Abstract

The electric quadrupole coupling constant of the ³¹Al ground state is measured to be $\nu_Q = \left|\frac{eQV_{zz}}{h}\right| = 2196(21)$ kHz using two different β -NMR (Nuclear Magnetic Resonance) techniques. For the first time, a direct comparison is made between the continuous rf technique and the adiabatic fast passage method. The obtained coupling constants of both methods are in excellent agreement with each other and a precise value for the quadrupole moment of ³¹Al has been deduced: $|Q(^{31}\text{Al})| =$ 134.0(16) mb. Comparison of this value with large-scale shell-model calculations in the sd and sdpf valence spaces suggests that the ³¹Al ground state is dominated by normal sd-shell configurations with a possible small contribution of intruder states. The obtained value for $|Q(^{31}\text{Al})|$ and a compilation of measured quadrupole moments of odd-Z even-N isotopes in comparison with shell-model calculations shows that the proton effective charge $e_p = 1.1e$ provides a much better description of the nuclear properties in the sd-shell than the adopted value $e_p = 1.3e$.

1 Introduction

The electric quadrupole moment Q provides a direct measure of the deviation of the nuclear charge distribution from a sphere. As the quadrupole moment is a sensitive probe to indicate changes in the shell structure, its measurement is an important tool in studying nuclei in and near the island of inversion. This region, comprising the Ne (Z=10), Na (Z=11) and Mg (Z=12) isotopes with neutron number around N=20, is characterized by the dominance of neutron excitations from the sd to the pf-orbits (known as intruder configurations) in the ground state.

The first experimental evidence for this effect was found in the measured nuclear masses and two-neutron separation energies of the $^{26-32}$ Na isotopes [1]. In the same year, Campi et al. made the first theoretical analysis of the observed experimental anomalies, performing constrained Hartree Fock calculations [2]. Later, β -decay studies revealed a low lying 2⁺ state in 32 Mg [3, 4], pointing to a deformed ground state in that nucleus. Further evidence for the existence of the island of inversion was provided by the measurement of B(E2)-values and nuclear moments of the neutron-rich Ne, Na and Mg isotopes (e.g. [5, 6, 7, 8, 9, 10, 11, 12]).

As new experimental results became available, shell-model calculations grew more important. Starting from the early calculations performed by Watt et al. [13] and Poves and Retamosa [14], new residual interactions in larger model spaces were developed [15, 16] taking into account particle-hole excitations of the neutrons across the reduced N=20 shell gap. For nuclei inside the island of inversion, theoretical predictions reproduce the observed nuclear properties quite well. For the neutron-rich ³¹⁻³⁴Al isotopes (Z=13) located at the border of the island of inversion, the interpretation of experimental results by means of theoretical models contributes to a better understanding of how the transition to the region of deformed nuclei occurs. A comparison between the measured nuclear magnetic moments of ³¹⁻³⁴Al [17, 18, 19, 20] and shell

Email address: marieke.derydt@fys.kuleuven.be (M. De Rydt).

model calculations shows that ³¹Al and ³²Al can be described as normal sdshell nuclei [17, 19]. For ³³Al and ³⁴Al, intruder configurations play a role in the ground state [19, 20] and in the low-energy level structure [21, 22]. This indicates a gradual transition from the Si isotopes, being normal in their ground states, to the deformed Mg isotopes inside the island of inversion.

As the nuclear quadrupole moment is even more sensitive to neutron excitations across N=20 than the magnetic moment, a measurement of Q can provide crucial and decisive information about the mixing between sd and pf configurations in the ground states of the neutron-rich Al isotopes. So far, the Q-moments of $^{31-32}$ Al have been studied with a limited accuracy in Refs. [23, 24]. This letter reports on the precision measurement of the 31 Al groundstate quadrupole moment, which is a crucial step in describing the systematics of the odd-mass Al isotopes towards the semi-magic nucleus 33 Al.

The quadrupole moment of ³¹Al was measured using two different β -nuclear magnetic resonance techniques, based on a pulsed and a continuous radiofrequent field respectively. This provides a unique opportunity to directly compare both methods and results. The two techniques can be used to determine magnetic moments (then we call it a β -NMR method) or quadrupole moments (then the term β -NQR or β -nuclear quadrupole resonance is adopted).

