#### Abstract

We study 119 B stars located in the Scorpius-Centaurus Association using data from NASA's TESS Mission. We see pulsations in 81 stars ( $68 \%$ ) across the full range of effective temperatures. In particular, we confirm previous reports of low-frequency pulsations in stars whose temperatures fall between the instability strips of SPB stars (slowly pulsating B stars) and $\delta$ Scuti stars. By taking the stellar densities into account, we conclude that these cannot be p modes and confirm previous suggestions that these are probably rapidly-rotating SPB stars. We also confirm that they follow two period-luminosity relations that are consistent with prograde sectoral g modes that are dipole $(l=m=1)$ and quadrupole ( $l=m=2$ ), respectively. One of the stars ( $\xi^{2} \mathrm{Cen}$ ) is a hybrid pulsator that shows regular spacings in both g and p modes. We confirm that $\alpha$ Cru has low-amplitude p-mode pulsations, making it one of the brightest $\beta$ Cephei stars in the sky. We also find several interesting binaries, including a very short-period heartbeat star (HD 132094), a previously unknown eclipsing binary ( $\pi$ Lup), and an eclipsing binary with high-amplitude tidally driven pulsations (HR 5846). The results clearly demonstrate the power of TESS for studying variability in stellar associations.

Key words: stars: oscillations,

## 1 INTRODUCTION

The Transiting Exoplanet Survey Satellite (TESS; Ricker et al. 2015) is providing high-precision photometry for bright stars across a large fraction of the sky, which allows a systematic study of pulsations in nearby stellar associations. We have used TESS light curves to examine the variability of more than a hundred B-type stars in the Scorpius-Centaurus Association (Sco-Cen; Sco OB2). This is the nearest OB association, with member stars having ages in the range 5-16 Myr (Blaauw 1946; Jones \& Shobbrook 1974; Balona \& Feast 1975; de Geus et al. 1989; De Zeeuw et al. 1999; Preibisch \& Mamajek 2008; Pecaut \& Mamajek 2016; Murphy et al. 2021; Wright et al. 2022).

Pulsating B stars are generally divided into two classes. At hotter effective temperatures (spectral types B0-B3) we have the $\beta$ Cephei stars, which pulsate in low-order pressure modes ( p modes; Stankov \& Handler 2005; Thoul 2009). At cooler temperatures (typically B3-B8) we find the Slowly Pulsating B-type stars (SPB stars), which pulsate in high-order gravity modes ( g modes; Waelkens 1991; De Cat et al. 2011). Both the p and g modes are known to be excited by a heat-engine mechanism acting on

[^0]the opacities of iron-group elements (Dziembowski \& Pamiatnykh 1993; Gautschy \& Saio 1993; Dziembowski et al. 1993).

Research into pulsating B stars has been greatly helped by photometry from space missions such as MOST, WIRE, CoRoT, BRITE, Kepler/K2, and TESS (for reviews, see De Cat et al. 2011; Bowman 2020). Current areas of research include understanding the driving mechanism in the low-metallicity stars of the Magellanic Clouds (Salmon et al. 2012), testing whether opacities need to be modified (Lenz 2011; Moździerski et al. 2019; DaszyńskaDaszkiewicz et al. 2017, 2020), and measuring the amount of internal rotation and mixing (Degroote et al. 2010; Pápics et al. 2017; Pedersen et al. 2021; Pedersen 2022).

Another topic of interest relates to the repeated reports of pulsations in stars that are cooler than expected for SPB stars, with effective temperatures falling between those of SPB stars and $\delta$ Sct stars (Handler et al. 2007, 2008; Majewska-Świerzbinowicz et al. 2008; Degroote et al. 2009; Saesen et al. 2010, 2013; Mowlavi et al. 2013, 2016; Moździerski et al. 2014; Lata et al. 2014; Balona et al. 2015, 2016; Daszyńska-Daszkiewicz et al. 2017; Balona \& Ozuyar 2020; van Heerden et al. 2020; Gaia Collaboration et al. 2022). These have sometimes been called 'Maia variables' but we avoid this term because they have not been established as a separate class of variables (e.g., Aerts \& Kolenberg 2005), and also because Kepler K2 photometry has shown that Maia itself (20 Tau = HD 23408 in
the Pleiades) is not actually a member of the group (White et al. 2017).

The large sky coverage of the TESS mission makes it ideally suited to studying B stars (e.g., Balona et al. 2019; Pedersen et al. 2019; Burssens et al. 2020). In this paper, we study variability in 119 B-type stars in Sco-Cen using data from TESS. We focus on pulsations, but also report on eclipsing binaries and other types of variability.

