ABSTRACT

We present a modification of the Press-Schechter (PS) formalism to derive general mass functions for primordial black holes (PBHs), considering their formation as being associated to the amplitude of linear energy density fluctuations. To accommodate a wide range of physical relations between the linear and non-linear conditions for collapse, we introduce an additional parameter to the PS mechanism, and that the collapse occurs at either a given cosmic time, or as fluctuations enter the horizon. We study the case where fluctuations obey Gaussian statistics and follow a primordial power spectrum of broken power-law form with a blue spectral index for small scales. We use the observed abundance of super-massive black holes (SMBH) to constrain the extended mass functions taking into account dynamical friction. We further constrain the modified PS by developing a method for converting existing constraints on the PBH mass fraction, derived assuming monochromatic mass distributions for PBHs, into constraints applicable for extended PBH mass functions. We find that when considering well established monochromatic constraints there are regions in parameter space where all the dark matter can be made of PBHs. Of special interest is the region for the characteristic mass of the distribution $\sim 10^2 M_{\odot}$, for a wide range of blue spectral indices in the scenario where PBHs form as they enter the horizon, where the linear threshold for collapse is of the order of the typical overdensities, as this is close to the black hole masses detected by LIGO which are difficult to explain by stellar collapse.

Key words: Dark Matter – Cosmology – Cosmology : theory

1 INTRODUCTION

In the last decades, the concordance cosmological model that includes a cosmological constant and cold dark matter (Λ CDM) has been established to explain the growth of large-scale structures and the late accelerating expansion of the Universe. Under this paradigm, the dark matter (DM) is cold and made up of non-relativistic and collisionless particles which behave as a pressureless fluid (Planck Collaboration et al. 2018). There are several candidates for the cold dark matter component, including weakly interacting massive particles (WIMP's, Arcadi et al. 2018; Schumann 2019), axions (Peccei & Quinn 1977; Marsh 2016), or ultralight axions (Hu et al. 2000; Schive et al. 2014) which can be described by a coherent scalar field (Matos & Urena-Lopez

2001; Matos et al. 2009), among others (Feng 2010). Nevertheless, there are no direct astrophysical observations or accelerator detections of these particles and the nature of dark matter is still unknown (Liu et al. 2017).

An alternative hypothesis is to consider that primordial black holes (PBHs) are an important fraction (or all) of DM (see Khlopov 2010; Carr et al. 2020; Carr & Kuhnel 2020; Green & Kavanagh 2020, for recent reviews). In pioneer works, Zel'dovich & Novikov (1966) and Hawking (1971) (see also Carr & Hawking 1974) discussed the possibility that overdensities in early stages of the Universe could collapse forming PBHs (see also Carr 1975 for PBH collapsing from cosmic strings). The idea of PBHs as the nature of dark matter has regained interest with the recent detection by the Laser Interferometer Gravitational-Wave Observatory (LIGO, Abbott et al. 2016) of gravitational waves (GW) produced by the merger of a pair of black holes with

^{*} E-mail: jmsureda@uc.cl

masses ~ $30M_{\odot}$ whose origin could be primordial (Bird et al. 2016; García-Bellido 2017; Sasaki et al. 2018; Jedamzik 2020). Although the standard scenario for the PBH formation is the collapse of overdense fluctuations which exceed a threshold value when they re-enter to the horizon, other mechanisms involving phase transitions or topological defects have been proposed for the PBH production in the inflationary/radiation epochs, for instance, collapse of cosmic strings (Hogan 1984; Hawking 1989; Polnarev & Zembowicz 1991; Nagasawa 2005), collapse of domain walls (Rubin et al. 2000, 2001; Liu et al. 2020; Ge 2020), bubble collisions (Hawking et al. 1982; Kodama et al. 1982; Deng & Vilenkin 2017; Deng 2020b), and softening of the equation of state (Canuto 1978; Khlopov & Polnarev 1980), among others.

PBHs can have any range of masses since they are not restricted to form from dying stars. However, the minimum possible mass of a BH can be estimated considering that for any lump of mass m, in order to form a black hole, its Compton wavelength, $\lambda_C = h/mc$, has to be smaller than its Schwarzschild radius. This leads to the lower bound of one Planck mass $M_{PBH} \sim 10^{-5}$ g. The upper mass could in principle be as large as $\sim 10^{50} g$ in some PBH formation scenarios (see Carr et al. 2020; Carr & Kuhnel 2020, and references therein).

Given that low mass PBHs can be close to their last evaporation stages via Hawking radiation (Hawking 1974, 1975), this introduces interesting prospects for their detection (Laha 2019; Ballesteros et al. 2019). For instance it is possible that the evaporation radiation affects the HI content of the universe at redshifts prior to the formation of the first stars (e.g. Mack & Wesley 2008). As PBHs are at least several orders of magnitude more massive than the most massive particles, they would constitute an extremely cold type of dark matter. As pointed out by Angulo & White (2010, see also Angulo et al. 2017), the early epochs of decoupling of neutralinos (candidates for DM) from radiation makes for the possibility of dark matter haloes with masses as low as one Earth mass. PBHs can therefore form haloes of even lower masses (Tada & Yokoyama 2019; Niikura et al. 2019b; Scholtz & Unwin 2019; Hertzberg et al. 2020a,b). These haloes of PBHs would emit radiation as their smaller members evaporate, and this could in principle be detected with current and future high energy observatories such as Fermi and the Cherenkov Telescope Array (e.g. Ackermann et al. 2018; Doro et al. 2013)

Estimates of the fraction of dark matter in PBHs (f)at different mass windows can be obtained from evaporation by Hawking radiation (Hawking 1974, 1975) and from their gravitational/dynamical effects, including GW observations (see Carr & Sakellariadou 1999; Carr et al. 2016b; Wang et al. 2018; Carr et al. 2020; Carr & Kuhnel 2020). Some of the stronger constraints for evaporating PBHs are imposed by standard big bang nucleosynthesis (BBN) processes and the extragalactic γ -ray background radiation (Carr et al. 2016a; Keith et al. 2020). Other bounds on f are obtained from the gravitational lensing effects of background sources (for instance stars in the Magellanic clouds) due to PBHs (Green 2016; Niikura et al. 2019b; Inoue 2018). Hawkins (2020) found a low probability for the observed microlensing of QSOs by stars in lensing galaxies and argued that an intriguing possibility is the lensing by PBHs. Another limit is provided by the capture of PBHs by stars, white dwarfs

or neutron stars (Capela et al. 2013). Recently, Scholtz & Unwin (2019) explore the capture probability of a PBH with ~ 10 earth masses by the Solar system as an alternative for the hypothetical planet nine. On the other hand, a passing PBH or PBH clumps could disrupt globular clusters and galaxies in clusters (Carr & Sakellariadou 1999; Green 2016; Carr & Kuhnel 2020). Although there are several observational constraints on f, most of them are for monochromatic PBH mass distributions. These can be turned into constraints for extended PBH mass distributions following certain statistical procedures (see for instance Carr et al. 2017; Bellomo et al. 2018)

One of the simplest approaches to determine the PBH mass distribution assumes that there is a characteristic scale, λ_c , for the fluctuations which collapse to a PBH; i.e. the density fluctuations have a monochromatic power spectrum, and hence all the PBHs have $M \sim M_c$ i.e. a monochromatic mass function. A natural extension is to consider that PBHs form in a wider range of masses (for instance from particular inflationary scalar field potentials), which was pursued by several authors (Dolgov & Silk 1993; García-Bellido et al. 1996; Clesse & García-Bellido 2015; Green 2016; Inomata et al. 2017, 2018; De Luca et al. 2020a) and a with steep powerlaw power spectrum for density fluctuations (Carr 1975).

Early works (e.g. Peebles & Yu 1970) showed that the index n of the primordial power spectrum $P(k) \propto k^n$ should be close to $n \sim 1$ in order for there to be homogeneity on large scales. This primordial power spectrum is referred to as the scale-invariant Harrison-Zeldovich-Peebles spectrum (Harrison 1970; Zeldovich 1972; Peebles & Yu 1970) and received further support when inflation was proposed as a possible stage of the very early Universe (Guth 1981). However, this prevents PBHs formed by direct collapse to constitute a sizeable fraction of the dark matter in the Universe (Carr 1975; Josan et al. 2009; Green & Liddle 1999).

Therefore, to increase the abundance of PBHs it is necessary to enhance the amplitude of the primordial power spectrum on specific scales. For instance, hybrid inflation models can provide spectral indices greater than one, i.e. blue spectral indices (Linde 1994). Kawasaki et al. (2013) studied PBH formation and abundance in an axion-like curvaton model with a blue-tilt ($n_b \sim 2-4$) in the power spectrum of primordial curvature perturbations (see also Gupta et al. 2018).

The probability distribution of density fluctuations in the early universe, typically assumed to be Gaussian, can also play an important role in the PBH production. Several authors have looked into the effect of non-Gaussian distributions, showing that these introduce changes in the abundance (enhancement or suppression) and clustering of PBHs, and hence they also change their allowed fraction as an energy component of the Universe (Bullock & Primack 1997; Hidalgo 2007; Young & Byrnes 2013, 2015; Franciolini et al. 2018).

In this paper, we investigate PBH formation in a modified Press-Schechter (PS from now on, Press & Schechter 1974) formalism that relates the amplitude of linear energy density perturbations to PBH abundance. PS has been widely used to estimate the mass distributions of gravitationally collapsed dark matter haloes, where the relation between the linear overdensity and the physical collapse are known via the spherical collapse model and its subsequent improvements. As this model is not applicable to PBHs, additional parameters and considerations are needed. Our first new parameter in the PS formalism for PBHs is the fraction of the linear fluctuation to undergo collapse. This allows to accommodate the widest variety of physical connections between the linear fluctuations and the actual physical condition for PBH formation. We also relate PBH formation with linear perturbations at a single epoch or at the time the fluctuation scale re-enters the horizon. We show how the modified PS formalism leads to extended PBH mass functions starting from a primordial power spectrum (PPS) of fluctuations with a broken power-law form with enhanced power on small scales.

In Section 2, we use a modified PS formalism to derive an extended PBH mass function starting from a broken power-law primordial power spectrum for two different PBH formation timings. The functional form of the obtained PBH mass function is described by a type of Schechter function with a power-law slope and an exponential cutoff. In Section 3, we introduce a new constraint for extended mass distributions looking at super massive black holes and also a new statistical analysis method to turn existing constraints on the PBH mass fraction f coming from monochromatic distributions into constraints for extended PBH mass functions. We then consider a series of monochromatic constraints and use them to derive the corresponding ones for the PS mass functions obtained in this work. In Section 4, we show the resulting fractions f for different choices of the Schechter function parameters, and we show that there are regions in parameter space where the entirety of the DM can be made up by PBHs. Finally, in Section 5, we summarise our main results and conclusions. Throughout this work we assume a flat cosmology with $\Omega_{m,0} = 0.315$; $\Omega_{dm,0} = 0.264$; $\Omega_{r,0} = 9.237 \times 10^{-5}$ and a Hubble constant $H_0 = 67.36 \,\mathrm{km \, s^{-1} Mpc^{-1}}$ consistent with measurements from the Planck satellite (Planck Collaboration et al. 2018).

2 THE PRIMORDIAL BLACK HOLE MASS FUNCTION

PBH formation is related to the density fluctuations in the early universe, which are quantified by the Primordial Power Spectrum. The standard PPS is parametrised by a powerlaw

$$P(k) = A_s \left(\frac{k}{k_0}\right)^{n_s},\tag{1}$$

where A_s is an arbitrary normalisation and n_s is the spectral index. These parameters are measured by the Planck collaboration at $k_0 = 0.05 \,\mathrm{Mpc}^{-1}$, obtaining $A_s = 2.101 \times 10^{-9} \,\mathrm{Mpc}^3$ and $n_s = 0.9649 \pm 0.0042$, i.e. a red-tilt power spectrum with no evidence for significant deviation of the power-law at $0.008 \,\mathrm{Mpc}^{-1} \lesssim k \lesssim 0.1 \,\mathrm{Mpc}^{-1}$ (Planck Collaboration et al. 2018).

We also consider a different PPS with a blue tilted spec-

Figure 1. Primordial power spectrum, P(k) as function of the wavenumber k for two cases, the power law given by Eq. (1) and the broken power law given by Eq. (2). We have considered $n_s = 0.9649$ for the power law spectrum and $n_b = 2$ with $k_{piv} = 10 \,\mathrm{Mpc}^{-1}$ for the broken power law.

trum at small scales, which will be referred to as the broken primordial power spectrum (BPPS). It is defined as

$$P(k) = \begin{cases} A_s \left(\frac{k}{k_0}\right)^{n_s} & \text{for } k < k_{piv}, \\ A_s \epsilon \left(\frac{k}{k_0}\right)^{n_b} & \text{for } k \ge k_{piv}, \end{cases}$$
(2)

where k_{piv} is the pivot wavenumber above which the spectral index is blue, i.e. $n_b > 1$ and ϵ is a constant introduced to ensure the continuity of P(k), defined as

$$\epsilon = \left(\frac{k_{piv}}{k_0}\right)^{n_s - n_b}.$$
(3)

Figure 1 shows the power spectrum as function of the wavenumber for a power law (Eq. (1)) and the broken powerlaw (Eq. (2)). Notice that for the latter, there is an enhancement for wavenumbers above than the pivot scale. Throughout this work, we have set $k_{piv} = 10 \text{ Mpc}^{-1}$. Notice that our choice of k_{piv} is conservative (see for example Hirano et al. 2015). Future CMB experiments as Primordial Inflation eXplorer (PIXIE) will be able to constrain the primordial power spectrum at wavenumbers between $50 \text{Mpc}^{-1} \leq k \leq 10^4 \text{Mpc}^{-1}$ (Chluba et al. 2012).

To obtain the mass function of primordial black holes, we adopt the formalism by Sheth et al. (2001), which is a Press-Schechter approach that solves the peaks-withinpeaks underestimate of the abundance of objects (another approach to calculate the PBH abundance is the peaks theory, see for instance Bardeen et al. 1986; Green et al. 2004; Young et al. 2014; Germani & Musco 2019; Young & Musso 2020). In this approach, the abundance depends on the linear overdensity above which objects collapse and form. The use of linear overdensities is what allows to use the PS formalism in the first place, as it adopts Gaussian statistics. There are similarities and differences with the formalism followed

for dark matter haloes (briefly discussed by Young & Musso 2020). We start highlighting the similar aspects.

