## ABSTRACT

**Context.** The combination of wideband receivers and spectrometers currently available in (sub-)millimeter observatories deliver wide-field hyperspectral imaging of the interstellar medium. Tens of spectral lines can be observed over degree wide fields in about fifty hours. This wealth of data calls for restating the physical questions about the interstellar medium in statistical terms.

**Aims.** We aim at gaining information on the physical structure of the interstellar medium from a statistical analysis of many lines from different species over a large field of view, without requiring detailed radiative transfer or astrochemical modeling.

**Methods.** We coupled a nonlinear rescaling of the data with one of the simplest multivariate analysis methods, namely the Principal Component Analysis, to decompose the observed signal into components that we interpret first qualitatively and then quantitatively based on our deep knowledge of the observed region and of the astrochemistry at play.

**Results.** We identify 3 principal components, linear compositions of line brightness temperatures, that are correlated at various levels with the column density, the volume density and the UV radiation field.

**Conclusions.** When sampling a sufficiently diverse mixture of physical parameters, it is possible to decompose the molecular emission in order to gain physical insight on the observed interstellar medium. This opens a new avenue for future studies of the interstellar medium.

**Key words.** ISM: molecules, ISM: clouds, ISM: photon-dominated region (PDR), Object: Orion B, Method: statistical

## 1. Introduction

Molecular clouds have a complex structure, with filaments hosting dense cores and immersed in a low density diffuse envelope. Large scale dust continuum maps obtained with *Herschel* have provided a breakthrough, by showing the tight relationship between the filaments and the dense cores. These maps however do not provide information on the gas dynamics or its chemical composition. Furthermore the relationship between the submillimeter dust emission and the gas column density is affected by the dust temperature and possible variations of the dust emissivity. Molecular line emission maps provide alternative means to study molecular cloud structure and relate it to the flow kinematics. Molecular line emission is linked to the underlying physical properties of the ISM, such as density, gas and dust temperatures, UV radiation field, and cosmic ray ionization rate. But these relationships are complex and their detailed study is a field in it-

self: astrochemical modeling (Le Boulrot et al. 2012; Agúndez & Wakelam 2013). Further complexity arises when considering radiative transfer to derive line intensities from the local chemical composition and physical structure.

The last few years have seen the installation of new wideband receivers and spectrometer at millimeter and submillimeter radiotelescopes. With these instruments, line surveys of several GHz bandwidth and several tens of thousands of spectral channels are the new default mode of observations. Combined with wide field imaging capabilities both for single dish and interferometers, hyperspectral imaging is now routinely carried out with these instruments.

The analysis and interpretation of these large datasets, consisting of thousands of spatial positions and tens of thousands of spectral channels, will benefit from the use of statistical tools. Principal Component Analysis (PCA) is one of the most widely used multivariate analysis method. It has been used to study the Interstellar Medium (ISM) using molecular emission maps (Ungerechts et al. 1997; Neufeld et al. 2007; Lo et al. 2009; Melnick et al. 2011; Jones et al. 2012).

<sup>★</sup> Based on observations carried out at the IRAM-30m single-dish telescope. IRAM is supported by INSU/CNRS (France), MPG (Germany) and IGN (Spain).

In this paper, we address the following question: can PCA provide a method to study the underlying physics of the ISM when applied to a large dataset of molecular emission, without performing either radiative transfer or astrochemical modeling?

The article is divided as follows. Section 2 presents the data used in this study. Section 3 describes the statistical method used in this paper and its implementation. Results are presented in Sect 4 first by analyzing the output of the PCA, and further by comparing these outputs with independent maps of physical conditions in Orion B in Sect. 5. The last section discusses these results.

## 2. Data

The data used in this paper is selected from the ORION-B project (PI: J. Pety), which aims at mapping with the IRAM-30m telescope a large fraction of the South-Western edge of the Orion B molecular cloud over a field of view of 1.5 square degrees in the full 3 mm atmospheric window at 200 kHz spectral resolution. Pety et al. (2016) describe in detail the data acquisition and reduction strategies. Table 1 lists the 12 transitions selected in this paper from the already observed frequency range (from 84 to 116 GHz), based on the inspection of the full data cube.

For each line, we focus on emission coming from a limited  $1.5 \text{ km s}^{-1}$ -velocity range centered on the peak velocity (*i.e.*,  $10.5 \text{ km s}^{-1}$ ) of the main velocity component along the line of sight. Averaging the three  $0.5 \text{ km s}^{-1}$  velocity channels allows us to get a consistent dataset from the radiative transfer and kinematics viewpoints. In particular, we avoid the need to disentangle 1) the effects of hyperfine structures of some lines, and 2) the complex velocity structure of the source (Orkisz et al. *subm.*).

The observed field of view covers  $0.81 \text{ deg} \times 1.10 \text{ deg}$  and contains the Horsehead nebula, and the H II regions NGC 2023, NGC 2024, IC 434, and IC 435. The angular resolution ranges from  $22.5$  to  $30.5''$ . The 12 resulting maps have a common pixel size of  $9''$  that corresponds to a Nyquist sampling for the highest frequency line observed (<sup>12</sup>CO(1–0) at 115.27 GHz). The maps thus contains  $315 \times 420$  pixels. At a distance of  $\sim 400 \text{ pc}$  (Menten et al. 2007), the maps give us access to physical scales between  $\sim 50 \text{ mpc}$  and  $10 \text{ pc}$ .