## 2 TESS DATA

Our sample of B-type stars in the Sco-Cen Association comes from Rizzuto et al. (2011), with a few additional stars that were considered members by Pecaut \& Mamajek (2016). TESS covers the sky in partially overlapping sectors, with each sector being observed for about 27 d (two orbits). Note that TESS has not yet covered a band within $6^{\circ}$ of the ecliptic plane that includes 56 B stars that lie in the Upper Scorpius region of Sco-Cen ${ }^{1}$. This leaves 109 B stars with TESS data from Cycle 1, as listed in Table 1. Most were observed in one of Sectors 10,11 or 12 (which covered from 26 March to 19 June 2019). Note that 10 stars having observations in both Sectors 10 and 11. The HD numbers for these stars are: 95324, 97583, 103079, 104900, 105937, 106490, 107696, 108257, 108483, and 109195. We also included 10 B stars that were missed in Cycle 1 (presumably because they landed in gaps between CCDs) but have data in Cycle 3 (Sectors 36, 37, 38 or 39). The HD numbers for these stars are: 90264, 93563, 113902, 114529, 123445, 137432, 138221, 138923, 139365, and 150638.

The light curves and Fourier amplitude spectra for all stars are shown in the on-line supplementary material. For most stars in our sample, 2-minute TESS light curves were available. We used the LIGHTKURVE package (Lightkurve Collaboration 2018) to download the PDCSAP ${ }^{2}$ light curves, which were calculated by the SPOC (Science Processing Operations Center). For 23 stars for which no 2-minute observations were available, we used light curves from the 30 -minute full-frame images (FFIs) produced by the MIT Quick Look Pipeline (QLP; Huang et al. 2020).

For $\beta$ Cen and $\alpha$ Cru, which are two of the brightest stars in the sample and are heavily saturated, we constructed 2-minute light curves ourselves from the pixel-level data. Due to the large size of the target pixel file of $\beta$ Cen, it was not processed by the TESS photometric pipeline. As a result, not only was there no available SPOC PDCSAP light curve, but the background had not been estimated and subtracted from the flux values in the target pixel file. We estimated the background using the tessbkgd ${ }^{3}$ python package, and calculated a simple aperture photometry light curve using lightrurve. For $\alpha$ Cru, a SPOC PDCSAP light curve was available but the selected pixels did not fully capture the bleed trails that result from saturation, and so aperture losses meant this light curve was of low quality. We instead generated a 'halo' photometry light curve from the unsaturated pixels in the wings of the PSF using the halophot ${ }^{4}$ package (White et al. 2017; Pope et al. 2019). The light curves for $\alpha$ Cru and $\beta$ Cen are discussed in Secs. 6.1 and 6.2.

[^1]
## 3 STELLAR PROPERTIES

The spectral types, effective temperatures and luminosities for our sample are listed in Table 1. Most spectral types were taken from the five-volume University of Michigan Catalogue (Houk \& Cowley 1975; Houk 1978, 1982; Houk \& Smith-Moore 1988; Houk \& Swift 1999). The exceptions were $\eta$ Cen, $\lambda$ Cru and $\mu$ Lup, which are known to be emission-line ( Be ) stars but are not classified as such in the Michigan Catalogue. For these stars we adopted the spectral types measured by Levenhagen \& Leister (2006).

We estimated effective temperatures from spectral types using an updated version of Table 5 of Pecaut \& Mamajek (2013) ${ }^{5}$. We note that there are no effective temperatures listed in the SIMBAD database for most of our stars. Zorec \& Royer (2012) give temperatures from Strömgren photometry for about half of the coolest 50 stars in our sample, and these agree to better than 0.02 in $\log \left(T_{\text {eff }}\right)$ in most cases. We have not listed uncertainties for effective temperatures in Table 1 but we suggest a reasonable value is $\pm 0.02$ in $\log \left(T_{\text {eff }}\right)$. An advantage of using spectral types rather than photometry to estimate effective temperatures is that the former are likely to be more reliable for binary systems.

We estimated stellar luminosities from $V$ magnitudes and parallaxes, using bolometric corrections by Pecaut \& Mamajek (2013). For most stars we used Gaia EDR3 parallaxes (Gaia Collaboration et al. 2021). We used Hipparcos parallaxes (van Leeuwen 2007) for 16 stars that do not have Gaia EDR3 parallaxes (these are mainly the brightest stars in our sample), and for one star whose EDR3 parallax is clearly wrong ( $\mu^{1}$ Sco = HD 151890). Table 1 also shows the projected rotational velocity $(v \sin i)$, which we took as the median of values in the SIMBAD database. For some stars without $v \sin i$ values in SIMBAD, we took measurements directly from the literature (Brown \& Verschueren 1997; Wolff et al. 2007; Zorec \& Royer 2012; Aerts et al. 2014).

The luminosities and effective temperatures of our sample are plotted in a Hertzsprung-Russell diagram in Fig. 1. Discussion of some individual stars is given in Sec. 6. We note that binarity is common among B stars, and so it is likely that properties for some stars are affected by binary companions. Indeed, Rizzuto et al. (2013) found that fewer than a quarter of B stars in Sco-Cen are single. The evolutionary tracks in Fig. 1 were calculated using Modules for Experiments in Stellar Astrophysics (MESA version 7184; Paxton et al. 2011, 2013, 2015) without rotation, for the chemical composition $(X, Z)=(0.72,0.014)$ and with OPAL opacity tables. For the convective-core boundary we adopted the Schwarzschild criterion and diffusive overshooting with the parameter $d_{\mathrm{ov}}=0.01$. We estimated the pulsational instability strips for $l=0 \mathrm{p}$ modes and $l=1$ and 2 g modes (red and blue regions in Fig. 1) by carrying out linear non-adiabatic analysis for selected models using the methods of Saio \& Cox (1980) for the nonradial pulsations and of Saio et al. (1983) for the radial pulsations.

