#### ABSTRACT

Aims. We investigate the physical and chemical conditions of molecular gas in the circumnuclear disk (CND) region of NGC 1068. Methods. We carried out a spectral line survey with the IRAM 30m telescope toward the center of NGC 1068 and mainly focused on the 2 mm band with a frequency coverage of 160.7-168.6 GHz and 176.5-184.3 GHz.

Results. Fifteen lines are detected in NGC 1068, eight of which are new detections for this galaxy. We derive the rotation temperatures

*Conclusions.* Based on the  $[HCO^+(2-1)]/[HOC^+(2-1)]$  ratio, we obtain a high ionization degree in the CND of NGC 1068. It is found that HC<sub>3</sub>N is concentrated in the east knot, while <sup>13</sup>CCH, CH<sub>3</sub>CN, SO, HOC<sup>+</sup>, CS, CH<sub>3</sub>CCH, and H<sub>2</sub>CO are concentrated in the west knot. Compared to the star-forming galaxies M 82 and NGC 253, the chemistry of NGC 1068 might be less strongly affected by the UV radiation field, and its kinetic temperature might be lower.

Key words. ISM: molecules - galaxies: ISM - galaxies: individual: NGC 1068 - galaxies: nuclei - galaxies: active

Bland-Hawthorn et al. 1997) and brightest  $(L_{IR} = 3 \times 10^{11} L_{\odot})$ Seyfert II galaxies with a starburst. It consists of a starburst ring (~15" from the central AGN) and a central nuclear disk (CND) (Schinnerer et al. 2000). It was established that the physical conditions between the starburst ring and the CND are different (Viti et al. 2014). The molecular gas in the CND is denser and hotter than the gas in the starburst ring. Multi-gas-phase components exist in the CND region (Viti et al. 2014). The gas temperature in the CND region is higher than 150 K, and the gas density is above  $10^5$  cm<sup>-3</sup> (Viti et al. 2014). The CND region could be spatially resolved into an east and a west knot. These knots are dominated by a fast and a slow shock, respectively (Kelly et al. 2017). The mass of the central torus was estimated to be 2  $\times$  $10^5 M_{\odot}$  (García-Burillo et al. 2014). With an AGN-driven outflow (García-Burillo et al. 2014) and a past inflow driven by a minor merger (Furuya & Taniguchi 2016), the torus shows a complex dynamical behavior (García-Burillo et al. 2016).

NGC 1068 is one of the best extragalactic targets for continuum and line observations in all wavelengths from X-rays to the radio domain (e.g., radio, Greenhill et al. 1996; millimeter, Schinnerer et al. 2000; infrared, Jaffe et al. 2004; optical, Antonucci & Miller 1985; UV, Antonucci et al. 1994; and X-ray, Kinkhabwala et al. 2002). These results show that the strong UV or X-ray field heavily influence the physical conditions, kinematics, and chemistry in the CND of NGC 1068 (Usero et al. 2004; Pérez-Beaupuits et al. 2009; García-Burillo et al. 2010; Nakajima et al. 2011, 2018; Aladro et al. 2011, 2015; Takano et al. 2014; Viti et al. 2014).

To better understand the chemistry in the CND of NGC 1068, we performed an observation of molecular lines at 3 mm bands (Qiu et al. 2018), and detected CH<sub>3</sub>OCH<sub>3</sub> for the first time in external galaxies. As a supplement to the previous report, this paper presents observations of molecular lines at the 2 mm band toward NGC 1068. The organization of this paper is as follows: we present the observations and data reduction in Sect. 2, and the main results are provided in Sect. 3. We discuss the physical and chemical properties of molecules in Sect. 4, and give a brief summary in Sect. 5.

# 2. Observations and data reduction

The observations toward the center of NGC 1068 (RA: 02:42:40.70 DEC: -00:00:48.0 J2000) were carried out in January 2017 with the IRAM 30m single-dish telescope at Pico Veleta Observatory (Spain)<sup>1</sup>. We used the Eight Mixer Receiver (EMIR) with dual polarization and the Fourier Transform Spectrometers (FTS) backend tuned. The frequency channel spacing was 195 KHz, and the instantaneous frequency coverage per sideband and polarization was 8 GHz. We used the standard wobbler-switching mode with a  $\pm$  110" offset and 1.5 second per phase. Each scan included eight subscans of 30 seconds. We checked pointing and focus every two hours.

The observations were performed using two tunings in the 2 mm window (160.7–168.6 GHz and 176.5–184.3 GHz) and in the 3 mm window (75.7–83.5 GHz and 91.4–99.2 GHz). The 3 mm spectra were obtained with a short integration time to supplement the line survey in the 2 mm window (Table 1). Figure 1 presents the full spectra. The molecular line temperature scale was converted from the antenna temperature  $T_A^*$  into the main beam temperature  $T_{mb}$ . The conversion relation between them is  $T_{mb} = (F_{eff}/B_{eff}) \times T_A^*$ , where  $F_{eff}$  and  $B_{eff}$  are the forward efficiency and main-beam efficiency of the telescope, respectively. The values assumed for  $F_{eff}$  and  $B_{eff}$  of each band are listed in Table 1. The main observation parameters, including band range, half-power bandwidth (HPBW), and spatial resolution, are also listed in Table 1.

