## Abstract

We developed a dual-linear-polarization HEMT (High Electron Mobility Transistor) amplifier receiver system of the 45-GHz band (hereafter Z45), and installed it in the Nobeyama 45-m radio telescope. The receiver system is designed to conduct polariza-

tion observations by taking the cross correlation of two linearly-polarized components, from which we process full-Stokes spectroscopy. We aim to measure the magnetic field strength through the Zeeman effect of the emission line of CCS ( $J_N = 4_3 - 3_2$ ) toward pre-protostellar cores. A linear-polarization receiver system has a smaller contribution of instrumental polarization components to the Stokes  $V$  spectra than that of the circular polarization system, so that it is easier to obtain the Stokes  $V$  spectra. The receiver has an RF frequency of 42 – 46 GHz and an intermediate frequency (IF) band of 4–8 GHz. The typical noise temperature is about 50 K, and the system noise temperature ranges from 100 K to 150K over the frequency of 42 – 46 GHz. The receiver system is connected to two spectrometers, SAM45 and PolariS. SAM45 is a highly flexible FX-type digital spectrometer with a finest frequency resolution of 3.81 kHz. PolariS is a newly-developed digital spectrometer with a finest frequency resolution of 60 Hz, having a capability to process the full-Stokes spectroscopy. The Half Power Beam Width (HPBW) of the beam was measured to be 37'' at 43 GHz. The main beam efficiency of the Gaussian main beam was derived to be 0.72 at 43 GHz. The SiO maser observations show that the beam pattern is reasonably round at about 10 % of the peak intensity and the side-lobe level was less than 3 % of the peak intensity. Finally, we present some examples of astronomical observations using Z45.

## 1. Introduction

The NRO 45-m radio telescope is one of the world largest millimeter-wave single-dish telescopes operated by the Nobeyama Radio Observatory (NRO) and located near the Yatsugatake mountains on the border of Nagano Prefecture and Yamanashi Prefecture in Japan. The observatory's longitude, latitude, and altitude are  $138^\circ 28' 13''$  (E),  $35^\circ 56' 27''$  (N), and 1349-m, respectively. The telescope is equipped with various receivers for observations at frequencies ranging from 20 GHz to 116 GHz, and used for various research fields such as star and planet formation, astrochemistry, and evolution of galaxies. However, no receivers that can conduct polarization observations are available at present. To open a new science window of polarization observations at millimeter wavelengths using the NRO 45-m telescope, we developed a 40 GHz ( $\approx 7$  mm) band, dual-polarization receiver. The dual-polarization receiver also has an advantage even for standard molecular line observations; by observing two orthogonal polarized components simultaneously, the signal-to-noise ratio can be improved by a factor of  $\sqrt{2}$  with the same observation time.

Magnetic fields are thought to play an important role in star formation (Shu et al. 1987). However, the role of magnetic field in star formation process remains controversial (Crutcher et al. 2010; Crutcher 2012). This is in part due to the difficulty of measuring the magnetic field strengths in molecular clouds. Previous Zeeman observations toward star-forming regions have been conducted mainly at low frequencies using H I and OH lines (e.g., Crutcher et al. 1993; Heiles & Troland

2004). These observations aim to measure the strengths of line-of-sight magnetic fields associated with interstellar clouds from the Stokes  $V$  spectra. Strong lines like OH ( $\approx 1.6$  GHz) and H<sub>2</sub>O masers ( $\approx 22$  GHz) have also been used for the Zeeman observations (e.g., Fiebig & Güsten 1989). These maser lines are thought to arise from the compact dense spots created by shocks near protostars. However, very few observations on molecules that probe dense molecular gas have been carried out so far (Crutcher et al. 1999; Falgarone et al. 2008). This is because among the molecules that have rotational transition lines with critical densities of  $10^4$  cm<sup>-3</sup>, there are only a few molecules that have large magnetic dipole moments to show observable Zeeman splitting, e.g., CN, CCS, and SO. Crutcher et al. (1999) measured the Zeeman effect of the CN ( $N = 1 - 0$ ) lines at 113 GHz. CN lines have critical densities of  $10^5$  cm<sup>-3</sup> and thus is the suitable tracer to detect dense gas. The Zeeman observations at higher frequencies like 100 GHz are challenging because the Zeeman splitting is often smeared by the line broadening due to internal motions. Therefore, the main targets of the CN Zeeman observations are massive star-forming regions which sometimes emit intense emission lines of CN and are expected to have stronger magnetic fields. These observations provide us important information of the magnetic fields in star-forming regions. However, the role of magnetic fields in the gravitational collapse of prestellar cores remain uncertain. To measure the strengths of magnetic fields associated with dense molecular cloud cores prior to star formation, we need other molecules that can trace the dense molecular gas and have relatively large dipole moments. One of such molecules is thioxoethenylidene radical, CCS, which is a carbon-chain molecule and known to be abundant in molecular clouds before star formation happens (Suzuki et al. 1992). CCS has a critical density of  $10^4$  cm<sup>-3</sup> and the Zeeman splitting is expected to be as large as 0.64 Hz/ $\mu$ G (Shinnaga & Yamamoto 2000), because CCS has an unpaired electron. CCS are often used as a good tracer of pre-protostellar cores and CCS emission tends to be strongest at the 40 GHz band in molecular clouds (Suzuki et al. 1992).

The 45 GHz band receivers designed to conduct the Zeeman observations are rare in the world. The Zeeman observations at the 40 GHz band can be conducted with the Very Large Array (VLA, Momjian & Sarma 2012). Since VLA is an interferometer, the spatially-extended emission is significantly filtered out. CCS emission is sometimes spatially extended, and therefore we consider that single dish telescopes have an advantage to detect CCS Zeeman splitting toward dense molecular cloud cores. The 45-GHz receiver is also useful to conduct other observations. For example, a number of carbon-chain molecules such as HC<sub>3</sub>N, HC<sub>5</sub>N and so on can often show strong emission at the 40 GHz band (Suzuki et al. 1992; Hirota & Yamamoto 2006). These molecules are abundant at early evolutionary stages of molecular clouds before star formation is initiated. Therefore, their spatial distributions give us a hint to uncover the evolutionary stages of molecular clouds and cores. Mapping observations using single dish telescopes are expected to be ideal to reveal the spatial distribution of prestellar gas in molecular clouds. Therefore, we consider it important to develop the new receiver at the 40 GHz band for the NRO 45-m telescope to do new astronomical sciences.

In the present paper, we describe the basic characteristics of the newly-developed 40-GHz

receiver system Z45 and show its performance. The detail and performance of the polarization observations is presented in a forthcoming paper of this project. Then, we describe the detail of the receiver system in Section 3. Observational results of the SiO masers from an evolved star, R-Leo, and continuum measurements of Saturn are presented in Section 4 and the size and shape of the system’s primary beam and the main beam efficiency of the antenna are derived. Then, we present in Section 5 some examples of observations of some molecular lines at the 40-GHz band. These observations show the high performance of Z45. Finally, we summarize the conclusion in Section 6.

## 2. A Primary Science Goal and Requirements

A primary science goal for the new receiver is to conduct the Zeeman measurements toward dense cores prior to star formation, i.e., pre-protostellar cores or prestellar cores in short.

### 2.1. Role of Magnetic Field in Gravitational Collapse of Prestellar Cores

The dynamical stability of a magnetized prestellar core is determined by an important parameter, mass-to-magnetic-flux ratio,  $\mu \equiv M/\Phi$  (e.g., Shu et al. 1987). If the mass-to-flux ratio is larger than the critical value  $\mu_{\text{cr}} \equiv 1/(2\pi G^{1/2})$ , the magnetic field cannot support the whole cloud against self-gravity. Such a cloud is called magnetically-supercritical and collapses dynamically to form stars. If the mass-to-flux ratio is smaller than the critical value, the magnetic field can support the cloud against self-gravity. Such a cloud is called magnetically-subcritical. A magnetically-subcritical cloud can contract quasi-statically in losing the magnetic flux due to ambipolar diffusion. When the central dense part of the subcritical core becomes magnetically-supercritical, it collapses dynamically to form stars (e.g., Nakamura & Li 2003). Thus, the evolution of the magnetized cores is controlled by magnetic field strength. In this project, we aim to measure the strengths of the magnetic field associated with prestellar cores through the Zeeman measurements and constrain the role of magnetic field in the dynamical evolution of the cores.