Following the standard PS formalism, the extended PBH mass function is defined as

$$\left(\frac{dn}{dM}\left(M\right)\right)_{PS} = \nu f\left(\nu\right) \frac{\rho_{DM}}{M^2} \frac{d\log\nu}{d\log M} = f\left(\nu\right) \frac{\rho_{DM}}{M} \frac{d\nu}{dM},$$
(4)

where ρ_{DM} is the dark matter density, and $\nu(M)$ can be interpreted as the peak height defined as

$$\nu\left(M\right) = \frac{\delta_c}{\sigma\left(M\right)},\tag{5}$$

being δ_c the linear threshold density contrast (or critical density contrast) for PBH formation and $\sigma(M)$ the variance of the density field. Notice that δ_c is the linear overdensity and its relation with the non-linear density (the physical one) depends on the physical mechanism by which a region collapses into a PBH. The relation between the linear and non-linear overdensity has been investigated by several authors (see for instance Yoo et al. 2018; Kawasaki & Nakatsuka 2019; Young et al. 2019; De Luca et al. 2019; Kalaja et al. 2019; Musco 2019). For instance, Musco et al. (2021) give a general prescription to obtain the non-linear critical density contrast. However, its calculation is beyond the scope of this work. Additionally, for the linear perturbations to be related to the physics of collapse, δ_c should be ideally similar, or of the order, of the typical amplitude of fluctuations $\langle |\delta|^2 \rangle^{1/2}$ at the time of collapse. Note that even if $\delta_c \ll \langle |\delta|^2 \rangle^{1/2}$, there is still a way to relate the perturbations with the shape of the PPS. We will check whether there are windows in the extended PS parameter space that allow PBHs as dark matter where this condition is met.

On the other hand, in PS it is assumed that the distribution of σ follows Gaussian statistics, as

$$f(\nu(M)) = \frac{2}{\sqrt{2\pi}} \exp\left(-\frac{1}{2}\nu(M)^2\right).$$
 (6)

The variance of the fluctuations of a smoothed density field is given by

$$\sigma^{2}(M) = 4\pi D^{2}(a) \int_{0}^{\infty} k^{2} P(k) \widehat{W}^{2}(R(M), k) dk, \quad (7)$$

where k is the comoving wavenumber, P(k) is the primordial power spectrum, D(a) is the growth factor of the fluctuations at certain scale factor a, and \widehat{W} corresponds to a window function. Several authors have investigated the effect of the choice of \widehat{W} on different power spectra and hence on the halo or PBH abundance under the PS and peaks theory approaches (Gow et al. 2020; Young 2020). For instance, Gow et al. (2020) found that, by considering a top-hat or a Gaussian smoothing function in a log-normal power spectrum, the amplitude difference in a range of masses is $\lesssim 20\%$ and the resulting mass distributions are very similar. For simplicity, we use the sharp (top-hat) k-space window function

$$\widehat{W}^{2}\left(R\left(M\right),k\right) = \begin{cases} 1, & k \leq k_{R} \\ 0, & k > k_{R} \end{cases},$$
(8)

where

$$k_R = \frac{2\pi}{R(M)},\tag{9}$$

 ${\cal R}$ is the comoving radius, and its dependence with the mass ${\cal M}$ is given by

$$M(a) = \frac{4\pi}{3} (a R)^3 \bar{\rho}(a),$$
(10)

where $\bar{\rho}$ is the background density. The mass defined in Eq. (10) corresponds to the total energy density within a sphere of radius R as a function of the scale factor a.

Notice that here we find the first difference between PS applied to PBH formation compared to halo formation. We want to associate a certain scale k_R with the mass of a PBH rather than with the total energy density. This can be interpreted in two ways, i) only a small fraction of the energy density within the horizon will undergo collapse; ii) only a fraction of the modes with wavenumber k will collapse forming a PBH. One can in principle consider any combination of these two scenarios bearing in mind that from a statistical point of view option (i) retains the strongest connection between the linear fluctuations and the actual non-linear collapse. These two possibilities can fit into the equations by proposing,

$$M_{PBH} = f_m \times M_H = \frac{4\pi}{3} (a R)^3 f_m \bar{\rho}(a), \qquad (11)$$

where f_m is the fraction of the energy density that collapses into a PBH and M_H is given by Eq. (10). Option (i) will result from considering $f_m = \beta$, where β corresponds to the fraction of energy density in the form of PBHs at the formation time (Carr et al. 2010),

$$\beta(a) = \frac{\rho_{PBH}(a)}{\rho(a)}; \tag{12}$$

while option (ii) will occur for $f_m = 1$, implying that $f_m \in [\beta, 1]$. Notice that the value of f_m is degenerate with the energy density and, therefore, with the scale factor a.

Notice that f_m is a different quantity than the fraction of the non-linear overdensity that undergoes collapse (γ in Musco 2019, for example). While the latter is related to the physical collapse in the non-linear regime, f_m arises from the assumption that there is an unknown relation between a non-linear overdensity and the linear overdensity. Additionally, we assume that f_m is spatially and temporally constant. As f_m can take values from β to one, it does not determine the relationship between the energy contained in the physical overdensity and that contained in the PBH which is formed from its collapse. In particular, there are two factors, the fraction of the mass that collapses inside a linear fluctuation, and the fraction of linear fluctuations that result in a collapse. f_m is only the former. This allows us to leave f_m as a free parameter to investigate if it is possible to have a significant fraction of DM as PBHs. In future studies one can corroborate whether the choice of f_m makes physical sense in terms of the actual, non-linear PBH collapse.

Note that for haloes the background density from where they collapse evolves as the haloes themselves. In contrast, for the PBH formation, the background density $\bar{\rho}$ evolves as radiation, whereas the PBH density evolves as matter.

Therefore, in contrast to the PS formalism for haloes that requires a single linear overdensity for collapse as its only parameter, the general PS for PBHs requires two parameters, δ_c and f_m , to encompass different possible relations between the linear overdensity and the actual physical overdensity for collapse.

Having a PBH mass function, we can compute the PBH number density and mass density. The number density of PBHs with mass between $M_{min} < M < M_{max}$ is given by

$$n_{PBH} = \int_{M_{min}}^{M_{max}} \frac{dn}{dM} (M') \, \mathrm{dM'}.$$
 (13)

Similarly, the PBH mass density, is defined as

$$\rho_{PBH} = \int_{M_{min}}^{M_{max}} M' \frac{dn}{dM} (M') \,\mathrm{dM'}.$$
 (14)

The average mass for the distribution can be computed as

$$\langle M \rangle_{PBH} = \frac{\rho_{PBH}}{n_{PBH}} = \frac{\int_{M_{min}}^{M_{max}} M' \frac{dn}{dM} (M') dM'}{\int_{M_{min}}^{M_{max}} \frac{dn}{dM} (M') dM'}.$$
 (15)

As we will be interested in determining which range of δ_c and f_m allow a large fraction of DM in PBHs, it is useful to discuss the mass limits of the integrals since these determine the overall normalisation of the PBH mass functions. The lower mass limit M_{min} is related to the emission via Hawking radiation (Hawking 1974, 1975) of a black hole. The evaporation lifetime, τ_{ev} , for a black hole with mass M is

$$\tau_{ev} = \frac{5120\pi G^2 M^3}{\hbar c^4} \sim 10^{64} \left(\frac{M}{M\odot}\right)^3 yr.$$
 (16)

The mass of a PBH in the last stages of evaporation depends mostly on the redshift of evaporation and we will refer to this mass as $M_{ev}(z)$. We typically set the minimum mass at $M_{min} = M_{ev}(z)$. In the treatment of the minimum mass we are assuming that BH evaporation is an instantaneous process. This is justified given that half of the PBH mass is lost only in the last eighth of its lifetime (see Appendix A).

Regarding the upper mass limit, since PBHs of the highest masses tend to be rare, it is possible that they will not be found within the causal volume at early times. We quantify this by defining the cumulative number density of PBHs above any mass M as

$$n_{PBH}(>M) = \int_{M}^{\infty} \frac{dn}{dM'} dM', \qquad (17)$$

and the cumulative number of PBHs is given by

$$N(>M) = V n_{PBH}(>M) = V \int_{M}^{\infty} \frac{dn}{dM'} dM', \qquad (18)$$

where V is the volume in a spherical region. We will refer

to the mass at which the cumulative number density equals one PBH per horizon volume as $M_{1pH}(z)$,

$$n(>M_{1pH}(z)) = 1/V_{Hubble}(z).$$
 (19)

Notice that $M_{1pH}(z)$ is a function of redshift because the Hubble volume V_{Hubble} increases with cosmic time, and it will enter in the calculations as the upper mass of PBHs that are in causal contact at redshift z, as is the case of fluctuations that enter the horizon. In our calculations we adopt $M_{max} = M_{1pH}(z)$. This upper limit will be important mostly in very high redshift calculations such as the epoch of nucleosynthesis, when the horizon size is much smaller than today which makes the minimum detectable comoving abundance of PBHs, $1/V_{Hubble}$, much higher.

Due to the definition of the mass function in Eq. (4)

$$\rho_{DM} = \int_{0}^{\infty} M' \left(\frac{dn}{dM}(M')\right)_{PS} dM', \qquad (20)$$

but this includes PBHs that have already evaporated and PBHs that are not likely to be found within the causal volume. Therefore, we normalise the mass function by

$$A_{n} = \frac{\int_{0}^{\infty} M \left(\frac{dn}{dM}\right)_{PS} dM}{\int_{M_{ev}(z=0)}^{M_{1PH}(z=0)} M \left(\frac{dn}{dM}\right)_{PS} dM},$$
 (21)

enforcing that the PBH mass function satisfies

$$\rho_{DM} = \int_{M_{ev}(z=0)}^{M_{1pH}(z=0)} M' A_n \left(\frac{dn}{dM}(M')\right)_{PS} dM'.$$
(22)

From now on, when we use the mass function of PBHs, we are considering the normalised mass function that satisfies (22).¹ This is

$$\frac{dn}{dM}(M) = A_n \left(\frac{dn}{dM}(M)\right)_{PS},$$
(23)

with the PS mass function as defined in (4). We emphasise that this normalisation factor does not take into account any evolution of the PBH distribution besides the evaporation (via Hawking Radiation) and the increasing maximum mass within the Horizon M_{1pH} . Some effects such as clustering of PBHs at early times can be important for monochromatic mass functions as studied in Inman & Ali-Haïmoud (2019). However, for extended mass functions these effects have not been studied in detail and are beyond the scope of this work.

An important point in the construction of the PBH mass function, is that the actual amplitude of linear fluctuations that are informative of the physical collapse of PBHs can, in principle, be taken either at a single epoch, or at different moments during the radiation domination era. In the first scenario, which we refer to as *Fixed Conformal Time*

¹ We are aware that the computation of the normalisation depends on M_{1pH} , which in turn depends on A_n , meaning that this is an iterative process. However, this process converges after a few iterations.

(FCT), all PBHs form with masses that correspond to linear overdensities taken roughly the same epoch. Adopting a scale factor of PBH formation allows us to make quantifications of the PBH mass function in this scenario. We adopt $a_{fct} \approx 2.04 \times 10^{-26}$, right after inflation, unless otherwise stated. Phase transitions (Kolb & Turner 1990; Gleiser 1998; Rubin et al. 2001; Jedamzik & Niemeyer 1999; Ferrer et al. 2019) could naturally provide such a mechanism as they are triggered by a change in the global conditions of the Universe. For more details or examples of this kind of scenarios, see Hawking et al. (1982); Moss (1994); Khlopov et al. (1998); Deng & Vilenkin (2017); Lewicki & Vaskonen (2019); Deng (2020a); Kusenko et al. (2020); Deng (2020b), where models like vacuum bubble nucleation or collisions are discussed, which can be considered as FCT-like scenarios. The second scenario, called *Horizon Crossing* (HC), consists of linking the formation of PBHs to the linear amplitude of fluctuations as the scale associated to the mass of PBHs enters the horizon. The main feature of this scenario is that smaller PBHs are formed first in the Universe and the more massive ones are formed later. This kind of scenario is well motivated (see for example Green & Liddle 1997, 1999; Green et al. 2004; Green 2016; Young & Byrnes 2013, 2015, where they use different approaches, such as critical collapse, to derive a PBH mass function using peaks theory or Press Schechter, for example, even in non-Gaussian regimes.), and is expected of any underlying PBH formation mechanism that requires the collapsing scale to be in causal contact. Then, these kind of models can be considered as HC-like.

The details of the physics of each formation mechanism are beyond the scope of this work. To first order we consider the choice of FCT or HC affecting only the effective PPS, more accurately, we only change the effective value of n_b and, consequently, the slope of the mass function. This will change other properties of the PBH distribution in turn, such as the formation scale factor which will depend strictly on the model used to describe the PBH formation. We do notice that these two scenarios are extremes of a continuous range of possibilities, which one could in principle parametrise. However, to simplify the algebra we only look at each of these two extremes in detail. Throughout the rest of the text we will refer to HC (FCT) as a HC-like (FCTlike) scenario.

Summarising, different formation mechanisms and considerations for the PPS will give different results for the Press-Schechter PBH mass function. In the following subsections, we discuss how to obtain the value of a typical overdensity as a function of the scale factor, $\langle |\delta|^2 \rangle^{1/2}(a)$, which we will compare with δ_c . Later we analyse the choice of $f_m = \beta$ and relate it with the calculations of $\langle |\delta|^2 \rangle^{1/2}(a)$. Finally, we obtain the mass function for the FCT and HC scenarios, considering a standard PPS and a broken PPS.

2.1 Typical overdensity $\langle |\delta|^2 \rangle^{1/2}$

It should be noted that the value of δ_c alone does not give enough information regarding the collapse of an overdensity. In order for it to be meaningful, it should be compared to the amplitude of a typical density contrast $\langle |\delta|^2 \rangle^{1/2}$ at the epoch or scale of interest.

In the FCT scenario where the linear fluctuations are

analysed at a fixed scale factor, the scale of interest is the one associated to the mean mass $\langle M \rangle$ of the distribution. Using the amplitude of fluctuations at the CMB, the amplitude of fluctuations at a_{fct} reads,

$$\left\langle |\delta|^2 \right\rangle_{a_{fct}}^{1/2} = \left\langle |\delta|^2 \right\rangle_{a_{cmb}}^{1/2} \frac{a_{eq}}{a_{cmb}} \left(\frac{a_{fct}}{a_{eq}} \right)^2 \left(\frac{k(\langle M \rangle)}{k_{piv}} \right)^{\frac{(n_b - n_s)}{2}},$$
(24)

where $a_{eq} \simeq 2.94 \times 10^{-4}$ and $a_{cmb} \simeq 9.08 \times 10^{-4}$ are the scale factors at equality and CMB respectively, and we use $\langle |\delta|^2 \rangle_{a_{cmb}}^{1/2} \sim 10^{-3}$. Also, we take into account the growth factors during matter and radiation domination, and the effect of the blue index n_b , where $k(\langle M \rangle)$ is given by Eq. (9).

