ABSTRACT

Aims. The 11-year solar cycle (Schwabe cycle) is the dominant pattern of solar magnetic activity reflecting the oscillatory dynamo mechanism in the Sun's convection zone. Solar cycles have been directly observed since 1700, while indirect proxy data suggest their existence over a much longer period of time but generally without resolving individual cycles and their continuity. Here we reconstruct individual solar cycles for the last millennium using recently obtained ^{14}C data and state-of-the-art models.

Methods. Starting with the ^{14}C production rate determined from the so far most precise measurements of radiocarbon content in tree rings, solar activity is reconstructed in three physics-based steps: (1) Correction of the ^{14}C production rate for the changing geomagnetic field; (2) Computation of the open solar magnetic flux; and (3) Conversion into sunspot numbers outside of grand minima. All known uncertainties, including both measurement and model uncertainties are straightforwardly accounted for by a Monte-Carlo method.

Results. Cyclic solar activity is reconstructed for the period 971 – 1900 (85 individual cycles) along with its uncertainties. This more than doubles the number of solar cycles known from direct solar observations. We found that lengths and strengths of well-defined cycles outside grand minima are consistent with those obtained from the direct sunspot observations after 1750. The validity of the Waldmeier rule (cycles with fast rising phase tend to be stronger) is confirmed at a highly significant level. Solar activity is found to be in a deep grand minimum when the activity is mostly below the sunspot formation threshold, during about 250 years. Therefore, although considerable cyclic variability in ^{14}C is seen even during grand minima, individual solar cycles can hardly be reliably resolved therein. Three potential solar particle events, ca. 994, 1052 and 1279 AD, are shown to occur around the maximum phases of solar cycles.

Conclusions. A new about 1000-year long solar activity reconstruction, in the form of annual (pseudo) sunspot numbers with full assessment of all known uncertainties, is presented based on new high-precision $\Delta^{14}\text{C}$ measurements and state-of-the-art models, more than doubling the number of individually resolved solar cycles. This forms a solid basis for new, more detailed studies of solar variability.

Key words. Sun:activity

1. Introduction

Cyclic variability with a period of about 11 years (*Schwabe cycle*) is the dominant pattern of solar magnetic activity (Hathaway 2015) reflecting the oscillating dynamo mechanism in the solar convection zone (Charbonneau 2020). However, the 11-year cycle is far from a perfect sine-wave and varies both in magnitude and length on a longer time scale (Usoskin 2017). Historically, the most common and the longest index of solar magnetic activity is the synthetic sunspot number (SN) based on direct solar observations by a cohort of astronomers worldwide since 1610 (Vaquero et al. 2016). Although the SN series is somewhat uncertain before ca. 1900 (Clette et al. 2014), it clearly depicts the dominance of the Schwabe cyclicity and its variability.

The overall level of solar activity and its secular variability over the last ten millennia has been reconstructed from decadal resolved cosmogenic radioisotopes ^{14}C and ^{10}Be (Solanki et al. 2004; Usoskin et al. 2004; Vonmoos et al. 2006; Delaygue & Bard 2011; Steinhilber et al. 2012; Usoskin et al. 2016; Wu et al. 2018b), but the 11-year cycle cannot be resolved from these datasets. Still, the existence of the 11-year solar cycle before 1610 can be found from cosmogenic radioisotopes for some periods (e.g., Miyake et al. 2013b; Gütler et al. 2013; Muscheler et al. 2016) with special emphasis on the 11-year cycle during grand minima (Beer et al. 1998; Miyahara et al. 2004; Moriya et al. 2019; Fogtmann-Schulz et al. 2019, 2020). The existence of climate cyclicity with an appropriate period was found also in fossil data for previous epochs (e.g., Luthardt & Rößler 2017; Li et al. 2018). However, the continuity of the 11-year cyclicity

was not proven, as most of those studies were based on spectral analyses of the data (e.g., Eastoe et al. 2019), showing spectral peaks in the range of 10–12 years but did not resolve individual solar cycles. Therefore, until recently we knew individual solar cycles only for the last 410 years since 1610, including a ≈ 70 -year spotless period of the Maunder minimum.

A major breakthrough has been made by Brehm et al. (2021) who measured annually-resolved $\Delta^{14}\text{C}$ in tree rings for the last millennium since the mid-10th century, with unprecedented accuracy. This dataset reveals continuous solar cycles for the last millennium, at least outside of the grand solar minima, and displays three abrupt enhancements potentially associated with solar particle events (SPEs): one known event in 994 AD (Miyake et al. 2013a) and two new ones in 1052 and 1279 AD. Brehm et al. (2021) provided an estimate of the solar modulation potential ϕ , which characterizes the flux intensity of galactic cosmic rays, but whose physical interpretation is unclear (Caballero-Lopez & Moraal 2004; Usoskin et al. 2005; Herbst et al. 2010; Asvestari et al. 2017a). It is not straightforward to convert ϕ into quantities useful for Sun-Earth relations, such as solar magnetic flux or solar irradiance.

Here we provide, for the first time, a physics-based quantitative reconstruction of solar magnetic activity since 971 AD, at a cadence that allows individual solar cycles to be resolved. Provided quantities are open solar magnetic flux (OSF, henceforth denoted as F_o) and the sunspot number (at least for the times outside deep grand minima). Within the grand minima we provide solar activity in the form of pseudo-sunspot numbers, as described below. The reconstruction includes a sequence of model steps, each based on the up-to-date knowledge of physical processes involved and the related uncertainties. We emphasize that the reconstruction does not involve any freely tunable ad-hoc parameters or normalization, since all model parameters were determined independently of this reconstruction.

2. Data

The series of the production rate of radiocarbon (denoted as Q henceforth) data for 971–1900 with uncertainties was obtained from Brehm et al. (2021) who computed it from the measured annual $\Delta^{14}\text{C}$ measurements with a pseudo-monthly resolution applying a most recent carbon-cycle box model (Büntgen et al. 2018) and correcting for the Suess effect (dilution of atmospheric concentration of ^{14}C because of the fossil fuel burning since the late 19th century). It is consistent with the earlier decadal ^{14}C production rate (Roth & Joos 2013) but resolving individual solar cycles. This data set contains several short 1-year interpolations corresponding to gaps in the raw $\Delta^{14}\text{C}$ dataset (1203, 1277, 1304, 1309, 1312, 1578, 1645, 1702, 1715) and one longer gap (6 years between 1043 and 1048). The solar cycle corresponding to the latter gap is marked as unreliable. During the analyzed period, an extreme solar event occurred ca. 994 (Mekhaldi et al. 2015; Miyake et al. 2013a) that may distort the ^{14}C production. The effect of this event was removed by subtracting the modelled production of $\Delta Q = 3.9$ at/cm²/sec (Mekhaldi et al. 2015) spread over the years 992, 993, 994 as 1, 1.9, 1 at/cm²/sec, respectively, before further analysis. Similarly we have removed the potential events of

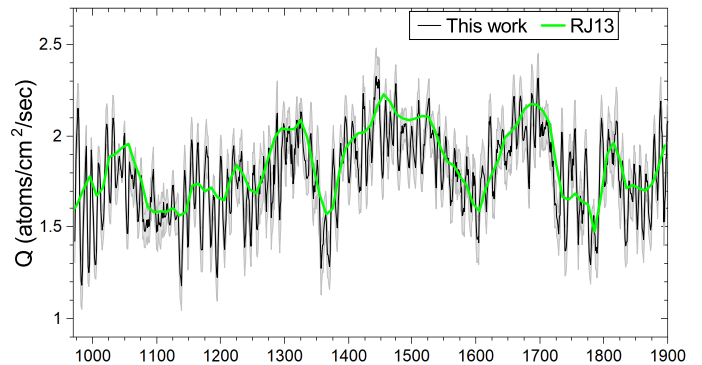

Fig. 1. The ^{14}C production rate Q (black curve) with 1σ uncertainties, obtained from Brehm et al. (2021), used here, after corrections for the 994, 1052 and 1279 AD events and smoothing (see Section 2). The green RJ13 curve depicts Q from Roth & Joos (2013).

1052 considered as 0.65×994 AD event, starting in 1051, and 1279, considered as 0.8×994 AD event, starting in 1279 (see Brehm et al. 2021). However, since the exact strength of these events is not well-known yet, we mark the corresponding cycles as not well-defined. The effect of removing these events is shown in Section 3.4.1. Because of the high level of noise in the Q -series, it was slightly smoothed (Savitzky-Golay filter of order 3 and framelength 9) before further processing. This Q -series is shown in Figure 1.

