Using high-resolution photoemission spectroscopy and first-principles calculations, we characterize superconducting $TlNi_2Se_2$ as a material with weak electronic Coulomb correlations leading to a bandwidth renormalization of 1.4. We identify a camelback-shaped band, whose energetic position strongly depends on the selenium height. While this feature is universal in transition metal pnictides, in $TlNi_2Se_2$ it lies in the immediate vicinity of the Fermi level, giving rise to a pronounced van Hove singularity. The resulting heavy band mass resolves the apparent puzzle of a large normal-state specific heat coefficient (Phys. Rev. Lett. 112, 207001) in this weakly correlated compound.

The discovery of high-temperature superconductivity in iron-chalcogenide $A_x Fe_{2-y} Se_2$ (A = Tl, K, Cs, Rb) [1, 2] has raised a lot of attention because their unique Fermi surface (FS) topology without hole pocket [3–8] challenges the electron-hole quasi-nesting scenario as the main Cooper pairing force in the Fe-based superconducting materials [9]. However, due to the phase separation associated with Fe vacancy ordering [10, 11] in $A_x Fe_{2-u} Se_2$, it is still unclear whether superconductivity in this compound is related to that of the other ironbased superconductors. Very recently, it has been found that the iso-structural material $TlNi_2Se_2$ with two more electrons on the 3d shell shows superconductivity with $T_c = 3.7 \text{ K}$ [12]. In contrast to $\text{Tl}(\text{K})_x \text{Fe}_{2-y} \text{Se}_2$, X-ray diffraction results indicate that this system is homogeneous without Ni vacancy or phase separation, and stoichiometric TlNi₂Se₂ was confirmed by energy dispersive X-ray spectroscopy [12]. A large normal-state Sommerfeld coefficient has been attributed to heavy fermion behavior [12], and its square root relationship with magnetic field in the mixed state suggests d-wave wave paring symmetry. On the other hand, thermal conductivity measurements suggest multiple nodeless superconducting gaps [13] in TlNi₂Se₂. Therefore, it is crucial to determine the electronic structure of $TlNi_2Se_2$ to understand the nature of the reported heavy fermions in this material and to establish possible connections with other unconventional superconductors.

In this letter, we present high-resolution angleresolved photoemission spectroscopy (ARPES) results on TlNi₂Se₂. Wide range photon energy dependent measurements reveal that the electronic structure exhibits three dimensionality, with four bands crossing the Fermi level (E_F) . Our density functional theory (DFT) calculations, renormalized by a factor of 1.4, match the experimentally determined band structure very well, indicating weaker correlation effects in $TlNi_2Se_2$ than in its cousin $Tl(K)_x Fe_{2-y} Se_2$ [3]. We reveal that the flat top of one of the bands (γ) exhibits an asymmetric back-bending feature resulting in a camelback shape near E_F at k = $(0,0,\pi)$, the Z point of the first Brillouin zone (BZ). This shape is captured by our DFT calculations and seems to be a general feature of transition metal pnictides [14]. This γ band forms four small FS lobes around the Z point, and between the lobes four flat parts resulting in a van Hove singularity (VHS) near E_F are identified. This finding provides a natural explanation to the heavy electrons feature inferred from electronic specific heat and the upper critical field measurements [12] in this weakly correlated system [15].

Large single crystals of TlNi₂Se₂ were grown by the self-flux method [12]. ARPES measurements were performed at SIS beamline of Swiss Light Source, and at the 1-cubed ARPES end-station of BESSY using VG-Scienta R4000 electron analyzers with photon energy ranging from 20 to 70 eV. The angular resolution was set to 0.2° and the energy resolution to $5\sim10$ meV. Clean surfaces for the ARPES measurements were obtained by cleaving crystals *in situ* in a working vacuum better than 5×10^{-11} Torr. We label the momentum (k) values with respect to the 1 Fe/unit cell BZ, with the high symmetry points defined in Fig. 1(a). The Fermi level of the samples was referenced to that of a gold film evaporated onto the sample holder. Raman data have been recorded at room temperature using a 514.5 nm laser source and the single mode of a Horiba Jobin Yvon-T64000 micro-Raman spectrometer equipped with a CCD camera.

