Applying electric field to charged and polar particles between metallic plates: Extension of the Ewald method

Kyohei Takae and Akira Onuki Department of Physics, Kyoto University, Kyoto 606-8502, Japan (Dated: March 9, 2021)

We develop an efficient Ewald method of molecular dynamics simulation for calculating the electrostatic interactions among charged and polar particles between parallel metallic plates, where we may apply an electric field with an arbitrary size. We use the fact that the potential from the surface charges is equivalent to the sum of those from image charges and dipoles located outside the cell. We present simulation results on boundary effects of charged and polar fluids, formation of ionic crystals, and formation of dipole chains, where the applied field and the image interaction are crucial. For polar fluids, we find a large deviation of the classical Lorentz-field relation between the local field and the applied field due to pair correlations along the applied field. As general aspects, we clarify the difference between the potential-fixed and the charge-fixed boundary conditions and examine the relationship between the discrete particle description and the continuum electrostatics.

I. INTRODUCTION

In many problems in physics and chemistry, the electrostatic potential and field acting on each constituting particle need to be calculated¹. A large number of simulations have been performed to accurately estimate the long-range electrostatic interactions among charged and polar particles^{2,3}. The Ewald method is a famous technique for efficiently summing these interactions using the Fourier transformation. It was originally devised for ionic crystals⁴ and has been widely used to investigate bulk properties of charged and polar particles under the periodic boundary condition in three dimensions (3D)^{5–8}. It has also been modified for filmlike systems bounded by non-polarizable and insulating regions under the periodic boundary condition in the lateral directions^{3,9–15}.

However, the Ewald method has not yet been successful when charged or polar particles are in contact with metallic or polarizable plates and when electric field is applied from outside. Such situations are ubiquitous in solids and soft matters. In idealized metallic plates, the surface charges spontaneously appear such that the electrostatic potential is homogeneous within the plates, thus providing the well-defined boundary condition for the potential within the cell¹⁶. Between two parallel plates, we may control the potential difference to apply an electric field. However, the electrostatic interaction between the surface charges and the particles within the cell is highly nontrivial. On the other hand, such surface changes are nonexistent for the magnetic interaction.

Each charged particle between parallel metallic plates induces surface charges producing a potential equivalent to that from an infinite number of image charges outside the cell. If a charged particle approaches a metal wall, it is attracted by the wall or by its nearest image. Some mathematical formulae including these image charges in the Ewald sum were presented by Hautman et al.¹⁷ and by Perram and Ratner¹⁸. In the same manner, for each dipole in the cell, an infinite number of image dipoles appear. A dipole close to a metal surface is attracted and

aligned by its nearest image. Accounting for these image dipoles, Klapp¹⁹ performed Monte Carlo simulations of 500 dipoles interacting with the soft-core potential, but without applied electric field, to find wall-induced ordering. The image effect is also relevant in electrorheological fluids between metallic plates 20,21 .

Inclusion of the image effect in molecular dynamics simulations of molecules near a conducting or polarizable surface is still challenging in a variety of important systems including proteins²², polyelectrolytes²³, and colloidal particles²⁴. Moreover, the effects of applied electric field remain largely unexplored on the microscopic level, while the continuum electrostatics is well established ^{16,25}. For example, the local electric field acting on a dipole is known to be different from the applied electric field in dielectrics and polar fluids ^{26,27}, where the difference is enlarged in highly polarizable systems. In contrast, a number of microscopic simulations have been performed on the effect of uniform magnetic field for systems of magnetic dipoles ^{7,8,28}.

In this paper, we hence aim to develop an efficient Ewald method to treat charged and polar particles between parallel metallic plates accounting for the image effect, where we apply an electric field with an arbitrary size. In the Ewald sum in this case, we can sum up the terms homogeneous in the lateral xy plane but inhomogeneous along the normal z axis into a simple form and can calculated them precisely. This one-dimensional part of the electrostatic energy yields one-dimensional (laterally averaged) electric field along the z axis for each particle.

Using our scheme, we present some numerical results under applied electric field, including the soft-core pair interaction and the wall-particle repulsive interaction. We confirm that accumulation of charges and dipoles near metallic walls gives rise to a uniaxially symmetric, homogeneous interior region. We also examine formation of ionic crystals²⁹ and that of dipole chains^{20,21,30} under electric field. Here, we are interested in the mechanisms of dipole alignment near metallic walls, which are caused by the image interaction or by the applied electric field. We shall also see that the classical local field relation^{26,27}

is much violated in our dipole systems because of strong pair correlations along the applied field.

The organization of this paper is as follows. In Sec.II, we will extend the Ewald scheme for charged particles between metallic plates. In Sec.III, we will further develop the Ewald scheme for point-like dipoles between metallic plates. In these two sections, we will present some numerical results. In Appendix B, we will clarify the difference between two boundary conditions at a fixed potential difference and at fixed surface charges. In Appendix D, we will compare the electrostatics of our discrete particle systems and the continuum electrostatics.

II. CHARGED PARTICLES

We consider N charged particles in a cell. Their positions and charges are r_i and q_i $(1 \le i \le N)$. We assume the charge neutrality condition,

$$\sum_{i} q_i = 0. \tag{2.1}$$

In terms of the electrostatic energy $U = U(\mathbf{r}_1, \dots, \mathbf{r}_N)$, the electrostatic force on particle i is given by

$$\boldsymbol{F}_{i}^{e} = q_{i}\boldsymbol{E}_{i} = -\frac{\partial}{\partial \boldsymbol{r}_{i}}U, \qquad (2.2)$$

where E_i is the electric field on particle *i*. There can also be neutral particles interacting with charged ones.

A. Ewald method for charged particles in the periodic boundary condition

When the bulk properties of charged particle systems are calculated, the periodic boundary condition is usually assumed in molecular dynamics simulation. In a $L \times L \times L$ cell, the electrostatic energy is written as^{2,3}

$$U_{\rm p} = \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{i,j}' \frac{q_i q_j}{|\boldsymbol{r}_{ij} + L\boldsymbol{m}|}, \qquad (2.3)$$

where $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$ is the relative positional vector, $\mathbf{m} = (m_x, m_y, m_z)$ is a 3D vector with three integer components, and the self terms $(j = i \text{ and } \mathbf{m} = (0, 0, 0))$ are excluded in the summation $\sum_{i,j}$. Here, \mathbf{E}_i is obtained from Eq.(2.2) with $U = U_{\rm p}$. In some papers^{14,15}, discussions have been made on the convergence of the Ewald sum under Eq.(2.1).

In the Ewald method, the Coulomb potential q_iq_j/r is divided into the short-range part $q_iq_j\psi_s(r)$ and the long-range part $q_iq_i\psi_{\ell}(r)$, where

$$\psi_s(r) = \operatorname{erfc}(\gamma r) \frac{1}{r}, \quad \psi_\ell(r) = \operatorname{erf}(\gamma r) \frac{1}{r}.$$
 (2.4)

Here, $\operatorname{erf}(u) = (2/\sqrt{\pi}) \int_0^u du e^{-u^2}$ is the error function and $\operatorname{erfc}(u) = 1 - \operatorname{erf}(u)$ is the complementary error function. The function $\psi_\ell(r)$ is the solution of $\nabla^2 \psi_\ell(r) =$

 $-4\pi\varphi_3(r)$, where $\varphi_3(r) = \varphi(x)\varphi(y)\varphi(z)$ is a normalized 3D Gaussian distribution with

$$\varphi(x) = (\gamma/\sqrt{\pi}) \exp(-\gamma^2 x^2). \tag{2.5}$$

The inverse γ^{-1} is an adjustable potential range. For $r \gg \gamma^{-1}$, we have $\psi_\ell \cong r^{-1}$. For $r \ll \gamma^{-1}$ it is finite as

$$\psi_{\ell}(r) = (2\gamma/\sqrt{\pi})(1 - \gamma^2 r^2/3 \cdots).$$
 (2.6)

As is well-known^{2,3}, the Ewald form of $U_{\rm D}$ reads

$$U_{p} = \sum_{\mathbf{m}} \sum_{i,j}' \frac{q_{i}q_{j}}{2} \psi_{s}(|\mathbf{r}_{ij} + L\mathbf{m}|) - \sum_{i} \frac{\gamma q_{i}^{2}}{\sqrt{\pi}}$$

$$+ \frac{1}{L^{3}} \sum_{\mathbf{p} \neq \mathbf{0}} \sum_{i,j} \frac{q_{i}q_{j}}{2} \Psi_{\ell}(k) e^{i\mathbf{k} \cdot \mathbf{r}_{ij}} + \frac{2\pi}{3L^{3}} \left| \sum_{i} q_{i} \mathbf{r}_{i} \right|^{2}, \quad (2.7)$$

where the second term is equal to $-\sum_i q_i^2 \psi_\ell(0)/2$ and the last two terms arise from $\sum_{\boldsymbol{m}} \sum_{i,j} q_i q_j \psi_\ell(|\boldsymbol{r}_{ij} + L\boldsymbol{m}|)/2$ including the self part. Use is made of the Fourier transformation $\psi_\ell(r) = (2\pi)^{-3} \int d\boldsymbol{k} \Psi_\ell(k) \exp[i\boldsymbol{k} \cdot \boldsymbol{r}]$, where

$$\Psi_{\ell}(k) = 4\pi \exp(-k^2/4\gamma^2)/k^2. \tag{2.8}$$

In the third term, k is discretized as

$$\mathbf{k} = (2\pi/L)(\nu_x, \nu_y, \nu_z), \tag{2.9}$$

and the term with $\boldsymbol{\nu}=(\nu_x,\nu_y,\nu_z)=(0,0,0)$ is excluded, where $\nu_x,\,\nu_y,$ and ν_z are integers $(0,\pm 1,\pm 2,\cdots)$. This discretization stems from the summation over \boldsymbol{m} in Eq.(2.3). The last term in Eq.(2.7) arises from the \boldsymbol{k} -integration at small $|\boldsymbol{k}|\lesssim L^{-1}$. However, it is negligible without overall polarization or for $\sum_i q_i \boldsymbol{r}_i \cong \boldsymbol{0}$. See Appendix A for the derivation of the last two terms.

B. Ewald method for charged particles between metallic plates under applied electric field

As in Fig.1, we consider a $L \times L \times H$ parallel plate geometry, where the plates at z=0 and H are both metallic. They are assumed to be smooth and structureless. We assume the periodic boundary condition along the x and y axes. We adopt the fixed-potential boundary condition. See Appendix B for discussions of another typical boundary condition with fixed surface charges.

We treat an infinite number of image charges. Let a particle i at $\mathbf{r}_i = (x_i, y_i, z_i)$ with charge q_i approach the surface at z = 0. For not strong applied electric field, it is acted by a growing attractive force produced by the closest image with the opposite charge $-q_i$ at 16 ,

$$\bar{\boldsymbol{r}}_i = (x_i, y_i, -z_i). \tag{2.10}$$

This force is written as $-\partial v_{\rm I}/\partial z_i = -q_i^2/(2z_i)^2$ for small z_i , so the potential due to this image is of the form,

$$v_{\rm I}(z_i) = -q_i^2/4z_i. (2.11)$$

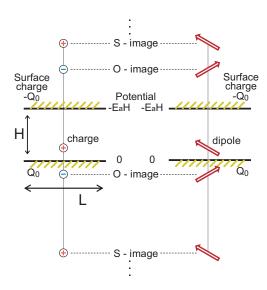

FIG. 1. (Color online) System of a capacitor with parallel metallic plates containing charges (left) and dipoles (right). For each charge or dipole at (x_j, y_j, z_j) , there appear O-images at $(x_j, y_j, -z_j - 2Hn)$ $(n = 0, \pm 1, \cdots)$ and S-images at $(x_j, y_j, z_j - 2Hn)$ $(n = \pm 1, \cdots)$. The electrostatic potential Φ is 0 at the bottom and is $-\Delta \Phi = -E_a H$ at the top. The surface charge is Q_0 at the bottom and $-Q_0$ at the top. As typical experiments, we may fix either of $\Delta \Phi$ or Q_0 .

