## **ABSTRACT**

Dust grains are classically thought to form in the winds of Asymptotic Giant Branch (AGB) stars. However, nowadays there is increasing evidence for dust formation in Supernovae (SNe). In order to establish the relative importance of these two classes of stellar sources of dust it is important to know what is the fraction of freshly formed dust in SN ejecta that is able to survive the passage of the reverse shock and be injected in the interstellar medium.

With this aim, we have developed a new code, GRASH Rev, that allows to follow the dynamics of dust grains in the shocked SN ejecta and to compute the time evolution of the mass, composition and size distribution of the grains. We consider four well studied SNe in the Milky Way and Large Magellanic Cloud: SN 1987a, Cas A, the Crab Nebula, and N49. These sources have been observed with both *Spitzer* and *Herschel* and the multiwavelength data allow to better assess the mass of warm and cold dust associated with the ejecta.

For each SN, we first identify the best explosion model, using the mass and metallicity of the progenitor star, the mass of <sup>56</sup>Ni, the explosion energy and the circumstellar medium density inferred from the data. We then run a dust formation model to compute the properties of freshly formed dust (Marassi et al. 2015). Starting from these input models, GRASH Rev self-consistely follow the dynamics of the grains considering the effects of the forward and reverse shock and allows to predict the time evolution of the dust mass, composition and size distribution in the shocked and unshocked regions of the ejecta.

For all the simulated models, we find good agreement with observations. Our study suggests that SN 1987A is too young for the reverse shock to have affected the dust mass. Hence the observed dust mass of 0.7 – 0.9  $M_{\odot}$  in this source can be safely considered as indicative of the mass of freshly formed dust in SN ejecta. Conversely, in the other three SNe, the reverse shock has already destroyed between 10 and 40% of the initial dust mass. However, the largest dust mass destruction is predicted to occur between  $10^3$  and  $10^5$  yr after the explosions. Since the oldest SN in the sample has an estimated age of 4800 yr, current observations can only provide an upper limit to the mass of SN dust that will enrich the interstellar medium, the so-called effective dust yields. We find that only between 1 and 8% of the currently observed mass will survive, resulting in an average SN effective dust yield of (1.<sup>55</sup> <sup>±</sup> <sup>1</sup>.48) <sup>×</sup> <sup>10</sup><sup>−</sup><sup>2</sup> *<sup>M</sup>*. This is in good agreement with the values adopted in chemical evolution models which consider the effect of the SN reverse shock. We discuss the astrophysical implications of our results for dust enrichment in local galaxies and at high redshift.

**Key words.** Supernovae: individual: SN 1987A, Cassiopeia A, Crab Nebula, SNR N49 - Dust, extinction - Galaxy: local interstellar matter - Galaxies: high-redshift.

## **1. Introduction**

It is observationally and theoretically well established that a considerable amount of dust is efficiently formed in regions around Asymptotic Giant Branch (AGB) stars (e.g. [Weigelt et al.](#page-11-0) [2002;](#page-11-0) [Woitke 2006;](#page-11-1) [Zhukovska et al. 2008;](#page-11-2) [Olofsson et al. 2010;](#page-11-3) [Schneider et al. 2014;](#page-11-4) [Dell'Agli et al. 2015\)](#page-10-0). This process is classically considered as the primary source of dust grains in galaxies (see however Schneider et al. 2014) and in the Milky Way the typical formation timescale is  $\sim 3 \times 10^9$  yr [\(Dwek & Scalo](#page-10-1) [1980;](#page-10-1) [Gehrz 1989;](#page-10-2) [Jones & Tielens 1994\)](#page-11-5).

On the contrary, supernova (SN) explosions in the interstellar medium (ISM) trigger shock waves which are able to quickly process dust grains and are considered the dominant mechanism of dust destruction in the ISM [\(Barlow 1978a,](#page-10-3)[b;](#page-10-4) [Draine](#page-10-5) [& Salpeter 1979a](#page-10-5)[,b;](#page-10-6) [Dwek & Scalo 1980;](#page-10-1) [Seab & Shull 1983;](#page-11-6) [McKee et al. 1987;](#page-11-7) [Jones et al. 1994,](#page-11-8) [1996;](#page-11-9) Lakićević et al. [2015;](#page-11-10) [Slavin et al. 2015\)](#page-11-11). A recent theoretical work on interstellar dust destruction in shock waves led to an estimated lifetime of ~  $6 \times 10^7$  yr and ~ 3 × 10<sup>8</sup> yr for carbonaceous and silicate grains in our Galaxy, respectively (Bocchio et al. 2014), which is much shorter than the assumed dust formation timescale from AGB stars. This leads to the conclusion that a large amount of dust must be re-accreted from the gas phase. However, while there seems to be viable mechanisms for re-formation of carbonaceous grains under low temperature and pressure conditions (e.g. [Dartois et al. 2005\)](#page-10-7), silicate grains are harder to form under ISM conditions [\(Jones & Nuth 2011\)](#page-11-12).

Although SNe are believed to be efficient interstellar dust destroyers, nowadays there is increasing observational evidence for the formation of non-negligible quantities of dust grains in the ejecta of SNe (e.g. [Matsuura et al. 2009;](#page-11-13) [Dunne et al. 2009;](#page-10-8) [Gall](#page-10-9) [et al. 2011;](#page-10-9) [Gomez 2014\)](#page-11-14). Given the relatively short timescale between the explosion of two SNe (estimated to be ∼ 40 yr in our Galaxy, [Li et al. 2011\)](#page-11-15), this would lead to an effectively shorter timescale for dust formation.

Rapid dust enrichment is also required by millimeter (mm) and sub-millimeter (submm) observations of  $z > 6$  galaxies [\(Watson et al. 2015\)](#page-11-16) and quasars (see [Valiante et al. 2014](#page-11-17) and references therein), which show that their ISM has already been enriched with  $\geq 10^8 M_{\odot}$  of dust. Theoretical models and numer-

ical simulations show that these large dust masses require efficient grain growth in the dense phases of the ISM [\(Valiante et al.](#page-11-17) [2014;](#page-11-17) [Michałowski 2015;](#page-11-29) [Mancini et al. 2015\)](#page-11-30), with both SN and AGB stars providing the first seed grains [\(Valiante et al. 2011\)](#page-11-31).

One important source of uncertainty on the role of SNe as efficient dust polluters is whether the dust formed in the ejecta survives the passage of the reverse shock. In fact, the observed supernova remnants (SNR) are still relatively young (age  $\leq 5000$  yr) and the reverse shock has not reached the centre of the ejecta yet. The measured mass of dust associated to the ejecta will therefore not be entirely released into the ISM but partly destroyed.

Only in four core-collapse SNe it has been possible to estimate the amount of dust in the ejecta, using observation from Spitzer and Herschel: SN 1987A, Cassiopeia A, Crab Nebula and SNR N49. The photometer instruments on these two satellites, covering together a large range of wavelengths from Mid-Infrared (MIR) through Far-Infrared (FIR) and submm, are able to measure the emission from both cold and warm dust in SNe. However, in order to estimate the dust mass responsible for the detected emission, correct assumptions must be made on the dust composition, size and temperature distribution. Depending on the choice of the dust composition and on the size/temperature of the smallest grains, the dust mass estimate can vary by almost a factor of 6 [\(Mattsson et al. 2015\)](#page-11-32). Furthermore, emission from cold dust in the molecular cloud surrounding a SN contaminates the emission from freshly-formed dust in the ejecta and different observations (e.g. polarisation measurements) are therefore needed to disentangle the two components [\(Dunne et al. 2009\)](#page-10-8). The difficulty in determining how much emission comes from dust in the remnant and how much from the ISM was also recognised in the recent analysis of a sample of SNRs in the LMC by Lakićević et al.  $(2015)$ : while they put constraints on the influence of the remnant on the nearby ISM, the data lacked the resolution and sensitivity to study the amount of dust within the remnants themselves.

In order to estimate the dust mass which is released into the ISM after the passage of the reverse shock, a numerical code that simulates the dust dynamics and processing in SNe is needed. Using numerical simulations, [Nozawa et al.](#page-11-33) [\(2006,](#page-11-33) [2007\)](#page-11-34) estimated that, depending on the energy of the explosion and on the density of the ISM, the fraction of dust surviving the reverse shock can vary between 0 and 80 %. [Bianchi & Schneider](#page-10-13) [\(2007,](#page-10-13) BS07) estimated that depending on the density of the surrounding interstellar medium, between 2 and 20 % of the initial dust mass survives the passage of the reverse shock.

In this work we present a new code called GRASH Rev that treats dust processing in a supernova explosion. This code couples all the dust processing included in the GRASH EX code [\(Bocchio et al. 2014\)](#page-10-14) with the dynamics and structure of the SN as modelled by BS07 but extending it to include the full dynamics of dust grains within the ejecta and in the surrounding ISM.

