Submitted to ApJ

ABSTRACT

We use more than a decade of radial velocity measurements for α Cen A, B, and Proxima Centauri from HARPS, CHIRON, and UVES to identify the $M\sin i$ and orbital periods of planets that could have been detected if they existed. At each point in a mass-period grid, we sample a simulated, Keplerian signal with the precision and cadence of existing data and assess the probability that the signal could have been produced by noise alone. Existing data places detection thresholds in the classically defined habitable zones at about $M\sin i$ of 53 M_{\oplus} for α Cen A, 8.4 M_{\oplus} for α Cen B, and 0.47 M_{\oplus} for Proxima Centauri. Additionally, we examine the impact of systematic errors, or "red noise" in the data. A comparison of white- and red-noise simulations highlights quasi-periodic variability in the radial velocities that may be caused by systematic errors, photospheric velocity signals, or planetary signals. For example, the red-noise simulations show a peak above white-noise simulations at the period of Proxima Centauri b. We also carry out a spectroscopic analysis of the chemical composition of the α Centauri stars. The stars have super-solar metallicity with ratios of C/O and Mg/Si that are similar to the Sun, suggesting that any small planets in the α Cen system may be compositionally similar to our terrestrial planets. Although the small projected separation of α Cen A and B currently hampers extreme-precision radial velocity measurements, the angular separation is now increasing. By 2019, α Cen A and B will be ideal targets for renewed Doppler planet surveys.

1. INTRODUCTION

Over the past two decades, hundreds of exoplanets have been detected with the radial velocity technique, opening a new subfield of astronomy. In 2009, the NASA Kepler mission (Borucki et al. 2011; Batalha et al. 2013) used the transit technique to dramatically advance our understanding of exoplanet architectures, especially for low-mass planets. Burke et al. (2015) used the Q1-Q16 Kepler catalog (Mullally et al. 2015) with the Christiansen et al. (2015) pipeline completeness parameterization to assess planet occurrence rates for Kepler G and K dwarfs. For exoplanets with radii $0.75 \le R_{\text{planet}} \le 2.5$ R_{\oplus} and orbital periods, $50 \le P_{\rm orb} \le 300$ days, they find an occurrence rate, $F_0 = 0.77$ planets per star, with an allowed range of $0.3 \le F_0 \le 1.9$. The Burke et al. (2015) Kepler data analysis suggests that most GK stars have rocky exoplanets and portends a bright future for the discovery of low-mass planets orbiting nearby GK stars with the radial velocity technique, once precision is improved.

At a distance of 1.3 parsecs, the three stars in the α Centauri system are our closest neighbors. The stars of the central, α Cen AB binary system orbit each other with a semi-major axis of 24 AU and an eccentricity of 0.524 (Pourbaix & Boffin 2016). Though planets are now known to be common, there has been theoretical speculation about whether planets would form in such a close binary system (Thébault et al. 2006, 2008, 2009). Simulations have shown that if planets do form in this system (Quintana & Lissauer 2006; Quintana et al. 2007; Guedes et al. 2008), there are regions where they can reside in dynamically stable orbits (Wiegert & Holman 1997; Quarles & Lissauer 2016) around either α Cen A and α Cen B. Furthermore, approximately 20% of known planets orbit stars that are components of binary star systems. Particularly interesting is the case of HD 196885 AB, a stellar binary system with a semi-major axis of 24 AU and an eccentricity of 0.409, similar to the orbit of α Cen AB, with a known planet orbiting the primary star (Correia et al. 2008; Fischer et al. 2009; Chauvin et al. 2007). The case of HD 196885 Ab provides empirical evidence that the formation of planets is not precluded around α Cen A or B.

The third star, Proxima Centauri, is a smaller M dwarf and orbits this pair with a semi-major axis between 8,700 and greater than 10,000 AU (Wertheimer & Laughlin 2006; Kervella et al. 2017b). The α Centauri system has long been a key target for Doppler planet searches from southern hemisphere observatories (Murdoch et al. 1993; Endl et al. 2001; Dumusque et al. 2012; Endl et al. 2015). While no planets

have yet been discovered around α Cen A or B (c.f. Dumusque et al. 2012; Hatzes 2013; Rajpaul et al. 2016), an Earth-mmass planet has been detected orbiting Proxima Centauri using the Doppler technique (Anglada-Escudé et al. 2016). This recent discovery has increased interest in the system and the proximity of these stars is an enormous advantage for missions that aim to obtain images of any exoplanets. As human exploration ventures beyond our solar system, these closest stars will surely be our first destination.

In this work, we publish radial-velocity observations of α Cen A and B, obtained at the Cerro Tololo Interamerican Observatory (CTIO) with the Echelle Spectrograph (ES) from 2008 - 2010 and the CTIO High Resolution (CHIRON) spectrograph. These data, together with archived data from the High Accuracy Radial Velocity Planet Searcher (HARPS) and the Ultraviolet and Visual Echelle Spectrograph (UVES) of α Cen B and Proxima Centauri are used to test planet detectability and place constraints on the mass and orbital periods of putative planets that may remain undetected around these three stars.

2. THE ALPHA CENTAURI SYSTEM

Alpha Centauri is a hierarchical triple-star system. The primary and secondary components, α Cen A and B, are main-sequence stars with spectral types G2V and K1V, respectively, that are gravitationally bound in an eccentric orbit with a semi-major axis of about 24 AU. The two stars currently have an angular separation of about 5 arcseconds, which is not resolvable with the naked eye. Their combined brightness of -0.27 magnitudes makes α Cen AB one of the brightest objects in the southern hemisphere. The third star in this system, α Cen C or Proxima Centauri, was discovered in 1915 (Innes 1915) and is a relatively faint V=11.1 magnitude M6V dwarf at a projected angular separation of 2.2 deg from α Cen AB.

