Submitted to ApJ

ABSTRACT

Weak gravitational lensing shear could be measured far more precisely if information about unlensed attributes of source galaxies were available. Disk galaxy velocity fields supply such information, at least in principle, with idealized models predicting orders of magnitude more Fisher information when velocity field observations are used to complement images. To test the level at which realistic features of disk galaxies (warps, bars, spiral arms, and other substructure) inject noise or bias into such shear measurements, we fit an idealized disk model, including shear, to unsheared galaxies in the Illustris TNG100 simulation. The inferred shear thus indicates the extent to which unmodeled galaxy features inject noise and bias. We find that γ_+ , the component of shear parallel to the galaxy’s first principal axis, is highly biased and noisy because disks violate the assumption of face-on circularity, displaying a range of intrinsic axis ratios (0.85 ± 0.11). The other shear component, γ_\times , shows little bias and is well-described by a double Gaussian distribution with central core scatter $\sigma_{\text{core}} \approx 0.03$, with low-amplitude, broad wings. This is the first measurement of the natural noise floor in the proposed velocity field lensing technique. We conclude that the technique will achieve impressive precision gains for measurements of γ_\times , but little gain for measurements of γ_+ .

1. INTRODUCTION

Weak gravitational lensing is a key tool in modern astrophysics because it enables mapping of gravitational potentials (see Bartelmann & Maturi 2017 for a recent review). The physical basis for this mapping is the gravitational deflection of light from a distant source (assumed here to be a galaxy) as it passes the potential on its way to the observer. The deflection itself is not measurable in the absence of constraints on the true source position, but variations in deflection angle across the face of a source galaxy manifest as anisotropic stretching (shearing) of the galaxy image. Measuring shear thus requires some knowledge of the unlensed shape of the source. Rather than attempt to model unlensed shapes on a source-by-source basis, weak lensing has proceeded on the assumption that unlensed sources *on av-*

erage have no preferred direction. Hence shear measurements are averaged over many source galaxies in a patch of sky. In this approach, an individual source carries little information because its unlensed shape is poorly constrained—a fundamental source of uncertainty called *shape noise*. This approach is well suited to modern wide-field imagers that collect data on many sources simultaneously, but limits the angular resolution of shear measurements.

Information about the unlensed condition of a source galaxy could enable shear constraints along the specific line of sight to that galaxy, hence enabling shear maps with better angular resolution. Blain (2002) suggested a method based on the fact that a circular orbit inclined to the line of sight produces an observed velocity pattern that is antisymmetric across its apparent minor axis and symmetric across its apparent major axis. This symmetry is disturbed by lensing, hence any observed asymmetry could be attributed to lensing. Morales (2006) extended this idea to disks, deriving a relation between

shear and the angle between the principal axes of the observed velocity and intensity fields. [de Burgh-Day et al. \(2015\)](#) analyzed velocity maps of nearby (hence unlensed) disk galaxies as well as simulated velocity maps, and found ~ 0.01 shear precision per source, compared to ~ 0.2 for traditional weak lensing.

However, these approaches constrain only one of two shear components. The component of shear directed along the unlensed major axis, which we define as γ_+ , preserves the symmetry of the velocity field but changes the apparent axis ratio. [Huff et al. \(2013\)](#) proposed to constrain γ_+ as follows: the Tully-Fisher relation (TFR; [Tully & Fisher 1977](#)) predicts the (3-D) rotation speed; this supports an inference of the inclination angle i using the measured line-of-sight speed; constraining i in turn constrains the unlensed axis ratio of a circular disk viewed at this inclination. Hence the observer can compare lensed and unlensed axis ratios to deduce γ_+ . [Wittman & Self \(2021, hereafter WS21\)](#) presented a Fisher Information Matrix (FIM) analysis of this method using an idealized disk model. They concluded that the shear precision is a function of inclination angle i , with face-on ($i=0$) galaxies offering more precision. They found that γ_+ , as well as the symmetry-violating shear component γ_\times , could be inferred to a precision of 0.01 or better (at least at $i \leq 25^\circ$) in this idealized model. However, they warned that their model accounted only for random measurement errors in the velocity and intensity fields. Nature may introduce additional variations, such as intrinsically noncircular disks upsetting the axis-ratio calculation, or warped disks that violate the assumed velocity symmetry. These variations would constitute the equivalent of shape noise—a fundamental limit on per-galaxy shear precision due to variance in unlensed galaxy properties.

