Synthesizing many-body interaction Hamiltonian is a central task in quantum simulation. However, it is challenging to synthesize interactions including more than two spins. Borrowing tools from quantum optics, we synthesize five-body spin-exchange interaction in a superconducting quantum circuit by simultaneously exciting four independent qubits with time-energy correlated photon quadruples generated from a qudit. During the dynamic evolution of the five-body interaction, a Greenberger-Horne-Zeilinger state is generated in a single step with fidelity estimated to be 0.685. We compare the influence of noise on the three-, four- and five-body interaction as a step toward answering the question on the quantum origin of chiral molecules. We also demonstrate a many-body Mach-Zehnder interferometer which potentially has a Heisenberg-limit sensitivity. This study paves a way for quantum simulation involving many-body interactions and high excited states of quantum circuits.

The synthesis of many-body interaction Hamiltonian plays a vital role in quantum simulation and quantum computing. Most quantum gates [1] rely on two-body interactions, based on which state-of-the-art quantum circuits have been built [2–4] and quantum supremacy has been claimed [2, 4]. However, to exploit the full degree of freedom in simulating emergent many-body physics with superconducting circuits, we need to synthesize arbitrary interaction between qubits [5, 6], although quantum algorithms can partially help [7, 8]. The anti-symmetric spinexchange interaction (Dzyaloshinskii-Moriya interaction) [9, 10] has been synthesized by breaking the time-reversal symmetry through Floquet modulation [11], enabling a three-qubit chiral quantum gate for entangling qubits more efficiently than the two-qubit gates [12]. Similar techniques have been applied to the synthesis of effective gauge field [13] and three-spin chirality Hamiltonian [14], which is a necessary element in simulating chiral spin liquid [15] and promising to realize the topological states of quantized light [16–18]. Four-spin ring-exchange interaction, which has been synthesized in optical lattices of cold atoms [19], is essential for toric codes in topological quantum computing [20]. However, interactions involving more than three spins have never been achieved in superconducting qubits, due to the difficulty in realizing ultrastrong coupling and eliminating lower order interactions [21-26].

Superconducting quantum circuits are a competitive platform for quantum simulation thanks to its remarkable scalability and tunability [27–29]. However, the direct capacitive or inductive coupling between superconducting qubits is limited to two-body interactions [30]. Recently, a quantum optics technique of entangling

non-interacting atoms with time-energy entangled photon pairs [31–33] is implemented in the strong coupling regime of superconducting circuits, realizing a three-body spin-exchange interaction with high fidelity [34]. Here we report the synthesis of five-body spin-exchange interaction with four time-frequency correlated photons in a superconducting circuit. By preparing a qudit in the fourth excited state, time-energy correlated photon quadruples are generated in cascade transitions and coupled to four independent qubits, such that all the four qubits are excited simultaneously while the qudit directly transits from the fourth excited state to the ground state. In this process, five-body spin-exchange interaction is synthe sized for the first time. Apart from the application in quantum simulation, such multi-spin interactions can be used as a nonlinear interferometer in Heisenberg-limit metrology since it generates multi-spin entanglement in a single step. It can also be used to simulate the quantum tunneling between left- and right-handed molecules, which is a step toward answering the question on the origin of chiral molecules.

The experiment is performed in a superconducting circuit where four transmon qubits are symmetrically coupled to a central transmon qudit (see Fig. 1(a)). All the five transmon circuits have a sinusoidal potential well that hosts multiple energy levels [35]. The four surrounding qubits Q_j with j=1 to 4 are used as two-level artificial atoms, while the central qudit Q_0 plays the role of a four-level atom, which generates cascade time-energy correlated photon quadruples. The transition frequency from the ground state $|0\rangle$ to the first excited state $|1\rangle$ of the transmon circuits are tunable from 4 to 6 GHz. The coupling strengths $g_j/2\pi$ between the surrounding qubits