2 Experiment

Neutron-rich ³¹Al nuclei were produced in a projectile fragmentation reaction, induced by a ³⁶S¹⁶⁺ primary beam (77 MeV/u) impinging on a 1212 μ m thick ⁹Be target. Selection of the secondary beam was done with the high-resolution fragment separator LISE at GANIL [25, 26]. Si-diodes have been used for the beam identification by standard energy loss versus time of flight measurements. Spin polarization of the fragments [27] was obtained by putting an angle of 2(1)° on the primary beam with respect to the entrance of the spectrometer. To get the highest polarization, a selection in the right wing of the longitudinal momentum distribution was made, giving a polarized ³¹Al production yield of about 10⁴ pps for a primary beam intensity of 1 μ A. A purity of 90% was achieved using a 1054 μ m thick ⁹Be wedge-degrader in the intermediate focal plane.

At the end of the LISE fragment separator, a β -nuclear magnetic/quadrupole resonance (β -NMR/NQR) set-up is installed. The ³¹Al-nuclei are implanted in a cubic Si-crystal for β -NMR or in an α -Al₂O₃ (corundum) crystal for β -NQR. No crystal cooling is needed since the spin-lattice relaxation time T_1 of ³¹Al ($t_{1/2} = 644(25)$ ms) in both crystals is sufficiently long to preserve the nuclear polarization for a few half lives. T_1 of ³¹Al in an α -Al₂O₃ crystal is estimated to be 4.8 s, using the $T_1T^2Q^2 = \text{const}$ law [28] and the measured relaxation time of ²⁷Al [29]. The implanted nuclei are exposed to an external magnetic field B_0 which induces a Zeemann splitting of the nuclear *m*-states. When a non-cubic crystal (e.g. Al₂O₃) is used as a stopper material, the quadrupole interaction with the electric field gradient causes an additional shift of the magnetic substates which results in a non-equidistant level spacing. Perpendicular to the external magnetic field, a radiofrequent (rf) field is applied. This rf-field is generated inside the coil mounted around the crystal, by a function generator and rfamplifier. The asymmetry in the β -decay of the polarized nuclei is observed in two sets of three thin plastic scintillators, one set is situated above the crystal, the other below. Scattering and noise events are reduced in this configuration by requiring a coincidence between the three detectors in each set. A schematic drawing of the β -NMR/NQR set-up is given in Fig. 1.

Fig. 1. A schematic overview of the β -NMR/NQR set-up.

The transition frequency between the magnetic sublevels m and m+1 under the influence of a Zeemann and an axially symmetric quadrupole interaction can be calculated using perturbation theory, provided that the Larmor frequency ν_L is much larger than $\frac{\nu_Q}{4I(2I-1)}$. Up to the second order, this series expansion is given by [30]:

$$\nu_m - \nu_{m+1} = \nu_L - \frac{3\nu_Q}{8I(2I-1)}(2m+1)\left(3\cos^2\theta - 1\right)$$
(1)
$$-\frac{\nu_Q^2}{32\nu_L}\frac{9}{4I^2(2I-1)^2} \left[6m(m+1) - 2I(I+1) + 3\right]\sin^4\theta$$

I is the nuclear ground-state spin and θ is the angle between the electric field gradient along the *c*-axis of the crystal and the external magnetic field B_0 . The Larmor frequency ν_L equals $\frac{g\mu_N B_0}{h}$ with *g* the nuclear g-factor. The quadrupole coupling constant ν_Q is defined as $\frac{eQV_{zz}}{h}$. In this expression, *Q* is the spectroscopic quadrupole moment (in mb) and V_{zz} the axially symmetric electric field gradient.

For ³¹Al $(I=5/2^+)$, five different transition frequencies exist. In table 1, these five frequencies are given in case the symmetry axis of the electric field gradient

is parallel ($\theta=0^{\circ}$) or perpendicular ($\theta=90^{\circ}$) to the direction of B_0 . For the 90° orientation, the quadrupole splitting is about two times smaller than for the 0° direction which implies that a double quadrupole moment window can be scanned with the same frequency settings.