The velocity-field method, unlike traditional image-based lensing, involves different physical arguments for γ_+ and γ_\times , hence we may expect different noise levels for each component. This may present challenges in combining information from multiple sources, but such challenges are best addressed after completely understanding the information provided by a single galaxy, which is the focus of this paper. This paper quantifies the noise floors using simulated galaxies, which enable high-fidelity mock observations from a variety of viewing angles. Although simulated galaxies may omit some details found in nature, modern simulations incorporate a variety of relevant physical processes and produce realistic distributions of satellites and neighbors, bulges, warps, and so on. Hence they offer a useful starting point free of the complications inherent in using noisy data obtained from a fixed, unknown viewing angle. Nevertheless, later

in the paper we will discuss how our results compare to observational work on closely related issues.

The remainder of this paper is organized as follows: §2 describes our methods; §3, the results; and §4 provides discussion and interpretation.

2. METHODS

Overview: we fit the idealized disk model of WS21, including the shear parameters γ_+ and γ_\times , to hundreds of unlensed simulated disk galaxies. The distribution of inferred shear parameters directly indicates the noise and bias due to unmodeled galactic structures, which is likely an irreducible source of error for the velocity field method. In this section we describe the model briefly (§2.1), then the galaxy selection (§2.2), Tully-Fisher calibration (§2.3), mock data preparation (§2.4), and parameter estimation (§2.5).

2.1. Idealized Model

We briefly recap the WS21 model and refer readers to that paper for more details. The model assumes an infinitesimally thin disk with no bulge, viewed at an angle i between the disk axis and the line of sight. The intensity field is described by $I = I_0 \exp(\frac{-2.99R}{r_{80}})$, where R is a radius in polar coordinates attached to the disk, r_{80} is the radius that encircles 80% of the light, and I_0 is the central intensity. The rotation curve is described by $v = v_{\max} \arctan \frac{R}{r_0}$ where r_0 is a scale length independent of r_{80} , and v_{\max} is prescribed by the TFR. The parameter A_{TFR} describes v_{\max} as a fraction of the TFR prediction, with a prior allowing for scatter at fixed luminosity. WS21 prescribed 4% scatter, but we adjusted this for Illustris as described below. Lensing parameters in WS21 include γ_+ , γ_\times , and the magnification μ ; we fix μ at unity to focus on the ability of galaxy features to mimic shear. The galaxy location on the sky and in velocity space is described by three nuisance parameters x_0 , y_0 , and v_0 . Table 1 summarizes the parameters.

2.2. Simulated Galaxies from Illustris TNG100

We select galaxies from the $z=0$ snapshot of Illustris TNG100-1 ([Nelson et al. 2019](#)), a magnetohydrodynamical simulation with a volume of 110.7^3 Mpc^3 in a Planck2015 cosmology. The dark matter and baryon particle masses are 7.5×10^6 and 1.4×10^6 respectively; the softening lengths are 0.74 kpc for dark matter and a minimum of 0.125 kpc for gas; and the median radius of star-forming gas cells is 355 pc, with a minimum gas cell size of 14 pc. Illustris TNG includes a wealth of physical effects such as radiative cooling, stochastic star formation, stellar feedback, and stellar evolution. Figure 1 shows a face-on view of a disk galaxy in our analysis,

