

Coastal Flood Risk in the Mortgage Market: Storm Surge Models' Predictions vs. Flood Insurance Maps*

Amine Ouazad[†]

May 2020

Abstract

Prior literature has argued that flood insurance maps may not capture the extent of flood risk. This paper performs a granular assessment of coastal flood risk in the mortgage market by using physical simulations of hurricane storm surge heights instead of using FEMA's flood insurance maps. Matching neighborhood-level predicted storm surge heights with mortgage files suggests that coastal flood risk may be large: originations and securitizations in storm surge areas have been rising sharply since 2012, while they remain stable when using flood insurance maps. Every year, more than 50 billion dollars of originations occur in storm surge areas outside of insurance floodplains. The share of agency mortgages increases in storm surge areas, yet remains stable in the flood insurance 100-year floodplain. Mortgages in storm surge areas are more likely to be complex: non-fully amortizing features such as interest-only or adjustable rates. Households may also be more vulnerable in storm surge areas: median household income is lower, the share of African Americans and Hispanics is substantially higher, the share of individuals with health coverage is lower. Price-to-rent ratios are declining in storm surge areas while they are increasing in flood insurance areas. This paper suggests that uncovering future financial flood risk requires scientific models that are independent of the flood insurance mapping process.

*The author thanks the National Oceanic and Atmospheric Administration for access to the SLOSH simulation data, Drechsler, Itamar, Alexi Savov, and Philipp Schnabl for access to the bank-level data, as well as Matthew E. Kahn, Jesse M. Keenan for comments on early versions of the paper. The usual disclaimers apply. The author acknowledges support from the HEC Montreal foundation.

1 Introduction

What is the amount of mortgage credit potentially exposed to the risk of catastrophic hurricane storm surges? Evidence suggests that flood insurance maps published by FEMA may not provide an accurate description of risk.¹ New estimates of floodplain boundaries (Wing, Bates, Smith, Sampson, Johnson, Fargione & Morefield 2018) suggest that up to 41 million Americans live within the 100-year floodplain, substantially above the number of Americans living within the 100-year floodplain of FEMA's flood insurance maps. As statistics from the Federal Reserve's Flow of Funds suggest that Americans owed about 11.2 trillion dollars of mortgage debt in 2019 (Goodman 2020), the exposure of lenders, securitizers, and households may be higher than suggested by flood insurance maps. Flood risk may cause defaults or prepayments among borrowers, and cause losses among lenders and securitizers. Yet, estimating the exposure of the mortgage market is challenging as (i) not all communities participate in FEMA's National Flood Insurance Program and thus flood risk may not be mapped comprehensively; (ii) in participating communities, the observed frequency of flooding due to precipitation events, fluvial flooding, or hurricane storm surges may not match the predicted frequency of FEMA's National Flood Hazard Layer; (iii) parts of the 100-year floodplain assume protection by a levee; and (iv) publicly available data may not include simple measures of mortgage structure or performance for loans outside of the conventional loan single-family market.

This paper provides a transparent and replicable assessment of flood risk in the mortgage market by matching the numerical simulations of a model of hurricane storm surges with individual mortgage files, household demographics, house prices and rents, and lenders' balance sheets. Such simulations predict storm surge height at a granular level, an assessment of flood risk that is independent of communities' willingness to participate in the flood insurance program. Such model acknowledges the impact of levees, yet does not exclude leveed areas from the simulation. Relying on scientific models rather than on flood insurance maps is key, as flood insurance maps are the outcome of a political economy process of community participation in the program as well as of community investment in mitigation efforts. Hence scientific models help us tease out the

¹Pralle (2019) suggests that three quarters of houses damaged during hurricane Harvey were outside of the 100-year floodplain; and that half of the buildings in New York City affected by Sandy were outside of the 100-year floodplain. Kousky (2018) provides a discussion of the design of Flood Insurance Rate Maps. Kousky & Kunreuther (2010) argues that better flood maps are required in St Louis.

flood risk that is driven by climate and weather processes separately from what is driven by social and political interactions. Mortgage originations in areas exposed to storm surges are 26% higher than the total volume of originations in FEMA's 100-year floodplains. The paper finds that areas exposed to storm surge risk that are not in flood insurance maps' 100-year floodplain tend to be substantially more African American and Hispanic, exhibit price trends that are lower than the national price trend – while prices tend to increase faster in FEMA's 100-year floodplain –. Borrowers in storm surge areas tend to take more interest-only and fewer fixed rate mortgages. The risk of storm surges is taken on by larger banks, with lower return on equity, less dependence on mortgage loans; lenders are more likely to be commercial banks than in other areas.

Hurricane storm surge height is derived at the neighborhood-level using the National Oceanic and Atmospheric Administration's (NOAA) Sea, Land, and Overland Surges from Hurricanes (SLOSH) model, for different hurricane categories and for different tide levels. The output of this model is combined with the United States Geological Survey's (USGS) Digital Elevation Model satellite measures of elevation, yielding a predicted surge height above ground level. Storm surge heights are matched with mortgage market data. Mortgage-level information comes from two sources: public data collected by the Federal Financial Institutions and Examinations Council (FFIEC) according to the Home Mortgage Disclosure Act; and confidential data on mortgage structure from the McDash data, a product of Black Knight financial. Mortgage-level information is matched to lenders' balance sheets, lenders' liquidity and capitalization, from the Federal Reserve of Chicago's Commercial Bank data. As such the assessment presented in this paper presents a novel replicable methodology that is mostly replicable using publicly available data.

