**The intricate interplay between novel lattice geometry and spontaneous symmetry-breaking states is at the forefront of contemporary research on quantum materials. Recently, the observation of unconventional charge and pairing density waves in a kagome metal CsV<sub>3</sub>Sb<sub>5</sub> brings out a new showcase for intertwined orders. While electronic instabilities in CsV<sub>3</sub>Sb<sub>5</sub> are widely believed to originate from the V 3*d*-electrons residing on the 2-dimensional kagome sublattice, the pivotal role of Sb 5*p*-electrons for 3-dimensional orders is yet to be understood. Here, using resonant tender x-ray scattering and high-pressure X-ray scattering, we report a rare realization of conjoined charge density waves (CDW) in CsV<sub>3</sub>Sb<sub>5</sub>. At ambient pressure, we discover a resonant enhancement at Sb *L*<sub>1</sub>-edge (2*s*→5*p*) at the 2×2×2 CDW wavevectors. The resonance, however, is absent at the 2×2 CDW wavevectors. Applying hydrostatic pressure, we find the CDW transition temperatures to separate, where the 2×2×2 CDW emerges 4 K above the 2×2 CDW at 1GPa. Our results establish the coexistence of the 2×2 CDW and the 5*p*-electron assisted 2×2×2 CDW in CsV<sub>3</sub>Sb<sub>5</sub>. The evolution of the conjoined CDWs under pressure suggests the joint importance of electronic and phononic fluctuations for the double dome superconductivity.**

Charge density waves (CDWs), a translational symmetry-breaking electronic fluid state of matter, are in the spotlight to unravel intertwined quantum materials. This includes cuprate high- $T_C$  superconductors as well as Moiré superlattices<sup>1-4</sup> and, most recently, non-magnetic kagome metals where the CDW emerges as a leading electronic instability near van Hove filling<sup>5-12</sup>. Intriguingly, due to the sublattice interference on the geometrically frustrated triangle network, CDWs are predicted to potentially feature finite angular momentum or time-reversal symmetry breaking<sup>7-12</sup>. An exotic CDW in combination with superconductivity has been discovered in the kagome superconductor family  $AV_3Sb_5$  ( $A=K, Rb, Cs$ ) (Fig. 1a)<sup>13-25</sup>. At ambient pressure, a CDW in  $AV_3Sb_5$  sets in between 78 K to 103 K. Concomitant electronic nematicity and time-reversal symmetry breaking have been observed<sup>15,16,22,24,25</sup>. Below  $T_{SC}\sim 3$  K, superconductivity (SC) emerges and displays an unconventional pair-density modulation in real space<sup>23</sup>.

While it is apparent that the CDW plays a key role in describing the exotic electronic phases in  $AV_3Sb_5$ , the microscopic origin of the CDW and its impact on superconductivity are still to be discovered. Like the conventional vs. unconventional paradigm for superconducting pairing, a CDW can be mediated by electronic interactions or phonons which is challenging to discriminate. This particularly applies to electronic kagome bands, where the  $3d$ -van Hove singularities at the M point imply particle-hole fluctuations favoring a  $2\times 2$  CDW (Fig. 1b)<sup>5-9</sup>. In experimental studies, the CDW in kagome metals appears to be 3-dimensional (3D) with a  $2\times 2\times 2$  superstructure<sup>17,18</sup>, indicating a non-trivial interlayer coupling and non-negligible lattice effects<sup>26</sup>. Still, a Landau theory analysis readily shows that the  $2\times 2\times 2$  CDW alone is incompatible with the first order phase transition (Fig. 1c,d), which could already point to a novel coexistence of  $2\times 2$  and  $2\times 2\times 2$  CDWs<sup>11,12</sup>. Turning to the superconducting phase, the intimate correlation between CDW and superconductivity extends to the temperature ( $T$ ) vs pressure ( $P$ ) phase diagram<sup>20-22</sup>. As depicted in Fig. 1a, the CDW transition temperature,  $T_{CDW}$ , monotonically decreases and eventually vanishes at  $P_{c2}$ . Near an intermediate pressure  $P_{c1}\sim 0.7$  GPa, the curvature of the resistivity at  $T_{CDW}$  changes sign. Interestingly, superconductivity also shows two turning points at  $P_{c1}$  and  $P_{c2}$  and forms a double dome structure. Using resonant tender x-ray scattering and high-pressure X-ray scattering, we demonstrate that the  $2\times 2$  CDW and a  $5p$ -electron assisted  $2\times 2\times 2$  CDW are coexisting and intertwined in  $CsV_3Sb_5$ . The conjoined CDWs we observe

transcend the phenomenology that could be derived from a sole V kagome sublattice near van Hove filling, and hence provides key information to understand the enlarged complexity of novel symmetry-breaking phases in CsV<sub>3</sub>Sb<sub>5</sub>.

