### ABSTRACT

We present a spectral analysis of *NuSTAR* and *NICER* observations of the luminous, persistently accreting neutron star (NS) low-mass X-ray binary Cygnus X-2. The data were divided into different branches that the source traces out on the Z-track of the X-ray color-color diagram; namely the horizontal branch, normal branch, and the vertex between the two. The X-ray continuum spectrum was modeled in two different ways that produced a comparable quality fit. The spectra showed clear evidence of a reflection component in the form of a broadened Fe K line, as well as a lower energy emission feature near 1 keV likely due to an ionized plasma located far from the innermost accretion disk. We account for the reflection spectrum with two independent models (RELXILLNS and RDBLUR\*RFXCONV). The inferred inclination is in agreement with earlier estimates from optical observations of ellipsoidal light curve modeling (RELXILLNS:  $i = 67^{\circ} \pm 4^{\circ}$ , RDBLUR\*RFXCONV:  $i = 60^{\circ} \pm 10^{\circ}$ ). The inner disk radius remains close to the NS ( $R_{in} \le 1.15 R_{ISCO}$ ) regardless of the source position along the Z-track or how the 1 keV feature is modeled. Given the optically determined NS mass of  $1.71 \pm 0.21 M_{\odot}$ , this corresponds to a conservative upper limit of  $R_{in} \le 19.5$  km for  $M = 1.92 M_{\odot}$  or  $R_{in} \le 15.3$  km for  $M = 1.5 M_{\odot}$ . We compare these radius constraints to those obtained from NS gravitational wave merger events and recent *NICER* pulsar light curve modeling measurements.

Keywords: X-ray binary - star: neutron (Cygnus X-2)

#### 1. INTRODUCTION

Measuring neutron star masses and radii remains crucial for determining the equation of state (EoS) of ultradense, cold matter (Lattimer & Prakash 2001). Numerous observational methods have been developed for obtaining NS mass and/or radius (Özel & Freire 2016) in order to narrow down the allowed region on the mass-radius (M-R) plane and rule out theoretical models. Notably, there have been enticing breakthroughs made via measuring the tidal deformability of NSs from the gravitational wave signature during NS-NS binaries merger events (e.g., GW170817: Abbott et al. 2019), as well as determining the compactness of millisecond pul-

sars through light curve modeling of modulations from hot spots on the NS surface as they rotate into and out of our line of sight (e.g., PSR J0030: Riley et al. 2019; Miller et al. 2019).

An additional method of independently determining NS radii can be obtained from modeling the reprocessed emission from the innermost accretion disk that has been externally illuminated. This is commonly referred to as the 'reflection' spectrum which has a series of narrow emission lines superimposed on a reprocessed continuum. Emission from the inner disk region (most prominently seen in the Fe K line) is broadened due to Doppler, general, and special relativistic effects (Fabian et al. 1989, 2000) which allows for a measurement of the position of the inner edge of the disk. Since the accretion disk must truncate at or prior to the NS surface, determining the inner disk radius provides a limit on the radius of the NS (Cackett et al. 2008; Ludlam et al. 2017a).

Table 1. Cyg X-2 Observation Information

Obs #	Mission	Sequence ID	Obs. Start Date	Exp. (ks)
1	NuSTAR	30001141002	2015-01-07 03:16:07	$\sim 23.7$
2	NuSTAR	80511301002	2019-09-10 13:06:09	$\sim 11.3$
	NICER	2631010101	2019-09-10 12:58:20	$\sim 12.7$
3	NuSTAR	80511301004	2019-09-12 02:06:09	$\sim 12.7$
	NICER	2631010201	2019-09-12 02:09:44	$\sim 12.1$

One system that has potential for demonstrating the power of NS reflection studies is the luminous, persistently accreting low-mass X-ray binary (LMXB) Cygnus X-2 (Cyg X-2), especially since it has an optically determined mass. The source was first observed in the X-rays via a sounding rocket in the 1960s (Byram et al. 1966). Cyg X-2 was tentatively classified as an NS when a weak X-ray burst was observed with the Einstein Observatory (Khan & Grindlay 1984) and later confirmed when RXTE observed a Type-I X-ray burst while the source was in a high-intensity state (Smale 1998). Cyg X-2 is classified as a 'Z' source based on the tracks traced out in hardness and color-color diagrams (Hasinger & van der Klis 1989). However, the exact shape and location on these diagrams varies depending on the overall intensity level (Kuulkers et al. 1996; Wijnands et al. 1997; Fridriksson et al. 2015), which can vary by a factor of  $\sim 4$  (Wijnands & van der Klis 2001). The neutral hydrogen column density along the line of sight is low ( $N_{\rm H} \sim 2 \times 10^{21} {\rm ~cm^{-2}}$ : HI4PI Collaboration et al. 2016) with the abundance of oxygen being slightly supersolar ( $A_{\rm O}/A_{\odot} = 1.1$ : Psaradaki et al. 2020).