Instead, for the HC scenario the scale of interest is the horizon mass at the mean formation scale factor $\langle a \rangle$ of the distribution,

$$\left\langle |\delta|^2 \right\rangle_{\langle a \rangle}^{1/2} = \left\langle |\delta|^2 \right\rangle_{a_{cmb}}^{1/2} \frac{a_{eq}}{a_{cmb}} \left(\frac{\langle a \rangle}{a_{eq}} \right)^2 \left(\frac{k(\langle a \rangle)}{k_{piv}} \right)^{\frac{(n_b - n_s)}{2}}.$$
(25)

In this scenario, $k(\langle a \rangle)$ is given by Eq. (9), with R as the Hubble radius evaluated at $\langle a \rangle$.

Notice that since the typical delta $\langle |\delta|^2 \rangle^{1/2}$ depends on $\langle M \rangle$ and $\langle a \rangle$ in each scenario respectively, its value will depend on the mass function parameters (n_b, M_*) .

With $\langle |\delta|^2 \rangle^{1/2}$ in hand we can calculate the ratio $\delta_c / \langle |\delta|^2 \rangle^{1/2}$ which should be of order unity, or at least less than unity, as explained earlier. If $\delta_c \gg \langle |\delta|^2 \rangle^{1/2}$ almost none of the density fluctuations would collapse into a PBH and Press-Schechter will not make sense anymore. Conversely, when $\delta_c \ll \langle |\delta|^2 \rangle^{1/2}$ some relation with the primordial power spectrum is still preserved.

2.2 Details on the f_m value

When choosing the minimum possible value of f_m one considers that all regions will form a PBH but only a fraction f_m of the energy density of each region will actually collapse into it. The minimum possible value of f_m , is defined as the value for which all linear overdensities with $\delta > \delta_c$ are associated with the formation of a PBH. This condition is accomplished when $f_m = \beta = \rho_{PBH}(a)/\rho(a)$ (see Eq (12)).

Given that ρ_{PBH} depends on the (mean) formation time, and therefore on f_m itself, obtaining this value is an iterative process, beginning with the assumption that $f_m = 1$ and then computing β , updating the f_m value with the resulting β value until convergence on β is reached.

As indicated in Section 2.1, a plausible scenario for PBH formation requires $\delta_c / \langle |\delta|^2 \rangle^{1/2} \sim 1$. In our formalism, this translates into finding the right parameters that lead to this result.

Then, we are interested in values of f_m that favour $\delta_c / \langle |\delta|^2 \rangle^{1/2} \sim 1$. To achieve this, we first calculate the value of $\langle |\delta|^2 \rangle^{1/2} (f_m, n_b, M_*)$ (see Eqs (24) and (25)). Then we take the expressions for $\delta_c(f_m, n_b, M_*)$ (Eqs (B15) (B29) for FCT and HC respectively) and solve

$$\delta_c(f_m, n_b, M_*) = \left< \left| \delta \right|^2 \right>^{1/2} (f_m, n_b, M_*)$$
 (26)

for f_m . 2.3 Fixed conformal time Mass Function

In this scenario, the background energy density is given by

$$\rho_{fct} = \left(\frac{\rho_{DM,0}}{a_{fct}^3} + \frac{\rho_{r,0}}{a_{fct}^4}\right),\tag{27}$$

where $\rho_{DM,0}$, $\rho_{r,0}$ are the z = 0 energy densities for dark matter and radiation respectively and a_{fct} is the scale factor of PBH formation. Although in this epoch the matter contribution can be neglected because $\rho_{DM}(a_{fct}) \ll \rho_r(a_{fct})$, we have included it in our analysis. It should also be noted that the energy density for radiation does not include the neutrino contribution. Then, we can directly derive the radius associated to a certain wavenumber k_R , using equation (10)

$$R(M) = \frac{1}{a_{fct}} \left(\frac{3}{4\pi\rho_{fct}}\right)^{1/3} \left(\frac{M}{f_m}\right)^{1/3}, \qquad (28)$$

with this, k_R can be written as

$$k_R(M) = C_{fct} \left(\frac{f_m}{M}\right)^{1/3},\tag{29}$$

where

$$C_{fct} = a_{fct} \left(\frac{32\pi^4 \rho_{fct}}{3}\right)^{1/3}.$$
 (30)

Note that M corresponds to the mass of the PBH since we included the factor f_m already. These are the necessary considerations for the FCT scenario. Now, things will be different when considering a standard PPS or a broken PPS due to the particular results on the calculation of $\sigma(M)$ (see eq. (7)).

In the construction of the mass function, we define a characteristic mass scale M_* that satisfies $\nu(M_*) \equiv 1$ and, since $\nu(M)$ depends directly on $\sigma(M)$, this parameter will be different for the two PPS considered and will also depend on f_m . In the mass function this parameter M_* is the mass where an exponential cut-off starts. This can be thought of as the characteristic mass in our mass distribution and, it is directly related with the linear critical density contrast δ_c .

2.3.1 Standard Power Spectrum

In this situation, the characteristic mass (see Appendix B1 for further details of the derivation) is given by

$$M_* = \left(\sqrt{\frac{4\pi \, a_{fct}^4 \, (A_s/k_0^{n_s}) C_{fct}^{n_s+3}}{n_s+3}}\right)^{\frac{6}{(n_s+3)}} \frac{f_m}{\delta_c^{\frac{6}{(n_s+3)}}}.$$
 (31)

The mass function for a standard PPS is then given by

$$\left(\frac{dn}{dM}\right)_{\text{fct}}^{\text{std}} = A_n \, \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \, \frac{n_s + 3}{3 \, M^2} \left(\frac{M}{M_*}\right)^{\frac{n_s + 3}{6}} \\ \times \exp\left[-\frac{1}{2} \left(\frac{M}{M_*}\right)^{\frac{n_s + 3}{3}}\right]. \tag{32}$$

2.3.2 Broken Power Spectrum

The first difference that appears in this scenario is that we have an extra scale that corresponds to the pivot wavenumber k_{piv} . This implies that there is a particular mass $M_{piv} = (C_{fct}/k_{piv})^3 f_m$ above which P(k) corresponds to Eq. (1). In the regime of PBHs with masses below M_{piv} , one analogously obtains²

$$M_* \equiv \left(\frac{\delta_c^2}{f_m^{3\alpha} A_{piv} S_2} - \frac{S_1}{S_2 f_m^{\alpha}}\right)^{\frac{-1}{\alpha}},\tag{33}$$

where $\alpha \equiv \frac{n_b+3}{3}$ and

$$A_{piv} \equiv \frac{4\pi \, a_{fct}^4 \left(A_s/k_0^{n_s}\right) C_{fct}^{(n_b+3)} k_{piv}^{n_s-n_b}}{(n_s+3)(n_b+3)}, \qquad (34)$$

$$S_1 \equiv (n_b - n_s) \left(\frac{C_{fct}}{k_{piv}}\right)^{-3\alpha},$$

$$S_2 \equiv (n_s + 3).$$
(35)

With this, the broken PPS mass function on the FCT scenario reads,

$$\left(\frac{dn}{dM}\right)_{\text{fct}}^{\text{brk}} = A_n \frac{S_2 \,\alpha \,\rho_{DM}(a)}{\sqrt{2 \,\pi \,M^{\alpha+2}}} \frac{\left(S_1 f_m^{-\alpha} + S_2 M_*^{-\alpha}\right)^{1/2}}{\left(S_1 f_m^{-\alpha} + S_2 M^{-\alpha}\right)^{3/2}} \\ \times \exp\left[-\frac{S_1 f_m^{-\alpha} + S_2 M_*^{-\alpha}}{2 \left(S_1 f_m^{-\alpha} + S_2 M^{-\alpha}\right)}\right].$$
(36)

As expected, if we choose $n_b = n_s$ we recover the expression for the standard PPS eq. (32). This also happens if we consider PBHs with $M > M_{piv}$ as a result of the existence of this pivot scale. Then, the final and most general expression for the FCT PBH mass function is

$$\left(\frac{dn}{dM}\right)_{\rm fct} = \begin{cases} \left(\frac{dn}{dM}\right)_{\rm fct}^{\rm brk} & \text{for } M < M_{\rm piv}, \\ \\ \left(\frac{dn}{dM}\right)_{\rm fct}^{\rm std} & \text{for } M \ge M_{\rm piv}, \end{cases}$$
(37)

2.4 Horizon crossing Mass Function

In this scenario, we are considering that the relevant amplitudes of linear fluctuations that can be linked to the physical formation of PBHs are restricted to the epoch of radiation domination. Under this prescription, the energy density is

$$\rho_{hc} \simeq \frac{\rho_{r,0}}{a_{hc}^4} \simeq \frac{3 H_0^2}{8 \pi G} \frac{\Omega_{r,0}}{a_{hc}^4}.$$
(38)

Since we are now considering that the size of the linear fluctuation matches the Horizon radius, we need to take into account that

$$R(a_{hc}) = \frac{c}{a_{hc}H(a_{hc})} = \frac{c a_{hc}}{H_0 \sqrt{\Omega_{r,0}}},$$
(39)

² the derivation of M_* is given in the appendix B1

MNRAS 000, 1-25 (2015)

where we have considered $H(a_{hc}) = H_0 \sqrt{\Omega_{r,0}} a_{hc}^{-2}$ of radiation domination. Thus the mass of the fluctuation using Eq. (10) reads

$$M(a_{hc}) = \frac{c^3 a_{hc}^2}{2 \, G H_0 \sqrt{\Omega_{r,0}}} f_m, \tag{40}$$

where we used equations (38) and (39). This last expression gives a relation between the scale factor, a_{hc} , at which a mode of Lagrangian mass M enters the horizon as

$$a_{hc} = \left(\frac{2 G H_0 \sqrt{\Omega_{r,0}}}{c^3}\right)^{1/2} \left(\frac{M}{f_m}\right)^{1/2}, \qquad (41)$$

allowing us to express k_R as a function of the mass of the PBH

$$k_R = C_{hc} \left(\frac{f_m}{M}\right)^{1/2},\tag{42}$$

with C_{hc} defined as

$$C_{hc} = \pi \left(\frac{2H_0\sqrt{\Omega_{r,0}c}}{G}\right)^{1/2}.$$
(43)

It is noteworthy that several authors give the relation of the PBH mass (or wavenumber) to the horizon mass in terms of the number of degrees of freedom of relativistic species at a certain epoch (e.g. Green & Liddle 1997; Nakama et al. 2017; Inomata et al. 2018; Gow et al. 2020). Here, we only consider radiation in Eq. (38) and the contributions of neutrinos, and other relativistic species are neglected in the construction of the mass function.

Just as we did above, we write our results for the mass function in terms of M_* . The meaning of this quantity remains the same but its relation with δ_c is different.

2.4.1 Standard Power Spectrum

For this kind of power spectrum, the computation of $\sigma(M)$ (see the full derivation in Appendix B2) leads to

$$M_* = \left[\sqrt{\frac{4\pi \left(A_s/k_0^{n_s}\right)}{n_s + 3}} \left(\frac{G}{\pi c^2}\right)^2 C_{hc}^{\frac{n_s + 7}{2}}\right]^{\frac{4}{n_s - 1}} \frac{f_m}{\delta_c^{\frac{4}{n_s - 1}}}.$$
(44)

This translates into the mass function

$$\left(\frac{dn}{dM}\right)_{\rm hc}^{\rm std} = A_n \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \frac{(n_s - 1)}{2} \frac{1}{M^2} \left(\frac{M_*}{M}\right)^{\frac{1 - n_s}{4}} \times \exp\left[-\frac{1}{2} \left(\frac{M_*}{M}\right)^{\frac{1 - n_s}{2}}\right].$$
(45)

Note that for this mass function we need $n_s > 1$ in order to avoid a negative or null mass function. This issue has already been addressed by Carr et al. (1994); Kim & Lee (1996); Green & Liddle (1999); Chisholm (2006); Young et al. (2014); Gupta et al. (2018), among others. Considering that $n_s = 0.9649 \pm 0.0042$ as measured by the Planck collaboration, we also explore the possibility of a broken PPS.

Figure 2. PBH mass functions for different scenarios, computed considering different values for n_b and M_* . The red and blue lines correspond to the FCT and HC formation scenarios, respectively. The grey area indicates the PBHs which have already evaporated by z = 0.

2.4.2 Broken Power Spectrum

As before, in this scenario, the wavenumber k_{piv} translates into a particular mass defined as $M_{piv} = (C_{hc}/k_{piv})^2 f_m$ due to the relation between M and k of Eq. (42). Then, M_* is defined (further details of its derivation are given in appendix B2) by

$$\delta_c^2 = A'_{piv} f_m^{\frac{n_b - 1}{2}} \left[S'_1 f_m^{-\alpha'} M_*^2 + S'_2 M_*^{2-\alpha'} \right], \qquad (46)$$

where in this scenario we defined $\alpha' = \frac{n_b+3}{2}$,

$$A'_{piv} \equiv \frac{4\pi \left(A_s/k_0^{n_s}\right)}{(n_s+3)(n_b+3)} \left(\frac{G}{\pi c^2}\right)^4 \frac{C_{hc}^{(n_b+7)}}{k_{piv}^{n_b-n_s}},\tag{47}$$

and

$$S_1' \equiv (n_b - n_s) \left(\frac{C_{hc}}{k_{piv}}\right)^{-2\alpha'},$$

$$S_2' = S_2 \equiv (n_s + 3).$$
(48)

Note that, in this scenario, if we want to find M_* from a certain value of δ_c we need to solve a transcendental equation. Then Eq. (46) is solved numerically for M_* . We can finally express our mass function for the broken PPS as

$$\left(\frac{dn}{dM}\right)_{\rm hc}^{\rm brk} = A_n \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \left[\left(\alpha'-2\right) S_2' M^{-\alpha'} - 2 S_1' f_m^{-\alpha'} \right] \\ \times \frac{\left[S_1' f_m^{-\alpha'} M_*^2 + S_2' M_*^{2-\alpha'}\right]^{1/2}}{\left[S_1' f_m^{-\alpha'} M^2 + S_2' M^{2-\alpha'}\right]^{3/2}} \\ \times \exp\left[-\frac{1}{2} \frac{\left[S_1' f_m^{-\alpha'} M_*^2 + S_2' M_*^{2-\alpha'}\right]}{\left[S_1' f_m^{-\alpha'} M^2 + S_2' M^{2-\alpha'}\right]} \right].$$
(49)

Here we can set n_s to the Planck value, however, the restriction will be on the blue spectral index n_b , requiring that $n_b > 1$. Once again, considering $n_b = n_s$ or $M > M_{piv}$, we recover the same expression as for the standard PPS (eq. (45)). It is also worth mentioning that $\sigma(M)$ must be a decreasing function in order to be consistent with the cosmological principle, i.e., larger scales are more homogeneous. A decreasing $\sigma(M)$ has a negative derivative implying that the mass function is positive. For higher masses $M > M_{piv}$, $\sigma(M)$ is an increasing function which does not satisfy the cosmological principle. To restore its consistency, we modify $\sigma(M)$ by considering that it has a constant minimum value for $M \ge M_{piv}$, implying that $(dn/dM)_{\rm hc} = 0$ for these masses. Therefore, our final definition for the HC mass function is

$$\left(\frac{dn}{dM}\right)_{\rm hc} = \begin{cases} \left(\frac{dn}{dM}\right)_{\rm hc}^{\rm brk} & \text{for } M < M_{\rm piv}, \\ \\ 0 & 0 \end{cases}$$
(50)

This functional form imposes an upper limit for the mass of the PBHs under this formation mechanism.