Figure 1 shows the 12 maps of the resulting brightness temperature multiplied by an ad-hoc factor in order that they can share the same color look-up table, even though the intrinsic brightness temperatures of the different lines differ by more than one order of magnitude. The relative calibration of the different lines is excellent because they were observed with the same

telescope at almost the same time, as the observed bandwidth was covered in only two frequency tunings. The noise for each map, along with the minimum, median, maximum, and variance values are listed in Table 1. The noise is computed by fitting a gaussian function to the negative part of the histogram of pixel brightnesses. This enables to compute the noise without needing to mask out the emission.

## 3. Principal Component Analysis

### 3.1. Principle

We use the following standard statistical terms: the dataset is composed of *samples* each described by individual *features*. In our case, each spatial pixel is a sample and each line intensity is a feature (the full dataset thus corresponds to a data matrix of  $132\,300$  samples times  $12$  features).

Principal Component Analysis (PCA) is a widely used multi-dimensional analysis technique (Jolliffe 2002), which can be defined in several mathematically equivalent ways. It aims at finding a new orthogonal basis of the feature space (whose axes are called principal components, or PCs), so that for each  $k$ , the projection onto the hyperplane defined by the first  $k$  axes is optimal in the sense that it preserves most of the variance of the dataset (or equivalently that the error caused by this projection is minimal). PCA thus defines successive approximations of the dataset by hyperplanes of increasing dimension.

This is equivalent to the diagonalization of the covariance matrix, so that the principal components are naturally uncorrelated. It can be thought of as finding the principal axes of inertia of the cloud of samples about their mean in feature space, and is thus a way to analyze the covariance structure of the data. The principal components are ordered by decreasing projected variance. As a result PC1 is the axis of largest variance in the data. PC2 is then the axis of largest variance *at constant PC1* (orthogonal to PC1) and so forth. Neglecting the axes of lowest variance then allows to define a low-dimensional hyperplane in which the dataset is approximately embedded. An important property to keep in mind is the linearity of PCA (it defines low-dimensional hyperplanes, and not general low-dimensional hypersurfaces).

A common variant<sup>1</sup> in the application of PCA is to normalize the variations of the dataset around the mean by the standard deviation of each features, before applying the PCA. This amounts to diagonalizing the correlation matrix instead of the covariance matrix. The correlation-based variant allows to avoid

<sup>1</sup> It actually goes back to one of the two earliest descriptions of PCA: Hotelling (1933)

**Fig. 1.** Maps of molecular emission in Kelvin main beam temperatures.

having one feature dominating the variance, and is indicated if the relative scales of the features are not relevant for the purpose of the analysis. As the relative intensity scales of the different molecules used here are largely affected by properties (dipole

moment, elemental abundances,...) that are not relevant for our analysis of the chemical variations across the map, we use here the correlation-based version of PCA.

**Fig. 2.** Effect of the asinh renormalization on the intensity distributions. *Left column:* before renormalization, *right column:* after renormalization, *Top row:*  $\text{N}_2\text{H}^+$ , *bottom row:*  $^{13}\text{CO}$ .

**Fig. 3.** Plot of the asinh function (solid line) showing the asymptotes when  $x \rightarrow 0$  (dash dotted line) and  $x \rightarrow +\infty$  (dotted line). The parameter  $a$  (here  $a = 1$ ) is traced with a thin vertical line

In this work, we used the PCA implementation available in the Python package `scikit-learn` (Pedregosa et al. 2011), which uses a singular value decomposition to compute the principal component axes.

### 3.2. Reparametrization of input data

#### 3.2.1. On the need of a reparametrization

As seen in Table 1, some of the tracers have large dynamical ranges (2 orders of magnitude for  $^{13}\text{CO}(1-0)$  and  $^{12}\text{CO}(1-0)$ ).

Figure 2 shows the histogram of the brightnesses temperatures of two lines with contrasting behavior in our dataset, namely  $^{13}\text{CO}(1-0)$ , and  $\text{N}_2\text{H}^+(1-0)$ . As the dynamic range is large both in intensity and number of pixels per bin, these histograms use the Bayesian Blocks algorithm (Scargle et al. 2013, using here the Python implementation from AstroML, see Vanderplas et al. 2012; Ivezić et al. 2014), which adapts the bin width to the underlying distribution. While the histogram

of the  $\text{N}_2\text{H}^+(1-0)$  is Gaussian to first order, the histogram of  $^{13}\text{CO}(1-0)$  exhibits heavy tails similar to power laws. As a result, extreme intensity values might dominate the covariance structure of the data, hiding the variations at the more common lower intensity values.

From the physical viewpoint, taking the logarithm of the brightness temperature is also desirable. PCA is a linear technique which decompose the data as a sum of uncorrelated components. Applying it to the logarithm of the data allows a decomposition as a product of factors, and thus describes the data structure in terms of ratios, products and power laws, more adapted to the underlying radiative transfer and chemical effects. Taking the logarithms of the data is the equivalent in astrochemistry to doing color-color magnitude diagram analysis in optical or UV studies. Pety et al. (2016) show that the line integrated brightness temperatures of our dataset is to first order correlated to the column density of matter along the line of sight. We expect this aspect to appear in our PCA analysis, and second order chemical variations around this trend, which would be revealed by line ratios, are thus better described as multiplicative –rather than additive– factors.

#### 3.2.2. Impact of noise

The presence of noise however causes the possibility of negative values in pixels where some lines are undetected. The logarithm transform cannot be applied to these negative noise values. In addition, as the logarithm stretches the lowest values compared to the largest ones, it will also tend to stretch the positive noise values of the undetected pixels, thus giving them more weight in the covariance of the data.