Due to the low column density, the source has been observed extensively in the optical as well. The stellar companion is an evolved, late-type A9III star in a 9.8444  $\pm$  0.0003 day orbit (Casares et al. 1998). From modeling of ellipsoidal light curves, the mass function of the system was estimated as  $f(M) = 0.66 \pm 0.03 M_{\odot}$  (Casares et al. 2010), which leads to an estimate of the NS mass of  $1.71 \pm 0.21 M_{\odot}$  for an inclination of  $62.5^{\circ} \pm 4^{\circ}$  (Orosz & Kuulkers 1999). Cyg X-2 is estimated to be located at a distance of 8 - 11 kpc (Cowley et al. 1979; Smale 1998), though optical observations tend toward the lower end of this ( $7.2 \pm 1.1$  kpc: Orosz & Kuulkers 1999). More recently, Ding et al. (2021) estimated a distance of  $11.3^{+0.9}_{-0.8}$  kpc using a Bayesian inference approach that utilized information from Gaia Early Data Release 3 and photospheric radius expansion bursts.

Due to the luminous and persistent nature of the source, the spectral properties have been studied considerably. The source spectrum is known to show a broad Fe line feature near 6.7 keV (Smale et al. 1993; Di Salvo et al. 2002; Shaposhnikov et al. 2009; Cackett et al. 2010; Mondal et al. 2018) due to reflection from the accretion disk, as well an emission line near 1 keV (Vrtilek et al. 1986; Chiappetti et al. 1990; Smale et al. 1993; Kuulkers et al. 1997; Di Salvo et al. 2002; Farinelli et al. 2009; Cackett et al. 2010) that likely originates from collisionally excited or photoionized material further out in the disk (Vrtilek et al. 1986). The source traces out the horizontal, normal, and flaring branches of the 'Z' with periods of irregular dipping activity while flaring; suggesting the presence of an extended accretion disk corona (ADC) during high intensity states (Vrtilek et al. 1988; Schulz et al. 2009; Bałucińska-Church et al. 2010, 2011). A detailed broadband spectral analysis of Cyg X-2 with *BeppoSAX* while the source was in the horizontal and normal branches was reported in Di Salvo et al. (2002). The continuum modeling suggested that the inner accretion disk moved closer to the NS as the inferred mass accretion rate increased as the source transitioned from the horizontal to the normal branch, but a full treatment of the reflection spectrum was not conducted.

Reflection modeling of Suzaku observations was performed in Cackett et al. (2010) using a DISKLINE component and blackbody reflection model (BBREFL) to obtain inner disk radius and inclination constraints. The disk was inferred to be close to the NS at  $R_{\rm in} \simeq 7.6 - 8.5 R_g$  (where  $R_g = GM/c^2$ ) when using single DISKLINE component and  $R_{\rm in} \simeq 6 - 14 R_g$  when using the full reflection model. Mondal et al. (2018) recently analyzed a NuSTAR observation of Cyg X-2 in the normal branch and flaring/dipping state. The reflection component is modeled with a different blackbody reflection model known as REFLIONXBB and the disk was inferred to be far from the NS at  $R_{in} \simeq 13.5 - 32.4 R_q$ in the non-dipping state. The inferred inclination in both of these studies ( $i \leq 25^{\circ}$ ), however, are at odds with the inclination measured from optical observations. This may be due to the thickness of the disk in the outer regions being able to partially obscure the blue-winged emission of the Fe K line (Taylor & Reynolds 2018).

Here we analyze the existing NuSTAR observations of Cyg X-2 while the source is in a non-dipping state in order to carefully obtain radius constraints from reflection modeling. Though one *NuSTAR* observation was reported on in Mondal et al. (2018), two additional *NuSTAR* observations were performed simultaneously with *NICER*. Hence we present the results of joint *NICER* and *NuSTAR* spectral modeling. The organization of the paper is as follows: §2 presents the observations and data reduction methodology, §3 reports the spectral modeling and results, §4 discusses the results and compares them to the current best constraints on NS mass and radius, §5 then provides the conclusion.

