## ABSTRACT

We present high quality (high signal-to-noise ratio and moderate spectral resolution) nearinfrared (near-IR) spectroscopic observations of 23 well-known broad-emission line active galactic nuclei (AGN). Additionally, we obtained simultaneous (within two months) optical spectroscopy of similar quality. The near-IR broad emission line spectrum of AGN is dominated by permitted transitions of hydrogen, helium, oxygen, and calcium, and by the rich spectrum of singly-ionized iron. In this paper we present the spectra, line identifications and measurements, and address briefly some of the important issues regarding the physics of AGN broad emission line regions. In particular, we investigate the excitation mechanism of neutral oxygen and confront for the first time theoretical predictions of the near-IR iron emission spectrum with observations.

## 1. Introduction

Strangely, the near-infrared (near-IR) spectra of broad-emission line active galactic nuclei (type 1 AGN) have been mostly ignored in this new era of infrared spectroscopy. The broad ( $\sim 1\% - 5\%$ the speed of light) emission lines observed in the optical and ultraviolet (UV) spectra of these type 1 AGN are the most direct tracers of the activity and immediate environment of supermassive black holes. However, despite 30 years of intensive spectrophotometric studies the geometry and kinematics of the broad emission line region (BELR) remains ill-defined. It is not clear whether the BELR gas has a spherical or disk-like distribution, and whether it consists of a large number of discrete clouds or is part of an outflowing, continuous gas distribution such as an accretion disk wind (see, e.g., review by Sulentic et al. 2000). The knowledge of the BELR geometry and kinematics is essential not only to our understanding of the relation between different types of AGN but also to studies that use the broad emission line widths to estimate black holes masses. These estimates would not be meaningful if the BELR was in outflow, and, if the gas was gravitationally bound but distributed in a disk, the resulting values would be underestimated for sources viewed face-on.

Our current, limited knowledge of the BELR physical conditions and scales was gained primarily through the application of sophisticated photoionization models to the observed emission line intensities and ratios (see, e.g., review by Ferland 2003) and through reverberation mapping studies of the (correlated) continuum and line variability (see, e.g., review by Peterson 1993). Both of these methods have relied so far on spectroscopic observations at optical and UV frequencies. Our goal is to extend these studies to the near-IR wavelengths.

Infrared broad emission lines offer several advantages: (i) since each emission line is formed most efficiently at a particular density and distance from the ionizing source (Baldwin et al. 1995), it is important to incorporate in photoionization and reverberation mapping studies multiple emission lines to map the entire BELR. In this respect, the near-IR broad emission lines are a vital addition to the lines observed at optical and UV frequencies; (ii) the near-IR broad emission lines trace mainly the low-ionization line (LIL) region, a region believed to have extreme properties such as very high densities  $(n > 10^{11} \text{ cm}^{-3})$ and a disk-like structure (Collin-Souffrin & Lasota 1988; Marziani et al. 1996). However, these properties were derived mainly based on observations of the two strongest Balmer lines,  $H\alpha$  and  $H\beta$ , and need additional verification; (iii) the near-IR broad emission lines are little affected by reddening and, therefore, can vield information on the amount of dust present in the BELR when compared to the optical Balmer lines; and (iv) coordinated spectroscopic observations at different wavelengths, which are necessary to cover simultaneously a large number of emission lines in the variable AGN, are easiest to realize at optical and near-IR frequencies.

An additional strong motivation for our observing program was to identify nearby AGN with near-IR broad emission lines sufficiently luminous to allow imaging with the newly commissioned and future near-IR interferometers, such as, e.g., VLTI and Ohana. The combination of an interferometric map and a reverberation-based velocity-delay map can be expected to yield the BELR structure and kinematics with almost no ambiguity (e.g., Gallimore et al. 2001). In the longer term we will also use these studies to measure the metric of the Universe by purely geometrical means, following Elvis & Karovska (2002). As these authors pointed out, by using reverberation mapping to measure the linear size and the three-dimensional structure of the BELR and an interferometer to measure its angular size it is possible to solve the triangle (as in stellar parallax), giving the angular diameter distance to the quasar. Mapping out angular diameter distance versus redshift gives the metric, and quasars are common and bright up to high redshifts  $(z \sim 3)$ , where the difference between  $\Lambda = 0.7$  and  $\Lambda = 0.0$  reaches 40%.

This paper presents near-IR spectra of a relatively large sample (23 sources) of type 1 AGN and is the first to include complementary contemporaneous optical spectra to allow the evaluation of commonly measured broad emission line ratios. We concentrate here on the detailed description of our near-IR and optical spectroscopic observations (Section 2), line identifications (Section 3), and flux and velocity width measurements of the most important near-IR and optical broad emission lines (Section 4). In Section 5 we briefly discuss our results in the context of the general BELR physics. The detailed theoretical analysis of these data will be presented in a series of forthcoming papers.

## 2. The Observations

We selected for observations well-known AGN with broad emission lines at redshifts such that most of the strong Paschen hydrogen lines fall in the near-IR atmospheric windows. In addition we required that our sources are bright enough in the near-IR (magnitudes  $J \leq 14$  mag) to allow us to obtain high signal-to-noise ratio (S/N ~ 100) spectra in a reasonable amount of exposure time. As of June 2006 our observed sample comprises 23 sources. In Table 1 we summarize their general properties.

We observed with the NASA Infrared Telescope Facility (IRTF), a 3 m telescope on Mauna Kea, Hawai'i. We used the SpeX spectrograph (Rayner et al. 2003) set in the short crossdispersed mode (SXD,  $0.8 - 2.4 \,\mu m$ ) and equipped with the  $0.8 \times 15''$  slit. This set-up gives an average spectral resolution of full width at half maximum (FWHM)  $\sim 400 \text{ km s}^{-1}$ . Before and/or after each source, we observed a nearby (in position and airmass) A0V star with well-known B and V magnitudes. These stars were used to correct the source spectra for telluric absorption (Vacca et al. 2003) and for flux calibration. Flats and arcs were taken with each source/telluric standard star pair. The data were collected during three observing runs in the period of 2004 May - 2006 June. We had clear skies and seeing in the range of  $\sim 0.7 - 1''$  for all nights with the exception of 2006 January 9 and 10 which were affected by clouds and had poor seeing of  $\sim 1.5''$ . In Table 2 we give the journal of observations.

The SpeX data were reduced using Spextool, an Interactive Data Language (IDL)-based software package developed for SpeX users (Cushing et al. 2004). Spextool carries out all the procedures necessary to produce fully reduced spectra. This includes preparation of calibration frames, processing and extraction of spectra from science frames, wavelength calibration of spectra, telluric correction and flux-calibration of spectra, and merging of the different orders into a single, continuous spectrum. The extraction width was adjusted interactively for each source to include all the flux in the spectral trace. The final spectra were corrected for Galactic extinction using the IRAF task onedspec.deredden with input  $A_V$  values derived from Galactic hydrogen column densities published by Dickey & Lockman (1990). The results are shown in Fig. 1, where we plot for each source the spectrum with the highest S/N. The spectral fits-files are available for download from the journal as a tar-file.

For all our sources we also obtained contemporaneous (within two months) optical spectroscopy with the FAST spectrograph (Fabricant et al. 1998) at the Tillinghast 1.5 m telescope on Mt. Hopkins, Arizona, in queue-observing mode. We used the 300 l/mm grating and a 3" slit. This set-up gives a spectral coverage of ~ 3720 - 7515 Å and an average spectral resolution of FWHM ~ 330 km s<sup>-1</sup>. The slit was rotated to the parallactic angle for all observations. In Table 3 we give the journal of observations.

The FAST data were reduced using standard routines from the IRAF software package. In particular the 2-dimensional spectral files were trimmed, overscan- and bias-subtracted, normalized, rectified and wavelength-calibrated. Subsequently the spectrum was extracted using a width that included all the flux in the trace and the 1dimensional spectral file flux-calibrated using photometric standard stars observed the same night. The final spectra were corrected for Galactic extinction (see above). The spectral fits-files are available for download from the journal as a tarfile.

