Iver Cairns, School of Physics, University of Sydney, NSW 2006, Australia. (cairns@physics.usyd.edu.au)

Abstract. We seek to reconcile observations of small source sizes in the 3 solar corona at 327 MHz with predictions of scattering models that incor-4 porate refractive index effects, inner scale effects and a spherically diverg-5 ing wavefront. We use an empirical prescription for the turbulence ampli-6 tude $C_N^2(R)$ based on VLBI observations by Spangler and coworkers of com-7 bact radio sources against the solar wind for heliocentric distances R \approx 8 10–50 R_{\odot} . We use the Coles & Harmon model for the inner scale $l_i(R)$, that 9 is presumed to arise from cyclotron damping. In view of the prevalent un-10 certainty in the power law index that characterizes solar wind turbulence at 11 various heliocentric distances, we retain this index as a free parameter. We 12 find that the inclusion of spherical divergence effects suppresses the predicted 13 source size substantially. We also find that inner scale effects significantly 14 reduce the predicted source size. An important general finding for solar sources 15 is that the calculations substantially underpredict the observed source size. 16 Three possible, non-exclusive, interpretations of this general result are pro-17 posed. First and simplest, future observations with better angular resolution 18 will detect much smaller sources. Consistent with this, previous observations 19 of small sources in the corona at metric wavelengths are limited by the in-20 strument resolution. Second, the spatially-varying level of turbulence $C_N^2(R)$ 21 is much larger in the inner corona than predicted by straightforward extrap-22 olation Sunwards of the empirical prescription, which was based on obser-23 vations between 10–50 R_{\odot} . Either the functional form or the constant of pro-24

SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA X - 3

- ²⁵ portionality could be different. Third, perhaps the inner scale is smaller than
- ²⁶ the model, leading to increased scattering.

1. Introduction

Refractive scattering of radiation by density turbulence in the Sun's corona and solar wind leads to angular broadening of embedded radio sources, and of cosmic sources observed through these media. The process is similar to the twinkling of stars and modified "seeing" caused by density turbulence in Earth's atmosphere and ionosphere. This scattering process has been investigated for many years using geometrical optics [e.g., Steinberg et al 1971] and the parabolic wave equation [e.g., Lee and Jokipii, 1975; Coles and Harmon 1989; Bastian 1994; Cairns 1998].

Scattering is thought to affect the observed properties of type II and III solar radio ³⁵ bursts in several ways: greatly increasing the angular sizes of the sources [e.g., Riddle ³⁶ 1974], causing the time profiles to have exponential decreases [e.g., Robinson and Cairns, ³⁷ 1998], and causing anomalously low brightness temperatures at decametric wavelengths ³⁸ [e.g., Thejappa & Kundu 1992].

The primary motivation of this paper is to investigate the constraints imposed on models 39 of density turbulence in the solar corona by recent observations at 327 MHz [Mercier et al., 40 2006, made by combining visibilities from the Giant Metrewave Radio Telescope (GMRT) 41 in Pune, India, and the Nancay Radioheliograph (NRH) in France. The maps of Mercier 42 et al. [2006] show structures ranging from the smallest observed size of 49'' to that of the 43 whole Sun, with dynamic ranges as high as a few hundred. These features make them the best meter wavelength snapshot maps of the solar corona to date. Mercier et al. [2006] 45 found the smallest steady angular size of type I solar noise storms to be 49'' in their high dynamic range, full disk, 17 second snapshots. We therefore adopt the smallest observed 47

SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA X - 5

source size of 49'' in these maps to be a canonical number for comparison with our model 48 predictions. The only other two-dimensional map showing small source sizes that we are aware of is that of Zlobec et al [1992], who observed a source as small as 30'' at 327 MHz. 50 However, the dynamic range of their map was severely limited, and included only a very 51 small range of size scales. It should be noted that the lower limit to the observed size is 52 imposed by the resolution of the instrument if scattering by density turbulence is weak 53 enough. The scattering calculations shown below imply that there is a possibility that 54 smaller solar sources will be detected in the future by instruments with improved angular 55 resolution. 56

In this paper we use a formalism based on the paraxial wave equation and the structure 57 function, together with observationally based models for the density turbulence that scat-58 ter the radiation, to predict the size of sources in the solar corona at 327 MHz. Our results 59 can be interpreted as the scatter-broadened image of an ideal point source in the solar 60 corona. We have used an empirical model for the amplitude $C_N^2(R)$ of coronal turbulence 61 that is based directly a fit to the scattering measure obtained from VLBI observations of 62 cosmic sources broadened by scattering in the outer solar corona and inner solar wind. 63 Here R is the heliocentric distance. We have assumed that this model is valid through-64 out the corona, specifically at smaller R. We also consider the effects of spherical and 65 plane wave propagation, variations of the inner scale $l_i(R)$ and power-law index α of the 66 turbulence on the predicted source sizes. In most cases, we find that the models predict 67 sizes that are at least an order of magnitude below the smallest observed size of 49'' at 68 327 MHz. Our formalism and analyses differ primarily from those of Bastian [1994] in the 69 models for $C_N^2(R)$ and the electron density profile $n_e(R)$, while our applications are to 70

X - 6 SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA

⁷¹ metric rather than centimetric and decimetric emissions. Since our predictions are much ⁷² smaller and Bastian's [1994] predictions much larger than 49" at 327 MHz, the analyses ⁷³ demonstrate the importance of knowing $C_N^2(R)$, $n_e(R)$, and $l_i(R)$ much better for future ⁷⁴ observations and predictions of solar sources. These quantities are also relevant to the ⁷⁵ heating and outward flow of the coronal plasma, with activity localized to specific ranges ⁷⁶ of R potentially leading to larger $C_N^2(R)$ and so enhanced scattering at, say, decimetric ⁷⁷ frequencies than expected at, say, metric frequencies.

