We introduce an extension of the Kitaev honeycomb model by including four-spin interactions that preserve the local gauge structure and hence the integrability of the original model. The extended model has a rich phase diagram containing five distinct vison crystals, as well as a symmetric π -flux spin liquid with a Fermi surface of Majorana fermions and a sequence of Lifshitz transitions. We discuss possible experimental signatures and, in particular, present finite-temperature Monte Carlo calculations of the specific heat and the static vison structure factor. We argue that our extended model emerges naturally from generic perturbations to the Kitaev honeycomb model.

Introduction. The famous Kitaev model on the honeycomb lattice [1] is an exactly solvable yet experimentally realistic model of a quantum spin liquid. In contrast to more conventional magnetic phases, quantum spin liquids retain extensive (quantum) fluctuations all the way down to zero temperature [2], where the spins appear to fractionalize into deconfined "spinon" quasiparticles coupled to appropriate gauge fields [3].

The Kitaev model is approximately realized in a family of strongly spin-orbit-coupled honeycomb materials, where its anisotropic spin interactions emerge between effective J = 1/2 angular momenta in the t_{2q} orbitals of 4d or 5d ions [4–7]. To determine the most accurate microscopic spin models for these Kitaev materials, including $(Na,Li)_2$ IrO₃ [8–16] and α -RuCl₃ [17–30], various extensions of the Kitaev model have been considered and analyzed with a wide range of techniques [31-51]. While these models are experimentally realistic and have rich phase diagrams in the classical limit, it is challenging to identify and characterize quantum phases in them. For a start, the honevcomb lattice may harbor many different quantum spin liquids [52, 53], and the Kitaev spin liquid, captured by the Kitaev model, is only one among these many candidates. In addition, a quantum spin liquid may also remain "hidden" by appearing on top of classical symmetry-breaking order [54].

From a more phenomenological point of view, the lowenergy physics of the Kitaev spin liquid is described by Majorana fermions (spinons) with Dirac nodes, coupled to an emergent \mathbb{Z}_2 gauge field [1]. At each plaquette of the honeycomb lattice, the \mathbb{Z}_2 gauge field may form a π flux, corresponding to a "vison" excitation. In turn, the presence of such a vison affects the kinetic energy of the spinons via the Berry phase π picked up by each spinon moving around it. For the pure Kitaev model, the spinons are governed by a nearest-neighbor hopping problem (cf. electrons in graphene) and, due to the lack of frustration, the ground state has no visons at any plaquettes [1, 55]. However, if the hopping problem is frustrated by competing hopping amplitudes, the presence of a vison may reduce the frustration and thus lower the kinetic

FIG. 1. Extended Kitaev model. (a) Honeycomb lattice with two sublattices A and B (black and white dots), three bond types x, y, and z (red, green, and blue bonds), and the sitelabeling convention around a plaquette p. (b)-(c) Representative (orange) paths $\langle ijkl \rangle_{yzx}$ (b) and $\langle ijkl \rangle_{yzy}$ (c) associated with the K_3 and K'_3 terms in Eq. (2), respectively; four-spin interactions along such paths give rise to Majorana hopping from any site i to all its third neighbors [59], as indicated by the dashed arrows. For the path $\langle ijkl \rangle_{yzx}$ (b), the symmetryrelated path $\langle ij'k' l \rangle_{xzy}$ is marked by blue.

energy of the spinons. Such a frustration in the hopping amplitudes is known to stabilize crystals of topological solitons, such as baby skyrmions or merons, in itinerant magnets [56–58], and one may thus expect it to stabilize analogous vison crystals in the Kitaev spin liquid.

In this Letter, we extend the Kitaev model by including four-spin interactions that preserve the exact solution of the model and emerge naturally from generic perturbations. By introducing frustrated further-neighbor hopping for the Majorana fermions, these additional interactions stabilize a rich variety of vison crystals, as well as a symmetric π -flux spin liquid with a vison at every plaquette. Interestingly, the π -flux spin liquid exhibits a Fermi surface of Majorana fermions undergoing two subsequent Lifshitz transitions. On a technical level, we first use a simple variational treatment to compute the zerotemperature phase diagram of our extended model. The validity of this approach is then confirmed by unbiased Monte Carlo (MC) simulations that also reveal the finite melting temperatures of the vison crystals.

Model. We consider a generalized Kitaev Hamiltonian

³Neutron Scattering Division and Shull-Wollan Center,

on the honeycomb lattice:

$$\mathcal{H} = \mathcal{H}_{K_1} + \mathcal{H}_{K_3},\tag{1}$$

where $\mathcal{H}_{K_1} = -K_1 \sum_{\langle ij \rangle_{\alpha}} \sigma_i^{\alpha} \sigma_j^{\alpha}$ is the usual [1] isotropic Kitaev Hamiltonian with ferromagnetic $(K_1 > 0)$ Ising interactions between the spin components σ^{α} along each $\alpha = \{x, y, z\}$ bond $\langle ij \rangle_{\alpha}$ [see Fig. 1(a)], and

$$\mathcal{H}_{K_3} = K_3 \sum_{\langle ijkl \rangle_{\alpha\beta\gamma}} \sigma_i^{\alpha} \sigma_j^{\gamma} \sigma_k^{\alpha} \sigma_l^{\gamma} - K_3' \sum_{\langle ijkl \rangle_{\alpha\beta\alpha}} \sigma_i^{\alpha} \sigma_j^{\gamma} \sigma_k^{\gamma} \sigma_l^{\alpha},$$
(2)

where $(\alpha\beta\gamma)$ is a permutation of (xyz) in each term, and $\langle ijkl\rangle_{\alpha\beta\gamma}$ is a path of length 3 consisting of bonds $\langle ij\rangle_{\alpha}$, $\langle jk\rangle_{\beta}$, and $\langle kl\rangle_{\gamma}$. Each term in \mathcal{H}_{K_3} is the product of the three terms in \mathcal{H}_{K_1} that correspond to the three bonds along the appropriate path. Different K_3 and K'_3 terms are related by space-group symmetries, simultaneously transforming the lattice and the spins; particular examples of their respective paths, with $(\alpha\beta\gamma) = (yzx)$, are depicted in Figs. 1(b) and 1(c). We remark that, for each path $\langle ijkl\rangle_{\alpha\beta\gamma}$ going around one "half" of a hexagon, connecting opposite vertices i and l, there is a symmetry-related path $\langle lk'j'i\rangle_{\alpha\beta\gamma} = \langle ij'k'l\rangle_{\gamma\beta\alpha}$ going around the other "half" of the hexagon [see Fig. 1(b)].