3. The method

The method of sunspot activity reconstruction consists of three consecutive steps

$$Q \xrightarrow{(1)} Q^* \xrightarrow{(2)} F_o \xrightarrow{(3)} \text{SN},$$

each performed 10000 times in a Monte-Carlo (MC) procedure as described below. Henceforth, the index i denotes the number of the realization, and j the year within the time series ($j=1$ corresponds to 971 AD).

3.1. Step (1): Reducing Q to the modern geomagnetic field

To remove the effect of the variable geomagnetic shielding, we reduced the production rate Q , obtained by Brehm et al. (2021), to Q^* corresponding to that for the reference geomagnetic field with the fixed dipole moment M_0 . The following sub-steps were used:

$$\begin{aligned} (1a) : \quad & M_{i,j} = M_j^{(k_i)}, \quad k_i = r_{[1-4]} \\ (1b) : \quad & Q_{i,j}(M_{i,j}) \rightarrow Q_{i,j}^*(M_0) \end{aligned} \quad (1)$$

First (step 1a), one of four archeomagnetic models, namely U16 (Usoskin et al. 2016), COV (Hellio & Gillet 2018), pfm9k.1b (Nilsson et al. 2014) and SHA (Pavón-Carrasco et al. 2014) was randomly chosen for each realization i . These models (shown in Figure 2) were

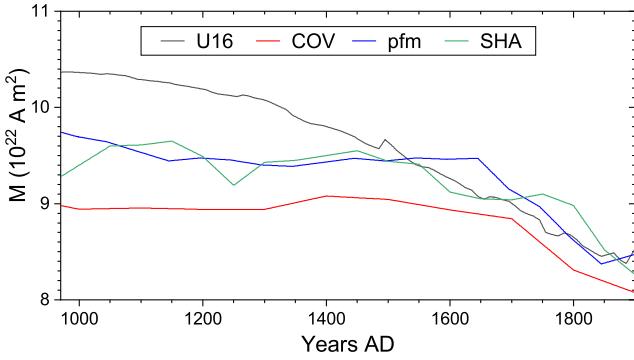

Fig. 2. Time variability of the virtual axial dipole moment (VADM) as presented in archeomagnetic models considered here U16 (Usoskin et al. 2016), COV-ARCH (Hellio & Gillet 2018), pfm9k.1b (Nilsson et al. 2014) and SHA (Pavón-Carrasco et al. 2014).

selected as representing the diversity of the main groups working in paleo/archeo-magnetic reconstructions, and covering the full range of uncertainties of archeomagnetic models for the last millennium. As the reference geomagnetic field we have considered recent IGRF (IGRF model – Thébaud et al. 2015) conditions with the dipole moment $M_0 = 7.75 \cdot 10^{22}$ A m² corresponding to the time when cosmic-ray spectra were directly measured in space (see Step 3).

The reduction (step 1b) to the reference field M_0 was performed using computations based on the Galactic cosmic-ray (GCR) spectra directly measured during the last decade (see Section 3.2.1 for more details). Using the measured spectra as an input, we computed (using the production model by Poluianov et al. 2016) expected values of $Q(M)$ for different values of the geomagnetic dipole moment M . The relation between $Q(M)$ and Q^* corresponding to the modern geomagnetic field is shown in Fig. 3, covering a modulation range of Q corresponding to a full solar cycle. One can see that the relation is nearly perfectly linear. Thus, Q -values at time t at which the dipole moment is $M(t)$ can be converted into the production rate at the modern value $M_0 = 7.75 \cdot 10^{22}$ A m², as $Q^*(t) = h(Q_M(t))$, where h is an appropriate linear relation as shown in Fig. 3.

The production rate Q^* reduced to the modern M_0 is shown in Figure 4.

3.2. Step (2): Open flux

This step includes conversion of the ¹⁴C production rate Q^* (reduced to the reference conditions) to the open solar magnetic flux F_0 :

$$(2a) : \quad F_{0i,j} = f(Q_{i,j}^*) + R_{i,j} \cdot \sigma_3, \quad (2)$$

where f is a functional relating Q^* to F_0 (see Equation 6), $R_{i,j}$ is a normally distributed random number with zero mean and unity standard deviation, and σ_3 is the uncertainty of the conversion (see below). The method used here to reconstruct the open solar flux (OSF) F_0 from Q^* is described below. In

Fig. 3. Dependence between Q -values computed for different geomagnetic dipole moments M , as denoted in the legend in units of $\cdot 10^{22}$ A m², and Q^* at the modern-day value of $M_0 = 7.75 \cdot 10^{22}$ A m². Q -values were calculated using GCR spectra directly measured by AMS for May 2011 through May 2017 (see Section 3.2.1).

Fig. 4. Radiocarbon production rate Q^* reduced to the modern geomagnetic shielding ($M_0 = 7.75 \cdot 10^{22}$ A m²) with $1\sigma_{Q^*}$ errors.

contrast to earlier works, it is based on direct cosmic-ray measurements over the last decades.

3.2.1. Use of direct space-era data

All previous models of cosmogenic isotope production were based on theoretically modelled GCR spectra, often parameterized by the so-called force-field model (Caballero-Lopez & Moraal 2004; Usoskin et al. 2005), which however has an intrinsic uncertainty related to the local interstellar spectrum of GCR (Herbst et al. 2010; Asvestari et al. 2017a). Since the spectrum of GCR beyond the Earth’s atmosphere and magnetosphere was unverifiable until recently, the associated model uncertainty was present in all previous computations based on the force-field approximation (e.g., Masarik & Beer 2009). This introduced uncertainties in the level of the OSF (or other solar activity indices), sometimes leading to blind ad-hoc ‘calibrations’ of the models.

The situation has been dramatically improved recently, when the space-borne *Alpha Magnetic Spectrometer* experiment (AMS – see Aguilar et al. 2018) provided direct measurements of GCR energy spectra above the atmosphere over a large part of solar cycle 24 from May 2011 through May 2017,

with a 27-day time resolution. Not only protons, but also heavier cosmic-ray species were measured, up to iron and nickel, thus providing, for the first time, direct data on GCR spectra and its variability over a solar cycle. The AMS instrument is installed onboard the International Space Station at a low orbit and spends most of the time inside the magnetosphere. However, thanks to the inclined ($\approx 52^\circ$) orbit, it receives also low-energy cosmic rays (rigidity down to 1 GV, energy 400 and 200 MeV/nuc for protons and heavier nuclei, respectively) over high-latitude parts of the orbit. This makes it possible to obtain directly measured spectra of GCR (> 1 GV) leading to the ultimate verification and, if needed, calibration of the ^{14}C production model. Contribution of even lower-energy (< 1 GV rigidity) GCR particles to ^{14}C production is very small ($\approx 0.5\%$, Asvestari et al. 2017a), because it is limited to the small-area polar regions, while the yield function grows rapidly with energy. Accordingly, we accounted for that part of the GCR spectrum not measured directly by AMS by extrapolating it with a best-fit force-field approximation below 1 GV. The uncertainties related to this extrapolation are negligible ($< 0.1\%$).

The globally averaged production rate of a cosmogenic isotope in the Earth's atmosphere at time t can be calculated as

$$Q(t) = \sum_k \int_0^\infty J_k(P, t) \cdot Y_k^*(P, t) dP, \quad (3)$$

where summation is over the type k of cosmic-ray particles (protons, helium, etc), $J_k(P, t)$ is the rigidity (momentum over charge) spectrum of cosmic-ray particles of type k near Earth but outside the atmosphere and magnetosphere,

$$Y_k^*(P, t) = \frac{1}{2} \int_{-\pi/2}^{\pi/2} H(P_c(\theta, t)) \cdot Y_k(P) \cos \theta d\theta \quad (4)$$

is the globally averaged yield function of the isotope production by cosmic-ray particles of type k with rigidity P , P_c is the local geomagnetic cutoff rigidity (e.g., Elsasser et al. 1956; Usoskin et al. 2010) at a given geomagnetic latitude θ and time t , $H(x)$ is the Heaviside step function, and $Y_k(P)$ is the yield function of the isotope production (Kovaltsov et al. 2012; Poluianov et al. 2016). As the global yield function Y_k^* of ^{14}C we used the one (Asvestari et al. 2017a) based on a recent computation by Poluianov et al. (2016), energy/rigidity spectra J_k of cosmic rays were taken as measured by the AMS experiment during 2011–2017, and the corresponding values of Q^* were calculated. Thus computed values of Q^* are shown in Figure 5 against count rates of a standard polar neutron monitor (NM), viz. Oulu NM data record available at <http://cosmicrays.oulu.fi>. Relation between them is very tight and can be parameterized as

$$Q^* = 0.0244 \cdot N^2 - 0.2908 \cdot N + 1.7147, \quad (5)$$

where Q^* is the global ^{14}C production rate in $\text{at}/\text{cm}^2/\text{s}$ for the modern epoch (M_0) and N is the count rate of a polar sea-level NM in $\text{Hz}/\text{counter}$.

