We study the far-from-equilibrium dynamical regimes of a many-body spin boson model with disordered couplings relevant for cavity QED and trapped ions experiments, using the discrete truncated Wigner approximation (DTWA). We focus on the dynamics of spin observables upon varying the disorder strength and the frequency of the photons, finding that the latter can considerably alter the structure of the system's dynamical responses. When the photons evolve at a similar rate as the spins, they can induce qualitatively distinct frustrated dynamics characterized by either logarithmic or algebraically slow relaxation. The latter illustrates resilience of glassy-like dynamics in the presence of active photonic degrees of freedom, suggesting that disordered quantum many body systems with resonant photons or phonons can display a rich diagram of non-equilibrium responses, with near future applications for quantum information science.

Introduction — When coupled to a reservoir, a quantum system can undergo drastic modifications both of its static and dynamical features: both local [1, 2] and global dissipation [3–8] can drastically morph the nature of quantum critical points, while non-ergodic systems can enter a regime of facilitated relaxation by coupling to a bath. Noticeable mechanisms include frustration relief by phonons in solids [9], melting of MBL insulators coupled to a bath [10–12], damping of non-equilibrium superconductivity [13–16] or of pumped magnons [17–19].

For a technological perspective, the dissipative and decohering effects of a bath are usually detrimental and pose an obstacle in developing quantum mechanical devices [20, 21]. On the other hand, in the field of quantum simulation, a phononic or photonic bath can become a resource and a medium to engineer effective interactions [22]. Examples include tunable long-rang interacting spin chains [23, 24], unidirectional photonics [25], exotic tree-like interactions [26], topological spin models [27, 28] and frustrated magnets [29–33], among the others. This success in interaction engineering is due to the ability to operate in a limit in which the bath responds faster than the system, and it becomes a conduit for the transfer of many-body excitations. Nevertheless, modern platforms ranging from trapped ions simulators [21, 23, 24, 34-36] to cavity QED [37-47] and superconducting quantum circuits [48, 49] can operate in regimes where the excitations of the quantum environment (phonons or cavity photons) can resonate with the constituents of the system. This opens the possibility for observing and simulating new physics when bath and system degrees of freedom can strongly couple and hybridize [50-53].

In this work we focus on the quenched dynamics of a many-body spin-boson quantum simulator with disordered couplings of variance σ . The model has recently attracted considerable interest as a paradigmatic instance of spin glasses [31, 33, 54, 55] and of quantum associative memories [30–32, 56–59]. In

these works the bosons are treated in a regime where they respond much faster than the spins, and mediate long-range interactions frustrated by disorder: dynamics can show both exponential fast relaxation similar to a paramagnet [60, 61] and logarithmically slow dynamics akin to glassy systems [60, 62–67]. Here, we further investigate how these dynamics are affected when the frequency of the photons (or phonons in a trapped ion implementation) is reduced and they can actively participate in spin relaxation. We find that the now dynamically active photons retain frustrated

FIG. 1. Qualitative portrait of the dynamical responses at large $\alpha = N_b/N_s$ and for an initial state with spins polarized in the \hat{x} direction. The axes give the photons frequency ωh^{-1} and disorder strength $\sigma h^{-1/2}$, and with scales set by the transverse field h. At $\sigma h^{-1/2} > 1$ and for large ωh^{-1} the spin magnetization experiences logarithmic relaxation due to the fast photons mediating a long-range frustrated interaction. Upon reducing ω/h , photons become active and the slow relaxation of the spins follows an algebraic decay. Large values of σ 'freeze' the dynamics of spins and their relaxation becomes critically slow for our simulations. For weak disorder we observe dynamical paramagnetism and a photon-assisted relaxation mechanism: the asymptotic transverse magnetization crosses over from a vanishing to a finite value upon reducing ω/h .

features but of a qualitatively different nature signaled by algebraic relaxation in spin observables. This suggests that glassy-like dynamics can be robust to finite frequency bosons in disordered trapped ions or cavity QED many-body simulators. Furthermore, by controlling a frustration parameter (the ratio between the number of spins and photonic modes) we are able to relax both types of slow dynamics as illustrated in Fig. 3.