## 4 ANALYSIS OF LIGHT CURVES

The light curves and Fourier amplitude spectra for all stars are shown in the Supplementary on-line material. For the 23 stars for which we used 30 -minute FFIs (see Sec. 2), the light curves are shown connected by a solid line rather than with dots, and the

[^2]

Figure 1. H-R diagram showing the variable stars in our Sco-Cen sample. Theoretical instability strips for $l=0 \mathrm{p}$ modes and $l=1$ and 2 g modes are shown in red, blue and purple (see Sec. 3). The small orange points show $\delta$ Sct stars observed by the Kepler Mission (Murphy et al. 2019).

Nyquist frequency of $24 \mathrm{~d}^{-1}$ is shown in the amplitude spectrum by a vertical dashed line.

Five of the stars have previously been classified as eclipsing binaries or ellipsoidal variables, and these are discussed individually in Sec. 6.8. Other light curves show variations typical of rotation or close binary companions, such as 13 Sco, V863 Cen, V1019 Cen, KT Lup, and HD 132094 (a heartbeat star with a very short period; see Sec. 6.4).

Many stars show clear pulsations and we include four examples in Figs. 2-5. In each figure we give the name, HD number, spectral type and (where available) the value of $v \sin i$. Figure 2 shows the previously-known $\beta$ Cep star $\alpha$ Lup (HD 129056; B1.5 Vn; Nardetto et al. 2013). Figure 3 shows HR 4879 (HD 111774; B7/8 V), which we find to be an SPB star with two closely-spaced modes. Figure 4 shows $\phi$ Cen (HD 121743; B2 V), which is seen to be a hybrid pulsator ( $\beta$ Cep and SPB). Finally, Fig. 5 shows HD 115583 (B9 V), which shows clear pulsations with two closely-spaced modes but is cooler than the standard SPB instability strip. We note that fine structure in the oscillation spectra of SPB stars that has been seen with long runs with CoRoT and Kepler (e.g. Degroote et al. 2010; Pápics et al. 2017) is not fully resolvable with only two sectors ( 54 d ) of TESS data.

In the H-R diagram (Fig. 1), we have indicated the 81 stars

Figure 2. TESS light curve and Fourier amplitude spectra of $\alpha$ Lup (HD 129056; B1.5 Vn), which is a previously-known $\beta$ Cep star (Nardetto et al. 2013).
that show pulsations ( $68 \%$ of the sample). The theoretical instability strips for $\beta$ Cep and SPB stars are overlaid. For comparison, we also

Figure 3. TESS light curve and Fourier amplitude spectra of HR 4879 (HD 111774; B7/8 V), an SPB star with two closely-spaced modes.

Figure 4. TESS light curve and Fourier amplitude spectra of $\phi$ Cen (HD 121743; B2 V), which is a hybrid pulsator ( $\beta$ Cep and SPB).

Figure 5. TESS light curve and Fourier amplitude spectra of HD 115583 (B9 V), which shows clear pulsations with two closely-spaced modes but is cooler that the standard SPB instability strip.
show the sample of $\delta$ Sct stars observed by Kepler (small orange points; Murphy et al. 2019).

To assist the comparison with the theoretical instability strips for $\beta$ Cep and SPB stars, we have indicated whether pulsations fall above or below a somewhat arbitrary threshold of $2.4 \mathrm{~d}^{-1}$. We did not attempt a detailed frequency analysis. Instead, for each star that shows probable pulsations, we have listed up to four frequencies in Table 1. In particular, we list the two strongest pulsation peaks both above and below the $2.4-\mathrm{d}^{-1}$ threshold (and excluding harmonics, which we have labelled with ' $H$ ' in the amplitude spectra in the on-line supplementary material). We note that it can be difficult to distinguish between rotation and low-frequency pulsation in B stars (e.g., Briquet et al. 2007; Lee 2021), and it is possible that some stars listed as pulsating are actually rotational variables, and vice versa. In the figures, we have used ' $R$ ' to label peaks that we attributed to rotation rather than pulsation, with the caveat that some of these may need to be revised. For example, in some stars we have been conservative in marking low-frequency peaks as being due to rotation rather than pulsation, but additional data may change these decisions. Examples include $v^{1}$ Cen (HD 121790; B2 IV/V), HR 5595 (HD 132955; B3 V) and HR 4549 (HD 103079; B4 V). We have also added the word 'binary' on plots where the low-frequency peaks in the amplitude spectrum are due to eclipses or ellipsoidal variations.

The uncertainties on the measured frequencies depend on the duration of the data set $(T)$ and the signal-to-noise ratio (SNR) of the peak in the amplitude spectrum. Specifically, we expect the frequency uncertainty to be approximately $0.44 \mathrm{SNR}^{-1} T^{-1}$ (Montgomery \& O'Donoghue 1999; Kjeldsen \& Bedding 2012). For light curves spanning a single $T E S S$ sector ( $T=27 \mathrm{~d}$, which applies to most stars in Table 1) and peaks with SNR in the range 50 down to 5 , the frequency uncertainty is therefore about $0.0003-0.003 \mathrm{~d}^{-1}$. These uncertainties are much smaller than the symbol sizes on the plots in this paper.

