Interplay of Valence and Semimetal-to-Insulator Transitions in SmS

Shinji Watanabe

Department of Basic Sciences, Kyushu Institute of Technology, Kitakyushu, Fukuoka 804-8550, Japan

Recent discoveries of a new type of quantum criticality arising from Yb-valence fluctuations in Yb-based metal in periodic crystal and quasicrystal have opened a new class of quantum critical phenomena in correlated electron systems. To clarify whether this new concept can be generalized to other rare-earth-based semimetal and insulator, we study SmS which exhibits golden-black phase transition under pressure. By constructing the model for SmS, we show that Coulomb repulsion between 4f and 5d orbitals at Sm drives first-order valence transition (FOVT) and semimetal-toinsulator transition (MIT) simultaneously, which explains the golden-black phase transition. We clarify the ground-state phase diagram for the FOVT and MIT by identifying the quantum critical point of the FOVT. We find that exciton condensates in both semimetal and insulator phases. Our result explains measured peak anomalies in the specific heat and compressibility in pressurized golden SmS and provides a cue to clarify recently-observed anomalies in black SmS.

Quantum critical phenomena not following conventional magnetic criticality have attracted great interest in condensed matter physics. Recent discovery of the quantum critical point (QCP) of valence transition in the Yb-based periodic crys- tal^{1} and quasicrystal²⁾ opens a new class of quantum criticality originating from Yb valence fluctuations.³⁾ So far, the valence QCP has been identified in the metallic Yb-based compounds. Then natural questions arise as: Are there any other systems for realizing the valence QCP? How does the valence transition occur in the semimetal and insulator? To address these questions we focus on SmS as a typical system showing the valence transition and the semimetal-to-insulator transition (MIT).

SmS has an NaCl type crystal structure of face-centered cubic. At ambient pressure, SmS is so-called Kondo insulator referred to as black phase (*b*-SmS). Under pressure above 6.5 kbar SmS undergoes isostructural phase transition from *b*-SmS to the golden phase (*g*-SmS) which is semimetal accompanied by the valence transition as Sm^{v+} from $v =$ 2.0(2) to 2.67(4).⁴⁻⁶⁾ SmS has been studied for the last five decades, $4-24$) but there remain several issues still unresolved. In *g*-SmS, a Schottkey-type anomaly was observed in the electric specific heat, thermal-expansion coefficient, and compressibility at low temperatures where the peak structure becomes prominent as pressure increases.20) It is controversial whether g -SmS has a real gap or a pseudo gap.^{16, 20}) Furthermore, anomalies in thermal conductivity and Seebeck effect have recently been discovered in *b*-SmS at ambient pressure.²⁵⁾

To resolve these issues in *g*-SmS and also to get insight into *b*-SmS, we propose a simple model to describe the goldenblack phase transition in SmS. We clarify the ground state phase diagram for the valence transition and MIT by identifying the valence QCP. We show that exciton condensates in both semimetal and insulator phases and our result explains measured anomalies in *g*-SmS under pressure and also gives a cue to clarify anomalies in *b*-SmS.

In the cubic system, the Sm 4 *f* orbitals for the total angular momentum $J = 5/2$ state are split into the Γ_7 doublet and Γ⁸ quartet while the fivefold degenerate 5*d*-orbitals at Sm are split into double degenerate e_g and triply degenerate t_{2g} orbitals. The band theory^{17–19, 24)} and Mössbauer spectroscopy studies $^{4)}$ on SmS indicate that the physics is governed by valence fluctuations involving electrons of the 4 *f* (Γ ₇ and Γ ₈) states and the conduction t_{2g} states, $e^- + 4f^5(\Gamma_7, \Gamma_8) \rightleftharpoons 4f^6$. The Γ ₇ doublet and Γ ₈ qualtet consist of the following orbitals: $|\Gamma_{7,\pm}\rangle = \sqrt{\frac{1}{6}} |\pm 5/2\rangle - \sqrt{\frac{5}{6}} |\mp 3/2\rangle$ and $|\Gamma_{8,\pm}^{(1)}\rangle$ $\binom{1}{8,\pm}$ = $\sqrt{\frac{5}{6}}$ = 5/2) + $\sqrt{\frac{1}{6}}$ = 3/2), $|\Gamma_{8,\pm}^{(2)}\rangle$ = | ± 1/2), respectively. This leads to the physical picture that the *f* (Γ ₇ and Γ ₈) states hybridize with the $d(t_{2g})$ states [see Fig. 1(a)], which describes the compensated metal with equal number of electrons and holes in *g*-SmS and the Kondo insulator in *b*-SmS.