This paper is organised as follows: in Section [2](#page-1-0) we first present the SN sample that we have considered to compare the model predictions with observational data. In Section [3](#page-2-0) we describe the corresponding SN explosion models and the properties of dust formed in their ejecta. In Section [4](#page-2-1) we present the structure of the numerical model, the grid used in the calculation, how we describe gas and dust dynamics, and the physical processes included in dust processing. In Sections [5](#page-6-0) and [6](#page-9-0) we present the main results and we discuss their astrophysical implications. Finally, in Section [7](#page-10-15) we draw our conclusions.

## <span id="page-1-0"></span>**2. Supernova sample**

We consider the four aforementioned core-collapse SNRs: SN 1987A, Cassiopeia A, Crab nebula and SNR N49. In Table [1](#page-1-1) we report some of their physical properties, as obtained from the literature: the type of SN, the explosion energy  $(E_{ex})$ , the mass of <sup>56</sup>Ni, the progenitor mass  $(M_{\text{prog}})$ , the estimated metallicity  $(Z)$ of the progenitor star, the age, the number density of the circumstellar ISM  $(n_0)$  and the measured dust mass associated with the ejecta  $(M<sub>dist</sub>)$ . Some of these quantities are directly estimated from the data, while others are obtained by comparing the observed properties with theoretical models. For example, the progenitor mass and explosion energy of SN 1987A are obtained by fitting the observed light curve and spectrum with a theoretical model [\(Nomoto et al. 1994,](#page-11-35) [2006\)](#page-11-36). Similarly, the mass of <sup>56</sup>Ni is estimated from comparison between theoretical and observed light curves. The uncertainties / approximations of the models are encoded in the final estimates of these physical quantities.

#### 2.1. SN 1987A

SN 1987A is a young SN located in the Large Magellanic Cloud (LMC) and exploded in 1987. Observational data in Table [1](#page-1-1) are from [Gomez](#page-11-37) [\(2013\)](#page-11-37) and references therein. The dust mass estimate has been updated following the recent work by [Matsuura](#page-11-38) [et al.](#page-11-38) [\(2015\)](#page-11-38), leading to a total dust mass of  $\sim 0.8$  M<sub> $\odot$ </sub>. However, a recent and new analysis of the infrared emission from SN1987A by [Dwek & Arendt](#page-10-16) [\(2015\)](#page-10-16) points to a lower dust mass of  $\sim 0.45$  M<sub> $\odot$ </sub>, mostly composed by silicate grains.

### 2.2. Cassiopeia A

Cassiopeia A (CasA) is a Galactic SNR resulting from a SN explosion occurred 335 years ago. The kinetic energy has been es-

timated to be  $\sim$  (2 – 3) × 10<sup>51</sup> erg [\(Laming & Hwang 2003\)](#page-11-39). The mass of the shocked and unshocked ejecta is  $\sim 3-4$  M<sub>o</sub> [\(Hwang](#page-11-40) [& Laming 2012\)](#page-11-40) and the mass of gas swept away in the circum-stellar medium is ~ 8 M<sub>☉</sub> [\(Hwang & Laming 2009;](#page-11-41) [Patnaude &](#page-11-42) [Fesen 2009\)](#page-11-42). Adding the mass of a neutron star remnant, the total mass of the progenitor is estimated to be  $\sim (15 \pm 3)$  M<sub>o</sub>. The mass of dust associated to the SNR inferred both from *Herschel* observations and 850  $\mu$ m polarimetry data is  $M_{\text{dust}} = 0.1 - 1 \text{ M}_{\odot}$ . Given the large uncertainty in the mass of  $56$ Ni, we adopt an intermediate value as input parameter of the simulation.

## 2.3. Crab nebula

The small progenitor mass (8-10  $M_{\odot}$ ), the low explosion energy (10<sup>50</sup> erg) and mass of synthesized <sup>56</sup>Ni (0.009-0.016 M<sub>o</sub>), which are significantly less than the energy and nickel mass expected for ordinary SNe, all suggest that the Crab could be the result of an electron-capture SN event [\(Smith 2013\)](#page-11-19). The adopted <sup>56</sup>Ni mass for the simulation is intermediate between the observed ones.

### 2.4. SNR N49

The estimated physical properties of N49 have been taken from [Park et al.](#page-11-27) [\(2012\)](#page-11-27). [Otsuka et al.](#page-11-28) [\(2010\)](#page-11-28) reports a mass of warm dust of ~ 0.1 – 0.4 M<sub>☉</sub>. Emission from a large mass of cold dust is also observed, but it is not possible to disentangle the contribution coming from dust in the unshocked ejecta from that in the parent cloud.

For this source, there is no estimate of the  $56$ Ni mass available. We therefore adopt the same value used to model SN 1987A.

## <span id="page-2-0"></span>**3. Structure of the ejecta and grain distribution**

Starting from a homogeneous set of solar metallicity presupernova models with masses in the range [13-130]  $M_{\odot}$  [\(Chie](#page-10-17)ffi [& Limongi 2013\)](#page-10-17) simulated by means of the FRANEC stellar evolutionary code [\(Limongi & Chie](#page-11-43)ffi [2006\)](#page-11-43), we have selected the most suitable model for each SN according to the physical properties listed in Table 1. These four selected models are then used as input for the dust formation code (BS07), where classical nucleation theory in steady state conditions was applied. Here we use the latest version of dust formation model, which implements an upgraded molecular network, as described in detail in [Marassi et al.](#page-11-44) [\(2015\)](#page-11-44). We follow the formation of six different dust grain species: amorphous carbon (AC), corundum  $(Al_2O_3)$ , magnetite (Fe<sub>3</sub>O<sub>4</sub>), enstatite (MgSiO<sub>3</sub>), forsterite  $(Mg_2SiO_4)$  and quartz  $(SiO_2)$ .

In Table [2](#page-2-2) we show the resulting dust composition and mass distribution. The grains that condense and accrete in SN ejecta follow a log-normal size distribution function of the form,

$$
m_i(a) = m_{\text{max},i} \exp\left[-\frac{\log_{10}^2(a/a_{0,i})}{2\sigma_i^2}\right],
$$
 (1)

where  $m_{\text{max},i}$  represents the distribution maximum,  $a_{0,i}$  is the centroid  $\sigma_i$  is the width of the distribution and troid,  $\sigma_i$  is the width of the distribution and

$$
M_{\text{dust},i} = \int_0^\infty m_i(a) \, da,\tag{2}
$$

is the total dust mass for the *i*-th grain species. Table [2](#page-2-2) shows  $a_0$ ,  $\sigma$  and  $M<sub>dust</sub>$  for the six dominant grain species in each SN.

In this work we consider a carbon grain density  $\rho =$ 2.2 g cm<sup>-3</sup>. However, presolar grain measurements indicate a wide range of density for carbonaceous grains formed in SNe wide range of density for carbonaceous grains formed in SNe (e.g. [Amari et al. 2005,](#page-10-18) [2014\)](#page-10-19). We explore this scenario in Appendix [A.](#page-12-0)

#### <span id="page-2-1"></span>**4. The GRASH Rev code**

#### 4.1. Gas dynamics

The dynamics of the expansion of a supernova is classically divided into three main stages (see Fig. [1\)](#page-3-0):

- 1. *Ejecta-dominated (ED) expansion phase:* as the supernova explodes a shock wave is triggered and propagates into the ISM (forward shock, FS). At the same time a reverse shock (RS) propagates into the ejecta. The ejecta is in free expansion.
- 2. *Sedov-Taylor (ST) phase:* the mass of the interstellar material swept up by the shock wave becomes comparable to the mass of the ejecta. The ejecta is in adiabatic expansion and the radiative cooling is negligible [\(Taylor 1950;](#page-11-45) [Sedov 1969\)](#page-11-46).
- 3. *Pressure-driven snowplough (PDS) phase:* the shock wave slows down to velocities  $\leq 200$  km/s and radiative cooling becomes the main cooling process. The outermost shell of the ejecta is pushed into the ambient medium due to the pressure of the hot gas inside it.

Finally, when the velocity of the shock front becomes low enough ( $\sim 10 \text{ km/s}$ ), the remnant merges with the ISM.

A unified and self-similar solution for the evolution of a SNR from the ED phase through the ST phase was found by [Truelove](#page-11-47)

<span id="page-3-0"></span>

Fig. 1: Position of the forward and reverse shocks (black lines) as a function of time from the ED phase through the PDS phase. In the inset we compare the position (solid line) and velocity (dotdashed lines) of the forward shock computed using the analytical solution (black lines) with the simulation by [Slavin et al. 2015](#page-11-11) (red lines).