The paper's findings cast a light on the importance of measuring flood risk using models based on weather phenomena, elevation, obstacles, and land cover rather than by relying on flood insurance maps. An extant literature has used storm models on a limited scale to assess coastal flood risk (Mercado 1994, Melton, Gall, Mitchell & Cutter 2010, Niedoroda, Resio, Toro, Divoky, Das & Reed 2010, Genovese & Green 2015). This paper uses the 35 basins of storm surge simulations for all Zip code areas at the national levels to study the correlation between the mortgage market's vulnerabilities and storm surge risk.

Recent work highlights the evolution of financial markets in response to climate risk (Hong, Karolyi & Scheinkman 2020). By providing a unique US-wide snapshot of current aggregate risk

in the mortgage market, the paper aims at providing “early warning” information to households, financial institutions, securitizers, and other players to help in the adaptation of the growing threat of climate risk. Indeed, climate risk is not a static concept (Kahn 2014, Kahn 2016). As households and lenders learn about the risk – including those described in this reproducible analysis with publicly available data –, lenders adjust their lending standards and households adapt their borrowing behavior to the looming issue of growing defaults. Hence this descriptive piece is not a forecast, but rather information that helps financial markets shift the equilibrium towards a more climate resilient mortgage portfolio.² A future test of climate adaptation in the mortgage market is to test the impact of such information disclosures on lenders’ underwriting standards and household demand for mortgage credit.

The paper proceeds as follows. Section 2 describes the data sets, their strengths and limitations, and the methodology that matches them to mortgage data. Section 3 then presents the core six facts of this paper. Section 4 concludes.

2 Data Set

Assessing the vulnerability of real estate assets, mortgage debt, and lenders’ financial statements to coastal flood risk requires four sources of data. First, data on the impact of hurricane storm surge heights or sea level rise at a fine-grained geographic level. Second, data on individual mortgages’ location, loan-to-value or equity, amortization. Third, information on households’ and individuals’ vulnerability. This includes household income, the type of dwelling (mobile home), minority status, education, and other relevant variables that are correlated with a household’s ability to repay the mortgage. Fourth, information on lenders’ vulnerability, by matching mortgage originations to lenders’ status (bank or non-bank lender), net income, balance sheet. We describe these information sources one by one.

²Keenan (2019) introduces climate adaptation in asset management (chapter 2) and in funding and financing options (chapter 4).

2.1 Coastal Flood Risk

Neighborhood-Level Hurricane Storm Surge Heights NOAA's Sea Lake and Overland Surge from Hurricanes (SLOSH) simulates the impact of hurricanes on storm surge heights using the transport equations and hurricanes' measures. The initial conditions of such equations are hurricanes' characteristics such as pressure, speed, and track. The transport equations have been present in the literature at least since Ekman's (1902) seminal work, published in English in Ekman (1905), which were not initially used for the forecasting of storm surge heights.³ A practical application to the modeling of storm surge dynamics is presented later in the work of Jelesnianski (1970). In this latter work, the model is tested for three storms of the Atlantic Seaboard on Atlantic City, NJ: the September 1944 Storm, hurricane Donna, and hurricane Carol. The availability of *measured* surges using gage records helps in comparing the predictions of the equations with the realizations of storm surge heights. In these three key examples, the model performs well and, when deviating from the observations, tends to underestimate storm surge heights. Jelesniansky & Chen (n.d.) compares measures from 570 tide gage and high water mark observations with the model's predictions for a larger set of storms. It reports that the model's predictions are within $\pm 20\%$ of observed heights. A recent assessment of model driven forecasts of storm surge heights is presented in Kalourazi, Siadatmousavi, Yeganeh-Bakhtiary & Jose (2019).

Ekman transport equations are at the core of the SLOSH model, which has become a central tool for NOAA's National Hurricane Center forecasts of storm surge heights (Glahn, Taylor, Kurkowski & Shaffer 2009). Parameters provided by hurricane forecasters lead to finite-difference simulations of the Ekman transport equations using storm position, the radius of maximum winds, and the pressure difference between the central and the peripheral pressure.⁴

Using model-driven predictions of storm surge heights rather than historical observations of water gage levels is key. There is indeed evidence that hurricane intensity has been increasing (Kossin, Knapp, Olander & Velden 2020), consistent with the prediction of numerical models that a warmer world leads to a higher intensity of hurricanes. Hence using historical observations of storm surge heights may not be a good indication of future storm surge risk. In this paper, we use SLOSH simulations to provide estimates of worst-case scenarios that may materialize as

³Ekman was a student of the founder of modern meteorology Vilhelm Bjerknes.

⁴Historical measures every few hours are provided in the National Hurricane Center's HURDAT2 data set.

hurricanes become more intense and sea levels rise.