Importantly, the exact solution of \mathcal{H}_{K_1} [1] is preserved by the additional terms in Eq. (2). Indeed, since \mathcal{H} commutes with the flux operator $W_p = \sigma_1^x \sigma_2^y \sigma_3^z \sigma_4^x \sigma_5^y \sigma_6^z$ at each plaquette p [see Fig. 1(a)], one can identify static \mathbb{Z}_2 flux or "vison" degrees of freedom at these plaquettes, each being present (absent) if the corresponding W_p takes eigenvalue -1 (+1). Following the Majorana fermionization $\sigma_i^\alpha = ib_i^\alpha c_i$, the Hamiltonian takes the form [60]

$$\begin{aligned} \mathcal{H} &= iK_1 \sum_{\langle ij \rangle_{\alpha}} u_{ij}^{\alpha} c_i c_j + iK_3 \sum_{\langle ijkl \rangle_{\alpha\beta\gamma}} u_{ij}^{\alpha} u_{kj}^{\beta} u_{kl}^{\gamma} c_i c_l \\ &+ iK_3' \sum_{\langle ijkl \rangle_{\alpha\beta\alpha}} u_{ij}^{\alpha} u_{kj}^{\beta} u_{kl}^{\alpha} c_i c_l \,, \end{aligned}$$
(3)

where $u_{ij}^{\alpha} = -u_{ji}^{\alpha} \equiv i b_i^{\alpha} b_j^{\alpha}$ is a \mathbb{Z}_2 gauge field along the α bond $\langle ij \rangle_{\alpha}$. Since these gauge fields are conserved quantities, $u_{ij}^{\alpha} = \pm 1$, providing a redundant description of the conserved gauge fluxes, $W_p = u_{12}^z u_{32}^x u_{34}^y u_{54}^z u_{16}^x = \pm 1$, Eq. (3) is quadratic in the Majorana fermions c_i , thus giving rise to free fermion ("spinon") excitations after a straightforward diagonalization [60]. From the perspective of the Majorana fermions, the K_1 terms describe first-neighbor hopping, while the additional K_3 and K'_3 terms describe third-neighbor hopping [59].

In analogy with how three-spin interactions may be obtained from a Zeeman field [1], the four-spin interactions in Eq. (2) can in principle be generated by a perturbative treatment of Heisenberg and/or symmetric off-diagonal (Γ) interactions on top of the pure Kitaev model. Taking a more universal approach and considering Eq. (3) as an effective low-energy theory for the Majorana fermions

FIG. 2. Phase diagram of the extended Kitaev model. Flux configurations of distinct vison crystals (colored phases) are depicted in separate panels; the presence (absence) of a flux is marked at each plaquette by gray (white) filling.

[61], we know that generic time-reversal-symmetric perturbations to \mathcal{H}_{K_1} must generate all Majorana terms that are consistent with the projective symmetries of the Kitaev spin liquid [53]. Given that all interaction terms are irrelevant and second-neighbor hopping terms are forbidden by time reversal, Eq. (3) is the most natural effective theory beyond the pure Kitaev model.

Phase diagram. The ground state of \mathcal{H}_{K_1} belongs to the zero-flux sector, characterized by $W_p = +1$ for all p [1, 55]. In the presence of the additional interactions, however, the ground state may belong to a wide range of different flux sectors, as shown by the T = 0 phase diagram in Fig. 2. This phase diagram is obtained from a simple variational analysis, by comparing the energies of the seven flux sectors appearing in the diagram on finite lattices of 48×48 unit cells [62]. Furthermore, it is fully consistent with unbiased finite-temperature MC simulations, discussed in a later section [63].

We first concentrate on the two fully symmetric noncrystal phases occupying most of the phase diagram: the zero-flux phase, which has no fluxes at any plaquettes, and the π -flux phase, which has a \mathbb{Z}_2 flux at each plaquette. For $K_3 = K'_3 = 0$, the creation of each \mathbb{Z}_2 flux with $W_p = -1$ costs a finite energy $\Delta \approx 0.15K_1$, and the ground state thus belongs to the zero-flux sector. For $K_3/K_1 > 0$, the K_1 and K_3 terms in Eq. (3) give rise to a frustrated Majorana hopping and hence an increase in the ground-state energy. However, due to the two paths between any two opposite sites *i* and *l* around a plaquette *p* [see Fig. 1(b)], there are two equivalent hopping terms $\propto iK_3c_ic_l$ in Eq. (3), which interfere constructively for $W_p = +1$ and destructively for $W_p = -1$. Consequently, as K_3/K_1 is increased, fluxes are effective in relieving

FIG. 3. Majorana nodal structures (dark blue) in the various π -flux phases: the Dirac phase (a), the first Fermi phase (b), the Lifshitz transition between the two Fermi phases (c), and the second Fermi phase (d). In the presence of generic furtherneighbor Majorana hopping terms [59], each Fermi surface is gapped out into six Dirac points (red circles).

frustration from the Majorana hopping and thus become energetically favorable. Since the effective interaction between nearby fluxes is attractive for small K'_3/K_1 [1], the corresponding phase transition between the zero-flux and the π -flux phases is strongly first order.

Increasing K'_3/K_1 , one can modify this interaction and stabilize various intermediate phases with nontrivial flux configurations. Indeed, there are five distinct translationsymmetry-breaking vison-crystal phases in Fig. 2, with their ordering wave vectors Q corresponding to either the K point or the M point(s) of the Brillouin zone (BZ). The two $Q = Q_{\rm K}$ crystals have supercells of three plaquettes, containing one vison ("1/3 flux crystal") and two visons ("2/3 flux crystal"), respectively. Since there are three different M points, $\boldsymbol{Q} = \boldsymbol{Q}_{\mathrm{M}}$ crystals can exhibit single- \boldsymbol{Q} or multi-Q ordering. The single-Q crystal is a stripy configuration, corresponding to a supercell of two plaquettes containing one vison ("1/2 flux crystal"), while the two triple-Q crystals have supercells of four plaquettes, containing one vison ("1/4 flux crystal") and three visons ("3/4 flux crystal"), respectively.

Majorana problems. For the different ground-state flux sectors discussed above, distinct configurations of the gauge fields $u_{ij}^{\alpha} = \pm 1$ lead to different Majorana Hamiltonians in Eq. (3). Consequently, each phase in Fig. 2 has its own Majorana band dispersion and a corresponding density of states. The low-energy physics, giving rise to universal signatures in experiments, is determined by the nodal structures of the Majorana fermions. For the zeroflux phase, including the pure Kitaev model, as well as for the 1/4 and 3/4 flux crystals, the Majorana fermions are gapless at Dirac points and thus have linear density of states at low energies. For the 1/3 and 1/2 flux crystals, the Majorana fermions are fully gapped and thus have zero density of states below the energy gap. For the 2/3flux crystal, there are two disconnected phases where the Majorana fermions are gapless at Dirac points and fully gapped, respectively (see Fig. 2).

