Abstract

Principal component analysis (PCA) is a commonly used statistical procedure for dimension reduction. An important issue for PCA is to determine the rank, which is the number of dominant eigenvalues of the covariance matrix. Among information-based criteria, Akaike information criterion (AIC) and Bayesian information criterion (BIC) are two most common ones. Both use the number of free parameters for assessing model complexity, which may suffer the problem of model misspecification. To alleviate this difficulty, we propose using the generalized information criterion (GIC) for PCA rank selection. The resulting GIC model complexity takes into account the sizes of eigenvalues and, hence, is more robust to model misspecification. The asymptotic properties and selection consistency of GIC are derived under the high-dimensional setting. Compared to AIC and BIC, the proposed GIC is better capable than AIC in excluding noise eigenvalues, and is more sensitive than BIC in detecting signal eigenvalues. Moreover, we discuss an application of GIC to selecting the number of factors for factor analysis. Our numerical study reveals that GIC compares favorably to the methods based on (deterministic) parallel analysis.

Keywords: GIC, high-dimensionality, model selection under misspecification, parallel analysis, PCA.

1 Introduction

Principal component analysis (PCA) is the most widely used statistical procedure for dimension reduction. Let $X \in \mathbb{R}^p$ be a random vector distributed from an arbitrary cumulative distribution function G with mean μ and covariance Σ . Consider the spectral decomposition $\Sigma = \Gamma\Lambda\Gamma^\top$, where $\Gamma = [\gamma_1, \dots, \gamma_p] \in \mathbb{R}^{p \times p}$ satisfies $\Gamma^\top\Gamma = I_p$, and $\Lambda \in \mathbb{R}^{p \times p}$ is a diagonal matrix with positive diagonal entries arranged in descending order

$$\lambda_1 > \lambda_2 > \dots > \lambda_{r_0} \gg \lambda_{r_0+1} > \dots > \lambda_p. \quad (1)$$

Here we assume the existence of a sufficient gap between λ_{r_0} and λ_{r_0+1} so that r_0 can be treated as the *target rank* of Σ . With a rigorous definition of r_0 , which will be given in Section 3.1, model (1) is called the *generalized spiked covariance model*. Then, the leading eigenvectors $[\gamma_1, \dots, \gamma_{r_0}]$ are the target of PCA for dimension reduction. In the sample level, let $\{X_i\}_{i=1}^n$ be a random sample, and let $S_n = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})^\top$ be the sample covariance matrix, where $\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$. Consider the spectral decomposition

$$S_n = \sum_{j=1}^p \hat{\lambda}_j \hat{\gamma}_j \hat{\gamma}_j^\top. \quad (2)$$

If r_0 is known, then PCA suggests to map the data $\{X_i\}_{i=1}^n$ onto the space spanned by the leading eigenvectors $[\hat{\gamma}_1, \dots, \hat{\gamma}_{r_0}]$ for the subsequent analysis. Since r_0 is usually unknown, an important issue of PCA is the determination of the target rank r_0 .

There are many methods developed to determine r_0 , and among them we mainly focus on the information-based criteria. Two commonly used information criteria for PCA rank selection are the Akaike information criterion (AIC) and the Bayesian information criterion (BIC). These methods adopt the number of free parameters as the penalty to prevent the selection of a saturated model. The difference between the two criteria is that AIC uses a constant 2 to weight the model penalty, while BIC uses $\ln n$. Statistical properties of AIC and BIC under the case of $n \rightarrow \infty$ and $p < \infty$ are studied in Fujikoshi and Sakurai (2016), wherein the authors show that AIC does not achieve selection consistency while BIC does. Later, the selection consistency of AIC and BIC under the case of $n \rightarrow \infty$ and $p/n \rightarrow c > 0$ are established in Bai, Choi and Fujikoshi (2018) by using random matrix theory. Both the

above-mentioned two works assume the validity of the *simple spiked covariance model*, i.e., model (1) with the constraint $\lambda_{r_0+1} = \dots = \lambda_p$, for theoretical developments.

Due to its sparseness when $r_0 \ll p$, the simple spiked covariance model provides a feasible alternative to its generalized counterpart (1). However, choosing r_0 via the model selection criteria derived under the simple spiked covariance model (such as AIC and BIC) may no longer be suitable, provided some of the tail eigenvalues in (1) are distinct from each other. This leads to the problem of PCA rank selection under model misspecification. There is a rich literature on model selection under misspecification; see Konishi and Kitagawa (1996), Lv and Liu (2014), Hsu, Ing and Tong (2019) and the references therein. Lv and Liu (2014) have introduced the generalized BIC (GBIC) and generalized AIC (GAIC) based on rigorous asymptotic expressions of the Bayesian and KL divergence principles in misspecified generalized linear models. Hsu, Ing and Tong (2019) have proposed the misspecification-resistant information criterion (MRIC) via an asymptotic expression for the mean squared prediction error of a misspecified time series model. These criteria, however, focusing on regression-type models, are not directly applicable to PCA rank selection. Konishi and Kitagawa (1996), on the other hand, have established an asymptotic expression of the KL divergence principle in a general misspecification framework, leading to their celebrated generalized information criterion (GIC). Although the framework considered in Konishi and Kitagawa (1996) is quite general, their derivation of GIC is reliant on some high-level assumptions, which may fail to hold for PCA; see Section 2.2 for details.

In this paper, we derive the GIC-based bias correction, b_r^{GIC} , to the KL divergence for the PCA rank selection problem, when a misspecified simple spiked covariance model is postulated. While b_r^{GIC} borrows the general idea of Konishi and Kitagawa (1996), it is obtained under mild moment and distributional assumptions, thereby alleviating the difficulty mentioned in the previous paragraph. Moreover, we show that b_r^{GIC} has an elegant expression in terms of the sizes of covariance eigenvalues. This expression not only provides a deeper understanding of the KL divergence principle in misspecified PCA models, but it also leads to a model selection criterion with a penalty term more adaptive to various spiked covariance structures than AIC and BIC, which simply depend on the number of free parameters. In particular, the proposed GIC for PCA rank selection is more capable than AIC in excluding

noise eigenvalues, and is more sensitive than BIC in detecting signal eigenvalues. Moreover, we also discuss an application of our GIC to selecting the number of factors for factor analysis (FA). Numerical study reveals that GIC compares favorably to the methods based on deterministic parallel analysis (DPA) proposed by Dobriban and Owen (2019).

The rest of this article is organized as follows. Our GIC-based PCA rank selection method is derived in Section 2, and its asymptotic properties are investigated in Section 3. Numerical studies and a data example are provided in Section 4. Section 5 presents the application of GIC to selecting the number of factors in FA. This article ends with a discussion in Section 6. All proofs are placed in the Appendix.

2 GIC for PCA Rank Selection

2.1 Review of AIC and BIC

The AIC for PCA rank selection starts from fitting $\{X_i\}_{i=1}^n$ with the *rank- r simple spiked covariance model* as the working model:

$$\Sigma_r = \Gamma_r \Lambda_r \Gamma_r^\top + \sigma_r^2 Q_r, \quad 0 \leq r \leq p-1, \quad (3)$$

where $\Gamma_r = [\gamma_1, \dots, \gamma_r]$, $\Lambda_r = \text{diag}(\lambda_1, \dots, \lambda_r)$ with $\lambda_1 > \dots > \lambda_r > \sigma_r^2 > 0$, and $Q_r = I_p - \Gamma_r \Gamma_r^\top$. The case of $r = 0$ is understood as $\Sigma_0 = \sigma_0^2 I_p$. The benefit of model (3) is that r can be directly explained as the target rank of interest, and a certain information criterion can be straightforwardly applied to determining a suitable value of r . Assume the Gaussian distribution assumption $X \sim N(\mu, \Sigma_r)$, and let

$$\theta_r = (\text{vec}(\Gamma_r)^\top, \lambda_1, \dots, \lambda_r, \sigma_r^2, \mu^\top)^\top. \quad (4)$$

The log-likelihood of θ_r (up to a constant term) is given by

$$\ell_n(\theta_r) = \int \ell(x|\theta_r) dG_n(x) \quad \text{with} \quad \ell(x|\theta_r) = -\frac{1}{2} \ln |\Sigma_r| - \frac{1}{2} \text{tr} \{ (x - \mu)(x - \mu)^\top \Sigma_r^{-1} \},$$

where G_n is the empirical distribution of $\{X_i\}_{i=1}^n$. Straightforward calculation shows that the MLE of θ_r , i.e., $\hat{\theta}_r = \text{argmax}_{\theta_r} \ell_n(\theta_r)$, consists of

$$\hat{\Gamma}_r = [\hat{\gamma}_1, \dots, \hat{\gamma}_r], \quad \hat{\Lambda}_r = \text{diag}(\hat{\lambda}_1, \dots, \hat{\lambda}_r), \quad \hat{\sigma}_r^2 = \frac{1}{p-r} \sum_{j>r} \hat{\lambda}_j, \quad \hat{\mu} = \bar{X}, \quad (5)$$

where $\widehat{\gamma}_j$'s and $\widehat{\lambda}_j$'s are defined in (2). Since $\text{tr}(S_n \widehat{\Sigma}_r^{-1}) = p$,

$$\ell_n(\widehat{\theta}_r) = -\frac{1}{2} \ln |\widehat{\Sigma}_r| - \frac{p}{2} \quad \text{with} \quad \widehat{\Sigma}_r = \widehat{\Gamma}_r \widehat{\Lambda}_r \widehat{\Gamma}_r^\top + \widehat{\sigma}_r^2 \widehat{Q}_r, \quad (6)$$

where $\widehat{Q}_r = I_p - \widehat{\Gamma}_r \widehat{\Gamma}_r^\top$. Then, AIC estimates r_0 by

$$\widehat{r}_{\text{AIC}} = \underset{r \leq q}{\text{argmax}} \left\{ \ell_n(\widehat{\theta}_r) - \frac{1}{n} b_r \right\} = \underset{r \leq q}{\text{argmin}} \left\{ \ln |\widehat{\Sigma}_r| + \frac{2}{n} b_r \right\}, \quad (7)$$

where $q \leq p - 1$ is a pre-determined upper bound of the model rank, and

$$b_r = \left\{ pr - \frac{r(r+1)}{2} \right\} + r + 1 + p \quad (8)$$

is the number of free parameters in θ_r . BIC estimates r_0 in a similar manner with AIC, except that BIC uses $\ln n$ as the weight for b_r/n :

$$\widehat{r}_{\text{BIC}} = \underset{r \leq q}{\text{argmin}} \left\{ \ln |\widehat{\Sigma}_r| + \frac{\ln n}{n} b_r \right\}. \quad (9)$$

Statistical properties of \widehat{r}_{AIC} and \widehat{r}_{BIC} have been studied in Fujikoshi and Sakurai (2016) for finite p case, and in Bai, Choi and Fujikoshi (2018) for diverging p case, both assume that the true model is the simple spiked covariance model. We remind the reader that the true model considered in this paper is the generalized spiked covariance model (1), while the rank- r simple spiked covariance model (3) is only a working model for rank selection.

Let θ_r^* be the population version of MLE from fitting the rank- r simple spiked covariance model (3). By (5), we have that θ_r^* consists of

$$\Gamma_r^* = [\gamma_1, \dots, \gamma_r], \quad \Lambda_r^* = \text{diag}(\lambda_1, \dots, \lambda_r), \quad \sigma_r^{*2} = \frac{1}{p-r} \sum_{j>r} \lambda_j, \quad \mu^* = \mu, \quad (10)$$

and the rank- r simple spiked covariance matrix induced by θ_r^* is given by

$$\Sigma_r^* = \Gamma_r^* \Lambda_r^* \Gamma_r^{*\top} + \sigma_r^{*2} Q_r^*,$$

where $Q_r^* = I_p - \Gamma_r^* \Gamma_r^{*\top}$. The notation θ_r^* and Σ_r^* will be used in the subsequent discussion.

Remark 1. Note that $\widehat{\Sigma}_r$ in (6) also minimizes the log-determinant divergence between S_n and Σ_r : $\mathcal{D}(S_n, \Sigma_r) = -\frac{1}{2} \ln |S_n \Sigma_r^{-1}| + \frac{1}{2} \text{tr}(S_n \Sigma_r^{-1}) - \frac{p}{2}$. Thus, if the Gaussian assumption is not valid, $\widehat{\Sigma}_r$ can still be explained as the minimum log-determinant divergence estimator.

