#### ABSTRACT

We identify new Y- and T-type brown dwarfs from the WISE All Sky data release using images obtained in filters that divide the traditional near-infrared H and J bands into two halves – specifically CH<sub>4</sub>s & CH<sub>4</sub>l in the H and J2 & J3 in the J. This proves to be very effective at identifying cool brown dwarfs via the detection of their methane absorption, as well as providing preliminary classification using methane colours and WISE -to-near-infrared colours. New and updated calibrations between T/Y spectral types and CH<sub>4</sub>s-CH<sub>4</sub>l J3-W2, and CH<sub>4</sub>s-W2 colours are derived, producing classification estimates good to a few spectral sub-types. We present photometry for a large sample of T and Y dwarfs in these filters, together with spectroscopy for 23 new ultra-cool dwarfs – two Y dwarfs and twenty one T dwarfs. We identify a further 8 new cool brown dwarfs, which we have high confidence are T dwarfs based on their methane photometry. We find that, for objects observed on a 4m-class telescope at J band magnitudes of ~20 or brighter, CH<sub>4</sub>s-CH<sub>4</sub>l is the more powerful colour for detecting objects and then estimating spectral types. Due to the lower sky background in the J-band, the J3 and J2 bands are more useful for identifying fainter cool dwarfs at J $\gtrsim$ 22. The J3-J2 colour is poor at estimating spectral types. But fortunately, once J3-J2 confirms that an object is a cool dwarf, the J3-W2 colour is very effective at estimating approximate spectral types.

#### 1. INTRODUCTION

Data from the NASA Wide-field Infrared Survey Explorer (WISE; Wright et al. Mainzer et al. 2011) have delivered unprecedented advances in our understanding of the properties and space densities of the coldest compact astrophysical sources identified outside our Solar System – the T- and Y-type brown dwarfs(e.g., Cushing et al. 2011; Kirkpatrick et al. 2011, 2012; Kirkpatrick et al. 2013). These very cold brown dwarfs have scientific impacts that span multiple astronomical arenas. In the field of star formation, they can deliver a historical record of the star formation process at very low masses and at epochs billions of years prior to the star forming regions we observe today. In the field of planetary atmospheric theory, they represent low-temperature atmospheres that can be readily observed without the contaminating glare of a host star, and without the photochemical complications introduced by host star irradiation. In the field of exoplanet searches, they provide nearby, lowluminosity search targets potentially hosting planetary systems of their own, which would have implications for the debate on what differentiates a low-mass brown dwarf from a highmass planet.

WISE readily identifies these very cold brown dwarfs as a result of their strong thermal infrared methane absorption. The shortest wavelength WISE band (hereafter W1) has a central wavelength of  $3.4\,\mu\mathrm{m}$ , which sits in the middle of the strong fundamental methane absorption band near  $3.3\,\mu\mathrm{m}$ . The second shortest WISE band (hereafter W2), has a central wavelength of  $4.6\,\mu\mathrm{m}$ , where the photosphere is reasonably transparent and so detects flux from deeper, hotter layers in the brown dwarf. As a result, cold brown dwarfs can be identified via their very red W1–W2 colour. WISE's relatively uniform all-sky coverage, coupled with

its ability to identify cool objects even when quite close to the Galactic plane, makes it the ideal data source from which to generate a complete thermal-infrared magnitude-limited sample of T and Y dwarfs in the Solar Neighbourhood. The generation of just such a T/Y-dwarf census is a key goal of the WISE Science Team brown dwarf collaboration. Large numbers of Y- and T-type brown dwarfs have been identified and spectroscopically confirmed to date by the WISE Science Team brown dwarf collaboration using both colour selection (see e.g., Mainzer et al. 2011; Cushing et al. 2011; Kirkpatrick et al. 2011, 2012; Tinney et al. 2012; Mace et al. 2013), and more recently supplemented by proper-motion selection from the All-WISE and NEOWISE samples (see e.g., Kirkpatrick et al. 2014; Schneider et al. Kirkpatrick et al. 2016). Additional cool brown dwarfs have been found by multiple teams independently working with public WISE data (e.g., 2014; Luhman 2014), while Pinfield et al. others have been identified from searches for cool companions to nearby stars companions to nearby stars (e.g., Luhman et al. 2011; Liu et al. 2012; Dupuy et al. 2015).

The WISE Science Team brown dwarf collaboration has largely selected targets for follow-up on the basis of photometry consistent with W1-W2 > 2.9 over the full range of WISE W2 magnitudes, plus somewhat bluer objects (i.e. down to W1-W2 = 2.0) if colours and magnitudes suggested a distance less than 20 pc. In many cases these objects are non-detections at W1 (i.e. their W1-W2 colours are 3- $\sigma$  upper limits). This substantially increases the observational phase space probed by this follow-up program, at the cost of increasing the number of "false positives" identified from the WISE data, which must then be eliminated by subsequent observations.

Follow-up observations require the identification and spectral classification of a near-infrared counterpart to the WISE source. Unfortunately, the coldest objects (i.e. the Y dwarfs) can be very faint in the near-infrared (i.e.  $J \sim H \gtrsim 22$ ), making them challenging targets even for 8 m-class ground-based telescopes. T dwarfs in WISE will be somewhat brighter in the near-infrared, and this gives medium-sized 4 m-class telescopes a role in targeting them as part of the completion of the WISE T/Y-dwarf census.

Methane imaging can play a useful role in this process. The discovery of very strong and broad methane absorption in the spectrum of the known T dwarf (Gl 229B Nakajima et al. 1996; Oppenheimer et al. 1996) made the use of this spectral signature for T-dwarf identification using specially designed imaging filters self-evidently obvious. This was confirmed when Rosenthal et al. (1996) use a circularly variable filter (i.e. an adjustable narrow band filter) to differentially re-detect Gl 229B. Subsequent use of methane imaging (rather than spectroscopy) to "winnow" out T dwarfs from wide-field survey data was first carried out by Herbst et al. (1999), while the first use of methane filters in blind searches for new T dwarfs was carried out by Mainzer & McLean (2003). At around the same time Tinney et (2005) began using specially constructed methane filters in the IRIS2 instrument at the Anglo-Australian Telescope to identify T dwarfs from lists of candidates from the 2MASS survey.