## 5 DISCUSSION

We see from Fig. 1 that pulsations occur across the full range of effective temperatures (see also Pedersen et al. 2019; Balona \& Ozuyar 2020). They do not seem to correspond exactly with the theoretical instability strips, although we note that (i) some effective temperatures and luminosities could be in error, and (ii) the boundaries of the theoretical instability regions are sensitive to the heavy element abundance $(Z)$, the opacity tables and rotation (e.g., Pamyatnykh 1999; Townsend 2005; Paxton et al. 2015; Moravveji 2016; Saio et al. 2017). In Fig. 6 we show the pulsation frequencies listed in Table 1 as a function of effective temperature, with the symbols colour-coded by the $v \sin i$ of the star. We again see that pulsations are present across the entire range of effective temperatures, with an overall tendency for lower-frequency pulsations to occur in cooler stars. We also see that the standard threshold of about $2-3 \mathrm{~d}^{-1}$ is not by itself a reliable way to distinguish $\beta$ Cep stars ( p modes) from SPB stars (g modes).

To decide whether the pulsations in a given star are p - or g modes, it is very helpful to know the mean density of the star. This is because the frequency of a particular p mode, such as the radial fundamental mode, scales from one star to another as the square root of the mean stellar density. Indeed, when plotting theoretical models it is common to scale the frequencies by dividing by $\sqrt{\rho}$ (e.g. Aerts et al. 2010). We show this for the observed pulsation frequencies in Figure 7, which is the same as Fig. 6 except that

Figure 6. Pulsation frequencies of B stars in Sco-Cen from TESS observations, using the values listed in Table 1. Symbols are colour-coded with $v$ sin $i$, and left as open circles when this is not available. The small orange points show $\delta$ Sct stars observed by Kepler (Murphy et al. 2019).
the frequencies have been divided by the square root of the stellar density. We made these rough density estimates for the stars in our sample as follows.

For each star, we estimated the radius using the StefanBoltzmann law ( $L \propto R^{2} T_{\text {eff }}{ }^{4}$ ), using the values in Table 1. We estimated masses from luminosities using a mass-luminosity relation (Eker et al. 2018), which we calibrated for Sco-Cen using published masses for 15 stars in our sample (Jang-Condell et al. 2015), as shown in Fig. 8. We found the relation to be
$\log M / \mathrm{M}_{\odot}=(0.26 \pm 0.02) \log L / \mathrm{L}_{\odot}-(0.042 \pm 0.045)$,
which we used to estimate the masses for our sample.
The relationship between pulsation periods and mean density is usually written as (e.g., Catelan \& Smith 2015, Sec. 5.2):
$P=Q\left(\frac{\rho}{\rho_{\odot}}\right)^{-0.5}$.
The quantity $Q$, called the pulsation constant, depends on the pulsation mode. For example, $Q$ is about 0.033 d for the fundamental radial mode in $\delta$ Sct stars (e.g., Breger 2000). It follows from Eq. 2 that the vertical axis in Fig. 7 shows $1 / Q$, where $Q$ is the pulsation constant (in days).

Stankov \& Handler (2005) suggested that $Q$ for $\beta$ Cep stars peaks at 0.033 d (the same value as $\delta$ Sct stars), which corresponds to $1 / Q=30.0 \mathrm{~d}^{-1}$. To verify this, we used the grid of stellar models calculated by Stello et al. (2009) using the Aarhus stellar evolution
code (ASTEC; Christensen-Dalsgaard 2008), and confirmed that the fundamental radial mode satisfies $1 / Q=30.2 \mathrm{~d}^{-1}$ across a range of masses and ages. In principle, all pulsations falling below this value cannot be p modes. However, we must remember that there are uncertainties in masses, both from uncertainties in luminosities and from scatter in the mass-luminosity relation (Fig. 8). An error of 0.2 in $\log M$, which is an extreme case, corresponds to a change of 0.1 in $\log (1 / Q)$, which is a change of up to $\sim 25 \%$ in $1 / Q$.

We see in Fig. 7 that with three exceptions, all stars with spectral type cooler than B2 show pulsations that fall below the pmode limit, which implies they must be g modes (or perhaps Rossby modes). The first exception is $\xi^{2}$ Cen (HD 113791; B3) which, as discussed in Sec. 6.3, has an unusually regular p-mode spectrum. The second is HR 4874 (HD 111597; B9 V), whose amplitude spectrum (Supplementary on-line material) has many peaks above $10 \mathrm{~d}^{-1}$ and this star appears to be a $\delta$ Sct pulsator (SIMBAD lists other references that give a spectral type of A0). The third exception is $\mu$ Lup (HD 135734; B8 Ve), which is a Be star (Levenhagen \& Leister 2006; Arcos et al. 2018) and so its anomalously highfrequency variations ( $33 \mathrm{~d}^{-1}$ ) presumably come from oscillations in the circumstellar disk.

