The Serpens cloud has received considerable attention in the last years, Abstract. in particular the small region known as the Serpens cloud core where a plethora of star formation related phenomena are found. This review summarizes our current observational knowledge of the cloud, with emphasis on the core. Recent results are converging to a distance for the cloud of $\sim 230 \pm 20$ pc, an issue which has been controversial over the years. We present the gas and dust properties of the cloud core and describe its structure and appearance at different wavelengths. The core contains a dense, very young, low mass stellar cluster with more than 300 objects in all evolutionary phases, from collapsing gaseous condensations to pre-main sequence stars. We describe the behaviour and spatial distribution of the different stellar populations (mm cores, Classes 0, I and II sources). The spatial concentration and the fraction number of Class 0/Class I/Class II sources is considerably larger in the Serpens core than in any other low mass star formation region, e.g. Taurus, Ophiuchus or Chamaeleon, as also stated in different works. Appropriate references for coordinates and fluxes of all Serpens objects are given. However, we provide for the first time a unified list of all near-IR sources which have up to now been identified as members of the Serpens core cluster; this list includes some members identified in this review. A cross-reference table of the near-IR objects with optical, mid-IR, submillimeter, radio continuum and X-ray surces is also provided. A simple analysis has allowed us to identify a sample of ~ 60 brown dwarf candidates among the 252 near-IR objects; some of them show near-IR excesses and, therefore, they constitute an attractive sample to study very young substellar objects. The review also refers to the outflows associated with the young sources. A section is dedicated to the relatively small amount of works carried out towards Serpens regions outside the core. In particular, we refer to ISO and to recent Spitzer data. These results reveal new centers of active star formation in the Serpens cloud and the presence of new young clusters, which deserve follow-up observations and studies to determine their characteristics and nature in detail. Finally, we give a short, non-exhaustive list of individually interesting Serpens objects.

1. Introduction

A considerable amount of work has been dedicated to the region known as the Serpens dark cloud (Galactic coordinates $l^{II} = 32^{\circ}$, $b^{II} = 5^{\circ}$) since it was recognized by Strom

et al. (1974) as a site of active star formation. The cloud extends several degrees around the young variable star VV Ser and forms part of the large local dark cloud complex called the Aquila Rift, which has been extensively mapped in several molecular line surveys (e.g. Dame & Thaddeus 1985, Dame et al. 1987, 2001, see the chapter by Prato et al.). A large scale extinction map has been presented by Cambrésy (1999) and Dobashi et al. (2005). Serpens is seen on optical images as a large area irregularly obscured by large amounts of dust; Fig. 1 reproduces the DSS *R* band photograph of a region $2^{\circ} \times 2^{\circ}$ in size. Several reflection nebulosities are distinguished, the most prominent of which are S 68 (Sharpless 1959, see also Dorschner & Gürtler 1963, van den Bergh 1966, Bernes 1977), illuminated by HD 170634, and a very red bipolar, reflection nebulosity, usually referred to as the Serpens object, the Serpens nebula, or the Serpens reflection nebulosity (SRN), illuminated by the pre-main sequence star SVS 2 (Strom et al. 1974, 1976, Worden & Grasdalen 1974, King et al. 1983, Warren-Smith et al. 1987, Gómez de Castro et al. 1988). In this work, we will refer to that nebulosity as SRN.

Relatively little work has been devoted to studying the large scale properties of the Serpens cloud, having been mainly concentrated around SRN and VV Ser, which are located towards the North of the large extinction map analysed by Cambrésy (1999). Cohen & Kuhi (1979) and Chavarría et al. (1988) conducted optical studies of the region and identified several H α emission line stars and some B, A and later spectral type stars associated with reflection nebulae. Loren et al. (1979) carried out a 2.6 mm line CO map over an area of ~ 300 square arc minutes and detected a dense H₂CO core of core show large scale extended far-IR emission and several point-like sources associated with some visible and invisible stars (Zhang et al. 1988b). The cloud core with several point-like sources embedded in extended emission shows up very prominently in all IRAS bands (Zhang et al. 1988a). More recently Schnee et al. (2005) have analysed recalibrated IRAS data to estimate dust column densities and dust temperatures. Assuming a distance of 700 pc to Serpens, Zhang et al. (1988b) estimate a total far-IR luminosity from the whole Serpens cloud of $\sim 3200~L_{\odot}$ and the dust mass inferred from the extended emission is $\sim 290 \text{ M}_{\odot}$. The actual distance to Serpens is most likely significantly smaller than the value assumed by Zhang et al. and, therefore, the luminosity and dust emitting mass should be corrected. In fact, the distance to Serpens has been a controversial point over the years, with suggested figures in the range from \sim 200 pc to \sim 700 pc. At present, a smaller distance value is commonly accepted. We analyse this issue in the next section.

After the discovery of the cloud core, observational efforts have concentrated in that area. The reason is the extreme richness in star formation activity found in the core, with all relevant phenomena taking place in a small region of just few arc minutes in diameter: pre-protostellar gaseous condensations; pre-stellar dust condensations; Class 0, Class I and Class II objects; different evidences of infalling gas; disks; molecular and atomic outflows and jets; clustering of young stellar objects (YSOs) in different evolutionary stages, etc. The Serpens core indeed represents a unique laboratory for studies of star formation processes and observable phenomena, and the inter-relation between them.

A first review article of the most relevant observational results up to ~ 1991 was written by us (Eiroa 1991). In this new contribution we concentrate mainly on results achieved during the last 15 years. We review observations related to the Serpens core

Figure 1. The Serpens molecular cloud as seen on the DSS *R*-band plates. Large scale irregular dark structures are clearly seen. The reflection nebulosities S 68 and SRN are indicated, as well as the position of VV Ser and of the H α emission line stars Ser G3/G6. Field size is $2^{\circ} \times 2^{\circ}$. Field centre: $\alpha_{2000} = 18^{h} 30^{m}$, $\delta_{2000} = 0^{\circ} 50'$. North to the top, East to the left. The image has been downloaded from the Canadian Astronomy Data Center (http://cadcwww.dao.nrc.ca/dss).

in particular, since this part of the cloud has continued to be the focus of the large observational effort carried out by many different research groups. Nonetheless, a section is also dedicated to recent work carried out in Serpens areas outside the core. The new results confirm and emphasize the role of Serpens as a key region for detailed studies of star formation and the understanding of all related phenomena.

2. The Distance of Serpens

The distance to Serpens has been a matter of controversy over the years. Until 1996 the distance to the Serpens molecular cloud was estimated from a handful of stars associated with reflection nebulae. Mainly through disagreements on spectral type and luminosity classes, the different distances obtained were the subject of much debate