The power of this technique for WISE followup comes from the fact that the identification of a near-infrared counterpart that shows methane absorption within a small distance on the sky from a WISE All-Sky or AlLWISE position uniquely identifies this near-infrared object as the counterpart to the WISE source. Following which, the strength of the methane absorption can then provide a spectral type estimate, reducing the necessity for spectroscopic follow-up in all cases.

# 2. IMAGING – ANGLO-AUSTRALIAN TELESCOPE (AAT)

Imaging observations were carried out on the AAT on the nights listed (as local dates) in Table 1 with IRIS2 (Tinney et al. 2005). IRIS2 is a near-infrared imager and spectrograph, with a single  $1024 \times 1024$  pixel detector giving an imaging field of view of 7.7′ on a side at a pixel scale of 0.4486''/pixel.

Data were obtained in seeing conditions ranging from 1.05" to over 2.0". Targets for observation were selected in 2011 from then extant catalogues using the pipeline software developed to produce the WISE Preliminary Data Release (for details see the Explanatory Supplement<sup>1</sup>), and in 2012 from the WISE All-Sky release. As the optimal candidate selection procedures were being developed at the same time as improved versions of the WISE pipeline, we report in Table 2 the WISE photometry for our observed sources as presented in the WISE All-Sky data release made in March 2012 (rather than the photometry based on which they were originally selected).

In general the selected candidates satisfy the criteria that they were detected in W2 and had W1–W2>2.0. The WISE processing pipeline records either detections at greater than 3- $\sigma$  significance, or 3- $\sigma$  upper limits. Requiring a W1 detection (or 3- $\sigma$  upper limit) and W1–W2>2.0, pushes the effective W2 detection floor much brighter than that imposed by the pipeline's 3- $\sigma$  detection threshold. Our faintest T and Y dwarf candidates typically had W2  $\lesssim$  15.5, which corresponds to a signal-to-noise ratio of

~10. Additional selection criteria have been found to greatly assist in improving the rejection of non-brown dwarf contaminants. Broadly we require the source was not identified as an artifact (i.e., known to be spurious), and that it wasn't flagged as blended (in which case it would have poorly determined photometry). For more details, including values of the specific flags used, see §2.1 of Kirkpatrick et al. (2012).

# 2.1. J-band imaging

Each candidate was initially observed in Jband with a planned exposure time of 54 minutes, broken up into thirty-six 90s pseudorandomly dithered exposures. On-line data reduction using the ORACDR pipeline system (Cavanagh et al. 2008)<sup>2</sup> would then produce a near-publication-quality processed sub-mosaic soon after the first 9 images of this dither pattern were completed. This processed image was then analysed using purpose-built Perl scripts that automated the extraction of photometry for the image (using SExtractor; Bertin & Arnouts 1996), followed by the photometric and astrometric calibration of that data using the 2MASS Point Source Catalog (PSC; Skrutskie et al. 2006).

This meant that within 5 minutes of the completion of the first 9-image sub-mosaic, we would know whether a J-band positional counterpart had been identified down to J $\approx$ 19.5. If a positionally matched candidate clearly emerged after this first sub-mosaic (when such an object emerged they usually did so at the  $>10-\sigma$  level), then the dithering sequence would be truncated, and methane imaging observations begun. In the absence of an "early" match the J-band imaging sequence was allowed to run to completion, providing imaging data to a depth of J $\approx$ 21.

### 2.2. Methane imaging

Once a plausible J-band counterpart had been identified, methane imaging observations were carried out with the CH<sub>4</sub>s and CH<sub>4</sub>l filters in IRIS2. The use of these filters for the study of cool brown dwarfs is described in Tinney et al. (2005) – we summarise just the salient points The IRIS2 methane filters (CH<sub>4</sub>s and CH<sub>4</sub>l) divide the H-band in half, sampling the wavelength ranges 1.520- $1.620 \,\mu\mathrm{m}$  and 1.640- $1.740 \,\mu\mathrm{m}$  (respectively). Flux in the CH<sub>4</sub>l filter is substantially depressed by methane absorption in T and Y dwarfs, and so the CH<sub>4</sub>s-CH<sub>4</sub>l colour provides a powerful means of determining T and Y dwarf classifications. filter observations are obtained by interleaving CH<sub>4</sub>s and CH<sub>4</sub>l observations (in an ABBA sense), while also dithering the telescope on sky. These data are also processed "on the fly" by ORACDR and deliver pairs of reduced images after every 7-9 pairs of images, which are then processed and differentially calibrated onto the CH<sub>4</sub>s-CH<sub>4</sub>l photometric system of Tinney (2005). As with the J-band imaging, et al. purpose-built scripts are run as soon as the first pair of CH<sub>4</sub>s and CH<sub>4</sub>l mosaics are produced. Once again, if a clear methane signature was detected the observing sequence was truncated, and observations moved on to the next WISE

<sup>&</sup>lt;sup>2</sup> See also http://www.oracdr.org/

candidate.

#### 2.3. Photometry

Following the initial processing done at the telescope, the ORACDR pipeline was used to reprocess these data for final analysis. A simple two-step process is followed: in the first step all images on each object are processed together to produce a flat-field and a first-pass mosaic, allowing the flattened images that went into this first-pass mosaic to be analysed to determine their photometric zero-point and image quality; in the second-pass, frames with poor image quality or poor photometric throughput are culled and the remaining images reprocessed to produce a final mosaic. Photometry was then obtained from the final mosaics on each field. by differentially calibrating onto the  $J_{MKO}$  or CH<sub>4</sub>s-CH<sub>4</sub>l systems using 2MASS PSC photometry for stars lying within the IRIS2 field of view.