We now formulate our model for SmS partly following the model for SmB_6 ^{26,27} At each site, the *f* and *d* hole is described by an orbital and spin index, denoted by the combination $\zeta \equiv (a, \tilde{\sigma})$ with $(a = \Gamma_8^{(1)}, \Gamma_8^{(2)}$ $S_8^{(2)}$, Γ_7 , $\tilde{\sigma} = \eta = \pm$) for *f* states and $(a = xy, yz, zx, \tilde{\sigma} = \sigma = \hat{\sigma}, \hat{\phi}$ for *d* states. The fields are given by the twelve component spinor

$$
\Psi_i = \left(\begin{array}{c} d_\zeta(i) \\ X_{0\zeta}(i) \end{array} \right)
$$

where $d_{\zeta}(i)$ destroys a *d* hole at site *i* and $X_{0\zeta}(i)$ = $|4f^6\rangle\langle 4f^5,\zeta|$ is the Hubbard operator that destroys an *f*-hole at site *i*. The tight-binding Hamiltonian for the hybridized *d*-*f* orbitals is

$$
H_0 = \sum_{\langle i,j \rangle} \Psi_i^{\dagger} h(i,j) \Psi_j \tag{1}
$$

where the hopping matrix is given by

$$
h(i, j) = \begin{pmatrix} h^d(i, j) & V(i, j) \\ V(i, j)^\dagger & h^f(i, j) \end{pmatrix}.
$$

Here, the diagonal elements are transfers within $5d(t_{2g})$ and $4f (J = 5/2)$ orbitals and the off diagonal elements are hybridization between them. To reproduce the local-densityapproximation and dynamical mean-field theory (DMFT) band structures, $17, 24$) we take transfers up to the third nearest neighbor (N.N.) Sm sites in $h^d(i, j)$ and up to the second N.N. Sm sites in $h^f(i, j)$ and $V(i, j)$.^{28, 29)}

The Coulomb repulsion between 4f and 5d orbitals is

$$
H_{U_{fd}} = U_{fd} \sum_{i\alpha\beta} X_{\alpha\alpha}(i) n_{i\beta}^d + U'_{fd} \sum_{\langle i,j\rangle} \sum_{\alpha\beta} X_{\alpha\alpha}(i) n_{j\beta}^d, \tag{2}
$$

where $U_{fd}(U'_{fd})$ is onsite (inter site) Coulomb repulsion and $\langle i, j \rangle$ denotes the N.N. Sm sites. Here, $X_{\alpha\alpha}(i)$ = $|4f^5, \alpha\rangle\langle 4f^5, \alpha|$ is the number operator of *f* hole in the $\alpha =$ $\Gamma^{(1)}_{\circ}$ $_8^{(1)}, \Gamma_8^{(2)}$ ⁽²⁾, and Γ_7 state and $n_{i\beta}^d = \sum_{\sigma} n_{i\beta\sigma}^d$ is the number operator of the *d* hole defined by $n_{i\beta\sigma}^d \equiv d_{i\beta\sigma}^{\dagger} d_{i\beta\sigma}$ ($\beta =$ *xy*, *yz*, *zx*, $\sigma = \uparrow$, \downarrow). Since other interactions such as the onsite and inter-site Coulomb repulsions between 5*d* orbitals are regarded to be included in the renormalized t_{2g} bands, they are neglected in this study.