# 2. OBSERVATIONS AND DATA REDUCTION

**Figure 1.** *Left:* The NuSTAR hardness ratio (HR) versus the 3 - 20 keV intensity. The shape of the symbols indicate the observation. The variation in coloring and shading between symbols indicate the spectral state where solid is the normal branch (NB), top half filled is the vertex (VX), left half filled is the horizontal branch (HB), and open indicates when the source dipping or in the flaring branch (Dip/FB). *Right:* The top row shows the *NuSTAR* the 3 - 20 keV light-curve of Cyg X-2 for (a) Obs1, (b) Obs2, and (c) Obs3. The lower panels show the hardness ratio (HR) during the observations. The color/shading of the symbols are coded based on the HID. Data were binned to 128 s.

**Figure 2.** The light curves of the simultaneous NuSTAR and NICER observations of Cyg X-2 for Obs2 (upper panel) and Obs3 (lower panel). Data were binned to 128 s.

NuSTAR has observed Cyg X-2 on three occasions. The sequence IDs, observation dates, and exposure time are given in Table 1. All data were reduced using CALDB v.20210427 and 'nupipeline' with 'statusexpr"STATUS==b0000xxx00xxx000" due to the source brightness having an excess of 100 counts  $s^{-1}$ . The background filtering report for Obs1 indicated periods of high background, hence we applied "saacalc=3 saamode=optimized tentacle=yes". Source regions of 100" radii centered on the source and a background region of same size but sufficiently far from the source were used for spectra and light curve extraction. The light curves were inspected for Type-I X-ray bursts, but none were present. The hardness ratio (HR: 10 - 16 keV/6.4 - 10 keV) versus 3 - 20 keVintensity, known as the hardness-intensity diagram (HID), is shown in Figure 1, as well as the light curves and hardness ratio versus time for each NuSTAR observation. The observations trace out the flaring to the horizontal branch in the HID and shows shifts in the overall intensity between the 2015 and 2019 observations.

*NICER* observed the source simultaneous with *NuSTAR* during Obs2 and Obs3. Information for each sequence ID is given in Table 1. Data were reduced and calibrated using the standard 'nicerl2' command and CALDB version 20200722. Additionally, the data were filtered to select for KP < 5 and COR\_SAX > 4 to mitigate the particle background at low-energies. The simultaneous light curves for these observations are shown in Figure 2, where the zero point indicates the start of the *NICER* observation for Obs2 and the beginning of the *NuSTAR* observation for Obs3. No Type-I X-ray bursts were present in the *NICER* data.

The *NuSTAR* and *NICER* data were divided into the different branches within each observation using good time intervals (GTIs) based on the HID and light curves shown in Fig-

 $^{a}$  = tied between all branches,  $^{b}$  = tied between NICER spectra

Note.— Errors are reported at the 90% confidence level. *NICER* is fit in the 0.5 - 10 keV energy band while *NuSTAR* is fit in the 3 - 30 keV band. A multiplicative constant is used on the *NICER* and FPMB data, while FPMA is fixed to unity. The input seed photon type in NTHCOMP is set to a single temperature blackbody (inp\_type=0). The BBODY normalization is defined as  $(L/10^{39} \text{ erg s}^{-1})/(D/10 \text{ kpc})^2$ . The DISKBB normalization is defined as  $(R_{in}/\text{km})^2/(D/10 \text{ kpc})^2 \times \cos \theta$ . The power-law normalization is defined as photons keV<sup>-1</sup> cm<sup>-2</sup> s<sup>-1</sup> at 1 keV. The unabsorbed 0.5 - 50 keV flux,  $F_{\text{unabs, } 0.5-50 \text{ keV}}$ , is given in units of  $10^{-8}$  ergs s<sup>-1</sup> cm<sup>-2</sup>.