 Q_j and the central qudit Q_0 are around 23 MHz, while those between the surrounding qubits are smaller than 1 MHz (see Supplementary Material [36] for details on the device, operation and readout). The Hamiltonian of the system in the rotating wave approximation is given by (we set $\hbar = 1$),

$$H = \sum_{n=1}^{4} \sum_{k=1}^{n} \nu_{k} |n_{0}\rangle \langle n_{0}| + \sum_{j=1}^{4} \omega_{j} |1_{j}\rangle \langle 1_{j}|$$

$$+ \sum_{n=1}^{4} \sum_{j=1}^{4} \sqrt{n} g_{j} (S_{n}^{+} \sigma_{j}^{-} + \sigma_{j}^{+} S_{n}^{-}),$$

$$(1)$$

where $|n_j\rangle$ is the *n*th (n=0,1,2,...) level of Q_j , $S_n^+ \equiv |n_0\rangle\langle(n-1)_0|$ are the raising operators between the adjacent levels of Q_0 , and $\sigma_j^+ \equiv |1_j\rangle\langle 0_j|$ are the raising operators of the qubit Q_j with S_n^- and σ^- being their corresponding lowering operators, ν_k is the *k*th transition frequency between the energy levels $|k_0\rangle$ and $|(k-1)_0\rangle$ of the qudit Q_0 , and ω_j is the transition frequency of the qubit Q_j .

The five-body spin-exchange interaction Hamiltonian can be realized by carefully arranging the transition frequencies of all qubits such that the four-photon resonance is satisfied, $\sum_{k=1}^4 \nu_k = \sum_{j=1}^4 \omega_j$, while the single photon, two-photon and three-photon resonances are avoided, as shown by the energy level diagram in Fig. 1(b). It is easy to know that when we drive all qubits with uncorrelated photons, even if the four-photon resonance is satisfied, the gubits cannot be simultaneously excited, because all possible quantum paths cancel out (see details in [36]). The key element in our approach is that the gudit emits four photons sequentially with different frequencies ν_4 , ν_3 , ν_2 and ν_1 . The total number of possible quantum paths between the states $|40000\rangle \equiv |4_00_10_20_30_4\rangle$ and $|01111\rangle$ is reduced by a factor of 4! = 24 compared with the case when the qubits are driven by uncorrelated photons. The quantum paths that could have cancelled the remaining 24 paths are removed by the constraint of the time-energy correlation between the four cascaded photons. The resulted effective Hamiltonian is,

$$H_{\text{eff}} = \lambda \Xi_4^- \sigma_1^+ \sigma_2^+ \sigma_3^+ \sigma_4^+ + h.c.,$$
 (2)

where $\Xi_n^- \equiv |0_0\rangle\langle n_0|$ is the lowering operator of the qudit from the *n*th excited state to the ground state, and λ is the effective coupling strength.

The controlling sequence diagram for the dynamics of $H_{\rm eff}$ is sketched in Fig. 2(a). We prepare the qubits in the initial state $|\Psi(0)\rangle = |01111\rangle$ at their idle frequencies. Then the four qubits are quickly biased to their interaction frequencies ω_j . After an interaction time τ , we bring the qubits to their readout frequencies for measurement. The detailed values of transition frequencies for qubit initialization and readout can be found in [36]. The results of the joint measurement of the wave function

FIG. 1. (a) Device image illustrating the five frequency-tunable transmon circuits labeled from Q_0 to Q_4 , with Q_0 surrounded by Q_1 to Q_4 . Due to the nonlinear Josephson inductance, the energy potential of transmons is sinusoidal (black line in the right panel), which allows us to isolate the m lowest energy levels (colored lines in the right panel) as a qubit (Q_1 to Q_4 with m=2) or qudit (Q_0 with m=5). Each circuit Q_j has its own flux bias line Z_j for fast frequency tuning, microwave line XY_j for SU(2) spin rotation, and readout resonator RR_j that couples to a common transmission line TL for dispersive readout of Q_j 's state. The dots are bumps for the flip-chip process. (b) Energy configurations of the qudit and four qubits for 5-body interaction.

(30001)

 $|\Psi(\tau)\rangle = c_1(\tau)|01111\rangle + c_2(\tau)|40000\rangle$, ignoring the insignificant terms, are shown in Fig. 2(b), where the experimentally obtained probabilities of $|c_1(\tau)|^2$ and $|c_2(\tau)|^2$ (colored dots with errorbars) are plotted in comparison with the numerical simulation (colored lines) obtained from the original Hamiltonian in Eq. (1). The Rabi oscillation between the two states is observed as expected. In the numerical simulation, we use the Lindblad master equation with the experimentally measured energy relaxation time $T_{1,j}$ and empirical pure dephasing time $T_{\varphi,j}$ ($\approx 6T_{2,j}^*$ where $T_{2,j}^*$ is the experimentally measured Ramsey Gaussian dephasing time) to capture the impact of decoherence [37, 38]. The values of $T_{1,j}$, $T_{2,j}^*$ are found in [36].