### 2.2. Zeeman Measurements with CCS

The Zeeman effect can be observed as the splitting of a spectral line into several components in the presence of a magnetic field. Since the displacement between the separated components can be given as a function of the magnetic field strength, the Zeeman observations allow us to measure the magnetic field strength directly. However, the detection of the Zeeman splitting toward prestellar cores is challenging because the interstellar magnetic field is subtle and the splitting frequency interval is narrow, often obscured by the Doppler broadening due to internal motions of the cores. To detect the Zeeman splitting, we need spectral lines that have large magnetic dipole moments. The low frequency lines have advantage to distinguish between the Zeeman splitting and the Doppler broadening. Hence, the previous Zeeman measurements have been carried out mainly with low-frequency HI and OH lines ( $\approx 1 - 2$  GHz), or the strong maser lines. However, the HI and OH lines can trace only low density gas of  $\lesssim 10^2 - 10^3 \text{ cm}^{-3}$ . On the other hand, the maser lines can trace only the high density, high

temperature spots near the stars. In other words, our knowledge of the magnetic fields associated with dense molecular gas remains limited. Recently, Falgarone et al. (2008) have successfully detected CN Zeeman splitting at a 100 GHz band. CN is one of the dense molecular gas tracers with a high critical density of  $\approx 10^5 \text{ cm}^{-3}$ . The target clouds are, however, strongly biased toward massive-star-forming regions or protostellar cores that have strong CN emission. To understand the role of magnetic fields in initiating the gravitational collapse of the cores, it is important to measure the magnetic field of the cores that do not contain any stars yet, i.e., prestellar cores.

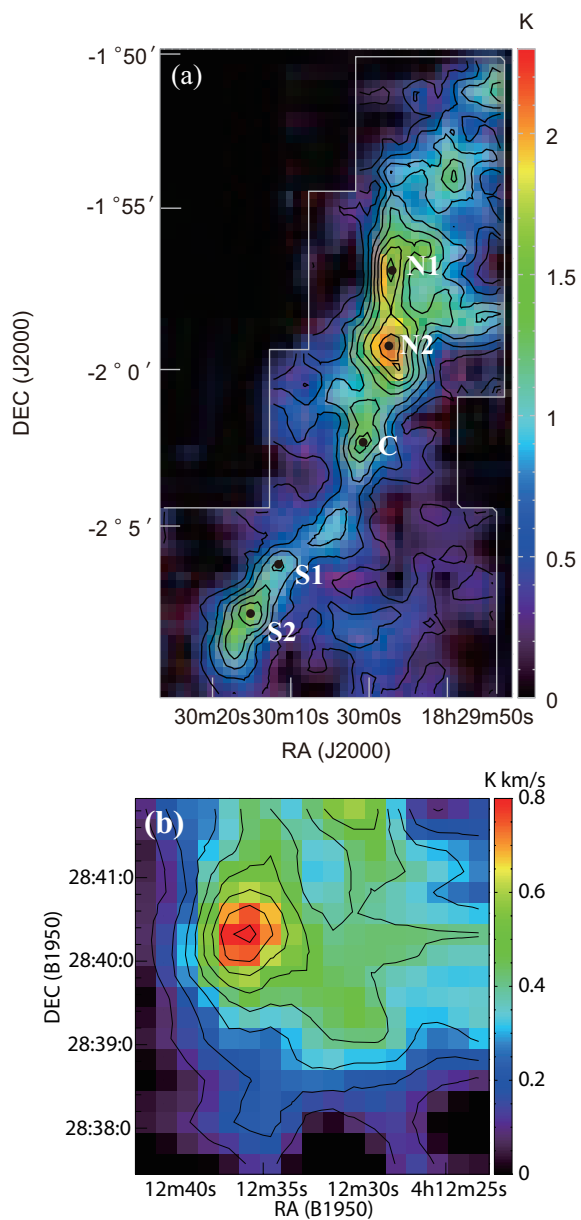

One of the good tracers of high-density molecular gas in prestellar phase is thioxoethenylidene radical, CCS, which is abundant in the early phase of core evolution prior to the protostellar formation. CCS also has a high Zeeman splitting factor of its GHz transitions ( $\approx 0.629 \text{ Hz } \mu\text{G}^{-1}$  for  $J_N = 4_3 - 3_2$  transition, Shinnaga & Yamamoto 2000). In particular, the 45 GHz line is one of the strongest CCS lines in prestellar cores with temperatures of about 10 K. Even if the emission of  $J_N = 4_3 - 3_2$  (45 GHz) is relatively strong ( $\gtrsim 1 \text{ K}$ ), the emission in the 100 GHz band (e.g.,  $J_N = 8_7 - 7_6$ ) is often very weak ( $\sim 0.1 \text{ K}$ ) (see figure 1 of Wolkovitch et al. 1997). Although the 22.3 GHz CCS ( $J_N = 2_1 - 1_0$ ) line sometimes has comparable strength to that of CCS ( $J_N = 4_3 - 3_2$ ), the beam dilution effect is often significant because of the lower frequency. Therefore, the 45 GHz CCS line is likely to be most suitable for the Zeeman measurements. Until now, Shinnaga et al. (1999b) reported the tentative detection of the magnetic field of  $160 \pm 42 \mu\text{G}$  toward L1521E using the  $J_N = 4_3 - 3_2$  line ( $\approx 45 \text{ GHz}$ ), and Levin et al. (2001) reported  $48 \pm 31 \mu\text{G}$  toward L1498, using the  $J_N = 3_2 - 2_1$  line ( $\approx 33 \text{ GHz}$ ).

To shed light on the issue of the role of magnetic field in star formation, we have developed a new 40 GHz-band receiver system (hereafter Z45) for the NRO 45m telescope and started a Zeeman measurement project, in which we attempt to measure the magnetic field strength using the Zeeman splitting of CCS ( $J_N = 4_3 - 3_2$ ). It is worth noting that at a distance of nearby star forming regions like Taurus ( $\approx 140 \text{ pc}$ ), the spatial resolution of the NRO 45-m telescope at 45 GHz is 6000 AU ( $\approx 0.03 \text{ pc}$ ), which is comparable to the typical sizes of prestellar cores.

We aim to measure the line-of-sight component of the magnetic fields using the Zeeman effect that appears in Stokes  $V$  as

$$V = \frac{dI}{d\nu} \Delta\nu. \quad (1)$$

Here  $I$  is the Stokes  $I$  profile,  $\nu$  is the frequency, and  $\Delta\nu$  is the Zeeman shift. Since the Stokes  $V$  profile is proportional to the first derivative of the Stokes  $I$ , it is not significantly affected by contamination of Stokes  $I$  through polarization leakage. Since Stokes  $V$  is peaked at the both edges of Stokes  $I$  profile, we need spectroscopy with a frequency resolution finer than the width of line edges (therefore finer than the full line width by 2 orders of magnitude) to avoid spectral dilution. Linear polarization (Stokes  $Q$  and  $U$ ) caused by the Zeeman effect responses to the magnetic field component perpendicular to the line of sight and is proportional to the second derivative of Stokes  $I$ ,  $d^2I/d\nu^2$  (Crutcher et al. 1993). We waive linear polarization Zeeman effect because of its hard

**Fig. 1.** (a) Integrated intensity map of CCS ( $J_N = 4_3 - 3_2$ ) toward Serpens South. The contours start at  $0.3 \text{ K km s}^{-1}$  with an interval of  $0.3 \text{ K km s}^{-1}$ . See Nakamura et al. (2014) for details. (b) Integrated intensity map of CCS toward L1495B. The velocity range is  $6 - 9 \text{ km s}^{-1}$ . detectability.

Several previous attempts to detect the CCS Zeeman splitting have been done, although no clear detection has been reported so far (Shinnaga et al. 1999b, Levin et al. 2001). In these previous measurements, the circularly-polarized components were measured directly with the dual circular-polarization receivers (Shinnaga et al. 1999a, Levin et al. 2001), for which careful polarization calibration is crucial to separate the instrumental polarization components from the obtained signals. Here, we developed a dual linear-polarization receiver system for which the contribution of instrumental polarization components to the Stokes  $V$  spectrum is small, compared to the circular polarization system (e.g., Heiles et al. 2001, 2004). Such system has been used for HI and OH Zeeman observations at the Arecibo telescope (Heiles et al. 2001, Heiles et al. 2004) and detected the Zeeman splitting of HI and OH successfully.