SLOSH predicts storm surges in feet as the Maximum Envelope of Water (MEOW) for a given hurricane, for instance a Hurricane with the characteristics of Katrina in 2005. By finding the maximum of storm surge height over possible hurricane characteristics, NOAA obtains the Maximum of MEOWs (MOM) for a given hurricane intensity on the Saffir-Simpson scale. MOM simulations are provided at a granular level: the MOM for the New York basin include 30,832 individual geographic cells, each with a storm surge prediction in feet. The cells are defined in polar coordinates. Smaller cells are about 250m by 250m. We intersect such cells with the finest possible level of geographic disaggregation: either the boundaries of the US Census Bureau's census tracts in their 2010 definitions (when working with Census demographics or public mortgage data), or the boundaries of Zip Code Tabulation Areas 5 (ZCTA5) (when working with confidential mortgage data, where data is available at the 5-digit ZIP code⁵).

The MOM simulations are obtained for 35 different basins,⁶ from the Penobscot Bay in Maine, down South to the Laguna Madre basin at the border between the United States and Mexico. Such basins include the New Orleans basin, as well as basins for Palm Beach and Biscayne Bay, among others. Basins cover all parts of the Atlantic coastline and coastal areas of the Gulf of Mexico. When basins overlap, we take the maximum of the MOMs for the two basins.

Sea Level Rise Forecasts Our second source of coastal flood risk is the series of Sea Level Rise layers provided by NOAA. In its "Global Sea Level Rise Scenarios for the United States National Climate Assessment," (Parris, Bromirski, Burkett, Cayan, Culver, Hall, Horton, Knuuti, Moss, Obeysekera et al. 2012) NOAA states that "we have very high confidence (>9 in 10 chance) that global mean sea level will rise at least 0.2 meters (8 inches) and no more than 2.0 meters (6.6 feet) by 2100." Using a survey of 90 experts from 18 countries, Horton, Rahmstorf, Engelhart & Kemp (2014) reports that the consensus forecast is 0.7-1.2m (2.3-3.9ft) in the unmitigated warming scenario, and 0.4-0.6m (1.3-2.0ft) in the mitigated scenario by 2100.

Consistent with these forecasts, we use NOAA's SLR water levels ranging from 0 to 6 feet, where such levels are relative to the local Mean Higher High Water datum. NOAA also provides

⁵There are minor differences between the boundaries of ZCTA5s and the boundaries of postal ZIPs.

⁶The current version of this paper does not consider the basins of Puerto Rico, the Virgin Islands, and Hawaii for computational reasons.

7-10 feet SLR forecasts for some parts of the coast, but we do not consider these in this analysis; they would also fall outside the range of forecasts of SLR in 2100. Both the East and the West coast SLR forecasts are considered, from Washington to California and from Maine to Texas. SLOSH basins, in comparison, only consider the East coast.

Sea level rise should lead to higher storm surges (Shepard, Agostini, Gilmer, Allen, Stone, Brooks & Beck 2012, Woodruff, Irish & Camargo 2013). Yet SLOSH storm surge simulations are performed at given sea level. This paper may thus underestimate the coastal exposure of mortgages to flood risk. In this paper we use SLOSH simulations at high tide to compensate for the lack of SLR in the simulations.

Flood Insurance Rate Maps: FEMA's Special Flood Hazard Areas The third source of information on coastal flood risk is FEMA's Flood Insurance Rate Maps. In such FIRM maps, the Special Flood Hazard Areas are strict boundaries of the 100-year floodplain, in which the annual probability of a flood is 1%. This paper uses the 2017 National Flood Hazard Layer.

Flood Insurance Rate Maps are relevant for the vulnerability of the mortgage market to flood risk. First, households borrowing using an agency-guaranteed mortgage are required to buy flood insurance since the 1973 Flood Disaster Protection Act.⁷ Second,

Yet, such FIRM maps have some significant limitations. First, they provide a strict binary boundary for the 100-year floodplain, which may give a false sense of security for borrowers in the immediate vicinity of the external boundary of the 100-year floodplain. In contrast, SLOSH models provide smooth predictions of hurricane storm surges. Measures from water gages are continuous as well. Second, some communities do not participate in the National Flood Insurance Program, which leads to (i) households' inability to purchase federal flood insurance and (ii) the absence of flood mapping.⁸ We compare flood zones below.

⁷Section 103, (3), (B) "GOVERNMENT-SPONSORED ENTERPRISES FOR HOUSING.--The Federal National Mortgage Association and the Federal Home Loan Mortgage Corporation shall implement procedures reasonably designed to ensure that, for any loan that is-- [...] purchased by such entity, the building or mobile home and any personal property securing the loan is covered for the term of the loan by flood insurance in the amount provided in paragraph (1)(A)."

⁸The list of participating communities is presented in the "[National Flood Insurance Program Community Status Book](#)."

Comparing Flood Zones Figure 1(a) maps the storm surge areas obtained using a Category 4 hurricane at high tide in the New Orleans basin. Hurricane Katrina was a Category 5 floodplain, so this could be considered a moderate scenario. Figure (b) presents the areas of the flood insurance maps' 100-year floodplain.

This visual representation sheds lights on the potential limits of using the flood insurance maps to assess flood risk in the mortgage market. First, while a Category 4 storm surge would affect all parts of the New Orleans metropolitan area except its northern part, the flood insurance areas cover a substantially smaller part of the metropolitan area. This is the National Flood Hazard Layer provided by FEMA in 2017. The discrepancies are substantial: a stretch from New Orleans to Laplace is unmapped, while the City of Kenner is assumed to be protected by a levee and is thus outside of the 100-year floodplain. The southern part of the state of Louisiana is mostly unmapped.⁹ Second, storm surge simulation models provide a continuous and granular visualization of storm surge risk, with surges ranging from no surge (in the northern counties of the New Orleans MSA) to more than 22 feet (in the city of New Orleans, on the Eastern side of Lake Pontchartrain).