3.2.2. Extension to 1957–2019

Using Equation 5 and the polar NM record we have extended the expected annual Q^* series backwards to 1957. These values

Fig. 5. Scatter plot of the ^{14}C global production rate Q^* , computed based on the AMS-02 data for the period 2011–2017, and a polar NM64 (Oulu) neutron monitor count rate for the same period, with the dot-dashed red line depicting the dependence (Equation 5).

are plotted in Figure 6 against OSF F_0 as assessed from in-situ space-borne data applying the kinematic correction since 1963 (Lockwood et al. 2009; Owens et al. 2017), extended to recent years according to (Owens, personal communication, 2019) and based on geomagnetic indices (Lockwood & Owens 2014). The values are highly significantly correlated (the Pearson's correlation coefficient $r = -0.86 \pm 0.03$, p -value $< 10^{-6}$), but the scatter is large, especially during the years between 1968 and 1980 (see Figure 7) likely because of the poor quality of in-situ solar wind data.

3.2.3. Expected relations between Q and F_0

Based on basic physical principles, a dependence between the isotope production rate and OSF is expected to be nearly exponential, $Q^* = Q_0 \cdot \exp(-F_0/\alpha)$, which leads to

$$F_0 = -\alpha \cdot \ln\left(\frac{Q^*}{Q_0}\right), \quad (6)$$

where $Q_0 = 2.5 \text{ at}/\text{cm}^2/\text{s}$ is the production rate in the absence of solar modulation (Poluianov et al. 2016), viz. by the local interstellar spectrum ($F_0=0$). The value of $\alpha = (17.2 \pm 0.2) \cdot 10^{14} \text{ Wb}$ was found as the least-squares best fit to the data points shown in Figure 6.

Figure 7 shows a comparison between the OSF, derived from space-borne measurements $F_0(\text{O17})$ (Lockwood et al. 2009; Owens et al. 2017) and F_0 calculated here from NM data using Equations 5 and 6, as well as the difference between them (panel B). One can see that the cycles are reproduced quite well, both in the mean level and in the amplitude. The two OSF series agree reasonably well, with the mean difference being 0.1 and the standard deviation 0.9 (both in units of 10^{14} Wb). These deviations directly enter the uncertainty of the F_0 reconstruction from Q , and we considered $\sigma_3 = 0.9 \cdot 10^{14} \text{ Wb}$ in

Fig. 6. Scatter plot of the annual solar open magnetic flux F_o (Lockwood et al. 2009; Owens et al. 2017) against the ^{14}C production rate Q^* estimated from NMs (see Figure 5). The red curve depicts the best-fit dependence (Equation 6).

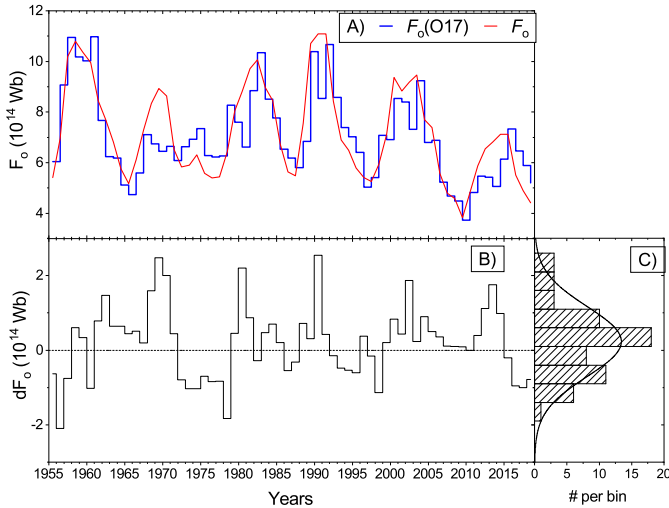

Fig. 7. Panel A: Evolution of annual open solar flux: $F_o(\text{O17})$ based on in-situ measurements (Owens et al. 2017) and F_o^* reconstructed here based on relations 5 and 6; Panel B: difference between them $dF = F_o - F_o(\text{O17})$. Panel C: histogram of the occurrence of dF values with the best-fit Gaussian (mean $0.1 \cdot 10^{14}$ Wb and $\sigma = 0.9 \cdot 10^{14}$ Wb).

Equation 2. It is very important that the low level of the current cycle 24 (2010–2018) is reproduced correctly, suggesting that the secular variability is also captured by the model.

3.2.4. Reconstruction of F_o .

In the next step, we apply the relation (2) to the Q^* over the whole time series, keeping in mind the found uncertainty of $\sigma_{F_o} = 0.9 \cdot 10^{14}$ Wb and a possible systematic bias of $0.1 \cdot 10^{14}$ Wb. OSF F_o reconstructed in this way is shown in Figure 8 with panel A depicting the whole time series and panel B displaying a blow-up of the period since 1700. For comparison, several other OSF reconstructions are shown, including the F_o determined from space-based measurements for the last decades as discussed in Section 3.2.1, and two reconstructions

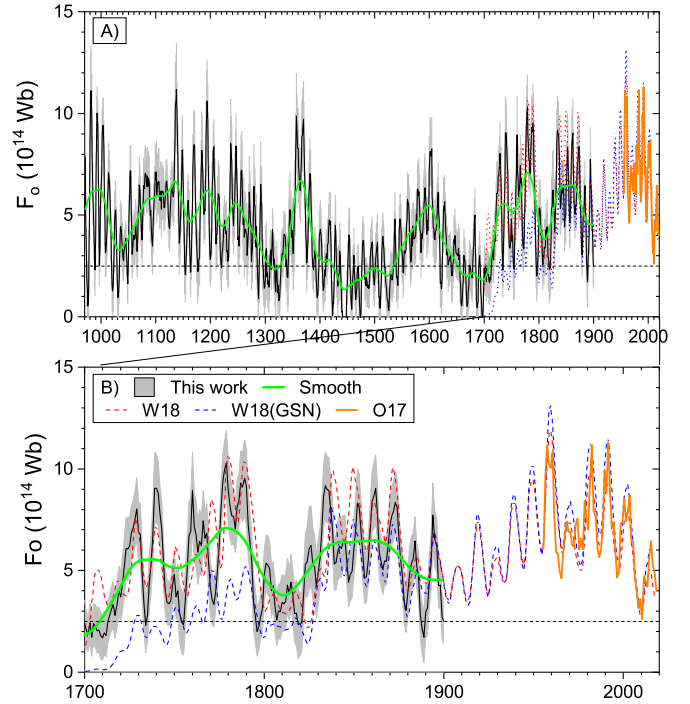

Fig. 8. Evolution of the reconstructed annual F_o . The mean curve (black) and 1σ uncertainties (grey shaded area) were computed by 10000 Monte-Carlo realizations (see text). The green curve represents the smoothed (22-yr SSA) variability. The mean level of $2.5 \cdot 10^{14}$ Wb defines the grand minima when solar magnetic activity drops below the sunspot formation threshold. Other reconstructions are shown for comparison: (Wu et al. 2018a, – W18) based on SATIRE-T model applied to ISN(v.2); the same SATIRE-T model but applied to the GSN (W18(GSN)), as well as the OSF reconstructed from space-based measurements (Owens et al. 2017, – O17). Panel B shows a zoom to the period after 1700. The data is available in the digital tabular form in CDS tables.

(Wu et al. 2018a) using the method entering the SATIRE-T model (Vieira & Solanki 2010; Krivova et al. 2010), but based on two different sunspot series: (ISN(v.2) available at SILSO, Clette & Lefèvre 2016), and GSN (Hoyt & Schatten 1998). We note that these two sunspot series serve as the conservative upper and lower bounds for the uncertainties of different sunspot series (Usoskin 2017). Before ca. 1880s the reconstruction lies mainly between the two colored curves, being closer to the ISN-based one during the 18th century. Note, however, that the model underlying the red and blue dashed curves in Figure 8 provides too low F_o during extended periods of particularly low activity, such as grand minima, because of the limitation of the earlier OSF models.