Interestingly, the Majorana fermions have more complex nodal structures in the π -flux phase. This phase is amenable to a full analytic understanding as, due to the perfect cancelation of all K_3 terms in Eq. (3), the Majorana problem has only one dimensionless parameter ratio $\kappa \equiv K'_3/K_1$. With a simple calculation [60], we find that there are in fact *three* distinct π -flux phases characterized by different Majorana nodal structures.

In particular, there is a π -flux phase where the Majorana fermions are gapless at Dirac points only, and another two π -flux phases where these Dirac points coexist with Fermi surfaces (i.e., nodal lines) of distinct topologies (see Fig. 3). The dashed lines in Fig. 2 indicate two subsequent Lifshitz transitions [64] separating these three phases as a function of increasing κ . For $\kappa < 1/5$, the only nodal structures are Dirac points. At the first Lifshitz transition, $\kappa = 1/5$, small pockets of Fermi surfaces appear around these Dirac points and gradually expand as κ is further increased. At the second Lifshitz transition, $\kappa = (\sqrt{2} - 1)/2 \approx 0.207$, these small pockets then connect with each other to form larger pockets. We remark that the Dirac points are located at exactly the same momenta for all values of κ .

Such a coexistence of Dirac points and Fermi surfaces is rather surprising and is not expected to be stable. Instead, due to the nature of the time-reversal and particlehole symmetries in the Majorana problem [65], one would anticipate only Dirac points to be generically present, as in all the other phases of Fig. 2. Indeed, we find that the Fermi surfaces exist due to the particular simplicity of the problem up to third-neighbor hopping terms [60] and that each Fermi surface is gapped out into six Dirac points (see Fig. 3) when generic fifth-neighbor hopping terms [59], respecting the projective symmetries of the system, are included in Eq. (3). However, assuming that such terms are small enough, *approximate* Fermi surfaces are still expected to be observable in experiments.

Experimental signatures. The phase diagram in Fig. 2 contains a rich variety of phases with all possible Majorana nodal structures in two dimensions, including Fermi surfaces, Dirac points, and fully gapped scenarios. Due to their distinct low-energy physics, these phases are characterized by different experimental signatures. First, we expect the low-temperature specific heat to behave as $C \propto T$ for Fermi phases, $C \propto T^2$ for Dirac phases, and $C \propto e^{-\Delta_v/T}$ for fully gapped phases, where the activated

FIG. 4. Dynamical spin structure factor $S_{zz}(\boldsymbol{q},\omega)$ [60] for the 1/3 flux crystal (a) and the 3/4 flux crystal (b) along the path M- Γ -K-M in the Brillouin zone [see inset of panel (a)] via the single-particle approximation of Ref. 69.

behavior should be controlled by the vison gap $\Delta_{\rm v}$ as it is actually smaller than the Majorana gap. Second, the various Majorana nodal structures may be distinguished by their low-energy fingerprints in spectroscopic probes, such as resonant inelastic x-ray scattering [66, 67]. Third, the Majorana Fermi surface in the π -flux phase leads to impurity-induced Friedel oscillations in the magnetic energy density [60]. In turn, such magnetic Friedel oscillations should be measurable with nuclear magnetic resonance (NMR) as they induce an oscillatory bond-length modulation via magnetostriction.

For the vison-crystal phases in Fig. 2, the spontaneous breaking of translation symmetry leads to further experimental signatures. First of all, due to magnetostriction, each vison crystal generates a characteristic bond-length modulation throughout the lattice, which can be picked up with NMR or elastic x-ray scattering. Moreover, the enlarged unit cell results in a larger number of distinct bands for the Majorana fermions and therefore, in contrast to the pure Kitaev model [68, 69], the dynamical spin structure factor [60], directly measurable by inelastic neutron scattering, has multiple peaks as a function of energy (see Fig. 4). Finally, unlike the fully symmetric phases, each vison-crystal phase has a finite-temperature phase transition at a critical temperature T_c .

Monte Carlo simulations. To verify the phase diagram in Fig. 2 and to extract the melting temperatures T_c of the vison crystals, we perform MC simulations of \mathcal{H} based on a Metropolis algorithm to update the "classical" \mathbb{Z}_2 fields $\{u_{ij}^{\alpha} = \pm 1\}$. The energy of each field configuration is computed by diagonalizing the quadratic Majorana Hamiltonian in Eq. (3) [70, 71] on $L \times L$ lattices with $L = \{6, 12, 18\}$ [60]. For each temperature, a single run contains 10000 MC sweeps for equilibration and another 20000 MC sweeps for measurement [72].

Figure 5 shows our results for the heat capacity C(T) and the static vison structure factor,

$$\rho_{\mathbf{v}}(\boldsymbol{k}) = \frac{1}{L^2} \sum_{p,p'} e^{i\boldsymbol{k}\cdot(\boldsymbol{X}_p - \boldsymbol{X}_{p'})} \langle W_p W_{p'} \rangle, \qquad (4)$$

for representative parameters of four different vison crystals, where X_p is the position of plaquette p, and k is the

FIG. 5. Temperature dependence of the specific heat and the appropriate static vison structure factor for (a) the 1/3 flux crystal with $K_3 = 0.165K_1$ and $K'_3 = 0.19K_1$, (b) the 1/4 flux crystal with $K_3 = 0.165K_1$ and $K'_3 = 0.22K_1$, (c) the 2/3 flux crystal with $K_3 = 0.165K_1$ and $K'_3 = 0.26K_1$, and (d) the 3/4 flux crystal with $K_3 = 0.19K_1$ and $K'_3 = 0.22K_1$ on $L \times L$ lattices (L = 6, 12, 18) containing $N = 2L^2$ sites.

ordering wave vector of each vison crystal, corresponding to either the K or the M point of the BZ. We first observe that, as for the pure Kitaev model, C(T) exhibits both a high- and a low-temperature peak, which correspond to spinon and vison excitations, respectively [70, 71]. However, the low-temperature peak signals the onset of visoncrystal ordering at $T = T_c$, as confirmed by the sharp growth of the corresponding Bragg peak in $\rho_{\rm v}(\mathbf{k})$. While the three lattice sizes $L = \{6, 12, 18\}$ do not facilitate a rigorous finite-size scaling analysis, the results in Fig. 5 suggest a first-order crystallization transition for all vison crystals, except for the 1/3 flux crystal [73]. Assuming that the transition into the 1/3 flux crystal is continuous, it is conjectured to be in the universality class of the two-dimensional 3-state Potts model, which in turn suggests that the height of the peak in $C(T)/L^2$ should be $\propto L^{\alpha/\nu}$ with critical exponents $\alpha = 1/3$, $\nu = 5/6$, and $\alpha/\nu = 2/5$ [74]. We note that, for each vison crystal, the critical temperature is $T_c \sim 10^{-2} K_1$.