Our statement that pulsations with $1 / Q$ below about $30 \mathrm{~d}^{-1}$ cannot be p modes is particularly important for the stars that lie between the accepted SPB and $\delta$ Sct instability strips (spectral types B9 and B9.5). As mentioned in the Introduction, there have been several reports of pulsations in B stars that are cooler than the

Figure 7. Scaled pulsation frequencies as a function of stellar effective temperature. Similar to Fig. 6 except that the frequencies have been divided by the square root of the mean stellar density (see text). Densities for the Kepler $\delta$ Sct stars (small orange points) were calculated using masses and radii from Murphy et al. (2019).

Figure 8. Mass-luminosity relationship used to estimate masses of stars in our sample. The masses for these 15 stars are taken from Jang-Condell et al. (2015).
standard range for SPB stars. Salmon et al. (2014) suggested the examples found by Mowlavi et al. (2013) in the young open cluster NGC 3766 are actually fast-rotating SPB pulsators, and this was endorsed by Saio et al. (2017). The idea, which was shown theoret-
ically by Townsend (2005), is that the instability strip for prograde sectoral modes in SPB stars is shifted towards lower luminosities and effective temperatures by rapid rotation. Looking at the $v \sin i$ values for our sample (colour-coded in Fig. 7), we indeed see that the majority of stars with spectral types B9 and B9.5 for which $v \sin i$ measurements are available are indeed rotating rapidly $(v \sin i$ is in the range 150 to $320 \mathrm{~km} \mathrm{~s}^{-1}$ for 16 of the 17 stars that have measurements, and 8 of the 9 among these in which we detected pulsations.).

### 5.1 Period-luminosity relations for fast rotators

Mowlavi et al. (2016) reported that the fast rotators in NGC 3766 followed two distinct period-luminosity ( $\mathrm{P}-\mathrm{L}$ ) relations. Saio et al. (2017) suggested that these two relations corresponded to prograde sectoral g modes that are dipole $(l=m=1)$ and quadrupole ( $l=$ $m=2$ ), respectively ${ }^{6}$. It is known that g-mode oscillations observed in a rapidly rotating stars are predominantly prograde sectoral modes (Van Reeth et al. 2016; Ouazzani et al. 2017; Pápics et al. 2017; Li et al. 2020). In such cases, the pulsation frequencies of g modes in the observer's frame are given as $v_{\mathrm{obs}}=v_{\text {corot }}+m f_{\text {rot }} \approx m f_{\text {rot }}$. The latter relation is obtained assuming the frequencies of $g$ modes

[^3]in the co-rotating frame $v_{\text {corot }}$ to be much smaller than the rotation frequency $f_{\text {rot }}$; i.e., $v_{\text {corot }} \ll m f_{\text {rot }}$. In other words, these g modes in rapidly rotating stars should have periods similar to $P_{\text {rot }} / m$.

Figure 1 shows that most SPB stars in the Sco-Cen association lie close to ZAMS, reflecting their very young ages. They are therefore expected to be rotating close to the critical rates. Assuming that they rotate at rates proportional to the critical rate of the ZAMS model corresponding to that luminosity, we can connect the rotation rate (and hence pulsation period $P_{\text {obs }} \approx P_{\text {rot }} / m$ ) with the luminosity as

$$
\begin{align*}
& \log \left(P_{\mathrm{obs}} / \mathrm{d}\right) \approx-\log \left(\Omega_{\mathrm{rot}} / \Omega_{\mathrm{crit}}\right)-0.60+ \\
& \quad 0.094\left(\log \left(L / \mathrm{L}_{\odot}\right)-1.91\right)-\log (m) \tag{3}
\end{align*}
$$

Here, $\Omega_{\text {rot }} / \Omega_{\text {crit }}$ expresses the rotation frequency as a fraction of its critical value. Equation 3 represents a period-luminosity relation for given values of $\Omega_{\mathrm{rot}} / \Omega_{\text {crit }}$ and $m$. Equation 3 was obtained by a linear interpolation using $\log L$ and $\log R$ of ZAMS models with masses of $3 \mathrm{M}_{\odot}$ and $6 \mathrm{M}_{\odot}$ (see also Saio et al. 2017), and can be applied for rotation rates greater than about 0.4 of the critical value. We verified that the equation is valid to within 0.01 for $1.6 \leq \log L / L_{\odot} \leq 3.0$, which covers the range of $g$-mode pulsators.

The P-L relations for $\Omega_{\text {rot }} / \Omega_{\text {crit }}=0.4$ and 0.8 are shown in Fig. 9 by dashed lines. Many of the rapidly rotating SPB stars fall in the region expected from these relations, consistent with our prediction. Furthermore, this figure shows that variable stars cooler and fainter than the standard SPB instability boundary $(1.5 \leq$ $\log \left(L / \mathrm{L}_{\odot}\right) \leq 2.0$; see Fig. 1) fall approximately on the $m=1 \mathrm{P}-\mathrm{L}$ relations, indicating they are likely to be rapidly rotating SPB stars (g-mode pulsators). It would clearly be valuable to obtain $v \sin i$ measurements for the stars that lack them.