## 3. The Emission Line Identifications

We have identified in our near-IR spectra all observed emission lines, both permitted and forbidden transitions (black and red dotted lines, respectively, in Fig. 1), as well as the rich permitted and forbidden transitions of iron, in particular of Fe II (green and cyan dotted lines, respectively, in Fig. 1). The line identifications were gathered from the literature (e.g., Morris & Ward 1988; Osterbrock et al. 1990; Oliva et al. 1994; Thompson 1995; Osterbrock & Fulbright 1996; Rudy et al. 2000; Vanden Berk et al. 2001; Rodríguez-Ardila et al. 2002a; Sigut & Pradhan 2003; Véron-Cetty et al. 2004; Riffel et al. 2006; Mazzalay & Rodríguez-Ardila 2007) and the vacuum rest-frame wavelengths were taken from the Atomic Line List v2.04<sup>1</sup>, with the exception of those of the permitted Fe II multiplets, which were taken from Sigut & Pradhan (2003), and those of molecular hydrogen, which were taken from Riffel et al. (2006).

In Table 4 we summarize the identified emission lines in the near-IR frequency range. For six prominent features we could not find a suitable identification using the Fe II multiplet list of Sigut & Pradhan (2003), but profile comparisons suggest that they are iron emission lines. We discuss these further in Section 5.4.3. We note that an extensive list of optical emission lines can be found in Vanden Berk et al. (2001).

### 4. The Measurements

We have measured the properties of the most important broad emission lines in the spectra of our sources. In order to obtain accurate measures, we have extracted "pure" broad line profiles which involved the following steps: (i) estimation and subtraction of the continuum; (ii) subtraction of blended emission lines of other elements; (iii) removal of the superposed narrow emission line component; and (iv) modeling and subtraction of the Fe II emission. These steps are discussed in detail in the following subsections.

On the extracted "pure" broad emission line profile we measured the flux, FWHM, and shift. The flux was measured with the IRAF task onedspec.splot by integrating the emission in the line, i.e., we did not assume a specific profile. The shift was measured as the velocity difference between the theoretical (vacuum) and observed wavelengths of the emission line center, where the emission line center was measured as the center of the width at half maximum. The instrumental width has not been removed from the FWHM values. All measurements were performed on the redshift-corrected spectrum (i.e., in the object's rest-frame). We note that the redshifts were taken from the NASA/IPAC Extragalactic Database (NED) and, therefore, are likely to be inhomogeneous in their definition of the object's rest-frame.

## 4.1. The Continuum

We have estimated for each broad emission line a local continuum. This task involved, firstly, defining the limits of the wings of the broad emission line, and, secondly, finding line-free continuum regions to each side of the broad emission line large enough to allow for a reliable fit. Since the emission line widths differ widely in our sources we did not attempt to define global line-free continuum regions but rather adjusted the fitted continuum regions individually for each object (and line) and chose them to be as close as possible to the wings and as large as possible. The local continuum was then fitted with a straight line in  $f_{\lambda}$  vs.  $\lambda$  space and subsequently subtracted.

## 4.2. The Blends

We have cleaned the spectrum of narrow emission lines of other elements within ~ 12000 km s<sup>-1</sup> (approximately the largest half-width at zero intensity observed) of the broad emission line's expected rest-frame wavelength by modeling the features with Gaussians and subtracting them from the spectrum using the IRAF task *onedspec.splot*. When required, narrow emission lines were first deblended using the option 'd' of this task before removal. In the case of the oxygen doublet [O III]  $\lambda\lambda$ 4959,5007 we did not assume a Gaussian profile but isolated the emission lines from the spectrum by interpolating the H $\beta$  profile under them.

In the case of the near-IR broad emission line  $Pa\epsilon$ , which is heavily blended with the [S III]  $\lambda 9531$  narrow emission line, we used either the  $Pa\alpha$  or  $Pa\beta$  profile (whichever had the higher S/N ratio; mostly this was  $Pa\beta$ ) as a template. Both these emission lines are excellent templates since they are observed relatively free of strong blends. We scaled the Paschen template profile to the peak intensity of Pa $\epsilon$  and subtracted it from the blend. From the result we isolated the [S III] profile and in turn subtracted this from the total blend to recover, at least in part, the original broad emission line.

We have also used the Paschen template technique described above for the broad emission line

<sup>&</sup>lt;sup>1</sup>The Atomic Line List is a compilation by Peter van Hoof and is hosted by the Department of Physics and Astronomy at the University of Kentucky (see http://www.pa.uky.edu/~peter/atomic/)

blends Pa $\gamma$  and He I 1.0830  $\mu$ m, and Pa $\delta$  and He II 1.0124  $\mu$ m. In the case of Pa $\gamma$  and He I, we first subtracted the scaled template profile corresponding to the broad emission line with the highest peak, since the peak of the weaker broad emission line is severely contaminated by flux from the wings of the stronger component.

Similarly, we have used the profile of the (unblended) O I 1.1287  $\mu \rm m$  broad emission line as a template in order to deblend the O I  $\lambda 8446$  broad emission line from the Ca II triplet. The only exceptions were PDS 456 and H 1821+643, where we used the Pa $\beta$  profile instead. In PDS 456, the O I 1.1287  $\mu \rm m$  profile is much narrower than that of O I  $\lambda 8446$ , and in H 1821+643, O I 1.1287  $\mu \rm m$  appears to be blue-shifted relative to O I  $\lambda 8446$  by  $\sim 1400~{\rm km~s^{-1}}.$ 

#### 4.3. The Narrow Component

The task onedspec.splot was also used to model the narrow component with a Gaussian and remove it from the broad emission line profile. The narrow line profile appears inflected (i.e., it is clearly distinguished from the broad line profile; see, e.g., Mrk 290 in Fig. 2) in 11/23 sources. In these cases the modeling and removal process is straightforward. In another two sources, namely, PG 0844+349 and Ark 120, the broad line profiles (with the exception of those of He I 1.0830  $\mu$ m) had a broad top, either flat or double-peaked. We interpreted this as indication that the contribution from the narrow line component is negligible and left the observed profiles unchanged.

The broad emission lines of the remaining 10/23 sources were peaked, but the transition between broad and narrow component was not perceptible. In these cases we estimated the contribution of the narrow component to the total profile by fitting to its top part a Gaussian with FWHM equal to that of the narrow emission line [O III]  $\lambda$ 5007. This method assumes that the FWHM of [O III]  $\lambda$ 5007 is representative of the narrow emission line region (NELR) and subtracts the largest possible flux contribution from this region.

No attempt was made to correct the broad line profiles of IRAS 1750+508 and PDS 456 for the presence of a narrow line component. The [O III] emission lines of IRAS 1750+508 show a very strong blue asymmetry, and those of PDS 456 are very weak and strongly blended with (optical) Fe  $\scriptstyle\rm II.$ 

## 4.4. The Fe II Subtraction

Most near-IR broad emission lines suffer from moderate to strong blending with Fe II emission features. The template subtraction process described in Section 4.2 isolates these automatically. However, it is necessary to judge if the isolated profile indeed corresponds to Fe II or rather belongs, in part or entirely, to a different, neighboring emission feature (e.g., to He II 1.0124  $\mu m$ in the case of Fe II 1.0132  $\mu$ m) or the wing of the broad emission line in question. To determine this, we compared the isolated profile to the profiles of two near-IR Fe II emission features which are relatively strong and observed unblended, namely, Fe II 1.0502  $\mu$ m and Fe II 1.1126  $\mu$ m. The Fe II 1.0502  $\mu$ m emission feature is in fact a blend of Fe II 1.0491  $\mu m$  and Fe II 1.0502  $\mu m.$ However, the former is expected to be weaker than the latter by a factor of  $\sim 7$  (Sigut & Pradhan 2003).

In the optical frequency range the continuum around H $\beta$ , He II  $\lambda$ 4686, and H $\gamma$  is contaminated by numerous Fe II multiplets which blend together to form a pseudo-continuum. We first subtracted this optical Fe II emission before fitting a local continuum. For this purpose we used the template based on the optical spectrum of I Zw 1 published by Véron-Cetty et al. (2004) and available in electronic format. The method generally used to subtract the Fe II emission from optical spectra was first introduced by Boroson & Green (1992). It consists of creating a spectral sequence by broadening (by convolution with Gaussians) and scaling of the Fe II template, which is subsequently packed together into a three-dimensional cube. This cube is then subtracted from a cube consisting in all three dimensions of the object's spectrum.