ures 1 and 2. The source went through the normal to extended flaring branch in Obs1 while in the high intensity state as reported in Mondal et al. (2018). We divide the data in a similar manner by separating the non-dip emission from the dipping by creating GTIs that divide the observation at t = 45 ks. Obs2 and Obs3 occurred while the source was in a lower intensity state. Obs2 traced out the upper normal branch (NB), vertex (VX), and horizontal branch (HB). The HB occurred from t < 7.5 ks, NB from t = 21.5 - 27.5 ks, and the VX from t = 7.5 - 21.5 ks and t > 27.5 ks. Obs3 occurred as the source was exiting a dipping period. Therefore, the first 5 ks were removed. The remaining data were divided between the NB (t = 5 - 10 ks) and HB (t > 10 ks). These GTIs were applied to the NuSTAR data through 'nuproducts' to extract spectra while the data were in the NB, HB, and VX. The NICER data were divided into these different branches by converting the NuSTAR GTIs into NICER mission elapsed time (MET) and then extracting the corresponding events through 'niextractevents'. Source and background spectra for NICER data were created using the '3C50' tool<sup>1</sup> (Remillard et al. 2021).

# 3. SPECTRAL MODELING AND RESULTS

We utilize XSPEC v12.11.1 to model all spectra simultaneously. To account for the cross calibration difference between NICER and NuSTAR, we use the CRABCORR multiplicative model (a.k.a. JSCRAB; Steiner et al. 2010). This model has two parameters: 1.)  $\Delta\Gamma$  that multiplies the spectrum by a power law difference  $(E^{-\Delta\Gamma})$  and 2.) a normalization, C, that serves in the same capacity as a multiplicative constant.  $\Delta\Gamma$  is set to 0 for the *NuSTAR* spectra and allowed to float for the NICER. Although the value of  $\Delta\Gamma$  is small, it is important to account for unavoidable mission-specific calibration differences that emerge when the Crab is observed. The multiplicative constant was allowed to vary for the FPMB and NICER while the FPMA was fixed at unity. The absorption column along the line of sight was modeled with TBFEO with abundances set to WILM (Wilms et al. 2000) and VERN (Verner et al. 1996) cross-sections. The column density,  $N_{\rm H}$ , and abundance of oxygen,  $A_{\rm O}$ , were allowed to vary but tied between all spectra regardless of spectral state. Errors are reported at the 90% confidence level from Markov Chain Monte Carlo (MCMC) with 50 walkers, a burn-in of  $1 \times 10^6$ , and chain length of  $5 \times 10^4$ .

<sup>&</sup>lt;sup>1</sup> https://heasarc.gsfc.nasa.gov/docs/nicer/tools/nicer\_bkg\_est\_tools.html

**Figure 3.** Ratio of the data to the models reported in Tables 2-4, where panels correspond to (a) C1, (b) C2, (c) RNS1, (d) RFX1, (e) RNS2, (f) RFX2, (g) RNS3, and (h) RFX3. Blue indicates the NB from Obs1, maroon is the VX from Obs2, and orange is the HB from Obs3. Data were rebinned for plotting purposes. Panels (i) and (j) show the unfolded spectra and model components for RNS3 and RFX3, respectively. The dot-dashed line is the disk component, dotted line is the power law component, dashed line is the collisional plasma, and the solid line indicates the reflection model with the corresponding illuminating component included.

In the interest of obtaining robust constraints on the inner disk radius, we focus on modeling the non-dipping spectra that have  $\geq 10^6$  cumulative counts per spectrum. This corresponds to the *NuSTAR* spectra of Obs1 in the NB, *NICER* and *NuSTAR* spectra of Obs2 in the VX, and *NICER* and *NuSTAR* spectra of Obs3 in the HB. These will be referred to by their branch nomenclature in Tables 2 – 4. We model the continuum with the phenomenological three component model of Lin et al. (2007). This model is comprised of a multi-temperature blackbody to account for the thermal disk emission (DISKBB: Mitsuda et al. 1994), a single temperature blackbody (BBODY) for emission from the NS surface or boundary layer region, and a power law (POW) component to model weak Comptonization. This continuum model is referred to as "C1" in Table 2. The ratio of the model to the data are shown in Figure 3(a). Additionally, we swap out the power law and single-temperature blackbody component for a more physical Comptonization model, NTHCOMP (Zdziarski et al. 1996; Zycki et al. 1999). Parameter values can be found in Table 2 under "C2" and the ratio of the model to the data are shown in Figure 3(b). The fits are of comparable statistical quality, though C1 provides a slightly better fit. The spectral parameters for the NB are relatively consistent with those reported in Mondal et al. (2018), but it is important to note that differences likely arise from the bright source flag being utilized when we reduced the *NuSTAR* data.

