### ABSTRACT

There is mounting evidence for the binary nature of the progenitors of gamma-ray bursts (GRBs). For a long GRB, the induced gravitational collapse (IGC) paradigm proposes as progenitor, or “in-state”, a tight binary system composed of a carbon-oxygen core (CO<sub>core</sub>) undergoing a supernova (SN) explosion which triggers hypercritical accretion onto a neutron star (NS) companion. For a short GRB, a NS-NS merger is traditionally adopted as the progenitor. We divide long and short GRBs into two sub-classes, depending on whether or not a black hole (BH) is formed in the merger or in the hypercritical accretion process exceeding the NS critical mass. For long bursts, when no BH is formed we have the sub-class of X-ray flashes (XRFs), with isotropic energy  $E_{iso} \lesssim 10^{52}$  erg and rest-frame spectral peak energy  $E_{p,i} \lesssim 200$  keV. When a BH is formed we have the sub-class of binary-driven hypernovae (BdHNe), with  $E_{iso} \gtrsim 10^{52}$  erg and  $E_{p,i} \gtrsim 200$  keV. In analogy, short bursts are similarly divided into two sub-classes. When no BH is formed, short gamma-ray flashes (S-GRFs) occur, with  $E_{iso} \lesssim 10^{52}$  erg and  $E_{p,i} \lesssim 2$  MeV. When a BH is formed, the authentic short GRBs (S-GRBs) occur, with  $E_{iso} \gtrsim 10^{52}$  erg and  $E_{p,i} \gtrsim 2$  MeV. We give examples and observational signatures of these four sub-classes and their rate of occurrence. From their respective rates it is possible that “in-states” of S-GRFs and S-GRBs originate from the “out-states” of XRFs. We indicate two additional progenitor systems: white dwarf-NS and BH-NS. These systems have hybrid features between long and short bursts. In the case of S-GRBs and BdHNe evidence is given of the coincidence of the onset of the high energy GeV emission with the birth of a Kerr BH.

*Keywords:* gamma ray bursts – hypercritical accretion – black holes – high energy emission

### 1. INTRODUCTION

On February 1974, at the same AAAS meeting in San Francisco where the discovery of GRBs by the Vela satellites was publicly announced (Strong et al. 1975), the possible relation of GRBs with the “moment of gravitational collapse” leading to a BH formation was advanced (see Gursky & Ruffini 1975). Damour & Ruffini (1975) considered, for definiteness, the vacuum polarization process occurring in an overcritical Kerr-Newman BH (KNBH). Evidence was given for: a) the formation of a vast amount of  $e^+e^-$ -baryon plasma; b) the energetics of GRBs of the order of  $E_{\max} \approx 10^{54} M_{\text{BH}}/M_{\odot}$  erg, where  $M_{\text{BH}}$  is the BH mass, implying their cosmological origin; c) the ultra-high energy cosmic rays with energy up to  $\sim 10^{20}$  eV originating from such an extreme electro-dynamical process. Soon after, the role of an  $e^+e^-$  plasma for the origin of GRBs was also considered by Cavallo & Rees (1978). It took almost thirty years to clarify some of the analogies and differences between these two processes of  $e^+e^-$ -pair creation leading, respectively, to the alternative concepts of “fireball” and “fireshell” (Aksenov et al. 2007, 2009).

Already in 1989, well before the establishment of the GRB cosmological nature and energetics, Eichler et al. (1989) gave support to the cosmological interpretation of GRBs and indicated in merging NS binaries their possible origin. They also pointed out the relevance of such NS-NS mergers for the occurrence of r-process, as well as for the emission of gravitational radiation, indicating the uncertainty in the determination of their rate of occurrence.

Following the launch of the Compton satellite and the observations by the BATSE detector (Meegan et al. 1992), a phenomenological classification based on the prompt  $T_{90}$  duration was advanced: GRBs were classified into long GRBs for  $T_{90} > 2$  s, and short GRBs for  $T_{90} < 2$  s (Klebesadel 1992; Dezalay et al. 1992; Kouveliotou et al. 1993; Tavani 1998).

Shortly after Narayan et al. (1992) indicated the possible cosmological origin of short GRBs originating in binary NS mergers. They also introduced the clear indication of the role of  $\nu\bar{\nu}$  annihilation leading to the formation of an  $e^+e^-$  plasma. This paper was followed by a large number of theoretical works including the gravitational wave emission in Newtonian, post-Newtonian, and general relativistic treatments (see, e.g., Rasio & Shapiro 1999), as well as the  $\nu\bar{\nu}$  annihilation leading to an  $e^+e^-$  plasma (see, e.g., Salmonson & Wilson 2002 and Rosswog et al. 2003 and references therein).

Soon after the paper by Narayan et al. (1992), Woosley (1993) also supported the cosmological origin of GRBs and introduced the concept of BH-Accretion-Disks, produced by the collapse of a very massive star. Such a system was indicated by its author as a *collapsar* and was assumed to be the origin of ultrarelativistic jets expected to occur by the same author in long GRBs. For a recent review see MacFadyen & Woosley (1999); MacFadyen et al. (2001); Woosley & Bloom (2006).

After the determination of the cosmological nature of GRBs (Costa et al. 1997; Metzger et al. 1997; van Paradijs et al. 1997) and the confirmation of their outstanding energy ( $\approx 10^{54}$  erg), we returned to our GRB scenario (Damour & Ruffini 1975). In a period of four years, from 1997 to 2001, we developed a fully relativistic GRB theoretical model examining, as well, the dynamics of the  $e^+e^-$  plasma originating the GRB emission (the fireshell model, see, e.g., Preparata et al. 1998; Ruffini et al. 1999, 2000, 2001a,b,c, and Section 2). The fireshell model applies to both short and long GRBs.

The origin of short GRBs from NS–NS (or NS–BH) binaries as “in-states” has been confirmed by strong observational and theoretical evidences (see, e.g., Goodman 1986; Paczynski 1986; Eichler et al. 1989; Narayan et al. 1991, 1992; Meszaros & Rees 1997; Rosswog et al. 2003; Lee et al. 2004; Berger 2014). In this article we address specifically some of the latest results within the fireshell model (Muccino et al. 2013; Ruffini et al. 2015b) on the possible presence or absence of a BH formation in NS–NS mergers, the consequent classification of short bursts into S-GRFs, when no BH is formed (see Section 6), and S-GRBs, when a BH is formed (see Section 7), and the computation of their occurrence rate (see Section 10).

The application of the fireshell model to the case of long GRBs followed a longer path for reaching a proper understanding of the overall phenomenon. The first application of our model to a long GRB was implemented on GRB 991216 (Ruffini et al. 2001a,b,c, 2002, 2004, 2006a). In these papers a clear difference between the thermal component observed at the transparency of the  $e^+e^-$  plasma, the Proper GRB (P-GRB) emission (Ruffini et al. 1999, 2000), and the non-thermal remaining part, later called prompt emission (Ruffini et al. 2001b), was evidenced. This fully relativistic approach was not readily accepted by the GRB community, also in view of its objective technical complexity and novelties in the theoretical physics scenario. Some authors attempted to describe the GRB phenomenon by simplified Newtonian approaches, e.g., those based on the concept of *magnetars* (Usov 1992; Dai & Lu 1998a,b; Kluźniak & Ruderman 1998; Zhang & Mészáros 2001). As the detailed observations of the X-ray afterglow by the *Swift*-XRT (Evans et al. 2007) were obtained, as well as the high energy emission by the Fermi-LAT (Atwood et al. 2009), our model has correspondingly evolved pointing out the precise common power-law behavior of the rest-frame 0.3–10 keV X-ray luminosity light curves (Pisani et al. 2013), as well as the nesting properties (Ruffini et al. 2014b). As pointed out in the present article, the concept of long GRBs has evolved into XRFs and BdHNe, depending on the possible presence or absence of a BH in their formation process (see also Ruffini et al. 2015a).

It is appropriate to recall that the quest for having progenitors for the collapsar hypothesized by Woosley (1993) led to an interesting direction of research dealing with a binary system composed of two very massive stars of  $\approx 50 M_{\odot}$  each. The large masses involved in these systems were introduced in order to form a BH at the end of their evolution. Similarly, the large amount of angular momentum of the system would guarantee the formation of an accretion disks needed in the collapsar model (Fryer et al. 1999). Up to six different scenarios were there envisaged leading to a *collapsar*, as well as a few leading, alternatively, to a variety of binary compact systems. The need for choosing low-metallicity massive stars followed from the expectation of the formation large BHs in their evolution (Fryer et al. 1999). The elimination of H from metal-rich massive stars would follow naturally, but the formation of a BH was not expected in their final stage of evolution (Woosley 1993).

The spatial and temporal coincidence of a long GRB explosion with an optical SN, first observed in the association between GRB 980425 and SN 1998bw, created a profound conceptual turmoil in the GRB community. Woosley and collaborators postulated the birth of a SN out of a collapsar (see, e.g., Woosley & Bloom 2006, and references therein).

In our approach, GRBs were supposed to originate from the BH formation, while SNe were expected to lead only to NSs (see, e.g., Ruffini 2015, and references therein). We consequently introduced a new paradigm to explain the coincidence of these two qualitative and quantitative different astrophysical events in space and time: the birth of a SN and the occurrence of a GRB. The induced gravitational collapse (IGC) paradigm was then introduced (see, e.g.,

Ruffini et al. 2001a, 2006b, 2007, 2008; Izzo et al. 2012b; Rueda & Ruffini 2012; Fryer et al. 2014). This approach differs from alternative descriptions of the GRB-SN coincidences occurring, e.g., in the *magnetars* and the *collapsar* models, where the two events are coming from a single progenitor star, and takes full advantage of the recent observations of SNe Ibc in interacting binary systems (Smartt 2009).

In a first formulation we considered a finely tuned process: the GRB triggering the explosion of a binary companion star very close to the onset of the SN (Ruffini et al. 2001a). This scenario soon led to the alternative IGC paradigm in which a  $\text{CO}_{\text{core}}$  undergoes a SN explosion in presence of a NS companion in a tight binary system. This is also by itself an unlikely event which in order to occur needs a fine tuning of the initial conditions of the binary system. This scenario was shown to be consistent with population synthesis analysis (Fryer et al. 1999, 2015). The SN explosion induces a hypercritical accretion of its ejecta onto the companion NS, leading to the formation of a more massive NS (MNS), when the NS critical mass  $M_{\text{crit}}$  is not reached, or to the formation of a BH with the associated GRB emission in the opposite case (see, e.g., Rueda & Ruffini 2012; Fryer et al. 2014). The IGC scenario was first tested and verified in GRB 090618 (Izzo et al. 2012c,b). It soon became clear that the occurrence of a GRB is far from being a single event, but it is part of an authentic laboratory composed of a variety of astrophysical relativistic phenomena preceding and following the prompt GRB emission.

We adopted as progenitor of our  $\text{CO}_{\text{core}}$ -NS binary system the massive binaries independently considered in Fryer et al. (1999) and Nomoto et al. (1994, 1995). In our case, the late evolution of such massive binary systems do not lead to a collapsar, nor to an hypernova, but to a much richer and vast number of possibilities, made possible by our IGC paradigm. Consistently with the considerations by Sakamoto et al. (2005), indicating that XRFs, X-ray rich bursts, and all long GRBs are part of a same population which we show to originate in the hypercritical accretion process of the SN ejecta onto a binary companion NS.

In agreement with the considerations by Soderberg et al. (2006); Guetta & Della Valle (2007); Liang et al. (2007) for a sub-classification of long bursts into low-luminous and high-luminous GRBs, we have divided the long bursts into two different scenarios depending on the distance between the  $\text{CO}_{\text{core}}$  and the NS binary companion (Becerra et al. 2015). Correspondingly two different sub-classes of long bursts, both originating in the hypercritical accretion process of the IGC scenario, have been shown to exist (Ruffini et al. 2015a; Becerra et al. 2015): the XRFs, which clearly include low-luminous GRBs, such as GRB 060218 (Campana et al. 2006), when no BH is formed (see Section 4), and the BdHNe, such as GRB 130427A (Ruffini et al. 2015a), when a BH is formed (see Section 5). Their occurrence rates have been computed (see Section 10). Instead of proposing just a new classification, we also give the description of its underlying physical origin: the hypercritical accretion process of the SN ejecta onto a binary companion NS, with the full associated theoretical treatments at the basis of the IGC paradigm.

To the above four sub-classes of long and short bursts, we have recently added a new hybrid sub-class of ultrashort GRBs (U-GRBs) which, as recently pointed out in Fryer et al. (2015), can originate during the further evolution of the BdHNe out-states. Indeed, nearly 100% of the NS-BH binaries which are the outcome of BdHNe remain bound. Their orbital velocities are high and even large kicks are unlikely to unbind these systems. They represent a new family of NS-BH binaries unaccounted for in current standard population synthesis analyses (see, e.g., Fryer et al. 2015, and Section 8).

The above considerations based on the IGC paradigm and the NS-NS paradigm as progenitors encompass and classify into sub-classes most of the known astrophysical systems related to GRBs. We finally recall the existence of a class of long GRBs occurring in a low density circumburst medium (CBM) with density  $\sim 10^{-3} \text{ cm}^{-3}$ , with hybrid short/long burst properties in their  $\gamma$ -ray light curves: 1) an initial spike-like harder emission and 2) a prolonged softer emission observed up to a hundred seconds. These bursts do not have an associated SN, even though in the case of a low value of the cosmological redshift its detection would not be precluded. The prototype of such systems is GRB 060614 (Della Valle et al. 2006). The progenitor for this class of long bursts has been identified in a binary system composed of a NS and a white dwarf (WD) (Caito et al. 2009). Their merger leads to a MNS with additional orbiting material, but not to an authentic GRB. We refer to these systems, historically addressed as disguised short GRB, as gamma-ray flashes (GRFs), see, e.g., GRB 060614, Caito et al. 2009 and GRB 071227, Caito et al. 2010).

In the following we adopt the term *burst* only for those systems leading to the BH formation, namely to S-GRBs, U-GRBs and BdHNe. We refer to the term *flash*, instead, only for those systems not leading to the BH formation, namely to S-GRFs, GRFs and XRFs (see Fig. 7).

The main topic addressed in the present article is to estimate the rates of occurrence of the XRFs, BdHNe, S-GRFs, S-GRBs, U-GRBs, and GRFs and to give a general description of these GRB sub-classes. In Section 2 we present a short summary on the fireshell model. In Section 3 we discuss the  $10^{52}$  erg lower limit in binary systems leading to BH formation. After describing the observational properties of the above sub-classes, their interpretation within the

IGC paradigm, the NS-NS merger scenario and the fireshell scenario, we present some prototypes (see Sections 4, 5, 6, 7, 8, and 9, respectively). We then proceed in Section 10 to estimate their observed occurrence rates and to compare and contrast our results with those outlined in the literature (see, e.g., Soderberg et al. 2006; Guetta & Della Valle 2007; Liang et al. 2007; Virgili et al. 2009, 2011; Rangel Lemos et al. 2010; Wanderman & Piran 2010, 2015; Kovacevic et al. 2014; Sun et al. 2015). We then draw some general conclusions in Section 11.

A standard flat  $\Lambda$ CDM cosmological model with  $\Omega_M = 0.27$ ,  $\Omega_\Lambda = 0.73$ , and  $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$  is adopted throughout the paper. A summary of acronyms used throughout the paper is shown in Table 1.

## 2. SUMMARY OF THE FIRESHELL MODEL

The fireshell model for GRBs (see, e.g. Ruffini et al. 2001a,b,c) has been introduced to explain the GRB phenomenon as originating in the gravitational collapse leading to the formation of a BH (Damour & Ruffini 1975). The GRB emission results by taking into proper account relativistic magneto-hydrodynamical effects, quantum-electrodynamical process, and relativistic space-time transformations.

The role of the relativistic magneto-hydrodynamical effects arising in the gravitational collapse of a globally neutral magnetized plasma has been first considered in Ruffini & Wilson (1975), where the occurrence of a local charge separation, during a globally neutral accretion process, led to the development of overcritical electric fields at the onset of a KNBH formation.<sup>1</sup> These overcritical fields and, consequently, the vacuum polarization process leading to the creation of an  $e^+e^-$  plasma, have been considered in Damour & Ruffini (1975), for the sake of definiteness in a KNBH, as the energy source of GRBs:<sup>2</sup> the pair creation process is fully reversible and as a result a highly efficient energy extraction mechanism occurs, which may deliver as much as  $E_{\text{max}} \approx 10^{54} M_{\text{BH}}/M_\odot \text{ erg}$ .

Later on, the concept of *dyadotorus* for a KNBH (Cherubini et al. 2009; Ruffini 2009) has been introduced to describe the region where pair creation occurs, leading to the formation of a BH. The dynamics of an optically thick *fireshell* of  $e^+e^-$  plasma of total energy  $E_{e^+e^-}^{\text{tot}}$ , i.e., its expansion and self-acceleration due to its own internal pressure, has been described in Ruffini et al. (1999). The effect of baryonic contamination, i.e., the remnant of the collapsed object, on the dynamics of the fireshell has been then considered in Ruffini et al. (2000), where it has been shown that even after the engulfment of a baryonic mass  $M_B$ , quantified by the baryon load  $B = M_B c^2 / E_{e^+e^-}^{\text{tot}}$ , the fireshell remains still

<sup>1</sup> Overcritical electric fields are defined as larger than the critical value  $E_c = m_e^2 c^3 / (h e)$ , where  $m_e$  is the electron mass,  $c$  the speed of light in the vacuum,  $h$  the reduced Planck constant, and  $e$  the electron charge.