The data reduction procedures are similar to those described in Qiu et al. (2018). Linear baseline subtraction and Gaussian profile fitting were made for all the detected lines. The data reduction was performed using the CLASS software of the GILDAS package<sup>2</sup>. We identified each molecular transition by referring to the frequencies from the NIST database recommended rest frequencies for observed interstellar molecular microwave transitions<sup>3</sup> and from the splatalogue database for astronomical spectroscopy<sup>4</sup>.

We performed a literature survey of previous observations made with single-dish telescopes toward NGC 1068. The lines detected by other research groups, together with those detected by us, are listed in Table 2. This table may serve as a reference source for future studies of this object. We assume a heliocentric systemic velocity  $v_{sys} \sim 1137$  km s<sup>-1</sup> (from NASA/IPAC Extragalactic Database (NED)<sup>5</sup>) for this source throughout.

### 3. Results

Overall, 15 lines belonging to 12 different molecular species are detected. Figure 2 shows the individual line profiles in velocity units, and Table 2 summarizes the parameters derived from Gaussian fitting with CLASS to the observed lines. The main results include the detection of the J = 2 - 1 transitions of <sup>13</sup>CCH, HCO<sup>+</sup>, HOC<sup>+</sup>, and HNC, and emission lines of CH<sub>3</sub>OH ( $J_{1,k-1} - J_{0,k}$ )E, SO<sub>2</sub> ( $5_{2,4} - 5_{1,5}$ ), and CH<sub>3</sub>CN ( $9_k - 8_k$ ). To our knowledge, these lines are detected for the first time in NGC 1068. In addition, we also detect the lines of CH<sub>3</sub>CN ( $5_k - 4_k$ ), N<sub>2</sub>H<sup>+</sup> (1 - 0), CH<sub>3</sub>OCH<sub>3</sub> ( $3_{2,2} - 3_{1,3}$ ), CH<sub>3</sub>OH ( $2_k - 1_k$ ), CS (2 - 1), HC<sub>3</sub>N (18 - 17), and HCN (2 - 1). CH<sub>3</sub>CN ( $5_k-4_k$ ), HC<sub>3</sub>N (18–17), and CH<sub>3</sub>OCH<sub>3</sub> ( $3_{2,2}-3_{1,3}$ ), have been detected or tentatively detected in previous observations (Qiu et al. 2018). To enhance the signal-to-noise ratios (S/N), we combined the data of Qiu et al. (2018) for these three transitions. CH<sub>3</sub>OCH<sub>3</sub> ( $3_{2,2} - 3_{1,3}$ ) was only marginally detected toward NGC 1068 by Qiu et al. (2018). No stronger line is known in this wavelength. For this line, we also combined the spectral data of Aladro et al. (2013) and found that the S/N increases from 1.6 to 2.3, probably supporting the potential existence of CH<sub>3</sub>OCH<sub>3</sub> in this galaxy. We checked the raw data of Qiu et al. (2018), and found that the CH<sub>3</sub>CCH (14<sub>0</sub> – 13<sub>0</sub>) line at 239 GHz is marginally detected, as shown in Fig. 2.

### 3.1. Line ratios

#### 3.1.1. HCN/HCO+

Table 3 lists the velocity-integrated intensity ratio of the J =2 – 1 transitions of five species, including<sup>13</sup>CCH, HCN, HCO<sup>+</sup>, HOC<sup>+</sup>, and HNC, detected in the CND of NGC 1068. The flux ratio of HCN to HCO<sup>+</sup> can be used to distinguish galaxies powered by starburst and AGN (Kohno et al. 2001; Krips et al. 2008; Imanishi et al. 2009; Izumi et al. 2016; Aladro et al. 2018; Li et al. 2019). AGN galaxies usually exhibit higher [HCN/HCO<sup>+</sup>] ratios than starburst galaxies because high X-ray radiation in AGNs can enhance the abundance of HCN (Kohno et al. 2001; Privon et al. 2017). Our observations show that the flux ratio of HCN-to-HCO<sup>+</sup> (J = 2 - 1) is  $1.82 \pm 0.03$  in the CND of NGC 1068. This is consistent with previous interferometer observations at other J-transitions. For example, the flux ratio of HCN-to-HCO<sup>+</sup> is 1.6–2.0 at J = 1 - 0 (Viti et al. 2014), 1.6–3.3 at J = 3 - 2 (Imanishi et al. 2016), and 2.1–2.8 at J = 4 - 3(Viti et al. 2014) in the nucleus of NGC 1068. Our single-dish and previous interferometer observational results confirm that the abundance of HCN is enhanced in the CND of NGC 1068, which maybe related to the outflow of AGN (García-Burillo et al. 2014).