There may be two different reasons for a non-detection: either the measurement is not sensitive enough to detect the line or the region just does not contain the species that emits the line. The latter case happens in particular in H II regions (e.g., IC 434), where  $^{12}\text{CO}(1-0)$  is photo-dissociated by the far UV photons. In this particular case, we could remove from our dataset all the samples (pixels) where no  $^{12}\text{CO}(1-0)$  is detected. This just assumes that no  $^{12}\text{CO}(1-0)$  detections at high sensitivity imply the absence of molecular gas. However, this method is not generic. For instance,  $\text{N}_2\text{H}^+(1-0)$  is only detected in dense cores (Pety et al. 2016), and restricting ourselves to these regions would drastically limit the scope of our study. If we wish to use this important tracer of the molecular gas while still covering the range of different chemical regimes present in our full map, we thus need to find an alternative. Moreover, in the 3 mm band, radio recombination lines, which emit in H II regions, could in principle be added to our dataset to study the formation of molecular gas.

Adding a thresholding step before taking the logarithm will only worsen the scope of undefined values. While there are PCA methods (see e.g. Ilin & Raiko 2010) that can take missing datapoints into account, they rely on the fact that these missing points have the same statistics than the measured points (i.e., when a value is missing, it is independent of the actual value). This is clearly not the case here as the missing values (undetected lines) are missing because they are below the sensitivity threshold. These are called censored values in statistics. We thus search for a function that is linear around 0 (in the noise dominated domain), and which is asymptotically equal to a logarithm for large values (compared to the noise level). The inverse hyperbolic sinus function,  $\text{asinh}(x)$ , fulfills these conditions. We thus

**Fig. 4.** Maps of molecular emission after reparametrization by the asinh function.

used the following function to reparametrize the data before applying PCA

$$T(x) = a \operatorname{asinh}(x/a), \quad (1)$$

where the parameter  $a$  is the typical value for which the function behavior changes from a linear to a logarithmic regime (see Fig. 3).

**Fig. 5.** Percentage of the explained correlation as a function of the number of components in the Principal Component Analysis, *dotted line*: cumulative percentage.

The only free parameter in the method is the threshold  $a$ . Appendix A discusses our choice, *i.e.*,  $a = 8 \times 0.08 = 0.64$  K equal to 8 times the median noise of the dataset. In short, we select the value of  $a$  that maximizes the correlations of the first 3 principal components with independent known measurements of the column density, volume density, and UV illumination (see Section 5). This appendix also demonstrates that our results are quite insensitive to the exact value of  $a$ .

The right column of Fig. 2 shows the result of the asinh transformation on the intensity distributions of two transitions representative of bright ( $^{13}\text{CO}(1-0)$ ) and weak ( $\text{N}_2\text{H}^+(1-0)$ ) averaged lines. In the case of the bright lines, the dynamic range is drastically reduced with the heavy tail being transformed into a second peak in the distribution but with no values above 3. In the case of  $\text{N}_2\text{H}^+$  the distributions before and after reparameterization are very similar. Figure 4 shows the 12 maps of the molecular emission after reparameterization by the asinh function, but before the normalization step of the PCA analysis. The brightness temperatures of all the maps have been compressed between about -0.5 and 3.5, with low signal-to-noise brightness temperatures between -0.5 and 0.5 being mostly untransformed.

## 4. Results

The PCA method exposes the correlations between the line brightness temperatures. The derived PCs give the main axes of correlated variations in the data set. As such, it does not directly yield physical information underlying the dataset. In this section, we describe the results of the application of this statistical method to our dataset and we start to discuss their possible physical interpretation based on our *a priori* astrochemical knowledge. The possible relations between these PCs and physical variables are investigated in a later section.

### 4.1. Correlation fraction explained by the different principal components

Figure 5 shows the percentage of the correlation explained by each PC (as a function of the principal component number) along with the cumulative explained correlation as a function of the number of principal components kept in the decomposition.

The first principal component explains the majority (60%) of the total correlation present in the original dataset. Thus a large part of the variations in the dataset occur along a single axis (*i.e.* all lines are strongly correlated to each other). The second principal component accounts for about 10% of the correlation. It is significantly less than the first component, but more than any other components. PC 3, 4 and 5 correspond to similar amounts of correlations (around 5% each) and PC6 slightly less (3.3%). PC1 to 6 collectively explain more than 90% of the correlation in our dataset. The remaining PCs have similar low amounts of explained correlation (from 2% for PC7 to 0.9% for PC11).

### 4.2. Discussion of the principal components

The PCs defined by our analysis represent new axes in the feature space (the full 12 PCs are simply a rotation of the initial basis of the feature space), deduced from the data itself. They can thus be expressed in terms of the original axes, as a linear combination of the (transformed) line intensities. Figure 6 displays the quantitative contribution of each initial feature (line) to each PC. An alternative view of the relationship between the PCs and the line intensities, namely the correlation wheels, is presented in Fig. 7.

Each sample (pixel brightness) can then be projected on the new axes, providing new coordinates commonly called *component scores*. The PCA method considers the pixels as independent samples, and thus ignores the spatial structure of the molecular emission. It is nevertheless possible to reconstruct the maps of the component scores. Figure 8 shows these projected maps. The chosen color look-up table emphasizes that positive (red-colored) and negative (blue-colored) values of the projected maps –corresponding to variations above and below the average along the considered axis– clearly extract a different spatial pattern per principal component.