3.3. Step (3): Conversion of F_o into sunspot number

The OSF F_o can be estimated from the sunspot number using a semi-empirical model (e.g., Solanki et al. 2002; Vieira & Solanki 2010), which also enters the SATIRE-T model (Krivova et al. 2010; Wu et al. 2018a) used for solar ir-

radiance reconstruction. It is based on solving a set of linear differential equations with several sources, considering a source term describing the emergence of active (ARs) and ephemeral regions (ERs) at the solar surface and their decay. The latter includes the transfer of flux from ARs and ERs into slowly and rapidly evolving components of the OSF. This model has recently been extended, improved and updated to take into account more recent observations of the number distribution of magnetic features with different levels of magnetic flux (Krivova et al. 2021). Instead of just ERs it also includes the flux emerging in the form of internetwork fields, combining the two under the term small-scale emergences (SSEs). All emerging magnetic bipoles are described by a single power-law distribution, which allows for a non-zero emergent flux even when there are no sunspots. Thus, in contrast to the earlier SATIRE-T model, the new model returns a non-zero F_o during grand minima, consistent with observational findings that it was of the order of $2 \cdot 10^{14}$ Wb and varied cyclicly during the MM (Beer et al. 1998; Owens et al. 2012; Asvestari et al. 2017b).

However, the inversion of the model (viz. $F_o \rightarrow \text{SN}$) is not possible analytically. We have therefore taken the following alternative path, using a semi-empirical approach based on a statistical inversion of the forward model.

One shortcoming of the employed forward model remains that it relies on sunspots to determine the strength of OSF. Therefore, at least the forward model cannot handle well fluctuations in the level of solar activity if this occurs at levels too low to produce sunspots. The clear variation in the production of cosmogenic isotopes (both ^{10}Be and ^{14}C) during grand minima (Beer et al. 1998; Asvestari et al. 2017b; Brehm et al. 2021) suggest, however, that variations in solar activity do take places at such times which are reflected in the number of sunspots only to a small extent (Vaquero et al. 2015). In the context of the inverted model used here, such variations formally translate into variations in sunspot number, although there were in reality hardly any sunspots on the solar disc at that time (Usoskin et al. 2015; Vaquero et al. 2015). To counter this, we have introduced a threshold of $F_b = 2.5 \cdot 10^{14}$ Wb with corresponds to zero sunspot (see Equation 7). We consider that solar cycles with $F_o < 2.5 \cdot 10^{14}$ Wb in the smoothed OSF series correspond to grand minima and cannot be robustly defined. This means that at times when the green curve in Figure 8 drops below the horizontal dashed line, we consider the variation in solar activity reconstructed by the model not to be dominantly caused by sunspots. Rather, such fluctuations are then considered to be mainly due to changes in the number of non-spot magnetic features on the solar surface, such as small-scale magnetic elements (e.g., Solanki 1993) forming network and plage. Such activity cycles dominated by non-spot variations have been marked by a dashed line in Figure 12 and by italic font in Table 1 listing all the cycles.

3.3.1. Statistical inversion

First, we composed a synthetic series of annual sunspot numbers (SN) based on the ISN(v.2) (Clette & Lefèvre 2016) since

Fig. 9. Synthetic sunspot number series, composed of ISN(v.2) after 1700 and GSN before that (black curve), and its ‘reconstruction’ after the chain $\text{SN} \rightarrow F_o \rightarrow \text{SN}'$ (red curve).

1700 and a scaled GSN (Hoyt & Schatten 1998) for the period 1610–1699. The latter is needed, since the ISN does not cover the Maunder minimum, and we want to include this low-activity period. This series is shown in Figure 9 as the thin black curve.

This series was split into 36 individual cycles between consecutive minima of 13-month smoothed SN and about 11-yr intervals during the Maunder minimum. We produced 1000 synthetic SN-series, formed by randomly permuting these 36 solar cycles and computing the corresponding 1000 OSF series using the equations applied in the SATIRE-T model. Thus, we have 1000 sets of the annual ‘input’ SN series and the corresponding ‘output’ OSF series.

Next, we searched for a relation which inverts the input and the output, viz. $F_o \rightarrow \text{SN}$ using an empirical approach. Because of the presence of distinct slow secular (Lockwood et al. 1999), dependent on the previous history (see Solanki et al. 2000), and oscillating 11-year components in the OSF, we first decomposed each F_o synthetic series into slow, F_s , and oscillating fast $F_f = F_o - F_s$ components. SN of the year j reconstructed from F_o is calculated as

$$\text{SN}_j = a \cdot (F'_{s_{j+1}})^2 + b \cdot (F'_{f_j} + F'_{f_{j+1}}),$$

$$F' = F_o - F_b, \quad (7)$$

where F'_s and F'_f are the slow and fast components (both expressed in units of 10^{14} Wb), obtained as the first component of the singular spectral analysis (SSA, cutoff period 5 years) of the F' series and the residual, respectively, and parameters are $a = 2.4 \pm 0.05$, $b = 11.5 \pm 0.1$ and $F_b = 2.2 \cdot 10^{14}$ Wb. The mean rms over the 1000 series was found to be 7.8 in SN units for this set of parameters. The use of other filters does not notably alter the final result but leads to larger error bars (rms 10–13). Thus, the model uncertainty of this step conversion was set as $\sigma_4=8$.

3.3.2. Testing the inversion

An example of the inversion for the reference series is shown as the red curve in Figure 9. One can see that all cycles are correctly reproduced in shape and their overall level (the mean difference is 1.9) but with a slightly reduced amplitude (maxima are lower, minima higher), the Pearson’s correlation coefficient

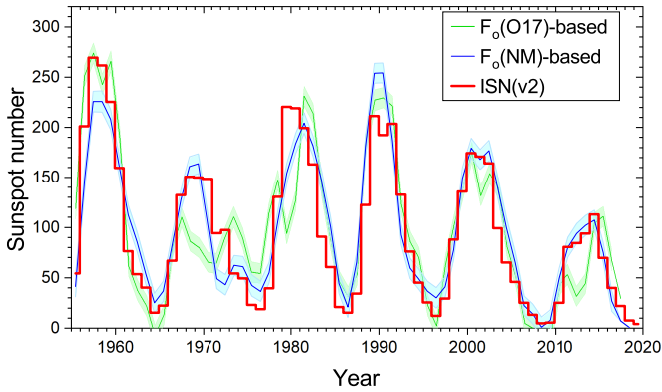

Fig. 10. Sunspot numbers, computed using Equation 7 from the F_o data for the instrumental era (see Figure 7) reconstructed by (Owens et al. 2017, – O17) and from NM data, along with the ISN(v.2).

is 0.963, rms=15. The Maunder minimum is reproduced very well.

We have tested the inversion method (Eq. 7) using the OSF reconstruction based on in-situ data by Owens et al. (2017) (see the blue curve F_o (O17) in Figure 7). The obtained sunspot numbers are shown in Figure 10 along with the ISN(v.2.0). One can see that the agreement is good (mean difference $d = 0.3$, Pearson’s correlation coefficient $r = 0.83^{+0.025}_{-0.04}$, rms = 35), except for the period 1963–1982, which was characterized by earlier quite uncertain magnetic-field in-situ data, so that they disagree with the cosmic-ray data (Figure 7). When the OSF computed from the cosmic-ray data (Section 3.2.1) is used, the agreement between the ‘reconstructed’ (blue curve) and the actual sunspot numbers improves significantly ($d = -0.03$, $r = 0.93^{+0.01}_{-0.02}$, rms = 26). Thus, we can conclude that the method provides a good way to reconstruct the sunspot number from OSF data.

3.4. Solar-activity reconstruction

The sunspot number reconstruction was performed with 10000 random realizations, each going through steps 1–3 and applying independent random numbers as described above in formulas 1 and 2. The sunspot number (in the units of ISN v.2), at least for times when solar activity is characterized by a sunspot cycle, as during recent decades, is computed as

$$(3a) : \quad \text{SN}_{i,j} = g(F_{O_{i,j}}) + R_{i,j} \cdot \sigma_4, \quad (8)$$

where the functional g is defined by Equation 7.