Table 1. Model parameters

Symbol	Typical value	Bounds	Unit	Description
A_{TF}	1	$[0, \infty)$	-	v_{max} as a fraction of the Tully-Fisher prediction
I_0	90	$[0, \infty)$	-	intensity S/N at center
i	varies	$[0, 90]$	deg	inclination angle
ϕ_{sky}	90	$[0, 180)$	deg	sky position angle of unlensed major axis
r_0	4	$[0, \frac{L}{2})^*$	pixel	rotation curve scale length
r_{80}	12.5	$[0, \frac{L}{2})$	pixel	radius of 80% encircled light
x_0	0	$(-\frac{L}{2}, \frac{L}{2})$	pixel	center of galaxy in x coordinate
y_0	0	$(-\frac{L}{2}, \frac{L}{2})$	pixel	center of galaxy in y coordinate
v_0	0	-	km/s	galaxy systemic radial velocity
γ_+	0	$(-1, 1)$	-	shear parallel to unlensed major axis
γ_\times	0	$(-1, 1)$	-	shear at 45° to unlensed major axis
μ	1	fixed	-	magnification

* L refers to the image side length in pixels (typically ≈ 50 pixels)

Figure 1. Stellar composite mock-up of subhalo 421835. This visualization was generated using Illustris’ visualization tool. We analyze this subhalo in later figures.

demonstrating realistic features that go far beyond the idealized model of a bulgeless exponential disk.

To access TNG100 data we use Illustris’ web-based Application Programming Interface (API) framework which allows for a search of all TNG runs and subhalo metadata. This is done via a specified object id search using the `requests` Python module. Our goal is to study massive, rotation-supported galaxies as these are the galaxies most likely to be targeted in observations if this shear inference method proves practical. Furthermore, because Illustris TNG has many galaxies, we begin with tight selection criteria aimed at producing a fairly uniform sample of subhalos:

- the total mass is required to be within 10% of $1.4 \times 10^{12} M_\odot$

- $\geq 40\%$ of the stellar mass is required to be in the disk and $\leq 30\%$ of the stellar mass is allowed to be in the bulge

Disk star particles are defined as those with specific angular momenta nearly as large as the maximum angular momentum of the 100 particles with the most similar binding energy; in other words with a circularity parameter (Abadi et al. 2003) $\epsilon > 0.7$. The fraction of bulge star particles is quantified as twice the fraction with $\epsilon < 0$.

These criteria yield 386 subhalos for the fitting described below.

2.3. TFR Calibration

We examine the TFR for our selected galaxies to verify that the (3-D) rotation speed can be predicted with reasonably small scatter. This is necessary to support inference of i by comparison with the line-of-sight rotation speed; i in turn predicts the unlensed axis ratio of a circular disk, which is compared with the observed axis ratio to infer γ_+ . Our tests do not hinge on reproducing the actual TFR observed in nature.

We calibrate the TFR on the selected galaxies by using two metadata attributes precomputed by Illustris: the K-band luminosity and the maximum circular speed. Figure 2 shows these two quantities for each galaxy as well as the best-fit relation $L \propto v_{\text{max}}^{4.3}$. The residual rms scatter about this relation is 22 km/s or about 10%. This is larger than the fiducial model of WS21, but in keeping with the fact that we are using K-band luminosity rather than a baryonic TFR that would require more mock photometry. According to WS21, scatter in the TFR at the 10% level is not a limiting factor on γ_+ inference, so we proceed with the K-band TFR. With this scatter, the prior on A_{TF} in our fitting procedure becomes $P(A_{\text{TF}}) \propto \exp -\frac{1}{2} \left(\frac{A_{\text{TF}} - 1}{\sigma_{A_{\text{TF}}}} \right)^2$ where $\sigma_{A_{\text{TF}}} = 0.1$.

Figure 2. Tully-Fisher relation for the selected halos. The best-fit relation is $L \propto v_{\max}^{4.3}$ with a scatter of 22 km/s or about 10%.