[& McKee](#page-11-47) [\(1999\)](#page-11-47) by comparing with the results of a hydrodynamical non-radiative simulation. They considered the following characteristic scales of length and time:

$$
R_{\rm ch} \equiv M_{\rm ej}^{1/3} \rho_0^{-1/3},
$$
  
\n
$$
t_{\rm ch} \equiv E_{\rm ex}^{-1/2} M_{\rm ej}^{5/6} \rho_0^{-1/3},
$$
\n(3)

where  $M_{\text{ej}}$  is the mass of the ejecta,  $\rho_0$  is the ISM density and  $E_{\text{ex}}$  is the explosion energy. The position of the forward ( $R_{\text{FS}}$ ) and reverse  $(R_{RS})$  shocks with respect to the centre of the ejecta for uniform ejecta are well described by:

$$
R_{\rm FS}(t^*) = 2.01R_{\rm ch}t^*(1 + 1.72t^{*3/2})^{-2/3},
$$
  
\n
$$
R_{\rm RS}(t^*) = 1.83R_{\rm ch}t^*(1 + 3.26t^{*3/2})^{-2/3},
$$
\n(4)

during the ED phase, while during the ST phase these two quantities can be approximated by:

$$
R_{\rm FS}(t^*) = R_{\rm ch}(1.42t^* - 0.254)^{2/5},
$$
  
\n
$$
R_{\rm RS}(t^*) = R_{\rm ch}t^*(0.779 - 0.106t^* - 0.533 \ln t^*),
$$
\n(5)

where  $t^* = t/t_{ch}$ .<br>When the four-

When the forward shock reaches velocities  $\leq 200$  km/s these equations do not represent a good approximation anymore and radiative cooling must be taken into account. Cioffi [et al.](#page-10-20) [\(1988\)](#page-10-20) found the fiducial time for the onset of the PDS phase to be,

$$
t_{\rm PDS} = 1.33 \times 10^4 \frac{E_{51}^{3/14}}{\zeta_{\rm m}^{5/14} n_0^{4/7}} \text{ yr},\tag{6}
$$

where  $E_{51} = E_{ex} / 10^{51}$  erg,  $\zeta_m = 1$  for solar abundances and  $n_0$  is the ISM number density. They found also that the forward shock can be approximated with the following analytical expression:

$$
R_{\rm FS} = R_{\rm PDS} \left( \frac{4}{3} t_{\rm PDS}^* - \frac{1}{3} \right)^{3/10},\tag{7}
$$

where  $t_{\text{PDS}}^* = t/t_{\text{PDS}}$  and,

$$
R_{\rm PDS} = 14 \frac{E_{51}^{2/7}}{\zeta_{\rm m}^{1/7} n_0^{3/7}} \,\text{pc} \tag{8}
$$

is the position of the forward shock at the time  $t_{\text{PDS}}$ .

The validity of these analytical solutions is guaranteed by the comparison with hydrodynamical simulations by Cioffi [et al.](#page-10-20) [\(1988\)](#page-10-20) and [Truelove & McKee](#page-11-47) [\(1999\)](#page-11-47). As a further check, we compare the analytical approximations with recent hydrodynamical simulations [\(Slavin et al. 2015\)](#page-11-11). In the inset in Fig. [1](#page-3-0) we show the analytical forward shock position and velocity (black lines) and those retrieved from Fig. 2 in [Slavin et al. 2015](#page-11-11) (red lines). The analytical solution is a good approximation throughout the considered time interval and the discrepancy in the position of the forward shock is never larger than  $\sim 2\%$ .

#### 4.2. Simulation grid dynamics

We divide the ejecta into  $N_s$  spherical shells and we assume that they all have the same width  $\Delta R = R_{ej}/N_s$ , where  $R_{ej}$  is the ejectaridius. The velocity of each shell is initially determined by the radius. The velocity of each shell is initially determined by the homologous expansion of the ejecta:

$$
v_j = v_{\rm ej} \frac{R_j}{R_{\rm ej}}, \qquad v_{\rm ej} = \sqrt{\frac{10E_{\rm ex}}{3M_{\rm ej}}}.
$$
\n(9)

where  $v_j$  is the velocity of the *j*-th shell and  $v_{ej}$  is the velocity of the ejecta radius. Additional *N*<sup>s</sup> spherical shells are defined to model the ISM around the expanding ejecta. We consider a maximum distance of  $R_{\text{max}}$  ~ 200 pc from the centre of the ejecta and divide the space between  $R_{ej}$  and  $R_{max}$  in  $N_s$  shells of equal width  $\Delta R_{\text{ISM}} = (R_{\text{max}} - R_{\text{ej}})/N_s$ . At the beginning of the simulation, these ISM shells are at rest these ISM shells are at rest.

We then let the system evolve. The simulation time step, ∆*t*, is uniquely determined by the dynamics of the reverse shock. It is defined as the time interval during which the reverse shock crosses one shell inside the ejecta, until it reaches the centre of it. At each given time, shells that have not yet been crossed by the reverse shock keep expanding homologously and adiabatically. This implies that the external and internal boundaries of each shell expand at their initial velocity, leading to a larger volume and to a lower density. The gas temperature in the shell changes according to:

$$
T_j' = T_j \left(\frac{V_j}{V_j'}\right)^{1/\gamma},\tag{10}
$$

where  $T_j$  and  $V_j$  are the temperature and volume of the *j*-th shell at a given time *t*, the primed variables are the same quantities at time *t*+ $\Delta t$  and  $\gamma$  is the adiabatic index (assumed to be  $\gamma_{SN} = 1.41$ , Chieffi [& Limongi 2013,](#page-10-17) for the gas in the ejecta and  $\gamma_{\rm ISM} = 5/3$ for the ISM). Similarly, shells in the ISM which have not yet been crossed by the forward shock remain at rest and their gas properties remain unchanged.

On the contrary, when a shell is invested by the reverse or forward shock, it experiences strong variations in density, velocity and temperature that are well described by the standard

Eq. [11\)](#page-4-0):

Rankine-Hugoniot jump conditions:

$$
\rho'_{j} = \frac{\gamma + 1}{\gamma - 1} \rho_{j},
$$
  
\n
$$
v'_{j} = v_{j} - \frac{2}{\gamma + 1} v_{\rm sh},
$$
  
\n
$$
T'_{j} = 2 \frac{\gamma - 1}{(\gamma + 1)^{2}} \frac{m}{k_{\rm B}} v_{\rm sh}^{2}
$$
\n(11)

where  $\rho'_j$ ,  $v'_j$  and  $T'_j$  are the density, velocity and temperature<br>of the *i*<sup>th</sup> shall (being it in the ejects or in the ISM) after of the *j*-th shell (being it in the ejecta or in the ISM) after the passage of the shock,  $m$  is the mean particle mass,  $k<sub>B</sub>$  the Boltzmann's constant and  $v_{\rm sh}$  is the velocity of the shock in the reference frame of the shell before being invested by the shock. This velocity corresponds to  $\tilde{v}_{RS}$  and  $v_{FS}$  for the reverse and forward shocks, whose analytical expressions can be found in Truelove & McKee (1999).

The velocity of shells between the reverse and forward shocks (hit by a shock at earlier times) is obtained interpolating between the velocity of the reverse and forward shock. As in [Bianchi & Schneider](#page-10-13) [\(2007\)](#page-10-13), we have compared the dynamical evolution predicted by the model with the output of numerical simulations by [van der Swaluw et al.](#page-11-48) [\(2001\)](#page-11-48) and [Del Zanna et al.](#page-10-21) [\(2003\)](#page-10-21), finding good agreement until  $t \sim 10^4$  yr.

The reverse shock velocity in the reference frame of the unshocked ISM reaches an inversion point at  $t = t_{rev}$  and then it achieves negative velocities, causing the implosion of part of the ejecta. This process has been investigated in detail through numerical simulations by Cioffi [et al.](#page-10-20) [\(1988\)](#page-10-20). Before reaching the centre of the ejecta, the temperature and pressure in the core of the ejecta increase, effectively reflecting the reverse shock, and leading to the so-called "echoes of thunder" described in their work. In order to qualitatively reproduce this mechanism we make the following approximation: for all the shells of the ejecta that are invested by the reverse shock after  $t_{rev}$  ( $j < j^*$  with  $j^*$  the shell invested by the reverse shock at  $t_{rev}$ ) we set the shell velocshell invested by the reverse shock at *t*rev), we set the shell velocity to zero, therefore assuming that the bouncing of the reverse shock would effectively cancel out the inward velocity. The velocity of these shells will remain zero until the end of the simulation and shells in between the  $j^*$ -th shell and the forward shock have velocities obtained from interpolation. During this phase, radiative cooling of the gas due to atomic processes starts to be important and it is taken into account using the cooling function by [Raymond et al.](#page-11-49) [\(1976\)](#page-11-49). The error made on the position of the outermost shell of the ejecta computed by this model is always smaller than a factor of ∼ 2 when compared with the results of numerical simulations (Cioffi [et al. 1988\)](#page-10-20). Moreover, since only a quarter of the ejecta is invested by the reverse shock after *t*rev, all these approximations affect only  $\leq 2\%$  of the dust mass.