From 10000 thus obtained SN series we computed the mean series $\langle \text{SN}(t) \rangle$ and its standard deviation $\sigma_{\text{SN}}(t)$, which are considered as the final mean reconstruction and its 1σ uncertainties. The final SN series is provided as a table at the CDS¹ and shown in Figures 11B and 12 with 1σ uncertainties and in comparison with other direct or indirect series. It is gratifying that individual solar cycles are clearly resolved outside of the grand minima. Figure 11A depicts a smoothed

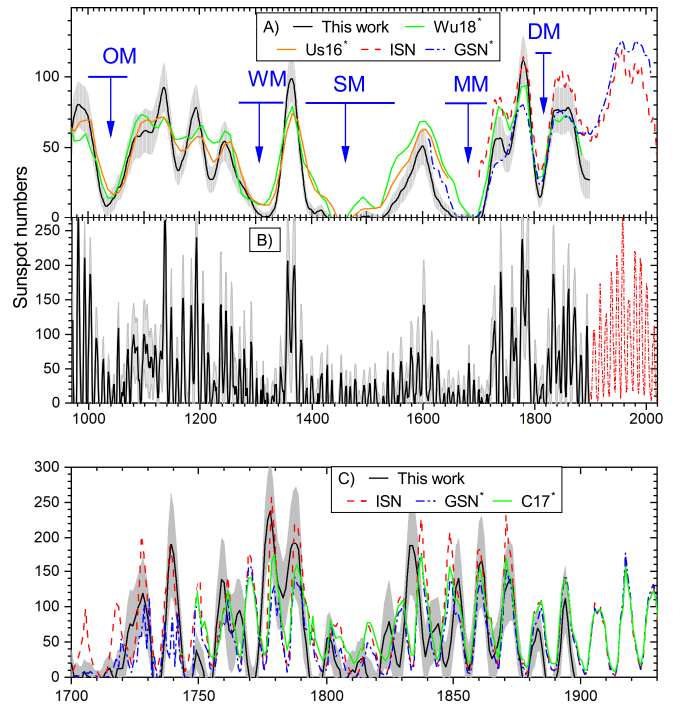

Fig. 11. Time evolution of the reconstructed sunspot numbers (black curve with $\pm 1\sigma$ grey-shaded uncertainties) in comparison with other direct and indirect sunspot number series. The final annual reconstruction is shown in panel B, and its zoom for the period after 1700 is shown in panel C. Panel A shows the smoothed (15-yr first SSA component) annual series in comparison with other similarly smoothed or decadal series. These series are: ISN(v.2, SILSO), GSN* (Hoyt & Schatten 1998); C17* (Chatzistergos et al. 2017); as well as two recent reconstructions based on ^{14}C –U16* (Usoskin et al. 2016) and W18* (Wu et al. 2018b) (symbol * indicates that the series is scaled up by a factor 1.667 to match the ISN v.2 definition). Blue arrows denote grand minima of solar activity: Oort (OM), Wolf (WM), Spörer (SM), Maunder (MM), and Dalton (DM) minima. The data are available in digital tabular form in CDS.

(15-yr first SSA component) SN-series with the corresponding uncertainties, in comparison with similarly smoothed ISN and GSN series as well as decadal ^{14}C INTCAL-based reconstructions by Usoskin et al. (2016) and a multi-proxy based one Wu et al. (2018b) (all series were properly scaled to match the ISN v.2 scale). The agreement with previous cosmogenic-proxy reconstructions, including U16 (Usoskin et al. 2016) and W18 (Wu et al. 2018b) ones, is very good (see Section 4.1.3).

Formally negative mean SN-values appear for about 250 years, about 80 of them are negative beyond the 1σ -uncertainty and only 6 remains negative at the 2σ level (Figure 12). Thus, formally negative SN-values are statistically consistent with zeros. For further analysis we keep the negative values since replacing them with zeros would distort the overall level.

We note that, while the uncertainties are large (mean 68 % uncertainty is about 34 in SN units), they are largely systematic (related to the model uncertainties), and thus do not affect the temporal evolution but only the level of activity. An important

Fig. 12. The same as Figure 11 but split into three subsequent time intervals 310-year each. Cycles, which are not well defined during the grand minima (see Section 3.3), are indicated with the dashed line.

advantage of the employed data is that their quality (and thus the SN reconstruction) is stable during the entire period.

3.4.1. The effect of the 994, 1052 and 1279 AD events

One confirmed peak of additional ^{14}C production in 994 AD (Miyake et al. 2013a) and possible peaks in 1052 and 1279 AD (Brehm et al. 2021) are known during the analyzed period. Since they are likely of non GCR origin and thus can distort the cyclic evolution of the reconstructed solar activity, we have removed them from the original Q series as described in Section 2. The effect of the removal of the 994 AD event is shown in Figure 13A. If the event is not corrected, a full solar cycle is ‘swallowed’ (a bump in the ^{14}C production is interpreted as very weak solar activity), while a formal (no ad-hoc tuning) correction of the effect restores a nearly perfect cycle with the maximum in 994 AD. Thus, the event of 994 is found to take place at the early declining phase of a strong solar cycle.

The effect of the removal of the potential event in 1052 is shown in Figure 13B. The correction fully restores the cyclic shape otherwise ‘swallowed’ by the event. The restored cycle has its maximum in 1053, thus the 1052 event took place near the maximum of a moderate cycle during the Oort grand minimum.

The effect of the removal of the event of 1279 is shown in Figure 13C, but it also affects the reconstructed OSF. Again,

Fig. 13. Evolution of the reconstructed sunspot numbers (blue curve with $\pm 1\sigma$ grey-shaded uncertainties) for the periods around the corrected events: 994 AD (panel A), 1052 AD (panel B) and 1279 (panel C). The red curve depicts sunspot numbers if no correction is applied. Red arrows indicate the time of the events.

this correction restores the cyclic shape. As can be seen from Figure 13C, this event likely occurred around the maximum phase of a moderate cycle.

Concluding, the new annual dataset makes it possible to correctly reconstruct the overall level and phases of individual cycles of solar activity. Because of uncertainties related to the event removal, we mark the related cycles as non highly reliable. The reconstructed SN cycles are analyzed in Section 4.

4. Solar activity cycles

We have analyzed the annual solar-activity series since 971 AD and identified individual solar cycles as presented in Table 1. A quality flag q was ascribed to each cycle so that it takes values from 0 to 5 as follows: 0 – cycle cannot be reliably identified (29 such cycles were found); 1 – cycle is greatly distorted, at least one of its ends cannot be defined (7 cycles); 2 – cycle can be approximately identified but either its shape or level is distorted (14 cycles); 3 – reasonably defined cycle (10 cycles); 4 – well-defined cycle with somewhat unclear amplitude (19 cycle); 5 – clear cycle in both shape and amplitude (6 cycles).

The series contains 85 full cycles (971–1900) with a mean cycle length of 10.8 years (see Section 4.2).

Table 1. Solar activity cycles as reconstructed here from annually resolved ^{14}C . Columns are: internal cycle number n ; years of minimum Y_{\min} and maximum Y_{\max} of each cycle, and the corresponding cycle-averaged sunspot number $\langle\text{SN}\rangle$ with 1σ uncertainties; cycle length (min-to-min) T in years; quality flag q , and comments. Periods of deep grand minima, when solar cyclic activity drops below the sunspot formation level, are marked in *italic*. Digital version of this Table is available in CDS.

* Transition from grand minimum to normal activity modes.

[†] Standard Schwabe cycles (www.ngdc.noaa.gov/stp/solar/solardataservices.html).

4.1. Activity levels

4.1.1. Distribution of activity levels

The distribution of the cycle-averaged sunspot numbers is shown in Figure 14A, where two clearly separated modes can be observed: the grand-minimum mode with $\langle\text{SN}\rangle < 20$ (well fitted with a Gaussian with the mean $m=1$ and $\sigma=8$), and a normal mode with $m=48$ and $\sigma=31$. The clear separation of the

modes confirms the earlier finding that grand minima form a special mode of solar activity, as discovered by Usoskin et al. (2014) using the INTCAL data for the last three millennia. The distribution of $\langle\text{SN}\rangle$ for the well-defined ($q \geq 4$) cycles can be fitted with a single-mode Gaussian distribution ($m=49$, $\sigma=36$).