<sup>2</sup> The role of an  $e^+e^-$  plasma for the origin of GRBs was also considered independently by Cavallo & Rees (1978).

optically thick and continues its self-acceleration up to ultrarelativistic velocities (Aksenov et al. 2007, 2009). When the fireshell reaches transparency condition, a flash of thermal radiation termed P-GRB is emitted (Ruffini et al. 1999, 2000). The dynamics of the fireshell up to the transparency condition is fully described by  $E_{e^+e^-}^{\text{tot}}$  and  $B$ : solutions with  $B \leq 10^{-2}$  are characterized by regular relativistic expansion; for  $B > 10^{-2}$  turbulence and instabilities occur (Ruffini et al. 2000).

The P-GRB emission is followed by the prompt emission (Ruffini et al. 2001b). The prompt emission originates in the collisions of the accelerated baryons left over after transparency, moving at Lorentz factor  $\Gamma \approx 100$ –1000, with interstellar clouds of CBM (Ruffini et al. 2002, 2004, 2005). These interactions give rise to a modified blackbody spectrum in the co-moving frame (Patricelli et al. 2012). The resulting observed spectral shape, once the constant arrival time effect is taken into account in the EQuiTemporal Surfaces (EQTS, see Bianco & Ruffini 2005a,b), is in general non-thermal, as the result of the convolution of a large number of modified thermal spectra with different Lorentz factors and temperatures. To reproduce the prompt emission light curve and spectra three additional parameters, all related to the properties of the CBM, are required: the CBM density profile  $n_{\text{CBM}}$ , the filling factor  $\mathcal{R}$  that accounts for the size of the effective emitting area, and a low-energy power-law index  $\alpha$  of the modified black body spectrum (Patricelli et al. 2012). These parameters are obtained by running a trial-and-error simulation of the observed prompt emission light curves and spectra.

To describe the dynamics of such an  $e^+e^-$ -baryon plasma from the vicinity of a BH all the way up to ultrarelativistic velocities at the infinity, both in the P-GRB and the prompt emission, the appropriate relative spacetime transformation paradigm has been discussed in Ruffini et al. (2001c). It relates the observed GRB signal to its past light cone, defining the events on the worldline of the source that is essential for the interpretation of the data. Particular attention has been there given to the explicit equations relating the comoving time, the laboratory time, the arrival time, and the arrival time at the detector corrected by the cosmological effects, consistently with the equation of motion of the system (see also Bianco & Ruffini 2004, 2005a,b, 2006), compared and contrasted with the corresponding treatments in the literature (see, e.g., Sari 1997, 1998; Waxman 1997; Panaitescu & Meszaros 1998; Panaitescu & Mészáros 1999; Rees & Meszaros 1998; Granot et al. 1999; Chiang & Dermer 1999).

As recalled above, the evolution of a baryon-loaded pair plasma, is generally described in terms of  $E_{e^+e^-}^{\text{tot}}$  and  $B$  and it is independent of the way the pair plasma is created. Given this generality, in addition to the specific case of the dyadotorus mentioned above, these concepts can be applied as well in the case of a pair plasma created via  $\nu\bar{\nu} \leftrightarrow e^+e^-$  mechanism in a NS merger as described in Narayan et al. (1992), Salmonson & Wilson (2002), and Rosswog et al. (2003), or in the hyper-accretion disks around BHs as described in Woosley (1993) and Zalamea & Beloborodov (2011), assuming that the created pair plasma is optically thick. The relative role of neutrino and weak interactions vs. the electromagnetic interactions in building the dyadotorus is currently topic of intense research.

In conclusion, the deeper understanding of the GRB phenomenon, occurring under very different initial conditions, has highlighted the possibility of using the general description of the dyadosphere (dyadotorus) to any source of an optically thick baryon-loaded  $e^+e^-$  plasma and, consequently, to apply the above fireshell treatment in total generality.

The generality of the fireshell approach clearly differs from alternative treatments purporting late activity from a central engine (see, e.g., the *collapsar* model in Woosley 1993, Popham et al. 1999, Woosley & Bloom 2006 and references therein, and the Newtonian *magnetar* model in Zhang & Mészáros 2001, Dai et al. 2006, Metzger et al. 2011, Bucciantini et al. 2012, Giacomazzo & Perna 2013, Lü & Zhang 2014, and references therein), and proposes a different explanation for the afterglow observations in long GRBs (see Pisani et al. 2013, and Aimuratov et al., in preparation).

### 3. ON THE $10^{52}$ ERG LOWER LIMIT IN BINARY SYSTEMS LEADING TO BH FORMATION

During the hypercritical accretion process onto the NS the total energy available to be released, e.g. in form of neutrinos and photons, is given by the gain of gravitational potential energy of the matter being accreted by the NS (Zel'dovich et al. 1972; Ruffini & Wilson 1973; Rueda & Ruffini 2012; Fryer et al. 2014). The total energy released in the star in a time-interval  $dt$  during the accretion of an amount of mass  $dM_b$  with angular momentum  $lM_b$  is given by (see, e.g., Sibgatullin & Sunyaev 2000; Becerra et al. 2015):

$$L_{\text{acc}} = \left( \dot{M}_b - \dot{M}_{\text{NS}} \right) c^2 = \dot{M}_b c^2 \left[ 1 - \left( \frac{\partial M_{\text{NS}}}{\partial J_{\text{NS}}} \right)_{M_b} l - \left( \frac{\partial M_{\text{NS}}}{\partial M_b} \right)_{J_{\text{NS}}} \right], \quad (1)$$

where  $J$  is the NS angular momentum. The last two terms of the above equation take into due account the change of binding energy of the NS while accreting both matter and angular momentum. We assume, as a norm, a typical NS mass of  $\approx 1.4 M_{\odot}$ , a value observed in galactic NS binaries (Zhang et al. 2011; Antoniadis 2015) and characteristic

of the XRFs (Becerra et al. 2016). We also assume a NS critical mass  $M_{crit}$  in the range from  $2.2 M_{\odot}$  up to  $3.4 M_{\odot}$  depending on the equations of state and angular momentum (see Becerra et al. 2016, 2015; Cipolletta et al. 2015, for details).  $L_{acc}$  is clearly a function both of the NS mass and of  $M_{crit}$ .

Since  $L_{acc} \propto \dot{M}_b$ , it evolves with time similarly to  $\dot{M}_B$ . We have shown that the accretion luminosity can be as high as  $L_{acc} \sim 0.1 \dot{M}_b c^2 \sim 10^{47} - 10^{51} \text{ erg s}^{-1}$  for accretion rates  $\dot{M}_b \sim 10^{-6} - 10^{-2} M_{\odot} \text{ s}^{-1}$  (see Becerra et al. 2016, 2015, for details). The duration of the accretion process is given approximately by the flow time of the slowest layers of the SN ejecta to the NS companion. If the velocity of these layers is  $v_{inner}$ , then  $\Delta t_{acc} \sim a/v_{inner}$ , where  $a$  is the binary separation. For  $a \sim 10^{11} \text{ cm}$  and  $v_{inner} \sim 10^8 \text{ cm s}^{-1}$  we obtain  $\Delta t_{acc} \sim 10^3 \text{ s}$ , while for shorter binary separation, e.g.  $a \sim 10^{10} \text{ cm}$  ( $P \sim 5 \text{ min}$ ),  $\Delta t_{acc} \sim 10^2 \text{ s}$ . These estimates are validated by our numerical simulations (see, e.g., Becerra et al. 2016, 2015; Fryer et al. 2015, 2014). From the above results we obtain that for systems with the above short orbital periods the NS collapses to a BH, namely BdHNe (Becerra et al. 2016), and a total energy larger than the separatrix energy of  $\approx 10^{52} \text{ erg}$  is released during the hypercritical accretion process. For systems with larger separations, in which the hypercritical accretion is not sufficient to induce the collapse of the NS into a BH, namely the XRFs (Becerra et al. 2016), the value of  $\approx 10^{52} \text{ erg}$  represents a theoretical estimate of the upper limit to the energy emitted by norm in the hypercritical accretion process. These considerations are derived from theoretical expectations based on the above mentioned masses for the accreting NSs and  $M_{crit}$ . Indeed, they are in satisfactory agreement with the observations of 20 XRFs and 233 BdHNe (considered up to the end of 2014) which we have used in our sample (see Table 2 and 3, respectively). The upper limit for the XRFs is  $(7.3 \pm 0.7) \times 10^{51} \text{ erg}$  (see Sec. 4.1), while the lower limit for the BdHNe is  $(9.2 \pm 1.3) \times 10^{51} \text{ erg}$  (see Sec. 5.1).

The same arguments apply to the fusion process of two NSs in a binary NS merger (Ruffini et al. 2015b). Therefore, from these general arguments, we can conclude that the energy emitted during the merger process leading to the formation of a BH should be larger than  $\approx 10^{52} \text{ erg}$ . Indeed, we find the upper limit for the S-GRFs of  $(7.8 \pm 1.0) \times 10^{51} \text{ erg}$  (see Sec. 6.1) and the lower limit for the S-GRBs of  $(2.44 \pm 0.22) \times 10^{52} \text{ erg}$  (see Sec. 7.1).

Such a separatrix energy is clearly a function of the initial NS mass undergoing accretion, by norm assumed to be  $\approx 1.4 M_{\odot}$ . It is also a function of the yet unknown precise value of  $M_{crit}$  for which only an absolute upper limit of  $3.2 M_{\odot}$  has been established for the non-rotating case (Rhoades & Ruffini 1974). As already pointed out in Ruffini et al. (2015b) for the case of binary NS mergers, the direct observation of the separatrix energy between S-GRFs and S-GRBs, and also (in this case) between BdHNe and XRFs, gives fundamental informations for the determination of the actual value of  $M_{crit}$ , for the minimum mass of the newly-formed BH, and for the mass of the accreting NS. It is appropriate to notice that a value of the mass of the accreting NS binary, larger than  $\approx 1.4 M_{\odot}$ , is *a priori* possible and would give interesting observational properties: an exceptional accreting NS with mass close to  $M_{crit}$  would lead to a BdHN with a value of the energy lower than the theoretical separatrix of  $\approx 10^{52} \text{ erg}$ . Conversely, the accretion on a NS with mass smaller than  $\approx 1.4 M_{\odot}$  should lead to an XRF with energy larger than  $\approx 10^{52} \text{ erg}$ . These rare possibilities will be precious in further probing the implications of the IGC paradigm, in estimating the NS masses, as well as in deriving more stringent limits on  $M_{crit}$  directly from observations.

Our theory of the hypercritical accretion, applied in the GRB analysis through the IGC paradigm in binary systems, introduces substantial differences with respect to the traditional ones. To appreciate these differences and gain familiarity in this novel approach, we recommend the reading of all the references quoted in this section.

## 4. THE X-RAY FLASHES

### 4.1. General properties

The observational features of long bursts with energy below  $\approx 10^{52} \text{ erg}$  are listed below and summarized in Fig. 1. These bursts are interpreted within the theoretical framework of the IGC as a new class which we indicate as XRFs.

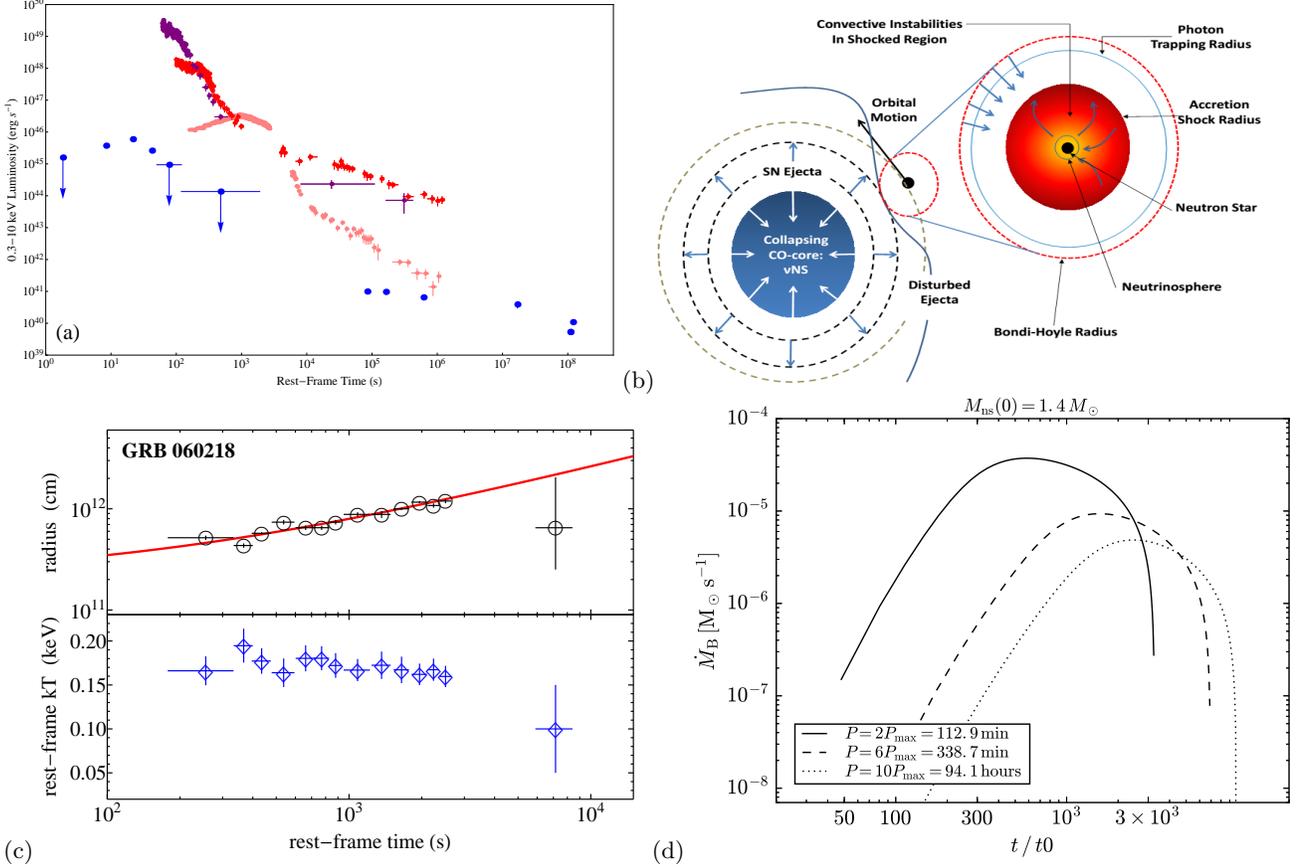

The upper limit on the energetic of the XRFs is  $(7.3 \pm 0.7) \times 10^{51} \text{ erg}$  as measured in GRB 110106B.

The isotropic energies are in the range  $(6.4 \pm 1.6) \times 10^{47} \lesssim E_{iso} \lesssim (7.3 \pm 0.7) \times 10^{51} \text{ erg}$  (see Fig. 8 and Amati & Della Valle 2013; Ruffini et al. 2015a).

The spectral peak energies are in the range  $4 \lesssim E_{p,i} \lesssim 200 \text{ keV}$  (see Fig. 8 and Amati & Della Valle 2013; Ruffini et al. 2015a) and increase monotonically with  $E_{iso}$ .

The cosmological redshifts are in the range  $0.0085 \leq z \leq 1.096$ , with an average value of  $\approx 0.43$  (see Table 2).

The prompt emission phase has a duration ranging between  $\sim 10^2 - 10^4 \text{ s}$  (see Fig. 1 (a)) with a spectrum generally characterized by a thermal component and power-law component. The radii of the thermal emitter are in the range of  $10^{10} - 10^{12} \text{ cm}$  and the temperatures vary in the range of  $0.1 - 2 \text{ keV}$  (see, e.g., Campana et al. 2006, and Fig. 1 (c)), depending on the values of the binary period and separation of the progenitor systems.

**Figure 1.** (a) Rest-frame 0.3–10 keV luminosity light curves of four selected XRFs: GRB 980425 (blue), GRB 060218 (pink), GRB 070419A (purple), and GRB 101219B (red). (b) A sketch of the CO<sub>core</sub>-NS binary progenitor and the hypercritical accretion process in the IGC scenario (reproduced from Fryer et al. 2014). (c) Upper panel: the evolution of the radius of the thermal component detected in GRB 060218 (black circles) and its linear fit (solid red curve). Lower panel: the decay of the corresponding rest-frame temperature (blue diamonds). Reproduced from Campana et al. (2006). (d) Mass accretion rate  $\dot{M}_B$  of the SN ejecta onto a NS companion of initial mass  $1.4 M_{\odot}$ , as function of time. Three cases are plotted for various selected orbital periods  $P > P_{\text{max}}$  (see legend).

The long lasting X-ray afterglow does not exhibit any specific common late power-law behavior (see Fig. 1 (a)).

For all XRFs at  $z \lesssim 1$ , an optical SN with a luminosity similar to the one of SN 2010bh (Bufano et al. 2012), occurs after 10–15 days in the cosmological rest-frame.

No high energy emission has ever been observed.

In view of the observed values of  $E_{p,i}$  which occur in the X-ray domain and also because of the low values of their  $E_{\text{iso}} < 10^{52}$  erg, we adopted the name XRFs for these soft and less energetic long bursts, a terminology already used in the literature on purely morphological grounds (see, e.g., Heise 2003; Amati et al. 2004; Soderberg et al. 2006).