1. Electrostatic potential and image charges

We write the electrostatic potential away from the particle positions $(r \neq r_i)$ as

$$\Phi(\mathbf{r}) = \phi(\mathbf{r}) - E_a z. \tag{2.12}$$

The electric field away from the particle positions is $E = E_a e_z - \nabla \phi$, where e_z is the unit vector along the z axis. We assume that the charged particles are repelled from the walls at short distances and that no ionization occurs on the walls. Then, the excess potential ϕ in Eq.(2.12) satisfies the boundary condition,

$$\phi(x, y, 0) = \phi(x, y, H) = 0. \tag{2.13}$$

From the bottom to the top, the potential difference is

$$\Delta \Phi = \Phi(x, y, 0) - \Phi(x, y, H) = HE_a.$$
 (2.14)

In the region 0 < z < H, $\phi(\mathbf{r})$ is the solution of the Poisson equation under the boundary condition (2.13),

$$-\nabla^2 \phi = 4\pi \sum_j q_j \delta(\mathbf{r} - \mathbf{r}_j). \tag{2.15}$$

To calculate $\phi(\mathbf{r})$, we consider its 2D Fourier expansion,

$$\phi = \frac{4\pi}{L^2} \sum_{\mathbf{y}, \mathbf{z}} \sum_{i} q_j G_k(z, z_j) e^{i \cdot (k_x(x - x_j) + k_y(y - y_j))}, \quad (2.16)$$

where $\nu_{\perp} = (\nu_x, \nu_y)$ and $(k_x, k_y) = (2\pi/L)(\nu_x, \nu_y)$ with ν_x and ν_y being integers. From Eq.(2.15) the Green function $G_k(z, z')$ satisfies

$$(k^2 - \partial^2/\partial z^2)G_k(z, z') = \delta(z - z'), \qquad (2.17)$$

where $k = (k_x^2 + k_y^2)^{1/2}$. Here, $G_k(0, z') = G_k(H, z') = 0$ from Eq.(2.13), so we solve Eq.(2.17) as^{18,25}

$$G_k(z, z') = \frac{1}{2k} e^{-k|z-z'|} - \frac{1}{2k \sinh(kH)}$$

$$\times \left[\sinh(kz) e^{-k(H-z')} + \sinh(kH - kz) e^{-kz'} \right], \quad (2.18)$$

which has the symmetry $G_k(z, z') = G_k(z', z)$. The first term in Eq.(2.18) arises from the 2D Fourier transformation of the direct Coulombic interaction, while the second term is induced by the surface charges on the metallic surfaces. Note that the term with $k_x = k_y = 0$ is included in Eq.(2.16), which give rise to a term independent of x and y. From Eq.(2.18) the long wavelength limit $G_0(z, z') = \lim_{k\to 0} G_k(z, z')$ becomes

$$G_0(z, z') = (z + z' - |z - z'|)/2 - zz'/H.$$
 (2.19)

To find image charges, we further use the expansion $1/\sinh(kH)=2\sum_{n\geq 0}e^{-kH(2n+1)}$ in Eq.(2.18) to obtain

$$G_k(z, z') = \frac{1}{2k} \sum_n \left[e^{-k|z - z' + 2Hn|} - e^{-k|z + z' + 2Hn|} \right],$$
(2.20)

where $n = 0, \pm 1, \pm 2, \cdots$. Since $2\pi \exp(-k|z|)/k = \int dxdy \exp(ik_x x + ik_y y)/r$, substitution of the above expansion into Eq.(2.16) yields $\phi(\mathbf{r})$ in the following superposition of Coulomb potentials,

$$\phi = \sum_{m} \sum_{j} \frac{q_j}{|\boldsymbol{r} - \boldsymbol{r}_j + \boldsymbol{h}|} - \sum_{m} \sum_{j} \frac{q_j}{|\boldsymbol{r} - \bar{\boldsymbol{r}}_j + \boldsymbol{h}|}, \quad (2.21)$$

where $\mathbf{m} = (m_x, m_y, m_z)$ with integer components and

$$\mathbf{h} = (Lm_x, Lm_y, 2Hm_z). \tag{2.22}$$

For each charge q_j at $\boldsymbol{r}_j = (x_j, y_j, z_j)$ in the cell, we find images with the opposite charge $-q_j$ at $(x_j, y_j, -z_j - 2Hn)$ $(n = 0, \pm 1, \cdots)$, giving rise to the second term in Eq.(2.21). We call them O-image charges. We also find those with the same charge q_j at $(x_j, y_j, z_j - 2Hn)$ $(n = \pm 1, \cdots)$ in the first term in Eq.(2.21), which are called S-image charges. See Fig.1 for these images.

The electrostatic energy $U_{\rm m}$ is now given by 17,18

$$U_{\rm m} = \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{ij}' \frac{q_i q_j}{|\boldsymbol{r}_{ij} + \boldsymbol{h}|} - \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{ij} \frac{q_i q_j}{|\bar{\boldsymbol{r}}_{ij} + \boldsymbol{h}|} - E_a \sum_{i} q_i z_i,$$
(2.23)

where $\bar{\boldsymbol{r}}_{ij} = \boldsymbol{r}_i - \bar{\boldsymbol{r}}_j = (x_i - x_j, y_i - y_j, z_i + z_j)$. In \sum_{ij}' , we exclude the self term with j = i for $\boldsymbol{m} = (0, 0, 0)$. The second term includes the direct image potential (2.11). For infinitesimal changes $\boldsymbol{r}_i \to \boldsymbol{r}_i + d\boldsymbol{r}_i$ and $E_a \to E_0 + dE_a$, the differential form of $U_{\rm m}$ in Eq.(2.23) is given by

$$dU_{\rm m} = -\sum_{i} q_i \mathbf{E}_i \cdot d\mathbf{r}_i - \sum_{i} q_i z_i dE_a. \tag{2.24}$$

2. Ewald representation

To obtain the Ewald representation, we divide the Coulomb potentials into the short-range and long-range parts as in Eq.(2.4). We then find

$$U_{\rm m} = \sum_{\boldsymbol{m}} \left[\sum_{i,j}' \frac{q_i q_j}{2} \psi_s(|\boldsymbol{r}_{ij} + \boldsymbol{h}|) - \sum_{i,j} \frac{q_i q_j}{2} \psi_s(|\bar{\boldsymbol{r}}_{ij} + \boldsymbol{h}|) \right]$$
$$- \sum_{i} \frac{\gamma q_i^2}{\sqrt{\pi}} + U_{\rm m}^{\ell} - E_a \sum_{i} q_i z_i,$$
(2.25)

where the first term is the short-range part and $U_{\rm m}^{\ell}$ is the long-range part (including the self terms) given by

$$U_{\rm m}^{\ell} = \sum_{\boldsymbol{m}} \sum_{i,j} \frac{q_i q_j}{2} \left[\psi_{\ell}(|\boldsymbol{r}_{ij} + \boldsymbol{h}|) - \psi_{\ell}(|\bar{\boldsymbol{r}}_{ij} + \boldsymbol{h}|) \right]$$

$$= \frac{1}{HL^2} \sum_{\boldsymbol{\nu}_{\perp} \neq \boldsymbol{0}} \sum_{i,j} \frac{q_i q_j}{4} \Psi_{\ell}(k) \left[e^{i\boldsymbol{k}\cdot\boldsymbol{r}_{ij}} - e^{i\boldsymbol{k}\cdot\bar{\boldsymbol{r}}_{ij}} \right]$$

$$+ \frac{2\pi}{L^2} \sum_{i,j} q_i q_j K_0(z_i, z_j). \tag{2.26}$$

Here, the wave vector \mathbf{k} is discretized as

$$\mathbf{k} = \pi(2\nu_x/L, 2\nu_y/L, \nu_z/H),$$
 (2.27)

where ν_x, ν_y , and ν_z are integers. The summation in Eq.(2.26) is over $\boldsymbol{\nu} = (\nu_x, \nu_y, \nu_z)$ with $\boldsymbol{\nu}_\perp = (\nu_x, \nu_y) \neq (0,0)$. The last term in Eq.(2.26) arises from the *one-dimensional* contributions with $\nu_x = \nu_y = 0$ and $\nu_z \neq 0$, where the contribution from $\boldsymbol{\nu} = (0,0,0)$ vanishes in the present case¹⁷. In Appendix C, we will derive

$$K_0(z,z') = \int_0^H du G_0(z,u) [\hat{\varphi}(u-z') - \hat{\varphi}(u+z')]$$

$$= \frac{2H}{\pi^2} \sum_{n\geq 1} \frac{\exp[-(\pi n/2\gamma H)^2]}{n^2} \sin(\frac{\pi nz}{H}) \sin(\frac{\pi nz'}{H}), \quad (2.28)$$

where $G_0(z, u)$ is given by Eq.(2.19) and $\hat{\varphi}(z)$ is a periodic function with period 2H. Use of $\varphi(z)$ in Eq.(2.5) gives

$$\hat{\varphi}(z) = \sum_{n=0,\pm 1,\cdots} \varphi(z - 2Hn), \qquad (2.29)$$

so $\hat{\varphi}(z) = \hat{\varphi}(-z)$ and $\int_0^H dz \hat{\varphi}(z) = 1/2$. From the first line of Eq.(2.26), $U_{\rm m}^{\ell}$ vanishes as z_i (or z_j) tends to 0 or H, while the first term in Eq.(2.25) diverges in this limit since it contains $v_{\rm I}(z_i)$ in Eq.(2.11).

3. Surface charges

In the parallel plate geometry, real charges are those within the cell and the excess electrons on the metal surfaces at z=0 and H. The image changes are introduced as a mathematical convenience. The surface charge densities are given by $\sigma_0(x,y) = E_z(x,y,0)/4\pi$ at

z=0 and $\sigma_H(x,y)=-E_z(x,y,H)/4\pi$ at z=H, where $E_z(x,y,z)=-\partial\Phi/\partial z.$ From Eq.(2.18) we obtain their 2D Fourier expansions,

$$\sigma_{0} = \frac{E_{a}}{4\pi} - \frac{1}{L^{2}} \sum_{\boldsymbol{\nu}_{\perp}} \sum_{j} q_{j} \frac{\sinh(kH - kz_{j})}{\sinh(kH)} e^{i\boldsymbol{k}\cdot(\boldsymbol{r}-\boldsymbol{r}_{j})},$$

$$\sigma_{H} = -\frac{E_{a}}{4\pi} - \frac{1}{L^{2}} \sum_{\boldsymbol{\nu}_{\perp}} \sum_{j} q_{j} \frac{\sinh(kz_{j})}{\sinh(kH)} e^{i\boldsymbol{k}\cdot(\boldsymbol{r}-\boldsymbol{r}_{j})}. \quad (2.30)$$

Here, $\boldsymbol{\nu}_{\perp} = (\nu_x, \nu_y), \ \boldsymbol{k} = (k_x, k_y, 0) = (2\pi/L)(\nu_x, \nu_y, 0),$ and $\exp[i\boldsymbol{k} \cdot (\boldsymbol{r} - \boldsymbol{r}_j)] = \exp[i(k_x(x - x_j) + i(k_y(y - y_j))].$

The total electric charges on the bottom and top surfaces Q_0 and Q_H are the surface integral of $\sigma_0(x, y)$ and that of $\sigma_H(x, y)$, respectively. We pick up the terms with $\nu_{\perp} = (0, 0)$ in Eq.(2.30) to obtain

$$Q_0 = -Q_H = \frac{1}{4\pi} L^2 E_a + \frac{1}{H} \sum_j q_j z_j.$$
 (2.31)

4. Local electric field

From Eqs.(2.25) and (2.26) we may calculate the local electric field \boldsymbol{E}_i on particle i using Eq.(2.2). The contribution from the first term in Eq.(2.25) is written as $\boldsymbol{E}_i^{\mathrm{s}}$, that from the first term in Eq.(2.26) as \boldsymbol{E}_i^{ℓ} , and that from the remaining terms as $E_i^0 \boldsymbol{e}_z$. Then,

$$\boldsymbol{E}_i = \boldsymbol{E}_i^{\mathrm{s}} + \boldsymbol{E}_i^{\ell} + E_i^0 \boldsymbol{e}_z. \tag{2.32}$$

Here, E_i^0 is determined by the z coordinates, z_1, z_2, \cdots , and use of Eqs.(2.28) and (C3) gives

$$E_i^0 = \frac{4\pi}{L^2} \left[Q_0 - \sum_j q_j \int_{-z_j}^{z_j} du \hat{\varphi}(u - z_i) \right]$$

= $E_a - \frac{8}{L^2} \sum_{n \ge 1} e^{-(\pi n/2\gamma H)^2} \frac{J_n}{n} \cos(\frac{\pi n z_i}{H}), \quad (2.33)$

where J_n depends on z_1, z_2, \cdots as

$$J_n = \sum_j q_j \sin(\frac{\pi n z_j}{H}). \tag{2.34}$$

The first line of Eq.(2.33) tends to a well-defined limit in the continuum theory in Appendix D. Note that the last term of Eq.(2.26) is expressed as $(4H/\pi L^2) \sum_{n\geq 1} e^{-(\pi n/2\gamma H)^2} J_n^2$ in terms of J_n .