### 2.3. System Requirements of the Receiver

Our primary goal is to detect the Zeeman splitting of the CCS emission line at 45.3 GHz with a concrete significance ( $> 5\sigma$ ) under the magnetic fields of  $\sim 100 \mu\text{G}$ . This introduces the science requirement to measure the Stokes  $V$  spectrum caused by the Zeeman splitting of 64 Hz. Our pilot observation toward TMC-1 showed the line edge profile of

$$\frac{dI}{d\nu} = 0.16 \text{ mK Hz}^{-1} \quad (2)$$

over  $\sim 20 \text{ kHz}$  that yields the Stokes  $V$  of 10 mK while Stokes  $I \simeq 2.5 \text{ K}$  (Kameno et al. 2014; Mizuno et al. 2014). To detect it within on-source time of 100 ks, the system noise must meet

$$T_{\text{sys}} < \left( \frac{10 \text{ mK}}{\text{SNR} = 5} \right) \sqrt{2 \times 20 \text{ kHz} \times 100 \text{ ks}} = 126 \text{ K}. \quad (3)$$

Therefore, we defined the system requirements of the receiver as:

1. Dual polarization capability to measure Stokes  $V$  together with Stokes  $I$ .
2. Systematic error of Stokes  $V$ ,  $\Delta V$ , must meet

$$\frac{\Delta V}{I} < 8 \times 10^{-4}. \quad (4)$$

3. The frequency fluctuation,  $\Delta\nu$ , should not be greater than 1/10 of expected Zeeman shift of 64 Hz, or the frequency stability of  $\Delta\nu/\nu < 1.3 \times 10^{-10}$  during typical observing time of 8 hours.
4. The system noise temperature should be below 126 K at 45.3 GHz. Since the beam propagation optics of the Nobeyama 45-m telescope adds noise temperature of 30 – 40 K, the receiver noise temperature must be as low as 50 K.

We examined which of linear or circular polarization reception is suitable to meet the system requirements, and concluded to adopt linear polarization system by following reasons.

In the linear polarization system, the transfer function of Stokes  $V$  is described as

$$V = \text{Im} \frac{\langle XY^* \rangle}{G_X G_Y^*}, \quad (5)$$

where  $X$  and  $Y$  stand for two orthogonal linear polarization components and  $G_X, G_Y$  are the voltage-domain complex gain of the receiving system. It is remarkable that parallel-hand correlations of  $\langle XX^* \rangle$  and  $\langle YY^* \rangle$  do not responses to Stokes  $V$ . Since receiver noise and atmospheric radiation do not correlate between  $X$  and  $Y$ , fluctuation of receiver gain or atmosphere will not cause significant systematic errors. The systematic error in Stokes  $V$  is caused by calibration error of relative phase between  $G_X$  and  $G_Y$  (hereafter,  $XY$  phase) and the real part of  $\langle XX^* \rangle$  that origins linear polarization of the target source or instrumental polarization. When we have the  $XY$  phase calibration error of  $\Delta\phi$  and linear polarization component of Stokes  $Q$  and  $U$ , the systematic error in Stokes  $V$ ,  $\Delta V$ , will appear as

$$\Delta V = ((D_X + D_Y^*)I + U \cos 2\psi - Q \sin 2\psi) \sin \Delta\phi, \quad (6)$$

where  $D_X$  and  $D_Y$  (D-terms) are voltage-based cross talk between  $X$  and  $Y$  polarization and  $\psi$  is

the parallactic angle. We got a perspective to achieve the required accuracy of  $\Delta V/I < 8 \times 10^{-4}$  by calibrating D-terms and  $XY$  phase with required accuracies of 0.01 and 0.01 rad, respectively.

For circular polarization system, the transfer function is

$$V = \frac{\langle RR^* \rangle}{G_R G_R^*} - \frac{\langle LL^* \rangle}{G_L G_L^*}, \quad (7)$$

where  $R$  and  $L$  stand for right-hand and left-hand circular polarization components, respectively. Since parallel-hand correlations directly response to Stokes  $V$ , calibration error in gain factor directly contributes to systematic error of Stokes  $V$ . We are not confident of calibrating the differential gain,  $\Delta|G_R - G_L|$ , with the required accuracy of  $8 \times 10^{-4}$  in single-dish observations where source emission is affected by time fluctuation of atmospheric attenuation and radiation.

To measure Stokes  $V$  with a linear-polarization system, a cross-correlation spectrometer is necessary to acquire  $\langle XY^* \rangle$ . Recent advances in digital signal processors allowed us to build a software-based polarization spectrometer, PolariS, with a reasonable cost (Mizuno et al. 2014). Installation of PolariS yields not only Stokes  $V$  but also full-Stokes polarimetry.

In order to keep coherence between two polarization signals and frequency stability, all of the LO signals should refer to a common hydrogen-maser frequency standard. The 1st LO signal should be shared in two polarizations to avoid difference of frequency. To maintain the frequency stability throughout the signal path, we employed the VLBI backend including IF transmitter, IF downconverter, baseband converter, and digitizer. Since calibration of  $XY$  phase is crucial for accuracy in Stokes  $V$ , a phase calibration unit composed by a wire grid should be equipped in front of the receiver feed to deliver linearly polarized in-phase waves into  $X$  and  $Y$ .

#### 2.4. Target Prestellar Cores

Since the Zeeman splitting of prestellar cores is expected to be subtle, careful target selection is also important. Target cores should have strong peak intensities and narrow line widths.

The critical magnetic field strength for the dynamical stability is about  $100 \mu\text{G}$  for cloud cores with densities of  $10^4 \text{ cm}^{-3}$ . This causes the splitting of about 60 Hz for the CCS ( $J_N = 4_3 - 3_2$ ) line. The typical velocity width of prestellar cores is about  $0.5 \text{ km s}^{-1}$  or less ( $\Delta V \lesssim 0.5 \text{ km s}^{-1} \approx 76 \text{ kHz}$  at 45 GHz). In nearby star-forming regions such as Taurus, several prestellar cores have strong CCS emission whose peak antenna intensity is greater than 1 K ( $T_{\text{A,peak}}^* \gtrsim 1 \text{ K}$ ). To detect the magnetic field of  $100 \mu\text{G}$  within about 30 hours, the target cores should satisfy the following two criteria: (1) the peak intensity should be stronger than 1 K in the antenna temperature scale, and (2) the line width should be as narrow as  $0.5 \text{ km s}^{-1}$ , or the line profile should have steep envelopes so that fitting of the Stokes  $V$  spectra, the first derivative of the Stokes  $I$  spectra, is easier. We note that we apply the Smoothed Bandpass Calibration (SBC) method developed by Yamaki et al. (2012) for the Zeeman observations. The SBC allows us to reduce the total observation time by a factor of a few.

Some properties of several target cores that meet the above criteria are listed in table 1. The positions of the cores in Serpens South and L1495B are shown in figures 1 (a) and 1 (b), respectively.

The CCS peak position of L1495B appears not to be accurate from the observations of Hirota et al. (2004) because of coarse grid. Therefore, we observed L1495B using the existing 40-GHz receiver S40 and spectrometer AC in an on-the-fly mode, and determined the position. The central dense part of L1495B appears round but the envelope has a large asymmetry. The positions of the cores in Serpens South is determined from the CCS integrate intensity map presented by Nakamura et al. (2014). These cores are our targets of Zeeman measurements.

### 2.5. *Other Sciences*

Using the new receiver system, other scientific observations are also feasible. For example, SiO masers from evolved stars or star-forming regions often show strongly-polarized emission (Herpin et al. 2006). The Stokes parameters derived from the masers give a clue to understand the magnetic field structure in the ambient gas around the objects. Since the SiO masers from evolved stars are often strong, it is possible to derive full-Stokes spectroscopy from the observed emission. The CH<sub>3</sub>OH ( $\approx 44.1$  GHz) maser lines also show the Zeeman effect, which is recently detected toward OMC-2 (Sarma & Momjian 2011). Our receiver has a capability to detect the Zeeman effect of this CH<sub>3</sub>OH line. The CH<sub>3</sub>OH maser lines arise from shocks in the protostellar outflows, and thus we can gain information of the magnetic fields associated with the gas shocked by the protostellar outflows. We can also obtain information of the magnetic field structures around the AGN jets. CO ( $J = 3 - 2$ ) line from high redshift galaxies can fall into this band, and if detected, we can derive the redshifts of high-z galaxies accurately.