It is relevant to mention that in Eq. (38) we are using an approximation when we assume that the background density is only composed of radiation. This consideration only holds until matter-radiation equality z_{eq} . Therefore, the mass function obtained in (50) is only valid for PBHs with $M \leq 4,7 \times 10^{17} M_{\odot}$ (imposing the same limit on the M_* value), linked to the amplitude of the linear fluctuation at z_{eq} . For the rest of this work, we consider PBH formation related to linear fluctuations that enter the horizon up to z_{eq} .

2.5 PBH mass function examples

We show examples of these mass functions for different scenarios in Figure 2. The red and blue lines shows the FCT and HC scenarios for two sets of parameters each one. In both, the solid line, corresponds to a higher M_* value, predicting PBHs with high mass in contrast with the dashed line. Also, for both scenarios, each line has a different slope, related to the distinct n_b values. The grey area, shows the region of PBHs evaporated today. We also show the values of $\langle M \rangle$ for some parameter choices in the HC and FCT scenarios in Table 1. This shows that the mean mass of the PBH distribution is larger for larger n_b values, approaching the value of M_* . This behaviour is expected as n_b is related

Table 1. Mean mass of the PBH distribution for different parameters and the HC and FCT scenarios.

n_b	$\langle M \rangle [M_{\odot}]$						
	$M_* = 1.39 \times 10^2 M_{\odot}$	$M_* = 9.1 \times 10^{-8} M_{\odot}$					
HC							
1.1	2.02×10^{-18}	8.13×10^{-19}					
2.0	2.22×10^{-14}	1.28×10^{-16}					
3.0	2.20×10^{-9}	6.23×10^{-14}					
4.0	2.12×10^{-4}	2.89×10^{-11}					
FCT							
1.1	1.03×10^{-5}	5.83×10^{-12}					
2.0	8.40×10^{-3}	1.95×10^{-10}					
3.0	3.64	4.14×10^{-9}					
4.0	$2.61 imes 10^1$	$1.71 imes 10^{-8}$					

to the mass function slope. Mass functions with low n_b values have steeper slopes giving more weight to the low mass population hence decreasing the resulting mean mass. It is worth to note that this behaviour becomes more relevant in the HC scenario, where the resulting mass functions are steeper for the same n_b value compared to the FCT scenario.

Since the broken PPS mass function can reproduce the standard PPS mass function scenario, we will focus on the broken PPS mass function as a general way to express our results. Notice that the mass functions defined in Eqs. (37)and (50) have several free parameters. Hereafter, we assume fiducial values for the cosmological parameters as mentioned above and $k_{piv} = 10 \text{Mpc}^{-1}$ leaving as free parameters n_b and M_* . We choose to fix $f_m = 1$ in each scenario but also adopt $f_m = \beta$ in some cases, (See Section 2.2). We consider only PBH mass functions that predict PBHs in the regime $M < M_{piv}$. This is reasonable, since $M_{piv} \gtrsim 10^{12} \,\mathrm{M_{\odot}}$ for FCT and HC formation scenarios and PBHs with higher masses tend to be very rare. We compute the slopes n of the PS PBH mass distributions at masses well below the characteristic mass M_* . The slopes depend mainly on the blue spectral index. The logarithmic slopes of the differential mass functions are $n = -(9 - n_b)/6$ and $n = -(9 - n_b)/4$ for FCT and HC respectively.

3 CONSTRAINTS ON THE FRACTION OF DARK MATTER IN PBHS

Once we already defined our different mass functions, we need to inspect the range of parameters of our modified PS scenario where it is possible to account for all the dark matter in the form of PBHs, so as to provide a range of linear parameters that can be later tested against physical PBH formation mechanisms.

The fraction of DM in the form of PBHs is usually expressed as

$$f = \frac{\rho_{PBH}}{\rho_{DM}},\tag{51}$$

being f = 1 the scenario where PBHs can constitute all DM in the Universe. Bear in mind that PBHs form from primordial inhomogeneities which after the PBH formation continue evolving during radiation domination in a scale dependent way, thus giving rise to the transfer function. This process reshuffles density fluctuations making PBHs essentially randomly distributed in space by the end of the epoch of radiation domination. This implies that they can be simply considered "very" cold dark matter (CDM) particles. Later on, during matter domination, when the density fluctuations grow into virialised structures, these are naturally formed by PBHs; i.e. dark matter haloes are PBH haloes. Notice that just as in CDM, most of the PBHs live inside dark matter haloes (eg. Angulo & White 2010)

In the following, we investigate different constraints on this fraction. In doing so we neglect the possibility that a fraction of the PBH population that collapsed to form dark matter haloes was expelled out of them due to two-body and other types of interactions. This is justified because massive PBHs decrease their potential energy to fall into the centre of the halo (and potentially merge) by kicking smaller PBHs out. To preserve the Virial equilibrium of the halo, the mass in PBHs kicked out must be of the order of the mass contributed by the most massive PBHs. This makes our approximation reasonable for steep mass functions where the mass in PBHs expelled outside the halo (only that of the massive ones) will be negligible compared to the total mass in PBHs in haloes. However, only in the case of the flattest mass functions (FCT scenario and large n_b values), this assumption may have some issues because in this case the fraction of mass in PBHs expelled out of haloes may become significant.

3.1 Constraint from super massive black holes mass function

The mass functions presented here allow for the existence of very massive PBHs along with a population of low mass PBHs, which does not occur with monochromatic PBH mass functions. Dark matter haloes collapse during matter domination from Lagrangian regions that contain PBHs already formed during the epoch of radiation. Therefore, they contain PBHs drawn from the universal PBH mass function. Depending on the volume that collapses, there is a maximum mass for the PBH that eventually falls into the dark matter halo, which we refer to as the central PBH in the Halo,

$$V_{\text{Halo}}(M_h) n_{\text{PBH}}(> M_c) = 1, \tag{52}$$

where V_{Halo} is the Lagrangian volume of the halo defined as

$$V_{\text{Halo}}(M_h) = \frac{M_h}{\rho_m},\tag{53}$$

with ρ_m and M_h corresponding to the comoving matter density and the halo mass respectively. In this work we assume that the most massive PBH sinks to the center of the halo; we will also consider the possibility that it will merge with other PBHs later in this section.

If M^* is large enough, a halo can contain central PBHs with masses exceeding even the largest known supermassive black holes (SMBH) observed in galaxies. This would be at odds with observations and can be used to constrain the parameter space comprised by the M_* , n_b parameters. Figure 3 shows examples of cumulative PBH mass functions with horizontal lines marking the inverse of the Lagrangian volume of dark matter haloes of different mass. The point where these lines intersect the PBH mass functions show the central PBH mass that will be found in haloes of such

Figure 3. PBH cumulative number density (17) for two different sets of parameters n_b and M_* , in the HC scenario, as a function of the PBH mass. The axis on the right also shows the logarithm of the number of PBHs within the comoving horizon. Black lines show the inverse of the Lagrangian volume of a halo with mass $10^9 M_{\odot}$ and $10^{12} M_{\odot}$ as indicated.

Figure 4. SMBHs mass function (dotted black line) with $\lambda = 0.01$ (Li et al. 2012) in comparison with different PBH mass functions in the HC (blue) and FCT (red) scenarios.

mass, typically. For example, the solid line indicates that both haloes represented in the figure have $M_c \sim 10^8 M_{\odot}$, while the dot-dashed line shows that, for those parameters, a halo with $M_h = 10^9 M_{\odot}$ has a central PBH with mass $M_c \sim 10^5 M_{\odot}$ and a halo with $M_h = 10^{12} M_{\odot}$ has a central PBH of $M_c \sim 10^{11} M_{\odot}$.

The general idea of this constraint is that the abundance of massive PBHs should, in no case, surpass that of the SMBHs in galaxies. Then, the constraint will be built by comparing the abundance of the most massive PBHs in haloes with that of the SMBHs in galaxies, obtained from observations. The latter can be obtained from the active galactic nucleus (AGN) mass function as

$$\left(\frac{dn}{dM}\right)_{SMBH} = \frac{1}{\lambda\left(M\right)} \left(\frac{dn}{dM}\right)_{AGN},\tag{54}$$

where $\lambda(M)$ corresponds to the duty cycle of AGNs, and the AGN mass function is that given by Li et al. (2012). For this work, we use $\lambda(M) = 0.01$, which is reasonable considering that we are interested in the SMBH mass function at z = 0 (Li et al. 2012). For the mass function of the most massive SMBHs in haloes we define the cumulative number density of SMBH as

$$n_{SMBH} \left(> M\right) = \int_{M}^{\infty} \left(\frac{dn}{dM}\right)_{SMBH} dM.$$
 (55)

Requiring that the PBH mass functions satisfy $n_{\rm PBH}(M) < n_{\rm SMBH}(M)$ (with $n_{\rm PBH}$ defined as the cumulative number density of PBH) would be too restrictive as $n_{\rm PBH}$ overestimates the number of PBHs because it also counts satellite PBHs in the halo. We solve this by considering only the most massive PBH of mass M_c within a halo, as defined above.

We adopt the halo mass function proposed by Tinker et al. (2008) to compute the cumulative number density of central PBHs

$$n_{\text{PBH}_{c}}(>M) = \int_{M}^{\infty} \left(\frac{dn}{dM} \left(M_{h}\left(M_{c}\right)\right)\right)_{\text{Halo}} \left(\frac{dM_{h}}{dM_{c}}\right) dM_{c},$$
(56)

where $M_h(M_c)$ is obtained implicitly through (53) and the Jacobian $\left(\frac{dM_h}{dM_c}\right)$ is obtained using (52).

Figure 4 shows the observational SMBH mass function (dotted black line) in comparison with PBH mass distributions in the HC (blue lines) and FCT (red lines) scenarios assuming a $n_b = 3.0$ and 3.5 for $M_* = 10^9 M_{\odot}$ and $10^{10} M_{\odot}$, respectively. Notice that for the latter M_* values, the high mass tails for the PBH mass function are below the SMBH one at all SMBH masses, and are therefore allowed.

We also study the effect of mergers of massive PBHs considering that PBHs with masses larger than the "sink-in mass" M_s have all fallen to the centre and merged with the central PBH. M_s is defined implicitly by requiring that the sink-in time into the centre of a halo of mass M_h is equal to the Hubble time at redshift z. i.e.,

$$\tau_{\rm dyn}(M_s, M_h, z) = H(z)^{-1}.$$
 (57)

The estimation of this dynamical time requires knowledge of the dynamical behavior of a massive object within a halo. This can be expressed in terms of the halo mass M_h and the PBH mass M_{PBH} (Binney & Tremaine 2008) as

$$\tau_{dyn} \left(M_{PBH}, M_h, z \right) = \frac{1.17}{\ln \left(\Lambda \left(M_{PBH}, M_h \right) \right)} \frac{r_{200}^2 \left(M_h, z \right) v_c \left(M_h \right)}{G M_{PBH}}$$
(58)

where

$$r_{200}(M_h, z) = \left(\frac{3M_h a^3(z)}{800\pi\rho_{m,0}}\right)^{\frac{1}{3}},$$
(59)

 $v_c(M_h) = \left(\frac{GM_h}{r_{200}(M_h)}\right)^{\frac{1}{2}},$ (60)

and

$$\Lambda\left(M_{PBH}, M_h\right) = 1 + \frac{M_h}{M_{PBH}}.$$
(61)

Then, we define the modified central PBH mass M'_c as

$$M'_{c}(M_{h}, z) = M_{c}(M_{h})$$
$$+V(M_{h}) \int_{\min(M_{s}(M_{h}, z), M_{c}(M_{h}))}^{M_{c}(M_{h})} \left(\frac{dn}{dM}\right)_{PBH} M dM,$$
(62)

accounting for the merger of all PBHs with $M > M_s$ present in the halo, assuming instantaneous merging, and neglecting the satellite PBHs correctly. Also, in case that $M_s \ge M_c$, no PBH has the time to fall to the centre and the mass of the central PBH is not modified by merging. To investigate whether this merging effect is relevant we calculate the sinkin mass M_s at z = 0 and the central mass M_c (Eq.52) in halos spanning a mass range of $10^5 - 10^{17} M_{\odot}$ for different PBH mass distributions. Figure 5 shows the sink-in mass (dotted black line) and values of central mass as function of the halo mass. We show three M_* values, $10^4 M_{\odot}$ (green), $10^8 M_{\odot}$ (red), $10^{12} M_{\odot}$ (blue) and two values for n_b for each $M_*, n_b = 2$ and $n_b = 3.5$ represented by solid and dashed lines, respectively. As we can see, M_s is greater than M_c at almost all M_h except in a small region when the halo mass is similar to the M_* value. This means that, in general, the central PBHs in these halos are not modified by mergers $M'_c \approx M_c^{-3}$. For the case when M_s is similar to M_* , the mass of the formed halo should satisfy $M_h \gg M_*$.

Finally, it will suffice to impose that $n_{\text{PBH}_c}(>M) \leq n_{\text{SMBH}}(>M)$ for all values of M, considering the cumulative number density of central PBHs as in (56). This translates into a permitted fraction of DM in the form of PBHs given by

$$f = \min\left(\left\{\frac{n_{SMBH} \,(>M)}{N_{PBH_c} \,(>M)}\right\}_{M > 10^7 M_{\odot}}\right),\tag{63}$$

where we consider the minimum value of this fraction in order to be in agreement with the SMBH mass function, even in the most restrictive scenario. Figure 6 shows the contours of different values of f in the n, M_* and n_b space for this criterion (Eq. 63) for the FCT and HC scenarios. As we can see, this constraint affects the scenarios where the mass functions predict PBHs with high masses ($\mathcal{O}(10^{10} M_{\odot})$) since these are the ones that can show disagreement with the observationally detected SMBHs.

In the remainder of this section, we present the other constraints on the fraction of DM in PBH, extracted from the literature.

³ Notice that for FCT, there are no M_c in halos with masses below ~ $10^7 M_{\odot}$ and ~ $10^{11} M_{\odot}$ for $M_* = 10^8 M_{\odot}$ and $M_* = 10^{12} M_{\odot}$ respectively when $n_b = 3.5$.

MNRAS 000, 1-25 (2015)

Figure 5. Sink-in mass $(M_s, \text{ black dotted line)}$ and central PBH mass (M_c) as function of the halo mass (M_h) for HC (top panel) and FCT (bottom panel) scenarios. The different colors correspond to different M_* values with $n_b = 2.0$ (solid lines) and $n_b = 3.5$ (dashed lines).