The interaction strength of the five-body spin-exchange interaction is estimated to be $\lambda/2\pi\approx0.8$ MHz, which is strong relative to the decoherence time and allows the generation of a five-spin Greenberger-Horne-Zeilinger (GHZ) state in a single step. At $\tau=170$ ns, the

(a) Sequence diagram for observing the system's FIG. 2. dynamic evolution. After preparing the system to the initial state $|01111\rangle$ by applying X_{π} rotation (a π rotation around x axis) to Q_1 to Q_4 , we quickly tune the transition frequencies of each qubit to activate the 5-body interaction. After a specific time τ , the occupational probabilities of the system for different computational state are measured. (b) The experimentally measured occupational probabilities of $|c_1(\tau)|^2$ for $|01111\rangle$ (blue dots) and $|c_2(\tau)|^2$ for $|40000\rangle$ (red dots) for different interaction times τ . Error bars represent statistical errors. Lines are the results obtained by numerical simulation, where 5 and 3 levels are considered for Q_0 and other qubits respectively. (c) The effect of noise on the evolution under the m-body spin-exchange Hamiltonian. The low-frequency noise is simulated by a random detuning between the two states in the interaction.

state evolves to $|\Psi\rangle=(|01111\rangle+e^{i\phi}|40000\rangle)/\sqrt{2}$ with ϕ being a trivial dynamical phase. The measured fidelity of the experimental data is estimated to be 0.685 ± 0.022 by directly measuring the four non-zero elements of the density matrix from the many-body interference, which is consistent with the lower bound obtained by quantum state tomography (see Supplementary Material [36])

and satisfies the criterion of global entanglement. In the traditional Sørensen-Mølmer approach [39] of single-step generation of GHZ state of N qubits, all the N+1 states in the symmetric subspace are involved, while in our approach only the two relevant states are involved, such that we can simulate the quantum tunneling between the left- and right-handed molecules.

Since early days of quantum mechanics, the origin of chiral molecules has puzzled generations of physicists [40– 45]. In particular, Hund argued that the parity operator commutes with the electromagnetic interaction Hamiltonian, which is responsible for the formation of molecules. Therefore, the eigenstates of molecules shall be eigenstates of the parity operator, i.e., a superposition of the left- and right-handed molecular states. As a consequence, chiral molecules are not in their eigenstates and shall not be stable. However, in real world chiral molecules are ubiquitous and stable, while a superposition of two chiral molecules is considered to be a Schrödinger cate state, which is unnatural and generally hard to realize. This contradiction between the quantum mechanical prediction and reality is called the Hund paradox [40].

To resolve the paradox, an argument is that the leftand right-handed molecules reside in two energy valleys and the tunneling strength between them is so small that it takes days (and even lifetime of the universe) for large chiral molecules to tunnel from one configuration to the other. During this process environmental noises induce decoherence and hinder the tunneling, which is similar to the quantum Zeno effect [44]. The two quantum states involved in the five-body interaction can be used to simulate the tunneling between the left- and right-handed molecular states, such that the effect of environmental noises can be investigated toward the question on the stablization of chiral molecules.

As a step in this direction, we simulate the suppressed tunneling between two chiral molecules due to the slow environmental noises, which can also be considered as a random potential difference between the two chiral molecules. To demonstrate this, we artificially inject arbitrary flux noises to the system during the five-body interaction. Each circuit Q_i is offset from its interaction frequency by a small amount of $\delta_{j,k}$, which is randomly chosen in a range of $[-\Delta_j, \Delta_j]$ but fixed for the kth pulse sequence. In the experiment, the noise strength $\Delta_0/2\pi \approx 5$ MHz for Q_0 between the transition from the state $|0_0\rangle$ to $|4_0\rangle$. The noise range $\Delta_j/2\pi$ is set to be about 5 MHz for all other qubits Q_i . Assuming that the noise is slow, an ensemble of 20 pulse sequences are applied to emulate the random white noise that shifts the energy of Q_j . For each sequence, we record the probabilities of the two states as a function of time. We average over 20 traces and find that the oscillation between the two states vanishes, as shown in Fig. 2(c). By exciting Q_0 to the second or third excited state and coupling

