutral site were used for reverse faulting earthquakes.

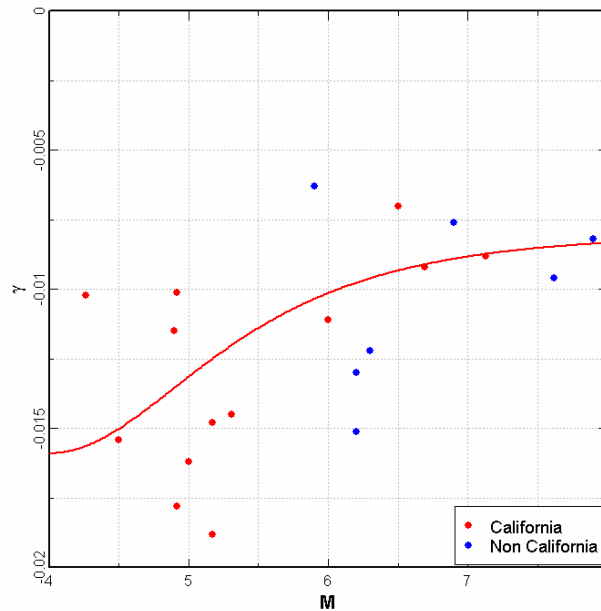

Figure 29: Estimates of γ from analysis of the extended data sets (Table 4). Red curve shows the model developed by a fit to the combined California earthquake data set.

Table 4: Estimate of Anelastic Attenuation Parameter γ For Individual Earthquakes

EQID	Earthquake	M	PEER-NGA Data Set		Expanded Data Set		Region

	Parkfield	6			-0.0111	308	California
	San Simeon	6.5			-0.0070	225	California

The combined extended data from the 13 California earthquakes was fit by a function form that produce a smooth transition from the value γ at magnitudes less than 5 to values at larger magnitudes. A continued linear decrease in the absolute value of γ was judged to not be appropriate based on analyses of simulated motions using the Atkinson and Silva (2000) model and because the value of γ computed for the **M** 7.9 Denali earthquake was similar to the values obtained for the larger California earthquakes in the range of **M** 6.5 to 7.1. Analyses of individual smaller magnitude earthquakes in the TriNet data set (Appendix D) did not indicate a continued decrease in γ . The resulting relationship is:

$$\gamma(pga)_{California} = -0.00804 - 0.00785 / \cosh\{\max(\mathbf{M} - 4, 0)\} \quad (19)$$

This relationship is plotted on Figure 29. The limited data for earthquakes from other regions (Kobe, Japan; Denali, Alaska; Chi-Chi main shock and aftershocks, Taiwan) are generally consistent with this relationship. The data indicate that the value of γ for Taiwan may be slightly greater than that for California, but the difference is much less than the 50-percent larger values obtained from the initial regressions using the full PEER-NGA data base.

We believe that our short-term solution should provide an appropriate model for California earthquake ground motions. The model parameters will be based on strong motion data

recorded within 70 km of earthquake ruptures, the region of primary concern for application of the model. We also believe that the model properly represents the attenuation of ground motion at larger distances in California. The issue we have raised points out the need to systematically collect and process all recordings from large earthquakes if there is interest in correctly modeling the attenuation of ground motions at large distances.

Equation (19) provides a relationship for γ for pga . The relationships for other spectral periods was constructed by using the period-dependence of γ computed from analysis of the broadband data from the three small southern California earthquakes and scaling the values by the relative difference in γ at pga , that is:

$$\gamma(T)_{California} = \gamma(T)_{Anza-YL-BBC} \times \frac{\gamma(pga)_{California}}{\gamma(pga)_{Anza-YL-BBC}} \quad (20)$$

Figure 30 compares the model developed for γ with values obtained from direct regression of the PEER-NGA data without imposing any distance truncation and without using truncated regression. The variation of γ with spectral period T is similar.

Figure 30: Comparison of the model developed for γ (Equations 19 and 20) versus values of γ obtained from regression without truncation (black points) of the PEER-NGA data set.

MODELING STEPS

The parameters of the ground motion model were developed through an iterative process that involved performing regressions for the entire spectral period range with some parts of the model fixed, examining the trend of remaining parameters with spectral period, developing smoothing models for these parameters with period, and then repeating the analysis to examine the variation of the remaining parameters. The major steps in the development of the parameters are summarized below. All analyses were performed using the PEER-NGA

data truncated at a maximum distance of $R_{RUP} = 70$ km. In addition, the magnitude scaling parameters c_2 and c_3 were fixed at 1.06 and 3.45 for all analyses and in the final model. As discussed in the model development section, $c_3 = 3.45$ represents scaling of low-frequency amplitudes proportional to seismic moment. Parameter c_2 was fixed at 1.06, the value derived from the Atkinson and Silva (2006) seismic source model. All previous applications of the general function form used by Ross Sadigh have yielded far-source high-frequency magnitude scaling coefficients that are consistent with this value. Preliminary analysis of the PEER-NGA data also produced values near 1.06. Parameter c_4 was examined by analyses of PEER-NGA data and TriNet data. It was concluded that a range of values for c_4 would provide satisfactory fits to the data with adjustments to the rate of attenuation occurring through changes of parameters c_5 and c_6 . The change in attenuation rate with distance was set to occur at $c_{RB} = 50$ km. A value near 50 km was consistently found in all preliminary analyses.

After extensive exploratory analysis of the data, we concluded that the PEER-NGA dataset does not sample a sufficiently wide range of motion and V_{s30} to allow the simultaneous estimation of all 3 nonlinear soil parameters (φ_2 , φ_3 , and φ_4). We thus decided to fix φ_4 through other supporting information. Both our preliminary analysis of the PEER-NGA data and our analysis of the simulated soil amplification factors from Silva (2004) suggested that φ_4 is about 0.1g in the case of pga . The empirical study of Choi and Stewart (2005) also indicate 0.1g is a viable value for φ_4 . We thus fix pga 's φ_4 at 0.1g. To fix φ_4 of other periods, we anchor the rock spectral shape of M6.5 at 10 km (Silva et al. Add referrecne) at 0.1g pga . The remaining two nonlinear parameters will adjust to the fixed value of φ_4 and they are more than sufficient to capture the nonlinear soil behavior existing in the PEER-NGA dataset.

In the preliminary analyses it was found that the data exhibited a statistically significant dependence on source depth parameterized as the depth to top of rupture, Z_{TOR} and that aftershocks showed a stronger dependence on depths than main shocks. Also, the data indicated that the style of faulting effects were weaker for aftershocks than for main shocks. Therefore, the analyses were performed with separate depth dependence and style of faulting effects for main shocks and aftershocks.

First Phase:

Step 1: The first phase of the analysis used only data from neutral sites. Sites with the hanging wall/foot wall flags set to 'fw' or 'hw' in the PEER-NGA database were removed. This simplification was performed to examine other portions of the model without interaction with the hanging wall function f_{HW} . In particular, regression with the full model showed high correlation between estimates of the hanging wall parameters and the parameters for style of faulting and soil nonlinearity. Using a simple model for the reference motion (without style of faulting, depth of rupture, and variable magnitude scaling) the parameters of the non-linear soil model (φ_2 and φ_3) were obtained from fits to the NGA data. At longer periods when the soil response becomes nearly linear, estimates of the nonlinear soil parameter φ_3 fluctuated wildly and had very large errors of estimation. Therefore parameter φ_3 for periods longer than 1.0 seconds were fixed to produce a smooth transition to linear behavior at spectral periods near 1.0 sec and greater.

Step 2: Using the smoothed values of φ_3 , regression analyses were performed to examine the variation of c_n and c_M with period. Parameter c_n was then smoothed and parameter c_M re-estimated, then smoothed.

Step 3: The next step was to assess parameters c_5 and c_6 which control the shape of the distance attenuation near the source. With the smoothed values of c_n and c_M from step 2, the variation of c_5 and c_6 with period was examined. Parameter c_5 was smoothed, parameter c_6 re-estimated, then smoothed. It should be noted that the variation of c_5 and c_6 with period and a constant value of c_4 accomplishes a similar effect to the variation of c_4 with period for fixed c_5 and c_6 in Sadigh et al. (1997).

Step 4: The final step in the first phase of the analysis was reassessment of the nonlinear soil model parameters. With the above model parameters fixed, parameters of φ_2 and φ_3 were re-estimated from the data. Parameter φ_3 was then smoothed, φ_2 re-estimated, then smoothed.

Second Phase:

Step 5: In the second phase of parameter development, the hanging wall and footwall data were included and the hanging wall functional form for f_{HW} was added to the model. Initially, the inclusion of the hanging wall data resulting in reverse and strike slip faulting having the same amplitudes ($c_{1a} \sim 0$). However, it was discovered that this result was largely due to data from the Chi-Chi main shock. When the Chi-Chi main shock was removed, c_{1a} increased to approximately 0.1 and the amplitude of the hanging wall coefficient c_9 was reduced. There is a large degree of coupling between these parameters. The value of c_{1a} is marginally statistically significant (t -values slightly greater than 2). The analysis by Chiou et al. (2000) found that when the geometric hanging wall effect was removed by using R_{RMS} , a style of faulting effect remained with reverse faulting earthquakes producing larger ground motions than strike-slip earthquakes. On this basis, we have assumed that there is a style of faulting effect for reverse faults. The value of parameter c_{1a} was estimated without the Chi-Chi main shock data.

The style of faulting effect for normal faults, c_{1b} was found to be statistically significant only when normal faulting flag F_{NM} was restricted to be 1 for rake angles in the range $-120^\circ \leq \lambda \leq -60^\circ$, that is normal-oblique earthquakes have the same level of ground motions as strike-slip earthquakes. Parameter c_{1b} is also only marginally significant with t -values slightly greater than 2.