C. Numerical example of charged particles between metallic plates under applied electric field

1. Model and method

This subsection presents results of molecular dynamics simulation of two-component charged particles between metallic plates at the fixed-potential condition.

The numbers of the two species are $N_1 = N_2 = 500$ and the charges are q and -q. All the particles have a common mass m and a common diameter σ . The average density is $n_0 = (N_1 + N_2)/HL^2 = 0.57\sigma^{-3}$ and the cell dimensions are $H = L = 12\sigma$.

The total potential energy consists of three parts as

$$U_{\text{tot}} = U_{\text{m}} + \sum_{i>j} v_s(r_{ij}) + \sum_i v_{\text{w}}(z_i).$$
 (2.35)

First, $U_{\rm m}$ is given by Eq.(2.25), where we set $\gamma=0.5$ and sum over k in the region $k \leq k_c=18\pi/L$. From the second line of Eq.(2.28), we calculated the one-dimensional electric field E_i^0 retaining the terms up to n=18, for which there is almost no error since $\exp[-(\pi n/2\gamma H)^2] \sim 10^{-10}$ at n=18. We also truncated the short-range part of the electrostatic interaction in Eq.(2.25) at 4σ . Second, $v_s(r)$ is the soft-core pair potential,

$$v_s(r) = 4\epsilon(\sigma/r)^{12} - C_0,$$
 (2.36)

where ϵ is the characteristic interaction energy. This potential is cut off at $r=r_{\rm cut}^s=4\sigma$ and C_0 ensures the continuity of $v_s(r)$ at this cut-off. Third, $v_w(z)$ is the repulsive potential from the walls written as

$$v_w(z) = w \exp(-z/\xi) + w \exp(-(H-z)/\xi),$$
 (2.37)

with $\xi = 0.01\sigma$ and $w = e^{40}\epsilon$. The minimum of z_i and $H - z_i$ was then about 0.4σ in our examples.

In this paper, the charge size is set equal to

$$q = |q_i| = 5(\epsilon \sigma)^{1/2}.$$
 (2.38)

Hereafter, units of length, density, electrostatic potential, electric field, and electric charge are σ , σ^{-3} , $(\epsilon/\sigma)^{1/2}$, $(\epsilon/\sigma^3)^{1/2}$, and $(\epsilon\sigma)^{1/2}$, respectively. The temperature T is in units of ϵ/k_B . Due to the choice (2.38), the typical magnitude of the Coulomb interaction among the particles is $q^2 n_0^{1/3} \sim 20$ per particle, while that of the image interaction in Eq.(2.11) is 10 at $z_1 \sim 0.5$.

The particles obey the equations of motions,

$$m\frac{d^2}{dt^2}\mathbf{r}_i = -\frac{\partial}{\partial \mathbf{r}_i}U_{\text{tot}}.$$
 (2.39)

We measure time in units of

$$\tau_0 = (m/\epsilon)^{1/2} \sigma. \tag{2.40}$$

We integrated Eq.(2.39) using the leap-frog method with the time step width being 0.002. With a Nosé-Hoover thermostat attached, we started with a high temperature liquid state, lowered T to a final value, and waited for a time interval of 10^4 . Next, we removed the thermostat, waited for another time interval of 10^4 , and took data. Thus, our simulation results were those in the NVE ensemble, where the average kinetic energy was kept at $3k_BT/2$ per particle. Hereafter, T has this meaning. In this paper, we treat equilibrium states with homogeneous T.

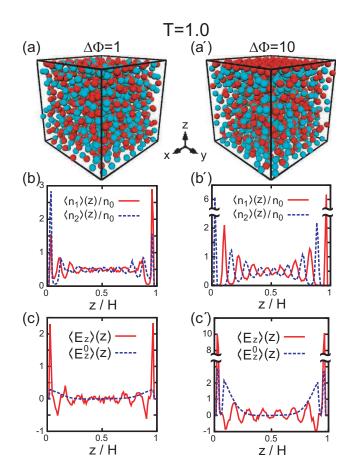

FIG. 2. (Color online) Simulation results of 1000 charged particles in liquid at T=1. They have a common diameter σ in a cubic cell with length 12. Snapshots of cations (in red) and anions (in blue) for $\Delta\Phi=1$ in (a) and 10 in (a'). Lateral density averages $\langle n_1 \rangle(z)$ and $\langle n_2 \rangle(z)$ divided by the space average n_0 are in (b) and (b'). Lateral averages $\langle E_z \rangle(z)$ (red bold line) and $\langle E_z^0 \rangle(z)$ (blue dotted line) are in (c) and (c'). Particles are attracted to the walls and screening occurs.

We also carried out simulations for $(\gamma, r_{\text{cut}}^s) = (0.3, 6)$ and (1, 6) for the situations in Fig.2. The results were essentially the same as those for the present choice (0.5, 4), while the long-range contributions (including E_i^0) become smoother with decreasing γ . See discussions on the choice of γ by Deserno and Holm³¹.

2. Charged particles at T = 1: Screening effect

In Figs.2 and 3, we show simulation results in liquid at T=1 for $\Delta\Phi=1$ and 10. In Fig.2(a)-(a'), snapshots of the particles are given. In Fig.2(b)-(b'), cross-sectional densities $\langle n_1 \rangle(z)$ and $\langle n_2 \rangle(z)$ are displayed, which show accumulation of the negative (positive) charges near the wall at z=0 (z=H). They are defined as follows. Let $\Delta N_{\alpha}(z)=\sum_{j\in\alpha}\theta(z_j-z)\theta(z+\Delta z-z_j)$ be the particle numbers in layers $[z,z+\Delta z]$ ($z=n\Delta z$ with $n=0,1,\cdots$) for the two species $\alpha=1,2$. The $\theta(u)$ is the step function

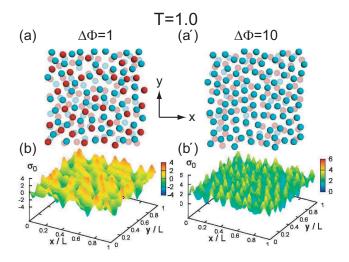

FIG. 3. (Color online) Top: Particle configurations in the first layer 0 < z < 1 (in red or blue) and in the second layer 1 < z < 2 (in lighter colors) for $\Delta \Phi = 1$ (left) and 10 (right). Bottom: Surface charge density $\sigma_0(x,y)$ at z=0 in Eq.(2.30) for $\Delta \Phi = 1$ and 10 in units of $(\epsilon/\sigma^3)^{1/2}$. Data are common to those in (a) and (a') of Fig.2.

being 1 for u > 0 and 0 for $u \le 0$. In this subsection, we set $\Delta z = H/100 = 0.12$, which is much smaller than the particle size. The laterally averaged densities for the two species are given by

$$\langle n_{\alpha} \rangle(z) = \langle \Delta N_{\alpha}(z,t) \rangle / L^2 \Delta z.$$
 (2.41)

Hereafter, $\langle \cdots \rangle$ represents the average over a time interval with width 10^3 .

In Fig.2(c)-(c'), we display the laterally averaged (local) electric field along the z axis calculated from

$$\langle E_z \rangle(z) = \sum_j \langle E_{zj} \frac{\theta(z_j - z)\theta(z + \Delta z - z_j)}{\Delta N(z)} \rangle, \quad (2.42)$$

where $q_j E_{zj} = -\partial U_{\rm m}/\partial z_j$ and $\Delta N(z) = \Delta N_1(z) + \Delta N_2(z)$. We can see that $\langle E_z \rangle(z)$ exhibits sharp peaks near the walls but tends to zero in the interior. This screening is achieved only by one or two layers of the accumulated charges. In the same manner, replacing E_{zj} in Eq.(2.42) by E_{zj}^s , E_{zj}^ℓ , and E_j^0 in Eq.(2.33), we may define the lateral averages $\langle E_z^s \rangle(z)$, $\langle E_z^\ell \rangle(z)$, and $\langle E^0 \rangle(z)$, respectively. For the examples in this subsection, we find $\langle E_z^\ell \rangle(z) \cong 0$ (less than 0.01) so that

$$\langle E_z \rangle(z) \cong \langle E_z^s \rangle(z) + \langle E_z^0 \rangle(z).$$
 (2.43)

In Fig.2(c)-(c'), $\langle E^0 \rangle(z)$ more smoothly varies than $\langle E_z \rangle(z)$ and tends to zero far from the walls, while $\langle E_z^s \rangle(z)$ exhibits sharp peaks near the walls and oscillates around zero far from the walls.

In Fig.3, we show snapshots of the particles in the two layers 0 < z < 1 and 1 < z < 2. For $\Delta \Phi = 1$, cations and anions are both attracted to the wall due to the image

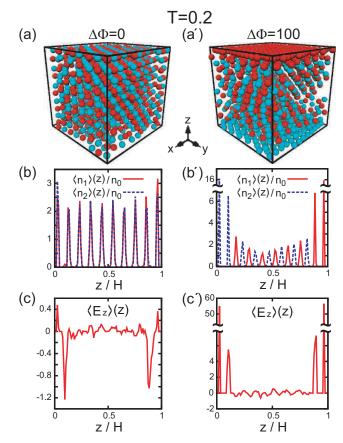

FIG. 4. (Color online) Simulation results of charged particles in crystal at T=0.2. Cations (in red) and anions (in blue) for $\Delta\Phi=1$ in (a) and 100 in (a'). Normalized lateral density averages $\langle n_1 \rangle (z)/n_0$ and $\langle n_2 \rangle (z)/n_0$ are in (b) and (b'). Lateral average $\langle E_z \rangle (z)$ are in (c) and (c'). For $\Delta\Phi=0$, both cations and anions are somewhat denser in the first layer with larger $\langle E_z \rangle$ with a negative $\langle E_z \rangle$ in the second layer. For $\Delta\Phi=100$, anions are closely packed in the first layer, while their lateral density gradually decreases from the second layer. These ordered configurations are nearly stationary.

interaction. For $\Delta\Phi=10$, only anions are attached in the first layer, but cations are richer in the second layer. We divide Eq.(2.31) by qL^2 to obtain

$$Q_0/qL^2 = E_a/4\pi q + \sum_j q_j z_j/qHL^2,$$
 (2.44)

where the second term is the areal density of excess cations at the top (with $z_j \cong H$) and is larger than the first term for strong screening³². The data in Figs.2(a)-(a') give $(E_a/4\pi q, \sum_j q_j z_j/qHL^2) = (0.0013, 0.106)$ for $\Delta \Phi = 1$ and (0.0013, 0.426) for $\Delta \Phi = 10$.