The recent astrometric analyses of α Cen A (van Leeuwen 2007; Pourbaix & Boffin 2016; Kervella et al. 2017a) yield an orbital parallax between 743 and 754 mas, corresponding to a distance of 1.33 to 1.35 pc away. The three stars in the α Centauri system are our closest stellar neighbors.

2.1. Doppler Analysis

Observations of α Centauri A and B were obtained with the 1.5-m telescope at the Cerro Tololo Interamerican Observatory (CTIO) in Chile. From 2008 - 2010, the refurbished Echelle Spectrometer (ES) was used to collect data. The ES was located in the Coudé room; however no other attempt was made to stabilize the thermal environment of the spectrograph and both diurnal

and seasonal variations resulted in temperature changes of several degrees in the Coudé room. Light from the telescope was coupled to this instrument with an optical fiber and a slit was positioned at the focus to set the resolution to $\sim 48,000$. However, the slit width was manually set with a micrometer and was not very precise, therefore, we expect that slight variations in the resolution occurred over time.

In 2011, we replaced the ES with the CHIRON spectrograph (Tokovinin et al. 2013). This instrument was also placed in the Coudé room and the optical fiber was changed to an octagonal fiber to reduce modal noise in our spectra. CHIRON was not in a vacuum enclosure, however the combination of thermal insulation and a thermally controlled space inside the Coudé room stabilized the temperature drifts to +/-2 K. There are four observing modes with CHIRON; for our observations of α Cen A and B we adopted a fixed-width slit at the focus of the optical fiber that provided an instrumental resolution of R $\sim 90,000$ at the expense of a $\sim 30\%$ light loss. A small fraction of light was picked off from the light path inside the spectrograph and sent to a photomultiplier tube to determine the photon-weighted midpoint and correct for the barycentric velocity during our observations.

The ES and CHIRON both use an iodine cell to provide the wavelength solution and to model Doppler shifts (Butler et al. 1996). The iodine cell is inserted into the light path for all of the program observations where radial velocities will be measured. The forward modeling process that we use also requires high-SNR, highresolution template observations and a very high resolution Fourier transform spectrum (FTS) of the iodine cell, obtained at the Pacific Northwest National Labs (PNNL) Environmental Molecular Sciences Laboratory (EMSL). Template observations are made without the iodine cell and are bracketed by several observations of bright, rapidly rotating B-stars through the iodine cell. The B-star observations are used to model the wavelength solution and the spectral line spread function (SLSF) of the instrument. The template observation is deconvolved with the SLSF, providing a higher resolution, iodine-free spectrum for modeling Doppler shifts. With the template observation, T_s and the FTS iodine spectrum, I_2 , the model is constructed as:

$$(T_s \times I_2) * SLSF \tag{1}$$

and a Levenberg-Marquardt least squares fitting is used to model the program observations. The error budget for the CHIRON radial velocity (RV) measurements accounts for instrumental errors (including variations in temperature, pressure, and vibrations), modal noise in the octagonal fiber, algorithm errors in the analysis, and the inclusion of velocity effects (granulation, spots, faculae) from the surface of the stars. For the α Centauri AB stars, flux contamination from the companion star turned out to be the most significant error source.

2.2. Spectroscopic Analysis

The stellar properties and chemical abundances of α Cen A and B were determined by using the spectral synthesis modeling code, Spectroscopy Made Easy (SME), described in Brewer et al. (2016), to analyze several iodine-free spectra obtained with the CHIRON spectrograph in 2012. The stellar parameters that we derive, as well as some comparison data that represent the range of values from the published literature with available uncertainties, are listed in Table 1.

Because we have analyzed 28 α Cen A and B spectra, the rms of those spectroscopic parameters is one way to assess uncertainties. However, for all spectroscopic parameters, we find that the rms is too small to provide a plausible estimate of uncertainties. Instead, we adopt the more conservative model parameter uncertainties that were established using the same SME modeling technique for more than 1600 stars observed with the Keck HIRES spectrograph (Brewer et al. 2016). Following Brewer et al. (2016), small empirical corrections were applied to the elemental abundances of α Cen AB to account for slight systematic trends that occur as a function of temperature with our analysis method.

Our spectroscopic analysis yields an effective temperature of 5766 \pm 25 K for α Cen A, and 5218 \pm 25 K for α Cen B. The effective temperature for α Cen A is consistent with the effective temperature measurement derived from angular-diameter measurements by Boyajian et al. (2013) and consistent with the G2V spectral classification (Perryman et al. 1997; van Leeuwen 2007). The calculated effective temperature for α Cen B is similarly consistent with the results of Boyajian et al. (2013) and the K1V spectral classification.

Both stars have a super-solar metallicity, [Fe/H]= 0.22 ± 0.03 and 0.24 ± 0.03 for α Cen A and B, respectively, consistent with other published values, e.g., Anderson & Francis (2011). We measure a C/O ratio of 0.47 ± 0.05 and Mg/Si of 1.05 ± 0.03 for α Cen A, similar to the solar value. The results for α Cen B are nearly identical with a C/O ratio of 0.49 ± 0.05 and a Mg/Si ratio of 1.05 ± 0.03 , the same as α Cen A. Because the ratios of abundances in stellar photospheres evolve slowly over main-sequence lifetimes (Pinsonneault et al. 2001; Turcotte & Wimmer-Schweingruber 2002), we can use the C/O and Mg/Si ratios as a proxy for disk compositions. Brewer & Fischer (2016) showed that most stars

have low C/O ratios, leaving the Mg/Si ratio important for regulating the geology of planetesimals. The implication is that any rocky planets forming around α Cen A or B could have a composition and internal structure that may be similar to the solar system terrestrial planets.