The paper is organized as follows. In § 2 we summarize the scattering formalism and observations of the density turbulence. Coronal density models are described in § 3. The results are presented in § 4, including estimates of the predicted angular broadening, and the implications for coronal density turbulence. The conclusions are presented in § 5.

2. Angular broadening

We first consider the angular broadening predicted by the empirical formula of Erickson (1964):

$$\theta = 50 \left(\frac{\lambda}{D}\right)^2 \text{ arcminutes }.$$
(1)

Here λ is the observing (free-space) wavelength in meters and D is the elongation in units of R_{\odot} . If we take $D = 1.056R_{\odot}$, which is where 327 MHz emission would originate according to the hybrid density model described below, then $\theta \simeq 50'$ for 327 MHz, which is much larger (60 times) than the observed 49". It points to a significant difference between the situation for observations of celestial background sources against the solar wind, for which Erickson's (1964) formula is well accepted, and observations of solar radio events

DRAFT

that originate in the solar corona. This difference will be specifically addressed in the Discussion section below.

2.1. Density turbulence

Density turbulence in the Sun's corona and solar wind is modeled here by writing the three-dimensional isotropic spatial power spectrum $S_n(k, R)$ of the fluctuating part δn of the electron density n_e as [cf., Lee & Jokipii 1975; Rickett 1977; Coles and Harmon, 1989; Bastian, 1994; Cairns 1998; Spangler, 2002]

$$S_n(k,R) = \langle (\delta n)^2 \rangle(k,R) = C_N^2(R)k^{-\alpha}e^{-k^2/q_i^2}$$
 (2)

Here k and R are the (isotropic) wavenumber and radial distance (in units of R_{\odot}), re-90 spectively, $C_N^2(R)$ models the level of turbulence, α is the power-law index, and q_i is the 91 wavenumber corresponding to the inner scale of the turbulence. While it is fairly well 92 established that the turbulence spectrum largely follows the Kolmogorov scaling (with 93 $\alpha = 11/3$) at scales larger than about 100 km, there is some evidence that it flattens, 94 with α decreasing to values as low as 3, at scales between a few km and a few hundred 95 km [Bastian, 1994]. There is also some evidence for variation of the turbulence power 96 law spectrum with heliocentric distance [e.g., Efimov et al., 2008]. Furthermore, there 97 is evidence for significant variation in the index between the slow and fast solar wind 98 [Manoharan et al., 1994]. We therefore retain α as a parameter. It may be noted that 99 some authors use a power law index of 5/3 to describe the one-dimensional Kolmogorov 100 spectrum; the index they refer to is equal to $\alpha - 2$. 101

The empirical model we use for $C_N^2(R)$ was originally mooted by Armstrong & Woo [1980] and later refined, based on VLBI observations between 10–50 R_{\odot} , by Spangler & X - 8 SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA Sakurai [1995] and Spangler [2002] among others:

$$C_N^2(R) = 1.8 \times 10^{10} \left(\frac{R}{10R_{\odot}}\right)^{-3.66}$$
 (3)

¹⁰² The dimensions of C_N^2 depend on α , being m^{- α -3}. The normalizations for C_N^2 differ by ¹⁰³ about a factor of a few and the power-law index with *R* ranges from -3.66 to -4 in these ¹⁰⁴ works, presumably due to solar wind variability.

The inner scale l_i is modeled using Coles & Harmon's [1989] model which agrees roughly with their observations,

$$q_i(R) = \Omega_i(R)/3V_A(R) \equiv 2\pi/l_i(R) = \frac{2\pi}{684 n_e(R)^{-1/2}} \quad \text{km}^{-1}$$
(4)

where Ω_i is the ion cyclotron frequency, V_A is the Alfvén speed and n_e is the electron density in cm⁻³. This model is interpreted conventionally in terms of cyclotron damping by MHD waves. We use this definition for the inner scale throughout this paper, except in two cases where we artificially set l_i equal to a very small value.

¹⁰⁹ A popular alternative prescription for C_N^2 supposes that C_N^2 is \propto the square of the ¹¹⁰ background electron density. Such a prescription has a constant of proportionality, which ¹¹¹ is often determined via observed values of the phase structure function (e.g., Bastian ¹¹² 1994). The magnitude of the phase structure function in turn, is very dependent on the ¹¹³ elongation to which it is referenced. We discuss this issue further in § 4.

2.2. Plane vs spherical wave propagation

Scattering depends quantitatively on whether the wavefront is planar (1-D) or spherical (3-D). When a source is embedded in the scattering medium, it is often appropriate to adopt a formalism that includes the spherically diverging nature of the wavefront. The geometry for spherically diverging propagation is shown in Figure 1.