## 4.3. Dust coupling

The dynamics of dust is governed by its coupling to the gas. Initially, dust is coupled to the unshocked ejecta and uniformly distributed. For a given shell, *j*, both gas and dust have the same velocity,  $v_j$ . The passage of the reverse shock in the *j*-th shell of the ejecta will affect the dynamics of both gas and dust in that shell. The gas is instantaneously modified according to Eq. [11](#page-4-0) and takes a velocity  $v'_j$ , while dust grains, having more inertia, decouple from the gas and move with an initial velocity (see

<span id="page-4-1"></span>
$$
|v_{\text{rel}}| = |v'_j - v_j|
$$
  
= 
$$
\frac{2}{\gamma + 1} v_{\text{sh}}
$$
 (12)

<span id="page-4-0"></span>with respect to the shocked gas.

In the model by BS07 dust grains were kept in the same shell for the whole simulation without considering their full dynamics. Also, once the reverse shock invested a given shell, the grains in that shell were assumed to be at constant velocity (given by Eq. [12\)](#page-4-1) in order to take the grain erosion upper limit, without considering the action of drag forces. However, depending on the gas and dust properties, dust grains modify their velocity according to the following equation [\(McKee et al. 1987\)](#page-11-7):

$$
\frac{dy_{\text{rel}}}{dt} = \frac{d\chi}{dt} \frac{y_{\text{rel}}}{2\chi} - \frac{F_{\text{D}}}{m_{\text{gr}}},\tag{13}
$$

where  $\chi$  is the shock compression,  $F_D$  the coupling force and  $m_{\text{gr}}$ the grain mass. The first term on the right-hand side is known as *betatron acceleration* [\(Cowie 1978;](#page-10-22) [Shull 1978\)](#page-11-50). In the presence of a magnetic field, *B*, charged (with charge  $|q|$ ) dust grains gyrate around magnetic field lines with a trajectory determined by the Larmor radius:

$$
r_{\rm L} = \frac{m_{\rm gr} v_{\rm rel, \perp}}{|q|B},\tag{14}
$$

where *v*<sub>rel,⊥</sub> is the component of the relative velocity between gas and dust which is perpendicular to magnetic field lines. A rapid increase in the gas density due to shock compression will then lead to an enhancement of the magnetic field strength and a consequent (betatron) acceleration and reduction of the Larmor radius. On the contrary, the coupling term reduces the grain velocity as a result of the combined effect of collisional (direct) coupling and of plasma drag [\(Draine & Salpeter 1979b\)](#page-10-6):

$$
FD = FD(collisional) + FD(plasma).
$$
 (15)

The relevant relations that define plasma drag are reported in Eqs. 3 - 6 of [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14).

In this model we do not describe the ionisation state of the gas. However, for a sufficiently high gas temperature we can consider the gas as fully ionised. Therefore the shocked gas is assumed to be composed by  $H^+$ ,  $He^{++}$  and  $O^+$ , which represent the most abundant species. In Fig. [2](#page-5-0) we show the ratio between plasma and collisional drag as a function of the gas temperature and for different grain sizes and drift velocities. Plasma drag has a negligible effect on the dynamics of small grains, while it exceeds collisional drag for ∼ 100 nm grains at gas temperatures  $\leq 5 \times 10^6$  K. However, if the velocity is sufficiently large (*v*rel <sup>∼</sup> 1000 km/s) plasma drag is negligible at all gas temperatures and for all grain sizes.

It has been shown that betatron acceleration efficiently affect the dynamics of interstellar dust grains invested by supernovatriggered shock waves [\(Jones et al. 1994,](#page-11-8) [1996;](#page-11-9) [Bocchio et al.](#page-10-14) [2014\)](#page-10-14). However, this process is probably not relevant for dust produced in SNe. There is evidence for magnetic field lines distributed radially inside the ejecta both from polarimetry observations (e.g. [Dunne et al. 2009\)](#page-10-8) and from numerical simulations (e.g. [Inoue et al. 2013;](#page-11-51) [Schure & Bell 2014\)](#page-11-52). In the case of symmetric ejecta, the velocity of grains is mostly oriented radially and betatron acceleration is therefore negligible inside the ejecta. In the ISM, shock compression is important during the PDS

<span id="page-5-0"></span>

Fig. 2: Ratio between plasma and collisional drag as a function of the gas temperature for different grain radii. Drift velocities are indicated by the line style ( $V_{\text{rel}}$  = 10, 100, 1000 km/s for solid, dotted and dashed lines, respectively).

phase, when the shock front is at low velocities ( $v_{\rm sh} \leq 200$  km/s) and the gas cools due to the emission of radiation. However, dust grains ejected from the interior of the SN are almost at rest with the post-shock gas during this phase (see Section [5\)](#page-6-0) and they are therefore not affected by the betatron acceleration. Hence we do not include betatron acceleration in this version of the code.

#### 4.4. Dust grain number matrix

In order to keep track of all the grains in the simulation we define a matrix,  $\mathfrak{M}$ , where - for each of the  $2N_s$  shells and for each relative velocity between grains and gas in the shell - we store the number of grains, their size and composition. Initially, the grains occupy the matrix elements corresponding to the shells in the ejecta and zero relative velocity. At each time step, grains are displaced according to the laws described above and the matrix elements are updated. A particular care is required when drag forces are too strong and grain velocities change too quickly during one simulation time step. In that case the time step is divided into  $n_i = 50$  time intervals (each of duration  $\delta t$ ) and the grain velocity,  $v_{t+\Delta t}$ , and position,  $d_{t+\Delta t}$ , are determined by a sub-grid model following:

$$
v_{t+\Delta t} = v_t + \sum_{i=1}^{n_i} \left(\frac{dv}{dt}\right)_i \delta t,
$$
  

$$
d_{t+\Delta t} = d_t + \sum_{i=1}^{n_i} v_i \delta t,
$$
 (16)

where  $v_i$  is the intermediate velocity at each time  $t + i\delta t$ .<br>Computing the change in grain radius a at each of the *n* time Computing the change in grain radius,  $a$ , at each of the  $n_i$  time intervals would have been too time-consuming and we therefore account for the grain erosion in this way:

$$
a_{t+\Delta t} = a_t + \frac{1}{2} \left( \frac{da}{dt} \Big|_{v=v_t} + \frac{da}{dt} \Big|_{v=v_{t+\Delta t}} \right),
$$
 (17)

where  $\frac{da}{dt}$  is the grain radius derivative calculated as described in Section [4.5](#page-5-1) and the subscript indicates the velocity at which the processing is calculated. The grain radius generally does not change very rapidly and the division in sub-grid time intervals is not necessary.

#### <span id="page-5-1"></span>4.5. Dust processing

We consider four main physical processes:

- 1. Sputtering due to the interaction of dust grains with particles in the gas;
- 2. Sublimation due to collisional heating to high temperatures;
- 3. Shattering into smaller grains due to grain-grain collisions;
- 4. Vapourisation of part of the colliding grains during graingrain collisions.

The sputtering process can be estimated following the formalism by [Tielens et al.](#page-11-53) [\(1994\)](#page-11-53) as revisited by [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14). The sputtering rate is expressed as:

$$
\frac{dN_{\rm sp}}{dt} = 2\pi a^2 \sum_{i} n_i < Y_i v > \tag{18}
$$

where  $\frac{dN_{sp}}{dt}$  is the number of sputtered atoms per unit time, *a* is the grain radius,  $n_i$  the number density of the *i*-th ion and

$$
\langle Y_i v \rangle = \int Y_i v f_{\text{skM}}(v) dv, \tag{19}
$$

where  $Y_i$  is the sputtering yield (assuming a semi-infinite target) of the *i*-th ion, *v* is the relative velocity between grain and gas particle (a combination of the thermal and drift velocities) and  $f_{skM}(v)$  is the skewed Maxwellian distribution [\(Shull 1978;](#page-11-50) [Guillet 2008;](#page-11-54) [Bocchio et al. 2014\)](#page-10-14). We use the same sputtering yields derived by [Tielens et al.](#page-11-53) [\(1994\)](#page-11-53) and used by BS07 and [Nozawa et al.](#page-11-33) [\(2006,](#page-11-33) [2007\)](#page-11-34).

