## ABSTRACT

Broad-lined type Ic supernovae (SNe Ic-BL) are a subclass of rare core collapse SNe whose energy source is debated in the literature. Recently a series of investigations on SNe Ic-BL with the magnetar (plus <sup>56</sup>Ni) model were carried out. Evidence for magnetar formation was found for the well-observed SNe Ic-BL 1998bw and 2002ap. In this paper we systematically study a large sample of SNe Ic-BL not associated with gamma-ray bursts. We use photospheric velocity data determined in a homogeneous way. We find that the magnetar+56Ni model provides a good description of the light curves and velocity evolution of our sample of SNe Ic-BL, although some SNe (not all) can also be described by the pure-magnetar model or by the two-component pure-56Ni model (3 out of 12 are unlikely explained by two-component model). In the magnetar $+56$ Ni model, the amount of  $56$ Ni required to explain their luminosity is significantly reduced, and the derived initial explosion energy is, in general, in accordance with neutrino heating. Some correlations between different physical parameters are evaluated and their implications regarding magnetic field amplification and the total energy reservoir are discussed.

 $Subject \ headings: stars: neutron \longrightarrow supernovae: general$ 

#### 1. INTRODUCTION

Over the past two decades, the discovery of broad-lined type Ic supernovae (SNe Ic-BL; see [Filippenko](#page-15-0) [1997,](#page-15-0) for the classification of known SNe) and superluminous SNe (SLSNe) has greatly enlarged the family of known corecollapse SNe (CCSNe). The association between longduration gamma-ray burst (GRB) 980425 and its spectroscopically associated Ic-BL SN 1998bw [\(Galama et](#page-15-1) [al.](#page-15-1) [1998;](#page-15-1) [Patat et al.](#page-16-0) [2001\)](#page-16-0), i.e. the so-called GRB-SN connection (e.g., [Woosley & Bloom](#page-16-1) [2006;](#page-16-1) [Cano et al.](#page-15-2) [2017\)](#page-15-2), ignited interest in these energetic and rare type of stripped-envelope CCSNe.

To date, the luminosity of most, if not all, GRB-SNe and SNe Ic-BL could be explained by radioactive heating arising from energy deposition from the radioactive decay of nickel and cobalt, which is nucleosynthesized during the explosion, into their daughter products [\(Cano](#page-15-3) [et al.](#page-15-3) [2016\)](#page-15-3). However, it appears that the luminosity of many SLSNe cannot be adequately explained in this scenario, and alternative energy sources have been proposed. As a consequence, it is now usually assumed that at least a subclass of SLSNe, type Ic SLSNe, are powered by millisecond magnetars [\(Kasen & Bildsten](#page-15-4) [2010;](#page-15-4) [Woosley](#page-16-2) [2010;](#page-16-2) [Chatzopoulos et al.](#page-15-5) [2012;](#page-15-5) [Inserra et al.](#page-15-6) [2013;](#page-15-6) [Nicholl et al.](#page-16-3) [2014;](#page-16-3) [Metzger et al.](#page-16-4) [2015;](#page-16-4) Mösta et [al.](#page-16-5) [2015;](#page-16-5) [Wang et al.](#page-16-6) [2015a;](#page-16-6) [Dai et al.](#page-15-7) [2016;](#page-15-7) [Kashiyama](#page-16-7) [et al.](#page-16-7) [2016\)](#page-16-7) although there is evidence for interaction between ejecta and circumstellar medium [\(Yan et al.](#page-16-8) [2015;](#page-16-8) [Wang et al.](#page-16-9) [2016d;](#page-16-9) [Chen et al.](#page-15-8) [2017\)](#page-15-8) at late times.

For SNe Ic-BL, shortcomings of one-dimensional (1D) <sup>56</sup>Ni model (e.g., [Iwamoto et al.](#page-15-9) [2000;](#page-15-9) [Nakamura et al.](#page-16-10) [2001\)](#page-16-10) stimulated the suggestion for a two-component  $56$ Ni model [\(Maeda et al.](#page-16-11) [2003\)](#page-16-11). In this model it is assumed that the ejecta are composed of two components, the outer fast-moving component (jet) and the inner slow-moving component (core). The former is responsible for the bright peak of the light curve, while the latter is responsible for the late-time exponential decay. This model is very useful for providing a better description of the ejecta structure and has been very successful in reproducing the luminosity of most SNe Ic-BL.

Recently, the application of the magnetar model to SNe Ic-BL was considered [\(Cano et al.](#page-15-3) [2016;](#page-15-3) [Wang et](#page-16-12) [al.](#page-16-12) [2016b,](#page-16-12)[c,](#page-16-13) [2017\)](#page-16-14), which are built upon the pioneering works of [Ostriker & Gunn](#page-16-15) [\(1971\)](#page-16-15), [Wheeler et al.](#page-16-16) [\(2000\)](#page-16-16), and [Thompson et al.](#page-16-17) [\(2004\)](#page-16-17). The proposition of the improved magnetar model [\(Wang et al.](#page-16-13) [2016c\)](#page-16-13), which takes into account the photospheric recession and acceleration of the ejecta by the spinning-down magnetar, provides an opportunity to examine the magnetar model against SNe Ic-BL in a self-consistent way. It was shown that the spin-down of the magnetar will lose a small fraction of its rotational energy to its light curve [\(Wang et al.](#page-16-12) [2016b\)](#page-16-12), while the remaining fraction is transferred into the kinetic energy of the ejecta. Evidence for the formation of stable magnetars following the explosions of SNe Ic-BL was subsequently found by [Wang et al.](#page-16-14) [\(2017\)](#page-16-14). Such a model can also naturally account for the mysterious origin of the huge kinetic energies of SNe Ic-BL [\(Wang et](#page-16-12)

## [al.](#page-16-12) [2016b\)](#page-16-12).

The discovery of relativistic SNe Ic-BL, 2009bb and 2012ap, through their bright late-time radio emission [\(Bietenholz et al.](#page-15-10) [2010;](#page-15-10) [Soderberg et al.](#page-16-18) [2010;](#page-16-18) [Chakraborti et al.](#page-15-11) [2011,](#page-15-11) [2015\)](#page-15-12) places the magnetar model on a more solid ground because such events require central engines to accelerate a tiny fraction of the ejecta to quasi-relativistic velocities [\(Margutti et al.](#page-16-19) [2014\)](#page-16-19). Actually there is a continuous distribution of various types of CCSNe on the kinetic energy profile of the ejecta [\(Soderberg et al.](#page-16-20) [2006\)](#page-16-20). The relativistic SNe Ic-BL lie in between ordinary SNe Ibc and energetic GRBs and are similar to the sub-energetic GRBs, e.g. GRB 100316D [\(Margutti et al.](#page-16-21) [2013\)](#page-16-21) and GRB 140606B [\(Cano et al.](#page-15-13)  $\overline{2015}$ . This may indicate that similar engines were operating in sub-energetic GRBs and SNe 2009bb and 2012ap.

Based on the above findings, here we test the hypothesis that all of SNe Ic-BL are powered by magnetars. Under such hypothesis, we assessed the validity of the derived fitting parameters and consider the statistical characteristics of SNe Ic-BL. Despite the paucity of observed SNe Ic-BL, the accumulation of such events has reached a level where a meaningful statistical results can start to be obtained. It is therefore very timely to confront a larger sample  $(N = 11)$  of SNe Ic-BL with the magnetar model.

To determine the uncertainties in the fitting parameters, [Wang et al.](#page-16-14) [\(2017\)](#page-16-14) developed a Markov chain Monte Carlo (MCMC) code on the basis of the magnetar model. This code was applied to SLSNe Ic [\(Liu et al.](#page-16-22) [2017\)](#page-16-22) to minimize the total errors arising from fitting the model to the SN light curves, and evolution of photospheric velocity and temperature, if available. In this paper we focus on the SNe Ic-BL not associated with GRBs. In what follows we use the words "SNe Ic-BL" to indicate SNe Ic-BL not associated with GRBs except when specifically mentioned otherwise.