The Raman spectra in Fig. 1(b) show one A_{1g} mode (177.9 cm⁻¹) and one B_{1g} (132.8 cm⁻¹) phonon, similar to the observation on the 122-ferropnictides [16], which share the same crystal structure. As illustrated in the inset, the intensity of these peaks are in perfect concordance with the four-fold symmetry of the crystal and the spectra are exempt of extra modes, which suggests that our TlNi₂Se₂ samples are not phase-separated and do not show Ni vacancy ordering, in agreement with a previous study [17] on isostructural KNi₂Se₂.

Fig. 1(c) shows the wide-energy photoemission spectra of $TlNi_2Se_2$. Clear double-peak features due to the spin-orbit interaction are identified for Se 3d states at binding energies $(E_B) = 54.0$ and 54.9 eV, Tl 5d states at $E_B = 12.9$ and 15.1 eV, and Ni 3p states with $E_B =$ 66.3 and E_B 67.9 eV (as shown in the inset), confirming the sample composition. In Fig. 1(d), we plot the LDA band structure calculated for the experimental lattice parameters [12] and $z_{Se}=0.355$. Four different bands are crossing the Fermi level, and the band structure exhibits non-negligible three-dimensionality. The density of states (DOS) near E_F is contributed mainly by the Ni 3d states with a partial Se 4p spectral weight, as seen from Fig. 1(d) (the Se 4p spectral weight is indicated by the line-width), and the calculated DOS in Fig. 1(e). We notice that one specific band, γ , shows a back-bending camelback-shaped feature at the Z point (as shown in the dashed-line circle in Fig. 1(d), leading to a flat band top sitting very close to E_F and contributing to a sharp peak in the DOS (inset of Fig. 1(e)). This gives us a first indication that the heavy electrons reported in $TlNi_2Se_2$ may originate from this flat band top. This band results from the hybridization of the Ni- d_{xy} and Se p_z orbitals and is a universal feature in transition metal pnictides and chalcogenides. The particular shape of its dispersion, with a back-bending feature near the Γ and Z points, is due to the combination of two opposite binding effects. Indeed, while the interaction of Ni- d_{xy} with Se-p_z is antibonding and causes the band to disperse upwards toward Z because of an increasing hybridization, the nearest-neighbor Ni- d_{xy} – Ni- d_{xy} interaction becomes bonding near this point, which explains the energy minimum. In most iron pnictides, the resulting saddle points are found in the unoccupied states [14], but the originality of TlNi₂Se₂ is that the Fermi level crosses it.

The inset is a close up of the Ni 3plevels. (d) LDA band structure plotted along high symmetry lines. The line-width indicates the Se 4p spectral weight. (e) Density of states from LDA calculations.

To fully explore the valence band structure in the three dimensional k-space, we performed ARPES experiments over a wide photon-energy range to cover more than one BZ in the k_z direction. In Figs. 2(a)-2(b), we plot normal emission ARPES intensities as a function of photon energy and their corresponding energy distribution curves (EDCs). Clear periodic variations of peak positions, especially for the γ band near E_F and the ϵ/ω band at $E_B \sim 1.2$ eV, are observed with tuning the k_z value by changing the photon energy, indicating strong three dimensionality of the band structure in TlNi₂Se₂. Using the nearly-free electron approximation with an inner potential of 17 eV, we estimate $h\nu = 34$ eV for the $k_z = 0$ plane, and $h\nu = 29/54$ eV for the $k_z = \pi$ planes. We plot the ARPES intensity along the Γ -M and Z-M directions in Figs. 2(c)-2(d), which are recorded with $h\nu = 34$ eV and 29 eV, respectively. The corresponding EDCs are shown in Figs. 2(e)-2(f). At first sight, the overall band structure of TlNi₂Se₂ shows great similarity with the iron pnictide BaFe₂As₂ [19] and cobalt pnictide BaCo₂As₂ [20]. The α, α' and β hole-like pockets observed at the BZ center (Γ point) in BaFe₂As₂ are fully filled in TlNi₂Se₂, with the bands topping ~ 0.6 eV below E_F . The γ and δ electron-like pockets located at the M point in BaFe₂As₂ are more than half filled in TlNi₂Se₂ and form hole-like

FIG. 3. (Color online) (a)-(b) FS mappings for the $k_z = 0$ and π planes, respectively, obtained by integrating the ARPES intensity within $E_F \pm 5$ meV. (c)-(d) same as (a)-(b) but recorded 555 meV below E_F .