**Figure 4.** Ratio of the data in the Fe K band to the continuum model C1 for the (a) NB, (b) VX, and (c) HB. Only one *NuSTAR* FPM is shown for clarity. Data were rebinned for plotting purposes.

There is clear evidence of a broadened Fe K line component in all spectra regardless of continuum model. Figure 4 shows the Fe line profile in each respective branch. Additionally, there is an emission line present in the *NICER* spectra at lower-energy ( $\sim 1 \text{ keV}$ ). As mentioned in the introduction, this feature has been reported previously with other X-ray missions.

We model the reflected emission in two separate ways corresponding to the input continuum. Starting from C1, we utilize the variation of RELXILL (García et al. 2014) known as RELXILLNS to account for reprocessed emission due to an illuminating blackbody component,  $kT_{bb}$ . The model parameters are as follows: an inner emissivity index  $(q_{in})$ , outer emissivity index  $(q_{out})$ , the break radius  $(R_{break})$  between the two emissivity indices, dimensionless spin parameter (a), redshift (z), inclination of the system (i), inner disk radius  $(R_{\rm in})$  in units of the innermost stable circular orbit (ISCO), outer disk radius  $(R_{out})$  in units of gravitational radii  $(R_q)$ , ionization parameter (log( $\xi$ )), disk density (log(N[cm<sup>-3</sup>])), iron abundance  $(A_{Fe})$ , and reflection fraction  $(f_{refl})$ . We tie the inner and outer emissivity indices to create a single emissivity profile, q, and therefore  $R_{break}$  becomes irrelevant. Cyg X-2 is a Galactic source so we fix the redshift parameter to z = 0. The outer disk radius is set at 1000  $R_q$  and

the spin parameter is fixed at a = 0. The choice of spin parameter is motivated by most NSs in LMXBs having  $a \leq 0.3$  (Galloway et. al. 2008; Miller et al. 2011) and the difference in the position of  $R_{\rm ISCO}$  between these two values being less than 1  $R_g$  (Ludlam et al. 2018). The reflection fraction,  $f_{refl}$ , is bound to positive values so that the RELXILLNS model encompasses both the illuminating blackbody from the continuum and reprocessed reflection emission component. These model fits are reported in Table 3 under "RNS1".

Conversely, when starting from C2 we use the reflection convolution model RFXCONV (Done & Gierlínski 2006) with the relativistic blurring kernal RDBLUR (Fabian et al. 1989) to emulate reprocessed emission from a Comptonization blackbody with general and special relativistic effects around a non-spinning compact object (i.e., a = 0). We choose RDBLUR so that this overall model and RNS1 are completely independent of each other. RFXCONV generates an angle-dependent reflection spectrum from the NTH-COMP input spectrum it is convolved with by combining the Compton reflected emission from PEXRIV (Magdziarz & Zdziarski 1995) above 14 keV (using the average 12–14 keV power-law index) with reflection emission from an ionized disk interpolated from REFLIONX (Ross & Fabian 2005) below 14 keV (using the average 2 - 10 keV power-law index). The reflected emission interpolated from REFLIONX and PEXRIV are scaled to match at 14 keV. The parameters of this convolution model are the relative reflection normalization ( $rel_{refl}$ ), the Fe abundance ( $A_{Fe}$ ), the inclination angle  $(\cos(i))$ , redshift (z), and ionization parameter  $(\log(\xi))$ . The parameters of the relativistic blurring kernal RDBLUR are the emissivity index (Betor 10:  $R^{Betor 10}$ ), inner disk radius in  $R_q$ , outer disk radius, and inclination (i). The outer disk radius is fixed at 1000  $R_q$  to be consistent with RELXILLNS and the inclination parameters are tied between RDBLUR and RFXCONV for consistency. We report the parameter values for this fit in Table 4 under "RFX1".