The structure of this paper is as follows. In Section [2](#page-1-0) we present the data available in the literature, along with a detailed analysis on the uncertainties of the data. Then in Section [3](#page-3-0) we present our fitting results of the known SNe Ic-BL. Section [4](#page-8-0) discusses the implications of the results. Particularly, Section [4.2](#page-9-0) discusses the estimation of the appearance of nebular features by early light curve modeling; Section [4.3](#page-10-0) discusses the correlations between the derived parameters; Section [4.4](#page-10-1) discusses the possibility of alternative models to interpret the light curves and velocity evolution of some SNe. A summary is given in Section [5.](#page-15-14)

## 2. SN SAMPLE AND DATA ANALYSIS

<span id="page-1-0"></span>[Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23) listed 12 SNe Ic-BL. However, the light curve of SN 2007D is missing and we are therefore left with 11 such events, as listed in Table [1.](#page-2-0) The modeling of SN light curves usually involves the bolometric luminosity. To construct a bolometric light curve, emission in passbands UV (ultraviolet), BVRI (optical) and IR (UVOIR) should be integrated. It is, however, commonplace that only the optical bands are available for the follow-up of an SN from very early times to late times. UV emission of an SN Ic-BL is usually strongest only at early stages, and its contribution to the total UVOIR bolometric flux can be more than 20% during the first

two weeks [\(Cano et al.](#page-15-15) [2011;](#page-15-15) [Lyman et al.](#page-16-24) [2014\)](#page-16-24), while late-time  $UV$  follow-up is frequently missing. IR emission, which is usually strong for the whole evolution stage (and can contribute as much as 50% of the total UVOIR bolometric flux after peak light, e.g., Figure 6 of [Tomita](#page-16-25) [et al.](#page-16-25) [2006,](#page-16-25) Figure 14 of [Valenti et al.](#page-16-26) [2008,](#page-16-26) and Figure 7 of [Olivares et al.](#page-16-27) [2015\)](#page-16-27), is only obtained for a few SNe. For this reason, different authors usually resort to different methods to construct the bolometric luminosity. To list some, the observations of SN 2003jd were available only in the BV RI bands, and the contributions from  $UV$  and  $IR$  bands were added by assuming the same fractional contributions to the bolometric light curve as SN 2002ap [\(Valenti et al.](#page-16-26) [2008\)](#page-16-26). The bolometric light curve of PTF10qts was obtained by increasing the integrated fluxes by 15% to account for the contribution from the unavailable UV and NIR bands [\(Walker et al.](#page-16-28) [2014\)](#page-16-28). Some authors, on the other hand, decide to not include the contribution of UV and/or NIR bands [\(Tomita et al.](#page-16-25) [2006;](#page-16-25) [Sahu et al.](#page-16-29) [2009;](#page-16-29) [Young et al.](#page-16-30) [2010;](#page-16-30) [Pignata et al.](#page-16-31) [2011\)](#page-16-31).

To reduce the above uncertainty, we decide to use the method developed by [Lyman et al.](#page-16-24) [\(2014,](#page-16-24) [2016\)](#page-16-32). In this method, the color defined by two optical bands are used to calculate the bolometric correction. In Table [1](#page-2-0) we list the color we used to calculate bolometric luminosity. In this calculation, we choose the color that has the least rms given in Table 2 of [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24) and at the same time the longest time coverage in the two passbands defining the chosen color. If these two conditions cannot be met simultaneously, we always choose the passbands that have the longest observational time. Such choice can minimize the errors that may be introduced by interpolation and/or extrapolation. Sometimes data are available only in a single passband for some time duration, e.g. the data of SN 2007bg before 7.2 days given in Table 3 of [Young et al.](#page-16-30) [\(2010\)](#page-16-30), while these data are crucial to constrain the fitting parameters, we set their bolometric corrections to the same as that at the closest time.

Another uncertainty in the construction of a bolometric light curve comes from the treatment of extinction. The Galactic extinction is well-understood and can be handled properly using the dust maps of [Schlegel et al.](#page-16-33) [\(1998\)](#page-16-33), and as revised by [Schlafly & Finkbeiner](#page-16-34) [\(2011\)](#page-16-34). The host extinction, however, can only be estimated for some SNe because of the poor quality of the Na <sup>I</sup> D lines in the measured spectra (which may be a poor proxy for the host extinction anyways, e.g., [Poznanski et al.](#page-16-35) [2011\)](#page-16-35). We list the extinction treatment in Table [1.](#page-2-0) Even for the same SN, the determined extinction could be different from different authors. Taking SN 2012ap as an example, [Milisavljevic et al.](#page-16-36) [\(2015\)](#page-16-36) adopted a total extinction of  $E(B - V)_{total} = 0.45$  mag, while [Liu et al.](#page-16-37) [\(2015\)](#page-16-37) adopted a value of  $E(B-V)_{total} = 0.87$  mag.

Further uncertainty comes from the different values of the cosmological parameters used in the literature to derive the luminosity distances to the various SNe. For SNe 2002ap, 2009bb, 2012ap, redshift-independent methods, e.g. Tully-Fisher measurements, were facilitated to derive the distances, as are available on NASA/IPAC Extragalactic Database (NED). Such linear distances are weightedly averaged, as listed in Table [1.](#page-2-0) For other SNe that no such linear distances are available, to min-

<sup>a</sup> None: No extinction was corrected; G: Corrected for Galactic extinction; H: Corrected for host extinction.

<sup>b</sup> The color used to calculate bolometric magnitude, following [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24). A hyphen in this column indicates that only one passband is available or no data in individual passbands are provided.

The distance used in the referenced paper, which is calculated according to the given distance modulus.

<sup>d</sup> The method used in this paper to calculate distance. L: Linear distance extracted from the NASA/IPAC Extragalactic Database (NED); C: The distance was calculated according to the latest Plank cosmological parameters.

<sup>e</sup> The distance adopted in this paper.

<sup>f</sup> [Corsi et al.](#page-15-17) [\(2012\)](#page-15-17) classified PTF10vgv as SN Ic based on its low Si II λ6355 absorption velocities, while [Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23) reclassified it as SN Ic-BL because of its broad-lined optical spectra. Here we follow [Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23).

imize distance uncertainties, we transform, according to the method described in [Cano et al.](#page-15-18) [\(2014\)](#page-15-18), the light curves in the literature to a common cosmology, i.e. the latest Plank results:  $H_0 = (67.8 \pm 0.9) \,\mathrm{km \,s}^{-1} \,\mathrm{Mpc}^{-1},$  $\Omega_m = 0.308 \pm 0.012$  [\(Ade et al.](#page-15-19) [2016\)](#page-15-19).

To compare the differences in distances, we also list in Table [1](#page-2-0) the distances used in the original papers. Nevertheless, because the redshifts of the SNe studied here are small (see Table 2 in [Modjaz et al.](#page-16-23) [2016\)](#page-16-23), it is found that the errors in the infrared-derived distances introduced by assuming different cosmological parameters are small, typically  $3 - 5\%$ . [Corsi et al.](#page-15-17) [\(2012\)](#page-15-17) did not give the distance modulus of PTF10vgv in their derivation of absolute magnitudes. We digitalized their Figure 2 and found  $\mu_{\text{PTF10vgv}} = 33.9 \,\text{mag}$ , based on which the light curve transformation was performed. In summary, the largest difference between our adopted distance and that used in the original paper is for SN 2002ap, for which we adopt 9.22 Mpc, rather than 7.94 Mpc in the original paper. The smallest difference is for SNe 2009bb, for which distances  $\sim 40 \,\text{Mpc}$  have been adopted in the relevant studies.

The photospheric velocity is another critical quantity that significantly impacts the light curve fitting results. Different velocity indicators in the spectra, e.g. Si II λ6355, Na <sup>I</sup> D λ5891, O <sup>I</sup> λ7774, Ca II λ8579, Fe II λ5169, usually give different results [\(Valenti et al.](#page-16-26) [2008;](#page-16-26) [Modjaz](#page-16-23) [et al.](#page-16-23) [2016\)](#page-16-23). This difference may be a result of the different depth of elements in the ejecta, the degree of element mixing, and the amount of deviation from spherical expansion. Recently [Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23) developed a way of measuring velocities for all SNe Ic-BL and SNe Ic in a homogenous way. In this paper we use the velocity data given by [Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23), when available. Using such a homogenous data set of velocity data reduces the bias in the resulting fitting parameters.

In principle, the above uncertainties all contribute to the errors in bolometric luminosities. In practice, we include errors (all added in quadrature) in bolometric corrections (rms given in Table 2 of [Lyman et al.](#page-16-24) [2014\)](#page-16-24) and in photometry given in the papers where the observational data were provided.

We calculated the extinction according to [Cardelli et](#page-15-20) [al.](#page-15-20) [\(1989\)](#page-15-20) by assuming the Milky Way extinction law. Cosmological expansion has been taken into account using the following equation [\(Hogg et al.](#page-15-21) [2002;](#page-15-21) [Lunnan et](#page-16-40) [al.](#page-16-40) [2016\)](#page-16-40)

$$
M = m - 5\log(D_L/10\,\text{pc}) + 2.5\log(1+z), \quad (1)
$$

where  $D<sub>L</sub>$  is the luminosity distance and z is the redshift. The last term in above equation is not a true K correction, but it is a good approximation.