The PL relations for rapidly rotating SPB stars in the ScoCen association we found are the same type as the relations for rapidly rotating SPB stars in the young open cluster NGC 3766 found by Mowlavi et al. (2016) and modeled by Saio et al. (2017). The presence of such $\mathrm{P}-\mathrm{L}$ relations in the young cluster and the OB association indicates many newly born B-type (single) stars rotate nearly critically.

## 6 NOTES ON INDIVIDUAL STARS

## 6.1 $\alpha$ Cru: confirmation of $\beta$ Cephei pulsations

The brightest star in the Southern Cross is a multiple system whose two most luminous components are $\alpha^{1} \mathrm{Cru}$ (HD 108248; B0.5 V; $V=1.28$ ) and $\alpha^{2} \mathrm{Cru}$ (HD 108249; B1 V; $V=1.58$ ). They are separated by only $4^{\prime \prime}$ and so the TESS light curve includes both (TESS pixels are $21^{\prime \prime}$ ). As described in Sec. 2, the extreme brightness of this target required us to use a pixel-level analysis to extract the light curve.

Our TESS light curve (Fig. 10) clearly shows low-amplitude pulsations, making it the second-brightest $\beta$ Cep star in the sky (after $\beta$ Cen). The $\beta$ Cep variability of $\alpha$ Cru from the TESS data was also noted in Table A. 1 of Bowman et al. (2022), although no frequencies were given. The amplitude spectrum in Fig. 10 shows modes at frequencies $3.048 \mathrm{~d}^{-1}$ (amplitude 0.25 ppt ) and $9.468 \mathrm{~d}^{-1}$ ( 0.21 ppt ), which were previously reported by Kołaczek-Szymański (2020), based on photometry from the SMEI and BRITE spacecraft. There are additional peaks at combination frequencies of the two strongest peaks, the strongest being at $15.548 \mathrm{~d}^{-1}(0.05 \mathrm{ppt})$. There appears to be a regularity and fine structure in the spectrum, and this star is clearly worthy of further study. It is not possible to tell
definitively whether the pulsations occur in $\alpha^{1} \mathrm{Cru}$ or $\alpha^{2} \mathrm{Cru}$ (or both), although the presence of combination frequencies shows that the two strongest modes must both occur in the same star. For the figures in this paper, we used the parameters of $\alpha^{1}$ Cru.

## 6.2 $\beta$ Cen: a multi-mode $\beta$ Cephei star

$\beta$ Cen (HD 122451; B1 III) is known to show multi-periodic pulsations, based on photometry spanning 146 d from the BRITEConstellation (Pigulski et al. 2016). It is an interferometric and double-lined spectroscopic binary with two nearly-equal components (Robertson et al. 1999; Ausseloos et al. 2006), and our luminosity is calculated from an absolute magnitude for the primary of $M_{V}=-4.03$ (Pigulski et al. 2016). Our TESS light curve, extracted from pixel-level data (Sec. 2), confirms a rich spectrum of pulsation modes (see Fig. 11), including some that were not detected with BRITE (the BRITE spacecraft are in low-Earth orbit, which results in an effective Nyquist frequency of $7.17 \mathrm{~d}^{-1}$; see Pigulski et al. 2016). The TESS amplitude spectrum shows additional peaks around $12 \mathrm{~d}^{-1}$ that are combination frequencies of the peaks around $5-6 \mathrm{~d}^{-1}$.

## 6.3 $\xi^{2}$ Cen: a hybrid pulsator with regular spacings

The light curve for $\xi^{2}$ Cen (HD 113791; B3) shows both $g$ and $p$ modes (Fig. 12). The $g$ modes appear to have a regular structure that has a similar period spacing to other SPB stars (Pápics et al. 2017; Aerts 2021; Szewczuk et al. 2021). Remarkably, we also see a regular pattern of p modes in $\xi^{2}$ Cen (top panel of Fig. 12). Such regularity is common in solar-like oscillators (Chaplin \& Miglio 2013) and also occurs in young $\delta$ Sct stars (Bedding et al. 2020), but is very unusual in $\beta$ Cep stars. One exception is V1449 Aql (HD 180642), for which CoRoT observations showed evidence for a large frequency spacing of $\Delta v=2.3 \mathrm{~d}^{-1}$ (Belkacem et al. 2009). In $\xi^{2}$ Cen, the spacing between the peaks yields a large frequency spacing of $\Delta v=3.46 \mathrm{~d}^{-1}$. Using the standard scaling relation that $\Delta v$ scales approximately with the square root of density (e.g. Aerts et al. 2010), this implies a mean stellar density of 0.087 in solar units. This is in reasonable agreement with the rough estimate of 0.073 that we made in Sec. 5. It is also interesting that the p modes peaks are broadened, possibly indicating damping similar to that seen in V1449 Aql (Belkacem et al. 2009, 2010). The bottom panel of Fig. 12 shows the amplitude spectrum in échelle format, after first removing low-frequency variations with a high-pass filter. The pattern with two clear ridges is very reminiscent of those seen in young $\delta$ Sct stars (Bedding et al. 2020). This star is clearly worthy of further study.

