Abstract

$\text{LiZn}_2\text{Mo}_3\text{O}_8$ has been proposed to contain $S = 1/2$ Mo_3O_{13} magnetic clusters arranged on a triangular lattice with antiferromagnetic nearest-neighbor interactions. Here, microwave and terahertz electron spin resonance (ESR), ^7Li nuclear magnetic resonance (NMR), and muon spin rotation (μSR) spectroscopies are used to characterize the local magnetic properties of $\text{LiZn}_2\text{Mo}_3\text{O}_8$. These results show the magnetism in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ arises from a single isotropic $S = 1/2$ electron per cluster and that there is no static long-range magnetic ordering down to $T = 0.07$ K. Further, there is evidence of gapless spin excitations with spin fluctuations slowing down as the temperature is lowered. These data indicate strong spin correlations which, together with previous data, suggest a low-temperature resonating valence-bond state in $\text{LiZn}_2\text{Mo}_3\text{O}_8$.

I. INTRODUCTION

Complex states of matter result from simple interactions which give rise to emergent properties appearing greater than the sum of their parts. There are many examples of such emergent phenomena from macroscopic systems, such as the flocking of birds, to quantum scale systems, such as superconductivity¹⁻³, spin liquids⁴, spin ice systems⁵, and heavy fermions⁶⁻¹⁰. In solid-state materials, utilizing the geometry of the crystal lattice to force a degenerate classical magnetic ground state (“geometrically frustrated magnetism (GFM)”¹¹) is a powerful approach to designing emergent quantum states. It has been proposed that GFM could possibly result in superconductivity via doping the resonating valence-bond state^{12,13}, be used as materials for quantum computing¹⁴, and harbor exciting low-temperature physics near quantum phase transitions¹⁵.

GFM materials usually have single ions as the magnetic building block on frustrated topologies such as triangular lattices¹⁶, kagome lattices^{17,18}, or corner-sharing tetrahedra¹⁹. $\text{LiZn}_2\text{Mo}_3\text{O}_8$ has a structure built by stacking two-dimensional triangular layers of Mo_3O_{13} clusters²⁰. Each Mo_3O_{13} cluster, or “molecule”, has a single unpaired electron and is expected to act as a $S = 1/2$ unit, similar to organic molecular magnet systems²¹. Due to the small distance between Mo_3O_{13} clusters via oxo bridges, there are strong inter-cluster superexchange interactions. A recent report²⁰ suggested that $\text{LiZn}_2\text{Mo}_3\text{O}_8$ thus represents an ideal geometrically frustrated triangular lattice antiferromagnetic system in which there is the formation of a condensed valence-bond state, where the formation of resonating valence bonds coexists with remnant paramagnetic spins, when cooled below $T \sim 100$ K.

Here we report microwave and terahertz range electron spin resonance (ESR), ^7Li solid state nuclear magnetic resonance (NMR), and muon spin rotation (μSR) spectroscopies of $\text{LiZn}_2\text{Mo}_3\text{O}_8$. The results of these local-probe measurements show that each Mo_3O_{13} cluster in fact behaves as a well localized $S = 1/2$ magnetic unit. Further, NMR and μSR measurements show a slowing of spin fluctuations yet no evidence for static magnetic order down to $T \sim 0.07$ K and are instead consistent with a gapless spin excitation spectrum expected for a resonating valence-bond state.