Figure 1

Similarly, when a plane wave illuminates the scattering medium, a 1-D planar formalism is standard. In this case an observer is typically sensitive only to scattering regions (eddies) with sizes of order the baseline length s. In the spherically diverging situation, however, the observer is sensitive to a range of eddy sizes given by sa/b, where a is the (continuously varying) distance of the scattering screen from the source and b is the distance of the observer from the source. In our situation, this is tantamount to saying that the effective baseline for spherical wave propagation is [Ishimaru, 1978]

$$s_{\text{eff}} = sR/(R_1 - R_0).$$
 (5)

¹¹⁸ This is the basic difference between Eqs (8) and (9) discussed below.

In the solar situation, radiation from an embedded coronal source is subject to scat-119 tering as it propagates to the observer. Since the radiation is generated near f_p and $2f_p$, 120 scattering effects are expected to be largest in the source and in its vicinity, assuming 121 that $f_p(R)$ decreases monotonically with increasing R. Spherical effects are expected to 122 arise in two ways. Firstly, scattering will maximally distort an initially plane wavefront 123 close to and in the source. Secondly, on a larger scale, the solar wind density is expected 124 to be spherically symmetric, with radiation being refracted towards the radial direction. 125 Accordingly, spherical divergence effects are expected to be vital. They are explicitly 126 calculated below and shown to be quantitatively important. In contrast, the planar for-127 malism is expected to be appropriate when the source, scattering region(s), and observer 128 are all far apart, as assumed in calculations for pulsars and other celestial sources. 129

2.3. Structure function

The starting points for the expression we use for the scattering angle are equations (4)-(7) of Coles et al [1987] that specify the structure function and the mutual coherence function using the parabolic wave equation (PWE) formalism that includes small-angle refractive scattering and diffraction, but not reflection. For the sake of completeness, we reproduce them below. The asymptotic forms of the gradient of the phase structure function D(s, R) are

$$\frac{\partial}{\partial R} D(s,R) = \frac{8\pi^2}{2^{\alpha-2} (\alpha-2)} \frac{\Gamma(1-(\alpha-2)/2)}{\Gamma(1+(\alpha-2)/2)} C_N^2(R) r_e^2 \lambda^2 s^{\alpha-2}, \text{ for } s_{\text{eff}} \gg l_i(R), \quad (6)$$

$$\frac{\partial}{\partial R}D(s,R) = \frac{4\pi^2}{2^{\alpha-2}}\Gamma\left(1 - \frac{(\alpha-2)}{2}\right)C_N^2(R)r_e^2\lambda^2 l_i(R)^{\alpha-4}s^2, \text{ for } s_{\text{eff}} \ll l_i(R), \quad (7)$$

where r_e is the classical electron radius, λ is the observing wavelength and s_{eff} is the effective interferometer spacing. It is noted that this formalism is valid only for $2 < \alpha < 4$; in particular, equations (6) and (7) diverge at $\alpha = 4$ owing to the behavior of the term $\Gamma(1 - (\alpha - 2)/2)$. It may also be noted that the branches (6) and (7) do not meet at $s_{\text{eff}} = l_i$; the ratio of (7) to (6) is equal to $(1/2)(\alpha - 2)(l_i/s)^{\alpha - 4}\Gamma(1 + (\alpha - 2)/2)$, and at $s_{\text{eff}} = l_i$ this is equal to unity only for $\alpha = 4$.

The effective interferometer spacing s_{eff} is equal to s for the case of plane wave propagation, but is equal to $sR/(R_1 - R_0)$ for spherical wave propagation, as discussed in § 2.2 and Figure 1. The phase structure function for the cases of plane wave and spherical wave propagation are

$$D_p(s) = \int_{R_0}^{R_1} \frac{\partial}{\partial R} D(s, R) \, dR \,, \quad \text{for plane wave propagation} \,, \tag{8}$$

$$D_s(s) = \int_{R_0}^{R_1} \frac{\partial}{\partial R} D\left(\frac{sR}{R_1 - R_0}, R\right) dR, \text{ for spherical wave propagation}, \qquad (9)$$

where the lower limit of integration R_0 is the radial distance from which scattering is assumed to be effective (we take this to be equal to the fundamental emission level), and the upper limit R_1 corresponds to the observer (here at $R_1 = 1$ AU). All quantities are assumed to have spherical symmetry and the path is assumed to be radial.

Scattering depends sensitively on the ratio of the radiation frequency f to the local electron plasma frequency $f_p(R)$ [Cairns, 1998]. Equations (16) and (22) of Cairns [1998] include the effects on refractive scattering that arise from $f_p(R)$ being non-zero and varying with position between the source and observer. By analogy with these equations we write

$$D_{pf}(s) = \int_{R_0}^{R_1} \frac{1}{1 - f_p(R)^2 / f^2} \frac{\partial}{\partial R} D(s, R) \, dR \tag{10}$$

for plane wave propagation and

$$D_{sf}(s) = \int_{R_0}^{R_1} \frac{1}{1 - f_p(R)^2 / f^2} \frac{\partial}{\partial R} D\left(\frac{sR}{R_1 - R_0}, R\right) dR$$
(11)

¹⁴⁰ for spherical wave propagation, respectively.