Figure 6. Level contours for f given by Eq. 63 for HC (left panel) and FCT (right panel) scenarios. The red lines indicate the $f_{\text{SMBH}} = 1$ contours. As the figure suggests, the regions where this constraint becomes more restrictive corresponds to the ones with high M_* , i.e., regions where their corresponding mass function predicts massive PBHs.

3.2 Monochromatic Constraints and extended PBH mass distributions

Most of the constraints for f are computed for a monochromatic mass function. One would want to calculate again these constraints but now, considering that the primordial black holes span a wide range of masses. Nevertheless, the physical processes in most of these observable constraints are not completely understood and many astrophysical parameters have to be assumed. Thus, for extended mass distributions the computation of f considering the mass dependence on the different physical processes becomes very difficult (Carr et al. 2017).

Some authors have developed methods to translate the constraints on monochromatic mass functions into extended ones (see for instance Carr et al. 2017; Bellomo et al. 2018). Based on these approaches, we propose an alternative formalism to constrain PBH extended mass functions from monochromatic bounds. This new method accounts for the fact that the physical processes used to constrain f are sensitive to PBHs only in a particular mass range, which accounts for a fraction of the total PBH mass in an extended mass function. It also accounts for the redshift evolution of the mass function due to PBH evaporation and the entrance of more massive PBHs to the Hubble volume as time progresses.

We consider different physical processes which independently provide constraints to the allowed DM fraction in PBHs assuming monochromatic distributions. Each underlying process is related to some observable output, which is assumed to be extensive in the number of PBHs, i.e., the total output is proportional to the number of PBHs. Then, the fraction f is interpreted directly as the ratio between the maximum allowed output and the measured value of that output. If this ratio is greater than one it means that the constraint, given by the maximum allowed value of the output, has not been reached. If it is less than one, it measures the maximum fraction of DM that PBHs can account for, such that when multiplied by the total measured value.

The inverse of f thus gives the observed output normalised by its maximum allowed value (which corresponds to the observational constraint), and is thus a measure of the normalised output function g(M). Due to the extensive nature of the output, and considering that an extended mass function for PBHs can be interpreted as the sum of different monochromatic populations, the average of the output function $\langle g(M) \rangle$ can be calculated using the mass function itself as the relevant statistical weight. This value of an effective output is interpreted as the resulting output from a combination of BH populations of different masses, with a distribution provided by the mass function,

$$\langle g(M) \rangle = \frac{\int_{max(M_{min},M_{ev}(z))}^{min(M_{max},M_{1pH}(z))} g(M) \frac{dn}{dM} dM}{\int_{max(M_{min},M_{ev}(z))}^{min(M_{max},M_{1pH}(z))} \frac{dn}{dM} dM}, \qquad (64)$$

where M_{min} and M_{max} are the mass limits where the observational constraint is sensitive, and we only consider PBHs such that they exist (e.g., they have not evaporated at that moment) within the causal volume by including $M_{ev}(z)$ and $M_{1pH}(z)$. Then, the multiplicative inverse of this $\langle g(M) \rangle$ is interpreted directly as the effective f for the PBH popula-

tion, characterised by a particular choice of the mass function. This procedure is general, and it only relies on the assumption of extensivity of the underlying physical quantity associated with the observational constraint.

Because the normalised output functions q(M) have support only on a domain that is a subset of the considered mass range for PBHs where the mass function is defined, the effective fraction f obtained as previously mentioned has to be corrected to account for the mass not constrained by q(M). Figure 7 illustrates a generic mass function and a particular output function g(M). For instance, consider two populations (A) and (B) of PBHs. The population (A) corresponds to the PBHs that can affect the observable measured by a particular constraint. For example, if some constraint is sensitive to objects with masses between M_{min} and M_{max} then, only PBHs within those masses will be considered on the calculation of the effective f. The population (B) corresponds to the whole population of PBHs, considering even the ones that cannot be detected by this constraint. For instance, if the population (B) holds more PBH mass than population (A), then the resulting effective f will be higher since the constraint will only act on a small fraction of our population and hence, a small fraction of the total PBH mass.

To correct for this, we define the constrained mass density as

$$\rho_{constr} = \int_{max(M_{min}, M_{ev}(z))}^{min(M_{max}, M_{1pH}(z))} \left(\frac{g(M)}{g_{\max}}\right) M \frac{dn}{dM} dM, \quad (65)$$

where $\frac{g(M)}{g_{\max}}$ will act as a filter function, varying from 1, at the maximum value of g(M), g_{\max} , and 0, whenever M is outside the domain of g(M).

We use this definition to compute the ratio between the total mass density in PBHs at redshift z (see eq. (14)) and the constrained mass density (65) at the same epoch, obtaining

$$C_M(z) = \frac{\int_{M_{ev}(z)}^{M_{1pH}(z)} M \frac{dn}{dM} dM}{\rho_{constr}}.$$
 (66)

The meaning of $C_M(z)$ is understood such that all the mass is constrained near the maximum of g(M), with the sensitivity of the constraint decreasing proportionally to the decrease in observable output away from the maximum g_{max} .

Additionally, the data to compute some of the observational constraints is obtained at a particular redshift z. Then, we need to introduce another correction to take into account the evolution of the mass function from this redshift z to the current epoch. Figure 8 illustrates a mass function whose limits are the evaporation mass M_{ev} and M_{1pH} today and at z = 1100. Notice that, within these limits, there is a difference in the mass function and mass density of PBHs when different redshifts are considered. Therefore, we introduce the C_z quantity to correct the resulting effective f by the mass function evolution as

$$C_{z}(z) = \frac{\int_{M_{vv}(z=0)}^{M_{1pH}(z=0)} M \frac{dn}{dM} dM}{\int_{M_{vv}(z)}^{M_{1pH}(z)} M \frac{dn}{dM} dM}.$$
 (67)

Thus, the corrected fraction of DM as PBHs is then

Figure 7. Schematic figure for the C_M correction. The blue line corresponds to an arbitrary extended mass distribution. The black line represents the g(M) function, which is only sensitive to masses within (M_{\min}, M_{\max}) and the red line shows the mass function weighted by g(M). This figure shows that when considering a particular g(M), related to some constraint, it is possible to have masses outside the regime where g(M) is sensitive.

Figure 8. Schematic figure for the C_z correction. The black solid line represents an arbitrary mass function. The red and blue vertical lines mark the evaporation (M_{ev}) and M_{1ph} masses at z = 0and z = 1100 respectively. Notice the number of PBHs in these boundaries change at different redshifts.

given by the fraction computed as $\langle g(M) \rangle^{-1}$, multiplied by the correction factors C_M and C_z , i.e.,

$$f_i = \left(\frac{C_M(z_i) C_z(z_i)}{\langle g_i(M) \rangle}\right),\tag{68}$$

where the subscript i was added to indicate that this is for a particular monochromatic constraint.

In the following, we apply this procedure to compute the allowed f for HC and FCT extended mass distributions for a range of values for the parameters M_* and n_b . We have chosen monochromatic constraints from evaporating PBHs, lensing and dynamical effects covering a wide range of masses; when there are multiple observables producing constraints on the same monochromatic PBH mass, we choose the more restrictive ones that span the widest range of masses, which are the most restrictive for extended mass distributions. This ensures that our combined constraints will be complete and contain all relevant observables. For a set of parameters (M_*, n_b) , the maximum allowed fraction of DM in the form of PBHs f, will be the minimum f_i from all considered constraints i.e.

$$f(M_*, n_b) = \min(f_i). \tag{69}$$

As a summary, the method to translate constraints on monochromatic mass distributions to constraints on extended mass distributions, described in this section, considers the following steps, for each monochromatic mass function constraint:

(i) If the analytic function of f is not given, we obtain data points from the f plot given in the literature.

(ii) We compute $\langle g(M) \rangle$ using Eq. (64).

(iii) We calculate the two corrections C_M and C_z given by Eq. (66) and Eq. (67) respectively, taking into account the redshift of the observations z_i .

(iv) The corrected f is then calculated using Eq. (68).

(v) Once we performed the previous steps for all the monochromatic mass distribution constraints, the resulting admitted fraction of DM in PBHs is given by the minimum fraction obtained Eq. (69).

It is worth to note that the observational constraints depend on different astrophysical assumptions and most of them have caveats on the black hole physics. Therefore, it is important to understand the physics behind each process which we briefly describe below.

3.2.1 Big bang nucleosynthesis (BBN)

The effect of low mass PBH evaporation on the BBN epoch has been already studied in several works (Miyama & Sato 1978; Vainer & Naselskii 1977; Zeldovich et al. 1977; Lindley 1980; Keith et al. 2020; Carr et al. 2020). The particles radiated by PBHs could affect the abundance of primordial light elements, for instance, enhancing the neutron-proton ratio, hence increasing the helium abundance. Also this radiation can break the Helium nuclei and decrease the amount of Deuterium at the moment of BBN. Here, we consider the measurements of the primordial mass fraction Y, the ratio D/H, ${}^{6}Li/{}^{7}Li$, ${}^{3}He/D$ which impose bounds on the β parameter (Eq. (12)) presented by Carr et al. (2010).

This parameter is associated to the current density parameter of non evaporated PBHs and therefore, related to f(M) as

$$f(M) \approx 3.81 \times 10^8 \beta'(M) \left(\frac{M}{M_{\odot}}\right)^{-1/2},$$
 (70)

where this expression is given by equation (55) in (Carr et al. 2020) and $\beta'(M)$ is related to $\beta(M)$ through

$$\beta'(M) \equiv \gamma^{1/2} \left(\frac{g_{*i}}{106.75}\right)^{-1/4} \beta(M), \tag{71}$$

where γ is related to the physics of the gravitational collapse and g_{*i} corresponds to the number of relativistic degrees of freedom which, contrary to γ , can be specified very precisely (as explained in Carr et al. 2010).

Finally, we use this f(M) (for a monochromatic distribution) to obtain the effective f with our method, considering a redshift $z = 10^{10}$ for these constraints.

3.2.2 Extragalactic γ -ray background

A primordial black hole with mass M can emit thermal radiation through the Hawking radiation mechanism. The emission rate for particles with spin s in the range of energies [E, E + dE] has been calculated by many authors (MacGibbon & Webber 1990; MacGibbon 1991; Carr et al. 2016a). This phenomenon can be used to constrain the fraction of PBHs by confronting the theoretical spectrum of radiation (photons) emitted from PBHs with observations, for instance, the diffuse extragalactic γ -ray background (EGB). Different experiments have measured the diffuse EGB in the energy range 1MeV-1000MeV (see Carr et al. 2020, and references therein). The observed extragalactic intensity is $I^{obs} \propto E^{-(1+\epsilon)}$, where ϵ parameterises the spectral tilt. From this relation, it is possible to estimate the fraction of PBHs as DM as

$$f(M)_{\gamma} \lesssim 2 \times 10^{-8} \left(\frac{M}{M_{\gamma}}\right)^{3+\epsilon}$$
 (72)

where $M > M_{\gamma}$, $M_{\gamma} \sim 5 \times 10^{14} \text{g}$ (~ $2.51 \times 10^{-19} M_{\odot}$) and ϵ takes a value between (0.1, 0.4). For this constraint, we assume a redshift z = 1160, a minimum mass $M_{min} = 2.52 \times 10^{-19} M_{\odot}$, $M_{max} = 6.4 \times 10^{-17} M_{\odot}$ and $\epsilon = 0.2$. Additionally, we consider the constraint on f when $M < M_{\gamma}$ in the interval $\sim 1.3 \times 10^{-20} M_{\odot} < M < 2.51 \times 10^{-19} M_{\odot}$ by taking data points from the f plot by Carr et al. (2020).

3.2.3 Galactic center γ -ray constraint

The current observations of the 511 keV gamma-ray line from the Galactic centre by the INTEGRAL observatory (Siegert et al. 2016) can be used to constrain the fraction of PBHs as dark matter with masses $M \sim 10^{-17} M_{\odot}$, as they could radiate positrons which eventually annihilate producing a γ -ray spectrum. We extract the data points from the constraint on f obtained by Dasgupta et al. (2019, see also, Laha 2019; DeRocco & Graham 2019) using the INTE-GRAL measurements in the interval $\sim 5.5 \times 10^{-17} M_{\odot}$ and $\sim 8.5 \times 10^{-17} M_{\odot}$. This constraint is relevant at z = 0.

3.2.4 Gravitational lensing constraints

Microlensing is the effect of an amplification of a background source during a short period of time produced by the passage of a compact object close to its line of sight. Paczynski (1986) suggested that a population of objects producing this effect could be detected within the Milky Way halo. Each microlensing event will occur when a compact object goes through what is called the microlensing "tube" which is directly related to the mass of the object, in our case, the PBH. The observable for this constraint is the number of observed events and, this is in turn related to the number density distribution as a function of mass, i.e., the mass function of the objects (Griest 1991; De Rújula et al. 1991). The microlensing of stars in the Magellanic clouds by massive compact halo objects (MACHOs) has been used to test the fraction of DM as PBHs (Paczynski 1986) in the range $\sim 10^{-8} M_{\odot} < M < 60 M_{\odot}$. Other campaigns to search lensing events of sources in the Magellanic clouds due to MACHOs are the EROS (Hamadache et al. 2006; Tisserand et al. 2007) and OGLE (Wyrzykowski et al. 2011) experiments. For these constraints we compute $\langle q(M) \rangle$ from the f(M) functional form of the curve plotted in Carr et al. (2016b, 2020). The range of masses that can be constrained are $5.8 \times 10^{-8} M_{\odot} \lesssim M \lesssim 5 M_{\odot}$ and $1.8\times 10^{-7} M\odot \lesssim M \lesssim 0.3 M\odot$ for EROS and OGLE measurements, respectively.

We also consider the limits on the abundance of compact objects which could produce a millilensing effect of radio sources (Wilkinson et al. 2001). This observable puts constraints on f in the interval $\sim 1 \times 10^5 M_{\odot} < M <$ $1 \times 10^9 M_{\odot}$. The femtolensing effect of gamma ray burst (GRBs) by compact objects also imposes a limit on f in the interval $5 \times 10^{-17} M_{\odot} \lesssim M \lesssim 1 \times 10^{-14} M_{\odot}$ (Marani et al. 1999; Nemiroff et al. 2001; Barnacka et al. 2012). Nevertheless Katz et al. (2018, see also Carr et al. 2020) claim that most of the GRBs are are inappropriate for femtolensing searches and hence f is not robustly constrained. The microlensing search of stars in the Milky way and M31 by PBHs with the Subaru Hyper Suprime-Cam provides a bound on f in the interval $3.6 \times 10^{-12} M_{\odot} \lesssim M \lesssim 6.8 \times 10^{-6} M_{\odot}$ (Niikura et al. 2019b). Recently, Smyth et al. (2020) point out that these constraints assume a fixed source size of one solar radius. By performing a more realistic analysis, they conclude that the current bounds are weaker by up to almost three orders of magnitude. All these constraints are at redshfit z = 0.