Figure 2 on the next page presents the 3 feet sea level rise scenario; in New Orleans the 6 feet and 3 feet scenarios are virtually identical at this scale. Such layers also suggest that the downtown parts of the metropolitan area will not be affected by the slow-moving sea level rise, even as they may be affected by more frequent and higher storm surges. 6 feet of sea level rise is on the upper bound of the likely scenarios, i.e. in the unmitigated global warming scenarios in 2100.

Overall, evidence suggests that NOAA's storm surge models provide a more conservative forecast of coastal flood risk.

Limits of the Measures This paper does not present fluvial flooding measures, which a new version of this paper will present at a granular level for the conterminous United States.

⁹Levee reliability is the focus of a complex and extent literature with both engineering, cost-benefit, and risk preference considerations, see for instance Tobin (1995), Wolff (2008), Rogers, Kemp, Bosworth Jr & Seed (2015) .

2.2 Mortgage data

This paper matches the predictions of storm surge models with instrument-level financial and economic data.

Home Mortgage Disclosure Act data Mortgage-level information on mortgage applications, originations and securitizations is provided by the Federal Financial Institutions and Examination Council and by the Consumer Financial Protection Bureau for the period of analysis (2012-2018). Data is collected according to the 1975 Home Mortgage Disclosure Act (codified in 12 USC Banks and Banking). In the so-called Loan Application Register (LAR), for each application, the data include the loan amount, the unique lender identifier (Respondent ID), the applicant income, race, gender, ethnicity, the census tract of the house¹⁰, the regulating agency, the loan type (conventional, FHA, VA-guaranteed, Farm Service Agency or Rural Housing Service), the property type (1-to-4 family, manufactured housing, multifamily), the loan purpose (home purchase, home improvement, refinancing), the owner-occupancy status. The outcome of the application is recorded (origination, denial, withdrawal by the household, incomplete application), as well as the potential securitization of the mortgage either by an agency (Fannie Mae, Ginnie Mae, Freddie Mac, Farmer Mac, thereafter the “GSEs”), or by private institutions. The file also reports securitizations independently of applications. In this paper we do not restrict or filter the file and include all originations, regardless of their nature. One important feature of HMDA is the stability of its codebook since 2004, providing a unique way to assess the evolution of mortgage originations and securitizations by location over time.

McDash The mortgage data come from the McDash data set compiled by Black Knight financial using data from the servicing industry. This data set covers about 75% of the mortgage market.¹¹ This data source is unique as it provides us with a granular view of the composition of the mortgage market since 1989, at the 5-digit ZIP code level. In addition, we obtained exclusive access to 5-digit ZIP code data, when other researchers have used 3-digit ZIP code data. An alternative

¹⁰The file uses the Census’ 2000 Tract boundaries until 2012, then adopts the 2010 Tract boundaries. We adjust the intersections accordingly.

¹¹This coverage fluctuates across years, is highest during the housing boom of 2001-2006, and somewhat lower during the housing bust. Hence increases in originations in McDash during the latter period are likely underestimated.

source of data, the HMDA data, is comprehensive within the reporting rules set by the FFIEC. Yet, such HMDA data does not include information on mortgage structure (ARM, IO, etc) except in 2018. In McDash we focus on first mortgages in 5-digit ZIP areas with at least 10 loans, and on mortgages for owner-occupied housing, where the property value at origination is above \$50,000 and the loan amount is above \$50,000. Given that the data comes from servicers, we always use the origination date and not the date where servicing rights were transferred to prevent double counting. Overall the displayed numbers are likely underestimates of the true volume of originations in at-risk areas.

2.3 Household and Individual Characteristics

American Community Survey Household, individual, and housing characteristics are extracted from the 5-year averages of the American Community Survey, at the Zip code tabulation area (ZCTA5) level. We use survey weights provided by the U.S. Census Bureau. The ZCTA5 level was used as the finest level of geographic disaggregation available in the McDash mortgage data set. More granular analysis at the census tract level is available.

2.4 Lender Characteristics

The Federal Reserve of Chicago's Commercial Bank data Data collected in accordance with the HMDA also provides a mortgage-level crosswalk with the identity of its lender (RSSDID) in the reporter panel until 2016 inclusive. Lenders submit a transmittal sheet alongside the loan application record (LAR). Such transmittal sheet is linked to the Federal Reserve's RSSDID. The Federal Reserve of Chicago provides researchers with reports reports of condition and income for all banks regulated by the Federal Reserve System, Federal Deposit Insurance Corporation, and the Comptroller of the Currency. As such we do not observe the liquidity and capital levels of non-bank lenders. We access such formatted using Drechsler, Savov & Schnabl's (2018) consistent data set.