The 1 keV feature is still present in the spectrum regardless of the reflection model utilized (see Figure 3 panels (c) and (d)). We proceed to model the 1 keV feature in the NICER data with a Gaussian emission line (GAUSS) to determine the line centroid energy and equivalent width. These fits are reported as "RNS2" and "RFX2" in Table 3 and 4 while the ratio of the overall model to the data are shown in Figure 3(e)and (f), respectively. The addition of the Gaussian line improved the fit by  $8.2\sigma$  when using RELXILLNS, but provides a marginal 2.5 $\sigma$  improvement from RFX1 to RFX2. We note that the seed photon temperature of the Comptonization model tends to an unphysically low value ( $kT_{bb} \leq 8 \text{ eV}$ ) in the VX branch with the addition of the Gaussian line, therefore we fix this parameter to the median value from RFX1. This was not an issue in the HB due to the NICER spectrum containing  $4.8 \times 10^6$  more counts than in the VX. All parameter values are consistent within the 90% confidence level when  $kT_{bb}$  is left free or fixed, hence this parameter does not have a notable impact on the results. Although the feature is present regardless of continuum and reflection modeling, the inferred equivalent width is smaller in RFX2 which may be

Table 5. Radial Estimates from Spectral Modeling

Note.— All values are given in units of km. The inner disk radius from reflection modeling was converted into km assuming a NS mass of  $M_{\rm NS} = 1.71 \pm 0.21 \ M_{\odot}$  (and  $a_* = 0$  in the case of values taken from Table 3). Estimates encompass the entire reported distance range to the source  $(9.15 \pm 3.05 \text{ kpc})$ . A color correction factor of  $f_{cor} = 1.7$  (Shimura & Takahara 1995) was used when converting the normalization of DISKBB and BBODY components into their emitting radius.  $R_{\rm BL, max}$  is the radial extent of the boundary layer from the surface of the NS using equation (25) from Popham & Sunyaev (2001). For C1 and fits labeled RNS, the inclination range from fitting RELXILLNS was used  $(i = 67^{\circ} \pm 4^{\circ})$ . For C2 and fits labeled RFX, the inclination range from fitting RDBLUR\*RFXCONV was used  $(i = 60^{\circ} \pm 10^{\circ})$ .

due to the low-energy turnover in the Comptonization model. Additionally, the strength of the emission line does appear to change with flux as reported by Vrtilek et al. (1986). Indeed, the energy of this line is too low to originate from the relativistic reflection component like the Fe L emission in Serpens X-1 (Ludlam et al. 2018). It could be a blend of Fe, Ni, and O transition lines that originate from collisionally ionized material far from the inner region of the accretion disk as proposed by Vrtilek et al. (1986).

We proceed to replace the Gaussian emission line component for a collisionally ionized plasma model MEKAL (Mewe et al. 1985, 1986; Liedhal et al. 1995) to determine how this interpretation impacts the inferred inner disk radius. The density of the material is fixed at  $10^{15}$  cm<sup>-3</sup> (Schulz et al. 2009) and the abundance of the plasma is tied between the spectra. The temperature and normalization is free to vary. This fit is referred to as "RNS3" and "RFX3" in Tables 3 and 4. Again, the seed photon temperature of the Comptonization component tended to an unphysical value of  $kT_{bb} \leq 3 \text{ eV}$ in the RFX3 VX branch and was fixed at the median value from RFX1. However, the results with this parameter fixed agrees within the 90% confidence level when  $kT_{bb}$  was free to vary. The ratio of the model to the data are shown in Figure 3(g) and (h). The addition of a MEKAL component represents a 7.6 $\sigma$  and 2.7 $\sigma$  improvement in comparison to RNS1 and RFX1, respectively. Figure 3(i) and (j) show the unfolded spectrum with the model components for RNS3 and RFX3, respectively. The MEKAL model predicts a narrow emission line in the Fe K band as well, but this is orders of magnitude below the broadened emission line from reflection. The normalization of the MEKAL component for the NB in RFX3 is lower in comparison to the VX and HB, but this could be due

to the lack of *NICER* data to anchor the component through modeling of the 1 keV feature. The exact nature of the 1 keV component is beyond the scope of this paper, but regardless of how the feature is modeled the inner disk radius still remains close to the NS.

#### 4. DISCUSSION

We present an analysis of the reflection spectrum in Cyg X-2 using three NuSTAR and two simultaneous NICER observations. The source traced out the flaring to horizontal branch within these observations. The data were divided into the respective branches and spectra with  $\geq 10^6$  cumulative counts were modeled according to different continuum conventions. This resulted in a spectrum of the source in the normal branch (NB) from the first NuSTAR observation, the vertex (VX) between the normal and horizontal branch (HB) during the second *NuSTAR* observation, and the HB in the third NuSTAR observation. Simultaneous NICER spectra were extracted for the VX and HB allowing for spectral modeling from 0.5 - 30 keV. The reflection spectrum was modeled with RELXILLNS and RFXCONV depending on the illuminating continuum component. Regardless of which reflection model was utilized, the inner disk radius remained close to  $R_{\rm ISCO}$  (1  $R_{\rm ISCO}$  = 6  $R_q$  for a = 0).