The model — We consider N_b bosonic modes with annihilation operators a_{λ} and N_s two level atoms with with an energy splitting tunable by a transverse field h; the latter are described by spin-half operators $\sigma_i^{x,y,z}$ with $i = 1, 2, ..., N_s$. We study their evolution under the hamiltonian [31–33]

$$H = \sum_{j,\lambda} g_{j\lambda} \sigma_j^x (a_\lambda + a_\lambda^{\dagger}) + h \sum_j \sigma_j^z + \sum_{\lambda} \omega_\lambda a_\lambda^{\dagger} a_\lambda \tag{1}$$

where we take $\omega_{\lambda} = \omega$ for all the bosons, and work in units of $\hbar = 1$. We choose couplings $g_{j\lambda}$ from a random gaussian distribution with zero mean $\langle g_{jk} \rangle = 0$ and variance

$$\langle g_{kl}g_{k'l'}\rangle - \langle g_{kl}\rangle \langle g_{k'l'}\rangle = \delta_{k,k'}\delta_{l,l'}\frac{\sigma^2\omega}{2N_t}$$
 (2)

where the scaling by $N_t = N_s + N_b$ ensures the extensivity of the hamiltonian, σ^2 has units of frequency and the choice $\langle g_{jk} \rangle = 0$ ensures that the bosons do not superradiate [33]. This hamiltonian is relevant to trapped ions and cavity QED experiments [29]; here we will focus on the latter where the bosonic modes are cavity photons. In these experiments, the couplings $g_{j\lambda}$ are proportional to the amplitude of the photon (boson) mode λ at the location of the j^{th} atom (spin), with the latter pinned at a given location in space [43, 68].

In the limit of large photons' frequency $\omega \gg h$, σ^2 the photons can be adiabatically eliminated [31, 33], and the hamiltonian (1) reduces to the following random transverse field Ising model

$$H_a = -\sum_{jk\lambda} \frac{g_{j\lambda}g_{k\lambda}}{\omega_{\lambda}} \sigma_j^x \sigma_k^x + h \sum_j \sigma_j^z.$$
 (3)

For $\omega_{\lambda} = \omega$, Eq. (3) has been studied as a quantum version [31, 69] of the Hopfield model and shows both thermal and quantum spin glass phase transitions [69–72]. For a sufficiently large ratio of bosonic modes to spins, $\alpha = N_b/N_s$, the spin glass undergoes a quantum phase transition to a paramagnetic phase at a critical disorder strength $\sigma_c^2/h \approx 1$ [33, 69]. On the other hand, when the system is in the classical limit $(h/\sigma^2 \ll 1)$, α acts as a frustration parameter, interpolating between a mostly separable interaction with ferromagnetic like ground states at small α [71], to a model with a spin glass ground state at large α [31, 33, 73]. Both α and h/σ^2 are controllable in multi-mode cavity QED experiments [32],

and in the following we use both as tunable knobs to cross over different dynamical regimes.

Distinctly from the previous body of literature [30, 33, 54, 55, 57–59, 74–76], we consider real-time dynamics in regimes where it is not possible to separate the energy scales in Eq. (1). Spins are initialized in a completely polarized state along the \hat{x} -direction, and photons are initialized in their vacuum state. Such a state can be achieved in cavity QED experiments by optically pumping the spins into an eigenstate of σ^z , followed by a $\pi/2$ pulse. Our choice is motivated by interest in slow frustrated relaxation dynamics occurring after a quench in a strong field cooled spin glass [62].

Methods — Since we study quench dynamics for any ω and h, we can not immediately work in the perturbative limit of Refs. [30, 32, 57-59, 74-76], or in the large N semi-classical limit of Refs. [33, 54, 55]. Instead, we employ a Discrete Truncated Wigner Approximation (DTWA) [77–84]. DTWA generalizes the Truncated Wigner Approximation (TWA) [85] to spin-half systems, by using the Wooters discrete Wigner function [86] to represent the quantum state. For initial product states, the discrete Wigner function is positive and it can be therefore efficiently sampled. In this work, we also perform the TWA sampling procedure of the photonic Wigner function as outlined in Ref. [78]. Each sample is then evolved according to the classical equations of motion of the spin-half hamiltonian, and time dependent observables are captured by averaging the observables over different samples. The accuracy of TWA and DTWA depends on the relevance of quantum jumps that occur at the next level in the approximation [85]. For long range models, such as the cavity QED problem studied here, DTWA is accurate at long times [77, 83], and it can capture dynamical phase transitions [87, 88], thermalization [89] and quantum glass dynamics [90]