3 Six Facts

3.1 Fact #1: The Volume of Mortgage Originations in Storm Surge Areas is Rising Sharply

Table 1 computes the total volume of originations in billions of dollars, in storm surge areas, i.e. more than 5 feet of storm surge during a Category 4 hurricane, panel (a); in special flood hazard areas, i.e. in the flood insurance maps 100-year floodplain, panel (b); in the 3 feet sea level rise area, panel (c); and in the 6 feet sea level rise area, panel (d).¹²

The volume of originations in storm surge areas jumps from 210 billion dollars in 2012 to 249 billion dollars annually in 2018, i.e. by about 18.5%. In contrast the total volume of originations declines from 2.1 trillion dollars to 2.0 trillion dollars, a 4.8% decline. This decline may be due to changes in reporting requirements. Yet these changes in reporting requirements also affect the volume of originations in storm surge areas, whose share in the total volume increases from 9.8% to 12.5%, a 2.7 percentage point increase. The volume of agency originations in storm surge areas is lower in 2018 than in 2012. This reflects the downward trend in agency originations. Overall, as the volume of agency originations in storm surge areas declines proportionately less than the volume of agency originations overall, the share of agency originations in storm surge areas increases between 2012 and 2018, from 8.6% to 11%, a 2.4 percentage point increase.

Similar findings obtain when focusing on areas with more than 10 feet of storm surge during a category 4 hurricane, instead of areas with more than 5 feet; or when focusing on category 5 hurricanes. Indeed, the volume of originations in such areas with more than 10 feet of surge in a cat. 4 hurricane is 221 billion dollars in 2018 (compared to 249 billion dollars in areas with more than 5ft of surge). There is also an increase in originations: from 181 billion dollars of originations in 2012, to 222 billion dollars of originations in 2018. Similar trends obtain when focusing on areas with more than 20 feet of storm surge (from 99 billion dollars in 2012, to 133 billion dollars in 2018).

¹²The total origination and agency origination volumes are of the same order of magnitude as those reported by the Urban Institute's Housing Finance at a Glance series. 2018 is the last year with public disclosure of HMDA. The 2019 data was not available at the time of writing this paper.

3.2 Fact #2: The Share of Mortgage Originations in Flood Insurance “Special Flood Hazard Areas” is Stable

This contrasts with the findings obtained when focusing on flood insurance maps’ 100-year floodplains. Table 1(b) suggests that the volume of originations in Special Flood Hazard Areas (the 100-year floodplain) is remarkably stable between 2012 and 2018, at 197.2 billion dollars versus 197 billion dollars, with some fluctuations in-between these two years. The share of mortgage originations in SFHAs is also stable, oscillating between 9.2% and 9.9% throughout this period.

A similar stability obtains when focusing on agency originations in SFHAs. The volume of agency originations in SFHAs declines, from 141 billion dollars to 109 billion dollars, with a share in SFHAs also remarkably stable between 9.2% and 9.9%.

3.3 Fact #3: Homeowners in Flood Zones Are More Likely to Borrow Using Non-Traditional Mortgages

The HMDA mortgage data presented above present a satisfactory aggregate overview of mortgage originations. They do not provide the structure of the mortgage, in particular whether the mortgage is a “simple” mortgage, fully amortizing with a fixed rate, or whether the mortgage has any of the complex features described in Amromin, Huang, Sialm & Zhong (2018): whether the mortgage is interest-only (and thus does not lead to reductions in principal amount), whether the mortgage is a fixed or adjustable rate mortgage (ARM), whether the mortgage was approved using full document or using low documentations, e.g. for self-employed individuals.

Table 2 and Figure 3 present aggregate statistics on complex mortgage originations by storm surge area. As before, a storm surge area is defined here as at least 5 feet of storm surge above ground level during a category 4 hurricane. A Zip code is in the storm surge area if the maximum surge height across computation cells is greater than 5 feet. The author has checked that other definitions of storm surge areas, for instance using 10 feet of surge, or a category 5 hurricane (such as Katrina) yield similar stylized facts.

The table finds a few such robust stylized facts. First, there is a persistently higher share of interest-only loans in Storm Surge Areas: 10.2% vs 2.3%. There is a persistently lower share of fixed rate mortgages in Storm Surge Areas: 79.8% vs 89.9%. There are more full documentation loans

and fewer no Income no Asset loans in Storm Surge Areas vs the rest of the US. This may suggest that while lenders give more complex mortgages, they ensure that households have better credit characteristics. The next section suggests that households in such areas are in fact significantly more vulnerable.

3.4 Fact #4: Households in Flood Zones are More Vulnerable

Table 3 compares household, individual, or housing characteristics in storm surge areas (SLOSH), sea level rise areas, and Special Flood Hazard areas. Data is from the 5-year average of the 2018 American Community Survey, at the ZCTA5 level.¹³ The “Rest of the United States” is made of areas that are in none of the other three categories.

Households in Storm Surge areas tend to be poorer than households in the rest of the U.S., with differences in household income ranging between \$1,295 (5ft Storm surge vs. rest of the U.S.) and \$2,055 (15ft Storm surge vs. rest of the U.S.). Despite such lower median incomes, households face higher monthly dollar owner costs, which translate into higher monthly owner costs as a percentage of income. Households in storm surge areas tend to be less likely to be living in owner-occupied housing. Yet we saw in the previous section that the total volume of mortgage originations is higher than in SFHA areas. This is due to the higher price of housing, as households in storm surge areas tend to live in more expensive metropolitan areas.

As the previous analysis suggests, focusing on storm surge areas is key in describing mortgage vulnerability to coastal flood risk. This is also the case here for households’ vulnerability. Households in sea level rise areas have significantly higher income, likely related to the higher amenity value of coastal areas not exposed to the short-term risk of hurricane storm surges.