## 3. Development

To conduct the Zeeman observations, we developed a new 40 GHz receiver of dual polarization. In the following, we describe the details of the receiver, focusing on optics, horn, and OMT (Ortho-Mode Transducer).

### 3.1. *Optics and Horn*

The NRO 45-m telescope adopts a beam-guide antenna design. The optics of the telescope is briefly described in figure 1 and table 1 of Nakajima et al. (2008).

To install the new receiver system in the NRO 45-m telescope, we developed a plane mirror, an ellipsoidal mirror, and a corrugated horn. We used the Gaussian optics to design the optics for the new receiver. Here, we focus on optics of the new receiver.

Using the GRASP9 software, we simulated the beam pattern with the physical optics. Assuming the edge taper levels of the sub-reflector and mirrors to be  $-12$  dB and  $-34$  dB, respectively, we designed the new optics based on the Gaussian beam propagation. We did not take into account the effects of blocking by the sub-reflector stays, surface errors of mirrors, and ohmic loss of the optical elements. In the GRASP9 calculations, we assigned the optical components such as the horn and mirrors in the virtual three-dimensional space, and divided their surfaces into small el-

**Fig. 2.** (a) Optics and the beam propagation design of the NRO 45-m telescope. PM and EM denote the plane and ellipsoidal mirrors, respectively. The developed 40-GHz band receiver system enclosed with the red box is installed in the receiver cabin. A signal from astronomical object focused by a Cassegrain system is reflected by a plane mirror, M1, and is led to a receiver system by a pair of mirrors (M2 and M3). (b) Blow-up of the red box in Fig.2a.

ements. Then, we calculated the electric fields at the elements on the horn surface by numerically solving Maxwell's equations, and repeatedly calculated the electric fields on the surface of the next optical component so that we obtained the electric field of the designed optical system.

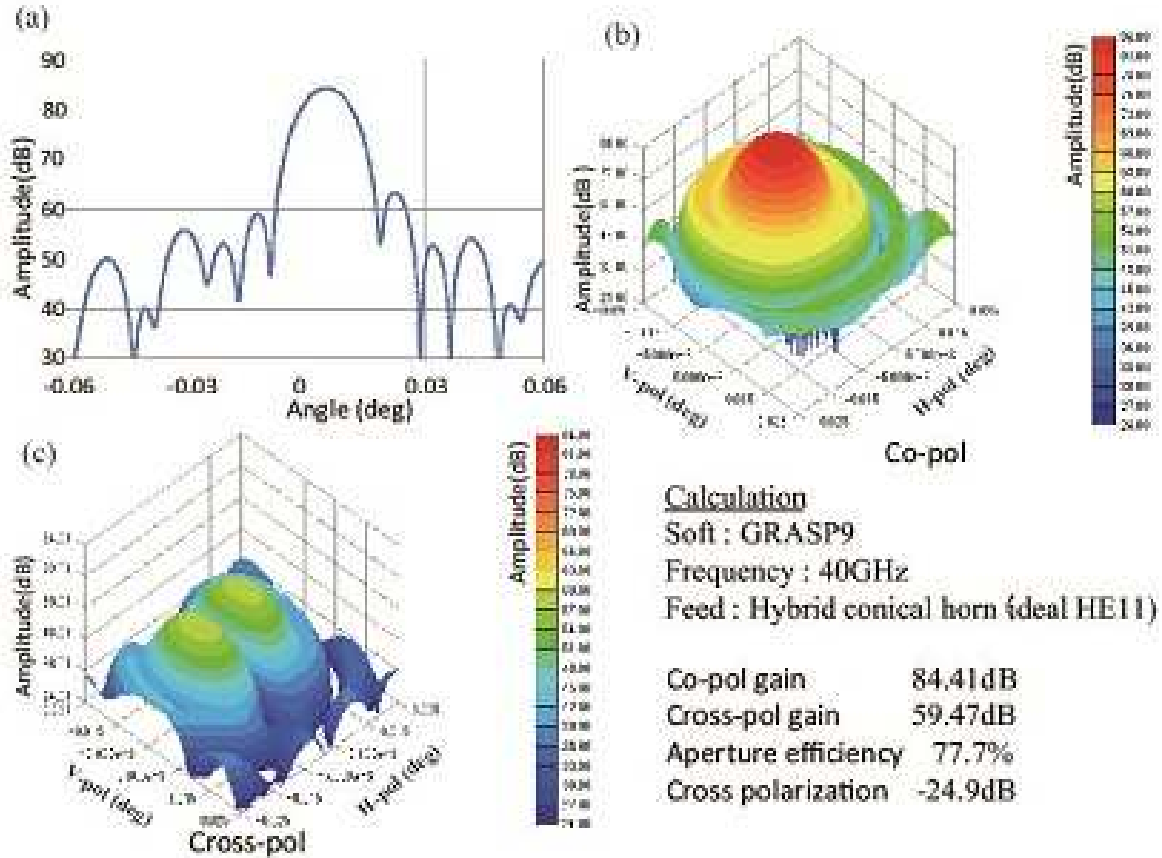

In figure 2, we show the design of the beam propagation of our developed system at 40 GHz. We also assumed the feed to be a hybrid conical horn (ideal HE<sub>11</sub>) in the simulations, because we designed the corrugated horn to have the beam pattern comparable to that of a hybrid conical horn. We have reduced the spillover loss by increasing the size of the mirrors as large as possible. In addition, we tried to minimize the beam bend angle at the ellipsoidal mirror in order to reduce the effect of the cross polarization coupling. Figure 3 shows the results of the simulations. The parameters of the Gaussian optics used for the simulation are summarized in table 2. The cross-polarization characteristics was computed to be  $-24.9$  dB. The co-polarization and cross-polarization gains were estimated to be  $84.4$  dB and  $59.5$  dB, respectively. An antenna directivity was estimated to be  $84.4$  dB, corresponding to an aperture efficiency of 0.78 for the NRO 45-m telescope. The first side-lobe level was calculated to be  $-20$  dB.

Corrugated horns are widely used as a feed horn for microwave antenna systems. This is because of their superb radiation performance. In particular, their high co-polar pattern symmetry and low cross polarization are best in our polarization observations. We repeatedly calculated a suitable corrugation pattern from the basic design using CHAMP and finally determined the design presented in figure 4. The physical dimensions of the corrugated horn are presented in table 3. In figure 5 we also present the photographs of the developed corrugated horn. The width of the grooves is 1.09 mm and the total number of grooves is 43. According to our calculation, a return loss was estimated to be at most 25 dB. A maximum cross polarization level lower than  $-35$  dB from the peak were achieved (figure 6). The simulated characteristics of the horn are presented in Fig. 6 which shows the similarity

**Table 2.** Parameters of the Gaussian optics used for the simulation. The dimensions are given in mm, otherwise indicated.

The subscript SR means sub-reflector.

**Fig. 3.** (a) Simulated beam pattern at 40 GHz on the V-polarization plane, measured when the elevation is equal to  $90^\circ$ . The horizontal axis corresponds to the angle measured from the vertical direction of the V-polarization plane. Note that the 45-m optical system has an offset of  $1.06585^\circ$  from the Cassegrain focus axis and thus the beam pattern has a peak slightly offset from angle= $0^\circ$ . (b) Bird's eye view of the simulated beam pattern and (c) Bird's eye view of the cross-polarization pattern. H-pol and V-pol denote the horizontal and vertical polarization directions, respectively. We used the GRASP9 physical optics software to design the optics assuming that the elevation of the telescope is equal to  $90^\circ$ .

of the beam patterns between E-plane and H-plane down to  $-20$  dB. These beam patterns are in good agreement with the theoretical beam pattern obtained by the radiation of the HE11 mode. We built the horn by the directly-dig method (Kimura et al. 2008).