Time scales — The non-equilibrium dynamics of our model can be understood from the interplay of two time scales: the time scale t_h at which spin flips in the σ^x basis, generated by the transverse field h, contribute non-perturbatively to the quantum evolution, and the time scale t_{ω} that signals when photons start to participate in the spin dynamics. In the following we briefly sketch their estimate, referring to the Supplemental Material (SM) for further details.

For the evaluation of t_h , we first observe that in the limit $\sigma^2/h \to \infty$, σ_i^x becomes a conserved quantity and spins remain frozen with expectation value $\langle \sigma_i^x \rangle = 1$, for $i = 1, 2, ..., N_s$. Applying, then, perturbation theory in small h, we find the time at which the transverse field starts to generate spin flips

$$t_h \simeq \frac{\sigma^2}{2h^2} \frac{\sqrt{\alpha + \alpha^2}}{1 + \alpha} \simeq_{(\alpha \gg 1)} \frac{\sigma^2}{2h^2}.$$
 (4)

After t_h , multiple spin flips affect dynamics, and we capture these processes with DTWA.

FIG. 2. Left panel: Effect of photon frequency on frustrated dynamics. System's parameters are $\alpha=10$, $N_t=1000$, and $\sigma/\sqrt{h}=2$; ω/h varies from 3.6 (dashed, bright green) to 10 (solid, dark blue), deep in the regime of validity of adiabatic elimination. Logarithmic relaxation is marked by black lines for intermediate values of photon frequencies; for $\omega/h>7.5$ relaxation is slower. Here dynamics are beyond the validity of the perturbative regime which holds up to $t\lesssim t_h\approx 2/h$. At a second timescale t_ω (marked by black crosses) logarithmic relaxation crosses over into a qualitatively different dynamical regime. Central panel: Dynamics beyond adiabatic elimination. The figure shows power law relaxation for $\omega/h=1$, $\alpha=10$, $N_t=1000$, and σ/\sqrt{h} varying from 2.1 (dashed, bright green) to 5 (solid, dark blue). The power law relaxation $t^{-\gamma}$ (with $\gamma\approx0.75$) starts after t_h when perturbation theory breaks down (marked by the black dots); for the parameters considered in this panel, t_ω occurs before t_h . Right panel: Photon assisted relaxation in the dynamical paramagnet. Dynamics of σ^z after a quench into the paramagnetic phase for $\alpha=10$, $\sigma/\sqrt{h}=0.7$ and with ω/h shown in the legend.

The second time scale t_{ω} is estimated by considering the first correction to the photon dynamics in adiabatic elimination

$$a_{\lambda}(t) = -\frac{1}{\omega} \sum_{j} g_{j\lambda} \sigma_{j}^{x}(t) - \frac{i}{\omega^{2}} \sum_{j} g_{j\lambda} \partial_{t} \sigma_{j}^{x}(t) + \dots (5)$$

Substituting Eq. (5) into the coupling term of Eq. (1), the leading order correction to the adiabatic eliminated hamiltonian reads

$$\delta H_a = -\frac{1}{\omega^2} \sum_{\lambda} g_{k\lambda} g_{j\lambda} \sigma_k^x(t) \operatorname{Re}\{(i\partial_t \sigma_j^x(t))\}.$$
 (6)