The lower panel of the descriptive table (Demographics) shows that storm surge areas display substantially higher fractions of African Americans (up to 7.1 ppt higher in storm surge areas vs. the rest of the United States), higher fractions of Hispanics (18.4% vs. 17.9% in the rest of the United States), and lower fractions of Whites (70.5% vs. 76.6% in the rest of the United States).

Individuals living in storm surge areas tend to be older, between 0.9 and 2.4 years older than individuals living in the rest of the United States. While older individuals may have higher sav-

¹³With 36,721 Zip code areas overall, and more than 3,000 per area, the margins of errors (MOEs) do not affect the significance of the difference between flood zones in this table.

ings and thus may be more resilient, other indicators suggest higher vulnerability. Individuals in flood risk areas tend to be significantly more likely to have no health coverage, with up to 15.1% uninsured in storm surge areas. The share of individuals below the poverty line is also higher (+0.4 ppt) in storm surge areas.

Finally, the table also reveals that there is a positive correlation between vulnerability and the height of a storm surge: when moving from areas affected by a 5 feet storm surge to an area affected by a 15 feet storm surge, household income declines (\$63,516 vs \$62,756), the fraction of individuals below the poverty line increases (14.8% vs 15.1%), the fraction of individuals with no health coverage stays constant, the fraction of African Americans is broadly stable (20.3% vs 20.1%). Monthly owner costs increase slightly or stay stable as a percentage of household income (23.4% vs. 23.5%). The fraction of mobile homes increases slightly from 5.53% to 5.77%.

3.5 Fact #5: Price-to-Rent Ratios Are Declining Relative to the Trend in Storm Surge Areas, while they are Increasing in Flood Insurance Areas

Finally we turn to the evolution of housing markets in storm surge areas and in FEMA's SFHAs. We proceed by looking at the price-to-rent ratio as an indicator of future rental risk as the price incorporates current and future values of rents. In the Gordon (1959) growth model applied to housing, the price of a real estate asset reflects its flow of rents net of taxes and maintenance costs, discounted by the difference of the discount factor and the growth rate of rents. In this framework, an increase (resp. a decline) in the price to rent ratio reflects the market's perception of rising (resp. declining) rents. Rents reflect the current flow utility of amenities.

If storm surge areas are facing more future risk than flood insurance SFHAs, we should observe that price-to-rent ratios are experiencing lower growth than flood insurance SFHAs. If, on the other hand, the current amenity value of the coast in storm surge areas is similar to the amenity value of the coast in flood insurance areas, we should observe no difference in the evolution of rents.

This is what we test by using Zillow's House Value Index (ZHVI),¹⁴ and its Zillow Rental Index (ZRI). Such price index is available for a subset of 7,439 Zip codes, 339 of which have more than

¹⁴Two other price indices are the Case Shiller index and the FHFA HPI index (formerly called the OFHEO index). A detailed comparison between the ZHVI and the Case-Shiller is provided by Zillow in [this document](#).

50% of their area in the Special Flood Hazard Area, and 967 of which have a maximum surge height (at any point of the Zip) above 15 feet. We consider the period 2012-2018, as in our analysis of mortgage originations. We then regress the log price to rent, and log rent on a series of indicator variables for each year; year indicator variables interacted with a indicator variable for whether the Zip has a maximum surge height above 15 feet; year indicator variables interacted with an indicator variable whether the Zip has more than 50% of its surface area in an SFHA.

The results presented in the upper panel Figure 4 suggest that price-to-rent ratios are declining significantly (at 95%) relative to the national house price trends in storm surge areas; yet they are increasing relative to the national trend in SFHA areas. The bottom panel suggests that rents evolve similarly at the national level and in each of these areas. These results suggest that housing market participants anticipate significantly more risk in storm surge areas than in flood insurance areas, even as they see no significant difference in *current* amenity value.

This supports the hypothesis that storm surge areas may be exposed to risk that is not typically measured when focusing on flood insurance areas.

3.6 Fact #6: Lenders in Storm Surge Flood Zones Are More Likely to Be Large Commercial Banks

Table 5 presents the characteristics and key ratios of lenders in storm surge areas and in flood insurance SFHA areas. The ratios are computed using the first quarter of 2012, the beginning of the expansion of mortgage credit in storm surge areas in Table 1. Each ratio is obtained by taking the mean of bank characteristics weighted by their volume of mortgage originations in the area. These ratios and characteristics are available for bank lenders. The last row of the table presents the share of non-bank lenders in the sample. The non-bank origination share is large overall, consistent with the evidence of Goodman (2020).

The evidence presented in this table supports the hypothesis that lenders in storm surge areas tend to be larger banks (about 3% larger, 719b\$ vs. 672\$) than in flood insurance areas. This is true both on average and for the median bank lender. There is a positive relationship between the storm surge height and the size of the bank lender. Such monotonicity between bank lender characteristics and surge height is typical of the findings of this paper.

Consistent with this larger size, the table suggests that banks in storm surge areas have marginally lower return on assets (0.238% vs. 0.243%) and marginally lower return on equity (2.26% vs. 2.3%). They tend to rely less on loans in their portfolio (58.2% in loans over assets vs. 58.4%), and they have similar leverage (equity over assets of 10.8% in all four zones).