(see Straižys et al. 1996 for details). Racine (1968) gave a first distance estimate (440 pc) based on the star HD170634 which he classified as a B7 V star. Strom et al. (1974) found the same distance to the same star independently from their IR data classifying it as an A0 (V:). Chavarria-K et al. (1988) obtained spectroscopy, $uvby\beta$ and JHKLM photometry for this one (A1 V) and three more stars: SAO 123590 (B4 V), SAO 123595 (B3 V), and SAO 123661 (B3), and obtained a distance of 245 ± 30 pc. Zhang et al. (1988), however, estimated 700 pc (with a large scatter) for three of the above four stars, having assigned luminosity class III (citing an unpublished reference) and found support from kinematics (CO and NH₃ lines). De Lara & Chavarria (1989) rechecked their spectra and confirmed the main sequence nature of the above sources, and moreover estimated d = 296 ± 34 pc based on 7 stars. Excluding HD170634 (claiming it to be a shell star) and adding two other reflection nebulae stars [CDF88] 1 and [CDF88] 7 de Lara et al. (1991) arrived at $d = 311 \pm 38$ pc and a mean total to selective extinction ratio $R = A_V/E(B - V) = 3.3 \pm 0.3$. This estimate was in use until Straižys et al. (1996) revised the distance using a completely independent method. They surveyed photometrically most stars down to magnitude 13 in a 6.5 square degrees region in the Vilnius photometric system of seven narrow bands (UPXYZVS). Spectral types and absolute magnitudes were found for 105 stars - of which 18 belong to the cloud. This sample included the earlier used stars, and it was noted that both SAO 123590 and SAO 123661 are close binaries. Applying the total to selective extinction ratio found by de Lara et al. (1991) for the stars in or behind the molecular cloud they found a distance of 259 ± 37 pc. This estimate was also supported by Festin (1998) who made use of the cloud as a screen when searching for foreground dwarfs in a 0.15 square degree area about 4 degrees to the South of the Cloud Core. Straižys et al. (2003) then investigated 473 stars across a larger area (5 \times 10 degrees) and found the front edge of the clouds in this area to be at 225 ± 55 pc and the cloud complex possibly 80 pc deep. These are believed to be part of the Aquila Rift large dark cloud complex, located at a distance of 200 ± 100 pc (Dame & Thaddeus 1985). Using 2MASS data Knude (2005) recently has estimated extinction and distances for 754 stars in the same area as that used by Straizys et al. (1996) and find a distance to the Serpens cloud of 210 ± 12 pc, estimating the extinction jump by using several physical indicators, among these the A_V vs. σ_{A_V} variation seen in MHD simulations. Thus, all recent and, likely, more reliable results are converging to a distance $\sim 230 \pm 20$ pc for the Serpens cloud.

3. An Overall Description of the Serpens Core

The early observations of Loren et al. (1979) found a nearly circular, high density H_2CO core approximately centred in SRN, while maps of the far-IR emission, NH₃ and other molecules showed a more elongated structure extending in a North-West/South-East direction with two broad peaks: a Southeastern (SE) clump with a broad peak close to SRN, extending towards the South from this object, and a second Northwestern (NW) clump peaking at a position close to the source FIRS 1, the most prominent object embedded in the Serpens core (e.g. Ho & Barrett 1980, Little et al. 1980, Nordh et al. 1982, Ungerechts & Güsten 1984, Harvey et al. 1984, Takano 1986, Zhang et al. 1988a, Torrelles et al. 1989). Estimated 60/100 μ m colour temperatures in the range ~ 20 - 30 K are similar to the kinematic gas temperatures found by Loren et al. (1979). The division of the internal structure of the gas and dust into two main subclouds or clumps has been confirmed by recent studies, including HIRES-IRAS images (Hurt & Barsony,

Figure 2. IRAS-CPC 100 μ m map of the Serpens core (taken from Zhang et al., 1988a). The dashed region approximately represents the position of SRN.

Figure 3. Integrated $C^{18}O J=1-0$ emission from the Serpens core (taken from Mc-Mullin et al., 2000). Black symbols represent some young embedded objects.

1996), submm/mm continuum maps (e.g. Casali et al. 1993, Davis et al. 1999, Kaas et al. 2004), and maps of several molecular lines coming from different isotopical species and tracing gas with different column densities, like CO. 13 CO, C 18 O, H₂CO, HCO⁺. N_2H^+ , CS, HCN, etc. (e.g. McMullin et al. 1994, 2000, White et al. 1995, Testi et al., 2000). Fig. 2 and 3 show the IRAS and $C^{18}O$ maps of the Serpens core respectively (Zhang et al. 1988a, and McMullin et al. 2000), where the extended core emission and the two broad SE and NW clumps of dust and gas show up very clearly. Davis et al. (1999) find some cavity-like submm structures (see Fig. 10); in particular, the most remarkable one is found between the NW and SE clumps (see also Fig. 11 in Kaas et al, 2004). In addition, small-scale gas and dust structures within each individual clump are seen in high resolution maps (e.g. Fig. 3). The complexity of the cloud core reflects density and temperature enhancements and the effects of the embedded stellar/protostellar population; Davis et al. (1999) suggest that the cavity-like submm structures may have been shaped by outflows from young objects in the core. Both NW and SE core clumps behave kinematically different (Testi et al. 2000); in this respect, it is interesting to note that the characteristics of the embedded YSO population within each individual clump show some differences, at least when the evolution of the sources is considered (see Sect. 5).

While there is an overall agreement between the results found by different groups concerning the structure, temperature, density and gas kinematics, a detailed comparison shows some points of disagreement. Those could be due to differences in beam sizes and/or the parameters and methods used to analyze the data. It would be interesting to clarify these discrepancies by carrying out new specific observations and analysis. Many molecules show self-absorbed line profiles in different core positions (see Loren & Wootten 1980 and Loren et al. 1981, for the earliest works), in particular close to embedded protostellar objects, and their kinematical behaviour suggests infall motions; furthermore, the SE and NW clumps seem to be undergoing global, large-scale (~ 0.2 pc) infalling motions (Williams & Myers 2000, Olmi & Testi 2002). The latter authors point out that the data are in qualitative agreement with the theoretical expectation of a slow contraction followed by rapid star formation in localized high density regions. A velocity gradient from East to West of $\sim 1 - 2 \text{ km s}^{-1} \text{ pc}^{-1}$ is observed in the most recent $C^{18}O$ maps (McMullin et al. 2000, Olmi & Testi 2002), supporting the early NH₃ velocity gradient claimed by Ungerechts & Güsten (1984); in apparent contradiction with previous $C^{18}O$ results (White et al. 1995), which did not find any evidence for such velocity gradient. Depending on the molecules and transition lines, temperatures are found in the range from ~ 15 K in the more diffuse parts of the core, up to ~ 50 K in condensations close to embedded young objects. The mean average temperature across the core is ~ 25 - 30 K (McMullin et al. 2000). These gas temperatures are similar to dust temperatures found across the cloud core and in the dust surrounding the embedded YSOs (e.g. Zhang et al. 1988a, Casali et al. 1993, Hurt & Barsony 1996, Larsson et al. 2000). Gas particle densities $n(H_2)$ are found in the range from $\sim 10^4$ cm⁻³ to values larger than 10^6 cm⁻³. Mass estimates based on the C¹⁸O (J = 1 - 0) transition line give values of ~ 250 - 300 M_{\odot} (McMullin et al. 2000, Olmi & Testi, 2002), while the C¹⁸O (J = 2 – 1) line gives \sim 1450 M_{\odot} (White et al. 1995). McMullin et al. (2000) argue that the estimate made on the J = 1 - 0 line is better than that based on J = 2 - 1 transition because the first is less sensitive to density and has a factor of 2-3 less opacity. Even allowing for larger uncertainties (but unrelated to the cloud distance), the difference seems to be significant and it is an open issue to be resolved. We remark that the cloud mass is a key parameter in evaluating the star formation efficiency and the global star formation properties of the cloud.