#### 3.1.2. HNC/HCN

HCN and its isomer HNC are tracers of dense gas, and commonly coexist in different environments (Gao & Solomon 2004; Aalto et al. 2012). Some galaxies exhibit a high HNC/HCN ratio, which may be caused by low temperature, high ion density, high optical depth, and/or IR pumping. Theoretical studies (Meijerink & Spaans 2005; Meijerink et al. 2007) suggest that the HNC/HCN ratio increases in X-ray dominated regions (XDRs) to a higher degree than that in photon-dominated regions (PDRs) and quiescent-cloud regions. Observations of three galaxies (Arp 220, NGC 4418, and Mrk 231), which have strong X-ray emission produced by embedded AGN, indicate a high HNC-to-HCN (J = 3 - 2) flux ratio of  $1.9 \pm 0.3$  in Arp 220, 1.5  $\pm$  0.2 in Mrk 231, and 2.3  $\pm$  0.3 in NGC 4418 (Aalto et al. 2007). Our observations show that the integrated line ratio of HNC to HCN (J = 2 - 1) toward the CND of NGC 1068 is  $0.16 \pm 0.03$ . This is in agreement with J = 3 - 2 and J = 4 - 3 line ratios  $(0.15 \pm 0.03 \text{ and } 0.19 \pm 0.02, \text{ respectively; Pérez-Beaupuits et})$ al. 2007, 2009). This means that we do not find enhanced HNC emission in the CND of NGC 1068, and an XDR exists here. Because the HNC line is narrower than that of HCN, we exclude the IR pumping scenario: the IR pumping dominated scenario will show a broader line width of HNC than HCN, as described in Aalto et al. (2002). The ammonia (NH<sub>3</sub>) observations show that some components of the molecular cloud have a higher temper-

<sup>&</sup>lt;sup>5</sup> http://ned.ipac.caltech.edu

ature of  $140 \pm 30$  K in the CND of NGC 1068 (Ao et al. 2011). A reasonable explanation of the lower HNC-to-HCN ratio is that the warmer molecular cloud leads to the HNC deficiency.

#### 3.2. Line profile

The line profile can be taken as a diagnostic tool to investigate the properties of CND molecular gas. Usero et al. (2004) found that all molecular line profiles in the CND of NGC 1068 are distributed asymmetrically. They therefore suggested that the east and west knots of the CND are chemically differentiated.

Previous interferometer observations of CO(1 - 0) showed that NGC 1068 has a circumnuclear molecular ring with diameter ranging from  $\sim 20''$  to 40'' (Schinnerer et al. 2000). The beam size of the IRAM 30m telescope at the 3 mm band is larger than the inner diameter of the two spiral arms of NGC 1068. In contrast, the beam sizes at the 2 mm and 1 mm bands are smaller than the inner diameter of the two spiral arms. The HPBW of HOC<sup>+</sup> (1 - 0) and (2 - 1), for instance, is about 27.5" at 89.5 GHz and 13.7" at 179.0 GHz, as shown in Fig. 3. Highresolution images show that the most prominent emission stems from the CND (Takano et al. 2014; Viti et al. 2014). Therefore, the molecular lines lying within the 2 mm and 1 mm bands can preclude most of the contamination from the two spiral arms. Using a similar method as Usero et al. (2004), we divided each line into its blue and red velocity components (see Fig. 4), which dominantly arise from the east and west knots, respectively. The line profiles in Fig. 4 show that the local systemic velocity of these lines ranges from  $v - v_{sys} = -200 \text{ km s}^{-1}$  to 200 km s<sup>-1</sup>. We defined the blue and red components as those lying within an interval of  $-200 < v - v_{sys} < 0$  km s<sup>-1</sup> and  $0 < v - v_{sys} < 200$ km s<sup>-1</sup>, respectively. The velocity-integrated intensities of the two components are listed in Table 4. As shown in Fig. 4, there are noticeable differences between the line shapes of the CND spectra. Some molecular lines, including HC<sub>3</sub>N (18 - 17), SiO  $(5_5 - 4_4)$ , SO<sub>2</sub>  $(14_{3,11} - 14_{2,12})$ , HNC (2 - 1), HCN (2 - 1), HCN (2 - 1), HCO<sup>+</sup> (2-1), HNCO (11-10), <sup>13</sup>CCH (2-1), and CH<sub>3</sub>CN (9-8), show a stronger blue component, while the others, including  $SO(5_5 - 4_4)$ ,  $HOC^+(2 - 1)$ , CS(5 - 4),  $CH_3CCH(14_k - 13_k)$ , and  $H_2CO(3_{1,2} - 2_{1,1})$ , show a stronger red component.

Interferometer observations showed that the SiO(3 - 2)transition is dominantly distributed in the east knot and the HNCO(6-5) emission in the west knot (Kelly et al. 2017). Therefore, we hypothesize that the molecular species whose blue-to-red flux ratios are higher than that of SiO are mainly located in the east knot, while those with blue-to-red flux ratios lower than that of HNCO are mainly located in the west knot. Our single-dish observations of SiO  $(5_5-4_4)$  and HNCO (11-10)suggest a blue-to-red flux ratio (R<sub>E/W</sub>) of 2.1 and 1.3, respectively. The blue-to-red flux ratio of HC<sub>3</sub>N is higher than that of SiO, and thus is mainly located in the east knot. The blue-to-red flux ratios of the  ${}^{13}CCH(2-1)$ ,  $CH_3CN(9-8)$ ,  $SO(5_5 - 4_4)$ ,  $HOC^+$  (2-1), CS (5-4), CH<sub>3</sub>CCH (14<sub>k</sub>-13<sub>k</sub>), and H<sub>2</sub>CO (3<sub>1,2</sub>- $2_{1,1}$ ) transitions are lower than that of the HNCO (11 – 10) lines, and thus mainly arise from the west knot. The  ${}^{13}CCH(2-1)$ ,  $CH_3CN(9-8)$ , and  $CH_3CCH(14-13)$  transitions include several multiple components, which may affect the determination of their blue-to-red flux ratios. However, as shown in Fig. 4, the strongest components have small frequency splits, suggesting that this effect can be neglected.