The scattering angle is conventionally defined using a coherence scale s_0 in the following manner [e.g., Coles et al., 1987; Bastian, 1994]:

$$\theta_c = \left(2\pi s_0/\lambda\right)^{-1},\tag{12}$$

where

$$D_*(s_0) = 1 (13)$$

and $D_*(s)$ is either equal to $D_{pf}(s)$, defined by (10), or $D_{sf}(s)$, defined by (11), in appropriate limits. This scattering angle θ_c can be interpreted as the predicted size of an idealized point source.

2.4. Density Models

A model for $n_e(R)$ in the corona and solar wind is required to be able to predict the angular broadening. The density model is required for computing the inner scale, which is defined in the next subsection. Since there is no universally accepted model, we initially consider four representative density models. One is the four-fold Newkirk density model for the corona, based on eclipse observations [Newkirk, 1961]:

$$n_{\rm 4n}(R) = 4 \times 4.2 \times 10^4 \times 10^{4.32/R} \,{\rm cm}^{-3}\,,$$
 (14)

The second model is derived from the frequency drift rate of interplanetary type III bursts [Leblanc et al., 1998]:

$$n_{\rm lb}(R) = 3.3 \times 10^5 R^{-2} + 4.1 \times 10^6 R^{-4} + 8 \times 10^7 R^{-6} \quad {\rm cm}^{-3} \,. \tag{15}$$

The third model considered is due to Aschwanden et al. [1995]. It is based on the drift rates of type III bursts [Alvarez & Haddock, 1973] in the outer corona and solar wind (f < 10 MHz) and assumes an isothermal barometric atmosphere for the lower corona:

$$n_{\rm a}(R) = \begin{cases} n_1 \left(\frac{R-1}{R_2}\right)^{-p}, & R > 1 + R_2 \\ n_Q \exp\left(-\frac{R-1}{\mu}\right), & R < 1 + R_2 \end{cases}$$
(16)

where p = 2.38, $n_Q = 4.6 \times 10^8 \text{ cm}^{-3}$, $n_1 = n_Q \exp(-p)$, $\mu = 0.1$ and $R_2 = p\mu$. The fourth model is a "hybrid", using the Aschwanden & Benz [1995] model for the lower corona and the four-fold Newkirk model multiplied by a normalization factor (to ensure continuity) in the upper corona. In other words, the density $n_{\text{hyb}}(R)$ of the hybrid model is

$$n_{\rm hyb}(R) = \begin{cases} A \, n_{\rm 4n}(R) \,, & R > 1 + R_2 \\ n_{\rm a}(R) \,, & R < 1 + R_2 \,, \end{cases}$$
(17)

where A = 0.324 is the normalization factor that ensures continuity.

DRAFT

Figure 2 shows $f_p(R) = 8.97 n_e(R)^{1/2}$ kHz for all four density models, with n_e in units of cm⁻³.

The figure shows that the highest frequency predicted for R > 1 by the Leblanc et al. 147 [1998] density model (Eq 15) is less than 100 MHz. Since our observing frequency is 327 148 MHz, this model is therefore unsuitable for our purposes. However, the four-fold Newkirk 149 model (14), Aschwanden & Benz [1995] model (16), and hybrid model can account for 150 $f_p = 327$ MHz for R > 1. However, since the Aschwanden & Benz [1995] model predicts 151 unrealistically low densities (and consequently f_p) for $R > 1 + R_2 = 1.23$, only the hybrid 152 model is considered further below. Fundamental emission at 327 MHz emanates from 153 a heliocentric distance of 1.055 R_{\odot} with this model. In order to avoid the singularity 154 in the integrand in Eqs (10) and (11), we start the integration at $R_0 = 1.056 R_{\odot}$. In 155 other words, we start the integration from a distance of approximately 700 km above 156 the height at which 327 MHz fundamental emission originates. This distance is smaller 157 than that corresponding to the frequency difference Δf between the minimum frequency 158 of fundamental emission at a given location and the local value of f_p , so that avoiding 159 the singularity is correct. This positive frequency difference exists because conservation 160 of energy and the wave dispersion relations force the standard nonlinear Langmuir wave 161 processes for fundamental and harmonic emission to produce radiation of order several 162 percent above f_p and $2f_p$ [e.g., Cairns, 1987a,b], with the value of $\Delta f/f_p$ depending on 163 the beam and plasma parameters. 164

2.5. Inner scale effects

¹⁶⁵ We next discuss the need for including inner scale effects in our treatment. In general, ¹⁶⁶ inner scale effects are important if the baseline is smaller than the inner scale.

DRAFT

X - 14SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA

Figure 3 shows the inner scale (in km) given by Eq (4), as a function of heliocentric distance for some of the density models discussed in the preceding section. Clearly, the inner scale is quite dependent upon the density model. The inner scale for the Aschwanden & Benz [1995] model far exceeds those for the other models, since the density with this model for R > 1.23 in unrealistically low; we have therefore chosen not to depict the l_i for this model in Figure 3. As explained in the preceding section, we choose to use only the hybrid model from now on, for it is by far the most realistic one.