The near-IR study of the dust properties by Eiroa & Hodapp (1989) showed that water ice absorption is widespread in the Serpens molecular cloud. They also detected solid CO absorption, further studied by Chiar et al. (1994), finding an unusually high ratio of CO to H₂O ice absorption. Ice features in the near- and mid-IR using Spitzer mid-IR spectroscopy and ground-based facilities have recently been studied by Knez et al. (2005), Pontoppidan et al. (2008), Boogert et al. (2008), and Öberg et al. (2008). The structure of the CO ice absorption has been studied by Pontoppidan et al. (2003b). Pontoppidan et al. (2003a) detected methanol in the wings of the 3.1 μ m water ice feature in the lines of sight to SVS 4-2 and SVS 4-9, the first detection of the molecule toward low-luminosity young stars. Pontoppidan et al. (2004) subsequently extended the L-band observations to the whole SVS 4 stellar complex (Eiroa & Casali 1989). Big jumps in calculated extinction and water ice absorption were found from source to source, even over projected distances of only 10 arcseconds. Thus, some of the sources probably lie behind and some in front of an obscuring cloud, as well as being embedded in the envelope of the Class 0 SMM 4 object (Casali et al. 1993). The water ice optical depth-to-extinction ratio was used to infer abundances of 9×10^{-5} relative to H_2 , corresponding to water ice mantle volumes around 40% of those in Taurus. In addition, it generally seems likely that methanol, with an abundance around 20% of that of water, is formed through grain-surface chemistry in pre-stellar low density conditions and cold temperatures (T < 20K), rather than in the gas phase. But the variation (detection) in abundance from source to source is puzzling and may indicate that the methanol formation is a transient phenomenon.

The ISOCAM CVF study of Alexander et al. (2003) extended mid-IR spectroscopy to 20 low-luminosity sources in Serpens. SVS 2 (the illuminating source of SRN) clearly shows the silicate feature in emission - see also Kessler-Silacci et al. (2006) for the 5-34 μ m Spitzer spectrum. 12 other sources show deep absorption features. Water ice absorption at 6 μ m is strong relative to silicate optical depth, compared to other regions. On the other hand, CO₂ absorption at 15.2 μ m is weak in Serpens compared to silicate depth. The study shows clear differences in grain chemistry from region to region, perhaps related to age or other factors. Ciardi et al. (2005) have recently resolved the silicate feature in the binary SVS 20 and find that the mid-IR spectrum of each YSO is dominated by amorphous silicate emission with some crystalline silicates. Differences in the dust properties toward each component of the binary might be explained by their different luminosities.

4. The Embedded Population

Data obtained during the last 15 years in the infrared, submillimeter, millimeter, radio continuum and X-rays spectral domains reveal a dense, rich, young, low mass stellar cluster embedded in the Serpens core. More than 300 objects in all evolutionary phases, from collapsing gaseous condensations to Class II/III pre-main sequence (PMS) stars coexist within the $\sim 0.5 - 0.7$ pc Serpens central core. Fig. 4 shows an impressive colour composite from images taken through the near-IR bands *J*, *H* and *K* of the Serpens core. Individual images have 1 minute exposure each and were recently obtained during first light of the HAWK-I near-IR camera attached on UT4 of ESO's Very

Figure 4. The Serpens core and the embedded near-IR cluster seen in a J, H, and K composite image taken by the ESO's near-IR imager HAWK-I attached on UT4 of the VLT. The central object surrounded by an elliptical nebulous ring with spiral-like arms is the young binary SVS 20. At the top, the pre-main sequence star SVS 2 and its edge-on disk are clearly distinguished. The bottom of the image shows the SVS 4 sub-cluster. In addition, nebulous objects, H_2 emission knots, a widespread reflection nebulosity, and many YSOs are clearly seen.

Large Telescope. In the following, we review how the cluster appears at the different wavelength ranges.

4.1. The Near- and Mid-IR Cluster: Tracing the Class I, Flat-spectrum and Class II Object Population

Because of severe extinction, sensitive IR observations are required to sample the stellar population embedded in the Serpens core. Eiroa & Casali (1992), Horrobin et al. (1997), Sogawa et al. (1997), Giovannetti et al. (1998), Kaas (1999), Hodapp et al.

Figure 5. K-image of the Serpens core (size $\sim 8' \times 6'$). Some of the embedded objects are identified. Figure taken from Kaas (1999).

(1996), Hodapp (1999), have used near-IR cameras to study the young stellar population embedded in the core, within a region $\sim 10'$ approximately centred in SRN. The achieved sensitivity is $K \sim 15 - 16.5$ mag. The images reveal a relatively large diffuse reflection nebula, about $2' \times 3'$ in size, in the center of the core, extending from the optical SRN towards the South up to the position of the SVS 4 complex (Strom et al. 1976, Eiroa & Casali 1989), some nebulous objects and knots, and a large number of red stellar objects, which are not visible in optical wavelengths (even up to 0.9 μ m, e.g. Gómez de Castro et al. 1987, Giovannetti et al. 1998). A variety of criteria has been used to identify near-IR embedded objects, e.g. near-IR excesses, variability, association with nebulosity. Fig. 5 reproduces the K-band image from Kaas (1999) where many YSOs are indicated. Table 1 gives names, J2000 equatorial coordinates, and JHK magnitudes of the (up to now) identified near-IR (JHK) YSOs. The table includes objects from the aforementioned works, as well as from other references. Further, by compiling the table, we have observed that some objects show a non-negligible brightness difference ($\Delta K > 0.5$) between different studies; these objects most likely belong to the young cluster and are therefore included in the table. A few of the objects listed in the table are located outside the Serpens central core; we have chosen to

Figure 6. *K* histogram of the near-IR Serpens objects.

include them for completeness. Klotz et al. (2004) have recently conducted a deeper (K completeness limit ~ 19 mag.) near-IR survey in a region $5' \times 10'$ in size. This work differs from the others because the observed area lies towards the SW from SRN, in a region where the obscuration is obviously smaller than in the core center (see Fig. 1 and 6 of Klotz et al. 2004). Klotz et al. suggest 14 further candidates as Serpens members, from which three may be brown dwarfs. These objects are also included in Table 1. Using Spitzer and Chandra data Winston et al. (2007) have identified more than 100 YSOs in Serpens; some of them have 2MASS counterparts. These 2MASS objects are included in Table 1 although some of them are also located outside the central gaseous/dusty core. Thus, the total number of identified near-IR Serpens object candidates in the central core or close to it is 252. The near-IR sources are distributed across the whole Serpens core, although there is a clear concentration towards the SE clump, either embedded in the near-IR nebula or relatively close to it (see Sect. 5).

Many of the Serpens objects appear to be binaries or forming part of small subclusters. The SVS 4 complex is the outstanding case, where ~ 10 objects appear to form a compact group, embedded in a common faint nebulosity spread over a field $\sim 35'' \times 35''$ in size. SVS 20 is an example of a binary with interesting properties (see Sect. 8 for a more detailed description of SVS 4 and SVS 20). Haisch et al. (2002, 2004) and Duchêne et al. (2007) have found a multiplicity fraction of $\sim 35\%$ in a limited sample of Serpens Class I/flat-spectrum sources.