We start by proving the different electronic origin of the 2×2 and 2×2×2 CDWs using resonant elastic x-ray scattering (REXS). As depicted in Fig. 2a, by tuning the photon energy to atomic absorption edges, orbital-resolved valence electrons that are involved in the CDW will be enhanced<sup>3</sup>. In the cuprate high- $T_c$  superconductors, CDW intensity resonates at both O  $K$ -edge ( $1s \rightarrow 2p$ )<sup>27</sup> and Cu  $L_3$ -edge ( $2p \rightarrow 3d$ )<sup>28,29</sup>, reflecting the  $d$ - $p$  hybridized wave function. Here we choose the Sb  $L_1$  edge ( $h\nu=4.7$  keV) to enhance the  $5p$ -electrons near the Fermi level (see supplementary materials for REXS at other edges). Comparing with the V  $L_3$  edge ( $h\nu=0.512$  keV) that has constrained scattering in reciprocal space (see supplementary materials), the higher photon energy of the Sb  $L_1$  edge allows us to reach both  $\mathbf{Q}_{CDW}^{2 \times 2}$  with integer  $L$  component and  $\mathbf{Q}_{CDW}^{2 \times 2 \times 2}$  with half-integer  $L$  component<sup>18</sup>. Moreover, since Sb  $5p_z$ -electrons form a large Fermi surface and directly contribute to the coupling between adjacent kagome layers, the Sb  $L_1$ -edge resonance can potentially be used to distinguish the 2×2 CDW and the interlayer coupled 2×2×2 CDW. Our main observations at the Sb  $L_1$  edge are summarized in Fig. 2c-f. All REXS data were collected in the reflection geometry at  $T = 10$  K (see Supplementary Materials). The Sb  $L_1$  edge is identified at  $h\nu=4.7$  keV in the fluorescence scan shown in Fig. 2c. Figure 2d and 2e reveal energy scans at  $\mathbf{Q}_{CDW}^{2 \times 2} = (\pm 0.5, 0, 2)$  and  $\mathbf{Q}_{CDW}^{2 \times 2 \times 2} = (\pm 0.5, 0, 2.5)$  (see more  $\mathbf{Q}$  points in the supplementary materials). Remarkably, we find a strong dip in scans at  $\mathbf{Q}_{CDW}^{2 \times 2}$ , which is in stark contrast to scans at  $\mathbf{Q}_{CDW}^{2 \times 2 \times 2}$  that show large resonant enhancement slightly below the Sb  $L_1$  edge. The dramatically different resonant response between  $\mathbf{Q}_{CDW}^{2 \times 2}$  and  $\mathbf{Q}_{CDW}^{2 \times 2 \times 2}$  demonstrates different electronic origins of the 2×2 and 2×2×2 CDWs in CsV<sub>3</sub>Sb<sub>5</sub>, where the Sb  $5p$  valence electrons are only involved in the formation of 2×2×2 CDW.

Having established the two conjoined CDWs with different charge contribution, we examine the CDW evolution under pressure. The experimental geometry of high-pressure diffraction is depicted in Fig. 3a. Figure 3b shows the integrated CDW intensity at  $P=0.5$  GPa  $< P_{c1}$ . Consistent with the ambient pressure measurement, the CDW peaks at  $\mathbf{Q}_{CDW}^{2 \times 2 \times 2}$  and  $\mathbf{Q}_{CDW}^{2 \times 2}$  emerge at the same

temperature around 77 K. Upon increasing pressure up to  $P=1 \text{ GPa} > P_{c1}$ , however, the degeneracy of the conjoined CDWs is lifted with a 4 K gap between  $T_{\text{CDW}}^{2 \times 2 \times 2}$  and  $T_{\text{CDW}}^{2 \times 2}$  (Fig. 3c). Figure 3d and 3e compare the  $2 \times 2$  and  $2 \times 2 \times 2$  CDW intensities at 57 K and 61 K, respectively. The absence of the  $2 \times 2$  CDW peak at 61 K provides evidence for the conjoined nature of CDWs in  $\text{CsV}_3\text{Sb}_5$ . In particular, the  $2 \times 2 \times 2$  CDW peak that precedes the  $2 \times 2$  peak at  $P > P_{c1}$  cast doubt on any scenario of a simple stacking order with a  $\pi$  phase shift between  $2 \times 2$  in-plane lattice distortions, as this should lead to a higher  $T_{\text{CDW}}^{2 \times 2}$  compared to  $T_{\text{CDW}}^{2 \times 2 \times 2}$ . Instead, our observations indicate a  $5p$ -electron assisted 3D CDW that could admix electronic and lattice fluctuations.