2.4. Mock Data Preparation

For each selected subhalo, we calculate the moment of inertia tensor of the star particles, and diagonalize the tensor to yield three principal axes $A \geq B \geq C$ (we use upper-case letters for intrinsic quantities, reserving lower-case a and b for the apparent semimajor and semiminor axes). According to Franx & de Zeeuw (1992), intrinsic disk ellipticity may account for a large part of the scatter in the TFR, hence we color-coded the points in Figure 2 by the intrinsic axis ratio $q_0 \equiv \frac{B}{A}$. Although q_0 does not seem to correlate with the scatter, the range of q_0 highlights the extent to which disks are not circular when viewed face-on; this will become important as follows. We choose the first principal axis to coincide with the x axis of a mock detector, and the second principal axis with the y axis. For views other than face-on, the second principal axis is foreshortened by a factor of $\cos i$. This forces any intrinsic noncircularity to manifest as an inference of $\gamma_+ > 0$, which stretches the x axis and shrinks the y axis.

Next we compute the K -band intensity field and the line-of-sight stellar velocity field. We choose a grid with 0.25 kpc/pixel, extending to $\frac{2}{3}$ of the `SubhaloStellarPhotometricsRad` attribute, which is the radius defined by a surface brightness of 20.7 mag arcsec $^{-2}$ in the K band. This yields grids with $\approx 50 \times 50$ pixels. The velocity of a pixel is taken to be the mean velocity of the star particles along that line of sight, while the intensity is the sum of the luminosities of those particles. Hence satellites, for example, will cause local departures from a smooth velocity field. We do not model

extinction, hence satellites on the far side of the galaxy may be more visible than in real data; dust lanes will not appear but because these are mock K -band observations dust lanes would have been minimal in any case. We assign uncertainties to each pixel using the WS21 recipe, which is meant to emulate achievable high signal-to-noise data as follows. The intensity field uncertainty is the same in each pixel, and is set to $I_0/90$. The velocity field uncertainty is set to 10 km/s at the center and scales inversely with the square root of the local intensity.

2.5. Least-Squares Optimization

We construct a data vector consisting of a concatenated list of intensity and velocity pixel values, and use an off-the shelf optimizer to find the best-fit model. Many of the parameters in our model are bounded by physical or geometric arguments. For example i is defined on $[0, 90^\circ]$, ϕ_{sky} is defined on $[0, 180^\circ)$, and the shear components are defined on $(-1, 1)$; see Table 1 for a full list of bounds. To enforce these bounds while efficiently searching for the best-fit model we use the Python function `scipy.optimize.least_squares` which implements the “Trust Reflective Region” method (Branch et al. 1999) for dealing with boundaries. Within the boundaries, `scipy.optimize.least_squares` does not directly support the use of priors. Therefore, we implement the TFR prior indirectly as follows. `scipy.optimize.least_squares` requires a user-defined function that returns a vector of residuals, which it then internally squares and sums to obtain a χ^2 value. Because $\chi^2 = -2 \ln \mathcal{L}$ where \mathcal{L} is the likelihood, the A_{TF} prior in §2.3 becomes simply $(\frac{A_{\text{TF}} - 1}{\sigma_{A_{\text{TF}}}})^2$ in χ^2 units. Hence we concatenate one element to the data array with the value $\frac{A_{\text{TF}} - 1}{\sigma_{A_{\text{TF}}}}$ which is then, internally to `scipy.optimize.least_squares`, squared to obtain the $\Delta\chi^2$ corresponding to the prior.

As a test of the code, we fitted mock data generated by the idealized model. The fitted parameters matched the input parameters to within one part in 10^6 .