Fig. 6 provides the histogram of the apparent K magnitude of the Serpens objects. The number of sources increases up to the sensitivity limit of the near-IR surveys, supporting the suggestion of Kaas (1999), and contradicting the presence of a turnover in the luminosity, as suggested earlier by Eiroa & Casali (1992) and Giovannetti et al. (1998). The histogram in Fig. 6 does not reflect the true luminosity and mass functions of the Serpens near-IR cluster since magnitudes are not corrected for extinction, but it

Figure 7. Left: Colour-magnitude diagrams of the Serpens objects. The continuous line represents main-sequence stars, while dashed-dotted lines are 1 Myr (blue colour) and 5 Myr (red colour) isochrones from Baraffe et al. (2003). Dashed lines represent reddening vectors, $A_V = 20$ mag. *K*-magnitudes have been scaled to a distance of 230 pc. Right: Colour-colour diagram of the Serpens objects. The continuous line represents main-sequence and giant stars while dashed lines are reddening vectors. Squares (red colour) in both diagrams are brown dwarf candidates (see text); the confirmed Serpens brown dwarf is represented by the filled square (yellow colour).

does show that a non-negligible number of Serpens objects are intrinsically very faint, and consequently very low-mass YSOs (see below and Sect. 6). Fig. 7 reproduces the colour-magnitude (H - K, K) and colour-colour (H - K, J - H) diagrams of the sources. Some objects are located in an "anomalous" position towards the left of the main-sequence line. This is likely due to source variability (photometry was not always obtained simultaneously), binarity, and/or scattering which can yield a blueing in H-Kcolour (for the most extreme case, SVS 1, see the comments by Kaas 1999). Many sources present an excess or lie along the reddening line with large extinction values. The colour-magnitude diagram suggests that some of the sources must be reddened, young, very low mass M stars and/or brown dwarfs, since in the colour-magnitude diagrams they are located in the area where substellar objects are expected. These brown dwarf candidates are identified in Table 1. EC 64 (GCNM 57, BD-Ser1) was identified as a young L0-L3 brown dwarf by Lodieu et al. (2002) and two more brown dwarf candidates have been suggested by Klotz et al. (2004). Winston et al. (2007) suggest objects with $m_K > 12.5$ as brown dwarfs candidates. In addition, Kaas et al. (2004) suggest a few brown dwarf candidates among the Serpens objects on the basis of ISO data and the estimated low, bolometric nebulosity $(L_{bol} \leq 0.04 L_{\odot})$.

Near-IR spectra of some objects have been taken by Aspin et al. (1994), Casali & Eiroa (1996a), Preibisch (1999), Hodapp (1999), Doppmann et al. (2005), Covey et al. (2006), Aspin & Greene (2007), Eiroa et al. (2008). Fig. 8 shows some representative K-spectra. The spectra usually show atomic absorption lines, e.g. NaI, CaI, as well as CO absorption bands, which correspond to late K and M spectral types, similar to Classical T Tauri stars. (As noted above, there is a brown dwarf spectroscopically confirmed by Lodieu et al. 2002). In some cases, the atomic and molecular bands appear in emission, most likely due to circumstellar disks; in addition, the spectra of some objects appear to be veiled by dust emission and are flat. The spectroscopic and photometric data suggest that the near-IR is mainly tracing the Class II population of

Figure 8. Near-IR spectra of some Serpens objects, including Class II, flatspectrum and Class I sources (Eiroa & Djupvik, unpublished).

the Serpens cluster. We note, however, that some flat-spectrum and Class I sources are detected in the near-IR (Kaas et al. 2004, Harvey et al. 2007a, Winston et al. 2007, see next paragraph) and show photospheric lines (e.g. Doppmann et al. 2005); even further, near-IR counterparts of very young Class 0 sources have been suggested by Hodapp (1999, see also Eiroa et al., 2005).

Serpens was observed within the ISO central programme in two filters centred at 6.7 and 14 μ m. 0.13 square degrees were covered by three overlapping maps, one centred in the core, a second one towards the West, and a third one towards the South (Kaas et al. 2004). A total of 421 sources were detected, out of which 392 sources were found at 6.7 μ m, 140 at 14 μ m, and 124 at both wavelengths. ISO is particularly useful to detect young sources with no near-IR excess but with a distinct mid-IR excess. On the basis of the spectral index α_{IR}^{7-14} the ISO sources separate into two distinct groups: "red" sources with IR excess (53 objects), which are YSOs surrounded by circumstellar dust, and "blue" sources (71 objects), which likely are field stars, although some of them could be Serpens Class III objects. Using ISO data and near-IR data Kaas et al. (2004) identify 20 Class I and 13 flat-spectrum protostars, and 43 Class II stars (i.e. embedded CTTs) among all the ISO sources. Serpens is one of the star formation regions observed by the c2d Spitzer project (Evans et al. 2003). The Spitzer/IRAC and MIPS observations extend to a large region (Harvey et al. 2006, 2007a, 2007b, see below). The young stellar population of the core, called Cluster A by Harvey and collaborators, is included in the analysis of the whole Serpens cloud by Harvey et al., while Winston et al. (2007) specifically analyze the Spitzer core data, extending their work to a region a bit larger than the dense central core. Fig. 9 shows a three colour, 4.5, 8.0 and 24 μ m Spitzer image of the core (Harvey et al. 2007a). By using Spitzer data, 2MASS, and Chandra observations, Winston et al. (2007) identify 229 Serpens candidate objects, out of which 138 are considered bona fide YSOs: 22 Class 0/I protostars, 16 flat-spectrum sources, 62 Class II stars, 17 transition disk candidates, and 21 Class III sources. The relative number of ISO and Spitzer Class 0/I to Class II sources in Serpens is considerably larger than in similar young clusters, like ρ Oph, Chamaeleon or Taurus; in fact, the number fraction Class I/Class II in the core is almost 10 times higher than 'normal' (Kaas et al. 2004, Schmeja et al. 2005, see Winston et al. 2007 for a comparison with other regions observed in the context of the c2d project), which indicates that the embedded population is extremely young and active.

Spitzer IRS spectra of five Serpens objects (EC 74, EC 82, EC 90, EC 92, and CK 4) have been studied by Lahuis et al. (2007). They detected H_2 S(2) and [NeII] emission towards EC 74, EC 82 and EC 92, indicative of a significant hot gas component in the disks (T > 500 K) and a [NeII] excitation mechanism through X-Rays or EUV.

4.2. The Submillimeter and Millimeter Cluster: Tracing the Class 0 and Prestellar Population

About a dozen of discrete sources embedded in the cloud core have been found by submm observations (Casali et al. 1993, White et al. 1995, Reipurth et al. 1996, Davis et al. 1999, Enoch et al. 2007, Wu et al. 2007). Fig. 10 shows the submm maps at 850 and 450 μ m of the core, after Davis et al. (1999). Several sources - SMM 1, SMM 5, SMM 6, SMM 9, SMM 10 - have been identified with near-IR and ISO/Spitzer sources (Casali et al. 1993, Hodapp 1999, Kaas et al. 2004, Winston et al. 2007) and some of them - SMM 2, SMM 3, SMM 4 - with IRAS and ISO far-IR sources (Hurt &

Figure 10. Submillimeter images of the Serpens core. Figure taken from Davis et al. (1999).

Barsony 1996, Larsson et al. 2000). An analysis of their SEDs shows that they form a cluster of very young, low to intermediate luminosity Class 0 objects (or borderline Class 0/Class I objects), with dust temperatures in the range $\sim 20 - 50 K$ (Casali et al. 1993, McMullin et al. 1994, 2000, Hurt & Barsony 1996, Wolf-Chase et al. 1998, Davis et al. 1999). Some sources have been modelled in terms of a stellar core, an accretion disk and an extended, massive envelope (Hogerheijde et al. 1999, Brown et al. 2000, Larsson et al. 2000). Kinematic infall signatures have been suggested for a number of the submm sources - SMM 2, SMM 3, SMM 4, SMM 9 (Hurt et al. 1996, Gregersen et al. 1997, Mardones et al. 1997, Williams & Myers 2000, Narayanan et al. 2002), although at least in the case of SMM 9 (S 68N) this interpretation is controversial (Wolf-Chase et al. 1998).