#### 4.2. Theoretical interpretation of XRFs within the IGC paradigm

In the IGC paradigm an XRF occurs when the CO<sub>core</sub>-NS binary separation  $a$  is so large (typically  $a > 10^{11}$  cm, see e.g., Becerra et al. 2015) that the accretion of the SN ejecta onto the NS is not sufficient for the NS to reach  $M_{\text{crit}}$ . Correspondingly, there is a critical or maximum value of the orbital period  $P_{\text{max}}$  (e.g.  $P_{\text{max}} \approx 28$  min for a NS with initial mass of  $1.4 M_{\odot}$ ) for which the NS collapses to a BH, namely for  $P > P_{\text{max}}$  the accretion rate is not sufficient to induce the gravitational collapse of the companion NS into a BH (see Figs. 1 (d)).

The hypercritical accretion of the SN ejecta onto the NS binary companion occurs at rates  $< 10^{-2} M_{\odot} \text{ s}^{-1}$  and can last from several hundreds of seconds all the way up to  $\sim 10^4$  s, until the whole SN ejecta flies beyond the NS binary orbit (see Fig. 1 (a)). The photons are trapped in the accreting material and the accretion energy is lost through a large associated neutrino emission (see, e.g., Zel'dovich et al. 1972; Ruffini & Wilson 1973; Rueda & Ruffini 2012; Fryer et al. 2014, and references therein). The upper limit of  $10^{52}$  erg of these sources is explainable by estimating the gravitational energy of the matter accreted onto the NS reaching a mass below  $M_{\text{crit}}$  at the end of the accretion process (see Sec. 3).

GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$	GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$
970508	0.835	$65 \pm 13$	081007	0.5295	$17 \pm 2$
980425	0.0085	$0.0064 \pm 0.0016$	100316D	0.059	$0.59 \pm 0.05$
980613	1.096	$50 \pm 10$	100816A	0.8049	$71 \pm 9$
990712	0.434	$69 \pm 13$	101219B	0.55	$63 \pm 6$
020819B	0.41	$69 \pm 18$	110106B	0.618	$73 \pm$
020903	0.251	$0.24 \pm 0.06$	120121B	0.017	$0.0139 \pm 0.0002$
031203	0.105	$0.99 \pm 0.10$	120422A	0.283	$2.4 \pm 0.8$
050416A	0.6528	$11 \pm 2$	120714B	0.3984	$8.0 \pm 2.0$
060218	0.033	$0.54 \pm 0.05$	130702A	0.145	$6.5 \pm 1.0$
070419	0.97	$24 \pm 10$	130831A	0.4791	$46 \pm 2$

**Table 2.** List of the XRFs considered in this work up to the end of 2014. For each source (first column) the values of  $z$  and  $E_{\text{iso}} \lesssim 10^{52}$  erg (second and third columns, respectively) are listed.

The resulting emission, dubbed Episode 1, exhibits a spectrum composed of a thermal component, possibly originating from the outflow within the NS atmosphere driven out by Rayleigh-Taylor convection instabilities, and a power-law component. The shorter the binary period, the larger the accretion rate (see Figs. 1 (f)) and the values of  $E_{\text{iso}}$  and  $E_{\text{p,i}}$ , and correspondingly the shorter the prompt emission duration (see Fig. 1 (a)). The excess of angular momentum of the system necessarily leads to a jetted emission, manifested in the power-law spectral component (Becerra et al. 2015). Indeed in the IGC simulations the typical radii inferred from the evolving thermal component coincide with the observed ones of  $10^{10}$ – $10^{12}$  cm.

In the IGC paradigm the in-state is represented by an exploding  $\text{CO}_{\text{core}}$  and a companion NS. The out-state is multiple system composed of a MNS, resulting from the accretion of part of the SN ejecta onto the binary companion NS, a  $\nu\text{NS}$ , originating from the SN event, and the remaining part of the SN ejecta shocked by the hypercritical accretion emission of the XRF. This energy injection into the SN ejecta leads to the occurrence of a broad-lined SN Ic (*hypernova*, see, e.g., Maeda & Nomoto 2003) with a kinetic energy larger than that of the traditional SNe Ic. The presence of  $^{56}\text{Ni}$  in the SN ejecta leads to the observed SN emission after  $\approx 10$ – $15$  days in the cosmological rest-frame which is observable for sources at  $z \lesssim 1$ .

Clearly the absence of hard  $\gamma$ -ray and GeV emissions is implicit in the nature of the hypercritical accretion process not leading to a BH and the corresponding rate of neutrino emission (see also Appendix A).

#### 4.3. Prototypes

In Fig. 1(a) we reproduce the rest-frame 0.3–10 keV luminosity light curves of four selected XRFs: GRB 980425 (Pian et al. 2000; Kouveliotou et al. 2004; Pian et al. 2004), associated with SN 1998bw (Galama et al. 1998), GRB 060218 associated with SN 2006aj (Campana et al. 2006; Soderberg et al. 2006), GRB 070419A (Evans et al. 2007, 2009) with an optical SN bump (Hill et al. 2007), and GRB 101219B (Evans et al. 2007, 2009) associated with SN 2010ma (Sparre et al. 2011). Their prompt emissions are represented by the above mentioned Episode 1. In Fig. 1 (c) we plot the evolution of both temperature and radius inferred from the thermal component observed in the Episode 1 emission of GRB 060218. The increasing radius and almost constant temperature are obtained from the thermal component observed in GRB 060218 (Campana et al. 2006). Details will appear in forthcoming publications (Pisani et al., and Becerra et al., in preparation). A complete list of XRFs is shown in Table 2.

## 5. THE BINARY-DRIVEN HYPERNOVAE

### 5.1. General properties

The observational features of long bursts with energy above  $\approx 10^{52}$  erg are listed below and summarized in Fig. 2. These bursts are interpreted within the theoretical framework of the IGC as a new class which we indicate as BdHNe.

The lower limit on the energetic of the BdHNe is  $(9.2 \pm 1.3) \times 10^{51}$  erg as measured in GRB 070611.

The observed isotropic energies are in the range  $(9.2 \pm 1.3) \times 10^{51} \lesssim E_{\text{iso}} \lesssim (4.07 \pm 0.86) \times 10^{54}$  erg (see Fig. 8 and Amati & Della Valle 2013; Ruffini et al. 2015a) and are in principle dependent on the NS mass which we have assumed, as an example,  $\approx 1.4 M_{\odot}$  (see sec. 3).

The spectral peak energies are in the range  $0.2 \lesssim E_{\text{p,i}} \lesssim 2$  MeV (see Fig. 8 and Amati & Della Valle 2013; Ruffini et al. 2015a) and increase monotonically with  $E_{\text{iso}}$ .

The cosmological redshifts are in the range  $0.169 \leq z \leq 9.3$ , with an average value of  $\approx 2.42$  (see Table 3).

The prompt emission phase of BdHNe exhibits a more complex structure than that of XRFs. Indeed three different regimes are found:

- a) A thermal emission with a decreasing temperature following a broken power-law behavior, and an additional non-thermal spectral component (a power-law), dominate the early emission in selected BdHNe (see, e.g., Izzo et al. 2012c, and Fig. 2 (a)). The existence of this thermal component was first identified in the GRB BATSE data by Ryde (2004, 2005). It has been then shown to occur in the case of BdHNe as GRB 090618 (Izzo et al. 2012c, and Fig. 2 (a)), GRB 101023 (Penacchioni et al. 2012), GRB 110709B (Penacchioni et al. 2013), and GRB 970828 Ruffini et al. (2015c). The characteristic radii inferred from the cooling thermal component are of the order of  $10^9$ – $10^{10}$  cm and the average expansion speed is  $\sim 10^8$ – $10^9$  cm s $^{-1}$  (Izzo et al. 2012c; Penacchioni et al. 2012, 2013; Ruffini et al. 2015c).
- b) This early emission is followed by the characteristic GRB emission (see Fig. 2 (d)), encompassing a thermal precursor, the P-GRB (Ruffini et al. 1999, 2000), followed by the prompt emission (Ruffini et al. 2002, 2004, 2005).
- c) The prompt emission is followed by a steep decay, then by a plateau and a late power-law decay. These features have been first reported in Nousek et al. (2006) and Zhang et al. (2006).

The late decay has typical slopes of  $-1.7 \lesssim \alpha_X \lesssim -1.3$  (Pisani et al. 2013) and shows a characteristic power-law behavior both in the optical and in X-rays. When computed in the source cosmological rest-frame, the late power-law decay in X-rays exhibits new features: overlapping and nesting (see Fig. 2 (c)). Overlapping has been proven in a sample of six BdHNe: GRBs 060729, 061007, 080319B, 090618, 091127, and 111228, (Izzo et al. 2012a; Pisani et al. 2013). The nested property of the BdHNe has been discussed in Ruffini et al. (2014b), where it has been shown that the duration (the luminosity) of the plateau phase is inversely (directly) proportional to the energy of the GRB emission: the more energetic the source, the smaller (higher) the duration (the luminosity) of the plateau.

For all BdHNe at  $z \lesssim 1$ , an optical SN with a luminosity similar to the one of SN 1998bw (Galama et al. 1998), occurs after 10–15 days in the cosmological rest-frame.

A distinctive high energy emission observed up to 100 GeV shows a luminosity light curve following a precise power-law behavior with index  $\approx -1.2$  (Fig. 2 (d) and Nava et al. 2014). The turn-on of this GeV emission occurs after the P-GRB emission and during the prompt emission phase.

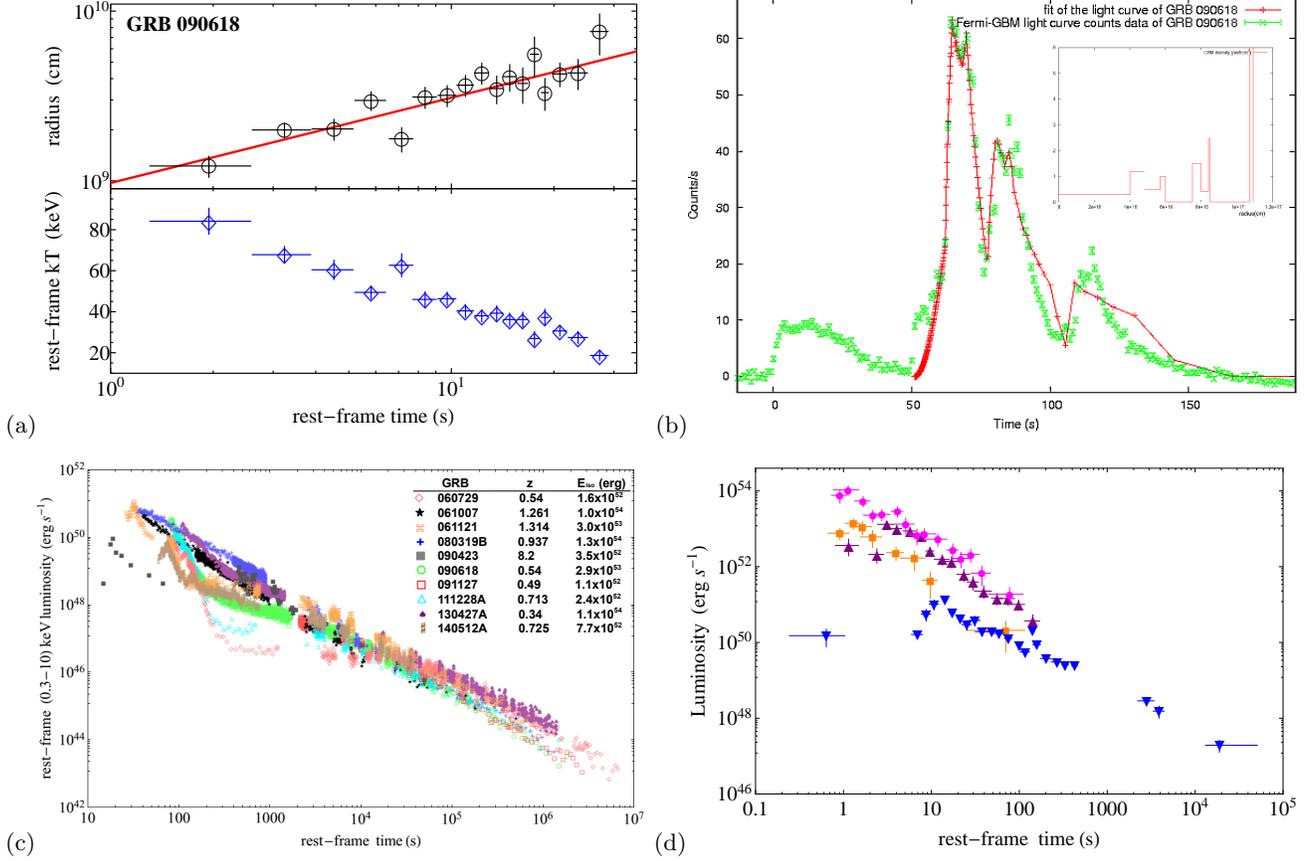

### 5.2. Theoretical interpretation of BdHNe within the IGC paradigm

In the IGC paradigm a BdHN occurs when the CO<sub>core</sub>-NS binary is more tightly bound ( $a \lesssim 10^{11}$  cm, see e.g., Becerra et al. 2015). The larger accretion rate of the SN ejecta, e.g.,  $\gtrsim 10^{-2}$ – $10^{-1} M_{\odot} \text{ s}^{-1}$ , leads the companion NS to easily reach its critical mass  $M_{\text{crit}}$  (Rueda & Ruffini 2012; Fryer et al. 2014; Becerra et al. 2015), leading to the formation of a BH. The electro-dynamical conditions encountered in the final accretion phase explain the existence of a vacuum polarization process leading to the creation of an  $e^+e^-$  plasma and to the formation of a KNBH with a large variety of new astrophysical phenomena. For the sake of clarity and independence on the physical regime encountered, in the IGC paradigm we have divided the activities of the BdHNe in a numbered set of distinct Episodes.

Episode 1 of BdHNe originates in the same hypercritical accretion process as the corresponding one of XRFs. The corresponding spectrum again exhibits an expanding thermal component and a power-law function (Izzo et al. 2012c; Ruffini et al. 2015c). The typical radii inferred from the thermal component are of the order of  $10^9$ – $10^{10}$  cm and the average expansion speed is  $\sim 10^8$ – $10^9$  cm s $^{-1}$  (see Fig. 2 (a) and Izzo et al. 2012c; Ruffini et al. 2015c).

Episode 2 corresponds to the authentic long GRB emission (see Fig. 2 (b)), stemming from the collapse of the companion NS to a BH. For its theoretical description we adopt the traditional fireshell model (see Ruffini et al. 2001a,b,c, and Section 2). The GRB emission occurs at Lorentz factor at the transparency of  $\Gamma = 10^2$ – $10^3$  (Izzo et al. 2012c; Ruffini et al. 2015c) and the spatial extension of the interaction of the fireshell with the circumburst medium goes all the way up to  $\sim 10^{16}$ – $10^{17}$  cm, reached at the end of Episode 2 (Izzo et al. 2012c). The BdHNe have  $E_{\text{iso}} \gtrsim 10^{52}$  erg and their  $E_{p,i} \gtrsim 200$  keV is in the hard  $\gamma$ -ray domain.

Episode 3 in BdHNe originates from the SN ejecta (Ruffini et al. 2015a). In this case an extra energy injection is delivered by the interaction of the GRB outflow with the SN ejecta resulting in an isotropic energy emission of  $10^{51}$ – $10^{52}$  erg. This interaction produces a flare at the beginning of Episode 3 (typically at a rest-frame time of  $\sim 10^2$  s) with the typical signature of an expanding thermal component in its spectrum. The radii inferred from this thermal

**Figure 2.** (a) Upper panel: the evolution of the radius of the thermal component detected in the Episode 1 of GRB 090618 (black circles) and its linear fit (solid red curve). Lower panel: the decay of the corresponding rest-frame temperature (blue diamonds). Reproduced from Izzo et al. (2012c). (b) The fireshell simulation (red line) of the light curve of Episode 2 of the prototype GRB 090618 (green data). The small inset reproduces the CBM profile required for the simulation. Reproduced from Izzo et al. (2012c). (c) The rest-frame 0.3–10 keV luminosity light curves of selected BdHNe. All these sources exhibit the overlapping of the late power-law decay, outlined in Pisani et al. (2013), and a nested structure, as outlined in Ruffini et al. (2014b). (d) The rest-frame 0.1–100 GeV luminosity light curves of selected BdHNe (reproduced from Ackermann et al. 2013): GRB 080916C (magenta circles), GRB 090902B (purple triangles), GRB 110731A (orange squares), GRB 130427A (blue reversed triangles).

component are  $\sim 10^{12}$ – $10^{13}$  cm and their evolution reveals a mildly relativistic expansion at  $\Gamma \approx 2$  (Ruffini et al. 2014b, 2015a). The rest-frame 0.3–10 keV luminosity light is then followed by a plateau phase and a late power-law decay. The late decay has been shown to exhibit a common power-law behavior and a nested structure (see, e.g., Pisani et al. 2013; Ruffini et al. 2014b, and Fig. 2 (c)). The possibility of using the late X-ray emission as a distance indicator has been explored by inferring the redshifts of GRBs 101023 and 110709B (Penacchioni et al. 2012, 2013), and has been applied to predict the occurrence of the SN associated to GRB 130427A after  $\sim 10$ – $15$  days in the cosmological rest-frame before its discovery (Ruffini et al. 2013), later confirmed by the observations (de Ugarte Postigo et al. 2013; Levan et al. 2013; Watson et al. 2013; Xu et al. 2013).

Episode 4, as predicted in the IGC paradigm and in analogy to XRFs, corresponds to the optical SN emission observable in all BdHNe at  $z \lesssim 1$  after  $\approx 10$ – $15$  days in the cosmological rest-frame. It is remarkable that these SNe have a standard luminosity, like the one of SN 1998bw (see, e.g., Melandri et al. 2014).