Since the strong Coulomb repulsion affects each *f* orbital we consider the following Hamiltonian in the hole picture within the restriction of prohibiting the doubly-occupied *f* orbitals:

$$
H = H_0 + H_{U_{fd}}.\t\t(3)
$$

To analyze the ground-state and finite-temperature properties of this model, we employ a slave boson formulation of the Hubbard operators, $26, \overline{27}$ writing $X_{\zeta 0}(i) = f_{i\zeta}^{\dagger} b_i$, where f_{ζ}^{\dagger} |0) = $|4f^5, \zeta\rangle$ creates an *f* hole in the Γ₈ quartet and Γ₇ doublet while $b^{\dagger} |0\rangle \equiv |4f^6\rangle$ denotes the singlet filled 4*f* shell, subject to the constraint $Q_i = b_i^{\dagger} b_i + \sum_{\zeta} f_{i\zeta}^{\dagger} f_{i\zeta} = 1$ at each site. We use the mean-field treatment by replacing the slave-boson operator b_i by its expectation value $\bar{b} = \langle b_i \rangle$. The total $f(d)$ hole number is given by $\bar{n}_f = \sum_{\alpha \eta} \langle n_i^f \rangle$ $\langle \bar{n}_d \rangle$ ($\bar{n}_d = \sum_{\beta} \langle n_{i\beta}^d \rangle$) with *n f* $f_{i\alpha\eta} \equiv f_{i\alpha\eta}^{\dagger} f_{i\alpha\eta}$ where $\eta = \pm$ denote the Kramers states.

For $H_{U_{fd}}$, we apply the mean-field approximation. The first term in Eq. (2) i.e. on site term is approximated as $U_{fd} \sum_{i\alpha\beta} [\langle X_{\alpha\alpha}(i) \rangle n_{i\beta}^d + X_{\alpha\alpha}(i) \langle n_{i\beta}^d \rangle]$. The second term in Eq. (2) is approximated as $U'_{fd} \sum_{\langle i,j \rangle \alpha \beta} [\langle X_{\alpha \alpha}(i) \rangle n_{j\beta}^d + X_{\alpha \alpha}(i) \langle n_{j\beta}^d \rangle]$ – $U'_{fd} \sum_{\langle i,j \rangle \alpha \eta \beta \sigma} [\langle X_{\alpha \eta 0}(i) d_{j\beta \sigma} \rangle d_{j\beta \sigma}^{\dagger} X_{0\alpha \eta}(i) +$ $X_{\alpha\eta}$ 0(*i*) $d_{j\beta\sigma}$ $\langle d_{j\beta\sigma}^{\dagger} X_{0\alpha\eta}(i)\rangle$].

A possibility of the formation of the exciton, which is a bound state of an electron and a hole, in semimetal and semiconductor has been discussed theoretically.^{8, 9, 12–15, 30–34)} The exciton formation by $H_{U_{fd}}$ in semimetal is intuitively understandable if we apply the hole-to-electron transformation to the *d* orbital in Eq. (3), which makes the sign change of U_{fd} and U'_{fd} in Eq. (2). Namely, the attractive force between an electron and a hole in semimetal gives rise to the exciton formation. This has indeed been confirmed by the microscopic theoretical calculation in the impurity model with the U_{fd} term.³²⁾ In SmS, the bound state of an electron and a hole is expected to be formed in the vicinity of $\text{Sm}^{15, 20, 22, 31)}$ [see Fig. 1(b)]. Hence we consider the exciton condensation characterized by the order parameter $\Delta_{\alpha\eta,\beta\sigma}(i, j) \equiv U'_{fd} \langle d_{j\beta\sigma}^{\dagger} X_{0\alpha\eta}(i) \rangle$. We consider the uniform condensation

$$
\Delta_{\alpha\eta,\beta\sigma}(\xi) = \frac{U'_{fd}}{N} \sum_{k} e^{ik \cdot r_{\xi}} \langle d_{k\beta\sigma}^{\dagger} f_{k\alpha\eta} \rangle \bar{b}
$$
(4)

with $r_{\xi} \equiv r_j - r_i$. The exciton formation by $\alpha \eta = \Gamma_{8+(-)}^{(1)}$ hole and $\beta \sigma = xy \downarrow(\uparrow)$ electron at the N.N. Sm sites is considered to be most probable since these orbitals give the largest hybridization between the N.N. Sm sites so that U'_{fd} is most effective [see Fig. 1(a)]. It is noted that some symmetry break-