For J band data this differential calibration is achieved by identifying objects in the field of view with 2MASS -0.2 < J - K < 1.5 and the converting those J magnitudes from the 2MASS photometric system to the MKO photometric system, using the equations determined by J. Carpenter in the 2MASS All-sky Survey Explanatory Supplement<sup>3</sup>. As the IRIS2 J,H,K,Ks filters are MKO ones (i.e. manufactured to the

prescriptions of Tokunaga et al. 2002), the result is J photometry on the MKO system.

For  $CH_4s$ ,  $CH_4l$  data, objects in the field-ofview for which transformations from the 2MASS to MKO photometric systems are reliable (i.e. have 2MASS colours in ranges where the Carpenter transformations are valid – see Tinney et al. 2005) are converted to MKO H, and then used to define zero-points for the  $CH_4s$  and  $CH_4l$  systems, and so determine  $CH_4s$ – $CH_4l$ . The resulting zero-points for a given field are typically determined to between  $\pm 0.02$ -0.1 mag, and the scatter about the zero-point determination is used to determine a standard error in the mean, which is then propagated to the finally quoted photometric uncertainties.

Table 2 presents J and CH<sub>4</sub>s-CH<sub>4</sub>l photometry from the AAT, as well as WISE W1 and W2 photometry from the All-Sky release – the official WISE designation for all sources combines the prefix "WISE" with the position designation in column 1 of the table – e.g. WISE J001505.87-461517.6. These are abbreviated thereafter with the letter "W" and the first four digits of the right ascension and declination of the designation – e.g. W0015-4615. Also listed in the table are spectral types resulting from spectroscopic observations in this paper (§5) and other programs, as well as estimated spectral types based on a new CH<sub>4</sub>s-CH<sub>4</sub>l calibration derived in §6.1.

PIRIS2 CH<sub>4</sub>sand CH<sub>4</sub>s-CH<sub>4</sub>lphotometry calibrated (as described in the text) on the system of Tinney et al. (2005)

 $<sup>^</sup>d$ Estimated spectral types using CH<sub>4</sub>s-CH<sub>4</sub>l and the calibration of §6.1.

<sup>&</sup>lt;sup>2</sup> The discovery name for this object is UGPS 3072227.51-054031.2 (Lucas et al. 2010) and  $J_{MKO}$  is from that paper.

While noting that the spectral type for this object has been the subject of some debate, we adopt the T9 type of Kirkpatrick et al. (2012)

discussed in the text and shown in Fig. 2, the CH<sub>4</sub>s-CH<sub>4</sub>l (and especially the CH<sub>4</sub>l) photometry is contaminated by a background galaxy. The J3-W2 photometry (§6.3) and the FIRE spectrum (§5) clearly show this to be a Y0. We do not include this object in the <sup>7</sup>The methane colour of W1141 suggests a spectral type of  $\approx$ T5.5, however the J-W2 colour is indicative of a type of T9 or later. As discussed in the text and shown in Fig. CH<sub>4</sub>s-CH<sub>4</sub>l calibration of §6.1.

<sup>&</sup>lt;sup>h</sup>143311.42-083736.4: A spectrum and spectral type for this object has also been published by Lodieu et al. (2012). Those values are in agreement with those presented here.

<sup>3012102.92-190656.9,</sup> J074551.79-015122.1, J164445.19-645628.9 and J185709.40-315345.5: a bright source has a position match with the WISE position. The  $CH_4$ s- $CH_4$ l colours indicates they are not T dwarfs.

J071939.54-173514.8: extended source at position with no methane absorption

<sup>&</sup>lt;sup>k</sup> 1083942.85-402938.9: is clearly an extended source (2.1"×3.0"), with no methane absorption. WISE source is likely this galaxy.

 $<sup>^{1}</sup>$  J130740.45-463035.1: a bright CH<sub>4</sub>s=16.60 source has a position match with the WISE position, and shows no proper motion since the 2MASS epoch.. The CH<sub>4</sub>s-CH<sub>4</sub>l colour indicates this object is not a T dwarf.

<sup>&</sup>quot;9150711.06-344026.0: this bright W2 source was observed as a poor conditions backup target and it has a position match with the WISE position, but the CH<sub>4</sub>s-CH<sub>4</sub>l colour indicates this object is not a T dwarf. Shows no proper motion since the 2MASS epoch)

 $<sup>^{3}</sup>$ 1190230.27-371246.1: very extended (3.5") source at position, making this galaxy the likely WISE source.

<sup>&</sup>lt;sup>o</sup> J203020.23-692043.1: has excellent position match object with J=19.51, however this is marginally resolved (2.2" fwhm) in 2.0" seeing, and shows no methane absorption. It is likely the WISE flux arises from this galaxy.

P J 203119.30-690500.3 has excellent position match object with J=20.44 and methane absorption. However the object is resolved at J (2.2" fwhm in 2.0") and H (1.84" fwhm in 1.39" seeing). Moreover, the methane colour suggests a spectral type of T4 which is inconsistent with the J-W2 and CH<sub>4</sub>s-W2 colours (which suggest a much later spectral type of >T9). This identification is therefore considered tentative.

<sup>4</sup> J224245.85-201511.0 has J=20.03 object 1.2" from the WISE position. However, this object has an almost identical J and J2 magnitudes which suggests methane absorption would be extremely weak

#### 3. IMAGING – MAGELLAN

Imaging observations were obtained using the FourStar imaging camera (Persson et al. 2013) on the Magellan Baade telescope between March 10, 2012 and January 5, 2017. FourStar is a near-infrared mosaic imager with four 2048×2048 pixel detectors giving an imaging field of view of 11' on a side at a pixel scale of 0.159"/pixel. It is equipped with a set of intermediate-band filters, originally specified for the measurement of photometric redshifts. These filters turn out to be almost ideally suited for observing very cool brown dwarfs (see Fig.1 in Tinney et al. 2012). In particular, the J3 filter ( $\lambda_{cen} \approx 1.29 \,\mu\text{m}$ , 90% of peak throughput range 1.210-1.366  $\mu$ m) collects almost all of the "methane free" J-band flux from late-T and Y dwarfs, while the J2 filter ( $\lambda_{cen} \approx 1.14 \,\mu\text{m}$ , 90% of peak throughput range  $1.067-1.224 \mu m$ ) is strongly impacted by methane absorption between  $1.1 \,\mu\text{m}$  and  $1.2 \,\mu\text{m}$ . All the observations described here were performed with the WISE target positioned in FourStar's Chip 2.