A new Episode 5, here introduced, is identified with the long-lived GeV emission. This emission is conceptually distinct in its underlying physical process from that of Episode 3. When LAT data are available, the majority of BdHNe observed by the *Fermi* satellite (Atwood et al. 2009) exhibit such an emission, similar to the one observed in S-GRBs (see Section 6). In Ruffini et al. (2015a) the further accretion of matter onto the newly-formed BH has been indicated as the origin of this GeV emission. An outstanding exception is GRB 151027A (Kovacevic et al., in preparation).

Also for BdHNe the in-state is composed of an exploding  $\text{CO}_{\text{core}}$  and a companion NS. The out-state is again multiple system. First, there is a GRB composed of the P-GRB and its prompt emission. Then there is a newly-formed BH,

produced by the hypercritical accretion of part of the SN ejecta onto the binary companion NS reaching  $M_{\text{crit}}$ . Again, there is a  $\nu$ NS originating from the SN explosion. Finally, there is the remaining part of the SN ejecta shocked by the GRB emission. The energy injection into the SN ejecta from both the hypercritical accretion phase and the GRB emission leads also in this case to the occurrence of a broad-lined SN Ic (*hypernova*, see, e.g., [Maeda & Nomoto 2003](#)) with a kinetic energy larger than that of the traditional SNe Ic.

### 5.3. Prototypes

In the following selected prototypes of BdHNe are given and illustrated in Fig. 2.

The first systematic time-resolved spectral analysis of an Episode 1 of a BdHN has been performed for GRB 090618 ([Izzo et al. 2012c](#)). In this source the typical radii inferred from the cooling thermal component are of the order of  $10^9$ – $10^{10}$  cm and the average expansion speed is  $\sim 10^8$ – $10^9$  cm s $^{-1}$  (see Fig. 2(a)). Similar results have been obtained for GRB 101023 ([Penacchioni et al. 2012](#)), GRB 110907B ([Penacchioni et al. 2013](#)), and GRB 980828 ([Ruffini et al. 2015c](#)).

The selected prototypes of Episode 2 emission have isotropic energies ranging from  $E_{\text{iso}} = 1.60 \times 10^{53}$  erg in GRB 970828 ([Ruffini et al. 2015c](#)), to  $E_{\text{iso}} = 1.32 \times 10^{54}$  erg in GRB 080319B ([Patricelli et al. 2012](#)). The amount of baryonic matter loaded before the P-GRB emission, the baryon load  $B \equiv M_B c^2 / E_{e^+e^-}^{\text{tot}}$ , where  $E_{e^+e^-}^{\text{tot}}$  is the pair plasma energy and  $M_B$  the engulfed baryon mass, is in the range from  $B = 1.98 \times 10^{-3}$  for GRB 090618 ([Izzo et al. 2012c](#)), to  $B = 7.0 \times 10^{-3}$  in GRB 970828 ([Ruffini et al. 2015c](#)). Correspondingly, their transparency emission occurs at Lorentz factors at the transparency ranging from  $\Gamma = 143$  in GRB 970828 ([Ruffini et al. 2015c](#)), to  $\Gamma = 490$  in GRB 090618, ([Izzo et al. 2012c](#)). The average density of the circumburst medium in these prototypes, inferred from description of the the interaction with the fireshell after its transparency ([Ruffini et al. 2002, 2004, 2005](#)), vary from  $0.6$  cm $^{-3}$  in GRB 090618 ([Izzo et al. 2012c](#)), to  $\approx 10^3$  cm $^{-3}$  in GRB 970828 ([Ruffini et al. 2015c](#)). The size of the corresponding emitting region,  $\sim 10^{16}$ – $10^{17}$  cm, is clearly incompatible with the radii inferred from Episode 1 and 3. This points to the different origins in the emission mechanisms of the above three Episodes.

The radii inferred from the expanding thermal components observed in the spectra of the flares at the beginning of Episode 3 are typically  $\sim 10^{12}$ – $10^{13}$  cm. This has been found in the cases of GRB 090618, (see, e.g., [Starling et al. 2010](#); [Ruffini et al. 2014b](#)), and GRB 130427A ([Ruffini et al. 2015a](#)). In both these sources, the expansion of the thermal emitter of Episode 3 proceeds at  $\Gamma \approx 2$  ([Ruffini et al. 2014b, 2015a](#)). After the initial emission in the spike of Episode 3, the rest-frame 0.3–10 keV luminosity light curve is then followed by a plateau phase and a late power-law decay. The overlapping of the late power-law decay and the nested structure are reproduced in Fig. 2 (c) for selected sources: GRB 060729, GRB 061007, GRB 080319B, GRB 090618, GRB 091127B, and GRB 111228A (considered in [Pisani et al. 2013](#)), GRB 061121 and GRB 130427A (considered in [Ruffini et al. 2014b, 2015a](#)), GRB 090423 ([Ruffini et al. 2014a](#)), and GRB 140512A (introduced here).

Episode 4 has been spectroscopically identified for the two closest BdHNe, e.g., GRB 091127–SN 2009 nz ([Cobb et al. 2010](#)) and GRB 130427A–SN 2013cq ([Xu et al. 2013](#)). In the cases of GRB 060729 ([Cano et al. 2011](#)), GRB 080319B ([Kann et al. 2008](#)), GRB 090618 ([Cano et al. 2011](#)), and GRB 111228A ([D’Avanzo et al. 2012](#)), at  $z \lesssim 1$ , the identification was possible through the detection of bumps in their Episode 3 optical light curves.

Turning now to the Episode 5 of BdHNe, the GeV emission has been studied in detail in the case of GRB 130427A ([Ruffini et al. 2015a](#)), as well as in other selected BdHNe (see Fig. 2 (d) and [Ackermann et al. 2013](#)). The turn-on has been identified as the on-set of the emission from the newly-formed BH ([Ruffini et al. 2015a](#)).

A complete list of BdHNe is shown in Table 3.

The ultra long GRBs ([Levan et al. 2014](#); [Boër et al. 2015](#)) are certainly BdHNe on the ground of their late x-ray rest frame luminosity ([Pisani et al.](#), submitted to ApJ).

**Table 3.** List of the BdHNe considered in this work up to the end of 2014. For each source (first columns) the values of  $z$  and  $E_{\text{iso}}$  (second and third columns, respectively) are listed.

GRB	$z$	$E_{\text{iso}}/(10^{52} \text{ erg})$	GRB	$z$	$E_{\text{iso}}/(10^{52} \text{ erg})$

## 6. THE SHORT GAMMA-RAY FLASHES

### 6.1. General properties

The observational features of short bursts with energy below  $\approx 10^{52}$  erg are listed below and summarized in Fig. 3. These bursts are interpreted within the theoretical framework of the NS-NS merger paradigm in the fireshell model as a new class which we indicate as S-GRFs.

The upper limit on the energetic of the S-GRFs is  $(7.8 \pm 1.0) \times 10^{51}$  erg as measured in GRB 100117A.

The isotropic energies are in the range  $(8.5 \pm 2.2) \times 10^{48} \lesssim E_{\text{iso}} \lesssim (7.8 \pm 1.0) \times 10^{51}$  erg (see Fig. 8 and Zhang et al. 2012; Calderone et al. 2015; Ruffini et al. 2015b).

The spectral peak energies are in the range  $0.2 \lesssim E_{\text{p},i} \lesssim 2$  MeV (see Fig. 8 and Zhang et al. 2012; Calderone et al. 2015; Ruffini et al. 2015b) and increase monotonically with  $E_{\text{iso}}$ .

The cosmological redshifts are in the range  $0.111 \leq z \leq 2.609$ , with an average value of  $\approx 0.71$  (see Table 4).

The prompt emission phase has a duration of a few seconds, and is expected to crucially be a function of the masses of the binary neutron stars.

The long lasting X-ray afterglow does not exhibit any specific common late power-law behavior (see Fig. 3 (a)).

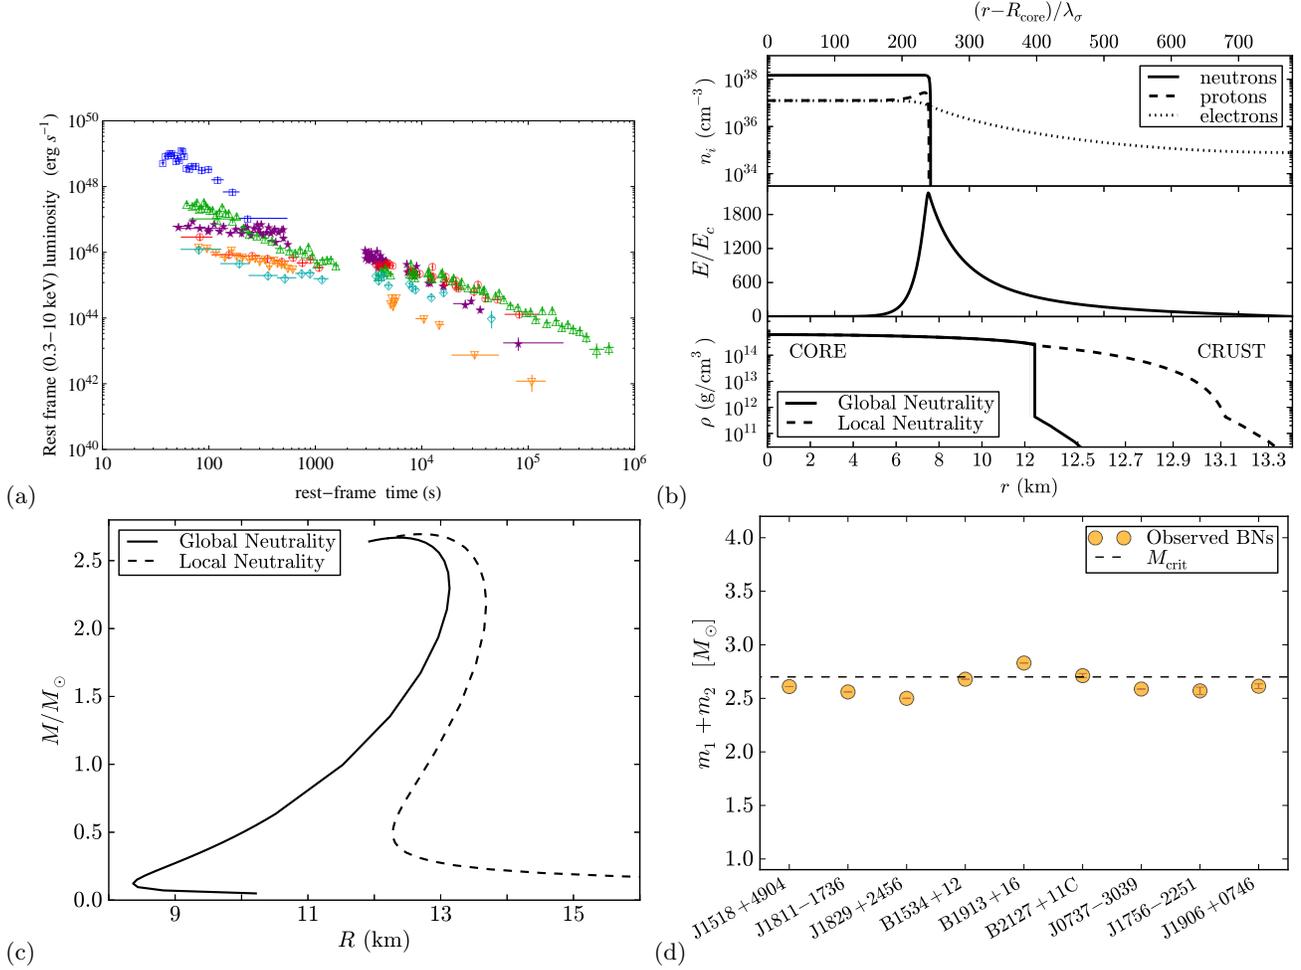

For all S-GRFs no SN association is expected, nor observed.

No high energy GeV emission is expected nor observed in absence of BH formation.

### 6.2. Theoretical interpretation of S-GRFs within the NS-NS merger paradigm in the fireshell model

As noted in the Introduction, current paradigms indicate mergers of NS-NS or NS-BH binaries as progenitors.

The extension of the IGC paradigm considerations to NS-NS mergers has led to a new classification of short bursts into two sub-classes depending upon the mass of the merged core, namely whether or not a BH is formed out of the merger (see Fig. 3 (d) and Ruffini et al. 2015b). This, in turn, depends on the NS equation of state and on the adoption of a global neutrality model, as opposed to the case of absence of electromagnetic structures when local

**Figure 3.** (a) Rest-frame 0.3–10 keV luminosity light curves of some selected S-GRFs: GRB 051210 (blue squares), GRB 051221 (green triangles), GRB 061201 (orange reversed triangles), GRB 070809 (light blue diamonds), GRB 130603B (purple stars), and GRB 140903A (red circles). See Table 4 for details on the sources. (b) Upper panel: particle density profiles in the NS core-crust boundary interface. Middle panel: electric field in the core-crust transition layer in units of  $E_c$ . Lower panel: density profile inside a NS star with central density  $\rho \sim 5\rho_{\text{nuc}}$ , where  $\rho_{\text{nuc}}$  is the nuclear density, from the solution of the TOV equations (locally neutral case) and the globally neutral solution presented in Belvedere et al. (2012). Here the density at the edge of the crust is the neutron drip density  $\rho_{\text{drip}} = 4.3 \times 10^{11} \text{ g cm}^{-3}$  and  $\lambda_\sigma = \hbar/(m_\sigma c) \sim 0.4 \text{ fm}$  denotes the  $\sigma$ -meson Compton wavelength. Reproduced from Oliveira et al. (2014) with their kind permission. (c) Mass-radius relation obtained with the local and the new global neutrality equilibrium configurations, by applying the NL3 nuclear model, with a critical mass of  $2.67 M_\odot$  for non-rotating NS (Belvedere et al. 2012). Figure reproduced from (Belvedere et al. 2012). (d) Plot of the galactic binary NSs with known total masses ( $m_1 + m_2$ , in solar masses). The horizontal dashed line marks the NS critical mass: systems beyond this value lead to BH formation. Reproduced from Ruffini et al. (2015b).

charge neutrality is imposed (see, e.g., Belvedere et al. 2012, and references therein, and Fig. 3 (c)). Also relevant is the very different density distribution in the crust and in the core between these two treatments, which could play an important role in the NS–NS mergers (see Fig. 3 (d) and Oliveira et al. 2014).

S-GRFs originate from NS–NS mergers with initial total mass  $m_1 + m_2$  leading to merged core with mass smaller than  $M_{\text{crit}}$ , therefore their outcomes are a MNS with additional orbiting material, or even a binary NS or WD companion (see, e.g., Bildsten & Cutler 1992, and references therein), due to the energy and momentum conservation laws (Ruffini et al. 2015b). As discussed in Sec. 2, even though a BH is not formed out of the merger, also for these systems the general description of the fireshell model can be applied. A viable mechanism for S-GRFs can be the creation of a pair plasma via  $\nu\bar{\nu} \rightarrow e^+e^-$  in a NS-NS merger (see, e.g., Narayan et al. 1992; Salmonson & Wilson 2002; Rosswog et al. 2003), where the maximum energy attainable in the process is  $\approx 10^{52} \text{ erg}$ , which represents indeed the upper limit to the energetic of these systems. Their energies are very similar to those emitted in XRFs. However, S-GRFs have  $E_{p,i}$  as high as  $\sim 2 \text{ MeV}$  (see, e.g., Ruffini et al. 2015b; Calderone et al. 2015; Zhang et al. 2012), therefore, in view of the hardness of their spectra, we adopted the name of S-GRFs to distinguish them from the corresponding XRFs.

GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$	GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$
050509B	0.225	$0.085 \pm 0.022$	090927	1.37	$27.6 \pm 3.5$

090515	0.403	$0.094 \pm 0.014$			

**Table 4.** List of the S-GRFs considered in this work up to the end of 2014. For each source (first columns) the values of  $z$  and  $E_{\text{iso}}$  (second and third columns, respectively) are listed.

S-GRFs coincide with the majority of the systems extensively discussed in Berger (2014). All S-GRFs have an extended X-ray afterglow (Berger 2014; Ruffini et al. 2015b). Similarly to XRFs, the rest-frame 0.3–10 keV luminosity light curve does not exhibit either a late common power-law behavior, or the nesting discovered in the BdHNe (see Fig. 3(a)). At the moment, there are still a large number of possible candidates for the description of the origin of the late X-ray afterglow emission: a) the interaction of the MNS with orbiting material or with a less massive binary NS or WD companion, b) the accelerated baryons interacting with the circumburst medium after the P-GRB emission, or c) the possible radioactive decay of heavy elements synthesized in the ejecta of a compact binary merger (Li & Paczyński 1998). In this light we recall the possibility of a *macronova* emission, a near-infrared/optical transient (a bump) in the late afterglow (see the case of GRB 130603B in Berger et al. 2013 and Tanvir et al. 2013).

As a general conclusion, in Ruffini et al. (2015b) the necessary absence of a SN was indicated. It has been predicted there that, since no BH is produced in the merger, S-GRFs should never exhibit high energy GeV emission, which is expected to originate in the newly-born BH (Ruffini et al. 2015b). No counterexample has been found as of today. In Ruffini et al. (2016) it has been shown that the absence of detection of GeV emission, necessary within the fireshell model, is indeed supported by the observations. The entire section 6.5 of that paper is dedicated to the GeV emission of S-GRFs and S-GRBs. As evidenced there, it is concluded that S-GRFs, due to the upper limits of the LAT observations, have, if any, GeV fluxes necessarily  $10^5$ – $10^6$  times weaker than those of S-GRBs, although their  $E_{\text{iso}}$  is only a factor  $10^2$  smaller (see also Appendix A).