pockets at the Γ point. One flat band (η) sits ~ 250 meV below E_F in TlNi₂Se₂, which is also observed near E_F in BaCo₂As₂ [20, 21]. Besides all these 3*d* states, the additional ζ band is observed in TlNi₂Se₂ around the M point. Our ARPES data suggest that TlNi₂Se₂ shares a universal band structure with BaFe₂As₂ and BaCo₂As₂, with a chemical potential shifted due to more 3*d* electrons in TlNi₂Se₂ (3*d*^{8.5}) than in BaFe₂As₂ (3*d*⁶) and BaCo₂As₂ (3*d*⁷). This is indeed what is expected from our LDA calculations, which match the experimental data very well with a renormalization factor of 1.4 as seen in Figs. 2(c)-2(d). TlNi₂Se₂ (3*d*^{6.5}), as we will discuss more later.

In Fig. 2(g), we plot the ARPES intensity along Γ -X-Z obtained with photon energy $h\nu = 54$ eV. The overall band structure is also in a good agreement with the renormalized LDA calculations. In order to examine the details for the bands near E_F , high resolution measurements have been recorded along Γ -X at the $k_z = 0$ plane $(h\nu = 41 \text{ eV})$. As shown in Fig. 2(h), the hole-like η band crosses E_F , with the intensity enhanced due to the matrix element effect. Similarly, Fig. 2(i) shows the band structure in the $k_z = \pi$ plane $(h\nu = 29 \text{ eV})$, cutting slightly off the Z-X direction (as illustrated by the yellow arrow in Fig. 3(c)), in order to well separate the γ and δ bands. In agreement with LDA, the γ , δ and η bands are observed, hybridizing with each other at their intersections.

In Figs. 3(a) and 3(b), we display the Fermi surface at $k_z = 0$ and π , respectively. The corresponding LDA calculations (slightly shifted upward by 7 meV) are also overlapped. As expected from the previous analysis of the band structure in the vicinity of E_F , the FS topology of TlNi₂Se₂ is quite different from that of $Tl(K)_x Fe_{2-\eta}Se_2$. The γ and δ bands, which form a pair of degenerate electron-like pockets at the M point in $Tl(K)_x Fe_{2-y} Se_2[3-6]$, become hole-like pockets crossing E_F at the Γ point. The δ band crosses the Z point with a smaller k_F and the γ band creates four small lobes because of the back-bending feature discussed before. The η band forms a small hole-like pocket near the X point, and the ζ band forms an electron-like pocket at the M point. In contrast, we find that the constant energy maps recorded at 550 meV below E_F for the $k_z = 0$ and π planes, which are, respectively, displayed in Figs. 3(c)and 3(d), are quite similar to the FSs of $Tl(K)_x Fe_{2-y} Se_2$, on which superconducting gaps are observed below T_c [6]. To illustrate this resemblance, we overlap on these figures the FSs obtained for $Tl(K)_x Fe_{2-y} Se_2$ in Ref. [6]. Similarly to the case of BaFe₂As₂ and BaCo₂As₂, TlNi₂Se₂ can be interpreted as a heavily electron doped TlFe₂Se₂ as a first approximation. Therefore, our results suggest that TlFe₂Se₂, the phase without vacancy ordering, is the superconducting compound of the iron-chalcogenide $Tl_xFe_{2-y}Se_2$, which is consistent with the STM results

FIG. 4. (Color online) (a) FSs plot near the Z point. (b) Three-dimensional band structure plot near the Z point. (c) High resolution ARPES results along C1-C2 in (a), recorded at T = 5 K. [10] and supports the conclusions derived from previous ARPES experiments on $AFe_{2-x}Se_2$ [3–8].