Image quality over the course of this program varied between 0.4'' and 0.7'' (see Table 3). Our observing and analysis techniques follow those previously described by us (Tinney et al. 2012, 2014), and involve observing each target with the FourStar J3 and J2 filters in a sequence of 60-120s pseudo-randomly dithered exposures. Targets are observed with net integration times ranging from 5 minutes to 1.0h. As with the AAT data, images are processed at the telescope using a modified version of the ORACDR<sup>4</sup> data reduction pipeline, and examined during observing to determine whether a counterpart had been detected. As for the AAT data, the final analysis involves running ORACDR twice for each jitter set, with individual exposures of poor image quality removed from the list used in the second-pass.

Photometric processing and calibration followed the procedures outlined above for AAT data, except for the final stage of calibration onto the J2/J3 photometric system, which followed that outlined in Tinney et al. (2012). That is, 2MASS sources in the field-of-view were calibrated onto the  $J_{MKO}$  system, and we used this MKO photometry for stars in the range  $0.4 < (J-K)_{MKO} < 0.8$  to define the zero-point for the J2 and J3 magnitude system. Table 4 presents J2 and J3 photometry from Magellan, as well as WISE W1 and W2 photometry (as contained in the March 2012 WISE All-Sky data release).

WIS	Q

#### 4. IMAGING SUMMARY

The WISE candidates observed naturally fall into a few classes:

- (a) a bright (i.e. J < 19.5) object is readily detected as a positional match with the WISE source. In 100% of cases, these objects are subsequently confirmed by methane imaging as T dwarfs;
- (b) a fainter (i.e. 19.5 < J < 21.5) object is detected as a positional match that (in some cases) we have been able to verify is a T- or Y-dwarf using either methane imaging, or spectroscopy obtained on other telescopes in parallel with this methane imaging program);
- (c) either a fainter (i.e. 19.5 < J < 21.5) object is detected as a positional match with photometry that is inconsistent with this object being a T/Y dwarf, or we observe the object to be resolved in good imaging at Magellan indicating the WISE source is most likely a galaxy; or
- (d) no counterpart is detected down to  $J\sim21.5-22$  these could either be contaminant sources (i.e. non-cool-brown-dwarfs whose WISE photometry mimics those of brown dwarfs due to confusion, photometric scatter, etc) or cool brown dwarfs fainter than  $J\sim22$ .

Finding charts for objects newly identified as being a T- or Y-dwarfs are provided in Fig. 1. Figure 2 shows expanded images at the position of the new Y0 dwarf W1141-3326. These show how the 2012  $\rm CH_{4}s-CH_{4}l$  photometry for this object was contaminated by confusion with a background source. The images from 2014 (by which time W1141-2236 had moved  $\approx 2''$  to the west) show W1141-2236 clearly separated from this background source. It is also clear that in the 2012 images,  $\rm CH_{4}s$  is more contaminated that  $\rm CH_{4}l$  making  $\rm CH_{4}s-CH_{4}l$  more

positive than it should be. We therefore exclude W1141-3336 from our updated  $CH_4s-CH_4l$ -to-spectral-type calibration in §6.1.

#### 4.1. Brown dwarf proper motions

Figure 1 highlights the complicating factor of proper motion when seeking to identify cool brown dwarfs. The charts for W2049-4431, W2159-4808, W1112-3857 and W1141-3326 (for example) all show substantial motion between the epoch of the *WISE* detection (mean *WISE* epochs are in the range 2010 Apr-Jun for these four targets) and the epoch of follow-up (from 2011 Sep to 2017 Jan).

The observed motions of our new WISE T and Y dwarfs are summarised in Table 5. We obtained astrometry for our J, CH<sub>4</sub>s, or J3 images by cross-matching against the 2MASS PSC and relying on WISE and the PSC being on the same co-ordinate system. The individual positional uncertainty of the WISE objects (0.3-0.5'') is the dominant source of uncertainty, so this is a good assumption. Note that we distinguish between the "apparent" motion of our targets from just two epochs as observed by WISE and our IRIS2 or FourStar follow-up imaging (here denoted  $\mu'$ ), and the true proper motion from an astrometric solution that includes parallax. The large WISE position uncertainties mean that the uncertainty in the right ascension and declination components of  $\mu'$  are very similar, so only a single uncertainty is quoted for both in the Table. This uncertainty includes an additional term added in quadrature of 100 mas to account for possible parallax motion not being accounted for in objects that could be as close as 10 pc away. Five of these brown dwarfs are the subject of our on-going astrometric program with FourStar, so we provide preliminary proper motion solutions (in this case including a parallax solution) for comparison. In each case the solutions agree, although the FourStar

astrometric solutions are between 10 and 20 times better than the WISE –IRIS2/FourStar estimates.

Motions of  $0.5'' \, \mathrm{yr}^{-1}$  are not uncommon, and the motions observed for the most rapidly moving brown dwarfs (W0032-4946  $\sim 1.5'' \, \mathrm{yr}^{-1}$ , W2159-4808  $\sim 1.4'' \, \mathrm{yr}^{-1}$ , W1141-3326  $\sim 0.95'' \, \mathrm{yr}^{-1}$  W1112-3857  $\sim 0.9'' \, \mathrm{yr}^{-1}$ , W2049-4431  $\sim 0.7'' \, \mathrm{yr}^{-1}$ ) highlight how identification via "blind" spectroscopy becomes substantially more difficult after just a few years. After 5 years the positional error box that must be searched can be as large as 20" on a side, and can contain multiple objects that would have to be spectroscopically observed in turn to find the correct T/Y-dwarf. In this situation methane imaging becomes an even more powerful tool to pick out the correct counterpart.