Parameter c_{1a} was found to decrease with increasing spectral period, becoming 0 at a period of 1.0 seconds and then decreasing to about -0.1 at long periods. This is consistent with the trends observed in previous empirical models (e.g. Abrahamson and Silva, 1997; Campbell and Bozorgnia, 2003; the soil model of Sadigh et al., 1997). At high frequency, this is consistent with an interpretation of higher stress drops (stress parameters) for reverse faulting earthquakes than for strike-slip earthquakes. However, the negative values of c_{1a} at long periods is not consistent with this concept, indicating that other factors may also be influencing the difference between the motions produced by the two styles of faulting. For normal faulting, the value of c_{1b} was approximately -0.25 and decreased in absolute value as the spectral period decreased. For spectral periods greater than about 1.0 second, the value of c_{1b} becomes very uncertain. If one speculates that the negative value of c_{1a} for reverse

faulting earthquakes at long periods is due to more compact dip-slip earthquakes being less efficient at producing long period motions than long strike-slip earthquakes, then perhaps the values of c_{1a} and c_{1b} should be similar in this period range. We have made this assumption in developing the period dependence of c_{1b} .

Step 6: With c_{1a} and c_{1b} fixed, the period variation of the hanging wall scaling factor, c_9 was defined. The smoothed value of c_9 decreases to 0 at long periods.

Step 7: The next step was completion of the soil amplification model, f_{Site} . The variation of φ_2 and φ_3 , with period was re-evaluated holding the previously smoothed parameters of the model fixed. This assessment resulted in modifications to φ_2 that indicated slightly more nonlinearity. These parameters were then smoothed and φ_1 , the linear scaling term, was recomputed and smoothed.

Step 8: The next step was to fix the remaining parameter for main shocks, the dependence on the depth to top of rupture defined by parameter c_7 . This parameter was found to decay to zero as the spectral period increases, consistent with the concept that it represents an increase in dynamic stress drop or the “stress parameter” with increasing depth of rupture.

Step 9: The remaining parameters in the ground motion model for main shock motions are the intercept term c_1 and the variance terms τ and σ . Because all of the other model parameters have been fixed, the aftershock data can now be removed from the analysis. The resulting effect on the intercept term c_1 is negligible (less than 0.01 percent) and produces a slight reduction in the inter-event variability τ .

The estimated values of c_1 exhibited noticeable steps at periods of 0.8, 4, and 8 seconds, as shown in Figure 31. These steps occur at periods where there are large reductions in the number of usable data, defined by the minimum usable frequency, as shown on Figure 32. The derivative of c_1 with respect to spectral period was computed numerically. These values, shown on Figure 33, show peaks that usually coincide with a sudden drop in the number of usable data (Figure 32). These observations suggest that the estimated values of c_1 may be biased by the systematic removal of weaker motion, which would tend to leave larger ground motion amplitudes in the remaining data. We therefore took the following steps to smooth parameter c_1 . We first estimated the bias due to data drop out at 0.8, 1.1, and 1.6 seconds. The bias is taken as the increase in the c_1 estimate when the dataset is replaced by the reduced set for the next longer spectral period. Secondly, at periods longer than 1.6 second, we impose a constant slope of -1.4 (the horizontal dotted line Figure 33), matching the trend in the data. As a result, the large-magnitude spectra do not reach constant displacement scaling at periods up to 10 seconds, the limit of our model. The resulting values for c_1 are shown by the red curve in Figure 21.

Figure 31: Variation of parameter c_1 with spectral period.

Figure 32: Variation of number of usable recordings as a function of spectral period.

Figure 33: Variation of the derivative of parameter c_1 with respect to spectral period.

FINAL MODEL FORMULATION

The final model formulation is given by the relationships:

$$\begin{aligned}
 \ln(SA_{1130ij}) = & c_1 + c_{1a} F_{RVi} + c_{1b} F_{NMi} + c_7 (Z_{TORi} - 4) \\
 & + c_2 (\mathbf{M}_i - 6) + \frac{c_2 - c_3}{c_n} \ln(1 + e^{c_n(c_M - \mathbf{M}_i)}) \\
 & + c_4 \ln(R_{RUPij} + c_5 \cosh(c_6 (\mathbf{M}_i - c_{HM}, 0)_{\max})) \\
 & + (c_{4a} - c_4) \ln(\sqrt{R_{RUPij}^2 + c_{RB}^2}) \\
 & + \left\{ c_{\gamma 1} + \frac{c_{\gamma 2}}{\cosh((\mathbf{M}_i - c_{\gamma 3}, 0)_{\max})} \right\} \cdot R_{RUPij} \\
 & + c_9 \cdot \cos^2 \delta_i \cdot \tanh\left(\frac{R_{RUPij}}{2}\right) \tan^{-1}\left(\frac{W_i \cos \delta_i}{2(Z_{TORi} + 1)}\right) \frac{1}{\pi / 2} \left\{ 1 - \frac{R_{JBij}}{R_{RUPij} + 0.001} \right\} \\
 & + \tau \cdot z_i
 \end{aligned} \tag{21a}$$

$$\begin{aligned}
 \ln(SA_{ij}) = & \ln(SA_{1130ij}) \\
 & + \phi_1 \cdot \left(\ln\left(\frac{V_{S30ij}}{1130}\right), 0 \right)_{\min} \\
 & + \phi_2 \cdot \left\{ e^{\phi_3((V_{S30ij}, 1130)_{\min} - 360)} - e^{\phi_3(1130 - 360)} \right\} \cdot \ln\left(\frac{SA_{1130ij} + \phi_4}{\phi_4}\right) \\
 & + \sigma \cdot z_{ij}
 \end{aligned} \tag{21b}$$

The predictor variables for this model are:

R_{RUP} = closest distance to the rupture plane (km)

R_{JB} = Joyner-Boore distance to the rupture plane (km)

δ = rupture dip

W = rupture width (km)

Z_{TOR} = depth to top of rupture (km)

F_{RV} = 1 for $30^\circ \leq \lambda \leq 150^\circ$, 0 otherwise (combined reverse and reverse-oblique)

F_{NM} = 1 for $-120^\circ \leq \lambda \leq -60^\circ$, 0 otherwise (only normal earthquakes, normal-oblique considered to be the same as strike-slip).

λ = rake angle

V_{S30} = Average shear wave velocity for top 30 m (m/s)

τ = inter-event standard error

σ = intra-event standard error

The coefficients of Equations (21a) and (21b) are listed in Table 5.

Table 5: Coefficients of Chiou and Youngs (2006) Empirical Ground Motion Model for the Average Horizontal Component

MODEL RESULTS

Inter-Event Residuals: Figure 34 shows the random intercept values c_1 for the main shocks. The horizontal lines define the population means. The difference between the individual values and the population mean define the inter-event residuals. The residuals do not exhibit a trend with magnitude. The values for California and non-California earthquakes do not show any trends with respect to the population mean, indicating that both sets of earthquakes are consistent with the model. The inter-event term for the Chi-Chi main shock is approximately $1.5 \times \tau$ below the population mean for pga (0.01 sec spectral acceleration), and becomes positive for periods of 1.0 seconds and greater. These results indicate that the data from the other active tectonic regions are consistent with ground motions from California earthquakes.