Discussion. By considering a natural extension of the honeycomb Kitaev model, we have found a rich spectrum of novel spin-liquid phases that are *not* adiabatically connected to the original Kitaev model, including a fully symmetric π -flux spin liquid, and five distinct symmetry-breaking spin liquids with various degrees of vison crystallization. In the future, it would be interesting to study how an external magnetic field affects our spin liquids. For the Dirac phases, it may generate non-Abelian gapped spin liquids with distinct Chern numbers of the Majorana fermions [1]. For the gapped phases, it may lead to nontrivial finite-field phase transitions between topologically distinct spin liquids. We thank Arnab Banerjee, Hiroaki Ishizuka, and Johannes Knolle for useful comments on the manuscript. Supplemental Material

DERIVATION OF THE MAJORANA HAMILTONIAN

The spin Hamiltonian \mathcal{H} in Eq. (1) of the main text is exactly solvable by means of a standard procedure described in Ref. 1 of the main text. The first step is to introduce four Majorana fermions b_j^x , b_j^y , b_j^z , and c_j at each site j of the honeycomb lattice, and express the spin components $\sigma_j^{x,y,z}$ in terms of these Majorana fermions as

$$\sigma_j^x = ib_j^x c_j, \qquad \sigma_j^y = ib_j^y c_j, \qquad \sigma_j^z = ib_j^z c_j. \tag{S1}$$

Due to the resulting enlargement of the local Hilbert space, the four Majorana fermions must be reconciled with the original spin degree of freedom via the local gauge constraint

$$-i\sigma_j^x \sigma_j^y \sigma_j^z = b_j^x b_j^y b_j^z c_j = 1.$$
(S2)

In turn, the corresponding gauge redundancy means that the expressions in Eq. (S1) for the spin components are not unique; for example, one can use Eq. (S2) to obtain the following equivalent expressions:

$$\sigma_j^x = -ib_j^y b_j^z, \qquad \sigma_j^y = -ib_j^z b_j^x, \qquad \sigma_j^z = -ib_j^x b_j^y. \tag{S3}$$

Employing Eqs. (S1) and/or (S3) appropriately, the two terms \mathcal{H}_{K_1} and \mathcal{H}_{K_3} of the spin Hamiltonian \mathcal{H} then become

$$\begin{aligned}
\mathcal{H}_{K_{1}} &= -K_{1} \sum_{\langle ij \rangle_{\alpha}} \sigma_{i}^{\alpha} \sigma_{j}^{\alpha} = -K_{1} \sum_{\langle ij \rangle_{\alpha}} \left(ib_{i}^{\alpha} c_{i} \right) \left(ib_{j}^{\alpha} c_{j} \right) = iK_{1} \sum_{\langle ij \rangle_{\alpha}} \left(ib_{i}^{\alpha} b_{j}^{\alpha} \right) c_{i} c_{j}, \\
\mathcal{H}_{K_{3}} &= K_{3} \sum_{\langle ijkl \rangle_{\alpha\beta\gamma}} \sigma_{i}^{\alpha} \sigma_{j}^{\gamma} \sigma_{k}^{\alpha} \sigma_{l}^{\gamma} - K_{3}' \sum_{\langle ijkl \rangle_{\alpha\beta\alpha}} \sigma_{i}^{\alpha} \sigma_{j}^{\gamma} \sigma_{k}^{\gamma} \sigma_{l}^{\alpha} \\
&= K_{3} \sum_{\langle ijkl \rangle_{\alpha\beta\gamma}} \left(ib_{i}^{\alpha} c_{i} \right) \left(-ib_{j}^{\alpha} b_{j}^{\beta} \right) \left(-ib_{k}^{\beta} b_{k}^{\gamma} \right) \left(ib_{l}^{\gamma} c_{l} \right) - K_{3}' \sum_{\langle ijkl \rangle_{\alpha\beta\alpha}} \left(ib_{i}^{\alpha} c_{i} \right) \left(-ib_{j}^{\alpha} b_{j}^{\beta} \right) \left(ib_{k}^{\alpha} c_{l} \right) \\
&= iK_{3} \sum_{\langle ijkl \rangle_{\alpha\beta\gamma}} \left(ib_{i}^{\alpha} b_{j}^{\alpha} \right) \left(ib_{k}^{\beta} b_{j}^{\beta} \right) \left(ib_{k}^{\gamma} b_{l}^{\gamma} \right) c_{i} c_{l} + iK_{3}' \sum_{\langle ijkl \rangle_{\alpha\beta\alpha}} \left(ib_{i}^{\alpha} b_{j}^{\alpha} \right) \left(ib_{k}^{\beta} b_{j}^{\beta} \right) \left(ib_{k}^{\alpha} b_{l}^{\alpha} \right) c_{i} c_{l}.
\end{aligned}$$
(S4)

Substituting Eq. (S4) into Eq. (1) of the main text, and introducing the \mathbb{Z}_2 gauge fields $u_{ij}^{\alpha} \equiv i b_i^{\alpha} b_j^{\alpha}$, one immediately recovers the Majorana Hamiltonian in Eq. (3) of the main text. Since the \mathbb{Z}_2 gauge fields are mutually commuting conserved quantities, $u_{ij}^{\alpha} = \pm 1$, this Majorana Hamiltonian is quadratic and hence exactly solvable.

QUADRATIC MAJORANA PROBLEMS

For each phase in Fig. 2 of the main text, the ground-state flux configuration can be represented with an appropriate gauge configuration $u_{ij}^{\alpha} = \pm 1$ (see Fig. S1). For all phases other than the zero-flux phase, the effective unit cell of the Majorana fermions is enlarged with respect to the honeycomb unit cell as a result of physical symmetry breaking (flux crystallization) and/or ostensible symmetry breaking (gauge freedom in representing each π flux). We label each site of the honeycomb lattice as $i \equiv (\Theta, \mathbf{R}, \lambda)$, where $\Theta = \{A, B\}$ is a sublattice index, \mathbf{R} is the lattice vector of the enlarged unit cell, and $\lambda = 1, \ldots, n$ specifies the particular honeycomb unit cell within the enlarged unit cell. Note that n = 1 for the zero-flux phase, n = 2 for the π -flux phase, and n > 2 for the flux-crystal phases.