3. RESULTS

We present one example in detail in Figure 3. The left column contains the data from TNG100, the middle column contains the least-squares optimized model, and the residual of the difference is displayed in the right column. The rows contain the velocity and intensity data and model fields as labelled. The “observed” intensity field has substructure near its center, which violates the idealized model of an axisymmetric disk, but there is little corresponding substructure in the velocity field. The key physical distinction between data and model here

Figure 3. An illustrative TNG100 subhalo (421835, at $z = 0$) viewed at $i=60^\circ$ from face-on. The top (bottom) row shows the velocity (intensity) field, while the left, middle, and right columns show the mock data, model, and residuals (in units of the uncertainty on each pixel) respectively. The idealized model does not include a bar nor spiral arms, hence these features appear in the residuals.

is that our model assumes a thin, planar, axisymmetric disk while the mock data from IllustrisTNG assume none of these things. Hence, any shear found by our model fitting may be attributed to galaxy features that violate this model, such as the apparent bar and spiral arms in the lower right panel of Figure 3. The purpose of this paper is to quantify the extent to which these features would contaminate γ_+ and/or γ_\times measurements using the velocity-field method as implemented by this model.

The extent to which these nonaxisymmetric features result in spuriously inferred shear may vary with viewing angle as well as from galaxy to galaxy. Hence, we repeat for each of the 386 galaxies viewed at a series of inclination angles (5, 20, 40, and 60 degrees).

3.1. Inferred shear

Figure 4 displays histograms of the inferred shear, broken down by component and by true inclination angle. Table 2 lists the mean and standard deviation of each of these distributions. Some of the distributions are non-Gaussian, so for a more complete description we tested Gaussian mixture models (GMM) with a range of Gaussian components and used the Bayesian Information Criterion to determine the preferred number of

Table 2. Distribution of inferred shear as function of inclination.

i (deg)	γ_+		γ_\times		
	mean	σ	mean	σ	σ_{core}
5	0.213	0.179	-0.016	0.103	0.033
20	0.176	0.138	-0.018	0.089	0.036
40	0.096	0.143	-0.015	0.076	0.029
60	0.084	0.214	-0.014	0.062	0.025

components in each case. The result is that γ_+ is best fit at each inclination by a single Gaussian, while γ_\times is best fit at each inclination by a double Gaussian. The resulting descriptive curves are overplotted in Figure 4. We discuss each component in more detail below.

3.2. γ_+

According to Figure 4, γ_+ is biased toward positive values, and shows large scatter ($\approx 0.1 - 0.2$) at all inclinations. The sign of the bias suggests that real galaxies depart substantially from the assumption of face-on circularity. We arranged all mock observations such that

Figure 4. Histograms for inferred γ_+ and γ_x with overlaid best fit functions. We use a Gaussian mixture model to determine the statistics of the distribution. A Bayesian Information Criterion analysis was conducted to determine the optimal number of model components. γ_+ is best fit in all cases by a single Gaussian, while γ_x is best fit by a double Gaussian.

the true first principal axis A was aligned with the detector’s x axis; hence if the second principal axis B is smaller, the galaxy appears as an ellipse with apparent major axis aligned with x , even when face-on. The model has no way to account for this other than introducing $\gamma_+ > 0$, which stretches the apparent x axis of the assumed circular disk. To confirm this hypothesis we plot inferred γ_+ against the intrinsic axis ratio $\frac{B}{A} \equiv q_0$ in Figure 5. The inverse relation between γ_+ and q_0 is clear. We also plot the predicted relationship $\gamma_+ = \frac{1-q_0}{1+q_0}$ which follows from inverting the well-known relationship $\frac{b}{a} = \frac{1-\gamma}{1+\gamma}$ where $\frac{b}{a}$ is the *apparent* axis ratio of a sheared circular disk.

The variation in face-on axis ratio explains much but not all of the spuriously inferred γ_+ : the inferred γ_+ is generally larger than predicted by the q_0 argument, particularly when viewed near face-on. One complicating factor is the anticorrelation with i : underestimating i lowers the *apparent* axis ratio prediction, which can compensate for overestimating γ_+ . This trend is revealed by the color gradient in the $i = 40^\circ$ and $i = 60^\circ$ panels of Figure 5. It is not clear why γ_+ remains overestimated in other panels of this figure where the trend with i is not strong.