Overview of the transition frequencies between the m-states in 31 Al.

Table 1

When a single rf-frequency (for β -NMR) or a correlated set of frequencies (for β -NQR) are applied such that they correspond to the frequency difference between two adjacent *m*-states, the polarization is destroyed or reversed. This can be observed as a change in the β -decay asymmetry. The latter quantity is defined as

Asymmetry
$$= \frac{N_{up} - N_{down}}{N_{up} + N_{down}} \simeq \frac{v}{c} A_{\beta} P$$
 (2)

 N_{up} is the number of coincident counts detected by the upper set of detectors, while N_{down} is the number of coincident counts recorded in the lower scintillators. A_{β} is the asymmetry parameter and depends on the β -decay properties of the nucleus under consideration. P is the initial polarization of the implanted ensemble, induced by the nuclear reaction.

Two techniques are commonly used: the continuous rf technique (CRF) [31, 32] and the adiabatic fast passage method (AFP) [18, 23]. Both are based on the principle of β -NMR [30]. In the CRF technique, the spin polarization is resonantly destroyed by mixing the *m* quantum states with a rf-field while the AFP method requires a pulsed production and rf system in order to reverse the population of the *m*-states. This letter describes and compares both techniques which have been applied in the same experimental conditions for the first time.

In the CRF method, ³¹Al nuclei are continuously implanted in the stopper crystal which is exposed to one (β -NMR) or several correlated (β -NQR) rffrequencies. At the same time, the asymmetry of the β -decay is measured. When the applied frequency (set) covers the Larmor frequency (β -NMR) or the quadrupole coupling constant (β -NQR), all *m*-states are equally populated. The polarization is destroyed and a resonance is observed when the β -asymmetry is plotted as a function of the rf-frequency. The resonance amplitude is proportional to the initial polarization *P* of the implanted ensemble. A broad rf-region is scanned in discrete steps. In order to cover a large frequency range in one step, frequency modulation is used. In case of NQR and for each value of ν_Q , all transition frequencies ν_i (Table 1) are applied simultaneously and modulated over 55% of the frequency step between two subsequent values. Typically, one set of frequencies is applied during several seconds (up to minutes). After going through all frequency steps and before starting the next scan, data without rf are taken as a reference. The process is repeated for 30 minutes up to several hours until sufficient statistics are collected.

The AFP method uses a pulsed beam which is implanted in the crystal during the time 'beam on' as outlined in Fig. 2. When the beam is switched off, a single rf-frequency (β -NMR) or a set of correlated frequencies (β -NQR) is applied for a few ms (rf-time) and swept over a certain rf-range around a central value. If the sweep range, the rf-field strength and the rf-time are chosen properly, the AFP-condition is fulfilled and the population of the *m*-states is reversed [30]. After the rf pulse sequence, the β -counting is started, typically for one lifetime. The AFP-cycle is concluded with the same rf-sequence in order to restore the original direction of the polarization. The different NQR frequencies are not applied simultaneously as in the CRF-method but according to a sequence (Fig. 2).

The duty cycle of the AFP-method is in most cases slightly below 50%, compared to 100% in the CRF technique. The resonance amplitude however is proportional to 2P (from +P to -P) when the AFP-condition is exactly met. Because the sensitivity of the method is proportional to the asymmetry change squared, the AFP-method can be up to two times more efficient than the CRF technique.

Fig. 2. Structure of one AFP-NQR cycle. A zoom is made of one rf-on period. It shows the order in which all five transition frequencies in 31 Al are applied.

In order to prove that the measured quadrupole coupling constants are independent of the experimental conditions, both methods were applied using a different magnetic field and a different crystal orientation. The continuous rf NMR and NQR were performed in an external field of 0.25 T. The measuring time per frequency was 10 s. For the NQR-measurement, the *c*-axis of the Al₂O₃ crystal was oriented parallel to the direction of B_0 . The corresponding transition frequencies are given in the middle column of Table 1. All AFP measurements were performed with $B_0=0.5$ T and θ was put to 90°. The transition frequencies are shown in the last column of Table 1.