The temperature and [Fe/H] for Proxima Centauri were derived from infrared K-band features in XSHOOTER spectra available from the ESO Public Archive. The observations were carried out in Period 92 using a slit width of 0.4'' ($R \sim 9100$) and were reduced following the standard recipe described in the XSHOOTER pipeline manual¹ (Vernet et al. 2011). The wavelength calibration for the spectra was based on telluric lines, using a modified version for XSHOOTER data of the IDL-based code xtellcor_general by Vacca et al. (2003). The Proxima Cen spectra were convolved with a Gaussian kernel to degrade the resolution to $R \sim 2700$, in order to use the Na I, Ca I, and H₂O-K2 indices calibrated to provide metallicity estimates for M dwarf stars by Rojas-Ayala et al. (2012). With this technique, we derive $T_{\rm eff} = 2879 \pm 50$ K and [Fe/H] $=0.08\pm0.12$ and a spectral type of M5.5V. The metallicity for Proxima Cen is slightly lower than that of α Cen A and B; however, the uncertainty in the Proxima Cen measurement is four times the uncertainty for α Cen A or B. Proxima Centauri should share the same chemical composition as α Cen A and B unless those stars had a significantly different accretion history than Proxima.

2.3. Isochrone Analysis

Using spectroscopic parameters (T_{eff}, [Fe/H], [Si/H]) and distance, we derive the best fit models to the Yale-Yonsei (Y^2) isochrones (Demarque et al. 2004) to estimate the stellar mass, radius, and age for α Cen A and B. Our stellar masses (listed in Table 1) agree well with other published values (Lundkvist et al. 2014; Pourbaix & Boffin 2016) and the radius is consistent with the angular-diameter measurement by Kervella et al. The isochrone-derived age for α Cen A is $5.17^{+1.03}_{-0.97}$ Gyr, slightly older than the Sun and consistent with previous age estimates. Our isochrone model for α Cen B gives a younger age with large uncertainties, $2.53^{+3.12}_{-1.89}$ Gyr. The posterior in the isochrone fit shows a peak at younger ages for α Cen B that is illconstrained by log g and distance. However, the ages for the two stars do agree within their uncertainties.

The log g, stellar mass, and radius of Proxima Cen were determined by adopting the age of \sim 5 Gyr that

we estimate for α Cen AB, and interpolating the temperature onto a solar-metallicity isochrone for main-sequence, low-mass stars from Baraffe et al. (2015). Because M dwarfs evolve very slowly after the pre-main-sequence phase, any errors in the adopted age of the star will not significantly affect the derived stellar model. The Baraffe et al. (2015) isochrones were only calculated for solar metallicity; therefore, the isochrone model parameters will not account for the slightly super-solar metallicity of Proxima Centauri. The isochrone model parameters for Proxima Cen are also compiled in Table 1.

2.4. Chromospheric Activity

The chromospheric activity of α Cen A and B was monitored Henry et al. (1996) by measuring emission in the cores of the Ca II H & K lines relative to continuum bandpasses (i.e., the $S_{\rm HK}$ values), scaled to the long-term Mount Wilson H & K study (Wilson 1978; Vaughan et al. 1978; Duncan et al. 1991; Baliunas et al. 1995). The $S_{\rm HK}$ values together with the B-V of the star can then be transformed to $\log R'_{\rm HK}$, which is the fraction of bolometric luminosity from the lower chromosphere after subtracting off photospheric contributions (Noyes et al. 1984). Using $\log R'_{\rm HK}$ instead of $S_{\rm HK}$ allows for a straight-forward comparison of chromospheric activity that is independent of spectral type.

Chromospheric activity provides a good way to estimate rotation periods and ages (Noyes et al. 1984), even for older and more slowly rotating stars. Both α Cen A and B are chromospherically quiet stars with estimated rotation periods of about 22 and 41 days, respectively (Morel et al. 2000). This is typical of stars that are about the age of the Sun. Coronal cycles have been measured at X-ray and UV wavelengths with periods of 19 and 8 years for α Cen A and B, respectively (Ayres 2014, 2015).

A recalibration of chromospheric activity-age relation and a calibration of stellar rotation to stellar age (gyrochronology) was carried out by Mamajek & Hillenbrand (2008). Their revised calibration returns activity and gyrochronology ages of 6.6 and 4.4 Gyr for α Cen A and 5.2 and 6.5 Gyr for α Cen B. Mamajek & Hillenbrand (2008) estimate uncertainty in these ages of about 1.5 Gyr for the activity calibration and 1.3 Gyr for their gyrochronology technique.

2.5. Stellar Ages

As described above, stellar ages can be estimated in several ways: from isochrone fitting, stellar activity, stellar rotation speed (gyrochronology), dynamical measurements of the visual binary orbit, or galactic kine-

Figure 1. Projected orbital plane of α Cen A and B. The angular separation reaches a temporary minimum just under 4" in 2017 and the angular separation begins to increase in 2018. By 2020, the separation exceeds 5".5 and ground-based, radial-velocity searches can resume without suffering significant contamination from the companion star.

matics. Furthermore, in the case of a binary star system, we expect that the stars are co-eval; both stars should yield an independent estimate for the age of the binary system. Taking the average of the stellar ages for both α Cen A and B estimated from the ages tabulated in Table 1, we calculate a weighted mean age for the α Centauri system of 5.03 ± 0.34 Gyr.

2.6. Stellar Orbits

Pourbaix et al. (1999) used published astrometry and radial velocity (RV) data from the European Southern Observatory Coudé Echelle Spectrograph to derive the orbital parameters for the α Cen A and B stellar binary system. Pourbaix & Boffin (2016) refined this binary star orbit by supplementing their previous analysis with 11 years of high-precision RV measurements from the HARPS spectrograph and some additional astrometric data from the Washington Double Star Catalog (Hartkopf et al. 2001). They derive an orbital period of 79.91 \pm 0.013 years and eccentricity of 0.524 \pm 0.0011, and masses $M_{\rm A}=1.133\pm0.005~M_{\odot}$ and $M_{\rm B}=0.972\pm0.0045~M_{\odot}$.

