(Dated: December 28, 2017)

Spin fluctuations were studied over a wide momentum (hQ) and energy (E) space in the frustrated d-electron heavy-fermion metal LiV_2O_4 by time-of-flight inelastic neutron scattering. We observed the overall $Q-\tilde{E}$ evolutions near the characteristic $Q=0.6$ Å⁻¹ peak and found another weak broad magnetic peak around 2.4 \AA^{-1} . The data are described by a simple response function, a highly itinerant magnetic form factor, and antiferromagnetic short-range spatial correlations, indicating that heavy-fermion formation is attributable to spin-orbit fluctuations with orbital hybridization.

PACS numbers: 71.27.+a, 75.25.-j, 75.40.Gb, 78.70.Nx

The many-body problem is central to modern condensed-matter physics, i.e., how does one describe a large number of intricately interacting particles in solids and liquids? The concept of quasiparticles constitutes the basis of this problem; a system can be successfully treated as a collection of independent quasiparticles [\[1\]](#page-3-1). Examples include heavy fermions (HF) in metals and Cooper pairs in superconductors, in which conduction electrons are coupled with spins and lattices.

In 1997, the heaviest fermion system among d-electron systems, the metallic spinel LiV_2O_4 (nominally $\text{V}^{3.5+}$, $3d^{1.5}$), was discovered [\[2\]](#page-3-2). The ratio of the heat capacity to temperature C/T steeply increases with a large Sommerfeld coefficient $\gamma \simeq 400 \text{ mJ} \text{ mol}^{-1} \text{ K}^{-2}$ below the characteristic temperature $T^* \simeq 20$ K [\[3](#page-3-3)[–5](#page-3-4)]. This followed the report of another d-electron HF system, Y(Sc)Mn₂, with $\gamma \simeq 140 \text{ mJ mol}^{-1} \text{K}^{-2}$ [\[6\]](#page-3-5). In both d-electron systems, the magnetic atoms form a geometrically frustrated pyrochlore lattice, suggesting a close connection between the HF and frustration.

 $LiV₂O₄$ exhibits a weak cusp in magnetic susceptibility at T^* but no magnetic order at any measured temperature, indicating strong frustration [\[3\]](#page-3-3). Instead, powder inelastic neutron scattering (INS), nuclear magnetic resonance (NMR), and muon spin resonance (μSR) detect spin fluctuations below ~ 80 K down to 20 mK, which increase to antiferromagnetic (AF) short-range fluctuations described by $Q \simeq 0.6 \,\text{\AA}^{-1}$ below T^* [\[7](#page-3-6)[–9\]](#page-3-7), where the magnitude of the momentum $p = \hbar Q$. The 0.6-Å⁻¹ nesting structure is also obtained by band calculations [\[10\]](#page-3-8).

In addition, the electrical resistivity is metallic over the entire temperature range below room temperature and further decreases below T^* [\[3\]](#page-3-3). This decrease is different from the Kondo upturn, which is the fingerprint of conventional f-electron HF systems based on the Kondo coupling between the localized f-electron momenta and

the conduction electrons. Further, the optical conductivity suggests that $\rm{LiV_2O_4}$ changes from a poor metal to a coherent Fermi-liquid metal around T^* as the temperature decreases, as in the vicinity of a Mott insulator [\[11\]](#page-3-9). Photoemission also resulted in a resonance peak in the electronic density of states at ∼ 4 meV above the Fermi level [\[12](#page-4-0)], which is also theoretically understood as the vicinity of the Mott insulator [\[13\]](#page-4-1).