While the electronic density of states stemming from the  $3d$ -van Hove singularity tends to favor a  $2 \times 2$  CDW, there are different lattice distortions that could correspond to it. Experimental studies of  $\text{AV}_3\text{Sb}_5$  found that the lattice distortion in the CDW phase is consistent with Star-of-David (SoD) or inverse-SoD patterns<sup>16,30,31</sup>. First principles calculations showed that the inverse-SoD is energetically favored at zero temperature but nearly degenerate with the SoD pattern at high temperature<sup>32,33</sup>. In the presence of Sb sublattices, both the kinetic energy ( $p_x$ - $p_z$  bonding) and Coulomb repulsion between  $5p$ -electrons are sensitive to the lattice distortions. Figure 2b displays an anti-phase movement of Sb2 atoms that is derived from a SoD and inverse SoD stacking. This movement keeps the inter-layer Sb2-Sb2 distance and hence balances the kinetic and potential energies of  $5p$ -electrons. Interestingly, already simplified model based on the  $5p$ -electron stabilized SoD and inverse SoD stacking provides a possible lattice solution of the conjoined CDWs (see supplementary materials). The critical role of Sb  $5p$ -electrons together with the precedent  $2 \times 2 \times 2$  CDW at  $P > P_{c1}$  strongly indicates that the, at least partly, correlation-driven CDW state is superseded by lattice effects under higher pressure which favour the  $2 \times 2 \times 2$  pattern. Indeed, first principles calculations have shown that the hydrostatic pressure at 1 GPa is sufficient to move the  $3d$ -van Hove singularity away from  $E_F$  and significantly suppress the charge susceptibility. With the results from REXS and high-pressure X-ray scattering, we demonstrate the coexistence of the  $2 \times 2$  CDW and the  $5p$ -electron assisted  $2 \times 2 \times 2$  CDW in  $\text{CsV}_3\text{Sb}_5$ . The observation of conjoined CDWs performatively goes beyond the minimal framework of kagome electronic bands near van Hove filling, and thus provides critical information to resolve the persisting puzzle of  $\text{CsV}_3\text{Sb}_5$ .

## Methods

### Sample preparation and characterizations

Single crystals of  $\text{CsV}_3\text{Sb}_5$  were grown from Cs ingot (purity 99.9 %), V powder (purity 99.9 %) and Sb grains (purity 99.999 %) using the self-flux method<sup>34</sup>. The mixture was put into an alumina crucible and sealed in a quartz ampoule under partial argon atmosphere. The sealed quartz ampoule was heated to 1273 K for 12 h and soaked there for 24 h. Then it was cooled down to 1173 K at 50 K/h and further to 923 K at a slowly rate. Finally, the ampoule was taken out from the furnace and decanted with a centrifuge to separate  $\text{CsV}_3\text{Sb}_5$  single crystals from the flux. The obtained crystals have a typical size of  $2 \times 2 \times 0.1 \text{ mm}^3$ . CDW transition is clearly observed in specific heat measurement as shown in the inset of Fig. 1d.

### Resonant elastic X-ray scattering

Resonant single crystal X-ray diffraction was performed at the 4-ID-D beamline of the Advanced Photon Source (APS), Argonne National Laboratory (ANL). The X-rays higher harmonics were suppressed using a Si mirror and by detuning the Si (111) monochromator. Diffraction was measured using a vertical scattering plane geometry and horizontally polarized ( $\sigma$ ) X-rays. The incident intensity was monitored by a He filled ion chamber, while diffraction was collected using a Si-drift energy dispersive detector with approximately 200 eV energy resolution. The probed absorption edges are close in energy (4.1-5.5 keV); thus, the use of this detector is key to reject the fluorescence background. The sample temperature was controlled using a He closed cycle cryostat and oriented such that X-rays scattered from the (001) surface.

### High-pressure X-ray diffraction

High-pressure single crystal x-ray diffraction was also measured at the 4-ID-D beamline of the APS, ANL. High pressure was generated using a modified Merrill-Bassett-type diamond anvil cell<sup>35</sup> fitted with a pair of Boehler-Almax anvils of 800  $\mu\text{m}$  culet diameter. A stainless-steel gasket was indented to 70  $\mu\text{m}$  and a sample chamber of 400  $\mu\text{m}$  diameter was laser cut. 4:1 methanol:ethanol was used as pressure media. Diffraction was measured in the transmission geometry in which X-rays penetrate through both diamond anvils and sample. The sample was cut into approximately  $80 \times 80 \times 40 \mu\text{m}^3$  and oriented such that the c-axis is parallel to the X-ray direction when  $\theta = 0$  degree. Temperature was controlled using a He closed cycle cryostat. Pressure was calibrated as a function of temperature using the Au lattice constant<sup>36</sup> and controlled in-situ using a He gas membrane. X-ray energy of 20 keV was used to minimize the diamond anvil attenuation. The incident intensity was measured using a  $\text{N}_2$  filled ion chamber, and diffraction was collected using a NaI scintillator.