Interferometric observations at 3 mm carried out by Testi & Sargent (1998) reveal 32 discrete sources widespread in the cloud core (Fig. 11), and 26 out of 32 are probably protostellar continuum condensations, with masses in the range 0.3 - 5.0 M_{\odot} . The sources are distributed into two groups: the more numerous is associated with the NW core clump and the second one with the SE clump. Seven of the 3 mm sources in the NW clump are also detected by Williams & Myers (2000). These authors also find 8 gaseous (CS and N₂H⁺) condensations in the NW clump, with high peak temperatures and low velocity dispersion, 6 of which without associated continuum sources. These quiescent cores have typical sizes of 5000 AU and display spectra indicative of infalling

motions; they are suggested to be pre-protostellar collapsing cores. A further turbulent, contracting, starless core was also found towards the West of S 68N by Williams & Myers (1999). Recently, SMM 1 has been observed at 1.3 and 3.3 mm with the PdB interferometer (Fuente et al. 2007).

Figure 11. 3 mm continuum image from the Serpens core. The positions of some submm sources and far-IR sources (PS1 and PS2) are indicated. Figure taken from Testi & Sargent (1998).

4.3. Radio Continuum Observations

Very few observations of the core have been made in the centimeter radio continuum (Rodríguez et al. 1980, 1989, Ungerechts & Güsten 1984, Snell & Bally 1986). FIRS 1 is the only source with detailed studies due to its unique radio properties (see Sect. 8). Smith et al. (1999) report several VLA sources in the region around the SVS 4 complex. Recently, Eiroa et al. (2005) have analysed 3.5 cm VLA data of the whole Serpens core. They find 22 radio continuum sources, 16 of which seem to be associated with YSOs. The radio sources are distributed into two groups: one associated with Class 0/Class I sources in the NW clump of the core, and a second one towards the SE clump, where the radio continuum sources are associated with all kind of objects - from Class 0 to Class

II sources. It is likely that the radio emission from the Serpens objects is produced by thermal jets, but the radio emission of some sources in the SE clump likely originates in coronally active PMS stars as suggested by Smith et al. (1999, see also Preibisch 2003, Eiroa et al. 2005). Further observations to estimate radio spectral indexes of the sources as well as their sub-arcsec structure would be very useful to determine the nature of the Serpens radio continuum objects. Recently, Forbrich et al. (2007) have searched for coronal radio emission from EC 95 using VLBI with a non-detection result.

4.4. X-ray Observations

X-ray emission has been studied by Preibisch (1998, 1999, 2003, 2004) using ROSAT and XMM. ROSAT detected very strong X-Ray emission associated with the flatspectrum source EC 95, one of the stars in the SVS 4 group (Sect. 8). XMM observations have detected ~ 50 sources in a field $\approx 30'$, several of them associated with YSOs. Among the X-ray sources, 4 are associated with Class I protostars, two with flat-spectrum sources, and at least 9 with Class II objects. X-ray Class I protostars are among the brighter Serpens Class I objects in the K-band, which could mean that these YSOs have higher bolometric luminosities and/or suffer less extinction than the X-ray undetected Class I objects. The X-ray Class I objects present a strong flare-like variability, with flare frequency a factor two higher than the flare frequency in typical T Tauri stars, although the Class II object EC74 shows a large variability in its X-ray luminosity (a factor of 10). The X-ray emission of Class I protostars is suggested to be due to the magnetic coupling between the protostars and their circumstellar disks. The X-ray emission of Class II objects is normally ascribed to magnetic dynamo processes in the stellar coronae of the PMS stars. We point out that 4 of the X-ray sources have VLA counterparts: the Class I object EC 53, the flat-spectrum source SVS 20, and the Class II sources EC 95 and EC 117.

A deep Chandra X-ray survey has been carried out by Giardino et al. (2007), with the aim to determine whether Class 0 protostars emit X-rays. A total of 85 X-ray sources are detected, none associated with Class 0 objects. The light curves and spectra of 35 YSOs are derived. These authors find a trend of decreasing absorbing column densities from Class I to Class III sources, and some evidence of decreasing

Figure 12. Light curve and spectra with spectral fit of the Class II object Chandra 79 (Giardino et al. 2007).

plasma temperatures. The Chandra source 79 (ISO 393, a Class II source) underwent a large, long duration flare (Fig. 12) for which Giardino et al. (2007) derive a semiloop length $L = 10 - 12R_{\odot}$, and suggest that the long flaring loop could be explained if the flare is due to a magnetic reconnection event of a flux tube linking the star's photosphere with the inner ring of a circumstellar disk. The spectrum of this YSO shows 6.4 keV Fe fluorescent emission compatible with reflection off a circumstellar disk irradiated by the hard X-ray continuum emission of the flare. Using the Chandra data, Winston et al. (2007) find that 60 YSOs have detectable X-ray emission: 9 of the X-ray sources are associated with Class I objects, 8 with flat-spectrum sources, 21 have Class II counterparts, 2 are transition disks. Twenty Class III sources are identified solely by their X-ray emission. Comparing with the relative numbers of Serpens YSOs in each evolutionary class, there appears to be no evidence of a trend in the detection rate of sources by class.

4.5. Outflows and Masers

Low spatial resolution observations by Bally & Lada (1983) detected a very large, $\sim 12' \times 17'$, CO outflow with both blueshifted and redshifted components approximately centred in SRN, which could not be ascribed to a single driven source. Higher resolution CO observations show widespread high velocity gas that extends over the core and resolved, molecular outflows associated with Class 0 and Class I YSOs (White et al. 1995, also Eiroa et al. 1992, Davis et al. 1999). NH₃, SiO, CS, HCO⁺, HCN compact outflows are associated with FIRS 1 (SMM 1), S 68N (SMM 9), SMM 3, SMM 4 and SMM 10 (Torrelles et al. 1992, McMullin et al. 1994, Curiel et al. 1996, Wolf-Chase et al. 1998, Hogerheijde et al. 1999, Williams & Myers 2000). It is interesting to note that some of these sources also show infall signatures (Sect. 4.2).

An H_2 jet with a point-like object (EC 41) at its apex close to the position of FIRS 1/SMM 1 was detected by Eiroa & Casali (1989, see also Rodríguez et al. 1989), although the relationship between the H_2 emission and the Class 0 object was unclear. Later studies (Curiel et al. 1996, Hodapp 1999) show that they more likely are unrelated objects and the H_2 jet is not driven by the Class 0 object which, on the other hand, is powering radio molecular line outflows, and a radio continuum jet (see Sect. 8). H₂ knots and jets widely distributed in the cloud core were detected by Herbst et al (1997, these authors provide equatorial coordinates of many H_2 condensations), Eiroa et al. (1997b) and Caratti o Garatti et al. (2006). Hodapp (1999) studied the proper motions of the jets located in the NW core clump; Fig. 13 shows these results. The H_2 emission has been associated with Class 0, Class I, flat-spectrum and Class II objects - SMM 3, SMM 4, SMM 9, GCNM 53 (ISO 276), EC 37, SVS 20 and EC 105. There is some ambiguity in certain cases, e.g. a jet could be associated with either the Class 0 object SMM 3 or the Class II source EC 105. Spectral imaging in H₂ using ISO-CAM-CVF data of the Serpens core have been presented by Larsson et al. (2002). These authors also present ISO-LWS maps of several forbidden lines in the far-IR.