Using this notation, the quadratic Majorana Hamiltonian in Eq. (3) of the main text takes the general form

$$\mathcal{H} = \sum_{\boldsymbol{R},\boldsymbol{R}'} \sum_{\lambda,\lambda'} i \mathcal{M}_{\boldsymbol{R}'-\boldsymbol{R},\lambda,\lambda'} c_{\boldsymbol{A},\boldsymbol{R},\lambda} c_{\boldsymbol{B},\boldsymbol{R}',\lambda'},$$
(S5)

where each $\mathcal{M}_{\mathbf{R}'-\mathbf{R},\lambda,\lambda'}$ is a product of gauge fields $u_{ij}^{\alpha} = \pm 1$ along a path connecting the sites (A, \mathbf{R}, λ) and $(B, \mathbf{R}', \lambda')$ occupied by the Majorana fermions $c_{A,\mathbf{R},\lambda}$ and $c_{B,\mathbf{R}',\lambda'}$. In terms of the momentum-space complex fermions

$$\psi_{A(B),\boldsymbol{q},\lambda} = \frac{1}{\sqrt{N}} \sum_{\boldsymbol{R}} c_{A(B),\boldsymbol{R},\lambda} e^{-i\boldsymbol{q}\cdot\boldsymbol{R}}, \qquad \psi^{\dagger}_{A(B),\boldsymbol{q},\lambda} = \psi_{A(B),-\boldsymbol{q},\lambda} = \frac{1}{\sqrt{N}} \sum_{\boldsymbol{R}} c_{A(B),\boldsymbol{R},\lambda} e^{i\boldsymbol{q}\cdot\boldsymbol{R}}, \tag{S6}$$

FIG. S1. Gauge representation of the flux configuration for the zero-flux phase (a), the π -flux phase (b), the 1/2 flux crystal (c), the 1/3 flux crystal (d), the 2/3 flux crystal (e), the 1/4 flux crystal (f), and the 3/4 flux crystal (g). In each case, bonds with $u_{ij}^{\alpha} = -1$ are denoted by thick lines. Note that the effective unit cell (blue dashed parallelogram) may contain several honeycomb unit cells, labeled by $\lambda = 1, \ldots, n$, each containing one A site (black dot) and one B site (white dot).

where N is the number of sites, the Hamiltonian in Eq. (S5) assumes the standard Bogoliubov-de Gennes form

$$\mathcal{H} = 2 \sum_{\pm q} \sum_{\lambda,\lambda'} \left(i \hat{\mathcal{M}}_{\boldsymbol{q},\lambda,\lambda'} \psi^{\dagger}_{\boldsymbol{A},\boldsymbol{q},\lambda} \psi_{\boldsymbol{B},\boldsymbol{q},\lambda'} + i \hat{\mathcal{M}}^{*}_{\boldsymbol{q},\lambda,\lambda'} \psi_{\boldsymbol{A},\boldsymbol{q},\lambda} \psi^{\dagger}_{\boldsymbol{B},\boldsymbol{q},\lambda'} \right) = 2 \sum_{\pm q} \left(\psi^{\dagger}_{\boldsymbol{A},\boldsymbol{q}} \psi^{\dagger}_{\boldsymbol{B},\boldsymbol{q}} \right) \begin{pmatrix} 0 & i \hat{\mathcal{M}}_{\boldsymbol{q}} \\ -i \hat{\mathcal{M}}^{\dagger}_{\boldsymbol{q}} & 0 \end{pmatrix} \begin{pmatrix} \psi_{\boldsymbol{A},\boldsymbol{q}} \\ \psi_{\boldsymbol{B},\boldsymbol{q}} \end{pmatrix},$$
$$\hat{\mathcal{M}}_{\boldsymbol{q},\lambda,\lambda'} = \sum_{\boldsymbol{r}} \mathcal{M}_{\boldsymbol{r},\lambda,\lambda'} e^{i\boldsymbol{q}\cdot\boldsymbol{r}}, \qquad \psi_{\boldsymbol{A}(\boldsymbol{B}),\boldsymbol{q}} \equiv \left(\psi_{\boldsymbol{A}(\boldsymbol{B}),\boldsymbol{q},1}, \dots, \psi_{\boldsymbol{A}(\boldsymbol{B}),\boldsymbol{q},n} \right)^{T}, \tag{S7}$$

where the summation is over pairs of momenta $\pm q$ due to the particle-hole redundancy $\psi_{A(B),q} = \psi_{A(B),-q}^{\dagger}$. Using the particular structure of this quadratic Hamiltonian, reflecting time-reversal symmetry, the Majorana energies at each momentum $\pm q$ are then given by the singular values of the $n \times n$ matrix $\hat{\mathcal{M}}_{q}$.

MAJORANA NODAL STRUCTURES

From Eq. (S7), the nodal structures of the Majorana fermions are characterized by vanishing singular values of $\hat{\mathcal{M}}_{\boldsymbol{q}}$ or, equivalently, by det $\hat{\mathcal{M}}_{\boldsymbol{q}} = 0$. Since det $\hat{\mathcal{M}}_{\boldsymbol{q}}$ is generically complex, det $\hat{\mathcal{M}}_{\boldsymbol{q}} = 0$ translates into two independent equations for its real and imaginary parts. Consequently, for each phase in Fig. 2 of the main text, any nodal structures are anticipated to be of codimension 2, corresponding to point nodes in two dimensions. Indeed, we generically find that the Majorana fermions are either fully gapped or gapless at discrete points only.

FIG. S2. Labeling convention for the π -flux phase, including the lattice constant a, the lattice vectors $\mathbf{R}_{1,2}$, and the four sites within each unit cell. The gauge configuration is also specified; bonds with $u_{ij}^{\alpha} = -1$ are denoted by thick lines.

FIG. S3. Contour plot of the function G(q) as a function of the momentum components q_x and q_y .