The first principal component is a linear combination of all tracers, with similar positive weights for all lines (Fig. 6). It thus describes correlated variations of all molecules, and these account for most of the variations in the dataset. It is a natural consequence of the fact that all lines are well correlated (positively) to each other. Pety et al. (2016) show that the emission of all lines is correlated to first order with the column density of matter along the line of sight. This component is thus probably related to the total column density, whose increase causes to first order an increase in all lines (in the linear approximation of PCA, non linear effects such as saturation of the  $^{12}\text{CO}$  line are not captured). The corresponding component map (Fig. 8) indeed resembles a map of column density. This relation between PC1 and the total column density of matter will be investigated more quantitatively in Sect. 5. Note that as PC1 has only positive coefficients for all lines, orthogonality ensures that all other PCs will represent contrasts between different lines.

The second principal component represents the axis of largest variation at constant PC1 (orthogonal to PC1). This axis of variations is dominated by positive contributions of  $\text{N}_2\text{H}^+$  and  $\text{CH}_3\text{OH}$ , and negative contribution of  $^{12}\text{CO}$  and  $^{13}\text{CO}$ . The first two tracers are chemically associated with dense and cold regions of the interstellar medium. For instance,  $\text{N}_2\text{H}^+$  is easily destroyed by CO, it can thus only be abundant in the gas phase when CO has been depleted on the grain surfaces (Pety et al. 2016). The component map shows strong positive values highlighting known dense cores, including the clumps in the head and in the neck of the Horsehead (Ward-Thompson et al. 2006).

The third principal component shows positive contribution of CCH and CN that are known to be sensitive to UV illumina-

**Fig. 6.** Bar plots showing the contribution of each line intensity to each principal component (with the fraction of the total correlation accounted for by each PC given as a percentage). The uncertainties (standard deviations) shown in red are obtained by bootstrapping as described in Sect. 4.3.

tion, and negative contribution of N $_2\text{H}^+$ , CH $_3\text{OH}$  and of the CO isotopologues, that trace gas shielded from the UV field. This component thus probably traces the chemical specificities of UV illuminated gas. The component map clearly shows positive values at the eastern edge of the cloud, illuminated by  $\sigma$  Ori, and in the star-forming region NGC 2024.

The fourth principal component is particular in the fact that its map almost only shows large (positive or negative) values in the regions of large positive values of PC2. It thus highlight further chemical variations inside dense cores. This component is completely dominated by opposite contributions of CH $_3\text{OH}$  and N $_2\text{H}^+$  and thus traces variations in the ratio of these two lines. The component map seems to highlight smaller size cores embedded in some of the clumps revealed by PC2, and thus probably highlights the chemistry of the densest cores (larger N $_2\text{H}^+$  to CH $_3\text{OH}$  ratios).

The fifth principal component shows positive contributions of sulfur species (CS and SO), and C $^{18}\text{O}$ , and negative contributions of  $^{12}\text{CO}$ , CCH, and CH $_3\text{OH}$ . Its large positive values highlight larger scale regions embedding the dense clouds shown by

PC2 (but with negative values where PC2 is very large), and this PC could thus trace the chemistry of moderately dense gas.

The sixth principal component shows negative contributions of HCN, HCO $^+$  and CN, which can all originate in photochemistry, and positive contributions from CCH, C $^{18}\text{O}$ ,  $^{13}\text{CO}$  and SO, which are usually associated with more shielded gas although CCH can also be bright in UV illuminated regions. Its component map shows a wide blue region around NGC 2024, similar to the large warm dust region seen in the dust temperature map of the region (Schneider et al. 2013). It could thus also be related to the radiation field, but trace a different aspect from PC3, characterized by lower CCH intensities relative to the other lines.

The remaining components are more difficult to interpret, but tend to describe opposite variations in pairs of lines that varied together in previous PC. PC7, 9 and 10 display opposite variations in pairs of line of the group HCN, HNC, CN and HCO $^+$ , whose variations were correlated in the previous PCs in which they had large weights (PC1 and 6). PC8 shows anticorrelated variations of SO and C $^{18}\text{O}$ , and its component map shows a striking spatial pattern with negative values (high SO/C $^{18}\text{O}$  ratios) in the Horsehead, the molecular gas at the base of the

**Fig. 7.** Correlation wheels, showing the initial line intensities as vector having as coordinates their correlation coefficients to each PC, represented in the planes of successive pairs of PCs. Uncertainties from our bootstrapping analysis (see Sect. 4.3) are presented as thin black contours around the arrows' heads (isodensity contours containing 68% of the distribution). Also represented in colored arrows are the correlations of our independent physical parameters with the PCs (red:  $\log N_{\text{H}_2}$ , green:  $\log n_{\text{H}}$ , blue:  $\log(U/\bar{U})$ ).

Horsehead, and the small scale clumps in NGC 2024, and positive values (low  $\text{SO}/\text{C}^{18}\text{O}$  ratios) in a dense filament stretching away from NGC 2024. PC11 is strongly dominated by CS, and thus shows specific variations of CS, mostly uncorrelated with the other lines (somewhat anticorrelated with  $\text{C}^{18}\text{O}$ ), and that were not described by the previous PCs. Its component map shows small scale spots of positive values, mostly surrounding NGC 2024 and NGC 2023. The fact that it appears so late in the decomposition can be explained by the small size of the high-

lighted region, thus having little weight in the correlation matrix. PC12 is completely constrained by orthogonality to the previous PCs and is thus only a consequence.