FIG. 3. (a) Sequence diagram for detecting magnetic field leveraging the m-body interaction, with m=5 here as an example. The magnetic field is synthesized by applying to each transmon circuit a square Z pulse to offset its transition frequency between states $|0\rangle$ and $|m-1\rangle$ ($|1\rangle$) for Q_0 (other qubits) by an amount of $-\Delta_B$ (Δ_B) for a time τ_B . The dynamical phase accumulated during this process can be detected by sandwiching itself between two m-body interaction operations with a fixed time $\tau_{\rm I} \sim 2\pi/8\lambda_m$. (b) The experimentally measured occupational probabilities of $|c_1(\tau_B)|^2$ (blue dots) and $|c_2(\tau_B)|^2$ (red dots) for different time τ_B . Lines are the fitting results. The fitted oscillation frequencies for m=3,4,5 are 14.9, 19.5 and 24.2 MHz respectively, agreeing well with the ratio of 3:4:5.

it to two or three qubits, we synthesize the three- or four-body spin-exchange Hamiltonian, $\lambda_3\Xi_2^-\sigma_1^+\sigma_2^++h.c.$ or $\lambda_4\Xi_3^-\sigma_1^+\sigma_2^+\sigma_3^++h.c.$, where $\lambda_3/2\pi\approx 2.25$ MHz and $\lambda_4/2\pi\approx 2.29$ MHz are the interaction strengths. The same noise strength has a smaller effect on the four- and three-body interaction, resulting from a larger interaction strength and a weaker noise-induced decoherence effect. The oscillation between the two states are still visible, although partially smeared by the noise, as shown in Fig. 2(c).

The many-body spin-exchange Hamiltonian can be used to build a Mach-Zehnder interferometer that has a Heisenberg-limit sensitivity [46]. In the m-body interferometer, we introduce an energy-splitting Hamiltonian $B_z(\sum_{j=1}^{m-1}\sigma_j^z-\Xi_{m-1}^z)$ where $\Xi_m^z\equiv |m_0\rangle\langle m_0|-|0_0\rangle\langle 0_0|$ and B_z is an artificial magnetic field. The dynamic phase induced by this Hamiltonian can be detected as follows. We first prepare the state $|0\rangle\otimes|1\rangle^{\otimes(m-1)}$ and then acti-

vate the m-body interaction for a fixed time $\tau_{\rm I} \sim 2\pi/8\lambda_m$ to steer the system to the GHZ state. In the experiment, $\tau_{\rm I}$ is slightly adjusted for an optimized GHZ state fidelity and set to be 60 ns (55 ns, 170 ns) for m = 3 (4, 5). Then we apply local magnetic field on each spin-1/2 particle, which is synthesized by applying a square Z pulse to each transmon circuit for a specific time τ_B and with a strength of $-\Delta_B$ (between states $|0\rangle$ and $|m-1\rangle$) for Q_0 and Δ_B for other qubits. $\Delta_B/2\pi$ is fixed to be around 5 MHz in the experiment. After activating the m-body interaction again for a time $\tau_{\rm I}$, we measure the occupational probabilities of $|c_1(\tau_B)|^2$ for $|0\rangle \otimes |1\rangle^{\otimes (m-1)}$ and $|c_2(\tau_B)|^2$ for $|m-1\rangle \otimes |0\rangle^{\otimes (m-1)}$. The controlling sequence for a 5-body interferometer is shown in Fig 3(a). The data is shown in Fig. 3(b). The oscillation frequency scales linearly with m. Although the sensitivity is not enhanced to the Heisenberg limit due to a lowered visibility of the oscillation for larger m, we note that the oscillation amplitude infers the off-diagonal term ρ_{off} of the GHZ state by $|c_1(\tau_B)|^2 = -|\rho_{\text{off}}|\cos(2\pi m\Delta_B \tau_B) + \text{const}$, which dramatically reduce the number of quantum operations required to benchmark the GHZ state fidelity compared with the traditional tomography method. We note that the GHZ state obtained from the all-to-all spin interaction can also be used to build a Heisenberg interferometer [47]. However, in that case all states in the symmetric subspace are involved and the approach is more prone to noise compared with the current approach, which only involves two states.

Conclusion. —We propose a method to synthesize multi-body interaction in a superconducting superconducting quantum circuit. We experimentally realized m-body interactions with m up to 5 and investigated the effect of noise on the many-body interactions, which is a step toward finding the quantum origin of chiral molecules. We further built a many-body interferometer and the linear m-scaling oscillation frequency of the interference pattern was demonstrated, which is promising for achieving Heisenberg-limited sensitivity. We demonstrated that the fidelity of the GHZ state obtained from such an interferometer has an enhanced precision compared with the conventional tomography method.