For SN PTF10vgv, only R-band luminosities were observed [\(Corsi et al.](#page-15-17) [2012\)](#page-15-17). To obtain bolometric luminosities, [Corsi et al.](#page-15-17) [\(2012\)](#page-15-17) assumed a bolometric correction  $M_{\text{bol}} - M_R = -0.496 \,\text{mag}$  based on the earlytime photospheric temperature  $T_{\text{phot}} \approx 10^4 \text{ K}$  of this SN. We use this bolometric correction to derive the bolometric light curve for SN PTF10vgv. Such a treatment is of course somewhat simplified because the temperature evolves rapidly during the early expansion. Another SN for which only R-band luminosities were observed is SN 2010ay [\(Sanders et al.](#page-16-39) [2012\)](#page-16-39). The luminosity and expansion velocity were combined to derive a temperature of 6900 K at peak light. This implies a bolometric correction  $M_{\text{bol}} - M_R = 0.29$  mag, according to which the bolometric luminosities are derived here. This treatment should not introduce too much bias because the observation duration of this SN is short, within 20 days before or after peak. For SN 1997ef, only V band data

<span id="page-3-2"></span>FIG. 1.— Comparison of bolometric luminosity of two representative SNe obtained by the method (cyan circles) of [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24) with that (red stars) given in the original papers. For SN 2002ap, the luminosity given by [Tomita et al.](#page-16-25) [\(2006\)](#page-16-25) includes contribution from BVRI and IR bands, while for SN 2009bb, the luminosity given by [Pignata et al.](#page-16-31) [\(2011\)](#page-16-31) includes contribution from BVRI bands only.

are provided by [Iwamoto et al.](#page-15-9) [\(2000\)](#page-15-9). According to the effective temperatures ( $\sim 6100 \,\mathrm{K}$ ) given in Table 3 of [Iwamoto et al.](#page-15-9) [\(2000\)](#page-15-9), we applied bolometric correction  $(M_{\text{bol}} - M_V = -0.05 \,\text{mag})$  to SN 1997ef. We will discuss the implications of the approximation in obtaining bolometric light curves for SNe 1997ef, 2010ay, and PTF10vgv in Section [4.3.](#page-10-0)

The root mean squares of the prescription of [Lyman et](#page-16-24) [al.](#page-16-24)  $(2014)$  are  $\sim 0.06$  mag, while the measurement errors of the light curve range from  $\sim 0.02$  mag to  $\sim 0.3$  mag. Therefore the uncertainties in the bolometric luminosity constructed by this method are usually dominated by measurement errors in the two individual bands from which bolometric corrections are calculated. The measurement errors of SNe 1997ef, 2010ay, and PTF10vgv are  $0.03 - 0.06$  mag,  $0.2 - 0.3$  mag, and  $0.02 - 0.2$  mag, respectively. As a result, if there had been two bands available for SNe 1997ef, 2010ay, and PTF10vgv, the uncertainties are likely slightly larger than that depicted in Figures  $2(a)$  $2(a)$ ,  $4(a)$  $4(a)$ , and  $3(f)$  $3(f)$  but dominated by measurement errors for those points whose measurements errors are large. Given this fact, for simplicity, we adopt the errors in an individual band as the errors of bolometric luminosity for SNe 1997ef, 2010ay, and PTF10vgv.[1](#page-3-1)

In Figure [1](#page-3-2) we compare the luminosity data provided by the original papers and that calculated according to [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24) for two representative SNe. We call the luminosity of these two SNe 'representative' because the luminosity of SN 2002ap given by the original paper includes the contribution from  $BVRI$  and  $IR$  bands, while the luminosity of SN 2009bb given by the original paper includes contribution only from  $BVRI$  bands. Another reason we choose these two SNe is that their luminosity is integrated according to observational data, while the luminosity of some other SNe are calculated in the original papers by assuming some contribution from unavailable bands (frequently the  $IR$  band).

In the comparison in Figure [1](#page-3-2) the data given in the original papers are transformed to the distances given in Table [1.](#page-2-0) From this figure it is evident that the method of [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24) is accurate for the first  $\sim 80 \,\text{days}$ , since the bolometric correction is calculated according to the luminosity data in this time period. Fortunately, most of the luminosity data in our sample have a time coverage that is not much longer than  $\sim 80 \,\text{days}$ . The data with  $t \geq 80$  days are enough to constrain most of the model parameters. Figure  $1(a)$  $1(a)$  shows that the contribution from the unavailable  $\ddot{UV}$  band is small for SN [2](#page-3-3)002ap even at very early stages<sup>2</sup>, while Figure  $1(b)$  $1(b)$ shows that the contribution from the unavailable UV and IR bands cannot be ignored.

### 3. FITTING RESULT

<span id="page-3-0"></span>As explained in [Wang et al.](#page-16-13) [\(2016c,](#page-16-13) [2017\)](#page-16-14), the model we have adopted is formulated by eight parameters. Although the model is dubbed a "magnetar model", it also includes a <sup>56</sup>Ni component. As a consequence, the model includes the usual parameters, the ejecta mass  $M_{\rm ej}$ , <sup>56</sup>Ni mass  $M_{\text{Ni}}$ , grey optical opacity  $\kappa$ , initial expansion velocity  $v_{\rm sc0}$ , and opacity to <sup>56</sup>Ni decay photons  $\kappa_{\gamma Ni}$ . In addition, the model includes magnetar parameters, the

<span id="page-3-1"></span><sup>1</sup> However, given the several sources of uncertainty in the bolometric correction derived from a single filter, we estimate that the minimum error in the latter must be at least 20%, if not larger.

<span id="page-3-3"></span><sup>&</sup>lt;sup>2</sup> The UV flux observed on 2002 February 3 (4 days before  $V$ band maximum) by XMM-Neutron contributes only  $\sim 4\%$  [\(Maz](#page-16-41)[zali et al.](#page-16-41) [2002\)](#page-16-41).

dipole magnetic field  $B_p$ , initial rotation period  $P_0$  and opacity  $\kappa_{\gamma,\text{mag}}$  to account for the leakage [\(Chen et al.](#page-15-22) [2015;](#page-15-22) [Wang et al.](#page-16-6) [2015a\)](#page-16-6) of high energy photons [\(Murase](#page-16-42) [et al.](#page-16-42) [2015;](#page-16-42) [Wang et al.](#page-16-43) [2016a\)](#page-16-43) from magnetars. Here the subscript "p" in  $B_p$  means the dipole field at the pole of the star (Shapiro  $\&$  Teukolsky [1983\)](#page-16-44). For the grey optical opacity  $\kappa$  we take the fiducial value  $\kappa = 0.1 \,\mathrm{cm}^2 \,\mathrm{g}^{-1}$ , as used in previous investigations [\(Wang et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14). We also include the unknown explosion time  $T_{\text{start}}$  of the SN in the MCMC code. In what follows, we use the name "magnetar model" to indicate the magnetar $+56$ Ni model, except specifically mentioned otherwise.

The magnetar model proposed by [Wang et al.](#page-16-13) [\(2016c\)](#page-16-13) traces the photospheric recession and therefore the emission from the photosphere and those material outside of the photospheric radius (hereafter referred to as nebular component, or nebula for short) can be isolated. We examined the spectra of SNe Ic-BL and try to figure out if the nebular emission is helpful in determining the appearance of nebular features in the spectra. It turns out that when the nebula emitted about 16% of the total emission, nebular features (e.g., forbidden lines) could begin to emerge in the SN spectra. If we assume that an SN begins to transition into nebular phase when the nebula radiates this percentage of emission, we can obtain the time  $T_{\text{Neb}}$  (since explosion in rest frame) by fitting the early-time light curve, as listed in Table [2.](#page-4-0) [3](#page-4-1) In the magnetar model, the early peak of the light curve of an SN is caused by the spin-down of the magnetar. Consequently the <sup>56</sup>Ni mass can be ignored for such early-time modeling.

<span id="page-4-0"></span>To determine the <sup>56</sup>Ni mass, it is necessary for the light curve to be observed at least for ∼ 110 days. We divide the observed SNe Ic-BL light curves into two classes: those with an observational duration  $t \gtrsim 100 \,\text{days}$  (class I) and with  $t \lesssim 100 \,\text{days}$  (class II). The reason for the choice of 100 days as the dividing boundary is because the lifetime of <sup>56</sup>Co is  $\sim$  110 days. If observational duration is longer than 100 days, the mass of <sup>56</sup>Ni can be constrained. In this case we allowed the <sup>56</sup>Ni mass to be a free parameter. In the opposite case, the  $^{56}{\rm Ni}$  mass cannot be constrained and the only parameters that can be constrained are the magnetar parameters because it is found that in the magnetar model the early peak of the light curve can be attributed to magnetar spin-down [\(Wang et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14).