In Fig. 5 we compare the line profiles of HCN, HNC, HCO<sup>+</sup>, and HOC<sup>+</sup> and those of the <sup>13</sup>C isomers. We find that the (J = 2 - 1)-to-(J = 1 - 0) flux ratios of HCN, HNC, and HCO<sup>+</sup> are

higher for the blue components than those for the red components, while there is no significant difference for HOC<sup>+</sup>. Under the assumption of  ${}^{12}C/{}^{13}C$ , Wang et al. (2014) suggested that the redshifted parts of HCN (1 – 0) and HCO<sup>+</sup> (1 – 0) have lower optical depths and more likely come from the spiral arms than from the nuclear region. Because the beam size of J = 2 - 1 is much smaller than that of J = 1 - 0, the different line profiles between the J = 2 - 1 and the J = 1 - 0 transitions may be attributed to the difference of their emission regions. The similar line profiles between the J = 2 - 1 lines of HCN and HCO<sup>+</sup> and their isotopic lines (H<sup>13</sup>CN (1 – 0) and H<sup>13</sup>CO<sup>+</sup> (1 – 0)) suggest that they may come from the same location. The J = 2 - 1 and J = 1 - 0 transitions of HOC<sup>+</sup> show similar profiles, suggesting that the molecule might be distributed in the CND region.

HCN and HCO<sup>+</sup> are tracers of dense gas. Their J = 2-1 transitions show similar line profiles and comparable velocities (see the lower panels of Fig. 5). Compared to the HCN (2-1) line, the HNC(2-1) line has a similar line center velocity, but a noticeably narrower line width. The HOC<sup>+</sup> (2-1)-to-HCO<sup>+</sup> (2-1) flux ratio in the blue component is higher than that in the red component. However, this is not the case for HNC and its isomer HCN. A possible explanation is that the J = 2 - 1 transitions of HCN, HNC, and HCO<sup>+</sup> are associated with each other in the CND of NGC 1068, while the HOC<sup>+</sup> (2 - 1) transition does not peak at the same position. This is consistent with the latest interferometer observation toward the center of the Seyfert II galaxy Mrk 273 (Aladro et al. 2018), which shows that the peak of the  $HOC^{+}(3-2)$  emission is not at the same position as the dense gas of HCN and HCO<sup>+</sup>. Further observations with higher spatial resolution of HOC<sup>+</sup> in the CND of NGC 1068 are required to investigate the origin of this offset.

#### 3.3. Rotation diagram

We applied the rotation diagram to derive excitation temperatures ( $T_{ex}$ ) and column densities ( $N_{tot}$ ) of the molecules we detected in our observations. With the assumption of local thermodynamic equilibrium (LTE), optically thin conditions, and negligible background temperature, we plot the populations of the upper levels ( $N_u$ ) against the corresponding excitation energies ( $E_u$ ) of the transitions (Fig. 6), using the equation

$$\ln\frac{N_u}{g_u} = \ln\frac{8\pi kv^2 \int T_s dv}{hc^3 A_{ul}g_u} = \ln\frac{N_{\text{tot}}}{Q(T_{\text{ex}})} - \frac{E_u}{kT_{\text{ex}}},\tag{1}$$

where k is the Boltzmann constant, v is the rest frequency of the transition,  $Q(T_{ex})$  is the partition function, h is the Planck constant, c is the light speed,  $A_{ul}$  is the spontaneous emission coefficient,  $g_u$  is the total degeneracy of upper energy level, and  $E_u/k$  is the upper level energy. The values of  $Q(T_{ex})$ ,  $A_{ul}$ ,  $g_u$ , and  $E_u/k$  are taken from the Cologne Database for Molecular Spectroscopy (CDMS) catalog<sup>6</sup> and the splatagogue astronomical spectroscopy database<sup>7</sup>.  $\int T_s dv$  is the detected transitionintegrated intensity.  $T_s$  is the source-averaged brightness temperature, corrected for beam dilution by  $T_s = T_{mb}(\theta_b^2 + \theta_s^2)/\theta_s^2$ , where  $\theta_b$  is the antenna HPBW and  $\theta_s$  is the source size. The antenna HPBW is estimated by HPBW(") = 2460/v(GHz). Following the assumption made by other researchers (e.g., Usero et al. 2004; Bayet et al. 2009; Krips et al. 2008; Aladro et al. 2013), we took a  $\theta_s$  value of 4" that was obtained based on the interfer-

<sup>&</sup>lt;sup>6</sup> https://cdms.astro.uni-koeln.de

<sup>&</sup>lt;sup>7</sup> http://www.cv.nrao.edu/php/splat/

ometric observations of <sup>12</sup>CO, HCN, and <sup>13</sup>CO (Helfer & Blitz 1995; Schinnerer et al. 2000).