These findings are substantially different than the ones from Beltratti & Stulz (2012). In their work, they found that banks that performed better between July 2007 and December 2008 tended to have lower returns and lower leverage. This paper finds that banks with a portfolio of mortgage loans most exposed to hurricane storm surges tend to have lower returns and similar leverage. One common finding with Beltratti & Stulz (2012) is that banks exposed to storm surges tend to rely less on their loan portfolio.

4 Conclusion

This paper presents an assessment of coastal flood risk in the mortgage market that relies on scientific simulations of storm surges rather than on flood insurance maps, which are inherently dependent on a community's decision to participate in the program. Relying on independent measures of storm surge risk presents a substantially different picture of coastal flood risk: there is a large and rising volume of mortgages at risk (constant in flood insurance areas), households are more likely to be African American or Hispanic, house prices exhibit lower trends, and lenders tend to be larger and are more likely to be commercial banks.

These findings suggest the importance of relying on measures of flood risk that are independent from flood insurance maps. Future research could explore the endogeneity of flood insurance mapping to the demographics of the neighborhoods, conditional on objective flood risk measures. Future research could also explore the optimal risk taking of financial institutions facing ambiguous flood risk in coastal areas.

Figure 1: Two Approaches to Flood Zones: Storm Surge model and Flood Insurance Maps

The upper panel shows a map of the simulated Maximum of MEOWs storm surge heights for a Category 4 hurricane at high tide. The storm surge heights in feet are above ground level. MEOW: Maximum Envelope Of Water. This is presented for the basin of New Orleans. The grey area is the New Orleans-Metairie, LA Metropolitan Statistical Area. The black boundaries are the Zip code tabulation areas (ZCTA5) used in the mortgage analysis. The bottom panel shows the boundaries of the 100-year floodplain in the National Flood Hazard Layer, provided by FEMA in 2017.

(a) Storm Surge Simulation – Category 4, High Tide – Surge Above Ground Level in Feet

(b) Flood Insurance 100-Year Floodplain – Federal Emergency Management Agency’s National Flood Hazard Layer

These figures focus on New Orleans. The paper considers the comprehensive set of basins of storm surge simulations. Source: mapping by the author using NOAA SLOSH simulations, FEMA NFHL, and US Census Bureau shapefiles.

Figure 2: Sea Level Rise Scenario: 3 Feet

This panel present the areas flooded in the case of a 3-feet sea level rise for the New Orleans-Metairie, LA Metropolitan Statistical Area.

