Spin-state crossover and hyperfine interactions of ferric iron in

MgSiO₃ perovskite

Abstract

Using density functional theory plus Hubbard U calculations, we show that the ground state of $(Mg,Fe)(Si,Fe)O_3$ perovskite, the major mineral phase in the Earth's lower mantle, has high-spin ferric iron (S=5/2) at both dodecahedral (A) and octahedral (B) sites. With increasing pressure, the B-site iron undergoes a spin-state crossover to the low-spin state (S=1/2) between 40 and 70 GPa, while the A-site iron remains in the high-spin state. This B-site spin-state crossover is accompanied by a noticeable volume reduction and an increase in quadrupole splitting, consistent with recent X-ray diffraction and Mössbauer spectroscopy measurements. The anomalous volume reduction leads to a significant softening in the bulk modulus during the crossover, suggesting a possible source of seismic-velocity anomalies in the lower mantle.

9 PACS numbers: 91.60.Pn, 76.80.+y, 91.60.Gf, 91.60.Fe

The total electron spin (S) of a transition-metal ion in a crystalline solid can change with 20 many factors, such as pressure, strain, or temperature, to name a few. This phenomenon, 21 known as spin-state crossover, is of great importance in spintronics, as it allows artificial 22 control of magnetic properties of materials, including coordination complexes with potential 23 for molecular switches [1]. Not as widely known, spin-state crossover also plays a crucial role in geophysics. A well studied example is ferropericlase, (Mg,Fe)O, the second most abundant mineral (~ 20 vol%) in the the largest single region (~ 55 vol%) of the Earth's interior the lower mantle. With increasing pressure, ferrous iron (Fe²⁺) in this mineral undergoes a 27 crossover from high-spin (HS) state, S=2, to low-spin (LS) state, S=0, in the pressure range of 40-55 GPa [2-6]. The intermediate-spin (IS) state, S=1, is not observed in 29 this mineral. The HS-LS crossover in ferropericlase directly affects the structural, elastic, 30 optical, and conducting properties of this mineral [6–11] and thus affects mantle properties. 31 [10, 12, 13].32

In contrast, the spin-state crossover in iron-bearing magnesium silicate (MgSiO₃) per-33 ovskite (Pv), the most abundant mineral ($\sim 75 \text{ vol}\%$) in the lower mantle, has been a source 34 of controversy for two main reasons. One is the coexisting ferrous and ferric iron (Fe³⁺) in 35 this mineral with an imprecisely estimated population ratio; the other is the lack of definitive tools to directly probe iron spin state at high pressures. Two techniques, X-ray emission spectroscopy (XES) and Mössbauer spectroscopy, have been widely used, but their interpretation can be ambiguous. The very similar XES spectra [14, 15] and Mössbauer spectra 39 [16–19] have been interpreted in terms of HS-IS and HS-LS crossover in (Mg,Fe)SiO₃ Pv. 40 Plenty of calculations on (Mg,Fe)SiO₃ Pv have been conducted [20–25], but consistency with experiments was not achieved until very recently [26, 27]. Now the spin state in (Mg,Fe)SiO₃ Pv is better understood: the observed increase of iron nuclear quadrupole splitting (QS) in Mössbauer spectra results from neither HS-IS nor HS-LS crossover, but from the change in the 3d orbital occupancy of the HS iron [27]. As to ferric iron in Pv, possibly more abundant 45 than ferrous iron (Fe³⁺/ \sum Fe might be as high as 2/3) [28, 29], its spin-state crossover has remained unclear, as described below.

Previous experiments investigating the iron spin state in aluminum-free MgSiO₃ Pv were focused mostly on ferrous iron [16, 18]. Nevertheless, it was still observed that the low concentration of ferric iron in the sample exhibited an increase in QS with pressure, which

suggests a crossover from HS (S=5/2) to LS (S=1/2) state in the pressure range of 30-70 GPa. In contrast, in Al-bearing samples, where ferric iron occupies the dodecahedral 52 (A) site, the QS remains unchanged up to 100 GPa, which suggests the A-site iron remains 53 in the HS state [17]. These results indicate that the ferric iron at the octahedral (B) site 54 undergoes a spin-state crossover. Such a mechanism was recently confirmed by experiments 55 using $(Mg_{1-x}Fe_x)(Si_{1-x}Fe_x)O_3$ Pv (x=0.1) samples: about half of the HS iron changes to LS state in the 45-60 GPa range while the other half remain in the HS state all the way to 150 GPa [30]. So far, the computational studies on $(Mg_{1-x}Fe_x)(Si_{1-x}Fe_x)O_3$ Pv have found a ground state with HS iron at the A-site and LS iron at the B-site (A-HS; B-LS) and an A-site HS-LS crossover that leads both A- and B-site iron to a final LS state (A:LS; B-LS) at high pressures [21, 22]. These predictions are inconsistent with experiments in two ways: 61 (1) the predicted transition pressure is too high; (2) the predicted HS iron concentration is 62 too low. 63