Proxima Centauri has a projected separation of $15,000 \pm 700$ AU from α Cen AB and a relative velocity with respect to α Cen AB of 0.53 ± 0.14 km s⁻¹ (Wertheimer & Laughlin 2006). Wertheimer & Laughlin (2006) used Hipparcos kinematic information and carried out Monte Carlo simulations to determine the binding energy of Proxima Cen relative to α Cen AB. They found a high probability that Proxima Cen is gravitationally bound and near apastron in a highly eccentric orbit. More recently, Kervella et al. (2017b) added published HARPS RV measurements

and likewise concluded that Proxima Centauri is gravitationally bound to the α Cen AB stars, traveling in an orbit with eccentricity of $0.50^{+0.08}_{-0.09}$ with an orbital period of $\sim 550,000$ years.

3. EXOPLANET SEARCHES

The three stars in the α Centauri system have been targets of different precision, radial-velocity surveys to search for exoplanets from southern hemisphere observatories (Endl et al. 2001; Dumusque et al. 2012; Endl et al. 2015). In 2012, a planet was announced orbiting α Cen B (Dumusque et al. 2012) using data from the HARPS spectrograph. While that putative signal was later shown to be a sampling alias in the time series data (Rajpaul et al. 2016), Anglada-Escudé et al. (2016) subsequently discovered a low-mass planet orbiting Proxima Centauri, a M5.5V star. The orbital period of Proxima Cen b is 11 days, which places this planet at the appropriate distance from its host star to fall within the habitable zone. This detection was a recordbreaking discovery because of the low mass of the planet, although the habitability of this world is now being debated. Airapetian et al. (2017) find that the planet orbiting Proxima Centauri will incur a significant atmospheric loss of oxygen and nitrogen in addition to a massive loss of hydrogen because of the high-energy flux from this relatively active M dwarf (Airapetian et al. 2017).

There are several reasons why Doppler planet searches around the binary stars α Cen A and B are well-motivated. The stars are bright, allowing for high cadence and signal-to-noise spectra. The declination of the stars is -60 degrees, close to a southern polar orbit, so that the observing season stretches between nine months and a year depending on the position of the observatory. Dynamical simulations (Wiegert & Holman 1997) show that any planets in the system are likely to be nearly aligned with the binary-star orbit; this implies that any RV amplitude would not be strongly attenuated by orbital inclination.

However, there are some challenges for planet detection, formation, and long-term stability around α Cen A or B. One key concern is that the semi-major axis of the binary star orbit is only about 24 AU (Pourbaix & Boffin 2016) and the orbital eccentricity of 0.524 means that the separation of the stars is only 16.3 AU at periastron passage. While Wiegert & Holman (1997) demonstrate that any existing planets would be dynamically stable if they orbit within a few AU of either star, the close proximity of the stars has led to theoretical speculation about whether planets could have formed in the first place around α Cen A or B (Barbieri et al. 2002; Quin-

tana et al. 2002; Quintana & Lissauer 2006; Quintana et al. 2007; Thébault et al. 2008, 2009). Encouragingly, 20% of detected exoplanets have been found in binary star systems orbiting one or the other star. An especially interesting case is the binary star HD 196885 AB. With a semi-major axis of 24 AU and an eccentricity of 0.409, this is a close analog of the α Cen AB binary pair. HD 196885 A is known to host a gas-giant planet with $M \sin i$ of $\sim 3 \ \rm M_{JUP}$ and an orbital period of 3.69 years (Correia et al. 2008; Fischer et al. 2009; Chauvin et al. 2007).

Doppler surveys generally avoid binary stars with separations less than ~ 5 arcseconds because additional RV errors can be incurred by flux contamination from the companion star. At the next periastron passage of α Cen AB (May 2035) the projected separation of the two stars will be less than 2 arcseconds. However, with an orbital plane that is only 11 degrees from an edgeon configuration, the projected separation of α Cen AB reached a secondary minimum of ~ 4 arcseconds in 2017. Figure 1 shows the relative orbit of α Cen B orbiting α Cen A, projected onto the plane of the sky. Beginning in 2012, the angular separation between the two stars decreased to 5.44" and flux contamination from the binary-star companion was observed in the radialvelocity measurements and was exacerbated on nights of poor seeing conditions.

For the CHIRON data, while there was code developed to scale the flux taking into account contamination, the improvement was insufficient for precision radial velocity measurements. The RVs listed in the Dumusque et al. (2012) paper were restricted to observations obtained through 2011 that had better than one arcsecond seeing. No HARPS radial velocities were published for 2012 because the seeing conditions were not adequate to avoid flux contamination during that year. Wittenmyer et al. (2014) and Bergmann et al. (2015) have presented methods for modeling flux-contaminated spectra to reach an rms of a few meters per second. However, this more complex modeling does not reach sub-meterper-second precision, the precision needed to contribute to the detection of planets with velocity semi-amplitudes less than one or two meters per second. The current small projected angular separation of α Cen AB may force a hiatus in ground-based Doppler programs for this system until 2019 or 2020.

3.1. Constraints from Existing Data

The existing Doppler planet searches allow us to place constraints on the mass-period parameter space where planets would have been detected if they existed. Conversely, we can see what type of planets would have escaped detection.

Data from the Echelle Spectrograph (ES), CHIRON, HARPS, and UVES were compiled to constrain exoplanet detections for α Cen A, B, and C (Proxima). Radial velocities of both α Cen A and B were obtained by our team using the ES between 2008 - 2011 and the CHIRON spectrograph between 2011 - 2013 at the 1.5m Cerro Tololo Interamerican Observatory (CTIO) in Chile. The HARPS spectrograph is located at the 3.6m ESO La Silla telescope. HARPS radial velocities of α Cen B were obtained between February 2008 and July 2011 and published by Dumusque et al. (2012). We also use published RVs of Proxima Centauri from HARPS that span 2005 - 2016, and published RVs from 2010 - 2016 at the Ultraviolet and Visual Echelle Spectrograph (UVES) on the Very Large Telescope at Cerro Paranal in Chile (Anglada-Escudé et al. 2016). Both CHIRON and UVES are calibrated using the iodine cell technique while HARPS is calibrated using the simultaneous Thorium-Argon reference method Tokovinin et al. (2013); Anglada-Escudé et al. (2016).