3. Charged particles at T = 0.2: Ionic crystals

In Figs.4 and 5, we show simulation results in crystal at T=0.2. For $\Delta\Phi=0$ the cations and anions form a

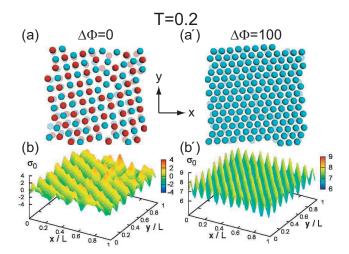

FIG. 5. (Color online) Particle configuration in the first layer 0 < z < 1 (in red or blue) and in the second layer 1 < z < 2 (in lighter colors) for $\Delta \Phi = 0$ in (a) and 100 in (a'). Surface charge density $\sigma_0(x,y)$ at z=0 for $\Delta \Phi=0$ in (b) and 100 in (b') in units of $(\epsilon/\sigma^3)^{1/2}$. Data are common to those in (a) and (a') of Fig.4. For $\Delta \Phi=0$, a square lattice (with defects) appears from the first layer. For $\Delta \Phi=100$, anions form a hexagonal lattice in the first layer, but are in a transition state in the second layer.

square lattice, as is well known for salts such as NaCl, from the first layer. However, for $\Delta\Phi=100$, we can see a hexagonal structure in the first layer 0 < z < 1 and a square lattice for z > 2, where the structure changes over in the second layer 1 < z < 2. In this case, the first layer is composed of anions only and the second layer is anion-rich, as can also be seen in Fig.4(b'). In the lower plates of Fig.5, the surface charge density $\sigma_0(x,y)$ varies nearly in one direction as a result of the complex charge distributions in the first few layers.

In addition, we examine Eq.(2.44). From the data in Figs.4(a)-(a') we have $(E_a/4\pi q, \sum_j q_j z_j/qHL^2) = (0,0.024)$ for $\Delta\Phi=1$ and (0.132,1.31) for $\Delta\Phi=100$. In the second example, the first layers next to the walls are nearly closely packed with cations or anions, as can be seen in Fig.5(a').

III. POLAR PARTICLES

In this section, we consider N polar particles at positions \mathbf{r}_j and with dipole moments $\boldsymbol{\mu}_j$. The derivatives of the electrostatic energy U give the electrostatic force \mathbf{F}_i^e and the electric field \mathbf{E}_i on dipole i as

$$F_i^e = -\frac{\partial}{\partial r_i} U, \quad E_i = -\frac{\partial}{\partial \mu_i} U,$$
 (3.1)

which are used in the equations of motions. There can also be neutral and charged particles.

A. Ewald method for dipoles in the periodic boundary condition

We first consider the electrostatic energy in the periodic boundary condition^{2,3,6}, which is written as $U_{\rm p}^{\rm d}$. Here, there is no applied electric field. In Eq.(2.3) we replace q_i by $\mu_i \cdot \nabla_i$, where $\nabla_i = \partial/\partial r_i$. Then, we obtain

$$U_{\mathrm{p}}^{\mathrm{d}} = \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{i,j}' (\boldsymbol{\mu}_i \cdot \nabla_i) (\boldsymbol{\mu}_j \cdot \nabla_j) \frac{1}{|\boldsymbol{r}_{ij} + L\boldsymbol{m}|}. \quad (3.2)$$

From Eq.(2.7) the Ewald representation is given by

$$U_{p}^{d} = \frac{1}{2} \sum_{\mathbf{m}} \sum_{i,j}' \boldsymbol{\mu}_{i} \cdot \stackrel{\leftrightarrow}{w}_{s} (|\boldsymbol{r}_{ij} + L\boldsymbol{n}|) \cdot \boldsymbol{\mu}_{j}$$

$$+ \frac{1}{2L^{3}} \sum_{\mathbf{k}}' \sum_{i,j} (\boldsymbol{k} \cdot \boldsymbol{\mu}_{i}) (\boldsymbol{k} \cdot \boldsymbol{\mu}_{j}) \Psi_{\ell}(k) e^{i\boldsymbol{k} \cdot \boldsymbol{r}_{ij}}$$

$$- \sum_{i} \frac{2\gamma^{3}}{3\sqrt{\pi}} |\boldsymbol{\mu}_{i}|^{2} + \frac{2\pi}{3L^{3}} \left| \sum_{i} \boldsymbol{\mu}_{j} \right|^{2}. \tag{3.3}$$

In the first term, we introduce the tensor $\overset{\leftrightarrow}{w}_s(r)$ by

$$\overset{\leftrightarrow}{w}_s(\mathbf{r}) = -\nabla\nabla\psi_s(r) = B(r)\overset{\leftrightarrow}{I} - C(r)\frac{1}{r^2}\mathbf{r}\mathbf{r}, \qquad (3.4)$$

where $\overset{\leftrightarrow}{I}$ is the unit tensor and

$$B(r) = \psi_s(r)/r^2 + 2\pi\varphi_3(r)/\gamma^2 r^2,$$

$$C(r) = 3B(r) + 4\pi\varphi_3(r),$$
(3.5)

with $\varphi_3(r) = \varphi(x)\varphi(y)\varphi(z)$ (see Eq.(2.5)). The third term in Eq.(3.3) is the counterpart of the second term in Eq.(2.7) following from the small-r expansion (2.6).

B. Ewald method for dipoles between metallic plates under applied electric field

We consider N dipoles between metallic plates in applied electric field E_a . The electrostatic potential Φ is written as Eq.(2.12). For each dipole $\boldsymbol{\mu}_i = (\mu_{xi}, \mu_{yi}, \mu_{zi})$ at $\boldsymbol{r}_i = (x_j, y_j, z_j)$, there arise S-image dipoles at $(x_i, y_i, z_i - 2Hn)$ $(n \neq 0)$ with the same moment $\boldsymbol{\mu}_i$ and O-image dipoles at $(x_i, y_i, -z_i - 2Hn)$ with the moment,

$$\bar{\mu}_i = (-\mu_{xi}, -\mu_{yi}, \mu_{zi}).$$
 (3.6)

See Fig.1 for these images. If a dipole at r_i approaches the bottom wall, its image at \bar{r}_i yields the dipolar electric field $-\partial v_{\rm I}^{\rm d}/\partial \mu_i = -(2z_i)^{-3}(\bar{\mu}_i - 3\bar{\mu_{zi}}e_z)$ at r_i . Thus the interaction energy from this closest image is written as

$$v_{\rm I}^{\rm d}(z_i, \theta_i) = [\boldsymbol{\mu}_i \cdot \bar{\boldsymbol{\mu}}_i - 3\mu_{zi}\bar{\mu}_{zi}]/2(2z_i)^3$$

= $-|\boldsymbol{\mu}_i|^2 (1 + \cos^2\theta_i)/16z_i^3$, (3.7)

where $\cos \theta_i = \mu_{zi}/|\boldsymbol{\mu}_i|$ with θ_i being the angle of $\boldsymbol{\mu}_i$ with respect to the z axis. This interaction energy is negative and grows for small z_i . In the vicinity of the wall, where

 $|v_{\rm I}^{\rm d}| \gg k_B T$ holds, dipoles are attracted to the walls and are oriented in the parallel direction ($\theta_i = 0$) or in the antiparallel direction ($\theta_i = \pi$) with respect to the z axis.

From the formulae in the previous section, we obtain the counterparts by replacing q_j by $\boldsymbol{\mu}_j \cdot \nabla_j$ for S-images and $-q_j$ by $\bar{\boldsymbol{\mu}}_j \cdot \nabla_j$ for O-images, where $\nabla_j = \partial/\partial \boldsymbol{r}_j$. From Eq.(2.21) the excess potential $\phi(\boldsymbol{r})$ for $\boldsymbol{r} \neq \boldsymbol{r}_j$ is obtained in the following superposition,

$$\phi = \sum_{m} \sum_{j} \nabla_{j} \cdot \left[\frac{\mu_{j}}{|\mathbf{r} - \mathbf{r}_{j} + \mathbf{h}|} + \frac{\bar{\mu}_{j}}{|\mathbf{r} - \bar{\mathbf{r}}_{j} + \mathbf{h}|} \right], \quad (3.8)$$

which surely vanishes at z=0 and H. The total electrostatic energy in the fixed-potential condition is written as $U_{\rm m}^{\rm d}$. From Eq.(2.23), we find

$$U_{\rm m}^{\rm d} = \frac{1}{2} \sum_{\boldsymbol{m}} \left[\sum_{i,j}' (\boldsymbol{\mu}_i \cdot \nabla_i) (\boldsymbol{\mu}_j \cdot \nabla_j) \frac{1}{|\boldsymbol{r}_{ij} + \boldsymbol{h}|} + \sum_{i,j} (\boldsymbol{\mu}_i \cdot \nabla_i) (\bar{\boldsymbol{\mu}}_j \cdot \nabla_j) \frac{1}{|\bar{\boldsymbol{r}}_{ij} + \boldsymbol{h}|} \right] - E_a \sum_i \mu_{iz}, \quad (3.9)$$

where the self-interaction terms are removed in $\sum_{i,j}'$ and h is given by Eq.(2.22). The direct image interaction energy in Eq.(3.7) is included in the above expression. From Eq.(3.1) the differential form of $U_{\rm m}^{\rm d}$ is given by

$$dU_{\rm m}^{\rm d} = -\sum_{i} (\boldsymbol{F}_{i}^{e} \cdot d\boldsymbol{r}_{i} + \boldsymbol{E}_{i} \cdot d\boldsymbol{\mu}_{i}) - \sum_{i} \mu_{zi} dE_{a}. \quad (3.10)$$

The Ewald representation of $U_{\rm m}^{\rm d}$ may be written as¹⁹

$$U_{\mathrm{m}}^{\mathrm{d}} = \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{i,j}' \boldsymbol{\mu}_{i} \cdot \stackrel{\leftrightarrow}{w}_{s} (|\boldsymbol{r}_{ij} + \boldsymbol{h}|) \cdot \boldsymbol{\mu}_{j}$$

$$+ \frac{1}{2} \sum_{\boldsymbol{m}} \sum_{i,j} \boldsymbol{\mu}_{i} \cdot \stackrel{\leftrightarrow}{w}_{s} (|\bar{\boldsymbol{r}}_{ij} + \boldsymbol{h}|) \cdot \bar{\boldsymbol{\mu}}_{j} - \sum_{i} \frac{2\gamma^{3}}{3\sqrt{\pi}} |\boldsymbol{\mu}_{i}|^{2}$$

$$+ \frac{1}{HL^{2}} \sum_{\boldsymbol{\nu}_{\perp} \neq \boldsymbol{0}} \sum_{i,j} \frac{\Psi_{\ell}(k)}{4} (\boldsymbol{k} \cdot \boldsymbol{\mu}_{i}) \boldsymbol{k} \cdot (e^{\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}_{ij}} \boldsymbol{\mu}_{j} + e^{\mathrm{i}\boldsymbol{k} \cdot \bar{\boldsymbol{r}}_{ij}} \bar{\boldsymbol{\mu}}_{j})$$

$$+ V_{\mathrm{m}}^{\mathrm{d}} - E_{a} \sum_{i} \boldsymbol{\mu}_{zi}. \tag{3.11}$$

The first and second terms represent the short-range part with $\overset{\leftrightarrow}{w}_s$ given in Eq.(3.4). The third term has appeared in Eq.(3.3). In the fourth long-range term, the summation is over $\boldsymbol{\nu}=(\nu_x,\nu_y,\nu_z)$ with $\boldsymbol{\nu}_\perp=(\nu_x,\nu_y)\neq \mathbf{0}$ and \boldsymbol{k} is given by Eq.(2.27). The fifth term $V_{\rm m}^{\rm d}$ arises from the contributions with $k_x=k_y=0$. From Eqs.(2.26), (2.28), and (C4), we find

$$V_{\rm m}^{\rm d} = \frac{2\pi}{L^2} \sum_{ij} \mu_{zi} \mu_{zj} \left[\hat{\varphi}(z_i - z_j) + \hat{\varphi}(z_i + z_j) - \frac{1}{H} \right]$$
$$= \frac{4\pi}{HL^2} \sum_{n \ge 1} e^{-(\pi n/2\gamma H)^2} K_n^2, \tag{3.12}$$

where K_n depends on z_1, z_2, \cdots as

$$K_n = \sum_{j} \mu_{zj} \cos(\frac{\pi n z_j}{H}). \tag{3.13}$$

The electric field E_i on dipole i can be calculated from Eq.(3.11). That is, the contribution from the first and second terms, that from the third and fourth terms, and that from the fifth and sixth terms are written as E_i^{ds} , $E_i^{\text{d\ell}}$, and $E_i^{\text{d0}}e_z$, respectively. Then,

$$\boldsymbol{E}_{i} = \boldsymbol{E}_{i}^{\mathrm{ds}} + \boldsymbol{E}_{i}^{\mathrm{d}\ell} + E_{i}^{\mathrm{d}0} \boldsymbol{e}_{z}. \tag{3.14}$$

From Eq.(3.12) E_i^{d0} is expressed as

$$E_i^{d0} = E_a - \frac{4\pi}{L^2} \sum_j \mu_{zj} \left[\hat{\varphi}(z_i - z_j) + \hat{\varphi}(z_i + z_j) - \frac{1}{H} \right]$$
$$= E_a - \frac{8\pi}{HL^2} \sum_{n>1} e^{-(\pi n/2\gamma H)^2} K_n \cos(\frac{\pi n z_i}{H}). \tag{3.15}$$

In the first line, if the particles $j \neq i$ are randomly distributed in the cell, the second term vanishes, and the self term with j=i is of order $\mu_{zi}\gamma/L^2$. Thus, if the boundary disturbances do not extend into the interior in a thick and wide cell, we have $E_i^{d0} \cong E_a$ (see Table 1 below). The first line of Eq.(3.15) is consistent with Eq.(D5) in Appendix D.