However, for the π -flux phase, if we only consider first-neighbor and third-neighbor Majorana hopping with amplitudes K_1 and K'_3 , respectively, the Majorana problem takes a particularly simple form. Using the labeling convention in Fig. S2, the matrix elements of the 2 × 2 matrix $\hat{\mathcal{M}}_q$ in Eq. (S7) are given by

$$\hat{\mathcal{M}}_{\boldsymbol{q},1,1} = \hat{\mathcal{M}}_{\boldsymbol{q},2,2} = K_1 + K_3' e^{-i\boldsymbol{q}\cdot(\boldsymbol{R}_1 + \boldsymbol{R}_2)} - K_3' e^{i\boldsymbol{q}\cdot(\boldsymbol{R}_1 - \boldsymbol{R}_2)},
\hat{\mathcal{M}}_{\boldsymbol{q},1,2} = K_1 e^{-i\boldsymbol{q}\cdot(\boldsymbol{R}_1 + \boldsymbol{R}_2)} + K_1 e^{-i\boldsymbol{q}\cdot\boldsymbol{R}_2} + K_3' e^{-i\boldsymbol{q}\cdot(\boldsymbol{2}\boldsymbol{R}_1 + \boldsymbol{R}_2)} - K_3' e^{-i\boldsymbol{q}\cdot\boldsymbol{R}_1} + K_3' + K_3' e^{i\boldsymbol{q}\cdot(\boldsymbol{R}_1 - \boldsymbol{R}_2)},
\hat{\mathcal{M}}_{\boldsymbol{q},2,1} = K_1 - K_1 e^{i\boldsymbol{q}\cdot\boldsymbol{R}_1} - K_3' e^{-i\boldsymbol{q}\cdot\boldsymbol{R}_1} + K_3' e^{i\boldsymbol{q}\cdot\boldsymbol{R}_2} + K_3' e^{i\boldsymbol{q}\cdot(\boldsymbol{R}_1 + \boldsymbol{R}_2)} + K_3' e^{2i\boldsymbol{q}\cdot\boldsymbol{R}_1},$$
(S8)

and the determinant of $\hat{\mathcal{M}}_{q}$ readily factorizes into the product form

$$\det \hat{\mathcal{M}}_{\boldsymbol{q}} = K_1^2 F(\boldsymbol{q}) \left[1 - 2\kappa(2+\kappa) - 2\kappa^2 G(\boldsymbol{q}) \right],$$
(S9)

where $\kappa \equiv K'_3/K_1$ is the dimensionless third-neighbor hopping amplitude, and the two functions F(q) and G(q) are

$$F(\boldsymbol{q}) = 1 + 2ie^{-3iq_y a} \sin\left(\sqrt{3}q_x a\right),$$

$$G(\boldsymbol{q}) = \cos\left(2\sqrt{3}q_x a\right) - 2\sin\left(2\sqrt{3}q_x a\right) \sin\left(3q_y a\right).$$
(S10)

While the function $F(\mathbf{q})$ is complex, and the solutions of $F(\mathbf{q}) = 0$ thus give point nodes at $q_x a = \pm \pi/(6\sqrt{3}) + 2\pi n_x/\sqrt{3}$ and $q_y a = \mp \pi/6 + 2\pi n_y/3$ as well as at $q_x a = \pm 5\pi/(6\sqrt{3}) + 2\pi n_x/\sqrt{3}$ and $q_y a = \mp \pi/6 + 2\pi n_y/3$ (with $n_x, n_y \in \mathbb{Z}$), the function $G(\mathbf{q})$ plotted in Fig. S3 is real, with a minimum value $G_{\min} = -3$, a maximum value $G_{\max} = 3/2$, and a critical value $G_{vH} = 1$ corresponding to a van Hove singularity. Consequently, the solutions of $1 - 2\kappa(2 + \kappa) - 2\kappa^2 G(\mathbf{q}) = 0$ generically correspond to nodal lines along the contours of Fig. S3 given by

$$G(\boldsymbol{q}) = G_0(\kappa) \equiv \frac{1 - 2\kappa(2 + \kappa)}{2\kappa^2} \,. \tag{S11}$$

To analyze these nodal lines, we plot $G_0(\kappa)$ in Fig. S4 and find three critical values of κ between 0 and 1:

$$\kappa_1 = 0.2, \qquad \kappa_2 = \frac{1}{2} \left(\sqrt{2} - 1 \right) \approx 0.207, \qquad \kappa_3 = 0.5.$$
(S12)

FIG. S4. Plot of the function $G_0(\kappa)$ as a function of the dimensionless parameter $\kappa = K'_3/K_1$.

For $\kappa < \kappa_1$, we obtain $G_0(\kappa) > G_{\text{max}}$, and Eq. (S11) has no solutions. For $\kappa_1 < \kappa < \kappa_2$, we obtain $G_{\text{vH}} < G_0(\kappa) < G_{\text{max}}$, and the solutions of Eq. (S11) are nodal lines surrounding the maxima of $G(\mathbf{q})$. Interestingly, these maxima coincide with the point nodes characterized by $F(\mathbf{q}) = 0$. Finally, for $\kappa > \kappa_2$, we obtain $G_{\min} \leq G_0(\kappa) < G_{\text{vH}}$, and the solutions of Eq. (S11) are nodal lines surrounding the minima of $G(\mathbf{q})$. In particular, for $\kappa = \kappa_3$, these nodal lines contract to point nodes as $G_0(\kappa) = G_{\min}$.

MAGNETIC FRIEDEL OSCILLATIONS

In principle, a non-magnetic impurity, such as a spin vacancy [see Fig. S5(a)], can be used as a "physical probe" to distinguish between the π -flux phases with Dirac points and Fermi surfaces of Majorana fermions. Such an impurity induces a local modulation of the bond energy $E_{\langle ij \rangle_{\alpha}} \propto \langle \sigma_i^{\alpha} \sigma_j^{\alpha} \rangle$, which decays with a power law as a function of distance; Friedel oscillations are expected to be present (absent) in this decay if the Majorana fermions are gapless at Fermi surfaces (Dirac points). We therefore calculate the radial Fourier transform of the bond-energy modulation,

$$\Delta E(p) = \frac{1}{N} \sum_{\langle ij \rangle_{\alpha}} e^{-ipr_{\langle ij \rangle_{\alpha}}} \left[E_{\langle ij \rangle_{\alpha}} - E_{\langle ij \rangle_{\alpha}}^{(0)} \right], \tag{S13}$$

in both phases [see Fig. S5(b)], where $r_{\langle ij\rangle_{\alpha}}$ is the distance of the bond $\langle ij\rangle_{\alpha}$ from the impurity, and $E_{\langle ij\rangle_{\alpha}}^{(0)}$ is the bond energy in the absence of the impurity. As expected, in the Dirac phase, $\Delta E(p)$ is peaked at p = 0, while in the Fermi phase, its peak is shifted to $p \approx 2q_F$, where q_F is the radius of the Fermi surface [see Fig. S5(c)].

