Using a model of force balance in Saturn's disk-like magnetosphere, we show that variations in hot plasma pressure can change the magnetic field configuration. This effect changes (i) the location of the magnetopause, even at fixed solar wind dynamic pressure, and (ii) the magnetic mapping between ionosphere and disk. The model uses equatorial observations as a boundary condition—we test its predictions over a wide latitude range by comparison with a *Cassini* high-inclination orbit of magnetic field and hot plasma pressure data. We find reasonable agreement over time scales larger than the period of Saturn kilometric radiation (also known as the camshaft period).

1. Introduction

Saturn's equatorial, rotating plasma disk is threaded by a magnetic field which changes from a quasi-dipolar geometry, at distances $\lesssim 12 \,\mathrm{R_S}$ (Saturn's radius $\mathrm{R_S} = 60280 \,\mathrm{km}$), to a "magnetodisk" in the outer region, where the radial field component is dominant at distances $\sim 1-2 \,\mathrm{R_S}$ from the equator (e.g Arridge et al. [2007]). This magnetodisk is supported by an azimuthal ring current whose solenoid-like field adds to the planetary dipole. In early studies, the ring current was represented by a bound annular region with four free parameters: a uniform half-thickness, inner and outer radii, and a current scaling parameter (e.g. Connerney et al. [1981]). In this model, current density J_{ϕ} was assumed inversely proportional to cylindrical radial distance ρ . This formalism ("CAN81 disk") was recently adapted to analyze Cassini magnetic data, establishing how ring current parameters depend on magnetopause size [Bunce et al., 2007].

More recently, a formalism for calculating self-consistent field and plasma distributions for the Jovian magnetodisk [Caudal, 1986] has been implemented for Saturn (Achilleos et al. [2010], hereafter A10). This approach integrates equations of force balance throughout a rotating, axisymmetric magnetosphere (§2). In §3, we use the A10 model to show that the variability of hot plasma pressure, as observed, affects the magnetospheric field structure—increased hot plasma content generally producing a more "inflated" or "disk-like" field geometry. To test the model's high-latitude structure, we compare its outputs with field and particle data from the Rev 40 high-inclination orbit of Cassini. We discuss the agreement between model and data and summarize our conclusions in §4.

2. Magnetodisk Model Inputs

We have improved A10's representation of the cold equatorial ion temperature over $10\text{--}25\,\mathrm{R_S}$, by combining temperatures for protons and water group ions from McAndrews et al. [2009] ($\sim 10\text{--}30\,\mathrm{R_S}$) and $Wilson\ et\ al.$ [2008] (5–10 $\mathrm{R_S}$), who analyzed energy spectra acquired by the ion mass spectrometer (IMS), a subsystem of the Cassini Plasma Spectrometer (CAPS) [Young et al., 2004]. Temperature moments versus equatorial distance, along with quartic fits, are shown in Fig. 1a,b (fit coefficients available on request). A10's initial study used only $Wilson\ et\ al.$ [2008]'s temperatures, with parabolic extrapolation beyond $10\,\mathrm{R_S}$. Using the updated profiles, we derived the single plasma temperature $T_c(\rho)$ required by the model, whose field lines are loci of constant, isotropic temperature. This was done as in A10, by taking weighted average moments for each ion species, then combining these according to a prescribed plasma composition.

To model hot plasma content, we used the equatorial product $P_h(\rho) V_{\alpha}(\rho)$ of hot plasma pressure (assumed constant along a field line) and unit flux tube volume (Caudal [1986], A10). We extended the Cassini Magnetospheric Imaging Instrument (MIMI) pressure dataset used in A10's initial study [Sergis et al., 2007] to cover 23 near-equatorial orbits in total, between October, 2004 and March, 2006. The hot pressure arises from ions (mainly H+ and O+) with energies >3 keV (e.g. Sergis et al. [2009]). The moments are computed in the spacecraft frame, from an incomplete sampling of the phase space. However, for ρ >12 R_S, energetic ions have typical thermal speeds ~10 times higher than the plasma flow speed. The resulting hot pressures are uncertain by factors of ~2-3, within the scatter of the presented data. We used pressure moments sampled every 10 minutes, taken from the dayside, equatorial magnetosphere: (i) absolute latitudes <5°,

(ii) Saturn local times 09:00–15:00, and (iii) locations between each orbit's last inbound and next outbound magnetopause crossings.