By replacing q_j by $\boldsymbol{\mu}_j \cdot \nabla_j$ in Eq.(2.30), we obtain the surface charge densities, $\sigma_0(x,y)$ at z=0 and $\sigma_H(x,y)$ at z=H, in the 2D Fourier expansions,

$$\sigma_{0} = \frac{E_{a}}{4\pi} - \frac{1}{L^{2}} \sum_{\boldsymbol{\nu}_{\perp}} \sum_{j} \boldsymbol{\mu}_{j} \cdot \nabla_{j} \frac{\sinh(kH - kz_{j})}{\sinh(kH)} e^{i\boldsymbol{k}\cdot(\boldsymbol{r} - \boldsymbol{r}_{j})},$$

$$\sigma_{H} = -\frac{E_{a}}{4\pi} - \frac{1}{L^{2}} \sum_{\boldsymbol{\nu}_{\perp}} \sum_{j} \boldsymbol{\mu}_{j} \cdot \nabla_{j} \frac{\sinh(kz_{j})}{\sinh(kH)} e^{i\boldsymbol{k}\cdot(\boldsymbol{r} - \boldsymbol{r}_{j})},$$
(3.16)

where $\boldsymbol{\nu}_{\perp} = (\nu_x, \nu_y)$ and $\boldsymbol{k} = (2\pi\nu_x/L, 2\pi\nu_y/L, 0)$. Integrating σ_0 and σ_H in the planar region 0 < x, y < L yields the total electric charges on the metallic surfaces,

$$Q_0 = -Q_H = \frac{1}{4\pi} L^2 E_a + \frac{1}{H} \sum_j \mu_{zj}.$$
 (3.17)

See Eq.(D6) for the counterpart in the continuum theory.

C. Numerical example for dipoles between metallic plates under applied electric field

1. Model and method

Next, we present results of molecular dynamics simulation of one-component spherical dipoles with number N=1000 between parallel metallic plates with H=L at fixed potential difference $\Delta\Phi$.

As in Eq.(2.35), the total potential energy is given by

$$U_{\text{tot}} = U_{\text{m}}^{\text{d}} + \sum_{i>j} v_s(r_{ij}) + \sum_i v_{\text{w}}(z_i),$$
 (3.18)

where $U_{\rm m}^{\rm d}$ is given by Eq.(3.11), $v_s(r)$ by Eq.(2.36), and $v_{\rm w}(z)$ by Eq.(2.37). Hereafter, in terms of σ and ϵ

in $v_s(r)$, units of length, density, electrostatic potential, electric field, electric charge, dipole moment, and temperature are σ , σ^{-3} , $(\epsilon/\sigma)^{1/2}$, $(\epsilon/\sigma^3)^{1/2}$, $(\epsilon\sigma)^{1/2}$, $(\epsilon\sigma^3)^{1/2}$, and ϵ/k_B , respectively. The average density $n_0 = N/HL^2$ is chosen to be 0.19, 0.38, and 0.57; then, L = 17.4, 13.8, and 12.0, respectively.

We cut off $v_s(r)$ and the short-range part of $U_{\rm m}^{\rm d}$ in Eq.(3.11) at $r=r_{\rm cut}^s=4$. In $U_{\rm m}^{\rm d}$, we set $\gamma=0.65$ and sum over k in the region $k\leq k_c=18\pi/L$. Thus, in $E_i^{\rm d0}$ in Eq.(3.15), the terms up to n=18 are summed. In addition, we note that the simulation results are rather insensitive to the choice of γ . To confirm this, we also performed simulations for $\gamma=0.5$ and 1 with $r_{\rm cut}^s=6$ for the case of $n_0=0.19$, T=1.0, and $E_a=0.058$. Then the numbers in the first line of Table 1 were changed only slightly with differences less than 5%.

The dipole moment has a fixed magnitude μ_0 as

$$\boldsymbol{\mu}_i = \mu_0 \boldsymbol{n}_i, \tag{3.19}$$

where n_i is the unit vector representing the direction of polarization. In this subsection, we set

$$\mu_0 = |\boldsymbol{\mu}_i| = 2(\epsilon \sigma^3)^{1/2}.$$
 (3.20)

Then our system is highly polarizable at high densities.

The total kinetic energy is assumed to be of the form,

$$K_{\text{tot}} = \sum_{i} \frac{m}{2} |\dot{r}_{i}|^{2} + \sum_{i} \frac{I_{1}}{2} |\dot{n}_{i}|^{2},$$
 (3.21)

where $\dot{\boldsymbol{r}}_i = d\boldsymbol{r}_i/dt$, $\dot{\boldsymbol{n}}_i = d\boldsymbol{n}_i/dt$, and I_1 is the moment of inertia. Regarding dipoles as spheres with diameter σ , we set $I_1 = m\sigma^2/10$. The Newton equations of motions for \boldsymbol{r}_i and \boldsymbol{n}_i are written as³³

$$m\frac{d^2}{dt^2}\mathbf{r}_i = -\frac{\partial}{\partial \mathbf{r}_i}U_{\text{tot}},\tag{3.22}$$

$$I_1 \mathbf{n}_i \times \frac{d^2}{dt^2} \mathbf{n}_i = -\boldsymbol{\mu}_i \times \frac{\partial}{\partial \boldsymbol{\mu}_i} U_{\text{tot}}, \qquad (3.23)$$

where $\mathbf{n}_i \cdot d^2 \mathbf{n}_i/dt^2 = -|\dot{\mathbf{n}}_i|^2$ from $\mathbf{n}_i \cdot \dot{\mathbf{n}}_i = 0$. The total energy $U_{\text{tot}} + K_{\text{tot}}$ is conserved in time. We integrated these equations in the NVE ensemble using the leap-frog method with the time step width being 0.002, as in the previous section (see below Eq.(2.40)). The translational and rotational kinetic energies were kept at $3k_BT/2$ and k_BT , respectively, per particle.

2. Highly polarizable liquids

In Fig.6, we show snapshots of spherical dipoles for $n_0=0.19$ and 0.38 in liquid at T=1 under $\Delta\Phi=1$ and 10. The colors of the spheres represent their polarization directions according to the color maps in Fig.7. We can see orientation enhancement with increasing $\Delta\Phi$. For $n_0=0.19$, chainlike associations are clearly visualized, whose lengths increase with increasing $\Delta\Phi$. For small $\Delta\Phi$ a large number of dimers appear.

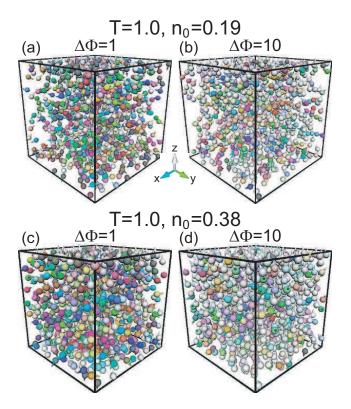

FIG. 6. (Color online) Snapshots of spherical dipoles in liquid at T=1: (a) $n_0=0.19$ and $\Delta\Phi=1$, (b) $n_0=0.19$ and $\Delta\Phi=10$, (c) $n_0=0.38$ and $\Delta\Phi=1$, and (d) $n_0=0.38$ and $\Delta\Phi=10$. Colors represent the orientation of μ_i as in Fig.7.

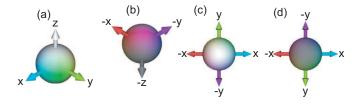

FIG. 7. (Color online) Color maps of polarization direction n_i on a sphere surface: (a) Diagonally downward view, (b) diagonally upward view, (c) top view, and (d) bottom view. Spheres become white (gray) as they are parallel (antiparallel) to the applied field.

In the top panels of Fig.8, we display particle configurations near the bottom wall in the two layers, 0 < z < 1 and 1 < z < 2, and the surface charge density $\sigma_0(x,y)$ in Eq.(3.16). In these cases, dipoles are accumulated on the walls and are oriented. For $\Delta \Phi = 1$, the image interaction (3.7) is strong enough to induce alignment both in the parallel and antiparallel directions along the z axis. For $\Delta \Phi = 10$ those in the parallel direction increase. In the bottom panels of Fig.8, the surface charge density in Eq.(3.16) are written, which are highly heterogeneous and fluctuating in time.

In Figs.9(a)-(a'), we display the laterally averaged density $\langle n \rangle(z)$ defined as in Eq.(2.41), where we write two curves for $\Delta z = H/100 = 0.138$ and H/20 = 0.69. We

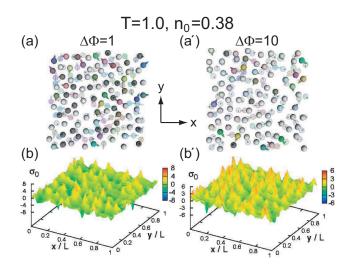

FIG. 8. (Color online) Top: Dipole configurations in the two layers 0 < z < 1 and 1 < z < 2 for $\Delta \Phi = 1$ (left) and 10 (right), according to the color maps in Fig.7. Bottom: Surface charge density $\Delta \sigma_0(x,y)$ at z=0 for $\Delta \Phi = 1$ and 10 in units of $(\epsilon/\sigma^3)^{1/2}$. Data are common to those in (a) and (a') of Fig.6.

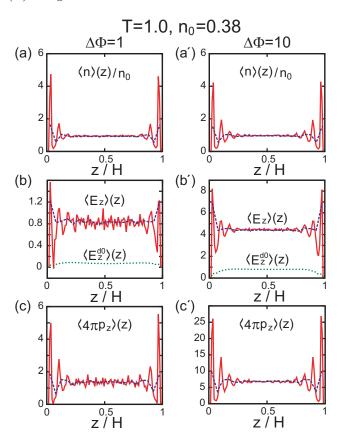

FIG. 9. (Color online) Simulation results of spherical dipoles for $n_0=0.38$ and T=1 in liquid, where $\Delta\Phi=1$ (left) and 10 (right). Normalized lateral density average $\langle n \rangle(z)/n_0$ is in (b) and (b'). Lateral average $\langle E_z \rangle(z)$ are in (c) and (c') and that $\langle 4\pi p_z \rangle(z)$ are in (d) and (d'). Here, $\Delta z=H/100$ (bold red lines) and $\Delta z=H/20$ (broken blue lines), where Δz is the smoothing length.

TABLE I. Data for 1000 spherical dipoles in liquid at T=1 in a $L \times L \times H$ cell (H=L) under applied potential difference $\Delta \Phi = HE_a = 1$ and 10 for three densities $n_0 = 0.19, 0.38$, and 0.57. Here, \bar{n} , $\bar{\mu}_z$, and $\bar{p}_z = \bar{n}\bar{\mu}_z$ are bulk values in the interior. Also given are bulk values of $\langle E^{\rm d0} \rangle(z)$ and $\langle E_z \rangle(z)$, dielectric constant $\varepsilon_{\rm e}$ in Eq.(3.29), local field factor γ_{ℓ} in Eq.(3.30), polarizability $\alpha_{\rm e} = \bar{\mu}_z / \langle E_z \rangle$.

recognize that the interior away from the walls is in a homogeneous, uniaxial equilibrium state under electric field for $H\gg 1$. In Table 1, the bulk density \bar{n} in the interior is slightly smaller than n_0 because the dipoles are accumulated near the walls. We determined the interior (bulk) values from the lateral averages with $\Delta z=H/20$.