#### 4.3. Studying the effect of noise

The noisy nature of our data can have two kinds of effects. It can first induce variability in our results (the results would vary for a different realization of the random noise). We verified the stabil-

**Fig. 8.** Principal component maps. These maps represent the value of each observed pixel when they are projected in the space of the principal components.

ity of our results by using a bootstrapping method. Bootstrapping is a method of choice to compute uncertainties on an estimator (here the PCA components) when the distribution of estimator values cannot be assumed to follow a simple distribution (Feigelson & Babu 2012). The idea of bootstrapping is to use a Monte Carlo method to create new resampled datasets of the same size as the original dataset by sampling with replacement from the original dataset. We construct 5000 such bootstrapped datasets and run the PCA algorithm on each. Because the PCA is invariant through the change of sign of the PCs, we ensure that the signs are consistent before computing the distribution of the PC coefficients to avoid overestimating the uncertainty. The results are presented both for the eigenspectra in Fig. 6, and the correlation wheels in Fig. 7.

The PC coefficients appear overall very stable, the variances being completely negligible for PC 1 and 2, and very small for PC 3 to 6. Only PC 7 and 8 show significant variability, with some coefficients changing sign. This can be understood as PCA results are particularly sensitive to noise when two PCs correspond to very close eigenvalues, and PC 7 and 8 have the closest eigenvalues with respectively 2% and 1.9% of the total correlation. Indeed, PCs with equal eigenvalues are degenerate in the sense that any basis of the subspace they define satisfies the definition of PCA. As a result, when eigenvalues are not exactly equal but very close, the noise can result in a random rotation of this group of PCs inside their subspace. Our results, which focus on the first few PCs, are thus unaffected by noise variability.

The second possible effect of noise is to bias the results. PCA is unbiased if the noise is spherical (i.e., has equal variance in all directions) in the final dataset on which PCA is applied (i.e. after standardization in our correlation-based variant). In this case, the noise can only hide the lowest PCs (that describe variations smaller than the noise level) and make them degenerate. In our case however, the noise levels on the different molecular lines are initially close but not equal (variations by a factor of 3 at most, see Table 1). The non-linear reparametrization keeps these relative variances. Finally, the last normalization step (by the standard deviation) gives final noise variances proportional to the ratios of noise standard deviation to total standard deviation of the reparametrized intensities. These differ by up to a factor of 14.8 between the lines, and possible biases may be present in our results, giving higher weight to the lines with the largest ratios of noise variance to total variance. However, it wasn't possible with the PCA method to both avoid giving higher weight to the brightest lines (which led us to use the correlation-based PCA), and at the same time ensure equal noise on all variables. We note that the previous PCA studies of molecular clouds were less concerned by noise-induced bias as they only used lines that were clearly detected in all pixels. Our choice allowed us to perform the principal component analysis on the full region, which led to the identification of two PCs associated with dense core chemistry.

## 5. Correlation of the principal component maps with *independently measured physical parameters maps*

In the previous section, we combined two sources of information to interpret the main principal components: 1) astrochemistry teaches us that some molecules trace certain physical conditions, 2) Orion B is an extremely well studied source, implying that the spatial structure of the source is well known. For instance, the molecular cloud is known to be illuminated by well-

defined young massive stars (see discussion in Pety et al. 2016). This allowed us to infer a link between the first three principal components and physical quantities such as the column density, the volume density, and UV illumination. In this section, we will quantitatively assert these potential relations by studying the correlation of each component map with a set of *independently measured* maps of physical parameters.

### 5.1. Independent measure of the physical quantities

The goal of this section is to find the principal component that is best associated to each of the physical parameters, not to assign an absolute physical meaning to some of the components. It is therefore not necessary to have absolute values of the *independently measured* physical parameters maps. Only the relative variation of each physical parameter is required to compute the correlation coefficient. Figure 9 shows the different maps of the physical quantities that we will correlate with the first 3 principal components. This section describes how these maps were obtained.

#### 5.1.1. Column density

The dust column density map is from the Hershel Gould Belt Survey (PI: P.Andre) Orion B map (André et al. 2010; Schneider et al. 2013)<sup>2</sup>. This map was obtained by fitting the far infrared Spectral Energy distribution by greybodies. We apply a logarithmic scaling to the data to reduce the dynamical range, the resulting maps is plotted in the left panel of Fig. 9.

#### 5.1.2. Volume density

Volume density is a difficult quantity to measure because one needs both a mass estimate and an associated volume. Density is thus dependent on the scale that it is computed at. We use the catalog of cores identified and characterized in Kirk et al. (2016). We compute masses from each cloud's 850  $\mu\text{m}$  flux using their equation (3). To do this, we assume a common temperature of 17 K for all clouds. From this mass and their observed size estimates we compute a volume density for each of the dense cores in our observed field of view. In this case correlation cannot be carried out over the full map but we correlate the density measured for each core with the value of the principal components measured in the nearest pixel. The data is shown as a scatter plot in the middle panel of Fig. 9.

#### 5.1.3. UV radiation field

We compute the UV radiation field by using the fact that PAH emissivity is roughly constant per unit H and unit radiation field (Draine & Li 2007). In practice, we use the WISE (Meisner & Finkbeiner 2014) 12  $\mu\text{m}$  maps divided by the column density clipped to a maximum value of  $10^{22} \text{ cm}^{-2}$ . We do not claim to have an absolute value of the UV radiation field but a quantity that should be proportional to it. The quantity  $\log(U/\bar{U})$  where  $\bar{U}$  is the mean value of  $U$  is shown in the rightmost panel of Fig. 9.