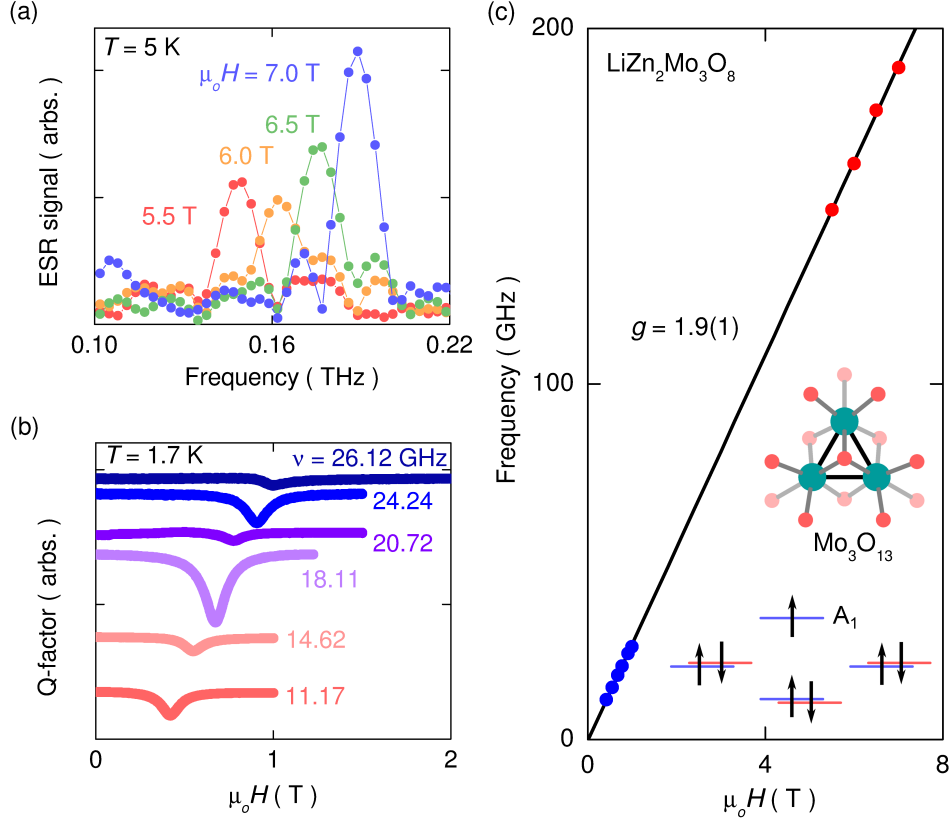

FIG. 1: ESR spectra of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ at different applied frequencies and fields in (a) the terahertz electromagnetic range and (b) the microwave range (offset for clarity). (c) The extracted g -factor for this range of fields and applied EM radiation are in good agreement with each other and are consistent with an isotropic g -factor from a single $S = 1/2$ magnetic electron per formula unit. The magnetic electron is delocalized over a Mo_3O_{13} cluster, shown in the inset with the corresponding molecular orbital diagram²⁰.

II. RESULTS

ESR

$\text{LiZn}_2\text{Mo}_3\text{O}_8$ powder was synthesized as previously reported²⁰. ESR measurements were performed at the National High Magnetic Field Laboratory (NHMFL) at Los Alamos National Laboratory (LANL) at temperatures from $T = 1.7$ K to $T = 120$ K in the frequency range of $\nu = 11$ GHz to $\nu = 40$ GHz. Fields up to $\mu_0 H = 15$ T were investigated, but only one resonance peak was observed, below $\mu_0 H = 2$ T. The sample microwave absorption was measured using a millimeter wave vector network analyzer manufactured by abmm and a custom-built, appropriately sized resonant cavity. The ESR spectra were measured using cavity perturbation techniques. The signal intensity

from the sample cavity of the GHz measurements agree with the number of spins expected for the ~ 1.0 mg sample of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ measured, assuming one unpaired spin per Mo_3O_{13} cluster, and is too large to originate from paramagnetic impurity spins. Terahertz-range ESR was measured at JHU on a home-built transmission-based time domain THz spectrometer using a helium cryostat at temperatures from $T = 5$ K to $T = 180$ K in the field range $\mu_0 H = 5.5$ T to $\mu_0 H = 7$ T using a crossed polarizer geometry²².

A single resonance peak is observed, centered at $g = 1.9$, and is persistent up to $T = 80$ K in the THz data with a smoothly decreasing intensity but no change in resonant frequency. The results at $T = 5$ K (THz) and $T = 1.7$ K (GHz) are shown in Fig. 1 (a) and 1 (b), respectively. The observed g -factor, extracted from a fit of the frequency dependence on applied field, Fig. 1 (c), is consistent with that expected for a $S = 1/2$ spin ($g = 2.0$) and implies minimal orbital contributions. The y -intercept of the g -factor plot is zero, indicative of a lack of a zero field gap. The combined ESR measurements place a strong constraint on possible g -tensor anisotropy²³, assuming additional resonances corresponding to anisotropic g -factor values are convoluted within the observed peak, or are outside the frequency/field range probed. By estimating the peak positions and resonance values, the g -factors are then constrained to $0.86 \leq g_1/g_2 \leq 1.15$ if the observed peak is a convolution of two resonances or $g_1/g_2 \leq 0.02$ if $g_2 = 1.9$ and an additional resonance lies above the field range measured. The observed peak being a convolution of two peaks is further unlikely as the powder spectrum (angular average) of a system with approximately uniaxial symmetry (g_{\parallel} and g_{\perp}) will have an asymmetric line shape for even small anisotropies, such as in some copper systems²⁴. These data demonstrate that the magnetism in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ arises from a single, isotropic $S = 1/2$ magnetic electron per cluster in a totally symmetric (A_1) orbital, which is delocalized over the Mo_3O_{13} cluster²⁰. This delocalization over a cluster can represent an intermediate between a tightly bound (*i.e.* fully localized) and completely itinerant electronic wavefunction (*i.e.* a metal) which may contribute to the interesting quantum physics observed in $\text{LiZn}_2\text{Mo}_3\text{O}_8$.