In order to ascertain the importance of inner scale effects, we compare l_i with the longest 174 baseline (that determines the smallest source size), assuming that the source is situated 175 at the fundamental emission level for 327 MHz, and the observer is at 1 AU. In order 176 to compute the longest baseline, we set $49'' = 1.22\lambda/s$, where 49'' is the observed source 177 size and λ is the (free space) observing wavelength (1 meter). This yields an effective 178 baseline of $s \sim 5$ km. In order to ascertain the relevance of the inner scale (i.e., whether 179 we should be using Eq 6 or 7) we need to compare the effective longest baseline s_{eff} with 180 the inner scale. It may be noted that a typical interferometer measurement involves a 181 range of baselines, and while the longest baseline we have computed above is the one that 182 limits the smallest observable source size, baselines shorter than this one do contribute 183 to the overall measurement. However, our approach is appropriate because the longest 184 baseline for a given source size is the largest length scale at which there is appreciable 185 power. Inner scale effects are relevant only for the branch for which the baseline is \ll the 186 inner scale, as in Eq 7. If the *longest* relevant baseline is smaller than the inner scale, then 187 it follows that the rest of the baselines in the problem automatically satisfy this criterion. 188 Our approach thus provides a useful estimate of the importance of inner scale effects. 189

DRAFT

Figure 3

As discussed above, $s_{\text{eff}} = s$ for plane wave propagation, while $s_{\text{eff}} = sR/(R_1 - R_0)$ for spherical wave propagation. We show the ratio of s_{eff} to l_i in Figure 4.

When considering plane wave propagation, $s_{\text{eff}} = s$, and the solid line in Figure 4 192 shows that s_{eff} is mostly > l_i . For heliocentric distances greater than about 30 R_{\odot} , s_{eff} 193 does become somewhat smaller than l_i , but most of the contribution to the scattering 194 kernel arises from distances well inside 30 R_{\odot} . We should therefore use Eqs (6) and 195 (10) for plane wave propagation. On the other hand, when considering spherical wave 196 propagation, $s_{\text{eff}} = sR/(R_1 - R_0)$, and the dotted line in Figure 4 shows that s_{eff} is $< l_i$ 197 for all R. The appropriate equations to use for spherical wave propagation are therefore 198 Eqs (7) and (11). 199

3. Results

3.1. Plane wave propagation

We first consider plane wave propagation, which is more appropriate for waves emanating from a background object that is far from the scattering medium.

202 3.1.1. $s_{ ext{eff}} \gg l_i$

Since Figure 4 shows that $s_{\text{eff}} > l_i$ for plane wave propagation for $R < 30R_{\odot}$, the appropriate branch to use is Eq (6). At heliocentric distances greater than about 30 R_{\odot} , s_{eff} becomes marginally less than the inner scale, but we have verified numerically that this is immaterial, since most of the contribution to θ_c takes place well within 30 R_{\odot} .

Figure 5 uses Eqs (6), (10) and (13) to predict the scattering angle $\theta_c(1 \text{ AU})$ at the Earth, in arcseconds, as a function of the power law index α for plane wave propagation at f = 327 MHz. The thin line is for fundamental emission and the thick line is for second harmonic emission. Removal of the refractive index effect in Eq (10), meaning the factor

Figure 4

Figure 5

X - 165UBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA of $(1 - f_p^2/f^2)^{-1}$, causes a negligible change in the result. The predicted source size is slightly smaller for second harmonic emission.

213 3.1.2. $s_{
m eff} \ll l_i$

Although Figure 4 demonstrates that $s_{\text{eff}} > l_i$ for plane wave propagation, we nevertheless investigate the predicted scattering angle for plane wave propagation, while using branch (7). The results are shown in Figure 6.

Evidently, the source sizes predicted approach the observed size for relatively steep turbulence spectra; for spectra that are steeper than Kolmogorov (i.e., $\alpha > 11/3$), the predicted source sizes exceed the observed one. In order to investigate inner scale effects we compute the scattering angle for plane wave propagation with the inner scale set to an artificially low value of 1 m, instead of being computed self-consistently from Eq 4. The results are shown using the heavy lines in Figure 7. When inner scale effects are thus removed, it is clear that the predicted source size increases, especially for flatter spectra.

Figure 7

Figure 6

3.2. Spherical wave propagation

As discussed earlier, spherical wave propagation is appropriate when the source is embedded in the scattering medium, as is the case here.

226 3.2.1. $s_{ ext{eff}} \ll l_i$

Since Figure 4 shows that $s_{\text{eff}} \ll l_i$ for spherical wave propagation, the appropriate branch to use is (7).

The solid line in Figure 7 predicts $\theta_c(1 \text{ AU})$ for spherical wave propagation, using (7), (10) and (13). Clearly, the predicted scattering angle is at least 25 times smaller than the observed one. The dashed line, on the other hand, is computed by artificially setting $l_i = 1$ m, while still using (7). This is tantamount to neglecting inner scale effects. We ²³³ observe that for flat spectra, inner scale effects substantially reduce (by over an order ²³⁴ of magnitude) the predicted θ_c , but that this difference is progressively reduced as α ²³⁵ increases. There are negligible differences between the results for fundamental and second ²³⁶ harmonic emission, and removal of the refractive index effect causes a negligible change ²³⁷ too.

238 $3.2.2.~s_{ ext{eff}} \gg l_i$

In keeping with the spirit of our treatment for plane wave propagation, we investigate the predicted scattering angle for spherical wave propagation while using branch (6), which assumes that $s_{\text{eff}} > l_i$. We do this despite Figure 4's prediction that s_{eff} is $< l_i$ for spherical wave propagation.