For comparison, the distribution of the cycle-averaged $\langle\text{SN}\rangle$ for the direct sunspot number series (ISN v.2, 1750–2019) is shown in Figure 14B. Although the statistics is low (24 full

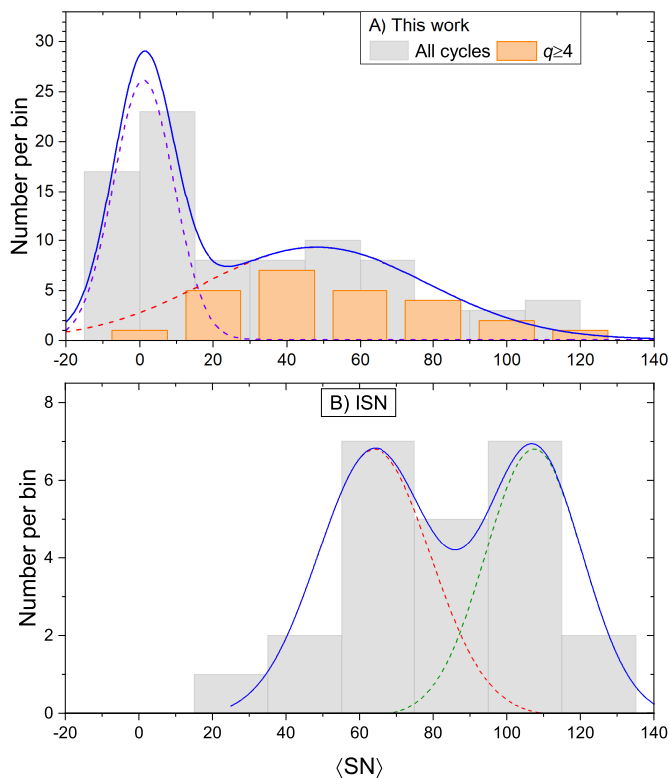

Fig. 14. Distribution of cycle-averaged $\langle \text{SN} \rangle$ sunspot numbers along with fitted bimodal Gaussians. Panel A: Sunspot numbers reconstructed here for 971–1900 (85 full cycles), the two curves are: grand-minimum mode (magenta dashed line, mean $m=1$, $\sigma=8$) and normal mode (red dashed line $m=48$, $\sigma=31$). Orange bars correspond to the well-defined cycle $q \geq 4$ ($m=49$, $\sigma=36$, 25 cycles). Panel B: ISN (v.2) sunspot numbers for 1750–2019 (24 full cycles) and includes two modes: normal one ($m=64$, $\sigma=16$) and grand-maximum one ($m=107$, $\sigma=13$).

cycles), two distinct modes can be found: a normal one ($m=63$ and $\sigma=16$), and the grand-maximum one ($m=107$, $\sigma=13$).

It is important that the distributions of the normal-mode activity, centered at about 50 $\langle \text{SN} \rangle$, cannot be distinguished in a statistical sense (p -value 0.07) for the direct SN observations and the reconstructed one. For the period of direct overlap between the series (1750–1900), the mean reconstructed $\langle \text{SN} \rangle$ value is 62 ± 10 , while it is 77 ± 8 for the ISN (v.2) series, implying that the difference is systematic but insignificant ($p=0.24$). A grand-minimum mode is clear in SN reconstructed here for the last millennium ($\approx 50\%$ of time) but absent in the ISN series, where only a short and shallow Dalton minimum is present. On the other hand, the ISN dataset contains the Modern grand maximum in the second half of the 20th century, while no grand maxima are found for the period 970–1900. A few high cycles can be seen in the reconstructed SN ca. 990, 1200, 1370 and 1790, but the Modern grand maximum is unique in the combination of both the level and length, over the last millennium, in agreement with earlier findings (e.g., Usoskin et al. 2003; Solanki et al. 2004; Usoskin et al. 2007). The very high cycles in the beginning of the series may be related to the not-yet-relaxed carbon-cycle model.

4.1.2. Grand minima

The last millennium was not very typical in solar activity as it covers the low phase of the Halstatt cycle with five Grand solar minima (Oort, Wolf, Spörer, Maunder and Dalton – see Figure 11A) with a total duration of about 430 years (Usoskin et al. 2016; Brehm et al. 2021). Thus, the Sun spent nearly half of the last millennium in the grand minimum mode, while the average fraction is about 17% for a 10000-year period (Usoskin et al. 2007; Inceoglu et al. 2015). Out of these 430 years, about 220 years can be identified as deep-minimum phases when the level of activity drops very low, below the sunspot formation threshold $F_{0 < 2.5 \cdot 10^{14} \text{ Wb}}$: 1300–1330 (Wolf minimum), 1410–1540 (Spörer minimum) and 1650–1710 (Maunder minimum), as marked in Table 1.

The reconstructed mean level of solar activity during the major grand minima is consistent with a SN of zero within the error bars (Figure 11A) for the Wolf, Spörer and Maunder minima, but is of the order of 10 for the shorter and shallower Oort and Dalton minima (in agreement with the direct SN data during the Dalton minimum).

Shapes of individual cycles are poorly defined (quality flag q is low) during the deep phases of the major minima. To check the robustness of the cycle assessment we have performed the following test. We produced 1000 synthetic noise-based series of $Q^{14}\text{C}$ with the statistical distribution (mean 2 and $\sigma = 0.22$, both in units of at/g/cm^2) corresponding to those (Brehm et al. 2021) of the actual dataset during the Spörer minimum (1400–1550). The synthetic series was processed further by applying the same method as described in Section 3, viz. identically to the main reconstruction. One such realization of the SN reconstructed from purely noisy series is shown in Figure 15A as the red curve, along with the main SN reconstruction for the period of the Spörer minimum. It exhibits a seemingly oscillating pattern with a typical length of 3–20 years and an amplitude of 10–20 in SN, some of these oscillations are comparable to the cycles reconstructed from the real data. For each of these 1000 noise-based reconstructions, we computed the FFT (amplitude) spectrum, and then took the upper 95th percentile of them, as shown by the red dotted line in Figure 15B. One can see that the spectrum is nearly flat, with the amplitude being 5–7 in SN. The FFT spectrum of the final reconstructed SN series, based on the real data, for the period of 1400–1550 is shown in black and contains peaks around 8.5, 11 and 13 years. These peaks are significantly higher than the 95% confidence level. The peak at about 9 years is consistent with a result for the Maunder minimum (Vaquero et al. 2015) based on sunspot observation.

Therefore, we conclude that, while the presence of the Schwabe cycle during the Spörer minimum is statistically significant, individual cycles are not robustly defined. Accordingly, we mark all cycles inside the deep grand minima as unreliable (quality flag $q=0$) and exclude them from the cycle length analysis. A similar pattern can be observed in the OSF evolution during a grand minimum (Figure 15C).

Cycles outside the grand minima are defined fairly reliably. However, there are several distorted or merged cycles: ca. 1100, 1360, 1560 and 1720 (see Table 1), which occurred shortly after

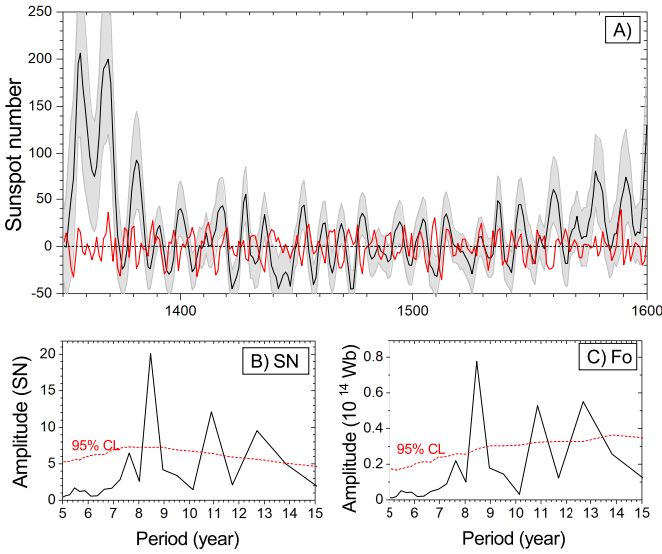

Fig. 15. Reconstructed solar activity around the Spörer minimum. Panel A: The black curve with grey-shaded error bars represents the main reconstruction and is identical to that in Figure 12, while the red curve depicts a reconstruction based on one realization of the simulated noise series (see text). Panel B: FFT spectrum (amplitude) of the main SN reconstruction (shown in Panel A) for the period 1400—1550, while the red dotted line depicts the upper 95th percentile of the FFT spectra of 1000 noise-based reconstructions for the same period (see text). Panel C: The same as panel B but for OSF.

the transition from a grand minimum to normal activity. This may be related to the fact that the relation between the heliospheric modulation of cosmic rays and solar magnetic activity can be inverted during grand minima, as shown observationally for the Maunder minimum (Beer et al. 1998; Usoskin et al. 2001) and proposed theoretically (Owens et al. 2012).