3.2.5 Neutron star capture and white dwarfs

Another constraint on the fraction of DM as PBHs is obtained from their capture by neutron stars in environments with high density, such as, the core of globular clusters. If a neutron star captures a PBH it can be disrupted by accretion of its material onto the PBH. Thus, the observed abundance of neutron stars imposes constraints on f at a certain range of masses. The f(M) function encoding the physics of the capture probability by neutron stars is given by

$$f_{NS}(M) = \frac{M}{4.7 \times 10^{24} \text{g}} \left(1 - \exp\left(-\frac{M}{2.9 \times 10^{23} \text{g}}\right) \right)^{-1},$$
(73)

where we have adopted the same values as Capela et al. (2013). Notice that this constraint is valid in the mass range $1.25 \times 10^{-15} M_{\odot} < M < 5 \times 10^{-9} M_{\odot}$. Additionally, the possibility that PBHs can trigger white dwarf explosions as a supernovae also provides a bound on f (Graham et al. 2015). The white dwarf distribution imposes constraints to PBHs

with masses between $\sim 1.2 \times 10^{-15} M_{\odot}$ and $\sim 1.6 \times 10^{-11} M_{\odot}$. Both constraints are relevant at z = 0.

Note, however, that Montero-Camacho et al. (2019) has recently stated that the NS constraint is no longer valid. One of the reasons is that it considers globular clusters as an environment with high DM density. This can happen if the clusters are from primordial origin, however this scenario is not fully determined. Montero-Camacho et al. (2019) also studied NS capture considering the environment on dwarf galaxies concluding that the survival of stars cannot rule out PBHs as DM. They also conclude that there is not an effective constraint from white dwarf survival.

3.2.6 X-ray binaries.

We know that there is a possibility that a PBH can accrete baryonic matter from the interstellar medium (ISM), forming an accretion disk which can radiate. Inoue & Kusenko (2017, see also Carr et al. 2020) considered that a PBH can accrete material through the Bondi-Hoyle-Lyttleton accretion. In this approach, the mass accreted onto a PBH can be converted in radiation, associated to a luminosity L, and hence, the number of accreting PBHs, emitting a luminosity L_x (in X-rays), can be estimated. Indeed, the luminosity function of X-ray binaries (XRB) restricts the maximum Xray output and hence, the number of accreting PBHs. This luminosity function has been obtained using Chandra observations (see for instance Mineo et al. 2012), with L_x spanning the range $10^{35} - 10^{41} \text{erg s}^{-1}$, implying constraints on PBH with masses ~ $5.7M_{\odot} - 2 \times 10^7 M_{\odot}$.

We translate this into our method by extracting data points from the $f_{XRB}(M)$ curve presented by Inoue & Kusenko (2017); Carr et al. (2020). This constraint applies to redshift z = 0.

3.2.7 Disruption of globular clusters and galaxies

Another important constraint comes from PBH dynamical effects on astrophysical systems like globular clusters (GC) and galaxies (G) (Carr & Sakellariadou 1999). A passing PBH could disrupt a GC due to tidal forces, thus the GC survival imposes the following bound on f

$$f_{GC}(M) = \begin{cases} \left(\frac{M}{3 \times 10^4 M_{\odot}}\right)^{-1} & 3 \times 10^4 M_{\odot} < M < 10^6 M_{\odot}, \\ 0.03 & 10^6 M_{\odot} < M < 10^{11} M_{\odot}, \end{cases}$$
(74)

which is relevant at z = 0. Besides individual PBHs, hypothetical clumps could also disrupt galaxies in clusters, resulting in an additional bound on f given by

$$f_G(M) = \begin{cases} \left(\frac{M}{7 \times 10^9 M_{\odot}}\right)^{-1} & 7 \times 10^9 M_{\odot} < M < 10^{11} M_{\odot}, \\ 0.05 & 10^{11} M_{\odot} < M < 10^{13} M_{\odot}, \end{cases}$$
(75)

where this is relevant at z = 1.

3.2.8 Disk heating

PBH encounters with (mainly old) disk stars could be responsible for disk heating in galaxies (Carr & Sakellariadou

1999; Carr et al. 2020). This dynamical effect is translated into a restriction on f for high mass PBHs as

$$f_{DH}(M) = \begin{cases} \left(\frac{M}{3 \times 10^6 M_{\odot}}\right)^{-1} & 3 \times 10^6 M_{\odot} < M < 3 \times 10^9 M_{\odot}, \\ \frac{M}{M_{halo}} & 3 \times 10^9 M_{\odot} < M < M_{halo}, \end{cases}$$
(76)

where a halo mass, M_{halo} , of $3 \times 10^{12} M_{\odot}$ is assumed and it is considered to be important at redshift z = 1.

3.2.9 Wide binaries

Binary star systems with wide separations could be disrupted by encountering PBHs (Chanamé & Gould 2004; Quinn et al. 2009). Observations of wide binaries in the Milky way impose a constraint on f as a function of the PBH mass, given by

$$f_{WB}(M) = \begin{cases} \left(\frac{M}{500M\odot}\right)^{-1} & 500M\odot < M \lesssim 10^3 M\odot, \\ 0.4 & 10^3 M\odot \lesssim M < 10^8 M\odot. \end{cases}$$
(77)

This constraint is relevant at z = 0.

3.2.10 Dynamical friction

PBHs could be dragged into the centre of the Milky Way due to dynamical friction of halo objects and stars. This possibility leads to constraints on f in the range of masses between $\sim 10^4 M_{\odot}$ and $\sim 10^{13} M_{\odot}$. To use our method to translate monochromatic constraints to extended ones, we extract the data points from the f curve presented by Carr et al. (2020).

3.2.11 Accretion by PBHs

The accretion of matter onto PBHs involves different effects that we can potentially observe. Even if there are numerous constraints related to this process, we consider here the constraints on PBHs with masses between ~ 10⁰ and 10⁴ M_{\odot} , presented by Serpico et al. (2020). In particular, they study the effects of disk-like or spherical accretion on the CMB anisotropies. In this work, we adopt the accretion scenario without a DM halo⁴ (explained in detail by Poulin et al. 2017). The relevant redshift for this process is considered as $z \sim 450$.

In general, constraints related to the accretion by PBHs depend on numerous assumptions and physical parameters. Therefore these must be considered with care (see Carr et al. 2020).

3.2.12 Large scale structure

Massive PBHs have the peculiarity that they can seed the large scale structure of the Universe (Carr & Silk 2018). To take this into account we consider the estimations for the constraint on f for this effect, given by Carr et al. (2020) who include constraints for PBH with masses in the range

⁴ This is because we start with the assumption that DM is composed by PBHs and then, we study the validity of this assumption by computing f. $\sim 10^2 - 10^{14} M_{\odot}$. The relevant redshift for this constraint is z = 0.

3.2.13 Gravitational waves

Gravitational waves are produced by the coalescence of black holes, which may be primordial in origin. They could also be produced during the formation of PBHs. Several authors studied the merger rates of PBHs in order to predict GW signals due to these mergers and compared them to the observations (see Sasaki et al. 2016; Eroshenko 2018, for example). Ali-Haïmoud et al. (2017) estimated the merger rate of PBH binaries in order to compute the maximum fraction f, obtaining potential constraints on PBHs with masses in the range $\sim 10 - 100 M_{\odot}$. Later, the LIGO/Virgo collaboration used the non-detection of GW events to put constraints on sub-solar mass PBHs (Abbott et al. 2018).

Additionally, the superposition of GW from independent sources produces a background signal known as stochastic gravitational wave background (SGWB). Wang et al. (2018) used this effect to compute constraints on f for PBHs of~ $1-100M_{\odot}$, using the first Advanced LIGO observation run. Recently, Raidal et al. (2019) provide updated constraints in the mass range ~ $10^{-1} - 10^3$ (assuming a log-normal mass function) from the observed merger rate of ten events by LIGO non-observations and also bounds from the stochastic GW background by comparing with the projected final sensitivity of LIGO. Wong et al. (2021) present constraints on f estimated from the third observing run of the LIGO-Virgo Collaboration and from the NANOGrav experiment 11-yr data. We have also considered these bounds in our analysis.

Even if these effects impose stringent constraints on f, it has been recently pointed out that a more detailed analysis to compute the merger rate of PBH binaries is needed (see Boehm et al. 2020). This result suggests that the constraints related to GW must be disputed if these are calculated by estimating a merger rate for PBH binaries. Nevertheless, several authors (De Luca et al. 2020b; Hütsi et al. 2021) claimed that such analysis on the growing PBH mass in an expanding universe should be reexamined.

3.2.14 Cosmic microwave background dipole

Under the assumption that there are supermassive PBHs in the intergalactic medium, they can induce peculiar velocities on galaxies due to gravitational interaction. The peculiar velocity of the Milky Way can be measured from the cosmic microwave background (CMB) dipole and used to constrain the fraction of this population of PBHs (Carr et al. 2020). The resulting constraint on f gives

$$f_{CMB}(M) = \left(\frac{M}{5 \times 10^{15} M_{\odot}}\right)^{-1/2} \left(\frac{t_0}{10^{10} \text{yr}}\right)^{-3/2} \Omega_{m0}^{-0.9} h^{-2},$$
(78)

where t_0 is the age of the Universe, Ω_{m0} is the matter density parameter and, h is the dimensionless normalised Hubble constant. Even though the CMB radiation originates at $z \sim 1100$, this effect is measured locally, implying that the relevant redshift is z = 0. This effect gives constraints on PBHs with masses between $\sim 7 \times 10^{16} M_{\odot}$ and $1 \times 10^{22} M_{\odot}$.

Table 2. Summary of all the constraints considered in this work. We include the respective mass regimes where they apply and the corresponding redshift for each one, along with the mass of the PBH that ends its evaporation at that redshift $M_{ev}(z)$. Also, the last column shows references which explain these constraints in more detail. Constraints marked with * are considered disputed for different reasons.

Although we have considered this limit, we will explore the M_* parameter up to $10^{15} M_{\odot}$, meaning that it is very unlikely to find PBHs within the mass regime of this process and hence, we do not expect to obtain an f(M) bound from this constraint.

In Table 2 we summarise these physical effects and the corresponding PBH masses that each one constrains, along with the relevant redshift, the mass of the PBH that evaporates at that time $M_{ev}(z)$ and references to the full details of these effects.

As mentioned before, Carr et al. (2017) and Bellomo et al. (2018) presented different methods to translate constraints on f from monochromatic mass functions to extended ones. The method by Carr et al. (CM17, 2017) computes the f of an extended mass distribution by integrating

monochromatic mass function. This M_{eff} is calculated by integrating the mass function normalised to unity weighted by a function g(M) encoding the physical processes of the observable. To compare these methods with the one presented in this work use the observations of gravitational lensing by MACHOS (see §3.2.4). The resulting f values for selected (n_b, M_*) values are shown in Table 3. It is worthy to mention that when the CM17 and BM8 methods are applied to our extended mass functions, the f is calculated only in the range of masses of the chosen observables. We found that the f values obtained from the MACHOS con-

the quotient between the mass distribution of log(M) and

the maximum allowed fraction for a monochromatic func-

tion. The method by Bellomo et al. (BM18, 2018) consist in

estimating f from an effective mass, M_{eff} , associated to a

straints are consistent among the three different methods. It is worth noting that the method presented in this work corrects the f value taking into account PBHs outside the limits of the observable universe as a function of redshift, as well as the evolution of the mass function from the redshift z to the current epoch through $M_{ev}(z)$ and $M_{1ph}(z)$. In addition, we found that f from BM18 is almost independent from the M_* value. Moreover, if f is calculated considering the minimum and maximum masses of the full extended mass distribution, this method could result in M_{eff} values outside the range of masses of the observable, and therefore, other considerations must be taken into account.

4 COMBINED CONSTRAINTS ON EXTENDED PBH MASS FUNCTIONS

To investigate whether PBHs under the HC and FCT formation scenarios can constitute all the dark matter in the Universe we confront different realisations for the mass functions with observational constraints at different mass regimes, mentioned in the previous section. As mentioned above, we assume fiducial values $n_s = 0.9649$, $k_{piv} = 10 \,\mathrm{Mpc}^{-1}$, and $f_m = 1$ in the HC (Eq. 50) and FCT (Eq. 37) mass distributions, leaving as free parameters the blue index n_b and M_* .⁵ Each realisation of the mass function will have a different pair (n_b, M_*) spanning the intervals $n_b \in [1.1, 4.0]$ and $M_* \in [10^{-30} M_{\odot}, 10^{15} M_{\odot}]$ in a grid of 50 points for each parameter.

For all the realisations, we compute the constraint on $f_{\rm SMBH}$ (Eq. 63), as explained above. Additionally, we employ the method described in Section 3.2 for obtaining the corresponding constraint on f_i for each process described in the same section.

Figure 9 (top panel) shows the resulting level contours for the maximum allowed fraction f of DM in PBHs obtained by combining the undisputed monochromatic constraints (see Table 2) according to Eq. 69, together with the constraint provided by SMBHs. The colours correspond to contours on f for values between 10^{-24} and 1. We present this as a function of the slope n of the PBH mass functions (bottom axis), n_b (top axis) and M_* . The left and right panels show the HC and FCT scenarios, respectively. In the HC

panel, the grey dashed contours represent the values of the average mass $\langle M \rangle_{PBH}$ (Eq. 15) of the PBH distributions with values from $10^{-18} M_{\odot}$ to $1 M_{\odot}$ from the bottom to the top, respectively. In the FCT panel, the grey dashed contours represent the values of the number density n_{PBH} (Eq. 13) with values from $\simeq 4 \times 10^{28} \text{Mpc}^{-3}$ to $\simeq 4 \times 10^{10} \text{Mpc}^{-3}$ from bottom to top, respectively. In both panels, the hatched region at low characteristic masses $(M_* \lesssim 10^{-21} M_{\odot})$, is excluded since in this range of parameters all PBHs have evaporated by the present time and hence, cannot account for the DM we see today. As can be seen, a large fraction of the parameter space is restricted to f < 1. However, the red contours that correspond to f = 1 enclose regions (white) where it is possible to have the DM composed entirely by PBHs, i.e., $f \ge 1$. The are two allowed regions in the HC scenario, one of them roughly at $M_* \sim 10^2 M_{\odot}$, with n_b from ~ 2.3 to 4. The other region corresponds to $M_* \sim 10^{-7} M_\odot$ and $n_b > 3.6$. In the FCT scenario, there are three allowed regions where f = 1. The first two regions are located at $M_* \sim 10^2 M_{\odot}$ and n_b in the ranges [1.1, 1.7] and [2.2, 4.0] respectively. The third region spans all the n_b range for $M_* \sim 10^{-7} M_{\odot}$ including even more values of M_* as n_b increases. Table 4 gives representative (n_b, M_*) values in such regions.