Fig. 1. (color online) (a) $\Gamma_8^{(1)}$ and d_{xy} orbitals. (b) Schematic picture of exciton bound-state formation. Electric band structures E_e for (c) $\varepsilon_f = -31.0$ and (d) ε_f = −27.0 at U_{fd} = 3.60. Slater-Koster parameters are set as $(dd\sigma) = 1, (dd\pi) = -0.3, (dd\delta) = -0.2, (ff\sigma) = -0.8, (ff\pi) = 0.6,$ $(f f \delta) = -0.4$, $(f f h) = 0$, $(df \sigma) = 0.9$, $(df \pi) = -0.4$, and $(df \delta) = 0.3$. The ratio of 2nd (3rd) N.N. to N.N. transfers is set to be −0.2 (1.0) for *dd* transfers, 0.8 for ff transfers and 0.125 for df hybridizations. In (c), ε_F denotes the Fermi level.

ing can occur by exciton condensation. 34 However, so far any change of the crystal symmetry from the space group $Fm\overline{3}m$ (No. 225) has not been reported on cooling in SmS. Hence, as a first step of analysis, we analyze the effect of the isotropic condensation as $\Delta = \Delta_{\Gamma_8^{(1)}, +, xy \downarrow}(\xi) = \Delta_{\Gamma_8^{(1)}, -, xy \uparrow}^*(\xi)$ for the N.N. Sm sites $r_{\xi=1 \sim 12}$ ∈ (±*a*/2, ±*a*/2, 0), (0, ±*a*/2, ±*a*/2), $(\pm a/2, 0, \pm a/2)$ [see Fig. 1(b)]. Since this state does not break symmetry of the Hamiltonian, Δ is not the order parameter in strict sense. Hence, we refer to ∆ as exciton condensation (EC) parameter hereafter.

We solve the mean-field equations at half filling $\bar{n} = \bar{n}_f + \bar{n}_f$ \bar{n}_d = 6 for \bar{b} , Lagrange multiplayer λ to require the constraint $\langle Q_i \rangle = 1$, \bar{n}_d , Re Δ , Im Δ , and the chemical potential μ selfconsistently. As typical values, we set $U'_{fd} = U_{fd}/10$ and the energy difference between Γ_8 qualtet and Γ_7 doublet $\Delta \varepsilon_f$ = 0.04 with $\varepsilon_{\Gamma_7} \equiv \varepsilon_f + \Delta \varepsilon_f$ where *f* level is defined by the energy of the Γ_8 qualtet as $\varepsilon_f \equiv \varepsilon_{\Gamma_8^{(1)}} = \varepsilon_{\Gamma_8^{(2)}}$. Here the energy unit is taken as the Slater-Koster parameter $(dd\sigma)$ and also hereafter. Numerical calculations are performed in the $N = 32³$ lattices for most cases. The band structures shown in Figs. 1(c) and 1(d) are calculated in the $N = 64³$ lattice.

The electric band structure $E_e \equiv -E$ for $\varepsilon_f = -31.0$ and $U_{fd} = 3.60$ at half filling $\bar{n} \equiv \bar{n}_f + \bar{n}_d = 6$ is shown in Fig. 1(c). Here, *E* is the energy band in the hole picture. The hybridized flat bands with Sm *f* character are formed around $E_e \sim -6.6$, which has a maximum at the Γ point while the dispersive bands with Sm *d* character have a minimum at the X point. The Fermi level $\varepsilon_F \equiv -\mu(T = 0)$ is located at the hybridized bands, which indicates semimetal since the present half-filled state is the compensated metal with the equal number of electrons and holes. Namely, the hole band and the electron band appear above and below ε_F respectively. This overall feature is similar to the DMFT band structure of *g*-SmS.24)

On the other hand, for $\varepsilon_f = -27.0$ and $U_{fd} = 3.60$ at half filling, the lower three bands are filled and upper three bands are empty as shown in Fig. 1(d), indicating the insulator with the energy gap, which are also analogous to the DMFT band structure of b -SmS.²⁴⁾