The level of the reconstructed activity is very low, below the sunspot-formation threshold, during the Maunder minimum, in agreement with all other datasets (Vaquero et al. 2015; Usoskin et al. 2015). It is interesting that, according to the new reconstruction, the deep phase of the Maunder minimum extended until about ca. 1710 in agreement with earlier results (Eddy 1976; Usoskin et al. 2015; Vaquero & Trigo 2015) but in contradiction with the formal ISN data series (Figure 11C).

4.1.3. Comparison with direct SN series

Comparison of the SN reconstructed here with other series based on direct sunspot observations is shown in Figure 11. All series were reduced to the ISN(v.2) definition. The lower-bound is represented by the GSN (Hoyt & Schatten 1998), which yields the lowest sunspot numbers among all series, while ISN(v.2) (Clette & Lefèvre 2016) forms the upper bound.

Figure 11A presents a comparison of smoothed (15-yr first SSA component) series. The reconstructed activity lies between the two bounds for the period of 1750–1900. It is closer to the GSN series in the 19th century, while being close to ISN (v.2) in the second half of the 18th century. ISN (v.2) falls $> 1\sigma$

above the reconstructed data around 1830–1870, ca. 1810 and before 1730, while GSN lies $> 1\sigma$ below the reconstructed series between ca. 1730 and 1780. Thus, the reconstructed SN is consistent with both ISN and GSN being somewhat close to the GSN one. The reconstructed SN goes quite low around 1900, probably related to the somewhat uncertain Suess-effect correction.

Figure 11C focuses on the last three centuries. One can see that we correctly reconstruct most of individual solar cycles, at least in the sense of times of their maxima and minima, which agree within ± 2 years with those in the actual sunspot numbers. Exceptions are the periods ca. 1840, when an extra cycle appeared distorting the neighbouring cycles, ca. 1725 when a long, possibly merged cycle appeared, and ca. 1770 when a cycle is distorted by a sudden in drop. The former two distortions may be related to a transition between grand-minimum (Dalton and Maunder minima, respectively) and normal modes of activity, as discussed above, while the latter one is related to a strong jump in ^{14}C production. Thus, out of eighteen cycles during the period 1700–1900, fifteen are reproduced correctly, three are distorted, but the total number of cycles is preserved.

Magnitudes of the cycles vary: while some reconstructed cycles cover the full extent of the directly measured sunspot cycles which drop to close to zero near activity minima, see ca. 1860, some have small magnitude, such as ca. 1790 (consequently the reconstructed series tends to underestimate the true amplitude of the SN series at such times). However, as visible from Figure 11A, the mean level is preserved.

The SN series obtained here does not follow any single SN series in the literature, but shows elements of different ones, being closer to one at some times, but to another at other times. The mean difference between the cycle-averaged SN values reconstructed here and those based on direct solar observations (all series are reduced to the ISN v.2 definition) for the 19th century are: 15 ± 3.2 for ISN (v.2) implying a significant systematic difference (ISN v.2 is systematically higher), -4.8 ± 3.3 for GSN implying that it is systematically lower, and 2.9 ± 3.8 for the series by Chatzistergos et al. (2017) implying their mutual consistency.

We conclude that the method correctly reconstructs the mean level and minimum/maximum dates of individual cycles, but the exact magnitudes of some sunspot cycles may be distorted.

4.2. Cycle lengths

Wavelet power spectrum of the reconstructed sunspot activity is shown in Figure 16A with ‘ridges’ (local maxima of the spectrum for each year) shown as black dots. The reconstructed series has been extended to cover the 20th century with the ISN(v.2) series.

One can see the dominant ≈ 11 -year Schwabe quasi-periodicity visible as the yellow-red ribbon at 8–16 years with several breaks corresponding to grand minima (Oort, Wolf, Spörer and Maunder minima) when the reconstructed cycles have low amplitude and are not reliable. It was proposed earlier that the typical length of the Schwabe cycle tends to in-

crease before/during grand minima (e.g., Fligge et al. 1999; Miyahara et al. 2006a), as based on poorer statistics. We confirm this pattern for the Maunder and Dalton minima but not for other minima (see Figure 16).

Another pronounced periodicity corresponds to the Suess/de Vries cycle of about 210 years, which appears very stable without any significant fluctuation. The 210-year periodicity manifests itself mostly as recurrence of grand minima within a cluster (Usoskin et al. 2007; Usoskin et al. 2016).

The so-called Gleissberg or centennial cycle is visible as a broad pattern at about 120 years, extending to shorter periods during 1700–1800, and being not very stable, in agreement with earlier findings (e.g., Ogurtsov et al. 2002).

A shortcoming of the wavelet analysis is that it yields an estimate of the general variability of the periods and does not provide information on individual cycles. Using dates of the solar cycle minima (Table 1), one can analyse lengths of individual solar cycles as shown in Figure 16B for all resolvable cycles ($q>0$, open circles), well-defined cycles ($q\geq 4$, filled circles) and the directly observed cycles (red stars). The length of individual resolvable cycles ($q>0$) generally agrees (red vs. light blue curves in Figure 16C) with the wavelet-based definition after a 3-point smoothing of the former, that roughly corresponds to the wavelet package extension. This confirms that our minimum-to-minimum cycle length definition is robust, since the wavelet-based definition considers the full variability within the wavelet package, not only minima or maxima.

The distribution of the cycle lengths is shown in Figure 17 along with fitted normal distributions: 10.8 ± 1.9 years for 56 resolvable cycles with $q>0$, (grey bars), 10.8 ± 1.4 years for well-defined cycles ($q\geq 4$, 25 cycles, blue bars), and 11.0 ± 1.1 years for the ISN (23 cycles, orange bars). We have tested the hypothesis of the equality of the cycle length distributions using the z -score test. All the three distributions (outside of the grand minima) cannot be considered as different at any reasonable significance level. Thus, we conclude that the cycle-length distribution of the reconstructed cycles outside deep grand minima is statistically consistent with that for the directly observed solar cycles after 1750.

4.3. Waldmeier rule

The Waldmeier rule states that cycles with faster rising SN are stronger. This rule is built on a statistically significant correlation between the length of the rising phase and the peak height of the cycles (Hathaway 2015; Usoskin et al. 2021). Since the amplitude of the cycle SN_{\max} is not well determined here, we considered a more robust quantity of the cycle-averaged sunspot number $\langle SN \rangle$ from Table 1. The relation between the length of the scending phase $T_{\text{as}} = Y_{\max} - Y_{\min}$ (in years) and $\langle SN \rangle$ for all 85 cycles appears insignificant (Pearson linear correlation coefficient $r\approx 0$). However, when only well-defined cycles (quality flag $q \geq 4$) are considered, the Waldmeier rule appears highly significant ($r = -0.58^{+0.12}_{-0.16}$, p -value=0.001, $N=25$) as