2.2 GIC for model complexity measure

AIC, penalizing model complexity based on the number of free parameters b_r , is obtained under the crucial assumption that model (3) is the true data generating distribution. However, this simple spiked model assumption can be easily violated in practical applications of high dimensional data. When (3) is used as a working model but the true model is (1), the GIC of Konishi and Kitagawa (1996), taking model misspecification into account, appears to be a more appealing alternative. To derive GIC in this case, one must establish an asymptotic expression for the bias incurred by using the within-sample prediction error to approximate the likelihood-based prediction error,

$$E \left\{ \int \ell(x|\hat{\theta}_r) dG_n(x) - \int \ell(x|\hat{\theta}_r) dG(x) \right\}, \quad (11)$$

which is suggested by the KL divergence principle. Here, the expectation is taken with respect to $X_1, \dots, X_n \stackrel{\text{i.i.d.}}{\sim} G$. Note that the true distribution G need not be Gaussian.

Theorem 2.1 in Konishi and Kitagawa (1996) suggests that (11) can be expressed as $n^{-1}b_r^{\text{GIC}} + o(n^{-1})$, where

$$b_r^{\text{GIC}} = E \left[\left\{ \frac{\partial \ell(X|\theta_r)}{\partial \theta_r} \Big|_{\theta_r = \theta_r^*} \right\}^\top \text{IF}_{T_r}(X; G) \right] \quad (12)$$

with the expectation being taken with respect to $X \sim G$. Here $\text{IF}_{T_r}(x; G)$ is the influence function of the MLE functional T_r from fitting the rank- r simple spiked model (3), i.e., $\theta_r^* = T_r(G)$ and $\hat{\theta}_r = T_r(G_n)$. The derivation of Konishi and Kitagawa (1996), however, is based on the functional Taylor series expansion of T_r around G under the assumption that T_r is second-order compact differentiable at G . The second-order compact differentiability is difficult to check and can be violated for eigenvalues and eigenvectors as functionals of G . It is known that even the sample mean is not compact differentiable (Beutner and Zähle, 2010). Furthermore, the proof of their Theorem 2.1 involves interchanging expectations and probability limits, such as $\lim_{n \rightarrow \infty} E \{o_p(1)\} = 0$, which is in general not true without imposing some smoothness conditions on G . In Theorem 1 we give a rigorous derivation for prediction error bias correction for PCA rank selection and show that the asymptotic expression given in Konishi and Kitagawa (1996) is still valid.

Theorem 1. *Assume the following two conditions:*

(i) *X has finite $4q^{\text{th}}$ moments for some $q > 1$.*

(ii) *The distribution of X satisfies the Lipschitz condition: there exist $c_o > 0$, $0 < \nu \leq 1$, $0 < \delta \leq 1$ such that $\sup_{v \in \mathbb{R}^p, \|v\|=1} P(|v^\top(X - \mu)| \leq \omega) \leq c_o(2\omega)^\nu$ for all $0 < \omega \leq \delta/2$.*

Then, $\lim_{n \rightarrow \infty} nE \left\{ \int \ell(x|\hat{\theta}_r) dG_n(x) - \int \ell(x|\hat{\theta}_r) dG(x) \right\} = b_r^{\text{GIC}}$ for any fixed r and p .

Whereas (i) imposes a mild moment restriction, assumptions like (ii) have been frequently used to derive information criteria in a rigorous manner. For example, under correct specification of the model and an assumption slightly stronger than (ii), Findley and Wei (2002) have presented the first mathematically complete derivation of AIC for vector autoregressions. As shown in Section 4 of Findley and Wei (2002), their stronger assumption is fulfilled by a rich class of multivariate distributions, including the Gaussian, t , and ε -contaminated Gaussian. Note that we assume in Theorem 1 the finiteness of p for mathematical tractability. We are not able to extend the result to the case of diverging p . Nevertheless, to the best of our knowledge there is no existent study for GIC-based PCA rank selection even for the fixed p case. The finiteness of p , however, is merely to establish Theorem 1. In the rest of the article, this assumption is no longer required in the development of our method nor for the selection consistency theorem.

It is worth emphasizing that b_r^{GIC} consists of two parts: the differential of log-likelihood $\partial \ell(x|\theta_r)/\partial \theta_r$ under the working model $N(\mu, \Sigma_r)$, and the influence function $\text{IF}_{T_r}(x; G)$ of MLE under the true G with the generalized spiked covariance matrix satisfies (1). Intuitively, b_r^{GIC} can be estimated by $\frac{1}{n} \sum_{i=1}^n \left\{ \frac{\partial \ell(X_i|\hat{\theta}_r)}{\partial \theta_r} \right\}^\top \text{IF}_{T_r}(X_i; G_n)$ using empirical data. However, a closer look at the calculation of b_r^{GIC} reveals that its estimation under the PCA rank selection problem involves the fourth moments of X , which can be unstable in practice. Fortunately, a neat expression of b_r^{GIC} that avoids calculating higher-order moments of X can be derived under the working assumption of Gaussianity on X .

Theorem 2. *Assume $X \sim N(\mu, \Sigma)$, where Σ satisfies the generalized spiked covariance*

model (1). Then, we have $b_r^{\text{GIC}} = b_{\Gamma_r}^{\text{GIC}} + b_{\Lambda_r}^{\text{GIC}} + b_{\sigma_r^2}^{\text{GIC}} + b_{\mu}^{\text{GIC}}$, $0 \leq r \leq p-1$, where

$$\begin{aligned} b_{\Gamma_r}^{\text{GIC}} &= \binom{r}{2} + \sum_{j \leq r} \sum_{\ell > r} \frac{\lambda_{\ell}(\lambda_j - \sigma_r^{*2})}{\sigma_r^{*2}(\lambda_j - \lambda_{\ell})}, \\ b_{\Lambda_r}^{\text{GIC}} &= r, \\ b_{\sigma_r^2}^{\text{GIC}} &= \frac{\frac{1}{p-r} \sum_{j>r} \lambda_j^2}{\left(\frac{1}{p-r} \sum_{j>r} \lambda_j\right)^2}, \\ b_{\mu}^{\text{GIC}} &= p \end{aligned}$$

account for the model complexity corresponding to Γ_r , Λ_r , σ_r^2 , and μ . Here $\binom{r}{2} = 0$ if $r \leq 1$, and $b_{\Gamma_r}^{\text{GIC}} = b_{\Lambda_r}^{\text{GIC}} = 0$ if $r = 0$.

One can see from Theorem 2 that b_r^{GIC} depends on the dispersion of λ_j 's, while the value of b_r does not. More insights for terms making up b_r^{GIC} are listed below:

- For $b_{\Gamma_r}^{\text{GIC}}$, recall that $pr - \frac{r(r+1)}{2}$ is the number of free parameters in Γ_r . We have

$$b_{\Gamma_r}^{\text{GIC}} - \left\{ pr - \frac{r(r+1)}{2} \right\} = \sum_{j \leq r} \xi_{j|r},$$

where

$$\xi_{j|r} = \sum_{\ell > r} \left\{ \frac{\lambda_{\ell}(\lambda_j - \sigma_r^{*2})}{\sigma_r^{*2}(\lambda_j - \lambda_{\ell})} - 1 \right\} = \frac{\lambda_j}{\sigma_r^{*2}} \sum_{\ell > r} \frac{\lambda_{\ell} - \sigma_r^{*2}}{\lambda_j - \lambda_{\ell}}, \quad j \leq r.$$

For a given r , $\xi_{j|r}$ can be explained as the difference of model complexity for the j -th eigenvector between models without and with the requirement of correctly specifying the rank- r simple spiked model (3). By the definition of σ_r^{*2} in (10), we have

$$\xi_{j|r} \geq \frac{\lambda_j}{\sigma_r^{*2}} \sum_{\ell > r} \frac{\lambda_{\ell} - \sigma_r^{*2}}{\lambda_j - \sigma_r^{*2}} = 0.$$

This indicates that counting the number of free parameters generally underestimates the model complexity of Γ_r , especially when $\{\lambda_{\ell} : \ell > r\}$ deviates from their mean σ_r^{*2} .

- For $b_{\sigma_r^2}^{\text{GIC}}$, we have

$$b_{\sigma_r^2}^{\text{GIC}} = \frac{\frac{1}{p-r} \sum_{j>r} \lambda_j^2}{\left(\frac{1}{p-r} \sum_{j>r} \lambda_j\right)^2} \geq 1,$$

where the equality holds if and only if the elements of $\{\lambda_j : j > r\}$ are all equal. That is to say, except for the case $\Sigma = \Sigma_{r_0}$, where the population covariance exactly

matches the simple spiked working covariance, counting the number of free parameters underestimates the model complexity for tail components. However, $b_{\sigma_r^2}^{\text{GIC}}$ can be more adaptive to the eigenvalue dispersion in assessing the complexity for tail components.

- For $b_{\Lambda_r}^{\text{GIC}}$ and b_{μ}^{GIC} , GIC counts the number of free parameters in Λ_r and μ . It indicates that the misspecification of a generalized spiked model by a simple spiked model has no impact on the complexity of leading r eigenvalues and mean vector.

From the observations above, we have

$$b_r^{\text{GIC}} \geq b_r \quad \forall (r, \theta_r). \quad (13)$$

A trivial case for the equality to hold is the case of full model $r = p - 1$, in which situation we have $b_{p-1}^{\text{GIC}} = b_{p-1} = \frac{1}{2}p(p+1) + p$. For $r < p - 1$, the equality in (13) holds if and only if $\Sigma = \Sigma_{r_0}$ and $r \geq r_0$ (see Remark 2 for details). As the simple spiked model (3) is rarely true, (13) implies that b_r generally underestimates the model complexity, in which situation model misspecification can be an issue.

With the expression of b_r^{GIC} , our GIC-based rank estimator is proposed to be

$$\hat{r}_{\text{GIC}} = \underset{r \leq q}{\operatorname{argmin}} \left\{ \ln |\hat{\Sigma}_r| + \frac{2}{n} \hat{b}_r^{\text{GIC}} \right\}, \quad (14)$$

where

$$\hat{b}_r^{\text{GIC}} = \left\{ \binom{r}{2} + \sum_{j \leq r} \sum_{\ell > r} \frac{\hat{\lambda}_\ell (\hat{\lambda}_j - \hat{\sigma}_r^2)}{\hat{\sigma}_r^2 (\hat{\lambda}_j - \hat{\lambda}_\ell)} \right\} + r + \frac{\frac{1}{p-r} \sum_{j>r} \hat{\lambda}_j^2}{\left(\frac{1}{p-r} \sum_{j>r} \hat{\lambda}_j \right)^2} + p \quad (15)$$

is the sample version of b_r^{GIC} obtained by plugging in the sample eigenvalues, and q is a pre-determined upper bound of the model rank. Note that $n^{-1}(b_{\Lambda_r}^{\text{GIC}} + b_{\sigma_r^2}^{\text{GIC}}) = o(1)$, while $n^{-1}b_{\Gamma_r}^{\text{GIC}} = O(1)$, and that b_{μ}^{GIC} is independent of the model rank r . This indicates that $b_{\Gamma_r}^{\text{GIC}}$ plays a dominant role in applying \hat{r}_{GIC} . The form of $b_{\Gamma_r}^{\text{GIC}}$ also indicates that GIC will prevent the selection of a model rank with nearly multiple eigenvalues, in which situation a large value of $\hat{b}_{\Gamma_r}^{\text{GIC}}$ is induced due to the division by $(\hat{\lambda}_j - \hat{\lambda}_\ell)$. This scenario, however, cannot be reflected by b_r that simply counts the number of free parameters.

We close this section by noting that the Gaussian assumption in Theorem 2 is merely used to get an explicit neat expression for b_r^{GIC} . This assumption is not critical in applying

\widehat{r}_{GIC} . In Section 3, we will rigorously investigate the asymptotic properties of $\widehat{b}_r^{\text{GIC}}$ and \widehat{r}_{GIC} under the high-dimensional setting and without requiring the Gaussian assumption.

Remark 2. *The derivation of b_r^{GIC} in Theorem 2 is under the assumption of distinct eigenvalues (1). For $\Sigma = \Sigma_{r_0}$, where the tail eigenvalues are equal, b_r^{GIC} can still be well-defined by setting $0/0 = 1$ for these terms $\frac{\lambda_j - \sigma_r^{*2}}{\lambda_j - \lambda_\ell}$. With this treatment, it is straightforward to show that $b_r^{\text{GIC}} = b_r$ if and only if $\Sigma = \Sigma_{r_0}$ and $r \geq r_0$.*

3 Rank Selection Consistency

3.1 The target rank

The selection consistency is meaningful only when there is a precise definition for the target rank r_0 of Σ . The aim of this subsection is to provide a rigorous definition for r_0 that is identifiable under model (1).

We start by reviewing some basic results of random matrix theory. Define the empirical spectral distribution (ESD) of Σ to be

$$F^\Sigma(t) = \frac{1}{p} \sum_{j=1}^p \mathcal{I}\{\lambda_j \leq t\},$$

where $\mathcal{I}\{\cdot\}$ is the indicator function. We remind the reader that the Gaussian assumption for X is no longer required in the rest of discussion. Instead, we assume the following conditions (C1)–(C4), which are commonly used in random matrix theory (Bai and Yao, 2012).