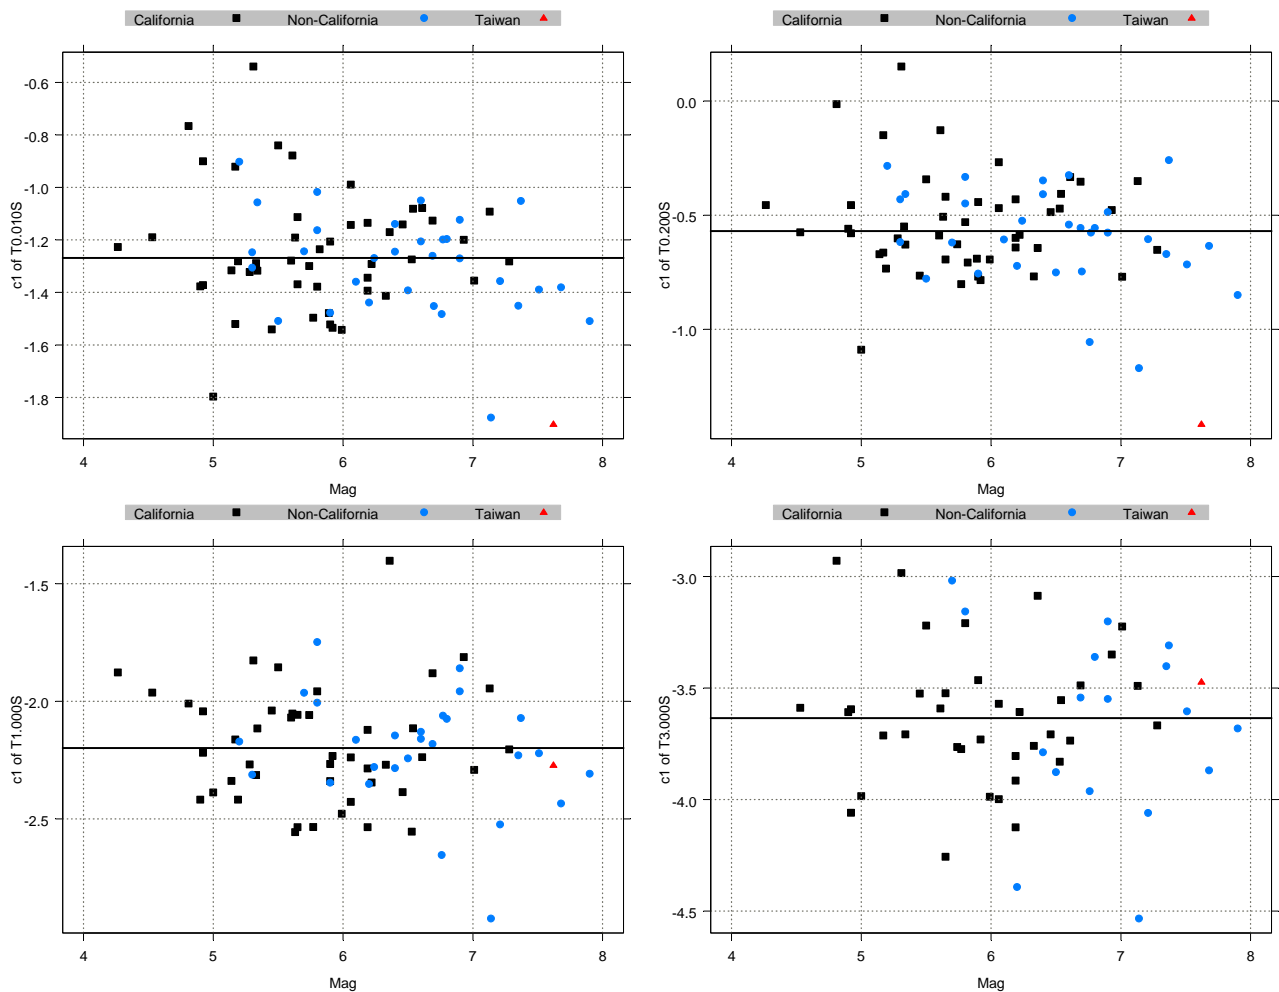

Figure 34: Inter-event values of the intercept c_1 for spectral periods of 0.01 sec (pga), 0.1, 1.0 and 3.0 seconds. The horizontal line denotes the population mean. Difference between population mean and individual value represents inter-event residual.

Intra-Event Residuals: Figure 35a through 35d show the intra-event residuals plotted versus magnitude and R_{RUP} for spectral periods of 0.01 (pga), 0.2, 1.0 and 3.0 seconds respectively. The distribution of residuals is further subdivided into comparisons with respect to R_{RUP} for California,

non-California, and Taiwan earthquakes, versus R_{RUP} for a range of magnitude intervals. The residuals do not exhibit any trends with respect to magnitude or distance.

Figures 36a through 36d show the intra-event residuals plotted versus V_{S30} both as a composite plot and for individual ranges of reference ground motion amplitude. Again, the residuals do not exhibit any systematic trends. Note that the soil model assumes that there is no deamplification of ground motions below the reference ground motion level of SA_{1130} for sites with V_{S30} greater than 1130 m/sec. Although there is very little data in the PEER-NGA data base for sites with V_{S30} greater than 1130 m/sec, the limited data, if anything, suggest a slight upward trend in the residuals. The site amplification model developed here does not account for the effect of the lower kappa expected for hard rock sites which would tend to lead to increases in high frequency ground motions.

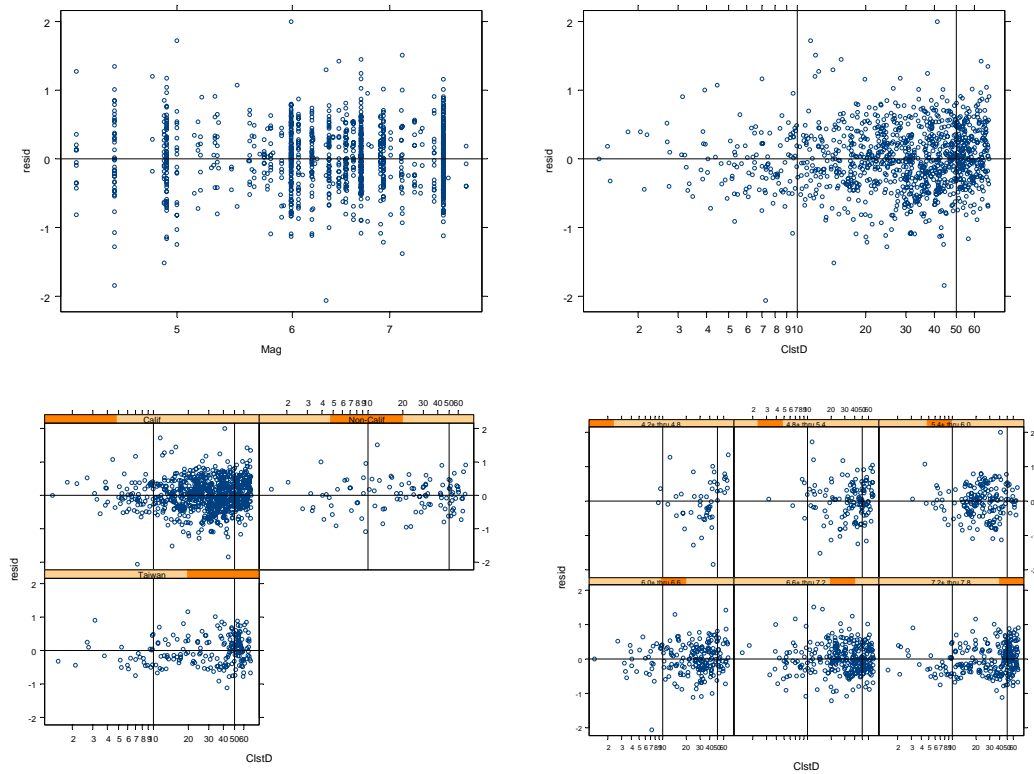

Figure 35a: Intra-event residuals for spectral period of 0.01 seconds (*pga*).

Figure 35b: Intra-event residuals for spectral period of 0.2 seconds.

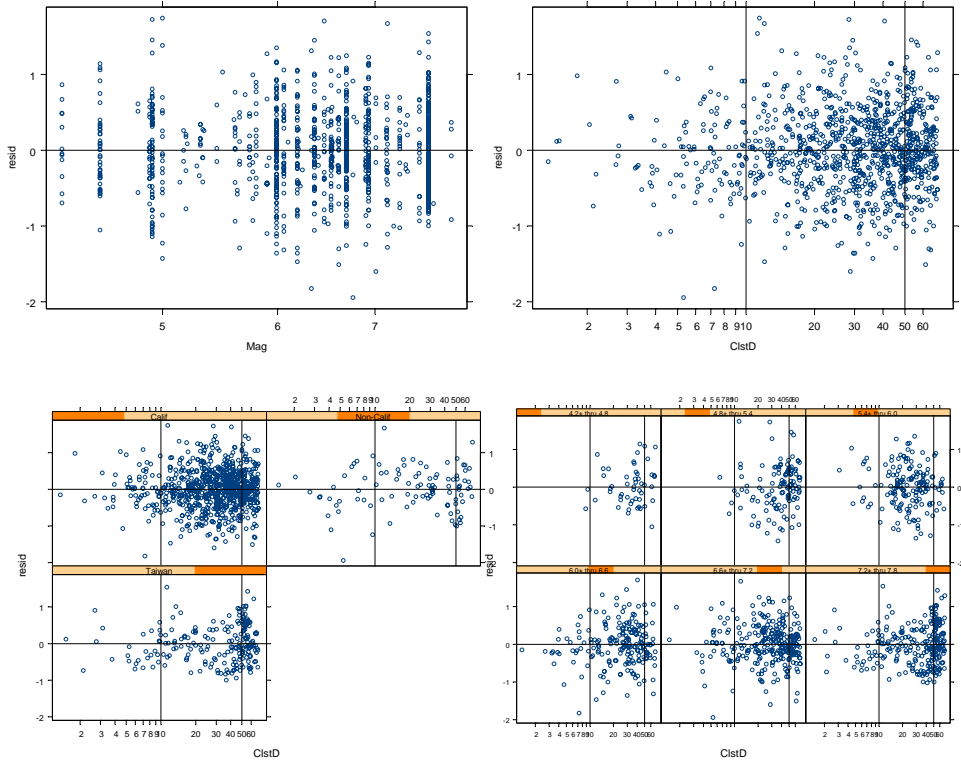

Figure 35c: Intra-event residuals for spectral period of 1.0 seconds.

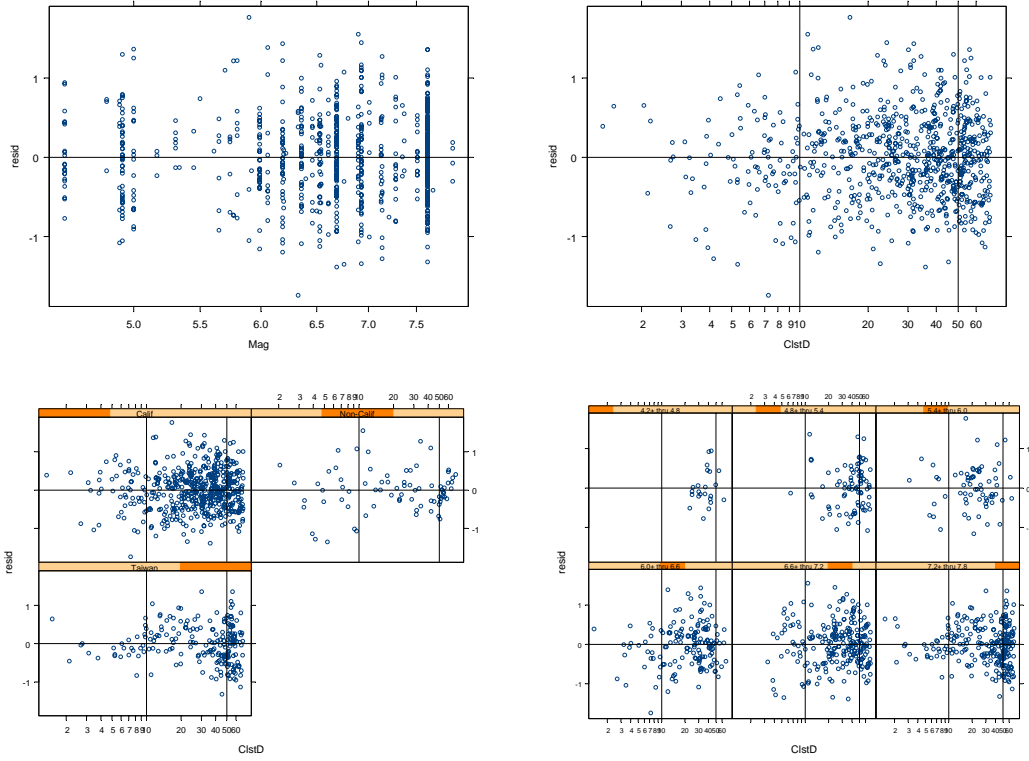

Figure 35d: Intra-event residuals for spectral period of 3.0 seconds.