GGD 29 was proposed as a suspected Herbig-Haro object by Gyulbudaghian et al. (1978), although later observations showed it to be a reflection nebulosity with a young star at its apex (Hartigan & Lada 1985, Warren-Smith et al. 1987). Thus, the first confirmed Herbig-Haro objects in the Serpens molecular cloud, HH 106/107 and HH 108/109, were discovered by Reipurth & Eiroa (1992). HH 106 and HH 107 are located towards the West and North of the central core (see e.g. Fig. 2 by Ziener & Eislöffel 1999). The emission line star ESO H α 279a (IRAS 18296+0116), located between

Figure 13. Proper motion vectors of H_2 emission knots in the NW clump of the Serpens core. Figure after Hodapp (1999).

both HH objects, has been suggested as the exciting source of a large bipolar flow with both HH 106 and HH 107 at its opposite ends (Aspin et al. 1994, Chini et al. 1997). HH 108/109 are located ~ 2.3° SE from the central core and likely are excited by the Class I object HH 108 IRAS/VLA 1, close to the Class 0 object HH 108 MMS (Chini et al. 1997, 2001, Siebenmorgen & Krügel 2000, Reipurth et al. 2004, Connelley et al. 2007). Gómez de Castro (1997) detected spectroscopically an HH condensation 88" eastwards from SVS 2, the exciting source of SRN. In addition, deep CCD H α and [SII] images of the core (Davis et al. 1999) and of a 3.15 square degrees of the large scale cloud (Ziener & Eislöffel 1999) have revealed many HH condensations, most of them concentrated in the core; Ziener & Eislöffel (1999) give equatorial coordinates of 29 HH objects and condensations. Fig. 14 shows some examples of HH objects in the Serpens core. Potential exciting sources of the HH objects have been suggested, e.g. FIRS1/SMM 1, EC 105, EC 92 and EC 117. Finally, HH 476 is located close to the emission line star group Ser G3-G6 (Cohen & Kuhi 1979, Ziener & Eislöffel 1999).

OH maser emission associated with FIRS 1 was detected by Rodríguez et al. (1989, see also Clark & Turner 1987, Mirabel et al. 1987). H_2O maser emission associated with FIRS 1 and S 68N has been observed by several groups (Blair et al. 1978, Rodríguez et al. 1978, 1980, Dinger & Dickinson 1980, Palla & Giovanardi 1989, Curiel et al. 1993, Wolf-Chase et al. 1998). Furuya et al. (2003) detected H_2O

Figure 14. Some examples of HH objects in the Serpens core. Figure after Davis et al. (1999).

maser emission towards several Serpens Class 0 sources; and recently Moscadelli et al. (2006) have carried out a detailed study of the spatial distribution and proper motions of the FIRS 1 H_2O maser, which is formed by two small clusters of features.

5. Spatial Distribution of YSOs in the Core

Eiroa & Casali (1992) noticed that the Serpens near-IR sources are concentrated towards the core. A more detailed analysis of the spatial distribution of Serpens YSOs has been made by Testi et al. (2000), Kaas et al (2004), Harvey et al. (2007a), Enoch et al. (2007), and Winston et al. (2007). The distribution shows a remarkable subclustering, with the youngest sources mainly concentrated towards the NW and SE core clumps, which is seen by Testi et al. (2000) as an observational support for hierarchical fragmentation within a cluster-forming core. The spatial distribution of the Serpens YSO core cluster is shown in detail in Fig. 15, where we plot the distribution of the sources grouped according to their evolutionary class. Table 2 gives a cross-correlation of the sources detected in the different wavelength regimes and their evolutionary classes. The near-IR cluster members are seen across the whole core, although their number is clearly smaller towards the field around FIRS 1 and S 68N in the NW clump; brown dwarf candidates follow this distribution. Most of the near-IR sources likely are Class II objects, although few of them are associated with the youngest Class I and Class 0 objects (Sect. 4.1). The embedded Class II population detected with ISO/Spitzer is also seen across the whole core, although predominantly towards the densest part of the core and more accentuated towards the SE clump. Class I, Class 0 and mm cores are exclusively seen towards the densest parts of the two core clumps (with only one exception). There are approximately the same number of Class I and Class 0 objects in each of the NW and SE clumps, but the number of mm cores is clearly larger towards the NW clump, which is the opposite of the spatial distribution for the near-IR and ISO

Figure 15. Spatial distribution of YSOs in the Serpens cloud core. The plotted area approximately corresponds to that observed by Testi et al. (1998, see our Fig 11). Symbols mean the following: dots (black): near-IR sources; crosses (magenta): Class II ISO sources; open triangles (blue): Class I ISO sources; open hexagons (green): Class 0 sources; filled triangles (red): mm cores; diamond (black): brown dwarf candidates.

Class II sources. These results suggest that star formation activity is currently taking place in both core clumps, but is more active in the NW one, while it was more efficient or began earlier in the SE one. It is interesting to recall that both clumps are clearly distinct as indicated by their kinematics (Testi et al. 2000). These authors and Kaas et al. (2004) estimate the mean stellar/protostellar density of the Serpens core in the range of $\sim 1000 \text{ pc}^{-3}$, and is even larger, several thousands, in localized subclusters (Eiroa & Casali 1989, Testi et al. 2000). This high stellar density is hardly exceeded by any other star formation region, specially if the youngest Class 0 and mm cores are considered (Kaas et al. 2004, Testi et al. 2000). Winston et al. (2007) find that the projected spacing of Class 0/I sources is only 5000 AU, similar to the Jeans's length and the radii of critical Bonnor-Ebert spheres; they suggest that the volumes of gas from which these objects accrete may overlap and competitive accretion could be taking place. Collisions

between protostellar envelopes may be common, which could explain the widespread high velocity gas and overlapping outflow lobes (White et al. 1995)

6. Luminosity and Mass Functions

Intrinsic luminosity functions in young stellar clusters are usually based on near-IR magnitude distributions; their evaluation is not simple because one has to deal with extinction estimates, variability and the contribution of accretion disks to the observed magnitudes. Eiroa & Casali (1992) and Giovannetti et al. (1998) first estimated a luminosity function on the basis of K-band magnitudes. A likely more reliable luminosity function of Serpens ISO Class II objects has been produced by Kaas et al. (2004). These authors compare their estimated Class II luminosity function to pre-main sequence evolutionary models and find that the Class II population is compatible with coeval formation about 2 Myrs ago and a three-segment power-law initial mass function, similar to other clusters like ρ Ophiuchi. Harvey et al (2007a) find for all clusters in the whole Serpens cloud (see next section) that the luminosity function peaks around a few times 10^{-2} L_o and drops to both lower and higher luminosites. Testi & Sargent (1998) find that the mass-spectrum of the 3 mm continuum sources is consistent with a stellar initial mass function, supporting the idea that fragmentation of cloud cores determines the stellar masses. Considering the masses of the different objects embedded in the Serpens core, the star formation efficiency has been estimated to be of the order of \sim 3-10 %, although higher figures are likely in the densest parts of the core clumps (Olmi & Testi 2000, Kaas et al. 2004). In addition, since the mm objects as well as the Class 0 and Class I protostars are not older than $\sim 10^5$ years, their coexistence in the cloud core with the younger Class II and near-IR cluster suggests that star formation has proceeded in several phases (Casali et al. 1993, Kaas et al. 2004), but see Testi et al. (2000) for an opposite view.

7. Other Sites of Active Star Formation in the Serpens Cloud

As already pointed out (Sect. 1) relatively few works have studied the Serpens cloud outside the dense core, although different sites are known in which active star formation is taking place, e.g., Clark (1991) identified IRAS sources close to dense molecular material, and the ISOCAM data of Kaas et al. (2004) detect some mid-IR excess sources located several arcminutes south from the Serpens core.