#### 5. OBSERVATIONS – SPECTROSCOPY

Follow-up spectroscopy is the "gold standard" for confirming a T- or Y-dwarf identification. Spectroscopic observations have therefore been carried out by members of the *WISE* Science Team brown dwarf collaboration on a variety of telescopes in parallel with our imaging program at the AAT and Magellan. We report here spectroscopy obtained on multiple nights between 2011 Sep 8 and 2017 Jan 05 (Table 6).

#### 5.1. Magellan/FIRE

The Folded-port Infrared Echellette (FIRE; Simcoe et al. 2008, 2010) at the 6.5m Walter Baade Telescope on Cerro Manqui at the Las Campanas Observatory, Chile, uses a 2048×2048 HAWAII-2RG array. In prism mode, it covers a wavelength range from 0.8 to  $2.5\,\mu\mathrm{m}$  at a resolution ranging from R=500 at J-band to R=300 at K-band for a slit width of 0.6". FIRE was used to obtain spectroscopy of T dwarf candidates on the nights listed in

a WISE designations follow Table 2

Table 6. FIRE reductions in this paper were carried out in two ways. Roughly half the spectra were processed in the same manner as the spectroscopy presented in Tinney et al. (2012) using the Figaro data reduction package, with telluric removal carried out using A0 spectra acquired immediately before or after the science target at similar airmass. Remaining objects were processed using the FIREHOSE package

for low-dispersion data following the procedure in the online "cookbook" <sup>5</sup>. For our faintest objects, pair subtraction prior to insertion into the pipeline greatly improved the accuracy of the sky-line fitting procedure. The combined spectrum was then corrected for telluric absorption and flux calibrated using observations of an A0 V star and the technique described in Vacca et al. (2003) and the XTELLCOR program from SpeXtool (see Cushing et al. 2004).

# 5.2. Keck/NIRSPEC

The Near-Infrared Spectrometer (NIRSPEC; McLean et al. 1998, 2000) at the 10m W. M. Keck Observatory on Mauna Kea, Hawaii, was used to obtain confirmation spectroscopy of several new T dwarfs. For spectroscopy, NIRSPEC uses a  $1024\times1024$  InSb array. The NIRSPEC observations employed the  $42''\times0''.57$  slit, providing a resolution R $\sim$ 1500. Our brown dwarf candidates were observed in the N3 configuration (see McLean et al. 2003) that covers part of the J-band window from 1.15 to 1.35  $\mu$ m. Data reduction made use of the publicly available REDSPEC package, with modifications to remove residuals from the sky-subtracted pairs prior to 1-D spectral extraction.

# 5.3. IRTF/SpeX

SpeX is a medium-resolution spectrograph and imager at NASA's 3m Infrared Telescope Facility (IRTF) on Mauna Kea, Hawai'i. It uses a  $1024\times1024$  InSb array for its spectroscopic observations (Rayner et al. 2003). We used the prism mode with a 0.5 wide slit to achieve a resolving power of  $R \equiv \lambda/\Delta\lambda \approx 150$  over the range 0.8-2.5  $\mu$ m. A series of 200s exposures were typically obtained at two different positions along the 15″ long slit. A0 dwarf stars were observed soon after or before the target

 $<sup>^{\</sup>it b}$  Data processing carried out with FIREHOSE package as described in the text.

 $<sup>^{</sup>c}$  Data processing carried out with Figaro package as described in the text.

<sup>d These are the same spectra used to obtain spectral types by Kirk-patrick et al. (2012), albeit independently classified in this paper (Fig. 3). In both cases we obtain the same types as Kirkpatrick et al.</sup> 

 $<sup>^5</sup>$  See http://www.mit.edu/people/rsimcoe/FIRE/ob\_data.htm for details.

and at similar airmass, and used for telluric correction and flux calibration. A set of exposures of internal flat field and argon arc lamps were obtained for flat fielding and wavelength calibration.

The data were reduced using Spextool (Cushing et al. 2004) the IDL-based data reduction package for SpeX. The raw images were first corrected for non-linearity, pair subtracted, and then flat fielded. For some of the fainter sources, multiple pair-subtracted images were averaged in order to facilitate tracing. The spectra were then optimally extracted (e.g., Horne 1986) and wavelength calibrated using the argon lamp exposures. Multiple spectra were then averaged and the resulting spectrum was corrected for telluric absorption and flux calibrated using observations of an A0 V star using the technique described in Vacca et al. (2003).

# 5.4. Spectral Types

The objects listed in Table 6 were spectrally classified using the near-infrared T0-to-T8 dwarf sequence of Burgasser et al. (2006), extended to later T and Y dwarfs by Cushing et al. (2011) and Kirkpatrick et al. (2012). (See Table 7 for the specifically adopted standard spectra). Assignment of types was performed by overplotting these standards onto the candidate spectra and determining by-eye which standard provided the best match. In some cases two adjacent standards, such as T8 and T9, provided an equally good match, so the candidate spectrum was assigned an intermediate type (in this example, T8.5). In Figure 3 we show the near-infrared spectra for all of our sources compared with the relevant spectral standard. We consider these types to have an uncertainty of  $\pm 0.5$  subtypes. Types which are more uncertain due to low signal-to-noise-ratio spectra (i.e.  $\pm 1$  sub-type) are marked with a

Table 7. Adopted Spectral Standards.

colon ":" next to the spectral type.

#### 6. DISCUSSION

# 6.1. An Updated CH<sub>4</sub>s-CH<sub>4</sub>l Spectral Type Calibration

Tinnev et al. (2005) have presented a calibration between the IRIS2 CH<sub>4</sub>s-CH<sub>4</sub>l colour and spectral type. Cardoso et al. (2015) have used very similar filters on the NICS instrument on the Telescope Nazionale Galileo and derived a calibration using the same functional form as Tinney et al. (2005), but with slightly different values. With the additional methane imaging data for later-type objects available in Table 2 we have updated this calibration to derive the relation shown in the upper panel of Fig. 4. A relation with a simple functional form (like that used by Tinney et al.) proved to be impossible to obtain, and so we have instead used a spline calibration, which we present as the sequence shown in Table 8. The scatter about this calibration over the whole spectral type range is 0.11 mag. More importantly for the use of CH<sub>4</sub>s-CH<sub>4</sub>l colours to estimate spectral types, the slope of the relation for types beyond T5 is very steep, so that typical measurement errors of  $\pm 0.1$  mags in the colour map

**Figure 3.** T and Y dwarf spectra listed in Table 6 plotted to demonstrate spectral classifications derived as described in the text. Each new spectrum *(black lines)* is over plotted with the relevant spectral standard *(magenta lines)*.

into uncertainties in spectral type estimates of less than  $\pm 0.3$  sub-types for all objects later than T5. We therefore adopt an uncertainty for our estimated T and Y types in Table 2 of better than 0.5 sub-types.