Thus, HF formation likely originates not from the conventional Kondo effect but from another novel electron correlation effect. The 0.6- \AA^{-1} AF spin fluctuations driven by frustration will play a key role in HF formation. However, the overall correlations of the spin fluctuations in a wide (Q, E) space are still unclear, where E denotes the energy. For example, many Q-dependent character-istic frequencies were reported around 0.6 Å⁻¹ [\[14\]](#page-4-2), requiring a simple description by a response function. In contrast, no magnetic peak has been reported, other than the 0.6- \AA^{-1} peak, hampering clarification of the spatial correlations. Different spatial-correlation models were also theoretically proposed, such as spin-orbit fluctuations with molecular V tetrahedra and one-dimensional (1D)-like chains [\[15,](#page-4-3) [16\]](#page-4-4).

In this study, we performed INS experiments on powder samples of $LiV₂O₄$ using a state-of-the-art timeof-flight spectrometer with large-solid-angle detectors, which allows us to investigate the spin fluctuations in a wide (Q, E) space. We used the direct geometry chopper spectrometer AMATERAS (BL14) at the MLF of the J-PARC spallation neutron source (Japan) [\[17](#page-4-5)]. The incident energy (E_i) was simultaneously set to 3.1, 7.7, 15, and 24 meV using the multi- E_i technique, and the E resolution under elastic conditions was approximately 2.0, 2.6, 3.6, and 4.5% to E_i , respectively. The main disk chopper speed was fixed at 300 Hz. The data were obtained by the UTSUSEMI software provided by the

MLF [\[18](#page-4-6)]. Scattering from the empty-container background measurements was subtracted, and the absolute intensities were obtained by normalization to measure the incoherent scattering intensity from the sample. A powder sample of $LiV₂O₄$ was synthesized by a solidstate reaction method [\[19](#page-4-7)]. Li is in natural abundance. Approximately 7.3 g of the sample was placed onto an aluminum foil and shaped into a hollow cylinder with a thickness of 3 mm and a diameter of 20 mm in order to mitigate the neutron-absorption effects of Li nuclei as much as possible. The cylinder was kept in the thin aluminum container with He exchange gas that was placed under a cold head in a He closed-cycle refrigerator.

FIG. 1: (Color online) (a), (b) Contour plots of the scattering intensity distribution in (Q, E) space. (c) Constant-E cross sections in the low- Q range (symbols). From the bottom, E_i $= 3.1, 15, 15, 15, 24,$ and 24 meV. The averaged E range was $\pm 0.1, \pm 0.3, \pm 0.3, \pm 0.3, \pm 0.8, \text{ and } \pm 0.8 \text{ meV}$. The vertical zero points are shifted by 2 mbarn \cdot st⁻¹ \cdot meV⁻¹ \cdot V⁻¹. The solid curves are fits of Eq. [\(2\)](#page-1-0) to the data (see text). The tiny horizontal bars represent the Q resolution, which can be neglected compared to the experimental line widths. (d) Constant-E cross sections averaged in the 2.5 ± 0.5 -meV range in (a) and (b). (e) Extraction of the magnetic component. The blue arrows indicate the magnetic peaks.

 $Results. - Figures 1(a) and 1(b) show the observed$ $Results. - Figures 1(a) and 1(b) show the observed$ $Results. - Figures 1(a) and 1(b) show the observed$ scattering intensity distributions in (Q, E) space. In the low- \check{Q} range below 1.5 Å⁻¹, which was previously reported [\[7,](#page-3-6) [14\]](#page-4-2), magnetic scattering is observed with fountain-like E evolution around 0.55 Å⁻¹ at 6 K [Fig. [1\(](#page-1-1)a)]. The scattering is paramagnetic around 0 Å^{-1} at 197 K [Fig. [1\(](#page-1-1)b)]. The constant- E cross sections of the 6-K data are shown in Fig. $1(c)$. As E increases, the scattering broadens in Q.

