Abstract

We discuss a matrix public key cryptosystem and its numerical implementation.

1 Introduction

In a symmetrical key cryptosystem, such as AES (Advanced Encryption Standard), two users Alice and Bob must first agree on a common secret key [1]. If Alice communicates the secret key to Bob, a third party, Eve, might intercept the key, and decrypt the messages. In order to avoid such a situation one can use an asymmetric public key cryptosystem, which provides a mechanism to securely exchange information via open networks [1].

In public key cryptography a user has a pair of cryptographic keys, consisting on a widely distributed public key and a secret private key. These keys are related through a hard mathematical inversion problem, such that the private key cannot be practically derived from the public key. The two main directions of public key cryptography are the public key encryption and the digital signatures. Public key encryption is used to ensure confidentiality. In this case, the data encrypted with the public key can only be decrypted with the corresponding private key. Digital signatures are used to ensure authenticity or prevent repudiation. In this case, any message signed with a user's private key can be verified by anyone who has access to the user's public key, proving the authenticity of the message.

A standard implementation of public key cryptography is based on the Diffie-Hellman (DH) key agreement protocol [2]. The protocol allows two users to exchange a secret key over an insecure communication channel. The platform of the DH protocol is the multiplicative group \mathbb{Z}_p of integers modulo a prime p . The DH protocol can be described as following:

1. Alice and Bob agree upon the public integer $g \in \mathbb{Z}_p$.
2. Alice chooses the secret integer a .
3. Alice computes $A = g^a \bmod p$, and publishes A .
4. Bob chooses the secret integer b .
5. Bob computes $B = g^b \bmod p$, and publishes B .
6. Alice computes the secret integer $K_A = B^a \bmod p = g^{ba} \bmod p$.
7. Bob computes the secret integer $K_B = A^b \bmod p = g^{ab} \bmod p$.

It is obvious that both Alice and Bob calculate the same integer $K \equiv K_A = K_B$, which then can be used as a secret shared key for symmetric encryption.

Assuming that the eavesdropper Eve knows p, g, A and B , she needs to compute the secret key K , that is to solve the discrete logarithm problem:

$$A = g^a \pmod{p}, \quad (1)$$

for the unknown a . If p is a very large prime of at least 300 digits, and a and b are at least 100 digits long, then the problem becomes computationally hard (exponential time in $\log p$), and it is considered infeasible. For maximum security it is also recommended that p is a safeprime, i.e. $(p-1)/2$ is also a prime, and g is a primitive root of p . This protocol is secure, assuming that it is infeasible to factor a large integer composed of two or more large prime factors.

Here, we discuss a public key cryptosystem, which extends the key exchange to a matrix protocol, and avoids the traditional number theory approach based on the discrete logarithm problem. The key exchange mechanism is based on a commutative function defined as the product of two matrix polynomials. We provide a detailed description of this encoding mechanism, and a practical numerical implementation.

2 Commutativity of Matrix Polynomials

Let us consider the complex matrix $X \in \mathbb{C}^{N \times N}$, and two complex matrix polynomials of the form:

$$P(X, a) : \mathbb{C}^{N \times N} \times \mathbb{C}^M \rightarrow \mathbb{C}^{N \times N}, \quad (2)$$

$$P(X, a) = \sum_{m=1}^M a_m X^m, \quad (3)$$

and

$$P(X, b) : \mathbb{C}^{N \times N} \times \mathbb{C}^K \rightarrow \mathbb{C}^{N \times N}, \quad (4)$$

$$P(X, b) = \sum_{k=1}^K b_k X^k, \quad (5)$$

where $a \in \mathbb{C}^M$ and $b \in \mathbb{C}^K$.

One can easily show that the product of these polynomials is commutative:

$$\begin{aligned} P(X, a)P(X, b) &= \left(\sum_{m=1}^M a_m X^m \right) \left(\sum_{k=1}^K b_k X^k \right) = \\ &= \sum_{m=1}^M \sum_{k=1}^K a_m b_k X^{m+k} = \\ &= \left(\sum_{k=1}^K b_k X^k \right) \left(\sum_{m=1}^M a_m X^m \right) = P(X, b)P(X, a). \end{aligned} \quad (6)$$

However, because the matrix product is non-commutative, we also have:

$$P(X, a)P(Y, b) \neq P(Y, b)P(X, a), \quad (7)$$

if $X \neq Y \in \mathbb{C}^{N \times N}$ and $a \in \mathbb{C}^M, b \in \mathbb{C}^K$.

3 Key Exchange Protocol

Using the above property, the proposed key exchange protocol can be formulated as following:

1. Alice chooses the secret vectors $a \in \mathbb{C}^{M_1}$ and $\tilde{a} \in \mathbb{C}^{M_2}$ (Alice's private key).
2. Alice randomly generates and publishes the matrix $U \in \mathbb{C}^{N \times N}$ (Alice's matrix public key).
3. Bob chooses the secret vectors $b \in \mathbb{C}^{J_1}$ and $\tilde{b} \in \mathbb{C}^{J_2}$ (Bob's private key).
4. Bob randomly generates and publishes the matrix $V \in \mathbb{C}^{N \times N}$ (Bob's matrix public key).
5. Alice computes and publishes the matrix $A = P(U, a)P(V, \tilde{a})$ (Alice's public key).
6. Bob computes and publishes the matrix $B = P(U, b)P(V, \tilde{b})$ (Bob's public key).
7. Alice calculates the secret matrix $S_a = P(U, a)BP(V, \tilde{a})$ (Alice's secret key).
8. Bob calculates the secret matrix $S_b = P(U, b)AP(V, \tilde{b})$ (Bob's secret key).