Using the decomposition (3.14) of the local field E_i , we define the laterally averaged electric fields $\langle E_z \rangle(z)$, $\langle E_z^{\text{de}} \rangle(z)$, $\langle E_z^{\text{de}} \rangle(z)$, and $\langle E^{\text{d0}} \rangle(z)$ as in Eq.(2.42). Hereafter, $\langle \cdots \rangle$ represents the average over a long time interval with width 10³. Along the z axis we thus have

$$\langle E_z \rangle(z) = \langle E_z^{\text{ds}} \rangle(z) + \langle E_z^{\text{d}\ell} \rangle(z) + \langle E^{\text{d}0} \rangle(z).$$
 (3.24)

If the boundary layers are much thinner than H, we have $\langle E^{\mathrm{d0}} \rangle(z) \cong E_a$ in the interior (see the sentences below Eq.(3.15)). For the examples in Table 1, we can indeed see $\langle E^{\mathrm{d0}} \rangle \cong E_a$. We also find that $\langle E_z^{\mathrm{d\ell}} \rangle(z)$ is of the same order as E_a^{34} . In the bulk region of our examples, the short-range contribution $\langle E_z^{\mathrm{ds}} \rangle(z)$ is thus dominant in the right hand side of Eq.(3.24), typically being about 90% of $\langle E_z \rangle$, so that

$$\langle E_z \rangle \cong \langle E_z^{\rm ds} \rangle.$$
 (3.25)

We also define the lateral average of the polarization,

$$\langle p_z \rangle(z) = \sum_i \langle \mu_{zj} \frac{\theta(z_j - z)\theta(z + \Delta z - z_j)}{L^2 \Delta z} \rangle.$$
 (3.26)

We plot $\langle E_z \rangle(z)$ in Fig.9(b)-(b') and $\langle p_z \rangle(z)$ in Fig.9(c)-(c') for $\Delta z = H/100$ and H/20, where the curves are more smooth for larger Δz . In the interior, they assume the bulk average values with small fluctuations. In Table 1, we give the average bulk values of $\langle E_z \rangle$, $\langle E^0 \rangle(z)$, and $\langle 4\pi E_z \rangle(z)$ at T=1 for three densities $n_0=0.19,0.38$, and 0.57 under $\Delta \Phi=1$ and 10.

In terms of the polarization variable,

$$\hat{\boldsymbol{p}}(\boldsymbol{r}) = \sum_{i} \boldsymbol{\mu}_{i} \delta(\boldsymbol{r}_{i} - \boldsymbol{r}), \tag{3.27}$$

we have $\langle p_z \rangle(z) = \int_0^L dx \int_0^L dy \int_z^{z+\Delta z} dz \hat{p}_z(\boldsymbol{r})/L^2 \Delta z$. Averaging over the particles in the interior and over a

long time yields the bulk average polarization,

$$\bar{p}_z = \langle \hat{p}_z \rangle = \bar{n}\bar{\mu}_z, \tag{3.28}$$

where $\bar{\mu}_z$ is the average of μ_{zi} in the interior. We define the effective dielectric constant by

$$\varepsilon_{\rm e} = 1 + 4\pi \bar{p}_z / E_a. \tag{3.29}$$

In Table 1, $\varepsilon_{\rm e}$ is much larger than unity, increasing with increasing n_0 and decreasing with increasing E_a . For $\Delta\Phi=10$, $\bar{\mu}_z$ approaches its maximum $\mu_0=2$, where the system is in the nonlinear response regime. In addition, for $n_0=0.57$ and $\Delta\Phi=1$, $\varepsilon_{\rm e}$ is given by a large value of 40. With lowering T at this density, we find occurrence of a ferroelectric phase transition around $T\cong0.5$, on which we will report shortly.

Furthermore, since E_i is the local electric field, its lateral average $\langle E_z \rangle$ along the z axis is related to the applied electric field E_a and the local polarization \bar{p}_z by

$$\langle E_z \rangle = E_a + 4\pi \gamma_\ell \bar{p}_z, \tag{3.30}$$

in the bulk region. The second term represents the Lorentz field with γ_{ℓ} being the local field factor^{26,27,35}. The classical value of γ_{ℓ} is 1/3. However, in Table 1, γ_{ℓ} considerably exceeds 1/3. It increases with decreasing n_0 but is rather insensitive to E_a . We may also introduce the polarizability $\alpha_{\rm e} = \bar{\mu}_z/\langle E_z \rangle$. Then, $\varepsilon_{\rm e}$ satisfies

$$\frac{\varepsilon_{\rm e} - 1}{1 + \gamma_{\ell}(\varepsilon_{\rm e} - 1)} = 4\pi \bar{n}\alpha_{\rm e},\tag{3.31}$$

which nicely holds in Table 1. The Clausius-Mossotti formula follows for $\gamma_{\ell}=1/3$. Here, we should suppose a thick cell $(H\gg 1)$ to avoid the boundary effect in the relations (3.29) and (3.30), though our system size is still not large enough.

In our case, the classical local field relation breaks down because of strong pair correlations along the z axis. To explain this, we assume a large homogeneous interior region in liquid for large H and L. There, we define the pair correlation functions $g(r,\theta)$ and $g_p(r,\theta)$ by

$$\langle \hat{n}(\mathbf{r}_0)\hat{n}(\mathbf{r}_0+\mathbf{r})\rangle = \bar{n}\delta(\mathbf{r}) + \bar{n}^2g(r,\theta),$$
 (3.32)

$$\langle \hat{n}(\mathbf{r}_0)\hat{p}_z(\mathbf{r}_0+\mathbf{r})\rangle = \bar{n}\bar{p}_z\delta(\mathbf{r}) + \bar{n}q_p(r,\theta), \tag{3.33}$$

where $\hat{n}(\boldsymbol{r}) = \sum_i \delta(\boldsymbol{r}_i - \boldsymbol{r}_0)$ is the density variable and $\hat{\boldsymbol{p}}(\boldsymbol{r})$ is defined in Eq.(3.27). These relations are independent of \boldsymbol{r}_0 from the translational invariance. The $g(r,\theta)$ and $g_p(r,\theta)$ depend only on r and $\theta = \cos^{-1}(z/r)$ from the rotational invariance around the z axis. For $r \gg 1$, we have $g(r,\theta) \to 1$ and $g_p(r,\theta) \to \bar{p}_z$. Also from the invariance with respect to the inversion $\boldsymbol{r} \to -\boldsymbol{r}$, they are even functions of $\pi/2 - \theta$ and we notice

$$\langle \hat{n}(\mathbf{r}_0)\hat{p}_x(\mathbf{r}_0+\mathbf{r})\rangle = \langle \hat{n}(\mathbf{r}_0)\hat{p}_y(\mathbf{r}_0+\mathbf{r})\rangle = 0.$$
 (3.34)

In Fig.10, we plot $g(r,\theta)$ and $g_p(r,\theta)/\bar{p}_z$ for T=1, $n_0=0.38$, and $\Delta\Phi=10$. They exhibit first peaks at

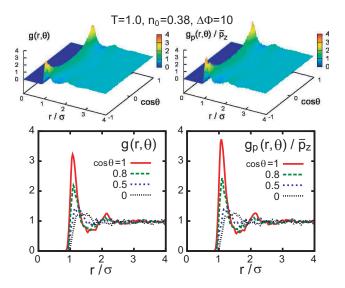

FIG. 10. (Color online) Pair correlation functions $g(r,\theta)$ (left) and $g_{\rm p}(r,\theta)/\bar{p}_z$ (right) of dipoles in liquid on the r-cos θ plane (top) and as functions of r for $\cos\theta=1,0.8,0.5$, and 0 (bottom), where $n_0=0.38,\,T=1$, and $\Delta\Phi=10$. They exhibit peaks at $r\sim1.1$ and at $r\sim2.2$ along the field ($\cos\theta\cong\pm1$).

 $r \sim 1.1$ and second peaks at $r \sim 2.2$. They are maximized for $\cos \theta = \pm 1$, so the associated dipoles are on the average oriented along the z axis. However, this tendency is not clearly visualized in Fig.6(d) at $n_0 = 0.38$, while it is evident in Fig.6(b) at $n_0 = 0.19$. For ferromagnetic fluids, similar behavior of the pair correlation function $g(r,\theta)$ was theoretically examined³⁰ and numerically calculated³⁶.

From the first term in Eq.(3.11), the short-range part of the local field in the interior is given by $\boldsymbol{E}_{i}^{\mathrm{ds}} \cong -\sum_{j\neq i} \stackrel{\leftrightarrow}{w}_{s} (|\boldsymbol{r}_{ij}|) \cdot \boldsymbol{\mu}_{j}$, where the contributions with $\boldsymbol{m} \neq (0,0,0)$ are neglected. From Eqs.(3.4) and (3.33) the lateral average of its z component is written in terms of $g_{\mathrm{p}}(r,\theta)$ for $\Delta z \ll 1$ as

$$\langle E_z^{\rm ds} \rangle \cong \int d\mathbf{r} [C(r)\cos^2\theta - B(r)]g_{\rm p}(r,\theta).$$
 (3.35)

If we set $g_p(r,\theta) = \bar{p}_z$, the integral is nearly equal to $4\pi\bar{p}_z/3$ from Eq.(3.5)³⁷. Use of Eq.(3.25) yields the correction to the classical value in the form,

$$\gamma_{\ell} - \frac{1}{3} \cong \int \frac{d\mathbf{r}}{4\pi} [C(r)\cos^2\theta - B(r)] [\frac{g_{\rm p}(r,\theta)}{\bar{p}_z} - 1].$$
 (3.36)

Here, we may well replace $C(r)\cos^2\theta - B(r)$ by $(3\cos^2\theta - 1)/r^3$, since $g_p(r,\theta)/\bar{p}_z - 1$ is small for $r/\sigma \gtrsim \gamma^{-1}$ in Fig.10. In Table 1, the above formula reproduces the numerical values of γ_ℓ with errors of order 10%.

3. Dipole chains

For ferromagnetic particles with permanent dipoles, chain formation was predicted³⁰ and has been studied

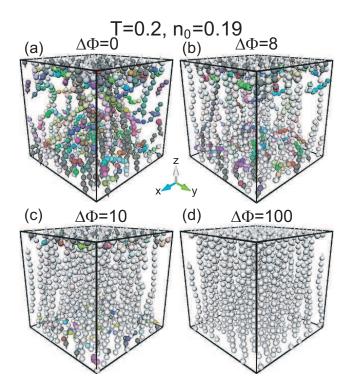

FIG. 11. (Color online) Chains of 1000 spherical dipoles at T=0.2 for $n_0=0.19$ in a $L\times L\times H$ cell (H=L). Potential difference $\Delta\Phi$ is set equal to 0, 8, 10, and 100. For small $\Delta\Phi$ dipoles parallel and antiparallel to the z axis are both attracted and aligned by the image interaction near the walls. They are written in white or in gray, respectively. For large $\Delta\Phi$, they are aligned along the z axis.

numerically^{7,8,13}. As electrorheological fluids, use has been made of colloids with a dielectric constant different from that of the surrounding fluid^{20,38}, which have induced dipole moments in electric field. Coating of colloids with urea (with a high molecular dipole moment of 4.6D) is known to increase the polarizability³⁹. Experiments on such dielectric particles have been performed extensively, but simulations including the image interaction under applied electric field were performed only for induced point dipoles oriented along the z axis²¹. Here, we present simulation results on permanent point dipoles. We show that they are attracted to the walls by the image dipoles and the surface charges due to the applied electric field.