The lower left panel of Fig. 4 shows an expanded version of this plot, along with the calibration relations due to Tinney et al. (2005) and Cardoso et al. (2015). The authors of the

latter have already noted that their calibration is systematically redder (in  $CH_4s-CH_4l$ ) for a given spectral type than the earlier calibration. Examination of their Fig. 4 suggests that this may be due to either a fortuitous observation of a sample of objects lying above the sequence of Tinney et al. (2005), or a systematic difference in the colour terms driven by the optics of NICS on the Telescopio Nazionale Galileo, or both. (The filters and detectors in both IRIS2

and NICS are identical, so the only the rest of the optical train can plausibly produce this difference.) The addition of further very late objects in our new sample of T and Y dwarfs brings our new calibration and that of Cardoso et al. (2015) into much closer alignment for all objects later than T7, while the differences at earlier types now seem consistent with cosmic scatter about the calibration.

The lower right panel of Fig. 4 plots the resulting estimated spectral types against actual spectral types, for objects from both this paper and Tinney et al. (2005). In the vast majority of cases the estimated spectral types predicted based on CH<sub>4</sub>s-CH<sub>4</sub>l colour are in line with the spectroscopic types – 70% of the objects plotted have estimated types agreeing with their observed types to within  $\pm 0.5$  types, and 91% agree to within  $\pm 1$  type. The most prominent exception is W1141-3326, which (as already noted) was found to be *much* later when a spectrum was acquired (Y0), than predicted (T5), due to confusion with a background object. Of the 5 objects observed to deviate by more than 1 whole spectral type from their predicted type, four are in the sense that the observed type was *later* than predicted. Indeed only one of 53 objects was found to be earlier than predicted by more than a whole spectral type, which reinforces the power of these filters for robustly and rapidly identifying (and approximately typing) T- and Y-type dwarfs – if imaging detects a methane absorption signature in an unresolved object (i.e. not a galaxy) near the position of a WISE or 2MASS candidate object, then it is almost certainly a legitimate match with the WISE or 2MASS candidate, making it a T or Y dwarf. If the estimated type that results is in "error" it is more likely to predict the object to be earlier, rather than later. (A similar result was found by Cardoso et al. 2015). These results give us confidence in the T dwarf iden-

Table 8. CH<sub>4</sub>s-CH<sub>4</sub>l versus Spectral Type

$\operatorname{SpT}$	CH <sub>4</sub> s-CH <sub>4</sub> l	$\operatorname{SpT}$	CH <sub>4</sub> s-CH <sub>4</sub> l	$\operatorname{SpT}$	CH <sub>4</sub> s-CH <sub>4</sub> l

tifications even for the eight T dwarfs in Tables 2 & 4 for which spectroscopy has not yet been obtained.

#### 6.2. J3-J2 versus Spectral Type

To observe fainter cool dwarfs (i.e.  $J\gtrsim21$  candidates where methane observations in the H-band with  $CH_4s, CH_4l$  filters on the 4m AAT became problematic) we made use of methane sensitive filters in the J-band (i.e. the J3 and J2 filters installed in FourStar). These J-band filters see a substantially lower sky background than the equivalent H-band filters, while the blue colours of late T and Y dwarfs mean they see essentially the same flux as in the H-band. This combination makes it feasible to target fainter objects down to  $J\sim22-24$  – and in one extreme case to  $J3\sim25$  (Faherty et al. 2014).

We take this opportunity to note that the faintest ground-based near-infrared detection of a Y-dwarf (WISE J085510.83-071442.5 at J3=24.8<sup>+0.5</sup><sub>-0.35</sub>) reported by Faherty et al. (2014) has been the subject of some debate (Schneider et al. 2016b; Luhman & Esplin 2016). The claimed discrepancy here is almost certainly not real, but rather a result of issues associated with conversion to a standard MKO J passband from

Figure 4. Upper panel – Methane-sensitive  $CH_4s-CH_4l$  as a function of A-Y spectral type. The uncertainties plotted are the combination of photon-counting uncertainties, aperture correction uncertainties and photometric calibration uncertainties. Typical uncertainties on spectral types (not plotted) are  $\pm 0.5$ . The plotted parametrisation is a spline constrained at the locations in Table 8. Root-mean-square (rms) scatter about the parametrisation is 0.18 mag for the whole range, 0.06 mag for L0-T2 dwarfs and 0.12 mag for T3-T8 dwarfs, and 0.45 mag for T9-Y0 dwarfs. The corresponding spectral type scatters are 0.6 sub-type for L0-T2 dwarfs and 0.43 sub-type for T3-T8 dwarfs, and 0.6 sub-type for T9-Y0 dwarfs. Lower right panel – Upper panel zoomed in on the T and Y dwarf region, with the previously published calibration relations due to Tinney et al. (2005) and Cardoso et al. (2016) also shown. Lower left panel – Comparison of the predicted spectral types from this  $CH_4s-CH_4l$  relation with observed spectral types (solid circles - Tinney et al. (2005); solid stars – this paper).

the measured bandpasses (in order of decreasing width): HST filter F125W 1.10-1.40  $\mu$ m for Schneider et al.; J3=1.21-1.37  $\mu$ m for Faherty et al.; and HST filter F127M 1.24-1.31  $\mu$ m for Luhman & Esplin. Faherty et al. measured  $J3=24.8^{+0.5}_{-0.35}$ , following which Schneider et al. reported F125W= $26.41\pm0.27$  and Luhman & Esplin a mean value of F127M= $24.45\pm0.1$  from 3 observations (all Vega-magnitudes). When one considers the different bandpasses, these magnitude differences make sense. F125W includes substantial water vapour and methane absorption in its wider band-pass than J3. So the F125W Vega-magnitude should be fainter In turn J3 includes slightly more than J3. molecular absorption than F127M, which selects out a Y-dwarf flux peak. The significant "discrepancy" that Schenider et al. note with the result of Faherty et al. is not in the observed detections in these three bands, but rather in J magnitudes derived after conversion from the measured bandpass. For the Faherty et al. J3 detection, this was done using an empirical colour correction based on (hotter) T and Y dwarfs, which is clearly not appropriate for this very cool object.