We find there are nine SNe that belong to class I, while the remaining two SNe fall in class II. Among the SNe in class I, three SNe, 1997ef, 2002ap, and 2007ru, were studied previously with our magnetar model [\(Wang](#page-16-12) [et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14). SN 2002ap was investigated using an MCMC code [\(Wang et al.](#page-16-14) [2017\)](#page-16-14), while SNe 1997ef and 2007ru were studied via manual fitting [\(Wang et al.](#page-16-12) [2016b\)](#page-16-12). We included them here to test the sensitivity of fitting parameters to the adoption of different photospheric velocities because the velocities used here (the

In these fits, we fixed  $\kappa = 0.1$  cm<sup>2</sup> g<sup>-1</sup>

.

All times in this table are in rest frame.

Notes.

<span id="page-4-1"></span><sup>&</sup>lt;sup>3</sup> This approach is desirable as it is sometimes difficult to identify an eruption as a SN or a tidal disruption event (TDE; [Brown et](#page-15-23) [al.](#page-15-23) [2016;](#page-15-23) [Dong et al.](#page-15-24) [2016;](#page-15-24) [Leloudas et al.](#page-16-45) [2016\)](#page-16-45). The indication of the early nebular phase is helpful to confirm the identity of a SN because a TDE does not have a nebular phase. We therefore encourage the modeling of the early-time light curve of a transient to give an estimate of the epoch at which nebular features may appear (if it is a SN) to help constrain the nature of the transient.

A hyphen indicates that this quantity cannot be constrained effectively. The data on the left of the vertical line are fitting parameters, while the data on the right are derived values. The MCMC code does not calculate the errors of these derived values. The references for the spectra are the same as in Table [1.](#page-2-0)

<span id="page-5-0"></span>FIG. 2.— The magnetar+<sup>56</sup>Ni model: best-fitting light curves (solid lines) of SNe 1997ef, 2002ap, 2007ru. The dashed and dot-dashed lines arise from photospheric and nebular emission, respectively. The vertical dotted lines mark the time when nebular emission lines becomes significant. The insets show the fit (red solid lines) to the evolution of photospheric velocities.

values given by [Modjaz et al.](#page-16-23) [2016\)](#page-16-23) are different from previous studies [\(Wang et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14) where we used the velocities provided in the original papers. In addition, doing so will give unbiased statistical results.

The newly fitted light curves of the three previously studied SNe 1997ef, 2002ap, and 2007ru are shown in Figure [2,](#page-5-0) where emission from the photosphere and nebula are shown as dashed and dot-dashed lines, respectively. The vertical dotted lines in this figure mark the epochs when nebular emission contributes 16% of the total emission, which we assume to be the time when nebular emission features, e.g. forbidden emission lines, begin to appear. The remaining six SNe in class I are shown in Figure [3,](#page-6-0) where we show the contribution from the magnetar and <sup>56</sup>Ni as dashed and dot-dashed lines, respectively. In Figure [4](#page-7-0) the light curves were fitted with a pure magnetar model (without  $56$ Ni contribution) because the <sup>56</sup>Ni masses of the these two SNe in class II cannot be determined. The best-fitting values are given in Table [2.](#page-4-0) Because the contribution of magnetar and <sup>56</sup>Ni to the total emission for the three SNe depicted in Figure [2](#page-5-0) were shown previously [\(Wang et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14), we will not show them in this paper, as we do in Figure [3.](#page-6-0)

For SNe 2007bg, 2010ah, and PTF10qts in Figure [3,](#page-6-0)

the magnetar contribution dies away rapidly, which is quite different from the light curves given by e.g. [Kasen](#page-15-4) [& Bildsten](#page-15-4)  $(2010)$ , where the light curves tend to flatten at late time. The decline rate is also faster than the light curves where the gamma-ray leakage has been taken into account [\(Chen et al.](#page-15-22) [2015;](#page-15-22) [Wang et al.](#page-16-6) [2015a\)](#page-16-6). This rapid decline of magnetar contribution is due to the rapid spin-down of the magnetar powering the SN Ic-BL. At very late times, the magnetar contribution will eventually flatten, as can be seen from the dashed lines in Figures 1 and 2 of [Wang et al.](#page-16-14) [\(2017\)](#page-16-14). This rapid spindown is why the magnetar can convert almost all of its rotational energy to the kinetic energy of ejecta of SNe Ic-BL and why the contribution of  $56\text{Ni}$  is necessary for SNe Ic-BL in the magnetar model.

The MCMC code can only be run for those SNe for which observational errors are given. For the velocity data given by [Modjaz et al.](#page-16-23)  $(2016)$ , we adopted the errors given in their paper. [Modjaz et al.](#page-16-23) [\(2016\)](#page-16-23) did not provide the velocity data for SN 2010ah, for which, following [Wang et al.](#page-16-14) [\(2017\)](#page-16-14), we set the velocity errors to be half of the measured values to account for the large differences given by different velocity measurements (see e.g., [Valenti et al.](#page-16-26) [2008\)](#page-16-26).

For some SNe, e.g. SNe 2007bg and 2007ru, the missing or sparse data coverage before peak luminosity makes

<span id="page-6-0"></span>Fig. 3.— The magnetar+56Ni model: best-fitting light curves (solid lines) of SNe 2003jd, 2007bg, 2009bb, 2010ah, PTF10qts, and PTF10vgv. The dashed lines are the contribution from magnetar, while the dot-dashed lines show the contribution from <sup>56</sup>Ni. The insets show the fit (red solid lines) to the evolution of photospheric velocities.

the upper limits before discovery indispensable for obtaining reliable results, see Figures  $2(c)$  $2(c)$  and  $3(b)$  $3(b)$ . Sometimes the model light curves almost pass through the bolometric limits, e.g. SNe 2003jd and 2007bg in Figure [3.](#page-6-0) We looked into the data and found that the bolometric limit of SN 2003jd is 0.6 days earlier than the explosion date, while the bolometric limit of SN 2007bg is 1.0 days earlier than the time when the model light curve reaches the same bolometric luminosity as the upper limit.

The best-fitting parameters listed in Table [2](#page-4-0) are generally similar to what we found before for SNe 1997ef, 1998bw, 2002ap, and 2007ru [\(Wang et al.](#page-16-12) [2016b,](#page-16-12) [2017\)](#page-16-14), where we had a detailed discussion on the reasonability of the determined parameters such as  $M_{\rm ei}$ ,  $M_{\rm Ni}$ ,  $B_p$ ,  $P_0$ ,  $\kappa_{\gamma,\text{mag}}$ . We also discussed the possible reasons for a larger value of  $\kappa_{\gamma,Ni}$  than the standard value  $\sim 0.027 \,\mathrm{cm}^2 \,\mathrm{g}^{-1}.$ 

From Table [2](#page-4-0) it is clear that usually the opacity to

<span id="page-7-0"></span>FIG. 4.— Light curves of SNe 2010ay, and 2012ap fitted by a pure-magnetar (without  $^{56}$ Ni) model. The insets show the fit (red solid lines) to the evolution of photospheric velocities.

<span id="page-7-1"></span>FIG.  $5.$ —  $^{56}$ Ni mass versus explosion energy, neutron star rotational energy, and the sum of these two energies. The ordinary SNe 1993J (IIb) and 1994I (Ic) are plotted as triangles. For clarity, only one <sup>56</sup>Ni error bar is shown for each SN. For SNe 1997ef and PTF10vgv whose bolometric light curves are constructed from single bands, we show the uncertainties in  $56$ Ni mass as horizontal magenta lines with rightward arrows.

magnetar high-energy photons  $\kappa_{\gamma,\text{mag}}$  can only be determined for SNe, e.g. 2002ap and 2003jd, observed to late stages ( $t \geq 300 \,\text{days}$ ) because only at such late stages (except for the early peak) does the magnetar contribution dominate the <sup>56</sup>Ni contribution. Table [2](#page-4-0) indicates that  $\kappa_{\gamma,\text{mag}}$  is also constrained for SNe 2009bb and PTF10vgv, despite their short observation duration. For PTF10vgv, the given value is favored because the ejecta mass is small and high-energy radiation from the magnetar will leak even at early stages. For SN 2009bb, the given value is caused by the significant contribution of

<span id="page-7-2"></span>Fig. 6.— Ejecta mass versus explosion energy, neutron star rotational energy, and the sum of these two energies. The ordinary SNe 1993J (IIb) and 1994I (Ic) are plotted as triangles. For clarity, only one ejecta mass error bar is shown for each SN.

magnetar to the light curve even at late stages.