Considering the latter as a perturbation, one can estimate via elementary arguments (see SM for details) the time at which corrections to adiabatic elimination become significant:

$$t_{\omega} = t_s \frac{\omega^2 t_s}{h^2 t_h}. (7)$$

In the equation above t_s is the rate of change of $\langle \sigma^x(t) \rangle$, which can be bound from below by 1/h and from above by t_h . For the lower bound, we estimate that $\langle \sigma^x(t) \rangle$ evolves fastest when the effective field produced by the photons is zero, and the spin precesses around σ^z . While for the upper bound, we estimate that the slowest $\langle \sigma^x(t) \rangle$ can evolve (while remaining partially polarized) is determined by the perturbation theory estimate in Eq. (4). From such bounds, we infer $\omega^2/(\sigma^2h^2) \lesssim t_\omega \lesssim \omega^2\sigma^2/h^4$. When $\sigma^2/h \sim 1$, the bounds on t_ω approach each other and we find $t_\omega \sim \omega^2/h^3$. When $\omega^2/h \gtrsim \sigma^2$ we have the timescales' separation

When $\omega^2/h \gtrsim \sigma^2$ we have the timescales' separation $t_{\omega} \gtrsim t_h$: in general, t_{ω} increases with the photons' frequency since it signals dynamical breakdown of the adiabatic elimination regime. Upon tuning ω we can

tune the ratio between t_h and t_ω and in the following we extract results in both regimes.

Dynamical responses — The quench dynamics of (1) organize into a rich set of responses comprising logarithmic, algebraic and exponential relaxation of spin observables, upon varying the disorder strength and the frequency of the photon, as summarized in Fig. 1. The model (3) undergoes a quantum phase transition from a paramagnet to a glass [31, 33]. Therefore, we start looking for signatures of dynamical paramagnetism [60, 91] and glassy dynamics which is typically characterized by slow sub-exponential relaxation [60, 62–67].

In the first panel of Fig. 2 we show that in the adiabatic limit $(\omega \gg h)$ the relaxation of $\sigma^x(t)$ has logarithmic character. In the same figure we illustrate that such logarithmic dynamics yields into another form of slow sub-exponential relaxation after t_{ω} . When $t \gtrsim t_{\omega}$ the role of photons cannot be neglected and the effective model in (3) ceases to describe the dynamics of the many-body spin-boson hamiltonian (1).

In the second panel of Fig. 2 we present dynamics in the non-adiabatic limit where $\omega \approx h$. Despite the inability of the photons to mediate a static disordered interaction for the atoms as in the large ω regime (cf. with the hamiltonian (3)), a form of sub-exponential relaxation, reminiscent of the glass phase, persists after t_h where perturbative dynamics do not hold anymore. In this parameter regime we have $t_\omega \lesssim t_h$ and therefore we do not observe any dynamical crossover. The now active photons are able to partially relieve frustration of the model and accelerate relaxation from a $\ln(ht)$ to a power law behavior $\sim t^{-\gamma}$ with $\gamma \simeq -0.75$ (see central panel of Fig. 2). Since the magnetization does not relax in a ex-

FIG. 3. Left panel: diagram of dynamical responses as a function of α and ω^{-1} for $\sigma > \sigma_c$. The critical value of α in general depends on σ , the value $\alpha_c \approx 0.37$ shown is for $\sigma/\sqrt{h} = 5$. Central panel: transition to exponential relaxation at $\alpha \lesssim 0.37$ (for $\sigma/\sqrt{h} = 5$ and $\omega/h = 1$). Right panel: transition from sub-exponential to exponential relaxation for $\alpha \lesssim \alpha_c \approx 3$ (here $\sigma/\sqrt{h} = 2$ and $\omega/h = 10$). System's parameters in all plots are $N_t = 640$; straight black lines mark the regimes of exponential relaxation in the central and right panels (the sampling error in σ^x is around $\approx 10^{-2}$, and we therefore do not display dynamics when σ^x is below such threshold). In the SM we plot both figures in log-log scale.

ponential fashion as it occurs in the paramagnetic phase, this algebraic relaxation reveals a dynamical frustration present when photons actively participate in dynamics and constitutes one of the central results of our work. In both regimes of strong spin-boson coupling addressed in the left and central panels of Fig. 2, the decaying magnetization and dynamics of photons lock at a common frequency $\propto \omega$.

