There is growing evidence that the superconducting semimetal FeSe $(T_c \sim 8 \text{ K})$ is in the crossover regime between weak-coupling Bardeen-Cooper-Schrieffer (BCS) and strong-coupling Bose-Einstein-condensate (BEC) limits. We report on longitudinal and transverse thermal conductivities, κ_{xx} and κ_{xy} , respectively, in magnetic fields up to 20 T. The field dependences of κ_{xx} and κ_{xy} imply that a highly anisotropic small superconducting gap forms at the electron Fermi-surface pocket whereas a more isotropic and larger gap forms at the hole pocket. Below $\sim 1.0 \text{ K}$, both κ_{xx} and κ_{xy} exhibit distinct anomalies (kinks) at the upper critical field H_{c2} and at a field H^* slightly below H_{c2} . The analysis of the thermal Hall angle $(\kappa_{xy}/\kappa_{xx})$ indicates a change of the quasiparticle scattering rate at H^* . These results provide strong support to the previous suggestion that above H^* a distinct field-induced superconducting phase emerges with an unprecedented large spin imbalance.

I. INTRODUCTION

The physics of the crossover between the weakcoupling Bardeen-Cooper-Schrieffer (BCS) and strongcoupling Bose-Einstein-condensate (BEC) limits gives a unified framework of quantum bound (superfluid) states of interacting fermions [1, 2]. In the region of this crossover, the size of the interacting pairs, which is represented by the coherence length ξ , becomes comparable to the average distance between particles, which is close to the inverse Fermi momentum $1/k_F$, i.e., $k_F \xi \sim 1$ [3-6]. The BCS-BEC crossover has hitherto been realized experimentally in ultracold atomic gases. On the other hand, in solids, almost all superconductors are in the BCS regime, where the superconducting gap energy Δ is usually several orders of magnitude smaller than the Fermi energy ε_F , $\Delta/\varepsilon_F \sim 1/k_F \xi \ll 1$, and it has thus been extremely difficult to access the crossover regime.

The iron-chalcogenide compound FeSe, comprised of two-dimensional Fe-Se layers [7], has recently stirred great interest because it exhibits several unique properties. At ambient pressure, the structural transition from tetragonal to orthorhombic crystal symmetry (nematic transition) occurs at $T_s \approx 90\,\mathrm{K}$, but, unlike other iron-based superconductors, no magnetic order occurs down to T=0, displaying peculiar electronic properties associated with the nematicity [8–16]. Significant enhancement of T_c has been reported under hydrostatic pressure [17, 18], and more recently in the form of one-unit-cell-thick films on SrTiO₃ [19, 20]. One of the most remarkable features of FeSe is its extremely small Fermi surface, which strongly deviates from predictions of first-

principles calculations [21, 22]. The low-temperature Fermi surface of FeSe consists of a small hole pocket centered at the Γ point and one or two small electron pockets at the M point [21–27]. Strikingly, all these pockets are very shallow and the Fermi energies of the hole and electron pockets are extraordinarily small, with $\varepsilon_F^h \approx 15 \text{ meV}$ and $\varepsilon_F^e \approx 10 \text{ meV}$. It has been shown that FeSe is a multigap superconductor with two distinct superconducting gaps of $\Delta \sim 2.5$ and 3.5 meV [28]. The comparable energy scale of ε_F and Δ indicates that superconductivity in FeSe is deep in the BCS-BEC crossover regime [28, 29]. Recent observation of giant superconducting fluctuations by far exceeding the standard Gaussian theory and a possible pseudogap formation well above T_c have been attributed to distinct signatures of the crossover [30].

Furthermore, FeSe has two unique features which may provide new insights into fundamental aspects of the physics of BCS-BEC crossover. The first feature is the electronic structure: FeSe is a compensated semimetal with equal numbers of electron and hole carriers, and hence it is essentially a multiband superconductor. In fact, as discussed in Ref. [31], this renders the crossover physics in FeSe distinguished from that in ultracold atomic gases. However, although the superconducting gap structure has been reported to be very anisotropic, the detailed gap structure in each band is still unclear. The second feature concerns the fate of the superfluid when the spin populations are strongly imbalanced. Although highly spin-imbalanced Fermi systems have been realized in ultracold atomic gases, the nature of the spinimbalanced superfluid is still largely unexplored experimentally due to the difficulty in cooling the systems to sufficiently low temperature [32–35]. In superconductors, the spin imbalance is introduced through Zeeman splitting in an applied magnetic field. The magnitude of the spin imbalance $P = (N_{\uparrow} - N_{\downarrow})/(N_{\uparrow} + N_{\downarrow})$, where N_{\uparrow} and N_{\perp} are the numbers of up and down spins, respectively,