An interesting feature is that the level contours exhibit a continuity in the mass function slope from $n \sim -1.9$ to -0.9. In the HC scenario, the top dotted lines correspond to a pivot mass $M_{piv} = 8.9 \times 10^{12} M_{\odot}$ when $f_m = 1$. The hatched region for $M_* > M_{piv}$ shows there are no HC mass functions defined there.

Regarding f_m , we also perform an iterative procedure to estimate $f_m = \beta$ such that all linear overdensities with $\delta > \delta_c$ are associated with the formation of a PBH. Applying the procedure explained in Section 2.2, in FCT we obtain $\beta \sim 5.8 \times 10^{-23}$, for all values of n_b and M_* , resulting in $M_{piv} \sim 3.45 \times 10^{10} M_{\odot}$ which is shown as the black dashed line in the FCT panel. In the HC scenario, this is slightly more complicated due to the strong dependence of β on M_* . The approach for this scenario, was to find the maximum M_* value such that $M_* < M_{piv}$. The resulting maximum effective $\log_{10}(M_*/M_{\odot}) \sim 8.8 - 9.8$ in the n_b range implying $M_{piv} \sim 7.78 \times 10^8 M_{\odot} - 1.2 \times 10^{10} M_{\odot}$. The black dashed line in the HC panel shows these values of maximum M_* .

The bottom panel of Figure 9 shows the combined constraints for f for a fixed value of $n_b = 2.5$ as a function of M_* for both, the FCT (red) and HC (blue) scenarios. In this figure, we also show the value of f including (solid lines) and excluding (dashed lines) the constraints from GW, where the two cases differ mostly in the region around $M_* \sim (10^1 - 10^4) M_{\odot}$. The inclusion of the GW constraints exclude the possibility that f = 1 in this range of M_* . We emphasise that the relation between f and M_* is different from the usual f(M) for monochromatic PBH distributions because, in this case, we consider an extended mass distribution; i.e., choosing a different n_b value will change drastically the results for $f(M_*)$.

We emphasise that these results for f are obtained discarding the disputed constraints. If one includes them without any additional considerations, PBHs as the sole component for DM get completely ruled out on the entire parameter space for both scenarios. In particular the NS constraint erases most of the allowed region around $M_* \sim 10^{-7} M_{\odot}$

⁵ It is worth to note that our first choice on f_m implies that only a fraction of regions with a linear overdensity higher than δ_c will be associated to the physical formation of a PBH.

Figure 9. Top panel: level contours for the fraction of PBHs as DM in HC (left panel) and FCT (right panel) for different values of the slope of the mass function and the characteristic mass M_* . The upper secondary axis gives the values for the blue index n_b . The red lines correspond to f = 1 and the allowed areas are represented in white. The grey dashed contours in the HC and FCT panels represent the values of the average mass $\langle M \rangle_{PBH}$ (Eq. 15) and the number density n_{PBH} (Eq. 13) of the PBH distributions, respectively. The hatched region for $M^* \lesssim 10^{-21} M_{\odot}$ is excluded since those mass functions predict that all of the PBHs have evaporated by the present time. In the HC scenario, the top dotted lines correspond to $M_{piv} = 8.9 \times 10^{12} M_{\odot}$ when $f_m = 1$. The hatched region for $M_* > M_{piv}$ shows there are no HC mass functions defined there. The black dashed line in both scenarios show M_{piv} for $f_m = \beta$. Bottom panel: fraction of PBHs as DM f for fixed $n_b = 2.5$ as a function of M_* . Red lines correspond to the FCT scenario and blue lines to the HC scenario. Dashed lines show the resulting f including constraints from GW.

for the FCT scenario and the Subaru constraint completely eliminates this region. Also, the constraints from the nonobservation of SGWB Wong et al. (2021), mergers Raidal et al. (2019) and accretion by PBHs Poulin et al. (2017); Serpico et al. (2020) eliminate the region around $M_* \sim 10^2 M_{\odot}$ in both scenarios. Particularly, the inclusion of the GW constraints for the parameters of Table 4 changes the f values from 1 to $\sim 10^{-2}$ (similar values are obtained including the accretion constraints). Therefore, understanding the physics of these constraints becomes crucial if we want to

rule out PBHs as a DM candidate. Notice that when the monochromatic constraints are combined, PBH with masses $10^{-16} - 10^{-11} M_{\odot}$ can comprise an important fraction (or the total) of the content of dark matter in the Universe (Carr et al. 2020; Carr & Kuhnel 2020). In the case of extended distributions, M_* values in this range are restricted mainly by the galactic centre γ -ray (INTEGRAL) and extragalactic γ ray background constraints, in the FCT scenario, and these same bounds in combination with those from BBN, in the HC scenario. However, it should be noted that $M_* \neq M_{\text{PBH}}$ where M_{PBH} is the mass of a PBH in a monochromatic population. The fact of M_* being close to the maximum mass of the distribution implies that, for a given value of M_* , all the constraints that affect lower masses must be considered. In this particular case, the abundance of PBHs with masses between $(10^{-24} - 10^{-16}) M_{\odot}$ is still high enough to disagree with the observations from the galactic centre γ -rays, extragalactic γ -ray background, and BBN for values of M_* between $(10^{-16} - 10^{-11})M_{\odot}$, thus ruling out that region of the parameter space.

4.1 Further analysis in the allowed windows

To check whether the parameters in the regions that allow all of DM in PBHs make sense physically, we evaluate the ratio $\delta_c/\langle |\delta|^2 \rangle^{1/2}$ (See Section 2.1) within them and show the results in Table 4. The large values found for this ratio for all allowed windows in both scenarios indicate that the less preferred possibility of having $f_m = 1$ can be discarded. Considering $f_m = \beta$ (i.e., that all regions will collapse into a PBH but only with a fraction f_m of its energy density) we see that for the HC scenario we obtain $\delta_c/\langle |\delta|^2 \rangle^{1/2} \sim 1$, at least for the window centered at $M^* \sim 100 M_{\odot}$. The second HC window with $M^* \sim 10^{-8} M_{\odot}$ is rejected since, even when considering $f_m = \beta$ we obtain $\delta_c \gg \langle |\delta|^2 \rangle^{1/2}$. In the FCT windows that allow all DM in PBHs, we find a similar result for $f_m = \beta$, namely, $\delta_c \sim \langle |\delta|^2 \rangle^{1/2}$ in the $M_* \sim 100 M_{\odot}$ window and $\delta_c \gg \langle |\delta|^2 \rangle^{1/2}$ in the second window. We explored changing the scale factor a_{fct} by several orders of magnitude and found that the resulting values of $\delta_c/\langle |\delta|^2 \rangle^{1/2}$ do not change significantly and remain within roughly the same order of magnitude.

We point out that in the evaluation of these quantities, the contribution of neutrinos and other relativistic species is taken into account, since it may affect the results for $\delta_c / \langle |\delta|^2 \rangle^{1/2}$ and β .

5 CONCLUSIONS

In this paper we used a modified Press-Schechter (PS) formalism to investigate the possibility that primordial black holes make up a fraction of the dark matter in the Universe. We modified the standard Press-Schechter formalism used to infer the abundance of DM haloes so that it can be applied to PBH formation since, in this case, there is no simple, known relation between the linear overdensity and the physics of PBH formation in an expanding background. This results in extra parameters for PS the first of which is the fraction of the overdensity to undergo collapse, f_m .

Table 4. Characteristic mass (M_*) , blue index (n_b) , and ratio between the corresponding critical density contrast over the typical overdensity $\left(\delta_c/\langle |\delta|^2 \rangle^{1/2}\right)$ where all DM can be composed by PBHs, i.e. f = 1, for $f_m = 1$ and $f_m = \beta$.

This parameter allows the formalism to use all the information from linear theory when it takes a value corresponding to the ratio of dark-matter to total energy densities at the median formation time. A second modification is that we also allow the relevant amplitudes of linear fluctuations to be measured either at a fixed conformal time or at horizon crossing. Following the modified Press-Schechter formalism, under both formation timings, we considered two primordial power spectra, the standard one and a broken power law to obtain the mass functions in terms of two additional free parameters, the blue index n_b and the pivot scale k_{piv} . We also use the standard linear density contrast threshold for collapse δ_c . This parameter is particularly meaningful since for linear theory to remain informative about the non-linear collapse, its value should be of the same order as the typical energy density fluctuations at the time of collapse. All these parameters are encoded in the characteristic mass, M_* , and mass function slope n.

To restrict these parameters, we introduce a new constraint for extended PBH mass distribution employing the SMBH mass function. This constraint arises from requiring that the abundance of massive PBHs should in no case exceed the abundance of SMBHs. This naturally imposes strong constraints for the high characteristic masses of $M_* > 10^{\bar{10}} M_{\odot}$. In addition, we used several observational constraints at different mass ranges coming from monochromatic PBH mass functions. We introduce a new approach to apply these monochromatic constraints to extended mass distributions through an output function g(M) encoding the underlying process for each observable such that the resulting allowed fraction is the inverse of the output i.e. $f \sim 1/g(M)$ (see Section 3.2). Moreover, we consider two new corrections to the PBH mass fraction f, which take into account the fraction of the mass that is constrained by any particular physical process (C_M) and the redshift evolution of the mass function (C_z) . We only consider PBHs such that they exist (e.g., not evaporated at the relevant redshift) within the causal volume. By using this formalism, we obtain that the bounds obtained in monochromatic mass function are weaker when they are translated to extended mass distributions. To obtain the final (and most restrictive) constraints on the free parameters M_* and n_b we compute the maximum allowed fraction as the minimum one out of all the undisputed constraints for that particular choice of mass function parameters.

For both, HC and FCT mass functions, we obtain that there are potential regions where all DM can be made of PBHs. In the HC scenario, these regions roughly correspond to a characteristic mass M_* of $\sim 10^2 M_{\odot}$ with n_b from ~ 2.3 to 4 and an M_* of $\sim 10^{-7} M_{\odot}$ with $n_b > 3.6$. In FCT the fraction f = 1 is allowed when $M_* \sim 10^2 M_{\odot}$ for $1.1 < n_b < 1.7$, or $2.2 < n_b < 4.0$, and $M_* \sim 10^{-7} M_{\odot}$ for all explored values of n_b .

We also verify if the linear perturbations are related to the physics of collapse, within the allowed windows, by evaluating $\delta_c / \langle |\delta|^2 \rangle^{1/2}$. We do this calculation considering $f_m = 1$ and $f_m = \beta$, where the latter is the preferred option as it ensures a strong relation between PBH formation and the linear perturbations. As indicated in Table 4, the windows centered at $M_* \sim 100 M_{\odot}$ are the only ones to satisfy the condition of $\delta_c / \langle |\delta|^2 \rangle^{1/2} \sim 1$ for $f_m = \beta$. We emphasise that the allowed, and physically sensible,

We emphasise that the allowed, and physically sensible, HC region for $M_* \sim 10^2$ for a wide range of n_b is interesting as it is of the order of black hole masses ($\sim 30M_{\odot}$) measured by LIGO from the gravitational waves of a binary black hole merger (Abbott et al. 2016; Jedamzik 2020). It is worth to note, that more stringent bounds on the characteristic mass M_* and n_b could could be obtained if more observational constraints are considered, for example, if we consider all the disputed bounds, indicated by * in Table 2, we completely rule out that DM is fully composed by PBHs in the scenarios studied in this work.

In summary, we have revisited the PS formalism to construct extended PBH mass distributions under two formation scenarios (i.e., FCT and HC). In constructing the mass function using the PS formalism, we have considered a broken power-law primordial power spectrum with a blue index for small scales. When neglecting the disputed constraints, we found regions for the mass function parameters which allow all the DM in the Universe to be made of PBHs. We encourage further investigation of these models to elucidate the true nature of dark matter.

APPENDIX A: BLACK HOLE EVAPORATION

The power radiated by an object with temperature T is given by

$$P = A\epsilon\sigma T^4,\tag{A1}$$

where A is the radiating surface area of the object, ϵ is the emissivity and σ is the Boltzmann constant, defined as

$$\sigma = \frac{\pi^2 k_B^4}{60\hbar^3 c^2}.\tag{A2}$$

For a black hole, we can consider the simple scenario of a Schwarzschild Black Hole. Then, its temperature is directly related to the mass of the BH M by

$$T(M) = \frac{\hbar c^3}{8\pi G k_B M}.$$
 (A3)

In this situation, the radiating surface area of the BH is given by the surface area of a sphere with radius r equal to the Schwarzschild radius r_s of the black hole. This is

$$A = 4\pi r_s^2 = \frac{16\pi G^2 M^4}{c^4},\tag{A4}$$

where the Schwarzschild radius is given by $r_s = 2GM/c^2$. Considering that the black hole radiates as a perfect black body ($\epsilon = 1$), the Power radiated by a black hole becomes

$$P = \frac{\hbar c^6}{15360\pi G^2 M^2}.$$
 (A5)

The power radiated by the black hole is nothing more than the rate of energy loss by the BH, and this, in turn, corresponds to the rate of mass loss for the BH

$$P = -\frac{dE}{dt} = -c^2 \frac{dM}{dt}.$$
 (A6)

Then, we can write

$$-\frac{dM}{dt} = \frac{\hbar c^4}{15360\pi G^2 M^2}$$
(A7)

and integrating this expression, we have that

$$t(M) = \frac{5120\pi G}{\hbar c^4} \left(M_0^3 - M^3 \right).$$
 (A8)

t(M) indicates the time needed for a black hole to go from its initial mass M_0 to the mass M. Evaluating this expression for M = 0, the evaporation lifetime τ_{ev} (Eq. (16)) is recovered.

We can evaluate this expression to find how much time it takes to a black hole to evaporate half of its mass.

$$t\left(\frac{M_0}{2}\right) = \frac{5120\pi G}{\hbar c^4} \left(M_0^3 - \frac{M_0^3}{8}\right),$$
 (A9)

where if we use the expression for τ_{ev} , we have that

$$t\left(\frac{M_0}{2}\right) = \frac{7}{8}\tau_{ev}.$$
 (A10)

Then, we can conclude that, independently of the initial mass M_0 of the BH, the time needed to evaporate half of its mass will be 7/8 of its complete lifetime. Therefore, a BH will evaporate its second half of its mass within the last eighth of its lifetime.

APPENDIX B: FURTHER MATHEMATICAL DETAILS

Here we give further details of all our analytical expressions for the mass functions.

B1 Fixed conformal time

B1.1 Standard Power Spectrum

The variance of the density field (7) for the power law spectrum (1) results in

$$\sigma^{2}(k) = 4\pi D^{2}(a) \int_{0}^{k_{R}} P(k)k^{2} dk = \frac{4\pi D^{2}(a) A_{s}}{k_{0}^{n_{s}}} \int_{0}^{k_{R}} k^{n_{s}+2} dk$$
$$= \frac{4\pi D^{2}(a) A_{s}}{k_{0}^{n_{s}}} \frac{k_{R}^{n_{s}+3}}{n_{s}+3}, \tag{B1}$$

where $D^2(a) = a_{fct}^4$ since a_{fct} lies within radiation domination.