Energetic ions can have a penetration depth which is comparable or even larger than the smallest grains considered in this work. For example a ~ 1 keV He<sup>+</sup> ion (corresponding to the energy of an ion in a hot gas with  $T_g \sim 8 \times 10^6$  K) has a penetration depth  $R_p \sim 10$  nm in graphite and therefore it is likely to cross grains of radius smaller than  $R_p$  without leading to any sputtering of the target. This effect was taken into account in models by [Jurac et al.](#page-11-55) [\(1998\)](#page-11-55) and Serra Díaz-Cano & Jones [\(2008\)](#page-11-56) and then adopted by [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14) for sputtering of interstellar carbonaceous grains in supernova-triggered shocks. Using a similar approach, here we extend the latter study to simulate this effect for all the target materials considered in GRASH Rev. The sputtering yield,  $Y_a$ , of a grain of radius  $a$  is then expressed as:

$$
Y_{\rm a} = Y_{\infty} f(x),\tag{20}
$$

where  $Y_{\infty}$  is the sputtering yield for a semi-infinite target,  $x =$  $a/(0.7R_p)$  and  $f(x)$  is a function that can be parametrised as:

<span id="page-5-2"></span>
$$
f(x) = 1 + p_1 \exp\left[-\frac{(\ln x/p_2)^2}{2p_3^2}\right] - p_4 \exp\left[-(p_5x - p_6)^2\right].
$$
 (21)

The function  $f(x)$  depends on the target material and the six parameters used are reported in Table [3.](#page-6-1) In general this function tends to unity for sufficiently large grains (with respect to  $R_p$ , i.e.  $x \to \infty$ ) and tends to zero for small grains (i.e.  $x \to 0$ ). For grain radii comparable to the ion penetration depth, the sputtering yield is enhanced and can reach values  $Y_a \sim 4Y_\infty$  for graphitictype grains. For a detailed explanation of the method used to retrieve the parameters involved in Eq. [21,](#page-5-2) the reader is referred to Appendix [B.](#page-12-1) Finally, since the mass of (sub-)nanoparticles

is negligible for all the SN models considered, we do not implement any molecule dissociation process (e.g. [Micelotta et al.](#page-11-57) [2010b,](#page-11-57)[a\)](#page-11-58) as was done in [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14).

<span id="page-6-1"></span>Table 3: Parameters for the analytical modelling of the sizedependent sputtering.

	$Al_2O_3$	Fe <sub>3</sub> O <sub>4</sub>	MgSiO <sub>3</sub>	$Mg_2SiO_4$	AC	SiO <sub>2</sub>
$p_1$	1.1	1.2	1.0	1.5	4.9	0.85
$p_2$	0.39	0.55	0.50	1.2	0.55	1.2.
p <sub>3</sub>	1.1	1.0	1.0	0.57	0.77	0.56
p <sub>4</sub>	1.9	1.9	1.8	1.1	4.7	1.1
p <sub>5</sub>	2.1	2.0	2.1	0.52	3.0	1.6
p <sub>6</sub>	0.78	0.80	0.76	0.37	1.2	0.29

Sublimation is implemented with the same method described by BS07, using the thermal sublimation rates by [Guhathakurta](#page-11-59) [& Draine](#page-11-59) [\(1989\)](#page-11-59) and [Draine & Hao](#page-10-23) [\(2002\)](#page-10-23). In agreement with BS07, we find this process to provide a negligible contribution to dust destruction for all the SN models.

Grain-grain collisions lead to the formation of craters in the two colliding grains. The matter ejected from the crater is fragmented or even vapourised and brought back to the gas phase. Shattering and vapourisation processes are implemented following equations by [Jones et al.](#page-11-8) [\(1994,](#page-11-8) [1996\)](#page-11-9). However, some of the grain materials present in this work were not in the original papers. We adopt values from the literature for the different grain properties (see Table [B.1\)](#page-13-0). For a detailed description of the computation of the relevant quantities the reader is referred to Appendix [C.](#page-12-2)

Given the low density of dust in the ejecta, grain-grain collisions are rare and shattering and vapourisation lead to minor processing with respect to sputtering. This result can be better understood if we calculate the timescale between grain-grain collisions,  $\Delta t_{\text{coll}}$ . Particles with a mean number density  $\bar{n}$  and a typical radius *a*, in motion in a given volume will have a mean free path:

$$
\lambda = \frac{1}{\pi a^2 \bar{n}},
$$
\nand the timescale between two collisions is given by:

$$
\Delta t_{\text{coll}} = \frac{\lambda}{\bar{v}},\tag{23}
$$

with  $\bar{v}$  the typical relative velocity between particles. As an example we consider a SN  $\sim 10^4$  yr after the explosion. The volume occupied by dust is roughly a sphere of radius 10 pc. Assuming  $0.5 M_{\odot}$  of silicate grains with an average radius of 50 nm, the mean grain number density is  $\bar{n} \sim 10^{-11} \text{ cm}^{-3}$ . Then, considering a mean relative velocity of  $\bar{v} \sim 500$  km/s, the timescale between grain-grain collisions is  $\Delta t_{\text{coll}} \sim 8 \times 10^5$  yr, showing that these events are rare. Furthermore, with the expansion of the ejecta and the dispersion of grains into the ISM, the frequency of collisions is even lower.

At each time step in the simulation the grains in all the cells of the matrix M are processed by the four mechanisms described above and the matrix is updated.

# <span id="page-6-0"></span>**5. Results**

We run the GRASH\_Rev code for four SNe with the following input parameters: the number density of the surrounding ISM,

<span id="page-6-2"></span>

Fig. 3:  $Mg_2SiO_4$  test particle trajectory, size and velocity in the ejecta of SNR N49. Green and red lines indicate particles initially placed at one-forth and half of the radius of the ejecta, respectively. The initial size of particles is 10, 100 and 1000 nm for dotted, solid and dashed lines, respectively. In the top panel, black lines indicate the positions of forward and reverse shock and the blue line is the boundary between the ejecta and the ISM.

the explosion energy, the progenitor mass  $(n_0, E_{\text{exp}}^{\text{mod}}, M_{\text{prog}}^{\text{mod}})$  listed in Table 1) and the initial dust mass, composition and size distribution ( $M_{\text{dust}}$ ,  $a_0$ ,  $\sigma$  for each grain species listed in Table 2). The number of shells used for the simulation grid is fixed and equal to  $2N_s = 800$ . However, we note that this represents a robust parameter; halving or doubling the number of shells the simulation output remains unchanged.

In the following sections we present the results of the simulations.

## 5.1. Test particle dynamics and processing

To better understand the behaviour of individual dust grains, we first illustrate the dynamics of a few test particles, giving as an input to the code their initial position, size and material.

We consider the simulation of SNR N49 and we define six test particles made of  $Mg_2SiO_4$  with radii of 10, 100 and 1000 nm initially placed at a distance of one-forth and half of the initial radius of the ejecta. In Fig. [3](#page-6-2) we show their trajectories

(upper panel), the size evolution (central panel) and relative velocities with respect to the gas. The position of forward and reverse shocks are indicated by black lines while the position of the boundary between the ejecta and the ISM by the blue line.

Initially all the particles are at rest with respect to the ejecta. When the reverse shock reaches the shell where the particles reside, the gas undergoes a jump in conditions (Eq. [11\)](#page-4-0) while dust grains are not instantaneously coupled and assume a velocity given by Eq. [12](#page-4-1) with respect to the gas. Immediately after the passage of the reverse shock, depending on the gas conditions and grain size, dust grains are slowed by drag forces and processed due to collisions with gas particles and other grains.

Small grains  $(a = 10 \text{ nm}, \text{dotted lines})$  are quickly stopped and destroyed within the ejecta, while larger grains (*a* = <sup>100</sup>, 1000 nm, solid and dashed lines, respectively) are eroded to a lower extent. Furthermore, 100 nm grains which were initially placed at one-forth of the ejecta (green lines) have enough inertia to cross the forward shock while 100 nm grains initially placed at half of the ejecta (red lines) are stopped and destroyed in ~  $10^5$  yr.

As soon as a grain crosses the forward shock, its relative velocity with respect to the unshocked ISM gas,  $v'_{\text{ISM}}$ , will be enhanced to

$$
v'_{\rm ISM} = v_{\rm ISM} + v_{\rm sh},\tag{24}
$$

where  $v_{ISM}$  is the relative velocity between the grain and the shocked ISM and  $v_{\rm sh}$  is the shock velocity. Because of the effect of drag forces, grains will again slow down in the unshocked ISM. In this medium, if the velocity of a grain is too low (e.g. green solid line in Fig. [3\)](#page-6-2), it can be reached by the faster forward shock and will cross the shock front a second time. This time, the relative velocity between grain and gas is reduced and the grain is almost at rest in the shocked gas, therefore avoiding further processing.

Hence, it is clear that the fate of individual grains depends not only on its initial size but also on its initial position within the ejecta.

#### 5.2. Dust mass evolution

In Fig. [4](#page-7-0) we show the time evolution of the dust mass following the SN explosion. The evolution starts at the end of the dust nucleation phase. Each line represents the evolution of a single SN (1987A: black, CasA: green, Crab: blue and N49: red) and the data points illustrate the dust mass estimated from the observations (see Section [2\)](#page-1-0). As a comparison we also show the mass evolution computed using the model by BS07, assuming no drag forces (dashed lines). In the inset we highlight results for the time interval  $t = 10^5 - 10^6$  yr in a logarithmic scale.