3 Results

In order to implement a successful β -NQR experiment on the ³¹Al ground state, a precise knowledge of the Larmor frequency ν_L is required. Therefore, a β -NMR measurement (Al implanted in Si) was performed prior to each NQR-measurement. The results are shown in Fig. 3. The upper panel shows the continuous rf NMR with a frequency modulation of 1.2 kHz. Using a fitting function that includes the Lorentzian line shape and the frequency modulation resulted in $\nu_L = 2909.3(2)$ kHz. Other fit parameters were the position of the baseline, the FWHM of the curve and the amplitude (proportional to the polarization).

The lower panel of Fig. 3 displays the AFP result, obtained with 1.54 kHz frequency modulation. The same fitting procedure was applied and a Larmor frequency $\nu_L = 5820.2(3)$ kHz was found.

The slightly better relative accuracy obtained with the AFP-method, stems from the fact that the relative frequency modulation was a little smaller compared to the one applied in the continuous rf NMR, resulting in a narrower resonance and a more precise value of ν_L . An absolute field calibration was not performed in this experiment as the NQR transition frequencies ν_i (see Table 1) do not directly depend on the magnetic field but only on the Larmor frequency and the unknown quadrupole coupling constant. Consequently, no magnetic moments were deduced.

The spectroscopic quadrupole moment of the ³¹Al ground state was initially measured with the continuous rf method. Starting from a broad scan, covering a wide range of |Q| and using a large frequency modulation (81.5 kHz), a resonance was found at $\nu_Q=2218(75)$ kHz (Fig. 4a). In the subsequent NQR, a zoom of the frequency region was made around the earlier observed resonance (Fig. 4b), applying a frequency modulation of 40.7 kHz. $\nu_Q=2188(25)$ kHz was obtained. The continuous rf results were confirmed by a measurement using the adiabatic fast passage technique with a modulation of 75.5 kHz, resulting in $\nu_Q=2215(47)$ kHz (Fig. 4c). The weighted mean of the three ν_Q 's is calculated to be $\overline{\nu}_Q$ (³¹Al)=2196(21) kHz. Since the quadrupole coupling constant of stable ²⁷Al was also determined in an α -Al₂O₃ crystal at room temperature, its value can be directly compared to $\overline{\nu}_Q$ (³¹Al). Using the known values $|Q(^{27}Al)| = 146.6(10)$ mb [33] and $\nu_Q(^{27}Al) = 2402.5(17)$ kHz

Fig. 3. β -NMR resonances obtained with the continuous rf technique (upper panel) and the AFP method (lower panel).

[34], the quadrupole moment of the ³¹Al ground state can be calculated as follows:

$$|Q(^{31}\text{Al})| = \frac{|Q(^{27}\text{Al})|\overline{\nu}_Q(^{31}\text{Al})}{\nu_Q(^{27}\text{Al})}$$
(3)

 $|Q(^{31}\text{Al})| = 134.0(16)$ mb is obtained. This result is more than one order of magnitude more precise and in agreement with the earlier measured quadrupole moment of ³¹Al (112(32) mb [24]).

A comparison of the NMR amplitudes given in Fig. 3 shows no large difference between the AFP-resonance and the continuous rf result. Within the errors, both amplitudes are the same. Also for the NQR measurements (indicated in Fig. 4) no clear difference in amplitude exists. The expected double effect has not been observed since the AFP-technique was not optimized and, as a consequence, the exact AFP-condition was never reached.

4 Discussion

Recently, the proton core polarization charges and the electric quadrupole moments of the neutron-rich Al isotopes have been investigated in the microscopic particle-vibration coupling (PVC) model [35]. The single particle wave functions used in this model are obtained from solving the Skyrme Hartee-Fock-Bogoliubov equation self-consistently while the phonon energies are deduced from the quasiparticle-random-phase approximation. The ³¹Al quadrupole mo-

Fig. 4. β -NQR resonances obtained with the continuous rf technique (a and b) and the AFP method (c).

ment was calculated for two different values of the Landau-Migdal (LM) interaction strength, resulting in $Q_{PVC}(^{31}\text{Al}) = 136$ mb and 139 mb, in excellent agreement with our experimental value. By comparing the calculated single particle quadrupole moment (without coupling to E2-excitations) with the quadrupole moment calculated in the PVC model, the authors deduced a proton core polarization charge of 1.03e and 1.08e for ³¹Al, depending on the LM interaction strength used.