The significant reduction of electron correlation strength in $TlNi_2Se_2$ (as indicated by a small renormalization factor of 1.4) as compared to $TlFe_2Se_2$ (renormalization factor of 2.5 [3]) is anticipated due to the increased filling of the electronic 3d shell. Indeed, in Ref. [20] it was argued that the stronger correlations in BaFe₂As₂ as compared to BaCo₂As₂ are driven by the lower band filling in the presence of strong Hund's coupling. The mass enhancement due to correlation effects in $TlNi_2Se_2$ is much smaller than that deduced from the specific heat coefficient by assuming 1.5 carriers/Ni and a spherical Fermi surface [12]. Here we suggest the large specific heat coefficient to be related to the flat band near the chemical potential, as unveiled by our DFT calculations and the ARPES data (Fig. 2(d)). To check the fine details of this γ band top, we performed high resolution measurements at T = 5 K, above T_c . As seen from the result in Fig. 4(c) and the corresponding EDC plot in Fig. 4(g), the top of the γ band sits at the S point, $\sim 2 \text{ meV}$ below the E_F along the Z-X direction (C1 in Fig. 4(a)), and bends back with the band bottom at $\sim 18 \text{ meV}$ below the E_F (indicated by the EDC taken at the Z point shown in the inset of Fig. 4(g)). Along the Z-M direction (C2 in Fig. 4(a)), the band top of γ is slightly above E_F , leading the γ band to double-cross E_F and forming small lobes. The γ band top along Z-M is estimated at ~ 15 meV above E_F from the high temperature data (150 K) divided by the Fermi function shown in Fig. 4(i). In Fig. 4(e), we plot the ARPES intensity along the momentum path passing through the S point and perpendicular to the Z-X direction (C3 in Fig. 4(a)). The corresponding EDC plot is also shown in Fig. 4(h). The γ band crosses E_F four times (passing through two small holelike lobes), and has a negative curvature at the S point along C1, as seen from Fig. 4(e), and the extracted band structure in Fig. 4(f). At the same time, the γ band has a positive curvature at the S point along the perpendicular direction C1 as shown in Figs. 4(c)-4(d). Therefore, our data confirms the picture discussed before and in particular the camelback shape and the VHS at the S points. This can be better visualised in the band structure plotted in Fig. 4(b). In fact, this VHS is guaranteed by the asymmetry of the back-bending feature as shown in Fig. 4(c) and the extracted band structure in Fig. 4(d) along the X-Z-M direction. The existence of the four flat parts of the dispersion very close to E_F provides a natural explanation for the specific heat coefficient in this weakly correlated system $TlNi_2Se_2$.

Because the VHS is very close to E_F , the FS topology of the γ band changes dramatically when slightly tuning the chemical potential. When we put the chemical potential > 15 meV above E_F , only the δ band crosses at the Z point and forms a hole-like pocket (Fig. 4(e) I). By putting the chemical potential at -15 meV $< E_B <$ 2 meV (for instance the red lines in Fig. 4(d)), the γ band crosses the chemical potential but only along the Z-M directions, forming four small hole-like lobes (Fig. 4(e) II). When the chemical potential is setting in the range of 2 meV < E_B <17 meV, the γ band crosses the chemical potential twice both along the Z-M and Z-X directions, forming a small electron-like pocket inside a concentric hole-like pocket (Fig. 4(e) III). Further shifting the chemical potential down to $E_B > 17$ meV, the inner electron pocket disappears, leaving two hole-like pockets at the Z point (Fig. 4(e) IV). All these Lifshitz transitions associated with VHS happen with the chemical potential varying by less than 30 meV, providing a possible explanation for why T_c of KNi_2Se_2 ($T_c \sim 0.8$ K) [22] is ~ 4 times smaller than that of TlNi₂Se₂. Because K is much more sensitive to air than Tl, a slight shift of chemical potential in KNi₂Se₂ is expected. The difference of DOS near E_F due to this small chemical potential variation cannot explain ~ 4 times smaller T_c in KNi₂Se₂. On the other hand, the FS topology change associated with VHS due to the chemical potential shift is one candidate interpretation for the large variation of superconductivity. Most interestingly, since the strength of the hybridization of Ni- d_{xy} with the Se- p_z orbital controls the position of the saddle point with respect to the Fermi level, the shape of the Fermi surface is highly sensitive to the height of the selenium atom over the Ni-Se plane. This may be related to the sudden T_c drop under pressure recently reported in $TlNi_2Se_2$ [23].

It is also worth mentioning that the end-member of the hole-doped BaFe₂As₂, the iron pnictide KFe₂As₂, shows some similarities with TlNi₂Se₂. First, a large specific heat coefficient ~ 94 mJ/mol K² is also reported in KFe₂As₂ [24]. Also, a similar pressure effect has been observed in KFe₂As₂ [25] and TlNi₂SeS[23]. Finally, a flat band bottom for the β band forming four small hole-like lobes at the M point due to hybridization with an electron band, has also been observed by ARPES [26, 27]. And recently a VHS [28] has been observed and suggested to be responsible for the nodal superconductivity reported in this material [25, 29, 30].