NMR

Cryogenic ^7Li NMR was measured in the range from $T = 285$ K to $T = 4.2$ K under an applied field of $\mu_0 H = 5.36$ T. The NMR lineshapes were measured by taking the fast fourier transform (FFT) of the spin echo. The high frequency ('d' peak) was out of the spectrometer bandwidth, so separately acquired FFT traces were convoluted. Data near $T = 4.2$ K were acquired by measuring

the integral of the spin echo intensity while scanning frequency. T_1 was measured by recording the spin echo integral while scanning the delay time after an inversion pulse. The ^7Li NMR spectra of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ are shown in Fig. 2 (b), displaying at least four peaks (labeled a-d). These peaks may arise from crystallographically distinct Li/Zn mixed occupancy interlayer sites (Fig. 2 (a)), each

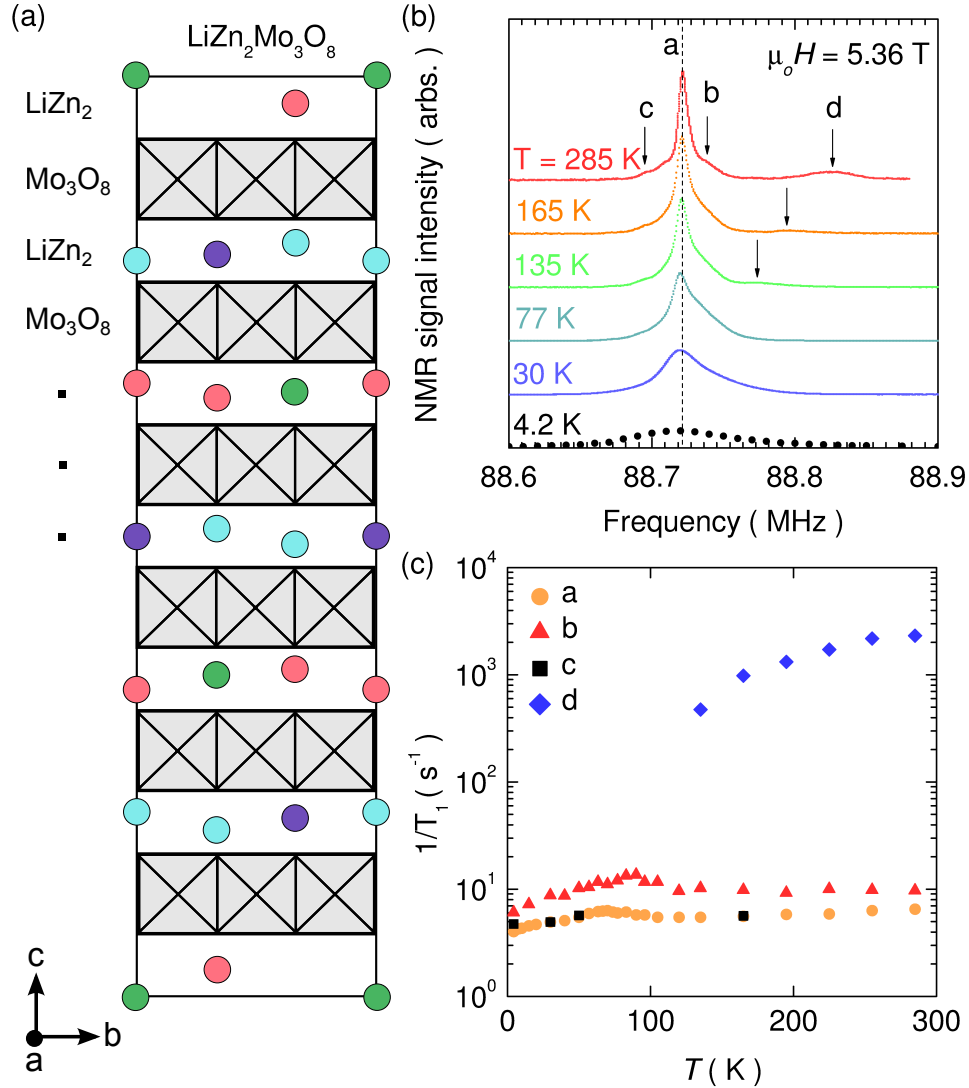

FIG. 2: (a) A schematic representation of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ crystal structure. Differently colored circles represent four distinct crystallographic, mixed Li/Zn sites. Gray boxes represent Mo_3O_8 layers. (b) ^7Li NMR FFT lineshapes taken at $\mu_0 H = 5.36$ T and point-by-point frequency scan obtained by spin echo integration at $T = 4.2$ K (offset for clarity). The spectra indicate four distinct lithium magnetic environments (a-d), consistent with four lithium crystal sites. (c) Spin-lattice relaxation rate as a function of temperature for each NMR peak. The data remain approximately constant as the temperature is lowered, lacking any evidence of the opening of a spin gap.

being in a unique magnetic environment. Alternatively, the ‘c’ peak could originate from a nuclear spin 3/2 to 1/2 satellite transition, offset from the main peak ‘a’ by a quadrupolar interaction. The ‘d’ peak has a comparatively large frequency shift that merges with the main peak ‘a’ as the temperature of the sample is lowered. The spin-lattice relaxation rate $((T_1)^{-1})$ as a function of temperature for each