Figure 36a: Intra-event residuals versus V_{S30} for spectral period of 0.01 seconds (*pga*).

Figure 36b: Intra-event residuals versus V_{S30} for spectral period of 0.2 seconds.

Figure 36b: Intra-event residuals versus V_{S30} for spectral period of 1.0 seconds.

Figure 36d: Intra-event residuals versus V_{S30} for spectral period of 3.0 seconds.

Figures 37a through 37d show the intra-event residual plotted versus $Z_{1.0}$ for those sites for which the depth to V_S of 1.0 km/sec is available in the PEER-NGA data base. Two plots are

shown on each figure. The depths for southern California sites in the PEER-NGA data base, as well as the modeling performed by Day et al. (2006), are based on the SCEC Version 2 3-D velocity model (Magistrale et al., 2000). The SCES web site contains an updated Version 4 velocity model for southern California. The major change between Version 2 and Version 4 is in the velocity gradient at shallow depths, with the depths to V_S of 1.0 km/s in the Version 4 model being systematically 60 percent of the depths in the Version 2 model. The depths to V_S of 2.5 km/s is similar in Version 2 and Version 4 of the SCEC models. At this time, we are not prepared to propose a model for the effect of sediment depth because of the uncertainty in the $Z_{1.0}$ depths for the southern California sites. We think that $Z_{1.0}$ is a more practical parameter to use than $Z_{2.5}$ because it is more likely to be available to a user based on site data.

The residuals do indicate that large sediment depths lead to larger ground motions. The residuals also indicate that very thin sediment depths lead to smaller long period motions (Figures 37c and 37d).

Figure 37a: Intra-event residuals versus $Z_{1.0}$ for spectral period of 0.01 seconds (*pga*). Plot on left shows sites with velocities based on SCEC Version 2 3-D velocity model and plot on right shows sites with velocities based on SCEC Version 4 3-D velocity model.

Figure 37b: Intra-event residuals versus $Z_{1.0}$ for spectral period of 0.2 seconds. Plot on left shows sites with velocities based on SCEC Version 2 3-D velocity model and plot on right shows sites with velocities based on SCEC Version 4 3-D velocity model.

Figure 37c: Intra-event residuals versus $Z_{1,0}$ for spectral period of 1.0 seconds. Plot on left shows sites with velocities based on SCEC Version 2 3-D velocity model and plot on right shows sites with velocities based on SCEC Version 4 3-D velocity model.

Figure 37d: Intra-event residuals versus $Z_{1,0}$ for spectral period of 3.0 seconds. Plot on left shows sites with velocities based on SCEC Version 2 3-D velocity model and plot on right shows sites with velocities based on SCEC Version 4 3-D velocity model.

Comparisons with Data for Individual Earthquakes: Appendix E contains plots showing the model fit to the data for individual earthquakes. The predicted ground motions in these plots include the inter-event random effect.

Nonlinear Soil Model: Figures 37a through 37b compare the site amplifications versus V_{S30} and ground motion amplitude predicted by the nonlinear soil model developed as part of this ground motion model with the site amplifications computed by Silva (2004) using equivalent linear site response analyses and by Choi and Stewart (2003) using empirical ground motion data. The soil model developed in this study compares well with the site response results computed by Silva (2004) for spectral periods of 0.01, 0.2, and 1.0 seconds and shows greater amplification at a spectral period of 3.0 seconds. The model compares well to Choi and Stewart's results at spectral periods of 0.01 and 1.0 seconds, is more nonlinear at a spectral period of 0.2 seconds, and shows greater amplification a period of 3.0 seconds.

Figure 38a: Nonlinear site amplification predicted by ground motion model developed in this study compared to those computed by Silva (2004) – on left, and Choi and Stewart – on right, for spectral period of 0.01 seconds (*pga*).

Figure 38b: Nonlinear site amplification predicted by ground motion model developed in this study compared to those computed by Silva (2004) – on left, and Choi and Stewart – on right, for spectral period of 0.2 seconds.

Figure 38c: Nonlinear site amplification predicted by ground motion model developed in this study compared to those computed by Silva (2004) – on left, and Choi and Stewart – on right, for spectral period of 1.0 seconds.

Figure 38d: Nonlinear site amplification predicted by ground motion model developed in this study compared to those computed by Silva (2004) – on left, and Choi and Stewart – on right, for spectral period of 3.0 seconds.

Comparison with Previous Model: Figures 39 and 40 compare the response spectra predicted by the ground motion model developed in this study with response spectra predicted by the models developed by Sadigh et al. (1997). The comparisons require an assessment of V_{S30} representative of the Sadigh et al. (1997) relationships. For soil, we have used a value of 310 m/s, the velocity suggested by Boore et al. (1997) as representative of generic soil. For generic rock, Boore et al. (1997) suggested a value of 620 m/s. However, we think that this may be higher than the average for the data used by Sadigh et al. (1997), which included recordings from many site that are now classified as NEHRP C. Therefore, we selected a velocity of 520 m/s for purpose of making the comparisons. Figures 41, 42, 43, and 44 provide comparisons of the magnitude and distance scaling for the two models. The model developed in this study produces ground motion estimates that are in general similar to those obtained using the Sadigh et al. (1997) model. The new model tends to produce lower ground motions in the distance range of 10 to 50 km and larger ground motions at larger distances. The models are more similar for soil than for rock, which is to be expected given that the majority of ground motion data is recorded on soil sites.

$V_{s30} = 520$; $Z_{1.0} = 0$ Km; SS; Z.TOR = 0 Km $V_{s30} = 520$; $Z_{1.0} = 0$ Km; SS; Z.TOR = 0 Km

$V_{s30} = 520$; $Z_{1.0} = 0$ Km; SS; Z.TOR = 0 Km $V_{s30} = 520$; $Z_{1.0} = 0$ Km; SS; Z.TOR = 0 Km

Figure 39: Comparison of median response spectra predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for soft rock. A V_{s30} of 520 m/s was used to represent the average conditions for Sadigh et al.'s (1997) rock model.

Vs30 = 310; Z1.0 = 0 Km; SS; Z.TOR = 0 Km Vs30 = 310; Z1.0 = 0 Km; SS; Z.TOR = 0 Km

Vs30 = 310; Z1.0 = 0 Km; SS; Z.TOR = 0 Km Vs30 = 310; Z1.0 = 0 Km; SS; Z.TOR = 0 Km

Figure 40: Comparison of median response spectra predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for firm soil. A V_{S30} of 310 m/s was used to represent the average conditions for Sadigh et al.'s (1997) soil model.