### 6.3. Prototypes

In Table 4 we indicate selected the prototypes of S-GRFs. For each of them, we list the values of  $E_{\text{iso}}$  and  $z$  used in order to evaluate their rate.

## 7. THE SHORT GRBS

### 7.1. General properties

The observational features of short bursts with energy above  $\approx 10^{52}$  erg are listed below and summarized in Fig. 4. These bursts are interpreted within the theoretical framework of the NS-NS merger paradigm in the fireshell model as a new class which we indicate as S-GRBs.

The lower limit on the energetic of the S-GRBs is  $(2.44 \pm 0.22) \times 10^{52}$  erg as measured in GRB 081024B.

The isotropic energies are in the range  $(2.44 \pm 0.22) \times 10^{52} \lesssim E_{\text{iso}} \lesssim (2.83 \pm 0.15) \times 10^{53}$  erg (see Fig. 8 and Zhang et al. 2012; Muccino et al. 2013; Calderone et al. 2015; Ruffini et al. 2015b).

The spectral peak energies are in the range  $2 \lesssim E_{\text{p},i} \lesssim 8$  MeV (see Fig. 8 and Zhang et al. 2012; Muccino et al. 2013; Calderone et al. 2015; Ruffini et al. 2015b) and increase monotonically with  $E_{\text{iso}}$ .

The cosmological redshifts are in the range  $0.903 \leq z \leq 5.52$ , with an average value of  $\approx 2.48$  (see Table 5).

GRB	$z$	$E_{\text{iso}}/(10^{52} \text{ erg})$	GRB	$z$	$E_{\text{iso}}/(10^{52} \text{ erg})$
060801	1.13	$3.27 \pm 0.49$	090510	0.903	$3.95 \pm 0.21$
081024B	3.05	$2.44 \pm 0.22$	140402A	5.52	$4.7 \pm 1.1$
090227B	1.61	$28.3 \pm 1.5$	140619B	2.67	$6.03 \pm 0.79$

**Table 5.** List of the S-GRBs considered in this work up to the end of 2014. For each source (first columns) the values of  $z$  and  $E_{\text{iso}}$  (second and third columns, respectively) are listed.

The P-GRB and the prompt emission components have a total duration of a few seconds, which is expected to crucially be a function of the masses of the binary neutron stars. (see Fig. 4 (a) and (b)).

Only in the case of GRB 090510 an X-ray afterglow has been observed not conforming to any known afterglow (see Fig. 4 (c)).

For all S-GRBs no SN association is expected nor observed.

In all S-GRBs an extremely high energy GeV emission has been observed (see Fig. 4 (d)). It is interesting that even in one case, which was outside the nominal *Fermi*-LAT field of view, evidence for high energy emission has been found (Ruffini & Wang, in preparation, and Ackermann et al. 2013).

### 7.2. Theoretical interpretation of S-GRBs within the NS-NS merger paradigm in the fireshell model

S-GRBs originate from NS-NS mergers with initial total mass  $m_1 + m_2$  leading to a merged core with mass larger than  $M_{\text{crit}}$  so that a BH is formed (Ruffini et al. 2015b). In order to conserve energy and momentum, the outcome of such S-GRBs is a KNBH with additional orbiting material, or a binary companion (Bildsten & Cutler 1992; Ruffini et al. 2015b). If we compare and contrast the different Episodes encountered in the description of the BdHNe (see Section 5) with those of S-GRBs, we find some remarkable analogies but also some differences in view of the simplicity of the underlying physical system of S-GRBs, which unlike the BdHNe, do not exhibit any of the extremely complex activities related to the SN (see Section 5).

Episode 1 corresponds here to the activity of the NS-NS merger before the gravitational collapse into a BH. Because of the compactness of the systems this process at times is not observable or it possibly corresponds to faint precursors observed in some short bursts (see, e.g., Troja et al. 2010 and Ruffini et al. 2016).

Episode 2 corresponds to the GRB emission stemming from the NS-NS merger. It is described within the fireshell model as composed of two components (see Sec. 2): the P-GRB emission, with a mainly thermal spectrum (see Fig. 4 (a)), and the prompt emission, with a characteristic non-thermal spectrum (see Fig. 4 (b)). Typically in all S-GRBs so far analyzed (see, e.g., GRB 090227B, Muccino et al. 2013, and GRB 140619B, Ruffini et al. 2015b) the baryon load is standard, e.g.,  $B \approx 10^{-5}$ , and is consistent with the crustal masses of NS-NS mergers (Belvedere et al. 2014; Ruffini et al. 2015b). The average densities of the circumburst medium where S-GRBs occur are  $\langle n_{\text{CBM}} \rangle \approx 10^{-5} \text{ cm}^{-3}$ , typical of the halos of GRB host galaxies (see, e.g., Muccino et al. 2013; Ruffini et al. 2015b). Most remarkable is that this model gives the theoretical explanation for the fulfillment of the  $E_{\text{p},i}-E_{\text{iso}}$  relation for the short bursts (see Fig. 8 and Zhang et al. 2012; Calderone et al. 2015; Ruffini et al. 2015b).

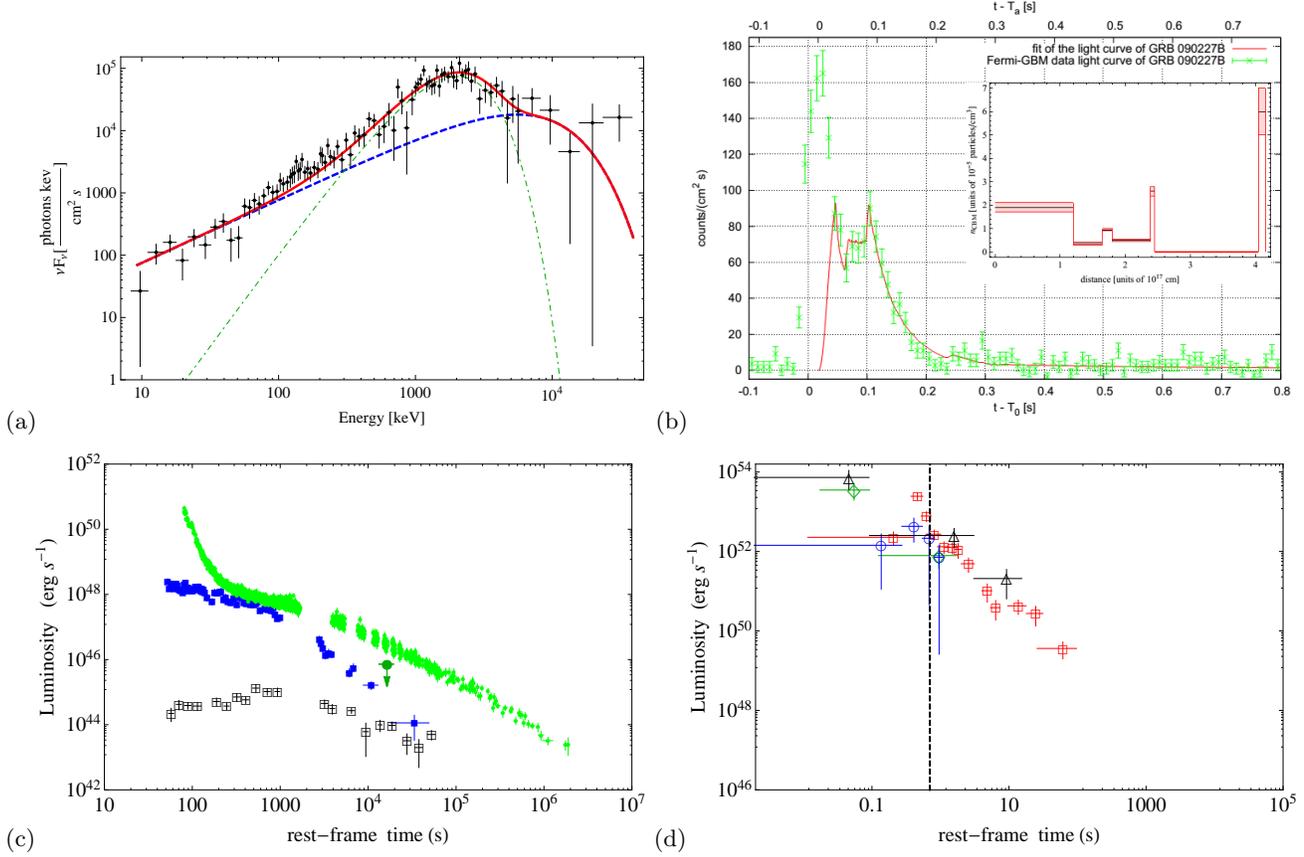

Episode 3, which corresponds to the traditional X-ray afterglow, is missing here in view of the absence of the SN and of all the characteristic processes originating from the interaction between the GRB and the SN ejecta, as in the case of BdHNe (see Section 5). At times S-GRBs have nonprominent X-ray or optical emissions (see Fig. 4 (c)).

Episode 4, identified with the optical emission of a SN, is here missing.

Episode 5 coincides with the long-lived GeV emission. All S-GRBs consistently exhibit this emission, which appears to be strictly correlated to the one observed in the BdHNe. By analogy with BdHNe, we assume that the GeV emission originate from the activity of the newly-born KNBH produced in the merger (Ruffini et al. 2015b). Indeed the presence of a BH is the only commonality between BdHNe and S-GRBs. By comparing and contrasting Figs. 2 (d) and 4 (d), we see that the turn-on of the GeV emission in S-GRBs occurs earlier and is energetically more prominent than the corresponding one of the BdHNe. To emphasize this point in Fig. 4 (d) we have represented by a dashed line the minimal turn-on time of the GeV emission of BdHNe (see Ruffini et al. 2016, and Ruffini et al., in preparation). The very high angular momentum, expected to occur in NS-NS mergers, and the very high luminosities of the S-GRBs, originating in the corresponding BH formation, offer the great opportunity to analyze some of the features expected in a KNBH.

### 7.3. Prototypes

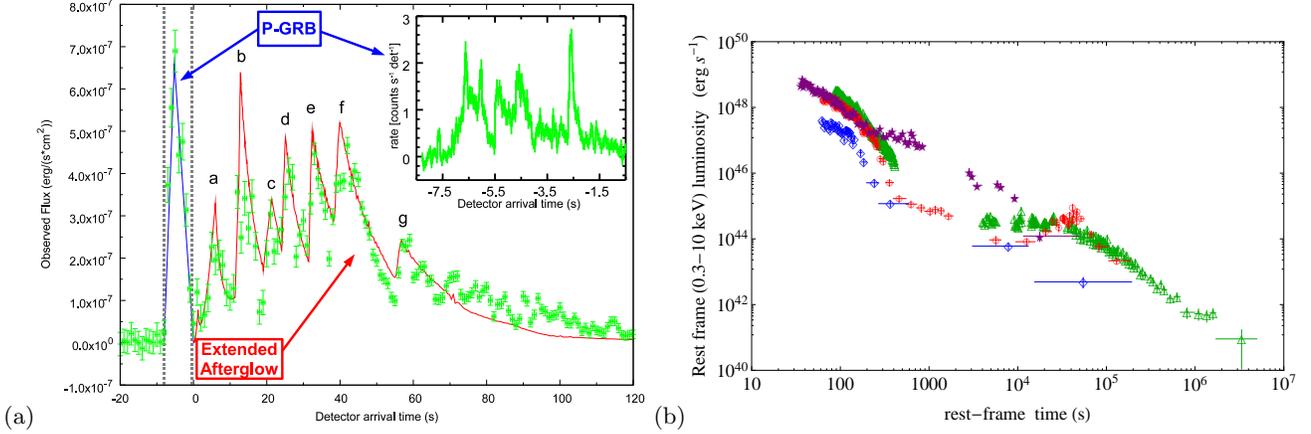

In Table 5 we list all the S-GRBs identified so far.

**Figure 4.** (a) The simulation of the observed P-GRB spectrum of the prototypical S-GRB 090227B: the dashed-dotted green line represents the BB emission, the dashed blue line corresponds to the early on-set of the prompt emission within the P-GRB computed from the fireshell simulation in the energy band 8–40000 keV; the sum of the two components is shown as a solid red line. Reproduced from [Muccino et al. 2013](#). (b) The NaI-n2 light curve of the prompt emission of the S-GRB 090227B (green data) and the simulation within the fireshell model (red curve). The small inset reproduces the CBM profile required for the simulation. Reproduced from [Muccino et al. 2013](#). (c) The available X-ray and optical luminosities of S-GRBs: the X-ray rest-frame 0.3–10 keV (blue filled squares) and the optical rest-frame 2–7 eV (black empty squares, taken from [De Pasquale et al. 2010](#)) luminosity light curves of GRB 090510, and the X-ray rest-frame 0.3–10 keV upper limit of GRB 140619B (green filled circle, see, e.g., [Ruffini et al. 2015b](#)). For comparison the rest-frame 0.3–10 keV luminosity light curve of one of the prototypes of BdHNe, GRB 090618 (green circles) is shown. (d) The rest-frame 0.1–100 GeV luminosity light curves of the S-GRBs 081024B (green diamonds), 090510 (red squares), 140402A (black triangles), 140619B (blue circles). The dashed vertical line marks the minimal turn-on time of the GeV emission of BdHNe. It is clear that in the case of S-GRBs the GeV emission turns on at shorter time scales and exhibits larger luminosities.

The first identified S-GRB 090227B has been analyzed by [Muccino et al. \(2013\)](#). The analysis of its P-GRB emission has found a baryon load  $B = 4.13 \times 10^{-5}$  and a Lorentz factor at the transparency condition  $\Gamma = 1.44 \times 10^4$ . The fit of the light curve of the prompt emission allowed the determination of the average number density of the circumburst medium, i.e.,  $\langle n_{CBM} \rangle = 1.9 \times 10^{-5} \text{ cm}^{-3}$ , which is typical of galactic halos where NS–NS mergers migrate, owing to natal kicks imparted to the binaries at birth (see, e.g., [Berger 2014](#)). These values are strikingly similar to those inferred for other S-GRBs: GRB 081024B ( $B = 4.80 \times 10^{-5}$ ,  $\Gamma = 1.07 \times 10^4$ , and  $\langle n_{CBM} \rangle = 5.0 \times 10^{-6} \text{ cm}^{-3}$ , [Aimuratov et al., in preparation](#)), GRB 090510 ( $B = 5.54 \times 10^{-5}$ ,  $\Gamma = 1.04 \times 10^4$ , and  $\langle n_{CBM} \rangle = 8.7 \times 10^{-6} \text{ cm}^{-3}$ , [Ruffini et al. 2016](#)), and GRB 140619B ( $B = 5.52 \times 10^{-5}$ ,  $\Gamma = 1.08 \times 10^4$ , and  $\langle n_{CBM} \rangle = 4.7 \times 10^{-5} \text{ cm}^{-3}$ , [Ruffini et al. 2015b](#)).

With the exception of GRB 090227B, which was outside the nominal *Fermi*-LAT field of view ([Ackermann et al. 2013](#)), the GeV luminosity light curves of the above four S-GRBs and that of the additional example recently identified, GRB 140402A ([Ruffini et al., in preparation](#)) follow a common behavior when computed in the source rest-frame (see Fig. 4 (d)).

**Figure 5.** (a) The fireshell simulation of the *Swift*-BAT prompt emission of GRB 060614 (taken from [Caito et al. 2009](#)). (b) The rest-frame 0.3–10 keV luminosity light curves of selected GRFs: GRB 050724 (red circles), GRB 060614 (green triangles), GRB 070714B (purple stars), and GRB 071227 (blue diamonds).

As pointed out in the introduction, U-GRBs originate from the NS-BH binaries produced in the BdHNe and nearly 100% of these binaries remain bound ([Fryer et al. 2015](#)). The lack of any observed source to date is mainly due to the extremely short duration of these systems ([Fryer et al. 2015](#)).

Interesting considerations, which may be of relevance for describing the U-GRB sub-class, can be found in [Popham et al. \(1999\)](#).

## 9. THE GAMMA-RAY FLASHES

### 9.1. General properties

The observational features of short bursts followed by an extended emission with energy below  $\approx 10^{52}$  erg are listed below and summarized in Fig. 5. These bursts are interpreted within the theoretical framework of a binary merger of a NS and a massive WD ([della Valle et al. 1992, 1994](#)) in the fireshell model as a new class which we indicate as GRFs.

The upper limit on the energetic of the GRFs is  $(9.8 \pm 2.4) \times 10^{51}$  erg as measured in GRB 070714B.

The isotropic energies are in the range  $(8.9 \pm 1.6) \times 10^{49} \lesssim E_{\text{iso}} \lesssim (9.8 \pm 2.4) \times 10^{51}$  erg.

The spectral peak energies are in the range  $0.2 \lesssim E_{\text{p,i}} \lesssim 2$  MeV.

The cosmological redshifts are in the range  $0.089 \leq z \leq 2.31$ , with an average value of  $\approx 0.54$  (see Table 6).

The  $\gamma$ -ray emission is composed of: 1) an initial spike-like harder emission and 2) a prolonged softer emission observed up to a hundred seconds (see Fig. 5(a)).

The long lasting X-ray afterglow does not exhibit any specific common late power-law behavior (see Fig. 5(b)).

No SN association is expected, nor observed also in the case of nearby sources ([Della Valle et al. 2006](#)).

No high energy GeV emission is expected nor observed in absence of BH formation.