The inferred inclination from reflection modeling (RELX-ILLNS:  $i = 67^{\circ} \pm 4^{\circ}$ , RDBLUR\*RFXCONV:  $i = 60^{\circ} \pm 10^{\circ}$ ) is consistent with the optical results ( $i = 62.5^{\circ} \pm 4^{\circ}$ : Orosz & Kuulkers 1999), but conflicts with the previously reported low inclinations from reflection modeling in Cackett et al. (2010) and Mondal et al. (2018). Again, one possible explanation could be the material further out partially obscuring the blue-wing emission of the Fe K line (Taylor & Reynolds 2018) at the time of the Suzaku observation reported in Cackett et al. (2010). This effect has been invoked to explain conflicting inclination measurements between reflection modeling and dynamical estimates in the black hole X-ray binary XTE J1550-564 (Connors et al. 2019). In the case of the Mondal et al. (2018) study that utilized the same NuSTAR observation from 2015, the differences between the results reported therein and here could be due to differences in how the data were reduced (e.g., bright source flag expression in 'nupipeline') and handled (e.g., our self-consistent reflection modeling and choice to tie various parameters across observations). The inclination varies more when using RFXCONV than from RELXILLNS, but this is likely due to difference in the relativistic convolution routines within each model as discussed in Ludlam et al. (2020). Further differences between the models may be due to the hard coded disk density in RFXCONV of  $10^{15}$  cm<sup>-3</sup>, while the RELXILLNS model has a variable disk density component that allows for conditions closer to the physical density expected in accretion disk of LMXBs. The hard-coded lower disk density in RFXCONV is likely responsible for the higher inferred iron abundance,  $A_{\rm Fe}$ , in comparison to the results from RELXILLNS which are closer to solar abundances.

The emissivity indices are lower than the q = 3 profile for Euclidean geometry, but are close to the expected shallower illumination profile from an extended disk corona around a slowly spinning compact object (Kinch et al. 2016, 2019). The ionization parameter is consistent with the value reported in Cackett et al. (2010), but higher than those found in Mondal et al. (2018). The Mondal et al. (2018) study also found subsolar Fe abundances, which may explain the lower inferred ionization since positive correlations between  $log(\xi)$ and  $A_{\rm Fe}$  have been observed previously when modeling reflection in X-ray binaries (e.g., Connors et al. 2019). Our choice to tie the  $A_{\rm Fe}$  between observations reduces the degeneracy while allowing the  $log(\xi)$  to be a free parameter.

#### 4.1. Radius Constraints

Apart from the inner disk radius returned by the reflection model components, we can calculate the inferred emission radius from the normalizations of the thermal disk component (DISKBB) and single-temperature blackbody (BBODY). The emitting blackbody radius is given assuming both a spherical and a narrow banded emission region on the surface of the NS with a vertical height that is 10% of the radial extent (Popham & Sunyaev 2001; Ludlam et al. 2021). Additionally, we can calculate the maximum radial extent of a boundary layer extending from the surface of the NS based on the mass accretion rate from Equation (25) in Popham & Sunyaev (2001) for comparison. It is important to note that the maximum radial extent using this equation does not account for spreading of the boundary layer in the vertical direction or effects from rotation of the NS. We report these values in Table 5 in units of km for each spectral model reported in Tables 2 - 4 and branch. The implausibly small inferred emitting radius of the blackbody component when assuming spherical emission supports the presence of a narrow banded emission region (Inogamov & Sunyaev 1999). The inner disk radius inferred from the disk component is larger than that inferred from the reflection modeling. The choice of spectral hardening factor does impact the inferred radius (e.g., Kubota et al. 2001). However, the inferred DISKBB radius is also known to be up to a factor of  $\sim 2.2$  smaller when accounting for zero-torque inner boundary condition expected for thin disk accretion (Zimmerman et al. 2005). This brings the inner disk radius values from the DISKBB component within the uncertainty of the reflection model. The relative agreement between the inferred radius measurements of each of these components is an encouraging crosscheck on the validity of the overall spectral modeling results.