Given the fitting results in Table [2,](#page-4-0) some correlations between different parameters can be examined. We show the correlations of energy versus <sup>56</sup>Ni mass, energy versus ejecta mass, explosion energy versus neutron star rotational energy, energy versus dipole magnetic field of the magnetar in Figures [5](#page-7-1)[-8,](#page-8-1) respectively. In the magnetar model, three forms of energy are considered here, i.e. the initial explosion energy  $E_{\text{exp}}$ , the neutron star's rotational energy  $E_{\text{NS}}$  and the sum of these two energies  $E_{\text{total}}$ . In the usual magnetar model that does not take into account the acceleration of the ejecta by the spinning-down magnetar, the kinetic energy of the ejecta is just the initial explosion energy. In our adopted model,

<span id="page-8-3"></span>Fig. 7.— Explosion energy versus neutron star rotational energy.

<span id="page-8-1"></span>FIG. 8.—  $B_p$  versus explosion energy, neutron star rotational energy, and the sum of these two energies. For clarity, only one  $B_p$ error bar is shown for each SN.

the kinetic energy is no longer a constant. Instead, it evolves from its initial value, i.e. the initial explosion energy, according to the energy injection of the magnetar. The evolution of kinetic energy can be clearly appreciated by inspecting the rapid rise of the photospheric velocities at early times, e.g. SNe 1997ef, 2007ru in Figure [2.](#page-5-0) This is why the reported (initial) velocities of these two SNe are significantly smaller than the maximum values attained in Figure [2.](#page-5-0)

#### 4. DISCUSSION

## 4.1. General implications

<span id="page-8-2"></span><span id="page-8-0"></span>The high fitting quality both for luminosities and velocities can be appreciated from Figures [2-](#page-5-0)[4.](#page-7-0) The only exception may be the velocity fitting result of SN 1997ef and to a lesser extent SN 2003jd. For SN 1997ef, the early-time velocities cannot be fitted because in our onezone model the velocity increases rapidly at very early times (acceleration phase) and then declines progressively faster because of the photospheric recession. Inspection of the velocity data of SN 1997ef indicates that the velocity evolution is flat during the period 40-65 days, which implies that the earlier time velocity should also be flat in our model. A possible way of getting better fitting results may be the introduction of a fast-moving shell in the ejecta, which makes the photosphere begin to recede at early times. After this fast shell becomes transparent, the inner compact component slows down the recession of the photosphere, resulting in the later-time flat evolution of the velocity. This hypothesis is also supported by the earlier appearance of nebular spectrum than our prediction (see Section [4.2](#page-9-0) for more discussion). The model velocity of SN 2010ah (Figure [3\)](#page-6-0) is also somewhat lower compared with the data. This is caused by the large observational errors which make the MCMC code difficult to differentiate between different fitting parameters.

The effect of adopting different velocity data on the derived parameters can be appreciated by comparing the values of the fitting parameters of SN 1997ef given in Table 1 of [Wang et al.](#page-16-12) [\(2016b\)](#page-16-12) and Table [2.](#page-4-0) It turns out that the values of  $M_{\text{Ni}}$ ,  $B_p$ ,  $\kappa_{\gamma,\text{Ni}}$ ,  $\kappa_{\gamma,\text{mag}}$ , and  $T_{\text{start}}$  are insensitive to the expansion velocity, while  $M_{\rm ei}$ ,  $P_0$ , and  $v_{\rm sc0}$ are sensitive to the expansion velocity. This is because the former group of parameters are determined by the light curve slope ( $\kappa_{\gamma,Ni}, \kappa_{\gamma,\text{mag}},$  and  $T_{\text{start}}$ ) or luminosity  $(M_{\text{Ni}}$  and  $B_p$ ), while the latter group of parameters are determined by the diffusion time scale of the SN [\(Arnett](#page-15-25) [1982;](#page-15-25) [Arnett et al.](#page-15-26) [2017\)](#page-15-26) because  $P_0$  and  $v_{\rm sc0}$  affect the expansion velocity.

From Table [2](#page-4-0) it is evident that in the magnetar (plus <sup>56</sup>Ni) model, the initial SN explosion energies are usually smaller than  $\sim 2.5 \times 10^{51}$  erg, i.e. the theoretical upper limit of explosion energy triggered by neutrino heating [\(Janka et al.](#page-15-27) [2016\)](#page-15-27). There is one exception, SN 2010ay, which has explosion energy  $\gtrsim 10^{52}$  erg. We note that the light curve and velocity evolution of SN 2010ay are poorly sampled and it is possible to attribute a fraction of the energy to magnetar by tuning up the rotational energy of the magnetar. We conclude that the explosion energy of all well-observed SNe Ic-BL can be explained by neutrino heating.

Table [2](#page-4-0) shows that the <sup>56</sup>Ni masses in this sample of SNe Ic-BL are usually smaller than  $0.1 M_{\odot}$ . The only two values  $0.28M_{\odot}$  and  $0.14M_{\odot}$  that are above  $0.1M_{\odot}$ are for PTF10qts and SN 2010ah, respectively. We note that the observational data of these two SNe are of poorest quality, except SNe 2010ay and 2012ap whose <sup>56</sup>Ni masses are not determined. The sparse luminosity data and large observational errors of these two SNe indicate that the derived values of <sup>56</sup>Ni mass should not be taken seriously. This implies that the <sup>56</sup>Ni masses of SNe Ic-BL have an upper limit  $0.2M_{\odot}$ , i.e. the maximal amount of

<sup>56</sup>Ni that can be synthesized by the spin-down of a magnetar [\(Nishimura et al.](#page-16-46) [2015;](#page-16-46) [Suwa & Tominaga](#page-16-47) [2015\)](#page-16-47).

Table [2](#page-4-0) also shows that the fitting parameters of the two relativistic SNe, 2009bb and 2012ap, are typical among this SNe Ic-BL sample. It is therefore unlikely to acquire more clue on the explosion mechanism of relativistic SNe solely from such fitting parameters, if the magnetar model is the right model for such SNe. A thorough comparison between SNe Ic-BL and those associated with GRBs is required to get more clue.

PTF10vgv is peculiar because of its low absorption velocities (typical of ordinary SNe Ic) and broad-lined optical spectra (typical of SNe Ic-BL). It has the lowest ejecta mass,  $0.7M_{\odot}$ , in the SNe Ic-BL sample (see Table [2\)](#page-4-0). Its opacity to magnetar photons,  $\kappa_{\gamma,\text{mag}} = 0.013 \,\text{cm}^2 \,\text{g}^{-1}$ , is also much lower than the values found for the other SNe Ic-BL. [Corsi et al.](#page-15-17) [\(2012\)](#page-15-17) constrained its progenitor radius to be  $R < (1-5) R_{\odot}$ , consistent with a compact Wolf-Rayet star. These peculiarities may indicate that PTF10vgv lies in the gap between SNe Ic and SNe Ic-BL.

The MCMC code can determine the explosion time accurately if the light-curve data are of high quality. The most excellent case is SN 1998bw, for which the explosion time was constrained to be  $-0.009_{-0.36}^{+0.32}$  days relative to the GRB trigger time [\(Wang et al.](#page-16-14)  $2017$ ).<sup>[4](#page-9-1)</sup> In Table [3](#page-10-2) we compare the explosion time determined in this work with those given in the literature. Also listed in this table are the discovery date and date of non-detection. The explosion time is computed according to the times  $T_{\text{start}}$  given in Table [2,](#page-4-0) after correcting for cosmological time dilation.

In the calculation of the explosion time, we frequently need the time of V -band maximum, which we consult [Modjaz et al.](#page-16-48) [\(2014\)](#page-16-48). Because the explosion time determined in this work is calculated according to the relevant time given in the original paper, the uncertainties of the explosion time are the errors given in the original paper, if available, or the errors of  $T_{\text{start}}$  given in Table [2,](#page-4-0) whichever is larger.

It can be seen from Table [3](#page-10-2) that the times determined in this work are generally in good agreement with those given in the literature. The only exception is SN 1997ef, for which our determination, which is almost coincident with the discovery date, is  $\sim$  5 days later than that given by [Mazzali et al.](#page-16-49) [\(2000\)](#page-16-49). Please note that the first bolometric data point in Figure [2](#page-5-0) is 4 days later than the discovery date.