peak is shown in Fig. 2(c). The large relaxation rate of the ‘d’ peak is consistent with thermally activated mobile Li atoms ($E_a = 372(26)$ K) at room temperature that freeze out upon cooling, in agreement with previously measured heat capacity data²⁰. The relaxation rate for the ‘a’ site remains approximately constant upon cooling until $T \sim 100$ K, then peaks and drops slightly as T approaches zero. The low temperature behavior of the relaxation rate indicates the slowing of spin fluctuations and the formation of short range spin correlations. The $(T_1)^{-1}$ measurements agree with bulk magnetic measurements and show that $\text{LiZn}_2\text{Mo}_3\text{O}_8$ does not approach any long-range magnetic ordering, as $(T_1)^{-1}$ would diverge approaching order. Because of the ^7Li NMR frequency (~ 88.7 MHz), only the low frequency component of spin fluctuations are detected. The bump in the rate of the ‘a’ and ‘b’ sites is most likely due to the merging of the ‘d’ site intensity and is not intrinsic to those Li sites. As can be seen from the data in Fig. 2(b), the ‘b’ peak is on the higher frequency side of the main peak ‘a’. The relaxation rate in Fig. 2(c) shows a maxima in peak ‘b’ at $T \sim 90$ K, compared to $T \sim 70$ K in peak ‘a’. If this were due to a structural distortion, then the maxima in the relaxation rate for peaks ‘a’ and ‘b’ would occur at the same temperature. Unfortunately, the $\text{LiZn}_2\text{Mo}_3\text{O}_8$ powder ^7Li NMR FFT lineshapes are too broad (due to powder averaging) to accurately measure the temperature dependence of the knight shift at low temperatures. A close look at the NMR FFT lineshapes, however, reveals a lack of any signature of a split off peak, which would indicate the low temperature bulk susceptibility is dominated by impurity spins, as is the case in other systems²⁵. This suggests that the signal from the bulk magnetization measurements is intrinsic to the Mo_3O_8 magnetic layers in $\text{LiZn}_2\text{Mo}_3\text{O}_8$.