The proper way to compute the UV radiation field from PAH emission would be to divide by the *volume density* but as we discussed in the previous paragraph, it is not possible to get a *full map* of volume density. We choose to use column density as a

<sup>2</sup> <http://www.herschel.fr/cea/gouldbelt/en/>

**Fig. 9.** Maps of the independently measured physical parameters,  $H_2$  column density (*left*), volumic density (*middle*), UV illumination (*right*)

**Table 2.** Spearman rank correlation coefficient between the principal components and the physical quantities.

	$\log N_{H_2}$	$\log n_H$	$\log(U/\bar{U})$
PC1	0.90	0.43	-0.66
PC2	-0.57	0.22	0.43
PC3	-0.20	0.06	0.42

PC9	-0.02	0.06	-0.11
PC10	-0.06	-0.10	-0.07
PC11	-0.03	-0.13	-0.04
PC12	0.04	0.11	-0.05

proxy for volume density even though it entails strong constraints on the spatial distribution of the gas along the line of sight. Since we are interested in relative variation of density and not absolute values it is sufficient to assume that the matter is clustered into clouds that are of similar spatial extents.

### 5.2. Correlation of principal component maps with physical parameters

We compute the Spearman rank correlation coefficient between each pair of principal component maps and physical parameters maps. We use the Spearman rank correlation instead of the Pearson linear correlation coefficient because the potential relations between the principal components and the physical parameters are most certainly non linear in nature. The rank coefficient used is only sensitive to the ordering of the values, and is thus not affected by the possible non-linearities of the correlation. Table 2 summarizes all these values and Fig. 10 shows the scatter plots for the most significant correlations discussed in the next paragraphs. An alternative way of exploring the correlations

between the independent physical quantities and the Principal Components is to represent the correlation between each physical parameters and the PCs in the correlation wheels of Fig 7.

For this analysis, it must be kept in mind that while the principal components are necessarily uncorrelated, the physical parameters considered here are correlated:  $N(H_2)$  is an integral of  $n_H$  along the line of sight and the two are thus strongly correlated,  $U$  is inversely proportional to  $N(H_2)$  by construction and they are thus anticorrelated. As a result, the principal components will tend to represent the uncorrelated part of the variations of the underlying physical parameters.

**Column density:** The component maps showing the highest correlation coefficient with  $N(H_2)$  is PC1. Spearman's rank correlation coefficient is extremely high, *i.e.* 0.90, and the scatter plot (Fig. 10, left panel) shows a strongly linear relation between PC1 and  $\log(N(H_2))$ .

As it is the first PC (axis of largest variation), it is unaffected by the decorrelation constraint that affects the other PCs. This first principal component can thus be interpreted as a global measure of total column density, as suspected in our previous discussion. Since  $n_H$  and  $U$  are positively and negatively correlated with  $N(H_2)$ , respectively, these physical parameters also exhibit relatively strong positive, resp. negative correlations with PC1.

**Volume density:** The PC most correlated to  $n_H$  is also PC1, due to the large correlation between  $N(H_2)$  and  $n_H$ . The next principal components most correlated with our limited sample of volume density measurements are PC2, which shows a Spearman's rank correlation coefficient of 0.22, and PC4, with a Spearman's rank correlation coefficient of -0.23.

As was discussed in Sect 4, PC2 and PC4 both trace chemical differences typical of dense cores. PC2 and PC4 can thus be interpreted as indicator of the presence of dense cores. Note that this comparison was only done with a limited sample of rather dense clouds. We can thus only say that PC2 traces increased density among dense clouds. Because of the opposite sign of

**Fig. 10.** Scatter plots of the first three principal components with the independent physical parameters. Contours in black and gray correspond to 68% and 95% of the samples respectively.

the correlation of the density with PC4, negative values of this PC probably trace an even higher density regime. As noted before, the behavior of PC2 in less dense region is probably anti-correlated with density, and these PCs are thus only indicative of density in the high density regime.

**Radiation field:** For the radiation field, the most correlated PC is again PC1 (negative correlation) as high column density tends to result in highly shielded gas. Not considering PC1 and PC2, the third principal component shows the highest correlation with our estimation of the radiation field, with a Spearman's rank coefficient of 0.42. It thus describes the part of the radiation field variations that are not correlated with the cloud column density. As a result, it highlights the part of the cloud where specific sources cause increased illumination. A strong positive correlation (0.43) with PC2 is also found, which is most likely an artifact due to the positive values of PC2 in the diffuse regions surrounding the molecular cloud (where most of the lines involved in PC2 are undetected, making PC2 irrelevant). PC6 also has a significant correlation with the radiation field (-0.26). These results thus confirm our previous discussion of PC3 and PC6.

These results can be inferred graphically from the correlation wheels of Fig 7, where the colored arrows tracing the location of  $N(\text{H}_2)$  (red),  $n_{\text{H}}$  (green) and  $U$  (blue) the PC space have a significant size only for the first 4 PCs. Furthermore, each arrow is roughly aligned with one of the PC : PC1 for  $N(\text{H}_2)$ , PC2 for  $n_{\text{H}}$  and PC3 for  $U$ .

## 6. Discussion

### 6.1. Comparison with other works

PCA has been extensively used in astronomy as a multivariate analysis tool starting from the work of Deeming (1964) on the classification of stellar spectra. Its use for the study of molecular maps of the ISM is more recent starting with the work of Ungerechts & Thaddeus (1987). Notable studies include Neufeld et al. (2007); Lo et al. (2009); Melnick et al. (2011), and Jones et al. (2012)

We first discuss the common points between these studies. On a technical aspect, all these studies apply only subtraction by mean and normalization by variance and do not attempt to introduce a non linear reparametrization of the observed intensities. The effect of noise is considered by limiting the number of observed lines to the set of brightest tracers (Lo et al. 2009) and masking regions of low emission (Jones et al. 2012). All of these studies identify the utility of PCA as a means of studying the correlations between molecular lines by studying the commonality between tracers and its variation, and as a tool to identify regions interesting for further study. With the notable exception of Ungerechts & Thaddeus (1987) rarely a discussion is made relating the principal components with the underlying physical parameters of the ISM although often, specific correlations or anticorrelations are discussed in a chemical view or by invoking opacity effects (Lo et al. 2009).