^{*}These authors contributed equally to this work.

is roughly estimated as $P \approx \mu_B H/\varepsilon_F$. In almost all superconductors, P is very small, $P \sim 10^{-3} \cdot 10^{-2}$ even near the upper critical field H_{c2} . On the other hand, in FeSe in the crossover regime, the Zeeman effect is particularly effective in shrinking the Fermi volume associated with the spin minority, giving rise to a highly spin-imbalanced phase where $\varepsilon_F \sim \Delta \sim \mu_B H$. Recent experiments of FeSe report a possible field-induced phase (dubbed B-phase) in the low-temperature and high-field region in the H-T phase diagram [28], but very little is known about its nature.

To shed light on the above issues, the detailed knowledge of the quasiparticle excitations in the superconducting state is crucial. Here we measured the thermal conductivity κ_{xx} and the thermal Hall conductivity κ_{xy} up to $\mu_0 H = 20 \,\mathrm{T}$. Both quantities are sensitive probes of the delocalized low-energy quasiparticle excitations [36, 37]. Our results reveal that a highly anisotropic small superconducting gap opens in the electron Fermi-surface pocket whereas a more isotropic and larger gap forms in the hole pocket. We also find that the quasiparticle scattering rate is strongly modified on entering the B-phase. We discuss that this field-induced phase is likely to present a highly anomalous inhomogeneous superconducting state that has not been addressed before, rather than a conventional Fulde-Ferrel-Larkin-Ovchinnikov (FFLO) state [38, 39].

II. EXPERIMENTS

High-quality single crystals of FeSe were grown by the chemical vapor transport method [40]. Both κ_{xx} and κ_{xy} were measured on the same crystal by the steady-state method, applying the thermal current $\dot{\boldsymbol{q}}$ in the ab plane with $\dot{\boldsymbol{q}} \parallel \boldsymbol{x}$ for $\boldsymbol{H} \parallel c$. The thermal gradients $-\nabla_x T \parallel \boldsymbol{x}$ and $-\nabla_y T \parallel \boldsymbol{y}$ were detected by RuO₂ thermometers, and $\kappa_{xx} = w_{xx}/(w_{xx}^2 + w_{xy}^2)$ and $\kappa_{xy} = w_{xy}/(w_{xx}^2 + w_{xy}^2)$ were obtained from the thermal resistivity $w_{xx} = \nabla_x T/q$ and thermal Hall resistivity $w_{xy} = \nabla_y T/q$. The effect of misalignment of the Hall contacts was eliminated by reversing the magnetic field at each temperature. We additionally determined electrical longitudinal and Hall resistivities, ρ_{xx} and ρ_{xy} , respectively, in the same setup. The experimental setup is schematically presented in the inset of Fig. 1(b).

III. RESULTS

A. Superconducting Gap Structure

Figure 1(a) and its inset show the T and H dependences of the in-plane resistivity ρ_{xx} , respectively. The temperature at which ρ_{xx} goes to zero is $\approx 8.0 \,\mathrm{K}$ in the present sample. The resistivity at the superconducting onset $\rho_{xx}(T_c^+) \approx 24 \,\mu\Omega$ cm is roughly two times larger than that reported in Ref. [28], and the magnitude

FIG. 1: (Color online) (a) Temperature dependence of the inplane resistivity $\rho_{xx}(T)$ in zero field. The inset shows the field dependence of $\rho_{xx}(H)$ for $H \parallel c$. From bottom to top, $T=0.31,\,0.61,\,1.0,\,1.4,\,2.1,\,2.6,\,4.7,\,6.6,\,9.1,$ and $12\,\mathrm{K}$. (b) Field dependence of κ_{xx}/T (red squares, left axis) and κ_{xy}/B (blue triangles, right axis) at $0.59\,\mathrm{K}$. The inset shows a schematic of the measurement setup for the thermal-conductivity tensor.