μSR

Muon-spin rotation (μSR) experiments^{26,27} were carried out using the MuSR spectrometer at the ISIS Pulsed Muon Facility at the Rutherford Appleton Laboratory which is equipped with a dilution refrigerator. In the μSR experiment, spin-polarized positive muons (μ^+ , momentum 28 MeV/c) were implanted into the $\text{LiZn}_2\text{Mo}_3\text{O}_8$ sample. The muons stop quickly (in $< 10^{-9}$ s), without significant loss of spin polarization. The observed quantity is then the time evolution of the

FIG. 3: Example μ SR spectra (the asymmetry function $A(t)$) for $\text{LiZn}_2\text{Mo}_3\text{O}_8$ measured at (a) $T = 120$ K and (b) $T = 0.07$ K in zero field and various longitudinal fields. The fits assume Kubo-Toyabe relaxation with an additional electronic relaxation included (see text). (c) The temperature dependence of Δ , measured in zero field. (d) The temperature dependence of λ measured in a longitudinal field of $\mu_0 H = 10$ mT.

average muon spin polarization $P_z(t)$, which can be inferred^{26,27} via the asymmetry in the angular distribution of emitted decay positrons, parameterized by an asymmetry function $A(t)$ proportional to $P_z(t)$. The intrinsic low spin-density in this material, due to the cluster-magnet structure, makes it attractive to study using μ SR at a pulsed source since the internal electronic fields are expected to be relatively small in comparison with other geometrically frustrated materials, particularly those based on rare earth ions. μ SR is known to be very sensitive to the properties of frustrated systems or those with spin liquid ground states²⁸, as well as magnetic systems with very small ordered moments^{29,30}. Example μ SR spectra measured on a sample of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ are presented in Fig. 3 (a) and (b). The zero-field data are characteristic of weak static moments which are nuclear in origin. The data can be fit by a Kubo-Toyabe relaxation function^{31,32} which models the effect on the muon of a static, random field distribution, multiplied by a slowly-relaxing exponential. The longitudinal Kubo-Toyabe function used in the analysis is given by

$$G_{\text{KT}}(t, B_{\text{ext}}) = 1 - \frac{2\Delta^2}{\omega^2} (1 - \cos \omega t e^{-\Delta^2 t^2 / 2}) + \frac{2\Delta^4}{\omega^4} \int_0^t d\tau \sin \omega \tau e^{-\Delta^2 \tau^2 / 2}, \quad (1)$$

where $\omega = \gamma_\mu B_{ext}$ and B_{ext} is the applied longitudinal magnetic field. The data are fit by the function $A(t) = A_1 G_{KT}(t, B_{ext}) e^{-\lambda t} + A_0$, where A_0 represents muons stopped in the sample holder and A_1 is the amplitude of the asymmetry from the sample. This function is parameterized by a variable Δ , the second moment of the field distribution. Fig. 3 (c) shows the fitted Δ as a function of temperature and it does not change, supporting the hypothesis of nuclear moments. These data thus demonstrate that no static electronic moments freeze out down to $T = 0.07$ K.

Application of a longitudinal field partially quenches the relaxation. If the observed behavior were only due to nuclear relaxation, then a field of order $\mu_0 H = 0.01$ T should be sufficient to completely quench it. The expected behavior if there was only nuclear relaxation is indicated by the dashed lines in Fig. 3 (b). Interestingly, there remains a significant relaxation even in a longitudinal field of $\mu_0 H = 0.2$ T, the maximum field available on this spectrometer. In fact, the unquenched relaxation observed at $\mu_0 H = 0.01$ T, which is very similar to that observed at $\mu_0 H = 0.2$ T, is most likely the result of slowly fluctuating electronic spins, which fluctuate all the way down to $T = 0.07$ K.

The temperature dependence of this unquenched relaxation rate λ at $\mu_0 H = 0.01$ T is shown in Fig. 3 (d). Clearly, there is a significant relaxation persisting at all temperatures, indicative of electronic spin fluctuations with dynamics not set by a thermal scale. There is, however, no signature of the valence-bond condensation at $T \sim 100$ K that was inferred from bulk magnetic susceptibility and heat capacity measurements²⁰. Rather than indicating the absence of valence-bond condensation, it is possible that the lack of a change at $T \sim 100$ K is due to the changes in the spin fluctuation spectrum being outside the muon timescale. Above and below the condensation temperature, the paramagnetic spins fluctuate at the exchange frequency ($J/\hbar \sim 10^{12}$ Hz), which is too fast to be detected by the muons since muons are sensitive to fluctuations in the $\nu = 10^5$ to $\nu = 10^{10}$ Hz frequency range. Further, the condensed valence-bonds do not contribute to the local B-field, therefore a transition into a dynamic condensed valence-bond state is effectively invisible to μ SR spectroscopy.