The dust mass estimated using GRASH Rev simulations are in good agreement with the observations, except for SNR N49 for which the dust mass predicted by GRASH Rev is ∼ 15% larger than the upper mass limit of the range of values inferred from observations  $(0.4 M_{\odot}$ , see Table [1](#page-1-1) and section [5.3\)](#page-7-1). A more detailed comparison between model predictions and observations is given in Section [5.3.](#page-7-1)

At times  $t \sim 10^3 - 10^4$  yr the reverse shock destruction predicted by GRASH Rev is less important than that predicted by BS07. In fact, during this time interval, because of the passage of the reverse shock dust is decoupled from the gas and travels in between the reverse and forward shocks where the gas conditions are milder. For  $t \ge 10^4$  yr, most of the grains reach regions behind the forward shock where gas conditions are harsh and dust erosion is efficient. For all the four SNe, we predict final dust masses which are  $\sim$  5 − 50% of those estimated using the model by BS07, where the displacement of grains and the effect of the forward shock were neglected.

<span id="page-7-0"></span>

Fig. 4: Dust mass evolution as a function of time for the four SNe considered in this study (1987A: black, CasA: green, Crab: blue and N49: red). Solid lines represent GRASH Rev results and dashed lines the results obtained by BS07 model using the same initial conditions. Data points represent the observed dust masses and the shaded region indicate the time interval when dust processing fades out.

#### <span id="page-7-1"></span>5.3. Dust mass distribution

In Fig. [5](#page-8-0) we show the predicted mass in different dust species as a function of the grain size for Cas A, Crab and N49. The initial mass distributions (obtained as described in Sect. [3\)](#page-2-0) are shown with solid lines, while the dust mass distributions at the time corresponding to the age of these SNe,  $t_{\text{obs}}$ , is represented by the histograms. Only the most abundant species are displayed here: Fe<sub>3</sub>O<sub>4</sub> (green), Mg<sub>2</sub>SiO<sub>4</sub> and SiO<sub>2</sub> (summed up together in orange) and AC (blue).We do not show the results for SN 1987A because the reverse shock has not yet affected the mass of dust formed in this SN (see Fig. [4\)](#page-7-0).

<span id="page-8-1"></span>

Table 4: Dust masses (expressed in  $M_{\odot}$ ) at the observation time,  $t_{\rm obs}$ , and at the end of the simulation,  $t_{\rm end}$ .

The dust mass distribution at the observation time is shifted towards small grains and reduced in mass as a result of dust processing (compare the entries in Tables 2 and [4\)](#page-8-1). This effect is more evident for the oldest SN remnant, N49. Furthermore, small grains are more affected by processing than large grains, reflecting the behaviour of test particles seen in Fig. [3.](#page-6-2)

In what follows, the dust size and composition predicted by GRASH Rev for these three SNe at their respective ages is compared with the dust properties adopted to estimate the dust mass from IR and submm observations.

For CasA our model predicts little destruction and the three dominant species are characterized by a mass distribution which is similar to the initial one. About  $0.77 M_{\odot}$  of dust is still unshocked and therefore only  $0.06 M_{\odot}$  of dust is likely to be warm and collisionally heated by the hot post-shock gas. These values are in good agreement with the mass of cold and warm dust obtained from fitting observations  $(0.1 - 1M_{\odot}$  from *Herschel* and polarimetry observations and 0.02−0.054 M from *Spitzer* data, [Rho et al. 2008;](#page-11-25) [Arendt et al. 2014\)](#page-10-24).

The Crab Nebula has been observed with *Herschel* at wavelenghts between 51 and 670  $\mu$ m by [Gomez et al.](#page-11-26) [\(2012\)](#page-11-26). They fit the observed emission with two-temperature blackbodies, inferring a dust mass of 0.11 (0.24)  $M_{\odot}$  when carbonaceous (silicate) grain optical properties are used to fit the data. At the time corresponding to the age of this SN, we predict a total dust mass of  $0.17 M_{\odot}$ , in good agreement with the observations, with an almost equal contribution from silicates (<sup>∼</sup> <sup>0</sup>.<sup>09</sup> *<sup>M</sup>*) and carbon grains ( $\sim 0.08 M_{\odot}$ ). However, the predicted grain composition is more complex than assumed to fit the data. The simulation predicts that ~ 0.023  $M_{\odot}$  of dust lies between the forward and reverse shock, probably emitting at high temperatures, while the warm dust mass inferred from the data is estimated to be  $6 - 8 \times 10^{-3} M_{\odot}$ . However, in order to fit the data, all grains are assumed to be either at high temperature ( $T_w \sim 55 - 63$  K) or at low temperature ( $T_c \sim 28 - 33$  K). Given the large range of predicted grain sizes, this assumption is likely to be a very poor approximation.

Observations of warm dust emission in N49 by [Otsuka et al.](#page-11-28) [\(2010\)](#page-11-28) indicate a dust mass of 0.1 (0.4)  $M_{\odot}$  if carbonaceous (silicate) grains are assumed as the main constituent of dust. The cold component is hard to detect observationally as it is strongly contaminated by the emission of dust in the parent cloud at a similar temperature. Only a single dust temperature has been used to fit the data [\(Otsuka et al. 2010\)](#page-11-28) and this could lead to a large uncertainty in the estimated dust mass [\(Mattsson et al.](#page-11-32) [2015\)](#page-11-32). GRASH Rev simulation predicts that in SNR N49 the reverse shock has already processed much of the ejecta and only  $0.04 M_{\odot}$  of dust is still in the unshocked region, emitting as cold dust. Hence, we predict a warm dust mass of  $\sim 0.48 M_{\odot}$ , dom-

<span id="page-8-0"></span>

Fig. 5: Dust mass distributions for CasA, Crab and N49 at formation (solid lines) and observation times (histograms). In each panel we show the three dominant dust species:  $Fe<sub>3</sub>O<sub>4</sub>$  (green),  $Mg_2SiO_4$  and  $SiO_2$  (summed up together in orange) and AC (blue).

inated by silicate grains, which is only  $\sim 15\%$  larger than the observed warm dust mass when silicate optical properties are assumed.

Given the uncertainties in inferring the dust mass from the data, we can conclude that the model predictions provide a reasonable estimate of the mass of dust that has survived the passage of the reverse shock. Based on our simulation, we can conclude that a dust mass of  $[0.7-0.9] M_{\odot}$ , such as the one observed in SN 1987A, can be safely considered to be representative of the efficiency of dust production in massive stars, as the ejecta have not yet been invested by the reverse shock. This conclusion does not apply to the other three SNe that we have considered, where at the estimated time from the explosions - between 10 and 40% of the freshly formed dust has already been destroyed. However, for none of the SNe considered, the reverse shock travelled to the center of the ejecta. This implies that current observations can not be used to estimate the mass of dust that will be injected in the interstellar medium, the so called *e*ff*ective dust yield*.

## 5.4. The effective SN dust yields

The final time of the simulation is assumed to be  $t_{\text{end}} = 10^6$  yr where the velocity of the forward shock is  $v_{\text{sh}} \le 10 \text{ km/s}$  and dust grains are either destroyed or embedded in the ISM gas. Table [4](#page-8-1) illustrates the predicted dust mass at the end of the simulation. We find that the effective dust masses injected in the ISM from these SNe will be significantly smaller than inferred from present observations: ∼ 1% of the currently detected mass for SN1987A and CasA, ∼ 8% for N49 and less than 1% for the Crab nebula. The resulting dust yields depend on the progenitor mass, explosion energy and the age of the SN, and lie in the range  $[4.21 \times 10^{-4} - 4.02 \times 10^{-2}] M_{\odot}$ . Grains in the Crab nebula<br>suffer a largest destruction. In fact, the Crab nebula has a low exsuffer a largest destruction. In fact, the Crab nebula has a low explosion energy and progenitor mass compared to the other SNe. This leads to the formation of smaller dust grains (e.g. AC grains have an average size of  $a_0 = 26$  nm while in the other three SNe  $a_0 \sim 90 - 100$  nm) and to a lower dust mass. For the same reason, silicate grains are destroyed more efficiently. As a result, more than 60% of the dust mass that will be injected in the ISM is in the form of carbonaceous grains. These grains, being larger than grains of other species, have more inertia and, depending on their initial position, can cross both the reverse and forward shock, reaching the unshocked ISM and surviving the explosion.

# <span id="page-9-0"></span>**6. Discussion and astrophysical implications**

The dust mass obtained from fitting observations is determined under several assumptions, which make the measurement rather uncertain.