To compare with recent experiments [30], we stabilize $(Mg_{1-x}Fe_x)(Si_{1-x}Fe_x)O_3$ Pv with x = 0.125 in all possible spin states using a 40-atom supercell shown in Fig. 1. We also calculate the iron nuclear electric field gradient (EFG) associated with each state, as the nuclear hyperfine interaction has proven to be a unique fingerprint to identify the spin states of transition-metal ions [27, 31]. The atomic structures were fully optimized with damped variable cell shape molecular dynamics [32] implemented in the QUANTUM ESPRESSO code [33], where the plane-wave pseudopotential method is adopted [34]. These states were also inde-70 pendently confirmed via the augmented plane-wave plus local orbitals (APW+lo) method 71 [35] implemented in the WIEN2k code [36], with which the EFGs were calculated. The EFGs 72 were converted to QSs with 57 Fe nuclear quadrupole moment Q=0.16 [37] and 0.18 barn for 73 the possible uncertainty. To treat $(Mg_{1-x}Fe_x)(Si_{1-x}Fe_x)O_3$ Pv, the density functional the-74 ory plus Hubbard U (DFT+U) method is necessary, as standard DFT exchange-correlation 75 functionals, the local density approximation (LDA) and generalized gradient approximation 76 (GGA), sometimes lead to unwanted metallic states (especially at high pressures), in which the iron spin states are not well defined. Since the Hubbard U of A- and B-site iron in each spin state is unknown, we have to stabilize the desired spin state with a trial U and then extract the self-consistent U, referred to as U_{sc} , using the linear response approach [38] in a recently developed iterative procedure. This procedure is equivalent to, but more efficient than the one published earlier [39], and has been successfully implemented [40]. More details are described in the EPAPS [41].

Within DFT+U, several combinations of iron spin states can be stabilized. The A-site ferric iron can be stabilized in HS, IS, and LS states. The B-site ferric iron can be stabilized not only in LS state, but also in HS state that has not found in previous calculations [21, 22]. The spin moments of the A- and B-site iron can be either parallel or anti-parallel. The U_{sc} of ferric iron in Pv, listed in Table I, mainly depends on the iron spin state, slightly depends on the occupied site, and barely depends on pressure and alignment of spin moments.

The relative enthalpy (ΔH) of each stabilized state is shown in Fig. 2, where the pre-90 viously perceived ground state (A-HS; B-LS) [21, 22] is used as a reference. Remarkably, 91 the actual ground state of (Mg,Fe)(Si,Fe)O₃ Pv has HS iron on both sites (A-HS; B-HS), 92 regardless of the choice of exchange-correlation functional (LDA or GGA) and Hubbard U $(U_{sc} \text{ or } 4 \text{ eV})$. These choices do not affect the spin-state crossover either: an HS-LS crossover only occurs in the B-site iron, while the A-site iron remains HS. As expected, the predicted transition pressure (P_T) depends on the exchange-correlation functional and Hubbard U: with LDA+ U_{sc} , $P_T = 41$ GPa; with GGA+ U_{sc} , $P_T = 70$ GPa; with GGA+U (U = 4 eV), $P_T = 29$ GPa. (Coordination complexes also show similar dependence [42, 43].) Notably, the alignment of iron spins (parallel or anti-parallel), barely affects P_T , as shown in Fig. 2(c). 99 The P_T predicted by LDA+ U_{sc} and GGA+ U_{sc} best agree with the P_T observed in Mössbauer 100 spectra, 50-60 GPa [30]. The LDA+ U_{sc} electronic density of states (DOS) of the two relevant 101 states (A-HS; B-HS and A-HS; B-LS) can be found in EPAPS [41]. 102

The calculated QSs of ferric iron (A- and B-site) and ferrous iron (A-site) [27] in various 103 spin states, along with the measured QSs [16, 18, 30], are shown in Fig. 3. Clearly, our 104 calculations on ferrous and ferric iron in Pv are consistent with Mössbauer spectra. The 105 HS-LS crossover in the B-site ferric iron also helps to explain the decrease in the XES 106 satellite peak (K β ') intensity [14, 15]. Interestingly, the QS of ferrous and ferric iron exhibit 107 exactly the opposite trends with respect to the spin moment. This can be understood via 108 their orbital occupancies. The LS ferrous iron, although occupying the A site, is effectively 109 located near the center of a Fe-O octahedron, as it is vertically displaced from the mirror 110 plane [24]. Its six 3d electrons doubly occupy the three orbitals with t_{2g} character and form 111

a charge density with cubic-like shape [24], which barely contributes to the EFG and leads to a very small QS. The HS ferric iron also has a small EFG (and thus QS), irrespective of A or B site. This is because its five 3d electrons (all spin-up) occupy all 3d orbitals, forming an almost spherically shaped electron charge distribution that leads to a small EFG (and thus QS). Similarly, the spin-up electrons in HS ferrous and LS ferric iron barely contribute to EFG, as their charge distributions are nearly spherical and cubic, respectively. It is their spin-down electrons that contribute to the EFGs and lead to larger QSs. This is why the spin moments of ferrous and ferric iron appear to affect the QSs in an opposite manner.