The rotation diagrams of the 14 molecular species detected in our observations are shown in Fig. 6. We combined previously published data for this plot. The derived values of  $T_{ex}$  and  $N_{tot}$ are listed in Table 5. Two components were considered to fit the rotation diagrams of 8 molecules, including CS, HCN, HCO<sup>+</sup>, HNC, SiO, CN, and CH<sub>3</sub>OH. Alternatively, the nonlinear data distribution in the rotation diagrams can be caused by finite optical depths (Goldsmith, & Langer 1999). In this scenario, Eq. 1 is modified to

$$\ln \frac{N_u}{g_u} = \ln \frac{N_{\text{tot}}}{Q(T_{\text{ex}})} - \frac{E_u}{kT_{\text{ex}}} - \ln C_\tau, \qquad (2)$$

where the optical depth correction factor  $\ln C_{\tau}$  is expressed with  $\ln C_{\tau} = \ln [\tau/(1 - e^{-\tau})]$ . However, using the method developed by Goldsmith, & Langer (1999), we found that the  $C_{\tau}$  value (< 0.005) is too low to fit the rotation diagrams.

The rotation temperatures of CS are consistent with the results derived by Aladro et al. (2013) within the errors, whereas the cold components of HC<sub>3</sub>N and HCN have slightly higher rotation temperatures than the values obtained by Aladro et al. (2013). For HCO<sup>+</sup>, HNC, and SiO, the rotation temperatures derived by Aladro et al. (2013) lie between those of the cold and warm components. Because the SO ( $5_6 - 4_5$ ) and CH<sub>3</sub>CN (12 - 11) transitions are strongly blended with the wings of the strong  $^{13}$ CO (2 - 1) and C<sup>18</sup>O (2 - 1) transitions, their fluxes represent upper limits; see Qiu et al. (2018). These two transitions were excluded in fitting the rotational diagrams. The rotation temperature of SO is lower than that derived by Aladro et al. (2013) (~22.8 ± 18.6 K). Because they deviate from the fitting lines, we did not use the transitions of SO ( $5_4 - 4_4$ ), HNCO ( $6_{1,6} - 5_{1,5}$ ), ( $5_{1,4} - 4_{1,3}$ ), and ( $5_{1,5} - 4_{1,4}$ ) in the rotation diagrams.

# 3.4. Molecular transitions detected with different single-dish telescopes

Some of the molecular transitions have been detected by singledish telescopes with different beam sizes. NGC 1068 consists of a starburst ring and a CND. As shown in Fig. 1 of Takano et al. (2019), the beam of the IRAM 30m telescope covers the CND and starburst ring at the 3 mm band, while the beam of the NRO 45m telescope only covers the CND. In the 1 and 2 mm windows, the JCMT beam covers the CND and starburst ring, while the beam of the IRAM 30m telescope only covers the CND. By comparing the main-beam temperatures of a certain transition detected by different telescopes, we could roughly estimate the size of the regions from which this molecule arises. This approach has been used by Takano et al. (2019) to study the molecular emission regions in NGC 1068 and NGC 253. The authors concluded that the distributions of molecules between these two galaxies are significantly different. Combining these results with the data in the literature, we calculated the ratios between the observed intensities by different telescopes for 28 transitions (see Table 6).

When the beams cover the same emission regions (i.e., the CND), the intensities measured by the telescope with the wider beam should be lower because of the beam-dilution effect, and thus the ratios shown in Fig. 7 should be higher than unity. However, we find that the ratios for  ${}^{13}CO(1-0)$ , CH<sub>3</sub>OH ( $2_k - 1_k$ ), HNC (1-0),  ${}^{13}CO(2-1)$ , HCN (3-2), C<sup>18</sup>O (1-0), CO (1-0), SiO (2-1), HCO<sup>+</sup> (1-0), and CS (2-1) are lower than unity, suggesting that the surrounding starburst ring may significantly contribute to these transitions. Theoretically, the line

intensity ratio decreases with increasing percentage of the line emission from the starburst ring. The lines with intensity ratios much higher than unity may be mainly distributed in the CND. This is supported by interferometer observations. For instance, <sup>13</sup>CN ( $1_{1/2}-0_{1/2}$ ), HC<sub>3</sub>N (11–10), HNCO ( $5_{0,5}-4_{0,4}$ ), and CH<sub>3</sub>CN ( $6_k - 5_k$ ) have high intensity ratios. The ALMA observations of Takano et al. (2014) showed that they are concentrated in the CND. Significant contributions from the ring have been revealed by ALMA for the <sup>13</sup>CO (1 – 0) emission, which has a low intensity ratio (Fig. 7). The intensity ratio of the CS (2 – 1) line is close to unity, again in agreement with the ALMA observations that reveal low contributions from the ring.

Assuming that the telescopes with different beam sizes detect the same molecular regions, we can derive the source size by the expression

$$\theta_s = \sqrt{\frac{I_2 \times \theta_{b2}^2 - I_1 \times \theta_{b1}^2}{I_1 - I_2}},$$
(3)

where  $I_1$  and  $I_2$  are the integrated intensities detected with two different telescopes, and  $\theta_{b1}$  and  $\theta_{b2}$  are the beam sizes of the corresponding telescopes. As shown in Fig. 7 and Table 6, the estimated source sizes are generally larger than 4". However, these calculations sensitively depend on the intensity ratio and on the assumption of a Gaussian brightness distribution. Low pollution from outside of the CND may substantially increase the estimated  $\theta_s$  value. Nevertheless, the assumption of  $\theta_s = 4''$ does not significantly affect the results we obtain from the rotation diagrams. With  $\theta_s$  increasing by a factor of two, the derived column densities would decrease by about 10%, while the rotation temperatures would be maintained at the same level.