In contrast to Boroson & Green (1992), in our cases we found it difficult to decide by eye unambiguously which pair of width and strength of the Fe II template gave the cleanest subtraction. Whereas it was rather clear which was the most appropriate strength, changing the width of the Fe II template (at this strength) by as much as several 1000 km s<sup>-1</sup> gave only slightly different results. This is due to the fact that the Fe II template "smears out" at larger widths, which leads to essentially subtracting a straight line over large continuum regions. (However, we note that the resulting differences were more pronounced at smaller widths, and in principle a minimum width could be determined.) This degeneracy was also noted by Vestergaard & Peterson (2005). Therefore, it seems necessary to constrain a priori the width of the Fe II template. We did so by using the widths measured for our unblended near-IR iron emission lines Fe II 1.0502  $\mu m$  or Fe II 1.1126  $\mu m$ , whichever had the higher S/N ratio (usually Fe II 1.0502  $\mu$ m). Three sources have near-IR Fe II emission lines narrower than the width of the Fe II template of  $1100 \text{ km s}^{-1}$ . In these cases we did not broaden the template. For two sources, namely, H 1821+643 and NGC 5548, we do not observe near-IR Fe II emission (except a weak near-IR Fe II emission 'hump'), but we do observe (weak) optical Fe II emission. In these cases we have not subtracted an Fe II template, but simply fit a local continuum using the spectral ranges  $\lambda 4435 - 4445$  Å and  $\lambda 5075 - 5085$  Å, where Fe II is expected to be very weak.

In many cases, and especially for strong iron emitters such as, e.g., PDS 456, no satisfactory optical Fe II subtraction using the template of Véron-Cetty et al. (2004) was possible. Strong emission residuals remained in particular in the range 4440 - 4700 Å and also around This is most likely due to the Fe II  $\lambda 4233$ . fact that the flux ratios between the individual Fe II emission lines differ from object to object, and thus between our sources and I Zw 1 (see also, e.g., Boroson & Green 1992). Therefore, in order to not leave large amounts of flux unaccounted for, we have re-added the corresponding, subtracted Fe II template to the continuumsubtracted spectrum, and, if present, subtracted the isolated He II  $\lambda$ 4686 profile, before measuring the Fe II emission in the range  $\lambda 4440 - 4700$ . The exception was the source NGC 4151 for which we measured the optical Fe II emission directly in the subtracted template, since its  $H\beta$  broad emission line has very extended wings stretching out to relatively short wavelengths. We note that measuring instead the flux of Fe II  $\lambda$ 4440–4700 directly in the subtracted template can lead to underestimating it by as much as  $\sim 40\%$  and typically by  $\sim 15\%$ .

## 4.5. Host Galaxy Absorption

Since our optical spectra were obtained through a rather large aperture in objects with strong host galaxy contribution, the H $\gamma$  and He I  $\lambda$ 5876 emission lines are affected by stellar absorption (see also Crenshaw & Peterson 1985). In these cases we used either the Pa $\alpha$  or Pa $\beta$  profile as a template to interpolate the H $\gamma$  profile over the strongest absorption lines (most notably G band at 4300 Å), which, when they add together, can appear rather wide.

The absorption lines contaminating He I  $\lambda$ 5876 (e.g., Na I  $\lambda$ 5896) were instead fitted with Gaussians and subtracted. We did not attempt to measure the He I  $\lambda$ 5876 emission line in PDS 456 and Mrk 590. In both sources this line was strongly absorbed, by telluric bands and by the host galaxy, respectively.

## 4.6. The Tables

In Table 5 we list our results individually for each measured broad emission line. Sources are omitted from the list if the spectrum did not cover the line. If not the entire broad emission line but more than half of it is covered by the spectrum, we list lower limits on the flux. The fluxes of selected Fe II emission lines are listed in Table 6 and are discussed further in Section 5.4. The fluxes of isolated narrow emission lines of other elements are listed in Table 7.

The main sources of measurement errors on the listed broad emission line parameters are the placement of the continuum and the setting of the extension of an emission line. Both of these depend to a large extent on the S/N of the data but also significantly on the subjective decision of the person conducting the measurements. For these reasons we have not attempted to derive individual errors for our measurements. However, the S/N of our data is relatively high and we estimate the error introduced by this quantity alone to be, e.g., a few per cent for the broad emission line fluxes. Measurement errors for the narrow emission line fluxes are due mainly to the approximation with a Gaussian and the placement of the 'narrow emission line continuum'. The Gaussian fit was adequate in the majority of cases, but in some objects this approximation might not account for all of the flux. In general we estimate that the listed values

are accurate to within  $\sim 10\%$ .

#### 5. The Near-IR Broad Emission Lines

The electron densities in the BELR are sufficiently high  $(n \gtrsim 10^8 \text{ cm}^{-3})$  that virtually all forbidden lines are collisionally suppressed, therefore, almost only permitted transitions contribute to this emission line region. We find that the near-IR spectra of our sources are dominated by permitted emission lines from few elements, namely, hydrogen, helium, oxygen, calcium, and iron. This is similar to what is observed in the optical frequency range.

#### 5.1. The Hydrogen Emission Lines

The observed near-IR hydrogen emission lines contain transitions from the Paschen and Brackett series. We have measured 5/11 observed Paschen emission lines, namely, Pa $\alpha$  to Pa $\epsilon$  (shown in Figs. 2-5), and the strongest observed Brackett emission line, namely, Br $\gamma$  (shown in Fig. 6). Although seen in the majority of our sources (21/23 objects), we have not measured the second strongest observed Brackett emission line, namely, Br $\delta$ , since it is strongly affected by telluric absorption. In the optical spectra of our sources we have measured the three strongest Balmer emission lines, namely, H $\alpha$ , H $\beta$ , and H $\gamma$ .

## 5.1.1. The Paschen and Balmer Series

The Pa $\alpha$  and Pa $\beta$  emission lines are not only two of the strongest emission lines observed in the near-IR, but they are also relatively free of blending features (only two, mostly weak narrow emission lines contaminate the blue wing of Pa $\beta$ , see Fig. 2). This makes them valuable tools to probe the physical conditions of the BELR. The optical Balmer emission lines, although stronger, suffer from blending with other features and, at least to some degree, are expected to be affected by dust absorption.

Given this importance of Pa $\alpha$  and Pa $\beta$ , it is worth comparing their widths. We do this in Fig. 7 where we plot separately their broad and narrow components (upper right and lower left filled circles, respectively), the latter plotted only for the cases where it is inflected. Taking the spectral resolution (FWHM ~ 350 km s<sup>-1</sup>) as an error range (dotted lines), as expected, the widths of these two emission lines are similar. However, in several sources we observe the Pa $\alpha$  emission line close to the atmospheric absorption window and this is reflected in Fig. 7. Whereas the scatter for the narrow component is evenly distributed, the scatter in the broad component measurements is mainly towards smaller values for Pa $\alpha$  relative to Pa $\beta$ . As an example, the two most deviant points at the lower and upper end of the broad component distribution correspond to Ark 564 and NGC 5548, respectively. And, as can be seen from Fig. 2, the Pa $\alpha$  broad emission lines in these two sources suffers from extreme atmospheric absorption.

All Paschen emission lines of higher order are strongly blended with emission lines from other elements. In particular,  $Pa\gamma$  is strongly blended with He I 1.0830  $\mu$ m and Fe II 1.0863  $\mu$ m, and its red wing also with Fe II 1.1126  $\mu$ m (see Fig. 3). The Pa $\delta$  emission line is heavily blended with the doublet Fe II  $\lambda 9956 + 9998$  on its blue side and with He II 1.0124  $\mu$ m or, in objects with strong iron emission, Fe II 1.0132  $\mu$ m and Fe II 1.0174  $\mu$ m on its red side (see Fig. 4). The strongest narrow emission line in the near-IR, namely, [S III]  $\lambda$ 9531 contaminates the peak and, therefore, in particular the narrow component of the  $Pa\epsilon$  emission line. In addition, in strong iron emitters, Fe II  $\lambda$ 9407 and Fe II  $\lambda$ 9573 blend in on the blue side and close to the emission line center, respectively (see Fig. 5).