### 9.2. Theoretical interpretation of GRFs within the NS-WD merger paradigm in the fireshell model

As we mentioned, the mergers of NS-WD binaries, notoriously very common astrophysical systems ([Cadelano et al. 2015](#)), can be the progenitors of another GRB sub-class: the GRFs. Possible evolutionary scenarios leading to NS-WD mergers have been envisaged e.g. in [Lazarus et al. \(2014\)](#); [Tauris et al. \(2000\)](#). Another less likely but yet possible scenario is the merger of a NS-WD binary produced, as recalled in Section 6.2, from an S-GRF. Namely, the merger of a not mass-symmetric NS-NS binary with total mass  $m_1 + m_2$  smaller than  $M_{\text{crit}}$ , that produce a MNS with a low-mass WD companion (see, e.g., [Bildsten & Cutler 1992](#), and references therein), due to the energy and momentum conservation laws ([Ruffini et al. 2015b](#)).

With the term GRFs we dubbed a class of long GRBs occurring in a CBM environment with low density, e.g.,  $\sim 10^{-3}$  cm<sup>-3</sup>, with a light curve in  $\gamma$ -rays composed of an initial spike-like hard emission, identified with the P-GRB, and prolonged softer emission, explained as the prompt emission (see Fig. 5 (a) and [Caito et al. 2009, 2010](#)). No associated SN has been ever observed, although in the case of the low value of the cosmological redshift its detection would not have been precluded ([Della Valle 2006](#)). The prototype of such systems is GRB 060614 ([Caito et al. 2009](#)).

Apart from the absence of any associated SN to a GRF, the identification of NS-WD binaries as progenitor systems of the GRFs comes from the following observational and theoretical evidences: a) the initial spike-like emission fulfills the  $E_{\text{p,i}}-E_{\text{iso}}$  relation for S-GRFs and S-GRBs ([Zhang et al. 2012](#); [Calderone et al. 2015](#); [Ruffini et al. 2015b](#)), both

GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$	GRB	$z$	$E_{\text{iso}}/(10^{50} \text{ erg})$
050724	0.257	$6.19 \pm 0.74$	061021	0.3462	$50 \pm 11$
050911	0.165	$0.89 \pm 0.16$	061210	0.409	$0.24 \pm 0.06$
060505	0.089	$2.35 \pm 0.42$	070506	2.31	$51.3 \pm 5.4$
060614	0.125	$21.7 \pm 8.7$	070714B	0.923	$98 \pm 24$
061006	0.438	$17.9 \pm 5.6$	071227	0.381	$8.0 \pm 1.0$

**Table 6.** List of the GRFs considered in this work up to the end of 2014. For each source (first columns) the values of  $z$  and  $E_{\text{iso}}$  (second and third columns, respectively) are listed.

originating in NS–NS mergers (Ruffini et al. 2015b); b) the value of the baryon load,  $B \approx 10^{-3}$  (Caito et al. 2009, 2010) points to a system more baryon-contaminated than the simpler and more compact NS–NS merger ( $B \approx 10^{-5}$ , see, e.g., Ruffini et al. 2015b); c) the fit of the prompt emission within the fireshell model provides CBM with low density, e.g.,  $\sim 10^{-3} \text{ cm}^{-3}$ , typical of the halos of the GRB host galaxies (Caito et al. 2009, 2010); d) the presence of a macronova emission in the optical afterglow of the prototype GRF 060614 (Jin et al. 2015).

In summary, we list below the different Episodes observed (or not) in GRFs.

Episode 1 does not exist due to the compactness of the NS–WD merger.

Episode 2 corresponds to the  $\gamma$ -ray emission stemming from the NS–WD merger. The fireshell theory still applies to these systems in view of the considerations presented in Section 2. Also in this case a viable mechanism consists in the pair creation via  $\nu\bar{\nu} \rightarrow e^+e^-$  during a NS–WD merger (see, e.g., Paschalidis et al. 2011). This is in line with the upper limit to the energetic of these systems in  $\gamma$ -rays is  $E_{\text{iso}} \approx 10^{52} \text{ erg}$ .

Episode 3 in GRFs, like in the cases of XRFs and S-GRFs, does not exhibit either a late common power-law behavior, or the nesting discovered in the rest-frame 0.3–10 keV luminosity light curves of BdHNe (see Fig. 5(b)). Also for GRFs, possible candidates for the explanation of the late X-ray afterglow emission are: a) the accelerated baryons interacting with the CBM after the P-GRB emission, or b) the possible radioactive decay of heavy elements synthesized in the ejecta of a compact binary merger (Li & Paczyński 1998).

Episode 4 is missing in view of the absence of the SN.

Episode 5, namely the GeV emission, does not occur for NS–WD mergers. This fact, together to the energetics of these systems,  $E_{\text{iso}} < 10^{52} \text{ erg}$ , implies that both of these necessary and sufficient conditions for the BH formation are not fulfilled. Therefore, in a NS–WD merger, in view of the limited mass of the WD component, the NS critical mass is never reached in the accretion process during the merger.

### 9.3. Prototypes

In Table 6 we list all the GRFs identified so far.

The prototype of GRFs is GRB 060614 and has been analyzed by Caito et al. (2009). From the analysis of its P-GRB emission a baryon load  $B = 2.8 \times 10^{-3}$  and a Lorentz factor at the transparency condition  $\Gamma = 346$  have been found. From the fit of the light curve of the prompt emission it has been inferred that this burst occurred in a CBM with density  $n_{\text{CBM}} = 2.3 \times 10^{-5} - 4.8 \times 10^{-3} \text{ cm}^{-3}$ , which is typical of galactic halos where NS–NS and NS–WD mergers occur (see, e.g., Berger 2014). Analogous results were obtained for the GRF 071227:  $B = 2.0 \times 10^{-4}$  and  $n_{\text{CBM}} = 1.0 \times 10^{-4} - 1.0 \times 10^{-2} \text{ cm}^{-3}$  (Caito et al. 2010).

Further analyses on other GRF examples will be presented elsewhere.

## 10. THE OBSERVED RATES OF SHORT AND LONG BURSTS

The observed GRB occurrence rate is defined by the convolution of both (likely redshift-dependent) luminosity function, which describes the fraction of bursts with isotropic equivalent luminosities in the interval  $\log L$  and  $\log L + d \log L$ , and cosmic GRB occurrence rate, which gives the number of sources at different redshifts. The definition of both of these functions is still an open issue and depends on *a priori* assumptions and some investigations have been carried out in the literature (see, e.g., Soderberg et al. 2006; Guetta & Della Valle 2007; Liang et al. 2007; Virgili et al. 2009; Rangel Lemos et al. 2010; Wanderman & Piran 2010; Guetta et al. 2011; Kovacevic et al. 2014, for long bursts, Virgili et al. 2011; Wanderman & Piran 2015, for short bursts, and Sun et al. 2015, for both long and short bursts). To complicate the matter, also the instrumental sensitivity threshold, the field of view  $\Omega_i$ , and the operational time  $T_i$  of the various detectors  $i$  observing GRBs introduce additional uncertainties to the problem.

In the following we ignore the possible redshift-evolution of the luminosity function. Thus, if  $\Delta N_i$  events are detected by various detectors in a finite logarithmic luminosity bin from  $\log L$  to  $\log L + \Delta \log L$ , the total local event rate density

of bursts between observed minimum and maximum luminosities,  $L_{\min}$  and  $L_{\max}$  respectively, is defined as (see [Sun et al. 2015](#))

$$\rho_0 \simeq \sum_i \sum_{\log L_{\min}}^{\log L_{\max}} \frac{4\pi}{\Omega_i T_i} \frac{1}{\ln 10} \frac{1}{g(L)} \frac{\Delta N_i}{\Delta \log L} \frac{\Delta L}{L}, \quad (2)$$

where

$$g(L) = \int_0^{z_{\max}(L)} \frac{f(z)}{1+z} \frac{dV(z)}{dz} dz, \quad (3)$$

and the comoving volume is given by

$$\frac{dV(z)}{dz} = \frac{c}{H_0} \frac{4\pi d_L^2}{(1+z)^2 [\Omega_M(1+z)^3 + \Omega_\Lambda]^{1/2}}, \quad (4)$$

where  $d_L$  is the luminosity distance. The dimensionless function  $f(z)$  describes the GRB cosmic redshift-dependent event rate density. In the following we assume no redshift dependency, therefore we set  $f(z) = 1$ . The maximum redshift  $z_{\max}(L)$  in Eq. (3) defines the maximum volume inside which an event with luminosity  $L$  can be detected. This redshift can be computed from the 1 s-bolometric peak luminosity  $L$ ,  $k$ -corrected from the observed detector energy band into the burst cosmological rest-frame energy band 1–10<sup>4</sup> keV ([Schaefer 2007](#)), and the corresponding 1 s-threshold peak flux  $f_{\text{th}}$ , which is the limiting peak flux to allow the burst detection (see [Band 2003](#), for details). Therefore,  $z_{\max}$  can be defined via (see, e.g., [Zhang et al. 2009](#); [Ruffini et al. 2014a](#))

$$f_{\text{th}} = \frac{L}{4\pi d_L^2(z_{\max})k}, \quad (5)$$

where we duly account for the  $k$ -correction.

Within the assumptions that the GRB luminosity function does not evolve with redshift and that  $f(z) = 1$ , we investigate the evolution with the redshift of the GRB rates by separating the bursts into several redshift bins. As suggested in [Sun et al. \(2015\)](#), this can be done in each redshift interval  $z_j \leq z \leq z_{j+1}$  by changing the integration limits of Eq. (3) into  $z_j$  and  $\min[z_{j+1}, z_{\max,j}(L)]$ , where  $z_{\max,j}(L)$  is the maximum redshift for the  $j^{\text{th}}$  redshift bin. Finally, from Eq. (2) we derive an event rate  $\rho_0^z$  in each redshift bin around  $z$ .

In the following we adopt the following fields of view and operational times for various detectors: *Beppo-SAX*,  $\Omega_{\text{BS}} = 0.25$  sr,  $T_{\text{BS}} = 7$  y; *BATSE*,  $\Omega_{\text{B}} = \pi$  sr,  $T_{\text{B}} = 10$  y; *HETE-2*,  $\Omega_{\text{H}} = 0.8$  sr,  $T_{\text{H}} = 7$  y; *Swift-BAT*,  $\Omega_{\text{S}} = 1.33$  sr,  $T_{\text{S}} = 10$  y; *Fermi-GBM*,  $\Omega_{\text{F}} = 9.6$  sr,  $T_{\text{F}} = 7$  y. We assume no beaming correction in computing the rates of the GRB sub-classes.

### 10.1. Rate of S-GRFs

The local rate of S-GRFs, obtained from the sample of sources listed in Table 4, is  $\rho_0 = 3.6_{-1.0}^{+1.4}$  Gpc<sup>-3</sup> y<sup>-1</sup> and it is in agreement with the estimates obtained from the whole short burst population detected by the *Swift-BAT* detector (and, therefore, including also S-GRBs and GRFs) and reported in the literature (1–10 Gpc<sup>-3</sup> y<sup>-1</sup>, see, e.g., [Clark et al. 2015](#), and references therein). In particular our local rates with  $f(z) = 1$  agrees with recent more precise estimates: a)  $4.1_{-1.9}^{+2.3}$  Gpc<sup>-3</sup> y<sup>-1</sup> for  $L_{\min} = 5 \times 10^{49}$  erg/s and for  $f(z)$  described by a power law merger delay model ([Wanderman & Piran 2015](#)); b)  $4.2_{-1.0}^{+1.3}$ ,  $3.9_{-0.9}^{+1.2}$ , and  $7.1_{-1.7}^{+2.2}$  Gpc<sup>-3</sup> y<sup>-1</sup> for  $L_{\min} = 7 \times 10^{49}$  erg/s and  $f(z)$  described as Gaussian, log-normal and power law merger delay models, respectively ([Sun et al. 2015](#)).

The evolution of the S-GRF rate in various redshift bins is shown in Fig. 6 (c). This rate decreases as a power law from the local value in the interval  $0.1 \leq z \leq 0.4$  to a value of  $0.042_{-0.025}^{+0.046}$  Gpc<sup>-3</sup> y<sup>-1</sup> in the interval  $1.0 \leq z \leq 2.7$ . Also in the case of S-GRFs the increasing sampled comoving Universe volume and the threshold of the detectors play a fundamental role in the observed decrease of their rate at larger distances.

### 10.2. Rate of S-GRBs

Previously we have identified and described four S-GRBs in [Ruffini et al. \(2015b\)](#), e.g., GRB 081024B, GRB 090227B, GRB 090510, and GRB 140619B. Here we present two additional new members of this class: GRB 060801 (at  $z \approx 1.13$  and with  $z_{\max} \approx 2.04$ , in this work) and GRB 140402A (at  $z \approx 5.52$  and with  $z_{\max} \approx 7.16$ , [Ruffini et al.](#) in preparation). From these six S-GRBs detected by the *Fermi* and the *Swift* satellites, we obtain via Eqs. (2)–(3) a local rate  $\rho_0 = (1.9_{-1.1}^{+1.8}) \times 10^{-3}$  Gpc<sup>-3</sup> y<sup>-1</sup>.

With only six sources, we could not build the evolution with the redshift of such systems.

### 10.3. Rate of XRFs

In [Kovacevic et al. \(2014\)](#), we have estimated an updated observed rate for the XRFs at  $z < 0.1$  based on the method outlined in [Soderberg et al. \(2006\)](#) and [Guetta & Della Valle \(2007\)](#). In this work, we consider the complete list of XRFs shown in [Table 2](#) and the method outlined in [Sun et al. \(2015\)](#). From [Eq. \(2\)–\(3\)](#) the local rate of XRFs is  $\rho_0 = 100_{-34}^{+45} \text{Gpc}^{-3} \text{y}^{-1}$ , where the attached errors are determined from the 95% confidence level of the Poisson statistic ([Gehrels 1986](#)). Within the extent of our different classification criteria and different choices for  $f(z)$ , our estimate is in agreement with those reported for low-luminous long GRBs in [Liang et al. \(2007\)](#) and [Virgili et al. \(2009\)](#), and in particular with the value of  $164_{-65}^{+98} \text{Gpc}^{-3} \text{y}^{-1}$ , obtained by [Sun et al. \(2015\)](#) with the same method.

In the IGC scenario the XRF out-states are NS–NS binary systems. For a reasonable sets of binary initial conditions, populations synthesis simulations performed by [Fryer et al. \(1999\)](#) provide a NS–NS formation rate (0.2–1600)  $\text{Gpc}^{-3} \text{y}^{-1}$ . NS–NS formation rate accounts for other possible channels in the population synthesis models, in addition to the one we considered from the XRFs. It is interesting, nevertheless, that our predicted rate is consistent with that obtained by [Fryer et al. \(1999\)](#) obtained.

For the same above reason, our rate of XFRs can be also compared with the NS–NS merger rate proposed by [Eichler et al. \(1989\)](#). In this historical paper, the NS–NS merger rate is derived from the strong assumption that each merger ejects always the same amount of material r-process classified and the heavy r-process material. [Eichler et al. \(1989\)](#) obtain a rough estimate of (140–14000)  $\text{Gpc}^{-3} \text{y}^{-1}$ , which is marginally consistent to the upper value of the local XRF rate.

The evolution of the XRF rate in various redshift bins is shown in [Fig. 6 \(a\)](#). It decreases from a value of  $95_{-63}^{+123} \text{Gpc}^{-3} \text{y}^{-1}$  in the interval  $0 \leq z \leq 0.1$  to a value of  $0.8_{-0.5}^{+1.1} \text{Gpc}^{-3} \text{y}^{-1}$  in the interval  $0.7 \leq z \leq 1.1$ . This effect is mainly due to the intrinsic low luminosities of the bulk of the XRF population ( $10^{46}$ – $10^{48}$  erg/s, see, e.g., [Bromberg et al. 2011](#)) and to the threshold of the detectors: at increasing sampled Universe comoving volumes, these low luminous XRFs become undetectable, therefore at higher redshifts the total XRF rate decreases.

### 10.4. Rate of BdHNe

We proceed now in estimating the rate of BdHNe from the total sample of 233 sources (see [Table 3](#)). From [Eq. \(2\)–\(3\)](#) the local rate of BdHNe is  $\rho_0 = 0.77_{-0.08}^{+0.09} \text{Gpc}^{-3} \text{y}^{-1}$ . Our estimate is in agreement with two recent estimates obtained from long bursts with  $L \geq 10^{50}$  erg/s and by assuming  $f(z) \neq 1$ : a) the value of  $1.3_{-0.7}^{+0.6} \text{Gpc}^{-3} \text{y}^{-1}$  obtained by [Wanderman & Piran \(2010\)](#), even though limited to the *Swift* long bursts and including long some bursts with  $E_{\text{iso}} < 10^{52}$  erg, obtained from a GRB inferred cosmic rate independent on the star formation rate; b) the value of  $0.8_{-0.1}^{+0.1} \text{Gpc}^{-3} \text{y}^{-1}$  obtained by [Sun et al. \(2015\)](#) with the same method and including the star formation rate dependence.

In the IGC scenario the BdHNe out-states are NS–BH binary systems. Following again the work by [Fryer et al. \(1999\)](#), populations synthesis simulations (which accounts also for alternative scenarios to that of the IGC model) provide a NS–BH formation rate of (0.02–1000)  $\text{Gpc}^{-3} \text{y}^{-1}$ . Also in this case, even though a straightforward comparison is not possible, the BdHNe rate is consistent with the NSBH formation rate obtained by [Fryer et al. \(1999\)](#).