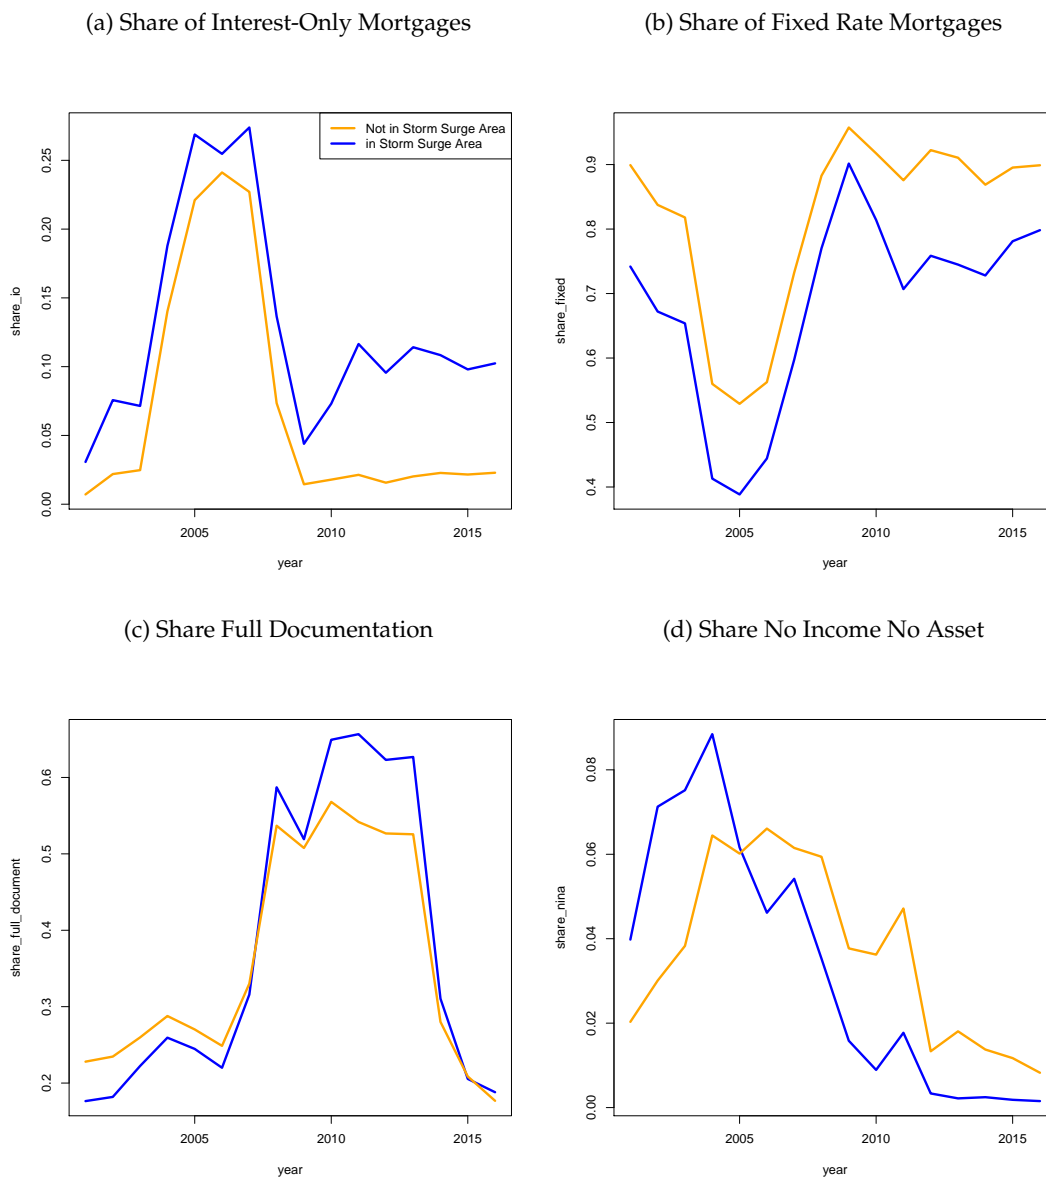

(a) 3 Feet of Sea Level Rise, NOAA's Simulations, Louisiana

Source: Mapping by the author using US Census Bureau and NOAA shapefiles.

Figure 3: Evolution of Mortgage Characteristics in the US outside and inside Storm Surge Areas

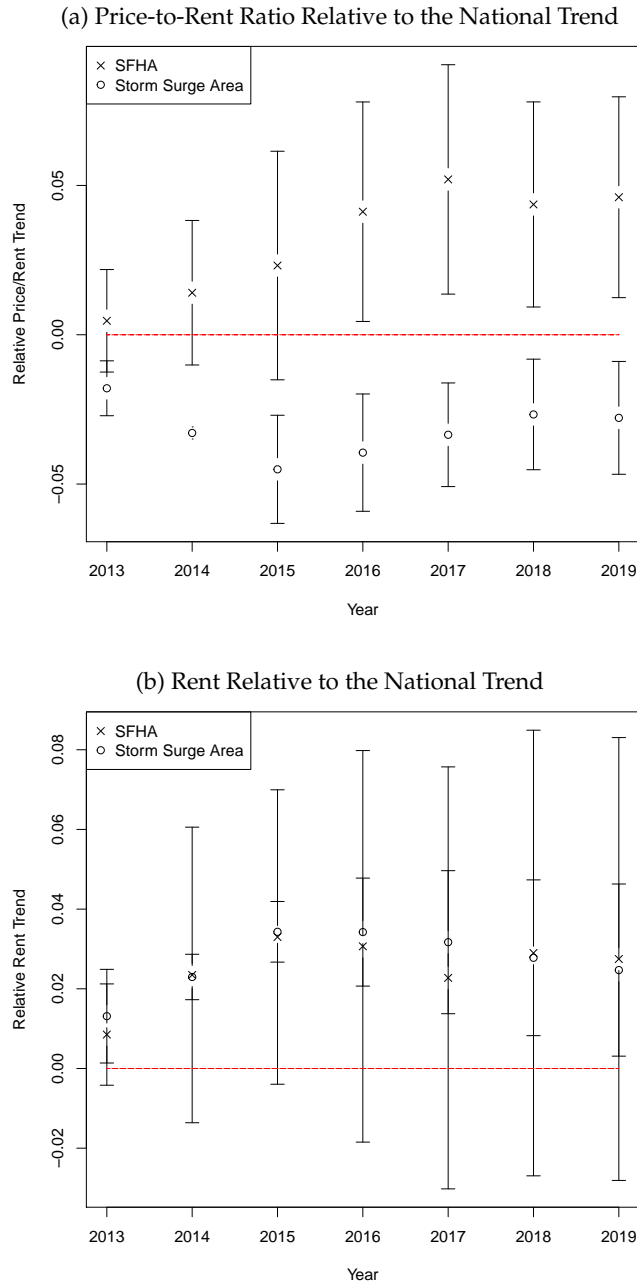

These figures compare the fraction of complex mortgages for storm surge areas (at least 5 feet of surge during a Category 4 hurricane) vs. other areas.

Source: Author's calculation using the McDash data set from Black Knight financial, NOAA's Storm Surge SLOSH simulations, US Census Bureau shapefiles.

Figure 4: Price-to-Rent Ratio Trends in Storm Surge Areas and in FEMA’s Insurance Map 100-Year Floodplain

The upper panel presents the evolution of the price-to-rent ratio relative to the national trend in Special Flood Hazard Areas (FEMA’s insurance map 100-year floodplain, black points); and the evolution of the same ratio in storm surge areas (SLOSH model, white circles). The bars represent 95% confidence interval, clustering by Zip code and by year. Vertical axis: 0.05 is 5%. Red dotted line for national trend.

Table 1: Aggregate Statistics on Mortgage Originations by Flood Risk Area – Home Mortgage Disclosure Act Data

These four panels present the unweighted sum of mortgage originations in the HMDA data, for four different types of flood zones: storm surge (at least 5 feet in a cat. 4 hurricane), flood insurance areas (SFHAs), and 3-6ft sea level rise. Data includes all originations. Agency originations: from Fannie Mae, Freddie Mac, Ginnie Mae, and Farmer Mac.