FIG. S5. (a) Local distortion of the Kitaev interactions ($\kappa \neq 1$) around a nonmagnetic impurity; the particular case of a spin vacancy corresponds to $\kappa = 0$. (b) Radial Fourier transform of the bond-energy modulation around the impurity for the π -flux phases with Dirac nodes (white circles) and Fermi surfaces (black squares) of Majorana fermions. (c) For the Fermi phase, the peak wave vector of Friedel oscillations is compared with the characteristic dimensions of the Fermi surfaces.

DYNAMICAL SPIN STRUCTURE FACTOR

The dynamical spin structure factor $S_{\mu\nu}(\boldsymbol{q},\omega)$ is probed experimentally by inelastic neutron scattering. At T = 0, it is given by the spatial and temporal Fourier transform of the spin-spin correlation function in the ground state:

$$S_{\mu\nu}(\boldsymbol{q},\omega) = \frac{1}{2\pi N} \sum_{i,j} \int_{-\infty}^{+\infty} dt \, e^{i\omega t - i\boldsymbol{q}\cdot(\boldsymbol{r}_j - \boldsymbol{r}_i)} \left\langle \sigma_i^{\mu}(t)\sigma_j^{\nu}(0) \right\rangle, \tag{S14}$$

where $\sigma_i^{\mu}(t) \equiv e^{i\mathcal{H}t}\sigma_i^{\mu}e^{-i\mathcal{H}t}$, and \mathbf{r}_i is the position of site *i*. For the general Hamiltonian \mathcal{H} in Eq. (1) of the main text, the spin-spin correlation function $\langle \sigma_i^{\mu}(t)\sigma_j^{\nu}(0)\rangle$ vanishes unless $\mu = \nu$. Moreover, its has an extremely limited range: $\langle \sigma_i^{\mu}(t)\sigma_j^{\mu}(0)\rangle$ is only nonzero if *i* and *j* are the same site (i = j) or if they are nearest-neighbor sites connected by a μ bond $\langle ij \rangle_{\mu}$. The structure factor in Eq. (S14) is thus generally given by

$$S_{\mu\nu}(\boldsymbol{q},\omega) = \delta_{\mu\nu} \left[S^{(0)}_{\mu\mu}(\omega) + 2\cos(\boldsymbol{q}\cdot\boldsymbol{n}_{\mu}) S^{(1)}_{\mu\mu}(\omega) \right], \qquad (S15)$$

where $S^{(0)}_{\mu\mu}(\omega)$ and $S^{(1)}_{\mu\mu}(\omega)$ are on-site and nearest-neighbor contributions,

$$S_{\mu\mu}^{(0)}(\omega) = \frac{1}{N} \sum_{i} S_{\mu\mu,i}^{(0)}(\omega), \qquad S_{\mu\mu,i}^{(0)}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt \, e^{i\omega t} \left\langle \sigma_{i}^{\mu}(t) \sigma_{i}^{\mu}(0) \right\rangle, \tag{S16}$$
$$S_{\mu\mu}^{(1)}(\omega) = \frac{1}{N} \sum_{\langle ij \rangle_{\mu}} S_{\mu\mu,\langle ij \rangle_{\mu}}^{(1)}(\omega), \qquad S_{\mu\mu,\langle ij \rangle_{\mu}}^{(1)}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt \, e^{i\omega t} \left\langle \sigma_{i}^{\mu}(t) \sigma_{j}^{\mu}(0) \right\rangle,$$

and \boldsymbol{n}_{μ} is the vector connecting the two sites i and j along any μ bond $\langle ij \rangle_{\mu}$. Note that $\langle \sigma_i^{\mu}(t) \sigma_j^{\mu}(0) \rangle = \langle \sigma_j^{\mu}(t) \sigma_i^{\mu}(0) \rangle$ and, consequently, $S_{\mu\mu,\langle ij \rangle_{\mu}}^{(1)}(\omega)$ is real due to time-reversal symmetry.

The general results in Eqs. (S15) and (S16) are simplified by the unbroken space-group symmetries in each phase of Fig. 2 in the main text. First of all, due to translation symmetry, there are only a finite number of inequivalent sites i and inequivalent μ bonds $\langle ij \rangle_{\mu}$, and the infinite averages in Eq. (S16) can thus be substituted with finite averages over the $n_{(0)}$ inequivalent sites and the $n_{(1)}$ inequivalent μ bonds. In particular, $n_{(0)} = n_{(1)} = 1$ for each symmetric phase, while $n_{(0)} = n_{(1)} = r$ for each flux crystal with a supercell of r plaquettes. Moreover, for all phases other than the 1/2 flux crystal, there is a threefold rotation symmetry around the center of some plaquette, which permutes the spin components as $z \to x \to y \to z$ and therefore implies $S_{xx}^{(0,1)}(\omega) = S_{yy}^{(0,1)}(\omega) = S_{zz}^{(0,1)}(\omega)$. For the 1/2 flux crystal, this rotation symmetry is spontaneously broken; if the flux stripes are perpendicular to the y bonds, as in Fig. S1(c), the remaining point-group symmetries still imply $S_{xx}^{(0,1)}(\omega) = S_{zz}^{(0,1)}(\omega)$.

In Fig. S6, we present the dynamical spin structure factor $S_{zz}(\boldsymbol{q},\omega)$ at T=0 for each flux-crystal phase along the high-symmetry path M- Γ -K-M in the Brillouin zone [see inset of panel (a)]. Following the few-particle approach in Ref. 69, we take the Lehmann representation of $S_{zz}(\boldsymbol{q},\omega)$ and restrict our attention to intermediate states containing a single Majorana excitation. If this approximation is valid, the calculated response should approximately satisfy the sum rule $\int d\omega S_{zz}^{(0)}(\omega) = 1$; for all of the results in Fig. S6, we find that $\int d\omega S_{zz}^{(0)}(\omega) > 0.6$. The energy dependence of the dynamical spin structure factor reflects the Majorana density of states in the inter-

The energy dependence of the dynamical spin structure factor reflects the Majorana density of states in the intermediate flux sector of the Lehmann representation (see Fig. S6). Due to the two fluxes created (or destroyed) by the spin operator σ_l^z , the Majorana fermions in the intermediate flux sector are perturbed with respect to the ground-state flux sector, and they may even form localized states around the site l. Such a localized state corresponds to a delta peak in the density of states and thus gives rise to a sharp feature in $S_{zz}(\mathbf{q},\omega)$. Physically, it can be understood as a magnon bound state, $\sigma_l^z = ib_l^z c_l$, of a bond Majorana fermion b_l^z and a matter Majorana fermion c_l .