Ungerechts et al. (1997) present a dataset of 360 spatial points in 32 lines of 20 chemical species including isotopologues toward the Orion A molecular cloud with the 14m FCRAO telescope. Using a Principal Component Analysis (PCA) they show that the chemical abundances of most species stay similar for the Orion ridge, and that the main differences stand up for the BN-KL region. They note that their first 3 PCs contain 80% of the observed correlation and use the component maps mainly to identify regions for further astrochemical study. They nevertheless discuss that data mostly lie in a 3D space spanned by the first three PC because the molecular emission probably depends on three physical parameters of the ISM the column density, volumic density and gas temperature. Melnick et al. (2011) compared the distribution of the ground state transition of water vapor with that of the ground state transition of  $\text{N}_2\text{H}^+$ , CCH, HCN, CN, and  $^{13}\text{CO}(5-4)$ . Water vapor is found to best correlate with species like  $^{13}\text{CO}(5-4)$  and CN, tracing the cloud surface up to a few magnitudes of extinction and is poorly correlated with  $\text{N}_2\text{H}^+$  tracing the shielded regions. Using MOPRA, Jones et al. (2012) have mapped the central molecular zone (CMZ) near the center of the Galaxy in 20 spectral lines in the 85.3 to 93.3 GHz range. They performed a PCA analysis using the strongest eight lines (HCN,  $\text{HCO}^+$ , HNC, HNCO,  $\text{N}_2\text{H}^+$ , SiO,  $\text{CH}_3\text{CN}$  and  $\text{HC}_3\text{N}$ ) in the restricted area around SgrB2 and SgrA where the  $\text{N}_2\text{H}^+$

line is stronger than  $10 \text{ K km s}^{-1}$ . The analysis recovers the overall similarity of the line maps. The main differences are found in the SgrA and SgrB2 cores between the bright lines HCN, HNC and  $\text{HCO}^+$  and the other species, and is attributed by Jones et al. (2012) to a difference in opacity. The other PCA components reveal specific regions where  $\text{CH}_3\text{CN}$ , HNC and SiO abundances are enhanced, possibly due to shocks or hot cores. Lo et al. (2009) studied the G333 molecular cloud with MOPRA. The PCA is performed on eight molecular lines with high S/N ratio ( $^{13}\text{CO}$ ,  $\text{C}^{18}\text{O}$ , CS,  $\text{HCO}^+$ , HCN, HNC,  $\text{N}_2\text{H}^+$ , CCH). The PCA analysis reveals differences between the regions traced by CCH and  $\text{N}_2\text{H}^+$ , and in star forming regions an anticorrelation between  $^{13}\text{CO}$ ,  $\text{C}^{18}\text{O}$  and  $\text{N}_2\text{H}^+$ , and between  $\text{N}_2\text{H}^+$  and  $\text{HCO}^+$ . PCA was also used by Neufeld et al. (2007) to separate the different regions impacted by supernovae shock waves.

While the previous analysis used integrated line intensities, PCA has also been used on spectral line profiles as a mean to extract information on the spatial properties of the turbulence (Heyer & Peter Schloerb 1997; Roman-Duval et al. 2011; Brunt & Heyer 2013), to study line absorption depth (Neufeld et al. 2015), or to measure cloud properties (Rosolowsky & Leroy 2006). To our knowledge no PCA analysis takes into account the full velocity profile of the molecular emission at every spatial position. Further inquiry on this subject is required as it can add a further dimension (the shape of the line profiles) to study the emission correlations.

### 6.2. Non-linearities and multiple physical regimes

Two important properties of PCA must be kept in mind. The first is that it is a linear method. It distinguishes the axes of variations in the dataset as linear combinations of the initial variables. Thus, non-linear (approximate) relations between the variables cannot be properly captured. In this case, a single relation could be described by several PCs, one describing the best linear approximation, and additional PCs describing directions in which the non-linear relation deviates from linearity. Using our non-linear transform, equivalent to a logarithm for high SNR values, alleviates part of the problem as it allows to describe power-law relations, but other non-linearities (such as saturation for the  $^{12}\text{CO}$  line) are still not captured.

Non-linear extensions of PCA exist (kernel-PCA, neural network-based dimensionality reduction such as the Self-Organizing Maps), but their results tend to be harder to interpret.

The second property is that PCA is based on the global correlation matrix of the data. If different physical regimes are present in the dataset, each with different relations between the variables, PCA will do a global (linear) approximation over the different regimes. Depending on the fraction of samples (pixels) representing the different regimes, it may give more weight to some regimes than others, neglect some regimes, or mainly represent one of the regimes.

### 6.3. Reduction of dimensionality

PCA is often used as a dimensionality-reduction tool (approximating the data by its projection on a lower dimensional hyperplane in feature space), by keeping only a subset of the PCs that account for a sufficiently large fraction of the variance in the dataset. We saw that PC1 to 6 explain more than 90% of the correlation structure of the data. Moreover, PC6 define a transition between several PC with similar levels (5% for PC3-4-5, 1-2% for the PCs after 6). The projection on the first 6 PC thus define

a 6-dimensional hyperplane in which the data is approximately embedded. However, we saw some striking spatial features appearing in later PCs, indicating meaningful axes of variations, such as PC8 and 11. The pattern of small scale spots shown by PC11 (corresponding to overbright CS) is particularly interesting, and its late apparition in the decomposition could simply be a consequence of the small fraction of pixels concerned. Thus, even PCs with lower fraction of explained correlation can contain important information, such as specific variations occurring in small regions only.