We have J2 and J3 photometry for a smaller range of spectral types than we have  $CH_4s$  and  $CH_4l$  – i.e. only spanning T5.5 to Y1. These data are plotted in the upper panel of Fig. 5. Recalling that our J3–J2 system is defined so that objects in the A-G spectral type range will have J3–J2=0, the observation of a significantly negative J3–J2 colour does clearly distinguish T and Y dwarfs from much hotter field stars. The simple linear fit to these data in the figure is parametrised as a function of a modified numeric spectral type n', such that n' = n - 60 (making n' = 4 equivalent to a Y0), as

$$J3 - J2 = -1.12 - 0.097 n'$$

with rms scatter of 0.19 mag.

Unfortunately, it would appear that the ability to observe fainter targets in J3/J2 comes at the penalty of obtaining less information on the spectral types of those objects. The J3-J2 colour appears to "saturate" at  $J3-J2 \approx -1.5$ for late-T and Y dwarfs – a range of spectral types over which CH<sub>4</sub>s-CH<sub>4</sub>l continues to become more-and-more negative for later objects. Moreover Y dwarfs are only  $\sim 0.5$  magnitudes more negative in J3-J2 than mid-T dwarfs, and the scatter about any trend is substantial at  $\pm 0.18$  mag. The equivalent numbers for CH<sub>4</sub>s-CH<sub>4</sub>l are  $\sim 3$  mag and  $\pm 0.45$  mag. This means that while J3-J2 can unequivocally identify a very cool brown dwarf's near-infrared counterpart (given the prior information that a cool dwarf is expected at that position from a large survey like WISE), it cannot provide a very good estimate of how cool that brown dwarf is.

### 6.3. J3-W2 versus Spectral Type

However, all is not lost, because the ability of J3–J2 to unequivocally associate a near-infrared source with a WISE thermal-infrared one, means that its J3–W2 colour is therefore determined. J3–W2 is primarily sensitive to effective temperature by sampling stellar flux in gaps between the strongest molecular absorptions over a long wavelength baseline, as has already been shown for J–W2 by Cushing et al. (2011) and Kirkpatrick et al. (2012) – as distinct to the methane colours  $CH_4s-CH_4l$  and J3-J2 which are sensitive to effective temperature by measuring the strength a specific molecular absorption.

As the lower panel of Fig. 5 demonstrates, J3-W2 shows a pronounced trend with spectral type, and while the scatter about a quadratic fit to these data is substantial (we again parametrise this fit as a function of a modified numeric spectral type n' such that n' = n - 60

**Figure 5.** Upper panel – Methane-sensitive J3–J2 as a function of T5.5-Y1 spectral type. The uncertainties plotted are the combination of photon-counting uncertainties, aperture correction uncertainties and photometric calibration uncertainties. Typical uncertainties on spectral types (not plotted) are  $\pm 0.5$ . The plotted linear fit is described in  $\S 6.2$ , and has rms  $0.19\,\mathrm{mag}$ .

Lower panel – Temperature-sensitive J3–W2 as a function of T5.5-Y1 spectral type. Along with the objects in Table 4, we also show nine objects with J3 and W2 (but without J2) from Tinney et al. (2014). The uncertainties are as for the upper panel. The plotted parametrisation is a quadratic fit described in §6.3, with rms 0.65 mag.

meaning a Y0 dwarf has n' = 4)

$$J3 - W2 = 1.99 + 0.4090 \, n' + 0.12313 \, n'^2$$

with rms=0.65 mag, it also spans a large range in J3-W2 of over 5.5 mag. This means that its discriminating power for assigning an es-

Figure 6. Temperature-sensitive  $CH_4s-W2$  as a function of T6-Y0 spectral type. Uncertainties are as for Figure 5. The plotted parametrisation is a quadratic fit described in §6.3, with rms 0.60 mag.

timated spectral type is similar to that of the CH<sub>4</sub>s-CH<sub>4</sub>l colour over this spectral type range. For convenience we show the value of this parametrisation as a function of spectral type in Table 9.

In Figure 6 we show the equivalent plot to the lower panel of Figure 5, but based on  $CH_4s-W2$  colour instead of J3-W2.  $CH_4s-W2$  colour has a similar "lever arm" on spectral type as J3-J2, spanning a smaller range in colours (3.5 mag.), with a slightly smaller rms of 0.60 mag. The equivalent polynomial fit is

$$CH_4s - W2 = 2.13 + 0.00519 n' + 0.20357 n'^2$$
.

It is important to note, however, that observation of a candidate WISE counterpart in J3 or CH<sub>4</sub>s (or indeed J or H) alone is not sufficient to make a cool brown dwarf identification. J2 or CH<sub>4</sub>l is essential to obtain a clear identification of methane absorption. Without that identification, the association of a chance (usually faint) background source will invariably result in a large, but completely spurious, J3-W2 or CH<sub>4</sub>s-W2 colour. Both J3 and J2 methane sensitive bands are to identify a near-

infrared, methane-absorbing counterpart, following which J3-W2 or CH<sub>4</sub>s-W2 can provide an estimate of how cool that object is.