### 3.2. Receiver

We have designed the cooled receiver whose schematic picture is shown in figure 7. The receiver consists of base, rotating platform, dewar, and calibration unit. The receiver is installed on the rotating platform to perform polarization calibration. It also has the calibration unit on the upper side of the receiver system. The design of the dewar is presented in figure 8. The dewar is cooled down to about 20 K. The HEMT amplifiers are connected to OMT with isolators. The specifications of the receiver system is summarized in table 4. A block diagram of the receiver system is shown in figure 9. The incoming signal is brought to a corrugated horn using plane and ellipsoidal mirrors. The

**Fig. 4.** Cutaway view of the corrugated horn

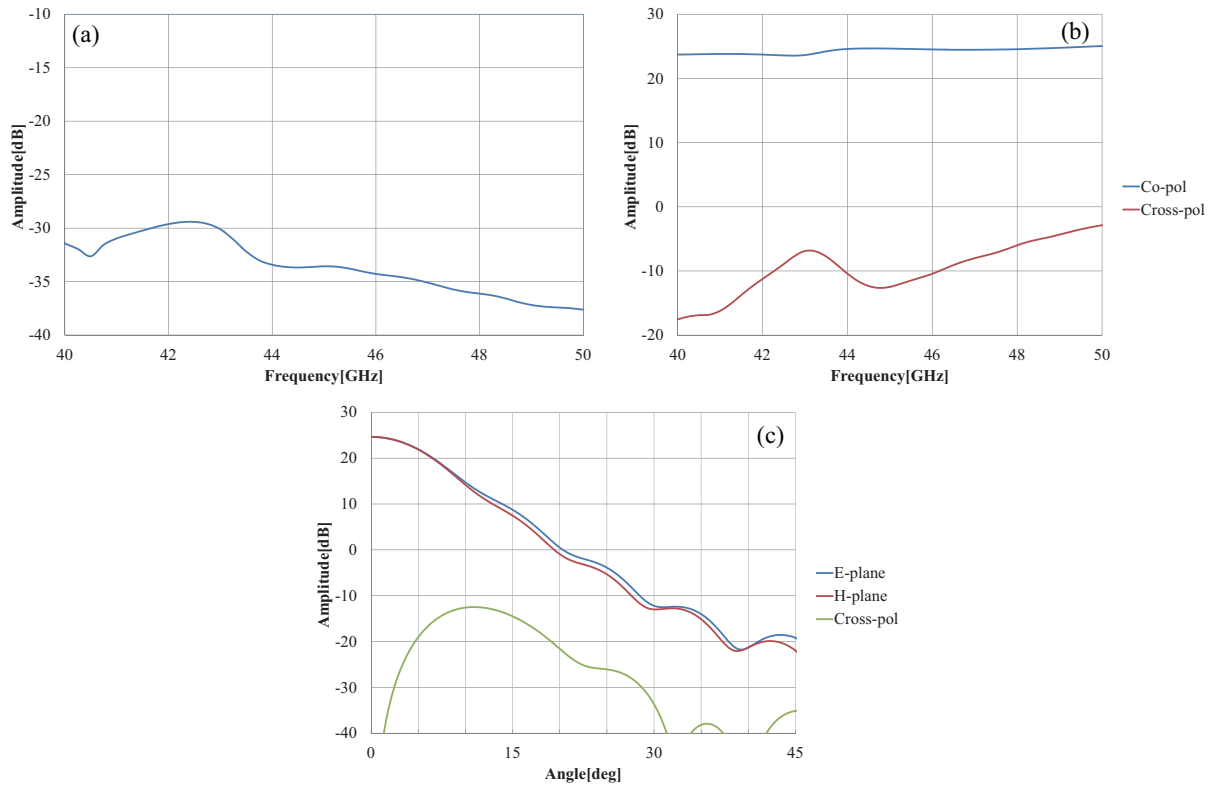

**Fig. 5.** Photographs of the developed corrugated horn

signal is split into two linearly-polarized components via OMT. Then, each component is amplified and down converted with a local signal with a frequency tripper using the upper sideband mixing scheme. The operation frequency range is from 42 to 46 GHz, which is limited by the frequency range of the local oscillator (LO) chain. IF frequency range is 4.0-8.0 GHz with a bandwidth of 4.0 GHz. The signal is amplified by a HEMT amplifier (Nitsuki 9837QC) whose noise temperature is around 29 K at 45 GHz. The HEMT amplifiers used are cryogenically-cooled InP monolithic microwave integrated circuits (MMIC's) made by AMMSys Inc, designed for the VSOP2 project, and their details are described in Nakano et al. (2012).

We adopt warm optics because of the following two reasons: (1) the limited cost of the receiver development and (2) the large contribution from the NRO 45-m beam transmission system to the total system noise temperature ( $\sim 30$  K).

**Table 3.** Physical dimensions of the corrugated horn

Material	Aluminum
Total length	115.00 mm
Length of the corrugation section	100.00 mm
Outer diameter of the aperture	58.00 mm
Inner diameter of the aperture	50.613 mm
Semi-flare angle	12.49°
Diameter of the circular waveguide	8.00 mm
Width of the grooves	1.09 mm
Depth of the grooves at the mode-launching section	2.86 mm
Depth of the grooves at the thread section	1.66 mm

**Fig. 6.** (a) Simulated return loss, (b) peak directivity as a function of frequency, and (c) beam profile of the corrugated horn at 40 GHz, as a function of angle. In panel (b), the blue and red curves denote the main-polarization and cross-polarization components, respectively. In panel (c), the blue, red, and green curves denote the E-plane, H-plane, and cross-polarization components, respectively.

**Table 4.** Specifications of the 40-GHz new receiver system

Type of receiver	HEMT
Optics system	warm
RF frequency	42–46 GHz
local oscillator	signal generator with frequency tripler
IF frequency	4–8 GHz
Polarization	dual linear polarization
Receiver noise temperature	$\sim 50$ K

The receiver system is connected to two spectrometers: SAM45 and PolariS. SAM45 is a highly flexible FX-type digital spectrometer (Kamazaki et al. 2012) having 16 sets of a 4096 channel, whose frequency resolution can reach 3.81 kHz ( $\approx 0.025$  km s<sup>-1</sup> at 45 GHz). It is used as a back end for other receivers such as H20, H40, TZ and FOREST of the NRO 45-m telescope (see Nakajima et al 2013a, 2013b for TZ and FOREST). Eight sets of SAM45 are connected to Z45: four of them are for the horizontal components, while the rest are for the vertical components.

PolariS is the software-based polarization spectrometer whose frequency resolution is 60 Hz. The PolariS consists of K5/VSSP32 digitizer by Nitsuki (Kondo et al. 2006) and a Linux-based PC with GPU. It is designed to process full-Stokes spectroscopy of  $2 \times 131072$  channels for bandwidth of 4 or 8 MHz and newly developed for our project. See Mizuno et al. (2014) for detail. SAM45 has a capability to process the full-Stokes spectroscopy, but has not been fully tested yet. Therefore, we use PolariS for our Zeeman observations.

We also designed a high pass filter that cancels out the contribution of the lower sideband. The cut off frequency, and the insertion loss of the LSB port are set to 38 GHz and 30 dB, respectively. The return loss of the USB is set to be larger than 20 dB. The details are shown in figure 10. In figure 11 we present the results of the simulation. We also measured the performance of the developed high pass filter in the lab and confirmed that the return loss and insertion loss are consistent with the simulation results.

One of the unique parts of the receiver is the calibration unit, wire grid, which is attached on the top of the optics holder (see e.g., figure 7). The wire grid is slanted off the horizontal with an angle of 27.5°. The inner diameter of the wire grid is 200 mm, so that the wire grid fully covers the beam near its waist. We mounted the wire grid unit on the top of optics holder for the calibration of polarization observations. The wire grid can be mounted and demounted by sliding up and down. The wire grid makes the incoming flux highly-polarized with a certain polarization angle with respect to the receiver, so that we can estimate the delay and phase between two linear polarizations.