In Fig. 7 we also compare the widths of the Paschen and Balmer emission lines. We chose to plot  $Pa\beta$ , since this line is observed relatively unaffected by atmospheric absorption, versus the two strongest Balmer emission lines, namely,  $H\alpha$  and  $H\beta$  (open triangles and squares, respectively). No significant difference is seen between the emission line widths of H $\alpha$  and Pa $\beta$ . However, there is a trend for the widths of the  $H\beta$  broad components to be larger than those of the  $Pa\beta$  broad components. This is most likely due to the well-known existence of a "red shelf" in the  $H\beta$  broad component (e.g., De Robertis 1985; Marziani et al. 1996), which is believed to be formed, at least in part, by emission from weak Fe II multiplets and He i  $\lambda 4922, 5016$  (Véron et al. 2002; Kollatschny et al. 2001). The H $\beta$  "red shelf" is observed in the majority of our sources, and especially the three objects with the largest width differences between the H $\beta$  and Pa $\beta$  broad components, namely, Mrk 876, Mrk 590, and NGC 5548, clearly show this feature.

This study is the first to systematically separate the narrow and broad components for both a large number of emission lines and a relatively large sample of type 1 AGN. Taking the Pa $\beta$ , H $\alpha$ , and H $\beta$  emission lines as representative, we find that in the majority of the cases the flux of the narrow component is less than ~ 10% of the flux of the broad component (Fig. 8, lower panel). Whether the narrow component appears inflected or not is, as expected, independent of the flux ratio between the narrow and broad components and depends only on their relative widths. From Fig. 8, upper panel, we obtain that the narrow component appears inflected when its width is below ~ 20% of that of the broad component.

## 5.1.2. Dust Extinction

Although the contribution of the narrow component to the total emission line flux is small compared to that of the broad component (see above), the physical conditions of the NELR are, contrary to those of the BELR, relatively well understood (e.g., Osterbrock & Ferland 2006). Therefore, independent measurements of the narrow component fluxes can yield important constraints on, e.g., the presence of dust within our line of sight which could also affect the BELR.

In Fig. 9 we compare our measured narrow emission line fluxes with the predictions from Case B recombination without dust (lower solid line), and including a dust extinction of  $A_{\rm V} = 1$ and 2 mag (middle and upper solid lines, respectively). The values expected from Case B recombination were calculated using the CLOUDY photoionization simulation code (last described by Ferland et al. 1998) and assuming a temperature of T = 15000 K and an electron density of  $n_e = 10^4 \text{ cm}^{-3}$ . The  $A_V$  values were transformed into  $A_{\lambda}$  values using the analytical expression for the interstellar extinction curve of Cardelli et al. (1989) and assuming a parameter of  $R_V = 3.1$ . Fig. 9 shows the emission line fluxes normalized such that the flux of the Pa  $\beta$  emission line (the near-IR line measured for all sources) was unity. The Case B curves were normalized such that the  $A_{\rm V} = 1$  mag curve at the wavelength of Pa  $\beta$ was unity. Since the measurement errors for the Pa  $\beta$  data point (roughly the size of the symbol)

correspond roughly to the separation between this curve and those for  $A_{\rm V} = 0$  and 2 mag, this representation simply makes the Pa  $\beta$  data point (and in general the near-IR data points) compatible with Case B recombination, irrespective of the amount of dust.

Fig. 9 shows that the observed narrow emission line ratios can be well reproduced by Case B recombination. The effects of dust, however, are clearly observable only in the Balmer emission line ratios, whereas they cannot be detected at a significant level using the Paschen and Brackett emission lines alone. We then assessed the extinction affecting the NELR in our sources based on which of the plotted curves fitted the Balmer emission lines best. For the large majority of our sources plotted in Fig. 9 (12/18 objects) we obtain that the dust extinction is of the order of  $A_{\rm V} \sim 1$  mag. This average seems to be independent of the type of narrow component (i.e., inflected or estimated). For three sources, namely, Mrk 817, NGC 4151, and NGC 4593, the dust extinction is much below this value, whereas for another three sources, namely, Mrk 876, Ark 564, and HE 1228+013, it appears to be as high as  $A_{\rm V} \sim 2$  mag.

Significant reddening of the narrow emission lines of the order obtained here has been observed before in type 1 AGN. Cohen (1983) measured the reddening in the inflected narrow components of 13 type 1 AGN using two to four Balmer lines. Correcting his values for Galactic extinction we obtain for his sample (which has 5 sources in common with ours) an average of  $A_{\rm V} \sim 1$  mag, similar to our result. Ward et al. (1987) estimated the NELR reddening of four objects, of which two, namely, NGC 3227 and NGC 4151, are included in our sample. These authors obtain on average a higher extinction of  $A_{\rm V} \sim 2$  mag. More recent studies, considering, however, only single objects, obtain values similar to our average (e.g., Crenshaw et al. 2001, 2002).

Given this result, the relevant question for our studies is whether the dust causing the observed extinction of the NELR affects also the broad components. This will depend on the location of the dust, i.e., if it is mixed in with the gas producing the narrow emission lines ("internal dust") or if it is located outside the NELR, e.g., in the host galaxy. Since the covering factor of the narrow emission line clouds is assumed to be very small (only a few per cent), our line of sight towards the BELR will not necessarily intercept these. However, dust external to the NELR will act like a screen and affect also the smallest scale components such as the BELR and the continuum emitted by the accretion disk. In a future paper we plan to study in detail the continuum spectral energy distributions of our sample, supplementing our simultaneous optical and near-IR observations with UV and X-ray archival observations. This will help determine if the continuum source suffers from similarly strong extinction as the NELR.

## 5.2. The Helium Emission Lines

The helium transitions observed in the near-IR are by far less numerous than the hydrogen emission lines, with only few lines clearly detectable for both neutral and singly-ionized helium. We have measured the strongest of the near-IR emission lines of neutral helium, namely, He I 1.0830  $\mu$ m, and also the strongest of the optical emission lines, namely, He I  $\lambda$ 5876. The He I 1.0830  $\mu m$  emission line is blended with Pa  $\gamma$  (and in strong iron emitters also with Fe II 1.0863  $\mu$ m), but, since it is a strong line, it can be easily separated from this using our template profile technique. The He I  $\lambda$ 5876 emission line is affected by host galaxy absorption, and we have corrected for it as described in Section 4.5. Conclusive evidence for the presence of Na 1  $\lambda$ 5896 in emission is observed only in HE 1228+013. In Fig. 10 we compare the isolated profiles of the two He I emission lines and discuss these further below.

The near-IR (and also optical) He II emission lines, and in particular their broad components, are not only relatively weak, but suffer from strong blending. Therefore, the extraction and measurement of the profiles of these emission lines are best performed on mean and root mean square (rms) spectra. In such spectra the constant or slowly varying components, such as, e.g., the wings of a (blending) broad emission line, do not appear, and the He II emission line can be reliably isolated (e.g., Peterson & Wandel 1999). In a future paper we will present results from our near-IR reverberation mapping campaign and will discuss in detail the profiles of the He II emission lines.

## 5.2.1. The Kinematics of the BELR

The helium and hydrogen emission lines can be used together to study the velocity structure of the BELR. Since emission lines corresponding to higher ionization potentials are expected to be produced at locations closer to the AGN's central ionizing source than emission lines corresponding to lower ionization potentials (e.g., Peterson 1993; Osterbrock & Mathews 1986, and references therein), helium is expected to emanate from locations closer to the center than those responsible for the hydrogen emission. Thus, comparison of the widths of the helium and hydrogen broad emission lines can give important clues regarding the kinematics of the emitting region.

11 we plot the widths of the two In Fig. He I emission lines versus those of the hydrogen emission lines  $Pa\beta$ ,  $H\alpha$ , and  $H\beta$ , separately for their (inflected) narrow and broad components. Fig. 11, left panel, shows that whereas the narrow components of the helium and hydrogen emission lines have similar widths, the broad component of He I  $\lambda$ 5876 is significantly wider than that of the hydrogen emission lines. E.g., the average FWHM ratio between the He I  $\lambda$ 5876 and Pa $\beta$ emission lines is  $\sim 1.5$ . This result is similar to previous findings (e.g., Osterbrock & Shuder 1982; Shang et al. 2007) and in accordance with the current picture that the BELR is dominated by Keplerian motion in the gravitational field of a central supermassive black hole (e.g., Peterson & Wandel 1999).