The Herbig-Haro objects HH 108-109, located $\sim 2.3^{\circ}$ South-East from the core (Reipurth & Eiroa 1992, Ziener & Eislöffel 1999), form a bipolar outflow excited by the Class 0/I source IRAS 18331–0035, which is seen at cm wavelengths as a subarc-sec radio jet (Reipurth et al. 2004). The IRAS source was detected at 1.3 mm by Chini et al. (1997), as well as a second, very cold object called HH 108 MMS; images at mm/submm wavelengths by Chini et al. (2001) show an emission bridge linking both sources. HH 108 MMS has only been detected in the FIR and mm/submm in emission (Chini et al. 2001) and in absorption at 14 μ m against a diffuse background (Siebenmorgen & Krügel 2000). A second absorbing core, Q1, at 14 μ m is also detected. HH 108 MMS is suggested to be an extremely young protostellar source either on the verge of collapse or just beginning the protostellar phase (Chini et al. 2001).

Chavarría et al. (1988) and de Lara et al. (1991) carried out a photometric and spectroscopic study of several intermediate mass stars associated with nebulosity, including the Herbig Ae star VV Ser. They also identified 13 probable H α emission stars. Cohen & Kuhi (1979) found a close group of 4 optically visible T-Tauri stars, which they called Ser/G3-G6, about 45' to the south of the SRN (see Fig. 1).

The area around Ser/G3-G6 was mapped in the ammonia 1.1 emission line by Clark (1990, 1991) who found an NH_3 core on each side of the complex, Ser/G3-6ne and Ser/G3-6sw; HH 476 is close to the Ser/G3-6sw core (Ziener & Eislöffel 1999). Those authors point out that IRAS 18263+0027 and IRAS 18265+0028) are within about 1 and 2 arcminutes from the Herbig-Haro object, respectively, but consider it more likely that its exciting source is one of the stars in the Ser/G3-G6 complex. Wu et al. (2002), on the other hand, identify IRAS 18265+0028 as the energy source of HH 476; a H_2O maser has been detected by Persi et al. (1994) at the position of this IRAS source. A survey at 6.7 and 14.3 μ m with ISOCAM in a 17' \times 19' field centred on Ser/G3-G6 reveals a cluster of about 40 IR excess sources out of 186 detections (Djupvik et al. 2006). This population consists mainly of Class II sources, but also a handful of Class I sources. Deep follow-up imaging in the 2.122 μ m 1-0 S(1) line of H_2 centred on the Ser/G3-6ne NH₃ core shows a number of knots and jets not seen in the optical. At the position of IRAS 18265+0028 there are two red and bright sources, ISO-NH3-90 and 94, which probably are Class I/Class 0 type YSOs. In addition, ISO-NH3-101 is a red source with apparent excess emission at 6.7 μ m, probably indicating H_2 line emission in this band.

Within the Legacy project From Molecular Cores to Planet-Forming Disks (c2d) of the Spitzer Space Telescope (Evans et al. 2003), a 0.9 deg^2 area in Serpens has been surveyed with IRAC and MIPS. A region about 2 degrees in DEC and 40 arc minutes in RA has been mapped in the 4 IRAC bands (3.6, 4.5, 5.8, and 8.0 μ m) and the 3 MIPS bands (24, 70 and 160 μ m), the MIPS scans being some 20% larger than the IRAC scans. This area was chosen to follow the $A_V = 6$ mag contour in the extinction map of Cambrésy (1999). Fig. 16 shows a composite image made from IRAC1, IRAC2, and IRAC4 filter. The map includes both the Cloud Core (Cluster A), the Ser/G3-G6 complex (Cluster B), and the region around VV Ser (Cluster C), to mention some known objects. Spitzer/IRAC reveals more than 250 Serpens sources distributed into the three mentioned areas (Harvey et al. 2006, Harvey et al. 2007a). This latter work presents detailed SEDs of the YSO objects in the whole area observed by Spitzer, traces the YSO luminosity function down to a limit of $\sim 10^{-3} L_{\odot}$, and shows the spatial clustering of the young objects according to their evolutionary classification. They also provide a table of Spitzer objects with counterparts at other wavelength ranges. Flaherty et al. (2007) have studied the infrared extinction law in the IRAC bands and the 24 μ m MIPS band. The extinction law is similar to that of other regions but it differs from the diffuse ISM, which could be due to different dust properties. In addition, Harvey et al. (2007b) find a close correlation between the coolest dust detected at 160 μ m and the dust associated with optical extinction. The region observed by Spitzer has been mapped at 1.1 mm by Enoch et al. (2007). They find 35 sources, most of them located in the Cluster A and Cluster B (Fig. 17). Those authors correlate the mm emission with the extinction map and find that most of the mm sources lie within regions of high extinction ($A_V > 10$ mag).

In the context of the Spitzer Gould Belt Legacy Survey, a new young embedded cluster (Fig. 18) associated with a filamentary dark cloud, located 3° to the South of

Figure 16. Colour image made from Spitzer IRAC1 (blue), IRAC2 (green), and IRAC4 (red) images. The inset images show the three Serpens stellar clusters at higher magnification. From Harvey et al. (2006).

Figure 17. Bolocam 1.1 mm map of Serpens with the positions of the 35 mm sources (taken from Enoch et al. 2007).

the Serpens cloud core, has been discovered by Gutermuth et al. (2008). Radial velocities from molecular line observations of the Serpens South complex carried out by the same authors are the same as that of the Serpens core, suggesting a common distance. The cluster consists of at least 54 Class I protostars and 37 Class II sources and it has a mean surface density of 430 pc⁻¹. The median projected distance between nearest neighbor YSOs is 13".2 or 3700 AU - Gutermuth et al. (2008) assume a distance of 260 pc. The large fraction of Class I protostars in the Serpens South cluster, larger than in the Serpens cloud core cluster, and the high density suggest a very recent initialization of star formation and a high star formation rate, ~ 90 M_{\odot} Myr⁻¹ (assuming a typical protostellar phase lifetime of 2×10^5 yr and 0.5 M_{\odot} per source). Doubtless, Serpens South will concentrate large observational efforts in the next future, searching for Class 0 objects, submm/mm dusty cores, outflows, etc.

Figure 18. Colour-composite of the new Serpens South cluster made from IRAC1 (blue), IRAC2 (green), and IRAC4 (red) images. From Gutermuth et al. (2008).

8. Objects of Particular Interest

The Gaseous Condensation S 68 NW: Williams & Myers (1999) detected a compact, starless core in CS (2-1) and N_2H^+ (1-0) with turbulent widths and infall asymmetry in the NW clump of the Serpens core close to S 68N, which was designated S 68NW. The line width was confirmed by Olmi & Testi (2000). This core is likely the youngest, individual evolutionary structure detected in Serpens.

SMM 4: This source is the brightest Class 0 object in the SE core clump (Casali et al. 1993, Hurt & Barsony 1996). Both Ward-Thompson & Buckley (2001) and Narayanan et al. (2002) showed that it possesses blue asymmetric line profiles in the optically thick main isotopes of HCO^+ and CS, and conclude that SMM 4 has an infalling, rotating envelope.