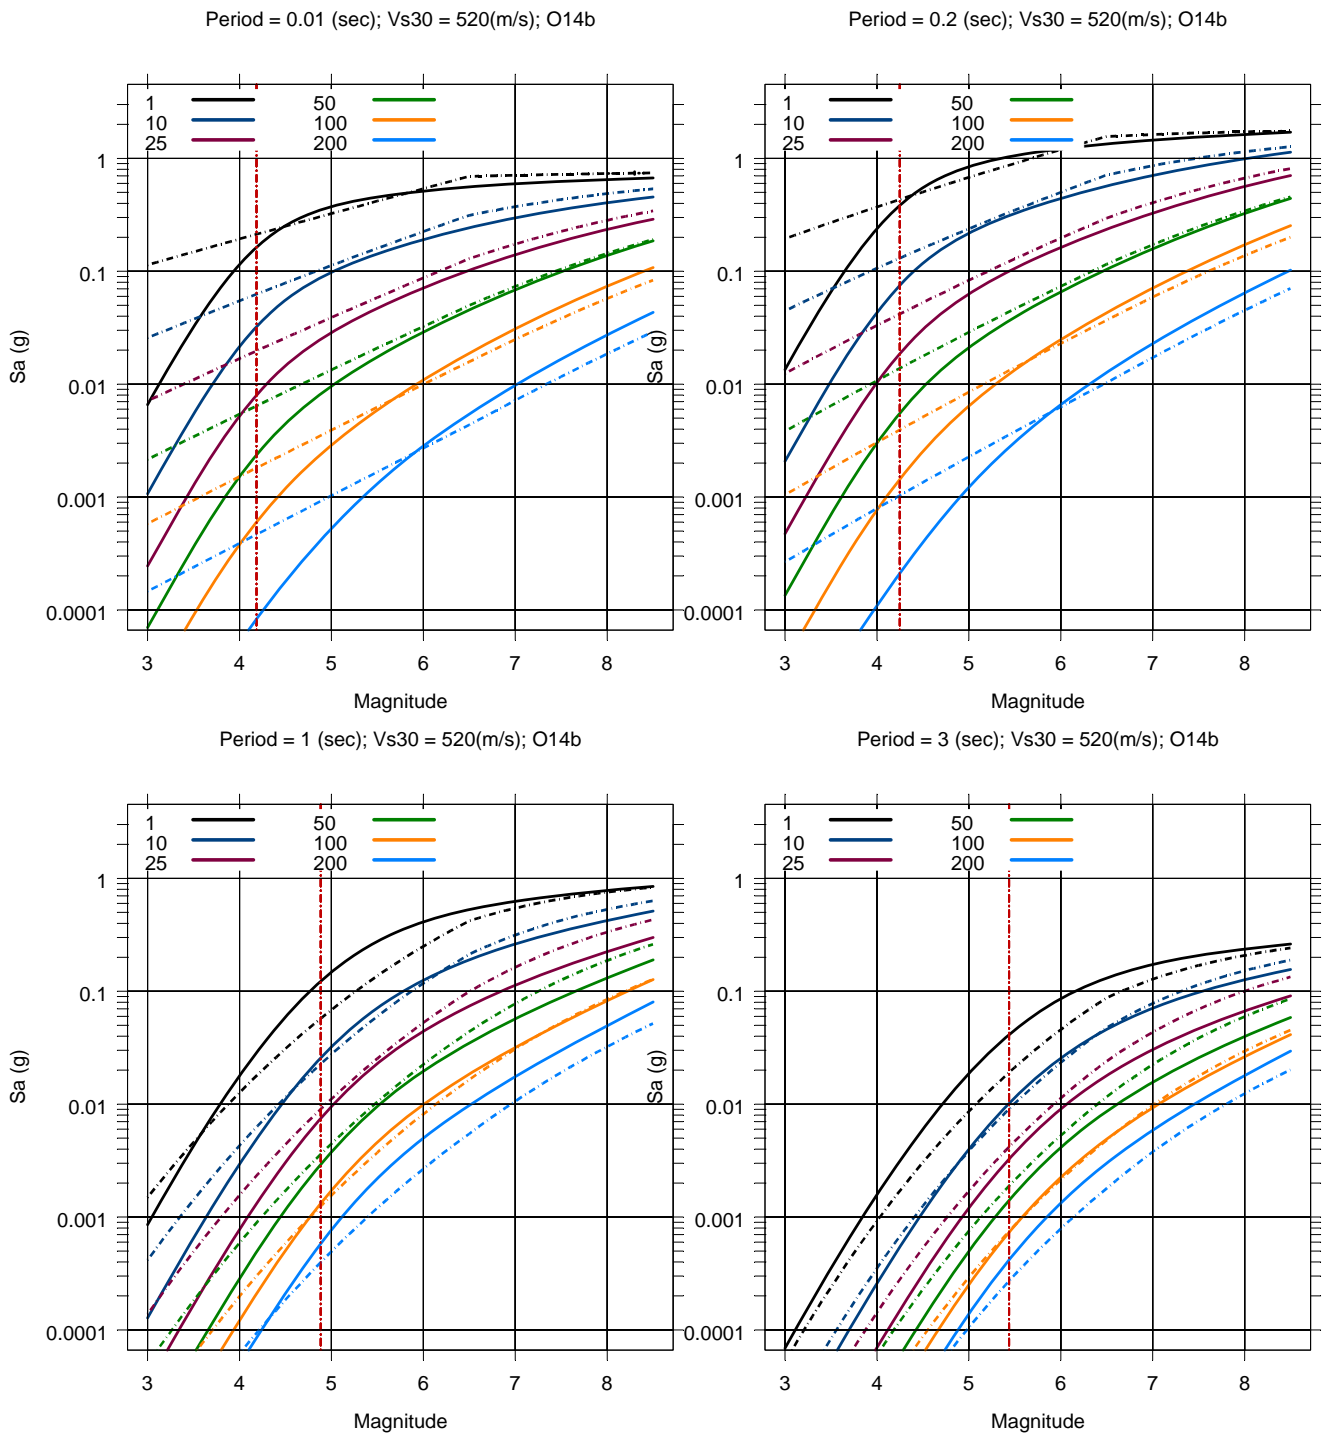

Figure 41: Comparison of magnitude scaling predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for soft rock. A V_{S30} of 520 m/s was used to represent the average conditions for Sadigh et al.'s (1997) rock model.

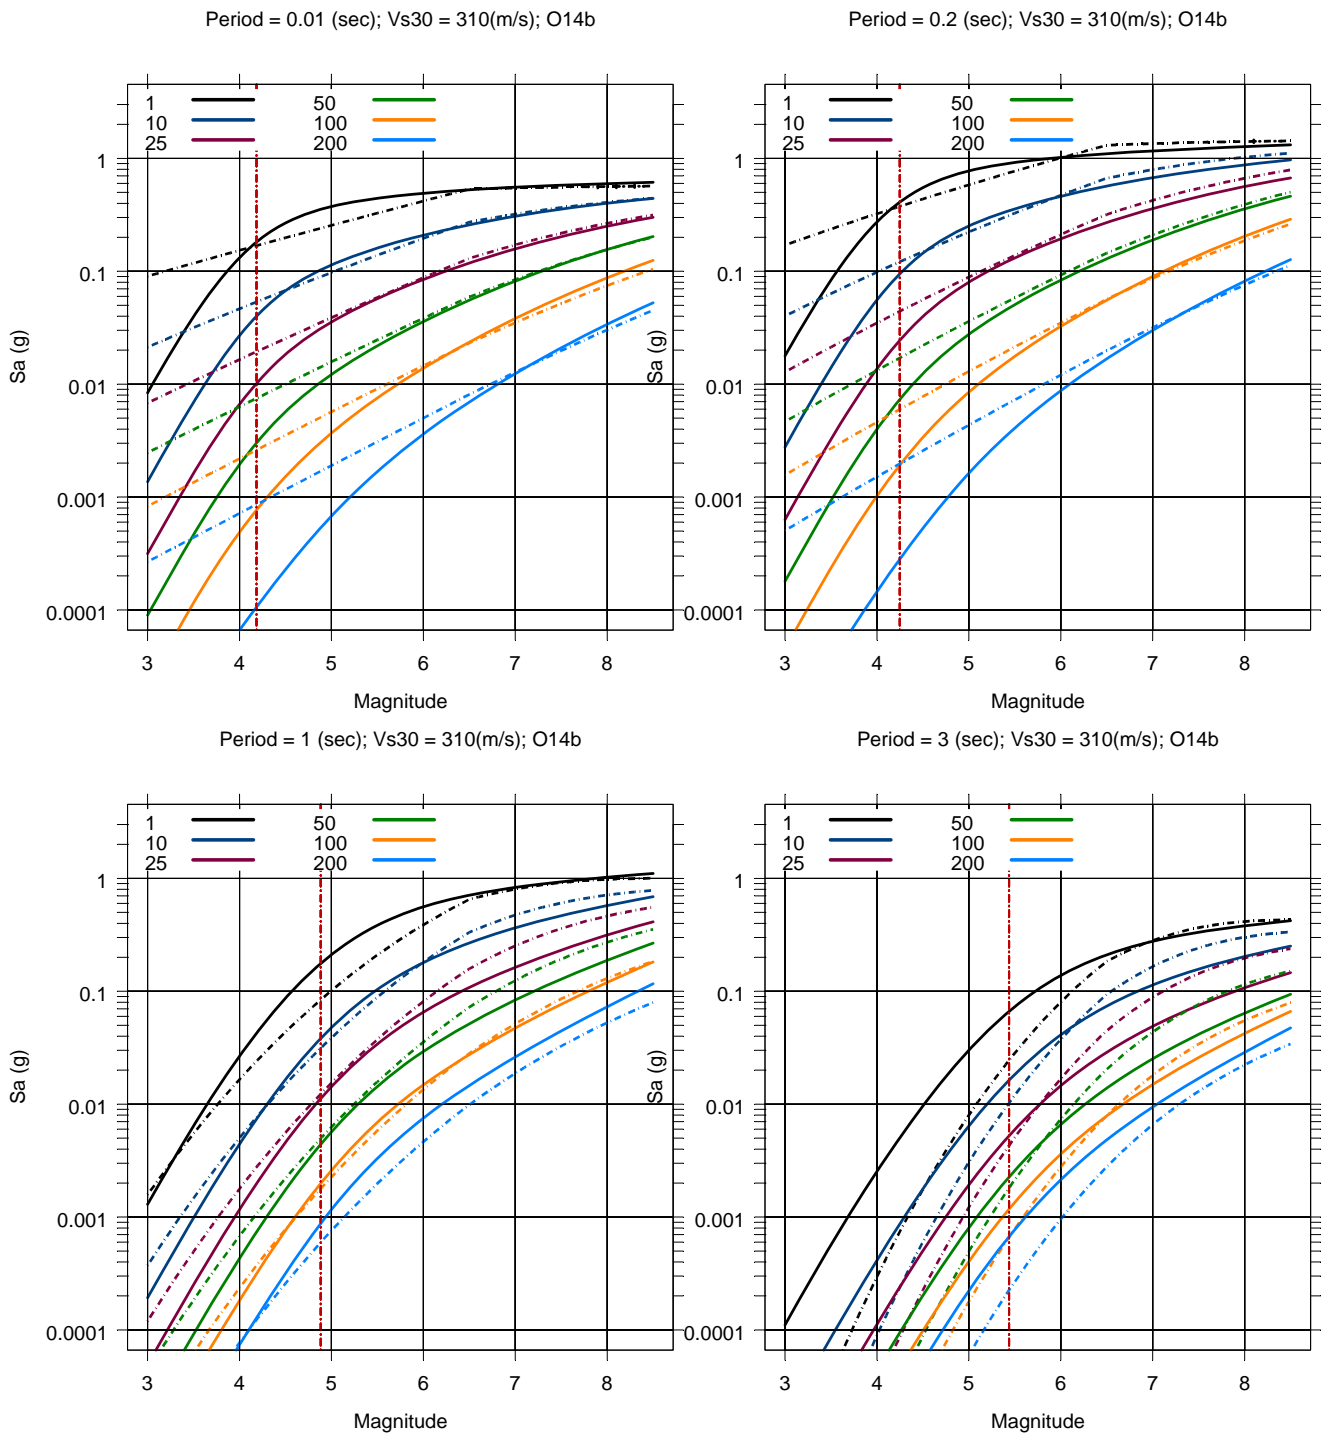

Figure 42: Comparison of magnitude scaling predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for soil. A V_{S30} of 310 m/s was used to represent the average conditions for Sadigh et al.'s (1997) soil model.