On the other hand, the broad component of He I 1.0830  $\mu$ m has widths rather similar to those of the hydrogen emission lines (Fig. 11, right panel). This is expected since He I 1.0830  $\mu$ m is one of the most optically thick helium emission lines, and, therefore, its emissivity should drop off significantly with increasing incident photon flux. This then renders the He I 1.0830  $\mu$ m emission line a less suitable probe of the BELR kinematics than the He I  $\lambda$ 5876 emission line.

#### 5.3. The Oxygen Emission Lines

We clearly observe in the near-IR spectra of all our sources two of the strongest emission lines of neutral oxygen, namely, O I  $\lambda$ 8446 and O I 1.1287  $\mu$ m (Fig. 12). Contrary to the hydrogen and helium emission lines discussed in the previous sections, which result mainly from recombination processes, the observed oxygen transitions are assumed to be the result of Ly $\beta$  fluorescence (e.g., Grandi 1980; Rudy et al. 1989). However, it is not clear if other excitation processes can also contribute (Rodríguez-Ardila et al. 2002b). In addition, contrary to hydrogen and helium, neutral oxygen emission is believed to be a pure broad-line phenomenon (Grandi 1980; Morris & Ward 1989).

In the following we report for the first time the detection of narrow components to O I emission lines and address the issue of the O I excitation mechanism. Understanding this mechanism is essential since O I emission lines are believed to be a suitable reddening indicator for the BELR (Netzer & Davidson 1979).

## 5.3.1. The Presence of Narrow Components

Grandi (1980) was the first to observe the spectral region around O I  $\lambda$ 8446 for a relatively large sample of Seyfert 1 galaxies (16 objects) and for three Seyfert 2 galaxies. Based on the lack of a detection of O I  $\lambda$ 8446 in the Seyfert 2 galaxies and the lack of a narrow component to O I in intermediate Seyfert galaxies (i.e., in Seyfert galaxies with otherwise inflected narrow components), such as, e.g., NGC 5548 and NGC 4151, he concluded that O I is emitted in the BELR only.

Like Grandi (1980), we do not observe narrow components of the O I emission lines in sources which have hydrogen emission lines with inflected narrow components. However, in all other sources, the O I profiles are similar to those of the *total* hydrogen profiles (Fig. 12). This suggests that O I emission can be produced in the NELR. In support of this interpretation are also the findings of Morris & Ward (1985), who found O I emission in two Seyfert 2 galaxies, namely, NGC 5506 and NGC 7314.

#### 5.3.2. The Excitation Mechanism

There are four excitation mechanisms which can lead to the production of O I  $\lambda$ 8446 emission: recombination, collisional excitation, continuum fluorescence, and Ly $\beta$  fluorescence (e.g., Grandi 1975, 1980). The O I 1.1287  $\mu$ m emission line, on the other hand, is believed to be the result of Ly $\beta$  fluorescence only.

In order to determine the principal excitation

mechanism for O I  $\lambda$ 8446 in our sources, we start by comparing the *photon* fluxes of the two oxygen emission lines. If Ly $\beta$  fluorescence dominates, every O I  $\lambda$ 8446 photon is produced via an O I 1.1287  $\mu$ m photon, and, therefore, we expect the photon flux ratio between the two oxygen emission lines to be unity. If, however, other processes also contribute, the O I  $\lambda$ 8446 emission will be enhanced relative to that of O I 1.1287  $\mu$ m.

Fig. 13, lower panel, shows the distribution of the photon flux ratios between the broad components of the O I 1.1287  $\mu$ m and O I  $\lambda$ 8446 emission lines. In all sources, with the exception of Mrk 590, this ratio is below unity, indicating that processes other than  $Ly\beta$  fluorescence contribute to the broad O I  $\lambda$ 8446 emission. For Mrk 590 we obtain a photon flux ratio of 1.13. Ly $\beta$  fluorescence contributes in our sources between  $\sim 20$ -85% of the broad O I  $\lambda 8446$  emission, with 14/23sources having a contribution from this process of  $\geq 60\%$ . In only three sources does this process not dominate, namely, in PDS 456 ( $\sim 20\%$ ), Ark 120  $(\sim 40\%)$ , and NGC 5548  $(\sim 40\%)$ , and in the remaining six sources, namely, Mrk 876, Mrk 110, Mrk 509, Mrk 817, Mrk 290, and NGC 4151,  $Ly\beta$ fluorescence accounts for only half of the broad Ο 1 λ8446 flux.

In Fig. 13, upper panel, we compare for the eight sources with detected narrow O I components the photon flux ratios between the O I 1.1287  $\mu m$  and O I  $\lambda 8446$  emission lines in the BELR and NELR. Three sources, namely, Mrk 509, H 2106-099, and Ark 564, have in both emission line regions similar contributions from  $Ly\beta$  fluorescence of  $\sim 50\%$ ,  $\sim 65\%$ , and  $\sim 75\%$ , respectively. In four other sources, namely, HE 1228+013, Mrk 110, Mrk 335, and H 1934–063, the Ly $\beta$  fluorescence contribution is higher in the NELR than in the BELR, with the largest differences found for Mrk 110 ( ${\sim}75\%$  in the NELR vs.  ${\sim}50\%$  in the BELR) and HE 1228+013 (a larger than unity photon flux ratio of 1.26 in the NELR vs.  $\sim 85\%$ in the BELR). For 3C 273 we find a smaller  $Ly\beta$ fluorescence contribution in the NELR than in the BELR ( $\sim 40\%$  vs.  $\sim 75\%$ ).

Since  $Ly\beta$  fluorescence cannot account for all of the O I  $\lambda$ 8446 emission line flux, neither in the BELR nor in the NELR, which of the other three possible excitation mechanisms could also contribute? This can be best assessed by the presence or lack of other O I emission lines. Continuum fluorescence implies the presence of lines such as, e.g., O I 1.3165  $\mu$ m, which is the strongest line produced by this process. Recombination and collisional excitation produce, e.g., O I  $\lambda$ 7774 (the quintet counterpart to O I  $\lambda$ 8446), with ratios of O I  $\lambda$ 7774/ $\lambda$ 8446  $\approx$  1.1 (taking the transition probabilities given in the Atomic Line List v2.04) and  $\approx 0.3$  (Grandi 1980), respectively.

The near-IR spectra of the seven sources in our sample with the highest redshifts cover the spectral region around O I  $\lambda$ 7774 and this emission line is clearly detected in all of them (see Fig. 14). O I  $\lambda$ 7774 is blended with Fe II  $\lambda$ 7712 and an unidentified feature which appears to be itself a blend of emission lines at  $\sim$  7875 Å and  $\sim$  7896 Å (see Section 5.4.3). Therefore, we have measured its flux using the profile of O I 1.1287  $\mu$ m, similar to the procedure adopted for O I  $\lambda$ 8446 (see Section 4.2 for details). The O I 1.3165  $\mu$ m emission line is convincingly detected in only 5/15sources with spectral coverage in this region (see Fig. 15). In 3C 273 this line is blended with the red wing of Pa $\beta$  and we used the O I 1.1287  $\mu$ m profile to measure it.

In Table 8 we list for a total of nine sources the fluxes for the broad components of O I 1.3165  $\mu$ m and O I  $\lambda$ 7774 (columns (4) and (6), respectively). A narrow component to the O I  $\lambda$ 7774 emission line was detected in 3C 273, but not in HE 1228+013. Similarly, O I 1.3165  $\mu$ m narrow components were detected in 3C 273 and Ark 564, but not in HE 1228+013 and H 1934-063. Of the nine sources listed in Table 8, seven have their broad O I  $\lambda$ 8446 emission dominated by Ly $\beta$  fluorescence (see column (3)). However, for PDS 456 this process is important only at the ~20% level and for Mrk 876 it accounts for only about half of the broad O I  $\lambda$ 8446 flux.

For 3/9 sources, namely, IRAS 1750+508, 3C 273, and HE 1228+013, both O I 1.3165  $\mu$ m and O I  $\lambda$ 7774 were detected, Based on their photon flux ratios relative to O I  $\lambda$ 8446, continuum fluorescence seems to contribute only a few per cent and recombination seems to account for the remaining ~ 10 - 20% of the broad O I  $\lambda$ 8446 emission line flux. However, for 3C 273 the situation in its NELR is different from that in its BELR. As mentioned above, Ly $\beta$  fluorescence accounts for only ~40% of its narrow O I  $\lambda$ 8446 emission

sion, and, whereas continuum fluorescence contributes only a few per cent, collisional excitation seems to be the dominant process. For the narrow components we obtain a photon flux ratio of O I  $\lambda$ 7774/ $\lambda$ 8446  $\sim$  0.21, after subtracting the fluorescence contribution off the O I  $\lambda$ 8446 flux.