(C1) For each i , X_i takes the form $X_i = \Sigma^{1/2}Z_i$, where $Z_i \in \mathbb{R}^p$ consists of i.i.d. random variables with mean 0, variance 1, and finite fourth moment.

(C2) $p/n \rightarrow c \in (0, \infty)$.

(C3) F^Σ converges weakly to H as $p \rightarrow \infty$, where H has bounded support.

(C4) The sequence of spectral norms of Σ is bounded.

The distribution H is called the limiting spectral distribution (LSD) of Σ . The LSD of the sample covariance matrix S_n exists and is determined by (c, H) .

Theorem 3 (Yao, Zheng and Bai, 2015). *Given (c, H) . Then, F^{S_n} converges to the generalized Marčenko-Pastur distribution $F_{c,H}$ as $n \rightarrow \infty$. The Stieltjes transform of $F_{c,H}$, $s_{c,H}(z) = \int \frac{1}{t-z} dF_{c,H}(t)$, $z \in \mathbb{C}^+$, is implicitly determined via $s_{c,H}(z) = \int \frac{dH(t)}{t\{1-c-cz s_{c,H}(z)\}-z}$. Moreover, $F_{c,H}$ and H share the same mean, i.e., $\int t dF_{c,H}(t) = \int t dH(t) = \mu_H$.*

A major difficulty of random matrix theory is that $F_{c,H}$ has no explicit form for an arbitrary H . One known result for $F_{c,H}$ is under the *simple spiked covariance model* assumption:

$$(C5) \quad H(t) = \mathcal{I}\{t \geq \sigma^2\} \text{ for some } \sigma^2 > 0.$$

Theorem 4 (Marčenko-Pastur Law). *Assume further the simple spiked covariance model (C5) and given c . Then, the probability density function of $F_{c,H}$ is given by*

$$f_{c,\sigma^2}(t) = \frac{1}{2\pi c\sigma^2 t} \sqrt{(t-a)(b-t)} \cdot \mathcal{I}\{a \leq t \leq b\}$$

with an additional point mass at $t = 0$ having probability $1 - 1/c$ if $c > 1$, where $a = \sigma^2(1 - \sqrt{c})^2$ and $b = \sigma^2(1 + \sqrt{c})^2$. The mean under $F_{c,H}$ is $\mu_H = \sigma^2$.

An eigenvalue λ_j is called a *generalized spike eigenvalue* if λ_j does not belong to the support of H , denoted by $\mathcal{S}(H)$. For the PCA rank selection problem, we assume that the generalized spike eigenvalues are larger than $\sup \mathcal{S}(H)$, so that these spike eigenvalues can be of the major interest. To study the asymptotic behavior of $\widehat{\lambda}_j$, define

$$\psi(\lambda) = \lambda \left\{ 1 + c \int \frac{t}{\lambda - t} dH(t) \right\} \quad \text{and} \quad \psi'(\lambda) = \frac{\partial \psi(\lambda)}{\partial \lambda}, \quad \lambda \notin \mathcal{S}(H).$$

Note that $\psi(\cdot)$ depends on (c, H) . The following results are modified from Bai, Chen and Yao (2010), Bai and Yao (2012), and Yao, Zheng and Bai (2015).

Theorem 5. *Let λ_j be a generalized spike eigenvalue with $\psi_j = \psi(\lambda_j)$, and let $b = \sup \mathcal{S}(F_{c,H})$.*

- (i) $\psi_j \notin \mathcal{S}(F_{c,H})$ (i.e., $\psi_j > b$) if and only if $\psi'(\lambda_j) > 0$.
- (ii) If $\psi'(\lambda_j) > 0$, then $\widehat{\lambda}_j \xrightarrow{a.s.} \psi_j$.
- (iii) If $\psi'(\lambda_j) \leq 0$ and $j = o(p)$, then $\widehat{\lambda}_j \xrightarrow{a.s.} b$.
- (iv) For any $k = o(p)$, $\frac{1}{p-k} \sum_{\ell > k} \widehat{\lambda}_\ell \xrightarrow{a.s.} \mu_H$.

These results show that a generalized spike eigenvalue λ_j is not guaranteed to be identifiable in general. The identifiability of the j th spike further requires $\psi'(\lambda_j) > 0$ so that the corresponding limiting value ψ_j can be separated from $\mathcal{S}(F_{c,H})$. Thus, a generalized spike eigenvalue λ_j is called a *distant spike* if $\psi'(\lambda_j) > 0$; otherwise, it is called a *close spike*. This definition also implies that for distant spikes $\lambda_j > \lambda_k$, one has $\psi_j > \psi_k > b$.

We are now in a position to define the *target rank* r_0 of a PCA model. Under the generalized spiked covariance model (1), we know from Theorem 5 that only distant spike eigenvalues can be separated from $\mathcal{S}(F_{c,H})$. This motivates the following definition of r_0 .

Definition 1. *Given (c, H) , define $r_0 = \sum_{j=1}^p \mathcal{I}\{\psi'(\lambda_j) > 0\}$ to be the number of distant spikes. We call r_0 the target rank of Σ for PCA rank selection calibrated by (c, H) .*

The definition of r_0 implies that $\psi_{r_0} > b$; hence, the rank- r_0 PCA subspace is identifiable under (c, H) . Consequently, for any given (c, H) , r_0 is the well-defined target rank of Σ , under which we can study the selection consistency of \widehat{r}_{GIC} .

3.2 Selection consistency of GIC

The asymptotic properties of \widehat{r}_{GIC} heavily depend on the asymptotic increment of the GIC penalty when one increases the model rank from $(j - 1)$ to j :

$$\kappa_j = \lim_{n \rightarrow \infty} \frac{1}{n} \left(\widehat{b}_j^{\text{GIC}} - \widehat{b}_{j-1}^{\text{GIC}} \right), \quad 1 \leq j \leq p - 1.$$

Define the function

$$\kappa(u) = c(u - 1)E \left\{ \frac{(T/\mu_H)}{u - (T/\mu_H)} \right\}, \quad u \in [b/\mu_H, \infty), \quad (16)$$

where the expectation is taken with respect to $T \sim F_{c,H}$. The function $\kappa(u)$ is well defined for $u > b/\mu_H$. As to the boundary point b/μ_H , it is defined by $\kappa(b/\mu_H) = \lim_{u \rightarrow b/\mu_H} \kappa(u)$ and is assumed bounded. We have the following results for the asymptotic increment κ_j .

Theorem 6. *Assume conditions (C1)–(C4).*

(i) $\kappa(u)$ is a strictly decreasing function. Moreover, $\kappa(u) \geq c$ and $\lim_{u \rightarrow \infty} \kappa(u) = c$.

(ii) For $j = o(p)$, we have

$$\kappa_j = \begin{cases} \kappa(\psi_j/\mu_H), & j \leq r_0, \\ \kappa(b/\mu_H), & j > r_0. \end{cases} \quad (17)$$

Note that the limiting value $\kappa(b/\mu_H)$ is independent of j .

The implications of Theorem 6 are threefold. First, we have

$$\kappa_j \geq c \quad \text{for } j = o(p). \quad (18)$$

For the rank-0 PCA model, $\lim_{n \rightarrow \infty} \frac{1}{n} b_0^{\text{GIC}} = \lim_{n \rightarrow \infty} \frac{1}{n} b_0 = c$. Since the asymptotic increment of $\frac{1}{n} b_r$ is c (Bai, Choi and Fujikoshi, 2018), (18) implies that

$$\lim_{n \rightarrow \infty} P(\widehat{r}_{\text{GIC}} \leq \widehat{r}_{\text{AIC}}) = 1. \quad (19)$$

That is, GIC tends to select a smaller model than AIC. Second, $\lim_{u \rightarrow \infty} \kappa(u) = c$ implies that for the model rank with a large eigenvalue, GIC tends to use the same penalty c as AIC does. Third, κ_j is an increasing function of j that attains the maximum value $\kappa(b/\mu_H)$ when $j > r_0$. That is, GIC places a higher penalty on the model rank for a smaller eigenvalue, and places the maximum penalty $\kappa(b/\mu_H)$ when the eigenvalue is smaller than the minimum distant spike λ_{r_0} . This is reasonable since an eigenvector associated with a smaller eigenvalue is more difficult to estimate, and one must pay a higher cost in its estimation. Thus, when there exists a sufficiently large gap between λ_{r_0} and $\mathcal{S}(H)$ in the sense that ψ_{r_0} and b are well separated, $\kappa(b/\mu_H)$ for $j > r_0$ is expected to be sufficiently larger than $\kappa(\psi_{r_0}/\mu_H)$. That is, one will undertake a large penalty when the model size goes beyond r_0 , and this property will drive GIC to select the target rank r_0 . Below we state the selection consistency of GIC.

Theorem 7. *Assume conditions (C1)–(C4) and $q = o(p)$. Then, \widehat{r}_{GIC} achieves selection consistency if and only if the following conditions are satisfied:*

$$(G1) \quad L_{\text{GIC}}(\psi_{r_0}/\mu_H) < 0,$$

$$(G2) \quad L_{\text{GIC}}(b/\mu_H) > 0,$$

where $L_{\text{GIC}}(u) = \ln u - (u - 1) + 2\kappa(u)$, and $\kappa(u)$ is defined in (16).

Note that “ $\ln u - (u - 1)$ ” in $L_{\text{GIC}}(u)$ corresponds to a decrement in negative log-likelihood and “ $\kappa(u)$ ” corresponds to an increment of model penalty, when the rank of model covariance increases. Following the terminology of Bai, Choi and Fujikoshi (2018), we call (G1)–(G2) the *gap conditions of GIC*. Condition (G1) gives the minimum size for the distant spike eigenvalue λ_{r_0} , while condition (G2) quantifies the maximum size for the upper bound b of $\mathcal{S}(F_{c,H})$. Recall from Theorem 6 that $\kappa(\cdot)$ achieves the maximum value at $\kappa(b/\mu_H)$, which implies that (G2) is usually not as critical as (G1) to the selection consistency of GIC.

The selection consistency of AIC and BIC under the simple spiked covariance model with diverging p has been established in Bai, Choi and Fujikoshi (2018). Following the proof of Theorem 7 with $2\kappa(\cdot)$ therein replaced by $2c$ and $(\ln n)c$, we can extend the results of Bai, Choi and Fujikoshi (2018) to the generalized spiked covariance model (1).

Theorem 8. *Assume conditions (C1)–(C4) and $q = o(p)$.*

(i) \hat{r}_{AIC} achieves selection consistency if and only if the following conditions are satisfied:

$$(A1) \quad L_{\text{AIC}}(\psi_{r_0}/\mu_H) < 0,$$

$$(A2) \quad L_{\text{AIC}}(b/\mu_H) > 0,$$

$$\text{where } L_{\text{AIC}}(u) = \ln u - (u - 1) + 2c.$$

(ii) \hat{r}_{BIC} achieves selection consistency if and only if the following conditions are satisfied:

$$(B1) \quad \lim_{n \rightarrow \infty} L_{\text{BIC}}(\psi_{r_0}/\mu_H) < 0,$$

$$(B2) \quad \lim_{n \rightarrow \infty} L_{\text{BIC}}(b/\mu_H) > 0,$$

$$\text{where } L_{\text{BIC}}(u) = \ln u - (u - 1) + (\ln n)c.$$

Some further observations for these selection criteria are listed below:

- For AIC, $\kappa_j \geq c$ from (18) implies that the gap condition (G1) of GIC is stronger than (A1) of AIC (denoted by “(G1) \succ (A1)” in the rest of the discussion). This is reasonable since the penalty of GIC involves the estimation of eigenvalues, and a larger ψ_{r_0}/μ_H is required to make the estimation of b_r^{GIC} stable, whereas the AIC

penalty involves only counting the number of free parameters without the need to estimate them. The benefit of adopting eigenvalues into the model penalty is that it makes GIC more robust to the form of H than AIC. In particular, the validity of (G2) is less affected by a large value of b due to the factor $2\kappa(b/\mu_H)$ (recall that $\kappa(\cdot)$ is a decreasing function and $\kappa(\cdot) \geq c$), while (A2) adopts a constant $2c$ for all b . In other words, we have “(A2) \succ (G2)”. The advantage of GIC comes from its robustness in that b_r^{GIC} does not require the rank- r working model (3) is the true model. GIC can thus be more adaptive to various structures of Σ than AIC, especially when the working model (3) is heavily violated.