²⁴³ The difference between fundamental and second harmonic emission are negligible.

²⁴⁴ 3.2.3. Spherical vs plane wave propagation

Although we have investigated several different cases, our attention has been focussed mainly on two issues: first, the difference between the source sizes predicted for plane wave and spherical wave propagation, and, second, the influence of the inner scale. We now compare the plane wave and spherical wave results directly in Figure 9, assuming fundamental emission, and employing an inner scale that is computed self-consistently using Eq (4).

It is clearly evident from Figure 9 that spherical divergence effects decrease the predicted scattering angle by around two orders of magnitude as compared to the plane wave case. This is best seen by comparing the same branch (say, $s_{\text{eff}} > l_i$) for the plane wave and spherical wave cases. Thus, spherical divergence effects should be quantitatively important for scattered solar radio emission and plane wave results should be used with great caution.

4. Discussion and Summary

The highest resolution meter wavelength observations of the solar corona reveal com-256 pact sources around 49" in size at 327 MHz. The main aim of this paper is to employ 257 an observationally-motivated model for the turbulence amplitude C_N^2 , and see what it 258 implies for the predicted scattering angle for radio sources located in the solar corona. 259 We reference our calculations to the same frequency (viz. 327 MHz) at which the small-260 est source size is observed. We employ the parabolic wave equation, together with the 261 standard asymptotic forms for the phase structure function, which are valid for situations 262 where the effective baseline is either much larger or much smaller than the inner scale. 263 We define the predicted scattering angle θ_c via Eq. (12) as the angle where the phase 264 structure function falls to 1/e times its peak value. Effectively, this means that the scat-265 tering angles predicted here should be interpreted as the scatter-broadened image of an 266 ideal point source in the solar corona. The real source will have an intrinsic size (i.e., it 267 will not be a point source) and the observable source will be the convolution of the in-268 trinsic source profile with θ_c , provided there are no instrumental limitations. The results 269 in this paper should therefore be regarded as lower limits to the observable source size 270 set by scattering. The general consensus now seems to be that there is not much about 271 the instrinsic source size that can be gleaned from scatter-broadened images [Bougeret & 272 Steinberg, 1977; Melrose, 1980; Bastian, 1994]. However, if the intrinsic source size and θ_c 273 are similar in size, then the observed source size will be larger than θ_c by a factor near $\sqrt{2}$. 274 Note that this factor cannot account for the large discrepancies between the minimum 275 source size observed at 327 MHz [Mercier et al., 2006] and those predicted here. If, on 276

SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATAX - 19 the other hand, the intrinsic source size is much larger, then scatter broadening does not play a significant role.

We have included refractive index effects that can be important when the radiation is 279 emitted near the fundamental plasma level, but found them to be relatively unimportant. 280 The inner scale is included via the Coles and Harmon [1986] model, interpreted in terms 281 of cyclotron damping of MHD waves, and so depends primarily on the ambient electron 282 density. We employ a hybrid model for the electron density that yields reasonable heights 283 for meter wavelength emission at the fundamental. In view of the uncertainity in its value 284 in the inner corona, the power law index α characterizing the turbulent spectrum is taken 285 to be a free parameter. We consider both plane wave and spherical wave propagation. 286 For the geometry we consider, where the source is embedded in the scattering medium, 287 the spherical wave description is arguably more appropriate. 288

We have thus explored a wide variety of effects. We observe that there is no significant 289 difference in the predicted scattering angle between fundamental and second harmonic 290 emission. We also find that the removal of the refractive index effect causes a negligible 291 change in the predicted scattering angle. We find that the spherical divergence effect 292 results in a significant lowering of the predicted scattering angle (by around 2 orders of 293 magnitude). We find that removing inner scale effects by artificially setting the inner 294 scale to be equal to a very small value (instead of determining it self-consistently from 295 Eq 4) results in a significant enhancement of the predicted source size. The enhancement 296 is greatest for flatter spectra, where it can be a factor of around 50, and it progressively 297 disappears for steeper spectra. 298

277

278

X - 205UBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA

As mentioned earlier, the power law index of the turbulent spectrum is a free parameter. There is a formal divergence at $\alpha = 4$ in Eqs (6) and (7), and we therefore limit the computations to a maximum value of $\alpha = 3.97$. The maximum value of the predicted scattering angle thus occurs at $\alpha = 3.97$.

For plane wave propagation, the predicted source size for Kolmogorov turbulence is 303 around 10'' lower than the observed one. For spherical wave propagation, we find that 304 the maximum value of the predicted scattering angle is at least 25 times smaller than 305 the observed one. It is emphasized that plane wave propagation is relevant to the well-306 accepted empirical formula of Erickson [1964], which predicts large source sizes, since it 307 pertains to observations of celestial sources through the solar wind. Even so, with current 308 estimates of $l_i(R)$ implying that $s_{\text{eff}} > l_i$ (Figure 4), additional scattering is required to 309 bring Erickson's result into quantitative agreement with the calculations here for plane 310 wave scattering. Alternatively, the inner scale $l_i(R)$ should be smaller than that predicted 311 by the Coles and Harmon [1989] model assumed here, so that $s_{\text{eff}} < l_i$. 312