of the magnetoresistance $\Delta \rho_{xx}(H)/\rho_{xx}(0)$ is roughly halved. Figure 1(b) depicts the H dependence of κ_{xx}/T and κ_{xy}/B (with $B = \mu_0 H$) at $T = 0.59 \,\mathrm{K}$. Usually, κ_{xy} , which is the nondiagonal element of the thermalconductivity tensor in a perpendicular field, is purely electronic. The ratio of κ_{xy}/T and electrical Hall conductivity, $\sigma_{xy}=\rho_{xy}/(\rho_{xx}^2+\rho_{xy}^2)$, is $(\kappa_{xy}/T)/\sigma_{xy}=1.05L_0$ at $\mu_0 H = 20 \,\mathrm{T}$, where $L_0 = \frac{\pi^2}{3} \left(\frac{k_B}{e}\right)$ is the Lorenz number, indicating that the Wiedemann-Franz law holds within experimental error. At low fields, κ_{xx}/T increases with convex curvature, compatible with the \sqrt{H} dependence expected for a nodal gap (see below), and becomes nearly independent of H between ~ 4 and 10 T. Above 2 T. κ_{xy}/B decreases in magnitude and then changes sign from negative to positive around $\mu_0 H_s \approx 12 \,\mathrm{T}$. Above H_s , both κ_{xx}/T and κ_{xy}/B increase steeply and decrease after exhibiting a narrow plateau-like ridge at around

The initial increase of κ_{xx}/T with a convex curvature at low fields is a signature of superconductivity with line nodes, where the Doppler shift of the quasiparticle spectrum in the presence of supercurrents around vortices gives rise to a \sqrt{H} increase in the population of delocalized quasiparticles [37]. The superconducting gap structure of FeSe is subject of extense discussion. A clear signature of the line nodes in the superconducting gap has been reported for very clean single crystals [28] or thin films [41] probed by scanning tunneling spectroscopy, thermal conductivity and magnetic penetration depth. In less clean crystals, however, a superconducting state with finite energy gap has been reported [42]. Moreover, even in very clean crystals, the nodes have been reported to disappear near the twin boundaries [43]. These re-

sults indicate that the line nodes are not symmetry protected and can be easily lifted by impurity and boundary scattering. The observed low-field convex curvature of κ_{xx}/T in Fig. 1(b) indicates the presence of line nodes or large superconducting gap anisotropy. Similar field dependence has been reported in FeSe with similar residual resistivity and magnetoresistance [44]. We note that this low-field behavior of κ_{xx}/T differs from that reported in FeSe with much smaller residual resistivity, in which κ_{xx}/T decreases rapidly with magnetic field [28], possibly be because in very clean FeSe, the extremely long quasiparticle mean free path is reduced by vortex scattering at low fields [45].

The nearly step-like behavior in the field dependence of κ_{xx}/T upon approaching 15 T is attributed to the multiband nature of superconductivity in FeSe [46–48]. A substantial portion of quasiparticles, which can be easily excited over the smaller gap, is already present at fields well below H_s , and therefore, κ_{xx}/T at high fields above $\sim 4\,\mathrm{T}$ is governed by the larger gap. Note that a nearly H-independent behavior at low fields and a subsequent steep increase of κ_{xx}/T with a concave curvature is observed in fully gapped superconductors, where quasiparticles are localized in the vortex core and thus are unable to transport heat until these vortices overlap each other [37].

B. Field-induced Superconducting Phase

Figures 2(a), (b), and (c) depict H dependences of κ_{xx}/T , κ_{xy}/B , and of the quasiparticle thermal Hall angle divided by B, $\tan \Theta_H/B \equiv \kappa_{xy}/(\kappa_{xx}^{qp}B)$, respectively, at $T = 0.59 \,\mathrm{K}$, while Figs. 2(d), (e), and (f) show the results at $T = 0.95 \,\mathrm{K}$. Two distinct anomalies (kinks) can be identified in both κ_{xx}/T and κ_{xy}/B . We first point out that the field marked by the dashed black line corresponds to H_{c2} because of the following reasons. First, above this field, κ_{xx}/T decreases rapidly with H, which is consistent with the large positive magnetoresistance in the normal state [49] [inset of Fig. 1(a)]. In addition, the fact that κ_{xx}/T is nearly independent of H below this field definitely indicates that the system at lower fields is not in the normal state. Second, the thermal conductivity has no fluctuation correction, in contrast to the resistivity, magnetic susceptibility, and specific heat, which all are subject to fluctuations, and, hence, often exhibits a kink anomaly at the mean-field upper critical field [50, 51]. Third, as will be shown later, this field is close to the superconducting onset temperature determined by the use of resistivity data. The fact that the admittedly weak kinks at H^* and H_{c2} occur at similar fields for the different measurements at temperatures 0.59 and 0.95 K lends strong confidence to the identification of H^* and H_{c2} .