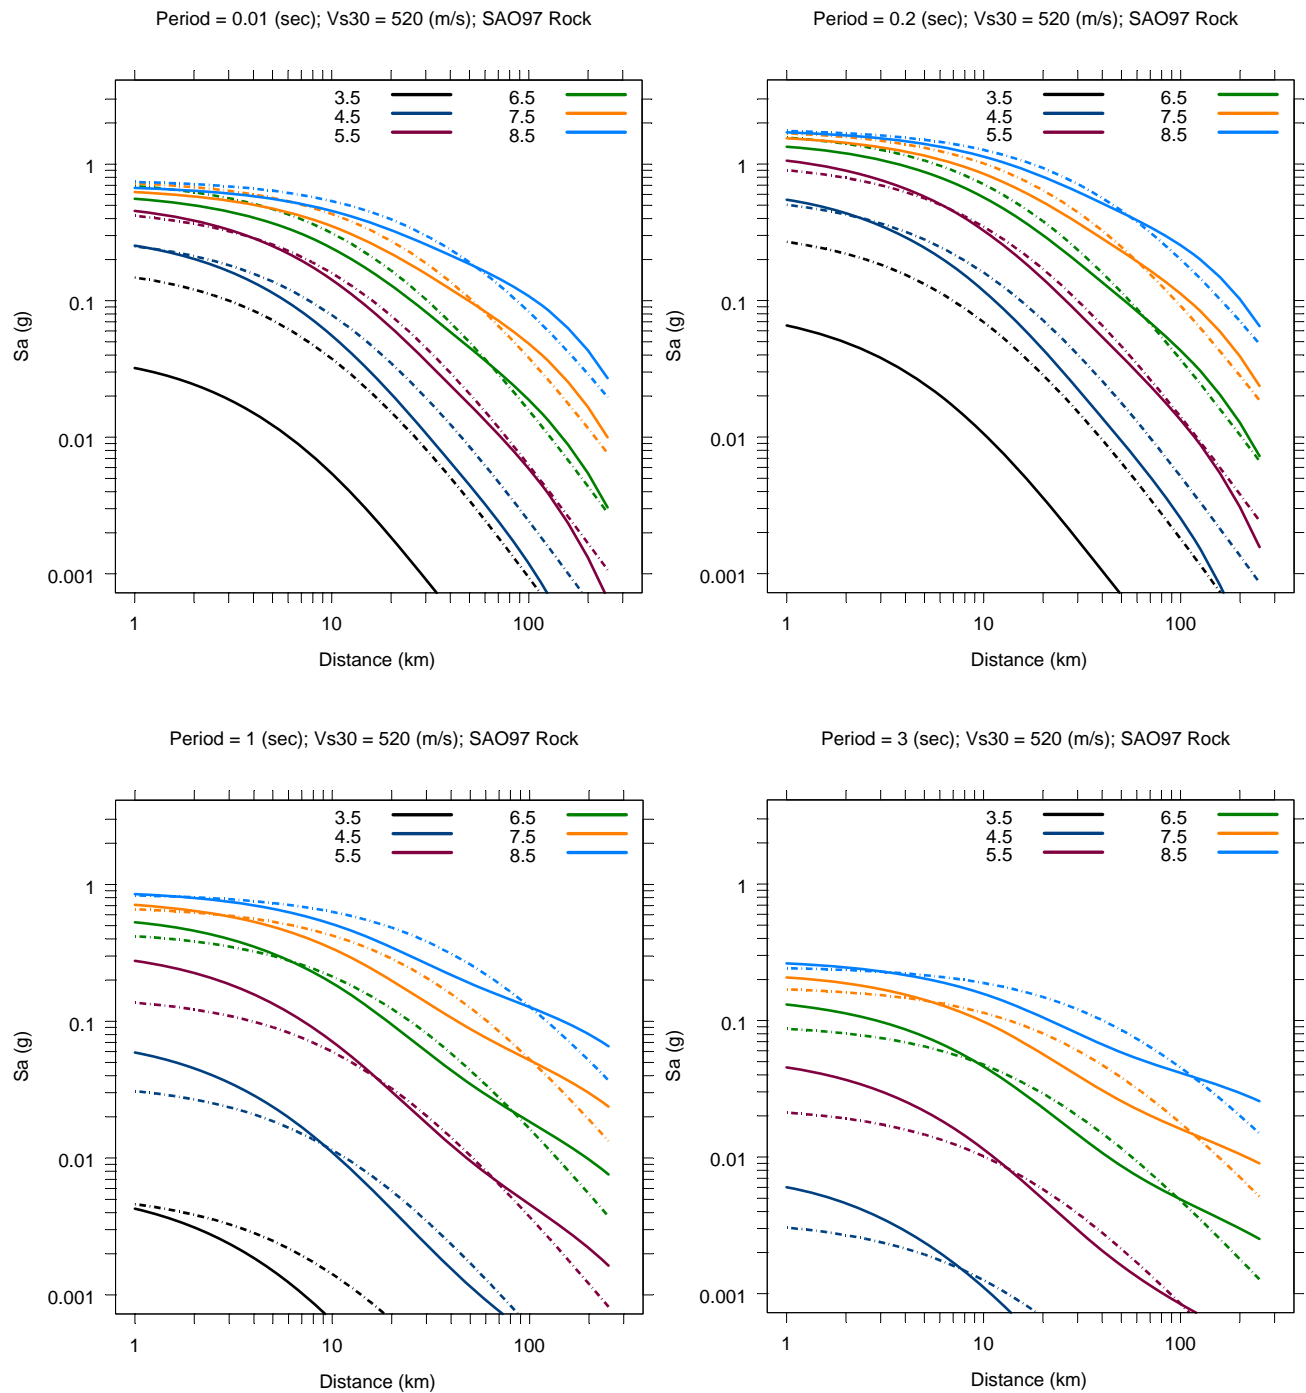

Figure 43: Comparison of distance scaling predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for soft rock. A V_{s30} of 520 m/s was used to represent the average conditions for Sadigh et al.'s (1997) rock model.