Figure 5 also demonstrates that constraints on γ_+ degrade as targets become more edge-on. This was pre-

dicted by the Fisher forecasts of WS21, and can be understood in terms of a uniform (face-on) velocity field allowing very little wiggle room in i .

3.3. γ_x

As illustrated in Figure 4, γ_x performs significantly better than γ_+ with a narrow peak at values close to the expected value of $\gamma_x = 0$. At each inclination the distribution of γ_x is best described by a GMM of degree $n=2$, which captures a sharp central peak plus low-amplitude broad wings. To compare with the Fisher forecast of WS21 we examine the width of the central peaks, listed in Table 1. The γ_x precision is several times worse than forecast, and the least favorable viewing angle is near face-on rather than near edge-on as forecast. There is no correlation between γ_x and other parameters such as q_0 , i , or γ_+ , so we conclude that the effects discussed in the preceding subsection are not responsible for the greater than expected scatter.

The bias in γ_x , although small, is statistically significant (the typical standard error in the mean in each row in Table 1 is 0.005). This suggests that spiral arms could be responsible for the bias and scatter. Spiral arms will have a greater effect near face-on orientation, and they can cause a bias as follows. We consistently orient the mock data such that the disk is rotating clockwise. Spiral arms that trail (which are the vast majority; Iye et al. 2019) will then trail in an Z-wise rather than S-wise direction on the sky. It is plausible that this could systematically affect the inference of the γ_x component. Warping of disks could also play a role, but it is more difficult to see why warps would become more important for face-on orientations, or create a systematic effect.

The systematic effect would not be seen in a straightforward average of real observations because any given galaxy is, immutably, seen as S-wise or Z-wise. Z-wise galaxies would have a small bias toward negative γ_x and S-wise galaxies would have a small bias toward positive γ_x .

3.4. Additional Tests

Some readers may find it surprising that galactic disks have such a range of intrinsic axis ratios, hence we spend much of §4 comparing the IllustrisTNG q_0 distribution to other evidence in the literature, with good agreement. In the remainder of this section, we focus on tests that can be done within IllustrisTNG itself.

First, it is natural to ask whether noncircularity is an artifact of using the star particles as tracers. We repeated the q_0 measurements using the mass distributions of the same galaxies. We find that the mass distributions have a more constricted range of q_0 , but are

Figure 5. *Top:* scatter plots of inferred γ_+ vs. q_0 for various i . We overlay the function $\gamma_+(q_0) = \frac{1-q_0}{1+q_0}$ which describes the expected shear along the major axis arising from the intrinsic axis ratio. We include a colorbar to illustrate the difference between the inferred i and the preset value, indicated at the top right of each panel. *Bottom:* the plots are repeated for γ_x . The dashed curve is omitted because q_0 is not expected to affect γ_x .

still markedly noncircular: the mean q_0 for mass is 0.92 (with a range of 0.64–1 across 386 galaxies) while the mean for K-band photometry is 0.84 (with a range of 0.42–1).

Second, putting aside the axis ratio question, one may ask whether velocity fields from gas cells perform better. Molecular gas in particular is expected to form a thinner disk, with lower velocity dispersion, than stars. We performed fits using molecular-gas velocity fields, and found that performance was worse. This can be attributed to the patchy nature of molecular gas, which forms clumps around the spiral arms. The low velocity dispersion of molecular gas does not provide a substantial advantage in our mock data because the uncertainty on the mean velocity of each pixel is assumed to be dominated by measurement uncertainty rather than intrinsic dispersion. It remains possible that an alternative modeling procedure could do better with molecular gas velocity fields, but that is beyond the scope of this paper. We also found that velocity fields from atomic gas did not perform well.