In addition, we searched for another unreported magnetic signal in the high-Q range above 1.5 \AA^{-1} . Figure $1(d)$ shows the cross sections at 2.5 meV. This energy was selected to avoid the elastic tail and minimize phonon contamination. A broad and very weak signal appears between 2 and 3 \AA^{-1} at 6 K, whereas strong phonon scattering with an intensity increasing with an increase in Q is observed at 197 K. Thus, to examine whether the 6-K broad peak is magnetic in origin, we subtract the 197-K data and correct with a Bose population factor as the phonon component from the 6-K data, as shown in Fig. $1(e)$. In the low-Q range, the phonon component was extrapolated from the high-Q data by the Q^2 term with a constant background to avoid the tail of paramagnetic scattering at 197 K. After this subtraction, the $2.4-\text{\AA}^{-1}$ broad peak still remained [open circles] in Fig. [1\(](#page-1-1)e)], indicating that another magnetic signal was found.

 $Analysis.$ We analyze the fountain-like E evolution around 0.55 Å^{-1} at 6 K. The differential cross section of INS is proportional to the imaginary part $\chi''(Q,\omega)$ of the generalized magnetic susceptibility $\chi(Q,\omega)$, where $E = \hbar \omega$ [\[20](#page-4-8)]. Following a standard way to describe the spin fluctuations in nearly AF metals such as $Cr_{0.95}V_{0.05}$ and $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ [\[21](#page-4-9), [22](#page-4-10)], we use

$$
\chi(Q,\omega) = \sum_{j=1}^{n} \chi_j \left[1 + \frac{(Q - Q_0)^2}{\kappa_0^2} - i \frac{\omega}{\Gamma_j} \right]^{-1}, \quad (1)
$$

where n is the number of spin fluctuation modes. This function corresponds to the expansion of the Lindhard function near the Fermi energy to describe a Fermi liquid [\[21](#page-4-9)[–24\]](#page-4-11). The imaginary part of Eq. [\(1\)](#page-1-2) is described by the following useful form [\[21\]](#page-4-9):

$$
\chi''(Q,\omega) = \sum_{j=1}^{n} \chi''_j(\omega) \frac{\kappa_0^4 + \kappa_j^4(\omega)}{\{\kappa_0^2 + (Q - Q_0)^2\}^2 + \kappa_j^4(\omega)}, \tag{2}
$$

where the ω evolutions are separated into the susceptibility at Q_0 ,

$$
\chi_j''(\omega) = \chi_j \frac{\omega \Gamma_j}{\omega^2 + \Gamma_j^2},\tag{3}
$$

and the Q width around Q_0 ,

$$
\kappa_j^2(\omega) = \kappa_0^2 \frac{\omega}{\Gamma_j}.\tag{4}
$$

FIG. 2: Fitting results in the $n = 1$ [(a)–(b)] and $n = 2$ models $[(c)-(f)]$. Subfigures (a), (c), and (e) show the $E = \hbar \omega$ dependence of the dynamic susceptibilities at Q_0 and $\chi''_j(\omega)$, and panels (b), (d), and (f) show that of the Q-width parameters, $\kappa_j^2(\omega)$. The solid lines are fits of Eqs. [\(3\)](#page-1-3) and [\(4\)](#page-1-4) to the data (see text).

If Eq. [\(1\)](#page-1-2) describes the data, an identical Γ_j will be obtained for both the susceptibility and the Q-width parts.

Figures $2(a)$ and $2(b)$ show the fitting results for an $n = 1$ model. The results coincide with Lee et al.'s INS report for both $\chi_1''(\omega)$ and Γ_1 [Fig. [2\(](#page-2-0)a)] [\[7\]](#page-3-6). However, $\kappa_1^2(\omega)$ is not proportional to E in the low-E region [Fig. [2\(](#page-2-0)b)]. This is rather consistent with Murani et al.'s INS report and the μ SR data, suggesting the coexistence of another slower component below 1 meV [\[9,](#page-3-7) [14\]](#page-4-2). Thus, we used an $n = 2$ model, and the fitting results are shown in Figs. [2\(](#page-2-0)c)-2(f). $\chi''_1(\omega)$, $\kappa_1^2(\omega)$, $\chi''_2(\omega)$, and $\kappa_2^2(\omega)$ are all fit well with $\Gamma_1 = 2.6$ meV and $\Gamma_2 = 0.7$ meV, where $\chi_1 = 0.43 \mu_{\rm B}^2 \text{meV}^{-1} \text{V}^{-1}, \ \chi_2 = 0.20 \mu_{\rm B}^2 \text{meV}^{-1} \text{V}^{-1},$ $Q_0 = 0.55$ \AA^{-1} , and $\kappa_0 = 0.28$ \AA^{-1} .