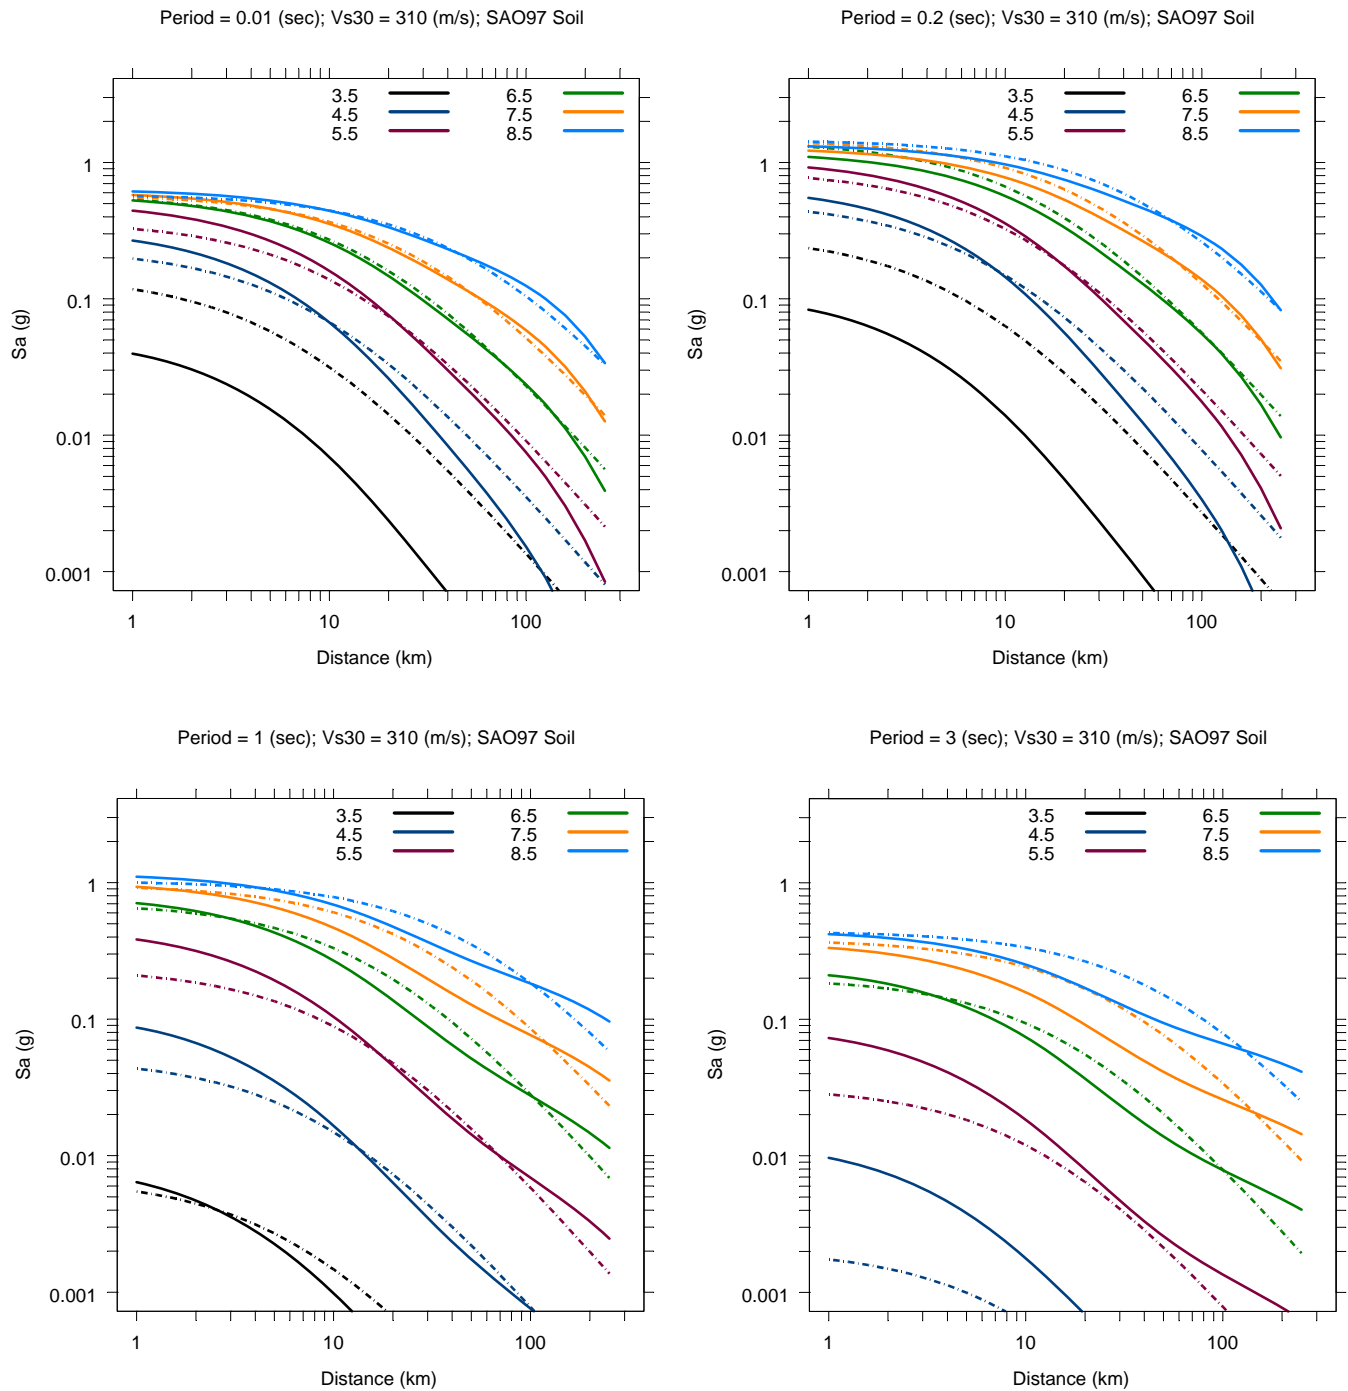

Figure 44: Comparison of distance scaling predicted by the model developed in this study (solid curves) and predicted by Sadigh et al. (1997) (dashed curves) for soil. A V_{s30} of 310 m/s was used to represent the average conditions for Sadigh et al.'s (1997) soil model.

Comparison with Data at Distances > 70 km: Figure 45 shows intra-event residuals for the two large California earthquakes that are in both the PEER-NGA data set and the extended TriNet data set. The residuals were computed using the event terms determined from the regression of the PEER-NGA data for $R_{RUP} \leq 70$ km. The model fit to the data for $R_{RUP} \leq 70$ km does a reasonable job of predicting the ground motions at larger distances when extrapolated using the model for γ given in Equation (19).

Figure 45: Intra-event residuals for the Northridge and Hector Mines *pga* data from the PEER-NGA and extended data sets. The residuals were computed using the event term for each earthquake determined in the overall regression of the PEER-NGA data for $R_{RUP} \leq 70$ km.

EXAMPLE CALCULATIONS

FORTRAN routine CY2006.FOR and the accompanying coefficients table file CY2006.C are provided to implement the model developed in this study. Example input and output files are provided for four scenarios: **M 5** and **M 7** strike-slip earthquakes and **M 5** and **M 7** reverse faulting earthquakes. The required input variables are indicated by the header record in the example input files. Note the routine reads a value for the source-site angle θ_{SITE} , but it is not presently used in the model. The routine accepts its main input and writes the output to the console. After invoking at the command prompt, the routine asks for the coefficient file and then loops over prompts for the input and output files.

Table 6 list the computed values of ground motion for the four example scenarios for spectral periods of 0.01, 0.2, 1.0, 3.0 seconds.

MODEL APPLICABILITY

The model developed in this study is considered to be applicable for estimation pseudo spectral accelerations (5% damping) for earthquakes in active tectonic regions in which the following conditions apply:

- $4 \leq M \leq 8.5$ for strike-slip earthquakes
- $4 \leq M \leq 8.0$ for reverse and normal faulting earthquakes
- $0 \leq R_{RUP} \leq 200$ km
- $150 \leq V_{S30} \leq 1500$.

The model was developed using the anelastic attenuation parameter γ constrained by data from California earthquakes. For application in other regions where distances greater than about 50 km are a major contributor to the hazard, the adjustments to the γ parameter may be warranted and can be performed using the hybrid approach developed by Campbell (2003).

In making such adjustments, we would stress the need for the user to obtain estimates of Q for the two regions that are based on consistent geometric spreading models. The site response portion of the ground motion model was constructed to force all ground motions to be the same for V_{S30} greater than 1130 m/s. As the rock velocity increases we expect the shallow crustal damping (i.e. “kappa”) to decrease, resulting in increases in high frequency motions. Data for such sites are not present in the PEER-NGA data base and this effect is not captured in our model. The model was developed using recordings from earthquakes with a maximum depth to top of rupture of 15 km and a maximum hypocentral depth of 19 km. The model predicts a linear increase in $\ln(psa)$ with increasing Z_{TOR} over this range. Application of the model in regions with very thick crust (e.g. $\gg 20$ km) is an extrapolation outside of the range of data used to develop the model parameters.

Appendix B

Estimation of Distance and Geometry Measures for Earthquakes without Finite Rupture Models

Approach

There are 110 earthquakes in the NGA data set that do not have finite fault models, and therefore have only epicentral and hypocentral distances listed in the flat file. Rupture distances and source-site geometry parameters were estimated for the recordings from these earthquakes by simulating 101 possible rupture planes for each earthquake, computing the distance measures for each site for each simulation, and then taking the median of these values for use in completing the metadata in the PEER-NGA data base. The estimated parameters include R_{RUP} , R_{JB} , R_{SEIS} , R_{RMS} , the source=site angle θ_{SITE} , the hanging wall and foot wall indicators F_{HW} and F_{FW} , and the fault rupture width W and depth to top of rupture, Z_{TOR} .

Simulation Process

The first step was to simulate the fault rupture dimensions. The rupture area, A , was simulated using the Wells and Coppersmith (1994) relationship for all fault types:

$$\log(A) = -3.49 + 0.91M \quad \sigma_{\log(Area)} = 0.24 \quad (\mathbf{B-1})$$

Figure B-1 shows the data for rupture area versus M for the finite rupture models in the PEER-NGA database. The black lines show a linear fit to the data (solid = mean, dashed = 90% confidence on mean). The blue line is Wells and Coppersmith (1994), which falls within the 90% confidence interval and provides a closer fit to the data for smaller magnitude earthquakes of primary interest in the simulation, as those earthquakes without finite fault models are principally of magnitude $< M 6$.

The aspect ratio of the rupture was then simulated using the relationship:

$$\log(AR) = (0.01752 - 0.00472F_{NM} - 0.01099F_{RV}) * (M - 4)^{3.097} \quad \sigma_{\log(AR)} = 0.16 \quad (\mathbf{B-2})$$

where F_{NM} and F_{RV} are (0,1) dummy variables for normal and revere earthquakes, respectively. This relationship was defined by fitting the aspect ratio data for the PEER-NGA finite fault model data set (Figure B-2). Correlation in the residuals between rupture area and aspect ratio was low (<0.3) and it was assumed that they were independent in the simulation.

Using the simulated values of A and AR , the rupture width W and rupture length L were computed assuming a rectangular fault rupture.

Figure B-1: Data for rupture area versus M from PEER-NGA finite fault model set. Symbol color denotes faulting style (black SS, red NM, and green RV). Black lines show fit and 90% confidence interval for fit to data. Blue dash-dot line shows Wells and Coppersmith (1994) relationship for all slip types.

Figure B-2: Data for aspect ratio versus M from PEER-NGA finite fault model set. Symbol color denotes faulting style (black SS, red NM, and green RV).

The next step was to locate the rupture plane in space. The vertical location of the simulated rupture with respect to the hypocenter was simulated using empirical distributions for hypocenter location derived from the PEER-NGA set of rupture models. The observed and smoothed empirical distributions are shown in Figure B-3. If the top of the simulated rupture plane extended above 0 depth, it was placed at 0 depth. The rupture plane dip was fixed at the value assigned to the earthquake.