### 6.4 HD 132094: a short-period heartbeat star

The star HD 132094 (spectral type B9) was not previously known to be a binary. However, its TESS light curve (Fig. 13) shows it is a member of the class of eccentric binaries with tidal distortions (socalled heartbeat stars) that were discovered in large numbers by the Kepler Mission (e.g., Thompson et al. 2012; Kirk et al. 2016). The period is $0.5865 \pm 0.0003 \mathrm{~d}$, which appears to be the shortest among previously published heartbeat stars (Kirk et al. 2016; KołaczekSzymański et al. 2021). The phase-folded light curve shows evidence for tidally-forced pulsations (not included in Table 1) and this star certainly deserves further study.

Figure 9. Period-luminosity diagram for the stars in our Sco-Cen sample (colour-coded with effective temperature), as well as $\delta$ Sct stars observed by Kepler (orange points; Murphy et al. 2019). Dashed lines show theoretical P-L relations for sectoral $g$ modes for rotation rates of 0.4 and 0.8 times the critical value (see Sec. 5.1).

Figure 10. TESS light curve and amplitude spectrum of the $\beta$ Cep star $\alpha$ Cru (see Sec. 6.1).

## 6.5 $\tau$ Lib: a heartbeat star with pulsations

The star $\tau$ Lib (HD 139365; B2.5) is known to be a spectroscopic binary, and photometry with the BRITE mission showed it to be a heartbeat star with a period of 3.41 d (Pigulski et al. 2018). This is confirmed by the TESS light curve from Sector 38, which gives

Figure 11. TESS light curve and amplitude spectrum of the $\beta$ Cep star $\beta$ Cen (see Sec. 6.2).
an orbital frequency of $0.290 \mathrm{~d}^{-1}$ and also shows clear pulsations (Fig. 14). The two strongest pulsation peaks are listed in Table 1, and we note that $f_{1}$ coincides with 16 times the orbital frequency.

Figure 12. TESS amplitude spectrum of the hybrid pulsator $\xi^{2}$ Cen from TESS Sectors 11, 37 and 38 , showing the regions with p modes (top panel) and g modes (middle panel). We also show the amplitude spectrum in échelle format (bottom panel) after first removing low-frequency variations (see Sec. 6.3).

Figure 13. Light curve of the heartbeat star HD 132094, folded at the orbital period.

Figure 14. TESS Light curve of $\tau$ Lib.The top panel is original light curve, the middle panel is the Fourier Transform of the original light curve, and the bottom panel is the Fourier Transform of the light curve after removing the first 9 harmonics of the orbital frequency.

Figure 15. TESS observations of $\pi \operatorname{Lup}(\mathrm{B} 5 \mathrm{~V})$ from Sector 11. The light curve (upper panel) shows it to be an eclipsing binary with pulsations. The amplitude spectrum after removing the eclipses (lower panel) shows pulsations.

## $6.6 \pi$ Lup: an eclipsing binary with pulsations

$\pi$ Lup (HR 5605; HD 133242; B5 V) is a multiple system with at least four components (Nitschelm 2004) but not previously known to be eclipsing. The TESS light curve (Fig. 15) shows two narrow eclipses with depths of $1 \%$ and separated by 15.50 d . The amplitude spectrum after removing the eclipses (shown in Fig. 15 and in the on-line supplementary material) shows peaks at $1.5 \mathrm{~d}^{-1}$ that are consistent with SPB pulsations, or possibly r modes.

Figure 16. TESS light curve of the star HR 5846 (A0 V), showing eclipses and tidally forced pulsations.

### 6.7 HR 5846: an eclipsing binary with tidally-forced pulsations

HR 5846 (HD 140285; A0 V). This star not in our sample because it does not have B spectral type but we mention it here because of its interesting light curve. The TESS data (Fig. 16) shows detached eclipses (period 2.1 d ) as well as pulsations at exactly 10 times the orbital frequency. These are presumably tidally forced g modes and have an unusually large amplitude (almost $1 \%$ ). Note that x-ray emission from HR 5846 was reported by Motch et al. (1997).

### 6.8 Other eclipsing and close binaries

Light curves for the following stars are shown in the on-line supplementary material:

- $\mu^{1}$ Sco (HD 151890; B1.5 +B) is known to be a semi-detached eclipsing binary with a period of 1.45 d (van Antwerpen \& Moon 2010). This is confirmed by the TESS light curve, which shows no sign of pulsations after prewhitening with the first 12 harmonics of the orbital frequency.
- V964 Cen (HD 115823; B5) is catalogued as a short-period detached eclipsing binary (Samus' et al. 2017) but the TESS light curve clearly shows it is actually an SPB star.
- V831 Cen (HD 114529; B7) is known to be a close binary (ellipsoidal variable) with a period of 0.642 d (Budding et al. 2010), which is confirmed by the TESS light curve.
- GG Lup (HD 135876; B7) is known to be a detached eclipsing binary with a period of 1.85 d (e.g., Budding et al. 2015). This is confirmed by the TESS light curve, which also shows low-amplitude variability outside of the eclipses (around $1.6 \mathrm{~d}^{-1}$ ) that may indicate tidally-forced pulsations.
- HR 4913 (HD 112409; V945 Cen; B8/9 V) is known to be a close binary (ellipsoidal variable) with a period 0.65 d (Harmanec et al. 2010), which is confirmed by the TESS light curve.