Next, we analyze the spatial correlations of the fluctuations from the obtained Q information. First, the value of Q_0 is equal to $0.72(2\pi/a) = 2\pi/\sqrt{2}a$, indicating the periodicity of $\sqrt{2}a = 4d_{\rm V-V}$, where a denotes the lattice con-stant of 8.24 Å in the pyrochlore lattice [\[4](#page-3-10)], and d_{V-V} denotes the distance between the nearest-neighbor V sites, as shown in Fig. $3(a)$. This strongly suggests that the fluctuations consist of AF bonds of four V atoms along the $\langle 110 \rangle$ direction. Second, the value of the Q-width κ_0 means ~ 5 Å of short correlation length. Third, as shown in Fig. [1\(](#page-1-1)e), the Q dependence of the intensity consists of a combination of a strong broad $0.6-\text{\AA}^{-1}$ peak and a weak

broad $2.4-\text{\AA}^{-1}$ peak. This combination is identical to that of the 4-meV mode observed in another highly frustrated spinel-type insulator, $GeCo₂O₄$ [\[25\]](#page-4-12), which is explained by AF di-tetrahedron spin correlations by singlecrystal INS [\[26\]](#page-4-13). Furthermore, this di-tetrahedron structure satisfies the first and second conditions. Thus, the fluctuations are most likely based on the di-tetrahedron in the spatial correlations.

We calculated the Q dependence of the intensities for several di-tetrahedron-based models, and three of these models are shown in Fig. [3\(](#page-3-11)b), where a localized theoretical magnetic form factor was used [\[27\]](#page-4-14). As expected, every model roughly reproduces the 0.6- \AA^{-1} and 2.4- \AA^{-1} positions, and the di- and tetra-tetrahedron models are also consistent with the experimental data for the 0.6- A^{-1} peak width.

However, the calculated intensities of the 2.4- \AA^{-1} peak are much stronger than the experimental data. To improve this, we incorporated the spatial expansion of the spin density distribution at each V site, considering that $LiV₂O₄$ exhibits metallic electrical resistivity. This itinerancy corresponds to the rapid decrease in the magnetic form factor in Q space. Further, band calculations indicate that the Fermi level is mainly crossed by V 3d t_{2q} orbital bands, which roughly split into a localized a_{1q} singlet and an itinerant e'_{g} doublet via a small trigonal crystal field, as schematically shown in Fig. [3\(](#page-3-11)a) [\[28,](#page-4-15) [29\]](#page-4-16). Thus, for simplicity, we approximated the magnetic form factor by $\alpha f_{\text{localized}}(Q) + (1 - \alpha) \exp(-Q^2/\Delta Q_{\text{itinerant}}),$ where $f_{\text{localized}}(Q)$ denotes the localized form factor [\[27](#page-4-14)] normalized at 0 \AA^{-1} , and α and $\Delta Q_{\text{itinerant}}$ are determined to fit the experimental data. The spatial spin correlation was set to the di-tetrahedron.

Figure [3\(](#page-3-11)c) shows a comparison among the experimental data, localized model 1, and model 2 with localization and itinerancy. The experimental data are well fit to model 2, which is much better than the model 1 with respect to the 2.4- \AA^{-1} intensity and the 0.6- \AA^{-1} peak profile. The model-2 fitting was obtained at $\alpha = 0.66$ and $\Delta Q_{\text{itinerant}} = 0.74 \text{ Å}^{-1}$. The value of α indicates α : $(1 - \alpha) = 1.0$: 0.5, which is in excellent agreement with the Hund-rule filling of 1 a_{1g} and 0.5 e'_{g} elec-trons/V, as shown in Fig. [3\(](#page-3-11)a). The $\Delta Q_{\text{itinerant}}$ value means 2.2 Å of spatial distribution at half width at half maximum, which is much larger than $(d_{V-V}/2) = 1.5$ A. This indicates that the itinerant components of the nearest-neighbor V spins considerably overlap with each other in the di-tetrahedron.