For deep ε_f , $\bar{n}_f = 1$ is realized since the energy gain by occupied *f* level overcomes the energy loss by U_{fd} . As ε_f increases, the energy gain decreases and at a threshold $\varepsilon_f = \varepsilon_f^{\nu}$ the *f* occupancy is expected to drop suddenly since large U_{fd}

Fig. 2. (color online) The ε_f dependence of \bar{n}_f (circle, left axis), energy gap (triangle, right axis), and 100| Δ | (filled diamond, right axis) for (a) U_{fd} = 3.60, (b) 3.48, and (c) 3.40. Dashed lines are guides for the eyes at (a) ε_f = ε_f^v , (b) ε_f^{QCP} , and (c) ε_f^{vc} .

forces a hole to pour into either the *f* or *d* orbital. On the contrary, for $U_{fd} = 0$, the *f* occupancy continuously changes as a function of ε_f . Hence, we expect that a critical value of U_{fd} between the first-order transition and crossover exists in the ground state.

The effect of the *f*-level change is examined in Fig.2(a) for U_{fd} = 3.60. As ε_f increases, \bar{n}_f decreases and shows a sudden drop at $\varepsilon_f = -30.43 \equiv \varepsilon_f^v$. This indicates that the FOVT takes place at $\varepsilon_f = \varepsilon_f^v$. We find that the energy gap defined by the difference between the bottom of the conduction band and the top of the valence band starts to open at $\varepsilon_f = \varepsilon_f^v$. These results indicate that U_{fd} drives the MIT and the FOVT simultaneously. At $\varepsilon_f = \varepsilon_f^v$, the energy balance $\tilde{\varepsilon}_f \approx \mu$ holds in the mean-field picture with $\tilde{\varepsilon}_f$ being the renormalized f level $\tilde{\varepsilon}_f \equiv \varepsilon_f + \lambda + U_{fd}\bar{n}_d + 6U'_{fd}\bar{n}_d$, where μ is located just at the point where the bottom of the conduction band touches the top of the valence band. As further ε_f increases from ε_f^v , $\tilde{\varepsilon}_f$ rises since \bar{n}_d increases as the result of charge transfer from the *f* orbital caused by U_{fd} . This results in the shift down of the fully filled valence bands in the electron picture [e.g. three bands located around $E_e = -\tilde{\epsilon}_f = -9.25$ in Fig 1.(d)]. Namely, to earn the energy gain of the chargetransfer-induced shift down of the filled valence bands, the energy gap opens for $\varepsilon_f > \varepsilon_f^v$.

For smaller U_{fd} , the magnitude of the \bar{n}_f jump at the FOVT diminishes. At $U_{fd} = 3.48$, the jump in \bar{n}_f vanishes and the slope $-\partial \bar{n}_f / \partial \varepsilon_f \equiv \chi_v$ diverges at $\varepsilon_f = -29.46$, as shown in Fig. 2(b). Here, χ_{ν} is the valence susceptibility and the QCP of the FOVT is identified to be (ε_f^{QCP}) Q^{CP} , U_{fd}^{QCP}) = (-29.46, 3.48) where the critical valence fluctuation diverges $\chi_v = \infty$. The enegy gap opens for $\varepsilon_f > \varepsilon_f^{QCP}$. For $U_{fd} < U_{fd}^{QCP}$, the valence crossover occurs. At $U_{fd} = 3.40$, \bar{n}_f decreases continuously as ε_f increases, as shown in Fig. 2(c). At $\varepsilon_f = -28.80 \equiv \varepsilon_f^{vc}$ which is defined as the valence-crossover point, χ_{ν} has a peak indicating the enhanced valence fluctuation. The energy gap opens for ε_f > -27.75 .