$$\langle SN \rangle = (-26 \pm 16) \cdot T_{\text{as}} + (197 \pm 90),$$

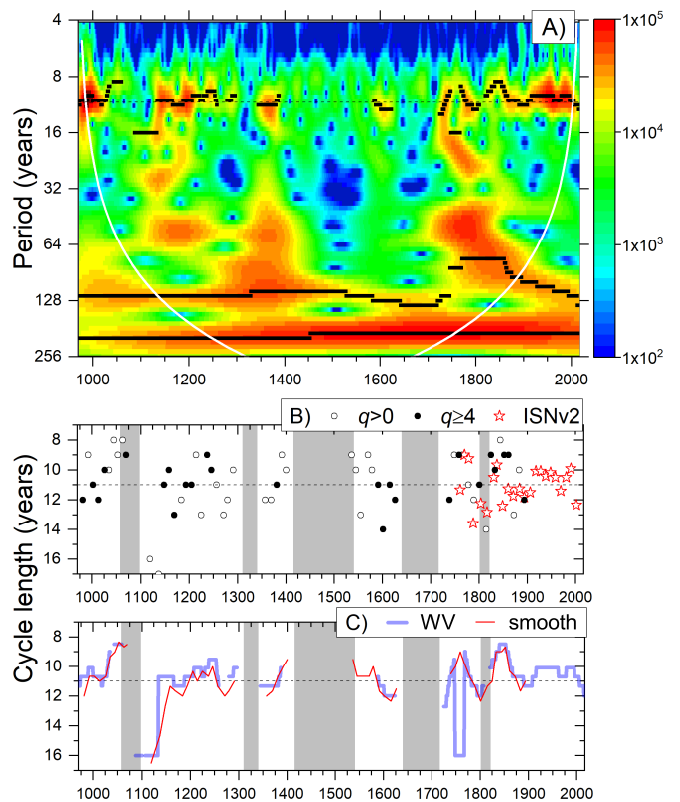

Fig. 16. Panel A: Wavelet power spectrum (Morlet basis, $k = 6$) of the reconstructed SN series, extended by ISN (v.2) after 1900. The white curve bounds the cone of influence (COI) where the spectrum is unreliable because of the proximity to the edges of the series. Black dots denote local maxima of the power ($>10^4$) in the period bands 7–16, 75–140 and 180–250 years. The horizontal dashed line marks the location of the 11-year period. Panel B: Cycle length (minimum-to-minimum) as function of time (assigned to the cycle maximum year) for resolvable ($q>0$, 56 cycles) reconstructed cycles (open dots) and for well-defined cycles ($q\geq 4$, 25 cycles, filled circles). Red stars are the cycle lengths, rounded to the nearest integer (to be reduced to the annual resolution), in the ISN(v.2) series (<http://www.sidc.be/silso/cyclesminmax>) for 1750–2019. The dashed line represents the mean cycle length of 11 years over the ISN series. The grey shading denotes grand minima of solar activity. Panel C: Comparison between the smoothed cycle-length evolution. The red *smooth* curve is the 3-point running mean of the individual cycle lengths ($q>0$). The light blue *WV* curve is the wavelet-defined period (identical to the upper black curve in panel A).

The Waldmeier rule for the direct SN series defined in the same way (i.e., the cycle-mean SN vs. length of the ascending phase rounded to an integer) yields the following relations

$$\begin{aligned} \langle SN \rangle &= (-14.5 \pm 7) \cdot T_{\text{as}} + (150 \pm 35) \\ (r &= -0.67 \pm 0.15, p < 0.001) \text{ for ISN (v.2) and} \\ \langle SN \rangle &= (-12.8 \pm 9) \cdot T_{\text{as}} + (137 \pm 45) \\ (r &= -0.53 \pm 0.15, p = 0.005) \text{ for GSN.} \end{aligned}$$

Thus, we confirm that the Waldmeier rule is valid also on the millennial scale, at least in the sense of the cycle-average

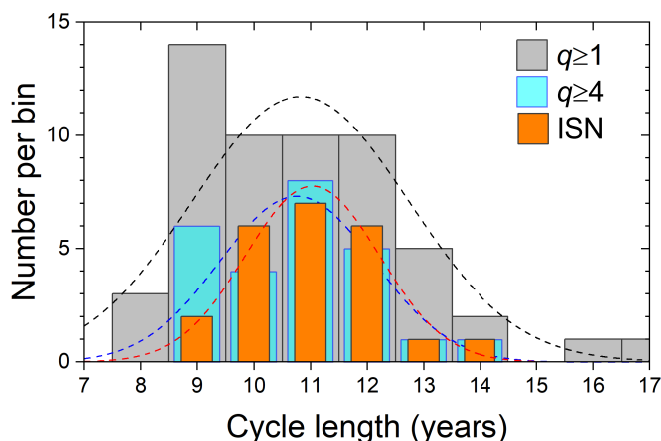

Fig. 17. Distribution of cycle lengths for all resolvable cycles with $q > 0$ (grey bars), well-defined cycles ($q \geq 4$, blue) and ISN (v.2) series (<http://www.sidc.be/silso/cyclesminmax>) for 1750–2019. Dashed lines represent the fitted normal distributions.

SN rather than cycle-peak SN, which is poorly defined in the reconstructed SN timeseries.

5. Summary and Conclusions

A new quantitative reconstruction of annually resolved solar activity, in the form of sunspot numbers (at least outside grand minima) with full uncertainty assessment, is presented for the period 971–1900. For the first time, individual solar cycles are presented for the whole of the last millennium, more than doubling the existing statistics of solar cycles. Overall, 85 solar cycles are reconstructed (the mean length 10.8 ± 1.9 years), of which 25 cycles are well-resolved (the mean cycle length 10.8 ± 1.4 years), 10 cycles are reasonably defined, 21 are poorly defined, and 29 cycles cannot be reliably identified. The unresolvable cycles correspond to the deep-minimum phase of solar activity during grand minima. The periods of low activity were abnormally frequent (about 40% of the time) during the last millennium covering a cluster of four grand minima (Usoskin et al. 2016). The new reconstruction agrees well, within the uncertainties, with the estimates of the sunspot numbers based on direct telescopic observations during the 18th and 19th centuries, in both the mean level and the mean cycle length. This greatly increases the number of the known solar cycles, from 36 cycles known for the period between 1610–2019, including 24 well-defined ones after 1755, 8 poorly resolved and 4 unresolvable cycles around the Maunder minimum, to 96 cycles (971–2019) including 50 well- and reasonably defined cycles, 17 poorly defined cycles, and 29 individually unresolvable cycles for the last millennium.

The grand minima form a separate mode of solar activity with solar activity dropping below the sunspot formation threshold during their deepest phases. The deepest grand minima were the Spörer minimum with the deep phase covering 1410–1540, Maunder minimum (1650–1710) and Wolf minimum (1300–1330), while the shorter Oort and Dalton minima did not drop to such a deep level (cf. Brehm et al. 2021).

A cyclic variation of solar activity was found even during the deep phases of the grand minima, agreeing with and extending earlier results (Beer et al. 1998; Miyahara et al. 2006b; Miyake et al. 2013b), but their significance is low since their magnitude is less than 1σ uncertainty. However, the variation in solar activity at such times was at a level that it produced none or at the most few sunspots.

The new data confirms that the Maunder minimum extended until at least 1710 in agreement with other datasets but in contradiction to the ISN series. It is found that in the record constructed from ^{14}C data distorted cycles appear at the transition phase between grand minima and normal activity, allowing for the possibility that the relation between solar activity and heliospheric modulation of cosmic rays may be different for the two modes (e.g., Owens et al. 2012). Alternatively, at the end of a grand minimum the solar dynamo may behave in ways not treated properly by the model used here to reconstruct SN.

Three sudden increases of ^{14}C production, in 994, 1052 and 1279 AD were removed from the initial dataset before the reconstruction. The fact that this step restores nearly perfectly cyclic solar variability around these dates supports our method of treating these events. The event of 994 AD, the second largest SPE known to date, took place at the early declining phase of a moderately strong solar cycle; the event of 1052 AD corresponded to the maximum phase of a moderate solar cycle; the event of 1279 AD took place at the maximum phase of a moderate solar cycle, but the phase may be affected by the removal procedure.

The validity of the empirical Waldmeier rule (cycles with faster ascending phase tend to be stronger, viz. have greater mean SN) is confirmed at a significant statistical level for well-defined cycles (quality flag $q \geq 4$) but is blurred out when all cycles are considered.

The new, first quantitative sunspot-number reconstruction at the annual time scale with full uncertainties, building on the important work of Brehm et al. (2021) and making use of a significantly improved reconstruction technique, opens up new avenues in solar and solar-terrestrial studies with implications for the solar dynamo (specifically the transition between grand-minimum and normal activity modes), reconstructions of solar irradiance, etc.

The results presented here form a big step forward compared with earlier reconstructions of solar activity, which, with few exceptions (Stuiver & Braziunas 1993; Miyahara et al. 2004; Fogtman-Schulz et al. 2017), have only provided decadal resolution over the last millennium or longer (e.g. Usoskin et al. 2003; Solanki et al. 2004; Vonmoos et al. 2006; Steinhilber et al. 2012; Wu et al. 2018b). The record of individually resolved solar cycles has been nearly tripled (doubled for well-resolved cycles) providing a basis for more precise solar and solar-terrestrial studies extending now over the whole last millennium.