The 1.5-m CTIO telescope is part of the Small to Moderate Aperture Research Telescopes (SMARTS) consortium. The ES was a recommissioned, fiber-fed spectrograph located at the 1.5-m CTIO telescope. The typical, single-shot precision of the ES was about 7 m s^{-1} . This spectrograph was replaced in 2011 with the CH-IRON spectrograph, which was immediately upgraded and recommissioned in 2012 with new optical coatings, a new CCD, better temperature control, and octagonal fibers (Tokovinin et al. 2013). While the short term velocity rms reached 0.5 m s⁻¹ for bright, single stars observed with CHIRON (Tokovinin et al. 2013), a serious short-coming for RV measurements of α Cen A and B RV measurements is that the front end fiber feed was designed with a 2".7 field of view to maximize the number of collected photons during poor seeing conditions on the 1.5-m telescope. When CHIRON was re-commissioned in 2012, the angular separation of α Cen A and B was only 5".5 and there was significant flux contamination from the companion star on nights when the seeing was worse than one arcsecond. By 2013, the angular separation of AB had decreased so the flux contamination increased and there were few nights when the rms of the RV measurements was less than three times the average scatter per night. We tested a new Doppler code that included a scaled flux from the companion star, as described by Bergmann et al. (2015); however, we were only able to reach a single-shot precision of $\sim 15 \text{ m s}^{-1}$ from the flux contaminated spectra for α Cen A and B. We prefer to retain the original velocities, rather than

Figure 2. Data of α Centauri A (top) and α Centauri B (bottom) taken at the CTIO Telescope from 2009 to 2012. The Echelle Spectrograph was switched to CHIRON in 2011, as shown by a dashed line on each graph. Observations are binned by night. Blue points represent the data points used in the simulations. Observations falling more than 3σ away from the average due to contamination were cut, shown here in orange.

velocities from our scaled flux analysis, because they more clearly identify nights with spectral contamination that should be rejected.

Figure 2 shows all of the binned RV measurements collected by the ES (left of the vertical dashed line) and CHIRON (right of the vertical dashed line) for α Cen A (top panel) and α Cen B (bottom panel). Flux contamination from the companion stars causes the velocities for α Cen A to decrease (shifting toward the velocity of α Cen B) and velocities for α Cen B to increase. The effect of flux contamination is apparent in Figure 2. The nights with poor seeing conditions that resulted in flux contamination were excluded from the published HARPS data (Dumusque et al. 2012). To eliminate nights at the CTIO with significant flux contamination, we determined an acceptable threshold for the measured

Figure 3. A histogram of the de-trended radial velocity measurements for each night at the CTIO Telescope of α Cen A (top) and α Cen B (bottom). Each histogram is fit to a Gaussian, shown in blue. Nights where data fall more than 3σ away (shown by red, vertical lines) most likely suffer contamination from the other star and are cut. Retained nights are shown in blue in Figure 2.

contamination. After subtracting out the binary trend from both data sets, the resulting RV measurements should be Gaussian distributed about zero. However, contaminated data will lie far away from the mean. We fit a Gaussian curve to the distribution of each data set and consider any data point more than 3σ away from the distribution's mean as suffering from considerable contamination. Figure 3 shows the distribution (black), fitted Gaussian curve (blue), and subsequent cuts (orange). The 3σ cuts frame the bulk of the observations, thereby excluding only nights that deviate significantly from the mean.

Data that is retained and used in the simulations are shown in Figure 2 in blue while cut data is plotted in orange. This contamination is visually obvious and increases with time following 2011 as the stars orbit closer and closer together (see Figure 1). All ve-

locities removed are skewed in the direction to be expected from contamination (e.g. down for α Cen A and up for α Cen B). Additionally, this choice of cut vets more data points from the set of α Cen B observations, which further suggests contamination since α Cen A is the brighter star and would therefore cause more significant contamination in α Cen B observations than the other way around.

In Table 2, we list the nightly-binned, radial-velocity measurements on nights where there was not significant flux contamination from the companion star for α Centauri A and B, resulting in 228 data points for α Cen A and 241 points for α Cen B. The uncertainty on our single measurements is of the order 5 m s⁻¹ for ES data and 1.1 m s⁻¹ for CHIRON data with regards to α Cen A. The uncertainty for α Cen B observations is approximately 4.4 m s⁻¹ for ES data and 1.2 m s⁻¹ for CHIRON data. Because the errors are not pure white noise, the error for each binned observations is taken to be the average of the formal errors of every point that night. The rms of the final, nightly-binned radial velocities is 7.2 m s⁻¹ for α Cen A over 4.13 years and 8.9 m s⁻¹ for α Cen B over 4.38 years.

Table 2. Relative, Binned RV Data from the Telescope

Star	JD-2440000	$RV \text{ m s}^{-1}$	Err m s ⁻¹	Source
A	14689.5270	-239.82	7.20	Echelle
A	14834.8477	-187.13	4.64	Echelle
В	14834.8350	119.94	4.05	Echelle
В	14835.8154	126.48	4.74	Echelle

4. SIMULATIONS

Using the cleaned and nightly-binned velocities for α Cen A and B from the ES and CHIRON spectrographs at CTIO, the published HARPS velocities for α Cen B, and the HARPS and UVES velocities for Proxima Cen, we carried out Monte Carlo simulations to assess whether planets of a given mass with orbital periods between 2 and 1000 days would have been detectable. The maximum orbital period of 1000 days was chosen because we expect that dynamical influences from the binary orbit of the α Cen AB stars would destabilize orbits of putative planets beyond about 2 AU (Wiegert & Holman 1997). We restricted the detectability simulations for Proxima Centauri (α Cen C) to the same time

baseline, searching for significant signals well beyond the habitable zone of the low-mass star. The minimum orbital period of 2 days is arbitrary, but avoids spurious 1-day sampling aliases in the CHIRON and HARPS data sets.