Discussion.— The observed dynamical magnetic susceptibility is well described by a simple function for a Fermi liquid [Eq. [\(1\)](#page-1-2)] and is accompanied with the high itinerancy in the magnetic form factor. These facts verify the treatments of spin fluctuations in itinerant systems, such as a series of self-consistent renormalization theories, demonstrating that the spin-fluctuation channel dominates HF formation [\[10,](#page-3-8) [30,](#page-4-17) [31\]](#page-4-18). Further, the

FIG. 3: (Color online) Modeling of the dynamical spatial correlations. (a) Unit cell of the pyrochlore lattice (upper) and energy scheme of the V orbitals (lower). (b), (c) Comparisons of the experimental and model-calculated Q dependencies of the intensities. All intensities are normalized at the maximum intensity Q. The experimental data (open circles) are identical to the magnetic scattering in Fig. [1\(](#page-1-1)e). The curves were calculated in the inset models, where the orange and green spheres denote the dynamically fluctuating up and down spins, respectively. In (b) and (c), localized [model 1 in (d)] and modified [model 2 in (d)] magnetic form factors were used, respectively. (d) Magnetic form factors normalized at 0 \AA^{-1} . The broken and dotted curves resolve the model-2 form factor into localized and itinerant components, respectively.

spin fluctuations are based on the AF di-tetrahedron in the spatial correlations. This strongly suggests that geometrical frustration causes the fluctuations as well as in $GeCo₂O₄$ [\[26](#page-4-13)], and that the large HF entropy originates from the high degeneracy driven by frustration.

Interestingly, the di-tetrahedron combines both theoretically proposed characteristics, the 1D-like chain along the $\langle 110 \rangle$ direction and the ferromagnetic tetrahedron units, which are accompanied by spin-orbit fluctuations [\[15](#page-4-3), [16\]](#page-4-4). In the former theory [\[16\]](#page-4-4), 1D correlations occur to release geometrical frustration, taking into account the fact that a pyrochlore lattice consists of 1D chains along the $\langle 110 \rangle$ directions, as shown in Fig. [3\(](#page-3-11)a). The V t_{2g} orbitals hybridize with each other to form the 1D Hubbard chain with a periodicity of $4d_{V-V}$. In the latter theory [\[15\]](#page-4-3), the ferromagnetic tetrahedra form to release frustration because a pyrochlore lattice is also regarded as the tetrahedra arranged in a face-centeredcubic lattice. The molecular orbital formation of the V_4 tetramer remarkably decreases the system energy. Further, the V_4 molecular orbital is half filled, which makes the inter-tetramer exchange interaction AF.

Summary.— We studied spin fluctuations over a wide (Q, E) space in LiV₂O₄ by INS. The observed data can be described by a simple response function, a highly itinerant magnetic form factor, and AF di-tetrahedron-based spatial correlations. With these characteristics, the large HF entropy is attributable to frustration with spin-orbit fluctuations and remarkable orbital hybridization. Our study will promote future studies of novel quasiparticles as a prototype in the longstanding many-body problem.

We thank Dr. S. Iikubo for assisting with the sample preparation and Dr. M. Yokoyama for providing the preliminary neutron machine time. The neutron experiments were performed with the approval of J-PARC (2012A0146 and partially 2012P0202). This study was financially supported by Grants-in-Aid for Young Scientists (B) (22740209 and 26800174) and Priority Areas (22014001) from the MEXT of Japan.