The evolution of the BdHN rate in various redshift bins is shown in [Fig. 6 \(b\)](#). It slightly decreases from the local value in the interval  $0.1 \leq z \leq 0.4$  to a value of  $0.17_{-0.04}^{+0.05} \text{Gpc}^{-3} \text{y}^{-1}$  in the interval  $3.6 \leq z \leq 9.3$ . As stated for the case of XRFs, this effect occurs because for increasing sampled Universe comoving volumes, only the most luminous BdHNe are detectable, even though in a less marked way than the case of the XRFs.

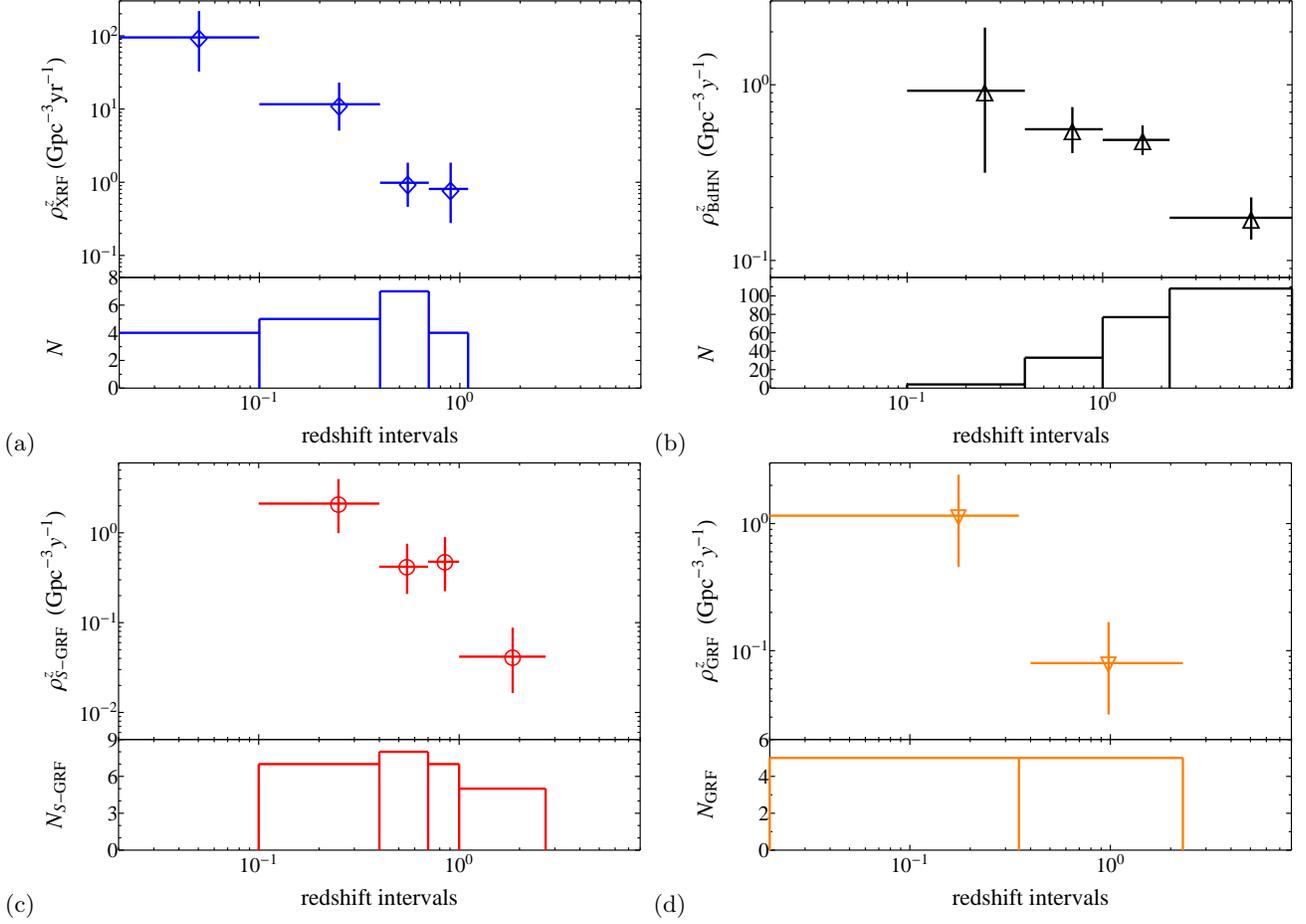

### 10.5. Rate of U-GRBs

As pointed out in [Section 8](#), nearly 100% of the BdHNe leads to bound NS–BH binaries, which are the progenitor systems of U-GRBs ([Fryer et al. 2015](#)). If we include the possibility of other channels of formation for these NS–BH binaries, we can safely assume the BdHN local rate as a lower limit for these U-GRBs, e.g.,  $\rho_0 = 0.77_{-0.08}^{+0.09} \text{Gpc}^{-3} \text{y}^{-1}$ . From this consideration, it appears that the U-GRBs have the second higher rate among the short bursts after the S-GRFs.

### 10.6. Rate of GRFs

We proceed now in estimating the rate of GRFs from the total sample of 10 sources (see [Table 6](#)). From [Eq. \(2\)–\(3\)](#) we obtain a local rate  $\rho_0 = 1.02_{-0.46}^{+0.71} \text{Gpc}^{-3} \text{y}^{-1}$ , and represent the first estimate for these kind for bursts originating from NS–WD mergers.

Due to the limited number of sources in our sample, we limited the study of the GRF rate evolution in two redshift bins, as shown in [Fig. 6 \(d\)](#). The rate starts from a value consistent with the above local rate, in the redshift interval

**Figure 6.** The evolution of the rate with the redshift for the considered GRB sub-classes: (a) the XRF, (b) the BdHNe, (c) the S-GRFs, (d) the GRFs. In each plot the upper panel shows the evolution rate with the redshift, while the lower panel displays the number of observed sources in each redshift bin. Because of the limited amount of sources, for S-GRBs no redshift bin evolution is shown. In the case of U-GRBs, there are no current detections.

$0 \leq z \leq 0.35$ , to a value of  $0.080^{+0.088}_{-0.048} \text{Gpc}^{-3} \text{y}^{-1}$ , in the interval  $0.35 \leq z \leq 2.31$ . Also for GRFs, the cutoff in the rate at higher redshift occurs because for increasing sampled Universe comoving volumes only the most luminous sources are detectable. However this effect, as in the case of S-GRFs, is more pronounced due to their intrinsically weaker luminosities, when compared to those of S-GRBs.

## 11. CONCLUSIONS

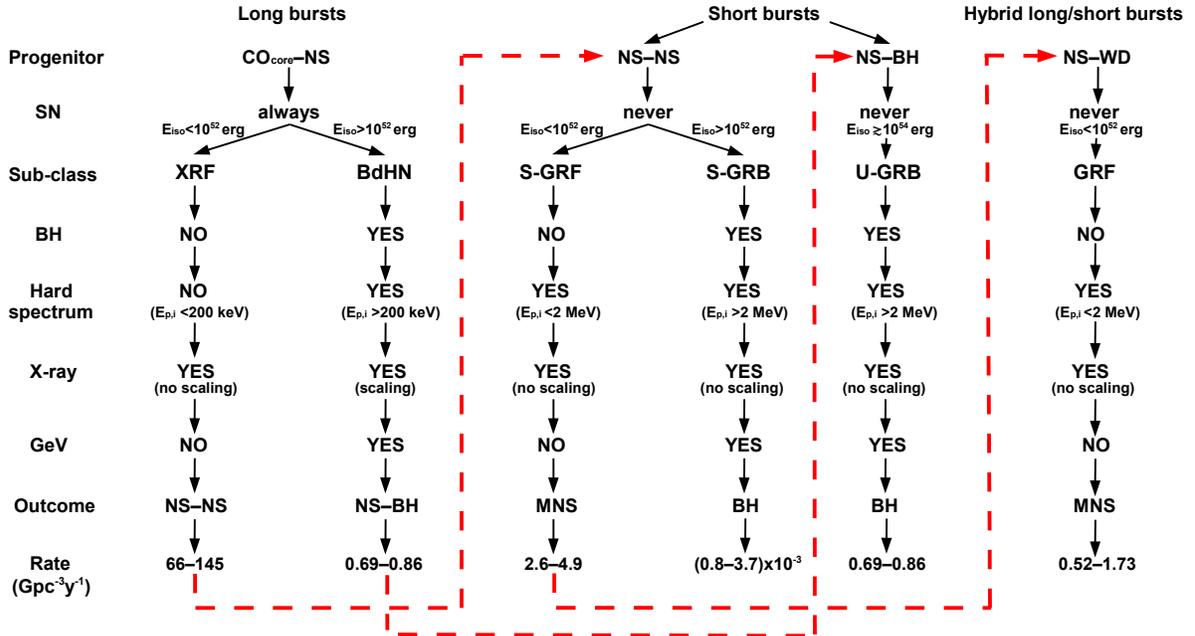

The remarkable progress reached in understanding the GRB phenomenon has been made possible by the outstanding spectral and temporal information acquired from X-rays,  $\gamma$ -rays and high energy observatories, as well as from optical and radio data obtained by telescopes all over the planet. At the same time this result has been fostered by a novel deeper theoretical understanding in the physics and astrophysics of WD (see, e.g., [Boshkayev et al. 2013](#)), NS (see, e.g., [Belvedere et al. 2014](#); [Cipolletta et al. 2015](#)) and BH (see, e.g., [Ruffini et al. 2010](#)). Consequently the understanding of the GRB phenomenon has evolved from an elementary paradigm based on a single jetted emission process as postulated in the fireball model (see, e.g., [Sari et al. 1998](#); [Piran 2005](#); [Meszaros 2006](#); [Gehrels et al. 2009](#), and reference therein) to an authentic astrophysical laboratory involving many-body interactions between different astrophysical systems encountering previously unexplored regimes and observational evidence.

In the Introduction we review the increasing number of GRB observations which have led likewise to the theoretical progress in the understanding of the GRB phenomena. While the role of NS–NS (or NS–BH) binaries as “in-states” of short GRBs has been widely accepted and confirmed by strong observational and theoretical evidence (see, e.g., [Goodman 1986](#); [Paczynski 1986](#); [Eichler et al. 1989](#); [Narayan et al. 1991, 1992](#); [Meszaros & Rees 1997](#); [Rosswog et al. 2003](#); [Lee et al. 2004](#); [Berger 2014](#); [Ruffini et al. 2015b](#)), the identification of the progenitor systems for long GRBs followed a more difficult path. Initially, theoretical models based on a single progenitor were proposed: a *collapsar* ([Woosley 1993](#)), or a *magnetar* (see, e.g., [Zhang & Mészáros 2001](#)). Then, the role of binary progenitor systems

composed of two very massive stars for long GRBs was recognized by (Fryer et al. 1999), where several different scenarios were there envisaged leading to a *collapsar* (Woosley 1993), as well as a few leading, alternatively, to a variety of binary compact systems. These considerations were addressed by our group in a set of papers assuming that the birth of a SN and the occurrence of a GRB were qualitatively and quantitatively different astrophysical events in space and time. This led to the necessity of introducing the IGC paradigm (see, e.g., Ruffini et al. 2001a, 2006b, 2007, 2008; Izzo et al. 2012b; Rueda & Ruffini 2012; Fryer et al. 2014; Ruffini et al. 2015a). In the IGC paradigm the long GRB-SN coincidence originates from CO<sub>core</sub>-NS binary progenitors system. This approach differs from alternative descriptions, e.g., the *magnetars* and the *collapsar* models, where the two events are coming from a single progenitor star.

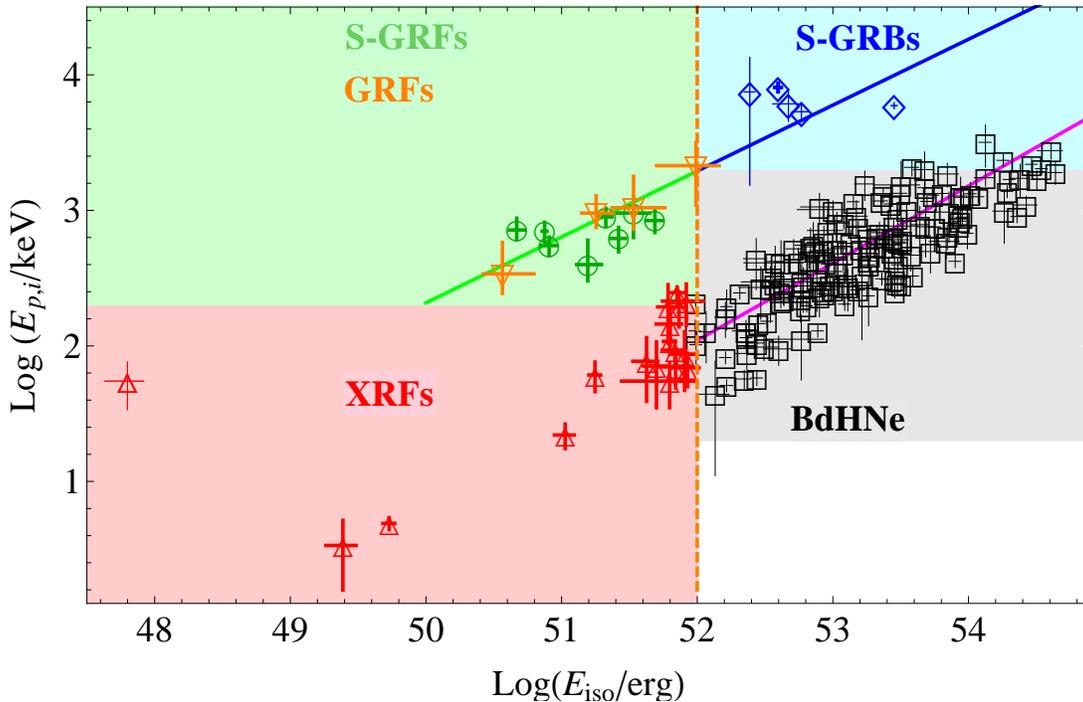

In Section 2, we review the fireshell model for GRBs (see, e.g. Ruffini et al. 2001a,b,c) and its general description which can be applied to any source of an optically thick baryon-loaded  $e^+e^-$  plasma, i.e., in the quantum-electrodynamical process expected in the formation of a BH (see, e.g., Preparata et al. 1998; Ruffini et al. 1999, 2000; Cherubini et al. 2009; Ruffini 2009), as well as in the case of a pair plasma created via  $\nu\bar{\nu} \leftrightarrow e^+e^-$  mechanism in a NS-NS merger (Narayan et al. 1992; Salmonson & Wilson 2002; Rosswog et al. 2003), or in the hyper-accretion disks around BHs (Woosley 1993; Zalamea & Beloborodov 2011).

In Section 3, we discuss the role of the  $10^{52}$  erg energy critical value introduced to discriminate between binary systems leading to the formation of a MNS (XRFs, S-GRFs and GRFs), with energy lower than the above critical value, and those leading to the formation of a BH (BdHNe, S-GRBs and U-GRBs), with energy larger than the above critical value. The value of  $10^{52}$  erg is derived by considering the hypercritical accretion process onto a NS leading to an energy release in form of neutrinos and photons, given by the gain of gravitational potential energy of the matter accreted in the NS. This includes the change of binding energy of the NS while accreting both matter and angular momentum (Becerra et al. 2016). A typical NS mass of  $\approx 1.4 M_\odot$  has been assumed, as observed in galactic NS binaries (Zhang et al. 2011; Antoniadis 2015). A NS critical mass in the range of  $2.2 M_\odot$  up to  $3.4 M_\odot$  depending on the equations of state and angular momentum (see Becerra et al. 2016, 2015; Cipolletta et al. 2015, for details) has been assumed.

**Figure 7.** Summary of the properties of long, short and hybrid long/short burst sub-classes discussed in the Introduction. The red dashed lines indicate the evolutionary tracks linking the out-states and the in-states of some of the sub-classes considered in this work.

In Section 4, we describe the properties of XRFs (see Fig. 8). In these systems the distance between the CO<sub>core</sub> and the NS companion is  $a > 10^{11}$  cm. The hypercritical accretion process is not sufficient to push the NS beyond its  $M_{\text{crit}}$  and an MNS is formed (see, e.g., Becerra et al. 2015, 2016). In Table 2 we list the XRFs considered in this work, as well as the spectral, temporal and luminosity analysis of selected prototype, e.g., GRB 060218. The complete

**Figure 8.** The  $E_{p,i}$ – $E_{iso}$  plane for XRFs, BdHNe, S-GRFs, S-GRBs, and the initial spike-like emission of the GRFs. The XRFs (red triangles) cluster in the red shaded region ( $E_{p,i} \lesssim 200$  keV and  $E_{iso} \lesssim 10^{52}$  erg), while the BdHNe (black squares) in the gray shaded one ( $E_{p,i} \gtrsim 200$  keV and  $E_{iso} \gtrsim 10^{52}$  erg); the Amati relation (Amati & Della Valle 2013) fulfilled by the BdHNe is plotted with a magenta solid line. The S-GRFs (green circles) and the initial spike-like emission of the GRFs (orange reverse triangles) cluster in the green shaded region ( $E_{p,i} \lesssim 2$  MeV and  $E_{iso} \lesssim 10^{52}$  erg), while the S-GRBs (blue diamonds) in the blue shaded one ( $E_{p,i} \gtrsim 2$  MeV and  $E_{iso} \gtrsim 10^{52}$  erg); the relation for short bursts (Ruffini et al. 2015b; Calderone et al. 2015; Zhang et al. 2012) is plotted with a green solid line for the S-GRFs and the GRFs, and in blue for the S-GRBs.

theoretical simulation of this prototype is presented in Becerra et al. (2016).