All hot pressures are shown as gray symbols in Fig. 1c, collapsed onto a single profile in ρ . For comparison, data for *Cassini* Rev 3 (February 14–23, 2005) are overlain in black (data from this orbit were previously analyzed by A10). Fig. 1d shows the median, 10% and 90% quantiles. Solid curves are cubic fits to these parameters, which correspond to "average", "disturbed" and "quiescent" ring current states (following *Sergis et al.* [2007] and A10). We assumed a zero-slope profile past $\sim 23\,\mathrm{R_S}$ (dashed lines in Fig. 1d), however this did not affect our conclusions. Repeating this parametrization, incorporating all local times, elevated the quantile pressures by $\sim 40\%$.

3. Comparison of Magnetodisk Models and Observations

Fig. 2 illustrates the model magnetodisk's response to ring current state. Left and right columns show calculations for fixed magnetopause radius $R_{MP}=25 R_{S}$ (average value for Saturn [Achilleos et al., 2008]), but for quiescent and disturbed states (Fig. 1d). Fig. 2a shows that field lines in the disturbed model become more radially "stretched" for $\rho\sim10-15 R_{S}$. The labeled field lines intersect northern ionospheric colatitudes $\theta_{i}=15^{\circ}$, 17° and 19° . These values are first order estimates, since we assume a centered dipole for the planet's internal field; Nichols et al. [2009] have used auroral observations and a more realistic internal field model to show that the northern auroral oval has a radius $\sim1.5^{\circ}$ smaller than the southern. The model magnetopause shielding field is valid for latitudes $\lesssim50^{\circ}$ [Caudal, 1986], and the labeled field lines exceed this limit for radial distances $\lesssim7 R_{S}$. Increased hot plasma content expands the equatorial distance of the labeled

field lines by $\sim 3-4\,\mathrm{R_S}$. The ionospheric colatitudes 15–17° are $\lesssim 1^\circ$ from the observed equatorward boundary of the northern auroral oval [Nichols et al., 2009]. Thus internal re-configuration of hot plasma, at fixed $\mathrm{R_{MP}}$, can influence ionosphere-disk magnetic mapping and equatorial width of the auroral current layer. A similar effect was noted by Grodent et al. [2008] from auroral observations of Jupiter.

In Fig. 2b, we plot equatorial magnetic and plasma pressure for both models. Field strength at $\rho \gtrsim 15 \,\mathrm{R_S}$ for the disturbed disk is more uniform than the quiescent model. Total model plasma pressure (disturbed) agrees well, as shown, with that of Sergis et al. [2010] (hereafter S10; derived directly from CAPS and MIMI pressures). The radial gradient of our profile differs from that of S10, however, which has consequences for azimuthal current (see below). Our disturbed disk's maximum plasma β of ~ 6.5 at $\rho \sim 14 \,\mathrm{R_S}$ is consistent with S10's $\beta_{max} \sim 3-10$ for $\rho \sim 11-14 \,\mathrm{R_S}$.

Fig. 2c compares equatorial volume forces. Again, the smaller gradient in the disturbed disk's magnetic pressure for $\rho \gtrsim 15\,\mathrm{R_S}$ is evident. The corresponding increase in total plasma pressure gradient is mainly balanced by increased curvature force of the more disk-like field. In the outer model disk, plasma pressure gradient becomes smaller than centrifugal force within a few $\mathrm{R_S}$ of the magnetopause. This result, arising from our improved pressure representation, differs greatly from A10's "transition distance" of $\sim 12\,\mathrm{R_S}$, but agrees with $Arridge\ et\ al.\ [2007]$, who deduced plasma pressure from Cassini magnetic data during current sheet encounters.

Fig. 2d compares the modeled equatorial azimuthal current density, associated with pressure gradient and centrifugal force, with S10's data-derived values. Considering cen-

trifugal (inertial) current, the model is in reasonable agreement with the data for $\rho \gtrsim 6 \,\mathrm{R_S}$. The discrepancy is mainly due to the difference between our approach (see A10) and S10 for computing currents. For centrifugal current, we assume A10's polynomial fit to plasma angular velocity ω obtained from high-energy particle anisotropies [Kane et al., 2008], combined with inner magnetospheric values from Wilson et al. [2008]. Combining our magnetic field model and profile for ion flux tube content produces the centrifugal term. S10 employed CAPS density and velocity moments from Wilson et al. [2008] and McAndrews et al. [2009], and their own CAPS ion moment computations, in order to derive and fit centrifugal volume force as a function of ρ . The ratio of our centrifugal force to that of S10 ranges from ~ 2 at $\sim 6 \,\mathrm{R_S}$ to ~ 0.5 at $\sim 12 \,\mathrm{R_S}$.