The location of the hypocenter along strike was simulated using data from Mai et al. (2005) for earthquakes $\leq M$ 6.5. This distribution is shown in Figure B-4.

Figure B-3: Empirical distributions for vertical location of hypocenter in rupture plane derived from the PEER-NGA rupture model data set (“Data”) and smoothed for use in simulations (“Model”).

Figure B-4: Distributions for horizontal location of hypocenter in rupture plane derived from data for $M \leq 6.5$ earthquakes presented in Mai et al. (2005) (“Data”) and smoothed for use in simulations (“Model”).

For each simulated rupture plane, the distance to all sites was computed in terms of R_{JB} , R_{SEIS} (assuming a minimum seismogenic depth of 3 km), R_{RMS} distance, and closest distance to rupture, R_{RUP} . The depth to top of rupture, Z_{TOR} and the source-site angle were also computed.

The values selected for use were the median values for each site from the 101 simulations. The median was chosen because most of the values enter regressions as logs.

Figure 3 in the main text shows the ratio of the estimated values of Joyner-Boore distance to the epicentral distance and the ratio of the estimated rupture distance to hypocentral distance for the 702 sites associated with the 110 earthquakes analyzed.

Ken Campbell provided the distances he obtained for the 1992 Big Bear M 6.46 earthquake based on a rupture model he developed for that event. Figure B-5 compares his estimates of R_{JB} and R_{RUP} to those obtained from this exercise. The values are close, indicating that the process provides reasonable estimates of rupture distance measures

Figure B-5: Comparison of estimated Joyner-Boore distances (R_{JB}) closest distance to rupture (R_{RUP}) obtained in this analysis to those obtained by Ken Campbell and used in Campbell and Bozorgnia (2003).

Appendix C

Estimation of V_{S30} at CWB's Free-Field Sites

Brian Chiou and K.L. Wen

(June 08, 2006)

Introduction

When V_{S30} measurement is missing, an estimate is typically calculated using an empirical relationship between V_{S30} and other site data, such as surface geology or Geomatrix's 3rd letter (C_3). This approach is used in the PEER-NGA project and has also been widely used in California (Wills and Silva, 1998; Wills and others, 2000; Wills and Clahan, 2004) and other regions. This short note reports our efforts to establish empirical $V_{S30} - C_3$ relationships for strong-motion sites in Taiwan. The Taiwan-specific relationship uses C_3 as the main predictor. It also uses station elevation to capture the within-category variation of V_{S30} . The use of elevation as a predictor leads to a significant improvement of mapping accuracy within a site category, particularly within Geomatrix's category D.

Data

V_{S30} data used in this study are derived from the P-S logging provided to the PEER-NGA project by NCREE, who manage the site investigation of strong-motion stations operated by CWB in Taiwan¹. During the period of 2000 - 2004 a total of 231 holes were drilled and logged. The site investigation project is still on going and more P-S logging data will become available in the next several years.

Dr. Walt Silva (PE&A) reviewed the P-S logging data from each of the 231 holes, smoothed the velocity profile, and computed V_{S30} from the smoothed profile. We selected 165 sites for use in our study. The remaining 66 strong-motion sites were not used because either the drill hole is less than 20 m deep or a Geomatrix C_3 classification has not been assigned yet.

Other site data are also collected. They include: (1). Geomatrix's 2nd and 3rd letters (D. Wells, pers. comm., 2004); (2) The site classification (PSC) by Lee et al. (2001); and (3) Station elevation (Lee et al., 2001).

Variation of V_{S30} within a Site Category

Histogram of the 165 V_{S30} data, grouped by C_3 , is shown in Figure C-1. This figure highlights two difficulties in using C_3 to map V_{S30} in Taiwan. First, categories A, B, and C are not distinguishable by V_{S30} . Secondly, the most populous category (D) is bimodal with a large V_{S30} variation within that category. The active tectonic in Taiwan leads to a strong correlation between elevation and geology (Lee et al., 2001). The higher the elevation the stiffer the surface material tends to be. This unique feature prompts us to explore if elevation could be used to explain the large V_{S30} variation in category D. V_{S30}

¹ Plots of the drilling logs can be viewed on CWB website at <http://www.cwb.gov.tw/V4/index.htm>.

data are plotted as a function of station elevation in Figure C-2. Except for a few outliers, the correlation of V_{S30} with elevation is clearly shown, particularly within Geomatrix-D category. The bimodal distribution observed in Figures 1 can be adequately modeled by the station elevation.

Mapping V_{S30} by C_3 and Elevation

Based on the trend noted in Figure C-2, the following functional form is selected to model V_{S30} as a function of station elevation (Elv , in meters),

$$\ln(V_{S30}) = \ln(\phi_1) + \frac{\ln(\phi_2) - \ln(\phi_1)}{1 + e^{(\ln(\phi_3) - \ln(Elv))/\phi_4}}$$

Interpretations of the unknown coefficients are as followed: ϕ_1 and ϕ_2 are the asymptotic V_{S30} as the elevation approaches 0 and ∞ , respectively; at the elevation of ϕ_3 meters, V_{S30} is the (geometric) average of the two asymptotes.

The above model was used to fit V_{S30} data in each of the five Geomatrix categories. The estimated coefficients (ϕ_i , $i=1, 4$) are listed in Table C-1 and the fitted curves are shown on the left hand plot in Figure C-3.

To show the difference between this mapping scheme and that used in California, V_{S30} estimates of the non-measurement sites are plotted in the right panel of Figure C-3. The solid lines are V_{S30} mapped by the new model; circles are V_{S30} mapped by California's model (Silva, 2004; see Note #34 in the site file NGA_Site_V017.XLS). In most cases the difference is not large. The larger difference occurs in Geomatrix-D category at elevation higher than 70m, as expected.

Appendix D

Processing and Model Fits to TriNet/ShakeMap Data (Incomplete)

Dataset

Ground-motion dataset used in this analysis was compiled by USGS (Boatwright, per. communication) from the TriNet. It includes PGA (in units of %g) and PGV (in units of cm/sec) from 252 earthquakes (Figure D-1). Since only the larger of the two horizontal components is provided, we divide the listed PGA value by 1.13 to adjust the value down to the expected level of average horizontal component. A subset of 102 events are selected and used in the analysis; see below for description of selection criteria. Epicenter location, focal depth, and local magnitude M_L of each earthquake are from the SCSN catalog. Moment magnitude (M_w) is based on the moment tensor solution catalog, also from SCSN.

Since most earthquakes are small in size and therefore without a finite source model, rupture distance is imputed using the same procedure as documented in Appendix ?. For site conditions, we used the V_{S30} value in the NGA database or estimated it using the same correlation between V_{S30} and geological unit as was used in NGA. The geological unit at the station coordinate is provided by Chris Wills using the recently refined CGS site-conditions map (Wills et al., 2005). For stations without geological unit and NGA V_{S30} , we used the site category given in the USGS data file (column 'C') to estimate V_{S30} using Table ? in Wills et al. (2001?):

- C=1, $V_{S30} = 674$ (m/sec)
- C=2, $V_{S30} = 423$ (m/sec)
- C=3, $V_{S30} = 281$ (m/sec)
- C=4, $V_{S30} = 165$ (m/sec).

Selection of Data Subset

When earthquake epicenter is outside or near the boundary of the strong-motion station network the majority of the recording stations often lie in a limited distance range. Such earthquakes are removed because they are not very useful to the characterization of distance attenuation. The removed earthquakes are plotted as blue circles in Figure 1.

Furthermore, the quality of PGA data degrades as distance increases. Because of the large number of records a full quality control is not feasible. Instead, we removed PGA from beyond the cutoff distance of $130 * (M-2)$ (km), slightly more generous than the cutoff distance of $100 * (M-2)$ (km) recommended by Boatwright et al. (2003) for northern California earthquakes. We also removed data that are obviously in errors. The final subset includes 102 earthquakes, ranging in magnitude from 3.39 to 5.17, and 9060 PGA data, with values ranging from 0.0007 to 24.5 (%g).

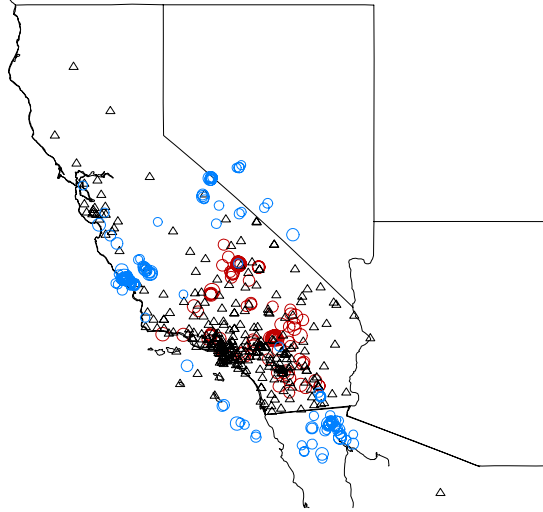

Figure D-1. Epicenter distribution of the TriNet data.

Following this figure are plots of the *pga* values for the individual earthquakes. The dashed line on each figure is the global model developed in this study and the solid line is the event-specific fit.

Appendix E

Individual Earthquake Fits for the Chiou and Youngs (2006) Ground Motion Model

The plots in this appendix show the fits to the individual earthquakes obtained as part of the overall regressions conducted to develop the ground motion model. The curves are color coded to indicate the value of V_{S30} used to make the ground motion estimates and the site data are color coded by NEHRP site class. Results are shown for pseudo spectral acceleration at spectral periods of 0.01, 0.2, 1.0 and 3.0 seconds.