Figures 2(g), (h), and (i) show the H dependence of κ_{xy}/B at higher temperatures. At $T=1.2\,\mathrm{K}$, no clear kink anomalies can be resolved, but κ_{xy}/B deviates from

the linear lines extrapolated from the lower and higher field regimes, as shown in Fig. 2(g). At T=1.9 and 2.3 K, only one kink anomaly is observed, which is attributed to H_{c2} because, as will be shown later, these fields are close to the onset of superconductivity.

Figure 3 displays the H-T phase diagram. The magnitudes of H^* and H_{c2} in the present crystal are slightly larger than those reported in Ref. [28]. We note that the superconducting onset temperature (black open circles) is close to H_{c2} determined by the thermal transport coefficients, (black closed circles) supporting that the higher-field anomaly shown by the dashed black line in Figs. 2(a)-(i) is indeed due to H_{c2} . In contrast to H_{c2} , H^* is nearly temperature independent and disappears when it meets the H_{c2} line. We stress that this fact is an important additional feature establishing the H-T phase diagram, which was not seen in our previous work [28]. We further note that the B-phase above H^* is not related to magnetic ordering, because of the following reasons. First, magnetic-torque measurements show no anomaly at H^* [28]. Second, the size of the hole pocket determined by magnetic quantum oscillations above 20 T coincides with that determined from angle-resolved photoemission in zero field, suggesting the absence of band folding [52]. Third, the H^* line is observable only in the superconducting regime.

It has been reported that ρ_{xy} is positive and increases linearly with H and that the magnetoresistance increases with H as $\Delta \rho_{xx}(H)/\rho_{xx}(0) \propto H^2$ at $\mu_0 H \gtrsim 18 \,\mathrm{T}$ [22]. Since FeSe is a compensated metal, with the same number of hole and electron charge carriers and only a single hole pocket, these H dependences indicate that the transport properties in the high-field region are governed by that hole band [49, 53]. In this situation, the scattering time τ_{qp} of the quasiparticles is proportional to the thermal Hall angle, $\tan \Theta_H/B \propto \tau_{\rm qp}$. The clear kink at H^* in $\tan \Theta_H/B$ [Figs. 2(c) and (f)] indicates that the quasiparticle scattering mechanism changes when crossing the H^* line, suggesting a modification of the superconducting gap structure. At H_{c2} , $\tan \Theta_H/B$ shows no discernible anomaly, while κ_{xx}/T shows a clear kink as shown in Figs. 2(a) and (d). Since κ_{xx} is proportional to the product of $\tau_{\rm qp}$ and the quasiparticle density $n_{\rm qp}$, $\kappa_{xx} \propto n_{\rm qp} \tau_{\rm qp}$, these results show that $\tau_{\rm qp}$ barely changes while $n_{\rm qp}$ is reduced below H_{c2} . Thus, the observed anomalies in the thermal transport coefficients strongly suggest the emergence of a new high-field superconducting phase (B-phase) which is distinctly different from the A-phase at lower fields.

IV. DISCUSSION

Although multigap superconductivity and a very anisotropic or nodal gap structure in FeSe have been suggested by several experiments, the detailed gap structure of electron and hole pocket has remained unclear. The combined results of the field dependence of κ_{xx} and the

FIG. 2: (Color online) Field dependences of (a) $\kappa_{xx}(H)/T$, (b) κ_{xy}/B , and (c) $\tan\Theta_H/B \equiv \kappa_{xy}/(\kappa_{xx}^{\rm qp}B)$ at $T=0.59\,{\rm K}$. (d), (e) and (f) are the results at $T=0.95\,{\rm K}$. (g), (h) and (i) show κ_{xy}/B at T=1.2, 1.9, and 2.3 K, respectively. $\kappa_{xx}^{\rm qp}$ is obtained by subtracting $\kappa_{xx}^{\rm ph}$ from κ_{xx} , where $\kappa_{xx}^{\rm ph}$ is estimated by using the Wiedemann-Franz law in the normal state at $20\,{\rm T}$, $\kappa_{xx}^{\rm ph}/T = \kappa_{xx}(20\,{\rm T})/T - L_0\sigma_{xx}(20\,{\rm T})$, and is assumed to be field independent. The dashed red and black lines represent magnetic fields, which correspond to H^* and H_{c2} , respectively. The dashed lines in (g) represent the linear extrapolations below H^* and above H_{c2} . Our detailed measurements of the thermal transport coefficients, κ_{xx} and κ_{xy} , with small steps in the field scans allow us to observe two distinct anomalies at H^* and H_{c2} , which have been missed in a previous study [44]. In $\tan\Theta_H/B$, no discernible anomaly is observed at H_{c2} . The observed kink in $\kappa_{xx}(H)/T$ at H^* is distinct from the previously reported observations in very clean FeSe [28], where κ_{xx}/T exhibits a tiny peak at H^* . This may be caused by the very large magnetoresistance in the cleaner sample, which leads to the rapid decrease of κ_{xx}/T at low H and above H_{c2} , smearing out the rapid increase just below H^* and features at H_{c2} .