We now discuss the regime of dynamical paramagnetism. For very small disorder ($\sigma^2/h \ll 1$), the transverse field dominates spin dynamics, and spins simply precess around the \hat{z} -direction until disorder-induced dephasing relaxes them. At moderate disorder strength, but still below the spin glass transition $\sigma_c^2 \approx h$, inhomogeneous dephasing plays a significant role, and magnetization swiftly finds a steady state (on timescales $\propto 1/\omega$), as shown in right panel of Fig. 2. In the adiabatic limit $\omega \gg h$, such steady state is completely depolarized similar to other transverse field Ising models, where quenches from states completely polarized in the σ^x direction result in a compete loss of magnetization [60, 91, 92]. At smaller ω the photons exchange energy effectively with the spins and this results in the latter relaxing towards a steady-state with finite σ^z similar to a low temperature quench into a paramagnetic phase [60, 91–93]. The relaxation to a finite σ^z , as ω/h decreasing, occurs as a crossover and it is shown in the right panel of Fig. 2. This can be captured by assuming the steady state is described by a thermal state with $H=h\sum_j\sigma_j^z+\omega\sum_\lambda a_\lambda^\dagger a_\lambda$, and with an effective temperature set by the requirement that the energy of the thermal ensemble should match the energy of the initial state. This results in an effective temperature that decreases linearly with ω/h and a thermal spin polarization σ^z consistent with the simulation results shown in the right panel of Fig 2 (See SM for details)

Tuning the ratio of spins and bosonic modes — So far we have discussed the dynamics at large values of α . In

the ground state of the classical Hopfield model (Eq. (3) with h=0) reducing α relieves frustration [70]. Similarly, we observe here a crossover from sub-exponential relaxation to an exponential relaxation by reducing α below some α_c . This is shown in Fig. 3, where we have included a quench at large disorder and small photon frequency, and we show a crossover to exponential relaxation around $\alpha=0.37$ (central panel).

We can obtain an approximate estimate for the crossover α_c as follows. If the system shows exponential relaxation, we can assume glassy dynamic are not preventing thermalization, and the steady state will be described by a Gibbs ensemble [62, 94]. In the limit of small h/σ^2 , and assuming that the photons are not condensed, the statistical Gibbs weight is associated to a classical Hopfield model coupled to N_b non-interacting photons (see SM for details). The classical Hopfield model has a phase transition between a paramagnetic phase above a temperature $T_c = \sigma^2 N_s (1 + \sqrt{\alpha})/2N_t$ and a variety of spin-glass states below T_c with the spins freezing in random directions [71]. Thus, we expect that if the effective temperature of the final state is above T_c , we will see paramagnetic relaxation, while below T_c , we might still observe glass like relaxation. To compute the effective temperature of the initial state, we compare the energy of the thermal states, U(T) and the energy of the initial state E, and solve for the temperature $T = U^{-1}(E)$. For the initial state discussed above (fully polarized along the \hat{x} -direction), we find a temperature $T = \sigma^2 N_s (1 + \sqrt{3})/4N_t$, and therefore we expect a crossover from paramagnet like relaxation to subexponential relaxation around $\alpha_c \approx (\sqrt{3} - 1)/2 \simeq 0.366$.

This is confirmed in the central panel of Fig. 3, where we find that above $\alpha \gtrsim 0.37$, relaxation dynamics turn from exponential to sub-exponential. For finite values of h/σ^2 , quantum fluctuations correct the estimate given above and reduce the critical temperature [69, 95, 96], with a resulting increased α_c . An instance of this effect

is illustrated in the right panel of Fig. 3 (see SM for the characterization of the sub-exponential relaxation in both regimes).

Following analogous arguments, we anticipate that sub-exponential relaxation will become exponential by increasing the energy of the initial state. To confirm such an expectation, we perform a composite quench starting from a fully polarized initial state along the \hat{x} -direction, and displacing at the same time all the photons by a uniform amplitude shift $\langle a(t=0)\rangle = 2N_s/\sqrt{N_t\omega/h}$. In the SM we show that, in this case, all relaxation dynamics turn into exponential $\propto \exp(-t/\tau)$ when the energy of the initial state is sufficiently high. The characteristic time τ increases with σ and decreases with ω .