Third, one may ask whether outliers can be identified and rejected based on observable criteria. However,

we found little correlation between a poor fit (as determined by χ^2) and spuriously inferred shear. We also visually inspected the 20 galaxies with the largest spurious shear to look for commonalities such as the presence of bars or satellites. We found no unambiguous trends. Bars, for example, may be overrepresented in the outliers, but a substantial fraction of outlying galaxies do not have bars. We also looked for a correlation between spurious shear and the presence of nearby galaxies which may induce tidal distortions in the target galaxy. For each IllustrisTNG galaxy of mass M and distance r from the target galaxy, we tabulate the tidal acceleration at the location of the target galaxy, $\frac{M}{r^3}$; we then keep the largest tidal acceleration experience by each target galaxy. We find no correlation between this tidal acceleration and spuriously inferred shear.

4. DISCUSSION & SUMMARY

The scatter and bias in γ_+ will be serious obstacles in attempting to make the velocity-field method competitive with traditional image-based weak lensing, at least for this component of shear. Image-based weak lensing yields a slightly larger shear uncertainty per galaxy

(~ 0.2 vs. $0.1\text{--}0.2$), but it involves far less expensive observations that collect many more source galaxies, and it makes no assumptions about the intrinsic shapes of galaxies. The mediocre γ_+ performance of the velocity-field method is due to scatter in the face-on axis ratio q_0 , which further causes a bias because galaxies can only scatter in one direction from the assumed value of $q_0 = 1$. Hence, our conclusion hinges on IllustrisTNG reproducing the q_0 distribution in the observed universe, at least qualitatively. The bulk of this section examines the literature on that issue and confirms the conclusion.

We briefly recap two methods of inferring q_0 from observations. The first (Ryden 2004, 2006) finds the distribution of q_0 that, when viewed from random angles, best matches the observed distribution of apparent axis ratios. In 12,764 SDSS galaxies Ryden (2004) found a median axis ratio of 0.85 and a scatter ≈ 0.1 in i band. Figure 6 shows that her best-fit distribution (blue curve) is quite similar to the distribution we extracted from Illustris (black curve). Ryden (2006) extended this type of analysis to include K -band data from 2MASS, as well as a breakdown into early and late spirals. She found a strong trend in median q_0 with Hubble type: from ≈ 0.98 for late spirals to ≈ 0.7 for early spirals. This is again comparable to the range in Illustris. If q_0 is indeed a strong function of Hubble type, a possible workaround for velocity-field shear inference is to adopt a prior on q_0 for each observed galaxy based on its Hubble type. However, there remains substantial scatter in q_0 at fixed Hubble type so this prior would remove only some of the scatter in inferred γ_+ .

The second method (Andersen et al. 2001; Andersen & Bershady 2002) is capable of inferring q_0 on a per-galaxy basis. Andersen et al. (2001) used intensity and velocity field data to compare the sky position angle (PA) of the photometric and kinematic major axes. Such a misalignment can be caused by lensing, but not in the nearby sample studied by Andersen et al. (2001). They attributed any misalignment to the disk having circular orbits but an intrinsically photometric ellipticity $\epsilon \equiv 1 - q_0$. They examined seven galaxies and found ϵ ranging from 0.02–0.20. Andersen & Bershady (2002) examined 28 galaxies and found $\epsilon = 0.06^{+0.064}_{-0.031}$; Ryden (2004) corrected this for selection effects and derived a distribution shown as the red curve in Figure 6. Our Illustris distribution differs from the two Ryden results by less than those two results differ from each other. We conclude that Illustris is accurately reproducing the intrinsic noncircularity of disk galaxies.

We note that velocity fields are typically measured for interstellar gas—e.g. Andersen et al. (2001) and Andersen & Bershady (2002) used the $H\alpha$ emission line—

while intensity fields are typically measured for stars, e.g. these references used broadband R and I images. Any misalignment between gas and stellar velocity fields would contribute to the ellipticity inferred by these authors, but would not manifest in our results because we used the stellar velocity field, nor in Ryden’s results which are based entirely on photometry. The consistency of these three results suggests that gas-star misalignments are a subdominant effect.