In Fig.11, we gives our examples of dipole chains at T=0.2 for $n_0=0.19$ under four potential differences $\Delta\Phi=0$, 8, 10, and 100. For $\Delta\Phi=0$ in (a), chains are formed near the walls, where dipoles are attracted to the walls and aligned in the directions parallel or antiparallel to the z axis due to the image interaction (3.7). For $\Delta\Phi=8$ in (b), even dipoles away from the walls form strings along the z axis. For $\Delta\Phi=10$ in (c), chains are stretched between the two plates, but antiparallel wall attachments still occur. For $\Delta\Phi=100$ in (d), all the dipoles are aligned along the z axis.

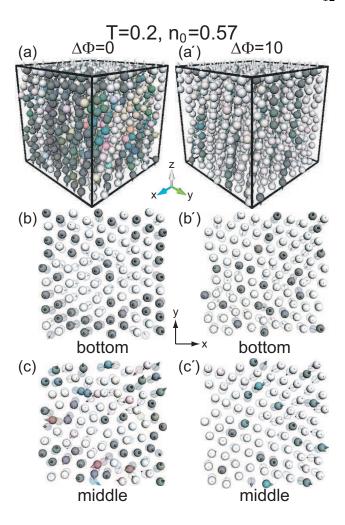

FIG. 12. (Color online) Chains of 1000 spherical dipoles at T=0.2 for $n_0=0.57$ in a $L\times L\times H$ cell (H=L) for $\Delta\Phi=0$ (left) and 10 (right). Shown also are cross-sectional configurations in the bottom two layers, 0< z<1 and 1< z<2, in (b) and (b') and those in the middle two layers, H/2+1< z< H/2+2 and H/2< z< H/2+1, in (c) and (c'). White (gray) particles are parallel (antiparallel) to the z axis. Colors are lighter for dipoles in the second layers.

We consider the average dipole moment over all the particles and that over those at the bottom defined by

$$\langle \mu_z \rangle_{\text{all}} = \sum_i \mu_{zi} / N, \quad \langle \mu_z \rangle_{\text{wall}} = \sum_{0 < z_i < 1} \mu_{zi} / N_{\text{w}}, \quad (3.37)$$

where $N_{\rm w}$ is the particle number in the layer $0 < z_i < 1$. For the data in Fig.11, we obtain $(\langle \mu_z \rangle_{\rm all}, \langle \mu_z \rangle_{\rm wall}) = (0,0), (0.67,0.09), (1.34,0.27), (1.91,0.69), (1.97,1.97)$ for $\Delta \Phi = 0$, 8, 10, 100, respectively. Here, we estimate the image interaction energy as $|v_{\rm I}^{\rm d}| \sim 4$ for $z_i \sim 0.5$ from Eq.(3.7) and the typical field energy as $\mu_0 E_a \sim 0.2 \Delta \Phi$. Comparison of these two energies yields a crossover potential difference about 20, in accord with Fig.11.

In Fig.12, we show dipole configurations for $n_0 = 0.57$ under two potential differences $\Delta \Phi = 0$ and 10. At this high density, a hexagonal lattice (with defects) appears

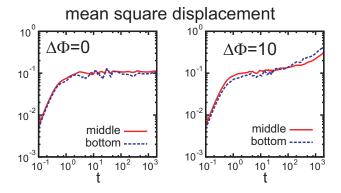

FIG. 13. (Color online) Mean square displacements for the particles near the walls and those far from them for $\Delta\Phi=0$ (left) and 10 (right), where T=0.2 and $n_0=0.57$. The data are the same as in Fig.12. Time t is in units of τ_0 in Eq.(2.40).

on the walls, extending between the top and the bottom in the form of chains. For $\Delta\Phi=0$, the cross-sectional configurations in the middle are glassy. We can see that the chains are somewhere curved, broken, branched, or even entangled. In the left panel of Fig.13, we plot the mean-square displacement,

$$M(t) = \langle |\boldsymbol{r}_i(t+t_0) - \boldsymbol{r}_i(t_0)|^2 \rangle, \qquad (3.38)$$

where the average over $t_0(<10^4)$ was taken. Furthermore, we took the average over the particles close to the walls and that over those in the interior separately, but there was no essential difference for these two groups of the particles, as shown in Fig.13. We notice that M(t) grows to saturate at a plateau value (~ 0.1) for $t \gtrsim 1$ in units of τ_0 in Eq.(2.40). We can also see a tendency of segregation between the chains parallel to the z axis and those antiparallel to the z axis. On the other hand, for $\Delta \Phi = 10$, the fraction of the chains parallel to the z axis increases and the orientational fluctuations decrease, where $\langle \mu_z \rangle_{\rm all} = 1.17$ and $\langle \mu_z \rangle_{\rm wall} = 0.99$ (see Eq.(3.37)). In this more ordered state, collective configuration changes are appreciable for $t \gtrsim 100$. In the right panel of Fig.13, this leads to very slow growth of M(t).

IV. SUMMARY AND REMARKS

In summary, we have extended the Ewald method for charged and polar particles between metallic plates in a $L \times L \times H$ cell, aiming to apply electric field E_a to these systems. In this problem, we should account for an infinite number of image charges and dipoles outside the cell. With this method, we have presented some results of molecular dynamics simulation.

In the previous papers by Hautman $et~al.^{17}$, by Perram and Ratner¹⁸, and by Klapp¹⁹, the conventional 3D Ewald method for periodic systems was applied to a doubly expanded $L \times L \times 2H$ cell, where the three axes were formally equivalent. Our scheme is essentially the same

as theirs, but we have treated the z direction differently from the lateral directions. In particular, we have divided the terms in the long-range part of the Ewald sum into those inhomogeneous in the xy plane (with nonvanishing k_x or k_y) and those homogeneous in the xy plane but inhomogeneous along the z axis (with $k_x = k_y = 0$ and $k_z \neq 0$) in Eqs.(2.26) and (3.11). The latter one-dimensional terms can be summed into simple forms in Eqs.(2.28) and (3.12), yielding the one-dimensional electric field E_i^0 in Eqs.(2.33) and (3.15). In our simulations, we have calculated E_i^0 very accurately. For dipole systems, $E_i^0 \cong E_a$ far from the walls for thick cells.

In applying electric field between metallic plates, we may control the potential difference $\Delta\Phi=HE_a$ or the surface charge Q_0 . The electrostatic energy, $U_{\rm m}$ or $U_{\rm m}^{\rm d}$, in the fixed-potential condition is related to that in the fixed-charge condition by the Legendre transformation, as shown in Appendix B. In the continuum electrostatics in Appendix D, we have also introduced the free energies $F_{\rm m}$ and $F_{\rm e}$ for these two cases^{16,25}.

Some remarks are given below.

- (1) We have assumed stationary applied field, but we may assume a time-dependent field $E_a(t)$ and examine various nonequilibrium phenomena. For example, when $\Delta\Phi$ was changed from 0 to 100, we observed complex dynamics of charged particles from the crystal in Fig.4(a) to that in Fig.4(a'). We also mention that melting due to electric field was observed in charged colloidal crystal²⁹.
- (2) We have assumed spherical dipoles, but real molecules are nonspherical and undergo hindered rotations. This feature should be included in future simulations. We should also consider mixtures of ions and nonspherical polar molecules bounded by metallic plates, where the ion-dipole interaction is crucial^{1,40}.
- (3) The classical result $\gamma_{\ell} = 1/3$ for the local field factor follows for a spherical cavity^{26,27}, leading to the Clausius-Mossotti formula for the dielectric constant. However, γ_{ℓ} becomes one of the depolarization factors for an ellipsoidal cavity³⁵, so it is sensitive to the environment around each dipole. In our case, γ_{ℓ} increases due to the pair correlations along the applied field as in Eq.(3.36). More systematic simulations are needed on this aspect.
- (4) Various systems such as charged colloids, polyelectrolytes, proteins, and water molecules should exhibit interesting behaviors close to metal surfaces without and with applied field^{22–24}. For polarizable surfaces, a simulation method similar to ours has recently been reported⁴¹.
- (5) We may well expect ferroelectric phase transitions in confined dipole systems (see the sentences below Eq.(3.29)). Furthermore, it is of great interest to examine the electric field effects in ferroelectric systems with impurities. We will shortly report on the electric field effect in orientational glass as a continuation of our previous work 33 .

ACKNOWLEDGMENTS

This work was supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan. K. T. was supported by the Japan Society for Promotion of Science. The numerical calculations were carried out on SR16000 at YITP in Kyoto University.

Appendix A: Derivation of Eq.(2.7)

The last two terms in Eq.(2.7) arise from the long-range part of the electrostatic energy, written as $U_{\rm p}^{\ell}$. We transform it as follows:

$$U_{p}^{\ell} = \frac{1}{2} \sum_{\mathbf{m}} \sum_{i,j} q_{i} q_{j} \psi_{\ell}(|\mathbf{r}_{ij} + L\mathbf{m}|)$$

$$= \frac{1}{2} \int_{\mathbf{k}} \Psi_{\ell}(k) \sum_{\mathbf{m}} \sum_{i,j} q_{i} q_{j} e^{i\mathbf{k} \cdot (\mathbf{r}_{ij} + L\mathbf{m})}, \quad (A1)$$

where $\int_{\mathbf{k}} = (2\pi)^{-3} \int d\mathbf{k}$ and $\Psi_{\ell}(k)$ is defined in Eq.(2.8). In the second line, we perform the summation over \mathbf{m} introducing a damping factor $\exp[-\epsilon |m_x| - \epsilon |m_y| - \epsilon |m_z|]$, where ϵ is a positive small number (not to be confused with the energy ϵ in $v_s(r)$ in Eq.(2.36)). The summation yields $\sum_{\mathbf{m}} \exp(i\mathbf{k} \cdot L\mathbf{m}) = \zeta(Lk_x)\zeta(Lk_y)\zeta(Lk_z)$, where

$$\zeta(u) = \sum_{m_x = 0, \pm 1, \dots} \exp[im_x u - \epsilon | m_x |)$$

$$\cong 2\epsilon / [\epsilon^2 + 2(1 - \cos(u))]. \tag{A2}$$

For Lk > 1, $\Psi_{\ell}(k)$ is finite, so we may replace $\zeta(Lk_{\alpha})$ by $2\pi \sum_{\nu_{\alpha} \neq 0} \delta(Lk_{\alpha} - 2\pi\nu_{\alpha})$, where $\alpha = x, y, z$. For $Lk \lesssim 1$, we may set $\zeta(Lk_{\alpha}) = 2\epsilon/[\epsilon^2 + L^2k_{\alpha}^2]$. Thus, $U_{\rm p}^{\ell}$ becomes

$$U_{p}^{\ell} = \frac{1}{2} \int_{\mathbf{k}} \Psi_{\ell}(k) \zeta(Lk_{x}) \zeta(Lk_{y}) \zeta(Lk_{z}) \sum_{i,j} q_{i} q_{j} e^{i\mathbf{k} \cdot \mathbf{r}_{ij}}$$

$$= \frac{1}{2L^{3}} \sum_{\mathbf{k} \neq \mathbf{0}} \Psi_{\ell}(k) \sum_{i,j} q_{i} q_{j} e^{i\mathbf{k} \cdot \mathbf{r}_{ij}}$$

$$+ \int_{\mathbf{k}} \frac{16\pi \epsilon^{3} \sum_{i,j} q_{i} q_{j} [e^{i\mathbf{k} \cdot \mathbf{r}_{i}} - 1] [e^{-i\mathbf{k} \cdot \mathbf{r}_{j}} - 1]}{k^{2} (\epsilon^{2} + L^{2}k_{x}^{2}) (\epsilon^{2} + L^{2}k_{y}^{2}) (\epsilon^{2} + L^{2}k_{z}^{2})}. \tag{A3}$$

The first term coincides with the third term in Eq.(2.7) with $\mathbf{k} = 2\pi L^{-1}(\nu_x, \nu_y, \nu_z) \neq (0, 0, 0)$. The second term arises from $k \lesssim L^{-1}$, where $\exp[\mathrm{i}\mathbf{k} \cdot \mathbf{r}_i] - 1 \cong \mathrm{i}\mathbf{k} \cdot \mathbf{r}_i$ and $\exp[-\mathrm{i}\mathbf{k} \cdot \mathbf{r}_j] - 1 \cong -\mathrm{i}\mathbf{k} \cdot \mathbf{r}_j$ for small k. Furthermore, $k_{\alpha}k_{\beta}$ may be replaced by $(k^2/3)\delta_{\alpha\beta}$ from the angle integration of \mathbf{k} , leading to the fourth term in Eq.(2.7).