In this letter, the ³¹Al quadrupole moment is interpreted in the framework of two large-scale shell-model approaches. ANTOINE calculations [36] are performed with the sdpf residual interaction [37] and the Monte Carlo Shell Model (MCSM) [38, 39] is used with the SDPF-M interaction [40]. Both models are very efficient in outlining the nuclear properties of isotopes that belong to the island of inversion. For the odd-mass neutron-rich Al-isotopes, four different calculations are made and presented in Fig. 5. Three of them are ANTOINE calculations: one with all neutrons confined to the sd-shell (0p-0h, squares), one with two neutrons forced into the $f_{7/2}p_{3/2}$ orbitals (2p-2h, triangles) and one without truncations in the $\nu(\text{sdf}_{7/2}p_{3/2})$ model space (free sdpf, diamonds). The fourth dataset is a MCSM calculation using the SDPF-M interaction in the $\nu(\text{sdf}_{7/2}p_{3/2})$ valence space (free SDPF-M, stars). In the ANTOINE calculations, protons are restricted to the sd-shell while the MCSM imposes no restrictions on the proton space. All calculations are performed using the standard effective charges $e_p = 1.3e$ and $e_n = 0.5e$ [41]. The experimental data (dots) are taken from this work and from Ref. [33].

Fig. 5. (Color online) An overview of the calculated and the measured quadrupole moments of the neutron-rich odd-mass Al ground-states $(I=5/2^+)$. All calculations were made using **the effective charges** $\mathbf{e_p} = \mathbf{1.3e}$ and $\mathbf{e_n} = \mathbf{0.5e}$. The contribution of intruders configurations in the ground state is given between brackets (if different from zero).

For ^{27–31}Al, 0p-0h calculations and calculations in the untruncated model space predict similar quadrupole moments. No intruder configurations are present in the ground states of ^{27–29}Al while a minor contribution (see Fig. 5) is predicted for ³¹Al. The theoretical Q-moments reproduce the observed trend but theory overestimates all experimental values by about 15%.

As the quadrupole moments of the odd-mass Al-isotopes are dominated by the odd $d_{5/2}$ proton hole, the proton effective charge has been rescaled to $e_p = 1.1e$ in order to obtain a quantitative agreement with the experimental value of ²⁷Al. Fig. 6 gives an overview of the experimental and rescaled theoretical Q-moments of ²⁷⁻³³Al, adopting the same color code as in Fig. 5.

All theoretical predictions for ³¹Al (N=18), calculated with the reduced effective proton charge, show a good agreement with the experimental value. Pure ν sd-calculations as well as calculations in the untruncated model space can explain the observed Q-moment. This indicates that the ³¹Al ground state is dominated by normal sd-configurations with a possible small admixture of intruder states.

For ³³Al (N=20), free ANTOINE and MCSM calculations predict an amount of 10% and 64% respectively of intruder configurations in the ground state, leading to an enhanced quadrupole moment compared to what is suggested by 0p-0h calculations. In case ³³Al has a pure sd ground-state configuration, a strong decrease of the quadrupole moment with respect to the ³¹Al value

Fig. 6. (Color online) An overview of the calculated and the measured quadrupole moments of the neutron-rich odd-mass Al ground-states $(I=5/2^+)$. All calculations were made using **the effective charges 1.1e and 0.5e** for protons and neutrons respectively.

should be observed, as expected for a 'normal' closed-shell nucleus. However, a recent report on the g-factor of ³³Al suggests a non-negligible contribution of neutron excitations across N=20 in the ground state [19]. A measurement of the ³³Al quadrupole moment will therefore provide decisive information about the structure of the Al isotopes at the N=20 shell closure.