For another 3/9 sources, namely, H 1821+643, Mrk 876, and PDS 456, the spectrum covered the location of both O I 1.3165  $\mu$ m and O I  $\lambda$ 7774, but only O I  $\lambda$ 7774 was detected. In H 1821+643 and Mrk 876 recombination seems to account for the remaining ~ 20 – 50% of the broad O I  $\lambda$ 8446 emission line flux, but PDS 456 has a photon flux ratio of O I  $\lambda$ 7774/ $\lambda$ 8446 ~ 0.24 (after subtracting the fluorescence contribution off the O I  $\lambda$ 8448 flux), similar to the value expected for collisional excitation.

In PG 0844+349, the spectral region around O I 1.3165  $\mu$ m was not covered, but the photon flux ratio between O I  $\lambda$ 7774 and O I  $\lambda$ 8446 indicates that recombination accounts for the remaining broad O I  $\lambda$ 8446 flux. On the other hand, in Ark 564 and H 1934–063, the spectral region around O I  $\lambda$ 7774 was not covered, but the photon flux ratio between O I 1.3165  $\mu$ m and O I  $\lambda$ 8446 indicates that continuum fluorescence is not as important as recombination or collisional excitation.

In summary,  $Ly\beta$  fluorescence is the dominant production mechanism of broad O I  $\lambda$ 8446 in just over half of our sources (14/23 objects). In roughly a third of our sources (6/23 objects)  $Ly\beta$  fluorescence accounts for about half of the broad O I  $\lambda$ 8446 flux, and in only a few sources it is not the dominant process. In one of these few sources, namely, PDS 456, collisional excitation dominates instead. For six sources we determine that recombination (and not collisional excitation) accounts for the remaining broad O I  $\lambda$ 8446 emission line flux. Continuum fluorescence is present, but does not seem to be important.

Rodríguez-Ardila et al. (2002b) were the first to present evidence that Ly $\beta$  fluorescence is not the only process contributing to the O I  $\lambda$ 8446 emission in AGN. We confirm their result using a sample more than three times as large. Similar to our findings, Rodríguez-Ardila et al. (2002b) concluded that continuum fluorescence does not contribute significantly, but since they had observations of O I  $\lambda$ 7774 for only one source they could not determine which of the two, recombination or collisional excitation, was in general the other important process. Their only source with available O I  $\lambda$ 7774 was H 1934–063, which is also part of our sample. This line was covered by their optical spectrum which extended further into the red than ours. For this source they obtain a photon flux ratio of O I  $\lambda$ 7774/ $\lambda$ 8446 ~ 0.2 (after subtracting the fluorescence contribution off the O I  $\lambda$ 8446 flux), suggesting that collisional excitation accounts for the remaining ~30% of the O I  $\lambda$ 8446 flux.

Recently, Matsuoka et al. (2007) presented O I  $\lambda$ 8446 and O I 1.1287  $\mu$ m emission line measurements for six quasars. They also concluded that O I  $\lambda$ 8446 emission is not produced by Lv $\beta$ fluorescence alone and identified collisional excitation as the other important process. However, this result was obtained based on comparisons of their observed O I emission line ratios with predictions from photoionization models, which did not include the contribution from recombination. Thus they could only distinguish between collisional excitation and continuum fluorescence. In addition, we note that for the one source in common with our sample, namely, 3C 273, they measured a similar O I  $\lambda$ 8446 flux, but a O I 1.1287  $\mu$ m flux a factor of  $\sim 2$  lower than our value.

#### 5.4. The Iron Emission Lines

We have detected in our near-IR spectra numerous emission lines from the rich spectrum of singly-ionized iron. Contrary to the Fe II emission lines seen in the UV and optical spectra of AGN, which often blend together and at places form a pseudo-continuum, several near-IR Fe II emission lines can be resolved and studied individually. This is important for at least three reasons: (i) the widths of the resolved near-IR Fe II emission lines can be used to broaden suitable UV and optical templates, which leads to a more reliable iron subtraction and thus measurement of the properties of contaminated features. We have used this method successfully in Section 4.; (ii) the fluxes of the resolved near-IR Fe II emission lines can be used to test theoretical iron emission models. We do this in Section 5.4.1.; and (iii) the profiles of the resolved near-IR Fe II emission lines can be compared to those of emission lines of other elements to help answer the long-standing question of where the iron in AGN is produced and excited (see Section 5.4.2).

## 5.4.1. Observed vs. Predicted Line Strengths

Theoretical iron flux templates have been developed in recent years in order to alleviate the problems inherent to empirical templates. Such problems are, e.g., the assumption that the source used to construct the template is typical of the AGN population, and the complications introduced by the severe blending of broadened AGN emission lines which makes the isolation of an iron template a difficult task. Furthermore, theoretical iron templates have the advantage that model parameters can be adjusted to fit observations, thus allowing one to constrain the excitation mechanism producing the Fe II spectrum.

The most elaborate theoretical predictions were presented by Sigut & Pradhan (2003). Given the relatively large size of our sample and the quality of our data we can now put these to test. For this purpose we have measured in our spectra the fluxes of six individual near-IR Fe II emission lines and of three blends. In addition, we have measured the flux of the optical Fe II 'hump' in the range 4440-4700 Å as detailed in Section 4 and of the near-IR Fe II 'hump' in the range 8150-8365 Å. Our results are listed in Table 6. Two sources, namely, H 1821+643 and NGC 5548, were omitted from this table since their Fe II emission was weak and only the optical and near-IR emission 'humps' could be convincingly detected. In Table 6 we also give the measured fluxes relative to that of the Fe II  $1.0491+1.0502 \ \mu m$  blend. We chose this blend since it is relatively strong and observed unaffected by emission from other elements.

In Table 9 we summarize for the six iron emission lines with the largest statistics, namely, the two Fe II 'humps, Fe II  $\lambda$ 9407, Fe II  $\lambda$ 9573, Fe II  $\lambda$ 9956 + 9998 and Fe II 1.0174  $\mu$ m, the average flux ratios relative to Fe II 1.0491+1.0502  $\mu m$  and also relative to Fe II 1.1126  $\mu m$ . Although not observed in all our sources, we have considered as a consistency check also ratios relative to the Fe II 1.1126  $\mu$ m emission line, since, contrary to Fe II 1.0491+1.0502  $\mu$ m, it is not a blend and similarly to this observed relatively free of contaminating emission. We list in Table 9 averages for the whole sample and also considering only those sources with the most reliable Fe II profiles for which all three of the emission lines Fe II  $\lambda$ 9956 + 9998, Fe II 1.0491+1.0502  $\mu$ m,

and Fe II 1.1126  $\mu$ m were detected (11/21 objects; see also Fig. 16).

The observed means of all considered flux ratios relative to Fe II 1.0491+1.0502  $\mu$ m are significantly ( $\geq 2\sigma$ ) different from the theoretical value expected by Sigut & Pradhan (2003) for their model A (see their Table 3). The only exception is Fe II  $\lambda$ 9407. The most significant deviations are observed for the optical and near-IR Fe II 'humps' and for the Fe II 1.0174  $\mu$ m emission line. On the other hand, all considered flux ratios relative to Fe II 1.1126  $\mu$ m are consistent with theoretical predictions. This is also the case for the flux ratio between the optical and near-IR Fe II 'humps'.

The mean ratios of the optical and near-IR Fe II 'humps' relative to Fe II 1.0491+1.0502  $\mu$ m for the whole sample are larger than the expected value by a factor of ~ 2 (significant at the  $6\sigma$  and  $5\sigma$  level, respectively). However, considering only the sources with the most reliable Fe II profiles the significance of the difference between observations and predictions reduces to 2  $\sigma$ .