- For BIC, it can be seen that (B2) is automatically satisfied for sufficiently large n , which implies “(G2) \succ (B2)”. Although this indicates the robustness of BIC to the size of b , the cost is that the validity of (B1) requires a diverging ψ_{r_0}/μ_H , i.e., “(B1) \succ (G1)”. This phenomenon is also found in Bai, Choi and Fujikoshi (2018), wherein the authors develop the selection consistency of BIC when $\lim_{n \rightarrow \infty} \{(\psi_{r_0}/\mu_H)/\ln n\} = \infty$. Briefly, the validity of BIC requires a large sample size n (such that (B2) is satisfied) and an extremely large value of ψ_{r_0}/μ_H (such that (B1) is satisfied), which can cause BIC to fail to identify r_0 when n and ψ_{r_0}/μ_H have only moderate sizes. Unlike BIC, which uses $(\ln n)c$ in (B1)–(B2), GIC uses in (G1)–(G2) the function $2\kappa(\cdot)$, which is adaptive to b and does not depend on n . As a result, GIC can achieve selection consistency even with finite ψ_{r_0}/μ_H .

In summary, GIC can be treated as an intermediate method between AIC and BIC, by observing that “(B1) \succ (G1) \succ (A1)” and “(A2) \succ (G2) \succ (B2)” (see also Remark 3 for more explanation). On one side, AIC is less affected by the small size of signal eigenvalues, but heavily depends on the correctness of the simple spiked model assumption, which can fail to apply for general H . On the other side, BIC is less affected by the form of H due to the diverging factor $\ln n$, but it can fail to apply when the signal eigenvalues are not large enough. As for GIC penalty, it is constructed under the generalized spiked covariance model (1) that uses the adaptive $\kappa(b/\mu_H)$ to control the effect of H , in which situation GIC achieves selection consistency with moderate signal eigenvalues. We will further examine

these issues via numerical studies in Section 4.

Remark 3. *BIC adopts a diverging weight $\ln n$ for b_r/n , which implies that $(\ln n)c > 2\kappa(\cdot) \geq 2c$ for n large enough. This extends (19) to $\lim_{n \rightarrow \infty} P(\hat{r}_{\text{BIC}} \leq \hat{r}_{\text{GIC}} \leq \hat{r}_{\text{AIC}}) = 1$. That is, GIC tends to select a model of size between BIC and AIC.*

3.3 The case of simple spiked covariance model

To get a better understanding of GIC behavior, this subsection concerns the special case of the simple spiked model given by (C5). Under (C5), $\psi(\lambda) = \lambda(1 + \frac{c\sigma^2}{\lambda - \sigma^2})$, and hence, $\psi'(\lambda_j) > 0$ if $\lambda_j > \sigma^2(1 + \sqrt{c})$. Thus, $\lambda_j > \sigma^2(1 + \sqrt{c})$ for $j \leq r_0$. Moreover, the LSD of S_n has an explicit form in Theorem 4 with $b = \sigma^2(1 + \sqrt{c})^2$. These properties further enable us to derive an explicit expression for κ_j as stated below.

Theorem 9. *Assume conditions (C1)–(C5). Then, for $j = o(p)$, we have*

$$\kappa_j = \begin{cases} c + \frac{c^2\lambda_j/\sigma^2}{(\lambda_j/\sigma^2 - 1)^2}, & j \leq r_0, \\ 2c + c\sqrt{c}, & j > r_0. \end{cases}$$

For $j \leq r_0$, the limit of κ_j goes to $2c + c\sqrt{c}$, when λ_j decreases to the critical value $\sigma^2(1 + \sqrt{c})$.

Theorem 9 explicitly quantifies the dependence of κ_j on the values of $(\lambda_j/\sigma^2, c)$ under the simple spiked model. Figure 1 presents plots of κ_j as a function of $\lambda_j \in [1, \infty)$ under (C5) with $\sigma^2 = 1$ and $c \in \{0.5, 1, 1.5\}$. One can see that κ_j achieves the maximum value $(2c + c\sqrt{c})$ for non-identifiable size of eigenvalues (i.e., $\lambda_j \in [1, 1 + \sqrt{c}]$), and decreases to the lower bound c as $\lambda_j \rightarrow \infty$. This also supports our previous findings that $b_r^{\text{GIC}} \geq b_r$, and that b_r^{GIC} and b_r tend to use the same penalty c for spikes with large λ_j values.

Under the simple spiked covariance model, Bai, Choi and Fujikoshi (2018) show that (A2) of AIC is automatically satisfied and, hence, AIC achieves selection consistency if and only if (A1) is satisfied. Since $\kappa(\cdot) \geq c$, (G2) of GIC is also satisfied under (C5). Thus, GIC achieves selection consistency if and only if (G1) is satisfied. This is stated in the following theorem. The proof is a direct consequence of Theorem 7 and Theorem 9 and is omitted.

Theorem 10. *Assume conditions (C1)–(C5) and $q = o(p)$. Then, GIC achieves selection consistency if and only if*

$$(G1)' \ln(\psi_{r_0}/\sigma^2) - (\psi_{r_0}/\sigma^2 - 1) + 2 \left\{ c + \frac{c^2 \lambda_{r_0}/\sigma^2}{(\lambda_{r_0}/\sigma^2 - 1)^2} \right\} < 0,$$

$$\text{where } \psi_{r_0} = \lambda_{r_0} \left(1 + \frac{c\sigma^2}{\lambda_{r_0} - \sigma^2} \right).$$

Comparing (G1)' with (A1), the required condition of GIC involves an extra term

$$\frac{2c^2 \lambda_{r_0}/\sigma^2}{(\lambda_{r_0}/\sigma^2 - 1)^2}. \quad (20)$$

One message is that under the simple spiked covariance model, c plays an important role in the performance of GIC. When $c < 1$, the difference (20) is less critical; hence, both GIC and AIC achieve selection consistency for moderate size of λ_{r_0}/σ^2 . When c goes farther beyond 1, the difference (20) increases quadratically; hence, GIC requires a relatively large λ_{r_0}/σ^2 to ensure the selection consistency as compared with AIC. This phenomenon can also be seen in Figure 1, where the difference between κ_j and c grows nonlinearly as c increases. We should emphasize that the argument above holds for the simple spiked covariance model only. For general H , (A2) of AIC can be violated, while (G2) of GIC can be more easily satisfied because $\kappa(b/\mu_H) \geq c$. $F_{c,H}$ rarely has an explicit form for general H , which complicates the theoretical comparison of GIC with conventional methods. In Section 4, we use simulation to compare the performance for different methods under various settings of (c, H) .

4 Simulation Studies and a Data Analysis

4.1 Simulation settings

We consider three settings of H for data generation:

(H1) A simple spiked covariance model with $H(t) = \mathcal{I}\{t \geq 1\}$. It gives $\psi(\lambda) = \lambda \left(1 + \frac{c}{\lambda-1} \right)$.

(H2) A generalized spiked covariance model with H being a continuous uniform distribution on $[1 - \theta, 1 + \theta]$. It gives $\psi(\lambda) = \lambda \left[1 + c \left\{ \frac{\lambda}{2\theta} \ln \left(\frac{\lambda-1+\theta}{\lambda-1-\theta} \right) - 1 \right\} \right]$.

(H3) A generalized spiked covariance model with H being a discrete uniform distribution on $\{1 - \theta, 1, 1 + \theta\}$. It gives $\psi(\lambda) = \lambda \left[1 + \frac{c}{3} \left\{ \frac{1-\theta}{\lambda-(1-\theta)} + \frac{1}{\lambda-1} + \frac{1+\theta}{\lambda-(1+\theta)} \right\} \right]$.

Note that $\mu_H = 1$ under (H1)–(H3), and $\theta \in (0, 1)$ in (H2)–(H3) is a quantity measuring the deviation from the simple spiked covariance model. For each (c, H) combination, we consider two settings of distant spike eigenvalues:

(L1) $\lambda_j = \{1 + \frac{1}{10}(r_0 - j + 1)\}\lambda_{\text{GIC}}$, $j = 1, \dots, r_0$, where $\lambda_{\text{GIC}} = \lambda_{\text{GIC}}(c, H)$ is the unique solution for $L_{\text{GIC}}\{\psi(\cdot)\} = 0$. It implies that condition (G1) of GIC is satisfied.

(L2) $\lambda_j = \{1 + \frac{1}{10}(r_0 - j + 1)\}\lambda_{\text{BIC}}$, $j = 1, \dots, r_0$, where $\lambda_{\text{BIC}} = \lambda_{\text{BIC}}(c, H)$ is the unique solution for $L_{\text{BIC}}\{\psi(\cdot)\} = 0$. It implies that condition (B1) of BIC is satisfied.

The remaining eigenvalues $\{\lambda_j\}_{j=r_0+1}^p$ are generated from H . Similarly, let $\lambda_{\text{AIC}} = \lambda_{\text{AIC}}(c, H)$ be such that $L_{\text{AIC}}\{\psi(\lambda_{\text{AIC}})\} = 0$. Since $\kappa(\cdot) \geq c$, we have $\lambda_{\text{GIC}} \geq \lambda_{\text{AIC}}$. Hence, provided that $\ln n > 2$, the gap condition (A1) of AIC is also satisfied under (L1)–(L2). Finally, the data $\{X_i\}_{i=1}^n$ is generated from $N(0, \Sigma)$ with $\Sigma = \text{diag}(\lambda_1, \dots, \lambda_p)$. We implement all methods with the candidate model size upper bound $q = 20$. For each setting, the selection rate of a rank- r model (over 200 replicates) is reported for $r \in \{0, 1, 2, \dots, 20\}$ under $r_0 = 5$, $n = 500$, $\theta = 0.8$, and $c \in \{0.5, 1, 1.5\}$.

4.2 Simulation results

Simulation results under (H1) are placed in Figures 2–3. The first column depicts the true eigenvalues $\{\lambda_j\}_{j=1}^p$ and the critical values of gap conditions $(\lambda_{\text{GIC}}, \lambda_{\text{AIC}}, \lambda_{\text{BIC}})$. One can see that $\lambda_{\text{BIC}} > \lambda_{\text{GIC}} > \lambda_{\text{AIC}}$ as expected, and $(\lambda_{\text{GIC}}, \lambda_{\text{AIC}}, \lambda_{\text{BIC}})$ are all increasing functions of c , indicating that conditions (G1), (A1), and (B1) become stricter as c increases. The second column of Figures 2–3 depicts the curves $\{L_{\text{GIC}}(u) : u \geq b\}$, $\{L_{\text{AIC}}(u) : u \geq b\}$, and $\{L_{\text{BIC}}(u) : u \geq b\}$, where the maximum value $b = (1 + \sqrt{c})^2$ for $\mathcal{S}(F_{c,H})$ is represented as the vertical dotted line. Recall that $L_{\text{GIC}}\{\psi(\lambda_{\text{GIC}})\} = 0$, which means the L_{GIC} curve intersects the horizontal dotted line (the x -axis) at $u = \psi(\lambda_{\text{GIC}})$, and (G1) of GIC is satisfied if ψ_{r_0} lies on the right of $\psi(\lambda_{\text{GIC}})$. Moreover, (G2) is satisfied if $L_{\text{GIC}}(b) > 0$. Similar explanations apply to L_{AIC} and L_{BIC} . Recall that Bai, Choi and Fujikoshi (2018) have shown that (A2) is satisfied under the simple spiked covariance model. This assertion can be observed in the simulation results, where $L_{\text{GIC}}(b) > L_{\text{AIC}}(b) > 0$ for all $c \in \{0.5, 1, 1.5\}$. As a result,

both GIC and AIC achieve selection consistency under (H1)+(L1) and (H1)+(L2). The selection rates are shown in the third column of Figures 2–3. It can be seen that both GIC and AIC consistently select rank-5 model. Note that condition (G1) is stronger than (A1) (i.e., $\lambda_{\text{GIC}} > \lambda_{\text{AIC}}$), and we can observe that AIC performs slightly better than GIC. As for BIC, it fails to identify the true rank r_0 under (H1)+(L1), but achieves selection consistency under (H1)+(L2). This is reasonable since condition (B1) is violated under (H1)+(L1) but is satisfied under (H1)+(L2) (the first column of Figures 2–3).

Simulation results under (M2) are placed in Figures 4–5. In this case, b has no closed form and is obtained numerically. The selection consistency of GIC can still be observed from the third column of Figures 4–5, indicating the generality of GIC to different forms of H . AIC is found to overestimate r_0 for $c \in \{0.5, 1\}$, even for the case of larger signal eigenvalues (L2). This can be expected since the condition $L_{\text{AIC}}(b) > 0$ of (A2) is violated for $c \in \{0.5, 1\}$ (the second column of Figures 4–5). One situation to the success of AIC is the case with a large c , where (A2) can be easier to attain, and we observe the selection consistency of AIC for $c = 1.5$. We remind the reader that it is difficult to determine a suitable size for c in practical applications, since the form of $F_{c,H}$ is rarely known. Moreover, c is not a tuning parameter but is determined from the data, which also limits the applicability of AIC. The inconsistency of AIC becomes more severe under (M3) as shown in Figures 6–7. In particular, condition $L_{\text{AIC}}(b) > 0$ is found to be violated for all $c \in \{0.5, 1, 1.5\}$ (the second column of Figures 6–7). AIC largely overestimates the model size in all situations, while GIC is still found to achieve selection consistency (the third column of Figures 6–7). As for BIC, we still detect in (M2)–(M3) the same observation: BIC achieves selection consistency for the case of (L2) only. This observation supports our findings that BIC is generally less affected by the form of H , but its validity heavily relies on the extremely large signal eigenvalues (see the discussion below Theorem 8). The simulation results under (M2)–(M3) demonstrate the limitation of AIC and BIC and at the same time support the adaptivity of GIC to general H with moderate size of signal eigenvalues.