## <span id="page-9-0"></span>4.2. Estimate the appearance of nebular features from early light curve modeling

In this paper we propose to calculate the time  $T_{\rm Neb}$ when the nebular features begin to emerge in the SN spectra. We searched the spectra from the references listed in Table [1.](#page-2-0) The lower limit of  $T_{\rm Neb}$  for an SN in question is the latest time at which a spectrum is photospheric, while the upper limit is the earliest time at which the spectrum is nebular. We list these constraints in Table [2.](#page-4-0)

The spectrum taken on 26 January, 1998 of SN 1997ef is photospheric [\(Mazzali et al.](#page-16-49) [2000\)](#page-16-49), while the first nebular spectrum is on  $+104$  days (in rest frame) post R-band maximum [\(Young et al.](#page-16-30) [2010\)](#page-16-30), implying the transition from photospheric to nebular occurred between these two dates. Next, the spectrum obtained  $+51$  days post  $B$ band maximum of SN 2003jd is photospheric, while the spectrum on  $+70 \text{ days}$  is nebular [\(Valenti et al.](#page-16-26) [2008\)](#page-16-26). For SN 2007bg, the spectrum taken at  $+25$  days post  $R$ band maximum for SN 2007bg is photospheric, while the spectrum on  $+58$  days is nebular [\(Young et al.](#page-16-30) [2010\)](#page-16-30). For SN 2007ru, the spectrum obtained 70 days after explosion for SN 2007ru is photospheric, while the spectrum on 200 days is nebular [\(Sahu et al.](#page-16-29) [2009\)](#page-16-29). Next, the spectrum of SN 2009bb on  $+45$  days past  $B$ -band maximum is photospheric, while the spectrum on  $+285 \,\text{days}$  is nebular [\(Pignata et al.](#page-16-31) [2011\)](#page-16-31). For SN 2012ap, the spectrum taken at  $+26$  days past B-band maximum is photospheric, while the spectrum on  $+218$  days is nebular [\(Milisavljevic et al.](#page-16-36) [2015\)](#page-16-36). For PTF10qts, the spectrum taken  $+21$  days past R-band maximum is photospheric, while the spectrum on  $+230$  days is nebular [\(Walker et al.](#page-16-28) [2014\)](#page-16-28). Finally, for PTF10vgv the spectrum obtained at  $+35$  days past R-band maximum is photospheric, while the spectrum on  $+72$  days is nebular [\(Corsi et al.](#page-15-17) [2012\)](#page-15-17).

For SN 2010ah, the spectrum of SN 2010ah on 7, March, 2010 is photospheric [\(Mazzali et al.](#page-16-38) [2013\)](#page-16-38), with no data later than this date being published. The same situation applies for SN 2010ay, of which that latest spectrum was obtained on  $+24$  days past R-band maximum is photospheric [\(Sanders et al.](#page-16-39) [2012\)](#page-16-39). For both of these events, the precise timing of the transition from the photospheric phase to the nebular can only be constrained to have occurred after these dates.

We can see from Table [2](#page-4-0) that our fitting constraints of  $T_{\text{Neb}}$  for SNe 2002ap, 2007ru, 2010ah, 2010ay, 2012ap, and PTF10qts are consistent with observations. For PTF10vgv,  $T_{\text{Neb}}$  (43 days) is slightly earlier than the lower limit 46.2 days. For SN 2009bb the given  $T_{\text{Neh}}$ (48 days) is 7 days earlier than observation. This may be caused by the helium envelope of this SN because earlytime optical spectra showed evidence for the presence of helium in this SN [\(Pignata et al.](#page-16-31) [2011;](#page-16-31) another SN that evidenced with some helium is SN 2012ap, [Milisavljevic](#page-16-36) [et al.](#page-16-36) [2015\)](#page-16-36). The helium envelope will delay the appearance of nebular lines. For SN 2007bg,  $T_{\text{Neb}}$  (77 days) is 9 days later than the upper limit. This discrepancy for SN 2007bg might be caused by the sparsity of data before peak time, see Figure [3\(](#page-6-0)b).

For 1997ef,  $T_{\text{Neb}}$  (153 days) is significantly later than the appearance of the first nebular spectrum, i.e. 119.8 days. The situation is less significant but also notable for SN 2003jd, for which we have 92 days versus 81.2 days. As mentioned in Section [4.1,](#page-8-2) a plausible reason for this large discrepancy may lie in the failure of our model to fit the early velocity data of these two SNe. We suggest that a fast-moving shell should be introduced for SN 1997ef. Such a shell will contribute a significant fraction of nebular emission and therefore made the appearance of nebular phase earlier.

In summary, we conclude that  $T_{\text{Neb}}$  determined in this way is in general a good guide for the emergence of nebular features, although it is not completely accurate. Other factors come into play in determining the emergence of nebular lines aside from the amount of nebular emission.

<span id="page-9-1"></span><sup>4</sup> Previously the burst time of GRB 980426 was constrained to coincide with that of SN 1998bw within  $(+0.7, -2.0)$  days (e.g., [Iwamoto](#page-15-28) [1999\)](#page-15-28).

<span id="page-10-0"></span>A hyphen indicates that the date was not specified in the original paper.

#### 4.3. Correlations

In the magnetar model, the required  $56$ Ni mass is, un-surprisingly, reduced significantly.<sup>[5](#page-10-3)</sup> It is therefore expected that the <sup>56</sup>Ni mass-energy relation will be quite different, as depicted in Figure [5,](#page-7-1) where we also plot the ordinary type IIb SN 1993J and type Ic SN 1994I. It is clear from this figure that the synthesized  $56$ Ni is consistent with ordinary striped envelope SNe. There is no clear increase of <sup>56</sup>Ni mass with increased energy, contrary to earlier findings [\(Mazzali et al.](#page-16-38) [2013;](#page-16-38) [Lyman et](#page-16-32) [al.](#page-16-32) [2016;](#page-16-32) [Toy et al.](#page-16-50) [2016\)](#page-16-50). In the magnetar $+$ <sup>56</sup>Ni model, the explosion energies are generally significantly lower than in pure-56Ni models, regardless whether it is the 1D <sup>56</sup>Ni model or two-component <sup>56</sup>Ni model. The explosion energy is no longer the sole decisive factor for <sup>56</sup>Ni synthesis. In this case the synthesis of <sup>56</sup>Ni may be determined by other factors, e.g. the radius, and/or density profile of the progenitor star [\(Smartt](#page-16-51) [2009\)](#page-16-51). Such diversity may reflect the mass, binarity, metallicity, mass-loss rate, rotation, and magnetic field of the main sequence star [\(Smartt](#page-16-51) [2009\)](#page-16-51).

For an SN Ic-BL, the bolometric corrections at late times can be  $\sim 1$  mag larger than that at peak times. This indicates that for SNe 1997ef and PTF10vgv, the light curves at late times should be brighter and flatter than shown in Figures  $2(a)$  $2(a)$  and  $3(f)$  $3(f)$ . As a result, the value of  $\kappa_{\gamma,Ni}$  should be larger. Another impacted parameter is  $M_{\text{Ni}}$ , although to a less extent. We estimate that  $M_{\text{Ni}}$  may be at most a factor of 2 larger. In Figure [5](#page-7-1) we show the <sup>56</sup>Ni masses of SNe 1997ef and PTF10vgv as points connected by horizontal magenta lines with rightward arrows to indicate the uncertainties introduced by this approximation. As is clear from Figure [5,](#page-7-1) this does not change our conclusion about the correlation between  $M_{\text{Ni}}$  and explosion energy. The <sup>56</sup>Ni mass of SN 2010ay cannot be constrained, so the uncertainties introduced by above approximation is irrelevant for SN 2010ay.

Table [2](#page-4-0) shows that the explosion energy of SN 2007ru is quite low, but the  ${}^{56}$ Ni mass  $M_{\text{Ni}}$  is not zero. This indicates that the <sup>56</sup>Ni of this SN was synthesized by the shock wave generated by the spinning-down magnetar [\(Nishimura et al.](#page-16-46) [2015,](#page-16-46) [2017;](#page-16-52) [Suwa & Tominaga](#page-16-47) [2015\)](#page-16-47). This is in agreement with expectations because the rotational energy of the magnetar powering SN 2007ru is the largest in the SNe Ic-BL sample. The magnetic field  $B_p$  is also strong enough to synthesize the needed <sup>56</sup>Ni. In the magnetar model, both the explosion shock and the magnetar-powered shock can synthesize <sup>56</sup>Ni. This complicates the <sup>56</sup>Ni mass-energy relation of SNe Ic-BL.

From Figure [6](#page-7-2) it is clear that the ejecta mass increases with energy. This is similar to earlier findings [\(Mazzali](#page-16-38) [et al.](#page-16-38) [2013;](#page-16-38) [Lyman et al.](#page-16-32) [2016\)](#page-16-32), but the energies are much lower than the values given by pure-56Ni models [\(Mazzali](#page-16-38) [et al.](#page-16-38) [2013;](#page-16-38) [Lyman et al.](#page-16-32) [2016\)](#page-16-32).

We also examined the relation between explosion energy and neutron star rotational energy, given in Figure [7.](#page-8-3) This figure implies that there is no clear correlation between these two energies. Figure [8](#page-8-1) shows magnetic field  $B_p$  and energy. No clear correlation is seen between these two quantities. Because  $B_p$  harbours a fraction of the toroidal magnetic field within the neutron star,  $B_p$ can serve as an indication of the magnetic energy present within the neutron star. If this is true, Figure  $8 \,\mathrm{may}$  $8 \,\mathrm{may}$  imply that the amplification of magnetic field in the neutron star is unrelated with the explosion energy.