- 1. Often, a single dust material and size is used to reproduce the dust emission. However, dust in SNRs is rich in composition and each material has a wide size distribution. This is reflected in the dust temperature distribution: for example small grains are heated to higher temperatures compared to larger grains and their emission per unit mass will be higher. [Mattsson et al.](#page-11-32) [\(2015\)](#page-11-32) noted that depending on the grain size/temperature distribution the measured dust mass can vary up to six times the original value but that most of the complication derives from the assumed grain material.
- 2. In many cases and especially in young SNe, most of the dust mass resides in the unshocked ejecta and is therefore likely to be cold with a similar temperature to that of dust in the parent cloud (radiative transfer calculations in SN1987A predict temperatures  $T_{\text{dust}} = 15 - 20 \text{ K}$ ; [Wesson et al. 2015\)](#page-11-60). The emission from these two sources comes from the same spatial region and are therefore entangled and further multiwavelength observations are therefore needed for a correct dust mass evaluation.
- 3. For CasA and the Crab Nebula, recent observations suggest that the unshocked ejecta have a clumpy density distribu-

tion [\(Lee et al. 2015;](#page-11-61) [Owen & Barlow 2015\)](#page-11-62). When this is taken into account, the inferred dust masses are generally larger. In dust formation/destruction models, a clumpy ejecta would also favour a larger dust mass as (*i*) the formation of dust grains would be more efficient, therefore creating larger grains and (*ii*) the higher contrast in density between the diffuse and clumpy gas would slow the reverse shock, leading to less dust processing.

In addition, the mass of the progenitor stars and the explosion energy for some SNe are also difficult to reconstruct from the available data. These do not impact the estimated mass of freshly formed dust<sup>[1](#page-9-1)</sup> but may affect the destruction efficiencies by the reverse shock. As an example, assuming an increase in the explosion energy by a factor 2 for Cas A leads to 60% smaller dust mass at  $t_{obs}$  than the value reported in Table 4. However, as it is clear from Figure 4, this model would still be in agreement with the observed dust mass, given the large errorbars. Hence, the uncertainties which affect the measured dust mass encompass the range of dust masses predicted by the model for different initial explosion parameters.

Given these uncertainties, the models described in this paper appear to well reproduce the dust masses in the four SNe that we have considered. The average effective dust yield is estimated to be  $(1.55 \pm 1.48) \times 10^{-2} M_{\odot}$ . This is in good agreement with the dust yield used in chemical evolution models based on BS07 dust yields with moderate destruction by the reverse shock. For a Salpeter initial mass function (IMF), the average dust mass injected by SNe in the ISM is  $(2.50 – 2.73) × 10<sup>-2</sup>M<sub>o</sub>$  for SN progenitors with metallicities  $0.1 Z_{\odot} \le Z \le 1 Z_{\odot}$  and a circumstellar medium density of 1 cm<sup>−</sup><sup>3</sup> [\(Valiante et al. 2009,](#page-11-63) [2011,](#page-11-31) [2014;](#page-11-17) see also Fig. 6 in [Schneider et al. 2014\)](#page-11-4).

In the Milky Way, the timescale between the explosion of two SNe has been estimated to be  $\sim$  40 yr [\(Li et al. 2011\)](#page-11-15). Using the mean effective dust yield that we have obtained leads to a SN dust production rate of  $(3.9 \pm 3.7) \times 10^{-4} M_{\odot} \text{ yr}^{-1}$ . This value can be compared to the dust production rate by AGB stars. Because be compared to the dust production rate by AGB stars. Because of source confusion in the Galactic plane, surveys have targeted the Magellanic Clouds to make a global census of dusty AGB stars, inferring dust production rates of ~ 2 × 10<sup>-5</sup>  $M_{\odot}/yr$  for the Large Magellanic Cloud (LMC, [Riebel et al. 2012\)](#page-11-64) and of ~  $8 \times 10^{-7}$  *M*<sub>○</sub>/yr for the Small Magellanic Cloud (SMC, [Boyer](#page-10-25) [et al. 2012\)](#page-10-25), with variations among the results of different surveys [\(Matsuura et al. 2013\)](#page-11-65), and in good agreement with theoretical predictions [\(Ventura et al. 2012b](#page-11-66)[,a,](#page-11-67) [2014\)](#page-11-68). Hence, even in the LMC, the current dust production rate by AGB stars appears to be more than one order of magnitude smaller than that estimated from our sample of four SNe. Yet, the relative importance of AGB stars and SNe as dust producers depends on the initial mass function and on the star formation history of each galaxy [\(Valiante et al. 2009\)](#page-11-63).

Yet, the importance of stellar sources of dust is limited by grain destruction in SN-driven interstellar shocks. The dust destruction timescale in the Milky Way has been estimated to be  $\tau_{\text{des,MW}} \sim 10^8, 10^9 \,\text{yr}$  by [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14) and [Slavin](#page-11-11) et al. (2015) respectively Rescaling these values by the ra[et al.](#page-11-11) [\(2015\)](#page-11-11), respectively. Rescaling these values by the ratio between the ISM mass in the Milky Way and in the LMC  $(M_{\text{ISM,MW}}/M_{\text{ISM,LMC}} \approx 100)$ , the dust lifetime in the LMC can be estimated as  $\sim 10^6 - 10^7$  yr, in agreement with the recent observational study by Lakićević et al. [\(2015\)](#page-11-10), which leads to

<span id="page-9-1"></span>As an example, changing the explosion energy adopted for CasA from  $1.5 \times 10^{51}$  erg to  $3 \times 10^{51}$  erg induces only a 5% difference in the dust mass. A similar difference is found if we increase the Ni<sup>56</sup> mass adopted for the Crab from  $0.014M_{\odot}$  to  $0.058M_{\odot}$ .

 $\tau_{\text{des-LMC}} \sim 2 \times 10^7$  yr. Then, assuming a total interstellar dust mass in the LMC of  $M_{\text{dust}} = 7.3 \times 10^5 M_{\odot}$  [\(Gordon et al.](#page-11-69) [2014\)](#page-11-69), the resulting dust destruction rate is  $dM_{\text{des,LMC}}/dt \sim$ <br> $3 \times 10^{-2} - 7 \times 10^{-1} M_{\odot} \text{ yr}^{-1}$ . These values are larger than the inferred dust production rates for SNe and AGB stars by a factor of > 100, therefore requiring dust accretion in the gas phase of the LMC. Even if the dust formation timescale in AGB stars and SNe appears to be longer than the destruction timescale, stellar dust production is nevertheless an important mechanism to provide the seeds for grain growth via gas accretion in denser regions (see however [Jones & Nuth 2011\)](#page-11-12).

The result of our study suggests that - among all the different dust species that are formed in the ejecta of SNe - carbonaceous grains are those which suffer the least destruction by the reverse shock, providing the dominant contribution to the effective SN dust yields. This implies that carbon dust may be present even in the ISM of young galaxies, with relatively unevolved stellar populations. This selection effect is even more pronounced if carbon grains are preferentially formed with densities lower than graphite ( $\rho < 2.2$  g cm<sup>-3</sup>, see Appendix [A\)](#page-12-0).<br>Finally it is not straightforward to use the

Finally, it is not straightforward to use the results of this study as a way to estimate the mass of dust produced by SNe in galaxies at high redshifts. In fact, although very little is known about their ISM conditions, if these SNe explode in a circumstellar medium of larger density, they experience a harder reverse shock and presumably a stronger dust destruction. As an example, if exploded in a circumstellar medium density of  $n_0 \sim 15 \text{ cm}^{-3}$  - a factor 10 larger than assumed here - the same simulation used to describe SN 1987A predicts a final dust mass of  $3.4 \times 10^{-4}$  M<sub>o</sub>, which is ~ 30 smaller than our standard run.

## <span id="page-10-15"></span>**7. Conclusions**

We have presented GRASH\_Rev, a new code which describes dust processing in a SN explosion, improving the existing BS07 model by treating the full dynamics of dust grains within the ejecta and in the surrounding ISM. We have applied the model to 4 well studied SNe in our Galaxy and in the LMC: SN 1987A, Cas A, the Crab Nebula and N49. Multi-wavelength observations with *Spitzer* and *Herschel* allow to infer the mass of warm and cold dust associated to the ejecta.

We find that our models are able to well reproduce the observed dust mass and can therefore be used to estimate the effective dust yield, hence the mass of dust produced by SNe that is able to enrich the ISM.

For SN 1987A, the ejecta have not yet been reprocessed by the reverse shock. Hence, the currently observed dust mass of  $[0.7 - 0.9] M_{\odot}$  is indicative of the efficiency of dust formation in SN ejecta. Conversely, between 10 and 40 % of the newly formed dust has already been destroyed in the other three SNe. The simulations show that sputtering due to the interaction of dust grains with particles in the gas represents the dominant destruction process because physical conditions in the ejecta cause sublimation to be almost negligible and grain-grain collisions to be extremely rare.