The four near-IR Fe II emission lines  $\lambda 9956 +$ 9998,  $1.0491+1.0502 \ \mu m$ ,  $1.0174 \ \mu m$ , and 1.1126 $\mu m$  descend from a common upper multiplet and are collectively termed the "1  $\mu$ m Fe II lines" (e.g., Rudy et al. 2000). Both the Fe II  $\lambda$ 9956 + 9998 and Fe II 1.1126  $\mu$ m emission line fluxes are observed versus that of Fe II 1.0491+1.0502  $\mu m$  to be larger than predicted by a factor of  $\sim 2$  (at the  $3\sigma$  and  $4\sigma$  level, respectively), irrespective of the sample considered. The most significant discrepancy between theory and observations is found for the Fe II 1.0174  $\mu$ m emission line. Its flux ratio relative to Fe II  $1.0491+1.0502 \ \mu m$  is on average a factor of  $\sim 5$  larger than predicted, significant at the 11 $\sigma$  level. A similar result is obtained if only the sources with the most reliable Fe II profiles are considered. The flux of this line relative to that of Fe II 1.1126  $\mu$ m is larger than the predicted value by a smaller factor of  $\sim 2$ , a result which becomes significant only if the most reliable measurements are considered.

In summary, our observations are consistent with the predictions of Sigut & Pradhan (2003) with two exceptions. The Fe II 1.0491+1.0502  $\mu$ m emission line flux is either overpredicted by theory or underestimated by our measurements by a factor of ~ 2, and by a similar factor the Fe II 1.0174  $\mu$ m emission line flux is either underpredicted by

theory or overestimated by our measurements.

Considering in particular the sources with the most reliable Fe II profiles, it is unlikely that we have underestimated the flux of Fe II 1.0491+1.0502  $\mu m$  by as much as a factor of ~ 2, given that this feature is observed relatively uncontaminated. On the other hand, the measurement of the Fe II 1.0174  $\mu m$  emission line is complicated by its proximity to the rather strong He II 1.0124  $\mu m$  emission line. However, in the five sources with the most reliable Fe II profiles considered in Table 9, namely, Mrk 110, H 2106-099, Mrk 335, Ark 564, and H 1934–063, the two profiles are rather well separated (see also Fig. 4). Therefore, it seems more likely that whereas the flux of Fe II 1.0491+1.0502  $\mu$ m is overpredicted by theory, the flux of Fe II 1.0174  $\mu m$  is underpredicted, and this by a similar factor of  $\sim 2$ . This is possible, if, e.g., the oscillator strengths used by Sigut & Pradhan (2003) for these two lines were in error. The Fe II 1.0491+1.0502  $\mu$ m blend is dominated by emission from the Fe II 1.0502  $\mu$ m line, and this line and Fe II 1.0174  $\mu m$  originate from the same upper level. Therefore, the population of this level seems to have been calculated correctly, but not the depopulation statistics. Alternatively, their computations might have to take into account the importance of collisional transitions among highly excited levels populated by  $Ly\alpha$  fluorescence, particularly pseudometastable levels, as suggested by Bautista et al. (2004).

Near-IR Fe II emission line measurements have been published so far for only six AGN. Rudy et al. (2000) and Rudy et al. (2001) find for the sources I Zw 1 and Mrk 478 values of -0.31and -0.37, respectively, for the logarithmic ratio between the Fe II 1.1126  $\mu m$  and Fe II 1.0502  $\mu m$ emission lines, similar to our mean, but they do not measure the Fe II 1.0174  $\mu$ m emission line flux. However, they call attention to the finding of Rudy et al. (1991) who measured in the emission-line star Lk H $\alpha$  101 the Fe II 1.0174  $\mu$ m flux to be stronger than predicted. The sample of Rodríguez-Ardila et al. (2002a) has 3/4 objects in common with our sample, namely, Mrk 335, Ark 564, and H 1934–063. For these we calculated based on the values given in their Table 2 averages of  $-0.47 \pm 0.04$ ,  $-0.40 \pm 0.06$ , and  $-0.06 \pm 0.11$ for the ratios log Fe II 1.0174  $\mu$ m/1.0502  $\mu$ m, log Fe II 1.1126  $\mu m/1.0502 \mu m$ , and log Fe II 1.0174  $\mu m/1.1126~\mu m,$  respectively, which are similar to our results.

## 5.4.2. The Iron Emitting Region

Understanding where and how Fe II emission is produced in AGN is important for at least two reasons. Firstly, since the Fe II atom has a complex structure, it emits through a large number of multiplets, thus acting as one of the main coolants of the BELR (Wills et al. 1985). Secondly, studies of Fe II abundance changes in AGN over cosmic time can give important clues regarding the chemical evolution of the Universe (Hamann & Ferland 1999).

The excitation mechanisms believed to produce Fe II most efficiently are  $Ly\alpha$  fluorescence and collisional excitation. In particular,  $Ly\alpha$  fluorescence is the process invoked for the production of the near-IR Fe II emission lines. In the previous subsection we concluded that the theoretical predictions of Sigut & Pradhan (2003) are generally consistent with our observations, which suggests that  $Ly\alpha$  fluorescence is indeed the dominant process. In this case then we also expect the profiles of the near-IR Fe II emission lines to be similar to those of hydrogen.

In Fig. 16 we compare the isolated profiles of the three Fe II emission lines  $\lambda 9956 + 9998$  (cyan),  $1.0491+1.0502 \ \mu m$  (blue), and  $1.1126 \ \mu m$  (red) to those of the hydrogen emission lines  $Pa\alpha$  and  $Pa\beta$  (black). About half of our sources are relatively weak iron emitters and, therefore, their Fe II profiles are rather noisy. However, for the strongest iron emitters Fig. 16 clearly shows that the Fe II and hydrogen emitting regions are, as expected, cospatial. This result is similar to that obtained by Boroson & Green (1992) based on comparisons of measured  $H\beta$  widths to modeled Fe II widths. Therefore, in the absence of near-IR spectra from which to measure the widths of the resolved Fe II emission lines, one can use the widths of available hydrogen emission lines instead in order to broaden suitable Fe II templates, as is already common practice (e.g., Marziani et al. 1996).

## 5.4.3. Unidentified Emission Lines

For six features we could not find a suitable identification using the Fe II emission line list

of Sigut & Pradhan (2003). However, comparisons of their profiles to those of the two near-IR iron emission lines Fe II 1.0491+1.0502  $\mu$ m and Fe II 1.1126  $\mu$ m, which are relatively strong and observed unblended, show that they are most likely so far unidentified iron emission lines. This interpretation is strengthened by the fact that the unidentified features are convincingly detected only in those eight sources that are amongst the strongest iron emitters in our sample, namely, PDS 456, 3C 273, HE 1228+013, PG 0844+349, Mrk 817, Ark 564, Mrk 79, and H 1934-063.

In Table 10 we list the rest frame wavelengths and observed fluxes of these unidentified near-IR emission lines. The given values, however, should be taken only as approximations. Although we measured the rest wavelength in that source where the feature appeared the narrowest, emission lines of AGN are often red- or blue-shifted relative to the system velocity. The measured flux, on the other hand, is overestimated, if the unidentified feature is in fact a blend of several emission lines.

In Fig. 17, left panel, we show the feature at 7161 Å. It is seen in PDS 456, but not in 3C 273, which is the only other of the above listed sources for which this spectral range is covered. The blends  $\lambda 7875 + 7896$  and  $\lambda 10703 + 10736$  are labeled in Figs. 14 and 3, respectively. In Fig. 17, right panel, we show the three unidentified features at 16890 Å, 16925 Å, and 17004 Å, which are most clearly observed in PDS 456, Ark 564, H 1934–063, and Mrk 79. These features are not convincingly detected in 3C 273, and the spectrum of HE 1228+013 does not cover them. We note that the features at 16925 Å and 17004 Å in PDS 456 were observed also by Simpson et al. (1999).

We thank Perry Berlind and Mike Calkins for the FAST observations and Susan Tokarz for the reduction of these data. We thank Richard Binzel for allowing us to use his IRTF remote observing set-up at MIT. H.L. thanks St. John's College, Oxford, for its hospitality during the last months of this work. H.L. acknowledges financial support from the Deutsche Akademie der Naturforscher Leopoldina grant number BMBF-LPD 9901/8-99. B.M.P. and M.C.B. are grateful for support by the National Science Foundation through grants AST-0205964 and AST-0604066 to the Ohio State University. M.C.B. is supported by a National Science Foundation Graduate Fellowship. M.K. is a member of the Chandra X-ray Center, which is operated by the Smithsonian Astrophysical Observatory under NASA Contract NAS8-03060. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics Space Administration.