The use of the reduced effective proton charge $e_p = 1.1e$ to describe the oddmass Al quadrupole moments can be justified in the framework of the full π sd shell. The standard effective charges $e_p = 1.3e$ and $e_n = 0.5e$ were established in 1988 by Brown and Wildenthal [41] based on a comparison of shell-model calculations with the experimental E2 γ -decay transition matrix elements and the not very precise static quadrupole moments known at that time. Since then, nine new and/or more precise static quadrupole moments of odd-Z even-N π sd-shell nuclei became available, including the present result for ³¹Al. Isotopes with an odd proton and an even neutron number are excellent probes to define the proton effective charge used in the π sd-shell as their quadrupole moments are mainly determined by proton configurations.

In Fig. 7, each odd-Z even-N π sd-isotope for which the ground-state quadrupole moment is measured, is represented by a data point with Q_{theo} as X-coordinate and Q_{exp} as Y-coordinate. All data scatter around the $Q_{exp} = Q_{theo}$ line. In the upper panel, the quadrupole moments are calculated using the ANTOINE sdpf residual interaction with protons in the sd shell and neutrons in the sdf_{7/2}p_{3/2} orbits using the standard effective charges $e_p = 1.3e$ and $e_n = 0.5e$. A rather large reduced χ^2 -value of 3.4 is found with respect to the $Q_{exp} = Q_{theo}$ curve. In the lower panel, Q_{theo} is determined using the reduced effective proton charge $e_p = 1.1e$. A much better agreement between experiment and theory

Fig. 7. Known quadrupole moments of π sd-shell nuclei with odd Z and even N. The theoretical values are obtained using the sdpf residual interaction with the protons restricted to the sd-shell and the neutrons allowed in the sdf_{7/2}p_{3/2} space. Scattering around $Q_{exp} = Q_{theo}$ is studied. In the upper panel, Q_{theo} is calculated with $e_p = 1.3e$ while the lower panel shows Q_{theo} values determined with $e_p = 1.1e$. The experimental errors are smaller than the symbol size.

 $(\chi^2_{red} = 1.5)$ is observed. The experimental data are taken from this work and from Refs. [42, 43].

Thus, based on a compilation of recent and remeasured quadrupole moments for odd-Z even-N π sd isotopes, it can be concluded that $e_p = 1.1e$ is a more realistic effective proton charge for the sd-shell than the previously adopted value 1.3e. This conclusion offers a strong argument to justify the use of the effective proton charge 1.1e in the discussion of the ³¹Al quadrupole moment.

5 Summary

In conclusion, the electric quadrupole coupling constant of ³¹Al, produced in a projectile-fragmentation reaction, was measured using two nuclear quadrupole resonance techniques, one based on a continuous rf-signal, the other on a pulsed sequence. The measured values are in good agreement with each other, leading to a mean value of $\nu_Q=2196(21)$ kHz. From this, the quadrupole moment of ³¹Al could be extracted: $|Q(^{31}Al)| = 134.0(16)$ mb.

The precise value of $|Q|^{31}$ Al)| together with other experimental quadrupole moments of odd-Z even-N sd-nuclei were used to determine the proton effective charge in the π sd-shell. Calculations performed with $e_p = 1.1e$ result in a better agreement with experiment than calculations using the standard effective proton charge $e_p = 1.3e$.

Comparison with shell-model calculations using the sdpf and SDPF-M residual interactions shows that the ground state of ³¹Al is dominated by normal sdshell configurations with a possible small admixture of neutron 2p-2h states. This points to a gradual transition from the deformed Mg isotopes to the normal Si ground states. A measurement of $Q(^{33}Al)$ would add important information to the study of the nuclear structure of the odd-mass Al-isotopes at the border of the island of inversion. The accurate value of $|Q(^{31}Al)|$, obtained in this work, will contribute to a correct interpretation of that new result.

We are grateful to the GANIL staff for the technical support and to Dr. E. Yagi for the useful help and advice with the X-ray diffraction analysis of the α -Al₂O₃ sample.