We now discuss the effect of the exciton condensation. The magnitude of the EC parameter $|\Delta|$ is plotted in Fig. 2(a) for U_{fd} = 3.60. As ε_f increases from deep ε_f , $|\Delta|$ in-

Fig. 3. (color online) (a) Ground-state phase diagram in the plane of *f*level and $4f$ -5*d* Coulomb repulsion. The FOVT line (open circle) terminates at the QCP (filled circle) from which the valence-crossover line extends (triangle with the dashed line). The MIT line (filled diamond) separates the semimetal phase and insulator phase. (b) Contour plot of the EC parameter $|\Delta|$ at $T = 0$.

creases since the hybridization $|\bar{\Delta}(\xi)|$ with $\bar{\Delta}(\xi)$ being $\bar{\Delta}(\xi) \equiv$ $\frac{1}{N} \sum_{k} e^{ik \cdot r_{\xi}} \langle d^{\dagger}_{kxy\sigma} f_{k\Gamma_{8}^{(1)}\eta} \rangle$ with $(\sigma, \eta) = (\uparrow, -), (\downarrow, +)$ for the N.N. Sm sites and $\bar{b} = \sqrt{\bar{z}}$ increase in Eq. (4) reflecting the change from the Kondo regime to the intermediate-valence regime. Here, *z* is the renormalization factor. At $\varepsilon_f = \varepsilon_f^{\nu}$, $|\Delta|$ shows a sudden rise since both $|\bar{\Delta}(\xi)|$ and \bar{b} jump into larger values reflecting the FOVT into the weakly-correlated state with wider band width. As further ε_f increases from ε_f^{ν} , $|\Delta|$ increases slightly and then decreases monotonically. This decrease is because $|\bar{\Delta}(\xi)|$ decreases as the renormalized *f* level $-\tilde{\varepsilon}_f$ goes down away from the $d(t_{2g})$ band in the electron picture [see Fig. 1(d)] while \bar{b} increases in Eq. (4). For $U_{fd} < U_{fd}^{QCP}$, the jump in $|\Delta|$ vanishes to be continuous function of ε_f [see Figs. $2(b)$ and $2(c)$].

From these results, the ground-state phase diagram is determined in Fig. 3(a). The FOVT line terminates at the QCP (filled circle), from which the valence-crossover line (dashed line) extends. The MIT line coincides with the FOVT line for $U_{fd} > U_{fd}^{\text{QCP}}$, while for $U_{fd} < U_{fd}^{\text{QCP}}$ the MIT line slightly deviates toward larger ε_f side as \dot{U}_{fd} decreases. Notable is that the EC parameter [|]∆[|] develops along the FOVT line and the valence-crossover line and is enhanced in the insulator phase in Fig. 3(b).

As pressure is applied to SmS, the *f* level increases since negative N.N. S ions approach the $4f$ electron at Sm [see Fig. 1(b)]. Hence, in the hole picture, ε_f decreases as pressure increases. Thus decreasing ε_f from the insulator phase to the semimetal phase for $U_{fd} > U_{fd}^{QCP}$ in Fig. 3(a) is considered to correspond to the pressure evolution from *b*-SmS to *g*-SmS.

To get insight into anomalous behaviors in *g*-SmS under pressure, let us analyze the finite-temperature properties of the semimetal phase for $\varepsilon_f < \varepsilon_f^v$ at $U_{fd} = 3.60$ [see Fig. 3(a)] as a typical case. Figure 4(a) shows the temperature dependence of the specific heat *C*(*T*). Notable is that a hump structure appears, which becomes prominent as ε_f decreases. Interestingly, we find that the EC parameter $|\Delta(T)|$ shows a steep increase in the temperature range where $C(T)$ has a peak as shown in Fig. 4(b). $|\Delta(T)|$ starts to have a non-zero value at T_c where \bar{b} starts to have a finite value [see Eq. (4) and vertical arrow in Fig. 4(a) indicates T_c . The transition of $\bar{b}(T)$ at $T = T_c$ is an artifact of the slave-boson mean-field treatment and in reality it should be a crossover to the heavy-fermion

Fig. 4. (color online) (a) Temperature dependence of the specific heat for each ε_f at $U_{fd} = 3.60$. Arrow indicates T_c at which \bar{b} starts to have a nonzero value. (b) Temperature dependence of $|\Delta|$ (left axis) and \bar{b} (right axis) at $U_{fd} = 3.60$.

formation on cooling. The steep increase in $|\Delta(T)|$ appears in the low-temperature region for $T < T_c$ and hence this effect is considered to be intrinsic. This point is, however, to be examined by future analysis beyond the mean-field theory. The peak structure of $C(T)$ becomes more remarkable as ε_f decreases, as seen for $\varepsilon_f = -33.8$ and -34.6 in Fig. 4(a).