FIRS 1 (IRAS 18273+0113, SMM 1): FIRS 1 (Harvey et al. 1984) is the most luminous source in the Serpens core. It is a Class 0 object of $\sim 50 L_{\odot}$ (Casali et al. 1993, Hurt & Barsony 1996, Larsson et al. 2000). Radio continuum observations detect a triple radio jet with a non-thermal component which is interpreted as a Herbig-Haro precursor (Rodríguez et al. 1989, Curiel et al. 1993, McMullin et al. 1994). The outflowing clumps in the jet have proper motions with tangential velocities of order 200 km/s, indicating a dynamical age of only 60 years. H₂O maser and *OH* emission are also detected close to FIRS 1 (e.g. Moscadelli et al. 2006). Molecular outflows in different molecules are also present (White et al. 1995, Torrelles et al. 1992, Curiel et al. 1996, Williams & Myers 2000, McMullin et al. 2000). An H_2 S(1) jet emerges from the centre of FIRS 1, though it is most likely unrelated to the radio sources (Eiroa & Casali 1989, Curiel et al. 1996, Hodapp 1999).

Testi et al. (2000) point out that star formation in the Serpens core is very SVS 4: inhomogeneous, occurring in various sub-clusters. The SVS 4 complex (Eiroa & Casali 1989) is a sub-cluster of ~ 10 sources situated some 2' South of the SRN, containing a mix of Class I, flat-spectrum and Class II sources (Kaas et al. 2004, Pontoppidan et al. 2004, Haisch et al. 2006). Some of the objects are associated with radio continuum sources (Smith et al. 1999, Eiroa et al. 2005). It is one of the densest young stellar (sub-)clusters known, with a stellar mass density of $\sim 10^5 M_{\odot} \ pc^{-3}$ (Eiroa & Casali 1989, Pontoppidan et al. 2004). Preibisch (1998, 1999) finds EC 95 (SVS 4-9) to be one of the brightest X-ray sources known among young stars. Its high X-ray luminosity, \sim 4×10^{31} erg s⁻¹, might be due to a very active magnetic corona, a fact partly supported by the radio spectral index (Smith et al. 1999, Forbrich et al. 2007). The infrared data places it well above the main sequence with a very young age in the range \sim $2-4 \times 10^5$ years (Preibisch 1999, Pontoppidan et al. 2004). A spectrum of the CO bandhead at 2.29 μ m in EC 95 indicates $v \sin(i) \sim 20-80$ km s⁻¹ (Casali & Eiroa 1996b), and reasonably rapid rotation consistent with enhanced X-ray emission: more recently, Doppmann et al. (2005) have measured $v \sin(i) = 56 \text{ km s}^{-1}$. EC 80 (SVS 4-3), and EC 89 (SVS 4-6) are also X-ray sources (Preibisch 2004, Giardino et al. 2007).

SVS 20: SVS 20 (EC 90) is the brightest K band source in the Serpens cluster. The source contains a number of peculiar features. Observations by Eiroa et al. (1987) revealed it to be a 1.6'' separation binary and the total luminosity and X-rays suggest

two stars of mass 1-4 M_{\odot} (Preibisch 2003). Both components have very similar near to mid-IR spectral energy distributions, although they have a brightness difference of $\Delta m \sim 1.5$ mag (Eiroa et al. 1987, Eiroa & Leinert 1987, Haisch et al. 2002) and are flat-spectrum sources (Kaas et al. 2004, Haisch et al. 2006). The *K* band spectrum of the brighter component, SVS 20S, is featureless, while SVS 20N has $Br\gamma$ and the 2.3 μ m CO bands in emission (Fig. 8). A nebulous ring-like structure possessing spiral arm-like features, $\sim 5000 \times 3000$ AU projected onto the sky, contains shock excited H₂ emission (Eiroa et al. 1997a, see Fig 4). The correct interpretation of the nebular morphology is a matter of debate. Eiroa et al. (1997a) interpret the emission as a circumbinary disk, while studies in polarized IR radiation led Huard et al. (1997) to describe it as a cavity excavated by an outflow.

Brown Dwarfs: The near-IR object EC 64 (GCNM 57) has been identified by Lodieu et al. (2002) as a young L0-L3 brown dwarf (BD-Ser 1). It shows deep water absorption consistent with an effective temperature of 2800 K, and an estimated mass of 0.05 M_{\odot} . Klotz et al. (2004), Kaas et al. (2004), Harvey et al. (2007a) and Winston et al. (2007) have suggested further brown dwarf candidates. Furthermore, on the basis of the near-IR diagrams Eiroa et al. (2006) suggested ~ 40 near-IR Serpens objects as good brown dwarf candidates, which are now increased to more than 60 candidates, considering the Spitzer/2MASS sources. Many of them show near-IR excess denoting remarkable circumstellar disks. These objects are identified in Table 1.

Outbursts and Disappearances. EC 81 and DEOS: EC 81 was a K = 12.2 mag. source, with some cometary nebulosity in the original EC listing (Eiroa & Casali 1992). Yet it was invisible in the images reported in Horrobin et al. (1997) which show it to have faded by more than 3.8 magnitudes over a period of 3 years. Harvey et al. (2007a) have found several knots of emission close to the nominal position of EC 81 and have suggested that this source may have been a small clump of excited gas. By contrast, Hodapp et al. (1996) reported an FU Orionis-type outburst in a faint source (DEOS), which brightened by more than 4 magnitudes in less than 9 months. Hodapp (1988) carried out a first photometric monitoring of DEOS (Fig. 19) and showed significant changes in the spectrum of the source. More recently, Kóspál et al. (2007) has monitored this source, also called OO Serpentis, from 1996 to 2006 using ISO, Spitzer and near- and mid-IR ground-based data. Their data show that the object is fading and is likely to reach its pre-outburst brightness around 2011; those authors suggest DEOS is a Class I object with an age of $< 10^5$ yr surrounded by an accretion disk and a dense envelope.

VV Ser: VV Serpentis (Chavarría et al. 1988) has attracted considerable attention in many studies of HAe stars. In spite of this, its basic stellar parameters remain rather uncertain: spectral type between B1 and A3, luminosity class III to V, rotational velocity between 85 and 230 km s⁻¹. Ripepi et al. (2007) provide a very good summary of the current published values. Photometrically VV Ser shows deep occultations from circumstellar matter (Herbst & Shevchenko 1999, Rostopchina et al. 2001) together with δ Scuti type pulsations, suggestive of a stellar mass close to 4 M_☉ and an effective temperature significantly lower than the value based on the empirical spectral types (Ripepi et al. 2007). Interferometric measurements resolve the near-IR emission (Eisner et al. 2003, 2004) which is interpreted as arising from the inner parts of a disk with grains of different sizes (see also Isella et al. 2006). Double-peaked 4.7 μ m CO emission is

Figure 19. Combined K band images of the DEOS region in 1998 (right) and 1994 (left). DEOS and its associated luminosity to the east appear much brighter in 1998 than in 1994. Taken from Hodapp (1999).

Figure 20. Spitzer composite image of VV Ser. Colours mean: 4.5 μ m (blue), 8.0 μ m (green), 24 μ m (red). Taken from Pontoppidan et al. (2007c).

also observed (Blake & Boogert 2004). Searches for PAH emission features have been carried out by Geers et al. (2006, 2007). Spitzer IRAC and MIPS images reveal the circumstellar disk (Pontoppidan et al. 2007c) and a large, bipolar nebulosity centred on VV Ser (Fig. 20), which is interpreted as due to quantum-heated PAHs and small carbonaceous/silicates of \sim 500 atoms (Pontoppidan et al. 2007b).

Acknowledgments. It is a pleasure to thank R. A. Gutermuth, P.M. Harvey, and S.T. Megeath for providing the Spitzer results prior to publication. C.E. is supported in part by Spanish Grants AYA 2005-00954 and CAM Ref. S-0505/ESP/0361.