Considering pressure gradient, we recall (discussion of Fig. 2b) considerable differences in plasma pressure gradients between our model and S10's values. Thus for $\rho \gtrsim 8 \, R_S$, our disturbed model's total pressure current seems reasonably consistent with S10's lower limits. Current density exceeds inertial at $\sim 8 \, R_S$ in both model and data. For $\rho \lesssim 8 \, R_S$, Sergis et al. [2010] find >25% of total current arises from pressure anisotropy. This is not included in our model at present.

In Fig. 3a,b, we compare model outputs with hot plasma and magnetic pressures for Cassini's Rev 40 orbit from the MIMI and Cassini magnetometer (MAG) [Dougherty et al., 2004]. The model assumes constant hot pressure P_h along field lines, hence the change in local pressure with altitude Z (from the equator) is equivalent to the change in the value P_{h0} at the equatorial crossings of the field lines sampled by the spacecraft.

Values of R_{MP} were determined by A10, who modeled individual field components during this orbit.

Hot pressures near the nightside current sheet crossing (CSX1) are well captured by a quiescent disk model, while the dayside crossing (CSX2) requires an "intermediate" state. Sharp "dropouts" in pressure near days ~67.5 and ~70 (decimal day of year) are also seen in the model, and coincide with the spacecraft's exit from and entry into the polar cap, characterized by open magnetic flux and relative absence of plasma. This region manifests in the model as field lines which do not cross the equator inside the magnetopause, hence are assumed to be devoid of plasma. Polar cap boundary crossings are also seen in nightside models, near days ~63.9 and ~65.9. For these local times, however, observed pressures are small, near noise level, and could obscure any dropout signature. Quasiperiodic "pulsations" are present in plasma and magnetic data, which we emphasize with vertical lines spaced by the nominal 10.75 hr planetary rotation period. These features are due to the quasi-periodic "camshaft" oscillations in the Kronian magnetosphere, whose period agrees with that of the Saturn kilometric radiation (e.g. Southwood and Kivelson [2007]; Kurth et al. [2007]; Provan et al. [2009]).

The change in magnetic pressure when crossing the current sheet is greater at CSX1 than CSX2. CSX1 occurs at $\rho \sim 15 \,\mathrm{R_S}$ in the "middle magnetosphere" where the field lines are most disk-like, hence produce a strong contrast in field strength between the inside and outside of the sheet (Fig. 2a). CSX2 occurs at $\rho \sim 20 \,\mathrm{R_S}$ towards the "outer region" where field lines are more "blunt" (larger radius of curvature), this contrast is thus reduced, and the cold plasma sheet is thicker (A10). Models with more disturbed disk and / or larger

R_{MP} show a change in magnetic pressure comparable to that seen at CSX1. However, the observed sheet transit is more rapid than the model analog, perhaps due to plasma sheet motion linked to camshaft oscillations.

Fig. 3c is a CAPS electron spectrogram for the same orbit. The decrease in cold electron plasma (counts) with distance from the equator is more pronounced near CSX1 than CSX2. This aspect reflects global force balance, which allows the cold population to maintain higher pressure for a given Z in regions where the field lines have larger curvature radii, and centrifugal confinement is weaker (e.g. A10, Caudal [1986]). Nightside data are better matched by a more quiescent disk and larger R_{MP} , both possible signatures of a thinner nightside plasma sheet, as described by Sergis et al. [2009]. The magnetosheath population seen after the outbound magnetopause crossing (MPX, early on day 70) shows peak energies similar to those near the exit from the polar cap (via the dayside cusp) at day \sim 67.5. Trajectory information in Fig. 3d includes northern ionospheric colatitude θ_i magnetically conjugate to Cassini's location. Regions with θ_i <13° are shown as a solid curve (also shown in Fig. 3c), and represent a model polar cap, located on field lines poleward of the auroral oval boundary [Badman et al., 2006].

4. Conclusions

Saturn's magnetospheric field can be significantly modified by internal changes in hot plasma pressure. Magnetic mapping between ionosphere and disk is also dependent on internal plasma state (as well as external solar wind pressure, e.g *Bunce et al.* [2008]). This result suggests a corresponding influence on the distribution of currents which flow between these regions and their associated auroral emissions. Comparing our models with

both field and plasma data allows identification of ring current state and its magnetic signatures.