The configuration diagram of the wire grid is shown in figure 12 (a). The photograph of the calibration unit in the receiver cabin is shown in figure 12 (b). The wire grid unit is demounted for the standard observations with the SAM45 spectrometer. Using the wire grid, we can make the

linearly polarized signals with polarization degree of more than 50 %. The details of the wire grid and calibration process using it are shown in a forthcoming paper (Mizuno et al. in preparation).

### 3.3. Ortho-Mode Transducer

To perform polarization observations, it is important to separate an incoming signal into two orthogonal linearly-polarized components. To do so, we developed a new double-ridged waveguide OMT for the new receiver. The design is basically similar to that of Asayama & Kamikura (2009). The OMT consists of a square double-ridged waveguide transmission followed by B $\phi$ ifot junction (Moorey et al. 2006) of two side arms with the central guide. We designed and optimized it using a 3D electromagnetic simulator (ANSYS Corporation, High Frequency Structure Simulator (HFSS) version 13.0). The designed OMT is shown in figure 13. The incoming signal is brought from

**Fig. 12.** (a) A overall view of the receiver system mounting the wire grid unit which slides down to the blue area during the actual observations. (b) Photograph of the wire grid unit

Port 1, the left edge of the OMT, and horizontal and vertical components come out of Port 3 and 2, respectively. For the Q band (40 GHz) design, a  $5.69 \times 5.69$  mm square waveguide is adopted for input and  $5.69 \times 2.84$  (WR-22) rectangular waveguides for the outputs. Frequency dependence of insertion loss, return loss, and cross-polarization coupling are shown in figure 14. We measured the performance of the developed OMT by using a network analyzer, and confirmed that the OMT has a return loss of more than 20 dB, a cross polarization coupling of lower than  $-30$  dB and an insertion loss of less than 0.3 dB across the observational frequency band.

### 3.4. Noise Temperature

To evaluate the performance of the receiver system, we measure the noise temperature by a standard Y-factor method using hot (300 K) and cold (77 K) loads in the laboratory. Figure 15 shows the measured noise temperatures for H and V polarizations as a function of the frequency. In the range of 42 to 46 GHz, the noise temperatures for both H and V polarizations are equal to about 50 K, being satisfied with the requirement of the development.

### 3.5. Installation

The receiver system was installed in the NRO 45-m telescope in March 2013 to measure its performance, and we demounted it in June 2013. After adjusting some parts in the laboratory, we reinstalled it in January 2014. The first astrophysical observations were conducted on April 2, 2013

**Fig. 13.** (a) Wire frame model of the waveguide structure. The vertical polarization (V pol.) goes through a further stepped transition. The horizontal polarization (H pol.) is split into the two side arms, and recombined by a power combiner. toward the SiO maser, T-Cep, whose coordinates are (R.A.[J2000.0], decl.[J2000.0])=(21:9:31.78, +68:29:27.2).

## 4. Performance of the New Receiver

### 4.1. System Noise Temperature

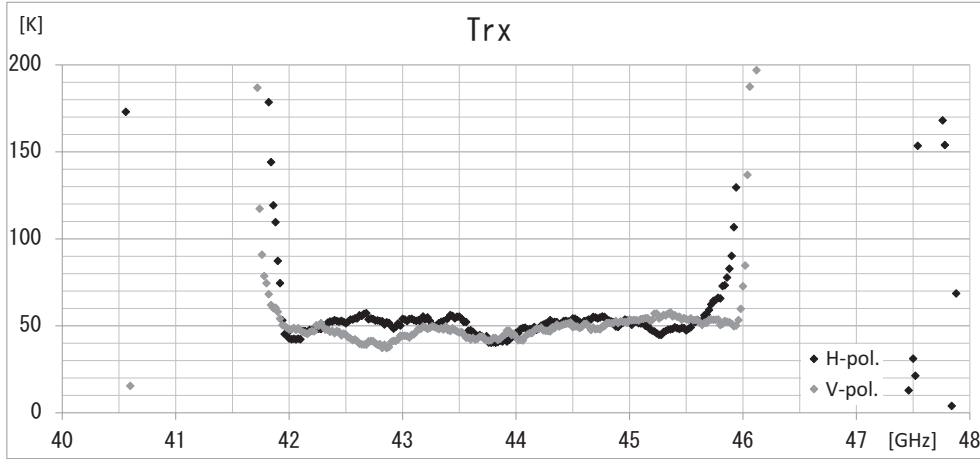

The noise temperatures of the system, including the atmosphere, were approximately 100 K at around 43 GHz for H and V polarization components at an elevation of  $60^\circ$ . The beam propagation system of the NRO 45-m telescope adds at least a noise temperature of about 30 K to the receiver system. Therefore, the measured system noise temperature is consistent with the measurement at the laboratory ( $T_{RX} \sim 50$  K). This system noise temperature is smaller than those of the current available single-polarization receivers such as S40 ( $\sim 150 - 300$  K) and H40 ( $\sim 180$  K).

### 4.2. Beam size, Main Beam Efficiency

We estimated the beam size and the main-beam efficiency of the NRO 45-m telescope based on the observations of SiO masers, and continuum observations of 3C 279 and Saturn in March 2013. To obtain the beam pattern, we mapped the SiO ( $J = 1 - 0, v = 1$ ) and SiO ( $J = 1 - 0, v = 2$ ) maser emission from an evolved star, R-Leo, in a On-The-Fly (OTF) mode. Both  $v = 1$  and  $v = 2$  lines are taken simultaneously. The coordinate of R-Leo is (R.A.[J2000.0], decl.[J2000.0]) = (09:47:33.49, +11:25:43.7). The parameters for the OTF observations are summarized in table 5. We obtained two maps, for each of which we scanned along either the Right Ascension or Declination direction, and combined them into a single map in order to reduce the scanning effects. We adopted a convolution scheme with a Gaussian function to calculate the intensity at each grid point of the final data with a spatial grid size of  $10''$ , about a fourth of the beam size. Since the SiO masers observed are very intense, the signal-to-noise ratios of the velocity-integrated intensity maps of the SiO masers is extremely high and thus sufficient to inspect the beam pattern obtained with the new receiver. In figures 16a

22  
**Fig. 14.** Simulated performance of the OMT. (a) The insertion loss, (b) return loss, and (c) cross polarization coupling of the OMT.

**Fig. 15.** Measured noise temperatures for the H and V polarizations.

and 16b, we present the velocity-integrated intensity maps of SiO maser emission from R-Leo taken with Z45 for both horizontal and vertical polarization components, respectively. The intensity is normalized to the maximum intensity. Since the SiO masers come from point sources, the intensity distribution should represent the beam pattern at 43 GHz. We show only  $v = 1$  transition emission although we take  $v = 2$  emission simultaneously. Both data show almost identical beam pattern. The beam patterns appear to be almost identical to both polarization components. The SiO intensity distributions are nearly circular above the 10% intensity level. However, at lower levels, there exists asymmetric intensity distribution below the 3% level. This level of the sidelobe is reasonably small and thus we conclude that the beam pattern is reasonably round. We note that the beam pattern shows some elongation in the northern, western, and south-east directions where asymmetric intensity distributions below the 3% level are seen. We believe that this elongation in the three directions is due to the structure of the sub-reflector stays of the NRO 45-m telescope. Similar elongation is observed in the beam patterns obtained with different receivers of the 45-m telescope (e.g., see Figure 11 of Nakajima et al. 2013a).

The half-power beam width (HPBW) of the telescope is estimated to be about  $37''$  at the frequency of 43 GHz, by fitting the emission with a two-dimensional Gaussian function. We also measure the beam sizes at various elevations summarized in table 6, and found that the dependence of beam size on elevation is very small for  $32^\circ < \text{EL} < 62^\circ$ . These measurements were done in 2014 March with images constructed with single scan data. We note that the beam size was also measured from the continuum observations of 3C 279, and the obtained HPBW is almost equal to that obtained from the SiO maser observations.

The main-beam efficiency,  $\eta_{\text{mb}}$ , was calculated to be 72% at 43 GHz, assuming that the brightness distribution of Saturn to be a uniform disk with an apparent effective radius of  $17''.4$  and a brightness temperature of 136 K (Ulich 1981). The observations of Saturn were conducted on June 9 2013. The effective diameter of Saturn was calculated as  $2 \times (\text{polar radius} \times \text{equatorial radius})^{1/2} =$

**Fig. 16.** Maps of the telescope beam constructed from SiO maser observations of R-Leo. Panel (a) and (b) are the integrated intensity of H and V-components, respectively. The contours are drawn at 0.5, 1, 2, 3, 5, 7, 10, 20, 30, 50, 70, 90 % intensity.