III. DISCUSSION

More detail about the local susceptibility comes from further analysis of the NMR and μ SR relaxation dynamics and comparison to bulk magnetization and neutron experiments. The measured μ SR (λ) and NMR ($(T_1)^{-1}$, from NMR FFT line ‘a’, Fig. 2 (b) and (c)) relaxation rates are related

FIG. 4: (a) NMR spin-lattice relaxation rate (of peak ‘a’, see Fig. 2 (b)) divided by temperature, $(T_1 T)^{-1}$, a measure of electron spin relaxation scales with μSR $\lambda \cdot T^{-1}$. Both datasets are compared to the previously reported bulk magnetic susceptibility, shown as a gray line. The data are self-consistent and indicate gapless, short range spin-spin correlations. The characteristic measurement frequencies for each technique are approximately $\omega_o = 8 \cdot 10^6$ Hz for μSR at $\mu_o H = 10$ mT and $\omega_o = 9 \cdot 10^7$ Hz for ^7Li NMR at $\mu_o H = 5.36$ T. (b) The bulk susceptibility divided by NMR $(T_1 T)^{-1}$ and μSR $\lambda \cdot T^{-1}$, a measure of relaxation rate as compared to inelastic neutron scattering data³³. The data show a slowing of spin fluctuations as the temperature is lowered, in agreement with the electron spin relaxation rate (Γ) extracted from inelastic neutron scattering (blue diamonds). The red line is a guide to the eye. The error bars on the μSR data were calculated by propagating errors on both the bulk susceptibility and μSR datasets.

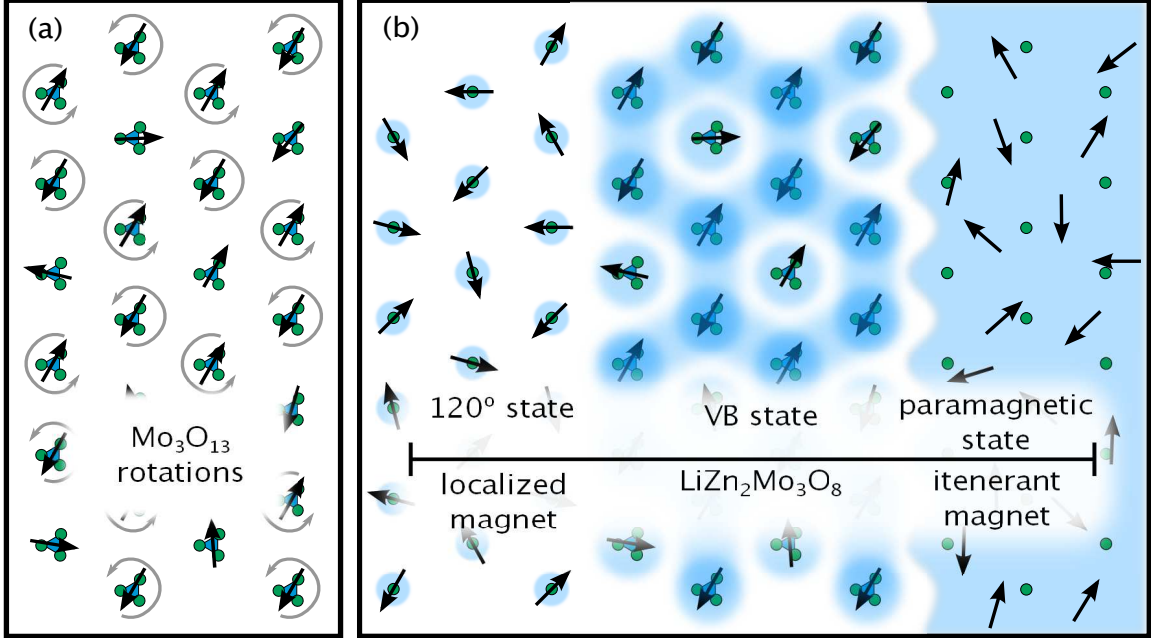

FIG. 5: Two possible microscopic origins of the valence-bond state in the cluster-based triangular lattice antiferromagnet $\text{LiZn}_2\text{Mo}_3\text{O}_8$. (a) Dynamic octahedral cluster rotations as proposed in Ref.³⁴. (b) Proximity to a metal-insulator-transition. A triangular lattice Heisenberg antiferromagnet has a 120° magnetic ground state in the fully localized limit. As the electron wavefunction becomes more delocalized, a valence-bond state, such as what we observe in $\text{LiZn}_2\text{Mo}_3\text{O}_8$, becomes energetically more favorable³⁵.