### 4. Discussion

#### 4.1. HOC<sup>+</sup> in XDR

Based on the observations of HCN and its isomer HNC in interstellar clouds, Herbst et al. (1976) hypothesized that if HNC is present in interstellar clouds, then HOC<sup>+</sup>, the energetically disfavored HCO+ isomer, is also present. Subsequently, the  $HOC^+(1-0)$  transition was detected toward Sgr B2 by Woods et al. (1983) and Ziurys & Apponi (1995), based on the experimental work of Gudeman & Woods (1982). So far, HOC<sup>+</sup> has been detected in diverse environments in our Galaxy and external galaxies, including diffuse clouds (Liszt et al. 2004), an ultracompact HII region (Rizzo et al. 2003), PDRs (Apponi et al. 1999; Fuente et al. 2003), dense molecular clouds (Apponi & Ziurys 1997), starburst galaxies (Fuente et al. 2005; Martín et al. 2009a; Aladro et al. 2015), and Seyfert galaxies (Usero et al. 2004; Aalto et al. 2015; Aladro et al. 2018). These observations suggest that HOC+ is widespread in the interstellar medium, with the [HOC<sup>+</sup>]-to-[HCO<sup>+</sup>] ratio varying from tens to some thousand. The formation routes of HOC+ and its isomer HCO<sup>+</sup> were described by Aladro et al. (2018) and references therein. Interferometer observations toward Mrk 273, a nearby Seyfert II galaxy, show a global HCO<sup>+</sup>/HOC<sup>+</sup> (J = 3-2) brightness temperature ratio of  $9 \pm 4$  and nuclear ratio of  $5 \pm 3$  (Aladro et al. 2018). HOC<sup>+</sup> was tentatively detected toward the nucleus of Mrk 231, which hosts a powerful AGN, with the HCO<sup>+</sup>/HOC<sup>+</sup> (J = 3 - 2) brightness temperature ratio ranging from 10 to 20 (Aalto et al. 2015). These values are generally lower than those in other sources, suggesting that the AGN might be associated with enhanced HOC<sup>+</sup>.

We detect the J = 2 - 1 transitions of both HCO<sup>+</sup> and HOC<sup>+</sup> in the CND of NGC 1068, allowing us to further investigate the association between AGN and the HOC<sup>+</sup> enhancement. Figure 3 presents the CO(1 - 0) map overlaid by beam sizes of the IRAM 30m telescope at the HOC<sup>+</sup> (1 - 0) and (2 - 1) lines. The HPBW at the HOC<sup>+</sup> (1 - 0) line is larger than the inner diameter of the starburst ring, while that of the HOC<sup>+</sup> (2 - 1) line is smaller. This means that the HOC<sup>+</sup> (2 - 1) emission dominantly arises from the CND region and not from the two spirals that are dominated by star formation. The situations are the same with the HCO<sup>+</sup> (1-0) and (2-1) transitions. Figure 8 shows the transitions of J = 1 - 0 and J = 2 - 1 of HCO<sup>+</sup> and HOC<sup>+</sup>, as well as the HCO<sup>+</sup>-to-HOC<sup>+</sup> temperature ratio profiles. The HCO<sup>+</sup>-to-HOC<sup>+</sup> temperature ratio of each velocity channel ranges from 32 to 109 and from 7 to 27 for the J = 1-0 and J = 2-1 transitions, respectively. These low values are consistent with the results of Usero et al. (2004), who suggested that the high electron density in the XDR may lead to a low [HCO<sup>+</sup>]/[HOC<sup>+</sup>] ratio. HCO<sup>+</sup> and HOC<sup>+</sup> in the XDR are produced through three chemical paths  $(CO + H_3^+, CO^+ + H_2, \text{ and } H_2O + C^+)$  (Maloney et al. 1996; Sternberg & Dalgarno 1995). The HCO<sup>+</sup> and HOC<sup>+</sup> fractions formed in these paths were illustrated by Usero et al. (2004) (see their Fig. 8). Our detections suggest that the integrated intensity ratio of HCO<sup>+</sup>/HOC<sup>+</sup> (J = 2 - 1) is 15.8 ± 3.0, which indicates an electron abundance with  $n(e^{-})/n(H_2) = 10^{-4.6}$  according to the XDR model of Usero et al. (2004). The CO +  $H_2^+$  and  $H_2O + C^+$ routes dominate the production of HCO<sup>+</sup> and HOC<sup>+</sup>. The high ionization degree suggests strong X/UV irradiation powered by AGN.

As shown in Fig. 8, the profiles of the HOC<sup>+</sup> (1-0) and (2-1)lines are noticeably asymmetrical with respect to  $v_{sys}$ . The asymmetry can be quantified by the ratio between the integrated fluxes in the blue and red parts relative to the central frequency. In Table 4 we compare the blue-to-red flux ratio of HOC<sup>+</sup> line with those of other lines. We find that the ratio for HOC<sup>+</sup> (2-1) is 0.93, differing from those of HNC (2 - 1) (~1.70), HCN (2 - 1) (~1.47), and HCO<sup>+</sup> (2 - 1) (~1.38). This might suggest that HOC<sup>+</sup> has a different distribution than HNC, HCN, and HCO<sup>+</sup>. We note that the spatial resolved observations toward Mrk 273 also showed different peak positions of the HOC<sup>+</sup>, HNC, HCN, and HCO<sup>+</sup> lines (Aladro et al. 2018). Therefore, we hypothesize that the formation of HOC<sup>+</sup> is more sensitive to the environments of the XDR than the formation of other molecules. Future interferometer observations of HOC+ in NGC 1068 would allow a firmer conclusion.