We close this subsection by noting that the difference between GIC and conventional methods (AIC and BIC) can be clearly seen from the behavior of the curves L_{GIC} , L_{AIC} , and L_{BIC} . The L -curve, when associated with a good selection criterion, should have a sufficiently

large value at b so that the second gap condition, e.g., (G2) of GIC, can be satisfied, and it also should decay rapidly to 0 so that the first gap condition, e.g., (G1) of GIC, can be satisfied. For the cases of AIC and BIC, both L_{AIC} and L_{BIC} are nearly linear, and the two curves are parallel with a constant difference $(\ln n - 2)c$. The reason is that both AIC and BIC adopt the penalty b_r with a constant asymptotic increment c . This constant increment leads to the inflexibility of b_r -based selection criteria. When comparing AIC and BIC, they differ only in their different weights for b_r . Consequently, while $L_{\text{BIC}}(b)$ largely exceeds $L_{\text{AIC}}(b)$ (i.e., (B2) is easily satisfied), the linearity also causes the solution of $L_{\text{BIC}}(u) = 0$ to largely exceed the solution of $L_{\text{AIC}}(u) = 0$ at the same time (i.e., (B1) is easily violated). As for GIC, L_{GIC} is a nonlinear function with a large value at b satisfying $L_{\text{GIC}}(b) \geq L_{\text{AIC}}(b)$, indicating that (G2) is more easily satisfied than (A2) of AIC. Moreover, L_{GIC} decays more rapidly to 0 than BIC, indicating that (G1) is more easily satisfied than (B1) of BIC. These advantages of GIC come from its adaptivity to general eigenvalue structure and lead to the better applicability of GIC.

4.3 Data analysis

We illustrate the proposed GIC rank selection by applying it to the dataset analyzed in Wu et al. (2011), which studies the habitual diet effect in the human gut microbiome. This dataset was also analyzed by Zheng, Lv and Lin (2020). It consists of $n = 91$ subjects, each with 301 measurements (214 for nutrient intake and 87 for gut microbiome composition). In our analysis, we first apply PCA to reduce the data dimension by preserving 99% of the variation. This leads to a resulting dimension $p = 71$ of principal components. We then apply GIC, AIC, and BIC (with $q = 20$) on the 91×71 data matrix (after componentwise standardization) to estimate the model rank.

The penalized log-likelihood of each method is presented in Figure 8 (a), which gives $\hat{r}_{\text{GIC}} = 7$, $\hat{r}_{\text{AIC}} = 12$, and $\hat{r}_{\text{BIC}} = 4$. The penalty functions \hat{b}_r^{GIC} and b_r are presented in Figure 8 (b), where b_r is a smooth curve, while \hat{b}_r^{GIC} is not a monotone function, indicating that \hat{b}_r^{GIC} is more adaptive to the underlying eigenvalue structures. Observe that \hat{b}_r^{GIC} has a peak at $r = 10$ that also results in a local minimum of the penalized log-likelihood of GIC at

$r = 10$ (Figure 8 (a)). This sudden large value of $\widehat{b}_{10}^{\text{GIC}}$ indicates that the values of the 10th and 11th eigenvalues are very close (see the eigenvalues in Figure 8 (c), where $\widehat{\lambda}_9 = 7.4073$, $\widehat{\lambda}_{10} = 6.8382$, $\widehat{\lambda}_{11} = 6.7148$, and $\widehat{\lambda}_{12} = 6.0254$). By using $\widehat{b}_r^{\text{GIC}}$, the selection procedure tends to avoid an estimate of the model rank of 10. This scenario of nearly multiple eigenvalues for $\{\widehat{\lambda}_{10}, \widehat{\lambda}_{11}\}$ (which usually results in unstable analysis results if the model rank is selected at 10), however, is not detected by b_r , since it simply counts the number of free parameters without considering the eigenvalue dispersion. To evaluate the estimated model rank from different methods, one can see in Figure 8 (c) that an elbow cutoff looks around $r = 8$ or $r = 9$, which supports the result of $\widehat{r}_{\text{GIC}} = 7$ better than $\widehat{r}_{\text{AIC}} = 12$. The estimate $\widehat{r}_{\text{BIC}} = 4$ is too small, and useful information can be lost. However, the scree plot method can be quite subjective and can depend on user bias. For a quantitative measure in evaluating the performance of different selection criteria, we also report in Figure 8 (d) the leave-one-out cross-validated (LOOCV) log-likelihood $\text{CV}(r) = \frac{1}{n} \sum_{i=1}^n \ell(X_i | \widehat{\theta}_r^{(-i)})$ at $r \in \{0, 1, 2, \dots, 20\}$, where $\widehat{\theta}_r^{(-i)}$ is the MLE of θ_r without using X_i . One can see that $\text{CV}(r)$ achieves the maximum at $r = 7$, and the value $\text{CV}(7)$ of GIC, is much larger than $\text{CV}(12)$ of AIC and $\text{CV}(4)$ of BIC. All the findings above support the selection result $\widehat{r}_{\text{GIC}} = 7$.

5 Application of GIC to Factor Analysis

5.1 Selecting the number of factors by GIC

Factor analysis (FA) is a popular technique that is used to reduce the number of variables into a few factors. Unlike PCA, which aims to find uncorrelated variates in low dimension that accounts for most of the data variation, FA targets at latent factors that explain the variability among correlated covariates. FA assumes that Σ takes the form

$$\Sigma = LL^\top + D, \quad (21)$$

where L is a $p \times q_0$ matrix of factor loading with $q_0 < p$ and $D = \text{diag}(d_1, \dots, d_p)$ consists of noise variances $\{d_j\}_{j=1}^p$. Note that D is not necessarily proportional to I_p . The factor loading matrix L , which is the main interest of FA, is unique up to any orthogonal transformation

multiplied on its right side. Similar to PCA, FA needs to determine the number of factors q_0 . There are many methods developed for this problem, we will specifically focus on the parallel analysis (PA; Horn, 1965) based methods, which is later advanced by Buja and Eyuboglu (1992) and becomes one of the most popular methods for q_0 selection. PA is a sequential test based method, where the null distribution is generated by permutations. The result of PA thus depends on the realization of the permutations and the pre-specified significance level. Recently, Dobriban and Owen (2019) propose a deterministic version of PA (DPA) by using random matrix theory. They show that DPA and PA have similar performance in terms of selecting q_0 , but DPA has some extra advantages of being reproducible, not requiring to specify the significance level, and having low computational loading. They also further modify DPA and propose two variants of it, namely, the deflated DPA (DDPA) and the DDPA+. The latter uses a more accurate estimation of the singular value when doing deflation. The authors show that DDPA+ has the best performance in selecting q_0 among these DPA-based methods and thus recommend DDPA+ for being used in practice.

The number of factors q_0 in the FA model (21) has certain connection to the target rank of Σ (see Definition 1) that GIC aims to estimate. For example, when $D = \sigma^2 I_p$, (21) becomes the simple spiked covariance model. Then, q_0 is exactly the target rank of Σ , provided that the smallest eigenvalue of LL^\top is larger than $\sqrt{c}\sigma^2$. Dobriban (2017, Section 5.2) also discusses an application of PA to the problem of PCA rank selection, indicating the similarity between the factor selection of FA and the rank selection of PCA. These facts motivate us to apply GIC to selecting q_0 in FA, despite finding sufficient conditions to ensure the equivalence of FA rank and PCA rank is beyond the scope of this article. In the next subsection, we will evaluate the performance of GIC in comparison with DPA-based methods via simulations.

5.2 Numerical comparison of GIC with DPA-based methods

We use the FA model (21) to conduct simulations. The factor loading is set to be $L = \Xi\Phi$, where the columns of $\Xi \in \mathbb{R}^{p \times 3}$ represent the directions of factor loadings, and $\Phi \in \mathbb{R}^{3 \times 3}$ is a diagonal matrix of signal sizes for the columns of Ξ . In our simulations, Ξ is generated by normalizing the columns of a $p \times 3$ matrix with i.i.d. standard Gaussian entries for each

simulation run. We consider the following four combinations for the distribution of X , the signal size Φ , and the noise D :

(FA1) $X \sim N(0, \Sigma)$ with $\Phi = \sqrt{c} \cdot \text{diag}(s, 10, 6)$ and $\{d_j\}_{j=1}^p \sim U(1, 2)$. This is the setting used in Dobriban and Owen (2019).

(FA2) $X \sim t_{30}(0, \Sigma)$ with $\Phi = \sqrt{c} \cdot \text{diag}(s, 10, 6)$ and $\{d_j\}_{j=1}^p \sim U(1, 2)$. This setting is modified from (FA1) by using multivariate t -distribution for data generation.

(FA3) $X \sim t_{30}(0, \Sigma)$ with $\Phi = \sqrt{c} \cdot \text{diag}(s, 6, 6)$ and $\{d_j\}_{j=1}^p \sim U(1, 2)$. This setting is modified from (FA2) by considering the case of nearly multiple eigenvalues.

(FA4) $X \sim t_{30}(0, \Sigma)$ with $\Phi = \sqrt{c} \cdot \text{diag}(s, 6, 6)$ and $\{d_j\}_{j=1}^p \sim U(5, 10)$. This setting is modified from (FA3) by using more noisy data due to the larger diagonals in D .

In all settings, $(n, p) = (500, 300)$, $c = 0.6$, $q_0 = 3$, and $s \in \{10, 15, 20, \dots, 70\}$. For the implementation of DPA, DDPA and DDPA+, we use authors' code with default setting (github.com/dobriban/DPA). As for PA (Buja and Eyuboglu, 1992), our simulation results indicate that it has similar performance as DPA, and is thus omitted from the comparison report. The means and standard deviations (over 200 replicates) of the number of factors being selected by GIC (with $q = 100$), DPA, DDPA, and DDPA+ are presented in Figure 9.

For (FA1), it is obvious that GIC performs best among all methods. In particular, GIC consistently selects $q_0 = 3$ with small variance for all s . DPA is found to underestimate q_0 for cases with strong signal $s > 30$, a phenomenon called “shadowing” by Dobriban (2017). DDPA does not suffer from “shadowing”, but it overestimates q_0 for all s . DDPA+ performs well in selecting $q_0 = 3$, except for the case of $s = 10$, a case with nearly multiple eigenvalues, where a severe underestimation of q_0 is detected. The above mentioned weak points (shadowing in DPA, overestimation in DDPA, and underestimation in DDPA+ for the case with nearly multiple eigenvalues) are not observed in GIC. For (FA2), we see a pattern similar to (FA1) except that DDPA has an even more severe problem of overestimation. In (FA2), data are generated from t_{30} instead of the Gaussian distribution. This implies that the deflation step of DDPA can be sensitive to the presence of outliers. Under (FA3), $\lambda_2 \approx \lambda_3$

for all s , and the problem of underestimation of DDPA+ is detected for all s . DDPA+ is also found to have larger standard deviation than GIC. On the other hand, recall that GIC is less affected by the presence of multiple eigenvalues, which has been discussed earlier in Section 2.2. This robustness is also supported by the empirical results under (FA3), where GIC consistently selects $q_0 = 3$ for all s . For the more noisy case (FA4), the problem of underestimation of DDPA+ becomes even more severe. DPA is also found to have selection bias for $s \leq 30$, despite it performs well for $s \leq 30$ under (FA1)-(FA3), indicating that DPA can be sensitive to higher noise level. As to GIC, we still observe its consistency for all s , except a slightly larger variation is detected.

In conclusion, our numerical studies demonstrate the superiority of GIC over DPA-based methods in selecting the number of factors. The superiority of GIC comes from its construction under the generalized spiked covariance model, and GIC is found to be robust to the signal size, to the underlying data generating distribution, to the presence of multiple eigenvalues, and to the noise levels.

Remark 4. *Like DDPA+, GIC is also a deterministic method without involving random permutations or the specification of tuning parameters. The computational burden of GIC is one single SVD for S_n only. We thus omit the comparison of computational time for GIC with DDPA+.*

6 Concluding Discussions

A novel GIC-based selection criterion is proposed to determine the rank of the PCA model. Unlike the conventional AIC and BIC, which simply count the number of free parameters, GIC takes into account the sizes of λ_j 's and is hence more adaptive to various structures of population covariance. The performance of GIA, AIC, and BIC is affected by (c, H) and the size of ψ_{r_0}/μ_H , and each method has its own merit under different scenarios:

- AIC requires the smallest size of ψ_{r_0}/μ_H among the three methods. The cost, however, is that AIC is very sensitive to deviations in H from the simple spiked covariance model, and is not suitable for the case of a small to moderate c .