### meV-resolution hard X-ray diffraction

High-precision X-ray scattering measurements shown in Fig. 1c,d was taken at 30-ID-C (HERIX), where the highly monochromatic X-ray beam of incident energy  $E_i = 23.7 \text{ keV}$  ( $\lambda = 0.5226 \text{ \AA}$ ) was focused on the

sample with a beam cross section of  $35 \times 15 \mu\text{m}^2$  (horizontal  $\times$  vertical). The total energy resolution of the monochromatic X-ray beam and analyzer crystals was  $\Delta E \sim 1.5$  meV (full width at half maximum). The measurements were performed in transmission geometry.

The phase diagram is separated by two characteristic pressures,  $P_{c1}$  and  $P_{c2}$ . The curvature of resistivity at  $T_{\text{CDW}}$  changes sign at  $P_{c1}$ . At the same pressure, superconductivity reaches its first peak. The green markers indicate pressures where the high-pressure X-ray diffraction measurement were performed (Fig. 3). **b**, A schematic of van Hove singularities at the M point of the hexagonal Brillouin zone. Theoretically, the van Hove filling induce Fermi surface instabilities with three nesting wavevector  $\mathbf{Q}_{1,2,3}$ . **c-d**, Integrated CDW intensity vs temperature measured at  $\mathbf{Q}_{\text{CDW}}=(3, 0.5, 0.5)$  (panel **c**) and  $(3, 0.5, 0)$  (panel **d**) using meV-resolution elastic X-ray scattering. A sharp jump of the order parameter at the CDW transition indicate a weak first order phase transition and are consistent with nuclear magnetic resonance measurement<sup>37,38</sup>. The intensity jump is much stronger in the out-of-plane CDW peak at  $(3, 0.5, 0.5)$  compared to the in-plane one at  $(3.5, 0.5, 0)$ . The inset of panel **c** shows the CDW peak intensity measured at 92.5 K and 92.75 K. The specific heat data shown in the inset of panel **d** reveal a sharp transition at 92.5 K, consistent with the diffraction data. The error bars in panels **c,d** represent 1 standard deviation assuming Poisson counting statistics.

**Figure 2: Sb  $L_1$ -edge REXS reveals conjoined CDWs in  $\text{CsV}_3\text{Sb}_5$ .** **a**, Schematic of the REXS process. The Sb  $2s$  to  $5p$  transition is allowed by the dipole selection rule. **b**, Anti-phase movement of the Sb2 atoms that is derived from a SoD and inverse SoD stacking between adjacent kagome layers. **c**, X-ray fluorescence near the Sb  $L_1$ -edge (4.7 keV). **d-e**, Photon energy scans at the  $\mathbf{Q}_{\text{CDW}}^{2 \times 2} = (\pm 0.5, 0, 2)$  and  $\mathbf{Q}_{\text{CDW}}^{2 \times 2 \times 2} = (\pm 0.5, 0, 2.5)$  taken at  $T = 10$  K. Resonant peaks in the energy scan of the  $2 \times 2 \times 2$  CDW demonstrate a Sb  $5p$ -electron assisted CDW. This resonance can be directly observed in energy-dependent  $L$ -scans shown in panel **f**. The error bars in panel **c** represent 1 standard deviation assuming Poisson counting statistics.

**Figure 3: Evolution of conjoined CDWs under pressure.** **a**, The experimental geometry of high-pressure X-ray diffraction. **b-c**, Normalized integrated CDW intensity vs temperature taken at  $\mathbf{Q}_{\text{CDW}}^{2 \times 2 \times 2} = (3, 0.5, 0.5)$  and  $\mathbf{Q}_{\text{CDW}}^{2 \times 2} = (3, 0.5, 0)$  at  $P = 0.5$  GPa and 1 GPa. Dashed lines mark the onset temperature of the  $2 \times 2 \times 2$  CDW (yellow) and  $2 \times 2$  CDW (blue). The high-pressure X-ray scattering were taken at 20 keV in a transmission geometry. **d-e**, Direct comparison of the CDW peak intensity of  $\mathbf{Q}_{\text{CDW}}^{2 \times 2 \times 2} = (3, 0.5, 0.5)$  and  $\mathbf{Q}_{\text{CDW}}^{2 \times 2} = (3, 0.5, 0)$  under 1 GPa. The measurements are taken at  $T = 57$  K and 61 K, which is below and above the onset temperature ( $T = 60$  K) of the  $2 \times 2$  CDW ( $L = 0$ ) under 1 GPa (blue dashed line in panel c). The error bars in panel **b-e** represent 1 standard deviation assuming Poisson counting statistics.