Photon losses — We now briefly comment on the effect of photon losses which is relevant for cavity QED We modify our simulations by adding experiments. Langevin damping and noise terms to the photon dynamics [97–100], and focus our attention to the effect of photon loss on the sub-exponential relaxation. We find (see SM) that the $\ln(ht)$ relaxation in the adiabatic limit remains for moderate loss, while for larger values of loss, relaxation accelerates. This occurs because, in the adiabatic limit, the primary effect of dissipation is to reduce the effective field produced by the photons and effectively move the adiabatic eliminated model towards the paramagnetic regime. For smaller ω , the effect of photon loss also accelerates relaxation as illustrated in the SM.

Perspectives — Our work illustrates that dynamics can display qualitative different features when neither photons [30–33, 54, 55, 57–59, 74–76, 101] nor atoms (as in photonic glasses [102–107]) can be adiabatically eliminated. Future work might consider different inhomogeneous spin-boson couplings enabling investigations of other phenomena such as supersolidity and topological defects [108, 109]. In such a framework, one could also access the fate of associative memory phases [30–33, 56–59] when photons cannot be integrated out. It is currently unclear whether photonic degrees of freedom could enhance memory retrieval or represent a hindrance. Other potential extensions include the interplay of active photons with multi-level atoms [110].

Furthermore, the effects of active photons on scrambling of atoms in cavity QED simulators [111, 112] (or trapped ions [113–115]) remain completely unexplored; this would represent a key future extension relevant for probing the dynamics of quantum information in open quantum systems.

Thermodynamics for in the weak coupling limit

At zeroth order in the weak coupling limit the thermal state is:

$$\rho(\beta) = e^{-\beta(h\sum_{i}^{N_s} \sigma_i^z + \omega \sum_{i}^{N_b} n_i)} / Z \tag{8}$$

where $Z = \text{Tr}[\rho(\beta)]$. The energy per spin of such a state is:

$$E(\beta) = -h \tanh(\frac{\beta h}{2}) + \omega \alpha n(\beta) \tag{9}$$

where $n(\beta) = (e^{\beta\omega} - 1)^{-1}$ is the Bose Einstein distribution function. Since our initial state has energy E = 0, the constraint $E(\beta) = 0$ determines the temperature of the steady state and in turn the steady state polarization:

$$\lim_{t \to \infty} \sigma^z(t) \approx -\tanh(\frac{\beta h}{2}) \tag{10}$$

Since $\tanh(\beta h/2) \in (0,1)$ for positive β , the constraint $E(\beta) = 0$ sets an upper bound on bosonic occupation: $n(\beta) < h/(\omega \alpha)$. Using the Bose Einstein distribution function, this yields a constraint on the temperature:

$$\beta^{-1} < \frac{\omega}{\ln(\omega\alpha/h + 1)} \tag{11}$$

and thus, for large alpha ($\alpha=10$ in our simulations), decreasing ω decreases the temperature and increases the $-\sigma^z$ polarization. A numerical solution of $E(\beta,\omega)=0$ for the effective temperature β^{-1} finds the effective temperature decreases linearly with ω in the window of frequencies considered in the main text. The spin polarization as a function of effective temperature is $\sigma^z=-\tanh(\frac{\beta h}{2})$ and is consistent with the steady state observed in simulations.

Thermodynamics for the Classical Hopfield Model

The partition function for Hamiltonian (1) in the main text becomes classical for h = 0 and for high temperature photons. In this limit, we study the classical partition function with Hamiltonian:

$$H = \sqrt{2} \sum_{j,\lambda} g_{j\lambda} \sigma_j^x x + \sum_{\lambda} \frac{\omega_{\lambda}}{2} (x_{\lambda}^2 + p_{\lambda}^2), \tag{12}$$