### 6.4. A synthetic view of Orion B

Using the physical interpretation of the principal components derived from the previous section it is possible to derive a synthetic view of the Orion B cloud rendered through a color image (see Fig. 11). The principal components 1 (column density), 2 (density) and 3 (UV illumination) are used in the following way: the column density is used to encode the luminosity, and the density and UV illumination are combined orthogonally to define a color.

$$\text{hue} = \text{atan}(uv, \text{density}) \quad (2)$$

In this way, it is possible to identify by color only, the physical properties associated with every line of sight.

Most of the region is composed of low density gas either obscured (green) or UV illuminated (yellow). Notable features are the moderately dense (orange) photodissociation regions that are present as the surface of pillars (e.g. around the Horsehead nebula) and as globules surrounding the NGC 2024 massive H II region in the upper part of the map. A sharp illumination gradient is visible at the base of the neck of the Horse with transition from illuminated (yellow) to shielded (green) gas.

Concerning the dust lane in front of NGC 2024, there is a clear sharp frontier between the northern and southern part, the north being strongly UV illuminated (yellow, orange, and red), the southern part much more obscured (cyan and green). The variation in the density of dense cores are visible with transitions from moderately dense (cyan) to higher density (dark blue) gas.

## 7. Conclusion

In order to study the correlations between maps of the emission of 12 bright lines belonging to the 3 mm band over the southwestern edge of the Orion B molecular cloud, we applied the principal component analysis to these data. Before this analysis, we applied a non-linear transformation that is close to linear around zero and is equivalent to a logarithmic transform at large values. The goal of this non-linear transform is two-fold. 1) Ratios of brightness temperatures are easier to interpret but PCA assumes that the relations in the input data set are linear. Applying the logarithm to the input data allows us to transform ratios of brightness temperatures into subtractions well adapted to a linear analysis. 2) Signal is only detected on a line-dependent subset of the field of view. Applying the logarithm to noisy brightness temperatures centered around zero is mathematically ill-defined. Having a linear transform around zero solves this problem. We tuned the transition value between the linear and logarithmic value that is typically 8 times the typical noise value of the dataset. We showed that the results are not very sensitive to this value.

The PCA delivers a set of maps that are linear combination of the input brightness temperatures, taking into account their

**Fig. 11.** Synthetic view of the Orion B molecular cloud. In this colormap, the intensity of each pixel is encoded by PC1 (column density) and the hue is encoded by the angle of the vector constructed using two orthogonal components PC2 (density) and PC3 (UV radiation field). It is possible to identify limiting cases. Magenta: dense PDR, yellow: diffuse PDR, green: diffuse non illuminated, blue: dense non illuminated

(anti-)correlations. While PCA does not use the spatial information of the input dataset, the output maps expose well-defined structures. We thus limited our analysis to the first few principal components that expose the largest correlations present in the initial dataset. The analysis of these correlations allowed us to propose some link between the first three components and physical parameters, as the column density, volume density, and UV radiation field. We quantified these links by computing the correlation coefficients of these principal components with independent measurements of the column density, volume density, and UV illumination. The first principal component is highly correlated to the column density measured from the dust extinction and has positive contributions from all molecules, as has been noted in Pety et al. (2016). The third principal component is well correlated to our estimation of the UV illumination, with positive contributions from CCH, CN and anticorrelations with  $\text{N}_2\text{H}^+$  and  $\text{CH}_3\text{OH}$ . The second principal component is correlated with the volume density in the dense cores with a combined positive contribution with  $\text{N}_2\text{H}^+$  and  $\text{CH}_3\text{OH}$  and a negative contribution from  $^{12}\text{CO}$  and  $^{13}\text{CO}$ .

The possibility to link linear combinations of the brightness temperatures of a set of 3 mm lines to physical quantities as the column density, volume density, or UV illumination opens an interesting avenue to analyze the large spectro-imaging data sets that (sub)-mm radioastronomy starts to produce. As PCA analysis only works on the brightness temperatures independent of their spatial relations, it also offers an easy possibility to compare with large grids of detailed 1D models of photo-dissociation regions. In future papers, we will continue to explore this with more advanced decomposition techniques that may take into account missing values, noise effects, or non-linear relations in the input dataset.

## Appendix A: Optimal value of $a$ in the asinh reparametrisation

The only free parameter in the asinh reparametrization is  $a$ , the parameter which marks the boundary between the linear and logarithmic regimes of the asinh function (see Fig. 3). As shown in Table 1 the noise across different lines is similar and we express  $a$  as the product of a constant factor  $K$  by the median noise 0.08 K. The quantity we choose to maximize is the mean of the absolute value of the correlation coefficient of the principal components with the physical maps  $N(\text{H}_2)$ ,  $U$ , and  $n_{\text{H}}$ , we note this quantity  $\langle |\rho| \rangle$ . Figure A.1 shows the evolution of this quantity with increasing values of  $K$ , a maximum value of  $\langle |\rho| \rangle$  around  $K = 8$  although an acceptable range of  $K$  values (reduction of  $\langle |\rho| \rangle$  by less than 5%) spans values from 3 to 40.