- BIC is the most robust method among the three to various forms of H , and to the size of c . The cost is that the selection consistency of BIC requires the largest size ψ_{r_0}/μ_H among the three methods, i.e., BIC only identifies directions with strong signals.
- GIC adapts to deviations in H from the simple spiked covariance model, and to the size of c . Moreover, the required size of ψ_{r_0}/μ_H for the selection consistency of GIC is between AIC and BIC, and does not diverge with $\ln n$ as does BIC.

In conclusion, there is no definite choice among the three criteria GIC, AIC, and BIC. Through the theoretical investigation of GIC, we have provided more insights for different behaviors of the three methods. In particular, GIC tends to select a model of a size between AIC and BIC (see Remark 3), and is a more robust selection criterion (against the form of H , the size of c , and the sizes of distant spike eigenvalues) for practical applications.

We have assumed $\kappa(b/\mu_H) < \infty$, and under this assumption the asymptotic increment of GIC is shown to be κ_j as discussed in Section 3.2. Also under this assumption the gap conditions are derived to ensure the selection consistency of GIC. The existence of finite $\kappa(b/\mu_H)$, however, depends on the characteristic of H . We have shown that $\kappa(b/\mu_H) = 2c + c\sqrt{c} < \infty$ under the simple spiked model assumption (C5), but we cannot extend this result to general H , due to the lack of the explicit form of $F_{c,H}$. We would like to emphasize whether or not the finiteness of $\kappa(b/\mu_H)$ will not hinder one from using the selection rule \widehat{r}_{GIC} because the expression for b_r^{GIC} remains unchanged. However, the gap conditions under diverging $\kappa(b/\mu_H)$ need to be modified to achieve selection consistency. Since this modification deserves separate treatment, it is not further pursued here.

Finally, the validity of applying GIC to selecting the number of factors in FA is based on the assumption that q_0 in (21) is equivalent to the target rank of Σ , which is rigorously defined in Definition 1. For the simple spiked covariance model, q_0 in FA coincides with the target rank in PCA. For more general cases beyond the simple spiked covariance model, it is of interest to have further investigations and to derive GIC specifically for the FA model (21).

Figure 1: The asymptotic increment κ_j of b_r^{GIC} as a function of $\lambda_j \in [1, \infty)$ under the simple spiked model (C5) with $\sigma^2 = 1$, where the vertical dotted line represents the lower bound $(1 + \sqrt{c})$ for distant spiked eigenvalues. κ_j achieves the maximum value $(2c + c\sqrt{c})$ for $\lambda_j \in [1, 1 + \sqrt{c}]$, and decreases to c as $\lambda_j \rightarrow \infty$. The horizontal dashed line corresponds to the asymptotic increment of b_r with a constant height c . (a) $c = 0.5$; (b) $c = 1$; (c) $c = 1.5$.

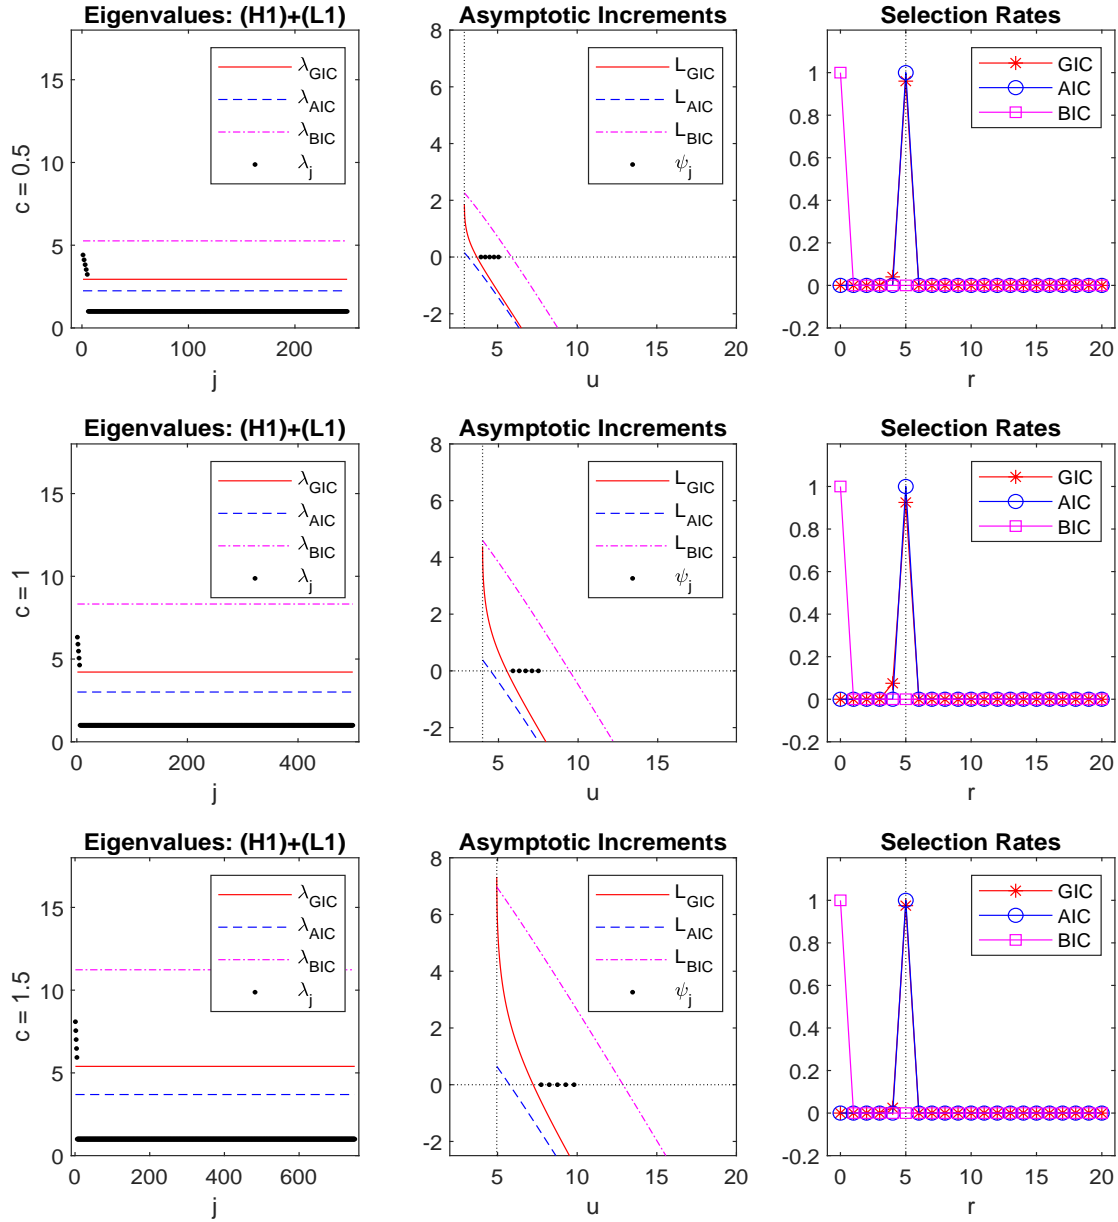

Figure 2: Simulation results under (H1)+(L1) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

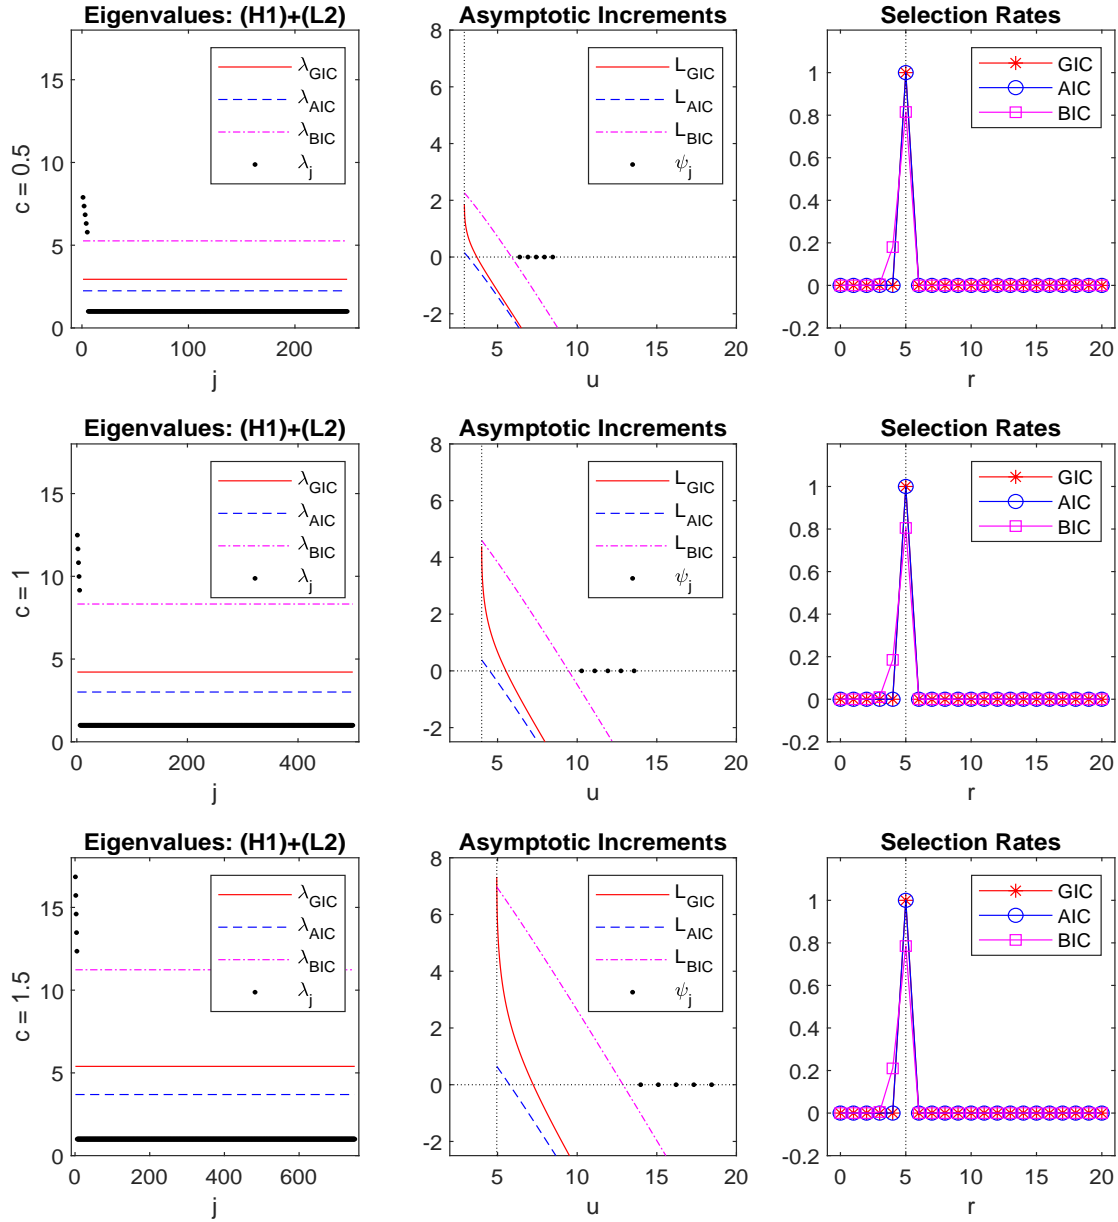

Figure 3: Simulation results under (H1)+(L2) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