For the detectability simulations, we established a grid in planet mass and orbital period parameter space for each of the stars (α Cen A, B, and Proxima Centauri) and injected a simulated Keplerian signal at each grid point, adopting stellar mass values from Pourbaix & Boffin (2016). For simplicity, our simulations assume circular orbits and single-planet architectures. Grid points are spaced on a hybrid log-linear scale to adequately sample the parameter space.

The simulations reveal the detectable $M \sin i$ of the planet. While our simulations test $M \sin i$ rather than planet mass, planets are expected to inherit the 79° orbital inclination of the binary star system (Wiegert & Holman 1997). Therefore, we expect that the $M \sin i$ value is close to the true mass of any planets around either α Cen A or B.

The statistical significance of the injected signal was determined by assuming the null hypothesis. In other words, we assess the probability that a signal of similar strength to our injected Keplerian signal would be produced by random errors in our data. Planets that are more massive or in closer orbits will produce stronger reflex velocities in the host stars that give rise to stronger, coherent signals. These planets are more easily detected as their signals are harder to reproduce by noise alone. Our simulations test what strength of signal is necessary to overcome the inherent noise in the data and produce a coherent, detectable signal from a planet. We tested planet detectability in the presence of both white noise and the red noise present in the reported RVs.

4.1. White-Noise Simulations

We simulated Keplerian RVs with identical temporal sampling and error bars as the observed data sets, preserving any window functions in the observations. Our white-noise simulations assume that the radial velocity scatter is completely captured by white noise that is scaled to the quoted error bars. The simulated radial velocities for the white-noise simulations were created with a random draw from a Gaussian distribution that was scaled to the formal error at the time of each observation. The mean of the formal errors for the binned ES and CHIRON data is 0.48 m s $^{-1}$ for α Centauri A and 0.51 m s $^{-1}$ for α Centauri B (but, as we show later, the systematic errors in the ES and CHIRON data are significantly larger). The binned HARPS data of α Centauri B have a mean error of 1.0 m s $^{-1}$. The standard

Figure 4. Comparing generated Keplerian signals to noise. An example periodogram of a significant detection (solid line) and an insignificant planetary signal (dashed-line) are given for white noise (black, top) and red noise (red, bottom). On both graphs, a blue, horizontal line marks the peak height that is greater than the maximum peak height in 99% of 1500 instances of pure noise. This corresponds to a p-value of less than 0.01 for the signal. Therefore, periodograms with peaks higher than this line are considered significant. The vertical, green, dashed line on both graphs marks the period of the generated signal.

error for the combined, binned HARPS and UVES data of Proxima Centauri are on average 0.94 $\rm m~s^{-1}$. We generated 1500 sets of time-series, white-noise RV data. The simulated radial velocities were created by adding realizations of white noise to theoretical Keplerian models at each mass-period grid point.

Using a Lomb-Scargle periodogram (Lomb 1976; Scargle 1982), the periodogram power for the simulated Keplerian velocities was then compared to the periodogram power of the 1500 white noise data sets at each grid point. The data sets that are dominated by white noise

produce a power spectrum with multiple low peaks at many periods, while a detectable Keplerian signal will produce a tall peak at the correct orbital period. Examples of significant vs. insignificant periodograms are given in Figure 4 for both white noise (top) and red noise (bottom).

To decide whether the RVs with an injected Keplerian signal would be detectable with current observations, we calculate a p-value at each grid point. The p-value gives the probability that the injected radialvelocity data produces the same signal as only random noise. The p-value is defined as the fraction of comparisons where the white-noise simulations yield a greater maximum peak height than the simulated Keplerian signal. Planets producing significant signals will more consistently give stronger periodogram peaks, resulting in lower p-values. Larger p-values indicate that the signal produced by the planet has no more significance than white noise alone. We adopt an arbitrary but often used threshold p-value of 0.01, meaning that fewer than 1 of 100 white noise simulations produced a periodic signal that was stronger than a simulated Keplerian signal. ²

Figure 5 shows the white noise detectability simulations for α Cen A, α Cen B, and Proxima Cen. The p-values and color gradients are scaled so that a boundary appears where Keplerian signals yield a p-value of 0.01. Signals with lower p-values (above this boundary) would have likely been detected if they existed, while Keplerian signals with p-values greater than 0.01 would be buried in the white noise given the stated errors of the CHIRON and HARPS programs. The CHIRON and HARPS data sets for α Cen B are kept separate as they are unique in their sampling and would lead to different aliasing as well as exhibit different instrumental errors. Analyzing the two data sets separately allowed our results to capture these differences. Additionally, while combining the two data sets helps to push white-noise detection limits lower, the red-noise simulations suffer instead. The CHIRON data, with more systematic errors, serve to reduce the sensitivity of the HARPS data rather than give better results. The upper right panel of Fig 5 has a dot indicating the mass and period of Proxima Cen b (Anglada-Escudé et al. 2016).

² The purpose of this analysis is to assess the strength an injected Keplerian signal requires to produce a signal significantly distinct from what would be produced by pure noise in the current observations. We consider each scenario individually and therefore do not make any adjustments to account for the multiple comparisons problem.