#### 4.4. Alternative models?

<span id="page-10-1"></span>In this paper we tested the hypothesis that all SNe Ic-BL are powered by a combination of input from a magnetar central engine and <sup>56</sup>Ni synthesized during the initial explosion. Next, we ask the question that can a pure-<sup>56</sup>Ni model or a pure-magnetar model give comparable results?

In Figure [9](#page-11-0) we show the best-fit 1D  $56$ Ni modeling result for the selected SNe, whose fitting parameters are listed in Table [4.](#page-14-0) It is well known that the  $1D<sup>56</sup>Ni$  model cannot give a satisfactory description for SNe with long observation durations [\(Iwamoto et al.](#page-15-9) [2000;](#page-15-9) [Nakamura](#page-16-10) [et al.](#page-16-10) [2001;](#page-16-10) [Maeda et al.](#page-16-11) [2003\)](#page-16-11). As a result the two-

<span id="page-10-3"></span><sup>&</sup>lt;sup>5</sup> Figure [1](#page-3-2) shows that for  $t \gtrsim 80 \,\text{days}$  the luminosity data calculated according to [Lyman et al.](#page-16-24) [\(2014\)](#page-16-24) are slightly different from that obtained by integrating individual bands. This will affect the derived <sup>56</sup>Ni mass. As a result, we call for further study on the luminosity data for  $t \gtrsim 80 \,\text{days}.$ 

<span id="page-11-0"></span>FIG. 9.— Light curves and velocity evolution of the selected SNe reproduced by the 1D pure-<sup>56</sup>Ni model. The dot-dashed lines in panel (h) are a fit to the first 50 days of luminosity data by fixing  $\kappa_{\gamma, Ni} = 0.027 \text{ cm}^2 \text{ g}^{-1}$ .

component model was employed to investigate most of the SNe in Figures [2](#page-5-0) and [3](#page-6-0) (SNe 1997ef, 2002ap, [Maeda](#page-16-11) [et al.](#page-16-11) [2003;](#page-16-11) SN 2003jd, [Valenti et al.](#page-16-26) [2008;](#page-16-26) SN 2007bg, [Young et al.](#page-16-30) [2010\)](#page-16-30). In Figure [9](#page-11-0) we do not show these well-studied SNe (1997ef, 2002ap, 2003jd).

From Figure [9](#page-11-0) it can be seen that the 1D  $^{56}$ Ni model can only account for the first ∼ 50 days data (SNe 2010ay,  $2012ap$ .<sup>[6](#page-12-0)</sup> For all well-observed SNe Ic-BL with observational time  $\geq 100 \text{ days}$  (SNe 2007bg, 2007ru, 2009bb in this figure), two-component model should be invoked.

We will not examine these SNe within the framework of two-component model in detail. SN 2010ay in Figure [9](#page-11-0) is particularly interesting because its peak luminosity  $\sim 3.0 \times 10^{43} \text{ erg s}^{-1}$  is comparable to some of the SLSNe, PTF10hgi  $(3.52 \times 10^{43} \text{ erg s}^{-1})$ ; [Inserra et al.](#page-15-6) [2013\)](#page-15-6), PTF11rks  $(4.7 \times 10^{43} \,\text{erg s}^{-1})$ ; [Inserra et al.](#page-15-6) 2013), and PS1-14bj  $(4.6 \times 10^{43} \text{ erg s}^{-1})$ ; [Lunnan et al.](#page-16-40) [2016\)](#page-16-40), see also Table 1 in [Liu et al.](#page-16-22) [\(2017\)](#page-16-22). Such SLSNe are usually assumed to be powered by magnetars because of the failure of <sup>56</sup>Ni model.

The parameters for SN 2010ay are in tension with a typical CCSN. The ratio of  ${}^{56}$ Ni mass to the ejecta mass is 0.19, close to the upper limits 0.2 expected for a CCSN [\(Umeda & Nomoto](#page-16-53) [2008\)](#page-16-53). The needed  $56$ Ni mass  $1.2 M_{\odot}$ <sup>[7](#page-12-1)</sup> is higher than that of all SNe Ib/c but SN Ic-BL 2007D [\(Drout et al.](#page-15-30) [2011;](#page-15-30) [Sanders et al.](#page-16-39) [2012\)](#page-16-39). We therefore conclude that SN 2010ay is unlikely to be explained by a pure-56Ni model, including the two-component model.

Another SN that is hard to explain by the <sup>56</sup>Ni model (including the two-component model) is PTF10vgv because its ejecta mass  $M_{\rm ej} = 0.24 M_{\odot}$  is smaller than  $M_{\rm Ni}$  = 0.25 $M_{\odot}$  (see Table [4\)](#page-14-0). Even if we double its expansion velocity to  $\sim 10000 \,\mathrm{km\,s^{-1}}$  (see Figure [9h](#page-11-0)) so that  $M_{\rm ej}$  is doubled, the ratio  $M_{\rm Ni}/M_{\rm ej}$  is still larger than 0.5. The situation becomes even worse for the  ${}^{56}\rm{Ni}$  model if we take into account the uncertainties in the bolometric light curve of PTF10vgv. As discussed in Section [4.3,](#page-10-0) the light curve of PTF10vgv at late times should be brighter than depicted in Figure  $9(h)$  $9(h)$ . This indicates that more  ${}^{56}$ Ni is needed. The solid lines in Figure  $9(h)$  $9(h)$ are the best-fitting result allowing  $\kappa_{\gamma,Ni}$  to vary. Table [4](#page-14-0) shows that  $\kappa_{\gamma,\text{Ni}} = 0.014 \text{ cm}^2 \text{ g}^{-1}$ , lower than the fiducial value  $\kappa_{\gamma, Ni} = 0.027 \,\mathrm{cm}^2 \,\mathrm{g}^{-1}$ .<sup>[8](#page-12-2)</sup> The dot-dashed lines in Figure  $9(h)$  $9(h)$  are the best-fitting result to the first 50 days of luminosity data after fixing  $\kappa_{\gamma, Ni} = 0.027 \,\mathrm{cm}^2 \,\mathrm{g}^{-1}$ . In this case the initial expansion velocity is  $\sim 14000 \,\mathrm{km \, s^{-1}}$ , much higher than the average velocity  $\sim 7500 \,\mathrm{km\,s^{-1}}$  of this SN. Even with such a high expansion velocity, the ratio  $M_{\text{Ni}}/M_{\text{ej}} = 0.32$  is still higher than the theoretical

upper limit 0.2. We therefore conclude that PTF10vgv cannot be explained by <sup>56</sup>Ni model. Recently, it is found iPTF16asu [\(Whitesides et al.](#page-16-55) [2017\)](#page-16-55) cannot also be explained by  $56$ Ni model.

For PTF10qts, [Walker et al.](#page-16-28) [\(2014\)](#page-16-28) obtained  $M_{\text{Ni}} =$  $0.35 \pm 0.1 M_{\odot}$ , based on a model fit to the nebular spectrum of this SN. Such an estimate of <sup>56</sup>Ni mass is consistent with the value given in Table  $4$  in the pure- $56$ Ni model. This seems to argue against our hypothesis that all SNe Ic-BL were powered by magnetars. However, on the one hand, as commented by [Walker et al.](#page-16-28) [\(2014\)](#page-16-28), any firm conclusions should not be drawn based on this result because of the low signal-to-noise ratio of the observed spectrum. On the other hand, for any SN Ic-BL with a long observational duration, some amount of <sup>56</sup>Ni is indeed required, although its amount is significantly lower than in the pure-56Ni model.

Now we turn to the pure-magnetar model. For those SNe whose  $M_{\text{Ni}}$  can be constrained, the small errors associated with  $M_{\text{Ni}}$ , as presented in Table [2,](#page-4-0) clearly indicate the necessity of including  ${}^{56}$ Ni to give the best-fitting results. The synthesis of  $^{56}$ Ni is also expected in a CCSN. Neglecting  $M_{\text{Ni}}$  will usually result in rather poor fitting quality, as shown in Figure [10](#page-13-0) with the best-fitting parameters listed in Table [5.](#page-14-1) In Figure [10](#page-13-0) we do not show the fitting result of SN PTF10qts because the poor data quality always allows for a "good" fitting. In Table [5](#page-14-1) we also compare the reduced  $\chi^2$  of the pure-magnetar model and magnetar $+56$ Ni model.