**Table 5.** Parameters of SiO maser observations

Observation mode	OTF
Box size	$3' \times 3'$
Time for scan	10s
Number of ONs per OFF	4
Separation between scans	$5''$
Map grid	$10''$
OFF-point separation	$-3'$ in the R.A. direction.
$T_{\text{sys}}$ (K)	200
Frequency resolution (kHz)	30.52
Convolution function	Gaussian
Observation Time	20 min

**Table 6.** Beam sizes

elevation	date and time (JST)	scan	beam size (major)	beam size (minor)	$T_{\text{sys}}$	wind speed ( $\text{m s}^{-1}$ )
$62^\circ.0$	2014 March 17 20:59	x	$38.4 \pm 0.05$	$35.6 \pm 0.06$	110	3.6
$57^\circ.3$	2014 March 17 23:33	x	$38.8 \pm 0.06$	$35.9 \pm 0.06$	110	0.5
$48^\circ.5$	2014 March 18 00:26	y	$38.4 \pm 0.06$	$36.2 \pm 0.06$	113	0.8
$44^\circ.2$	2014 March 18 00:49	x	$37.2 \pm 0.06$	$36.2 \pm 0.06$	116	0.3

$2 \times (9.''2 \times 8.''3)^{1/2}$ . The brightness temperature of 136 K was derived by the linear interpolation of the values at 31.4 GHz (133.0 K) and 90.0 GHz (149.3 K) to 43 GHz.

We have conducted similar measurements of the main-beam efficiency using Saturn and Mars in 2013, 2014, and 2015. For all the measurements except observations of Mars done on March 2014, the beam efficiency was measured as 0.7 – 0.75. The main-beam efficiency measured on March, 2014 was  $\sim 0.6$ , smaller by a factor of 1.2. A possible cause of this smaller main-beam efficiency might be the effects of snow on February, 2014 when Nobeyama was hit by terribly heavy snow. But, the actual reason remains uncertain.

## 5. Examples of Astronomical Observations

Here, we show some examples of astronomical observations using the new receiver Z45. As for polarization observations, we show their detail in a separate paper including the calibration method (Mizuno et al. in preparation). Since Z45 is a dual-polarization receiver and is connected to 8 sets of a 4096 channel spectrometer SAM45, one can obtain up to 8 molecular line emission simultaneously. The rms noise levels can be reduced by a factor of  $\sqrt{2}$  to combine H- and V-polarization components of single lines observed simultaneously into one. The typical system temperature of Z45 is less than half of the existing 40 GHz receiver S40 under the same atmospheric conditions. Thus, the observation time can be reduced significantly. To achieve the same noise level, the total observation time using Z45 is reduced by a factor of about 10 compared to S40.

### 5.1. Observations of Various Molecular Lines at 40 GHz

In figure 17, we show the results of multi-molecular line observations at 40 GHz band toward cyanopolyne peak of TMC-1 [TMC-1(CP)], whose coordinates are (R.A. [J2000], decl. [J2000]) = (04:41:42.5, 25:41':27.0"). Frequencies of observed molecular lines are listed in table 7, which are adopted from Kaifu et al. (2004).

At the 40 GHz band, CS ( $J = 1 - 0$ ) is one of the important molecular lines to especially trace the dense molecular gas. However, CS ( $J = 1 - 0$ ) and C<sup>34</sup>S ( $J = 1 - 0$ ) at frequencies of 48.990978 GHz and 48.206915 GHz are out of bandwidth and cannot be observed using Z45 for now. <sup>13</sup>CS, isotopologue of CS, at 46.247567GHz can be observed. We plan to extend the bandwidth to cover up to  $\sim 50$  GHz in future.

Observations were done in 2014 March and April. As a back end we used SAM45 with frequency resolution of 3.81 kHz, corresponding to 0.025 km s<sup>-1</sup> velocity resolution at 45 GHz. The typical system temperature during the observations was 130–160 K. We use the position offsetting ( $\Delta R.A., \Delta decl.$ ) = (30', 30') from TMC-1 (CP) as a emission free off position. We obtained CCS, HC<sub>3</sub>N, and HC<sub>5</sub>N simultaneously in 2014 March. Other lines were also obtained simultaneously in 2014 April. The telescope pointing was checked by observing a SiO maser source, NML Tau, and the typical pointing offset were within 5" during the whole observation period. The standard chopper wheel method was used to convert the output signal into the antenna temperatures ( $T_A^*$ ) and corrected

**Table 7.** Molecular lines observed toward TMC-1.

Molecule	Transition	Rest Frequency (GHz)
DC <sub>3</sub> N	$J = 5 - 4$	42.215595
HCS <sup>+</sup>	$J = 1 - 0$	42.674202
HNCO	$J_{KaKc} = 2_{02} - 1_{01} F = 3 - 2$ & $F = 2 - 1$	43.963000
CCS	$J_N=3_4 - 2_3$	43.981023
H <sup>13</sup> CCCN	$J = 5 - 4$	44.084190
H <sub>2</sub> C <sub>4</sub>	$J_{KaKc} = 5_{15} - 4_{14}$	44.471164
CC <sup>34</sup> S	$J_N=4_3 - 3_2$	44.497599
HC <sub>5</sub> N	$J = 17 - 16$	45.264721
CCS	$J_N=4_3 - 3_2$	45.379033
HC <sub>3</sub> N	$J = 5 - 4$	45.490316
CCCS	$J = 8 - 7$	46.245623
<sup>13</sup> CS	$J = 1 - 0$	46.247567

for the atmospheric attenuation. The integration time of the source is about 200–600 seconds. The achieved rms noise levels are in the range from 0.03 to 0.08 K at the velocity resolution of about 0.075 km s<sup>-1</sup>.