Figure 5. White-noise simulations. Mass vs. period grids showing the significance at which a planet of such a mass and period would have been detected assuming only the reported errors for observations of (a) α Centauri A from ES and CHIRON, (b) Proxima Centauri from HARPS and UVES, (c) α Centauri B from ES and CHIRON, and (d) α Centauri B from HARPS. A p-value of less than 0.01 (indicated by shades of blue) is considered significant. Green vertical bands mark the conservative habitable zone where liquid water could persist for most of the stellar lifetime and the lighter green covers the optimistic habitable zone (as defined by Kopparapu et al. (2013)). A power law was fit to the detectability border of the α Cen B ES and CHIRON data and is plotted on the α Cen B HARPS grid as a dashed line. The location of Proxima Cen b is indicated with a dot.

4.2. Red-Noise Simulations

Our analysis using the white-noise simulations described above will not account for any systematic or quasi-periodic instrumental errors, analysis errors, photospheric jitter, or even actual planets. To investigate the impact of systematic errors or red noise sources, we treat the reported residual velocities from subtracting out the binary orbit from the observations as coherent noise. This is a worst-case scenario and we note that it is possible to improve detectability by de-correlating some of these noise sources using techniques like line bisector variations or FWHM variations to estimate photon noise (e.g. Dumusque et al. 2012; Rajpaul et al. 2016; Anglada-Escudé et al. 2016).

These residual velocities are assumed to capture uncorrected observational errors, including instrumental errors and stellar jitter. The residual velocities would also contain any potential planetary signals. For this red noise simulation, we simply interpreted the residual velocities as pure red noise, and continued the same simulation described for white noise, adding Keplerian signals parameterized by each point of a mass-period grid. A comparison of the red and white noise analysis can be useful for highlighting possible planetary signals as well as quasi-periodic errors in our radial velocity data.

For the Monte Carlo, red noise simulations, the radial-velocity residuals were added to 1500 freshly generated white noise realizations and to the theoretical Keplerian signal at each point of a mass-period grid. The periodograms of the red-noise simulations now contain stronger power than the white-noise simulations, meaning the simulated Keplerian signal must generally have

Figure 6. Red-noise simulations. Mass vs. period grids showing the significance at which a planet of such a mass and period would have been detected assuming that the current data of (a) α Centauri A from ES and CHIRON, (b) Proxima Centauri from HARPS and UVES, (c) α Centauri B from ES and CHIRON, and (d) α Centauri B from HARPS is simply red noise. The color scale to p-value is the same as for Figure 5. A power law was fit to the detectability border given by the white-noise simulations and is plotted here as a black line. The orange parameter space indicates areas where planets could still remain undetected. The conservative and optimistic habitable zones are the same as Fig 5. Proxima Centauri b is indicated on subfigure (b) by a dot.

a larger amplitude to reach a p-value of 0.01 (see Figure 4). Figure 6 shows the red noise simulations for α Cen A from CHIRON (upper left), Proxima Centauri (upper right), α Cen B from CHIRON (lower left) and α Cen B from HARPS (lower right). Solid, black lines on each plot show a power law that was fit to the detectability border from the white-noise simulations for each data set.

5. RESULTS

Our white-noise simulations are summarized in Figure 5. Because both the original error bars and times of observation are retained, the white-noise simulations will preserve our ability to identify window functions in the sampling of our data. These simulations exclude planets in the conservative habitable zone of each star with a $M\sin i$ of greater than $53\pm13~{\rm M}_{\oplus}$ for α Cen A, 8.4 ± 1.5

 M_{\oplus} for α Cen B, and $0.47\pm0.08~M_{\oplus}$ for Proxima Centauri. However, this is an overly optimistic scenario. Doppler measurements are known to have contributions to the derived radial velocities that arise from instability of the instrument, errors in the analysis, and velocities in the stellar photosphere from spots, faculae, granulation, p-mode oscillations, or meridional flows (e.g., Santos et al. 2000; Saar & Fischer 2000; Queloz et al. 2001; Wright 2005; Lagrange et al. 2010; Meunier et al. 2010; Borgniet et al. 2015). These velocities can obscure the Doppler signals that arise from orbiting exoplanets. The white noise simulations will not capture these noise sources because of an implicit assumption that the measurement errors are captured by the formal RV uncertainties.

In contrast, our red-noise simulations, shown in Figure 6, represent a worst-case scenario. For these simu-

Figure 7. Difference in detectability between the red-noise simulations and the white-noise simulations from subtracting the two detectability borders for α Centauri A (top), α Centauri B (middle) and α Centauri C (bottom). Peaks indicate periodicities in the residual radial velocities that could correspond to stellar noise, systematic errors, or even planetary signals. Negative differences are not shown. We assume negative values to arise from over-fitting the data or white noise alone and so hold no physical meaning. A blue, dashed line in the bottom, Proxima Centauri plot indicates the orbital period of Proxima Cen b.

lations, we assume that the time-series radial velocities contain only coherent noise. This noise is added directly to random white noise and the generated Keplerian signals, effectively preserving any temporal coherence in the noise.

In practice, radial velocities can be treated with Gaussian Process Regression (Rajpaul et al. 2016) or decorrelated using line bisectors or the FWHM of the cross correlation function (Dumusque et al. 2012) to mitigate the impact of non-Keplerian radial velocities on exoplanet detectability. Red noise has also been empirically modelled (Tuomi et al. 2013) Therefore, our red-noise simulations slightly underestimate planet detectability. The white-noise and red-noise simulations together frame the mass-period boundary where existing Doppler surveys constrain the existence of planets orbiting the α Centauri stars.

The boundary between parameter space where planets would be detected or missed in the presence of white noise (Fig. 5) or red noise (Fig. 6) is approximately defined by the lowest mass at each period for which the p-value of the generated Keplerian RV exceeds our threshold of 0.01. This border for the white-noise simulations is both lower and smoother compared to the red-noise simulations. To more closely investigate these differences, we subtract the detectability border of the white-noise simulations, M_{WN} , from the detectability border of the red-noise simulations, M_{RN} . This difference is plotted as a function of period in Figure 7 for α Cen A (top), α Cen B (middle), and for Proxima Cen (bottom). Peaks in this difference plot will occur due to quasi-periodic noise sources or planetary signals. Interesting to note is the peak at around 675-720 days that can be seen in both the CHIRON and HARPS observations of α Cen B. Additionally, similar peaks appear in both the α Cen A and α Cen B CHIRON data near 65, 150, and 575 days. The bottom plot in Figure 7 includes a vertical, dashed line at the period of Proxima Centauri b, around which a clear peak can be seen.