MONTE CARLO IMPLEMENTATION

The Monte Carlo (MC) simulations are implemented on an $L \times L$ honeycomb lattice with dimensions $L_1 = La_1$ and $L_2 = La_2$ and periodic boundary conditions (PBC) in both directions (see Fig. S7). However, using these boundary conditions, a naive numerical implementation would be extremely tedious, and we therefore simplify the procedure by removing a single bond from the lattice.

Indeed, since the Hilbert space is enlarged by the introduction of the Majorana fermions, any state in the Majorana representation must be projected back into the physical Hilbert space. Due to this projection, distinct states in the

FIG. S6. Upper panel of (a)-(f): Dynamical spin structure factor $S_{zz}(q,\omega)$ at T = 0 along the path M- Γ -K-M [see inset of (a)] for various phases in Fig. 2 of the main text. Each response is convolved, as a function of energy, with a Lorentzian broadening function of width $\eta = 0.05K_1$. Lower panel of (a)-(f): Majorana density of states $\rho(\omega)$ for each phase. Red vertical lines are δ peaks corresponding to additional localized states that appear in the intermediate flux sector of the Lehmann representation.

Majorana representation may correspond to the same physical state, and certain states in the Majorana representation may not correspond to any physical state at all. In fact, each physical state can be represented by 2^{N-1} distinct Majorana states, and the total fermion number, $N_b + N_c$, including bond and matter fermions, is even for all of them:

$$(-1)^{N_b}(-1)^{N_c} = \left[\prod_{\langle jk \rangle_\alpha} u_{jk}^\alpha\right] \left[\prod_{\langle jk \rangle_z} w_{jk}\right] = +1,$$
(S17)

where $u_{jk}^{\alpha} \equiv i b_j^{\alpha} b_k^{\alpha}$ (as in the main text) and $w_{jk} \equiv i c_j c_k$. The remaining Majorana states with odd fermion number do not correspond to any physical state as they are annihilated by the projection. The partition function is then

$$Z = \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}_{\text{even}}} \operatorname{Tr}_{\{w_{jk}\}_{\text{even}}} e^{-\beta \mathcal{H}} + \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}_{\text{odd}}} \operatorname{Tr}_{\{w_{jk}\}_{\text{odd}}} e^{-\beta \mathcal{H}},$$
(S18)

where $\operatorname{Tr}_{\{u_{jk}^{\alpha}\}_{\text{even}}}(\operatorname{Tr}_{\{u_{jk}^{\alpha}\}_{\text{odd}}})$ sums over all bond-fermion configurations $\{u_{jk}^{\alpha}\}$ with $\prod_{\langle jk \rangle_{\alpha}} u_{jk}^{\alpha} = +1$ (-1), while $\operatorname{Tr}_{\{w_{jk}\}_{\text{even}}}(\operatorname{Tr}_{\{w_{jk}\}_{\text{odd}}})$ sums over all matter-fermion configurations $\{w_{jk}\}$ with $\prod_{\langle jk \rangle_{z}} w_{jk} = +1$ (-1).

For the relatively small system sizes accessible with MC, it is important to take proper care of the even/odd projections, which in turn makes the MC implementation extremely tedious. However, the computation is simplified tremendously if we remove a single bond $\langle gh \rangle_y$ from the lattice (see Fig. S7) by switching off all interactions that involve both sites g and h [70]. In this case, the Hamiltonian \mathcal{H} does not depend on u_{qh}^y and, by switching between

FIG. S7. Honeycomb lattice for the Monte Carlo simulations. We employ periodic boundary conditions in both directions but remove a single y bond (marked by the cross) to avoid a tedious numerical procedure.

 $u_{gh}^y = \pm 1$, one can switch the bond-fermion parity $\prod_{\langle jk \rangle_{\alpha}} u_{jk}^{\alpha}$ without affecting the spectrum of the matter fermions at all. The partition function in Eq. (S18) can then be written as

$$Z = \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}'} \left[\operatorname{Tr}_{\{w_{jk}\}_{\text{even}}} e^{-\beta \mathcal{H}} + \operatorname{Tr}_{\{w_{jk}\}_{\text{odd}}} e^{-\beta \mathcal{H}} \right] = \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}'} \operatorname{Tr}_{\{w_{jk}\}} e^{-\beta \mathcal{H}}, \tag{S19}$$

where $\operatorname{Tr}_{\{u_{jk}^{\alpha}\}'}$ sums over all configurations of those bond fermions that do not correspond to the removed bond $\langle gh \rangle_y$, and $\operatorname{Tr}_{\{w_{jk}\}}$ sums over all configurations of the matter fermions. Finally, the partition function takes the form

$$Z = \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}'} \prod_{n} \left(e^{\beta \epsilon_n [\{u_{jk}^{\alpha}\}']/2} + e^{-\beta \epsilon_n [\{u_{jk}^{\alpha}\}']/2} \right) \equiv \frac{1}{2^{N-1}} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}'} e^{-\beta F_w [\{u_{jk}^{\alpha}\}']} \equiv \frac{Z'}{2^{N-1}}, \quad (S20)$$

where $\epsilon_n[\{u_{jk}^{\alpha}\}']$ are the non-negative single-particle energies of the matter fermions for a given configuration $\{u_{jk}^{\alpha}\}'$ of the bond fermions. From this simplified partition function, all other thermodynamic quantities can then be obtained as described in Ref. 70. In particular, the internal energy and the heat capacity are given by

$$U = \left\langle E_w[\{u_{jk}^{\alpha}\}'] \right\rangle, \qquad E_w[\{u_{jk}^{\alpha}\}'] \equiv -\sum_n \frac{\epsilon_n[\{u_{jk}^{\alpha}\}']}{2} \tanh \frac{\beta \epsilon_n[\{u_{jk}^{\alpha}\}']}{2},$$
$$C = \beta^2 \left[\left\langle E_w[\{u_{jk}^{\alpha}\}']^2 - \frac{\partial E_w[\{u_{jk}^{\alpha}\}']}{\partial \beta} \right\rangle - \left\langle E_w[\{u_{jk}^{\alpha}\}'] \right\rangle^2 \right], \qquad (S21)$$

where $\langle \cdots \rangle$ denotes the thermal average over all bond-fermion configurations $\{u_{ik}^{\alpha}\}'$:

$$\left\langle O_w[\{u_{jk}^{\alpha}\}']\right\rangle \equiv \frac{1}{Z'} \operatorname{Tr}_{\{u_{jk}^{\alpha}\}'} \left[O_w[\{u_{jk}^{\alpha}\}'] e^{-\beta F_w[\{u_{jk}^{\alpha}\}']} \right].$$
(S22)

Note that the same simplification in the partition function could also be achieved by removing several bonds from the lattice; we remove only one bond to minimize any accompanying finite-size effects.