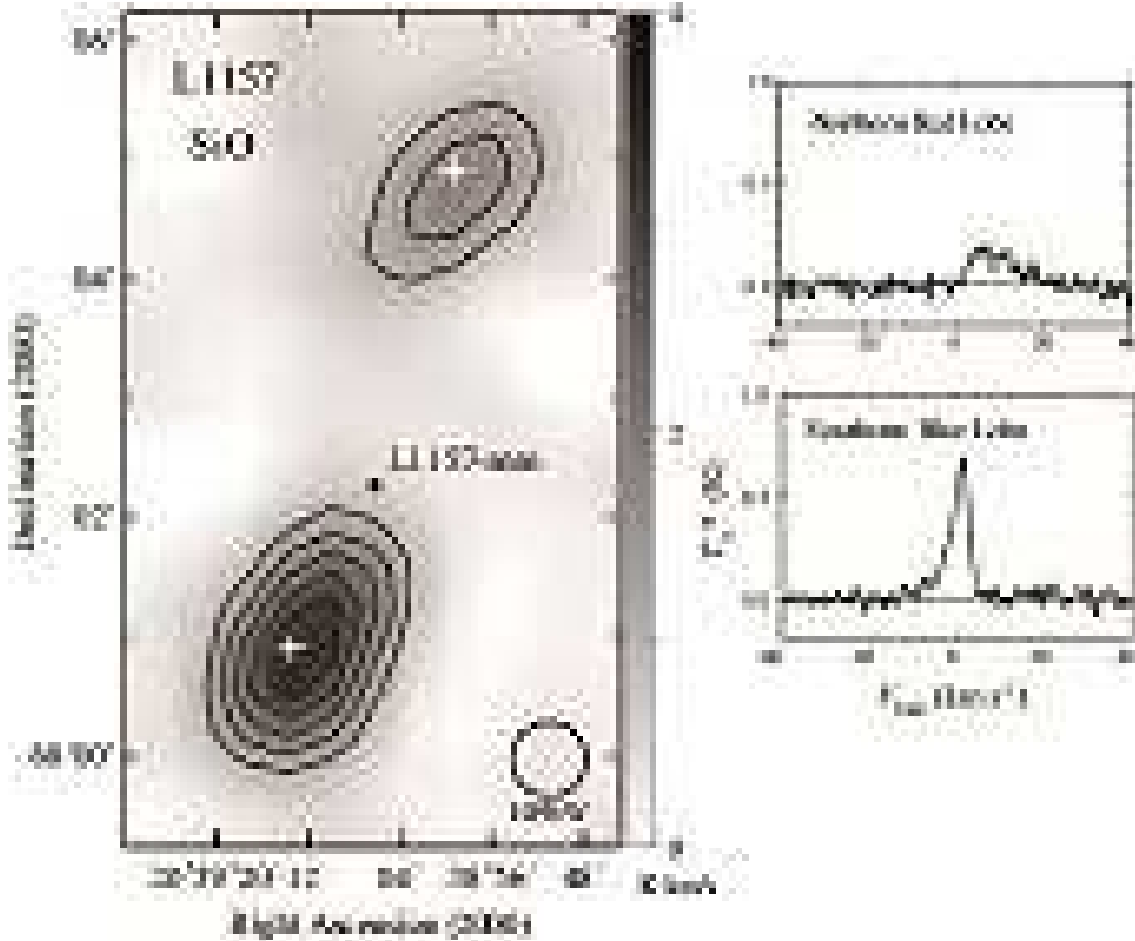

In figure 17, we show the obtained line profiles of 12 molecular lines toward TMC-1 (CP). Carbon-chain molecules such as CCS, CCCS, HC<sub>3</sub>N, and HC<sub>5</sub>N show strong emission. These molecules are known to be abundant in the early stage of prestellar evolution. Because of high sensitivity of Z45, we can also detect weak lines such as CC<sup>34</sup>S ( $J_N = 4_3 - 3_2$ ), DC<sub>3</sub>N, and H<sup>13</sup>CCCN. Using these lines, we can estimate the optical depth (e.g., CCS and CC<sup>34</sup>S) and [D/H] to understand deuterium fractionation in molecular clouds (e.g., HC<sub>3</sub>N and DC<sub>3</sub>N). We note that the CC<sup>34</sup>S, CCCS, and HCS<sup>+</sup> peak intensities shown in figure 17 are about 40, 50, and 100 % stronger than those of Kaifu et al. (2000), respectively. We suspect that this is partly due to the flux calibration problem of the back end system SAM45 (e.g., non-linearity). Similar problems were reported for other observations using with the SAM 45 backend system (e.g., Nakamura et al. 2014). Therefore, the line intensities shown here may have significant errors. For the Zeeman measurements, we use the newly-developed spectrometer, PolariS, instead of SAM45.

## 5.2. Mapping Observations

Figure 18 is an example of mapping observations toward L1157 in SiO ( $J = 1 - 0, v = 0$ ). We carried out the observations in 2014 April in the OTF mode. The coordinate of L1157 is (R.A.[J2000.0], decl.[J2000.0])= (20:39:06.19, 68d2'15.9"). We spent about 3 hours to obtain the map. We used SAM45 at frequency resolution of 3.81 kHz as a back end. The typical system temperature during the observations was 120–140 K. We use the position offset ( $\Delta$ R.A.,  $\Delta$ decl.)=(30', 30') from the L1157 position as a emission free off position. The telescope pointing was checked every 1

**Fig. 17.** Twelve molecular lines in table 7 observed toward TMC-1(CP) (RA[J2000]=04h41m42.5s and Dec[J2000]=25d41'27.0'') with the Z45 receiver. The spectra were integrated for 200-600 seconds. The achieved rms noise level was  $\Delta T_{\text{rms}} = 0.03\text{-}0.08$  K at the velocity resolution  $\Delta V \simeq 0.075$  km s<sup>-1</sup>.

**Fig. 18.** Intensity map of the SiO( $J = 1 - 0, v = 0$ ) emission line at 43.4 GHz around the outflow source L1157 integrated over the velocity range  $-10 < V_{\text{LSR}} < 20 \text{ km s}^{-1}$ . Filled circle denotes the position of the driving source L1157-mm (RA2000=20h39m06.19s, Dec2000=68d02'15.9'', Umemoto et al. 1992, Bachiller et al. 2001). Contours start from  $\int T_A^* dV = 1.0 \text{ K km s}^{-1}$  with an increment of  $0.5 \text{ K km s}^{-1}$ . HPBW of Z45 is shown in cycle at the right bottom corner. Two condensations in the north and south to the driving source correspond to the outflow lobes (Umemoto et al. 1992, Mikami 1992). SiO spectra observed in the blue lobe (sampled at 20h39m13.6s and 68°00'54'') and red lobe (20h38m59.3s and 68°04'54'') are shown in the right panels. Observed points are also indicated by the crosses.

hr by observing a SiO maser source, IRC+60427, and the typical pointing offset was within  $5''$  during the whole observation period. The standard chopper wheel method was used to convert the output signal into the antenna temperatures ( $T_A^*$ ) and corrected for the atmospheric attenuation.

L1157 is the Class 0 object which is associated with a powerful outflow (Umemoto et al. 1992, Bachiller et al. 2001). SiO( $J = 1 - 0, v = 0$ ) line can be often used to detect young outflow. Our map clearly shows the bipolar outflow from L1157-mm. The extent of the outflow lobes looks similar to the maps of higher transition SiO lines presented in Fig. 7 of Bachiller et al.(2001). We can also detect the faint redshifted lobe in northern part of L1157-mm.

Another example of mapping observations is presented in figure 1(b) and 1(c) of Nakamura et

**Table 8.** Characteristics of Z45

Type of receiver	HEMT
RF frequency	42–46 GHz
IF frequency	4–8 GHz
$T_{RX}$	$\sim 50$ K
Polarization	dual linear
back end	SAM45, PolariS
Beam size (HPBW)	37''
Beam efficiency	0.72 (43GHz)

al. (2014), who showed the CCS ( $J_N = 4_3 - 3_2$ ) and HC<sub>3</sub>N ( $J = 5 - 4$ ) integrated intensity maps of about  $10' \times 20'$  area of Serpens South infrared dark cloud (see figure 1 for CCS integrated intensity map). Nakamura et al. (2014) showed that pre-protostellar clumps in Serpens South has very strong CCS and HC<sub>3</sub>N emission. It confirms that these carbon-chain molecules are abundant in prestellar phase and suitable for searching for future star formation sites in molecular clouds. High sensitivity of Z45 allows us to carry out these large-scale mapping observations of nearby star-forming regions in reasonable amount of observational time.

## 6. Conclusions

We developed a dual-polarization HEMT receiver system in the 40-GHz band and installed in the NRO 45-m telescope. We named the new receiver Z45, which is designed to conduct Zeeman measurements of CCS ( $J_N = 4_3 - 3_2$ ). The receiver system is designed to conduct polarization observations by taking the cross correlation of two linearly-polarized components, from which we can process full-Stokes spectroscopy. A linear-polarization receiver system has a smaller contribution of instrumental polarization components to the Stokes  $V$  spectra than that of the circular polarization system, so that our system has an advantage of measuring the line-of-sight magnetic field strength, using the Stokes  $V$  spectra. Table 8 summarizes the characteristics of Z45. The typical receiver noise temperature including atmosphere is in the range from 100 K to 150 K for the frequency of 42-46 GHz. The receiver has an intermediate frequency (IF) band of 4.0–8.0 GHz. We developed ortho-mode transducer and corrugated horn. The receiver system is connected to two back ends, SAM45 and PolariS. SAM45 can be used for standard observations like a position-switch (PS) and on-the-fly (OTF) mapping observations. Zeeman measurement can be done with the PolariS spectrometer. On the basis of SiO maser observations and continuum observations of Saturn, we also measured beam size and main beam efficiency to be 37'' and 0.72 in the 43 GHz. To demonstrate the performance of the new system, we have carried out several observations such as PS and OTF observations, which demonstrate the high sensitivity of Z45 allows us to map over wider field and detect faint lines in a short time.

This work is supported in part by a Grant-in-Aid for Scientific Research of Japan (24244017) and the National Science Foundation under Grant (NSF PHY11-25915). We are grateful to the staffs at the Nobeyama Radio Observatory for operating the NRO 45-m telescope. The Nobeyama Radio Observatory is a branch of the National Astronomical Observatory of Japan, National Institutes of Natural Sciences; (<http://www.nro.nao.ac.jp/index-e.html>).