# 4.2. M-R Plane

Given that the inner accretion disk is close to the  $R_{\rm ISCO}$ in all cases, we explore the constraints that this translates to on the M-R plane for NSs, and hence the EoS of ultradense, cold matter. The radius of the ISCO around a compact object in units of gravitational radii is dependent upon the dimensionless spin parameter,  $a = cJ/GM^2$ , of the compact object (Bardeen et al. 1972). The spin therefore enables a translation from ISCO to gravitational radii. This can then be converted into kilometers given the NS mass estimate of  $1.71 \pm 0.21 \ M_{\odot}$  for Cyg X-2 (Casares et al. 2010). Figure

**Figure 5.** Mass and radius constraints from NS gravitational wave events and *NICER* pulsar light curve modeling in comparison to reflection modeling of Cyg X-2. Panels differ by the M-R constraints from the combined GW170817 (Abbott et al. 2019) and GW190425 (The LIGO Scientific Collaboration et al. 2020) signatures using a (a) piece-wise polytropic model and (b) speed-of-sound model through a Bayesian framework as reported in Raaijmakers et al. (2021). These are denoted by the black dotted line. The solid cyan region indicates the conservative radiusconstraints for Cyg X-2 based on the reflection modeling reported in Table 3. The solid grey region indicates where causality is violated (i.e., sound speed within the NS exceeds the speed of light). Select EoS from Lattimer & Prakash (2001) are shown to demonstrate the behavior on the M-R plane for a given internal composition. Pulsar light curve modeling of *NICER* data for PSR J0740+6620 are indicated by dashed lines from Riley et al. (2021) (R+2021: orange) and Miller et al. (2021) (M+2021: maroon). The dot-dashed lines indicate the results for light curve modeling of PSR J0030+0452 reported in Riley et al. (2019) (R+2019: orange) and Miller et al. (2019) (M+2019: maroon). Confidence contours correspond to the 68% and 95% credible regions.

5 plots the range that the more conservative constraints from RELXILLNS of  $R_{\rm in} \leq 1.15 \ R_{\rm ISCO}$  for a = 0 corresponds to on the M-R plane used to characterize the EoS. Note that a higher spin value corresponds to a smaller gravitational radius for  $R_{\rm ISCO}$ , therefore we are presenting the most conservative upper limit when using a = 0. This is then compared to M-R estimates from gravitational wave signatures of binary NS and pulsar light-curve modeling. The combined gravitational wave constraints from the double NS mergers GW170817 (Abbott et al. 2019) and GW190425 (The LIGO Scientific Collaboration et al. 2020) are determined through a Bayesian framework as reported in Raaijmakers et al. (2021) for both a piece-wise polytropic model (Fig 5a) and speedof-sound model (Fig 5b). Additionally, the NICER pulsar light-curve modeling results for PSR J0030+0425 (Riley et al. 2019; Miller et al. 2019) and PSR J0740+6620 (Riley et al. 2021; Miller et al. 2021) are shown. The allowed region on the  $M{-}R$  plane for Cyg X-2 could be further narrowed down in the future by obtaining improved mass constraints with better optical light curve data and ellipsoidal modeling. Disk reflection is able to provide an upper limit on the NS radii but it is not able to rule out plausible EoSs on its own. Each of these methods have their own systematic uncertainties (see discussions in Ludlam et al. 2017a; Riley et al. 2019; Miller et al. 2019; Raaijmakers et al. 2021, and references therein), but they can provide independent checks

of constraints from the others on the M-R plane.

# 5. CONCLUSION

We perform a spectral analysis of NuSTAR and NICER observations of Cygnus X-2 while the source was in the normal branch, vertex, and horizontal branch constrain the inner disk radius via reflection modeling. A broad Fe line component was detected in all states, as well as a 1 keV emission line where NICER data was available. The reflection spectrum was modeled in two different ways assuming: (1) an illuminating blackbody component and (2) a Comptonization thermal component. The low-energy emission line was not able to be modeled by the reflection component suggesting that it originated further out in the accretion disk. Regardless of the reflection model utilized or how the 1 keV feature was accounted for, the inner disk radius remained close to the NS. We utilized these measurements to place an upper limit on the radius of the NS. When taken in comparison to state-ofthe-art methods, disk reflection can provide an independent check of constraints on the M-R plane.