# 4.2. Comparison of the molecules in NGC 1068, M82, and NGC 253

To investigate the roles of AGN and starburst on molecular chemistry, we compared the molecular lines detected in NGC 1068 and in the two nearby typical starburst galaxies M 82 and NGC 253. M 82 is a prototype starburst galaxy with a high star formation rate (~9  $M_{\odot}$  yr<sup>-1</sup>, Strickland et al. 2004) at a distance of ~3.6 Mpc (Freedman et al. 1994). NGC 253 is an almost edge-on barred spiral galaxy with an active nuclear starburst (~3.6  $M_{\odot}$  yr<sup>-1</sup>, Strickland et al. 2004 at a distance of ~3 Mpc (Mouhcine et al. 2005). The star formation in M 82 and NGC 253 is in the middle and later stages, respectively. The unbiased line surveys of NGC 253 (Martín et al. 2006) and M 82 (Aladro et al. 2011) at the millimeter band have revealed that the two galaxies have clearly different chemical characteristics. In Figs. 9 and 10 we compare the rotation temperatures, column densities, and fraction abundances of nine detected molecular

species in three galaxies, including SiO, CH<sub>3</sub>CN, HC<sub>3</sub>N, SO<sub>2</sub>, SO, HNCO, CS, CH<sub>3</sub>OH, and CH<sub>3</sub>CCH. The molecular rotation temperatures in NGC 1068 are generally lower than the temperatures in M82 and NGC 253. The only exception is the warm component of CS. CS is a dense-gas tracer. Its high temperature probably suggests that the IR-photon heating, resulting from dust emission, is effective inside of the CS molecular cloud. Therefore, we conclude that the interior of the dense molecular cloud in the CND of NGC 1068 is more severely obscured by dust than the interiors in M82 and NGC 253. The heavy dust obscuration significantly shield molecules from a strong UV/X-ray radiation field, leading to the enhancement of complex molecules such as CH<sub>3</sub>OCH<sub>3</sub>.

As shown in the upper panel of Fig. 10, the column densities of molecular species in NGC 1068 are higher than those in M 82 and NGC 253 by one to two orders of magnitude, suggesting that NGC 1068 is a rich reservoir of molecules. The fraction abundance of SiO in NGC 1068 is clearly larger than those in M 82 and NGC 253 (see the lower panel of Fig. 10). This is consistent with the interferometer observations of SiO (3-2), which suggest that SiO is enhanced by a fast shock in the east knot of CND of NGC 1068 (Kelly et al. 2017).

The  $[c-C_3H_2]/[HC_3N]$  ratio can be used to trace the evolutionary stages of the star formation (Fuente et al. 2005). Taking the column density of  $c-C_3H_2$  obtained by Nakajima et al. (2011), we derive  $[c-C_3H_2]/[HC_3N] = 0.07$  for NGC 1068, which is lower than that in M82 (~ 2) and NGC 253 (~ 0.2). This suggests that the UV radiation field plays a less important role in the chemistry of NGC 1068 than that in M82 and NGC 253, where HC<sub>3</sub>N is significantly dissociated and the cyclic molecule  $c-C_3H_2$  is more resistant to UV photons.

CH<sub>3</sub>CCH has a small dipole moment (0.75 Debye), and thus its rotation temperature should be close to the kinetic temperature of the molecular cloud. It follows that the kinetic temperature in NGC 1068 is the lowest of the three galaxies. Through a large velocity gradient (LVG) analysis, Krips et al. (2008) obtained that the kinetic temperature of M 82 is 60–100 K. However, there are two solutions for the kinetic temperature of NGC 1068 (20 K and 60–240 K). The lower solution is close to the rotational temperature of CH<sub>3</sub>CCH (28.0 ± 3.4 K).

The profile of the SO  $(5_5 - 4_4)$  line suggests that SO is concentrated in the west knot of CND. Based on models of ice evaporation process, Viti et al. (2004) suggested that SO is much more abundant than  $SO_2$  at the beginning of the high-mass star formation, while the reverse is the case in the hot core. The ALMA 1.1 mm continuum emission showed that an ongoing star formation signature existed in the southwestern direction of the AGN with a distance of about 2 arcsecond (Imanishi et al. 2016). Therefore, it is likely that SO is enhanced by star formation in the west knot of the CND in NGC 1068. In ocntrast, the blue-tored flux ratio of the SO<sub>2</sub>  $(5_5 - 4_4)$  line (~2.05) is close to that of the SiO (55 - 44) line (~2.08). Therefore, we infer that SO<sub>2</sub> is more concentrated in the east knot. Figure 10 shows that SO<sub>2</sub> is more abundant than SO in both NGC 1068 and NGC 253. This can be explained by the chemical model of Viti et al. (2004), according to which SO<sub>2</sub> is more abundant than SO within the postshock gas. Previous observations have shown that the nuclear molecular clouds of NGC 253 are dominated by large-scale lowvelocity shocks (Martín et al. 2006) and that the east and west knot of NGC 1068 are dominated by a fast and a slow shock, respectively (Kelly et al. 2017). Figure 10 also shows that the abundance ratio of SO/SO<sub>2</sub> in NGC 1068 is lower than that in NGC 253. SO<sub>2</sub> can be photodissociated by interstellar UV radiation to form SO (Willacy & Millar 1997). The lower [SO]/[SO<sub>2</sub>]

ratio in NGC 1068 is consistent with our conclusion that the UV radiation field plays a less important role in the chemistry of NGC 1068 than in that of NGC 253.