By substituting the relation of k_R in terms of the mass given by (29), Eq. (B1) can be rewritten as

$$\sigma^{2}(M) = \frac{4\pi a_{fct}^{4} A_{s}}{k_{0}^{n_{s}}} \frac{C_{fct}^{n_{s}+3} f_{m}^{\frac{n_{s}+3}{3}}}{(n_{s}+3)} M^{-\frac{(n_{s}+3)}{3}}.$$
 (B2)

In addition, the ν parameter (5) reads as

$$\nu = \frac{\delta_c}{\sigma(M)} = \frac{\delta_c}{f_m^{\frac{n_s+3}{6}}} \sqrt{\frac{(n_s+3)}{4\pi \, a_{fct}^4(A_s/k_0^{n_s})C_{fct}^{n_s+3}}} M^{\frac{n_s+3}{6}}.$$
(B3)

(B3) We define a characteristic mass, M_* , such that $\nu(M_*) = 1$, given by

$$\frac{\delta_c}{f_m^{\frac{n_s+3}{6}}}\sqrt{\frac{(n_s+3)}{4\pi \,a_{fct}^4(A_s/k_0^{n_s})C_{fct}^{m_s+3}}}M_*^{\frac{n_s+3}{6}} = 1. \tag{B4}$$

Then, the characteristic mass results in

$$M_* = \left(\sqrt{\frac{4\pi \, a_{fct}^4 \, (A_s/k_0^{n_s}) C_{fct}^{n_s+3}}{(n_s+3)}}\right)^{\frac{6}{(n_s+3)}} \frac{f_m}{\delta_c^{\frac{6}{(n_s+3)}}}.$$
 (B5)

The threshold density contrast for PBH formation can be expressed as

$$\delta_c = \sqrt{\frac{4\pi \, a_{fct}^4 \, (A_s/k_0^{n_s}) C_{fct}^{n_s+3}}{(n_s+3)}} \left(\frac{f_m}{M_*}\right)^{\frac{n_s+3}{6}}.$$
 (B6)

We can rewrite the Eq. (B3) in terms of M_* as $\nu = \left(\frac{M}{M_*}\right)^{\frac{n_s+3}{6}}$ and its derivative with respect to M results as

$$\frac{d\nu}{dM} = \frac{ns+3}{6} \frac{1}{M_*} \left(\frac{M}{M_*}\right)^{\frac{ns-3}{6}},\tag{B7}$$

$$\left(\frac{dn}{dM}\right)_{\text{fct}}^{\text{std}} = \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \frac{ns+3}{3} \frac{1}{M^2} \left(\frac{M}{M_*}\right)^{\frac{ns+3}{6}} \times \exp\left[-\frac{1}{2} \left(\frac{M}{M_*}\right)^{\frac{ns+3}{3}}\right].$$
(B8)

B1.2 Broken Power Spectrum

The variance of the density field $\sigma^2(M)$, in this scenario is obtained substituting Eq. (2) into the definition in Eq. (7). This reads as

$$\sigma^{2}(M) = \frac{4\pi D^{2}(a)A_{s}}{k_{0}^{n_{s}}} \left[\int_{0}^{k_{piv}} k^{n_{s}+2} dk + \int_{k_{piv}}^{k_{R}} k_{piv}^{n_{s}-n_{b}} k^{n_{b}+2} dk \right],$$
(B9)

where $D^2(a) = a_{fct}^4$. Integrating the last equation, we obtain

$$\sigma^{2}(M) = \frac{4\pi D^{2}(a)A_{s}}{k_{0}^{n_{s}}} \left[\frac{k^{n_{s}+3}}{n_{s}+3} \bigg|_{0}^{k_{piv}} + k_{piv}^{n_{s}-n_{b}} \frac{k^{n_{b}+3}}{n_{b}+3} \bigg|_{k_{piv}}^{k_{R}} \right],$$

$$= \frac{4\pi a_{fct}^{4}A_{s}}{k_{0}^{n_{s}}} \left[\frac{k_{piv}^{n_{s}+3}}{n_{s}+3} + k_{piv}^{n_{s}-n_{b}} \left(\frac{k_{R}^{n_{b}+3}}{n_{b}+3} - \frac{k_{piv}^{n_{b}+3}}{n_{b}+3} \right) \right],$$

$$= \frac{4\pi a_{fct}^{4}A_{s}}{k_{0}^{n_{s}}} k_{piv}^{n_{s}-n_{b}} \left[\frac{(n_{b}-n_{s})k_{piv}^{n_{b}+3} + (n_{s}+3)k_{R}^{n_{b}+3}}{(n_{s}+3)(n_{b}+3)} \right]. (B10)$$

We substitute k_R as given by Eq. (29), then Eq. (B10) results in

$$\sigma^{2}(M) = A_{piv} f_{m}^{\frac{n_{b}+3}{3}} \left(S_{1} f_{m}^{-\alpha} + S_{2} M^{-\frac{(n_{b}+3)}{3}} \right), \quad (B11)$$

where we included the definitions of A_{piv} , S_1 and S_2 given by Eqs. (34) and (35), respectively. Furthermore, $\nu(M)$ (Eq. 5) in this scenario reads as

$$\nu(M) = \frac{\delta_c}{\left[A_{piv} f_m^{\frac{n_b+3}{3}} \left(S_1 f_m^{-\alpha} + S_2 M^{-\frac{(n_b+3)}{3}}\right)\right]^{1/2}}.$$
 (B12)

By defining a characteristic mass M_* as the mass which satisfies $\nu(M_*) = 1$, we have

$$1 = \frac{\delta_c}{\left[A_{piv} f_m^{\frac{n_b+3}{3}} \left(S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}}\right)\right]^{1/2}}, \quad (B13)$$

where M_* is then computed as

$$M_* \equiv \left(\frac{\delta_c^2}{A_{piv} f_m^{\frac{n_b+3}{3}}} S_2 - \frac{S_1 f_m^{-\alpha}}{S_2}\right)^{-\frac{3}{n_b+3}}, \quad (B14)$$

and δ_c is given by

$$\delta_c = \left[A_{piv} f_m^{\frac{n_b+3}{3}} \left(S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}} \right) \right]^{1/2}.$$
 (B15)

With the definitions in Eqs. (B14) and (B15) we rewrite (B12) as

$$\nu(M) = \left(\frac{S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}}}{S_1 f_m^{-\alpha} + S_2 M^{-\frac{(n_b+3)}{3}}}\right)^{1/2},$$
 (B16)

and its derivative with respect to M, results in

$$\frac{d\nu}{dM} = \frac{S_2(n_b+3)}{6M^{\frac{(n_b+6)}{3}}} \frac{\left(S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}}\right)^{1/2}}{\left(S_1 f_m^{-\alpha} + S_2 M^{-\frac{(n_b+3)}{3}}\right)^{3/2}}.$$
 (B17)

MNRAS 000, 1-25 (2015)

Replacing Eqs. (B16) and (B17) in Eqs. (6) and (4), we obtain the PBH mass function for this scenario

$$\left(\frac{dn}{dM}\right)_{\text{fct}}^{\text{brk}} = \frac{(n_b+3)S_2}{3M^{\frac{(n_b+9)}{3}}} \frac{\rho_{DM(a)}}{\sqrt{2\pi}} \frac{\left(S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}}\right)^{1/2}}{\left(S_1 f_m^{-\alpha} + S_2 M^{-\frac{(n_b+3)}{3}}\right)^{3/2}} \\ \times \exp\left[-\frac{1}{2} \frac{S_1 f_m^{-\alpha} + S_2 M_*^{-\frac{(n_b+3)}{3}}}{S_1 f_m^{-\alpha} + S_2 M^{-\frac{(n_b+3)}{3}}}\right].$$
(B18)

B2 Horizon crossing

B2.1 Standard Power Spectrum

In this scenario, $\sigma(k)$ is given by Eq. (B1), were $D^2(a) = a_{hc}^4$ and a_{hc} is given by Eq. (41). Replacing k_R by the definition given in Eq. (42), we have

$$\sigma^{2}(M) = \frac{4\pi A_{s}}{k_{0}^{n_{s}}} \left(\frac{2GH_{0}\sqrt{\Omega_{r,0}}}{c^{3}}\right)^{2} \frac{C_{hc}^{n_{s}+3}}{n_{s}+3} \left(\frac{f_{m}}{M}\right)^{\frac{n_{s}-1}{2}}$$
$$= \frac{4\pi A_{s}}{k_{0}^{n_{s}}} \left(\frac{G}{\pi c^{2}}\right)^{4} \frac{C_{hc}^{n_{s}+7}}{n_{s}+3} \left(\frac{f_{m}}{M}\right)^{\frac{n_{s}-1}{2}}.(B19)$$

With Eq. (B19), $\nu(M)$ is expressed as

$$\nu(M) = \delta_c \left(\frac{k_0^{n_s} (n_s + 3)}{4\pi A_s C_{hc}^{n_s + 7}}\right)^{1/2} \left(\frac{\pi c^2}{G}\right)^2 \left(\frac{M}{f_m}\right)^{\frac{n_s - 1}{4}},$$
(B20)

where M_* is obtained by defining $\nu(M_*) = 1$ and solving for M_* . This results in

$$1 = \delta_c \left(\frac{k_0^{n_s}(n_s+3)}{4\pi A_s C_{hc}^{n_s+7}}\right)^{1/2} \left(\frac{\pi c^2}{G}\right)^2 \left(\frac{M_*}{f_m}\right)^{\frac{n_s-1}{4}}, \quad (B21)$$

then

$$M_* = \frac{f_m}{\delta_c^{\frac{4}{n_s - 1}}} \left[\sqrt{\frac{4\pi \left(A_s/k_0^{n_s}\right)}{n_s + 3}} \left(\frac{G}{\pi c^2}\right)^2 C_{hc}^{\frac{n_s + 7}{2}} \right]^{\frac{4}{n_s - 1}}.$$
(B22)

We can solve δ_c as a function of M_* from Eq. (B22) as

$$\delta_c = \left(\frac{4\pi A_s C_{hc}^{n_s+7}}{k_0^{n_s} (n_s+3)}\right)^{1/2} \left(\frac{G}{\pi c^2}\right)^2 \left(\frac{M_*}{f_m}\right)^{\frac{1-n_s}{4}}, \quad (B23)$$

and replacing this result in Eq. (B20) we can rewrite $\nu(M)$ as

$$\nu(M) = \left(\frac{M}{M*}\right)^{\frac{n_s-1}{4}}.$$
 (B24)

Then, the derivative of $\nu(M)$ with respect to M is given by

$$\frac{d\nu}{dM} = \frac{n_s - 1}{4} \frac{1}{M_*} \left(\frac{M}{M_*}\right)^{\frac{n_s - 5}{4}}.$$
 (B25)

By replacing these results in Eqs. (6) and (4) we obtain

$$\left(\frac{dn}{dM}\right)_{\rm hc}^{\rm std} = \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \frac{(n_s - 1)}{2M^2} \left(\frac{M_*}{M}\right)^{\frac{1 - n_s}{4}} \times \exp\left(-\frac{1}{2}\left(\frac{M_*}{M}\right)^{\frac{1 - n_s}{2}}\right). \quad (B26)$$

B2.2 Broken Power Spectrum

Here, $\sigma(k)$ is given by Eq. (B10). We follow the same procedure as before, obtaining

$$\sigma_{hc}^{2}(M) = A_{piv}^{'} f_{m}^{\frac{n_{b}-1}{2}} \left[S_{1}^{'} f_{m}^{-\alpha'} M^{2} + S_{2}^{'} M^{\frac{(1-n_{b})}{2}} \right], \quad (B27)$$

where we used $A_{piv}^{'},\,S_{1}^{'}$ and $S_{2}^{'}$ given by Eqs. (47) and (48) respectively. $\nu(M)$ is then given by

$$\nu(M) = \frac{\delta_c}{\sqrt{A'_{piv} f_m^{\frac{n_b-1}{2}}} \left[S'_1 f_m^{-\alpha'} M^2 + S'_2 M^{\frac{(1-n_b)}{2}}\right]^{1/2}}.$$
(B28)

With this, we define M_* (satisfying $\nu(M_*) = 1$) trough

$$\delta_{c}^{2} = A_{piv}^{'} f_{m}^{\frac{n_{b}-1}{2}} \left[S_{1}^{'} f_{m}^{-\alpha'} M_{*}^{2} + S_{2}^{'} M_{*}^{\frac{(1-n_{b})}{2}} \right], \quad (B29)$$

which must be solved numerically. Then, we write Eq. (B28) in terms of M_* as

$$\nu(M) = \left(\frac{S_1' f_m^{-\alpha'} M_*^2 + S_2' M_*^{\frac{(1-n_b)}{2}}}{S_1' f_m^{-\alpha'} M^2 + S_2' M^{\frac{(1-n_b)}{2}}}\right)^{1/2}, \qquad (B30)$$

and its derivative with respect to ${\cal M}$ reads

$$\frac{d\nu}{dM} = \frac{\left[\left(\frac{n_b-1}{2}\right)S'_2 M^{\frac{1-n_b}{2}} - 2S'_1 f_m^{-\alpha'} M\right]}{2} \\ \times \frac{\left(S'_1 f_m^{-\alpha'} M_*^2 + S'_2 M^{\frac{(1-n_b)}{2}}\right)^{1/2}}{\left(S'_1 f_m^{-\alpha'} M^2 + S'_2 M^{\frac{(1-n_b)}{2}}\right)^{3/2}}.$$
 (B31)

Using these results, we obtain

$$\left(\frac{dn}{dM}\right)_{\rm hc}^{\rm brk} = \frac{\rho_{DM}(a)}{\sqrt{2\pi}} \frac{\left[\left(\frac{n_b-1}{2}\right)S_2'M^{\frac{1-n_b}{2}} - 2S_1'f_m^{-\alpha'}M\right]}{2} \\ \times \frac{\left(S_1'f_m^{-\alpha'}M_*^2 + S_2'M_*^{\frac{(1-n_b)}{2}}\right)^{1/2}}{\left(S_1'f_m^{-\alpha'}M^2 + S_2'M^{\frac{(1-n_b)}{2}}\right)^{3/2}} \\ \times \exp\left[-\frac{1}{2}\frac{\left(S_1'f_m^{-\alpha'}M_*^2 + S_2'M_*^{\frac{(1-n_b)}{2}}\right)}{\left(S_1'f_m^{-\alpha'}M^2 + S_2'M_*^{\frac{(1-n_b)}{2}}\right)}\right] (B32)$$

This paper has been typeset from a $T_{\ensuremath{\underline{E}}} X/I\ensuremath{\underline{A}} T_{\ensuremath{\underline{E}}} X$ file prepared by the author.