to the local dynamical spin susceptibility since

$$\frac{\lambda}{T} \simeq \frac{1}{T_1 T} \simeq \frac{\sum |A(\mathbf{q})|^2 \chi''(\mathbf{q}, \omega_o)}{\omega_o} \quad (2)$$

where $A(\mathbf{q})$ is the appropriate wave vector dependent form factor for NMR³⁶ or μSR , ω_o is the NMR or μSR frequency, and $\chi''(\mathbf{q}, \omega_o)$ is the imaginary part of the dynamical electron spin susceptibility. Fig. 4(a) shows $\lambda \cdot T^{-1}$ (μSR) and $(T_1 T)^{-1}$ (NMR) scaled for comparison to the bulk magnetic susceptibility. These data show, consistent with the bulk susceptibility, that the local magnetism in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ is fluctuating at all accessible temperatures, with an increase in short-range spin-spin correlations, and reduction in the electron spin fluctuation rate, as the temperature is lowered. The discernible deviation or bump of $(T_1 T)^{-1}$ and $\lambda \cdot T^{-1}$ in the range $50 \text{ K} < T < 100 \text{ K}$ is likely due to the freezing of lithium ions. For NMR, this bump originates from the merging of the ‘d’ (mobile lithium) peak with the main NMR peak ‘a’ as the lithium ions freeze. The bump in the μSR data is due to changes in μ^+ ion diffusion as the lithium ions freeze, as is well known other systems with mobile lithium ions^{37–40}. More importantly, the trend of in-

creasing $(T_1 T)^{-1}$ as T approaches zero indicates the onset of short-range spin correlations that do not have a gap in the excitation spectrum. This is in agreement with the dynamical susceptibility extracted from inelastic neutron scattering³³, which shows an increase as the temperature is lowered and was suggestive of gapless spin excitations. Fig. 4 (b) shows previously reported²⁰ bulk susceptibility divided by the μ SR ($\lambda \cdot T^{-1}$) and NMR $(T_1 T)^{-1}$ which demonstrates the slowing of spin fluctuations as the temperature is lowered. A fit of $\chi''(E)$ to the momentum averaged neutron data yields the relaxation response (from Ref.³³)

$$\chi''(E) = \frac{\chi' E \Gamma}{E^2 + \Gamma^2} \quad (3)$$

where Γ is the electron spin relaxation rate and χ' is the \mathbf{Q} -average of the real part of the dynamical susceptibility at $E = 0$. The NMR and μ SR relaxation rate data can be compared to the Γ energy scale by

$$\frac{\lambda}{T} \simeq \frac{1}{T_1 T} \simeq \frac{\chi''(E)}{E} = \frac{\chi' \Gamma}{E^2 + \Gamma^2} \quad (4)$$

in the limit of $E \rightarrow 0$. This implies that

$$\frac{\chi'}{(\lambda \cdot T^{-1})} \simeq \frac{\chi'}{(T_1 T)^{-1}} = \Gamma \quad (5)$$

allowing us to directly compare the μ SR, NMR, and inelastic neutron scattering relaxation rates, assuming $\chi'(\mathbf{Q}) \rightarrow \chi_{DC}(\mathbf{Q} = 0)$ (*i.e.* no strong form factor effects). As can be seen in Fig. 4 (b) as the temperature approaches zero, the spin fluctuations as probed by all techniques slow down. This indicates that the μ SR and NMR relaxation rates grow faster than the bulk susceptibility, resulting from an overall slowing of electron spin fluctuations.