sign of κ_{xy} provide important information on this issue. The sign change of κ_{xy} at H_s evidences that the quasiparticles responsible for the thermal conduction are electron-like at low fields and hole-like at high fields. Therefore, the large gap anisotropy found at low fields should correspond to the electron pocket, whereas the concave increase above H_s and saturation of κ_{xx}/T below H_s indicate that the superconducting gap of the hole pocket is more isotropic and that its amplitude is larger than that of the electron pocket.

Next we discuss the field-induced superconducting B-phase. We stress that this phase represents a highly unusual superconducting state because both electron and hole pockets are largely spin imbalanced with $P \approx \mu_B H^*/\varepsilon_F \approx 0.1$, as illustrated in the inset of Fig. 3. The nearly temperature-independent behavior of H^* suggests that this anomaly is not an artifact of a single broad peak of the H_{c2} anomaly, because in that case the two anoma-

lies at H^* and H_{c2} should follow parallel lines. One of the candidates of the B-phase may be a Fulde-Ferrell-Larkin-Ovchinnikov (FFLO) phase [38, 39], where the Cooperpair formation occurs between Zeeman-split parts of the Fermi surface and a new pairing state $(k \uparrow, -k+q \downarrow)$ with finite q is realized. The FFLO state has been reported in layered heavy-fermion and organic superconductors for magnetic fields parallel to the 2D plane [54, 55]. However, we want to point out that the B-phase is unlikely to be a conventional FFLO phase. In fact, the B-phase coexists with the vortex-liquid state where the resistivity is finite. This is different from heavy-fermion and organic systems, where possible FFLO phases occur within the vortex-lattice state. Moreover, the FFLO state is stabilized when a large part of the spin-up Fermi surface is connected to the spin-down surface by a single q vector. For the lowest Landau-level solution, the superconducting order parameter changes spatially as $\Delta(r) \propto \cos(q \cdot r)$

FIG. 3: (Color online) Field-temperature (H-T) phase diagram of FeSe in perpendicular field determined by the thermal-transport measurements. Black filled circles represent the upper critical field H_{c2} and filled red squares represent H^* that separates A- and B-phases. The black open circles represent superconducting onset temperatures at which the resistivity becomes 90% of the value extrapolated from the normal-state value under magnetic field, and the green open triangles represent the irreversibility fields determined by zero resistivity [inset of Fig. 1(a)]. The inset illustrates the electronic structure of hole and electron pockets at fields around H^* . Both Fermi surfaces are highly spin imbalanced.

where $q \parallel H$. However, since the Fermi surface of layered FeSe is cylindrical, the spin-up Fermi surface cannot be connected to a large part of the spin-down Fermi surface by a single q for $H \parallel c$. This analysis leads us to consider that the B-phase may be an FFLO phase involving higher Landau levels, where q lies in the two-dimensional plane.

Moreover, what makes FeSe distinctly different from ultracold atomic gases is that FeSe is a multiband system where the interplay between the formation of bound pairs and superconductivity may lead to rich physics [31]. Thus, the field-induced *B*-phase appears to be a previously unidentified kind of inhomogeneous superconducting state with an unprecedented large spin imbalance, which apparently is associated with the BCS-BEC crossover in a multiband system.

V. SUMMARY

In summary, we measured thermal longitudinal and thermal Hall conductivities in FeSe in the BCS-BEC crossover regime. The field dependences of thermal transport coefficients imply that the quasiparticle structure is strongly band-dependent; a highly anisotropic small superconducting gap forms at the electron Fermi-surface pocket whereas a more isotropic and larger gap forms at the hole pocket. The analysis of the thermal Hall angle provides evidence for the emergence of a highly anomalous inhomogeneous superconducting state, which is likely to be caused by the extremely high spin polarization. The strongly band-dependent quasiparticle structure and the emergent highly spin polarized phase may be important and unique features of the BCS-BEC crossover in the multiband superconducting system.