Since the largest dust destruction occurs between  $10<sup>3</sup>$  and  $10<sup>5</sup>$  yr after the explosion, current observations which sample relatively young SNe (with age < 4800 yr) provide only an upper limit on the effective dust yield. Our models indicate that only between 1 and 8% of the currently observed dust mass will contribute to the enrichment of the ISM, with an average SN effective dust yield of  $(1.55 \pm 1.48) \times 10^{-2} M_{\odot}$ , largely dominated by carbonaceous grains. This is in good agreement with the IMF-averaged yields adopted in chemical evolution models [\(Valiante et al. 2009,](#page-11-63) [2011,](#page-11-31) [2014;](#page-11-17) [de Bennassuti et al. 2014;](#page-10-26) [Schneider et al. 2014\)](#page-11-4) which account for SN reverse shock destruction. When compared to dust destruction efficiencies in SNdriven interstellar shocks recently estimated by theoretical models [\(Bocchio et al. 2014;](#page-10-14) [Slavin et al. 2015\)](#page-11-11) and observations (Lakićević et al. [2015\)](#page-11-10), these figures imply that SNe may be net dust destroyers, pointing to grain growth in the ISM as the dominant dust enrichment process both in local galaxies and at high redshifts [\(Valiante et al. 2014;](#page-11-17) [de Bennassuti et al. 2014;](#page-10-26) [Michałowski 2015;](#page-11-29) [Mancini et al. 2015\)](#page-11-30).

# <span id="page-12-0"></span>**Appendix A: Carbonaceous grain density**

Carbonaceous grains formed in SNe exhibit a large range of density (1.6 to 2.2  $\rm g$  cm<sup>-3</sup>) as it is revealed by various measurements from presolar grains (e.g. [Amari et al. 2005,](#page-10-18) [2014\)](#page-10-19). In our work we assumed graphitic-type grains with a density of 2.2 g cm<sup>-3</sup>. In this appendix we consider low-density ( $\rho = 1.6$  g cm<sup>-3</sup>) amor-<br>phous carbon grains and we show the impact of this change on phous carbon grains and we show the impact of this change on the amount of carbonaceous dust surviving the explosion of a SN.

We consider as an example the case of SN 1987A and rerun the dust formation model lowering the density of carbonaceous grains. In Fig. [A.1](#page-12-3) we show the initial dust mass distribution for graphitic-type ( $\rho = 2.2$  g cm<sup>-3</sup>, black line) and for low-density amorphous carbon grains ( $\rho = 1.6$  g cm<sup>-3</sup> red line). While the amorphous carbon grains ( $\rho = 1.6$  g cm<sup>-3</sup>, red line). While the total carbonaceous dust mass formed in the two cases is very total carbonaceous dust mass formed in the two cases is very similar ( $M_{\text{TOT}} = 7.15 \times 10^{-2} M_{\odot}$  and  $7.02 \times 10^{-2} M_{\odot}$  for high- and low-density carbon grains, respectively), the mass distribution in the case of a lower density is shifted towards larger grains  $(a<sub>0</sub>$  is shifted from  $\sim$  90 nm to  $\sim$  160 nm in the case of low-density grains).

<span id="page-12-3"></span>

Fig. A.1: Dust mass distribution assuming graphitic-type ( $\rho$  = 2.2 g cm<sup>-3</sup>, black line) or amorphous carbon ( $\rho = 1.6$  g cm<sup>-3</sup>, red line) orains red line) grains.

We then updated the GRASH\_Rev code taking into account the carbonaceous grain processing described by [Bocchio et al.](#page-10-14) [\(2014\)](#page-10-14). In particular, the lower density of the material shows its biggest impact on the sputtering yield, which is enhanced by up to an order of magnitude over a large range of energies and grain sizes (see Figs. 3 and 4 in [Bocchio et al. 2014\)](#page-10-14). However, the mass distribution of low-density carbon grains is shifted towards larger grains which are therefore less affected by sputtering than smaller, higher-density grains. This cancels out the enhancement of the sputtering yield. The resulting mass of carbon dust surviving the explosion of SN 1987A is then enhanced by a factor ∼ 3 from  $M_{AC} = 8.5 \times 10^{-3} M_{\odot}$  to  $2.5 \times 10^{-2} M_{\odot}$ .

# <span id="page-12-1"></span>**Appendix B: Size-dependent sputtering**

With the use of the *Stopping and Range of Ions in Matter* soft-ware<sup>[2](#page-12-4)</sup> (SRIM, [Ziegler et al. 1985\)](#page-12-5) it is possible to simulate the sputtering of targets of different materials as they are hit by projectile ions. The simulations provide both the sputtering yield (for a semi-infinite target),  $Y_{\infty}$ , and the position  $(x, y, z)$  and  $z$  coordinates) of the impinging ions after their interaction with the target.

The target materials and densities used in GRASH rev are listed in Table [B.1.](#page-13-0) We consider He ions with an energy of 1 keV as projectiles. In order to estimate the position of the displaced target atoms we follow the same approximation adopted by [Serra](#page-11-56) Díaz-Cano & Jones [\(2008\)](#page-11-56): a projectile loses most of its energy at a depth of  $R_D \sim 0.7R_p$ . We then assume that target atoms are displaced to a distance of  $R<sub>D</sub>$  from their original position. In this way, we can approximately reconstruct the distribution of displaced target atoms.

We simulate the bombardment of  $n_{\text{TOT}} = 10^6$  ions for each material. At the end of the simulation we then have the 3D coordinates of the impinging ions and targets. We consider different grain radii,  $a$ , and we count the number of impinging ions,  $n_i$ , which are enclosed in a sphere of radius 2*a* around the grain centre. In this way we only account for ions that triggered a collisional cascade in the target and exclude transmitted ions. Furthermore, we count the number of targets,  $n_t$ , whose position is outside the grain volume and that are associated to ions that triggered collisional cascades in the target. We then estimate the correction to the sputtering yield due to the effect of the grain size as:

$$
Y_{\rm a} = \left(\frac{n_{\rm i} - n_{\rm t}}{n_{\rm TOT}} Y_{\rm \infty} + \frac{n_{\rm t}}{n_{\rm TOT}}\right). \tag{B.1}
$$

In Fig. [B.1](#page-13-1) we show the resulting ratio  $f(x) = Y_a/Y_\infty$  as a function of  $x = a/R<sub>D</sub>$  (plus signs) for graphitic-type grains. We then fit our results (red line) with the parametric function in Eq. [21.](#page-5-2) The parameters resulting from the fit are reported in Table [3](#page-6-1) for all the materials.

# <span id="page-12-2"></span>**Appendix C: Shattering and vapourisation parameters**

Shattering and vapourisation parameters are calculated following the method by [Tielens et al.](#page-11-53) [\(1994\)](#page-11-53) and [Jones et al.](#page-11-9) [\(1996\)](#page-11-9) and based upon material properties found in the literature. The critical energy density for vapourisation,  $\epsilon_{th,v}$ , is calculated starting from the surface binding energy,  $E<sub>b</sub>$ , as follows:

$$
\epsilon_{\text{th,v}} = 2 \frac{E_{\text{b}}}{m_{\text{p}} M},\tag{C.1}
$$

where  $m_p$  is the proton mass and *M* is the molar mass of the considered material. Then, the critical relative velocity between grains to set the vapourisation process is given by:

$$
v_{\text{th,v}} = 2(2\epsilon_{\text{th}}^{\text{v}})^2, \tag{C.2}
$$

and the corresponding pressure in the shocked solid is obtained as [\(Tielens et al. 1994\)](#page-11-53):

$$
P_{\text{th,v}} = \frac{\rho_0 v_{\text{th,v}}(v_{\text{th,v}} - c_0)}{s}.
$$
 (C.3)

<span id="page-12-4"></span><sup>2</sup> SRIM is a collection of software packages which calculates the transport of ions in matter, calibrating the results on the available experimental data.

<span id="page-13-1"></span>

Fig. B.1: Ratio  $Y_a/Y_\infty$  as a function of  $x = a/R_D$  for graphitictype target material and for impinging He ions. Plus signs represent results from SRIM simulations while the red solid line indicates the analytical approximation.

The critical pressure,  $P_{th,sh}$ , above which grains undergo fragmentation is assumed equal to the Young's modulus of the material. The critical velocity for the onset of crater formation is given by [\(Jones et al. 1994\)](#page-11-8):

$$
v_{\text{th,sh}} = \sqrt{4/3} \frac{P_{\text{th,sh}}}{\rho_0 c_0},\tag{C.4}
$$

and the critical energy density results:

$$
\epsilon_{\text{th,sh}} = \frac{1}{2} \left( \frac{v_{\text{th,sh}}}{2} \right)^2.
$$
 (C.5)

In Table [B.1](#page-13-0) we report all the values for vapourisation and shattering critical parameters that we have adopted in GRASH\_rev.