Figure 5(a) shows the ε_f dependence of the specific-heat coefficient $\gamma \equiv \lim_{T \to 0} C(T)/T$. As ε_f decreases from ε_f^{ν} , $γ$ increases with satisfying $γ ≈ \bar{b}^{-2} = z^{-1}$. This indicates that the low-*T* limit of the specific heat reflects the (semi)metallic ground state while the peak (hump) structure arises at low temperatures. Namely, the ground state evolves into the Kondo regime as \bar{n}_f approaches 1 while $|\Delta|$ decreases as ε*^f* decreases.

These features were observed in *g*-SmS under pressure.20) In the high-pressure side of *g*-SmS, a Schottky peak appears in $C(T)$ ($P = 10.1$, 15.9 kbar), whose temperature shifts to the lower *T* side as pressure increases. Thus increase in γ and decrease in the pseudo gap estimated from the Schottky specific heat in g -SmS under pressure²⁰⁾ are explained by our results in the semimetallic band, as shown in Fig. 5(a). Then, these results support the pseudo gap^{20, 24)} but no real gap in g -SmS.

We find that the compressibility $\kappa = \frac{\partial \bar{n}}{\partial \mu}$ also shows a peak at low temperatures as shown in Fig. 5(b). Emergence of the peak structure in κ implies that total charge fluctuations are enhanced. Similarly to the specific heat, the peak in $\kappa(T)$ is enhanced as ε_f decreases, whose temperature shifts to the lower-*T* side. This also explains the temperature dependence of the compressibility in g -SmS under pressure.²¹⁾

We have clarified the role of the *f*-level shift as a key parameter to understand the effect of applying pressure to SmS. It should be noted that applying pressure also enhances the *d*-*f* hybridization. This effect brings the tendency to make the Sm valence $v = 2 + \bar{n}_f$ slightly smaller than the values obtained by the f -level shift only. Here we list v at the FOVT for $\varepsilon_f \to \varepsilon_{f^-}^v(\varepsilon_{f^+}^v)$ as 2.69 (2.44) at $U_{fd} = 3.60$ and 2.89 (2.29) at $U_f/d = 4.00$. As U_{fd} increases, the magnitude of the valence jump increases. Experimentally, in *b*-SmS, the Sm valence was observed as $v \sim 2$ with error bar about \sim 0.2 at the boundary of the golden-black phase transition for *T* = 4.5 K.⁵⁾ The gradual rise from $v \sim 2$ in *b*-SmS with increasing pressure was also detected by the Mössbauer measurement.⁴⁾ Recently, experimental technique for evaluating U_{fd} directly in the rare-earth compounds has been developed

Fig. 5. (color online) (a) The ε_f dependence of γ (circle, left axis), $5/\bar{b}$ (inverted triangle, left axis), and $|\Delta(T = 0)|$ (diamond, right axis) at U_{fd} = 3.60. (b) κ vs *T* at $U_{fd} = 3.60$.

in the X-ray spectroscopy measurement.³⁵⁾ Direct evaluation of the U_{fd} value in SmS by this method is interesting future subject.

We have studied the isotropic condensation of the exciton as a first step analysis. It is interesting to examine whether the symmetry is not broken by exciton condensation. Detailed analysis of the crystal symmetry in *g*-SmS and also in *b*-SmS at low temperatures is interesting future subject.

To summarize, we have clarified the mechanism of the interplay of the FOVT as well as MIT and exciton condensation in SmS. Our study provides a unified view to resolve the longstanding issues in SmS. Our formulation can be generalized to the other Sm-based systems and hence this study opens a new stage for the quantum valence criticality, which offers the guide to explore the valence QCP in Sm-based compounds experimentally.