## 5. Summary

We reported an observation toward the nuclear region of NGC 1068 at the 2 mm bands. The chemical properties of the CND in NGC 1068 were investigated. Our main conclusions are as follows.

1. Fifteen emission lines toward the center of NGC 1068 are detected, eight of which are the first detection in this source. Based on the line profile diagnosis of molecular gas in CDN, we infer that HC<sub>3</sub>N and SO<sub>2</sub> are mainly concentrated in the east knot of the CND, while <sup>13</sup>CCH, CH<sub>3</sub>CN, SO, HOC<sup>+</sup>, CS, CH<sub>3</sub>CCH, and H<sub>2</sub>CO are in the west knot of the CND.

2. The CND of NGC 1068 is highly ionized with an ionization degree of  $X(e^{-}) \sim 10^{-4.6}$ . The high ionization degree is consistent with the spacial distribution of HOC<sup>+</sup>, which is enhanced in XDR and is mainly distributed in the CND of NGC 1068 and not in the surrounding starburst ring.

3. Based on the rotation-diagram, we derived the column densities and rotation temperatures of 14 molecular species in NGC 1068. With these results, we find that the physical conditions and chemical environments in NGC 1068 may significantly differ from those in NGC 253 and M 82: the UV radiation filed in NGC 1068 is lower than that in M 82 and NGC 253, and NGC 1068 has the lowest kinetic temperature.

It is clear that the CND of NGC 1068 has complex chemical environments. This paper demonstrates that the data obtained by single-dish telescopes can provide significant supplements to interferometer observations in investigating the physical and chemical environments of galaxies.

Acknowledgements. We thank the anonymous referee for the useful comments that improved the manuscript. This work was supported by the Natural Science Foundation of China (NSFC) awarded to YZ (No. 11973099) and the China Postdoctoral Science Foundation funded project (No. 2019M653144) awarded to JJQ. JSZ thanks the support of NSFC (No. 11590782). LWJ appreciates support by the Guangzhou Education Bureau (No. 1201410593). JJQ wishes to thank Dr. Jun-Zhi Wang for his useful suggestions and Mr. Deng-Rong Lu for his help with the data reduction. XDT acknowledges support by the Heaven Lake Hundred-Talent Program of Xinjiang Uygur Autonomous Region of China. We wish to express my gratitude to the staff at the IRAM 30m telescope for their kind help and support during our observations

**Notes:** The fluxes are in  $T_{\rm mb}$  scale. We do not give the uncertainties, which cannot be found in the corresponding literature.

<sup>(a)</sup> We fit a Gaussian profile with the velocity and width fixed to the velocity of the  $HC_3N(10 - 9)$  transition.

<sup>(b)</sup> Two velocity components are included for the Gaussian fitting. The total flux of the CN (1 - 0) transition is 9400 ± 1000 mK km s<sup>-1</sup>.

<sup>(c)</sup> Three velocity components are included for the Gaussian fitting.

<sup>(d)</sup> CH<sub>3</sub>OH  $(J_{1,J-1} - J_{0,J})$ E and SO<sub>2</sub>  $(5_{2,4} - 5_{1,5})$  are blended. We fit their profiles with velocities and widths fixed to those of the CH<sub>3</sub>OH  $(2_k - 1_k)$  and SO<sub>2</sub>  $(14_{3,11} - 14_{2,12})$  transitions, respectively.

<sup>(e)</sup> CH<sub>3</sub>CN ( $12_0 - 11_0$ ),  ${}^{13}$ CO (2 - 1), SO ( $5_6 - 4_5$ ) and C<sup>18</sup>O (2 - 1) are blended. The integrated intensities of SO ( $5_6 - 4_5$ ) and CH<sub>3</sub>CN ( $12_0 - 11_0$ ) are upper limits.

<sup>(f)</sup> The total flux of the CN (2 – 1) transition is  $6100 \pm 700 \text{ mK km s}^{-1}$ .

<sup>(g)</sup> This transition was newly discovered in the spectra of Qiu et al. (2018).

Columns 3 and 4 list the detected integrated intensities with the NRO 45m (or IRAM 30m) and IRAM 30m (ro JCMT 15m) telescopes, respectively. Column 5 lists the ratios between the intensities given in Cols. 3 and 4. Columns 6 and 7 list the beam sizes of the NRO 45m (or IRAM 30m) and the IRAM 30m (or JCMT 15m) telescopes, respectively. Column 8 lists the estimated source sizes. Columns 9 and 10 list the references for the data listed in Cols. 1 and 2, respectively. **Reference:** (1) this work; (2) Qiu et al.