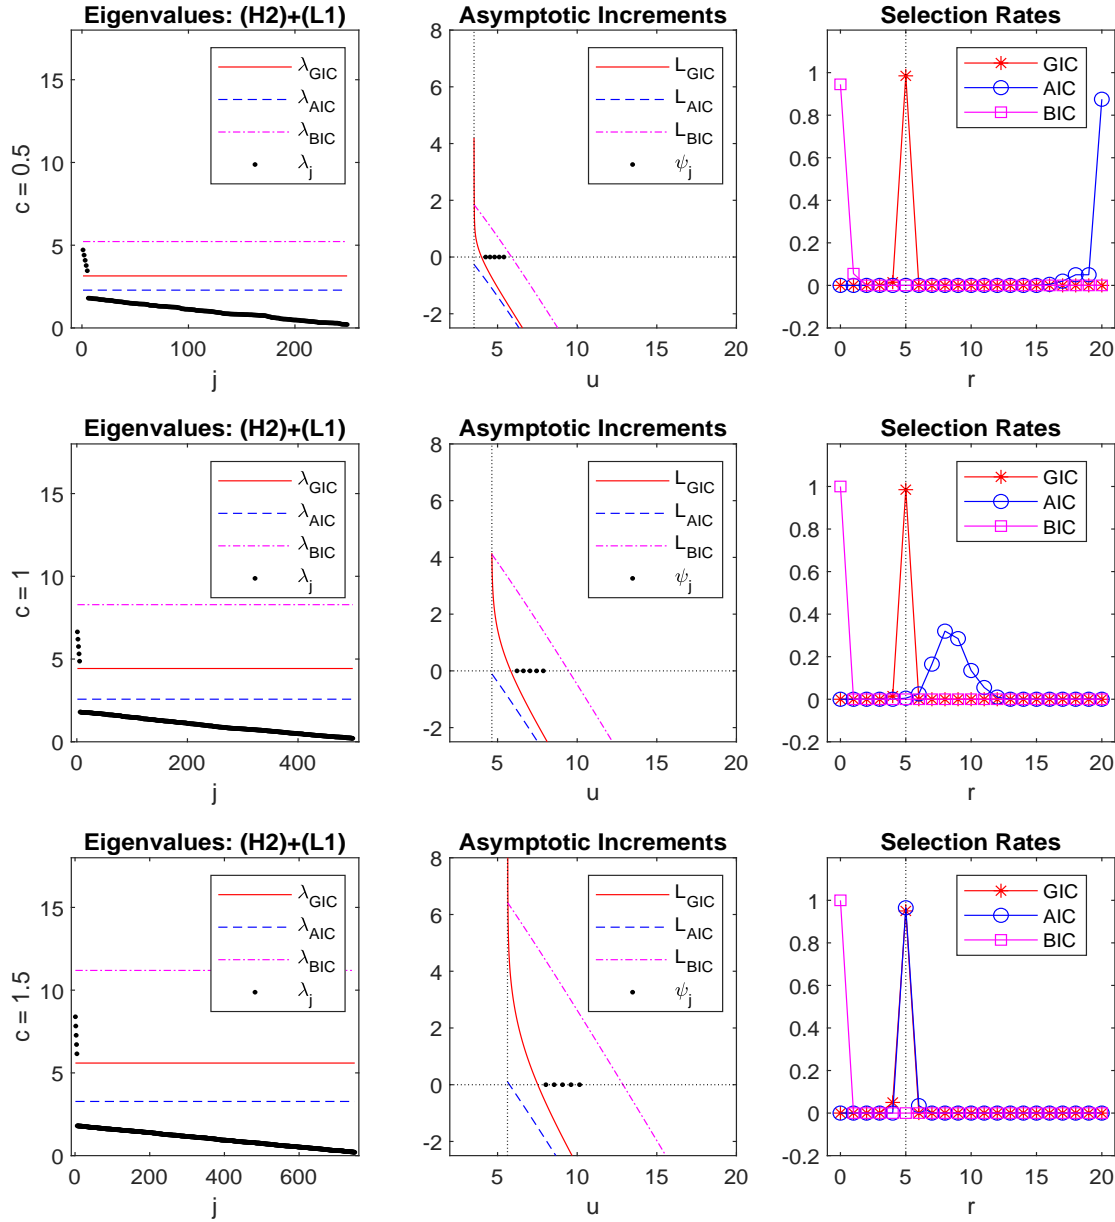

Figure 4: Simulation results under (H2)+(L1) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

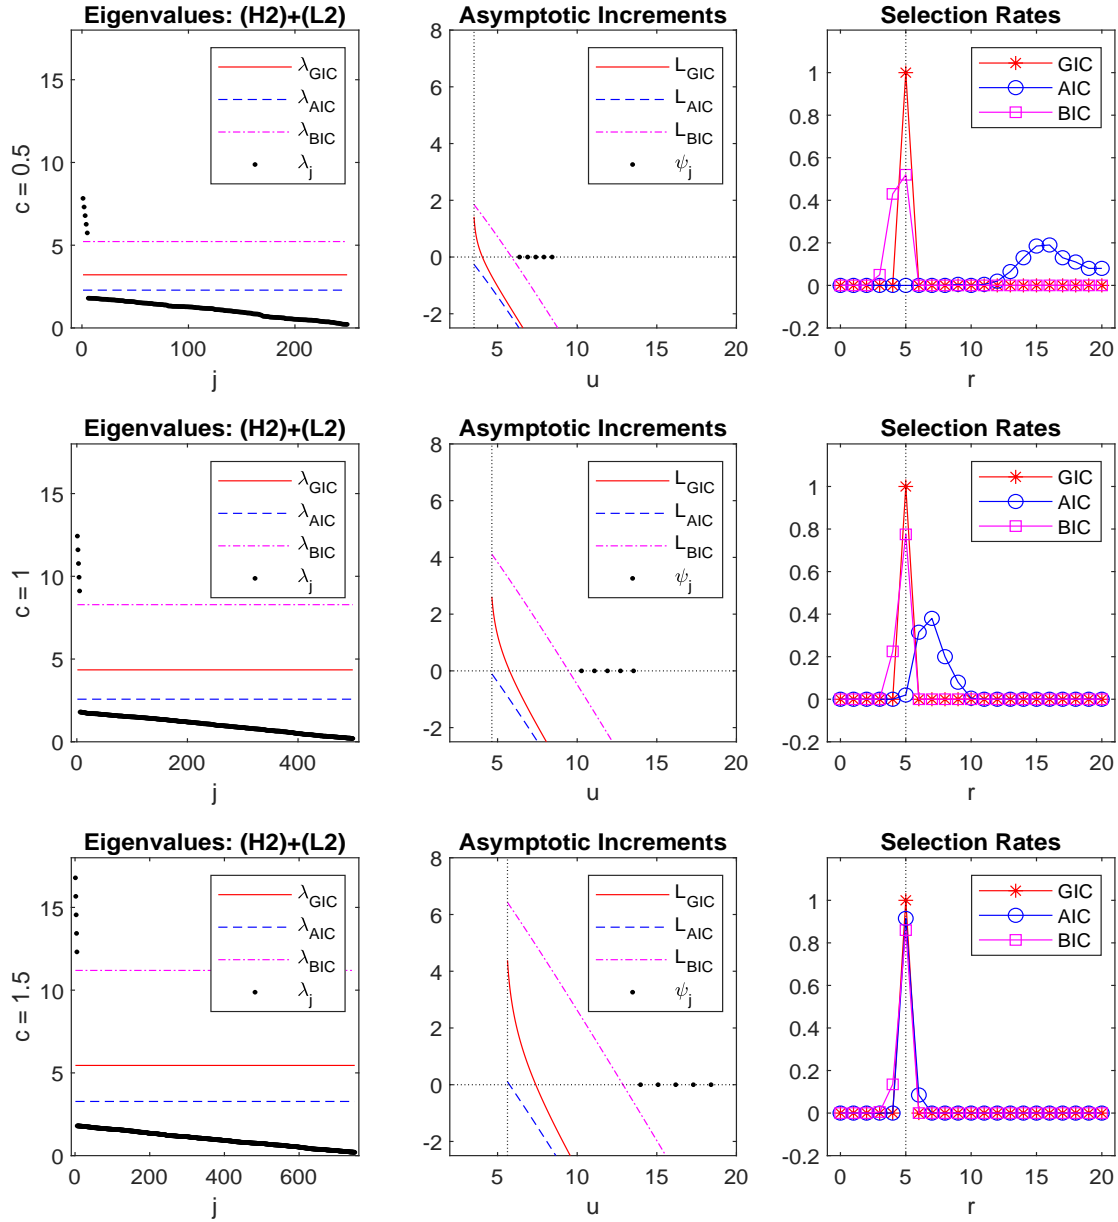

Figure 5: Simulation results under (H2)+(L2) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

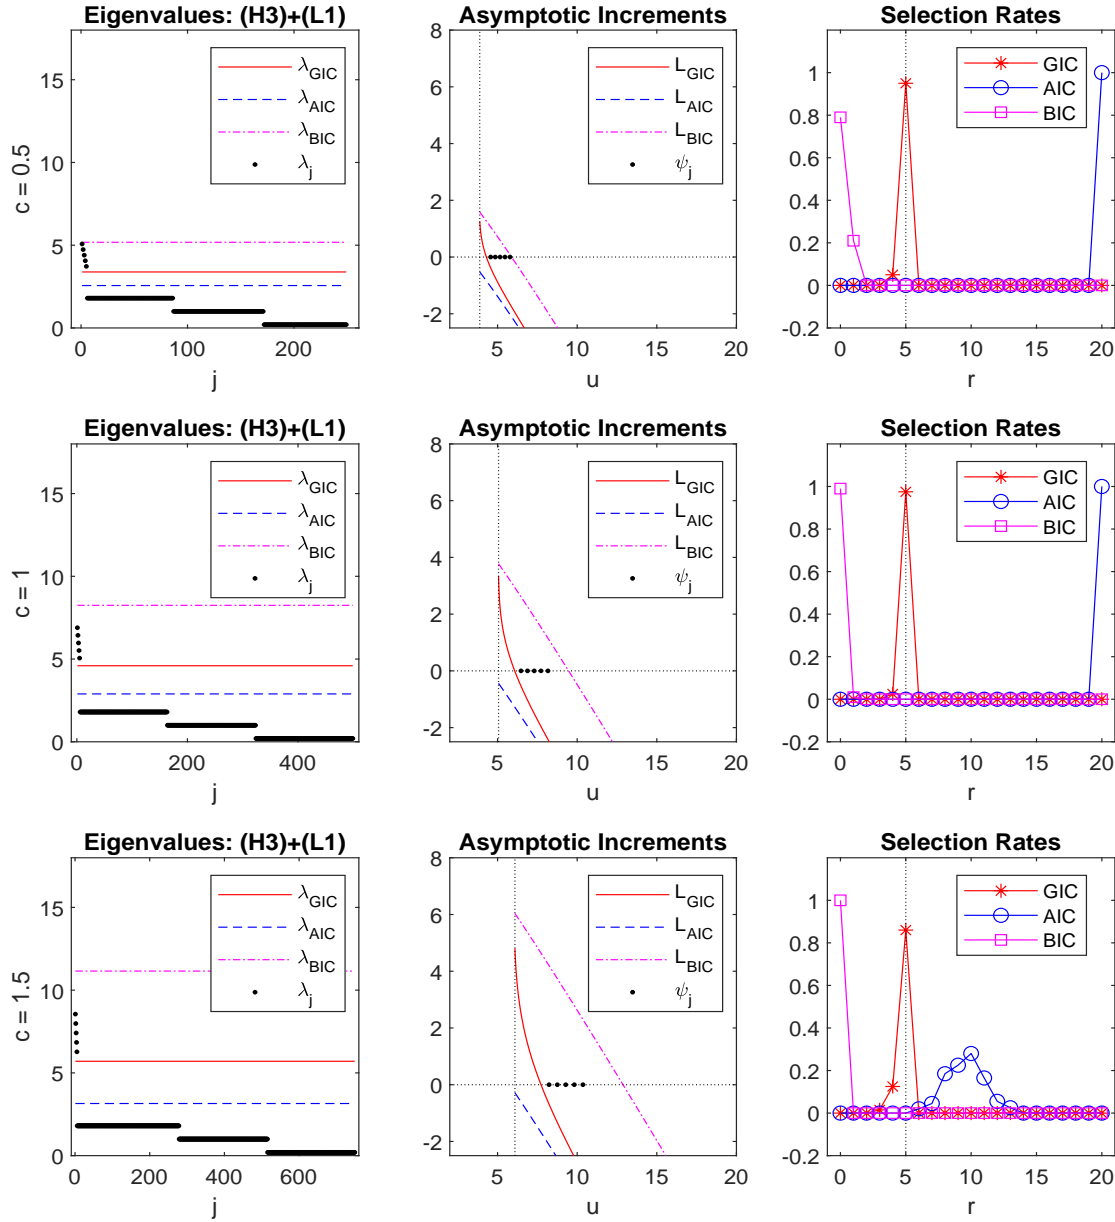

Figure 6: Simulation results under (H3)+(L1) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