TABLE 5—Continued

NOTE.—Columns: (1) object name; (2) continuum flux at the line's vacuum rest wavelength; (3) flux and (4) FWHM of the broad component (uncorrected for instrumental broadening). Note that the latter is omitted if the line was measured using the Pa $\alpha$  or Pa $\beta$  template.; (5) shift of the broad component's center relative to the expected vacuum rest wavelength. Note that we give only shifts corresponding to more than two pixels on the detector (for SpeX spectra > 320 km s<sup>-1</sup> and for FAST spectra > 270 km s<sup>-1</sup>).; (6) type of subtracted narrow component, where i: inflected, and e: estimated (see Section 4.3); (7) flux and (8) FWHM (uncorrected for instrumental broadening) of the narrow component.

Fig. 1.— IRTF SpeX near-infrared spectrum of PDS 456 shown as observed flux versus rest frame wavelength. Identified emission lines are marked by dotted lines and labeled: black, permitted transitions; green, permitted Fe II multiplets (not labeled); red, forbidden transitions; cyan, forbidden Fe transitions with only those higher than [Fe II] labeled. [*The spectral plots for all sources are available in colour in the electronic edition of the journal. The spectra used to create these plots are available for download as a tar-file.*]

Fig. 2.— IRTF SpeX profiles of the broad emission lines  $Pa\alpha$  (red) and  $Pa\beta$  (black) in velocity space relative to the expected rest frame wavelength (thick lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted blends and narrow components are also shown (thin lines). [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 3.— IRTF SpeX profiles of the emission line blend Pa $\gamma$ , He I 1.0830  $\mu$ m, O I 1.1287  $\mu$ m, Fe II 1.0502  $\mu$ m, Fe II 1.0863  $\mu$ m, and Fe II 1.1126  $\mu$ m (blue, thick lines) compared to the profiles of Pa $\alpha$  and Pa $\beta$  (black). Profiles are shown in velocity space relative to the expected rest frame wavelength indicated by the vertical dotted lines (black for the Paschen lines, blue for He I, O I and Fe II, magenta for the unidentified feature). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The isolated Fe II profiles (magenta) are also shown. [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 4.— IRTF SpeX profiles of the emission line blend  $Pa\delta$ , He II 1.0124  $\mu$ m, Fe II  $\lambda$ 9812, Fe II  $\lambda$ 9956+9998, Fe II 1.0132  $\mu$ m, and Fe II 1.0174  $\mu$ m (cyan, thick lines) compared to the profiles of  $Pa\alpha$  and  $Pa\beta$  (black). Profiles are shown in velocity space relative to the expected rest frame wavelength indicated by the vertical dotted lines (black for the Paschen lines, cyan for Fe II and He II). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted narrow emission line blends (cyan, thin lines) and the isolated Fe II and He II profiles (magenta) are also shown. [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 5.— IRTF SpeX profiles of the emission line blend Pa $\epsilon$ , [S III]  $\lambda$ 9531, Fe II  $\lambda$ 9407, and Fe II  $\lambda$ 9573 (green, thick lines) compared to the profiles of Pa $\alpha$  and Pa $\beta$  (black). Profiles are shown in velocity space relative to the expected rest frame wavelength indicated by the vertical dotted lines (black for the Paschen lines, green for Fe II and [S III]). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The isolated Fe II profiles (magenta) are also shown. [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 6.— IRTF SpeX profiles of the broad emission line  $Br\gamma$  (red) compared to the profiles of  $Pa\alpha$  and  $Pa\beta$  (black) in velocity space relative to the expected rest frame wavelength (thick lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted blends and narrow components are also shown (thin lines). [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 7.— The full width at half maximum (FWHM) of the broad and narrow *inflected* components (upper right and lower left symbols, respectively) of Pa $\beta$  vs. Pa $\alpha$  (filled circles), H $\alpha$  (open triangles), and H $\beta$  (open squares). The compared emission lines have similar widths (solid line) within the error range given by the spectral resolution (dotted lines). However, in several sources the broad Pa $\alpha$  component suffers slightly from atmospheric absorption, and there is a trend for the H $\beta$  broad component to be wider than that of Pa $\beta$ . The latter effect is most likely due to the presence of the H $\beta$  "red shelf".

Fig. 8.— Upper panel: The ratio between the full width at half maximum (FWHM) of the narrow and broad components versus their flux ratios for the cases where the narrow component was inflected (filled circles) and estimated (open circles). Included are the emission lines  $Pa\beta$ ,  $H\alpha$  and  $H\beta$ . Lower panel: A histogram of the flux ratios between the narrow and broad components plotted in the upper panel.

Fig. 9.— Narrow component emission line fluxes compared to expectations from Case B recombination (for a temperature of T = 15000 K and an electron density of  $n_e = 10^4$  cm<sup>-3</sup>). From bottom to top the dust extinction assumed was  $A_V = 0, 1$  and 2 mag. The measurement points and the Case B solid lines were normalized to the flux of Pa $\beta$ .

Fig. 10.— Profiles of the broad emission lines He I  $\lambda$ 5876 (black) and He I 1.0830  $\mu$ m (magenta) in velocity space relative to the expected rest frame wavelength (thick lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted blends and narrow components are also shown (thin lines).

Fig. 11.— The full width at half maximum (FWHM) of the broad and narrow *inflected* components (upper right and lower left symbols, respectively) of He I  $\lambda$ 5876 and He I 1.0830  $\mu$ m vs. the hydrogen emission lines Pa $\beta$ , H $\alpha$ , and H $\beta$  (filled circles, open triangles, and open squares, respectively). Emission lines are considered to have similar widths (solid line) if they lie within the error range given by the spectral resolution (dotted lines).

Fig. 12.— IRTF SpeX profiles of the broad emission lines O I  $\lambda$ 8446 (magenta) and O I 1.1287  $\mu$ m (blue) compared to the profiles of Pa $\alpha$  and Pa $\beta$  (black) in velocity space relative to the expected rest frame wavelength (thick lines). The O I  $\lambda$ 8446 emission line blends with the IR Fe II 'hump', Ca II triplet, Pa14, Pa13, and Pa12 (magenta vertical dotted lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted narrow components and blends of narrow emission lines are also shown (thin lines). [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 13.— Lower panel: The distribution of the photon flux ratios between the O I 1.1287  $\mu$  and O I  $\lambda$ 8446 emission lines for the broad components. Upper panel: The photon flux ratios between the broad components of the O I 1.1287  $\mu$  and O I  $\lambda$ 8446 emission lines vs. those of the narrow components.

 $f_{\lambda}$  (normalized)

relative velocity [km s<sup>-1</sup>]

Fig. 14.— IRTF SpeX profiles of the broad emission lines O I  $\lambda$ 7774 (magenta) and O I 1.1287  $\mu$ m (blue) in velocity space relative to the expected rest frame wavelength (thick lines). The O I  $\lambda$ 7774 emission line blends with Fe II  $\lambda$ 7712 and an unidentified feature (magenta vertical dotted lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The narrow components of O I 1.1287  $\mu$ m are also shown (blue thin lines).

Fig. 15.— IRTF SpeX profiles of the broad emission lines O I 1.3165  $\mu$ m (magenta) and O I 1.1287  $\mu$ m (blue) in velocity space relative to the expected rest frame wavelength (thick lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted narrow components of O I 1.1287  $\mu$ m are also shown (blue thin lines).

Fig. 16.— IRTF SpeX profiles of the iron emission lines Fe II 9956 + 9998 (cyan), Fe II 1.0491+1.0502  $\mu$ m (blue), and Fe II 1.1126  $\mu$ m (red) compared to the profiles of Pa $\alpha$  and Pa $\beta$  (black) in velocity space relative to the expected rest frame wavelength (thick lines). The profiles have been continuum-subtracted and normalized to the same peak intensity (of the broad component). The subtracted narrow components of the Paschen lines are also shown (thin lines). [*The spectral plots for all sources are available in colour in the electronic edition of the journal.*]

Fig. 17.— IRTF SpeX profiles of the unidentified emission features at 7161 Å (left panel) and at 16890 Å, 16925 Å, and 17004 Å (right panel).