Our data demonstrate the gapless, dynamic nature of spin correlations in $\text{LiZn}_2\text{Mo}_3\text{O}_8$. Previous *ab-initio* density functional theory (DFT) calculations on a $\text{Mo}_3\text{O}_{13}\text{H}_{15}$ cluster with the same formal electron count as a single Mo_3O_{13} cluster in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ predict the magnetic electron occupies a singly degenerate A_1 irreducible (totally symmetric) orbital. This orbital is delocalized over a single Mo_3O_{13} cluster, yet due to $\text{LiZn}_2\text{Mo}_3\text{O}_8$ being an electric insulator²⁰, the electron wavefunction remains confined to the cluster. The strong constraints on the anisotropy of the g -tensor for a C_{3v} symmetric Mo_3O_{13} cluster imposed by the ESR data are consistent with DFT calculations. The calculations and ESR measurements show that, similar to some radical anion species⁴¹, the magnetic electron of a Mo_3O_{13} cluster in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ is isotropic in g -factor but anisotropic in electron density over the cluster. This suggests that the observed magnetic response

of $\text{LiZn}_2\text{Mo}_3\text{O}_8$ does not arise from single ion physics and the lack of any long-range magnetic order originates from a collective interacting $S = 1/2$ cluster-magnet system. The cluster-delocalized nature of the magnetic electron may also act, among additional interactions, as an energetic destabilization of long-range magnetic order (see Fig. 5).

The antiferromagnetic interactions between cluster spins is mediated by superexchange through Mo-O-Mo oxo-bridges, with the triangular arrangement of clusters in the Mo_3O_8 layers yielding the frustrated magnetic state. The NMR and μSR data show that, as the temperature approaches $T = 0$, the respective relaxation rates decrease, instead of increasing as would be expected if approaching a long-range ordered magnetic state⁴². Comparison to bulk neutron data in Fig. 4 (b) shows that both bulk and local measurements show slowing spin fluctuations as the temperature is lowered. Remarkably, the spin fluctuations slow by a factor of ~ 4 from $T \sim 300$ K to $T \sim 4$ K, which is a low rate of slowing. This is consistent with a spin-frustrated system where the spin-spin correlation length (ξ) does not grow much as the temperature is lowered. The spin correlation length is related to the relaxation rate Γ by $\Gamma \sim \xi^{-z}$, where z is the dynamical exponent. In $\text{LiZn}_2\text{Mo}_3\text{O}_8$, the correlation length does not grow much as the temperature is lowered, which is in contrast to other known materials^{43,44}. This shows that the low frequency spin dynamics of the electrons in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ is behaving unconventionally and is consistent with the unusual condensed valence-bond magnetic state.

IV. CONCLUSION

We can speculate why $\text{LiZn}_2\text{Mo}_3\text{O}_8$ does not display a 120° magnetic state, as theoretically predicted⁴⁵⁻⁴⁷ and observed⁴⁸ for a nearest-neighbor, antiferromagnetically coupled triangular lattice of spins. The simplest classical explanation would be if the spins are not Heisenberg in nature, and thus susceptible to well-known states such as cooperative paramagnetism for Ising spins⁴⁹; this seems unlikely considering our ESR data. The observed physical properties of a spin liquid state, besides being intrinsic to the spin liquid, can also be attributed to disorder, as conclusively demonstrating the spin liquid state is difficult⁴. The NMR data on $\text{LiZn}_2\text{Mo}_3\text{O}_8$ are suggestive of a minimal defect spin concentration and thus the origin of the magnetic response in this material arises from the Mo_3O_8 magnetic layers. The lack of magnetic ordering (120° state) and the dynamic nature of the spins must arise from more than simple nearest-neighbor, triangular lattice interactions. This does not unequivocally rule out more subtle disorder effects, such as a

microscopic distribution of exchange interactions due to Li/Zn mixing between magnetic layers. It is more likely that (static or dynamic) structural distortions predicted to energetically stabilize the condensed valence-bond state³⁴ in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ could contribute to the observed slow spin dynamics. Another realistic possibility in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ is that the more delocalized nature of the spins about the Mo_3O_{13} cluster plays an intricate role, pushing the system closer to the delocalized limit (where the additional degree of freedom and kinetic energy gain of delocalization promotes spin dynamics over spin ordering, see Fig. 5), which is known to result in valence bond states³⁵. However, the possibility of longer than nearest neighbor interactions or other effects such as ring exchange⁵⁰ causing the dynamic nature of the spins in $\text{LiZn}_2\text{Mo}_3\text{O}_8$, cannot be ruled out. Regardless of the microscopic details, the data clearly show the dynamic spins in $\text{LiZn}_2\text{Mo}_3\text{O}_8$ are strongly correlated, making $\text{LiZn}_2\text{Mo}_3\text{O}_8$ a spin liquid candidate. Most importantly, our results demonstrate the utility of using cluster-based systems to induce collective magnetic interactions and geometrically frustrated magnetism.