Although the details may vary with galaxy selection and wavelength, this body of work consistently implies that disks are not intrinsically circular, which leads to a bias of ≈ 0.1 on the γ_+ inference. Even if the mean effect of intrinsic ellipticity could be removed from the shear inference—an open question, considering the unknown PA of the intrinsic ellipticity—there remains a scatter of the same order, possibly reducible only through careful selection of very late types if the Ryden (2006) results are correct. This casts serious doubt on the viability of the kinematic method for inferring γ_+ .

This issue does not affect γ_\times , where we see promising precision gains compared to traditional weak lensing. The γ_\times scatter has a tight central core with $\sigma_{\text{core}} \approx 0.03$, dramatically smaller than the ~ 0.2 from image-based weak lensing. The scatter is larger than predicted by the idealized model of WS21, as expected from galaxies with realistic features such as spiral arms and warps; this work documents for the first time how much scatter is contributed by such features.

It is instructive to compare our γ_\times results with those of de Burgh-Day et al. (2015), whose inference method involves a *nonparametric* disk model created by reflecting the data itself. In their method, the inferred value of γ_\times is that which minimizes the asymmetry when unlensed; γ_+ is not constrained. They tested this method on idealized disks similar to those created by our parametric model, and found uncertainties ≈ 0.005 with mock data similar in quality to ours. This is in line with the WS21 Fisher prediction, and suggests that the $\gtrsim 0.03$ scatter we see is largely due to galaxy features not captured by our parametric model. Surprisingly, when de Burgh-Day et al. (2015) applied this method to two actual (nearby, hence unlensed) galaxies, the γ_\times precision was much tighter, ≈ 0.001 . It is unclear how higher precision was obtained from less idealized data.

It is possible that, for γ_\times inference, nonparametric galaxy models are more robust against features such as bars, warps, and spiral arms. This suggestion is tentatively supported by the small γ_\times bias in our mock data, which were prepared with all galaxies oriented Z -wise. Future work on γ_\times could include further testing of nonparametric models and perhaps comparison with model

Figure 6. Understanding the scatter in γ_+ : *Left:* Distribution comparison for our sample of 386 subhalos in the K band, Ryden’s correction of Andersen & Bershadsky (2002) in the I band, and Ryden (2004) in the i band. Our sample is best described by a lognormal distribution peaking at $\ln(\epsilon) = -2.14 \pm 0.83$, we include the equivalent axis ratio values at the top for clarity. *Right:* Corner plot showing that q_0 is anticorrelated with γ_+ but has no correlation with γ_x . Contours show 68.27%, 95.45%, and 99.73% confidence intervals.

extensions for bars, warps, and arms. Nevertheless, while the inference of γ_x from the velocity field could benefit from further modeling work, it clearly enables substantial precision gains over traditional image-based weak lensing. We also note that additional model parameters are unlikely to ameliorate the γ_+ issue, which is caused by the degeneracy of the two existing parameters γ_+ and q_0 ; the latter parameter was fixed in our tests but the degeneracy is clear. Hence, practical applications of velocity-field lensing will require strategies that take advantage of precise measurements of *one* component of shear defined relative to each source galaxy’s sky orientation. For mass mapping this may require using pairs of differently oriented galaxies (Blain 2002); however mass *models* can naturally be fit to the data regardless of widely varying precision on the two shear components along a given line of sight. For cosmic shear, cosmological models can predict the correlations of randomly selected shear components just as they can

predict the auto- and cross-correlations of both components, although the reduction in model discrimination power may be substantial.

Finally, we note that this method and traditional weak lensing will have different sources of *systematic* error, which could enable cross-checks between the methods. Initial applications of the velocity-field method will presumably focus on a small number of well-resolved sources for which PSF modeling will be a subdominant source of error. Traditional weak lensing, in contrast, uses large numbers of poorly resolved galaxies for which PSF modeling is the dominant systematic error. Measuring even one component of shear more precisely along selected lines of sight could potentially test the calibration of traditional weak lensing surveys.