 $\sigma^x = \pm 1$, and real classical coordinates $x = \sqrt{2}\Re a$ and $p = \sqrt{2}\Im a$. For the initial state considered in the main text, $\sigma^x = 1$ and x = p = 0, yielding $\langle H \rangle = 0$. To identify an effective temperature $(T = 1/\beta)$ for the steady state, we shift the boson fields and consider the model:

$$H = H_s + H_b =$$

$$= -\sum_{ik\lambda} \frac{g_{j\lambda}g_{k\lambda}}{\omega} \sigma_j^x \sigma_k^x + \frac{\omega}{2} \sum_{\lambda} (x_{\lambda}^2 + p_{\lambda}^2),$$
(13)

where x_{λ} and p_{λ} are the canonically conjugated coordinates of the bath. If we implement the disorder in $g_{j\lambda}$ with binary random variables, the spin part of the hamiltonian becomes the Hopfield model in different units $H_s = sH_h$, where $s = \sigma^2 N_s/2N_t$ and H_h is the Hopfield hamiltonian [71]. In the paramagnetic phase, the Hopfield model has internal energy [71]

$$U(\beta) = \frac{\alpha}{2} \left(1 - \frac{1}{1 - \beta} \right),\tag{14}$$

therefore, our model has internal energy per unit spin

$$U(\beta) = s\frac{\alpha}{2} \left(1 - \frac{1}{1 - s\beta} \right) + \alpha \beta^{-1}. \tag{15}$$

Imposing $U(\beta) = \langle H \rangle = 0$, we find the effective temperature in the main text.

Time Scales

To obtain t_h in the main text, we apply perturbation theory on the bare hamiltonian H, and treat $V_h = h \sum_j \sigma^z$ as the perturbation to the hamiltonian

$$H_0 = \sum_{j,\lambda} g_{j\lambda} \sigma_j^x (a_\lambda + a_\lambda^{\dagger}) + \sum_{\lambda} \omega_\lambda a_\lambda^{\dagger} a_\lambda, \tag{16}$$

which has eigenstates labeled by the eigenvalues of σ_j^x : $\sigma_j^x |\{s_k\}\rangle = s_j |\{s_k\}\rangle$. For each subspace given by the quantum numbers $\{s_j\}$ the photons can be diagonalized by a displacement operator. Therefore the energies for the states labeled by $\{s_j\}$ and photon numbers n_λ are:

$$H_0 = -\sum_{jk\lambda} \frac{g_{j\lambda}g_{k\lambda}}{\omega_{\lambda}} s_j^x s_k^x + \sum_{\lambda} \omega_{\lambda} n_{\lambda}. \tag{17}$$

Since V can only flip one spin we will estimate t_h from the time the perturbation V will take to flip one spin. Focusing on the j^{th} spin, the energy difference after the flip is

$$\Delta E_j = -\sigma^2 \sum_{k\lambda} \frac{\xi_{j\lambda} \xi_{k\lambda}}{2N_t} \sigma_k^x = -\sigma^2 \sum_{k\lambda} \frac{\xi_{j\lambda} \xi_{k\lambda}}{2N_t},\tag{18}$$

where $\xi_{j\lambda}\sqrt{\sigma^2\omega/2N_t}=g_{j\lambda}$ such that $\xi_{j\lambda}$ has variance 1. The average magnitude of ΔE_j is given as:

$$\langle (\Delta E_j)^2 \rangle = \frac{\sigma^4}{4N_t^2} \sum_{kk'\lambda\lambda'} \langle \xi_{j\lambda} \xi_{j\lambda'} \xi_{k\lambda} \xi_{k'\lambda'} \rangle =$$

$$= \frac{\sigma^4}{4N_t^2} (N_b N_s + N_b + N_b^2) \approx \sigma^4 \frac{\alpha + \alpha^2}{4(1+\alpha)^2}.$$
(19)

This gives the energy denominator in perturbation theory, and we estimate:

$$t_h \simeq \frac{\sigma^2}{2h^2} \frac{\sqrt{\alpha + \alpha^2}}{1 + \alpha} \simeq_{(\alpha \gg 1)} \frac{\sigma^2}{2h^2}.$$
 (20)

In the main text, we quoted the perturbation theory estimate t_{ω} . This is obtained by considering

$$V_{\omega} = -\frac{1}{\omega^2} \sum_{\lambda} g_{k\lambda} g_{j\lambda} \sigma_k^x(t) \operatorname{Re}\{(i\partial_t \sigma_j^x(t))\}$$
(21)

as a perturbation to the adiabatic eliminated hamiltonian H_a . The Heisenberg equation of motion gives $i\partial_t \sigma_j^x \sim \sigma^y$, and for any eigenstate of the σ_i^x operators, this perturbation can only flip one spin at a time.