Appendix B: Fixed charge boundary condition

As illustrated in Fig.1, we may fix the surface changes, Q_0 and Q_H , at z=0 and $H^{16,25}$, as well as the potential difference $\Delta\Phi$. Here, we consider the fixed charge

boundary condition, where we assume $Q_H = -Q_0$ without ionization on the surfaces. See Appendix D for the continuum theory for these two boundary conditions.

For charged particles, let $U_{\rm e} = U_{\rm e}(\boldsymbol{r}_1,\cdots,Q_0)$ be the electrostatic energy appropriate for the fixed-charge condition, which includes the contribution from the excess electrons on the metal surfaces. For infinitesimal changes $\boldsymbol{r}_i \rightarrow \boldsymbol{r}_i + d\boldsymbol{r}_i$ and $Q_0 \rightarrow Q_0 + dQ_0$, $U_{\rm e}$ is changed as

$$dU_{e} = -\sum_{i} q_{i} \mathbf{E}_{i} \cdot d\mathbf{r}_{i} + HE_{a} dQ_{0}, \qquad (B1)$$

where E_a is a dynamic variable at fixed Q_0 . The expressions for E_i are the same in the two cases at fixed E_a and at fixed Q_0 . Then, from Eqs.(2.24) and (B1), U_e and U_m are related by

$$U_{\rm e} = U_{\rm m} - HL^2 E_a^2 / 8\pi + HE_a Q_0.$$
 (B2)

For dipoles, the electrostatic energy $U_{\rm e}^{\rm d}$ under the fixed-charge condition satisfies

$$dU_{e}^{d} = -\sum_{i} (\boldsymbol{F}_{i}^{e} \cdot d\boldsymbol{r}_{i} + \boldsymbol{E}_{i} \cdot d\boldsymbol{\mu}_{i}) + HE_{a}dQ_{0}, \quad (B3)$$

which should be compared with Eq.(3.10). As in Eq.(B2), $U_{\rm e}^{\rm d}$ and $U_{\rm m}^{\rm d}$ are related by

$$U_{\rm e}^{\rm d} = U_{\rm m}^{\rm d} - HL^2 E_a^2 / 8\pi + HE_a Q_0.$$
 (B4)

Appendix C: Derivation of Eq.(2.28)

In Eq.(2.26), $K_0(z, z')$ is given by the lateral integral,

$$K_0(z, z') = \frac{1}{4\pi} \int dx dy \sum_{\mathbf{m}} [\psi_{\ell}(|\mathbf{r} - \mathbf{r}' + \mathbf{h}|) - \psi_{\ell}(|\mathbf{r} - \bar{\mathbf{r}}' + \mathbf{h}|)], \tag{C1}$$

where $\mathbf{r} = (x, y, z)$, $\mathbf{r}' = (x', y', z')$, $\bar{\mathbf{r}}' = (x', y', -z')$, and 0 < x, y < L. After the integration, the right hand side becomes a function of z and z' independent of x' and y'. We then twice differentiate $K_0(z, z')$ with respect to z and use the relation $\nabla^2 \psi_\ell(r) = -4\pi \varphi(x) \varphi(y) \varphi(z)$, where $\varphi(x)$ is defined by Eq.(2.5). Some calculations yield

$$\frac{\partial^2}{\partial z^2} K_0(z, z') = -\hat{\varphi}(z - z') + \hat{\varphi}(z + z'), \tag{C2}$$

where $\hat{\varphi}(z)$ is defined by Eq.(2.29). The above relation is integrated to give Eq.(2.28) under $K_0(0,z') = K_0(H,z') = 0$. Furthermore, Eqs.(2.19) and (2.28) give

$$\frac{\partial K_0(z,z')}{\partial z'} = \int_0^z du [\hat{\varphi}(u+z') + \hat{\varphi}(u-z')] - \frac{z}{H}, \quad (C3)$$

$$\frac{\partial^2 K_0(z, z')}{\partial z \partial z'} = \hat{\varphi}(z + z') + \hat{\varphi}(z - z') - \frac{1}{H},\tag{C4}$$

where we have used $\int_0^H du [\hat{\varphi}(u+z')+\hat{\varphi}(u-z')]=1$ from the periodicity of $\hat{\varphi}(u).$

Appendix D: Continuum theory of electrostatics

We compare the results in the text and those of continuum electrostatics 16,25 . We consider charged particles in a polar medium between parallel metallic plates under applied electric field E_a . The system is in the region 0 < x, y < L and 0 < z < H. We assume $L \gg H$ to neglect the edge effect. We do not assume the (artificial) periodic boundary condition in the x and y axes.

In this appendix, the physical quantities are smooth functions of space after spatial coarse-graining. In addition to the electrostatic potential $\Phi(\mathbf{r}) = \phi(\mathbf{r}) - E_a z$, we introduce the charge density $\rho(\mathbf{r})$ and the polarization $\mathbf{p}(\mathbf{r})$. The electric field $\mathbf{E} = -\nabla \Phi = E_a \mathbf{e}_z - \nabla \phi$ and the electric induction $\mathbf{D} = \mathbf{E} + 4\pi \mathbf{p}$ are defined. For simplicity, we assume the overall charge neutrality condition $\int d\mathbf{r} \rho = 0$ without ionization on the walls. Hereafter, the integral $\int d\mathbf{r}$ is performed within the cell.

From the relation $\nabla \cdot \mathbf{D} = 4\pi \rho$, we may define the effective charge density by

$$\rho_e = \rho - \nabla \cdot \boldsymbol{p},\tag{D1}$$

which satisfies $\nabla \cdot \boldsymbol{E} = -\nabla^2 \phi = 4\pi \rho_e$. Let $\rho_{e\boldsymbol{k}}(z) = \int d\boldsymbol{r}_{\perp} e^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_{\perp}} \rho_e$ be the 2D Fourier transformation in the xy plane, where $\boldsymbol{k} = (k_x, k_y)$ and $\boldsymbol{r}_{\perp} = (x, y)$. As in Eq.(2.16), the excess potential ϕ is written as

$$\phi(\mathbf{r}) = 4\pi \int_{\mathbf{k}} \int_{0}^{H} dz' G_{k}(z, z') \rho_{e\mathbf{k}}(z') e^{i\mathbf{k}\cdot\mathbf{r}_{\perp}}, \quad (D2)$$

where $\int_{\pmb{k}} = (2\pi)^{-2} \int dk_x dk_y$ and the Green function $G_k(z,z')$ is given in Eq.(2.18).

First, we consider the lateral averages (0 < x, y < L),

$$\bar{\phi}(z) = \int dx dy \ \phi/L^2, \quad \bar{p}_z(z) = \int dx dy \ p_z/L^2,$$

$$\bar{\rho}(z) = \int dx dy \ \rho/L^2, \quad \bar{\rho}_e(z) = \int dx dy \ \rho_e/L^2. \quad (D3)$$

Then, we find $\bar{\rho}_e = \bar{\rho} - d\bar{p}_z/dz$ and Eq.(D2) becomes

$$\bar{\phi}(z) = 4\pi \int_0^H du G_0(x, u) \bar{\rho}_e(u), \tag{D4}$$

where $G_0(z, z')$ is given in Eq.(2.19). The average electric field $\bar{E}_z(z) = E_a - d\bar{\phi}(z)/dz$ is calculated as

$$\bar{E}_z(z) = -4\pi \bar{p}_z(z) + 4\pi Q_0/L^2 + 4\pi \int_0^z du \bar{\rho}(u).$$
 (D5)

The total surface charge at z = 0 is denoted by Q_0 ; then, that at z = H is $Q_H = -Q_0$. From Eq.(D4) we obtain³²

$$Q_0 = \frac{L^2}{4\pi} E_a + \frac{1}{H} \int d\mathbf{r} [z\rho(\mathbf{r}) + p_z(\mathbf{r})]. \tag{D6}$$

This formula corresponds to Eqs.(2.31) and (3.17). The above relation itself readily follows if we set $\rho = \nabla \cdot \mathbf{D}/4\pi$ in the integral $\int d\mathbf{r} z \rho$.

Second, we consider the electrostatic energy $U_{\rm m}$ in the fixed-potential condition. Its discrete versions are in Eqs.(2.23) and (3.9). The continuum version reads

$$U_{\rm m} = \int d\mathbf{r} \left[\frac{1}{2} \rho_e \phi - E_a (z\rho + p_z) \right]. \tag{D7}$$

For small incremental changes ($\rho \to \rho + \delta \rho, \mathbf{p} \to \mathbf{p} + \delta \mathbf{p}, \dots$), $U_{\rm m}$ in Eq.(D7) is changed as

$$\delta U_{\rm m} = \int d\mathbf{r} [\Phi \delta \rho - \mathbf{E} \cdot \delta \mathbf{p} - (z\rho + p_z) \delta E_a], \quad (D8)$$

which corresponds to Eqs. (2.24) and (3.10). On the other hand, the electrostatic energy $U_{\rm e}$ in the fixed-charge condition should satisfy

$$\delta U_{\rm e} = \int d\mathbf{r} (\Phi \delta \rho - \mathbf{E} \cdot \delta \mathbf{p}) + H E_a \delta Q_0, \tag{D9}$$

which is the counterpart of Eqs.(B1) and (B3). Then, $U_{\rm e}$ and $U_{\rm m}$ are related by Eq.(B2) or (B4), leading to 16,25

$$U_{\rm e} = U_{\rm m} - \frac{HL^2}{8\pi} E_a^2 + HE_a Q_0 = \int d\mathbf{r} \frac{|\mathbf{E}|^2}{8\pi}.$$
 (D10)

Third, we remark on the polarization p. So far it has been treated as an independent variable. Without ferroelectric order, p is usually related to E by 16 ,

$$\boldsymbol{p} = \chi \boldsymbol{E},\tag{D11}$$

in the linear response regime. From $D = \varepsilon E$, the electric susceptibility χ and the dielectric constant ε are related by $\varepsilon = 1 + 4\pi\chi$. In this situation, we may introduce the following free energy contribution,

$$F_{\rm p} = \int d\mathbf{r} \frac{1}{2\chi} |\mathbf{p}|^2, \tag{D12}$$

which is an increase in the free energy due to mesoscopic ordering of the constituting dipoles. The polarization free energy is needed to examine the thermal fluctuations of $\mathbf{p}^{25,42}$. We then treat the sum, $F_{\rm m} = U_{\rm m} + F_{\rm p}$ or $F_e = U_{\rm e} + F_{\rm p}$, as the electrostatic free energy in the fixed-potential or fixed-charge condition. Since its functional derivative with respect to \mathbf{p} is given by $-\mathbf{E} + \chi^{-1}\mathbf{p}$ from Eqs.(D8), (D9), and (D12), its minimization yields Eq.(D11). Eliminating \mathbf{p} , we rewrite $F_{\rm m}$ and $F_{\rm e}$ as

$$F_{\rm m} = \int d\mathbf{r} (\rho \Phi - \frac{\varepsilon}{8\pi} |\mathbf{E}|^2) + \frac{HL^2}{8\pi} E_a^2, \tag{D13}$$

$$F_{\rm e} = \int d\mathbf{r} \frac{\varepsilon}{8\pi} |\mathbf{E}|^2. \tag{D14}$$

The second term in $F_{\rm m}$ in Eq.(D13) is a constant at fixed E_a , so we may redefine the electrostatic free energy as

$$F'_{\rm m} = F_{\rm m} - HL^2 E_a^2 / 8\pi = F_{\rm e} - Q_0 (\partial F_{\rm e} / \partial Q_0),$$
 (D15)

which is the Legendre transform of $F_{\rm e}$. The two expressions, $F'_{\rm m}$ and $F_{\rm e}$, have both been used in the literature. In the Ginzburg-Landau scheme, Yaakov $et~al.^{43}$ used $F'_{\rm m}$ and one of the present authors 40 used $F_{\rm e}$ for ions in a mixture solvent, where ε depends on the local solvent composition and is inhomogeneous.