#### 6.4. New Y Dwarfs

W0302-5817 is one of two new Y dwarfs presented for the first time in this paper. Its spectrum (obtained in 2017 Jan) is of low signalto-noise but does clearly indicate a Y0 spectral type. This allows us to make a distance estimate using both its J3 and W2 photometry. The mean correction between  $J_{MKO}$  and J3 for cool dwarfs  $(J_{MKO}-J3 = 0.20\pm0.03)$  and the median  $J_{MKO}$  absolute magnitude for Y0 dwarfs  $2014, M_J = 20.32 \pm 1.25, giving$ (Tinney et al. a median  $M_{J3}=20.12\pm1.25$ ), gives a distance for W0302-5817 lying in the range 24-7.5pc. A better estimate can be obtained using W2 (the median absolute magnitude for a Y0 has much lower scatter –  $M_{W2} = 14.65 \pm 0.35$ ), which predicts  $d=17.5\pm3.5$  pc. This places W0302 on the outer edge of the 20 pc sample of nearby brown dwarfs.

W1141-3326 is the second new Y dwarf presented here. As noted earlier, despite being observed with CH<sub>4</sub>s,CH<sub>4</sub>l filters in mid-2012, it took some time to obtain spectra for this object, because confusion with background sources meant its CH<sub>4</sub>s-CH<sub>4</sub>l colour was that of a mid-T dwarf, and so it was not made a high priority 2). A high quality spectrum was (see Fig. eventually obtained in 2014 March, and it is an excellent match to the template Y0 spectrum. W1141-3326's W2 photometry indicates a likely distance in the range 11.4-8.0 pc. This is a distance fully consistent with the preliminary trigonometric distance presented in Tinney et al. (2014) of  $9.5\pm0.4$  pc.

Both W1141-3326 and W0302-5817 are targets of our on-going parallax program with FourStar on the Magellan Baade telescope (Tin-

ney et al. 2014).

# 6.5. Comparison with Extant Spectroscopy

Table 10 compares previously published spectral types for objects where we present new spectra, as well as objects where we identify the object as a T dwarf but do not have spectroscopy. For W1433-0837 and W1448-2534 we obtain the same spectral types from completely independent spectra and typing processes, while for W2212-6931 we obtain a type different by only 0.5 sub-types, which we consider to be consistent - especially as examination of Fig. 8 in Schneider et al. (2015)suggests that W2212-6931 has the narrowest  $1.3 \,\mu \text{m}$  peak of of all the T9 objects shown, and so is possibly the closest to T9.5 in that group on their classification system.

We have not been able to obtain a spectrum for W0404-6420, and the T9 classification of Schneider et al. (2015) is 2 sub-types later from that estimated by our CH<sub>4</sub>s-CH<sub>4</sub>l photometry. This is 3-4 times larger larger than the 0.43-0.6 sub-type scatters observed in our calibration (Fig. 4), which reinforces our view that while a methane absorption detection is robust for identifying a cool brown dwarf, and the colour provides an estimate of the spectral type, spectroscopy remains the "gold standard" for a firm classification.

#### 7. CONCLUSION

Our results show that – despite using a modest 4m-class telescope like the AAT on targets at  $J\sim20$  – methane imaging is an effective technique for refining cool dwarf candidate lists arising from an external survey. These are magnitudes at which near-infrared spectroscopy on a 4m telescope would be almost impossible, or at least prohibitively expensive. Methane imaging observations make both identifications and

Table 10. Comparison with Extant Spectroscopy

Object	CH <sub>4</sub> s-CH <sub>4</sub> l "Type"	SpT (this paper)	SpT (other)	Reference
W0404-6420	$T7.1 \pm 0.5$		Т9	Schneider et al. 2015
W1055 - 1652	> T8.2	$T9\pm0.5$	T9.5	Martin et al. 2018
W1433 - 0837	• • •	$T8\pm0.5$	Т8	Lodieu et al. 2012
W1448 - 2534	$T6.4 \pm 0.5$	$T8\pm0.5$	Т8	Thompson et al. 2013
W2212 - 6931	$Y0.2 {\pm} 0.5$	$T9.5 \pm 0.5$	T9	Schneider et al. 2015

first-estimates of the spectral type in a single observation – without having to obtain spectra for the multiple candidate targets that can usually be found in the substantial positional error boxes that arise from a survey like WISE.

2.52

Cool brown dwarfs from a large area, but shallow, survey like WISE will reside quite close to the Sun, and almost invariably have significant proper motions. As such the position error box to search in a follow-up program grows with time. Indeed it has been our experience, that substantial proper motions (i.e. > 0.2''/year) are so ubiquitous for WISE brown dwarfs, that once follow-up extended more than a few years beyond the baseline of the WISE mission, any objects which do positionally match with the WISE source to better than about half an arcsecond, are invariably found to not be cool brown dwarfs, but rather background sources.

We have shown that methane imaging observations – either in the H-band using CH<sub>4</sub>s & CH<sub>4</sub>l filters or in the J-band using J2 & J3 filters - can rapidly and efficiently identify and pre-

liminarily classify cool brown dwarf candidates that arise from large, all-sky surveys like WISE.

We have presented data identifying 21 new T dwarfs and 2 new Y dwarfs from the WISE All-Sky Survey using methane imaging (in addition to the Y dwarf W1639 previously published by Tinney et al. 2012). In many cases these identifications were made for objects using a 4m-class telescope (the AAT) for objects at J≥20 – magnitudes at which near-infrared spectroscopy on such a telescope would be either impossible or prohibitively expensive.

We present a further 5 late T dwarfs (W0309-5016, W0628-8057, W2017-3421, W2211-4758) and 3 early T dwarfs (W0042-5840, W2302-7134, W2354-8140) with methane identifications, for which typing spectroscopy is required.

CGT gratefully acknowledges the support of ARC Australian Professorial Fellowship grant DP0774000 and ARC Discovery Outstanding Researcher Award DP130102695. We are grate-

ful for the extraordinary support we have received from the AAT's technical staff – K. Fiegert, Y. Kondrat, S. Lee, R. Paterson, and D. Stafford. Australian access to the Magellan Telescopes was supported through the National Collaborative Research Infrastructure Strategy of the Australian Federal Government. Travel support for Magellan and AAT observing was provided by the Australian Astronomical Observatory.