The high fitting quality of the magnetar $+56$ Ni model can be most easily appreciated by comparing the reproduced light curves of SN 2002ap by these two models. The situation of SN 2002ap in the pure-magnetar model is similar to SN 1998bw in this same model, see Figure 8 of [Moriya et al.](#page-16-56) [\(2017\)](#page-16-56). The ejecta masses given by the pure-magnetar model are frequently unreasonable, e.g. SNe 2002ap, 2010ah and PTF10vgv. For SN 1997ef, the magnetar $+56$ Ni model is favored not only because of the smaller reduced  $\chi^2$  compared to the pure-magnetar model, but also because of the broad peak of this SN, as found by [Iwamoto et al.](#page-15-9) [\(2000\)](#page-15-9). Comparing Figures  $2(a)$  $2(a)$  and  $10(a)$  $10(a)$  indicates that the magnetar + <sup>56</sup>Ni model captures the broad peak of this light curve better than the pure-magnetar model, see Figure 1 in [Wang et al.](#page-16-12)  $(2016b)$  for a clearer rendering.<sup>[9](#page-12-3)</sup>

For SNe 2003jd, 2007ru, 2010ah, and PTF10vgv, the contribution of  $56$ Ni is not necessary to give an acceptable fitting result. However, the velocity fitting result of PTF10vgv (see Figure [10\)](#page-13-0) is not good enough. The low velocities are required for PTF10vgv in the puremagnetar model because of the slow decline rate of the light curve.

The above results indicate that the magnetar $+56$ Ni model is the best model in reproducing the light curves and velocity evolutions of the SNe Ic-BL sample, although some SNe can also be described by the twocomponent <sup>56</sup>Ni model (e.g., SN 2002ap), while some others (e.g., SNe 2003jd, 2007ru, and 2010ah) can also be well reproduced by the pure-magnetar model.

<span id="page-12-0"></span> $^6$  The 1D  $^{56}{\rm Ni}$  model can also account for the light curves of SNe 2010ah and PTF10qts with  $\sim 100 \,\text{days}$  data. However, this may be the result of the poor quality of the data.

<span id="page-12-1"></span>[Sanders et al.](#page-16-39)  $(2012)$  estimated the <sup>56</sup>Ni mass of SN 2010ay to be  $0.9 \pm 0.1 M_{\odot}$ . However, if the most luminous data point in the light curve of SN 2010ay is adopted, a  $^{56}$ Ni mass of  $1.2M_{\odot}$  was derived [\(Sanders et al.](#page-16-39) [2012\)](#page-16-39), consistent with our result. [Wang](#page-16-54) [et al.](#page-16-54) [\(2015b\)](#page-16-54) found that  $M_{\text{Ni}} = 2M_{\odot}$  is required to meet the peak luminosity of SN 2010ay for a <sup>56</sup>Ni model. This higher value results from adopting a different bolometric correction by [Wang](#page-16-54)

<span id="page-12-2"></span>[et al.](#page-16-54) [\(2015b\)](#page-16-54). <sup>8</sup> As discussed in Section [4.3,](#page-10-0) the late-time light curve of SN 1997ef should be slightly flatter than shown in Figure [9\(](#page-11-0)h). After taking into account this fact the derived  $\kappa_{\gamma Ni}$  would be close to the fiducial value.

<span id="page-12-3"></span><sup>9</sup> We note that the two-component model cannot capture the broad peak of SN 1997ef, see the inset (circles versus dotted line) of Figure 4 of [Maeda et al.](#page-16-11) [\(2003\)](#page-16-11). This indicates that the magnetar $+56$ Ni model is the best to account for SN 1997ef.

<span id="page-13-0"></span>Fig. 10.— Light curves and velocity evolution of the SNe (except for PTF10qts) in Figures [2](#page-5-0) and [3](#page-6-0) reproduced by the pure-magnetar model.

TABLE 4 BEST-FITTING PARAMETERS FOR THE SELECTED SNE USING THE 1D  $^{56}\rm{Ni}$  model.

Notes. In these fits, we fixed  $\kappa = 0.1 \text{ cm}^2 \text{ g}^{-1}$ . For those SNe where  $\kappa_{\gamma, Ni}$  cannot be constrained (marked as hyphen), we set  $\kappa_{\gamma, Ni}$  =  $0.027 \text{ cm}^2 \text{ g}^{-1}$ . For those SNe whose  $M_{\text{Ni}}$  cannot be constrained, i.e. 2010ay and 2012ap,  $\chi^2/\mu$  is the result of pure-magnetar model. PTF10vgv-27 is the best-fitting parameters for the first 50 days of luminosity data after fixing  $\kappa_{\gamma,Ni} = 0.027 \text{ cm}^2 \text{ g}^{-1}$ .

**Notes.** In these fits, we fixed  $\kappa = 0.1 \text{ cm}^2 \text{ g}^{-1}$ .

We note that different models usually give different explosion times, as can be found by comparing  $T_{\text{start}}$  presented in Tables [2,](#page-4-0) [4,](#page-14-0) and [5.](#page-14-1) Tables [2](#page-4-0) and [5](#page-14-1) show that the explosion times determined by the magnetar $+56$ Ni model are all later than that determined by the puremagnetar model, with PTF10vgv the only exception. This can be well understood. To account for the late-time light curves, the spin-down timescales of the magnetars in the pure-magnetar model have to be longer than in the magnetar $+56$ Ni model. This will result in slow rise rate and therefore the explosion times must be somewhat earlier. The slow rise rates in the pure-magnetar model suffer from some tension with the upper limits of the light curves of SNe 2003jd, 2007bg, 2007ru, as can be seen from Figure [10.](#page-13-0)

Comparison of  $T_{\text{start}}$  in Tables [2](#page-4-0) and [4](#page-14-0) shows that the explosion times in the magnetar+56Ni model are usually later than that in the  $56$ Ni model, except for PTF10vgv. This can be understood by comparing the spin-down timescale of the magnetar,  $\tau_{sd}$ , with the <sup>56</sup>Ni decay timescale,  $\tau_{\text{Ni}} = 8.8 \text{ days}$ . It is found that the spin-down timescales of the magnetars powering these SNe are all shorter than  $\tau_{\text{Ni}}$ , with only one exception,  $\tau_{sd}$  (PTF10vgv) = 15.9 days. If  $\tau_{sd} < \tau_{Ni}$ , the energy of the magnetar is released more rapidly in the magnetar model than in the <sup>56</sup>Ni model, the rise time in the magnetar model is shorter than in the <sup>56</sup>Ni model. This is why the explosion time of PTF10vgv in the magnetar model is earlier than in the <sup>56</sup>Ni model because in this case  $\tau_{sd} > \tau_{Ni}$ . By this way, it is not difficult to understand why the explosion time of SN 1997ef is almost coincident with the discovery date in the magnetar $+56$ Ni model. From Table [2](#page-4-0) it is found that  $\tau_{sd} = 0.01$  days for this SN. The energy was almost explosively released.

# 5. CONCLUSIONS

<span id="page-15-14"></span>The mechanism for the formation of SNe Ic-BL is still unclear. Recently there is evidence that SNe Ic-BL are powered by magnetars [\(Wang et al.](#page-16-14) [2017\)](#page-16-14). Indeed, for all of the SNe Ic-BL that were observed to phases  $\gtrsim 300 \,\text{days}$ when the contribution from  $56$ Ni decays significantly, there is evidence for magnetar formation.

Motivated by this evidence, we studied a sample of  $N = 11$  SNe Ic-BL and obtain their light curve fitting parameters. From this study it is evident that the sample of SNe Ic-BL can be reasonably described by the magnetar $+56$ Ni model. The magnetar $+56$ Ni model naturally reduces the needed  $56$ Ni and simultaneously accounts for the origin of the huge kinetic energies observed in SNe Ic-BL, with only one exception, SN 2010ay, whose large explosion energy could be attributed to the large photometric uncertainties. We also examine the possibility for the pure-<sup>56</sup>Ni or pure-magnetar model to explain the light curve and velocity evolution. It is found that SNe 2010ay, PTF10vgv, and iPTF16asu (3 out of 12) are unlikely explained by the (two-component)  $^{56}$ Ni model, while some SNe 2003jd, 2007ru, and 2010ah (not all in the sample) are compatible with the pure-magnetar model.

Our results indicate that the synthesized <sup>56</sup>Ni mass does not increase with explosion energy or neutron star rotational energy. The  ${}^{56}\rm{Ni}$  mass is consistent with ordinary SNe. The relation between magnetic field and explosion energy seems to indicate that the amplification of magnetic field of the neutron star is independent of the explosion energy. To get a more robust statistical result, more high-quality observations are definitely needed.

We thank the anonymous referee for constructive suggestions. We are grateful to Maryam Modjaz and Yuqian Liu for sending us the photospheric velocity data before the publication of their paper.