The crucial result of this paper is that the predicted source sizes are considerably smaller 313 than the observed lower limit of 49" when spherical wave propagation and inner scale 314 effects are included, as they should be for sources in the solar corona. This broad trend of 315 the models substantially underpredicting the source size can be interpreted in three ways 316 that are not exclusive and can occur in combination. First, it could imply that source 317 sizes much smaller than those that have been observed so far actually exist in the solar 318 corona, and can potentially be observed. All the instances of observations of small sources 319 to date have been limited by the instrument resolution; it is therefore quite likely that 320 smaller sources can be detected when instrument resolutions are improved. Second, this 321

broad trend can be taken to imply that our naive extrapolation of the empirical form for 322 the turbulence amplitude $C_N^2(R)$ to the inner corona is not justified. The results could 323 be taken to imply that $C_N^2(R)$ in the inner corona is far higher than suggested by the 324 empirical formula (3). This could be due to the functional form for $C_N^2(R)$ increasing 325 more rapidly with decreasing R or due to a larger normalization factor or both effects. 326 Third, the model (4) may significantly overestimate $l_i(R)$, meaning that the turbulent 327 cascade extends to smaller length scales (larger q) and leads to more scattering. These 328 proposals all appear reasonable, and we regard all three as viable. 329

Finally, we discuss the connection between our work and that of Bastian [1994]. The 330 methodology is similar, and we investigate similar issues such as the effects of the inner 331 scale, turbulence index α , and spherical versus planar wave propagation. Bastian's [1994] 332 findings are contrary to ours: we find that our model predictions are substantially below 333 the minimum observed size of 49", while Bastian's [1994] model predictions are substan-334 tially above 49". Thus, a priori, both models need revision. A major difference is in the 335 choice of a model for C_N^2 . Bastian [1994] uses a model for C_N^2 which is proportional to 336 the square of the background electron density and assumes the density model of Riddle 337 (1974), which also involves a constant of proportionality. These two constants of propor-338 tionality are absorbed into one and fixed by normalizing the structure function $D_{20}(10 \text{km})$ 339 for a baseline of 10 km, an observing wavelength of 20 cm, and an elongation of 5 R_{\odot} . In 340 contrast, as explained earlier, the C_N^2 model we use is determined by an empirical fit to 341 VLBI scattering observations between 10–50 R_{\odot} ; this was motivated by the need to use 342 a C_N^2 model that is derived as directly as possible from observations. A minor matter is 343 that Bastian [1994] discusses the disk to limb variation in the predicted scattering angle. 344

DRAFT

X - 225UBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA

whereas our treatment is valid only for sources that are reasonably close to disk center. In order to do so, we would need to use the general formalism used here, together with an integration path that incorporates the appropriate extra path length needed for sources that are displaced from the disk center.

An appropriate means of comparing the normalizations of the two treatments is thus to compare the normalizations of the structure function. Using (10) - (13), we write the structure functions as

$$D_{sf}(s) = \frac{4\pi^2 s^2}{\lambda^2} \theta_{csf}^2,$$

$$D_{pf}(s) = \left(\frac{2\pi s}{\lambda}\right)^{\alpha - 2} \theta_{cpf}^{\alpha - 2},$$
 (18)

where $\theta_{csf}(s)$ is the value of θ_c for spherical wave propagation using branch (7) and $\theta_{cpf}(s)$ corresponds to plane wave propagation for branch (6). Then using our models for $C_N^2(R)$, $l_i(R)$, and $n_{hyb}(R)$ we find that $D_{sf}(s) = 2.8 \times 10^{-3}$ rad² for s = 10 km, $\lambda = 91$ cm (corresponding to 327 MHz), $\alpha = 11/3$ and a starting height corresponding to 327 MHz fundamental emission. The same prescription and parameters yield $D_{pf}(s) = 7.7 \times 10^{-3}$ rad^{5/3}. Since the structure functions we derive are based on integrations over heliocentric distance, we cannot assign a specific elongation to them.

In comparison, Bastian normalizes C_N^2 by assuming $D_{20\text{cm}}(10\text{km}) = 4-12 \text{ rad}^2$, based on measurements of by Coles and Harmon [1989] and Armstrong et al. [1990] of cosmic sources (implying primarily planar wave effects) at an elongation of 5 R_{\odot} . In order to normalize Bastian's [1994] values for the structure function to a wavelength of 91 cm, we concentrate on the structure function for spherical wave propagation. Inspection of Eqs [11] and [18] reveals that $D_{sf}(s) \propto \lambda^2$. Therefore, $D_{20\text{cm}}(10\text{km})/D_{91\text{cm}}(10\text{km}) = 21$. Bastian's [1994] range of values for $D_{20\text{cm}}(10\text{km})$ thus corresponds to $D_{91\text{cm}}(10\text{km}) =$ ³⁶⁶ 82 - 250 rad². The difference in $D_{91cm}(10\text{km})$ between the two prescriptions is thus a ³⁶⁷ factor of $\approx (30 - 90) \times 10^3$, corresponding to a factor $\approx 170 - 300$ in θ_c .