In Section 5 we consider the BdHNe, for which the binary separation between the CO<sub>core</sub> and the NS binary companion is  $a < 10^{11}$  cm and the hypercritical accretion process trigger the gravitational collapse of the NS into a BH (see, e.g., Becerra et al. 2015, 2016). We show here an updated list of BdHNe (see Table 3), as well as a diagram summarizing some of the key properties and prototypes (see Fig. 8), analyzed within the IGC paradigm and the fireshell model (see, e.g., GRB 090618 and GRB 130427A).

In Section 6, we outline the properties of S-GRFs listed in Table 4 and shown in Fig. 8. These systems coincide with the short bursts considered in Berger (2014). They originate in NS-NS mergers leading to the formation of a MNS and possibly a binary companion, in order to fulfill the conservation of energy and momentum (Ruffini et al. 2015b).

In Section 7 we present S-GRBs originating in NS-NS mergers leading to the formation of a BH (see Fig. 8). We give, in Table 5, their updated list. We then describe their prototypes, analyzed within the fireshell model (see, e.g., GRB 090227B and GRB 140619B), and outline the key role of the P-GRB identification for their description, as well as the analysis of the GeV emission.

In Section 8, motivated by the results obtained by Fryer et al. (2015), where it was shown that nearly 100% of the NS-BH binaries, namely the out-states of the BdHNe, remain bound, we add the description of this not yet observed, but theoretically predicted sub-class of U-GRBs, unaccounted for in current standard population synthesis analyses.

In Section 9, we review the properties of the GRFs listed in Table 6 and shown in Fig. 8. We recall and describe the results obtained from the sources analyzed within the fireshell model (see, e.g., GRB 060614, Caito et al. 2009 and GRB 071227, Caito et al. 2010).

The most important result of the present article is the estimate the rates of occurrence of the XRFs, BdHNe, S-GRFs, S-GRBs, U-GRBs, and GRFs sub-classes. In Section 10, we introduce the procedure outlined in Sun et al. (2015) for estimating the local rates and their evolution with the redshift of the above sub-classes of long and short bursts, assuming no beaming (note: the recent observation of the absence of GeV emission associated to a BdHNe may limit this assumption). By ignoring possible redshift-evolution of the GRB sub-classes luminosity functions and assuming that the GRB cosmic event rate density is redshift-independent (e.g.,  $f(z) = 1$ ), the above method duly

takes into account observational constraints, i.e., the detector solid angle coverage of the sky  $\Omega$  and sensitivities which in turn define a maximum volume of observation depending on the intrinsic luminosity of the sources (see Section 10 and Soderberg et al. 2006; Guetta & Della Valle 2007; Liang et al. 2007; Virgili et al. 2009, 2011; Rangel Lemos et al. 2010; Wanderman & Piran 2010, 2015; Kovacevic et al. 2014; Sun et al. 2015 for details). We obtain:

- an S-GRF local rate of  $\rho_0 = 3.6_{-1.0}^{+1.4} \text{ Gpc}^{-3} \text{ y}^{-1}$  (see Section 10.1);
- an S-GRB local rate of  $\rho_0 = (1.9_{-1.1}^{+1.8}) \times 10^{-3} \text{ Gpc}^{-3} \text{ y}^{-1}$  (see Section 10.2);
- an XRF local rate of  $\rho_0 = 100_{-34}^{+45} \text{ Gpc}^{-3} \text{ y}^{-1}$  (see Section 10.3);
- a BdHN local rate of  $\rho_0 = 0.77_{-0.08}^{+0.09} \text{ Gpc}^{-3} \text{ y}^{-1}$  (see Section 10.4; for the above reason this rate coincides with that of the U-GRBs, see Section 10.5);
- a GRF local rate of  $\rho_0 = 1.02_{-0.46}^{+0.71} \text{ Gpc}^{-3} \text{ y}^{-1}$  (see Section 10.6).

The local rates of S-GRFs, XRFs, and BdHNe, are in agreement, within the extent of the different classification criteria, with those reported in the literature. The local rates of S-GRBs and GRFs are, instead, new ones following from the classification proposed in this work. The evolution with the redshift of the rates of XRFs, BdHNe, S-GRFs, and GRFs is shown in Fig. 6. It is certainly of interest to compare and contrast these results obtained from the direct observations of the sources in our new classification with the results computed from population synthesis models. Any possible disagreement will give the opportunity to identify possible missing links in the evolutionary phases within population synthesis analysis.

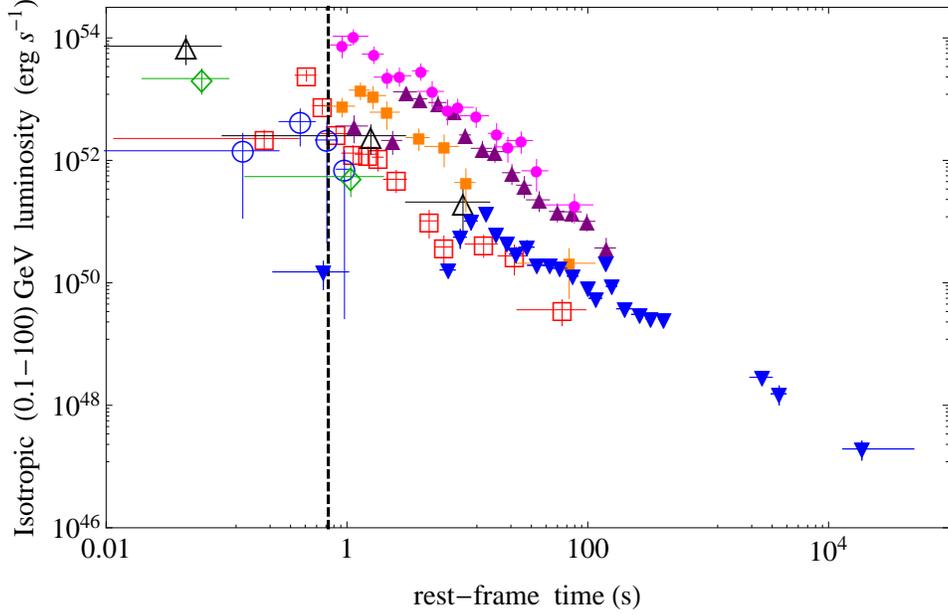

We are now in a position to apply the above rates of S-GRFs, S-GRBs and U-GRBs to assess the detectability and the expected number of gravitational wave detections by LIGO from NS-NS and NS-BH binaries (Ruffini et al., in preparation). We are also ready to apply the above BdHN rate to give an estimate of the contribution of GRBs to cosmic rays (Ruffini et al., in preparation).

Before concluding, in support of the classification proposed in this article, we recall that the luminosity light curves of the GeV emission is uniquely observed in both BdHNe and S-GRBs. In both cases it follow a precise power-law behavior with time  $\propto t^{-1.2}$  (see Nava et al. 2014, Ruffini et al. 2016 and Fig. 9). An outstanding conclusion of this paper is that in both BdHNe and S-GRBs, where the presence of the BH is predicted, the turn-on of this GeV emission occurs after the P-GRB emission and at the beginning of the prompt emission phase (see Figs. 2 (d) and 4 (d)). This commonality, in such different systems, as well as their energy requirements (see Tab. 7 and Fig. 9) are naturally explained if we assume, as indicated in Ruffini et al. (2015a,b), that this GeV emission originates by accretion processes in the newly-born BH. We have pointed out in Ruffini et al. (2016) how the total energy of the GeV emission can be expressed in term of the gravitational binding energy of matter accretion into Kerr BHs (see Ruffini & Wheeler 1969, in problem 2 of § 104 in Landau & Lifshitz 2003). This energetics requirement could not be fulfilled in the case of accretion onto a NS, in view of the much smaller value of the gravitational binding energy when compared to the case of a rotating BH (see e.g. Sibgatullin & Sunyaev 2000). On the general issue of the origin of the jetted GeV emission, and not just of its energetics, we refer to the last paragraph of the conclusions of the paper by Ruffini et al. (2016).

We have added a Table. 7 with the values of the GeV emission for both the case of S-GRBs and BdHNe. These energy releases up to  $\approx 10^{54}$  erg can be explained by the occurrence of accretion onto a rotating BH with mass in the range of 3–10  $M_{\odot}$ . It is also clear from Fig. 9 that S-GRBs and BdHNe have GeV emission sharing a common luminosity pattern and originating, in both cases, from a newly-born Kerr BH (Ruffini et al. 2015a,b). This picture includes also the first scenario of an IGC considered in Ruffini et al. (2001a) where an exploding  $CO_{\text{core}}$  is in a close binary system with an already formed BH companion. In view of the hypercritical accretion process of the SN ejecta onto an already formed BH, these systems have  $E_{\text{iso}} \gtrsim 10^{54}$  erg and  $E_{\text{p},i} \gtrsim 2$  MeV. Their out-states are a binary composed of a more massive BH and a  $\nu\text{NS}$ . Such systems, which we refer to as BH-SNe, are expected to be the late evolutionary stages of X-ray binaries such as Cyg X-1 or Cyg X-3 (see, e.g., Giacconi & Ruffini 1978).

In conclusion we have computed the occurrence rate of short and long bursts following a new classification and obtaining figures in good agreement with the ones derived from population synthesis models. Essential to the classification have been the following new considerations:

- 1) the binary nature of the progenitors and their separation;
- 2) the essential role of the hypercritical accretion process onto a NS member of a close binary system. The possible reaching of  $M_{\text{crit}}$  by the accretion process and the formation of a BH;

**Figure 9.** The rest-frame 0.1–100 GeV isotropic luminosity light curves of selected BdHNe (filled symbols) and all S-GRBs with available LAT data (empty symbols). BdHNe: GRB 080916C (magenta circles), GRB 090902B (purple triangles), GRB 110731A (orange squares), GRB 130427A (blue reversed triangles). S-GRBs: GRB 081024B (green diamonds), GRB 090510 (red squares), GRB 140402A (black triangles), GRB 140619B (blue circles). Also in this case the dashed vertical line marks the minimal turn-on time of the GeV emission of BdHNe.

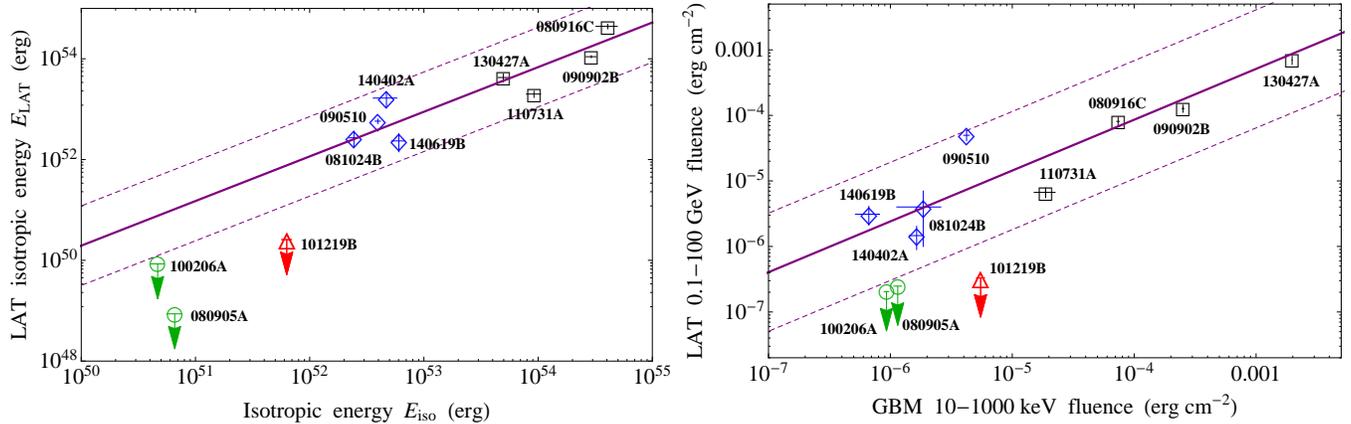

source	$z$	$E_{p,i}$ (MeV)	$E_{iso}$ ( $10^{52}$ erg)	$E_{LAT}$ ( $10^{52}$ erg)
S-GRBs				
081024B	$2.6 \pm 1.6$	$8.7 \pm 4.9$	$2.44 \pm 0.22$	$2.70 \pm 0.93$
090510	0.903	$7.89 \pm 0.76$	$3.95 \pm 0.21$	$5.78 \pm 0.60$
140402A	$5.52 \pm 0.93$	$6.1 \pm 1.6$	$4.7 \pm 1.1$	$16.6 \pm 5.3$
140619B	$2.67 \pm 0.37$	$5.34 \pm 0.79$	$6.03 \pm 0.79$	$2.34 \pm 0.91$
BdHNe				
080916C	4.35	$2.76 \pm 0.37$	$407 \pm 86$	$440 \pm 47$
090902B	1.822	$2.19 \pm 0.22$	$292 \pm 29$	$110 \pm 5$
110731A	2.83	$1.16 \pm 0.12$	$49.5 \pm 4.9$	$42.5 \pm 7.4$
130427A	0.3399	$1.25 \pm 0.15$	$92 \pm 13$	$19.9 \pm 2.9$

**Table 7.** List of the prompt and GeV emission properties of selected BdHNe and S-GRBs. We listed  $z$ ,  $E_{p,i}$ ,  $E_{iso}$  (in the rest-frame energy band 1–10000 keV), and  $E_{LAT}$  (in the rest-frame energy band 0.1–100 GeV).

- 3) the activity of the newly-born BHs originating the energetic prominent GeV emission, which can be explained in terms of the gravitational energy release by accreting matter onto a Kerr BH.

This classification is now open to a verification by the addition of new GRBs sources and offer new possibilities of theoretical and observational activities including:

- 1) the reaching of new observational constraints on the value of the NS critical mass  $M_{crit}$  and the minimum mass of a BH, which play a fundamental role in defining the separatrix among the different classes of our classification.
- 2) having elucidated the role of the activities of the newly-born BH in explaining the energetics of the GeV emission, in order to identify its microphysical process, the study of fundamental issues of general relativistic quantum electrodynamical processes appears to be open to further lines of inquiry (see, e.g., [Ruffini et al. 2010](#), and references therein);

**Figure A1.** For the sources in Tab. 7 (BdHNe as black squares and S-GRBs as blue diamonds), as well as for 2 S-GRFs (green circles) and 1 XRF (red triangle) which did not exhibit GeV emission although they were in the optimal position ( $< 65^\circ$  from the LAT boresight) for its detection, we plot: (Left:) the relation between  $E_{iso}$  of the prompt emission observed by the *Fermi*-GBM instrument and the total isotropic energy in the 0.1–100 GeV energy band observed by the *Fermi*-LAT instrument (or the corresponding upper limit if not detected); and (Right:) the relation between the 10–1000 keV fluence observed by the *Fermi*-GBM instrument and the total 0.1–100 GeV fluence observed by the *Fermi*-LAT instrument (or the corresponding upper limit if not detected). The purple solid line is the relation between the plotted quantities of BdHNe and S-GRBs, and the dashed lines are the corresponding dispersion.

- 3) it is conceivable that the sizable enlargement of the database of GRBs and of their spectral and luminosity time variability may open the possibility of further enlarging the above classification.

We thank the Editor and the Referee for their comments which helped to improve the presentation and the contextualization of our results. This work made use of data supplied by the UK Swift Science Data Center at the University of Leicester. J.A.R. acknowledges the support by the International Cooperation Program CAPES-ICRANet financed by CAPES-Brazilian Federal Agency for Support and Evaluation of Graduate Education within the Ministry of Education of Brazil. M.K. and Y. A. are supported by the Erasmus Mundus Joint Doctorate Program Grant N. 2013–1471 and 2014–0707, respectively, from EACEA of the European Commission. M.M. acknowledges the partial support of the project N 3101/GF4 IPC-11, and the target program F.0679 of the Ministry of Education and Science of the Republic of Kazakhstan.

## APPENDIX

### A. ON THE NON-OBSERVED GEV EMISSION IN S-GRFS AND XRFs

In Fig. A1 we compare and contrast the sources in Tab. 7, all exhibiting a GeV emission, with 2 S-GRFs and 1 XRF which, as theoretically expected within the fireshell model, do not exhibit any GeV emission. All these sources were in the optimal position ( $< 65^\circ$  from the LAT boresight) for the detection of the GeV emission.

In the Left panel we plot the values of  $E_{iso}$  and of the isotropic energy in the *Fermi*-LAT energy band or the corresponding upper limits if not observed. These upper limits were obtained by using the unbinned likelihood analysis which was performed assuming an integration time of 100 s after the flash trigger, a radius of the source region of  $10^\circ$  and a zenith angle cut of  $100^\circ$ . This plot observationally supports the theoretical expectation, made in Ruffini et al. (2016) and quoted in section 6.2 above, that S-GRFs have, if any, GeV fluxes necessarily  $10^5$ – $10^6$  times weaker than those of S-GRBs, although their  $E_{iso}$  is only a factor  $10^2$  smaller.

Motivated by a request of the Referee, we also plotted in the Right panel, the values of the fluence observed by *Fermi*-GBM and by *Fermi*-LAT or the corresponding upper limits if not observed (computed as above).

From both plots it is clear that the upper limits to the GeV emission of S-GRFs and XRFs are much lower than what one may expect from the extrapolation to lower energies of the one observed in BdHNe and S-GRBs. This is a further clear observational support to the absence, theoretically implied by the fireshell model, of any GeV emission associated to S-GRFs and XRFs (see sections 4.2 and 6.2 above).