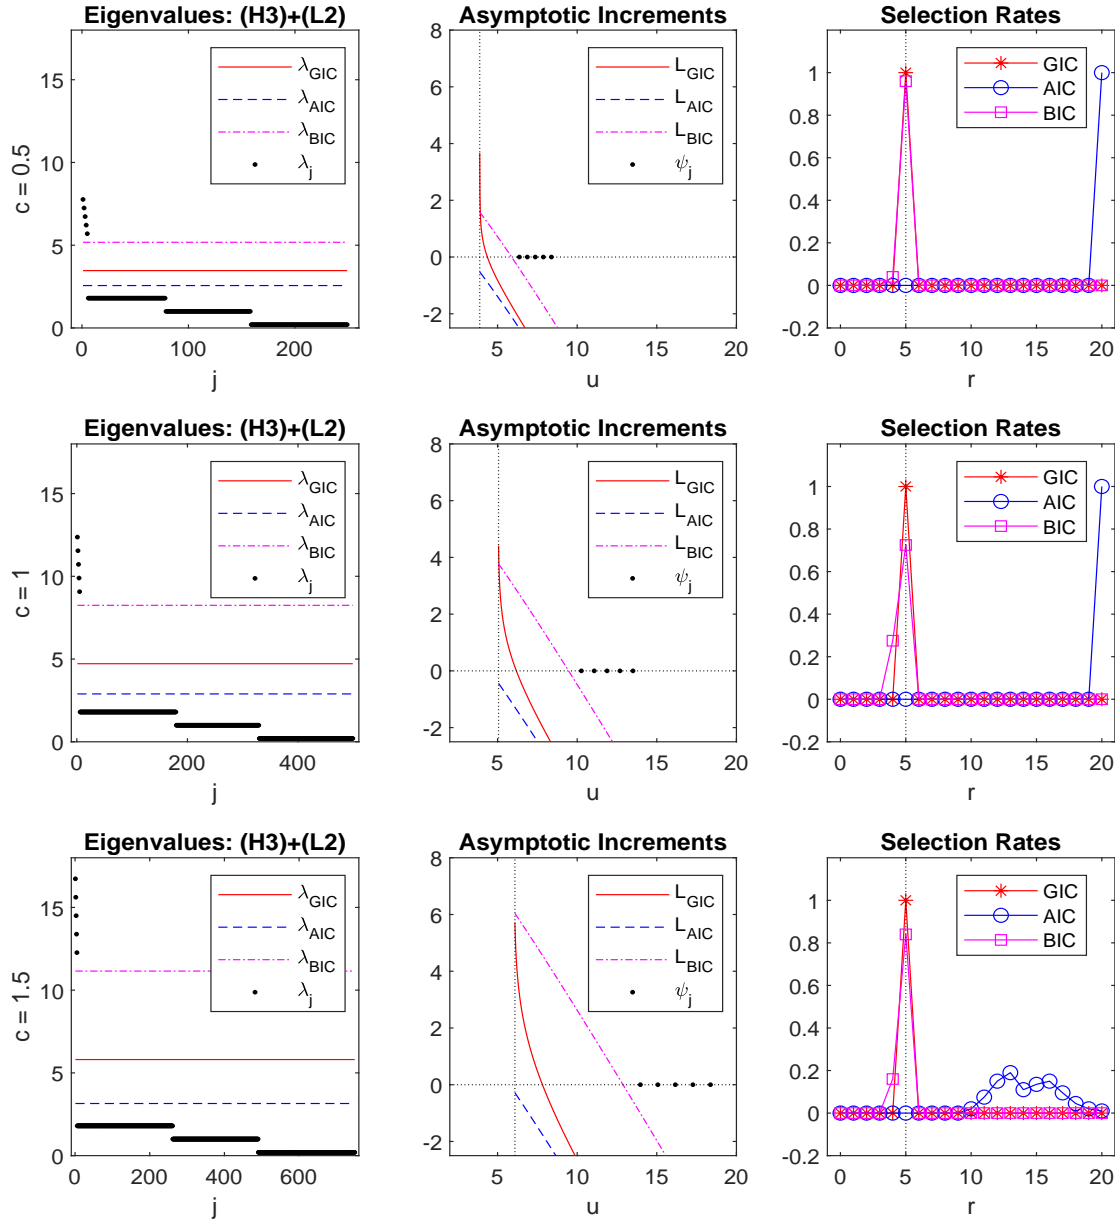

Figure 7: Simulation results under (H3)+(L2) at different values of $c \in \{0.5, 1, 1.5\}$ (from top to bottom). The first column plots the true eigenvalues, where the horizontal lines represents λ_{GIC} (the red solid line), λ_{AIC} (the blue dashed line), and λ_{BIC} (the magenta dash-dotted line). The second column plots the curves of L_{GIC} , L_{AIC} , and L_{BIC} , where the vertical dotted line represents the value of b , and the horizontal dotted line represents the value of 0. The values $\{\psi_j : j = 1, \dots, 5\}$ of distant spikes are also reported. The third column reports the selection rate for each rank r , where the vertical dotted line indicates the true model size $r_0 = 5$.

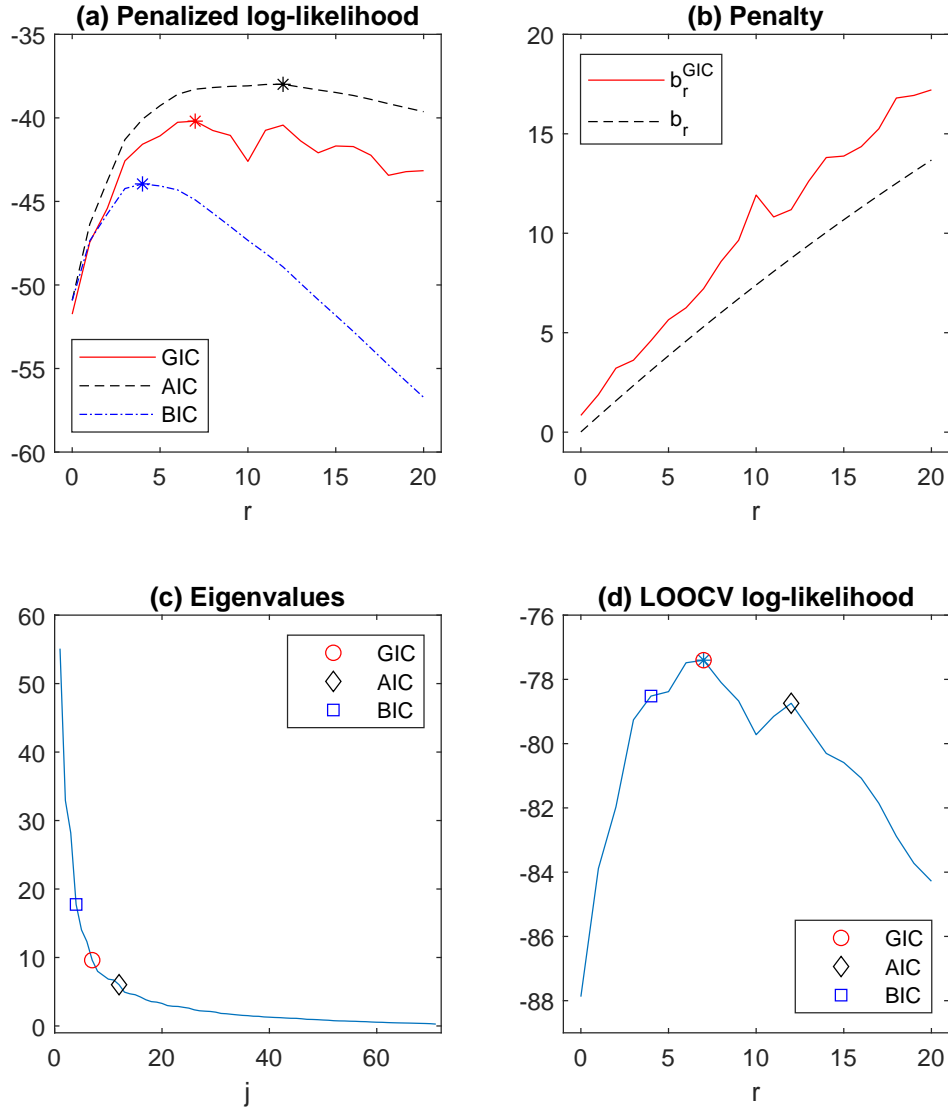

Figure 8: Data analysis results. (a) Penalized log-likelihood from different criteria, where “*” indicates the maximum value for each method. These maximum values correspond to $\hat{r}_{\text{BIC}} = 4$, $\hat{r}_{\text{GIC}} = 7$, and $\hat{r}_{\text{AIC}} = 12$. (b) Values of \hat{b}_r^{GIC} and b_r . (c) Eigenvalues of the sample covariance matrix, where $\hat{\lambda}_4$, $\hat{\lambda}_7$, and $\hat{\lambda}_{12}$ corresponding to the BIC, GIC, and AIC are indicated on the plot. (d) The values of LOOCV log-likelihood $\text{CV}(r)$, where “*” indicates the maximum value. The values at the estimated model rank from each method are also indicated.

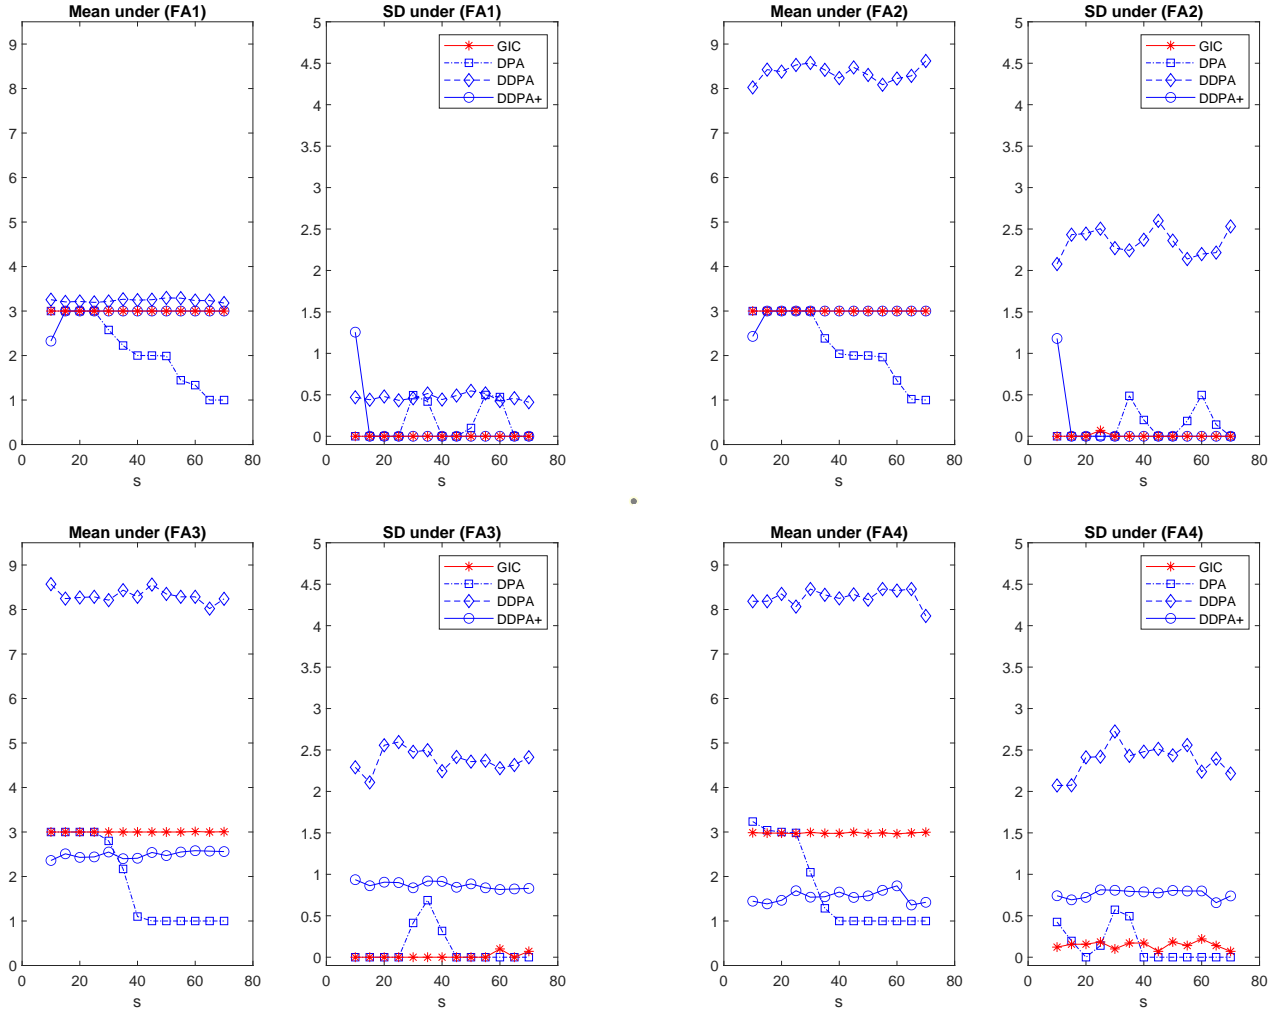

Figure 9: The means (Mean) and standard deviations (SD) of the selected number of factors from GIC, DPA, DDPA, and DDPA+ at different signal sizes s under (FA1)-(FA4). The true number of factors is $q_0 = 3$ for all settings.