This large difference $\approx (30 - 90) \times 10^3$ in the normalization of the structure function 368 is primarily indicative of a corresponding difference in the normalization of C_N^2 between 369 the two treatments; this is because neglect of inner scale effects increases θ_c by less than 370 a factor of 10 for Kolmogorov turbulence in Figure 7. In this connection, we note that 371 Bastian's [1994] normalization for $D_{20cm}(10 \text{ km})$ is based on values of D(s) measured at 372 an elongation of 5 R_{\odot} . We also note (e.g., Fig 1 of Coles & Harmon [1989]) that values 373 of D(s) measured at larger elongations can be considerably lower (by as much as a few 374 orders or magnitude, depending upon the elongation). This is significant, since the model 375 for C_N^2 that we use in this paper is based on observations between 10 and 50 R_{\odot} . 376

In summary, the foregoing results demonstrate conclusively that spherical wave prop-377 agation effects are vital for solar sources, with plane wave predictions several orders of 378 magnitude larger than the spherical predictions. Similarly, inner scale effects are quan-379 titatively important, while fundamental versus harmonic radiation effects are relatively 380 small. The results and discussion above demonstrate the importance of accurate models 381 for $C_N^2(R)$ and to a lesser extent models of $l_i(R)$ and $\alpha(R)$. This paper's prescription for 382 C_N^2 (Eq [3]) is empirical and directly based on observations (but extrapolated to smaller 383 R), does not have any normalization constants that need to be determined, and leads to 384 scattered sizes for a point source that are smaller than the minimum source size observed 385 to date (49'') by Mercier et al. [2006]). Thus smaller source sizes than 49'' may be observ-386 able. In contrast, another well-known prescription [Bastian, 1994] predicts much stronger 387 scattering with source sizes always larger than 49": while this is inconsistent with the 388

X - 24SUBRAMANIAN & CAIRNS: CONSTRAINING CORONAL TURBULENCE WITH RADIO DATA

³⁸⁹ minimum source size observed to date at 327 MHz, it may provide the extra scattering ³⁹⁰ required to account for Erickson's empirical angular broadening result for cosmic sources ³⁹¹ viewed through the solar wind.

While this paper's results extend and confirm previous theoretical results pertaining to 392 spherical vs. plane wave effects and provide the first explanation of the small source sizes 393 recently observed, it is also clear that more observational and theoretical work is required 394 on $C_N^2(R)$ especially, but also on $l_i(R)$ and $\alpha(k, R)$. This includes temporal variations over 395 the solar cycle but also spatial variations between radio source regions and other regions 396 of the corona. Increases in $C_N^2(R)$ and decreases in $l_i(R)$ would lead to more scattering. 397 Work on both $n_e(R)$ and $\delta n(R)/n_e(R)$ may be useful [e.g., Efimov et al., 2008; Cairns et 398 al., 2009. It is quite possible that scattering observations and theory will provide useful 399 constraints on these five quantities and therefore on the processes heating the solar corona 400 and accelerating the solar wind. 401

Figure 1. Geometry for spherically diverging wavefront, which is appropriate to a situation where the source is embedded in the scattering medium

Figure 2. The plasma frequencies predicted by the four density models in the text are plotted against the height $h = R - R_{\odot}$ above the photosphere (in units of R_{\odot}). The solid line uses the Leblanc et al model (15), the dotted line uses the Aschwanden & Benz model (16), the dashed line uses the 4*Newkirk model (14) and the dash-dot line uses the "hybrid" model (17).

Figure 3. The inner scales (in units of km) predicted by some density models in the text are plotted against the height $h = R - R_{\odot}$ above the photosphere (in units of R_{\odot}). The solid line uses the Leblanc et al model (15), the dashed line uses the 4*Newkirk model (14), and the dash-dot line uses the hybrid model (17).

Figure 4. The ratio s_{eff}/l_i is plotted against the height $h = R - R_{\odot}$ above the photosphere (in units of R_{\odot}). The solid line shows the ratio for plane wave propagation (i.e., with $s_{\text{eff}} = s$), while the dotted line shows the ratio for spherical wave propagation (i.e., with $s_{\text{eff}} = sR/(R_1 - R_0)$). The hybrid density profile is used for determining the density and the inner scale.

Figure 5. Predicted θ_c (1 AU) in " at 327 MHz for plane wave propagation, as a function of α , using (6), (10) and (13). The observed source size is 49". The thin line is for fundamental emission and the thick line is for second harmonic emission.

Figure 6. Predicted θ_c (1 AU) in " at 327 MHz for plane wave propagation as a function of α , using Eqs (7), (10) and (13). The solid line is for fundamental emission and the dotted line is for second harmonic emission. The heavy lines are computed with l_i set at an artificially low value of 1 m, while still using branch (7).

Figure 7. Predicted θ_c (1 AU) in " at 327 MHz for spherical wave propagation as a function of α , using (7), (11) and (13). The observed source size at 327 MHz is 49". There is negligible difference between fundamental and second harmonic emission. The solid lines are computed with l_i from prescription (4), while the dotted lines are computed with l_i set to an artificially low value of 1 m, while still using branch (7).

Figure 8. Predicted θ_c (1 AU) in " at 327 MHz for spherical wave propagation as a function of α , using (6), (11) and (13).. The difference between the predictions for fundamental and second harmonic emission is negligible.

DRAFT

Figure 9. Direct comparison of θ_c (1 AU) for spherical (solid lines) and plane wave (dotted lines) propagation. Fundamental emission is assumed.