6. DISCUSSION

6.1. Detectability

We have carried out simulations to show how past Doppler surveys of the α Centauri stars constrain the probability of exoplanets over the mass-period parameter space shown in Figures 5 and 6. While the Doppler technique can only derive $M \sin i$, rather than the true planet mass, the dynamical influences of the binary star system mean that any stable planets are likely to be nearly co-planar with the 79° inclination of the stellar binary system (Wiegert & Holman 1997). This suggests that the $M \sin i$ is approximately the actual planet

mass for prospective planets around α Cen A or B. We show that Earth analogs could still exist around either α Cen A or B and would not have been detected by the past decade of precision radial velocity searches. Continued, high-cadence, high-precision radial velocity observations could still reveal Earth-sized planets within this star system, even within the habitable zones of each of the three stars.

At each point in the parameter space of $M \sin i$ and orbital period, we sample a Keplerian signal at the actual time of the observations with added white noise scaled to the errors to provide a baseline of planet detection space. These simulations exclude planets within the conservative habitable zone of each planet with a $M \sin i$ of greater than 53 M_{\oplus} for α Cen A, 8.4 M_{\oplus} for α Cen B, and $0.47~\mathrm{M}_{\oplus}$ for Proxima Centauri on average. This result for α Cen B comes from the HARPS data set; the CHIRON data set excludes planets in the habitable zone of α Cen B to greater than 23.5 M_{\oplus} . We then repeat our analysis using the actual velocity scatter after subtracting the binary star orbit as "red" noise in addition to the white noise. We assess the probability that this signal could have been produced by noise alone by calculating a p-value, the fraction of comparisons where noise-only simulations yield greater periodogram power than the Keplerian signal at any grid point. The color scales of Figures 5 and 6 pivot around a p-value of 0.01, which would be marginally detectable.

Both the white-noise and the red-noise simulations preserve the cadence of observations. Because observations are a discrete sampling of a continuous signal, aliases appear in periodograms that can be mistaken for true, astrophysical signals. These commonly correspond to periodicities of the sidereal year, sidereal day, solar day, and synodic month (Dawson & Fabrycky 2010). For example, reduced sensitivity can be seen in all four data sets presented in Figure 5 around 300-400 days, which likely corresponds to the annual constraints the Earth's orbit around the Sun places on observations.

We subtract the white-noise mass-period boundary that occurs at a p-value of 0.01 from that same boundary in the red-noise simulations to highlight periodicities present in the residual radial velocities. Even after implementing the cuts described in section 3.1, we acknowledge that some of the remaining RV measurements may still be affected by small amounts of contamination, which effectively contributes to the red noise. The peaks apparent in Figure 7 could correspond to quasi-periodic systematic errors, stellar jitter, or even planetary signals. For example, peaks that appear consistently in the CHIRON data for both α Cen A and α Cen B (e.g. at 65, 150, and 575 days), are indicative of instrumen-

tal or systematic errors since it is improbable that both stars will exhibit the same astrophysical velocity signals. Also potentially interesting are the periods where peaks in the CHIRON and HARPS data of α Cen B align (e.g. at around 700 days). Because these peaks appear in observations from two different instruments with different data reduction pipelines, it seems unlikely that the same peaks would arise in both data sets from instrumental or systematic error; however, these peaks could still be the result of astrophysical velocity signals. In the case of Proxima Centauri, it is illustrative to note a distinct signal at the period of the recently discovered Proxima Cen b. A Keplerian signal would produce a red noise source in the velocities of that star; this peak is likely due to the signal produced by Proxima Cen b that is retained in the residual radial velocities.

Radial velocity precision approaching 10 centimeters per second will ultimately be needed to detect exoplanets with smaller masses and longer orbital periods in the yet to be probed parameter space around α Cen A and B. There are several challenges for reaching such high RV precision. Some of the issues should be relatively straightforward to address. For example, the p-mode oscillations of α Cen A have a radial velocity amplitude of $1-3 \text{ m s}^{-1}$ (Butler et al. 2004), which adds random scatter to radial velocities. The p-mode amplitudes in α Cen B are much weaker with a semi-amplitude of only 0.08 m s^{-1} (Kjeldsen et al. 2005); however, changing granulation patterns also introduce radial velocity scatter at the level of 0.6 m s^{-1} for both stars on timescales ranging from 15 minutes to several hours (Dumusque et al. 2012; Del Moro 2004). Both p-mode oscillations and granulation change on relatively short periods, allowing the observing strategy to be tailored to dramatically reduce these noise sources. For example, a series of exposures over ten minutes is sufficient to average over the high frequency p-mode signals.

Additional challenges to higher RV precision include requirements of higher stability for next generation spectrographs (temperature and pressure stability), improved wavelength calibration, calibration of both CCD stitching and random pixel position errors, and mitigation of modal noise for multi-mode fibers (Fischer et al. 2016). It seems likely that ongoing efforts to address these engineering challenges will be successful. Techniques for modeling or decorrelating Doppler velocities that arise from stellar photospheres are less mature. Significant progress on disentangling stellar noise sources is required so that clean orbital velocities can be obtained. Currently, the two stars are separated by less than 5", giving rise to cross contamination between the two stars and preventing high-precision, radial-velocity

measurements. As the separation between α Cen A and B begins to increase in 2019, radial velocity measurements will help to push constraints even lower and could ultimately lead to the discovery of Earth-like planets.