Since the eigenstates of H_a are analytically inaccessible, we focus on the limit when h/σ^2 is small and use

$$H_0' = -\sum_{ik\lambda} \frac{g_{j\lambda}g_{k\lambda}}{\omega_{\lambda}} \sigma_j^x \sigma_k^x \tag{22}$$

to compute the energy denominator. This limit is appropriate for the spin glass region of parameter space when $\sigma^2 > h$. Therefore, we can again use the energy denominator ΔE_j calculated above. To obtain the average magnitude of the perturbation V_{ω} , we consider the action of V_{ω} on the fully polarized state, and estimate $|i\partial_t \sigma_j^x| \approx 1/t_s$. This gives an estimate for the magnitude of the perturbation as:

$$V_{\omega} \approx \sum_{\lambda k} \frac{\sigma^2}{\omega} \frac{1}{t_s} \xi_{j\lambda} \xi_{k\lambda}.$$
 (23)

The average magnitude squared is then:

$$\left\langle V_{\omega}^{2}\right\rangle = 4\frac{\sigma^{4}}{\omega^{2}t_{s}^{2}}\frac{\alpha + \alpha^{2}}{(1+\alpha)^{2}},\tag{24}$$

and perturbation theory then yields:

$$t_{\omega} \approx \frac{\sqrt{\langle (\Delta E)^2 \rangle}}{\langle V_c^2 \rangle} = t_s \frac{\omega^2 t_s}{h^2 t_h},\tag{25}$$

as in the main text.

Photon Losses

To study the effects of photon loss, we add to the photon dynamics Langevin damping and noise [97–100]:

$$\partial_t a_\lambda = i\omega a_\lambda - \kappa a_\lambda + \kappa \xi_\lambda + \sum_j g_{j\lambda} \sigma_\lambda^x,\tag{26}$$

where κ is the single photon loss rate and ξ_i is a unit variance Gaussian white noise process. In Fig. 6, we show that for small κ/h , the $\ln(t)$ relaxation is maintained for large ω . In the same figure, we also show the effect of κ in the limit of small ω . Due to the slow convergence of the Euler-Maruyama algorithm [116–118], we can not access time scales where a power law fit is distinguishable from an exponential or logarithmic fit. We plan to improve numerical convergence at strong loss in forthcoming work.

FIG. 4. Transition from sub-exponential relaxation as a function of α . The left panel shows the same data as for the center panel of Fig. 3, but on a $\ln(\sigma^x)$ - $\ln(th)$ scale. It depicts power-law relaxation for $\alpha > 0.72$. The right panel shows the same data as the right panel of Fig. 3 on a $\ln(th)$ scale. It shows logarithmic-like relaxation for $\alpha > 5$.

FIG. 5. Effect of the initial state energy on slow relaxation. Exponential relaxation when the energy of the initial state is increased by a shift the photon amplitude, $\langle a(0) \rangle = 2N_s/\sqrt{N_t\omega/h}$. Both plots are computed for $\alpha=1$, and $N_t=640$. The left plot is for $\omega/h=10$; for the $\sigma/\sqrt{h}\approx 2$ line, the $\ln(ht)$ relaxation (Fig. 2 of the main text) turns now into an exponential. The plot also shows an example (the $\sigma/\sqrt{h}=6$ line) of the region of Fig. 1 labeled 'Slow spins' for large ω/h and σ/\sqrt{h} . Here the dynamics are too slow to exhibit a distinguishable relaxation behavior. The right plot shows similar exponential relaxation away from the regime of adiabatic elimination of the photons ($\omega/h=1$).

FIG. 6. Sub-exponential relaxation with dissipation. The left plot is computed for $\sigma/\sqrt{h}=2$, $\omega/h=10$, $N_t=150$, $\alpha=10$ and with κ/h shown in the legend. This plot shows that logarithmic relaxation holds for finite κ . The right plot shows faster relaxation upon increasing losses, in the regime where the adiabatic elimination of the photons breaks down; system's parameters $\sigma/\sqrt{h}=3$, $\omega/h=1$, $\alpha=1$, $N_t=150$, with κ/h shown in the legend.