The LDA+ U_{sc} compression curves and bulk modulus $(K \equiv -VdP/dV)$ of $(Mg_{1-x}Fe_x)(Si_{1-x}Fe_x)O_3$ 120 Pv (x = 0.125) along with the experimental data (x = 0.1) [30] are shown in Fig. 4. At 121 low pressures (< 45 GPa), the experimental data falls on the calculated compression curve 122 corresponding to the (A-HS; B-HS) state. Starting from \sim 45 GPa, the data points deviate 123 from the (A-HS; B-HS) curve and then join the (A-HS; B-LS) curve at ~ 60 GPa. Starting from ~ 100 GPa, the data deviates from the curve again. This, however, is very likely to result from the questionable accuracy of the Au pressure scale used in the experiment, as already discussed in the case of (Mg,Fe)SiO₃ Pv [44]. Notice that the observed volume 127 reduction further confirms the B-site HS-LS crossover, as the previously perceived A-site 128 HS-LS crossover barely leads to a volume reduction, evident from the compression curves 129 (A-HS; B-LS and A-LS; B-LS) shown in Fig. 4(a). The B-site spin-state crossover and the 130 observed volume reduction in the 45-60 GPa range can be qualitatively understood via the 131 Fe³⁺ electronic configurations and Fe-O distances at A and B sites. With all 3d orbitals 132 occupied, HS iron has spherically-shaped electron charge density and the largest radius 133 compared with other spin states, favoring longer Fe-O distances. Residing in the large do-134 decahedral cage, the A-site iron can easily maintain longer Fe-O distances and thus remain 135 in HS state. In contrast, the Fe-O octahedron has smaller size and shorter Fe-O distances. 136 With increasing pressure, the internal octahedron bond lengths can be shortened enough to 137 induce the HS-LS crossover. Since the 3d electrons of the B-site LS iron only occupy the 138 t_{2q} -like orbitals pointing away from oxygen, the associated Fe-O distances are significantly 139 shorter than those of the HS iron at the same pressure. Therefore, the spin change of the 140 B-site iron is accompanied by a noticeable octahedral (and thus unit-cell) volume reduction. 141 Such volume reduction leads to anomalous softening in bulk modulus, as described below. 142

At finite temperatures, the spin-state crossover passes through a mixed-spin (MS) state 143 (namely, HS and LS coexist) within a finite pressure range that increases with temperature. 144 During the crossover, the thermodynamic properties of the MS state exhibit anomalous 145 behavior that may affect mantle properties. One example is the softening in bulk modules 146 and its effect on the compressional wave velocity, as already seen in ferropericlase [7, 10, 11]. 147 To estimate such anomaly in (Mg,Fe)(Si,Fe)O₃ Pv, we employ a thermodynamic model similar to that used in Ref. [10]. Here, we do not include vibrational free energy, as it 149 barely affects the magnitude of the anomaly, slightly increases the transition pressure, and 150 uniformly decreases the bulk modulus, as shown in the case of ferropericlase [10, 11]. Indeed, 151 the calculated V(P) curve of (Mg,Fe)(Si,Fe)O₃ Pv in the MS state (using LDA+ U_{sc}) at room 152 temperature (300 K), shown as the dashed line in Fig. 4(a), exhibits a volume reduction 153 $(\sim 1.2\%)$ around the predicted P_T , 41 GPa. This reduction leads to a significant softening 154 in bulk modulus, as shown in Fig. 4(b). The softening is still prominent at 2000 K, the 155 temperature near the top of the lower mantle (\sim 660 km deep). Given the abundance of 156 iron-bearing Pv and the possibly high population of ferric iron, this softening may have a 157 noticeable impact on the mantle properties, including possible anomalies in the seismic wave 158 velocities. 159

In summary, with a series of DFT+U calculations, we have shown that the actual ground 160 state of (Mg,Fe)(Si,Fe)O₃ perovskite has high-spin ferric iron on both A and B sites. It 161 is the B-site ferric iron that undergoes a crossover from high-spin to low-spin state with 162 increasing pressure, while the A-site iron remains in the high-spin state. The calculated 163 quadrupole splittings and the compression curves are consistent with experiments. The 164 volume reduction accompanying the B-site HS-LS crossover leads to a significant softening 165 in bulk modulus, which suggests a possible source of seismic-velocity anomalies in the lower 166 mantle. This work, one more time, demonstrates that the nuclear hyperfine interaction, 167 combined with first-principles calculations, can be a useful tool to identify the spin states of 168 transition-metal ions in solids under high pressures. 169