One can see that both Alice and Bob obtain the same secret key $S \equiv S_a = S_b$, since the matrix polynomials satisfy the commutativity property. Also we assume that we always have $U \neq V$.

Assuming that the eavesdropper Eve knows U, V and A, B , the hard problem is to compute S , which requires the unknown private key vectors a, \tilde{a} or b, \tilde{b} . We should note that the number of elements (M_1, M_2, J_1, J_2) in these vectors is also unknown.

One may attempt to find these quantities directly from A and B . For example we have:

$$A = \sum_{m=1}^{M_1} \sum_{n=1}^{M_2} a_m \tilde{a}_n U^m V^n = \sum_{k=1}^K \alpha_k \Psi^{(k)}. \quad (8)$$

Thus, we obtain a system of equations, $\Psi\alpha = A$, with the unknown $\alpha_k = a_m \tilde{a}_n$, $k \equiv (m, n)$. The columns of the matrix Ψ , $\Psi^{(k)} = U^m V^n$, and the matrix A are written as vectors by stacking their constituent columns. In total there are $K = M_1 M_2$ columns in Ψ , and each column has N^2 elements. Therefore, the resulted system is badly underdetermined if $M_1, M_2 \gg N$. Thus, we should consider that $M_1, M_2, J_1, J_2 \gg N$, in order to increase the security.

4 Practical Implementation Aspects

The goal of this section is to discuss some practical aspects regarding the numerical implementation of the proposed matrix public key cryptosystem. We choose the C language for implementation, and the standard GCC compiler on a desktop running Ubuntu 14.04 LTS. We focus only on building a simulation environment, where we can test the functionality of the algorithms. The code is listed in the Appendix 1, and here we provide a detailed discussion of its main components. The required compilation and run steps are:

```
gcc -O3 -lm keys.c -o keys
./keys > results.txt
```

The program starts by setting the size of the required square matrices. We choose the size value $N = 4$, which means that all the matrices will contain $NN = N*N = 16$ double precision complex numbers. This value of N is enough to obtain a secret key with the length $K = NN*8 = 128$ bytes.

Since this is a simulation only, we choose also to use the standard random number generator from `C`, `rand()`, in order to initialize the variables in the problem. Of course in a real application `rand()` is a poor choice, and should be avoided, however our goal here is to simply show that the proposed algorithm works. For a secure implementation one can use successive applications of secure hash functions (`sha256`), or secure ciphers (`AES`), to generate the required pseudo-random numbers.

The private keys, $a, \tilde{a}, b, \tilde{b}$, are stored in the byte arrays `a`, `aa`, `b`, `bb`, and they are generated with the `private_key(...)` function. The private keys are stored as byte arrays of length `M1*16`, `M2*16`, `J1*16`, `J2*16`. Longer private keys will provide a better security. For simulation purposes, the `M1`, `M2`, `J1`, `J2` values are randomly generated in the range `[NN, 2*NN-1]`, such that the condition $M_1, M_2, J_1, J_2 \gg N$ is marginally satisfied (one can make them much longer if necessary).

Each double precision complex number needs `16 bytes` to store it. The real and imaginary part of the complex numbers are generated with the `drand()` function. This function is designed to generate “dense” double precision random numbers in the `(0, 1)` interval. For each decimal in the mantissa, we use a separate `rand()` call, until the precision gets below $2 \cdot 10^{-16}$, which is the machine epsilon for double precision numbers.

The matrix public keys, U and V , are stored in the byte arrays `U` and `V`, and are generated with the `matrix_public_key(...)` function. Each array holds `NN` double precision complex numbers in `NN*16 bytes`, using the same approach described above for the `private_key(...)` function.

The public keys, A and B , are stored in the byte arrays `A` and `B`, and are generated with the `public_key(...)` function. Since these are also double precision complex matrices with the size `NN`, they will need `NN*16 bytes` of storage.

The power matrices U^m are also normalized as following:

$$\|U^m\|_F^{-1} U^m \leftarrow U^m, \quad (9)$$

where $\|\cdot\|_F$ is the Frobenius norm. Thus, all the polynomials are rewritten as:

$$P(U, a) = \sum_{m=1}^M a_m \|U^m\|_F^{-1} U^m, \quad (10)$$

This way, the elements of the power matrices will be in the same “range”, while the polynomial commuting properties described before are preserved. Also, since the order U, V or V, U cannot be specified exactly, we made the convention that if the first element of U is smaller than the first element of V , then the order U, V is switched to V, U . This makes irrelevant the order in which the arguments, U and V , are passed to the functions.

The secret keys, S_a and S_b , are stored in the byte arrays `Sa` and `Sb` with a length `K = NN*4`, and they are computed with the `secret_key(...)` function. The secret keys are extracted from the matrices S_a and S_b , each containing `NN` elements. The computation of these matrices is affected by rounding errors, due to the finite floating point number representation, and inherently will lead to $S_a \neq S_b$, which of course is undesirable. In order to counter the accumulation of the floating point rounding errors, we extract the significand of each double precision number, and from the significand we extract a `4 byte` unsigned integer (see the code for more details). Thus, from each double precision complex number we extract two unsigned integers in the range `[0, 232 - 1]`. The `128 bytes` corresponding to these `32` integers form the secret keys, and are stored into the byte arrays `Sa` and `Sb`.

For illustration purposes, the results obtained for one instance run are given in Appendix 2. One can see that both Alice and Bob compute the same secret key (`Sa = Sb`), using completely different secret and public keys.

5 Conclusion

In conclusion, we have presented a matrix public key cryptosystem, which avoids the cumbersome key generation of the traditional number theory approach. The key exchange mechanism is ensured by the commutative property of the product of two matrix polynomials. Also, we have provided a detailed description of this encoding mechanism, and a practical numerical implementation.