### 6.9 Other stars

These stars are ordered by spectral type:

- $\tau$ Sco (HD 149438; B0 V) is not catalogued as a $\beta$ Cep star and no line profile variations have been reported (Telting et al. 2006). The TESS light curve shows no evidence for variability and we can rule out $\beta$ Cep pulsations down to a level of about 50 ppm .
- $\beta \mathrm{Cru}$ (HD 111123 ; $\mathbf{B} 0.5$ III) is known to be a multi-periodic $\beta$ Cep star, which is confirmed by the TESS light curve. Aerts et al. (1998) found it to be a spectroscopic binary in an eccentric 5-yr orbit, in which the primary ( B 0.5 III ) is the $\beta$ Cep variable and the secondary is a B 2 V star. The strongest modes in the TESS data have frequencies of $5.230,5.487,5.969$, and $3.529 \mathrm{~d}^{-1}$, which
agree with those found by Cuypers et al. (2002) using photometry spanning 17 d from the star tracker on the WIRE satellite. The TESS light curve from Sector 11 for this star has been analysed in detail by Cotton et al. (2022).
- $\alpha$ Lup (HD 129056; B1.5 Vn) is known to be a single-mode $\beta$ Cep star (Lampens \& Goossens 1982; Mathias et al. 1994; Nardetto et al. 2013). The TESS light curve confirms the mode at $3.848 \mathrm{~d}^{-1}(7.0 \mathrm{ppt})$, and subtracting this mode shows much weaker peaks $(0.6-0.7 \mathrm{ppt})$ at $3.318,3.916$ and $3.976 \mathrm{~d}^{-1}$.
- $v$ Cen (HD 120307; B2) This system is a spectroscopic binary with an orbital period of 2.625 d . Using photometry from the SMEI and BRITE spacecraft, Jerzykiewicz et al. (2021) found variations with this period due to the reflection effect. The TESS 2-minute light curve confirms these variations. After removing them, we find some irregular variability but no evidence for coherent pulsations.
- $\gamma \operatorname{Lup}$ (HD 138690; B2 IV; $V=2.77$ ) This is a visual binary with nearly equal components separated by about half an arcsecond (Herschel 1847). One of the components is a spectroscopic binary with an orbital period of 2.850 d . It was not previously reported as a $\beta$ Cep star. Using photometry from the SMEI and BRITE spacecraft, Jerzykiewicz et al. (2021) found variations at the orbital period due to the reflection effect. The TESS 2-minute light curve confirms these variations. After removing them, the light curve appears to show several low-amplitude peaks in the range 1.5 to $15 \mathrm{~d}^{-1}$ that may indicate SPB and $\beta$ Cep pulsations, but these are not listed in the table.

## 7 CONCLUSIONS

We have examined the light curves of 119 B-type stars in the Sco-Cen Association that have been observed by TESS. Pulsations are seen in 81 stars ( $68 \%$ ), covering the whole spectral range in the $\mathrm{H}-\mathrm{R}$ diagram. In particular, we confirm the presence of lowfrequency pulsations in stars whose effective temperatures lie between those normally associated with SPB and $\delta$ Sct stars. By taking the stellar densities into account, we conclude that these cannot be p modes and confirm previous suggestions that these are probably rapidly-rotating SPB stars. We also confirm that they follow two period-luminosity relations that are consistent with prograde sectoral g modes that are dipole $(l=m=1)$ and quadrupole ( $l=m=2$ ), respectively.

One of the stars ( $\xi^{2}$ Cen; Sec. 6.3) is a hybrid pulsator that shows regular spacings in both $g$ and $p$ modes. In particular, the p modes show a remarkable regularity that is reminiscent of solarlike oscillations. Our sample also includes several interesting binaries, including a very short-period heartbeat star (HD 132094; Sec. 6.4), a previously unknown eclipsing binary ( $\pi$ Lup; Sec 6.6), and an eclipsing binary with high-amplitude tidally driven pulsations (HR 5846; Sec. 6.7). Overall, the results show the power of TESS for studying variability in bright stars.

## ACKNOWLEDGEMENTS

We thank Jim Fuller, Mike Ireland, Andrzej Pigulski, Aaron Rizzuto and Rich Townsend for helpful discussions. We also thank the referee for a very thorough review with many useful comments. We gratefully acknowledge support from the Australian Research Council through Discovery Project DP210103119, and from the Danish National Research Foundation (Grant DNRF106) through its funding for the Stellar Astrophysics Center (SAC). We
are grateful to the entire TESS team for providing the data used in this paper. This work has made use of data from the European Space Agency (ESA) mission Gaia, (https://www. cosmos. esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www. cosmos.esa.int/web/ gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement. This work made use of several publicly available python packages: astropy (Astropy Collaboration 2013, 2018), echelle (Hey \& Ball 2020), lightkurve (Lightkurve Collaboration 2018), matplotlib (Hunter 2007), nUMPY (Harris et al. 2020), and scipy (Virtanen et al. 2020).
